Involving IRBs In The Drug Approval Process

Everyone knows that the Food and Drug Administration is slow, bureaucratic, inflexible, and unimaginative. After all, haven't we all heard and read such allegations on numerous occasions? Moreover, many of us in the pharmaceutical field have had some personal experiences that have confirmed—or at least seem to have supported—just such conclusions regarding that federal agency.

Consequently, it strikes us as strange that there is little notice or interest when the FDA advances a proposal that would be expected to (a) speed up drug approval, (b) reduce government involvement, (c) provide a major departure from current drug approval processing, and (d) represent innovative thinking on the entire regulation of early drug testing.

We refer to FDA's proposals to expand the role, function, and responsibility of Institutional Review Boards (IRBs). These are the local review committees which are now set up and operating in many private and public institutions, and which serve as a sort of peer review group to examine and pass upon the suitability of proposed research involving human subjects or patients prior to the start of such studies.

Evidently, the general track record to date of these IRBs has been quite satisfactory. Experience seems to have shown that they are effective and that they work rather well in accomplishing their objective of protecting human subjects from undue risks.

The FDA has taken note of this performance and has advanced the thought that IRBs might provide an excellent vehicle to expedite Phase I testing in the consideration of Investigational New Drugs (INDs). Phase I is the initial testing in humans that involves short-term studies in a small number of normal subjects or patients to test the properties of the drug and levels of toxicity, metabolism, and pharmacologic effects.

After basic information about the drug is obtained in these preliminary studies, and assuming the results are favorable and encouraging, the effectiveness and relative safety of the drug are then studied by larger and more detailed investigations in patients; this is referred to as Phase II. Finally, at Phase III, more extensive testing is performed on patients to systematically assess the drug's safety and effectiveness.

For various reasons, many compounds tested never get beyond Phase I. Moreover, this is a time-consuming process that requires practically the same degree of scientific review resources to evaluate as the subsequent phases which involve many more human subjects. Consequently, Phase I drains off a considerable, and perhaps disproportionate, fraction of FDA's available resources for conducting medical reviews.

And at the same time, a parallel process is being conducted by the IRBs. If not identical, the process is very similar and the ultimate objectives are comparable. Furthermore, it has been argued that due to local familiarity, the IRB is able to assess the situation far better than any agency hundreds of miles away with only a batch of papers on which to make its judgments and render a decision.

Consequently, certain officials within the FDA—along with a few outside clinical investigators—have raised the question of whether it might eliminate duplication, expedite drug approval processing, lower research costs, and conserve scarce resources if the FDA were to reduce its review functions during the Phase I/early-Phase II period of the IND, conditioned upon a willingness of the IRBs to accept increased responsibilities in this area. Such a transfer would not change the standards of human subject protection and, hence, would not put patients at any greater risk than under the present arrangement.

The FDA informally has been "floating" this idea for at least a year. And, in the *Federal Register* of September 11, FDA formally described its interest in pursuing such a possible arrangement by publishing a summary of the issue and inviting comments from all interested parties. The *FR* item asks for views on five specific points as well as inviting responses to the general proposition.

The FDA appears to be genuinely interested in achieving some positive result in this matter. FDA Commissioner Arthur Hull Hayes, Jr., has supplemented the *FR* notice with a personal mailing to a broad spectrum of individuals and groups to call their attention to this issue and to invite the widest possible response.

On the surface, this concept (of using local IRBs to a greater extent as a trade-off for reducing most FDA oversight during Phase I and early-Phase II drug studies) makes a good deal of sense to us. But, as noted above, for some strange reason the idea seems to have generated little interest or publicity among any of the usually vocal and active groups on the drug scene: the lay press, broadcast media, consumer advocates, pharmaceutical trade organizations, Congress, or special interest groups.

It would be most regrettable—indeed, even tragic—if one of the few real potential solutions to reducing government "red tape" and the so-called "drug lag" were allowed to die simply because of apathy and neglect on the part of all concerned.

Quantitative Evaluation of Pharmaceutical Effervescent Systems I: Design of Testing Apparatus

NEIL R. ANDERSON ˣ, GILBERT S. BANKER, and GARNET E. PECK

Received February 4, 1981, from the *School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication May 13, 1981.

Abstract □ Two new devices were developed to monitor the reactivity of pharmaceutical effervescent systems. The first method monitored carbon dioxide pressure generation during the effervescent reaction in a plastic pressure vessel fitted with a pressure gauge. The second method monitored weight loss, attributed to carbon dioxide loss to the atmosphere, by means of a double cantilever beam and an electromagnetic proximity transducer. In the pressure device, the quantification of an effervescent reaction was accomplished by measuring the dissolution time of the effervescent system and the pressure generated. Quantification of an effervescent reaction using the beam device utilized the total carbon dioxide weight loss, the rate of weight loss, and the effervescent reaction lag time.

Keyphrases □ Effervescent pharmaceuticals—quantitative evaluation, design of testing apparatus □ Reactivity—quantitative evaluation of effervescent pharmaceuticals, design of testing apparatus □ Instrumentation—design of testing apparatus to quantitate reactivity of effervescent pharmaceuticals

Acid–base reactions between alkali metal carbonates or bicarbonates and citric or tartaric acid have been used for many years to produce effervescent pharmaceutical preparations on the addition of water. The greatest problem with effervescent products is the loss of reactivity with time due to their premature reaction on exposure to moisture. Even exposure to atmospheric moisture when opening and closing a multiple-dose container can rapidly destroy reactivity.

BACKGROUND

Studies to design improved effervescent tablet systems have suffered from the absence of methodology to quantitate effervescent reactions. To study the rate of an effervescent reaction such as between sodium bicarbonate and citric acid in excess water, producing carbon dioxide, water, and sodium citrate, one can theoretically measure the increase in one reaction product or the decrease in one reactant. The obvious element to measure continuously would be the carbon dioxide generated. This procedure would permit measurement of the amount of carbon dioxide generated by a particular system as well as the rate of the reaction.

Chemical analysis of carbon dioxide, following total evolution of the gas, can be accomplished by several means. However, none of the methods permits the direct kinetic determination of carbon dioxide evolution during various time points in the process of a rapidly reacting system. Carbon dioxide can be measured by a volumetric method using the Chittick apparatus (1), by a combination of gas measurement and gas absorption, or by a weight loss method (2). Carbon dioxide is also determined by absorption on liquid or solid media, measuring the amount of gas evolved by weighing (3). The use of the absorption method has been modified many times by using different detection methods to determine the amount of gas absorbed (4–6). None of these methods is satisfactory for quantitating an effervescent reaction that is completed in <30–60 sec.

One possible method of continuously monitoring carbon dioxide evolution is to monitor the pressure generated in a closed system. However, this approach may not simulate the normal effervescent tablet reaction occurring in an open container of water at constant atmospheric pressure.

A simple, continuous, immediate response weight loss procedure was thought to offer the most direct and applicable technique to determine the total amount of carbon dioxide evolved, the reaction rate, and other characteristics of the reaction process. Development of such a system requires the development of an adequately sensitive weighing system, providing immediate response and continuous recording. The response characteristics must be rapid to quantitate totally a reaction that is completed in 30 sec or less and sensitive enough to measure accurately weight losses <1 g from an initial mass of ~100 g.

Transducers capable of responding quickly to applied forces have been used in the pharmaceutical industry for more than 20 years. Strain-gauge transducers have been shown (7, 8) to be widely and successfully used in instrumenting tableting machines in research, development, and production capacities. A device was developed (9) for the continuous recording of the flow of powders or granular material from various hoppers with strain gauges. Later, an instrument was developed (10) to determine granule strength using strain gauges in a beam apparatus similar to the flow device. Taylor (11) developed a flowing measure instrument with strain gauges and a specially designed double-cantilever beam, and the same equipment was adapted to quantify suspension pourability (12). While the newer strain-gauge devices permit continuous recording of applied loads, such systems are not adequately sensitive to monitor carbon dioxide loss during an effervescent reaction.

This report describes a new balance system utilizing an electromagnetic proximity transducer and a specifically designed double-cantilever beam that is sensitive enough for the continuous gravimetric measurement of carbon dioxide loss during an effervescent reaction. Utilizing the proximitor balance system as well as pressure generation measurements, effervescent systems and reactions were quantitated as to their reaction

rates, carbon dioxide losses, dissolution times, and lag times to initiation of reaction. A reactivity index was developed, and a correlation between the two new methods of examining effervescent reactions was found.

EXPERIMENTAL

Instrumentation—Reactivity testing based on monitoring pressure generation of effervescent tablet systems was done in a cylindrical plastic pressure vessel especially designed for effervescent tablets. The pressure generated during the effervescent reaction in the vessel was measured by a 0–60 psi pressure gauge[1] mounted on the pressure vessel. The volume of the pressure vessel was ~250 ml. Attached to the side of the vessel was the sample tablet holder(Figs. 1A and 1B). The tablet holder was cylindrical in design and built perpendicularly into the side of the pressure vessel. The end opening to the interior of the vessel consisted of two perpendicular crosspieces, which held the sample tablet out of the interior of the vessel in the filling position (Fig. 1A), but allowed the water in the vessel to flow into the sample holder to cover the tablet when placed in the vertical test position (Fig.1B). A pressure-tight, clear plastic screw cap sealed the system at the exterior end of the cylindrical sample holder.

The new balance system for the continuous recording of carbon dioxide weight loss utilized a double-cantilever beam with a proximity transducer to monitor beam deflection. The proximity transducer consisted of a probe and a proximitor. The actual transducer consisted of a flat coil of wire located in the ceramic tip of the probe. This probe then became a gap-to-voltage transducer used to measure distances and change in distances to any electrically conductive material. The probe was driven by a radio frequency (RF) voltage developed by the proximitor. The output signal from the proximitor to a chart recorder was at a voltage proportional to the distance between the probe and the conductive surface.

Basically, the proximitor takes the voltage supplied to it from a power supply and converts it to an RF signal. This signal is then applied to the probe and the probe coil, which radiates this signal into the surrounding area as a magnetic field. If there is no conductive surface to interfere with the magnetic field there is no RF signal loss. However, as a conductive surface approaches the probe and interferes with the magnetic field, eddy currents are generated on the surface of the material, the RF signal is lost, and power is consumed. As the surface moves closer to the probe, more and more power is absorbed and the RF signal decreases. The proximitor measures the RF signal voltages and sends out an output voltage equal to the negative RF signal peaks (13). The output voltages can then be directly measured on a volumeter or used to drive a chart recorder.

The new beam/proximitor (b/p) balance system (Fig. 2) consisted of a double-cantilever beam specifically designed for a maximum load of 100 g to be placed on the 5.1-cm sample pan. The proximity transducer probe[2] was mounted directly below the electrically conductive surface needed for the proximity measurement. The proximitor[2] itself was housed

with an 18-v power supply. A line filter[3] was needed to filter out electrical noise, and a voltage divider was needed to reduce the input voltage to the recorder to match the 100-mv span on the recorder[4]. The b/p balance was housed during tests in a plexiglass hood to reduce the possibilities of air currents affecting the balance.

The double-cantilever beam system of the balance was designed and constructed to provide a linear response in beam deflections to various load weights. The b/p balance was then designed to measure weight loss by monitoring beam deflections with the proximitor and probe. Using this design, the b/p balance could monitor up to a 1-g weight loss from an initial load of up to 100 g.

Pressure Vessel Test Method—With the pressure vessel placed in the horizontal filling position (Fig. 1A), the cap of the tablet holder was removed and 150 ml of deionized, distilled water (20°) was quickly transferred into the pressure device through the tablet holder. Any water adhering to the tablet holder was removed to prevent premature reaction. The tablet to be tested was placed in the tablet holder, and the cap was replaced and secured. The pressure vessel was then lifted to the vertical test position (Fig. 1B), causing the water to contact the tablet in the tablet holder and produce the effervescent reaction. At 5-sec intervals, the pressure was read from the pressure gauge and recorded. The dissolution time of the effervescent tablet, as observed through the transparent cap of the tablet holder, was recorded, as well as the pressure that developed at the dissolution time. Finally, the entire device was shaken for a few seconds and the final pressure was recorded.

[a] As measured by an analytical balance and the beam/proximitor balance.

Balance Test Method—Polypropylene beakers (100-ml) were used as the effervesecent tablet reaction vessels. Because the effervescent reaction was violent enough to cause a loss of water as well as carbon dioxide from the beaker, a circular beaker cover (7.0 cm in diameter) was made from high density polyethylene material. This cover had a rectangular slot, 2.9 × 0.6 cm, cut in the center through which the effervescent tablets were dropped into the beaker.

After prestressing the balance beam with a 100-g load for 30–40 min to stabilize the base (0% span) and top lines (90% span) on the recorder, ~80 ml of deionized, distilled water at 20° was measured into the reaction beaker and the total weight of the beaker, cover, water, and tablet was adjusted to 100 g or 90% of full recorder span with 20° water. With the recorder on "standby" and the chart speed set at 12.7 cm/min, the tablet was set on its edge at the edge of the slot in the cover. After initial beam vibration had subsided, the tablet was gently dropped through the slot into the beaker. Immediately after the tablet entered the water, the recorder was turned to "record," and the effervescent reaction was monitored for at least 2 min. The tablet dissolution time was determined visually and indicated on the recording.

Calibration of Balance—After prestressing the beam with a 99-g load, the b/p balance was calibrated by placing various known loads, 10 mg–1 g, on the balance. The recorder span was set at 90%. The actual recorder response to the various loads was in very close agreement to the theoretical response. Only slight deviations occurred at even the 20- and 10-mg loads (Table I).

The recorder span (90%) reproducibility was measured by repeatedly adding and removing a 1-g weight from the b/p balance loaded with 99 g. Table II shows the precision and reproducibility resulting from the three trials performed.

Tests were run to compare reacting effervescent tablet carbon dioxide weight loss values obtained with the b/p balance to values obtained with a commercial balance. Effervescent tablets[5] were reacted in a beaker of water, and the weight loss was noted after 2 min of reaction time on a commercial analytical balance[6] and compared to the weight loss of tablets run on the experimental balance. The data in Table III show close agreement in the total weight loss after 2 min between the b/p balance and the commercial analytical balance, which further verified the accuracy of the b/p unit.

Materials—Several different experimental effervescent tablets were made for effervescent reactivity testing with the pressure vessel and b/p balance methods. Each tablet system was a 3-g tablet containing a stoichiometric ratio of acid and base (Table IV). A standard 3-g tablet was made of citric acid–sodium bicarbonate (1.3:1.7). All materials were either USP, NF, or pharmaceutical grade.

The materials were first passed through a 30-mesh screen and then through an 80-mesh screen, mixed, and compressed on a hydraulic press[7] between 25.4-mm, flat-faced, beveled-edge tooling. The compression force generated for each tablet was 897 kg/cm^2 and was held for a 5-sec dwell time. All operations were conducted at 23–25° and a relative humidity of ≤30%.

RESULTS AND DISCUSSION

The standard tablets were run in the pressure device first. Table V shows the pressure and dissolution time results of the 28 standard formulation tablets run. The standard tablets were then run on the b/p balance to measure carbon dioxide loss (Table VI).

The experimental effervescent tablets were then run in the pressure device and on the b/p balance. The resultant carbon dioxide weight loss values and gas pressure values were divided by the corresponding values obtained from the standard tablets to generate relative pressure values and relative weight loss values listed in Table VII. Figure 3 shows the relationship between the relative values obtained from the two test methods. The calculated correlation coefficient for the graph was 0.937.

[7] Carver laboratory press model C, Fred S. Carver and Co., Summit, N.J.

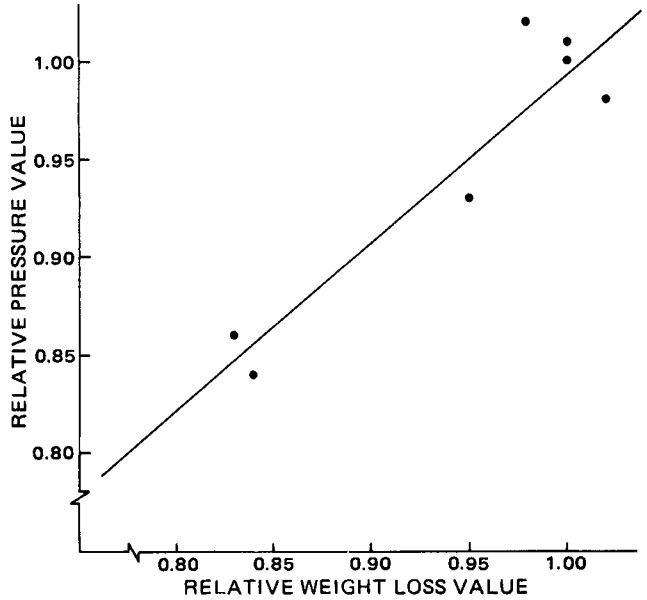

Figure 3—*Relationship between the relative pressure values from the pressure monitoring device and the relative weight loss values from the beam/proximitor balance (Table IV).*

The correlation was judged to be good considering that the sensitivity of the pressure gauge on the pressure device was 2 psi/division and the sensitivity of the b/p balance was 0.0111 g/division.

The milligrams of carbon dioxide lost at any time (t) during an effervescent reaction were designated W_t and could be calculated from the chart recording (Fig. 4) by multiplying the number of divisions corresponding to the weight loss at time t by 11.1 mg/division. The final weight loss measured 2 min after the reaction was started was designated W_F. Plotting log ($W_F - W_t$) *versus* time produced a graph like the one in Fig. 5. The graph can be divided into three segments corresponding to the three events observed during the effervescent reactions. Period A of Fig. 5, the distance between the y-axis and the time at which the graph first approaches linearity, represents an induction period or lag time during which the tablet is wetted by the water and the effervescent reaction is initiated. Period C represents the period after the effervescent reaction has ceased and when carbon dioxide is slowly coming out of solution. Period B represents the actual time of the effervescent reaction of the tablet. In this section of the graph, a straight line can be drawn, the slope determined by linear regression, and an observed first-order rate constant (k) can be calculated for the reaction.

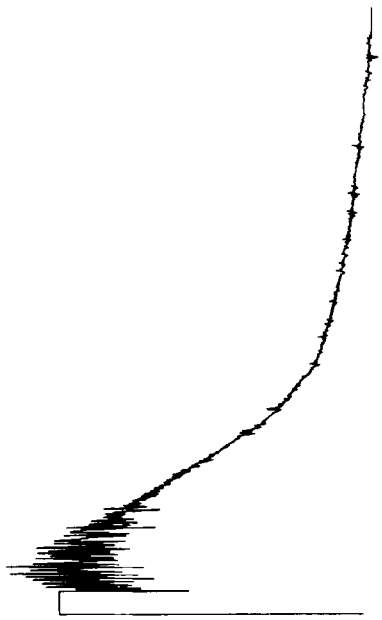

Figure 4—*Typical chart recording from a beam/proximitor balance effervescent tablet run.*

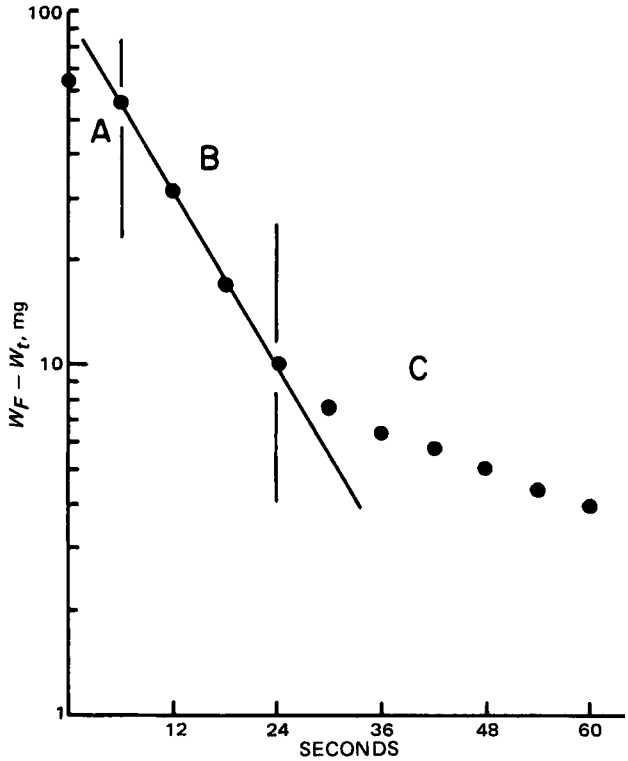

Figure 5—*Example plot of beam/proximitor balance data treatment using log* ($W_F - W_T$) versus *time relationship.*

In a statistical evaluation of reactivity, a single measurement of both the reaction rate and the total carbon dioxide evolved is required since differing effervescent systems could conceivably have a fast reaction rate and yet produce little carbon dioxide (and vice versa). Therefore, Eq. 1 can be used to quantitate each effervescent tablet system for both k and W_F in a single indicator, the index of reactivity (I_R):

$$I_R = kW_F \qquad \text{(Eq. 1)}$$

SUMMARY

While the described pressure monitoring device did not lend itself to effervescent reaction characterization or rate determinations, the results obtained did correlate with weight loss data obtained from the balance device. The pressure monitoring device could be used as an effective, quick screening device for experimental effervescent system reactivity or as a possible quality control instrument.

Quantitative Evaluation of Pharmaceutical Effervescent Systems II: Stability Monitoring by Reactivity and Porosity Measurements

NEIL R. ANDERSON ˣ, GILBERT S. BANKER, and GARNET E. PECK

Received February 4, 1981, from the *School of Pharmacy and Pharmaceutical Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication May 13, 1981.

Abstract □ The stability of selected effervescent tablet systems was monitored by means of mercury intrusion porosimetry and by a cantilever beam/proximity transducer balance. The porosity measurements proved to be useful in elucidating tablet pore structure changes over time. The measured parameter, percent pores greater than the experimental range, was a useful measure of porosity for statistical evaluations. The study showed that compression pressure and manufacturing conditions are not significant factors in the stability of an effervescent tablet system when nonhygroscopic materials are used.

Keyphrases □ Effervescent pharmaceuticals—quantitative evaluation, monitoring of stability by reactivity and porosity measurements □ Stability—of effervescent pharmaceuticals, monitoring by reactivity and porosity measurements □ Tablets—effervescent, measurement of stability by reactivity and porosity measurements

Accelerated stability tests are used in the systematic design of solid dosage forms to examine the changes in physical characteristics brought about by environmental stress conditions. To use any stability test successfully, the characteristics being monitored must be quantitatively measured.

The greatest problem with effervescent tablet products is their loss of reactivity with time, particularly from contact with moisture. Methods of quantitatively characterizing effervescent tablet systems are limited and do not lend themselves to direct measurement. However, a balance device utilizing a double-cantilever beam with a proximity transducer was recently developed to allow continuous recording of carbon dioxide weight loss from rapidly reacting effervescent systems (1). That study also described treatment of the data obtained, including calculation of an index of reactivity (I_R) to quantify the effervescent reactions.

A previous study (2) investigated the stability of a hydrolizable drug, aspirin, in relation to the porosity characteristics of the dosage form by means of mercury intrusion porosity measurements. Since effervescent tablets based on citric acid and sodium bicarbonate react prematurely, with carbon dioxide being generated and liberated, the porosity characteristics of such a tablet might be expected to change as the premature reaction proceeds. Therefore, mercury intrusion porosity data might provide useful information on the physical changes in effervescent systems with aging or decomposition, as well as data that might be correlated with other tablet reactivity measurements, resulting in a more quantitative method of stability assessment.

The present studies were undertaken to determine the stability of several experimental effervescent tablets. An index of reactivity (1) was developed as a stability indicator. The mercury intrusion measurement of the porosity of the effervescent tablets, used to monitor structural changes in the effervescent tablets with time under the influence of water vapor and high temperature, was also developed as a stability indicator.

EXPERIMENTAL

Materials—The compositions of the effervescent tablets used are listed in Table I. All materials were passed through a number 30 screen and then through a number 80 screen, mixed, and compressed at room temperature with a relative humidity (RH) of either 20 or 60%. The effervescent tablets contained a stoichiometric ratio of acid to base, with the tablets containing a base other than sodium bicarbonate equivalent to 1.9 g of sodium bicarbonate. Because of the large amount of sodium glycine carbonate and sodium dihydrogen citrate required in such formulations, the total weight of these tablets (Table I) was reduced by 63.5 and 25%, respectively. Corrections were later made so that the carbon dioxide loss data were reported as equivalent to a 1.9-g sodium bicarbonate formula.

Experimental Design—The stability study was designed as a factorial experiment to investigate the effects of the tablet manufacturing conditions (I), tablet formulations (J), tablet compression pressures (K), storage conditions (L), and storage times (M). The dependent variables measured were the index of reactivity, I_R, and a measure of the tablet porosity.

Large 25.4-mm, flat-faced, beveled-edge tablets were compressed at two different compression pressures, 897 or 1077 kg/cm^2, using a motorized hydraulic press[1]. Similar 12.7-mm tablets were also compressed to densities equal to the 25.4-mm tablets. The densities were measured on a commercial air comparison pycnometer[2] (Table II). The 12.7-mm tablets were required to accommodate the porosity measuring device used in the study. Prior to compression, the raw materials were oven dried at 120° for 24 hr, weighed out, mixed, and exposed to the manufacturing environment for 1 hr. The effervescent tablets were either compressed at an ambient relative humidity of ≤20% or at 60% RH. The relative humidity was monitored by means of a sling psychrometer[3].

During the high humidity stability test, the tablets were stored in glass bottles[4] without caps in a sealed rigid plastic case, equipped with a small fan for air circulation, containing a saturated salt solution of sodium chloride to produce 75% RH at 25°. The humidity was monitored by a hygrometer[5] placed inside the case. The second storage condition of the stability test was 50°, achieved in an oven[6]; tablets were stored in the oven in capped glass bottles[4].

The tablets were stored in the glass bottles in an alternating stack of 25.4- and 12.7-mm tablets with a polystyrene plastic disk[7] as filler on the top and bottom of each stack. Enough tablets were placed in a bottle to complete the necessary samplings at 0, 2, and 4 weeks of storage at each condition. For each bottle of sample tablets, a backup bottle containing one tablet of each size, along with the disks, was stored.

The general procedure for setting up and running the stability test started with the establishment of the 20 or 60% RH manufacturing conditions. The compression equipment was then moved to the location providing that condition. The five different effervescent tablet formulations to be compressed at two different compression pressures were coded and assigned an order of compression using a random number table. The raw materials for each of the 10 combinations (five formula-

	12.7	909	1.726

[a] Pressure calculated by geometric and force transmission considerations for 12.7 mm tablets.

tions × two pressures) were then weighed out, and enough of both of the 25.4- and 12.7-mm tablets were compressed to meet the sampling and backup requirements of the stability test.

The tablets were then randomly placed in the glass bottles, labeled, and placed in the appropriate storage condition. Initial values of the reactivity and porosity measurements were taken. This procedure was repeated until all 20 combinations (five formulations × two pressures × two manufacturing conditions) were compressed and stored and initial values were taken.

At the appropriate times, the top 25.4- and 12.7-mm tablets in each sample bottle were removed from storage and their reactivities and porosities were determined. The tablets were sampled and measured in the same order as they were made, using one tablet per measurement.

The total stability study was replicated a second time in the described manner. The second replication was needed to provide some measure of the error between test measurements and between the manufacture of the tablets to make statistical tests on the major factors after the study.

The data collected in the study was analyzed statistically by analysis of variance. The experimental design contained three inherent restrictions on randomization, which were accounted for in the design of the statistical analysis model (3–5). The first restriction occurred when all tablet compression work was done under one manufacturing condition prior to the second condition. Second, each tablet formulation was compressed in turn at the high or low compression pressure prior to the other pressure being used. Third, the tablets were assigned storage conditions and had to be sampled at the specified storage times in the same order that they were made. With these errors accounted for in the model, property tests could be run on the dependent variables after the study was concluded.

The analysis of variance for the study design is shown in Table III. This design was used for the analysis of each dependent variable of reactivity and porosity measured at both storage conditions for 0, 2, and 4 weeks of storage. Analysis of variance was done by computer using a statistical library program[8].

Pooling of the error terms was performed to determine the mean square error (MS_{error}) to facilitate F testing by having a single MS_{error} with greater degrees of freedom (6). Pooling was performed as indicated in Table III.

[c] The error terms were pooled within the various sections as indicated by underlining. The pooled errors were then used to test the significance of those factors and interactions within the respective sections. [d] First restriction of randomization error. [e] Second restriction of randomization error. [f] Third restriction of randomization error.

In the case of significant two-way interactions from analysis of variance of a dependent variable, a Newman–Keuls sequential range test (6) was performed on the means involved to determine significant differences.

The effervescent tablet porosity measurements were performed on a commercial mercury intrusion porosimeter using a method described previously (2, 7). In this procedure, several characteristics of a tablet's pore structure were calculated and could be used to express tablet porosity. However, statistical evaluation requires that a single dependent variable value be used. In this study, the calculated value of the percent pores greater than the experimental range (PPGTER) was used as the dependent variable value for porosity. The selection of the PPGTER values was based on the fact that moisture can interfere with mercury intrusion in pore-size distribution determinations within the experimental range (8, 9). Even though each tablet was pretreated by drying at room temperature under vacuum[9] for 15 hr as part of the mercury intrusion determinations, the effervescent reaction, however slow it may be, would not have ceased; therefore, water would still have been produced and been available to interfere with the measurements. The PPGTER value is not significantly influenced by moisture.

The true densities of the tablets required for the porosity calculations were determined by an air comparison technique using a commercial pycnometer[3]. Room air was used as the gas. Before each determination, a zero measurement check was made to correct for possible zero offset. Measurements were carried out by starting at an initial pressure of 1 atm and compressing the gas to 2 atm.

The reactivity of the 25.4-mm effervescent tablets at the selected storage times was determined by means of the beam/proximitor (b/p) balance previously described (1).

RESULTS AND DISCUSSION

As already mentioned, tablets containing sodium glycine carbonate and sodium dihydrogen citrate required weight reductions of 63.5 and 25%, respectively, and did not contain base equivalent to the 1.9 g of sodium bicarbonate in the standard tablet. From the standpoint of density and porosity, the weight reduction was not a factor. However, in trying to relate the reduced weight tablets to the standard tablet by means of the index of reactivity, I_R, the weight reduction is very crucial because:

$$I_R = kW_F \qquad \text{(Eq. 1)}$$

where W_F is the final weight loss of carbon dioxide from the effervescent solution and k is the rate constant of the effervescent reaction (1). Therefore, the data collected for the reduced tablets were multiplied by a correction factor. This factor was determined by measuring W_F on the b/p balance from tablets containing the full 1.9 g of sodium bicarbonate equivalent and from the reduced tablets. Dividing W_F for the full-base tablets by W_F for the reduced-base tablets gave a factor by which each data point generated on the b/p balance by the reduced tablets could be multiplied to yield data representative of tablets containing base equivalent to 1.9 g of sodium bicarbonate.

Analysis of variance of the adjusted I_R means revealed, at the 0.01 level, significant differences in I_R values with the following factors:

J = tablet formulation
L = storage condition
M = storage time
$J \times I$ = interaction
$J \times L$ = interaction
$J \times M$ = interaction
$L \times M$ = interaction
$I \times J \times M$ = interaction
$I \times K \times M$ = interaction
$J \times K \times M$ = interaction
$J \times L \times M$ = interaction
$I \times J \times K \times M$ = interaction

The individual factors of compression pressure (K) and manufacturing conditions (I) were not significant.

Analysis of variance showed that I_R appears to be a function not only of J but also of L and M. The single effects are supported by examination of the four significant two-way interactions involving the factors. Newman–Keuls (NK) tests were run, and the means were plotted for each interaction (Figs. 1–4).

Figure 1 shows the I_R means plotted for the interaction of tablet formulation and manufacturing conditions ($J \times I$). Figure 1 clearly shows the difference in I_R values according to the different formulas and supports the analysis of variance finding that manufacturing conditions did not have any significant effect on I_R values in that only the citric acid–sodium glycine carbonate tablet showed any significant difference, 0.01 level, between the two manufacturing conditions. With only this one difference, the total interaction is of doubtful significance.

Table IV—General Physical Observations

Tablet	Storage	Observations
A	75% RH	Some swelling, surface rough
A	50°	No change
B	75% RH	Surface rough, some swelling
B	50°	No change
C	75% RH/50°	No change
D	75% RH	Some swelling
D	50°	Very enlarged and porous ("sponge")
E	75% RH	Enlarged
E	50°	Very enlarged and porous ("sponge")

Investigation of the $J \times L$ interaction (Fig. 2) shows significant differences in the I_R means caused by storage conditions, with the citric acid–sodium bicarbonate and citric acid–sodium glycine carbonate tablets recording the largest I_R losses. The I_R values of the glutaric acid–sodium bicarbonate tablet support the observation (Table IV) that this composition was better, or was more stable, at 75% RH storage than at 50° storage in that its I_R value was greater after the former. Tablet E appeared to be equally low in I_R value in either storage condition.

A study of the $J \times M$ interaction in Fig. 3 shows that the I_R definitely decreased with storage time for all tablets. Moreover, there were no significant differences between the 2- and 4-week values of I_R for each tablet. The loss of stability appeared to take place during the first 2 weeks of storage.

The obvious relationship between L and M is supported by the interaction in Fig. 4. There was a significant loss of I_R at 50° between 0, 2, and 4 weeks. There was also a significant loss of I_R between 0, 2, and 4 weeks at 75% RH storage. The losses at 50° were significantly less than the losses at 75% RH storage. This result can be explained by the fact that only the glutaric acid–sodium bicarbonate and Tablet E lost a significant amount of reactivity at 50° storage whereas all tablets lost reactivity at the 75% RH storage condition.

The three-way and four-way interactions, calculated by analysis of variance to be statistically significant, were ignored since the significance

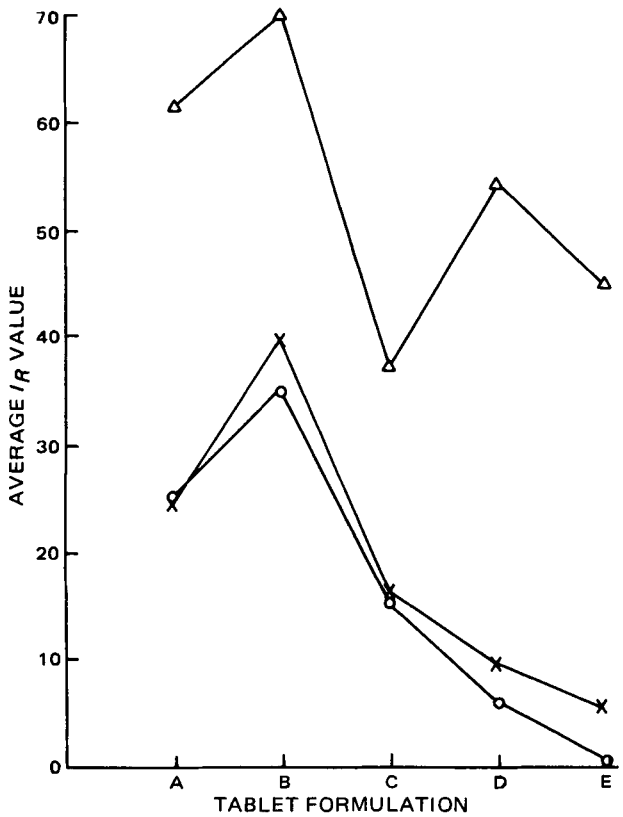

Figure 3—*Index of reactivity analysis for* J × M *interaction. in the higher order interactions was probably caused by the strong common factor of storage time (M).

Analsis of Tablet Porosity Using PPGTER—Analysis of variance shows four significant differences in PPGTER values, at the 0.01 level, caused by the factors of J, M, $J \times M$, and $J \times L$. None of the other factors and interactions were significant. In a plot of both interactions (Figs. 5 and 6), the sodium dihydrogen citrate–sodium bicarbonate tablet values of PPGTER remain approximately constant.

Analysis of $J \times L$ by NK testing and plotting (Fig. 5) shows significant differences within tablets at the two storage conditions with the exception of the sodium dihydrogen citrate–sodium bicarbonate tablet formulation. The citric acid–sodium bicarbonate and citric acid–sodium glycine carbonate tablets appeared to have low PPGTER values at 50° and high values at 75% RH. The reverse was true for glutaric acid–sodium bicarbonate and Tablet E where the PPGTER values at 75% RH storage were lower than those at 50° storage. This interchange of values, causing the differences to perhaps cancel each other, probably eliminated the significance of L from the analysis of variance. Analysis of the $J \times M$ interaction (Fig. 6) shows that there was no significant difference between the citric acid–sodium bicarbonate and citric acid–sodium glycine carbonate tablets. The sodium dihydrogen citrate–sodium bicarbonate

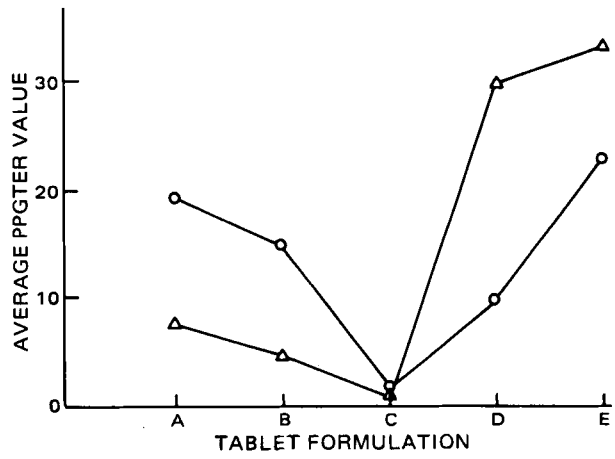

Figure 5—*Percent pores greater than experimental range (PPGTER) analysis for* J × L *interaction. Key:* ○, *75% RH storage condition;* △, *50° storage condition; A, citric acid–sodium bicarbonate; B, sodium glycine carbonate–citric acid; C, sodium dihydrogen citrate–sodium bicarbonate; D, glutaric acid–sodium bicarbonate; and E, Tablet E.*

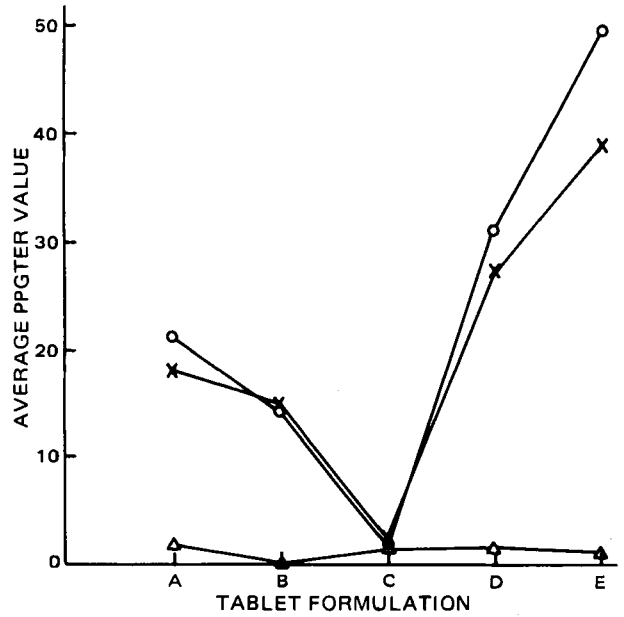

Figure 6—*PPGTER analysis for J × M interaction. Key: △, initial (0 week); ×, 2 weeks of storage; ○, 4 weeks of storage; A, citric acid–sodium bicarbonate; B, sodium glycine carbonate–citric acid; C, sodium dihydrogen citrate–sodium bicarbonate; D, glutaric acid–sodium bicarbonate; and E, Tablet E.*

tablets appeared to be lower in value and remained unchanged. As already shown, most of the significance came from the glutaric acid–sodium bicarbonate and Tablet E alone being greatly different from their initial values compared with the other tablets. The values at 2 and 4 weeks showed no significant differences, indicating that the loss in PPGTER stability occurred within the first 2 weeks of storage.

Analysis of variance of I_R values shows the sodium glycine carbonate–citric acid tablet to be good in comparison with the standard tablet (citric acid–sodium bicarbonate). There is also an indication that while

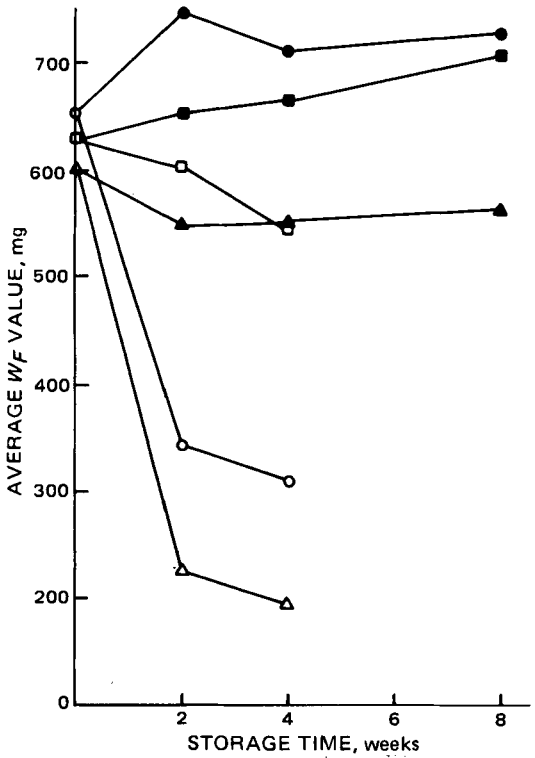

Figure 7—*Average final weight loss of carbon dioxide (W_F) at each storage condition and time for Tablets A (△), B (○), and C (□). Open figures represent the 75% RH storage condition; closed figures represent the 50° storage condition.*

low in its I_R value, the sodium dihydrogen citrate–sodium bicarbonate tablet is quite stable. When restricting the discussion to these three formulations, analysis of variance of PPGTER shows that the sodium

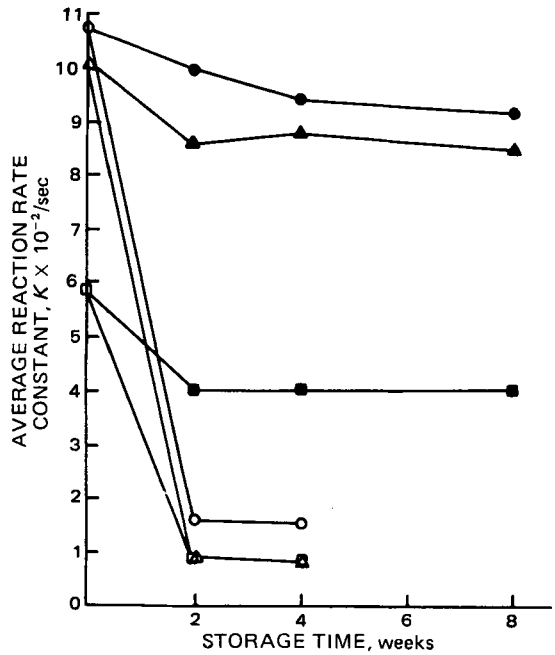

Figure 9—*Average reaction rate constant (k) at each storage condition and time for Tablets A (△), B (○), and C (□). Open figures represent the 75% RH storage condition; closed figures represent the 50° storage condition.*

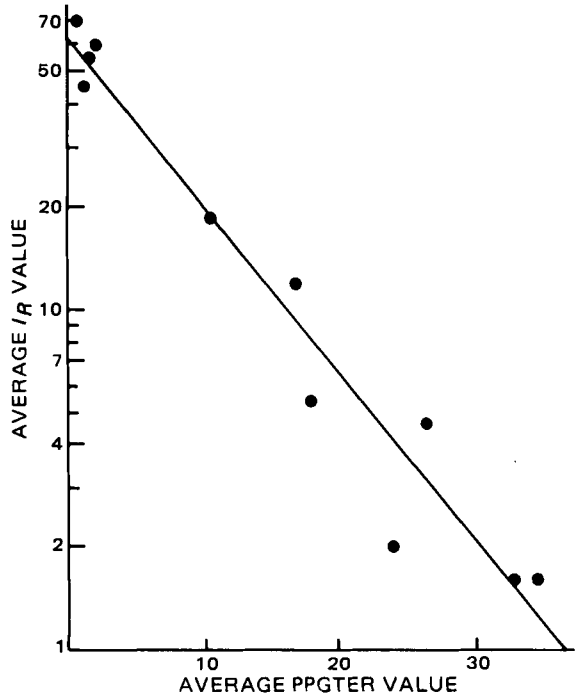

Figure 10—*Relationship between* I_R *and PPGTER.*

dihydrogen citrate composition underwent the least amount of internal structural changes, with the sodium glycine carbonate composition being second best. In addition, plots of the different reactivity data parameters (k, W_F, and I_R) in Figs. 7–9 show that the sodium glycine carbonate–citric acid tablet and the standard tablet were quite similar in initial reaction rate (Fig. 9); but on storage at 75% RH, the standard tablet lost ~67% of its carbon dioxide-producing capacity (W_F) compared with a 50% loss for the sodium glycine carbonate composition tablet (Fig. 7). The sodium dihydrogen citrate–sodium bicarbonate tablet retained its carbon dioxide-producing capacity at both storage conditions (Fig. 7); therefore, the low I_R values of the tablet (Fig. 8) were caused by low reaction rates (k) alone and not a combination of both W_F and k losses over time as would be indicated by Eq. 1.

It was shown that both the I_R PPGTER values are significantly affected by storage time. It appears that a correlation should exist between PPGTER and I_R. If it is assumed that the loss of reactivity is caused by the slow premature reaction of the tablets, then the loss of the reacting compounds to form the escaping carbon dioxide could alter the pore structure of the tablet by causing new pores to be formed and old pores to become larger.

A correlation does exist between PPGTER and I_R and is shown when the average PPGTER values for 0, 2, and 4 weeks in 75% RH storage are plotted against the log of the average I_R values at 0, 2, and 4 weeks of storage at 75% RH for the standard tablet, citric acid–sodium glycine carbonate, glutaric acid–sodium bicarbonate, and Tablet E (Fig. 10). For those tablets whose stability decreases in the 75% storage condition, the log of I_R decreases as the PPGTER increases.

Thus far, porosity has been limited to a discussion of PPGTER only.

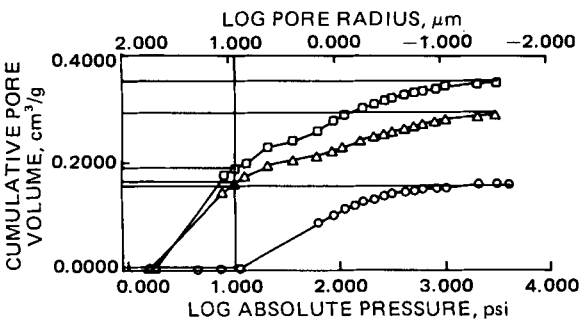

Figure 11—*Cumulative pore volume of the citric acid–sodium bicarbonate tablet in the 75% RH, 25° storage condition. Key: ○, initial (0 week); △, 2 weeks of storage; and □, 4 weeks of storage.*

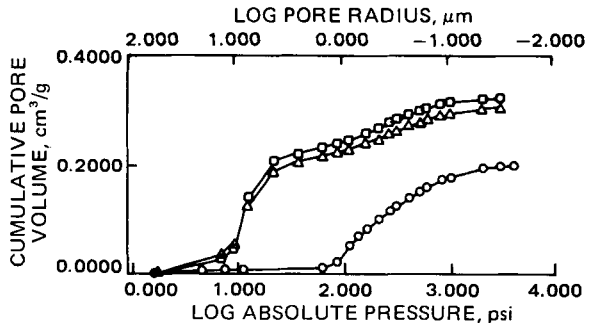

Figure 12—*Cumulative pore volume of the sodium glycine carbonate–citric acid tablet in the 75% RH 25° storage condition. Key: ○, initial (0 week); △, 2 weeks of storage; and □, 4 weeks of storage.*

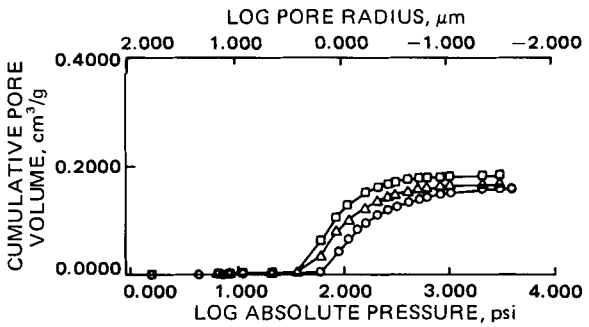

Figure 13—*Cumulative pore volume of the sodium dihydrogen citrate–sodium bicarbonate tablet in the 75%, RH, 25° storage condition. Key: ○, initial (0 week); △, 2 weeks of storage; and □, 4 weeks of storage.*

Mercury intrusion measurements can be presented graphically to illustrate the changes that occur in the tablet pore structure.

Examination of the mercury intrusion data[10] for the standard tablet stored in the 75% RH condition (Fig. 11) shows that at 10 psi, the smallest pore intruded by mercury was ~9 μm in radius. In the initial porosity determination, a negligible amount of mercury was intruded at pressures of <10 psi when compared to the total amount intruded. However, at the 2- and 4-week determinations, the amount of mercury intruded into pores ~≥9 μm in radius amounted to ~50% of the total mercury intrusion. In addition, the 2- and 4-week determinations revealed a greater total amount of mercury intruded compared to the initial determination. This finding indicates that as the tablet is exposed to the relative humidity of the storage condition, the pore structure of the tablet increases in total

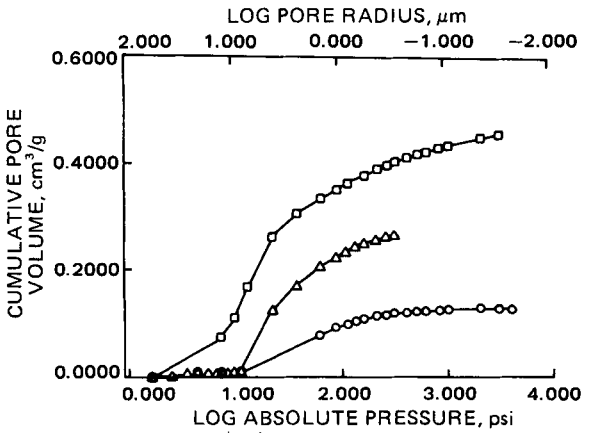

Figure 14—*Cumulative pore volume of the glutaric acid–sodium bicarbonate tablet in the 75% RH, 25° storage condition. Key: ○, initial (0 week); △, 2 weeks of storage; and □, 4 weeks of storage.*

[10] Although mercury intrusion measurements were made up through 15,000 psi, there was no significant intrusion beyond 4000 psi, and the mercury intrusion data plots are therefore not plotted beyond 4000 psi.

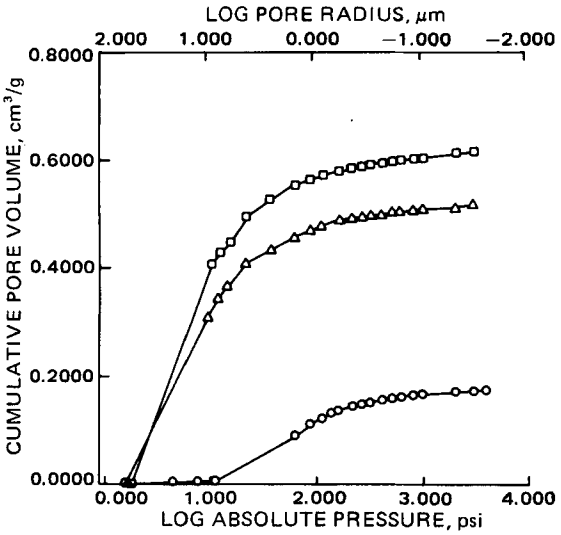

Figure 15—*Cumulative pore volume of Tablet E in the 75% RH, 25° storage condition. Key:* ○, *initial (0 week);* △, *2 weeks of storage; and* □, *4 weeks of storage.*

volume and the larger pores become a larger part of the pore-size distribution.

The use of the PPGTER values as a porosity indicator is supported by the distribution plots (Figs. 11–15). Tablets with storage time and storage condition combinations that produced large PPGTER values show up in the plots as having increased total mercury intrusion, with the distribution shifted toward the large pore sizes. For example, the $J \times M$ interaction in the PPGTER analysis in Fig. 6 shows that the glutaric acid–sodium bicarbonate and Tablet E had very high PPGTER values after 2 and 4 weeks. Figures 14 and 15 dramatically show the shift to larger pore sizes and the increased total mercury intrusion volume.

With the mercury intrusion plots, the differences in tablet pore structure caused by the different storage conditions for the standard, sodium glycine carbonate, glutaric acid, and sponsor composition tablets can be visualized as well as the stability of the sodium dihydrogen citrate composition tablet. Some resistance to higher humidity storage can be seen in the glutaric acid tablet (Fig. 14), supporting the earlier I_R data, in that a dramatic shift in pore distribution to large pore sizes occurred at the 4-week point and not at the 2-week point, as was seen with some other formulations (Figs. 11, 12, and 15).

SUMMARY

1. Mercury intrusion porosimetry was shown to be a useful tool in helping to elucidate pore structure changes in effervescent tablets.

2. The use of the index of reactivity (I_R) proved to be a successful indicator of effervescent tablet reactivity, combining both the amount of carbon dioxide generation and the reaction rate of the effervescent reaction.

3. The stability study of the selected experimental effervescent systems appeared to show that the manufacturing condition factor had little effect on the stability of the effervescent tablets studied, including the standard tablet of citric acid–sodium bicarbonate, which is well known as being sensitive to manufacturing conditions. This lack of effect on the standard tablet could be due to the materials used to make the tablets not having been exposed to the different manufacturing conditions long enough to influence stability significantly.

4. Statistical analysis did not demonstrate a statistically significant compression pressure factor (K). The stability of effervescent tablets apparently was not affected by the pressure at which the tablets were manufactured.

5. The study of effervescent systems showed that the stability of the effervescent tablet was dependent on the tablet formulation, storage conditions, and length of time the tablet was stored.

6. The citric acid–sodium glycine carbonate tablet appears to have better reaction properties and reaction property stability than does the standard citric acid–sodium bicarbonate tablet. The sodium dihydrogen citrate–sodium bicarbonate tablet appears to be inferior in reaction properties and reaction property stability to the standard tablet. However, the sodium dihydrogen citrate composition tablet was the only system to retain high W_F values in the 75% RH storage condition (Fig. 8), although its reaction rate (K) was lower than the other tablets and did decrease with time (Fig. 10).

Prediction of Stability in Pharmaceutical Preparations XIX: Stability Evaluation and Bioanalysis of Clofibric Acid Esters by High-Pressure Liquid Chromatography

EDWARD R. GARRETT [x] **and MICHAEL R. GARDNER**

Received February 9, 1981, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication April 9, 1981.

Abstract □ Specific, sensitive, reversed-phase high-pressure liquid chromatographic assays of clofibric acid esters, clofibrate and etofibrate, and their hydrolysis products, clofibric acid and its monoglycolate and nicotinic acid and its monoglycolate, have been developed in aqueous solution and in biological fluids. Sensitivities of 100 ng/ml of injected mobile phase, a 10-fold increase over existing methods, are reported. Plasma concentrations as low as 200 ng/ml can be analyzed easily in the miscible phase after acetonitrile denaturation. The compounds and their products can be extracted with haloalkane solvents. The extracts were evaporated, reconstituted, and assayed in minimal amounts of mobile phase, resulting in sensitivities of 10 ng/ml of plasma. Conditions are presented that minimize interferences with plasma components. The assay was used to determine the stability of the clofibric acid esters in aqueous solutions, to establish log k–pH profiles at various temperatures, and to evaluate Arrhenius parameters. Hydrolysis was by specific acid–base catalysis. The initial product of etofibrate solvolysis at pH > 6 is the monoglycol ester of clofibric acid; at pH < 3, it is the monoglycol ester of nicotinic acid. Clofibric acid esters are highly unstable to mild alkali (1–3 hr at pH 10 and 30°); even in the estimated pH range of maximum stability, they have half-lives of 100–200 days at 30°. They have half-lives of 4–7 min at 37.5° in fresh dog plasma, and data presented indicate that clofibric acid monoglycolate is an inital product of etofibrate solvolysis.

Keyphrases □ Clofibric acid—esters, stability evaluation and bioanalysis by high-pressure liquid chromatography □ High-pressure liquid chromatography—stability evaluation and bioanalysis of clofibric acid esters □ Stability—prediction and bioanalysis using high-pressure liquid chromatography, clofibric acid esters

The pharmacokinetics of clofibrate, the ethyl ester of clofibric acid, a drug that decreases cholesterol and triglyceride levels (1–4), has not been reported. Only the derived clofibric acid (Scheme I), presumably the only observable material in plasma from clofibrate administration, has been monitored in plasma and urine.

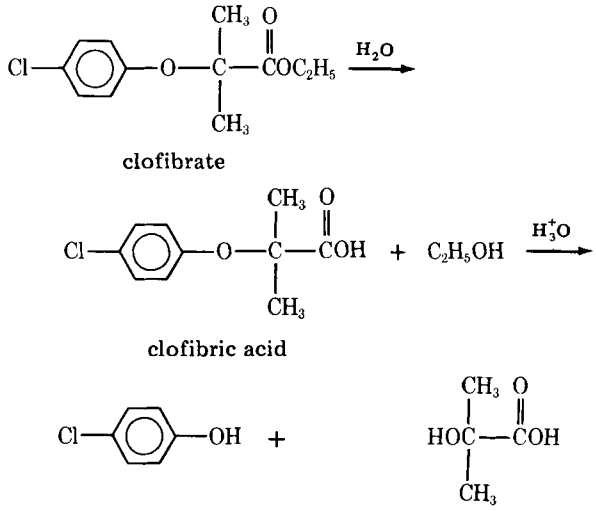
BACKGROUND

Thorp (1) stated that clofibrate was rapidly hydrolyzed by tissue and serum to clofibric acid. His assay was of low sensitivity and was based on spectrophotometric determination in dilute alkali of p-chlorophenol. Subsequent authors (5–7) stated that clofibrate was rapidly hydrolyzed during or after absorption.

GLC assays of clofibric acid have shown sensitivities of 1 μg/ml of plasma (8–10). Recently, a GLC method was proposed (11) for the simultaneous assay of clofibric acid and clofibrate with a sensitivity limit of 10 μg/ml. It was proposed that sensitivity could be increased to 1 μg/ml by evaporation and reconstitution in less solvent.

An evaluation of potential toxicity of the clofibric acid product of clofibrate led to temporary withdrawal of clofibrate from the market in 1979 (12). This fact renewed interest in other clofibric acid esters such as etofibrate (Scheme II), a glycol diester of clofibric acid and nicotinic acid, another hypolipidemic agent. It was postulated that efficacy could be effected through the intact molecule or the monoglycolate esters rather than through the biohydrolytic release of clofibric acid, the presumed source of the adverse reaction (12, 13).

Differences in hypolipidemic effects between clofibrate and etofibrate and possible differences in their rates of clofibric acid release *in vivo* had been discerned (12). The monoester products of microsomal transformations (Scheme II) and their etofibrate precursor were characterized by TLC, GLC, and mass spectroscopy (12), and studies were conducted on their stabilities to GI and blood esterases (13).



Scheme I—Hydrolysis of clofibrate.

This paper presents specific and simultaneous assays of clofibrate, clofibric acid, and etofibrate and its monoesters (Schemes I and II). The high-pressure liquid chromatographic (HPLC) and extracting techniques developed resulted in sensitivities of 10 ng/ml of plasma, a 100-fold increase over existing methods. The determination of the partitioning of these compounds into organic solvents as a function of pH permitted optimal extraction conditions. The methods were applied to the determination of the log k–pH stability profiles of the clofibric acid esters and their stabilities in plasma. Optimum conditions were established for their assays in biological fluids where transformations during storage and analysis did not occur.

EXPERIMENTAL

Materials—The following analytical grade materials were used: di-[1] and monobasic sodium[2] and potassium[3] phosphates, anhydrous sodium acetate[2], acetic acid[2], volume concentrates of sodium hydroxide and hydrochloric acid[4], boric acid[1], ACS methylene chloride[5], and GLC, TLC, and UV grade chloroform and acetonitrilie[6]. Pure (GLC and TLC) clofibrate, etofibrate, clofibric acid, nicotinic acid, and clofibric acid monoglycolate reference standards[7] were used as received. The nicotinic acid monoglycolate[7] contained 5% glycol dinicotinate by TLC and GLC since further purification by distillation was not possible. The monoester

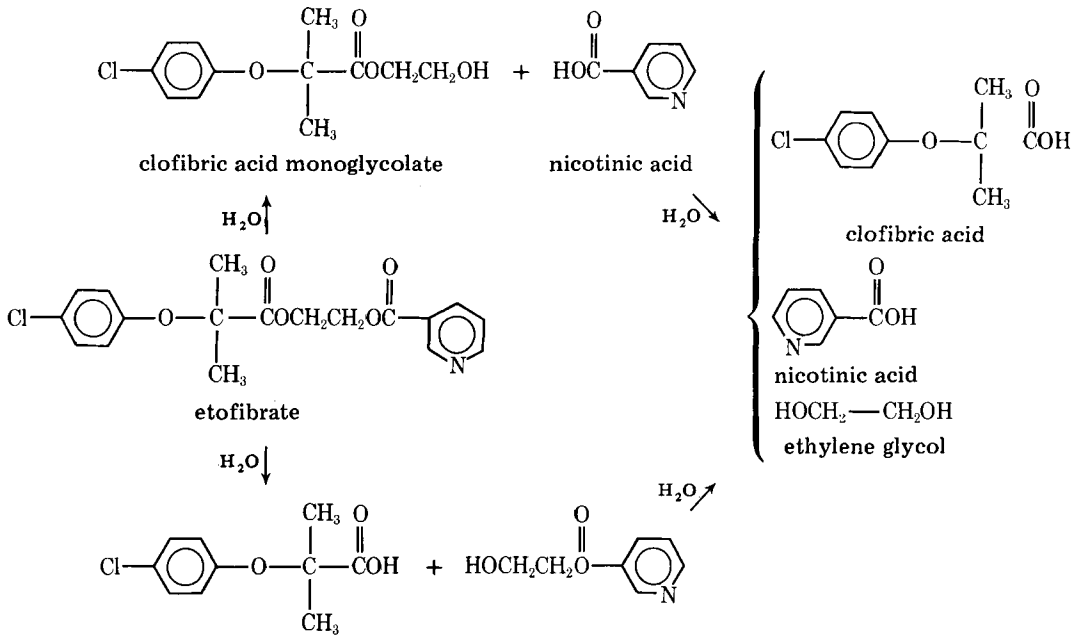

Scheme II—Pathways of etofibrate hydrolysis.

is thermolabile, and considerable transesterification takes place at distillation temperatures.

Apparatus—A high-pressure liquid chromatograph[8] equipped with a variable wavelength UV detector[8] was used with a reversed-phase alkylphenyl column[9] and a radial compression C_{18} reversed-phase column[10]. A guard column[11] was used. Areas under the chromatogram peaks were measured by an integrator[12].

HPLC Procedures—Prepared buffer solutions of sodium acetate of known molarity were adjusted to a measured pH with acetic acid and filtered through a 0.45-μm filter. Solutions were generally 0.10 or 0.05 *M* and were adjusted to pH 3.74 or 3.5, respectively. The mobile phases were mixtures of this buffer and acetonitrile or methanol. Their composition and the HPLC conditions and retention times of various substances are given in Table I. The mixed mobile phase was degassed under vacuum with simultaneous ultrasonication for 1 min.

The variable-wavelength detector was adjusted to 225 nm for the simultaneous analysis of clofibrate and clofibric acid or of etofibrate, clofibric acid monoglycolate, and clofibric acid. The maximum absorbance of clofibrate and clofibric acid was 223.5 nm with a weak absorbance maximum at 277 nm and a negligible absorbance at 254 nm in water. The detector was set in the 263–268-nm range for the simultaneous analysis of nicotinic acid and nicotinic acid monoglycolate where the solvent peaks had less interference than at 225 nm. Both nicotinic acid and its monoglycolate had maximum absorbances at 263 and 225 (or less) nm in mobile phase III with a minimal absorbance at 238 nm.

Solubilities of Clofibric Acid Esters—Plots of the spectrophotometric absorbance of clofibrate in water at its λ_{max} of 223.5 nm against molecular concentration at room temperature showed an initial straight line through the origin of slope 1138, the molar absorptivity. Absorbance at higher concentrations was characterized by a line of slope 67.4 and an intercept of 0.42 absorbance. These two straight line segments intersected at a clofibrate concentration of 4.0×10^{-4} *M*, which was the solubility of clofibrate in water at room temperature. A previously reported (13) solubility was 0.004% (1.65×10^{-4} *M*) at 22° in pH 7.4 phosphate buffer.

Etofibrate (1 mg) was added to 10 ml of various solutions in the pH 1–11 range (theoretically 2.75×10^{-4} *M*). The solutions were vortexed and filtered in a 0.45-μm syringe system. An aliquot (1.00 ml) of the filtrate was diluted to 3.00 ml with acetonitrile that was 1.69×10^{-4} *M* in the internal standard, thymol. A 25-μl aliquot was injected onto HPLC System III (Table I), and the etofibrate concentration was determined from a prepared calibration curve, concentration *versus* peak height ratio, of etofibrate to thymol.

At room temperature, the solubility of etofibrate, pKa 6.41 (12), at pH values ≥ 4 was 2.0×10^{-5} *M* with solubilities of 3.8×10^{-5} *M* at pH 3, 1.99×10^{-4} at pH 2, and $> 2.5 \times 10^{-4}$ *M* at pH 1. A previously reported (13) solubility was 0.002% (5.5×10^{-5} *M*) at 22° in pH 7.4 phosphate buffer. Thus, the best procedure in alkaline stability studies at 20–30° was to add pH 2 solutions of etofibrate to the reaction solutions at the higher pH values so that the final concentration was $\sim 10^{-5}$ *M* in etofibrate.

The solubility of clofibric acid monoglycolate was reported previously (13) as 0.4% (0.0155 *M*) in pH 7.4 phosphate buffer.

Hydrolysis Kinetics—Weighted amounts of clofibrate, sufficient to give $1.4–3.8 \times 10^{-4}$ *M* clofibrate solvents in 10 ml of solvent or $2.9–3.3 \times 10^{-4}$ *M* etofibrate in 20 ml of hydrochloric acid, were dissolved with vortexing in buffer thermally preequilibrated at the reaction temperature. Aliquots (50 and 200 μl for clofibrate and etofibrate acid solvolysis, respectively) were taken at timed intervals and mixed with reaction-quenching solution (50 and 400 μl for clofibrate and etofibrate acid solvolysis studies, respectively), which contained the internal standard, morphine sulfate for clofibrate studies and thymol for etofibrate. The quenching solution had sufficient hydrochloric acid or sodium hydroxide and acetate buffer solution to adjust the final pH of the quenched solution to the 4–5 range of high stability.

Either a 25% methanol concentration in, or mobile phase composition of, the quenched solution of the clofibrate solvolysis studies gave a finer separation of the solvent front from clofibric acid in the chromatogram of System I (Table I). The quenched solution for all etofibrate studies in acid solution always had the same composition as the mobile phase and was injected onto System III. In these clofibrate studies, the total concentrations of clofibric acid and clofibrate in the assayed quenched solutions were $0.7–2.0 \times 10^{-4}$ and $2–5 \times 10^{-5}$ *M* in morphine, respectively. The total concentration of etofibrate and its acid solvolysis products was 1×10^{-4} *M* in the assayed quenched solution and 1.75×10^{-4} *M* in thymol.

The samples were tightly capped and kept refrigerated until inserted in the automatic injector to inject 25 μl. Some fast reaction studies in the alkaline range were effected by vigorous mixing, for a few seconds, 5 ml of thermally preequilibrated stock solutions of clofibrate with 5 ml of thermally equilibrated sodium hydroxide of twice the concentration desired in the final reacting mixture to be maintained in the constant-temperature bath.

System II (Table I) was used for the clofibrate solvolysis studies in borate buffer (pH 9–10 at 60°) and in 0.01, 0.03, and 0.06 *N* NaOH at 30° and for all other solvolysis studies for etofibrate that were not done in acid. The quenching solutions were prepared from concentrated buffer solutions and acetonitrile so that the solvent compositions of the quenched solutions to be injected approached those of the mobile phases.

[a] Additional studies were performed for clofibric acid using the alkylphenyl column. The systems all had plasma interferences with clofibric acid and were, with (parenthetical) retention times (minutes) of clofibric acid: 50:50 acetonitrile–0.1 *N* acetate, pH 7 (1.8); 40:60 acetonitrile–0.1 *N* acetate, pH 3.75 (4.21); 50:50 methanol–0.1 *N* acetate, pH 3.75 (5.62); and 50:50 methanol–0.1 *N* acetate, pH 7.0 (3.36), with plasma interferences at 2.49, 3.47, 4.03, and 7.08 min. Some separation was effected with 40:60 methanol–0.1 *N* acetate, pH 3.75 (8.97) with plasma peaks at 4.81, 5.83, and 7.56 min. System IV gave the best separation of clofibric acid and plasma peaks that interfered with the peak for morphine. [b] Nicotinic acid and nicotinic acid monoglycolate were better separated on the RCM 100 C_{18} column with 35:65 acetonitrile–0.05 *N* acetate, pH 3.5, with retention times of 0.60 (NA), 1.00 (NAG), 2.50 (CA), and 3.25 min (CAG) where ETO and thymol hung up on the column. [c] All peaks were detected spectrophotometrically at 225 nm, except that NAG and NA were detected at 266 nm. [d] Fifty microliters were injected into Systems II and V–VII; 25 μl was used in the other systems.

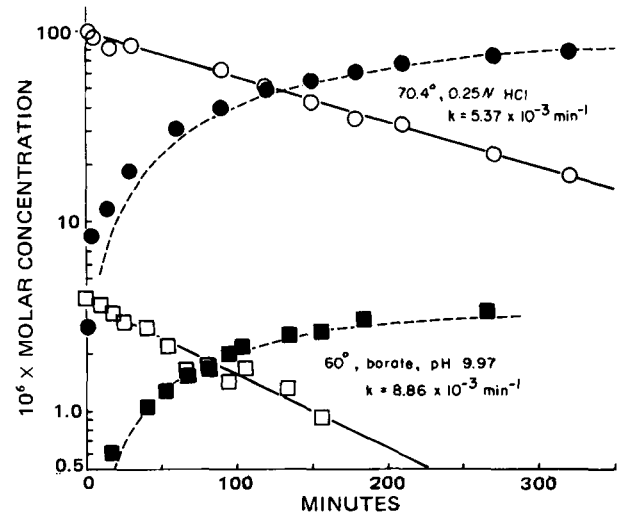

Figure 3—*Semilogarithmic plots of clofibrate (solid line) and clofibric acid (dashed line) concentrations* versus *time for solvolyses in the acidic (System I) and buffered regions (System II). The samples were injected in pH 4–5 mobile phase. The clofibric acid concentrations were fitted to [clofibric acid] = C_∞ (1 − e^{-kt}), where C_∞ is the clofibric acid concentration formed at infinite time and* k *(Table III) is the apparent first-order rate constant for the first-order degradation of clofibrate.*

This procedure minimized negative injection peaks.

In these clofibrate studies, the total concentrations of clofibrate and clofibric acid in the degrading and quenched solutions were 6.91 and 3.46 × 10^{-4} *M*, respectively. The maximum concentrations of etofibrate and its solvolysis products in the degrading solutions at higher temperature and in the quenched solution were 4 and 1 × 10^{-5} *M*, respectively. Etofibrate was maintained in solution under these conditions.

Calibration curves, usually at 1.0–40 × 10^{-5} *M* clofibrate (Systems I and III) or 0.1–1.25 × 10^{-5} *M* clofibrate (System II), were constructed with appropriate amounts of concentrated stock solutions of clofibrate, clofibric acid, etofibrate, clofibric acid monoglycolate, nicotinic acid monoglycolate in acetonitrile, nicotinic acid in pH 5 acetate buffer, and either thymol (acetonitrile) or morphine sulfate (aqueous as internal standards in 2 ml of mobile phase. Either 25 or 50 μl was injected onto the HPLC systems (Table II).

Buffer Solutions for Solvolyses Studies—Phosphate buffers were prepared by mixing 0.10 *N* (for clofibrate solvolyses) and 0.05 *N* (for etofibrate solvolyses) mono- and dibasic potassium phosphate to obtain the desired pH. Borate buffers were prepared by mixing 0.10 or 0.05 *N* boric acid and sodium borate, or by mixing 0.025 *N* boric acid with concentrated sodium hydroxide to an appropriate pH. Appropriate amounts of sodium chloride were added to maintain 0.1 ionic strengths.

The pH meter was standardized at the reaction temperature with two standard buffers with known pH values at that temperature that straddled the pH of the desired reaction solution. The pH values of the prepared buffered solutions were read at the reaction temperature.

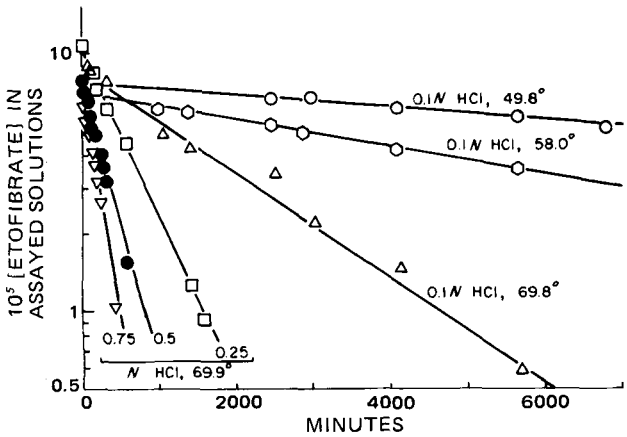

Figure 4—*First-order plots of etofibrate concentrations in hydrochloric acid* versus *time. The reacting solutions before dilution for injection on System III and pH 4–5 mobile phase were 2.9–3.3* × 10^{-4} M.

Partition Studies as Functions of pH—Solutions of 1.25 × 10^{-5} *M* clofibric acid and clofibrate, separate and in combination, were prepared in 0.1 and 0.01 *N* HCl, in 0.1 *N* acetate buffer adjusted to pH 3.0, 4.0, and 5.0, and in 0.1 *N* phosphate buffer adjusted to pH 6.0 and 7.0. Aliquots (2 ml) were extracted with 2 ml of methylene chloride with 5 min of mild shaking. After centrifugation for 5 min, the aqueous layer was removed by aspiration. Then 1 ml of the organic layer was evaporated under nitrogen in a reaction vial and reconstituted in 100 μl of acetonitrile–water containing morphine sulfate (3.13 × 10^{-5} *M*) as an internal standard; 25 μl was injected onto the HPLC system with mobile phase I (Table I).

The quantity extracted was determined from a calibration curve (Table II). Clofibric acid was extracted 102 ± 5% at pH 1–4, 60% at pH 5, 16% at pH 6, and 0 and 0.3% at pH 7.0 when alone and admixed with clofibrate. Clofibrate was extracted 85 ± 3% over this pH range with no significant effects when alone; but when combined with clofibric acid, it showed only 20% extraction.

When 1.00 ml of pH 2.5 aqueous solution containing 1.25 × 10^{-5} *M* clofibric acid and clofibrate was extracted with 4 ml of methylene chloride, analysis revealed that 104 ± 4% of the clofibric acid and 57 ± 2% of the clofibrate were extracted. When 1.00 ml of plasma adjusted to pH 2.5 was used, there was an interference of the plasma with the clofibric acid peak, but the recovery of clofibrate was similar.

When the same procedure was used on spiked pH 2.5 aqueous solution with chloroform as the extracting solvent, 78 ± 3% of the clofibrate and 95 ± 2% of the clofibric acid were extracted. From pH 2.5 plasma, 89% of the clofibrate was extracted, whereas the plasma impurity interfered with the clofibric acid assay.

Similar studies were made on 2 ml of buffer solutions that were 5.56 × 10^{-6} *M* each in etofibrate and clofibric acid and its monoglycolate at unit pH intervals of 1–10. Each buffer solution was extracted with 3 ml of methylene chloride by shaking for 10 min, aspirating off the aqueous phase, and evaporating under nitrogen 2 ml of the methylene chloride layer. The residue was reconstituted in 500 μl of mobile phase that was 1.50 × 10^{-5} *M* in the compounds and 1.63 × 10^{-5} *M* in thymol. A 50-μl aliquot was injected using System II. All of the etofibrate and clofibric acid monoglycolate was extracted at pH 2–10, with 77% of the etofibrate extracted at pH 1.0. The clofibric acid extraction was 97–100% at pH 1–4, 69.5% at pH 5, 20.3% at pH 6, and negligible at pH ≥7.

Assays of Clofibrate and Clofibric Acid in Plasma—*Procedure A: Acetonitrile Deproteinization of Plasma*—Acetonitrile (0.5 or 1.0 ml) was added to an equal volume of human or dog plasma. The mixture was vortexed and centrifuged for 10 min at 3000 rpm; the internal standard morphine sulfate was added to the supernate, and 25 μl was injected in System I (Fig. 1A) or III (Table I). The latter system adequately, but not completely, separated the peak of a plasma impurity and clofibric acid in this procedure (Fig. 1B) but gave a good calibration curve for both (Study F, Table II) at plasma concentrations of 5.0–40 × 10^{-5} *M*. When such acetonitrile-denatured plasma was stored overnight and reassayed,

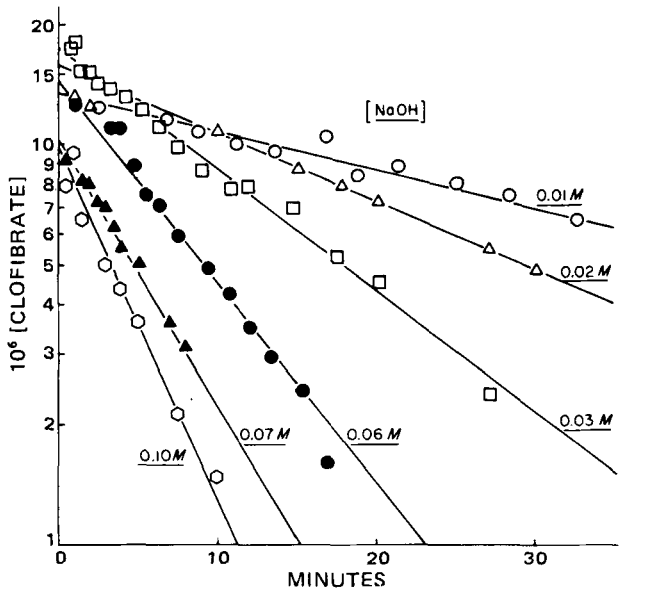

Figure 5—*First-order plots of clofibrate concentrations* versus *time at 30° in various concentrations of sodium hydroxide (System I at 0.02, 0.07, and 0.10* M *NaOH and System II at 0.01, 0.03, and 0.06* M *NaOH).*

Table II—Typical Statistics[a] of HPLC Assays of Clofibrate (CF), Clofibric Acid (CA), Clofibric Acid Monoglycolate (CAG), Etofibrate (ETO), Nicotinic Acid Monoglycolate (NAG), and Nicotinic Acid (NA) in Accordance with $10^5\ C \pm s_{10^5 c.x} = (m \pm s_m)X + b \pm s_b$

[a] The concentrations, C, of clofibrate and clofibric acid are the molarities injected into the mobile phase except for Studies F and G. Regressions were performed on $10^5 \times C$. The constants m and b are the slope and intercept, respectively, where $s_{10^5 c.x}$, s_m, and s_b are the standard errors of estimate (14) of $10^5 \times$ concentration on the measured parameter of the slope and intercept, respectively. The dependent variables, X, are the parameters of measurement, *i.e.*, peak height (PH), $10^{-3} \times$ peak area (PA), peak height ratio to that of the internal standard (PHR), and peak area ratio to that of the internal standard (PAR). The values of n and r^2 are the numbers of data pairs and the square of the correlation coefficient, respectively. [b] The internal standard was $5.9 \times 10^{-5}\ M$ morphine sulfate in the injected solutions of Studies A, B, and F; $1.625 \times 10^{-5}\ M$ thymol in Studies C, D, and H; and $1.75 \times 10^{-4}\ M$ thymol in Study E. [c] For $0.93xxx$. [d] For $0.97xxx$. [e] Concentration in original plasma diluted 1:1 with acetonitrile and supernate injected. [f] Concentration in original plasma that was extracted and evaporated, with the residue reconstituted in 100 μl of mobile phase before injection. [g] Plasma components interfered with the peak of morphine. [h] Concentration in original plasma (outdated human) that was diluted 1:2 with acetonitrile and the supernate injected. [i] For $0.98xxx$. [j] Concentration in original dog plasma diluted 1:3 with acetonitrile and the supernate injected. Both Studies I and J were effected on same spiked plasma studies.

the peak height ratios to the internal standard did not change significantly, although the clofibric acid–plasma peak interference was more pronounced.

Clofibric acid concentrations were best determined by injecting another aliquot into System IV (Table I and Fig. 1C), although plasma components did interfere with the morphine sulfate peak.

Procedure B: Chloroform Extraction of Plasma—Plasma (0.5 or 1.0 ml) was extracted with 4 ml of chloroform with mild shaking for 10 min and was centrifuged for 10 min at 3000 rpm. The aqueous layer was aspirated, and 2 or 3 ml of chloroform was evaporated to dryness and reconstituted in 100 μl of mobile phase containing morphine sulfate as the internal standard. This procedure is more sensitive than Procedure A. Aliquots can be injected into Systems I–III for clofibrate assay (Fig. 1A) and into System IV, where plasma interferences are minimized, for clofibric acid assay (Fig. 1C and Study G, Table II).

Assays of Etofibrate and Its Solvolytic Products in Plasma—*Procedure C: Acetonitrile Deproteinization of Plasma*—Acetonitrile, with or without internal standard thymol, was added to 0.5, 1, or 2 ml of

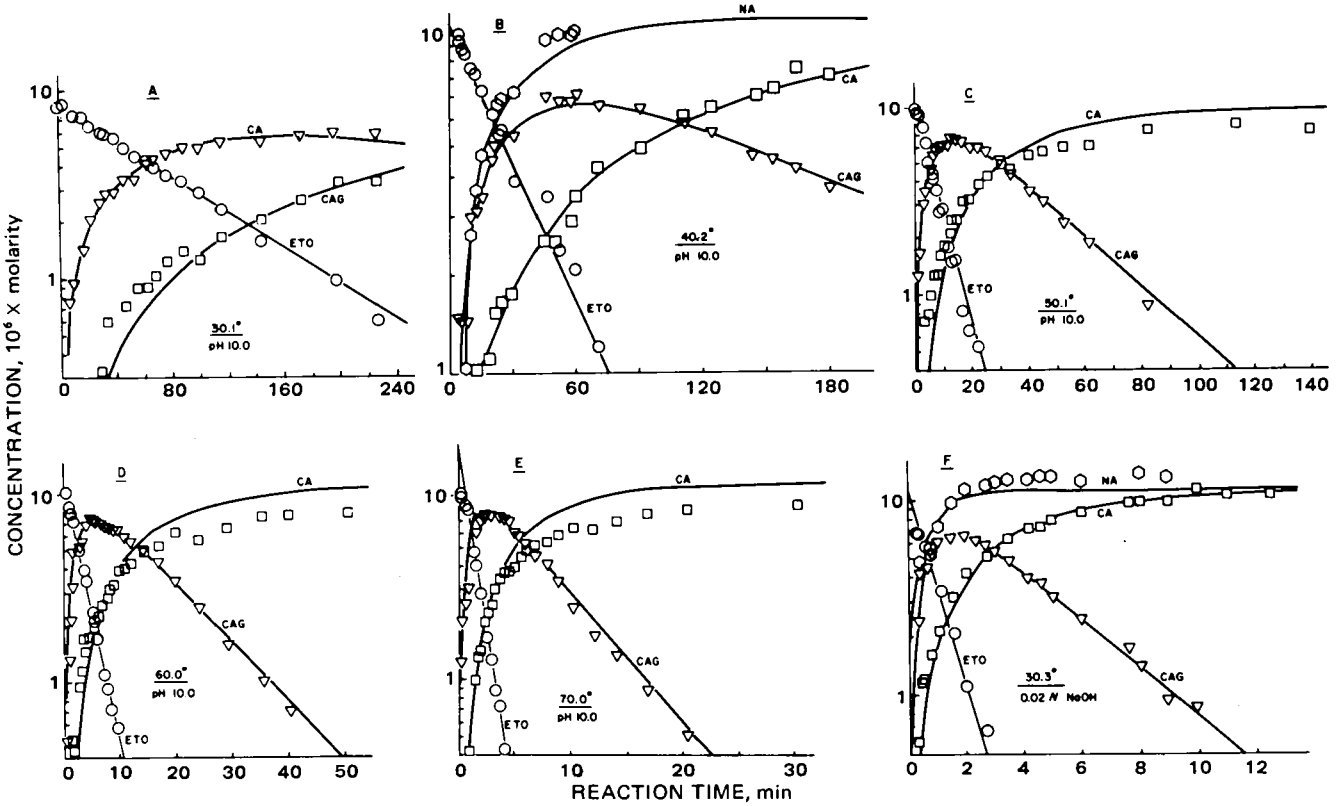

Figure 6—*Semilogarithmic plots of assayed concentrations of etofibrate (ETO), clofibric acid monoglycolate (CAG), clofibric acid (CA), and nicotinic acid (NA)* versus *time for etofibrate degradation in borate buffers and sodium hydroxide. The lines through the CAG, CA, and NA values were calculated from the kinetic parameters given in Table IV.*

human or dog plasma in 1:1, 2:1, 3:2, or 3:1 ratios. The mixture was vortexted and centrifuged for 10 min at 3000 rpm, and an aliquot was injected into Systems II, V, or VI (Table I). At 1:1 and 1:2 mixture ratios, Systems II and VI gave minimal or negligible plasma peak interferences with etofibrate, clofibric acid monoglycolate, and thymol (Fig. 1E) but significant interferences with clofibric acid in fresh dog plasma (Fig. 1E and Study I, Table II). Good calibration curves were established for clofibric acid in outdated human plasma (Fig. 1F and Study H, Table II) at plasma concentrations of $0.4–5.0 \times 10^{-5}$ *M*. Plasma constituents had retention times similar to those of nicotinic acid and nicotinic acid monoglycolate in these systems and thus interfered with their assay.

Clofibric acid in plasma was best assayed separately in System IV (Fig. 1C), V, or VII (Fig. 1G and Study J, Table II) where it was well separated from plasma interferences, although etofibrate was held on the column. The last system could also assay for clofibric acid monoglycolate. Etofibrate-spiked plasma ($1.28 \times 10^{-}$ *M*) diluted 1:2 with acetonitrile showed no change in the etofibrate peak for more than 24 hr.

Procedure D: Methylene Chloride Extraction of Plasma—Plasma (1.0 ml) was adjusted to pH 2.5 with 125 μl of 1 *N* HCl with vortexing, extracted with 3 ml of methylene chloride, shaken at low speed for 10 min, and centrifuged for 10 min at 3000 rpm. The aqueous protein phase was aspirated and discarded. An aliquot of the methylene chloride layer (1.00 ml) was evaporated under nitrogen at room temperature and reconstituted in mobile phase that was 1.625×10^{-5} *M* in thymol, and an aliquot was injected onto System VI. This system assayed for etofibrate and clofibric acid monoglycolate (Fig. 1D) but had plasma peak interferences with the other solvolytic products of etofibrate. Clofibric acid could be assayed by injection of an aliquot into System IV (Fig. 1C), V, and possibly VII (Fig. 1G) where plasma interferences with clofibric acid peaks were minimal.

Clofibric acid could be assayed to 5×10^{-6} *M* concentrations in plasmas by reextracting 1 ml of methylene chloride into 1.00 ml of pH aqueous buffer with System VI.

RESULTS AND DISCUSSION

Reversed-Phase HPLC Assays of Clofibric Acid Esters and Their Products for Degradation Studies—HPLC Systems I–III were used for clofibric acid esters and their degradation products. Typical chromatograms (Studies A–C and F of Table II) are given in Figs. 2A–2G. The aliquots of degrading solutions taken with time were neutralized to the relatively stable region of pH 4–5. The quenched solution had the same composition as the mobile phase used. Morphine sulfate or thymol, added in the quenching solution, were internal standards.

Calibration curves of concentration against peak height, peak areas, and their ratios to the respective parameters of the internal standard showed excellent linear regressions (Table II). In general, it could not be concluded that one measured parameter was significantly better than another.

The standard errors of estimation (14) of clofibrate and clofibric acid concentrations were $\sim 0.6 \times 10^{-5}$ *M* (1.46 μg/ml) and 0.3×10^{-5} *M* (0.64 μg/ml), respectively, for calibration curves prepared with System I (Study A of Table III) in the $2.5–40 \times 10^{-5}$ *M* range (5–100 μg/ml) and indicated analytical sensitivities of 1–3 μg/ml. The standard errors of estimation of concentration of etofibrate and its degradation products were $\sim 0.30 \times 10^{-5}$ *M* (1.0 μg/ml) for calibration curves prepared with System III (Study E of Table II) in the $1–12.5 \times 10^{-5}$ *M* range (3.6–45 μg/ml of etofibrate) and indicated analytical sensitivities of 2.0 μg/ml.

The radial compression systems gave sharper peaks, lessened retention time, and heightened sensitivities for clofibrate, etofibrate, and their degradation products in Systems II and V–VII (Table I) when injected in the mobile phase. The standard errors of estimation of concentrations were $1–2 \times 10^{-7}$ *M* for clofibrate (24–48 ng/ml), etofibrate (36–72 ng/ml), and clofibric acid (21–52 ng/ml) and its monoglycolate (26–52 ng/ml) (Studies C and D of Table II with System II and 225 nm detection) for calibration curves in the $1–12.5 \times 10^{-6}$ *M* range (200–2500 ng/ml). Thus, analytical sensitivities of 100 ng/ml were indicated. System VI gave similar results (Fig. 2G). Solvent front interferences with nicotinic acid and nicotinic acid monoglycolate on these systems at 225-nm detection were minimized at 263-nm detection, but sensitivities were 200–400 ng/ml (Study D of Table II and Figs. 1B and 1F).

Decreased acetonitrile and methanol content in the mobile phase with acetate buffer increased the retention times of all components and permitted separation of clofibric acid from plasma components (Table I). The use of methanol in the mobile phase gave higher retention times than acetonitrile and well-separated plasma components and clofibric acid peaks (Fig. 1C).

Reversed-Phase HPLC Assays of Clofibric Acid Esters and Their Solvolytic Products in Plasma—Partition studies showed that clofibrate, etofibrate, and clofibric acid monoglycolate could be well extracted

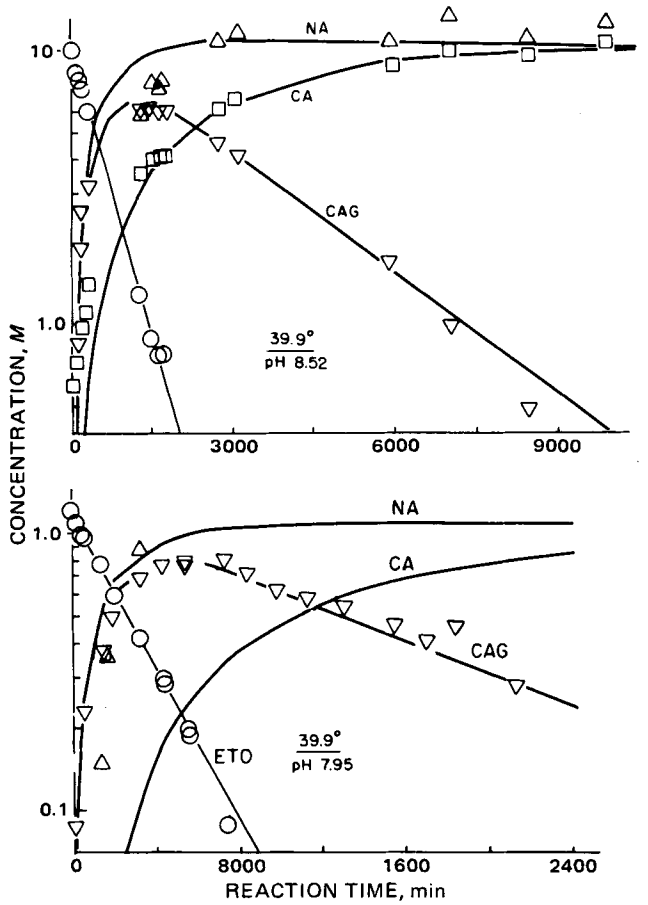

Figure 7—*Semilogarithmic plots of assayed concentrations of etofibrate (ETO), clofibric acid monoglycolate (CAG), clofibric acid (CA), and nicotinic acid (NA)* versus *time for etofibrate degradation in phosphate buffers. The lines through the CAG, CA, and NA values were calculated from the kinetic parameters given in Table IV.*

at a pH > 2 with chloroform or methylene chloride (Procedures B and D). Clofibric acid was completely extracted at pH < 4 and negligible at pH > 7. The haloform extracts could be evaporated to dryness and reconstituted in 100 μl of mobile phase for injection. Assays of clofibrate,

[a] The pH values for sodium hydroxide and hydrochloric acid solutions were calculated from $pH = pK_w + \log f_{NaOH}[NaOH]$ and $pH = -\log f_{HCl}[HCl]$, respectively, from the pK_w values and activity coefficients, f_{NaOH} and f_{HCl}, available in the literature (15) for the designated temperatures. The pK_w values at respective temperatures were: 13.83, 30°; 13.52, 40°; 13.26, 50°; 13.02, 60°; and 12.78, 70°

etofibrate, and clofibric acid monoglycolate could be effected in Systems I (Fig. 1A), II, III, and VI (Fig. 1D and Table I). While the clofibric acid peaks had retention times similar to plasma components in this system, no such interferences occurred with Systems IV (Fig. 1C), V, and VII (Table I). These extraction procedures with reconstitution with System II and V–VII provided assays sensitive to 10 ng/ml of plasma from 1 ml of plasma.

A more facile, but less sensitive assay used acetonitrile deproteinization of plasma (Procedures A and C). The supernate, after addition of acetonitrile to plasma in 1:1, 2:1, 3:2, or 3:1 ratios, was injected directly into the system. The standard error of estimation of clofibrate and clofibric acid concentrations was 1–1.5 × 10^{-5} M (2–3 μg/ml) for calibration curves prepared with System III (Fig. 1B and Study F of Table II) for plasma concentrations of 5–40 × 10^{-5} M (10–100 μg/ml). Analytical sensitivities of 5–6 μg/ml were indicated.

The use of the radial compression systems increased plasma assay sensitivities *via* acetonitrile denaturation (Figs. 1E–1G). The standard errors of estimation of plasma concentrations of etofibrate and clofibric acid and its monoglycolate were 0.5–2 × 10^{-6} M (100–400 ng/ml) for calibration curves prepared with System VI or VII (Studies H–J of Table II) for plasma concentrations in the 4–50 × 10^{-6} M range (0.8–10 μg/ml). Thus, analytical sensitivities of 0.2–0.8 μg/ml were indicated.

Kinetics of Solvolyses—At constant pH, clofibrate and etofibrate degrade by apparent first-order processes. Representative semilogarithmic plots of concentrations *versus* time are given for hydrochloric acid solutions (Figs. 3 and 4), sodium hydroxide solutions (Figs. 5 and 6), borate buffers (Figs. 3 and 6 and Tables III and IV), and phosphate buffers (Fig. 7), where the apparent first-order rate constant, k, was obtained from the slopes in accordance with:

$$\log C = -\frac{kt}{2.303}t + \log C_0 \qquad \text{(Eq. 1)}$$

where C and C_0 are the concentrations at time t and time zero, respectively.

The pH values of the degrading buffer solutions were experimentally determined at the study temperature. The pH values for hydrochloric acid were calculated from

$$pH = -\log \gamma[HCl] \qquad \text{(Eq. 2)}$$

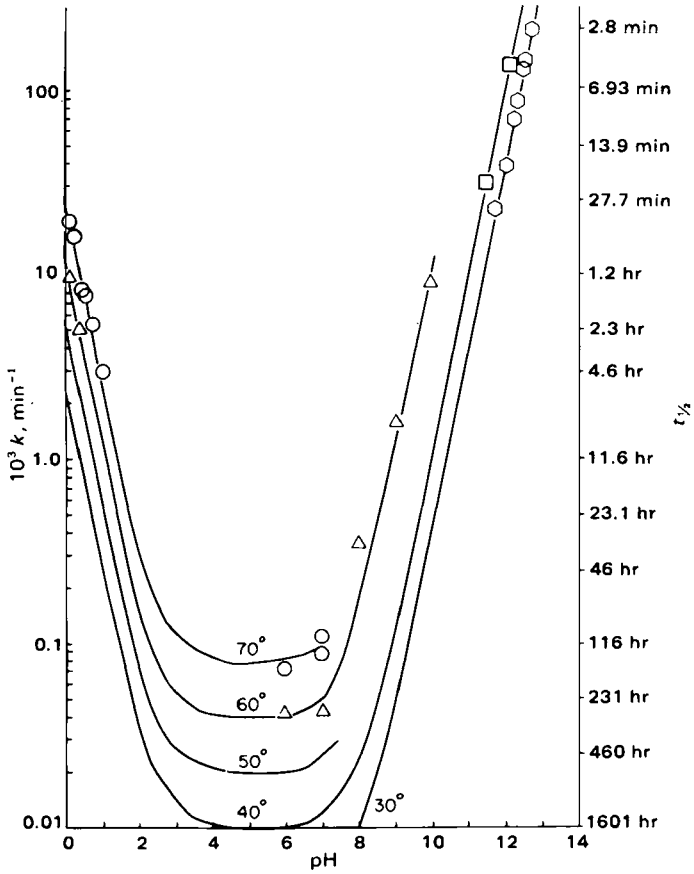

Figure 9—*Fitted log* k–*pH profiles for the hydrolyses of clofibrate at various temperatures. Corresponding half-lives are given on the right.*

where γ is the mean activity coefficient for the hydrochloric acid solution. For sodium hydroxide:

$$pH = pK_w - pOH = pK_w + \log \gamma[NaOH] \qquad \text{(Eq. 3)}$$

where γ is the mean activity coefficient for the sodium hydroxide (15). Values of $pK_w = -\log K_w$ are given in Footnote *f* of Table I; K_w is the hydrolysis constant for water.

The aparent first-order rate constants for clofibrate, etofibrate, or clofibric acid monoglycolate hydrolysis can be characterized in terms of actual concentrations of strong acid or alkali as:

$$k = k_{HCl}[HCl] \qquad \text{(Eq. 4)}$$

and:

$$k = k_{NaOH}[NaOH] \qquad \text{(Eq. 5)}$$

The bimolecular rate constants, k_{HCl} and k_{NaOH}, at various temperatures were obtained from the slopes of plots of k *versus* these concentrations (Table V).

Log *k*–pH Profiles (16) and Solvolysis Routes–When activities of hydrogen, a_H, and hydroxide, a_{OH}, ions are considered as catalytic species:

$$a_H = 10^{-pH} \qquad \text{(Eq. 6)}$$

$$a_{OH} = 10^{-pOH} = 10^{-(pK_w - pH)} \qquad \text{(Eq. 7)}$$

the acid and alkaline branches of the log k–pH profiles (Figs. 9–11) that characterize the attack of hydrogen- and hydroxyl-ion activities, respectively, conform to:

$$\log k = \log k_H - pH \qquad \text{(Eq. 8)}$$

and:

$$\log k = \log k_{OH} + pH - pK_w \qquad \text{(Eq. 9)}$$

The profiles at the temperatures where no studies were made were constructed so as to be consistent with the Arrhenius parameters, ΔH_a and ln P, calculated or determined from the slopes and intercepts of the Arrhenius plots (Fig. 12).

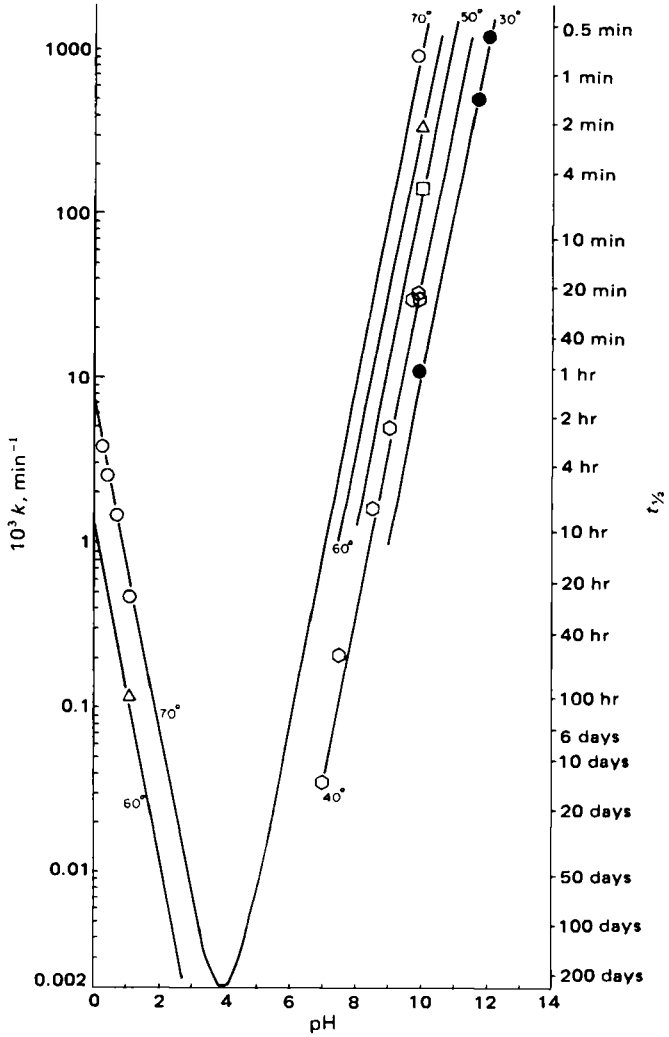

Figure 10—*Fitted log* k–*pH profiles for the hydrolyses of etofibrate at various temperatures. Corresponding half-lives are given on the right.*

The constants are given in Table V and can be used to calculate the apparent first-order rate constant for hydrolysis at any pH and temperature using:

$$k = k_H a_H + k_{OH} a_H + k_0 \qquad \text{(Eq. 10)}$$

when Eqs. 6 and 7 and the Arrhenius equation:

$$\ln k_H \text{ or } \ln k_{OH} = \ln P - \Delta H_a/1.987(1/T) \qquad \text{(Eq. 11)}$$

where T is degrees plus 273° and ΔH_a is in calories per mole, are considered.

A pH-independent component, k_0^{CF}, had to be considered in the case of clofibrate solvolysis (Fig. 9 and Table V) to account for first-order rate constants between pH 6 and 7 that were higher than those predicted from the sum of the extrapolation of the acid and alkaline branches of the clofibrate log k–pH profile.

The predicted minimum in the log k–pH profile for etofibrate (Fig. 10) is probably not exact but should be displaced a few 10ths of a pH unit to the right since etofibrate is protonated in the region of acid solvolysis. In addition, hydrogen-ion attack on a nonprotonated compound would be faster.

Pharmaceutical Significances of Stability Studies—The high solvolytic instability of clofibric acid esters, even in mildly alkaline solutions, requires that the microscopic environment be kept as acidic as possible (pH 4) in the formulation of liquid and solid dosage forms. Alkaline lubricants and excipients should not be used, and granulations should be kept as free of water as possible. Even at 30° and pH 4–6, the half-lives of clofibrate and etofibrate in aqueous solutions are predicted (Figs. 9 and 10) to be 120 and 240–2000 days, respectively; at pH 7, they

[a] Estimates are crude for the hydrolysis of the glycol ester of nicotinic acid since studies were not carried out long enough. [b] The pH values for sodium hydroxide and hydrochloric acid solutions were calculated from $pH = pK_w + \log f_{NaOH}[NaOH]$ and $pH = -\log f_{HCl}[HCl]$, respectively, from the pK_w values and activity coefficients, f_{NaOH} and f_{HCl}, available in the literature (15) for the designated temperatures. [c] Estimated fraction of clofibrate hydrolyzed to the monoglycol ester of clofibric acid where 1 − f is the estimated fraction hydrolyzed to clofibric acid and the monoglycol ester of nicotinic acid.

would be 160 and 20 days, respectively. Thus, these compounds must be assayed immediately and not stored in samples of biological tissues and fluids. Extraction from plasma into haloalkane solvents or mixing plasma with equivalent volumes of acetonitrile can maintain the integrity of the esters for several days prior to assay.

Routes of Solvolyses—The primary product of clofibrate solvolysis is clofibric acid at all pH values (Fig. 3), although *p*-chlorophenol can be generated in strong acidic solutions (Scheme I).

The routes of etofibrate solvolysis differ for the acidic and alkaline regions. The initial products of acid hydrolysis were nicotinic acid monoglycolate and clofibric acid (Scheme II), and no clofibric acid monoglycolate was observed (Fig. 13). The initial products of solvolyses at pH > 7 were nicotinic acid and clofibric acid monoglycolate, and the latter subsequently hydrolyzed to clofibric acid and ethylene glycol (Figs. 6 and 7). No nicotinic acid monoglycolate was observed within the level of analytical sensitivities.

If the products of etofibrate (ETO) solvolyses in the alkaline region are only clofibric acid monoglycolate (CAG) and nicotinic acid (NA) and if no glycol ester of nicotinic acid (NAG) (Scheme II) is generated, then the concentration of clofibric acid monoglycolate may be calculated from the expression (17):

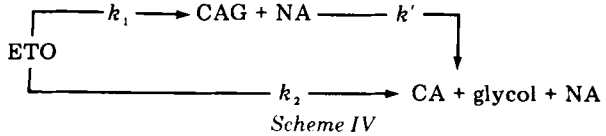
$$[CAG]' = [ETO]_0 \frac{k}{k' - k}(e^{-kt} - e^{-k't}) \qquad \text{(Eq. 12)}$$

where $[ETO]_0$ is the initial etofibrate concentration and $[CAG]'$ is clofibric acid monoglycolate concentration on the presumption that the sole route of hydrolysis is as shown in Scheme III, where k and k' are the apparent first-order rate constants for the sequential hydrolyses.

$$ETO \xrightarrow{k} CAG + NA \xrightarrow{k'} CA + glycol + NA$$

Scheme III

If nicotinic acid monoglycolate is generated but is so low in concentration that it cannot be observed, Scheme IV could be postulated.



Scheme IV

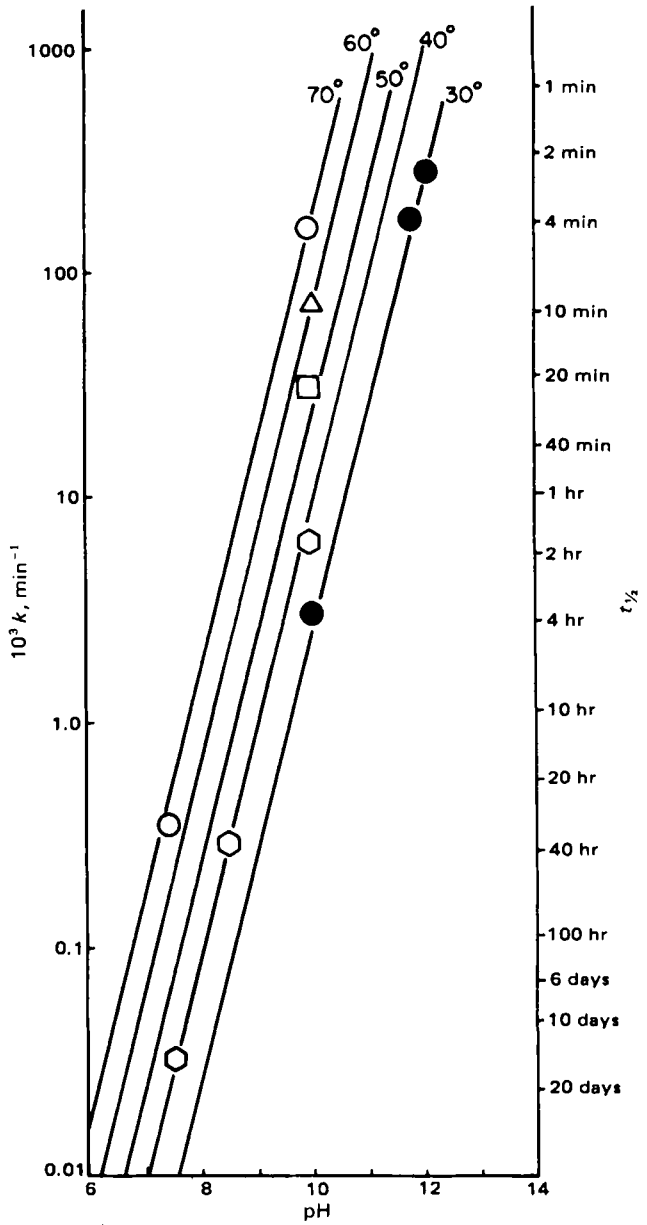


Figure 11—*Fitted log k-pH profiles for the hydrolyses of clofibric acid monoglycolate at various temperatures. Corresponding half-lives are given on the right.*

There is no storage in this form due to its extremely rapid hydrolysis, and $k = k_1 + k_2$ and (18):

$$[CAG] = [ETO]_0 \frac{k_1}{k' - k}(e^{-kt} - e^{-k't})$$

$$= f[ETO]_0 \frac{k}{k' - k}(e^{-kt} - e^{-k't}) \qquad \text{(Eq. 13)}$$

where:

$$f = [CAG]/[CAG'] = k_1/k \qquad \text{(Eq. 14)}$$

This signifies that the ratio, f, of the experimental concentration of clofibric acid monoglycolate to the theoretical concentration, calculated on the premise of no nicotinic acid monoglycolate intermediate, is constant at all specified times.

The apparent first-order rate constant, k', for the solvolysis of clofibric acid monoglycolate could be obtained from the terminal slope of the plots of its generation with time (Figs. 6 and 7) from etofibrate. It was also obtained by the apropriate adjustment of the f and k' values of Eq. 13 that gave the best fit to the time course of generated clofibric acid monoglycolate in Figs. 6 and 7. These values are listed in Table IV and demonstrate that negligible etofibrate is solvolyzed through a nicotinic acid monoglycolate intermediate above a pH of 7. Separate studies of

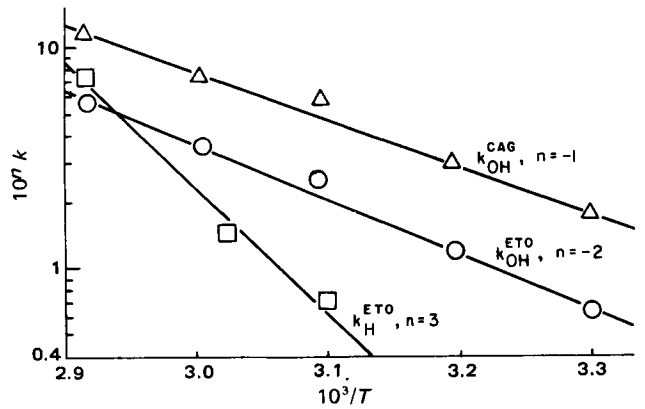

Figure 12—*Arrhenius plots of bimolecular rate constants for the alkaline solvolyses of etofibrate (ETO) and clofibric acid monoglycolate (CAG) and the acid solvolysis of etofibrate (ETO).*

clofibric acid monoglycolate solvolyses at these pH values confirmed the k' values estimated by this procedure. The lines through the concentrations of nicotinic and clofibric acids in Figs. 6 and 7 were drawn in accordance with:

$$[NA] = [ETO]_0 (1 - e^{-k_1 t}) \quad \text{(Eq. 15)}$$

$$[CA] = [ETO]_0 - [ETO] - [CAG] \quad \text{(Eq. 16)}$$

where [CAG] was calculated from Eq. 13.

A similar approach was used to estimate k'', the apparent first-order rate constant at a given pH for the acidic hydrolysis of nicotinic acid monoglycolate (Fig. 13). However, the k'' values given in Table IV are crude estimates since these kinetic studies were not conducted for adequate lengths of time.

Stabilities of Clofibric Acid Esters in Plasma—Clofibrate stability was monitored by HPLC assay in fresh dog plasma. The apparent half-lives of $1–2 \times 10^{-5}$ *M* clofibrate in plasma were 9.75 min at 24° and 4.57 min at 37.6° using Procedure B (Fig. 14). When Procedure A was used for assay of degrading 1.83×10^{-4} *M* clofibrate in fresh plasma at 24.6°, degradation was apparent zero order (7.0×10^{-7} mole/liter/min) and an apparent time for half-degradation was 130 min (curve A of Fig. 15). A similar study by Procedure A, conducted at room temperature, showed a half-degradation time of 125 min for 5.8×10^{-3} *M* clofibrate in fresh plasma. The fact that apparent first-order degradation of clofibrate with an apparent half-life of 10 min at 24° occurs at low concentrations (curve B of Figs. 14 and 15) indicates that the plasma enzymes responsible for clofibrate solvolysis are readily saturated and give slower degradation rates at higher plasma concentrations.

The stability of etofibrate in fresh dog plasma assayed by Procedure C gave apparent half-lives of 4.4 min for 3.6×10^{-5} *M* etofibrate in two separate studies (Fig. 16).

The apparent half-life for an initial plasma concentration of etofibrate ($[ETO]_0 = 5.9 \times 10^{-5}$ *M*), assayed by Procedure D, was 6.9 min ($k = 0.100$ min^{-1}) with an apparent terminal half-life of 11.2 min for clofibric acid monoglycolate solvolyses ($k' = 0.0619$ min^{-1}) (Fig. 16). The maximum peak height ratio of 0.37 for this compound at 10 min corresponded to an approximate concentration of 2.85×10^{-5} *M* clofibric acid monoglycolate. On the assumption that the degradation pathway is solely through clofibric acid monoglycolate (Scheme III), the maximum concentration, $[CAG]_{max}$, can be estimated (17) from:

$$[CAG]_{max} = [ETO]_0 (1/k')(k/k')^{k'/(k'-k)} = 2.7 \times 10^{-5} M \quad \text{(Eq. 17)}$$

The coincidence of this calculated maximum and that experimentally determined provides strong evidence that clofibric acid monogycolate is the primary product of etofibrate solvolysis in plasma.

With Procedure C at 37.5°, 1.19×10^{-4} *M* etofibrate in plasma showed a half-life of 5.7 min ($k = 0.121$ min^{-1}) by the solvolysis route through clofibric acid monoglycolate. The latter had a half-life of 5.8 min (0.119 min^{-1}) when the data were fit as described by Eqs. 13, 14, and 16; $f = 1$ (Fig. 17). Solubility in plasma is expected to be much greater than in buffer due to high protein binding (13). Using Procedure C, clofibric acid monoglycolate, 4.25×10^{-5} *M* in plasma, showed a half-life of 11.5 min (Fig. 17).

Table V—Estimated Kinetic Parameters (16) for the Hydrolyses of Clofibrate (k^{CF}), Etofibrate (k^{ETO}), and the Glycol Esters of Clofibric Acid (k^{CAG}) and Nicotinic Acid (k^{NAG})

[a] These heats of activation (kilocalories per mole) and ln *P* values were obtained from Fig. 12 in accordance with the Arrhenius function $\ln k = \ln P - (\Delta H_a/R)(1/T)$, where $R = 1.987$ cal/degree and ΔH_a is in calories per mole. The values of k_{OH}^{ETO} obtained from the best linear fit of this function were used in the log *k*–pH profile at 50 and 70° and were 210 and 590, respectively. Similarly, the values of k_{OH}^{CAG} at 50° was 47.5. [b] Bimolecular rate constants in liters/mole/min for hydrogen- and hydroxide-ion catalysis obtained from intercepts of the alkaline and acid branches, respectively, of the log k *versus* pH profile (Fig. 9 for clofibrate, Fig. 10 for etofibrate, and Fig. 11 for the monoglycol ester of clofibric acid) where the logarithm of the apparent first-order rate constant for solvolysis is $\log k = \log k_{OH} + pH - pK_w$, where pH is calculated from $pH = pK_w + \log f_{NaOH}[NaOH]$ in the former case, and $\log k = \log k_{aH} - pH$, where $pH = -\log f_{HCl}[HCl]$ in the latter. The pK_w values and activity coefficients, f_{NaOH} and f_{HCl}, were obtained from the literature (15). [c] Estimates of heats of activation (kilocalories per mole) of these rate processes were calculated from $\Delta H_a = 1.987 \times (\ln k_{T_1} - \ln k_{T_2})/[(1/T_2) - (1/T_1)]$, where T_1 and T_2 are the respective temperatures in degrees Kelvin (°C + 273) for the two studies. [d] Bimolecular rate constants for sodium hydroxide- and hydrochloric acid-catalyzed solvolysis obtained from slopes of plots of the apparent first-order rate constants against sodium hydroxide and hydrochloric acid, respectively (Fig. 8). [e] Apparent first-order rate constants for pH-independent solvolysis of clofibrate. [f] Actually 58.0°.

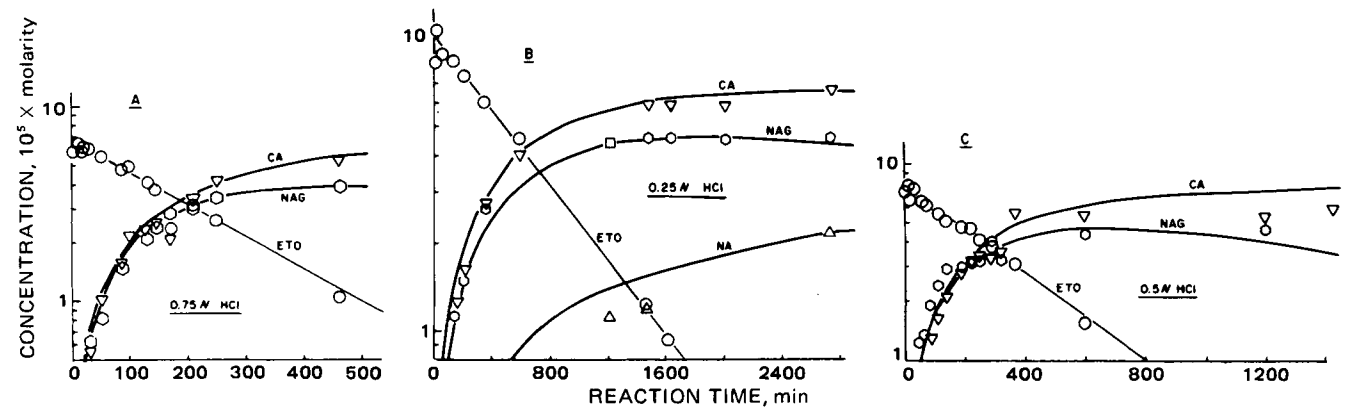

Figure 13—*Semilogarithmic plots of assayed concentrations of etofibrate (ETO) and solvolysis products, nicotinic acid monoglycolate (NAG), clofibric acid (CA), and nicotinic acid (NA), degrading at 69.9° in hydrochloric acid with an original concentration of 3×10^{-4} M etofibrate.*

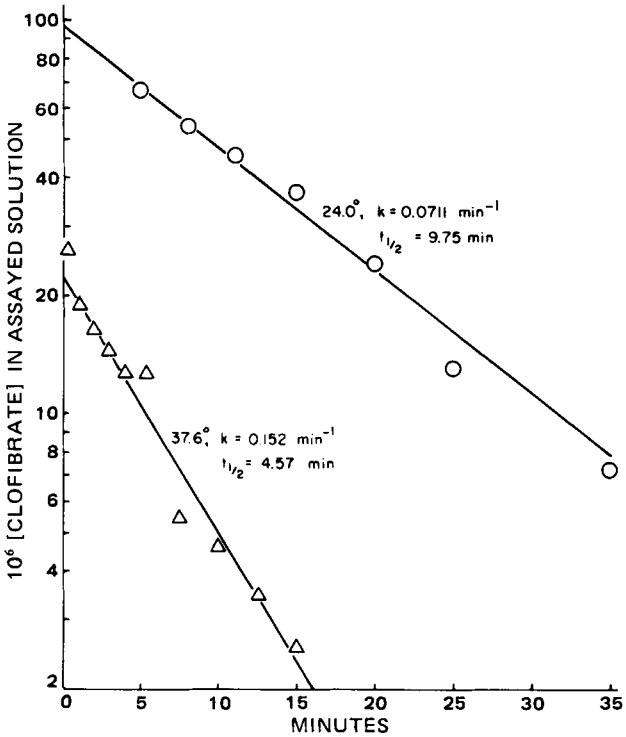

Figure 14—*Semilogarithmic plots of clofibrate concentrations with time in fresh dog plasma where blood was withdrawn 2–4 hr before by Procedure B. Aliquots (3.00 and 2.00 ml) of the 4-ml chloroform extracts of 1.00 ml of plasma were evaporated and reconstituted in 100 μl of mobile phase for injection in the 24 and 37.6° studies, respectively. The respective initial clofibrate concentrations were 1.00 and 1.77 × 10^{-5} M.*

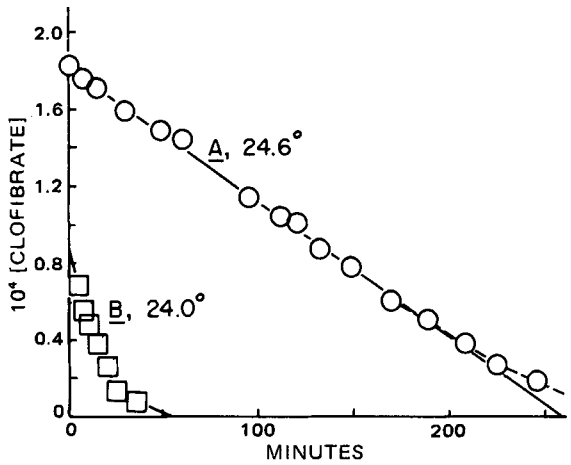

Figure 15—*Linear plots of clofibrate concentration with time at 24.5° in fresh dog plasma, 1.5 hr after withdrawal, as assayed by Procedure A for curve A with an initial plasma concentration of 1.83 × 10^{-4} M and as assayed by Procedure B for curve B with an initial plasma concentration of 1 × 10^{-5} M. The ordinate is for assayed concentrations (curve B) and plasma concentrations (curve A).*

In summary, etofibrate was readily hydrolyzed at 37.5° in fresh dog plasma with apparent half-lives of 4.4–6.9 min. The major product of this solvolysis was the glycol monoester of clofibric acid with a half-life of 5.8–11.5 min. Although the 4–5-min half-life of etofibrate determined previously (13) in diluted human blood (2.5% blood in isotonic pH 7.4 phosphate buffer) agreed with the present values, the half-lives of clofibrate (24 min) and clofibric acid monoglycolate (48 min) in diluted blood (15% blood in isotonic pH 7.4 phosphate buffer) were much greater than the present 5.8–11.5 min in whole dog plasma.

It was claimed (13) that the major route of etofibrate solvolysis in diluted blood is at the clofibric acid ester linkage, in contrast to the present findings in undiluted dog plasma that the major route is by the splitting

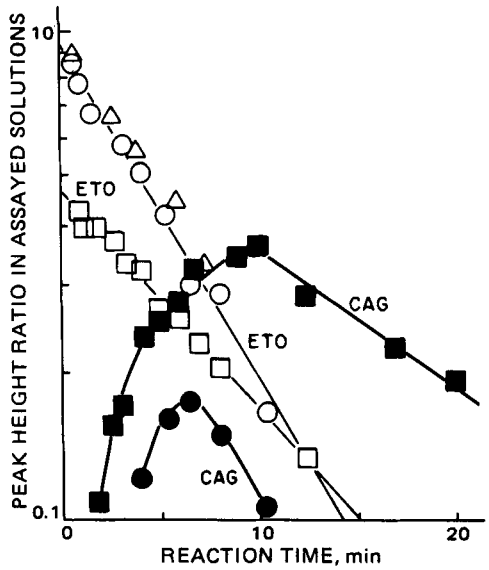

Figure 16—*Semilogarithmic plots of assayed etofibrate (open symbols) and clofibric acid monoglycolate (solid symbols) concentrations with time at 37.5° in fresh dog plasma. Procedure C was used for assay of degrading 3.6 × 10^{-5} M etofibrate in original plasma (○, ●, ▲). Procedure D was used for the assay of degrading 5.9 × 10^{-5} M etofibrate in original plasma (□, ■).*

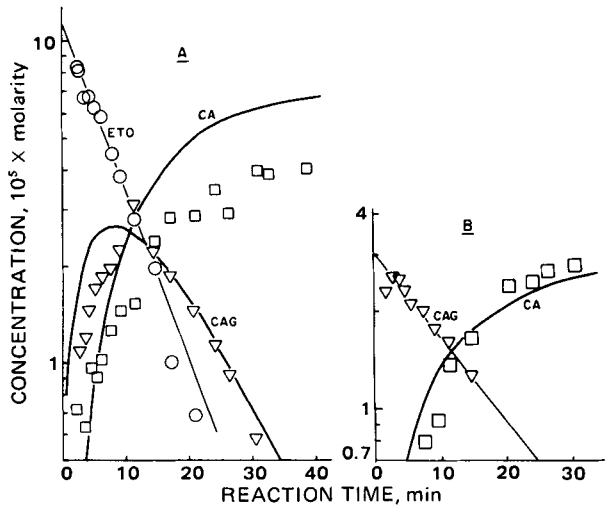

Figure 17—*Semilogarithmic plots of assayed (Procedure C) concentrations of etofibrate (ETO), clofibric acid monoglycolate (CAG), and etofibric acid (CA) for degradation of 1.19 × 10^{-4} M etofibrate (A) and 4.23 × 10^{-5} M clofibric acid monoglycolate (B) by Procedure C in fresh dog plasma. The lines through the CAG and CA values in A were calculated in accordance with Eqs. 13 and 16 for f = 1 (Eq. 14). The line through the CA values in B was calculated in accordance with [CA] = $[CAG]_0(1 - e^{-k_2 t})$.*

of the nicotinic acid ester linkage. The differences in results could be due to the fact that the present study used fresh dog plasma and the earlier study used diluted human blood with etofibrate concentrations in great excess of its solubility. The solvolyses of etofibrate and the half esters in highly diluted blood were not first order in the previous study as they were in the present study. The previous first-order semilogarithmic plots of diluted blood concentrations *versus* time showed a diminishing slope indicating decreasing esterase activity with time, which is contrary to what would be expected for saturable enzyme kinetics.

These discrepancies need clarification by further studies.

Effect of 4-Dimethylaminomethyl-1-(3-hydroxyphenyl)-1-nonen-3-one Hydrochloride and Related Compounds on Respiration in Rat Liver Mitochondria

N. W. HAMON ˣ, D. L. KIRKPATRICK, E. W. K. CHOW, and J. R. DIMMOCK

Received February 5, 1981, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada.* Accepted for publication May 14, 1981.

Abstract □ 4-Dimethylaminomethyl-1-(3-hydroxyphenyl)-1-nonen 3-one hydrochloride (II) was shown to stimulate respiration in rat liver mitochondria at levels of 2.5 μmoles or less; but at levels higher than 5.0 μmoles, respiration was inhibited when succinate and 3-hydroxybutyrate were the substrates. Compound II caused inhibition of respiration in the presence of glutamate over the dose range studied. The stimulating effect of II was attributed to its functioning as an uncoupling agent. Its inhibiting properties were considered to be due to its behaving like antimycin A in blocking transport of electrons between cytochromes b and c_1. The effect of II on respiration in mitochondria varied with the pH of the medium. A conjugated styryl ketone, which contained a nuclear hydroxy function and was structurally related to II, also stimulated respiration at low doses while inhibiting respiration at higher concentrations. Etherification of the hydroxy group led to compounds in which only stimulation of respiration was noted.

Keyphrases □ Respiration, mitochondria—effect of 4-dimethylaminomethyl-1-(3-hydroxyphenyl)-1-nonen-3-one hydrochloride and styryl ketone derivatives □ Mannich bases—prepared from styryl ketones, effect on respiration in mitochondria □ Styryl ketones—preparation of Mannich bases

A number of Mannich bases (I) derived from styryl ketones containing chlorine or hydrogen atoms in the aromatic ring have been shown to inhibit the electron transport chain in mitochondria of both rat liver cells and yeast (1, 2). These compounds were considered to exert their effect by competition with coenzyme Q_{10} (1). Recently, 4-dimethylaminomethyl-1-(3-hydroxyphenyl)-1-nonen-3-one hydrochloride (II), which is a Mannich base with a nuclear hydroxy group, was synthesized (3). Although it had little action against murine P-388 lymphocytic leukemia in contrast to some dichlorinated derivatives of I (4), it displayed anti-inflammatory analgesic properties as well as antifungal activity (3).

Therefore, the questions were asked whether II would affect mitochondrial function and, if so, whether its site of action would differ from that in series I. In addition, if II affected the electron transport chain, which is found in the inner membrane of the mitochondria, it could be a carrier group to which other molecular entities may be attached *via* the hydroxyl group. Furthermore, two related α,β-unsaturated ketones, III*a* and III*d*, differed in their activity towards P-388 lymphocytic leukemia (3), which could be due to a variation in effect on mitochondria. Thus, it was of interest to examine the effects of II, III*a*, III*d*, and the related compounds III*b* and III*c* on the electron transport chain in rat liver mitochondria.

DISCUSSION

Table I indicates the effect of II on respiration in rat liver mitochondria using three different substrates. In the case of succinate and 3-hydroxybutyrate, respiration was stimulated at low concentrations; at higher doses of II, inhibition of respiration was noted. When glutamate was the substrate, no stimulation of respiration was noted and only inhibition of respiration was found over the dose range studied.

The inhibiting effect of II at 5 μmoles with succinate as the substrate was considered. The related compounds I*a* and I*b* caused inhibition of respiration by competition with coenzyme Q_{10}, which could be reversed by addition of coenzyme Q_{10} (1). Therefore, a possible site for the respiration-inhibiting action of II might be similar. However, addition of coenzyme Q_{10} to mitochondria whose respiration had been inhibited by II did not alter the percentage of respiration inhibition, so the mode of action of II appears to differ from that of I.

IIIb: R = CH_2OCH_3
IIIc: R = CH_3
IIId: R = H

of electrons along the cytochromes. On occasion, this blockade and cytochromes may be discerned by examining the difference in the visible spectra of cytochromes in both the oxidized and reduced states (5). During respiration, electrons are transported along the cytochromes from coenzyme Q_{10} to oxygen (Scheme I), and the cytochromes become reduced during this process. After a blockade has occurred, the cytochromes prior to the block become reduced and the cytochromes after the block become more oxidized due to the pseudoreversibility of the respiration chain.

Examination of the visible spectra of II showed the presence of cytochrome b with its Soret band at 430 nm and its α band at 563 nm, suggesting a block between cytochromes b and c_1. The visible spectra of antimycin A was identical to that obtained for II. Since antimycin A is known to block between cytochromes b and c_1 (6), a similar mode of action for II was suggested. To confirm the site of action, respiration was examined in the presence of an inhibiting concentration of II, and then tetramethyl-*p*-phenylenediamine was added, which caused respiration to return to 95% of the rate prior to the addition of II. This result suggests that the block by II occurs between cytochromes b and c_1. Antimycin A was shown to act in a similar manner. After respiration was inhibited by this compound, tetramethyl-*p*-phenylenediamine caused the respiration rate to return to normal.

The reason for stimulation of respiration by II at low doses was also investigated with succinate as the substrate. Since II and coenzyme Q_{10} are α,β-unsaturated ketones, both compounds possibly might act as recipients of electrons from various flavoproteins (Scheme I), and these electrons are subsequently transferred to the cytochromes. Coenzyme Q_{10} was removed from the mitochondria; in the presence of succinate, neither succinoxidase nor succinate cytochrome c reductase was active, but activity was partially restored by the addition of coenzyme Q_{10}. Substitution of II for coenzyme Q_{10} did not permit respiration to occur, and it seems unlikely, therefore, that II acts in a capacity similar to this coenzyme. This finding substantiates the observation of earlier workers that a number of electron acceptors related to coenzyme Q_{10} failed to stimulate its action (7) and that mitochondria may have a specific requirement for this coenzyme.

Table I—Effect of II on Respiration in Rat Liver Mitochondria Using Succinate, Glutamate, and 3-Hydroxybutyrate as the Substrates[a]

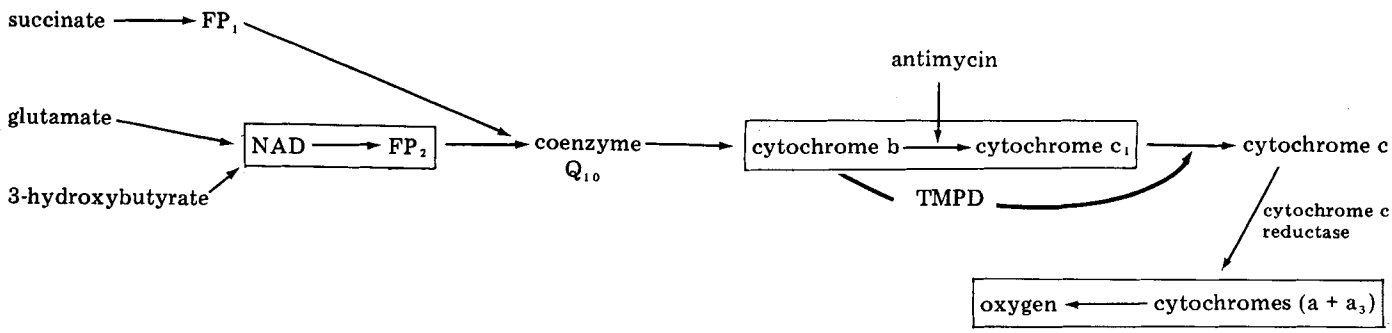
Concentration, μmoles	Substrate: Succinate[b] Inhibition, % ± *SE*	Glutamate[c] Inhibition, % ± *SE*	3-Hydroxybutyrate[d] Inhibition, % ± *SE*
0.05	−18.80 ± 3.18	1.70 ± 1.70	−15.45 ± 3.20
0.1	−28.64 ± 7.52	0.00 ± 0.00	−21.16 ± 1.85
0.25	−47.90 ± 0.62	6.65 ± 1.60	−48.03 ± 4.01
0.5	−59.53 ± 11.38	17.80 ± 4.22	−48.10 ± 2.64
1.0	−75.34 ± 11.85	49.26 ± 6.24	−57.88 ± 10.77
1.25	−77.68 ± 6.17	51.28 ± 9.87	−41.93 ± 1.65
2.5	−36.06 ± 3.20	62.08 ± 0.95	83.10 ± 1.42
5	73.43 ± 1.72	66.17 ± 2.28	98.04 ± 1.11
10	97.43 ± 0.72	81.52 ± 2.51	—

[a] Figures prefaced by a negative sign indicate stimulation of respiration. [b] At a concentration of 0.125 μmole, stimulation of respiration was 29.78% (*SE* = 8.09). At concentrations of 3.75, 4.25, 7.5, and 12.5 μmoles, the percentage inhibition of respiration was 8.34 (*SE* = 3.74), 49.52 (*SE* = 5.30), 58.87 (*SE* = 1.65), 92.79 (*SE* = 1.92), and 99.70 (*SE* = 0.30), respectively. [c] At concentrations of 0.75, 15, 20 and 25 μmoles, the percentage inhibition was 13.70 (*SE* = 6.35), 81.13 (*SE* = 3.61), 85.50 (*SE* = 1.80), and 86.87 (*SE* = 1.13), respectively. [d] At a concentration of 0.75 μmole, stimulation of respiration was 58.88% (*SE* = 5.50).

Increased respiration in mitochondria could occur by II acting as an uncoupling agent, especially since II is a phenolic compound and some substituted phenols (such as 2,4-dinitrophenol) are known to be uncoupling agents. In the case of 2,4-dinitrophenol, respiration is stimulated at low concentrations and inhibited at higher concentrations (8, 9), which is a situation similar to that found with II. Uncouplers do not interfere with the transport of electrons from the flavoproteins to oxygen, but adenosine triphosphate (ATP) is not formed during this process, *i.e.*, oxidation and phosphorylation no longer function in unison. Uncouplers may be identified by their effect on the P:O ratio, that is, the number of moles of adenosine diphosphate (ADP) phosphorylated to produce adenosine triphosphate per gram atoms of oxygen consumed (10). In tightly coupled mitochrondria with succinate as the substrate, such a ratio should be 2 (Scheme I).

The effect of II on the P:O ratio was examined, and it was found that utilization of inorganic phosphate decreased while oxygen consumption was unchanged from that of the control. This result caused the P:O ratio to fall to 25% of the value obtained in the absence of II. As well as uncoupling of oxidative phosphorylation (11), 2,4-dinitrophenol and some related phenols also stimulate latent adenosine triphosphatase activity of normal mitochondria (12, 13). If II acted in the same manner as 2,4-dinitrophenol, one would expect to see stimulation of adenosine triphosphatase along with the uncoupling effects, *i.e.*, a decreased P:O ratio. It was found that low concentrations of II (0.20–2.00 μmoles) caused stimulation of adenosine triphosphatase activity and a subsequent increase in hydrolysis of adenosine triphosphate to adenosine diphosphate. Higher concentrations of II (3 μmoles or greater) caused inhibition of this enzyme.

In a study of a series of uncoupling agents, 2,4-dinitrophenol caused stimulation and subsequent inhibition of respiration in the presence of both succinate and glutamate. However, in the case of the uncoupler 3-nitrophenol, stimulation of mitochondrial respiration occurred in the presence of succinate but not glutamate, a situation identical to that found with II (8). With both 3-nitrophenol and II, electron-attracting groups are present in the *meta* position to the phenolic function, which may reflect similar structural requirements for the mode of action of these two compounds.



Scheme I—The rectangles indicate the sites where ADP is converted into ATP. Flavoproteins are represented as FP_1 and FP_2.

Table II—Effect of II on Respiration in Rat Liver Mitochondria Using Succinate as the Substrate at pH Levels of 6.4, 6.9, and 7.4 [a]

Concentration, μmoles	pH 6.4[b] Inhibition, % ± SE	pH 6.9[c] Inhibition, % ± SE	pH 7.4[d] Inhibition, % ± SE	Levels of Significance (p) between pH Values of 6.4 and 6.9	6.9 and 7.4	6.4 and 7.4

[a] Figures prefaced by a negative sign indicate stimulation of respiration. [b] At a concentration of 0.75 μmole, stimulation of 28.13% (SE = 0.85) occurred. At a concentration of 6.00 μmoles, inhibition of 65.80% (SE = 6.92) occurred. [c] At a concentration of 0.75 μmole, stimulation of 60.22% (SE = 0.95) occurred. At a concentration of 3.50 μmoles, inhibition of 37.27% (SE = 12.71) occurred. [d] At concentrations of 0.05, 0.10, and 0.125 μmoles, stimulation of respiration was 18.80% (SE = 3.18), 28.64% (SE = 7.52), and 29.78% (SE = 8.09), respectively. At concentrations of 3.75 and 12.50 μmoles, the percentage inhibition of respiration was 8.34 (SE = 3.74) and 99.70 (SE = 0.30), respectively.

A recent study revealed that the amount of I inhibiting respiration in mitochondria obtained from both normal rat liver and from a Morris hepatoma varied according to the pH of the medium (14). In general, the compounds had increased respiration-inhibiting properties as the pH was lowered. The three pH values chosen were 7.4, that of normal physiological conditions; 6.9, which is claimed to be the pH of certain tumors (15, 16); and 6.4, which has been reported to be the pH of some tumors after administration of glucose while normal tissue was unaffected (15, 16). Thus, the question was raised as to whether the effect of II would vary markedly with such pH changes. If respiration was inhibited, preferentially at lower pH levels, some selectivity towards tumors may be possible under certain conditions.

Table II shows that at the lower stimulating concentrations of II, the percentage increase in respiration generally fell as the pH of the medium was lowered. This respiration-stimulatory effect became less pronounced as inhibiting concentrations of II were approached. When inhibition of respiration occurred at concentrations greater than 2.50 μmoles, there was mainly an optimal inhibition of respiration at pH 6.9 but less inhibition at pH 6.4 than at pH 7.4. Hence, these results of inhibition differ from those reported for series I (14).

Finally, the conjugated styryl ketones (III), which are related to II, were evaluated for their effect on respiration in rat liver mitochondria (Table III). At the optimal dose levels, II and III*a*–III*d* increased the survival time in mice with P-388 lymphocytic leukemia by 6, 25, 13, 5, and 4%, respectively; little correlation between effect on respiration and anticancer activity was seen. The ethers III*a*–III*c* caused moderate stimulation of respiration over the dose range studied, and no inhibition of respiration was noted. However, at concentrations of >1.0 μmole, for example, inhibition of respiration may occur at the same time as stimulation but the latter effect predominates. The phenolic compound III*d* behaves in a similar manner to the corresponding Mannich base II, and hence the observed inhibition of respiration appears to be associated with the presence of a phenolic group.

This study has shown that a Mannich base derived from a nuclear hydroxy conjugated styryl ketone (II) has uncoupling action at low concentrations while at higher doses it acts like antimycin A in blocking electron transport between cytochromes b and c_1. The effect on mitochondria varies depending on the pH of the medium. While III*d* showed a similar biphasic response as II, etherification of the hydroxy group of III*d* produced derivatives III*a*–III*c*, which showed only slight stimulating effects on respiration.

EXPERIMENTAL[1]

Syntheses of Compounds—Compounds II, III*a*, and III*b* were prepared according to literature methodology (3). (*E*)-1-(*m*-Methoxymethyloxyphenyl)-1-nonen-3-one (III*b*), prepared by the same scheme as III*a* in a 58% yield, was a yellow oil, bp 187°/0.3 mm [lit. (17) bp 177°/0.16 mm].

Anal.—Calc. for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75. Found: C, 73.42; H, 8.70.

(*E*)-1-(*m*-Methoxyphenyl)-1-nonen-3-one (III*c*) was prepared as follows. A mixture of 2-octanone (5.13 g, 0.04 mole), *m*-methoxybenzaldehyde (4.42 g, 0.0325 mole), and sodium hydroxide (0.68 g, 0.017 mole) in water (20 ml) was heated under reflux for 24 hr with mechanical stirring. On cooling, the aqueous layer was extracted three times with benzene (20 ml), and the combined organic phases were washed twice with water (20 ml) and dried with anhydrous magnesium sulfate. Removal of benzene by a water aspirator afforded a yellow oil, which was purified by distillation to give III*c* as a colorless oil, bp 144–146°/0.35 mm, in a 52% yield.

Anal.—Calc. for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00. Found: C, 77.94; H, 8.98.

Effect of II and III*a*–III*d* on Mitochondria Isolated from Rat Livers—Pellets of mitochondria obtained from the livers of male Wistar rats were isolated by the literature methodology (1) and suspended in 3.4 m*M* tromethamine hydrochloride[2] buffer (pH 7.40) containing 0.25 m*M* sucrose and 1 m*M* ethylene glycol bis(aminomethyl)tetraacetate at 0°. The protein content was 4 mg/ml as determined by a modification (18) of a previously reported procedure (19). The medium for the determination of mitochondrial respiration was that described previously (1) and will be referred to subsequently as the respiration media. Compounds III*c* and III*d* were dissolved in absolute ethanol and II in 10 m*M* tromethamine hydrochloride buffer (pH 7.40), while the oils III*a* and III*b* were added directly to the mitochondrial suspension. The media and methodology required for generating the data recorded in Tables I and II were those employed previously (1) using an oxygen monitor[3]. At least four determinations per compound were obtained at each dose level.

Effect of II and Antimycin A on Visible Spectra of Cytochromes—A mitochondrial suspension (0.5 ml containing 4 mg protein/ml) was placed in two 1-cm cells containing the respiration media (pH 7.40, 2.5 ml). Solutions of disodium succinate (15 μmoles) in 7.5 μl of 10 m*M* tromethamine hydrochloride buffer (pH 7.4) and adenosine diphosphate (1 μmole) in 1 μl of 10 m*M* tromethamine hydrochloride were placed in each cell. One cell was aerated by agitation while toluene was added to the other one. The visible spectra[4] of oxidized and reduced cytochromes were then recorded between 390 and 590 nm.

The two cells containing mitochondria, disodium succinate, and adenosine diphosphate in the respiration media (pH 7.4) were aerated by agitation. Compound II (5.0 μmoles in 10 m*M* tromethamine hydrochloride buffer, pH 7.4) was added to one cell and allowed to stand at room temperature for 3 min. Just before the spectrum was recorded, II was added to the reference cell. This addition eliminated the interference caused by II with the difference spectrum. The spectrum was then recorded between 590 and 490 nm. A fresh reference cell was prepared and aerated, II was added, and the spectrum recorded between 490 and 390 nm. All determinations were carried out at room temperature.

Mitochondria, disodium succinate, and adenosine diphosphate in the respiration media were added to the cells in the quantities indicated above. Antimycin A[2] (0.009 μmoles in 2 μl of 10 m*M* tromethamine hydrochloride buffer, pH 7.4) was added to one cell; after both were aerated, the difference spectra were recorded.

Effect of II and Antimycin A on Tetramethylphenylenediamine Bypass—Mitochondria (0.5 ml containing 4 mg protein/ml) were added to the respiration media (2.5 ml) in the cell of an oxygen monitor at 37°, and uptake of oxygen started with the addition of disodium succinate

[1] Elemental analyses were carried out by Mr. R. E. Teed, Department of Chemistry and Chemical Engineering, University of Saskatchewan. Boiling points are uncorrected.

Table III—Effect of IIIa–IIId on Respiration in Rat Liver Mitochondria Using Succinate as the Substrate [a]

Concentration, μmoles	IIIa Stimulation, % ± *SE*	IIIb [b] Stimulation, % ± *SE*	IIIc Stimulation, % ± *SE*	IIId [c] Stimulation, % ± *SE*
0.01	7.93 ± 6.32	7.23 ± 2.87	12.09 ± 4.77	26.43 ± 6.46
0.1	25.75 ± 1.30	14.99 ± 5.10	20.74 ± 4.26	86.07 ± 13.64
1.0	27.98 ± 8.35	22.74 ± 8.89	25.45 ± 16.09	−47.23 ± 7.31
2.5	27.38 ± 10.70	13.45 ± 5.29	5.59 ± 2.52	−87.56 ± 4.63
5.0	20.18 ± 6.00	8.19 ± 3.30	14.63 ± 5.92	—
50.0	5.72 ± 3.66	16.25 ± 1.95	23.74 ± 5.37	—

[a] Figures prefaced by a negative sign indicate inhibition of respiration. [b] At a concentration of 10 μmoles, stimulation of 11.39% (*SE* = 1.13) occurred. [c] At a concentration of 5.0 μmoles or greater, 100% inhibition occurred.

(15 μmoles in 7.5 μl of 10 m*M* tromethamine hydrochloride buffer, pH 7.4). Respiration was inhibited by either antimycin A (0.009 μmole) or II (5.0 μmole), and then tetramethyl-*p*-phenylenediamine (0.013 μmole) in 10 m*M* tromethamine hydrochloride buffer, pH 7.4 (25 μl), was added. The change in the rate of oxygen uptake was recorded.

Effect of II on Succinoxidase and Succinate–Cytochrome c Reductase Reactions—Acetone-treated particles were prepared from rat liver mitochondria by the literature method (20), and 0.5 ml of a suspension of these particles (3 mg protein/ml) was placed in the cell of an oxygen monitor containing monobasic potassium phosphate (100 μmoles), disodium succinate (150 μmoles), cytochrome c[5] (0.2 mg), and sufficient sucrose solution to produce 3 ml of a 0.2 *M* solution with a pH of 7.4. After 9-min incubation at 37°, various quantities of coenzyme Q_{10}[2] solutions (4 mg in 2 ml of ethanol, 95% w/v) and II (1.25 μmoles in 2.5 μl of 10 m*M* tromethamine hydrochloride buffer, pH 7.4) were added, and the effect on oxygen uptake was recorded. This experiment was carried out four times.

A mixture of the acetone-treated particles (10 μl, 3 mg protein/ml), monobasic potassium phosphate (180 μmoles), and cytochrome c (15 mg), with or without II and coenzyme Q_{10} (20 μg) in a total volume of 3 ml of water, was placed in the cell of an oxygen monitor. After incubation at 30° for 10 min, 0.1 ml of a solution containing disodium succinate (135 μmoles) and potassium cyanide (3 μmoles) in water was added, and the reaction was monitored at 550 nm[6] for 30 min. This determination was carried out in duplicate.

Effect of II on P:O Ratio—The P:O ratio of aerobic phosphorylation of mitochondria in the presence of II (1.25 μmole) was carried out at 30° using the literature methodology (21). The quantity of inorganic phosphate was determined by the method described previously (22). In an experiment involving three separate determinations, 1.43 (±0.38 *SE*) μmoles of inorganic phosphate were taken up, and 1.05 (±0.03 *SE*) μatoms of oxygen was consumed in the absence of II, indicating a P:O ratio of 1.36. In the presence of II, 0.26 (±0.14 *SE*) μmole of inorganic phosphate and 1.03 (±0.11 *SE*) μatoms of oxygen were utilized, indicating a P:O ratio of 0.25, *i.e.*, 18% of the P:O ratio of the control value.

In a second experiment involving three separate determinations, 1.33 (±0.30 *SE*) μmoles of inorganic phosphate and 0.685 (±0.003 *SE*) μatom of oxygen were consumed in the absence of II, producing a P:O ratio of 1.94. In the presence of II, 0.41 (±0.04 *SE*) μmole of inorganic phosphate and 0.66 (±0.03 *SE*) μatom of oxygen were used, producing a P:O ratio of 0.61, *i.e.*, 31% of the control values.

Effect of II and 2,4-Dinitrophenol on Adenosine Triphosphatase Activity—The adenosine triphosphatase activity of mitochondria was determined by the literature method (23). Compound II was dissolved in 10 m*M* tromethamine hydrochloride buffer (100 μmoles/ml), and 2,4-dinitrophenol was dissolved in absolute ethanol (200 μmoles/ml). The media (1.5 ml), as described in the literature (23), were added to a number of centrifuge tubes (15 ml), and varying concentrations of II or 2,4-dinitrophenol were added to each tube. The reaction was commenced by the addition of a suspension of mitochondria in 3.4 m*M* tromethamine hydrochloride buffer (pH 7.4) (0.5 ml containing 2 mg protein/ml), and the combined reaction mixture was incubated at 37° for 15 min. After quenching with ice-cold trichloroacetic aid (2 ml, 10% w/v), the reaction mixture was centrifuged at 35,000 rpm (average radius of 8.5 cm) for 5 min to remove protein. The liberated inorganic phosphate in the supernate was determined using a modification (22) of a literature method (24) involving measurement[7] of the absorbance at 700 nm.

The amounts of inorganic phosphate liberated at varying concentrations of II, given in parentheses, were as follows. All figures indicate micromole quantities, and those prefaced by a negative sign indicate that the inorganic phosphate concentration was less than the control values, *i.e.*, inhibition of latent adenosine triphosphatase activity occurred: −0.0243 (0.20), 0.0845 (0.40), 0.1874 (0.60), 0.3256 (0.80), 0.3462 (1.00), 0.5086 (1.20), 0.3844 (1.40), 0.4535 (1.60), 0.4322 (1.80), 0.2412 (2.00), 0.0074 (2.50), −0.0784 (3.00), −0.1874 (4.00), and −0.2058 (5.00). The amounts of inorganic phosphate liberated when 2,4-dinitrophenol was used in place of II were as follows: 0.7754 (0.20), 0.5604 (1.00), 0.5898 (2.00), 0.5990 (3.00), −0.3675 (10.00), and −0.4116 (20.00). The figures obtained were the average values of six determinations.

Screening of Compounds—Details of the anticancer screening of II, IIIa, and IIId were described earlier (3). Compounds IIIb and IIIc were evaluated by the Drug Research and Development Division of the National Cancer Institute, Bethesda, Md., using their protocols (25), and were administered as a suspension in saline with polysorbate 80[8] by the intraperitoneal route on 9 successive days using male CD_2F_1 mice and male $B_6D_2F_1$ mice, respectively. The maximum increases in median survival times were 13% (100 mg/kg) for IIIb and 5% (100 mg/kg) for IIIc. There were five out of six survivors on Day 5 when IIIc was administered at 200 mg/kg and six out of six survivors on Day 5 at a dose of 100 mg/kg. No mortalities for IIIb were noted at a dose of 200 mg/kg.

Pharmacokinetic Interactions of Tolazamide and Oxyphenbutazone in Dogs

S. E. ABIDI *, A. H. KIBBE ˣ, R. W. CLEARY, A. B. JONES, and E. C. HARLAND

Received October 14, 1980, from the *Department of Pharmaceutics University of Mississippi, University, MS 38677.* Accepted for publication May 13, 1981. * Present address: School of Pharmacy, West Virginia University, Morgantown, WV 26506.

Abstract □ The described pharmacokinetic analysis involved two separate studies on nine dogs randomly assigned to three groups of three dogs each. In the first study, the effect of varying the dosage of tolazamide was examined. The second study concerned the effect of varying the dosage of oxyphenbutazone on tolazamide. A 3 × 3 Latin square was used to study both effects. Each group received each treatment, with a minimum of 1 week separating each session. The pharmacokinetics of tolazamide followed a two-compartment open model. The hybrid rate constants, α and β, were not significantly different at the three dosages when measured by a three-way analysis of variance. The only significant difference at the three dosage levels of tolazamide was in the apparent volume of distribution. In the pharmacokinetic interaction associated with intravenous administration of one dose of tolazamide and three doses of oxyphenbutazone, the apparent volume of distribution and the hybrid rate constant α did not change significantly while the hybrid rate constant for tolazamide, β, seemed to decrease with increasing oxyphenbutazone.

Keyphrases □ Pharmacokinetics—tolazamide and oxyphenbutazone interactions, dogs □ Tolazamide—pharmacokinetic interactions with oxyphenbutazone, dogs □ Oxyphenbutazone—pharmacokinetic interactions with tolazamide, dogs

Enhanced hypoglycemic effects have been reported when patients, stabilized on a sulfonylurea (tolbutamide or tolazamide), have had phenylbutazone and/or its analog, oxyphenbutazone, added to the treatment regimen (1). Hussar (2) suggested that phenylbutazone/oxyphenbutazone enhanced the hypoglycemic effects of tolbutamide or tolazamide.

Other investigators (3) found significant prolongation of the half-life of tolbutamide when phenylbutazone was administered at the same time. However, there have been few studies on this pharmacokinetic interaction and its clinical significance. None of the studies dealt with the pharmacokinetic parameters involved in the interaction of oxyphenbutazone and tolazamide when administered simultaneously.

There are three possible mechanisms for a pharmacokinetic interaction that enhances the hypoglycemic effects of tolazamide and other sulfonlyureas in the presence of phenylbutazone or oxyphenbutazone:

1. Inhibition of drug metabolism, *i.e.*, a decrease in metabolism of tolazamide/sulfonylurea, which could be caused by the presence of oxyphenbutazone or phenylbutazone.
2. Displacement of tolazamide/sulfonylurea from protein binding sites, which could result in increased blood concentrations of unbound, pharmacologically active tolazamide/sulfonylurea or its metabolites and could also produce high urinary concentrations of unchanged drug and its metabolites.
3. Inhibition of the excretion of tolazamide/sulfonylurea by a direct effect on the kidney.

The purpose of this study was to determine if a measurable pharmacokinetic interaction existed between tolazamide and oxyphenbutazone and which mechanism might explain it.

EXPERIMENTAL

Experimental Design—A 3 × 3 Latin square was used to study the effect of varying dosage on tolazamide pharmacokinetics. A similar Latin square design was used for the tolazamide–oxyphenbutazone interaction study, in which the dose of tolazamide was kept constant and the doses of oxyphenbutazone were varied.

Nine dogs were randomly assigned to three groups of three dogs each. Each group received each treatment, with a minimum of 1 week of rest separating each session.

The study was conducted over 3 months, with the sequence of treatments in accordance with a Latin square design (Table I). In the first study, Treatments A, B, and C were 5, 20, and 35 mg of tolazamide/kg, respectively. In the second study, Treatments A, B, and C were 10, 15, and 20 mg of oxyphenbutazone/kg, respectively, all with 20 mg of tolazamide/kg.

Typical Sampling Times—Zero time for tolazamide sampling was taken to be the midpoint of the tolazamide injection. Sampling times were 2, 5, 10, and 30 min and 1, 2, 4, 6, 8, 12, and 24 hr after the tolazamide injection.

Animals—Nine mongrel dogs, 9.0–16.5 kg, were obtained from the local animal shelter. These animals were vaccinated and given appropriate treatment for parasites; after acclimation, they were certified as healthy.

A catheter was surgically placed in the jugular vein so that the tip was

[a] A is 5, B is 20, and C is 35 mg of tolazamide/kg of body weight.

in the anterior vena cava. The catheter was directed subcutaneously from the jugular vein to a 2.0-cm incision in the back between the scapulae. It was attached to a 18-gauge needle with an infusion cap to allow for ease of sample removal.

Preparation of Material—The dogs were weighed the afternoon prior to treatment. The amount of the drug to be administered was determined according to the corresponding dose for that treatment session and the weight of the animal. Tolazamide and oxyphenbutazone solutions for intravenous injection were prepared and filtered through a 0.22-μm filter to ensure sterility.

Treatment—Food, but not water, was withdrawn from the dogs 12 hr prior to administration. Food was allowed *ad libitum* after the collection of the 4-hr sample. Dogs 1–9 received 5, 20, or 35 mg of tolazamide/kg of body weight iv in the first phase of the study.

In the second phase, Dogs 1–9 received intravenous injections of 20 mg of tolazamide/kg of body weight, immediately followed by 10, 15 or 20 mg of oxyphenbutazone/kg of body weight iv. Intravenous administration was selected to avoid any problem with drug absorption that would prevent determination of the volume of distribution.

The dose of tolazamide was selected to obtain measurable blood concentrations of the drug for at least three to five biological half-lives. This procedure allowed reproducible measurement of the magnitude of peak concentrations as well as accurate measurement of the lower values at the end of the experiment. Blood samples were withdrawn through a catheter or by venous puncture. A 3.0-ml blood sample was mixed with heparin and centrifuged immediately after mixing. The plasma was separated, transferred into a screw-capped culture tube (7 mm), and frozen at −20° until assayed.

Preparation and Extraction of Plasma Standards—A standard solution of tolazamide was prepared by dissolving 100 mg of tolazamide in 5 ml of 0.1 *N* NaOH in a 100-ml volumetric flask and brought to volume with distilled water.

Aliquots of the standard solution of tolazamide containing 5, 10, 20, 30, 40, 50, and 60 μg were placed in 50-ml screw-capped centrifuge tubes. To each centrifuge tube, 0.5 ml of dog plasma was added and mixed well. An aliquot (0.2-ml) of the internal standard solution containing 20 μg of trihexyphenidyl was then added to each centrifuge tube. To these samples, 1 ml of buffer solution (0.5 *M* KH_2PO_4,Na_2HPO_4) of pH 6 was added. Then 20 ml of chloroform was added to each centrifuge tube. The centrifuge tubes were shaken for 20 min on a table shaker and centrifuged for 5 min at 100 × *g* to break the emulsion. The aqueous phase was removed by aspiration, and 10 ml of the organic phase was transferred to a 10-ml sample vial. Samples were evaporated at room temperature in a hood overnight. The residue was dissolved in 20 μl of chloroform and analyzed by gas chromatography (GC).

Plasma Specimens—Aliquots (0.5 ml) of the plasma samples were placed in 50-ml centrifuge tubes, and the samples were processed in the same manner as the plasma standards. Duplicate aliquots from each sample were analyzed. Analysis was carried out on a gas chromatograph[1] equipped with a flame-ionization detector and a glass column (U-shaped, 183 cm length × 2-mm i.d.) packed with 3% OV-17 on 100–200 mesh Gas Chrom Q. Nitrogen was the carrier gas at a flow rate of 65 ml/min, and the rates for air and hydrogen were 250 and 45 ml/min, respectively. The column oven was operated isothermally at 180°, the flash heater was at 230, and the detector was at 280°. Under these conditions, tolazamide and trihexyphenidyl had retention times of 4 and 20 min, respectively.

[a] Not significant.
[b] Significant at the 1% level.

When using peak height ratios of tolazamide to internal standard, the calibration data (over concentration ratios of 0.25–3.00 and peak height ratios of 0.10–1.25) were linear with a correlation coefficient of 0.994.

Assay Specificity—To ensure assay specificity, a standard solution (1 mg/ml) of tolazamide was prepared in chloroform. Similarly, a standard solution of the internal standard (1 mg/ml) was prepared.

Five microliters of the standard solution of tolazamide were placed in a sample vial, and 2 μl were analyzed by GC. Retention times under the described conditions were 4 min for tolazamide and 20 min for trihexphenidyl.

As a further check on specificity, the following experiment was performed on one dog's plasma extract. Plasma extract (20 μl) was chromatographed on precoated TLC plates of silica gel F-254 of 250-μm thickness. A reference sample containing 20 μg of pure tolazamide was utilized. The plate was developed in a solvent system of chloroform–methanol–formic acid (59:4:1). The zones of tolazamide were located by examination of the chromatogram using a UV lamp (254 nm).

The R_f value (0.59) of tolazamide from all plasma extracts was identical to that of the pure tolazamide sample. The zones were removed separately and extracted with chloroform (3 × 2 ml). To each extract was added 0.1 ml of internal standard, and the total was evaporated to dryness. The residue was reconstituted in 15 μl of chloroform and analyzed. The chromatogram showed identical retention times for the TLC extract of pure tolazamide and for the samples obtained from separately extracted spots from dog plasma extracts.

Data Analysis—Results obtained from analysis of the plasma samples were corrected to reflect the plasma tolazamide concentration. These plasma concentrations and their corresponding times were utilized to calculate the pharmacokinetic parameters for each animal using AUTOAN (4).

Analysis of variance was performed to determine the significance of the differences between pharmacokinetic parameters due to treatment effect, variation among subjects and time period, and overall residual effect.

RESULTS AND DISCUSSION

The pharmacokinetic analysis involved two separate studies on an equal number of dogs. In the first study, the effect of varying the tola-

[a] T is 20 mg of tolazamide/kg of body weight, and A is 10, B is 15, and C is 20 mg of oxyphenbutazone/kg of body weight.

zamide dose was examined. In the second study, the effect of varying the oxyphenbutazone doses on tolazamide was analyzed.

The data were analyzed by a two-compartment open model. In the statistical analysis, only three major parameters, α, β, and V_d extrapolated ($V_d$ext), were utilized because they are key factors in explaining a two-compartment open model. Other parameters change with changes in α and β.

Dose-Related Pharmacokinetics of Tolazamide—The pharmacokinetics of tolazamide were studied after intravenous administration of three different doses in each of nine dogs to determine if any dose-dependent changes in tolazamide kinetics were apparent (Table I). The plasma concentration data obtained at each dosage was biphasic (Fig. 1). Therefore, the data were analyzed by a two-compartment open model.

The hybrid rate constants, α and β, and the apparent volume of distribution, $V_d$ext, after intravenous administration of three different dosages of tolazamide in nine dogs are reported in Table II. The hybrid rate constant, α, which represents the rapid distribution of the drug in the body, did not change significantly. Similarly, β, which represents the loss of the drug from the body, did not change significantly with the change in the dosage levels of tolazamide.

A possible explanation for the lack of a significant difference in subject, group, and subject/group could be that mongrel dogs were used and these animals do not represent a genetically controlled breed. The only significant difference observed was in the apparent volume of distribution $V_d$ext at the three dose levels of tolazamide (Table III). It is entirely feasible that $V_d$ext might change without changing α or β as dose increases. Wagner and Pernarowski (5) suggested that the $V_d$ext will vary as a function of dose if the drug has the property of changing its diffusivity or permeability. The pharmacokinetics of tolazamide associated with intravenous administration was dose independent as measured by α and β.

Tolazamide Pharmacokinetics in Presence of Three Oxyphenbutazone Dosages—Results from the pharmacokinetic analysis of the

blood concentration data obtained from a dog that received 20.0 mg of tolazamide/kg iv followed by 10.0, 15.0, or 20.0 mg of oxyphenbutazone/kg are depicted in Fig. 2, which shows a biphasic trend. Therefore, blood concentration data were analyzed by a two-compartment open model. Tables IV and V contain the estimated pharmacokinetic parameters and statistical analysis data for these animals.

The parameters α, β, and $V_d$ext obtained from nine dogs after intravenous administration of 20.0 mg of tolazamide/kg followed by one of the three dosages of oxyphenbutazone were analyzed by a three-way analysis of variance. For tolazamide, α and $V_d$ext did not change significantly in the presence of the three oxyphenbutazone doses. However, β was significantly different for tolazamide in the presence of these three oxyphenbutazone doses.

Thus, it can be concluded that oxyphenbutazone only affects the β hybrid rate constant of tolazamide. This effect of oxyphenbutazone appears to be more pronounced as its dose increases. From the data reported here, only a trend can be seen, as depicted graphically in Fig. 3. The decrease in β with increasing dose of oxyphenbutazone represents a decrease in the overall elimination rate of tolazamide from the body. The value for β that was calculated from the first experiment in which the dogs received tolazamide alone cannot statistically be included in the analysis of the second experiment, but it was of the same order of magnitude.

These changes can be explained on the basis of three possible mechanisms of interaction of tolazamide and oxyphenbutazone.

The first possible mechanism involves inhibition of the tolazamide metabolism caused by the presence of oxyphenbutazone. A possible explanation could be that oxyphenbutazone may promote the synthesis of a form of cytochrome P-450 that has a lower metabolic capacity for tolazamide. Induction of this hepatic microsomal monooxygenase system is well established in animals (6). Some inducing agents can also decrease the microsomal oxidative capacity for a substrate (7). Any one or a combination of several of these changes could be the reason for the significant differences in β.

The second possible mechanism involves the displacement of tolazamide from protein binding sites. The values of α and $V_d$ext for tolazamide were not significantly different at the three oxyphenbutazone doses. This finding suggests that there might be little or no competitive displacement of tolazamide from protein binding sites in the presence of oxyphenbutazone.

The third possible mechanism could be inhibition of tolazamide excretion. Many acidic drugs and their metabolites are actively secreted

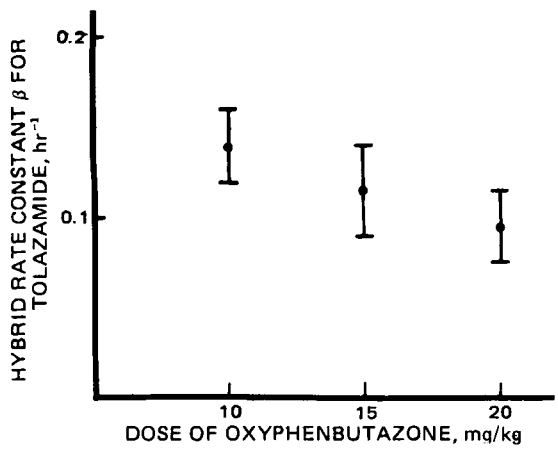

Figure 3—*Mean hybrid rate constant β obtained from nine dogs for tolazamide* versus *dose of oxyphenbutazone.*

by the proximal tubular active transport mechanism, and drug–drug interactions may result from competition with this system. Since tolazamide and oxyphenbutazone are weakly acidic drugs, they might compete for active secretion by the proximal tubular active transport mechanism. The hypoglycemic action of acetohexamide is enhanced by the simultaneous administration of phenylbutazone by the same mechanics (8). Similarly, the hypoglycemic action of tolbutamide is enhanced by the presence of phenylbutazone (9). The value of β for tolazamide seems to decrease with increasing oxyphenbutazone, which could result in an enhanced hypoglycemic effect of tolazamide.

Influence of Food and Fluid Volume on Chlorothiazide Bioavailability: Comparison of Plasma and Urinary Excretion Methods

PETER G. WELLING ˣ and RASHMI H. BARBHAIYA *

Received February 23, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication May 13, 1981.

* Present address: Department of Drug Metabolism and Pharmacokinetics, Bristol Laboratories, Syracuse, NY 13201.

Abstract □ The bioavailability of chlorothiazide from oral tablets was examined under fasting and nonfasting conditions in healthy male volunteers. Bioavailability was determined from urinary excretion data and plasma chlorothiazide concentrations. Two fasting treatments and one nonfasting treatment yielded similar plasma chlorothiazide profiles, characterized by sharply ascending and descending segments until 12–13 hr postdosing, followed by a prolonged period with variable and erratic chlorothiazide levels. A triexponential function that adequately described mean data from each treatment could not be applied to individual plasma curves because of their variable nature. Chlorothiazide absorption was not influenced by different accompanying water volumes in fasted individuals but was doubled when tablets were administered immediately after a standard meal. Urinary excretion of chlorothiazide correlated well with plasma drug concentrations; 48-hr urinary recovery accounted for 24.7% of a 500-mg dose in nonfasted subjects compared to 12.3 and 14.9% in fasted subjects receiving the drug with 20 and 250 ml of water, respectively. Observed relationships between chlorothiazide dosage and absorption efficiency are consistent with previous suggestions that chlorothiazide absorption from the GI tract is saturable and site specific.

Keyphrases □ Chlorothiazide—effect of food and fluid volume on bioavailability, plasma and urinary excretion methods compared □ Bioavailability—chlorothiazide, effect of food and fluid volume, plasma and urinary excretion methods compared □ Diuretics—chlorothiazide, influence of food and fluid volume on bioavailability, plasma and urinary excretion methods compared

Chlorothiazide is poorly absorbed after oral doses. Less than 25% of orally administered compound is recovered in urine, compared to >90% following intravenous injection (1–4). Inefficient GI absorption of chlorothiazide may be partly due to its low aqueous solubility but also may be related to saturable and site-specific absorption (5, 6).

The presence of food and the variation in fluid volumes with which a drug is administered can markedly influence drug bioavailability (7–9) with possible clinical consequences (10). The poor and possibly site-specific absorption characteristics of chlorothiazide make it conducive to a bioavailability study under varying dosage conditions.

This report describes chlorothiazide bioavailability following oral doses of commercial tablets to healthy male volunteers in fasting and nonfasting states and with small and large accompanying water volumes. Plasma concentrations and urinary excretion of chlorothiazide were compared using recently described high-pressure liquid chromatographic (HPLC) procedures (11).

EXPERIMENTAL

Subjects—Nine healthy male volunteers[1], 22–33 years of age (mean 27) and weighing 62–88 kg (mean 74), participated in the study after giving informed consent. No subject had histories of drug allergy.

Protocols—Subjects were instructed to take no drugs for 1 week before the study and no drugs other than chlorothiazide during the study. No caffeine-containing beverages were permitted for 1 day before or during the plasma and urine sampling periods following each chlorothiazide dose.

Chlorothiazide[2] was administered as three oral treatments: Treatment A, two 250-mg tablets with 250 ml of water following an overnight fast; Treatment B, two 250-mg tablets with 20 ml of water following an overnight fast; and Treatment C, two 250-mg tablets with 250 ml of water given immediately after a standard breakfast (cornflakes with milk, 150 ml (5 oz) orange juice, two poached eggs, two slices of toast, and one cup of caffeine-free coffee).

Subjects were randomly divided into three groups of three, and the treatments were administered according to a 3 × 3 Latin square design at 1-week intervals. Each treatment was given after an overnight fast; no food, apart from the standard breakfast for those receiving Treatment

by the proximal tubular active transport mechanism, and drug–drug interactions may result from competition with this system. Since tolazamide and oxyphenbutazone are weakly acidic drugs, they might compete for active secretion by the proximal tubular active transport mechanism. The hypoglycemic action of acetohexamide is enhanced by the simultaneous administration of phenylbutazone by the same mechanics (8). Similarly, the hypoglycemic action of tolbutamide is enhanced by the presence of phenylbutazone (9). The value of β for tolazamide seems to decrease with increasing oxyphenbutazone, which could result in an enhanced hypoglycemic effect of tolazamide.

C, was permitted until 4 hr after each chlorothiazide dose, after which time normal eating and drinking were permitted.

On the morning of each treatment, 250 ml of water was ingested on rising, at least 1 hr before dosing. Chlorothiazide was administered at 8 am. Tablets were swallowed whole, without chewing.

Blood samples (10 ml) were taken from a forearm vein into vacuum tubes[3] containing heparin as anticoagulant immediately before and then serially to 48 hr after dosing. Urine was collected immediately before and then quantitatively at intervals up to 48 hr after dosing. Plasma was separated by centrifugation, and plasma and urine samples were stored at −20° until assayed, generally within 2 weeks.

Analytical—Concentrations of chlorothiazide in plasma and in urine were determined by the HPLC methods described previously (11). The methods, both involving extraction steps prior to chromatography, are linearly sensitive to chlorothiazide concentrations of 2–100 μg/ml in urine and 10–750 ng/ml in plasma with coefficients of variation of <10% within these concentration ranges. The occasional plasma samples that contained chlorothiazide concentrations of >750 ng/ml were appropriately diluted with water and reassayed. Dilution with water had no effect on the extraction efficiency of chlorothiazide or the internal standard.

Data Analysis—The irregular nature of plasma chlorothiazide curves in individual subjects precluded data description in terms of a general mathematical function. However, the means of plasma curves obtained from each treatment were fitted to a triexponential function using

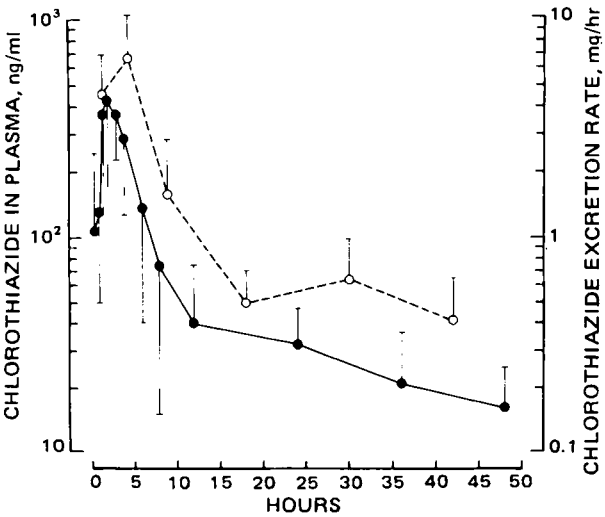

Figure 2—*Mean plasma concentrations (●) and urinary excretion rates (○) of chlorothiazide following Treatment B.*

[3] Vacutainer.

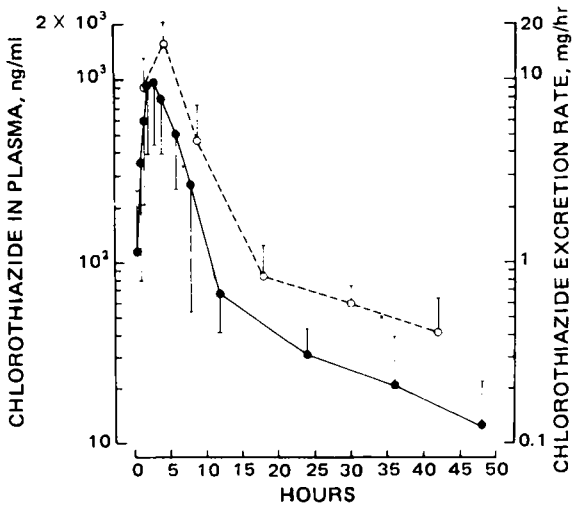

Figure 3—*Mean plasma concentrations (●) and urinary excretion rates (○) of chlorothiazide following Treatment C.*

standard graphical procedures. Improved parameter estimates, together with statistical analysis, were obtained using the computer program NREG (12) on a digital computer[4].

Plasma and urine data from the three treatments were compared by analysis of variance for a crossover design. Differences between individual treatments were examined by Tukey's test (13).

Reagents—Human plasma for assay standardization was purchased[5]. Human drug-free urine was obtained from male donors as required. Chlorothiazide[6], hydrochlorothiazide[6], and hydroflumethiazide[7] of reference standard quality for chromatography and methanol[8], acetonitrile[8], acetic acid[9], sodium perchlorate[10], and perchloric acid[11] of analytical grade quality were used as received.

RESULTS

Plasma Chlorothiazide Levels—The mean plasma chlorothiazide levels resulting from each treatment are shown in Figs. 1–3. For comparison, the mean plasma curves are combined in Fig.4.

The overall characteristics of the chlorothiazide plasma curves were similar for all treatments. Levels reached peak values at 2–3 hr and then

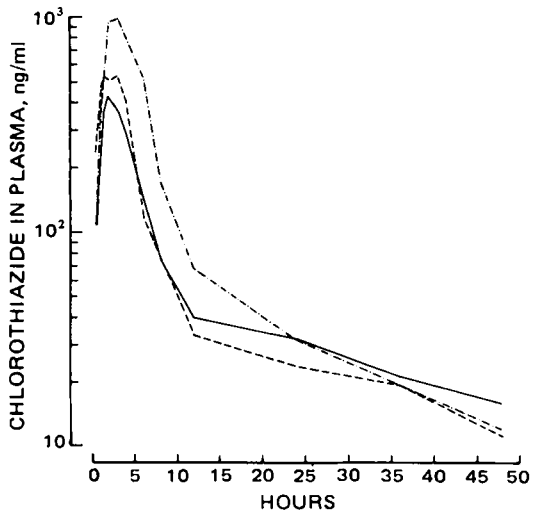

Figure 4—*Mean plasma concentrations of chlorothiazide following Treatments A (- -), B (—), and C (-•-•-).*

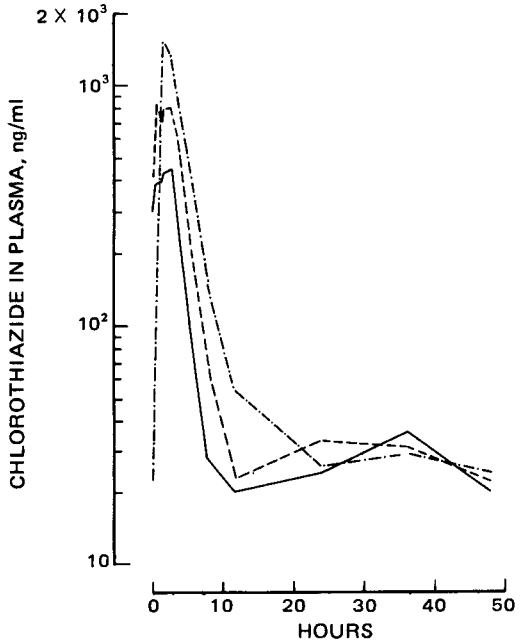

Figure 5—*Plasma concentrations of chlorothiazide in one subject following Treatments A (- -), B (—), and C (- • - •).*

declined rapidly until 12–13 hr. At later sampling times, mean chlorothiazide levels declined more slowly.

Despite the similarity in the plasma chlorothiazide profiles from the treatments, significant differences existed between treatments in the absolute values obtained. Chlorothiazide concentrations at each sampling time were statistically indistinguishable between the two fasting treatments, A and B. However, Treatment C gave rise to drug concentrations that were significantly higher compared to both fasting treatments at 2, 3, 4, 6, and 8 hr and significantly higher than Treatment A alone at 1.5 hr and then Treatment B alone at 12 hr. The mean peak chlorothiazide level from Treatment C (1107 ± 577 ng/ml) was approximately twofold higher than the levels from Treatments A (513 ± 205 ng/ml) and B (681 ± 214 ng/ml); the mean trapezoidal area under the plasma level *versus* time curve from 0 to 48 hr for Treatment C (6.4 ± 2.5 μg/hr/ml) was also twofold larger than the areas for Treatments A (3.0 ± 1.0 μg/hr/ml) and B (3.4 ± 1.1 μg/hr/ml). The mean time of peak levels from Treatment C (3.7 ± 2.1 hr) was significantly longer than those from Treatments A (2.0 ± 0.8 hr) and B (2.1 ± 1.0 hr).

Analysis of the mean chlorothiazide profiles in Figs. 1–4 in terms of a simple, triexponential function yielded the values in Eqs. 1–3 for Treatments A–C, respectively:

$$C' = -1627e^{-0.70t} + 1526e^{-0.38t} + 56.6e^{-0.026t} \quad \text{(Eq. 1)}$$

$$C' = -2626e^{-0.73t} + 2547e^{-0.43t} + 48.7e^{-0.029t} \quad \text{(Eq. 2)}$$

$$C' = -2914e^{-0.58t} + 2658e^{-0.26t} + 108e^{-0.046t} \quad \text{(Eq. 3)}$$

In the equations, C' is the plasma chlorothiazide concentration at time t. The coefficients of determination between mean plasma levels and those predicted from the respective equations were 0.97, 0.98, and 0.95.

The high coefficients of determination imply that chlorothiazide plasma levels may be adequately described by such a function following oral doses and that the mean terminal phase plasma half-life varied from 15 to 27 hr. Examination of individual chlorothiazide curves, however, shows that the apparent slow terminal elimination phase was largely artifactual, resulting from the averaging of individual data. Typical drug level curves for one subject are shown in Fig. 5. The steeply ascending and descending segments are well defined for all treatments, but drug levels during the post 12-hr period are erratic, exhibiting a "saw-tooth" effect. Thus, it was not possible to describe this section of the curve mathematically.

If the sharply descending portion of the chlorothiazide concentration curve is considered separately, the mean half-lives obtained from this segment are 2.2 ± 0.7, 2.2 ± 1.0, and 2.5 ± 0.8 hr from Treatments A, B, and C, respectively.

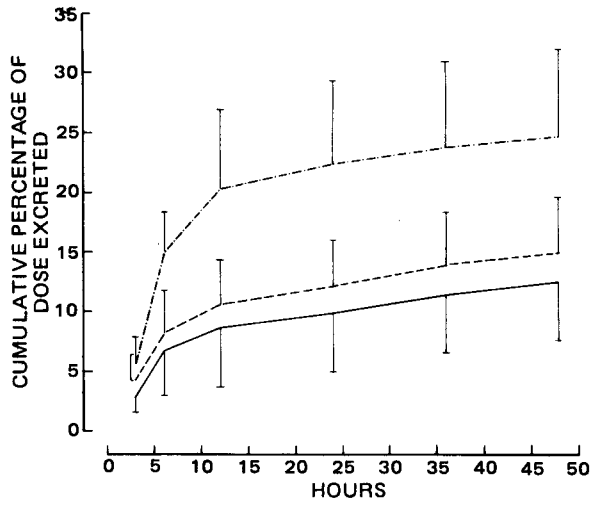

Figure 6—*Mean cumulative percentage of chlorothiazide dose excreted in urine following Treatments A (- -), B (—), and C (- • - •). Error bars indicate one standard deviation.*

Urinary Excretion of Chlorothiazide—The mean cumulative excretion of chlorothiazide during the 48-hr postdosing period is shown in Fig. 6. Following Treatment A, 8.6% of the administered dose was recovered at 12 hr, 9.8% at 24 hr, and 12.3% at 48 hr. Following Treatment B, recoveries at these times were 10.5, 12.1, and 14.9%, respectively. In contrast, the recoveries from Treatment C were 20.3, 22.3, and 24.7% at 12, 24, and 48 hr, respectively. The recovery values from Treatment C were significantly higher than those from both fasted treatments at all urine sampling intervals. The urinary recovery of chlorothiazide from the fasting treatments was similar to values reported previously (3, 4).

The renal clearances of chlorothiazide, calculated by dividing the quantity of drug recovered in 48-hr urine by the area under the chlorothiazide plasma curve during the same time period, were 3.56 ± 1.07, 37.3 ± 1.06, and 3.46 ± 11.0 ml/min from Treatments A, B, and C, respectively. The high renal clearance of chlorothiazide indicate that it is eliminated by both renal filtration and secretion.

DISCUSSION

Until recently, the low circulating levels of chlorothiazide following therapeutic doses prevented accurate description of its pharmacokinetics; bioavailability determinations were based on urinary excretion data (3). The recent development of a sensitive assay for chlorothiazide in plasma (6) has made it possible to examine the pharmacokinetics of chlorothiazide in plasma and to compare quantitatively the plasma profiles and urinary excretion rates resulting from oral chlorothiazide doses.

The plasma profiles obtained in the present study were similar to those reported by Shah et al. (3). In their study, peak chlorothiazide plasma levels of 245 and 500 ng/ml were obtained in two subjects 3 hr after a 500-mg tablet dose. Plasma levels during the 12–48-hr sampling period also exhibited a variable, saw-tooth effect.

The cause of the variable chlorothiazide plasma levels during later sampling times is not clear but may be related to drug release from extravascular storage depots or to an enterohepatic cycling effect. It is a consistent phenomenon and occurred in every subject.

The close similarity of plasma profiles and urinary excretion rates of chlorothiazide following the Treatments A and B indicates that, unlike some therapeutic agents (14–16), chlorothiazide absorption is not influenced by the accompanying fluid volume when taken on an empty stomach. However, chlorothiazide absorption efficiency is doubled when taken immediately following a meal.

The increased but delayed absorption of chlorothiazide in nonfasting individuals can possibly be explained in terms of an altered stomach emptying rate and saturable, site-specific absorption. Solid food delays stomach emptying (7) and is likely to reduce the rate at which chlorothiazide passes the absorption site and the drug concentration at the absorption surface. These combined effects give rise to more efficient but somewhat slower drug absorption into the systemic circulation. Propantheline bromide, a potent inhibitor of stomach emptying and intestinal motility, has been shown to increase GI absorption of chlorothiazide in dogs (5). Increased systemic availability in the presence of food, due

to nonsaturation of specific absorption sites, was demonstrated previously for riboflavin (17).

Increasing the accompanying water volume in fasted subjects might be expected to increase the dissolution rate of chlorothiazide and to accelerate the stomach emptying rate (7). However, neither factor should markedly alter the absorption efficiency of chlorothiazide. Faster stomach emptying would increase the rate at which drug passes the active absorption site and, hence, reduce its bioavailability. Faster dissolution should have little effect since chlorothiazide has been shown to be only 25% bioavailable when dosed as an oral solution (6).

It is instructive to compare chlorothiazide plasma levels and urinary excretion as indicators of chlorothiazide bioavailability. The mean urinary recoveries of chlorothiazide from Treatments A, B, and C were 12.3, 14.9, and 24.7% of the dose, respectively, while the respective areas under the plasma curves to 48 hr were 3.0, 3.4, and 6.4 μg hr/ml, indicating excellent agreement between plasma and urine data. The overall correlation between the percentage of dose excreted and the areas under the plasma level curves was 0.726 ($p < 0.001$), while the correlation between peak drug levels in plasma and percent excretion was somewhat lower at 0.480.

Similarly, the mean ratios of the percentage of dose excreted between Treatments A and B, A and C, and B and C were 0.87, 0.51, and 0.63; the equivalent ratios of areas under the plasma curves between these treatments were 0.92, 0.47, and 0.57.

To compare the kinetics of chlorothiazide recovery in urine with those of drug loss from plasma, the urinary excretion rates following the three treatments were calculated at the midpoint of each urine collection interval and the mean values were plotted along with the plasma levels in Figs. 1–3. Comparison of the curves indicates close similarity between the urinary excretion rates and plasma chlorothiazide levels throughout the entire sampling period.

Chlorothiazide absorption, which is normally poor, is doubled by the presence of food. This fact, together with the insensitivity of chlorothiazide absorption to varying fluid volumes, supports the view that chlorothiazide absorption is saturable and occurs at a particular site in the GI intestinal tract (5, 6). For optimal absorption, chlorothiazide tablets should be taken with or immediately after meals.

Tray Drying of Pharmaceutical Wet Granulations

J. T. CARSTENSEN* [x] **and M. A. ZOGLIO**[‡]

Received August 5, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706 and [‡]Merrell-National Laboratories, Cincinnati, OH 45201. Accepted for publication May 15, 1981.

Abstract □ It is shown that in tray drying wet granulated materials, the expected log–linear plots give slopes that are inversely proportional to the bed depth, rather than to the depth squared. A model is proposed for this giving diffusion coefficents of the order of magnitude expected for liquid-water diffusion. The temperature dependence also suggests that this is the rate-limiting process rather than vapor diffusion.

Keyphrases □ Tray drying—wet granulated materials, mathematical models □ Models, mathematical—tray drying of wet granulated materials □ Granulations—tray drying, mathematical models

The drying of granulations is an important pharmaceutical operation and tray drying is a frequently used method of water removal. The way in which drying takes place from a tray (1–3) can be visualized in several ways. The drying could be a function of the individual granule rather than of the mass of granules, *i.e.*, the bed. In that case, the bed thickness would not be a factor (in fluid bed drying it is not of great importance). However, bed thickness is important, and the drying is a function of the properties of the bed. In this case there are two possibilities: (*a*) either the movement through the void space between the granules is important (*i.e.*, the vapor diffusion is rate determining), or (*b*) the drying is primarily from the *bed* surface, and liquid movement up through the bed maintains a water concentration profile in the bed.

BACKGROUND

In the following discussion, the nomenclature outlined in Fig. 1 will be used. The bed is l-cm deep, has a porosity of ϵ (*i.e.*, a solids fraction of $(1 - \epsilon)$). It has a cross-sectional area of A cm^2. The density of an anhydrous granule is ρ gm/cm^3. The wet granulation before drying contains C^* g of moisture per g of anhydrous solid, and after drying contains c g of moisture per g of anhydrous solid. If c is the equilibrium concentration, then $C^* - c = C_0$ is the initially removable moisture concentration, and $C' - c = C$ is the moisture concentration which is removable at time t. The latter is the quantity which will be dealt with in the following discussion. Granules containing c g of moisture/g of anhydrous weight will be denoted dry. If x is a distance coordinate measured from the top of the bed (Fig. 1), then the diffusional equation governing the situation is Fick's law, *i.e.*, at time t:

$$\partial C/\partial t = D\partial^2 C/\partial x^2 \qquad \text{(Eq. 1)}$$

where D is the diffusion coefficient of water. Crank (4) solved this equation using the following boundary conditions: $C = 0$ at $x = 0$, for t

to nonsaturation of specific absorption sites, was demonstrated previously for riboflavin (17).

Increasing the accompanying water volume in fasted subjects might be expected to increase the dissolution rate of chlorothiazide and to accelerate the stomach emptying rate (7). However, neither factor should markedly alter the absorption efficiency of chlorothiazide. Faster stomach emptying would increase the rate at which drug passes the active absorption site and, hence, reduce its bioavailability. Faster dissolution should have little effect since chlorothiazide has been shown to be only 25% bioavailable when dosed as an oral solution (6).

It is instructive to compare chlorothiazide plasma levels and urinary excretion as indicators of chlorothiazide bioavailability. The mean urinary recoveries of chlorothiazide from Treatments A, B, and C were 12.3, 14.9, and 24.7% of the dose, respectively, while the respective areas under the plasma curves to 48 hr were 3.0, 3.4, and 6.4 μg hr/ml, indicating excellent agreement between plasma and urine data. The overall correlation between the percentage of dose excreted and the areas under the plasma level curves was 0.726 ($p < 0.001$), while the correlation between peak drug levels in plasma and percent excretion was somewhat lower at 0.480.

Similarly, the mean ratios of the percentage of dose excreted between Treatments A and B, A and C, and B and C were 0.87, 0.51, and 0.63; the equivalent ratios of areas under the plasma curves between these treatments were 0.92, 0.47, and 0.57.

To compare the kinetics of chlorothiazide recovery in urine with those of drug loss from plasma, the urinary excretion rates following the three treatments were calculated at the midpoint of each urine collection interval and the mean values were plotted along with the plasma levels in Figs. 1–3. Comparison of the curves indicates close similarity between the urinary excretion rates and plasma chlorothiazide levels throughout the entire sampling period.

Chlorothiazide absorption, which is normally poor, is doubled by the presence of food. This fact, together with the insensitivity of chlorothiazide absorption to varying fluid volumes, supports the view that chlorothiazide absorption is saturable and occurs at a particular site in the GI intestinal tract (5, 6). For optimal absorption, chlorothiazide tablets should be taken with or immediately after meals.

Tray Drying of Pharmaceutical Wet Granulations

J. T. CARSTENSEN* [x] **and M. A. ZOGLIO**[‡]

Received August 5, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706 and [‡]Merrell-National Laboratories, Cincinnati, OH 45201. Accepted for publication May 15, 1981.

Abstract □ It is shown that in tray drying wet granulated materials, the expected log–linear plots give slopes that are inversely proportional to the bed depth, rather than to the depth squared. A model is proposed for this giving diffusion coefficents of the order of magnitude expected for liquid-water diffusion. The temperature dependence also suggests that this is the rate-limiting process rather than vapor diffusion.

Keyphrases □ Tray drying—wet granulated materials, mathematical models □ Models, mathematical—tray drying of wet granulated materials □ Granulations—tray drying, mathematical models

The drying of granulations is an important pharmaceutical operation and tray drying is a frequently used method of water removal. The way in which drying takes place from a tray (1–3) can be visualized in several ways. The drying could be a function of the individual granule rather than of the mass of granules, *i.e.*, the bed. In that case, the bed thickness would not be a factor (in fluid bed drying it is not of great importance). However, bed thickness is important, and the drying is a function of the properties of the bed. In this case there are two possibilities: (*a*) either the movement through the void space between the granules is important (*i.e.*, the vapor diffusion is rate determining), or (*b*) the drying is primarily from the *bed* surface, and liquid movement up through the bed maintains a water concentration profile in the bed.

BACKGROUND

In the following discussion, the nomenclature outlined in Fig. 1 will be used. The bed is l-cm deep, has a porosity of ϵ (*i.e.*, a solids fraction of $(1 - \epsilon)$). It has a cross-sectional area of A cm^2. The density of an anhydrous granule is ρ gm/cm^3. The wet granulation before drying contains C^* g of moisture per g of anhydrous solid, and after drying contains c g of moisture per g of anhydrous solid. If c is the equilibrium concentration, then $C^* - c = C_0$ is the initially removable moisture concentration, and $C' - c = C$ is the moisture concentration which is removable at time t. The latter is the quantity which will be dealt with in the following discussion. Granules containing c g of moisture/g of anhydrous weight will be denoted dry. If x is a distance coordinate measured from the top of the bed (Fig. 1), then the diffusional equation governing the situation is Fick's law, *i.e.*, at time t:

$$\partial C/\partial t = D\partial^2 C/\partial x^2 \qquad \text{(Eq. 1)}$$

where D is the diffusion coefficient of water. Crank (4) solved this equation using the following boundary conditions: $C = 0$ at $x = 0$, for t

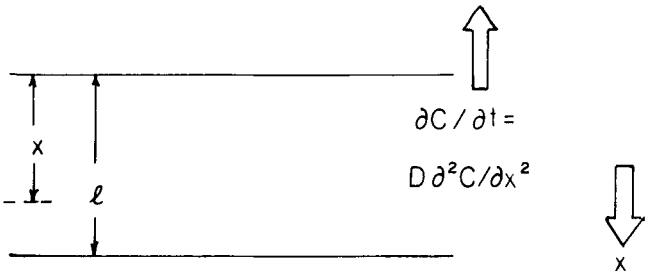

Figure 1—*Schematic of drying from a bed.*

> 0 (no moisture on the surface); $C = C_0$ for $0 < x < l$ at $t = 0$ (the same amount of moisture exists at each point throughout the interior at time zero); and $\partial C/\partial x$ at $x = 0$ equals zero for $t > 0$. Under these conditions it can be shown that Eq. 1 leads to the equation:

$$\ln(M/M_0) = -\{\pi^2 D/(4l^2)\}t + \ln(8/\pi^2) = -kt - 0.2 \quad \text{(Eq. 2)}$$

where M is the amount of removable water or the volume multiplied by $(C' - c)$. The equation is valid after a short lag time, and is based on the stated boundary conditions. For tray drying of granulations, the condition that the surface moisture for $t > 0$ is zero, is questionable. In Eq. 2, k is a drying rate constant given by:

$$k = -\pi^2 D/(4l^2) \quad \text{(Eq. 3)}$$

This equation predicts that the drying data (after a short lag time) should be log-linear when the amount of removable moisture is plotted *versus* time. This drying profile is encountered frequently (*e.g.*, in the so-called falling-rate period). The drying rate constant should have the same temperature dependence as D, the diffusion coefficient for liquid water. Furthermore, k should be inversely proportional to the second power of the bed thickness.

If vapor diffusion through the bed is the rate-limiting step (3–9), it is the movement through the void space of the bed which is rate-limiting. The change from constant to falling rate was postulated (10) to be the change from a process where there is capillary action within the granule to one where there is moisture movement within the void space of the bed. Beyond this some authors (11–13) considered the drying as a receding front down through the bed. This was shown to be feasible (14), and for a fine powder the diffusion coefficient is equal to that of water vapor diffusion.

In this type of drying there will be a dry part containing c g of moisture/g of anhydrous solid (x cm in Fig. 1) and a wet part containing C_0 g of moisture/g of dry solid [the lower $(l - x)$ cm in Fig. 1]. Drying occurs by vapor diffusion over a thickness of x cm through a free cross-section of $A\epsilon$ cm^2. Fick's law now takes the form:

$$-(1/|A\epsilon|)\, dM/dt = \Pi P/x \quad \text{(Eq. 4)}$$

for a steady state where Π is a permeability constant, and P is the water vapor pressure. This is assumed equal to zero in the air stream. There is C_0 g of moisture/g of dry solid in the lower $(l - x)$ cm of the bed and it is apparent that P is a function of C_0.

Figure 1 shows that in drying a section of thickness dx, the amount of water removed is:

$$-dM = C_0\rho(1 - \epsilon)A\, dx \quad \text{(Eq. 5)}$$

Introducing Eq. 5 into Eq. 4 then gives:

$$[C_0\rho\{(1 - \epsilon)/\epsilon\}]dx/dt = P\Pi/x \quad \text{(Eq. 6)}$$

which can be integrated, taking initial conditions into account, to give:

$$x = F \cdot \sqrt{t} \quad \text{(Eq. 7)}$$

where:

$$F^2 = 2P\Pi\epsilon/\{C_0(1 - \epsilon)\rho\} \quad \text{(Eq. 8)}$$

The removable moisture content in the bed at time t (neglecting the amount in the vapor phase) is $M = C_0(l - x)A(1 - \epsilon)\rho$, and that at time zero it is $M_0 = C_0 lA(1 - \epsilon)\rho$ (Fig. 1), so that:

$$M/M_0 = 1 - (x/l) = 1 - (F/l) \cdot \sqrt{t} \quad \text{(Eq. 9)}$$

Equation 9 predicts a drying rate which is a square root of time dependence and where the rate constant is K, given by:

$$K = F/l \quad \text{(Eq. 10)}$$

i.e., inversely proportional to bed depth.

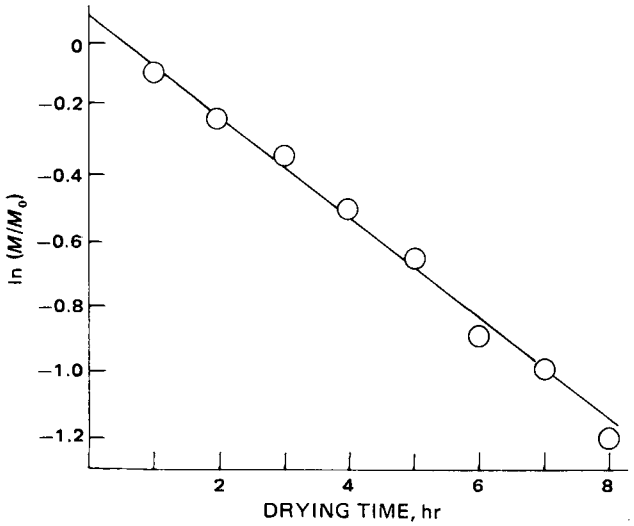

Figure 2—*Typical drying profile in tray drying.* T = *50°*, l = *1.91 cm (3/4 in.).*

The above hypotheses (Eq. 2 and Eq. 9) are *a priori* possible for tray drying. The model leading to Eq. 9 would seem more logical in the drying of wet granulations. Several reports (15–18) have reported this type of drying. Some investigators (17, 18) have shown that the equilibrium granule is primarily a fairly coarse and porous body. In tray drying the bed is loosely spread and fairly shallow (19–21), and movement in the highly porous space is probably not rate limiting. Nevertheless, the present report will show that some inconsistencies exist relating to Eq. 9, and the purpose of the present report is to probe which of the two situations (if any) actually exists. If neither applies an alternate model consistent with the data presented will be suggested.

EXPERIMENTAL

Granulations were made in the following manner: 5.75 kg of lactose USP and 0.8 kg of cornstarch USP were mixed in a sigma-type blender[1], 2 liters of cornstarch paste containing 10% cornstarch were added, and the mass kneaded for 15 min. It was passed through a No. 4 hand screen and spread onto a drying tray, which was placed in a tray drying oven[2]. The tray was removed at given intervals and weighed *in toto* on a balance[3]. The temperature was recorded on a digital readout thermometer[4]. Weights were usually monitored every hour for the complete drying period. Experiments were carried out at five bed depths and four different temperatures, as shown in Table I.

DISCUSSION

It should first be stated that the drying curves in this study were all semilogarithmic in time (Fig. 2). Hence, Eq. 9 is not obeyed in the strictest sense. Equation 2, however, is not strictly obeyed either. The drying curves have intercepts close to zero[5] (or slightly above), certainly not close to −0.2. The least-squares fit values for the slopes and intercepts are shown in Table I. Adherence to the semilogarithmic relation $\ln(M/M_0) = -k^*t$ seems excellent under all conditions.

The conventional diffusion model leading to Eq. 2 requires that the rate constants, k, be inversely proportional to the second power of the bed depth. A plot of $\ln k$ *versus* $\ln l$ is shown in Fig. 3. This plot has a slope of ~−1.0 and hence k appears to be inversely proportional to l and not inversely proportional to l^2. The model leading to Eq. 2 fails on two points. Equation 9 would appear to fail based on the time dependence, but the bed thickness effect, on the surface, would be of the correct dependence. The following presents a probe of whether Eq. 9 could indeed be the correct model. This is in spite of the time dependence failure. This may

40°	1.27	0.24	0.059	0.116	0.998	3.193	−2.154	−3.096
40°	1.91	0.65	0.0311	0.1028	0.999	3.193	−2.275	−3.382
40°	1.91	0.65	0.110	0.1093	0.984	3.193	−2.214	−3.503
40°	2.54	0.93	0.019	0.0697	0.999	3.193	−2.663	−3.442

[a] It is shown at a later point that the activation energy for k is 8,000 cal/mole. The adjustment to 12.5° ($1/T = 0.0035$) has hence been made by the formula: $\ln k(12.5°) = \ln k - 4000(0.0035 - 1/T) = \ln k - 14 + 4(1000/T)$ where $\ln k$ is the value listed in the next to the last column. The average value of $\ln k$ at a 2.54-cm depth (six values) is −3.822 with a standard error of the mean of 0.078 and the average vaue of $\ln k$ at a bed depth of 1.91 cm (three values) is −3.446 with a standard error of the mean of 0.035. The means and 95% confidence limits are shown in Fig. 3. The least squares fit of $\ln k(25°)$ regressed on $\ln l$ for all the values (11 points) is: $\ln k(25°) = -1.14 \ln l - 2.754$ (correlation coefficient: −0.938).

not be serious since it has been shown (23) that in limited ranges, square root relations may have the appearance of semilogarithmic plots.

To evaluate this, theoretical values of M/M_0 have been calculated for various drying times, t, according to Eq. 9 (Table II). The total drying time, θ, for situations given by Eq. 9 are the points in time where M reaches zero at $x = l$, *i.e.*, where $(F/l) \cdot \sqrt{\theta} = 1$. If, for example, this were 9 hr, then $(F/l) = 1/3$. Values for θ are shown in the headings of Table II for four chosen values of (F/l). Once (F/l) is fixed one can calculate M for various times; four time values (t = 1, 2, 3, and 4 hr) are chosen here and are shown in Table II. The value of $\ln(M/M_0)$ calculated for each value of t is shown in the table. For each value of (F/l) there are hence four values of t and $\ln(M/M_0)$. The least-squares fit of:

$$\ln(M/M_0) = -k''t + b \qquad \text{(Eq. 11)}$$

has been calculated and the least-squares fit parameters for slope ($-k''$) and intercept (b) shown (Table II). The correlation coefficients are good, showing that the square root data are well approximated by a log–linear equation (Eq. 2) for the four chosen values of (F/l). The intercepts are close to zero. An explanation for the approximation is given in *Appendix I*.

It is seen from the last two lines in Table II that there is a connection between the calculated values of k'' and the chosen values of (F/l). This is presented graphically in Fig. 4, and good linearity seems to exist demonstrated by the fact that the least-squares fit:

$$\ln k'' = 2.24 \ln(F/l) + 1.055 \qquad \text{(Eq. 12)}$$

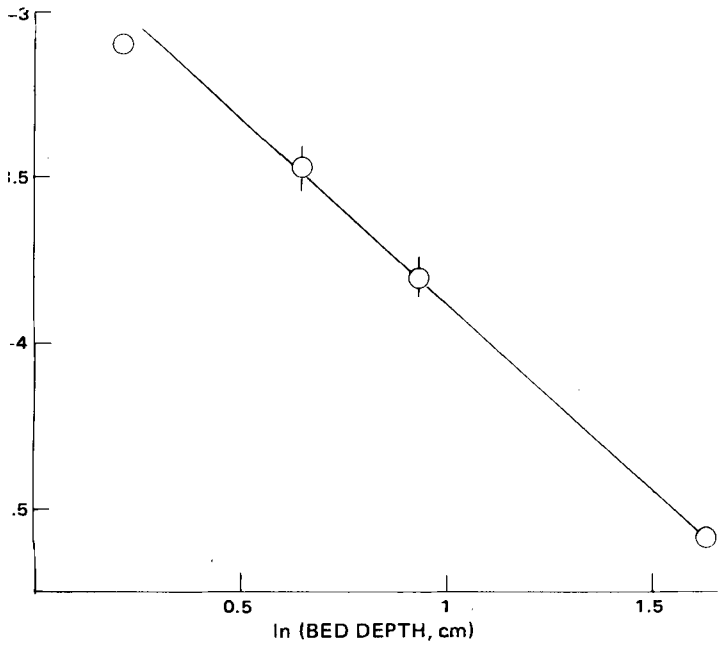

Figure 3—*Drying rate constants (adjusted to standard temperature) as a function of bed depth. Detailed data are shown in Table I. Least-squares fit is ln k = −1.14, ln l −2.754.*

has a correlation coefficient of 0.997. Hence k'' is approximately inversely proportional to the bed depth squared. Equations 2 and 9 are therefore experimentally indistinguishable. When the amount of removable moisture is plotted logarithmically *versus* time, approximately straight lines will occur in both cases. According to either model, however, the drying rate constants should be inversely proportional to the bed depth squared (or raised to a power higher than 2). Over a longer period of drying time the approximation leading to Eq. 11 is less precise and the treatment, so far, would favor some model based on the general principles leading to Eq. 2.

The original boundary conditions leading to Eq. 5 are that $C = 0$ at the surface, that C equals a non-zero value at the interior, and that dC/dx is equal to zero at $t > 0$ right at the surface of the bed. Other reasonable concentration profiles can be visualized in the interior as shown in Fig. 5. In this figure it is assumed that the moisture content increases steadily (although not linearly) down through the bed; it attains its largest value at the bottom ($x = l$) and is smallest at the surface ($x = 0$). The profile will change with time; both $C(l)$ and $C(0)$ will decrease. If it is assumed that $C(l)$ is proportionally larger than $C(0)$ at all times, so that:

$$C(l) = \gamma C(0) \qquad \text{(Eq. 13)}$$

at all times (where γ is a time-independent constant), then it is possible to find a trigonometric function such that Eqs. 1 and 13 are both satisfied and that the drying rate constant k will be inversely proportional to the bed depth, l. The function:

$$C(x,t) = (\beta \sin \lambda x + \cos \lambda x) \cdot \exp(-\lambda^2 Dt) \qquad \text{(Eq. 14)}$$

is a solution to Eq. 1 (β and λ are constants discussed later). It will obey Eq. 13 provided that:

$$\gamma = \beta \sin \lambda l + \cos \lambda l \qquad \text{(Eq. 15)}$$

which is simply a numerical requirement implying time independence.

For k ($= \lambda^2 D$) to be proportional to l^{-1}, it is necessary that λ^6 be proportional to $l^{-1/2}$, or:

$$\lambda = \alpha \cdot l^{-1/2} \qquad \text{(Eq. 16)}$$

For the function to be monotonically increasing in the interval (*i.e.*, having no maximum, which would occur if the trigonometric argument

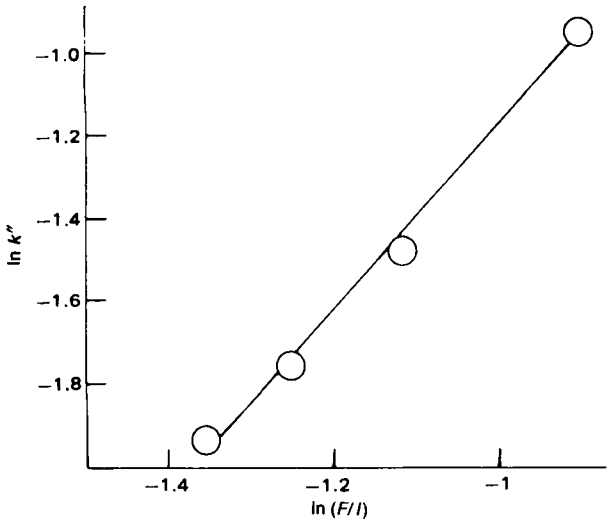

Figure 4—*Data from Table II (9 hr drying time); ln* M/M_0 *plotted as a function of time according to Eq. 9 for data adhering to Eq. 17.*

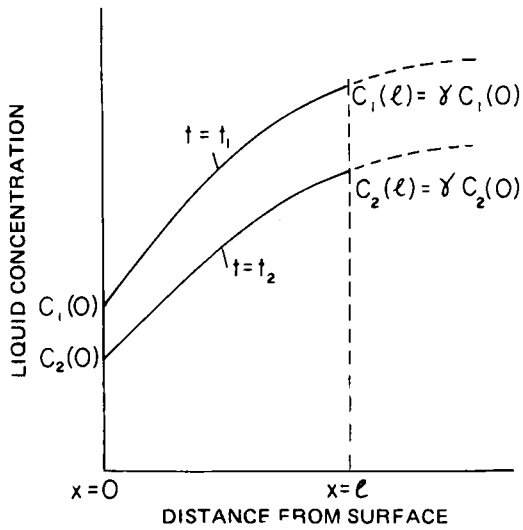

Figure 5—*Anticipated moisture concentration profiles in a tray (bed) at two different times,* t_1 *and* t_2. *Curves are according to Eq. 14, and boundary conditions are according to Eq. 13.*

could have the value $\pi/2$, *Appendix II*), it is necessary that:

$$\lambda l < \pi/4 \qquad \text{(Eq. 17)}$$

Inserting this in Eq. 16 gives:

$$\alpha l^{1/2} < \pi/4 \quad \text{so} \quad \alpha \leq \pi/(4\sqrt{l}) \qquad \text{(Eq. 18)}$$

The amount of moisture in the bed at time t is now given by:

$$M = A(1-\epsilon)\rho e^{-\lambda^2 Dt}\int_0^l (\beta \sin \lambda x + \cos \lambda x)dx =$$

$$A(1-\epsilon)\rho e^{-\lambda^2 Dt}(1/\lambda)(\sin \lambda l - \beta \cos \lambda l + \beta) \qquad \text{(Eq. 19)}$$

and at time zero it is:

$$M_0 = A(1-\epsilon)\rho(1/\lambda)(\sin \lambda l - \beta \cos \gamma l + \beta) \qquad \text{(Eq. 20)}$$

Combining Eqs. 19 and 20:

$$\ln(M/M_0) = -k^* t \qquad \text{(Eq. 21)}$$

where:

$$k^* = (\alpha^2 D/l) \qquad \text{(Eq. 22)}$$

This has the correct dependence on l (as opposed to Eqs. 3 and 12). The treatment developed produced three models, two of them conventional (denoted A and B below) and one proposed (denoted C below), the latter based on a trigonometric concentration profile with boundary conditions different from A. The drying curves predicted by the three models are:

model A; $\ln(M/M_0) = -kt - 0.2$ (see Eq. 2)

where $k = -\pi^2 D/(4l^2)$ (see Eq. 3)

model B; $\ln(M/M_0) = -k''t + b$ (see Eq. 11)

where k'' is approximately proportional to $l^{-2.5}$ (see Eq. 12)

model C; $\ln(M/M_0) = -k^*t$ (see Eq. 21)

where $k^* = (\alpha^2 D/l)$ (see Eq. 22)

Models A and B fail on two counts: (*a*) the experimental drying curves are log-linear with zero or slightly positive intercepts (Table I), and (*b*) the drying rate constants are experimentally proportional to l^{-1}, not l^{-2}. This prevents calculation of D, the diffusion coefficient, by these models. Model C, on the other hand, predicts zero intercepts and proportionality of drying rate constants to l^{-1} when the fraction of removable moisture is plotted log-linearly in time. This is in accord with experimental results, and permits order of magnitude calculation of D. A test for the reasonability of the model is therefore such a calculation, which should result in values of D in the range expected for a diffusion coefficient, and having a predictable temperature dependence.

It is seen from the inequalities in Eq. 18 that at the limit, α is equal to $\pi/(4\sqrt{l})$, which when inserted in Eq. 22 gives an upper limit for k of $D\pi^2/(16l^2)$. The upper limit for D is then:

$$D = 16kl^2/\pi^2 \qquad \text{(Eq. 23)}$$

At 50°, for instance (Table I), l = 2.54 cm, and k = 0.1 hr^{-1}, so that:

$$D = (16)\,(0.1)\,(2.54)^2/(3600)\,(3.14)^2 = 28 \times 10^{-5}\ cm^2/sec, \qquad \text{(Eq. 24)}$$

which is a reasonable upper limit. Wilburn, *et al.* (23) quote a value of 2×10^{-5} cm^2/sec at 30° for the liquid diffusion coefficient of water. On the other hand, the D-value in Eq. 24 is not in line with the vapor diffusion coefficient for water [which at 8° is 0.25 cm^2/sec, (24)].

The value for D determined in Eq. 24 is an upper limit.

A second criterion is the temperature dependence. It is seen from Eq. 22 that k^* should have the same temperature dependence as D:

$$\ln k^* = \ln D + \ln(\alpha^2/l) = -E_d/RT + N \qquad \text{(Eq. 25)}$$

where N is a constant, and E_d is the activation energy for the diffusion coefficient of water. The data in Table I (2.54-cm bed depth) have been plotted in this fashion in Fig. 6. The least-squares fit line is

$$\ln k^* = -(4015/T) + 1.021\ (r^2 = 0.99) \qquad \text{(Eq. 26)}$$

where r^2 is the correlation coefficient. Although the value for E_d (8030 cal/mol) is somewhat higher than that for the self-diffusion of water (E_d = 4000 cal/mole) (24), it is orders of magnitude different from the value of E_d for water vapor.

The model C, where the positional dependence of moisture concentration is a single argument trigonometric term, and where the

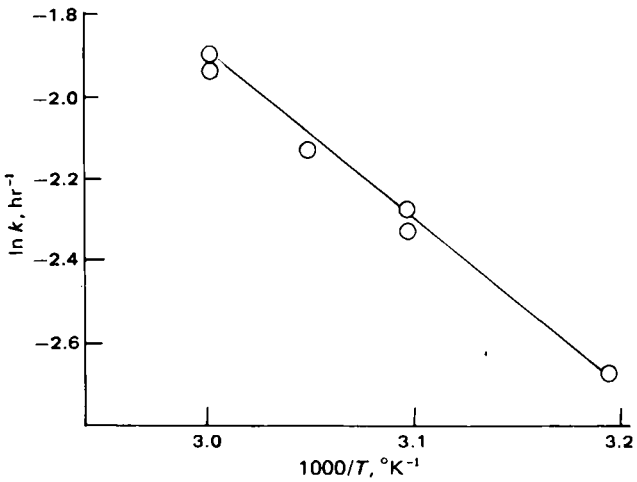

Figure 6—*Arrhenius plot of drying rate constants, 2.54-cm bed.*

boundary restriction is that the moisture concentration on the bottom of the tray (during steady state) is a constant (*i.e.*, time-dependent) factor times that on the surface, predicts a behavior in agreement with experimental data. The drying data are log–linear with a zero intercept. The drying constant is inversely proportional to bed depth and the drying rate constant is logarithmically linear with inverse temperature. The absolute magnitude of calculated diffusion coefficients and their temperature dependence are in fair agreement with that expected for liquid-water diffusion.

APPENDIX I

If the approximation:

$$y = 1 - (F/l) \cdot \sqrt{t} \simeq Ae^{-kt}, (A \simeq 1) \qquad \text{(Eq. A1)}$$

holds, then:

$$(1 - y)^2 = (F/l)^2 \cdot t \simeq (1 - Ae^{-kt})^2$$
$$\simeq (1 - 2A + A^2) + t[2Ak(1 - A)] + t^2[Ak^2(2A - 1)] \qquad \text{(Eq. A2)}$$

where the exponential expansion $e^x \simeq 1 + x + x^2/2$ has been truncated for third and higher power terms. The requirements for the approximation in Eq. A2 is that like power terms have equal coefficients, *i.e.*:

$$1 - 2A + A^2 \simeq 1 \qquad \text{(Eq. A3)}$$

$$(F/l)^2 = 2Ak(1 - A) \qquad \text{(Eq. A4)}$$

$$t^2Ak^2(2A - 1) \simeq t2Ak(1 - A) \qquad \text{(Eq. A5)}$$

The last requirement is that $t^2Ak^2(2A - 1)$ be zero or negligible, and this is equivalent to it being significantly smaller than the t term.

The requirement in Eq. A3 is fulfilled when $A \simeq 1$ or $A \simeq 2$. Table II shows that $A \simeq \exp(-0.2) = 0.8$, *i.e.*, that $A \simeq 1$. The second requirement is that $(F/l)^2 = 2Ak(1 - A) \simeq 0.32k$, which in logarithmic form becomes:

$$\ln k = 2 \ln(F/l) - 1.14 \qquad \text{(Eq. A6)}$$

which compares favorably with Eq. 12, and predicts that k should be proportional to l^{-2} as stated in the text.

The times for which the approximation can hold are deduced from Eq. A5 which can be rearranged to:

$$t < 2(1 - A)/k \qquad \text{(Eq. A7)}$$

where k is the range 0.1–0.4 in Table II (or 0.1–0.2 in Table I), and A is ~0.8, so that:

$$t < (2 \cdot 0.8/0.1) \text{ to } (2 \cdot 0.8/0.4) = 4\text{–}16 \qquad \text{(Eq. A8)}$$

as upper limits. The t values in Table II correspond to this. The k, (F/l), and t ranges used in Table II are within the bounds of the approximation.

APPENDIX II

The function:

$$y = \beta \sin \lambda x + \cos \lambda x \qquad \text{(Eq. A9)}$$

has the derivative:

$$\partial y/\partial x = \beta\lambda \cos \lambda x - \lambda \sin \lambda x \qquad \text{(Eq. A10)}$$

This equals zero when:

$$\tan \lambda x = \beta \qquad \text{(Eq. A11)}$$

β is at least 1 (since C is higher at the bottom of the tray than at the surface), so since $\tan(\pi/4) = 1$, it is necessary that in this limit:

$$\lambda l < \pi/4 \qquad \text{(Eq. A12)}$$

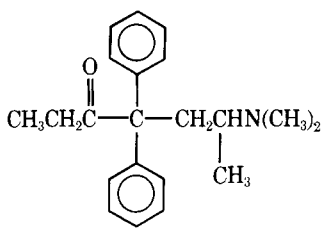
Received September 8, 1980, from the * *Division of Biological and Medical Research, Argonne National Laboratory, Argonne, IL 60439,* and the ‡ *Rockefeller University, New York, NY 10021.* Accepted for publication March 25, 1981. § Present address: Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030.

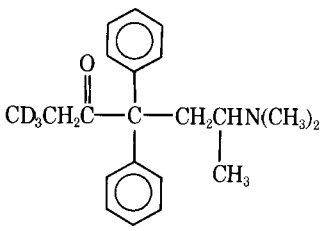
Abstract □ A new technique for simultaneous stereoselective kinetic studies of methadone enantiomers was developed using three deuterium-labeled forms of methadone and GLC–chemical-ionization mass spectrometry. A racemic mixture (1:1) of (*R*)-(−)-[$^2H_5$]methadone (*l*-form) and (*S*)-(+)-[$^2H_3$]methadone (*d*-form) was administered orally in place of a single daily dose of unlabeled (±)-[$^2H_0$]methadone in long-term maintenance patients. Racemic (±)-[$^2H_8$]methadone was used as an internal standard for the simultaneous quantitation of [$^2H_0$]-, [$^2H_3$]-, and [$^2H_5$]methadone in plasma and urine. A newly developed extraction procedure, using a short, disposable C_{18} reversed-phase cartridge and improved chemical-ionization procedures employing ammonia gas, resulted in significant reduction of the background impurities contributing to the ions used for isotopic abundance measurements. These improvements enabled the measurement of labeled plasma methadone levels for 120 hr following a single dose. This methodology was applied to the study of methadone kinetics in two patients; in both patients, the analgesically active *l*-enantiomer of the drug had a longer plasma elimination half-life and a smaller area under the plasma disappearance curve than did the inactive *d*-form.

Keyphrases □ Methadone—enantiomers, quantitation in humans using stable isotope labeling □ Enantiomers—of methadone, quantitation in humans using stable isotope labeling □ Narcotics—methadone, quantitation of enantiomers in humans using stable isotope labeling

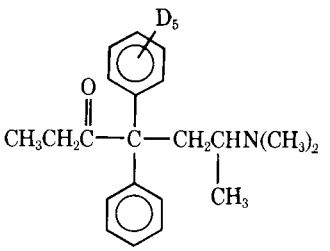
Racemic methadone is used in maintenance therapy of heroin addicts (1, 2). The (*R*)-(−)-enantiomer (*l*-form) is the more pharmacologically active isomer in experimental animals and humans (3, 4). In addition, small amounts of the (*S*)-(+)-enantiomer (*d*-form) may be converted to an active enantiomer of dimepheptanol by hepatic microsomal drug-metabolizing enzymes (5). It has been shown that the binding of methadone and other narcotics to specific opiate receptors is stereospecific (6–12). It was also shown that several aspects of narcotic disposition, including metabolism, may be stereoselective (13, 14).



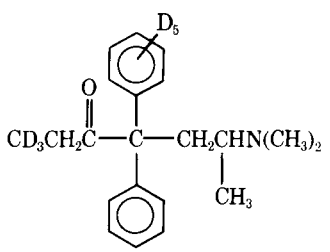
(±)-methadone



(*S*)-(+)-[$^2H_3$]methadone



(*R*)-(−)-[$^2H_5$]methadone



(±)-[$^2H_8$]methadone internal standard

BACKGROUND

Little work has been devoted to clarifying the disposition and pharmacokinetic differences between active and inactive enantiomers of methadone (4, 13). Such studies have been hindered by rapid and extensive drug distribution into tissues, with resultant low plasma levels, and by ethical constraints on the use of large amounts of radioisotopes in research patients.

Stable isotope-labeled compounds are now used often as tracers for the quantitation of drugs and drug metabolites in biological fluids (15, 16). Racemic [$^2H_3$]methadone (17) and [$^2H_5$]methadone (18) have been used as internal standards or tracers in the determination of methadone in plasma by GLC–chemical-ionization mass spectrometry. The pharmacokinetics of (*R*)-(−)- and (*S*)-(+)-methadone in maintenance patients using the separate enantiomers of [$^2H_5$]methadone as tracers were reported (13). In that study, kinetic differences were found between the two enantiomers in three clinically well-stabilized methadone maintenance patients; in each case, (*R*)-(−)-methadone had a significantly longer elimination half-life than the inactive enantiomer.

Exploration of these differences in normal patients as well as in patients whose drug disposition may be altered by liver disease, alcoholism, multiple drug abuse, or anticonvulsant therapy, etc., requires the performance of three sequential studies in each patient. Multiple studies are more difficult and expensive; the status of the patient may also change. Ideally, one would like to quantitate and trace both enantiomers simultaneously in the same patient using stable isotope tracers.

Three forms of deuterium-labeled methadone were synthesized: the two enantiomers, (*R*)-(−)-[$^2H_5$]methadone and (*S*)-(+)-[$^2H_3$]methadone, and racemic (±)-[$^2H_8$]methadone. Technology for the simultaneous measurement of all three labeled forms as well as unlabeled racemic (±)-methadone was developed using GLC–chemical-ionization mass spectrometry. In addition, clinical studies were carried out using these stable isotopic tracers; significant differences in the disposition and pharmacokinetics of the two enantiomers were observed in each patient.

EXPERIMENTAL

Synthesis—(*S*)-(+)-[$^2H_3$]Methadone was prepared from ethyl-2,2,2-[$^2H_3$]magnesium bromide and (*S*)-(+)-4-dimethylamino-2,2-diphenyl-valeronitrile according to known procedures (17). (*R*)-(−)-[$^2H_5$]Methadone was prepared from ethyl bromide and (*R*)-(−)-4-dimethylamino-2-phenyl-2-[$^2H_5$]phenyl-valeronitrile (18). Racemic (±)-[$^2H_8$]methadone was prepared by coupling ethyl-2,2,2-[$^2H_3$]magnesium bromide with racemic 4-dimethylamino-2-phenyl-2-[$^2H_5$]phenyl-valeronitrile by analogy to known procedures (18). Hydrochloride salts were prepared by dissolving the free bases in 25 ml of anhydrous ethanol and passing dry hydrogen chloride gas into the ice-cold solution. The ethanolic hydrogen chloride solution was then treated with 100 ml of ether and chilled at −10° until crystallization was complete. The salts were recrystallized twice from ethanol–ether (1:10).

Standard Solutions—Aqueous stock solutions, 1 mg/ml of (±)-[$^2H_0$]methadone, (*S*)-(+)-[$^2H_3$]methadone, (*R*)-(−)-[$^2H_5$]methadone, and (±)-[$^2H_8$]methadone hydrochloride, were prepared separately. Aliquots of these standard solutions were added to methadone-free plasma and urine obtained from healthy adult donors to establish standard curves. The plasma solution of combined enantiomers of unlabeled methadone and [$^2H_3$]- and [$^2H_5$]methadone was prepared gravimetrically. Concentrations ranged from 25 to 800 ng/g of plasma for methadone and

from 5 to 200 ng/g of plasma for $[^2H_3]$- and $[^2H_5]$methadone. Urine concentrations ranged from 0.1 to 10 μg/ml of urine for each methadone species.

Sample Preparation—*Plasma Analysis*—Plasma (1 g) was mixed with 1 ml of the internal standard, $[^2H_8]$methadone (200 ng/ml), and allowed to equilibrate at room temperature for 45 min. The sample solution was poured into a 10-ml syringe barrel fitted with a C_{18} silica gel cartridge[1]. Prior to use, the cartridge was conditioned by washing with 2 ml of methanol followed by 4 ml of water. The sample solution was forced through the cartridge with the syringe plunger and was followed by 2 ml of water and 3 ml of 0.01 *M* NH_4OH. The methadone was eluted with 6 ml of ethyl acetate and an additional 3 ml of 0.01 *M* NH_4OH (19).

The aqueous layer was discarded, and the organic phase was evaporated under nitrogen. The residue was dissolved in 3 ml of 0.3 *N* HCl and was shaken with 4 ml of *n*-heptane to remove residual lipids. After two extractions with *n*-heptane, the methadone-containing aqueous layer was separated and adjusted to pH 9–10 with 3 ml of 0.6 *M* NH_4OH. The aqueous layer was then extracted with 6 ml of ethyl acetate, and the organic layer was washed with an additional 3 ml of 0.6 *M* NH_4OH and evaporated under nitrogen. The residue was reconstituted with 10 μl of methanol, and the entire sample was analyzed. Recovery of methadone by this procedure was 40–70%.

Urine Analysis—Urine (1 ml) was mixed with 1 ml of internal standard (10 μg/ml). The sample was adjusted to pH 9–10 with 3 ml of 0.6 *M* NH_4OH, and the solution was extracted with 6 ml of ethyl acetate. The aqueous layer was discarded, and the organic phase was evaporated under nitrogen. The residue was reconstituted with 50 μl of methanol. A 2–3-μl aliquot was used for analysis. Recovery was 85–90%.

Mass Spectrometric Analysis—Analyses were performed using a quadrupole mass spectrometer[2] operating at an ion source temperature of 160° with a 0.5-torr ion source pressure of ammonia reagent gas (20). Samples were introduced through the GLC inlet system and were analyzed on a 1.8-m × 1.0- mm i.d. glass column packed with 10% OV-17 on Chromosorb W-HP (100–120 mesh) at a column temperature of 250° and a helium flow rate of 9 ml/min. Under these conditions, the retention time of methadone was 3.5 min. Isotopic ratios were measured by monitoring the intensity of the protonated molecular ions at *m/z* 310, 313, 315, and 318 for $[^2H_0]$-, $[^2H_3]$-, $[^2H_5]$-, and $[^2H_8]$methadone, respectively, using a microprocessor-based data system[3].

Standard isotope dilution curves were prepared for each methadone series in plasma and urine by plotting the observed, corrected isotopic ratio against the mole ratio of $[^2H_0]$methadone/$[^2H_8]$methadone, $[^2H_3]$methadone/$[^2H_8]$methadone, and $[^2H_5]$methadone/$[^2H_8]$methadone. In all cases, plasma and urine blank values were determined daily with each set of samples. The isotopic ratio data were mathematically treated to correct the values for the small cross-contributions to the ion intensities by the individual deuterated methadone species using the following methods.

Patients and Clinical Procedures—*Patient 1*—Patient 1, a 24-year-old male, began to use alcohol at age 11 and heroin at age 13. He began methadone maintenance treatment at age 18 with no subsequent problems with illicit narcotics or other drug abuse. He had a history of chronic alcoholism since age 21 but was detoxified and remained alcohol free for 9 months prior to the present study. He was stabilized on 80 mg of methadone/day and received no other medications. Physical examination revealed no significant abnormalities. Laboratory findings included: Hgb 15.0, Hct 44, WBC 6.2 with normal differential, normal urinalysis, hepatitis B antigen negative, SGOT 15, alkaline phosphatase 59, bilirubin 0.3, 5′-nucleotidase 6, total protein 6.7, albumin 4.0, and BUN 16, all within normal limits.

Patient 2—Patient 2, a 37-year-old male, began to use illicit narcotics at age 17. He entered a methadone maintenance treatment program at age 30 and subsequently remained free of heroin abuse. Over the past 10 years, he consumed no alcohol nor used other drugs. At age 33, he was told of abnormal liver function test results and subsequently had a liver biopsy, which showed chronic active hepatitis. At the time of these studies, he was receiving 100 mg of methadone/day with no other medications. Positive findings on physical examination revealed spider angiomata on the face and thorax and enlarged firm, nontender liver but an otherwise normal physical examination. Laboratory results included: Hgb 16.6, Hct 49.3, WBC 6.7 with normal differential, normal urinalysis, and hepatitis B antigen negative. His SGOT was 67 (upper normal 25), alkaline phosphatase was 127 (upper normal 82), bilirubin was 0.5, 5′-nucleotidase was 18 (upper normal 14), total protein was 7.4, and BUN was 18.

Both patients were admitted[4] for metabolic studies, and oral and written informed consent was obtained. The oral daily dose of methadone was substituted by a single dose of the same amount of stable isotopic methadone (containing equal amounts of *d*-$[^2H_3]$- and *l*-$[^2H_5]$methadone) for each patient on 1 study day. On the following day, oral dosing with unlabeled methadone was resumed. Multiple blood specimens were obtained on the study day and once daily thereafter. On several days following the initial study day, multiple blood samples also were obtained and analyzed for protocols unrelated to the results reported here. Six-hour urine collections were made on the 1st study day, and 24-hr collections were made daily thereafter.

Table II—Summary of Plasma Disappearance Half-Life and Area under the Curve (*AUC*)

Patient	Enantiomer	$T_{1/2\beta}$, hr	$(AUC)_0^{119}$, ng hr	Plasma Compartment, %
1	(*S*)-(+)-	28.1 ± 0.7	5296	1.58
	(*R*)-(−)-	37.9 ± 4.4	4002	1.19
2	(*S*)-(+)-	34.8 ± 2.4	4795	1.14
	(*R*)-(−)-	58.9 ± 4.8	2596	0.62

Data Analysis—Each isotopic species of methadone contributes a known, but variable, fraction to the ion intensity measured at a given mass. The ion intensity at a given mass (I_x), can be described as the sum of the individual fractional ion intensities according to:

$$I_x = A_1X_1 + A_2X_2 + \ldots A_nX_n \qquad \text{(Eq. 1)}$$

where *A* is the fractional ion abundance listed in Table I, X_n is the unknown fractional contribution to be determined, and I_x is the measured ion intensity at a given mass. The set of four linear equations, which consists of one equation for each ion measured, can be solved by linear least-squares techniques described previously (21, 22). The corrected ion intensity ($I_{x'}$) was normalized to the corrected ion intensity ($I_{318'}$) of the internal standard to give a set of three corrected isotope ratio values (R_{310}, R_{313}, and R_{315}) for each sample. The actual mole ratio for each component in a sample was obtained from linear calibration curves as described[5].

Plasma drug concentration *versus* time data were fitted to a three-exponential decay function using the SAAM 27 computer program (23). Areas under the curves were calculated using computer routines that employ the trapezoidal rule to perform the integration. The kinetic data for both patients are summarized in Table II.

RESULTS AND DISCUSSION

The isotopic composition of the various deuterated methadone species was determined by ammonia GLC–chemical-ionization mass spectrometry. The data, expressed as the fractional ion abundances of the various species, are listed in Table I. Multiple isotopic tracer studies employed in the present work were complicated by isotopic overlap of the various deuterated compounds. The problem was minimized, but not

eliminated completely, by using isotopic tracers separated by two or more mass units. The worst case of isotopic overlap occurred between [$^2H_3$]-methadone and [$^2H_5$]methadone, where the latter contributed 5.19% of its relative ion intensity to the ion intensity of [$^2H_3$]methadone measured at m/z 313.

The problem can be viewed as a special case of mixture analysis, where each component of the mixture contributes a small portion to the measured abundance of the other components. Mathematically, ion intensity can be expressed as a set of simultaneous linear equations describing all isotopic contributions to the ions being measured. These equations can be solved by simple matrix algebraic techniques (21, 22, 24). The ratio of (*S*)-(+)-[$^2H_3$]methadone to (*R*)-(−)-[$^2H_5$]methadone in plasma varies only between 2:1 and 1:2, even though the actual total drug concentration in plasma may range over a 40-fold span during a single clinical study. The relative isotopic cross-contribution of one enantiomer to the other is <10% between the two isotopic species. Both [$^2H_0$]methadone and [$^2H_8$]methadone are present in relatively constant amounts (200 ng/g) in plasma; consequently, there is very little interference (typically 0.1–0.2%) between the latter two species and the two *in vivo* kinetic tracers.

In plasma studies, the intensity of the background spectrum, often referred to as "matrix interference," depends strongly on the isolation procedure used to recover methadone from biological samples and on the reagent gas used for chemical-ionization mass spectrometry. It is imperative in these studies to minimize matrix interference to quantitate the low levels of isotopically labeled methadone expected in plasma.

Data presented in Table III show that simple solvent extraction of buffered control plasma containing only [$^2H_8$]methadone had an ion intensity ~20–30 times that of the background level obtained with the pure standard determined with isobutane as the reagent gas. This interference effectively precludes measurement of drug levels below 45 ng/g. Using a short C_{18} silica gel cartridge to recover methadone reduces ion contamination, especially for (*R*)-(−)-[$^2H_5$]methadone, so that detection limits fall to 6–12 ng/g. However, use of the highly selective ammonia reagent gas further decreases the background for masses m/z 313 and 315 so that the detection limits fall to 3–5 ng/g (20).

A simple solvent extraction is sufficient to recover methadone from urine and gives results identical to those of the pure standard obtained using ammonia reagent gas. The lower detection limit in the calibration curve and in the individual patient studies is usually ~1–5 ng/g for [$^2H_3$]- and [$^2H_5$]methadone or approximately twice the blank plasma background level. Two advantages from using the C_{18} silica gel cartridges for extracting methadone from plasma are that the GLC column lifetime is improved markedly and analysis time is shortened to ~5 min/sample since no interfering peaks elute from the column after methadone.

The present data illustrate the practicality of using multiple stable isotopic tracers in a clinical research protocol. Previous studies, using only a single isotopic tracer, required three separate stable isotopic tracer experiments to explore the behavior of the separate enantiomers. Such studies were exceedingly tedious, both with respect to performance of the clinical study and the time required for the analyses. During such lengthy studies, the patient's status is subject to change. Thus, the multiple, simultaneous stable isotopic tracer technique described here offers significant advantages in studying complex drug systems such as methadone in a steady-state, multiple-dose protocol.

Data from Patient 1 (Table II and Fig. 1) reconfirm earlier observations that (*R*)-(−)-methadone is metabolized ~1.35 times slower than (*S*)-(+)-methadone (13). Plasma drug level data *versus* time were fitted to a three-exponential decay function, where the half-life is that of the terminal exponential component. In both cases, (*S*)-(+) methadone reaches and maintains a higher peak plasma level over the first 48 hr of the study than does the (*R*)-(−)-methadone. Thereafter, the (*R*)-(−)-methadone curve crosses the (*S*)-(+)-methadone concentration curve and remains higher for the rest of the study. The area under the plasma disappearance curve was integrated over the first 119 hr. These data indicate that (*S*)-(+)-methadone has a higher plasma level and, therefore, higher relative bioavailability following an oral dose than does (*R*)-(−)-methadone. The total plasma compartment for methadone (both enantiomers) accounts for only 1.8–2.8% of the administered dose.

The second patient (Fig. 2) displays similar pharmacokinetic behavior but with two differences: (*a*) the plasma disappearance half-life of *R*-(−)-methadone is 1.69 times as long as that of the (*S*)-(+)-enantiomer, compared with the more normal 1.35-fold difference observed in the first patient; and (*b*) the integrated area under the plasma disappearance curves of *S*-(+)-methadone is 1.85 times greater than that of the (*R*)-(−)-enantiomer. The significance of these observations is not yet clear; Patient 1 had a history of chronic alcohol misuse, and Patient 2 had a history of chronic acute hepatitis.

The described methodology for plasma drug level measurements can also be applied to measure urinary excretion of unmetabolized methadone

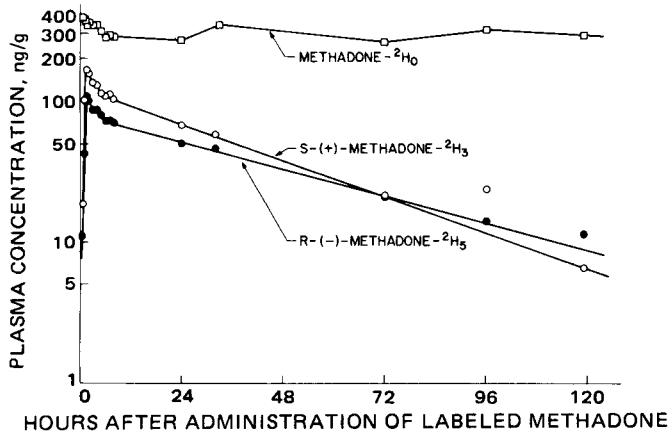

Figure 1—*Plasma methadone disappearance curves for methadone, (R)-(−)-[$^2H_5$]methadone, and (S)-(+)-[$^2H_3$]methadone determined in Patient 1.*

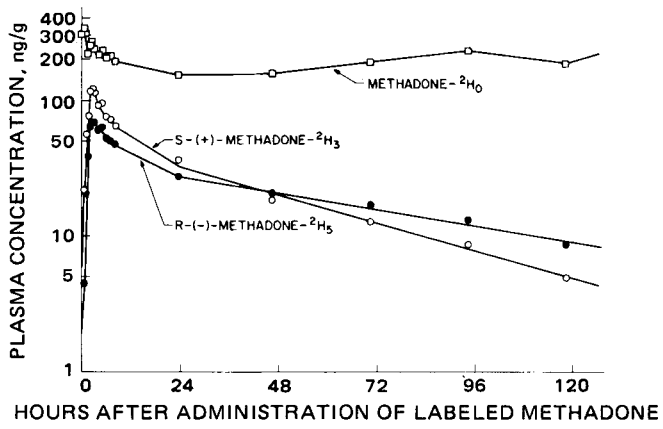

Figure 2—*Plasma methadone disappearance curves for methadone, (R)-(−)-[$^2H_5$]methadone, and (S)-(+)-[$^2H_3$]methadone determined in Patient 2.*

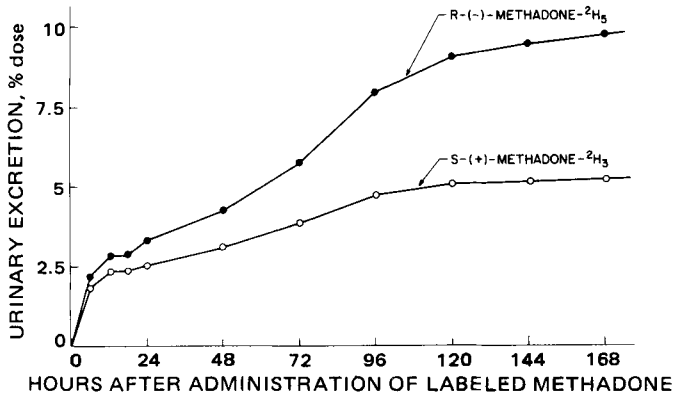

Figure 3—*Cumulative urinary excretion of (R)-(−)-[$^2H_5$]methadone and (S)-(+)-[$^2H_3$]methadone determined in Patient 1.*

enantiomers. Data presented in Fig. 3 illustrate the cumulative urinary excretion of the two methadone enantiomers in Patient 1. (*S*)-(+)-methadone reaches a cumulative excretion plateau value of 5.2% by 120 hr. In contrast, the (*R*)-(−)-methadone continues to be excreted throughout the study; by 168 hr, 9.8% of the dose was excreted as the unmetabolized drug. The urinary data, together with the plasma drug level data, suggest a differential renal clearance mechanism for the excretion of the unchanged methadone enantiomers. Full assessment of each step of the disposition of the separate enantiomers of methadone and its metabolites, including hepatic uptake metabolism, biliary excretion, fecal excretion, and urinary clearance, is needed before the mechanisms underlying the observed differences in overall disposition can be evaluated (25).

enantiomers. Data presented in Fig. 3 illustrate the cumulative urinary excretion of the two methadone enantiomers in Patient 1. (*S*)-(+)-methadone reaches a cumulative excretion plateau value of 5.2% by 120 hr. In contrast, the (*R*)-(−)-methadone continues to be excreted throughout the study; by 168 hr, 9.8% of the dose was excreted as the unmetabolized drug. The urinary data, together with the plasma drug level data, suggest a differential renal clearance mechanism for the excretion of the unchanged methadone enantiomers. Full assessment of each step of the disposition of the separate enantiomers of methadone and its metabolites, including hepatic uptake metabolism, biliary excretion, fecal excretion, and urinary clearance, is needed before the mechanisms underlying the observed differences in overall disposition can be evaluated (25).

Abstract □ The effect of surface charge and particle size on the gel structure of aluminum hydroxycarbonate gel was studied through the use of a specially designed tension cell. Surface charge has a major effect on the coefficient of bulk compressibility. The charged state is more compressible at lower tensions while the neutral gel is more compressible at higher tensions. In addition, physical properties of gels having a small particle size are more profoundly influenced by interparticle forces than are gels consisting of larger particles. The effect of surface charge and particle size on gel structure is applied to physical properties such as viscosity and dewatering.

Keyphrases □ Aluminum hydroxycarbonate gel—gel structure, effect of surface charge and particle size □ Gels—aluminum hydroxycarbonate, effect of surface charge and particle size on structure □ Physicochemistry—effect of surface charge and particle size on gel structure of aluminum hydroxycarbonate gel

Investigation of the structure of aluminum hydroxide gel at an atomic level has led to improved understanding of the arrangement of atoms and the types of bonds present in the various materials collectively known as aluminum hydroxide (1–4). An equally important type of structure, gel structure, which deals with the manner in

0022-3549/82/0100-0043$01.00/0

which the aluminum hydroxide particles are arranged in space, has not been as extensively studied. For this reason, a series of studies was initiated utilizing a specially designed tension cell to elucidate various relationships between gel structure and physical properties. The role of surface charge and particle size in determining the gel structure of aluminum hydroxycarbonate gel was examined in this study.

BACKGROUND

The tension cell was designed for the study of the gel structure of aluminum hydroxide (5) and was developed from experimental methods used to study clays and related porous materials (6). The tension cell was used to measure the coefficient of bulk compressibility for two aluminum hydroxycarbonate gels having a pH-dependent surface charge and a substantially different particle size.

The coefficient of bulk compressibility, α, is used by soil physicists to describe the degree of consolidation of a solid particle or colloidal matrix on the application of an external load or stress and is typically defined as (7, 8):

$$\alpha = -\frac{1}{V}\frac{dV}{d\sigma} \qquad \text{(Eq. 1)}$$

where σ represents an applied stress and V is the volume of the system, including both the particle volume and the pore volume. When the tension cell is used, the stress is supplied by applying a small negative pressure or tension, τ. Since the cross-sectional area of the tension cell chamber is constant, the coefficient of bulk compressibility may be expressed in terms of L, the length of the column of gel in the tension cell, and the applied tension:

$$\alpha = -\frac{1}{L}\frac{dL}{d\tau} \qquad \text{(Eq. 2)}$$

The coefficient of bulk compressibility may be readily calculated if an empirical relationship between the applied tension and the corresponding length of the column at equilibrium can be established. Such a relationship may be obtained through trial and error testing of various mathematical relationships. A particularly successful equation is:

$$L = A(e^{-\beta\tau} + B) \qquad \text{(Eq. 3)}$$

where A, B, and β are constants adjusted to best fit the (τ, L) data pairs. Upon determining the proper empirical form, the coefficient of bulk compressibility is calculated by substituting Eq. 3 into Eq. 2.

EXPERIMENTAL

Two aluminum hydroxycarbonate gels were obtained commercially, and the coefficient of bulk compressibility was determined with the tension cell following dilution to 9.3% equivalent aluminum oxide.

The zero point of charge (ZPC), the pH at which the net surface charge is zero, is an important property of colloidal systems that possess a pH-dependent surface charge. At this pH, the densities of the positive and negative charges are equal (9). The zero point of charge of aluminum hydroxycarbonate gels 1 and 2 was determined to be 6.34 and 7.60, respectively, by a titration procedure (10). The desired surface charge was obtained through adjustment of the pH relative to the zero point of charge by the addition of small quantities of hydrochloric acid or sodium hydroxide to produce a positive, neutral, or negative surface charge. Aluminum hydroxycarbonate gel 1 was adjusted to pH 5.70, 6.34, and 7.40; gel 2 was adjusted to pH 5.50 and 7.00.

The rate of acid neutralization was determined by pH-stat titration at pH 3 and 25° (11).

The relative particle size of the two aluminum hydroxycarbonate gels was determined by measuring the rate of sedimentation of 100 ml of a 1% (w/v) dilution of each gel in a 100-ml graduated cylinder following pH adjustment to equal the zero point of charge. The sedimentation rate is expressed as t_{50}, the time required to settle halfway from the initial height in the 100-ml cylinder to the equilibrium sediment height.

The previously described tension cell procedure (5) was used to determine the equilibrium water outflow as a result of applied tensions up to 15 cm of water. Two modifications were made in the tension cell apparatus to provide more convenient and precise measurements. Since the gel undergoes a decrease in volume due to the outflow of water, the applied tension will decrease during the experiment. This undesirable effect was previously minimized through the manual readjustment of the height of the tension cell chamber by 0.05 cm for every 1.5 ml of water outflow so that the applied tension remained essentially constant.

This procedure was replaced with a digital motor-drive system, which readjusted the tension on sensing a downward movement of the upper gel surface. The motor triggering mechanism consisted of a pair of platinum electrodes sealed in glass tubing, which were positioned to contact the gel surface. As long as the electrodes contacted the surface, a very small dc current (<0.1 μamp) moved through the completed circuit. As outflow of water from the gel proceeded, the gel surface dropped below the electrodes, interrupting the current and activating the digital motor-drive system. The sample chamber was raised to reestablish contact between the electrodes and the gel surface. This apparatus maintained the applied tension within 0.03 cm. A vernier system was attached to the digital motor drive so the accumulated height changes of the tension cell chamber could be measured. At each tension level setting, the overall displacement of the tension cell was equal to the length change of the gel column.

A second modification was made to record automatically the water outflow as a function of time. Water flowed dropwise from the outlet tube and entered a small volumetric flask, which was fitted with a cover having a capillary opening. The flask rested on a weighing pan, which was displaced linearly according to the amount of water in the flask. The downward movement of the weighing pan was monitored with a linear variable differential transformer whose output was continuously recorded. Thus, the equilibrium outflow of water at a particular tension could be easily determined. Equilibrium times ranged from 8 to 48 hr. In every case, the equilibrium outflow of water was equal to the volume change of the gel.

RESULTS AND DISCUSSION

The applied tension is related to the amount of work required, per mole of water, $\Delta\overline{G}_{H_2O}$, to remove water from the system (12):

$$\Delta\overline{G}_{H_2O} = -\rho g \overline{V}\tau \qquad \text{(Eq. 4)}$$

where ρ is the density of water, $\overline{V}$ is the molar volume of water, and g is the acceleration due to gravity. To remove dn_{H_2O} moles of water from the system requires that an amount of work equal to δW be done on the system:

$$\delta W = \Delta\overline{G}_{H_2O}\, dn_{H_2O} \qquad \text{(Eq. 5)}$$

Equation 5 may be rewritten with the aid of Eq. 4 to give:

$$\delta W = -\rho g \tau A\, dL \qquad \text{(Eq. 6)}$$

where A is the area of the tension cell chamber and dL represents a small displacement of the length of the gel column. The work of compression, δW, is expended against the efforts of the gel to retain its original particle arrangement or gel structure. A large work of compression implies either that cohesive forces (van der Waals) are present, tending to prevent the distortion of the particles into a smaller space, or that interparticle repulsive forces (coulombic) are present, which resist a closer approach of particle surfaces.

Although the work of compression is a macroscopic concept, it is ultimately tied to phenomena occurring on a microscopic scale. As illustrated in Fig. 1, each particle may be viewed as residing in a potential well, the depth and width of which are controlled by interparticle force fields. Movement of any particle along some trajectory from one well to another requires that the particle attain sufficient energy to pass over the interposed barrier. If thermal energy is insufficient, there is no appreciable translational motion and the system gels. In such cases, the necessary energy may be provided by applying an external stress such as shear or, in this case, a pressure gradient (tension). The extent to which particles are free to move under an applied external stress is directly dependent on the nature of adjacent energy barriers.

The work of compression is further illustrated in Fig. 2 (A and B) by the shaded regions that are proportional to the work of compression required to displace the gel from a length of 4.5–4.0 cm. The work required to compress the neutral aluminum hydroxycarbonate gel over this range is approximately twice that required to compress the charged aluminum hydroxycarbonate gel, indicating that cohesive forces present in the neutral gel tend to prevent the movement of the particles to a greater extent than the repulsive forces present in the positively charged system.

It is clear that Eq. 3 is a suitable mathematical expression to describe the tension *versus* gel column length relationship since the solid lines

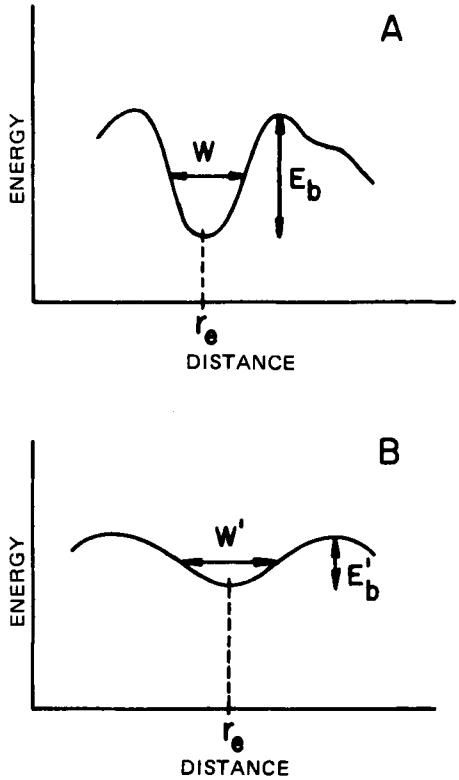

Figure 1—*Energy–distance profiles. Key: A, high particle density gel; B, low particle density gel; E_b, depth of the potential well; W, characteristic width of the potential well; and r_e, equilibrium position of the particle.*

representing the fitted equation coincide with the data points. Thus, the data in Fig. 2 were used to calculate the compressibility curves shown in Fig. 3.

The coefficient of bulk compressibility of aluminum hydroxycarbonate gel 1 is clearly affected by the presence of surface charge (Fig. 3, A and B). At tension levels less than ~9 cm, the positively charged system was considerably more compressible than the neutral gel. This result is similar to the previously observed effect of surface charge on the viscosity of aluminum hydroxycarbonate gel in which the maximum viscosity occurred when the pH equaled the zero point of charge (10).

The underlying mechanism explaining both phenomena is that when

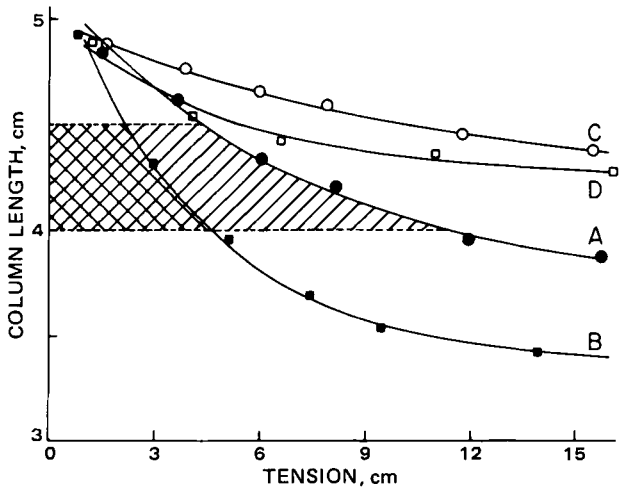

Figure 2—*Change in the column length as a result of applied tension. Shaded areas indicate the relative work of compression required to displace aluminum hydroxycarbonate gels 1 and 2 from a length of 4.5 to 4.0 cm. Key: A, gel 1 at pH 6.34 (ZPC = 6.34); B, gel 1 at pH 5.7; C, gel 2 at pH 7.0 (ZPC = 7.60); D, gel 2 at pH 5.5; data points are from tension cell experiments and the solid lines were obtained by fitting Eq. 3 to the data points.*

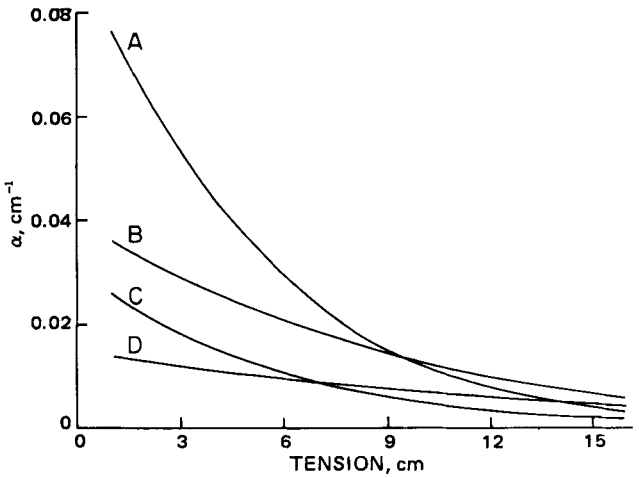

Figure 3—*Effect of tension on the coefficient of bulk compressibility, α. Key: A, gel 1 at pH 6.34 (ZPC = 6.34); B, gel 1 at pH 5.7; C, gel 2 at pH 7.0 (ZPC = 7.60); and D, gel 2 at pH 5.5.*

sufficient coulombic repulsion is developed to overcome van der Waals attractive forces, the particles are free to move in a less restricted manner. Particles are considered to be more free or mobile under the influence of repulsion than attraction since repelling particles tend to utilize the entire space of the system, whereas attractive forces usually produce structures that confine the particles to rigid, linear chains so that considerable unused space exists (13). Since the charged particles are not so severely confined in space, consolidation of the colloidal matrix in response to water removal may readily take place, leading to a more compressed system. In addition, the absence of attractive forces tending to lock the particles into position permits shear rather easily. At the zero point of charge, however, substantial cohesive forces (van der Waals) resist distortion of the gel structure to form some new structural arrangement.

However, as seen in Fig. 3 (A and B) the charged gel was less compressible than the neutral gel when the applied tension exceeded 9 cm of water. This is a consequence of the initial freedom of movement of the charged particles during consolidation and leads to a more efficiently packed collection of particles. This dense collection of particles is able to resist further compaction more effectively than the neutral gel due to the substantially increased level of coulombic repulsion. In addition, when the aluminum hydroxycarbonate gel is at the zero point of charge, the initial randomness or disorder of the gel structure is locked into place by van der Waals cohesive forces, preventing the formation of an efficiently packed particle network. Consequently, the compressibility of the neutral gel is greater than that of the charged gel at high tensions.

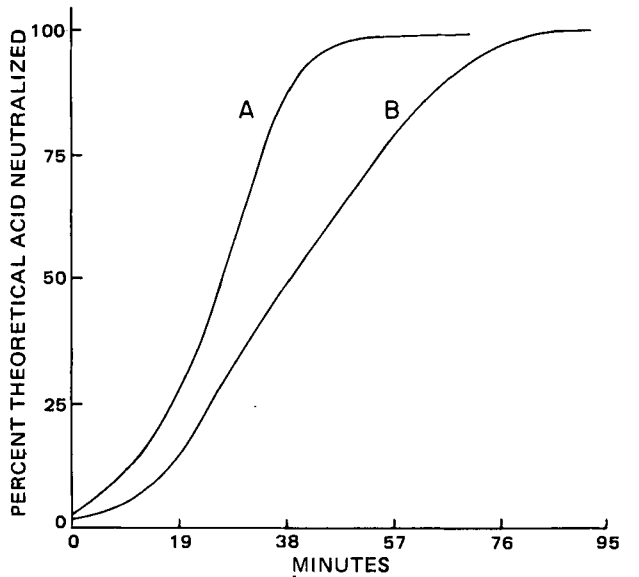

Figure 4—*Rate of acid neutralization at pH 3.0 and 25°. Key: A, gel 1; and B, gel 2.*

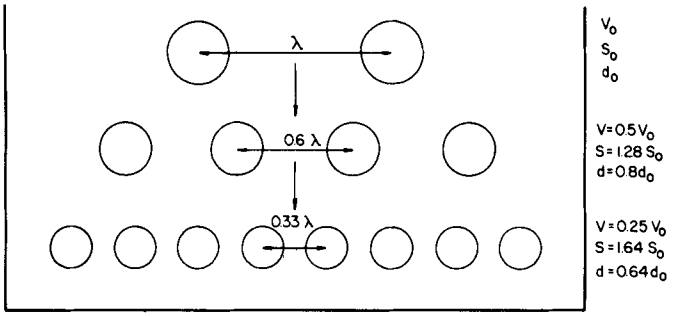

Figure 5—*Effect of particle density on interparticle distance. Key: λ, interparticle distance; V, volume of each particle; S, total surface area; and d, diameter of each particle. The volume of each particle is reduced by 50% in each step while the total volume of the particles is constant.*

A practical consequence of this behavior is that the charged state permits more convenient water removal, but only when the water content is below that corresponding to a tension of 9 cm of water. Above 9-cm water tension, the neutral state is more desirable for operations involving water removal.

The zero point of charge of gel 2 was 7.6. This gel is believed to have a smaller particle size and, therefore, a greater surface area than gel 1 since this gel became too viscous to mix as the pH was brought to the zero point of charge. It was not possible to adjust the pH to 7.6 where the maximum viscosity occurs because of the high viscosity. This behavior is in contrast to that of gel 1, which became more viscous as the pH was adjusted to its zero point of charge but still remained fluid at the zero point of charge.

The smaller particle size of gel 2 was confirmed by comparing the rate of settling of 1% equivalent aluminum oxide dilutions of gels 1 and 2. The t_{50} value for the sedimentation of gel 1 was 1.8 hr while gel 2 required 4.3 hr for an equivalent degree of sedimentation. The more rapid rate of acid neutralization by gel 2 at pH 3 (where both aluminum hydroxycarbonate gels will be highly charged) also reflects its smaller particle size (Fig. 4).

It was not possible to repeat exactly the tension cell experiment for gel 2 since the viscosity was too great at the zero point of charge. However, the effect of charge on the gel 2 structure was similar to that observed for gel 1 (Fig. 2, C and D). Gel 2 was more compressible when in a highly charged state, *i.e.*, at pH 5.5, up to a tension of ~7 cm of water (Fig. 3, C and D). The less charged state, *i.e.*, at pH 7.0, was more compressible at higher tension levels. The point at which the charged gel became more compressible than the neutral gel (7 cm of water) occurred at a lower tension than was observed for gel 1 due to the much greater charge on gel 2.

The most striking difference between gels 1 and 2 was that gel 2 was less compressible regardless of its charge. Since the same types of forces are present in both gels and each gel has the same equivalent aluminum oxide content, the factor responsible for the difference in behavior must be the smaller particle size and, consequently, the greater surface area of 2. Reducing the particle size while maintaining a constant solids concentration will cause gel 2 to have a higher particle density.

The effect of particle density may be illustrated by the example provided in Fig. 5 in which individual particle volume is sequentially halved in a one-dimensional arrangement of particles. Such a system is especially relevant since linear chains are frequently formed under the influence of van der Waals attractive forces (13). Although surface area does not increase substantially upon two subdivisions, the average interparticle distance decreases signficantly. Consequently, a gel having a smaller particle size is much more likely to form an extended chain-like network when cohesive interparticle forces exist.

The effect of particle density for the general case of three-dimensional particle arrays with either attractive or repulsive interparticle forces present may be further clarified through the microscopic energy–distance profiles of Fig. 1 (A and B). As was shown, a higher particle density leads to a smaller average interparticle separation distance. Since forces depend inversely on separation distance, the net restoring force exerted on a given particle by all others during a small displacement of the particle from its equilibrium position is greater (as in Fig. 1A). A low particle density yields the opposite effects (as in Fig. 1B) so that particles are less influenced by one another and are not held as tightly in place. This conclusion follows for coulombic-type forces as well as van der Waals forces so that gel 2 is predicted to be less compressible than gel 1 in both its charged and discharged states. The experimental results observed in Fig. 3 support this conclusion.

Comparison of Effects of Cyanide and Acetylcholine on Renal Hemodynamics and Sodium Excretion

RONALD L. WILLIAMS *[x], JAMES E. PEARSON [‡], and FRANCISCO M. GONZALEZ [‡]

Received March 18, 1981, from the *Department of Pharmacology and the [‡]Department of Medicine, Louisiana State University Medical Center, New Orleans, LA 70112. Accepted for publication May 14, 1981.

Abstract □ The present study compared the effects of acetylcholine to cyanide under the same experimental conditions of renal clearance in anesthetized dogs. Since cyanide is one of the few drugs for which the mechanism of action is known (cytotoxic hypoxia), some insight may be gained into the renal effects of acetylcholine since both produce direct natriuresis and diuresis. Infusion of 0.2 μg/kg/min of acetylcholine and 12.0 μg/kg/min of sodium cyanide into the left renal artery resulted in similar effects, *i.e.*, increased fractional excretion of sodium, potassium, calcium, and magnesium. These effects were immediate and ipsilateral. Both agents increased the renal plasma flow to the same extent. In addition, regression plots of the relation between changes in sodium excretion and changes in renal plasma flow were similar for both agents. The pattern of similar renal functional changes suggested that acetylcholine is not a mere renal vasodilator but that its action is also mediated through alterations on direct tubular transport of ions.

Keyphrases □ Hemodynamics, renal—effects of cyanide and acetylcholine compared □ Cyanide—effects on renal hemodynamics and sodium secretion, comparison with acetylcholine □ Acetylcholine—effects on renal hemodynamics and sodium secretion, comparison with cyanide

May and Carter (1) showed that something other than simple vasodilation is responsible for the saluretic action of cholinergic drugs. When they infused cholinergic drugs into the renal portal system of chickens, there was an ipsilateral saluresis; however, noncholinergic drugs (isoproterenol, papaverine, and dopamine) produced no saluresis despite similar renal vasodilation.

BACKGROUND

The prevalent conclusion has been that vasodilating agents induce changes in sodium excretion mainly by altering renal blood flow (2, 3). Using autoperfused kidneys, no correlation was found between changes in renal perfusion pressure and changes in sodium excretion for either acetylcholine or isoproterenol (4). Itskovitz and Campbell (5) infused seven different vasodilators into isolated blood-perfused canine kidneys at constant pressure. Despite similar hemodynamic effects on renal blood flow, perfusion pressure, and intrarenal distribution of blood flow, their effects on glomerular filtration rate (*GFR*), sodium excretion, and urine flow were dissimilar. Acetylcholine was by far the most natriuretic. Eledoisin, one of the vasodilators examined, actually decreased sodium excretion.

Stein *et al.*, (6) showed that acetylcholine (in micropuncture studies) decreased fractional and absolute sodium reabsorption in the proximal tubule. During this depression of proximal tubular reabsorption of sodium, there was no redistribution of glomerular filtration to outer cortical nephrons. Hayslett *et al.* (7), using a split-droplet method of micropuncture, infused acetylcholine into the abdominal aorta of rats and obtained a natriuresis despite a 50% reduction of glomerular filtration and renal blood flow. However, they interpreted the natriuresis to be due to intrarenal hydrostatic pressure and extraepithelial physical factors.

This study investigated renal vasodilation and the relation between hemodynamic and natriuretic changes by comparing intrarenal infusion of cyanide to that of acetylcholine.

EXPERIMENTAL

Materials and Methods—Five mongrel dogs were anesthetized with pentobarbital sodium, 30 mg/kg iv. Both ureters were cannulated through an abdominal midline incision, and the cannulas were positioned ~2 cm below the ureteral pelvic junction. A femoral vein and artery were cannulated, and the arterial cannula was connected to a transducer with a three-way stopcock for recording blood pressure with a polygraph. Arterial blood samples were obtained through the three-way stopcock.

Solutions containing creatinine, *p*-aminohippurate, and normal saline were infused at a rate of 5 ml/min through the venous system using a dual-syringe constant-flow infusion pump. A 27-gauge hypodermic needle, attached to a number 10 polyethylene tube, was placed in the left renal artery in the direction of blood flow. Through this renal arterial system, a solution of isotonic sodium chloride was continuously infused at a rate of 0.1 ml/min.

Solutions of drugs were also infused through the system at the same rate by changing the renal arterial infusate to one containing test drugs dissolved in normal saline. Both acetylcholine and sodium cyanide were infused into the same animal under the same experimental conditions. One to two hours was allowed for equilibration, and then collections of 10-min urine samples from each kidney were begun. Blood samples, drawn every 20 min from the femoral artery, were heparinized and centrifuged, and the plasma was immediately removed. At least three control urine samples were collected before these agents were infused into the kidney. The order of drug infusion was altered in some experiments.

Analysis—Chloride concentrations in urine and plasma were determined using a titrametric chloridometer; sodium and potassium concentrations in urine and in plasma were determined using a flame photometer with an internal lithium standard; a modification of a previous method (8) was used in the creatinine determinations. *p*-Aminohippurate determinations were made using a reported method (9). Tubular maximal secretion rates of *p*-aminohippurate were obtained by infusing high concentrations intravenously and then subtracting the amount filtered from the total excreted (10). The osmolalities were determined by freezing-point depression.

In addition to the electrolyte excretion rates, the glomerular filtration rates, the effective renal plasma flow, and the tubular rejection fraction of sodium were calculated. Calcium and magnesium were measured by atomic absorption spectrophotometry. Statistical methods for regression lines and significance of mean differences were taken from Snedecor (11).

Table I—Comparison of Intrarenal Infusion of Acetylcholine to that of Sodium Cyanide[a]

Parameter	Acetylcholine, 0.88 nmole/kg/min Δ[b]	*SE*	Sodium Cyanide, 0.25 μmole/kg/min Δ	*SE*
V, ml/min	1.03	±0.22	2.89	±0.72
C_{osm}, ml/min	0.99	±0.24	2.48	±0.57
GFR, ml/min	1.3	±1.8	3.0	±1.0
C_{PAH}, ml/min	11	±5.0	11	±3.8
$U_{Na^+}V$, μEq/min	145	±32	359	±109
$U_K V$, μEq/min	9	±4	28	±18
$U_{Ca^{2+}}V$, μEq/min	14	±6	15	±7
$U_{mg^{2+}}V$, μEq/min	4.0	±2	3.8	±1.2

[a] All drugs were infused into the left renal artery. [b] Each value is the mean change from five dogs obtained by subtracting the changes in the right, control kidneys from changes in the left, infused kidneys; Δ = (left kidney: drug period − control period) − (right kidney: drug period − control).

0022-3549/82/0100-0047$01.00/0

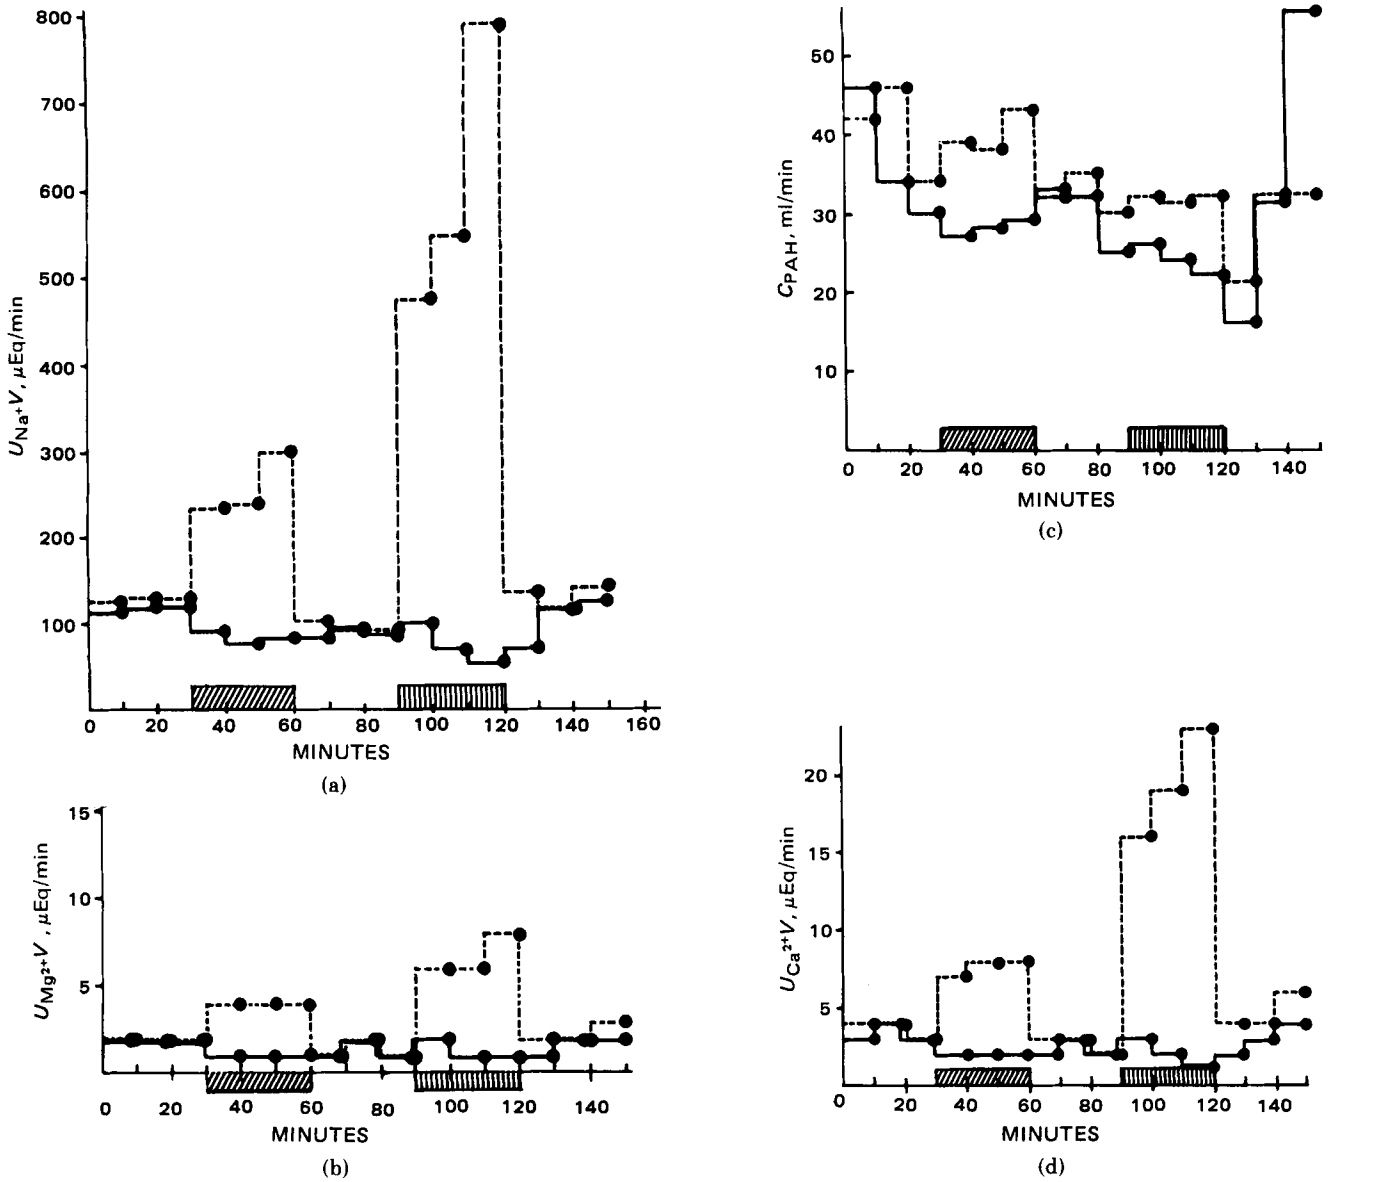

Figure 1—*Comparison of renal effects of cyanide and acetylcholine during infusion into the left renal artery. Key: - - -, left; —, right;* ▨, *acetylcholine bromide (0.2 μg/kg/min); and* ▥, *sodium cyanide (12.0 μg/kg/min).*

RESULTS

The effects of acetylcholine and local hypoxia on renal function were compared during the infusion of 0.2 μg/kg/min of acetylcholine bromide and 12.0 μg/kg/min of sodium cyanide into the left renal artery of the same animal at different times (Figs. 1*a* and 1*b*). (Converted to a molar basis, the infusion rate would be 0.88 nmole of acetylcholine bromide and 0.25 μmole of sodium cyanide/kg/min, respectively.) During the infusion of each drug, there were immediate ipsilateral increases in sodium, potassium, and calcium excretion, in osmolar clearance, creatinine clearance, *p*-aminohippurate (PAH) clearance, and urine flow. When either drug infusion was stopped, there was an immediate return to control values, even for cyanide.

Both acetylcholine and cyanide actually increased *p*-aminohippurate secretion from the tubules (Fig. 2).

The relationship between changes in sodium excretion ($U_{Na^+}V$) and changes in renal plasma flow (*RPF*) are shown in Figs. 3 and 4. The regression line for acetylcholine (Fig. 3) was $U_{Na^+}V = 8.71\ (RPF) + 29$ with a correlation coefficient of 0.83 ($p < 0.05$); the regression line for cyanide (Fig. 4) was $U_{Na^+}V = 11.5\ (RPF) + 44$ with a correlation coefficient of 0.89 ($p < 0.05$). Therefore, with the assumption of a linear relationship, cyanide produced the same effect as acetylcholine on sodium excretion and renal blood flow.

To exclude systemic influences from direct renal effects during acetylcholine or cyanide infusion into the left renal artery, the data were arranged in Table I in the following manner: (*a*) mean changes in the excretion of fluid and electrolytes were calculated along with their respective standard errors; and (*b*) each change was obtained by subtracting the changes in right, noninfused kidneys from the changes in left, experimental kidneys. Both acetylcholine and sodium cyanide produced increased excretion of each electrolyte.

DISCUSSION

Both agents increased renal blood flow and increased tubular secretion of *p*-aminohippurate. The natriuretic effects of cholinergic drugs are of the muscarinic type inhibited by atropine (12, 13). Intrarenal infusion of the muscarinic agent bethanechol (12) produced natriuresis, which was unrelated to washout of the medullary concentration gradient. No correlation was shown (14) between sodium excretion and medullary blood flow when acetylcholine was infused into a renal artery. It was postulated (13) that cholinergic drugs produce saluresis by direct action on the renal tubule, but the influence of vasodilation could not be eliminated. Cyanide, which is known to depress the energy from the electron transport system for active sodium reabsorption, also produces vasodilation. Vasodilation does not explain the natriuresis of cyanide and, therefore, may not explain the natriuresis of acetylcholine. Although a correlation between two variables does not prove a cause and effect relationship, this comparison of acetylcholine with cyanide does add indirect evidence that acetylcholine acts directly on renal tubular sodium transport in some way.

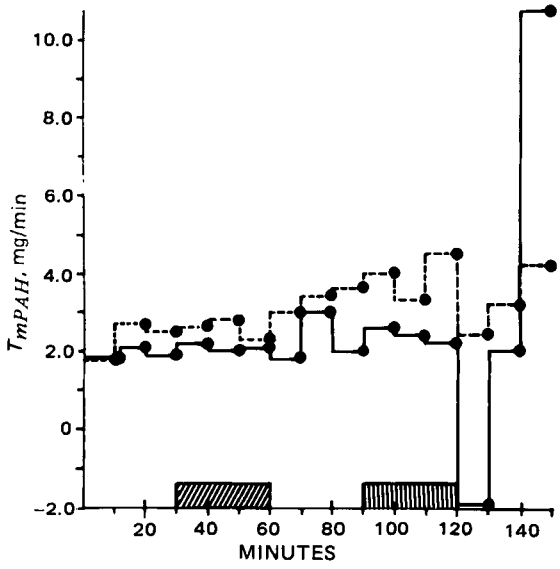

Figure 2—*Effects of intrarenal acetylcholine bromide and cyanide on tubular secretion of* p-*aminohippurate* (T_{mPAH}) *Key: - - -, left; — right;* ▨, *acetylcholine bromide (0.2 μg/kg/min); and* ▥, *sodium cyanide (12.0 μg/kg/min).*

The direct natriuretic effect of cholinergic agents was shown in chicken (12, 15) and dog (13, 16–18) kidneys. Some workers concluded direct tubular effects from micropuncture studies (6, 19); others interpreted the saluretic effect to be a result of intrarenal physical alterations due to hemodynamic changes from vasodilation (2, 3, 7). However, papaverine, a noncholinergic vasodilator, was found to be natriuretic in anesthetized sheep but not in conscious sheep (20). In conscious sheep, there was an inverse relationship between sodium excretion and changes in renal blood flow. In fact, there was a reduction in sodium excretion from the conscious animals despite an increase in renal blood flow. Cholinergic agents were shown (1) to be natriuretic in chickens, but noncholinergic vasodilators were not natriuretic even though blood flow was increased. The natriuretic action of acetylcholine cannot be explained by a redistribution of blood flow to shorter cortical nephrons (6).

The physiological importance of acetylcholine is an interesting question

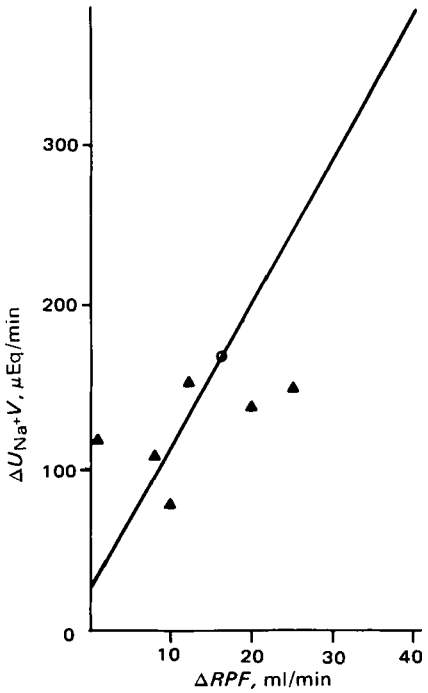

Figure 3—*Linear regression for changes in sodium excretion* ($U_{Na^+}V$) *and changes in renal plasma flow* (RPF) *during infusion of acetylcholine bromide into the left renal artery* ($y = bx + c$, $\Delta U_{Na^+}V = 8.71$ (ΔRPF) + 29, $\bar{y} = 172 \pm 47$, $\bar{x} = 16 \pm 4$, $r = 0.83$, *and* $p < 0.05$).

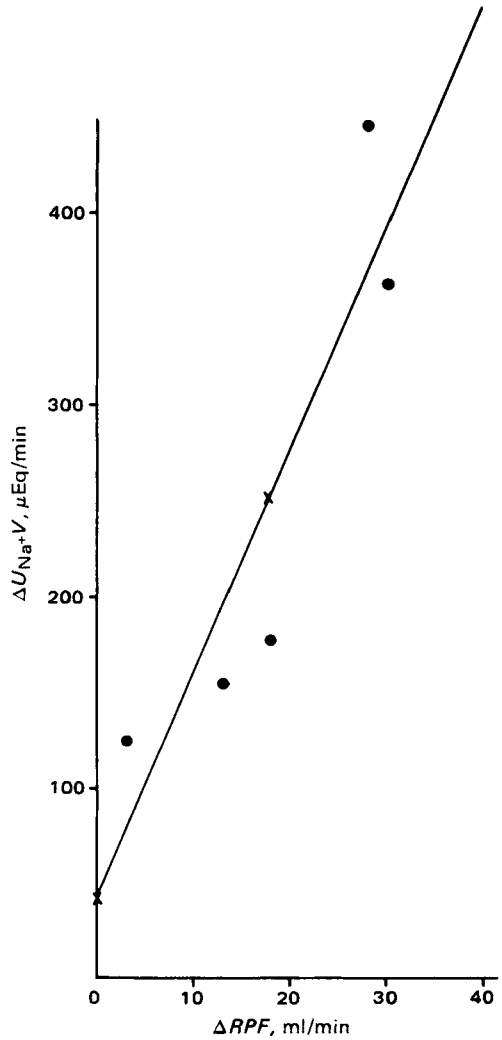

Figure 4—*Linear regression for changes in sodium excretion and changes in renal plasma flow* (RPF) *during infusion of sodium cyanide into the left renal artery* ($y = bx + c$, $\Delta U_{Na^+}U = 11.5$ (ΔRPF) + 44, $\bar{y} = 254 \pm 14$, $\bar{x} = 18 \pm 11$, $r = 0.89$, *and* $p < 0.05$).

since renal tubules were shown (21) to be directly innervated by autonomic nerves. In addition, the renal effects of acetylcholine are similar to cyanide, which inhibits aerobic metabolism equally in the renal cortex and outer medulla (10, 22, 23), resulting in natriuresis. Cyanide-induced natriuresis was one of the first observations relating sodium transport in the kidney to oxidative metabolism (24). Surprisingly, cyanide does not inhibit *p*-aminohippurate secretion (25); therefore, its clearance can be used to measure effective renal plasma flow. Cyanide also increases renal blood flow (23, 26).

In this study, the slopes of the lines for the function $U_{Na^+}V = b(RPF) + c$, where b is the slope of the line and c is the y intercept for a line ($y = bx + c$), for acetylcholine and cyanide were not significantly different (Figs. 3 and 4), assuming linear regression. The pattern of electrolyte excretion was apparently the same for each drug, including that of sodium, potassium, calcium, and magnesium. Just as cyanide acts on both the proximal and more distal portions of the nephron (23), so does acetylcholine according to micropuncture work (6). Therefore, *in vivo* comparison of acetylcholine and cyanide under identical clearance conditions in dogs substantiates that acetylcholine is not merely a vasodilator but either acts directly on tubular transport or increases the permeability and back-leak of sodium, causing a net increase in sodium excretion. There were increases in volume of urine flow, osmolar clearance, and excretion of potassium, calcium, and magnesium. Both acetylcholine and cyanide increased effective renal plasma flow.

Kinetics of Chlorambucil Hydrolysis Using High-Pressure Liquid Chromatography

DULAL C. CHATTERJI ˣ, RUSSELL L. YEAGER, and JOSEPH F. GALLELLI

Received October 23, 1980, from the *Pharmaceutical Development Service, Pharmacy Department, Clinical Center, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication May 12, 1981.

Abstract □ A stability-specific high-pressure liquid chromatographic (HPLC) method was developed to assay intact chlorambucil (I) in the presence of its hydrolytic decomposition products. The HPLC method was used to follow the degradation kinetics of I over pH 1.0–10.0 in the presence of various buffers with and without added chloride ion. In the absence of chloride ion, the hydrolysis of I followed first-order kinetics and the pH rate profile showed a sharp inflection around pH 2.5 attributable to the ionization of the nitrogen mustard and a shallower inflection around pH 5.0 attributable to the ionization of the carboxylic group. The rate was pH independent over pH 6.0–10.0 and independent of buffer species in the absence of chloride ion. In the presence of chloride ion, the kinetics of I hydrolysis was still first order. However, the degradation half-life at a particular pH and buffer concentration increased linearly with chloride concentration. Kinetic evidence is presented to show that the mechanism of chloride stabilization involves the attack of chloride ion on the unstable cyclic ethyleneimmonium intermediate to give back I. Implications of the kinetic data obtained on the fate of orally administered I are discussed.

Keyphrases □ Chlorambucil—kinetics of hydrolysis, high-pressure liquid chromatography □ Hydrolysis—chlorambucil, analysis of kinetics using high-pressure liquid chromatography □ High-pressure liquid chromatography—analysis of chlorambucil hydrolysis kinetics □ Kinetics—chlorambucil hydrolysis, high-pressure liquid chromatography

Nitrogen mustards were one of the first classes of cancer chemotherapeutic agents systematically studied, and they still are used clinically (1). Although the general mechanisms of hydrolysis and alkylation for nitrogen mustards are well known (1–6), little detailed kinetic data are available on their hydrolysis. One reason for the lack of comprehensive kinetic work on the mustards has been the lack of suitable stability-specific analytical methods.

BACKGROUND

Most early work on the kinetics of mustards was performed by estimating the amount of free chloride ion liberated. However, this indirect method of determining intact nitrogen mustards and subsequent kinetic analysis can lead to incorrect stability estimates (3). Furthermore, the stabilizing effect of chloride on mustard hydrolysis cannot be quantitatively evaluated with this method. More recent reports (4, 5) on the hydrolysis of melphalan using stability-specific high-pressure liquid chromatography (HPLC) produced some useful information on the kinetics of melphalen hydrolysis and on the effect of chloride ion on its stability.

Chlorambucil (I), an aromatic nitrogen mustard, is considered stable enough to be administered primarily as an oral dosage form. However, there are no reported data on the stability of I over the GI pH range at 37°. It was recently shown (3), using a stability-specific HPLC method for I, that the half-life of I degradation was only 25 min at pH 3.0 and 37°. Since pH 3.0 is not unrealistic for the stomach, these data showed potential stability problems for orally administered I. Thus, a kinetic study of I hydrolysis over the pH range of the GI system seemed warranted.

EXPERIMENTAL

Materials—Chlorambucil USP reference standard was used for all kinetic studies. Water was double distilled in an all-glass apparatus, and glass-distilled solvents[1] were used for HPLC. All other chemicals were reagent grade.

Buffers—Citrate buffers (pH 2.0–7.0), acetate buffers (pH 3.5–5.5), phosphate buffers (pH 6.0–9.0), and borate buffers (pH 8.5–10.0) were prepared from the 0.25 *M* stock solutions of citric acid, acetic acid, monobasic sodium phosphate, and boric acid, respectively, by the addition of sodium hydroxide solution to the desired pH. Addition of chloride ion was avoided except when specified. Ionic strength was maintained con-

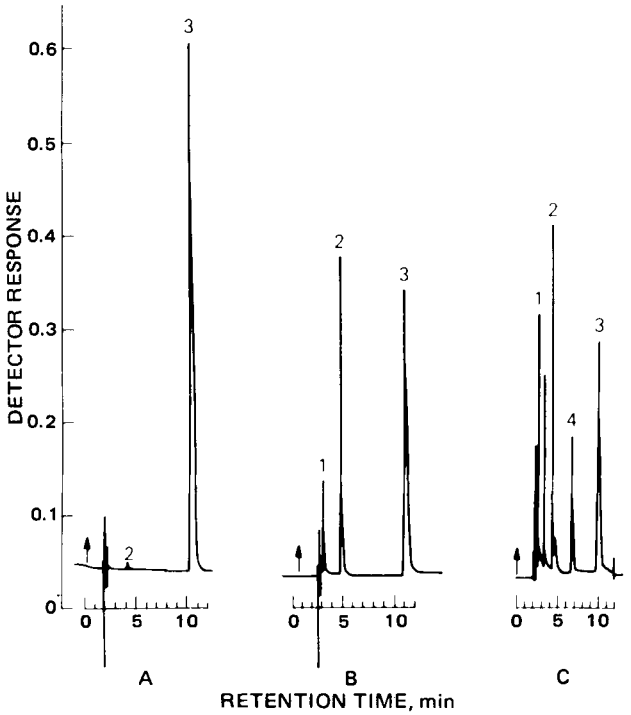

Figure 1—*Chromatogram obtained by the described HPLC method. Key: A, freshly prepared solution of I in water, 200 μg/ml; B, solution of I degraded ~50% in water; and C, solution of I degraded ~50% in 0.05* M *acetate buffer, pH 3.5.*

stant where noted with potassium nitrate. Other ingredients, when added, were weighed into the buffers before adjustment of pH.

Equipment—The high-pressure liquid chromatograph[2] was equipped with a fixed-volume loop injector[3] and a fixed-wavelength detector[4]. A 250- × 4.6-mm i.d. reversed-phase column[5] was used. All pH measurements[6] were taken at room temperature. All kinetic runs were carried out in a constant-temperature water bath[7] capable of maintaining the temperature within ±0.1°. Chloride-ion determinations were made with an automatic chloride titrator[8].

Kinetic Studies—Solutions of I were prepared by adding stock solution of I in acetone to 25.0 ml of buffer preequilibrated at the desired temperature for at least 30 min. The concentration of I in the final solution was ~0.04 mg/ml, and acetone concentration in the final reaction mixture was <1%. The solutions were kept in the constant-temperature water bath and were assayed for intact I at various time intervals. In several cases, the solutions were also assayed for chloride-ion production as described previously (3).

HPLC Assay Method—Separation was performed on a reversed-phase column[5] and methanol–acetonitrile–0.01 *M* acetate buffer, pH 4.5 (65:5:30), at a flow rate of 1.6 ml/min was used as the mobile phase. A 10-μl full loop volume was quantitatively injected, and the recorder was set at 0.32 aufs (254-nm detector). The peak due to I had a retention time of ~10.6 min and was the last to elute in the chromatogram. The peak height of I was used to calculate the amount of intact I present in the sample.

RESULTS AND DISCUSSION

Chromatography—The reversed-phase liquid chromatography permitted the analysis of intact I in the presence of its major hydrolytic degradation products in various buffer systems. Figure 1A shows the chromatogram of a freshly prepared solution of I in water. Peak 3, with a retention time of 10.6 min, was due to I; the small peak (peak 2), with a retention time of 4.0 min, was attributed to the monohydroxy product (II). When completely degraded solutions of I, both in water alone and in various buffer systems, were chromatographed, no peak corresponding to the retention time of I was observed. Therefore, none of the final degradation products interfered with the assay for intact I. During the degradation of I in water, peak 2 was the first to appear and increased through approximately one half-life of I, after which time it began decreasing.

Peak 1, which eluted close to the solvent front, increased steadily throughout the degradation; Fig. 1B shows a typical chromatogram when ~50% of I had degraded in water. Based on the mechanism of I hydrolysis, peak 2 was attributed to II and peak 1 was attributed to the dihydroxy product (III). This is also consistent with the order of elution of these peaks, where the dihydroxy compound, III, eluted faster than the monohydroxy compound, II, which, in turn, eluted faster than the relatively nonpolar I. The order of elution was similar to that reported for the reversed-phase HPLC of melphalan (4). Therefore, major intermediate degradation products in water alone do not interfere with the assay.

When I degrades in the presence of various buffers, other peaks, in addition to those due to II and III, also appear. Thus, Fig. 1C shows the chromatogram of a solution of I degraded in 0.05 *M* acetate buffer, pH 3.0. The peaks, in addition to those due to I–III, were probably due to the degradation products resulting from the attack of nucleophilic buffer species on reactive cyclic ethyleneimmonium intermediates. Thus, based on the time course of appearance and disappearance and also the retention time of peaks, peak 4 in Fig. 1C was tentatively attributed to the

Table I—Effect of pH and Buffer Concentration on Rate and Half-Life of I Hydrolysis at 37°

monoacetyl derivative of I. Similarly, when the solvents contained substantial amounts of methanol or ethanol, other peaks that probably were due to the methoxy- or ethoxy-substituted compounds appeared. No further attempts were made to isolate and identify these peaks, and the major concern was to make sure that these peaks did not interfere with the assay of intact I.

The peak height due to I was linearly related with its concentration over 10–200 μg/ml. Therefore, peak heights were used to calculate the amount of intact I present in the sample. Acetone was used as the solvent for the stock solution, because I degrades slowly in hydroxylic solvents such as methanol or ethanol.

Kinetic Studies—Hydrolysis of I followed first-order kinetics over pH 1.0–10.0 as determined from linear semilogarithmic plots of the amount of intact I remaining *versus* time. Table I summarizes the rates of I hydrolysis in various buffers and pH values in the absence of added chloride ion. Table II shows the rates in the presence of added chloride ion. The rate of I hydrolysis was relatively independent of buffer species and concentration but was strongly influenced by pH and chloride-ion concentration. Therefore, the effects of pH and chloride-ion concentration are discussed separately.

Effect of pH—Figure 2 shows the pH rate profile for I hydrolysis at 37° in buffered solutions with 0.1 *M* ionic strength where no chloride ion was added. The profile shows a sharp inflection around pH 2.5 and a shallower one around pH 5.0, followed by a plateau region at pH 6.0–10.0

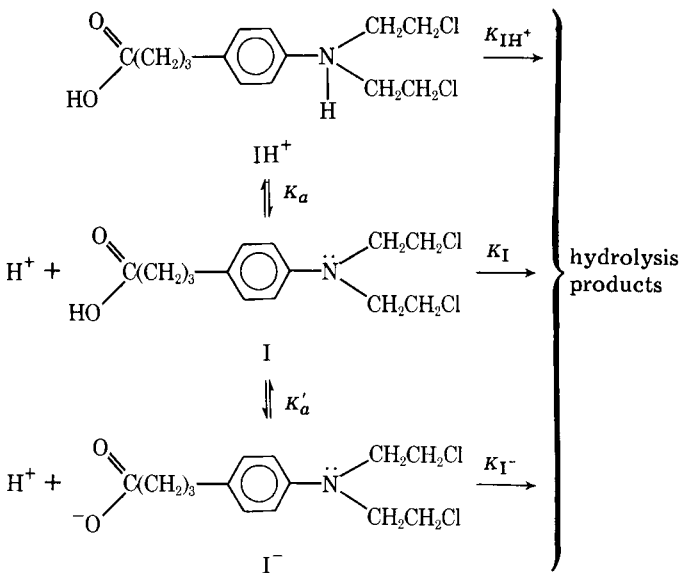
The pH-independent rate of I hydrolysis at pH 6.0–10.0 excludes the possibility of a significant hydroxide-ion catalysis for I hydrolysis over pH 1.0–10.0. In addition, the decreasing rate of I hydrolysis as the pH was lowered suggests that hydrogen-ion catalysis is also not important in this range. Thus, change in the rate of I hydrolysis with pH in this range must be attributable to the ionization of reactive functional groups in I.

The sharp inflection around pH 2.5 is attributable to the ionization of the nitrogen mustard of I. The mechanism of nitrogen mustard hydrolysis is known to involve the attack of unprotonated nitrogen mustard to expel chloride, forming an unstable cyclic ethyleneimmonium intermediate. This is followed by the attack of water and other nucleophiles to give subsequent products (1–6). The availability of a free electron pair on the nitrogen mustard is essential for its reactivity (1), and protonation of this nitrogen makes the compound much less reactive. The pKa of the nitrogen mustard of I was reported (2) to be on the order of 2.5. Therefore, as pH increases from 1.0 to 4.0, more of I would be in the unprotonated form and the rate of I hydrolysis should increase. The sharp inflection (Fig. 2) near the pKa of I strongly supports the mechanism that the unprotonated nitrogen mustard is the reactive species.

This mechanism alone, however, does not explain the shallow inflection around pH 5.0. If the ionization of the nitrogen mustard was the only determinant in the rate of I hydrolysis, a plateau above pH 4.5 (*i.e.*, 2 pH units above the pKa) would be expected. However, the difference in rate constants in the final plateau region (pH >6.0) and that of the plateau range of pH 4.0–4.5 is real. Experiments in this pH region (pH 3.0–5.5) were done at very frequent pH intervals (Fig. 2 and Table I), often repeated three times each, and ionic strength was strictly maintained, thus leaving little doubt that there is an inflection between pH 4.5 and 6.0.

Since the rate of I hydrolysis in the pH 4–6-range is totally independent of hydrogen ion, hydroxide ion, or buffer catalysis (acetate, citrate, and phosphate buffer concentration had no effect on the rate, Table I), the increase in rate with increasing pH in this range must be attributed to ionization of another group in I that would affect the rate of I hydrolysis. The only ionizable group in I (except the nitrogen mustard) is the carboxylic group, and thus the inflection must be attributed to this group. The inflection region around pH 5.0 is also consistent with the ionization constant of an aliphatic carboxylic group.

A slightly higher rate of hydrolysis of I^- over I is also not unreasonable. The ionization of the carboxylic group and resultant formal negative charge on the alkyl substituent is expected to have some long-range electron-donating inductive effect on the nitrogen mustard, making it slightly more reactive than I where the carboxylic group is unionized. Therefore it is suggested that the second inflection point is due to the ionization of the carboxylic group and that the plateau area, in the 6.0–10.0-range, is the limiting rate of ionized I^- (Scheme I).



Scheme I

This mechanism is supported by calculation of rate at any particular pH. Thus, for the reaction shown in Scheme I, it can be shown that:

$$K_{obs} = (K_{IH^+}[H^+]^2 + K_I[H^+]K_a + K_{I^-}K_aK'_a)\frac{I_t}{D} \quad \text{(Eq. 1)}$$

where K_{obs} is the observed rate constant; K_a and K'_a are the ionization constants of the species IH^+ and I, respectively; and:

$$I_t = [IH^+] + [I] + [I^-] \quad \text{(Eq. 2)}$$

$$D = [H^+]^2 + K_a[H^+] + K_aK'_a \quad \text{(Eq. 3)}$$

The value of K_{IH^+} can be estimated from pH 1 data and thus shown to be negligible. The value of K_{I^-} can be obtained from the limiting rate at pH >6, which was experimentally found to be 0.0440 min^{-1} (Table I). The pKa value was reported (2) to be on the order of 2.5; that of pKa′, the ionization constant of an aliphatic carboxylic group, should be on the order of 5.0. The value of K_I should be close to the rate between pH 3.5 and 4.0, which was experimentally found to be between 0.032 and 0.035 min^{-1}. The solid line in Fig. 2, obtained using Eq. 1 and $K_{IH^+} = 0.0$ min^{-1}, $K_I = 0.0335$ min^{-1}, $K_{I^-} = 0.0440$ min^{-1}, pKa = 2.4, and pKa′ = 4.9 (all realistic values), represented the best fit of the theoretical line to the

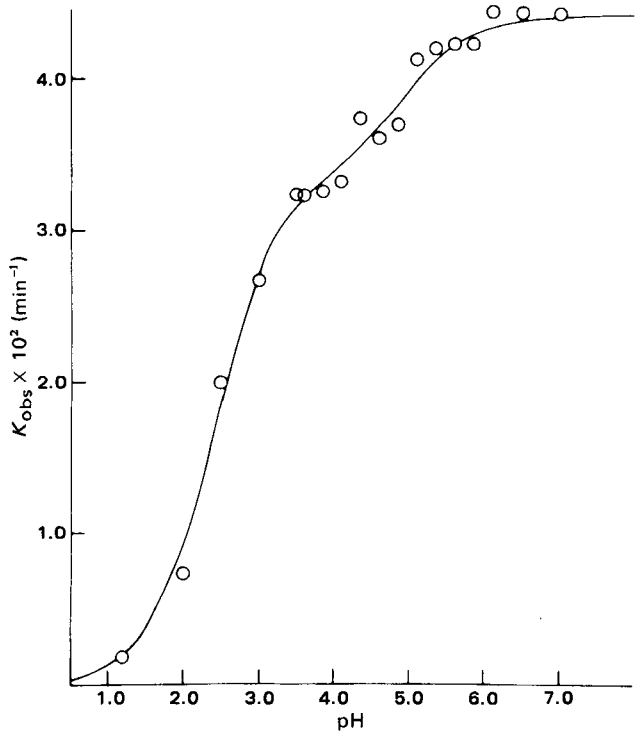


Figure 2—*The pH rate profile for degradation of I in the absence of added chloride ion at 37°. The solid line is the best fit theoretical line using Eq. 1 and values mentioned in the text. Circles are experimental points. All points above pH 2.0 were determined in 0.01* M *citrate buffer, 0.1* M *ionic strength.*

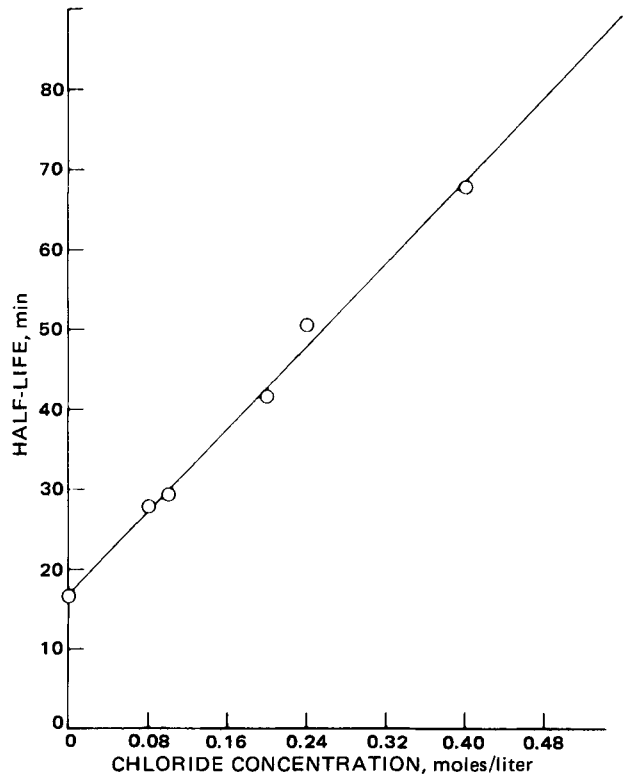

Figure 3—*Plot of adjusted half-life (see text) for I hydrolysis* versus *the concentration of added chloride ion.*

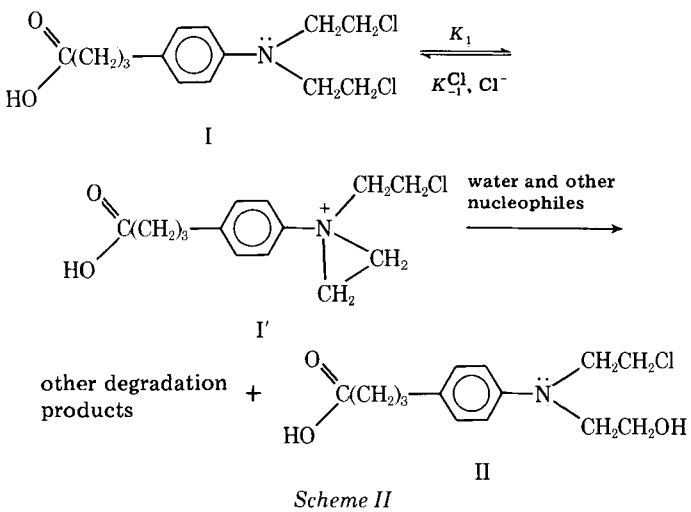
experimental points. This result supports the proposed kinetic analysis (Scheme I) for the hydrolysis of I.

Effect of Chloride Ion—Hydrolysis of I followed first-order kinetics in the presence of excess chloride ion. However, at a particular pH and fixed buffer concentration, the rate of I hydrolysis decreased in the presence of added chloride ion. As seen in Table II, the half-life of I hydrolysis increased with increasing chloride concentration. Although the rate of I hydrolysis was relatively independent of buffer concentrations in the absence of added chloride ion, it was strongly influenced by buffer concentration when excess chloride ion was present.

The absence of significant effects of other ions, buffer species, and specific hydrogen-ion or hydroxyl-ion catalysis (except for the pH effect on the ionization of I and consequent effects on the rate) strongly suggest that the stabilizing effect of chloride ion in I hydrolysis is a specific one. Based on these observations, the mechanism of chloride stabilization probably involves the reverse attack of chloride ion on the cyclic ethyleneimmonium intermediate (I^+) to give back parent I (Scheme II). The same mechanism was recently suggested (5) for the chloride-ion stabilization of melphalan hydrolysis.



Scheme II

The cyclic intermediate, I′, is susceptible to attack by water and other nucleophiles present in the reaction mixture. It is reasonable, therefore, to suggest that chloride ion competes with water and other nucleophiles to attack I′. The attack of water and all other nucleophiles except chloride ion yields irreversible degradation products, while the attack of chloride ion yields I. It follows that stabilization would increase as the ratio of chloride ion to other nucleophiles (including water) is increased. This relation qualitatively explains why the half-life of I hydrolysis increases with increasing concentration of added chloride ion.

The rate of I hydrolysis increases when the concentration of nucleophilic buffer species (*i.e.*, imidazole) increases in the presence of a constant excess concentration of chloride ion (compare values of Runs 2, 3, and 6 with those of Runs 12–14 in Table II). However, except for a minor ionic strength effect, buffers and other ions had no significant effect on rate when no chloride ion was added (Table I). This result can be explained by Scheme II, where increasing the concentration of other species competing to attack I′ results in a smaller share of I′ available for chloride attack and, hence, reduces stabilization. Without chloride ion, attack of I by all species leads to irreversible degradation products. Therefore, increasing the buffer concentration only changes the ratio of degradation products without affecting the rate of I hydrolysis.

This mechanism of chloride-ion stabilization is also substantiated by the kinetic analysis of the results in the presence of added chloride ion. If it is assumed that the concentration of the reactive intermediate, I′, reaches steady state, then applying classical steady-state kinetics dictates (Appendix) that, in the presence of constant excess chloride ion, the loss of I is first order with respect to I and that the half-life of I hydrolysis is related linearly to the chloride-ion concentration if all other conditions remain constant.

To check these criteria, experiments were designed to study the kinetics of I hydrolysis at a fixed pH and buffer concentration in the presence of various amounts of sodium chloride concentration. Since ionic strength would influence the rate by affecting the pKa if the pH was in the inflection region of the pH rate profile for I hydrolysis, these experiments were performed in 0.02 *M* phosphate buffer (pH 7.0), which was well within the plateau region (Fig. 2). At this pH, small changes in K_a and K'_a of I would have a minimal effect on the rate. To account for the ionic strength effect of added chloride ion on the rates, rate constants for I hydrolysis were also determined in 0.02 *M* phosphate buffers (pH 7.0) in the presence of various concentrations of potassium nitrate. The adjusted rate constants at any chloride-ion concentration were calculated by:

$$K_{adj} = K_{obs}\frac{K_0}{K'} \quad \text{(Eq. 4)}$$

where K_{adj} is the adjusted rate constant, K_{obs} is the observed rate constant at a specified sodium chloride concentration, K' is the rate constant in the absence of added chloride ion but in the presence of the same molar concentration of potassium nitrate as the concentration of sodium chloride added to determine K_{obs}, K_0 is the rate constant in the absence of any other added ion except the 0.02 M phosphate buffer (pH 7.0), and $(t_{1/2})_{adj} = 0.693/K_{adj}$.

Plotting the concentrations of I remaining against time gave first-order plots, and Fig. 3 shows the plot of adjusted half-lives against sodium chloride concentrations. The good linear plot in Fig. 3 lends strong support to Scheme II.

Physiological Implications—The preceding kinetic data suggest that I is reasonably stable at 37° to 0.1 N HCl (half-life ~12 hr). However, the stomach pH varies from 1.5 to 5.0 (7); if the pH is ~3.0, a 25-min half-life at 37° (Table I) would mean that ~10% drug would degrade in 4 min. Even in the presence of a substantial chloride-ion concentration in the stomach (*e.g.*, 0.1 M), the half-life of I would be ~50 min at pH 3.0 and 37° (still a very fast rate for an orally administered drug). Therefore, the amount of drug available for absorption apparently would be a function of stomach pH at a particular time. Thus, there is a serious potential for inconsistency in the availability of orally administered I.

The hydrolysis rate of I in human plasma at 37° was ~10–20 times slower than in the buffer of pH 7.4. This stabilization was attributed to the binding of I with plasma proteins as suggested previously (8, 9). The similar favorable effect of the proteins in the GI tract on the stability of orally administered I was not investigated in this study.

APPENDIX: EFFECT OF CHLORIDE ION ON KINETICS OF I HYDROLYSIS

For the reaction shown in Scheme II:

$$I \underset{K_{-1}^{Cl}}{\overset{K_1}{\rightleftharpoons}} I' + Cl^- \xrightarrow[H_2O,\ \text{other nucleophiles}]{K_x} \text{II + other products}$$

Scheme AI

where K_1 is the first-order rate constant of initial cyclization of I, K_{-1}^{Cl} is second-order rate constant for chloride-ion attack on I′ to yield I, and K_x is the pseudo-first-order rate constant for breakdown of I′ by all nucleophiles (including water), except chloride ion, to yield II and other degradation products:

$$-dI/dt = K_1[I] - K_{-1}^{Cl}[Cl^-][I'] \quad \text{(Eq. A1)}$$

$$dI'/dt = K_1[I] - K_{-1}^{Cl}[Cl^-][I'] - K_x[I'] \quad \text{(Eq. A2)}$$

If I′ is assumed to be very unstable and its concentration reaches steady state, then at steady state:

$$dI'/dt = 0 \quad \text{(Eq. A3)}$$

and

$$K_1[I] - K_{-1}^{Cl}[Cl^-][I'] - K_x[I'] = 0 \quad \text{(Eq. A4)}$$

Collecting terms and simplifying (Eq. A4) gives:

$$I' = \frac{K_1}{K_{-1}^{Cl}[Cl^-] + K_x}[I] \quad \text{(Eq. A5)}$$

Substituting Eq. A5 into Eq. A1 gives:

$$\frac{-dI}{dt} = K_1[I] - \frac{K_{-1}^{Cl}K_1[Cl^-]}{K_{-1}^{Cl}[Cl^-] + K_x}[I] \quad \text{(Eq. A6)}$$

Simplifying Eq. A6 gives:

$$\frac{-dI}{dt} = \frac{K_1K_x}{K_{-1}^{Cl}[Cl^-] + K_x}[I] \quad \text{(Eq. A7)}$$

If chloride ion is in excess, its concentration does not change significantly by the chloride ion liberated during the hydrolysis of I. Therefore, the term $K_1K_x/(K_{-1}^{Cl}[Cl^-] + K_x)$ in Eq. A7 is constant and designated as K_{obs}:

$$K_{obs} = \frac{K_1K_x}{K_{-1}^{Cl}[Cl^-] + K_x} \quad \text{(Eq. A8)}$$

and:

$$-dI/dt = K_{obs}[I] \quad \text{(Eq. A9)}$$

Equation A9 shows that loss of I in the presence of a fixed excess concentration of chloride ion should be the first order with respect to I with the rate constant K_{obs}. Inverting Eq. A8 yields:

$$\frac{1}{K_{obs}} = \frac{K_{-1}^{Cl}[Cl^-]}{K_1K_x} + \frac{K_x}{K_1K_x} \quad \text{(Eq. A10)}$$

Cancelling terms and multiplying Eq. A10 with 0.693 gives:

$$\frac{0.693}{K_{obs}} = \frac{0.693\,K_1^{Cl}}{K_1K_x}[Cl-] + \frac{0.693}{K_1} \quad \text{(Eq. A11)}$$

Equation A11 shows that the plot of the observed half-life ($0.693/K_{obs}$) versus the chloride-ion concentration should be a straight line, with the intercept representing the half-life when no chloride ion is present.

Stability of Intravenous Nitroglycerin Solutions

ANDREA H. SCHEIFE ˣ, JOSEPH A. GRISAFE, and LEON SHARGEL

Received September 24, 1980, from the *College of Pharmacy and Allied Health Professions, Northeastern University, Boston, MA 02115.* Accepted for publication May 15, 1981.

Abstract □ The stability of intravenous nitroglycerin solutions prepared from either sublingual tablets or a 10% nitroglycerin–lactose adsorbate (powder) was examined under various conditions. Nitroglycerin concentration was measured by high-pressure liquid chromatography. Nitroglycerin stock solutions (0.8–1.0 mg/ml) prepared from tablets or powder in 0.9% saline were stored upright in refrigerated multidose vials for 6 months without a significant decrease in concentration. Storage of the solutions at room temperature resulted in a 20% loss after 3 months. Intravenous nitroglycerin solutions (0.2 mg/ml) prepared from tablets or powder in either 0.9% saline or 5% dextrose in water were stored in glass intravenous bottles at temperatures between 6 and 38° for 24 hr with a maximum loss of 18%. Stability was not affected by light. Solutions in contact with rubber stoppers, plastic intravenous bags, or plastic administration sets exhibited decreased nitroglycerin concentration characteristic of sorption. Nitroglycerin concentrations decreased to a greater extent when the administration sets were equipped with plastic burets. Brief contact of nitroglycerin solutions with a plastic syringe did not result in decreased concentration. The stability of intravenous nitroglycerin solutions packaged in glass was not dependent on light, the vehicle, or the source of nitroglycerin. Contact with rubber or plastic surfaces should be minimized.

Keyphrases □ Nitroglycerin—intravenous solutions, stability, effect of temperature, light, source, and packaging □ Stability—effect of temperature, light, source, and packaging on intravenous nitroglycerin solutions □ Vasodilators—nitroglycerin, stability of intravenous solutions

Intravenous nitroglycerin is used clinically in various cardiovascular conditions (1–5). At present, only an investigational nitroglycerin formulation is commercially available for intravenous infusions. Consequently, many pharmacists prepare intravenous nitroglycerin solutions from sublingual nitroglycerin tablets (6, 7) or from a nitroglycerin–lactose adsorbate (8, 9). The stablity of nitroglycerin tablets was defined after the advent of single-tablet assays, particularly automated single-tablet assays (10–15). However, initial stability data on nitroglycerin in intravenous solutions were anecdotal (16) or conflicting (17, 18). Recently, the results of several investigations were reported (19–24).

This investigation examined the stability of nitroglycerin parenteral solutions under various conditions of temperature, exposure to light, packaging materials, nitroglycerin source, vehicle, administration set, and time.

EXPERIMENTAL

Assay—Nitroglycerin was measured by a modified high-pressure liquid chromatographic (HPLC) method (25). A high-pressure liquid chromatograph[1] equipped with a universal liquid chromatographic injector[2], UV absorbance detector[3] (254 nm), and a strip-chart recorder[4] was used for all analyses. Samples (25 μl) were chromatographed at room temperature on a microparticulate, reversed-phase, 30 cm × 4-mm i.d. column[5] with an eluting mobile phase of 60% methanol in water at a flow rate of 2 ml/min. The inlet pressure varied from 2400 to 3000 psi and was noted on a daily basis. The retention time of nitroglycerin was ~4 min, and samples could be injected every 5 min.

The technique was sensitive to injections of >100 ng of nitroglycerin. Precision was 1.0% over a solution range of 190–300 μg of nitroglycerin/ml. Standard solutions were prepared from 0.4-mg sublingual nitroglycerin tablets[6] and 10% (w/w) nitroglycerin–lactose adsorbate[7] (powder). Standard curves were linear ($r \geq 0.99$) over the concentration range used.

Stability Study—The stability of nitroglycerin solutions with initial concentrations of 0.8 or 1.0 mg/ml (stock) and 0.2 mg/ml (intravenous) was tested.

Stock Solutions—Nitroglycerin stock solutions were pipetted into 5-ml multidose vials[8] for stability testing. Rubber stoppers[9] (20 mm) were fitted to the vials with a metal tear-off seal[10].

Vials containing 5 ml of nitroglycerin solution (1.0 mg/ml) prepared from tablets in 0.9% saline were stored in groups of three under conditions of varied temperature, light, and contact with the rubber stopper (Solutions VRT, VU, VF, VO, and VR, Table I).

In addition, five vials containing 5 ml of nitroglycerin solution (0.8 mg/ml) prepared from tablets in 0.9% saline (Solution VT) and five vials containing 5 ml of nitroglycerin solution (0.8 mg/ml) prepared from powder in 0.9% saline (Solution VP) were stored under fluorescent light at 22–30° in an upright position.

Intravenous Solutions—Intravenous nitroglycerin solutions (0.2 mg/ml) were prepared in 250-ml plastic bags of 0.9% saline[11] or in 250-ml glass bottles of 0.9% saline[12] or 5% dextrose in water[13]. Initially, 50 ml of the saline or 5% dextrose solution was removed from the container; a glass syringe was then used to add 50 ml of freshly prepared nitroglycerin stock solution. Containers were inverted throughout the stability study. A tubing clamp attached to the bags and a glass rod inserted into the bottles sealed the administration ports.

Intravenous nitroglycerin solutions were first prepared in saline from a tablet nitroglycerin stock solution. Five bags and five bottles containing the nitroglycerin solutions were stored under each condition of light and temperature (Solutions PRT, PF, PR, PO, GRT, GF, GR, and GO, Table II).

Five solutions of tablet nitroglycerin in bottles of saline (Solution GT) were compared to five solutions of tablet nitroglycerin in bottles of 5% dextrose solution (Solution GD) and to five solutions of powder nitroglycerin in bottles of saline (Solution GP). These solutions were stored between 26 and 28° under fluorescent light. At the same time, solutions of tablet nitroglycerin were prepared in 10 bottles and five bags of saline. Administration tubing[14] (1.8 m) was connected to each bag (Solution PTu) and five bottles (Solution GTu). The tubing was immediately filled with solution and then continually perfused at 0.5 ml/min by gravity.

Administration tubing (2.1 m) with a buret[15] was connected to the remaining five bottles (Solution GBu) and was similarly filled and perfused. One hundred milliliters of solution remained within the buret chamber throughout the perfusion. Solutions PTu, GTu, and GBu were sampled simultaneously from the container and the terminal end of the administration set. All containers and tubing were stored between 26 and 28° under fluorescent light.

Two-tailed t tests (26) were used to compare the sample means. When

Table I—Nitroglycerin Stock Solutions [a]

Symbol	Initial Nitroglycerin Concentration, mg/ml	Nitroglycerin Source[b]	Storage		
			Position	Light Exposure	Temperature
VRT	1.0[c]	Tablets	Upright	Fluorescent	22–30°
VU	1.0[c]	Tablets	Inverted	Fluorescent	22–30°
VF	1.0[c]	Tablets	Upright	Dark (foil-wrapped)	22–30°
VO	1.0[c]	Tablets	Upright	Dark	38°
VR	1.0[c]	Tablets	Upright	Dark	6°
VT	0.8[d]	Tablets	Upright	Fluorescent	22–30°
VP	0.8[d]	Powder	Upright	Fluorescent	22–30°

[a] Containers were multidose vials (5 ml) with rubber stoppers, and the vehicle was (1.0 mg/ml) saline. [b] Tablets were 0.4-mg sublingual tablets, and powder was 10% (w/w) nitroglycerin–lactose adsorbate. [c] Vials were prepared from the same nitroglycerin solution. [d] The stability of nitroglycerin solutions (0.8 and 1.0 mg/ml) was measured at the same time.

Table II—Nitroglycerin Intravenous Solutions (Initial Concentration, 0.2 mg/ml)

Symbol[a]	Container[b]	Administration Set	Perfusion Rate, ml/min	Nitroglycerin Source[c]	Vehicle[d]	Storage	
						Light Exposure	Temperature
GRT	Bottle	—	—	Tablet	Saline	Fluorescent	28–30°

[a] Stability of solutions GRT through PR was measured separately from that of solutions GT through GBu. [b] Bottle was inverted glass infusion bottle, 250 ml; bag was plastic infusion bag, 250 ml. [c] Tablets were 0.4-mg sublingual tablets; powder was 10% (w/w) nitroglycerin-lactose adsorbate. [d] Saline was 0.9% saline.

the data could be fitted to the equation of a straight line, slopes were statistically tested (27) for difference.

RESULTS

To assess the uniformity of the nitroglycerin source, solutions were prepared from different samples of tablets or powder (five tablets or ~20 mg of powder/sample). The HPLC peak height responses were 34.4 ± 1.5 cm/mg of tablet and 296 ± 14 cm/mg of powder.

Although a glass syringe was used in this study to transfer nitroglycerin solutions, hospital personnel often use plastic, disposable syringes. The concentration in 50 ml of a nitroglyerin solution (1.0 mg/ml) was measured before and after two successive 1-min exposures to a 50-ml plastic syringe. Concentration did not change significantly after contact with the syringe.

USP XX (28) specifications allow the average potency of sublingual nitroglycerin tablets to vary 20% from the labeled strength. The concentration of nitroglycerin stock solutions (1.0 mg/ml) prepared from tablets in saline and stored upright in multidose vials under fluorescent light at 22–30° decreased 20% after 87 days and 35% after 6 months (Solution VRT, Table III). When the vials were stored at 38° (VO), nitroglycerin concentration decreased 20% after 50 days and 67% after 6 months. Solutions that were protected from light (VF) showed decreases of 20% after 98 days and 31% after 6 months. When vials were stored inverted (VU), the concentration decreased 20 and 58% after 2 days and 6 months, respectively. In nitroglycerin solutions stored upright at 6° (VR), no change in concentration was observed over 6 months. Nitroglycerin stock solutions prepared from tablets at 0.8 mg/ml (VT) declined in concentration by 20% in 87 days and by 41% in 6 months. Similar solutions prepared from powder (VP) had concentration decreases of 20 and 43% after 82 days and 6 months, respectively.

The observed concentration changes were linear with time during the study for all solutions except those stored inverted (VU). The rate of concentration change in solutions stored at 22–30° under fluorescent light differed from that in solutions stored at 6 or 38° ($p < 0.001$, Fig. 1) but did not significantly differ from that in solutions protected from light. The rate of concentration change was independent of the initial concentration (0.8 or 1.0 mg/ml) and the source of the nitroglycerin (powder or tablet). The concentration of solutions stored inverted differed significantly from that in solutions stored upright after 1 month ($p < 0.001$, Fig. 2).

The concentration of intravenous nitroglycerin solutions (0.2 mg/ml) stored in plastic bags differed from the initial concentration after 1.3 hr, regardless of storage temperature or exposure to light ($p < 0.05$). After 8 hr, the concentration of solutions stored under fluorescent light at 28–30° (Solution PRT) in the dark at 28–30° (PF), 38° (PO), or 6° (PR)

Table III—Stability of Nitroglycerin Stock Solutions

Variables[a]	Predicted[b] Time for Nitroglycerin Concentration to Decrease 20%, days	Decrease in Nitroglycerin Concentration, %		
		1 Month	3 Months	6 Months
Tablet solutions, 1.0 mg/ml

22–30°, light, inverted (VU)	2	39[c]	58[c]	58[c]
22–30°, dark upright (VF)	98	2	26[c]	31[c]
22–30°, light, upright (VRT)	87	5	29[c]	35[c]
0.8 mg/ml solutions				
22–30°, light, upright				
Tablets (VT)	87	5[c]	18[c]	41[c]
Powder (VP)	82	13[c]	28[c]	43[c]

[a] Nitroglycerin solutions were prepared in 0.9% saline and packaged in multidose vials. Variables included initial concentration; nitroglycerin source, and storage conditions. [b] Values were predicted by least-squares method except VU, which was estimated graphically. [c] Significantly different from initial ($p < 0.05$).

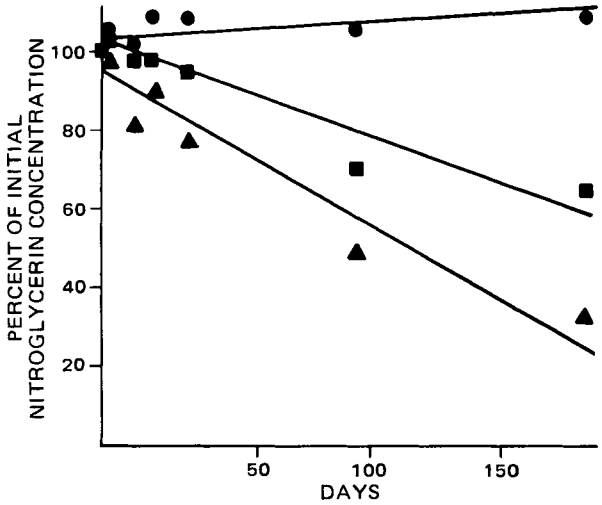

Figure 1—*Effect of temperature on nitroglycerin stock solutions, (p < 0.001). Solutions (1.0 mg/ml) were prepared from tablets in saline, packaged in multidose vials and stored upright. Key: ●, 6°, Solution VR; ■, 22–30°, Solution VRT; and ▲, 38°, Solution VO.*

decreased 44, 38, 46, and 14%, respectively. The concentration decrease of solutions stored at 28–30° under fluorescent light differed from that of solutions stored at 6° ($p < 0.001$) but did not differ from that of solutions protected from light for 52 hr. After 27 hr, the concentration decrease of solutions stored at 38° (68%) differed significantly ($p < 0.001$) from that of solutions stored at 28–30° (61%).

The concentration of intravenous nitroglycerin solutions (0.2 mg/ml) stored in glass bottles under fluorescent light at 28–30° (Solution GRT) or in the dark at 28–30° (GF), 38° (GO), or 6° (GR) did not differ significantly from the initial value after 52 hr. The rate of concentration change did not differ among these solutions. In a separate comparison, the concentration of nitroglycerin solutions stored in glass bottles decreased <18% after 24 hr at 26–28° under fluorescent light when solutions were prepared from powder in saline (GP), tablets in 5% dextrose solution (GD), or tablets in saline (GT). The rate of concentration change was independent of the vehicle (5% dextrose solution or saline) and of the source of nitroglycerin (tablet or powder).

At 1.3 hr, the nitroglycerin concentrations (expressed as a percentage of the initial value) in solutions stored in plastic bags were as follows:

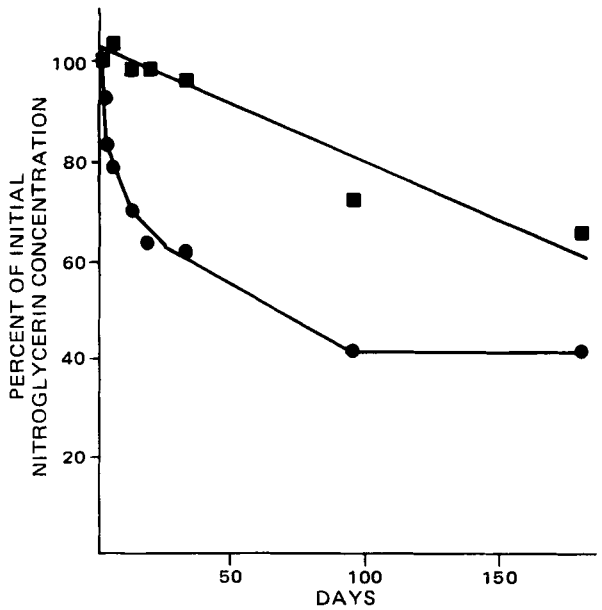

Figure 2—*Effect of contact with the rubber stopper of multidose vials on nitroglycerin concentration (p < 0.001). Solutions (1.0 mg/ml) were prepared from tablets in saline and stored at 22–30° under fluorescent light. Key: ●, stored inverted, Solution VU; and ■, stored upright, Solution VRT.*

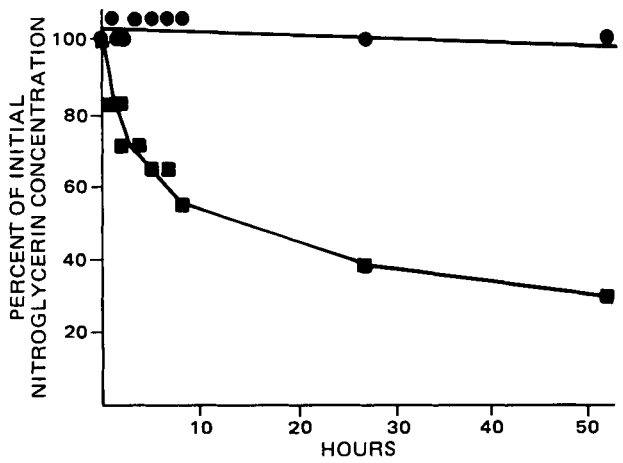

Figure 3—*Effect of glass and plastic intravenous containers on nitroglycerin concentration (p < 0.01). Solutions (0.2 mg/ml) were prepared from tablets in saline and stored at 28–30° under fluorescent light. Key: ●, glass bottles, Solution GRT; and ■, plastic bags, Solution PRT.*

under fluorescent light at 28–30°, 85%; in the dark at 28–30°, 87%; at 6°, 90%; and at 38°, 79%. Similarly, after 1.3 hr, solutions stored in glass bottles under identical conditions had concentrations that were 100, 103, 108, and 105% of the initial value, respectively. The values for solutions stored in plastic bags were different in all instances from the values for solutions stored in glass bottles ($p < 0.01$, Fig. 3).

When intravenous nitroglycerin solutions were packaged in glass (G) or plastic (P) containers and perfused through administration sets, concentration decreases occurred in the bulk solution remaining in the container and the solution perfusing the administration set. Concentration changes in the bulk solution were not significantly different from those in similar solutions without an administration set. However, concentration changes following perfusion of the administration sets were significant in all solutions ($p < 0.001$).

The mean concentration decrease of the solution perfusing administration tubing for 8 hr from a glass container (GTu) was 37% of nitroglycerin concentration in the container and differed ($p < 0.02$) from that of the solution perfusing tubing with a buret (50%, GBu). The mean decrease after perfusion of tubing from a glass container also differed from that of identical tubing attached to a plastic bag (27%, PTu, $p < 0.02$, Table IV). The largest decrease in nitroglycerin concentration occurred during the 1st hr of perfusion. After 4 hr, concentrations no longer changed with time and decreases in concentration remained as follows: tubing from glass bottle, 35%; tubing with buret from glass bottle, 55%; and tubing from plastic bag, 20% (Fig. 4).

Following an 8-hr perfusion, the mean decrease from the initial nitroglycerin concentration for the total administration system (container

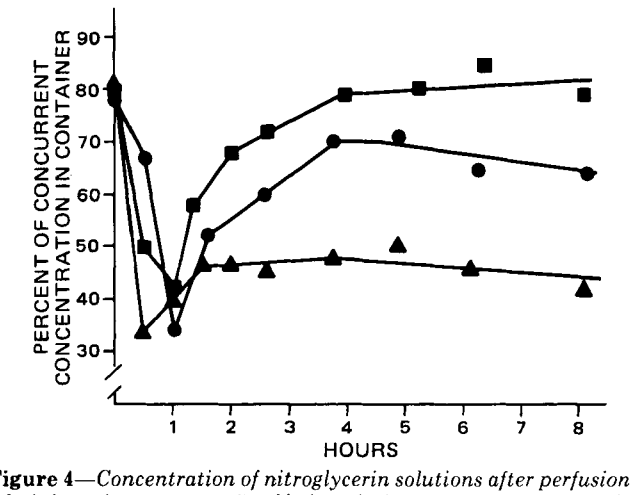

Figure 4—*Concentration of nitroglycerin solutions after perfusion of administration sets at 0.5 ml/min relative to concurrent container concentration (p < 0.001). Key: ■, plastic intravenous bag, tubing without buret, solution PTu; ●, glass intravenous bottle, tubing without buret, Solution GTu; and ▲, glass intravenous bottle, tubing with buret, Solution GBu.*

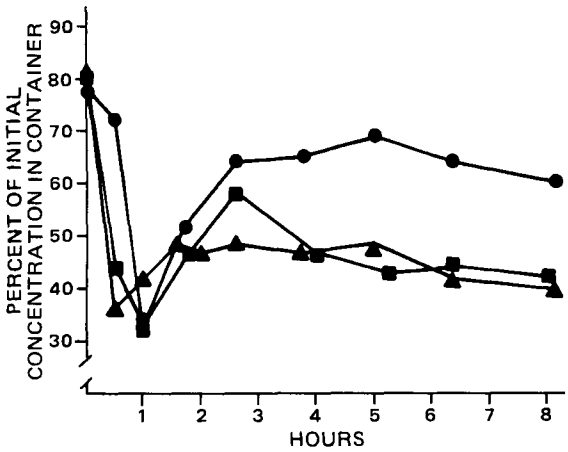

Figure 5—*Decrease from initial nitroglycerin concentration in container after perfusion of sets at 0.5 ml/min ($p < 0.001$). plus administration set) was 38% for tubing with a glass bottle (GTu), 51% for tubing with buret and a glass bottle (GBu), and 50% for tubing with a plastic bag (PTu). The decrease that occurred when tubing was used with a plastic bag differed ($p < 0.01$) from that of the system of tubing and a glass bottle but did not differ from that of the system of tubing with buret and a glass bottle (Table IV, Fig. 5).

DISCUSSION

The stability of nitroglycerin stock solutions (0.8–1.0 mg/ml) did not depend on exposure to light or the nitroglycerin source. However, nitroglycerin concentration significantly decreased with time in solutions stored at elevated temperatures or in contact with rubber stoppers (Figs. 1 and 2). Nitroglycerin stock solutions in upright multidose vials were refrigerated for ~6 months without a significant decrease in concentration. Storage of the vials at room temperature resulted in a 20% decrease in nitroglycerin concentration after ~3 months (Table III). The marked decrease in nitroglycerin concentration following contact of solutions with rubber stoppers suggests that any vial found inverted or on its side should be discarded or that an all-glass packaging system (*e.g.*, ampul) should be used.

The stability of intravenous nitroglycerin solutions (0.2 mg/ml) was not dependent on the vehicle, nitroglycerin source, or exposure to light. Storage in glass bottles for 24 hr at 6–38° resulted in a maximum loss of 18%. However, during storage in plastic infusion bags or during perfusion of plastic administration sets, nitroglycerin concentration decreased significantly with time (Figs. 3–5). Administration tubing with a buret removed more nitroglycerin from solution than did tubing without a buret. The increased stability realized by packaging nitroglycerin solutions in glass rather than plastic was negated when administration tubing with a buret was used instead of tubing without a buret (Table IV and Fig. 5).

Other studies have similarly reported minimal concentration changes in nitroglycerin solutions refrigerated in multidose vials for up to 6 months (19, 20). Autoclaving nitroglycerin solutions (400 μg/ml) at 121° for 20 min resulted in a 5% decrease in concentration (19). However, storage of nitroglycerin solutions in inverted multidose vials for 1 month resulted in a 45% decrease in nitroglycerin concentration (18).

Similar losses of nitroglycerin from solutions stored in plastic bags have been reported, but reports on the stability of nitroglycerin solutions stored in glass bottles were conflicting (17, 18, 20–23). However, stability in glass bottles was greater than that in plastic bags (18, 21–23). Contact of solutions with plastic administration sets resulted in 15–75% decreases in nitroglycerin content (21, 23, 24).

Nitroglycerin formulations may exhibit instability by degradation, volatilization (29, 30), intertablet migration (11, 30), and sorption by packaging materials (13, 15, 30, 32). Nitroglycerin degrades by hydrolysis to mono- or dinitroglycerin (15) and, at elevated temperatures, to nitric acid and glycerol (33). Microbial degradation also has been reported (34). Sorption of nitroglycerin by rubber surfaces was reported for aqueous solutions (18) and propylene glycol–ethanol solutions (35) of nitroglycerin. Nitroglycerin was recovered by methanolic extraction from plastic bags (22) and was reported to leave an oily residue on glass (36).

Table IV—Effect of the Administration Set or System on the Stability of Nitroglycerin Solutions

Administration System[a]	Mean Decrease in Nitroglycerin Concentration, %[b]	
	Administration Set Alone	Administration System
Glass bottle, tubing with buret (GBu)	50[c]	51[d]
Glass bottle, tubing without buret (GTu)	37	38
Plastic bag, tubing without buret (PTu)	27[c]	50[d]

[a] Container and administration set. [b] Percent decrease in the nitroglycerin concentration of solutions perfused through administration sets (0.5 ml/min). [c] Significantly different from GTu ($p < 0.02$). [d] Significantly different from GTu ($p < 0.01$).

The sorption of nitroglycerin during perfusion of the plastic administration sets in this study may have occurred by two processes. Nitroglycerin may have first adsorbed onto the tubing in a concentrated layer and then absorbed into the plastic matrix while nitroglycerin from the solution replenished the concentrated layer. Until the surface layer was saturated, adsorption was rapid with respect to the perfusion rate, and nitroglycerin was largely removed from solution. As saturation of the concentrated layer occurred, the extraction ratio of nitroglycerin declined; nitroglycerin concentration in the solution emerging from the tubing rose to a constant fraction of that in the container (Fig. 4). While adsorption may have accounted for the initially rapid clearance of nitroglycerin by the tubing, a greater quantity of nitroglycerin probably was removed by absorption (37).

Adsorption and absorption were capacitance (surface area) and perfusion rate limited. The nitroglycerin concentration decreased faster and remained lower when the surface area perfused by the solution was increased by the use of administration tubing with a buret rather than tubing without one (Fig. 4). Similarly, concentration decreases were more rapid and extensive at slower perfusion rates (24) as a result of the increased contact time between the solution and the surface of the administration set.

The reversible nature of nitroglycerin sorption to plastic could account for the observation that the tubing attached to bags removed a smaller percentage of nitroglycerin than did identical tubing attached to bottles (Table IV). Adsorption of the concentrated layer may have reached equilibrium during the first 1 or 2 hr of perfusion when the nitroglycerin concentration in the bag was relatively high. As the nitroglycerin level decreased in the bag, the solution perfusing the tubing was too dilute relative to the concentrated layer, and nitroglycerin desorbed into the solution. Consequently, the effect of the tubing on the nitroglycerin concentration was lessened.

The short contact of nitroglycerin solutions with a plastic syringe, unlike the longer contact with administration sets, was not associated with a decrease in nitroglycerin concentration. Plastic syringes may be used for the transfer of nitroglycerin solutions, but prolonged storage of nitroglycerin solutions in plastic syringes may result in a decreased concentration.

Preparation and Screening of Some New Thioacetals, Sulfones, and Derivatives of 4-Dichloromethylbenzoyl and 4-Trichloromethylbenzoyl Chloride as Potential Antimalarials

EVA H. MØRKVED *x **and MARSHALL W. CRONYN** *‡

Received October 22, 1980, from the *Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway and the ‡ Department of Chemistry, Reed College, Portland, OR 97202. Accepted for publication May 15, 1981.

Abstract □ The preparation and screening of some potential antimalarials are reported. The new compounds which are inactive as antimalarials are several benzene-, benzyl-, and fluorene thioacetals, β-disulfones derived from these thioacetals, α-chlorobenzyl sulfones, amides, and thioesters derived from 4-dichloromethylbenzoyl chloride and 4-trichloromethylbenzoyl chloride. The known compounds bis(4-aminophenyl)sulfone and 4′-aminophenyl-4-aminobenzene thiolsulfonate also were prepared and showed some antimalarial activity.

Keyphrases □ Antimalarials—preparation of new thioacetals, sulfones, and 4-dichloromethylbenzoyl and 4-trichloromethylbenzoyl chloride derivatives □ Thioacetals—preparation of potential antimalarials □ Sulfones—preparation of potential antimalarials □ Derivatives—of 4-dichloromethylbenzoyl and 4-trichloromethylbenzoyl chloride, preparation of potential antimalarials

Malaria is still an important health problem in tropical areas. Various factors contribute to this situation including the development of malaria strains resistant to known antimalarials. This development has led to at least one recent antimalarial program (1). The purpose of the present work was to prepare potential antimalarials based on two model systems of known antimalarials, 1,4-bis(trichloromethyl)benzene which has been known as an active antimalarial for many years (2), and derivatives of bis(4-aminophenyl)sulfone which are more useful as suppressives than as therapeutic agents (3).

The synthesized compounds (Scheme I) share similarities with known antimalarials (2, 3). The trichloromethylaryl derivatives had no antimalarial activity, but the α-disulfone VIII*b* and the thiolsulfonate IX*b* showed some antimalarial activity.

RESULTS AND DISCUSSION

Thioacetals may be prepared by various methods (4–6) among which the reaction of *gem*-dihalides with sodium thiolates is a convenient one. Compound I*a* (Table I) was prepared from benzal chloride and a triethylammonium thiophenolate whereas VII*a* was formed easily from the *gem*-dihalide and a thiophenol. Acid-catalyzed reactions between 4-(trichloromethyl)benzaldehyde and various thiophenols gave the thioacetals I*c*, I*d*, and III*a*.

Two methods considered for the preparation of β-disulfones were a reaction of triethylammonium sulfinates with *gem*-dihalides or an oxi-

Preparation and Screening of Some New Thioacetals, Sulfones, and Derivatives of 4-Dichloromethylbenzoyl and 4-Trichloromethylbenzoyl Chloride as Potential Antimalarials

EVA H. MØRKVED *x **and MARSHALL W. CRONYN** *‡

Received October 22, 1980, from the *Organic Chemistry Laboratories, Norwegian Institute of Technology, University of Trondheim, N-7034 Trondheim-NTH, Norway and the ‡ Department of Chemistry, Reed College, Portland, OR 97202. Accepted for publication May 15, 1981.

Abstract □ The preparation and screening of some potential antimalarials are reported. The new compounds which are inactive as antimalarials are several benzene-, benzyl-, and fluorene thioacetals, β-disulfones derived from these thioacetals, α-chlorobenzyl sulfones, amides, and thioesters derived from 4-dichloromethylbenzoyl chloride and 4-trichloromethylbenzoyl chloride. The known compounds bis(4-aminophenyl)sulfone and 4′-aminophenyl-4-aminobenzene thiolsulfonate also were prepared and showed some antimalarial activity.

Keyphrases □ Antimalarials—preparation of new thioacetals, sulfones, and 4-dichloromethylbenzoyl and 4-trichloromethylbenzoyl chloride derivatives □ Thioacetals—preparation of potential antimalarials □ Sulfones—preparation of potential antimalarials □ Derivatives—of 4-dichloromethylbenzoyl and 4-trichloromethylbenzoyl chloride, preparation of potential antimalarials

Malaria is still an important health problem in tropical areas. Various factors contribute to this situation including the development of malaria strains resistant to known antimalarials. This development has led to at least one recent antimalarial program (1). The purpose of the present work was to prepare potential antimalarials based on two model systems of known antimalarials, 1,4-bis(trichloromethyl)benzene which has been known as an active antimalarial for many years (2), and derivatives of bis(4-aminophenyl)sulfone which are more useful as suppressives than as therapeutic agents (3).

The synthesized compounds (Scheme I) share similarities with known antimalarials (2, 3). The trichloromethylaryl derivatives had no antimalarial activity, but the α-disulfone VIII*b* and the thiolsulfonate IX*b* showed some antimalarial activity.

Scheme I

dation of the thioacetals I, IIIa, and VIIa. However, only one of the halide atoms of benzal chloride was replaced by an aryl sulfinate and IVa was obtained, but only 9-fluorenone and water-soluble products were formed from 9,9-dichlorofluorene and the same aryl sulfinate. Oxidations of thioacetals with a solution of peracetic acid in dry methylene chloride yielded the corresponding β-disulfones in excellent yields, provided a large excess (12 molar equivalents) of the peracid was used. Reactions of the thioacetal Ia with the usual oxidation mixture, peracetic acid in acetic acid, yielded benzaldehyde and the known thiol sulfonate IXa. The formation of IXa most likely occurs *via* the *O*-protonated thioacetal *S*-oxide (7, 8). Such compounds are known to be extremely sensitive to acids and decompose to a resonance-stabilized sulfoxonium ion and a sulfenic acid. A nucleophilic attack by the sulfenic acid on the sulfoxonium ion will give a sulfenic ester which spontaneously fragments to form benzaldehyde and a disulfide (9), the latter being oxidized to the thiolsulfonate IXa. Alternatively, an attack by water on the sulfoxonium ion would give benzaldehyde and a thiophenol, which will lead to the thiolsulfonate *via* a sulfinic acid under these reaction conditions (10, 11).

Recently IXa was prepared (12) by the fragmentation of a benzenesulfonohydrazide by hydrochloric acid in acetic acid, with the arylsulfinic acid postulated as an intermediate.

Reactions of the β-disulfones IIc and IId with sodium hypochlorite gave chlorination of the α-methylene group and Va and Vb were formed, respectively. An attempt to prepare Va from the thioacetal Ic by chlorination using sulfuryl chloride, and subsequent oxidation of the crude product using peracetic acid in dry methylene chloride, resulted in loss of one sulfhydryl group, and compound IVc was obtained in good yield. Reactions of sulfides with sulfuryl chloride give various products depending on the reaction conditions; α-chlorination usually occurs (13), but recently thioacetals have been found to undergo *S*-oxidation by sulfuryl chloride in the presence of wet silica gel (14). Therefore, if the thioacetal Ic undergoes both *S*-oxidation and α-chlorination by sulfuryl chloride, the product IVc may be accounted for by a mechanism involving the formation of a sulfoxonium ion and simultaneous loss of a sulfenic acid.

Side-chain chlorinations of 4-methylbenzoyl chloride and 1,4-dimethylbenzene are to a large extent dealt with in the patent literature; a common problem to these reactions are mixtures of polychlorinated products which are not easily separated. However, 4-dichloromethylbenzoyl chloride was prepared in satisfactory yield by a peroxide-catalyzed chlorination of 4-methylbenzoyl chloride in carbon tetrachloride. The 4-trichloromethylbenzyl derivatives required the preparation of either pentachlorinated 1,4-dimethylbenzene or 4-trichlormethylbenzoyl chloride which could be reduced to the aldehyde. The radical chlorination methods reported previously (15–19) were unsatisfactory for the preparation of large quantities of these compounds. A zinc chloride-catalyzed chlorination of 1,3-benzenedicarboxylic acid by 1,4-bis(trichloromethyl)benzene[1] gave good yields of 4-trichloromethylbenzoyl chloride. Similar reactions were reported recently (20–24) but the objectives were to prepare various benzenedicarbonyl chlorides instead of 4-trichloromethylbenzoyl chloride.

1,4-Bis(trichloromethyl)benzene is an active antimalarial and various derivatives of this compound were prepared earlier (25). The prepared derivatives were tested[2] for activity in suppression of *Plasmodium gallinaceum* in the mosquito *Aedes aegypti*. The antimalarial test results showed that the chlorinated compounds were inactive but the previously known α-disulfone VIIIb suppressed the sporozoites completely in the mosquito salivary glands when administered in a 0.01% concentration of the mosquito feed. The only other compound which showed some antimalarial activity was the thiolsulfonate IXb. However, 4-trichloromethylbenzaldehyde showed activity earlier[3].

EXPERIMENTAL[4]

4-Methylbenzoyl Chloride—This was prepared from 4-methylbenzoic acid and thionyl chloride, bp_{36} 124–127° [lit. (26), bp_{36} 125°].

[1] Dr. R. F. Horvath, Research Department, Diamond Alkali Co., personal communication.

[2] Tests by Walter Reed Army Medical Center, Washington DC.

[3] National Institutes of Health, Cancer Research Department, Bethesda Md.

[4] IR spectra were recorded on a Perkin-Elmer 254 grating spectrometer. All melting points are uncorrected and were obtained on a Büchi "Tottoli" melting-point apparatus. Elemental analyses were carried out at Galbraith Laboratories. Peracetic acid (40%) was obtained from Becco. Raney nickel No. 28 was obtained from W. R. Grace & Co., and lithium tri-*tert*-butoxyaluminum hydride was obtained from Ventron Corp.

4-Dichloromethylbenzoyl Chloride (X)—A carbon tetrachloride solution of 4-methylbenzoyl chloride was heated under reflux and chlorinated for 6 hr in the presence of catalytic amounts of benzoyl peroxide to give X (86%), $bp_{0.12-0.2}$ 88–93°, mp 43–59°; recrystallized from carbon tetrachloride, mp 45–47° [lit. (18) bp_{745} 285–286°, mp 44–45°].

4-Trichloromethylbenzoyl Chloride (XI)—A mixture of 1,4-bis(trichloromethyl)benzene (15.7 g, 50 mmoles), 1,3-benzenedicarboxylic acid (4.15 g, 25 mmoles), and zinc chloride (~200 mg) was protected from moisture. The mixture was heated at 185° for 4.5 hr until 95% of the 5% aqueous sodium hydroxide (40 ml, 50 mmoles) connected to the reaction flask was neutralized by the hydrogen chloride formed. The dark liquid reaction mixture was distilled under reduced pressure to give 14.2 g of a clear liquid, $bp_{0.4-0.45}$ 93–100°. This mixture of XI and 1,3-benzenedicarbonyl chloride was redistilled under reduced pressure on a polytef spinning band column and gave 1,3-benzenedicarbonyl chloride as the lower boiling fraction and 7.2 g (56%) of XI, mp 27.5–28.5°, $bp_{0.2-0.15}$ 88–91°; index of refraction, n_D^{25} = 1.5822, [lit. (18) bp_{756} 296°].

4-Trichloromethyl Benzaldehyde (27)—A stirred solution of XI (12.9 g, 50 mmoles) in 75 ml of dry tetrahydrofuran was cooled to −70°. A solution of lithium tri-*tert*-butoxyaluminum hydride (15.3 g, 60 mmoles) in 80 ml of dry tetrahydrofuran was added over 1.5 hr through a pressure-equalizing dropping funnel fitted with a polyethylene jacket filled with 2-ethoxyethanol and carbon dioxide. The reaction mixture was kept at −65° for 1 hr after all the reducing agent had been added, and for 15 min after ethanol (2 ml) had been added. The solution was poured onto a vigorously stirred mixture of 300 g of ice, 100 ml of 5% aqueous hydrochloric acid, and 100 ml of methylene chloride. The aqueous phase was extracted with another 100 ml of methylene chloride and the combined methylene chloride extracts were washed with 5% aqueous hydrochloric acid, aqueous sodium bicarbonate, and water, and were dried over magnesium sulfate. The residue, after filtration and removal of the solvent gave 11.1 g (99%) of 4-trichloromethyl benzaldehyde; IR (film): 1710 cm^{-1}.

An attempt to prepare 4-trichloromethyl benzaldehyde from VI*f* and Raney nickel (28) gave a mixture of VI*f* and 4-trichloromethyl benzaldehyde.

Peracetic Acid in Methylene Chloride—Solutions were prepared by extraction of 40% peracetic acid in acetic acid with four volumes of methylene chloride. The aqueous phase was removed and the organic phase was dried over magnesium sulfate. The strength of the peracid solution was determined by titration with 0.1 *M* sodium thiosulfate (29).

Thioacetals—*Bis(4-acetamidothiophenyl)phenylmethane* (*Ia*)—Triethylamine (12.1 g, 120 mmoles) was added to a solution of 4-acetamidothiophenol (20 g, 120 mmoles) and benzal chloride (9.65 g, 60 mmoles) in 120 ml of dry benzene. A second layer formed, and the two-phase solution was heated under reflux for 55 hr. The lower phase crystallized slowly. The crystalline material was filtered after cooling, stirred with water, and was recrystallized three times from ethanol to give I*a*; IR (mineral oil) 3300 and 1660 cm^{-1}.

Bis(4-aminothiophenyl)phenylmethane Dihydrochloride (*Ib*)—This was obtained by acid hydrolysis of I*a* in boiling methanol and hydrochloric acid.

Bis(thiophenyl)-4-trichloromethylphenyl Methane (*Ic*)—A solution of *p*-toluenesulfonic acid (~100 mg) in 80 ml of benzene was dried by heating to reflux under a Dean-Stark trap. The solution was cooled, the trap was drained, and 4-trichloromethyl benzaldehyde (50 mmoles, crude) was transferred into the reaction flask. Thiophenol (11 g, 100 mmoles) was added, and the reaction mixture was heated to reflux under a Dean-Stark trap for 3 hr. Approximately 500 mg (55.5%) of water was formed. The benzene solution was cooled and was extracted with two 50-ml portions of 2% aqueous sodium hydroxide, and two 50-ml portions of water and dried over magnesium sulfate. Compound I*c* was obtained from the benzene extract.

Bis(4-acetamidothiophenyl)-4-trichloromethylphenyl Methane (*Id*)—4-Acetamidothiophenol and 4-trichloromethyl benzaldehyde were used in the same procedure as described for I*c* except that chloroform was used as a solvent. Compound I*d* was recrystallized from acetonitrile; IR (mineral oil): 3300–3250, and 1680 cm^{-1}.

Bis(4-aminothiophenyl)-4-carbomethoxyphenyl Methane Dihydrochloride (*Ie*)—Compound I*d* was treated with boiling methanol and hydrochloric acid for 1.5 hr; IR (mineral oil): 1700 cm^{-1}.

Bis(thiobenzyl)-4-trichloromethylphenyl Methane (*IIIa*)—The method described for I*c* was used to prepare III*a* from thiobenzyl alcohol and 4-trichloromethyl benzaldehyde.

9,9-Bis(4-acetamidothiophenyl)fluorene (*VIIa*)—A solution of

9,9-dichlorofluorene (2.35 g, 10 mmoles) and 4-acetamidothiophenol (3.34 g, 20 mmoles) in 50 ml of dry acetonitrile was heated under reflux for 18 hr. Compound VII*a* was obtained after removal of the solvent and recrystallization; IR (mineral oil): 3310–3250, and 1660 cm^{-1}.

β - Disulfones—*Bis(4-acetamidophenylsulfonyl)phenylmethane* (*II*a)—A 3.7 *M* solution of peracetic acid in methylene chloride (16.2 ml, 60 mmoles) was added to a suspension of I*a* (2.11 g, 5 mmoles) in 170 ml of dry methylene chloride over 15 min and the reaction mixture was stirred for 114 hr. The crystalline material removed by filtration gave II*a* after recrystallization; IR (mineral oil): 3350, 3310, 3280, 1670, 1315, and 1150 cm^{-1}.

Bis(4-aminophenylsulfonyl)phenylmethane (*II*b)—This compound was obtained by heating a suspension of II*a* in methanol and hydrochloric acid for 3 hr. When II*b* was recrystallized from methanol, the compound crystallized with solvent molecules, whereas using acetone as solvent would give pure II*b*; IR (mineral oil): 3460, 3360, 1320, and 1130 cm^{-1}.

Bis(phenylsulfonyl)-4-trichloromethylphenyl Methane (*II*c)—This compound was prepared by oxidation of I*c* by the method described for II*a*; IR (mineral oil): 1330, 1161, and 1150 cm^{-1}.

Bis(4-acetamidophenylsulfonyl)-4-trichloromethylphenyl Methane (*II*d)—This compound was prepared from I*d* by the method described for II*a*; IR (mineral oil): 3400, 1690, 1330, and 1150 cm^{-1}.

Bis(4-aminophenylsulfonyl)-4-trichloromethylphenyl Methane (*II*e)—Compound II*d* was acid hydrolyzed in hot ethanol and hydrochloric acid to give II*e* which was recrystallized; IR (mineral oil): 3460, 3390, 1310–1320, and 1135–1145 cm^{-1}.

4-Bis(phenylsulfonyl)methylbenzoic Acid (*III*f)—A 0.054 *M* aqueous solution of sodium hydroxide (74.5 ml, 4 mmoles) was added to a solution of II*c* (490 mg, 1 mmole) in 40 ml of tetrahydrofuran. The reaction mixture was stirred for 22 hr at ambient temperature. The tetrahydrofuran was removed under reduced pressure and the aqueous solution was extracted with two 30-ml portions of chloroform. The aqueous solution was acidified with 5% aqueous hydrochloric acid and extracted with two 30-ml portions of chloroform. The combined chloroform extracts were washed with water, dried over magnesium sulfate, and gave II*f* which was stirred with benzene; IR (mineral oil): 1690 cm^{-1}. Two recrystallizations of II*f* from acetonitrile gave a compound with mp 264–265°; IR (mineral oil): 3400 and 1730 cm^{-1}.

Anal.—Calc. for $C_{20}H_{16}O_7S_2$—C, 55.54; H, 3.73; S, 14.83. Found: C, 56.59, 56.35; H, 4.08, 3.87; S, 14.32.

Bis(benzylsulfonyl)-4-trichloromethylphenyl Methane (*III*b)—This was prepared from III*a* by the method described for II*a*; IR (mineral oil): 1320, 1150, and 1125 cm^{-1}.

4-Bis(benzylsulfonyl)methylbenzoic Acid (*III*c)—A 0.6 *M* aqueous solution of sodium hydroxide (20 ml, 12 mmoles) was added to a solution of III*b* (1.55 g, 3 mmoles) in 180 ml of tetrahydrofuran. The reaction mixture was stirred for 17 hr at ambient temperature. The organic solvent was removed under reduced pressure and the solution was acidified with 5% aqueous hydrochloric acid. Compound III*c* was extracted from the aqueous phase with chloroform and recrystallized.

Bis(phenylsulfonyl)-4-trichloromethylphenyl Chloromethane (*V*a)—A 5.25% aqueous solution of sodium hypochlorite (10 ml, 7 mmoles) was added to a solution of II*c* (490 mg, 1 mmole) in 25 ml of tetrahydrofuran. The solution was stirred at ambient temperature for 5 min and the organic layer yielded V*a* which was recrystallized; IR (mineral oil): 1350, 1330, 1320, and 1150 cm^{-1}.

Bis(4-acetamidophenylsulfonyl)-4-trichloromethylphenyl Chloromethane (*V*b)—This compound was prepared from II*d* and sodium hypochlorite by the method described for V*a*; IR (mineral oil): 3310, 3270, and 1670 cm^{-1}.

9,9-Bis(4-acetamidophenylsulfonyl)fluorene (*VII*b)—Oxidation of VII*a* by the method described for II*a* gave VII*b*; IR (mineral oil): 3310, 3280, 1670, 1350, and 1162 cm^{-1}. An attempt to prepare VII*b* from 9,9-dichlorofluorene and two molar equivalents of triethylammonium-4-acetamidophenyl sulfinate in acetonitrile yielded 90% of 9-fluorenone and 12% of IX*a* after heating the reaction mixture under reflux for 39 hr.

9,9-Bis(4-Aminophenylsulfonyl)fluorene (*VII*c)—This compound was prepared from VII*b* by acid hydrolysis in hot methanol and hydrochloric acid; IR (mineral oil): 3440, 3350, 1315, and 1150 cm^{-1}.

α-Chlorobenzyl Sulfones—*4-Acetamidophenyl-α-chlorobenzyl sulfone* (*IV*a)—A solution of triethylammonium-4-acetamidophenyl sulfinate (15 g, 50 mmoles), and benzal chloride (4.03 g, 25 mmoles) in 30 ml of *N,N*-dimethylformamide was heated at 100–105° for 46 hr. The reaction mixture was poured into 400 ml of water and the oily precipitate that formed hardened slowly. The IV*a* crystals were filtered after 24 hr, washed with water, and air dried; IR (mineral oil): 3360, 1700, 1325, and 1145 cm^{-1}.

4-Aminophenyl-α-chlorobenzyl Sulfone (*IV*b)—This compound was prepared from IV*a* by acid hydrolysis with 11.6 *M* aqueous hydrochloric acid at 100° for 17 hr; IR (mineral oil): 3400, 3450, 1295, and 1140 cm^{-1}.

4-Trichloromethylphenyl Phenylsulfonyl Chloromethane (*IV*c)—A solution of sulfuryl chloride (0.92 ml, 11.3 mmoles) in 60 ml of *n*-pentane was added to a boiling solution of Ic (3.44 g, 8.09 mmoles) in 100 ml of *n*-pentane during 1 hr (13). The reaction mixture was heated under reflux for an additional 2 hr. The *n*-pentane was removed under reduced pressure. The residue was dissolved in 200 ml of methylene chloride and a 1.59 *M* solution of peracetic acid in methylene chloride (61 ml, 97 mmoles) was added with stirring over 30 min. The reaction mixture was stirred at ambient temperature for 144 hr. The solution was concentrated under reduced pressure to 20 ml and white crystals precipitated upon addition of 5 ml of cyclohexane. The crystals were separated by filtration and washed with cyclohexane to give IV*c* which was recrystallized; IR (mineral oil): 1320 and 1150 cm^{-1}.

Derivatives of 4-Dichloromethylbenzoyl Chloride (X)—*4-Dichloromethylbenzanilide* (*VI*a)—This compound was prepared from a solution of X and aniline in benzene; IR (mineral oil): 3330 and 1640 cm^{-1}.

4'-Carboxy-4-dichloromethylbenzanilide (*VI*b)—This compound was prepared from a solution of X, 4-aminobenzoic acid, and pyridine in tetrahydrofuran; IR (mineral oil): 3310 and 1690–1640 cm^{-1}.

4-Acetamidophenyl-4-dichloromethyl Thiolbenzoate (*VI*c)—This compound was prepared from a solution of X, 4-acetamidothiophenol, and pyridine in tetrahydrofuran, IR (mineral oil): 3300 and 1660 cm^{-1}.

Derivatives of 4-Trichloromethylbenzoyl Chloride (XI)—*4-Trichloromethylbenzanilide* (*VI*d)—A solution of XI and aniline in tetrahydrofuran gave VI*d*; IR (mineral oil): 3310 and 1650 cm^{-1}.

4'-Nitro-4-trichloromethylbenzanilide (*VI*e)—A solution of XI, 4-nitroaniline, and triethylamine in acetonitrile gave VI*e*; IR (mineral oil): 3390 and 1670 cm^{-1}.

S-(Phenyl)-4-trichloromethyl Thiolbenzoate (*VI*f)—A solution of XI, thiophenol, and triethylamine in tetrahydrofuran gave VI*f*; IR (mineral oil): 1660 cm^{-1}.

S-(4-Acetamidophenyl)-4-trichloromethyl Thiolbenzoate (*VI*g)—A solution of XI, 4-acetamidothiophenol, and triethylamine in tetrahydrofuran gave VI*g*; IR (mineral oil): 3250 and 1660 cm^{-1}.

α-Disulfones and Thiolsulfonates—*Bis(4-acetylaminophenyl Sulfone)* (*VIII*a)—This was prepared (30) from 4-acetamidophenyl sulfinic acid and potassium permanganate, mp 245° [lit. (30) mp 245–250° dec.].

Bis(4-aminophenyl Sulfone) (*VIII*b)—Acid hydrolysis of VIII*a* in hydrochloric acid, methanol, and *N*-methyl-2-pyrrolidone at 100° for 2 hr gave VII*b*. Compound VIII*b* was recrystallized from a mixture of *N*-methyl-2-pyrrolidone and water, mp 215° dec. (31); IR (mineral oil): 3490, 3400, 1320, and 1125 cm^{-1}.

Anal.—Calc. for $C_{12}H_{12}N_2O_4S_2$; C, 46.14; H, 3.88; N, 8.97; S, 20.53. Found: C, 48.87; H, 4.10; N, 8.89; S, 20.39.

4'-Acetamidophenyl-4-acetamidobenzene Thiolsulfonate (*IX*a)—Compound I*a* (6.35 g, 15 mmoles) was suspended in 55 ml of acetic acid, and 30% hydrogen peroxide (8.55 g, 75 mmoles) was added during 30 min. The temperature of the reaction mixture was kept below 35° with occasional ice cooling during the addition of hydrogen peroxide. Stirring was continued for 37 hr. The suspension was poured into 450 ml of water and the undissolved material was filtered, and washed with water giving 4.34 g (81.5%) of IX*a*, mp 219–221° dec. Recrystallization from a mixture of *N,N*-dimethylformamide and water gave 3.22 g (59%) of IX*a*, mp 223–224° dec. [lit. (30) mp 236–237° dec.].

4'-Aminophenyl-4-aminobenzene Thiolsulfonate (*IX*b)—This compound was prepared by acid hydrolysis of IX*a* in hydrochloric acid and methanol, mp 185–186° dec. [lit. (30) mp 183°].

GLC Analysis of Trifluoperazine in Human Plasma

J. I. JAVAID *x, H. DEKIRMENJIAN ‡, and J. M. DAVIS *

Received March 6, 1981, from the **Illinois State Psychiatric Institute, Chicago, IL 60612*, and the ‡*National Psychopharmacology Laboratory, Knoxville, TN 37923.* Accepted for publication May 21, 1981.

Abstract □ This report describes a sensitive gas chromatographic procedure for the measurement of trifluoperazine in human plasma. Trifluoperazine was extracted into heptane–2-propanol by a two-step procedure and analyzed directly without derivatization. Prochlorperazine was employed as an internal standard because its structural and extraction characteristics were similar to trifluoperazine. The use of a nitrogen detection system reduced the number of interfering peaks. The within-day coefficient of variation in the method, over a 0.2–20-ng/ml concentration range was 9.4%.

Keyphrases □ Trifluoperazine—gas chromatographic measurement in human plasma □ Gas chromatography—measurement of trifluoperazine in human plasma □ Tranquilizers—trifluoperazine, gas chromatographic measurement in human plasma

The relationship between plasma concentrations of various psychoactive drugs and their clinical effects was recently discussed (1, 2). It was shown that drug concentrations can vary widely among patients receiving identical doses (3–6). Based on such interindividual variations in plasma levels of psychoactive drugs, it was suggested that

0022-3549/82/0100-0063$01.00/0

Derivatives of 4-Trichloromethylbenzoyl Chloride (XI)—*4-Trichloromethylbenzanilide* (*VI*d)—A solution of XI and aniline in tetrahydrofuran gave VI*d*; IR (mineral oil): 3310 and 1650 cm^{-1}.

4'-Nitro-4-trichloromethylbenzanilide (*VI*e)—A solution of XI, 4-nitroaniline, and triethylamine in acetonitrile gave VI*e*; IR (mineral oil): 3390 and 1670 cm^{-1}.

S-(Phenyl)-4-trichloromethyl Thiolbenzoate (*VI*f)—A solution of XI, thiophenol, and triethylamine in tetrahydrofuran gave VI*f*; IR (mineral oil): 1660 cm^{-1}.

S-(4-Acetamidophenyl)-4-trichloromethyl Thiolbenzoate (*VI*g)—A solution of XI, 4-acetamidothiophenol, and triethylamine in tetrahydrofuran gave VI*g*; IR (mineral oil): 3250 and 1660 cm^{-1}.

α-Disulfones and Thiolsulfonates—*Bis(4-acetylaminophenyl Sulfone)* (*VIII*a)—This was prepared (30) from 4-acetamidophenyl sulfinic acid and potassium permanganate, mp 245° [lit. (30) mp 245–250° dec.].

Bis(4-aminophenyl Sulfone) (*VIII*b)—Acid hydrolysis of VIII*a* in hydrochloric acid, methanol, and *N*-methyl-2-pyrrolidone at 100° for 2 hr gave VII*b*. Compound VIII*b* was recrystallized from a mixture of *N*-methyl-2-pyrrolidone and water, mp 215° dec. (31); IR (mineral oil): 3490, 3400, 1320, and 1125 cm^{-1}.

Anal.—Calc. for $C_{12}H_{12}N_2O_4S_2$; C, 46.14; H, 3.88; N, 8.97; S, 20.53. Found: C, 48.87; H, 4.10; N, 8.89; S, 20.39.

4'-Acetamidophenyl-4-acetamidobenzene Thiolsulfonate (*IX*a)—Compound I*a* (6.35 g, 15 mmoles) was suspended in 55 ml of acetic acid, and 30% hydrogen peroxide (8.55 g, 75 mmoles) was added during 30 min. The temperature of the reaction mixture was kept below 35° with occasional ice cooling during the addition of hydrogen peroxide. Stirring was continued for 37 hr. The suspension was poured into 450 ml of water and the undissolved material was filtered, and washed with water giving 4.34 g (81.5%) of IX*a*, mp 219–221° dec. Recrystallization from a mixture of *N,N*-dimethylformamide and water gave 3.22 g (59%) of IX*a*, mp 223–224° dec. [lit. (30) mp 236–237° dec.].

4'-Aminophenyl-4-aminobenzene Thiolsulfonate (*IX*b)—This compound was prepared by acid hydrolysis of IX*a* in hydrochloric acid and methanol, mp 185–186° dec. [lit. (30) mp 183°].

GLC Analysis of Trifluoperazine in Human Plasma

J. I. JAVAID *x, H. DEKIRMENJIAN ‡, and J. M. DAVIS *

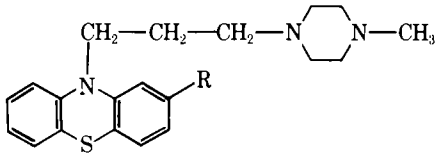
Received March 6, 1981, from the **Illinois State Psychiatric Institute, Chicago, IL 60612*, and the ‡*National Psychopharmacology Laboratory, Knoxville, TN 37923.* Accepted for publication May 21, 1981.

Abstract □ This report describes a sensitive gas chromatographic procedure for the measurement of trifluoperazine in human plasma. Trifluoperazine was extracted into heptane–2-propanol by a two-step procedure and analyzed directly without derivatization. Prochlorperazine was employed as an internal standard because its structural and extraction characteristics were similar to trifluoperazine. The use of a nitrogen detection system reduced the number of interfering peaks. The within-day coefficient of variation in the method, over a 0.2–20-ng/ml concentration range was 9.4%.

Keyphrases □ Trifluoperazine—gas chromatographic measurement in human plasma □ Gas chromatography—measurement of trifluoperazine in human plasma □ Tranquilizers—trifluoperazine, gas chromatographic measurement in human plasma

The relationship between plasma concentrations of various psychoactive drugs and their clinical effects was recently discussed (1, 2). It was shown that drug concentrations can vary widely among patients receiving identical doses (3–6). Based on such interindividual variations in plasma levels of psychoactive drugs, it was suggested that

0022-3549/82/0100-0063$01.00/0



I: R = CF_3
II: R = Cl

an effective treatment regimen for the individual patient may be approached by monitoring the blood levels of the drug and relating them to clinical outcome. Therefore, specific and sensitive methods for measuring neuroleptic drug levels in schizophrenic patients (7, 8) are needed.

Trifluoperazine (I), a phenothiazine neuroleptic, is commonly used for the treatment of schizophrenia. Although a TLC method for the measurement of trifluoperazine and its metabolites in rat tissues was reported (9), the method was not sensitive enough to measure the low therapeutic levels in humans. The present report describes a specific and sensitive method for measuring trifluoperazine in biological fluids. Prochlorperazine (II) was the internal standard. The method was applied to measure plasma trifluoperazine concentrations in schizophrenic patients treated with the drug.

EXPERIMENTAL

Materials—Trifluoperazine hydrochloride[1] and prochlorperazine maleate[1] were used. Heptane[2] and 2-propanol[2] were glass distilled. All other reagents were analytical grade.

The gas chromatograph[3] was equipped with a nitrogen–phosphorus detector; 3% OV-101 on 80–100-mesh support[4] was used as packing material. The highest purity[5] air, helium, and hydrogen available were used.

Procedures—Blood was drawn into tubes[6] containing ethylenediaminetetraacetate (1 mg/ml of blood) from patients receiving trifluoperazine. Rubber[6] stoppers were avoided since it was reported (10) that contact with the stopper may alter the distribution of drugs between plasma and red blood cells. The plasma and red blood cells were separated by centrifugation and stored at −16° until analysis. For determining recoveries and preparing standard curves, outdated plasma was used since there were no differences in recoveries with fresh and outdated blood.

Extraction from Plasma—Five-milliliter plasma samples, (unknown, drug-free, and plasma standards containing known amounts of the drug) were transferred to 15-ml test tubes, and prochlorperazine (as the internal standard) was added to unknown samples and plasma standards. To each tube, 1.0 ml of 2 *N* NaOH was added, and the mixture extracted with 5 ml of heptane–2-propanol (9:1, v/v). After shaking for 20 min, the tubes were centrifuged to separate the organic and aqueous layers.

The upper organic layer was transferred to another 15-ml tube containing 1 ml of 0.1 *N* HCl. The mixture was shaken for 15 min, and the organic layer was discarded by aspiration after centrifugation. The acid layer was transferred to a 5-ml centrifuge tube containing 0.1 ml of 5 *N* NaOH, and the mixture was extracted with 0.3 ml of heptane–2-propanol after shaking for 5 min and centrifuging as described. The organic layer (3–5 μl) was then injected into the gas chromatograph.

Chromatographic Conditions—The instrument was set according to the instruction manual provided by the manufacturer, except that the off-set current applied to the detector was increased until an optimum signal-to-noise ratio was obtained to maximize sensitivity. Generally, the detector voltage was set to give a 20% deflection of the recorder chart at the range setting of 1 and an attenuation of 32 at a 190° oven temperature.

When a 0.9 m glass column (2-mm i.d.), packed with 3% OV-101 was used, the chromatographic conditions were as follows: isothermal column temperature, 250°; injection port temperature, 300°; detector temperature, 300°; carrier gas (helium) flow, 30 ml/min; air flow, 50 ml/min; hydrogen flow, 3 ml/min; range, 1; and attenuation, 2–32.

Calculations—A standard curve was prepared with every analysis by plotting the ratio of peak heights for trifluoperazine and prochlorperazine against various concentrations of trifluoperazine added to the drug-free plasma samples. The inverse of the slope of the line thus obtained was used to calculate the trifluoperazine concentration in unknown samples.

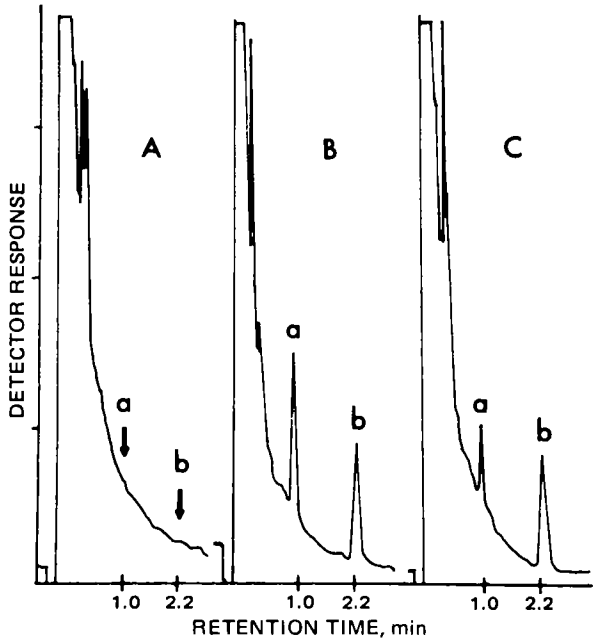


Figure 1—*Typical chromatogram of drug-free plasma carried through the procedure (A), drug-free plasma to which trifluoperazine (a) and prochlorperazine (b) were added (B), and plasma from a patient receiving trifluoperazine (C). Prochlorperazine was added as an internal standard.*

RESULTS

Figure 1 shows a typical chromatogram obtained for the analysis of trifluoperazine with the internal standard, using a 0.9 m column packed with 3% OV-101 at 250°. There were no interfering peaks at the retention times for trifluoperazine and prochlorperazine (Fig 1A). The peaks for trifluoperazine and prochlorperazine were symmetrical, and relationship was linear between the peak height and concentration of each drug injected into the chromatograph. There was also a linear relationship when the ratios of the peak height of trifluoperazine to the peak height of prochlorperazine were plotted against the various concentrations of trifluoperazine ($y = 0.055 + 0.126x$, $r = 0.996$).

Recovery of Extraction Procedure—The recoveries of trifluoperazine and prochlorperazine were determined by adding varying concentrations of the standard solution to drug-free plasma. These samples were then extracted and analyzed by the described procedure. The recoveries were calculated by comparing the extracted samples with the standard curves obtained by directly injecting the methanolic solutions of the drugs without extraction.

Trifluoperazine recovery from plasma averaged 79% and was constant over a wide concentration range (0.2–100 ng/ml). The average recovery of prochlorperazine from plasma was 72%.

Table I—Accuracy of Trifluoperazine Determination in Human Plasma [a]

Added, ng/ml	Determined, ng/ml	*SD*	Number of Determinations
20.0	20.77	1.1	9
2.0	2.17	0.13	10
0.2	0.23	0.02	10
0.1	0.16	0.07	6

[a] Different concentrations of trifluoperazine were added to drug-free plasma, and samples were then analyzed by the described procedure.

Table II—Reproducibility of Trifluoperazine Determination over Time [a]

Amount Added, ng/ml	Amount Determined over Time, ng/ml: 1 Day	3 Days	4 Days	6 Days	8 Days	33 Days	Average ± *SD*
1.0	0.93	1.03	0.83	0.83	0.82	1.1	0.92 ± 0.11
2.0	1.9	1.70	1.70	1.60	2.0	2.4	1.88 ± 0.27
4.0	4.3	3.7	3.6	4.4	3.3	3.8	3.85 ± 0.39
8.0	8.0	7.7	7.6	7.5	7.7	7.8	7.72 ± 0.16

[a] Different concentration of trifluoperazine were added to drug-free plasma and kept frozen in aliquots. Each aliquot was thawed on the day of analysis.

Accuracy and Reproducibility—The accuracy of the method was determined by adding different concentrations of trifluoperazine and analyzing six to 10 samples for each concentration according to the described procedure. These results are summarized in Table I. The within-day coefficient of variation over the concentration range of 0.2–20 ng/ml plasma was calculated as 6.7%.

To determine the day-to-day reproducibility, four different trifluoperazine concentrations were added to drug-free plasma and the samples were analyzed over the next several days. The average day-to-day coefficient of variation over the 1.0–8.0-ng/ml concentration range was calculated as 9.4%. These results (Table II) also indicate that the trifluoperazine in plasma samples was stable for at least 1 month when kept frozen.

Specificity and Sensitivity—Evidence for the specificity of the method was provided by characteristic retention times of trifluoperazine and prochlorperazine and the lack of interfering peaks in drug-free plasma when the samples were analyzed by the described procedure. Ten commonly used psychoactive drugs and three metabolites of trifluoperazine were also screened for interference in the assay by directly injecting their methanolic solutions under the described chromatographic conditions. The retention times of these drugs relative to trifluoperazine were as follows: butaperazine, 5.92; clomipramine, 0.50; desipramine, 0.33; desmethyltrifluoperazine, 0.83; diazepam, 0.58; fluphenazine, 2.50; haloperidol, 2.00; 7-hydroxytrifluoperazine, 2.42; imipramine, 0.25; mesoridazine, 5.83; piperacetazine, 10.00; prochlorperazine, 2.18; thioridazine, 2.75; 2-trifluomethylphenothiazine, 0.17; and trifluoperazine, 1.00. None of the drugs tested interfered with the assay of trifluoperazine or prochlorperazine.

Although 0.1 ng of trifluoperazine/ml could be measured by the described procedure, the coefficient of variation was too large (43.8%, Table I) for quantitative purposes. Hence, the actual sensitivity of the method to quantitate trifluoperazine in plasma was 0.2 ng/ml (coefficient of variation of 8.7%, Table I) when 5 ml of plasma sample was used.

Trifluoperazine Levels in Clinical Samples—The described method was used for measuring plasma concentrations of trifluoperazine in patients who received therapeutic doses for schizophrenia. The steady-state plasma levels in 21 patients receiving different doses of trifluoperazine are shown in Fig. 2. Although there were large interindividual differences in steady-state plasma concentrations in patients receiving identical doses of trifluoperazine, there was good correlation between drug concentation in plasma and dose administered ($r = 0.93$). However, some patients received other medication along with trifluoperazine. These data are given to show the applicability of the method in patients treated with trifluoperazine.

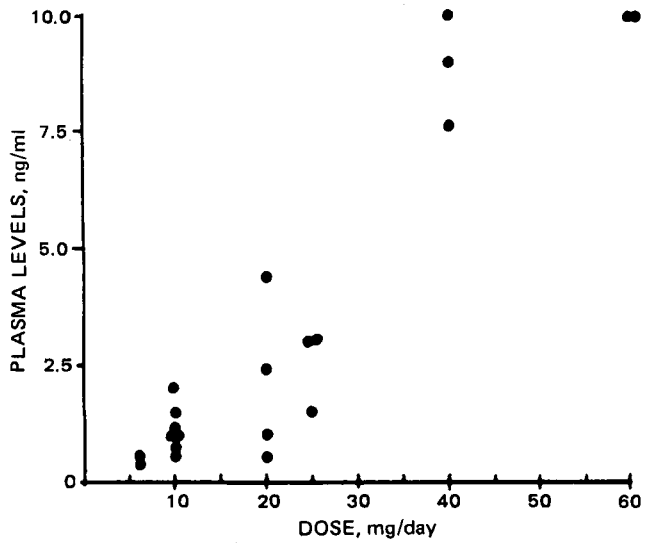

Figure 2—*Trifluoperazine concentrations in plasma from patients receiving different doses of the drug.*

DISCUSSION

The described procedure is sensitive enough to measure low therapeutic levels, is specific, and is reproducible for trifluoperazine. Detector response for trifluoperazine and prochlorperazine was linear over a wide concentration range, and retention times were similar.

In one experiment where trifluoperazine was added to drug-free plasma without any preservative and the sample was analyzed over the next 33 days, the sample was stable when kept frozen. However, during more than 1 year of analysis of plasma samples from patients, samples were found to be more prone to losses without any preservative.

Although there are no systematic studies on the stabilities of neuroleptics, it was reported (11) that amitriptyline hydrochloride in aqueous solutions is broken down by heavy metal contaminants. If this is also the case for neuroleptics, all the glassware should be acid washed and rinsed thoroughly with distilled water. This procedure minimizes occasional problems with the assay. Furthermore, 0.5 mg of sodium metabisulfite or ascorbic acid/ml of plasma should be added to samples to avoid loss by oxidation. In addition, all standard solutions should be stored in dark bottles or covered with aluminum foil. Although trifluoperazine standard solutions were stable for up to 3 weeks when kept at −16° in the dark, the prochlorperazine standard was stable for only 1 week.

The steady-state plasma concentrations of trifluoperazine showed interindividual variability in patients receiving identical doses. Such interindividual variabilities are characteristic of most of the drugs and represent the differences in absorption, distribution, metabolism, and excretion due to genetic, physiological, and environmental differences. Steady-state plasma concentrations were similar to those reported for another high potency neuroleptic, fluphenazine (12, 13), but were much lower than with chlorpromazine (14) or butaperazine (7). In one patient, the pharmacokinetics of trifluoperazine after a single dose were also studied using the described procedure. Highest concentrations were obtained in 4 hr after oral drug administration and then decreased over the next 24 hr.

Although radioreceptor assay was recently introduced (15) for measuring total neuroleptic concentrations, this assay did not differentiate between the parent compound and active metabolites. Furthermore, the lower limit of sensitivity of the radioreceptor assay for trifluoperazine is 2.2 ng/ml (15) because <200 μl of plasma or serum must be used in the assay system; at higher protein concentrations, the nonspecific inhibition in the binding system becomes significant. On the other hand, the lower limit of sensitivity of the described method is 0.2 ng/ml, because 5 ml of the plasma can be used for extraction.

GLC with nitrogen detection is becoming increasingly popular for measuring low drug levels in therapeutic conditions. The nitrogen detector is 10–100-fold more sensitive than the conventional flame-ionization detector and is as sensitive as the electron-capture detector for nitrogen-containing compounds. The selectivity of the nitrogen detector reduces the number of interfering peaks and decreases the time for sample analysis. The method described here for trifluoperazine determination does not require any derivatization and takes only 3 min for each sample analysis after extraction.

Contribution of Lungs to Total Body Clearance: Linear and Nonlinear Effects

JERRY M. COLLINS ˣ and ROBERT L. DEDRICK

Received October 29, 1980, from the *Biomedical Engineering and Instrumentation Branch, Division of Research Services, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication May 13, 1981.

Abstract □ The contribution of the lungs to the total body clearance of drugs is examined in a framework that emphasizes their anatomical position. For intravenous administration, the lung is the only organ other than blood that can account for a total body clearance in excess of the cardiac output. Systemic arterial drug concentration and tissue drug exposure are inversely proportional to total body clearance. Although the role of the lung has been overshadowed by that of the liver, several examples are presented to demonstrate that a relatively small amount of pulmonary activity can produce a large reduction in systemic arterial drug concentration. For oral administration, first-pass elimination by the liver and lungs in series results in a synergistic increase in total body clearance. Nonlinear effects caused by saturation of elimination pathways are also examined. Increased emphasis on experimental investigation of the pulmonary contribution is warranted, especially for drugs with high apparent clearance.

Keyphrases □ Lungs—role in total body clearance, linear and nonlinear effects □ Pharmacokinetics—role of lungs in total body clearance, linear and nonlinear effects □ Pulmonary metabolism—role in total body clearance, linear and nonlinear effects

Application of the techniques used to study hepatic drug metabolism to the lung has led to a growing literature on pulmonary metabolism. Although smaller in weight than the liver (600 *versus* 1500 g for humans), the processing of the entire cardiac output (*versus* 25% for the liver) places the lungs in a unique position for drug metabolism.

This report describes the contribution of the lungs to drug metabolism, including interaction with other drug-eliminating organs. Both saturating and nonsaturating conditions were examined.

BACKGROUND

Of the three types of clearance mechanisms (metabolism, excretion, and irreversible binding), this report concentrates on metabolic clearance. Transport, including excretion, of volatile substances is a primary function of the lungs; however, this topic was previously detailed (1). Uptake and/or binding of substances by the lung was documented by Junod (2). He suggested that the lungs can function as a capacitor that dampens out large variations in plasma concentration by rapid uptake and slow release processes. While such a role could have major importance for the pharmacodynamics of drug effect, reversible uptake or binding makes no net contribution to apparent clearance. Only irreversible binding decreases the total amount of drug delivered to the systemic circulation.

The demonstration of drug metabolism at the cellular (3) and subcellular level (4, 5) was a first step in the stimulation of more interest in pulmonary metabolism. Although some metabolic activity was shown in subcellular preparations from the lungs, recent work (6) raised the possibility that pulmonary activity has been substantially underestimated due to undetermined methodological factors. The isolated perfused lung preparation was shown to possess 10 times more drug clearance capability than was projected on the basis of experiments using subcellular preparations.

The isolated perfused lung has had a major role in demonstrating the importance of pulmonary metabolism. An earlier report (7) detailed the capability of this preparation to extract certain endogenous substances, especially the prostaglandins (8), serotonin (9), and other hormones. Metabolic clearance by the isolated perfused lung has now been demonstrated for many exogenous substances including drugs such as mescaline (10), isoproterenol hydrochloride (11), and the tetrahydrocannabinols (12) and chemicals such as *N*-methylaniline (13), aldrin (14), and trichloroethylene (15).

Direct comparisons of lung and liver elimination capacity were made by Roth and coworkers for three substances. In all cases, the effect of blood flow limitation increased the relative role of the lungs *versus* the liver when organ clearance was compared with organ enzyme capacity. Using literature values (16, 17) for benzpyrene in rats with induced enzymes, Roth and Wiersma (18) calculated nearly equal organ clearances for the liver and lungs, despite the fact that the liver contained 64 times more total enzyme capacity than the lungs. Similar calculations were reported (10) for data on mescaline metabolism in homogenates of rabbit lungs and liver. Approximately equal organ clearances were predicted, despite five times more enzyme capacity in the liver. For serotonin, Wiersma and Roth (6) found 17 times as much activity in the liver as in the lungs and predicted five times more clearance in the liver than the lungs. Their predictions for the perfused liver agreed well with their experimental results, but they underpredicted perfused lung clearance by a factor of 10. This discrepancy may be attributed to either suboptimal lung homogenate experiments or strong binding of serotonin by lung tissue.

The demonstration of *in vivo* pulmonary metabolism fully established the key role of the lungs in the overall process of drug elimination from the body. Two studies (19, 20) demonstrated a pulmonary extraction for phenol of ~60% in the rat by comparing the area under the plasma concentration–time curve following intravenous and intra-aortic administration.

0022-3549/82/0100-0066$01.00/0

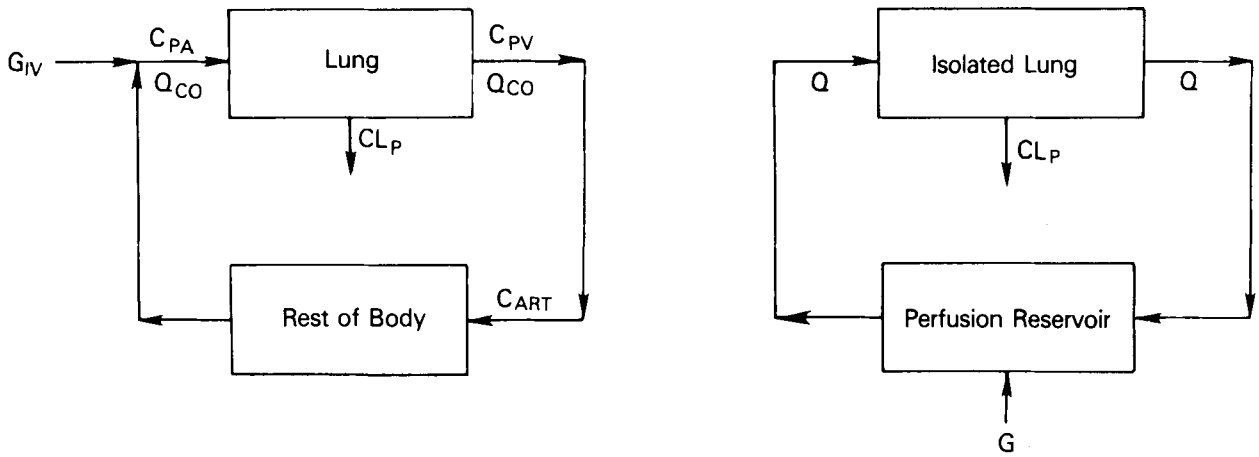


Scheme I—Pulmonary clearance in vivo *(left) and in isolated perfused lung (right).*

Pulmonary clearance should be examined for drugs that exhibit an apparent clearance in excess of liver blood flow. The lungs and blood are the only organs capable of generating an apparent clearance greater than the cardiac output. Elsewhere, a major role was suggested for pulmonary clearance of fluorouracil (21) and thymidine on the basis of high apparent clearance (5 and 25 liters/min, respectively) and the apparent lack of substantial clearance by the blood; however, direct confirmation of the lung's role has not been made. An apparent clearance of 14 liters/min for nitroglycerin was reported (20).

When indicated for patient care, placement of a pulmonary artery catheter in combination with any peripheral arterial drug measurement effectively isolates the lungs *in vivo* for determination of pulmonary extraction. The high apparent clearance of lorcainide, 1.7 liters/min, suggests a possible pulmonary role, but Jahnchen *et al.* (23) was unable to measure any concentration differences in samples obtained from catheters in the pulmonary artery and the aorta.

Kates and Leier (24) determined an apparent clearance of 4.4 liters/min for dobutamine based on mixed venous blood obtained *via* a pulmonary artery catheter as the reference concentration. Unfortunately, no peripheral measurements were reported. With more widespread appreciation of the potential role for pulmonary metabolism, especially in cases in which apparent clearance exceeds liver blood flow, it is anticipated that more investigators will directly determine pulmonary clearance. However, the clearance contribution of the lung *in vivo* will be difficult to determine for drugs with an apparent clearance of ≤500 ml/min. If the apparent clearance is 500 ml/min and only the lung eliminates the drug, pulmonary extraction is ~10%, which may be difficult to measure. On the other hand, if the liver were the exclusive organ of elimination, an easily measured difference of ~30–50% would be expected.

KINETIC ANALYSIS

The basic equations needed for kinetic analysis of pulmonary clearance are presented. Most examples in this section can be conceptualized in terms of a steady-state analysis, in which the rate of drug elimination equals a constant rate of drug input to the body. Variables are defined in the *Appendix*.

Exclusive Pulmonary Clearance–Scheme I (left) illustrates the role of the lung *in vivo* for the case in which the lungs eliminate a drug administered by intravenous infusion. Apparent clearance is G_{iv}/C_{art} or G_{iv}/C_{pv} (21):

$$Cl_{app} = Q_{co}E_p/(1 - E_p) \quad \text{(Eq. 1)}$$

Equation 1 illustrates a key principle of pulmonary elimination, namely that the apparent clearance will exceed organ blood flow and cardiac output whenever E_p is greater than 50%. This result is a direct consequence of first-pass elimination since only $(1 - E_p)$ of the delivered dose is actually available to systemic tissues (*i.e.*, tissues that obtain their drug supply *via* the arterial system).

Clearance by the perfused lung (Scheme I, right) is usually calculated from the decline in concentration observed in samples taken from the reservoir. When appropriately calculated, this method yields identical results to those obtained when steady state is achieved during single-pass operation and clearance is calculated from pulmonary extraction:

$$Cl_{organ} = Q_{co}E_p \quad \text{(Eq. 2)}$$

This quantity is always less than the clearance suggested by Eq. 1 for *in vivo* elimination. The key difference is that organ clearance is referred to reservoir concentration, which is equivalent to C_{PA}, while *in vivo* clearance is referred to C_{PV} (or C_{art}). To compare perfused lung experiments with the *in vivo* situation, E_p should be measured (or calculated as $E_p = Cl_{organ}/Q_{co}$) and used to evaluate Eq. 1. Perfused lung experiments are often operated at flow rates below cardiac output, which requires correction of the observed pulmonary extraction before substitution into Eq. 1.

Pulmonary extraction may be expressed in terms of intrinsic pulmonary clearance, Cl_p, and blood flow:

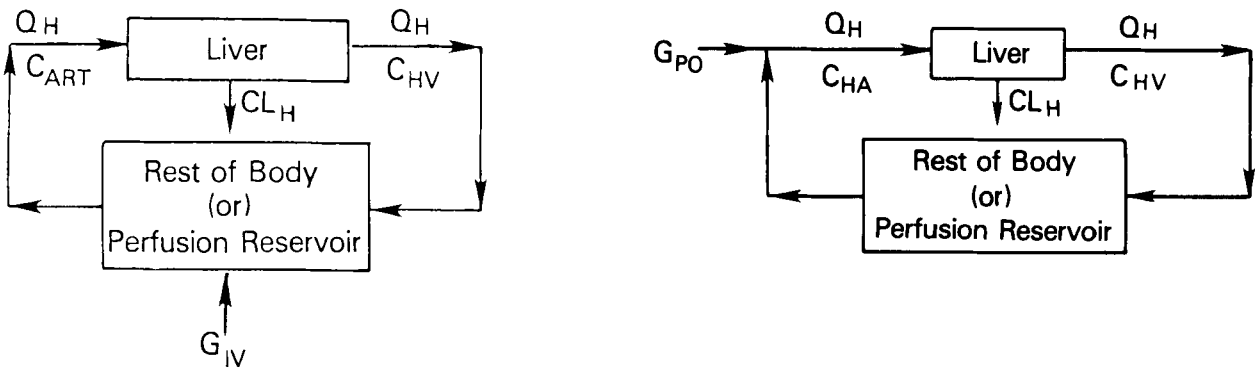
$$E_p = Cl_p/(Cl_p + Q_{co}) \quad \text{(Eq. 3)}$$

It will be assumed that the clearance process follows Michaelis–Menten kinetics:

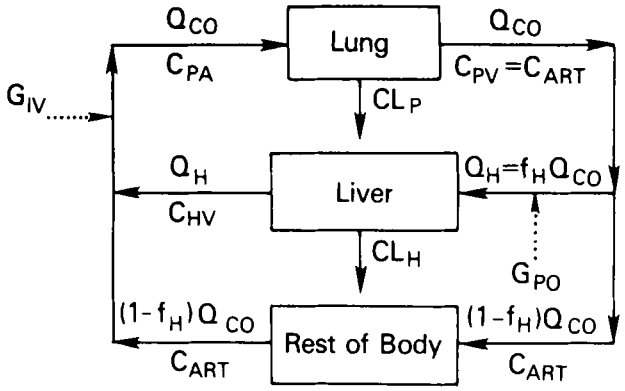
$$Cl_p = V_{max,p}/(K_M + C_{PV}) \quad \text{(Eq. 4)}$$

Substitution of Cl_p from Eq. 4 into Eq. 3 yields:

$$E_p = V_{max,p}/(Q_{co}K_M + Q_{co}C_{PV} + V_{max,p}) \quad \text{(Eq. 5)}$$



Scheme II—Hepatic clearance for in vivo *intravenous infusion or in an isolated perfusion circuit (left) and for oral (or portal vein or hepatic artery) infusion (right). For simplicity, the hepatic artery and portal vein are combined into a single input.*



Scheme III—Simultaneous pulmonary and hepatic clearance. For simplicity, the hepatic artery and portal vein are combined into a single input.

If Eqs. 1 and 5 are combined and simplified:

$$Cl_{app} = V_{max,p}/(K_M + C_{PV}) = Cl_p \qquad \text{(Eq. 6)}$$

Equation 6 shows that the apparent clearance of the lungs (calculated on the basis of peripheral arterial blood concentration) during intravenous infusion is equal to intrinsic clearance.

Exclusive Hepatic Clearance—Scheme II (left) depicts clearance by the liver during *in vivo* intravenous infusion or in an isolated perfusion circuit. Apparent clearance for the liver is based on a reference concentration in arterial blood (or reservoir blood), while the elimination mechanisms operate at the liver concentration, which may be approximated by C_{HV}. Therefore, flow limitation is expressed as:

$$Cl_{app} = Q_H E_H = Q_H Cl_H/(Q_H + Cl_H)$$
$$= Q_H V_{max,H}/(Q_H K_M + Q_H C_{HV} + V_{max,H}) \qquad \text{(Eq. 7)}$$

The role of the liver following oral administration or hepatic artery or portal vein infusion is analogous to the role of the lungs during intravenous or other systemic administration. As shown in Scheme II (right), the liver receives the full drug input before it reaches the measurement location. Since the liver is the sole organ of elimination in this example, $C_{art} = C_{HV}$:

$$Cl_{app} = Cl_H = V_{max,H}/(K_M + C_{art}) \qquad \text{(Eq. 8)}$$

Thus, there is no flow limitation, and the intrinsic clearance of the liver is fully expressed.

Simultaneous Pulmonary and Hepatic Clearance—When the lungs and liver both eliminate a drug, the relative contribution of each organ to apparent clearance should be determined. Scheme III illustrates both the lungs and liver as eliminating organs *in vivo*. For intravenous administration, apparent clearance (G_{iv}/C_{art}) is the sum of the individual clearances:

$$Cl_{app} = Cl_P + Q_H Cl_H/(Q_H + Cl_H) = Cl_P + Q_H E_H \qquad \text{(Eq. 9)}$$

From this formula, the relative clearance contributions of the lungs and liver are:

$$\left(\frac{\text{lung}}{\text{liver}}\right) = \left(\frac{Cl_P}{Q_H E_H}\right) \qquad \text{(Eq. 10)}$$

Equation 10 is applicable to both linear and nonlinear kinetic regions. For nonlinear kinetics, Cl_P and E_H are not constants but are functions of C_{art} and C_{HV}. For linear kinetics ($C \ll K_M$), the expression for the Cl_P (Eq. 4) reduces to:

$$Cl_P = V_{max,P}/K_M \qquad \text{(Eq. 11)}$$

The expression for $Q_H E_H$ (Eq. 7), reduces to:

$$Q_H E_H = \frac{Q_H V_{max,H}}{Q_H V_{max,H}/(Q_H K_M + V_{max,H})} \qquad \text{(Eq. 12)}$$

Thus, the relative clearance contributions of the lungs and liver are:

$$\left(\frac{\text{lung}}{\text{liver}}\right) = \left(\frac{V_{max,P}/K_M}{Q_H V_{max,H}/(Q_H K_M + V_{max,H})}\right) \qquad \text{(Eq. 13)}$$

For oral administration, the apparent clearance (G_{po}/C_{art}) can be viewed as a modification of the expression for intravenous administration (Eq. 9). Due to the elimination by the liver of a certain fraction, E_H, of the administered dose, only the remainder is available for elimination by the lungs. Once this remainder, $1 - E_H$, leaves the liver, it is immaterial to the lungs whether the drug was given intravenously or orally. Hence, the right side of Eq. 9 can be divided by the available dose, $1 - E_H$, to yield an expression for apparent clearance for oral administration:

$$Cl_{app} = Cl_P/(1 - E_H) + Q_H E_H/(1 - E_H) = Cl_P/(1 - E_H) + Cl_H \qquad \text{(Eq. 14)}$$

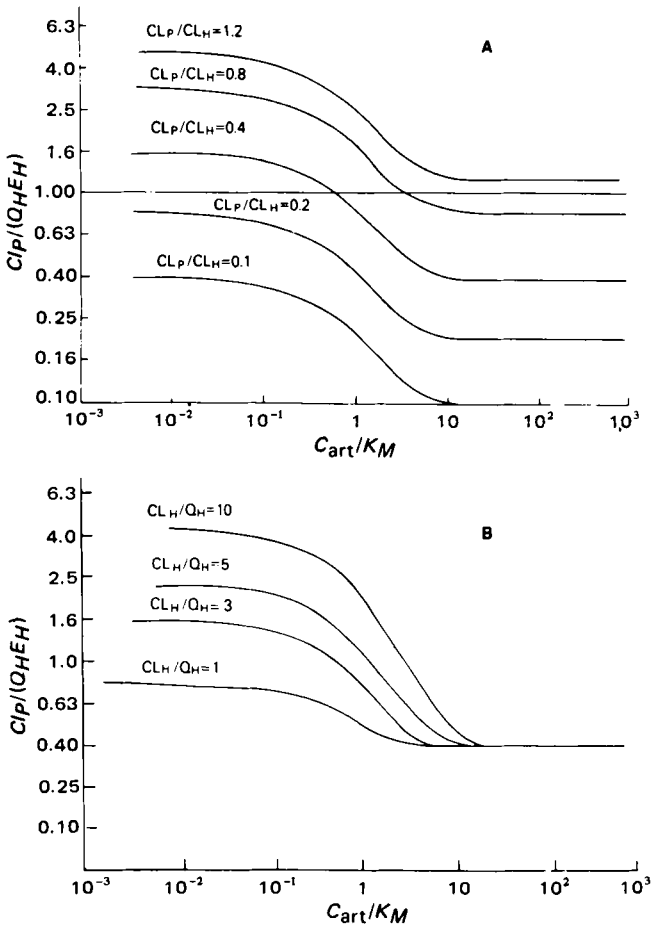


Figure 1—*Ratio of pulmonary clearance to hepatic clearance for intravenous infusion (Eq. 10) A:* Cl_H *fixed at three times* Q_H, *with* Cl_p/Cl_H *variable. B:* Cl_p/Cl_H *fixed at 0.4, with* Cl_H/Q_H *variable.*

It can be seen from Eq. 14 that the contributions of the lungs and liver to apparent clearance are interconnected. The contribution of pulmonary clearance is magnified by hepatic first-pass elimination, $1 - E_H$. Thus, there is no simple relationship similar to Eq. 10 that can be used to evaluate the relative clearance of the two organs.

RESULTS

The importance of pulmonary clearance for the determination of drug concentration is clearcut whenever the elimination capacity of the lungs is greater than that of any other organ (such as the liver). Even when the pulmonary elimination capacity is less than that of the liver, pulmonary clearance can dominate nonpulmonary clearance, or at least have a substantial impact on apparent clearance. For intravenous administration, hepatic clearance may not be fully expressed due to flow limitation so the relative impact of the lungs is enhanced. For oral administration, the coupling of pulmonary and hepatic clearances can accentuate the pulmonary impact.

Figures 1A and 1B demonstrate the relative contribution of the lungs and liver to overall drug elimination during intravenous infusion (Eq. 10). It is assumed that K_M is identical for liver and lung tissue. When $C_{art} \ll K_M$, elimination processes in both the lungs and liver are linear. At these low concentrations, the lung–liver elimination ratio is maximal since hepatic elimination is flow limited but pulmonary elimination is not. As the arterial concentration increases, the lung–liver elimination ratio

decreases since elimination processes are beginning to saturate, organ extraction is decreasing, and flow limitation is less pronounced. Finally, at $C_{art} \gg K_M$, the elimination ratio is simply the ratio of enzyme capacity, $V_{max,P}/V_{max,H}$.

As shown in Figs. 1A and 1B, for some parameter combinations the dominant role for elimination can be held by either organ or can shift from the lungs to the liver as C_{art} increases. For the lungs to dominate in the linear region, the following relationship must be satisfied, based on Eq. 13:

$$\left(\frac{V_{max,P}}{K_M}\right) > \left(\frac{Q_H V_{max,H}}{Q_H K_M + V_{max,H}}\right) \quad (15)$$

The liver always dominates in the zero-order region as long as $V_{max,H} > V_{max,P}$. As a reference point, the weight ratio of the lungs to the liver in humans is ~0.6 kg/1.5 kg or 0.4 (25). Since the clearances of both the lungs and liver are referred to the same arterial concentration, the mass elimination ratio (organ extraction times mass input to organ) is identical to the clearance ratio.

As already discussed, the contribution of the lungs to apparent clearance for oral administration is difficult to separate from the contribution of the liver. Figure 2 presents one possible interpretation of the lung's importance. Only the linear kinetic region is considered; Cl_{app} was calculated from Eq. (14) for various combinations of pulmonary and hepatic intrinsic clearance. The ability of the lungs to increase apparent clearance is rather substantial. As one example, a pulmonary elimination capacity that is 40% of hepatic capacity (*i.e.*, equivalent capacity per unit of weight multiplied by the organ weight ratio) produces a 133% increase in apparent clearance when the hepatic intrinsic clearance is three times the hepatic blood flow (75% extraction).

As a second example, a pulmonary elimination capacity of only 5% of hepatic capacity (*i.e.*, one-eighth the capacity per unit of weight multiplied by the organ weight ratio) increases Cl_{app} by 55% when hepatic clearance is 10 times the hepatic blood flow (91% extraction).

Since arterial concentration and systemic tissue exposure are inversely related to Cl_{app}, a relatively small amount of pulmonary activity can have a large impact. The mass elimination ratio does not provide the same perspective. The lungs account for 18% of mass elimination in the first example and only 3% in the second. These lower rates of mass elimination (as well as lower total elimination capacities) may lead one to ignore their role, while consideration of changes in Cl_{app} or systemic arterial concentration underscores the potential importance of pulmonary elimination.

DISCUSSION

Except for regionalized delivery such as topical, intraarterial, or intrathecal, the anatomical position of the lung presents it with the opportunity to modify the amount of drug available to the target tissues. Previous pharmacokinetic analyses focused primarily on the role of hepatic metabolism while essentially ignoring the lungs. In an earlier study that focused on the role of drug binding and GI or hepatic metabolism, Gillette and Pang (26) commented on the lack of flow limitation for the lung and the interactions of the liver with other organs for oral administration.

The role of the liver overshadowed that of the lungs in previous analyses for three major reasons:

1. The larger size of the liver may permit a greater total enzyme capacity. The actual magnitude of this difference is less for humans (1.5–2.5 times) than for other mammalian species: seven to 10 times for rats, eight times for rabbits, five times for monkeys, and three to four times for cats and dogs.

2. The well-known role of the liver in controlling the entry of exogenous substances into the body makes it a likely organ for drug elimination. Since the lungs play a major role in the regulation of endogenous substances, they might be expected to regulate exogenous substances also.

3. Lower specific enzyme activity (units per gram) has often been found in lung tissue compared with liver tissue. It was noted earlier that this apparently lower specific enzyme activity may be the result of suboptimal experimental conditions. In addition, interorgan differences in enzyme affinity for a drug (K_M) may offset a lower enzyme amount. Other studies (27) isolated an enzyme with a 10-fold lower K_M value in lung than liver tissue. Since intrinsic clearance under nonsaturating conditions is the ratio of enzyme capacity (V_{max}) to K_M, the lung can possess a larger intrinsic clearance than the liver, despite lower enzyme levels. On the other hand, studies by Gram (5) showed similar K_M values for other enzymes in the liver and lung. Finally, flow limitation can prevent expression of intrinsic clearance of the liver but not the lungs; thus, the lung can dominate even if it has lower intrinsic clearance.

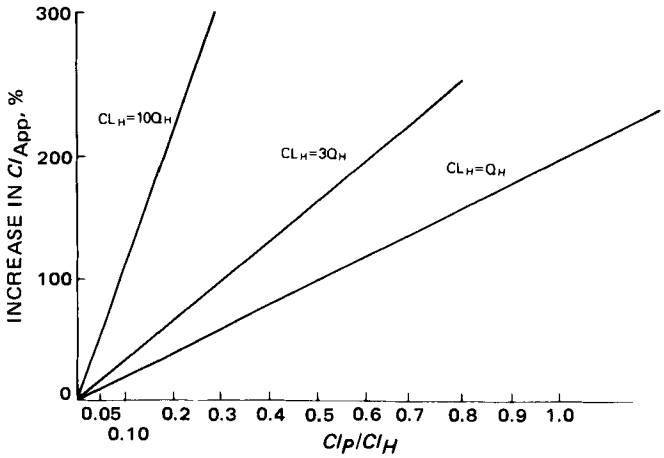

Figure 2—*Increase in apparent clearance for oral administration at various levels of pulmonary intrinsic clearance added to existing hepatic intrinsic clearance. Only the linear kinetic region is considered.*

Although it is suspected that the liver is a more important organ than the lungs for most drugs, the reasons for its dominance probably have been overstressed. Additional investigations are warranted to establish the actual pulmonary contribution, especially for drugs with high apparent clearance.

The concept of apparent clearance is especially relevant for a description of the lung's role in pharmacokinetics since it is simply a ratio of dose rate to arterial drug exposure. The related concept of organ clearance can be misleading when applied to the role of the lungs since it fails to account for first-pass effects. It is especially important that this difference is realized when the results from isolated perfused lung experiments are interpreted.

The synergism between the lung and liver for oral (or hepatic artery or portal vein) administration is especially noteworthy. The anatomical relationship of these organs results in a powerful filter, which can either protect systemic tissues from undesired exogenous chemicals or prevent achievement of therapeutic drug levels. For these two organs, neither the ratio of mass eliminated nor the ratio of elimination capacities is always a useful indicator of the control of tissue drug exposure. Although the liver may be responsible for the elimination of most of the drug mass eliminated from the body, the lung can still have a substantial impact on arterial drug concentration.

APPENDIX

Cl_p = intrinsic pulmonary clearance, $V_{max,P}/(K_M + C_{art})$
Cl_H = intrinsic hepatic clearance, $V_{max,H}/(K_M + C_{HV})$
Cl_{app} = apparent clearance, G/C_{art}
E_P = pulmonary extraction, (in–out)/in
E_H = hepatic extraction, (in–out)/in
G = drug input rate
Q = blood flow
C_{art} = arterial blood concentration
C_{PV} = pulmonary vein blood concentration
C_{PA} = pulmonary artery blood concentration
C_{HV} = hepatic vein blood concentration
K_M = half-saturating concentration (Michaelis constant)
V_{max} = maximal drug elimination capacity of whole organ
f = fraction of cardiac output which perfuses liver
co = cardiac output
P = pulmonary
H = hepatic
ia = intraarterial
iv = intravenous
po = oral

Comparison of Serum Bilirubin Levels in Humans and Two Monogastric Animal Species After a Single Administration of Sulfisoxazole

ROBERT L. SUBER*§x, JOHN C. GUDAT‡, and GEORGE T. EDDS*

Received January 27, 1981, from the *Department of Preventive Medicine and Toxicology, and the ‡Department of Pathology, Clinical Chemistry, University of Florida, Gainesville, FL 32610. §Present address: National Center for Toxicological Research, Pathology Services Project, Jefferson, AR 72079. Accepted for publication May 29, 1981.

Abstract □ Administration of sulfonamides during periods of hepatobiliary failure or hepatic immaturity increases the toxic potential of unconjugated or indirect bilirubin. A small but statistically significant increase of indirect, or unconjugated bilirubin was noted in dogs after oral administration of sulfisoxazole (100 mg/kg). A similar increase was not observed in swine after oral or intravenous administration of sulfisoxazole (100 mg/kg) or in humans (~28 mg/kg) after oral administration or in dogs (100 mg/kg) after intravenous administration. Total and conjugated bilirubin showed small but statistically significant increases and were significantly correlated in dogs after oral and intravenous administration of sulfisoxazole (100 mg/kg) and in swine after oral administration of sulfisoxazole (100 mg/kg). There was a significant negative correlation between conjugated and indirect bilirubin, while total bilirubin increased in dogs after oral and intravenous administration of sulfisoxazole. These data illustrate a difference in species and administration route when attempting to assess the potential toxicity of bilirubin.

Keyphrases □ Sulfisoxazole—comparison of serum bilirubin levels after a single administration, dogs, pigs, humans □ Bilirubin—serum levels after a single administration of sulfisoxazole, dogs, pigs, humans □ Toxicity—potential, indirect bilirubin serum levels after a single administration of sulfisoxazole

Sulfisoxazole [4-amino-*N*-(3,4-dimethyl-5-isoxazolyl)]-benzenesulfonamide is a white-yellowish, odorless, slightly bitter, crystalline powder with a pK of 4.9 (1). It is distributed in the extracellular fluid and fails to enter cells (2–5) resulting in a plasma concentration which is three times higher than that produced by an equal quantity of sulfanilamide (4). Sulfonamides, as a class of chemotherapeutic agents, are considered to be toxic since they may precipitate in the kidney, producing crystalluria (5). The infrequency of renal toxicosis (crystalluria) with sulfisoxazole is due to the exceptionally high water solubility of the free and conjugated (acetyl) fractions within the physiological pH range (6, 7).

Clinical toxicities have been induced by sulfisoxazole competing for the same binding sites as warfarin (8) and furosemide (9, 10), inducing hemolytic anemia due to glucose-6-phosphate dehydrogenase deficiency (11), inhibition of anticoagulant factor VIII (12), hypersensitivity (13), anorexia (14), agranulocytosis (14), and aplastic anemia (14). A case of myocarditis, myositis, and vasculitis associated with severe eosinophilia following sulfisoxazole therapy has been reported (15). Kernicterus has been reported in premature infants with increased levels of serum bilirubin after treatment with sulfisoxazole (4, 16, 17).

Kernicterus occurred when unconjugated or indirect bilirubin was less than 20 mg% in 24 infants, less than 17 mg% in 15 infants, and less than 15 mg% in 11 infants. These occurrences were enhanced by prior acidosis, hypercapnia, and hypothermia (4).

Plasma samples from six adult patients showed that sulfisoxazole concentrations above 5 mg/100 ml had a significant displacing effect on bilirubin *in vitro* (18). When comparing the displacing effects of salicylic acid, salicyluric acid, and aspirin at sulfisoxazole concentrations of 10 mg/100 ml, the most pronounced effect was observed when sulfisoxazole displaced bilirubin from plasma sam-

Table I—Mean Control Values of Serum Bilirubin in Humans, Dogs, and Swine [a]

	Total Bilirubin, mg/dl	Conjugated Bilirubin, mg/dl	Indirect Bilirubin, mg/dl
Humans	0.54 ± 0.10	0.41 ± 0.05	0.13 ± 0.02
Dogs	0.21 ± 0.06	0.08 ± 0.04	0.13 ± 0.03
Swine	0.35 ± 0.04	0.19 ± 0.06	0.15 ± 0.05

[a] The mean value ± 1 *SD* of eight samples before oral and intravenous administration of sulfisoxazole in six dogs and six swine. The mean value ± 1 *SD* for humans are calculated from time zero samples for six human subjects.

ples of six adults and 13 infants *in vitro* (18). The displacement of bilirubin is due to competition for similar binding sites on the albumin molecule (19).

Considering these observations and the importance of sulfisoxazole as an antibiotic in treating urinary tract infections, this study was initiated to define a non-rodent animal model which could be used in drug-safety screening of sulfonamides.

EXPERIMENTAL

Model—The trial consisted of six male human volunteers 25–30 years old, weighing 70–80 kg; three female dogs ~2 years old, weighing 20.0 ± 1.0 kg; and six female pigs ~3 months old, weighing 20.0 ± 1.0 kg. The human volunteers were administered 2.0 g of sulfisoxazole in a single oral dose and blood samples were taken at 0, 1, 2, 4, 6, and 8 hr after administration. The dogs were administered 100 mg/kg by intravenous and oral routes in two replicates for each route with a 30-day rest period between each administration. The pigs also were administered 100 mg/kg by intravenous and oral routes with a 21-day rest period between administration. Blood samples were taken at 0.5, 1, 2, 3, 4.5, 6, 9, 12, 22, 32, 44, 56, and 72 hr after intravenous administration and 0, 1, 2, 4, 6, 8, 10, 12, 14, 23, 32, 44, 56, 76, and 96 hr after oral administration in dogs and swine. All animals were maintained on a commercial diet[1,2] with *ad libitum* access to water and were housed in metabolism cages.

Materials—A 12.5% solution of sulfisoxazole[3] was prepared with lithium hydroxide. The solution was filtered and placed in sterile 50-ml ampuls[4]. This solution was used for both the oral and intravenous administration of the drug in dogs and swine and for oral administration to the human subjects. Due to the potential toxicity of intravenous sulfisoxazole administration and its removal from the drug market, intravenous administration of the drug to humans was not allowed[5].

Blood samples were taken from the cephalic vein in dogs and humans and from the anterior vena cava in swine. Human samples were drawn directly into 7-ml sterile silicone-coated tubules[6]. Ten-milliliter samples were taken by a sterile syringe with a 20-gauge needle from the dogs and pigs and transferred to sterile silicone-coated tubes[6]. The samples were centrifuged (2000×*g*) for 10 min, the serum extracted, protected from light, refrigerated, and analyzed within 30 min for total and conjugated (glucuronidated) bilirubin.

Serum Bilirubin—Serum was analyzed for total and conjugated (direct or glucuronidated) bilirubin on a discrete automatic analyzer[7] using a commercial standard[8].

The conjugated method is a modification of the Van den Bergh diazo reaction (20). Under acidic conditions, *p*-nitrobenzenediazonium tetrafluoroborate is coupled to the glucuronidated bilirubin which is measured as an end point reaction at 540 and 600 nm. The normal range in humans is considered to be 0.00 to 0.36 mg/dl[8].

The total bilirubin (the conjugated and unconjugated fractions) was determined also using a derivation of the Van den Bergh reaction (20). A surfactant[9] was used to solubilize the unconjugated (free) bilirubin, which along with the water-soluble glucuronidated bilirubin reacts with *p*-nitrobenzenediazonium tetrafluoroborate in an acid medium to measure an end point reaction at 540 and 600 nm. The normal total bilirubin concentration in humans is <1.5 mg/dl[8]; in dogs, the normal level is <0.5 mg/dl (17); and in swine is <0.6 mg/dl (21).

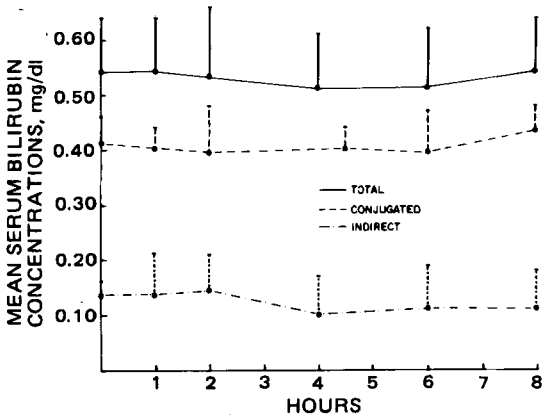

Figure 1—*Serum bilirubin concentrations in humans after oral administration of sulfisoxazole (mean ± 1* SD).

Interferences in these methods are due to hemolyzed samples and light degradation of the bilirubin. All analyses were conducted within 30 min of sampling on serum which was kept in a cool, dark environment.

Total, conjugated, and indirect bilirubin were analyzed for statistical differences[10]. The ANOVA program also produced a correlation coefficient (*R*) for parameters with a significant correlation.

RESULTS

Due to the lack of metabolic heterogenicity of humans, dogs, and swine, each species was used as its own control. The mean values for serum bilirubin were then used as initial or baseline values (Table I).

Humans, Oral Administration—An analysis of variance evaluation after oral administration of sulfisoxazole resulted in no statistical difference in mean total, conjugated, and indirect bilirubin levels (Fig. 1). The lack of significance could be due to the low therapeutic dose (2.0 g, ~28 mg/kg) administered to the human subjects, the fact that humans are able to reduce the *in vivo* effects of sulfisoxazole on the hepato-biliary system, or the sampling period being too short, and additional samples should have been taken over a longer trial period.

Dogs, Intravenous Administration—The mean total bilirubin concentration in six dogs administered sulfisoxazole intravenously exhibited statistically significant ($p < 0.01$) linear increases at 4.5 ($p < 0.05$), 6.0 ($p < 0.1$), 9.0 ($p < 0.01$), and 12.0 ($p < 0.01$) hr with the maximum levels occurring at 6 and 12 hr (Fig. 2). By the next sampling period (22 hr), the mean total bilirubin concentration had decreased to levels which were not significantly different from control values until the 56-hr sampling period ($p < 0.01$).

The mean conjugated bilirubin levels also showed statistically significant increases at 4 hr ($p < 0.01$) and continued throughout the sampling period ($p < 0.01$). There was a significant ($p < 0.01$) maximum mean

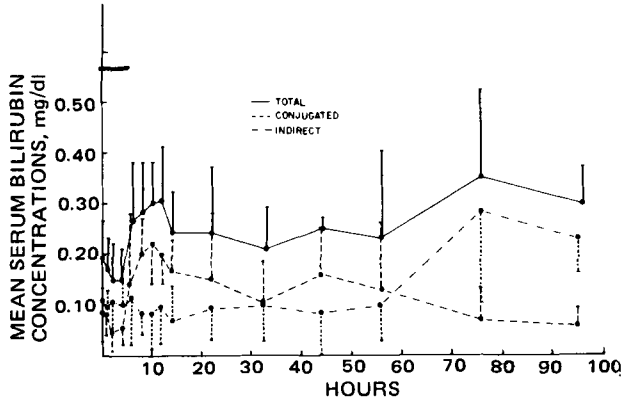

Figure 3—*Serum bilirubin concentrations in dogs after oral administration of sulfisoxazole (mean ± 1 SD).*

conjugated bilirubin concentration at 12 hr, which coincided with the maximum mean total bilirubin concentration (Fig. 2). A second increase was observed at 56 hr ($p < 0.01$) which coincided with the second increase in total bilirubin (Fig. 2). The mean indirect bilirubin concentration (Fig. 2) was not significantly different from the control level throughout the sampling period.

The mean total bilirubin was significantly correlated with mean conjugated bilirubin ($R = 0.75, p = 0.0001$) and with mean indirect bilirubin ($R = 0.31, p = 0.004$) after intravenous administration. The significant correlation of total and conjugated bilirubin is undoubtedly due to the concomitant increase in glucuronidation activity as total bilirubin levels increased. If the glucuronidation enzyme system is not capacity limited, the possibility of kernicterus due to increased indirect bilirubin is minimized after intravenous administration of sulfisoxazole in the dog. This enzyme system acts to maintain a reduced or limited indirect bilirubin concentration and reduces the toxicity of displaced protein-bound bilirubin or increased heme degradation. This was further emphasized by the significant negative correlation of conjugated and indirect bilirubin ($R = -0.39, p = 0.0002$). As the level of conjugated bilirubin increased, the potentially toxic indirect bilirubin level decreased.

A second explanation would be that sulfisoxazole alters the function of the normal hepatocyte to increase conjugated bilirubin regurgitation into the general circulation, instead of being excreted into the bile. The resulting increase in total bilirubin would be the result of the increased level of regurgitated, conjugated bilirubin, along with the normal level of indirect bilirubin.

Dogs, Oral Administration—When sulfisoxazole was administered orally to dogs, there was a significant linear increase in mean total ($p < 0.01$), conjugated ($p < 0.001$), and indirect ($p < 0.0001$) bilirubin (Fig. 3). Total bilirubin reached its first significant peak at 12 hr ($p < 0.01$) and a higher concentration at 76 hr ($p < 0.01$) (Fig. 3). The mean total bilirubin levels were significantly increased at 8 ($p < 0.05$), 10 ($p < 0.01$), and 12 ($p < 0.01$) hr. A second higher peak occurred at 76 hr ($p < 0.01$) and remained greater than the control levels at the end of the sampling period, 96 hr ($p < 0.01$) (Fig. 3). The mean conjugated bilirubin levels also increased linearly ($p < 0.001$) during the sampling period. Significant increases ($p < 0.05$) were observed at 8, 10, and 12 hr (Fig. 3), the same

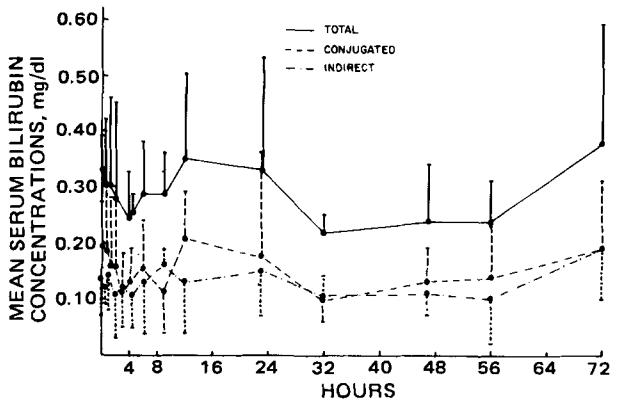

Figure 4—*Serum bilirubin concentrations in swine after intravenous administration of sulfisoxazole (mean ± 1 SD).*

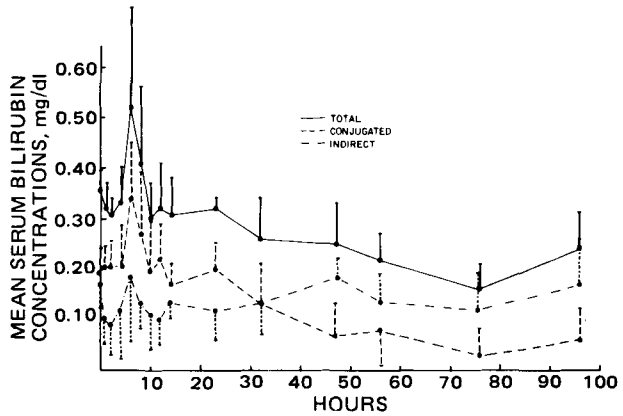

Figure 5—*Serum bilirubin concentrations in swine after oral administration of sulfisoxazole (mean ± 1 SD).*

periods in which total bilirubin was significantly increased. After the 12-hr period, the mean conjugated bilirubin had returned to levels which were not significantly different from control levels. The mean conjugated bilirubin reached its maximum concentration (0.22 mg/dl) at 10 hr, while the maximum total bilirubin (0.31 mg/dl) occurred at the 12-hr sampling period (Fig. 3). The mean indirect bilirubin was not significantly different from control levels until the 76- and 96-hr periods ($p < 0.01$). Mean indirect bilirubin reached a maximum of 0.28 mg/dl at 76 hr but had begun to decline by the end of the trial.

Total bilirubin was significantly correlated with conjugated bilirubin ($R = 0.06, p = 0.0001$) and with indirect bilirubin ($R = 0.56, p = 0.00001$) while conjugated bilirubin was also negatively correlated with indirect bilirubin ($R = -0.31, p = 0.003$). The significant correlation of total and conjugated bilirubin is explained by an increase in glucuronidation as increased heme degradation or increased indirect bilirubin occurs. It may also be due to regurgitation of conjugated bilirubin into the general circulation. The significant correlation of indirect and total bilirubin illustrated that the glucuronidation activity could not account for conjugation of all the bilirubin present. The negative correlation of indirect and conjugated bilirubin is supportive evidence that toxic, indirect bilirubin levels can be reduced to prevent kernicterus, if glucuronidation activity can be stimulated.

Swine, Intravenous Administration—Analysis of variance using mean bilirubin concentrations revealed no statistical difference among the six pigs or during time intervals for total, conjugated, or indirect serum bilirubin after intravenous administration of sulfisoxazole. The mean total conjugated and indirect bilirubin were increasing at the end of the trial but were not significantly different from control levels (Fig. 4).

Total bilirubin was significantly correlated with conjugated bilirubin ($R = 0.86, p = 0.0001$) and with indirect bilirubin ($R = 0.61, p = 0.0001$) after intravenous administration of sulfisoxazole.

Swine, Oral Administration—After oral administration of sulfisoxazole, mean total bilirubin was significantly increased ($p < 0.01$) to 0.52 mg/dl at 6 hr (Fig. 5). A parallel significant ($p < 0.01$) increase was also observed in mean conjugated bilirubin at 6 hr, 0.34 mg/dl (Fig. 5). A significant ($p < 0.0001$) linear decrease occurred over the trial period in conjugated bilirubin. Mean indirect bilirubin was not significantly different from control values at any time after oral administration of sulfisoxazole. However, indirect bilirubin levels did exceed conjugated levels after the 32-hr sampling period and remained at an increased level throughout the remainder of the trial (Fig. 5).

Total bilirubin was significantly correlated with conjugated bilirubin ($R = 0.81, p = 0.0001$) and with indirect bilirubin ($R = 0.42, p = 0.0001$) after oral administration of sulfisoxazole.

Comparison of Bilirubin Levels in Dogs, Swine, and Humans—Control values for total and conjugated bilirubin were higher in humans than in swine and lowest in dogs (Table I). The indirect bilirubin levels in all three species were similar.

A significant increase in total bilirubin occurred in dogs at 12 hr (Fig. 2) after intravenous administration of sulfisoxazole but did not occur in swine (Fig. 4) after administration of the same dose. After oral administration of sulfisoxazole, a significant increase in total bilirubin occurred in dogs (Fig. 3) and swine (Fig. 5) at 6 and 12 hr, respectively, with another increase in dogs at 76 hr. In humans, this increase was not observed over the same time period, probably due to the difference in the oral dosage (Fig. 1).

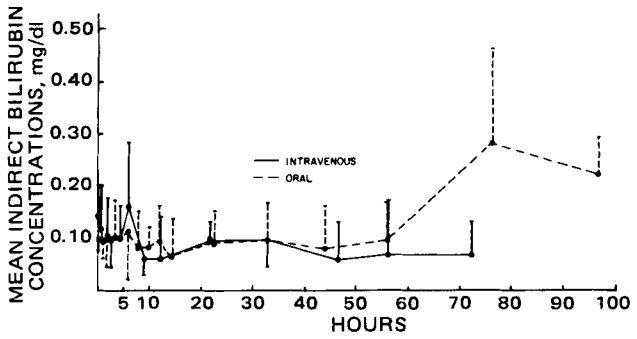

Figure 6.—*Comparison of the indirect bilirubin concentrations in dogs after intravenous and oral administration of sulfisoxazole (mean ± 1* SD).

Initially, total bilirubin levels were higher in swine than in dogs (Table I) but after intravenous administration of sulfisoxazole, total bilirubin was significantly ($p < 0.01$) higher in dogs between 3 and 15 hr (Fig. 2). Total bilirubin levels after oral administration were higher in swine than in dogs until the 56 hr period when the levels in dogs were significantly increased ($p = < 0.01$) (Fig. 3). Even after administration of sulfisoxazole, the total bilirubin increases in dogs and swine did not reach the control or treated levels in humans.

Conjugated bilirubin levels were not significantly increased in swine after intravenous administration of sulfisoxazole even though the control levels were greater in swine than in dogs. Conjugated bilirubin levels were significantly increased in dogs after intravenous administration of sulfisoxazole, exceeded the levels in swine after 3 hr, and reached a maximum at 12 hr after administration. After oral administration of sulfisoxazole, conjugated bilirubin levels were elevated in swine at 6 hr and showed a statistically significant increase in dogs at 10 hr after administration of the drug. The conjugated bilirubin levels in dogs and swine after intravenous or oral administration of sulfisoxazole did not reach the control or treated conjugated bilirubin levels in humans at any of the sampling periods.

Potentially toxic indirect bilirubin showed a statistically significant, but clinically small, increase after oral administration of sulfisoxazole in dogs (Fig. 6). There were no statistically significant increases in indirect bilirubin after oral administration in humans or swine or after intravenous administration of sulfisoxazole to dogs or swine.

DISCUSSION

Small but statistically significant increases in total and conjugated bilirubin occurred when sulfisoxazole was administered orally to dogs and swine but only when administered intravenously to dogs. The maximum increases occurred at different times, depending on species and route of administration. This species variation is further reflected by the indirect bilirubin exceeding conjugated bilirubin levels in dogs and swine when sulfisoxazole was administered orally. While toxic levels of bilirubin have not been established, these results show that the oral route of administration does increase the potentially toxic, indirect bilirubin concentration at a time far removed from the initial single dose in dogs and swine.

The small but statistically significant increase of total and conjugated bilirubin, after oral administration of sulfisoxazole, suggests that the absorption of the oral dosage form may cause the hepatocytes to increase the normal rate of heme degradation or to increase conjugated bilirubin regurgitation into the general circulation. This suggestion is supported by the intravenous dose given to dogs increasing only the total and conjugated bilirubin and not significantly affecting the indirect bilirubin level.

The lack of significant effects in humans and the lack of correlation between humans and dogs or swine could be due to the shorter sampling period in humans, the reduced dosage given to humans, or the species variation which exists even though all are monogastric.

When comparing the correlation coefficient of total and conjugated bilirubin in dogs ($R = 0.75, p = 0.0001$) and swine ($R = 0.85, p = 0.0001$) after intravenous administration, these parameters are more closely correlated in the pig. This is also true for the significant correlation of indirect and total bilirubin in dogs ($R = 0.31, p = 0.004$) and swine ($R = 0.61, p = 0.0001$) after intravenous administration of the drug. When sulfisoxazole is administered orally, the total and conjugated bilirubin levels are more closely correlated in swine ($R = 0.81, p = 0.0001$) than in dogs ($R = 0.60, p = 0.0001$) but indirect bilirubin is more closely correlated to total bilirubin in dogs ($R = 0.56, p = 0.0001$) than in swine ($R = 0.42, p = 0.0001$). In addition, conjugated and indirect bilirubin are negatively correlated after intravenous ($R = -0.39, p = 0.0002$) and oral ($R = -0.31, p = 0.003$) administration only in the dog.

It is evident that the route of sulfisoxazole administration affects the bilirubin level differently in these three species of animals. The potentially toxic indirect bilirubin level is significantly increased only after oral administration in one of the three species (dogs). This observation would be consistent with the first-pass effect (23) which states that oral administration of drugs results in peripheral venous concentrations exclusively *via* the hepatic portal system. This phenomenon, coupled with the reduced or impaired metabolic capability of the dog, would explain the increase in unconjugated bilirubin in this one-animal model. As a non-rodent model, the dog presents an acceptable model to be used in the preliminary evaluation of potentially-toxic, drug-induced effects on bilirubin metabolism after oral administration of the compound.

Reversed-Phase High-Pressure Liquid Chromatographic Determination of Serum Methotrexate and 7-Hydroxymethotrexate

ROBERT G. BUICE [x] **and PARAMJEET SIDHU**

Received February 2, 1981, from the *College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication May 29, 1981.

Abstract □ A reversed-phase high-pressure liquid chromatographic method for determining methotrexate and 7-hydroxymethotrexate in human serum is presented. A mobile phase of acetate buffer (0.2 *M*, pH 5.5 with 0.03 *M* ethylenediaminetetraacetate), methanol, and acetonitrile (85.3:8.4:6.3), passed through a μBondapak C_{18} column at 1.5 ml/min produced excellent resolution of sharp, symmetrical bands. An improved extraction process, using a sample preparation cartridge, resulted in analytical recoveries in excess of 90% for methotrexate and 70% for 7-hydroxymethotrexate, permitting the determination of serum concentrations of 2.20 and 2.13 × 10^{-7} *M*, respectively, using only 200 μl of serum. UV detection at 313 nm provided adequate sensitivity for each component. While the reproducibility for 7-hydroxymethotrexate was approximately equal to previous methods, that for methotrexate was greatly improved. Serum methotrexate data at selected time points following high dose methotrexate therapy are presented.

Keyphrases □ Methotrexate—reversed-phase high-pressure liquid chromatographic determination □ 7-Hydroxymethotrexate—reversed-phase high-pressure liquid chromatographic determination □ High-pressure liquid chromatography—determination of methotrexate and 7-hydroxymethotrexate.

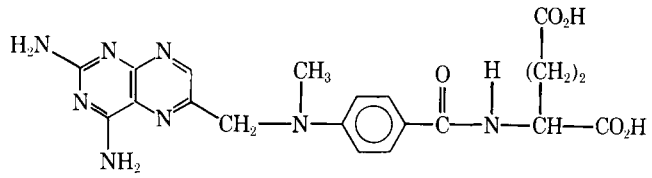
The effectiveness of high dose methotrexate therapy followed by leucovorin rescue was greatly enhanced by the observation that patients at high risk of serious toxicity might be detected by monitoring serum methotrexate (I) concentrations (1). Numerous analytical methods of I have been reported, including a spectrophotofluorometric method (2), several radioimmunoassays (3–7), a competitive protein binding method (8), an enzyme inhibition method (9), and a ligand-binding procedure (10). While recent work (11, 12) established the specificity of several such methods within certain concentration limits, potential cross-reactivity with I metabolites still raises doubt about these and other similar assay methods.

BACKGROUND

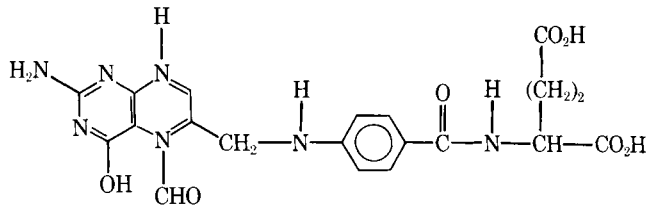
The major potentially-interfering metabolite of I, 7-hydroxymethotrexate (IV), has been reported in high concentrations in patient urine (13) and serum (14). Moreover, since the relatively low aqueous solubility of IV has caused some concern that this metabolite might be responsible for nephrotoxicity (13), it also should be monitored. More recently (11), in high dose methotrexate patients, a minor metabolite, 2,4-diamino-10-methylpteroic acid (III), was detected in later (48 hr) serum samples in concentrations that might impede quantitation of low I concentrations.

This potential cross-reactivity from metabolites, coupled with the possible need to quantitate certain metabolites, initiated the development of several high-pressure liquid chromatography (HPLC) methods (13–20). While these methods provide reasonable sensitivities, all require relatively large biological fluid samples (1–3 ml) and only one (19) reports an acceptable reproducibility for I (±3% at 10^{-5} *M*).

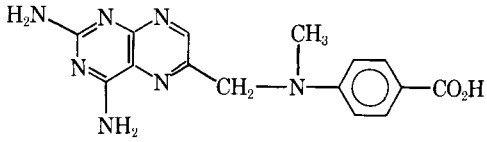
Moreover, most of these methods employ lengthy extractions with analytical recoveries varying from 40% (18) to 70% (15). Donehower *et al.* (11) used preparative HPLC and reported a 90% recovery of I, although a large serum sample (3 ml) was required. Lankelma and Poppe (17) used on-column concentration and reported a 70.2% analytical recovery of I, although again, a large serum sample (3 ml) was required.



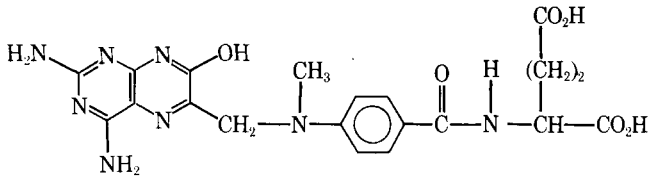
I



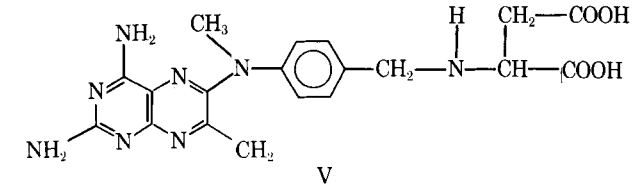
II



III



IV



V

Another study (15), included no internal standard, but reported a day-to-day variation as high as 13.4%. Finally, other reported HPLC chromatograms (14, 16, 20) show poor resolution of I and IV. The present report describes an improved and relatively simple HPLC method for the quantitation of I and IV in the serum of patients receiving methotrexate therapy.

EXPERIMENTAL

Materials and Methods—Methanol and acetonitrile, used for the mobile phase, were HPLC grade solvents. Acetate buffer for the mobile phase was prepared using deionized water and reagent grade sodium acetate. All other chemicals were reagent grade. Analytical samples of I[1], leucovorin calcium[1] (II), III[1], IV[2], and the internal standard, *N*-[4-

b	0 (IV)	0.010		0.98842 $n = 1$
c	12	0.050	0.99372 ± 0.00562 $n = 3$	0.98794 ± 0.00173 $n = 3$
d	24	0.005	0.99955 ± 0.00032 $n = 3$	0.99392 ± 0.00391 $n = 3$

[a] Molar concentration of I = (μg/ml) × (2.2×10^{-6}); molar concentration of IV = (μg/ml) × (2.13×10^{-6}). [b] Prior to Sep Pak treatment, 200 μl of this solution was added to each serum sample.

[(2,4-diamino-6-quinazolinyl)methylamino]benzoyl]aspartic acid[3] (V), were used as received.

Blood samples were obtained from patients at selected time points (0, 12, and 24 hr) following completion of 6-hr high dose methotrexate infusions (3500–5000 mg/m^2). Although it was not possible to obtain a sample from every patient at each preselected time point, a total of five samples were obtained at postinfusion time (0 hr), 11 at 12 hr, and six at 24 hr. Samples were centrifuged and the serum was stored at −5° until required for assay.

Serum concentrations of I and IV were determined using an HPLC system equipped with a 30-cm × 4-mm i.d. reversed-phase column[4]. Separation was followed by UV absorbance detection at 313 nm. A mobile phase consisting of buffer A (0.2 *M* acetate buffer, pH 5.5 with 0.03 *M* ethylenediaminetetraacetate), methanol, and acetonitrile (85.3:8.4:6.3) was passed through the column at a flow rate of 1.5 ml/min. Prior to analysis, the serum samples were processed by a reversed-phase sample preparation cartridge[5].

To each 200-μl serum sample was added 200 μl of internal standard (Table I), 400 μl of tromethamine (0.01 *M*, pH 9), and 1 ml of water. This mixture was vortexed 60 sec and passed through a sample preparation cartridge which had been pretreated with 10 ml of methanol and 10 ml of buffer B (0.2 *M* acetate buffer, pH 5.5). The cartridge was then treated with an additional 5 ml of buffer B, 1 ml of 0.1 *N* NaOH, and another 1 ml of buffer B. The cartridge was vacuum dried and the compounds of interest were eluted with 2 ml of methanol. The methanol was evaporated to dryness under nitrogen and the residue reconstituted in the mobile phase for injection. Analytical recoveries exceeded 90% for I and 70% for IV in the 10^{-7} *M* concentration range.

Four separate calibration curves were required to cover a concentration range of 2.20×10^{-7}–2.20×10^{-4} *M*. Conditions needed for each curve are presented in Table I. The large differences in I and IV concentrations in 0-hr samples required that each compound be determined from separate 200-μl portions of serum (calibration curves a and b). All other I and IV concentrations (12 and 24 hr) were determined simultaneously on single 200-μl serum samples. All samples were assayed in duplicate. Zero and 12-hr samples were quantitated using ratios of peak areas determined by a calculating integrator[6]. Ratios of peak heights were used to quantitate each compound in the 24-hr samples. Fresh calibration curves for I and IV were prepared daily in serum. Correlation coefficients of these curves are presented in Table I.

RESULTS

While most previous methods employed either methanol or acetonitrile as the organic portion of the mobile phase (11, 14, 15, 20), the present system attained maximum resolution of I, IV, and internal standard by combining these solvents. A flow rate of 1.5 ml/min resulted in a symmetrical band for each compound. Faster flow rates produced slightly sharper bands but reduced resolution. Representative HPLC chromatograms resulting from the quantitation of I and IV in 12- and 24-hr patient samples are presented in Fig. 1. Data from all sample determinations, together with percent deviations of duplicates, are presented in Table II.

Although metabolite III was previously reported in later (48 hr) samples, none was detected in any samples of the present study. Moreover, injections of analytical samples clearly show that III, due to its long retention time on this system (28.1 min), cannot interfere with the present assay. Ordinarily, no interference from II would be anticipated since rescue therapy is normally initiated 24-hr postinfusion (1). Furthermore, the retention of II on this system (4.3 min) was much shorter than either of the compounds of interest.

As illustrated in Fig. 1, no interfering bands appeared in the serum blanks of 12-hr samples (calibration curve c). As anticipated, quantitation of samples containing higher concentrations of I and IV (calibration

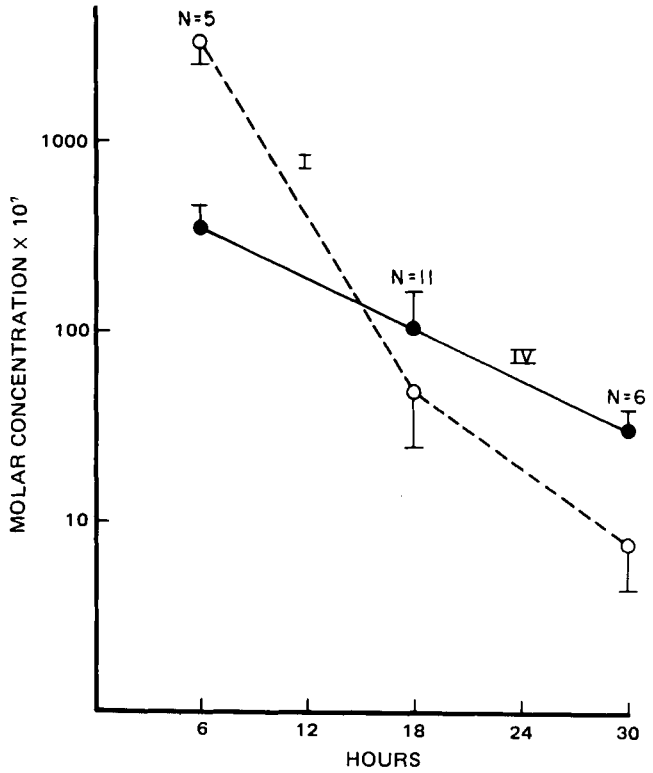

Figure 2—*Serum I (○) and IV (●) concentrations (mean ±SD) at selected time points following initiation of 6-hr high dose infusions (3500–5000 mg/m²).*

curves a and b) involved no interference from serum. Several low concentration (10^{-7}–10^{-6} *M*) samples, while showing no serum interference with I, did reveal a minute serum band slightly overlapping IV. Since the overlap was extremely slight, contribution to the peak height of IV was considered insignificant (Fig. 1).

Attempts to quantitate 24-hr serum samples using ratios of peak areas consistently resulted in poor reproducibility for I and IV. This appears to be characteristic of this calculating integrator in the absence of a completely horizontal baseline. Therefore, all 24-hr samples were quantitated using ratios of peak heights. Patient serum concentration data (mean ±*SD*) determined by this method are presented in Fig. 2.

The reproducibility of the method and the durability of the sample preparation cartridge were simultaneously evaluated by conducting multiple determinations on a single, spiked serum sample (10^{-6} *M* I) using the same cartridge. In duplicate studies, the first six consecutive determinations consistently produced a coefficient of variation which was less than 3%, although over the six repetitions all peak heights were reduced ~10%, suggesting a slightly declining cartridge efficiency. However, in the present study all patient samples were assayed in duplicate with each repetition using a new cartridge. No cartridge was reused.

DISCUSSION

The described method separates all three compounds of interest and produces sharp, symmetrical bands. UV detection at 313 nm, instead of at 254 nm, results in a twofold increase in assay sensitivity to IV, while sensitivity to I is approximately equal at either wavelength. This is consistent with previous reports (14, 20).

The high extraction efficiency resulting from this sample preparation procedure permitted the quantitation of serum I and IV concentrations as low as 2.20 and 2.13 × 10^{-7} *M*, respectively, using only 200 μl of serum. Previously reported methods require 1 ml of serum or more. These data suggest that the present method is readily adaptable to small animal pharmacokinetic studies. Moreover, the small volume of serum required makes the method highly useful in patient pharmacokinetic studies that require large numbers of data points, often from patients who are weakened by disease.

Data presented in Table II show excellent reproducibility for I, although that for IV shows no improvement over previously reported work. This is further evidenced by the calibration curve correlation coefficients given in Table I. The small contaminant which slightly overlapped the IV band in a few 10^{-7} *M* patient samples did not appear to influence reproducibility, suggesting that reproducibility differences in I and IV result from the extraction process.

This procedure results in only minimal column stress since ~800 injections of serum extracts may be made before the column begins to degenerate. Since a sample preparation cartridge can be used up to four times with no significant difference in assay results, the expense of this extraction is relatively small.

Theoretical and Experimental Studies of Transport of Micelle-Solubilized Solutes

GREGORY E. AMIDON *x, WILLIAM I. HIGUCHI, and NORMAN F. H. HO

Received February 9, 1981, from the *University of Michigan, Ann Arbor, MI 48109.* Accepted for publication April 27, 1981.
*Present address: Pharmacy Research, The Upjohn Company, Kalamazoo, MI 49001.

Abstract □ A physical model describing the simultaneous diffusion of free solute and micelle-solubilized solute across the aqueous boundary layer, coupled with partitioning and diffusion of free solute through a lipoidal membrane, is derived. *In vitro* experiments utilizing progesterone and polysorbate 80 showed excellent agreement between theoretical predictions based on independently determined parameters and experimental results. The physical model predicts that micelles can assist the transport of solubilized solute across the aqueous diffusion layer, resulting in a higher solute concentration at the membrane surface than would be predicted if micelle diffusion is neglected. At high surfactant concentrations, the aqueous diffusion layer resistance can be eliminated and the activity of the solute at the membrane can approach the bulk solute activity. This mechanism could explain observed enhanced absorption rates *in vivo* when both micelle solubilization occurs and the aqueous diffusion layer is an important transport barrier. The importance of determining and defining the thermodynamic activity of the diffusing solute is emphasized.

Keyphrase □ Diffusion—transport of micelle-solubilized solutes, theoretical and experimental □ Solutes—micelle solubilized, transport, theoretical and experimental □ Micelles—theoretical and experimental transport, solutes

The effects of micelle solubilization on the solubility and intestinal absorption of nonpolar solutes are well documented (1–8). Investigations have been performed to delineate the role of surfactants in diffusional transport. As a result of these studies, it is clear that several factors must be considered, such as the thermodynamic activity of the solute, diffusivities of the free solute and micelles, membrane permeability, and the importance of the aqueous diffusion layer in determining the overall transport rate.

BACKGROUND

In a diffusional process (*e.g.*, intestinal absorption), a difference in the thermodynamic activity determines the direction of and driving force for the net transport of mass. Therefore, when micelle solubilization occurs and the thermodynamic activity of solute is lowered, a decreased diffusional rate is expected. On this basis, decreased absorption rates of salicylic acid in the presence of polysorbate 60 from rat intestinal segments were explained (1).

However there are numerous examples of increased absorption rates *in vivo* when solubilizing agents are present (2, 3). For example, the serum blood levels of indoxole when administered in a polysorbate 80 solution to humans were three to four times higher than comparable doses with an aqueous suspension or hard capsule (4). It was shown (5, 6), however, that membrane permeabilities may change in the presence of surfactant, possibly resulting in a net increase in the absorption rate even with a decreased thermodynamic activity of solute in bulk aqueous solution.

Another reason for enhanced absorption in the presence of solubilizing agents is associated with the diffusion of solute in the aqueous phase (*i.e.*, within the aqueous diffusion layer). Westergaard and Dietschy (7) pointed out that, in addition to the importance of bulk solute concentration and membrane permeability in determining absorption rates, the aqueous boundary layer is an important barrier to transport *in vivo* and should be evaluated. They concluded that the apparent functions of the micelle were to overcome the diffusion layer resistance *in vivo* and to deliver a maximum solute concentration to the membrane surface. It was also suggested (8) that the diffusion coefficient of the free solute–micelle complex is important in quantitatively assessing absorption in the presence of micelles.

Thus, it is clear that an evaluation of the aqueous diffusion layer and the physicochemical events occurring within it is necessary in the development of a realistic physical model. Furthermore, micellar diffusion, membrane permeation, and the thermodynamic activity of the solute in the surfactant solution need to be included in any complete analysis. This report presents a comprehensive physical model incorporating all of the principles just discussed. *In vitro* experiments along with independent determinations of all physicochemical parameters defined in the physical model were carried out utilizing progesterone and the nonionic surfactant polysorbate 80. Therefore, theoretical predictions based on independent estimates of the important parameters and experimentally determined fluxes can be compared.

The physical model is defined for two hydrodynamic conditions: the

stagnant diffusion layer case and the more well-defined hydrodynamic case for the surface of a rotating disk. For this latter situation, the fluid flow within the aqueous diffusion layer is well defined (9) and more easily controlled; it provides insight into actual events occurring within the diffusion layer and places the physical model on a more sound theoretical basis. For hydrodynamic conditions that are not ideal (*i.e.*, many *in vivo* absorption situations), the stagnant diffusion layer approach permits an evaluation of the aqueous diffusion layer resistance to diffusion.

A rotating-membrane diffusion cell similar to that used by Albery *et al.* (10) was employed for the present *in vitro* diffusion experiments. Proper design provides for well-defined hydrodynamics on each side of the rotating semipermeable membrane. Dimethicone (dimethylpolysiloxane[1]) membranes were utilized since they have been shown to maintain their integrity in the presence of surfactants (11) and buffers (12) and are quite permeable to the solutes investigated.

THEORY

Description of Model—The physical model involving the simultaneous diffusion of both free solute and solute solubilized in micelles is shown in Scheme I. Two aqueous compartments are separated by a semipermeable, lipid-like membrane, which permits only the passage of free solute. The donor compartment contains free solute, surfactant, and solute solubilized by the surfactant. It is assumed that the receiver compartment is at an equivalent surfactant concentration. This assumption is not necessary but simplifies the mathematics.

Furthermore, equilibrium between free solute and that solute solubilized in the micelle is assumed to occur at each point in the aqueous phase and in the diffusion layer. This equilibrium distribution coefficient is denoted by k^*; for the present model, it is assumed to be a constant.

The bulk of each aqueous phase is assumed to be well mixed by convection and, therefore, of uniform concentration in each compartment. Adjacent to the membrane is a region of relatively stagnant solution. It is primarily within this region (the aqueous diffusion layer) that concentration gradients of species may exist between the well-stirred bulk and the membrane surface. Under ideal hydrodynamic conditions, such as those of a rotating disk[2], the fluid flow near the surface can be mathematically described and an explicit relationship for the effective diffusion layer thickness can be obtained (13). When hydrodynamic conditions are not well defined, a stagnant diffusion layer model can be used.

Both free solute and micelles that may contain solubilized solute are assumed to diffuse independently across the aqueous diffusion layer. However, only free solute is assumed to partition into and diffuse through the membrane. Therefore, the components of the micelle are conserved in each compartment so that the surfactant concentration is assumed to be constant throughout each bulk phase and the diffusion layers.

Stagnant Diffusion Layer Model—When the aqueous diffusion layer is assumed to be a stagnant solvent layer, the steady-state flux equation for each diffusion layer ($i = 1, 2$) can be written as the sum of the flux of the micelle-solubilized solute and the free solute:

$$J_1 = \frac{D_1^*}{H_1}(C_{b1}^* - C_{s1}^*) + \frac{D_1'}{H_1}(C_{b1}' - C_{s1}') \qquad \text{(Eq. 1)}$$

$$J_2 = \frac{D_2^*}{H_2}(C_{s2}^* - C_{b2}^*) + \frac{D_2'}{H_2}(C_{s2}' - C_{b2}') \qquad \text{(Eq. 2)}$$

where J is the steady-state flux; D is diffusivity; H is effective diffusion layer thickness; C is concentration; the asterisk and prime superscripts denote the micelle-solubilized species and the free solute, respectively; and the subscripts b and s denote the bulk and membrane surface for the donor, 1, and receiver, 2, sides.

The following free solute–micelle-solubilized solute equilibrium is assumed to hold above the critical micelle concentration (CMC) of the surfactant:

$$k^* = \frac{C_i^*}{C_i'(SAA)} \qquad \text{(Eq. 3)}$$

where k^* is the equilibrium distribution coefficient, C_i^* and C_i' are the micelle-solubilized solute concentration and free solute concentration per liter of solution, and (SAA) is the surfactant concentration[3]. This relationship permits the free solute concentration (thermodynamic activity) to be calculated when micelles are present.

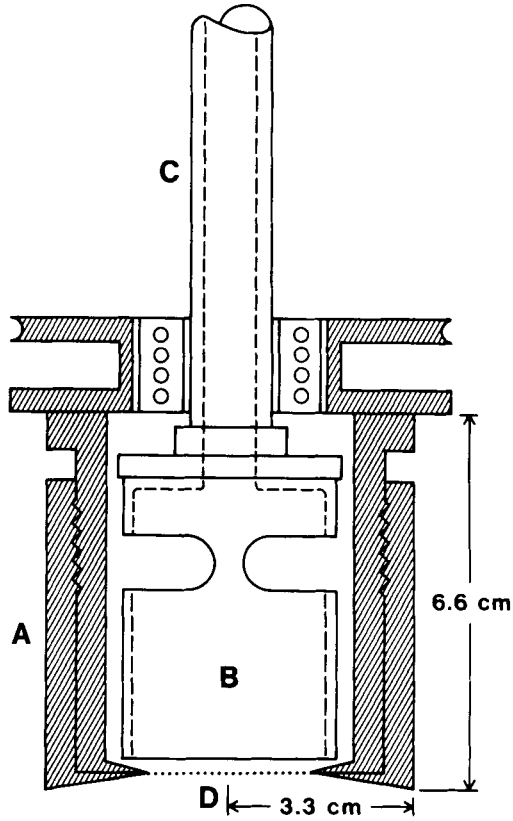

Figure 1—*Schematic diagram of rotating-membrane diffusion cell. Key: A, outer stainless steel cylinder; B, stationary cylindrical baffle; C, sampling port; and D, semipermeable membrane.*

The total bulk and surface concentration for each aqueous compartment can be written:

$$C_{bi} = C_{bi}^* + C_{bi}' = C_{bi}'[1 + k^*(SAA)] \qquad \text{(Eq. 4)}$$

$$C_{si} = C_{si}^* + C_{si}' = C_{si}'(1 + k^*(SAA)] \qquad \text{(Eq. 5)}$$

Eqs. 1 and 2 can be rewritten:

$$J_1 = P_1(C_{b1} - C_{s1}) \qquad \text{(Eq. 6)}$$

$$J_2 = P_2(C_{s2} - C_{b2}) \qquad \text{(Eq. 7)}$$

where P is permeability and:

$$P_i = \frac{D_{\text{eff}}}{H_i} \qquad \text{(Eq. 8)}$$

The effective diffusion coefficient, D_{eff}, is defined as:

$$D_{\text{eff}} = \frac{D_i' + k^*(SAA)D_i^*}{[1 + k^*(SAA)]} \qquad \text{(Eq. 9}a\text{)}$$

An identical way of expressing the effective diffusion coefficient is:

$$D_{\text{eff}} = f'D' + f^*D^* \qquad \text{(Eq. 9}b\text{)}$$

where f' and f^* are the fractions of the total solute in the free form and solubilized form, respectively.

It is evident from Eq. 9*b* that the diffusivity of each aqueous diffusion layer becomes essentially the diffusivity for the micelle-solubilized solute, D^*, when the surfactant concentration is large. At premicellar concentrations and low micellar concentrations, the diffusivity is essentially the diffusivity for free solute, D'.

The steady-state flux of solute through the semipermeable membrane (J_m) can be written as:

$$J_m = \frac{D_m}{H_m}(C_{m1}' - C_{m2}') \qquad \text{(Eq. 10)}$$

where C_{m1}' and C_{m2}' are the free solute concentrations in the membrane at each interface and D_m is the solute diffusivity in the membrane of thickness H_m.

[2] Other geometries such as flow across a flat surface or laminar flow down a tube provide equally well-defined hydrodynamics.

[3] Here (SAA) is equivalent to the concentration of micelles in solution. Therefore, $(SAA) = (SAA)_T - \text{CMC}$, where $(SAA)_T$ is the total surfactant concentration. For surfactants with low CMC values (such as polysorbate 80, CMC $\simeq$ 0.006%): $(SAA) \simeq (SAA)_T$.

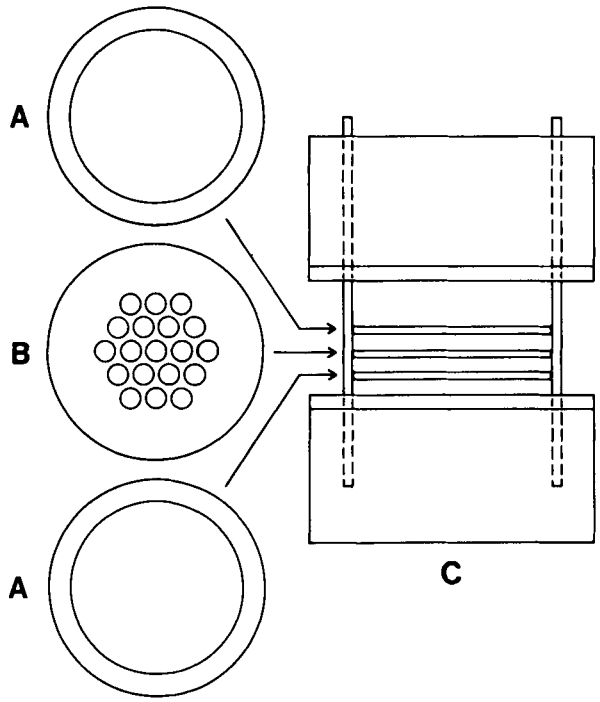

Figure 2—*Membrane support and spacers (each 50-μm thick).*

The membrane–aqueous phase partition coefficient, K, is:

$$K = \frac{C'_{mi}}{C'_{si}} \qquad \text{(Eq. 11)}$$

Combining Eqs. 10 and 11 gives:

$$J_m = \frac{KD_m}{H_m}(C'_{s1} - C'_{s2}) \qquad \text{(Eq. 12)}$$

When the surfactant concentration is the same on each side,[4] the membrane flux can be written in terms of the total solute concentration:

$$J_m = P_m(C_{s1} - C_{s2}) \qquad \text{(Eq. 13)}$$

where:

$$P_m = \frac{KD_m}{H_m[1 + k^*(SAA)]} \qquad \text{(Eq. 14)}$$

The membrane permeability is a function of the surfactant concentration since it is related to the free solute concentration at the membrane surface.

At steady state, the flux of solute through each region must be equal; therefore:

$$J_1 = J_m = J_2 \qquad \text{(Eq. 15)}$$

and:

$$J = P_{\text{eff}}(C_{b1} - C_{b2}) \qquad \text{(Eq. 16)}$$

where the effective permeability coefficient, P_{eff}, is:

$$P_{\text{eff}} = \frac{1}{\frac{1}{P_1} + \frac{1}{P_m} + \frac{1}{P_2}} \qquad \text{(Eq. 17)}$$

The total solute concentration at each interface is given by:

$$C_{s1} = \frac{\left(\frac{1}{P_m} + \frac{1}{P_2}\right)C_{b1} + \left(\frac{1}{P_1}\right)C_{b2}}{\frac{1}{P_1} + \frac{1}{P_m} + \frac{1}{P_2}} \qquad \text{(Eq. 18)}$$

[4] This assumption is not necessary but simplifies the mathematics that follow.

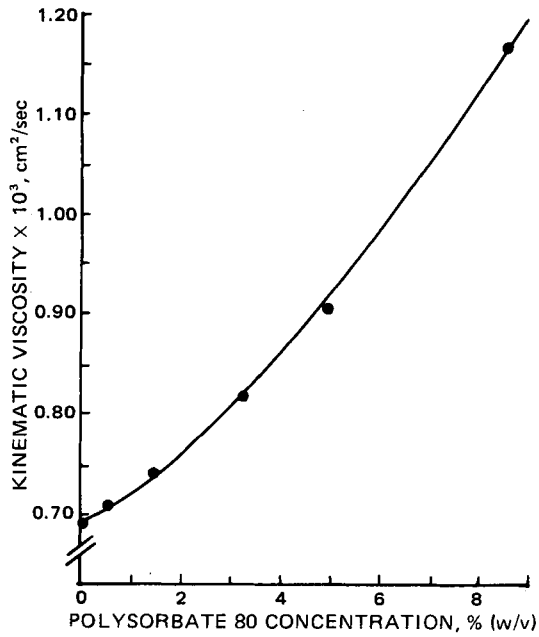

Figure 3—*Kinematic viscosity of polysorbate 80 solutions at 37°.*

$$C_{s2} = \frac{\left(\frac{1}{P_2}\right)C_{b1} + \left(\frac{1}{P_1} + \frac{1}{P_m}\right)C_{b2}}{\frac{1}{P_1} + \frac{1}{P_m} + \frac{1}{P_2}} \qquad \text{(Eq. 19)}$$

Convective Diffusion Layer Model—For the ideal hydrodynamics near the surface of a rotating disk, the convective diffusion equation for mass transfer can be solved (13). The solution predicts solvent movement even immediately adjacent to the rotating surface. Therefore, instead of a stagnant diffusion layer, a dynamic convective diffusion layer is more appropriate. Within this layer (normally ≤50 μm) and extending out into the bulk, there is a gradual transition from an essentially diffusional process at the disk surface to one in which the major transport mechanism is convection.

Under these rotating-disk conditions, the effective diffusion layer thickness is:

$$H = 1.61\nu^{1/6}D^{1/3}\omega^{-1/2} \qquad \text{(Eq. 20)}$$

0.942	3.22	—	2.69
1.96	2.13	—	1.82
2.03	—	1.76	1.46
5.04	1.56	—	1.43

and the steady-state mass flux of solute, J, through the convective diffusion layer can be written:

$$J = \frac{D\,\Delta C}{H} = 0.62D^{2/3}\nu^{-1/6}\omega^{1/2}(C_b - C_s) \qquad \text{(Eq. 21)}$$

where D is the aqueous diffusion coefficient, ν is the kinematic viscosity, and ω is the disk rotation speed in radians per second.

For the simultaneous convective diffusion of free solute and micelle-solubilized solute, Eq. 21 can be modified to:

$$J = 0.62D_{eff}^{2/3}\nu^{-1/6}\omega^{1/2}(C_b - C_s) \qquad \text{(Eq. 22)}$$

where the effective diffusion coefficient, D_{eff}, is defined in Eq. 9*a*.

When the flux of solute through the convective diffusion layer on each side of the semipermeable membrane is given by Eq. 22 and the membrane permeability coefficient is given by Eq. 13, the following equation predicts the total flux of solute (J):

$$J = P_{eff}(C_{b1} - C_{b2}) \qquad \text{(Eq. 23)}$$

where:

$$P_{eff} = \frac{1}{\frac{1}{P_1^c} + \frac{1}{P_m} + \frac{1}{P_2^c}} \qquad \text{(Eq. 24)}$$

and the permeability of each convective diffusion layer, P_i^c, is:

$$P_i^c = \frac{D_{eff}}{H_i} = 0.62D_{eff}^{2/3}\nu^{-1/6}\omega^{1/2} \qquad \text{(Eq. 25)}$$

Both D_{eff} and ν may be functions of surfactant concentration. For simplicity, it is assumed here, as it was in the stagnant diffusion layer model, that the surfactant concentrations in both the donor and receiver sides are equal.

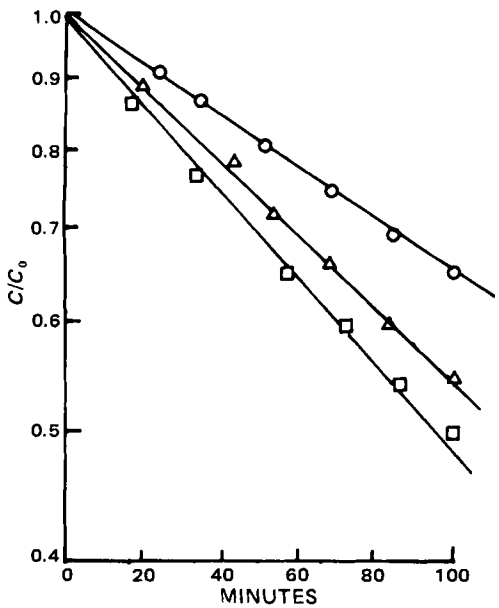

Figure 5—*Semilogarithmic plot of the fraction of radiolabeled capric acid remaining in the donor phase when the receiver side diffusion layer resistance is eliminated by adjustment of pH. Key: ○, 60 rpm; △, 120 rpm; and □, 300 rpm.*

Table II—Reproducibility of Effective Permeability Coefficient Determinations

	Rotation Speed, radians/sec		
	6.28 (60 rpm)	12.57 (120 rpm)	31.42 (300 rpm)
n	5	8	5
$P_{eff} \times 10^4$	6.58	9.77	13.67
$SD \times 10^4$	0.370	0.589	0.733
CV, %	5.6	6.0	5.4

Equation 24 can be rewritten as:

$$\frac{1}{P_{eff}} = \frac{1}{P_1^c} + \frac{1}{P_m} + \frac{1}{P_2^c} \qquad \text{(Eq. 26)}$$

and, using Eq. 25, the following can be derived:

$$\frac{1}{P_{eff}} = 2\left[\frac{\nu^{1/6}}{0.62D_{eff}^{2/3}}\right]\omega^{-1/2} + \frac{1}{P_m} \qquad \text{(Eq. 27)}$$

If one diffusion layer is eliminated, then Eq. 27 reduces to:

$$\frac{1}{P_{eff}} = \left[\frac{\nu^{1/6}}{0.62D_{eff}^{2/3}}\right]\omega^{-1/2} + \frac{1}{P_m} \qquad \text{(Eq. 28)}$$

Thus, Eqs. 27 and 28 offer a convenient way of testing the validity of Eq. 20 for the diffusion layer thickness on each side of the semipermeable membrane.

Diffusion Cell and Membrane Preparation—A diagram of the rotating-membrane diffusion cell is shown in Fig. 1. An outer stainless steel cylinder is connected to a variable-speed motor by a pulley and belt system. In this way, the outer cylinder can be rotated at a variety of speeds with ease. A stationary cylindrical baffle attached to the hollow sampling port is suspended inside the outer cylinder. To allow proper fluid flow inside the cell, two grooves ~1-cm wide are cut 3 cm from the bottom of the inner baffle, which is open.

The outer cylinder can be further disassembled by unscrewing to allow the membrane to be positioned at the bottom of the cell and screwed tightly into place. In addition, at each edge of the membrane, the cylinder is beveled at an angle of ~10° so that fluid flow at the edge is not dis-

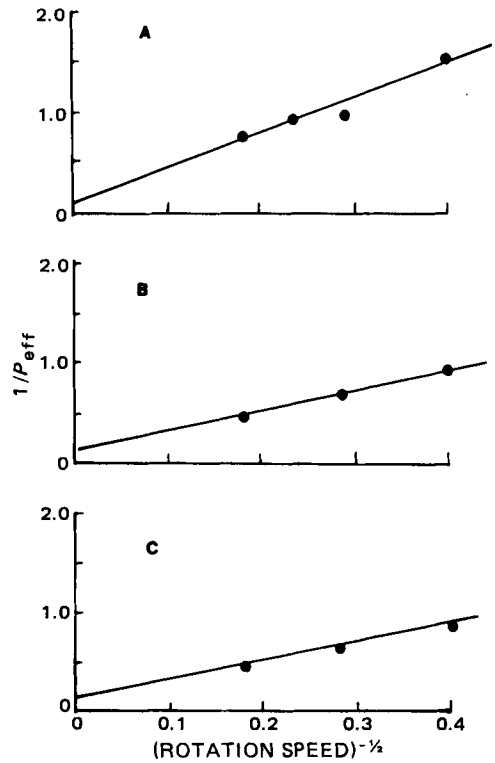

Figure 6—*Permeability coefficient dependence on rotation speed when both donor and receiver side diffusion layer resistances are important (A), outer diffusion layer resistance is eliminated (B), and inner diffusion layer resistance is eliminated (C).*

turbed (10). The cell is immersed in an outer solution of 450 ml, while the inner volume is 70 ml.

Dimethicone, a two-component room temperature vulcanizing dimethyl polysiloxane rubbber, was used as the model membrane. This material forms a nonpolar continuum and is lipid-like in nature, so partitioning and membrane diffusion rather than pore permeation occurs. Unlike more conventional lipid-impregnated membrane filters, it has been shown to be impermeable to ions and buffers and is unaffected by surfactants. These properties, along with the relatively simple procedure for preparing these membranes in the laboratory, indicated it would be a good candidate for model studies.

The membranes were prepared by mixing the catalyst with elastomer base and applying a vacuum to eliminate air bubbles. Then the elastomer was applied to both sides of the membrane support screen shown in Fig. 2. A spacer was placed on each side of the support and was compressed using an appropriate form at 1362 kg (3000 lb) of pressure.

The support and spacers were each 50-μm thick, resulting in a total membrane thickness of ~150 μm. The holes in the support were 0.556 cm in diameter. Preliminary observations using membranes without the supporting structure indicated that the membrane would not remain sufficiently rigid during the experiments. Since this would disturb the hydrodynamics at the surface and affect the diffusion layer thickness, a support was necessary. The membranes were measured with a micrometer at several places to obtain an average thickness.

Each membrane was allowed to cure for ~12 h. They were each removed and soaked in double-distilled water for ~15 min before use. The total area of membrane exposed to the solutions during the experiments was 6.16 cm^2, and the area of the holes through the support screen was 4.36 cm^2.

EXPERIMENTAL

Materials—Commercially available progesterone[5], radiolabeled progesterone[6], and radiolabeled capric acid[7] were used as received. The purity of the radioactive materials was checked periodically using TLC and were shown to be >98%. Polysorbate 80[8] and all other chemicals were used as received. Double-distilled water, degassed by boiling, was the only solvent used in preparing the permeant solutions.

Preparation of Solutions—All surfactant solutions were prepared by weighing polysorbate 80 into an appropriately sized volumetric flask and diluting with double-distilled water, previously degassed by bringing to a near boil, to obtain the correct percent weight/volume concentration of surfactant at 37°. This solution was allowed to equilibrate at 37° overnight before use. Saturated solutions were prepared by adding excess progesterone to surfactant solutions and equilibrating overnight. Before use, these solutions were filtered through two glass fiber filter papers[9] to eliminate particulates. Radioactive solutions were prepared by adding an aliquot of radiolabeled material to the test solution ~15 min before the experiment was begun.

Solubility Determination—The solubility of progesterone at several polysorbate 80 concentrations was determined by sealing ~5 ml of surfactant solution and excess progesterone in 15-ml ampuls and shaking in a 37° waterbath for 48 hr. Aliquots of equilibrated samples were filtered[9], diluted in ethanol USP, and assayed spectrophotometrically[10] at 240 nm. An identical solution, containing no progesterone and prepared in the same way, was used as a blank, and the absorbance was compared to a series of standards.

Viscosity and Density Determinations—The specific gravity of surfactant solutions was determined at 37° using a 25-ml pycnometer; the corresponding density, ρ, was calculated by calibrating the pycnometer with water (ρ = 0.993 g/cm^3 at 37°). Determinations of the kinematic viscosity, ν, were made with a viscometer[11]. The viscosity, η, was calculated from:

$$\nu = \eta/\rho \qquad \text{(Eq. 29)}$$

Diffusion Coefficient Determinations—Aqueous diffusion coefficients at 37° were determined using a small-volume diaphragm cell (14, 15). The apparatus consisted of two well-stirred reservoirs separated by two silver filter membranes[12]. Each membrane was 50-μm thick with a pore diameter of 1.2 μm. This pore diameter was large enough to permit the facile passage of micelles. The diffusion cell constant was determined using 0.1% benzoic acid in 0.01 *N* HCl for which the aqueous diffusion coefficient was known to be 1.4 × 10^{-5} cm^2/sec (16).

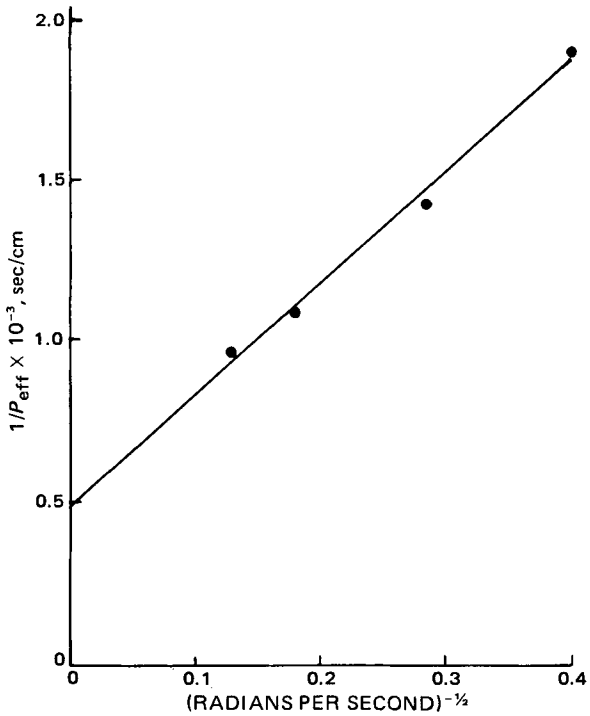

Figure 7—*Permeability coefficient dependence on rotation speed for progesterone.*

Subsequently, either the diffusion coefficient or the effective diffusion coefficient of progesterone in the presence of micelles was determined. Utilization of Eq. 9 permits the diffusion coefficient of the micelle to be factored out of the effective diffusion coefficient.

The effective diffusion coefficient was determined: (a) when only trace amounts of radiolabeled progesterone were present and (b) with surfactant solutions saturated with progesterone and containing sufficient radiolabeled progesterone to permit assay. In this way, any change in diffusivity with a change in progesterone concentration could be determined. All samples were assayed by adding the radioactive sample to 10 ml of liquid scintillation fluid[13] and counting in a liquid scintillation counter[14].

Diffusion Cell Characterization—To test the applicability of Eq. 20 to each side of the rotating membrane, radiolabeled capric acid was used. Since initial experiments showed this solute to have high membrane permeability, it was well suited for testing each diffusion layer separately by adjusting the pH in the donor and receiver solutions. For example, at sufficiently high pH in the receiver compartment, the diffusion of hydroxide ion from the bulk to the membrane surface essentially induces ionization of the permeant at the membrane surface. This results in "sink" conditions at the membrane surface being maintained with respect to the unionized species. If the membrane is impermeable to the ionized species, the receiver side diffusion layer resistance is eliminated or "shorted out." In this manner, the receiver side diffusion layer can be eliminated and the applicability of Eq. 20 to the donor side diffusion layer can be tested.

Prior to the start of each experiment, the prewashed membrane was positioned in the diffusion cell, which had been preheated in an oven to 37°. Then 70 ml of an appropriate solution (either 0.01 *N* HCl or 0.1 *M* phosphate buffer at pH 7.2) was added to the inner compartment. A visual inspection for leaks around the membrane was made. The diffusion cell was then immersed in an outer solution of 450 ml contained in a water-jacketed beaker to maintain the temperature of the outer solution and the diffusion cell at 37° for the duration of the experiment. The cell was rotated at 60, 120, or 300 rpm; 0.10-ml samples were withdrawn from both donor and receiver sides periodically. Assay for capric acid was by

liquid scintillation counting, and samples were corrected for quench if necessary. A series of steady-state experiments could be done in succession by completely replacing the receiver solution with fresh solution at the end of a run and, if necessary, replenishing the donor compartment with test permeant solution.

Micelle Solubilization Studies—The rotating-membrane diffusion cell was utilized for all transport experiments. The inner compartment served as the donor phase and the volume was 70 ml. The outer compartment volume was either 420 or 450 ml, depending on the experiment performed. Samples were taken using either a 100 or 500-μl Eppendorf micropipet[15]. Radioactive samples were assayed by liquid scintillation counting. Correction for quench was done when necessary. Nonradioactive progesterone was assayed by high-pressure liquid chromatography (HPLC) utilizing reversed-phase chromatography[16].

Two types of experiments were conducted to demonstrate clearly the influence of progesterone concentration on transport in the presence of polysorbate 80. Constant initial solute concentration experiments were carried out by adding an aliquot of radiolabeled progesterone (approximately the same concentration for each experiment) to 70 ml of surfactant solution, and saturated solution experiments were performed by adding surfactant solutions previously saturated with nonradiolabeled progesterone to the donor compartment. An identical surfactant solution with no progesterone was used as the receiver phase in each case.

In all experiments, samples were taken from the donor and receiver phases and assayed by liquid scintillation counting or HPLC. All experiments were conducted at 37° and a rotation speed of 60 rpm.

RESULTS AND DISCUSSION

The aqueous solubility of progesterone at 37° was determined to be 12.0 μg/ml, and the total solubility of progesterone increased linearly with increasing surfactant concentration over the range studied. The slope of the line is related to the micelle-free solute equilibrium distribution coefficient, k^*, by:

$$C_T = C^* + C' = C'[1 + k^*(SAA)] \qquad \text{(Eq. 30)}$$

The slope of the line was 1.26×10^{-1} mg/ml percent and corresponded to a value of 10.5 for the equilibrium distribution coefficient. This result is consistent with independent but less reliable measurements conducted in this laboratory using dialysis tubing.

The kinematic viscosity is shown in Fig. 3. The density increased linearly with surfactant concentration from a value of 0.993 g/cm^3 for pure water at 37° to 1.002 g/cm^3 for an 8.5% (w/v) polysorbate 80 solution.

The effective diffusion coefficients at several surfactant concentrations, as determined by using the small-volume diaphragm cell, are presented in Table I. The effective diffusion coefficient decreased as the surfactant concentration increased due to incorporation of more solute into the micelles. The effective diffusion coefficient was determined for both tracer levels of progesterone and saturated solutions. As shown, there was little difference between the diffusion coefficients at comparable surfactant concentrations and it is concluded that D_{eff} does not vary significantly with progesterone concentration.

By utilizing Eq. 9*a*, the diffusion coefficient of the micelle–solute complex (D^*) can be evaluated if the micelle-free solute equilibrium coefficient (k^*) and the free solute diffusion coefficient (D') are known. These values are shown in Table I, assuming a free solute diffusivity of 8.5×10^{-6} cm^2/sec and a micelle-free solute equilibrium coefficient of 10.5. For the progesterone–polysorbate 80 system under investigation, D^* is not constant.

Diffusion Cell Characterization—Typical results of the rate of loss of radiolabeled capric acid from the donor phase for three rotation speeds are shown in Fig. 4 when both the donor and receiver phases are 0.01 *N* HCl solutions. The diffusion layers on each side of the semipermeable membrane, thus, are important barriers to transport. The rate of loss of capric acid from the donor phase, for the same three rotation speeds, with 0.1 *M* phosphate buffer at pH 7.2 as the receiver side solution is shown in Fig. 5. The donor side diffusion layer is the only diffusion layer offering resistance to diffusion in this second case.

The effective permeability of the diffusional resistance under quasi-steady-state conditions can be conveniently assessed from the slope of the semilogarithmic plots by:

$$\ln (C_t/C_0) = \frac{-A}{V} P_{eff} t \qquad \text{(Eq. 31)}$$

where C_t is the concentration of solute remaining in the donor phase at time t, C_0 is the initial concentration, V is the volume of the donor phase, and A the area of the membrane available for transport. The area in these studies is the area of the holes in the membrane support (4.36 cm^2). Equation 31 can be modified to correct for any buildup of solute in the receiver compartment when necessary.

7.2	2.0[a]	3	1.836	1.62	0.18

[a] Denotes donor compartment.

The reproducibility of the effective permeability coefficient determinations utilizing the rotating-membrane diffusion cell is shown in Table II. Duplicate experiments in which both donor and receiver compartments were prepared from 0.01 *N* HCl solutions were performed. The average permeability and the standard deviation determmined at 60, 120, and 300 rpm are given. The coefficient of variation for each speed was between 5 and 6%. These deviations include sampling and assay errors as well as some variations in membrane thickness. Each experiment was done with a new membrane. Generally, the observed reproducibility compares with that observed for published work with other diffusion cell systems, indicating satisfactory reproducibility for each experiment.

The applicability of Eq. 20 to the diffusion layer thickness on each side of the membrane can be tested by utilizing Eqs. 27 and 28. Figure 6 depicts the results obtained when the inverse of the permeability is plotted against the inverse square root of the rotation speed for three different conditions. Both the donor and receiver side diffusion layers are important in Fig. 6A, and Eq. 27 should apply. The theoretical slope is 3.672 × 10^3, assuming a diffusion coefficient for capric acid (17) of 7.5 × 10^{-6} cm^2/sec and a kinematic viscosity of 6.96 × 10^{-3} cm^2/sec. Figures 6B and 6C show the results obtained when the outer and inner diffusion layer resistance are eliminated by buffering at pH 7.2. Consequently, Eq. 28 should apply. The theoretical slope is half of that for Eq. 27 or 1.836 × 10^3. The intercept corresponding to the inverse of the membrane permeability should be the same in each case.

Table III presents results from duplicate experiments like those given in Fig. 6. The average slope of 3.56 × 10^3 agrees quite closely with the theoretical prediction of 3.672 × 10^3 when both diffusion layers are included. When the outer or inner diffusion layer is eliminated, the average of the experimentally determined slope is 1.87 or 1.62 × 10^3, respectively. The Student *t* test for significance of difference between two means at the 5% level of confidence indicates there is no statistical difference between the latter two slopes. The 11–16% coefficient of variation for each case can be attributed in part to the 5–6% variation observed in each determination.

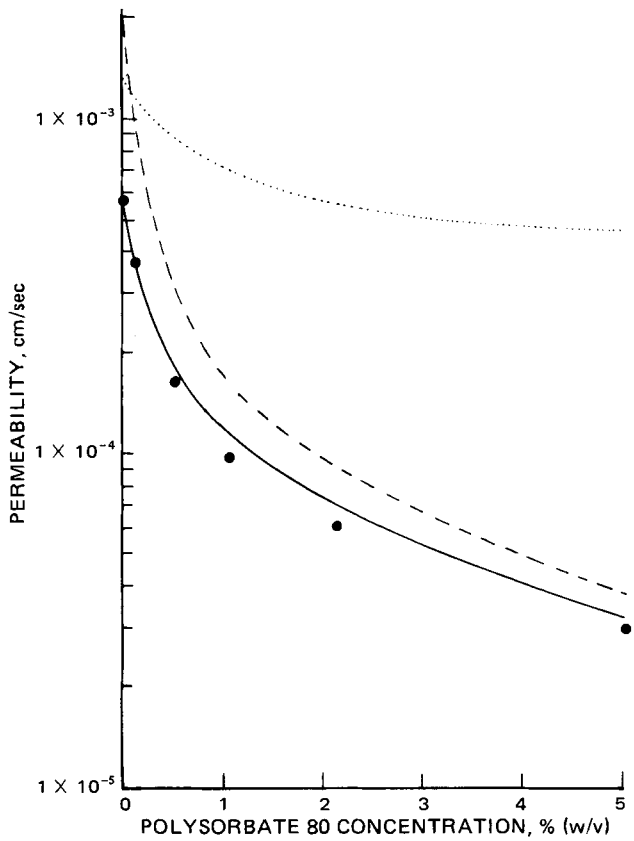

Figure 9—*Theoretical predictions of* P_{eff} (—), P_m (- - -), *and* P_i (· · ·) *as a function of polysorbate 80 concentration based on independent estimates of the physicochemical parameters. Key:* ●, *experimentally determined* P_{eff}.

Table IV—Experimentally Determined Permeability Coefficients and Fluxes from Constant Initial Concentration and Saturated Solution Studies

Polysorbate 80 Concentration, %	Constant Initial Concentration Case, P_{eff} × 10^4, cm/sec	Saturated Solution Case	
		Flux from Saturated Solution × 10^9, g/cm^2 sec	P_{eff} × 10^4, cm/sec
0	5.87	7.05	5.87
0.1	3.75	—	—
0.126	—	9.42	2.89
0.5	1.65	—	—
0.52	—	14.65	1.78
1.05	0.965	—	—
2.04	—	16.98	0.62
2.09	0.612	—	—
5.0	0.30	—	—

Because of the close agreement between theory and experiment, these results indicate that the aqueous diffusion layer thickness on each side of the rotating membrane is equal within the limits of experimental error. Therefore, Eq. 20 applies for each diffusion layer thickness. This diffusion cell system also has the advantage of permitting easy and quantitative control of the aqueous diffusion layer thickness and gives more insight into the events occurring within it. The ability to extrapolate to infinite rotation speed also permits the diffusion layer resistance to be factored out, thereby permitting an estimate of the membrane permeability coefficient.

Equation 27 can be utilized to determine the membrane permeability coefficient and the aqueous diffusion coefficient of progesterone, and results are presented in Fig. 7. The membrane permeability coefficient is estimated from the intercept to be 2.0 × 10^{-3} cm/sec for a 190-μm thick membrane. The aqueous diffusion coefficient, estimated from the slope in Fig. 7, is 8.5 × 10^{-6} cm^2/sec. This value is close to the diffusion coefficient of 7.9 × 10^{-6} cm^2/sec as determined by the small-volume diaphram cell method.

Micelle Solubilization Studies—The appearance of radiolabeled progesterone in the receiver compartment is shown in Fig. 8 for several polysorbate 80 concentrations. In these studies, the donor compartment contained approximately equivalent initial concentrations of radiolabeled progesterone. A decreasing slope as the surfactant concentration is increased is seen, reflecting a decreasing permeability. The effective permeability coefficients as determined from the slope of the lines in Fig. 8 are given in Table IV and are included in Fig. 9 along with theoretical estimates from the model. The theoretical estimates were based on Eqs. 24 and 25 and independent estimates of all relevant physicochemical parameters.

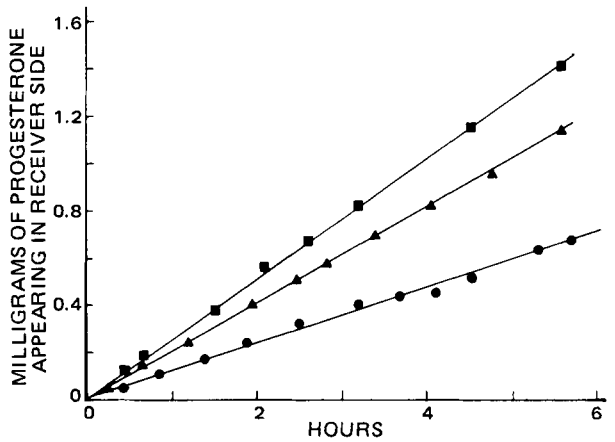

Figure 10—*Appearance of progesterone in the receiver compartment from saturated solutions. Key: (polysorbate 80 concentration)* ■, *2.04%;* ▲, *0.52%; and* ●, *0.126%.*

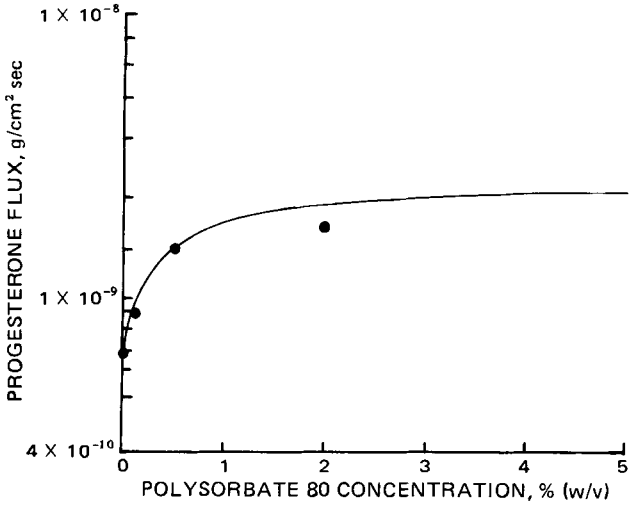

Figure 11—*Flux of progesterone from saturated solutions as a function of polysorbate 80 concentration. Key: —, theory; and ●, experimental.*

There is very good agreement between experimental results and the theoretical model. The predicted change in the permeability coefficient of the aqueous diffusion layer resistance is also included (P_i). It approaches a limiting value at high surfactant concentrations, corresponding to the permeability coefficient of the diffusion layer when only micelles are transported. The effective permeability coefficient continues to decrease, however, since the thermodynamic activity of progesterone continues to decrease with increasing surfactant. The theoretical curve labeled P_m is obtained when the aqueous diffusion layer is completely neglected.

The decreasing flux as a function of surfactant concentration is a result of the decreasing aqueous permeability coefficient and also the decreasing thermodynamic activity of progesterone. The decreasing effective permeability coefficient is in part the result of the changing aqueous diffusion layer permeability coefficient given in Eqs. 8 and 25. As the surfactant concentration increases, more progesterone is incorporated within the micelle and most of the progesterone diffuses through the diffusion layer solubilized in the micelle. The smaller diffusivity of the micelle determines the aqueous permeability coefficient at high surfactant concentrations. The thermodynamic activity of progesterone is also affected by the surfactant concentration since the concentration of free progesterone in the aqueous phase is lower due to micelle solubilization. This situation is reflected in the membrane permeability, P_m, and also in the bulk aqueous phase through Eq. 4.

Saturated Solution Studies—The rate of appearance of progesterone in the receiver side is shown in Fig. 10 for three surfactant concentrations. The donor phase was presaturated with progesterone, and the appearance of solute in the reciever side was followed using HPLC. The corresponding fluxes of progesterone from each of these saturated solutions is shown in Fig. 11, and the corresponding effective permeability coefficients are tabulated in Table IV. The solid line in Fig. 11 is the theoretical prediction based upon Eqs. 23 and 24 and is included to show the close agreement between experimental results and theoretical predictions based on the physical model and independent estimates of the relevant physicochemical parameters.

As was the case for the constant initial progesterone concentration studies, the effective permeability coefficient for the trilaminar resistance decreases with increasing surfactant concentration. However, a larger total bulk solute concentration, C_{b1}, is possible due to micelle solubilization. For the progesterone–polysorbate 80 case, the increased solubility of progesterone offsets the decreased permeability; the net result is an increase in flux as the surfactant concentration increases. In effect, the micelles act as carriers of solute across the aqueous diffusion layer to the membrane surface. In this way, the diffusion layer resistance can be eliminated or shorted out. At high surfactant concentrations, saturated solution conditions can be reached at the membrane surface and the membrane is the only resistance to diffusion. For progesterone, this plateau occurs at ~2% polysorbate 80 and there is little further increase in flux.

High-Performance Liquid Chromatographic Determination of Suprofen in Drug Substance and Capsules

AVINASH L. LAGU *, RICHARD YOUNG, EUGENE McGONIGLE, and PHILIP A. LANE ˣ

Received March 2, 1981, from the *Pharmaceutical Analysis Section, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication May 15, 1981. *Present address: Eli Lilly and Co., Indianapolis, IN 46206.

Abstract □ A rapid, simple, stability-indicating assay procedure for suprofen, a new analgesic agent, in suprofen drug substance and in capsules was developed using high-performance liquid chromatography. Suprofen was extracted from the sample matrix with methanol and diluted with internal standard solution, and an aliquot was chromatographed on a reversed-phase column using acetonitrile–pH 3.0 buffer solution as the mobile phase. The selectivity of the chromatographic system for intact suprofen was demonstrated by resolving suprofen from synthetic intermediates, potential impurities, and reaction products resulting from accelerated stress conditions. The method is linear, quantitative, and reproducible. Either peak height or peak area ratios can be used for quantitation.

Keyphrases □ Suprofen—high-performance liquid chromatographic determination in drug substance and capsules □ High-performance liquid chromatography—determination of suprofen in drug substance and capsules □ Analgesics—high-performance liquid chromatographic determination of suprofen in drug substance and capsules

Suprofen, α-methyl-4-(2-thienylcarbonyl)benzeneacetic acid (I), is a potent, new analgesic agent (1, 2) and inhibitor of prostaglandin synthetase (3, 4). Two analytical methods were previously reported for suprofen drug substance; a TLC method (5) was used to monitor suprofen stability and a high-performance liquid chromatographic (HPLC) method (6) was used to determine suprofen and its known metabolites in plasma.

This paper describes a rapid, simple, stability-indicating HPLC method for suprofen in suprofen drug substance and in capsules containing either 100 or 200 mg of suprofen.

EXPERIMENAL

Apparatus—The liquid chromatograph[1], equipped with a constant-displacement pump[2] and a UV detector[3] (254 nm), was operated at ambient temperature. Chromatograms were traced on a strip-chart recorder[4] or drawn by computer[5]. All analyses were performed using a 3.9-mm × 30-cm reversed-phase column[6]. Generally, an automatic sampler[7] was used to inject samples onto the column, but a septumless injector[8] or a fixed-loop injector[9] was also used. Peak height and peak area integrations and calculations were performed by computer[5].

Materials—All chemicals were reagent grade unless noted otherwise and were purchased from commercial sources. 4-Nitrobenzoic acid[10], acetonitrile[11], and methanol[11] were used without additional purification.

Chromatographic Conditions—The mobile phase was acetonitrile–pH 3.0 buffer solution (3:2). The pH 3.0 buffer solution was prepared by adding a 0.02 *M* dibasic sodium phosphate heptahydrate solution to a 0.01 *M* citric acid monohydrate solution until the solution pH was between 2.97 and 3.04. At least 500 ml of this solution was passed through a 0.22-μm filter[12], and 400 ml was thoroughly mixed with 600 ml of acetonitrile. The solution was sonified[13] for 15 min to degas the mixture and then equilibrated in the HPLC system at a rate of 0.5 ml/min.

Internal Standard Solution—The internal standard was 4-nitrobenzoic acid prepared as a 1.2 mg/ml solution in methanol.

Standard Solution—Suprofen standard, ~50 mg, was accurately weighed and transferred into a 25-ml volumetric flask; then it was dissolved and diluted to volume with methanol. Five milliliters of this solution was pipetted into a 10-ml volumetric flask. The flask was then diluted to volume with internal standard solution.

Standard Chromatogram—Two microliters of the standard solution were injected into the liquid chromatograph. The peak heights and peak areas obtained were used in the calculations for suprofen.

Suprofen Synthetic Intermediates, Impurities, and Reaction Products from Accelerated Stress Studies—α-Hydroxy-α-methyl-4-(2-thienylcarbonyl)benzeneacetic acid (II), 4-carboxy-α-methylbenzeneacetic acid (III), methyl-α-methyl-4-(2-thienylcarbonyl)benzeneacetic acid (IV), ethyl-4-(2-thienylcarbonyl)benzene (V), 4-acetyl-α-methylbenzeneacetic acid (VI), α-methyl-4-(2-thienylcarbonyl)benzene acetonitrile (VII), (1-bromoethyl)-4-(2-thienylcarbonyl)benzene (VIII), diethyl-2-methyl-2-[4-(2-thienylcarbonyl)phenyl]-1,3-propanedioate (IX), 4-fluorophenyl-2-thienylmethanone (X), α-methyl-4-(2-thienylcarbonyl)benzene acetamide (XI), 2-fluorophenyl-2-thienylmethanone (XII), 3-fluorophenyl-2-thienylmethanone (XIII),

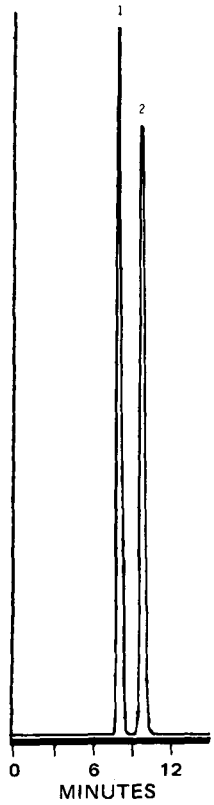

Figure 1—*Typical chromatogram obtained from a suprofen(I) capsule sample. Key: peak 1, internal standard; and peak 2, suprofen.*

α-methyl-4-(5-chloro-2-thienylcarbonyl)benzeneacetic acid (XIV), 2-[4-(2-thienylcarbonyl)phenoxy]propanoic acid (XV), methyl-4-(2-thienylcarbonyl)benzene (XVI), and 4,4-carbonylbis(α-methylbenzeneacetic acid) (XVII) were obtained[14] and chromatographed as methanolic solutions (~2 mg/ml).

Accelerated Stress Studies—Accelerated degradation of suprofen was accomplished by several methods:

1. Suprofen drug substance (50.6 mg) was heated at its melting point of 124° for 1 hr in an oil bath.
2. Suprofen drug substance (50.5 mg) was dispersed in 5.0 ml of 1 *N* HCl and kept at 50° for 72 hr.
3. Suprofen drug substance (50.6 mg) was dispersed in 5.0 ml of 1 *N* NaOH and kept at 50° for 72 hr.
4. Suprofen drug substance (50.2 mg) was dispersed in 5.0 ml of 3% hydrogen peroxide solution and kept at 50° for 72 hr.

After 72 hr, the acid and base samples were neutralized and diluted to 25.0 ml with methanol. The excess peroxide was destroyed by gently heating the solution and then diluting to 25.0 ml with methanol. The sample heated at its melting point was made to 25.0 ml with methanol.

TLC Studies—TLC evaluation of the accelerated stress samples was carried out by spotting the equivalent of 100 μg of suprofen on silica gel plates[15] and developing them 15 cm in tanks lined with adsorbent paper in each of the following systems: System I, *n*-hexane–chloroform–methanol–strong ammonia (50:30:20:1), suprofen R_f 0.18; System II, *n*-hexane–dioxane–acetic acid (80:20:1), suprofen R_f 0.12; and System III, chloroform–methanol–methyl ethyl ketone (40:30:30), suprofen R_f 0.48. Visualization was by short wavelength UV light (254 nm).

Suprofen Recovery Studies—To simulate 100 mg of suprofen capsules, an accurately known amount of suprofen drug substance was transferred to a 50- ml volumetric flask containing 120 ± 2 mg of placebo. For 200-mg suprofen capsules, an accurately known amount of suprofen drug substance was transferred to a 100-ml volumetric flask containing 135 ± 2 mg of placebo. For both studies, 10 individual synthetic samples were prepared. The 200-mg study was conducted by two different operators on different days. Methanol was added to the flasks, which were then shaken[16] for 15 min. After the flasks were made to volume with methanol and thoroughly mixed, a portion of the solution was filtered[17]

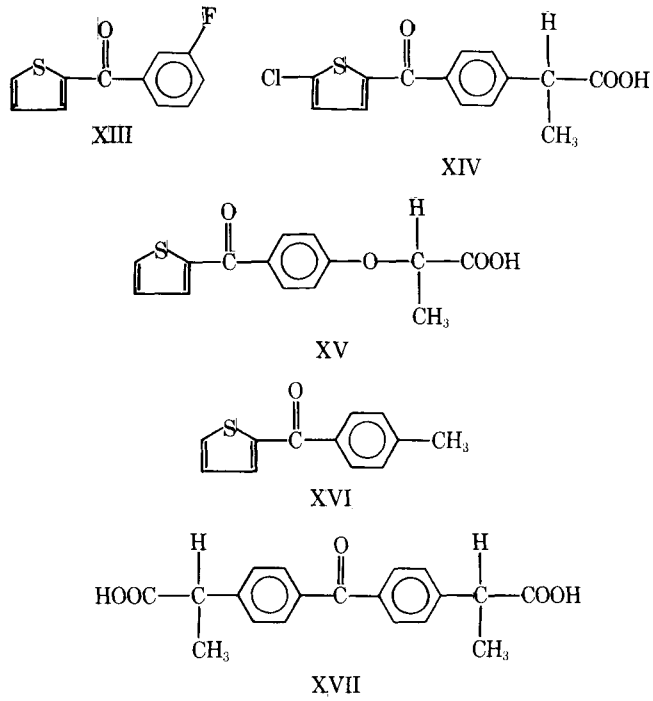
using a syringe equipped with a Swinny adapter. A 5.0-ml aliquot of the filtrate was pipetted into a 10-ml volumetric flask, which was then diluted to volume with internal standard solution. Then 2-μl portions were injected into the liquid chromatograph using either manual or automated injection techniques.

The suprofen recovery was calculated from:

$$\text{percent suprofen} = \frac{R_{sam}}{R_{std}} \times \frac{W_{std}}{W_{sam}} \times D \times 100 \qquad \text{(Eq. 1)}$$

where R_{sam} and R_{std} is the peak area or peak height ratio of suprofen to the internal standard for the sample and standard, respectively; W_{std} is the weight of suprofen standard; W_{sam} is the amount of suprofen taken; and D is a dilution factor, which is equal to 2 for the 100-mg spiked placebo capsules and 4 for the 200-mg spiked capsules.

Suprofen in Capsules—The contents of 20 suprofen capsules were weighed to determine the average capsule fill weight (C_{avg}) and were thoroughly mixed. For 100-mg suprofen capsules, duplicate 220 ± 3-mg



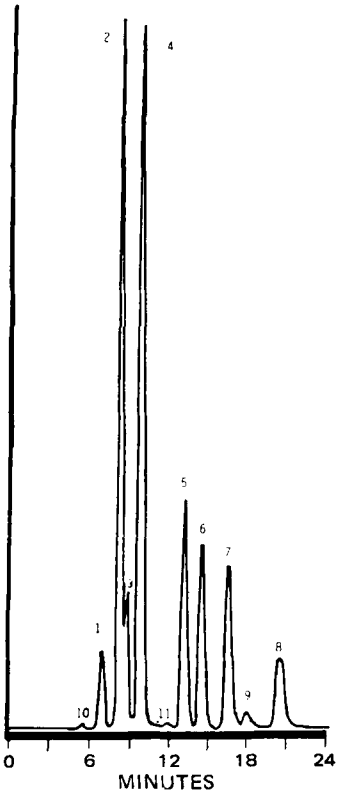


Figure 2—*Chromatogram showing separation of I from various structurally related compounds. Key: peak 1, III; peak 2, XV; peak 3, XVII; peak 4, I; peak 5, VII; peak 6, XVI; peak 7, X; and peak 8, IX. Peak 9 is an impurity in IX. Peaks 10 and 11 are unknown impurities.*

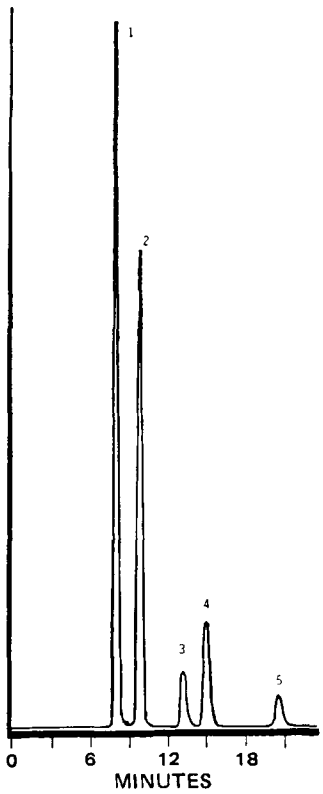

Figure 3—*Chromatogram showing separation of I from various structurally related compounds. Key: peak 1, VI; peak 2, I; peak 3, XIV; peak 4, XIII; and peak 5, VIII.*

samples were accurately weighed and transferred to a 50-ml volumetric flask. For 200-mg suprofen capsules, duplicate 335 ± 3-mg samples were accurately weighed and transferred to a 100-ml volumetric flask. The samples were assayed as already described and calculated as follows:

$$\text{milligrams of suprofen per capsule} = \frac{R_{sam}}{R_{std}} \times \frac{W_{std}}{W_{sam}} \times D \times C_{avg} \quad \text{(Eq. 2)}$$

Suprofen Drug Substance—The suprofen content of suprofen drug substance was determined by treating it like a suprofen standard solution. If samples are assayed for purity, the internal standard need not be added, although a fixed-loop injector should be used. The suprofen content may be calculated using Eq. 1 with a dilution factor (D) equal to 1.

System Suitability—The chromatographic system is considered to be performing satisfactorily if the internal standard has a retention time of 6.5–8.0 min, suprofen has a retention time of 9.0–11.0 min, and the calculated resolution between the two compounds is at least 2.0.

RESULTS AND DISCUSSION

The resolving power of the chromatographic system was demonstrated by chromatographing suprofen and a structurally related series of compounds that arise from various synthetic schemes as intermediates (V and VII–X), potential impurities (II, IV, and XI–XVII), or reaction products (III and VI) resulting from stress studies. The resolution of suprofen and the internal standard in a typical capsule sample is demonstrated in Fig. 1. Several mixtures of suprofen and the structurally related compounds were prepared and chromatographed to show the resolution obtained. The chromatograms resulting from these mixtures are shown in Figs. 2–4. Compounds II, VI, and XI were not totally resolved from the internal standard; if their presence in the sample is suspected, the internal standard should be deleted and the sample reinjected using a fixed-loop injector. Each compound was chromatographed with suprofen, and the relative retention time and resolution (R) were calculated with respect to suprofen (Table I).

Suprofen drug substance that was thermally stressed at its melting point afforded 97.8% recovery of suprofen with no extraneous peaks observed in its chromatogram. The sample subjected to peroxide oxidation afforded 97.4% recovery of suprofen. The chromatogram of this sample showed an extra peak with a retention time of 5.5 min. The suprofen sample subjected to acid hydrolysis afforded quantitative recovery of suprofen and did not show any extra chromatographic peaks. The sample subjected to base hydrolysis turned yellow during the 72-hr interval and afforded 92.8% recovery of suprofen. The chromatogram of this sample showed two extra small peaks at 6 and 7 min.

The stressed samples were qualitatively examined by TLC for any additional unknown spots using basic (System I), acidic (System II), and aprotic (System III) solvent systems. TLC evaluation was chosen because

Table II—Suprofen Recovery: 100-mg Dose Using Peak Height Ratio

Operator 1[a]			Operator 2[b]		
Suprofen Added, mg	Suprofen Found, mg	Recovery, %	Suprofen Added, mg	Suprofen Found, mg	Recovery, %
100.6	103	102	102.6	106	103
100.4	103	103	101.4	101	99.6
101.1	102	101	100.4	100	99.6
100.2	102	102	101.8	104	102
100.2	98.6	98.4	102.0	102	100

[a] Average recovery = 101 ± 1.76% (SD), and percent deviation = ±1.74%. [b] Average recovery = 101 ± 1.56% (SD), and percent deviation = ±1.55%.

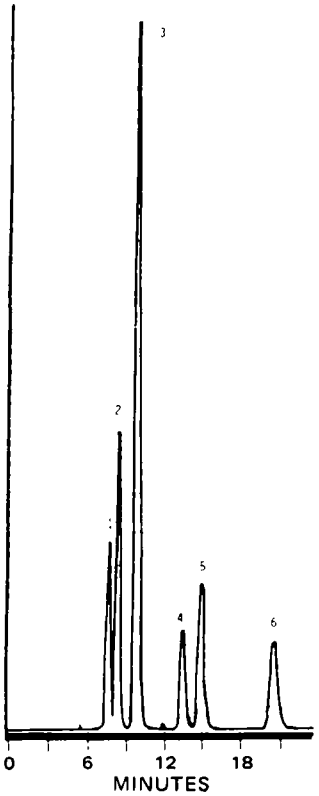

Figure 4—*Chromatogram showing separation of I from various structurally related compounds. Key: peak 1, II; peak 2, XI; peak 3, I; peak 4, XII; peak 5, IV; and peak 6, V.*

all substances present in the stressed sample would be carried through the TLC system. If an unknown UV-absorbing substance in the sample did not migrate in the system, it would still be detectable at the origin. Qualitatively, each of the three systems afforded identical results. The thermally stressed sample and the acid hydrolysis sample showed only the presence of suprofen. The peroxide-stressed sample, in addition to suprofen, showed a faint origin spot, which was in qualitative agreement with the HPLC results, which showed one extra peak. The base hydrolysis sample showed two extra spots, a small origin spot and a spot that was not totally resolved from suprofen. These results were also in qualitative agreement with the HPLC findings.

Since the HPLC system resolved suprofen from its synthetic intermediates, potential impurities, and reaction products from accelerated stress studies, showed drug loss due to decomposition in accelerated stress studies, and showed the presence of the same number of additional peaks from those studies compared to TLC, it was concluded that the method was stability indicating for suprofen.

Using peak height ratios, the detector response was demonstrated to be linear over the range of 0.0997–2.00 $\mu g/\mu l$ of suprofen (10–200% of label claim). Linear regression analysis of the data yielded a slope of 0.978, an intercept of −0.00995, and a coefficient of determination (r^2) of 0.9996. Using area ratios, the detector response was linear over the range of 0.200–1.50 $\mu g/\mu l$ of suprofen (20–150% of label claim). Linear regression analysis of the data yielded a slope of 1.01, an intercept of +0.00194, and coefficient of determination of 0.9999. Thus, the detector response was linear with either peak height ratios or peak area ratios.

The results of recovery studies conducted by two operators on 100 and 200-mg suprofen spiked placebo capsules are shown in Tables II and III,

	195	195	1.000
	197	197	1.000

[a] Theoretical height/area ratio = 1.000.

respectively, using peak height ratios to quantitate suprofen. Quantitative recovery of suprofen was obtained at both concentration levels. The overall recovery for the 30 samples was 100 ± 1.45%. The equivalence of quantitating suprofen by either peak area ratios or peak height ratios is shown in Table IV, where actual suprofen capsules were assayed and quantitated by both techniques. As shown, the ratio of the peak height result to the peak area result was essentially unity, indicating no difference between peak area and peak height results.

Measurements of Ionization Constants and Partition Coefficients of Guanazole Prodrugs

ABDULGADER A. ALHAIDER, CYNTHIA D. SELASSIE, SWEE-ONG CHUA, and ERIC J. LIEN ˣ

Received January 22, 1981, from the *Section of Biomedicinal Chemistry, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication May 15, 1981.

Abstract □ A series of guanazole prodrugs, which are less water soluble than the parent compound and have relatively higher molecular weights, was recently synthesized, and their antineoplastic activities were measured *in vitro*. In the present work, the ionization constants and partition coefficients of these compounds were measured for the first time. In contrast to guanazole, which is a weak base, guanazole prodrugs have been shown to be weak to moderate acids due to the electronic effects of the acyl group and the heterocyclic ring. Possible tautomeric and resonance structures are presented to account for the pKa values observed. Both the inductive and resonance effects of the substituent are important in determining the values of the ionization constant. The preparation of the prodrugs not only altered the lipophilicity but also drastically changed the acid–base property of the parent compound. The observed true partition coefficient values in most guanazole prodrugs studied were higher than those calculated from the π-constants. Under highly ionized conditions, the small amount of water in the octanol layer has a significant effect in trapping a substantial amount of the ionized species in the octanol layer and gives rise to a higher log P value than expected. Under nonionized conditions, intramolecular hydrogen bonding plays an important factor in electron delocalization and reduction of hydrogen bonding with water molecules, causing the nonionized species of the guanazole prodrugs to be more lipophilic than expected.

Keyphrases □ Guanazole–prodrugs, ionization constants and partition coefficients □ Ionization constants—guanazole prodrugs □ Partition coefficients—guanazole prodrugs □ Prodrugs—guanazole, ionization constants and partition coefficients □ Antitumor agents—guanazole prodrugs

Guanazole, a known ribonucleotide reductase inhibitor was shown to have antitumor activity against the murine leukemias L-1210 and K-1964, carcinoma, and reticulum cell sarcoma A-RCS (1). Brockman *et al.* found that guanazole acts by inhibiting the incorporation of adenine, hypoxanthine, and uridine into DNA to a much greater extent than into RNA (2).

BACKGROUND

Guanazole has been shown to be effective clinically in patients with acute and chronic myelogenous leukemias (3). In addition to the side effects observed in therapy with guanazole, such as hematological toxicity and some myelosuppression (4, 5), guanazole has some biopharmaceutical disadvantages. Pharmacokinetic studies on guanazole have shown that 95% of the drug was excreted in the urine of mice within 3 hr and most of it was unchanged (6). It also has a very short half-life: 30 min in mice (7), 68 min in rats (8), and 5 hr in humans (8, 9). Thus, a high dose or continuous administration is necessary to obtain the required therapeutic effect. The short half-life of guanazole can be attributed to its high polarity and its low molecular weight.

To circumvent these problems, a series of new guanazole prodrugs was prepared by acylation of guanazole by various organic anhydrides and acid chlorides (10). The antineoplastic activity *in vitro* against leukemia L-1210 has already been studied. The results showed that four of the prodrugs had comparable or greater *in vitro* activity than guanazole itself. (*In vivo* testing is presently being conducted by the National Cancer Institute.)

To carry out structure–activity relationship studies to serve as guidelines for further molecular modification, it is necessary to have pertinent physicochemical parameters for the guanazole prodrugs. However, these properties of the new compounds are not available in the literature. This need prompted the investigation of the ionization constants (pKa) and partition coefficients (log P) since these are the most important physicochemical constants used in structure–activity relationship studies (11).

Guanazole prodrugs have a triazole structure with two ionization sites, deprotonation and protonation. However, under the present experimental conditions, pKa values represent only the deprotonation process. Since the optical properties of the undissociated forms differ from those of the dissociated forms, UV spectroscopy was utilized to measure the pKa values of the prodrugs.

The partition coefficient (log P) may be measured at a pH in which the drug is partially ionized and partially nonionized (12, 13). However, the ionized form of a molecule does not partition into octanol (13). The true partition coefficient may be calculated from the observed value, the buffer pH, and the pKa of the compound. Therefore, the apparent partition coefficient is pH dependent (14–16) and should be converted to the "true" (corrected) partition coefficient, which is pH independent as indicated by the following:

$$P_{corr} = \frac{C_o}{C_a(1-\alpha)} = \frac{P_{app}}{(1-\alpha)} \qquad \text{(Eq. 1)}$$

where P_{corr} is the corrected partition coefficient, P_{app} is the apparent partition coefficient, C_o is the concentration of the drug in the organic phase, C_a is the concentration of the drug in the aqueous phase, and α is the degree of ionization calculated from the Henderson–Hasselbalch equation (17) as follows. For acids:

$$\alpha = \frac{1}{1 + \text{antilog}\,(\text{pKa} - \text{pH})} \qquad \text{(Eq. 2)}$$

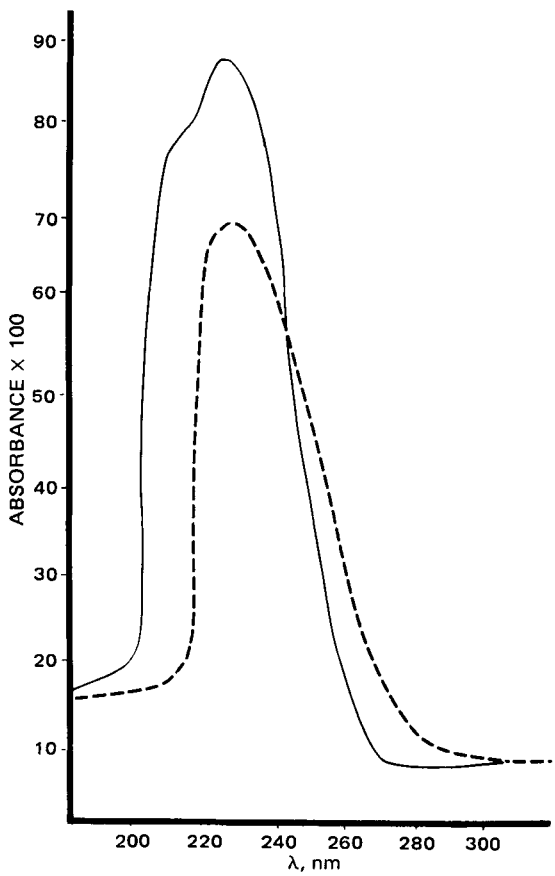

Figure 1—*UV spectrum of 3,5-diacetamido-1,2,4-triazole. Key: —, pH 4.50; and - - -, pH 12.50.*

V	3-Amino,5-heptafluorobutyramido-1,2,4-triazole	H	COC_3F_7
VI	3,5-Dibenzamido-1,2,4-triazole	COC_6H_5	COC_6H_5
VII	3,5-Di(*p*-nitrobenzamido)-1,2,4-triazole	$COC_6H_4NO_2$	$COC_6H_4NO_2$

For bases:

$$\alpha = \frac{1}{1 + \text{antilog}\,(\text{pH} - \text{pKa})} \qquad \text{(Eq. 3)}$$

An aqueous phase with a suitable buffering system is required to enhance the dissolution and ionization or to maintain a particular pH with an organic solvent. However, the effects of buffer species on the apparent partition coefficient were not studied until recently (12). It was found that phosphate buffer is the best system for measuring the true partition coefficient for quantitative structure–activity relationship work for both acidic and neutral drugs whenever the drug is soluble in this system. For many drugs, it is necessary to correct for the discrepancies when different buffer systems are used.

Due to the limited solubility, the phosphate buffer is not suitable for some of the prodrugs studied. It was also observed that the degree of ionization of some prodrugs is very high with most of the buffer systems. Accordingly, the small amount of water molecules in the octanol layers may trap a reasonable amount of the ionized species, giving rise to a higher log *P* value than predicted (12, 18).

EXPERIMENTAL

Materials—A UV spectrometer[1] equipped with a digital recorder, a pH meter[2], and an automatic electrobalance[3] were used. Buffer solutions such as hydrochloric acid–potassium chloride (pH 1.0–2.5), acetate (pH 3.6–5.9), phosphate (pH 6.0–8.0), tromethamine (pH 7.2–9.0), borate (pH 9.2–10.7), and bicarbonate (pH 9.28–10.1) were prepared as reported (19). They were then stored as 0.1 *N* solutions and diluted to the proper ionic strength (17, 20). The pH values were then adjusted by using 0.1 *N* HCl or 0.1 *N* NaOH.

Compounds—Guanazole prodrugs (Table I) were synthesized previously (10). Guanazole (3,5-diamino-1,2,4-triazole) was obtained commercially[4]. The melting point (158°) of salicylic acid[5] was determined to check for purity.

Purification of Octanol—Octanol[6] was purified by shaking with 1 *N* sodium hydroxide, 1 *N* sulfuric acid, and 5% sodium bicarbonate and then drying with excess anhydrous magnesium sulfate and fractional distillation (21, 22). The purified solvent did not show any UV-absorbing impurities (200–800 nm) for the boiling range of 192–195°.

Determination of Ionization Constants—A previously described procedure (17) was used for the determination of ionization constants. Its accuracy was checked with an authentic sample of salicylic acid (at 25°), and the result (2.94) was in close agreement with that reported (2.97) (23). The concentration of the buffers utilized for compounds I–VII was 0.05 *M*.

Determination of Apparent and True (or Corrected) Partition Coefficients—An accurate weight of the drug under investigation was dissolved in a suitable buffer solution to make up the stock solution (100 ml). The problem of low solubility was circumvented by the use of 2% C_2H_5OH, 1% $(CH_3)_2SO$, or 0.05 *N* NaOH (pH 12.4). Aliquots of the stock solution were partitioned between the 1-octanol–aqueous system (each phase being presaturated with the other) in 50-ml glass-stoppered bottles. These two phases were vigorously shaken by hand to ensure rapid distribution. The bottles were then placed in a horizontal bottle shaker for 3–4 hr at room temperature (25 ± 1°), followed by centrifugation of 10 ml of the aqueous layer for 20 min. Alternatively, the partitioned phases were centrifuged for 1 hr at 2000 rpm after 2 min of vigorous shaking.

Standard curves were run from duplicate samples using two separate weighings of the drug. In most cases, a 1:1 (v/v) ratio of 1-octanol to buffer (25 ml:25 ml) was used. The drug concentration in the aqueous phase after centrifugation was measured from UV absorbance and deduced from the standard curve. The apparent partition coefficient was calculated from the equation:

$$P_{app} = C_{octanol}/C_{aqueous} \qquad \text{(Eq. 4)}$$

where $C_{octanol}$ and $C_{aqueous}$ are the prodrug concentrations in the octanol and aqueous phases, respectively. Based on the apparent partition coefficient and its corresponding pH and pKa values, the true or corrected partition coefficient value was calculated from Eq. 1.

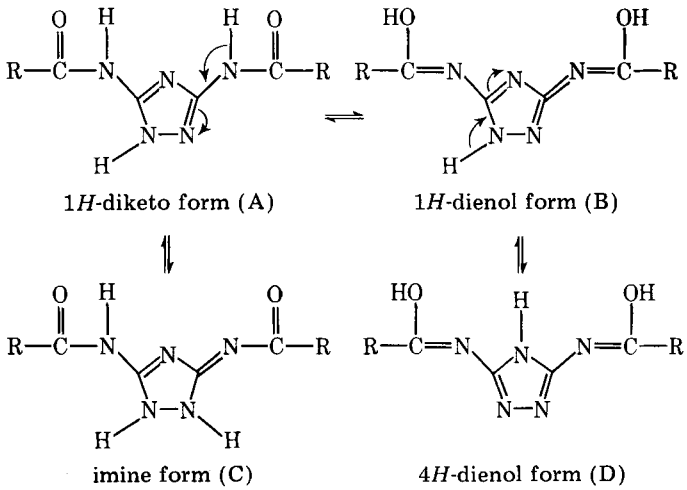
[a] The pKa of the dipropionated form was used.

RESULTS AND DISCUSSION

The ionization constants and both the apparent and true (corrected) partition coefficients of Compounds I–VII were measured for the first time in this study and are listed in Table II.

Dedichen (24) first measured the basicity constants of 1,2,4-triazole and some of its 2-amino-3,5-dialkyl substituted products. The applicability of Hammett's equation to the triazole ring was shown previously (25, 26). In addition, it was found (27) that basicity increases in the presence of an electron-donating group but decreases in the presence of an electron-withdrawing group. By employing the Hückel approach in conjunction with the linear combination of atomic orbitals–molecular orbital (LCAO–MO) method, the protonation center in 1*H*-1,2,4-triazole was shown to be the N-4 ring nitrogen atom (28). The basicity constants of a series of 5-(3)-substituted 3-(5)-amino-1,2,4-triazoles was determined by potentiometric titration (29). A high degree of quantitative correlation between the pKa values and the Hammett constants was found. Furthermore, the pKa from 3,5-diamino-1,2,4-triazole was 4.43, which was attributed to the conjugate acid of N-4 of the triazole ring (29). On the other hand, the ionization constants of the deprotonation of the heteroimino group of a series of 1,2,4-triazole derivatives were measured previously (30) and were in the range of 6.10–11.08. Consequently, it appears



Scheme I

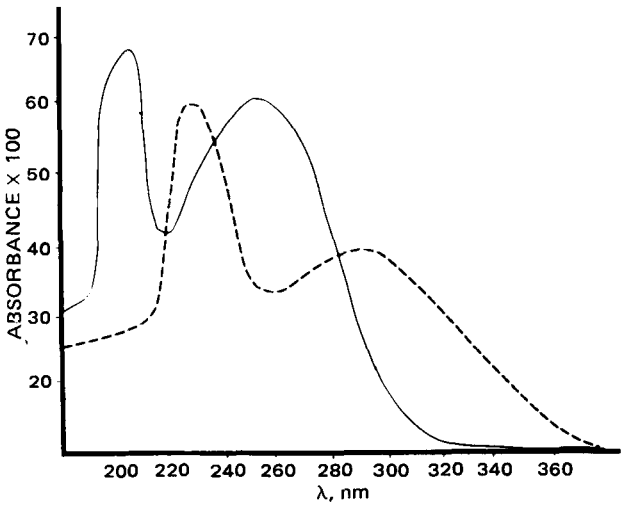


Figure 2—*UV spectrum of 3,5-dibenzamido-1,2,4-triazole. Key: —, pH 5.00; and - - -, pH 12.50.*

that the pKa values determined in this study (Table II) belong to the deprotonation process of the weakly acidic amido —NHCO— group or the 1,2,4-triazole ring rather than to the protonation of any basic nitrogen.

This finding was utilized in determining the percent ionization at the pH values used to measure the ionization constants of the compounds.

Some work has been published on the tautomerism of 1,2,4-triazole derivatives (26, 31, 32); however, nothing has yet been reported concerning the tautomeric isomers of guanazole derivatives. Nevertheless, a theoretical postulate can be drawn for the possible tautomeric isomers of guanazole derivatives as shown in Scheme I.

It has been shown (33) by IR spectral comparison of amidine analogs that alkyl groups (Y) tend to prefer attachment to the amino system 2A rather than to 2B but that the reverse is true for aryl groups.

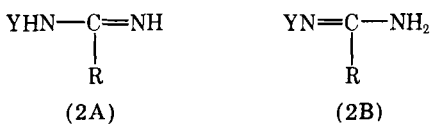
Chua *et al.* (34) quantified the energy differences between the two possible tautomers by applying the basicity method (35), which depends on the formation of the cation for both the tautomeric forms A and B, and comparing their basicities to fixed models of A and B. From their findings, it appears likely that the tautomeric structure A is the predominant structure for I–III. On the other hand, the tautomeric structures B and C are more likely for IV–VII.

Apparently, there are two different kinds of tautomerism: the imino and keto-enol types. Furthermore, there are four possibilities for dissociation. A comparison of the UV spectra of the neutral and the anion species is important in determining the dissociation site. It was found (27) that the splitting off of a proton attached to the heteronitrogen atom of 3-nitro-1,2,4-triazole-5-carboxylic acid causes a marked (50 nm) bathochromic shift in the UV spectrum while dissociation at the carboxyl group of 1-methyl-5-nitro-1,2,4-triazole-3-carboxylic acid gives a very small (5 nm) bathochromic shift.

The UV spectrum of I (Fig. 1) at various pH values shows a negligible bathochromic shift (4 nm) of the B band of the triazole ring. Therefore, the dissociation process and the possible canonical forms of I–III can be represented by Scheme II.

Likewise, the UV spectra of the neutral and the anionic species of VI is shown in Fig. 2. For the neutral form, there are two absorption maxima, one at 260 nm, which is characteristic of the aromatic ring and is analogous to the K-band (36), and one at 215 nm for the B-band, which is characteristic of the heteroaromatic ring. The splitting off of the proton causes a very strong bathochromic shift of 20 and 40 nm for the B- and K-bands, respectively. Therefore, the removal of the proton causes a delocalization of electrons in both rings, which indicates a possible pathway for the deprotonation process and the resulting resonance structures (Scheme III).

The UV spectrum of VII is shown in Fig. 3. There is a red shift (14 nm) for the K-band as compared to VI, which is attributable to the electron-withdrawing activity of the nitro group. However, the B-band remains



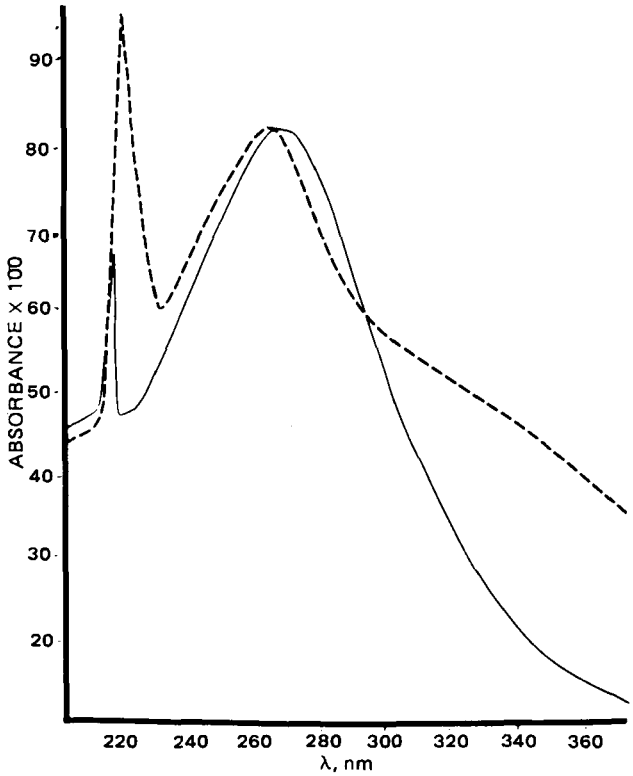


Figure 3—*UV spectrum of 3,5-di(p-nitrobenzamido)-1,2,4-triazole. Key: —, pH 4.50; and - - -, pH 12.50.*

the same as that of VI. Deprotonation causes the solution to change from colorless to yellowish, but a negligible change is observed for both the K- and B-bands. The contributing structures for the visible absorption may be illustrated as shown in Scheme IV.

From Table II, it appears that there is a substantial dependence of the ionization constants on the electronic character of the substituent. The inductive and resonance effects both contribute to the ionization constant in a collective manner.

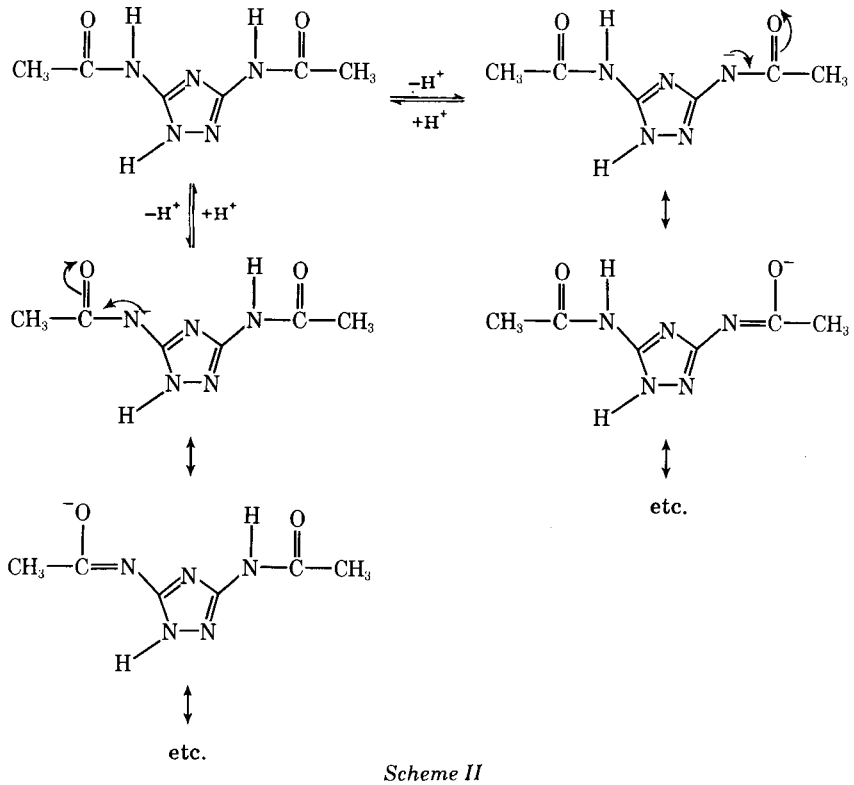
It was shown (11) that changing the electronic properties of the substituent groups may affect the prototropic equilibria and result in a more active tautomeric form of a particular drug. This investigation found that, in contrast to guanazole which is a weak base, guanazole prodrugs range from weak to moderate acids. Preparation of the prodrugs not only altered the lipophilicity but also drastically changed the acid–base property of the parent compound.

Table II shows the measured and calculated values of the partition coefficients of the prodrugs examined. It was shown (37) that log P is not entirely additive. It has been suggested (38) that the additivity of π-values will break down when there is mutual interaction between substituents (intramolecular hydrogen bonding, steric, and field effects) or when a substituent cannot be dissolved to its maximal potential (39).

The nature of the interaction between guanazole derivatives and both octanol and water can be illustrated by Scheme V.

The preferred interaction of guanazole with the aqueous or organic layers probably would be determined in part by the electronic properties of the X substituent. Electron-withdrawing groups would inhibit hydrogen bonding of the type shown on the right side of Scheme V due to the delocalization of the lone-pair electrons but enhance hydrogen bonding of the type shown on the left side of Scheme V. Octanol, being more nucleophilic than water (40), would compete more effectively in binding with the hydrogen of the amino nitrogen. The differences between the observed and calculated values of log P in Table II can be rationalized in part from the substituent effect on the availability of the lone-pair electrons.

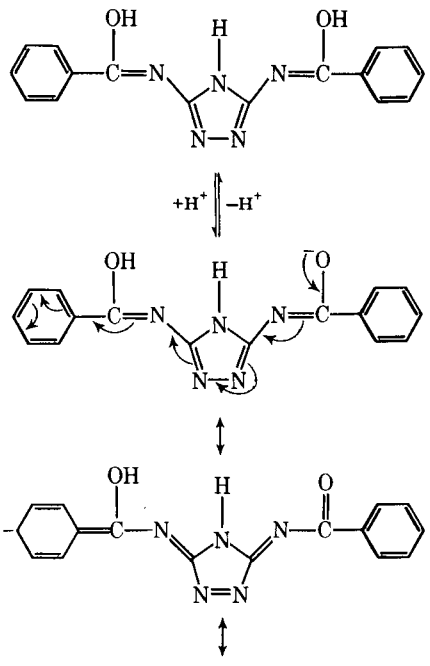
Although the true partition coefficient takes into account the ionization of the drug at a given pH, the assumption that the ionized species of an ionizable drug is insoluble in the nonaqueous layer may be incorrect. First, the small amount of water in the octanol layer is expected to accommodate some concentration of the ionized species (12, 18). Thus, the observed log P would be higher than the calculated value. The partition coefficients of ring-substituted aspirin were measured at different pH values (18). It was found that the discrepancies between the observed and



Scheme II

calculated values correlated well with the calculated lipophilicities, which was attributed to ion-pair formation with buffer counterions (41).

Second, the ionized species may have a different conformation than that of the nonionized form. The partition coefficient (log P = 4.33) of salicylic acid in a 1-octanol–bicarbonate buffer (pH 9.20) system has been shown to be very different from that in a 1-octanol–acetate (pH 4.00) system (log P = 2.87). Wang and Lien (12) considered the first factor as well as the effect of the ionic strength of the buffer to rationalize such a deviation. The difference in the intramolecular hydrogen bonding between the ionized and the nonionized forms may also play a significant role. At a pH of 9.2, the deprotonated form of salicylic acid is predominant (Scheme VI).



Scheme III

Therefore, the ionized form is more capable of intramolecular hydrogen bonding than the nonionized form and gives rise to a higher log P. However, the ionized form also has a higher preference to a hydrogen bond with water molecules than the nonionized form. This decreases the log P. The net effect on log P depends on the buffer species used as well as the pH value.

Compared to the calculated values, the higher values of the observed log P for I–III can be attributed to both the inductive effect of the substituent and the intramolecular hydrogen bonding between the carbonyl group and the triazole ring. Compounds IV–VI, with a high degree of ionization (low $1 - \alpha$ values) at the given pH values, may be trapped by the small amount of water molecules in the octanol layer, giving a higher log P value. Compound VII has an observed log P value only slightly higher than the expected value.

Compound VII can be considered a nitrobenzene derivative substituted at position 4. It can be considered similar to a dinitro-benzene derivative where each nitro group can nullify the effect of the other, resulting in a smaller difference between the observed and calculated log P. Furthermore, at pH 7.40, the degree of ionization of VII is relatively small (5%). Accordingly, the amount of ionized drug trapped by the small amount of water in the octanol layer is negligible. The observed value of log P did not deviate significantly from the calculated value.

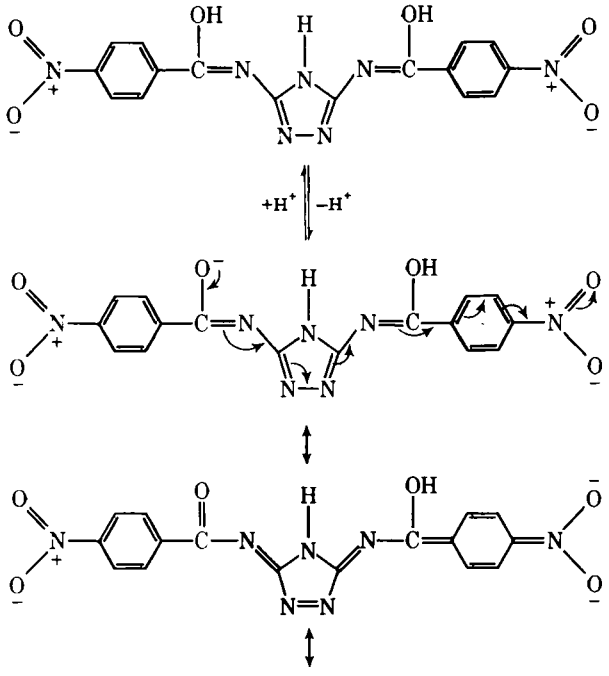
The partition coefficient of salicylic acid was measured utilizing two different procedures:

1. After 2 min of vigorous shaking, the two layers were partitioned for 3–4 hr at 25° in a bottle shaker, and the aqueous layer was centrifuged for 20 min.
2. After 2 min of vigorous shaking, the two layers were centrifuged together for 30–45 min in a centrifuge tube.

The apparent partition coefficients from both methods were identical. However, the pH values, after partitioning from the first and second methods, were 8.90 and 9.20, respectively. Therefore, the true partition coefficient was lower in the first method (4.33 *versus* 4.63). The difference can be attributed to the efficiency of the first method over that of the second in getting clear separation of the aqueous from octanol layer or to the temperature effect that might happen under the longer period of centrifugation in the second method.

Selection of the proper method depends on the compounds being investigated and the volume ratio (42). The first method should be more desirable for a compound that needs a long period of time to reach equilibrium, *i.e.*, phenol (43). For highly ionized compounds, it is advisable to have an efficient separation to minimize any emulsification or clouding of the phases.

In this study, the separation of the two layers with phosphate buffer



etc.

Scheme IV

was more efficient than other systems used under the same experimental conditions. This finding is in agreement with earlier data (12).

Distribution coefficients (D) of ionizable compounds have been used in structure–activity correlations (43). From the mathematical formula for D, it can be shown that D is the same as the apparent partition coefficient:

$$D = AH_1/(AH_w + A^-)$$

$$(P_{app} = C_o/C_w = AH_1/(AH_w + A^-)$$

$$D/(1 - \alpha) = AH_1/(AH_w + A^-)(1 - \alpha) = AH_1/AH_w = P_{corr}$$

where α = degree of ionization = $A^-/(AH_w + A^-)$. AH_1 and AH_w and the free acid concentration in the lipid and the water layer, respectively, and A^- is the concentration of the anion in the water layer.

Heterogeneity of Biochemical Actions among Vasodilators

FORREST C. GREENSLADE, CYNTHIA K. SCOTT ˣ, KATHRYN L. NEWQUIST, KATHRYN M. KRIDER, and MARK CHASIN

Received December 22,1980, from the *Division of Biochemical Research, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication May 14, 1981.

Abstract □ Thirty-four vasodilators were screened in several *in vitro* biochemical assays related to smooth muscle excitation–contraction coupling, binding to β_1^-, β_2^-, and α-adrenergic receptors, inhibition of phosphodiesterase activity, and antagonism of calcium accumulation. Isoproterenol and perhexiline only exhibited binding to β-adrenergic sites. Ergocryptine, tolazoline, and amotriphene only bound to α-adrenergic receptors. Leniquinsin, papaverine, proquazone, dioxyline, hoquizil, quazodine, and theophylline were active only as phosphodiesterase inhibitors. Isoxsuprine, nylidrin, and bencyclane bound to α- and β-receptors. Pentoxifylline bound to β_1-sites and inhibited phosphodiesterase. Cyclandelate bound to β_2-sites and blocked calcium accumulation. Cinnarizine and flunarizine antagonized calcium accumulation and bound to α-sites. Prazosin bound to α-sites and inhibited phosphodiesterase. Ethaverine and dipyridamole were inhibitors of phosphodiesterase and calcium accumulation. Nafronyl bound to β_2- and α-sites and antagonized calcium accumulation. Mebeverine bound to β_2- and α-receptors and inhibited phosphodiesterase activity and calcium accumulation. Verapamil bound to α-sites, and blocked phosphodiesterase and calcium accumulation. Quinazosin bound to β_2- and α-receptors and antagonized both phosphodiesterase activity and calcium accumulation. Vasodilators that were inactive in all assays included niacin, nicotinyl alcohol, inositol nicotinate, amyl nitrite, sodium nitroprusside, diazoxide, hydralazine, and protoveratrine. Vasodilators should not be considered as a single drug class since they act on various mechanisms related to coupling of neuronal excitation to muscular contractility.

Keyphrases □ Vasodilators—biochemical mechanisms □ Adrenergic receptors—α, β_1, and β_2, effect of various vasodilators □ Calcium—effect of various vasodilators on intracellular accumulation, red blood cells □ Phosphodiesterase—inhibition by various vasodilators

The treatment of cardiovascular diseases such as hypertension (1, 2), angina pectoris, cardiac failure (3, 4), and certain peripheral vascular diseases (1, 5, 6) utilizes drugs that produce vasodilation. Vasodilation results from an increase in the internal diameter of blood vessels, presumably through relaxation of vascular smooth muscle. Significant progress has been made in elucidating the biochemical mechanisms controlling smooth muscle contractility. Molecular events in that process include the interaction of catecholamines with specific adrenergic receptors of the smooth muscle cell membrane, the activities of enzymes that regulate cellular levels of cyclic AMP, the control of cellular calcium-ion transport and storage, and the interaction of calcium with the contractile proteins of the smooth muscle cell (7–9).

By using this concept of excitation–contraction coupling in smooth muscle as a working hypothesis, the mechanism of action of various vasodilators has been studied. Thirty-four vasodilators (1, 2, 5, 10, 11) were tested in three types of *in vitro* screening models: (*a*) binding to α- and β-adrenergetic receptor sites, (*b*) inhibition of cyclic AMP phosphodiesterase, and (*c*) inhibition of intracellular calcium accumulation. The results suggest that vasodilator drugs interact with a variety of distinct events in the excitation–contraction coupling mechanisms of vascular smooth muscle.

EXPERIMENTAL

Adrenergic Radioreceptor Assays—*β-Adrenergic Receptor Binding Assays*—Sarcolemma-enriched membranes from guinea pig hearts were prepared as described previously (12). Guinea pigs were killed by cervical dislocation, and the hearts were immediately placed in ice-cold physiological saline. Hearts (20–25 g) were minced in 10 volumes of 2.5 m*M* imidazole buffer (pH 7.4) containing 0.1 m*M* ethylenediaminetetraacetic acid (I) and briefly homogenized with a tissue homogenizer. The homogenate was centrifuged for 1 min at 22×*g*.

The supernatant fraction was rehomogenized and recentrifuged five times. The pooled supernatant fractions were passed through three layers of cheesecloth and centrifuged at 1600×*g* for 20 min. The resulting pellet was resuspended in 200 ml of 10 m*M* [tris(hydroxymethyl)aminomethane hydrochloride] buffer (II), pH 7.5, containing 0.1 *M* sucrose and homogenized using a conical polytef[1]/glass tissue grinder. The homogenate was centrifuged at 1600×*g* for 20 min.

These resuspension, homogenization, and centrifugation steps were then repeated. The pellet was resuspended in 50 ml of 0.4 *M* sucrose in 10 m*M* II (pH 7.5) and osmotically shocked by slow dilution into 1 liter of 0.25 m*M* I in 5 m*M* II (pH 7.0) buffer. The membranes were collected by centrifugation at 1600×*g* for 30 min, and the pellet was suspended in 20 ml of 0.4 *M* sucrose in 10 m*M* II (pH 7.5). The suspension was diluted with three volumes of a 13 m*M* II buffer (pH 7.0) containing 1.3 *M* KCl, 2.6 m*M* I, and 0.4 *M* sucrose. After stirring for ~16 hr at 4°, the extract was diluted with an equal volume of buffer [1 *M* KCl–2 m*M* I–10 m*M* II (pH 7.0)]. After centrifugation at 1600×*g* for 30 min, the pellet was washed three times in 100 ml of 0.1 *M* sucrose in 10 m*M* II (pH 7.0) buffer. The final pellet was suspended in 0.1 *M* sucrose and stored in liquid nitrogen.

Bronchial tree membranes were prepared from either fresh guinea pig lungs or lungs stored at −100°. Bronchial trees were exposed by combing through the lungs several times with a steel animal hairbrush to strip them of alveolar tissue. Extraneous tissue was removed by scraping with a scalpel. The bronchial trees were placed in a small volume of ice-cold II (pH 7.4) containing 1 m*M* $MgCl_2$ and 0.25 *M* sucrose. Then they were finely minced and homogenized by four 10-sec bursts with a tissue homogenizer.

The homogenate was filtered through a single layer of cheesecloth, and the filtrate was centrifuged for 10 min at 400×*g*. The pellet was discarded, and the supernate was centrifuged for 10 min at 20,000×*g*. The resulting pellet was washed in 50 m*M* II (pH 7.5) containing 10 m*M* $MgCl_2$ and centrifuged at 28,000×*g* for 10 min. The pellet was resuspended in 75 m*M*

The homogenate was centrifuged at 1600×*g* for 20 min.

These resuspension, homogenization, and centrifugation steps were then repeated. The pellet was resuspended in 50 ml of 0.4 *M* sucrose in 10 m*M* II (pH 7.5) and osmotically shocked by slow dilution into 1 liter of 0.25 m*M* I in 5 m*M* II (pH 7.0) buffer. The membranes were collected by centrifugation at 1600×*g* for 30 min, and the pellet was suspended in 20 ml of 0.4 *M* sucrose in 10 m*M* II (pH 7.5). The suspension was diluted with three volumes of a 13 m*M* II buffer (pH 7.0) containing 1.3 *M* KCl, 2.6 m*M* I, and 0.4 *M* sucrose. After stirring for ~16 hr at 4°, the extract was diluted with an equal volume of buffer [1 *M* KCl–2 m*M* I–10 m*M* II (pH 7.0)]. After centrifugation at 1600×*g* for 30 min, the pellet was washed three times in 100 ml of 0.1 *M* sucrose in 10 m*M* II (pH 7.0) buffer. The final pellet was suspended in 0.1 *M* sucrose and stored in liquid nitrogen.

Bronchial tree membranes were prepared from either fresh guinea pig lungs or lungs stored at −100°. Bronchial trees were exposed by combing through the lungs several times with a steel animal hairbrush to strip them of alveolar tissue. Extraneous tissue was removed by scraping with a scalpel. The bronchial trees were placed in a small volume of ice-cold II (pH 7.4) containing 1 m*M* $MgCl_2$ and 0.25 *M* sucrose. Then they were finely minced and homogenized by four 10-sec bursts with a tissue homogenizer.

The homogenate was filtered through a single layer of cheesecloth, and the filtrate was centrifuged for 10 min at 400×*g*. The pellet was discarded, and the supernate was centrifuged for 10 min at 20,000×*g*. The resulting pellet was washed in 50 m*M* II (pH 7.5) containing 10 m*M* $MgCl_2$ and centrifuged at 28,000×*g* for 10 min. The pellet was resuspended in 75 m*M*

II (pH 8.1) containing 25 m*M* $MgCl_2$ and collected by centrifugation at 28,000×*g*. The final pellet was suspended in the same buffer and stored in liquid nitrogen.

The β-adrenergic binding assays were conducted according to the method of Mukherjee *et al.* (13). The frozen membrane preparation was thawed and maintained on ice. The incubation mixture contained 25 μl of the test drug, 50 μl of [^{3}H]dihydroalprenolol[1] (40,000 cpm; 9 nmoles), and 100 μl of the membrane preparation. A 15-min incubation at 37° was initiated by the addition of the membrane preparation and vortexing. The incubation was terminated by adding 5 ml of ice-cold 75 m*M* I containing 25 m*M* $MgCl_2$ (pH 8.1) and immediately collecting the membranes on glass fiber filter disks. The membranes were washed five times with 5 ml of the same ice-cold buffer. The filter disks were dried in an oven and counted in a scintillation solution[2]. Along with each set of test compounds, incubations were conducted with 1.5×10^{-4} *M* propranolol. Binding of [^{3}H]dihydroalprenolol at this high concentration of propranolol was considered to represent nonspecific binding to β-adrenergic receptor sites.

α-Adrenergic Receptor Binding Assay—Membranes were prepared from frozen type II mature rabbit uteri according to the method of Willliams *et al.* (14). After thawing, fat was removed and endometrial cells were scraped free with a scalpel. Uteri were sliced, finely minced with scissors in a solution containing 0.25 *M* sucrose, 5 m*M* II (pH 7.4), and 1 m*M* $MgCl_2$, and then homogenized four times. After filtration through cheesecloth, the homogenate was centrifuged at 400×*g* for 10 min. The supernatant liquid was then centrifuged for 10 min at 39,000×*g*. The resulting pellet was homogenized using a polytef/glass tissue grinder in 50 m*M* II (pH 7.4) containing 10 m*M* $MgCl_2$. The resuspended pellet was centrifuged for 10 min at 39,000×*g*, and the resulting pellet was washed with the same buffer. The final pellet was homogenized in the same buffer and used fresh in the binding assay.

The incubation consisted of 25 μl of test drug, 50 μl of [^{3}H]dihydroergocryptine[3] (~40,000 cpm, 2 pmoles), and 100 μl of the membrane preparation. A 15-min incubation, conducted at 25°, was terminated by addition of 5 ml of room temperature 10 m*M* $MgCl_2$ in 50 m*M* II (pH 7.5). Membranes were collected by fiber filtration and washed with 5 ml of the same buffer at room temperature. Phentolamine at 1.5×10^{-4} *M* was used to define nonspecific binding to the membranes.

Phosphodiesterase Assay—Phosphodiesterase was prepared from rat brain or Cynomolgus monkey abdominal artery by the method of Chasin and Harris (15). Tissues were homogenized in 5–10 volumes of 0.05 *M* II (pH 7.5), and the homogenates were centrifuged for 20 min at 39,000×*g*. The supernate was adjusted to 50% saturation by slow addition of an equal volume of neutral, saturated ammonium sulfate. The precipitate was allowed to form for 1 hr in an ice bath and was collected by centrifugation at 39,000×*g* for 20 min. The precipitate was dissolved in a minimum volume of 0.05 *M* II (pH 7.5) and dialyzed overnight against 20 volumes of the same buffer. The enzyme preparation was stored at 4°.

The enzyme inhibition assay was conducted in plastic scintillation vials. A small drop was produced in the bottom of the vial, which contained 50 μl of II, 50 μl of the [^{3}H]cyclic AMP substrate solution, 50 μl of test drug, and 50 μl of diluted enzyme preparation in 1 mg of bovine serum albumin and 1 mg of snake venom nucleotidase/ml of 0.05*M* II buffer at pH 8.0. The vials were incubated for 10 min at 37° with vigorous shaking. The reaction was terminated by the addition of 0.5 ml of washed anion-exchange resin (200–400 mesh, 50% settled volume).

The phosphodiesterase activity was measured as [^{3}H]adenosine using a modified Bray's scintillation cocktail.

Calcium Transport Assay—The assay for inhibition of calcium accumulation was conducted as described by Scott *et al.* (16). Blood was obtained in heparin from healthy human volunteers, and the red blood

cells were collected by centrifugation at 270×*g*. The cells were washed four times and resuspended in 10 m*M* II (pH 7.3) containing 135 m*M* NaCl, 4.5 m*M* KCl, and 15 m*M* chlorine chloride (III). The cells (400 μl packed red blood cells), 10 μl of test drug solution, and 490 μl of III were preincubated in 12 × 75-mm plastic tubes at 24° for 1 hr. A 100-μl solution of [^{45}Ca]calcium chloride[4] (~1 × 10^6 cpm, specific activity 9.85 mCi/mg) was added, and the tubes were incubated with moderate shaking for 30 min at 37°.

The incubation was terminated by addition of 2 ml of 0.1 m*M* lanthanum chloride in III. Tubes were centrifuged at 270×*g* for 10 min, and the supernate was removed. The cells were washed in 2 ml of buffer and recentrifuged, and the supernate was again removed. Each tube was vortexed, and 200 μl was transferred to a glass scintillation vial. A 200-μl aliquot of 60% perchloric acid was added, the vials were shaken, and then 400 μl of 50% hydrogen peroxide was added with shaking. The vials were heated to 70–80° for 30 min. After cooling, 8 ml of ethylene glycol monomethyl ether was added to each vial, followed by 10 ml of a toluene-phosphor solution (6g of 2,5-diphenyloxazole/liter of scintillation grade toluene). Radioactivity was measured by liquid scintillation spectroscopy.

Drugs—Drugs used as standards in these assays included niacin[5], pentoxifylline[6], dipyridamole[7], amiquinsin[8], leniquinsin[8], dioxyline[9], protoveratrine[9], amylnitrite[9], nicotinyl alcohol[10], sodium nitroprusside[10], cyclandelate[11], cinnarizine[12], flunarizine[12], verapamil[13], nafronyl[14], quazodine[15], ethaverine[16], prazosin[17], quinazosin[17], hoquizil[17], mebeverine[18], diazoxide[19], etazolate hydrochloride[20], phenoxybenzamine[21], bencyclane[22], papaverine[23], nylidrin[23], and amotriphene[24]. Other drugs were obtained commercially.

Drugs were dissolved immediately prior to assay in distilled water, using dimethyl sulfoxide or dimethylformamide as solubilization aids if necessary.

RESULTS

Table I shows the compounds that exhibited binding only to β-adrenergic receptors. Two control compounds were run as assay validation standards. In the competition assays using guinea pig heart and lung membranes and [^{3}H]dihydroalprenolol as the radioligand, the nonselective β-adrenergic antagonist propranolol had high binding affinity. The cardioselective β-blocker atenolol had lower affinity for sites on both heart and lung membranes than did propranolol, the affinity being higher for heart membrane binding sites than for lung membrane sites. The binding sites on guinea pig heart and lung membranes labeled by [^{3}H]-dihydroalprenolol have been characterized as β_1- and β_2-adrenergic, respectively (17).

Two vasodilators exhibited binding affinity for β-adrenergic receptors. Isoproterenol had the highest affinity for both β_1- and β_2-receptors. Perhexiline had lower affinity. Neither compound showed measurable affinity for α-adrenergic receptors. The compounds did not inhibit cyclic AMP phosphodiesterase activity, nor did they block Ca^{2+} accumulation.

Table II shows the vasodilator compounds that bound only to α-adrenergic binding sites. The standard α-antagonist phentolamine had high affinity, and phenoxybenzamine also bound to α-sites. In addition, phenoxybenzamine inhibited the accumulation of calcium 45 into erythrocytes. Ergocryptine and tolazoline also had relatively high affinity for α-adrenergic receptors, while amotriphene exhibited marginal affinity. The three compounds were inactive in the other assays.

Table III lists the active compounds in the phosphodiesterase inhibition assay. The potent phosphodiesterase inhibitor etazolate hydrochloride served as a control standard. Leniquinsin was the most potent of the vasodilators tested with rat brain phosphodiesterase. Papaverine, proquazone, and dioxyline were slightly less potent. Hoquizil and quazodine were less potent, and theophylline was the least potent of the active agents tested. All active compounds tested inhibited phosphodiesterase activity in Cynomolgus monkey abdominal artery. This group of vasodilators was inactive in all other assays.

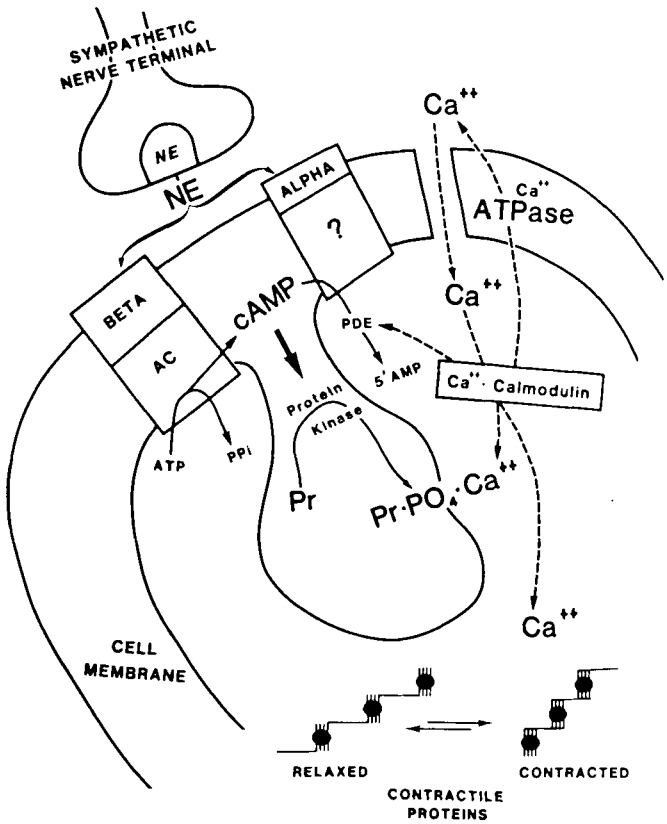

Figure 1—*Possible mechanisms of vascular smooth muscle excitation–contraction coupling.*

Thirteen vasodilators tested were active in more than one assay (Table IV). Isoxyprine, nylidrin, and bencyclane bound to β_1-, β_2-, and α-adrenergic receptors. Pentoxifylline had a low level of affinity for β_1-receptors, and it also inhibited phosphodiesterase activity. Cyclandelate bound to β_2-adrenergic receptors and inhibited accumulation of calcium.

Two compounds, cinnarizine and flunarizine, inhibited accumulation of calcium 45 ion in human red blood cells. Both compounds exhibited some affinity for α-sites. As previously reported (18, 19), prazosin bound to α-receptors. Ethaverine and dipyridamole were phosphodiesterase inhibitors and also inhibited calcium 45 ion accumulation.

Nafronyl was active in three assays. It had low binding affinity for β_2- and α-receptors and inhibited calcium accumulation. Mebeverine also bound to β_2- and α-receptors and inhibited phosphodiesterase activity. Verapamil bound to α-receptors and inhibited both phosphodiesterase activity and calcium 45 ion accumulation.

One compound, quinazosin, was active in four of the five assays. Quinazosin bound to β_2- and α-receptors. It also inhibited phosphodiesterase activity and calcium 45 ion accumulation.

Niacin, nicotinyl alcohol, inositol niacinate, amyl nitrite, sodium nitroprusside, diazoxide, hydralazine, and protoveratrine were inactive in all five assays at the highest concentration listed (150 μ*M*).

DISCUSSION

Vasodilation results from relaxation of vascular smooth muscle and leads to enhanced blood flow and/or reduced peripheral resistance (4, 20). Pharmacologically, vasodilators have been classed in two groups. One group acts indirectly on sympathetic innervation to the arterioles, thereby relieving functional vasoconstriction, and the other acts directly on the smooth muscle of the arterioles. Drugs classically categorized as sympathetic depressants include centrally acting agents such as the dihy-

droergot alkaloids, ganglionic blocking drugs (e.g., pentolinium and mecamylamine), and agents such as guanethidine, which block norepinephrine release at neuroeffector junctions. Drugs categorized as acting on smooth muscle include β-adrenergic stimulating agents such as isoproterenol, isoxsuprine, and nylidrin and α-adrenergic blocking agents such as phenoxybenzamine and tolazoline. Other direct acting vasodilators presumably act on contractile mechanisms of the smooth muscle cell (5).

The biochemical mechanisms that underlie the coupling of sympathetic nervous excitation and smooth muscle contractility are beginning to be understood. Figure 1 shows an hypothesized pathway involving a complex series of biochemical events (7, 8, 21–23), by which adrenergic neurotransmitters regulate smooth muscle contractility. With respect to vasodilation, the following pathway is proposed:

1. Norepinephrine binds to specific β-adrenergic sites on the muscle cell surface.
2. The increased activity of a closely coupled enzyme, adenylate cyclase, elevates cellular cyclic AMP levels.
3. The cellular content of cyclic AMP regulates the activity of a second enzyme, cyclic AMP-dependent protein kinase, which functions to phosphorylate (and thus activates) certain proteins in the sarcoplasmic reticulum. The activated proteins in the sarcoplasmic reticulum control the storage and release of Ca^{2+} ions, which ultimately regulate the contraction of the actin–myosin fibrils of the muscle cell.
4. The heat-stable protein calmodulin binds calcium and activates phosphodiesterase to return cellular cyclic AMP levels back to normal. Simultaneously, calmodulin activates the calcium-stimulated ATP phosphohydrolase (the so-called calcium pump) to return intracellular levels of calcium to baseline levels.

The biochemical events elicited by stimulating α-adrenergic sites are less well understood. Three hypotheses have been proposed:

1. α-Receptor stimulation may inhibit adenylate cyclase or stimulate cyclic AMP phosphodiesterase activity, leading to a decrease in cellular cyclic AMP levels.
2. α-Receptor stimulation causes increased guanylate cyclase activities and increased cyclic GMP levels, leading to physiological actions opposing cyclic AMP.
3. α-Receptors function as calcium ionophores, resulting in increased Ca^{2+} influx.

Most of the vasodilators tested were active in one or more of the assays and thus might be expected to act at some specific point in the described excitation-contraction coupling pathways for vascular smooth muscle. The compounds that were inactive in these assays may act on related mechanisms. For example, papaverine, nitroglycerin, diazoxide, and hydralazine all increased the cyclic AMP content in vascular smooth muscle (24). Furthermore, Chidsey and Gottlieb (20) reviewed studies that suggested that certain vasodilators (diazoxide, minoxidil, and sodium nitroprusside) interfere with some calcium movements responsible for initiation or maintenance of contractile state. These vasodilators might alter the availability of calcium ion to contractile proteins through compartmentalization rather than modification of cellular content.

Several vasodilators exhibit multiple activities. Nylidrin and isoxsuprine, vasodilators classically described as β-adrenergic stimulants, showed affinity for β-receptors. However, these compounds also exhibited affinities for α-receptors. The multiple activities of these drugs is consistent with earlier work (25), which showed that isoxsuprine relaxed a variety of nonvascular smooth muscles through mechanisms independent of β-receptors. These investigators suggested that, in addition to its sympathomimetic action, isoxsuprine may have a papaverine-like, direct effect as well as an adrenergic blocking action. Although radioreceptor assays do not distinguish between agonists and antagonists, these results suggest that this compound more likely acts by blocking α-adrenergic receptors than by inhibiting phosphodiesterase activity. Furthermore, work reviewed by Coffman (6) indicated that the effects of isoxsuprine and nylidrin are not completely antagonized by β-adrenergic blocking agents.

Previous findings (18) indicate that prazosin interacts with both the active site of phosphodiesterase and with α-receptors (18). Subsequent data suggest that prazosin binds to two different populations of binding sites, possibly relating to pre- and postsynaptic α-receptors (19).

The α-blocking agent phenoxybenzamine also was found to be an inhibitor of Ca^{2+} accumulation. The acknowledged calcium antagonist verapamil (26) also exhibited affinity for α-receptors, as well as phosphodiesterase inhibition. The finding that several vasodilators exhibited activity in two of three assays (α-receptor, phosphodiesterase inhibition, and calcium accumulation) suggests a close relationship of three biochemical steps. On the other hand, the finding that some vasodilators were only active in one of these three assays supports the contention that these are closely related but independent mechanisms.

The mechanisms closest to the control of contractile protein function evidently involve the transport, storage, and cellular content of calcium ion. Cinnarizine and flunarizine, for example, inhibit accumulation of calcium ion in human red blood cells (18) and have been reported to produce long-lasting inhibition of calcium-induced contraction in isolated vascular preparations of rat and rabbit (11). Other vasodilators such as papaverine, nafronyl, bencyclane, cyclandelate, dihydroergotamine, xanthinol niacinate, and pentoxifylline were reported by the same investigators to be less potent as inhibitors of Ca^{2+}-induced vasospasms. In this regard, flunarizine appears to possess a degree of selectivity in that (in contrast to the majority of reports) it had little effect on spontaneous myogenic activity (11). Flunarizine also prevents blood hyperviscosity induced by ischemic occlusion (26, 27), an effect apparently related to changes in red blood cell flexibility (28). This drug's vasodilator activity and its effects on red blood cell deformability both probably result from inhibition of Ca^{2+} accumulation (16).

With respect to vasodilation, drug actions in the smooth muscle cell resulting in reduced Ca^{2+} available for interaction with the troponin–actin–myosin complex lead to relaxation of the muscle and dilation of the blood vessel.

The biochemical screening models used in this study were predicted on our working hypothesis and were established to ascertain whether vasodilator drugs might have their effects on specific points in these pathways. Several vasodilators previously were shown to act through cyclic AMP-related mechanisms. Papaverine, for example, is a well-

accepted model compound of a vasodilator acting through cyclic AMP phosphodiesterase inhibition (29, 30), and isoproterenol has been shown to elevate cyclic AMP levels through stimulation of adenylate cyclase. It is clear that elevated intracellular cyclic AMP levels can lead to vasodilation and that compounds that interact with either the α-adrenergic receptor or cyclic AMP phosphodiesterase may be potential vasodilators.

The presence of calcium is a necessary component of smooth muscle contraction. Several workers showed that agents that normally contract vascular smooth muscle *in vitro* cannot cause contraction when calcium is omitted from the incubation or when calcium accumulation into the tissue is blocked. Therefore, agents capable of inhibiting calcium accumulation (*e.g.* flunarizine) may act by preventing vasoconstriction and result in a net vasodilation *in vivo* (31).

It is not certain how directly the results using biochemical screening models can be extrapolated to *in vivo* conditions involving vascular smooth muscle. However, several general findings provide a basis for further experimentation and future working hypotheses.

Vasodilators must be considered a heterogeneous drug class. For example, from a therapeutic point of view, vasodilators used in the treatment of hypertension and peripheral vascular disease require different pharmacological properties. In the treatment of peripheral vascular disease, reduction of blood pressure is undesirable, whereas it is obviously a criterion for vasodilators used in hypertension (1). The optimal requirements for peripheral and cerebral vasodilators may also differ.

The actions of vasodilators clearly involve heterogeneous physiological and biochemical mechanisms related to smooth muscle contractility. It is proposed that both the therapeutic utility and side-effect pattern of a vasodilator will depend on the specific profile of the excitation–contraction coupling mechanisms altered by the drug. Additional research on this series of drugs and on future compounds will provide more specific criteria for classifying vasodilator drugs.

Liposome Disposition *In Vivo* II: Dose Dependency

MARK E. BOSWORTH and C. ANTHONY HUNT ˣ

Received August 28, 1980, from the *School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication May 18, 1981.

Abstract □ The dose-dependent disposition of extruded multilamellar (diameter ~1 μm) negatively charged liposomes containing entrapped [^{14}C]inulin was studied in mice. Mice received 1500, 300, or 15 μmoles of liposomal lipid/kg iv. Carbon 14 levels were measured in the blood, liver, spleen, and carcass for 72 hr. A pronounced saturation effect, consistent with the known dose behavior of other colloids, was seen at early times; it was manifested by higher dose values in the blood and spleen but by lower liver values as the dose increased. This dose effect was attenuated in the liver but was maintained in the spleen at later times, and percent dose values approached plateau values in all tissues for all doses at later times. [^{14}C]Inulin was used as the liposomal marker because of its inability to enter cells (or, presumably, leave them if delivered there by liposomes) in its free form. An early decline in carbon 14 levels (over the first 48 hr) was seen in the liver for the low and medium doses. Because of the known ability of blood factors to cause liposomes to leak their contents, this decline was interpreted as being a loss of [^{14}C]inulin from extracellularly bound liposomes during this period. Moreover, the plateau carbon 14 levels at later times were interpreted as approximating the true level of intracellular inulin delivery by the liposomes.

accepted model compound of a vasodilator acting through cyclic AMP phosphodiesterase inhibition (29, 30), and isoproterenol has been shown to elevate cyclic AMP levels through stimulation of adenylate cyclase. It is clear that elevated intracellular cyclic AMP levels can lead to vasodilation and that compounds that interact with either the α-adrenergic receptor or cyclic AMP phosphodiesterase may be potential vasodilators.

The presence of calcium is a necessary component of smooth muscle contraction. Several workers showed that agents that normally contract vascular smooth muscle *in vitro* cannot cause contraction when calcium is omitted from the incubation or when calcium accumulation into the tissue is blocked. Therefore, agents capable of inhibiting calcium accumulation (*e.g.* flunarizine) may act by preventing vasoconstriction and result in a net vasodilation *in vivo* (31).

It is not certain how directly the results using biochemical screening models can be extrapolated to *in vivo* conditions involving vascular smooth muscle. However, several general findings provide a basis for further experimentation and future working hypotheses.

Vasodilators must be considered a heterogeneous drug class. For example, from a therapeutic point of view, vasodilators used in the treatment of hypertension and peripheral vascular disease require different pharmacological properties. In the treatment of peripheral vascular disease, reduction of blood pressure is undesirable, whereas it is obviously a criterion for vasodilators used in hypertension (1). The optimal requirements for peripheral and cerebral vasodilators may also differ.

The actions of vasodilators clearly involve heterogeneous physiological and biochemical mechanisms related to smooth muscle contractility. It is proposed that both the therapeutic utility and side-effect pattern of a vasodilator will depend on the specific profile of the excitation–contraction coupling mechanisms altered by the drug. Additional research on this series of drugs and on future compounds will provide more specific criteria for classifying vasodilator drugs.

Liposome Disposition *In Vivo* II: Dose Dependency

MARK E. BOSWORTH and C. ANTHONY HUNT ˣ

Received August 28, 1980, from the *School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication May 18, 1981.

Abstract □ The dose-dependent disposition of extruded multilamellar (diameter ~1 μm) negatively charged liposomes containing entrapped [^{14}C]inulin was studied in mice. Mice received 1500, 300, or 15 μmoles of liposomal lipid/kg iv. Carbon 14 levels were measured in the blood, liver, spleen, and carcass for 72 hr. A pronounced saturation effect, consistent with the known dose behavior of other colloids, was seen at early times; it was manifested by higher dose values in the blood and spleen but by lower liver values as the dose increased. This dose effect was attenuated in the liver but was maintained in the spleen at later times, and percent dose values approached plateau values in all tissues for all doses at later times. [^{14}C]Inulin was used as the liposomal marker because of its inability to enter cells (or, presumably, leave them if delivered there by liposomes) in its free form. An early decline in carbon 14 levels (over the first 48 hr) was seen in the liver for the low and medium doses. Because of the known ability of blood factors to cause liposomes to leak their contents, this decline was interpreted as being a loss of [^{14}C]inulin from extracellularly bound liposomes during this period. Moreover, the plateau carbon 14 levels at later times were interpreted as approximating the true level of intracellular inulin delivery by the liposomes.

Recently, there has been considerable interest in liposomes (phospholipid vesicles) as an *in vivo* drug delivery system. There are now ample data showing that liposome encapsulation can drastically alter the blood kinetics and tissue distribution of numerous compounds. Their potential uses in drug therapy, which were recently reviewed

0022-3549/82/0100-0100$01.00/0

(1, 2), are a direct result of these kinetic properties.

BACKGROUND

When the fate of intravenously administered liposomes is followed (*e.g., via* an entrapped aqueous space marker), the marker (and presumably the liposomes) accumulate to a significant extent in organs that contain cells of the reticuloendothelial system. This accumulation occurs principally in the liver and spleen where, depending on the liposome type, animal species, and postadministration time, up to 90% of the injected dose of the marker may be found.

The significance of this reticuloendothelial localization was noted by other investigators (3). The reticuloendothelial system is a diffuse system with cells positioned along the vasculature in the liver, spleen, and bone marrow, in the lung alveoli, and in the tissue interstices. One of its functions is to phagocytize colloidal and particulate material such as effete red blood cells, denatured proteins, cellular debris, foreign organisms, and exogenously administered substances such as colloidal carbon or gold (the term "colloid" can arbitrarily encompass suspensions with particle sizes ranging from 10 Å to several microns).

An extensive literature exists on the *in vivo* fate of these "inert" colloids (e.g., carbon and gold) (4). After intravenous administration, they are taken up primarily by reticuloendothelial cells in the liver and spleen by a two-step process, first involving binding to the cell and then phagocytosis; the latter step is presumed to take place quickly after the binding (5). In fact, this assumption is made whenever the blood disappearance rate of one of these colloids is used as a general indicator of reticuloendothelial system function (4). This dose-dependent process exhibits saturability in two respects. First, as the dose (*i.e.*, number of particles) is increased, the rate of colloid removal from the blood is decreased (6). Second, the tissue distribution changes with the dose (5). At very low, nonsaturating doses, for which blood flow to the reticuloendothelial tissues is the rate-limiting factor in the removal of the colloid from the blood, 95% or more of the colloid dose is taken up by the liver and the rest by the spleen. As the dose increases, the spleen takes up an increasingly larger fraction of the dose due to the saturation of the liver uptake. At extremely high doses, the lung and bone marrow can take up significant fractions also, in what amounts to a system-wide mobilization in response to a saturating dose (7).

Because liposomes are colloidal, and because of their well-documented reticuloendothelial system localization, it is reasonable to expect them to behave similarly to other colloids. The present study examined the possible dose dependency of liposome blood kinetics and tissue distribution. Other researchers reported limited evidence that suggests that liposome disposition may be dose dependent (8–10). The possibility of a time dependence in the dose effect was examined in the present study by following blood and tissue levels for 72 hr. An appropriate liposome marker, [^{14}C]inulin, was used to assess the extent to which the liposomes delivered their entrapped contents intracellularly.

EXPERIMENTAL

Chemicals—Purified egg yolk lecithin, sodium dipalmitoyl phosphatidate, cholesterol, and α-tocopherol (vitamin E) were chromatographic grade[1]. [Carboxy-^{14}C]inulin[2] was 2.3 μCi/mg, and scintillation reagents[3,4] were used. All other chemicals were analytical reagent grade or better. Phosphate-buffered saline (I) contained 92 m*M* sodium chloride, 23 m*M* dibasic sodium phosphate, and 11 m*M* monobasic sodium phosphate. Prior to use, phosphatidic acid was obtained by chloroform extraction of a solution of sodium phosphatidate in 0.4 *N* HCl with 20% methanol.

Preparation of Liposomes—Liposomes were prepared essentially as previously described (10) and were composed of egg lecithin, phosphatidic acid, cholesterol, and α-tocopherol in the molar ratios 4:1:1:0.05. The lipids were dissolved in chloroform, mixed in a round-bottom flask, and subsequently evaporated to dryness under vacuum. The buffer (I) containing 5 m*M* [^{14}C]inulin was added to the dried lipid to give a concentration of 37.5 μmoles of lipid/ml and then was agitated by hand (at room temperature after nitrogen sparging) until all of the lipid was suspended. This suspension was then placed in a 25-mm stirred ultrafiltration cell[5] fitted with a 1.0-μm pore size polycarbonate membrane[6] and extruded twice at a flow rate of ~10 ml/min, controlled by nitrogen pressure.

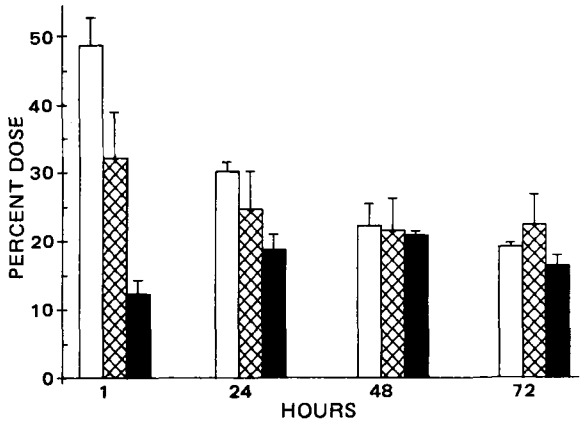

Figure 1—*Percent of injected carbon 14 dose in the liver for low (□), medium (▨), and high (■) doses at four times [mean ± 1* SD (n = *3, 10, and 4 for low, medium, and high doses, respectively)]. Equality of low and high doses was tested, and the differences between doses were statistically significant at 1 and 24 hr but not at 48 and 72 hr (one-tailed unpaired* t *test, α 0.05).*

Liposomes for the high dose were concentrated by adding 0.3 ml of 50% (w/v) sucrose to 1.1 ml of liposomes, centrifuging at 12,000 × *g* for 15 min, removing the upper concentrated liposome layer, and resuspending it in I to give a final concentration of 112.5 μmoles of lipid/ml. Liposomes were dialyzed overnight at 5° against I in dialysis cells fitted with 0.8-μm pore size membranes[6] to remove nonentrapped inulin and to improve the size distribution by removing the smallest liposomes (11). At least 10 buffer changes were done for each cell during the dialysis.

Tissue Distribution Studies—Liposomes were taken off dialysis and kept at 5° throughout the injection period. Male ICR mice, 18–24 g, were injected with 37.5, 7.5, or 0.375 μmoles of lipid/mouse (high, medium, and low doses, respectively) intravenously *via* the tail vein with 0.25–0.35-ml injection volumes. Mice receiving imperfect injections were not used. To determine the percentage of free inulin in each dose, a sample was applied to a 5 × 120-mm column of Sephadex[7] G-200-120 equilibrated and subsequently eluted with I; the eluate fractions were analyzed by scintillation counting, and the percent of inulin entrapped was calculated based on the carbon 14 recovered in the void volume and free inulin fractions.

Mice were anesthetized with ether at 1, 24, 48, or 72 hr after injection, and ~0.5–1.0 ml of blood was quickly removed from the jugular vein with a heparinized syringe. The mice were then sacrificed; the livers, spleens (and, in some instances, the brain, kidneys, and lungs) were removed and frozen for later analysis. In some cases, an aliquot of the blood was cen-

Table I—Data [a] for Various Organs at 1 hr after Liposome Doses

Dose	Blood Levels, percent dose/ 1.0 ml (Ref.)	Percent Entrapped in Blood	Lungs	Kidneys	Brain
Low	0.39 ± 0.1 (3)	[b]	0.09	—	—
Medium	1.1 ± 0.71 (9)	10.1 ± 2.0 (3)	0.23 ± 0.04 (4)	0.825 ± 0.28 (4)	0.095, 0.18
High	10.4 ± 1.1 (4)	93, 95	0.75, 0.97	—	—

[a] Percent dose: mean ± 1 *SD* (*n*), or individual values where $n \leq 2$. [b] Blood values were too low to measure.

trifuged and a plasma sample was applied to a Sephadex column as described previously to determine the percent entrapped.

Tissue Analysis for Total Radioactivity—Duplicate aliquots of liver (0.14–0.24 g), spleen (0.04–0.08 g), whole blood (0.2 ml), and the radiolabeled liposome dose (0.05 ml) were transferred to preweighed combustion cups, which were reweighed and then allowed to air dry. The remaining carcass was placed in a container with 75 ml of water and homogenized using a wet milling device[8]. Duplicate samples of the resulting slurry (1.3–2.0 g) were weighed into combustion cups and allowed to air dry for 24 hr. Dried samples were analyzed for total carbon 14 by scintillation counting following combustion in a sample oxidizer[9].

Combustions were carried out in series, samples alternating with empty combustion cups or combustion cups containing a known amount of [^{14}C]inulin. Counts per minute were subsequently corrected for variations in quench by use of a quench curve. Results for duplicate samples were averaged, and the total radioactivity in the liver, spleen, carcass, and 1.0 ml of blood was calculated and converted to percent dose. Analysis of experimental samples and control samples of known radioactivity showed that the duplicate determinations were consistently within 5% of their mean.

***In Vivo* Clearance of Free Inulin**—In a separate study, similar doses of [^{14}C]inulin in identical volumes of I were administered to mice, which were subsequently sacrificed and analyzed as described to determine the *in vivo* clearance of free inulin.

RESULTS

Free inulin was cleared rapidly by the kidney. Its half-life in blood after intravenous injection was 10–15 min, with 0.5% of the dose remaining in blood, 2.5% in the liver, and 0.15% in the spleen at 1 hr. Carcass values at 1 hr averaged 6.9%, due presumably to residual inulin in the bladder; this value was minimized by urine removal from the bladder prior to freezing the carcass. The 24-hr value for the carcass was <1%. Thus, the presence of free inulin after the liposome doses may have contributed slightly to the 1-hr carcass data but was negligible at later times and in all other tissues.

Table I shows the 1-hr carbon 14 levels for various organs and blood, as well as the percent entrapped in blood, following the liposome doses.

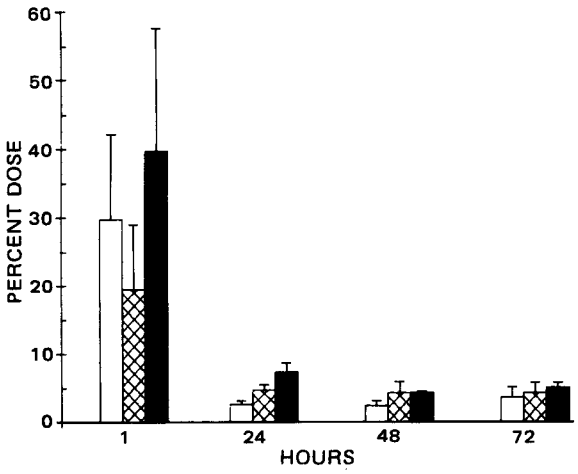

Figure 3—*Percent of injected carbon 14 dose in the carcass. Significant differences between doses were found at 24 and 48 hr but not at 1 and 72 hr (symbols and other details as in Fig. 1).*

[8] Brunwell Scientific, Rochester, N.Y.
[9] Packard Instrument Co., Downer's Grove, Ill.

Blood values, expressed as percent dose per 1.0 ml, exhibited a definite dose dependency; the values at 24, 48, and 72 hr were identical to background in all cases. Lung, brain, and kidney levels, done only in limited cases as controls, were negligible.

The other principal tissues of interest are the liver, spleen, and carcass. Figure 1 shows the results for the liver; a definite dose effect, seen as higher relative levels for the lower doses, is shown at the 1-hr time point. This effect completely diminished by 72 hr, and a similar plateau was approached by all three doses. The spleen results (Fig. 2) also showed a dose dependency but one that differed from that in the liver; the effect was maintained over the 72 hr, and higher relative levels were seen as the dose was increased. The carcass results (Fig. 3), show evidence of a dose effect at later time, which was significant at the 24- and 48-hr time points; the levels fell rapidly after 1 hr and reached a plateau. Figure 4 shows the results for the totals *in vivo*; here there is no evidence for a dose effect, and all values approach a similar plateau[10].

The reproducibility of the radioactivity measurements was also assessed. The average percent difference between duplicate samples was 6.07%, with a standard deviation of 4.23%.

DISCUSSION

The results can best be evaluated by comparison with the results one would expect for inert colloids and for liposomes (based on certain preconceived notions). Figure 5 depicts these expected dose study results. Curves A and B are plots of percent of injected dose found in all reticuloendothelial tissues *versus* time for low and high doses, respectively, of a colloid such as gold. The delayed uptake for the higher dose reflects the saturation phenomenon already mentioned. In both cases, however, all of the dose is eventually found in reticuloendothelial tissues.

The liposome case is different for two important reasons. First, it is now well known that certain factors in blood can destabilize liposomes with respect to the leaking out of their entrapped contents (13, 14). When this "leakiness" effect occurs, a significant portion of the entrapped

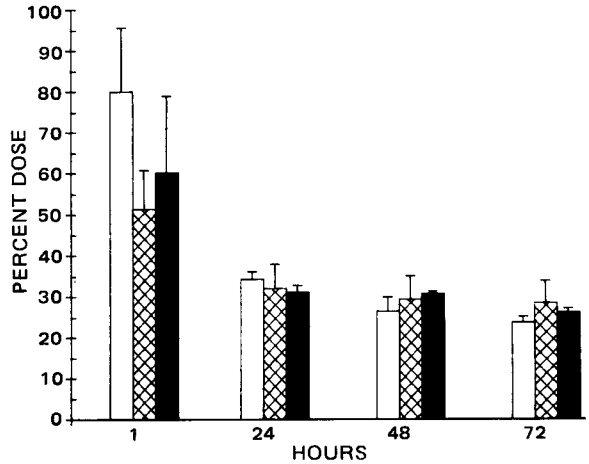

Figure 4—*Percent of injected carbon 14 dose found* in vivo *at four times. No evidence for a dose effect was seen here (symbols and other details as in Fig. 1).*

[10] In a subsequent series of studies, the mole fraction of cholesterol in the liposomes was increased to 50%, which results in liposomes with substantially increased stability in plasma (12). Following the same protocol used here and using liposome of the same size and dose, the total percent dose *in vivo* at 1 hr was 105 (*SD* ± 13%, $n = 5$); eventual plateau levels in liver and spleen were approached more slowly than in these studies.

marker can be released quickly into the blood, resulting in a <100% distribution of the marker to reticuloendothelial tissues.

The second reason is more important as far as evaluating liposome tissue distribution and concerns the nature of the entrapped marker. Most compounds that have been entrapped in liposomes have physical properties that preclude their use as accurate indicators of intracellular delivery by liposomes because these compounds are often capable of entering and leaving the target cells on their own or are metabolized to compounds that can. The resulting situation is depicted in curve E of Fig. 5, in which the tissue levels rise and fall with time due to the exit of the marker. This pattern has, in fact, been almost universally observed when tissue levels have been taken after administration of liposome-entrapped compounds.

The principal disadvantage with such data is that it is impossible to ascertain what fraction of the dose was delivered to the tissue in question. It was felt, however, that these data could be gotten using the appropriate entrapped marker. [^{14}C]Inulin was chosen because its size and polarity prevent it from entering cells on its own (or leaving, if it is delivered there *via* liposomes). It also has simple kinetics and is not metabolized. In short, it is a marker compound that should remain in the tissue to which it is delivered. The result should be tissue levels that reach plateaus at later times but, because of the leakiness effect, approach values of <100%. This situation is depicted for two different doses in curves C and D of Fig. 5.

The results of this study lead to several general conclusions. In all of the principal tissues studied (liver, spleen, carcass, totals *in vivo*) and for all doses, the levels approach plateaus at later times. This evidence supports the hypothesis that tissue level plateaus would be seen with a marker compound such as inulin; an argument will be presented later as to why these plateaus approximate the true level of intracellular delivery of the inulin by the liposomes. Furthermore, there is a pronounced dose effect at early times that is lost (in the liver) at the later times. This dose effect is consistent with that seen for other colloids such as carbon or gold; *i.e.*, the liposomes are subject to saturation kinetics, manifested by elevated relative blood and spleen levels and depressed relative liver levels as the dose increases.

As is the case for other colloids, the liver is the dominant organ in liposome disposition; because of its large blood flow and high clearance capacity relative to the other vascular reticuloendothelial tissues (*i.e.*, spleen and bone marrow), the extent to which the liver disposition of the liposomes is saturated determines the amount of colloid that is taken up by the other tissues. In other words, a delayed liver uptake results in elevated blood levels over a longer time, allowing the spleen, which is thought to have a higher cellular intrinsic activity for colloid uptake (4), to sequester a large fraction of the injected dose. The carcass values reported here (*i.e.*, everything but blood, liver, and spleen) include the bone marrow, and perhaps the slight dose effect seen in the carcass is due to uptake by the marrow.

These results also raise some intriguing questions. It is obvious that the data for the liver do not fit the predictions as depicted by curves C and D of Fig. 5. Only the high dose data fit the expected pattern of a continuous rise of the tissue levels to the eventual plateau. However, the data for the low and medium doses show a pattern with an early decline in levels followed by the plateau. Such a decline can be accounted for in only two ways.

First, a fraction of the marker that has been delivered to the cells at early times somehow partitions out of the cells at later times. However, the assumption was made earlier that the inulin marker, once delivered inside cells, would not partition out. The second explanation is that the marker levels in the liver at early times are not entirely constituted of intracellular inulin. Since the blood levels at 1 hr are very low for these two doses and since the half-life for removal of free inulin from the blood is very fast, a significant fraction of the inulin in the liver at 1 hour must be located in extracellularly bound liposomes.

It is the hypothesis of the present study that the following events occur in the liver disposition of the liposomes. If one postulates the presence of extracellularly bound liposomes, one must contend with the long-held belief that for colloids, removal from the blood can be considered the equivalent of intracellular uptake (*i.e.*, uptake occurs rapidly after binding). Data are available that show that these two phases of uptake are separable under specialized conditions *in vitro* (15), but only recently has evidence been reported that unambiguously shows that, *in vivo*, a colloid's binding to and uptake into Kuppfer cells can be very distinct events, separated by long periods of time (16, 17). In fact, Kavet and Brain (18), in their recent review on the quantification of endocytosis, emphasized that "... ingestion is not a necessary consequence of attachment. Thus, particles may become cell-associated without being interiorized and unless detected as such may be falsely included with the intracellular compartment."

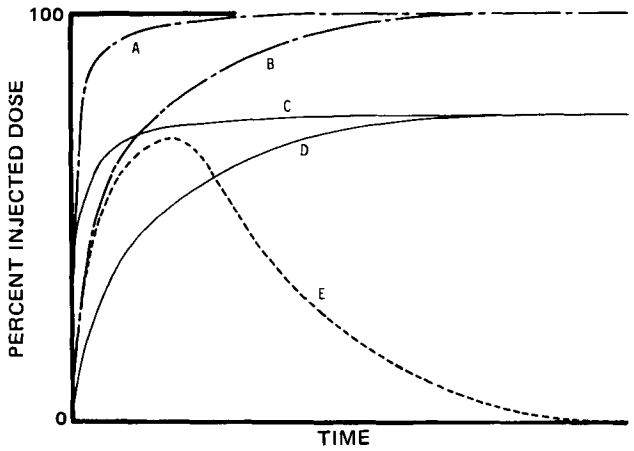

Figure 5—*Expected results for a plot of percent dose in reticuloendothelial time after intravenous administration of two different doses of colloidal gold (curves A and B), two different doses of liposome-entrapped [^{14}C]inulin (curves C and D), or a liposome-entrapped marker that can partition out of cells (curve E). These curves assume that cellular uptake of colloid occurs rapidly after binding to the tissue.*

This fact is crucial in the case of liposomes since it is very likely that extracellularly bound liposomes are just as susceptible to the destabilizing influences of blood as are free-floating liposomes. Thus, what is suggested is that: (a) tissue levels measured after administration of a liposome-entrapped marker may include substantial levels of extracellularly bound, liposome-entrapped marker, even several hours after the dose is given, and (b) these tissue levels may decline because of the slow release of marker from extracellular liposomes due to the destabilizing effect of blood.

One final piece of evidence must be considered, however, to explain completely the disposition of the three doses. Recent evidence suggests that the blood destabilizing effect may itself be saturable (13, 14); *i.e.*, as larger numbers of liposomes are incubated with a given volume of blood, a smaller fraction of the total liposome-entrapped marker is released. The liver data are thus explained as follows. In the low dose case, the liver quickly binds most of the liposome-entrapped insulin dose (part of the inulin is released from the liposomes on the initial mixing of the dose with the blood so that the initial liver value is probably <100% of the dose). However, because the intracellular uptake is slow, the bound liposomes continue to release inulin until they are taken up inside the cells. Thus, what is seen is a decline in liver levels over time until the remaining inulin is entirely intracellular and the plateau is reached[11].

In the high dose case, the initial liver binding is saturated so the relative liver levels (*i.e.*, on a percent dose basis) are low and blood levels are high. Thus, the levels of extracellular liposomes (circulating and bound) remain elevated for longer periods and are exposed to the blood's destabilizing factors longer. However, since this latter system is probably also saturated [it was calculated that the ratio of milligrams of lipid to milliliters of blood is similar to that causing saturation in *in vitro* systems (12)], the liposomes leak their contents at a relatively much slower rate. The net result is that the slowing down of the two processes of uptake (a combination of binding and endocytosis) and blood-induced liposome leakiness are offsetting effects. Thus, at later times the relative amount of inulin taken up inside cells is similar for the two doses (the medium dose is apparently an intermediate effect).

As mentioned previously, the dose behavior of the spleen conforms to the present expectations in that higher relative levels are seen as the dose increases. However, this effect, unlike that in the liver, is still evident at 72 hr. Two factors may be responsible: (*a*) the amount of colloid available to the spleen initially is largely a function of the amount bound by the liver, and (*b*) the actual intracellular uptake may be faster in the spleen so that most of what was initially bound there was also endocytosed. The carbon 14 levels in several other tissues (brain, lungs, and kidneys) were also measured (Table I). However, since the initial experiments indicated

[11] The composition of the liposomes used here was selected because of its intermediate stability in plasma (10, 14). It was conjectured that liposomes without cholesterol would rapidly lose a large fraction of their contents after injection, whereas maximally stable liposomes may result in tissue levels of carbon 14 that decline too slowly to confirm a specific final plateau level.

that very little of the dose could be found in these tissues, they were not analyzed routinely.

The liposomes used were fairly large in size (average size ~1 μm) and had a relatively narrow size distribution. This was accomplished by the use of two techniques in the sizing procedure, extrusion through 1.0-μm pore-size membranes (19) followed by dialysis against 0.8-μm membranes (11). It was felt that the excellent reproducibility seen in the tissue levels (the high dose studies were done on two separate occasions, and the medium dose study on three) was evidence of the liposome batch-to-batch reproducibility that these sizing techniques afford. The lipid composition used in the study was chosen based on *in vitro* liposome–plasma stability studies (14). The object was to choose a composition such that the liposomes were stable enough to retain most of their entrapped contents *in vivo*, yet unstable enough so that if significant long-term extracellular liposome tissue binding did take place, the marker would be released in a reasonable period (~72 hr) and thus would not be included as part of a plateau tissue level value. The decline in liver levels for the low and medium doses took place over the first 24–36 hr, which was fast enough to allow observation of the plateaus by 72 hr.

CONCLUSIONS

The results of this study have several general implications. First, it is obvious that the liposomal dose (or liposome number) is an extremely important determinant of *in vivo* disposition. It is unfortunate that *in vivo* work is still appearing in which the liposome dose is not given and is difficult or impossible to determine from the other details given [the dose in terms of micromoles of lipid/kg of body weight is currently acceptable, but the ideal would be the additional specification of liposome size and number (20)].

Second, the present data suggest that, after administration of a liposome-entrapped marker, a significant fraction of the marker may be located in extracellularly bound liposomes for long periods. Therefore, a general reinterpretation of the significance of tissue levels for most compounds administered in liposomes is needed. Specifically, tissue levels cannot be taken as an indicator of the intracellular delivery of the entrapped compound by the liposomes.

The present data suggest, however, that tissue level plateaus after administration of a liposome-entrapped compound such as inulin may be a valid indicator of intracellular delivery. This would be important for several reasons. It is necessary information for potential entrapped compounds so large or polar that their cellular uptake in the free form is zero. Moreover, for compounds that can penetrate cells to a limited extent and whose efficacy (and intracellular delivery) can benefit from a localized liposomal extracellular slow release effect, it is still important to know what fraction is delivered to cells *via* liposomes because the drug's intracellular destination may be different by different entry routes.

Finally, it is apparent that the *in vivo* system is very complex, with at least two saturable processes affecting liposome disposition and uptake by the reticuloendothelial system (which includes binding and endocytosis) and the destabilizing factors in blood. These processes compete, and their interplay determines the total organ binding and intracellular delivery of a liposome-entrapped compound. In this study, the complexity of this interplay was evidenced by the time dependence of the dose effect such that levels in the tissues approached similar relative values at later times. This finding, however, may not be true in general since the relative magnitudes of these saturable processes probably depend on (and vary at different rates with) liposome physical properties and the animal's physiological properties. These reasons make it even more important that the dose behavior of a given liposome type be well studied so that its therapeutic efficacy can be optimized.

Phase Equilibria of Nafcillin Sodium–Water

JOSEPH B. BOGARDUS

Received November 28, 1980, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication May 20, 1981

Abstract □ The phase diagram for the binary system nafcillin sodium–water, was determined using differential scanning calorimetry (DSC) and polarized light microscopy. In the temperature range of −20–30°, three crystalline forms and an amphiphilic liquid crystalline phase were detected. The stable crystalline form of nafcillin sodium (form α) and water exhibit a eutectic mixture containing 28% drug (w/w) at −1°. In more dilute solutions a lower temperature eutectic (−5°) occurs. The composition and form of nafcillin sodium in this eutectic are not known. The form in the −5° eutectic was found to be metastable above 28% concentration and converted to form α. Two other crystalline forms were observed at 9° (form β) and 22° (form γ) at concentrations above 40%. The crystalline forms could not be further characterized due to their transient nature and existence in highly concentrated mixtures. A lamellar mesophase is present near ambient temperature in mixtures containing more than 55% nafcillin sodium. The phase equilibria were highly susceptible to supercooling. Temperature cycling methods were devised which gave reproducible DSC data and allowed construction of the phase diagram.

Keyphrases □ Nafcillin sodium—phase equilibria in water □ Phase diagram—nafcillin sodium–water binary system □ Crystals—forms of nafcillin sodium in aqueous solutions, determined by differential scanning calorimetry and polarized light microscopy □ Differential scanning calorimetry—determination of phase diagram for nafcillin sodium–water system □ Polarized light microscopy—determination of phase diagram for nafcillin sodium–water system

In the drug phase, polymorphic forms and solvates can have a large influence on solubility and dissolution properties (1). Liquid crystalline phases can also occur in pharmaceutical systems, although few examples of mesophase formation by drug compounds have been reported (2, 3). In the solution phase, the influence of salt forms and ionic equilibria on solubility is well understood (4). The difficulties involved in solubility determination for highly insoluble substances was recently studied (5). For such compounds the dissolution rate may strongly retard the approach to equilibrium.

Problems also occur in determining the solubility of compounds which are moderately to highly soluble in water. Nucleation and crystallization of metastable solutions are often inhibited by high solute concentrations or the presence of impurities. The potential for solute-solute interactions becomes greater as drug concentration increases. For example, doxycycline hydrochloride forms a dimer in moderately concentrated solutions which accounts for approximately half of the apparent solubility of the compound in water (6).

In the present investigation phase equilibria of a water-soluble antibiotic, nafcillin sodium (I), with water were studied. Preliminary observations using the polarizing microscope indicated that highly concentrated I–water mixtures formed an amphiphilic liquid crystalline phase. The present study was initiated to further investigate this unusual phase behavior and to determine the phase diagram.

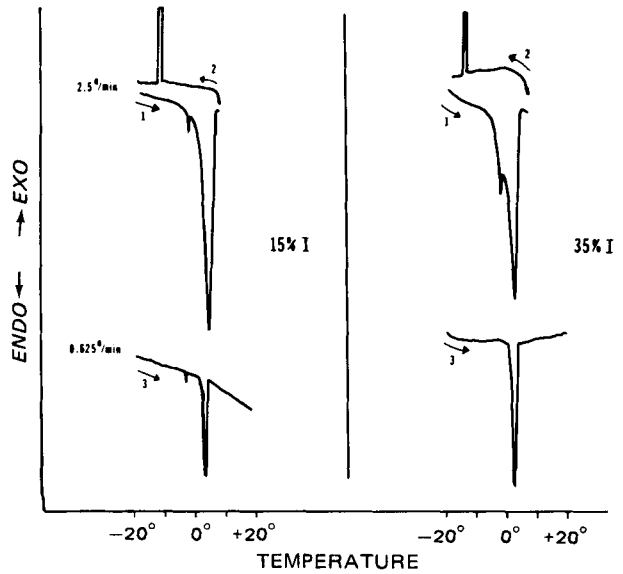

Figure 1—*DSC scans for 15 and 35% nafcillin sodium–water mixtures. Scans 1 and 2 were run at 2.5°/min while scan 3 was obtained at 0.625°/min. Prior to scan 1 the samples were cooled from ambient temperaure to −20° at 2.5°/min.*

EXPERIMENTAL

Transition temperatures were determined using a differential scanning calorimeter[1]. Solutions of I and water were prepared by weight at room temperature and one drop was placed in the aluminum sample pan using a capillary pipet. After sealing, the pan was placed in the sample holder and an empty pan was used as the reference. The low-temperature cell cover supplied with the instrument was filled with dry ice and acetone for cooling the detector cell, which was continuously purged with dry nitrogen. Samples were used within 4 hr to avoid possible effects due to penicillin hydrolysis.

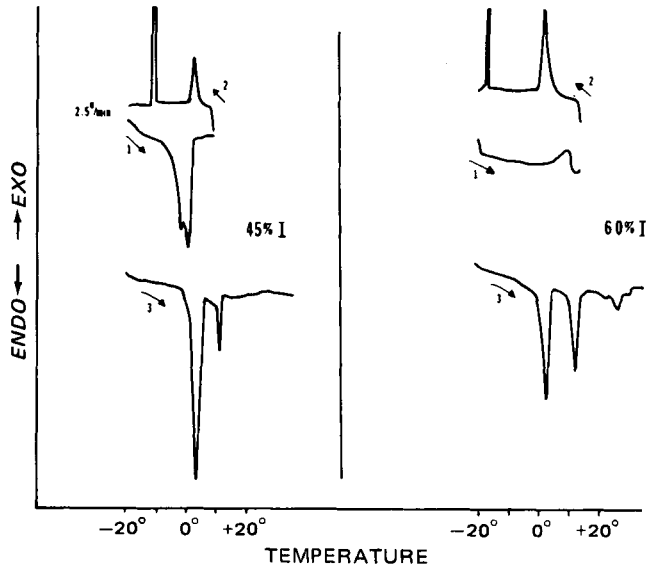

Figure 2—*DSC scans for 45 and 60% nafcillin sodium–water mixtures. All scans were run at 2.5°/min. Prior to scan 1 the samples were cooled from ambient temperature to −20° at 2.5°/min.*

Temperature calibration was checked using water, cyclohexane (mp 6.5°), benzene (mp 5.5°), and indium (mp 157°). At the slowest scanning rate, 0.625°/min, the melting transition of water occurred over a 3° range. This behavior was attributed to inefficiency of heat transfer in the system and the large heat of fusion of water. Under the same conditions, the hydrocarbons and indium gave much narrower peaks. The transition temperature was chosen to be the temperature at which ~10% of the total peak height of a transition had occurred. This convention was adopted to allow comparison of large and small transitions in a single scan and to account for variation in sample weight. This method gave melting points for the standards equal to literature values (7). The instrument output was plotted using an X–Y recorder.

The DSC measures the differential heat (millicalories per second) required to keep the sample and reference at the same temperature. Thus, less heat per unit time is required when scanning slowly than when scanning rapidly. The scanning rate is not indicated on the X–Y recorder but the longer time required to scan a peak at a slower scan rate will cause the apparent peak area to be smaller.

A polarizing microscope[2] with a camera attachment was used to observe and photograph the phases. Samples were either equilibrated in a test tube and quickly transferred to a slide for observation or cooled directly on the microscope slide. Although the temperature could not be closely controlled using these methods, the crystalline forms and phase transitions were clearly and reproducibly observed.

Nafcillin sodium monohydrate was used as received[3]. Distilled water which had been redistilled from an all-glass apparatus was used.

RESULTS

The thermal behavior of I–water mixtures was investigated up to 70% I (w/w). At this concentration high viscosity and poor reproducibility prevented further study. Figures 1 and 2 show representative DSC scans over the concentration range studied. Considerable difficulty was encountered in obtaining reproducible data due to the tendency of cooled solutions to supersaturate. The repetitive scanning sequence shown in the figures induced crystallization and provided reproducible DSC data. The transition temperatures from the equilibrium data (scan 3) were used to construct the phase diagram shown in Fig. 3.

After the outline of the phase diagram was established the phases were examined microscopically to determine the nature of the physical changes associated with the thermal processes. Several phase regions were photographed under polarized light and the results are shown in Figs. 4–9. Further identification, such as isolation and spectrometric analysis, was not possible due to the narrow temperature range of existence for the phases.

DISCUSSION

DSC Analysis of Nafcillin Sodium–Water Mixtures—The 15% I scans (Fig. 1) are representative of data obtained in the 5–28% concentration range. A small sharp endotherm occurred at −5° on the shoulder of a large broad endotherm at 0° (scan 1). At the upper temperature limit (6°) the scanning direction was reversed and the sample recooled to −20° (scan 2). This cooling resulted in an exothermic transition between −10 and −20°. The exact temperature of the exotherm varied between samples and was concentration dependent. In some runs a small shoulder was detected on the low temperature side of the exotherm indicating the reversibility of the −5° transition.

Upon warming the sample a second time (scan 3) the −5° endotherm was unchanged although the large endotherm occurred over a narrower temperature range. The apparently smaller area of the transition in scan 3 is due to a fourfold reduction in scanning rate compared to scans 1 and 2. The thermal data at this concentration are typical of a simple eutectic transition followed by melting of crystalline ice at 0°. The melting of an eutectic in a binary system at constant pressure is invariant according to the Gibbs Phase Rule. In DSC this results in an endothermic transition during heating which proceeds until one of the three phases disappears. Solubility equilibrium of the remaining phases, ice and solution, is mo-

novariant at constant pressure resulting in a gradual endothermic transition over a wider range of temperature.

The lack of significant freezing point depression in this system is due to the surface activity of I. The critical micelle concentration of I is approximately 20–30 mg/ml (8). Thus, under the conditions of the present study, I is largely present in the system as micelles resulting in minimal freezing point depression of water.

At 35% I (Fig. 1, right side), the data in scans 1 and 2 are qualitatively similar to the 15% mixture. The temperature of the ice-melting endotherm in scan 1 is slightly depressed due to the higher concentration. A major difference exists between the two concentrations. Although present in scan 1, the −5° eutectic point is absent in scan 3. These data indicate that at 35% I the −5° eutectic is metastable since it occurs in the first warming cycle (scan 1) but not in the second (scan 3).

The method employed for scans 1 and 2 (warming to 6–8° and refreezing) was found to be necessary to eliminate the −5° endotherm in scan 3. If the sample is warmed to room temperature (instead of 6–8°) and refrozen, a profile similar to scan 1 is repeatedly obtained. In some runs at this concentration, a small endotherm at 7–8° can be detected. This endotherm becomes prominent at higher concentrations, as shown in Fig. 2. These data can only be explained by the existence of a less soluble (more stable) form of I, different from that present in the −5° eutectic.

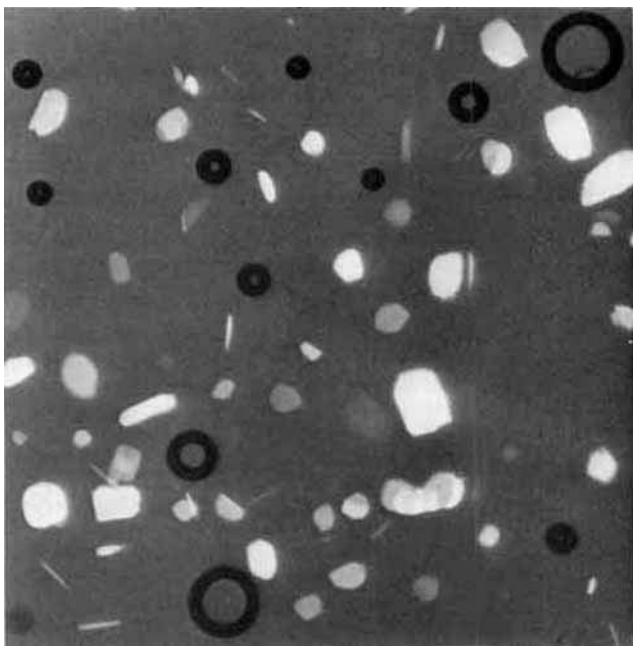

Figure 7—*Region* f, *form* β *(plates) and solution contaminated with Form* γ *(needles). Long axis* $\simeq$*400* μ*m (Initial concentration = 60%).*

The thermal behavior of 45% I solutions is shown in Fig. 2. Scan 1 is again similar to that found at lower concentrations having an apparent −5° eutectic closely followed by the apparent ice-melting endotherm. In the cooling cycle, scan 2, an exotherm occurs at about 2° in addition to the exotherm at −12°. In scan 3 the system is quite different from the lower concentrations. The −5° metastable eutectic is eliminated during scans 1 and 2 and endotherms at −1° and 9° are observed.

At this concentration the −1° transition is due to the dissolving of the eutectic mixture of ice and I. The peak areas indicate that most of the sample is present as the eutectic mixture. Microscopic studies show that the form of I in this eutectic is not the same as that found below 28% concentration. The two-phase region above the eutectic temperature contains crystalline I (denoted form α) and solution.

At 9° the undissolved form α undergoes an endothermic transformation to another crystalline phase, form β. The newly formed crystals of form β at 45% I gradually dissolve and the system becomes an isotropic solution above 18°. These relationships may be seen more clearly in the phase diagram, Fig. 3.

At 60% I (Fig. 2, right side), transitions in scan 1 are absent below 5°. At this temperature, a broad exotherm–endotherm pair occurs due to crystallization and subsequent dissolution of form α I. The cooling process (scan 2) shows a large exotherm due to crystallization of form α in addition to the exotherm for formation of the ice–form α eutectic at −17°. The effect of scan 1 was to induce crystallization of form α allowing the stable eutectic to deposit upon cooling. The warming curve (scan 3) contains the eutectic transition at −1° followed by conversion of form α to form β at 9°. The amount of form α converted to form β is larger at 60% than it was as 45% based on the peak areas. These processes are followed by three small endotherms attributed to the conversion at 22° of form β to a third crystalline phase, form γ, the possible transformation of form γ to a lamellar liquid crystalline phase at 27°, and the dissolution of the liquid crystalline phase to form isotropic solution at 30°.

The small size of the higher temperature endotherms is due to the lower concentrations of crystalline or liquid crystalline material remaining in the systems, since most of the sample is present as an isotropic solution. These conclusions were confirmed microscopically.

Phase Diagram—The various regions of the phase diagram are identified in the legend for Fig. 3.

Regions b *and* c—Freezing of dilute (<28%) aqueous I solutions first causes ice to crystallize below approximately 0° and the system (region

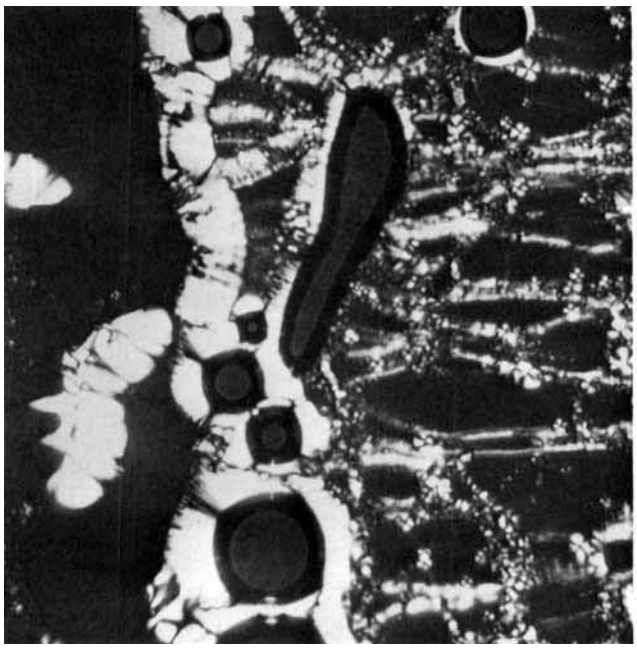

Figure 9—*Region* h, *solution and lamellar mesophase. Long axis* ≃*400 μm (Initial concentration = 60%).*

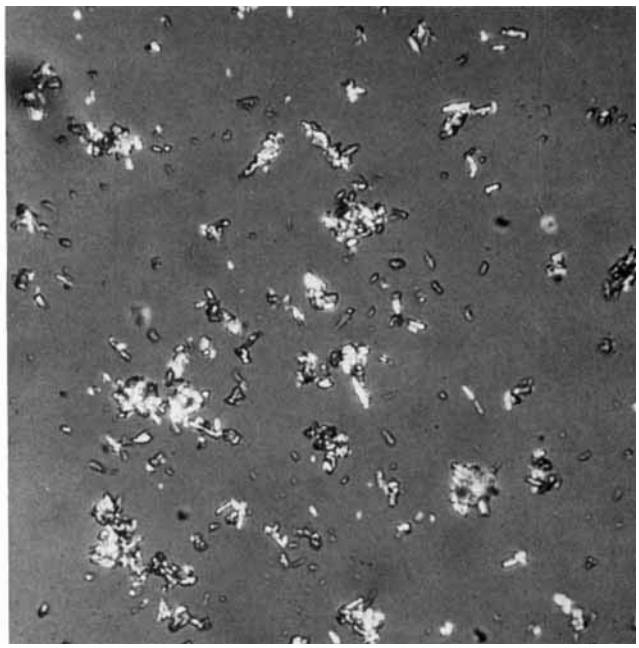

Figure 10—*Nafcillin sodium monohydrate used to prepare all samples. Long axis* ≃*400 μm.*

b) contains ice and solution. Further cooling leads to the −5° eutectic (region *c*), which is stable below 28% I. Above this concentration, the −5° eutectic is easily formed on cooling, indicated by the horizontal dashed line. But between −5 and −1°, the system is not stable and form α crystallizes. The diagonal dashed line shows a possible metastable extension of the ice–solution equilibrium line to the eutectic temperature. The eutectic is expected to contain at least 50% I.

Attempts were made to determine the nature of I in the −5° eutectic. Region *c*, shown in Fig. 4, has a silvery appearance. Figure 5 is a photograph of region *b*, ice and solution, taken just after melting of the eutectic. In the herringbone pattern, the dark channels are solution and the bright lines are ice.

The form of I in this eutectic has the thermodynamic properties of a phase. The sharp and constant eutectic temperature over a wide concentration range indicates that the phase has a fixed composition independent of the initial concentration. If I were in a glassy or amorphous state, no eutectic transition would occur. Only a broad endotherm for melting of ice would be expected (9). Possible explanations for the nature of I in this eutectic are that it is a liquid crystalline mesophase, crystalline forms β or γ, or an unknown crystalline form.

The first explanation, a liquid crystalline phase, is thought to be most consistent with the physical chemical properties of the system. Microscopy does not show discrete crystals, but instead a silvery appearance is observed. During crystallization of ice, the micelles are concentrated into increasingly smaller volumes of solution. The limit of condensation of the micelles would occur at some critical point and the result would probably be a liquid crystalline phase. This hypothesis is the basis of the "R" theory of Winsor (10) in which micellar and liquid crystalline structural features are unified into an order of progression from dilute to concentrated systems. At saturation, micellar solutions usually form amphiphilic liquid crystalline phases (10). Thus, the crystallization of ice from solution follows the horizontal 0° line up to 28% I, as shown in Fig. 3. Instead of forming form α and the eutectic at −1°, the crystallization of ice proceeds and the system continues to be two phases indicated by the diagonal dashed line in the phase diagram. The eventual limit is the formation of the −5° eutectic, which is expected to occur above 50% I.

The existence of the −5° eutectic may be a consequence of the micellar structures in solution. The shape and size of the micelles can change as a function of concentration or ionic strength (11). It is possible that at low concentrations, crystallization of form α would not be favorable because of incompatible micellar structure. At higher concentrations the micelles may become more similar in structure to the packing in form α allowing crystallization to take place.

Regions d *and* e—The eutectic temperature of water–form α mixtures is −1°, shown by the horizontal boundary of region *d* from 28 to 65% I (Fig. 3). It is the point of intersection of the ice–solution and form α–solution phase boundaries. Thus, at concentrations below 28%, ice crystallizes first on cooling the isotropic solution, whereas form α crystallizes first between 28 and 40%.

The crystalline nature of form α is shown in Fig. 6. The sample in Fig. 6 was equilibrated by immersing a test tube containing isotropic solution in an ice–water bath which caused the sample temperature to be in region *e*. Stirring induced crystallization and at this temperature the sample is a thick paste. A small amount of sample was then applied to a precooled slide and photographed immediately.

Crystals of form α are typically splinter-like with high birefringence. The rounded edges are due to dissolution of the crystals into the surrounding isotropic solutions as the sample becomes warmer.

The upper boundary temperature for region *e* (form α and solution) is 9° from 35 to 65% I. Between 28 and 43% I, equilibrium of form α with isotropic solution occurs. At 9° and 43% I, however, an intersection point occurs and the system is invariant. The three phases in equilibrium are form α, form β, and solution. The remaining fraction of form α in suspension is unstable and upon warming to 9°, it converts endothermically to form β. The system is invariant at this temperature until all form α is converted to form β. Such a transformation is called an incongruent melting point (12).

The phenomena of incongruent melting points is common in binary alloys as well as in aqueous solutions of hydrated salts. In phase equilibria, an incongruent melting point occurs when a compound is physically unstable and decomposes (transforms) at a temperature below its melting point; that is, it has no true melting point. Common salts with incongruent melting points are sodium chloride, calcium chloride, and sodium sulfate.

Sodium sulfate decahydrate forms a simple eutectic with water at −1.3° (12). The hydrated salt is in equilibrium with saturated solution up to 32.4°. At this temperature (the incongruent melting point), the decahydrate is unstable and converts to the anhydrous crystalline form. Thus, the invariant system contains the decahydrate, anhydrate, and solution. Thermal arrest occurs until the transformation is complete.

The analogous phase behavior of I and inorganic salts suggests that the observed crystalline forms differ in the degree of hydration in the crystalline state. This proposal is consistent with the small range of temperature in which the forms are stable. The similar crystal energies can be rationalized by small changes in spatial arrangement or solvation resulting in different crystalline forms. The alternate explanation of polymorphism cannot be ruled out at present.

Regions f *and* g—Form β is in equilibrium with solution in region *f* (9–22°, <43% I). The crystal habit of this form (Fig. 7) consists of brightly colored, reflective plates with rectangular faces. The rounded edges are due to dissolution as the slide warmed under the microscope. Samples

of this form are usually contaminated with needle-shaped crystals, which are the higher temperature form γ. This was shown by the following experiment. A tube containing 60% I at 15° containing needles and plates was slowly warmed in a water bath. As the temperature increased, samples were periodically taken and observed with the microscope. The sample temperature was directly monitored with a thermometer and a thermal arrest occurred at 22°, consistent with the DSC data. At this temperature, the plates gradually disappeared and the number of needles increased due to the transformation of form β to form γ. These forms are also related by an incongruent melting point.

When a sample at ambient temperature is cooled to 10–20° to induce crystallization of form β, a small amount of metastable form γ is often obtained, since the temperature region for form γ is passed during cooling. The high viscosity of the system and small difference in stability of the forms allows the metastable form γ to remain in suspension at a temperature where form β is the stable crystalline form. Form γ can be removed from mixtures by warming to near 22° and recooling. If samples of form β are rapidly warmed, the crystals dissolve directly to isotropic solution without the intermediacy of form γ or the mesophase.

Figure 8 shows the acicular habit of form γ which is present between 22 and 26°, above 50% I. These crystals are difficult to grow and were prepared by repeatedly cooling the sample below 22° and warming to obtain the large crystals shown. Form γ is a small fraction of the total sample which is largely isotropic solution.

Region h—When I and water are mixed on a microscope slide at room temperature, a layer of liquid crystalline phase forms on the interface between solid and saturated solution. The mesophase is also easily formed by peripheral evaporation of a drop of solution placed between slide and cover slip. Figure 9 shows the liquid crystalline phase formed from a 60% I sample. Its microscopic texture clearly identifies it as a lamellar mesophase (13). It is indistinguishable from authentic samples prepared with lecithin or docusate sodium. Growth tends to occur on the surfaces of bubbles causing the high birefringence (10). The oily streak texture shown in Fig. 9 is also characteristic of lamellar forms (13). Light pressure on the cover slip causes the viscous phase to flow showing that it is not a solid crystalline phase.

The thermal characteristics of the mesophase could only be approximated by DSC. The slow and erratic nature of its formation and the small thermal changes involved make the boundaries of region *h* uncertain. In addition, the relationship between form γ and the mesophase is not clear since it is difficult to obtain reliable data at such high concentrations. Microscopic samples have been observed in which the mesophase and needles of form γ are present simultaneously so that the conditions for formation of these phases must be quite similar.

In a lamellar mesophase, the amphiphilic molecules are arranged in bilayers with polar groups oriented to the aqueous regions separating the layers. This arrangement was proved for a number of substances using small angle X-ray scattering data (10). The hydrophobic portions form the interior of the bilayers and the thickness of the bilayer is about 40 Å. The lamellar mesophase commonly appears in aqueous systems containing fatty acid soaps, surfactants, and phospholipids. It is only one of several known amphiphilic liquid crystalline phases.

Relationship of the Low Temperature Forms with the Monohydrate—The form of I in commercial use is a monohydrate. Figure 10 shows the bulk form of I used to prepare all samples. It would be reasonable to expect that this crystalline form would be the same as one of the forms identified in this study. Seeding experiments, however, indicate that they are not related. Small amounts of monohydrate were seeded into supersaturated solutions at the temperatures of the three other forms. In each case the seed dissolved, although it did so more slowly at the lower temperatures. Crystallization eventually occurred but control samples indicated that seeding had no effect. The monohydrate appears to be a higher energy form (more soluble) than forms α, β, or γ.

Implications in Freeze-Drying—Although nafcillin sodium is not supplied in a freeze-dried form, several comments should be made regarding the importance of such equilibria in freeze-drying processes. Simple freezing may cause the drug to be present in a metastable state. This may lead to difficulties in the drying process as well as poor physical properties of the dried material (9, 14). These problems are especially serious when the drug is present at high concentration. Gatlin and DeLuca (14) have shown that the physical state of cefazolin sodium and nafcillin sodium in the dried product could be changed by thermal treatment prior to freeze-drying. If processed directly, the frozen drug solutions led to amorphous products, whereas if the frozen solutions were warmed to near the eutectic temperature and refrozen the resulting products were crystalline. The warming–cooling cycle in the frozen state induced crystallization of the drug which was amorphous after the initial freezing.

A single crystalline drug form should not always be expected in frozen or subambient systems. Equilibria beyond the usual eutectic state can occur with drugs in a small temperature range. The nafcillin sodium–water phase diagram shows that the initial drug concentration is an important factor. The form of I in the −5° eutectic (0–28% I) is different from the form α crystals found at higher concentrations. It is expected that this would lead to differences in the respective freeze-dried products.

Depending upon the cooling conditions above 0° the crystalline form of I can easily be altered. Forms β or γ can crystallize and allow little or no form α, the stable form at low temperatures, to be present in the frozen state. This is possible because the forms are similar in energy. In some cases, thermal treatments of the solution may be necessary in the 0–20° range to initiate crystallization of the form desired for freeze-drying.

Rapid and Simple GLC Determination of Valproic Acid and Ethosuximide in Plasma of Epileptic Patients

ROBERTO RIVA[x], FIORENZO ALBANI, and AGOSTINO BARUZZI

Received September 24, 1980, from the *Institute of Neurology, School of Medicine, University of Bologna, Via Ugo Foscolo, Bologna, Italy.* Accepted for publication May 13, 1981.

Abstract □ A GLC method for the determination of valproic acid and ethosuximide in plasma was developed. The procedure involved a single solvent extraction of drugs from acidified plasma samples, followed by a GLC injection of the unconcentrated organic phase. This rapid, sensitive, specific, and reproducible method has been used for 2 years for the routine determination of plasma levels of valproic acid and ethosuximide in epileptic patients who receive other antiepileptic drugs simultaneously.

Keyphrases □ Valproic acid—GLC determination in plasma of epileptic patients □ Ethosuximide—GLC determination in plasma of epileptic patients □ Antiepileptic agents—GLC determination of valproic acid and ethosuximide in plasma □ GLC—determination of valproic acid and ethosuximide in human plasma

The use of valproic acid in the treatment of primary generalized epilepsy (particularly petit mal epilepsy) has been reported (1–3). Optimal plasma concentrations of valproic acid are between 40–50 and 100 μg/ml of plasma (1), and the importance of monitoring valproic acid in epileptic patients was discussed (4, 5).

Ethosuximide was introduced 25 years ago in the clinical therapy of petit mal epilepsy (6). There have been several studies (7–9) on the therapeutic use of ethosuximide in epilepsy and on the importance of monitoring plasma ethosuximide concentrations.

Numerous GLC methods are available for the determination of valproic acid (10–18) and ethosuximide concentrations (17, 19–21) in human plasma. However, almost all of these methods require evaporation to concentrate the drugs. This step is crucial because these drugs (particularly valproic acid) are very volatile. A microextractive technique without evaporation of the organic phase is sometimes used to avoid irregular evaporation or decreased sensitivity due to volatility. However, these techniques require a high level of precision due to the minute volumes used.

This report describes a GLC method without evaporation, utilizing 1 ml of plasma. This method has been used in this laboratory for more than 2 years for routine analyses.

EXPERIMENTAL

Reagents—Stock solutions of valproic acid[1] and ethosuximide[2] were prepared by dissolving the drugs in water. Caproic acid[3] (marker for valproic acid) and α,α-dimethyl-β-methyl succinimide[4] (marker for ethosuximide) were dissolved in chloroform[3]. Stock solutions were stored at 4°.

Apparatus—The gas chromatograph[5] was equipped with a flame-ionization detector and a recorder–integrator[6]. The glass column, 1 m long × 3-mm i.d., was packed with 10% diethylene glycol–succinate–phosphate, on 80–100-mesh Supelcoport[7]. The following flow rates were used: hydrogen, 15 ml/min; air, 250 ml/min; and carrier gas (nitrogen), 40 ml/min. The temperature of the column was 145° for valproic acid and 190° for ethosuximide, and the injector temperature was 225° for both drugs.

Extraction Procedure—To 1 ml of plasma containing unknown concentrations of the drugs was added 0.5 ml of 1 *N* HCl and 0.5 ml of chloroform containing 100 μg/ml of caproic acid or 100 μg/ml of α,α-dimethyl-β-methyl succinimide. After being shaken gently for 15 min and centrifuged at 2500 rpm for 10 min, the aqueous phase was discarded and 1–2 μl of the organic phase was injected into the chromatograph.

Plasma samples from patients taking both drugs were extracted into chloroform containing both markers. Calibration curves were prepared by adding exact volumes (5, 10, 20, 40, 100, and 200 μl) of a standard so-

[a] Mean of 10 determinations.

lution of valproic acid or ethosuximide (1 mg/ml) to 1 ml of drug-free plasma. These plasma samples were treated as already described for samples containing unknown concentrations.

RESULTS AND DISCUSSION

Typical chromatograms of extracts from plasma of two patients undergoing multiple antiepileptic drug therapy, one receiving valproic acid and the other receiving ethosuximide, are shown in Fig. 1. There was no interference from endogenous plasma compounds or from other antiepileptic drugs.

Calibration curves from plasma extract showed a linear correlation between concentration and the respective reading: $y = 0.044x - 0.039$, $r = 0.995$, for valproic acid; and $y = 0.023x - 0.034$, $r = 0.992$, for ethosuximide. To calculate these curves, a least-squares linear regression method was used. The minimal concentration detectable for both drugs was ~1–2 μg/ml of plasma.

Analytical recoveries of substances were established as follows. Various amounts (5, 10, 20, 40, 100, and 200 μg) of valproic acid or ethosuximide were dissolved in 1 ml of drug-free plasma. After acidification, plasma samples were extracted into 0.5 ml of pure chloroform. Then 0.2 ml of a solution containing the marker (100 μl/ml) in chloroform was added to 0.2 ml of the organic phase.

A series of external standards was prepared by adding 0.5 ml of the marker solution (100 μg/ml) to 0.5 ml of chloroform containing various amounts (5, 10, 20, 40, 100, and 200 μg) of valproic acid or ethosuximide.

Analytical recoveries were calculated by comparing peak area ratios of the extracted standards to the ratios of the external standards. Expressed as concentrations in micrograms per milliliter, they were as follows (theoretical values of 5, 10, 20, 40, 100, and 200): 5.0, 10.1, 20.3, 40.7, 102.3, and 202.8 for valproic acid and 4.4, 8.9, 18.0, 35.6, 88.8, and 176.4 for ethosuximide.

Reproducibility was determined by performing 10 replicate analyses of four control samples containing 10, 30, 60, and 100 μg/ml of both drugs on different days over 4 months. The results are shown in Table I.

The total time required to analyze 22 plasma samples (plasma samples from 16 patients and six calibrators) was ~1.6 hr.

This method has been utilized for 2 years, analyzing ~1600 plasma samples from patients being treated with valproic acid and ~250 plasma samples from patients being treated with ethosuximide. Only ~30 samples contained both drugs.

If these drugs appear together in the same plasma, they may be extracted simultaneously, as described, and injected onto the column at two different temperatures. At the highest temperature (190°), valproic acid and its marker elute in front of the solvent; at the lowest temperature (145°), ethosuximide and its marker have a retention time of 20 and 16 min, respectively.

GLC Determination of Bromperidol in Tablets

ROBERT P. MARTIN ˣ, STEVEN W. K. LUM, EUGENE J. McGONIGLE, and H. R. GUBLER *

Received February 2, 1981, from the *Research Laboratories, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication May 14, 1981. *Present address: Cilag-Ltd., Schaffhausen, Switzerland.

Abstract □ A GLC procedure for the determination of bromperidol in 3-, 6-, and 10-mg tablets is described. The method is stability indicating in the presence of compounds structurally related to bromperidol and stress reaction products of bromperidol.

Keyphrases □ Bromperidol—GLC determination in tablets □ GLC—method for determining bromperidol in tablets □ Tranquilizers—bromperidol, determination by GLC, tablets

Bromperidol is a new, potent, neuroleptic formulated in 3-, 6-, and 10-mg tablets; its chemical structure is similar to haloperidol. Analytical methods for haloperidol have included TLC (1), paper chromatography (2), spectrophotometry (3–5), titrimetry (6), polarography, and gas chromatography (7, 8), but only limited resolution data have been submitted for these methods. A TLC and a high-performance liquid chromatographic method for the determination of bromperidol were reported (9). These procedures are selective for bromperidol in the presence of three possible impurities and several other butyrophenones, but resolution from stress reaction products was not demonstrated, limiting data to support stability-indicating properties.

This paper describes a rapid, stability-indicating GLC procedure applicable to the determination of bromperidol in 3-, 6-, and 10-mg tablets. Selectivity in the presence of stress reaction products of bromperidol and other structurally related compounds is demonstrated.

EXPERIMENTAL

Reagents and Chemicals—Reagent grade octacosane (internal standard), cyclohexane, ethyl acetate, and sodium hydroxide were used.

Instrumentation and Apparatus—The gas chromatograph[1] was equipped with an autosampler, a flame-ionization detector, and on-column injection. A laboratory data system[2] was used to carry out peak integration or peak height measurement. However, peak heights could also be determined manually using an attenuation setting of 4×10^3 in combination with a 10-mv strip-chart recorder (1.5 min/cm).

Chromatographic Conditions—A 0.9-m (3 ft) × 2-mm i.d. glass column, packed with 3% SE-30 on 80–100-mesh Gas Chrom Q[3], was conditioned for 24 hr at 240° with a helium flow of ~30 ml/min. For sample determinations, the column temperature was adjusted to 230° with a detector temperature of 300° and an injection port temperature of 250°. The carrier gas was helium at a flow rate of 40 ml/min. Oxygen and hydrogen were maintained at 240 and 35 ml/min, respectively.

Preparation of Internal Standard—Approximately 100 mg of octacosane was accurately weighed into a 100-ml volumetric flask, dissolved in 10.0 ml of cyclohexane, and diluted to volume with ethyl acetate (for a concentration of 1 mg/ml).

Preparation of Bromperidol Standard Solution—Approximately 24 mg of a suitable bromperidol reference standard was accurately weighed into a stoppered 50-ml centrifuge tube and dissolved in 20.0 ml of the internal standard solution. Then 20.0 ml of 0.1 *M* NaOH was added. After shaking for 30 min, the mixture was centrifuged to ensure phase separation.

RESULTS AND DISCUSSION

Accuracy and precision were demonstrated in two ways. First, placebo tablets in the presence of known concentrations of bromperidol were assayed by the desired procedure. Results obtained for six replicate determinations of synthetic preparations representative of 3-, 6-, and 10-mg bromperidol tablets show average recoveries of 100.9 ± 0.2, 102.2 ± 0.2, and 101.0 ± 1.2%, respectively (Table I). No interference was encountered from the excipients. A typical chromatogram is shown in Fig. 1.

For each formulation, the area response was linear with concentration. Table II presents the maximum error at 90 and 110% of label claim resulting from the use of a single standard representative of 100% of label claim instead of a calibration curve. Since the maximum error was within the precision of the method, the use of a standard at the nominal concentration in place of a series of concentrations was justified.

Accuracy and precision were also evaluated by comparing results obtained using the described procedure with results obtained by an independent UV spectrophotometric procedure. In the latter method, the

drug was extracted from the tablet matrix using isopropyl alcohol–0.1 *M* hydrochloric acid (9:1) and diluted to a final bromperidol concentration of 15 μg/ml with isopropyl alcohol–0.1 *M* hydrochloric acid. The bromperidol present in the sample was calculated by comparing the absorbance of the sample at 242 nm to a similarly prepared solution of standard at a known concentration. Table III shows the agreement between results obtained by both procedures using actual 3- and 6-mg bromperidol tablets. Equivalent results were obtained independent of whether ground composites or whole tablets were assayed. Table III also shows data collected on representative 10-mg tablet lots.

The data in Table IV demonstrate that peak heights can be used interchangeably with peak areas for quantitation. These data were determined using individual determinations of 3-, 6-, and 10-mg tablets calculated by both techniques. Overall results as well as differences between individual results were within experimental error.

To demonstrate the stability-indicating properties of the method, the chromatographic response of several compounds structurally related to bromperidol were compared to bromperidol and octacosane (the internal standard) to establish resolution properties. Each compound was dissolved in ethyl acetate–cyclohexane (9:1), and the resulting solutions were chromatographed. Besides bromperidol, only seven compounds produced discernible peaks. All compounds were chromatographed individually; Table V presents the relative retention times and weight responses relative to bromperidol (the first compound). Compounds not observed were concluded to have either eluted with the solvent front or been strongly retained by the packing. However, none of the compounds interfered with the determination of bromperidol.

To defend further the resolution properties of the method and, therefore, the stability-indicating properties, a weighed amount of bromperidol drug substance was heated in a capillary tube at 260° (melting point of bromperidol is 158°). After ~30 min at this extreme temperature, the sample was partially discolored near the top of the tube; analysis for bromperidol indicated a drug loss of ~25%. However, no extra peaks were observed in the resulting chromatogram. Examination of the analytical regions of the resultant chromatogram using GLC–mass spectrometry indicated that thermal stress reaction products of bromperidol did not elute with the drug or internal standard.

In addition to the thermal stress experiment, an accurately weighed 25-mg sample of bromperidol was mixed with 2 ml of 30% hydrogen peroxide and allowed to stand for 1 hr. The sample was mixed with 10 ml of methanol to consume excess peroxide and evaporated to dryness under nitrogen. GLC analysis of the residue indicated as little as 10% intact drug remaining. Examination of the oxidized sample of bromperidol by GLC–mass spectrometry in the analytical regions indicated that reaction products of bromperidol did not elute with the internal standard or bromperidol.

This GLC method is specific for bromperidol in the presence of structurally related compounds and stress reaction products of bromperidol. In addition, the procedure is accurate, reproducible, and suitable for stability or release analyses of bromperidol tablets.

High-Performance Liquid Chromatograhic Determination of Metoprolol in Plasma

M. T. ROSSEEL *x, F. M. BELPAIRE *, I. BEKAERT ‡, and M. G. BOGAERT *

Received November 28, 1980, from the **Heymans Institute of Pharmacology and the ‡Department of Cardiology, University of Gent Medical School, De Pintelaan 135, B-9000 Gent, Belgium.* Accepted for publication May 20,1981.

Abstract □ A high-performance liquid chromatographic method is presented for the determination of metoprolol in human plasma. Metoprolol was extracted from plasma by a single extraction procedure with 4-methylpropranolol as the internal standard. Chromatography was done on a reversed-phase column with fluorescence detection. The minimum detectable concentration was 5.0 ng/ml of plasma. The standard curve was linear in the range evaluated, 10–300 ng/ml. The within-run coefficient of variation was 2.3–6.0%, and the day-to-day variation was 6.8%. The method is free from interference by major metoprolol metabolites.

Keyphrases □ Metoprolol—high-performance liquid chromatographic analysis in plasma □ β-Adrenergic blocking agents—metoprolol, high-performance liquid chromatographic analysis in plasma □ High-performance liquid chromatography—analysis of metoprolol in plasma

Metoprolol is a cardioselective β-adrenergic blocking agent used in the treatment of hypertension and angina. Analysis of metoprolol in plasma has been performed with electron-capture GLC after derivatization (1, 2), and a GC–mass spectroscopy method was recently developed (3).

This report describes a high-performance liquid chromatographic (HPLC) method for the determination of metoprolol in plasma using reversed-phase ion-pair chromatography with fluorescence detection. The same approach has been used for other β-adrenergic blocking drugs such as propranolol (4, 5), atenolol (6, 7), and sotalol (8).

EXPERIMENTAL

Reagents—The following were used: metoprolol tartrate[1], α-hydroxymetoprolol[1], and *O*-desmethylmetoprolol[1] as the *p*-hydroxybenzoic acid salts; and 4-(2-hydroxy-3-isopropylaminopropoxy)phenylacetic acid[1], 2-hydroxy-3-(4-methyoxyethylphenoxy)propanoic acid[1], and 4-methylpropranolol[2] as the hydrochloride salts. Methanol[3] was HPLC grade. 1-Heptanesulfonic acid[4] in acetic acid was used. Glass double-distilled water was passed through a 0.45-μm filter[5]. Methylene chloride was reagent grade and distilled just before use.

Instrument Conditions—The microprocessor-controlled high-per-

drug was extracted from the tablet matrix using isopropyl alcohol–0.1 *M* hydrochloric acid (9:1) and diluted to a final bromperidol concentration of 15 μg/ml with isopropyl alcohol–0.1 *M* hydrochloric acid. The bromperidol present in the sample was calculated by comparing the absorbance of the sample at 242 nm to a similarly prepared solution of standard at a known concentration. Table III shows the agreement between results obtained by both procedures using actual 3- and 6-mg bromperidol tablets. Equivalent results were obtained independent of whether ground composites or whole tablets were assayed. Table III also shows data collected on representative 10-mg tablet lots.

The data in Table IV demonstrate that peak heights can be used interchangeably with peak areas for quantitation. These data were determined using individual determinations of 3-, 6-, and 10-mg tablets calculated by both techniques. Overall results as well as differences between individual results were within experimental error.

To demonstrate the stability-indicating properties of the method, the chromatographic response of several compounds structurally related to bromperidol were compared to bromperidol and octacosane (the internal standard) to establish resolution properties. Each compound was dissolved in ethyl acetate–cyclohexane (9:1), and the resulting solutions were chromatographed. Besides bromperidol, only seven compounds produced discernible peaks. All compounds were chromatographed individually; Table V presents the relative retention times and weight responses relative to bromperidol (the first compound). Compounds not observed were concluded to have either eluted with the solvent front or been strongly retained by the packing. However, none of the compounds interfered with the determination of bromperidol.

To defend further the resolution properties of the method and, therefore, the stability-indicating properties, a weighed amount of bromperidol drug substance was heated in a capillary tube at 260° (melting point of bromperidol is 158°). After ~30 min at this extreme temperature, the sample was partially discolored near the top of the tube; analysis for bromperidol indicated a drug loss of ~25%. However, no extra peaks were observed in the resulting chromatogram. Examination of the analytical regions of the resultant chromatogram using GLC–mass spectrometry indicated that thermal stress reaction products of bromperidol did not elute with the drug or internal standard.

In addition to the thermal stress experiment, an accurately weighed 25-mg sample of bromperidol was mixed with 2 ml of 30% hydrogen peroxide and allowed to stand for 1 hr. The sample was mixed with 10 ml of methanol to consume excess peroxide and evaporated to dryness under nitrogen. GLC analysis of the residue indicated as little as 10% intact drug remaining. Examination of the oxidized sample of bromperidol by GLC–mass spectrometry in the analytical regions indicated that reaction products of bromperidol did not elute with the internal standard or bromperidol.

This GLC method is specific for bromperidol in the presence of structurally related compounds and stress reaction products of bromperidol. In addition, the procedure is accurate, reproducible, and suitable for stability or release analyses of bromperidol tablets.

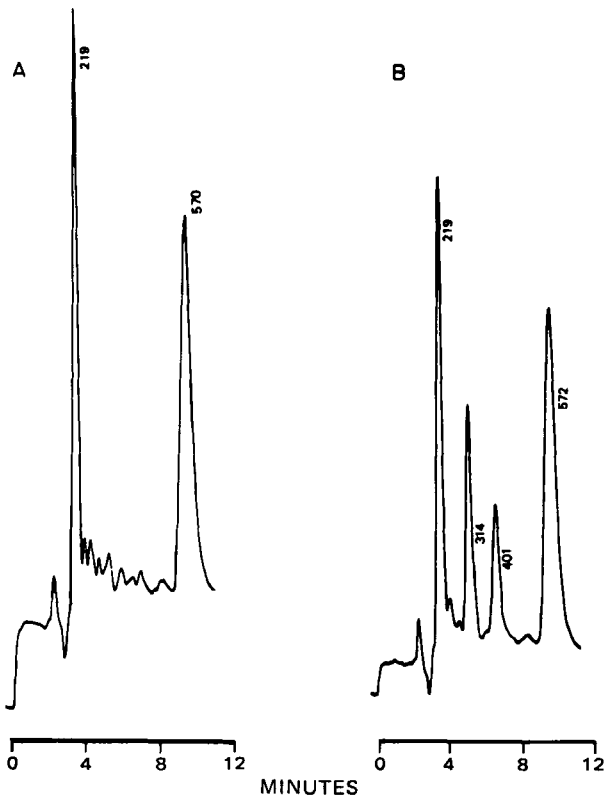

Figure 1—*Liquid chromatograms of 1-ml plasma extracts. Key: A, blank plasma sample of a cardiac patient spiked with 30 ng/ml of the internal standard (570 sec); and B, plasma of the same patient 4 hr after oral intake of 100 mg of metoprolol and spiked with 30 ng/ml of the internal standard. Retention times were 401 and 572 sec for metoprolol and the internal standard, respectively. The plasma metoprolol concentration in this patient was calculated to be 46 ng/ml. The peak at 314 sec is probably α-hydroxymetoprolol.*

formance liquid chromatograph[6] was equipped with a fluorescence detector[7]. The effluent was monitored at an excitation wavelength of 220 nm with a 295-nm UV interference filter to set the emission wavelength.

A reversed-phase column[8] (25-cm long × 4-mm i.d.) was maintained at 40°. The flow rate of the helium-degassed mobile phase was 1.0 ml/min. Samples were injected into the chromatograph *via* an injector[9] equipped with a 10-μl loop.

Mobile Phase—1-Heptanesulfonic acid (25 ml) in acetic acid was mixed with 1 liter of distilled water (Solvent A), and 25 ml of the same acid solution was mixed with 1 liter of methanol (Solvent B). The mobile phase was a mixture of Solvents A and B (15:85 v/v).

Procedure—One milliliter of plasma, 30 μl of the internal standard solution (1 μg/ml in methanol), 0.5 ml of 1.0 *N* NaOH, and 4 ml of methylene chloride were added to a 10-ml glass-stoppered centrifuge tube. The mixture was vortexed for 30 sec and then centrifuged for 5 min at 5000 rpm. The organic phase was transferred to a 6-ml glass-stoppered conical tube, evaporated to dryness under nitrogen at room temperature, and reconstituted in 15 μl of the mobile phase. An aliquot of this solution was injected.

RESULTS AND DISCUSSION

The efficiency of the extraction recovery for metoprolol (100 ng/ml) was 76.9% with a coefficient of variation of 3.1%. Over the 10–300-ng/ml plasma range studied, the standard curve was linear. The standard curves analyzed over 1 month (n=11) gave a mean regression (±*SD*) of y = 0.0104 (±0.0008)x + 0.0054 (±0.0050) with r = 0.9987 (±0.0011), where y is the metoprolol peak height divided by the 4-methylpropranolol peak height and x is the concentration of metoprolol (nanograms of free base per milliliter).

Table I—Within-Run Accuracy and Precision for Metoprolol [a]

Concentration, ng/ml	Mean Result, %	*CV*,%
30	103.1	6.0
50	105.6	5.3
100	100.9	2.3

[a] n = 5.

The reproducibility of the method was demonstrated by a day-to-day coefficient of variation of 6.8% (n=11) using pooled plasma spiked with metoprolol (50 ng/ml) and analyzed over 1 month. The within-run coefficients of variation and accuracy are given in Table I.

The detection limit of this assay with the described instrumentation and procedure was ~5 ng/ml of plasma.

Assay of samples spiked with a number of commonly used cardiovascular drugs showed that procainamide interferes with the internal standard. Plasma samples obtained from 40 cardiac patients taking drugs such as nitrates and other antianginal agents, antiarrhythmic agents, diuretics, antibiotics, theophylline, aspirin, dipyridamole, and benzodiazepines were analyzed. Only in quinidine-treated patients was there a problem since quinidine metabolites interfered with metoprolol on the chromatogram.

An example of the chromatogram obtained from the plasma of a cardiac patient is shown in Fig. 1 along with the chromatogram of plasma of the same patient sampled 4 hr after receiving 100 mg of metoprolol orally.

The metabolites of metoprolol, α-hydroxymetoprolol, *O*-desmethylmetoprolol, 4-(2-hydroxy-3-isopropylaminopropoxy)phenylacetic acid, and 2-hydroxy-3-(4-methoxyethylphenoxy)propanoic acid, eluted at 322, 342, 312, and 215 sec, respectively, which separated them from metoprolol (411 sec) and the internal standard (587 sec). Only the two basic metabolites, α-hydroxymetoprolol and *O*-desmethylmetoprolol, were recovered from extracted spiked plasma. In humans, *O*-desmethylmetoprolol concentrations are low, but α-hydroxymetoprolol concentrations can be detected (9–11). In some patient samples, a peak was seen that could be attributed to α-hydroxymetoprolol (Fig. 1).

The described HPLC assay provides a specific, sensitive, and quantitative method for the determination of metoprolol in plasma.

Stability of Phenylpropanolamine Hydrochloride in Liquid Formulations Containing Sugars

R. H. BARRY, M. WEISS ˣ, J. B. JOHNSON, and E. DeRITTER

Received July 28, 1980, from *Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication May 15, 1981

ABSTRACT □ Stability studies with a decongestant syrup formulation containing phenylpropanolamine hydrochloride in a sugar vehicle indicated a loss of phenylpropanolamine hydrochloride. To ascertain the biological significance of this indicated chemical loss, the degraded formulation was administered to human volunteers and the urinary excretion of phenylpropanolamine hydrochloride was determined. The excretion and chemical assay patterns were in good agreement, indicating that the sugar vehicle was both chemically and biologically incompatible with phenylpropanolamine hydrochloride. A control formulation made with phenylpropanolamine hydrochloride in a sorbitol vehicle showed good chemical stability and urinary excretion patterns. Further studies showed chemical losses with phenylpropanolamine hydrochloride in the presence of fructose, dextrose, and 5-(hydroxymethyl)-2-furaldehyde but not with levulinic acid. Possible mechanisms for the sugar–phenylpropanolamine hydrochloride interaction are discussed.

Keyphrases □ Phenylpropanolamine hydrochloride—stability in liquid formulations containing sugars □ Stability—of phenylpropanolamine hydrochloride in liquid formulations containing sugars □ Adrenergic agents—phenylpropanolamine hydrochloride, stability in liquid formulations containing sugars

While formulating a decongestant syrup containing phenylpropanolamine hydrochloride, it was observed that the stability pattern indicated a loss of phenylpropanolamine hydrochloride. Initial formulations contained sucrose with either corn syrup or an invert sugar composition in the vehicle.

Since it was surmised that the sugars had interacted with the phenylpropanolamine hydrochloride, stability experiments were done with phenylpropanolamine hydrochloride in aqueous vehicles containing dextrose, fructose, and sucrose–corn syrup, with a sorbitol vehicle as the control. In addition, 5-(hydroxymethyl)-2-furaldehyde and levulinic acid were tested since these compounds are produced from the hydrolysis of dextrose and fructose.

To ascertain the biological significance of the indicated chemical loss of phenylpropanolamine hydrochloride, a urinary excretion study was performed using the initial formulation in the sucrose–corn syrup vehicle. After storage at 5 and 55° for 1 month, comparisons were made with a formulation containing sorbitol.

EXPERIMENTAL

Analytical Methods—Initially, the phenylpropanolamine hydrochloride[1] in the sucrose[2]–corn syrup[3] formulations was determined using the ion-pair–methyl orange procedure (1, 2). For subsequent experiments using dextrose[4], fructose[4], 5-(hydroxymethyl)-2-furaldehyde[5], and levulinic acid[5], phenylpropanolamine hydrochloride was determined by the ninhydrin procedure of Burke *et al.* (3). A periodate oxidation method (4) was used for the determination of phenylpropanolamine hydrochloride in urine.

Urinary Excretion Tests—All preparations were given orally to nonfasted subjects. Pooled urine samples were collected for 24 hr prior to dosage for measurements of blank excretion values. After the morning dosage, urine was collected for 24 hr. Urinary phenylpropanolamine hydrochloride was determined by a reported method (4).

In agreement with earlier results (4), the present experiments indicated that 90–100% of a 50-mg phenylpropanolamine hydrochloride dose was excreted by humans in the urine. With the 15–25-mg doses administered in the present experiment, only 70–80% was excreted. A relatively constant amount of phenylpropanolamine hydrochloride apparently is metabolized and not recovered in the urine (*e.g.*, 10% of a 50-mg dose equals 5 mg, which is 20% of a 25-mg dose).

Table I—Effect of Sucrose and Corn Syrup on Phenylpropanolamine Hydrochloride Stability

	Formula			
	1	2	3	4
Phenylpropanolamine hydrochloride, % (w/v)	0.15	0.15	0.15	0.15
Sucrose, % (w/v)	40	—	—	40
Corn syrup, % (w/v)	—	40	—	—
Sorbitol, % (w/v)	—	—	40	—
Initial pH	6.0	6.0	5.9	4.5
Retention of phenylpropanolamine hydrochloride (3 days/70°), %	93	54	97	67

RESULTS

The assay data in Table I show that the phenylpropanolamine hydrochloride losses in the presence of sucrose and corn syrup were significant after 3 days at 70°. The sucrose effect was much greater at pH 4.5 than at pH 6. Practically no change occurred with sorbitol.

The data in Table II compare the effect of dextrose and fructose (the hydrolytic cleavage products of sucrose) on phenylpropanolamine hydrochloride stability at pH 4, 6, and 7. As pH increased, the degradation rate and degree of color development increased. At pH 4, there was only a slight rise in pH, whereas pH decreased at pH 6 and 7. Precipitation was noted in all samples after 1 week of storage at 70° and was visibly greater at pH 6 and 7 than at pH 4. The magnitude of these changes was significantly greater for dextrose than for fructose. Formula 5, containing 5 mg of phenylpropanolamine hydrochloride/ml, 35% sucrose, 15% corn syrup, 11% ethanol, and 20% propylene glycol, was the formulation used for the human excretion studies reported in Table III.

Table IV shows the effects of 5-(hydroxymethyl)-2-furaldehyde and levulinic acid on phenylpropanolamine hydrochloride stability at pH 4, 6, and 7 and on sorbitol at pH 6. Sorbitol had no effect, and levulinic acid had no significant effect. In contrast, there was a loss of phenylpropanolamine hydrochloride from interaction with 5-(hydroxymethyl)-2-furaldehyde. While no pH changes occurred, the solution darkened and a dark precipitate developed. Recovery of this precipitate by centrifugation indicated that it was water insoluble, methanol soluble, and very slowly soluble in chloroform. By comparison, precipitates from dextrose–phenylpropanolamine hydrochloride solutions were water insoluble and methanol soluble but appeared to be chloroform insoluble.

Table III shows the urinary excretion data from formulations containing phenylpropanolamine hydrochloride. The first formulation (A-5°) initially contained 24.4 mg of phenylpropanolamine hydrochloride/5 ml in the sugar vehicle already described. After 1 month at 55° (A-55°), ~38% of the phenylpropanolamine hydrochloride was lost with 15.2 mg/5 ml retained. Formulation B, which assayed 26.8 mg of phenylpropanolamine hydrochloride/10 ml, was made in a sorbitol vehicle and was stable.

In all three cases, the amount of phenylpropanolamine hydrochloride recovered in the 24-hr urine samples was in proportion to the amount of "undegraded" phenylpropanolamine hydrochloride administered, or ~71–78% of the dose.

[a] No significant changes observed after storage at elevated temperatures.

DISCUSSION

The analytical data reported here indicate that there was an interaction of phenylpropanolamine hydrochloride with sugars containing aldose or ketose functional groups or with 5-(hydroxymethyl)-2-furaldehyde, a degradation product of dextrose or fructose. Levulinic acid, another possible degradation product, was unreactive. Sucrose *per se* is not expected to be reactive with phenylpropanolamine hydrochloride until hydrolysis to carbonyl-containing cleavage products occurs as a function of time, temperature, and pH of the vehicle. As expected, there was no chemical loss of phenylpropanolamine hydrochloride in sorbitol solutions.

If phenylpropanolamine hydrochloride combines with the carbonyl groups of the aldose or ketose sugars or with a reactive carbonyl degradation product, the resulting interaction product may or may not undergo biological transformation after ingestion to release phenylpropanolamine hydrochloride. The urinary excretion data, although limited, appear to suggest that the interaction product does not revert to free phenylpropanolamine hydrochloride after ingestion. If degraded phenylpropanolamine hydrochloride were converted *in vivo* to free phenylpropanolamine hydrochloride, the group ingesting this dose (containing 62% of the amount found in A-5°, the refrigerated control) would have excreted ~19 mg of phenylpropanolamine hydrochloride rather than 10.8 mg.

Possible Interaction Mechanisms—While the present study did not attempt to elucidate the nature of the interaction of phenylpropanol-

amine hydrochloride with the aldose or ketose sugars, the literature was reviewed with regard to the various possibilities concerning this interaction.

Oxazolidine Formation—β-Amino alcohols, such as ephedrine (5–8), pseudoephedrine (5, 7–9), phenylpropanolamine (9–11), and phenylephrine (12, 13), can form oxazolidines with aliphatic and aromatic aldehydes and ketones. The elimination of water from the reaction between the carbonyl group and the vicinal amino and hydroxyl groups of the amino alcohol is usually accomplished by azeotropic distillation (9, 10) or with a dehydrating agent (13) but can occur in an aqueous medium (11). Oxazolidine formation depends on thermodynamic and steric factors. In some cases, the product may exist as a mobile tautomeric system with the corresponding Schiff base (9, 11).

Stability of oxazolidines to hydrolysis is reportedly variable (6, 9). However, oxazolidines usually can be cleaved by heating with acids to yield the amino alcohol and the carbonyl compound (5, 6, 11, 13). The oxazolidine from the interaction of ephedrine and benzaldehyde was marketed in an oily nasal inhalant and was presumably active topically (6). Oxazolidine formation from interaction of sympathomimetic β-amino alcohols with aldose and ketose sugars or with 5-(hydroxymethyl)-2-furaldehyde has not been reported. 5-(Hydroxymethyl)-2-furaldehyde is readily formed by the acid-catalyzed hydrolysis of glucose or fructose (14) or by heating glucose in water (15).

Tetrahydroisoquinoline Formation—Cyclization of norphenylephrine [1-(3-hydroxyphenyl)-2-amino-ethanol] with various carbonyl compounds (*via* a Pictet–Spengler type of reaction but requiring no acidic catalyst) was reported (16) to yield tetrahydroisoquinolines and not oxazolidines as previously reported. The reaction probably proceeds *via* a Schiff base intermediate and appears to be characteristic of β-amino alcohols with a phenolic hydroxyl *para* to the site of cyclization. Similarly, tetrahydroisoquinolines can be formed in sucrose-coated tablets of norphenylephrine (17) from 5-(hydroxymethyl)-2-furaldehyde and levulinic acid, products of the thermal decomposition of sucrose.

The formation of isoquinolines from interaction of phenylpropanolamine and aldose or ketose sugars or their decomposition products has not been reported. This possibility seems remote since a phenolic group in the benzene nucleus is apparently required to promote cyclization.

Browning (Carbonyl–Amine) Reactions—Nonenzymic browning reactions involving the carbonyl group of aldose or ketose sugars with primary or secondary amines are well known (18, 19). The browning of lactose, galactose, dextrose, dextrates, and 5-(hydroxymethyl)-2-furaldehyde with *dl*-amphetamine, its *N*-methyl derivatives, and *d*-amphetamine was studied extensively (20–26). The carbonyl group of the sugar or 5-(hydroxymethyl)-2-furaldehyde and the amine presumably form colored products *via* a Schiff base-type reaction or by formation of glycosyl amines, *N*-glycosides, or certain compounds formed by Amadori rearrangement (27). Isoglucosamines (amino ketones, not Schiff base), if formed by rearrangement, would be expected to be resistant to hydrolysis unlike the glycosamines, most of which easily darken and undergo further decomposition (27).

No experimental data indicate which of the foregoing interaction possibilities is the principal one involved in the phenylpropanolamine hydrochloride–sugar interaction. It is felt that Schiff base formation probably occurred under the test condition with further rearrangement(s) to produce a compound(s) that did not revert to free phenylpropanolamine hydrochloride either *in vivo* or *in vitro*.

Synthesis of 7,7-Diaryl-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines

R. L. WILLIAMS ˣ **and SANDRA NEERGAARD**

Received April 6, 1981, from the *Department of Chemical Sciences, Old Dominion University, Norfolk, VA 23508.* Accepted for publication June 2, 1981.

Abstract □ The synthesis and characterization of various 7,7-diaryl-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines are reported. Convulsant activity was observed with a dipyridyl compound.

Keyphrases □ Histamine—condensation reactions to form 7,7-diaryl-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines □ Spirocyclic-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines—synthesis and characterization □ Convulsants—activity in rats, synthesized dipyridyl compound

As part of a continuing research program in the condensation reactions of histamine (I) with various carbonyl compounds, the synthesis of several novel diaryl-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines will be described. While a variety of condensation products were previously described (1–3), an examination of this Pictet-Spengler type reaction of histamine with diaryl ketones has not been reported.

In general, previously reported methods for the condensation of histamine with aldehydes involved the reaction of histamine dihydrochloride in a basic media with the appropriate aldehyde. Good yields of the aldehyde and ketone condensation products can also be realized by refluxing histamine free base with the desired carbonyl compounds in *n*-butanol. Under these conditions, the Schiff-base intermediates undergo ring closure at the C-5 position of the imidazole ring and the products can then be isolated by removal of the reaction solvent.

This rather simple synthesis has been successfully adapted to include examples of both acyclic and, more recently, cyclic ketones such as 9-fluorenone and 1,8-diazafluorene (Scheme I). The resulting 7-spirocyclic-4,5,6,7-tetrahydroimidazo-[4,5-*c*]pyridines (V and VI) as well as the acyclic ketone analogs (II–IV) have all been characterized by NMR, IR, and elemental analysis (Tables I and II).

Table II—Spectral Data for Diaryl-4,5,6,7-tetrahydroimidazo-[4,5-c]pyridines

Compound	IR Spectrum (KBr): ν_{max}, cm^{-1}	^{1}H-NMR Spectrum (deuterodimethylsulfoxide), ppm
II	3100–2800 (bd), 1610, 750, and 695	2.5 (t, 2H, C-4, CH_2), 2.7 (t, 2H, C-5, CH_2), and 7.16–7.4 (m, 11H, Ar, C-2)
III	3250–2850 (bd), 1610, 775, and 745	2,6 (t, 2H, C-4, CH_2), 2.9 (t, 2H, C-5, CH_2), 7.2 (m, 2H, Ar), 7.6 (5H, Ar, C-2), and 8.3 (2H, Ar)
IV	3100–2600 (bd), 1610, 750, and 695	2.16 (t, 2H, C-4, CH_2), 2.7 (t, 2H, C-5, CH_2), 2.9 (d, 2H, CH_2), 3.4 (d, 2H, CH_2), 7.2 (m, 10H, Ar), and 7.6 (S, 1H, C-2)
V	3200–2850 (bd), 1620 and 745	3.3 (t, 2H, C-4, CH_2), 3.75 (t, 2H, C-5, CH_2), 8.06 (S, 1H, C-2), and 7.6 (m, 8H, Ar)
VI	3200–2800 (bd), 1620, 1580, 790, and 755	2.6 (t, 2H, C-4, CH_2), 3.1 (t, 2H, C-5, CH_2), 6.8 (m, 2H, Ar), 7.8 (m, 3H, Ar, C-2), and 8.3 (m, 2H, Ar)

RESULTS AND DISCUSSIONS

The condensation of histamine free base (I) and a variety of aromatic and heteromatic ketones has given rise to a series of novel 4,5,6,7-tetrahydroimidazo-[4,5-c]pyridines. The proposed structures are supported by pertinent spectral data and are consistent with ring closure at C-5 of the imidazole ring with concomitant loss of the characteristic aromatic proton at 6.9 ppm.

A preliminary gross behavioral evaluation of each of these compounds in mice at three different dose levels (33, 54, and 66 mg/kg) has shown that the dipyridyl compound (III) exhibits a marked degree of convulsant activity. None of the other compounds were found to produce convulsions at the same dose levels. Research is currently in progress to establish the possible mode of action of this novel heterocyclic system.

EXPERIMENTAL[1]

All syntheses were carried out by dissolving the appropriate ketone in *n*-butanol and treating the stirred solution with one equivalent of histamine-free base in *n*-butanol. The solutions were refluxed and monitored using TLC (cellulose; *n*-butanol–acetic acid–water, 4:1:1) until no further ketone could be detected. Removal of the solvent under reduced pressure followed by repeated dilutions with methanol and then with acetone caused the precipitation of the crude free bases of the condensation products. The resulting free bases were converted to their corresponding hydrochlorides which could be recrystallized from ethanol–acetone.

NMR spectra were recorded on a Varian T-60 spectrometer in deuterodimethylsulfoxide using tetramethylsilane as the internal standard. All C, H, and N analyses were performed by the M-H-W Laboratories, Phoenix, Ariz.

Quality Control of Phenylbutazone II: Analysis of Phenylbutazone and Its Decomposition Products in Drugs by High-Pressure Liquid Chromatography

H. FABRE ˣ, B. MANDROU, and H. EDDINE

Received June 2, 1980, from the *Laboratoire de Chimie Analytique, Faculté de Pharmacie, 34060 Montpellier Cedex, France.* Accepted for publication June 17, 1981.

Abstract □ A rapid, sensitive, accurate, and reproducible procedure for the simultaneous separation and determination of phenylbutazone and three major degradation products is proposed using reversed-phase high-pressure liquid chromatography and UV detection. The method is ~20 times more sensitive than TLC and allows an accurate determination of degradation products without decomposition during the analysis.

Keyphrases □ Phenylbutazone—analysis by high-pressure liquid chromatography, decomposition products □ High-pressure liquid chromatography—analysis of phenylbutazone and its decomposition products □ Degradation—phenylbutazone, analysis by high-pressure liquid chromatography

An earlier report (1) outlined the difficulties relative to the establishment of an analytical procedure to detect the intermediate products of oxidation and hydrolysis of phenylbutazone (I). These products are 4-hydroxyphenylbutazone (II), *N*-(2-carboxycaproyl)hydrazobenzene (III), and *N*-(2-carboxy-2-hydroxycaproyl)hydrazobenzene (IV). GLC and TLC are not reliable procedures to monitor the stability of I, because artifacts are formed. TLC can only be used with special precautions as a qualitative and quantitative test to determine I–IV (1).

Reversed-phase high-pressure liquid chromatography (HPLC) is often used in stability studies because it is selective and rapid, and it is particularly recommended when the compound is easily oxidized and when extraction procedures may be degradative. No sample preparation is required for aqueous solutions and reversed-phase HPLC is especially attractive for injections of I because I undergoes decomposition in aqueous medium. Re-

versed-phase HPLC was recently reported (2) to determine I and II metabolites in biological fluids, but there are no literature references relative to the determination of I and its main degradation products *in vitro*. The present study reports a rapid, sensitive, and accurate procedure for simultaneously quantitating I–IV, and an application for injections with lidocaine is given.

EXPERIMENTAL

Material and Reagents—A high-pressure liquid chromatograph[1] with a variable-wavelength UV detector[2], a 10-μl automatic loop injection system, an integrator, and a reversed-phase column[3] were used. Compounds I–IV were used as received[4]. Tromethamine, citric acid, and dimethyl phthalate (V) were analytical reagent grade. Acetonitrile was HPLC reagent grade. Injections (1 g of phenylbutazone, and 50 mg of lidocaine/5 ml of aqueous solvent) were commercial formulations[5]. Distilled water was filtered through a 0.45-μm filter[6]. The *mobile phase* was

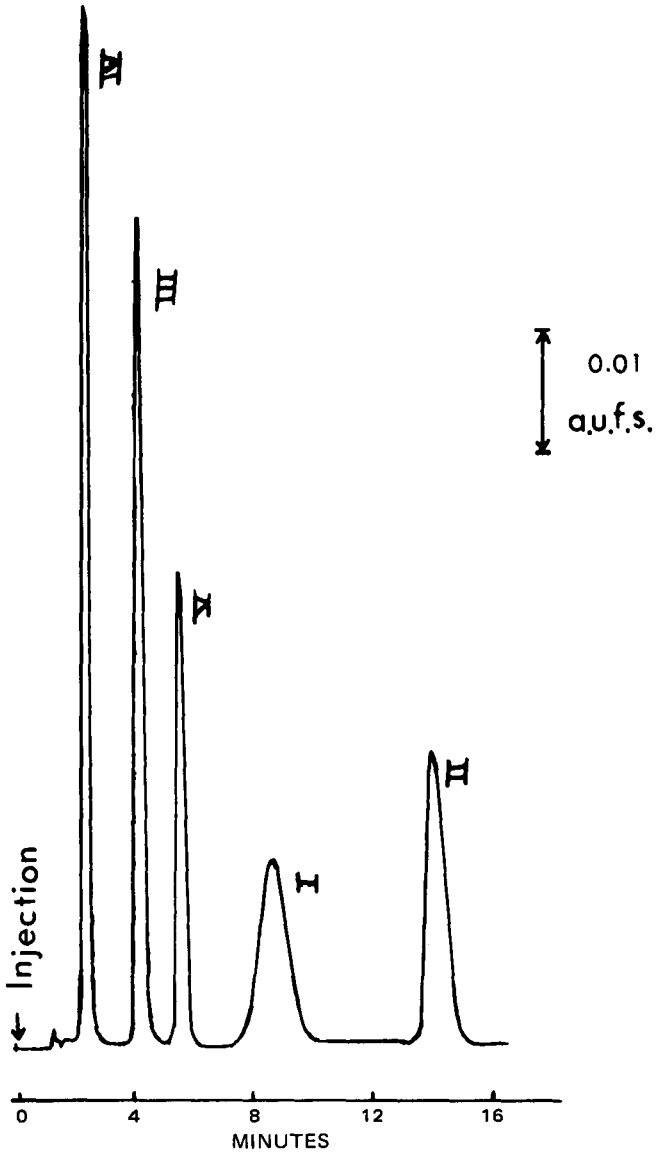

Figure 1—*Chromatogram of a standard solution of I (65.0 μg/ml), II (52.5 μg/ml), III (58.0 μg/ml), IV (68.0 μg/ml), and V (59.6 μg/ml). The mobile phase was 0.1 M tromethamine citrate buffer (pH 5.25)–acetonitrile (60:40); flow was 1.8 ml/min; and pressure was 83 bars. Detector sensitivity 0.1 aufs; chart recorder speed was 0.5 cm/min; and λ = 237 nm.*

0.1 *M* tromethamine citrate buffer[7] (pH 5.25)–acetonitrile (60:40); the mixture was previously degassed.

Standard Solutions—A mixed stock standard solution was prepared in the mobile phase, using I–IV (1000 μg of each per ml). This solution was suitably diluted and an equal volume of internal standard solution (100 μg/ml of V in the mobile phase) was added to give a concentration of 12.5–125 μg of each compound/ml.

Test Solutions—Recoveries of I–IV were carried out on laboratory prepared injections (analogous to commercial formulations) with and without added amounts of II, III, and IV (0.5, 2, and 3.0%, respectively, with respect to I). These solutions and the commercial formulations were suitably diluted in the mobile phase and internal standard was added to match the calibration graph.

Chromatography—Duplicate injections (10 μl) of each solution were injected under the following isocratic conditions: flow rate, 1.8 ml/min;

[1] Spectra-Physics SP 8000.
[2] Schoeffel model SF 770.
[3] 5-μm RP 18, 25-cm length × 4.6-mm diameter, laboratory-made column.
[4] Courtesy of Geigy Laboratories, Basel, Switzerland.
[5] Geigy Laboratories. Injections did not have the same reference numbers as those previously used (1).
[6] Millipore.

[7] Made by dissolving 24.2 g of tromethamine in 70 ml of water, adjusting the pH to 4.7 with citric acid, and diluting to 100 ml with water. The pH 5.25 buffer solution was prepared with a 5-ml aliquot diluted to 100 ml.

pressure, 83 ± 2 bars; chart speed, 0.5 cm/min, detector sensitivity, 0.04–0.1 aufs; and oven temperature, 20°. The chromatograms were recorded at 237 nm.

RESULTS AND DISCUSSION

The maximum absorbance wavelengths in the mobile phase were 267 (I) and 237 (II–IV). A weak absorbance of V was observed at 267 nm; 237 nm was most suitable for the simultaneous determination of I–V. In injections, lidocaine did not absorb at 237 and 267 nm at the concentration used (125 μg/ml) for the determination of II–IV.

A chromatogram of a standard solution is shown in Fig. 1 and Table I lists the retention times of each compound.

Figure 1 and Table I show a good resolution of each compound. The resolution obtained was always better than 1 for I–V.

A calibration graph was plotted of peak area ratio of the solute to the internal standard against solute concentration. The calibration graph was linear in the concentration range studied and went through the origin, using peak areas as well as peak heights. The correlation coefficients of the linear regression analysis were always better than 0.999 using peak areas as well as peak heights.

The minimum amount detectable, defined as the amount (in micrograms) that gives a peak height equal to twice the background, and the sensitivity, defined as the change in area value (measured at the maximum detector sensitivity) resulting from a concentration change of one unit (milligrams per liter) are given in Table II.

The repeatability tested by five replicates and evaluated by the coefficient of variation was 0.978 (I), 1.064 (II), 1.210 (III), and 1.510% (IV). The average data of duplicate assays for recovery studies on laboratory prepared injections with and without added amounts of II–IV are given in Table III.

A comparative separation of I–IV was carried out on a silica column[8]. With hexane–chloroform–methanol–formic acid (400:200:20:1) as a mobile phase, retention times were ~4 (I), 8 (II), 12 (III), 17 (IV), and 25 min for benzenesulfonamide used as an internal standard. Reversed-phase HPLC was faster (14 min) and more convenient than normal HPLC. The insignificant amounts of II–IV (probably present in the reference drug) detected by injecting 10 μl of a concentrated solution of I (2.5 g/liter) and the accuracy obtained for the determination of trace II–IV reveal that reversed-phase HPLC allows the determination of I–IV without decomposition during analysis.

With GLC, artifact peaks were observed when degradation products were present, and it is suggested (3) that the breakdown of the degradates occurs at the injection port maintained at 230°. HPLC is achieved at ambient temperature and prevents this drawback.

With TLC, a significant oxidation of I on the plate was observed during analysis (1). The iron present in the silica coating was responsible (1) for the accelerated air oxidation of I. The absence of degradation with the HPLC procedure is consistent with this hypothesis. The analysis time (13 min), the absence of air exposure, and the presence of citric acid (chelating agent for iron) in the mobile phase (used as an eluting agent and as a solvent in the preparation of solutions) contribute to prevent the degradation of I.

A commercial injection formulation was analyzed by the proposed HPLC procedure. Compound I was 1000.2 mg (100.0% of the labeled strength), III was 14.92 mg (1.49% with respect to theoretical I content), IV was 21.8 mg (2.18% with respect to theoretical I content), and II was not detected. The results are in agreement with other data (4) that shows II is so readily hydrolyzed into IV that it cannot be found in alkaline solution, and the major products of I degradation in injections are III and IV.

Reversed-phase HPLC is a sensitive (20 times more than TLC) and convenient procedure that can be used to evaluate the purity of phenylbutazone and to monitor its stability in pharmaceutical formulations. Because the metabolites of I have been identified as similar to the degradation products *in vitro*, the method is suggested to be applicable to pharmacokinetic studies.

Active Conformation of Polycyclic Antidepressants

Keyphrases □ Antidepressants, polycyclic—active conformation □ Conformation, active—of polycyclic antidepressants

To the Editor:

A 300-MHz ^{1}H-NMR study of a series of polycyclic (tetracyclic and pentacyclic) antidepressant agents of the amitriptyline type indicated a preferred conformation in solution in which the alkylamino side chain is folded toward the polycyclic skeleton and its positively charged dimethylammonium ion is oriented above the adjacent aromatic ring.

Amitriptyline (I) and imipramine, prototype tricyclic antidepressant drugs, are potent inhibitors of active reuptake of biogenic amines in nerve endings. The therapeutic effects of these drugs may be related to this activity[1] (1–5). Reuptake inhibition may lead to an accumulation of neurotransmitters, *e.g.*, norepinephrine and serotonin, at the receptor site and to a subsequent increase in activity. The preferred conformation of the tricyclic antidepressant at the biogenic amine uptake jump may be crucial to their antidepressant activity.

Of particular significance is the conformation of the alkylamino side chain *vis-à-vis* the tricyclic skeleton (6, 7). X-ray structure determinations (8–13) indicated that in the crystalline state the side chain is almost fully extended, away from the tricyclic skeleton. However, it was suggested (6, 14) that the active conformation of the alkylamino side chain in polycyclic antidepressants is folded toward the aromatic ring. We present evidence for the amitriptyline-type series in favor of this hypothesis and

pressure, 83 ± 2 bars; chart speed, 0.5 cm/min, detector sensitivity, 0.04–0.1 aufs; and oven temperature, 20°. The chromatograms were recorded at 237 nm.

RESULTS AND DISCUSSION

The maximum absorbance wavelengths in the mobile phase were 267 (I) and 237 (II–IV). A weak absorbance of V was observed at 267 nm; 237 nm was most suitable for the simultaneous determination of I–V. In injections, lidocaine did not absorb at 237 and 267 nm at the concentration used (125 μg/ml) for the determination of II–IV.

A chromatogram of a standard solution is shown in Fig. 1 and Table I lists the retention times of each compound.

Figure 1 and Table I show a good resolution of each compound. The resolution obtained was always better than 1 for I–V.

A calibration graph was plotted of peak area ratio of the solute to the internal standard against solute concentration. The calibration graph was linear in the concentration range studied and went through the origin, using peak areas as well as peak heights. The correlation coefficients of the linear regression analysis were always better than 0.999 using peak areas as well as peak heights.

The minimum amount detectable, defined as the amount (in micrograms) that gives a peak height equal to twice the background, and the sensitivity, defined as the change in area value (measured at the maximum detector sensitivity) resulting from a concentration change of one unit (milligrams per liter) are given in Table II.

The repeatability tested by five replicates and evaluated by the coefficient of variation was 0.978 (I), 1.064 (II), 1.210 (III), and 1.510% (IV). The average data of duplicate assays for recovery studies on laboratory prepared injections with and without added amounts of II–IV are given in Table III.

A comparative separation of I–IV was carried out on a silica column[8]. With hexane–chloroform–methanol–formic acid (400:200:20:1) as a mobile phase, retention times were ~4 (I), 8 (II), 12 (III), 17 (IV), and 25 min for benzenesulfonamide used as an internal standard. Reversed-phase HPLC was faster (14 min) and more convenient than normal HPLC. The insignificant amounts of II–IV (probably present in the reference drug) detected by injecting 10 μl of a concentrated solution of I (2.5 g/liter) and the accuracy obtained for the determination of trace II–IV reveal that reversed-phase HPLC allows the determination of I–IV without decomposition during analysis.

With GLC, artifact peaks were observed when degradation products were present, and it is suggested (3) that the breakdown of the degradates occurs at the injection port maintained at 230°. HPLC is achieved at ambient temperature and prevents this drawback.

With TLC, a significant oxidation of I on the plate was observed during analysis (1). The iron present in the silica coating was responsible (1) for the accelerated air oxidation of I. The absence of degradation with the HPLC procedure is consistent with this hypothesis. The analysis time (13 min), the absence of air exposure, and the presence of citric acid (chelating agent for iron) in the mobile phase (used as an eluting agent and as a solvent in the preparation of solutions) contribute to prevent the degradation of I.

A commercial injection formulation was analyzed by the proposed HPLC procedure. Compound I was 1000.2 mg (100.0% of the labeled strength), III was 14.92 mg (1.49% with respect to theoretical I content), IV was 21.8 mg (2.18% with respect to theoretical I content), and II was not detected. The results are in agreement with other data (4) that shows II is so readily hydrolyzed into IV that it cannot be found in alkaline solution, and the major products of I degradation in injections are III and IV.

Reversed-phase HPLC is a sensitive (20 times more than TLC) and convenient procedure that can be used to evaluate the purity of phenylbutazone and to monitor its stability in pharmaceutical formulations. Because the metabolites of I have been identified as similar to the degradation products *in vitro*, the method is suggested to be applicable to pharmacokinetic studies.

establish that the alkylammonium terminus of the side chain is oriented toward and above the plane of the aromatic ring.

The following polycyclic antidepressants were synthesized and evaluated as antidepressants according to their ability to inhibit serotonin uptake into human blood platelets: 6-(3-dimethylaminopropylidene)-13,14-dihydro-6*H*-cyclohepta[1,2-*b*:4,5-*b*′]dinaphthalene (II), 7-(3-dimethylaminopropylidene)-14,15-dihydro-7*H*- cyclohepta[1,2-*a*:4,5-*b*′]dinaphthalene (III), 5-(3-dimethylaminopropylidene)-12,13-dihydro- 5*H* -benzo[4,5]cyclohepta[1,2-*b*]naphthalene (IV), 7-(3-dimethylaminopropylidene) - 12,13-dihydro-7*H*-benzo[4,5]cyclohepta-[1,2-*a*]naphthalene (V), and 7-(3-dimethylaminopropylidene) - 7*H*-benzo[4,5]cyclohepta[1,2 - *a*]naphthalene (VI). These naphthalene variations of the amitriptyline theme that showed comparable activity to the parent drug[2] offered a favorable opportunity to study the conformation of the alkylamino side chain *vis-à-vis* the aromatic ring in solution.

The 300-MHz ^{1}H-NMR chemical shifts of the dimethylamino groups [$\delta N(CH_3)_2$] of I–VI hydrochloride salts in deuterochloroform solution are recorded in Table I. Under the conditions of a superconducting magnet, small differences of chemical shifts (0.001 ppm) in very dilute solutions are detectable and significant. Consider the two symmetric systems, I and II. The long range effect of the naphthalene nuclei in II (as compared with the benzene rings of I) is manifested in the shielding of 0.047 ppm. The unsymmetrical structure of III–VI may exhibit π diastereoisomerism (geometrical isomerism). The presence in each case of the *E* and *Z* isomers is reflected in the ^{1}H-NMR spectrum, which exhibits two vinylic triplets [*e.g.*, δ_1(III) 6.028 (J = 5.9 Hz), δ_2(III) 5.884 (J = 5.9 Hz), $\Delta\delta$ 0.144]. The expected nonequivalence is probably due to an inductive effect and to the proximity of the vinylic proton to the corresponding aromatic nucleus. More significantly, in each pair of *E*, *Z* isomers, the remote dimethylamino protons are also magnetically nonequivalent, leading to two singlets representing the *E* and *Z* isomers.

The barriers for conformational inversion of the seven-membered ring in amitriptyline-type drugs are low. A dynamic NMR study of II revealed a $\Delta G_c^{\neq}$ value of 15.6 kcal/mole (in deuteroacetonitrile). In the more rigid 5-(3-dimethylaminopropylidene)-5*H*-dibenzo[*a*,*d*]cycloheptene, $\Delta G_c^{\neq}$ equals 22.6 kcal/mole (15). Thus, it is unlikely that the two $N(CH_3)_2$ absorptions in each of compounds III–VI are due to two different conformations of the same geometrical isomer. The magnetic nonequivalence of the *N*-methyl groups cannot be ascribed to an inductive effect in view of the number of bonds separating the *N*-methyl protons from the structural perturbation (*E versus Z*) in the polycyclic skeleton. The spatial magnetic environment of the *E*-$N(CH_3)_2$ and *Z*-$N(CH_3)_2$ protons apparently are not identical, thus leading to the observed shifts. The *E*,*Z* assignments (Table I) are based on comparison with the symmetrical drugs I and II. The data indicate that whenever the alkylamino side chain is *Z* to the naphthalene nucleus, δ-$N(CH_3)_2$ is shielded relative to an alkylamino side chain *Z* to the benzene nucleus (II *versus* I, *E*-IV *versus* *Z*-IV, and *E*-V *versus* *Z*-V). In the linearly annelated derivative (*Z*-IV), the long range diamagnetic shielding effect of the naphthalene nucleus is more pronounced than in the angularly annelated derivative *Z*-V, indicating a variation in the proximity of the side chain to the naphthalene (also note *Z*-III *versus* *E*-III).

The observed diamagnetic effect as revealed in the shielding of the *N*-methyl protons is attributed to a preferred conformer of the alkylamino side chain *vis-à-vis* the polycyclic skeleton. The side chain is folded toward the polycyclic system, and the dimethylamino group is oriented above and not in the plane of the aromatic ring (Fig. 1). Such geometry permits interaction between the ammonium-ion terminus and the aromatic π-electron cloud so that the *N*-methyl groups are exposed to the diamagnetic ring current of the aromatic ring. Consistently with

[2] The synthesis of II–VI (hydrochlorides) and their structure–activity relationships will be reported elsewhere.

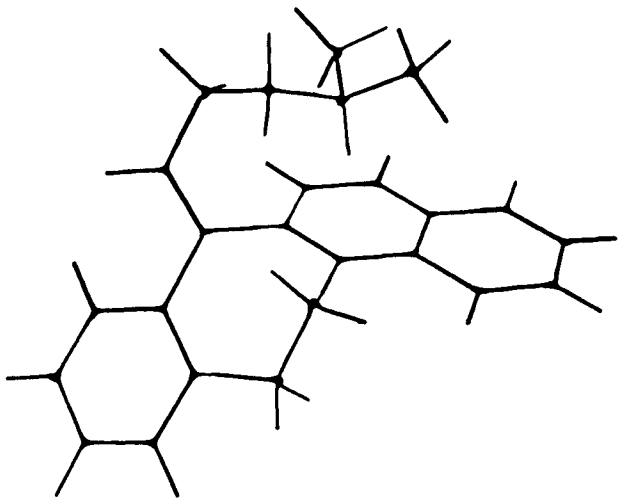

Figure 1—*Preferred conformation of Z-V.*

this picture, the *N*-methylpiperidinylidene analogs of III–VI [*e.g.*, 7-(1-methyl-4-piperidinylidene)-12,13-dihydro-7*H*-benzo[4,5]cyclohepta[1,2-*a*]naphthalene (VII)], in which the nitrogen atoms are rigidly immobilized and positioned away from the polycyclic skeletons, were found to be inactive as inhibitors of serotonin uptake into human blood platelets. The rather considerable difference in $\Delta\delta$ values between IV [$\delta(E\text{-IV}) - \delta(Z\text{-IV}) = 0.096$ ppm] and I–II [$\delta(\text{I}) - \delta(\text{II}) = 0.047$ ppm] should be noted. This difference may be rationalized by considering the conjugation effect of the remote aromatic cycle (*trans* to the side chain) on the diamagnetic ring current of the adjacent aromatic cycle (*cis* to the side chain). The delocalization of the π-electron cloud into the *trans*-aromatic cycle (*via* the exocyclic double bond) weakens the diamagnetic effect of the *cis*-aromatic cycle. This diminution is more pronounced in II (*trans*-naphthalene) than in *Z*-IV (*trans*-benzene) and in *E*-IV than in I. In fact, the order of the net diamagnetic ring current effect is *Z*-IV > II > I > *E*-IV, with the strongest shielding produced by *Z*-IV with its *cis*-naphthalene, *trans*-benzene configuration.

The higher shielding effect in VI relative to V [$\delta(Z\text{-V}) - \delta(Z\text{-VI}) = 0.061$ ppm; $\delta(E\text{-V}) - \delta(E\text{-VI}) = 0.056$ ppm] may be due to the different geometries of the two polycyclic systems. The CH=CH bridge in VI flattens the ring system somewhat, drawing the aromatic surface nearer to the alkylamino side chain. However, the difference in $\Delta\delta$ values between V and VI is very small. It may be concluded that the impact of the *E*,*Z* parameter on the net diamagnetic shielding (due to spatial orientation and conjugation) does not vary significantly from V to VI. A potential energy map for the antidepressant iprindole (as a free base) shows a conformer in which the side chain is folded back toward the plane of the tricyclic system (16). Likewise, in the potent antidepressant *N*,*N*-dimethylspiro[5*H*-dibenzo[*a*,*d*]cyclohepten-5,1′-cyclohexane]-4′ amine, the cyclohexane ring may adopt a boat conformation in which the *N*-methyl group is oriented above the aromatic ring (12, 17).

In a recent conformational structure–activity relationship study of compounds related to tricyclic antidepressants, the projected height of the nitrogen atom over the plane of the nearest aromatic ring seemed to be the most important structural feature (7). The $C^{\gamma}H_2C^{\beta}H_2C^{\alpha}H_2N(CH_3)_2$ side chain of imipramine hydrochloride in a nonaqueous medium (such as deuterochloroform) was shown to exist almost entirely in one fixed conformation with a *gauche* C^{α}–C^{β} and a *trans* C^{β}–C^{γ} fragment (18). The less flexible amitriptyline-type ring system with its rigid exocyclic double bond may be responsible for the preferred active conformation in which the alkylamino side chain is not only folded toward the polycyclic skeleton but its positively charged dimethylammonium ion is oriented above the most adjacent aromatic ring. This effect is manifested even in deuteromethanol solution, which resembles the aqueous physiological environment in which the polycyclic antidepressant agents function: $\Delta\delta(CD_3OD) = \delta(E\text{-III}) - \delta(Z\text{-III}) = 0.045$ ppm. Thus, the preferred conformation of the polycyclic antidepressants in solution is at variance with the conformation in the crystalline state.

Potential Errors in Determining Freundlich and Langmuir Constants from Adsorption Isotherms

Keyphrases □ Adsorbents—determination of Freundlich and Langmuir constants, potential errors □ Freundlich constants—potential errors in determination □ Langmuir constants—potential errors in determination

To the Editor:

Numerous pharmaceuticals have been shown to be adsorbed on various adsorbents such as charcoal and kaolin (1–4). Adsorption data are generally presented as Freundlich constants (Eq. 1) and/or Langmuir constants (Eq. 2):

$$\frac{x}{m} = kC^n \quad \text{(Eq. 1)}$$

$$\frac{x}{m} = \frac{\alpha C}{1 + \beta C} \quad \text{(Eq. 2)}$$

where x/m is the amount of drug (grams) adsorbed per gram of adsorbent, C is the equilibrium concentration of unbound drug, k and n are Freundlich constants, and α and β are Langmuir constants.

Freundlich constants are obtained from the logarithmic form of Eq. 1:

$$\log \frac{x}{m} = \log k + n \log C \quad \text{(Eq. 3)}$$

Equation 3 is a straight line equation. When experimental data are plotted as log x/m *versus* log C, the slope equals n and the intercept yields log k. The use of log–log graph paper is popular in plotting such data. Ganjian *et al.* (5) recently utilized log–log graphs to evaluate Freundlich constants for cimetidine adsorption on charcoal, talc, kaolin, and magnesium trisilicate. The intercept was evaluated by directly reading values on the y-axis (*i.e.*, log x/m) where the x-axis shows a value of 1.0. According to Eq. 3, this is correct when the value of C equals 1.0 (log C = 0). Hence, Eq. 3 reduces to

$$\log \frac{x}{m} = \log k \quad \text{(Eq. 4)}$$

and since log–log paper is used, the intercept values read are k values.

Although the x-axis shows the printed value of 1.0 on log–log graph paper, any exponent value of concentration must be considered. In this plot (Fig. 1, Ref. 5), the value of C at the printed value of 1.0 equals 1.0×10^{-5} M. Ganjian *et al.* read the intercept value at the 1.0×10^{-5} M value of C. This is incorrect. To read intercept values graphically, the authors need at least 6-cycle logarithmic graph paper to obtain a value of C = 1.0. The value of an intercept could also be obtained by solving Eq. 3 for log k. Using values obtained by these authors (Table I, Ref. 5) and citing kaolin as an example:

$$\log (4.02 \times 10^{-4}) = \log k + n \log (1 \times 10^{-5})$$

$$= 5.12 \times 10^{-1}$$

The values so obtained are listed in Table I. The value of n remains unaffected. The order of adsorbents according to k value and the value of k are dramatically changed.

Table I—Corrected Freundlich Constants for Adsorption of Cimetidine onto Various Adsorbents

Adsorbent	n[a]	$k \times 10^4$, g(adsorbed)/g(adsorbent)	Corrected Value[b], $k \times 10^1$
Kaolin	0.621	4.02	5.12
Magnesium trisilicate	0.943	3.43	178
Talc	0.384	2.91	0.24
Charcoal	0.347	256	13.91

[a] Reported values (Table I, Ref. 5). [b] The value k evaluated at C = 1.0 M.

Table II—Effect of Equilibrium Concentration Units on the Freundlich Constant

Adsorbent	Freundlich Constant k, g(adsorbed)/g(adsorbent) C, moles/liter	C, g/liter	C, mg %
Kaolin	5.12×10^{-1}	1.65×10^{-2}	9.45×10^{-4}
Magnesium trisilicate	1.78×10^{1}	9.67×10^{-2}	1.26×10^{-3}
Talc	2.42×10^{-2}	2.89×10^{-3}	4.94×10^{-4}
Charcoal	1.39	2.04×10^{-1}	4.13×10^{-2}

The second potential error lies with the usage of proper units. Although concentration is generally expressed in molar or molal quantities, Freundlich isotherms are generally obtained by expressing C values as milligrams percent or grams percent. Since k is an adsorbent capacity when C = 1, the choice of units is particularly important. Using a unit molar concentration when the experimental range is $\sim 1 \times 10^{-5}$ M yields an order of adsorbents that does not coincide with the experimental results of evaluation using other techniques, *e.g.*, Langmuir's equation.

The Freundlich constant k can be readily calculated at any unit concentration. If C is converted into another concentration, C', using a factor f, then Eq. 1 is rewritten as:

$$\frac{x}{m} = \frac{k}{f^n} C'^n f^n \quad \text{(Eq. 5)}$$

where $k/f^n = k'$, a Freundlich constant using another unit concentration. For kaolin, the difference between Freundlich constants calculated using moles/liter and g/liter is $252.34^{0.621}$ (molecular weight of cimetidine = 252.34 g). Similarly, other values can be calculated.

Table II shows the effect of units on the Freundlich constant k. The order of adsorbents according to adsorption capacity (k) can be visually observed from Freundlich isotherms. The order of adsorbents according to the corrected value is magnesium trisilicate > charcoal > kaolin > talc. If isotherm slopes can be visually imagined extending 6 cycles to the right, this order is correct, at least theoretically. However, this order does not reflect its proper order within the experimental range. This result is best achieved by use of other appropriate units such that a unit equilibrium concentration falls reasonably within the experimental range. An equilibrium concentration of 1 mg % (3.962×10^{-5} M) falls well within the range of experimental data. The order obtained is charcoal > magnesium trisilicate > kaolin > talc. This order coincides well with the experimental data.

The Langmuir equation (Eq. 2) can be rearranged to yield the following linear equation.

$$\frac{C}{\frac{x}{m}} = \frac{1}{\alpha} + \frac{\beta}{\alpha} C \quad \text{(Eq. 6)}$$

The plot of $C/(x/m)$ *versus* C yields the value of α from

0022-3549/82/0100-0125$01.00/0

the reciprocal of an intercept and β can be evaluated from the slope.

A visual observation of the intercepts of a Langmuir isotherm (Fig. 2, Ref. 5) shows the order of adsorbents according to α to be charcoal > talc > kaolin > magnesium trisilicate. The calculated values (Table II, Ref. 5) show the order to be charcoal > kaolin > talc > magnesium trisilicate. The discrepancy arises because the calculated value of α for talc is in error[1] and should be ~71.4 (based on an estimated $1/\alpha$ value of 1.4×10^{-2} from Fig. 2, Ref. 5). The corrected values will show that the order coincides well with visually observed intercept values.

It should be noted that, for Langmuir plots, the use of units other than moles/liter for C will not change the order of adsorbents according to α values, since α is evaluated when C equals zero. However, numerical values of α will change.

It is to be expected that the order of adsorbents would be retained regardless of the equation utilized. This would be true if the adsorption isotherms did not cross over, as in this case. The difference in order is due to the fact that the Freundlich constant k is evaluated at unit equilibrium concentration and the Langmuir constant α is evaluated at zero equilibrium concentration. If the isotherms crossed over between zero and a unit concentration, the order of adsorbents would be different.

Potential Errors in Determining Freundlich and Langmuir Constants from Adsorption Isotherms: A Response

Keyphrases □ Adsorbents—determination of Freundlich and Langmuir constants, potential errors, reply □ Freundlich constants—potential errors in determination, reply □ Langmuir constants—potential errors in determination, reply

To The Editor:

In a recent publication (1) we calculated Freundlich and Langmuir constants for the adsorption of cimetidine on various adsorbents. A number of points in this article have been criticized by Hajratwala (2) and we wish to respond to some of these criticisms.

We believe the author has incorrectly assumed that the intercepts on which our values were based were read directly from the graph. Actually, both intercepts and slopes were calculated using standard linear regression methods. We also fail to see why 6-cycle paper would be necessary in any case. In addition, we feel that the calculation of the parameters based on a single point, as the author has done, is inappropriate. The accuracy of the values obtained is questionable given the closeness of the logarithmic values employed.

With respect to the use of units, we wish to point out that physical chemistry texts (3, 4) employ molarity as the unit for concentration in determining Freundlich parameters, not milligrams percent or grams percent as suggested by Hajratwala. Indeed, we are puzzled as to why this should make a difference in any case. We agree that utilizing different units will yield different values for the constants. However, one need only state which units are used and this should not affect the relative order of constants.

Finally, we acknowledge the error in Table II as pointed out by the author. The value for α is indeed 70.4 (the intercept being 1.42×10^{-2}) and the correct value of β is 15.2 $\times 10^4$ M^{-1}. We regret the miscalculation. There is a typographical error in Table II as Hajratwala notes; however, we feel that this was a misreading. The correct units are neither g(adsorbed)/mg(adsorbent) as printed nor g(adsorbed)/g (adsorbent) as stated by Hajratwala, but g(adsorbed)/M-g(adsorbent). The capital "M" (for molarity) was obviously misread as a lower case "m."

alkyl-3-methyltriazenes were reported previously (2, 3). The triazenes were tested against *T. rhodesiense* (Wellcome CT strain) in the mouse (ICR/HA Swiss) (4). Test and control mice were 6 weeks old and weighed 28–30 g. No differences in response between male and female mice have been reported. Each mouse was infected with an intraperitoneal injection of 0.05 ml of a 1:50,000 dilution of heparinized heart blood drawn from donor mice infected 3 days earlier.

Drugs were administered subcutaneously as a single dose in peanut oil 2 hr after injection. Untreated mice died between 4.2 and 4.5 days after injection. Surviving animals were observed for 30 days and mice surviving after this time were considered cured. The surviving mice were not checked for parasitemia. Test data are given in Table I. The activities of some of the compounds against Sarcoma-180 in the mouse are also included.

The activities reported in Table I suggest that triazenes have curative effects against *T. rhodesiense* in mice. However, high doses are required to produce these effects. It has been suggested that similarities exist between some metabolic pathways of the predominant bloodstream form of the African trypanosome and tumor cells (5) and it was shown that a number of anticancer agents are active against *T. rhodesiense* (6). This correlation was also suggested by the data in Table I when a comparison was made of those activities for the compounds on which both types of data were determined. Compounds 2 and 4 are active in both test systems. Compounds 1 and 3 also were reported to be active against murine leukemia L-1210 in the mouse while the *p*-phenyl analog of II (compound 5) is inactive against *T. rhodesiense*, S-180, and L-1210 (7).

Table I—Activity of II against *T. rhodesiense* Infection in Mice

	R	R′	Dose, mg/kg ip	Antitrypanosomal Activity[a]	Anticancer Activity[b]

13	*p*-CN	$CH_2C_6H_4$-*p*-CH_3	424	Inactive	Inactive[e]
14	*p*-CN	$CH_2C_6H_4$-*p*-Cl	424	Inactive	Inactive[e]

[a] Cures per five treated animals. [b] Activity is given as $-\log C$; C is the moles/kg required to give an increase life span of 130% of control. Tumor was S-180 in the mouse. [c] Duplicate. [d] From reference 2. [e] From reference 3.

The exact mechanism of the anticancer action of the trianzenes is not known but it is known that the 3,3-dialkyltriazenes undergo extensive metabolic *N*-dealkylation to produce alkylating intermediates (8). This metabolic pathway to activation could be host-mediated or it could also be present in the African trypanosome and be involved in the mechanism of action of the triazenes against this parasite. The antitrypanosomal activities of triazenes are being studied further.

Comparison of Equilibrium Times in Dialysis Experiments Using Spiked Plasma or Spiked Buffer

Keyphrases □ Equilibrium dialysis—comparison of spiked plasma and spiked buffer □ Protein binding—effect of spiked plasma and spiked buffer on equilibrium dialysis

To the Editor:

When the plasma protein binding of a drug is to be determined using equilibrium dialysis *in vitro*, the drug can be added to either the buffer side or the plasma side of a dialysis cell. Adding drug to the plasma will dilute the plasma proteins if the drug has to be added as a solution. Adding the drug solution to the buffer avoids this difficulty. However, the approach to equilibrium is slower when the buffer is spiked than when the plasma is spiked. Under conditions where the equilibrium conditions can change

The exact mechanism of the anticancer action of the trianzenes is not known but it is known that the 3,3-dialkyltriazenes undergo extensive metabolic *N*-dealkylation to produce alkylating intermediates (8). This metabolic pathway to activation could be host-mediated or it could also be present in the African trypanosome and be involved in the mechanism of action of the triazenes against this parasite. The antitrypanosomal activities of triazenes are being studied further.

Comparison of Equilibrium Times in Dialysis Experiments Using Spiked Plasma or Spiked Buffer

Keyphrases □ Equilibrium dialysis—comparison of spiked plasma and spiked buffer □ Protein binding—effect of spiked plasma and spiked buffer on equilibrium dialysis

To the Editor:

When the plasma protein binding of a drug is to be determined using equilibrium dialysis *in vitro*, the drug can be added to either the buffer side or the plasma side of a dialysis cell. Adding drug to the plasma will dilute the plasma proteins if the drug has to be added as a solution. Adding the drug solution to the buffer avoids this difficulty. However, the approach to equilibrium is slower when the buffer is spiked than when the plasma is spiked. Under conditions where the equilibrium conditions can change

0022-3549/82/0100-0127$01.00/0

with time, as is seen with quinidine (1), it is important to realize the difference in the time to approach equilibrium between adding drug to plasma and buffer.

For the following discussion, the associating and dissociation rates are assumed to be fast in comparison to the diffusion across the dialysis membrane. Furthermore, it is also assumed that there is the same volume V on both sides of the dialysis membrane, and no net flux of water takes place. In addition, the rate of transfer across the membrane is assumed to be covered by a clearance term Cl_T, which is the same in both directions, and the unbound concentration on each side. The binding is assumed to be linear and no net loss of drug occurs during dialysis.

The rate of change in the buffer side can be expressed by:

$$\frac{dA_B}{dt} = -Cl_T C_B + Cl_T \alpha C_p \qquad \text{(Eq. 1)}$$

where A_B is the amount on the buffer side, α is the unbound fraction in plasma, C_B the buffer concentration, and C_p the plasma concentration of drug. The rate of change in the plasma side is expressed by:

$$\frac{dA_p}{dt} = -Cl_T \alpha C_p + Cl_T C_B \qquad \text{(Eq. 2)}$$

where A_p is the amount on the plasma side.

When the drug initially is placed on the plasma side, the concentration on the buffer side is then described by:

$$C_B = \frac{C_0 \alpha}{1+\alpha}\left[1 - e^{-(k_T\alpha + k_T)t}\right] \qquad \text{(Eq. 3)}$$

where t is time, C_0 initial concentration, and k_T the ratio Cl_T/V.

When the drug initially is placed on the buffer side, the buffer side concentration is described by:

$$C_B = \frac{C_0}{1+\alpha}\left[\alpha + e^{-(k_T\alpha + k_T)t}\right] \qquad \text{(Eq. 4)}$$

In both cases the concentration approaches the equilibrium concentration $(C_0\,\alpha)/(1+\alpha)$ when $t \to \infty$. One can determine from Eqs. 3 and 4 the time that is needed to reach a value that is only a fraction, δ, away from the equilibrium concentration; *i.e.*, the time required to reach a buffer concentration of $[(C_0\,\alpha)/(1+\alpha)]\,(1-\delta)$ if the drug is placed initially on the plasma side and $[(C_0\,\alpha)/1+\alpha]\,(1+\delta)$ if it is placed initially on the buffer side. The ratio of the times to reach these concentration is then:

$$R = \frac{t_B}{t_p} = \frac{\ln\left\{\left[\left(\frac{C_0\alpha}{1+\alpha}\right)(1+\delta)\Big/\frac{C_0}{1+\alpha}\right] - \alpha\right\}}{-(k_T\,\alpha + k_T)} \qquad \text{(Eq. 5)}$$

$$\frac{\ln\left\{\left[-\frac{C_0\,\alpha}{1+\alpha}(1-\delta)\Big/\frac{C_0\,\alpha}{1+\alpha}\right] + 1\right\}}{-(k_T\,\alpha + k_T)} \qquad \text{(Eq. 5)}$$

where t_p and t_B are the times to reach equilibrium when the drug is initially added to the plasma and buffer side, respectively. Cancelling the common terms gives:

$$R = \frac{t_B}{t_p} = \frac{\ln\delta + \ln\alpha}{\ln\delta} = 1 + \frac{\ln\alpha}{\ln\delta} \qquad \text{(Eq. 6)}$$

Equation 6 indicates that the closer to the true equilibrium value one wants to be, the closer the ratio is to unity. The stronger the binding and the larger the deviation from the true equilibrium concentration, the greater the advantage of spiking the plasma side.

Stability of Heparin and Other Fractions of Glycosaminoglycan Sulfates in Human Digestive Juices

Keyphrases □ Heparin—stability in human digestive juices □ Glycosaminoglycan sulfates—stability in human digestive juices □ Absorption, intestinal—stability of heparin and glycosaminoglycan sulfates

To the Editor:

The oral administration of heparin has been a subject of controversy (1) because of its uncertain absorption in the GI tract and its stability in digestive juices. Its N-sulfate groups are easily hydrolyzed in an acidic medium, with consequent impairment of biological activity. Some authors (2) also affirmed that intestinal flora degrades and metabolizes heparin.

However, according to recent studies (3, 4), some fractions of glycosaminoglycan sulfates, strictly correlated to heparin, exerted antithrombotic and hypolipidemic activities after oral administration. Furthermore, it was proved that intestinal absorption took place when some fractions of glycosaminoglycan sulfates, labeled with fluorescein (5), were administered intraduodenally (6).

Special excipients to suppress ionization of the functional groups of glycosaminoglycan sulfates and, thus, to promote their GI absorption (7) were studied. It was found that, if biopolymer is administered in micellar suspension with monoolein and bile salts, the intestinal absorption of heparin greatly increases with increasing mucosa permeability (8). For example, the rectal administration to rats of heparin and other glycosaminoglycan sulfates in a 2-mg/kg dose in an oily emulsion prolonged the time of coagulation; only 1 mg/kg, administered by the same route, activated the lipoprotein lipase-inducing system (9).

To evaluate if and to what extent human digestive juices can degrade glycosaminoglycan sulfates, we investigated the stability and biological activity of heparin and a standardized mixture[1] of fractions of glycosaminoglycan sulfates, containing a heparin-like substance with a low molecular weight and condroitin sulfate B, in cat and human gastric and duodenal juices.

Glycosaminoglycan sulfates and heparin were incubated at concentrations of 190 and 238 USP/ml, respectively, for up to 3 hr in digestive juices[2] at 37°. To evaluate the in-

[1] Sulodexide.
[2] Gastric juice of the cat was obtained by a Heidenhain gastric pouch. Human gastric juice was obtained from a probe of five volunteers who had previously been given an injection of 3 U of cholecystokinin kg/hr iv.

with time, as is seen with quinidine (1), it is important to realize the difference in the time to approach equilibrium between adding drug to plasma and buffer.

For the following discussion, the associating and dissociation rates are assumed to be fast in comparison to the diffusion across the dialysis membrane. Furthermore, it is also assumed that there is the same volume V on both sides of the dialysis membrane, and no net flux of water takes place. In addition, the rate of transfer across the membrane is assumed to be covered by a clearance term Cl_T, which is the same in both directions, and the unbound concentration on each side. The binding is assumed to be linear and no net loss of drug occurs during dialysis.

The rate of change in the buffer side can be expressed by:

$$\frac{dA_B}{dt} = -Cl_T C_B + Cl_T \alpha C_p \qquad \text{(Eq. 1)}$$

where A_B is the amount on the buffer side, α is the unbound fraction in plasma, C_B the buffer concentration, and C_p the plasma concentration of drug. The rate of change in the plasma side is expressed by:

$$\frac{dA_p}{dt} = -Cl_T \alpha C_p + Cl_T C_B \qquad \text{(Eq. 2)}$$

where A_p is the amount on the plasma side.

When the drug initially is placed on the plasma side, the concentration on the buffer side is then described by:

$$C_B = \frac{C_0 \alpha}{1+\alpha}\left[1 - e^{-(k_T\alpha + k_T)t}\right] \qquad \text{(Eq. 3)}$$

where t is time, C_0 initial concentration, and k_T the ratio Cl_T/V.

When the drug initially is placed on the buffer side, the buffer side concentration is described by:

$$C_B = \frac{C_0}{1+\alpha}\left[\alpha + e^{-(k_T\alpha + k_T)t}\right] \qquad \text{(Eq. 4)}$$

In both cases the concentration approaches the equilibrium concentration $(C_0\,\alpha)/(1+\alpha)$ when $t \to \infty$. One can determine from Eqs. 3 and 4 the time that is needed to reach a value that is only a fraction, δ, away from the equilibrium concentration; *i.e.*, the time required to reach a buffer concentration of $[(C_0\,\alpha)/(1+\alpha)]\,(1-\delta)$ if the drug is placed initially on the plasma side and $[(C_0\,\alpha)/1+\alpha]\,(1+\delta)$ if it is placed initially on the buffer side. The ratio of the times to reach these concentration is then:

$$R = \frac{t_B}{t_p} = \frac{\ln\left\{\left[\left(\frac{C_0\alpha}{1+\alpha}\right)(1+\delta)\Big/\frac{C_0}{1+\alpha}\right] - \alpha\right\}}{-(k_T\,\alpha + k_T)} \qquad \text{(Eq. 5)}$$

$$\frac{\ln\left\{\left[-\frac{C_0\,\alpha}{1+\alpha}(1-\delta)\Big/\frac{C_0\,\alpha}{1+\alpha}\right] + 1\right\}}{-(k_T\,\alpha + k_T)} \qquad \text{(Eq. 5)}$$

where t_p and t_B are the times to reach equilibrium when the drug is initially added to the plasma and buffer side, respectively. Cancelling the common terms gives:

$$R = \frac{t_B}{t_p} = \frac{\ln\delta + \ln\alpha}{\ln\delta} = 1 + \frac{\ln\alpha}{\ln\delta} \qquad \text{(Eq. 6)}$$

Equation 6 indicates that the closer to the true equilibrium value one wants to be, the closer the ratio is to unity. The stronger the binding and the larger the deviation from the true equilibrium concentration, the greater the advantage of spiking the plasma side.

[a] The values are expressed as percent of initial activity.

fluence of dilution, stability tests were carried out in which the concentrations of heparin and the standardized mixture of glycosaminoglycan sulfates were 19 and 23.8 USP/ml, respectively. Anticoagulant and lipoprotein–lipase-inducing activities were measured in relation to the time of incubation by means of *in vitro* and *in vivo* quantitative methods. Lipoprotein–lipase activity was measured by a turbidimetric method[3].

Anticoagulant action *in vivo* was evaluated by thrombin time with an aliquot of the same plasma used for the determination of lipoprotein–lipase releasing action *in vivo* by the ediol method. All coagulation times were determined automatically.

The biological activity pattern of heparin and other glycosaminoglycan sulfates remained unchanged during the experimental time period, although some variability in biological assessment occurred (Table I).

The confirmed biological activity shows that the nature and conformation of even the more labile chemical groups of glycosaminoglycan sulfates remain unaltered, despite being incubated in chemically and enzymatically aggressive environments such as digestive juices.

Adsorption of Methotrexate onto Glassware and Syringes

Keyphrases □ Methotrexate—adsorption onto glassware and syringes □ Adsorption—methotrexate onto glassware and syringes

To the Editor:

Methotrexate, a potent antifolate, is a widely used antineoplastic agent (1). With the advent of high-dose therapy and citrovorum-factor rescue, monitoring of plasma concentrations of methotrexate is recommended (1–4). However, the potential interference of active metabolites, such as 7-hydroxymethotrexate and 4-amino-4-deoxy-N^{10}-methylpteroic acid, renders many assay methods nonspecific (5). A need for re-evaluation of past pharmacokinetic studies has been advocated (6). Hence, development of specific and sensitive assay methods is required. In our recent development of a high-performance liquid chromatographic (HPLC) assay for methotrexate and its metabolites in biological fluids (7), erratic results were often found when series dilutions of methotrexate in water-miscible organic solvents such as methanol were made. These organic solvents were used to enhance the aqueous solubility of methotrexate (8).

Additional studies were carried out to explore the potential interaction between methotrexate and glassware or syringes. This communication reports the results of our preliminary adsorption studies, and discusses its implication in quantitative analysis.

Stock solutions (0.1 mg/ml) of methotrexate were prepared in distilled water, methanol, or 80% ethanol (with 20% water, v/v) using 100-ml volumetric flasks[1]. Series dilutions were made to concentrations of 50, 10, and 1 μg/ml. After mixing and equilibration overnight, the methotrexate concentration was determined directly by the HPLC method described earlier (7). A cation-exchange

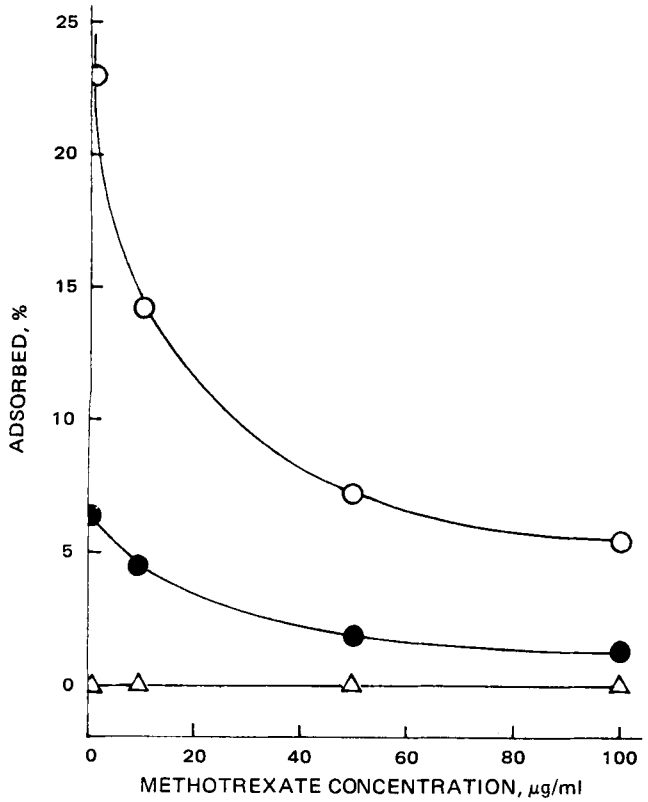

Figure 1—*Effect of concentration and diluent on methotrexate adsorption onto a volumetric flask. Key: ○, methanol; ●, 80% ethanol; and △, water.*

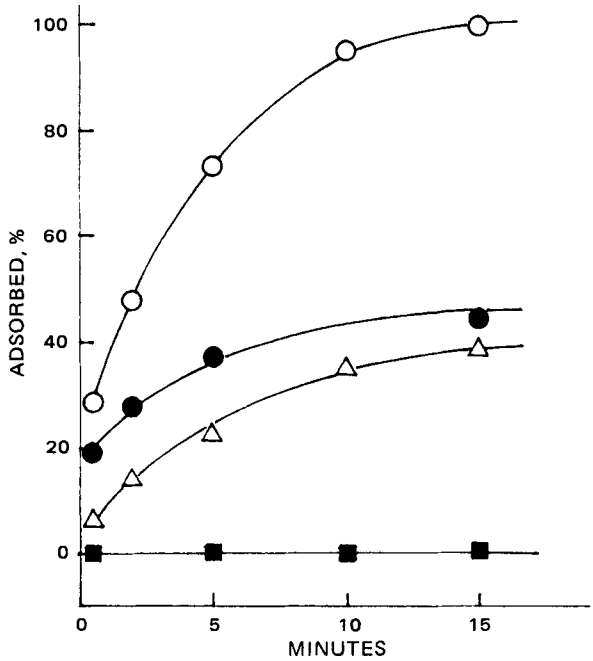

Figure 2—*Effect of exposure time on methotrexate adsorption by the syringe. Key: ○, methanol (0.1 μg/ml); ●, methanol (10 μg/ml); △, 80% ethanol (10 μg/ml); and ■, water (0.1 μg/ml).*

column[2] was used. The mobile phase was prepared by mixing 10 parts of acetonitrile with 90 parts of 0.02 *M* monobasic ammonium phosphate solution acidified with phosphoric acid (0.2%) to pH 2.7. The flow rate was set at 2 ml/min; the retention time for methotrexate was 7 min. *p*-Aminobenzoic acid was used as an internal standard to ensure the proper series dilution and HPLC injection; it was dissolved together with methotrexate in the preparation of stock solutions. No adsorption problem with *p*-aminobenzoic acid was encountered. Experiments were run at least in duplicate.

Figure 1 shows that the extent of adsorption was solvent and concentration dependent. The aqueous solution had no adsorption problem. However, methotrexate showed significant adsorption onto the flask in methanol or 80% ethanol. For example, the adsorption of methotrexate at 1 μg/ml was ~23% in methanol and 7% in 80% ethanol. As shown in Fig. 1, the percentage of methotrexate lost to the volumetric flask increased as the concentration decreased. It is possible that the extent of adsorption may be much greater when the concentration is <1 μg/ml (9).

Further evidence for methotrexate adsorption onto the glassware was supported by the following study. After adsorption equilibration overnight, various drug solutions were withdrawn into syringes[3]. The methotrexate concentrations in the syringes were then measured as a function of time. As shown in Fig. 2, the adsorption of methotrexate increased with the length of contact time in the 15-min period of the study. Again, methotrexate showed a higher degree of adsorption in methanol as compared with the 80% ethanol solution. The extent of adsorption also increased as methotrexate concentration decreased. It appears that the phenomenon of drug adsorption onto syringes used for the HPLC analysis has never been reported in the literature. Adsorption of butaperazine onto quartz cells was reported earlier (10).

A previous study (9) showed that the pH of the solution may influence the magnitude of adsorption. Our preliminary results showed that the adsorption of methotrexate in alcoholic solutions was reduced at lower (pH 2–4) or higher (pH 8–9) pH values.

It should be pointed out that the syringes used in this study were used not only in the preparation of drug standard solutions but also for sample delivery in HPLC assays. If methotrexate is prepared in solvents other than water, serious errors in the determination of the drug concentrations may result. Our preliminary findings also showed that 4-amino-4-deoxy-N^{10}-methylpteroic acid, a methotrexate metabolite (8), had a similar adsorption problem. The results of the present study clearly indicate that the potential adsorption of methotrexate and its metabolites onto glassware and other contact surfaces should be considered as a source of variability in quantitative analysis.

Pharmacokinetic and Biopharmaceutic Parameters During Enterohepatic Circulation of Drugs

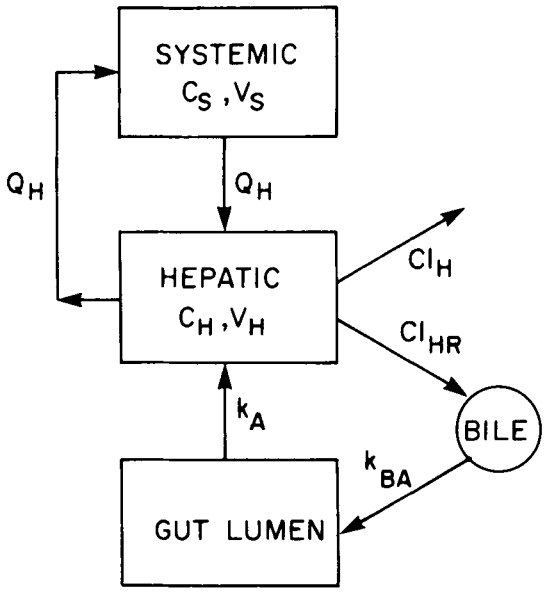
Keyphrases □ Enterohepatic circulation—model, evaluation of pharmacokinetic parameters □ Pharmacokinetics—evaluation of parameters, enterohepatic circulation model

To the Editor:

As research in the area of enterohepatic circulation continues in this laboratory, several aspects of its impact on the interpretation of pharmacokinetic and biopharmaceutic studies have become apparent. Simulation techniques have been used to investigate the effect of enterohepatic circulation on various pharmacokinetic and biopharmaceutic parameters under various conditions.

The simple first-pass perfusion model in Scheme I was used for the simulations. In the model, V_H and V_S are the effective hepatic and systemic volumes[1], Q_H is the blood flow to the liver, and Cl_H and Cl_{HR} are the irreversible and recirculating hepatic organ clearances, respectively. The biliary excretion component was assumed to be continuous in the present model to avoid the complexities associated with gallbladder storage and subsequent excretion into the duodenum. The more complex model was addressed previously (1) and will be investigated further, but the concepts presented here are generally applicable to both situations. For the purpose of the oral absorption simulations, the absorption rate constant, k_A, was set at 0.693 hr^{-1}. Simulations were performed under conditions of intact enterohepatic circulation (k_{BA} = 1.0) and under conditions of bile duct cannulation, *i.e.*, interrupted enterohepatic circulation (k_{BA} = 0.0).

Blood concentration–time data following intravenous and oral doses were simulated using several sets of parameter values. Representative examples from the total number of simulations are presented in Tables I–III. The



Scheme I—Pharmacokinetic first-pass perfusion model used to describe the systemic blood concentrations of drugs that undergo enterohepatic recycling. Key: Q_H, hepatic blood flow; Cl_H and Cl_{HR}, irreversible and recirculating hepatic organ clearances, respectively; and k_A and k_{BA}, the absorption and bile transport processes, respectively.

effect of enterohepatic circulation on blood clearance (Cl_B), oral clearance (Cl_O), elimination half-life ($t_{1/2\beta}$), and the volume of distribution ($V_{d_{area}}$) are presented in Table I. The influence of enterohepatic circulation on the time (T_{max}) of the maximum observed blood concentration (C_{max}) and the elimination half-life following oral dosing are presented in Table II. Table III contains the blood clearance (Cl_B) and oral clearance (Cl_O) parameters along with the absolute bioavailability under intact (F_I) as well as bile duct-cannulated (F_C) conditions. In addition, the ratio of the area under the curves following intravenous doses (AUC_{IV}) under intact and bile-duct-cannulated conditions (R_{IV}) as well as the ratio of the area under the curves following oral doses (AUC_O) under intact and bile duct-cannulated conditions (R_O) are presented in Table III.

The results of these simulations indicate that enterohepatic circulation increases the apparent volume distribution and prolongs the half-life of elimination when compared to identical blood clearances without it. The more extensive the recycling, the more prolonged the half-life and greater the volume increase (Table I). The data presented in Table II indicate that the pharmacokinetic complexities associated with enterohepatic circulation are affected by the effective hepatic and systemic volumes of distribution. The time (T_{max}) of the maximum observed blood concentrations (C_{max}) following oral doses are a function of both the interrelationship of systemic to hepatic effective volumes of distribution as well as the extent of enterohepatic circulation (Table II).

For example, comparison of cases G–I with cases J–L in Table II indicates that when the effective systemic volume of distribution is smaller than the effective hepatic volume of distribution, more extensive recycling results in longer elimination half-lives and lower C_{max} values, but results

[1] Effective volume is the product of the physiological volume of the organ or pooled tissues times its retention factor.

[a] I, intact, uncannulated; and C, cannulated.

in earlier T_{max} values. However, when the effective systemic volume of distribution is larger than the effective hepatic volume, more extensive recycling not only results in longer elimination half-lives and lower C_{max} values, but also in much later T_{max} values. For comparison with case L, the T_{max} value is 8 hr for a drug with an elimination half-life of 125 hr, but without enterohepatic circulation.

The importance of recycling on estimates of the absolute bioavailability of a drug is shown by comparing the absolute bioavailability simulated in intact, uncannulated (F_I), and bile duct-cannulated (F_C) animals. It is apparent that bioavailability in cannulated animals is less than or equal to the bioavailability in uncannulated animals. This observation is supported by the fact that the ratios of areas under the oral curves (R_O) are decreased more extensively by bile duct cannulation than are the ratios of the areas under the intravenous curves (R_{IV}).

Although enterohepatic circulation affects the shapes of the blood concentration–time curves by increasing the apparent volume of distribution and half-life (Table I) and by altering the C_{max} and T_{max} values (Table II), it will not alter the areas under the blood concentration–time curves unless the enterohepatic circulation is interrupted (Table III) or altered in some way. An interruption can result from bile duct cannulation in the experimental setting, from the oral ingestion of ion-exchange resins, or from changes in the intestinal contents and microflora that may decrease or inhibit drug reabsorption.

Thus, enterohepatic circulation influences the bio-

pharmaceutic and pharmacokinetic parameters associated with a drug. The process needs to be better understood to allow reasonable interpretation of the pharmacokinetic data obtained for drugs that are recycled. The data presented here reflect the simplest case; discontinuous recycling, which is associated with gall bladder storage and emptying, is even more complex (1).

BOOKS

REVIEWS

Basic Clinical Pharmacokinetics. By MICHAEL E. WINTER, with BRIAN S. KATCHER and MARY ANNE KODA-KIMBLE. Applied Therapeutics, P.O. Box 31-747, San Francisco, CA 94131. 1980. 231 pp. 14.8 × 22.7 cm. Price $22.00.

Pharmacokinetics and biopharmaceutics are well-established disciplines. Their contributions in describing drug disposition, and predicting plasma drug concentrations and changes in drug concentrations are generally recognized. During the past decade, evaluation of drug concentrations in biological fluids has found wide acceptance as part of drug therapy monitoring. The authors view this book as a practical guideline for the clinician in evaluating drug monitoring.

The book is divided into two parts. The first part gives a brief overview of the basic principles of pharmacokinetics dealing with bioavailability, rate of administration, desired plasma concentration, volume of distribution, clearance, elimination, steady-state concentrations, interpretation of plasma drug concentrations, selection of appropriate equations, and creatinine clearance. At the end of the first part, a very instructive diagram is given for evaluation and interpretation of plasma levels. This diagram will be very helpful for any clinician confronted with blood level data interpretation.

Part 2 discusses the clinical pharmacokinetics of drugs usually monitored by a clinical pharmacokinetics service. The following drugs are covered: digoxin, lidocaine, procainamide, quinidine, theophylline, gentamicin, phenobarbital, and phenytoin. For each of these drugs, therapeutic and toxic plasma levels, bioavailability, if applicable, and the most important pharmacokinetic parameters (*i.e.*, volume of distribution, clearance, and elimination half-life) are covered. Where applicable, the influence of age, disease, and other concomitantly given drugs on drug disposition is discussed.

This section, which is well referenced, is followed by a selection of typical clinical cases, along with the pharmacokinetic approach for solution. The calculations are listed stepwise so that even one who is inexperienced in pharmacokinetics can easily follow. This section will be of great value to anyone interested in or practicing clinical pharmacokinetics, as well as for teaching undergraduate and graduate students. Although only a few drugs are discussed in detail, once one masters these problem cases, the principles can be applied and tailored to many more drugs.

The book contains three appendixes: I, nomograms for calculating body surface area of children and adults; II, a listing of equations used throughout the text; and III, a glossary of terms and abbreviations.

In summary, this is a well-written and well-designed text which incorporates the most important basic principles of basic and clinical pharmacokinetics. As such, the book will be of great value to all those involved in clinical pharmacokinetics and drug monitoring, particularly those who are entering the field. The authors have to be congratulated for writing such a well-organized guideline to the practical approach of drug level monitoring.

GC/MS Assays for Abused Drugs in Body Fluid. NIDA Research Monograph 32. By RODGER L. FOLTZ, ALLISON F. FENTIMAN, and RUTH B. FOLTZ. National Institute on Drug Abuse, Division of Research, 5600 Fishers Lane, Rockville, MD 20857. 1980. 202 pp. 14 × 23 cm. Price $5.00. (Available from Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. Specify GPO stock no. 017-024-01015-4.)

This monograph, prepared by authors who are well versed in the areas of analytical methodology and drug abuse, should be valuable to investigators interested in quantitating drugs in biological fluids. This work is actually a compilation of assays used for measuring the levels of drugs most often misused.

This volume (13 chapters) includes an introduction and a discussion of experimental considerations and operations common to all of the assays (Chapter 2), and each remaining chapter is devoted to a particular drug that is commonly abused. The inclusion of Chapter 2 (which deals with the basics of obtaining internal standards, preparing calibration curves, sample extractions, performance evaluation of the gas chromatograph–mass spectrometer, *etc.*) is an ideal approach since it greatly reduces excessive repetition that would have been required in each of the succeeding chapters. The authors recommend that investigators concentrate on Chapter 2 along with the specific chapter for the drug in question.

Each succeeding chapter is devoted to one of the following drugs of abuse: phencyclidine, methaqualone, methadone, Δ^9-tetrahydrocannabinol and two of its metabolites (11-hydroxy-Δ^9-THC and 11-nor-9-carboxy-Δ^9-THC), cocaine and its major metabolite (benzoylecgonine), morphine, diazepam and its major metabolite (*N*-desmethyldiazepam), amphetamine, methamphetamine, 2,5-dimethoxy-4-methylamphetamine, and mescaline. Each chapter begins with a brief historical description of the drug followed by a synopsis of its pharmacological effects. A discussion on pharmacokinetics and metabolism examines which biological fluid should be chosen for assay and whether metabolites should be quantitated. Then the sensitivity and selectivity of most of the techniques (*e.g.*, spectrometry, gas chromatography, and radioimmunoassay)

pharmaceutic and pharmacokinetic parameters associated with a drug. The process needs to be better understood to allow reasonable interpretation of the pharmacokinetic data obtained for drugs that are recycled. The data presented here reflect the simplest case; discontinuous recycling, which is associated with gall bladder storage and emptying, is even more complex (1).

This diagram will be very helpful for any clinician confronted with blood level data interpretation.

Part 2 discusses the clinical pharmacokinetics of drugs usually monitored by a clinical pharmacokinetics service. The following drugs are covered: digoxin, lidocaine, procainamide, quinidine, theophylline, gentamicin, phenobarbital, and phenytoin. For each of these drugs, therapeutic and toxic plasma levels, bioavailability, if applicable, and the most important pharmacokinetic parameters (*i.e.*, volume of distribution, clearance, and elimination half-life) are covered. Where applicable, the influence of age, disease, and other concomitantly given drugs on drug disposition is discussed.

This section, which is well referenced, is followed by a selection of typical clinical cases, along with the pharmacokinetic approach for solution. The calculations are listed stepwise so that even one who is inexperienced in pharmacokinetics can easily follow. This section will be of great value to anyone interested in or practicing clinical pharmacokinetics, as well as for teaching undergraduate and graduate students. Although only a few drugs are discussed in detail, once one masters these problem cases, the principles can be applied and tailored to many more drugs.

The book contains three appendixes: I, nomograms for calculating body surface area of children and adults; II, a listing of equations used throughout the text; and III, a glossary of terms and abbreviations.

In summary, this is a well-written and well-designed text which incorporates the most important basic principles of basic and clinical pharmacokinetics. As such, the book will be of great value to all those involved in clinical pharmacokinetics and drug monitoring, particularly those who are entering the field. The authors have to be congratulated for writing such a well-organized guideline to the practical approach of drug level monitoring.

GC/MS Assays for Abused Drugs in Body Fluid. NIDA Research Monograph 32. By RODGER L. FOLTZ, ALLISON F. FENTIMAN, and RUTH B. FOLTZ. National Institute on Drug Abuse, Division of Research, 5600 Fishers Lane, Rockville, MD 20857. 1980. 202 pp. 14 × 23 cm. Price $5.00. (Available from Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. Specify GPO stock no. 017-024-01015-4.)

This monograph, prepared by authors who are well versed in the areas of analytical methodology and drug abuse, should be valuable to investigators interested in quantitating drugs in biological fluids. This work is actually a compilation of assays used for measuring the levels of drugs most often misused.

This volume (13 chapters) includes an introduction and a discussion of experimental considerations and operations common to all of the assays (Chapter 2), and each remaining chapter is devoted to a particular drug that is commonly abused. The inclusion of Chapter 2 (which deals with the basics of obtaining internal standards, preparing calibration curves, sample extractions, performance evaluation of the gas chromatograph–mass spectrometer, *etc.*) is an ideal approach since it greatly reduces excessive repetition that would have been required in each of the succeeding chapters. The authors recommend that investigators concentrate on Chapter 2 along with the specific chapter for the drug in question.

Each succeeding chapter is devoted to one of the following drugs of abuse: phencyclidine, methaqualone, methadone, Δ^9-tetrahydrocannabinol and two of its metabolites (11-hydroxy-Δ^9-THC and 11-nor-9-carboxy-Δ^9-THC), cocaine and its major metabolite (benzoylecgonine), morphine, diazepam and its major metabolite (*N*-desmethyldiazepam), amphetamine, methamphetamine, 2,5-dimethoxy-4-methylamphetamine, and mescaline. Each chapter begins with a brief historical description of the drug followed by a synopsis of its pharmacological effects. A discussion on pharmacokinetics and metabolism examines which biological fluid should be chosen for assay and whether metabolites should be quantitated. Then the sensitivity and selectivity of most of the techniques (*e.g.*, spectrometry, gas chromatography, and radioimmunoassay)

that have been applied to the analysis of the drug are presented. However, quantitation by gas chromatography–mass spectrometry–single-ion monitoring, which is far more reliable and sensitive than most other methods, is emphasized. A detailed description of gas chromatographic–mass spectrometric methodology is provided. In addition, each chapter has its own reference section, which provides ample documentation.

This monograph enables the investigator to choose the best analytical method for a particular drug based on the materials and equipment available. In addition, the design of basic experimental protocols should be greatly facilitated with the information contained within this volume. Although this book is intended for those in the field of drug abuse, it should be helpful to anyone interested in undertaking an analysis of any drug by gas chromatography–mass spectrometry.

Pharmacological and Biochemical Properties of Drug Substances, Vol. 3. Edited by MORTON E. GOLDBERG. American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, D.C., 20037. 1981. 495 pp. 16 × 24 cm. Price $39.00 (Vols. 1–3, $90.00).

The third volume of this series presents 16 new monographs on a variety of therapeutic agents and topics, bringing the total number of monographs in this series to 52. Most of these reviews (in this volume as well as in the previous two) are concerned with specific drugs and are extensively referenced.

Although Dr. Goldberg's own research has emphasized central nervous system pharmacology, the book covers a wide variety of therapeutic classes such as cardiovascular agents, chemotherapeutic agents, and pulmonary/antiallergy agents, to name a few. The members of the editorial board also are cited for various areas of expertise.

Volume 3 contains three monographs covering topical steroid therapy, eicosanoids and pulmonary function, and one entitled, "Assessing Drug Concentration/Effect Correlations: Implications for Research and Therapy."

The author encourages readers to write to him or one of the editors if it is felt that a drug or topic deserves consideration for future volumes.

Renewed Attention Regarding Drug Stability

An interview with an aeronautical engineer was recently published in a general circulation magazine. What made the interview unusual was the subject matter: namely, lighter-than-air vehicles, otherwise known as dirigibles, zeppelins, or just plain "balloons."

The engineer brought out the usefulness of such aircraft to harvest logs out of dense forests, to deliver construction materials to otherwise inaccessible sites such as mountain tops, to bring heavy beams or piers into place in constructing bridges or tall buildings, and an assortment of other such uses. But he also lamented the fact that the entire field of lighter-than-air craft has been virtually ignored for the past 40 years as the appeal and glamour of air travel has moved, in turn, from propeller planes, to jet aircraft, to rockets, and to space vehicles.

All of this is just human nature; people's attention and interest are naturally drawn to the new, the exciting, the complex. Thirty years ago, we used the "times tables" to perform our simple multiplications; 20 years ago, we used a slide rule for this purpose; 10 years ago, we were using pocket calculators; today, we have small computers to do the job for us.

In light of this trend, it is not surprising that the pharmaceutical research community has shown less interest in the chemical and physical stability of drug substances and of drug products than in bioavailability, pharmacokinetics, drug metabolism, bioequivalence, and the other new and more glamorous areas of research. These latter areas have captured the drug researchers' fancy and have been accorded the lion's share of interest for at least the past 10 to 15 years.

But just as in the case of lighter-than-air vehicles, there is much to be learned concerning drug stability, as well as much to be done in the way of potentially important applications of that knowledge.

We were particularly reminded of this situation when we reviewed a document issued by the World Health Organization in late Summer 1981. The paper was entitled, "Stability of Pharmaceutical Substances and Simple Methods of Detecting Their Degradation," and it was prepared by Dr. M. Perez of the Analytical Laboratories of Roussel-Uclaf in Romainville, France.

The paper is the second in a series and details the results of a stability survey conducted on an additional 132 pharmaceutical substances. The practical significance of such research was indicative in the finding that 59 of the substances in this latest study were determined to be degradable under the conditions employed, while the remaining 73 substances were judged to be stable under the standardized adverse conditions utilized.

Even more recently, we have read announcements or reports that indicate a renewed interest in drug stability on the part of several pharmaceutical groups in this country.

For example, in October 1981, the United States Pharmacopeia, the American Society of Hospital Pharmacists, and the Food and Drug Administration jointly announced that they would be proceeding to undertake a "program to learn more about the shelf-life stability of drugs under actual market conditions." The program is to be titled "The Drug Stability Testing Program," and it is based on the success of a pilot stability study conducted on digoxin tablets during the preceding year. The results of the latter study, and a description of the study procedure, were published in the December 1981 issue of the *American Journal of Hospital Pharmacy*.

In November 1981, the Extension Services in Pharmacy at the University of Wisconsin announced that their annual Industrial Pharmacy Management Conference, to be presented in late March 1982, would be devoted to the theme "Dating of Pharmaceuticals, Update 1982." This conference will attempt to examine and review all that has happened on this subject since it was initially addressed as the theme of the first Wisconsin conference when this pharmacy management series was launched in 1969.

Finally, in December 1981, the American College of Apothecaries adopted a resolution titled "Uniform Expiration Dating for Pharmaceuticals." The body of the resolution lends support to the proposal for nationwide uniform dating as a part of FDA's Good Manufacturing Practices regulations—all of this out of recognition of the variable stability among drugs and the importance of stability information in ensuring quality pharmaceuticals for the patient.

None of these individual actions or programs is particularly dramatic. Indeed, some of them are not even new.

Nevertheless, they are significant because they address an important subject that has been largely neglected in recent years. Consequently, we applaud such efforts. Moreover, we encourage all within the pharmaceutical community to give their moral and professional support to these and to similar efforts directed at (a) elucidating more information concerning drug stability and instability and (b) the application of this information for the benefit of patients and those practitioners who serve them.

LITERATURE SURVEY

Vitamin D: An Update

K. THOMAS KOSHY

Received from *The Agricultural Division, The Upjohn Company, Kalamazoo, MI 49001.*

Keyphrases □ Vitamin D—an update, literature survey □ Literature surveys—vitamin D, an update

CONTENTS

This article reviews the current status of the most promising areas of research and development on vitamin D during the last 15 years. Many pharmacists are involved in the manufacture and sale of vitamin D preparations, yet few are aware of the enormous scientific effort that was expended to find that vitamin D is inactive *per se* and that its biological activity is primarily due to one of its metabolites. Since this metabolite acts in true hormonal fashion vitamin D is now considered by biochemists as a prohormone. The findings of the mode of action of vitamin D are well documented.

In the early 1920's, cod liver oil was known to cure rickets and xerophthalmia. The name vitamin D was given to the antirachitic substance in cod liver oil (1–3), and differentiated from vitamin A by the fact that vitamin A activity in the oil was lost by heating while that of vitamin D was not. Hess and Steenbock discovered, independently (4–7), that the antirachitic activity of this vitamin could be induced by UV irradiation of rachitic animals or their food. Steenbock's discovery that antirachitic activity could be induced by irradiation of foods, particularly of the sterol fraction, ultimately led to the identification of the structure of vitamin D and to the eradication of rickets as a major medical problem (5, 6, 8).

It was later discovered that vitamin D occurs in two active forms, ergocalciferol and cholecalciferol. Ergocalciferol is the synthetic form derived by the irradiation of ergosterol and is designated as vitamin D_2 (9, 10). Cholecalciferol, the natural form, was identified (11, 12) and designated as vitamin D_3. Vitamins D_2 and D_3 are equally active in humans and other mammals, but D_2 is virtually inactive in birds. Thus, poultry feeds must be fortified with D_3.

BIOSYNTHESIS OF VITAMIN D_3

Vitamin D_3 is synthesized in the skin from 7-dehydrocholesterol (7-DHC) when the skin is exposed to sunlight. Okano *et al.* (13) first demonstrated this when they irradiated skins from vitamin D-deficient rats and isolated vitamin D_3 from saponified skin extracts. The sequence of steps leading to the cutaneous photosynthesis of vitamin D_3 from 7-DHC was recently demonstrated (14). In Caucasian skin, all of the epidermal strata contain 7-DHC, but the highest concentration is in the stratum basale and the stratum spinosum.

When irradiated, 7-DHC is photochemically converted by a fast reaction to previtamin D_3 throughout the epidermis and the dermis. Once formed in the skin, previtamin D_3 is isomerized to D_3 by a slow nonphotochemical rearrangement at a rate dictated by skin temperature. At

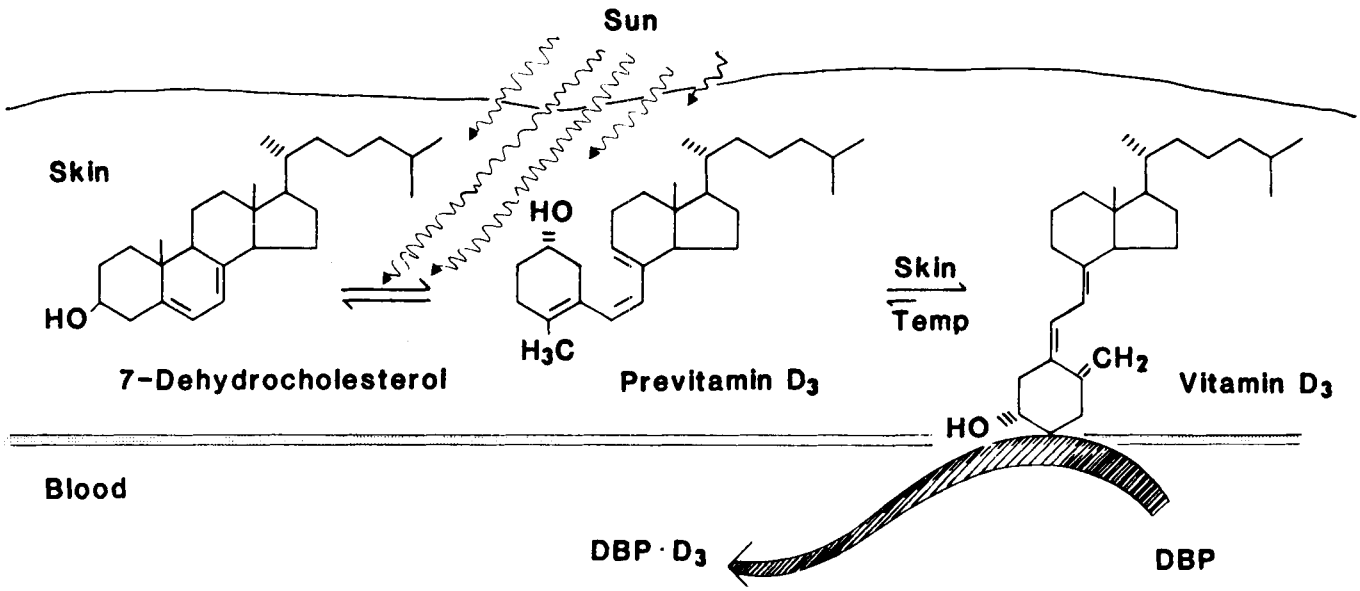


Scheme I—Diagram of the formation of previtamin D_3 in the skin, its thermal conversion to vitamin D_3, and transport by binding proteins (DBP) in plasma into the general circulation (Ref. 14).

37 ± 1° this thermal reaction is more rapid *in vivo* than *in vitro*. This difference is presumed to be due to the removal of vitamin D_3 by a specific binding protein from the skin into the circulating blood. Thus the skin serves as the site for the synthesis of 7-DHC, a reservoir for the storage of the primary photoproduct, previtamin D_3, and the organ where the slow thermal conversion of previtamin D_3 to D_3 occurs. The third process permits the skin to continuously synthesize D_3 and release it into the circulation for up to 3 days after a single exposure to sunlight. Scheme I illustrates this sequence of events.

COMMERCIAL VITAMIN D

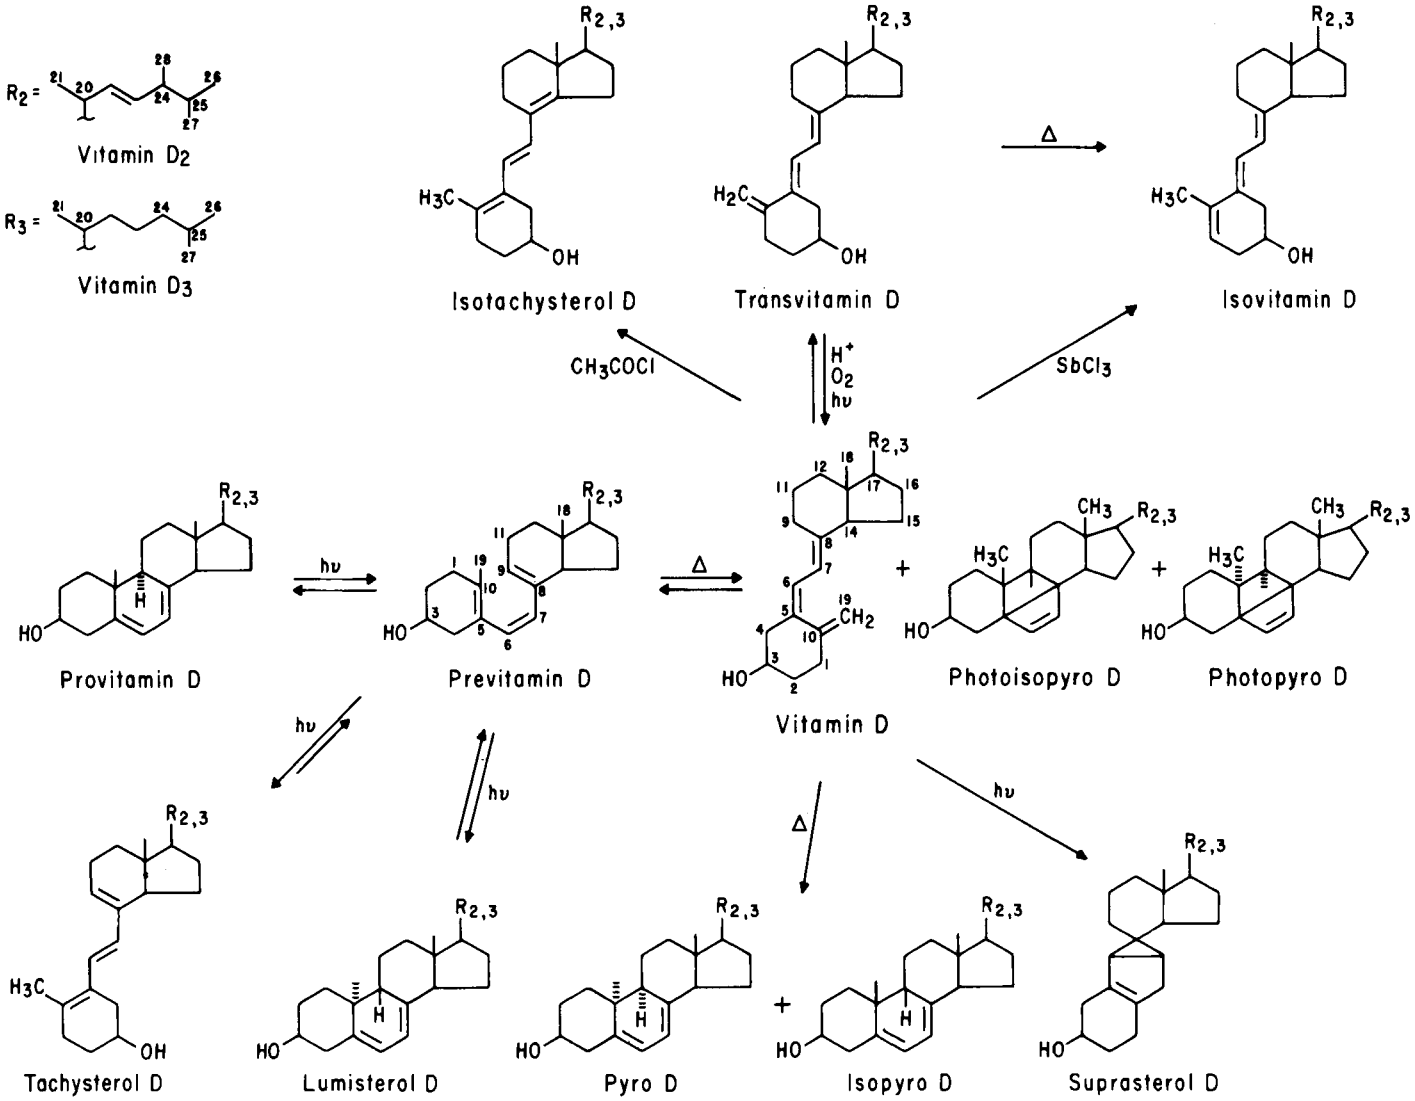
Vitamins D_2 and D_3 are prepared commercially by irradiation of the provitamins ergosterol and 7-DHC, respectively. The resulting previtamins are isolated and heated under carefully controlled conditions to produce the respective vitamins. A number of by-products are formed during these irradiation and heating steps, some of which are removed during the final cleanup steps. Scheme II shows the known degradation products (15, 16) that may be present in the synthetic vitamin D concentrates. Some of the by-products have biological activity, but others such as lumisterol, the suprasterols, and the pyro- and isopyrocalciferols have no antirachitic activity. Tachysterol and *trans*-vitamin D have only slight antirachitic activity. Thus, biological activity is primarily due to vitamin D and previtamin D (17). The biological activity of previtamin D is attributed to its *in vivo* conversion to vitamin D (18).

Vitamin D is a 9,10-seco steroid and is treated as such in the numbering of its carbon skeleton. The important aspects of vitamin D chemistry center about its *cis*-triene structure. This structure gives vitamin D and related compounds a characteristic UV absorption maximum at 265 nm and a minimum at 228 nm. An index of purity of the vitamin D compounds is a value of 1.8 for the ratio of the absorbance at 265 nm to that at 228 nm. The *cis*-triene structure makes vitamin D and related compounds susceptible to oxidation and other chemical transformations. Under even mild acidity, it isomerizes to form the 5,6-*trans*-isomer and isotachysterol. Upon mild heating, the 5,6-*trans*-vitamin D is converted to isovitamin D. At higher temperatures, vitamin D is converted to the pyro, isopyro and the supra forms. All of these transformation products have lower biological activity than vitamin D.

It was mentioned earlier that vitamin D exists in thermal equilibrium with previtamin D. Studies showed that the amount of previtamin formed and the rate of equilibration markedly increased with time between 0 and 100° (19, 20). Vitamin D concentrates are available commercially in a resin form, as a solution in peanut oil, and as a dry concentrate in a gelatin beadlet matrix. The vitamin D concentrates usually contain other fat soluble vitamins, especially vitamin A. Therefore, in the analysis of vitamin D concentrates and multivitamin products, the vitamin D must be released and separated from other fat-soluble vitamins prior to its determination. This is accomplished by an alkaline saponification followed by suitable chromatographic steps to purify the vitamin D from interfering ingredients.

Because of the thermal equilibrium with previtamin D, there is disagreement regarding the optimum saponification conditions. Most published reports show optimum saponification for 20–30 min under refluxing conditions. Thompson *et al.* (21), in their procedure for the analysis of vitamin D in fortified milk at the level of 8.8–11.7 ng/g, found that saponification overnight at room temperature produced negligible loss of vitamin D.

The instability of vitamin D has been a challenge in the isolation, identification, and quantitation of its metabolites from biological samples in which their concentrations are in the range of 0.02–30 ng/g of the tissues. However, there now are fairly reliable methods for the isolation and analysis of all major metabolites of vitamin D. Vitamin D and its metabolites can be kept stable in the dry form in an inert atmosphere and protected from light in a freezer. In solution it is stable in nonacidic vegetable oils and in certain organic solvents containing an antioxidant such as α-tocopherol (Vitamin E) and stored in the same conditions as the dry form.



Scheme II—Photochemical, thermal, and chemical reaction pathways in the synthesis of vitamin D (Refs. 15, 16, and 176).

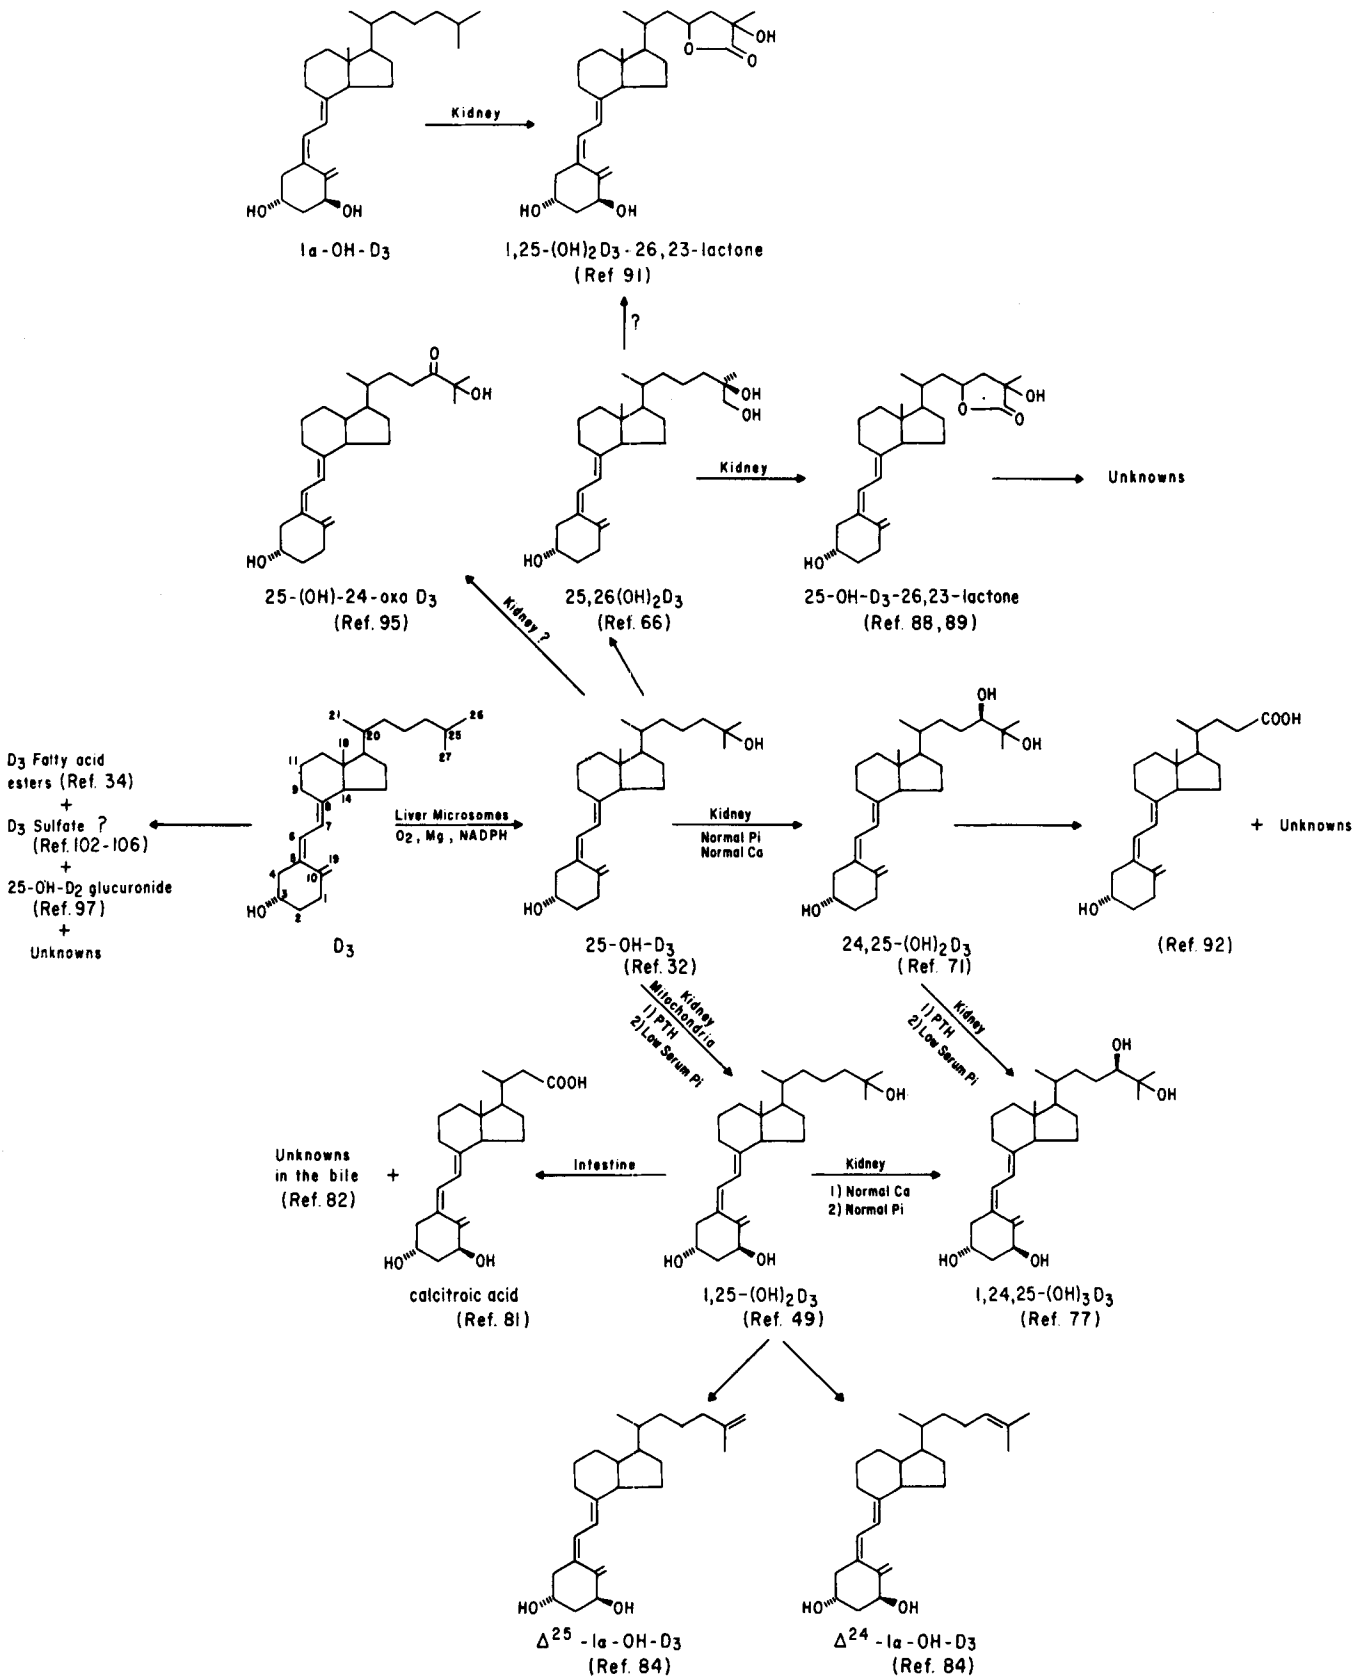
The original reference standard of vitamin D was a solution of irradiated ergosterol in olive oil. The present international standard is a solution of pure crystalline cholecalciferol in olive oil containing 0.025 μg/1 mg of solution. One international unit (IU) is equivalent to 0.025 μg of crystalline D_3 or 1 μg of D_3 is equivalent to 40 IU. The USP reference standards are crystalline ergocalciferol or cholecalciferol packed in sealed ampuls. The USP standards and the international standards are equivalent in that 1 μg of each is equivalent to 40 IU.

METABOLITES OF VITAMIN D_3

For 30 years following its discovery, relatively little was known about the synthesis of vitamin D or its metabolic fate in humans. It was thought that vitamin D acted directly on the target tissues of intestine and bone. However, the time lag reported by Carlsson (22) between the administration of vitamin D_3 and its physiological response appeared to argue against this concept. After intravenous administration of 10 IU of vitamin D_3, there was a lag of 10–12 hr before intestinal calcium transport response occurred (23). This led investigators to suspect that vitamin D_3 was metabolically altered before it became biologically active.

The transport of vitamin D in blood has been studied in considerable detail in animals. It has been shown that the chylomicrons and lipoproteins of the blood are initially important in the transport of vitamin D (24, 25). It was found (25) that upon incubation of blood with radioactive vitamin D or immediately following injection into blood, as much as 50% of the radioactivity in the blood was associated with the lipoprotein fractions. However, as time passed there was progressive shift of the radioactivity from the lipoprotein to the α_2-globulin fraction. The nature of the binding between vitamin D and this protein fraction is not known, but it appears that the vitamin is not easily dissociated from this protein. It was shown (26) that with time, after vitamin D absorption, there is a decreasing association of vitamin D with lipoproteins and an increased association with other protein fractions. The association of vitamin D activity with α_1- and α_2-globulin fractions of plasma was clearly demonstrated (27, 28).

25-Hydroxyvitamin D_3—Major developments in the metabolic study of vitamin D_3 came after radiolabeled compounds with high specific activities were synthesized. Selective ^3H-labeled and random ^{14}C-labeled vitamin D_3



Scheme III—Schematic pathway of vitamin D metabolism.

were prepared in the mid-1960's and used successfully in the isolation and identification of its major metabolites. Other factors that contributed to this success were the development of milder extraction procedures and novel chromatographic techniques.

Norman *et al.* (29) administered [^{3}H]vitamin D orally and intraperitoneally to rats and then extracted the kidney and intestinal tissues with a mixture of methanol–chloroform as described by Bligh and Dyer (30). After chromatography on silicic acid columns and thin-layer

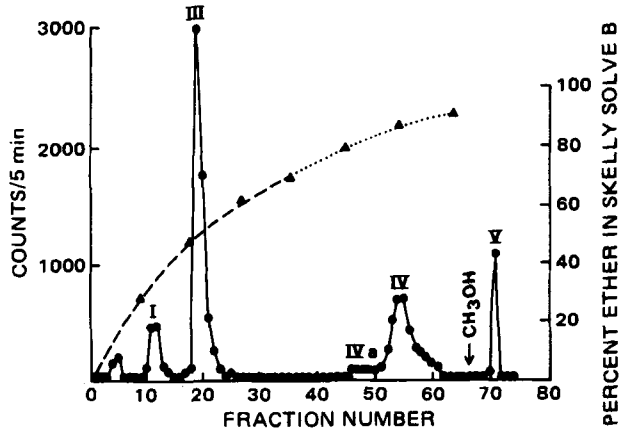


Figure 1—*Silicic acid chromatography of vitamin D_3 and its metabolites. Peaks III and I are vitamin D and its esters, respectively. Peaks IVa and V are unidentified at this time, and peak IV is 25-hydroxyvitamin D_3. (Ref. 32).*

plates, at least three other chloroform-soluble radioactive compounds were detected, all of which showed partial vitamin D activity. The aqueous methanol-soluble radioactive compounds were totally without vitamin D activity.

Biologically active metabolites of vitamin D were found (31) in the bone, liver, and serum of rats that had been given [^{3}H]vitamin D. As before (29), the aqueous-soluble metabolites from the tissues and the feces did not have vitamin D activity. At least three biologically active metabolites were isolated from the chloroform-soluble portion of the extract. One of these, designated as peak IV, was found in large amounts in the liver, blood, and bone. In 1938 Blunt *et al.* (32) conducted the classic experiment which led to the identification of this major metabolite as 25-hydroxy-vitamin D_3 (25-OH-D_3).

In this experiment, one hog was dosed with [^{3}H]vitamin D_3 and 800 ml of serum was collected when the peak IV radioactivity was expected to peak. Four other hogs were maintained on a diet supplemented with 250,000 IU of vitamin D_3 daily for 26 days. The plasma from these hogs (6.8 liters) was treated with ammonium sulfate to precipitate the proteins, which were then extracted with methanol–chloroform. This extract was combined with a similar extract from the serum of the hog that had received the [^{3}H]vitamin D_3 and subjected to chromatography on a 25-g silicic acid column eluted with an ether–Skellysolve B gradient followed by ether and finally stripping the column with methanol. This chromatographic system is reproduced in Fig. 1, which shows the radioactivity profile of the column eluate in order of increasing polarity of the metabolites. Peaks III and I are vitamin D_3 and its fatty acid esters, respectively.

The column eluate representing peak IV was purified further on a partition column using diatomaceous earth[1] as the solid support, 80:20 methanol–water as the stationary phase and Skellysolve B as the mobile phase. In this manner, 1.3 mg of the pure metabolite was obtained. This metabolite was positively identified as 25-OH-D_3 (32) by using GLC, UV, NMR, and mass spectrometry. This discovery was a milestone in the subsequent identification of other metabolites and in our current understanding of the physiological roles of these metabolites. Scheme III shows the metabolic pathway of vitamin D and all its currently known metabolites.

Two other groups of investigators (33, 34) independently found clues to the metabolic hydroxylation of vitamin D. It was soon established that 25-hydroxylation of vitamin D_3 takes place primarily in the liver (35, 36) and that 25-OH-D_3 is the major form of the circulating vitamin in human plasma (37) and is the primary metabolite of vitamin D_2 (38). This metabolite has been chemically synthesized (39).

Although the liver is the major site of 25-hydroxylation of vitamins D_2 and D_3, there is evidence suggesting that it is not the only site. It was shown (40) that homogenates of small intestine and kidney from the chick are capable of hydroxylating vitamin D_3 at position C-25. It was also shown (41) that hepatectomized rats can convert vitamin D_3 to 25-OH-D_3. Initially it was believed that the D_3-25-hydroxylase was located in the mitochondrial fraction of liver cells; however, careful investigation demonstrated that it is principally located in the liver microsomes, and that the enzymatic reaction is supported by reduced NADPH, molecular oxygen, and magnesium (42).

Initially, 25-OH-D_3 was considered to be the main biologically active metabolite of vitamin D. But soon it was discovered that physiological concentrations of 25-OH-D_3, like vitamin D_3, are incapable of stimulating either intestinal calcium transport or bone calcium mobilization (43–45).

1,25-Dihydroxyvitamin D_3—Earlier work (46) showed that the exhaled water from rats dosed with [1α-^{3}H]vitamin D_3 contained less radioactivity than the air from others dosed with vitamin D_3 labeled at the [24,25,26,27-$^3H_9$]-, [7-^{3}H]-, [6-^{3}H]-, and [3-^{3}H]- positions. Lawson *et al.* (34, 47), investigating the nature and localization of vitamin D metabolites by using [4-^{14}C,1α-^{3}H]-vitamin D_3, discovered a metabolite of vitamin D in the chick intestinal nuclei which was more polar than 25-OH-D_3 and which had lost its tritium group from position C-1. This metabolite, designated as peak P, was found in varying amounts in liver, kidney, bone, and blood and was localized in the intestinal nuclei.

It was postulated that the peak P metabolite was similar to the fraction designated "peak 4B" by Haussler *et al.* (33). The peak P metabolite had at least three times the biological activity of an equivalent amount of vitamin D_3 and was derived from 25-OH-D_3. However, the site of its synthesis was not obvious. Another study (48) established that this active metabolite was 1-oxygenated 25-OH-D_3 and that it was produced in the kidney. A short time later, Lawson *et al.* (49) identified peak P to be 1α,25-dihydroxyvitamin D_3 [1,25-$(OH)_2D_3$]. This finding was confirmed by other investigators (50, 51) who found that 1,25-$(OH)_2D_3$ was part of peak V in the silicic acid column profile of vitamin D metabolites shown in Fig. 1.

It is now known that the formation of 1,25-$(OH)_2D_3$ is feedback regulated depending on the need for calcium in the blood. It is also known that 25-OH-D_3 is the main circulating form of all the known metabolites of vitamin D_3. There is as yet no reliable data on the concentration of vitamin D_3 in the blood, but it is believed to be very low (~2–3 ng/ml). The blood level of 25-OH-D_3 was initially determined by competitive protein binding methods

[1] Celite.

(52–54) which showed values of 15–38 ng/ml in normal humans. Since then, more reliable and precise high-performance liquid chromatographic (HPLC) methods have been developed (55–58) but the mean values were in the same range.

The endogenous level of 25-OH-D_3 in the cow was determined by HPLC (59, 60). It was generally in the range of 40–58 ng/ml of serum or plasma (mean 48 ± 5 ng/ml, n = 24), which is higher than that in the human. Following a single intravenous dose of 4 mg of 25-OH-D_3 to a cow, the average serum level declined from a high of 227 ng/ml at 1-hr postinjection, to 51 ng/ml after 51 days, showing an elimination half-life of ~10 days (61). These and other studies have confirmed the earlier findings that 25-OH-D_3 is the major circulating form of vitamin D in the blood of humans and cows.

The concentration of 1,25-$(OH)_2D_3$ in the human serum is very low, between 20 and 40 pg/ml. The concentration is determined by ligand binding methods after extensive cleanup of the serum extract. The most recent procedures use fractionization of the extract by HPLC to purify 1,25-$(OH)_2D_3$ from interfering materials prior to quantitation. Mean plasma values of 35 ± 3 (62), 34 ± 11 (63), and 31 ± 9 (64) pg/ml were reported in normal healthy adults. None was detected in the blood of anephric men (64), confirming that 1-hydroxylation takes place in the kidney. At the present time, 1,25-$(OH)_2D_3$ is considered to be the most potent known metabolite of vitamin D controlling calcium and phosphorus absorption from the intestine and mobilization of these elements from the bone when necessary.

Other Metabolites of Vitamin D_3—*25,26-Dihydroxyvitamin D_3*—It became known during the isolation and identification of 25-OH-D_3 that there were other metabolites in certain tissues and blood following administration of physiological doses of radioactive vitamin D. Suda *et al.* (65) prepared extracts of hog plasma containing these metabolites in a manner similar to the one used by Blunt *et al.* (32). The peak V portion in Fig. 1 was resolved into at least three components, designated V*a*, V*b*, and V*c*, on a second silicic acid column. The V*c* portion was rechromatographed on a diatomaceous earth[1] partition column specially designed for peak V metabolites (66). The V*c* peak was resolved into four peaks. The major peak V*c*3 was further purified on a Sephadex LH-20 column and a radiochemically pure fraction was obtained. This fraction was identified as 25,26-dihydroxyvitamin D [25,26-$(OH)_2D_3$]. This metabolite was about one-half as active as 25-OH-D_3 in the stimulation of intestinal calcium transport. The concentration of this metabolite is very low in the normal human; a value of 0.8 ± 0.4 ng/ml has been reported (67).

24,25-Dihydroxyvitamin D_3—Omdahl and DeLuca (68) reported that the inhibition of intestinal calcium transport due to dietary strontium results from a block of the kidney hydroxylase which produces 1,25-$(OH)_2D_3$ from 25-OH-D_3. They also found that when the synthesis of 1,25-$(OH)_2D_3$ was suppressed, a new metabolite appeared which behaved like the peak V*a* metabolite already described. This metabolite is made exclusively by the kidney (69, 70) and was identified as 24,25-dihydroxyvitamin D_3-[24,25-$(OH)_2D_3$] (71). This metabolite can be produced *in vitro* by incubating 25-OH-D_3 with kidney mitochondria from chickens fed a high calcium diet. It can also be produced *in vivo* in hogs.

Although the structure of 24,25-$(OH)_2D_3$ was determined (71) and confirmed by synthesis (72), the stereochemical configuration of the 24-hydroxyl group was not known. Tanaka *et al.* (73) showed that the trimethylsilyl ethers of 24*R*- and 24*S*-$(OH)_2D_3$ could be separated by HPLC and that the biologically active form was 24*R*,25-$(OH)_2D_3$. The concentration of this metabolite in the plasma of normal animals and humans is low. For example, Taylor *et al.* (74) reported a value of 1.68 ± 0.82 ng/ml among seven normal volunteers. In these subjects, the 25-OH-D_3 level was 8.8–35.7 ng/ml. Other investigators (62, 63, 67) have reported values of ~2 ng/ml of plasma.

It was demonstrated (75, 76) that under normal or hypercalcemic conditions, 24,25-$(OH)_2D_3$ is the major circulating metabolite of 25-OH-D_3. Like 1,25-$(OH)_2D_3$, it is capable of supporting growth, elevating serum calcium, and calcifying bones of rats on a normal calcium, normal phosphorus diet. Their data also demonstrated that 24,25-$(OH)_2D_3$ is capable of inducing intestinal calcium transport at dose levels similar to 1,25-$(OH)_2D_3$. The one major difference is that unlike the latter, 24,25-$(OH)_2D_3$ has little ability to mobilize calcium from the bone. The finding that nephrectomy blocks the biological activity of 24,25-$(OH)_2D_3$ led to the discovery that this metabolite can serve as a substrate for 25-OH-D_3-1-hydroxylase in the kidney, yielding a new, more polar metabolite, 1,24,25-trihydroxyvitamin D_3.

1,24,25-Trihydroxyvitamin D_3—1,24,25-trihydroxyvitamin D_3 [1,24,25-$(OH)_3D_3$] was first prepared (77) *in vitro* from tritium-labeled 24,25-$(OH)_2D_3$ by incubation with chicken kidney homogenates. A total of 50 μg of the labeled compound was incubated in 0.5 μg (120,000 dpm/μg) portions with 1.5 ml of the kidney homogenate at 37° for 30 min. The homogenates were combined and extracted as in previous experiments (71). The extract was subjected to several column chromatographic steps to obtain a radiochemically pure metabolite more polar than the starting material. This metabolite was identified as 1,24,25-$(OH)_3D_3$ by UV and mass spectrometry, and its reactivity to periodate treatment.

The biological activity of 1,24,25-$(OH)_3D_3$ parallels the biological activity reported for 24,25-$(OH)_2D_3$ (76). It is preferentially more active in inducing intestinal calcium transport than in mobilizing calcium from bone and is ~60% as effective as vitamin D_3 in the cure of rachitic lesions. Although on a weight basis it is less active both in the magnitude and duration of response than 1,25-$(OH)_2D_3$, it is probably much more active than 24,25-$(OH)_2D_3$ (77). There is no conclusive data on the concentration of 1,24,25-$(OH)_3D_3$ in the blood. It is known to be lower than that of 1,25-$(OH)_2D_3$ and, therefore, in the low picogram per milliliter range in the plasma.

1α-OH-24,25,26,27-Tetranor-D_3-23-carboxylic Acid (Calcitroic Acid)—During the studies on the metabolism of 1,25-$(OH)_2D_3$, the possibility that it might be converted to more active forms was investigated. In 1976, 26,27-^{14}C-labeled 25-OH-D_3 was synthesized and enzymatically converted to the corresponding 1,25-$(OH)_2D_3$ compound (78). When injected into vitamin D-deficient animals, this compound lost up to 20% of its 26,27-^{14}C in the expired air as carbon-14 dioxide within 24 hr, demonstrating the ex-

istence of a side-chain oxidation reaction of 1,25-$(OH)_2D_3$ (78, 79). This side-chain oxidation appeared to require 1α-hydroxylated metabolites, since nephrectomy abolished carbon-14 dioxide expiration from radiolabeled 25-OH-D_3 but did not affect the amount of carbon dioxide 14 expired from 1,25-$(OH)_2$[26,27-^{14}C]D_3-dosed rats (79). Removal of the jejunum, ileum, and colon drastically reduced the carbon-14 dioxide expired by these rats, implicating an intestinal site of side-chain oxidation (80).

In vivo experiments (81) using doses of 3α-^{3}H- and 26,27-^{14}C-labeled, 1,25-$(OH)_2D_3$ were conducted with examination of tissue extracts for metabolites relatively enriched in tritium. This study culminated in the isolation and identification of the major side-chain oxidized metabolite of 1,25-$(OH)_2D_3$ as 1α,3β-dihydroxy-24,25,26,27-tetranor-D_3-23-carboxylic acid, which was named calcitroic acid.

Calcitroic acid was found in the liver and intestinal tissue, but very little was present in the blood. The amount of calcitroic acid in the organic soluble extracts of the liver and intestine accounted for only 4–6% of the administered dose. It was recently found (82) that the water-soluble metabolites in rat bile are predominantly acids. As much as 13% of the dose present in bile after 24 hr was calcitroic acid. This means that substantial amounts of unknown metabolites of 1,25-$(OH)_2D_3$ remain in bile.

The function of the side-chain oxidation of 1,25-$(OH)_2D_3$ is not known. One possibility is that side-chain oxidation and biliary excretion are a route for inactivation and excretion of 1,25-$(OH)_2D_3$. Alternatively, metabolites of 1,25-$(OH)_2D_3$ in bile may be reabsorbed by the intestine and have biological function there (82). Calcitroic acid was chemically synthesized from 24-oxocholesterol acetate and its biological activity compared with 1,25-$(OH)_2D_3$ (83). It stimulated intestinal calcium transport 6 hr after intravenous administration, but the response was significantly less than that of an identical base of 1,25-$(OH)_2D_3$. It had no effect in the mobilization of calcium from the bone.

Δ^{24}-1α-Hydroxy- and Δ^{25}-1α-Hydroxyvitamin D_3—Onisko *et al.* (84), in their study of the metabolism of 1α,25-dihydroxy[3α-^{3}H]vitamin D_3 in the rat, found two minor radioactive compounds in the bile. These were identified as Δ^{24}-1α-hydroxyvitamin D_3 and Δ^{25}-1α-hydroxyvitamin D_3. The two compounds were present in the same ratio that is obtained by standard chemical dehydrations of the 25-hydroxy group. It is assumed that the isomers arise *via* a nonenzymatic elimination process in bile. The biological significance of these products is not known.

25-Hydroxyvitamin D_3-26,23-lactone—During the course of developing an assay procedure for 24,25-$(OH)_2D_3$ and 25,26-$(OH)_2D_3$ in human plasma, a previously unidentified compound was detected in chick plasma (85, 86). This compound was a contaminant in the assay of 24,25-$(OH)_2D_3$ or 25,26-$(OH)_2D_3$ when only a single chromatographic column was used for pre-assay purification; however, it could be resolved by HPLC on a microparticulate silica column (87). This metabolite was extracted from the plasma of chickens and was identified (88) as 25-hydroxyvitamin D_3-26,23-lactone (25-OH-D_3-26,23-lactone) from its UV, mass, Fourier transform IR, and PMR spectra. Hollis *et al.* (89) found that 25,26-$(OH)_2D_3$ is the precursor for 25-OH-D_3-26,23-lactone and the transformation takes place in the kidney, but its biological importance is not yet known.

1α,25-Dihydroxyvitamin D_3-26,23-lactone—After the discovery of 25-OH-D_3-26,23-lactone, Tanaka *et al.* (90) investigated if 1,25-$(OH)_2D_3$ would undergo a similar transformation to the corresponding lactone. They found that kidney extracts from chicks given large doses of vitamin D_3 readily converted 1,25-$(OH)_2D_3$ to 1,24-25-$(OH)_3D_3$, but produced only trace amounts of the lactone. However, when they incubated 25-OH-D_3-26,23-lactone with kidney homogenates from rachitic chickens known to be rich in 1-hydroxylase activity and deficient in other vitamin D hydroxylases, they isolated a compound which was identified as 1α,25-dihydroxyvitamin D_3-26,23-lactone [1,25-$(OH)_2D_3$-26,23-lactone]. They postulated that because 1α-hydroxylase activity is generally low under the conditions in which the lactone is formed, the *in vivo* 26,23-lactonization of 1,25-$(OH)_2D_3$ would likely be minimal.

Another investigator (91) fed the synthetic analog of vitamin D_3, 1α-hydroxyvitamin D_3 (1α-OH-D_3), to rats and isolated 1,25-$(OH)_2D_3$-26,23-lactone from the blood. The biological potency or significance of this metabolite is not established, and to the author's knowledge, it has not yet been isolated from human blood.

*25,26,27-Tris-*nor*-vitamin D_3-24-carboxylic Acid*—It was pointed out earlier that when 1-hydroxylation is inhibited, 25-OH-D_3 is metabolized to 24,25-$(OH)_2D_3$ (71), which in turn acts as the precursor for 1,24,25-$(OH)_3D_3$ (77). Recently, 24,25-$(OH)_2$ was found to rapidly metabolize to an acid with the loss of three terminal carbons on the side chain. This compound was identified as 25,26,27-tris-*nor*-vitamin D_3-24-carboxylic acid (92). The biological significance of this metabolite is not known.

25-Hydroxy-24-oxocholecalciferol—During the course of investigating renal 24-hydroxylase activity, it was found (93) that kidney homogenates from chicks supplemented with vitamin D_3 metabolized 25-OH[26,27-$^3H_6$]D_3 *in vitro* to three unknowns designated A, C, and E. Production of unknown A increased in parallel with the increase in the amount of 25-$(OH)D_3$ added as a substrate, while that of unknown C was fairly constant irrespective of substrate increase (94). Unknown A was less polar than 25-OH-D_3. This unknown was identified (95) as 25-hydroxy-24-oxocalciferol. The biological significance of this metabolite is unknown, and to this author's knowledge, there has been no confirmation of its presence *in vivo* in humans or animals.

25-Hydroxyvitamin D_2-25-β-D-glucuronic Acid—Previous studies (96) showed that the principal route of excretion of vitamin D metabolites in humans is through the bile. But the identity of most of the biliary metabolites is unknown. Avioli *et al.* (96) also found that in human subjects administered [^{3}H]vitamin D_3, only 8–9% of the biliary radioactivity was extractable with chloroform and that biliary excretion of vitamin D_3 was negligible. Upon treatment with β-glucuronidase, an additional 40% of the biliary radioactivity became chloroform soluble, but only ~5% of the liberated radioactivity appeared to be free vitamin D_3.

Examination of the biliary metabolites of vitamin D_2 in chickens revealed that the major metabolite was 25-hy-

droxyvitamin D_2-25-β-D-glucuronic acid (25-OH-D_2-25-glucuronide) (97). It has long been known that vitamin D_2 is much less active than vitamin D_3 in the chicken while the two forms are equally active in mammals. It was shown earlier (98) that vitamin D_2 is more rapidly removed from the chick blood than vitamin D_3 and excreted into the bile.

It was also reported (99) that the two forms of the vitamin are hydroxylated at C-25 equally by chick liver preparations. Several studies have long established that 25-OH-D_3 is the main circulating form of vitamin D_3 in humans and cows (55–61). But other studies (100, 101) demonstrated that the chick is unable to raise the blood levels of 25-OH-D_2 and other D_2 metabolites to the D_3 metabolite levels. Based on these facts, one may conclude that the facile formation of 25-OH-D_2-25-glucuronide in chicks and its removal from circulation is the reason that chicks and other birds discriminate against vitamin D_2. LeVan *et al.* (97) reported from their preliminary experiments that chicks dosed with [^{3}H]vitamin D_3 produce only small amounts of the 25-glucuronide. Experiments are in progress in their laboratories to see whether the 25-glucuronides of vitamin D metabolites occur in mammalian bile or if this pathway is peculiar to avian species.

Vitamin D Sulfate—Initial experiments with radiolabeled vitamin D showed very little radioactivity in the aqueous portion after the kidney, intestine, serum, or plasma was extracted with a mixture of chloroform and methanol (29, 31). However, the formation of water-soluble conjugates from vitamin D or its metabolites has always been suspected. Thus, several investigators reported the presence of vitamin D sulfate (D-sulfate) in human (102–104) and cow milk (102, 104, 105).

Lakdawala and Widdowson (103) collected milk from 34 women from 3–8 days postpartum and analyzed for D-sulfate. The D-sulfate concentration was 17.8 ng/ml between the 3rd and 5th days and 10.0 ng/ml between the 6th and 8th days, respectively. These authors noted that even in winter, breast milk protected the infants from rickets whereas cow milk did not. Sahashi *et al.* (102) found the concentration of D-sulfate in cow milk and human milk to be 204 and 950 IU/liter (5 and 24 ng/ml), respectively. These figures were all based on a nonspecific colorimetric method.

Very recently, (106) a more specific HPLC method was used for the analysis of human milk whey from six Caucasian mothers between 1 and 8 days postpartum using 1α,2α-[^{3}H]vitamin D sulfate as a tracer to monitor the recovery of the endogenous D-sulfate. No endogenous D-sulfate was found in any of the samples (detection limit, 1 ng/ml). This result was contradictory to that reported by others (102–105). Hollis's (106) contention was that the primary source of antirachitogenic activity in human milk is due to nonconjugated metabolites of vitamin D, primarily 25-OH-D_3. Yet, according to another report by Hollis *et al.* (107), the nonconjugated metabolites in human and cow milk are very low; human milk contained 320 ± 80 pg/ml (n = 5) of 25-OH-D_3. The concentrations of 24,25-$(OH)_2D_3$ and 1,24,25-$(OH)_3D_3$ in the same samples were 42 ± 3 and 12 ± 2 pg/ml, respectively. These results are puzzling when one considers the fact that the large majority of infants in the world are raised primarily on breast milk for up to 6–8 months without any gross manifestations of vitamin D deficiency.

Unidentified Metabolites of Vitamin D_3—Leading investigators are certain that there are many unidentified metabolites of vitamin D. For example, according to Onisko *et al.* (84), there remain substantial amounts of unknown metabolites of 1,25-$(OH)_2D_3$ in the bile. These are water-soluble, negatively-charged compounds, which are rendered chloroform-soluble after methylation. These are likely to be due to unknown carboxylic acid metabolites.

Most of the experiments leading to the discovery of the currently known metabolites have followed the injection of radioactive vitamin D_3 as a single dose to rachitic animals. Experiments with administration of radioactive vitamin D_3 daily for 1–2 weeks (108), have led to the discovery of a number of new metabolites of vitamin D_3, both polar and nonpolar, that have yet to be identified. Whether any of these will have important functions or whether they represent biochemical curiosities or inactivation products remains to be seen.

METABOLITES OF VITAMIN D_2

The only chemical difference between vitamins D_2 and D_3 is in the side chain. Vitamin D_2 has an extra methyl group on the 24th carbon and a double bond between the 22nd and 23rd carbons (Scheme II). The virtual inactivity of vitamin D_2 in birds has long been known. However, the major metabolic pathways of the two forms of vitamin D in birds and mammals are analogous. Thus, 25-OH-D_2 was isolated and identified from porcine blood (38). The 25-OH-D_2 is further converted in the kidney to 1,25-$(OH)_2D_2$, which was isolated and identified (109). The hydroxylases that act on the vitamin D_3 series have been shown to act on vitamin D_2 compounds as well (110). Thus, the liver possesses vitamin D_2-25-hydroxylase and the kidney possesses 1α-hydroxylase. The current opinion is that the primary metabolites of vitamin D_2 would undergo further metabolism like vitamin D_3, but little work has been carried out with humans or animals, primarily because of the unavailability of suitable radiolabeled tracers.

SUMMARY OF THE METABOLIC SCHEME OF VITAMIN D

The currently known metabolic pathway of vitamin D is shown in Scheme III. Vitamin D_3 from the diet or that generated in the skin is absorbed into the blood. There is as yet no reliable figure on its concentration in blood. A portion of the vitamin D is converted into fatty acid esters (34) which are distributed in all vital organs and blood. The fatty acid esters have lower biological potency than vitamin D. Not much research has been conducted on the role of fatty acid esters in the total picture of vitamin D metabolism. A portion of the vitamin D is believed to be available in lactating mammals as D-sulfate (102–105), but this theory has been contradicted by other investigators (106, 107).

Vitamin D is stored to a considerable extent in the body. The liver is thought to be a storage organ, but more recent studies have shown that fat is the major storage site (111). Depletion of vitamin D in the animals depends on the turnover of the fat depots, which usually takes considerable time.

Vitamin D_3 *per se* has no biological activity. It is hydroxylated at carbon 25 to 25-OH-D_3 (35, 36) in the liver. The liver 25-hydroxylase system requires NADPH, mo-

lecular oxygen, and magnesium and is located in the microsomal fraction. Initially, it was thought that this 25-hydroxylation was feed-back regulated (112) to reduce the chances of toxicity to over-intake of vitamin D_3. However, later studies (113) with rats that received weekly or triweekly doses of vitamin D_3 showed that the amount of 25-OH-D_3 in plasma correlated with an increase in vitamin D intake, irrespective of the dose administered. Thus, it seems that vitamin D is efficiently mobilized to 25-OH-D_3 in the liver and then bound to a plasma-binding protein where it acts as a reservoir in the blood. However, other 25-hydroxylases are also present in the liver. These act on cholesterol, dihydrotachysterol, and other analogs of vitamin D such as 1α-hydroxyvitamin D_3 (114–116).

The major circulating form of vitamin D metabolites in the blood is 25-OH-D_3 (37, 55–58). It is transported to the kidney by a specific protein and further hydroxylated on carbon C-1 to 1,25-$(OH)_2D_3$ or on C-24 to 24,25-$(OH)_2D_3$ depending on the circumstances. Under conditions of hypocalcemia, the parathyroid glands are stimulated to secrete parathyroid hormone (PTH), which in turn stimulates synthesis of 1,25-$(OH)_2D_3$. The 1,25-$(OH)_2D_3$ immediately proceeds to the intestine where it functions to stimulate intestinal calcium absorption without PTH. In addition, 1,25-$(OH)_2D_3$ together with the PTH hormone functions to mobilize calcium from previously formed bone. These two functions result in the elevation of serum calcium to normal levels that suppress PTH secretion and, hence, 1,25-$(OH)_2D_3$. Like hypocalcemia, hypophosphatemia directly stimulates synthesis of 1,25-$(OH)_2D_3$, which then independently stimulates the elevation of serum inorganic phosphate.

The mechanism of action of 1,25-$(OH)_2D_3$ was proved (50, 117) after techniques were developed for making [^{3}H]-1,25-$(OH)_2D_3$ from [^{3}H]-25-OH-D_3 *in vitro* from kidney homogenates. Using this technique, these investigators were able to correlate the presence of 1,25-$(OH)_2D_3$ in the intestine and bone, which accounted for 98 and 80% of the total radioactivity in the respective target tissues, with the simultaneous induction of intestinal calcium transport and bone calcium mobilization. These data strongly supported the earlier findings that 1,25-$(OH)_2D_3$ is the biologically active form of vitamin D_3 responsible for maintaining calcium and phosphorus homeostasis and that no further metabolism is required.

Under normocalcemic or hypercalcemic conditions, renal 1α-hydroxylation is inhibited and side-chain hydroxylation of 1,25-$(OH)_2D_3$ occurs, resulting in the formation of the most polar metabolite known so far, 1,24*R*,25-$(OH)_3D_3$ (77). Under these conditions 25-OH-D_3 also undergoes side-chain oxidation to form 24*R*,25-$(OH)_2D_3$ (71) and 25,26-$(OH)_2D_3$ (66). Of these two, 24*R*,25-$(OH)_2D_3$ is the more prominent. There is evidence suggesting that the intracellular concentration of phosphorus is a more important regulator than PTH for determining whether the hydroxylation of 25-OH-D_3 in the kidney occurs on either the C-1α or the C-24 positions (118). The ability of 24*R*,25-$(OH)_2D_3$ to stimulate both intestinal calcium transport and a weak bone mineralization response is believed to be dependent on its 1α-hydroxylation in the kidney to form 1,24*R*,25-$(OH)_3D_3$.

Thus, under normal conditions, one of the end products of both 1,25- and 24*R*,25-dihydroxyvitamin D is the same, *i.e.*, 1,24*R*,25-$(OH)_3D_3$. 1,24*R*,25-$(OH)_3D_3$ is only ~10% as active as 1,25-$(OH)_2D_3$ on a molar basis. It is more effective in stimulating calcium transport than bone mineralization (77, 119).

The low biological activity of 24*R*,25-$(OH)_2D_3$ and 1,24*R*,25-$(OH)_3D_3$ and their rapid metabolism and excretion in the chick prompted speculation that the purpose of 24-hydroxylation of 25-OH-D_3 and 1,25-$(OH)_2D_3$ is to introduce a hydroxyl group proximal to the 25 position to provide facile oxidative cleavage (120). Yet, it is puzzling that these two 24-hydroxylated metabolites are prominent circulating metabolites. Recently, it was reported (121) that small doses of 24*R*,25-$(OH)_2D_3$ increased intestinal calcium transport in anephric patients, suggesting that the compound *per se* is active and 1α-hydroxylation is not absolutely necessary.

When the body does not need 24*R*,25-$(OH)_2D_3$ or 1,24*R*,25-$(OH)_3D_3$, the former is converted to 25,26,27-tris-*nor*-vitamin D_3-24-carboxylic acid (92). The 25,26-$(OH)_2D_3$ undergoes more extensive transformations. After it was synthesized, its biological activity was studied in vitamin D-deficient rats and their nephrectomized counterparts. The results suggested that, like 24*R*,25-$(OH)_2D_3$, it requires renal 1α-hydroxylation before it can stimulate an intestinal calcium transport response (122). As discussed earlier it is also oxidized to calcitroic acid (81) and to 25-OH-D_3-26,23-lactone (88).

VITAMIN D AS A PROHORMONE

Vitamin D is virtually absent from the plant world and is found only in specific substances such as fish liver oils, egg yolk, and to a very small degree, in unfortified milk. A notable exception to this is the existence of conjugated forms of 1,25-$(OH)_2D_3$ in the South American plant *Solanum glaucophyllum* and *Cestrum diurnum* in the southern United States (123, 124). Vitamin D is unique in that under normal circumstances it is formed in the skin in sufficient quantities when humans and animals are exposed to sunshine, and extra supplementation is unnecessary. The previtamin D_3 that is formed in the skin is slowly released into the body as vitamin D_3. This process permits the skin to continuously synthesize and release vitamin D_3 into circulation for up to 3 days after a single exposure to sunlight (Scheme I and Ref. 14).

Because of changes in modern lifestyle and because the urban areas around the world are contaminated with UV-absorbing materials, it may be that insufficient amounts of vitamin D are produced in the skin. Vitamin D_3 is also unique in that it has to be metabolized in sequence to 25-OH-D_3 and to 1,25-$(OH)_2D_3$ or to some as yet unidentified metabolite before it becomes physiologically active, not only in its ability to prevent and cure rickets, but also to maintain calcium and phosphorus homeostasis. In this respect, 25-OH-D_3 only acts as a precursor for 1,25-$(OH)_2D_3$ and also for 24*R*,25-$(OH)_2D_3$ which is also biologically active.

Since 1,25-$(OH)_2D_3$ acts on tissues remote from its production site, it meets the criteria and definition of a hormone. In true hormonal form, its biogenesis is regulated by hypocalcemia or hypophosphatemia. PTH plays a vital role in the biochemistry of vitamin D_3. If 1,25-$(OH)_2D_3$ is accepted as a hormone, then vitamin D_3 can be considered as a prohormone and 25-OH-D_3 as a prehormone. Since the

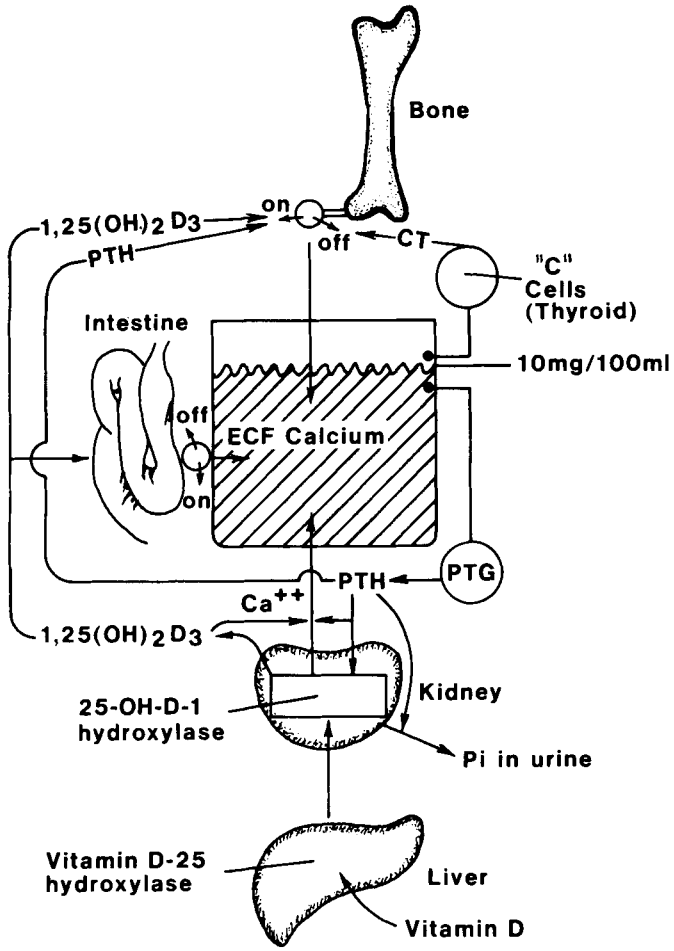

Figure 2—*Diagram of the calcium homeostatic mechanisms involving the vitamin D endocrine system (Ref. 132).*

kidney is the sole site of manufacture of 1,25-$(OH)_2D_3$, the kidney can be considered as the endocrine organ.

REGULATION OF CALCIUM HOMEOSTASIS AND VITAMIN D METABOLISM

The normal serum calcium level is maintained at ~10 mg/100 ml of ionized calcium. The accompanying anion is inorganic phosphorus. When the calcium level falls, the parathyroid glands which serve as the hypocalcemic detection organ are immediately stimulated to produce PTH. PTH is transported to the kidney, liver, and bone (125, 126). In the kidney it causes a phosphate diuresis which is vitamin D independent (127). PTH also stimulates renal reabsorption of calcium. Whether vitamin D is involved in this process is not absolutely established, but available evidence suggests that it is dependent on the existent serum 1,25-$(OH)_2D_3$ (128, 129).

Another, less rapid, calcium-conserving process occurs when PTH stimulates renal 25-OH-D-1-hydroxylase to produce 1,25-$(OH)_2D_3$ (130) and 1,24*R*,25-$(OH)_3D_3$; 1,25-$(OH)_2D_3$ stimulates intestinal calcium absorption without PTH involvement (128, 129). PTH is initially secreted in response to hypocalcemia within minutes, and its lifetime is measured in minutes (125, 126). In contrast, the action of 1,25-$(OH)_2D_3$ requires hours and its lifetime is measured in hours. Thus, PTH serves in a short-term renal process for restoring the calcium level, whereas the action of 1,25-$(OH)_2D_3$ is more prolonged. In the bone, the secreted PTH, together with 1,25-$(OH)_2D_3$, stimulate the transfer of calcium from the bone fluid compartment to the extracellular fluid compartment and into general circulation.

The three sources of calcium described restore serum calcium to the normal level, at which time PTH secretion is suppressed, shutting down the entire calcium mobilizing system. On the other hand, in cases of hypercalcemia, C cells of the thyroid secrete calcitonin, which suppresses mobilization of calcium from the bone and probably stimulates excretion of calcium and phosphorus in the kidney (131). In this manner the vitamin D endocrine system efficiently controls calcium homeostasis as shown in Fig. 2 (132).

In addition to phosphate, PTH, and 1,25-$(OH)_2D_3$, sex-related regulatory phenomena are known to affect calcium absorption. For example, there is a great need for calcium in egg-laying birds. Egg-laying birds have a high level of 1-hydroxylase activity in their kidneys, while nonlaying mature females or males have little 1-hydroxylase activity but higher 24*R*-hydroxylase activity (133, 134). During pregnancy and lactation, plasma 1,25-$(OH)_2D_3$ is elevated in both rats and humans (135, 136) to meet increased calcium demand. Growth hormone and prolactin are believed to provide the stimuli for increased 1-hydroxylase activity (137). These data suggest that sex hormones and other endocrine systems are also involved in the calcium regulatory processes.

Several review articles discuss the biogenesis of vitamin D, its metabolism, the mechanism of action of the metabolites in maintaining calcium and phosphorus homeostasis, and the clinical applications of vitamin D metabolites (132, 138–149).

CLINICAL APPLICATIONS OF VITAMIN D METABOLITES

It is beyond the scope of this article to go into a detailed discussion of the clinical applications of vitamin D metabolites. Of all the metabolites, 25-OH-D_3 and 1,25-$(OH)_2D_3$ are the most important and both are available commercially as prescription products in the United States and West European and Scandinavian countries. The clinical uses of these two compounds are for bone diseases related to abnormal calcium and phosphorus deficiencies in the blood.

As already mentioned, 25-OH-D_3 is the major circulating form of vitamin D_3 and has to be converted to 1,25-$(OH)_2D_3$ to function in the restoration of calcium and phosporus serum levels. The normal serum level of 25-OH-D_3 is 20–40 ng/ml, whereas that of 1,25-$(OH)_2D_3$ is only 20–40 pg/ml. The serum level of 25-OH-D_3 can go up depending on the vitamin D intake or exposure to sunshine, whereas that of 1,25-$(OH)_2D_3$ is constant and regulated according to the calcium level in the serum. In addition, 25-OH-D_3 is much less toxic than 1,25-$(OH)_2D_3$; therefore, 25-OH-D_3 is preferred in all calcium deficiency diseases where renal 1-hydroxylase activity is not impaired by lack of PTH stimulation or the inability of the kidney to produce this enzyme.

Since the discovery of the major metabolites of vitamin D_3, several synthetic analogs were made and researched not only to elucidate the mechanism of vitamin D_3 metabolism, but also as possible substitutes for 25-OH-D_3 and

1,25-$(OH)_2D_3$. Of these, the most prominent one is 1α-hydroxyvitamin D_3 (1α-OH-D_3) which is hydroxylated very readily in the liver to 1,25-$(OH)_2D_3$ (150). Except for a few specific diseases, the rationale for the use of these D_3 metabolites in the treatment of bone diseases is clouded by the interplay of the other less active metabolites and also by the several hormones and enzymes involved in the bone mineralization and bone formation processes. For example, 24,25-$(OH)_2D_3$ was until recently considered as the first of a series of metabolites in the excretionary route for 25-OH-D_3. In normocalcemic animals, 24-25-$(OH)_2D_3$ is the predominant dihydroxylated metabolite, and even though only a few humans have been treated to date with this metabolite, it was reported (149, 151) that it may have an important adjunctive role in the treatment of bone diseases.

Rickets—Rickets was originally thought of as a bone disease, but later found to be a blood disease in the sense that it appeared when the calcium and phosphorus levels in the blood were low. This led scientists to believe that the product of calcium and phosphorus concentrations in the blood was the determining factor in the production of rickets and this measure was used as a diagnostic test. With the mandatory practice of fortifying fresh and evaporated milk, rickets as a nutritional disease has almost been eliminted in the western world.

In addition to vitamin D-deficiency rickets, there are the vitamin D-dependent and vitamin D-resistant hypophosphatemic rickets. Vitamin D-dependent rickets is an inherited disease in children that occurs even when the patients take the daily requirement of vitamin D. These children develop aminoaciduria. The disease is treated by high doses of vitamin D (152), pharmacological doses of 25-OH-D_3 (153), or as little as 1 μg/day of 1,25-$(OH)_2D_3$ (153, 154). It is now believed that this disease is a defect of 1-hydroxylation of 25-OH-D_3. The cure with large doses of vitamin D_3 or 25-OH-D_3 is probably due to the 25-OH-D_3 interacting directly with the receptors.

Vitamin D-resistant hypophosphatemic rickets is more common and is characterized by low blood phosphorus, normal calcium serum concentration, and either normal or reduced intestinal calcium absorption. Studies using a strain of mice having the same genetic and phenotypic characteristics as the human in the development of this disease demonstrated that there is a generalized defect in phosphate transport reactions, especially in the kidney and the intestine (155, 156). Patients with this disease are given large doses of phosphate to counteract the large losses in the urine. Large doses of phosphate can bring about excessive secretion of PTH, which has to be corrected by the administration of 1,25-$(OH)_2D_3$ or 1α-OH-D_3. Thus, the treatment of this type of rickets is a complicated system of checks and balances.

Hypoparathyroidism—PTH secreted by the parathyroid gland senses hypocalcemia (Scheme III). Hypoparathyroid patients do not have this ability and therefore do not metabolize 25-OH-D_3 to 1,25-$(OH)_2D_3$. As a result, the serum calcium levels drop while inorganic phosphate may rise. Previously, such patients were treated with large doses of vitamin D, but now these cases can be treated better with 1,25-$(OH)_2D_3$ or 1α-OH-D_3 at doses of 0.68–2.7 μg/day plus sufficient dietary calcium (157–159). These small doses caused a marked increase in serum calcium concentration and urinary calcium excretion, without significant changes in renal calcium clearance or urinary hydroxyproline excretion. These results suggest that the correction of hypocalcemia involved primarily a stimulation of intestinal calcium absorption rather than a stimulation of skeletal calcium absorption.

Pseudohypothyroidism—Pseudohypothyroid patients secrete sufficient amounts of PTH in response to hypocalcemia, but the kidney and bone do not respond. The result is that patients become hypocalcemic in the presence of large circulating levels of PTH. These patients are treated satisfactorily with oral 1,25-$(OH)_2D_3$ or 1α-OH-D_3 plus calcium. In pharmacological amounts 25-OH-D_3 has also been used successfully for this condition.

Renal Osteodystrophy—Patients with renal osteodystrophy have lost the ability to make 1,25-$(OH)_2D_3$, the calcium-mobilizing hormone. This disease is complicated by the fact that the kidney fails to excrete phosphate, thereby causing a secondary hyperparathyroidism. This in turn can cause excessive erosion of bone calcium giving rise to osteitis fibrosa. Inadequate amounts of 1,25-$(OH)_2D_3$ may also lead eventually to bone resistance to PTH (160). Patients with renal osteodystrophy have been successfully treated with 1,25-$(OH)_2D_3$, 25-OH-D_3, and 1α-OH-D_3 (161–164).

Both 25-OH-D_3 and 1,25-$(OH)_2D_3$ are approved in the United States for the treatment and management of patients undergoing renal dialysis for diseases associated with chronic renal failure or hypocalcemia. At the present time, these are the only clinical conditions for which the two compounds have received approval from the Food and Drug Administration.

The cause for renal osteodystrophy is multifunctional, involving more than excess PTH and/or 1,25$(OH)_2D_3$ deficiency. The exact reasons for the development of one form of bone disease *versus* another remains to be clarified. Although the availability of vitamin D metabolites has substantially improved the therapeutic outlook, the relative merits of 1,25-$(OH)_2D_3$ and 25-OH-D_3 in the management of this bone malfunction remain controversial.

Three predominant forms of renal osteodystrophy are recognized. These are osteitis fibrosa, osteomalacia, and a combination of the two. From available but unpublished clinical data, one might make the following conclusions.

1. Osteitis fibrosa patients with serum calcium <10 mg/dl and phosphorus <5 mg/dl respond about equally to either 1,25-$(OH)_2D_3$ or 25-OH-D_3. Patients on 1,25-$(OH)_2D_3$ treatment may require closer observation because the fluctuation in serum calcium is probably greater than during treatment with 25-OH-D_3. Treatment with either compound is contraindicated for patients with serum calcium >11 mg/dl. If the hypercalcemia is marginal (10–11 mg/dl), 25-OH-D_3 is preferable to 1,25-$(OH)_2D_3$ because it may be less likely to cause an abrupt rise in serum calcium.

2. For patients with pure osteomalacia and serum phosphorus levels <5 mg/dl, 25-OH-D_3 is clearly the treatment of choice. If the calcium level in these patients is >10 mg/dl, a low calcium diet may permit sufficient doses of 25-OH-D_3 to be administered without provoking significant hypercalcemia (>11 mg/dl).

3. In patients with mixed osteomalacia and osteitis fibrosa (serum phosphorus <5 mg/dl), positive responses

have been reported with both 1,25-$(OH)_2D_3$ and 25-OH-D_3. Overall mineralization might be promoted better with 25-OH-D_3 than with 1,25-$(OH)_2D_3$. This is probably because of the role played by 24,25-$(OH)_2D_3$ (149, 151) generated from 25-OH-D_3 in the bone formation process.

Steroid-Induced Osteoporosis—Administration of glucocorticoids results in the thinning of the bones or osteoporosis. The exact reason for this disease is not known. Even though reports on the effect of glucocorticoids on the metabolism of vitamin D conflict, some indicate that administration of either 25-OH-D_3 or 1,25-$(OH)_2D_3$ is beneficial in correcting this problem (165).

Postmenopausal and Senile Osteoporosis—There is convincing evidence that sex hormones may affect vitamin D metabolism and calcium absorption (133–137). It has been shown that intestinal calcium absorption and serum levels of 1,25-$(OH)_2D_3$ diminish with age (165, 166). It has also been suggested that osteoporotic patients may have lower levels of 1,25-$(OH)_2D_3$ in their plasma than controls (167). In addition, there is evidence that the intestinal calcium absorption of osteoporotic patients can be enhanced by 1,25-$(OH)_2D_3$, but not by vitamin D_3 itself. This suggests that age- and sex-related factors prevent the metabolism of vitamin D_3 to its active forms. Several clinical trials are ongoing with 25-OH-D_3, 1,25-$(OH)_2D_3$, and 1α-OH-D_3 for the treatment of this fairly common disorder.

In one study (168), oral administration of 25-OH-D_3 for 3 months to six patients with postmenopausal osteoporosis was effective in raising low intestinal calcium absorption and in augmenting the production of 1,25-$(OH)_2D_3$ and 24,25-$(OH)_2D_3$. If 24,25-$(OH)_2D_3$ is important for bone formation as has been suggested (149, 151) then 25-OH-D_3 may be preferred over 1,25-$(OH)_2D_3$, since the latter is not converted to 24,25-$(OH)_2D_3$ in the body.

Anticonvulsant Drug-Induced Osteomalacia—There is a high incidence of osteomalacia among patients treated with the antiepileptic drug combination of phenytoin[2] and phenobarbital. This condition is generally treated with vitamin D (~4000 IU daily). It is obvious that this disease can be treated with lower doses of the more active metabolites. Stamp *et al.* (169) reported good results with 25-OH-D_3.

Hepatic Disorders—Since vitamin D is first hydroxylated in the liver, it seems that 25-OH-D_3 would be indicated for people with hepatic disorders. Cirrhosis of the liver does not appear to cause markedly reduced 25-OH-D_3 levels in the blood. If patients with hepatic disorders also have bone diseases associated with low serum calcium levels, it is quite likely that they would benefit from 25-OH-D_3 administration.

TOXICITY OF VITAMIN D AND ITS METABOLITES

Vitamin D_3 is toxic at high doses. Since it is converted in sequence to 25-OH-D_3 and to 1,25-$(OH)_2D_3$, and since 1,25-$(OH)_2D_3$ is the most biologically active form, it is not surprising that the margin of safety is lowest for 1,25-$(OH)_2D_3$ and highest for vitamin D_3. The recommended daily intake of vitamin D is 400 IU (10 μg). There is a considerable safety factor between the normal intake and the toxic dose, yet there are diseases like sarcoidosis and idiopathic hypercalcemia in which patients are overly sensitive to vitamin D. However, because there is an ample concentration of 25-OH-D_3 in normal human blood, there is no need to take more than 400 IU/day unless recommended by a physician. Continued daily intake exceeding 100,000 IU produces toxic manifestation. The symptoms include generalized weakness, nausea, vomiting, constipation, polyuria, dehydration, and elevated serum calcium and phosphorus levels. These adverse effects are reversible if the vitamin is withdrawn in time.

The crucial steps in the metabolism of vitamin D_3 are tightly controlled and feedback regulated. However, large doses of vitamin D_3 can overcome control of the 25-hydroxylation step. Haddad and Stamp (170) found a concentration of >600 ng/ml of 25-OH-D_3 in the serum of patients on long-term treatment with 5 mg (200,000 IU) of vitamin D for hypoparathyroidism or sex-linked hypophosphatemic rickets. So it is possible that the toxic effect of excessive intake of vitamin D_3 in normal individuals may be due to the abnormally high level of 25-OH-D_3 in the blood. The toxic symptoms are calcification of the heart, lungs, kidneys, and other soft tissues. Large doses of vitamin D will cause a marked demineralization of the bone at the same time that it causes hypercalcemia and nephrocalcinosis.

ANALYSIS OF VITAMIN D AND ITS METABOLITES

Biological and Chemical Methods—Biological and chemical methods are the oldest and probably the most widely accepted methods for the analysis of vitamin D. The biological methods can be divided into three groups: curative, prophylactic, and those based on calcium absorption into the blood stream. All are based on the administration of measured doses of a standard vitamin D preparation to a group of test animals and comparison of the biological responses with a similar group given the substance under test. A third group of test animals is used as controls. However, these methods are costly, do not distinguish vitamin D from other biologically active isomers and metabolites, and individual variations in the responses of the test animals are high. These tests and specific methods are detailed elsewhere (171–173).

The most widely used chemical method is the antimony trichloride colorimetric method. Antimony trichloride also reacts with vitamin A, and because vitamin A occurs along with D in many biological samples and is also an ingredient in many commercial products, it is necessary to remove it and other interfering substances prior to reaction with the reagent. This is generally achieved by saponification with alcoholic potassium hydroxide, extraction of the unsaponifiable fraction with petroleum ether, and cleanup on chromatographic columns. The procedure for the determination of vitamin D in pharmaceutical preparations is detailed elsewhere (172).

This method is applicable with suitable modifications to biological samples like fish liver oils, fortified milk, *etc.*, but the colorimetric procedures are being replaced when possible by more specific instrumental methods, usually HPLC. To the author's knowledge, there are no reported colorimetric procedures for vitamin D metabolites.

GLC—Although GLC procedures have been used extensively for the determination of numerous physiologically important steroids and hormones, only a few inves-

[2] Dilantin, Parke-Davis.

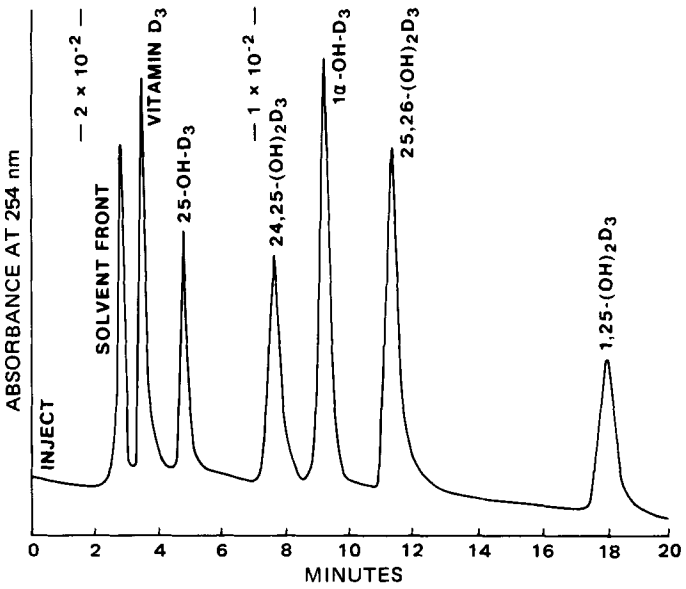

Figure 4—*Chromatogram of vitamin D_3 and its metabolites. A mixture of 40 ng of vitamin D_3, 30 ng of 25-OH-D_3, 25 ng of 24,25-$(OH)_2D_3$, 40 ng of 1α-OH-D_3, 40 ng of 25,26-$(OH)_2D_3$, and 25 ng of 1,25-$(OH)_2D_3$ were injected in 10 μl of 10% isopropanol in Skellysolve B using a U-6 K injector (Waters). With 10% isopropanol in Skellysolve B at 3000 psi pressure and two Zorbax-SIL (DuPont) (2.1 mm × 25 cm) columns in series, a flow rate of 0.5 ml/min was achieved (Ref. 177).*

tigators have attempted to develop similar techniques for vitamin D. The major problems with the GLC analysis of vitamin D are due to its open ring structure incorporating three conjugated double bonds in a 5,6-*cis* configuration. The 5,6-*cis* double bond causes less controllable thermal cyclization into the pyro- and isopyrocalciferols at operating GLC temperatures, resulting in two peaks. Another reason for the lack of interest in GLC analysis is that vitamin D concentration in biological systems is low and the samples generally contain structurally similar compounds requiring extensive sample cleanup. GLC methods for vitamin D analysis were reviewed previously (174, 175). In recent years, HPLC has become the most popular technique for analyzing vitamin D and 25-OH-D_3 and also serves as an important purification step prior to the ligand-binding methods for 1,25-$(OH)_2D_3$,24,25-$(OH)_2D_3$, and 25,26-$(OH)_2D_3$.

Competitive Protein-Binding Methods—It was once believed that 25-OH-D_3 was the most important biologically active metabolite of vitamin D. This belief, coupled with the fact that 25-OH-D_3 is the most abundant of all metabolites in the blood, stimulated a great deal of interest in its analysis.

Proteins with high binding capacity for 25-OH-D_3 were discovered and were utilized in the development of several competitive protein-binding assay procedures (52–54). Similar competitive protein binding methods are also available for vitamin D_3 and its more polar metabolites with much lower concentrations in the blood.

Several different binding proteins have been discovered with either greater binding capacity or greater specificity for a particular metabolite. Under standardized conditions, competitive protein-binding methods are used extensively because the sample volume is very small (0.1–1 ml), sensitivity is unattainable by other methods, sample manipulation is minimal, and a large number of samples can be analyzed simultaneously. The disadvantages are interference from related compounds that compete with the binding-proteins and lack of precision. The interference from related compounds is now minimized greatly by the use of HPLC.

HPLC—The main advantage of HPLC over GLC is that the problems associated with thermal cyclization and degradation are eliminated. Vitamin D and related compounds have a molar extinction coefficient of ~15,000 at 254 nm which allows the use of the most common and stable spectrophotometric detector available for HPLC. Therefore, HPLC is currently the technique of choice for vitamin D analysis. It is invaluable for the analysis of 25-OH-D_3 in biological samples and is also used extensively for purifying the more polar metabolities prior to their analysis by ligand binding methods. Since HPLC is nondestructive the fractions of interest can be collected and used for further tests if necessary.

The photochemical and thermal byproducts of vitamin D synthesis are shown in Scheme II. Until the advent of HPLC it was almost impossible to determine the actual vitamin D content of such a complex synthetic mixture. The separation achieved by Tartivita *et al.* (176) is shown in Fig. 3. Figure 3A is the chromatogram of a crude synthetic mixture and Fig. 3B is of commercial vitamin D in the resin form. These chromatograms were obtained on a 30-cm × 4-mm i.d. commercial microparticulate silica column. The mobile phase was a 70:30:1 mixture of chloroform (free from ethanol and water), *n*-hexane, and tetrahydrofuran at a flow rate of 1 ml/min. Using this system, vitamin D_3 was quantitated in a resin sample containing

Table I—Representative HPLC Systems for the Analysis of Vitamin D and Metabolites

Column No.	Mobile Phase	Compounds Separated or Analyzed	Sample Matrix	Reference
1[a], 50 cm × 2.1 mm	10% isopropanol in Skellysolve B	All known metabolites of D_2 and D_3	Synthetic mixture	177
2[b], 5 μm, 25 cm × 2.1 mm	Acetonitrile–methanol–water (90:5:5)	25-OH-D_3	Human serum	55
2, 5 μm, 22 cm × 6.2 mm	1.5% Water in methanol	D_2 and D_3	Human serum	58
1, 5 μm, 22 cm × 6.2 mm	9% Water in methanol	25-OH-D_3 and 25-OH-D_2	Human serum	58
3[c], 10 μm, 60 cm × 6 mm	*n*-Hexane–isopropanol (88:12)	1,25-$(OH)_2$D	Human serum	62
1, 22 cm × 6.2 mm	10% Isopropanol in hexane	25-OH-D, 24,25-$(OH)_2$D, 1,25-$(OH)_2$D	Human serum	63
1, 25 cm × 4.6 mm	Isopropanol–hexane (1:24 v/v)	25-OH-D and 25-OH-D_3	Human serum	64
1, 25 cm × 4.6 mm	Isopropanol–hexane (1:9 v/v)	24,25-$(OH)_2$D, 25,26-$(OH)_2$D and 1,25-$(OH)_2$D	Human serum	64
2, 25 cm × 4.6 mm	Water–methanol (1:49 v/v)	D_2 and D_3	Human serum	64
1, 6 μm, 25 cm × 6.2 mm	*n*-Hexane–isopropanol–methanol (87:10:3)	25-OH-D_3, 24,25-$(OH)_2D_3$ and 1,25-$(OH)_2D_3$	Human serum	178
1, 25 cm × 4.5 mm	10% Isopropanol in hexane	25-OH-D, 24,25-$(OH)_2$D, 25,26-$(OH)_2$D, 1,25-$(OH)_2$D	Human serum	67
1, 25 cm × 4.5 mm	2.5% Isopropanol in hexane	25-OH-D_2 and 25-OH-D_3	Human serum	67
4[d], 25 cm × 2.6 mm	Acetonitrile–methanol (1:1)	D_3	Fortified milk	179
5[e], 10 μm, 25 cm × 4 mm	1.25% Isopropanol in cyclohexane	D_3	Instant nonfat dried milk	180
6[f], 50 cm × 4.6 mm	Chloroform–*n*-hexane–acetic acid (70:30:1)	D_3	Cod liver oil	181
7[g], 25 m × 3 mm	5% Water in methanol	D_3	Cod liver oil	182
3, 30 cm × 4 mm	0.4% Ethanol in chloroform	D_3	Livestock feed supplement	183
8[h], 25 cm × 4.2 mm	5% Water in methanol	D_3	Livestock feed supplement	184
5, 25 cm × 4.2 mm	30% Chloroform in *n*-hexane	D_3	Livestock feed supplement	185
2, 5 μm, 25 cm × 2.1 mm	Acetonitrile–methanol–water (90:5:5)	25-OH-D_3	Bovine tissues and chicken egg yolk	186, 187
3, 30 cm × 4 mm	Chloroform–hexane–tetrahydrofuran (70:30:1)	Photochemical and thermal isomers	Synthetic mixture and commercial D_3 resin	176
9[i], 5–10 μm, 20–30 cm × 4.6 mm	0.3–0.53% Amyl alcohol in *n*-hexane	D	Commercial D resin powder	188
9, 5–10 μm, 15–60 cm × 3–6.25 mm	0.15–0.7% Amyl alcohol in *n*-hexane	D	Multivitamin preparations	189

20×10^6 IU/g with a relative standard deviation of 1.37%.

HPLC has been frequently used for the quantitative analysis of 25-OH-D_3 in human serum (55–58). It has also been used extensively for the separation of minor constituents into purer fractions prior to their determination by any one of the appropriate protein-binding assays. Figure 4 shows the separation of a synthetic mixture of all the important metabolites of vitamin D_3 obtained by Jones and DeLuca (177). This separation was achieved using two 25-cm × 2.1-mm i.d. microparticulate silica columns in series and 10% isopropanol in Skellysolve B as the mobile phase at a flow rate of 0.5 ml/min. On the same column, they showed the difficult separation of 25-OH-D_3 from 25-OH-D_2 using 2.5% isopropranol in Skellysolve B at a flow rate of 0.7 ml/min

HPLC also has been used for the analysis of vitamin D and all its metabolites in a variety of matrixes. These include milk and milk products, cod liver oil, animal feed supplements, vitamin D concentrates, multivitamin preparations, chicken egg yolk, cow tissues (liver, kidney, and muscle), cow blood, and human blood. A summary of representative HPLC systems from the literature is shown in Table I.

CONCLUSION

After three decades of comparative inactivity, a surge of interest in vitamin D during the last 15 years has resulted in our understanding of the biogenesis of vitamin D_3, the identification of the major metabolites, the establishment of the metabolic pathway, and the hormonal nature of the metabolites. Vitamin D_3 *per se* is now known to be biologically inactive, while 1,25-$(OH)_2D_3$ (or some other as yet unidentified metabolite) has been established as the principal hormone responsible for maintaining calcium and phosphorus homeostasis. The kidney is the endocrine organ in the vitamin D hormonal functions. Extensive research is still underway in elucidating the role of other endocrine organs in the regulation of vitamin D metabolism and its physiological functions. Other unanswered questions deal with the mechanisms of (*a*) the active forms of vitamin D in the transport of calcium from the intestine into general circulation, (*b*) bone calcium mobilization, and (*c*) renal control of phosphorus concentration in the blood. Meanwhile, two principal metabolites, 25-OH-D_3 and 1,25-$(OH)_2D_3$, are available as prescription products in several western countries for the treatment of vitamin D deficiency diseases.

ACKNOWLEDGMENTS

The author wishes to thank D. W. Knuth of The Upjohn Company for his help in the preparation of this article. He also wishes to acknowledge Prof. H. F. DeLuca of The University of Wisconsin, Madison, Wisconsin whose extensive research and writings on this subject were very helpful as resource material.

RESEARCH ARTICLES

Quantitation of Lipophilic Chloroethylnitrosourea Cancer Chemotherapeutic Agents

ROBERT J. WEINKAM‡x and TSUI-YUN J. LIU*

Received February 27, 1981, from the **Brain Tumor Research Center, Department of Neurological Surgery, School of Medicine, University of California, San Francisco, CA 94143* and the ‡*Department of Medicinal Chemistry, School of Pharmacy, Purdue University, West Lafayette, IN 47907.* Accepted for publication June 2, 1981.

Abstract □ A simple and rapid quantitative method for the derivatization and determination of lipophilic chloroethylnitrosoureas is described. This procedure involves the ether extraction of the chloroethylnitrosourea from plasma and conversion of the parent drug to an *O*-methylcarbamate by reaction in anhydrous methanol. The product *O*-methylcarbamate may be separated with gas chromatography (GC) and detected with nitrogen-specific GC detectors or with mass spectrometry using multiple-ion detection. The lower limit of detection for each method was ~100 ng/ml plasma.

Keyphrases □ Cancer chemotherapeutic agents—lipophilic chloroethylnitrosoureas, quantitation □ Chloroethylnitrosoureas—quantitation by gas chromatography □ Gas chromatography—quantitation of lipophilic chloroethylnitrosourea cancer chemotherapeutic agents

The described assay was applied to 1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine, I), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine, II), 1-(2-chloroethyl)-3-(4-*trans*-methylcyclohexyl)-1-nitrosourea (semustine, III), 1-(2-chloroethyl)-3-(2,6-dioxo-3-piperidyl)-1-nitrosourea (IV), and 1-(2-chloroethyl)-3-(4-amino-2-methyl-5-pyrimidinyl)methyl-1-nitrosourea (V)[1]. The clearance curve for IV from rat plasma is presented as an example of the application of this method to the determination of biodistribution parameters.

BACKGROUND

The chloroethylnitrosoureas are a class of highly effective and widely used cancer chemotherapeutic agents (1–3). Analysis of these drugs in plasma at therapeutically significant concentrations has proven to be difficult. Although several methods of analysis have been reported, none are generally applicable to patient pharmacokinetic analyses. As a consequence, only carmustine pharmacokinetics has received detailed study (4).

Chloroethylnitrosoureas are thermally labile and decompose at or below 100° so that the parent compounds cannot be analyzed with gas chromatography (GC) (5). Compounds of this class are readily separated with high-performance liquid chromatography (HPLC) (6); however, the low wavelength and molar absorptivity of the nitrosourea chromophore

[1] These compounds are commonly referred to by their respective code designations BCNU, CCNU, Methyl-CCNU, PCNU, and ACNU.

RESEARCH ARTICLES

Quantitation of Lipophilic Chloroethylnitrosourea Cancer Chemotherapeutic Agents

ROBERT J. WEINKAM‡x and TSUI-YUN J. LIU*

Received February 27, 1981, from the **Brain Tumor Research Center, Department of Neurological Surgery, School of Medicine, University of California, San Francisco, CA 94143* and the ‡*Department of Medicinal Chemistry, School of Pharmacy, Purdue University, West Lafayette, IN 47907.* Accepted for publication June 2, 1981.

Abstract □ A simple and rapid quantitative method for the derivatization and determination of lipophilic chloroethylnitrosoureas is described. This procedure involves the ether extraction of the chloroethylnitrosourea from plasma and conversion of the parent drug to an *O*-methylcarbamate by reaction in anhydrous methanol. The product *O*-methylcarbamate may be separated with gas chromatography (GC) and detected with nitrogen-specific GC detectors or with mass spectrometry using multiple-ion detection. The lower limit of detection for each method was ~100 ng/ml plasma.

Keyphrases □ Cancer chemotherapeutic agents—lipophilic chloroethylnitrosoureas, quantitation □ Chloroethylnitrosoureas—quantitation by gas chromatography □ Gas chromatography—quantitation of lipophilic chloroethylnitrosourea cancer chemotherapeutic agents

The described assay was applied to 1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine, I), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine, II), 1-(2-chloroethyl)-3-(4-*trans*-methylcyclohexyl)-1-nitrosourea (semustine, III), 1-(2-chloroethyl)-3-(2,6-dioxo-3-piperidyl)-1-nitrosourea (IV), and 1-(2-chloroethyl)-3-(4-amino-2-methyl-5-pyrimidinyl)methyl-1-nitrosourea (V)[1]. The clearance curve for IV from rat plasma is presented as an example of the application of this method to the determination of biodistribution parameters.

BACKGROUND

The chloroethylnitrosoureas are a class of highly effective and widely used cancer chemotherapeutic agents (1–3). Analysis of these drugs in plasma at therapeutically significant concentrations has proven to be difficult. Although several methods of analysis have been reported, none are generally applicable to patient pharmacokinetic analyses. As a consequence, only carmustine pharmacokinetics has received detailed study (4).

Chloroethylnitrosoureas are thermally labile and decompose at or below 100° so that the parent compounds cannot be analyzed with gas chromatography (GC) (5). Compounds of this class are readily separated with high-performance liquid chromatography (HPLC) (6); however, the low wavelength and molar absorptivity of the nitrosourea chromophore

[1] These compounds are commonly referred to by their respective code designations BCNU, CCNU, Methyl-CCNU, PCNU, and ACNU.

0022-3549/82/0200-0153$01.00/0

(λ_{max} 232 nm, ϵ 6000) causes this approach to lack sensitivity even when variable-wavelength UV detectors are used. An assay limit of 2–5 μg/ml of plasma was found with II (7, 8). Compound V is an exception to this generalization, as the pyrimidinyl substituent is a superior chromophore (9). Both HPLC and GC analyses are hindered by the fact that the chloroethylnitrosourea group is difficult to derivatize.

Radiolabeled chloroethylnitrosoureas, especially I and II, have been used for the measurement of tissue concentrations of parent drug either without separation (10, 11) or after isolation of unchanged drug with TLC (12) or HPLC[2]. This approach is sensitive but the use of radioactive tracers in patients is limited. The colorimetric assay developed by Loo and Dion (13) has a lower detection limit than HPLC but does not possess sufficient sensitivity to assay patient plasma samples. This assay involves the acid-catalyzed decomposition of nitrosourea to nitrous acid which is subsequently trapped and analyzed using the Bratton–Marshall method (14). This approach lacks the specificity necessary to distinguish between parent drug and biologically active metabolites that retain the nitrosourea moiety.

Recently reported polarographic methods have the requisite sensitivity but are susceptible to interference from plasma components and also lack specificity (15). Patient pharmacokinetic studies of carmustine biodistribution have been performed using direct sample insertion chemical-ionization mass spectrometry (5). The method was successful because of the relatively high lipophilicity and volatility of I and is not applicable to less volatile analogs such as II and IV.

The described analytical procedure may be applied to different chloroethylnitrosourea analogs. The parent nonpolar chloroethylnitrosoureas may be extracted from plasma and converted to a stable *O*-methylcarbamate by reaction in anhydrous basic methanol. The *O*-methylcarbamate products may be separated with GC and detected at high sensitivity with multiple-ion detection mass spectrometry or with nitrogen-specific GC detectors.

EXPERIMENTAL

Materials—Reagents used to convert chloroethylnitrosoureas[3] to *O*-methylcarbamates were 0.2 *M* trimethylanilinium hydroxide in anhydrous methanol[4], 10% freshly distilled triethylamine[5] in anhydrous methanol[5], 10% reagent grade pyridine[5] in anhydrous methanol[5], and 2% sodium methoxide in anhydrous methanol prepared by reacting sodium metal with anhydrous methanol.

Instrument Conditions—GC separations of *O*-methylcarbamate derivatives of chloroethylnitrosoureas were performed on instruments equipped with 1.5 m long, 2-mm i.d. glass columns packed with 3% OV-1 on 100–120 mesh Supelcoport[6]. An instrument equipped with a flame-ionization detector[7] and an instrument equipped with a nitrogen-specific detector[8] used helium carrier gas at a flow rate of 40 ml/min. An instrument interfaced to a mass spectrometer[9] operating in the multiple-ion detection mode and equipped with a chemical-ionization source used methane[10] as a combined carrier and reagent gas. In each case, an injection port temperature of 210° was used. Column oven temperatures were varied according to the nitrosourea derivative being analyzed.

Derivatives of I and II were eluted using linear temperature programming with an initial temperature of 70° increasing 4°/min starting at the time of injection. The derivative of I eluted in ~2 min at 80° and II eluted in ~6.5 min at 95°. Isothermal column oven conditions may be used for other derivatives and derivatives of II and III may be eluted at 110° with retention times of ~2.0 and 3.0 min, respectively. Compounds IV and V may be eluted at 160° as *N*-methyl-*O*-methylcarbamates with retention times of ~2.0 and 3.0 min, respectively. GC–mass spectrometric operations were performed at an ion-source pressure of 1.0 mm methane and temperature of 200°.

Extraction and Derivative Formation—Chloroethylnitrosoureas, 0.05–1.0 μg, were added to 1.0 ml of plasma or to 1.0 ml of 0.05 *M* phosphate buffer (pH 7.4) and extracted with 3.0 ml of ether. The 2.0-ml ether layer was removed and placed into a 3.0-ml cone-shaped interior vial[11] containing 1.0 μg of a reference chloroethylnitrosourea. The ether was evaporated to dryness under a nitrogen stream at ambient temperature. Approximately 50 μl of derivatizing reagent was added. Compounds IV and V were derivatized with 0.2 *M* trimethylanilinium hydroxide in anhydrous methanol[4]. Compounds I–III were derivatized with 2% sodium methoxide in anhydrous methanol. The reagent–chloroethylnitrosourea mixture was heated at 50° for 20 min in the capped cone-shaped vial[11]. Approximately 1 μl of this mixture was injected onto the chromatograph column and the peak height ratios were determined. These peak height ratios were compared with those obtained from the analysis of the same amounts of chloroethylnitrosoureas added directly to ether and avoiding the extraction step to determine extraction efficiency.

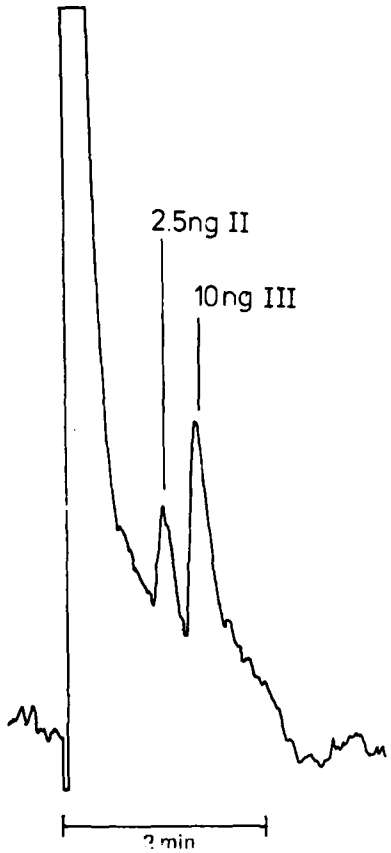

Figure 1—*A chromatogram of O-methylcarbamates derived from II and III. Separations were performed using a 3% OV-1 column at 110° and detected using a nitrogen-specific detector. The amounts injected on-column were calculated from the amounts of II (50 ng) and III (250 ng) extracted from 1 ml of water, derivatized with 20 μl of 2% sodium methoxide in anhydrous methanol and injected assuming 100% conversion at each step.*

Derivatization conditions were optimized by comparison of absolute peak heights obtained from heating derivatizing reagents with chloroethylnitrosoureas at different temperatures and for various times. Optimal peak heights were obtained on heating the reagent mixtures at 50° for 20 min. No decrease in peak heights was observed on heating for longer periods.

Analysis of IV with V as Standard—A 0.1–0.5-ml plasma sample containing IV was mixed[12] with 3.0 ml of ether. The ether (2.0 ml) was removed and placed in a 3.0-ml cone-shaped vial[11] containing 10 μl of a 100 μg/ml stock solution of V in ether (1.0 μg, 3.5 nmoles). The ether was evaporated to dryness under a nitrogen stream at ambient temperature. Approximately 20 μl of 0.2 *M* trimethylanilinium hydroxide in anhydrous methanol[4] was added, mixed, and heated at 50° for 20 min in a capped cone-shaped vial. Approximately 1.0 μl of this mixture was injected onto the column. The eluted peaks were detected with mass spectrometry using multiple-ion detection of ions *m/z* 183.1 for IV and *m/z* 191.1 for V-derived products. The peak height ratio of 183.1/193.1 was determined, and the plasma IV concentration was calculated by reference to a standard curve obtained using the described procedure with known concentrations of IV in plasma. Alternatively, the eluted GC peaks

may be detected with a nitrogen-specific detector and the peak height ratios determined. The plasma concentration was calculated by reference to a standard curve obtained using this detection method.

Analysis of Other Chloroethylnitrosoureas—The described procedure for the analysis of IV may be followed for the analysis of plasma containing V by using IV as a standard.

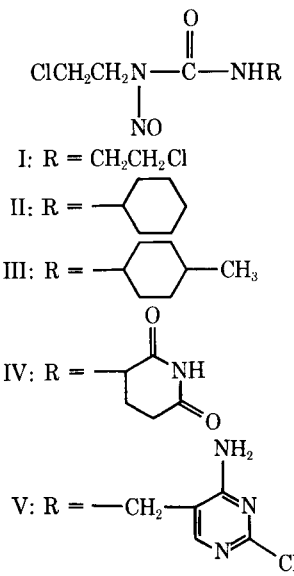
Compounds I–III may be quantified by mixing 0.1–0.5 ml of plasma containing a chloroethylnitrosourea with 3.0 ml of ether. The ether (2.0 ml) was removed and placed in a 3.0-ml cone-shaped vial containing 1.0 μg of a standard chloroethylnitrosourea. Recommended standards are II for quantification of I or III, and III for quantification of II. Approximately 20 μg of 2% sodium methoxide in anhydrous methanol was added, mixed, and heated at 50° for 20 min in a capped cone-shaped vial. Approximately 1.0 μl of this mixture was injected onto the column.

The eluted peaks were detected with mass spectrometry using multiple-ion detection of ions *m/z* 138.1 or 102.1 for I, *m/z* 158.1 for II, and *m/z* 172.1 for III-derived products. The respective peak height ratios may be determined and used to calculate plasma concentration by reference to a standard curve obtained using the described procedure for analysis of known amounts of sample and reference chloroethylnitrosourea. Eluted GC peaks may be detected using a nitrogen-specific GC detector to obtain the corresponding peak height ratios which may also be used to calculate plasma concentrations.

Clearance from Rat Plasma—Male Fisher-344 rats, 230–290 g, were anesthetized by an intraperitoneal injection of pentobarbital and catheters were inserted into the saphenous artery and vein. After intravenous administration of 100 USP units of heparin sodium, rats were administered 22.2–22.9 mg of IV/kg iv for 20 sec. Samples of arterial blood were removed through the arterial catheter at 1, 2, 4, 6, 10, 15, 30, 60, 90, 120, and 180 min following intravenous administration. Individual 0.2–0.5-ml samples were placed in 1.5-ml capped micro test tubes and centrifuged[13] immediately at 8000×*g* for 30 sec. A known volume (0.1–0.3 ml) of plasma was removed and analyzed as described.

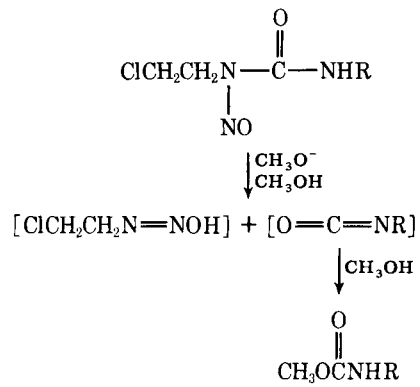
RESULTS AND DISCUSSION

Clinically studied chloroethylnitrosoureas are a class of drugs that share a common reactive nitrosourea moiety but may contain a variety of *N*-substituents, some of which are shown in Scheme I. The described assay employs the known base-catalyzed decomposition reaction of 3-substituted 1-(2-chloroethyl)-1-nitrosoureas to 2-chloroethylazohydroxide and *N*-substituted isocyanates (16–21). In this assay, the decomposition reaction is carried out in anhydrous methanol where the intermediate isocyanates react to yield *N*-substituted-*O*-methylcarbamates (22) as shown in Scheme II. The carbamate products are formed in >90% yield and retain the characteristic R-substituent of the different chloroethylnitrosoureas and their biologically active metabolites (23, 24). The *O*-methylcarbamate derivatives are readily separated by GC and may be detected using a variety of methods.



Scheme I—The structure of lipophilic chloroethylnitrosourea cancer chemotherapeutic agents.

[13] Eppendorf model 5412 centrifuge.



Scheme II—The reaction of chloroethylnitrosourea in basic anhydrous methanol leads to the formation of 2-chloroethyldiazotate and substituted isocyanate. The isocyanate reacts with solvent methanol to give a stable O-methylcarbamate derivative.

The assay procedure requires that the nitrosourea be extracted from plasma. All of the analogs studied (Scheme I) are lipophilic and are readily extracted from aqueous media by organic solvents. The least lipophilic analog, IV, has an octanol/water partition coefficient of 2.3. The extraction efficiency of this compound from 0.5 ml of plasma by a sixfold volume excess of ether is high. When ratios of known amounts of IV to V are plotted against observed peak height ratios, the same slope is obtained from the analyses of known amounts of both compounds following extraction of both components from plasma, and following extraction of IV from plasma using V as a standard. These results confirm that both compounds may be extracted from 0.5 ml of plasma by 3.0 ml of ether in >90% efficiency.

The decomposition of chloroethylnitrosoureas to alkylisocyanates is catalyzed by organic and inorganic bases. Although the choice of catalyst is not critical, 2% sodium methoxide in anhydrous methanol is a convenient reagent compatible with GC nitrogen-specific detectors and with mass spectrometric detection under chemical-ionization conditions. This reagent may be used for the analysis of IV and V as well as the other chloroethylnitrosoureas listed in Scheme I. Trimethylanilinium hydroxide in anhydrous methanol may be used for the analysis of IV and

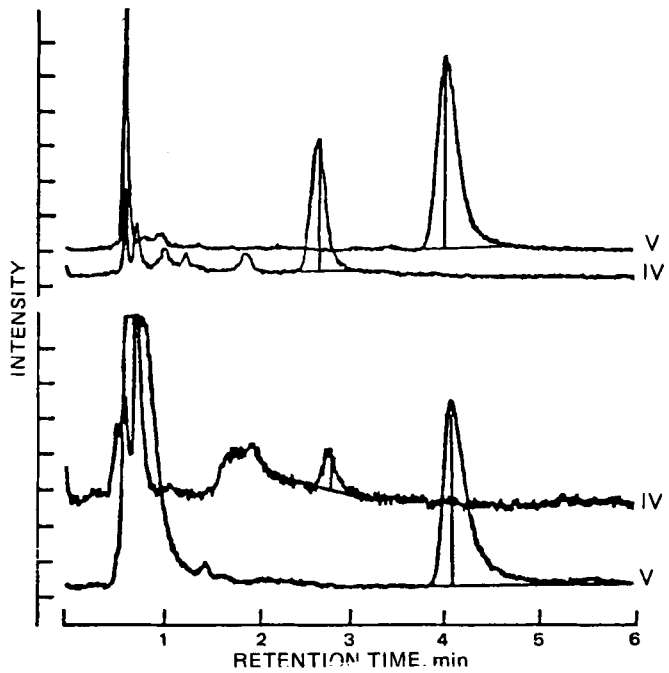


Figure 2—*GC–mass spectrometric selected ion traces for IV and V obtained from rat plasma following the described assay procedure for IV using V as a standard. The upper portion of the figure is the analysis of V in rat plasma following intravenous administration of a 22.5-mg/kg bolus of IV. The lower portion shows the data output operating near the limit of detection in which an estimated 2.0 ng of derivative was injected on-column.*

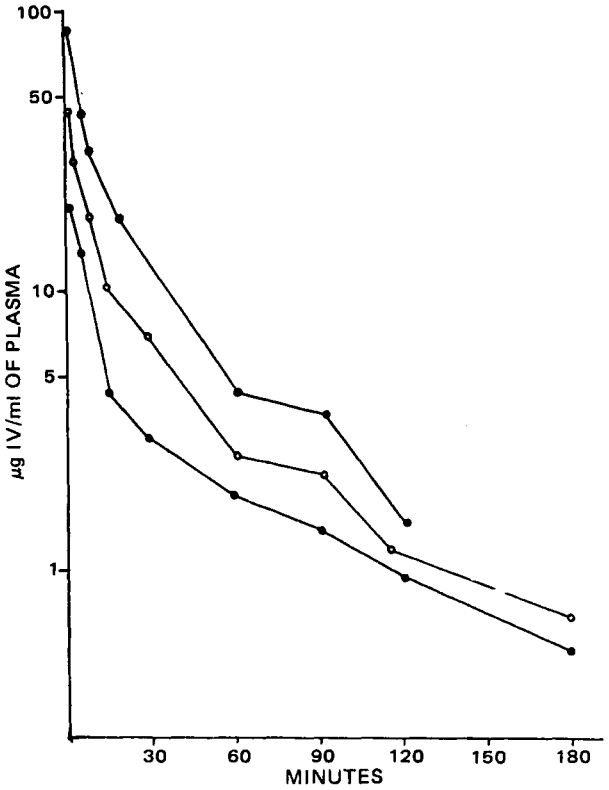

Figure 3—*Plasma clearance curves obtained following the intravenous administration of 22.5-mg/kg bolus of IV to 230–290-g male Fisher-344 rats. Compound IV was analyzed following the procedure using V as a standard. The GC eluate was monitored using mass spectrometry multiple-ion detection.*

V but is not recommended for the analysis of other analogs. This reagent acts as an on-column methylating agent as well as a basic catalyst.

Reaction of a chloroethylnitrosourea at 50° for 20 min in the reagent forms the *O*-methylcarbamate (Scheme II). Injection of the mixture onto the GC column at an injection port temperature of 210° pyrolyzes the trimethylanilinium ion and transfers a methyl group onto the nitrogen of the *O*-methylcarbamate. The resulting *N*,*N*-disubstituted carbamate has good GC characteristics. *N*-Methylation also facilitates chemical-ionization induced fragmentation to the $(MH-HOCH_3)^+$ ion, thereby concentrating the ion current at a single mass and improving detection sensitivity. However, the on-column methylation of I–III and derived *O*-methylcarbamates is not complete under these conditions, so that the use of this reagent leads to partial methylation and generation of two GC peaks for each compound.

GC peak detection was performed using flame-ionization detectors, nitrogen-specific detectors, and multiple-ion detection mass spectrometry. Flame-ionization detection of plasma-extracted I has a detection limit of 100 ng injected on-column. This rather high limit is due, in part, to the poor separation between the volatile I derivative and plasma contaminants. Although the flame-ionization detection limit may be lower for other chloroethylnitrosourea analogs and GC column packings, this method was not pursued because the nitrogen-specific GC detector proved to be a much more sensitive and selective device with approximately the same cost and complexity as the flame-ionization detector.

Figure 1 shows a chromatogram obtained from the rapid elution of 2.5 ng of II- and 10.0 ng of III-derived products injected on-column. This detection limit is well within that needed to perform pharmacokinetic studies and is similar to that observed using mass spectrometric detection. The values for on-column injection were calculated from the amounts of II and III extraction from water, derivatized, and injected, assuming 100% efficiency at each step. The selectivity of the nitrogen-specific detector for compounds containing the C–N bond provides chromatograms of neutral plasma ether extracts that are relatively free from interfering peaks.

Multiple-ion mass spectrometric monitoring of GC peaks is a sensitive and selective detection method. A GC-selected ion trace of IV and V derivatives where IV was extracted from plasma using V as a standard is shown in Fig. 2. The monitored ions are the *N*-methyl-*O*-methylcarbamate derivative $(MH-HOCH_3)^+$ fragment ions *m/z* 183.1 for IV and 193.1 for V. The upper portion of Fig. 2 shows the analysis of a rat plasma sample following administration of IV. The lower portion shows the detection limit of IV at 2 ng injected on-column. This amount was calculated from the amount of IV added to plasma and injected on-column assuming 100% efficiency of extraction, derivatization, and sample transfer. The actual amount of *O*-methylcarbamate injected may be less.

Table I—Plasma Clearance Pharmacokinetic Parameters Calculated [a] from the Clearance Curves Obtained Following a 22.5-mg/kg iv Bolus Dose of IV to 230–290-g Male Fisher-344 Rats

V_1	0.65 (0.36)	liters/kg
V_2	1.07 (0.70)	liters/kg
V_{dss}	1.72 (0.79)	liters/kg
k_{10}	0.061 (0.015)	min^{-1}
k_{12}	0.080 (0.039)	min^{-1}
k_{21}	0.051 (0.014)	min^{-1}
AUC	508 (111)	μg min/ml
Clearance	0.036 (0.011)	liters/min

[a] The data were fit to a two-compartment open model (25). Values presented are the mean ±*SD* of five separate experiments.

The described detection method was used to measure the clearance of IV from rat plasma following intravenous administration of a 22.5 mg/kg bolus. The detection limit in rat plasma was 100 ng/ml using 300-μl plasma sample volumes. Clearance curves were obtained for five animals. Three of these curves are shown (Fig. 3). The clearance curves were fitted to two exponentials using a computer program for nonlinear iterative curve fitting. The data were further analyzed by a two-compartment model for biodistribution (25). Mean pharmacokinetic parameters calculated from the five clearance curves (Table I) illustrate the suitability of the described analytical method for the determination of pharmacokinetic parameters.

Comparison of the biodistribution parameters of IV with those of the more lipophilic analog I (26) show that the volume of distribution and compartment volumes are comparable. The major difference between the two agents is that the area under the clearance curve for I, *AUC* = 359 ± 68 μg min/ml, following administration of a 26 mg/kg iv bolus to male Fisher-344 rats, is significantly less than that for IV. The importance of a prolonged presence of parent drug in plasma is not clear in the case of the chloroethylnitrosoureas because the parent agent must be chemically converted to reactive intermediates and, therefore, cleared from plasma to be active.

CONCLUSIONS

The described assay leads to the formation of chloroethylnitrosourea derivatives that retain the R group characteristic of the analogs in this series. As a consequence, this method has the potential to be applied to the analysis of biologically active hydroxylated II and III metabolites. For example, hydroxylated II metabolites may be extracted from plasma or incubation medium with ether (27) and analyzed by the described procedures since ring-hydroxylated II analogs can be separated as *O*-methylcarbamates on OV-1 GC columns[14].

High-Pressure Liquid Chromatographic Analysis of Indocyanine Green

P. L. RAPPAPORT and J. J. THIESSEN ˣ

Received August 12, 1980, from the *Faculty of Pharmacy, University of Toronto, Toronto, Canada, M5S 1A1.* Accepted for publication May 18, 1981.

Abstract □ The development of a specific high-pressure liquid chromatographic (HPLC) assay, having a quantitative detection limit of 0.4 μg/ml, is described for plasma indocyanine green. In a preliminary study, the HPLC method demonstrated that the traditional spectrophotometric procedure inaccurately quantitates the dye's degradation in aqueous medium since degradation products that absorb light at 770 nm are formed. In a further study, the spectrophotometric method yielded an erroneously low clearance of indocyanine green in the rabbit. In addition, the HPLC assay points to the possibility of metabolite formation of the dye *in vivo*.

Keyphrases □ Indocyanine green—high-pressure liquid chromatographic analysis □ High-pressure liquid chromatography—analysis of indocyanine green □ Dyes—indocyanine green, high-pressure liquid chromatographic analysis

Indocyanine green, an organic anion, has been used to determine cardiac output (1, 2), hepatic blood flow (3–5), and hepatic function (3–9). Analytical methods have been based on the dye's absorbance at 775–800 nm. These procedures employ either direct, continuous measurements of dye in circulating whole blood with a densitometer (1, 2, 10) or standard spectrophotometric analysis of harvested plasma following discrete blood sampling (3–9).

BACKGROUND

In vitro studies (10–12) determined that aqueous solutions of indocyanine green degrade quickly in a concentration-dependent fashion. However, in the presence of plasma or albumin, dye stability is much improved.

In vivo experiments demonstrated a saturable process for indocyanine green uptake by the liver (13, 14) and a biexponential decline in plasma levels for rats, rabbits, dogs, and humans (5, 6, 9, 15). Elimination of unchanged dye by the liver into bile has been thought to be the sole method for indocyanine green clearance. Evidence for this reported absence of metabolites was obtained from paper chromatographic analysis of plasma and bile samples (3, 5, 16, 17).

The reliability of this information depends on the perceived specificity of the spectrophotometric analysis method. Another procedure was needed to examine the existing methods critically. This report describes a high-pressure liquid chromatographic (HPLC) method for analysis of indocyanine green. Preliminary data are presented, highlighting discrepancies between the HPLC and spectrophotometric methods for the determination of *in vitro* dye stability and *in vivo* pharmacokinetics.

EXPERIMENTAL

HPLC Instrumentation—A high-pressure pump[1], a high-pressure injector[2], UV detector[3] (225 nm), and a recorder[4] comprised the chromatographic apparatus. Chromatography was performed on a reversed-phase column[5], using a reversed-phase precolumn[6] to extend column life. The mobile phase, at a flow of 2 ml/min, was composed of 47 parts of acetonitrile[7], 3 parts of methanol[7], and 50 parts 0.05 *M* KH_2PO_4–Na_2HPO_4 buffer[8] (pH 6). A spectrophotometric scan[9] of indocyanine green[10] in reagent grade water[11] showed a peak at 770 nm ($\epsilon = 1.43 \times 10^5$) and another at 210 nm ($\epsilon = 5.17 \times 10^4$). To minimize interference from plasma constituents and to maximize detector performance, a nonoptimal wavelength (225 nm) was used for detection purposes (ϵ ~60% of that at 210 nm).

Preparation of Standards—For the preparation of calibration curves, methanolic solutions of indocyanine green (20, 15, 10, 7, 4, 2, 1, 0.5, 0.2,

High-Pressure Liquid Chromatographic Analysis of Indocyanine Green

P. L. RAPPAPORT and J. J. THIESSEN ˣ

Received August 12, 1980, from the *Faculty of Pharmacy, University of Toronto, Toronto, Canada, M5S 1A1.* Accepted for publication May 18, 1981.

Abstract □ The development of a specific high-pressure liquid chromatographic (HPLC) assay, having a quantitative detection limit of 0.4 μg/ml, is described for plasma indocyanine green. In a preliminary study, the HPLC method demonstrated that the traditional spectrophotometric procedure inaccurately quantitates the dye's degradation in aqueous medium since degradation products that absorb light at 770 nm are formed. In a further study, the spectrophotometric method yielded an erroneously low clearance of indocyanine green in the rabbit. In addition, the HPLC assay points to the possibility of metabolite formation of the dye *in vivo*.

Keyphrases □ Indocyanine green—high-pressure liquid chromatographic analysis □ High-pressure liquid chromatography—analysis of indocyanine green □ Dyes—indocyanine green, high-pressure liquid chromatographic analysis

Indocyanine green, an organic anion, has been used to determine cardiac output (1, 2), hepatic blood flow (3–5), and hepatic function (3–9). Analytical methods have been based on the dye's absorbance at 775–800 nm. Figure 1—*HPLC chromatograms obtained for indocyanine green (a) and diazepam (b) using an RP-18 column (250 × 4.6-mm i.d.) and a mobile phase of 47% acetonitrile–3% methanol–0.05 M phosphate buffer (pH 6) at 2.0 ml/min. Detection was at 225 nm. Key: A, diazepam (0.15 μg/0.25 ml) in blank rabbit plasma; B, indocyanine green (0.1 μg/0.25 ml) and diazepam (0.15 μg/0.25 ml) in blank rabbit plasma; and C, indocyanine green (10 μg/0.25 ml) and diazepam (1.5 μg/0.25 ml) in blank rabbit plasma.*

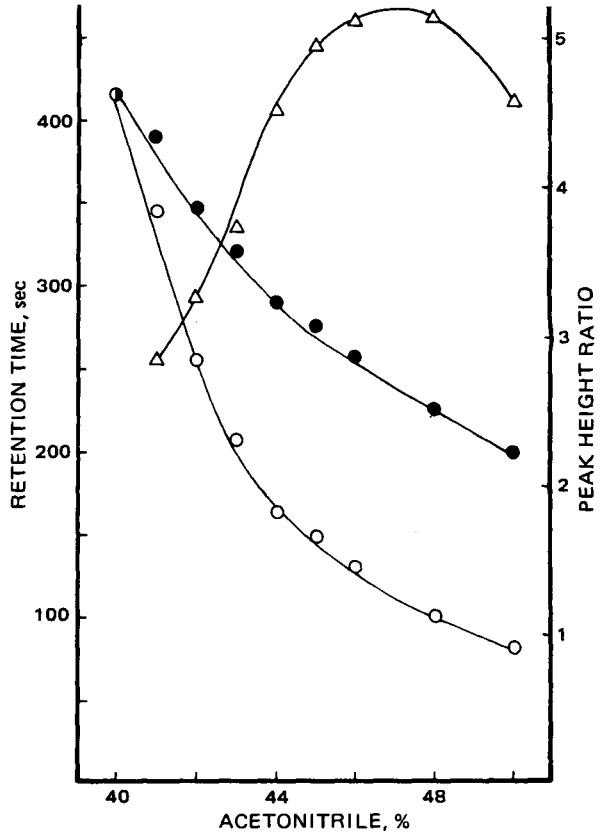

Figure 2—*Effect of acetonitrile concentration in the mobile phase on the retention times of indocyanine green (○) and diazepam (●) and on the indocyanine green/diazepam peak height ratio (△). The aqueous part of the mobile phase was composed of a 0.025 M phosphate buffer (pH 4). The mobile phase was run at 1.6 ml/min on an RP-18 column (250 × 3.2-mm i.d.).*

and 0.1 μg in 0.1 ml) were evaporated to dryness at 40° under a gentle dry nitrogen stream. After this step, standards could be stored in a desiccator under vacuum for 1 week with no detectable degradation. At the time of sample analysis, blank rabbbit plasma (0.25 ml) was added to each tube and allowed to stand for 30 min with intermittent vortexing. After this point, standards were processed in the same manner as *in vivo* samples.

HPLC Sample Preparation—A fixed plasma volume (0.25 ml) was used for all samples. Concentrated samples (>80 μg/ml) were diluted with blank rabbit plasma. Acetonitrile in a 1.6:1 (v/v) ratio with plasma was added in four aliquots (0.1 ml each for 0.25 ml of plasma), with vortexing after each addition. Methanolic diazepam[12] (5, 1.5, or 0.15 μg in 50 μl) was then added as the internal standard, and the mixture was vortexed for 20 sec. The sample was centrifuged(1700×*g*) for 2 min, and a volume of the supernate was injected onto the column. Due to recognized degradation of indocyanine green, the maximum allowable time between sample precipitation and column injection was 30 min.

Spectrophotometric Analysis—The plasma sample (0.25 ml) was diluted with 3.3 ml of reagent grade water. The absorbance of the solution was measured (800 nm) using similarly prepared blank rabbit plasma as the reference.

Stability of Aqueous Solutions—An indocyanine green solution (20 μg/ml in reagent grade water) was exposed to a constant amount of room light (420 lux) at 23°. The solution was sampled periodically to determine the amount of parent dye remaining.

For HPLC analysis, 100 μl of this solution and 100 μl of acetonitrile were added to a tube containing diazepam (0.26 μg). The mixture was vortexed and injected onto the column. Indocyanine green standards were prepared as already described. At the time of analysis, methanolic diazepam (0.26 μg in 0.05 ml) was added to the standards and evaporated. After reconstitution with 0.2 ml of 50% acetonitrile–reagent grade water, the standard was subjected to HPLC analysis.

Spectrophotometric analysis[13] (770 nm) was performed on the solution without a dilution step. The absorbance measurement of a freshly prepared dye solution served as the standard for comparison.

Stability of Plasma Solutions—Standard plasma samples containing 80, 40, 8, 4, or 0.8 μg of indocyanine green in 2.0 ml of fresh blank plasma were prepared as already described. The samples were kept at 6° in polyethylene tubes and 0.25 ml of each was sampled seven times over 10 weeks. A calibration curve, obtained from freshly prepared standards analyzed at the same time as the samples, was used for quantitation of dye degradation.

Indocyanine Green *In Vivo* Study—Indocyanine green was reconstituted with 5% dextrose–water to give a concentration of 8.8 mg/ml. A 25.6-mg/kg dose was administered intravenously[14] to a rabbit over 4 min. Thirteen blood samples (1.5 ml) were collected over 6 hr. Harvested plasma was kept at 6° until analysis later that day.

Calculations—The unknown indocyanine green concentrations in samples analyzed spectrophotometrically or by HPLC were obtained with reference to calibration curves constructed from identically prepared standards. Dye clearance values were calculated using the total area under the indocyanine green concentration *versus* time curve.

RESULTS AND DISCUSSION

retention time was ~7 min, and the quantitative limit of detection for the dye in plasma was 0.4 μg/ml.

The composition of the mobile phase was examined with the following results. The acetonitrile concentration is critical for successful resolution of indocyanine green and diazepam and for optimization of peak shape (Fig. 2). The use of methanol in the ternary solvent system sharpens and reduces the retention time of the internal standard peak without appreciably affecting indocyanine green retention. With respect to the buffer, the salt strength is more important than pH for successful retention of indocyanine green.

The quantitation of indocyanine green in samples varies with the plasma volume (Table I), even when the ratio of precipitant to plasma is constant (1.6:1 v/v). This result may be accounted for by an interfering component in blank rabbit plasma, which exhibits the same retention time as diazepam. Although the diazepam equivalent of this peak only approaches 5% with 0.25-ml samples, the interference is more pronounced with larger sample volumes when the amount of diazepam added remains constant. Therefore, samples with dye concentrations greater than the upper limit of the standard curve (80 μg/ml) were diluted to varying degrees to allow analysis of a constant volume (0.25 ml).

Calibration curves were linear over the concentration range used. The intra-assay coefficient of variation ranged from 2% for 40-μg/ml samples to 8% for 0.4-μg/ml samples (n = 6). The interassay variability was 5–11% for all standards except the 0.4-μg/ml standard, which was 20% (n = 8). The slope variance of standard curves was calculated as 10% (n = 10).

Spectrophotometric Analysis—The lower limit of quantitative detection of indocyanine green in plasma was 2 μg/ml when using 0.25 ml of plasma and the described dilution. The interassay coefficient of variation for all standards was 11–14% (n = 3).

It was reported (18) that different plasma samples yield calibration curves that vary widely, but no explanation for this result has been found. A similar observation was made in this investigation when blank plasma from different rabbits was used. The slopes of calibration curves varied by 32%. This variability is independent of any differences in the inherent absorbance of blank samples at 800 nm. The problem was also not alleviated by protein precipitation using acetonitrile prior to spectrophotometric measurement. Thus, although the source of the variability has not been resolved, it demonstrates a disturbing characteristic of the spectrophotometric method.

Stability Studies of Aqueous Solutions—Once an accurate, reproducible HPLC method for indocyanine green was developed, preliminary studies were conducted to examine the stability of the dye in aqueous solution. Figure 3 illustrates the inadequacy of the spectrophotometric method in the detection of dye degradation in aqueous media. The discrepancy between the two methods results from degradation products of indocyanine green, which absorb a significant amount of light at 770 nm.

Table I—Quantitation Efficiency (Mean ± *SD*) Observed for Indocyanine Green (2 μg) when Added to Plasma Containing 0.735 μg of Diazepam (n = 6)

Plasma Volume, ml	Quantitation Efficiency, %
0.125	91.8 (1.4)
0.25	86.9 (1.8)
0.5	78.5 (2.0)
1.0	72.1 (4.6)

By modifying the mobile phase flow rate, these degradation products can be resolved (Fig. 4). Spectral analysis of the eluate fractions corresponding to these peaks showed that peaks a and b exhibited absorbance at 770 nm. It is unlikely that these peaks represent dye aggregates as described earlier (12, 19), since eluates were below the aggregate-forming concentration (<5 μg/ml) and the ionic strength of the solvent (mobile phase) was constant in all cases. Thus, it was felt that these peaks (Fig. 4) represent products of an irreversible degradation of parent dye. Barbier and DeWeerdt (16) showed two chromatographically distinct species that appear on storage of aqueous dye solution. The "fast" and "slow" fractions exhibited spectral peaks in the visible region at 780 and 783 nm, respectively.

The evidence from these experiments provides another reason why reports using the spectrophotometric method should be questioned.

Dye Stability in Plasma—Standard plasma samples analyzed by the HPLC method exhibited no detectable degradation after 10 weeks of storage at 6°, a finding in agreement with results obtained spectrophotometrically (10, 12).

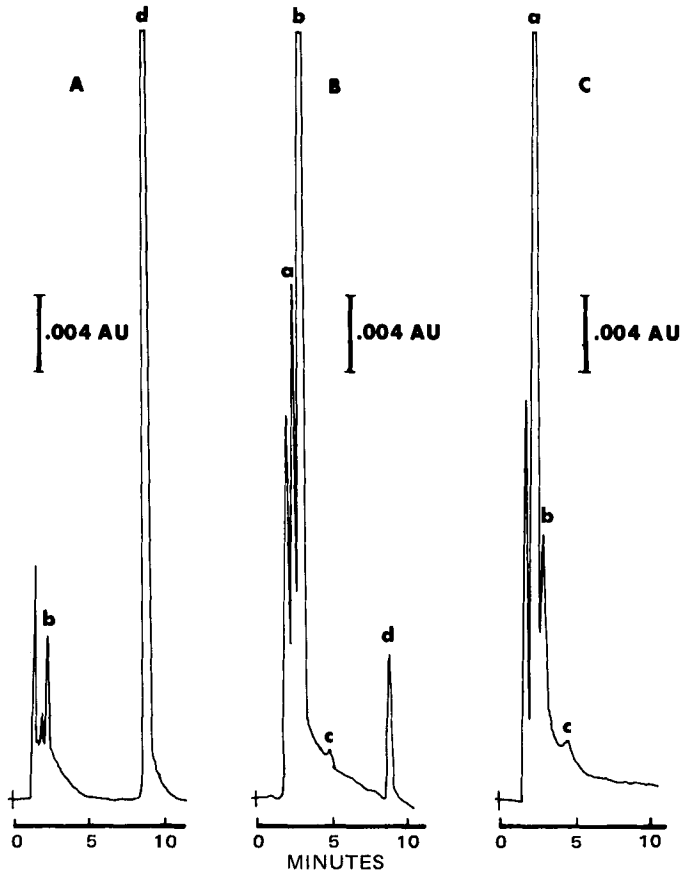

Figure 4—*HPLC chromatograms obtained from aqueous indocyanine green solutions that were freshly prepared (A), 1 day old (B), and 7 days old (C). An RP-18 column (250 × 4.6-mm i.d.) and a mobile phase of 47% acetonitrile–3% methanol–0.05 M phosphate buffer (pH 6) at 1.0 ml/min were employed. Peaks a, b, and c are degradation products of indocyanine green; and peak d is indocyanine green.*

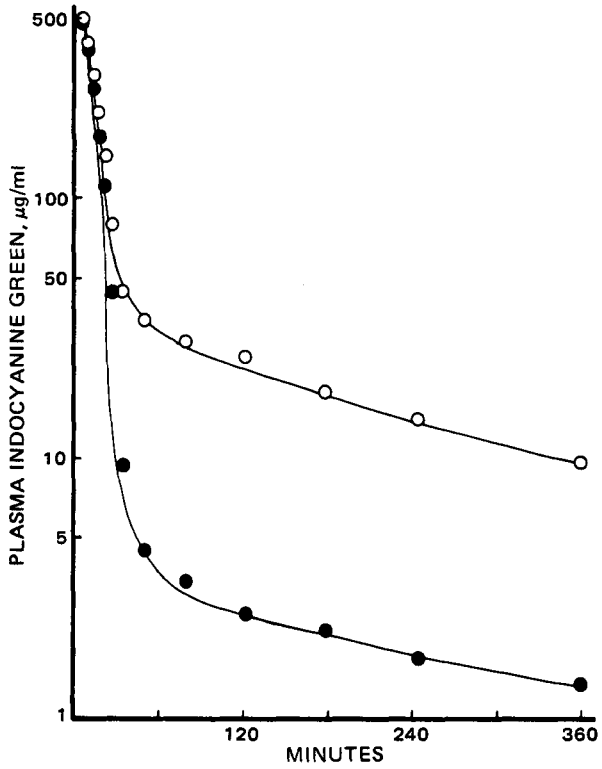

Figure 5—*Plasma indocyanine green observed in a rabbit following a 25.6-mg/kg dose as examined with HPLC (●) and spectrophotometric (○) methods.*

Indocyanine Green *In Vivo* Study—Having established that the HPLC method was more specific for the parent dye in examining aqueous stability, a preliminary study of *in vivo* pharmacokinetics was conducted in a rabbit. Figure 5 illustrates the plasma concentration *versus* time profiles obtained when the same samples were analyzed by the two methods. Initially, indocyanine green concentrations were similar by both procedures. However, after the steep declining phase, their difference became more pronounced. The use of the spectrophotometric method resulted in an erroneously low dye clearance (spectrophotometric method, 1.58 ml/min/kg; HPLC, 2.65 ml/min/kg).

It was questioned whether the observed difference in plasma indocyanine green (Fig. 5) was an artifact or a consequence of the nonspecificity of the spectrophotometric assay. One step in resolving this question was to collect plasma from a rabbit given normal saline rather than indocyanine green. Relative to water, samples collected over 5 hr exhibited an absorbance of 0.0058–0.0067 (790 nm), demonstrating that no time-related changes were found in the inherent absorbance of indocyanine green-free plasma. In view of the plasma stability studies, dye degradation after sample collection was also not responsible for the difference since both analyses were performed on the day of the *in vivo* experiment. It was thus concluded that an *in vivo* degradation product or metabolite of the dye was potentially responsible for the discrepancy seen in Fig. 5.

To evaluate the "metabolite" hypothesis further, the HPLC solvent front eluate was collected for *in vivo* samples, plasma standards, and a plasma blank. It was suspected that the discrepancy noted in Fig. 5 was due to an indocyanine green product eluting in the solvent front (similar to Fig. 4). Spectrophotometric scans of the solvent front eluates of plasma blank and dye standards showed no detectable absorbance in the 600–800-nm region (Fig. 6). However, all solvent front eluates from *in vivo* samples showed some absorbance in this region (Fig. 6). The absorbance pattern was similar to that of parent indocyanine green. However, the ratio of the absorbance at 770 nm to that at 700 nm was 2.4 for the indocyanine green peak eluates and 1.9 for solvent front eluates. For reasons discussed earlier with respect to dye degradation, it is unlikely that the component found in the solvent front eluate represents a dye aggregate. Therefore, it is postulated that indocyanine green undergoes some degradation or metabolism in the body prior to its excretion. The fact that the unknown substance elutes from the HPLC column prior to the parent dye is suggestive of a compound that is more polar than indocyanine green.

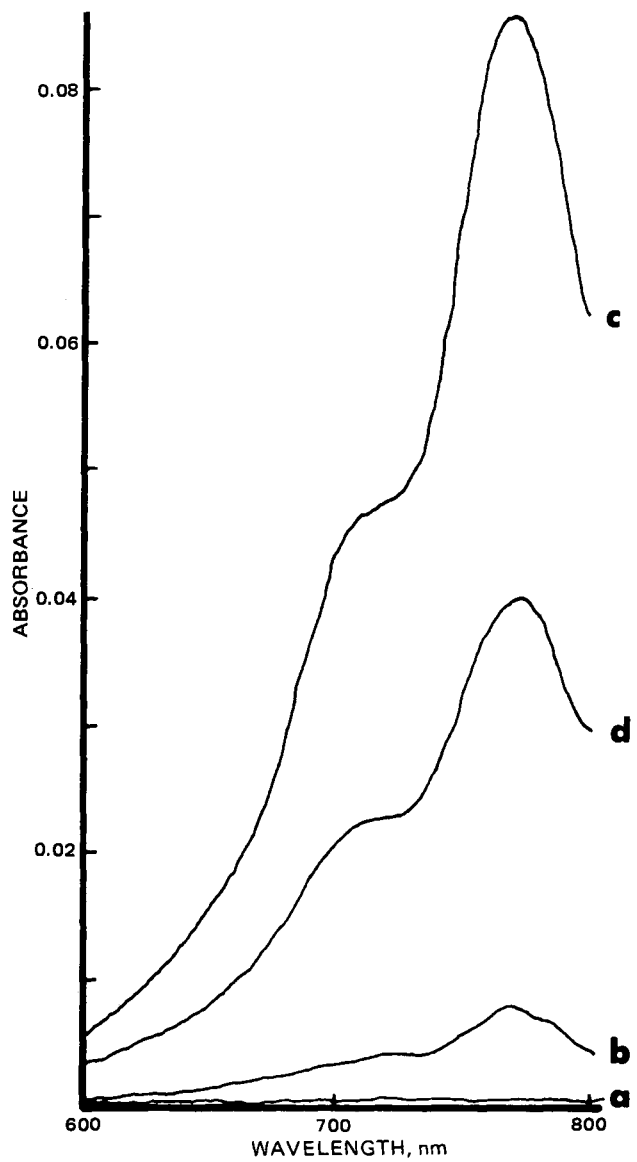

Figure 6—*Spectrophotometric scans of collected HPLC solvent front eluates from processed plasma samples harvested from a rabbit receiving 25.4 mg of indocyanine green/kg. Key: a, instrument baseline (blank solvent in both cells); b, plasma sample 26-min postdose (40 μl of supernate injected); c, plasma sample 120-min postdose (250 μl of supernate injected); and d, plasma sample 360-min postdose (250 μl of supernate injected).*

Only one literature report was found suggesting indocyanine green metabolism. Nambu (20), using ascending chromatography, found three bands in bile samples collected from a dog administered indocyanine green. The three bands exhibited absorbance at 770 nm in a pattern similar to that of the present studies.

The present study demonstrated that the described HPLC method is more specific for indocyanine green then the traditional spectrophotometric methods. This observation demands a reexamination of reports on indocyanine green's stability and *in vivo* pharmacokinetics. Furthermore, the nature of the degradation products/metabolites needs to be elucidated. These aspects are under investigation.

Analysis of Oral Suspensions Containing Sulfonamides in Combination with Erythromycin Ethylsuccinate

L. ELROD, Jr.[x], R. D. COX, and A. C. PLASZ

Received March 23, 1981, from the *Analytical Research Department, Abbott Laboratories, North Chicago, IL 60064.*
Accepted for publication May 28, 1981

Abstract □ The sulfonamides and erythromycin ethylsuccinate in combination oral suspensions were determined by high-performance liquid chromatography and automated turbidimetry, respectively. The chromatographic procedure was rapid, specific, and stability-indicating for sulfisoxazole acetyl and the trisulfapyrimidines using a reversed-phase system with UV detection at 254 nm. Erythromycin ethylsuccinate did not interfere with the sulfonamide analysis and these compounds were assayed with relative standard deviations (*RSD*) ranging from ±2.1 to ±3.1%. Erythromycin ethylsuccinate was determined as erythromycin with *RSD* values of ±1.3 or ±3.5% without interference by the sulfonamides present.

Keyphrases □ Sulfonamides—analysis of oral suspensions in combination with erythromycin ethylsuccinate, high-performance liquid chromatography □ Erythromycin ethylsuccinate—analysis of oral suspensions with sulfonamides, high-performance liquid chromatography □ High-performance liquid chromatography—analysis of oral suspensions containing sulfonamides in combination with erythromycin ethylsuccinate

Oral suspensions containing sulfonamides in combination with erythromycin ethylsuccinate have recently been developed for the treatment of acute otitis media. This paper presents the analysis of the sulfonamides and erythromycin ethylsuccinate present in two oral suspensions: erythromycin as erythromycin ethylsuccinate at 200 mg/5 ml and sulfisoxazole as sulfisoxazole acetyl at 600 mg/5 ml (I) and erythromycin as erythromycin ethylsuccinate at 200 mg/5 ml and trisulfapyrimidines: sulfadiazine, sulfamerazine, and sulfamethazine, each at 200 mg/5 ml (II).

Sulfonamide dosage forms are commonly assayed by nitrite titrations or colorimetric methods based on a previous (1) procedure. In mixtures containing more than one sulfonamide or in complex biological matrixes, paper and thin layer chromatography (TLC) have been used to quantitate the individual drugs (2–5). Often these chromatographic separations are followed by the Bratton and Marshall procedure (6–9). The current USP assay (10) of trisulfapyrimidine oral suspensions uses such a procedure and requires several hours to complete.

Use of gas-liquid chromatography (GLC) in the analysis of sulfonamides has been reported (11–14), but derivatization is generally required. High-performance liquid chromatography (HPLC) was used in this study to quantitate the individual sulfonamides. Separations of sulfonamides using ion exchange (15–17), reverse phase (18–24), normal phase (25–28), and ion pairing (29–30) are reported in the recent literature.

Numerous analytical techniques have been reported for the analysis of erythromycin and its various esters. Included are chemical methods based on ultraviolet–visible spectrophotometry (31–34) or fluorometry (35) in addition to GLC (36, 37), TLC (38–41), HPLC (42–45), and microbiological techniques (46–48). Since the microbiological assay is the official methodology required for the determination of erythromycin potency (49), an automated turbidimetric method was employed in this work.

EXPERIMENTAL

Reagents—Acetanilide[1], benzanilide[1], and potassium phosphate[2] (monobasic and dibasic) were obtained commercially and used without further purification. Sulfisoxazole acetyl[3,4], erythromycin base[3], erythromycin ethylsuccinate[5], sulfadiazine[3], sulfamerazine[3], and sulfamethazine[3] were of pharmaceutical quality and were used as received. Acetonitrile[6], chloroform[6], and methanol[6] were HPLC grade. Oral suspensions I[5] and II[5] were prepared from granules prepared in house.

Analysis of Oral Suspensions Containing Sulfonamides in Combination with Erythromycin Ethylsuccinate

L. ELROD, Jr.[x], R. D. COX, and A. C. PLASZ

Received March 23, 1981, from the *Analytical Research Department, Abbott Laboratories, North Chicago, IL 60064.*
Accepted for publication May 28, 1981

Abstract □ The sulfonamides and erythromycin ethylsuccinate in combination oral suspensions were determined by high-performance liquid chromatography and automated turbidimetry, respectively. The chromatographic procedure was rapid, specific, and stability-indicating for sulfisoxazole acetyl and the trisulfapyrimidines using a reversed-phase system with UV detection at 254 nm. Erythromycin ethylsuccinate did not interfere with the sulfonamide analysis and these compounds were assayed with relative standard deviations (*RSD*) ranging from ±2.1 to ±3.1%. Erythromycin ethylsuccinate was determined as erythromycin with *RSD* values of ±1.3 or ±3.5% without interference by the sulfonamides present.

Keyphrases □ Sulfonamides—analysis of oral suspensions in combination with erythromycin ethylsuccinate, high-performance liquid chromatography □ Erythromycin ethylsuccinate—analysis of oral suspensions with sulfonamides, high-performance liquid chromatography □ High-performance liquid chromatography—analysis of oral suspensions containing sulfonamides in combination with erythromycin ethylsuccinate

Oral suspensions containing sulfonamides in combination with erythromycin ethylsuccinate have recently been developed for the treatment of acute otitis media. This paper presents the analysis of the sulfonamides and erythromycin ethylsuccinate present in two oral suspensions: erythromycin as erythromycin ethylsuccinate at 200 mg/5 ml and sulfisoxazole as sulfisoxazole acetyl at 600 mg/5 ml (I) and erythromycin as erythromycin ethylsuccinate at 200 mg/5 ml and trisulfapyrimidines: sulfadiazine, sulfamerazine, and sulfamethazine, each at 200 mg/5 ml (II).

Sulfonamide dosage forms are commonly assayed by nitrite titrations or colorimetric methods based on a previous (1) procedure. In mixtures containing more than one sulfonamide or in complex biological matrixes, paper and thin layer chromatography (TLC) have been used to quantitate the individual drugs (2–5). Often these chromatographic separations are followed by the Bratton and Marshall procedure (6–9). The current USP assay (10) of trisulfapyrimidine oral suspensions uses such a procedure and requires several hours to complete.

Use of gas-liquid chromatography (GLC) in the analysis of sulfonamides has been reported (11–14), but derivatization is generally required. High-performance liquid chromatography (HPLC) was used in this study to quantitate the individual sulfonamides. Separations of sulfonamides using ion exchange (15–17), reverse phase (18–24), normal phase (25–28), and ion pairing (29–30) are reported in the recent literature.

Numerous analytical techniques have been reported for the analysis of erythromycin and its various esters. Included are chemical methods based on ultraviolet–visible spectrophotometry (31–34) or fluorometry (35) in addition to GLC (36, 37), TLC (38–41), HPLC (42–45), and microbiological techniques (46–48). Since the microbiological assay is the official methodology required for the determination of erythromycin potency (49), an automated turbidimetric method was employed in this work.

EXPERIMENTAL

Reagents—Acetanilide[1], benzanilide[1], and potassium phosphate[2] (monobasic and dibasic) were obtained commercially and used without further purification. Sulfisoxazole acetyl[3,4], erythromycin base[3], erythromycin ethylsuccinate[5], sulfadiazine[3], sulfamerazine[3], and sulfamethazine[3] were of pharmaceutical quality and were used as received. Acetonitrile[6], chloroform[6], and methanol[6] were HPLC grade. Oral suspensions I[5] and II[5] were prepared from granules prepared in house.

Equipment—The chromatographic system consisted of a constant flow pump[7], a septumless injector[8], a UV detector[9] operated at 254 nm, a computing integrator[10] and a strip-chart recorder[11]. The analytical column (4-mm i.d. × 300 mm) was prepacked with fully porous 10-μm silica particles to which octadecylsilane was chemically bonded[12]. Turbidimetric measurements were made with a turbidimeter[13] system containing a dilutor module and a reader module operated at 600 nm.

Sulfonamide Analysis by HPLC—*Mobile Phase*—The mobile phase for I and II consisted of water/acetonitrile (60:40) and water/acetonitrile (80:20), respectively. In preparing the mobile phases, appropriate volumes of acetonitrile were diluted to 1 liter with distilled water. The solutions were filtered through 0.45-μm polycarbonate membranes[14] and degassed under vacuum.

Chromatographic Conditions—The flow rate for I was 1.5 ml/min with a column pressure of ~1800 psi and the detector was operated at 0.32 aufs. The flow rate for II was 1.0 ml/min with a column pressure of ~700 psi and the detector operated at 0.10 aufs. The analytical column was at ambient temperature for all separations.

Internal Standard Solution—A 0.33 mg/ml solution of benzanilide in acetonitrile was prepared as the internal standard for I. A 0.20 mg/ml solution of acetanilide in acetonitrile was prepared as the internal standard for II.

Standard Solution—Approximately 50 mg of sulfisoxazole acetyl was accurately weighed into a 50-ml volumetric flask for I. The drug was dissolved and diluted to volume with the internal standard solution giving a concentration of 1.0 mg/ml. For II, ~20 mg each of sulfadiazine, sulfamerazine, and sulfamethazine were accurately weighed into a 100-ml volumetric flask. The mixture was dissolved and diluted to volume with the internal standard solution giving concentrations of 0.20 mg/ml for each drug.

Sample Preparation—A 1-ml aliquot of I was withdrawn with a disposable syringe and extracted with three 15-ml portions of chloroform. The bottom layers were combined and diluted to 50 ml with chloroform. A portion of the chloroform solution was filtered through a 0.45-μm silver membrane[15] and a 2-ml aliquot of the filtrate was evaporated to dryness under dry nitrogen. The residue was dissolved in 5 ml of the internal standard solution giving a drug concentration of ~0.96 mg/ml.

For II, a 1-ml aliquot of the suspension was withdrawn with a disposable syringe and transferred to a 200-ml volumetric flask containing ~100 ml of methanol/water (60:40). The suspension was mixed for 15 min on a mechanical shaker and diluted to volume with methanol/water (60:40). A portion of the solution was filtered through a 0.45-μm silver membrane[15] and a 1-ml aliquot of the filtrate was evaporated to dryness under nitrogen. The residue was dissolved in 1 ml of the internal standard solution giving concentrations for each drug of ~0.20 mg/ml.

Analysis and Calculation—For I and II, respectively, 5- and 4-μl injections of both the standard and sample preparations were made. Peak area ratios for duplicate injections were calculated and averaged as follows:

$$ST \text{ or } SL = \frac{PA_1}{PA_2} \qquad \text{(Eq. 1)}$$

where ST is the standard peak area ratio, SL is the sample peak area ratio, PA_1 is the peak area of the sulfonamide, and PA_2 is the peak area of the internal standard.

The concentrations of the sulfonamides in 5 ml of suspension were calculated by:

$$\text{sulfonamide content per 5 ml} = \frac{SL}{ST} \times \text{conc} \times 5 \text{ ml} \times DF \qquad \text{(Eq. 2)}$$

where conc is the concentration of sulfonamide standard (mg/ml) and DF is the appropriate dilution factor.

Erythromycin Ethylsuccinate Analysis with Turbidimetric Finish—*Dilution Buffer*—A 20% phosphate buffer was prepared by dissolving 192.6 g of dibasic potassium phosphate and 7.4 g of monobasic potassium phosphate in 1 liter of distilled water. The solution was further diluted 100 ml to 2 liter with distilled water (solution pH 8.0 ± 0.1).

Sample Preparation—A 5-ml aliquot of I or II was transferred to a

Assay Procedure and Calculation—Erythromycin determinations were performed turbidimetrically as described for a variety of antibiotics (49).

RESULTS AND DISCUSSION

Sulfonamide Analysis—In the sulfonamide analyses for I and II, high-performance liquid chromatography (HPLC) offered the desired accuracy, sensitivity, and specificity. By operating the UV detector at 254 nm, erythromycin ethylsuccinate carried through with the sample work-up does not interfere in the sulfonamide assay.

In Figs. 1 and 2, respectively, synthetic solutions of sulfisoxazole acetyl (1.0 mg/ml) and trisulfapyrimidines (0.20 mg/ml) are spiked with several possible degradation products and chromatographed. As shown in the figures, the degradation products are well resolved from the drug and internal standard peaks, making the HPLC analyses stability indicating. Figures 3 and 4, respectively, show authentic samples of I and II carried through the HPLC assay procedure. Total elution time for both I and II was ~11 min under the chromatographic conditions chosen.

Linearity of response for the sulfonamides contained in I and II was demonstrated by plotting the peak area ratio of the drugs to the internal standards *versus* drug concentrations (mg/ml). For sulfisoxazole acetyl, detector response was linear to at least 1.5 mg/ml. For the trisulfapyrimidines, detector response was linear to at least 0.30 mg/ml for each compound. The linearity curve for each sulfonamide assayed essentially intersected the origin and the correlation coefficient was >0.999 for each curve.

Precision data for the sulfonamide assay in I and II are presented in Tables I and II, respectively. Analyses for I were performed over a 5-day

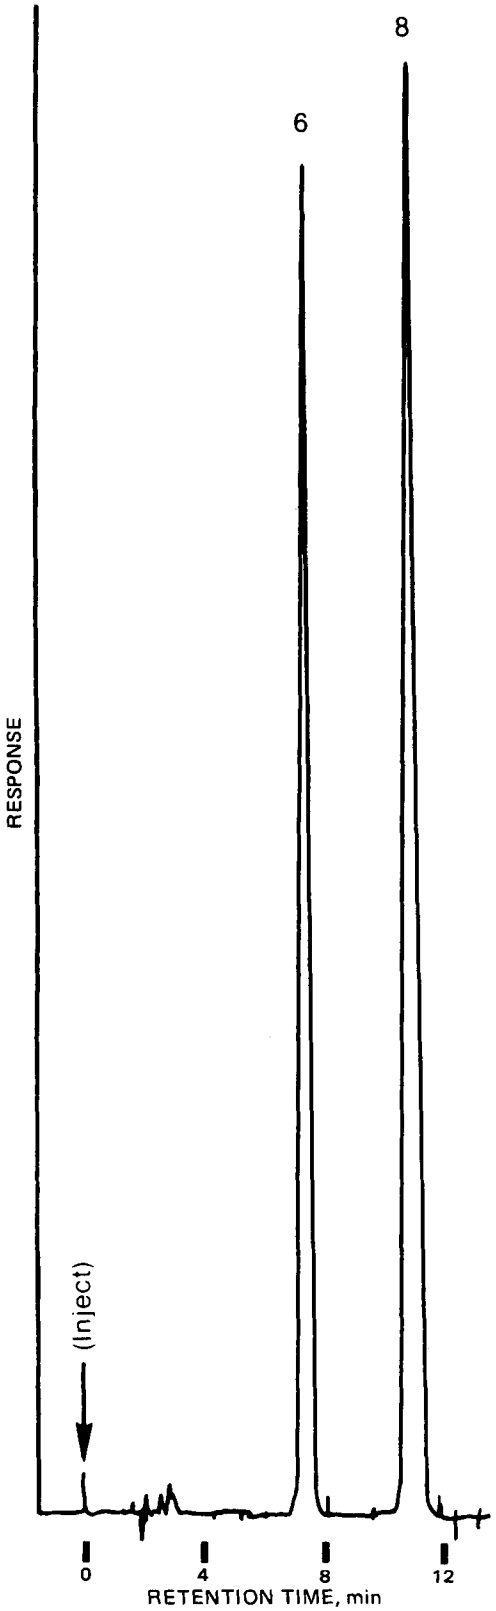

Figure 3—*Chromatogram of an authentic assay preparation of I. Key: 6, sulfisoxazole acetyl; 8, benzanilide (internal standard).*

period by two different analysts, preparing fresh suspensions each day. As shown in Table I, the average assay was 108.1% of the label claim amount, and the relative standard deviation of the procedure was ±2.1%. For II, analyses were performed by two different analysts over a 2-day period, and results were calculated as percent theory on a weight basis. Each sample shown in Table II represents a freshly prepared suspension and as shown, the relative standard deviations ranged from ±2.1 to ±3.1%.

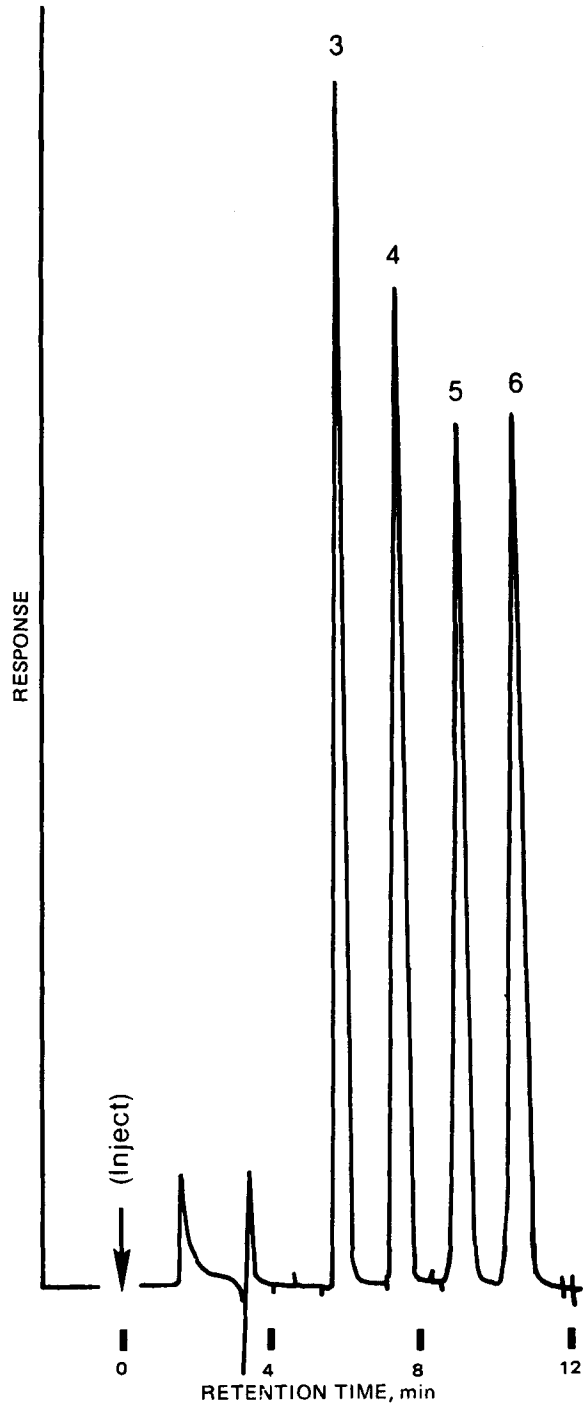

Figure 4—*Chromatogram of an authentic assay preparation of II. Key: 3, sulfadiazine; 4, sulfamethazine; 5, sulfamerazine; 6, acetanilide (internal standard).*

To determine if sulfisoxazole acetyl was recovered quantitatively in the sample preparation of I, portions of the drug were added at 75–125% of the formulation level to a suspension placebo. The resulting mixtures were extracted and assayed as described. The erythromycin ethylsuccinate and excipients were maintained at the same level as for I. The standard addition–recovery results are summarized in Table III and as shown, an average recovery of 100.2% was obtained.

A correlation of the sulfisoxazole acetyl analysis by HPLC and sodium nitrite titration (USP methodology) was made for I to determine if the presence of erythromycin ethylsuccinate or excipients interfered in the titration procedure. Suspensions containing placebo, placebo plus sulfisoxazole acetyl, and placebo plus acetyl sulfisoxazole and erythromycin ethylsuccinate were titrated and simultaneously analyzed for sulfisoxazole acetyl by HPLC. The suspensions were prepared by accurately weighing quantities of each drug substance that would be present in I,

Table IV—Percent Sulfisoxazole Acetyl Recovered by Sodium Nitrite Titration and HPLC in I

and these suspensions were sampled by weighing an appropriate volume accurately. From the analysis, the weight of suspension sampled and the weight of total suspension prepared, the percent recovery of sulfisoxazole acetyl was calculated. In addition, two commercial sulfisoxazole acetyl suspensions were titrated and simultaneously assayed by HPLC.

In Table IV the results of the sodium nitrite titrations and the HPLC analysis are summarized. For those suspensions containing sulfisoxazole acetyl but no erythromycin ethylsuccinate, the HPLC results and titrations agreed with experimental error. However, for those suspensions containing erythromycin ethylsuccinate, the titration results were invariably higher than the HPLC results. The extent of this high bias ranged from 5.4–7.0% in the sodium nitrite titrations. Placebo alone titrated identically to a solvent blank and no response was observed from the placebo preparations by HPLC. A placebo suspension containing erythromycin ethylsuccinate gave a higher sodium nitrite titer than the placebo alone. A possible explanation for the higher titer in this preparation is the reversible reaction of nitrous acid with the tertiary aliphatic amine group of erythromycin ethylsuccinate (50).

Erythromycin Ethylsuccinate Analysis—Automated turbidimetric analysis for a variety of antibiotics are in wide use. To determine the precision of this technique for I and II, freshly prepared suspensions of each were assayed over 5 days. The precision data are summarized in Table V as percent label claim in terms of erythromycin activity/5 ml of suspension. For I the percent label claim averaged 98.5% with a relative standard deviation of ±1.3%. For II the percent label claim averaged 101.5% with a relative standard deviation of ±3.5%.

To determine if erythromycin ethylsuccinate was recovered quantitatively in the sample preparation of I, accurately weighed quantities of the drug were added to a placebo suspension. Sulfisoxazole acetyl and excipients were at the same levels as in the actual product. The usual sample work-up and analysis was performed using quadruplicate dilutions of the methanol solution. In Table VI, the standard addition–recovery data collected over 5 days by two analysts are presented. As shown, a mean recovery of 97.7% was obtained.

Gas Chromatographic Analysis of Meperidine and Normeperidine: Determination in Blood after a Single Dose of Meperidine

PEYTON JACOB III ‡x, JEAN F. RIGOD ‡, SUSAN M. POND *‡, and NEAL L. BENOWITZ *‡

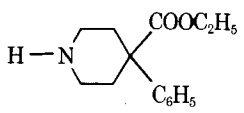
Received February 13, 1981, from the *Division of Clinical Pharmacology, Department of Medicine, School of Medicine, University of California, San Francisco, CA 94143 and the ‡Division of Clinical Pharmacology, San Francisco General Hospital, San Francisco, CA 94110. Accepted for publication June 25, 1981.

Abstract □ A method is described for the determination of meperidine and its pharmacologically active metabolite, normeperidine, in blood, plasma, and urine using gas chromatography with nitrogen–phosphorus detection. Structural analogs of both meperidine and normeperidine were used as internal standards. Unlike previously reported assays, this procedure was sensitive and convenient enough for use in pharmacokinetic studies of both meperidine and normeperidine following single doses of meperidine. The assay was sensitive to 5 ng of meperidine/ml and 2.5 ng of normeperidine/ml extracted from a 1-ml biological sample. The between-assay coefficients of variation at these concentrations were 9.4 and 10.4%, respectively.

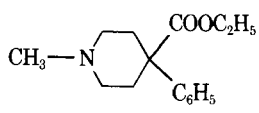
Keyphrases □ Meperidine—gas chromatographic analysis in blood □ Normeperidine—gas chromatographic analysis in blood after single dose of meperidine □ Gas chromatography—analysis of meperidine and normeperidine in blood □ Analgesics—meperidine, gas chromatographic analysis in blood

Normeperidine (I), the *N*-demethylated metabolite of the analgesic drug meperidine (II), is pharmacologically active (1) and may cause seizures in humans (2). Therefore, blood levels of I should be determined when delineating the side effects and drug interactions that occur with II. To carry out such studies after single doses of II, a sensitive and specific gas chromatographic (GC) assay for I and II in biological fluids was developed. The assay allows measurement of II up to 24 hr and I up to 48 hr after a single dose of II.

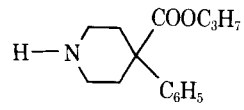
Previously published methods with adequate sensitivity for the measurement of I in plasma after a single dose have involved GC–mass spectrometry with selected ion monitoring (3, 4), radioimmunoassay (5), or GC using electron-capture detection (6). GC methods with flame-ionization detection (7–10) may be satisfactory for determining therapeutic concentrations of II, but have marginal sensitivity for the determination of plasma I concentrations (7–9) following single doses of the parent drug.



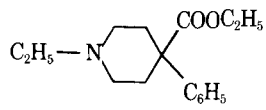
I



II



III



IV

This report describes the GC determination of I and II using a nitrogen–phosphorus detector, which is highly selective toward nitrogen-containing compounds such as II and its derivatives. The assay is significantly faster and more convenient than previously reported GC methods, and is applicable to whole blood, plasma, or urine.

EXPERIMENTAL

Materials—Meperidine hydrochloride and normeperidine hydrochloride were obtained[1]. Heptafluorobutyric anhydride and sodium cyanoborohydride were obtained commercially[2]. Normeperidinic acid *n*-propyl ester (III) was synthesized by a previous method (6). *N*-ethylnormeperidine (IV) was synthesized as will be described. All other chemicals and solvents were analytical reagent grade.

Synthesis of *N*-Ethylnormeperidine Hydrochloride—Sodium cyanoborohydride (100 mg) was added to a solution of normeperidine hydrochloride (250 mg) and acetaldehyde (0.5 ml) in 50 ml of 50% aqueous

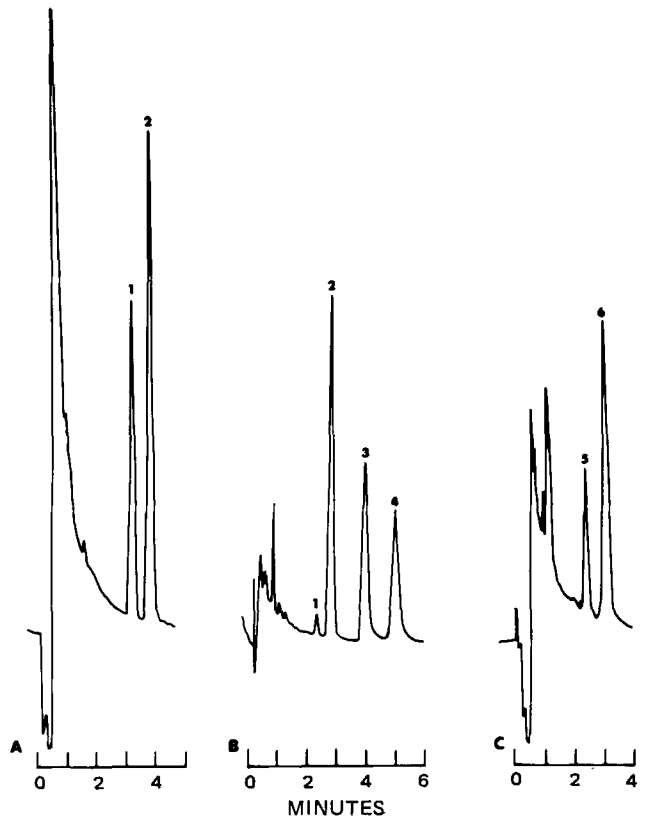

Figure 1—*Chromatograms of extracts containing normeperidine (I) and meperidine (II). Key: A, plasma containing 28 ng of II/ml; B, urine sample containing 108 and 1300 ng/ml of II and I, respectively; and C, plasma containing 10 ng of I/ml. GC conditions are described in the text; and 1 = II; 2 = IV; 3 = I; 4 = III; 5 = heptafluorobutyryl derivative of I; and 6 = heptafluorobutyryl derivative of III.*

ethanol. The solution was stirred and the pH was maintained at 6–7 by the dropwise addition of aqueous sodium acetate. After 2 hr, the pH was adjusted to 2 by the addition of concentrated hydrochloric acid. This procedure was done in a fume hood because hydrogen cyanide is evolved.

The solution was extracted twice with 20-ml portions of methylene chloride. The extracts were discarded and the aqueous phase was brought to pH 12 with aqueous sodium hydroxide. The basic aqueous phase was extracted twice with 20-ml portions of methylene chloride, and the combined extracts were dried over anhydrous potassium carbonate and then evaporated under reduced pressure. The oily residue was dissolved in 3 ml of absolute ethanol, acidified to pH 2 with concentrated hydrochloric acid, and then diluted with 25 ml of anhydrous ether, added in portions with stirring and scratching with a glass rod. The product slowly crystallized and was collected by filtration and air dried. A white crystalline powder (57 mg) was obtained, mp 170.5–172° [lit. (11) mp 171°]. GC analysis indicated a purity of >99.5%.

Instrumentation—GC analyses were performed using an instrument[3] equipped with dual nitrogen–phosphorus detectors. The nitrogen (carrier gas), air, and hydrogen flow rates were 30, 50, and 5 ml/min, respectively. Columns used for II analyses or for simultaneous II and underivatized I analyses (urine) were 1.8 m × 2-mm i.d. glass. The columns were configured for on-column injection, packed with 2% polyethylene glycol and 2% potassium hydroxide on 100–120 mesh chromatographic diatomaceous earth[4], and operated at 190° for determination of II in blood and 205° for simultaneous determination of I and II in urine. Columns used for derivatized I analyses were 1.8 × 2-mm i.d. glass, packed with 3% methyl silicone liquid phase on 100–120 mesh base-deactivated chromatographic diatomaceous earth[5] operated at 205°.

The injection port and detector temperatures were 250 and 300°, respectively. A strip-chart recorder[6] was used for recording chromatograms.

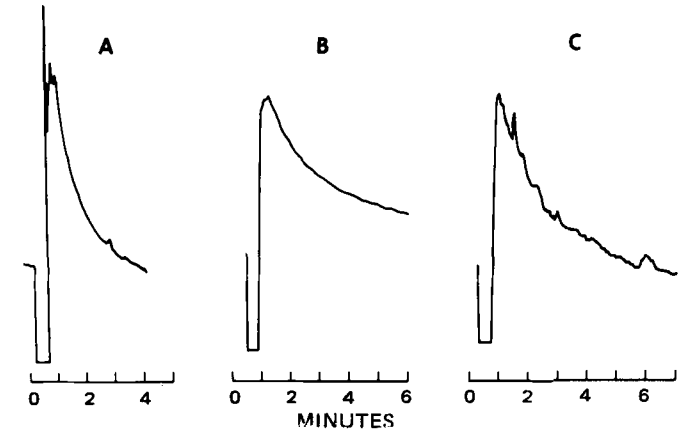

Figure 2—*Chromatograms of extracts of drug-free plasma and urine specimens. Key: A, plasma extracted for II; B, urine extracted for both I and II; and C, plasma extracted for I and derivatized with heptafluorobutyric anhydride.*

All extractions were carried out by agitating for 3 min on a multiple-tube vortex mixer[7]; an analytical evaporator[8] was used for evaporating solvent from extracts with a nitrogen stream.

Assay Procedure—A flow diagram of the extraction procedure is shown in Scheme I. To 1-ml samples of whole blood, plasma, or urine contained in 13-mm × 100-mm culture tubes were added 100-μl aliquots of an aqueous solution of the internal standards, III (for normeperidine) and IV (for meperidine). Methanolic 2 *N* potassium hydroxide (0.5 ml) was added, and the samples were extracted with 3 ml of toluene.

After centrifuging for 5 min, the aqueous layers were frozen by placing the tubes in a dry ice–acetone bath, and the toluene layers were poured into culture tubes containing 0.5 ml of 0.2 *N* sulfuric acid. The tubes were vortexed for 3 min and then centrifuged. The aqueous layers were frozen, the toluene layers discarded, and the aqueous acid layers were allowed to thaw. Aqueous 2 *N* potassium hydroxide (1 ml) was added, and the samples were extracted with 2 ml of toluene and then centrifuged.

At this stage, if the concentrations of I and II were expected to be high

Coefficient of variation, %	9.4	8.2	6.4	6.1	6.0	4.7	10.4	8.4	5.2	4.0	3.9	1.9

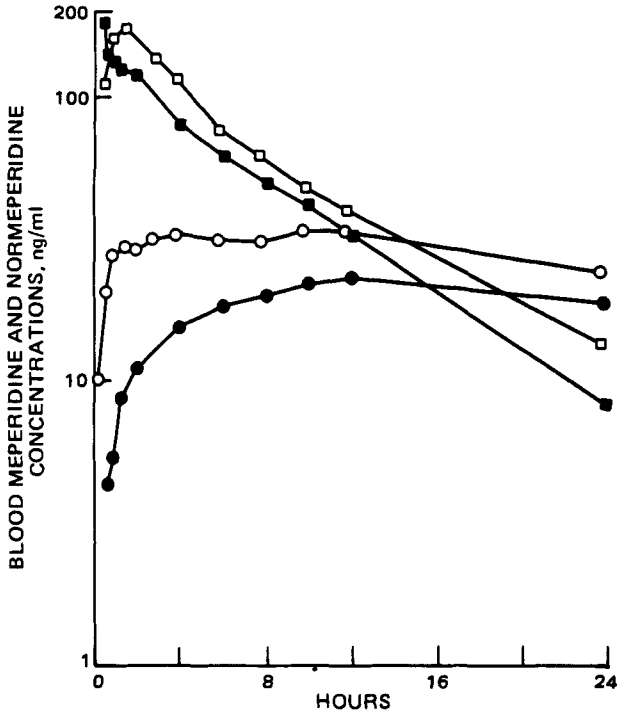

Figure 3—*Blood II (■) and I (●) concentrations following administration of 50 mg iv of II; blood II (□) and I (○) concentrations following administration of 100 mg po of II in a human subject.*

(*e.g.*, as in urine), the toluene extracts were analyzed by GC for both I and II. The retention times were 2.30, 2.75, 4.00, and 4.95 min for II, IV, I, and III, respectively. The extraction recoveries of I and II from urine averaged 70 and 73%, respectively, over the concentration range of 1–20 μg/ml.

The toluene extracts from blood or plasma were back-extracted with 0.5 ml of 0.2 *N* sulfuric acid. The sulfuric acid layers were made basic with 1 ml of 2 *N* aqueous potassium hydroxide and extracted with 0.5 ml of toluene. The toluene layers were transferred to vials containing anhydrous potassium carbonate (~40 mg) to dry the solvent. Aliquots (2–4 μl) of the toluene extracts were injected into the chromatograph for analysis of II. Examples of chromatograms from plasma extracts are presented in Fig. 1. The retention times of II and the internal standard (IV) were 3.30 and 3.85 min, respectively. Extraction recovery from blood over 5–200 ng/ml averaged 67%.

Heptafluorobutyric anhydride (10 μl) was added to the remaining toluene extracts. The tubes were capped and heated at 60° for 15 min on a heating block to derivatize I and its internal standard. After cooling to room temperature, 2 ml of 2 *N* sodium hydroxide was added and the tubes were vortexed for 5 min to destroy excess heptafluorobutyric anhydride. Following centrifugation, the toluene layers were transferred to clean tubes containing 1 ml of 0.2 *N* sulfuric acid.

After extraction for 1 min and centrifugation, the toluene layers were transferred to small vials and evaporated to dryness under a nitrogen stream. Butyl acetate (50 μl) was added to reconstitute the samples, and 2–6 μl was injected into the chromatograph for analysis of I (Fig. 1).

The retention times for the heptafluorobutyryl derivatives of I and III were 2.48 and 3.05 min, respectively. Extraction recoveries from blood averaged 66% over 2.5–100 ng/ml. Chromatograms of blank plasma and urine extracts (Fig. 2) were free from interfering peaks under the extraction conditions employed. The detection limit for each substance was ~1 ng/ml for 1-ml plasma samples.

Standard Curves—Standards were prepared by spiking drug-free blood, plasma, or urine samples with known amounts of drug and internal standard. Standards with at least four different concentrations over the expected range were run with each batch of samples and used to construct standard curves. The amounts of IV added were 2.5 μg for urine and 50 ng for blood or plasma; the amounts of III were 1 μg for urine and 25 ng for blood or plasma. Regression equations relating peak height ratios of standards to their concentrations were used to determine concentrations of I and II. The regression lines were linear over all concentrations studied (0–200 ng/ml for blood, and 0–20 μg/ml for urine) and passed through the origin.

Analytical Variables—Between-run precision was determined by analyzing identical plasma standards with six consecutive runs. Coefficients of variation for six concentrations representative of the therapeutic ranges found in plasma are presented in Table I.

Pharmacokinetic Study in a Human Subject—A healthy male volunteer, age 38 and weight 72 kg, was given 50 mg iv of meperidine hydrochloride over 1 min. One week later, the same subject was given 100 mg po of meperidine hydrochloride in solution. Twelve blood samples were collected over the 24 hr following drug administration and plasma separated for analysis of I and II (Fig. 3).

RESULTS AND DISCUSSION

Losses of basic drugs due to adsorption on glassware and/or GC columns may be variable and reduce the precision of an assay if the internal standard is not chemically similar to the drug being measured. Therefore, an internal standard that is a structural analog of II was used. Sharp peaks and baseline separation of II and IV (the internal standard) were obtained on both polyethylene glycol–potassium hydroxide (Fig. 1) and base-deactivated methyl silicone columns. Good reproducibility was obtained even at concentrations as low as 5 ng/ml (Table I). Consequently, this assay can be used to measure plasma II concentrations for as long as 24 hr after a single dose.

The described procedure is suitable for the analysis of large numbers of samples and its sensitivity should greatly facilitate studies of the kinetic behavior of normeperidine in meperidine drug interactions and in patients with disease states in which normeperidine kinetics may be altered (2).

Thiamine Whole Blood and Urinary Pharmacokinetics in Rats: Urethan-Induced Dose-Dependent Pharmacokinetics

J. D. PIPKIN* and V. J. STELLA*

Received February 23, 1981, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication May 20, 1981. * Present address: Squibb Institute for Medical Research, New Brunswick, NJ 08903.

Abstract □ The whole blood pharmacokinetics of thiamine after intravenous administration of thiamine hydrochloride (4, 12, and 36 mg/kg) to rats anesthetized continuously with ether (inhalation) or urethan (1 g/kg ip) were studied. Urinary excretion of thiamine after intravenous administration of thiamine hydrochloride to rats lightly anesthetized with ether was also investigated. At any particular dose, thiamine displayed apparent classical two-compartment model behavior in the time range studied. Under urethan anesthesia, thiamine displayed apparent dose-dependent kinetics as measured by the changes in the pharmacokinetic parameters, AUC, $V_{d(area)}$, $t_{0.5\beta}$, and total body clearance, Cl_{TB}, with dose. However, when ether anesthesia was used, thiamine displayed dose-independent pharmacokinetic behavior. These results suggest that care should be taken in the interpretation of pharmacokinetic data obtained in anesthetized animals, particularly when urethan anesthesia is used.

Keyphrases □ Thiamine—whole blood and urinary pharmacokinetics after urethan and ether administration, rats □ Urethan—effect on whole blood and urinary pharmacokinetics of thiamine □ Anesthetic agents—urethan and ether, effect on whole blood and urinary pharmacokinetics of thiamine, rats □ Pharmacokinetics—of thiamine, effect of urethan and ether administration to rats

Obtaining reliable and accurate blood concentration *versus* time data is crucial in determining a drug's true disposition in any animal species. To minimize pain and discomfort to laboratory animals and provide convenience to the researcher, experiments are often carried out under anesthesia. Reported are some observations on the apparent effects of urethan anesthesia on the pharmacokinetics of thiamine in rats.

Urethan is used as an anesthetic agent for laboratory and agricultural animals. Administered intraperitoneally, it produces a long-lasting narcosis and therefore is used primarily for prolonged, terminal experiments. As opposed to barbituates, urethan has a wide margin of safety and gives a more stable, longer anesthesia (1). Thiamine pharmacokinetics at a dose of 4 mg/kg iv in rats under urethan anesthesia were reported previously (2–4). The present study examined the dose-independent kinetics in unchanged thiamine urinary excretion and the pharmacokinetics of thiamine in whole blood in lightly ether-anesthetized rats. The apparent dose dependency of thiamine pharmacokinetics under urethan anesthesia was also studied.

EXPERIMENTAL

Materials and Methods—Male Sprague-Dawley rats[1], 230–400 g, were used. Prior to intravenous thiamine hydrochloride[2] administration *via* the dorsal penis vein (5) at three dose levels (4, 12, and 36 mg/kg), the rats received either urethan or ether as the anesthetic agent. Urethan[2] was administered intraperitoneally as a 500-mg/ml solution at a dose of 1.0 g/kg; however, some rats required additional urethan, the total not exceeding 2.0 g/kg, to induce continuous anesthesia during the experiment. Ether[3] was administered by inhalation using two different methods. The first method, called light ether anesthesia, involved initially anesthetizing the animal sufficiently to permit the injection and removing the animal to a restraining cage for the remainder of the blood sampling phase. Ether was not administered at any other point in this experiment. The second method used, the "open technique" (6), involved continuous ether; *i.e.*, after initially being anesthetized, the animal was kept unconscious by a constant supply of ether vapors. Forced air was conducted over liquid ether to an open funnel maintained over the nose and mouth of the rat for the remainder of the experiment. Since hypothermia may accompany general anesthesia, each rat's body temperature was monitored by a rectal thermistor probe and the animal was maintained at 37 ± 1° by means of a thermostatically-controlled, heated surgical table. After dosing with thiamine hydrochloride, a total of 10 100-μl blood samples were collected from the tail vein. Free thiamine (nonphosphorylated) in whole blood was determined as previously described (3).

In rats where urinary thiamine was determined, light ether anesthesia was used. Subsequently, the rats were placed in metabolism cages. Urine was collected from the rats at set time intervals after dosing and the free thiamine in urine was determined by standard methods (7–10). The turnover of endogenous thiamine in urine, *i.e.*, urinary excretion of thiamine under conditions of normal dietary intake, was determined in rats over the 24-hr interval prior to intravenous administration of exogenous thiamine hydrochloride. In other words, the rats were placed in individual metabolism cages 24 hr prior to exogenous thiamine administration and urine collected during this period was assayed for thiamine. The amount of thiamine excreted in this 24-hr period for each animal was assumed to be the turnover of endogenous thiamine.

Calculations—The time course of thiamine in blood displayed apparent two-compartment model behavior (Figs. 1–3). Individual rat blood concentration–time profiles were fit to Eq. 1 using two programs, a simplex optimization of the parameters[4] (11, 12), and the NONLIN program (13).

$$C_B = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where C_B is the blood levels in μg/ml and A, B, α, and β are standard symbols used to describe classical two-compartment behavior.

The significance of differences between mean pharmacokinetic parameters for each dose was evaluated by a one-tailed t-test, single clas-

[a] Biexponential parameters determined by fitting blood concentration *versus* time data to Eq. 1 using simplex and NONLIN programs. [b] Mean ± *SE* from five animals. [c] Mean ± *SE* from 11 animals. [d] Not significantly different at $p = 0.05$.

sification Model I ANOVA, and the Student–Newman–Keuls multiple comparison test (14). The exact test applied will be discussed. The parameters calculated (Eqs. 2–5) and compared were area under the curve (AUC), volume of distribution [$V_{d(area)}$], half-life of elimination from blood ($t_{0.5\beta}$), and total body clearance (Cl_{TB}), which were calculated from individual rat blood concentration-time profiles derived by fitting Eq. 1 to the data and employing Eqs. 2–5 (15):

$$AUC_{0\to\infty} = A/\alpha + B/\beta \quad \text{(Eq. 2)}$$

$$V_{d(area)} = \frac{\text{dose}}{\beta(AUC_{0\to\infty})} \quad \text{(Eq. 3)}$$

$$t_{0.5\beta} = 0.693/\beta \quad \text{(Eq. 4)}$$

$$Cl_{TB} = \text{dose}/AUC_{0\to\infty} \quad \text{(Eq. 5)}$$

where $AUC_{0\to\infty}$ is the area under the curve, zero time to infinity.

For urine studies, the doses of thiamine on a milligram per kilogram basis were converted to absolute amounts by using the rat weight. The fraction of the exogenous thiamine dose excreted in the urine was determined by plotting the total amount of thiamine excreted in the 24-hr postdosing minus the amount of thiamine excreted from normal thiamine turnover, determined from the 24-hr predosing, *versus* the dose administered. A linear plot suggests apparent dose-independent elimination kinetics with the slope indicative of the fraction of dose excreted in the urine. Similarly, the fraction of dose excreted in the urine in any time interval may be determined. The terminal half-life for thiamine elimination was determined from a plot of the logarithm of the amount of unchanged drug remaining to be excreted *versus* time. Renal clearance was estimated by dividing the urinary excretion rate by the whole blood concentration at the midpoint of the urine collection period.

RESULTS

Figures 1, 2, and 3 compare the mean blood thiamine concentrations after urethan and light ether anesthesia where thiamine hydrochloride was administered intravenously at 4, 12, and 36 mg/kg, respectively. The curves drawn in Figs. 1–3 were generated by Eq. 1 using the mean pharmacokinetic parameters (Tables I–III) obtained by averaging the parameters determined by computer fitting individual animal blood thiamine concentration *versus* time data.

Tables I–III compare the effects of various anesthetic agents on the pharmacokinetic behavior of thiamine. In addition to the use of light ether anesthesia as a control, continuous ether administration sustaining the rats' unconsciousness throughout the entire sampling period (as was the case with the urethan anesthesia) was used for further comparison at the 36-mg/kg dose. Included in Tables I–III are the parameters A, α, B, β, and the calculated model-dependent parameters, $V_{d(area)}$ and $t_{0.5\beta}$, as well as the model-independent parameters, $AUC_{0\to\infty}$ and Cl_{TB}.

Analyses by an unpaired Student t test of these pharmacokinetic parameters indicated no significant differences between the mean parameters for light ether and urethan anesthesia after intravenous treatment with 4 mg of thiamine hydrochloride/kg. At a dose of 12 mg of thiamine hydrochloride/kg, analyses of pharmacokinetic parameters for light ether and urethan anesthesia by a Student t test indicated highly significant differences between mean $AUC_{0\to\infty}$ ($p < 0.005$), $t_{0.5\beta}$ ($p < 0.1$), and Cl_{TB} ($p < 0.005$), but no significant difference between the mean volumes of distribution.

At a dose of 36 mg of thiamine hydrochloride/kg, the pharmacokinetic parameters for urethan anesthesia were compared with both modes of ether anesthesia, light ether (ether administered only initially), and ether administered continuously. Analyses of variance indicated highly significant differences between mean $AUC_{0\to\infty}$ ($p \ll 0.001$), $t_{0.5\beta}$ ($p \ll 0.001$), and Cl_{TB} ($p \ll 0.001$). No significant difference between the mean volumes of distribution for urethan *versus* light ether anesthesia was seen. When continuous ether-treated animals were compared to those treated with light ether, a significant increase in volume of distribution and Cl_{TB} was noted, but the half-lives were unaffected by the different mode of ether administration.

As shown, urethan markedly affected all of the thiamine pharmaco-

kinetic parameters (with the exception of the volume of distribution) after intravenous administration of thiamine hydrochloride at 12 and 36 mg/kg. Dose-independent pharmacokinetic parameter changes were observed under light ether anesthesia as demonstrated by comparing the $AUC_{0\to\infty}$/dose. The Student–Newman–Keuls multiple comparison test (15) applied to the mean $AUC_{0\to\infty}$/dose parameter for each anesthetic agent used and at each dose of thiamine hydrochloride, indicated no significant difference among means from light ether-anesthetized animals. This was consistent with results from the urinary excretion studies. The pattern for excretion of thiamine by the renal route is shown in Fig. 4. After taking into account the turnover of endogenous thiamine, ~75% of the exogenous thiamine dose administered was excreted unchanged in the first 2 hr and the amount of thiamine excreted unchanged in 48 hr accounted for 96% of the administered dose as shown in Fig. 5. The urinary excretion rate of thiamine in light ether-anesthetized rats closely parallels the time course of whole blood concentrations, with approximately the same terminal half-life for all the doses studied. In addition, the renal clearance closely correlated with Cl_{TB} for rats anesthetized with ether, since the primary elimination route at these doses is the renal route.

As opposed to the results for thiamine pharmacokinetics after ether anesthesia, the Student–Newman–Keuls test indicated significant differences between mean $AUC_{0\to\infty}$/dose values for urethan and ether-anesthetized animals, and also suggested that differences between the mean $AUC_{0\to\infty}$/dose values at each dose of thiamine hydrochloride for urethan-anesthetized animals were significant.

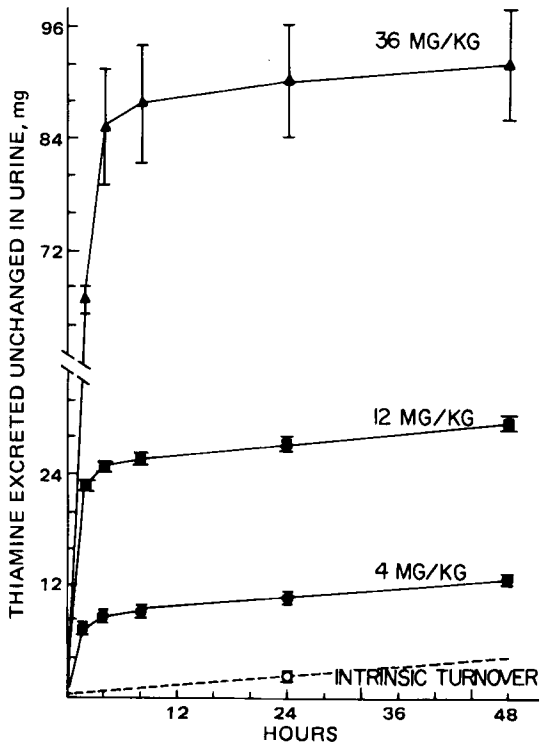

Figure 4—*Cumulative urinary excretion patterns of thiamine after administration of thiamine hydrochloride in rats at 4, 12, and 36 mg/kg iv and the intrinsic turnover of thiamine from the diet.*

DISCUSSION

In the present investigation, urethan anesthesia significantly prolonged the half-life of thiamine in rats after administration of thiamine hydrochloride at 12 and 36 mg/kg relative to the 4-mg/kg dose. Total body clearance significantly decreased, primarily due to the increased half-life (decreased β) and not due to the small changes, if any, in volumes of distribution.

Urinary excretion of unchanged thiamine is the principal elimination route of thiamine in the dose range studied. Since thiamine appears to be exclusively eliminated by the renal route, total body clearance and renal clearance are approximately equal. The total body clearance of thiamine in rats anesthetized with ether (~19 ml/min/kg) is greater than the glomerular filtration rate (10 ml/min/kg) in rats (16). This result is consistent with the known tubular secretion of thiamine and other quaternary ammonium drugs (17–19). Thiamine is also known to be reabsorbed from the renal tubules by a saturable process (19).

The mechanism of urethan alteration of thiamine elimination after thiamine hydrochloride administration is most likely very complex, since urethan changes a number of physiological parameters. It suppresses hematopoiesis and is hepatotoxic (20). Urethan also causes acute changes in blood and blood vessels, hemolysis, and red blood cell breakdown (1). Hemodynamic alterations caused by urethan are slow to occur, and other factors may alter or accelerate these hemodynamic effects (21). It was shown (22) that urethan in anesthetic doses increases the hematocrit,

[f] Not significantly different at $p = 0.05$.

decreases blood pressure, increases plasma glucose, and causes local tissue damage to intra-abdominal organs and loss of blood plasma from circulation.

Ether is also known to alter many hemodynamic functions (23). To dramatize these effects, ether was administered continuously in the 36-mg/kg base study. The use of continuous ether anesthesia compared to light ether anesthesia significantly affected only the volume of distribution, and in an increasing direction. As noted, mean pharmacokinetic parameters for thiamine disposition in rats under urethan were significantly different from those in rats under light ether and continuous ether anesthesia.

Hypothermia may accompany general anesthesia due to hemodynamic alterations and general depression of the temperature regulating centers in the hypothalamus (24). Hypothermia was recently shown to alter the pharmacokinetics of pancuronium in the cat (25) and propranolol in the dog and humans (26). It was found (25) that pancuronium was eliminated more slowly and the volume of distribution and total plasma clearance was less in the cat when body temperature was lowered by 10°. Another investigation (26) reported that cooling to 26° markedly reduced the apparent volume of distribution and the total body clearance of propranolol in dogs. Although hypothermia may alter a drug's disposition kinetics, the temperature decreases examined previously were large (≥10°) and in the present investigation the animals under continuous anesthesia were maintained under thermal control.

Most striking and perhaps most consequential to thiamine disposition and elimination may be the pronounced hypocalcemic effect of urethan in rats. This effect was studied (27) with ether and halothane anesthesia. Urethan administered intraperitoneally at anesthetic doses significantly lowered serum calcium within 15 min after injection and this effect lasted for more than 20 hr.

The relationship between calcium and thiamine is well documented. Calcium and magnesium deficiencies alter thiamine distribution in the rat brain and liver. Calcium also plays a significant role in binding thiamine to nerve membrane structure (28–30). Although it is suspected that the hypocalcemic effect of urethan may bear primary consideration in the alteration of thiamine elimination, hemodynamic changes may also contribute.

Since it is not usually necessary to maintain animals under continuous anesthesia during many simple pharmacokinetic studies, the use of urethan or continuous ether anesthesia is no longer common practice. However, for many experiments where significant surgery is required or the animals are exposed to painful techniques, continuous anesthesia is desirable. The results of the present study demonstrate the care which must be taken in the interpretation of pharmacokinetic data otained in anesthetized animals, particularly when urethan anesthesia is used.

Abstract □ The binding of the carotenoid crocetin to human and bovine plasma albumin was studied using absorption and fluorescence techniques. Shifts in the absorption spectrum of crocetin, quenching of the albumin fluorescence, and competitive binding studies all provided information about the binding of crocetin to albumin. These studies suggest that crocetin binds to plasma albumin by occupying the free fatty acid binding sites. The binding constants for the first two binding sites are in the 10^5–10^7 M^{-1} range and are an order of magnitude less than the values reported for other conjugated polyene fatty acids. The importance of this strong plasma albumin binding to the pharmacology of crocetin is discussed.

Keyphrases □ Crocetin—binding to plasma albumin, bovine and human □ Serum protein binding—crocetin, bovine and human serum albumin □ Binding—crocetin, with bovine and human serum albumin

An important function of plasma albumin is to bind metabolites and drugs that are relatively insoluble in aqueous media. The protein complex serves as the transport system that conveys the metabolite or drug to the site of action. Drug binding can influence the therapeutic, pharmacodynamic, and toxicological actions of drugs. The binding of drugs by albumin and plasma protein was reviewed earlier (1, 2).

One of the most important metabolites transported by plasma albumin is free fatty acid, the form in which fat is released from the adipose tissue storage deposits (3). Although the plasma free fatty acid concentration is quite variable, the molar ratio of free fatty acid to albumin in the plasma usually is in the range of 0.5–2.0 and rarely exceeds 3.0 (4, 5). The binding and transport of a drug can be influenced by changes in the plasma free fatty acid concentration. Competitive binding between fatty acids and other organic compounds is examined in a recent review article on fatty acid binding to plasma albumin (6).

BACKGROUND

Crocetin (8,8′-diapocarotenedioic acid) is a dicarboxylic acid that is a member of the class of terpene lipids called carotenoids. Crocetin occurs as the glycoside in varieties of gardenia and members of the crocus family, particularly saffron. It is slightly soluble in aqueous solutions (20 μM at pH 8) that are basic and very soluble in organic bases such as pyridine. Solid crocetin is brick red while solutions are bright yellow.

A recent study demonstrated that the intramuscular injection of crocetin in rabbits fed an atherosclerosis-producing diet resulted in greatly reduced severity of the atherosclerosis (7, 8). The physiological mechanism of crocetin activity is not understood, but there is evidence that it might involve the prevention of hypoxia (8–10). More recently, crocetin has been used to treat cerebral edema in cats (11), to increase fermentation yields (12), for cancer therapy (13, 14), to treat spinal cord injury (15), to treat skin papillomas (16, 17), and to treat hypertension in rats (18).

The original investigations were based on the premise that crocetin would be a free molecular species in plasma solution. It was suggested (8) that a long, rigid molecule of relatively low molecular weight might increase oxygen diffusivity in the plasma. Since crocetin possesses these molecular characteristics, it was selected as a likely candidate for these investigations. Although crocetin has been found to bring about a large increase in oxygen diffusivity in plasma, even in the presence of increased plasma protein levels (8), it was thought that it would bind to plasma albumin and perhaps other plasma components. Absorption and fluorescence techniques were used to study the binding of crocetin to plasma albumin.

EXPERIMENTAL

Crystalline bovine plasma albumin and human plasma albumin were obtained commercially[1]. Solutions of each protein (0.1 mM) were prepared and treated with charcoal[2] in an acidic medium by a previous method (19) to remove endogenous free fatty acids. The albumin–charcoal mixtures were centrifuged[3] for 80 min at 20,200×g and 4°. The pH of the clarified solution was adjusted to 8.0 using 2 M NaOH. Albumin concentrations were determined by measuring UV absorbance of the solution at 280 nm.

The concentrations of the crocetin[4] solutions were determined from the absorbance at 420 nm. A value of 1.1×10^5 liters/mole/cm (420 nm) was found for the molar absorptivity of crocetin in saline solution at pH 8.0. This is similar to the value (114,900 liters/mole-cm) measured for a mixed solvent[5] (25% ethanol in water).

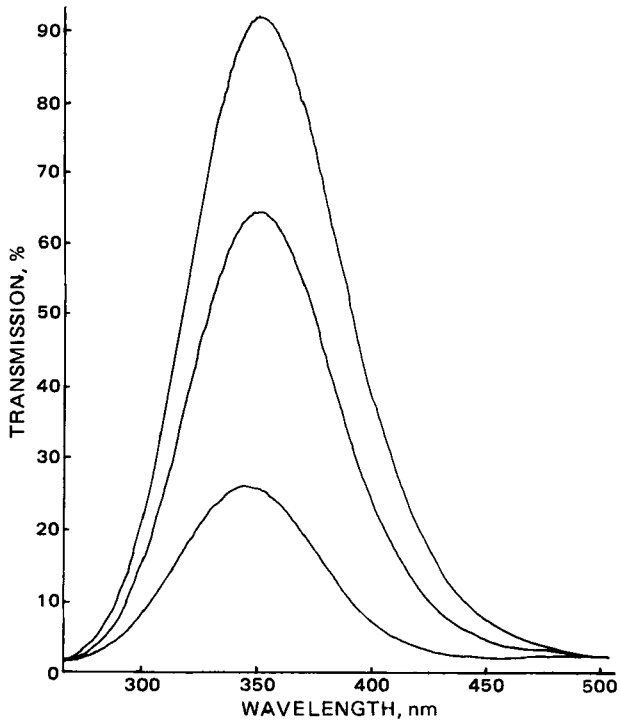

Figure 1—*Fluorescence emission spectrum of bovine plasma albumin in the presence of crocetin. The wavelength of excitation was 280 nm; the media contained 0.53 μM bovine albumin, 0.16 M NaCl, and 0.01 M buffer (pH 8.0); and the molar ratios of crocetin to albumin were 0, 4, and 17 from top to bottom.*

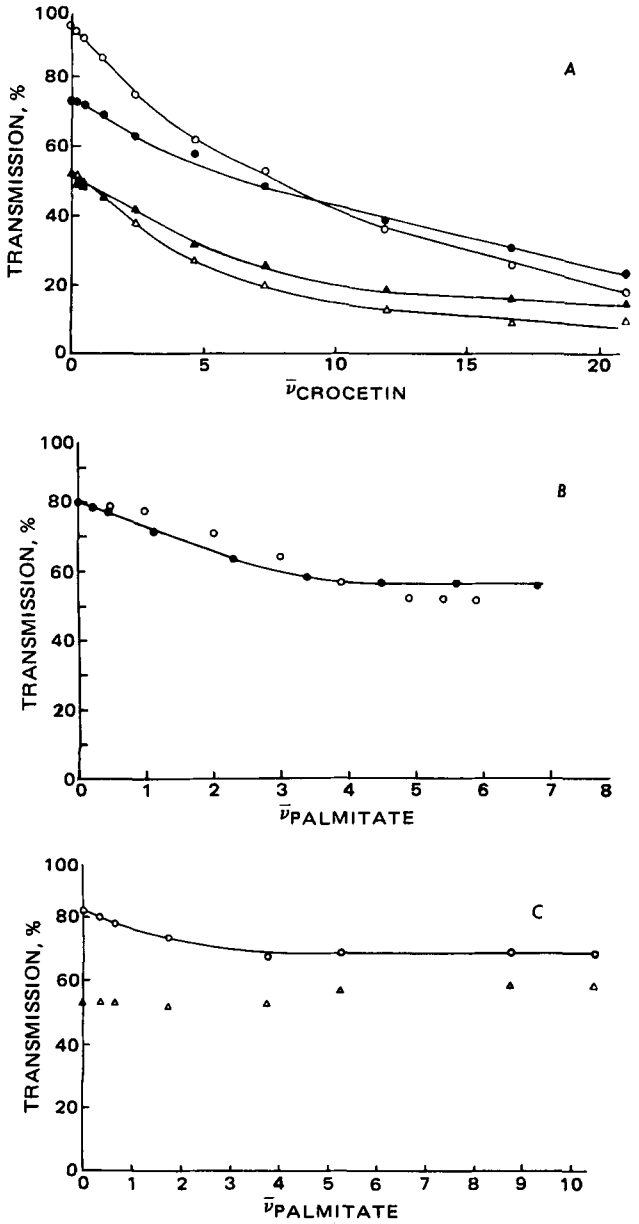

Figure 2—*Fluorescence titration curves for plasma albumin. Excitation was at 280 nm and emission was at 350 nm. Figure 2A shows the quenching of tryptophan emission by crocetin binding to bovine albumin (○) and human albumin (△), to bovine albumin with added palmitate ($\bar{\nu}$ = 4.0) (●), and the human albumin with added palmitate ($\bar{\nu}$ = 3.9) (▲). The bovine and human albumin concentrations were 0.53 and 0.54 μM, respectively. Each data point represents an average of at least two measurements. Figure 2B shows the quenching of tryptophan emission by palmitic acid at pH 8.0 and 0.62 μM bovine albumin (●), and at pH 7.4 and 0.10 mM bovine albumin (○) (pH 7.4 results taken from Ref. 20). Figure 2C shows the quenching of tryptophan emission by palmitate in samples with added crocetin, $\bar{\nu}$ (crocetin) = 1.7 (○) and $\bar{\nu}$ (crocetin) = 7.1 (△). Bovine albumin concentration was 0.64 μM with 0.16 M NaCl and 0.01 M buffer at pH 8.0.*

All absorbance measurements were made with a spectrophotometer[6], and fluorescence measurements were recorded at room temperature with either a spectrophotofluorometer[7] or a fluorometer[8]. Quartz cells (1 cm) were used in all fluorescence measurements. The solutions for the fluorescence titrations were prepared by adding 1.00 ml of albumin (~5 μM) to each of a series of 10-ml volumetric flasks. Various amounts of crocetin (0–9.00 ml of ~10 μM) were added to the flasks which then were diluted to 10.00 ml with buffer. This series gave crocetin to albumin ratios[9] ($\bar{\nu}$) from zero to ~20. All solutions were buffered at pH 8.0 with a 0.01 M tromethamine buffer[10] which contained 0.16 M NaCl.

Table I—Effect of Crocetin on Albumin Fluorescence in the Presence of Palmitate

Molar Ratio of Crocetin to Bovine Plasma Albumin[a]	Relative Fluorescence	Molar Ratio of Crocetin to Human Plasma Albumin[b]	Relative Fluorescence
0.0	65	0.0	38
0.2	66	0.2	35
0.5	65	0.4	34
1.1	68	0.9	38
2.2	67	1.8	35
4.5	64	3.6	40
6.7	63	5.4	33
11.2	64	9.1	25
15.7	55	12.7	19
20.2	51	16.4	12

[a] For $\bar{\nu}_{palmitate}$ = 9.0, the concentration of bovine albumin was 0.51 μM at pH 8.0. [b] For $\bar{\nu}_{palmitate}$ = 8.0, the concentration of human albumin was 0.53 μM at pH 8.0.

Sodium palmitate solutions were prepared by adding buffer solution to sodium palmitate[1]. The palmitate–albumin solutions were then prepared by adding the warm (60°) standard palmitate solution dropwise to the albumin solutions while they were being stirred magnetically. The final palmitate–albumin solution was used either directly in a palmitate–albumin fluorescence titration or in a competitive palmitate–crocetin binding experiment. For the competitive binding experiment, 2.00 ml of the palmitate–albumin solution was added to a 10-ml volumetric flask. After various amounts of crocetin were added, the solutions were diluted to the mark. In a similar procedure, crocetin–albumin solutions were used in competitive palmitate titrations.

For the difference spectra, 3.00 ml of crocetin (~5 μM) was placed in standard 1-cm cells located in both the sample and reference beams. The difference spectra were recorded after 5-μl aliquots of albumin (~0.5 mM) were added to the sample cell.

All final solutions contained 0.01 M buffer and 0.16 M sodium chloride at pH 8.0. All solutions, including the substrates (crocetin and palmitate) and the substrate–albumin preparations, were optically clear. All measurements were made at room temperature.

RESULTS

The fluorescence emission spectrum of both bovine and human plasma albumin were altered when crocetin was added to the solution. Figure 1 illustrates the alteration for bovine albumin at pH 8.0 and 0.53 μM. The excitation wavelength for these spectra was 280 nm. The relative fluorescence intensity for bovine albumin shifted and was strongly quenched as the crocetin concentration increased. This reduction in relative fluorescence intensity was strictly a reduction in the tryptophan fluorescence from albumin because no emission was observed from either free or albumin-bound crocetin at room temperature. The shift in the wavelength of maximum fluorescence was only from 350 to 345 nm with excess crocetin. The maximum reduction in fluorescence intensity was 81% ($\bar{\nu}$ = 21).

Similar changes in the fluorescence spectrum of human plasma albumin were observed. However, with human albumin, the tyrosine component of the luminescence is much more conspicuous, and it is impossible to determine if the tryptophan fluorescence spectrum is shifted. After excess crocetin is added to human albumin, the tyrosine emission is stronger than the tryptophan emission. The maximum reduction in fluorescence intensity was also 81% ($\bar{\nu}$ = 21) for human albumin.

The extent of binding was evaluated by using the decrease in relative fluorescence intensity at 350 nm (0.54 μM, pH 8.0). The entire fluorescence spectrum was not recorded for most samples.

The decrease in relative fluorescence intensity was nonlinear for both proteins with most of the change occurring before a molar ratio of ~8. The intersection of lines drawn through the linear segments of the curves was used to determine this value. This procedure will also be employed in subsequent evaluations.

Since these fluorescence titrations were performed at an excitation wavelength of 280 nm and an emission wavelength of 350 nm, a filter

[9] The $\bar{\nu}$ value is the molar ratio of total acid (palmitic acid or crocetin) to total albumin present in the solution; ν is the molar ratio of bound acid (palmitic acid or crocetin) to total albumin present in the solution.

[a] For $\bar{\nu}_{crocetin}$ = 3.5, the concentration of human albumin was 0.54 μM at pH 8.0.

fluorometer[11] gave accurate and reproducible results except in palmitate–albumin solutions where $\bar{\nu}$ was >8. Under these elevated palmitate conditions, the relative fluorescence was higher than anticipated. There was a slight excitation emission crossover with this set of filters and it was assumed that the higher relative intensity values indicate scattering of radiation by palmitate micelles. This hypothesis could also explain why Spector and John (20) observed that the absorbance of free fatty acid–albumin solutions was identical to that of an albumin solution of the same concentration to which no fatty acid was added where the $\bar{\nu}$ did not exceed a critical value (usually 7). This fluorescence anomaly with palmitate did not occur when a spectrophotofluorometer with narrow slits was employed.

Bovine plasma albumin was titrated with palmitate under the same experimental conditions as outlined for crocetin (pH 8.0 and albumin ~0.5 μM). The results for 0.62 μM bovine albumin at pH 8.0 are shown in Fig. 2B. The results reported by Spector and John (20) are also presented (0.10 mM bovine albumin at pH 7.4). The palmitate results for the two experimental conditions are similar. For both data sets most of the change occurred when the molar ratio of palmitate to albumin reached 4. The maximum reduction in fluorescence intensity was 35% for the earlier study and 31% for the present study.

Under their conditions (20–22), 99% or more of the palmitate present in solution is bound to albumin. When the association constant for the fourth binding site ($6.78 \times 10^5\ M^{-1}$) (22) is used in an equilibrium calculation where the first three palmitate ions are assumed to be 100% associated, only 75% of the remaining palmitate should be bound to the albumin at 0.62 μM. However, the observed difference in the magnitude of fluorescence quenching between data sets is <10%, suggesting that the level of palmitate binding at pH 8.0 and 0.62 μM bovine albumin is greater than anticipated from the reported association constant.

A large positive correction like the 432% value calculated for unbound palmitate association in human albumin solution (23) may also be necessary for bovine plasma albumin. These results along with earlier results for octanoate (24) and palmitate (20) indicate that free fatty acid binding is not strongly influenced by pH changes between 7.4 and 8.0. Consequently, the experimental conditions of pH 8.0 and 0.5 μM albumin required in this study should provide a valid assessment of long-chain acid binding to plasma albumin.

Albumin was titrated with crocetin to which palmitate had been added. Both bovine (0.53 μM) and human (0.54 μM) plasma albumin were used in this series of competitive experiments at pH 8.0. First, palmitate was added to bovine albumin ($\bar{\nu}$ = 4.0) and then the solution was titrated with crocetin. The results for this experiment are shown in Fig. 2A and contrasted with the curve for bovine albumin without palmitate. The lower curves in Fig. 2A are for human albumin with palmitate ($\bar{\nu}$ = 3.9) and without palmitate.

In these experiments the maximum reduction in fluorescence intensity was 67 and 71% for bovine and human albumin, respectively. The relative amounts of quenching from $\bar{\nu}$ = 4 to 21 in the experiments without palmitate were 73 and 70% for bovine and human albumin, respectively. The magnitude of fluorescence quenching between $\bar{\nu}$ (crocetin) = 4 to 21 is approximately the same when either palmitate or crocetin is bound to the protein in a 4:1 molar ratio. This observation would tend to imply that crocetin binds to plasma albumin by occupying the four strongest free fatty acid sites. The high-affinity free fatty acid binding sites of albumin were then saturated with palmitate and the solutions were later titrated with crocetin. The results for bovine albumin (0.51 μM, $\bar{\nu}$ = 9.0 for added palmitate) and human albumin (0.53 μM, $\bar{\nu}$ = 8.0 for added palmitate) are given in Table I. No significant change in the relative fluorescence intensity was observed until the crocetin molar ratio became greater than 10. At this point, crocetin started to replace part of the bound palmitate because there was a decrease in relative fluorescence intensity.

[11] Turner filters; 7-54 (excitation) and 7-60 (emission).

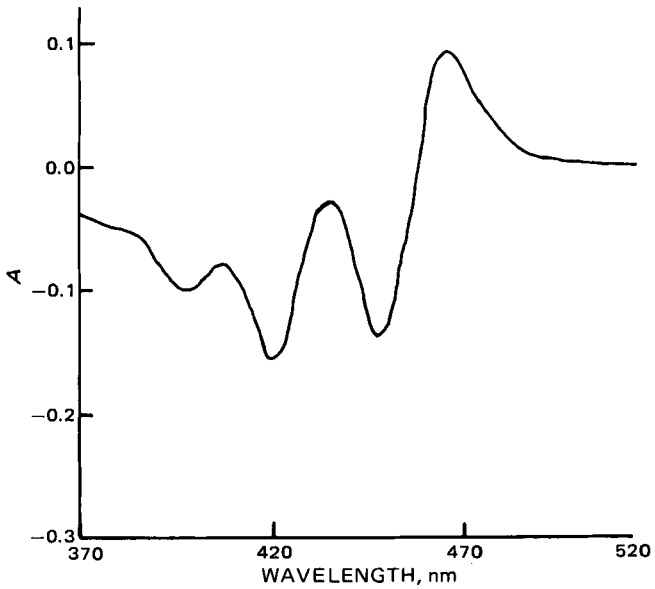

Figure 3—*A typical difference spectrum for the bovine plasma albumin–crocetin system where* ΔA *is the maximum positive absorbance at 465 nm. The bovine plasma albumin–crocetin complex was located in the sample cell and a solution of crocetin with the same concentration was located in the reference cell.*

In a second competitive experiment, albumin was titrated with palmitate to which crocetin had been added. The results for bovine plasma albumin ($\bar{\nu}_{crocetin}$ = 1.7 and 7.1) are shown in Fig. 2C. The maximum reduction in fluorescence intensity ($\bar{\nu}_{crocetin}$ = 1.7) was 16%. The relative amount of quenching from $\bar{\nu}$ = 1.7 to 6.8 in the experiment without crocetin (Fig. 2) was 18%. Most of the change occured before a molar ratio (palmitate to albumin) of 2 was reached. When this value is included with $\bar{\nu}_{crocetin}$ = 1.7, the sum is similar to $\bar{\nu}$ = 3.6 for the palmitate titration without crocetin (Fig. 2B). Thus, the magnitude of fluorescence quenching from $\bar{\nu}_{palmitate}$ = 1.7 to 6.8 was about the same when either crocetin or palmitate was bound to the protein in a 1.7:1 molar ratio. Most of the reduction in fluorescence occurred before $\bar{\nu}$ = 3.6 under both experimental conditions.

For the more concentrated crocetin ($\bar{\nu}$ = 7.1), no change in fluorescence intensity was observed until $\bar{\nu}_{palmitate}$ was ~8. Above 8, a slight increase in intensity was observed. This same observation was made when palmitate was added to human plasma albumin to which crocetin had been added. The results for human albumin ($\bar{\nu}_{crocetin}$ = 3.5) are presented in Table II. There is a very slight increase in the relative fluorescence after $\bar{\nu}_{palmitate}$ reaches 8. The data for these competitive binding experiments support the previous proposition that crocetin binds to the regular free fatty acid binding sites.

Changes in the UV absorption spectra of bovine and human plasma albumin occur when crocetin is added to the solution. There is also a change in the visible absorption spectrum of crocetin when mixed with the proteins. The changes in the UV spectra of proteins have been used to study the binding of lauryl sulfate (25) but at the concentration levels required for crocetin the changes were exceedingly small, which prevented the collection of meaningful data. However, the change in the visible absorption spectrum was used to estimate the binding constants for crocetin.

When bound to either human or bovine plasma albumin, the characteristic absorption spectrum of crocetin was observed, but λ_{max} shifted from 420 nm to longer wavelengths. The magnitude of the shift is proportional to the albumin to crocetin ratio until it reaches a maximum value of ~427 nm. Experimentally, the shift was measured by comparing the spectrum of the crocetin–albumin complex to the spectrum of aqueous crocetin of the same concentration. The difference spectrum was recorded automatically using a double-beam instrument. A typical difference spectrum for the bovine albumin–crocetin system is illustrated in Fig. 3. The magnitude of the spectral shift was recorded as ΔA which is the maximum positive absorbance at 465 nm.

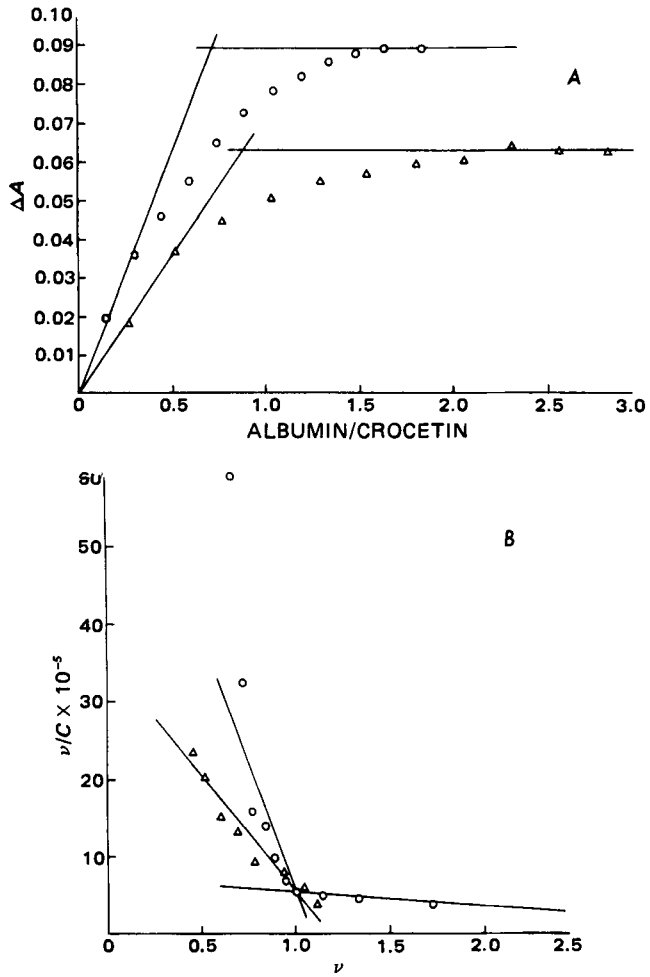

Figure 4—*The changes in the absorption spectra of crocetin (5.0 μM, pH 8.0) on binding albumin. Figure 4A shows the effect of bovine albumin (○) and human albumin (Δ) on the absorption maximum of crocetin as measured by ΔA. The horizontal lines represent ΔA_{max}. Figure 4B shows Scatchard analysis of the data presented in Fig. 4A. Key: ○, bovine albumin; and Δ, human albumin. It was assumed that the maximal ΔA represents 100% binding. The free crocetin concentration is given by C = (1 − $\Delta A/A_{max}$) × 5.0 μM. Albumin was added as microliter aliquots to the sample cell from a stock solution. The lines illustrate the slopes used to determine binding constants.*

Data obtained for crocetin (5.0 μM) binding to bovine albumin and for crocetin (4.2 μM) binding to human albumin at room temperature and pH 8.0 are shown in Fig. 4. The increase in ΔA is shown in Fig. 4A. The initial linear increase in ΔA extrapolates to a maximal value of ~0.7 mole of bovine albumin and 0.9 mole of human albumin/mole of crocetin. There is no additional increase in ΔA when bovine albumin exceeds the ratio of 1.6 moles of albumin/mole of crocetin or human albumin exceeds a ratio of 2. This result was interpreted to indicate that no further binding occurs and that under these experimental conditions, only a vanishingly small amount of free crocetin remains in solution.

A Scatchard plot (26) derived from the data of Fig. 4A is shown in Fig. 4B. It was assumed that maximal ΔA represents 100% binding. Therefore, the percentage of crocetin binding was determined by $\Delta A/\Delta A_{max} \times 100$.

The slope of a Scatchard plot is the binding constant, and a nonlinear curve indicates either nonequivalent binding sites or site–site interactions. Data is limited to the region between $\nu = 0.4$ and 1.7 because of experimental conditions. The slope (binding constant) for bovine albumin at $\nu = 1$ is $9 \times 10^6\ M^{-1}$. The second site has a binding constant on the order of $3 \times 10^5\ M^{-1}$. The fluorescence experiments indicated that there are several additional sites that are not observed under these experimental conditions. The binding data for human albumin is similar, but the slope on the Scatchard plot is not as steep. The slope (binding constant) at $\nu = 1$ is $4 \times 10^6\ M^{-1}$. The second binding site constant could not be evaluated for human albumin.

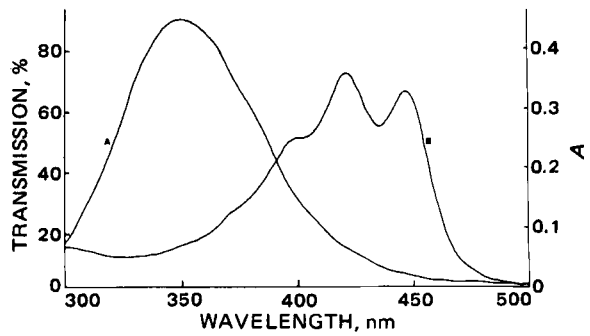

Figure 5—*Fluorescence spectrum of 0.57 μM bovine plasma albumin excited at 280 nm (A). The absorption spectrum of 3.3 μM crocetin (B). Both solutions were prepared with 0.01 M buffer and 0.16 M NaCl at pH 8.*

The experimental strategy of these binding experiments involved varying the albumin concentration while maintaining the crocetin concentration constant. With the addition of 55 μl of albumin to 3.00 ml of crocetin solution, the crocetin concentration was reduced by 1.6%. This small decrease in concentration did not significantly alter the absorbance of the sample. For 55 μl of albumin, the decrease in absorbance at 465 nm was only 0.002, and ΔA was corrected for this small change.

The range of values for the binding of the first 2 moles of crocetin to albumin (10^5–$10^7\ M^{-1}$) was somewhat less than the range of values obtained for the binding of other long-chain fatty acids (6) and conjugated polyene fatty acids (27, 28). Nonetheless, the evidence clearly indicates a similarity in the binding of crocetin and other long-chain fatty acids to plasma albumin.

DISCUSSION

During the preliminary binding studies, some of the properties of crocetin in aqueous solution were examined. Spectrometric titration data at 420 nm indicated that a time-dependent rearrangement occurs. When the time interval between pH and absorbance measurements increased, the equivalence point in the titration curve (*A versus* pH) shifted to a higher pH. On the high pH plateau, the solution was bright yellow; the spectrum observed is shown in Fig. 5. When the pH was lowered into the low pH plateau, a new band at either 297 or 360 nm was observed. Solution conditions determine which band is established after acid is added. Molecular aggregation by either micelle or liquid crystal formation may occur below pH 7.5.

The spectra of buffered crocetin solutions were monitored for 41 days. At pH 7.43, the absorbance dropped more than 50% in 21 hr. By the end of 41 days, the solution was clear with essentially no absorption above 200 nm. The process is reversible because the initial yellow color and spectrum returned when the pH was increased to 8.94 at the end of the 41 days. A much slower irreversible reduction in absorption was observed for a solution buffered at pH 8.66. This reduction is most likely a result of decomposition brought on by the higher hydroxide ion concentration. The hydroxide ion could attack a central carbon–carbon double bond and cause a cleavage of the molecule in a process analogous to the β-carotene–vitamin A process. The reversible loss of color with time is baffling.

The reversible color change and molecular aggregation prevented continuation of the binding study at pH 7.5. The lowest possible value on the high pH plateau was selected (pH 8.0). When the concentration of crocetin is increased above $2 \times 10^{-5}\ M$ at pH 8, a yellow precipitate forms. This restricted the binding studies to the concentration range presented previously. Finally, binding studies by equilibrium dialysis are not possible because crocetin binds very strongly to the dialysis membrane.

Fluorescence spectroscopy is one of the most useful tools for energy transfer studies. The conditions required for long-range energy transfer in proteins have been summarized (29) and energy transfer data has been used to calculate the mean distance between the tryptophan residue of human albumin and conjugated linear polyene fatty acids (28). A prerequisite for energy transfer is that the absorption spectrum of the energy acceptor must overlay the fluorescence spectrum of the donor. Figure 5 shows that this prerequisite is met in the binding of crocetin.

The magnitude of the fluorescence quenching observed for crocetin binding to bovine and human plasma albumin is greater than that observed for long-chain fatty acids. The maximum reduction in fluorescence

intensity for crocetin binding to both proteins was 81%, while the maximum reduction reported for free fatty acid binding was 45% [oleate and other free fatty acids are less than 45% (20)]. However, the degree of quenching is similar to that reported for polyene fatty acids bound to albumin (~68 and 90% for *cis*-eleostearic and *cis*-parinaric acids for bovine albumin, respectively (27), and ~61 and 84%, respectively, for human albumin) (28).

Since crocetin has a carboxyl group at both ends of the hydrocarbon chain, one might anticipate that the structural changes within the nonpolar binding pocket would be more dramatic. This would translate as greater changes in the tryptophan environment and, in turn, greater fluorescence quenching. Because the monocarboxylic polyene acids produce similar quenching and because the strongest hydrophobic interactions probably occur along the carbon chain and not at the deepest point of penetration within the binding pocket, we conclude that radiationless energy transfer causes most of the fluorescence quenching. However, this does not preclude the possibility of greater structural changes when crocetin binds to albumin. The highly efficient energy transfer process conceals any additional quenching due to structural changes, but the blue shift in the fluorescence of bovine albumin illustrates that there are environmental changes that occur as crocetin binds.

The results clearly indicate that crocetin binds strongly to albumin. Competitive binding experiments with palmitate suggest that crocetin binds to the same albumin binding sites that are employed by free fatty acids. When crocetin is added to whole blood *in vitro*, its visible absorption spectrum is red shifted, indicating albumin binding. From these results it is suggested that plasma albumin may serve as the primary transport vehicle for crocetin. Other possibilities, such as plasma lipoprotein transport, cannot be eliminated at this time, but regardless of the transport vehicle, only exceedingly small quantities of free, unbound crocetin can be present in the plasma. Thus, the mechanism by which crocetin reduces the effects of experimental atherosclerosis and increases oxygen diffusivity must reflect strong plasma albumin binding. There are a number of possible mechanisms. First, the increase in oxygen diffusivity could be a direct consequence of crocetin binding to the albumin. An increase in the level of plasma protein results in a large decrease in the diffusion rate of oxygen through blood plasma (10). However, crocetin was found to bring about a large increase in the oxygen diffusivity in plasma, even in the presence of increased plasma protein levels (8). By binding to albumin, crocetin may offset the decrease in diffusivity which would otherwise occur. There are other more indirect mechanisms that may be responsible for crocetin's observed activity. On a purely speculative basis the following possibilities are proposed: (*a*) a rearrangement of crocetin to form a pseudoprostaglandin, initiated by free radical peroxidation, (*b*) crocetin or crocetin–cholesterol liquid crystal formation, (*c*) membrane interactions, or (*d*) perhaps the involvement of the molecular species responsible for the reversible color change.

Synthesis and Biological Investigations of Some 5*H*-1,3,4-Oxadiazolo[3,2-*a*]pyrimidin-5-ones

FARID S. G. SOLIMAN ˣ, RAGAB M. SHAFIK, and MAGDA DARWISH

Received May 20, 1981, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria, A.R. Egypt.* Accepted for publication June 16, 1981.

Abstract □ The synthesis of some substituted 7-hydroxy-5*H*-1,3,4-oxadiazolo [3,2-*a*]pyrimidin-5-ones, a class of bicyclics with unexplored pharmacotoxicological properties, is described. Reacting the 2-phenyl derivative with bis(2,4,6-trichlorophenyl)benzylmalonate afforded a linear pyrano-oxadiazolopyrimidinedione. The assigned structures were verified by IR, ^{1}H-NMR, and mass spectral studies. Six compounds of the series were screened for *in vitro* antibacterial and antifungal activities. The effect of four compounds on alkaline phosphatase enzyme was also examined.

Keyphrases □ 5*H*-1,3,4-Oxadiazolo[3,2-*a*]pyrimidin-5-ones—synthesis, screening for antibacterial and antifungal properties and phosphatase inhibition □ ^{1}H-NMR—characterization of 5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones □ Mass spectrometry—characterization of 5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones

A number of syntheses of substituted 5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones (I) have been described in the literature. The 7-hydroxy derivative of I was first produced from 2-amino-1,3,4-oxadiazole and carbon suboxide (1). Ethyl 2-substituted-5-oxo-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidine-6-carboxylates were prepared by fusing 2-amino-5-substituted-1,3,4-oxadiazoles with ethyl ethoxymethylenemalonate and subsequent ring closure of the formed 2-(β,β-dicarbethoxyvinylamino)-1,3,4-oxadiazole derivatives (2). Analogously, 7-methyl-2-substituted-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones have been obtained from 2-aminooxadiazoles and ethyl acetoacetate (2). Reacting 2-amino-1,3,4-oxadiazoles with acetylenemono- or acetylenedicarboxylates afforded the 2-substituted or the 2-substituted-7-carboxylate derivatives of I, respectively (3). 6-Acetyl-2-phenyl-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-one was obtained *via* interaction of *N'*-2-(5-phenyl-1,3,4-oxadiazolyl)-*N*,*N*-dimethylformamidine with diketene (4). Furthermore, the preparation of some 6,7-dihydro derivatives of I was achieved either by cyclizing 3-(β-chloropropionyl)-2-imino-5-substituted-1,3,4-oxadiazolines (5) or through cycloaddition of diphenylketene with 2-arylideneamino-1,3,4-oxadiazoles (6). On the other hand, class II mesoionic 1,3,4-oxadiazolo[3,2-*a*]pyrimidine-5,6-diones, which can be regarded as isoelectronic and isosteric to xanthines, have been postulated among different bicyclic mesoionic heteroaromatic structures, called mesoionic purinone analogs (7).

There has been no report concerning the bioactivities of such compounds. In contrast, some bioisosteric sulfur analogs derived from 5*H*-1,3,4-thiadiazolo[3,2-*a*]pyrimidin-5-one reportedly possess herbicidal and pesticidal potencies (8). In addition, a number of class-II mesoionic 1,3,4-thiadiazolo[3,2-*a*]pyrimidine-5,7-diones were either shown to display *in vitro* antibacterial activities (9, 10) or acted as inhibitors of adenosine-3',5'-monophosphate phosphodiesterase (11).

As a continuation of previous work (12), the synthesis of various 7-hydroxy-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-one derivatives was undertaken, and some representative compounds were screened for *in vitro* antimicrobial activity. Because of the potency of the mesoionic

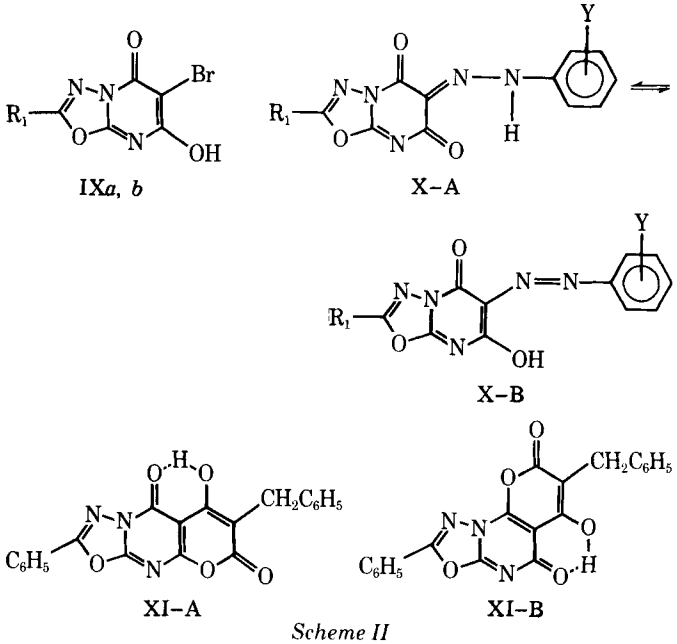
[a] The abbreviation b is broad, bm is broad medium, bs is broad strong, m is medium, and s is strong. [b] For potassium bromide disc. [c] Overlapped by the Nujol absorption bond.

thiadiazolopyrimidines, the similarity in structural features of the adopted ring system (I) to xanthines, and the reported association of antimicrobial activities with 1,3,4-oxadiazoles (13, 14) and pyrimidine derivatives (15–17), the effect on alkaline phosphatase enzyme was also studied. The susceptibility of the 1,3,4-oxadiazole moiety to attack with potassium hydroxide (2) and amines (18) may be important to the predicted bioactivity of the prepared compounds.

RESULTS AND DISCUSSION

Chemistry—The reactions outlined in Schemes I and II were followed for the synthesis of the desired compounds. The key intermediates, 2-amino-5-aryl-1,3,4-oxadiazoles (V) were prepared by first condensing the chosen aldehydes (II) with semicarbazide hydrochloride (III) in the presence of sodium acetate followed by oxidative ring closure of the resulting aldehyde semicarbazones (IV) with aqueous iodine–potassium iodide in presence of sodium carbonate (19). A previous report (20) showed that the exclusion of sodium carbonate in the cyclization of IV*a* and IV*b* leads to the formation of the corresponding 5-aryl-2,4-dihy-



IXa, b X-A X-B XI-A XI-B

Scheme II

dro-3*H*-1,2,4-triazol-3-ones (VI*a*) and (VI*b*) in low yields alongside their parent aldehydes II*a* and II*b*, respectively. The synthesis of the semicarbazones, IV*c* and IV*d*, and their respective oxadiazoles, V*c* and V*d*, have not been reported previously.

Reacting equimolar quantities of V with unsubstituted or monosubstituted bis(2,4,6-trichlorophenyl)malonates (VII) in boiling chlorobenzene afforded high yields of substituted 7-hydroxy-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones (VIII). The reaction involved an intermediate ketene–carboxylate which formed *in situ* from VII at elevated temperatures (21). The IR and ^{1}H-NMR data of VIII (Tables I and II) indicated mostly forms VIII-A and/or VIII-B rather than VIII-C. This is analogous to the structures previously assigned to some related hydroxypyridone systems (22).

The mass spectral data of representative compounds of VIII are recorded in Table II. Compounds VIII*a*, *d*, *e*, and *f* showed molecular ions of relatively low intensity (12–32%). Although the benzoyl cations constituted the base peak of the spectra of VIII*a*, *d*, and *e*, the spectrum of VIII*f* showed the *p*-methoxybenzoyl cation (*m/z* 135) at a lower abundance (56%). All mass spectra showed an ion corresponding to the loss of a fragment (*m/z* 43) from the parent molecule which might be HCNO.

The reactivity of position 6 in the 6-unsubstituted analogs of VIII towards electrophilic attack was considered in order to search for more diverse derivatives. Treatment of VIII*a* or VIII*d* with bromine yielded the corresponding 6-bromo derivatives IX*a* and IX*b*, respectively. Diazocoupling of VIII*a*, *d*, or *g* with either diazotized aniline or an appropriate diazotized sulfonamide in aqueous acetic acid medium provided 6-phenylazo- or 6-(4-substituted sulfonamidophenylazo) derivatives, respectively (X, Table III). The IR (KBr) spectrum of X*a* displayed a broad weak O–H and/or N–H stretching absorption band between 3150–2800 cm^{-1}, suggesting that the azo forms (X-A) exist in equilibrium with their hydrazono tautomers (X-B).

On the other hand, when VIII*a* was condensed with bis(2,4,6-trichlorophenyl)benzylmalonate (VII*e*) in refluxing bromobenzene, a single product was isolated for which the elemental analysis and molecular ion peak coincided with the tricyclic derivative XI-A or XI-B. The linear structure XI-A was shown to be consistent with the IR (KBr) spectrum, since it revealed the tertiary amide–carbonyl stretching absorption at 1690 cm^{-1}. If the angular isomer XI-B was formed it would have displayed this band at a lower frequency.

Determination of Antimicrobial Activity[1]—Compounds VIII*a*, *b*, *d*, *e*, *f*, and *g*[2] were tested for *in vitro* activity against four bacteria: *Staphylococcus aureus* (209 P), *Escherichia coli* (K802N), *Salmonella gallinarum* (595), and *Klebsiella pneumoniae* (SK&F 4200); and three fungi, *Candida albicans* (B-311, BC-759), and *Trichophyton mentagrophytes* (AAB-995). Microtiter twofold broth dilution methods were used to determine the minimum inhibitory concentrations of the compounds in micrograms per milliliter at which the growth of the test cultures are completely suppressed.

The antibacterial activity was determined in trypticase soy broth. The compounds were run at concentrations of 0.2–200 μg/ml. Log cultures of the bacterial strains were diluted so that the inoculum was 10^5 cfu/ml in the test. The microtiter plates were incubated at 37° overnight and observed for inhibition of growth.

The antifungal activity was determined in Sabouraud glucose broth and the compounds were run at concentrations of 0.2–200 μg/ml. Log cultures of the *Candida* strains were used for the inoculum which was 10^5 cfu/ml in the test. Spore suspensions in the glucose broth were prepared from cultures grown on glucose broth agar slants for the *T. mentagrophytes* inoculum. The plates were incubated at 30° and observed for growth at 24 and 48 hr.

Dimethyl sulfoxide–methanol mixture (1:50) was used as the solvent for the compounds. A control without the test compound was included for each organism. Gentamicin and amphotericin B were used as standard antibiotics for comparison against the bacterial and fungal species utilized, respectively.

None of the compounds exhibited antimicrobial activity.

Inhibition of Alkaline Phosphatase[3]—Compounds VIII*d*, *e*, *f*, and *g* were tested for *in vitro* inhibitory activity of alkaline phosphatase following a reported method (23).

The butanol extractable alkaline phosphatase of the human placenta was partially purified as previously described for human liver alkaline phosphatase (24). The enzyme activity was measured at 25° by determining the hydrolysis rate of *p*-nitrophenyl phosphate using the change in absorbance at 410 nm with a spectrophotometer[4]. The reaction mixture contained 1.0 *M* tromethamine hydrochloride (pH 9.4), 10^{-3} *M* substrate, and 50 μl of enzyme in a final volume of 3 ml. The appropriate quantity of the compound dissolved in dimethyl sulfoxide (10^{-2}–10^{-4} *M* concentrations) was incubated with the enzyme in the reaction-buffer at room temperature for 10 min and the reaction was initiated by the addition of the substrate. A control containing dimethyl sulfoxide was included in all determinations.

No inhibition of enzyme activity was observed by any of the compounds tested.

EXPERIMENTAL[5]

Aldehyde Semicarbazones (IV)—These compounds were prepared by treating the appropriate aromatic aldehyde (II) with an equimolar amount of semicarbazide hydrochloride (III) and sodium acetate in aqueous ethanol. The semicarbazones were purified by recrystallization from ethanol.

***o*-Benzyloxybenzaldehyde Semicarbazone (IV*c*)**—The yield was 98% (mp 180–182°); IR: 3440, 3140 shouldered at 3340, 3260, and at 3200 (N–H), 1680 (C=O), 1580 (C=N, and aromatics), 1245, and 1020 (C–O–C) cm^{-1}.

Anal.—Calc. for $C_{15}H_{15}N_3O_2$: C, 66.9; H, 5.6; N, 15.6. Found: C, 66.6; H, 5.6; N, 15.9.

***p*-Benzyloxy-*m*-methoxybenzaldehyde Semicarbazone (IV*d*)**—The yield was 97% (mp 163–164°).

Anal.—Calc. for $C_{16}H_{17}N_3O_3$: C, 64.2; H, 5.7; N, 14.0. Found: C, 64.3; H, 5.8; N, 13.8.

2-Amino-5-aryl-1,3,4-oxadiazoles (V)—These were prepared from IV by a reported method (19).

2-Amino-5-(*o*-benzyloxyphenyl)-1,3,4-oxadiazole (V*c*)—This compound was recrystallized from ethanol, mp 207–209°. The yield was 59%; IR: 3250, 3080 (N–H), 1650 (C=N), 1590 (δN–H and aromatics), 1240, and 1025 (C–O–C) cm^{-1}.

Anal.—Calc. for $C_{15}H_{13}N_3O_2$: C, 67.4; H, 4.9; N, 15.7. Found: C, 67.5; H, 5.2; N, 16.0.

2-Amino-5-(*p*-benzyloxy-*m*-methoxyphenyl)-1,3,4-oxadiazole (V*d*)—This compound was recrystallized from aqueous ethanol, mp 209–210°. The yield was 34%; IR: 3360 (N–H), 1665 (C=N), 1580 shouldered at 1600 (δ N–H and aromatics), 1500, a band split at 1245 and at 1225, and 1030 (C–O–C) cm^{-1}.

Anal.—Calc. for $C_{16}H_{15}N_3O_3$: C, 64.6; H, 5.1; N, 14.1. Found: C, 64.5; H, 4.8; N, 13.6.

Substituted 7-hydroxy-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-ones (VIII, Table I)—The appropriate bis(2,4,6-trichlorophenyl)-malonate (VII, 1 mmole) was added in one portion to a hot suspension of the amine (V, 1 mmole) in chlorobenzene (15 ml). The mixture was refluxed for 30–60 min. After cooling the crystallized solid was filtered, washed with light petroleum (bp 40–60°), and dried. In some cases, the cooled reaction mixture was treated with an equal volume of light petroleum to precipitate all the product. The compound was recrystallized from the appropriate solvent.

6-Bromo-7-hydroxy-2-phenyl-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-one (IX*a*)—Bromine (0.05 ml, 1 mmole) was added in one portion to a stirred solution of VIII*a* (0.23 g, 1 mmole) in acetic acid (30 ml) at room temperature. The color of bromine was immediately discharged with liberation of hydrogen bromide and precipitation of the bromo derivative. After 2 hr at room temperature the product was filtered, washed with ethanol, dried, and recrystallized from acetic acid, mp 265–267° dec. The yield was 0.23 g (74.4%).

Anal.—Calc. for $C_{11}H_6BrN_3O_3$: C, 42.9; H, 2.0; Br, 25.9; N, 13.6. Found: C, 42.6; H, 2.2; Br, 26.0; N, 13.6.

6-Bromo-7-hydroxy-2-(*p*-methoxyphenyl)-5*H*-1,3,4-oxadiazolo[3,2-*a*]pyrimidin-5-one (IX*b*)—This compound was prepared by brominating VIII*d* (0.26 g, 1 mmole) with bromine (0.05 ml, 1 mmole) as described for IX*a*. It was recrystallized from acetic acid, mp 248–251° dec. The yield was 0.27 g (79.6%); IR (KBr): 3200–2300 (OH and NH), a band split at 1690 (C=O) and at 1660, a band split at 1615 and at 1600, 1510 shouldered at 1530 (C=N, C=C, and aromatics), 1270, and 1015 (C–O–C) cm^{-1}; mass spectrum: *m/z* (relative abundance, %), 339 (38) (M^+ of ^{81}Br), 338 (15), and 337 (35) (M^+ of ^{79}Br).

Anal.—Calc. for $C_{12}H_8BrN_3O_4$: C, 42.6; H, 2.4; Br, 23.6; N, 12.4. Found: C, 42.7; H, 2.6; Br, 24.0; N, 12.0.

7-Hydroxy-2-phenyl-6-phenylazo-5*H*-1,3,4-oxadiazolo[3,2-*a*]-pyrimidin-5-one (X*a*, Table III)—To a stirred solution of VIII*a* (0.23 g, 1 mmole) in ethanol (10 ml) at 10° was added a cold solution of aniline (0.09 ml, 1 mmole) and sodium nitrite (0.08 g, 1.1 mmole) in 50% aqueous acetic acid (10 ml). After stirring for 1 hr, the reaction mixture was re-

[4] Pye Unicam SP-100.

[5] Melting points were determined in open-glass capillaries and are uncorrected. IR spectra were recorded for Nujol mulls, unless otherwise specified, on a Beckman 4210; or for potassium bromide disks on a Perkin-Elmer 421 spectrophotometer. ^{1}H-NMR spectra were determined on a Varian EM 360 spectrometer using deuterated dimethyl sulfoxide as solvent, unless otherwise indicated, and tetramethylsilane as the internal standard. Mass spectra were obtained using a Varian Mat 111 (80 ev) instrument and peaks of relative intensity below 5% of the base peak were omitted. Microanalysis, for samples dried over phosphorus pentoxide at 70° under reduced pressure, was carried out at the Microanalytical Unit, University of Cairo, A.R. Egypt.

frigerated overnight and a yellow product was collected, washed with water, dried, and recrystallized.

2-Aryl-7-hydroxy-6-(*p*-substituted phenylazo)-5*H*-1,3,4-oxadiazolo [3,2-*a*]pyrimidin-5-ones (X*b–d*, Table III)—The appropriate sulfonamide (1 mmole) was dissolved in acetic acid (20 ml) and the solution was cooled to 5°. A cold solution of sodium nitrite (1.1 mmole) in water (5 ml) was added and the resulting diazonium salt solution was filtered into a stirred solution of the proper VIII (1 mmole) in acetic acid (50–100 ml) at 10°. The reaction mixture was then worked up as described for X*a*, and the yellow crude product crystallized from the suitable solvent.

Reaction of VIII*a* with Bis(2,4,6-trichlorophenyl)benzylmalonate. (VII*e*)—Equimolar amounts of VIII*a* (0.23 g, 1 mmole) and VII*e* (0.55 g, 1 mmole) were refluxed in bromobenzene (25 ml) for 3 hr. The product (XI-A) that separated out on cooling was filtered, washed with light petroleum, and dried. It was recrystallized from a large volume of boiling ethanol, mp 306–308°. The yield was 72%; IR (KBr): 3650–2900 (OH), 1750 (C=O, α-pyrone), 1690 (C=O, amide), a band split at 1620 and 1605, 1585, 1560, 1505 (C=N, C=C, and aromatics), 1255, and 1025 (C–O–C) cm^{-1}; mass spectrum: *m/z* (relative abundance, %) 387 (69) (M^+).

Influence of Benzalkonium Chloride on the Dissolution Rate Behavior of Several Solid-Phase Preparations of Cholesterol in Bile Acid Solutions

KENNETH M. FELD, WILLIAM I. HIGUCHI ˣ, and CHING-CHIANG SU

Received April 28, 1980, from *The College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication June 2, 1981.

Abstract □ Cholesterol dissolution rate accelerators, such as benzalkonium chloride, function by reducing the interfacial barrier that exists between the negatively-charged bile acid micelle and the negatively-charged cholesterol surface. It has been proposed that this reaction is accomplished by the binding of the positively-charged accelerator to the negatively-charged micelle. An earlier report showed that different solid preparations of cholesterol give different dissolution rates under the same conditions and these differences can be primarily accounted for by variations in the interfacial transport constant (*P*). By using the rotating disk dissolution apparatus and the Levich theory it has been possible to study the dissolution behavior of different cholesterol solid phases as a function of the benzalkonium chloride concentration. It was shown that the ratios of *P* values for the different phases are relatively constant over the range of the accelerator concentrations. This suggests that the accelerators act primarily on the micelle to enhance dissolution rate.

Keyphrases □ Benzalkonium chloride—effect on dissolution of cholesterol preparations in bile acid solutions □ Dissolution—cholesterol preparations, effect of benzalkonium chloride, bile acid solutions □ Cholesterol—effect of benzalkonium chloride on dissolution, bile acid solutions □ Gallstone kinetics—effect of benzalkonium chloride on dissolution of cholesterol preparations in bile acid solutions

Physicochemical studies of gallstone (cholesterol) dissolution kinetics have been performed in these laboratories (1–7). Theoretical treatment (2) showed that *in vivo* dissolution of cholesterol gallstones occurred at much lower rates than expected if dissolution were totally diffusion controlled. It was proposed that interfacial factors may be

Influence of Benzalkonium Chloride on the Dissolution Rate Behavior of Several Solid-Phase Preparations of Cholesterol in Bile Acid Solutions

KENNETH M. FELD, WILLIAM I. HIGUCHI ˣ, and CHING-CHIANG SU

Received April 28, 1980, from *The College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication June 2, 1981.

Abstract □ Cholesterol dissolution rate accelerators, such as benzalkonium chloride, function by reducing the interfacial barrier that exists between the negatively-charged bile acid micelle and the negatively-charged cholesterol surface. It has been proposed that this reaction is accomplished by the binding of the positively-charged accelerator to the negatively-charged micelle. An earlier report showed that different solid preparations of cholesterol give different dissolution rates under the same conditions and these differences can be primarily accounted for by variations in the interfacial transport constant (*P*). By using the rotating disk dissolution apparatus and the Levich theory it has been possible to study the dissolution behavior of different cholesterol solid phases as a function of the benzalkonium chloride concentration. It was shown that the ratios of *P* values for the different phases are relatively constant over the range of the accelerator concentrations. This suggests that the accelerators act primarily on the micelle to enhance dissolution rate.

Keyphrases □ Benzalkonium chloride—effect on dissolution of cholesterol preparations in bile acid solutions □ Dissolution—cholesterol preparations, effect of benzalkonium chloride, bile acid solutions □ Cholesterol—effect of benzalkonium chloride on dissolution, bile acid solutions □ Gallstone kinetics—effect of benzalkonium chloride on dissolution of cholesterol preparations in bile acid solutions

Physicochemical studies of gallstone (cholesterol) dissolution kinetics have been performed in these laboratories (1–7). Theoretical treatment (2) showed that *in vivo* dissolution of cholesterol gallstones occurred at much lower rates than expected if dissolution were totally diffusion controlled. It was proposed that interfacial factors may be

important *in vivo*. It was also shown (1–3) that *in vitro* dissolution of cholesterol gallstones in simulated and in human bile was dominated by an interfacial barrier at the crystal-solution interface. Kwan *et al.* (6) studied the interfacial process as a function of bile acid type and concentration, bile acid/lecithin ratio, and electrolyte type and concentration. He found that the interfacially-controlled dissolution rate increased with increasing bile acid concentration, increasing bile acid/lecithin ratio, and increasing electrolyte concentration.

BACKGROUND

The elimination of this interfacial barrier by appropriate measures is expected to be clinically significant. Studies by Prakongpan *et al.* (4, 5) showed that when quaternary ammonium compounds were added to the bile acid–lecithin solutions, dissolution rates were enhanced tremendously and approach the diffusion-controlled rates at high concentration. Previous studies (8) on the acceleration effect of primary, secondary, and

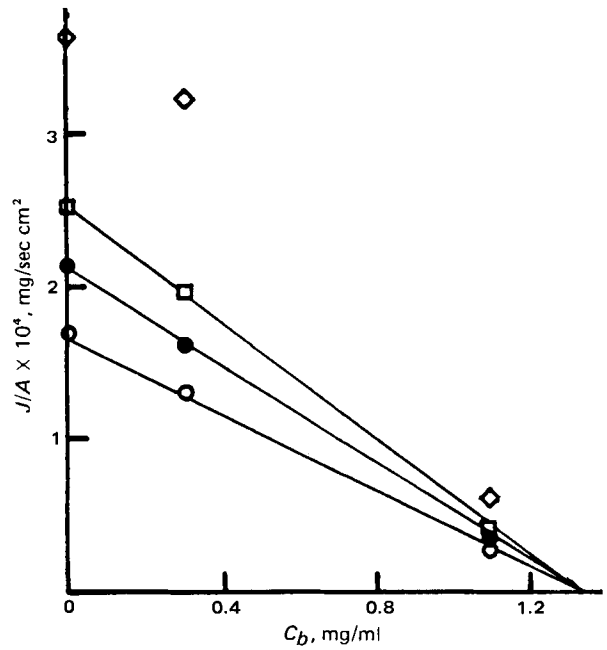

Figure 2—*Dissolution rate* versus *bulk concentration for the rapid (II) pellets in 5% sodium cholate, 0.1* M *phosphate buffer, and 0.25% benzalkonium chloride at pH 8.0. Key:* ○, *20;* ●, *50;* □, *150; and* ◇, *450 rpm.*

tertiary amines, quaternary ammonium compounds, steroidal amines, and other surfactants, found that the cationic surfactants and the steroidal amines were effective, but the nonionic and anionic surfactants were not.

Other work (8) led to the following interpretations regarding dissolution mechanisms. Since the surface reaction rate increases with increasing micelle concentration (increasing bile acid concentration) and since the dissolution rate is very sensitive to electrolytes, it was concluded that the micelle is the primary carrier of cholesterol in the rate-limiting step. It was proposed that increasing the counterion concentration results in the reduction of the electrical repulsion which exists between the negatively-charged bile acid micelle and the negatively-charged cholesterol surface. The observation that only cationic surfactants were effective cholesterol dissolution accelerators was interpreted as: (*a*) adsorption of aliphatic long-chain cations on the cholesterol surface aids reduction of the electrical repulsion between the negatively-charged cholesterol surface and the negatively-charged micelle, and/or (*b*) the formation of mixed micelles which reduce the net negative charge on the micelle, thus easing the approach of the micelles to the charged surface.

Patel and Higuchi (9, 10) carried out a systematic study of cholesterol dissolution rate acceleration mechanisms. Using membrane transport

[a] Each J/A value is an average of two experiments and the range refers to the high and low values.

methods, the concentrations of bound and unbound accelerators were determined in the simulated bile acid solutions at low concentrations of accelerators. From the determinations of bound and unbound amine in simulated bile and from data on cholesterol dissolution rate acceleration, it was shown that the amount of bound amine correlated with the efficacy of cholesterol monohydrate dissolution rate acceleration and that the charged form of the amine was important. The electrophoretic mobility of chenodeoxycholate micelles was measured as a function of the amine concentration using the moving boundary electrophoresis method. In addition, particle microelectrophoresis studies showed that there was no significant surface charge variation on cholesterol particles as a function of amine concentration. From an analysis of these data, it was proposed that the predominant mechanism by which the amines enhanced the dissolution rate involved reducing the electrical charge of the bile acid micelles.

The present investigation studied the action of dissolution rate accelerators upon different solid cholesterol phases and attempted to determine the extent to which the donor phase may influence interfacial transfer acceleration kinetics.

THEORY

The rotating disk dissolution rate equation described previously (5) is appropriate for the present study. The following may be used to describe dissolution rate (11):

$$J = \frac{A(C_s - C_b)}{1.612D^{-2/3}\,\nu^{1/6}\,\omega^{-1/2} + 1/P} \qquad \text{(Eq. 1)}$$

where:

J = dissolution rate
A = apparent surface area of the pellet (cm^2)
D = diffusion coefficient (cm^2/sec)
ν = kinematic viscosity (cm^2/sec)
ω = angular velocity of rotation (radians/sec)
C_s = saturation solubility (mg/ml)
C_b = bulk concentration (mg/ml)
P = permeability coefficient (interfacial transport constant, cm/sec)

EXPERIMENTAL

Solutions—Sodium cholate test solutions were prepared by adding equivalent portions of cholic acid with sodium hydroxide. The pH of the solutions was then adjusted to 8.0. Dissolution rate accelerators (benzalkonium chloride) and buffers were added as needed. The solutions were allowed to equilibrate for 1 day before use.

Materials—Commercially obtained cholesterol[1] was recrystallized three times from 95% ethanol. Radioactive cholesterol monohydrate was prepared by mixing 100 μCi of [4-^{14}C]cholesterol with a given amount of the purified cholesterol at 60° in 400 ml of 95% ethanol. The solutions were then allowed to stand undisturbed for 2 days at room temperature. The crystals were filtered and dried *in vacuo* for 24 hr. The purified crystals were stored in the dark and in a container saturated with water vapor at room temperature.

crystallizing 10 g of cholesterol in 400 ml of 95% ethanol. A melt preparation (III) was obtained by heating sample I at 160° for 10 min. Pellets of each sample were prepared and experiments were run as described previously (5). Cholic acid was recrystallized three times from 95% ethanol and the purity was checked and confirmed by TLC. Benzalkonium chloride[1] was used as received.

Differential scanning calorimetric thermograms were obtained for the three cholesterol samples. Thermograms of samples I and II showed endotherms at 80°, corresponding to the release of water from cholesterol monohydrate. This endotherm was absent from thermograms of sample III. Samples I–III showed endotherms at 150° for melting. In general, these thermograms agree with those obtained previously (12).

Assessment of the Experimental Systems Based on the Solid Preparation Study—Test solutions of 5% sodium cholate, 0.1 *M* phosphate buffer, and 0.0, 0.25, and 0.5% benzalkonium chloride at pH 8.0 were used. These conditions were chosen because the diffusion control/interfacial control ratios would be small to moderate and thus allow for reliable determinations of P values. If a test solution with 1.0% benzalkonium chloride were used, the melt pellets would dissolve ~100% diffusion controlled and the uncertainty in the P value determination would be too great.

RESULTS AND DISCUSSION

The dissolution rates for the various cholesterol pellets were determined in partially saturated solutions at various rotational speeds at 37°. Tables I–III show the dissolution rates as a function of rotational speed and partial saturation for samples I–III. As can be seen, there are significant differences in the dissolution rates among pellet types.

Dynamic solubilities were determined by plotting dissolution rate (J/A) against bulk concentration (C_b). Figures 1–3 show the results of the experiments carried out in 5% sodium cholate, 0.1 *M* phosphate buffer, and 0.25% benzalkonium chloride solutions at pH 8.0. By extrapolation of the data to zero J/A the dynamic solubilities can be determined. This was done with the data in Figs. 1–3 except for the 450-rpm experiments where deviations from Eq. 1 were noted (the possible cause of these deviations is discussed later). Figures 1–3 show a linear decrease in dissolution rate with increasing partial saturation. This indicates that the dissolution kinetics are proportional to ΔC over the entire range of saturation. These figures show that the dynamic solubility is ~1.35, 1.30, and 1.65 mg/ml for the sample I, II, and III pellets, respectively. The tabulated dissolution rates for the three solid preparations in this system are shown in Tables I, II, and III, respectively.

Figures 4–6 show the Levich plots of the described data. The deviations from linearity clearly show the presence of the interfacial barrier in the dissolution process. If cholesterol dissolution were completely diffusion controlled, a plot of J/A *versus* $\omega^{1/2}$ would give a straight line through the origin.

From a best fit analysis (using a kinematic viscosity of 6.99×10^{-3} cm^2/sec), based on a 15% correction (5) of Eq. 1, it was possible to obtain values for C_s, P, and D, where P is the interfacial transport constant and D is the diffusivity. The calculated dissolution rates using the best fit values were compared to the experimental dissolution rates and Figs. 4–6 show the good agreement between the two. The same analysis was done for the three pellet types in 0.0 and 0.50% benzalkonium chloride solutions. Figures 7–9 show the Levich plots for the 0.50% benzalkonium chloride system. Again, a good fit between experiment and theory is seen. It should be noted that the points at 450 rpm ($\omega^{1/2} = 6.86$) were not weighted in this analysis.

A possible explanation for the high J/A value at 450 rpm in some of the experiments is the following. Microscopic examination of individual crystals of cholesterol monohydrate in bile acid solutions showed that

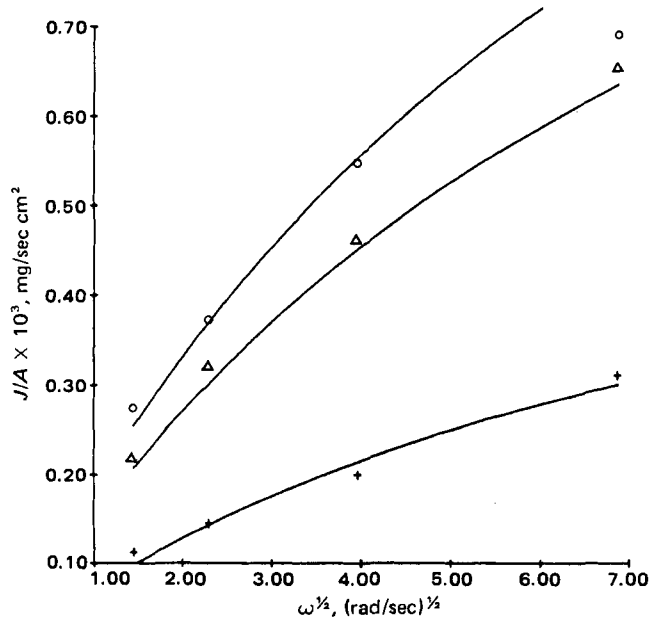

Figure 6—*Best-fit analysis of the melt pellets (III) in 5% sodium cholate, 0.1* M *phosphate buffer, and 0.25% benzalkonium chloride at pH 8.0. Key:* C_b, ○, *0.0;* △, *0.3; and* +, *1.0 mg/ml.*

	1.72 (50 rpm)			
	1.76 (150 rpm)	1.79	3.32	1.16

surface etching occured. Within 2 hr, a definite saw-tooth pattern developed along the crystal edge. At high rotational speeds in the rotating disk experiments it is possible that the effective surface area might be increased or that some shearing of the peaks along the crystal surface takes place. This reaction, along with normal micellar dissolution, could result in a positive deviation in the apparent dissolution rate from that expected from theory.

Tables IV–VI summarize the results of the partial saturation experiments and the least-squares analysis. It can be seen that the C_s values obtained for the normal pellets (sample I) and the rapid pellets (sample II) are nearly equivalent, while the C_s values obtained for the melt pellets (sample III) was ~20% higher in all cases. It should be noted that the solubilities for samples I and II obtained from the partial saturation experiments agreed with the saturation solubilities of cholesterol (13).

The D values reported here are somewhat smaller than those obtained earlier (14, 15) for bile salt–lecithin systems. Since cholesterol dissolution is essentially surface controlled, the error in determining D values from the present dissolution-rate would be rather large; therefore, significances should not be attached to differences between the D values reported here and those determined using conventional methods (see *Appendix*).

Possible Meaning of *P* in Relation to the Dissolution Process—In general, the solubilization process involves contact of the solvent with the solid surface, where an interaction occurs; this is followed by the transport of the solute or product molecules away from the interface into the bulk. The dissolution of cholesterol in bile acid solutions can be regarded as following this mechanism. The slow or rate-determining step in this process is the approach of the micelle to the cholesterol surface and the subsequent transport of cholesterol molecules into the micellar phase. This process is associated with the interfacial transport constant P.

To understand how the benzalkonium chloride acceleration effects may be dependent on the solid phase of cholesterol, a more detailed consideration of the process is necessary. The model in Fig. 10 is proposed.

Step 1: The micelle moves from the bulk solution through the aqueous diffusion layer to a region close to the pellet surface.

Step 2: Molecules from the solid surface may disengage as a function of their configurations and energies. These molecules remain close to the solid surface and can be thought of as part of the adsorbed layer.

Step 3: Solubilization of these relatively free molecules occurs at the crystal-solution interface as a result of micelle surface "collisions." This solubilization process is a function of a steady-state concentration of the free cholesterol near the surface. The larger the k_1 value, the greater the concentration of free cholesterol and the greater the dissolution value.

A large k_1 would essentially mean a high concentration of accessible cholesterol for solubilization by the micelles during collision.

In context of the present experiments, k_1 may be related to several factors. A low intrinsic activation energy for molecular disengagement would contribute to a large k_1. A large microscopic surface area at the pellet surface or a high density of active sites may also lead to a large effective k_1. The results of the present study suggest that the activational free energy (or the effective activation free energy) for the cholesterol molecule disengagement from the surface of the melt preparation is lower than that for the monohydrate preparations. This might have arisen from the possibly greater general state of disorganization of the surface molecules in the anhydrous melt, or from other factors such as crystalline defects which may have been more preponderant in the melt preparations.

This description of the dissolution process, together with earlier studies (9) on the influence of long-chain alkyl ammonium ions upon cholesterol dissolution rates in sodium chenodeoxycholate solutions, may be used to examine the present results with benzalkonium chloride. Table VII summarizes the P values and their ratios for all of the experiments. The P_{II}/P_I and the P_{III}/P_I ratios are relatively constant (~2.0 and 7.0, respectively) over the benzalkonium chloride concentration range, up to 0.5%. The ratios change only ~10–15% over a four- to fivefold range of rates.

Constancy in the P_{II}/P_I and the P_{III}/P_I ratios would be consistent with the following analysis. If the relevant surface charge densities for all three cholesterol preparations were essentially the same, and if the addition of benzalkonium chloride to the system did not significantly influence the surface charges, then the mechanism proposed earlier (9, 10) (*i.e.*, the partial neutralization of the negative micellar charge) may dominate and would predict that k_2 (Fig. 10) would be essentially the same in the experiments with all cholesterol samples. Then, if the k_1 values are not influenced by benzalkonium chloride or if k_1 values are affected the same

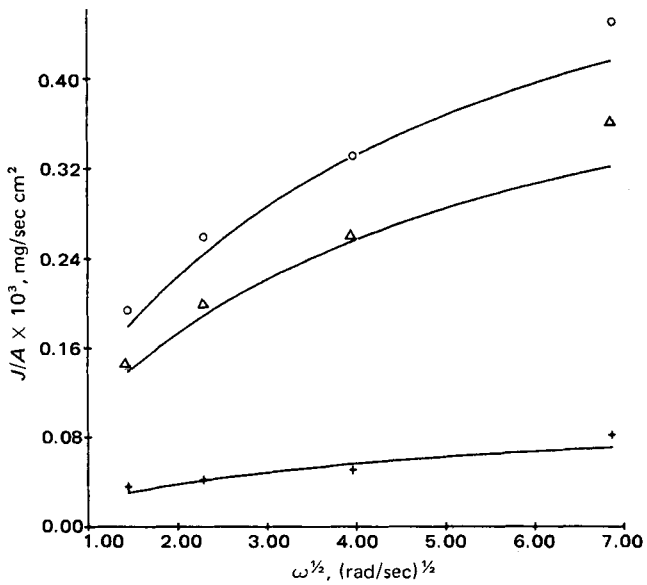

Figure 8—*Best-fit analysis of the rapid (II) pellets in 5% sodium cholate, 0.1* M *phosphate buffer, and 0.5% benzalkonium chloride at pH 8.0. Key:* C_b, ○, *0.0;* △, *0.3; and* +, *1.1 mg/ml.*

Table VII—Summary of the P Values Obtained as a Function of Benzalkonium Chloride Concentration

Percent Benzalkonium Chloride in Solution	$P \times 10^4$, cm/sec				
	I	II	III	P(II)/P(I)	P(III)/P(I)
0.0	0.51	0.96	3.32	1.90	6.53
0.25	1.62	3.28	10.62	2.02	6.55
0.50	2.19	4.85	15.87	2.20	7.25

Table VIII—Summary of the C_s Values Obtained as a Function of Benzalkonium Chloride Concentration

Percent Benzalkonium Chloride in Solution	C_s, mg/ml				
	I	II	III	C_s(II)/C_s(I)	C_s(III)/C_s(I)
0.0	1.45	1.37	1.79	0.95	1.23
0.25	1.35	1.29	1.63	0.96	1.21
0.50	1.36	1.33	1.63	0.97	1.20

(percentage-wise) for all three samples, then constancy of the P ratios should be expected.

A corollary analysis might assume, for example, that there are interactions between benzalkonium chloride and the cholesterol surface to reduce the surface charge density. However, if the initial surface charge densities and the benzalkonium chloride surface effects are essentially the same for all preparations, then again k_2 would be expected to be the same for the three preparations. For this situation, if the initial k_1 values are not affected by the benzalkonium chloride or if they are affected the same, the constancy of the P ratios would again be expected.

The first of these two interpretations may easily explain the behavior difference between sample I and sample II since both of these are cholesterol monohydrates with the same differental scanning colorimetric patterns and essentially the same solubilities (Table VIII). In terms of the proposed model, sample I and sample II might differ only in that their k_1 (or their apparent k_1) values are different because of differing microscopic surface areas or crystallite sizes. The conditions associated with k_2 might be expected to be identical for these two preparations.

The constancy of the P_{III}/P_I ratio is more difficult to predict since sample III is anhydrous cholesterol that had undergone a melting step. The present data suggest, however, that the proposed mechanism may be correct even in this instance; although k_1 may be significantly greater for the melt than for the sample I monohydrate, it is relatively uninfluenced by benzalkonium chloride. The electrical characteristics of the melt pellet surface is similar to that for the monohydrate under the present dissolution kinetics conditions so that the primary effect of benzalkonium chloride is the reduction of the micellar charge and facilitating step 3 *via* the enhancement of k_2.

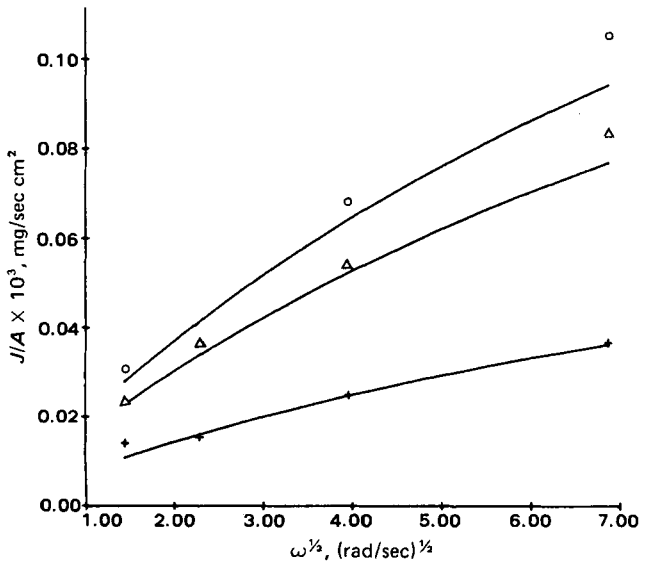

Figure 9—*Best-fit analysis of the melt (III) pellets in 5% sodium cholate, 0.1 M phosphate buffer, and 0.5% benzalkonium chloride at pH 8.0. Key:* C_b, ○, *0.0;* △, *0.3; and* +, *1.0 mg/ml.*

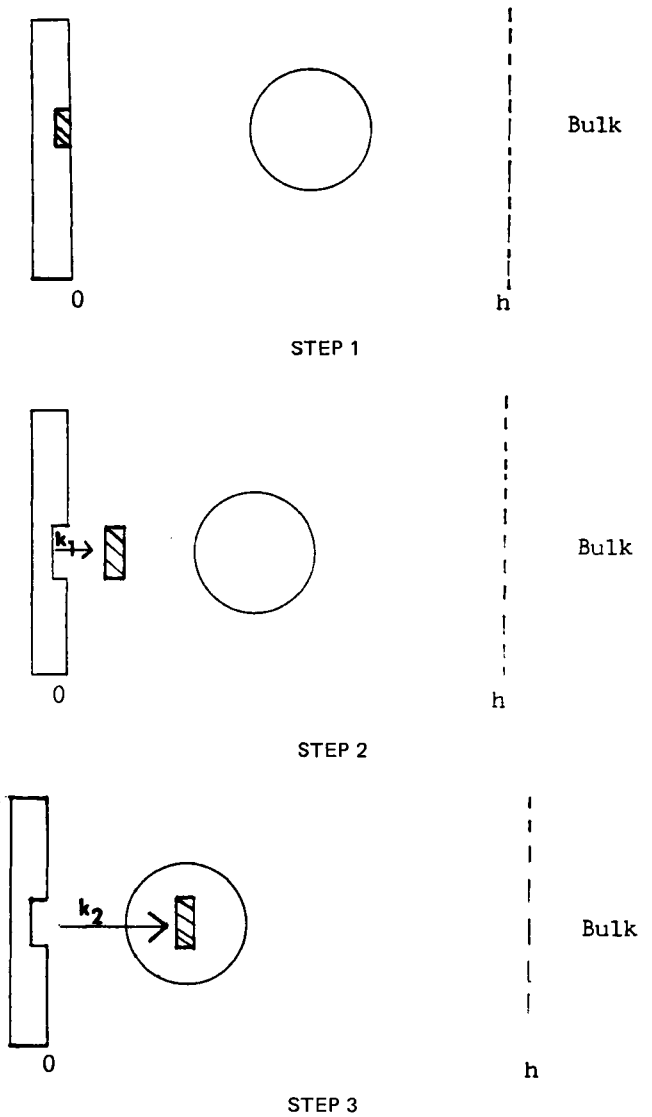

Figure 10—Step 1—*The micelle moves from the bulk solution through the aqueous diffusion layer to a region close to the pellet surface.* Step 2—*Molecules from the solid surface may disengage as a function of their configurations and energies. These molecules remain close to the solid surface and can be considered part of the adsorbed layer.* Step 3—*Solubilization of these relatively free molecules occurs at the crystal-solution interface as a result of micelle surface "collisions." The symbol* k_2 *is the rate constant for the solubilization of the (surface) free cholesterol by the micelle.*

APPENDIX

Sensitivity of the Best Fit Analysis to P—To relate the present results to their sensitivities to P, the parameters C_s and D must be considered. As already shown, there was good agreement between the solubilities obtained from the best fit analysis and those obtained from extrapolation of the partial saturation data. Diffusivities obtained from the best fit analysis were in fairly good agreement with those obtained experimentally. Diffusivity measurements were made at 37° in a small volume diaphragm diffusion cell employing a modified Keller's method (14). The D values determined experimentally in 0.0, 0.25, and 0.50% benzalkonium chloride solutions were 1.52, 1.40, and 1.28×10^{-6} cm^2/sec, respectively. These compare with the best fit D values of 1.25, 1.04, and 1.08×10^{-6} cm^2/sec.

Because of the good agreement between experimental and best fit parameters for C_s and D, an assessment of P can now be made. It must be remembered that as a system approaches total diffusion control, P becomes very large (surface equilibrium is fast) and therefore, $1/P$ becomes small. The smaller the $1/P$ ratio, the less sensitive the best fit results will be to small changes in P. Another look at the systems studied shows that the diffusion control/interfacial control ratios are small to moderate except for the melt pellets in 5% sodium cholate, 0.1 M phosphate buffer, and 0.50% benzalkonium chloride at pH 8.0 where the diffusion control/interfacial control ratio is ~90%. By making small changes in P, the sensitivity of the best fit results can be seen. It can be shown that if P is varied by ±10% there is little change in the best fit results. However, a change in P greater than 10% will result in marked deviation of the experimental results and the theoretical curves. For the case where the diffusion control/interfacial control ratio is ~90%, the uncertainty in P can be as high as 25%.

Particle Size Reduction by a Hammer Mill I: Effect of Output Screen Size, Feed Particle Size, and Mill Speed

B. R. HAJRATWALA

Received May 15, 1981, from the *Pharmaceutics Department, Wayne State University, Detroit, MI 48202.* Accepted for publication June 30, 1981.

Abstract □ A hammer mill is an impact mill commonly used in pharmaceutical manufacturing for reducing particle size for a variety of drugs. Commercial grade ammonium sulfate was milled as a model powder. This salt was sieved to obtain particle size fractions with average diameters of 1.3, 0.9, and 0.72 mm which were used as feed particles. The milled material was analyzed for particle size distribution (PSD) using standard sieves. At a moderate speed (~2500 rpm), the feed size did not result in a significantly changed arithmetic mean diameter, $d_{\bar{x}}$ of milled particles. A new particle size reduction constant, k, is proposed as a result of a linear relationship between $d_{\bar{x}}$ and output screen size, d_{ss}. As d_{ss} decreases, the PSD range of milled particles narrows; as mill speed increases (~5000 rpm), $d_{\bar{x}}$ decreases. The decrease is of a greater magnitude for larger d_{ss} (2 mm) than for a smaller d_{ss} (1 mm). At low speeds (~1000 rpm), the PSD is wider compared to medium and high speeds.

Keyphrases □ Particle size—reduction by hammer mill, effect of output screen size, feed particle size, and mill speed □ Pharmaceutics—particle size reduction by a hammer mill □ Hammer mill—particle size reduction, pharmaceutics

The hammer mill is an impact mill commonly used in pharmaceutical manufacturing for reducing particle size for a variety of drugs (1–3). Milling is an essential unit operation in tablet and capsule manufacture, yet very little has been reported about factors that affect milling (4, 5).

The present report examines the effect of related parameters such as output screen size, feed particle size, and mill speed on particle size reduction by a hammer mill. Commercial grade ammonium sulfate was used as a model substance due to its low cost and large particle size distribution.

EXPERIMENTAL

Equipment—A laboratory bench-type hammer mill[1], USP standard testing sieves[2], and a laboratory sieve vibrator[3] were used. The sieve sizes used were: 2.0, 1.6, 1.0, 0.8, 0.63, 0.4, 0.315, and 0.1 mm for preparation and analysis.

Particle Size Reduction—Ammonium sulfate was sieved to obtain various particle size fractions with average diameters of 1.3, 0.9, and 0.72 mm. Sieve sizes used were 1.6, 1.0, 0.8, and 0.63 mm. The particles were stored at room temperature (25 ± 3°) and at a constant humidity (60 ± 2%, to prevent agglomeration of particles) until required for milling.

The mill was equipped with three free-swinging hammers with impact edges and variable rotational speed control. The material was fed as 5 g portions.

The total amount milled for each experiment was 50 g. The mill was fitted with round-hole design output screens with 2.0-, 1.5-, or 1.0-mm sizes. They were 3.03-, 3.06-, and 1.23-mm thick, respectively. The milled material was collected in a closed plastic bag and analyzed for particle size distribution using the standard vibrating nested sieve method.

All data were obtained in duplicate and were virtually identical in all cases.

Evaluation of $d_{\bar{x}}$ and σ—The mean diameter, $d_{\bar{x}}$, was obtained from arithmetic probability plots. The particle size at 50% was taken as $d_{\bar{x}}$.

The standard deviation, σ, was also obtained from the arithmetic probability plots. The difference in particle sizes at 84.13 and 50% size was taken as σ.

RESULTS AND DISCUSSION

The rate at which a mill is fed is an important variable. Various amounts of feed material were milled to determine the optimum feed rate. This was determined experimentally by noting the discharge rate (grams per second) of milled material. Five grams was the optimum amount,

1.0	0.34 ± 0.24	0.28 ± 0.15	0.22 ± 0.15

[a] Feed particle size range, 1.6–1.0 mm.

giving the maximum discharge rate for this mill with ammonium sulfate as the feed material.

This mill had a maximum speed of 6000 rpm. (Any reference to a constant speed implies that the speed setting on the mill was not changed during the experiment). Milling was done at three preselected settings. A low speed (setting 2, ~1000 rpm), a medium speed (setting 4, ~2500 rpm), and a high speed (setting 8, ~5000 rpm) were arbitrary selections.

Effect of Output Screen Size at Moderate Milling Speed—The evaluation of particle size data utilizing histograms has limited use. It is convenient to express data as arithmetic probability or normal probability plots (1).

Figures 1–3 show the effect of output screen size (d_{ss} represents diameter of screen openings) on the particle size distribution of milled product for various sizes of feed material. Although milled material may show a log-normal distribution (4), the particle size distributions for milled particles in this study show a linear relationship on arithmetic probability plots indicating near normal distribution. Some plots show departure from linearity at extremes indicating nonasymptotic distribution; however, the usefulness of the data is not reduced.

Table I shows that the output screen size, d_{ss}, has a significant effect on the arithmetic mean size, $d_{\bar{x}}$, of the milled particles. Since the average feed particle size does not show a significant effect at setting 4, the data can be pooled.

It is expected that decreasing d_{ss} would decrease the particle size of the milled particles, as was confirmed in this study. However, no relationship between d_{ss} and milled particle size has been reported. It is also not known how decreasing d_{ss} would affect the magnitude of σ for the particle size distribution of the milled particles.

A simple relationship may be hypothesized between d_{ss} and $d_{\bar{x}}$ of the milled particles and may be expressed as:

$$d_{\bar{x}} = k/d_{ss} \qquad \text{(Eq. 1)}$$

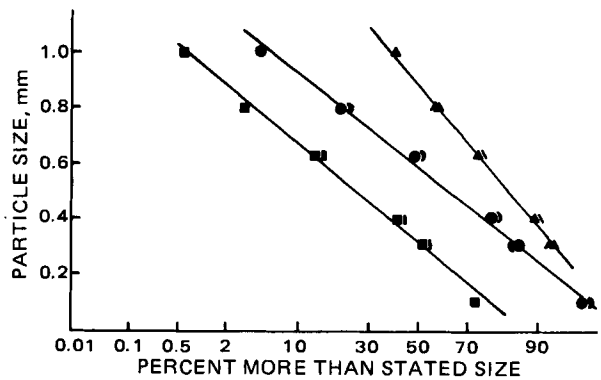

Figure 4—*Effect of varying milling speed on the particle size distribution,* d_{ss} *= 2.0 mm. Feed particle size range, 1.6–1.0 mm. Key (speed):* ▲, *setting 2 (~1000 rpm);* ●, *setting 4 (~2500 rpm); and* ■, *setting 8 (~5000 rpm).*

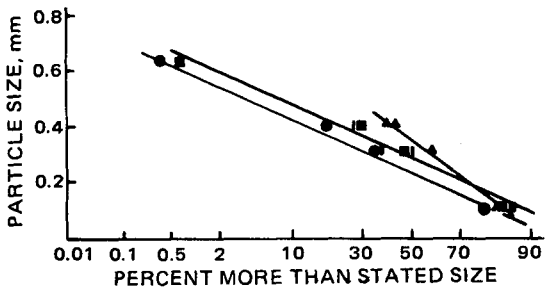

Figure 5—*Effect of varying milling speed on the particle size distribution,* d_{ss} *= 1.0 mm. Feed particle size range, 1.6–1.0 mm. Key (speed): ▲, setting 2 (~1000 rpm); ■, setting 4 (~2500 rpm); and ●, setting 8 (~5000 rpm).*

based on data in Table I where k is a particle size reduction factor. The value of k for Table I data is 0.294 (n = 9, SD = 0.022). This means that $d_{\bar{x}}$ is about one-third less in size than the output screen size, regardless of the feed particle size range used in this experiment, at a moderate milling speed setting of 4 on this mill.

The effect of d_{ss} on the particle size range distribution of milled particles can be seen by comparing its standard deviation. As d_{ss} decreased, σ decreased, *i.e.*, the particle size distribution became narrower. The distributions were unaffected by the feed particle size due to a narrowing of the angle of particle discharge range as output screen size became smaller.

It should be noted that the thickness of the 1-mm output sieve is approximately half of the 2- and 1.5-mm sieves. Decreasing the thickness of the output screen should increase the range of particle discharge angles (6). Thus, the observed data for the 1-mm size should be viewed with caution.

Effect of Milling Speed—The speed at which a mill operates is an important factor in particle reduction. At any given speed, as the material is fed, a mill slows down due to attrition of particles by the hammers until most of the material is discharged and the speed returns to the unloaded speed.

Figures 4 and 5 show the effect of milling speed on the milled product at varying output screen sizes. The arithmetic mean, $d_{\bar{x}}$, and standard deviation (σ) of the milled particles are shown in Table II.

It was expected that milling at higher speeds would further reduce the average particle size of the milled product due to the decreased angle of particle discharge (6). However, the extent of reduction or its effect on the range of particle size distribution of the milled particles has not been reported.

At settings 2, 4, and 8, the mill speeds are ~1000, 2500, and 5000 rpm, respectively. Table II shows that as the mill speed increases, the arithmetic mean of the milled particle decreases. This decrease is of a greater magnitude for the larger output screen size (2 mm) than for the smaller output screen size (1 mm).

At low speeds, the standard deviation of the milled particles is larger compared to medium and high speeds. This is reasonable because at lower speeds the particles are not expected to be discharged at a steeper angle. As the rotational speed increases, the angle of discharge reaches some optimum value, *i.e.*, the particles cannot be discharged at an angle lower than the optimum, and a leveling off of the standard deviation is observed.

Figure 6 shows the effect of output screen size and speed on the average particle size of the milled particles. The feed particle size range was 1.6–1.0 mm.

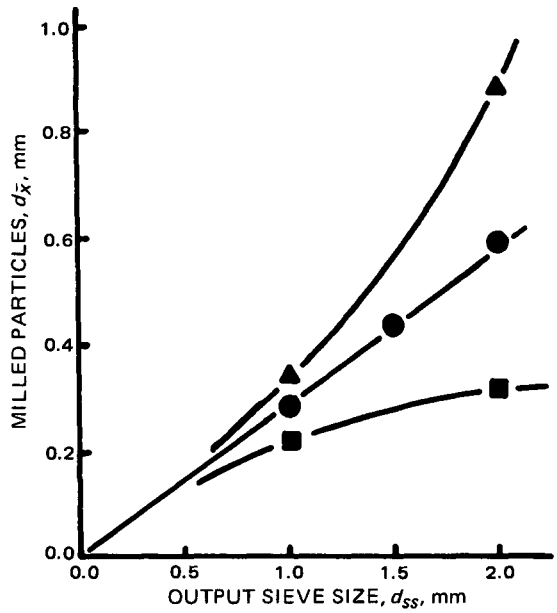

Figure 6—*Effect of* d_{ss} *on* $d_{\bar{x}}$ *of the milled particles at varying milling speeds. Key (speed): ▲, setting 2 (~1000 rpm); ●, setting 4 (~2500 rpm); and ■, setting 8 (~5000 rpm).*

The plot shows that Eq. 1 holds true at a moderate speed in this experimental series, the slope of the line being particle size reduction factor k. Equation 1 does not hold true at a low milling speed (setting 2) or at a high milling speed (setting 8). The equation plot passes through the origin as it would be expected; if the output screen size were zero, then no milled particles would be obtained.

Further work is in progress to determine the mathematical relationship of a change in k and to study milling characteristics of other selected pharmaceuticals.

Solubility and Ionization Characteristics of Doxepin and Desmethyldoxepin

KORAL EMBIL and GEORGE TOROSIAN[x]

Received February 23, 1981, from the *College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication June 11, 1981.

Abstract □ The thermodynamic pKa values for doxepin and its metabolite desmethyldoxepin were determined by the solubility method to be 8.96 and 9.75, respectively at 25°. The intrinsic solubilities for doxepin and desmethyldoxepin were linearly dependent upon ionic strength. The intrinsic solubilities at zero ionic strength and 25° were determined to be 1.13×10^{-4} *M* for doxepin and 3.95×10^{-4} *M* for desmethyldoxepin. The solubility experiment was repeated at different temperatures and a constant ionic strength of 0.167 *M*. The change in enthalpy (6.71 kcal/mole) and entropy (−4.16 cal/mole °K) of solution for doxepin was determined from a van't Hoff plot for this nonideal system. The apparent partition coefficient between hexane and water for the doxepin free base was determined to be 13,615 at an ionic strength of 0.067 *M*.

Keyphrases □ Doxepin—solubility and ionization characteristics □ Desmethyldoxepin—solubility and ionization characteristics □ Solubility—of doxepin and desmethyldoxepin, ionization characteristics □ Ionization—of doxepin and desmethyldoxepin, solubility

Doxepin hydrochloride is one of a class of psychotherapeutic agents known as dibenzoxepin tricyclic compounds. To further understand its *in vivo* behavior, the fundamental physicochemical properties of doxepin and one of its metabolites, desmethyldoxepin, were studied. These properties may partially explain the ability of the drug to cross membranes and accumulate and/or distribute in various tissues. The ease of extraction of the drug from biological samples, even at pH values at which the protonated species predominate, may be explained by the magnitude of the partition coefficient and the intrinsic solubility of the free base.

The apparent ionization constants for similar tricyclic compounds were determined earlier using the solubility method (1). Similarly, the solubility method was also used to obtain an apparent pKa value for phenytoin (2).

In this paper, apparent pKa values were determined for doxepin and desmethyldoxepin at different ionic strengths and were used to calculate the thermodynamic pKa values for each compound. In addition, the intrinsic solubilities at zero ionic strength were also determined.

EXPERIMENTAL

Materials—Doxepin and desmethyldoxepin were gifts[1]. Sodium chloride, sodium hydroxide, sodium carbonate, hydrochloric acid, and hexane were all reagent grade and used as obtained.

Determination of pKa—The intrinsic or saturated solubility of doxepin and desmethyldoxepin at different pH values was determined and plotted using the following (3, 4):

$$\mathrm{pH} = \mathrm{pKa} - \log\left(\frac{S}{S_0} - 1\right) \qquad \text{(Eq. 1)}$$

where S_0 is the intrinsic solubility of the free base, and S is total solubility and includes both protonated and unprotonated forms of the drug.

The experiment was carried out by determining the solubility of the compound at several pH values. Ten 15-ml culture tubes with polytef[2]-lined screw caps were silylated[3] and maintained at 25° to minimize the separation of the drug as an oil. Into each pair of tubes, 1 ml of 0.05 carbonate buffer (pH 9.0–10.8) was added.

The solubility for each compound was determined at four to six different pH values at constant ionic strength. The intrinsic solubility (S_0) was obtained by measuring the amount of drug in solution at 25° after the pH was adjusted to 12.6 with sodium hydroxide. This pH provided a ratio in excess of 1000:1 in favor of the unprotonated species. Five milliliters of stock solution (1.0×10^{-3} *M* of doxepin hydrochloride or 4.5×10^{-3} *M* desmethyldoxepin hydrochloride) was added to all tubes, approximating a 10-fold excess of drug as the free base.

The tubes were capped, sealed with paraffin film[4], and equilibrated in a water bath at 25° for 5 hr and centrifuged[5] at 25° and 3000 rpm for 30 min. The supernate was then transferred into a clean culture tube to minimize the redispersion of excess drug present as an oil. The solutions that did not exhibit a Tyndall effect were assayed spectrophotometri-

cally[6] at 292 nm and their pH values were recorded[7]. The absorbances were then converted into concentrations using a standard curve.

Determination of Thermodynamic Parameters—The van't Hoff plot was obtained by determining the intrinsic solubility of doxepin at different temperatures, but at constant ionic strength and plotting the natural log of the mole fractions (X_2) *versus* the reciprocal of the absolute temperatures. The thermodynamic parameters ΔH and ΔS, the change in ethalpy and entropy, respectively, were obtained from the slope and intercept, (5):

$$\ln X_2 = \frac{\Delta S}{R} - \frac{\Delta H}{R}\left(\frac{1}{T}\right) \qquad \text{(Eq. 2)}$$

where R is the gas constant and T is the absolute temperature.

The procedure to determine these parameters was identical to that for the pKa determination, except that 16 tubes were used for each temperature (5, 10, 13, 18, and 25°), and sufficient sodium hydroxide was used to adjust the pH to a constant 12.6. The solutions were brought to temperature (to minimize pressure changes inside the tubes) prior to capping. The tubes were then equilibrated at the selected temperature. After equilibration, the tubes were transferred immediately into a refrigerated centrifuge and spun at 7000 rpm for 40 min at a constant temperature.

The supernate of replicate tubes were combined, transferred into a clean tube and centrifuged[8] at 7000 rpm for an additional 1 hr. The resultant supernate (10 ml) was then spectrophotometrically analyzed as described previously. The data obtained from the doxepin solubilities were converted to mole fractions using the appropriate specific gravity of the solution in question. Specific gravities were determined with a 25-ml pycnometer.

In all cases, the differences in weight per milliliter between the samples and distilled water was less than 1%; hence, the thermodynamic values were obtained from these data without the correction for volume changes upon mixing.

Determination of Partition Coefficient—The conditions were identical to those used in the pKa determination except that four 20-ml tubes were used, each containing 15 ml of doxepin stock solution (7.5×10^{-2} *M*), sufficient sodium hydroxide to obtain a constant pH of 12.6, and 0.5 ml of hexane. After equilibration, the tubes were centrifuged[4] at 2500 rpm for 20 min, and both phases were assayed spectrophotometrically at 292 nm for doxepin content. Saturation of both phases by doxepin was confirmed by repeating the assays at various time intervals during the equilibration period of 5 hr and observing that the drug concentration in both phases remained constant. Excess free base of doxepin was clearly visible in the container forming a separate phase of oil droplets within the aqueous layer. The drug concentration in each phase was calculated, adjusted for volume differences, and used to determine the apparent partition coefficient.

RESULTS AND DISCUSSION

Figure 1 shows the linear relationship of the intrinsic solubility of doxepin and desmethyldoxepin free base obtained at the corresponding ionic strengths. The reduction of the intrinsic solubility with increasing ionic strength may be due to a salting-out effect. The intrinsic solubility at zero ionic strength and 25° was determined from the intercept of the least-squares regression to be 1.13×10^{-4} *M* with a standard error of $\pm 3.12 \times 10^{-6}$ *M* for doxepin and 3.95×10^{-4} *M* with a standard error of $\pm 1.75 \times 10^{-6}$ *M* for desmethyldoxepin.

Tricyclic antidepressants have a high surface activity and it was speculated (1) that they may form micelles. It is therefore possible that the true solubilities may be slightly lower than those indicated. However, discontinuities in the spectrophotometric standard curves which would suggest association, have not been observed over the solubility range. In addition, no Tyndall effect has been detected visually. Therefore, associated species or micelles do not appear to be formed at the concentrations studied for doxepin and desmethyldoxepin.

Figure 2 shows a typical plot of $-\log(S/S_0 - 1)$ *versus* pH (Eq. 1) for doxepin and desmethyldoxepin at an ionic strength of 0.05 *M*. For each compound, the apparent pKa was obtained from the intercept of the least-squares regression line over a range of ionic strengths. For each determination of the apparent pKa, the intrinsic solubility was used at the appropriate ionic strength required. At low ionic strengths of <0.01 *M*, the equation relating pKa to ionic strength (I) is described by (6):

$$pKa^T = pKa^A - 0.505\sqrt{I} \qquad \text{(Eq. 3)}$$

where pKa^T is thermodynamic pKa and pKa^A is apparent pKa.

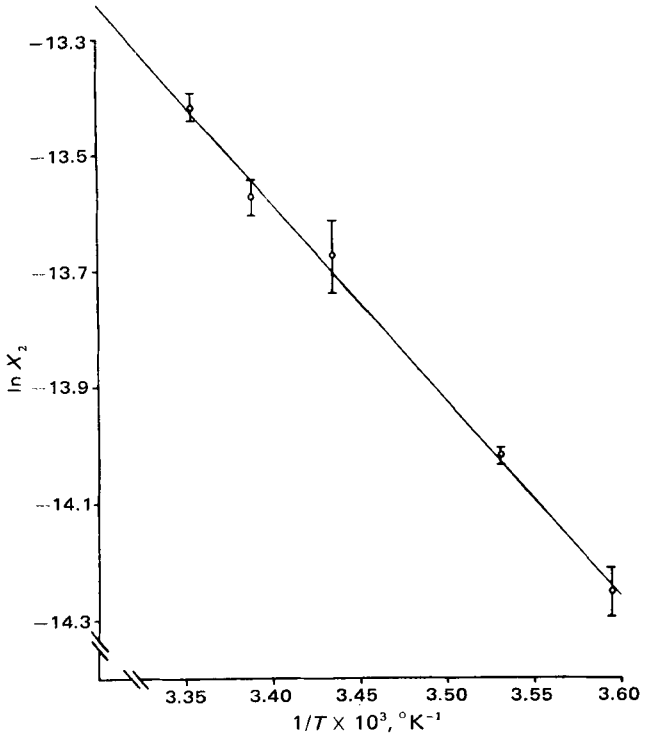

Figure 4—*The van't Hoff plot of ln* X_2 versus 1/T, *in degrees K, for doxepin at an ionic strength of 0.167* M. *Error bars indicate one standard error around the mean with each point representing four to eight determinations.*

Figure 3 shows the least-squares regression line representing the relationship between the apparent pKa values and the square root of the ionic strength of the system at which they were determined (Eq. 3). The y-intercept yields a pKa^T of doxepin at zero ionic strength of 8.96 with a standard error of ±0.05. This value substantially differs from the value of 8.0 (7) but is similar to the apparent pKa of other tricyclics with a similar alkyl side chain, such as chlorpromazine and imipramine whose apparent pKa values are 9.3 and 9.5, respectively (1).

For desmethyldoxepin, a pKa^T value of 9.75 with a standard error of ±0.05 was obtained from the intercept of the least-squares regression line. This value is in the same range as other demethylated tricyclic compounds such as desipramine, whose apparent pKa is 10.2 (1). The increase in the pKa of desmethyldoxepin over that of doxepin may be due to the loss of a methyl group and its replacement by a hydrogen atom on the amine side chain. Hydrogen bonding between the solvent water and the hydrogen atom on the secondary amine of desmethyldoxepin displaces the hydrogen from the nitrogen, causing the nitrogen to be more electron rich, hence, increasing its basic character. This increased basicity leads to a weaker conjugate acid and an increase in pKa (8).

The linearity of the van't Hoff plot ($r^2 = 0.979$) indicates that the number of water molecules necessary for solvation is temperature independent in the range tested. The slope and the intercept of the van't Hoff plot yielded the thermodynamic values for the change in entropy and enthalpy of solution (Fig. 4). The change in enthalpy of solution was 6.71 with a standard error of ±0.19 kcal/mole, a positive value indicating that the system absorbed heat from its surroundings as would be expected from a nonpolar molecule with low aqueous solubility. The change in entropy of solution was −4.16 with a standard error of ±0.64 cal/mole °K.

The apparent partition coefficient for doxepin in hexane–water was determined at pH 12.6 and was 13,615: 1 with a standard deviation of ±360. The high value of the partition coefficient in hexane–water indicates the large lipid solubility of doxepin. The log of the partition coefficient was 4.13 and compares well with other tricyclic psychotherapeutic agents such as imipramine and chlorpromazine whose log octanol–water partition coefficients are 4.62 and 5.32, respectively (9). Preliminary experiments were able to extract 90% of 6.25×10^{-4} *M* doxepin contained in 30 ml of water with a single 3-ml sample of hexane by vortexing for 5 min at pH 7.5. This is 1.5 units below its pKa and the base should be substantially protonated; yet the extraction at a somewhat unfavorable pH took place with ease, apparently due to its large partition coefficient.

However, only 75% of 6.33×10^{-4} *M* desmethyldoxepin was extracted at pH 8.7, 1.3 units below its pKa but otherwise similar conditions. Although the partition coefficient of desmethyldoxepin was not determined in hexane–water, we speculate that it cannot be as large as that of doxepin. Based on our calculations, using a direct proportionality of 90% doxepin with a partition coefficient of 13,615:1 to 75% desmethyldoxepin extracted under similar conditions, the partition coefficient of desmethyldoxepin for hexane–water was estimated to be about 10,000:1.

Nitrogen–Phosphorous Detection of Phencyclidine in Blood Serum

S. STAVCHANSKY ˣ and A. LOPER

Received April 6, 1981 from the *College of Pharmacy, Drug Dynamics Institute, The University of Texas, Austin, TX 78712.* Accepted for publication June 10, 1981.

Abstract □ A method for quantitating phencyclidine in the blood serum of rhesus monkeys with a solvent extraction procedure followed by gas chromatography with nitrogen–phosphorous detection is reported. Phencyclidine was extracted with ether from 0.5 ml of serum (pH 13.5) made basic with 2*M* NaOH, followed by back-extraction into 0.5 *M* sulfuric acid. After the addition of 2 *M* sodium hydroxide, phencyclidine was extracted into a small volume of ether for concentration and injection into the gas chromatograph. The limit of quantitation of phencyclidine in serum was 5 ng/ml. Recovery averaged 51.9 ± 4.3%. Standard curves were linear between 5–50 ng/ml and 100–2000 ng/ml. Comparison between serum and aqueous standards indicated no interference by serum components in the extraction procedure. Pentobarbital, caffeine, and the monohydroxy metabolites of phencyclidine did not interfere with the analysis. This procedure is a rapid and sensitive method for determination of serum phencyclidine levels in animal studies requiring analysis of large numbers of samples.

Keyphrases □ Phencyclidine—analysis using gas chromatography with nitrogen–phosphorous detection, rhesus monkey blood serum □ Gas chromatography—nitrogen–phosphorous detection of phencyclidine in rhesus monkey blood serum □ Drugs of abuse—phencyclidine, analysis using gas chromatography with nitrogen–phosphorus detection, rhesus monkey blood serum

The popularity of phencyclidine [1-(1-phenylcyclohexyl)piperidine] as a drug of abuse has stimulated interest in determination of the drug in body fluids (1, 2). Persons who have ingested phencyclidine (I) often show signs of intoxication even when serum levels are low (10 ng/ml) (3). TLC methods and qualitative, presumptive tests which indicate the presence, but not the concentration, of I in biological matrixes were reported previously (4, 5).

Spectrophotometric quantitation of I after solvent extraction of specimen suffers from the lack of adequate detection limits (4). Homogeneous enzyme immunoassays for I in urine show cross-reactivity with analogs and inactive metabolites of I (6, 7). Radioimmunoassay for I in plasma is sensitive enough for quantitation at plasma levels of ~1 ng/ml (8–10), but some cross-reactivity (2–5%) is seen with hydroxylated metabolites of I in two of these radioimmunoassay procedures (9, 10).

Investigation of an ion-selective electrode for I indicates that potentiometric analysis may provide adequate specificity for the parent drug (11). The reported sensitivity of this electrode is poor compared with radioimmunoassay or gas chromatographic (GC) methods. Preconcentration of sample could possibly lower detection limits; however, this has not been evaluated for use with the phencyclidine-selective electrode.

BACKGROUND

Numerous GLC assays have been used for separation of phencyclidine in biological matrixes. Flame-ionization detection after GC separation of serum extracts cannot provide sufficient sensitivity (4, 12, 13). GC with mass spectrometry lowers detection limits to as little as 5 ng of I/ml in plasma, whole blood, and urine (14–18). Analytical procedures using GC with nitrogen–phosphorous detection provide sensitivity comparable to mass spectrometry (3, 19, 20). However, the solvent extraction procedures reported for sample cleanup prior to separation and subsequent quantitation by nitrogen–phosphorous detection are too laborious for rapid processing of many specimens, or require a larger volume of specimen than is available in studies with small animals.

The analytical procedure reported here combines a rapid extraction procedure for 0.5 ml of blood serum with GC separation and nitrogen–phosphorous detection. This method is particularly useful for analyses in pharmacokinetic studies of phencyclidine in small animals.

EXPERIMENTAL

Apparatus—GC was performed with a gas chromatograph equipped with a nitrogen–phosphorous detector[1]. A 122-cm coiled glass column, 0.2-cm i.d., was silylated with 2% trimethylchlorosilane in hexane and packed with 3% SP-2250-DB on a 100–120 mesh support[2]. The column was conditioned overnight at 250° with a helium flow of 15 ml/min. Gas flows were a helium carrier flow of 25 ml/min and a hydrogen flow of 2.5 ml/min. Air was maintained at a constant pressure of 40 psi. Inlet temperature was 195°, column temperature was 185°, and the detector temperature was 210°. Background current was set at 4×10^{-11} amp.

Reagents—Phencyclidine hydrochloride and two monohydroxy metabolites [4-phenyl-4-piperidinocyclohexanol and 1-(1-phenylcyclohexyl)-4-hydroxypiperidine] were obtained from the National Institute on Drug Abuse. Melting point determinations[3] and electron-impact mass spectrometry[4] were used to confirm identity and purity of the compounds. TLC of phencyclidine produced only one spot on silica gel G, 250-μm plates[5]. Plates were developed with chloroform–ethyl acetate–acetone–triethylamine (38:30:30:2). Spots were visualized by charring with sulfuric acid and heat.

Ketamine hydrochloride[6], caffeine[7], and pentobarbital sodium[8] were used as received. Nanograde ether[9] was distilled in glass each day after

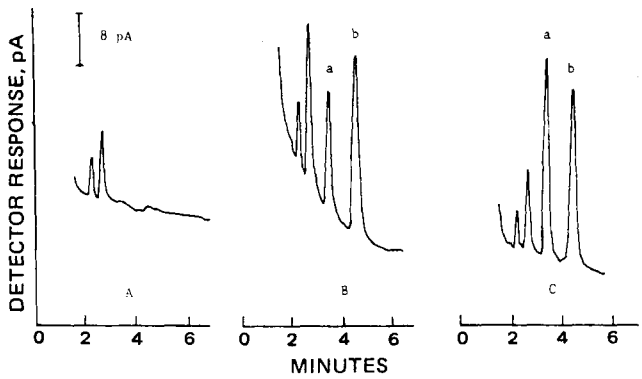

Figure 1—*Chromatograms obtained from extraction and assay of 0.5 ml of blood serum from a rhesus monkey (A), from a 0.5-ml serum sample spiked with 25 ng of phencyclidine and 50 ng of ketamine (B), and from 0.5 ml of serum obtained from a 6.7-kg male rhesus monkey 1.5 hr after intravenous administration of 1.6 mg of phencyclidine/kg (C). Estimated concentration of phencyclidine (a) was 75.4 ng/ml. The concentration of ketamine (b) was 100 ng/ml.*

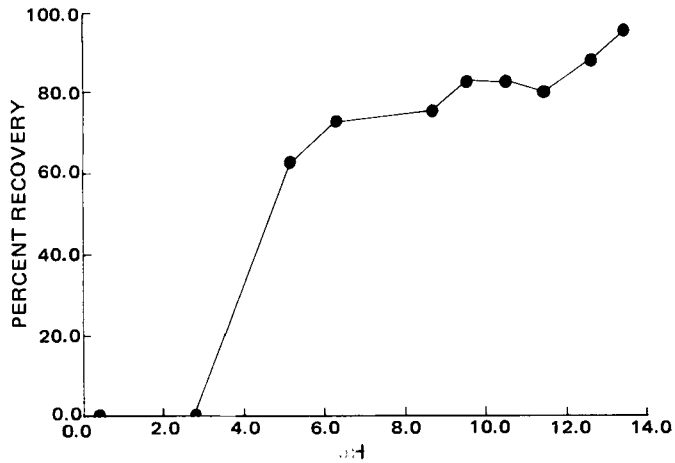

Figure 2—*Recovery of phencyclidine from aqueous solutions of varying pH. Maximum recovery occurs at pH 13.5.*

the addition of aluminum lithium hydride. All other materials were reagent grade.

Procedure—Serum (0.5 ml) obtained from rhesus monkeys was pipetted into a silylated glass tube with a screw cap with an inert liner. For serum phencyclidine concentrations of ~5–20 ng/ml, 50 μl of aqueous ketamine hydrochloride solution (200 ng/ml) was added to each tube as an internal standard. Serum concentrations of 20–100 ng of phencyclidine/ml required 50 μl of aqueous ketamine hydrochloride solution (1 μg/ml), and phencyclidine levels of 100–2000 ng/ml required 50 μl of ketamine solution (10 μg/ml). All stock solutions of phencyclidine and ketamine hydrochloride were prepared with deionized water. Preparation of stock solutions with methanol did not affect extraction and quantitation of phencyclidine and internal standard.

Serum was adjusted to a pH of 13.5 with 0.5 ml of 2 *M* NaOH. Ether (2 ml) was added to each tube. The tubes were placed on a vortex mixer for 60 sec to extract the free bases of phencyclidine and internal standard into the organic phase. The aqueous and organic phases were separated by centrifuging at 3000 rpm for 2 min, and then freezing the aqueous layer in a dry ice–acetone bath. The organic layer was decanted into a second tube containing 0.5 ml of 0.5 *M* H_2SO_4. Phencyclidine and internal standard were back-extracted from the ether into the aqueous layer by vortexing for 30 sec.

Samples were centrifuged at 3000 rpm for 1 min and immersed in a dry ice–acetone bath. The organic layer was discarded, and the aqueous layer was allowed to return to room temperature. The aqueous layer, 0.5 ml of 2 *M* NaOH, and 250 μl of distilled ether were vortexed together for 30 sec and centrifuged for 1 min. After the aqueous phase was frozen in dry ice–acetone, the ether layer was decanted into a conical vial. A small amount of anhydrous potassium carbonate was added to each sample to remove residual moisture. The ether layer was allowed to evaporate to a volume of 10–50 μl. One to five microliters of the sample was injected into the gas chromatograph. After every six injections, a 30-min wait was necessary to allow slow-eluting compounds to be eliminated from the column.

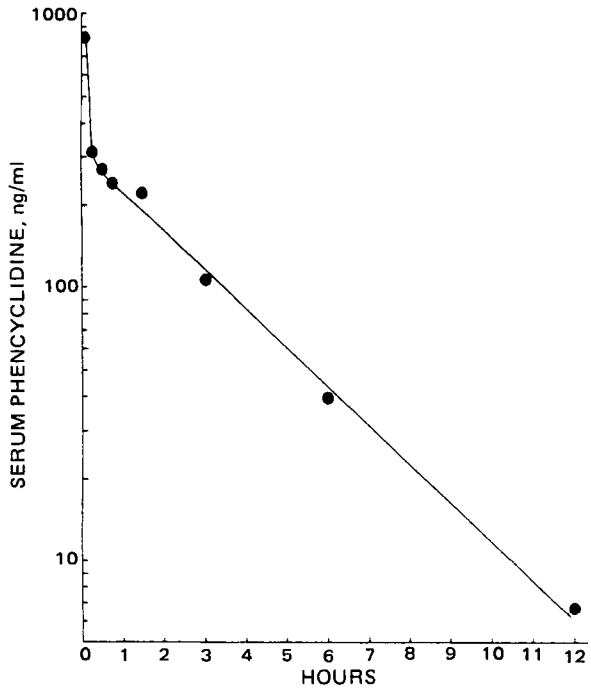

Figure 3—*Semilogarithmic plot of serum levels of phencyclidine in a 5.0-kg male rhesus monkey after administration of a 1.6 mg/kg iv dose.*

Table I—Phencyclidine Recovery from Serum Standards

Phencyclidine Concentration, ng/ml	Mean Recovery[a] ± *SD*, %
4.9	53.7 ± 15.3
9.8	50.5 ± 4.2
48.9	59.5 ± 3.5
97.8	49.1 ± 1.2
489.0	51.2 ± 4.2
978.0	47.5 ± 2.0

[a] Average of six determinations.

A calibration curve was constructed by plotting peak height ratio of phencyclidine to internal standard against the phencyclidine concentration. Serum standards were prepared by addition of appropriate aliquots of aqueous phencyclidine solutions (50 ng/ml, 0.5 μg/ml, or 5 μg/ml) to 0.5 ml of blank serum obtained from dogs or rhesus monkeys. Standard concentrations ranged from 5 to 2000 ng/ml. Standards were extracted and assayed in the same manner as the samples. Standards were also prepared in deionized water and treated identically to serum standards to determine if serum components affected extraction or quantitation of phencyclidine or internal standard.

Recovery of Phencyclidine—Serum standards containing either 4.9, 9.8, 48.9, 97.8, 489.0, or 978.0 ng of phencyclidine/ml and no internal standard were extracted by the same procedure. The final ether extracts were allowed to evaporate to dryness and then reconstituted with 10–100 μl of ethyl acetate containing 2 μg of ketamine/ml. One to five microliters was injected into the gas chromatograph. Peak height ratios of phencyclidine to ketamine were compared with those ratios obtained from ethyl acetate solutions containing 1 or 5 μg of phencyclidine/ml and 2 μg of ketamine/ml.

A profile of phencyclidine recovery *versus* pH of an aqueous solution was constructed. The pH was adjusted with either sulfuric acid or sodium hydroxide solutions. Phencyclidine was present in a concentration of 50 ng/ml. One milliliter of aqueous solution and 2 ml of ether were vortexed for 60 sec and centrifuged at 3000 rpm for 2 min. The ether layer was decanted into a conical vial after freezing the aqueous layer in a dry ice–acetone bath. After evaporation of the ether, samples were reconstituted and treated as already described.

Interference by Other Compounds—Fifty microliters of 1 mg/ml methanolic pentobarbital sodium or caffeine solution was added to 1 ml of deionized water. Methanolic solutions of the two monohydroxy metabolites were used to prepare urine samples containing 1 mg/ml of each metabolite. The resulting samples were extracted and quantitated by the same procedure used for serum to check for interference with phencyclidine or ketamine peaks.

RESULTS AND DISCUSSION

Figure 1 shows representative chromatograms for a serum blank from a male rhesus monkey, a serum blank spiked with phencyclidine, and

Table II—Summary of Linear Regression Analysis of Composite Standard Curves for Phencyclidine in Serum or Water[a]

Standard Curve	Equation	Correlation Coefficient	Standard Error of the Estimate
Serum, 5–50 ng/ml	$y = 0.013x - 0.005$	0.993	0.024
Serum, 100–2000 ng/ml	$y = 0.014x - 0.613$	0.999	0.348
Water, 5–50 ng/ml	$y = 0.014x - 0.005$	0.996	0.020
Water, 100–2000 ng/ml	$y = 0.014x + 0.262$	0.999	0.112

[a] No significant difference between equations for serum and water exists.

Table III—Day-to-Day Coefficient of Variation in Peak Height Ratios for Phencyclidine Serum Standards

Standard Concentration, ng/ml	Number of Determinations	Coefficient of Variation, %
4.9	5	8.3
9.8	5	9.0
14.7	3	6.3
19.6	1	—
48.9	9	4.2
97.8	6	5.5
489.0	5	3.0
685.0	4	8.9
978.0	4	15.7
1958.0	2	8.4

serum obtained 1.5 hr after administration of a 1.6 mg/kg iv dose of phencyclidine to a 6.7-kg male rhesus monkey. Retention times of phencyclidine and internal standard are 3.6 and 4.7 min, respectively. Chromatography of phencyclidine and ketamine at 185° produced good resolution of the two peaks (R = 1.5, 99.7% resolution). Reducing the temperature below 185° produced peak broadening. The lower viscosity of the stationary phase of the SP-2250-DB packing relative to 3% OV-17 allowed operation at lower column temperatures, thus preventing the thermal degradation of phencyclidine to 1-phenylcyclohexene (16). The chromatogram of the serum blank shows two unidentified peaks eluting at 2.3 and 2.7 min. These peaks do not interfere with the analysis. However, small interfering peaks (not evident in this chromatogram) with retention times of 3–5 min were seen with some serum samples. This serum background limited quantitation of phencyclidine in rhesus monkey serum to ~5 ng/ml.

Application of this extraction and quantitation technique to human serum[10] or plasma[11] resulted in a frequent appearance of interfering peaks with retention time of 4–5 min. This interference could not be assigned to pentobarbital, which produced no interfering peaks in the chromatogram, or to caffeine, which produced a peak at 6 min. Extraction and quantitation of the monohydroxy phencyclidine metabolites produced a broad peak at 12 min. Human serum obtained with evacuated collection tubes[12] suitable for trace analysis did not exhibit these large interfering peaks in the chromatogram. This suggests that the interferences seen with serum and plasma extracts might be artifacts of collection or storage. GC–mass spectrometry of extracts containing the interfering substance indicated that it is a basic compound with a probable molecular ion at m/z 86. Further studies are planned to elucidate the structure of this substance.

Hexane and ethyl acetate, as well as ether, were initially evaluated as extracting solvents, since they contained few impurities which interfered with nitrogen–phosphorous detection. However, hexane produced emulsification upon vigorous mixing with serum. The less volatile ethyl acetate (relative to ether) increased the time required to concentrate the final extract.

The percent recovery of phencyclidine from aqueous solutions of varying pH values is shown in Fig. 2. Maximum recovery was 95% at pH 13.5. The single extraction step used in these determinations was not adequate to produce a serum extract free from interference; therefore, phencyclidine was back-extracted into 0.5 M sulfuric acid. Virtually 100% of the phencyclidine should partition into the aqueous layer at this pH (pH < 1) (Fig. 2). Final extraction of phencyclidine from a basified aqueous phase into as small a volume of ether as practical (250 μl) reduced the time required to concentrate the final extract. The average recovery of phencyclidine from serum standards was 51.9 ± 4.3% after the necessary back-extraction steps (Table I).

Linear relationships were found between peak height ratio and phencyclidine serum concentration for concentrations from 5–50 and 100–2000 ng/ml. Above 2000 ng/ml, detector response was no longer linear. The least-squares regression equations are shown in Table II. Statistical analyses (21) indicated no significant difference (p = 0.01) existing between serum and aqueous standard curves at all concentrations. Thus, serum components do not appear to affect the extraction and quantitation procedures. Within-day coefficients of variation in peak height ratios (n = 6) for the 48.9 and 489.0 ng/ml standards were 3.9 and 1.6%, respectively. The day-to-day variation in peak height ratios is presented in Table III. The coefficient of variation is <10% for all but the 978.0 ng/ml standard. The day-to-day coefficient of variation averaged 7.7% over all concentrations.

Serum phencyclidine levels after administration of a 1.6 mg/kg iv dose to a rhesus monkey are shown in Fig. 3. The animal was fasted overnight prior to receiving the dose. After 12 hr, no detectable levels of phencyclidine were present in the serum. The biological half-life, calculated after computer fit of the data to a biexponential equation, was 2.1 hr, which agrees with phencyclidine half-lives in rhesus monkeys reported earlier (14). This rapid extraction procedure, combined with satisfactory detection limits provided by GC with nitrogen–phosphorous detection, is advantageous in animal studies involving numerous small serum samples. In addition, this assay procedure deserves further investigation for clinical use.

Mechanism of Action of Granaticin: Inhibition of Ribosomal RNA Maturation and Cell Cycle Specificity

PETER HEINSTEIN

Received December 10, 1980 from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, W. Lafayette, IN 47907.* Accepted for publication May 21, 1981.

Abstract □ Granaticin, an antibiotic produced by *Streptomyces* species was found to be cytotoxic (ED_{50} 3.2 μg/ml) against human oral epidermoid carcinoma (KB) cells. At ED_{50} concentrations RNA synthesis was inhibited to the greatest extent. Prelabeling of RNA in KB cells, followed by addition of granaticin (2.13 μg/ml) showed that ribosomal RNA maturation was inhibited. The inhibition of the formation of functional ribosomal RNA was determined by sucrose gradient centrifugation and showed that the accumulation of 45S preribosomal RNA was dependent on granaticin concentration and on the time granaticin was in contact with the KB cells. The effect of granaticin (6.3 μg/ml) on KB cells in the different cell cycle phases showed preferential inhibition (93%) of cell survival in the G_2 phase. However, RNA synthesis was only 20% inhibited by granaticin in KB cells in the G_2 phase. From these results, it was concluded that ribosomal RNA maturation was not the only site of action of granaticin toxicity.

Keyphrases □ Granaticin—cytotoxicity, mechanism of action, in human oral epidermoid carcinoma cells □ Cytotoxicity—granaticin, mechanism of action, in human epidermoid carcinoma cells □ Anticancer agents—granaticin, mechanism of action

Granaticin, an antibiotic produced by the *Streptomyces* species was first reported (1) as a fermentation product of *Streptomyces olivaceus*. Its structure was clarified by Keller-Schierlein *et al.* (2). Subsequently, granaticin or its L-rhodinoside, granaticin B, was isolated from *S. violaceoruber* (3), *S. litmogenes* (4), and *S. thermoviolaceus* (5). Granaticin was active against Gram-positive bacteria (6) and showed anticancer activity against P-388 lymphocytic leukemia in mice and cytotoxicity against human oral epidermoid carcinoma (KB) cells (7).

BACKGROUND

Granaticin was reported to inhibit RNA synthesis in bacteria (8). This inhibition was originally attributed to the interaction of granaticin with the DNA template. More recently, the mechanism of action of granaticin in bacteria has been attributed to the inhibition of aminoacylation of leucyl-tRNA by interaction with an aminoacyl-tRNA synthetase (9). It was not determined whether or not this inhibition was due to binding of granaticin to tRNA. Another report (10) showed that granaticin inhibited viral RNA-dependent DNA polymerase isolated from RNA tumor viruses, *i.e.*, Rauscher murine leukemia virus, simian sarcoma virus type 1, and avian myeloblastosis virus. From the sequential addition of granaticin to the reaction, it was proposed that granaticin interacts with the template (RNA) and not the reverse transcriptase. However, direct binding of granaticin to templates was not shown.

Since these results indicated an inhibitory action of granaticin on RNA metabolism, the mechanism of action of granaticin in mammalian cells was studied. In the present study, the effect of granaticin on the formation of functional ribosomal RNA in KB cells, on the uptake of uridine by KB cells and its subsequent phosphorylation, and on the cell cycle traverse of KB cells was investigated.

MATERIAL AND METHODS

Stock solutions of granaticin A[1] were prepared by dissolving 3 mg of granaticin in 0.03 ml of dimethyl sulfoxide and diluting to 10 ml with basal salt solution (11), pH 7.2.

Human oral epidermoid carcinoma cells[2] (KB cells) were grown in monolayer cultures with basal medium supplemented with 10% heat denatured (57°) fetal calf serum containing 100 U of penicillin and 100 g of streptomycin/ml (12, 13). Cells were maintained at 37° in an atmosphere of 5% CO_2 in air and subcultured every 2–3 days. For experiments, cells were detached from the glass support with trypsin–ethylenediaminetetraacetic acid[3], collected by centrifugation, washed and suspended in fresh medium, plated at a density of 5×10^4–1×10^5 cells/ml, and incubated for 3 hr at 37° to allow attachment to the support before an experiment was initiated.

Macromolecular synthesis was measured by the addition of [^{3}H]thymidine[4] (1 μCi/ml cells; 26.1 μCi/μmole) for DNA synthesis, [^{3}H]uridine[4] (1 μCi/ml cells; 22 μCi/μmole) for RNA synthesis, and [^{3}H]lysine[4] (1 μCi/ml cells; 50.4 μCi/μmole) for protein synthesis. Cells were disrupted and the macromolecules were precipitated with an equal volume of ice cold 10% trichloroacetic acid in 0.1 *M* pyrophosphate. The precipitates were collected on glass fiber filters[5], washed three times with trichloroacetic acid in 0.01 *M* pyrophosphate and two times with 0.1 *N* hydrochloric acid, and their radioactivity was determined.

Cell populations synchronized in the S-phase were obtained by a double-thymidine blockade (14–18). KB cells in the different phases were then treated with granaticin and RNA synthesis was measured through the incorporation of [^{3}H]uridine into acid-insoluble fractions. Cell survival after treatment with granaticin (6.2 μg/ml) for 1 hr in different phases of the cell cycle was measured by suspending washed cells in fresh medium. The cell suspension was diluted 1:1000, plated into plastic dishes, and incubated at 37° for 7 days. The number of colonies was determined under a microscope after staining with Giemsa.

The labeling, extraction, and isolation of nucleolar and cytoplasmic ribonucleic acid was described previously (19). KB cells at a concentration of 3.3×10^6 cells/ml were incubated with 1 μCi/ml [^{3}H]uridine (22 μCi/μmole) and 30 ml of medium. Identical incubations contained 2–5 μg of granaticin/ml of medium. Cells were harvested after 1–4 hr at 37°.

The uptake of [^{3}H]uridine and its subsequent conversion to uridine monophosphate, uridine diphosphate, and uridine triphosphate was measured by incubating 1.6–2.4×10^5 KB cells/ml with 1.1 μCi/ml

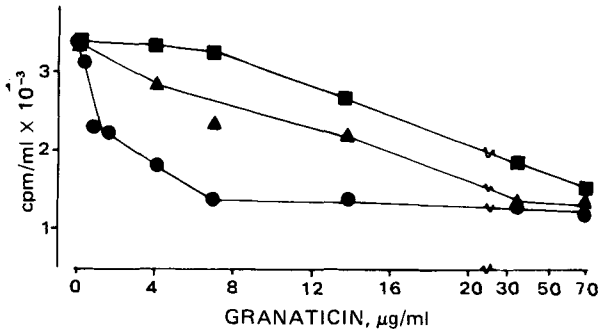

Figure 1—*Effect of granaticin on macromolecular synthesis. KB cells at a concentration of 1×10^5 cells/ml were plated 3 hrs before granaticin was added. DNA synthesis (■) was measured by the incorporation of [^{3}H]thymidine, RNA synthesis (●) was measured by the incorporation of [^{3}H]uridine, and protein synthesis (▲) was measured by the incorporation of [^{3}H]lysine. Granaticin was added 10 min before the radioactive precursor was added. The amount of acid-precipitated radioactivity was measured after the cells were in contact with granaticin for 1 hr.*

Table I—Effect of Granaticin on KB Cell Growth

Granaticin[a], μg/ml	Cells/ml × 10^{-5} [b] 24 hr	48 hr	72 hr
0	3.3	4.6	9.3
1.4	3.2	4.0	7.5
6.9	3.0	3.6	5.7
13.8	2.8	2.6	2.4
34.4	0.6	0.7	0.8

[a] Granaticin at the indicated concentrations remained in contact with the cells for 2 hr. The cells were then washed and incubated with fresh medium for 24, 48, and 72 hr. The number of cells remaining were determined by counting an aliquot in an eosinophil counter. Values are the average of three experiments.
[b] Cells were seeded at a concentration of 5 × 10^4 cells/ml 3 hr before granaticin was added.

[^{3}H]uridine (22 μCi/μmole) and with and without 1–2.75 μg of granaticin/ml. Aliquots were removed immediately after the addition of [^{3}H]-uridine and after 2 and 4 hr. The reaction was stopped with an equal volume of ice cold 10% trichloroacetic acid in 0.1 *M* pyrophosphate. The acid soluble fractions were analyzed by TLC followed by scintillation

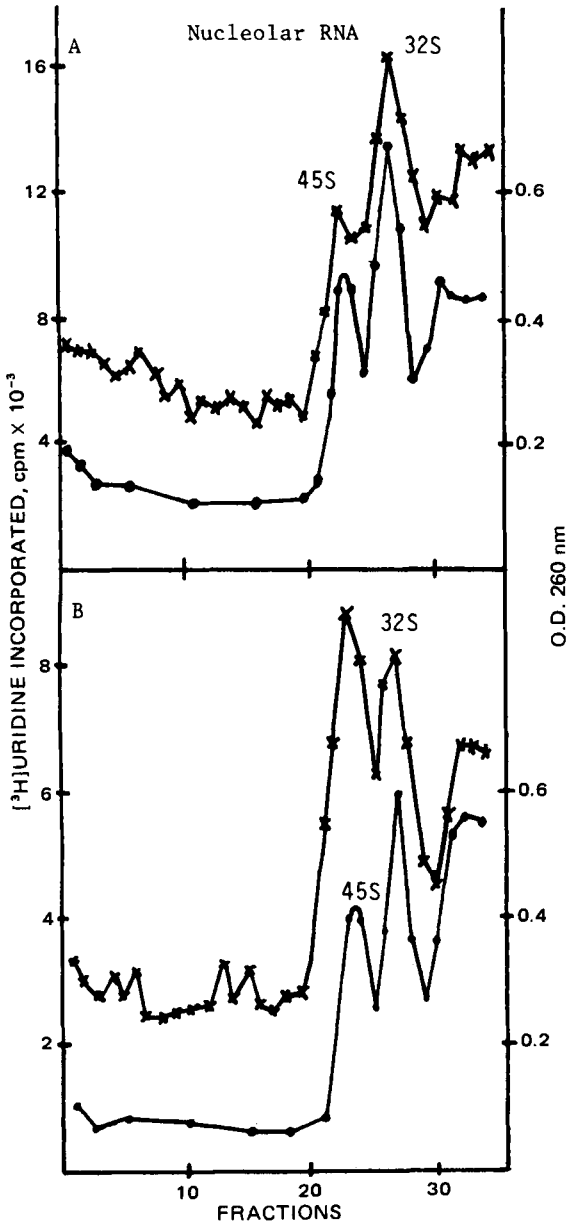

Figure 2—*Sucrose gradient analysis of nuceolar RNA from KB cells. RNA was labeled by the exposure of a total of 1 × 10^8 cells (3 × 10^6 cells/ml) for 1 hr to [^{3}H]uridine in the absence (A) or presence (B) of granaticin (2.13 μg/ml). Fractions were collected through a needle from 15–30% gradients and centrifuged for 12 hr at 20 × 10^3 rpm in an SW 40 rotor.*

counting (20) after the addition of cold uridine mono-, di-, and triphosphate[6] or by the method of Cheung and Suhadolnik (21).

Radioactivity was measured in a liquid scintillation spectrometer[7] in 10 ml of toluene scintillation cocktail or commercial scintillation solution[8] for water-soluble samples.

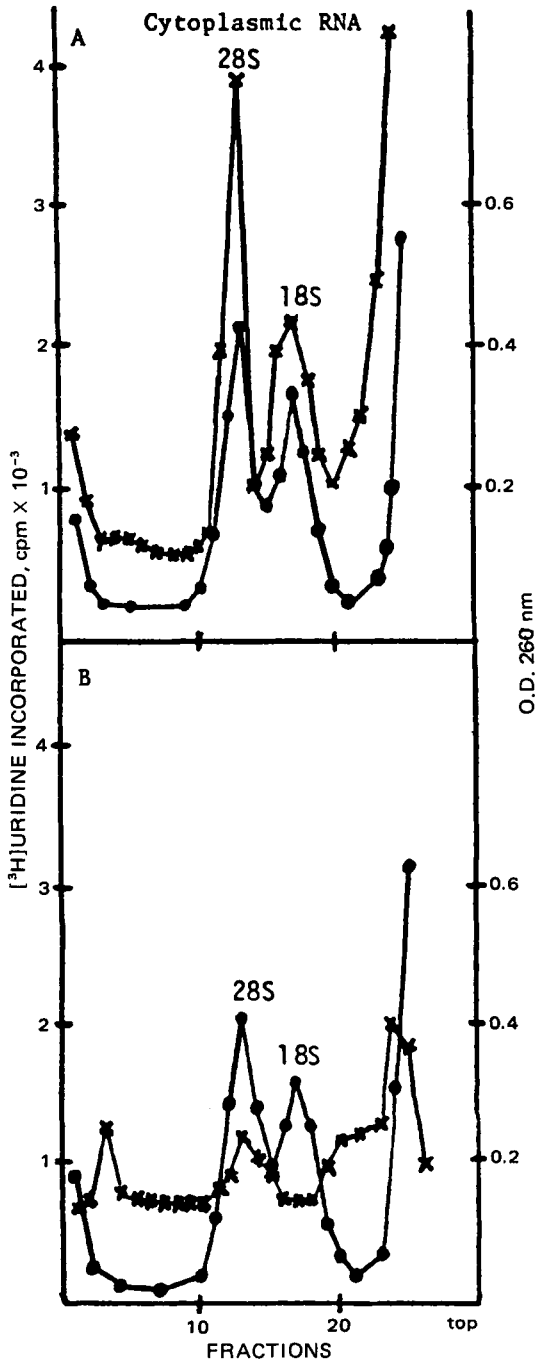

Figure 3—*Sucrose gradient analysis of cytoplasmic RNA from KB cells. Experimental condition was identical to the conditions in Fig. 2, except that the 15–30% sucrose gradients were centrifuged for 16 hr at 22 × 10^3 rpm. (A, control incubation; and B, 2.13 μg of granaticin/ml).*

RESULTS

To determine a concentration of granaticin that would allow study of the inhibition of cellular processes without excessive cell death, the effect of granaticin on cell survival was measured (Table I). Granaticin at a concentration of 1.4 mg/ml for 2 hr caused a 3% reduction in cell numbers

Table II—Effect of Granaticin Concentration and Contact Time on the Maturation of Ribosomal RNA in KB Cells [a]

Granaticin, μg/ml of medium	Incubation, hr	RNA Percent of control [b] 45S	32S	28S	18S
2.16	1	94	48	59	5
2.16	2	86	32	9	0
3.20	1	79	32	42	0
3.20	2	75	11	6	0
5.00	1	53	0	0	0

[a] Cells were seeded at a concentration of 3×10^6 cells/ml and treated with different concentrations of granaticin for 1–2 hr. [b] The radioactivity associated with the 45S, 32S, 28S, and 18S fractions was determined and is expressed as percentage of the radioactivity in control incubations without granaticin, analyzed after 1 and 2 hr.

after 24 hr compared to incubations without granaticin. In addition, the damage to the cells appeared to be permanent, since the reduction in cell number was 14 and 19% after 48 and 72 hr, respectively, at the same granaticin concentration. The cytotoxic effect of granaticin was more pronounced at higher concentrations of the inhibitor (Table I). From these results, concentration of 2 μg of granaticin/ml of cells (in some experiments up to 5 μg/ml) were used for subsequent experiments. In addition, the exposure time of the cells to granaticin was 1–2 hr to minimize cell death.

Synthesis of macromolecules was monitored by measuring the incorporation of radioactively labeled thymidine, uridine, and lysine into acid-insoluble fractions. Addition of granaticin at various concentrations, 10 min before the radioactive precursor was added to the cell cultures, showed (Fig. 1) that the formation of ribonucleic acid was inhibited 50% at a granaticin concentration of ~2 μg/ml. At this same granaticin concentration, DNA and protein synthesis were not appreciably affected.

The ribonucleic acids synthesized in the presence and absence of granaticin were analyzed by differential separation using sucrose gradient centrifugation of the cytoplasmic and nucleolar ribonucleic acids as described previously (19). The results (Figs. 2 and 3) indicated an accumulation of 45S RNA in the nucleoli of granaticin-treated cells (Fig. 3B) compared to untreated control cells (Fig. 2A). Similarly, virtually no 18S and very little 28S RNA apeared in the cytoplasm of granaticin-treated cells (Fig. 3B) compared with untreated cells (Fig. 3A). These results were obtained after 1-hr exposure of the cells to [^{3}H]uridine in the presence or absence of granaticin (2.13 μg/ml/hr). In similar experiments (Table II), KB cells were labeled with [^{3}H]uridine and exposed to granaticin

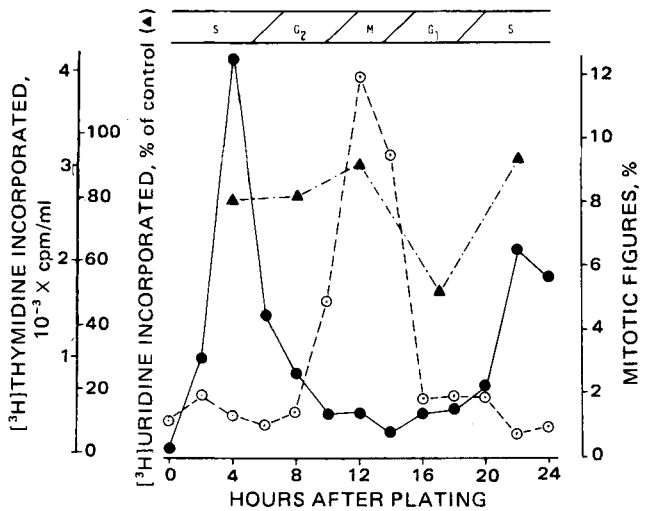

Figure 4—*Traverse of KB cells through the cell cycle after a double-thymidine block. The thymidine was removed at zero hr after plating. Cell-cycle phases were identified through the incorporation of [^{3}H]-thymidine into DNA (●) and through counting of the mitotic figures (⊙) after staining with hematoxylin. The effect of granaticin (6.3 μg/ml for 30 min) on RNA synthesis in KB cells in different phases of the cell cycle was measured by the incorporation of [^{3}H]uridine (▲) (0.4 μCi/ml) reported as percentage of control incubations. Typical values for control incorporations of [^{3}H]uridine into RNA were: S-phase, 780 cpm/mg of protein; G_2-phase, 450 cpm/mg of protein; M-phase 120 cpm/mg of protein; and G_1-phase, 1320 cpm/mg of protein. Each point represents the average of three measurements.*

Table III—Effect of Granaticin on the Uptake and Conversion of [^{3}H]Uridine into Uridine Monophosphate, Uridine Diphosphate, and Uridine Triphosphate [a]

Granaticin, μg/ml	Incubation, hr	Uridine, %	Uridine Monophosphate, %	Uridine Diphosphate, %	Uridine Triphosphate, %
0	0	87.9	6.0	4.0	2.1
0	2	74.0	12.2	10.5	3.3
0	4	72.0	11.4	12.2	4.7
2.75	0	84.7	7.2	5.1	3.0
2.75	2	74.0	11.0	11.3	3.7
2.75	4	70.9	12.9	11.6	4.4

[a] [^{3}H]Uridine (1.1 μCi/ml, 22 μCi/μmole) was added to 1.6–2.4 × 10^5 KB cells/ml and incubated with and without 2.75 μg of granaticin/ml for the time indicated. Separation of uridine and its mono-, di-, and triphosphate ester was by TLC.

concentrations of 3.2 and 5 μg/ml for 1 and 2 hr. The results extend and support the data in Figs. 2 and 3.

Summation of the radioactivity associated with the sucrose gradient fractions representing 45S, 32S, 28S, and 18S RNA, in the control incubation and in incubations of KB cells with granaticin, showed that higher granaticin concentrations (3.2 and 5 μg/ml) have a more drastic effect on the maturation of ribosomal RNA than incubations with 2.16 μg of granaticin/ml of medium (Table II). In addition to granaticin concentration, the incubation time of granaticin with KB cells affected maturation of ribosomal RNA. After a 2-hr incubation at 2.16 or 3.2 μg of granaticin/ml of medium, the inhibition of the formation of functional ribosomal RNA was more pronounced than inhibition after a 1-hr incubation (Table II). At 5 μg of granaticin/ml of medium, no radioactivity was found in 32S, 28S, and 18S ribosomal RNA after a 1-hr incubation (Table II). In all experiments where contact time or granaticin concentration was varied, the maturation of 45S RNA was inhibited to a greater extent than the synthesis of 45S RNA (Table II).

No inhibitory effect of granaticin at a concentration of 2.75 μg/ml for 2 or 4 hr was observed on intracellular accumulation of [^{3}H]uridine and on the subsequent conversion of [^{3}H]uridine to uridine monophosphate, uridine diphosphate, and uridine triphosphate (Table III).

Possible cell cycle specificity of granaticin was investigated in synchronized KB cells. The degree of synchronization was determined by [^{3}H]thymidine incorporation and by counting mitotic figures. A typical profile is reproduced in Fig. 4. Synchronized KB cultures were used to measure [^{3}H]uridine incorporation in the different cell-cycle phases in the presence and absence of granaticin (Fig. 4). Similarly synchronized cell cultures were used to measure the cell survival after treatment with granaticin in the different cell-cycle phases (Fig. 5). [^{3}H]Uridine incor-

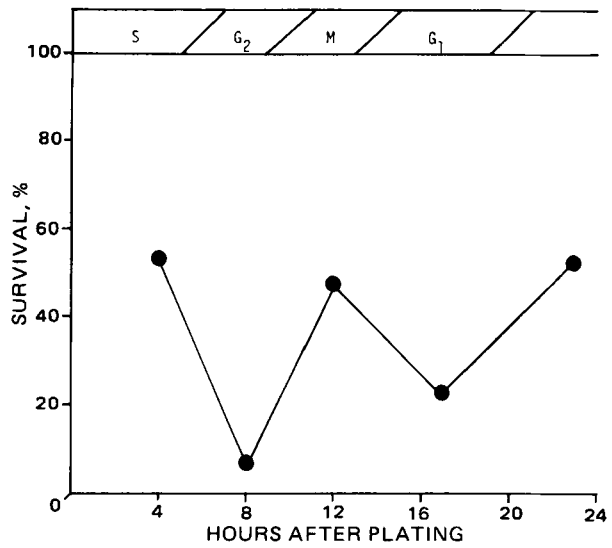

Figure 5—*Effect of granaticin on the survival of synchronized KB cells. Synchronized S-phase KB cells were incubated for 1 hr with 6.3 μg/ml granaticin at 4, 8, 12, 17, and 23 hr after removal of the thymidine block, diluted 1:1000, and grown in monolayers for 7 days. Thereafter, stained colonies were counted and represented as percentage of control incubations without granaticin. Each point represents the average of three measurements.*

poration was inhibited 50% by the addition of granaticin to cells in the G_1-phase (Fig. 4). Little or no effect of granaticin on RNA synthesis was observed in the mitotic and early S-phase and only minimal inhibition (20%) in the late S- and G_2-phases (Fig. 4). However, the effect of granaticin on the cell survival in the different phases was much more pronounced. Almost no cells survived in the G_2-phase (Fig. 5). Similarly, only 25% of the G_1-phase treated cells survived. Survival in the S- and M-phases was ~50% (Fig. 5).

DISCUSSION

In previous studies with bacterial systems granaticin inhibited RNA synthesis *in vivo* (8, 9) and in cell-free incubations (22). In addition, granaticin inhibited reverse transcriptase (10). In both cases, interaction of granaticin with the template was proposed. Although the most recent result with *Bacillus subtilis* (9) indicated that granaticin inhibition was due to the failure to charge leucyl-tRNA, it was not clear if granaticin exerted its inhibitory properties through binding to the tRNA molecule or to the proteins involved in this process. Inhibition of the reverse transcriptase was attributed to the interaction of granaticin with the template (RNA) for this enzyme (10). This conclusion was drawn from sequential addition experiments and, therefore, does not prove interaction of granaticin with the template.

The present results show that RNA synthesis is affected by granaticin at concentrations where protein DNA synthesis is not inhibited. Subsequent analysis of the synthesized RNA showed that maturation of the 45S ribosomal RNA precursor is inhibited. This inhibition was dependent on the granaticin concentration in the incubation mixtures as well as on the duration of incubation. These results may indicate that granaticin binds to 45S RNA and therefore maturation cannot occur. However, similar results would have been obtained if granaticin interacted with one or more of the enzymes (23) involved in the processing of 45S RNA to functional ribosomal RNA.

An indication that granaticin at higher concentrations interacts with other vital processes in mammalian cells was apparent from a comparison of the results of the cell cycle inhibition experiments (Figs. 4 and 5). If inhibition of RNA synthesis was the only site of action of granaticin, then the inhibition of RNA synthesis (Fig. 4) and cell survival (Fig. 5) should have yielded comparable values. Inhibition of RNA synthesis by granaticin in cells in the different phases of the cell cycle was not of the same magnitude as the inhibition of cell growth in the same phases. The magnitude of inhibition in each phase should have been the same if inhibition of RNA synthesis was the only site of action of granaticin toxicity. This type of inhibition was not found. Although 7% of the granaticin-treated G_2-cells did survive (Fig. 5), only 18% inhibition of RNA synthesis was observed in cells treated with granaticin in the same phase (Fig. 4). It should be emphasized that these experiments were done with a granaticin concentration of 6.3 μg/ml. At concentrations of 2 μg/ml, comparable to the inhibition studies in Figs. 2 and 3, this difference in cell survival and inhibition of RNA formation was not apparent.

A number of other compounds inhibit maturation of ribosomal RNA (24). The compounds studied in greatest detail are nucleoside analogs which, in addition to inhibiting the processing of ribosomal RNA, also inhibited *de novo* precursor synthesis (24). Although granaticin cannot be classified as a purine or pyrimidine analog and, therefore, should not inhibit *de novo* nucleoside synthesis, the effect of granaticin on the uptake and phosphorylation of [^{3}H]uridine to the corresponding nucleotides was tested and found to be negative. Camptothecin inhibited ribosomal RNA synthesis (25); however, in this case it appeared to inhibit transcription and not the maturation of preribosomal RNA.

Solubility in Binary Solvent Systems I: Specific *versus* Nonspecific Interactions

WILLIAM E. ACREE, Jr., and J. HOWARD RYTTING ˣ

Received February 24, 1981, from the *Pharmaceutical Chemistry Department, The University of Kansas, Lawrence, KS 66045.* Accepted for publication June 29, 1981.

Abstract □ Solubilities are reported for benzil in carbon tetrachloride–alkane (isooctane, *n*-octane, cyclooctane) systems at 25° and in similar binary mixtures containing cyclohexane plus alkane. The results of these measurements are compared to solution models previously developed for solubility in systems containing specific solute–solvent interactions and to models for purely nonspecific interations. A stoichiometric complexation model based primarily on specific solute–solvent interactions requires several equilibrium constants to mathematically describe the experimental solubilities in binary carbon tetrachloride mixtures. However, there was no direct experimental evidence to suggest complexation between benzil and carbon tetrachloride. In comparison, expressions derived from the Nearly Ideal Binary Solvent (NIBS) model for nonspecific interactions predict experimental solubilities with a maximum deviation of 5% and an overall deviation of 1.0%. The success of the NIBS approach for this system is significant because the mole fraction solubility of benzil changes by a factor of 14 in the carbon tetrachloride–isooctane system.

Keyphrases □ Solubility—binary solvent systems, specific *versus* nonspecific interactions □ Solvent systems—binary, specific *versus* nonspecific interactions, solubility □ Solute–solvent interactions—specific *versus* nonspecific, binary systems

A knowledge of the thermodynamic activity of a drug in a given environment is important in drug design and drug product formulation. The development of an effective drug often involves altering its solubility through either structural modifications or complexation. Ideally, the ability to predict solubility based solely on molecular interactions between the dissolved drug and surrounding solvent molecules is desired. For practical applications, a less fundamental approach must often suffice.

BACKGROUND

Studies of solute–solvent interactions generally have focused on integral thermodynamic properties of binary mixtures. Recently, thermodynamic excess properties of a solute at high dilution in binary solvent mixtures (1–5) have been useful in studying the effects of solution nonideality. Equilibrium constants and enthalpies of hydrogen bond formation have been calculated from the heats of solution of proton donors in mixtures containing a proton acceptor and relatively nonpolar solvent (6, 7). GLC studies on a binary liquid phase provide another method for determining the thermodynamic properties of a solute near infinite dilution, and for investigating association complexes between the solute and one of the solvent components (4, 8–12). Experimental solubilities of iodine and stannic iodide in binary solvent mixtures containing benzene were explained through preferential solvational models (13, 14).

The interpretation of solution nonideality generally has followed two dissimilar lines: the "physical" approach originated by van Laar (15) and the "chemical" approach proposed by Dolezalek (16). The physical approach may be described by a random distribution of molecules throughout the entire solution, while the chemical approach may be characterized by a specific geometric orientation of one molecule with respect to an adjacent molecule.

Even in systems known to contain specific interactions, the need to properly account for nonspecific interactions is recognized. Arnett, *et al.* (7) attempted to separate specific and nonspecific interactions with a "pure base" calorimetric method for determining enthalpies of hydrogen bond formation. The sensitivity of the numerical results to the selection of the model compound and the solvent (17) points out the difficulty in separating physical and chemical contributions of solution nonideality. Bertrand (18) demonstrated that neglecting nonspecific interactions in a chloroform–triethylamine system led to an appreciable error in the enthalpy of complex formation determined with an ideal associated solution model.

Recent solubility determinations of polar organic solutes in binary solvent mixtures containing a polar organic solvent and a nonpolar solvent (such as isooctane) have shown the value of considering nonspecific as well as specific interactions.

For example, do large differences between the solubility of a substance in two pure solvents necessarily indicate complex formation, or can these differences sometimes be just as adequately described with simple mixing models based on nonspecific interactions? One report (19) showed that solubilities of polar nonelectrolytes in polar nonaqueous solvents could not be predicted with the solubility parameter approach of Scatchard and Hildebrand. Another report (20) showed that large differences in the solubilities of polar organic substances could be mathematically described by models that assume stoichiometric solvate species. In many of the systems studied (20), nonspecific interactions were considered unimportant because of the large contributions from specific interactions and the fact that the solubility parameter approach was not adequate.

A zero-parameter equation was developed (3, 5) which predicted solubilities in 35 systems containing naphthalene, stannic iodide, iodine, and benzil as solutes where nonspecific interactions dominate with an average deviation of 2.2% and a maximum deviation of 25%. The maximum deviation occurred in a system (benzil-benzene–cyclohexane) in which complex formation was suggested, and if this system is excluded from calculations, the maximum deviation becomes 6%. The success of the equation is striking because the mole fraction solubility of benzil changes by a factor of 14 in the carbon tetrachloride–*n*-hexane system (5).

The present report describes how nonspecific interactions may contribute significantly to the total nonideality of a solution. Equilibrium constants calculated *via* solvational complexation models may not always represent only specific solute–solvent interactions, but also the failure of the model to properly describe nonspecific interactions. This phenomenon was further examined by measuring additional solubilities for benzil in carbon tetrachloride–alkane (isooctane, *n*-octane, cyclooctane) systems and in similar binary mixtures containing cyclohexane–alkane. These systems were selected primarily because the experimental solubilities of benzil are considerably different in each of the pure solvents. The experimental values in the binary mixtures are interpreted with models for either specific or nonspecific interactions.

EXPERIMENTAL

Reagents—Benzil[1] was recrystallized several times from methanol giving a melting point of 95.0 ± 0.5° [lit. (21) mp 95.2°]. Cyclohexane[2], *n*-heptane[3], *n*-octane[4], isooctane[3], cyclooctane[4], and carbon tetrachloride[5] were all stored over molecular sieves[6] to remove possible trace amounts of water. Binary solvent mixtures were prepared by weight so that compositions could be calculated to 0.0001 mole fraction.

Solubility Determinations—Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature bath at 25° for several days. Random duplicate samples were allowed to equilibrate for longer periods, but no significant differences in saturation solubility were observed. Aliquots of saturated benzil solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and then diluted quantitatively with

cyclohexane. Concentrations were determined spectrophotometrically[7] at 390 nm.

Experimental solubilities of benzil in several binary solvent mixtures are given in Table I. The measurements were reproducible to within 1.5%.

THEORETICAL

Stoichiometric Complexation Model—Stoichiometric complexation models have been used frequently to quantitatively explain enhanced solubilities of a polar organic solute in binary mixtures containing an inert hydrocarbon and a polar cosolvent. The basic model assumes complexation between the solute, S, and an interacting cosolvent, L (19,20):

$$S + L \rightleftharpoons SL \overset{+L}{\rightleftharpoons} SL_2 \overset{+L}{\rightleftharpoons} \ldots SL_n$$

Scheme I

Each reaction is described by an appropriate equilibrium constant with concentrations expressed in molarities:

[7] Cary 118.

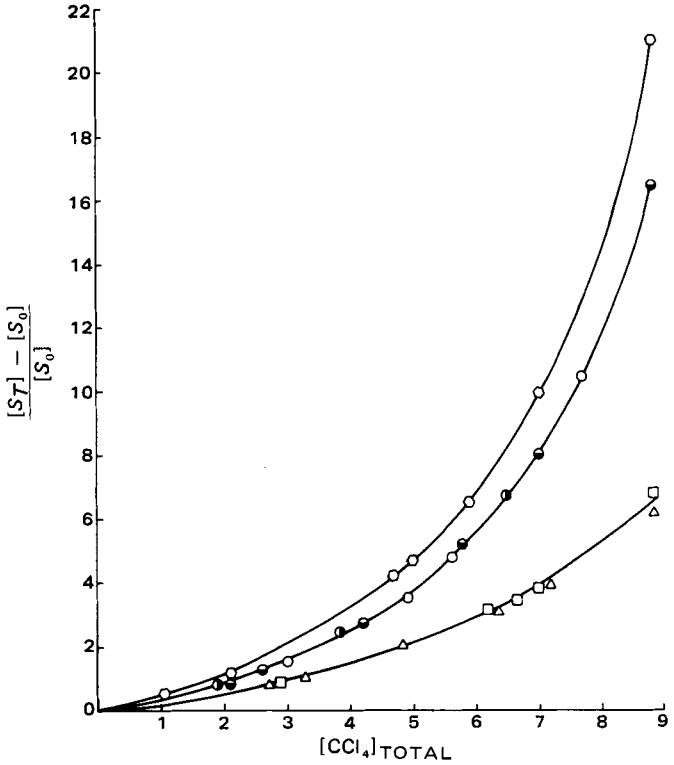

Figure 1—*Graphical determination of* $K_{1:1}$ *from plots of fractional change in solubility* versus *carbon tetrachloride molarity for benzil in several binary solvents consisting of carbon tetrachloride and* ○, n-*octane;* ◒, n-*heptane;* ◑, n-*hexane;* ○, *isooctane;* △, *cyclohexane; and* □, *cyclooctane. Solubilities in solvent mixtures containing cyclohexane,* n-*hexane, and* n-*heptane are from Ref. 5. The basic model requires additional solute–solvent complexes to explain curvature from the linearship. (See Eqs. 5 and 6).*

$$K_{1:1} = \frac{[SL]}{[S_0][L]_f} \qquad \text{(Eq. 1)}$$

$$K_{1:n} = \frac{[SL_n]}{[SL_{n-1}][L]_f} \qquad \text{(Eq. 2)}$$

where $[S_0]$ is the saturation solubility of solute in pure inert hydrocarbon (assumed to represent the free solute concentration in binary mixtures as well) and $[L]_f$ is the free (uncomplexed) ligand.

This particular model assumes only a single solute molecule is present in each complex, but the mathematical form of the resulting equations is not significantly altered by additional solute molecules per complex. The total solubility of solute in any system, $[S_T]$, can be expressed as:

$$[S_T] = [S_0] + K_{1:1}[S_0][L]_f + K_{1:1}K_{1:2}[S_0][L]_f^2 + \ldots \qquad \text{(Eq. 3)}$$

The total concentration of complexing agent, $[L_T]$, is:

$$[L_T] = [L]_f + K_{1:1}[S_0][L]_f + 2K_{1:1}K_{1:2}[S_0][L]_f + \ldots \qquad \text{(Eq. 4)}$$

In the absence of solute, the total concentration of interactive cosolvent $[L_T]$ is equal to $[L]nf$ only if the extent of self-association is negligible. Furthermore, the mathematical form of Eq. 3 predicts that plots of solubility *versus* cosolvent concentration should be concave upward in solvents incapable of self-association.

If only 1:1 complexes are present, Eqs. 3 and 4 can be combined to give:

$$\text{fractional change in solubility} = \frac{[S_T]-[S_0]}{[S_0]} = \frac{K_{1:1}}{1+K_{1:1}[S_0]}[L_T] \qquad \text{(Eq. 5)}$$

A plot of the fractional change in solubility *versus* ligand added gives a straight line. Graphical methods are cumbersome for higher order complexes, and a first approximation often assumes the amount of ligand in complexes is small; $[L_T] = [L]_f$. This additional stipulation enables Eq. 3 to be rewritten as:

$$\frac{[S_T]-[S_0]}{[S_0][L_T]} = K_{1:1} + K_{1:1}K_{1:2}[L_T] \qquad \text{(Eq. 6)}$$

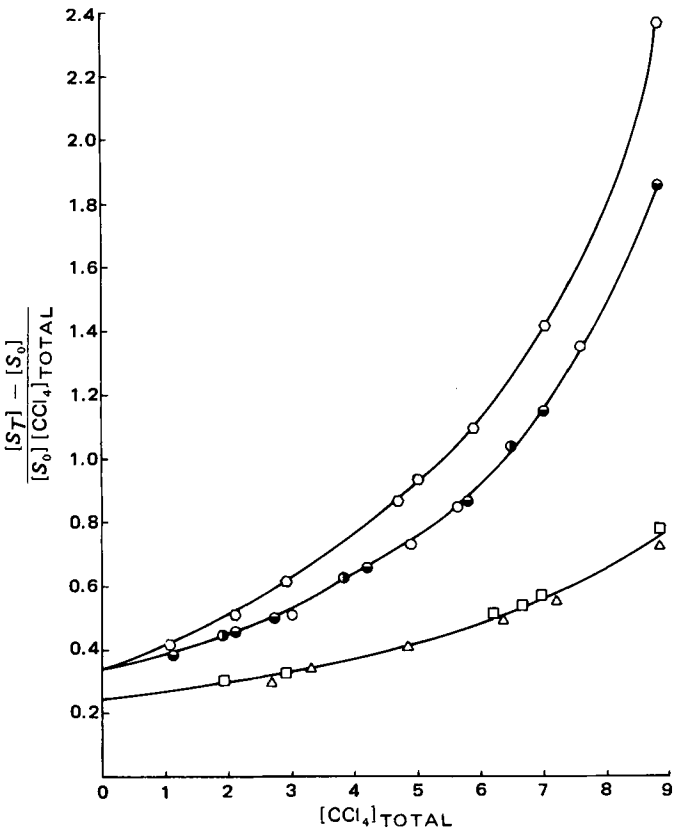

Figure 2—*Determination of* $K_{1:1}$ *and* $K_{1:2}$ *for the interaction of benzil with carbon tetrachloride in several binary solvents at 25°. (See Eq. 6). The binary mixtures contained* ○, *carbon tetrachloride and* n-*octane;* ◒, n-*heptane;* ◑, n-*hexane;* ○, *isooctane;* △, *cyclohexane; and* □, *cyclooctane.*

$K_{1:2}$ is calculated from the slope of the linear portion of $([S_T]-[S_0])/[S_0][L_T]$ *versus* $[L_T]$ and $K_{1:1}$ is determined from the intercept. Applying Eqs. 5 and 6 to systems not involving complexation should theoretically give equilibrium constants of zero. Thus, the model might be expected to distinguish between complexing and noncomplexing systems through the relative magnitudes of calculated equilibrium constants. However, non-negligible K values can be obtained in systems where complexation does not occur.

This particular model includes the basic assumption that the free solute concentration $[S_0]$ is independent of solvent composition, an assumption that is not always supported by experimental evidence. Solubilities of iodine in binary mixtures of *n*-hexane–cyclohexane (0.0460–0.00860 *M*), *n*-hexane–carbon tetrachloride (0.0460–0.116 *M*), and *n*-hexane–chloroform (0.0460–0.176 *M*) depend on solvent composition (22). Yet the violet color of iodine in each of the pure solvents indicates the absence of molecular complexes (23). Similar variations are observed for the benzil solubilities in the binary mixtures of saturated hydrocarbons given in Table I.

Examination of the behavior of Eqs. 3 and 4 in isooctane–cyclohexane mixtures, where association with benzil is considered unlikely, reveals that the equations compensate for variations in $[S_0]$ with solvent composition (0.0353–0.0978 *M*) either by adjusting numerical values of $K_{1:n}$ or by assuming additional solute–solvent complexes. The larger the true variation in the concentration of uncomplexed solute, the larger this compensation becomes. Eventually a point can be reached when the equilibrium constants derived from Eqs. 3 and 4 no longer represent specific solute–solvent interactions, but rather the failure of the particular model to properly describe nonspecific interactions.

Figures 1 and 2 show the graphical determination of potential equilibrium constants calculated from Eqs. 5 and 6 for benzil solubilities in binary mixtures containing carbon tetrachloride. The various cosolvents appear to be grouped along three different curves: one for isooctane, a second for the three normal hydrocarbons (*n*-hexane, *n*-heptane, and *n*-octane), and a third curve for the two cyclic hydrocarbons (cyclohexane and cyclooctane). Presumed equilibrium constants calculated in mixtures containing cyclohexane are not identical to values calculated in

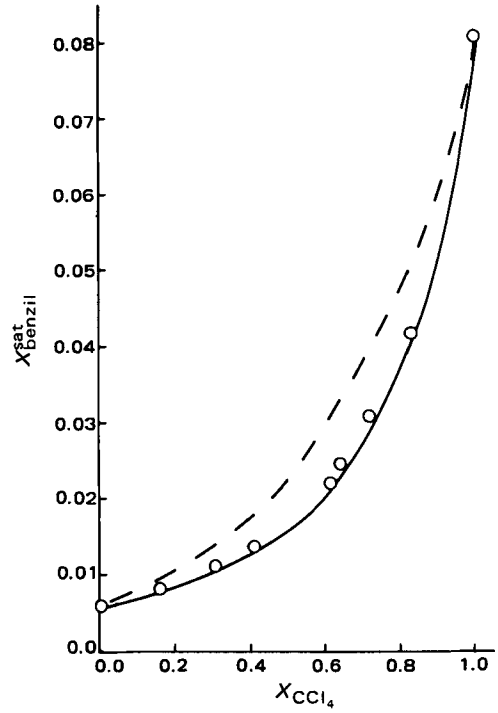

Figure 3—*Comparison between experimental solubilities (*○*) and the NIBS predictions for benzil in binary mixture of carbon tetrachloride and isooctane using Eq. 7 (- - -), and Eqs. 8 and 9 (—). The free energy of mixing data for the binary solvent* ($\Delta\overline{G}^{ex}_{12}$) *is taken from Ref. 40.*

isooctane mixtures. More importantly, the model requires several constants to represent mathematically the experimental data, and yet there appears to be no experimental evidence suggesting complexation between benzil and carbon tetrachloride.

Dipole moment measurements of benzil in benzene and carbon tetrachloride have been interpreted as evidence for specific interactions of benzil with benzene but not with carbon tetrachloride (24). The GLC retention behavior of carbon tetrachloride and chloroform on a benzil stationary phase has been interpreted (25) in terms of London or simple dispersion forces in the case of carbon tetrachloride and in terms of hydrogen bonding in the case of chloroform. Actual numerical values of the equilibrium constants are not reported to avoid the suggestion that a complex is formed between benzil and carbon tetrachloride. Since the *y*-intercept in Fig. 2 gives a presumed $K_{1:1}$, $K_{1:1}$ would range from 0.25–0.35 depending on the choice of cosolvent.

The Nearly Ideal Binary Solvent Model—The Nearly Ideal Binary Solvent (NIBS) approach developed by Bertrand *et al.* was shown to provide reasonable estimates for enthalpies of solution (2), GLC partition coefficients (4, 8), and solubilities (3, 5) in systems containing only nonspecific interactions. However, the approach fails for systems with specific solute–solvent or solvent–solvent interactions. The general expressions, derived from the NIBS model, for predicting solubilities in systems of nonspecific interactions depend on two models of solution nonideality:

$$RT\ln(a_3^{solid}/X_3^{sat}) = (1-X_3^{sat})^2[X_1^0(\Delta\overline{G}_3^{ex})_{X_1^0=1} + X_2^0(\Delta\overline{G}_3^{ex})_{X_2^0=1} - (\Delta\overline{G}_{12}^{ex})] \quad \text{(Eq. 7)}$$

$$RT\ln(a_3^{solid}/X_3^{sat}) = (1-\phi_3^{sat})^2[\phi_1^0(\Delta\overline{G}_3^{ex})_{X_1^0=1} + \phi_2^0(\Delta\overline{G}_3^{ex})_{X_2^0=1} - \overline{V}_3(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)^{-1}(\Delta\overline{G}_{12}^{ex})] \quad \text{(Eq. 8)}$$

$$RT\left[\ln(a_3^{solid}/\phi_3^{sat}) - (1-\phi_3^{sat})\left(1-\frac{\overline{V}_3}{(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)}\right)\right] = (1-\phi_3^{sat})^2[\phi_1^0(\Delta\overline{G}_3^{fh})_{X_1^0=1} + \phi_2^0(\Delta\overline{G}_3^{fh})_{X_2^0=1} - \overline{V}_3(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)^{-1}(\Delta\overline{G}_{12}^{fh})] \quad \text{(Eq. 9)}$$

Equations 7 and 8 are based on the Regular Solution model (23) and Eq. 9 is based on the Flory–Huggins model (26–30). In these expressions, a_3^{solid} is the activity of the solid solute relative to the pure hypothetical supercooled liquid, X_i is mole fraction, ϕ_i is volume fraction, $\overline{V}_i$ is the molar volume of a pure liquid, and $\Delta\overline{G}_{12}^{ex}$ is the molar excess Gibbs free

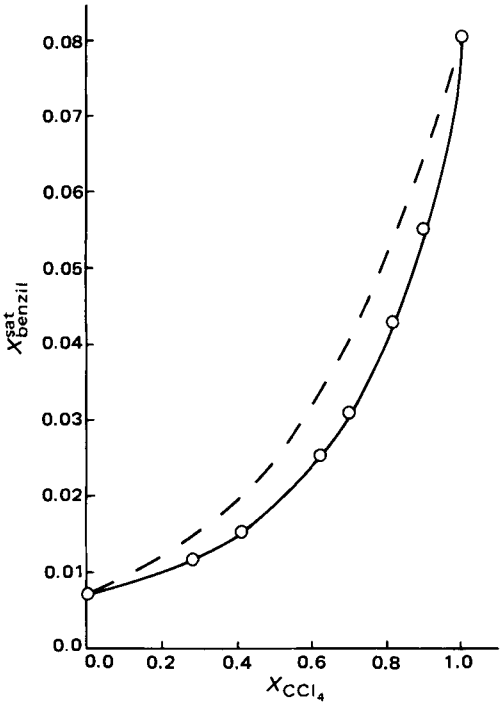

Figure 4—*Comparison between the experimental solubilities (O) and the NIBS predictions for benzil in binary mixtures of carbon tetrachloride and* n*-octane using Eq. 7 (---), and Eqs. 8 and 9 (——). The free energy of mixing for the binary solvent is taken from Ref. 41.*

energy of the binary solvent mixture relative to Raoult's law[8]. The superscript (0) denotes the initial binary solvent composition calculated as if the solute were not present. With these equations, solubility data measured in each pure solvent can be used to calculate the excess partial molar Gibbs-free energy of the solute $[(\Delta\overline{G}_3^{ex})^*_{X_1^0=1}, (\Delta\overline{G}_3^{fh})^*_{X_1^0=1}]$. These quantities are then combined with the excess free energy of the binary solvent to predict solubility in mixed solvents using a reiterative process. The quantity $(1 - X_3^{sat})$ or $(1 - \phi_3^{sat})$ is taken as unity in the first approximation and convergence is quite rapid unless the solubility is large.

Graphical comparisons of experimental and calculated values are shown in Figs. 3 and 4 for benzil in isooctane–carbon tetrachloride and in *n*-octane–carbon tetrachloride mixtures. Properties used in the calculation include: a_3^{solid} (0.224) calculated from the enthalpy of fusion (22.15 cal/g) (21) at the melting point, and $\overline{V}_3$ (183 cm^3/mole) estimated from the density of the liquid at 102° and the coefficient of thermal expansion for benzophenone calculated over 50–95° (31). In general, Eqs. 8 and 9 are comparable with overall average (rms) deviations of 1.4 and 1.0%, respectively and are superior to Eq. 7 which has an average (rms) deviation of 10.0%[9]. These observations are in agreement with earlier findings (2–5) that Eq. 7 is inferior to the other two predictive expressions for systems in which the molar volumes differ substantially.

RESULTS AND DISCUSSION

Although experimental solubilities can be described by equations derived from stoichiometric complexation models, the basic assumption that free solute concentration is independent of solvent composition is not always supported by experimental evidence. Solubilities of benzil in binary mixtures of nonpolar solvents such as isooctane–cyclohexane are found to vary with solvent composition. If carbon tetrachloride is included as a nonpolar solvent for benzil, experimental solubilities exhibit a 22-fold range in carbon tetrachloride–isooctane mixtures. Stoichiometric complexation models that attribute all solubility enhancement to the formation of molecular complexes require several equilibrium constants to describe benzil solubility in binary mixtures containing carbon tetrachloride.

Much smaller ranges have been observed for iodine solubilities in binary mixtures of *n*-hexane–benzene (0.046–0.588 *M*) (32), cyclohexane–benzene (0.083–0.543 *M*)(14), and carbon tetrachloride–benzene (0.116–0.588 *M*) (33) where specific solute–solvent interactions are expected to occur. Charge transfer complexes between iodine and benzene are well documented (34–36). Based on these observations, the range of solubilities encompassed in binary solvent mixtures does not always provide a clear indication of the complexing nature of the system. Caution should be exercised in inferring specific complex formation models in the absence of independent physical evidence for complexation, particularly if the model requires several relatively small equilibrium constants to describe the system.

The success of the NIBS approach in predicting the binary solvent effect on solubilities, covering up to a 14-fold range (mole fraction), suggests the possibility that this model may provide a foundation for approximations of the physical interactions even in a system containing chemical interactions such as association between the solute and a complexing solvent. Extensions of the basic NIBS model to systems containing 1:1 solute–solvent complex were shown to provide reasonable correlations of GLC partition coefficients with a mixed liquid phase (4). Through standard thermodynamic relationships, the expression of the NIBS model for a 1:1 solute–solvent complex (Eq. 25 of Ref. 4) can be applied to the solubility of solid substances, without requiring the solubility of the uncomplexed solute to be independent of solvent composition. Similar models have been suggested (37–39) to study the solubility of gases and solids in complexing systems.

[8] For a binary mixture, the excess molar Gibbs free energy over the predictions of the Flory–Huggins equation is related to the defined excess free energy by: $\Delta\overline{G}_{12}^{fh} = \Delta\overline{G}_{12}^{ex} + RT\,[\ln(X_1^0\overline{V}_1 + X_2^0\overline{V}_2) - X_1^0 \ln \overline{V}_1 - X_2^0 \ln \overline{V}_2]$.

[9] rms deviations (%) $= (100/N^{1/2})\,\{\sum^{n} [\ln(X^{sat}_{calc}/X^{sat}_{exp})]^2\}^{1/2}$. These values were averaged for the six different binary solvent systems. The carbon tetrachloride–cyclooctane system was not included in these calculations because the excess Gibbs free energy was unavailable in the literature.

Effect of Polyisobutylene on Ethylcellulose-Walled Microcapsules: Wall Structure and Thickness of Salicylamide and Theophylline Microcapsules

S. BENITA and M. DONBROW ˣ

Received November 12, 1980, from the *Department of Pharmacy, School of Pharmacy, Hebrew University-Hadassah Medical School, P.O.B. 12065, Jerusalem, Israel.* Accepted for publication May 20, 1981.

Abstract □ Microcapsules were prepared by the ethylcellulose coacervation process which is based on the differential thermal solubility in cyclohexane. When a protective colloid, polyisobutylene, was present in adequate concentration, individually film-coated core particles formed. However, they were accompanied by small empty coacervate droplets, detectable by microscopic observation. Below the critical colloid concentration, the product had the form of an aggregate, in contrast to individual film-coated microcapsules. Increase of colloid concentration yielded microcapsules of higher drug content, because the coating became progressively thinner; there was a corresponding increase in the release rate of drugs from the microcapsules. Since the initial wall polymer/drug ratio and the particle size are constant, the drug content varied with the thicknesses of the wall membrane. This is shown here by removal of empty coacervate droplets by repeated decantations, enabling determination of drug content by chemical analysis. In contrast to results reported in the literature, in the presence of a protective colloid, microcapsule drug content decreased with decreasing particle size of the drug. This was caused by more complete uptake of the wall polymer on the increased surface of core material. The effect of protective colloid concentration on the apparent loss of wall polymer as empty droplets closely paralleled its effect on the size of stabilized coacervate droplets when core material was absent. It is proposed that stabilized droplet formation is a side reaction when core material is present, causing changes in wall thickness. This reaction not only affects the efficiency of the coating process but may be utilized to control wall thickness. First-order constants for drug release from salicylamide and theophylline microcapsules followed the same pattern as wall thickness and confirmed the validity of the measurements.

Keyphrases □ Polyisobutylene—effect on ethylcellulose-walled microcapsules □ Microencapsulation—effect of polyisobutylene on ethylcellulose-walled microcapsules, wall structure and thickness of salicylamide and theophylline microcapsules □ Coacervation—ethylcellulose effect on polyisobutylene on microencapsulation process

Although ethylcellulose is the most widely used coating material in microencapsulation, the basic coacervation process has been carried out under a variety of conditions (1, 2). Previous experimental results demonstrate that changes in the basic technique, essentially temperature reduction of a hot cyclohexane solution, markedly influence the quality and characteristics of the microcapsules formed. Among variations introduced has been the use of protective colloids such as polyethylene (2, 3), butyl rubber (4, 5), and polyisobutylene (6). Observation of microcapsules prepared in the absence of a protective colloid (7–9) reveals aggregates of coated particles, whereas individual microcapsules consisting of single core particles uniformly coated are formed when a protective colloid is present (3).

Dhruv *et al.* proposed (10, 11) that the extent and integrity of microencapsulation in the gelatin–acacia coacervation system is largely dependent on the coacervate volume, which changes with various experimental parameters in the absence of core material. The effects of polyisobutylene on the basic ethylcellulose coacervation process was recently studied (12). The polyisobutylene concentration was shown to control the phase coacervation volume and the final ethylcellulose coacervate droplet size. The present work investigated the effect of polyisobutylene concentration and particle size of core material on the wall/core ratio and drug release from microcapsules. It was attempted to relate these parameters to the underlying causes revealed by earlier studies.

EXPERIMENTAL

Materials—Ethylcellulose[1] (*N*-type) had an ethoxyl content of 47.5–49.0%. The viscosity of a 5% (w/w) solution in toluene–ethanol (80:20 w/w) was 100 cps[1]. Polyisobutylene[2] had a molecular weight of 380,000. Salicylamide[3] conformed to NF XIV and theophylline[4] conformed to BP 1973.

Preparation of Microcapsules—The method of preparation, developed with modifications from an earlier technique (1), was described elsewhere (12). The core and wall materials[5] were added to the stirred cyclohexane–polyisobutylene solution (250 or 300 rpm). The mixture was then heated to 80°, and allowed to cool at a controlled stirring rate to 45°.

0022-3549/82/0200-0205$01.00/0

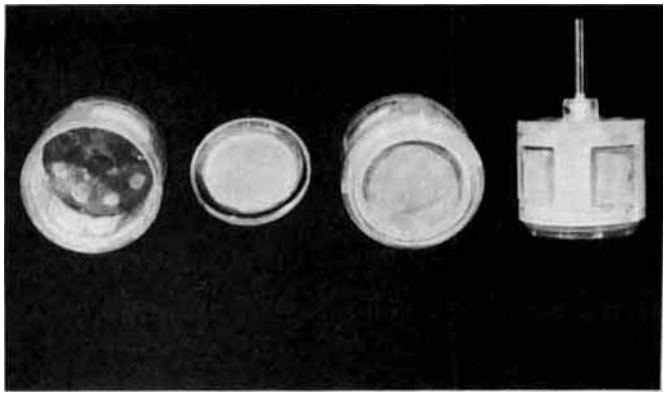

Figure 1—*Rotating basket showing dissembled parts used for release of drugs from microcapsules.*

It was cooled very rapidly using ice to 25° and stirred for another 15 min.

The microcapsules were separated from the solution by decantation and rinsed with three 200-ml portions of cyclohexane to remove any polyisobutylene adsorbed at the microcapsule interface and any empty wall polymer coacervate droplets. They were collected by vacuum filtration and oven-dried at 50° for 30 min, yielding a free-flowing powder.

All batches were duplicated. When the content of active ingredient deviated more than 3–4% between batches, a triplicate was performed. The effect of each experimental parameter was studied while the other parameters were kept constant for each drug. Segregation of the core materials was effected by standard mesh sieves.

Solubility of Drugs in Coating Solution and Drug Losses—Analysis of the clear supernatant layer obtained when the drug suspension was allowed to settle at 80° showed that the solubilities of salicylamide and theophylline in the coating polymer-protective colloid mixture were <0.02 and <0.01%, respectively. The particle size distribution of the core material, checked microscopically, did not appear to change significantly during the microencapsulation process. No uncoated drug particles were observed in the apparatus or in the batch after the process.

Evaluation of the Microcapsules Prepared—*Determination of Microcapsule Content*—The microcapsules were dissolved in chloroform and assayed spectrophotometrically at 306 and 276 nm for salicylamide and theophylline, respectively, using a calibration curve based on standard solutions in chloroform. Ethylcellulose did not absorb in chloroform at these wavelengths.

Determination of Loss of Wall Polymer—The percentage loss was calculated as follows for each batch prepared. The total weight of microencapsulated product obtained, *i.e.*, core and coating material, W_T, in a given batch was obtained from:

$$W_T = W_0/F \qquad \text{(Eq. 1)}$$

where W_0 is the initial amount of drug used and F is the fractional drug content of isolated product, by weight, determined experimentally. The assumption that none of the drug is lost or remains uncapsulated was validated earlier. The weight of the coat in the product, W_{EC}, is given by

$$W_{EC} = W_T - W_0 \qquad \text{(Eq. 2)}$$

If W_{EO} is the initial amount of wall polymer available for microencapsulation, then:

$$\text{percent loss of wall polymer} = \frac{100\,(W_{EO} - W_{EC})}{W_{EO}} \qquad \text{(Eq. 3a)}$$

$$= 100\left[1 + \frac{W_0}{W_{EO}}(1 - 1/F)\right] \qquad \text{(Eq. 3b)}$$

For the case in which $W_0 = W_{EO}$, this simplifies to[6]:

$$\text{percent loss of wall polymer} = 100\,(2 - 1/F) \qquad \text{(Eq. 3c)}$$

For an example, see Table I, 8% (w/w) polyisobutylene. The calculation for a 100-g system is as follows:

[6] The authors acknowledge the reviewer's suggestion to write the equation as a function of the fractional drug content.

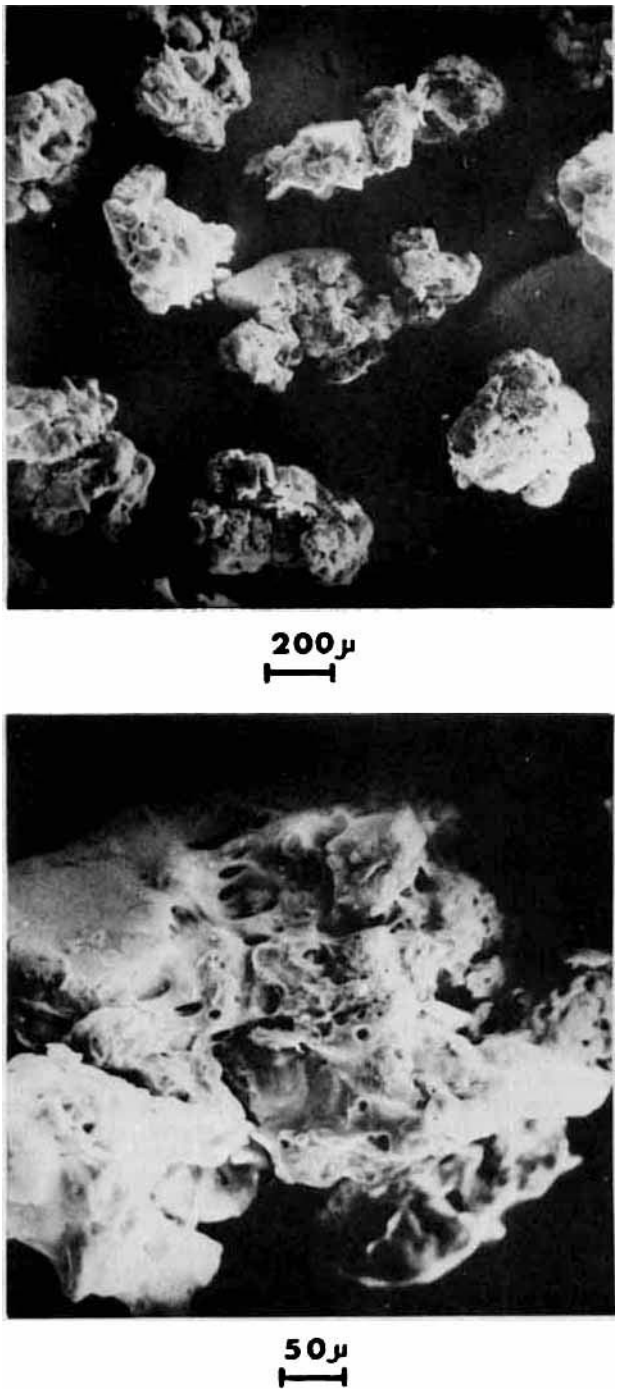

Figure 2—*Scanning electron micrographs of ethylcellulose-microencapsulated salicylamide prepared in the absence of polyisobutylene (5% salicylamide and 5% ethylcellulose at 300 rpm).*

$$W_T = \frac{5}{0.907} = 5.512$$

$$W_{EC} = 5.512 - 5 = 0.512$$

$$\text{ethylcellulose loss} = 89.76\%\ \text{(w/w)}$$

Wall Thickness—The wall thickness of the microcapsules was calculated from the particle size of the core material and the relative densities of the wall and core material. Quantitative expression of the relationship requires use of a shape factor, and because particle shape and size vary widely, even within batches of a single core material, it is generally assumed that the core particles are spherical and the capsule wall is uniform. This enables the use of a simplified model in which the microcapsule is considered to be composed of two spheres. Using the appropriate

relationship (13), expressed in terms of fractional drug content[6], a mean spherical wall thickness is estimated as:

$$r_2 - r_1 = \left\{\left[\frac{d_c}{d_{EC}}\left(\frac{1}{F} - 1\right) + 1\right]^{1/3} - 1\right\} r_1 \qquad \text{(Eq. 4)}$$

where r_1, r_2 are the mean radii of the microcapsules and the core particles, and d_{EC}, d_c are the densities of ethylcellulose and the core materials. The densities of the microcapsules and the core and wall materials were determined in cyclohexane using a pycnometer. Dried materials were used and volume adjustment was completed in a few seconds to avoid imbibition and swelling. The results were duplicated exactly and were within 2% of literature values.

Microscopic Studies—Optical[7] and scanning electron microscopy[8] were used to evaluate the quality of the coating obtained under the various conditions used.

Release of Microencapsulated Material—Release of active ingredients from the microcapsules was measured using a rotating basket dissolution apparatus similar to that described in the USP XIX, modified by use of a 100-ml perspex basket in place of the wire mesh, the wall of which was pierced by four windows and covered by a nylon screen (80–100 mesh) bonded permanently by means of epoxy resin to the inner wall, to prevent exit of the microcapsules (Fig. 1). The upper side was pierced by eight holes, sealed with the same nylon screen, and the perspex hollow-ring screw-on base contained a nylon screen insert. The basket was rotated at 100 rpm (±3%) by means of a constant-rate adjustable stirrer[9], using a covered beaker containing 1 liter of water at 37 ± 0.5°. Drug release was determined spectrophotometrically[10] using a flowcell with a pump[11] and automatic recording (sample size, 50–100 mg). There was no turbulence, as checked by measurement of dissolution rate of standard pellets of pure benzoic acid.

The wavelengths used for salicylamide and theophylline were 298 and 272 nm, respectively. Dissolution experiments were duplicated and were closely reproducible.

RESULTS AND DISCUSSION

Appearance of Microencapsulated Core Materials—From the preliminary experimental results, it was observed that the presence of polyisobutylene at a minimal concentration was vital to the formation of individual microcapsules. The use of concentrations between 0 and 2% failed to give good reproducible microcapsules. The final product obtained after sieving (1190–840 μm) was composed mainly of large irregular aggregated masses, which were dispersions of core material in ethylcellulose as shown by scanning electron microscopy (Fig. 2). Microscopically, it was impossible to distinguish individually coated particles inside the mass.

Deasy *et al.* (9) obtained a product with surface properties closely similar to the aggregates shown in Fig. 2. The particle size of their product ranged between 1190 and 300 μm, and although an increase in the proportion of finer aggregates was achieved by drastic increase in agitation rate and slowing down of the cooling rate, the nature of the coated particles was essentially unchanged.

The minimum polyisobutylene enabling formation of individually microencapsulated core particles was 3%. However, high turbulence in the system at this concentration, in which the viscosity was low, led to losses of wall polymer by adhesion to the container walls during the cooling phase, while reduced agitation led to adhesion to the stirrer and bottom of the vessel. Such losses were negligible under the experimental conditions used when 5% protective colloid was added.

Photomicrographs (Fig. 3) of salicylamide and theophylline microcapsules in cyclohexane show that each particle was uniformly coated and no aggregation of the microcapsules occurred even after decantation and separation (Fig. 4). The coacervated polymer droplets formed a smooth continuous coat around each particle, markedly different from the surface characteristics of pure salicylamide. Clearly, the presence of an adequate polyisobutylene concentration in the coacervation process

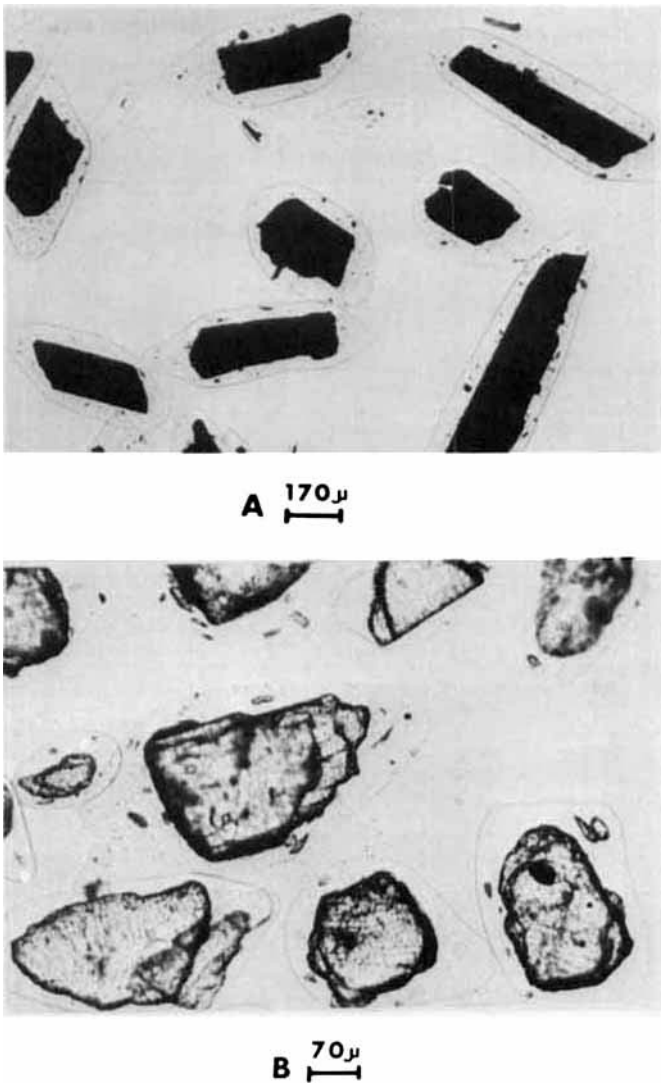

Figure 3—*Photomicrographs of theophylline microcapsules, A (5% theophylline, 5% ethylcellulose, and 5% polyisobutylene at 250 rpm) and salicylamide microcapsules, B (5% salicylamide, 5% ethylcellulose and 5% polyisobutylene at 300 rpm).*

enables formation of such a continuous wall, which may be termed a film-coat, as opposed to the spongy aggregate matrix obtained in the absence of protective colloid or at a low concentration.

These different forms have perhaps not been adequately distinguished in the literature; both are produced by the same basic cooling coacervation method according to the experimental conditions used, and both are described as microcapsules. The particle size of those possessing a matrix-type wall would be expected to be inadequate as a parameter for their characterization and their properties would be expected to vary considerably even at constant particle size, depending on porosity and shape factors and the number of core particles entrapped. On the other hand, in the film-coat type, the shape of the core particle is maintained even when these are highly asymmetrical (Fig. 5). The film thickness appears enlarged in the photomicrographs (Fig. 3) because of swelling of the coat in the original solution or pure cyclohexane. For this reason, no direct measurement of the film thickness could be performed using an optical microscope. Experiments were performed with other solvents such as glycerin and liquid paraffins, but in this case it was difficult to distinguish the wall clearly.

Effect of Polyisobutylene Concentration—In studies of the influence of the protective colloid concentrations, it is not expected that the mean drug content of the microcapsules would change if the initial amounts of wall and core material and the particle size were kept constant, provided the drugs are insoluble in the hot and cold solvent mixtures and the core and wall materials are totally incorporated in the final microcapsules obtained. Alternatively, such losses of core and wall material that do occur should be independent of protective colloid concentration. However, routine microscopic and scanning electron microscopic observation of the products led to detection of varying amounts of empty spherical particles of wall material in the different batches which evidently were solidified coacervate droplets (Fig. 6). They were removed by the repeated decantation to obtain drug-filled microcapsules alone. Since quantitative recovery of empty shells proved to be laborious and some microcapsules were lost in the separation, the drug content of the

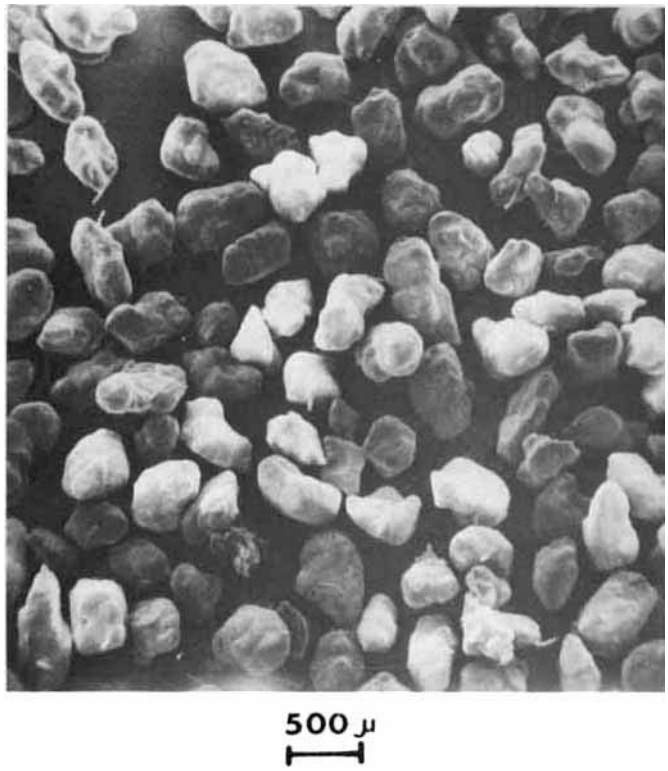

Figure 4—*Scanning electron micrograph of salicylamide microcapsules (see text).*

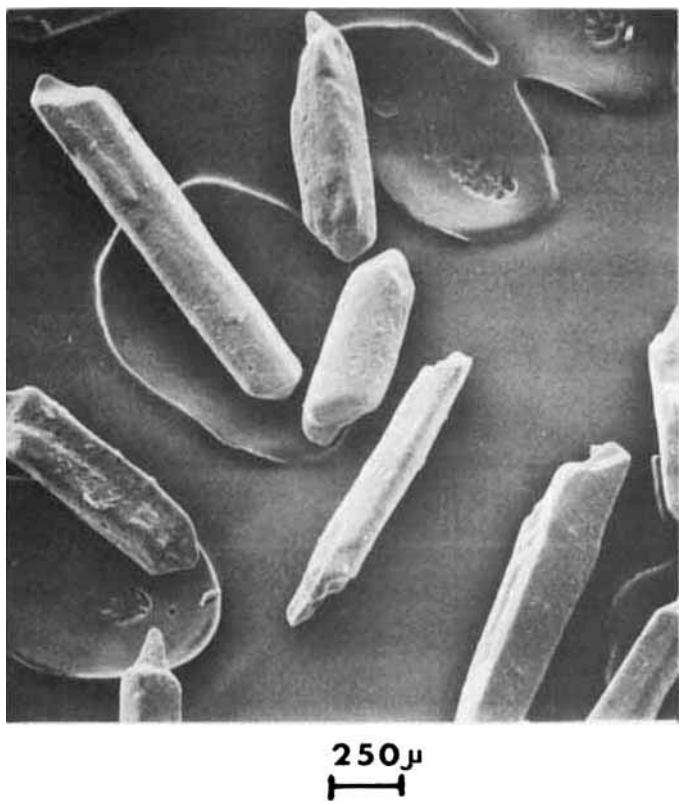

Figure 5—*Scanning electron micrograph of theophylline microcapsules (see text).*

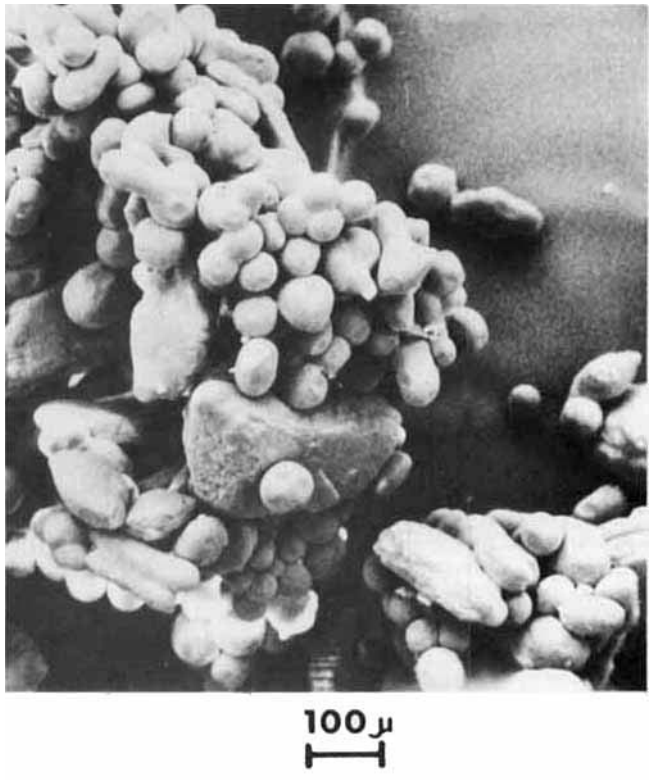

Figure 6—*Scanning electron micrograph of salicylamide microcapsules (250–300 μm) with empty spherical coacervate droplets (40–60 μm).*

purified microcapsules was determined analytically. Then, from the initial quantities of materials used, assuming that all the available drug had been microencapsulated uniformly (as was confirmed by experimental observation) the amount of wall polymer in the microcapsules was calculated and hence the amount "wasted."

This method, described in the experimental section, has not yet been applied to the microencapsulation process. Use of equations for concentric spheres (13) enabled estimation of mean equivalent sphere coat thickness. This calculation probably gives a reasonably true value for salicylamide but a hypothetical one for theophylline due to the crystal shapes (Fig. 3). Repeat batches treated in this way proved to have reproducible drug contents, indicating that stirring conditions, cooling rate, and the separation process were well controlled (Table I).

The drug content of the microcapsules, as seen in Table I, was constant up to 7% of polyisobutylene, but then rose sharply indicating decrease of uptake of wall material by the core particles, which is shown calculated as percentage ethylcellulose loss. The equivalent wall thickness also expresses this trend, and since drug release rate from the microcapsules followed first-order kinetics (Figs. 7A and 7B), release-rate constants[12] were evaluated for the series; they are inversely related to the mean wall thickness in salicylamide (Table I). The same protective colloid effects are evident in the preparation and data of theophylline microcapsules (Table II), although with this core material, the concentration effect is gradual rather than drastic.

Relation to Wall Polymer Coacervation—In considering possible causes of the observed decrease of coating efficiency, it is tempting to assume that excess wall polymer was used, so that decreasing its quantity will eliminate the losses. However, halving the amount of ethylcellulose to 2.5% (w/w) at the 5% level of polyisobutylene, with the other conditions as in Table I, yielded microcapsules which, after purification, contained 87.9% salicylamide, corresponding to 72.4% loss of ethylcellulose, compared with 4.5% loss at 5% wall polymer. Initial studies over a wider range of core and wall concentrations confirms this trend and will be reported upon completion.

In ethylcellulose coacervation studies performed in the absence of core material (12) under the same conditions used in Table I, the phase coacervation volume, which was small at low concentrations of protective colloid, rose sharply at first and flattened out to give a constant value between 5 and 7% of polyisobutylene. Above this level of additive, the

[12] A full analysis of the release kinetics of microcapsules made by this method is the subject of the second part of this investigation.

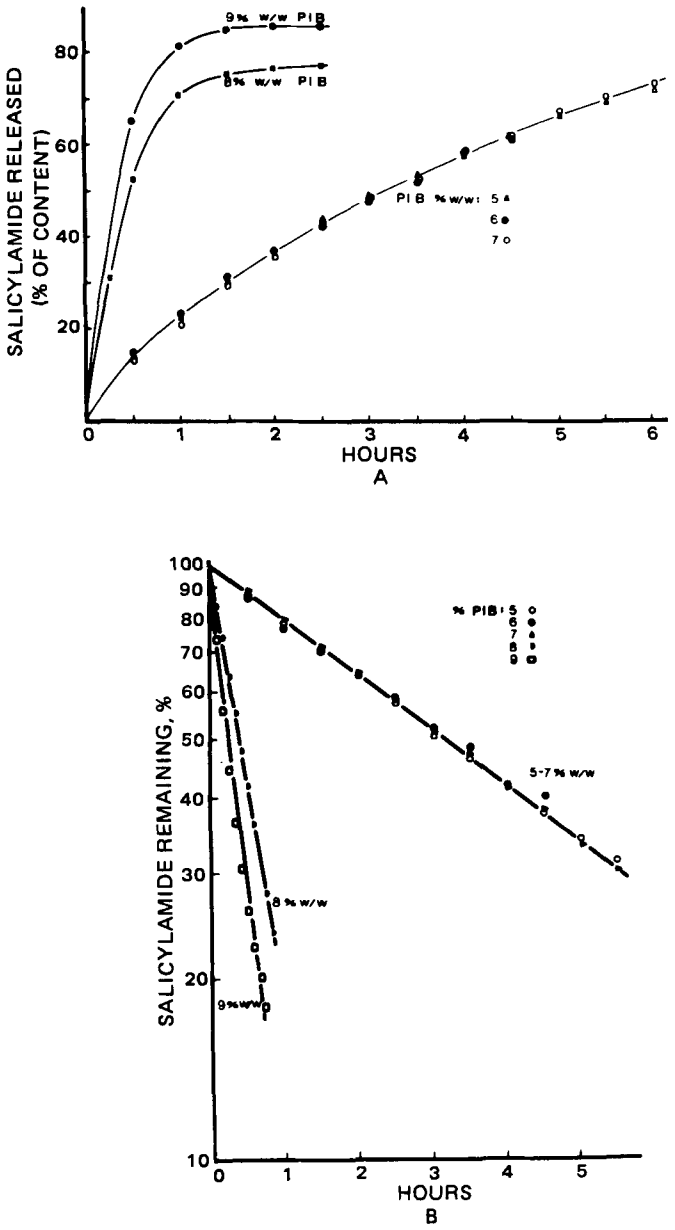

Figure 7—*Salicylamide release from microcapsules prepared using different polyisobutylene concentrations; linear plot (A) and first-order plot (B).*

coacervation volume rose very steeply toward 100% of the total volume, reached at 10% additive. Values (Table I) ran in a manner closely similar to drug content. The coacervate droplet size in the absence of core material was shown to change inversely to the phase coacervation volume (12). The relation of the effects of polyisobutylene on coacervation and microencapsulation parameters are more clearly evident graphically (Fig. 8). Microcapsule wall thickness remained relatively constant as did release rate from the microcapsules and coacervate droplet size at 5–7% polyisobutylene; above this range they changed steeply, with thickness and droplet size falling and release rate rising. The related function, loss of ethylcellulose, followed an inverse pattern to wall thickness. It is clearly indicated that the coating ability for salicylamide falls off drastically as the protective colloid concentration exceeds a critical value, at which the droplet size also undergoes drastic change and the coacervation volume rises (Table I).

It seems that the microcapsule coating process reflects more fundamental changes arising from the coacervation process.

The sudden increase in coacervation volume above 7% in the absence of core material was considered due to a combination of decrease in coacervate drop size and increase in viscosity, the former effect resulting from stabilization of the droplets by adsorption of polyisobutylene as a protective colloid at an earlier stage in droplet growth (12). Such stabi-

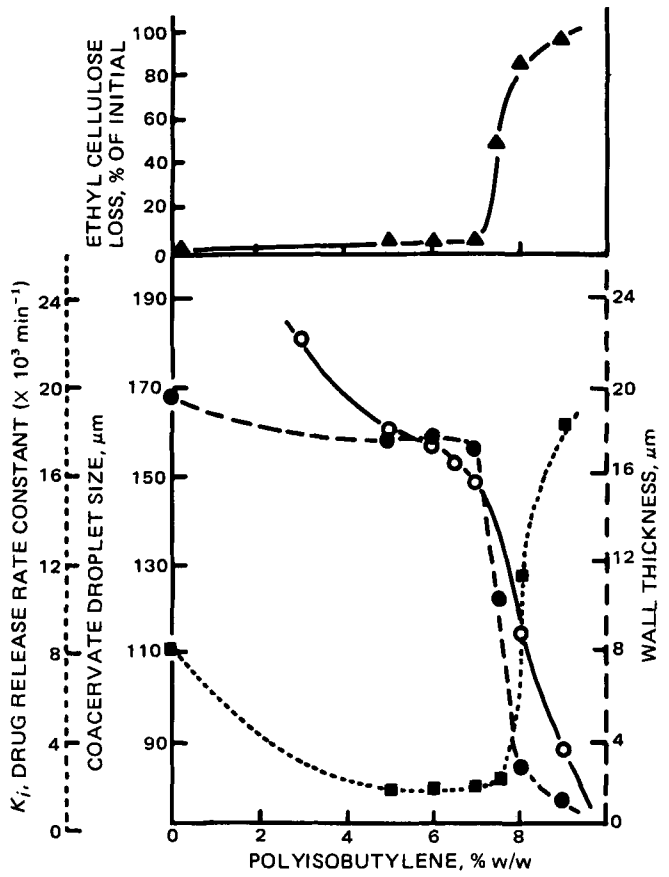

Figure 8—*Effect of polyisobutylene concentration on coacervate and microcapsule parameters (core material: salicylamide; see Table I for conditions). Key: ●, wall thickness; ○, coacervate droplet size; ▲, ethylcellulose loss; and ■, first-order release rate constant* (k_i).

lized coacervate droplets, suspended in the solvent, were unable to coat core material when the two were mixed and stirred together at room temperature. Therefore, it is proposed that the mechanism of the effects observed on increasing the protective colloid concentration above a critical level is that diffusion and growth of wall polymer from the coacervate microdroplets separating out during cooling is inhibited by increase in viscosity, and a larger proportion of droplets are stabilized when they are still small, becoming less available for use in coating.

Effect of Particle Size—The drug content of the microcapsules decreased with reduction in core particle size (Tables II and III). With a fixed amount of core material, particle size reduction leads to increase in the specific surface. The corresponding minimization in the loss of wall polymer may be attributed to the availability of the additional surface for entrapment of separating coacervate droplets. It can also be seen that at equivalent particle sizes there is a tendency for ethylcellulose loss to vary from one drug to another, probably due to differences in particle shape or surface energy[13].

The variation in drug content of the microcapsules as a function of particle size is reflected in the drug release rates, which change inversely with wall thickness[14] (Tables II, III). However, the precise quantitative relationship cannot be tested without allowing for size distribution and shape factors, considerations that are beyond the scope of this study.

The particle size effect fits the mechanism proposed. Considering the coating and stabilization of empty droplets as competitive processes, the former will be favored at the expense of the latter by surface area increase of the core material, which should enhance the rate of uptake of the separating ethylcellulose.

In fact, the results obtained in this work are in contradiction to those published in the literature. It is well accepted that at a constant ratio of coat polymer to drug, decrease of particle size leads to a decrease in wall thickness and an increase in release rate (13). This is true only if in the specific microencapsulation process all the coating polymer is used up in building the wall. Microencapsulation using ethylcellulose coacervated in the presence of protective colloid gives a unique system in which the latter prevents empty stabilized coacervated droplets from interacting with microcapsules, and encourages formation of a continuous uniform film coat which retains the shape of the core material.

The results also show that by means of particle size change, the effective coating efficiency may be varied between high and low levels with consequent change of wall thickness while retaining a true film coating. The question of whether the amount of initial wall material used is in excess or not has a different relevance in a system in which the concentration of protective colloid is one of the major controlling factors in the efficiency of the coating process. By choice of suitable protective colloid concentration or particle size, full efficiency can be achieved without changing the initial wall polymer concentration.

[13] Although different stirring rates were employed, this factor was found insufficient to account for the differences between the two drugs.

[14] There is a tendency for release rate to rise as core particle size falls, at equivalent wall thickness, probably due to surface area increase.

Investigation of Digoxin, Quinidine, and Disopyramide Interactions in Rats Utilizing Parotid Saliva, Blood, and Other Tissues

G. JOHN DiGREGORIO[x], ANTHONY J. PIRAINO, EILEEN K. RUCH, and PETER J. BASSECHES

Received February 26, 1981, from the *Hahnemann Medical College and Hospital, Philadelphia, PA 19102.* Accepted for publication June 26, 1981.

Abstract □ Blood, parotid saliva, heart, liver, and kidney concentrations of digoxin and quinidine were determined in rats chronically treated with digoxin and in nontreated (control) rats after the administration of quinidine (20 mg/kg ip) and disopyramide (10 mg/kg ip). The results indicated that digoxin concentrations increased significantly and proportionally in parotid saliva and plasma after quinidine, but did not increase after disopyramide. With the exception of the liver, which showed an increase in digoxin concentrations, tissue concentrations of digoxin did not differ from control animals. In rats pretreated chronically with digoxin, quinidine concentrations in plasma, parotid saliva, or heart tissue did not differ significantly from control animals, but were significantly lower than controls in liver and kidney tissues. The results presented here lend additional support to the hypothesis that the increase in digoxin plasma concentration following quinidine administration is primarily due to interference with renal excretion and displacement of digoxin by quinidine binding sites. Furthermore, it was demonstrated that disopyramide has little or no effect on plasma digoxin levels in rats.

Keyphrases □ Digoxin—interaction with quinidine and disopyramide in parotid saliva, blood, and other tissues □ Quinidine—interaction with digoxin and disopyramide in parotid saliva, blood, and other tissues □ Disopyramide—interaction with digoxin and quinidine in parotid saliva, blood, and other tissues

Considerable attention has been focused on the mechanism of the drug interaction between digoxin and quinidine (1–7). Several mechanisms have been proposed, but because of the limited flexibility of the human model, they cannot be supported by hard experimental evidence. Relatively few animal studies have been employed to evaluate the digoxin–quinidine interaction.

The present investigation evaluated the interaction between digoxin and quinidine and digoxin and disopyramide in rats. Blood, parotid saliva, and tissue concentrations of digoxin were determined in rats pretreated chronically with digoxin and later administered single doses of quinidine or disopyramide. In addition, blood, parotid saliva, and tissue concentrations of quinidine were determined in rats chronically pretreated with digoxin and later administered a single dose of quinidine.

EXPERIMENTAL

Reagents and Materials—all reagents were analytical grade, and all aqueous solutions were made with glass-distilled water. Digoxin[1] and pentobarbital sodium[2] were obtained in the injectable form. Quinidine[3] and disopyramide[4] were obtained in powdered form and appropriate solutions were made. Cannulas for the collection of whole blood and parotid saliva were fabricated from polyethylene 50 and 10 tubing[5]. Samples collected were assayed for digoxin and quinidine content using enzyme immunoassay kits[6] in accordance with the manufacturer's instructions.

Experiment 1—*Comparison of Digoxin Concentrations in Parotid Saliva, Plasma, Heart, Liver, and Kidney Tissues of Rats Administered Quinidine, Disopyramide, and Saline*—Male Wistar rats, 150–170 g, were housed in individual cages and provided with a standard diet of laboratory chow[7] and distilled water containing digoxin (2.5 μg/ml) *ad libitum*. The volume of water consumed and weight gained were recorded daily for each animal. After 8 days of drinking digoxin-containing water, a total of 37 animals were divided into three experimental groups, A, B, and C (Scheme I). These groups were designated to receive saline, quinidine (20 mg/kg ip) and disopyramide (10 mg/kg ip), respectively.

All animals were prepared surgically for collection of parotid saliva and whole blood using pentobarbital (50 mg/kg ip) anesthesia according to an earlier method (8). A tracheotomy was performed and with the aid of a dissecting microscope, the right brachial artery, right femoral artery, and both parotid ducts were surgically exposed for cannulation. The brachial and femoral arteries were cannulated with polyethylene 50 tubing and the parotid ducts were cannulated with tapered polyethylene 10 tubing. The femoral artery was used to obtain blood samples. The brachial artery was used for the constant infusion of the secretagogue, pilocarpine (0.25 mg/ml) at a rate of 0.21 ml/min. The parotid cannulas were directed into a disposable glass culture tube for the collection of saliva.

Following surgery, Group A animals received an intraperitoneal challenge injection of saline, Group B, an intraperitoneal challenge injection of quinidine, and Group C received an intraperitoneal challenge injection of disopyramide. Thirty minutes after the intraperitoneal challenge, the collection of parotid saliva was started and continued over

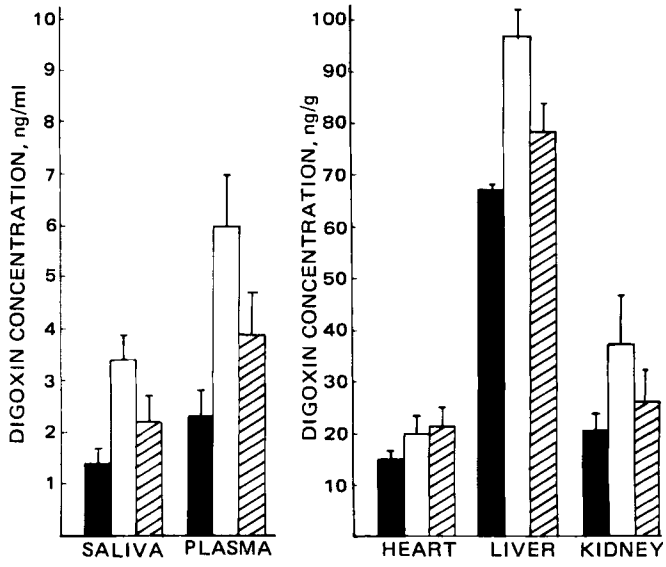

Figure 1—*Comparison of digoxin concentrations in parotid saliva, plasma, heart, liver, and kidney tissues of digoxin chronically treated rats after saline (■, Group A), quinidine (□, Group B), and disopyramide (▨, Group C).*

the next 30 min. Subsequently, 5 ml of whole blood was removed from the femoral artery and placed in a heparinized tube. The animal was then sacrificed and the heart, liver, and kidneys were removed; whole blood was centrifuged and the plasma was removed. All samples were frozen until the assay. The sequence of these events is presented in Scheme I.

Heart, liver, and kidney samples were weighed and 0.75–1.00 g of tissue was homogenized in 5 ml of 0.9% sodium chloride and mixed with 10 ml of methylene chloride (9). After centrifugation, 5 ml of the organic layer was decanted and evaporated. The residue was dissolved in 5 or 10 ml of distilled water (10). All samples were assayed for digoxin content by enzyme immunoassay.

Experiment 2—*Comparison of Quinidine Concentration in Parotid Saliva, Plasma, Heart, Liver, and Kidney Tissues of Rats Pretreated with Digoxin and Saline*—Male Wistar rats, 150–170 g, were housed in individual cages and given a standard diet of laboratory chow *ad libitum*. Control animals (Group A) were provided tap water *ad libitum*, while experimental animals (Group B) were provided tap water containing digoxin (2.5 μg/ml) *ad libitum* (Scheme II). Water consumption and weight gain were recorded daily for both groups. After 8 days, both groups of rats underwent surgical preparation as described for Experiment 1.

Quinidine (20 mg/kg ip) was administered to Group A and Group B animals. Parotid saliva was collected over 30 min after which each animal was sacrificed and blood, liver, heart, and kidney samples were removed. Samples were handled in a manner similar to that described in Experiment 1. However, in this experiment, samples were assayed for quinidine concentration using enzyme immunoassay.

RESULTS

As described, the rats given digoxin-containing water (2.5 μg/ml) for 8 days were divided into three groups based on the administration of a second drug on the 8th day (Table I): Group A (control animals), which received only digoxin, Group B (quinidine animals), and Group C (disopyramide animals).

Daily digoxin consumption and body weight in these three groups were compared. Using the Student *t* test, no significant differences in the daily digoxin consumption or body weights could be found among any of the groups ($p > 0.05$).

Comparison of Digoxin Concentrations in Parotid Saliva, Plasma, and Heart, Liver, and Kidney Tissues of Rats Administered Quinidine, Disopyramide, and Saline—Digoxin concentrations in the parotid saliva, plasma, liver, kidney, and heart tissues in rats consuming digoxin for 8 days were measured in each of three experimental groups with the following results (Fig. 1).

The digoxin content of saliva and plasma collected from Group A (control) animals was 1.4 ± 0.3 and 2.3 ± 0.5 ng/ml, respectively. Heart, liver, and kidney tissue displayed digoxin concentrations of 14.8 ± 1.7, 67.0 ± 1.0, and 19.7 ± 3.8 ng/g, respectively.

Group B (quinidine treated) rats displayed a digoxin concentration in parotid saliva of 3.4 ± 0.5 ng/ml and a plasma concentration of 6.0 ± 1.0 ng/ml. When the hearts, livers, and kidneys of these animals were homogenized and analyzed they were found to contain 20.0 ± 4.0, 96.4 ± 5.7, and 37.1 ± 9.4 ng/g of digoxin, respectively.

Group C (disopyramide treated) rats displayed saliva and plasma digoxin levels of 2.2 ± 0.5 and 3.9 ± 0.8 ng/ml, respectively. Analysis of their heart, liver, and kidney tissue revealed digoxin levels of 21.7 ± 3.5, 78.4 ± 7.1, and 26.0 ± 6.2 ng/mg, respectively.

When evaluated using the Student *t* test, the digoxin content of parotid saliva, plasma, and liver was significantly higher in Group B rats than in control animals $p < 0.01$, $p < 0.005$, and $p < 0.005$, respectively. No significant differences in digoxin concentration could be found between control rats and Group C animals for any tissue studied ($p > 0.05$).

The mean ratios (±*SE*) between parotid saliva digoxin concentrations and those found in plasma were 0.60 ± 0.10, 0.69 ± 0.11, and 0.68 ± 1.20 for the Group A, B, and C rats, respectively. For Groups A, B, and C, the mean ratios (±*SE*) between the digoxin concentrations found in liver and in plasma were calculated to be 33.8 ± 8.7, 29.0 ± 8.60, and 35.2 ± 10.40; for kidney and plasma, 8.0 ± 1.60, 8.9 ± 2.10, and 8.7 ± 1.70; and finally for heart and plasma, 9.3 ± 2.80, 5.3 ± 1.60, and 7.3 ± 1.80.

Comparison of Quinidine Concentration in Parotid Saliva, Plasma, Heart, Liver, and Kidney Tissues of Rats Pretreated with Digoxin and Saline—Control animals displayed quinidine concentrations (Fig. 2) of 0.3 ± 0.1 ng/ml (parotid saliva) 1.1 ± 0.8 ng/ml (plasma), 1.0 ± 0.2 ng/g (heart), 0.6 ± 0.2 ng/g (liver), and 1.3 ± 0.4 ng/g (kidney). Parotid saliva and plasma were analyzed in Group B rats and found to contain quinidine in concentrations of 0.4 ± 0.04 and 0.9 ± 0.1 ng/ml, respectively. Homogenates of heart, liver, and kidney tissues taken from these animals contained 0.6 ± 0.2, 0.3 ± 0.05, and 0.5 ± 0.1 ng of quinidine/g, respectively. When these quinidine concentrations were compared with those obtained in control animals using the Student *t* test, the following results were noted. No significant variation between the groups was found for quinidine concentrations detected in parotid saliva ($p > 0.05$), plasma ($p > 0.05$), or heart tissue ($p > 0.05$). The quinidine concentrations in the liver and kidney tissue of Group A animals were significantly higher than those of Group B animals ($p < 0.05$).

DISCUSSION

Some controversy exists concerning the mechanism of the interaction reported to occur between quinidine and digoxin. The most frequently

B	10	259 ± 4.6	104.0 ± 5.0
C	10	253 ± 7.9	122.2 ± 8.0

[a] Group A animals received digoxin only; Group B received digoxin and quinidine; and Group C received digoxin and disopyramide. [b] Mean (±*SE*) of weights of rats fed over 8 days. [c] Mean (±*SE*) of digoxin consumed per 24 hr from drinking water containing 2.5 μg of digoxin/ml over 8 days.

proposed mechanisms include the displacement of digoxin by quinidine from tissue binding sites (2, 5) and the interference by quinidine with renal digoxin excretion (11).

During the 8 days of digoxin consumption, animals in all groups consumed approximately the same quantity of digoxin. In addition, the mean weights after pretreatment with digoxin did not differ from group to group. The results indicated that during these 8 days, all the animals reacted similarly, so there was little or no intra-individual variation at the time of the experiment.

Results of the present investigation support two possible mechanisms for this interaction: (*a*) quinidine interferes with the renal excretion of digoxin although renal clearance of digoxin has not been measured, and (*b*) quinidine interferes with digoxin tissue binding sites.

Following quinidine administration, digoxin concentrations increased significantly in plasma and parotid saliva compared with control animals. The increases were proportional because the saliva/plasma ratios for control animals and the experimental group did not significantly differ from each other. In liver tissue, digoxin concentrations increased after quinidine administration; however, kidney and heart digoxin concentrations did not significantly differ from those of control animals. The increase in plasma was greater than any of the tissue concentration changes. Subsequently, the liver and cardiac muscle tissue/plasma concentration ratios actually decreased after quinidine administration, whereas the kidney/plasma ratio did not significantly change. These results were similar to other findings (12) where the corresponding digoxin tissue/serum ratios decreased in dogs after quinidine.

Assuming the increase in plasma digoxin concentrations involves an interference with renal digoxin excretion by quinidine, proportional increases in the plasma and parotid saliva digoxin concentrations and possible increases in tissue concentrations would be expected. This hypothesis is supported by previous investigations (13–15) that demonstrated that increasing the plasma concentrations of various drugs causes proportional increases in the free nonprotein-bound plasma drug levels as well as those in the parotid saliva. However, if the increases in plasma digoxin concentration after quinidine administration were due solely to a decrease in plasma protein or tissue digoxin binding, one would anticipate that: (*a*) parotid saliva concentrations would increase to a greater proportion than plasma with a subsequent increase in the saliva/plasma ratio, and/or (*b*) tissue digoxin concentrations would decrease significantly due to the displacement of digoxin by quinidine.

As previously discussed, saliva/plasma ratios did not change from control values, but the liver and cardiac digoxin tissue concentrations showed a tendency to decrease when compared with the plasma concentrations. It is for these reasons that the present results support more than one mechanism for this interaction which may involve tissue binding sites and renal clearance.

Other investigators (1, 16) reported that various antiarrhythmic agents (including disopyramide) had little or no effect on digoxin blood levels. Results also indicate that there are no significant differences between digoxin concentrations in plasma, parotid saliva, and heart, liver, and kidney tissues determined before and after disopyramide administration.

In the second experiment, quinidine concentrations in blood and parotid saliva showed no significant differences between control and digoxin-treated animals. In addition, quinidine concentrations tended

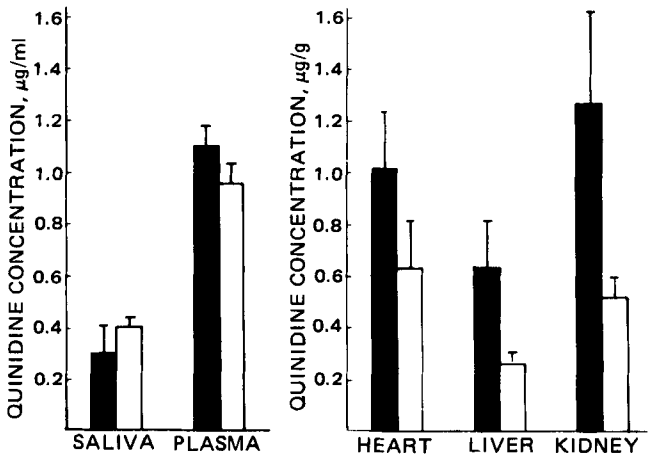

Figure 2—*Comparison of quinidine concentrations in parotid saliva, plasma, heart, liver, and kidney tissues in control rats (■, Group A) and in digoxin chronically treated rats (□, Group B).*

to decrease in liver and kidney tissue. As previously discussed, if the interaction was mainly due to the ability of quinidine to displace digoxin from plasma proteins binding sites, the free plasma concentrations of quinidine or parotid saliva quinidine would be expected to decrease. However, if quinidine significantly occupied tissue binding sites previously occupied by digoxin then the quinidine tissue concentrations would tend to increase over control. In neither instance did the earlier results correlate with an interference of plasma protein or tissue binding. However, if the interaction of quinidine–digoxin was controlled only by a renal mechanism, then quinidine concentrations in plasma and/or parotid saliva would probably not differ from those of controls as observed. However, while one would expect that quinidine concentrations in kidney would increase under this mechanism, the results presented here actually show the opposite effect, suggesting the possibility that more than one mechanism is involved. Studies are in progress to investigate these findings further.

Structure–Activity Relationships Among Substituted *N*-Benzoyl Derivatives of Phenylalanine and Its Analogs in a Microbial Antitumor Prescreen I: Derivatives of *o*-Fluoro-DL-phenylalanine

THEODORE T. OTANI ˣ and MARY R. BRILEY

Received May 15, 1981, from the *Laboratory of Pathophysiology, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication June 11, 1981.

Abstract □ Twelve derivatives of *o*-fluoro-DL-phenylalanine containing fluorine, chlorine, methoxy, and nitro radicals in various positions of the aromatic ring of the benzoyl group were prepared and tested in a *Lactobacillus casei* system. It was found that most substitutions in the benzoyl phenyl ring resulted in a compound exhibiting greater growth-inhibiting activity than the nonsubstituted benzoyl-*o*-fluorophenylalanine. The greatest activity was observed in the *ortho*-substituted fluoro compound and the *meta*- and *para*-substituted chloro and nitro compounds. With the methoxy group, the position of substitution appeared unimportant, since all three methoxy isomers exhibited essentially equal inhibition. Nitro substitution in the *ortho* position had a protective effect in that the product was less active than the unsubstituted benzoyl-*o*-fluoro-DL-phenylalanine.

Keyphrases □ Structure–activity relationships—substituted *N*-benzoyl derivatives of phenylalanine, microbial antitumor prescreen □ Phenylalanine—substituted *N*-benzoyl derivatives, microbial antitumor prescreen □ Antitumor agents, potential—microbial antitumor prescreen, substituted *N*-benzoyl phenylalanine derivatives

Previous studies on the effect of *N*-acylated amino acids and amino acid analogs on the growth of *Lactobacillus casei* in an antitumor prescreen indicate that certain acyl groups could activate an otherwise inert amino acid or amino acid analog to inhibit the growth of the organism (1–4). *N*-Chloroacetyl (1–3) and *N*-trifluoroacetyl (4) derivatives of certain amino acids exhibited modest but significant inhibition. However, among the acyl amino acids studied, the *N*-benzoyl derivatives showed the greatest inhibition, especially the benzoyl derivatives of phenylalanine analogs (5, 6). The nature and the position of the substituent in the aromatic ring of phenylalanine are apparently of some importance in the action, since substituents at various positions in the ring resulted in compounds of different activity. Of the seven benzoyl derivatives of ring-substituted phenylalanine and phenylalanine analogs studied earlier, benzoyl-*p*-chloro- and benzoyl-*m*-fluorophenylalanine showed the greatest inhibition (5, 6). Among the *N*-chloroacetyl derivatives of *p*-halophenylalanines the activity decreased in order from the *p*-iodo through the *p*-bromo and the *p*-chloro to the *p*-fluoro derivatives (7).

This study attempted to find out whether substituents in the aromatic ring of the benzoyl moiety would similarly affect the inhibitory activity of these compounds and whether more potent inhibitors could be devised by combination of the appropriate substituted benzoyl and phenylalanine moieties. Thus, a systematic study was undertaken to observe the effect of varying the substituents (a) to the benzoyl moiety while keeping the amino acid portion constant, and (b) to the amino acid while keeping the benzoyl moiety unchanged.

In this study, the amino acid moiety was *o*-fluoro-DL-phenylalanine, and the aroyl part included 12 ring-substituted benzoyl derivatives[1].

EXPERIMENTAL

o-Fluoro-DL-phenylalanine was obtained commercially[2]. Its purity was checked by paper chromatography in four separate solvent systems (*cf.* Ref. 2), elemental analysis, and by nitrous acid gasometric analysis of primary amino nitrogen (8). When necessary it was recrystallized from water–ethanol. The acylating agents were obtained from commercial sources and purified, by distillation or recrystallization when necessary.

The acyl derivatives were prepared by the Schotten–Baumann procedure (*cf.* Ref. 9). The liquid acylating agents were added in 1.2 mole excess directly into the reaction mixture in six equal portions over a 1-hr period. Solids were added as an ethyl acetate solution, also in six equal portions over a 1-hr period. The reaction in most cases was carried out between 0 and 5°. However, when the acylating agent solidified at that temperature, the reaction was carried out at 10°.

The purity of the prepared acyl derivatives was ascertained by elemental analysis, melting point determination, and by nitrous acid gasometric determination of primary amino nitrogen (8) (Table I).

For the microbiological assay, the acyl compounds were dissolved in one equivalent of sodium hydroxide. In some cases, warming was required to dissolve the compound. At this point, the pH of the test solution was ~6.

A modification was made on the sterilization procedure of the test compounds so that a larger number of compounds could be tested each time. The all-glass filtration procedure for sterilization was replaced with one using sterilizing filter units[3] (0.22-μm pores) attached to plastic syringes[4].

The assay medium was a riboflavin-supplemented riboflavin assay medium[5] containing 0.03 μg of riboflavin[6]/ml in the final assay system.

The system was incubated at 37.5° for 19 hr, and then bacteria growth was terminated by immersing the tubes in boiling water for 10 min. After the suspension was cooled in an ice bath for 10 min, the growth was determined turbidimetrically on a photoelectric colorimeter[7] equipped with a red filter (660 nm).

The organism used was *Lactobacillus casei* 7469[8], which was carried on agar[9], subcultured bimonthly, and transferred to a broth[9] for the preparation of the inoculum. The inoculum was a 1:20 diluted suspension of the washed bacteria in 10 ml of normal saline. Details of the assay procedure were described previously (1).

The extent of growth in the inoculated control (containing no test compound), the inhibitor control (containing 6-mercaptopurine[10]), and in some of the compounds previously studied, varied with different lots

[1] This paper is part of a continuing study of the effect of *N*-acylation of amino acids and of amino acid analogs on the growth of microorganisms used as a prescreen for antitumor activity and is the first of a series of papers describing the inhibitory effect of substituted benzoyl derivatives of various phenylalanine analogs.

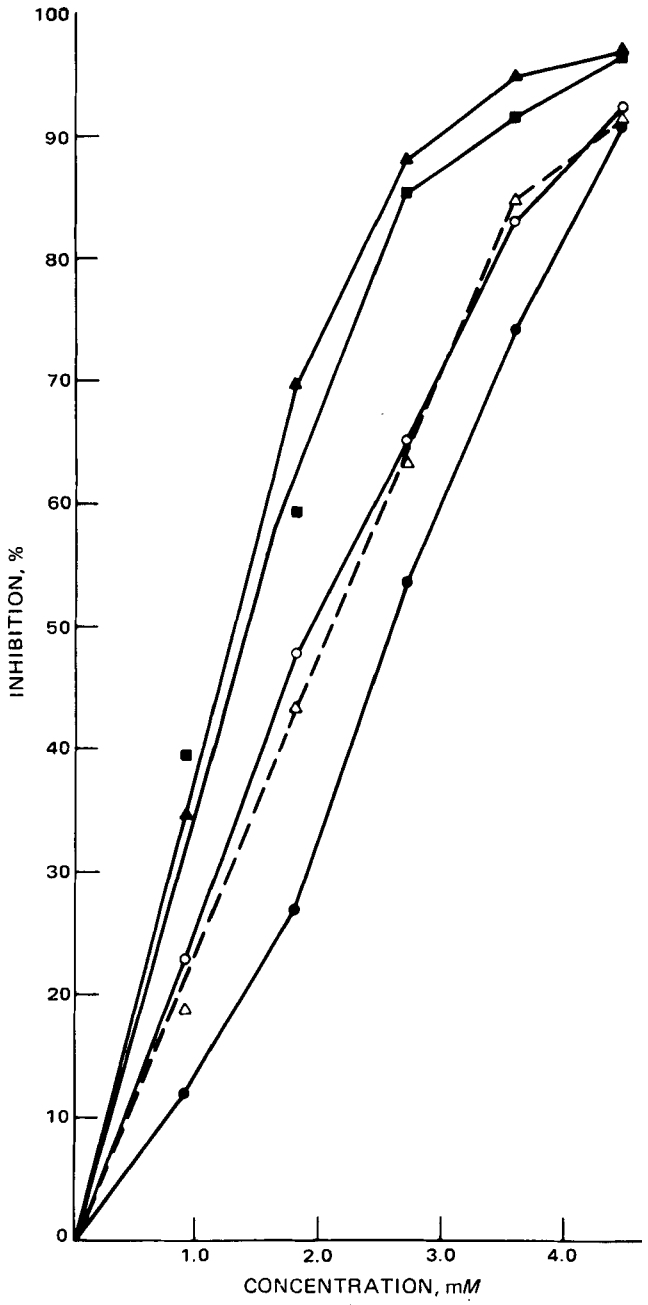

Figure 1—*Inhibition curves of some substituted benzoyl-o-fluoro-DL-phenylalanines: determination of ID_{50}. Key:* ●, *o-fluorobenzoyl-o-fluoro-DL-phenylalanine;* ▲, *m-chlorobenzoyl-o-fluoro-DL-phenylalanine;* ■, *p-chlorobenzoyl-o-fluoro-DL-phenylalanine;* ○, *m-nitrobenzoyl-o-fluoro-DL-phenylalanine; and* △, *p-nitrobenzoyl-o-fluoro-DL-phenylalanine.*

of the riboflavin assay medium used. Therefore, in this study and all subsequent studies of this series, the comparison of the extent of growth was made using medium of the same lot. In addition, the pH of the assay medium was adjusted uniformly to 6.40 by the addition of an appropriate amount of 0.5 *N* HCl before addition of the test compounds. The pH of the final system, determined on an aliquot of the medium containing an equivalent amount of the test compounds as the experimental tubes, was 6.20, and was within 0.1 pH units of the control tubes containing no test compounds.

RESULTS AND DISCUSSION

Most of the substituted *N*-benzoyl derivatives of *o*-fluoro-DL-phenylalanine showed considerable inhibitory activity. Of the 12 compounds tested, nine showed inhibition of ≥50% (Table II). These compounds may be considered to be positive according to the protocol of the microbial antitumor prescreen (10), and will be tested further in mammalian tumor systems.

Of the remaining three compounds, *m*-fluorobenzoyl- and *p*-fluorobenzoyl-*o*-fluoro-DL-phenylalanine, though slightly less active, nevertheless showed almost as much inhibiting activity as the more active chloroacetyl (2, 3) and trifluoroacetyl (4) derivatives studied earlier. The *o*-nitrobenzoyl compound showed about the same activity as most of the active *N*-chloroacetyl amino acids studied previously (3).

Comparison of activity within each group of derivatives (Table II) showed that the nature and the position of the substituents in the benzoyl ring were important to the inhibitory capacity of the compounds. For example, the substitution of a fluorine atom at the *ortho* position in the benzoyl ring of the fluorobenzoyl-*o*-fluoro-phenylalanines resulted in the most active derivative of this series, showing 69% inhibition at 1 mg/ml. Though not as pronounced, fluorine substitution at the *meta* or the *para* position in the benzoyl ring yielded derivatives of appreciable activity (39–47%), the *meta* isomer being slightly more active than the *para* isomer.

With the chlorobenzoyl and nitrobenzoyl derivatives, the *meta* and

p-Nitrobenzoyl	3.01	0	28	70
Benzoyl	3.48	2	12	31

[a] For details of assay, see Ref. 1. [b] Turbidity readings of the inoculated control tubes (containing no test compound) were 182–194 Klett units. At least three duplicate determinations were made for each compound. The duplicate values in each determination agreed within ±5 Klett units; *e.g.*, the standard deviation of a compound showing a mean value of ~20% inhibition was 2.7 and the standard error was 0.95. [c] Final concentration in assay system.

the *para* isomers were the most active of the three isomers. Hence, *m*-chlorobenzoyl- and *p*-chlorobenzoyl-*o*-fluoro-DL-phenylalanine showed nearly complete inhibition at 1 mg/ml, while the corresponding *o*-derivative showed an inhibition of 51%, and *m*-nitrobenzoyl- and *p*-nitrobenzoyl-*o*-fluoro-DL-phenylalanine exhibited activity of ~70%, while the corresponding *ortho* isomer showed only 17% inhibition.

When the substituent was a methoxy group, the position of substitution in the benzoyl ring appeared unimportant since all three isomers of methoxybenzoylphenylalanine exhibited about the same degree of inhibition (54%).

To allow comparison of relative activities, the degree of inhibition of each compound at 4.47 m*M* was determined (Table III). This concentration is equivalent to 1 mg/ml final concentration in the assay system of *N*-chloroacetyl-D-β-hydroxynorleucine B, the most active *N*-acyl alicyclic amino acid studied earlier (2).

The most active benzoyl ring substituted *o*-fluoro-DL-phenylalanines were *o*-fluorobenzoyl, *m*-chlorobenzoyl, *p*-chlorobenzoyl, *m*-nitrobenzoyl, and *p*-nitrobenzoyl derivatives, all of which showed essentially complete inhibition at 4.47 m*M*.

An inhibition curve was constructed for each of these compounds (Fig. 1). This showed that the most active of these compounds were *m*-chlorobenzoyl- and *p*-chlorobenzoyl-*o*-fluoro-DL-phenylalanine, with ID_{50} values of 1.30 and 1.40, respectively. The next active compounds were the *m*-nitrobenzoyl and *p*-nitrobenzoyl derivatives (ID_{50} 1.95 and 2.10, respectively), and the least active was *o*-fluorobenzoyl-*o*-fluoro-DL-phenylalanine (ID_{50} 2.60). Thus, when the amino acid moiety was phenylalanine containing an electronegative group, *i.e.*, fluorine, in the *ortho* position, a large electronegative group such as chlorine or a nitro group in the *meta* position of the benzoyl ring appeared to increase the inhibitory capacity.

Table III—Comparison of the Effect of Equimolar Concentrations of Benzoyl Ring Substituted Derivatives of *o*-Fluoro-DL-phenylalanine on the Growth of *L. casei* 7469 [a]

Derivative of *o*-Fluoro-DL-phenylalanine	Inhibition[b], %
o-Fluorobenzoyl	94
m-Fluorobenzoyl	61

o-Chlorobenzoyl	66
m-Chlorobenzoyl	97
p-Chlorobenzoyl	96
o-Methoxybenzoyl	76
m-Methoxybenzoyl	75
p-Methoxybenzoyl (anisoyl)	74
o-Nitrobenzoyl	28
m-Nitrobenzoyl	92
p-Nitrobenzoyl	92
Benzoyl	44

[a] Maximum growth in inoculated control tube (containing no test compound) was 182–194 Klett units. For explanation of extent of variation of values, see Table II footnotes. [b] Concentration was 4.47 m*M* and was the final concentration in the assay system. For details of assay, see Ref. 1.

Table IV—Effect of Substituted Benzoic Acids on the Growth of *L. casei* 7469 [a]

Substituted Benzoic Acid	Inhibition[b], %
o-Fluorobenzoic Acid	6
m-Fluorobenzoic Acid	10
p-Fluorobenzoic Acid	7
o-Chlorobenzoic Acid	7
m-Chlorobenzoic Acid	32
p-Chlorobenzoic Acid	32
o-Methoxybenzoic Acid	3
m-Methoxybenzoic Acid	10
p-Methoxybenzoic Acid (anisic acid)	6
o-Nitrobenzoic Acid	9
m-Nitrobenzoic Acid	30
p-Nitrobenzoic Acid	34

[a] See Table II footnotes for details of the assay. [b] Concentration was 4.47 m*M*.

Most of the other seven derivatives showed striking activity (54–76% inhibition). This inhibition was considerably greater than that of compounds with no substituent on the benzoyl ring; benzoyl-*o*-fluoro-DL-phenylalanine inhibited 44%.

The activity of *o*-nitrobenzoyl-*o*-fluoro-DL-phenylalanine (28%), the least active of all the derivatives of the series, was less than that of the unsubstituted benzoyl derivative, *N*-benzoyl-*o*-fluoro-DL-phenylalanine. However, its inhibition was as great as most of the inhibiting chloroacetyl derivatives, which inhibited ~15–35% (3).

Thus, except for *o*-nitrobenzoyl-*o*-fluoro-DL-phenylalanine, all substituents in the benzoyl ring have an inhibitory enhancing effect, whatever the electronic nature of the substituent (*i.e.*, electron-withdrawing or electron-donating).

The position of these substituents in the benzoyl ring appeared to be important, especially when the substituent was strongly electronegative, such as in the chlorine, fluorine, and nitro groups. The data are not yet sufficient to draw conclusions about the relationship between the substituent of the benzoyl ring and that of the phenyl ring of phenylalanine. Only a more restrictive observation applying only to the derivatives of *o*-fluoro-DL-phenylalanine could be made. Subsequent studies will give further information on the role of the amino acid moiety in the inhibitory capacity.

The inhibition is not likely due to the release of hydrolytic products of the substituted benzoyl amino acids, *i.e.*, the release of the ring-substituted benzoic acid or the *o*-fluoro-DL-phenylalanine. Except for *m*-chlorobenzoic acid, *p*-chlorobenzoic acid, *m*-nitrobenzoic acid, and *p*-nitrobenzoic acid, all of which showed ~32–34% inhibition, the substituted benzoic acid had essentially no inhibitory activity (Table IV). For those substituted benzoic acids showing some activity, the benzoyl amino acids containing these groups were decidedly more active than the non-substituted benzoic acid. *o*-Fluoro-DL-phenylalanine was shown to be inactive in this assay system (3). Furthermore, it was demonstrated previously (3) that no notable degree of hydrolysis occurred during incubation.

There is insufficient data to propose a possible inhibition mechanism from these experiments. However, based on earlier studies on proteases (11, 12) where aromatic ring-rich dipeptides were shown to be superior substrates of some of these enzymes, and knowing that proteolytic enzymes are commonly produced by microorganisms, it is reasonable to speculate on the involvement of these aroyl phenylalanine analogs in the inhibition of such enzymes.

Potentiometric Study of Molecular Complexes of Weak Acids and Bases Applied to Complexes of α-Cyclodextrin with *para*-Substituted Benzoic Acids

KENNETH A. CONNORS ˣ, SHU-FEN LIN, and ALBERT B. WONG*

Received March 23, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication June 15, 1981. *Present address: Elizabeth Arden Research Center, Indianapolis, IN 46285.

Abstract □ The theory of the potentiometric method for studying complexes of ionizable substrates was developed, and graphical techniques are described for obtaining stability constant estimations from the data. The method described is for a system in which the conjugate acid and base forms of the substrate (S) are capable of forming 1:1 (SL) and 1:2 (SL_2) complexes with the ligand (L). It was applied to complexes of α-cyclodextrin (cyclohexaamylose) with 10 *para*-substituted benzoic acid derivatives. Letting K_{11a} and K_{12a} be stability constants for the conjugate acid forms of the substrates, and K_{11b}, K_{12b} for the conjugate base forms, it was found that K_{12b} is zero for all substrates, K_{12a} is zero for seven of the substrates, and $K_{11a} > K_{11b}$ in every case. Hammett plots yielded ρ_{11a} and ρ_{11b} values of −0.31 and 0.77, respectively, which was interpreted to mean that K_{11a} mainly represents binding at the carboxylic acid site, and K_{11b} describes binding at the site of the *para*-substituent. This model of the complexing suggests that K_{12a} represents binding at the *para*-substituent, and therefore K_{12a} should vary roughly with substituent as K_{11b} does; this trend was observed.

Keyphrases □ Complexation—potentiometric study, α-cyclodextrins with *para*-substituted benzoic acids □ Stability constants—α-cyclodextrins with *para*-substituted benzoic acids, potentiometric studies □ α-Cyclodextrins—complexes with *para*-substituted benzoic acids, potentiometric study

If the conjugate acid and base forms of a weak acid–base substrate form cyclodextrin (also called cycloamylose) complexes of different strengths, then addition of cyclodextrin to a solution of the substrate will result in a pH change. Cramer *et al.* (1) reported a change in the apparent dissociation constant of *p*-nitrophenol in the presence of α-cyclodextrin (cyclohexaamylose). A method was described previously based on the measurement of apparent dissociation constants as a function of cyclodextrin concentration in order to extract complex stability constants for both the conjugate acid and base forms of the substrate, assuming 1:1 stoichiometry (2). Miyaji *et al.* (3) developed a similar technique. A potentiometric method for 1:1 and 1:2 stoichiometric systems was also described (4, 5).

Evidence is accumulating (5–7) that in α-cyclodextrin systems both 1:1 and 1:2 complexes must be considered when measuring complex stability constants[1]. The potentiometric method offers a rapid and convenient experimental approach to this problem for ionizable substrates. The present report describes the theory of the method, and examines new graphical techniques for evaluating the stability constants. These techniques are applied to the study of complexing between α-cyclodextrin and a series of *p*-substituted benzoic acids.

THEORY

Let L represent cyclodextrin and HA a neutral weak acid substrate. For 1:1 and 1:2 stoichiometry, there are four complexation equilibria:

$$HA + L \rightleftarrows HAL$$

Scheme I

$$A^- + L \rightleftarrows AL^-$$

Scheme II

$$HAL + L \rightleftarrows HAL_2$$

Scheme III

$$AL^- + L \rightleftarrows AL_2^-$$

Scheme IV

These equilibria have corresponding stability constants:

$$K_{11a} = \frac{[HAL]}{[HA][L]} \quad \text{(Eq. 1)}$$

$$K_{11b} = \frac{[AL^-]}{[A^-][L]} \quad \text{(Eq. 2)}$$

$$K_{12a} = \frac{[HAL_2]}{[HAL][L]} \quad \text{(Eq. 3)}$$

$$K_{12b} = \frac{[AL_2^-]}{[AL^-][L]} \quad \text{(Eq. 4)}$$

where brackets signify molar concentrations, and activity coefficients are assumed to be constant. Thus, the stability constants may be interpreted as thermodynamic quantities with the experimental solvent as the reference state.

There are three acid–base equilibria in this system:

$$HA \rightleftarrows H^+ + A^-$$

Scheme V

$$HAL \rightleftarrows H^+ + AL^-$$

Scheme VI

$$HAL_2 \rightleftarrows H^+ + AL_2^-$$

Scheme VII

They have the acid–base dissociation constants:

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad \text{(Eq. 5)}$$

$$K_{a11} = \frac{[H^+][AL^-]}{[HAL]} \quad \text{(Eq. 6)}$$

$$K_{a12} = \frac{[H^+][AL_2^-]}{[HAL_2]} \quad \text{(Eq. 7)}$$

From Eqs. 1–7 these relationships are found:

$$K_{11a}K_{a11} = K_aK_{11b} \quad \text{(Eq. 8)}$$

$$K_{12a}K_{a12} = K_{a11}K_{12b} \quad \text{(Eq. 9)}$$

Letting S_t and L_t be the total molar concentrations of substrate and ligand, respectively, the mass-balance equations are:

$$S_t = [HA] + [A^-] + [HAL] + [AL^-] + [HAL_2] + [AL_2^-] \quad \text{(Eq. 10)}$$

$$L_t = [L] + [HAL] + [AL^-] + 2[HAL_2] + 2[AL_2^-] \quad \text{(Eq. 11)}$$

For later convenience the quantities A, B, M, and, N are defined:

$$A = 1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2 \quad \text{(Eq. 12)}$$

$$B = 1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2 \quad \text{(Eq. 13)}$$

$$M = K_{11a}[L] + 2K_{11a}K_{12a}[L]^2 \quad \text{(Eq. 14)}$$

$$N = K_{11b}[L] + 2K_{11b}K_{12b}[L]^2 \quad \text{(Eq. 15)}$$

[1] The weak acid–base is the substrate (S), α-cyclodextrin is the ligand (L), and stoichiometric relationships are expressed in the form SL and SL_2, these complexes having 1:1 and 1:2 stoichiometry, respectively.

0022-3549/82/0200-0217$01.00/0

Algebraic combination leads to:

$$S_t = [HA]\left[\frac{A[H^+] + BK_a}{[H^+]}\right] \quad \text{(Eq. 16)}$$

$$L_t = [L] + [HA]\left[\frac{M[H^+] + NK_a}{[H^+]}\right] \quad \text{(Eq. 17)}$$

Eliminating [HA] from Eqs. 16 and 17 gives a general relationship between [L] and L_t:

$$L_t = [L] + S_t\left[\frac{M[H^+] + NK_a}{A[H^+] + BK_a}\right] \quad \text{(Eq. 18)}$$

The electroneutrality equation for this system is:

$$[Na^+] + [H^+] = [OH^-] + [A^-] + [AL^-] + [AL_2^-] \quad \text{(Eq. 19)}$$

where it is supposed that sodium is the counterion to the substrate. Combining Eq. 19 with the preceding expressions gives:

$$[Na^+] + [H^+] - [OH^-] = \frac{S_t BK_a}{A[H^+] + BK_a} \quad \text{(Eq. 20)}$$

The quantity $[Na^+]/S_t$ is the analytical fraction of substrate in the conjugate base form. Equation 20 is the general equation relating hydrogen-ion concentration to free ligand concentration [L]. By means of Eqs. 18 and 20, $[H^+]$ is related to total ligand concentration L_t. In these equations, $[Na^+]$, S_t, and L_t are independent variables; $[H^+]$ and [L] are dependent variables.

Equation 20 can be cast in a more useful form. If $[Na^+] \gg ([H^+] - [OH^-])$, then Eq. 20 becomes:

$$[Na^+] = \frac{S_t BK_a}{A[H^+] + BK_a} \quad \text{(Eq. 21)}$$

For a solution in which L_t is 0, it follows that [L] = 0, A = 1, B = 1, and Eq. 21 becomes:

$$[Na^+]_0 = \frac{S_t K_a}{[H^+]_0 + K_a} \quad \text{(Eq. 22)}$$

A series of measurements of $[H^+]$ as a function of L_t is made at constant S_t and $[Na^+]$; hence $[Na^+] = [Na^+]_0$, and these equations give:

$$\frac{[H^+]_0}{[H^+]} = \frac{A}{B} = C \quad \text{(Eq. 23)}$$

Defining a quantity $\Delta pH = pH - pH_0$:

$$\Delta pH = \log C \quad \text{(Eq. 24)}$$

Equation 24 describes the change in the solution pH as a function of free ligand concentration for fixed $[Na^+]/S_t$. If $[Na^+]/S_t = \frac{1}{2}$, then the pH can be interpreted as pKa′ (apparent dissociation constant), and Eq. 24 becomes $\Delta pKa' = \log C$, or:

$$\Delta pKa' = \log\left[\frac{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2}{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2}\right] \quad \text{(Eq. 25)}$$

which is the equation used previously (5) to interpret the cinnamic acid–α-cyclodextrin system. This derivation shows the level of approximation involved in interpreting ΔpH as ΔpKa′.

More generally, the exact Eq. 20 must be used. Defining the operational dissociation constant K_a' by Eq. 26:

$$K_a' = \frac{[H^+]([Na^+] + [H^+] - [OH^-])}{S_t - ([Na^+] + [H^+] - [OH^-])} \quad \text{(Eq. 26)}$$

Substitution into Eq. 26 from Eq. 20 leads to $K_a/K_a' = A/B = C$, or $\Delta pKa' = \log C$. That is, Eq. 25 is general, provided the dissociation constants are evaluated by Eq. 26, which takes into account solvent dissociation. An important feature of this equation is that C is a ratio of polynomials. If $\Delta pK_a' = 0$ at all L_t, then $K_{11a} = K_{11b}$ and $K_{12a} = K_{12b}$.

On chemical grounds, and also by means of Eq. 18, it can be seen that the limits of [L] are $[L] = L_t$ and $[L] = L_t - 2S_t$. In the potentiometric method, S_t must be appreciable in order to provide buffer capacity; hence it is seldom permissible to set $[L] = L_t$, as may often be done in other experimental techniques (such as spectroscopy).

One approach to obtaining the stability constants is to treat them as adjustable parameters, and to curve-fit the data using Eqs. 18 and 25. Although it is possible to achieve good fit to the experimental points (2, 8), it was observed that an apparently infinite number of satisfactory solutions can be obtained in this way (8). Therefore, the curve-fitting approach was abandoned, and graphical techniques leading to unique solutions have been developed.

General Evaluation of Stability Constants—The experimental data consist of ΔpKa′ values measured as a function of L_t, at constant S_t and reaction conditions. Since $\Delta pKa' = \log C$, the quantity C is available. This is related to the stability constants by:

$$C = \frac{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2}{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2} \quad \text{(Eq. 27)}$$

The problem is to evaluate the stability constants from these data. Considerable experience with such systems has shown that it is seldom necessary to invoke all four constants, and some important special cases of Eq. 27 suffice to account for most of these systems. These cases are treated in the following section.

To find the stability constants, Eq. 18 must be solved for [L], but this requires the stability constants. The following approach is effective. In this work, the ratio $[Na^+]/S_t = 1/2$, so $[H^+] = K_a$, to a level of accuracy acceptable for the present purpose. Since $C = K_a/K_a'$, this gives $[H^+] = K_a/C$. Substitution into Eq. 18 gives:

$$L_t = [L] + S_t\left[\frac{M}{2A} + \frac{N}{2B}\right] \quad \text{(Eq. 28)}$$

The value of [L] is estimated by combining Eq. 28 with the appropriate special case of Eq. 27. In this development the quantity C is incorporated into the expression for [L] to the greatest extent possible. This has two advantages: first, since the stability constants are needed in the calculation, their introduction in the form of experimental C values ensures that the correct values are being used; and second, the solution of the equation for [L] is usually simplified, since much of the algebraic complexity is possessed by the numerical C values. The particular equations for [L] will be given when the special cases are discussed.

The general approach is to make a plot of C *versus* L_t. From the shape of this curve, the system is tentatively assigned to one of the special cases. The free ligand concentration [L] is calculated, and stability constants are evaluated from the appropriate linear plot. Iterations are carried out until the stability constants are essentially unchanged.

The following treatment considers systems in which C is greater than unity. If C is less than unity, it is convenient to work with its reciprocal, $C' = 1/C$. Then all of the equations are applicable with the subscripts a and b interchanged.

Special Cases—*Case I:* $K_{12a} = 0$, $K_{12b} = 0$—Equation 27 becomes:

$$C = \frac{1 + K_{11a}[L]}{1 + K_{11b}[L]} \quad \text{(Eq. 29)}$$

A plot of C *versus* [L] or L_t will approach a limiting value at high ligand concentration. Diagnosis of Case I behavior is tentative because Eq. 27 also results in this type of curve.

The ligand concentration is calculated with:

$$[L] = L_t - \frac{S_t}{X + 1} \quad \text{(Eq. 30)}$$

where:

$$X = \frac{(C + 1)(R - C)}{(C - 1)(R + C)} \quad \text{(Eq. 31)}$$

and $R = K_{11a}/K_{11b}$. The parameter R is estimated by extrapolating a plot of log C *versus* $1/L_t$ to $1/L_t = 0$, since C approaches R as L_t approaches infinity. A plot is then made according to:

$$\frac{C - 1}{[L]} = K_{11a} - CK_{11b} \quad \text{(Eq. 32)}$$

which is obtained from Eq. 29. The constants K_{11a} and K_{11b} are obtained from this plot, which will be linear for a Case I system. The calculated R is compared with the initial estimate; if they differ significantly, the process is repeated.

Case II: $K_{11b} = 0$, $K_{12a} = 0$, $K_{12b} = 0$—From Eq. 27:

$$C = 1 + K_{11a}[L] \quad \text{(Eq. 33)}$$

where C is a linear function of ligand concentration. Of course, any system will approach linearity at sufficiently low ligand concentration, so L_t must be made large enough to determine if curvature exists. The free ligand concentration is obtained with Eq. 34.

$$[L] = L_t\frac{-(C - 1)S_t}{2C} \quad \text{(Eq. 34)}$$

Case III: $K_{11b} = 0$, $K_{12b} = 0$—Equation 27 becomes:

$$C = 1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2 \quad \text{(Eq. 35)}$$

[a] Hammett substituent constant. [b] X in X—C_6H_4—COOH.

The plot of C *versus* L_t will reveal curvature that is concave upward; [L] is calculated with:

$$[L] = \frac{2C(L_t - S_t) + 2S_t}{2C - S_t K_{11a}} \quad \text{(Eq. 36)}$$

The linear form of Eq. 35 is:

$$\frac{C-1}{[L]} = K_{11a} + K_{11a}K_{12a}[L] \quad \text{(Eq. 37)}$$

Case IV: $K_{12b} = 0$—Equation 27 becomes:

$$C = \frac{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2}{1 + K_{11b}[L]} \quad \text{(Eq. 38)}$$

The plot of C *versus* L_t will approach a linear segment of positive slope at high L_t. The equation of this line is:

$$C = R + RK_{12a}[L] \quad \text{(Eq. 39)}$$

where $R = K_{11a}/K_{11b}$. This gives part of the desired information. The concentration [L] is given by:

$$K_{11b}[L]^2 + \left[1 + S_t K_{11b}\left(\frac{3}{2} - \frac{R}{2C}\right) - L_t K_{11b}\right][L] - \left[L_t - \frac{S_t(C-1)}{C}\right] = 0 \quad \text{(Eq. 40)}$$

Several methods have been devised to extract the stability constants. It is a general result from Eq. 27 that:

$$\frac{dC}{d[L]} = \frac{BM - AN}{B^2[L]} \quad \text{(Eq. 41)}$$

Thus the slope at [L] = 0 is equal to $K_{11a} - K_{11b}$. This result, together with the value of R from Eq. 39, gives the stability constants. Another method constructs, on the C *versus* [L] plot, lines such that the quantity $[L]_X$ is found as the value of [L] when $C = R$. Then it is easily shown that:

$$K_{11b} = \frac{R-1}{RK_{12a}[L]_X^2} \quad \text{(Eq. 42)}$$

However, both of these approaches rely on data at very low [L], and it is in this region that the relative error in [L] is the greatest. A better procedure is to measure K_{11b} by a different, independent, experimental method, such as spectroscopy. This will usually be straightforward, the Case IV diagnosis having shown that $K_{12b} = 0$. The linear plot according to Eq. 43 is made:

$$\frac{C-1}{[L]} + CK_{11b} = K_{11a} + K_{11a}K_{12a}[L] \quad \text{(Eq. 43)}$$

This plot is also useful for confirming Case I systems, which should yield a slope equal to zero.

EXPERIMENTAL

Materials—α-Cyclodextrin[2] was dried at 95° for 48 hr. A sample of α-cyclodextrin recrystallized from water and dried under reduced pressure over phosphorus pentoxide for 12 hr (9) gave identical results. The benzoic acids[3] were recrystallized until their melting points agreed with literature values. Water was redistilled from alkaline permanganate.

Procedures—*Potentiometric Studies*—A stock solution of the substrate was prepared such that its final diluted concentration would be 0.003–0.004 M, and the substrate was half-neutralized with 0.10 M NaOH. It was filled to the mark with 0.10 M NaCl.

α-Cyclodextrin was weighed into 5-ml volumetric flasks in amounts to cover its full solubility range. Portions of the substrate stock solution (4.0-ml) were pipetted into each flask, and the solutions were brought to volume with 0.10 M NaCl. They were equilibrated at 25.0°; to ensure adequate mixing, a 10-mm stirring bar was added and driven by a submerged water-driven magnetic stirrer. The solution was transferred to a 5-ml test tube and the combination pH electrode was lowered into the solution (which was protected from contact with the atmosphere). The pH was measured[4] and pKa′ was calculated according to Eq. 26. Reproducibility on duplicate solutions was 0.003 pH units or better. All studies were at 25.0° and ionic strength was 0.10 M.

Substrates with ionizable *para*-substituents (compounds 1–3 in Table I) have pKa values separated sufficiently (10–12) that the measurement of pKa′ for the carboxylic acid group leaves the *para*-substituent in its nonionized state.

Variation of S_t by a factor of 2 resulted in no significant variation in the stability constants.

Spectrophotometric Studies—For Case IV systems, K_{11b} was measured spectrophotometrically[5]. The substrate was dissolved in pH 9.18 tromethamine buffer, ionic strength 0.10 M; S_t was $5.6–8.4 \times 10^{-5}$ M. The data were analyzed by the double-reciprocal linear form with a weighted least-squares treatment (13). The wavelengths of observation were: for CH_3CO—C_6H_4COOH, 253 nm; NC-C_6H_4COOH, 231 and 237 nm; and O_2N-C_6H_4COOH, 265 and 315 nm. Values of K_{11b} were not wavelength dependent.

RESULTS

This potentiometric method was applied to 10 benzoic acid derivatives. All of these compounds gave positive ΔpKa′ values and hence C values greater than unity, apparently a general result for carboxylic acids (2). These systems could be described as Case I or Case IV systems[6].

Figure 1 shows the plot of C *versus* L_t for *p*-hydroxybenzoic acid, a typical Case I system, and Fig. 2 is the corresponding linear plot according to Eq. 32. Figure 3 shows *p*-cyanobenzoic acid, a Case IV system, and Fig. 4 is the linear plot according to Eq. 43. Usually two iterations sufficed to yield final estimates of the stability constants.

Table I shows the stability constants evaluated in this way. For all of these systems, K_{12b} is zero by definition, since they can be adequately described by Cases I or IV. For Case I systems, K_{12a} is zero. However, this assignment can be tested by treating a Case I system as if it were Case IV, making the plot according to Eq. 43. The values of K_{12a} in Table I were evaluated in this way. For compounds 1–7, K_{12a} is clearly not significantly different from zero, whereas substrates 8–10 possess very significant K_{12a} values. For Case I systems, the relative standard deviation of K_{11a} ranges from 0.6–1.3%, and of K_{11b} from 1.4–4.3%. The precision of Case IV systems is poorer, as seems reasonable, since these are three-parameter systems.

DISCUSSION

The Potentiometric Method—For complexing systems in which the

full four-parameter equation (Eq. 27) is not required, this potentiometric method with graphical treatment of the data is simple, rapid, and effective. Because of the linear graphing forms, the usual least-squares statistical treatment is appropriate. The error in the abscissa is much smaller than that in the ordinate, as is required by the conventional treatment. The great sensitivity of the quantity $(C - 1)/[L]$ at low [L] values made it necessary to reject some data points at very low [L] in the plots according to Eqs. 32 and 43. At least 10 points were used in every plot.

The assumption that activity coefficients are constant as L_t changes is fundamental to the interpretation of potentiometric data in terms of

[a] At 25°; ionic strengths differ.

1:1 and 1:2 complex formation. It is conceivable that the observation of finite 1:2 stability constants represents a measurement of changing activity coefficients rather than actual 1:2 complexation. Gelb *et al.* (4) described evidence that ionic activity coefficients are not changed as a consequence of changes in cyclodextrin concentration. That K_{12a} for several acids was found to be negligible (Table I) suggests further that activity coefficient changes are not responsible for the observed 1:2 stability constants. Nevertheless, the role of cyclodextrin in modifying the properties of the solvent cannot be overlooked as a possible complicating factor in such studies.

Several studies of the benzoic acid–α-cyclodextrin system were described earlier and are listed chronologically in Table II. The earliest potentiometric result (2) was obtained by curve-fitting, and is now rejected. It is evident that the method proposed in the present paper is capable of generating stability constants consistent with those obtained by other techniques and in other laboratories.

An advantage of potentiometry is that it yields information about the complexing of both the conjugate acid and base forms of the substrate. A limitation is that it can serve as an independent method only when the system includes two (or fewer) complex equilibria, *i.e.*, when the equation

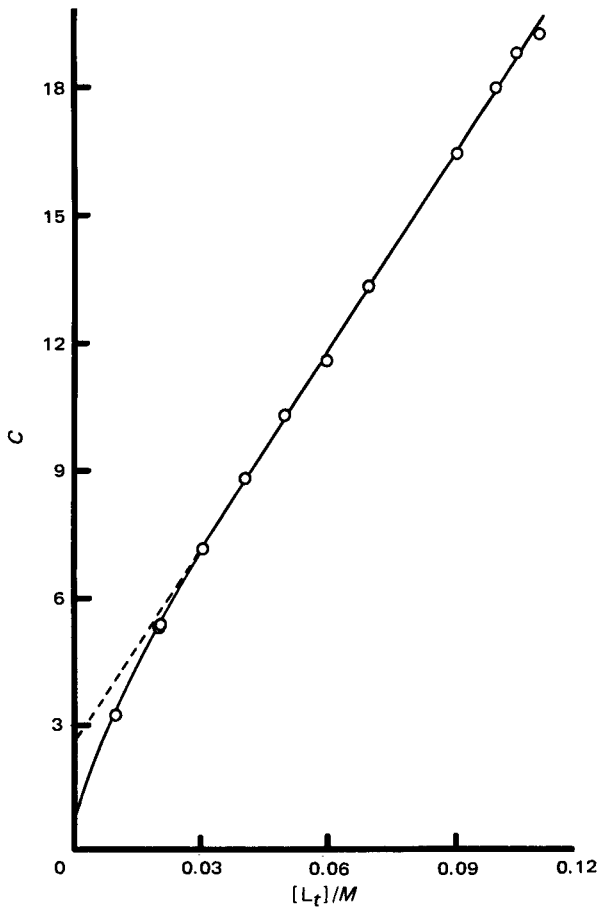

Figure 3—*Plot of* C versus L_t *for the 4-cyanobenzoic acid–α-cyclodextrin system.*

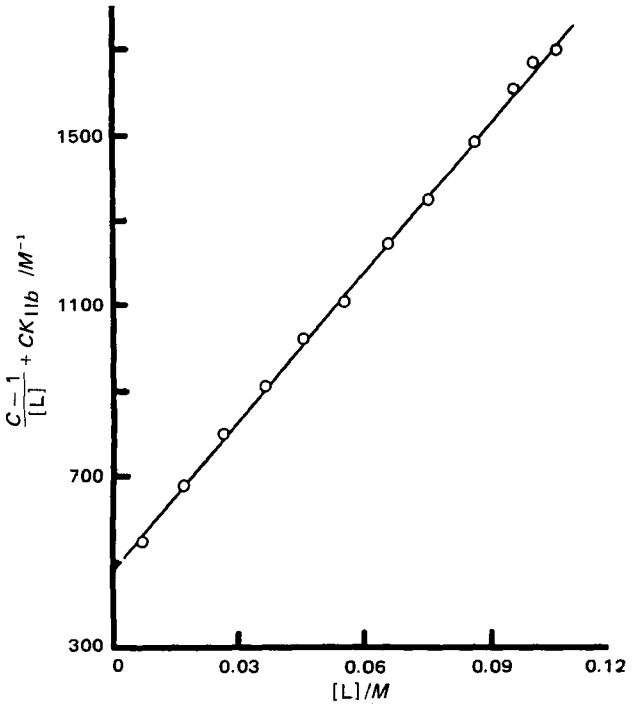

Figure 4—*Plot of Eq. 43 for the 4-cyanobenzoic acid–α-cyclodextrin system.*

has two parameters. For the three-parameter Case IV system, it was judged necessary to make use of a separate experimental determination of one of the parameters. This combination of several techniques is essential if the equation has four parameters, as in the cinnamic acid system (5).

Interpretation of Stability Constants—An earlier report (20) introduced a model of cyclodextrin complex formation helpful in interpreting the present data. The substrate (guest) is symbolized g–G, the lower and upper case letters signifying two binding sites; the cyclodextrin (host) is represented h–H because the two rims of the cavity are chemically different. It was shown that it is possible for four 1:1, four 2:1, and four 1:2 complexes to be present in a system. However, if there are no 2:1 complexes present, it is a reasonable inference that only one end (e.g., H) of the host can be entered. It follows that there can be only two 1:1 complexes (gH and GH) and one 1:2 complex. The 1:2 complex is formed by the addition of a host molecule to either of the 1:1 complexes.

The observed K_{11} value for the system is the sum of the stability constants for the isomeric 1:1 complexes, hence:

$$K_{11} = K_{gH} + K_{GH} \qquad \text{(Eq. 44)}$$

The 1:2 complex can be formed *via* the gH or the GH route:

$$gH + h\text{–}H \overset{K'}{\rightleftarrows} GHHg$$

Scheme VIII

$$GH + h\text{–}H \overset{K''}{\rightleftarrows} GHHg$$

Scheme IX

The observed 1:2 stability constant is given by (20):

$$K_{12} = \frac{K'K''}{K' + K''} \qquad \text{(Eq. 45)}$$

It is also seen that:

$$\frac{K'}{K''} = \frac{K_{GH}}{K_{gH}} \qquad \text{(Eq. 46)}$$

Writing $K' = aK_{GH}$, with Eq. 46, it follows that $K'' = aK_{gH}$. Combination with Eq. 45 gives:

$$K_{12} = \frac{aK_{gH}K_{GH}}{K_{gH} + K_{GH}} \qquad \text{(Eq. 47)}$$

The factor a is a measure of the extent of interaction between the two sites in a 1:2 complex. If the two binding sites are independent, $a = 1$ and

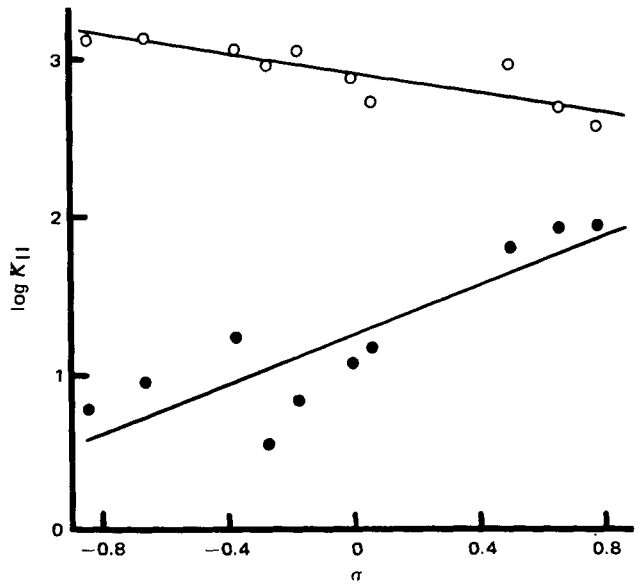

Figure 5—*Hammett plots of* K_{11a} (○) *and* K_{11b} (●) *data from Table I.*

the isomeric stability constants K_{gH} and K_{GH} can be evaluated with Eqs. 44 and 47. For the *para*-substituted benzoic acids it seems improbable that the sites are independent because of their proximity (the two sites being the X-end and the COOH-end of the molecule). Nevertheless, the model is useful in describing the nature of K_{11} and K_{12}, since it shows that K_{12} is actually a constant for the formation of a 1:1 complex from an already formed 1:1 complex. The model leads to interpretations in terms of binding sites.

Figure 5 is a Hammett plot of the K_{11a} and K_{11b} data in Table I. The obvious result is that these quantities vary with substituent constant in opposite ways. The slopes (rho values) are −0.31 (0.07 *SD*) for K_{11a} and +0.77 (0.17 *SD*) for K_{11b}. Casu and Ravà (14) studied K_{11a} for some of these acids; their constants are significantly different from those in Table I, but the general behavior is the same, namely that rho is negative. Electron-withdrawing X groups decrease complex stability in the conjugate acid series.

This behavior is explicable if K_{11a} primarily represents binding at the COOH-end of the substrate molecule. The binding interaction will be increased by an increase in electron density at the binding site, and will be associated with a negative rho value. This hypothesis is supported by PMR data on benzoic acid (17), which indicate that the carboxyl group enters the cavity.

The value of K_{11b} is always smaller than K_{11a} for the same substrate. This also is consistent with the view that K_{11a} represents mainly COOH-site binding. Upon ionization of this group, its affinity for the cavity will be greatly decreased because of the high polarity of COO^- and the nonpolarity (relative to the solvent) of the cavity. Therefore K_{11b} represents binding at the remaining site, namely X. Thus the more electron-withdrawing the X group, the larger is K_{11b}. Since K_{11b} describes X-site binding, the correlation with σ for X is not expected to be as precise as when the substituent is distant from the reaction site.

If K_{11a} describes COOH-site binding (mainly), then K_{12a} must represent mainly binding at the X-site. Therefore, this model predicts that K_{12a} should respond to X-substituent effects the same way that K_{11b} does, since they describe roughly the same process. Table I shows that this is indeed the case, in a general way; both K_{11b} and K_{12a} tend to increase together, and to tend in the opposite sense to K_{11a} along the σ scale.

The Hammett plot suggests that if a substituent with sufficiently large σ were available, K_{11b} would become larger than K_{11a}. This might not result in $\Delta pKa'$ becoming negative, however, because K_{12a} will also increase.

These correlations clearly show trends rather than highly precise relationships, and factors other than electronic density must play a role. For example, K_{11b} for substrates 1–3 seems anomalously high. These are the only X groups capable of functioning as hydrogen-bond donors, and this capability may increase complex stability. The trend in K_{12a} for compounds 8–10 appears to oppose that for K_{11b}, and this may be the result of some additional factor, which could be size, shape, polarity, or polarizability. In fact, K_{12a} for these substrates seems to be a resultant

of the electronic density effect measured by σ, and the X-site polarity as measured by group dipole moments. These moments are, for X = $COCH_3$, 3.00 D; CN, 4.39; and NO_2, 4.21 (21). An increase in site polarity will tend to decrease the site binding constant (20), and both K_{11b} and K_{12a} may reflect this effect superimposed on the electron density effect.

This model of complexing suggests that K_{12} values are especially useful, leading to the question: Why is K_{12} ever equal to zero (for a two-site substrate)? According to Eq. 47, K_{12} can be zero only if $a = 0$ or if one of the site binding constants (K_{gH} or K_{GH}) is zero. This leads to the following argument. If the given site assignments are correct, K_{12b} represents binding at the COO^- site (since K_{11b} mainly describes X-site binding), and it was found that $K_{12b} = 0$ for all substrates. The existence of finite K_{12a} values (substrates 8–10) means that a is finite for these acid substrates, and suggests that it will also be finite in the corresponding base substrates. It follows that K_{12b} is zero as a consequence of the site binding constant for COO^- being zero. Letting K_{gHb} represent this quantity, and K_{GHb} the site binding constant for the X-site in the conjugate base series, it follows that:

$$K_{11b} = K_{gHb} + K_{GHb} = K_{GHb} \qquad \text{(Eq. 48)}$$

i.e., K_{11b} can be identified solely with the binding at site X.

Extension to the acid series requires the assumption that K_{GHb} for binding to X in the base series is identical with K_{GHa} for binding to X in the acid series. If approximately so, then $K_{11a} = K_{gHa} + K_{GHa} = K_{gHa} + K_{GHb} = K_{gHa} + K_{11b}$, and the site binding constant K_{gHa} for the COOH site is given approximately by $K_{11a} - K_{11b}$.

With these estimates of K_{gHa} ($K_{11a} - K_{11b}$) and K_{GHa} (K_{11b}), Eq. 47 leads to estimates of a for these substrates, since:

$$K_{12a} = \frac{aK_{gHa}K_{GHa}}{K_{gHa} + K_{GHa}} = \frac{aK_{11b}(K_{11a} - K_{11b})}{K_{11a}} \qquad \text{(Eq. 49)}$$

For compound number 8, $a = 0.51$; number 9, $a = 0.38$; and number 10, $a = 0.33$. Because of the several approximations, these calculations are unlikely to be accurate, but they are reasonable in magnitude. The interpretation of complex stability data in terms of this model and Eqs. 44 and 47 seems to be a potentially useful means for describing, understanding, and perhaps predicting complex formation behavior.

Reversed-Phase Ion-Pair Chromatography of Tetracycline, Tetracycline Analogs, and Their Potential Impurities

JÖRGEN HERMANSSON[x] and MATS ANDERSSON

Received December 17, 1980, from the *National Board of Health and Welfare, Department of Drugs, Division of Pharmacy, Box 607, S-751 25 Uppsala, Sweden.* Accepted for publication May 15, 1981.

Abstract □ Methods are presented for the separation of tetracycline, tetracycline analogs, and their potential impurities by reversed-phase ion-pair chromatography. The mobile phase consisted of a phosphate buffer with tripropylamine or *N,N*-dimethyloctylamine as counterions and acetonitrile as the organic modifier. The chromatographic properties of the tetracyclines were significantly improved by addition of the tertiary amines. The best result was obtained with *N,N*-dimethyloctylamine as the counterion, which gave good separation efficiency and peak symmetry for most of the substances studied. Addition of the tertiary amines to the mobile phase also significantly affected the capacity factors of the tetracyclines. Stability studies of the tetracyclines showed a fast degradation of chlortetracycline to isochlortetracycline and of lymecycline to tetracycline in phosphate buffer solutions of different pH. The purity of pharmaceutical preparations of tetracyclines was also investigated.

Keyphrases □ Tetracycline—potential impurities of the drug and its analogs, reversed-phase ion-pair chromatography □ High-performance liquid chromatography—tetracycline, tetracycline analogs, and their potential impurities □ Counterions—*N,N*-dimethyloctylamine, tripropylamine, in reversed-phase ion-pair chromatography of tetracycline, tetracycline analogs, and their possible impurities

The most important impurities in tetracycline and tetracycline analogs are the epimerized, dehydrated, and epimerized dehydrated forms of the tetracyclines. Thus, quatrimycin (epitetracycline), anhydrotetracycline, and epianhydrotetracycline are the most frequently found impurities in tetracycline. Epianhydrotetracycline has been reported to be toxic in humans, but the exact safety level in pharmaceutical preparations is not known. Permitted concentrations of epianhydrotetracycline and other impurities are fixed by the European Pharmacopoeia.

BACKGROUND

Various chromatographic techniques, such as TLC (1, 2) and paper chromatography (3), have been used to analyze tetracycline, but they are

0022-3549/82/0200-0222$01.00/0

of the electronic density effect measured by σ, and the X-site polarity as measured by group dipole moments. These moments are, for X = $COCH_3$, 3.00 D; CN, 4.39; and NO_2, 4.21 (21). An increase in site polarity will tend to decrease the site binding constant (20), and both K_{11b} and K_{12a} may reflect this effect superimposed on the electron density effect.

This model of complexing suggests that K_{12} values are especially useful, leading to the question: Why is K_{12} ever equal to zero (for a two-site substrate)? According to Eq. 47, K_{12} can be zero only if $a = 0$ or if one of the site binding constants (K_{gH} or K_{GH}) is zero. This leads to the following argument. If the given site assignments are correct, K_{12b} represents binding at the COO^- site (since K_{11b} mainly describes X-site binding), and it was found that $K_{12b} = 0$ for all substrates. The existence of finite K_{12a} values (substrates 8–10) means that a is finite for these acid substrates, and suggests that it will also be finite in the corresponding base substrates. It follows that K_{12b} is zero as a consequence of the site binding constant for COO^- being zero. Letting K_{gHb} represent this quantity, and K_{GHb} the site binding constant for the X-site in the conjugate base series, it follows that:

$$K_{11b} = K_{gHb} + K_{GHb} = K_{GHb} \qquad \text{(Eq. 48)}$$

i.e., K_{11b} can be identified solely with the binding at site X.

Extension to the acid series requires the assumption that K_{GHb} for binding to X in the base series is identical with K_{GHa} for binding to X in the acid series. If approximately so, then $K_{11a} = K_{gHa} + K_{GHa} = K_{gHa} + K_{GHb} = K_{gHa} + K_{11b}$, and the site binding constant K_{gHa} for the COOH site is given approximately by $K_{11a} - K_{11b}$.

With these estimates of K_{gHa} ($K_{11a} - K_{11b}$) and K_{GHa} (K_{11b}), Eq. 47 leads to estimates of a for these substrates, since:

$$K_{12a} = \frac{aK_{gHa}K_{GHa}}{K_{gHa} + K_{GHa}} = \frac{aK_{11b}(K_{11a} - K_{11b})}{K_{11a}} \qquad \text{(Eq. 49)}$$

For compound number 8, $a = 0.51$; number 9, $a = 0.38$; and number 10, $a = 0.33$. Because of the several approximations, these calculations are unlikely to be accurate, but they are reasonable in magnitude. The interpretation of complex stability data in terms of this model and Eqs. 44 and 47 seems to be a potentially useful means for describing, understanding, and perhaps predicting complex formation behavior.

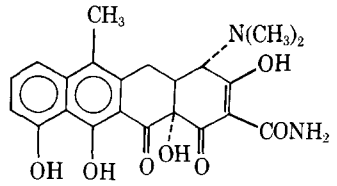
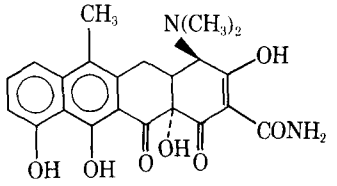
II



III

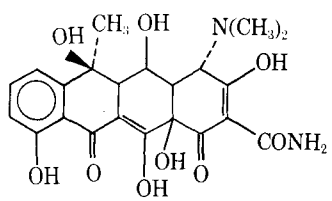


IV

usually not sensitive enough to allow detection of small amounts of impurities with good precision.

Ion-exchange column chromatography has also been used for analysis of tetracycline and tetracycline analogs, but the separation efficiency is not good with typical plate height (H) values >5 mm (4, 5). However, better results were reported with various reversed-phase systems (6–9). The mobile phases used in these methods have pH values between 1.5 and 5. Tetracyclines were reported to undergo epimerization between pH 3 and 5, and dehydration at low pH (10–12). This means that chromatography of tetracyclines in mobile phases with pH between 1.5 and 5 is unsuitable due to possible formation of degradation products during the chromatographic run, or during the dissolution process of tetracycline preparations.

The present report describes studies of reversed-phase ion-pair chromatographic systems using mobile phases of pH 8.0. These chromatographic systems can be used for separation and quantitation of



V

XII

tetracycline, tetracycline analogs, and related impurities. The purpose of this work was to develop chromatographic systems suitable to use in the study of small amounts of impurities (<0.1 %) in pharmaceutical preparations of tetracycline and tetracycline analogs.

EXPERIMENTAL

Apparatus—The high-performance liquid chromatographic system consisted of a high-pressure pump[1] and injection port[2]. UV detection was utilized with a detector[3] set at 280 nm. Columns (150 × 4.5-mm i.d.) were made of No. 316 stainless steel with a polished inner surface and equipped with modified end connections[4] and stainless steel frits[5] (2 μm).

Chemicals—The following chemicals were analytical grade and were used as supplied: acetonitrile[6], tripropylamine[7], and *N,N*-dimethyloctylamine[8]. All other chemicals used were analytical reagent grade and were used without further purification.

Samples of drug substances were obtained directly from the manufacturer or collected in the factory by drug inspectors. The drug preparations were bought in Swedish pharmacies. In most cases, reference samples of potential impurities were provided by the drug manufacturers. The following substances were used: tetracycline (I), quatrimycin (epitetracycline, II), anhydrotetracycline (III), epianhydrotetracycline (IV), oxytetracycline (V), doxycycline (VI), 6-epidoxycycline (VII), methacycline (VIII), demeclocycline (IX), epidemethylchlortetracycline (X), chlortetracycline (XI), epichlortetracycline (XII), isochlortetracycline (XIII), epianhydrochlortetracycline (XIV), anhydrochlortetracycline (XV), and lymecycline (XVI).

Column Packing—The columns were packed by a modification of the ordinary balanced-density slurry technique described previously (13). The support[9] was suspended in chloroform, and acetone was used as the driving liquid in the pump which was operated at 5000 psi. After packing, the column was washed with hexane followed by acetonitrile before equilibration with the mobile phase.

Chromatographic Technique—The chromatographic analyses were performed at room temperature. The mobile phases were prepared from 0.05 or 0.1 M monobasic sodium phosphate and the pH was adjusted to 8.2 (for the tripropylamine systems) or 8.0 (for the *N,N*-dimethyloctylamine system) with sodium hydroxide after addition of tripropylamine or *N,N*-dimethyloctylamine. An appropriate amount of acetonitrile was added and the mobile phase was thermostated at room temperature and degassed in an ultrasonic bath before use. The interstitial volume of the column, V_m, was obtained by injection of water.

Four different mobile phases were used for the purity control of the tetracyclines.

Mobile Phase A—A mixture of 0.1 M monobasic sodium phosphate, 30% acetonitrile, and 0.0194 M *N,N*-dimethyloctylamine was adjusted to pH 8.0 with sodium hydroxide.

Mobile Phase B—Mobile phase B contained 0.05 M monobasic sodium

phosphate, 35% acetonitrile, and 0.0097 *M* *N,N*-dimethyloctylamine adjusted to pH 8.0 with sodium hydroxide.

Mobile Phase C—This phase contained 0.1 *M* monobasic sodium phosphate, 20% acetonitrile, and 0.0194 *M* *N,N*-dimethyloctylamine adjusted to pH 8.0 with sodium hydroxide.

Mobile Phase D—A mixture of 0.1 *M* monobasic sodium phosphate, 28% acetonitrile, and 0.0194 *M* *N,N*-dimethyloctylamine was adjusted to pH 8.0 with sodium hydroxide.

Calculation of Chromatographic Parameters—The chromatographic behavior of the tetracycline substances is expressed by the capacity factor, the plate height, and the asymmetry factor. The capacity factor, k', is calculated by:

$$k' = (t_R - t_m)/t_m \quad \text{(Eq. 1)}$$

where t_R and t_m are elution times for retained and unretained solutes, respectively. The plate height, H, is obtained from the chromatogram by:

$$H = (L/16)(w_t/t_R)^2 \quad \text{(Eq. 2)}$$

where L is the column length and w_t is the peak width at the baseline. The asymmetry factor was calculated by drawing a perpendicular to the baseline from the vertex formed by the two peak tangent lines. The back part of the peak baseline divided by the front part gives the asymmetry factor.

Standard Solutions for Chromatographic Experiments—Standard solutions were freshly prepared just before use. The substances were dissolved in mobile phases which did not contain the tertiary amine. Twenty microliters of the solutions were injected.

Tetracycline Preparations—Tablets, dragees, capsules, suspensions, and ampuls were used for this investigation. Five tablets or dragees were ground and put into a 250-ml volumetric flask. Methanol (200 ml) was added and the flask was sonicated for 10 min in an ultrasonic bath and the contents were diluted to 250 ml with methanol. An appropriate amount of this solution was then centrifuged and an aliquot was taken out and diluted with methanol to give a final concentration of 20 μg/ml (used for quantitation of active substance in the drug preparations) or 1 mg/ml (used for quantitation of impurities in the drug preparations) of active substance. One milliliter of this solution was evaporated with nitrogen at 40° and the residue was dissolved in 1.0 ml of the mobile phase (without addition of the tertiary amine). Twenty microliters of this solution were then injected on the column. The substance in the capsules was accurately weighed and dissolved in the same way and to the same concentration as for tablets and dragees. Ampuls were also handled in the same way. An aliquot of the suspensions (~10 ml) was accurately weighed and put into a volumetric flask and extracted with 100 ml of 0.1 *M* HCl in an ultrasonic bath for 10 min and finally diluted to 150 ml with

Drug Substances—Drug substances were dissolved as described for tetracycline preparations to a final concentration of ~1 mg/ml. A 20-μl aliquot was injected onto the column.

RESULTS AND DISCUSSION

Compounds I–IV were used as model compounds in the present study. Tetracycline has three ionization stages in the pH range of 1–12. The first pKa 3.30 involves the ionization of the acidic hydroxy group at the 3-position; the pKa values for the dimethyl amino function and the hydroxy group at position 12 are 7.68 and 9.69, respectively (14). This makes it possible to utilize ion-pair chromatography with a cationic counterion like a tertiary or quaternary amine with a mobile phase at pH 8.0 (15, 16).

Regulation of the Capacity Factor by Addition of Counter Ion—Chromatographic studies of I and its potential impurities were performed using a phosphate buffer at pH 8.2 or 8.0 and acetonitrile as organic modifier in the mobile phase. Tripropylamine and *N,N*-dimethyloctylamine were used as counterions. Twenty percent (v/v) acetonitrile was used in the tripropylamine systems and 28% in the *N,N*-dimethyloctylamine system.

One advantage of reversed-phase ion-pair chromatography is the presence of the counterion in the mobile phase, which makes it possible to regulate the capacity factor by changing the type or the concentration of the counterion. Figures 1, 2a, and 2b illustrate the regulation of the capacity factor of I, II, and the dehydrated forms III and IV by increasing the concentration of tripropylamine from zero to 0.095 *M*, and *N,N*-dimethyloctylamine from zero to 0.039 *M*. It can be seen that I and III have higher capacity factors than their corresponding epi forms, II and IV, respectively. A likely cause of this effect is that I and III have conformations which favor the formation of internal hydrogen bonding, giving the molecule a more hydrophobic character. The possibility of regulating the capacity factor of I and II is rather limited both with tripropylamine and *N,N*-dimethyloctylamine as counterions, while the capacity factors for the dehydrated substances are influenced to a large extent by the increasing concentration of counterion. The possibility of

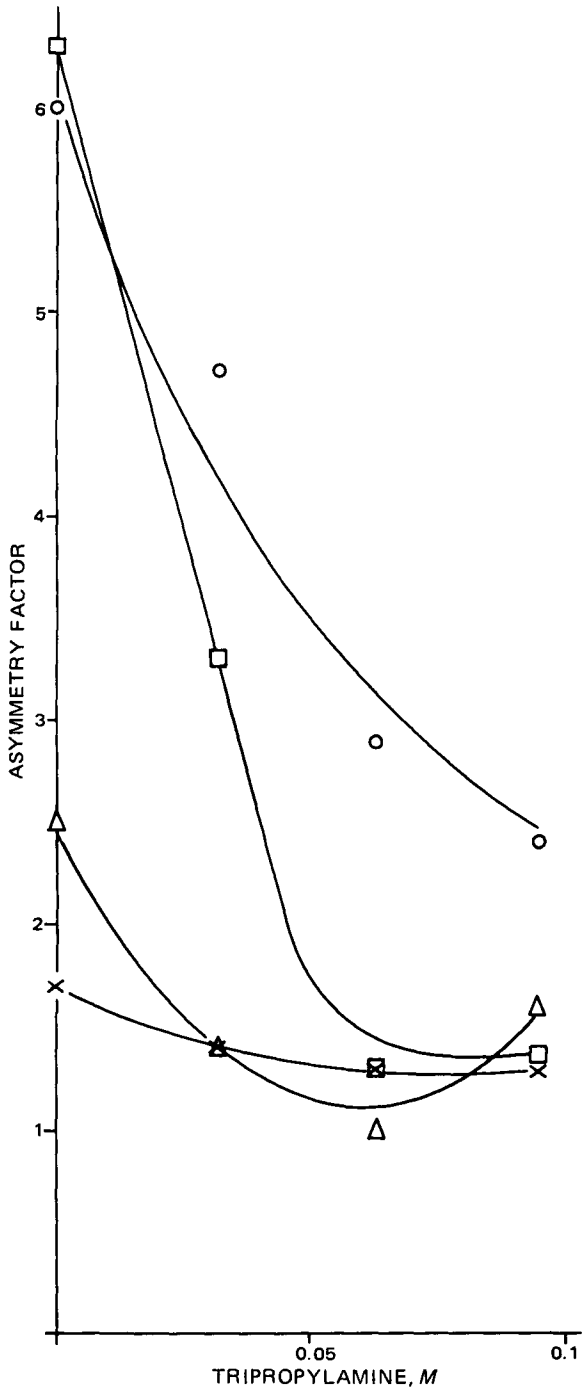

Figure 3—*Effect of the concentration of tripropylamine on peak symmetry. Key: See Fig. 1.*

regulating the capacity factors of the tetracyclines is more pronounced with *N,N*-dimethyloctylamine than with tripropylamine as counterion. This may be partly an effect of one more methylene group in *N,N*-dimethyloctylamine than in tripropylamine giving the *N,N*-dimethyloctylamine ion-pairs a more hydrophobic character.

Selectivity Change by Varying the Counterion Concentration—The influence of the nature and the concentration of the counterion on the separation factor α, is demonstrated in Tables I and II. The selectivity between II and I is better in the tripropylamine system, while the selectivity between IV and III is better in the *N,N*-dimethyloctylamine system. However, the separation factors for I and II are sufficiently large even in the *N,N*-dimethyloctylamine system to permit baseline separation at all *N,N*-dimethyloctylamine concentrations. It can also be seen that the selectivity between II and I is almost uninfluenced by an increase in the counterion concentration, while the selectivities between I and IV and also between IV and III increase with increasing counterion concentration. This effect on the separation selectivity is more

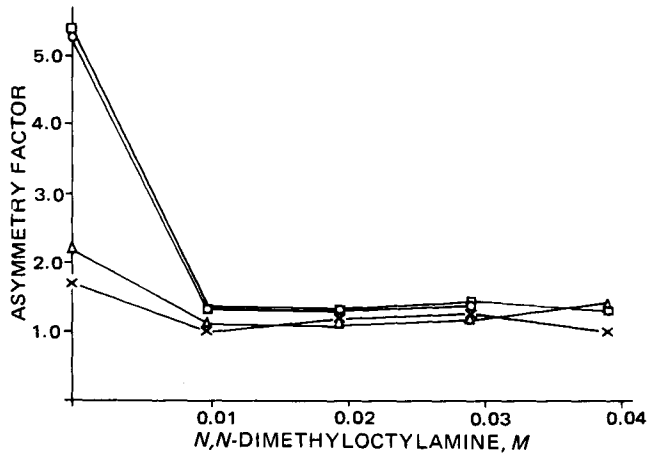

Figure 4—*Effect of the concentration of* N,N-*dimethyloctylamine on peak symmetry. Key: See Fig. 1.*

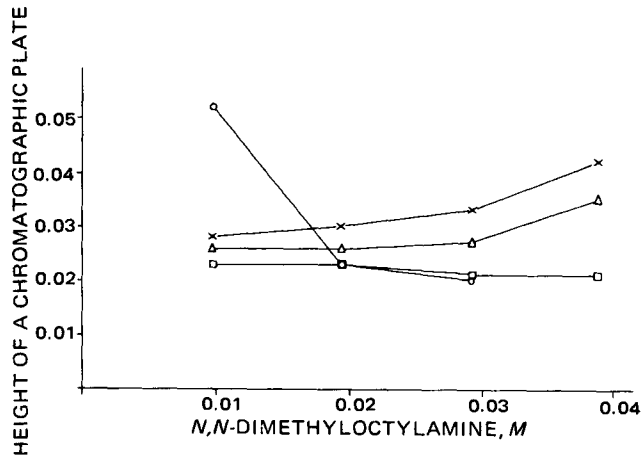

Figure 6—*Effect of the concentration of* N,N-*dimethyloctylamine on the separation efficiency. Key: See Fig. 1.*

pronounced with *N,N*-dimethyloctylamine than with tripropylamine as counterion.

Peak Symmetry and Separation Efficiency—Figure 3 demonstrates the variation in peak symmetry of the tetracyclines with increasing concentration of tripropylamine. Compounds III and IV show considerable tailing without the addition of the tertiary amine. However, tailing is significantly reduced by increasing the concentration of tripropylamine and the asymmetry factors; I, II, and IV are <2 with a tripropylamine concentration of 0.095 *M*, while III at this tripropylamine concentration still show significant tailing.

Table IV—Purity of Tetracycline Substances and Drug Preparations on the Swedish Market

Substances	Smallest Amount of Impurity, %		Largest Amount of Impurity, %		Impurity Limits in Substance, %

A much more pronounced effect on the peak symmetry of the tetracyclines was observed by the addition of *N,N*-dimethyloctylamine to the mobile phase. Figure 4 shows the variation in the asymmetry factor of I and its potential impurities with increasing *N,N*-dimethyloctylamine concentration in the mobile phase. With a *N,N*-dimethyloctylamine concentration as low as 0.01 *M*, all four tetracyclines have an asymmetry factor of <1.5. Positive effects on peak symmetry by addition of *N,N*-dimethyloctylamine were demonstrated for hydrophobic amines like imipramine, desipramine (17), and zimelidine and its metabolites (18), when chromatographed in the cationic forms. The separation efficiency of the tetracyclines is considerably improved by addition of the tertiary amines, tripropylamine, or *N,N*-dimethyloctylamine, to the mobile phase in accordance with peak symmetry. Relations between *H* and the concentration of the tertiary amines are demonstrated in Figs. 5 and 6.

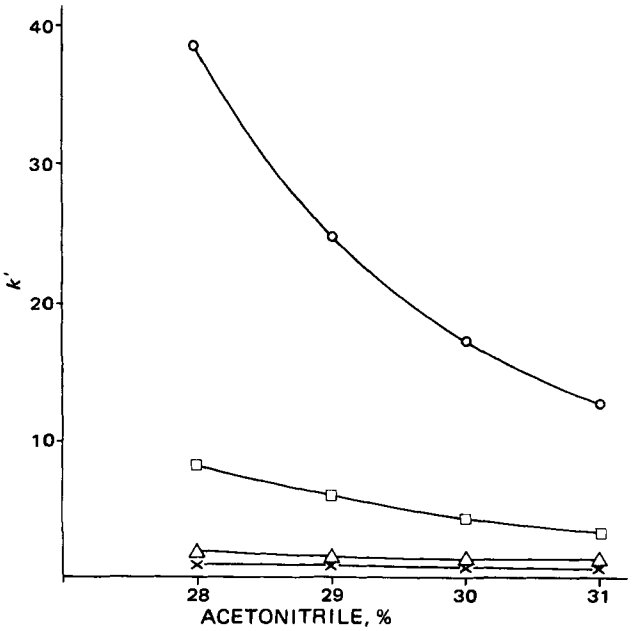

Figure 7—*Regulation of capacity factors by varying the acetonitrile concentration. The mobile phase contained a pH 8.0 sodium phosphate buffer with 0.0194* M N,N-*dimethyloctylamine and varying concentrations of acetonitrile. Key: See Fig. 1.*

Regulation of the Capacity Factor for Varying Acetonitrile Concentration—From the data presented, it follows that chromatography of the tetracyclines as *N,N*-dimethyloctylamine ion-pairs gives better chromatographic performance than when using tripropylamine as the counterion. A *N,N*-dimethyloctylamine concentration of ~0.02 *M* was sufficient to give good separation efficiency and symmetrical peaks of I–IV. Accordingly, in the following studies, the *N,N*-dimethyloctylamine system was used. From Fig. 1 it can be seen that the capacity factors of dehydrated III and IV are rather high with a *N,N*-dimethyloctylamine concentration of 0.02 *M* and 28% acetonitrile in pH 8.2 phosphate buffer.

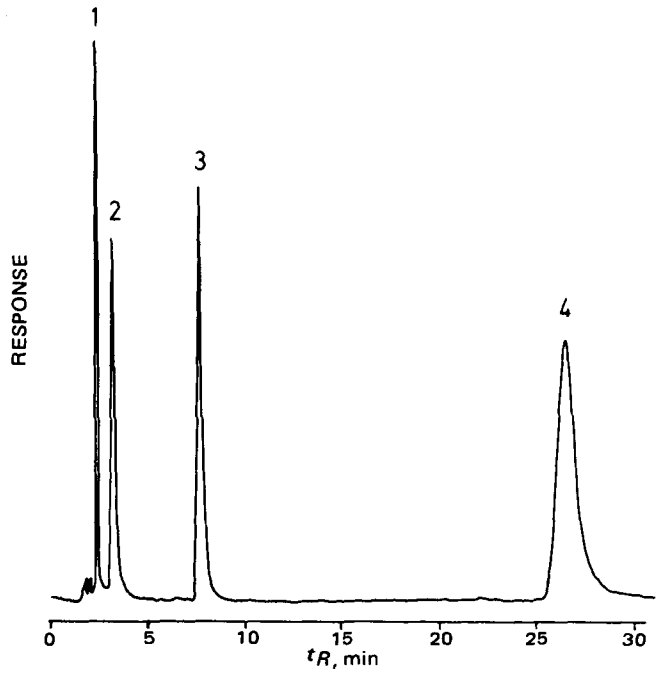

Figure 8—*Separation of I and its impurities. The mobile phase consisted of pH 8.0 sodium phosphate buffer containing 0.0194* M N,N-*dimethyloctylamine and 30% (v/v) acetonitrile at a flow rate of 1 ml/min. Key: 1, II (240 ng); 2, I (268 ng); 3, IV (246 ng); and 4, III (650 ng).*

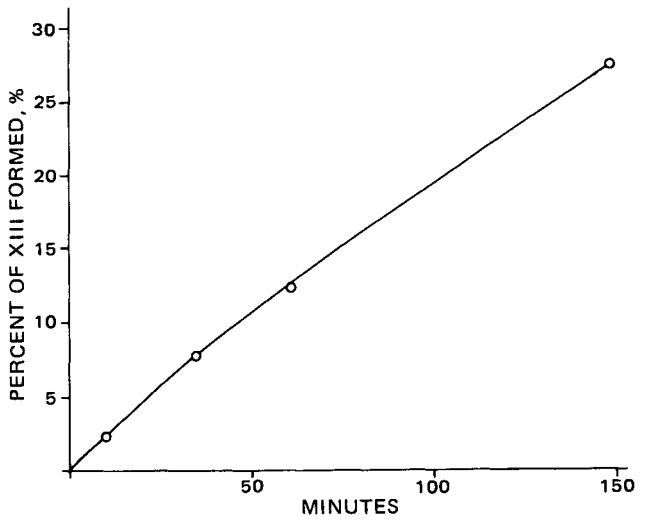

Figure 9—*Degradation rate of XI to XIII. Initial concentration of XI was 1.076 mg/ml, dissolved in mobile phase C without addition of tertiary amine.*

To optimize the separation time of the four tetracycline substances without loss of selectivity and peak symmetry, the influence of the acetonitrile concentration in the mobile phase on the capacity factor was determined. The results are demonstrated in Fig. 7. As expected, there is a drastic decrease of the capacity factor of III with a small increase in the acetonitrile concentration, but the capacity factors of I, II, and IV are influenced only to a limited extent. Figure 8 shows a separation of I, II, III, and IV by using a mobile phase consisting of 30% acetonitrile in pH 8.0 phosphate buffer and 0.0194 *M* *N,N*-dimethyloctylamine as the counterion.

Chromatography of Tetracycline Analogs and Potential Impurities—A suitable mobile phase composition to separate tetracycline analogs from their impurities was found to be pH 8.0 phosphate buffer with 30% acetonitrile and 0.0194 *M* *N,N*-dimethyloctylamine as the counterion (mobile phase A). The chromatographic data presented in Table III indicate that some of the substances have rather high capacity factors in mobile phase A, giving high retention times. Three alternative mobile phases were used, allowing regulation of the capacity factors over a wide range. Capacity factors for some of the tetracyclines in mobile phases B–D are also presented in Table III.

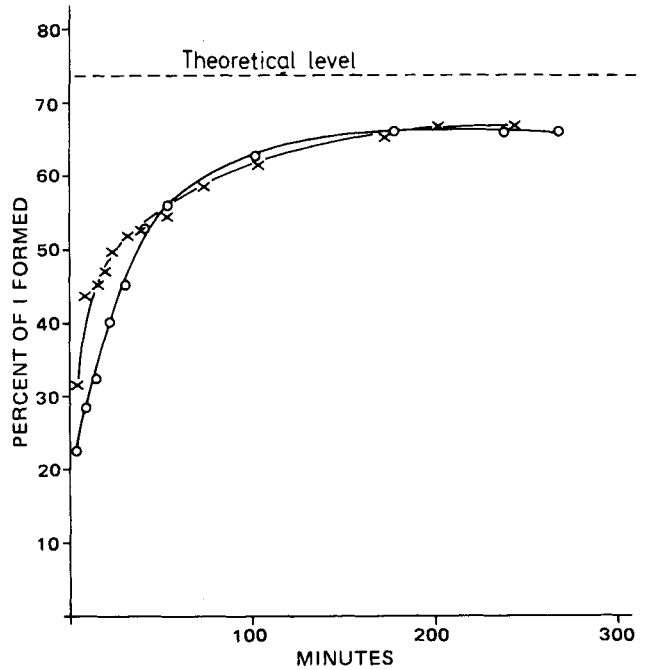

Figure 10—*Degradation rate of XVI to I. Key: ×, XVI (0.994 mg/ml) dissolved in pH 2.2 phosphate buffer; and ○, XVI (1.005 mg/ml) dissolved in pH 7.5 phosphate buffer.*

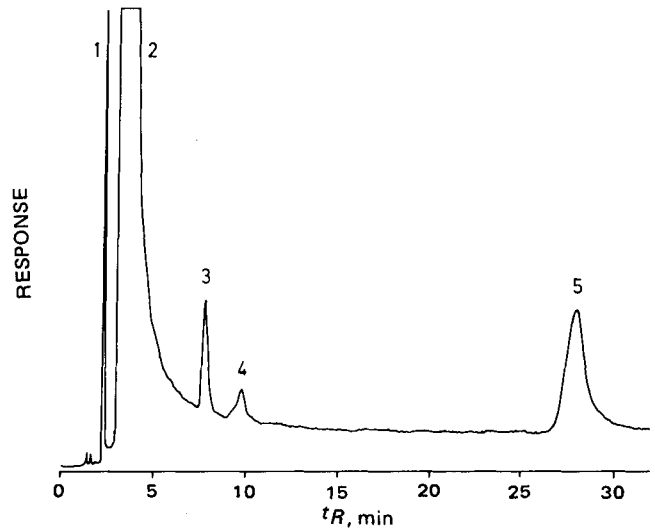

Figure 11—*Separation of I and its impurities from a tablet extract. Conditions were the same as in Fig. 8. Injection of 20 μl of a tablet extract with an initial concentration of 1.231 mg/ml is shown. Key: 1, II; 2, I; 3, IV (0.15%); 4, unknown impurity or tablet constituent; and 5, III.*

Stability of Tetracyclines—Tetracyclines have been reported (16) to undergo some degradation reactions like dehydration (at low pH) and epimerization between pH 3 and 5 in water solution. Stability tests of the tetracyclines were performed to exclude the possibility that the detected impurities were artifacts due to degradation during the chromatographic run, and to learn how to handle the dissolved substances before injection on the column. The commercial tetracyclines containing potential impurities were dissolved in the mobile phase without addition of the tertiary amine. A concentration of ~1 mg/ml of the tetracyclines was used, which allowed detection of the impurities to <0.1%. Repeated injections of the solutions were made over a minimum of 70 min, and the quantity of impurity was measured.

Two of the studied tetracycline substances showed significant degradation during the experimental period. Figure 9 shows the rate of rearrangement of XI to XIII. This study was performed by using a solution of XI with an initial concentration of 1.076 mg/ml. The substance was dissolved in mobile phase C without addition of the tertiary amine.

Figure 10 shows the degradation rate of XVI to I measured as percent I produced at pH 2.2 and 7.5 (phosphate buffer). The initial concentrations of (XVI) were 0.994 and 1.005 mg/ml, respectively. Mobile phase A was used for the quantitation of I produced. The molecular weights of I and XVI are 444 and 602.6, respectively, which means that 73.7% I produced corresponds to fully degraded XVI. The discrepancy between the theoretical and the observed I levels is not yet clearly understood. Compound XVI is a condensation product of I, lysine, and formaldehyde.

The described experiments show a fast degradation rate of XVI at acidic and neutral pH. This degradation means that there is a potential risk of formaldehyde liberation during therapy with XVI preparations. The liberation of formaldehyde during the degradation of XVI was determined by preparing the 2,4-dinitrophenylhydrazone derivative of formaldehyde followed by quantitation on a normal-phase column. Due to the fast degradation of XI and XVI, use of the described method is not recommended in the purity control of the drug substances.

Purity Control of Tetracycline Substances and Pharmaceutical Preparations—Figure 11 demonstrates the separation of tetracycline tablet extract containing small amounts of the impurities II, IV (0.15%), and III (0.6%). Table IV summarizes the content of impurities found in tetracycline, tetracycline analogs, and pharmaceutical preparations. There is good correlation of the impurity levels found in the drug substances and in the pharmaceutical preparations.

The precision of the method was evaluated to some extent by analyzing six samples containing 1 μg of III/ml. The relative SD was 6.5% at this concentration level. A concentration of 1 μg/ml corresponds to 0.1% impurity by injection of a tetracycline solution containing 1 mg/ml, which was the usual concentration of tetracycline used in the purity control studies.

Standard curves constructed by plotting peak areas *versus* sample concentrations show good linearity in the concentration range for all substances, with correlation coefficients >0.9994 in all cases.

Hydration and Percutaneous Absorption III: Influences of Stripping and Scalding on Hydration Alteration of the Permeability of Hairless Mouse Skin to Water and *n*-Alkanols

CHARANJIT R. BEHL *x, MICHAEL BARRETT, GORDON L. FLYNN, TAMIE KURIHARA, KENNETH A. WALTERS, OLIVIA G. GATMAITAN, NANCY HARPER, WILLIAM I. HIGUCHI, NORMAN F. H. HO, and CARL L. PIERSON

Abstract □ The influence of hydration on the permeability of stripped and scalded skins of hairless mice was investigated *in vitro* using water and *n*-alkanols as test permeants. Irrespective of pretreatment, the permeation rates of water, methanol, and ethanol were unaffected by aqueous immersion of skin sections in a diffusion cell, consistent with earlier data on unprocessed skins. The permeation rates of butanol and hexanol also were insensitive to hydration, differing from earlier studies on normal, intact skin in which both solutes' rates doubled after 10 hr of soaking. Following both pretreatments, the permeability of octanol declined over the first 5–10 hr of maceration, but remained invariant thereafter. The decline was most pronounced for the scalded skins. With untreated skin, octanol permeability initially increased and then declined before assuming a constant value. This study indicates that the barrier properties of the epidermis and dermis are not particularly sensitive to extended hydration except in the case of octanol. Scalding at 60° for 60 sec rapidly hydrates the skin, altering tissue permeability to about the same extent as a 10-hr (or longer) immersion in water at 37°. Octanol's unique hydration profile is explained by locating the origin of permeability decline in tissue beneath the horny exterior of the skin.

Keyphrases □ Permeability—of hairless mouse skin to water and *n*-alkanols after stripping and scalding □ Absorption, percutaneous—influence of stripping and scalding on permeability of water and *n*-alkanols, hairless mouse skin □ Hydration—alteration of permeability of stripped and scalded mouse skin to water and *n*-alkanols

It is known that the permeability of intact hairless mouse skin is altered by aqueous maceration, and that increases in permeation rates upon extended immersion of the skin in saline are a function of chemical structure for small, nonelectrolyte penetrants. Thus, the processes of hydration are complex, and probably involve more than one isolated phase of the skin membrane. A more thorough understanding of such hydration phenomena will add to the mechanistic understanding of the skin's barrier behavior.

Recently, effects of hydration on hairless mouse skin permeability were examined using water and *n*-alkanols as test permeants (1). These *in vitro* studies showed that hydration-induced permeability increases were a function of the penetrant lipophilicity. The permeabilities of the polar solutes, water, methanol, and ethanol, were not changed by hydration, while the permeabilities of the moderately lipophilic compounds, butanol and hexanol, asymptotically doubled in 10 hr of hydration. Permeation rates of the more lipophilic heptanol also increased to an asymptote, but only by ~50% in 10 hr. Octanol, the most lipophilic solute, showed an initial increase of ~50% in 5 hr, but then declined by ~25% by the 10th hr, undergoing a net increase in permeability of ~25%.

The skin hydration studies were extended to the Swiss mouse using water, methanol, ethanol, and butanol as permeants (2). In contrast to the hairless mouse skin results, water permeability increased up to 30 hr of hydration, and showed signs of leveling off between 30 and 43 hr. The permeabilities of methanol and ethanol also increased, but plateaued by 15 hr. Permeation rates of butanol increased over the first 15 hr and then declined almost linearly up to 48 hr. The hydration effect profile differences between the Swiss mouse and its hairless counterpart are

Standard curves constructed by plotting peak areas *versus* sample concentrations show good linearity in the concentration range for all substances, with correlation coefficients >0.9994 in all cases.

It is known that the permeability of intact hairless mouse skin is altered by aqueous maceration, and that increases in permeation rates upon extended immersion of the skin in saline are a function of chemical structure for small, nonelectrolyte penetrants. Thus, the processes of hydration are complex, and probably involve more than one isolated phase of the skin membrane. A more thorough understanding of such hydration phenomena will add to the mechanistic understanding of the skin's barrier behavior.

Recently, effects of hydration on hairless mouse skin permeability were examined using water and *n*-alkanols as test permeants (1). These *in vitro* studies showed that hydration-induced permeability increases were a function of the penetrant lipophilicity. The permeabilities of the polar solutes, water, methanol, and ethanol, were not changed by hydration, while the permeabilities of the moderately lipophilic compounds, butanol and hexanol, asymptotically doubled in 10 hr of hydration. Permeation rates of the more lipophilic heptanol also increased to an asymptote, but only by ~50% in 10 hr. Octanol, the most lipophilic solute, showed an initial increase of ~50% in 5 hr, but then declined by ~25% by the 10th hr, undergoing a net increase in permeability of ~25%.

The skin hydration studies were extended to the Swiss mouse using water, methanol, ethanol, and butanol as permeants (2). In contrast to the hairless mouse skin results, water permeability increased up to 30 hr of hydration, and showed signs of leveling off between 30 and 43 hr. The permeabilities of methanol and ethanol also increased, but plateaued by 15 hr. Permeation rates of butanol increased over the first 15 hr and then declined almost linearly up to 48 hr. The hydration effect profile differences between the Swiss mouse and its hairless counterpart are

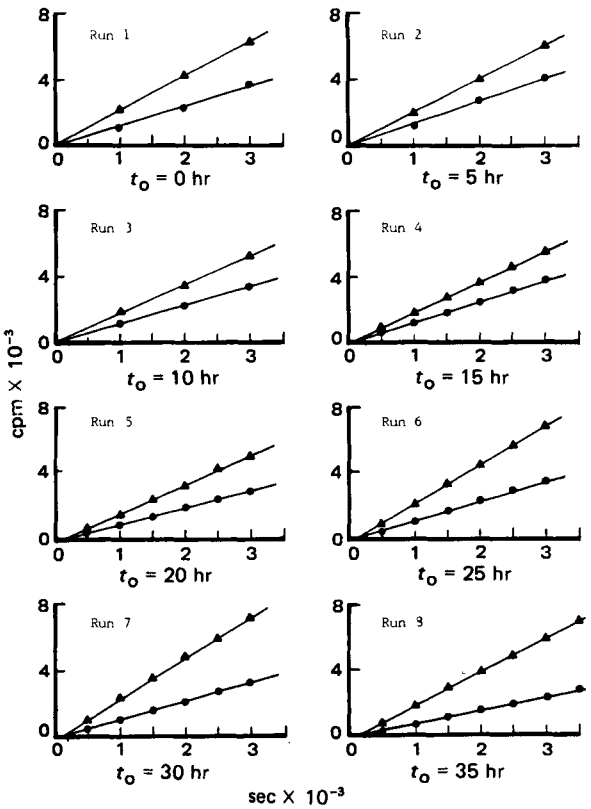

Figure 1—*Series of amount penetrated (cpm) versus time profiles for a set of eight sequential permeation runs on a single piece of stripped (25×) skin. The initial time of hydration for each run in terms of the total elapsed time (t_0) is indicated under each plot. This is one set of data for the methanol–butanol series. Key: ●, methanol; and ▲, butanol.*

apparently due to the abundant follicular presence in the Swiss species.

In both of the previous studies, unaltered full thickness skins consisting of the stratum corneum, the viable epidermis and the dermis were employed. It is well known that different strata of the skin control permeation rates of different solutes, depending on the relative oil/water partition coefficients of the permeants (3–5). Therefore, it is likely that different layers of the skin are responsible for the observed hydration-induced permeability increases or lack of increases. The present study was undertaken to study the influences of hydration on hairless mouse skins that were either scalded to alter thermally the properties of the stratum corneum (6) or stripped to completely remove the stratum corneum.

EXPERIMENTAL

Chemicals—[^{3}H]water[1], [^{3}H]methanol[1], [^{14}C]ethanol[2], [^{14}C]hexanol[2], [^{14}C]heptanol[2], and [^{14}C]octanol[2] were used as received. The radiochemicals were diluted into 0.9% sodium chloride irrigation medium[3] (saline) to prepare solutions for the permeation experiments. The final chemical concentrations in the diffusional medium were 10^{-4} *M* or lower.

Animals—Male hairless mice, SKH-hr^{-1} strain[4], were given free access to food and water. The mice were housed individually in shoebox cages to prevent them from damaging each other's skin; bedding was changed at least once a week. They were visually examined at least once a day to ascertain their general health.

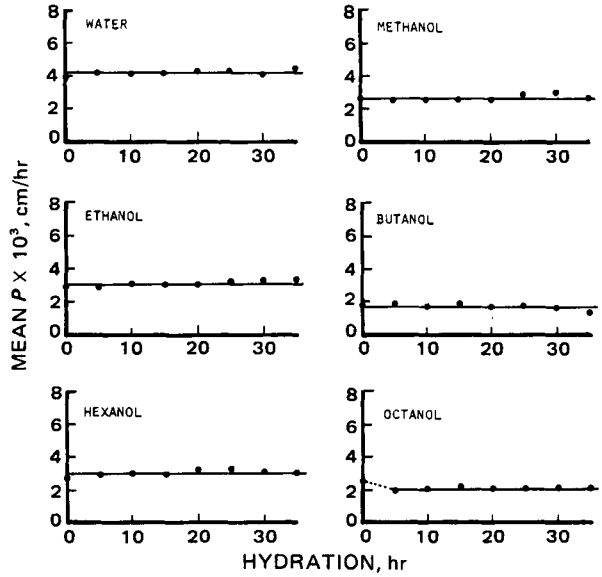

Figure 2—*Plots of average permeability coefficients (P) of the stripped (25×) skins versus hydration time for water, methanol, ethanol, butanol, hexanol, and octanol.*

Scalding Procedure—The dorsal surface of a mouse freshly sacrificed by spinal dislocation was scalded for 60 sec at 60° by immersing the dorsum in water contained in a jacketed apparatus through which water (60°) was perfused from a constant-temperature water bath (6). Both the abdominal and the dorsal surfaces were scalded before running the permeation experiments. Since scalding softens the stratum corneum, extra care was exercised in handling the skin. The skins were excised and mounted in diffusion cells within a few minutes after scalding, and the permeation experiment was started within 30 min.

Stripping Procedure—The abdominal surface of a mouse, freshly sacrificed by spinal dislocation, was stripped 25 times with adhesive tape (5, 7), using a fresh piece of tape each time. The abdominal surfaces were stripped with the adhesive tape because this site is easier to strip than the back. This choice did not affect the results because no site-to-site variations were observed in previous hydration-induced permeability alterations (1). Since removal of the stratum corneum causes the skin to shrink and fold over itself, making it difficult to handle and to excise from the animal, great care was observed in processing the stripped skins.

Radioisotopic Assay—The concentration of the radiolabeled permeant was determined by placing discrete samples in a cocktail[5] and assaying on a liquid scintillation counter[6]. Whenever possible, the technique of dual labels (1, 2, 4, 6–11) was used to economize the study and improve experimental precision.

Permeation Procedure—Two-compartment glass diffusion cells were employed to determine skin permeability. The mouse age was controlled (age 60 days) as much as possible, to avoid any age-related effects (4). The

[a] Skins of Mouse 2 and Mouse 3 were damaged after ~5 hr of experiment. [b] The standard deviations represent mouse-to-mouse variability, not in the estimate of hydration-induced alterations (or lack of them). [c] The skins were damaged.

external medium of diffusion was normal saline. The half-cell contents were stirred at 150 rpm and all permeation experiments were carried out at 37°. The half-cell facing the stratum corneum was always the donor chamber and the half-cell facing the dermis was always the receiver chamber. Therefore, net diffusion was from the stratum corneum to the dermis side. Complete hydration profiles were obtained on each piece of skin by running six to nine sequential experiments, with thorough rinsing between runs (1).

Data Analysis—The data were plotted as receiver compartment concentration (in counts per minute) *versus* time. The permeability coefficients were calculated from (1):

$$P = \frac{V}{A}\frac{(dC/dt)}{\Delta C} \qquad \text{(Eq. 1)}$$

where:

P = the permeability coefficient (centimeters per hour)
A = the diffusional area (~0.6 cm^2)
ΔC = the concentration difference across the membrane, which was taken to be equal to the donor concentration (counts per minute)
V = the half-cell volume (1.4 ml)
dC/dt = the quasisteady-state slope (counts per minute per cubic centimeter per hour)

RESULTS

Figure 1 contains a representative set of eight subplots obtained in sequential permeation experiments carried out on one piece of skin over 35 hr using [^{3}H]methanol and [^{14}C]butanol as dual permeants. A linear relationship between the receiver concentration *versus* time was obtained, indicating a good approximation of steady-state transport conditions. This permeation behavior is consistent with that reported for the intact, unaltered skins of hairless (1) and Swiss (2) mice. Slopes of these linear plots were used to compute permeability coefficients.

Table I contains a summary of results for the stripped abdominal skins. Three mice were used for each of the permeants, and eight sequential permeation experiments were run on each skin.

Data from sequential runs performed on scalded skins were processed as indicated in Fig. 1. One of the experiments, the methanol/butanol set, was of long duration (>40 hr) and involved nine separate experiments on each piece of tissue spaced at 5-hr intervals. Table II contains a summary of results for the scalded skins.

Two skins, one abdominal and one dorsal, were employed for each of the permeants, and [^{3}H]methanol was used as a copermeant with all alkanols. The individual permeability coefficients of the abdominal and the dorsal skins are quite similar, indicating that the data are not a function of the anatomical site. This observation is consistent with the earlier studies where the abdominal and the dorsal permeabilities were found to converge beyond the age of ~50 days (4).

Since methanol was used as a reference permeant, it is possible to normalize the data for ethanol, butanol, hexanol, and octanol to methanol permeability at a given hydration time. This procedure levels out animal-to-animal variability and results in more precise data. The standard deviations associated with the average ratios are much smaller than those associated with the average permeability values (Table II).

DISCUSSION

In vitro diffusion through membranes from body tissues or from synthetic materials is one of the most general means of characterizing the physicochemical attributes of physiological and synthetic barriers. With

a judicious choice of permeants, the mass transfer mechanisms of the membranes can be determined and related fundamentally to permeant chemical structure. However, all such research presumes the membranes in question to be physically stable over the experimental time frame. However, diffusional experiments are by their nature lengthy, and over the extended membrane contact time with usually liquid external media there is ample opportunity for solvation to modify basic membrane integrity. Therefore, the effects of solvation must be considered during the assessment of barrier properties.

In the case of biological membranes, the media bathing the tissue is usually aqueous and made osmotically physiological with salts. It is the influence of such aqueous solutions that must be assessed. Since biological membranes are polyphasic, with each distinct phase presumably having a unique hydration sensitivity, a full understanding of hydration phenomena promises to be of mechanistically interpretive value. Certain skin preparations such as tape-stripped skin may be useful for simulating the influences of abrasive and disease related damage on the permeability of skin. Thus, the stability of processed skins to solvation are also of interest.

Effect of Hydration on Permeability of Stripped Skin—The skin becomes exceedingly permeable as a result of the stripping procedure used, which effectively removes the entire stratum corneum. Table III contains a comparative list of the average permeability coefficients of normal skins (abstracted from earlier studies) and stripped skins. The stripping procedure made the skin most permeable to water; a more than 300-fold increase was noted. Both methanol and ethanol demonstrate about half as much enhancement.

As the permeants become more lipophilic, the ratio drops almost exponentially, indicating a declining role of the stratum corneum with increased lipoidal characteristics of the permeants. The permeability coefficients for the alkanols through the stripped skin decline by only a factor of two from methanol to octanol, in contrast to the systematically increasing permeability coefficients of normal skin. The former pattern is *prima facie* evidence that transport of these compounds through the dermis and residual epidermis does not involve a lipid/water partitioning step. This evidence reaffirms conclusions previously made by these authors and by Scheuplein and Blank (12).

With the possible exception of octanol, there does not appear to be any change in permeability of the stripped skin sections to water or the *n*-alkanols over >35 hr of hydration (Fig. 2). It was previously reported (1)

Table III—Permeabilities of Stripped and Unaltered Skins of Hairless Mice

Compound	$P \times 10^3$, cm/hr: Skin[a] Unaltered[b]	Stripped	Ratio, $P_{stripped}/P_{unaltered}$
Water	1.3 ± 0.2	420.0 ± 18.9	323.0

Hexanol	38.8 ± 15.6	302.5 ± 19.6	7.8
Octanol	97.8 ± 13.5	207.4 ± 8.0	2.1

[a] Hydrated skins. [b] Abstracted from Ref. 1.

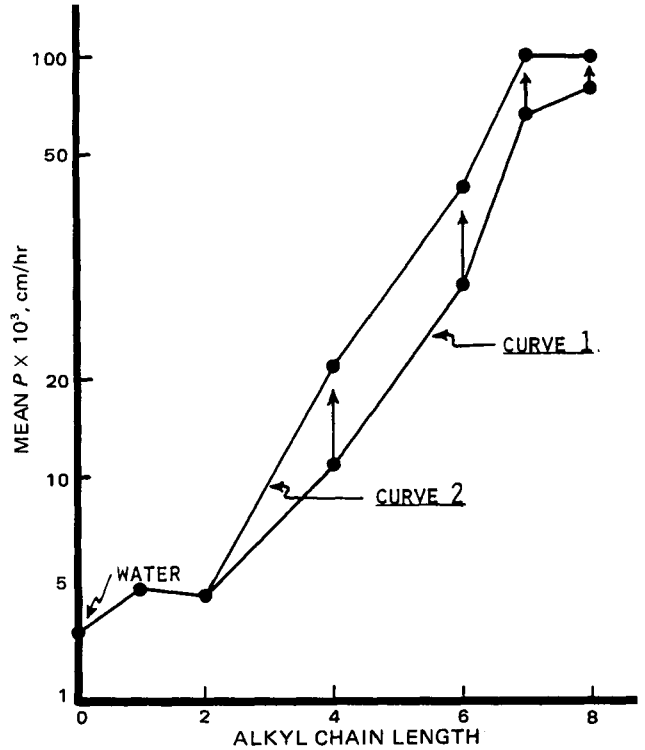

Figure 4—*Semilogarithmic plots of average permeability coefficients* versus *alkyl chain length for skins in their natural state of hydration (curve 1) and for skins which were exposed to saline in the diffusion cells for a minimum of 10 hr. Raw data for these plots were abstracted from Ref. 1.*

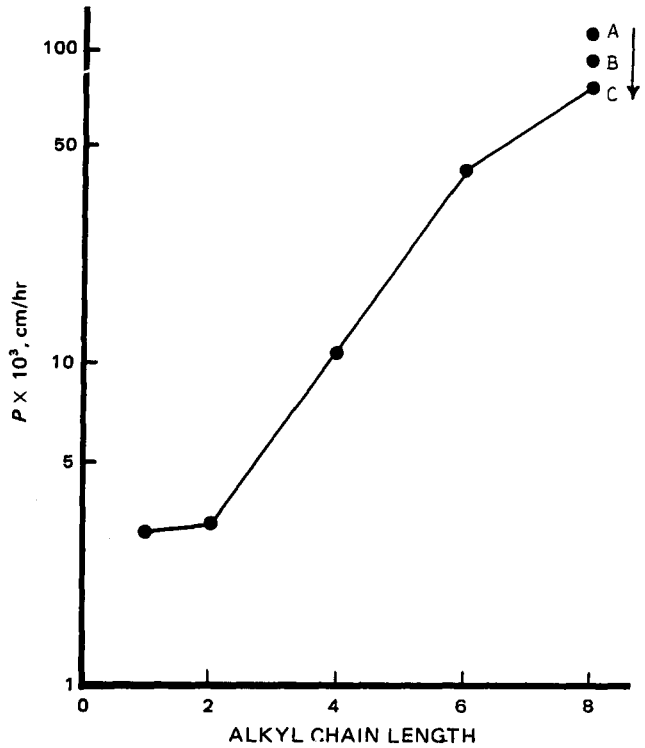

Figure 5—*Semilogarithmic plot of average permeability coefficients* (P *values*) versus *alkyl chain length for the scalded (60°; 60 sec) skins. Data for methanol, ethanol, butanol, and hexanol obtained at different times of hydration, were averaged. The individual permeabilities of octanol at ~0 and 5 hr of hydration are presented (points A and B, respectively). The remaining octanol data by hydration times of 10, 15, 20, 25, and 30 hr were averaged (point C).*

that the permeability coefficients of butanol and hexanol doubled over 10 hr of soaking. Considering the large increases in absolute permeability coefficients of the permeants caused by stripping and the hydration insensitivity of the membrane to their permeation after stipping, it appears that the effect of water with intact skin originates in the horny layer.

Because both butanol and hexanol increase exponentially on the log *P versus* alkyl chain length plot, it is evident that the effects are within the lipoid region of the stratum corneum. Whether they represent a physicochemical change in the diffusional medium or a physical rearrangement of the critical phase cannot be determined at this time. For the length of time they were carried out, the data for methanol are consistent with earlier studies where its permeation rate was found to be invariant in both abdominally and dorsally isolated dermis for hydration times of up to 800 hr (8).

The data for octanol may be interpreted differently. Its hydration–permeability profile, previously reported (1), is mechanistically revealing (Fig. 3). There is a 50% increase in permeation rates in the first 5 hr of hydration, and a 25% decrease by the 10th hr, followed by invariant permeability thereafter. To aid the discussion, data from previous hydration effect studies (1) were abstracted and are presented (Fig. 4) in terms of the alkyl chain profiles of the unhydrated skins (curve 1) and the hydrated skins (curve 2). Both curve 1 and curve 2 contain the following three segments: (*a*) a lower plateau evident for the polar solutes, water, methanol, and ethanol, signifying that their permeation occurs through some sort of highly polar, presumably aqueous pores present in the stratum corneum (4); (*b*) a steep rise in the permeability coefficients between ethanol and heptanol, which is linear when the data are obtained in the fully hydrated state (curve 2). [This segment demonstrates that the permeation process of these penetrants is controlled by their partitioning into the lipid regions of the stratum corneum (3, 4)]; and (*c*) the beginning of a second plateau near octanol, meaning that a third mechanism becomes important for the more hydrophobic compounds.

This mechanism has a permeation rate that is controlled by aqueous tissue resistance encountered in the viable epidermis and the dermis (3–5); *i.e.*, at an alkyl chain length of eight, the rate-controlling stratum changes from the horny layer to the viable epidermis and dermis. Based on this information and previous observations that octanol permeability increases somewhat with incremental stripping of the skin (7), it can be concluded that the control rate of octanol transport is significantly biphasic. Due to the wide difference in lipophilicity, it is reasonable that the stratum corneum and the dermis might influence the permeability of octanol (a transition compound) in an opposite manner, as a function of hydration time. Therefore, the initial increase in the permeability coefficients of octanol (Fig. 3) may be due to maceration of the stratum corneum. (Both competing processes occur simultaneously.)

If this argument is true, hydration of the stripped skin should slightly decrease its permeability to octanol. The hydration profile depicted in Fig. 2 indicates that this is probably the case. There seems to be some decrease in octanol permeability in the first 5 hr of hydration. This is less evident based on the stripped skin data alone but a statistically significant and similar effect is noted with scalded skin. It is curious that the other alkanols studied are not, as far as can be judged, similarly affected in stripped skin. At the present time, it is not possible to ascribe the ob-

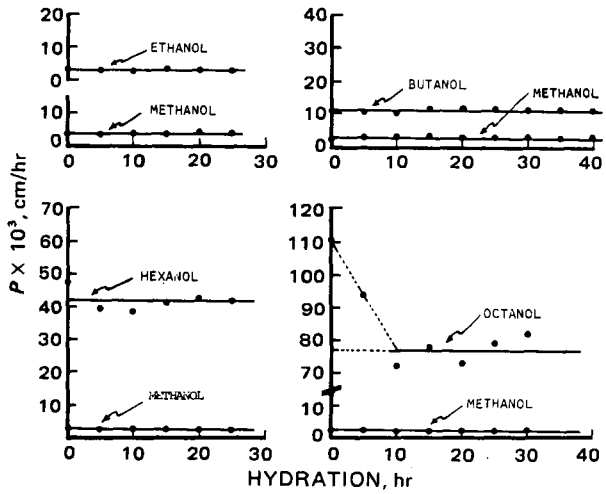

Figure 6—*Plots of average permeability coefficients* (P) *of the scalded (60°, 60 sec) skins* versus *time of hydration for methanol, ethanol, butanol, hexanol, and octanol. Methanol was used as a copermeant with all other alkanols to serve as a control solute.*

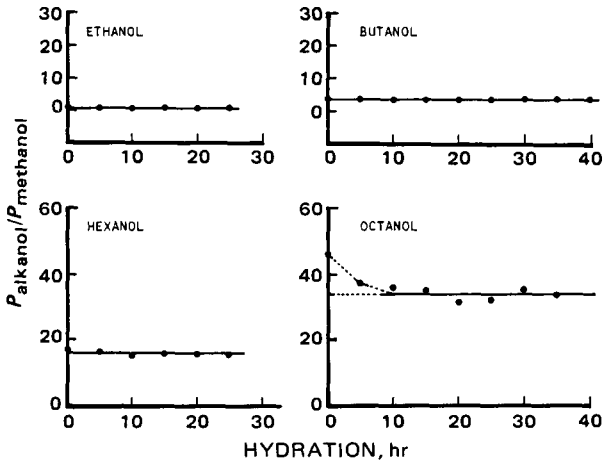

Figure 7—*Plots of normalized permeabilities (permeability of alkanol/permeability of methanol) of ethanol, butanol, hexanol, and octanol versus time of hydration.*

served octanol effect to any specific property of the molecule, *i.e.*, hydrophobicity or molecular size.

Effects of Hydration on Permeability of Scalded Skins—Figure 5 graphically illustrates the alkyl chain length profiles of the scalded skin permeabilities. Since no definite hydration–permeability trends are apparent through hexanol, data obtained at different hydration times were averaged for water, methanol, ethanol, butanol, and hexanol and these averages are plotted. Data for octanol were averaged only after 10 hr of hydration when its skin permeability coefficient was stabilized.

Octanol permeabilities at ~0 and 5 hr of hydration are also displayed in Fig. 5. A smooth sigmoidal curve is obtained when the points representing the fully equilibrated skin permeabilities are joined. This plot contains the three segments of curve 2 (Fig. 4) discussed previously, *i.e.*, the lower plateau, steep rise in the P values, and a second plateau. The absolute numbers plotted in Fig. 4 (curve 2) and in Fig. 5 are also, in agreement within ±50%. This close qualitative and quantitative parallelism between the two situations is significant and indicates that permeation in the normal, fully hydrated skin, and the scalded skin, occurs *via* the same mechanism.

There did not appear to be any significant increases or decreases caused by aqueous immersion in the permeability of scalded hairless mouse skin to the *n*-alkanols through hexanol. Neither the averages of the actual permeability coefficients (Fig. 6) nor their ratios to concurrently studied methanol permeability coefficients (Fig. 7) varied with hydration time. Water, methanol, and ethanol were previously shown to be unaffected by hydration in normal skin (1) but there were measurable hydration-associated increases in the permeabilities of butanol and hexanol (and heptanol). These were obliterated by scalding. The conclusion that scalding rapidly hydrates the skin was substantially reinforced by these extended studies. Moreover, the absolute permeability coefficients of the scalded skins were close in magnitude to those reported for fully hydrated normal skin. Therefore, 60-sec scalding not only rapidly hydrates the skin, but alters its permeability to about the same extent as does the 10 hr (or longer) aqueous soaking at 37°. This conclusion can aid in the interpretation of burned skin permeability data regardless of whether the skin is scalded (6, 9) or branded (10, 11).

Octanol appeared to behave differently. Its permeation rates gradually declined between 0 and 10 hr of hydration, and remained mostly unaltered thereafter. In view of the discussion and the theory of the switching-over of the rate-controlling mechanisms presented in the earlier section, it can be hypothesized that the observed decline probably was due to the effects of hydration on the epidermis–dermis. The data reported here further support the tentative interpretation presented to explain the up and down trends observed in octanol hydration–permeability profiles (1).

Glucosylated Albumin and Its Influence on Salicylate Binding

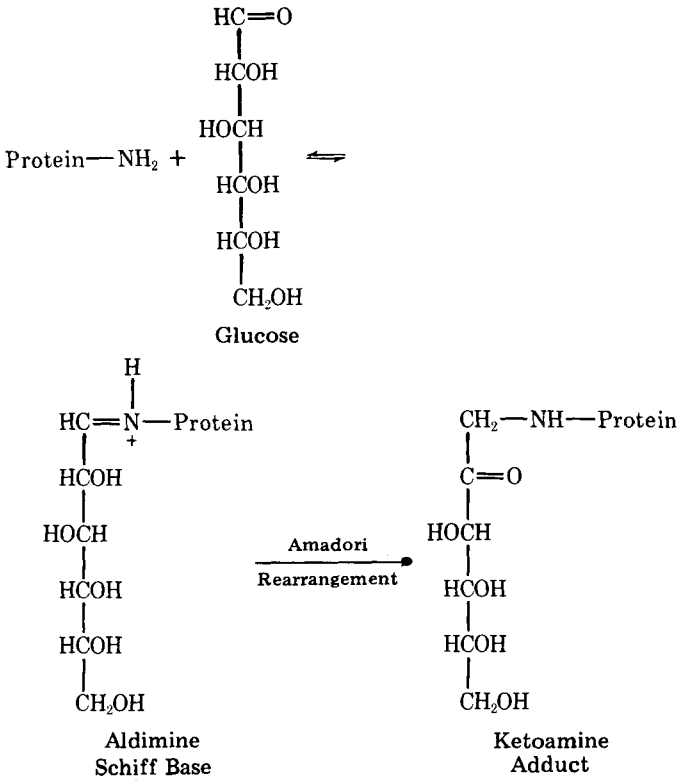
K. A. MEREISH, H. ROSENBERG[x], and J. COBBY

Received March 27, 1981, from the *College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication June 16, 1981.

Abstract □ Human serum albumin was incubated at 37° in 0.01 *M* phosphate buffer (pH 7.4) under sterile conditions for up to 10 days with labeled [^{14}C]glucose (1–25 mg/ml). Glucose incorporated into albumin was calculated following extensive dialysis of the incubation mixture. The results indicated that glucose reacted with albumin by a nonenzymatic process involving Schiff base formation and Amadori rearrangement to a stable ketoamine derivative. The degree of glucosylation was dependent on the reaction time, glucose concentration, and pH. Glucosylation was enhanced when albumin was fatty acid free. Glucosylated albumin was separated from unmodified albumin by cation exchange chromatography on carboxymethylcellulose and quantitated colorimetrically with 2-thiobarbituric acid. Salicylate binding studies revealed that the glucosylated component had a decreased salicylate binding capacity accompanied by a reduction in the number of classes of binding sites.

Keyphrases □ Albumin, serum—effect of glucosylation on salicylate binding, human □ Glucosylation—human serum albumin, effect on salicylate binding □ Binding—salicylate, effect of glucosylation of human serum albumin

It is generally recognized that the major threat to life and function posed by diabetes mellitus is the insidious development of long-term complications such as atherosclerosis, microangiopathic vascular disease, and neuropathy (1, 2). Many investigators speculate that frequent lapses in diabetic control are associated with an increased incidence and rate of progression of the diabetic complications. Although the mechanism by which hyperglycemia may lead to these complications is unknown, recent attention has been focused on the nonenzymatic condensation of glucose with proteins to yield stable covalent adducts (3). Such nonenzymatic glucosylation could result in altered protein structure, function, stability, and immunological response (2).



Scheme I—Proposed nonenzymatic reaction sequence involved in the formation of glycosylated proteins.

BACKGROUND

The demonstration of increased amounts of the glucosylated form of hemoglobin A (hemoglobin Alc) in diabetics was the first example of posttranslational protein modification correlated with elevated blood glucose concentrations (3). Evidence was recently published linking the development of corneal opalescence in diabetes with glucosylation of lens crystallins (4, 5). The nonenzymatic glucosylation of human serum proteins (6–8), insulin (9), and collagen (10) were also reported. Mechanistically, the nonenzymatic interaction of glucose and protein occurs by way of a ketoamine linkage involving the free amino group at the *N*-terminus or the ϵ-amino groups of lysine residues (Scheme I).

To establish a closer link between hyperglycemia and secondary complications of diabetes, experiments were initiated to compare the extent to which fatty acid-free albumin and albumin bound with fatty acids are susceptible to glucosylation *in vitro*. The hypothesis that enhanced rates of nonenzymatic protein glucosylation may contribute to the pathophysiology of diabetes is valid if such glucosylation is accompanied by altered protein function. To determine whether the glucosylation of albumin could result in altered protein function, salicylate binding to glucosylated, partially glucosylated, and nonglucosylated albumin was compared.

EXPERIMENTAL

Preparation of Glucosylated Albumin—Albumin[1] (Fraction V) solutions of 47.5 mg/ml were prepared in 0.01 *M* phosphate buffer, pH 7.4. Following the addition of D-[^{14}C]glucose[2] to final concentrations

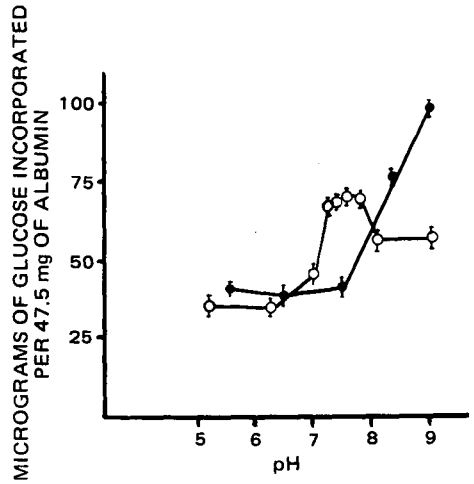


Figure 1—*Dependence of glucose incorporation into albumin on pH and composition of incubation buffer. Albumin (47.5 mg/ml) was incubated at 37° in 0.01 M phosphate buffer (○) and 0.1 M tromethamine buffer (●) containing 10 mg/ml (1 μCi) of [^{14}C]glucose. After 24 hr, samples with the indicated pH were dialyzed, lyophilized, and counted for radioactivity. Values are the means of four determinations ±SD.*

ranging from 1–25 mg/ml, the solutions were sterilized by ultrafiltration and incubated for up to 10 days in capped, sterile vials at 37°. At the end of each incubation period, 1-ml samples were removed and dialyzed against several 1000-fold volumes of distilled water for 24 hr at 4°. A portion of the dialysate was monitored for the presence of free glucose by the glucose oxidase method[3]. The remainder was lyophilized and counted for radioactivity. Incubated samples were compared to control samples which were prepared by dissolving identical quantities of albumin and [^{14}C]glucose in phosphate buffer and immediately dialyzing against distilled water for 24 hr.

Influence of pH on the Glucosylation of Albumin—Albumin (47.5 mg/ml) was incubated at 37° in 0.01 *M* phosphate buffer and 0.1 tromethamine buffer containing 10 mg/ml of D-[^{14}C]glucose (1 μCi). The pH of the reaction solutions was varied from 5.0–9.0. After 24 hr of incubation, the samples were dialyzed, lyophilized, and counted for radioactivity.

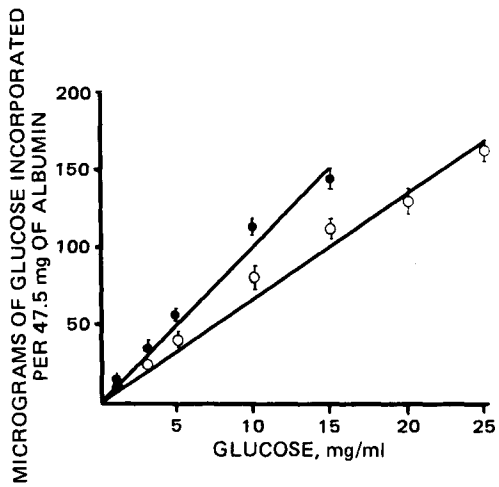

Figure 2—*Incorporation of glucose into albumin and fatty acid-free albumin as a function of glucose concentration. Albumin (○) and fatty acid-free albumin (●) were incubated at 37° in 0.01* M *phosphate buffer, pH 7.4, containing the indicated concentrations of [^{14}C]glucose. After 24 hr the incubated samples were dialyzed, lyophilized, and counted for radioactivity. Values are the means of four determinations* ±SD.

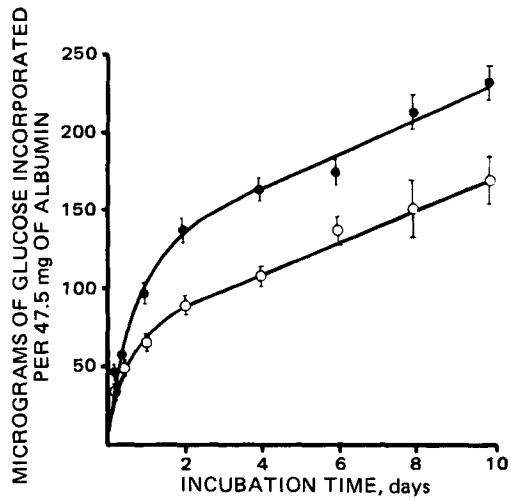

Figure 3—*Incorporation of glucose into albumin and fatty acid-free albumin as a function of incubation time. Albumin (○) and fatty acid-free albumin (●) were incubated at 37° in 0.01* M *phosphate buffer, pH 7.4, containing 10 mg/ml [^{14}C]glucose. Aliquots were removed at the indicated times, dialyzed, lyophilized, and counted for radioactivity. Values are the means of four determinations* ±SD.

Galactosylation of Albumin—Albumin (47.5 mg/ml) was incubated with 1 μCi of D-[6-^{3}H]galactose (1 mg/ml) in 0.01 *M* phosphate buffer, pH 7.4, at 37°. After 36 hr the reaction samples were treated as described previously.

Glucosylation of Albumin with D-[2-^{3}H] and D-[5-^{3}H]glucose—Albumin (47.5) mg/ml) was incubated with 1 μCi D-[2-^{3}H]glucose (10 mg/ml) in 0.01 *M* phosphate buffer, pH 7.4 at 37°. In an identical incubation, albumin was reacted with 1μCi D-[5-^{3}H]glucose (10 mg/ml). After 36 hr of incubation, the reaction samples were treated as described previously.

Thiobarbituric Acid Test for Glucosylated Protein—Glucosylated protein was detected using a modification of the thiobarbituric acid procedure of Flückiger and Winterhalter (11). This assay measures 5-(hydroxymethyl)-2-furaldehyde released upon hydrolysis of ketoamine adducts of proteins (Scheme II).

Samples of glucosylated albumin (5 mg) were placed in 15-ml culture tubes and dissolved in distilled water (1 ml). After the addition of 1.0 *N* oxalic acid (0.5 ml), the tubes were gently shaken, capped, and placed in a heating block at 100° for 5 hr. The tubes were subsequently cooled and

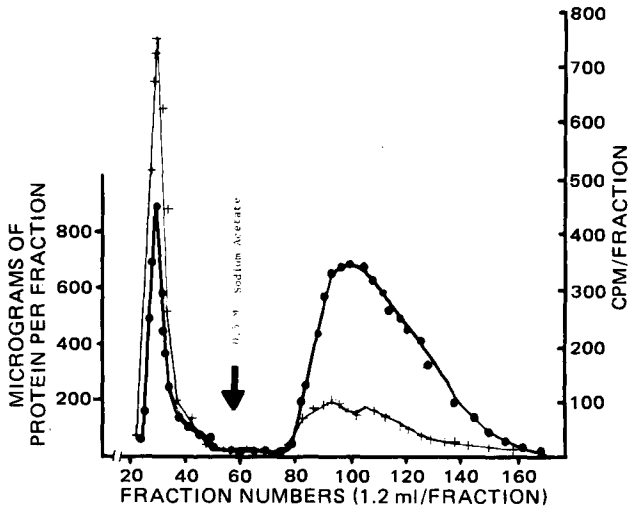

Figure 4—*Separation of human serum albumin into glucosylated and nonglucosylated components by chromatography on carboxymethylcellulose. Samples in 0.01* M *sodium acetate, pH 4.65, were applied to a column (17 × 2 cm) of carboxymethylcellulose and eluted using a 200-ml gradient of 0.01–0.5* M *sodium acetate, pH 4.65. Elution with 0.5* M *sodium acetate is indicated by the arrow.*

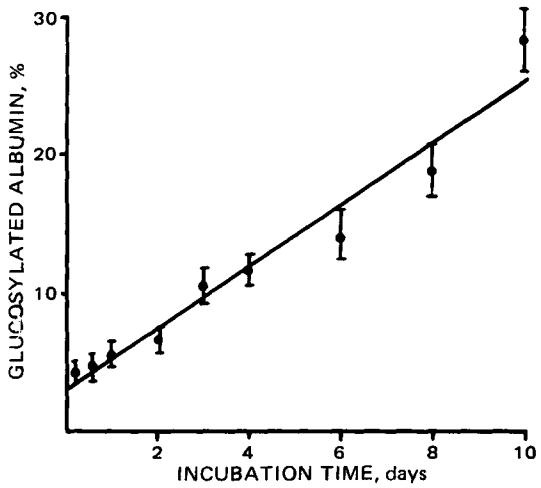

Figure 5—*Percentage glucosylated albumin as a function of incubation time. Albumin (47.5 mg/ml) was incubated at 37° in 0.01* M *phosphate buffer, pH 7.4, containing 10 mg/ml glucose. Aliquots were removed at the indicated times, dialyzed, lyophilized, and 10 mg was subjected to carboxymethylcellulose chromatography to separate the glucosylated fraction. Values are the means of four determinations* ±SD.

cold 40% trichloroacetic acid (0.25 ml) was added to precipitate the protein. The contents were then centrifuged at 2000×*g* for 10 min. An aliquot (1 ml) of the supernate was removed and added to a solution of 0.05 *M* aqueous 2-thiobarbituric acid (0.5 ml). After mixing and an incubation period of 15 min at 37°, the absorbance of each sample was measured at 443 nm.

Chromatographic Separation of Glucosylated and Nonglucosylated Albumin—Glucosylated and nonglucosylated albumin were separated using cation exchange chromatography on carboxymethylcellulose (6). Carboxymethylcellulose was suspended in 0.01 *M* sodium acetate buffer, pH 4.65, and packed in a 30 × 1.7-cm column to a length of 20 cm. Samples (50 mg) in the sodium acetate buffer were applied to the column and eluted with a 200-ml gradient of 0.01–0.5 *M* sodium acetate buffer, pH 4.65. Fractions (1 ml) were collected and assayed for protein content by an earlier method (12). An aliquot (0.1 ml) of each fraction was monitored for radioactivity.

Utilizing larger columns, 1-g quantities of glucosylated and nonglucosylated albumin were separated for use in the salicylate binding studies. Separated fractions were dialyzed against water for 24 hr and then lyophilized prior to their use in salicylate binding studies.

Salicylate Binding Capacity of Glucosylated and Nonglucosylated Albumin—The salicylate binding properties of nonglucosylated, 5–10% glucosylated, 25–30% glucosylated, and 100% glucosylated albumin were compared by the equilibrium dialysis method[4]. Albumin (47.5 mg/ml) was dialyzed against 1.2, 1.0, 0.8, 0.6, 0.5, 0.4, 0.25, and 0.125 mg/ml sodium salicylate. After 2.5 hr of dialysis, the solutions were acidified and extracted with 1 ml of chloroform. The concentration of salicylate in the chloroform extracts was assayed at 310 nm (13).

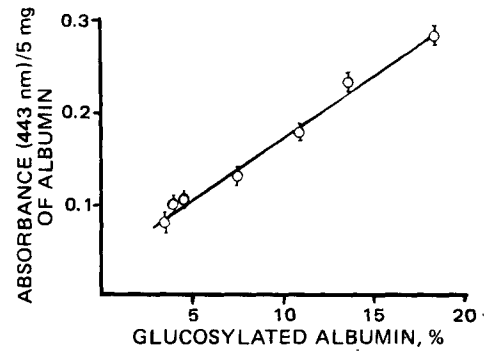

Figure 6—*Formation of 5-(hydroxymethyl)-2-furaldehyde from glucosylated albumin. Albumin (47.5 mg/ml) was incubated at 37° in 0.01* M *phosphate buffer, pH 7.4, containing 10 mg/ml of glucose. Aliquots were removed at different times, dialyzed and lyophilized. Ten milligrams was subjected to carboxymethylcellulose chromatography to determine the percentage of glucosylated albumin formed. Another 5 mg was subjected to the 2-thiobarbituric acid test. Values are the means of four determinations* ±SD.

RESULTS AND DISCUSSION

Incubation of [^{14}C]glucose with human serum albumin at physiological pH, temperature, and albumin concentration resulted in the incorporation of labeled glucose into protein. This radioactivity was not removed by extensive dialysis against distilled water, suggesting a covalent linkage between glucose and albumin. To determine the nature of the linkage between glucose and albumin, the glucosylated albumin was treated with oxalic acid, resulting in the release of 5-(hydroxymethyl)-2-furaldehyde, which was detected by the characteristic colored adduct formed with 2-thiobarbituric acid (Scheme II). Formation of 5-(hydroxymethyl)-2-furaldehyde is characteristic of monosaccharides bound to protein by a ketoamine linkage (3).

Additional evidence for the ketoamine linkage was provided by studies in which albumin was separately incubated with 1 μCi of D-[2-^{3}H]glucose and D-[5-^{3}H]glucose having identical specific activities. In the case of glucose labeled in the 5-position, the glucosylated albumin had a specific activity of 670 cpm/mg of albumin. In contrast, albumin incubated with glucose labeled in the 2-position showed a specific activity of 267 cpm/mg of albumin. These results indicated loss of the label from the 2-position of the sugar, thus implying the occurrence of an Amadori rearrangement during the reaction. Obviously, glucosylation of albumin occurred by the same mechanism as in the formation of hemoglobin Alc; that is, glucose reacted with the amino groups of albumin to form aldimine linkages, which subsequently underwent an Amadori rearrangement to form the more stable ketoamine linkages (Scheme I).

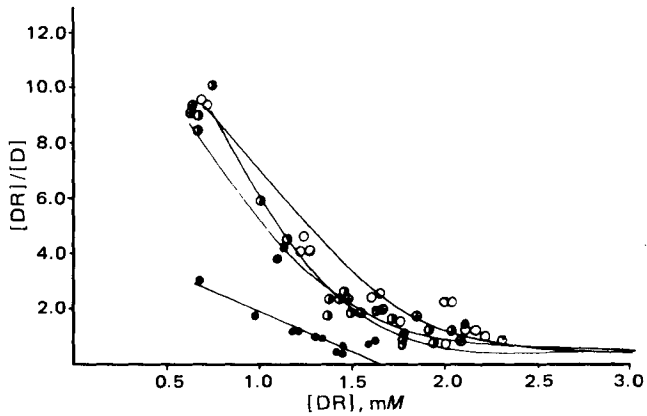

Figure 8—*Rosenthal plot for salicylate bound to nonglucosylated, partially glucosylated, and completely glucosylated human serum albumin. Key: ⊕, 5–10% glucosylated albumin; ◑, 25–30% glucosylated albumin; ○, nonglucosylated albumin; and ●, completely glucosylated albumin.*

The degree of nonenzymatic glucosylation of human serum albumin was dependent on the pH and composition of the incubation buffer (Fig. 1). The reaction between glucose and albumin most likely occurs by means of a nucleophilic attack by an unprotonated amino group on the glucose molecule. At physiological pH, few of the primary groups exist in the unprotonated state. This situation may account for the relatively slow rate of the glucosylation reaction.

At physiological pH and temperature, human serum albumin as well as fatty acid-free albumin incorporated labeled glucose in a concentration-dependent manner (Fig. 2). However, at every glucose concentration employed, glucose incorporation into fatty acid-free albumin was significantly greater than that incorporated by albumin bound with fatty acids. Perhaps common sites were utilized in the covalent binding of glucose and the ionic binding of fatty acids. In diabetes, the increased levels of albumin glucosylation may adversely affect fatty acid transport and, thus, may contribute to the pathogenesis of the disease.

The rate of glucose incorporation into albumin and fatty acid-free albumin was also dependent on the reaction time (Fig. 3). In both cases, during the initial 2 days of incubation the rate of glucose uptake was faster than in the succeeding days. This indicated that some sites on the albumin molecule were more easily glucosylated than others. The initial rate of glucose incorporation into fatty acid-free albumin was considerably faster than into albumin. This suggests that the process of defatting the albumin resulted in the release of additional sites that were capable of being glucosylated. However, the preparation of fatty acid-free albumin was accomplished at a pH below 3.0 for a period of not less than 8 hr (14, 15). This treatment may have caused the hydrolysis of glucose molecules already covalently bound to albumin, thereby releasing additional sites for glucosylation.

Nonenzymatic glycosylation of albumin by means of a ketoamine linkage can occur with hexoses other than glucose. Calculations based on the amount of radioactivity incorporated into albumin revealed that 9.95 μg of galactose and 8.8 μg of glucose were bound to albumin following identical incubations in which galactose and glucose (1 mg/ml) were reacted separately with albumin (47.5 mg/ml) under physiological conditions for 36 hr. This incorporation of galactose into albumin is not surprising in view of the reported glycosylation of hemoglobin with other sugars and sugar–phosphates (3).

Glucosylated albumin was readily separated from unmodified albumin by cation exchange chromatography on carboxymethylcellulose (Fig. 4). Prior to the *in vitro* incubation with glucose, albumin was found to be 5–10% glucosylated as determined by the chromatographic separation of the glucosylated from nonglucosylated components. In addition, the percentage of glucosylated albumin increased proportionally with time (Fig. 5).

Figure 6 illustrates the results obtained when glucosylated albumin is subjected to the 2-thiobarbituric acid test. It is evident that 5-(hydroxymethyl)-2-furaldehyde generation is directly dependent on the percentage of glucosylated albumin formed, suggesting the basis for a practical colorimetric assay to monitor the degree of diabetic control. Until now, only hemoglobin Alc has been considered as a diagnostic indicator for the long-term control of diabetes. Measurement of glucosylated albumin may be more advantageous, since the half-life for albumin is only 20 days (16) compared with 120 days for erythrocytes. Assuming that glucosylated and nonglucosylated albumin have the same turnover rate, one would expect fluctuations in blood glucose to be detected more sensitively by changes in glucosylated albumin than in glucosylated hemoglobin. Moreover, unlike hemoglobin Alc values, the amount of glucosylated albumin is not influenced by hemolytic disorders.

The results obtained from the salicylate binding studies indicate that the percentage of salicylate bound to totally glucosylated albumin is significantly lower than that for nonglucosylated or partially glucosylated albumin (Fig. 7). Analysis of the data by means of a Rosenthal plot (17) suggests that nonglucosylated and partially glucosylated albumin possess more than one class of binding sites, whereas 100% glucosylated albumin appears to possess only one class of binding sites (Fig. 8). The fact that the glucosylated component of albumin has a significantly decreased capacity to bind salicylate may have little significance for the diabetic, since the glucosylated fraction comprises a relatively small proportion of total albumin. Even at 25–30% glucosylation, there is no significant decrease in the salicylate binding capacity.

Effect of Carboxylic Acids on Permeation of Chlorpromazine Through Dimethyl Polysiloxane Membrane

M. R. GASCO ˣ, M. TROTTA, and M. E. CARLOTTI

Received February 19, 1981, from the *Istituto di Chimica Farmaceutica e Tossicologica dell'Università di Torino, Corso Raffaello 31, Torino, Italy.* Accepted for publication July 2, 1981.

Abstract □ The effect of carboxylic acids on the permeation of chlorpromazine was investigated through a dimethyl polysiloxane nonpolar membrane. The permeability of the diffusate, at pH 5.8, increases considerably in the presence of carboxylic acids or phosphate, probably due to an ion-pair formation between the relative anions and chlorpromazine.

Keyphrases □ Chlorpromazine—permeation through a dimethyl polysiloxane membrane, effect of carboxylic acids □ Diffusion—chlorpromazine, through a dimethyl polysiloxane membrane, effect of carboxylic acids □ Carboxylic acids—effect on chlorpromazine diffusion through a dimethyl polysiloxane membrane

Previously reported studies (1–3) on the diffusion and permeation of drugs through polymeric membranes have contributed much to the knowledge of drug diffusion; a dimethyl polysiloxane polymer would be useful to investigate drug permeation through a membrane.

The permeation of molecules through a nonpolar membrane in the presence of other molecular species, has been studied previously (2, 4, 5). Many factors, including complex and ion-pair formation (6, 7), can influence the physiological availability of drugs. Nakano (8) studied the influence of a variety of substances, such as adsorbents and excipients, on the permeation of chlorpromazine through a model membrane. All the examined compounds, dissolved in citrate or dimethylglutarate buffers, decrease the permeation of the drug.

The present study examined the variation of chlorpromazine permeation through a nonpolar membrane in the presence of many acids to understand the effect of different organic anions on drug permeability. The selected carboxylic acids, the majority of them being physiological, had different structures.

EXPERIMENTAL

Materials—Nonreinforced dimethyl polysiloxane[1] sheeting in a labeled thickness of 5 ml (12.5×10^{-3} cm), thoroughly rinsed and treated as described previously (2), was used.

Chlorpromazine hydrochloride[2] as well as, citric[3], tartaric[3], acetic[3], glutaric[3], adipic[3], isocitric[4], oxaloacetic[4], malic[3], α-ketoglutaric[3], succinic[3], fumaric[3], and aconitic[4] acids were obtained commercially.

Instruments—A pH meter[5], a spectrophotometer[6], and a plate tensiometer[7] were used.

Determination of Critical Micelle Concentration (CMC)—The CMC of chlorpromazine in the presence of bicarboxylic acids was determined by measurement of surface tension with a plate tensiometer at 37 ± 0.5° in 50×10^{-3} *M* solution of acid. The ionic strength was maintained at 0.146 *M* by adding sodium chloride.

Diffusion Studies—The diffusion cell was constructed according to one used previously (9). The glass cell consisted of donor and receptor compartments (the volume of each compartment was 22 ml) and a membrane (available area was 3.14 cm^2) placed between them. Twenty-two milliliters of 0.01 *N* HCl was added to one arm and an equal volume of the test solution was placed in the other arm. The concentration of diffusible chlorpromazine in the desorbing solution was kept to a zero value to maintain diffused chlorpromazine in a dissociated form. The diffusing solutions were always corrected with sodium hydroxide or with hydrochloric acid, according to the desired pH, since preliminary experiments showed that phosphate and carboxylate anions can change drug permeation considerably. All solutions were warmed in a jacketed container maintained at 37 ± 0.1°. The content of each compartment was rotated by a magnet attached to an electric motor; the rotating speed was ~300 rpm.

Analytical Methods—At scheduled times an aliquot (0.5 ml) of the receptor solution was pipetted out for UV determination, and the same volume of 0.01 *N* HCl was added to the receptor compartment to replace the reduced volume. The 0.5-ml aliquot of the desorbing solution was transferred into a volumetric flask, and 4.5 ml of water was added. The drug concentrations were determined spectrophotometrically at 254 nm (log ε 4.49) for more diluted solutions and at 305 nm (log ε 3.63) for more concentrated solutions, or when additives interfered with the measurement at 254 nm.

Determination of the Apparent Diffusion Constant—Equation 1, derived by Garrett and Chemburkar (1) for a steady-state diffusion, was used to obtain the apparent diffusion constant *D*:

$$D = \frac{C_1 X V}{t C_2 S} \qquad \text{(Eq. 1)}$$

where C_1 is the concentration of diffusate in the desorbing solution, X is the thickness of the membrane, S is the available area of membrane, V is the volume of the desorbing solution, and C_2 is the concentration of the diffusate.

Diffusion Studies with Increasing Phosphate Concentration—Solutions at pH 5.8 with 2×10^{-3} *M* chlorpromazine and increasing phosphate concentrations ($1–70 \times 10^{-3}$ *M*) were prepared. The steady-state diffusion of chlorpromazine through the membrane was studied at 37° (Fig. 1).

Diffusion Studies of Chlorpromazine at Various pH—The solutions of chlorpromazine were kept at a concentration of 2×10^{-3} *M* when the pH range was within 3.5–6.0 and at a concentration of 5×10^{-4} *M* when the pH was >6.0. The required pH was obtained with hydrochloric acid or sodium hydroxide. The steady-state diffusion of chlorpromazine from these solutions through a 5-ml thick dimethyl polysiloxane membrane into 22 ml of 0.01 *N* HCl was studied at 37°. The pH values of diffusing solutions were noted before and after the experiments and were unchanged. The samples were removed at intervals of 20 min over a 2-hr period (Fig. 2, curve a).

In another series of tests, the effect of phosphate on the steady-state diffusion of chlorpromazine was studied at different pH. Diffusing 2 ×

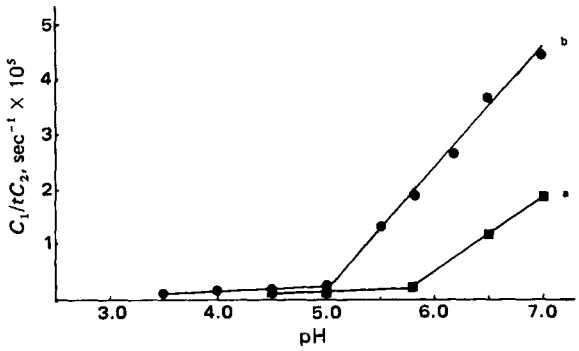

Figure 2—*Specific concentration rate of chlorpromazine through a membrane into 0.01 M HCl desorbing solution at 37° versus the pH of the diffusing drug solution. Key: a, without phosphate; and b, with a phosphate concentration 25 times the molarity of chlorpromazine.*

10^{-3} *M* chlorpromazine solutions in the pH range 3.5–6.0 and 5×10^{-4} *M* at pH >6.0, each containing phosphate concentration 25 times the molarity of the drug, were prepared (Fig. 2, curve b) and examined.

Diffusion Studies of Chlorpromazine in the Presence of Carboxylates—Experiments relative to the permeation of chlorpromazine in the presence of carboxylates were carried out at pH 5.8 and 37°. The diffusing solutions contained $1–3 \times 10^{-3}$ *M* of chlorpromazine and a carboxylate concentration 25 times the molarity of the drug.

RESULTS AND DISCUSSION

Effect of Phosphate on the Diffusion Rate of Chlorpromazine—The rate of steady-state diffusion through dimethyl polysiloxane membranes of an almost constant concentration (C_2) of chlorpromazine increases with the increasing phosphate concentration (Fig. 1). The specific diffusion rate of chlorpromazine is invariant at an acid concentration 21 times higher than the molarity of the drug. The permeation increase could be ascribed to ion-pair formation between chlorpromazine and the phosphate anions. An ion-pair interaction between dialkylaminoalkylphenothiazines and pteridines was also verified (10). The same interaction was proved between phosphate and antidepressive tricyclic drugs (11).

These results show that it is impossible to study the influence of a carboxylic anion on the permeability of chlorpromazine in the presence of other anions (such as phosphate). Therefore, all diffusion experiments were carried out without buffering the solutions, but using only hydrochloric acid or sodium hydroxide to adjust the pH.

Effect of pH on the Diffusion Rates—The diffusion of chlorpromazine varies according to pH. As shown by Fig. 2, curve a, chlorpromazine diffusion is very low at low pH values, because with a pKa of 9.3 (12), it is almost completely ionized. As pH increases, the chlorpromazine diffusion rate also increases, owing to the formation of undissociated hydrochloride. Figure 2, curve b, shows that the specific diffusion rates of chlorpromazine, in the presence of a constant excess of phosphate in the pH 5.5–7.0 range, are higher than those obtained using only the drug as a consequence of the formation of an ion-pair.

Oxaloacetic	2.91	25.42

[a] Specific rate of concentration increase of desorbing solution.

Effect of Carboxylates on Rate Diffusion of Chlorpromazine—Since the rate of steady-state diffusion of an almost constant concentration (C_2) of chlorpromazine increased in the presence of oxaloacetic acid, the permeation rate of chlorpromazine was determined in the presence of other carboxylic acids. The linear dependence of the diffusion rates for the same membrane area, thickness, and volume of the diffusing solution, showed that rate diffusion through the membrane was directly proportional to the concentration of the diffusing drug. The lag times are negligible.

Rates of chlorpromazine concentration increase in 22 ml of 0.01 *N* HCl desorbing solution, C_1/t, are shown in Fig. 3 as a function of the respective concentration C_2 of the drug in the diffusing solution.

Apparent diffusion constants (D) were computed from the specific rates and are summarized in Table I. From D values it can be observed that the effect of permeation varies among the carboxylic acids. The apparent diffusion constant (D) depended on the acid concentrations up to a maximum of 21 times that of the drug and afterward remained invariant for all examined solutions where the acid concentration was 25 times higher than that of the drug.

The difference in the drug permeability in the presence of acids could also be explained by an ion-pair formation, probably dependent on D for its stability. To understand the behavior of the acids, the apparent diffusion constants of chlorpromazine in the presence of bicarboxylic acids were plotted against the chlorpromazine critical micelle concentration (CMC), determined in the presence of a fixed concentration of the same

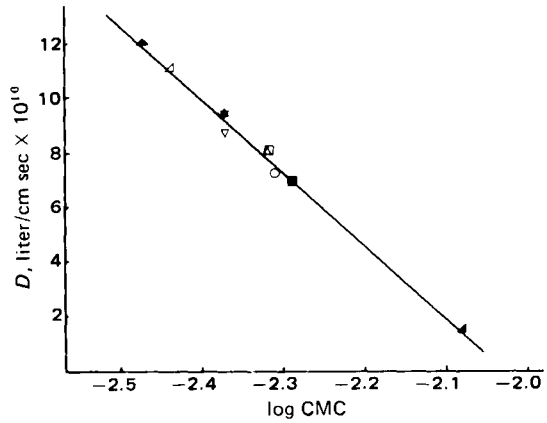

Figure 4—*Apparent diffusion constant D of chlorpromazine into 0.01 N HCl desorbing solution in the presence of bicarboxylic acids versus log CMC of chlorpromazine determined in 50 × 10^{-3} M solution of the same acid (μ = 0.146 M). Key: ◢, sodium chloride; ■, adipic; ○, malic; □, malonic; △, fumaric; ▽, tartaric; ★, glutaric; ◺, oxoglutaric; and ▲, succinic acids.*

acid. The CMC describes the lipophilicity of amphiphilic substances (13); the CMC value of chlorpromazine in the presence of acid could be an indirect measure of the lipophilicity of the ion-pair. Figure 4 shows an almost linear correlation between D and the CMC for the different bicarboxylic acids.

Chlorpromazine was selected for this study since it is representative of many tricyclic drugs and its behavior toward carboxylic acids may be important in GI absorption. Ion-pair formation between chlorpromazine and dietary carboxylic acids (such as citric, tartaric, and acetic acid) would give a favorable absorption in GI lumen. Furthermore, these findings could be useful for the development of dosage forms. It was shown (14) that certain drugs can be absorbed in their undissociated state, either directly or by ion-pair or complex formation. The behavior of chlorpromazine in humans might also be ascribed to the interactions of the drug with some of the physiological acids studied.

Effect of Albumin Conformation on the Binding of Phenylbutazone and Oxyphenbutazone to Human Serum Albumin

A. ABD ELBARY*, J. J. VALLNER ˣ, and C. W. WHITWORTH

Received March 9, 1981, from the *School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication June 29, 1981. *Present address: Faculty of Pharmacy, Cairo University, Cairo, Egypt.

Abstract □ The binding of phenylbutazone (I) and oxyphenbutazone (II) to human serum albumin over pH 6.9–9.3 was studied by difference spectrophotometry and equilibrium dialysis. At each pH tested, there was higher binding affinity of I to human serum albumin than II. Equilibrium dialysis showed that over the pH 7–8.2 range both agents had a single high-affinity site and several sites of lower affinity, with the highest binding constant and number of binding sites at pH 7.4 for both I and II. Both techniques showed that the affinity of both drugs to albumin was higher for the neutral form than for the basic form and this transition occurred in both cases around the neutral region (7–7.4). Both the ionized and unionized forms of I and II participated in the binding. In the neutral region, magnesium ion increased the affinity of both drugs to albumin while chloride ion decreased it slightly.

Keyphrases □ Phenylbutazone—effect of albumin conformation on binding to human serum albumin □ Oxyphenbutazone—effect of albumin conformation on binding to human serum albumin □ Albumin, human serum—effect of conformation on binding of phenylbutazone and oxyphenbutazone □ Binding—of phenylbutazone and oxyphenbutazone, effect of albumin conformation, human serum albumin

Drug–protein binding studies are important for prediction of drug dynamics in the body (1). The affinity of such interaction can possibly be used to correlate therapeutic and toxicological effects, as well as drug distribution and excretion. Most *in vitro* drug–protein interaction studies are conducted in isotonic pH 7.4 buffer. Data reduction in terms of binding constants assumes that for a partially ionized drug each species is bound with equivalent affinity (2).

It was reported (3) that conformational changes occur in serum albumin over pH 6–9. Zurawski and Foster (4) established that two conformational states exist in bovine serum albumin over this pH region. They called the form at neutral pH (pH 6–7) the "N" form and the form at higher pH (around pH 9) the "B" (base) form. Thus, the conformational change that occurs is the N to B or B to N transition. It was recently shown (5–7) that the same conformational change occurs in human serum albumin over pH 6–9. The N to B transition is seemingly dependent on pH but may also occur to some extent with ionic strength of the buffer and buffer ion composition. Calcium ion and chloride ion affect this transition (5–10) as well as the binding of drug to the protein.

BACKGROUND

While the macromolecule conformation changes with varying pH, ionization of the drug may also occur over such a pH range. A method was presented recently (2) to distinguish which species of a partially ionized acidic or basic drug bind to the protein and to enable determination of the binding site constant (3) for the interaction. In addition, this method aids in the detection of significant changes in the protein binding site that may result from pH perturbation. Since the blood pH in patients may vary between 6.8 and 7.8 (11), significant changes in drug binding to albumin or other plasma proteins could take place with a change in blood or local change in organ (*e.g.*, liver) pH. This pH range could not be predicted in any one individual; at best these pH differences usually would be only a few tenths of a pH unit (*i.e.*, respiratory acidosis or alkalosis).

The present study used equilibrium dialysis and UV difference spectroscopy to investigate the effect of albumin conformational state on the binding of phenylbutazone and oxyphenbutazone to human serum albumin at various pH values.

EXPERIMENTAL

Materials—The human serum albumin used was previously investigated for purity[1] (12). Phenylbutazone (I) and its metabolite oxyphen-

butazone (II) were obtained commercially[2]. All other chemicals were analytical grade[3,4] and all solutions were prepared in deionized water.

Binding Studies—Binding studies of I and II to human serum albumin were carried out using UV difference spectroscopy and equilbirium dialysis techniques. In all binding studies, the albumin (1.45 × 10^{-5} *M*) was dissolved in phosphate buffer adjusted to various pH values, *i.e.*, 6.8, 7.0, 7.4, 7.8, and 8.2, and pH 9.3 borate buffer. All buffer solutions were made isotonic using sodium chloride or magnesium chloride.

Difference Spectrophotometry—The tandem technique (13) was employed in the split-beam mode[5]. Identical 10-μl increments[6] of either I or II (1.50 × 10^{-3} *M*) were added to the buffer cell in the reference beam and to the albumin cell in the sample beam to give final concentrations of I or II of 4.97 × 10^{-6}–6.4 × 10^{-5} *M*, representing drug to protein ratios of 0.34–4.4. To maintain a constant albumin concentration in each beam after drug addition, a volume of albumin equal to that of the drug added, but twice the concentration of the albumin already in the cell, was added to the protein cell. Drug concentration was kept constant by the addition of an identical volume of buffer to the buffer cell in the reference compartment. Resulting difference spectra were subsequently recorded.

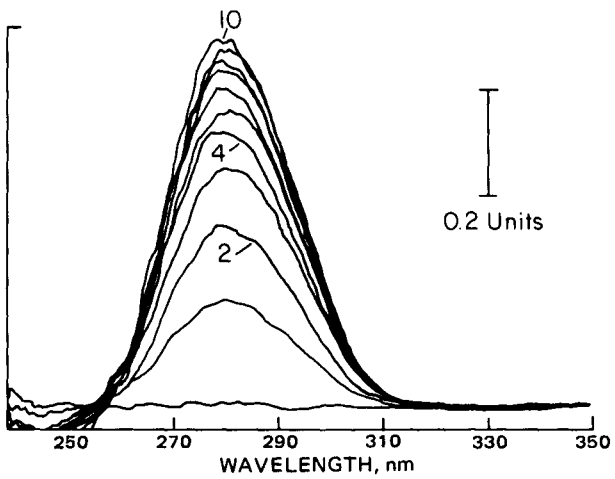

Figure 2—*Difference spectrophotometric titration of 1.45 × 10^{-5} M albumin with II at pH 7. Each curve represents the addition of 10 μl of II solution (1.5 × 10^{-3}) to 3 ml (initially) of buffer in the reference compartment and to 3 ml of albumin in the sample compartment. The numbers 2, 4, and 10 indicate the number of increments added.*

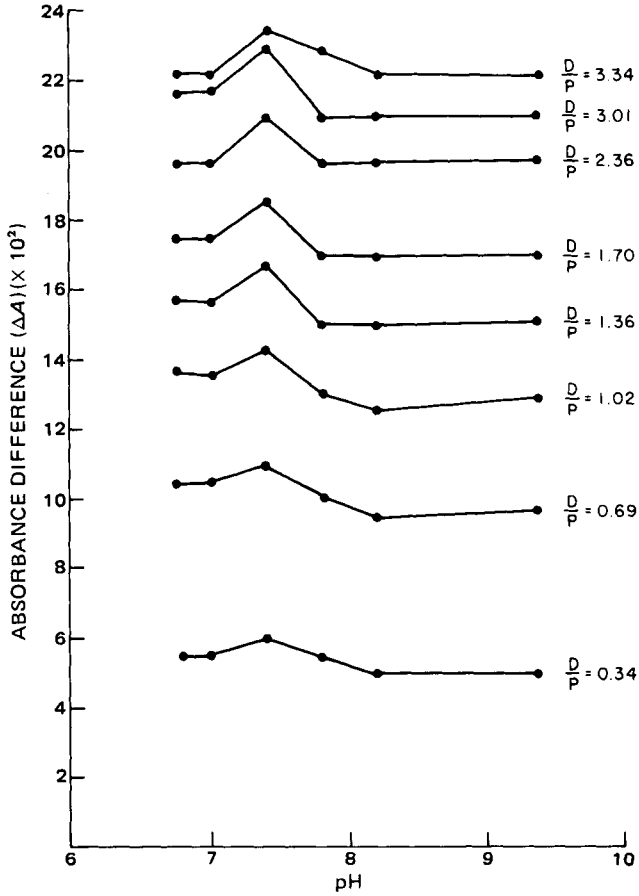

Figure 3—*Effect of pH on the absorbance differences (ΔA) of I–albumin complex.*

Equilibrium Dialysis—Equilibrium dialysis experiments were performed with an equilibrium dialyzer[7] using cell compartments of 10 ml total volume. Hydrated cellulose membranes[8] were prepared and used as suggested by the manufacturer. The concentrations of I or II used ranged from 7.6 × 10^{-6} to 1.5 × 10^{-3} *M*. Equilibrium was achieved within 4 hr for the lowest concentration and took as long as 15 hr for the highest concentration. Determination of the free drug was carried out spectrophotometrically; both I and II had a maximum at 264 nm in phosphate buffer. Standard calibration curves were constructed for each drug at each pH. Control experiments were conducted using buffer solution instead of protein.

Effect of Chloride and Magnesium Ions—The binding of I and II to albumin was also studied in phosphate buffer containing no sodium chloride and in phosphate buffer containing 1 × 10^{-3} *M* magnesium chloride. The equilibrium dialysis technique was used and phosphate buffers of pH 7.4 and 7.8 were selected for I and II, respectively.

RESULTS AND DISCUSSION

Both I and II were shown to bind to human serum albumin at different pH by the technique of difference spectroscopy and equilibrium dialysis. Examples of difference absorption spectra obtained for the association of I and II with albumin are shown in Figs. 1 and 2. In the case of I, the spectra were characterized by positive peaks at 282 ± 2 nm and negative troughs at 244 ± 2 nm. In the case of II, the spectra were characterized by a positive peak at 280 ± 2 nm and negative peak at 244 ± 2 nm. Families of curves were generated by incremental addition of I or II to albumin. At each pH examined, the absorbance difference spectra (Δ*A*) of I was larger than II. This indicates that I has a higher affinity for albumin than II (since their molar absorptivities are equivalent).

Absorbance difference curves at different pH were generated by plotting the change in absorbance measured as the difference in intensity of the peak (280 or 282 nm) and trough (244 nm) for I and II, respectively,

Table I—Primary Association Constant of Phenylbutazone (I) and Oxyphenbutazone (II) and Number of Sites Calculated at Different pH from Scatchard Plots

pH	K_1, liters/mole		N_1		N_2 ($N_t - N_1$)		K_2	
	I	II	I	II	I	II	I	II
7.0		$2.20 \pm 0.15 \times 10^5$		1.42		6.2		$4.76 \pm 0.84 \times 10^3$
7.4	$5.06 \pm 0.86 \times 10^5$	$3.53 \pm 0.74 \times 10^5$	1.25	1.30	8.1	8.0	$5.63 \pm 0.61 \times 10^3$	$4.20 \pm 0.19 \times 10^3$
7.8	$2.96 \pm 0.57 \times 10^5$	$1.97 \pm 0.64 \times 10^5$	1.30	1.25	3.5	2.7	$7.08 \pm 1.03 \times 10^3$	$9.70 \pm 0.84 \times 10^3$
8.2	$1.92 \pm 0.74 \times 10^5$	$1.62 \pm 0.31 \times 10^5$	1.55	1.45	3.5	4.0	$5.60 \pm 5.1 \times 10^3$	$7.67 \pm 0.59 \times 10^3$

versus pH (Figs. 3 and 4). These figures indicate that a change in pH influences the difference spectra produced as a result of the drug-protein interaction. In the case of I (Fig. 3) the curves indicate a maxima in the difference spectra at pH 7.4. The absorbance difference is slightly higher in the slightly acidic region over that observed in alkali.

This difference may indicate that I is bound more to albumin in the neutral region. In the case of II (Fig. 4), the effect of changing pH on the difference spectra was more pronounced. At all drug–albumin ratios used, the absorbance difference was larger in the neutral or slightly acidic region than in the alkaline region. An abrupt decrease occurred around pH 7–7.4. This decrease was more pronounced at higher drug–albumin ratios. The inflection points of these curves was at pH 7.8 indicative of the greatest change. This higher value of ΔA obtained in the neutral region indicates that II has a higher affinity to the N form of the albumin.

Data obtained from the equilibrium dialysis studies were plotted according to Scatchard (14) (Figs. 5 and 6). Each plot is curved and, therefore, the data were analyzed in terms of two classes of binding sites using the computer program of Perrin *et al.* (15). Results of the Scatchard plot analysis are given in Table I. There is a single high affinity binding site for both I and II and several sites of lower interaction potential (Table I). It should be pointed out that the range of I and II concentrations used in the binding studies varied considerably, from 7×10^{-6} to 1×10^{-3} M; previous literature reports use a narrower concentration range.

Considering the effect of pH on the association constants of I and II, Table I shows that K for both drugs decreases with increasing pH. In addition, at pH 7.4 the largest number of sites seems to be present. At each pH used, the association constant of I was larger than that of II.

Other workers calculated similar albumin association constants for both I and II. Solmon *et al.* (16) reported that albumin has only one binding site for I with an affinity constant of 1.17×10^5 M^{-1}. However, the concentration of I used by these workers was always less than that of albumin. Chignell (17) showed that albumin had three binding sites for I, one binding site of high affinity ($K = 1 \times 10^5$ M^{-1}), and two others with lower affinity ($K = 4 \times 10^4$ M^{-1}). For II he reported two association constants $k_1 = 2.28 \times 10^5$ M^{-1} and $k_2 = 3.7 \times 10^4$ M^{-1}. Two association constants were also reported (18) for I, $k_1 = 2.37 \times 10^{-5}$ M^{-1} $k_2 = 4.56 \times 10^4$ M^{-1}, and for II, $k_2 = 2.32 \times 10^5$ M^{-1} and $k_3 = 1.16 \times 10^4$ M^{-1}. The report indicated that K for II was very large and the affinity constants (K_2 and K_3) calculated assumed $n_1 = 1$; the first molar equivalent of II was so strongly bound as to be virtually removed from solution.

The pKa of I and II are 4.5 and 4.7, respectively (19). To determine whether the ionized and/or unionized species of these two drugs is bound to albumin, the method recently reported (2) for the determination of the site binding constant of each species of a partially ionized drug was applied to the equilibrium dialysis data. The method appeared applicable over the pH range examined for each compound and indicated that both species of I and II were responsible for the binding. The site binding constants for the ionized species were 1.40×10^5 and 1.16×10^5 for I and II, respectively. The site binding constants for the unionized species of I and II were much greater, approaching 2.93×10^8 and 1.18×10^8, respectively. However, the overall affinity or binding constant would be expected to be only somewhat greater than ionized drug since only a very small proportion of each drug is present in the unionized form, consequently adding little to the overall constant. Alternatively, it may be possible that a conformational change in the protein occurs and is re-

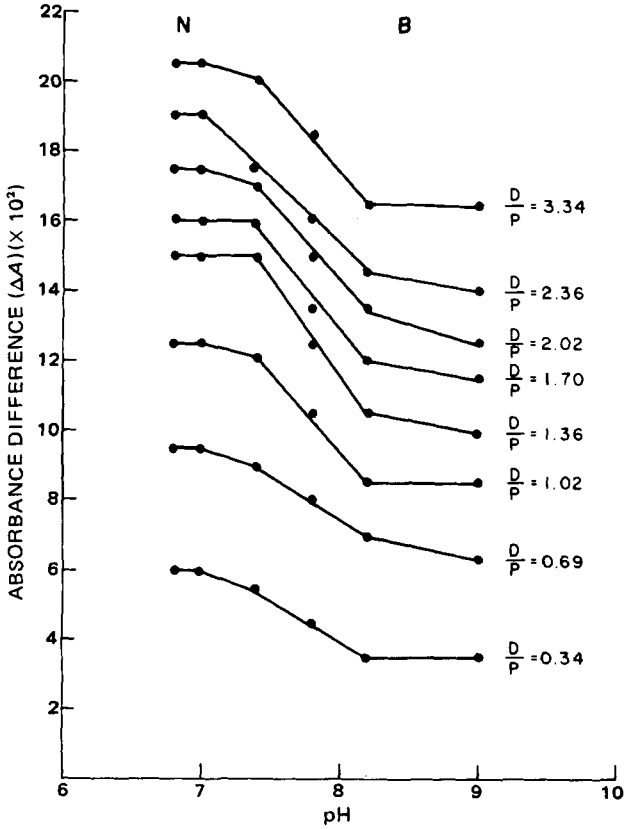

Figure 4—*Effect of pH on the absorbance differences (ΔA) of II–albumin complex.*

sponsible for marked differences in affinity between various drug forms.

The effect of chloride and magnesium ions on the binding of I and II to albumin was opposite in nature. Chloride ions reduced the amount of drug bound. This was most evident in the neutral pH region for both drugs. The mechanism is possibly one of displacement of drug from albumin as postulated earlier (6, 10). Magnesium ion increased the binding of both drugs in the same pH region. The increase was as much as 10% in the presence of magnesium at pH 7.4. Cations, especially divalent cations, have been found to affect the N to B transition of the protein (6, 7) and this is possibly the reason for the increased binding. The effects of both chloride and magnesium ions were greater on the high affinity sites than on the sites in the second class of binding.

The UV difference spectroscopy and equilibrium dialysis data indicated that albumin has a higher affinity for I than II at each pH examined. Oxyphenbutazone is less hydrophobic (more polar) than phenylbutazone, and the importance of hydrophobic interactions in the binding of drugs to protein was noted previously (17, 20, 21).

With either method of examining binding it is evident that pH affects the affinity of the interaction. It is also apparent that the binding affinity of each drug is higher in the neutral region (N form of protein) than in the alkaline region (B form). This fact, coupled with the results of absorbance difference *versus* pH which show a marked transition (inflection) in the neutral pH region, indicate that the N to B transition of albumin may be responsible for the changes in the affinity of the complex with pH.

Pharmacokinetics of Hydrochlorothiazide in Fasted and Nonfasted Subjects: A Comparison of Plasma Level and Urinary Excretion Methods

RASHMI H. BARBHAIYA*§, WILLIAM A. CRAIG‡, H. PERRI CORRICK-WEST*, and PETER G. WELLING*x

Received March 30, 1981, from the *School of Pharmacy, Veterans Administration Hospital, and the ‡School of Medicine, University of Wisconsin, Madison, WI 53706. Accepted for publication July 1, 1981. §Present address: Department of Drug Metabolism and Pharmacokinetics, Bristol Laboratories, Syracuse, NY 13201.

Abstract □ The bioavailability of hydrochlorothiazide from 50-mg oral tablet doses was examined in healthy male volunteers under fasting and nonfasting conditions. Bioavailability was examined from plasma levels and urinary excretion of unchanged drug. The pharmacokinetics of hydrochlorothiazide in plasma could be described in terms of a triexponential function, and the mean drug half-lives determined from the three exponents were 1.0, 2.2, and 9.0 hr. Changing the accompanying fluid volume had no significant effect on hydrochlorothiazide absorption in fasted subjects. Plasma drug levels were significantly reduced in nonfasted individuals, compared with those in fasted individuals. A similar trend was observed in the urinary excretion of hydrochlorothiazide, but differences between treatments were not significant ($p > 0.05$). Mean 48-hr urinary recovery of hydrochlorothiazide was 70.5% of the dose in nonfasted subjects, and 73.5 and 75.0% of the dose in fasted subjects receiving the drug with 20 and 250 ml of water, respectively. The cumulative urinary excretion of hydrochlorothiazide correlated poorly ($r = 0.27$) with areas under plasma drug level curves, although the correlation between the means of these values for each of the three treatments was high ($r = 0.996$). Close similarity was observed between urinary excretion rates of hydrochlorothiazide and the time course of drug concentrations in plasma.

Keyphrases □ Hydrochlorothiazide—pharmacokinetics, fasted and nonfasted subjects □ Pharmacokinetics—hydrochlorothiazide, fasted and nonfasted subjects □ Diuretics—hydrochlorothiazide, pharmacokinetics in fasted and nonfasted subjects

High-pressure liquid chromatographic (HPLC) procedures were described to measure hydrochlorothiazide in plasma and urine (1). Preliminary clinical data obtained in that study indicated that the elimination of hydrochlorothiazide from plasma is biphasic in nature, and that its urinary excretion rate closely resembles its concentration profile in plasma.

This report describes studies in which previously described methods (1) were used to examine the plasma levels and urinary excretion of hydrochlorothiazide following single oral doses to healthy male subjects, under fasting and nonfasting conditions, and with large and small accompanying fluid volumes.

EXPERIMENTAL

Subjects—Eight male volunteers[1], 23–35 years of age (mean 28) and weighing 64–84 kg (mean 78) participated in the study after passing a physical examination and giving informed consent. No subject had a history of drug allergy.

Protocols—Subjects were instructed to take no drugs for 1 week before, and no drugs other than hydrochlorothiazide during the study. No caffeine-containing beverages were permitted from 1 day before each hydrochlorothiazide dose until the end of the plasma and urine sampling periods.

Hydrochlorothiazide[2] was administered as three single-dose oral treatments: treatment A, one 50-mg tablet with 250 ml of water, following overnight fast; treatment B, one 50-mg tablet with 20 ml of water, following overnight fast; and treatment C, one 50-mg tablet with 250 ml of water, immediately following a standard breakfast.

The treatments were administered according to a randomized crossover design, and subjects received each treatment 1 week apart.

Subjects were instructed to eat no food after 8 pm, and no liquid after 10 pm, on the day preceding each study. No further food apart from the breakfast in treatment C was permitted until 4 hr after each drug dose. After that time normal eating and drinking were permitted.

On a treatment morning, 250 ml of water was ingested on arising, at least 1 hr before dosing. The drug was administered at 8 am, the tablets being swallowed whole. No further liquid intake was permitted until 4-hr postdose. The standard breakfast consisted of cornflakes with milk, ~150 ml of orange juice, two poached eggs, two slices of toast, and a cup of caffeine-free coffee.

Blood samples (10 ml) were taken from a forearm vein into vacuum tubes[3] (containing heparin as anticoagulant) immediately before and then serially through 24-hr postdose. Urine was collected immediately before and then quantitatively at intervals through 48-hr postdose. Plasma was separated from blood by centrifugation, and plasma and urine samples were stored at −20° until assayed, generally within 2 weeks.

Analytical—Concentrations of hydrochlorothiazide in plasma and urine were determined by the HPLC methods described previously (1). The methods are linearly sensitive to hydrochlorothiazide concentrations of 2–100 μg/ml in urine, and 10–750 ng/ml in plasma. The coefficients of variation from multiple determinations within these concentration ranges were within 10% of the mean.

Analysis of the Data—Plasma hydrochlorothiazide concentrations

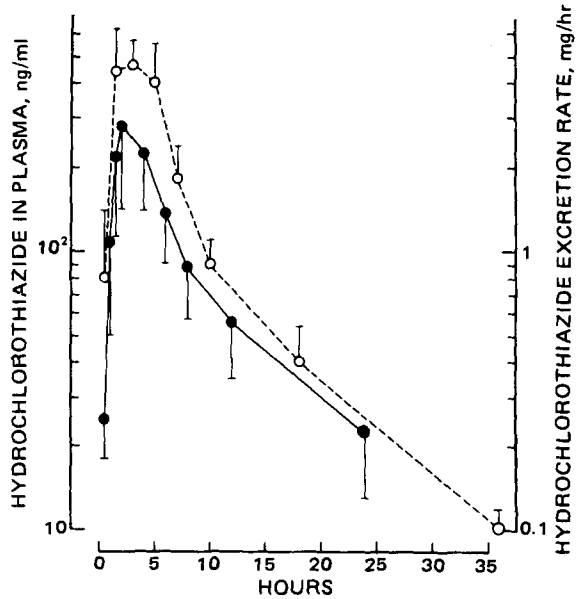

Figure 1—*Mean plasma concentrations (●) and urinary excretion rates, (○) of hydrochlorothiazides following treatment A, 50-mg tablet dose with 250 ml of water on a fasted stomach. Error bars indicate ±1* SD.

from each individual subject were fitted to a triexponential function of the form:

$$C = Xe^{-\alpha t} + Ye^{-\beta t} + Ze^{-\gamma t} \qquad \text{(Eq. 1)}$$

where C is the drug concentration in plasma at time t and other values are constants.

Initial estimates of parameter values were obtained by standard graphical methods. Improved estimates, together with statistical analysis, were obtained by nonlinear regression using the NREG computer program (2). Plasma hydrochlorothiazide levels at each sampling time, urinary excretion data, and pharmacokinetic parameter values were examined for subject and treatment effects by analysis of variance for crossover design. When significant treatment effects were obtained by analysis of variance, differences between treatments were examined by Tukey's test (3).

Reagents—The sources of reagents and solvents were described previously (1).

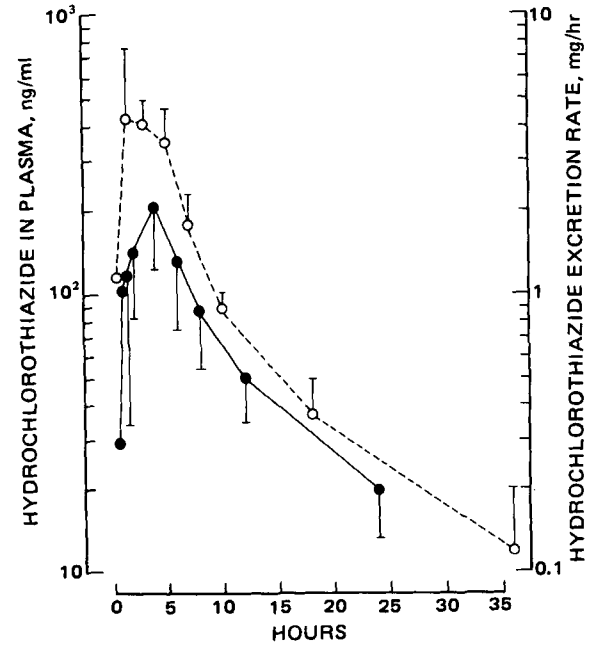

Figure 3—*Mean plasma concentrations (●) and urinary excretion rates (○) of hydrochlorothiazide following treatment C, 50-mg tablet dose with 250 ml of water immediately following a standard meal.*

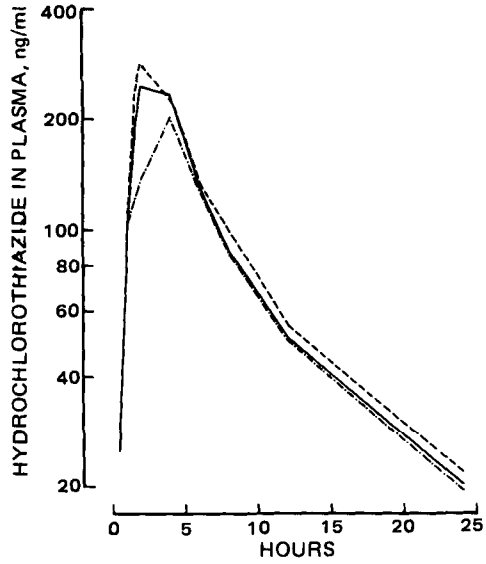

Figure 4—*Mean plasma concentrations of hydrochlorothiazide following treatments A (– –), B (—), and C (– · – ·).*

RESULTS

Plasma Hydrochlorthiazide Levels—The mean plasma hydrochlorothiazide concentration curves from the three treatments are shown in Figs. 1–3. For comparison between treatments, the curves are combined in Fig. 4.

The mean plasma drug profiles obtained from the two fasting treatments were almost identical. Mean peak drug concentrations of 310 and 291 ng/ml were obtained ~2.5-hr postdosing from treatments A and B, respectively (Table I). After this time, the drug levels declined rapidly to 12 hr, and at a slower rate to 24 hr.

The nonfasting dose of hydrochlorothiazide yielded drug profiles in plasma similar to the fasting treatments, but the drug concentrations tended to be lower. Plasma drug levels from treatment C were significantly lower ($p < 0.05$) than those from treatment A at 2 hr, and from treatment B at 4 hr. From Table I, the C_{max} and AUC^{24} values from treatment C were significantly lower than those from treatment A, while treatment B yielded intermediate values.

Analysis of individual drug curves in terms of Eq. 1 yielded the numerical values for the rate constants α, β, and γ shown in Table II. Almost identical mean values were obtained for each of the constants from the different treatments. The mean coefficients of determination, r^2, obtained from nonlinear regression analysis $[(\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2]$ were 0.91 ± 0.03, 0.93 ± 0.06, and 0.92 ± 0.08 for treatments A, B, and C, respectively.

Urinary Excretion of Hydrochlorothiazide—The mean cumulative urinary recovery of hydrochlorothiazide at each collection interval is shown in Fig. 5. The 24- and 48-hr mean recovery values are given in Table I. Overall recovery of hydrochlorothiazide was 75.0, 73.5, and 70.5% of the dose from treatments A, B, and C, respectively. While urinary recovery exhibited a similar trend to plasma levels, there were no significant

Table I—Pharmacokinetic Parameter Values (±1 *SD*, *n* = 8) for Hydrochlorothiazide

differences in the urinary recovery from the different treatments. The renal clearance of hydrochlorothiazide was ~300 ml/min, and there were no significant treatment effects in this value.

DISCUSSION

Information on the pharmacokinetics and bioavailability of the thiazide diuretics has been restricted by a lack of suitable analytical procedures. Early studies utilized colorimetry (4) but HPLC methods are now favored because of their greater sensitivity and specificity (5). Plasma hydrochlorothiazide concentrations are approximately 100-fold lower than those in urine, and previous studies concerning plasma drug levels have used gas chromatography with electron-capture detection (6–8).

The HPLC procedures used in this study are suitable for analysis of both urine and plasma hydrochlorothiazide levels following single therapeutic doses. Initial studies using these assay procedures (1) indicated that elimination of hydrochlorothiazide from plasma was biphasic. They also suggested that, while there is poor agreement between the areas under plasma level curves and cumulative urinary excretion of hydrochlorothiazide (9, 10), there is close similarity between the time course of plasma drug levels and urinary excretion rates.

The present study confirms these observations. While the biphasic decline of drug levels in plasma is based largely on data points obtained at 12 and 24 hr, this elimination pattern was reported previously (1, 9). The half-lives calculated from the mean values of γ, α, and β in Table II are ~1.0, 2.2, and 9.0 hr, respectively, and these values were unaffected by the different treatments. The largest of these, the terminal half-life for hydrochlorothiazide in plasma, is similar to values reported previously (1, 10).

The mechanism underlying biphasic elimination of hydrochlorothiazide from plasma is unclear. Hydrochlorothiazide accumulates in erythrocytes, but equilibrium of drug between plasma water and blood cells is reached in 4 hr after an oral dose (10). The pattern of hydrochlorothiazide elimination from plasma is different from that of chlorothiazide. In the case of hydrochlorothiazide, biphasic elimination is clearly evident in individual subjects, as shown in Fig. 6. However, in the case of chlorothiazide, while mean plasma levels could be described by a triexponential function, profiles in individual subjects were erratic and exhibited a sawtooth effect (11, 12).

The plasma drug levels obtained from the different treatments showed that the efficiency of hydrochlorothiazide absorption from oral tablets was not markedly influenced by fluid volume, but decreased when the drug was taken after a meal. The urinary excretion data showed a similar trend, but the treatment effects on drug excretion were not significant.

Table II—Values of Rate Constants (±1 *SD*, $n = 8$) Obtained by Fitting Individual Plasma Hydrochlorothiazide Profiles to Eq. 1

Treatment	Rate Constant, hr^{-1}		
	α	β	γ
A	0.32 ± 0.08	0.078 ± 0.18	0.67 ± 0.22
B	0.32 ± 0.08	0.078 ± 0.18	0.65 ± 0.52
C	0.28 ± 0.09	0.078 ± 0.011	0.74 ± 0.52

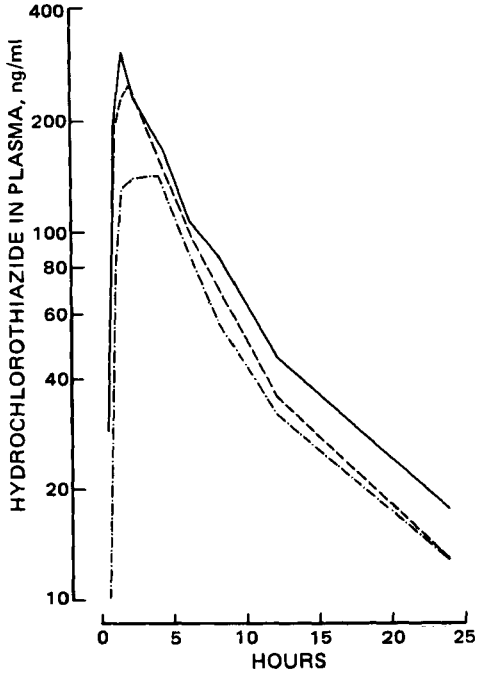

Figure 6—*Plasma concentrations of hydrochlorothiazide in one subject following treatments A (– –), B (—), and C (– · – ·).*

These results are inconsistent with a previous report in which hydrochlorothiazide absorption was increased by food (7). Procedural differences between the studies may account for this. In the present study, both fasted and nonfasted subjects were permitted normal food intake after 4-hr postdosing. In the previous study, fasted subjects received no solid food until 10-hr postdosing, while nonfasted subjects received three regular meals during that period. Prolonged abstinence from food by the fasted subjects may have affected drug absorption due to altered GI secretion and motility. The previous study also employed a higher dose of hydrochlorothiazide (75 mg).

The different effects of food on the GI absorption of hydrochlorothiazide and chlorothiazide (11) are possibly related to dose size. Chlorothiazide was shown to be poorly absorbed from 250 and 500 mg doses; less than 25% of the administered dose was recovered in urine (12, 13). Absorption was improved to only a small extent when chlorothiazide was administered as a solution, compared to tablets (12, 13), but doubled when chlorothiazide tablets were administered immediately following a meal (11). However, hydrochlorothiazide was efficiently absorbed from 50–75-mg oral doses (6–9).

The poor bioavailability of oral chlorothiazide may be due to saturable and site-specific absorption (5, 11). The structural similarity of the two compounds suggests that hydrochlorothiazide may be absorbed by a mechanism similar to chlorothiazide, but the lower dose of hydrochlorothiazide precludes saturation of the absorption mechanism. While food may increase the bioavailability of oral chlorothiazide by reducing the rate at which drug is presented to the absorption site (11), this mechanism would be less important for lower doses of hydrochlorothiazide. The inhibitory effects of food appear to dominate with this compound (14, 15), but these effects are small and are unlikely to be clinically significant.

The negligible effect of altered fluid volume on hydrochlorothiazide absorption was unexpected. Hydrochlorothiazide has a low aqueous solubility (9), and large accompanying fluid volumes have been shown to increase the absorption of a number of lipophilic drugs (16). Previously, increased absorption has been attributed to more efficient drug dissolution or faster stomach emptying (14). In the case of hydrochlorothiazide, these effects appear to be negligible. This is possibly related to the efficient absorption of hydrochlorothiazide in general; an increase in absorption due to increased fluid volume would be difficult to detect. It could be speculated that any potential increase in drug release in the GI tract may be offset by saturable absorption, but other studies would be needed to confirm this.

Although an official dissolution test exists for hydrochlorothiazide tablets (17), there have been differing reports on the ability of *in vitro* dissolution rates to accurately predict *in vivo* drug bioavailability (18, 19).

Correlations between individual areas under hydrochlorothiazide

plasma curves and cumulative excretion in the present study were poor. Correlation coefficients between AUC^{24} and Au^{48} (48-hr urinary excretion), and between C_{max} and Au^{48} for all subjects were 0.25 and 0.27, respectively. Poor correlations between these parameters, which have been reported previously (9, 10), appear to be due to the variability of individual data and to the relatively small treatment effects, rather than to the lack of a true relationship. The correlation coefficient between mean AUC^{24} and Au^{48} values, and between mean C_{max} and Au^{48} values for each treatment were 0.996 and 0.997, respectively.

The previous suggestion that the rate of hydrochlorothiazide excretion in urine closely resembles the time course of plasma levels (1) is confirmed in this study. Mean urinary excretion rates of hydrochlorothiazide are plotted together with plasma levels in Figs. 1–3. In each case, the overall urinary excretion rates exhibited a similar triphasic pattern to those in plasma.

The high renal clearance of hydrochlorothiazide suggests that, like chlorothiazide, it is eliminated by both renal filtration and active secretion.

Pharmacokinetic Comparison of Sublingual Lorazepam with Intravenous, Intramuscular, and Oral Lorazepam

DAVID J. GREENBLATT ˣ, MARCIA DIVOLL, JEROLD S. HARMATZ, and RICHARD I. SHADER

Received May 21, 1981, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine* and the *New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication July 7, 1981.

Abstract □ Ten healthy volunteers received single 2-mg doses of lorazepam on five occasions in random sequence. Modes of administration were: A, intravenous injection; B, deltoid intramuscular injection; C, oral tablets in the fasting state; D, sublingual dosage of oral tablets in the fasting state; and E, sublingual dosage of specially formulated tablets in the fasting state. Kinetic variables were determined from multiple plasma lorazepam concentrations meaured during 48 hr postdose. After intravenous lorazepam, mean (±*SE*) values were: elimination half-life ($t_{1/2\beta}$), 12.9 (±0.8) hr; volume of distribution, 1.3 (±0.07) liters/kg; total clearance, 1.21 (±0.1) ml/min/kg. Absorption of intramuscular lorazepam was rapid. Peak plasma levels were reached at 1.15 hr after dosage, with absorption half-life averaging 14.2 (±4.7) min. Absorption of oral and sublingual lorazepam tended to be less rapid than intramuscular injection, although differences were not significant. Times of peak concentration were 2.37, 2.35, and 2.25 hr postdose for trials C, D, and E, respectively; values of absorption half-life were 32.5, 28.5, and 28.7 min. Absolute systemic availability for trials B, C, D, and E averaged 95.9, 99.8, 94.1, and 98.2%, respectively; none of these differed significantly from 100%. Values of $t_{1/2\beta}$ were highly replicable within individuals regardless of the administration route. Thus, sublingual lorazepam is completely absorbed and is a suitable administration route in clinical practice.

Keyphrases □ Lorazepam—sublingual, pharmacokinetics compared with intravenous, intramuscular, and oral dosage forms □ Pharmacokinetics—sublingual lorazepam, comparison with intravenous, intramuscular, and oral dosage forms □ Dosage forms—sublingual lorazepam, pharmacokinetics compared with intravenous, intramuscular, and oral dosage forms

Lorazepam is a 3-hydroxy-1,4-benzodiazepine derivative in clinical use as an antianxiety and sedative agent (1, 2). Clinical situations may arise in which oral administration of a sedative is unwise or not possible, and intravenous dosage is precluded because a physician is not available. In such circumstances, intramuscular injection usually is the only alternative. The present study assessed the pharmacokinetics of lorazepam given sublingually to determine the possible clinical role of this administration route as an alternative to oral or intramuscular administration.

EXPERIMENTAL

Subjects—Ten healthy male and female volunteers, 24–39 years of age, participated after giving written informed consent (Table I). They were free of any identifiable medical disease. Subject 10 was taking oral contraceptive steroids, but no other medications were being used on a regular basis.

0022-3549/82/0200-0248$01.00/0

plasma curves and cumulative excretion in the present study were poor. Correlation coefficients between AUC^{24} and Au^{48} (48-hr urinary excretion), and between C_{max} and Au^{48} for all subjects were 0.25 and 0.27, respectively. Poor correlations between these parameters, which have been reported previously (9, 10), appear to be due to the variability of individual data and to the relatively small treatment effects, rather than to the lack of a true relationship. The correlation coefficient between mean AUC^{24} and Au^{48} values, and between mean C_{max} and Au^{48} values for each treatment were 0.996 and 0.997, respectively.

The previous suggestion that the rate of hydrochlorothiazide excretion in urine closely resembles the time course of plasma levels (1) is confirmed in this study. Mean urinary excretion rates of hydrochlorothiazide are plotted together with plasma levels in Figs. 1–3. In each case, the overall urinary excretion rates exhibited a similar triphasic pattern to those in plasma.

The high renal clearance of hydrochlorothiazide suggests that, like chlorothiazide, it is eliminated by both renal filtration and active secretion.

Pharmacokinetic Comparison of Sublingual Lorazepam with Intravenous, Intramuscular, and Oral Lorazepam

DAVID J. GREENBLATT ˣ, MARCIA DIVOLL, JEROLD S. HARMATZ, and RICHARD I. SHADER

Received May 21, 1981, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine* and the *New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication July 7, 1981.

Abstract □ Ten healthy volunteers received single 2-mg doses of lorazepam on five occasions in random sequence. Modes of administration were: A, intravenous injection; B, deltoid intramuscular injection; C, oral tablets in the fasting state; D, sublingual dosage of oral tablets in the fasting state; and E, sublingual dosage of specially formulated tablets in the fasting state. Kinetic variables were determined from multiple plasma lorazepam concentrations meaured during 48 hr postdose. After intravenous lorazepam, mean (±*SE*) values were: elimination half-life ($t_{1/2\beta}$), 12.9 (±0.8) hr; volume of distribution, 1.3 (±0.07) liters/kg; total clearance, 1.21 (±0.1) ml/min/kg. Absorption of intramuscular lorazepam was rapid. Peak plasma levels were reached at 1.15 hr after dosage, with absorption half-life averaging 14.2 (±4.7) min. Absorption of oral and sublingual lorazepam tended to be less rapid than intramuscular injection, although differences were not significant. Times of peak concentration were 2.37, 2.35, and 2.25 hr postdose for trials C, D, and E, respectively; values of absorption half-life were 32.5, 28.5, and 28.7 min. Absolute systemic availability for trials B, C, D, and E averaged 95.9, 99.8, 94.1, and 98.2%, respectively; none of these differed significantly from 100%. Values of $t_{1/2\beta}$ were highly replicable within individuals regardless of the administration route. Thus, sublingual lorazepam is completely absorbed and is a suitable administration route in clinical practice.

Keyphrases □ Lorazepam—sublingual, pharmacokinetics compared with intravenous, intramuscular, and oral dosage forms □ Pharmacokinetics—sublingual lorazepam, comparison with intravenous, intramuscular, and oral dosage forms □ Dosage forms—sublingual lorazepam, pharmacokinetics compared with intravenous, intramuscular, and oral dosage forms

Lorazepam is a 3-hydroxy-1,4-benzodiazepine derivative in clinical use as an antianxiety and sedative agent (1, 2). Clinical situations may arise in which oral administration of a sedative is unwise or not possible, and intravenous dosage is precluded because a physician is not available. In such circumstances, intramuscular injection usually is the only alternative. The present study assessed the pharmacokinetics of lorazepam given sublingually to determine the possible clinical role of this administration route as an alternative to oral or intramuscular administration.

EXPERIMENTAL

Subjects—Ten healthy male and female volunteers, 24–39 years of age, participated after giving written informed consent (Table I). They were free of any identifiable medical disease. Subject 10 was taking oral contraceptive steroids, but no other medications were being used on a regular basis.

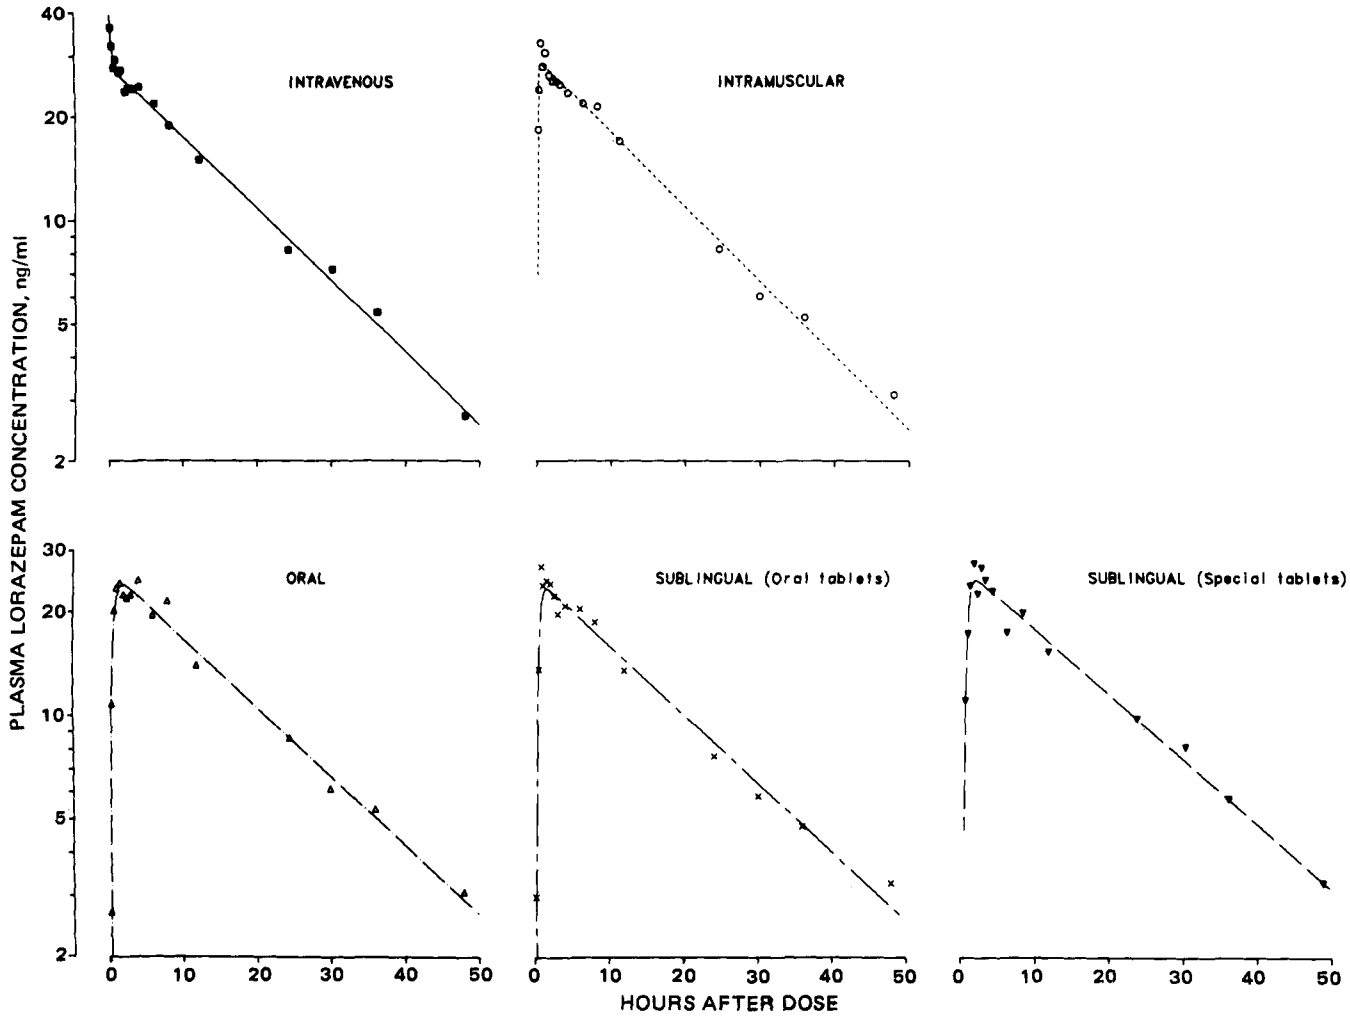

Figure 1—*Plasma lorazepam concentrations and pharmacokinetic functions of best fit following administration of lorazepam to subject 8 by each of the five administration routes.*

Design—A randomized, single-dose, five-way crossover design was utilized. Each subject received single 2-mg doses of lorazepam[1] on five occasions separated by at least 1 week. The administration modes were:

A. Intravenous lorazepam, 1 ml of a 2 mg/ml injectable preparation, infused into an antecubital vein over a 30-sec period.
B. Intramuscular lorazepam, 1 ml of the 2 mg/ml injectable preparation, given by a physician as a single deltoid intramuscular injection.
C. Oral lorazepam, administered as two standard 1-mg tablets (*in vitro* dissolution rate, 80% in 1 hr) with 100–200 ml of tap water.
D. Sublingual lorazepam, administered as two standard 1-mg oral tablets placed under the tongue and held for 15 min.
E. Sublingual lorazepam, administered as two special 1-mg sublingual tablets (*in vitro* dissolution rate, 84% in 1 hr) placed under the tongue and held for 15 min.

For trials A and B, no restrictions were placed upon the ingestion of food or liquid. For trials C, D, and E, subjects fasted overnight prior to drug administration and remained fasting for 3 hr postdose.

Procedure—Venous blood samples were drawn into heparinized tubes from an indwelling butterfly cannula or by separate venipuncture, prior to lorazepam administration, and at the following times after each dose: 5 min, and 0.25, 0.5, 0.75, 1.0, 1.5, 2.0, 2.5, 3, 4, 6, 8, 12, 24, 30, 36, and 48 hr. After intravenous dosage, a sample was also drawn just after the

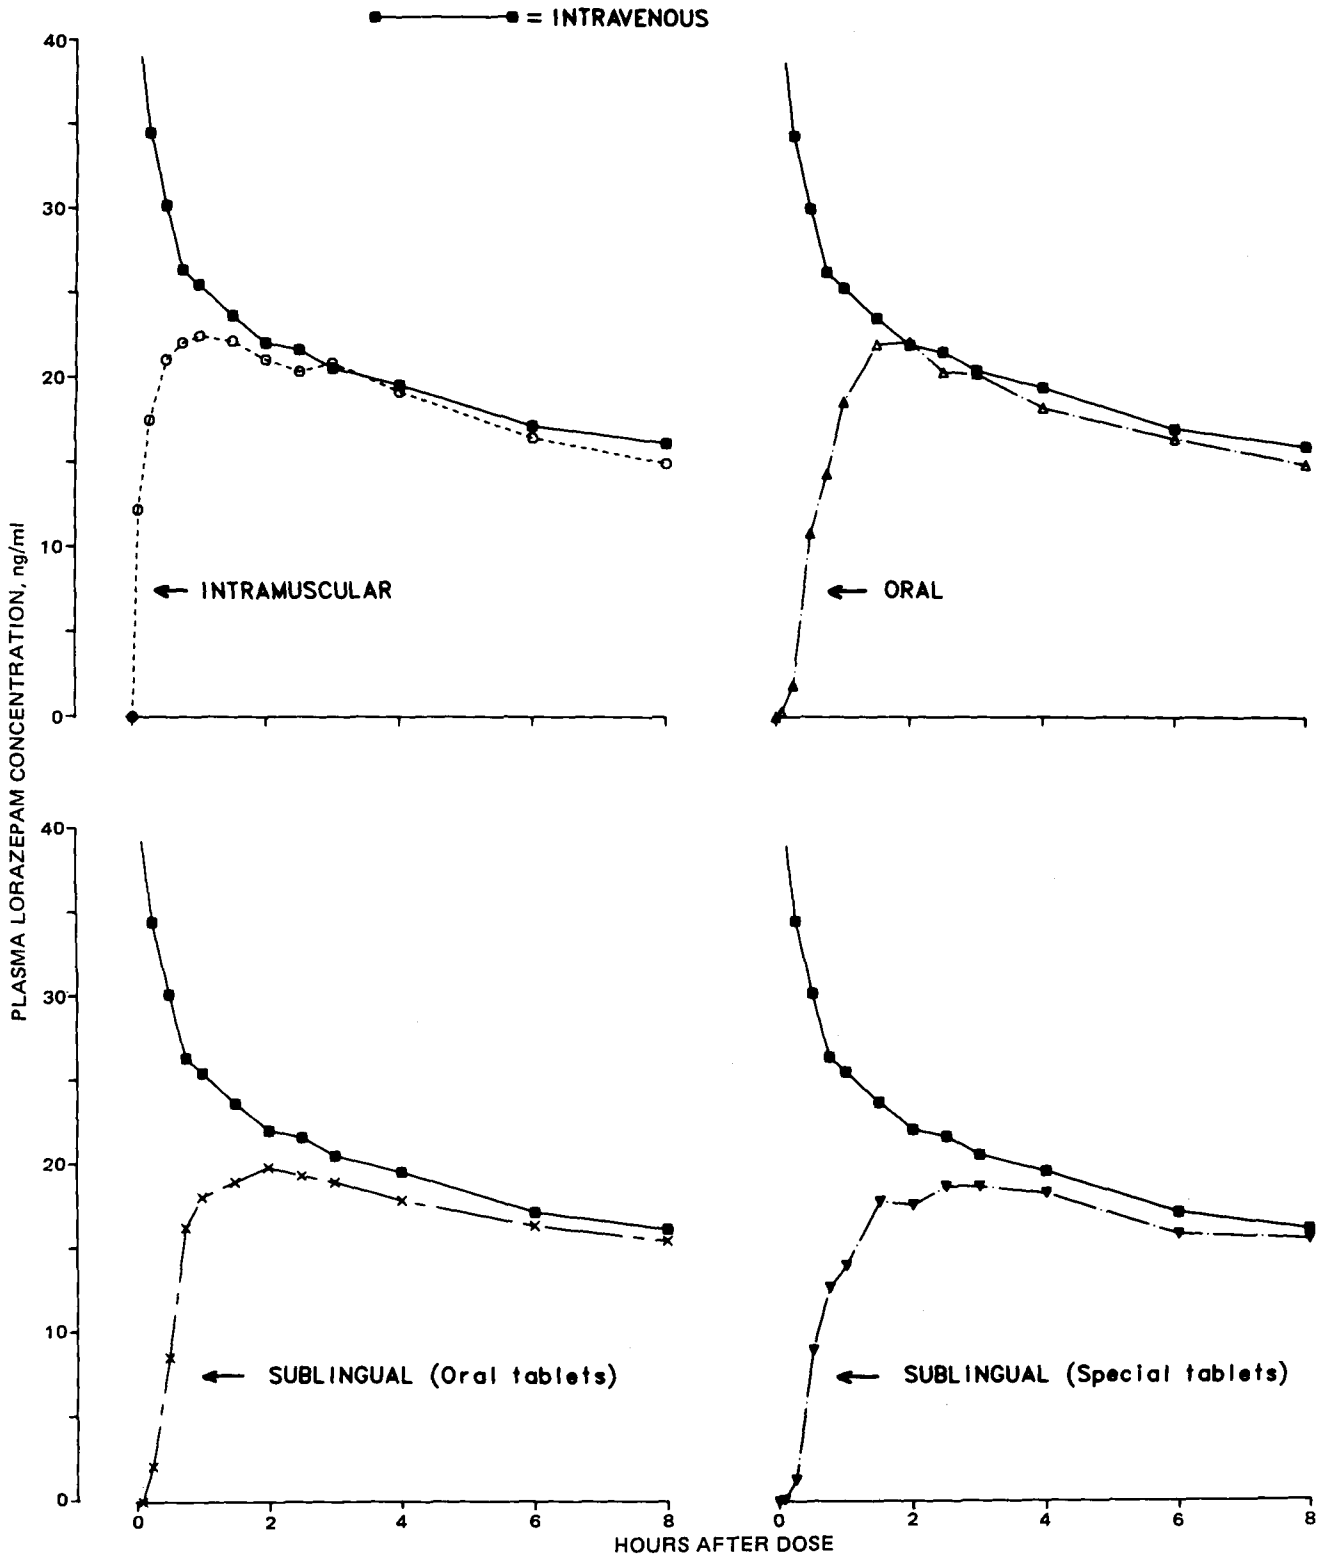

Figure 2—*Plasma lorazepam concentrations for the first 8 hr after dosage by the four extravascular administration routes compared with that observed after intravenous dosage. Each point is the mean for all 10 subjects at the corresponding time.*

infusion. Blood samples were centrifuged, and the plasma was separated and stored at −20° until assay.

Analysis of Plasma Samples—Lorazepam concentrations in all plasma samples were determined by electron-capture GLC after addition of oxazepam as the internal standard (2–4).

Analysis of Data—Plasma lorazepam concentrations following each subject trial were analyzed using iterative nonlinear least-squares regression techniques described previously (5, 6). Data points were fitted to a linear sum of exponential terms. After intravenous lorazepam, coefficients and exponents from the fitted function were used to calculate the following kinetic variables: initial (α) distribution half-life ($t_{1/2\alpha}$), elimination half-life ($t_{1/2\beta}$), volume of central compartment (V_1), total volume of distribution using the area method (V_d), total clearance, and total area under the plasma concentration curve from time zero to infinity (AUC).

After the four extravascular modes of administration, fitted functions were used to calculate the apparent half-life of absorption, lag time elapsing prior to the start of absorption (t_0), and elimination half-life ($t_{1/2\beta}$). The area under the plasma concentration curve from time zero until the last detectable plasma concentration was calculated using the

Table II—Effect of Route of Administration on Lorazepam Pharmacokinetics

Variable	Mean (±SE) Values[a] for Trial A Intravenous	B Intramuscular	C Oral	D Sublingual	E Sublingual	Value of F Two-Way ANOVA	Value of P

trapezoidal method. To this was added the residual area extrapolated to infinity, calculated at the last detectable plasma concentration divided by β, yielding the total *AUC*.

Statistical Analysis—Two-way analysis of variance was used to analyze differences in kinetic variables among the various treatments. The absolute systemic availability (completeness of absorption) of the four extravascular routes of lorazepam administration were calculated by dividing each subject's total *AUC* for a particular route of administration by the corresponding value of *AUC* following intravenous lorazepam administration to the same individual.

RESULTS

Intravenous Lorazepam (trial A)—Disappearance of lorazepam from plasma following intravenous injection was described by a linear sum of two exponential terms for subjects 1–9, and by a sum of three exponentials for subject 10. Mean kinetic variables for lorazepam were: $t_{1/2\alpha}$, 8.7 min; $t_{1/2\beta}$, 12.9 hr; V_1, 0.52 liters/kg; V_d, 1.30 liters/kg; and total clearance, 1.21 ml/min/kg (Table I).

Intramuscular Lorazepam (trial B)—All subjects noted mild to moderate local discomfort associated with the injection. This was transient and resolved shortly after the injection without specific treatment.

Peak lorazepam concentrations averaged 26 ng/ml, and were reached an average of 1.5 hr postdose (Table II, Figs. 1 and 2). In all subjects, peak plasma concentrations were reached within 3 hr of dosage. In no case did a lag time elapse prior to the start of absorption. The mean value of absorption half-life was 14.2 min (Fig. 3), and that of $t_{1/2\beta}$ was 13.1 hr. Absolute systemic availability of intramuscular lorazepam averaged 96% of the intravenous value; this was not significantly different from 100% (Table II, Fig. 4).

Oral Lorazepam (trial C)—Peak plasma lorazepam concentrations averaged 25 ng/ml and were attained an average of 2.4 hr postdose (Table II, Figs. 1 and 2). A lag time elapsed prior to the start of absorption in nine of the 10 subjects; the mean lag time was 11.8 min. The mean value of absorption half-life was 32.5 min (Fig. 3), and that of $t_{1/2\beta}$ was 14.1 hr. Mean systemic availability was 99.8% (Table II, Fig. 4).

Sublingual Lorazepam (trial D)—Peak plasma lorazepam concentrations after sublingual administration of the standard oral tablets averaged 23.3 ng/ml and were attained an average of 2.3 hr after dosage (Table II, Figs. 1 and 2). A lag time elapsed prior to the start of absorption in nine of the 10 subjects; the mean lag time was 22.7 min. The mean absorption half-life was 28.5 min, and $t_{1/2\beta}$ averaged 13.2 hr. Mean systemic availability was 94.1%.

Sublingual Lorazepam (trial E)—The kinetic profile of sublingual lorazepam administered as special tablets was very similar to that following sublingual administration of standard oral tablets described for trial D. Peak plasma concentrations averaged 20.7 ng/ml and were attained at 2.25 hr after dosage. A lag time elapsed prior to administration in eight of 10 subjects, and averaged 14.9 min. Absorption half-life averaged 28.7 min, while $t_{1/2\beta}$ averaged 14.4 hr. Mean systemic availability was 98%.

Comparison among Administration Routes—Values of $t_{1/2\beta}$ were highly consistent within subjects among the five trials (Table II, Fig. 5). Two-way analysis of variance indicated that differences attributable to administration route did not approach significance.

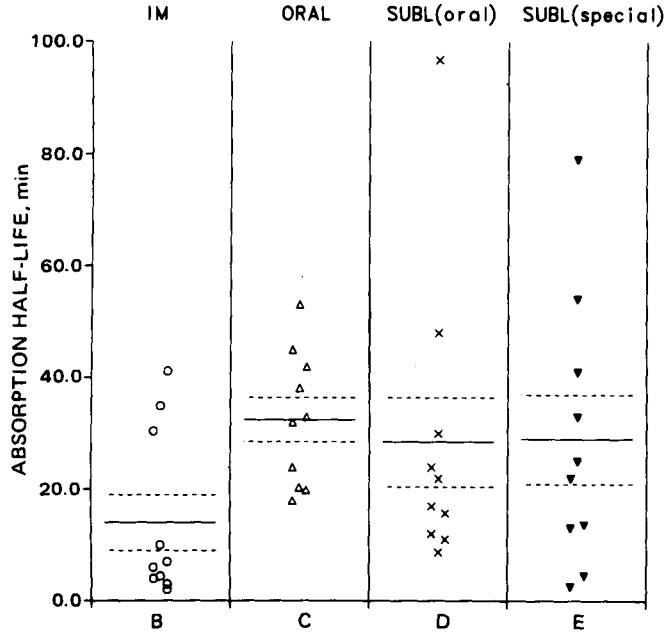

Figure 3—*Lorazepam absorption half-life following each of the four extravascular administration routes. Individual and mean (±SE) values for all subjects are shown. See Table II for statistical analysis.*

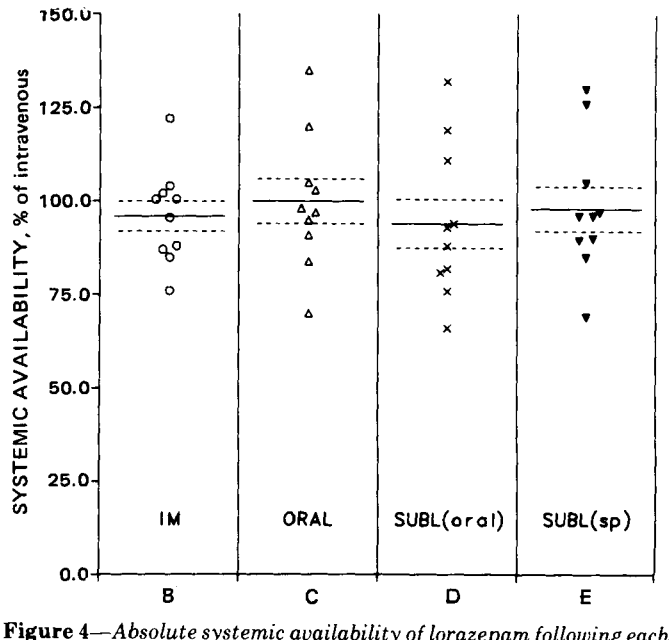

Figure 4—*Absolute systemic availability of lorazepam following each of the four extravascular administration routes. Individual and mean (±SE) values for all subjects are shown. See Table II for statistical analysis.*

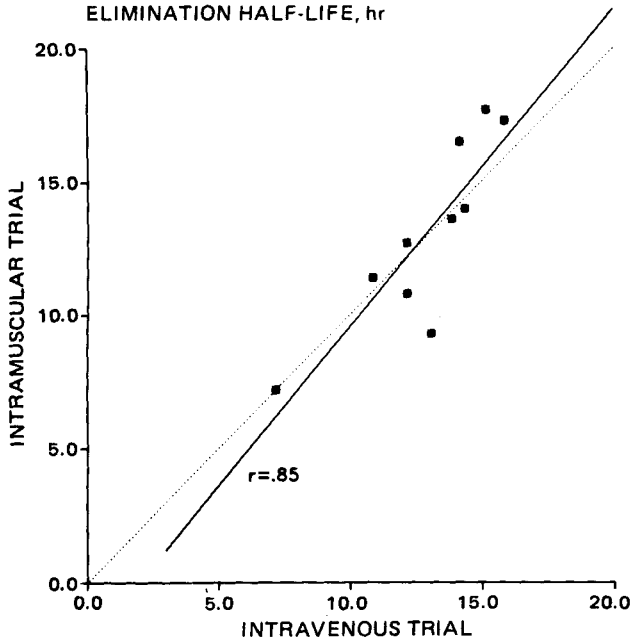

Figure 5—*Values of lorazepam elimination half-life following intravenous (trial A) and intramuscular (trial B) administration routes to the 10 subjects. Solid line was determined by least-squares regression analysis; dotted line is the line of identity.*

Differences among the four extravascular trials in peak plasma lorazepam concentrations and time of peak concentration approached but did not attain significance ($0.05 < p < 0.1$). Both variables indicated a trend for higher peak plasma levels reached sooner after the dose following intramuscular injection then after oral or sublingual administration. However, differences among trials C, D, and E were minimal (Table II). A similar trend was observed in absorption half-life. Although differences among the four extravascular trials did not reach significance, absorption half-life following intramuscular injection (trial B) was only half as long as that following the oral and sublingual routes (Table II, Fig. 3). However, differences among trials C, D, and E were minimal. Finally, no lag times were observed following intramuscular injection, whereas a lag time elapsed prior to the start of absorption in the majority of subjects following oral or sublingual administration.

Absolute systemic availability among the four extravascular modes of administration were highly comparable (Table II, Fig. 4). Mean values for trials B, C, D, and E were 96, 100, 94, and 98%, respectively. Differences among the four routes did not approach significance. Furthermore, in no case did the mean value of absolute systemic availability differ significantly from 100%.

DISCUSSION

The kinetic profile of lorazepam in the present study is similar to that reported previously from this laboratory (5–7) and elsewhere (2, 8, 9). In the present group of subjects, the range of values for $t_{1/2\beta}$ was 7–21 hr. This is similar to the range of 8–24 hr noted previously using different healthy young volunteers (5–7). It is also important to note that values of $t_{1/2\beta}$ were highly replicable within a given subject upon repeated administration of lorazepam.

The kinetics of intramuscular and oral lorazepam also are similar to patterns described previously (5–7). Deltoid intramuscular injection of lorazepam leads to rapid absorption of the drug; the completeness of absorption from the injection site is very close to 100%. Absorption of oral lorazepam is somewhat slower than that of intramuscular injection, probably due to the time required for drug dissolution and gastric emptying. Absorption of orally administered lorazepam was close to 100%.

The pattern of lorazepam absorption following sublingual administration resembles that of oral lorazepam. In the majority of cases, a lag time elapsed prior to the start of absorption, after which first-order absorption proceeded with a half-life averaging ~29 min. As in the case of oral lorazepam, the completeness of absorption of sublingual lorazepam, whether administered as standard oral tablets or specially-formulated tablets, was nearly 100%.

Thus, the rate and completeness of lorazepam absorption following sublingual administration are comparable to that observed following oral dosage on an empty stomach. In clinical terms, sublingual and oral dosage of lorazepam are likely to be therapeutically equivalent. Sublingual administration could also substitute for intramuscular injection, although the onset of clinical activity following the sublingual route may be slightly slower than that observed after intramuscular injection. Findings from the present study of sublingual lorazepam apply only to the tablet preparations studied. More rapid absorption of sublingual lorazepam might occur with formulations having more rapid dissolution rates.

DNA-Binding Specificity and RNA Polymerase Inhibitory Activity of Bis(aminoalkyl)anthraquinones and Bis(methylthio)vinylquinolinium Iodides

WILLIAM O. FOYE ˣ, OPA VAJRAGUPTA*, and SISIR K. SENGUPTA‡

Received November 21, 1980, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication June 9, 1981. *Present address: School of Pharmacy, Mahidol University, Bangkok, Thailand. ‡Present address: Boston University Medical Center, Boston, MA 02118.

Abstract □ The determination of DNA-binding specificities for a series of bis(methylthio)vinylquinolinium iodides and two bis(aminoalkyl)-anthraquinones was accomplished by spectral analysis, equilibrium dialysis, elevation of melting temperature, and inhibition of DNA function as a template for *Escherichia coli* RNA-polymerase transcription activity *in vitro*. Studies of complex formation were carried out by comparison of difference spectra of the compounds in the presence of native double-stranded DNA and separated-strand DNA. Base specificity of the interaction between DNA and the compounds was demonstrated for both series, particularly for the anthraquinones, for the guanine–cytosine base pair. Comparison of the difference spectra of the compounds in the presence of DNA with varied base-pair ratios showed a strong preference of the anthraquinones for the guanine–cytosine base pair, but the quinolinium compounds showed no preference. The linear-binding isotherm for the quinolinium compounds indicated one type of binding site, while two types of binding sites were apparent for the anthraquinones. Since only one anthraquinone was active in leukemia tests, factors other than DNA binding must account for the activity of the antileukemic derivative.

Keyphrases □ DNA—binding specificity of bis(aminoalkyl)anthraquinones and bis(methylthio)vinylquinolinium iodides □ Bis(aminoalkyl)anthraquinones—DNA binding specificity and RNA polymerase inhibition □ Bis(methylthio)vinylquinolinium iodides—DNA binding specificity and RNA polymerase inhibition

A series of 1-methylquinolinium-2-dithioacetic acid zwitterions (1, 2) and derivatives (3) showed appreciable anticancer activity against P-388 lymphocytic leukemia growth in mice. Since the structures of these compounds differ in several respects from those of other antileukemic agents, no obvious clue to a possible mechanism of anticancer action was apparent. However, the planar nature of the quinoline ring suggested binding to DNA as a possible factor in their action, and accordingly, DNA binding studies were carried out. At the same time, two structurally similar anthraquinone derivatives (4), one having good antileukemic activity and the other inactive, were measured and examined for any differences in their binding ability. Chloroquine, a known intercalating agent for DNA, was used as a control substance.

The methods used to determine DNA binding ability involved spectral analysis, equilibrium dialysis, elevation of melting temperature, and *in vitro* inhibition of cell-free RNA transcription. In addition, studies of complex formation of the compounds with DNA were carried out using native double-strand and single-strand DNA, and also using DNA from various sources with different base-pair ratios. Absorption spectra of the compounds in the presence of DNA with different base-pair ratios were compared to determine any base-pair specificities in the DNA binding. It was thought that use of several different techniques could provide more information on DNA binding than one method alone.

EXPERIMENTAL[1]

Materials — 5,8-Dihydroxy-1,4-bis[2-(hydroxyethyl)aminoethyl] amino-9,10-anthracenedione (I) and 5,8-dihydroxy-1,4-bis[4-(dimethylaminobutyl)amino]-9,10-anthracenedione(II) were used. 1-Methyl-2-bis(2-methylthio)vinylquinolinium iodide(III), 1,6-dimethyl-2-bis(2-methylthio)vinylquinolinium iodide(IV), 1-methyl-6-methoxy-2-bis(2-methylthio)vinylquinolinium iodide(V), and 1,6-dimethyl-2-[2-methylthio-2-(1-morpholino)vinyl]quinolinium iodide (VI) were previously reported (3). Chloroquine (VII), calf thymus DNA type I sodium salt [43% guanosine–cytidine (G–C)], *Escherichia coli* DNA type VIII (50% G–C), *Clostridium perfringens* DNA type XII (27% G–C), *Micrococcus lysodeikticus* DNA type XI (72% G–C), bovine serum albumin, RNA polymerase type I from *E. coli*, adenosine 5′-triphosphate disodium salt (ATP), cytidine 5′-triphosphate sodium salt type III (CTP), uridine 5′-triphosphate sodium salt type III (UTP), and guanosine 5′-triphosphate sodium salt type III (GTP) were all obtained commercially[2]. Tromethamine[3] and [8-^{14}C]adenosine 5′-triphosphate tetrasodium salt[4], [8-^{14}C]ATP, (40 Ci/mmole) were also obtained commercially.

Spectral Analysis—Stock solutions of the compounds were made 1 × 10^{-4} *M* in 5 m*M* tromethamine hydrochloric acid buffer, pH 7.4. Beer's law curves were prepared from the regressed absorbance values, and solutions of 1.5–3.5 × 10^{-5} *M* were scanned in the UV and visible regions. Molar absorptivities are listed in Table I. Spectra were observed in the presence of calf thymus DNA solutions at concentrations of 1.5 × 10^{-5}–5 × 10^{-4} *M*, and are shown in Figs. 1 and 2 for the anthraquinones.

Equilibrium Dialysis—These experiments were carried out using an earlier method (5) with 5-ml glass dialysis cells and a membrane with

[1] Absorption spectra were taken with a Beckman DB spectrophotometer. Melting temperatures were measured with a Gilford 250 spectrophotometer equipped with a baseline reference compensator, analog multiplexer No. 6046 and a No. 2527 thermoprogrammer. Measurement of inhibition of DNA function as a template for *E. coli* RNA polymerase was done using a Packard Tricarb LSC model 3320 liquid scintillation spectrometer.

VI	434	30,245
VII	338	13,225

[a] Observed in 5 m*M* tromethamine hydrochloric acid buffer (pH 7.4).

a molecular weight limit of 12,000[5]. Solutions of calf thymus DNA ranging from 1.0×10^{-5} to 1.5×10^{-3} *M* were made in 5 m*M* tromethamine hydrochloric acid buffer (pH 7.4), and a concentration of 1×10^{-4} *M* of compound was prepared in the same medium. Concentrations at equilibrium (24 hr, 25°) were measured by absorption spectra and determinations for each compound were made in duplicate or triplicate. Concentrations of free and bound species were calculated as previously described (6, 7). The correlation coefficient for each compound tested was >0.91. Binding parameters K_{app} and B_{app} are listed in Table II.

Melting Temperature Determination—The temperature in a heated cell was increased at the rate of 1°/min. The concentration of calf thymus DNA was 1.0×10^{-4} *M* nucleotide phosphorus, and the buffer was 5 m*M* tromethamine hydrochloric acid (pH 7.4). Concentrations of compounds used were 1×10^{-4} and 1×10^{-5} *M* for the anthraquinones and 1×10^{-4} *M* for the quinolinium compounds. Absorbance was measured at 260 nm. The temperature at which 50% hyperchromicity is attained (T_m) for the compounds tested is recorded in Table III.

Inhibition of *E. coli* RNA Polymerase—Stock solution H was prepared from: tromethamine hydrochloric acid (1.376 g); potassium chloride (2.795 g); 2-mercaptoethanol (0.195 g); magnesium chloride (0.508 g); bovine serum albumin (0.125 g); and distilled water to make 100 ml.

Stock solution I was prepared from: ATP sodium salt (0.117 g); CTP sodium salt (0.109 g); UTP sodium salt (0.105 g); GTP sodium salt (0.114 g); and distilled water to make 10 ml.

Stock solution J contained [8-^{14}C]ATP (0.01 mCi, 0.13 mg/0.5 ml, 30 μl), and distilled water to make 200 μl.

Stock solution K consisted of 100 units of *E. coli* RNA polymerase diluted with 60% glycerol–40% tromethamine hydrochloric acid buffer containing 0.2 m*M* 1,4-dithiothreitol, 0.01 m*M* ethylenediaminetetraacetic acid, and 10 m*M* magnesium chloride to give 2 units/10 μl. It was stored below 0°.

Stock solution L was prepared from calf thymus DNA solution, 5 m*M* in nucleotide phosphorus (absorption coefficient at 260 nm of 6600 M^{-1}/cm, 0.083 g); ethylenediaminetetraacetic acid (0.056 g); and 5 m*M* tromethamine hydrochloric acid buffer (pH 7.4) to make 50 ml. Solution L was stored below 0°. Other DNA solutions were prepared in the same way.

The liquid scintillation solution contained 2,5-diphenyloxazole (6.000 g); 1,4-bis[2-(5-phenyloxazolyl)]benzene (0.200 g); toluene (1400 ml); and methanol (600 ml).

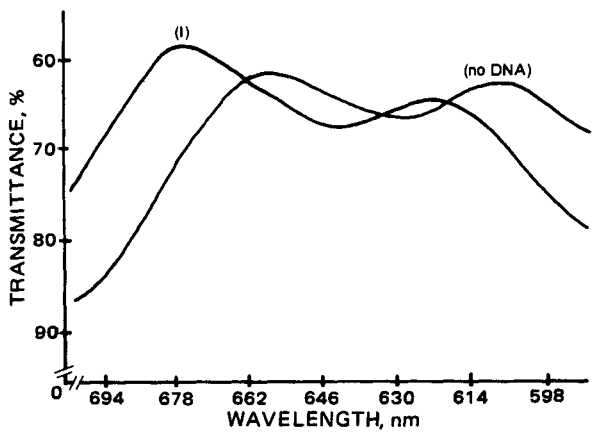

Figure 1—*Influence of DNA on the visible spectrum of I. DNA was used at a concentration of* 25.0×10^{-5} M.

Table II—Equilibrium Constants for Binding of I–VII to Calf Thymus DNA [a]

Compound	K_{app}	B_{app}
I	1.31×10^6	0.341
II	2.61×10^6	0.341
III	7.47×10^4	0.063
IV	1.31×10^3	0.075
V	1.05×10^3	0.085
VI	8.70×10^4	0.077
VII	8.08×10^5	0.138

[a] Determined in 5 m*M* tromethamine hydrochloric acid buffer (pH 7.4).

The gain setting for maximum efficiency of the scintillation spectrometer was determined at 40%. The activity of RNA polymerase was determined by measuring the amount of [8-^{14}C]ATP rendered acid insoluble as determined by the filter paper disk assay of Bollum (8).

The assay mixture contained in 0.125 ml consisted of pH 8.0 tromethamine hydrochloric acid buffer (5.000 μmoles); magnesium chloride (1.250 μmoles); potassium chloride (18.750 μmoles); 2-mercaptoethanol (1.250 μmoles); CTP sodium salt (0.019 μmole); GTP sodium salt (0.019 μmole); UTP sodium salt (0.019 μmole); [8-^{14}C]ATP tetrasodium salt (6,500 cpm) (0.019 μmole); calf thymus DNA, (5.000 μg); and bovine serum albumin, (62.500 μg).

DNA (5.0 μg) solutions were preincubated with each compound (1.0×10^{-5}–5.0×10^{-5} *M*) in 25 μl of 5 m*M* tromethamine hydrochloric acid buffer (pH 7.4) for 10 min at 37° prior to the assay of RNA polymerase activity. The reference blank contained DNA in buffer solution.

The assay mixture was prepared by adding 50 μl of solution H, 10 μl of solution I, 10 μl of solution J, 20 ml of distilled water, 5.0 μl of preincubated DNA and the test compound in 25 μl, and 10 μl of *E. coli* RNA polymerase solution (2 units). The mixture was incubated for 10 min at 37°, and the enzyme reaction was terminated by the addition of 25 μl of cold 5% trichloroacetic acid containing 1% tetrasodium pyrophosphate and by chilling in an ice water bath for 15 min.

The acid insoluble material from a 100-μl aliquot of each incubation mixture was spotted uniformly on a 2.5-cm circular millipore filter (0.45 μm pore size), kept at room temperature for 15 min, and washed three times by being swirled in 10 ml of 5% trichloroacetic acid containing 1% tetrasodium pyrophosphate, followed by two washings each of 2.5% trichloroacetic acid and 95% ethanol. Filters were dried and placed in 15 ml of scintillation liquid. Radioactivity was counted in the scintillation spectrometer and all assays were run in triplicate. Inhibition of RNA polymerase activity by the test compounds was recorded (Tables IV and V).

Comparison of Absorption Spectra of Compounds in the Presence of Native Double-Stranded DNA and Separated-Strand DNA—One milliliter of a test compound solution (2.0–5.0×10^{-4} *M*, in tromethamine hydrochloric acid buffer, pH 7.4) was added to 1 ml of either native double-stranded calf thymus DNA (1.25×10^{-4}–5.0×10^{-4} *M*) or to 1 ml of separated-strand DNA solution. Strand separation was done by heating calf thymus DNA solution at 98° for 30 min and immediately

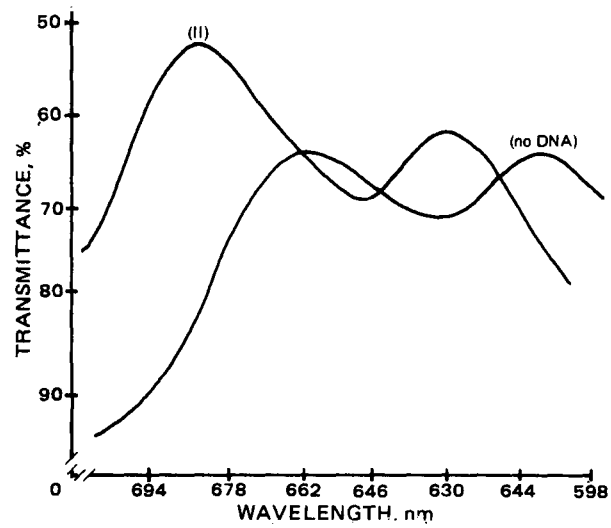

Figure 2.—*Influence of DNA on the visible spectrum II; DNA was used at a concentration of* 40.0×10^{-5} M.

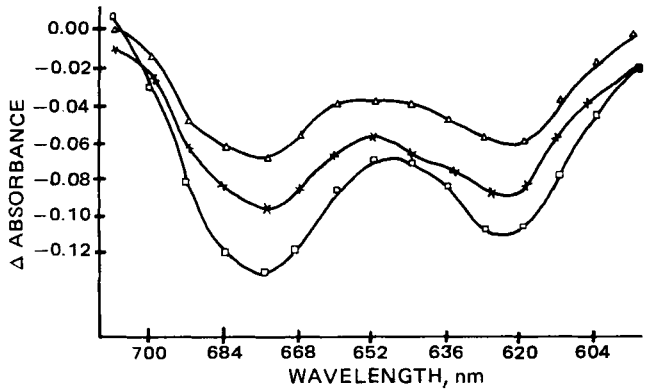

Figure 3—*Difference spectra of free and DNA-bound test compounds. The concentration used was 2.0 × 10⁻⁵ M I and the DNA concentration used was 1.25 × 10⁻⁵ M. Key:* △, C. perfringens *DNA; X, calf thymus DNA; and* □, M. lysodeikticus *DNA.*

cooling the solution at 0°. The control solution used was 5 m*M* tromethamine hydrochloric acid buffer, pH 7.4. Difference spectra were recorded in the visible region.

Inhibition of DNA Function as Template for *E. coli* RNA Polymerase with Varied Base Ratio DNA–DNA from the following sources was used: *C. perfringens* (27% G–C); calf thymus (43% G–C); *E. coli* (50% G–C); and *M. lysodeikticus* (72% G–C). RNA polymerase activity was measured as described and results are tabulated in Table VI. Concentrations used were 1×10^{-4} *M* for the anthraquinones and 1.5×10^{-3} *M* for the quinolinium compounds.

Comparison of Absorption Spectra of Compounds in the Presence of Varied Base Ratio DNA. One milliliter of a test compound solution (2.0×10^{-5}–5.0×10^{-4} *M* in 5 m*M* tromethamine hydrochloric acid buffer, pH 7.4) was added to 1 ml of the various DNA solutions (1.25×10^{-5} *M*, based on phosphorus). The buffer (5 m*M*, pH 7.4) was used as a control. Difference spectra were recorded in the visible region, and the data are plotted in Figs. 3 and 4 for the anthraquinones.

DISCUSSION

Spectral Analysis—The interaction of the compounds with calf thymus DNA resulted in a consistent bathochromic/hypochromic shift in the visible spectrum around 20–30 nm for the anthraquinones and 20–50 nm for the quinolinium compounds. In comparison, chloroquine showed an average shift of 10 nm in the presence of calf thymus DNA.

Equilibrium Dialysis—These experiments using calf thymus DNA were done at ambient temperature at pH 7.4. For determining binding parameters, Scatchard plots were employed using the expression:

$$r/C_f = K_{app}(B_{app} - r) \qquad \text{(Eq. 1)}$$

where r is the ratio of bound compound to DNA nucleotide phosphorus, C_f is the concentration of free compound, K_{app} is the apparent binding constant, and B_{app} is the apparent number of binding sites per nucleotide phosphorus. The binding parameters K_{app} and B_{app} are shown in Table II. These values were obtained from the nearly linear portion of the isotherm at small values of r for a strong binding.

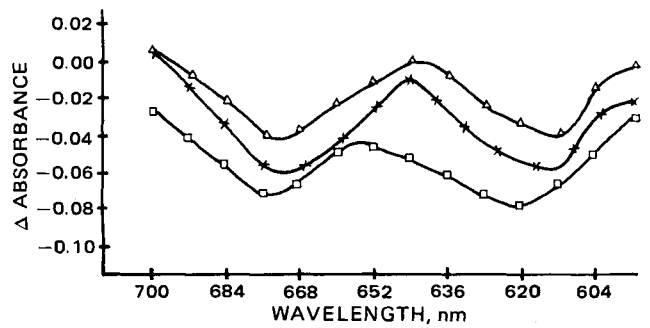

Figure 4—*Difference spectra of free and DNA-bound test compounds. The concentration used was 2.0 × 10⁻⁵ M II and the DNA concentration used was 1.25 × 10⁻⁵ M. Key:* △, C. perfringens *DNA; X, calf thymus DNA;* and □, M lysodeikticus *DNA.*

Table III—Melting Temperature Determination [a]

Compound	T_m	ΔT_m
DNA (calf thymus) [b]	62.0°

1.0×10^{-6}	0.00	0.00	0.00	0.00	0.00

Scatchard plots of the binding data for the anthraquinones yielded biphasic curves, which indicates that two binding sites are involved, a stronger and a weaker (Figs. 5 and 6). The stronger binding data were derived from the linear region of the plot at small values of r. The other slope at higher values of r indicates the presence of a weaker binding site. The strong binding is most likely associated with intercalation of the anthraquinone ring into DNA base pairs (9, 10). The weaker binding may be associated with the secondary binding of the side chains by electrostatic interaction with the anionic exterior of the DNA helix.

Association constants for the anthraquinone derivatives are of the same order of magnitude as those found for daunorubicin and doxorubicin (9, 10), lower than that for dactinomycin (11, 12), and greater than that for chloroquine (13). The apparent number of binding sites per nucleotide obtained for the strong binding site is 0.34, indicating that binding of these compounds involves approximately three adjacent phosphate groups on the DNA.

The linear binding isotherms of the quinolinium compounds indicate that only one type of binding site is involved on the DNA helix. The association constants are lower than those obtained for either the anthraquinones or chloroquine. The compounds of this group bind at approximately one of every contiguous 8–12 phosphate groups on the DNA. The binding abilities of the compounds of this type were essentially the same, indicating little effect from the 6-substituents.

Melting Temperature Elevation—Thermal denaturation studies were done at pH 7.4, using calf thymus DNA. The results shown in Table III indicate that all of the compounds bind to and stabilize the DNA helix toward temperature denaturation. Thermal stabilization did not vary much between the members in each series, but the anthraquinones caused a greater T_m increase than either the quinolinium compounds or chloroquine, and much greater than the usual tetracyclic intercalating agents (9). This suggests the possible formation of a covalent bond *via* a radical reaction induced at higher temperature (14).

Inhibition of *E. coli* RNA-Polymerase Activity—Inhibition of DNA function as a template for *E. coli* RNA polymerase was carried out *in vitro* using graded concentrations of the compounds. Results are listed in

Table VI—Inhibition of *E. coli* RNA Polymerase Using Varied DNA Base Ratios

DNA (% G–C)	Inhibition, %						
	I	II	III	IV	V	VI	VIII
C. perfringens (27%)	46.43	41.17	20.79	18.18	14.39	25.21	5.05
Calf thymus (43%)	79.74	78.68	26.52	35.66	26.17	22.58	25.78
E. coli (50%)	81.12	89.49	33.84	36.66	28.24	41.42	45.19
M. lysodeikticus (72%)	97.53	93.86	48.93	40.17	48.94	46.54	51.51

Tables IV and V. The anthraquinones were the stronger inhibitors, giving 80–90% inhibitions at concentrations of 10^{-4} *M*. The quinolinium compounds gave 47–67% inhibitions at concentrations of 10^{-3} *M*, which were comparable to the inhibitory ability of the same concentrations of chloroquine (13).

Studies of Complex Formation—Comparison of the visible absorption spectra of the compounds in the presence of native double-stranded and separated-strand DNA (calf thymus) was made. The difference spectra showed marked quenching in absorptivities in the spectrum of the double-stranded DNA (Figs. 3 and 4) but very little change in the spectrum of the separated-strand DNA. The requirement for double-stranded DNA with all the compounds tested indicated that the double-helical structure is necessary for strong binding, and that both strands are involved.

Base specificity for the interaction between DNA and the compounds tested was clearly demonstrated by the inhibition of DNA function as measured by inhibition of *E. coli* RNA-polymerase activity with different base ratios of guanosine and cytidine. The extent of transcription inhibition is shown in Table VI. It is apparent that there is a preference for the G–C base pair, since the degree of inhibition is greatest, with both series of compounds, with the DNA source having the highest G–C base pair ratio. The anthraquinones appeared to have a greater preference for this base pair than the quinolinium compounds, as indicated by extent of inhibition.

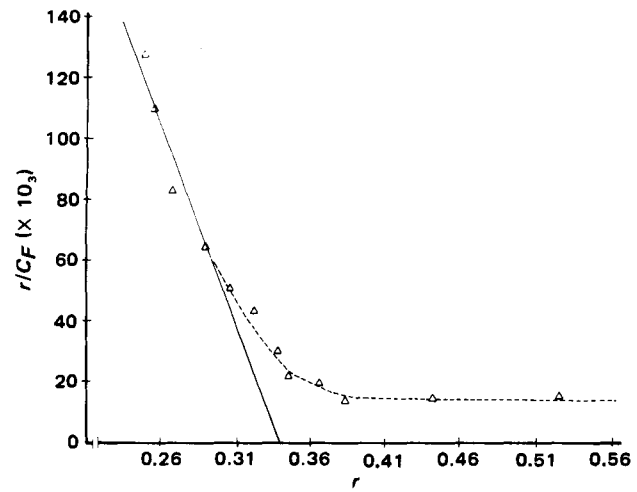

Figure 5—*Scatchard plot of I.*

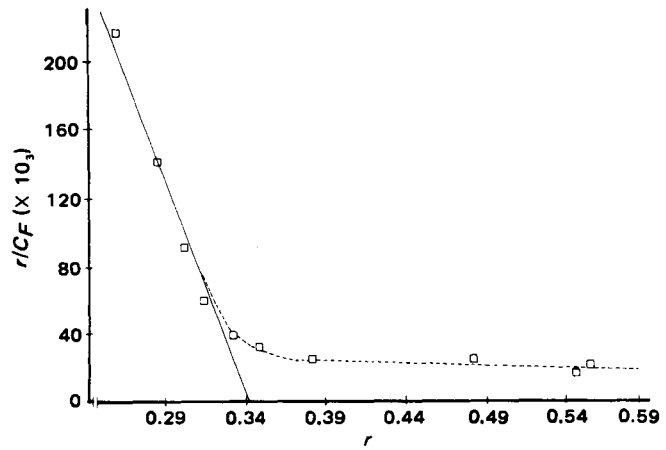

Figure 6—*Scatchard plot of II.*

Comparison of the absorption spectra of the compounds in the presence of the varied DNA base ratios was also carried out to further delineate the tendency toward base-pair specificity in DNA binding. The difference spectra for the anthraquinones (Figs. 3 and 4) revealed a proportionality to the G–C contents of the DNA species used, but the quinolinium derivatives showed no difference in depressive effect on the extinction coefficients in the spectra, indicating no G–C specificity. This illustrates the advantage of employing more than one method of measurement.

A probable mode of action of the methylthiovinylquinolinium iodides is an inhibition of nucleic acid biosynthesis with formation of a molecular complex with DNA. Only one type of binding site is apparently involved. The complex formed involves both strands of the DNA double helix and may result from the insertion of the planar ligand between base pairs of the helix, the intercalation model of Muller and Crothers (15) and Lerman (16).

The binding parameters of the four compounds in this series are of the same order of magnitude. Although a marginal preference of G–C base-pair binding was shown by the extent of inhibition of RNA transcription, this was not detectable by comparison of the visible absorption spectra of the compounds in the presence of varied DNA base ratios. One can assume that the biochemical technique is definitely more sensitive and meaningful than the spectral methods for distinguishing those agents with borderline DNA base-pair specificities of binding. The presence of a 6-substituent has little effect on the extent of DNA binding.

The binding studies of the two anthraquinones indicate that both compounds bind to DNA with comparable strength. Binding isotherms indicate two binding sites on DNA for these compounds. The stronger binding is presumed to be intercalation between successive base pairs; the weaker binding is considered to be an electrostatic interaction involving DNA phosphate groups and the amino side chains. Comparison of absorption spectra and the extent of RNA transcription inhibition with varied DNA base ratios show a preference for binding with the G–C base pair. Since the binding parameters of the two anthraquinones are essentially the same, the strong antileukemic activity of the active compound (I) could be due to additional factors such as *in vivo* metabolic activation, pharmacokinetic behavior of biologically active components, or alternative action sites in the cell apparatus other than nuclei (14).

It is apparent from these *in vitro* methods of studying DNA binding ability that some differences in anticancer activity, such as between the anthraquinones and the quinolinium compounds, may be correlated with the relative binding strengths to DNA. On the other hand, these methods may fail to distinguish between active and inactive compounds, as seen with the anthraquinones, where other biological factors may become determinant.

Antitumor Agents XLVII: The Effects of Bisbrusatolyl Malonate on P-388 Lymphocytic Leukemia Cell Metabolism

IRIS H. HALL ˣ, Y. F. LIOU, K. H. LEE, M. OKANO, and STEPHEN G. CHANEY *

Received February 19, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, and the *Department of Biochemistry, School of Medicine, University of North Carolina at Chapel Hill, NC 27514.* Accepted for publication July 15, 1981.

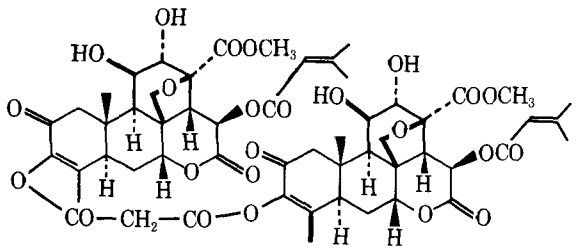
Abstract □ Bisbrusatolyl malonate, which was shown previously to be active against P-388 lymphocytic leukemia cell growth, was investigated for inhibitory effects on nucleic acid and protein synthesis. DNA and RNA synthesis as well as protein synthesis were markedly inhibited at 10, 25, and 50 μmole final concentrations *in vitro*. The major sites of inhibition of nucleic acid synthesis appeared to be DNA polymerase, messenger and transfer RNA polymerases, orotidine-5′-monophosphate decarboxylase, phosphoribosyl pyrophosphate amino transferase, and dihydrofolate reductase. Moderate inhibition of nucleotide kinase activities and oxidative phosphorylation processes occurred after drug treatment. Cyclic adenosine monophosphate levels were reduced. Protein synthesis was inhibited during the elongation step of peptide synthesis. The data suggested that bisbrusatolyl malonate interfered with the peptide bond formation. However, the ongoing polypeptide synthesis must be completed before the drug can bind to the ribosome effectively.

Keyphrases □ Bisbrusatolyl malonate—effects on P-388 lymphocytic leukemia cell metabolism □ Antitumor agents—effects of bisbrusatolyl malonate on P-388 lymphocytic leukemia cell metabolism □ RNA—synthesis, effect of bisbrusatolyl malonate, P-388 lymphocytic leukemia cells □ DNA—synthesis, effect of bisbrusatolyl malonate, P-388 lymphocytic leukemia cells □ Protein synthesis—effect of bisbrusatolyl malonate, P-388 lymphocytic leukemia cells

Antineoplastic activity against P-388 lymphocytic leukemia growth was established previously for bisbrusatolyl esters (1, 2). One of these derivatives, bisbrusatolyl malonate at 0.6 mg/kg/day ip, gave T/C % values of 271, 197, and 188 in BDF_1 male mice (2) in a P-388 tumor model sensitive to quassinoids (2). This agent was shown to suppress *in vitro* DNA synthesis by 45%, RNA synthesis by 48%, and protein synthesis by 83% at 10 μM concentration after 90 min incubation. A number of enzymes involved in nucleic acid metabolism, *e.g.*, DNA polymerase and dihydrofolate reductase, were inhibited *in vitro* by this ester (2). A detailed study of the effects of bisbrusatolyl malonate on P-388 lymphocytic leukemia cellular metabolism was conducted and its effects on nucleic acid and protein metabolism are now reported.

EXPERIMENTAL

Bisbrusatolyl malonate (I) was synthesized and characterized previously in the literature (2). The P-388 lymphocytic leukemia tumor line was maintained in DBA/2 male mice (~20 g). For the *in vitro* studies,



I

P-388 cells were harvested from the peritoneal cavity 10 days after administering 10^6 P-388 lymphocytic leukemia cells intraperitoneally into BDF_1 male mice (~20 g) on day 0 (3). In the *in vivo* studies, BDF_1 male mice were inoculated with 10^6 P-388 cells intraperitoneally, and on days 7, 8, and 9 the mice were administered 0.6 mg/kg/day bisbrusatolyl malonate intraperitoneally. The biochemical studies were performed on cells harvested from the peritoneal cavity on day 10.

The *in vitro* incorporation studies (4) were conducted using 1 μCi [6-^{3}H]thymidine (21.8 Ci/mmole), [6-^{3}H]uridine (22.4 Ci/mmole), or [4,5-^{3}H(N)]L-leucine (56.5 Ci/mmole) with 10^6 P-388 cells in minimum essential medium, pH 7.2, in a total volume of 1 ml, incubated for 60 min at 37°. Thymidine incorporation into DNA was terminated with perchloric acid containing pyrophosphate which was filtered on glass fiber paper by vacuum suction. RNA and protein assays were terminated with trichloroacetic acid and collected on nitrocellulose membranes by vacuum suction. The acid-insoluble precipitates on the filter papers were placed in scintillation vials and counted. *In vivo* thymidine incorporation into DNA was determined by injecting into the animal 10 μCi of [^{3}H]-methylthymidine (24.7 Ci/mmole) intraperitoneally 1 hr before sacrifice. The DNA was isolated (5) and the [^{3}H]thymidine content determined in scintillation fluid[1] and corrected for quenching. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as the standard. The results were expressed as dpm/mg of DNA isolated. Uridine incorporation into RNA was determined in an analogous manner with 10 μCi of [^{3}H]uridine (20 Ci/mmole) and the RNA extracted (6). Leucine incorporation into protein was determined by the method of Sartorelli (7) with 10 μCi[^{3}H]L-leucine (56.5 Ci/mmole). The control values for DNA synthesis were 202,098 dpm/mg of DNA, 235,360 dpm/mg of RNA for RNA synthesis, and 99,102 dpm/mg of protein isolated for leucine incorporation.

On day 10 after *in vivo* administration of the drug, the number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (8). The *in vitro* UV binding studies were conducted with I (50 μg/ml) incubated with DNA (38 μg/ml) in 0.1 *M* phosphate

The biochemical studies were performed on cells harvested from the peritoneal cavity on day 10.

The *in vitro* incorporation studies (4) were conducted using 1 μCi [6-^{3}H]thymidine (21.8 Ci/mmole), [6-^{3}H]uridine (22.4 Ci/mmole), or [4,5-^{3}H(N)]L-leucine (56.5 Ci/mmole) with 10^6 P-388 cells in minimum essential medium, pH 7.2, in a total volume of 1 ml, incubated for 60 min at 37°. Thymidine incorporation into DNA was terminated with perchloric acid containing pyrophosphate which was filtered on glass fiber paper by vacuum suction. RNA and protein assays were terminated with trichloroacetic acid and collected on nitrocellulose membranes by vacuum suction. The acid-insoluble precipitates on the filter papers were placed in scintillation vials and counted. *In vivo* thymidine incorporation into DNA was determined by injecting into the animal 10 μCi of [^{3}H]-methylthymidine (24.7 Ci/mmole) intraperitoneally 1 hr before sacrifice. The DNA was isolated (5) and the [^{3}H]thymidine content determined in scintillation fluid[1] and corrected for quenching. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as the standard. The results were expressed as dpm/mg of DNA isolated. Uridine incorporation into RNA was determined in an analogous manner with 10 μCi of [^{3}H]uridine (20 Ci/mmole) and the RNA extracted (6). Leucine incorporation into protein was determined by the method of Sartorelli (7) with 10 μCi[^{3}H]L-leucine (56.5 Ci/mmole). The control values for DNA synthesis were 202,098 dpm/mg of DNA, 235,360 dpm/mg of RNA for RNA synthesis, and 99,102 dpm/mg of protein isolated for leucine incorporation.

On day 10 after *in vivo* administration of the drug, the number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (8). The *in vitro* UV binding studies were conducted with I (50 μg/ml) incubated with DNA (38 μg/ml) in 0.1 *M* phosphate

buffer (pH 7.2) from 0–24 hr and measured over the range of 200–340 nm (8).

The *in vitro* enzymatic studies were conducted with I present in a final concentration of 10 μM. The *in vitro* and *in vivo* enzymatic assays have been described previously (4). Nuclear DNA polymerase activity was determined on isolated P-388 cell nuclei (9) using the incubation medium of Sawada *et al.* (10), except that [^{3}H]methylthymidine triphosphate (78.1 Ci/mmole) was used. The insoluble nucleic acids were collected on glass fiber papers. The control value was 24,568 dpm/mg of nuclear protein. Messenger, ribosomal, and transfer RNA polymerase enzymes were isolated using different concentrations of ammonium sulfate (11), and the individual polymerase activities were measured using [5,6-^{3}H]-uridine-5-triphosphate (23.2 Ci/mmole). Insoluble ribonucleic acids were collected on nitrocellulose filters (11, 12). Control values for messenger, ribosomal, and transfer RNA polymerase activities were 1807, 2987, and 2270 dpm/mg of nucleic protein, respectively. Ribonucleotide reductase activity was measured by a previous method (13) using [^{14}C]cytidine-5′-diphosphate (25 Ci/mmole). The deoxyribonucleotides were separated from ribonucleotides by polyethyleneiminecellulose TLC. The control value for the reductase was 22,392 dpm/mg of protein. Deoxythymidine kinase, deoxythymidylate monophosphate kinase, and deoxythymidylate diphosphate kinase activities were measured by spectrophotometric assay (14) based on the disappearance of nadide at 340 nm. Control values using a postnuclear supernate (600×*g* for 10 min) were a change in absorbance of 0.365, 0.182, and 0.368 o.d. units/hr/mg of protein, respectively. Enzymes of the pyrimidine synthetic pathway were also measured. Carbamyl phosphate synthetase activity was determined by a previous method (15). The colorimetric determination of citrulline was also performed according to a previous method (16), resulting in 3.26 mg of citrulline formed/hr/μg of protein. Aspartate carbamyl transferase activity was carried out in the presence of aspartate transcarbamylase (15) and the colorimetric determination (17) of the carbamyl aspartate that formed resulted in 0.301 μmole formed/hr/mg of protein. Orotidine-5′-phosphate decarboxylase activity was measured using a 16,300×*g* (20 min) supernate by a technique (18) using [^{14}C]carbonyl orotidine-5′-monophosphate (34.9 mCi/mmole). The control value was 39,059 dpm/mg of protein. Thymidylate synthetase activity was determined by a method (19) utilizing a postmitochondrial supernate (9000×*g* for 10 min) with 5 μCi of [5-^{3}H]deoxyuridine monophosphate (11 Ci/mmole), giving a control value of 12,374 dpm/hr/mg of protein. Dihydrofolate reductase activity was determined using a 600×*g* (10 min) supernate by a spectrophotometric method (20) based on the disappearance of reduced nadide resulting in a value of 0.761 o.d. unit/hr/mg of protein for 10-day P-388 cells. [^{14}C]-Formate incorporation into purines was measured by a method (21) using 0.5 μCi of [^{14}C]formic acid (4.95 mCi/mmole). Purine separation was achieved by silica gel TLC eluting with *n*-butanol–acetic acid–water (4:1:5). Using guanine and adenine standards, the appropriate spots were scraped and the radioactivity determined. The control value for purine synthesis was 10,621 dpm/mg of protein. Phosphoribosyl pyrophosphate amino transferase activity was determined by a spectrophotometric method (22) at 340 nm using a 600×*g* (10 min) supernate, resulting in a control value of 0.806 o.d. unit/hr/mg of protein. Inosinic acid dehydrogenase activity was determined by a spectrophotometric method (23) at 340 nm. The control value for 10-day P-388 cells was 0.133 o.d. unit/min/μg of protein for a 600×*g* (10 min) supernate. Deoxyribonuclease activity was measured at pH 5.0 by a modification of the deDuve method (24). Ribonuclease and acid cathepsin activities were determined at pH 5.0 by a previous method (25). The control deoxyribonuclease activity was 1.72 μg of DNA hydrolyzed/min/mg of protein; ribonuclease activity was 7.24 μg RNA hydrolyzed/min/mg of protein. Cathepsin activity was 65.7 μg of azocasein hydrolyzed/min/mg of protein for 10-day P-388 cells.

Table II—*In Vitro* Effects of Bisbrusatolyl Malonate on Enzymatic Activities of P-388 Lymphocytic Leukemia Cells

Enzyme (n = 6)	% Control: Control (0.05% Polysorbate 80)	% Control: Bisbrusatolyl Malonate, 10 μM

$p \leq 0.005$. [c] $p \leq 0.010$.

Histone phosphorylation was determined by injecting 10 μCi of [γ-^{32}P]adenosine triphosphate (27 Ci/mmole) intraperitoneally. The nuclei were isolated 1 hr later and the histone chromatin protein extracted (26). Nonhistone chromatin phosphorylation by nucleic protein kinase was determined on isolated nuclei (9), utilizing 2 mmoles of [γ-^{32}P]adenosine triphosphate. Chromatin protein was collected on nitrocellulose membrane filters (27) and cyclic adenosine triphosphate levels were determined with a commercial radioimmunoassay kit[2] using iodine 125. Methyl transferase activity was determined by a method (28) using 0.05 μCi of [$^{14}CH_3$]*S*-adenosyl-L-methionine (53 mCi/mmole). The control value for histone phosphorylation was 1211 dpm/mg of chromatin protein isolated; nonhistone phosphorylation was 2391 dpm/mg of protein, and cyclic adenosine phosphate was 1.25 pmoles/10^6 cells. Methyl transferase activity for the control was 217 dpm/mg of protein. Oxidative phosphorylation studies were carried out on 9-day P-388 cells (29). Oxygen consumption was measured with a Clark electrode connected to an oxygraph. The reaction vessel contained 55 μmoles of sucrose, 22 μmoles of monobasic potassium phosphate, 22 μmoles of potassium chloride, 90 μmoles of succinate or 60 μmoles of α-ketoglutarate as substrate, and 22 μmoles of adenosine triphosphate. The final I concentration was 10 μmoles. After the basal metabolic level (state 4) was reached, 0.257 μmole of adenosine diphosphate was added to the vessel to obtain the adenosine diphosphate-stimulated respiration rate (state 3). Basal respiration (state 4) using succinate as substrate resulted in 11.44 μl O_2 consumed/min/mg of protein and 10.0/μl of O_2 consumed/min/mg of protein using α-ketoglutarate. The adenosine diphosphate stimulated respiration rate for succinate was 20.76, and for α-ketoglutarate 10.17 μl of O_2 consumed/min/mg of protein.

The studies on the effects of I on protein synthesis were conducted on P-388 cells harvested on day 10. P-388 lymphocytic leukemia lysates were

[2] Becton Dickinson.

prepared by the method of Kruh *et al.* (30). The following were isolated from P-388 lysates by literature techniques: run-off ribosomes (31), pH 5 enzyme (30), and uncharged transfer RNA (32).The P-388 lymphocytic leukemia cell initiation factors for protein synthesis were prepared by the method of Majumdar (33) O^{3}H methionyl transfer RNA was prepared from P-388 cell transfer RNA (tRNA) by a previous method (34). The effect of I on endogenous protein synthesis (35) of P-388 lysates was carried out in a reaction mixture (0.5 ml) containing 10 m*M* tromethamine hydrochloride (pH 7.6), 76 m*M* KCl, 1 m*M* adenosine triphosphate, 0.2 m*M* guanosine triphosphate, 15 m*M* phosphocreatine, 2 m*M* $MgCl_2$, 1 m*M* dithiothreitol, 0.1 m*M* of each of the 19 essential amino acids, 0.9 mg/ml creatine phosphokinase, and 20 μCi [^{3}H]leucine (56.5 Ci/mmole). An aliquot of the reaction mixture was incubated at 30°. After 90 sec of incubation, I or the standards pyrocatechol violet or emetine was added to a final concentration of 100 μ*M*. At 1-min intervals, 50-μl aliquots were removed from the reaction tubes and spotted on filter papers[3] and then treated for 10 min in boiling 5% trichloroacetic acid, followed by 10 min in cold 5% trichloroacetic acid and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1), and ether. The filter papers were dried and counted in scintillation fluid.

The effects of I, pyrocatechol violet, and emetine on the ribosome profile (35) of P-388 cell lysate were assayed using the described reaction medium (500 μl). Following drug addition (100 μ*M* final concentration) the reaction was incubated for 4 min at 37°. The reaction was terminated in ice and gradient buffer [1 ml of tromethamine hydrochloride (pH 7.6) 10 m*M* KCl, and 1.5 m*M* $MgCl_2 \cdot 6H_2O$] was added. The mixture was layered over 36 ml of 10–25% linear sucrose gradient (35), prepared in gradient buffer, and centrifuged for 165 min at 25,000 rpm in a swinging bucket rotor[4] at 4°. The absorbance profile at 260 nm was determined using a flow cell (light path 0.2 cm) attached to a spectrophotometer[5].

The reaction mixture (50 μl) for the polyuridine directed polyphenylalanine synthesis (36) contained 50 m*M* tromethamine hydrochloride (pH 7.6), 12.5 m*M* magnesium acetate, 80 m*M* KCl, 5 m*M* phospho-

creatine, 0.05 mg/ml creatine phosphokinase, 0.36 mg/ml polyuridine[6] (A_{280}/A_{260} = 0.34), 0.5 μCi [^{14}C]phenylalanine (536 mCi/mmole) 75 μg uncharged P-388 cell transfer RNA, 70 μg of P-388 cell pH 5 enzyme preparation, and 0.9 A_{260} of P-388 cell run-off ribosomes. After incubation for 20 min at 30°, a 35-μl aliquot was spotted on filter paper[3] and processed as described previously.

The reaction medium (200 μl) used to measure the formation of the 80S initiation complex and the methionyl puromycin reaction (37) contained 15 m*M* tromethamine hydrochloride (pH 7.6), 80 m*M* KCl, 1 m*M* adenosine triphosphate, 0.5 m*M* guanosine triphosphate, 20 m*M* phosphocreatine, 0.2 mg/ml creatine phosphokinase, 3 m*M* magnesium acetate, 0.1 m*M* ethylenediaminetetraacetic acid, 1 m*M* dithiothreitol, 0.1 m*M* of each of the 19 essential amino acids, 3 mg of P-388 cell lysates, 100 μg/ml chlortetracycline[7], 3 × 10^5 cpm [^{3}H]methionine-transfer ribonucleic acid$_f$ (Met-tRNA$_f$), and 20 μg/ml polyadenosine–uridine–guanosine (poly AUG) and 5 μl of drug. The incubation was carried out at 23° and after 2 min aliquots were withdrawn to analyze for 80S complex formation. Puromycin (10 μg/ml) was then added to the reaction medium. The incubation was continued for another 6 min and aliquots were withdrawn to analyze for reaction of the 80S complex with puromycin. All aliquots (50 μl) were diluted to 250 μl with buffer [20 m*M* tromethamine hydrochloride (pH 7.6), 80 m*M* KCl, 3 m*M* magnesium acetate, 1 m*M* dithiothreitol, and 0.1 m*M* ethylenediaminetetraacetic acid], layered on 11.8 ml of a 15–30% linear sucrose gradient, and centrifuged for 3 hr at 36,000 rpm in a swinging bucket rotor[8]. Fractions (0.4 ml) were collected and precipitated with 10% trichloroacetic acid on filter papers and counted.

The reaction mixtures (75 μl) for the ternary complex formation (37) contained 21.4 m*M* tromethamine hydrochloride (pH 8.0), 80 m*M* KCl,

0.26 m*M* guanosine triphosphate, 21.4 m*M* dithiothreitol, 10 μg of bovine serum albumin, 5 pmoles of P-388 cell [^{3}H]methionine-transfer ribonucleic acid$_f$ (Met-tRNA$_f$, 1 × 10^4 cpm), 100 A_{260}/ml of crude P-388 cell initiation factors, and 10 μl of drug or standard. The incubation was conducted for 5 min at 37° and terminated by the addition of 3 ml of cold buffer [21.4 m*M* tromethamine hydrochloride (pH 8.0), 80 m*M* KCl, 2.14 m*M* dithiothreitol]. The samples were filtered through 0.45 μm filters[9], washed twice in buffer, and counted.

The reaction mixture (75 μl) for the 80S initiation complex (38) formation contained 1.9 m*M* magnesium acetate, 5 A_{260}/ml polyadenosine–uridine–guanosine[5], and 100 A_{260}/ml of 80S P-388 cell ribosomes in addition to the components necessary for the ternary complex formation reaction. Incubation was 10 min at 37° which was then cooled to 4° and titrated to 5 m*M* with magnesium acetate. After 5 min at 4°, the samples were diluted with cold buffer [21.4 m*M* tromethamine hydrochloride (pH 8.0) 80 m*M* KCl, 5 m*M* magnesium acetate, and 2.14 m*M* dithiothreitol] and filtered as indicated for the ternary complex formation experiment.

Amino acid-transfer RNA activation steps were determined by a previous method (39). The reaction medium contained 0.1 m*M* tromethamine hydrochloride (pH 7.4), 0.2 m*M* adenosine triphosphate, 0.3 mg/ml pH 5 enzyme from P-388 cells, and 2.5 μCi/ml of [^{14}C]phenylalanine (536 mCi/mmole), [^{3}H]leucine (56.5 Ci/mmole), or [^{3}H]methionine (80.0 Ci/mmole) in a total volume of 1 ml. After incubation at 37° for 20 min, 2 ml of ice cold 10% trichloroacetic acid was added and the activated amino acid-transfer RNA collected on nitrocellulose filters.

RESULTS AND DISCUSSION

In vitro incubation of I at 10-, 25-, and 50-μ*M* concentrations indicated that DNA synthesis was inhibited by relatively the same degree (42–46%) for all three concentrations employed (Table I). RNA synthesis was inhibited at 10 and 25 μ*M* but not at 50 μ*M*. The inhibition of protein synthesis *in vitro* followed a dose response curve for the doses employed in this study. Homogenized and whole cells demonstrated approximately the same degree of inhibition of DNA, RNA, and protein synthesis at 10 μ*M* final concentration of drug indicating that I inhibition of macromolecular synthesis was not due to the inhibition of radiolabeled precursor transport across the tumor cell membrane. The *in vitro* effects of I at 10 μ*M* on several of the enzymes required for nucleic acid synthesis (Table II) indicated that the major inhibition sites are at DNA polymerase, thymidine monophosphate kinase, purine synthesis, and methyl transferase, all of which were suppressed ~50% by I *in vitro*. Minor sites of *in vitro* inhibition included RNA polymerase, thymidine kinase, orotidine monophosphate decarboxylase, dihydrofolate reductase, phosphoribosyl pyrophosphate amino transferase, and oxidative phosphorylation processes, both basal and adenosine diphosphate stimulated respiration using succinate or α-ketoglutarate as substrate.

Examination of the effects of I on lysosomal hydrolytic enzymatic activities indicated that lysosomal membranes were stabilized by the drug. Thus, nucleases and proteolytic enzymatic activities of the lysosomes of the P-388 cells would not play a decreased role in nucleic acid and protein turnover, thereby resulting in erroneous incorporation values of radiolabeled precursors into synthetic macromolecules.

In vivo administration (Table III) of I at 0.6 mg/kg on days 7, 8, and 9 showed that the incorporation of thymidine, uridine, and leucine into DNA, RNA, and protein were drastically reduced (*i.e.*, at least 50% for nucleic acids and 66% for protein synthesis). Examination of the enzymes involved in nucleic acid synthesis indicated that DNA polymerase activity was inhibited 56%, messenger RNA polymerase activity was inhibited by 39%, and transfer RNA polymerase was inhibited by 50%. The suppression of the nucleic acid polymerase activities would indicate that template activity is interfered with by the drug binding in some manner. However, the UV spectrophotometric studies indicated only marginal interaction between DNA and I after incubation for 24 hr. Nucleotide kinase activity was inhibited moderately (23–37%). Orotidine-5′-monophosphate decarboxylase was inhibited significantly, inhibition being far greater *in vivo* (73%) than *in vitro* (31%). This difference may be due to a metabolite or may reflect slow binding between enzyme and drug. No other enzyme in the pyrimidine pathway was inhibited by I. Purine synthesis was inhibited 45%; one of the key regulatory sites of purine synthesis, phosphoribosyl pyrophosphate amino transferase was inhibited 41%. However, another enzyme that plays a significant role in one carbon transfer for both pyrimidine and purines, dihydrofolate reductase, was 88% inhibited *in vivo* whereas *in vitro* it was only 29% inhibited. Cyclic adenosine triphosphate levels were inhibited by 80%. Oxidative phosphorylation after *in vivo* administration of the drug was moderately inhibited (34–25%). Although a moderate loss of energy from this process could influence all synthetic pathways of the tumor cell. The number of tumor cells per milliliter was reduced by 56% after dosing for 3 days with I at 0.6 mg/kg.

In comparison to brusatol's effects on P-388 lymphocytic leukemia cell metabolism at 100 μg/kg/day (4), I was found to inhibit DNA polymerase and dihydrofolate reductase activities more effectively than brusatol both *in vivo* and *in vitro*. Furthermore, I inhibited thymidine nucleotide kinases enzymatic activities where no inhibition of the kinases was observed

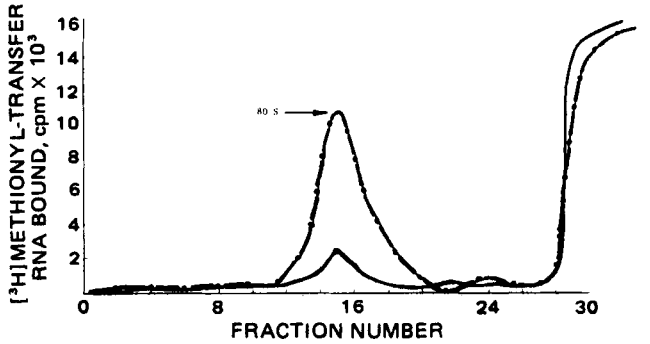

Figure 5—*Formation of the methionyl puromycin reaction of P-388 cell system (linear sucrose gradient centrifugation). Key: ——, control and puromycin; - · - · -, bisbrusatolyl malonate and puromycin.*

with brusatol. Brusatol caused a massive increase in cyclic adenosine monophosphate levels which was not observed for I. Brusatol caused a greater magnitude of inhibition of nucleic acid and protein synthesis in P-388 cells than I; however, this greater suppression did not correlate with increased antileukemic activity (T/C % = 158) for brusatol.

When the effect on protein synthesis of the P-388 cells was examined in detail, I clearly mimicked the action of brusatol and bruceantin. Previous studies with bruceantin in a yeast system (40) and brusatol in a rabbit reticulocyte system (41) have shown that these drugs bind preferentially to the free 80S subunit and subsequently inhibit any peptidyl transferase reaction. Thus, they allowed elongation of preformed polypeptide chains and formation of a new 80S initiation complex, but prevented utilization of that 80S initiation complex in the elongation steps of protein synthesis. The malonate ester has a similar mode of action.

Figure 1 shows that at a 1 μM concentration there is a lag of 6–7 min before inhibition by I becomes fully effective. This behavior is similiar to the initiation inhibitor pyrocatechol violet and suggests that preformed polypeptide chains are being completed prior to the onset of inhibition. This hypothesis is further confirmed by examining the ribosome profile following drug treatment of lysates prelabeled with [^{3}H]leucine (Fig. 2). At 1 μM, I causes accumulation of an 80S peak (presumably the 80S initiation complex). Since no radioactivity is associated with this peak, it is evident that 1 μM I also allows completion and release of the prelabeled polypeptide chain. These results are comparable to what one might expect to see from an initiation inhibitor (pyrocatechol violet). However, at higher concentrations (10 and 100 μM) I mimics the elongation inhibitors emetine and tetracycline. That is, inhibition occurs without any lag (Fig. 1) and results in freezing the preformed polypeptide chain on the ribosome (Fig. 2). This observation is consistent with previous data showing that at low concentrations, bruceantin binds only to free 80S subunits; however, at sufficiently high concentrations, it will also bind directly to the 80S elongation complex (41).

Further evidence that I acts as an elongation inhibitor comes from studies on polyuridine directed polyphenylalanine synthesis. Figure 3 shows the inhibition curve for polyphenylalanine synthesis carried out with purified run-off ribosomes isolated from 10-day P-388 cells. Clearly, the drug is effective as an inhibitor of polyuridine directed and endogenous protein synthesis. Since polyuridine directed protein synthesis does not require normal initiation or termination reactions, these data strongly suggest that I is an elongation inhibitor.

Confirmation of this hypothesis comes from detailed studies of the individual initiation and elongation steps. The initiation steps of protein synthesis were evaluated using a fractionated P-388 cell system. Bisbrusatolyl malonate (Table IV) had little or no effect on the formation of either the ^{3}H-ternary complex[10] or the 80S ^{3}H-initiation complex[11]. Bisbrusatolyl malonate also had no effect on the amino acid transfer RNA activation reactions with phenylalanine, leucine, and methionine (Table V).

Finally, the formation of the 80S initiation complex[11] and peptide bond formation were assayed as described previously (41). Addition of polyadenine–uridine–guanosine (poly AUG) to the P-388 lysate resulted in the formation of a detectable 80S initiation complex which was not inhibited by the addition of I (Fig. 4). Addition of puromycin to this reaction mixture caused formation of methionyl puromycin and consequent release of [^{3}H]methionine from the 80S complex (Fig. 5). This reaction was completely blocked by I.

[10] eIF·GTP[^{3}H]methionyl-transfer RNA.
[11] 80S·AUG·eIF·GTP[^{3}H]methionyl-transfer RNA.

In conclusion, I does not significantly affect the individual initiation steps leading to the formation of stable 80S initiation complex in P-388 cells. However, it does inhibit both polyuridine directed polyphenylalanine synthesis and the formation of the first peptide bond between puromycin and the [^{3}H]methionyl transfer RNA bound to the initiation complex. The data derived from these experiments suggests that I is a potent inhibitor of the peptidyl transferase reaction. The apparent runoff of polyribosomes to the 80S ribosomes suggests that the ribosome must complete its elongation and termination cycles before this drug can bind and usually must complete the initiation steps before the bound drug becomes an effective inhibitor. This pattern of inhibition is almost identical to that observed previously with the other quassinoids, bruceantin and brusatol (40), in rabbit reticulocytes and yeast cells.

In P-388 lymphocytic leukemia cells, I is a potent inhibitor of nucleic acids synthesis by inhibiting key sites in pyrimidine and purine synthesis and DNA and RNA polymerase activities. In addition, it is a potent inhibitor of protein synthesis by inhibiting the elongation step of polypeptide synthesis.

NOTES

Improved and Rapid High-Performance Liquid Chromatographic Assay for 13-*cis*-Retinoic Acid or All-*trans*-retinoic Acid

RICKEY SHELLEY, J. C. PRICE ˣ, H. WON JUN, D. E. CADWALLADER, and A. C. CAPOMACCHIA

Received June 11, 1980, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication May 15, 1981.

Abstract □ A rapid, specific, and sensitive reversed-phase high-performance liquid chromatographic (HPLC) assay for the quantitative determination of all-*trans*- retinoic acid (I) or 13-*cis*-retinoic acid (II) in rat serum without extraction or lyophilization is described. Chromatographic separation from retinol, serum components, and retinol acetate standard was achieved on octadecylsilane-coated particles with acetonitrile–1% ammonium acetate as the eluent. Serum samples (100 μl) containing as little as 10 ng of retinoid were analyzed. Serum level profiles of rats dosed with the retinoids demonstrated the utility of the assay and indicated elimination half-lives of 0.58 and 0.92 hr for I and II, respectively.

Keyphrases □ High-performance liquid chromatography—assay for 13-*cis*-retinoic acid and all-*trans*-retinoic acid □ 13-*cis*-Retinoic acid—high-performance liquid chromatographic analysis □ All-*trans*-retinoic acid—high-performance liquid chromatographic analysis

High-performance liquid chromatographic (HPLC) assay procedures for all-*trans*-retinoic acid (I) or 13-*cis*-retinoic acid (II) in serum samples differ markedly in sample preparation. One previously reported method employed lyophilization followed by extraction with methanol before analysis by reversed-phase chromatography. By this method as little as 50 ng of retinoic acid was detected in 0.5 ml of human plasma samples (1). Another report (2) showed a sensitivity limit of 25 ng/ml of plasma with reversed-phase chromatography after extraction of samples containing 1 ml of plasma with a mixture of hexane, methylene chloride, and isopropanol. In another study (3), 0.5 ml of serum was extracted with ethyl acetate, followed by evaporation and dissolution of the residue in mobile phase. Normal-phase adsorption chromatography was employed to achieve a sensitivity of 10–20 ng/ml of serum. A fourth method (4) required no extraction step and had a detection limit of 100 ng of retinoic acid when 400 μl of serum was mixed with methanol and centrifuged for 20 min and the supernatant liquid was analyzed directly by reversed-phase chromatography.

The present study describes a simple timesaving method for determining serum I or II by reversed-phase liquid chromatography with no extraction or lyophilization steps. Only 100 μl of serum is required, and many samples can be analyzed in a short time. Sensitivity compares favorably with other reported assay procedures.

EXPERIMENTAL

Key: 1, solvent; 2, retinol (present in all serum samples); 3, internal standard; 4, I; and 5, II.*

and reagents were high grade, commercially available materials.

Chromatography—Analyses were performed on a liquid chromatograph[4] operated at ambient temperature and equipped with a UV detector (340 nm). Separations were performed on a 3.2-mm × 25-cm reversed-phase column containing 5-μm octadecylsilane-coated particles[5]. A guard column, containing 30–40 μm octadecylsilane-coated pelicular material, was employed to protect the main column. Samples were introduced into the column through a 100-μl sample loop by way of a loop filler port and sample injection valve. Chromatograms were traced on a strip-chart recorder (20 cm/hr), and peak heights were determined by an integrator–peak detector.[6] The mobile phase was acetonitrile–1% ammonium acetate solution (75:25 v/v).

Calibration—Stock solutions (0.1 mg/ml) of I and II were prepared in acetonitrile and stored at −10°. In addition, an internal standard stock solution (10 μg/ml) of III was prepared. Periodic chromatographic and spectrophotometric analyses showed that these stock solutions could be stored without alteration for 1 month at −10°. Similar stability was reported previously (5).

Blood from untreated male white rats[7] was collected from the tails (6) in serum separation tubes and centrifuged to generate a serum pool. The serum was immediately transferred to 15-ml screw-capped vials and frozen. Known amounts of I stock solutions and 50 μl of the internal standard solution were added to 100 μl of drug-free serum samples in 15-ml screw-capped test tubes.

Each sample was further diluted with acetonitrile to a final volume of 400 μl to achieve I concentrations of 0.1–7.5 μg/ml (10–750 ng/100-μl sample) and a constant III concentration of 5.0 μg/ml. Samples of II and the internal standard were obtained in the same manner. The samples were shaken vigorously on a vortex mixer, and the precipitate was separated by centrifugation (2 min at 3500 rpm). The resulting supernatant liquid was injected onto the chromatograph for analysis. In a separate calibration, water was substituted for serum in essentially the same procedure to determine whether the serum had significantly affected the assay.

Calibration curves of the peak height ratios (retinoic acid to internal standard) *versus* the retinoid concentration were prepared from the analysis of the serum and water samples at each concentration of I and II.

Serum Level Profiles—Serum concentrations of the retinoids of the male rats, weighing an average of 390 g, were determined after intravenous injection into the tail vein using the described method. All rats were fasted for 24 hr before injection. Injected retinoids were in saline solution. For I, six rats were given a bolus intravenous injection of 1.0 mg; blood samples were taken from each rat at 0.5, 1, 2, 3, 4, and 5 hr after injection. For II, eight rats received 1.25 mg iv; blood samples were taken at 0.5, 1, 1.75, 2.5, 3.25, 4, and 4.75 hr after injection. Samples were taken and analyzed as described for the calibration experiments.

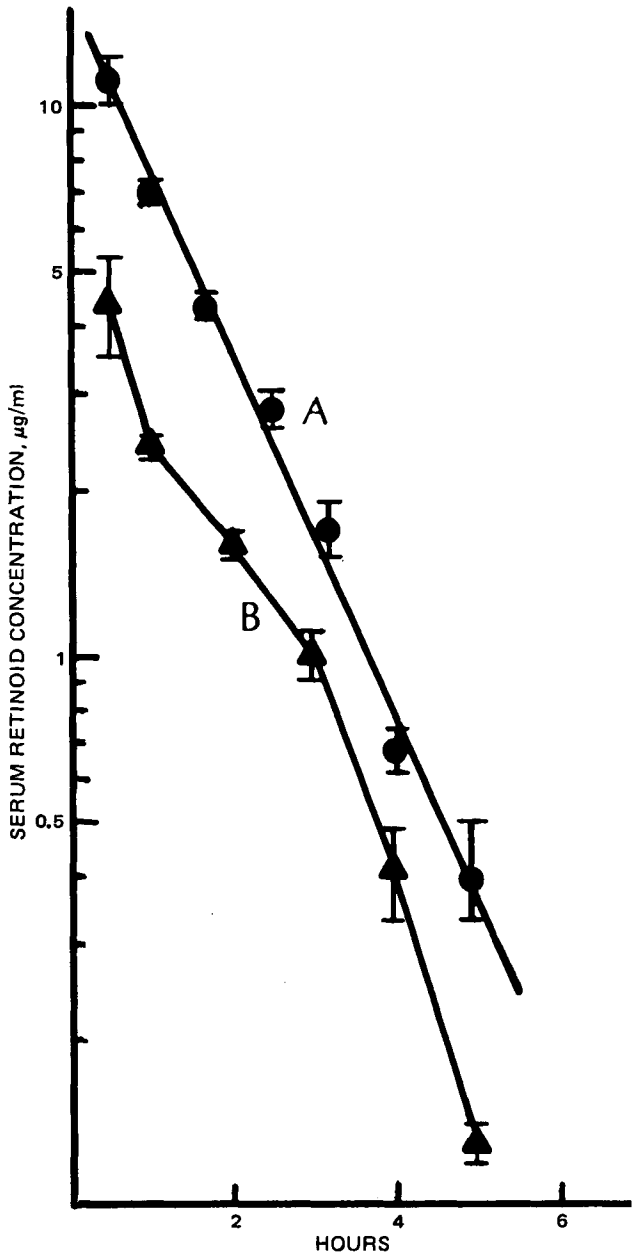

Figure 2—*Average serum concentrations of II (A) and I (B) following rapid intravenous injections of 1.25 and 1.0 mg, respectively. Each point represents data averaged from at least six rats. Bars show the standard deviation of the data.*

RESULTS AND DISCUSSION

Chromatograms of serum containing the internal standard and the internal standard plus I or II are shown in Fig. 1. All serum chromatograms showed the presence of retinol, which did not interfere with the assay. No other interfering peaks were observed.

Separation of all I from the internal standard, retinol (present in all serum samples), and the solvent front was obtained after adjusting the mobile phase of acetonitrile–1% ammonium acetate to a ratio of 75:25 (v/v) and the flow rate to 1.6 ml/min. The 1% ammonium acetate aqueous solution was needed to obtain complete separation of I from the solvent

9	750	187.5	7500	3.021 ± 0.098	2.678 ± 0.103

[a] Samples of nine were determined over 3 weeks, three samples per week. [b] Contained in 0.1 ml of rat serum. [c] Detected quantity represents the calculated theoretical quantity of retinoid injected into the chromatograph.

front (Fig. 1B). Under these conditions, the retention times for I, retinol, and III were 3.0, 3.9, and 5.9 min, respectively. In addition to the spiked serum samples, a drug-free sample was run to determine if there were any absorbing substances in the region of I (Fig. 1A). Separation of II from the internal standard, retinol, and the solvent front was achieved under the same conditions as for I (Fig. 1C). The retention time for II was 2.6 min.

The results of calibration procedures for I and II in rat serum samples are shown in Table I. Linear regression analysis of chromatogram peak height ratios of sample to standard *versus* concentration showed correlation coefficients of 0.9999 for both I and II for a sample size of 10–750 ng (100–7500 ng/ml). At a sample size of 10 ng of retinoic acid, the standard deviations for data pooled from 3 different days were ±33% for I and ±36% for II and probably represent the lower working limits for the assay. At the 80-ng sample size, reproducibility was much better, with standard deviations of 7 and 13%, respectively, for the two acids. Single-day determinations usually showed lower standard deviations.

The peak height ratios of retinoids to the internal standard at each concentration for the serum and water samples were compared to determine the percent recovery of I and II from the serum samples. The recoveries of I and II were 102.9 ± 5.6% and 91.7 ± 5%, respectively.

Figure 2 shows the applicability of the assay to monitor serum levels in rats after single doses of the retinoids. Both serum level profiles showed log-linear elimination phases with correlation coefficients of ~0.99. The elimination half-lives of I and II were 0.58 and 0.92 hr, respectively. The elimination curve for I, possibly indicating saturation or storage, tends to confirm previous observations (7).

Quantitative Analysis of Ethynodiol Diacetate and Ethinyl Estradiol/Mestranol in Oral Contraceptive Tablets by High-Performance Liquid Chromatography

G. CARIGNAN, B. A. LODGE ˣ, and W. SKAKUM

Received August 6, 1980, from the *Bureau of Drug Research, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario, K1A 0L2, Canada.* Accepted for publication July 7, 1981.

Abstract □ A procedure is described for the assay of ethynodiol diacetate and ethinyl estradiol/mestranol by HPLC using two UV detectors at 210 and 280 nm. The system was acetonitrile 38% (v/v) in water as mobile phase on a 250 × 3.2-mm i.d. RP-2 column, with butylated hydroxytoluene as the internal standard. There was >99% recovery from synthetic preparations and the coefficient of variation was <2.0% for formulations.

Keyphrases □ Oral contraceptives—quantitative analysis of ethynodiol, estradiol, and mestranol by high-performance liquid chromatography □ Ethynodiol—quantitative analysis by high-performance liquid chromatography, oral contraceptive tablets □ Ethinyl estradiol—quantitative analysis by high-performance liquid chromatography, oral contraceptive tablets □ Mestranol—quantitative analysis by high-performance liquid chromatography, oral contraceptive tablets □ High-performance liquid chromatography—quantitative analysis of ethynodiol, estradiol, and mestranol in oral contraceptive tablets

Ethynodiol diacetate is a synthetic steroid showing progestogenic activity. It is used in oral contraceptives in admixture with either ethinyl estradiol or mestranol. Compendial procedures (1–3) are limited to raw material or to single ingredient formulations, except the USP XX (1) which describes the analysis of the ethynodiol diace-

[a] Samples of nine were determined over 3 weeks, three samples per week. [b] Contained in 0.1 ml of rat serum. [c] Detected quantity represents the calculated theoretical quantity of retinoid injected into the chromatograph.

front (Fig. 1B). Under these conditions, the retention times for I, retinol, and III were 3.0, 3.9, and 5.9 min, respectively. In addition to the spiked serum samples, a drug-free sample was run to determine if there were any absorbing substances in the region of I (Fig. 1A). Separation of II from the internal standard, retinol, and the solvent front was achieved under the same conditions as for I (Fig. 1C). The retention time for II was 2.6 min.

The results of calibration procedures for I and II in rat serum samples are shown in Table I. Linear regression analysis of chromatogram peak height ratios of sample to standard *versus* concentration showed correlation coefficients of 0.9999 for both I and II for a sample size of 10–750 ng (100–7500 ng/ml). At a sample size of 10 ng of retinoic acid, the standard deviations for data pooled from 3 different days were ±33% for I and ±36% for II and probably represent the lower working limits for the assay. At the 80-ng sample size, reproducibility was much better, with standard deviations of 7 and 13%, respectively, for the two acids. Single-day determinations usually showed lower standard deviations.

The peak height ratios of retinoids to the internal standard at each concentration for the serum and water samples were compared to determine the percent recovery of I and II from the serum samples. The recoveries of I and II were 102.9 ± 5.6% and 91.7 ± 5%, respectively.

Figure 2 shows the applicability of the assay to monitor serum levels in rats after single doses of the retinoids. Both serum level profiles showed log-linear elimination phases with correlation coefficients of ~0.99. The elimination half-lives of I and II were 0.58 and 0.92 hr, respectively. The elimination curve for I, possibly indicating saturation or storage, tends to confirm previous observations (7).

tate–ethinyl estradiol mixtures.

Ethynodiol diacetate has been quantitatively assayed by argentimetric titration of its ethinyl group (2), by UV determination after its acidic conversion to a conjugated diene (1), by colorimetric reaction with antimony trichloride (3), and by GLC analysis (4).

The estrogenic components have been analyzed using such methods as argentimetry (2), colorimetry (1, 3, 5), fluorometry (2), UV spectrophotometry (6), GLC (6), TLC with fluorescent detection (7), and high-performance liquid chromatography (HPLC) (8–10).

This paper describes a simple, rapid HPLC procedure to assay quantitatively mixtures of ethynodiol diacetate with either ethinyl estradiol or mestranol using simultaneous measurements of UV absorption at 210 and 280 nm.

EXPERIMENTAL

Apparatus—A modular HPLC system consisting of a pump[1] operated at 1.75 ml/min, two variable-wavelength UV detectors (set at 210 and 280 nm, respectively)[2,3], and a 7000-psi loop injector[4] (equipped with a 20-μl loop) were used. The column (250 × 3.2-mm i.d.) was ethylsilane chemically bonded to totally porous, irregularly shaped microparticulate silica[5].

Peak retention times and areas were obtained with two reporting integrators[6].

Reagents—Ethynodiol diacetate, ethinyl estradiol, and mestranol were USP reference standards. Butylated hydroxytoluene[7] was recrystallized from methanol, acetonitrile was HPLC grade[8], and water was double-distilled in glass.

Mobile Phase—Acetonitrile 38% (v/v) in water (filtered through a membrane[9] and degassed while filtering under a vacuum not exceeding 500 mm Hg) was used.

Internal Standard Solution—A solution of butylated hydroxytoluene in aqueous acetonitrile (80% v/v) was prepared at a concentration of 50 μg/ml.

Standard Preparations—*Ethynodiol Diacetate–Ethinyl Estradiol Standard*—A solution of ethynodiol diacetate with ethinyl estradiol in internal standard solution was prepared at the same concentration as in the sample preparation (based on label claim).

Ethynodiol Diacetate–Mestranol Standard—A solution of ethynodiol diacetate with mestranol in internal standard solution was prepared at the same concentration as in the sample preparation (based on label claim).

Sample Preparation—Not less than 20 tablets were weighed and finely powdered (60 mesh). An amount of powder equivalent to one tablet was accurately weighed into a 15-ml centrifuge tube with a polytef-lined cap. Two milliliters of internal standard solution were added. The tube was capped and vigorously shaken for 30 min. The tube was then centrifuged to obtain a clear solution.

Table II—Standard Curves for Ethinyl Estradiol, Mestranol, and Ethynodiol Diacetate

Steroid	Weight Range Injected, mg	Wavelength, nm	Curve, $y = mx + b$	Correlation Coefficient
Ethinyl estradiol	0.2–1.2	210	0.827×-0.003	0.9999
		280	0.835×-0.022	0.9998
Mestranol	0.2–1.2	210	$0.895 \times +0.002$	0.9996
		280	0.784×-0.013	0.9998
Ethynodiol diacetate	2.0–12	210	0.303×-0.007	0.9999

Recovery Study—Sufficient inert materials (4.67 g of lactose, 4.67 g of cornstarch, 0.5 g of povidone, 0.1 g of calcium stearate) to make a total weight of 10 g (after drying) were added to a solution in 10 ml of alcohol of about 2.5 mg of ethinyl estradiol, 5.0 mg of mestranol, and 50.0 mg of ethynodiol diacetate, each accurately weighed. This mixture was shaken to homogenize, then dried at room temperature using reduced pressure.

A 200-mg portion of this synthetic preparation was treated as in sample preparation.

Procedure—Aliquots (20 μl) of standard preparation or sample preparation (synthetic preparation) were successively injected into the chromatograph. The peak area ratios of ethynodiol diacetate and the estrogen to the internal standard were calculated on the 210-nm detector and the peak area ratio of the estrogen to internal standard was calculated on the 280-nm detector for both standard and sample preparations. The quantities of active ingredients per tablet were calculated using the following formula:

$$C_u = 2 \times C_s \times \frac{R_u}{R_s} \times \frac{W_t}{W_u} \qquad \text{(Eq. 1)}$$

where:

C_u = active ingredient per tablet, milligrams
C_s = concentration of active ingredient in standard preparation, milligrams per milliliter
R_u = area ratio of active ingredient to internal standard in sample preparation
R_s = area ratio of active ingredient to internal standard in standard preparation
W_u = weight of sample taken, milligrams
W_t = average weight per tablet, milligrams

RESULTS AND DISCUSSION

All chromatograms were as expected with respect to the shape of the peaks, and complete baseline resolution was achieved between the solvent front, ethinyl estradiol, mestranol, internal standard, and ethynodiol diacetate (Table I). An unidentified impurity definitely not either of the monoacetates (as determined by basic degradation) or either of the diene degradation products (as determined by acidic degradation), was detected while analyzing the ethynodiol diacetate–ethinyl estradiol formulations. It had a retention close to that of mestranol. Several solvent systems on different reversed-phase columns failed to improve separation. Spectrometric study showed its absorption maximum was at ~235 nm with no absorption at 280 nm. This impurity was found in all commercial formulations studied (two manufacturers), and it appeared to be an ethynodiol diacetate degradation product.

To overcome the problem of the same impurity (No. 1, Table I) appearing in ethynodiol diacetate–mestranol formulations, detection using 280-nm wavelength seemed more appropriate for the estrogenic component. However, since ethynodiol diacetate has no measurable absorbance at 280 nm, it was necessary to use 210 nm for its determination. A second impurity (K^1 = 11.62) did not conflict with other components in the mixture.

Linearity of response *versus* concentration was studied for the three steroids at both wavelengths (Table II). All standard curves were found to be linear in the concentration ranges studied and passed close to the origin. Their correlation coefficients were nearly ideal (>0.9996).

Table III shows the accuracy of the procedure for a synthetic preparation. Recovery was >98% for each steroid at its determination wavelength, and reproducibility was excellent (*RSD* <1.3%).

Quantitative analysis of three commercial dosage forms are listed in Table IV. All results are within compendial limits (90–110%). Coefficients of variation are <2.0%. A difference of 2.4% is reported for mestranol

Table III—Recovery of Steroids from a Synthetic Preparation

Steroid	Added, μg	Recovery at 210 nm[a] μg	%	CV	Recovery at 280 nm[a] μg	%	CV

analyses between the two wavelengths used, whereas analysis of the synthetic formulation revealed a variation of 0.8%, which is relatively minor. Variations reported for ethinyl estradiol (~1.5%) are the same for tablets and the synthetic formulation.

CONCLUSIONS

This HPLC procedure, using dual wavelength detection, is fast and accurate. It has been specially designed for single dosage form analysis as required in the USP–NF content uniformity test, and would advantageously replace the long, open-column chromatography procedure.

Effect of the pH–Zero Point of Charge Relationship on the Interaction of Ionic Compounds and Polyols with Aluminum Hydroxide Gel

DHIREN N. SHAH *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received December 12, 1980, from the **Department of Industrial and Physical Pharmacy and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication June 26, 1981.

Abstract □ The adsorption of magnesium nitrate, docusate sodium, and mannitol by chloride-containing aluminum hydroxide gel or aluminum hydroxycarbonate gel can be directly related to the surface charge characteristics of the aluminum hydroxide gel as determined by the pH–zero point of charge (ZPC) relationship. Magnesium cation is completely adsorbed under pH conditions where the gel has a negative surface charge, *i.e.*, when the pH is above the ZPC. Docusate sodium is more strongly adsorbed when the pH–ZPC relationship causes the surface charge of aluminum hydroxycarbonate gel to be positive indicating adsorption of the docusate anion. However, adsorption also occurred when the pH was above the ZPC suggesting that adsorption of the hydrophobic portion of docusate anion by van der Waals forces also contributes to the overall adsorption mechanism. Mannitol is adsorbed under all pH conditions. However, greater adsorption occurs when the pH is above the ZPC. Maximum hydrogen bonding is believed to occur when mannitol acts as the proton donor and the negative aluminum hydroxycarbonate gel surface serves as the proton acceptor.

Keyphrases □ Aluminum hydroxide—gel, adsorption of ionic compounds and polyols, effect of pH–zero point of charge □ Aluminum hydroxycarbonate—gel, adsorption of ionic compounds and polyols, effect of pH–zero point of charge □ Adsorption—ionic compounds and polyols to aluminum hydroxide and aluminum hydroxycarbonate, effect of pH–zero point of charge

The zero point of charge (ZPC) is an important property of colloidal systems possessing a pH-dependent surface charge. The ZPC is the pH at which the net surface charge is zero; at this pH the densities of the positive and negative charges are equal. The apparent surface charge can be controlled by adjusting the pH to be either below or above the ZPC to produce a positive or negative surface charge, respectively (1). Figure 1—*Effect of pH on the fraction of magnesium cation bound by a chloride-containing aluminum hydroxide gel.*

tant effect which the relationship between pH and ZPC exerts on the physical properties of aluminum hydroxide gel (2). The present study investigates the influence that the surface charge characteristics of aluminum hydroxide and aluminum hydroxycarbonate gel have on the adsorption of ionic solutes such as magnesium nitrate or docusate sodium as well as mannitol, a neutral polyol.

EXPERIMENTAL[1]

The chloride-containing aluminum hydroxide gel was prepared by reacting aluminum chloride and potassium hydroxide as described previously (2). The ZPC of this gel was determined by a titration procedure (2) and was found to be 9.65. The bulk pH was 8.00 when diluted with distilled water to 3% equivalent aluminum oxide. Two aluminum hydroxycarbonate gels were obtained commercially. Aluminum hydroxycarbonate gel number 1 had a ZPC of 6.95 and a bulk pH of 6.5 at 3% equivalent aluminum oxide, while gel 2 had a ZPC of 6.32 and a bulk pH of 6.25 under the same conditions.

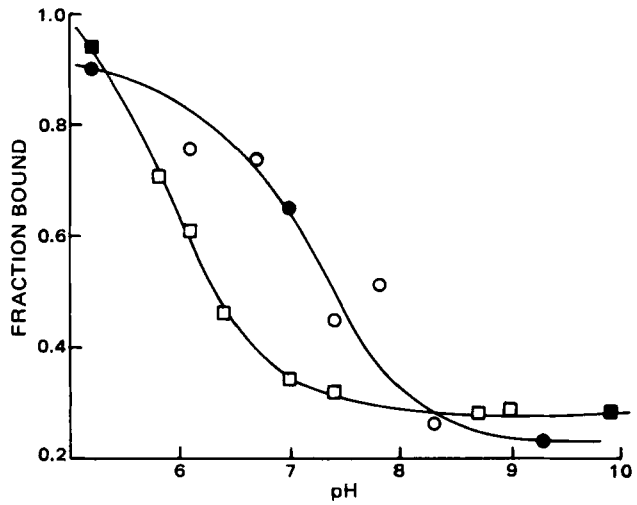

Figure 2—*Effect of pH on the fraction of docusate anion bound by gel 1 (○, ●) and gel 2 (□, ■). The open data points were determined without adjusting the ionic strength and the closed data points were determined at a constant ionic strength of* 5×10^{-3}.

[1] All chemicals used were either official or reagent grade.

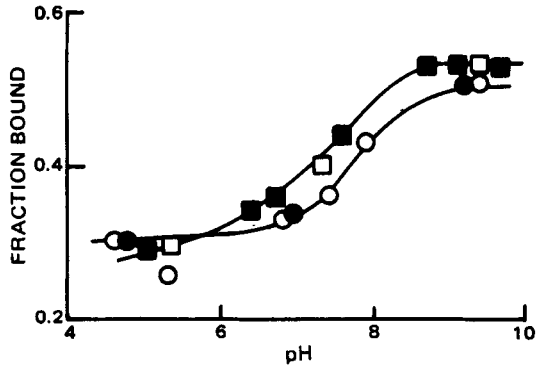

Figure 3—*Effect of pH on the fraction of mannitol bound by gel 1 (○, ●) and gel 2 (□, ■). The open data points were determined without adjusting the ionic strength and the closed data points were determined at a constant ionic strength of* 5×10^{-3}.

The fraction of magnesium nitrate, docusate sodium, or mannitol adsorbed by the aluminum hydroxide gel at different pH conditions was determined by first adjusting portions of the gel to the desired pH by addition of 0.1 *N* HCl or 0.1 *N* KOH. The maximum change in ionic strength due to the pH adjustment was 5×10^{-3}. A second series of samples was prepared at an ionic strength of 5×10^{-3} by adding an appropriate quantity of potassium chloride to each sample following pH adjustment. No significant difference in adsorption was observed between the first series in which the ionic strength varied up to 5×10^{-3} and the second series in which all samples had an ionic strength of 5×10^{-3}. Adsorption is normally related to ionic strength, but the small quantities of acid or base needed to adjust the pH did not cause a large enough ionic strength differential to significantly affect adsorption. Thus, the data at constant and variable ionic strength were pooled.

Following pH adjustment, an adsorbate solution was added to produce a mixture containing 9.8×10^{-2} *M* equivalent aluminum oxide and either 6×10^{-4} *M* $Mg(NO_3)_2$, 3.2×10^{-4} *M* docusate sodium, or 3×10^{-2} *M* mannitol. The docusate sodium concentration was selected to be below the critical micelle concentration which was reported to be 6.8×10^{-4} *M* in water (3). The mixtures were equilibrated by shaking at 25° for 2 hr, the pH was determined, the sample was centrifuged at 15,000 rpm (27,000 × *g*) for 30 min, and the supernate was analyzed. Magnesium was determined by chelatometric titration (4), docusate sodium was determined by the official assay (5), and mannitol was determined by a microcolorimetric method (6).

RESULTS AND DISCUSSION

The fraction of magnesium cation adsorbed by the chloride-containing aluminum hydroxide gel was strongly pH dependent (Fig. 1). Virtually no adsorption occurred below pH 8, while complete adsorption of magnesium cation occurred at pH 11. It is interesting to note that 50% of the magnesium cation was adsorbed at pH 9.65 which corresponds to the ZPC of the chloride-containing aluminum hydroxide gel. Thus adsorption of magnesium cation can be directly related to the surface charge as predicted from the pH–ZPC relationship. At pH conditions below the ZPC, the positively-charged aluminum hydroxide surface will not interact with the magnesium cation, while a strong attraction occurs when the pH is above the ZPC, producing a negative surface charge. A sigmoidal adsorption curve is commonly observed for the adsorption of transition metal ions on various metal oxide surfaces (7, 8).

The adsorption of the anionic surface active agent, docusate sodium, is somewhat more complex, but a strong dependence on the pH–ZPC relationship is evident in Fig. 2. Gel 1 had a ZPC of 6.95, while the ZPC of gel 2 was 6.32. In both cases, the ZPC corresponded approximately with the midpoint of the fraction bound curve with greater adsorption occurring when the pH was below the ZPC. However, a minimum of ~20% of the docusate anion was adsorbed even under pH conditions where the apparent surface charge of the aluminum hydroxycarbonate gel was negative.

Although docusate sodium is known to hydrolyze in alkaline solutions (9), the amount of degradation occurring at pH 10 during 4 hr (the time required for the fraction bound study) was negligible. It is believed that adsorption of the hydrophobic portion of docusate anion occurred even though repulsive forces exist between the negatively-charged hydrophilic

portion of docusate anion and the negatively-charged aluminum hydroxycarbonate surface.

The adsorption of polyols, although occurring by hydrogen bonding rather than electrostatic attraction (10, 11), was also affected by the pH–ZPC relationship (Fig. 3). The extent of mannitol adsorption by either gel 1 or 2 is much less than was observed for the adsorption of the magnesium cation or the docusate anion, reflecting the weaker adsorption mechanism of hydrogen bonding in comparison to electrostatic attraction. However, the fraction of mannitol adsorbed increased from ~30% at pH conditions below the ZPC to 50% when the pH was above the ZPC. Hydrogen bonding occurs more readily when mannitol serves as the proton donor and the negatively-charged oxygen at the aluminum hydroxycarbonate gel surface serves as the proton acceptor. This condition exists when the pH is above the ZPC and coincides with the region of maximum adsorption of mannitol.

The results of this study suggest that the pH–ZPC relationship will provide a useful guideline for predicting adsorption reactions in the formulation of antacid dosage forms and may also be useful in predicting drug interactions arising from the coadministration of drugs and aluminum hydroxide-containing antacids.

TLC and GLC Determination of Aromatic Amine Impurities in Bulk *p*-Aminobenzoic Acid and in Its Potassium and Sodium Salts

Keyphrases □ *p*-Aminobenzoic acid—aromatic amine impurities determined by GLC and TLC □ TLC—determination of aromatic amine impurities in *p*-aminobenzoic acid □ GLC—determination of aromatic amine impurities in *p*-aminobenzoic acid

To the Editor:

The current USP monograph (1) for *p*-aminobenzoic acid lacks a requirement for limiting the amount of aromatic amine impurities in the finished bulk drug. The carcinogenicity of these possible amine impurities prompted this laboratory to adapt the derivatization and GLC technique of Bruce and Maynard (2) to identify and quantitate these compounds. A TLC confirmatory test using a portion of the underivatized sample solution was also developed.

A finely ground 5-g sample of bulk *p*-aminobenzoic acid or its salts, in a 50-ml stoppered centrifuge tube, was extracted by shaking with 25 ml of benzene for 5 min. After centrifuging, the benzene layer was transferred to a separator and extracted with two 15-ml portions of 2% aqueous sodium bicarbonate. The aqueous layers were discarded, and the benzene layer was dried through anhydrous sodium sulfate.

A 2-ml portion of the extract was derivatized in a separator with 25 μl of heptafluorobutyric anhydride. After 30 min at room temperature, 10 ml of benzene was added, the organic layer was washed with three 10-ml portions of water, and the water was discarded. The benzene layer was diluted to 50 ml with benzene and 5 μl was injected into a gas chromatograph equipped with a 15-μCi ^{63}Ni-electron-capture detector, a 1.8 m × 4-mm i.d. spiral glass tube packed with 6% OV-101 and 9% OV-210 (1:1) coated on acid-washed silanized high-performance flux calcined diatomite support (100–120 mesh). Inlet, column, and detector temperatures were 225, 140, and 325°, respectively. Argon–methane (95:5) at a flow rate of 50 ml/min was used as the carrier gas.

For TLC, 5 ml of the dried benzene sample extract was evaporated to 200 μl, and 20 μl was applied to a silica gel GF plate. After 10-cm development with benzene–ethyl acetate–acetic acid (90:5:5), the plate was sprayed with 1% *p*-dimethylaminobenzaldehyde in ethanol containing 5% HCl.

sponding heptafluorobutyric anhydride derivatives are also reported with the approximate nanogram amounts of the parent amine needed for half-scale deflection at the electron-capture detector settings.

Eight samples of *p*-aminobenzoic acid, two samples of its sodium salt, and one sample of its potassium salt were analyzed in duplicate. Salt forms from three different lots contained no detectable aromatic amine impurities. Four of the acid samples contained benzocaine at levels of 3–65 ppm, while one sample of the acid contained 25 ppm of aniline. The TLC procedure confirmed the presence of both amine impurities. The derivatized samples were analyzed by GC–mass spectrometry and the mass spectral patterns of the samples matched those of derivatized standards of aniline and benzocaine.

The presence of benzocaine as an impurity was unexpected and cannnot be explained without knowledge of the synthesis process employed by the manufacturer. The aniline found in one sample could have been a contaminant of toluene used as a starting material for the synthesis of the *p*-aminobenzoic acid. The presence of aniline is significant because of its possible harmful effects on the body.

In synthesizing *p*-aminobenzoic acid, the process usually starts with toluene, followed by nitration, reduction, and oxidation reactions. The reported analytical procedure will determine the primary aromatic amine impurities formed in the synthesis of *p*-aminobenzoic acid or its salts. The 10 amines listed in Table I were added at levels of 1–5 ppm to the uncontaminated lots of free acid and recoveries of 90% or better were achieved using the derivatization technique.

The Antitumor and Mammalian Xanthine Oxidase Inhibitory Activity of 5-Methyl-6-substituted Pyrrolo(2,3-*d*)pyrimidine-2,4-diones

Keyphrases □ Antitumor agents—potential, 5-methyl-6-substituted pyrrolo(2,3-*d*)pyrimidine-2,4-diones □ Xanthine oxidase—potential inhibitors, 5-methyl-6-substituted pyrrolo(2,3-*d*)pyrimidine-2,4-diones

To the Editor:

Gout is a disease that is a consequence of hyperuricemia. The objective of drug therapy in gout is to ameliorate inflammatory arthritis and to control serum urate concentration to <6 mg/100 ml. The two drug treatments currently used to decrease urate levels are the blocking of uric acid renal tubular reabsorption with probenecid or sulfinpyrazone and to block the enzymatic activity of xanthine oxidase. This enzyme catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid.

Table I—The Xanthine Oxidase Inhibitory Constant (K_i) of 5-Methyl-6-substituted Pyrrolo(2,3-*d*)pyrimidine-2,4-diones and Allopurinol

R[a]	K_i[b], *M*
$-CH_3$	1.5×10^{-5}
$-C_2H_5$	*NA*[c]
$-CH_2CH(CH_3)_2$	*NA*
$-C_6H_5$	4.0×10^{-6}
$-CH_2C_6H_5$	*NA*
$-CH_2C_6H_4$-*p*-OH	*NA*
Allopurinol	8.0×10^{-8}

[a] R refers to structure II in the text. [b] Inhibitory constant. [c] No activity.

Allopurinol (I) is used currently as a xanthine oxidase inhibitor. A series of substituted pyrrolo(2,3-*d*)pyrimidine-2,4-diones (II) was synthesized (1) and tested for inhibition of xanthine oxidase activity. A drug as potent as allopurinol would provide an alternative therapy for the gout patient.

The activity of buttermilk xanthine oxidase (1, 2) was measured *in vitro* by a previous method (2). [The activity of xanthine oxidase from humans is similar to that obtained from cow's milk (2).] The assay was performed at pH 8.0 in 0.1 *M* sodium phosphate buffer. Allopurinol[1], the pyrrolo(2,3-*d*)pyrimidine-2,4-diones, and hypoxanthine[2] were dissolved in 0.1 *M* sodium phosphate buffer, pH 8.0. Uric acid production was monitored at 300 nm in a UV spectrophotometer[3] at 36° after 1 μl (0.035 units) of xanthine oxidase was added to each reaction mixture. The hypoxanthine concentration varied from 0.06 to 0.10 m*M*, and the inhibitor concentration varied from 0 to 5×10^{-2} m*M*. The inhibitor constant (K_i) for each drug was determined by using a Dixon plot where 1/Vr is plotted against inhibitor concentration (3). Allopurinol was used as the standard xanthine oxidase inhibitor.

Table I lists the K_i for allopurinol and the six pyrrolo(2,3-*d*)pyrimidine-2,4-diones that were tested. Only two of the tested compounds showed any *in vitro* inhibition. The phenyl substituted compound had the most activity but it was low compared to allopurinol.

Because of the similarity of these compounds to normal purines, one compound, 5,6-dimethylpyrrolo(2,3-*d*)-pyrimidine-2,4-dione, was tested for *in vivo* activity against two transplantable mouse lymphoid tumor systems: H-5 ascites tumor[4] in A/J male mice[5] and L-1210 leukemia[6] in $B6D2F_1$ male mice[5].

Ascites fluid (0.1 ml) from a tumor-bearing mouse and containing 10^5 cells[7] was injected intraperitoneally on day zero. Each experimental group contained six male mice (20–25 g) (4). The drug was injected intraperitoneally on days 1, 5, and 9 at a 120-mg/kg dose. The T/C was 85.4% for the L-1210 leukemia and 83.5% for the H-5 ascites tumor. A 360-mg/kg dose at day 1 or 40 mg/kg on days 1–9 in the L-1210 tumor also gave a T/C of 85.4%. A T/C value ≤85% indicates that the compound is probably producing a toxic response (4). This compound did not cause any deaths in control A/J or $B6D2F_1$ mice at the doses used, nor did it cause any visible toxicity, such as weight loss.

The probable toxic response of this compound in tumor-bearing mice hindered the testing of other substituted pyrrolo(2,3-*d*)pyrimidine-2,4-diones for antitumor activity.

Studies on Herbal Remedies I: Analysis of Herbal Smoking Preparations Alleged to Contain Lettuce (*Lactuca sativa* L.) and Other Natural Products

Keyphrases □ Pharmacognosy—analysis of smoking preparations alleged to contain lettuce (*Lactuca sativa* L.) □ Psychotropics—alleged, analysis of lettuce (*Lactuca sativa* L.) in smoking preparations

To the Editor:

In this communication we would like to draw attention to the availability in health food stores and other outlets of three so-called "narcotic substitute" smoking products[1] that allegedly contain distillates of lettuce. Preparation 1 ("Hashish") and preparation 2 ("Opium") are recommended by their manufacturer for legal, social smoking, while preparation 3 ("Hash Oil") is suggested for application to marijuana cigarettes to enhance potency and taste. According to the package inscriptions, all three preparations contain "*Lactuca sativa*" (Garden Lettuce) and "*Turnera diffusa*" (Damiana) distillates. In addition, preparation 1 is claimed to be fortified with African Yohimbe bark, and preparation 2 with *Lactuca virosa* (Wild Lettuce) and *Nepeta cataria* (Catnip) distillates, as well as Chinese ginseng root. Ingredient proportions are not stated on the package labels.

It was suggested to us[2] that the smoking of preparation 2, without additives, may have been responsible for producing apparent psychotropic effects experienced by two teenagers. In an attempt to provide a rationale for this observation, the literature was searched for any ethnomedical and biological activities of Garden and Wild Lettuce and Damiana, and to whether or not any of the known constituents of these plants belong to classes of psychotropic substances.

Extracts of both *L. sativa* and *L. virosa* have been claimed to possess narcotic properties (1, 2), while the latter plant has been associated with hypnotic and sedative effects (3). Experimentally, extracts of *L. sativa* have exhibited *in vitro* antitubercular properties (4) and hypotensive activity in dogs (5). *T. diffusa* extracts reputedly show mild stimulant (2), purgative (3), and aphrodisiac (1, 3) activities.

An early study indicated that *L. sativa* and *L. virosa* contain a mydriatic alkaloid, which was identified as the tropane derivative hyoscyamine on the basis of the melting point of its aurochloride (6). The presence of a mydriatic alkaloid, although disputed, was presumably confirmed in later studies on *L. virosa* (7, 8). *L. virosa* has been shown to contain *N*-methyl-β-phenethylamine (9), and *T. diffusa* has been stated to contain the xanthine derivative, caffeine (10). Tropane alkaloids, phenethylamines, and xanthines were recently classified, respectively, as deliriant psychodysleptics, visionary psychodysleptics, and excitatory psychoanaleptics (11).

All three preparations were examined phytochemically to determine if any of these amines could be detected. Three extraction procedures, namely, a general alkaloidal method (12), and methods for the specific extraction of phenethylamines (13) and caffeine (14), were applied to 2-g portions of each product. No alkaloidal spots corresponding to reference hyoscyamine, *N*-methyl-β-phenethylamine[3], or caffeine were detected by TLC on silica gel using several solvent systems (15). Dragendorff's reagent, as well as other reagents useful for the detection of phenethylamines (ninhydrin) (15) and xanthines (iodine and ferric chloride) (15) were used for plate visualization.

Therefore, it appears that any psychotropic effects experienced by the smoking of these lettuce-Damiana distillates are not due to the presence of tropane alkaloids, phenethylamines, or xanthine bases.

Ascites fluid (0.1 ml) from a tumor-bearing mouse and containing 10^5 cells[7] was injected intraperitoneally on day zero. Each experimental group contained six male mice (20–25 g) (4). The drug was injected intraperitoneally on days 1, 5, and 9 at a 120-mg/kg dose. The T/C was 85.4% for the L-1210 leukemia and 83.5% for the H-5 ascites tumor. A 360-mg/kg dose at day 1 or 40 mg/kg on days 1–9 in the L-1210 tumor also gave a T/C of 85.4%. A T/C value ≤85% indicates that the compound is probably producing a toxic response (4). This compound did not cause any deaths in control A/J or $B6D2F_1$ mice at the doses used, nor did it cause any visible toxicity, such as weight loss.

The probable toxic response of this compound in tumor-bearing mice hindered the testing of other substituted pyrrolo(2,3-*d*)pyrimidine-2,4-diones for antitumor activity.

Burger's Medicinal Chemistry, 4th Ed., Part III. Edited by MANFRED E. WOLFF. Wiley, 605 Third Ave., New York, NY 10016. 1981. 1354 pp. 18.5 × 26 cm. Price $100.00.

This book is part of an excellent series in the medicinal chemistry field. With contributions by a number of knowledgeable and literate authors, the contents include drugs acting on the central nervous system, the autonomic nervous system, the cardiovascular system, and the renal system. The book is a well-balanced blend of the theoretical and practical aspects of the field and its potential application to new discoveries.

Each chapter is well planned, emphasizes biochemical rationale, structure–function relationships, and metabolism, and is adequately referenced to provide the reader with sources of more detailed information. This text is also characterized by thoughtful attention to pedagogy, since the prose does more than fill the space between structures and equations. The book contains many useful tables, graphs, and other illustrations and is replete with numerous structures.

Professor Wolff has assembled an informative and excellent text, so it is regrettable that the major limitation of this potentially useful text appears to be its price. Overall, the present volume together with Parts I and II of the series offers a high quality and useful source of information with broad application across the biomedical sciences. Professor Wolff upholds the series' reputation as one of the classic and indispensable reference works for those in teaching and research.

Principles of Medicinal Chemistry. Edited by WILLIAM O. FOYE. Lea & Febiger, 600 S. Washington Square, Philadelphia, PA 19106. 1981. 931 pp. 18 × 26 cm. Price $45.50. (Canada $54.50).

This book assembles 39 chapters of information associated with textbooks intended for undergraduate courses in organic medicinal chemistry. The first six chapters give effective coverage of general introductory principles; thereafter, with the exception of Chapters 27–29 (which provide good introductions to drugs of plant origin and subsequent chapters on chemotherapeutic agents), the book proceeds systematically through major pharmacological or therapeutic classes of drugs.

Discussions are generally restricted to organic agents, although actions of some inorganic agents such as iodine and iodides, sodium nitroprusside, and gold sodium thiosulfate are cited. The last chapter is also an exception to the overall organic medicinal chemical content in that it incorporates a very good introduction to radiopharmaceuticals. Finally, there is an appendix containing useful compilations of pKa values for a number of drugs and pH values for body fluids.

The authors of the chapters dealing with the pharmacological classes of agents have used a variety of formats to cover their topics. In general, they discuss pharmacological actions, absorption, distribution, metabolism and excretion, clinical uses, and structure–activity relationships and give appropriate examples. Often this information is set out against a background survey of biochemistry pertaining to the group under consideration. In some of these chapters, the explanations of the agents' pharmacological actions, based on the structural reasons for their ability to fit into a biochemical sequence, are impressive. The overall quality of these chapters, despite differing organizational styles, is very good.

While the individual chapters impress as compact, self-contained entities, some readers may notice instances of redundancy. For example, the scheme for catabolism for certain neurotransmitters is repeated in detail in several chapters and the pharmacology of a number of therapeutic agents is given several times. It is possible that such repetition cannot be avoided in a multiauthored work. In addition, while background pharmacology, biochemistry, and the clinical uses of the agents are almost always thoroughly treated, chemical properties such as acidity, basicity, and chemical stability are sometimes not discussed. Perhaps inclusion of such coverage would not only help students appreciate some pharmaceutically important properties but would also help them relate structure and chemical properties to absorption, distribution, metabolism, excretion, and biological actions.

In summary, all chapters bear evidence of careful scholarly preparation. They are generally thorough and current in their coverage and are quite readable. The book meets its objectives very well and should afford excellent reading for medicinal chemists, pharmacologists, and students in pharmacy and related disciplines.

Toxicants and Drugs: Kinetics and Dynamics. By ELLEN J. O'FLAHERTY. Wiley, 605 Third Ave., New York, NY 10016. 1981, 398 pp. 16 × 24 cm. Price $42.50.

This useful book approaches a complex subject with a disarming frankness not usually found in such texts. In the preface, the author states that the first chapter reviews algebra and calculus at a level designed to give nonmathematicians—even antimathematicians!—confidence that they can "do" kinetics. After hopefully instilling such confidence and expertise, the reader is eventually lead into sophisticated concepts relating to disposition in saturable and nonlinear systems, the plateau principle of chronic exposure, receptor theory, pharmacodynamics and dose–response relationships. The book is a gem. A useful list of definitions of various symbols is included as a separate section and as an added bonus, a number of interesting problems taken from examples in the

BOOKS

REVIEWS

Burger's Medicinal Chemistry, 4th Ed., Part III. Edited by MANFRED E. WOLFF. Wiley, 605 Third Ave., New York, NY 10016. 1981. 1354 pp. 18.5 × 26 cm. Price $100.00.

This book is part of an excellent series in the medicinal chemistry field. With contributions by a number of knowledgeable and literate authors, the contents include drugs acting on the central nervous system, the autonomic nervous system, the cardiovascular system, and the renal system. The book is a well-balanced blend of the theoretical and practical aspects of the field and its potential application to new discoveries.

Each chapter is well planned, emphasizes biochemical rationale, structure–function relationships, and metabolism, and is adequately referenced to provide the reader with sources of more detailed information. This text is also characterized by thoughtful attention to pedagogy, since the prose does more than fill the space between structures and equations. The book contains many useful tables, graphs, and other illustrations and is replete with numerous structures.

Professor Wolff has assembled an informative and excellent text, so it is regrettable that the major limitation of this potentially useful text appears to be its price. Overall, the present volume together with Parts I and II of the series offers a high quality and useful source of information with broad application across the biomedical sciences. Professor Wolff upholds the series' reputation as one of the classic and indispensable reference works for those in teaching and research.

Principles of Medicinal Chemistry. Edited by WILLIAM O. FOYE. Lea & Febiger, 600 S. Washington Square, Philadelphia, PA 19106. 1981. 931 pp. 18 × 26 cm. Price $45.50. (Canada $54.50).

This book assembles 39 chapters of information associated with textbooks intended for undergraduate courses in organic medicinal chemistry. The first six chapters give effective coverage of general introductory principles; thereafter, with the exception of Chapters 27–29 (which provide good introductions to drugs of plant origin and subsequent chapters on chemotherapeutic agents), the book proceeds systematically through major pharmacological or therapeutic classes of drugs.

Discussions are generally restricted to organic agents, although actions of some inorganic agents such as iodine and iodides, sodium nitroprusside, and gold sodium thiosulfate are cited. The last chapter is also an exception to the overall organic medicinal chemical content in that it incorporates a very good introduction to radiopharmaceuticals. Finally, there is an appendix containing useful compilations of pKa values for a number of drugs and pH values for body fluids.

The authors of the chapters dealing with the pharmacological classes of agents have used a variety of formats to cover their topics. In general, they discuss pharmacological actions, absorption, distribution, metabolism and excretion, clinical uses, and structure–activity relationships and give appropriate examples. Often this information is set out against a background survey of biochemistry pertaining to the group under consideration. In some of these chapters, the explanations of the agents' pharmacological actions, based on the structural reasons for their ability to fit into a biochemical sequence, are impressive. The overall quality of these chapters, despite differing organizational styles, is very good.

While the individual chapters impress as compact, self-contained entities, some readers may notice instances of redundancy. For example, the scheme for catabolism for certain neurotransmitters is repeated in detail in several chapters and the pharmacology of a number of therapeutic agents is given several times. It is possible that such repetition cannot be avoided in a multiauthored work. In addition, while background pharmacology, biochemistry, and the clinical uses of the agents are almost always thoroughly treated, chemical properties such as acidity, basicity, and chemical stability are sometimes not discussed. Perhaps inclusion of such coverage would not only help students appreciate some pharmaceutically important properties but would also help them relate structure and chemical properties to absorption, distribution, metabolism, excretion, and biological actions.

In summary, all chapters bear evidence of careful scholarly preparation. They are generally thorough and current in their coverage and are quite readable. The book meets its objectives very well and should afford excellent reading for medicinal chemists, pharmacologists, and students in pharmacy and related disciplines.

In the preface, the author states that the first chapter reviews algebra and calculus at a level designed to give nonmathematicians—even antimathematicians!—confidence that they can "do" kinetics. After hopefully instilling such confidence and expertise, the reader is eventually lead into sophisticated concepts relating to disposition in saturable and nonlinear systems, the plateau principle of chronic exposure, receptor theory, pharmacodynamics and dose–response relationships. The book is a gem. A useful list of definitions of various symbols is included as a separate section and as an added bonus, a number of interesting problems taken from examples in the

literature are provided at the end of each chapter. Some helpful hints but no answers are given, however.

No doubt pharmacokineticists will differ with the author in some of her interpretations, but this should not be viewed as particularly unusual nor detrimental. No one, however, could argue with the avowed purpose of the book, which is "to bridge the gap between pure mathematical theory, at the one extreme, and the indiscriminate application of simple standard models to data that they may not adequately describe, at the other." To this end, the author has made a notable contribution. Researchers in pharmacology, toxicology, and drug metabolism will find it a valuable addition to their bookshelf.

Psychotropic Drugs. Plasma Concentration and Clinical Response. Edited by GRAHAM D. BURROWS and TREVOR R. NORMAN. Dekker, 270 Madison Ave., New York, NY 10016. 1981. 528 pp. 15 × 23 cm. Price $68.00 (20% higher outside the U.S. and Canada).

This book is well written and highly readable, with an avowed purpose of presenting all evidence, pro and con, of the relationship between plasma concentrations and clinical response of psychotropic drugs. Never mind that we have to wait until Chapter 5 before the question is first addressed—the preceding chapters are useful summaries of the mechanism of action, methodology, and pharmacokinetics of tricyclic antidepressants and antipsychotic agents.

If this puts the reader in a mood to skip around before settling down to read the book straight through, then he or she may as well read the last chapter first—a perceptive overview of the subject by Hollister. His rather pessimistic estimation of the value of measuring plasma concentrations may disappoint some readers, but be sure to judge his reasons fairly before dismissing his conclusions. We learn, for example, that the rationale behind measurement of plasma concentrations of antianxiety drugs has been for pharmacokinetics and not for monitoring treatment. This is corroborated in the chapter on benzodiazepines.

Perusal of the remaining chapters in this interesting book—on zimelidine, lithium, antipsychotic agents, butyrophenones, sedatives, hypnotics, and anticonvulsants—is revealing since, with only one exception, the various authors conclude that the relationships between plasma concentration and clinical response showed "no consensus," were "questionable" or "futile," or "correlate poorly" or that the measurements were "naive" or "uninformative." The exception is, of course, lithium. This all might make one long for the simpler days of the sulfonamides and clear correlations between plasma concentrations, therapeutic response, and side effects.

As minor criticisms of the book, this reviewer found Chapter 8 on chlorpromazine to be too exhaustive in its historical treatment and too vituperative in defense of the author's own analytical method. In addition, separate chapters on zimelidine and pharmacokinetics of tricyclic antidepressants and cerebrospinal fluid seem unnecessary.The terminology "plasma levels" also appears, which smacks of jargon, yet attempts to eliminate it will be a losing battle.

The book, in general, will be valuable to pharmacologists, clinicians, drug metabolism scientists, and analytical chemists in this field.

Adrenergic Activators and Inhibitors. Part II. (Handbook of Experimental Pharmacology, Vol. 54/II.) Edited by L. SZEKERES. Springer-Verlag, 44 Hartz Way, Secaucus, NJ 07094. 1981. 936 pp. 17 × 25 cm. Price $224.20.

This book is the second part of the latest volume in the well-known *Handbook* series and contains two sections and 14 chapters. The first section covers the effects of autonomic drugs on organ systems other than the nervous and cardiovascular systems. There are chapters on the respiratory system, skeletal muscles, digestive system, endocrine glands, genitals, kidneys, urinary tract, eyes, and sweat glands. The second section covers kinetics, toxic effects, biotransformation, and clinical implications. All types of adrenergic drugs are covered in great detail, including receptor agonists and blocking agents, indirect-acting agonists, false transmitters, and neuron-blocking agents.

As expected, this handbook is well-referenced. The material presented is fairly up to date, with the latest references dating from 1978. There are more than 10,000 items in the author index and about 13,500 separate entries in the subject index.

Each chapter includes some discussion of functional anatomy, location and classification of receptors, and general effects of the drug types of interest. Species variation in drug response are fully covered. In fact, some unusual and exotic species are included. For example, the apocrine sweat glands of the camel, the black rhinoceros, and the slow loris are described.

It may be unfair to criticize the second part of a two-set volume without seeing the first part. However, there are some obvious deficiencies. For example, in the chapter on the respiratory system, there is an obvious error of calculation in a table showing the selectivity index for metaproterenol. There is no mention of the effects of beta blockers on childbirth. In the chapter on the kidney, only receptor agonists and blocking agents are covered; the other types of adrenergic drugs are not considered. However, these minor deficiencies do not detract from the quality of this book.

This volume is an invaluable resource for all researchers in pharmacology and, together with Volume I, should be available to every serious student of pharmacology.

Toward a Standardized ID System for Drugs

In his writings, and particularly in *1984*—the well-known novel predicting the totality of government bureaucratic involvement in society and our private lives—George Orwell forecast that numbers would gradually replace names as the common means of identifying virtually everyone and everything.

We are now only a couple of years away from that fateful date, and already we see that much of what Orwell predicted has come to pass. For example, it seems more important today for a person to have a Social Security number than it is to have a name. Just try filing your income tax, or getting a driver's license, or registering in college, or opening an interest-bearing account, or cashing a check, or filing a health insurance claim form, and so on *ad infinitum*, without giving a Social Security number. One quickly finds that, if not impossible, it is very difficult at best. But yet, none of these activities has even a remote bearing on Social Security or the intended purpose in issuing Social Security numbers.

Numerous other examples—from the universal price codes appearing on packaged food products, to long-distance direct dial telephone numbers, to nine-digit zip codes, to personal charge account numbers—can be cited from everyday life that also illustrate how numbers and numeric codes have virtually taken over how we now operate in daily living.

All this is happening because, whether we like it or not, these systems generally work. They provide fast access, ready location, foolproof identification, ease of information storage, and similar advantages. As we move closer to the computerized age, such benefits will continue to grow in both kind and degree.

But one area has somehow remained outside of, or at most on the fringes of, our otherwise successful efforts to manage various affairs and activities by developing and applying useful and logical numbering systems.

That area is drug identification. True, we do have a "National Drug Code," and NDC numbers do appear in drug company catalogs, on product labels, and in a few other places. But NDC numbers are not in wide use and it is clearly evident that they are not now—and never will become—an adequate and useful substitute for the drug or drug product name in a manner comparable to Social Security numbers as identifiers for people.

Why is this?

Even a cursory familiarity with the NDC system makes the answer clearly evident. Namely, the NDC numbering system has virtually no consistency or standardization.

Each NDC number is comprised of three segments: the first segment is unique to the manufacturer, and that portion is reasonably satisfactory (although such things as company mergers have created some room for improvement even there); the second segment is used to identify the drug entity; and the third segment identifies the dosage form. It is in these latter two portions of the NDC numbering system that there is absolutely no consistency or standardization.

Each individual drug company is completely free to use whatever number it wishes to identify the drug and the dosage form. The result, of course, is that there is no uniformity because everyone uses a different number to identify both the same drug moiety and the same dosage form.

How much better it would be if the system were standardized so that a single, uniform number was applied to tetracycline, and similarly that another single, uniform number was used to designate 250-mg capsules. The composite NDC number then would be light years more useful as a means of drug identification, of simplifying such public health measures as poison prevention and treatment, of inventorying and stocking pharmacy shelves, of processing drug reimbursement claims, of more rational drug prescribing, and so on.

Washington rumors are that federal budgetary squeezes may cause the Food and Drug Administration to close down its office that runs the NDC system, thereby abandoning the system itself. Undoubtedly, had the present NDC numbering system been more effective, it would have enjoyed much greater use, thereby making its elimination less attractive to the budget-cutters.

In a concurrent development, the National Association of Pharmaceutical Manufacturers—the so-called "generic manufacturers association"—recently recommended to FDA that a set of uniform drug identification numbers based on the active ingredients be established at the federal level. This proposal was primarily prompted by legislation or regulations being adopted at the state level concerning drug product identification. The NAPM even went a step further with its suggestion by generating a proposed alpha numeric "ID list" covering over 600 drug entities in specific dosage forms.

Based upon our review, the NAPM identification scheme itself is not as useful as it would be if drug entity and dosage form were two separate components of the composite ID number, and if each of these two elements were standardized separately.

However, that really is only a detail of implementation. The key point is the recommendation that *the system itself be standardized.* In that, they have our wholehearted support.

Critics will claim that the NAPM has its self-interest reasons for urging the adoption of such a standardized system. That is true; just as it is also true that the brand name segment of the drug industry had its self-interest motives for opposing a standardized approach years ago when the NDC system was originally developed.

The important consideration now is the broader picture of all that can be done using today's and tomorrow's computer technology if only there were a compatible drug numbering system. It is ironic that the industry that was so far-sighted as to pioneer in the use of the metric system on a commercial level is now the laggard in permitting full adaptation to a standardized drug numbering system, with its associated technological benefits.

Clearly, it is a time for statesmanship in the board rooms of the nation's major drug companies.

Effects of Phenobarbital on the Distribution Pharmacokinetics and Biological Half-Lives of Model Nonmetabolizable Organic Anions in Rats

DENNIS J. SZYMANSKI * and JANARDAN B. NAGWEKAR ˣ

Received August 6, 1980, from the *Pharmaceutics Division, College of Pharmacy and Allied Health Professions, Wayne State University, Detroit, MI 48202.* Accepted for publication July 6, 1981. *Present address: Travenol Laboratories, Inc., Morton Grove, IL 60053.

Abstract □ The blood level pharmacokinetics of model nonmetabolizable and nonprotein bound anionic compounds (pKa 3.3–3.4), namely, benzoylformic acid (I), D-(−)-mandelic acid (II), and *p*-methyl benzoylformic acid (III), which are excreted in the urine in the unchanged form, were studied in control and phenobarbital-treated rats to determine the effects of phenobarbital on distribution and elimination pharmacokinetic parameters. These compounds were used, also, because they represent three different compartment models in the untreated rats: a three-compartment open model (I), a two-compartment open model (II), and a one-compartment open model (III). The three-compartment open model (I) in the control rats was reduced to a two-compartment open model with only one kinetically distinguishable peripheral tissue compartment in the phenobarbital-treated rats. The pharmacokinetics of II were described by a two-compartment open model in both control and phenobarbital-treated rats but the apparent distribution volumes of the central and peripheral compartments were found to be significantly smaller in phenobarbital-treated rats. One-compartment open model pharmacokinetics were observed for III in both the control and phenobarbital-treated rats with no significant difference in apparent distribution volumes. The transmembrane transport of these compounds, which exist in the body fluids as anions, was previously reported to occur *via* the aqueous pores of the tissue cell membranes. The decrease in the apparent distribution volumes of these organic anions in the phenobarbital-treated rats was explained in terms of the possible effect of phenobarbital in increasing the protein and phospholipid concentrations of the cell membranes of tissues other than liver. This narrows the size of the aqueous pores of the central and tissue compartment cell membranes and hinders the diffusion of these compounds through the aqueous pores. Regardless of the compartment model displayed by these compounds, the biological half-life of each compound was significantly shorter in the phenobarbital-treated rats than in the control rats. This effect was attributed to the possible induction effect of phenobarbital on the renal tubular secretion carrier mechanism of these compounds in rats.

Keyphrases □ Phenobarbital—effect on pharmacokinetics of nonmetabolizable organic anions, rats □ Pharmacokinetics—effect of phenobarbital, nonmetabolizable organic anions, rats □ Nonmetabolizable organic anions—effect of phenobarbital on pharmacokinetics, rats

It has been shown in humans and animals that concomitant administration of many metabolizable drugs with phenobarbital results in a decrease in their biological half-lives as well as in pharmacological activity (1, 2). In most instances these effects are attributed to the enzyme-inducing property of phenobarbital which results in the increased rate of metabolism of concomitantly administered drugs. The enzyme-inducing property of phenobarbital is due to its ability to increase the synthesis of drug-metabolizing enzymes in the liver (1–3).

BACKGROUND

Phenobarbital was shown to increase general protein synthesis by its direct action on the hepatic endoplasmic reticulum (4, 5) and to increase the concentration of microsomal phospholipids by reducing their rate of catabolism (6) and/or by increasing their rate of biosynthesis (5). The liver appears to have been extensively investigated for these effects of phenobarbital and, in keeping with the objective of such studies, mainly metabolizable drugs have been used in these investigations. The kidney has been infrequently investigated to show the effect of phenobarbital (7).

In addition to the effect in the liver and kidney, phenobarbital may also increase protein and phospholipid concentrations in other tissues. Since proteins and phospholipids are the major components of tissue plasma membranes, it is conceivable that chronic administration of phenobarbital might alter the transmembrane transport or distribution of certain concomitantly administered drugs into various tissues. Consequently, this may decrease the biological half-lives of these drugs and affect pharmacological responses. This consideration is important because, for a drug to exert pharmacological activity, it must first reach its site(s) of action.

The extent of pharmacological response to a drug is dependent not only on the drug–receptor interaction but also on the drug concentration at the receptor site(s). It is known that the distribution rate of a drug to the site(s) of action is governed by many processes occurring simultaneously; these processes include metabolism, binding to plasma and/or tissue proteins, and renal and nonrenal excretion.

Studies of the effect of phenobarbital on the distribution pharmacokinetics of drugs would be difficult if conducted with concomitantly administered drugs that are subject to metabolism and binding to plasma and/or tissue proteins. These factors may obscure and complicate identification of the effect of phenobarbital on the distribution pharmacokinetic parameters of the drugs.

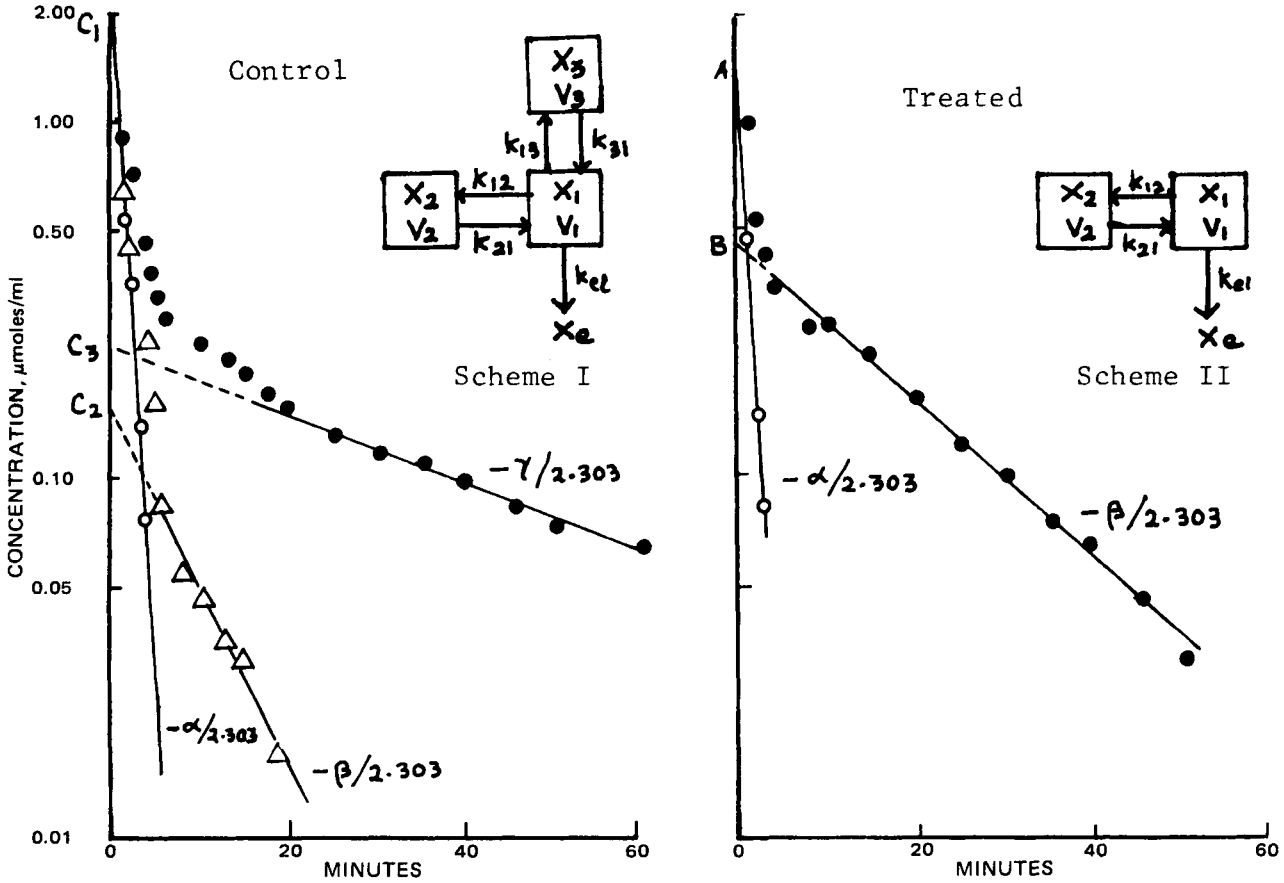

Figure 1—*Semilogarithmic plots showing blood concentrations of benzoylformic acid declining triexponentially in control rats and biexponentially in phenobarbital-treated rats following intravenous administration.*

Scheme I—Three-compartment open model; Scheme II—Two-compartment open model. Key: ●, observed data points; △, ○, data points obtained upon feathering by the residual method.

To demonstrate the effect of phenobarbital on the distribution and biological half-lives of certain compounds, the pharmacokinetics of benzoylformic acid (I), D-(−)-mandelic acid (II), and *p*-methyl benzoylformic acid (III) were studied. These compounds served as model compounds since they are neither metabolized, bound to plasma proteins, nor reabsorbed in the renal tubules. They are excreted in the urine of rats entirely in the unchanged form (8–10). Second, these compounds (pKa 3.3–3.4, referred to in this study as organic anions because they remain completely ionized in the blood) distribute between the body compartments by diffusion through the "aqueous pores" of cell membranes, which presumably are lined with proteins and phospholipids (10). Consequently, it was reasonable to assume that any alteration in the composition of tissue cell membranes might reduce the transmembrane transport of these anions due to a possible decrease in mean pore size. Third, these compounds are represented by three distinctly different compartment models in untreated rats. The pharmacokinetics of I, II, and III have been described (10) by a three-compartment open system, a two-compartment open system, and a one-compartment open system, respectively.

EXPERIMENTAL

Materials—The following were used: D-(−)-mandelic acid[1], mp 131–133°, $[\alpha]_D^{25°}$ − 153°; benzoylformic acid[1], mp 67–69°; *p*-methyl benzoylformic acid, mp 97–99°, synthesized by the method of Kindler *et al.* (11); and sodium phenobarbital[2] USP, granular.

Methodology—Male Sprague–Dawley rats weighing between 170 and 230 g (most weighed ~200 g) were used in the study. The pharmacokinetics of I, II, and III were studied in phenobarbital-treated rats and in control rats. To pretreat the rats, 2 ml of isotonic solution containing a 20-mg/kg dose of sodium phenobarbital was administered intraperitoneally daily to each rat for 5 days in the study of II, 4 days in the study of I, and 3 days in the study of III. The control rat used in each study was pretreated daily with 2 ml normal saline intraperitoneally for 5, 4, and 3 days, respectively.

Food, but not water, was withheld from the rats 12–14 hr prior to the study as well as during the course of the experiment. A given compound was injected intravenously to the rats 24 hr after the last dose of sodium phenobarbital in each study. Five milliliters of normal saline was administered intraperitoneally to each rat 20 min prior to the intravenous administration of the substrate compound being studied to be consistent with previous procedures (8–10). The rat was anesthetized with ether for less than a minute prior to the intravenous injection of a fixed dose of the compound in a 2-ml isotonic solution. The fixed doses of I, II, and III used were 7.5 mg (~250 μmoles/kg), 5 mg (~165 μmoles/kg), and 5 mg (~151 μmoles/kg), respectively. Each compound was injected as its sodium salt by adding equivalent amounts of sodium hydroxide. The solutions were made isotonic with sodium chloride. One blood sample was obtained from each rat upon its decapitation at predetermined time after the administration of the compound. After decapitation, blood was collected in 30-ml beakers which were previously coated with 0.2 ml (40 U) of heparin to prevent coagulation. The blood samples were analyzed on the same day that they were collected.

Because of the voluminous work involved in extracting a compound from numerous blood samples and then analyzing it by GC, blood samples for the pharmacokinetic studies of I and II were collected in two or three portions on two or three different days, each portion involving 5–8 rats. Each portion represented a proper distribution of blood sampling times. For instance, in the control study of II, one study portion included 2-, 4-, 8-, 10-, 15-, 25-, and 50-min blood sampling times and the other study portion included 3-, 5-, 20-, 30-, and 40-min blood sampling times. In the control study of I, one study portion included 2-, 4-, 6-, 8-, 15-, 25-, 45-, and 60-min blood sampling times, the second portion included 1-, 3-, 5-, 10-, and 40-min blood sampling times, and the third study portion included 13-, 18-, 20-, 30-, 35-, and 50-min blood sampling times. For each study portion, a standard curve for the compound was prepared for quantitative determination of the blood samples. In the case of III, all

blood samples were obtained in a single study portion since each group of control and phenobarbital-treated rats involved only seven blood samples.

GLC Analysis—I, II, and III were quantitatively determined by GC using a flame ionization detector[3]. These procedures were essentially the same as those described previously (10).

Phenobarbital Pretreatment—*Mandelic Acid (II)*—A 5-day pretreatment schedule for rats with phenobarbital was chosen because numerous literature reports have indicated that a maximum drug metabolizing enzyme induction effect of phenobarbital is produced within ~3 days of pretreatment with a daily 20–100-mg/kg ip dose of phenobarbital. It was felt that if there was an effect of phenobarbital, a 5-day treatment period would be adequate to produce a maximum effect on the pharmacokinetic behavior of II.

Since phenobarbital treatment influenced the pharmacokinetics of II, it was of interest to determine if the maximum effect of phenobarbital on the pharmacokinetics of the compound was produced in a 5-day treatment. Therefore, the pharmacokinetics of II were also studied in rats treated with a daily 20-mg/kg ip dose of phenobarbital for 1 day and for 10 days.

Benzoylformic Acid (I)—It was noted that a substantial effect of phenobarbital on the pharmacokinetics of II could occur in rats even after a 1-day treatment and that a maximum effect occurred after a 5-day treatment. Possibly, the maximum effect of phenobarbital on the pharmacokinetics of the compound might have occurred after treating rats with phenobarbital for less than 5 days. To determine this possibility with I, the pharmacokinetics were studied in 4-day phenobarbital-treated rats. Additional pharmacokinetic studies of the compound were carried out in 6- and 10-day phenobarbital treated rats where each rat received a daily 20-mg/kg ip dose of phenobarbital.

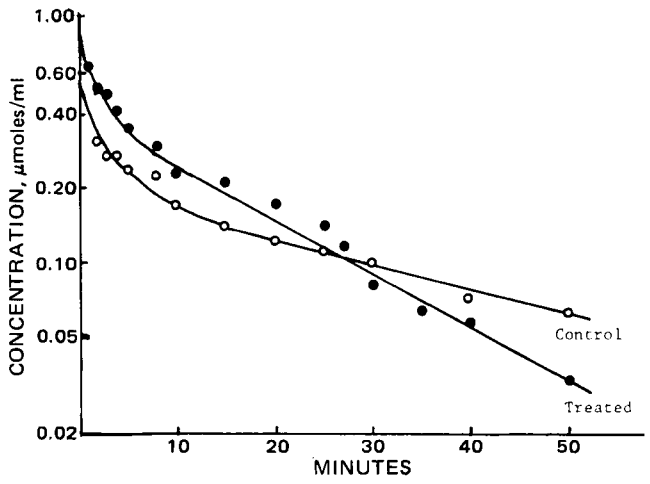

Figure 2—*Biexponential semilogarithmic plots of blood concentrations of mandelic acid obtained in control (○) and phenobarbital-treated (●) rats. The solid lines are the NONLIN least-squares regression lines for the data of respective groups of rats.*

[3] Hewlett-Packard Model 5720.

p-Methyl Benzoylformic Acid (III)—Since the maximum effects of phenobarbital on the pharmacokinetic parameters of II and I were observed in rats after 4 to 5 days of phenobarbital treatment, it was thought possible that the maximum effect of phenobarbital treatment on the pharmacokinetic parameters of III would be observed in less than 4 days of phenobarbital treatment. Therefore, the pharmacokinetics of III were studied in 3-day phenobarbital-treated rats.

To determine if the maximum effect on the pharmacokinetic parameters of the compound was produced after a 3-day phenobarbital treatment, additional pharmacokinetic studies of the compound were carried out in 5-day phenobarbital-treated rats. In that study, each rat also received a daily 20 mg/kg ip dose of phenobarbital.

Overall Urinary Recovery of the Tested Compounds in Phenobarbital-Treated Rats—Studies were done to determine if intravenous doses of II (5 mg), I (7.5 mg), and III (5 mg) are recovered in the urine of phenobarbital-treated rats entirely in the unchanged form. After administering intravenous doses of II, I, and III to rats treated with phenobarbital (20 mg/kg ip) for 5, 4, and 3 days, respectively, urine samples were collected for 12–24 hr for II and I and for 3–5 hr for III.

Binding of Tested Compounds by Blood from Phenobarbital-Treated Rats—The fact that I, II, and III are negligibly bound to whole blood of untreated rats has been demonstrated previously (8, 10). Therefore, the binding of these compounds was studied only with blood from rats treated with phenobarbital for 3–5 days. These determinations were carried out at 37° by the equilibrium dialysis method previously described for these compounds (10). The amount of a given compound used in these studies was calculated on the basis of its apparent distribution volume of the central compartment determined in the phenobarbital-treated rats from the blood level studies described later.

RESULTS

In previous demonstrations (8, 10), all of the intravenously administered doses of I, II, and III were recovered unchanged in untreated rat

urine. In the present study, virtually 100% of the dose of each compound administered to phenobarbital-treated rats was recovered unchanged in the urine, indicating negligible metabolism of the compounds in the rats. The urinary recoveries of II, I, and III were 99.13 ± 0.12(n = 3), 99.47 ± 0.3(n = 4), and 98.1 ± 1.0%(n = 5), respectively.

Negligible binding of the tested compounds to plasma proteins in untreated rats has been demonstrated previously (8, 10). From the equilibrium dialysis studies, the binding of these compounds to the whole blood of phenobarbital-treated rats varied from 0.4 to 3.3%, which is negligible.

Pharmacokinetics of I in Control and Phenobarbital-Treated Rats—The blood level data obtained for I in the control and phenobarbital-treated rats were plotted on semilogarithmic graph paper. Since these plots indicated multiexponential concentration decline of the compound, they were resolved into all possible linear exponential segments upon feathering the data by the method of residuals. While the data for the control rats could be resolved into three linear exponential segments, the data for the phenobarbital-treated rats could be resolved into only two linear exponential segments. This indicates that I shows characteristics of a three-compartment model in the control rats (Scheme I, Fig. 1), as was observed previously in saline-untreated rats (10). But I shows characteristics of a two-compartment model in the phenobarbital-treated rats (Scheme II, Fig. 1).Therefore, the blood levels of the compound obtained in the control rats and the phenobarbital-treated rats were analyzed according to the three-compartment model kinetics and two-compartment model kinetics, respectively. As shown in Schemes I and II, the fact that elimination of I occurs from the central compartment only by urinary excretion (10) is asserted by demonstrating that the intravenous dose of the compound is completely recovered in the urine.

In Schemes I and II, X_1, X_2, and X_3 represent the amounts of I at time t in the central compartment, tissue compartment I, the tissue compartment II, respectively; V_1, V_2, and V_3 represent the apparent distribution volume for the compound in the respective compartments. The variable X_e is the amount of the compound excreted in the urine up to time t. The variable K_{el} is the apparent first-order rate constant of elimination of the compound from the central compartment, and k_{12}, k_{21}, k_{13}, and k_{31} are the apparent first-order rate constants for the transfer of the compound between the given compartments.

The general solution for the three-compartment open model is given by the following equation (12):

$$C = C_1 e^{-\alpha t} + C_2 e^{-\beta t} + C_3 e^{-\gamma t} \qquad \text{(Eq. 1)}$$

where C is the concentration of the compound in the blood at any time t. The concentrations in Fig. 1 are normalized on the basis of the intravenous dose of 7.5 mg of I/200 g rat body weight. The preliminary estimates of the intercepts (C_1, C_2, and C_3) and slopes ($-\alpha/2.303$, $-\beta/2.303$, and $-\gamma/2.303$) due to the three linear exponential segments (Fig. 1) were obtained by the least-squares method. Using the preliminary estimates of C_1, C_2, C_3, α, β, and γ, the initial estimates of K_{el}, k_{12}, k_{21}, k_{13}, and k_{31} were obtained using the appropriate well-known equations (12). The preliminary estimate of V_1 was obtained from V_1 = dose/$C_1 + C_2 + C_3$. Using the initial estimates of these rate constants and V_1, the blood level data of the control rats were analyzed by the NONLIN least-squares program (13) and refined estimates of V_1, k_{12}, k_{21}, k_{13}, k_{31}, and K_{el} with their standard deviations and those of α, β, and γ without their standard deviations were obtained. Using the estimated values of these parameters, the values of V_2 and V_3 were calculated using the appropriate equations (12). Values of V_{ss} ($V_1 + V_2 + V_3$), blood clearance or body clearance ($K_{el}V_1$), and elimination phase ($t_{1/2} = 0.693/\gamma$) were calculated. The estimated and derived pharmacokinetic parameters are listed in Table I. The apparent volume of the central compartment (V_1) refers to the blood volume and the fluid volume of highly perfused tissues which are readily accessible to the compound, and V_2 and V_3 refer to the apparent volumes of fluids of the "shallow" and "deep" tissues, respectively.

The general solution for the two-compartment open model is given by the following equation:

$$C = A e^{-\alpha t} + B e^{-\beta t} \qquad \text{(Eq. 2)}$$

where C is the concentration of the compound in the blood at time t. Preliminary estimates of the intercepts (A and B) and slopes ($-\alpha/2.303$ and $-\beta/2.303$) for the two linear exponential segments (Fig. 1) were obtained by the least-squares method. Using the preliminary estimates of A, B, α, and β, the initial estimates of k_{12}, k_{21}, and K_{el} were obtained by using known equations (12). The preliminary estimate of V_1 was obtained from V_1 = intravenous dose/$A + B$. Using the initial estimates of k_{12}, k_{21}, K_{el}, and V_1, the blood level data of I obtained in the phenobarbital-treated rats were analyzed by the NONLIN least-squares program (13) and the refined estimates of V_1, k_{12}, k_{21}, and K_{el} with their standard deviations and those of α and β without their standard deviations were obtained. Using the estimated values of these parameters, V_2 [V_1 (k_{12}/k_{21})] was calculated. The values of V_{ss} ($V_1 + V_2$), elimination phase ($t_{1/2} = 0.693/\beta$), and body clearance ($K_{el}V_1$) were also calculated. The estimated and derived pharmacokinetic parameters of the compound obtained in the 4-day phenobarbital-treated rats are listed in Table I and those obtained in the 6- and 10-day phenobarbital-treated rats are listed in Table II.

[a] Compared to the control.

of blood level data obtained for II both in the control and the phenobarbital rats indicated that blood levels of the compound declined biexponentially (Fig. 2). Therefore, these data were analyzed according to two-compartment model kinetics, with the elimination of the compound occurring from the central compartment. The blood concentrations in Fig. 2 are normalized on the basis of the 5 mg iv dose/200 g rat body weight; the blood level data were treated with Eq. 2. The preliminary estimates of the intercepts (A and B) and slopes ($-\alpha/2.303$ and $-\beta/2.303$) due to the two resolved linear exponential segments were obtained by the least-squares method. Using the estimates of A, B, α, and β, the initial estimates of V_1, k_{12}, k_{21}, and K_{el} were obtained by the method described previously. The refined estimates of V_1, k_{12}, k_{21}, and K_{el} with their standard deviations and those of α and β without their standard deviations were obtained using the NONLIN least-squares program (13). Using computer estimated values of these parameters, the estimates of V_2, V_{ss}, elimination phase ($t_{1/2}$), and $K_{el}V_1$ were calculated. The estimated and derived pharmacokientic parameters of II obtained in the control rats and the 5-day phenobarbital-treated rats are listed in Table III and those obtained in the 1-day and 10-day phenobarbital-treated rats are listed in Table IV.

Pharmacokinetics of III—The blood levels of III in both the control rats and the phenobarbital-treated rats declined monoexponentially (Fig. 3), indicating a one-compartment open model. The concentrations in Fig. 3 are normalized on the basis of the 5 mg iv dose of III/200 g rat body weight. The blood level data were treated according to the following equation:

$$\log C = \log C_0 - K_{el}t/2.303 \qquad \text{(Eq. 3)}$$

where C is the concentration of the compound at time t, C_0 is the concentration of the compound at zero time, and K_{el} is the apparent first-order rate constant of elimination of the compound. Values of C_0 for the compound were determined from the intercepts obtained by extrapolating the respective least-squares lines to zero time (Fig. 3). The volumes of distribution and the biological half-lives ($t_{1/2}$) were calculated according to the equations V_d = intravenous dose/C_0 and $t_{1/2} = 0.693/K_{el}$. The value of K_{el} was calculated from the slope ($-K_{el}/2.303$) of the least-squares lines. The pharmacokinetic parameters thus determined for the compound in the control rats as well as in the 3- and 5-day phenobarbital-treated rats are listed in Table V. The body clearance ($K_{el}V_d$) of the compound was also calculated.

Statistical Considerations and Treatment—Since only one blood sample was obtained from a rat at a given time following the intravenous administration of the compound under study, each data point in Figs. 1–3 and other pharmacokinetic studies represents the concentration of the compound in a single rat. This procedure was the same as that employed in previous pharmacokinetic studies (10) of these compounds in saline-untreated rats where the correlation coefficient observed between the concentration and time values was >0.991. There were reasons for using this procedure, instead of performing the study in a single rat by collecting the blood samples over the duration of the study following intravenous administration of a compound.

If a complete pharmacokinetic study of a compound were performed in a single rat, the total volume of blood that would have been withdrawn would have amounted to as high as 6 ml. The sensitivity of the assay procedures for these compounds at low intravenous doses would have necessitated the withdrawal of 0.2–0.3 ml of blood in each sampling during the initial period and 0.5–0.7 ml of blood in each sampling during the later period of the kinetic study. This would have been true especially in the case of I and II which confer upon the body the characteristics of multicompartment models. Withdrawal of such a high blood volume (about 40% of the total blood volume of a 200 g rat) would have been undesirable. In conjunction with the blood level pharmacokinetic studies carried out previously (10), the pharmacokinetics of these compounds were also studied from urinary excretion data (14) by performing (unlike in the blood level studies) complete pharmacokinetic studies in individual rats, since the sensitivity of the same assay procedure used for blood samples was not prohibitive in the quantitative determination of the amounts of compounds excreted in the urine. In these urinary excretion studies (14) a minimum subject-to-subject variation was observed in the excretion rates and elimination phase half-lives of these compounds, thereby supporting the assumption that rats showed minimum variations in the blood concentrations and half-lives of the compounds.

Therefore, in each pharmacokinetic study, a single blood concentration value of the compound was obtained per rat per time with the basic assumptions of the regression model that the single concentration variate corresponding to a given time is independently and normally distributed and the samples along the regression line have a common variance (15). The high correlation coefficient values between the two variates, concentration and time, support this assumption.

The standard deviation values indicated in Tables I–IV for the pharmacokinetic parameters V_1, k_{12}, k_{21}, k_{13}, k_{31}, and K_{el} of I and V_1, k_{12}, k_{21}, and K_{el} of II are the computer estimated values. According to the NONLIN least-squares program, the computer also estimated the values of α, β, and γ, but without their standard deviations. The standard deviations of these parameters and other derived pharmacokinetic parameters of I and II were estimated by the following procedures:

To estimate the standard deviation of β, the data points of a given study obtained exclusively in the elimination β-phase were plotted according to the equation $\ln C = \ln B - \beta t$. The standard deviation ($\hat{\sigma}c, t$) about the least-squares regression line thus obtained was estimated by the following formula (16):

$$\hat{\sigma}c,t = \left[\frac{\Sigma(\ln C)^2 - \frac{(\Sigma \ln C)^2}{n} - \beta^2\left\{\Sigma t^2 - \frac{(\Sigma t)^2}{n}\right\}}{n-2}\right]^{1/2}$$

The standard deviation of the slope ($\hat{SD}\beta$) was then calculated by the formula (16):

$$\hat{SD}\beta = \frac{\hat{\sigma}c,t}{\sqrt{\Sigma t^2 - \frac{(\Sigma t)^2}{n}}}$$

The standard deviations of α ($= K_{el}k_{21}/\beta$), V_2 ($= k_{12}V_1/k_{21}$), body clearance ($BC = K_{el}V_1$), V_{ss} ($= V_1 + V_2$), and $t_{1/2\beta}$, (0.693/β) were estimated by the general approximate formulas (17, 18):

$$\sigma\alpha = [\{(\sigma K_{el}/K_{el})^2 + (\sigma k_{21}/k_{21})^2 + (\sigma\beta/\beta)^2\}(\alpha)^2]^{1/2}$$

$$\sigma V_2 = [\{(\sigma k_{12}/k_{12})^2 + (\sigma V_1/V_1)^2 + (\sigma k_{21}/k_{21})^2\}(V_2)^2]^{1/2}$$

$$\sigma BC = [\{(\sigma K_{el}/K_{el})^2 + (\sigma V_1/V_1)^2\}(BC)^2]^{1/2};\ \sigma V_{ss} = [\sigma V_1^2 + \sigma V_2^2]^{1/2}$$

and

$$\sigma t_{1/2\beta} = 0.693 \cdot \sigma\beta/\beta^2$$

In the case of I a direct comparison of V_2, V_3, α, and β, the pharmacokinetic parameters of a three-compartment model in control rats, cannot be made with V_2, α, and β, the parameters of a two-compartment model in phenobarbital-treated rats. For this reason, and because of the complex equations from which V_2 and V_3 are obtained (12) for the three-compartment model, no attempt was made to determine the standard deviations of V_2, V_3, α, and β for I in control rats. However, because it is appropriate to compare the three-compartment parameters γ, $t_{1/2\gamma}$, and body clearance ($K_{el}V_1$) with the equivalent two-compartment parameters β, $t_{1/2\beta}$ and body clearance ($K_{el}V_1$), respectively, the standard deviations of these parameters were determined as described and used for determining statistical differences between the corresponding parameters (Table I).

In the case of III, which followed one-compartment model kinetics, the standard deviation of K_{el} was obtained as follows. First, the standard deviation ($\hat{\sigma}c,t$) about the least-squares regression line from the plot of ln$C$ *versus* t was obtained by (16):

$$\hat{\sigma}c,t = \left[\frac{\Sigma(\ln C)^2 - \frac{(\Sigma \ln C)^2}{n} - K_{el}^2\left\{\Sigma t^2 - \frac{(\Sigma t)^2}{n}\right\}}{n-2}\right]^{1/2}$$

The standard deviation of the slope ($\hat{SD}_{K_{el}}$) was then calculated from (16):

$$\hat{SD}_{K_{el}} = \frac{\hat{\sigma}c,t}{\sqrt{\Sigma t^2 - \frac{(\Sigma t)^2}{n}}}$$

The standard deviation of concentration of the compound at zero time (C_0) was estimated from the standard deviation of the slope of a least-squares regression line obtained by plotting C *versus* $e^{-K_{el}t}$ according to the equation $C = C_0e^{-K_{el}t}$.

For the three compounds used in the study, statistically significant differences between corresponding pharmacokinetic parameters obtained in the control and phenobarbital-treated rats were determined using t test statistics at $p \leq 0.05$.

DISCUSSION

Benzoylformic Acid (I)—The three-compartment model noted for I with two kinetically distinguishable peripheral tissue compartments in the control rats was reduced to a two-compartment model with one kinetically distinguishable peripheral tissue compartment in the 4-day phenobarbital-treated rats as well as in 6- and 10-day phenobarbital-treated rats. The pharmacokinetic parameters determined for the compound in 6- and 10-day phenobarbital-treated rats (Table II) were very similar to those determined in 4-day phenobarbital-treated rats. This indicates that the maximum effects of phenobarbital treatment on the pharmacokinetic parameters of the compound were indeed produced after a 4-day treatment with phenobarbital.

Since different compartment models are observed in the control and phenobarbital-treated rats, V_1, K_{el}, γ, $k_{el}V_1$, and $t_{1/2}$ elimination phase are the only pharmacokinetic parameters obtained for the compound in control rats which may be compared with the corresponding pharmacokinetic parameters in the phenobarbital-treated rats. It was observed that K_{el} and β of I in phenobarbital-treated rats were significantly greater than K_{el} and γ in the control rats. The $t_{1/2}$ of the compound in phenobarbital-treated rats was significantly shorter than that in control rats. Although there was a tendency for V_1 to decrease and $K_{el}V_d$ to increase in the phenobarbital-treated rats, these changes were not significant ($p = 0.05$) (Table I).

Mandelic Acid (II)—Table III shows that, except for $K_{el}V_1$, all pharmacokinetic parameters of II in the phenobarbital-treated rats were significantly different from those in the control rats. The parameters V_1, V_2, V_{ss}, and $t_{1/2\beta}$ decreased, and K_{el}, α, and β increased in the phenobarbital-treated rats compared with the corresponding parameters in the control rats.

The comparison of the pharmacokinetic parameters (Table IV) of the compound in the 1- and 10-day phenobarbital-treated rats with those of the 5-day treated rats indicated that the effects of phenobarbital treatment are seen on certain parameters even after a 1-day treatment with phenobarbital, but the maximum effects on all parameters were certainly obtained after a 5-day phenobarbital treatment. The pharmacokinetic parameters obtained in the 10-day phenobarbital-treated rats were not significantly different from those obtained in the 5-day phenobarbital-treated rats. Some of the pharmacokinetic parameters noted in the 10-day phenobarbital-treated rats are very similar to those in the 5-day phenobarbital-treated rats.

***p*-Methyl Benzoylformic Acid (III)**—Table V shows that the pharmacokinetic parameters of III from the 5-day phenobarbital-treated rats were very similar to those obtained in the 3-day phenobarbital-treated rats, indicating that the maximum pharmacokinetic effects were produced in 3-day phenobarbital-treated rats.

Except for V_d, all pharmacokinetic parameters of III determined in 3-day phenobarbital-treated rats were significantly different from those determined in the control rats. The values of K_{el} and $K_{el}V_d$ increased and $t_{1/2}$ decreased in phenobarbital-treated rats as compared with control rats.

Effects of Phenobarbital Treatment on the Pharmacokinetic Parameters of the Compounds—The effect of phenobarbital treatment on some pharmacokinetic parameters of the compounds studied seemed to depend on whether the compound conferred the characteristics of a one-, two-, or three-compartment model on the body. The effect on some other pharmacokinetic parameters appeared to be model independent. These effects are as follows:

1. The biological half-lives ($t_{1/2}$) of all compounds were significantly shorter in the phenobarbital-treated rats than those in the control rats.
2. The elimination rate constants (K_{el}) of the compounds from the central compartment were significantly greater in phenobarbital-treated rats than in the control rats.
3. The disposition rate constants (β) in phenobarbital-treated rats, which are a function of elimination and distribution of the compounds, were significantly greater than the corresponding disposition rate constants in the control rats (γ in the case of I and β in the case of II).
4. The distributive phases observed for I and II were shorter in the phenobarbital-treated rats than in the control rats.
5. A reduction in the apparent distribution volumes of the peripheral tissue compartments for I in phenobarbital-treated rats became evident by the fact that a three-compartment model in the control rats was reduced to a two-compartment model in the phenobarbital-treated rats. In the case of II (which displayed two-compartment model characteristics in both control and phenobarbital-treated rats), the apparent distribution volume of the peripheral tissue compartment (V_2) was significantly smaller in the phenobarbital-treated rats than that in the control rats.
6. The apparent distribution volume of the central compartment (V_1) of II was significantly smaller in the phenobarbital-treated rats than in the control rats. However, V_1 of I (three-compartment in control rats) and V_d of III observed in the phenobarbital-treated rats were not found to be significantly different from those observed in the control rats.
7. The body clearance ($K_{el}V_d$) of III was significantly greater in phenobarbital-treated rats than in the control rats. In the case of I and II, although there was a tendency for body clearance ($K_{el}V_1$) to be greater in the phenobarbital-treated rats, such increases were not significantly different, most probably because the increase in K_{el} was offset by a simultaneous decrease of V_1.

Thus, the major effects produced by the phenobarbital treatment were to shorten the biological half-lives of the compounds used, irrespective of the pharmacokinetic model displayed, and to reduce the apparent distribution volumes of the peripheral tissue compartments of the compounds which displayed multicompartment model pharmacokinetics.

The known *in vivo* effects of phenobarbital treatment are to induce drug metabolizing microsomal enzymes (1, 3), to increase the bile flow (19, 20), and increase the liver (21) and kidney (7) blood flows. These effects potentially can shorten the biological half-lives of compounds, but since the compounds used in this study were not metabolized and were excreted in the urine entirely in the intact form by the phenobarbital-treated rats, the enzyme induction effect was not expected to influence their biological half-lives. The increase in the biliary flow and liver blood flow was also expected to have little or no effect on the kinetic dispositions of these compounds. Since the increased blood flow to the kidney is compensated by the autoregulation of the kidney to yield a constant blood flow to the glomerulus (7), no effect on the glomerular filtration rates of the compounds is expected. However, recent reports (7) have shown that the renal tubular secretion rates of *p*-aminohippuric acid increased in phenobarbital-treated rats. This effect was attributed to the increase in the renal tubular transport system available for the compound in rats. Since I, II, and III are secreted by the renal tubules of rats (9, 22), the contribution of this factor in increasing K_{el} of the compounds or in shortening their biological half-lives is possible.

The effects of phenobarbital treatment on the distribution pharmacokinetic parameters of the compounds that displayed multicompartment pharmacokinetics appear to be consistent with the hypothesis that phenobarbital treatment of rats may also increase the concentration of proteins and phospholipids in the membranes of tissue cells other than those of liver and kidney. Consequently, the rate of diffusion of the ionic species of the compounds through the aqueous pores of the tissue cell membranes decreases. One mechanism which has been widely recognized (23–29) for transmembrane transport of solutes is diffusion through aqueous pores. Previous pharmacokinetic studies (10, 22) of I, II, and several of their *para*-alkylated homologs, showed that the alkyl groups in these model organic anions decreased the apparent distribution volumes of the peripheral tissue compartments in rats, instead of increasing such distribution volumes as might have been expected due to the presence of lipophilic alkyl groups. Therefore, it was proposed (10, 22) that the distribution of these organic anions from the central compartment to the peripheral tissue compartments occurs mainly through aqueous pores of the tissue cell membranes.

No direct evidence has been obtained to show that the concentration of proteins and phospholipids of various tissue cell membranes increased resulting in reduction of the aqueous pore size of the membranes. However, the rationalization of the results of this study on the basis of the following considerations supports this possible effect of phenobarbital treatment in rats. It was previously indicated(10, 22) that the anionic forms of the compounds studied interact with the components (proteins and phospholipids) of the lining of aqueous pores while diffusing through them by means of intermolecular forces such as electrostatic interaction, hydrogen bonding, and hydrophobic bonding. By considering the slight differences in the chemical structures of these anions, the variations in the composition of cell membranes of various tissue cells (30), the possible differences in the degree of intermolecular interactions with aqueous pore lining, and the heteroporosity (31–33) of the membranes, the existence of a three-compartment open model for I and a two-compartment open model for II was explained (10).

It is also recognized that the membranes of most organs are heteroporous, with pore size ranging from 8 to 320 Å, with a mean pore size range of 70–120 Å (31–33), and that only about one-fourth of the total pore size constitutes the effective space for the diffusion of solute molecules through a pore (34). Therefore, the possible phenobarbital treatment induced reduction in the aqueous pore size would be expected to cause greater intermolecular interactions of the anions with the constituents of the pore lining and cause a decrease in the penetration of the anions into the tissue. This may decrease the apparent distribution volume occupied by the anions in that tissue.

The two peripheral tissue compartments noted for I in the control rats, were thought to be due to those organs whose aqueous pores exhibit weak hydrogen bonding with the I molecules and due to those organs whose aqueous pores exhibit strong hydrogen bonding with the I molecules (10, 22). In the phenobarbital-treated rats, only one peripheral tissue compartment was kinetically distinguishable. This may be due to the phenobarbital affecting the size of aqueous pores in the two tissue compartments such that the strengths of hydrogen bonding of the I anions with the aqueous linings of one tissue compartment were similar to those of the other tissue compartment.

It may be pointed out that the decrease in the distribution volumes observed in the phenobarbital-treated rats is for the compounds that display multicompartment characteristics and exist in the blood in the ionized form. Such changes in the distribution volume may not be observed for multicompartment model compounds that exist in the blood in the nonionized form. These compounds generally have greater membrane solubility and are expected to diffuse through the entire membrane surface of which aqueous pores constitute only a fractional surface area. Furthermore, if the shortening of the biological half-lives of these compounds is due to the stimulation by phenobarbital of their renal tubular secretion mechanism, changes in the biological half-lives may not be observed for compounds not involved in renal tubular secretion but are excreted in the urine due to glomerular filtration. Studies with model drugs supporting these hypotheses are presented elsewhere (35).

Ascorbic Acid Absorption in Humans: A Comparison among Several Dosage Forms

SUSANNA YUNG ‡, MICHAEL MAYERSOHN *x, and J. BARRY ROBINSON ‡

Received May 11, 1981, from the * *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721* and the ‡ *Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada.* Accepted for publication July 20, 1981.

Abstract □ There have been few studies conducted to determine the efficiency of ascorbic acid absorption in humans. Differences in the extent of its absorption among individuals may contribute to the outcome of clinical trials. Ascorbic acid absorption in four subjects was investigated from several oral dosage forms containing 1 g of the vitamin (solution, tablet, chewable tablet, and timed-release capsule). Approximately 85% of an intravenous dose was recovered in the urine as ascorbic acid and its major metabolites. In contrast, only ~30% of the dose was recovered from the solution and tablet forms. A considerably smaller fraction of the dose (~14%) was recovered from the timed-release capsule. There was considerable intersubject variation in ascorbic acid absorption and there appeared to be good and poor absorbers of the vitamin. Consideration should be given to the influence of the extent of ascorbic acid absorption on the results of clinical trials.

Keyphrases □ Ascorbic acid—comparison of absorption of several dosage forms, humans □ Absorption—ascorbic acid, comparison of several dosage forms, humans □ Vitamin C—comparison of absorption of several dosage forms, humans

Since the claim (1–3) that the daily consumption of large quantities of ascorbic acid may have beneficial effects for such conditions as the common cold, numerous investigations have been conducted to evaluate the efficacy of large doses of this vitamin for reducing the frequency and duration of cold symptoms (4–8). The results of these studies remain controversial (9, 10) although there is at least some tentative support for the clinical claims. Several studies have been criticized for lack of adequate control and for poor experimental design, factors which may have substantially influenced their results and conclusions. Perhaps equally as important is an understanding and the proper control of variables that may affect the absorption or bioavailability of the vitamin from the oral form. At present little is known about the absorption and disposition of ascorbic acid administered exogenously. Since ascorbic acid appears to be absorbed in humans by a specialized process (11, 12), the rate and extent of its absorption may be influenced by the relative efficiency of different oral dosage forms, size of the dose, and physiological conditions along the GI tract. The present study was designed to examine ascorbic absorption from various commercially available oral dosage forms.

EXPERIMENTAL

Protocol—Four healthy adult subjects participated in the study (three males and one female, 25–32 years of age) after giving informed written consent. Each subject ingested 1 g of ascorbic acid/day for a period of not less than 2 weeks prior to the experiments, in order to saturate body stores of the vitamin. Saturation of body stores was determined in the following manner. After the 2-week dosing period, 1 g of ascorbic acid (powder dissolved in water) was ingested on an empty stomach. Total urine was collected for the subsequent 24 hr and assayed for total vitamin. This procedure was repeated 3–7 days later. Between these two test doses the subjects ingested 1 g of ascorbic acid/day. The body stores were accepted as being saturated if the total amount of vitamin excreted during 24 hr from each test dose was within ±10% of each other.

Two days prior to and during an experimental day the subjects avoided the ingestion of ascorbic acid either in the form of vitamin preparations or foods known to be high in ascorbic acid content. One day prior to the experiment, blank urine samples were obtained by collecting total urine for several hours during two collection periods (one in the morning and one in the afternoon). The bladder was voided at the beginning of the collection period and the exact time of the collection interval and urine volume was noted.

On the experimental day the subjects ingested the assigned dosage form of the vitamin on an empty stomach after an overnight fast. Food was withheld for the next 3–4 hr. The dosage forms were ingested with 200 ml of water. The chewable tablets were thoroughly chewed prior to swallowing. The dosage forms ingested were:

A. 1 g of ascorbic acid powder dissolved in water[1]
B. 1 g of ascorbic acid tablets[2] (two 500-mg tablets)
C. 1 g of ascorbic acid chewable tablets[3] (two 500-mg tablets)
D. 1 g of ascorbic acid timed-release capsules[4] (two 500-mg capsules)

Each subject was randomly assigned to a specific schedule for ingestion of the different dosage forms according to a 4 × 4 Latin square design. In addition to the above dosage forms, 1 g of ascorbic acid was given intravenously 1 week after the completion of these experiments. The injectable solution[5] (4 ml) was injected into an arm vein over 3–4 min (500 mg/2-ml vial).

The bladder was voided immediately after drug administration. Urine was then collected during frequent and known time intervals during the subsequent 24 hr. The total volume of each collection was recorded and a 15-ml aliquot was taken and transferred to a vial which contained sufficient metaphosphoric acid such that a 4% solution of the acid was obtained with 15 ml of urine. The vial was shaken to dissolve the acid and stored in a refrigerator and assayed within 4 days. After the 24-hr collection period, the subjects resumed daily ingestion of 1 g of ascorbic acid until 2 days prior to the next experiment. A period of 1 week elapsed between successive experiments.

Analytical—All dosage forms were assayed to determine ascorbic acid

content according to USP methods (13). Urine was assayed by the 2,4-dinitrophenylhydrazine method outlined by Pelletier (14) to determine concentrations of ascorbic acid and its two major metabolites, dehydroascorbic acid and diketogulonic acid. This assay method is based upon the formation of a colored osazone from dehydroascorbic and diketogulonic acids and it offers a means of differentiating the three compounds. The final solutions were measured colorimetrically at 520 nm. Concentrations of the compounds were determined from previously prepared standard curves and amounts excreted during a collection interval were calculated from the product of concentration and urine volume. The urinary excretion data were corrected for blank values determined from the urine samples collected on the day prior to each experiment.

Data Analysis—Urinary excretion data were used to calculate ascorbic acid excretion rate as a function of time. Initial estimates of the absorption rate constant (K_a) and the elimination rate constant (K) were obtained from semilogarithmic graphs of excretion rate *versus* time by the method of residuals. Using these initial estimates, the data obtained after the oral administration of ascorbic acid were fit by nonlinear regression analysis employing the equation appropriate for a one-compartment model and assuming first-order absorption and elimination. Since the urinary excretion data suggested the existence of a lag time (T_{lag}) between the time of dosing and the time when ascorbic acid excretion began, the equation incorporated T_{lag} as a parameter to be estimated. The computer-generated values for the above parameters were used to calculate the maximum excretion rate (ER_{max}) and the time of occurrence of this maximum (T_{max}). The excretion rate *versus* time data obtained after intravenous administration of the vitamin were fit to the equation appropriate for a two-compartment model. Initial estimates of the coefficients and exponents of the equation were obtained graphically using the method of residuals. These data were then fit by nonlinear regression analysis as already mentioned.

The bioavailability or extent of ascorbic acid absorption from each of the forms administered was determined from the total amount of the vitamin excreted into the urine during 24 hr (*i.e.*, the sum of ascorbic, dehydroascorbic, and diketogulonic acids). This value was then corrected for the actual dose ingested based on the assay of the dosage forms. Similarly, since ER_{max} depends on the actual dose ingested, this value was corrected for the actual assayed content of the vitamin. The extent of absorption was expressed either as a percentage of the dose recovered or as a percentage of the intravenous dose recovered.

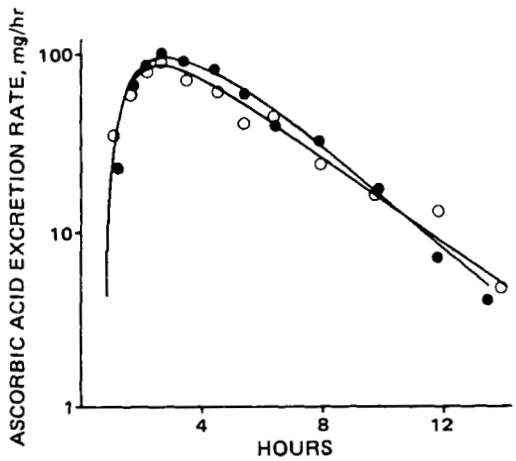

Figure 2—*Urinary excretion rate of ascorbic acid as a function of time in one subject after the ingestion of 1 g of ascorbic acid as a solution (●) or as a tablet (○). The solid lines represent the best fit of the data.*

Table II—Maximum Ascorbic Acid Excretion Rate (ER_{max}) from Various Dosage Forms
