Figure 3—*Variation in the dimethylsilyl NMR (60 MHz) spectral region for XV (2.3×10^{-2} M) as a function of time (min) in dioxane–0.05 M tromethamine (pH 7.4) mixture (60:40) at 27°. The chemical shift of* tert*-butyldimethylsilanol (−0.30 δ) is relative to XV (0 δ).*

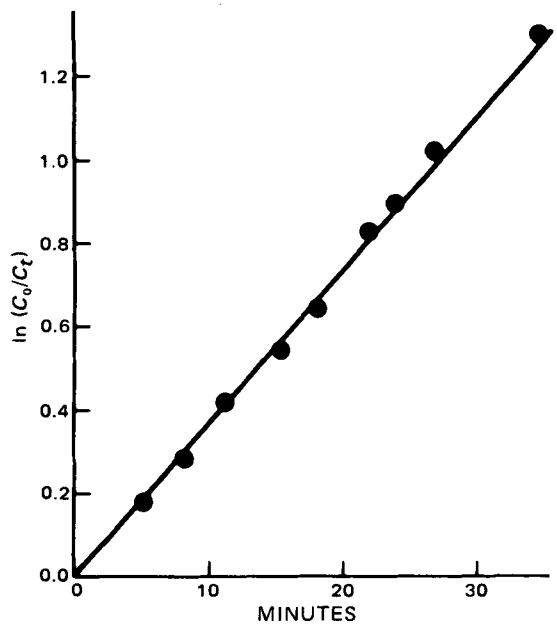

Figure 4—*Pseudo first-order kinetic plot for hydrolysis of XV (2.3×10^{-2} M) in dioxane–0.05 M tromethamine buffer (pH 7.4) mixture (60:40) at 27°. Substrate concentration terms C_0 and C_t were determined by NMR (see text and Fig. 3).*

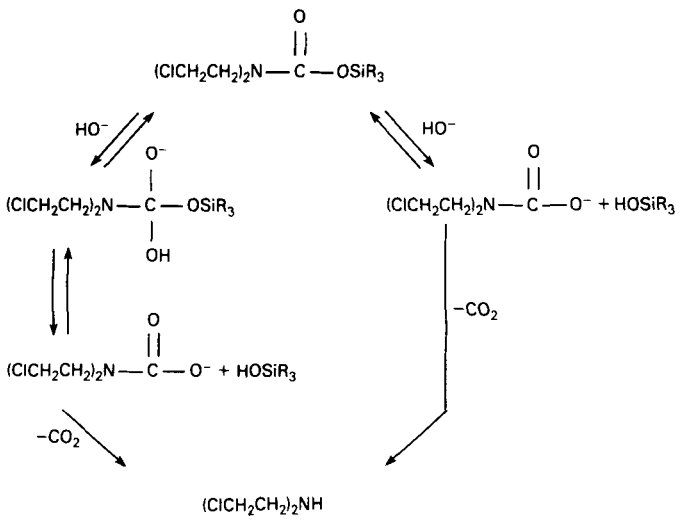

Scheme III

measurement of prodrug hydrolysis kinetics was applied to solutions containing each of the five *O*-aryldimethylsilyl-*N*,*N*-bis(2-chloroethyl)-carbamates (2.5×10^{-2} mmoles) in a mixture of dioxane (0.5 ml) and tromethamine buffer (0.5 ml, 0.05 *M*, pH 7.4). For these reactions at 27 ± 1°, linear least-squares fits (± ~5% average slope-error) gave the following pseudo first-order rate constants: *p*-OCH_3, 1.65×10^{-4} sec^{-1} ($\tau_{1/2}$ 70.0 min); *p*-CH_3, 1.69×10^{-4} sec^{-1} ($\tau_{1/2}$ 68.3 min); *p*-H, 3.87×10^{-4} sec^{-1} ($\tau_{1/2}$ 29.8 min); *p*-F, 1.17×10^{-3} sec^{-1} ($\tau_{1/2}$ 9.9 min); and *p*-Cl, 1.58×10^{-3} sec^{-1} ($\tau_{1/2}$ 7.3 min).

^{18}O-Labeling Studies—A freshly prepared sample of silanol-free XXI (10 mg) was dissolved in a magnetically stirred mixture of dioxane (0.4 ml), tromethamine buffer (0.2 ml of 0.2 *M*, pH 7.4), and ^{18}O-enriched water (0.2 ml, >95 g-atom % ^{18}O). After 3 hr at room temperature, the reaction mixture was extracted with fractionally distilled pentane (3 × 1 ml), and the extract was then analyzed by mass spectroscopy to determine the relative proportion of ^{16}O- and ^{18}O-containing *tert*-butyldimethylsilanol. The (M^+, −57) ions observed at *m/z* 75 and 77 arise from loss of *tert*-butyl and had a normalized intensity of 99.87 and 100.00%, respectively. When unlabeled silanol (5 mg) was extracted from a simulated reaction mixture containing normal water, the ion intensities at *m/z* 75 and 77 were 100.00 and 4.78%, respectively, whereas use of 50:50 v/v mixture of water and ^{18}O-labeled water (18 hr of contact time) led to extraction of silanol having ion intensities at *m/z* 75 and 77 equal to 100.00 and 14.94%, respectively.

Anticancer Screening—Selected compounds (Table II) were evaluated against L-1210 lymphoid leukemia and P-388 lymphocytic leukemia in either male or female mice. Pertinent details and the results of these tests are given in Table II.

RESULTS AND DISCUSSION

Syntheses—The methodology for constructing *O*-triorganosilyl derivatives of phosphoramide mustard was developed by first pursuing the synthesis of diester model compounds IV–VII (Scheme I). These materials were prepared by reaction of common precursor III with the corresponding triorganochlorosilane and sodium iodide in acetonitrile solvent (16). The same demethylation–silylation procedure was used to convert common precursor VIII into target compounds IX–XI. Proton NMR spectra of these products showed two-proton amido resonance signals and were devoid of detectable methoxy signals, indicating that *N*-silylation of the amide functionality (17, 18) is not a significant side reaction.

O-Triorganosilyl carbamate derivatives of nor-nitrogen mustard (XIV–XIX, Scheme II) were obtained by Breederveld's (19) reaction sequence, namely, *N*-silylation followed by insertion of carbon dioxide into the Si—N bond, which requires excess amine as a catalyst and presumably (19) involves triorganosilyl group-transfer from an *N*-triorganosilyl-*N*,*N*-bis(2-chloroethyl)amine to the carbamic acid derivative or nor-nitrogen mustard.

The *N*-triorganosilyl-*N*,*N*-bis(2-chloroethyl)amines can be isolated (*e.g.*, XII and XIII); however, they readily decompose and were usually converted *in situ* to the final carbamate product. Biscarbamoyldisiloxane XX was similarly prepared from 1,3-dichloro-1,1,3,3-tetramethyldisiloxane, while *tert*-butyldimethylsilyl carbamate XXI was obtained by direct addition of *tert*-butyldimethylsilanol to 2-chloroethyl isocyanate. The silanol–isocyanate addition reaction has not been reported previously, and has been shown[5] to be generally applicable to variously structured triorganosilanols and alkyl/aryl isocyanates. Accordingly, it was possible to convert *p*-isocyanatophenylmustard into carbamate derivative XXII by reaction with the appropriate silanol.

Tert-butyldimethylsilyl (XXIII) and *tert*-butyldiphenylsilyl (XXIV) esters of the anticancer drug chlorambucil (20) were prepared by direct *O*-silylation using the sodium salt of this carboxylic acid. The anticancer agents cyclophosphamide (21), fluorouracil (22), ftorafur (23), benzohydroxamic acid (24), and hydroxyurea (25) were also silylated by conventional methods and gave derivatives XXV–XXX, respectively. By analogy to structurally related systems (14, 17, 26, 27), the triorganosilyl groups in compounds XXV–XXX may undergo either positional exchange (between oxygen and nitrogen bonding sites) or rotational isomerization; however, these dynamic processes are not a central issue in the present study. On the other hand, it is worthwhile to note that ^1H-NMR spectra for XXV–XXX were consistent with the presence of a single (major) isomer. The connectivities used to represent compounds XXV–XXX are the best guess structures as opposed to definite assignments of bonding.

Hydrolysis Kinetics—Hydrolytic unmasking of the candidate triorganosilyl prodrugs was first examined by ^1H-NMR monitoring of the dimethylsilyl spectral region for the phosphoramide mustard derivative X, using an organic solvent (dioxane)–aqueous buffer mixture to achieve sufficient substrate solubility for these continuous-wave measurements. Gradually decreasing intensity for the dimethylsilyl absorption of X was accompanied by increasing signal intensity for the dimethylsilyl moiety in the hydrolysis byproduct, *tert*-butyldimethylsilanol (δ −0.30, relative to X). The sum of these two resonance signals, which remained constant, provides a relative measure of the initial concentration of X, C_0, while the diminishing signal intensity for X is a relative measure of substrate concentration at time *t*, C_t. For hydrolysis of X at pH 7.4[6], 27°, a least-squares fit of $\ln(C_0/C_t)$ *versus* *t* (Fig. 1) indicated a good linear correlation and gave the pseudo first-order rate constant (k') and half-life ($\tau_{1/2}$) listed in Table I.

Spectra (Fig. 2) obtained with diester V under analogous reaction conditions showed the conversion of starting material into *tert*-butyldimethylsilanol (δ −0.30, relative to V) and a monoester intermediate (δ −0.08, relative to V), which undergoes comparatively slow hydrolysis to afford the fully unmasked phosphoramidic mustard.[7] Kinetic analysis based on the decreasing signal intensity of V afforded the monodesilylation rate data given in Table I. Multiplication of the 3.8-min half-life for V by a correction factor of 2 gives a value which is ~four times less than the 28.6-min half-life for X. This relatively small difference in half-lives is presumably due to leaving group effects, since the steric bulk about the back-side tetrahedral face of silicon is virtually the same in each compound. Pro(phosphoramide mustards) IX and XI were similarly examined by NMR in an attempt to determine the influence of the triorganosilyl group on hydrolytic stability; however, compound IX was too reactive to study by this method, and the *tert*-butyl signals from XI and its silanol byproduct were extensively overlapped at 60 MHz.

Alkaline hydrolysis of *O*-triorganosilyl carbamic acid mustards can occur by initial attack of hydroxide ion at either the carbonyl carbon, as in *O*-alkyl carbamates (28), or at silicon to give the conjugate base of carbamic acid mustards (Scheme III), which would then undergo relatively rapid decarboxylation to release nor-nitrogen mustard. While both reaction pathways lead to formation of the same bis-alkylating agent, the silicon-attack route would appear to allow for greater control over the rate of nor-nitrogen mustard release. Differentiation between the two mechanistic possibilities was first approached by studying structure–reactivity relationships. Extension of the NMR kinetic method to hydrolysis of *O*-trimethylsilyl carbamate XIV was precluded by this compound's exceedingly short lifetime in aqueous media; however, production of triorganosilanol from compounds XV, XVI, and XVIII could be conveniently monitored from changes in the methylsilyl or silyl-bearing

[5] K. C. Fichter and G. Zon, unpublished results.

[6] This and related pH values refer to the aqueous buffer component used to prepare the mixed solvent system. The true pH of such mixtures is poorly defined. Since the purpose of the present kinetic measurements was to evaluate *relative* substrate reactivities, and roughly gauge the stabilities of these potential prodrugs for possible correlation with *in vivo* biological activity, no attempt was made to devise either a more refined pH measurement or a more realistic *in vitro* kinetic system.

[7] Lutidine buffer causes a solvent-induced chemical shift separation between the dimethylsilyl signals for V and the monoester intermediate. The signals were accidentally isochronous in the dioxane–tromethamine buffer mixture used for studying X.

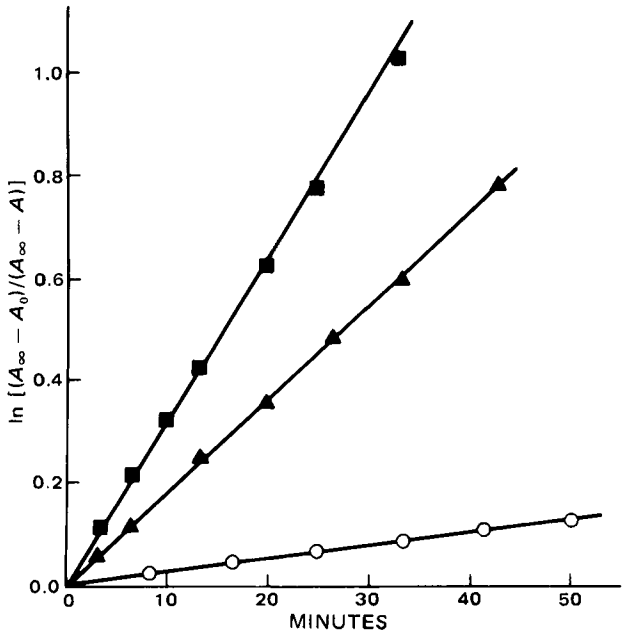

Figure 5—*Pseudo first-order kinetic plots for hydrolysis of XV (2.7 × 10^{-2} M) in 50:50 dioxane–0.10 M tromethamine buffer (pH 8.4, ■; pH 7.4, ▲; pH 6.4, ○) at 27°. The UV absorbance (A) values were measured at 226 nm (see text for details).*

methylene spectral region, as seen from representative spectra obtained with XV (Fig. 3). For each of these compounds, the signal for the triorganosilanol byproduct appeared at higher field (lower δ), relative to starting material, due to removal of the carbonyl group deshielding effect. In all cases, the formation of triorganosilanol obeyed a first-order rate law (*e.g.*, Fig. 4); however, the substrate half-life values (Table I) revealed only a twofold reactivity range for this series of SiR_3 groups: XVIII, 13.3 min; XV, 18.1 min; and XVI, 27.0 min.

Previous studies of the alkaline hydrolysis of carbamates have employed UV spectroscopy to measure reaction kinetics (28). When this method was applied to compound XV in mixtures of dioxane and tromethamine buffer at pH 6.4, 7.4, and 8.4 (27°), the absorbance (A) at 226 nm afforded linear plots of $\ln[(A_\infty - A_0)/(A_\infty - A)]$ *versus* t (Fig. 5), and the calculated rate constants (Table I) increased with elevated concentrations of hydroxide ion. The UV-derived rate constant for hydrolysis of XV at pH 7.4 (3.03×10^{-4} sec^{-1}) is about one-half the magnitude of the rate constant (6.37×10^{-4} sec^{-1}) for production of *tert*-butyldimethylsilanol from XV measured by NMR under the same reaction conditions. This difference can be accommodated by assuming the existence of carbamic acid mustard, since the absorbance at 226 nm is most likely due to carbonate ion which is formed by decarboxylation of this metastable intermediate (28).

Compounds XVI–XVIII have phenyl substituents that obscure the 226 nm UV region. Kinetic data (Table I) for hydrolysis of these silylated carbamates at pH 7.4 were thus obtained from absorbance changes measured at 260 nm, and correspond to the rate of triorganosilanol production rather than carbonate formation. This interpretation is supported by the fact that the UV- and NMR-derived half-lives for two of these compounds are essentially equivalent: XVI, 27.2 and 27.0 min, respectively; XVIII, 12.8 and 13.3 min, respectively.

It is enlightening to compare the relative rates of desilylation in the homologous series of carbamates represented by XV–XVIII. The order of increasing substrate stability ($\tau_{1/2}$) at pH 7.4 is XVIII (13.0 min[8]) <XV (18.1 min) <XVI (27.1 min[8]) <XVII (34.2 min), which parallels the approximate order of increasing steric bulk of the triorganosilyl group in each compound. This correlation of relative reactivity with substrate structure is consistent with a hydrolysis mechanism involving hydroxide ion attack at silicon (Scheme III); however, the ratios of rate constants cover a surprisingly small range of values: XV/XVIII = 0.72, XVI/XVIII = 0.48, and XVII/XVIII = 0.38. In view of the fact that steric hindrance to S_N2 attack at silicon can lead to a more pronounced deceleration of solvolysis rates[9], and that the rate of hydroxide attack at the carbonyl

carbon in carbamates is also subject to steric retardation (28), the *O*-silyl carbamate hydrolysis mechanism was further probed by a Hammett-type kinetic study. Proton NMR measurements using a series of *para*-substituted *O*-aryldimethylsilyl carbamate derivatives of nor-nitrogen mustard afforded desilylation rate constants which correlated linearly with the σ^o substituent constant (Fig. 6) and indicated that the reaction constant, ρ, for dioxane–tromethamine buffer (pH 7.4) was equal to 2.39. The sign and magnitude of this ρ value indicate mechanistic similarity to the alkaline solvolysis of *para*-substituted aryldimethylsilanes (ρ = 1.94 for σ^o), which is known to occur by nucleophilic attack of hydroxide ion at silicon (30). Another line of evidence in support of S_N2 attack at silicon in the *O*-silyl carbamates derives from the approximately equal ρ value of 2.18 measured for ethanolysis of the corresponding series of *N*-aryldimethylsilylamines (Fig. 7), wherein silicon must be the reaction center.

The preceding mechanistic rationale can be justifiably countered by arguing that a ρ value of ~2 does not exclude the possibility of attack at

[8] Average value obtained from NMR and UV measurements.

[9] For example, triethylsilylacetate hydrolizes 38-times slower than trimethylsilyl acetate (29).

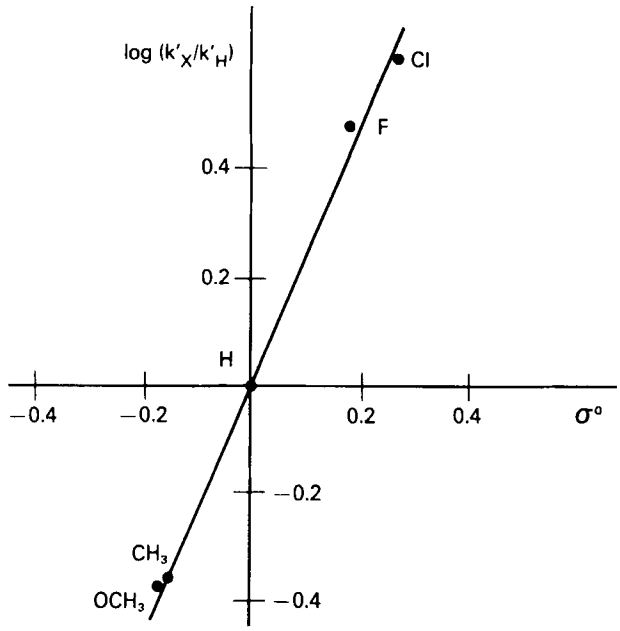

Figure 6—*NMR-derived Hammett plot (r = 0.996) for the hydrolysis of* para-*substituted* O-*aryldimethylsilyl-*N,N-*bis(2-chloroethyl)carbamates in 50:50 dioxane–0.05* M *tromethamine buffer (pH 7.4) at 27°; for details and the values of* k', *see* Experimental *section. the carbamate carbonyl position, since electron-withdrawing aryl substituents would be expected to facilitate the formation of a negatively charged tetrahedral intermediate. The carbonyl-attack mechanism for hydrolysis of *O*-triorganosilyl carbamates was therefore ruled out by determining that reaction of model compound XXI in dioxane–tromethamine buffer (pH 7.4) containing a 50:50 mixture of water and ^{18}O-enriched water leads to formation of a 50:50 mixture of ^{16}O- and ^{18}O-containing silanols. Hydroxide ion attack at the carbonyl carbon in XXI cannot lead to complete incorporation of oxygen 18, as was observed, since the results of a control reaction (see Experimental) demonstrated that oxygen exchange in *tert*-butyldimethylsilanol is relatively slow (<10%) under the conditions used for hydrolysis, and a presolvolytic mechanism[10] gives an oxygen 18 content which cannot exceed ~17%. Granted that S_N2 attack at silicon also holds for analogs of XXI, the previously mentioned insensitivity to steric effects at the silicon reaction center in compounds XV–XVIII can only be speculated on. One possibility is a leveling effect which results from the fact that all of these SiR_3 moieties have relatively large R groups. An alternative explanation is that the well-known propensity for pentacoordination during nucleophilic substitution at silicon leads to either a late transition state or intermediate (32) wherein the rate of O—SiR_3 bond cleavage is primarily controlled by leaving group stability, which is a constant factor in structures XV–XVIII.

Extension of the kinetic studies to the hydrolysis of other triorganosilylated derivatives of anticancer agents focused upon evaluating the release rate of fluorouracil from compound XXVI, as there is widespread interest in developing new classes of *in vivo* precursors to fluorouracil (33–40), but apparently no available information on systems which utilize organosilicon chemistry. Proton NMR spectra obtained with compound XXVI in dioxane–tromethamine buffer (pH 7.4) revealed that the two dimethylsilyl singlets arising from the chemically nonequivalent silyl groups in XXVI decrease in intensity at the same rate, with concomitant appearance of the *tert*-butyldimethylsilanol signal. Evidently, a monosilylated intermediate is too short-lived to be detected by low-resolution NMR under these reaction conditions (Table I), which led to a half-life for XXVI of only 1.08 min. At a buffer pH of 6.4, these spectral changes were too fast to measure, while at pH 8.4 the half-life of XXVI was 1.14 min. The increase in reaction rate with decreasing pH suggests that hydrolysis in the pH range of 6.4–8.4 proceeds by hydrogen ion catalysis; *i.e.*, protonation at the N_1 and/or N_3 positions.

Anticancer Screening—Selected compounds were screened according to standard protocol (41) for either L-1210 or P-388 leukemias in either male or female mice. The hydrophobicity of these samples generally required the use of either hydroxypropylcellulose or aqueous polyoxyethylene sorbitan monooleate as the vehicle for intraperitoneal injections. For L-1210, the inoculum was 10^5 cells; for P-388, the inoculum was 10^6 cells. Mean survival time was used as the evaluation parameter: a test/control percentage (T/C%) ≥125 indicates activity. Compounds VI, VII, XI, XXV, and XXVI were inactive against the L-1210 lymphoid leukemia; compounds XVI, XXI, and XXVIII–XXX were inactive in the P-388 test system. Table II summarizes pertinent data for those compounds which exhibited activity. Since it was not possible to have the parent (nonsilylated) drugs tested in parallel with these active analogs, an evaluation of prodrug *versus* parent drug activities could only be made in a highly qualitative manner by comparisons with screening data which had been previously obtained with the parent drug against the same type of cancer using similar vehicles, dose/injection, and treatment schedules. A computer-assisted search was conducted[11], and it was found that reasonable comparisons could be made for phosphoramide mustard, nor-nitrogen mustard, and ftorafur, but not for *p*-aminophenyl mustard (XXII) and chlorambucil (XXIII). The 138% T/C obtained with X is much less than the 265% T/C value given by phosphoramide mustard at a single-dose injection of 200 mg/kg, whereas the 131% T/C determined for XXVII is essentially identical to the 130% T/C value exhibited by ftorafur under similar test conditions. Except for compound XVI, which was inactive, silylmustard XIII and *O*-silylcarbamates XIV–XVIII and XX covered a range of activities (T/C% ~150–200) roughly equal to that of the parent nor-nitrogen mustard (T/C% 210 at 37.5 mg/kg, 1 × 10), although the modality for treatment within this set of compounds was variable.

CONCLUSIONS

Kinetic measurements have demonstrated that triorganosilyl groups in *O*-silyl esters of phosphoramide mustard, *N*-silyl nor-nitrogen mustards, *O*-silylcarbamoyl nor-nitrogen mustards, and *O*-silylated fluorouracil can be used as hydrolytically labile moieties for the design of new classes of potential anticancer prodrugs. Relative hydrolysis rates, pH

[10] If it is assumed that C—OSi bond cleavage in a tetrahedral *O*-silyl carbamate ion is slow relative to proton shifts and SiR_3 migration between the three oxygen atoms in this intermediate, then a 50:50 mixture of water and ^{18}O-enriched water would scramble one ^{18}O-label among a total of six oxygens, and thus lead to ~17% incorporation at the C—OSi linkage prior to its fragmentation.

[11] NCI Automated Information Section of the Drug Evaluation Branch.

effects, Hammett studies, and ^{18}O-labeling data are all consistent with rate-limiting hydroxide ion attack at silicon in the *O*-silyl carbamates; however, increasing steric bulk about the silicon reaction center has a relatively small rate-retarding influence (<5-fold).

On the other hand, long-range electronic effects caused by *para* substituents in *O*-aryldimethylsilyl carbamates are substantial, as evidenced by a ρ value of 2.39 in dioxane–tromethamine buffer (pH 7.4).

Such electronic control may therefore be useful for fine-tuning the release of an active agent by a prodrug. Triorganosilylation of cyclophosphamide, fluorouracil, benzohydroxamic acid, and hydroxyurea obliterated the activity of these anticancer agents, whereas analogous alterations of phosphoramide mustard, nor-nitrogen mustard, *p*-aminophenylmustard, chlorambucil, and ftorafur led, in general, to retention of anticancer activity. The especially encouraging screening results obtained for *O*-tribenzylsilyl carbamate derivative XVIII have led to its recent selection by NCI for further evaluation in its tumor panel testing program. These screening results and studies of additional triorganosilylated anticancer prodrugs will be reported in the future.

Interaction of Povidone with Aromatic Compounds III: Thermodynamics of the Binding Equilibria and Interaction Forces in Buffer Solutions at Varying pH Values and Varying Dielectric Constant

J. A. PLAIZIER-VERCAMMEN ˣ **and R. E. DE NÈVE**

Received July 21, 1981 from the *Faculteit Geneeskunde en Farmacie, Vrije Universiteit Brussel, Laarbeeklaan, 103 B-1090 Brussels, Belgium.* Accepted for publication August 31, 1981.

Abstract □ The complex formation of a series of aromatic compounds with povidone was studied in buffer solutions and organic solvent mixtures by equilibrium dialysis. For all the ligand molecules studied, a linear relationship was found between r, the number of moles of bound ligand per mole of povidone, and the free ligand concentration. The binding constants and the free energies of binding ($-\Delta F$), were greater for compounds in the nonionic state and increased with the number of hydroxyl groups which were capable of forming hydrogen bonds. They decreased with temperature elevation. The thermodynamic data showed entropy gains during the binding process accompanied by small negative enthalpy values. The increased ability to form hydrogen bonds and the increase in ionization of the ligand molecule was reflected in more negative ΔH and decreasing ΔS values. (The thermodynamic values were interpreted on the basis of the "iceberg" concept of water structure.) From these entropy and enthalpy changes, hydrogen and hydrophobic bondings appeared to be the most important types of binding. In organic solvent mixtures, the association constants lowered with increasing ethanol or propylene glycol concentration; a line relationship between the free energy and the dielectric constant of the solvent mixtures was observed.

Keyphrases □ Povidone—interaction with aromatic compounds, thermodynamic considerations □ Complexation—evaluation of povidone–aromatic compound interaction, thermodynamic considerations □ Thermodynamics—interaction of povidone with aromatic compounds

Two types of binding appear to be important in the complexing of ligand molecules onto povidone. It was suggested (1) that hydrogen bonding plays a role, since substituted groups capable of hydrogen bonding enhanced complex formation. However, ligand molecules in the nonionic form, showed a greater tendency to form complexes than when in the ionic state (2–4), indicating the importance of hydrophobic binding. The thermodynamics of binding (5–10) and the thermodynamic properties of the interaction between povidone and small molecules have been reported previously (2, 4, 11–17).

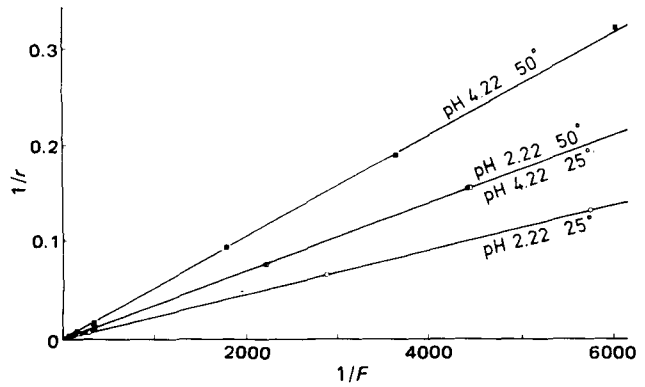

Figure 1—*Influence of temperature on complex formation of 4-hydroxysalicylic acid with povidone. The 4-hydroxysalicylic acid concentration was* 2.5×10^{-4}–2.00×10^{-2} M, *the povidone concentration was 6.00% (*8.57×10^{-5} M*).*

However, the influence of the dissociation of the ligand molecule on the thermodynamic constants has not been studied. To achieve more insight into the binding process, this study evaluated how the thermodynamic constants are affected by the degree of ionization of the ligand molecules and by the dielectric constant of the solvent.

EXPERIMENTAL

Materials—Povidone[1] (molecular weight 700,000) was used as the macromolecule.

The following ligand molecules were studied: benzoic acid[2], nicotinic acid[3] (niacin), isonicotinic acid[2] (isoniazid), salicylic acid[4], salicylamide[2], salicylic acid hydrazide[5], 4-hydroxysalicylic acid[6], 5-hydroxysalicylic acid[4] (gentisic acid), and 5-nitrosalicylic acid[6].

The following buffer solutions were used: hydrochloric acid–potassium chloride buffer (18), pH 1.30 and 1.93; McIllvaine buffers (19), pH 2.20–5.60; a phosphate buffer (18), pH 7.00; a boric acid–sodium tetraborate buffer (20), pH 7.20; and a boric acid–sodium hydroxide buffer (18), pH 9.20 with sodium chloride. The solutions were brought to the ionic strength given in Table I. Sodium chloride showed no tendency to complex with povidone (21). The pH of the solutions was always checked potentiometrically[7] and adjusted, if necessary.

To control the influence of the dielectric constant on complex formation, water–ethanol and water–propylene glycol mixtures were prepared in various proportions, providing a range of dielectric constants. The dielectric constants of the mixtures were measured with a meter[8] at 25.0 and 35.0°.

Equilibrium Dialysis—The ligand–macromolecule interactions were investigated using the method of equilibrium dialysis described previously (22–26).

Dialysis cells[9] similar to those described by Neuhoff (27) were used. The regenerated cellulose membranes were freed of soluble material by leaching in frequently refreshed water and were then immersed in the respective buffers. The two compartments of the dialysis cells were filled, one with solution, the other with the same ligand solution containing the macromolecule.

The cells were rotated at 5 rpm in a constant temperature bath until equilibrium was reached. The povidone-free compartment was analyzed for free ligand. Experiments were carried out at 25.0 and 50.0° with the buffer solutions, and at 25.0 and 35.0° with the ethanol–water and propylene glycol–water mixtures.

Spectrophotometric Analysis—The ligand molecules, with UV absorption bands between 224 and 320 nm, were spectrophotometrically[10] determined in the samples from the dialysis experiments.

RESULTS AND DISCUSSION

The polymer concentration, as well as the range of cosolute concentration, are indicated in Table I.

Preliminary experiments indicated that the binding constants were independent of povidone concentration. For the experiments carried out on the solvent mixtures, a Donnan correction (28) was taken into account.

Theory of Multiple Equilibria—The principles and concepts, fundamental to an understanding of macromolecular binding, have been reported (22–26, 29–30). If no interaction phenomena take place (25–26, 30–33), reversible binding can be described by the equation:

$$r = \frac{nkF}{1 + kF} \qquad \text{(Eq. 1)}$$

where r is the number of moles of cosolute bound per mole of polymer, n is the number of binding sites per mole of macromolecule, F is the molar concentration of free ligand at equilibrium, and k is the intrinsic binding constant (in liters per mole) for the cosolute on the binding sites.

The data were evaluated using a rearrangement of Eq. 1 in a double reciprocal plot, as suggested by Klotz (34):

$$\frac{1}{r} = \frac{1}{nkF} + \frac{1}{n} \qquad \text{(Eq. 2)}$$

The results could also be described by the Freundlich isotherm:

$$r = nkF^{1/m} \qquad \text{(Eq. 3)}$$

where $m = 1$.

Association Constants and Thermodynamics in Buffer Solutions—A characteristic set of results is shown in Fig. 1, where $1/r$ was plotted against $1/F$; the slope of this plot was $1/nk$, and the intercept on the ordinate was $1/n$. Straight lines nearly intersecting the origin were obtained; the other derivatives under investigation behaved similarly. From Eq. 1 it can be seen that this implies $kF \ll 1$, which is equivalent to Eq. 3 where $m = 1$. From Eq. 2, it is observed $1/n$ equals zero, or n is infinite, indicating a large number of adsorption sites. The fraction of the drug bound to povidone did not vary significantly with drug concentration and the binding process appeared nonsaturable.

The results were in accordance with other sources (2, 4, 14, 17, 35, 36) reporting on the complex formation between povidone and ligand molecules. It has been found (2, 14, 25) that the y-axis intercept values ($1/n$) are often determined with great uncertainty, implying it has no physical meaning. In this case, it is preferable to use the values of $nk = k_1$ (25) since it is a measure of the strength of the binding, while n only indicates the binding capacity.

The association constants, nk, deduced from the slopes for povidone–cosolute systems in buffer solutions at different temperatures, are listed in Table I. The thermodynamic functions could be compared with each other because parameters such as the nature of buffer ions and ionic strength had no influence on the binding tendency (1) and consequently, on the thermodynamic functions.

The association constants, for all the derivatives under investigation, were largest at 25.0°, except for benzoic acid in the undissociated form (pH 3.40) (Table I).

The increase in the number of hydroxyl functions substituted on the benzene ring involved higher association constants (4-hydroxysalicylic acid > salicylic acid > benzoic acid), suggesting the importance of hydrogen bonding.

However, the compounds generally interacted to a lesser degree in the ionic than in the nonionic state, suggesting the importance of the hydrophobicity of the substances in the binding process. An exception was 5-nitrosalicylic acid, which showed an increasing binding tendency at higher pH values.

From the association constants, $nk = k_1$ (see Table I) and its temperature dependence, thermodynamic functions for the binding of one mole of ligand with one mole of povidone could be obtained (Table II). For all the ligand molecules, the largest free energy ($-\Delta F$) values were obtained at 50.0° (Table II). From the thermodynamic data listed in Table II, it was clear that the binding process involved a gain in entropy ($+\Delta S$) and that the enthalpies varied from small positive values (benzoic acid, pH 3.40) to small negative values. The standard free energy of binding could be computed from the thermodynamic relation:

$$\Delta F^\circ = -RT \ln k_1 \qquad \text{(Eq. 4)}$$

where $k_1 = nk$, R is the gas constant, and T the absolute temperature.

Assuming no significant temperature dependence of enthalpy change occurring within the temperature range used, the standard enthalpy change ΔH° for the association of one mole of ligand with one mole of macromolecule was estimated from:

$$\ln \frac{nk_{T_1}}{nk_{T_2}} = \frac{-\Delta H^\circ}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad \text{(Eq. 5)}$$

Table II—Thermodynamic Data for the Binding of One Mole of Ligand by One Mole of Povidone in Buffer Solutions at Varying pH

The 5-hydroxysalicylic acid concentration was 2.50 × 10⁻⁴–1.00 × 10⁻² M, the povidone concentration was 5.00% (7.14 × 10⁻⁵ M). Key: 1, water; 2, 5% (v/v) propylene glycol; 3, 10% propylene glycol; 4, 20% (v/v) propylene glycol; 5, 50% (v/v) propylene glycol.*

where T_1 and T_2 represent the absolute temperatures under investigation. The relationship:

$$\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ \qquad \text{(Eq. 6)}$$

permitted calculation of the entropy of binding.

The thermodynamic functions calculated from $nk = k_1$ do not necessarily refer to a single site on the macromolecule. However, their values are useful in considering the nature of the binding, in comparing the binding of different ligand molecules by the same macromolecule, or in analyzing the effect of factors such as pH and ionic strength on the binding (25).

For the ligand molecules investigated, both ΔH° and ΔS° decreased while the degree of dissociation increased. An exception was 5-nitrosalicylic acid, where ΔH° and ΔS° increased with an increase in the degree of dissociation.

From the four types of binding, which could be considered in complex formation of ligands with povidone, *i.e.*, ion–dipole, dipole–dipole, hydrogen, and hydrophobic bonding, the latter appeared to play an important role. Indeed, if complex formation was only due to hydrogen bonding, both ΔH° and ΔS° should be negative (37). However, ΔS° showed a positive value which is characteristic of not only hydrophobic (5, 38–40), but also electrostatic bonding (5–6). Although the ligand molecules also were investigated as ions, this last type of bonding was unlikely to occur since povidone has no ionizable groups (41). The results ruled out the possibility of electrostatic bonding because of the positive influence of the dielectric constant (D) of the solution and the ionic strength (1) on the binding (5). On the other hand, positive enthalpies

	20.0	67.2	64.5	14.7	12.9
	50.0	53.4	51.2	8.4	7.3

(9) and large positive entropies are characteristic of hydrophobic bondings. It is believed that entropy plays a dominant role in this process (38). From the results [*i.e.*, negative enthalpies (Table II) and the decrease of complex formation with increasing temperature] it could be deduced that the binding process was not only due to hydrophobic bondings (5, 42), but also to exothermic reactions, such as Van der Waals forces or hydrogen bondings.

Positive entropies are associated with many reactions involving the binding of ligand molecules onto povidone. They were generally attributed to the formation of hydrophobic bonds (2, 4, 11, 12, 15, 17) although hydrogen bonding cannot be overlooked (2, 12, 14, 15).

The results are interpreted on the basis of the "iceberg" concept (43) which assumes that hydrocarbon groups, present both in the polymer and in the aromatic cosolutes, are surrounded in aqueous solution with one or more layers of water molecules which are more highly ordered than the molecules in ordinary liquid water. Those layers are referred to as icebergs. In polar groups, such as carboxylic groups and anions, there will also be true hydration about the substituent group.

The entropy changes occurring during the binding process are solely due to the disordering of the icebergs that accompany both the polymer and the cosolute molecules (5). The complex formed will be accompanied by an iceberg which is less ordered compared to the icebergs of the two separate entities which results in a proportional gain in entropy. In studies concerning the interaction of povidone with aromatic compounds, it was calculated (12) that the net enthalpy change was associated with: (*a*) the heat needed to overcome any specific interactions (*i.e.*, true hydration) between water and the macromolecule and between water and the ligand molecule; (*b*) exothermic interaction between the dehydrated entities; and (*c*) exothermic interaction between the water and the bound system (*i.e.*, reformation of true hydration), and is essentially constant with a value of −5 kcal/mole. This value represented the interaction of the polar groups of the polymer with the π-electron system of the aromatic cosolutes (12). By subtracting this value from ΔH° in Table II, the net enthalpy changes associated with the disordering of the water molecules in the icebergs around the polymer and the cosolute can be computed before the binding and the reformation of hydrogen bonds in the icebergs around the complex. These positive enthalpies, and the entropy values are responsible for the hydrophobic bonds.

Ionic groups or substituents capable of hydrogen bond formation may also contribute to the enthalpy values of bonding. Furthermore, hydrogen bonds are able to weaken hydrophobic bonds (5). The results (Table II)

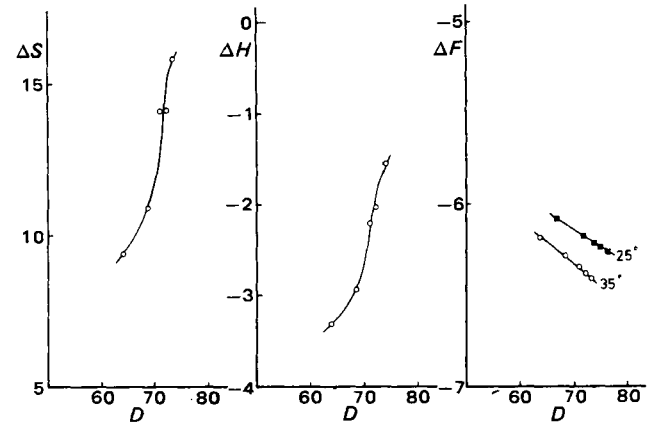

Figure 4—*Complex formation between 4-hydroxysalicylic acid and povidone. Change in free energy (ΔF°), enthalpy (ΔH°), and entropy (ΔS°) as a function of the ethanol concentration and the dielectric constant.*

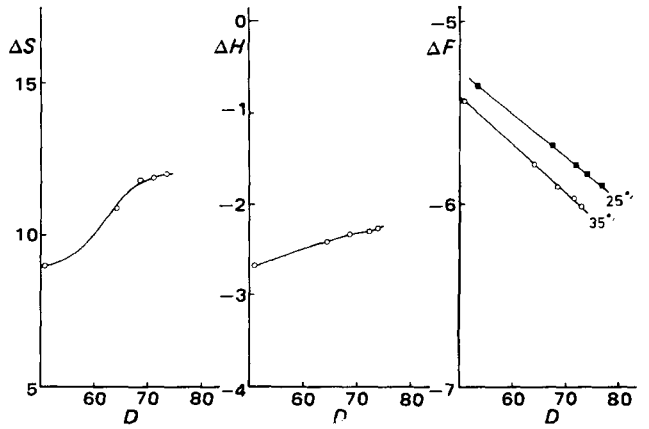

Figure 6—*Complex formation between 5-hydroxysalicylic acid and povidone. Change of free energy (ΔF°), enthalpy (ΔH°), and entropy (ΔS°) as a function of the propylene glycol concentration and dielectric constant.*

agreed with this iceberg concept in that the increase in the ability to form hydrogen bonds (from benzoic acid over salicylic acid to 4- and 5-hydroxysalicylic acid) and the increase in ionization of the ligand molecules is reflected in more negative enthalpy and decreasing entropy values. Therefore, hydrogen bonding was associated with higher binding constants while hydrophobic bonding was associated with the lower constants. One exception was 5-nitrosalicylic acid which, in the case of the bulky nitro group, steric hindrance would be a significant factor (2). The thermodynamic constants obtained for a series of aromatic compounds (12) can be interpreted similarly. From positive enthalpies and high positive entropy values for benzene, both thermodynamic constants diminish more and more with an increasing number of hydroxyl functions substituted on the benzene ring (more possibilities for hydrogen bonding) and are smallest for ionized ligand molecules. It is concluded that both types of bondings, hydrophobic and hydrogen, must play a role in the binding process.

Povidone contains hydrophilic (pyrrolidine ring) and hydrophobic (vinyl chain) groups. A molecular model of the povidone macromolecule shows that the pyrrolidine ring and the paraffin backbone are accessible for the ligand molecules (16). Therefore, it is assumed that the hydrophilic segment is responsible for hydrogen bonding, the paraffin backbone for hydrophobic bonding.

Thermodynamics in Solvent Mixtures—For three ligand molecules, isotherms were determined in a series of ethanol–water mixtures and for one ligand molecule in propylene glycol–water mixtures. A characteristic set of experimental data is shown in Fig. 2, where r is plotted as a function of the free ligand concentration F. In these solvent mixtures, the shape of the isotherms are the same as in the buffer solutions.

From the isotherms, the association constants were determined and summarized in Table III with the measured dielectric constants of the different solvent mixtures. With the aid of the association constants obtained at two temperatures, the thermodynamic functions were computed and represented as a function of the dielectric constants in Figs. 3–6.

From Table III it is noted that the association constants and therefore, the free energies ($-\Delta F$), diminish with increasing ethanol or propylene glycol concentration. For these same concentrations, the association constants are largest at 25.0°; for all the solvent mixtures, the reactions are exothermic ($\Delta H°$ negative), accompanied by high positive entropy values (Figs. 3–6). For the three ligand molecules under investigation, a linear relationship is found between the free energy ($-\Delta F$) and the dielectric constant of the solvent.

This relationship can be written as:

$$-\Delta F° = cst + k'D \qquad \text{(Eq. 7)}$$

or

$$\ln nk = cst + k'D \qquad \text{(Eq. 8)}$$

The shape of the $\Delta H°$ and $\Delta S°$ curves indicated that enthalpy and entropy are connected.

A decrease in bond formation with a decrease in dielectric constant is generally attributed to hydrophobic bonds (4, 5, 44, 45). However, the decrease in dielectric constant influenced the solubility of the ligand molecule; therefore, changes in the solubility of ligand are responsible for the change in the binding tendency.

The correlation between degree of binding, solubility, and dielectric constant of solvent mixtures is being investigated.

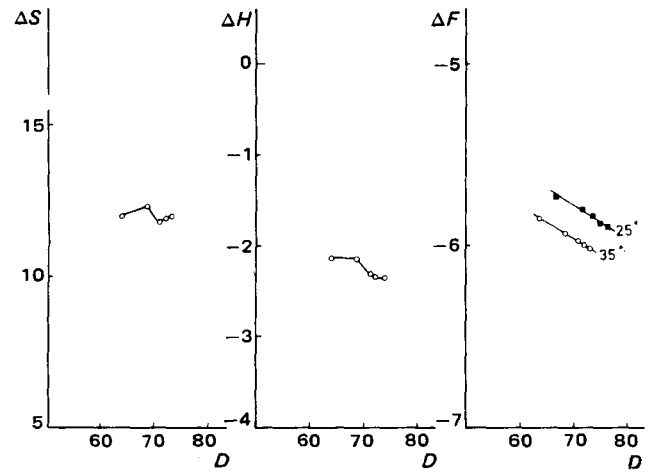

Figure 5—*Complex formation between 5-hydroxysalicylic acid and povidone. Change of free energy (ΔF°), enthalpy (ΔH°), and entropy (ΔS°) as a function of the ethanol concentration and dielectric constant.*

Nitro- *para*- and *meta*-Substituted 2-Phenylindolizines as Potential Antimicrobial Agents

CLAUDIO L. K. LINS, JOHN H. BLOCK ˣ, and ROBERT F. DOERGE

Received May 20, 1980, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97321.* Accepted for publication June 26, 1981.

Abstract □ Some *para*- and *meta*-substituted nitro-2-phenylindolizines were prepared and tested as potential antimicrobial agents. The syntheses were accomplished *via* the Chichibabin–Stepanow synthesis, using the properly substituted α-picoline and phenacyl bromides followed by direct nitration.

Keyphrases □ Antimicrobial activity—potential, nitro *para*- and *meta*-substituted 2-phenylindolizines □ 2-Phenylindolizines—potential antimicrobials, nitro *para*- and *meta*-substituted, synthesis □ Heterocycles—*para*- and *meta*-substituted 2-phenylindolizines, preparation, potential antimicrobials

Earlier reports (1–4) have generated considerable interest in the fundamental chemistry of the indolizine heterocyclic system (I). However, there have been few reports of the biological activity of indolizines (5–7), and no systematic study has been reported.

BACKGROUND

One report (8) considered 2-(4-fluoro-2-methylphenyl)indolizine and 2-(4-fluoro-2-methylphenyl)-7-methylindolizine as carcinogens, but failed to mention whether these compounds were actually tested for carcinogenic properties. 2-(4-Cyclohexylphenyl)indolizine was reported to be noncarcinogenic when painted on the skin of experimental animals (9).

Another report (10) considered 1-indolizinealanine to be a tryptophan antimetabolite. Preliminary tests (11) reported that indolizine-1-acetic acid, the structural analog of indole-3-acetic acid(heteroauxin), showed some auxinlike activity.

1-Diethylaminomethyl-3-methyl-2-phenylindolizine reportedly possessed central nervous system (CNS) depressant activity (12). No useful activity was found for some 1-aminoalkyl-2-phenylindolizines, which were screened for their effects on the CNS in mice and in cats (13). The compounds were stimulants at low doses, depressants at higher doses, and caused death by convulsions.

The 2,3-bis(*p*-methoxyphenyl)indolizines were reported to possess antiexudative activity (14). It was previously reported (15) that 2-(4-fluoro-3-methylphenyl)indolizine decreased the duration of paralysis caused by the drug zoxazolamine when tested in rats. No anti-inflammatory activity for 2-(*p*-methylphenyl)-1-phenylindolizine and 2-(*p*-bromophenyl)-1-(*p*-methoxyphenyl)indolizine was found (16) relative to the reference indoxole.

Rosseels *et al.* (17) found that 3-acetyl-2-alkyl-1-nicotinoylindolizines showed anti-inflammatory activities equivalent to acetylsalicylic acid, and 2-ethyl and 2-*n*-propyl-1-nicotinoylindolizines possessed analgesic activities greater than that of antipyrine.

Two earlier reports (18, 19) stated that N^1-substituted hydrazides of indolizine-2-carboxylic acid were more active than iproniazid in the inhibition of monoamine oxidase. Antonini *et al.* (20) also found that 3-(3-aminopropyl)-2-methylindolizine possessed antiserotonin antihis-

tamine and antiacetylcholine properties with some CNS activity.

Some reports (21, 22) considered 2-alkyl-3- and 2-alkyl-1-(4-dialkylaminoalkoxybenzoyl)indolizine derivatives as antianginal agents. Other groups (23, 24) reported that 2- and 3-benzoylindolizine derivatives showed hemodynamic characteristics similar to those of amiodarone with noncompetitive antiadrenergic properties.

It was reported (25) that 2-[4-(2-indolizinyl)phenyl]propionitrile and propionic acid derivatives have analgesic, antipyretic, and anti-inflammatory activities. The indolizine analog of pindolol was found to have nonselective β-adrenergic blocking activity (26).

The chemotherapeutic effectiveness of numerous heterocyclic compounds containing a nitro moiety is well documented. Nitrofurazine (II) is used in urinary tract infections and is effective against both Gram-positive and Gram-negative organisms (27, 28). Metronidazole (III) is an effective trichomonacidal agent used in vaginal infections (29). Outside of the United States, ipronidazole (IV) and tinidazole (V) are used for their antimicrobial action (30, 31). Niridazole (VI) and the open-chain analog, nithiazide (VII), are known to have antibacterial activities (32, 33).

There is a need for the development of new antimicrobial agents because of resistance developed by the microbial organisms, toxic side effects, limited spectrum of activity, and inability to concentrate in desired tissues using the compounds now available. The antimicrobial properties of indolizines have not been studied. For this reason, a preliminary investigation of the antimicrobial action of substituted phenylindolizines with and without the nitro group was conducted.

RESULTS AND DISCUSSION

Preparation of Compounds—All the compounds prepared were *para*- and *meta*-substituted 2-phenylindolizines (Table I, compounds XI*a–i*). They were prepared from α-picoline (VIII) and phenacylbromides (IX) *via* the Chichibabin–Stepanow synthesis (34) (Scheme I). The α-picoline and phenacyl bromides were combined to form a pyridinium salt (X) (Table II, compounds Xa–i), which was cyclized in refluxing aqueous sodium bicarbonate to the corresponding indolizine (XI). The indolizines in solution were unstable in light, especially when in chloroform.

A mechanism for the Chichibabin–Stepanow synthesis was postulated earlier (35). Nitration of 2-phenylindolizine derivatives (XI) was accomplished with nitric acid (d = 1.4) in the presence of concentrated sulfuric acid at 0° (36). The mechanism by which 2-phenylindolizines are nitrated was recently discussed (37). The orientation of the nitro group appears to depend on the reagent and experimental conditions. Nitration of indolizines in a mixture of nitric and sulfuric acid occurs at the 1-position (36), but nitration in acetic anhydride occurs at the 3-position (38). Thus, in acetic anhydride, it is presumably the free indolizine which is nitrated at the position commonly susceptible to electrophilic attack. With nitric or sulfuric acid as the solvent, 1-nitration predominates because the attached species is a 3-protonated indolizine. UV studies show that indolizines are almost completely protonated at the 3-position (39).

The first step of the proposed mechanism (Scheme II) for the nitration of indolizines using a nitric and sulfuric acid mixture is protonated at the 3-position (XIV). Protonation blocks position 3 from further electrophilic attack. The second step is the nitronium ion attack at the 1-position, forming 1-nitroindolizinium cation (XV). In the presence of a base, proton removal occurs, yielding compound XVII. With excess nitronium ions,

further nitration can occur at position 3, forming 1,3-dinitroindolizinium cation (XVI). In a basic environment, proton removal occurs giving compound XVIII.

The nitro derivatives XI*j*, XVII*a–f*, and XVIII*a–f* used in this study were purified by alumina-column chromatography and preparative TLC. They rapidly turned green if not protected from air and sunlight. In some situations the reaction mixture contained both the 1-nitro (XII) and 1,3-dinitro indolizine (XIII); in others only the 1,3-dinitroindolizine (XIII) could be isolated. Because the compounds did not exhibit the desired biological activity, no attempt was made to improve yields.

Biological Results—Compounds XI*j*, XVII*a–f*, and XVIII*a–f* were evaluated *in vitro* for antibacterial activity against Gram-negative *Escherichia coli* and Gram-positive *Staphylococcus aureus* bacteria. A preliminary disk-agar diffusion test was done using nitrofurazone[1] and chloramphenicol[1] as standards. None of the test compounds exhibited any antimicrobial activity against the organisms tested. Negative results were also obtained when the indolizine was placed directly onto the test agar.

EXPERIMENTAL

Antimicrobial Evaluation—The bacteria used were Gram-negative *E. coli* and Gram-positive *S. aureus*[2]. Before antimicrobial testing, the compounds in solution were sterilized using a fritted-glass filtering disk[3] (40).

The disk-agar diffusion method following the Kirk–Bauer procedure (41) was used for preliminary testing. The basic concept is that the size of the zone of inhibition correlates with the antimicrobial activity of the agent being tested.

The standard procedure requires the use of a special agar for susceptibility testing of microorganisms[4] and a standard inoculum applied in a potency for each of the chemotherapeutic agents being tested.

The experimental disks[5] were placed in a methanol solution containing varying amounts of the indolizine and then were air dried and placed on the top of the agar. The pure compounds (5 mg) were also placed directly on the top of the agar. Disks previously soaked in methanol and then air dried were used as blanks.

Chemistry—Melting point values were determined using an open capillary melting point apparatus[6] and are uncorrected. The NMR spectrometer[7] was used with tetramethylsilane as an internal standard and deuterated chloroform as a solvent. IR[8] and UV[9] spectra were recorded on suitable double-beam spectrophotometers. Mass spectra were obtained with a single-focusing magnetic mass spectrophotometer equipped with a data recording system[10]. Elemental analyses were performed by high-resolution mass spectrometry[11].

Analytical TLC plates were precoated with silica gel[12]. The preparative TLC plates were coated with silica gel[13] (20 × 20 cm, 2 mm). The three methylene chloride–hexane developing systems used were A (1:3), B (1:1), and C (3:1). Spots were visualized with UV light at 254 nm. The purity of each compound was confirmed in each of the TLC systems and in a 40% acetonitrile high-pressure liquid chromatography (HPLC) system[14] using a persilated octadecylsilane column[15]. All compounds gave spectral data consistent with the proposed structure.

The necessary phenacyl bromides were prepared by bromination of the corresponding acetophenone in methanol (42).

Synthesis of *m*-Substituted 2-Phenylindolizines (Table I)—A typical synthesis will be described for 2-(*m*-methylphenyl)indolizine (XI*i*). 3′-Methylacetophenone (3.4 g, 0.025 mole) was diluted with 10 ml of anhydrous methanol in a 25-ml triple-necked flask. Bromine (4.0 g, 0.025 mole) diluted in 2.5 ml of anhydrous methanol was added dropwise for 10 min. If the reaction mixture became clear, more bromine was added until a dark red color persisted. After 30 min of stirring, the mixture was poured into a beaker containing chipped ice. The resulting crystals were washed several times with cold water. (When the substituted phenacyl

[a] Reference 36. [b] Empirical formula confirmed by high resolution mass spectrometry[11].

bromide was a liquid it was washed in a separator.) The crystalline material was transferred to a 50-ml flask and α-picoline (2.25 g, 0.025 mole) in 25 ml of anhydrous methanol was added. The solution was refluxed for 30 min. A precipitate formed, which was filtered and washed with cold water and recrystallized from hot ethyl acetate or ether. The white crystalline solid was then placed in a 50-ml round-bottom flask containing sodium bicarbonate (2.10 g, 0.025 mole) in 25 ml of water. The mixture was refluxed for 10 min. The resulting yellow precipitate was filtered, washed with water, and recrystallized from ethyl acetate. Yields and analytical data are found in Table I.

Synthesis of Nitroindolizines (Table III)—*1,3-Dinitro-2-phenylindolizine* (*XVIII*a)—2-Phenylindolizine (XI*a*) (2.0 g, 10.4 mmoles) dissolved in 10 ml (0.155 mmole) of nitric acid (d = 1.4) was warmed according to Borrows *et al.* (36) to form green-orange crystals (mp 233–238°). The crystals were recrystallized from acetic acid to give 0.40 g (14%) of compound XI*a* as a dark yellow solid: mp 245–246°. Compound XI*a* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.43). UV (CH_3OH): 220 (log 4.27), 252 (4.04), 300 (3.85), and 355 (4.25) nm; mass spectrum: *m/z* 283 (M+, 100%).

2-(p-Nitrophenyl)indolizine (*XI*j)—Nitric acid (d = 1.4; 0.35 ml, 5.43 mmoles) was added dropwise over a 5-min period to an ice-cold stirred solution of 0.50 g (2.59 mmoles) 2-phenylindolizine (XI*a*) in concentrated sulfuric acid (36). A yellow-brown precipitate (0.40 g) was formed and recrystallized first from acetonitrile, and then acetone–charcoal yielding 0.30 g (50%) 2-(*p*-nitrophenyl)indolizine (XI*b*); mp 236–237°, which appeared as one spot when analyzed by TLC (solvent system B, R_f 0.43). UV (CH_3OH): 240 (log 3.52), 300 (2.93), and 340 (3.15) nm; mass spectrum: *m/z* 238 (M+, 100%).

1-Nitro-2-(p-nitrophenyl)indolizine (*XVII*a)—Nitric acid (d = 1.4; 0.8 ml, 12.4 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 2.0 g (8.40 mmoles) of 2-(*p*-nitrophenyl)indolizine (XI*j*) in 2.0 ml of concentrated sulfuric acid (36). A green–yellow precipitate was formed and recrystallized from acetonitrile and then from acetone with charcoal, yielding 0.07 g (3%) of XVII*a* as yellow needles (mp 235–236° dec.). Compound XVII*a* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.43). UV (CH_3OH): 220 (log 4.50), and 275 (4.33) nm; mass spectrum: *m/z* 283 (M+, 100%).

1-Nitro-2-(p-bromophenyl)indolizine (*XVII*b) *and 1,3-Dinitro-2-p-bromophenyl)indolizine* (*XVIII*b)—Nitric acid (d = 1.4; 0.1 ml, 1.55 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 0.35 g (1.29 mmoles) 2-(*p*-bromophenyl)indolizine (XI*b*) in 2.0 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The dark red solution was stirred for 38 min at 0°. The mixture was poured into a beaker containing 20 g of crushed ice and yielded 0.30 g of a dark green solid; mp 150–165°. The precipitate was placed in an alumina column, and compound XVIII*b* was eluted using a mixture of 1:1 hexane–methylene chloride as the eluant. The eluate was evaporated under vacuum and the residue was recrystallized from acetone, yielding 0.012 g (3%) of a dark yellow precipitate (mp 153–155° dec.). Compound XVII*b* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.70). UV (CH_3OH): 214 (log 4.23), 260 (4.52), and 286 (4.32) nm; mass spectrum: *m/z* 316 (M+, 95%) and 318 (M + 2, 100%).

Changing the solvent to methylene chloride–hexane (3:1) caused the elution of compound XVIII*b*. The eluate was evaporated under vacuum and yielded 0.05 g (15%) of a light yellow precipitate (mp 265–266° dec.). Compound XVIII*b* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.45). UV (CH_3OH): 210 (log 4.23) and 236 (4.50) nm; mass spectrum: *m/z* 361 (M+, 89%) and 363 (M + 2, 100%).

1-Nitro-2-(m-bromophenyl)indolizine (*XVII*c)—Nitric acid (d = 1.4; 0.175 ml, 2.72 mmoles) was added dropwise over 5 min to an ice-cold stirred solution of 0.75 g (2.76 mmoles) of 2-(*m*-bromophenyl)indolizine (XI*c*) in 10 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The light yellow solution was stirred for 38 min at 0°. The mixture was poured into a beaker containing 20 g of crushed ice and filtered under vacuum using a sintered-filter funnel with medium porosity. The red-yellow precipitate was recrystallized from acetonitrile and yielded 0.12 g (14%) yellow needles (mp 174–175° dec.). Compound XVII*c* appears as one spot when analyzed by TLC (solvent system C, R_f 0.73). UV (CH_3OH): 215 (log 4.30), 242 (4.48), and 295 (4.17) nm; mass spectrum: *m/z* 191 (100%), 316 (M+, 48%), and 318 (M + 2, 52%).

1,3-Dinitro-2-(p-chlorophenyl)indolizine (*XVIII*c)—Nitric acid (d = 1.4; 0.175 ml, 2.72 mmoles) was added dropwise over 10 min to an ice-cold stirred solution containing 0.65 g (2.86 mmoles) of 2-(*p*-chlorophenyl)indolizine (XI*d*) in 10 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The mixture turned light yellow immediately and turned dark red after the addition of the final 0.05 ml of nitric acid.

The solution was stirred for 38 min, keeping the temperature at 0°. The mixture was poured into a sintered-filter funnel containing 20 g of crushed ice. After washing the filter with cold water several times, 0.30 g of a green-yellow precipitate (mp 130–145°) was recovered. The solid was placed in an alumina column and eluted with a mixture of 3:1 methylene chloride–hexane. The eluate was evaporated under vacuum. The green-yellow precipitate was recrystallized from acetonitrile and yielded 0.030 g (3%) yellow crystals (mp 215–216° dec.). Compound XVIII*c* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.43). UV (CH_3OH): 235 (log 4.37) nm; mass spectrum: *m/z* 272 (100%) and 317 (M+, 25.2%).

1-Nitro-2-(m-chlorophenyl)indolizine (*XVII*d)—Nitric acid (d = 1.4; 0.08 ml, 1.24 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 0.30 g (1.32 mmoles) 2-(*m*-chlorophenyl)-indolizine (XI*e*) dissolved in 2.0 ml of concentrated sulfuric acid. The light yellow solution was stirred for 38 min at 0°. The mixture was poured in a beaker containing 20 g of crushed ice. A red precipitate formed at once. The suspension was adjusted to pH 10.5 by adding 20% KOH solution. A bright yellow precipitate (0.3 g, mp 150–165° dec.) was recovered. The precipitate was recrystallized from acetonitrile and yielded 0.07 g (18%) of yellow needles (mp 190–191° dec.). Compound XVII*d* appeared as one spot when analyzed by TLC (solvent system B, R_f 0.49). UV (CH_3OH): 215 (log 4.29), 242 (4.46), and 295 (4.15) nm; mass spectrum: *m/z* 227 (100%) and 272 (M+, 25%).

1,3-Dinitro-2-(p-methoxyphenyl)indolizine (*XVIII*d)—Nitric acid (d = 1.4; 0.1 ml, 1.55 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 0.33 g (1.48 mmoles) of 2-(*p*-methoxyphenyl)indolizine (XI*f*) dissolved in 2.0 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The reddish-brown mixture was stirred for 38 min at 0°. The solution was poured into a beaker containing 20 g of crushed ice and basified to pH

10.5 by adding 20% KOH solution. A yellow precipitate (0.40 g, mp 160–165°) was recovered. The precipitate was placed in an alumina oxide column and eluted with a mixture of methylene chloride–hexane (3:1). The eluate was evaporated under vacuum apparatus and yielded 0.010 g (2.2%) yellow crystals (mp 268–269°). Compound XVIII*d* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.43). UV (CH_3OH): 210 (log 3.43) and 234 (3.72) nm; mass spectrum: *m/z* 313 (M+, 100%).

1,3-Dinitro-2-(m-*methoxyphenyl*)*indolizine* (*XVIIIe*)—Nitric acid (*d* = 1.4; 0.1 ml, 1.55 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 0.33 g (1.4 mmoles) 2-(*m*-methoxyphenyl)indolizine (XI*g*) dissolved in 2.0 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The orange-yellow solution was stirred for 38 min at 0°. The mixture was poured into a beaker containing 20 g of crushed ice and basified with 20% KOH solution until pH 10.5. The yellow precipitate (0.14 g, mp 130–145° dec.) was recrystallized from acetonitrile and yielded 0.08 g (17%) rust-red needles(mp 183–184° dec.). Compound XI*j* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.66). UV (CH_3OH): 220 (log 4.25), 236 (4.39), 290 (4.07) nm; mass spectrum: *m/z* 69 (100%) and 314 (M+, 95.5%).

1-Nitro-2-(p-*methylphenyl*)*indolizine* (*XVIIe*) *and 1,3-Dinitro-2-*(p-*methylphenyl*)*indolizine* (*XVIIIf*)—Nitric acid (*d* = 1.4; 0.1 ml, 1.55 mmoles) was added dropwise over 5 min to an ice-cold stirring solution containing 0.30 g (1.44 mmoles) 2-(*p*-methylphenyl)indolizine (XI*h*) dissolved in 2.0 ml of concentrated sulfuric acid in a 50-ml round-bottom flask equipped with a magnetic stirring bar. The dark yellow solution was stirred for 38 min at 0°. The mixture was poured into a beaker containing 20 g of crushed ice and adjusted to pH 10.5 by adding 20% KOH solution. The yellow suspension was filtered using a sintered-glass funnel and the yellow precipitate was dried overnight in a vacuum desiccator (0.36 g, mp 130–145° dec.). The precipitate was recrystallized from acetonitrile and then acetone. A greenish-yellow precipitate (0.12 g, mp 160–195°) was recovered. The solid was purified in an alumina oxide column using 1:3 methylene chloride–hexane. The filtrate was evaporated under vacuum. TLC using solvent system C showed two spots: starting material XI*h* (R_f 0.80) and compound XVII*e* (R_f 0.67). The nitroindolizine XVII*e* was separated by preparative TLC with solvent system B. The yellow band (R_f 0.53) was scraped off the plate and extracted with acetone. Yellow crystals were recovered yielding 0.02 g (5%), mp 178–179° dec. UV (CH_3OH): 210 (log 4.08), 255 (4.56), and 280 (4.22) nm; mass spectrum: *m/z* 252 (M+, 100%).

Further elution of the column using 1:1 methylene chloride–hexane followed by a more polar 3:1 mixture yielded 0.05 g (12%) of a bright yellow compound (mp 235–236° dec.). Compound XVIII*f* appeared as one spot when analyzed by TLC (solvent system C, R_f 0.38). UV (CH_3OH): 235 (log 4.40) and 265 (4.04) nm; mass spectrum: *m/z* 297 (M+, 100%).

1-Nitro-2-(m-*methylphenyl*)*indolizine* (*XVIIf*)—Nitric acid (*d* = 1.4; 0.1 ml, 1.55 mmoles) was added dropwise over 5 min to an ice-cold stirred solution containing 0.30 g (1.44 mmoles) of 2-(*m*-methylphenyl)-indolizine (XI*i*) dissolved in 2.0 ml of concentrated sulfuric acid in a 50-ml round-bottom flask containing a magnetic stirring bar. The light yellow mixture was stirred for 38 min at 0° and poured into a beaker containing 20 g of crushed ice. The solution was adjusted to pH 10.5 by adding 20% KOH. The yellow suspension was filtered using a sintered-filter funnel. The yellow precipitate was dried overnight under vacuum. The compound (0.33 g, mp 100–125° dec.) was recrystallized from acetonitrile and then acetone, yielding 0.03 g (mp 160–165° dec.) greenish-yellow crystals. TLC using solvent system C showed two spots; one from the starting material, XI*i* (R_f 0.86) and the other from compound XVII*f* (R_f 0.69). The nitro derivative was purified by preparative TLC using solvent system B. The yellow band (R_f 0.66) was scraped off from the plate and placed in a Hirsch funnel. The silica gel was washed several times with acetone until all yellow color disappeared. The filtrate was concentrated under vacuum yielding 0.02 g (5%) sparkling yellow crystals (mp 179–180° dec.), which turned light green immediately on contact with air. UV (CH_3OH): 210 (log 4.07), 240 (4.39), 294 (4.06), and 350 (4.07); mass spectrum: *m/z* 252 (M+, 100%).

Synthesis and Bioevaluation of a Series of Alkyl Ethers of *p*-*N*,*N*-Bis(2-chloroethyl)aminophenol

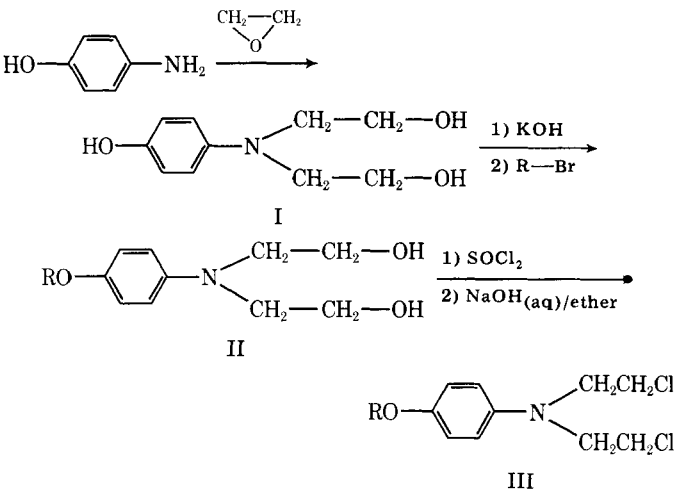
J. W. WISE, J. E. WYNN ˣ, R. L. BEAMER, and C. T. BAUGUESS

Received July 6, 1981, from the *Department of Basic Pharmaceutical Sciences, College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication September 4, 1981.

Abstract □ A series of even numbered normal alkyl ethers (C_2–C_{14}) of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol were synthesized and evaluated as to acute toxicity in mice and effects on survival in L-1210 leukemic mice. All of the ether derivatives demonstrated significantly lower acute toxicity than the parent phenol mustard. Significant survival times (≥125%) were obtained with all compounds except the hexyl derivative. The decyl ether produced the greatest significant increase and the ethyl ether the lowest significant increase in mean survival time. Significant survival times were produced at four dosage levels for the butyl, decyl, and dodecyl derivatives, three dosage levels for the octyl and tetradecyl derivatives, and one dosage level for the ethyl derivative.

Keyphrases □ Alkyl ethers—synthesis of alkyl ethers *p*-*N*,*N*-bis(2-chloroethyl)aminophenol □ Bioevaluation—alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, toxicity in HA/ICR mice □ Antitumor activity—alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, survival in L-1210 leukemic mice

Phenol mustard, *p*-[*N*,*N*-bis(2-chloroethyl)amino]-phenol, has demonstrated a low therapeutic index (1). Less toxic derivatives of phenol mustard have resulted from the synthesis of various esters of the phenol (1–3).



IIa, IIIa: R = CH_3—CH_2—
IIb, IIIb: R = CH_3—$(CH_2)_2$—CH_2—
IIc, IIIc: R = CH_3—$(CH_2)_4$—CH_2—
IId, IIId: R = CH_3—$(CH_2)_6$—CH_2—
IIe, IIIe: R = CH_3—$(CH_2)_8$—CH_2—
IIf, IIIf: R = CH_3—$(CH_2)_{10}$—CH_2—
IIg, IIIg: R = CH_3—$(CH_2)_{12}$—CH_2—

Scheme I

In an effort to develop latent derivatives of phenol mustard, a series of its substituted benzoate esters were studied (1). The results lent support to the hypothesis that hydrolysis of esters of *p*-[*N*,*N*-bis(2-chloroethyl)amino]-phenol to the free phenol mustard is a necessary step for antitumor activity (1). The effectiveness of aniline mustard, *N*,*N*-bis(2-chloroethyl)aniline, in the treatment of advanced plasma cell tumors has been demonstrated (4). The results indicated that aniline mustard was the optimally active compound in this system, and only those compounds that could be metabolized to a phenolic mustard demonstrated activity.

A series of alkyl ethers of phenol mustard should provide potentially latent nitrogen mustard derivatives with variable metabolic routes (5, 6). Such compounds would be expected to demonstrate antineoplastic activity with a reduction in host toxicity. In addition, lipophilicity would increase with the length of the alkyl chain. The specific objectives of this investigation were to: (*a*) synthesize a series of even-numbered, normal alkyl ethers (C_2–C_{14}) of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, (*b*) determine the acute toxicity as measured by the LD_{50} for each compound studied, and (*c*) determine the effect of each compound on the prolongation of life of L-1210 leukemic mice.

The compounds evaluated in this project were synthesized using Scheme I.

EXPERIMENTAL

Chemistry[1]—p-N,N-*Bis(2-hydroxyethyl)aminophenol* (*I*)—Twenty grams (0.18 mole) of *p*-aminophenol was added to a flask containing 200 ml of absolute methanol and equipped with a reflux condenser. The solution was stirred mechanically until dissolution occurred and then was cooled to 0°. Twenty grams (0.45 mole) of ethylene oxide was added to the cold reaction mixture. Stirring was continued and the reaction was allowed to reach room temperature. The resulting crystals were filtered and recrystallized from ethanol. The product had a melting point of 139.5–141° compared with the reported value of 140° (7).

[1] All IR spectral data were obtained from chloroform solutions of the derivatives on sodium chloride plates using a Beckman Model Acculab-4 spectrophotometer. Nuclear magnetic resonance spectra were obtained from deuterated chloroform solutions of the derivatives using a Hitachi-Perkin-Elmer model R-24 high resolution spectrometer with tetramethylsilane as the internal standard. The reported melting points were obtained using a Thomas Hoover capillary melting point apparatus and are uncorrected. The reported content of hydrogen, carbon, and nitrogen were obtained from analyses performed by Galbraith Laboratories, Knoxville, Tenn. All lyophilization was accomplished using a VirTis Model 10 freeze-dryer.

Synthesis and Bioevaluation of a Series of Alkyl Ethers of *p*-*N*,*N*-Bis(2-chloroethyl)aminophenol

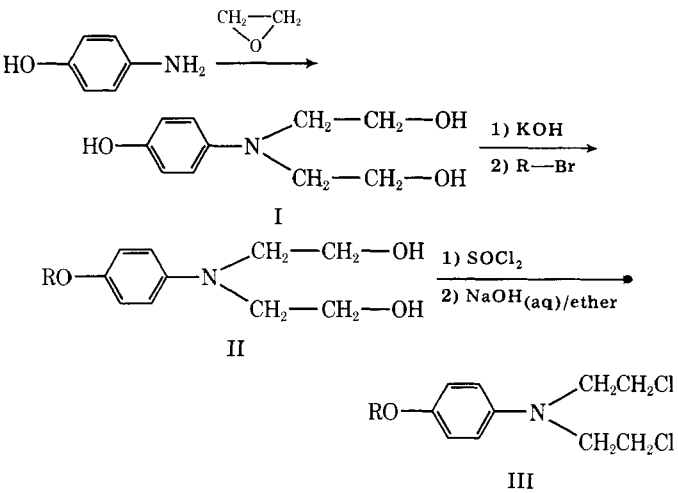
J. W. WISE, J. E. WYNN ˣ, R. L. BEAMER, and C. T. BAUGUESS

Received July 6, 1981, from the *Department of Basic Pharmaceutical Sciences, College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication September 4, 1981.

Abstract □ A series of even numbered normal alkyl ethers (C_2–C_{14}) of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol were synthesized and evaluated as to acute toxicity in mice and effects on survival in L-1210 leukemic mice. All of the ether derivatives demonstrated significantly lower acute toxicity than the parent phenol mustard. Significant survival times (≥125%) were obtained with all compounds except the hexyl derivative. The decyl ether produced the greatest significant increase and the ethyl ether the lowest significant increase in mean survival time. Significant survival times were produced at four dosage levels for the butyl, decyl, and dodecyl derivatives, three dosage levels for the octyl and tetradecyl derivatives, and one dosage level for the ethyl derivative.

Keyphrases □ Alkyl ethers—synthesis of alkyl ethers *p*-*N*,*N*-bis(2-chloroethyl)aminophenol □ Bioevaluation—alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, toxicity in HA/ICR mice □ Antitumor activity—alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, survival in L-1210 leukemic mice

Phenol mustard, *p*-[*N*,*N*-bis(2-chloroethyl)amino]-phenol, has demonstrated a low therapeutic index (1). Less toxic derivatives of phenol mustard have resulted from the synthesis of various esters of the phenol (1–3).



IIa, IIIa: R = CH_3—CH_2—
IIb, IIIb: R = CH_3—$(CH_2)_2$—CH_2—
IIc, IIIc: R = CH_3—$(CH_2)_4$—CH_2—
IId, IIId: R = CH_3—$(CH_2)_6$—CH_2—
IIe, IIIe: R = CH_3—$(CH_2)_8$—CH_2—
IIf, IIIf: R = CH_3—$(CH_2)_{10}$—CH_2—
IIg, IIIg: R = CH_3—$(CH_2)_{12}$—CH_2—

Scheme I

In an effort to develop latent derivatives of phenol mustard, a series of its substituted benzoate esters were studied (1). The results lent support to the hypothesis that hydrolysis of esters of *p*-[*N*,*N*-bis(2-chloroethyl)amino]-phenol to the free phenol mustard is a necessary step for antitumor activity (1). The effectiveness of aniline mustard, *N*,*N*-bis(2-chloroethyl)aniline, in the treatment of advanced plasma cell tumors has been demonstrated (4). The results indicated that aniline mustard was the optimally active compound in this system, and only those compounds that could be metabolized to a phenolic mustard demonstrated activity.

A series of alkyl ethers of phenol mustard should provide potentially latent nitrogen mustard derivatives with variable metabolic routes (5, 6). Such compounds would be expected to demonstrate antineoplastic activity with a reduction in host toxicity. In addition, lipophilicity would increase with the length of the alkyl chain. The specific objectives of this investigation were to: (*a*) synthesize a series of even-numbered, normal alkyl ethers (C_2–C_{14}) of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, (*b*) determine the acute toxicity as measured by the LD_{50} for each compound studied, and (*c*) determine the effect of each compound on the prolongation of life of L-1210 leukemic mice.

The compounds evaluated in this project were synthesized using Scheme I.

EXPERIMENTAL

Chemistry[1]—p-N,N-*Bis(2-hydroxyethyl)aminophenol* (*I*)—Twenty grams (0.18 mole) of *p*-aminophenol was added to a flask containing 200 ml of absolute methanol and equipped with a reflux condenser. The solution was stirred mechanically until dissolution occurred and then was cooled to 0°. Twenty grams (0.45 mole) of ethylene oxide was added to the cold reaction mixture. Stirring was continued and the reaction was allowed to reach room temperature. The resulting crystals were filtered and recrystallized from ethanol. The product had a melting point of 139.5–141° compared with the reported value of 140° (7).

[1] All IR spectral data were obtained from chloroform solutions of the derivatives on sodium chloride plates using a Beckman Model Acculab-4 spectrophotometer. Nuclear magnetic resonance spectra were obtained from deuterated chloroform solutions of the derivatives using a Hitachi-Perkin-Elmer model R-24 high resolution spectrometer with tetramethylsilane as the internal standard. The reported melting points were obtained using a Thomas Hoover capillary melting point apparatus and are uncorrected. The reported content of hydrogen, carbon, and nitrogen were obtained from analyses performed by Galbraith Laboratories, Knoxville, Tenn. All lyophilization was accomplished using a VirTis Model 10 freeze-dryer.

Synthesis of p-N,N-*Bis(2-hydroxyethyl)aminophenyl Alkyl Ethers* (*II a–g*)—Ten grams (0.05 mole) of I was dissolved in a reaction flask containing 300 ml of ethanol, 200 ml of water, and 7 g of KOH. This mixture was stirred and heated to reflux. An excess (0.15 mole) of the appropriate alkyl bromide (ethyl, butyl, hexyl, octyl, decyl, dodecyl, or tetradecyl) was introduced and reflux was continued for 24 hr. Excess solvent was removed *in vacuo* and the residue was mixed with ether. The ether solution was filtered to remove potassium bromide. The ethereal filtrate was extracted three times with 10% KOH solution to remove unreacted starting material. The ether layer was evaporated *in vacuo*. With the exception of the butyl, octyl, and tetradecyl derivatives, solid products suitable for analysis were obtained after cooling to 0°. The butyl and octyl derivatives were recrystallized from a methanol–water system, and lyophilized to yield analytically pure product. The tetradecyl derivative was purified by recrystallization from an acetone–water system. The new compounds were characterized by physical data (Table I) and IR and NMR spectra.

Synthesis of p-N,N-*Bis(2-chloroethyl)aminophenyl Alkyl Ethers* (*III* a–g)—Three-tenths of a mole of the appropriate derivative of II was dissolved in a minimum amount of chloroform. Five milliliters of absolute ethanol, then 1 ml of thionyl chloride, was added during continuous stirring. The reaction mixture was cooled to 0° on dry ice, 10 ml of thionyl chloride was added and the solution was allowed to reach room temperature. The mixture was concentrated *in vacuo* to remove solvent and excess thionyl chloride. Upon standing, solid products were obtained for the decyl and dodecyl derivatives. These products were recrystallized from an ethanol–water system and light-colored crystals were obtained. The ethyl, butyl, hexyl, and octyl derivatives were initially isolated as the hydrochloride salt. These products were converted to the free base by mixing with 10% NaOH and extracting with ether. Evaporation of the ether yielded oils suitable for analysis for the ethyl and hexyl derivatives. The butyl and octyl derivatives were recrystallized from an acetone–water system and lyophilized to yield analytical samples. The tetradecyl derivative was initially isolated as the free base and purified by recrystallization from an ethanol–water system. The ethyl, butyl, and octyl derivatives existed as black crystalline solids below 15° and as oils at room temperature. The hexyl derivative was an oil at 0° and room temperature. The tetradecyl derivative existed as a brown semi-solid below 15° and as an oil at room temperature. The final products were characterized by physical data (Table II) and IR and NMR spectra.

Biological Evaluation—*Test Animals*—DBA/2 mouse strain[2], BDF_1 mouse strain[2], HA/ICR mouse strain[3], and L-1210 leukemic mice (tumor source)[4] were used.

Instruments—The necessary equipment included an electronic cell counter[5], a channelizer[5], a dilutor[5], an *x-y* recorder[5], a hemocytometer[6], and a microscope[7].

Materials—Counting diluent[5], red blood cell-lysing reagent[5], crystal violet[8], Giemsa stain[9], isotonic diluting solution[10], trypan blue[11], and

[a] Administered in propylene glycol. [b] The T/C% value represents the ratio of the sum of the number of days the animals in a treated group survived (T) to the sum of the number of days the animals in the control group survived (C) multiplied by 100.

Wright's stain[8] were obtained commercially. The ether derivatives of III were prepared in the laboratory, and their physical and analytical data are reported in Table III.

Pretoxicity Testings—Groups of two healthy (HA/ICR) male mice were injected intraperitoneally with 500[12], 100, 10, 1, or 0.1 mg of test drug/kg in propylene glycol to evaluate the dose range for the pharmacological screen and LD_{50} determination.

Pharmacological Screen and LD_{50} Evaluation—Five groups, each with six HA/ICR mice, were selected. A gross screen was conducted for acute toxicity, and results were recorded during the 3 hr following injection. The mice were observed and weighed every day for 21 days, and the mortalities were recorded daily. A linear regression and correlation coefficient program (8) and a graphic method (9) were applied to determine the LD_{50} for each drug test.

Transplantation Procedures—Sterile equipment was used under aseptic conditions. DBA/2 (6–9 week old) host mice bearing L-1210 leukemia for 6–7 days were the tumor donors, and were sacrificed under ether vapor, immersed in 0.1% benzalkonium chloride, and swabbed with 70% ethanol. A 10-ml hypodermic syringe equipped with a 20-gauge needle (flushed with heparin at 1000 USP U/ml) was inserted into the abdominal cavity of the mouse and aspirated to obtain the lymphoid leukemia L-1210 cells (10). The leukemia cells were placed in a container over ice. One drop of ascitic fluid was prepared for microscope examination. Cell morphology was determined by staining with Wright's or Giemsa stain to differentiate the leukocytes and lymphoblasts (11). Ascitic fluid containing at least 95% lymphoblasts or lymphocytes was used for transplantation in DBA/2 mice for tumor maintenance and in BDF_1 mice for antileukemic studies. Cell counts and viability were determined using an electronic counter and a hemocytometer, respectively, as described in a recent report (3). The inoculum contained 1×10^5 cells in 0.1 ml. A 1-ml tuberculin syringe equipped with a 25-gauge needle was used to inject 0.1 ml of diluted ascitic L-1210 cells into the DBA/2 or BDF_1 mice. All inoculations of L-1210 cells were made within 1 hr after cell removal from the host mouse to ensure a viable transplant.

In Vivo *Determination of Antileukemic Activities by Survival Times*—On Day 0, the tumor was implanted into BDF_1 male mice; the number of survivors was recorded daily during the test period. The doses used were below the LD_{10} value of each test drug to minimize drug toxicity (12). The test solutions were injected within 15 min after preparation at a dose volume not to exceed 0.01 ml/g of body weight. The test drug solutions were administered intraperitoneally to each test group on Days

[12] Compounds III*d*, III*e*, and III*f* were limited by solubility to an upper dosage of 400 mg/kg.

2 and 5. The experiment was evaluated on the day of death for the last animal in a test group or after 30 days (12).

RESULTS AND DISCUSSION

Chemistry—The starting material (I) was obtained in 90% yields using a modification of the condensation of ethylene oxide with *p*-aminophenol reported previously (7). The ether intermediates (II*a–g*) were then obtained by reacting I with the appropriate alkyl bromide. The conditions for the Williamson synthesis of *p*-nitrophenyl ethers (13) were modified to produce II*a–g*. Because I has a higher pKa than *p*-nitrophenol, more base and a more polar solvent system were used to enhance the formation of the phenolate nucleophile. The reaction proceeded *via* a S_N2 displacement of the bromide by the phenolate nucleophile (14).

The primary isolation and purification step was the formation of the potassium salt of unreacted I and subsequent extraction with ether. Theoretical yields for II*a–g* ranged from 45 to 82% (Table I). The alkyl ethers of I were stable, low-melting solids with solubility in a variety of organic solvents. The IR spectra of these intermediates exhibited characteristic —OH absorption as a broad band between 3600 and 3100 cm^{-1}. The sharp absorption at 1240 cm^{-1} confirmed the presence of the ether function. The aliphatic and aromatic C—H stretching frequencies appeared in the region of 3150–2850 cm^{-1}. The intensity of the aliphatic absorption varied with the size of the alkyl substituent. The aromatic ring stretching occurred at 1520 cm^{-1}. The NMR spectra of these compounds, using $CDCl_3$ as a solvent, contained four distinct absorption patterns. A triplet (2H) (quartet for the ethyl derivative, II*a*) centered at 3.9 ppm, was observed for the methylene group adjacent to the ether oxygen. The remaining methylene groups in the alkyl side chain appeared, in the range of 1.6 to 2.0 ppm, as a multiplet for II*b* and II*c* and as a sharp singlet for the remaining homologs. The terminal methyl group absorbed as a triplet (3H) in the region of 1.2–1.4 ppm. The ethylene bridge yielded two triplets integrating for four protons each. The triplet at 3.3 ppm was assigned to the $—CH_2—$ groups adjacent to the nitrogen and the triplet at 3.7 ppm was assigned to the $—CH_2—$group adjacent to the —OH group. The alcoholic proton absorption appeared as a singlet (2H) in the region of 4.0–4.3 ppm. The four aromatic protons appeared as a typical A_2B_2 multiplet centered in the region of 6.6–6.7 ppm. Analytical purity was determined by elemental analysis (Table I).

The final products (III*a–g*) were obtained using thionyl chloride as the chlorinating agent. The vigor of the reaction was controlled by cooling to <0° and allowing the reaction mixture to slowly reach room temperature. The generation of hydrochloride gas in this reaction led to the formation and isolation of the hydrochloride salts of the ethyl, butyl, hexyl, and octyl derivatives. The IR spectra of the hydrochloride salts contained a strong absorption at 2400 cm^{-1} and medium absorptions at 3620 and 3650 cm^{-1}, confirming the presence of a tertiary amine salt. The NMR spectra of the hydrochloride salts contained a singlet at 7.0 ppm (N—H) and the aromatic protons displayed an AA'BB' pattern which appeared as two doublets centered at 6.8 and 7.7 ppm. Following neutralization with base, the N—H absorptions disappeared from both the IR and NMR spectra and the NMR pattern for the aromatic protons merged into a typical A_2B_2 multiplet centered at 6.6 ppm.

All of the final products (III*a–g*) were isolated and characterized as their free bases in yields ranging from 49 to 89%. The hydrochloride salts were neutralized by extracting ether solutions of the salts with 10% NaOH. Compounds III*a* and III*c* were isolated as oils suitable for analysis following the evaporation of the ether solution. All other products were recrystallized to yield analytically pure oils or solids (Table II). (Compounds III*b* and III*d* were also lyophilized.) The final products (III*a–g*) demonstrated solubility in ether, chloroform, ethanol, and methanol and were nearly insoluble in water. Upon chlorination of the dihydroxy intermediates (II*a–g*), the broad free OH band on the IR spectra disappeared and absorptions characteristic of halogenated hydrocarbons appeared at 1220 and 750 cm^{-1}. The NMR spectra of the nitrogen mustard derivatives (III*a–g*) demonstrated the loss of 2—OH protons. In addition the eight ethylene protons appeared as a sharp singlet in the region of 3.6–3.9 ppm. Other absorptions in the NMR spectra of compounds III*a–g* appeared as described for their precursors (II*a–g*). The purity of the nitrogen mustard products (III*a–g*) was determined by elemental analysis (Table II).

Biological Evaluation—The LD_{50} values for compounds III*a–c* were obtained using probit analysis and linear regression (Table III) (8, 9). Determination of exact LD_{50} values for compounds III*d–g* was restricted by the limited solubility of those compounds in propylene glycol. The LD_{50} values for compounds III*d–g* presented in Table III represent the highest doses that could be administered in propylene glycol. No deaths occurred at those dose levels, therefore, the LD_{50} values are considerably higher. As anticipated, the ether derivatives of phenol mustard demonstrated much less toxicity than reported for phenol mustard or for its unhindered benzoate and fatty acid esters (1, 3). In this series the butyl derivative (III*b*) exhibited the highest toxicity, 714 μm/kg, compared to a 74.8–162.4 μm/kg[13] range for the phenol mustard (1). The remaining compounds, III*a* and III*c–g*, demonstrated LD_{50} values comparable to, or higher than, cyclophosphamide, 1078 μm/kg in HA/ICR mice, an effective antineoplastic agent that is less toxic than clinically useful nitrogen mustards (3).

Table IV—Summary: Optimum Dose and Survival Time for the *p*-*N*,*N*-bis(2-chloroethyl)aminophenyl Alkyl Ethers

Compound Number (Derivative)	Optimum Dose		T/C, %
	mg/kg	μmoles/kg

III*d* (Octyl)	125	361	137
III*e* (Decyl)	125	335	163
III*f* (Dodecyl)	75	187	154
III*g* (Tetradecyl)	100	233	136

The effect of compounds III*a–g* on the prolongation of life of L-1210 leukemic mice was determined. A comparison of the survival of treated groups (T) to untreated control groups (C) was performed. A calculated T/C ratio ≥125% implied that the drug treatment significantly increased the life span. Table III summarizes the T/C% survivals produced at each dose level for each compound, the number of animals used per dosage level, and the mean survival for each animal group. The doses producing optimum survival for each compound are summarized in Table IV.

The decyl derivative (III*e*) produced the highest mean survival time (T/C% values) in the series, 163% at a dose of 335 μm/kg (125 mg/kg) as illustrated in Table IV. The ethyl derivative (III*a*) demonstrated the lowest significant optimum T/C% values in this series, 126% at 382 μm/kg (100 mg/kg). This was the only dose level at which significant survival (≥125%) was obtained for the ethyl derivative (III*a*). The butyl (III*b*), decyl (III*e*), and dodecyl (III*f*) derivatives produced significant survival at four dosage levels each and the octyl (III*d*) and tetradecyl (III*g*) derivatives at three dosage levels. Only the hexyl derivative (III*c*) failed to produce a significant T/C% value at any of the dosage levels investigated.

The differences in the observed toxicities and T/C% survival times may possibly be attributed to differences in both the metabolism and lipophilic character of the compounds studied. The ethyl ether of *p*-nitrophenol has been shown to undergo *O*-dealkylation both at a rapid rate *in vitro* and to a great extent (78%) *in vivo* (5). Conjugation of the phenolic mustard resulting from the *O*-dealkylation of III*a* would result in enhanced elimination, lower toxicity, and reduced antineoplastic activity. The butyl ether of *p*-nitrophenol has been shown to undergo *O*-dealkylation at a much slower rate and to a lesser extent than the ethyl ether (5). The (ω-1)-hydroxylation pathway has been reported to be a primary metabolic route for the butyl ether of *p*-nitrophenol in rabbits (6). Longer chain alkyl ethers of *p*-nitrophenol undergo *O*-dealkylation at a negligible rate and to a lesser extent *in vivo* and the (ω-1)-hydroxylation pathway is probably most important in their metabolism (5, 6). The lower LD_{50} value and the activity observed against L-1210 mouse leukemia for the butyl derivative (III*b*) may be attributed to the role of these metabolic pathways, as well as the solubility of the parent compound and the (ω-1)-hydroxy metabolite. The observation of lower toxicity for the longer chain ether derivatives, hexyl (III*c*)–tetradecyl (III*g*), is consistent with the expectation of negligible *O*-dealkylation for any of them. For the octyl (III*d*)–tetradecyl (III*g*) derivatives, the lower toxicity, coupled with an increase in the lipid solubility of both the parent compounds and their (ω-1)-hydroxy metabolites, should contribute to the observed antileukemic activity.

The lack of a significant prolongation of life in leukemic mice, at any of the dosage levels evaluated for the hexyl derivative (III*c*), cannot be explained on the basis of expected metabolism nor by the anticipated solubility properties of the compound and its (ω-1)-hydroxy metabolite. The role played by a complex combination of these factors may be important and could serve as the basis for a future investigation. An additional possibility is that in an aqueous solution of these compounds, a freely rotating alkyl sidechain could fold back and assume a conformation that would allow interaction between the sidechain and the ring and/or

[13] Unpublished data from these laboratories.

the bis(2-chloroethyl)amino moiety. In an attempt to gain further insight into this consideration, stereomodels and atomic models were constructed for the final products (IIIa–g). From both model types it appeared that the hexyl side chain was the appropriate length to allow the terminal methyl group to sterically affect the nitrogen atom. The ethyl and butyl side chains were too short for such an interaction and side chains longer than hexyl appeared subject to repulsion by the chloroethyl groups, thus, reducing their steric interaction with the nitrogen atom. Such an interaction between the nitrogen atom and the hexyl side chain could sterically hinder the participation of the nitrogen atom in the formation of the aziridinium ion intermediate. Such an interaction could reduce the reactivity of the hexyl derivative (IIIc) which would in turn reduce its antileukemic effectiveness and contribute to its relatively low toxicity.

Comparison of the Absorption, Excretion, and Metabolism of Suxibuzone and Phenylbutazone in Humans

YUKIHIRO YASUDA *x, TAKASHI SHINDO *, NARUO MITANI *, NAOBUMI ISHIDA *, FUMITOSHI OONO ‡, and TAKAMASA KAGEYAMA §

Received March 9, 1981, from the * *Research Laboratory, Taiho Pharmaceutical Co., Ltd., Kawauchi-cho, Tokushima, 771-01, Japan*, ‡ the *Second Department of Internal Medicine, School of Medicine, Kouchi University, Okatoyo-machi, Nangoku-shi, Kouchi, 781-51, Japan*, and the § *Department of Orthopedic Surgery, Sagamihara National Hospital, Kamitsuruma, Sagamihara-shi, 228, Japan.* Accepted for publication August 21, 1981.

Abstract □ The absorption, excretion, and metabolism of a single oral dose of suxibuzone, a new nonsteroidal anti-inflammatory agent, in healthy male volunteers were compared with those of phenylbutazone. After oral administration of either suxibuzone or phenylbutazone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone were found in the plasma; phenylbutazone was the main metabolite of suxibuzone and phenylbutazone. In the urine, *p*-γ-dihydroxyphenylbutazone and several glucuronide conjugates also were found. Spectrometric and/or enzymatic analysis showed that these glucuronide conjugates were suxibuzone glucuronide, 4-hydroxymethylphenylbutazone glucuronide, 4-hydroxymethyloxyphenbutazone glucuronide, oxyphenbutazone glucuronide, and phenylbutazone glucuronides (two types: *O*-glucuronide and C-4-glucuroxide) after suxibuzone administration, and oxyphenbutazone glucuronide and phenylbutazone glucuronide after phenylbutazone administration. The conjugates specific to suxibuzone administration, suxibuzone glucuronide, 4-hydroxymethylphenylbutazone glucuronide, and 4-hydroxymethyloxyphenbutazone glucuronide, were excreted in the first 6 hr urine. These findings and the pharmacokinetics of these metabolites in the plasma and urine show that suxibuzone is a prodrug of phenylbutazone.

Keyphrases □ Suxibuzone—*in vivo* absorption, excretion, and metabolism compared to phenylbutazone, humans □ Phenylbutazone—*in vivo* absorption, excretion, and metabolism compared to suxibuzone, human □ Pharmacokinetics—suxibuzone and phenylbutazone, *in vivo* humans □ Anti-inflammatory agents—suxibuzone and phenylbutazone, *in vivo*, humans

Suxibuzone is a derivative of phenylbutazone, in which the proton at the C-4-position of the pyrazolidine ring is replaced by a β-carboxypropionyloxymethyl group. The outstanding feature of the drug is that it has extremely low ulcerogenicity (1, 2) although its anti-inflammatory, analgesic, and antipyretic properties are as strong as those of an equimolar dosage of phenylbutazone (3).

This feature of suxibuzone can be understood by comparing the biological fates of suxibuzone and phenylbutazone; however, there have been no studies on metabolism of suxibuzone in humans. Therefore, the present study compared the metabolic pathways and pharmacokinetics of suxibuzone and phenylbutazone in humans.

EXPERIMENTAL

Materials—Suxibuzone[1], phenylbutazone[1], oxyphenbutazone[1], and γ-hydroxyphenylbutazone[1] were used as received. 4-Hydroxymethylphenylbutazone[2] was synthesized and purified.

Chromatography—HPLC was performed using a μ-Bondapak C_{18} column (30 × 0.4-cm i.d.)[3], which was fitted with a 254-nm UV detector. For low-resolution liquid chromatography, a column (20 × 2.5 cm) packed with Amberlite XAD-2 resin (coarse grade 35–50 mesh)[4] or Dowex-1 resin (200–400 mesh)[5] was used.

GC was carried out under the following conditions: column 5% Silicon GE SE-30 on Chromosorb W AW-DMCS 60–80 mesh[6], 2 m × 3-mm i.d.; column temperature, 275°; nitrogen flow rate, 60 ml/min; and detector, flame ion detector.

TLC was carried out using commercial silica gel plates[7] with the following solvent systems (SS):

SS 4: chloroform–methanol–formic acid (100:20:5)
SS 5: chloroform–methanol–acetone–formic acid (100:20:20:5)

Spectrometric Measurements—Direct inlet mass spectra were measured under the following conditions: ionizing energy, 75 eV; ionizing current, 200 μA; and acceleration voltage, 7 kV. GC–mass spectrometry was performed with a mass spectrometer under similar conditions, except that the ionizing energy was 24 eV and by GC under the conditions described above. Field desorption–mass spectrometry was carried out using a carbon emitter; acceleration voltage, 7 kV; and cathode voltage, −6 kV.

UV spectra were measured in methanol solution. NMR spectra were recorded in deuterated methanol with tetramethylsilane as internal standard.

Treatment of Subjects and Collection of Samples—Six male volunteers (weight, 54–68 kg; age, 27–35 years), who had had no other medication for at least 2 weeks before the experiments, were randomly divided into two groups and given a single 426-mg (3 capsules) oral dose of suxibuzone[8] or an equimolar amount, 300 mg (3 tablets), of phenylbutazone[9]. Four weeks after the first administration, the test was repeated on the two groups but interchanging the drug.

Blood was withdrawn at intervals during the first 7 days after drug administration and mixed with heparin to rapidly separate the plasma. Urine was collected quantitatively for the first 7 days, and feces were collected for the first 2 days. The excreta were kept frozen until analyzed.

Identification and Quantitative Analysis of Metabolites in Plasma—Plasma (6 ml) taken from blood of three volunteers 2 and 4 hr after drug administration was used for identification of metabolites. The sample was diluted with 9 ml of saline, adjusted to pH 2 with 2 *N* HCl, and extracted twice with 6 volumes of benzene–cyclohexane (1:1 v/v). The organic phase was divided into two portions, which were evaporated under nitrogen gas.

One residue was dissolved in a small amount of methanol and chromatographed on a reversed-phase column, using a mobile phase of a linear gradient of methanol in 0.05 *M* KH_2PO_4(0–100% methanol, 8%/min; flow rate, 2.0 ml/min) on a high-pressure liquid chromatograph[10] (4).

The other residue was dissolved in 100 μl of a freshly prepared solution of anhydrous chloroform and *N,O*-bis(trimethylsilyl)trifluoroacetamide[11] (I) (1:4 v/v) and stood for 1 hr at room temperature. The resulting trimethylsilylated derivatives were then analyzed by GC[12] and GC–mass spectrometry[13].

Plasma samples (2 ml) separated 2, 4, 8, 12, 24, 48, 96, and 168 hr after drug administration, were analyzed quantitatively by GC using tetraphenylethylene as an internal standard. The recoveries of suxibuzone, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone added to plasma at concentrations of 5–20 μg/ml were all more than 90%. The detection limits were 0.1 μg/ml for suxibuzone, and 0.05 μg/ml for other metabolites.

Identification of Free Metabolites in Urine—Samples of 5–10 ml of pooled urine were acidified and extracted with benzene–cyclohexane and the remaining aqueous phase was then extracted twice with 6 volumes of methylene chloride. The organic phases were then treated as described for plasma and the metabolites were identified by HPLC, GC, and GC–mass spectrometry.

Identification of Conjugated Metabolites in Urine—Pooled urine samples (500–1000 ml) were adjusted to pH 2 and extracted with benzene–cyclohexane to eliminate free metabolites. The aqueous phase was then saturated with sodium chloride and extracted twice with 6 volumes of ethyl acetate, and the organic layer was evaporated to dryness. The

residue was dissolved in distilled water (containing 1% v/v methanol) and the glucuronide fraction was obtained by the method of Kamil *et al.* (5). The glucuronide fraction was analyzed by TLC on silica gel. Samples were spotted on the gel and developed in two dimensions with solvent systems SS 1 and SS 2. The material visualized by reaction with naphthoresorcinol (blue) or anisaldehyde (green-gray), which were not seen on chromatography of control urine, were scraped off, dissolved in 5 ml of 0.067 (1/15) *M* acetate buffer (pH 5.5), and incubated with 1000 U of β-glucuronidase[14] at 37° for 3 hr. The samples were then treated in a way similar to that described for identification of free metabolites.

The four kinds of glucuronides (II, III, IV, V) were isolated and identified as follows. The 0–6 hr urine samples from three volunteers were

combined and used for isolation of II and III; 12–24 hr urine samples were used for isolation of IV. In addition, bile from rats treated orally with phenylbutazone was used as a source of V to obtain a sufficient amount for spectrometric measurement. Each urine sample (1000 ml) was adjusted to pH 2 with concentrated HCl and extracted twice with 6 volumes of methylene chloride. The aqueous phase was applied to an Amberlite XAD-2 column, and the fraction eluted with 20–80% methanol was purified by the method of Kamil *et al.* (5). The glucuronide mixture thus obtained was separated on a Dowex-1 column with 60% methanol in 0.01 *N* HCl and by preparative TLC with SS 2.

The isolated glucuronides were then subjected to spectrometric measurements. For mass spectrometry, the glucuronides were converted to their methyl and methyl acetyl derivatives as follows. The glucuronide fraction was dissolved in a small amount of methanol (~500 μl), mixed with 5 volumes of ethereal diazomethane, and kept for 20 min at room temperature. The methylated glucuronides were dissolved in anhydrous pyridine (500 μl), mixed with an equal volume of anhydrous acetic acid, stood overnight, and then precipitated by adding distilled water.

Bile was collected by cannula from the bile duct of rats (male Wistar, 200–250 g) over a 24-hr period after receiving 200 mg/kg phenylbutazone by stomach tube. Fifty milliliters of the bile was diluted with 8 volumes of a saline solution. The aqueous phase remaining after extraction of free metabolites was saturated with sodium chloride and extracted twice with 6 volumes of ethyl acetate. The extract was evaporated under reduced pressure, and the residue was dissolved in a small amount of methanol and subjected to preparative TLC with SS 2. The fraction that released phenylbutazone on β-glucuronidase treatment was eluted with methanol and purified further with HPLC on a reversed-phase column using 40% methanol (flow rate, 1.0 ml/min) as a mobile phase. The samples obtained were characterized by UV[15], mass spectrometry, and NMR[16] spectra.

Quantitative Analysis of Metabolites in Urine—Samples (5 ml) of urine collected 0–6, 6–12, 12–24, 24–48, 48–72, 72–96, and 96–168 hr after drug administration were used to assay for metabolites. Each urine sample (pH 2) was extracted with 10 ml of 0.1 *M* phosphate buffer (pH 7.0). The aqueous phase was acidified and extracted twice with 20 ml of methylene chloride and the extracts were treated in the same way as plasma extracts. This procedure eliminated interfering peaks in the chromatogram.

For determination of the amounts of conjugated metabolites, the aqueous phase obtained after extraction with benzene–cyclohexane was used. The extracts with ethyl acetate were treated with a mixture of 3000

[15] Model 124, Hitachi, Tokyo, Japan.

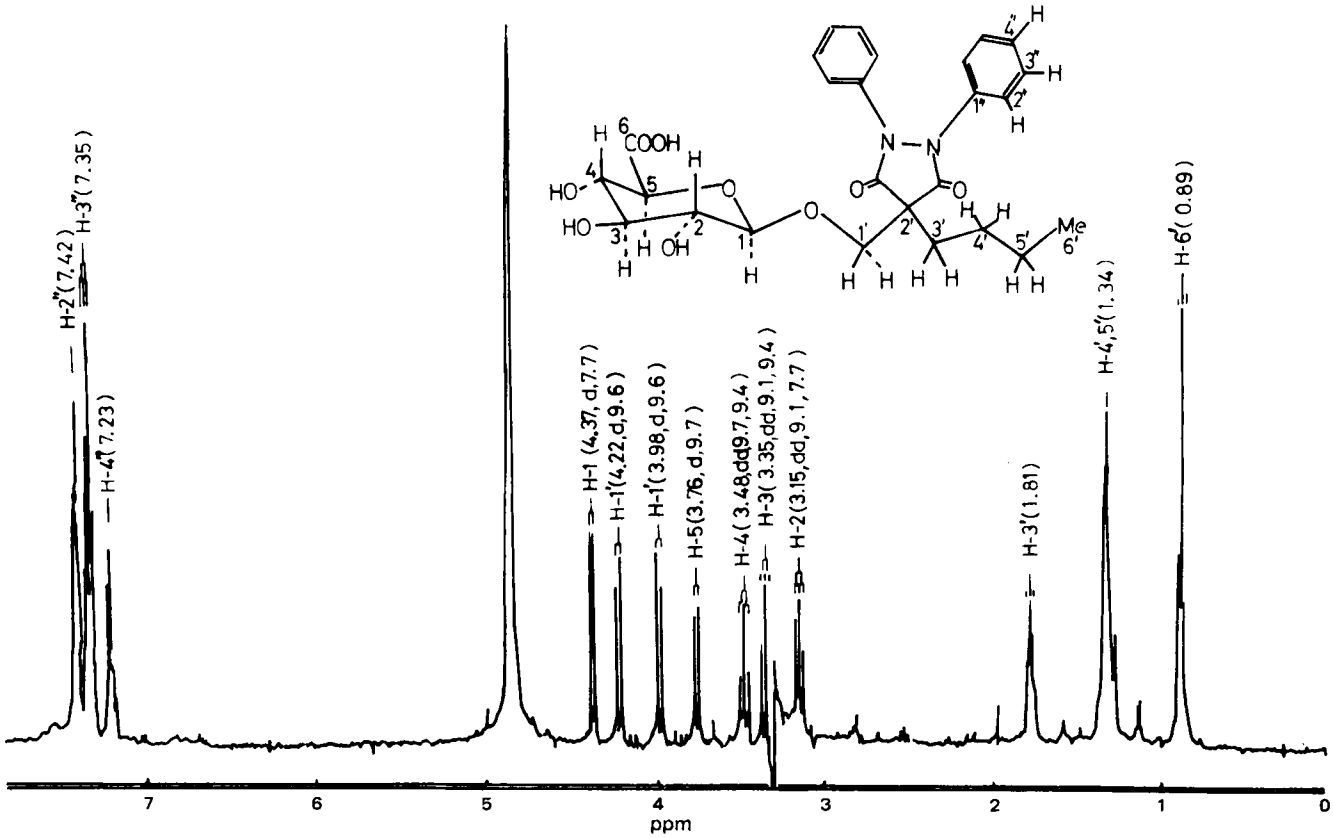

Figure 5—*NMR spectrum of II.*

U of β-glucuronidase and 10 U of sulfatase[17] in acetate buffer (pH 5.5) at 37° for 3 hr, and the concentrations of the respective aglycones released were determined by GC as described previously.

The recoveries of synthetic reference compounds in the range of 10–40 μg/ml by these extraction procedures were all >90%.

Quantitative Analysis of Suxibuzone and Phenylbutazone in Feces—The daily feces were homogenized with 3 volumes of water, adjusted to pH 2, and extracted with 5 volumes of benzene-cyclohexane. The concentrations of suxibuzone and phenylbutazone were determined by GC by procedures similar to those described for urine samples.

RESULTS

Identification of Metabolites in Plasma—The metabolites in plasma were first analyzed by HPLC. Three specific metabolites with retention times of 10.5, 10.0, and 9.4 min were observed in plasma after suxibuzone administration. These metabolites were identified as phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone by comparing their retention times to those of authentic samples. No unchanged suxibuzone or 4-hydroxymethylphenylbutazone, a possible metabolite of suxibuzone, was detected. The plasma extract was also analyzed by GC and GC-mass spectrometry after trimethylsilylation of the metabolites. Three metabolites with retention times of 4.0, 7.9, and 6.8 min, corresponding to those of trimethylsilylated phenylbutazone, trimethylsilylated oxyphenbutazone, and trimethylsilylated γ-hydrophenylbutazone, respectively, were observed. These metabolites were confirmed further by GC-mass spectrometry. The trimethylsilylated derivatives had characteristic fragments at m/z 380(M^+), 337, 308, and 246 like trimethylsilylated phenylbutazone, at 468, (M^+), 425, 396, 334, and 246 like trimethylsilylated oxyphenbutazone, and at 468(M^+), 376, 351, 338, and 246 like trimethylsilylated γ-hydroxyphenylbutazone, respectively. No conjugates were detected in the residual aqueous phase of plasma remaining after extraction with benzene–cyclohexane. Thus, the main metabolites in human plasma after suxibuzone administration were confirmed to be phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone. These metabolites were the same as those observed in plasma after phenylbutazone administration.

Quantitative Analysis of Metabolites in Plasma—The time courses of changes in the mean plasma phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone concentrations after administration of suxibuzone and phenylbutazone are shown in Fig. 1. The plasma phenylbutazone concentration was higher than that of other metabolites after administration of either suxibuzone or phenylbutazone. The mean plasma phenylbutazone concentration reached a maximum of 35.96 and 38.51 μg/ml as soon as 4 hr after administration of suxibuzone and phenylbutazone, respectively, and then decreased slowly between 8 and 168 hr, corresponding to elimination half-lives of 61.8 ± 5.0 (*SE*) hr on suxibuzone administration and 72.3 ± 3.6 hr on phenylbutazone administration. These values are comparable to that of 70.9 ± 5 hr reported by Levi *et al.* (6).

Change in the plasma oxyphenbutazone concentration exhibited similar time courses after administration of suxibuzone and phenylbutazone; it reached a maximum of ~7 μg/ml after 48 hr and decreased to 3–4 μg/ml within 168 hr.

On the other hand, the time course of change in the plasma γ-hydroxyphenylbutazone concentration after suxibuzone and phenylbutazone administrations were somewhat different; namely, it remained <0.1 μg/ml for at least 168 hr after phenylbutazone administration, but reached a maximum of ~1 μg/ml at 4 hr after suxibuzone administration. The difference between its concentrations 2–24 hr after administration of phenylbutazone and suxibuzone was statistically significant ($p < 0.05$).

These results show that suxibuzone was rapidly decomposed to phenylbutazone and that the plasma levels of phenylbutazone and oxyphenbutazone after suxibuzone administration were as high as those after phenylbutazone administration.

Identification of Metabolites in Urine—As in plasma, phenylbutazone, oxyphenbutazone, and γ-hydroxyphenylbutazone were extracted from urine with benzene–cyclohexane. A metabolite extracted with methylene chloride and derivatized with I exhibited a specific peak with a retention time of 13.0 min on GC. This metabolite was determined as p-γ-dihydroxyphenylbutazone by GC–mass spectrometry. The mass spectrum of this trimethylsilylated derivative had characteristic fragment ions at m/z 556(M^+), 426, 334, 246, 181, 93, and 77, like those reported previously (7). No unchanged suxibuzone or 4-hydroxymethylphenylbutazone was detected in the urine and the specifically determined metabolites were the same as those found in the urine of subjects treated with phenylbutazone.

Enzymatic Identification of Conjugated Metabolites—An enzy-

[17] Type V, Sigma Chemical Co.

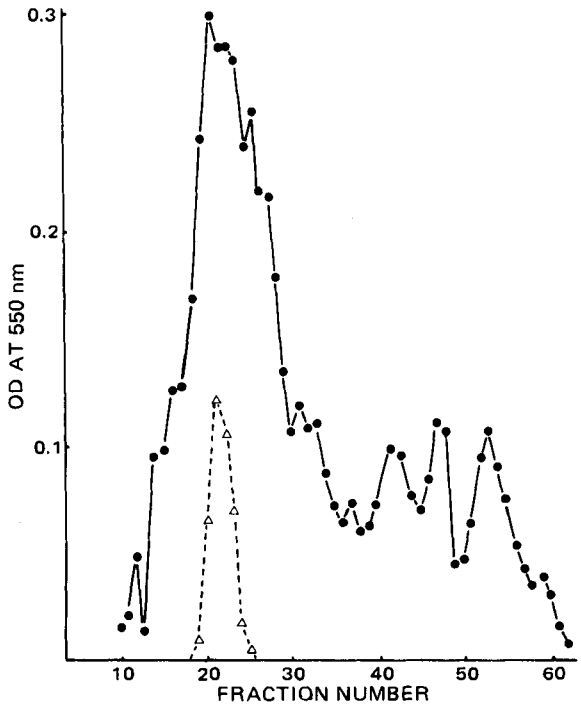

Figure 6—*Elution pattern of IV on Dowex-1. Key: ●, orcinol reaction, OD at 550 nm; △, IV, TLC(SS 2), OD at 254 nm.*

matic method was used to identify conjugated metabolites. The glucuronide mixture was separated by two-dimensional TLC, and the spots of material located by color reactions were analyzed by GC–mass spectrometry after hydrolysis with β-glucuronidase and derivatization with I. Typical thin layer chromatograms of glucuronides in urine after administration of suxibuzone and phenylbutazone are shown in Fig. 2. Analysis of each spot on the chromatogram after suxibuzone administration by GC showed that spot C_1 corresponded to trimethylsilylated phenylbutazone, spots C_2 and C_3 to trimethylsilylated oxyphenbutazone, and spot C_4 to trimethylsilylated suxibuzone and trimethylsilylated phenylbutazone, respectively. Chromatograms of urine samples after phenylbutazone administration gave spots C_1 and C_2 which corresponded to trimethylsilylated phenylbutazone and trimethylsilylated oxyphenbutazone, respectively. When the trimethylsilylated suxibuzone derivative of spot C_4 was analyzed by GC–mass spectrometry, the mass fragments coincided with those of the authentic compound; *m/z* 510(M^+), 485, 395, 380, 264, 183, 173, 105, 93, and 77. This confirms that spot C_4 contains suxibuzone glucuronide. Spots C_2 and C_3 both contained trimethylsilylated oxyphenbutazone. Spot C_3 was found only in the 0–6 hr urine sample after suxibuzone administration, whereas spot C_2 was observed after both suxibuzone and phenylbutazone and gradually became larger with increase in the plasma concentration and urinary excretion of oxyphenbutazone (Figs. 1 and 3). Hence, spot C_2 is considered to correspond to oxyphenbutazone glucuronide. Similarly, spot C_1 was expected to be phenylbutazone glucuronide (V) and the glucuronides (III,II) corresponding to spots C_3 and C_4 appeared only after suxibuzone administration.

Structures of Metabolites II and III—Compounds II and III were isolated on a preparative scale by the procedure shown in Fig. 4. Parts of both metabolites were converted to their methyl (II/1,III/1) and methyl acetyl (II/2,III/2) derivatives. The mass and NMR spectra (Fig. 5) show that II and III are 4-hydroxymethylphenylbutazone glucuronide and 4-hydroxymethyloxyphenbutazone glucuronide, respectively; *i.e.*, conjugates in which the oxymethyl residue at the C-4-position of the pyrazolidine ring is attached to glucuronic acid *via* an O—C bond. In the mass spectra of the methyl derivatives II/1 and III/1, the presence of glucuronyl residue was indicated by molecular ions at *m/z* 528 and 558, respectively, together with corresponding aglycone fragment ions at *m/z* 338 and 368. (Under the conditions used, III was dimethylated at the carboxyl group of glucuronic acid and at the hydroxyl group of one of the phenyl rings.) This was confirmed by the mass spectra of the methyl acetyl derivatives II/2 and III/2; namely, molecular ions were observed at *m/z* 654 and 684, respectively, indicating triacetylation at the three hydroxyl groups of glucuronic acid. The existence of an oxymethyl residue was deduced from subsequent fragmentation of *m/z* 338 to 308 (loss of $CH_2{=}O$) for II/1 and

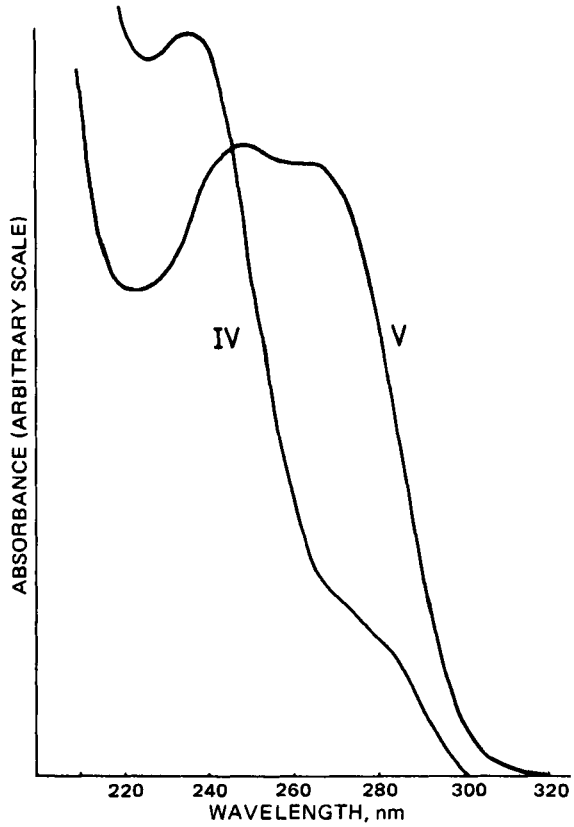

Figure 7—*UV spectra of IV and V.*

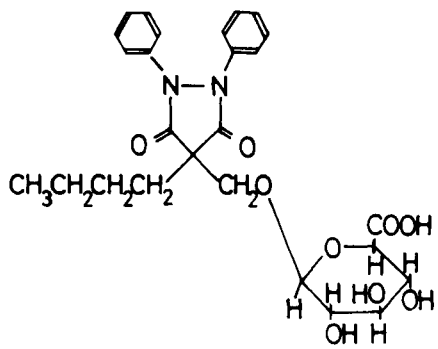
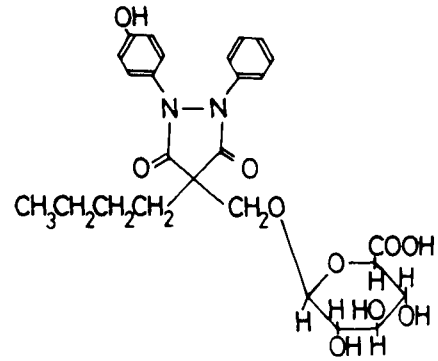
of *m/z* 368 to 338 for III/1. Furthermore, the ion set of *m/z* 338, 308, 264, and 183 observed for II/1 coincided with that of authentic 4-hydroxymethylphenylbutazone. The fragment ions at *m/z* 368, 338, 294, and 213 observed for III/1 were each shifted by *m/z* 30 relative to the corresponding fragment ions generated from 4-hydroxymethylphenylbutazone. This suggests the involvement of a methoxy groups in one of the phenyl rings (*e.g.*, $CH_3OC_6H_4N^+{=}NC_6H_5$ for the fragment ion at *m/z*

II



III



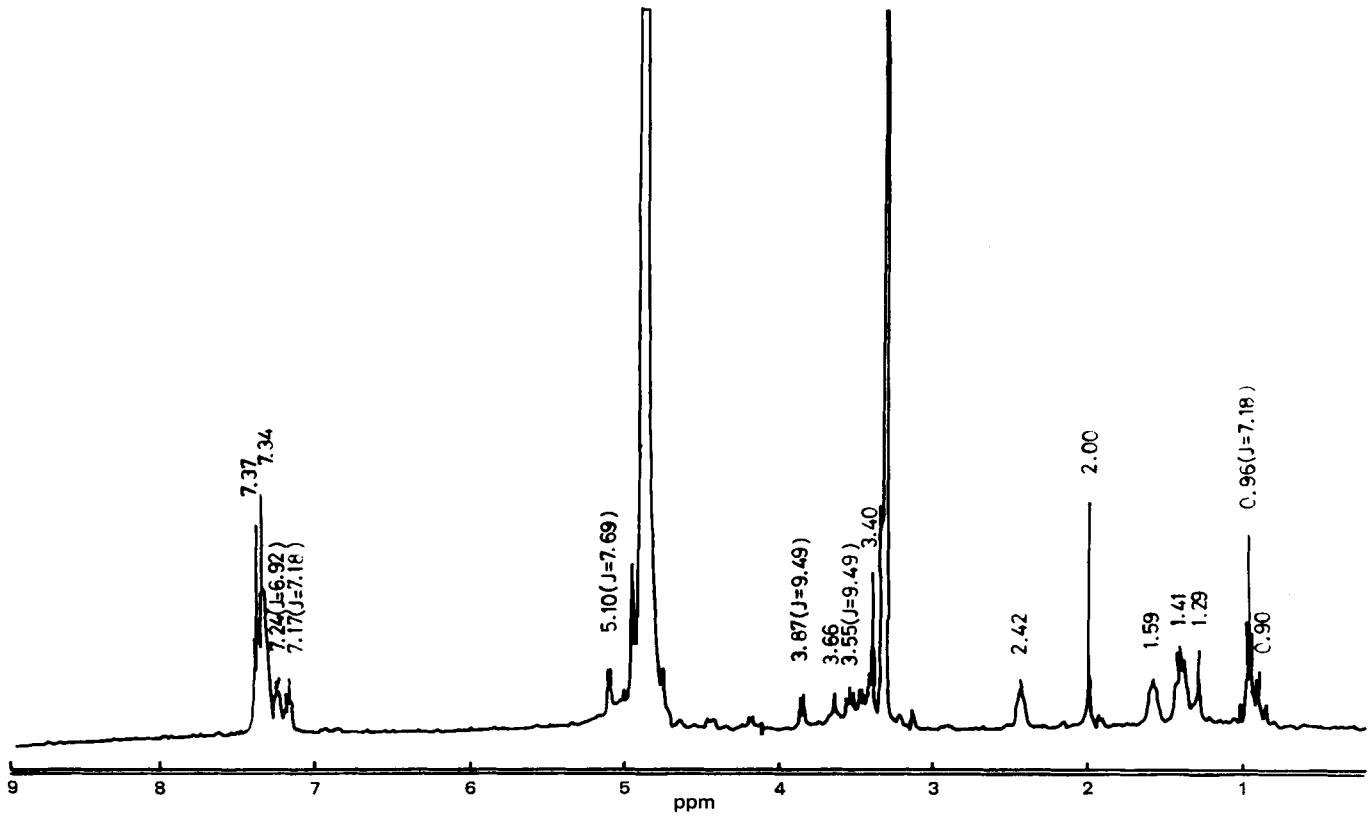


Figure 8—*NMR spectrum of V.*

213) and consequently suggests that the hydroxyl group in one of the phenyl rings is not attached to glucuronic acid. Confirmation of the assignments of the positions of glucuronidation in II and III were obtained from NMR spectra. The 400-MHz spectrum of II is shown in Fig. 5. Of significance for the assignment of glucuronidation at the oxygen of oxymethyl group is the appearance of an anomeric proton of glucuronic acid at δ4.37 ppm and of methylene protons of the oxymethyl group at δ4.22 and δ3.98 ppm, both of which are separated into a doublet with a geminal coupling constant of 9.6 Hz. The anomeric proton of glucuronic acid in III appeared at δ4.36 ppm, which is very close to that in II. The doublet signals (J = 9.0 Hz) of aromatic protons at δ6.72 and δ7.22 ppm established the existence of the hydroxyl group at the *para*-position of one of the phenyl rings in III. The proposed structures of II and III are shown.

The aglycones of 4-hydroxymethylphenylbutazone and 4-hydroxymethyloxyphenbutazone obtained by hydrolysis of II and III seemed to be converted to phenylbutazone (or trimethylsilylated phenylbutazone) and oxyphenbutazone (or trimethylsilylated oxyphenbutazone), respectively, during the process of hydrolysis with β-glucuronidase and/or trimethylsilylation with I under the conditions used. Hence, the spot C_4 was concluded to be that of a mixture of suxibuzone glucuronide and II, while spot C_3 was concluded to be that of III.

Structures of IV and V—The existence of C-4-phenylbutazone glucuronide in humans; *i.e.*, a conjugate in which the pyrazolidine ring is directly attached to glucuronic acid *via* a C—C bond and which is not hydrolyzed by β-glucuronidase, was demonstrated previously (8). On the other hand, the existence in humans and animals of a phenylbutazone glucuronide that can be hydrolyzed by β-glucuronidase (9, 10) was reported. Since there is little of this hydrolyzable phenylbutazone glucuronide in human urine, the structure of this compound(V) was first elucidated using bile of rats treated with phenylbutazone and then the identity of the material in rats and humans confirmed by TLC. C-4-phenylbutazone glucuronide (IV) was isolated from human urine.

The elution pattern of IV is shown in Fig. 6. Compound IV was identified as C-4-phenylbutazone glucuronide by mass spectrometry and UV studies (Fig. 7). The presence of glucuronic acid in the methyl ester of

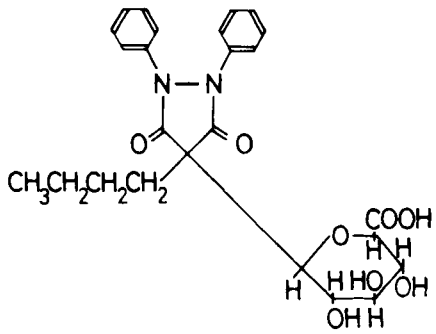
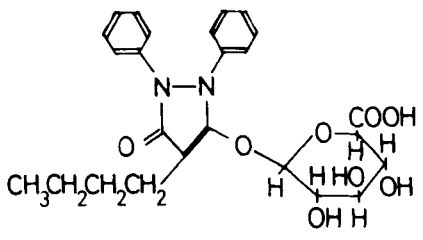
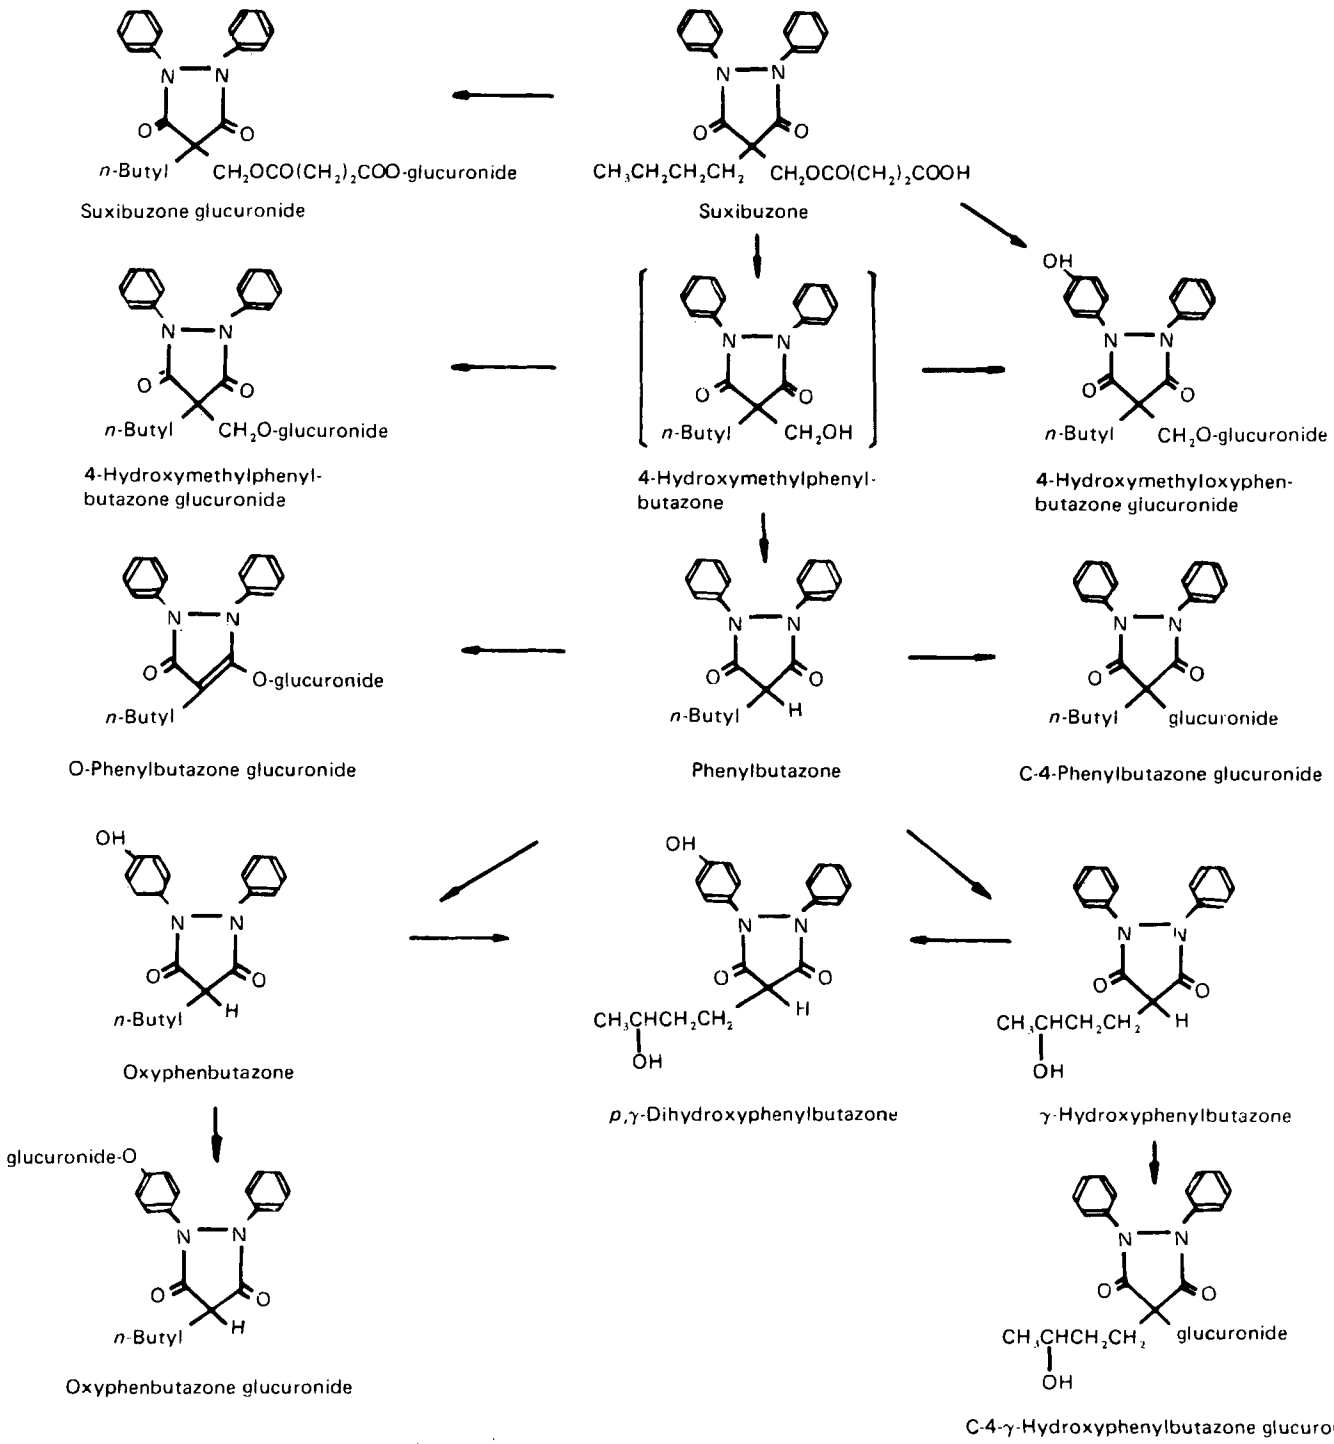
IV



V





Scheme I—Metabolic pathway of suxibuzone in humans.

IV was evidenced by a molecular ion at m/z 498 and a corresponding aglycone fragment ion at m/z 308. The UV spectrum of IV revealed the presence of diphenyldioxopyrazolidine ring with an intact 1,3-dicarbonyl system exhibiting a UV absorbance maximum (λ_{max}) at 236 nm. These data coincide well with those reported previously (8).

Since V was labile under the conditions used for derivatization with diazomethane and with I, the molecular ion was detected by field desorption–mass spectrometry. The field desorption–mass spectrum of V showed two ion peaks of a molecular ion at m/z 484 and a fragment ion at m/z 308 corresponding to its aglycone. Positive evidence for an O—C attachment of glucuronic acid was obtained from the UV and NMR spectra of V (Figs. 7 and 8). The UV spectrum indicated the presence of an enolic dioxopyrazolidine ring exhibiting a UV absorption at λ_{max} = 250 and ~265 nm instead of at λ_{max} = 236 nm for IV with an intact 1,3-dicarbonyl system. The NMR spectrum established an O—C attachment of glucuronic acid more directly by exhibiting downfield shifts of an anomeric proton of the glucuronic acid at δ5.10 ppm (J = 7.69 Hz) and of allylic protons of the n-butyl side chain at δ2.42 ppm. From these results it was concluded that V is an O-phenylbutazone glucuronide. The proposed structures of IV and V are as shown.

When co-chromatographed by two-dimensional TLC with solvent systems SS 1 and SS 2, IV and V migrated together giving a single spot. Hence, spot C_1 in Fig. 2 is considered to contain both O-phenylbutazone glucuronide and IV. With solvent system SS 5, however, IV and V were separated by TLC exhibiting R_f values of 0.46 and 0.51, respectively. The methanol extracts of spot C_1 after suxibuzone or phenylbutazone administration were chromatographed with solvent system SS 5 using IV and V as reference compounds. The band corresponding to that of V was eluted with methanol and treated with β-glucuronidase and the release of phenylbutazone was confirmed by GC. The band corresponding to that of IV did not release phenylbutazone on β-glucuronidase treatment.

Quantitative Analysis of the Metabolites in Urine—Figure 3 shows

the molar percentages of doses of suxibuzone and phenylbutazone excreted as various metabolites in the urine in different times. (Since 4-hydroxymethylphenylbutazone was obtained by hydrolysis of its conjugate with β-glucuronidase and was observed as phenylbutazone on GC, the ratio of II to *O*-phenylbutazone glucuronide by TLC separation was determined first. The amount of each metabolite was then calculated from the ratio and the total amount observed as phenylbutazone. The amount of III and oxyphenbutazone glucuronide were determined by similar treatments.) As seen in Fig. 3, the composition of metabolites excreted in the first 6-hr urine samples after administration of suxibuzone and phenylbutazone were different. The 0–6 hr urine after suxibuzone administration mostly contained the metabolites specific to suxibuzone administration; namely, suxibuzone glucuronide, II, and III. The amounts of these metabolites excreted were 0.12% of the dose of suxibuzone for suxibuzone glucuronide, 0.45% for II, and 0.44% for III. The amounts of these metabolites were negligible in urine samples collected at later times after suxibuzone administration.

Only the urinary excretion of γ-hydroxyphenylbutazone differed after administrations of suxibuzone and phenylbutazone; those of phenylbutazone, oxyphenbutazone, and their conjugates were similar. The percentages of the urinary excretion of phenylbutazone and *O*-phenylbutazone glucuronide during 168 hr after drug administration were 0.93 and 0.79%, respectively, of the dose of suxibuzone, and 1.20 and 0.95%, respectively, of the dose of phenylbutazone. Similarly, in the 0–168 hr samples, oxyphenbutazone and its conjugate amounted to 0.49 and 2.73%, respectively, of the dose of suxibuzone, and 0.63 and 3.42%, respectively, of the dose of phenylbutazone. On the other hand, the excretion of γ-hydroxyphenylbutazone in the first 24-hr urine samples was 2.44% of the dose of suxibuzone. This was 15 times that after phenylbutazone administration and seems to reflect the concentrations in the plasma. At more than 24 hr after administration of suxibuzone and phenylbutazone, the excretions of γ-hydroxyphenylbutazone were similar.

The cumulative urinary excretion of the metabolites measured amounted to ~8% of the dose within 168 hr after administration of either suxibuzone or phenylbutazone.

Excretion in Feces—The fecal excretions of suxibuzone and phenylbutazone are summarized in Table I. The percentages of excreted phenylbutazone were <1% of the dose, after both suxibuzone and phenylbutazone administration. No unchanged suxibuzone was detected in the feces; therefore, the absorptions of both drugs appear to be complete.

DISCUSSION

On the basis of the present results on suxibuzone and phenylbutazone in humans and findings on phenylbutazone by other groups (7, 8, 11–15), a scheme for the biotransformation of suxibuzone is shown in Scheme 1.

Analysis of urinary metabolites elucidated possible pathways of biotransformation from suxibuzone to phenylbutazone. No unchanged suxibuzone was observed in the plasma, but the excretion of suxibuzone glucuronide in the urine suggests that part of the oral dose of suxibuzone is absorbed in an unchanged form and excreted as the glucuronide. Detection of II suggests that suxibuzone was hydrolyzed by esterases (9) to give 4-hydroxymethylphenylbutazone, which is considered to be labile and to decompose to phenylbutazone spontaneously unless otherwise conjugated with glucuronic acid at the oxymethyl side chain. The excretion of III indicates the existence of a pathway in which unchanged suxibuzone or an intermediary between suxibuzone and phenylbutazone (*e.g.*, 4-hydroxymethylphenylbutazone) undergoes oxidation at the *para*-position of one of the phenyl rings. Consequently, this means that part of the unchanged suxibuzone absorbed can yield oxyphenbutazone without being metabolized to phenylbutazone. If this type of pathway exists for producing γ-hydroxyphenylbutazone (*e.g. via* a 4-hydroxymethyl-γ-hydroxyphenylbutazone), it could explain the significantly higher plasma level of γ-hydroxyphenylbutazone during a 24-hr period after suxibuzone administration. [The higher plasma level of γ-hydroxyphenylbutazone after suxibuzone administration may contribute to the lower plasma level of uric acid than that after phenylbutazone administration (10), since γ-hydroxyphenylbutazone was reported to enhance the excretion of uric acid (16).] The excretions of these metabolites specific to suxibuzone in the first 6 hr urine may be the cause of the slightly (though not significantly) lower plasma level of phenylbutazone after suxibuzone administration.

Although V hydrolysed by β-glucuronidase in rat or human urine could not be detected previously (7, 8), a hydrolyzable *O*-phenylbutazone glucuronide was isolated, the existence of which has already been suggested (9, 10). Hence, phenylbutazone undergoes two different types of glucuronidation and is excreted in the urine.

Most ester-type drugs are considered to be hydrolyzed by esterases bound to the intestinal mucosa, so the form of the drug which enters the portal venous blood will be greatly affected by the activities of these esterases (17–19). This also seems to be the case for suxibuzone, judging from the rate of hydrolysis of suxibuzone determined using homogenates of intestine of various animals and from the metabolites detected in plasma and urine (9). For example, in dogs, in which the intestine have very low esterase activity, unchanged suxibuzone was detected in the plasma; but in rats, in which the intestine has high esterase activities, no suxibuzone was detected in the plasma and no suxibuzone glucuronide or II were found in the urine. In humans the esterase activity of the intestine is reported to be relatively high (18, 19), and no unchanged suxibuzone was detected in the plasma or feces. Moreover, the changes in concentration of metabolites in the plasma exhibited almost the same time courses after the administration of suxibuzone and phenylbutazone. These observations imply that most of the suxibuzone administered orally is hydrolyzed to phenylbutazone by intestinal esterases before transfer to the portal venous blood.

The results obtained in the present study indicate that suxibuzone is a prodrug of phenylbutazone in humans. The metabolic fate and pharmacokinetic properties of suxibuzone ensure that this drug is as effective as phenylbutazone. The reason why suxibuzone is less ulcerogenic than phenylbutazone is considered to be that suxibuzone remaining in GI tracts is not as harmful as phenylbutazone to GI mucosa, since the unchanged suxibuzone does not inhibit the function of mitochondria and prostaglandin synthetases (unpublished data).

Oral Hydrocortisone Pharmacokinetics: A Comparison of Fluorescence and Ultraviolet High-Pressure Liquid Chromatographic Assays for Hydrocortisone in Plasma

ROGER D. TOOTHAKER *¶, GLORIA M. SUNDARESAN ‡, JOHN P. HUNT ‡, THOMAS J. GOEHL ‡, KEITH S. ROTENBERG ‡, VADLAMANI K. PRASAD ‡, WILLIAM A. CRAIG §, and PETER G. WELLING *x

Received March 30, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706, the ‡Division of Biopharmaceutics, United States Food and Drug Administration, Washington, DC 20204, and the §Veterans Administration Hospital, Madison, WI 53705. Accepted for publication September 2, 1981. ¶Present address: Department of Pharmaceutics, BG-20, School of Pharmacy, University of Washington, Seattle, WA 98195.

Abstract □ Three fasted, male subjects received single 10-, 30-, and 50-mg oral doses of hydrocortisone tablets on separate occasions. Endogenous hydrocortisone was suppressed by giving 2 mg of dexamethasone 9 hr prior to dosing. Plasma samples obtained serially for 8 hr after hydrocortisone dosing were assayed by reversed-phase high-pressure liquid chromatography (HPLC) with UV detection and by normal-phase HPLC with fluorescence detection of the dansylhydrazine derivative of hydrocortisone. The two assay methods yielded equivalent plasma hydrocortisone concentrations. Metabolite interference was absent in both assay methods. Drug concentrations in plasma from all three doses of hydrocortisone were described by one-compartment open-model kinetics, with first-order absorption and elimination, and an absorption lag time. Mean C_{max} values of 199, 393, and 419 ng/ml were obtained at 1.0, 1.0, and 1.7 hr following the 10-, 30-, and 50-mg doses, respectively. Hydrocortisone was cleared from plasma with an elimination half-life of ~1.5 hr. Within the dosage range studied, plasma levels of hydrocortisone were related, but not directly proportional, to dose size. This apparent lack of proportionality may be due to reduced drug availability or altered distribution with increasing dose.

Keyphrases □ High-pressure liquid chromatography—comparison of fluorescence and UV high-pressure liquid chromatographic assays for hydrocortisone in plasma, humans □ Hydrocortisone—comparison of fluorescence and UV high-pressure liquid chromatographic assays for hydrocortisone in plasma, humans □ Pharmacokinetics—comparison of fluorescence and UV high-pressure liquid chromatographic assays for hydrocortisone tablets in plasma, humans

A number of high-pressure liquid chromatographic (HPLC) assays for hydrocortisone in biological fluids have recently appeared in the literature. Most of these employ UV detection of underivatized hydrocortisone (1–7), while others are based on detection of a fluorescent hydrocortisone derivative (8, 9).

In this report two assay methods, one using normal phase HPLC with fluorescence detection of the dansyl derivative of hydrocortisone and the other using reversed-phase HPLC with UV detection of hydrocortisone, were compared by assaying plasma samples obtained during an 8-hr period from three healthy volunteers who had ingested hydrocortisone tablets. The plasma concentration *versus* time data permits preliminary description of the pharmacokinetics of exogenous hydrocortisone.

EXPERIMENTAL

Materials—Materials used in the HPLC–fluorescence assay have been described previously (8). For the HPLC–UV assay, chemical standards of hydrocortisone[1] and internal standard Δ^4-pregnene-17α, 20β,21-triol-3,11-dione[1] were analytical grade. Reagent grade methylene chloride[2] was distilled prior to use. All other solvents and chemicals were reagent grade and were used as supplied. Plasma for construction of standard curves was obtained from healthy volunteers between 7 and 9 am subsequent to administration of 2 mg of dexamethasone at 11 pm the previous day (10).

Subjects—Three male volunteers (22–45 years old) underwent complete physical examinations including blood and urine analyses after giving informed consent. Vital signs and laboratory values for all subjects were normal. The subjects weighed 64–75 kg, and their heights ranged from 178 to 180 cm.

Protocol—Subjects were instructed to take no drugs for at least 1 week before the study, and no drugs other than the required doses of dexamethasone and hydrocortisone during the study. No caffeine-containing beverages were permitted for 1 day before or during the plasma sampling period following each dose of hydrocortisone. Each hydrocortisone dose was administered after overnight fast, and no food was permitted until 4 hr postdose.

Each subject received 10-, 30-, and 50-mg doses of hydrocortisone at least 1 week apart according to a randomized design. Each hydrocortisone dose was given as 1 or more 10-mg tablets[3], which were swallowed whole.

At 11 pm on the day before hydrocortisone administration, subjects received 20 ml (2 mg) of dexamethasone elixir[4] with 180 ml of water orally. Hydrocortisone was administered at 8 am the following morning with 180 ml of water.

Heparinized blood samples (10 ml) were taken from a forearm vein immediately before and then at 0.25, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, and 8 hr postdose Subjects were ambulatory during the sampling period. Plasma was obtained by centrifugation and divided into two portions. Both portions were frozen at −20°: one portion was packed in dry ice and sent by air freight to the Food and Drug Administration laboratories for fluorimetric analysis; the other was assayed in this laboratory by the HPLC–UV method.

Fluorimetric Assay—The fluorimetric HPLC assay of plasma samples was carried out using a previously described method (8).

UV Assay—The HPLC–UV assay used was a modified version of a previously described method (1). Plasma (1 ml) containing 200 ng internal standard, and 0.1 ml of 2 *N* aqueous sodium hydroxide was vortexed with 10 ml of methylene chloride for 1 min and then centrifuged for 15 min at 500×*g*. Plasma and the creamy interface were aspirated off, and the organic layer was transferred to a clean tube and evaporated to dryness at room temperature under nitrogen. The tube walls were rinsed with 1 ml of methylene chloride which was evaporated as described previously. The residue was reconstituted in 100 μl of the HPLC mobile phase (60% aqueous methanol) and a 20-μl aliquot was injected into the chromatograph. The liquid chromatograph consisted of a 2.1 × 70-mm precolumn[5] and a 4.6 × 250-mm reversed-phase analytical column[6], through which mobile phase, 60% aqueous methanol, was pumped at a rate of 1.0 ml/min. Column effluent was monitored at 254 nm with a fixed wavelength detector[7]. Elution times for hydrocortisone and internal standard were 10 and 8 min, respectively. Calibration was by the method of peak height ratios. For plasma samples that yielded hydrocortisone and internal standard peak height ratios of <0.1 (hydrocortisone concentrations <25 ng/ml), a second injection was performed and the peak height ratios

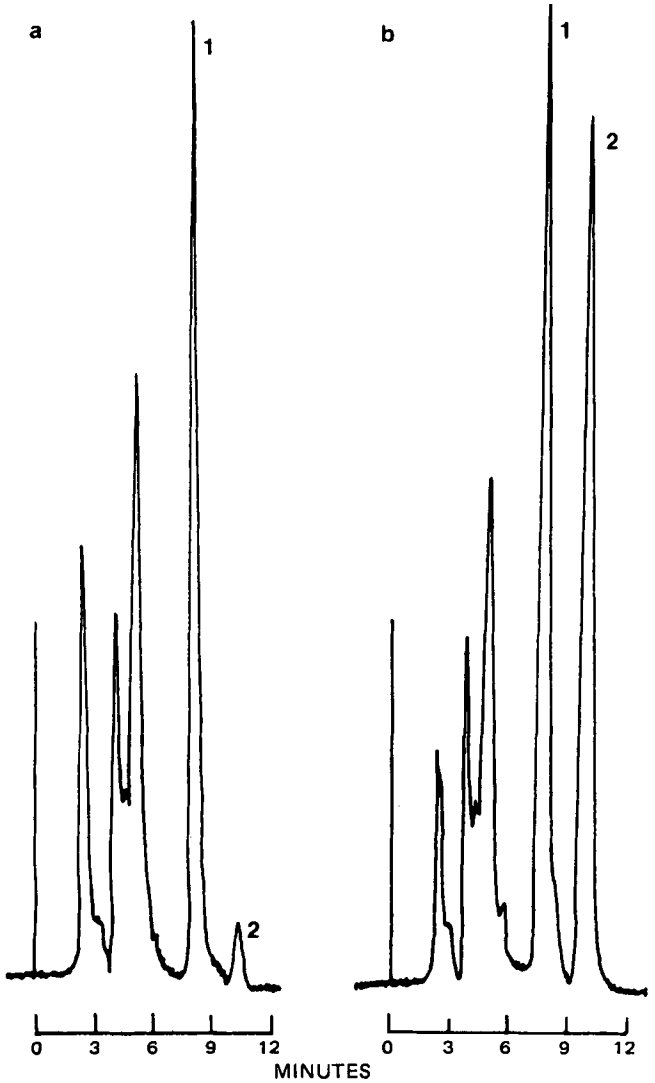

Figure 1—*Representative Chromatograms from HPLC–UV assay of hydrocortisone, peak 2, and internal standard, peak 1, extracted from human plasma.* a—*Dexamethasone—suppressed plasma containing 200 ng/ml internal standard and 11 ng/ml hydrocortisone (endogenous).* b—*Sample plasma containing 200 ng/ml internal standard and 149 ng/ml hydrocortisone (dosed + endogenous).*

obtained from the two injections were averaged. The endogenous hydrocortisone concentration in predose plasma was subtracted from all postdose values to obtain circulating levels of drug resulting from administered hydrocortisone. The assay was linearly sensitive to plasma hydrocortisone concentrations between 5 and 700 ng/ml. Coefficients of variation from multiple replicates ($n = 6$) were within 4% at the higher drug concentrations and within 8% at the lower drug concentrations. Assay recovery was 82 ± 2% for hydrocortisone and 83% for internal standard (single determination).

Pharmacokinetic and Statistical Analysis—Plasma hydrocortisone concentration data from all three doses were adequately described in terms of the one-compartment open pharmacokinetic model with first-order absorption and elimination and an absorption lag time. Thus, the hydrocortisone concentration C in plasma at any time t after dosing was shown by (11):

$$C = \frac{FD}{V}\left(\frac{k_a}{k_a - k_{el}}\right)\left[e^{-k_{el}(t-t_0)} - e^{-k_a(t-t_0)}\right] \qquad \text{(Eq. 1)}$$

where k_a and k_{el} are the first-order absorption and elimination rate constants, t_0 is the absorption lag time, F is the fraction of dose (D) absorbed, and V is the apparent distribution volume of drug in the body.

Equation parameters were obtained by nonlinear regression of individual hydrocortisone concentration data sets using the program NREG (12) on a digital computer[8].

[8] Univac Model 1100.

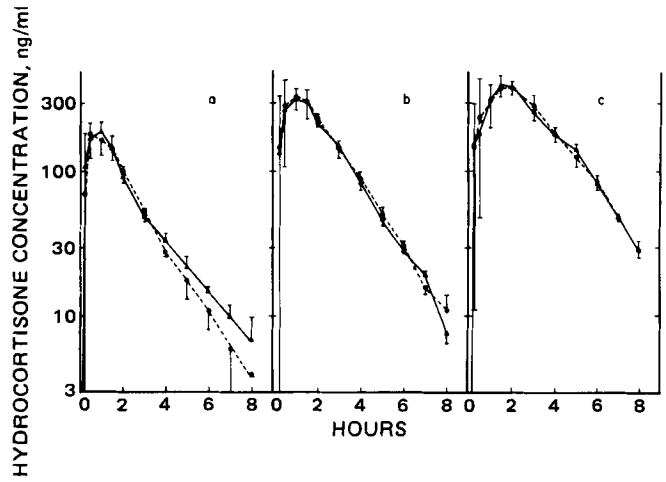

Figure 2—*Mean hydrocortisone plasma concentration* versus *time curves for three subjects (±1 SD) at dosages of* a, *10-mg;* b, *30-mg; and* c, *50-mg. Key:* ▲—▲, *UV;* ●---●, *fluorescence.*

Comparison of the hydrocortisone concentration values obtained by the two assay procedures was by paired t test. Pharmacokinetic parameters were analyzed for dose and assay effects by ANOVA. Factors shown to have a significant effect by ANOVA were further analyzed using Tukey's significant difference test (13).

RESULTS

Figure 1 shows two representative chromatograms from the HPLC–UV assay. Figure 1*a* illustrates the low level of endogenous hydrocortisone in suppressed plasma. The standard curve for hydrocortisone concentrations between 5 and 700 ng/ml in plasma was given by:

$$Y = -0.014\ (\pm 0.010) + 0.00497\ (\pm 0.00003)\ X \qquad \text{(Eq. 2)}$$

where $r = 0.999$ and $n = 6$.

Comparisons of the UV and Fluorescence Assays—Mean plasma hydrocortisone concentrations obtained using the two assay methods are shown in Fig. 2. Drug concentrations obtained by the different assays at each sampling time were compared by paired t test, and a significant difference between assays was obtained at only 2 of the 33 sampling times (11 sampling times at each dose level). The linear regression of the results obtained at all sampling times with the UV assay *versus* those obtained with the fluorescence assay is shown in Fig. 3. The regression had a slope

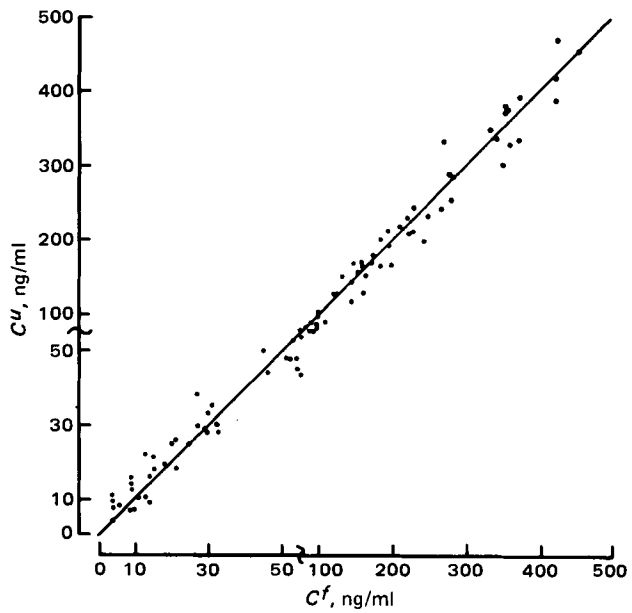

Figure 3—*Plasma hydrocortisone concentrations as obtained by UV detection* (C^u) versus *those obtained by fluorescence detection* (C^f). *Y = 0.992x + 1.59; n = 94, r = 0.987.*

Table I—Mean Values of Pharmacokinetic Parameters Obtained Following 10-, 30-, and 50-mg Oral Doses of Hydrocortisone, with Analysis by HPLC–UV Assay

Parameter	Value			Statistic
	10-mg dose	30-mg dose	50-mg dose	
k_a, hr^{-1}	7.7 ± 7.3[a]	7.7 ± 6.3	1.4 ± 0.5	AB > C[b]
t_0, hr	0.18 ± 0.07	0.26 ± 0.14	0.13 ± 0.23	B > A > C
k_{el}, hr^{-1}	0.47 ± 0.06	0.54 ± 0.04	0.43 ± 0.03	NSD[c]
$t_{1/2el}$, hr	1.50 ± 0.17	1.29 ± 0.09	1.62 ± 0.09	NSD
C_{max}[d], ng/ml	199 ± 29	393 ± 58	419 ± 45	CB > A
T_{max}[e], hr	1.0 ± 0.5	1.0 ± 0.5	1.7 ± 0.3	C > AB
C_{max}/D[f], 10^{-6}/ml	19.9 ± 2.9	13.1 ± 2.0	8.4 ± 0.9	A > B > C
F/V[g], 10^{-6}/ml	23.5 ± 3.6	17.0 ± 2.5	13.7 ± 1.5	A > B > C
AUC_{trap}[h], ng hr/ml	474 ± 48	958 ± 113	1559 ± 142	C > B > A
r^2[i]	0.98 ± 0.02	0.99 ± 0.02	0.99 ± 0.01	NSD

[a] Standard deviation (n = 3). [b] A = 10-mg dose, B = 30-mg dose, C = 50-mg dose. [c] No significant differences ($p > 0.05$). [d] Maximum observed concentration of hydrocortisone in plasma. [e] Time of observed C_{max}. [f] Maximum concentration of hydrocortisone in plasma divided by dose. [g] The fraction of the dose which is adsorbed, expressed as a concentration in the apparent distribution volume; obtained by dividing the function FD/V, from Eq. 1, by the dose. [h] Area under plasma hydrocortisone concentration profile calculated by trapezoidal rule with end correction. [i] Coefficient of determination from nonlinear regression analysis of plasma data using Eq. 1 [$r^2 = (\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2$].

of 0.99, an intercept that was not significantly different from zero, and a correlation coefficient of 0.987 ($p < 0.001$).

Pharmacokinetic Analysis—No statistical differences were observed in the values of any pharmacokinetic parameters resulting from the two assay methods. Therefore, only those values obtained using the HPLC–UV assay are presented in Table I.

The high coefficients of determination that resulted from analysis of individual data sets indicated that hydrocortisone plasma profiles following oral doses are adequately described by a one-compartment kinetic model. Following the 10- and 30-mg doses, hydrocortisone was absorbed rapidly and peak drug levels in plasma were obtained 1 hr postdose. Following the 50-mg dose, hydrocortisone was absorbed at a slower rate, yielding peak drug levels in plasma at ~1.7 hr. For all three dosages, description of the absorption phase of drug profiles was improved by incorporation of a lag time. After achieving peak values, drug levels declined with a mean half-life of 1.3–1.6 hr; this value was independent of dose size.

Although the maximum concentrations of hydrocortisone in plasma, and also the areas under the drug concentration *versus* time curves, increased with increasing drug doses, they were not dose-proportional. Both C_{max} and AUC_{trap} increased twofold when hydrocortisone dose was increased threefold from 10 to 30 mg. When the dose was further increased 1.6-fold to 50 mg, the value of AUC_{trap} increased in proportion to the dose, while C_{max} increased by a factor of 1.1. When the values of C_{max} and FD/V were normalized for dose, there was a progressive decrease in both of these values as the dose was increased from 10 to 50 mg.

DISCUSSION

HPLC assays for hydrocortisone in biological fluids have the advantage of greater compound specificity than previously used fluorescence (14, 15), competitive protein binding (16), enzyme immunoassay (17), and radioimmunoassay (18) procedures. HPLC assay with a fluorescence detector was claimed to be more sensitive than other analytical methods (8).

The results of this study show that an HPLC assay with UV detection, which requires no derivatization step, is equally specific and sensitive to the HPLC fluorescence assay. Both procedures are capable of measuring hydrocortisone concentrations in plasma following therapeutic doses, are free of interference from hydrocortisone metabolites and endogenous substances in plasma, and are also capable of measuring endogenous hydrocortisone levels following suppression by dexamethasone. The HPLC–UV assay is simpler and less time consuming than the HPLC fluorescence procedure and is therefore the method of choice.

The pharmacokinetic parameter values obtained in the clinical studies are largely in agreement with those published previously. While the elimination phase of plasma hydrocortisone levels was well defined, the short duration of the absorption phase, and also an apparent lag time, does not permit accurate description of this phase. Therefore, the use of first-order kinetics in the present interpretation does not preclude the possibility of alternative absorption mechanisms.

Mean elimination half-lives of hydrocortisone were 90, 77, and 97 min, respectively, following the 10-, 30-, and 50-mg doses. Previous studies using intravenous hydrocortisone have reported drug half-lives between 58 and 161 min (19–23). Circulating levels of hydrocortisone were quite variable at each dose level, which is consistent with previous observations (24, 25).

Additional studies are necessary to confirm the apparent lack of proportionality between circulating levels of hydrocortisone and the administered dose, although similar results to those obtained in this study were reported in subjects receiving oral cortisone acetate (26).

A number of possible factors might cause dose-nonproportionality in hydrocortisone plasma levels. Drug absorption efficiency may be reduced at higher doses due to limited tablet dissolution or to reduced transport across the GI epithelium. Hydrocortisone levels may also be influenced by changes in drug–protein binding. At low drug concentrations, hydrocortisone binds predominantly to the high affinity, low capacity protein transcortin (19, 27). At drug levels >200 ng/ml, binding sites on the transcortin molecule become saturated, and binding to the low affinity, high capacity binding sites of plasma albumin accounts for an increasing proportion of the bound drug. Due to the preponderance of low affinity binding at high drug levels, the percentage of circulating hydrocortisone in the bound form decreases. In the present study, hydrocortisone plasma concentrations >200 ng/ml were achieved with the 30- and 50-mg doses. Reduced overall binding of drug following the higher doses would permit a greater proportion of the drug to enter extravascular fluids, causing a reduction in plasma levels. The reduced binding of hydrocortisone to plasma proteins at high drug concentrations may also increase hepatic clearance during the first-pass, resulting in a smaller proportion of administered drug reaching the systemic circulation (28).

While circulating levels of endogenous hydrocortisone remain constant following dexamethasone suppression (10), further suppression of endogenous levels may result from the administered hydrocortisone by a feedback mechanism. However, suppressed endogenous hydrocortisone levels are low compared with the levels that resulted from administered compound, and further reduction in suppressed levels would not have noticeably affected the results.

Studies have been initiated to examine the dose-proportionality of hydrocortisone pharmacokinetics following parenteral doses.

Acrylic Microspheres *In Vivo* V: Immunological Properties of Immobilized Asparaginase in Microparticles

PETER EDMAN and INGVAR SJÖHOLM ˣ

Received February 2, 1981, from the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, Box 578, 751 23 Uppsala, Sweden.* Accepted for publication September 3, 1981.

Abstract □ L-Asparaginase was immobilized in microparticles of polyacrylamide. Such particles were then injected by intramuscular/subcutaneous, intraperitoneal, or intravenous routes into mice to investigate the immunological consequences of the immobilization. Entrapment of L-asparaginase in microparticles did not prevent the formation of antibodies in intensively treated animals. Intraperitoneal and intravenous injections of particles produced significantly higher antibody levels than soluble L-asparaginase. Antigen administered intramuscularly/subcutaneously in microparticles elicited, however, a weak immune response. Dependent on the route of administration, the particles may thus function as an adjuvant. A modified Arthus reaction in the foot pads of immunized mice indicated that antigenicity decreased when L-asparaginase was immobilized in microparticles. Injection of free L-asparaginase, intramuscularly/subcutaneously (2 × 20 IU) in the preimmunized mice produced no effects on the serum level of L-asparagine, whereas intramuscular/subcutaneous injection of L-asparaginase in microparticles produced a depression of the serum concentration. It is concluded that the intramuscular/subcutaneous injection of L-asparaginase in microparticles is the choice route of administration with respect to duration and the immunological reaction.

Keyphrases □ L-Asparaginase—immunological properties of immobilized L-asparaginase in microparticles □ Microparticles—immunological properties of immobilized L-asparaginase □ Immunological properties—of immobilized L-asparaginase in microparticles

Exogenous enzymes have been used increasingly in biological systems to test their usefulness in treating genetic disorders, *e.g.*, lysosomal storage diseases (1, 2), or for therapeutic purposes, *e.g.*, L-asparaginase to depress circulating L-asparagine in the treatment of acute lymphatic leukemia (3). These enzymes are often used in the immobilized or polymerized form in order to prolong their duration (4–6). However, the desired prolonged effect is seemingly in conflict with the efforts to decrease their immunological properties manifested by the production of antibodies and hypersensitivity reactions, which is enhanced when exposure to the exogenous protein is prolonged. Thus, enzymes in liposomes have been shown to be immunogenic[1]. The liposomes have even, in some instances, been shown to exert adjuvant effects (7). This effect may be due partly to leakage of enzyme molecules out of the liposomes or lysis of the liposomes, but the findings that the adjuvant properties are related to the composition of the liposomes (7, 8) suggest that the adjuvant effects are inherently connected with the liposomes themselves. Likewise, polymethylmethacrylate has been shown to increase the immunogenic properties of simultaneously administered influenza virons (9). The adjuvant effect is strongly correlated to the route of administration, with intravenous or intraperitoneal injections of the immobilized systems generally producing relatively higher antibody titers (7, 10).

The present study was undertaken to investigate the immunological consequences of the utilization of microparticles of polyacrylamide as carrier of exogenous proteins *in vivo*. The polymer itself is not immunogenic (11), but immobilized proteins are partly localized on the surface of the microparticles during the preparation as evidenced by their interaction with cellular surface structures (12) or affinity chromatography material (13). Even if the major portion of the immobilized protein is secluded inside the microparticles, the fraction on the surface should exert immunological properties. The aim was to find the optimal route for the administration of immobilized L-asparaginase.

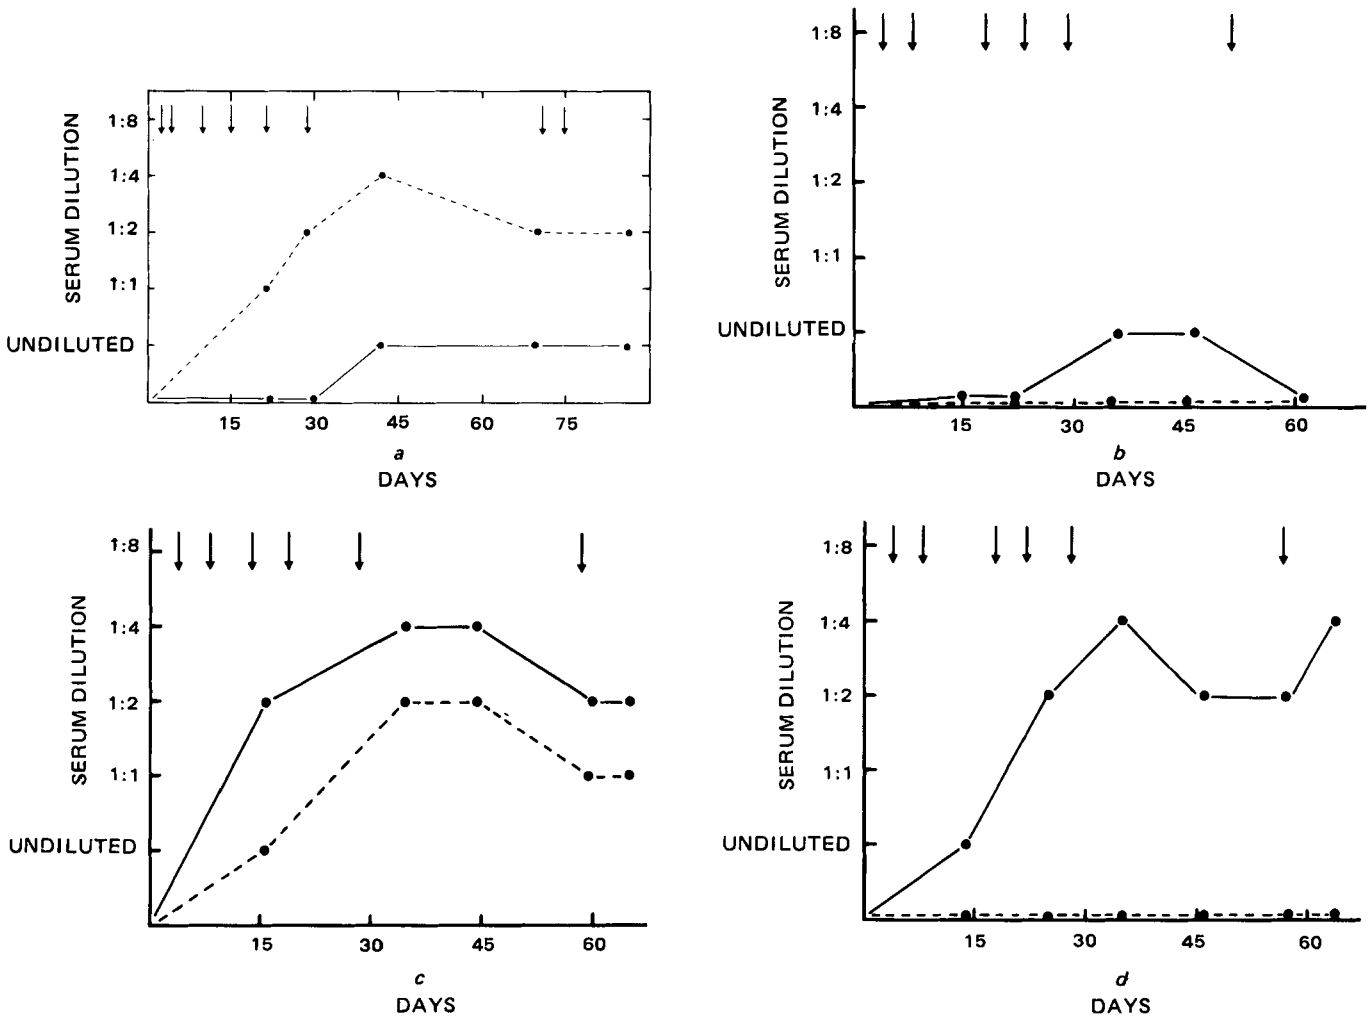

Figure 1—*Antibody response in mice after immunization with* L-*asparaginase in microparticles or in soluble form. 5 IU of* L-*asparaginase was administered on the days indicated by arrows at the top of the graphs. The antibody titer of the serum is measured by Ouchterlony double diffusion as described under* Materials and Methods. *(a)* L-*Asparaginase was given im/sc in microparticles (●—●) or in free form (●- - -●), with Freund's complete/incomplete adjuvant in the back of mice*[10]. *(b)* L-*Asparaginase was given im/sc in microparticles (●—●) or in free form (●- - -●), in 0.1 ml of physiological saline in the back of mice*[9]. *(c)* L-*Asparaginase was given ip in microparticles (●—●) or in free form (●- - -●) in physiological saline in mice*[10]. *(d)* L-*Asparaginase was given iv in microparticles (●—●) or in free form (●- - -●) in physiological saline in mice*[9].

muscle, were used without further purification. Acrylamide[3], *N,N'*-methylenebisacrylamide[3], *N,N',N',N'*-tetramethylethylenediamine[2], tromethamine[2], α-ketoglutaric acid[2], nadide[2] (NADH, reduced form), L-asparagine monohydrate[4], Nessler's reagent[2], and other chemicals were of analytical grade. L-Asparaginase[5] from *Escherichia coli* was used without further purification.

Preparation of Microparticles—Microparticles[6] (TC% = 8–25[7]) with immobilized L-asparaginase were prepared according to a reported method (5) by emulsion polymerization of acrylamide and bisacrylamide with L-asparaginase. In a typical example, the aqueous phase was composed of 5.0 ml of acrylamide (6% w/v) and *N,N'*-methylenebisacrylamide (2% w/v) in 0.005 *M* phosphate buffer, pH 7.4.

The protein was dissolved in the acrylic monomer solution. After the addition of 100 μl of ammonium peroxydisulfate (500 mg/ml in water) to the water phase, it was immediately homogenized with 200 ml of chloroform–toluene (1:4) containing a detergent[8], polyoxyethylene–polyoxypropylene (0.5 g), to produce a w/o emulsion. The polymerization was initiated by adding 1.0 ml of *N,N,N',N'*-tetramethylethylenediamine to the emulsion. The microparticles were isolated by centrifugation, washed several times with buffer, and after the last washing suspended in physiological saline. The mean diameter of the microparticles was ~0.25–0.30 μm.

[8] Pluronics F-68, Ugine Kuhlman, Paris, France.

Assay of Native and Immobilized L-Asparaginase—L-Asparaginase activity was determined by direct nesslerization of the ammonia produced by its reaction with L-asparagine (5, 15). The absorbance was determined at 500 nm. Enzyme and substrate blanks were included in all assays. A standard curve was prepared with ammonium sulfate. One unit of activity is defined as the amount of enzyme catalyzing the formation of 1.0 μmole of ammonia/min at 37°.

Determination of L-Asparagine—Assay of serum of L-asparagine was performed according to a reported fluorometric method (16). Blood was taken from the tail vein or the orbital plexus of 4 to 5 mice and centrifuged at 4° for 15 min to obtain serum. The serum samples were pooled to obtain 60 μl of serum and carefully mixed with 150 μl of 5% trichloroacetic acid. After centrifugation at 4° for 10 min, the supernate was extracted three times with diethylether and the L-asparagine was analyzed.

Animals—Male mice[9,10] were used throughout. At the start of the experiments they weighed 20 g.

Immunization Procedures—Groups of 10 mice were injected with L-asparaginase (5 IU in microparticles or in soluble form) by different routes: intramuscular/subcutaneous, intraperitoneal, and intravenous. The enzyme was administered in physiological saline (intramuscular/subcutaneous, intraperitoneal, and intravenous) or in Freund's complete/incomplete adjuvant (intramuscular/subcutaneous). The animals received booster injections after 4, 8, 18, 22, 28, and 52 days. Blood samples were taken before the first injection and after 2, 4, 5, 8, and 10 weeks.

[a] Mice were challenged by injection into the left hind foot pad of either 10 μl of L-asparaginase (80 IU/ml) or 10 μl of immobilized L-asparaginase in microparticles (80 IU/ml, dry weight 23.1 mg/ml) and into the right food pad of 10 μl of physiological saline or 10 μl of microparticles not containing any enzyme (dry weight 23.1 mg/ml). [b] The thickness of the foot pads was measured 3 hr after provocation. [c] The significance of the difference was calculated by variance analysis. [d] These groups were previously injected with 50 IU L-asparaginase ip in microparticles or in soluble form.

The blood was collected from the tail vein or from the orbital plexus, pooled, and centrifuged at 4° to obtain serum. Each mouse received 35–45 IU of L-asparaginase during the study.

Antibody Determination—The antibody titer was assayed by double immunodiffusion in agar gel as described previously (17). The titer was determined by the highest dilution of serum which produced precipitation with the antigen (5 μg of L-asparaginase in 10 μl of physiological saline was placed in the center well).

Mice, pretreated with immobilized or native L-asparaginase by different routes of administration, were tested for the Arthus reaction (18). The enzyme, 10 μl containing 0.8 IU in soluble form or in microparticles (dry weight 0.23 mg), was injected into the left foot pad of the hind leg. The right foot pad, which served as control, was injected with the same volume, 10 μl, of microparticles not containing any enzyme, or with physiological saline.

Three hours later, and again at 24 and 48 hr, the thickness of both foot pads was measured with a micrometer gauge and the ratio between the two calculated.

Autoradiography—Whole body autoradiography was performed according to the method of Ullberg (19). ^{14}C-Labeled microparticles (4.1 mg; 400,000 dpm) were injected intramuscularly/subcutaneously in some mice with physiological saline in the back. After 2 months the animals were sacrificed with ether and frozen in hexane–solid carbon dioxide (−78°). The mice were embedded in a gel of carboxy-methylcellulose and cut into 20- or 60-μm sagittal sections with a microtome. The sections were cut at −15–20° and freeze-dried. The slices were pressed against photographic films which were exposed for up to 6 months.

RESULTS

Antibody Production in Mice after Treatment with L-Asparaginase in Microparticles—L-Asparaginase was immobilized in microparticles as described previously. The microparticles were injected in mice by different routes and the antibody titers obtained were followed up to ~2.5 months by double immunodiffusion tests. The results are shown in Figs. 1*a*–1*d* and compared with the response obtained after treatment with the same amounts of free, soluble enzyme given under identical conditions.

Immobilization of L-asparaginase in microparticles of polyacrylamide did not prevent the formation of specific antibodies in intensively treated animals. However, it is evident from Fig. 1*a* that the immune response after intramuscular/subcutaneous injection in Freund's adjuvant is weak and significantly weaker than after injection of soluble enzyme. A weak precipitin line was detectable only in undiluted serum. Any antibody production after intramuscular/subcutaneous injection of soluble enzyme in physiological saline is not detectable (Fig. 1*b*), presumably as a consequence of the short half-life of the enzyme.

Figures 1*c* and 1*d* demonstrate the adjuvant effect of the microparticles

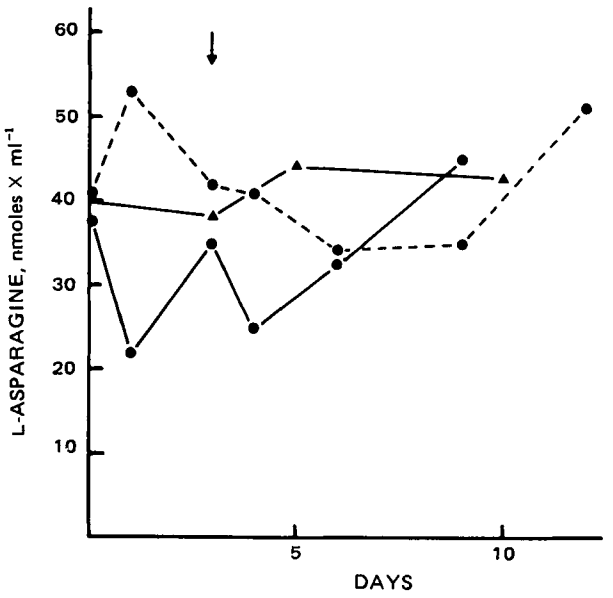

Figure 5—*L-Asparagine concentration in serum. Each point represents pooled serum from 4–5 mice[10] given im/sc 2 × 20 IU of asparaginase (with an interval of 3 days) immobilized in microparticles (●—●) or in free form (●---●). The animals were preimmunized with free* L*-asparaginase given ip. The arrow shows the time for the second injection of 20 IU* L*-asparaginase in microparticles or in free form. The normal* L*-asparagine concentration (▲—▲) was obtained from a control group given only physiological saline.*

administered as intraperitoneal and intravenous injections. After intraperitoneal injection of L-asparaginase in microparticles, a rapid and high production of specific antibodies was seen and in addition, high titers were obtained after intravenous injection. Intravenous injection of native L-asparaginase did not produce any antibodies which could be detected by immunodiffusion, while intraperitoneal injection was effective in producing high amounts of antibodies. The abdomen is drained by the lymphatic vessels, and it is obvious that the strong response is a consequence of the administration of the L-asparaginase close to the lymph nodes.

Studies with a Modified Arthus Test—Under standardized conditions the level of circulating specific antibodies can be estimated in different Arthus tests, in which an antigen–antibody complex mediated hypersensitivity reaction is provoked in different tissues.

Table I presents results from an Arthus reaction test in the foot pads of mice immunized in different standardized ways. The reaction is expressed as the ratio of the thickness of the foot pad injected with the sample (L-asparaginase in soluble or immobilized form) to that of the foot pad injected with empty microparticles or with physiological saline. Mice treated with L-asparaginase intraperitoneally and intramuscularly/subcutaneously were used for the Arthus reaction. Independent of the state of the antigen (immobilized or soluble) with which the mice were immunized, all mice gave an Arthus reaction 3 hr after injection when both native and immobilized L-asparaginase had been used. The swelling at the sites of injection were retracted after 24 hr. L-Asparaginase in the microparticles gave the same or smaller response (thickness of the left foot pads) than the same dose of soluble enzyme. However, the reaction was partly unspecific, in the sense that the microparticles themselves produced an increase in the size of the foot pads, which was significantly larger than that produced by physiological saline. In fact, the response given by the enzyme in microparticles was statistically not significantly larger than that given by the particles themselves. Consequently, the response measured as the ratio of the thickness of the two foot pads was significantly lower with the enzyme administered in microparticles than with soluble enzyme. This means that the antigenicity of the enzyme is decreased by immobilization in microparticles.

L-Asparaginase Effect in Preimmunized Mice—The capacity of differently immunized mice to neutralize and inhibit the effect of L-asparaginase administered in different ways has also been studied. Figures 2–5 show the results obtained from mice in which the serum concentration of L-asparagine was followed as a measure of the L-asparaginase activity and duration. Normally, intramuscular injection of 2 × 2.5 IU of L-asparaginase in microparticles or 5–10 IU injected intravenously depresses the L-asparagine to almost 0 values for 5–7 days, but in the preimmunized animals, considerably higher doses have to be used for any effects on the L-asparagine. Even 50 IU of the enzyme produced only a small and transient effect. Figure 2 illustrates the effects obtained after intraperitoneal injection of 50 IU of L-asparaginase in microparticles or in native form into mice previously treated with free L-asparaginase by the intramuscular/subcutaneous route. Only small effects on the serum level were obtained and no significant differences could be detected between free and immobilized enzyme. Similar results were obtained when the same amount of enzyme in microparticles or in soluble form was injected intraperitoneally into mice pretreated with microparticles given by the intramuscular/subcutaneous route (Fig. 3). A 10–20% reduction of the serum concentration of L-asparagine was achieved the day after injection, but the level was soon normalized.

The results shown in Fig. 4 illustrate the effect of enzyme in microparticles and native enzyme given intramuscularly/subcutaneously in two doses (2 × 20 IU, with an interval of three days) into mice previously treated with immobilized L-asparaginase in microparticles by the intraperitoneal route. Injection of free enzyme did not produce any depression of the serum level of L-asparagine, while some reduction of the serum concentration was achieved when the particles were given intramuscularly/subcutaneously.

Figure 5 shows the changes seen after intramuscular/subcutaneous injection of 2 × 20 IU of L-asparaginase in free or immobilized forms into mice previously treated with native L-asparaginase intraperitoneally. In this case, injection of immobilized enzyme produced lower levels the day after injection, but they were normalized again after 3 days. The same procedure was repeated after the second injection; low values (25–30 nmoles) were found the day after injection, which were normalized again after 2–3 days. Intramuscular injection of L-asparaginase in free solution did not affect the serum concentration of L-asparagine at all.

Whole Body Autoradiography after Intramuscular Subcutaneous Injection of Microparticles in Mice—Figure 6 shows the distribution of C^{14}-labeled microparticles 2 months after intramuscular/subcutaneous injection. The particles were encapsulated at the injection site, and no radioactivity could be detected in the liver or spleen.

DISCUSSION

The microparticle is a macroporous bead in which the immobilized macromolecules are partly entrapped, partly fixed in the polymer bundles forming the network (20). Consequently, a fraction of the immobilized molecules, and their antigenic determinants, will be exposed on the

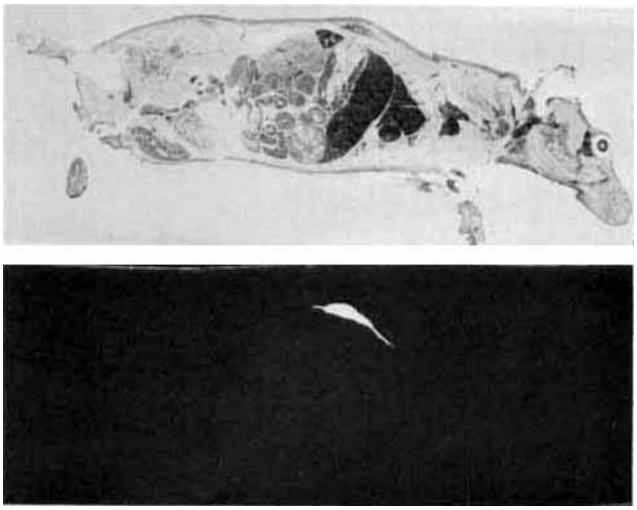

Figure 6—*Whole body autoradiogram of a mouse 2 months after im/sc injection of C^{14}-labeled microparticles (400,000 dpm in 4.1 mg). Bottom: Corresponding tissue section 20 μm.*

surface of the microparticles, and this fraction will be larger, the smaller the beads are. The polyacrylamide forming the microparticle is not immunogenic itself. Therefore, it is to be expected that the immunological response provoked by the immobilized proteins will be determined by the immunogenic properties of the exposed macromolecules and, providing the microparticle has no adjuvant effect, will be related to the size of the particles and will be smaller than that exerted by the native macromolecule administered under the same conditions. As shown, this hypothesis holds true when L-asparaginase is injected intramuscularly with Freunds adjuvant. As a result, soluble enzyme slowly diffuses out from the oil depot with a strong immunological response, which is amplified by the adjuvant. On the other hand, the microparticles stay at the site of injection, as shown by the autoradiogram, and are not reached by the immunocompetent cells to any significant degree. Consequently, there is a low immunological response. When the microparticles are given in saline, the response is quantitatively the same, while the soluble L-asparaginase is rapidly distributed and degraded with poor reaction as a result. The reaction in the two strains of mice used is the same in this respect.

After intraperitoneal administration of L-asparaginase in microparticles, high antibody production could be seen both in the diffusion test and in the modified Arthus reaction, which was stronger than with soluble enzyme. This is a surprising result, as it is known that the particles are rapidly cleared from the abdomen and the circulation and taken up by cells belonging to the reticuloendothelial system in bone marrow, liver, and spleen (21), and thereby are prevented from a primary reaction with the immune system. However, it is apparent that the rapid uptake in the macrophages triggers a secondary response mediated *via* some lymphocyte activating factor (LAF as found in ref. 22). In this sense the microparticles may function as an adjuvant, considerably improving the immunological response.

The distribution of the microparticles after intravenous injection is the same as after intraperitoneal injection, and the antibody production is consequently the same. However, the immune response after intravenous injection of free L-asparaginase is significantly impaired and no antibodies could be detected in the double immunodiffusion tests. The $t_{1/2}$ of the enzyme is short and the direct effect on the lymph system is not obtained in the same way as after intraperitoneal administration.

The modified Arthus test employed gives information not only about the antibody production in the mice, but also, in this modification, about the antigenicity of the L-asparaginase in soluble and in immobilized form. The antibody-mediated reaction on injection of different samples in the foot pads is estimated from the degree of the edema produced, when the sample is injected in one foot and the appropriate control in the other. It can be seen in Table 1 that the injections of microparticles with L-asparaginase produce a much smaller reaction than native enzyme, despite the fact that the unspecific reaction from the microparticles themselves is stronger than from physiological saline. Thus, it can be concluded that the antigenicity is decreased as a consequence of the immobilization in the microparticles.

Earlier studies have shown that the optimal way of administration of immobilized L-asparaginase is the intramuscular/subcutaneous route, when the duration of the effect on the L-asparagine level *in vivo* is considered. The present results also indicate that the intramuscular injection is the preferred way of administration as far as the immunological response is concerned, giving the smallest antibody production. In addition, the effect of L-asparaginase given in microparticles as intramuscular/subcutaneous injection in immunized animals is more pronounced than of intraperitoneal injection. Thus, 50 IU of L-asparaginase given intraperitoneally gave a slight decrease in the L-asparagine level, while an intramuscular/subcutaneous 2 × 20 IU dose slightly decreased the level for 5–7 days.

High-Pressure Liquid Chromatographic Determination of Amitriptyline and Its Major Metabolites in Human Whole Blood

GABRIELLE A. SMITH ˣ, PIERRE SCHULZ, KATHLEEN M. GIACOMINI, and TERRENCE F. BLASCHKE

Received January 23, 1981, from the *Division of Clinical Pharmacology, Department of Medicine, Stanford University Medical Center, Stanford, CA, 94305.* Accepted for publication August 12, 1981

Abstract □ A sensitive, specific, high-pressure liquid chromatographic method using an internal standard was developed for the determination of amitriptyline and its major metabolites in whole blood. Analysis was carried out on a microparticulate silica column with a mobile phase consisting of acetonitrile–methanol–aqueous ammonium hydroxide (93:7:0.4). Linear calibration curves ranging to 250 ng/ml were obtained for all compounds using UV absorbance detection at 220 nm. The lower limit of detection was 2 ng/ml for amitriptyline and 10-hydroxyamitriptyline, and 6 and 16 ng/ml for nortriptyline and its 10-hydroxylated metabolite, respectively. Human whole blood samples collected after single intravenous and single oral doses can be analyzed using this procedure.

Keyphrases □ High-pressure liquid chromatography—determination of amitriptyline and its major metabolites in whole human blood □ Amitriptyline—high-pressure liquid chromatographic determination in whole human blood, major metabolites determined □ Metabolites—of amitriptyline, determination by high-pressure liquid chromatography

Amitriptyline, 10,11-dihydro-*N*,*N*-dimethyl-5*H*-dibenzo[*a*,*d*]cycloheptene-Δ^5,γ-propylamine (I) is a commonly used tricyclic antidepressant. It undergoes extensive metabolism in humans, the major pathways being *N*-demethylation and hydroxylation at the 10-position. The major metabolites of I, 10-hydroxyamitriptyline (II), nortriptyline (IV), and the *trans* (V) and *cis* (VI) isomers of 10-hydroxynortriptyline are shown in Fig. 1.

Various methods have been described for measuring I and its major metabolites in biological fluids, including radioimmunoassay (1), UV spectrometry (2), GC with flame ionization (2, 3) or nitrogen detection (3, 4), GC–mass spectrometry (5), and high-pressure liquid chromatography (HPLC) using UV absorbance detection (6, 7). Except for the procedure using mass spectrometry, no method has sufficient sensitivity to separate and quantitate I and its major metabolites in single-dose pharmacokinetic studies.

This paper describes a specific HPLC method for the measurement of I, II, IV, V, and VI in human whole blood. Detection is by UV absorbance and no derivitization is required prior to analysis. The sensitivity is sufficient to measure accurately the low drug and metabolite concentrations observed during single-dose pharmacokinetic studies in humans.

EXPERIMENTAL

Reagents and Materials—Propranolol hydrochloride[1] (internal standard) was obtained commercially and was used as the salt. Amitriptyline hydrochloride[2], [^{14}C]amitriptyline hydrochloride (specific activity 7.1×10^{-3} mCi/mg), nortriptyline hydrochloride[3], 10-hydroxyamitriptyline[2], and *cis*- and *trans*-10-hydroxynortriptyline[2] were used as provided. Acetonitrile and methanol were purchased as glass-distilled solvents[4]. The water used in extraction was glass-distilled. Aqueous ammonium hydroxide (58%)[5] was analytical reagent grade.

Standard Solutions—Methanolic solutions of amitriptyline hydrochloride, nortriptyline hydrochloride, and the hydroxylated metabolites were prepared at a concentration of 5 ng/μl. The concentration of the internal standard was 10 ng/μl, also in methanol. New solutions of amitriptyline hydrochloride and nortriptyline hydrochloride were made every 3 weeks; the remainder were freshly prepared every 6–8 weeks. All were stored at 4°, with no detectable decomposition during the storage period.

Sample Preparation—A 10-μl aliquot containing 100 ng of the internal standard was dispensed with a syringe[6] into a 15-ml culture tube fitted with a polytef-lined screw cap. One milliliter of hemolyzed whole blood, 1.0 ml of water, 100 μl of 5.0 *M* NaOH, and 6.0 ml of hexane–*n*-butanol (98:2) were added. The mixture was shaken[7] for 10 min followed by centrifugation at 2800 rpm for 5 min. The tube was then immersed in an acetone–dry ice bath until the aqueous phase was frozen. The organic phase was poured into a second tube with an elongated cone (capacity ~50 μl) at its base, and the still-frozen aqueous phase was quickly washed with another 1.0 ml of hexane–*n*-butanol which was then added to the extract. This combined extract was evaporated to dryness at 40° under vacuum on a vortex evaporator[8]. One-hundred microliters of the mobile phase used in the chromatography was added to the resulting residue. The tube was capped, vortexed for 30 sec, and centrifuged for 5 min. All of the mixture was drawn into a 100-μl syringe[6] and injected into the chromatograph.

Apparatus—The modular high-pressure liquid chromatograph consisted of a constant-flow pump[9], a valve-type injector[10], a variable

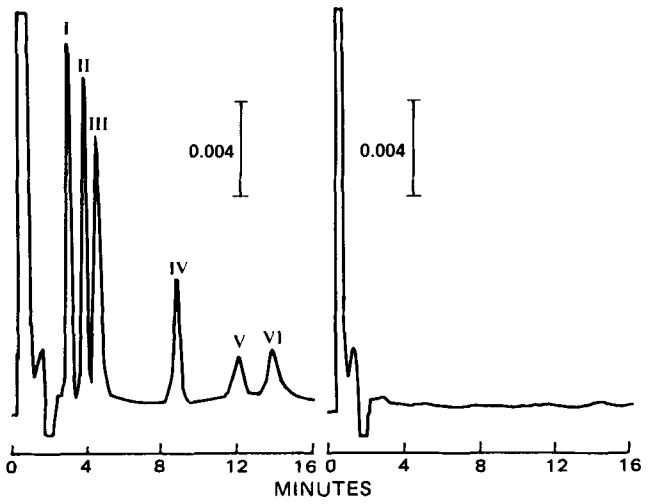

Figure 2—*Chromatograms of extracts from blank human whole blood (right) and blank blood spiked with 100 ng of I, II, III (internal standard), IV, V, and VI per milliter (left).*

wavelength absorbance detector[11] (set at 220 nm), and a strip-chart recorder[12] (0.5 cm/min). A stainless-steel column (250 mm × 2.0-mm i.d.) packed with 5-μm silica[13] was obtained commercially and fitted with a water-jacket[14].

Chromatographic Conditions—The mobile phase was acetonitrile–methanol–aqueous ammonium hydroxide (93:7:0.4). The flow rate was 1.5 ml/min with a column inlet pressure of 3100 psi. Column temperature was maintained at 22° by using a water-jacket connected to a constant temperature water bath. Overnight the flow rate was reduced to 0.1 ml/min.

Calibration—The assay was calibrated by analyzing 1.0-ml aliquots of blank hemolyzed whole blood to which 5–250 ng of I and II, 10–250 ng of IV, V, and VI, and 100 ng of the internal standard had been added. In each sample, the peak height ratio of each tricyclic component relative to the internal standard was calculated. These ratios were plotted against concentration to determine the linearity of the extraction and detector response for each species. In addition, each ratio was divided by the amount of the corresponding component in that sample to give a normalized peak height ratio. These normalized ratios were averaged, and the mean value for each tricyclic component was used to determine the amount present in unknown samples. The precision of the assay was estimated by calculating the coefficient of variation (*CV*) for each set of normalized peak height ratios.

To determine whether the method was valid for plasma samples as well as for whole blood, a calibration curve was prepared using duplicate 1.0-ml plasma aliquots spiked to 25, 100, and 250 ng/ml with each species. The linearity and precision of this assay were calculated as described.

Reproducibility—Aliquots (1 ml) of hemolyzed normal human whole blood were spiked with 25, 100, or 200 ng of each species and assayed in quintuplicate using the described method. Absolute peak heights were measured and the *CV* was calculated for each concentration.

To ascertain whether the assay would be useful if it were carried out from various blood volumes, the same procedure was used to determine the reproducibility of extraction from 0.5, 1.5, and 2.0 ml of whole blood spiked with 100 ng/ml of I and its metabolites. Each volume was assayed in quadruplicate. The rationale for this experiment was that clinically and in pharmacokinetic studies, concentrations of I and its metabolites in a particular blood sample may be lower or higher than those of the standards. To keep the concentrations within the range of the standards, it is necessary to use variable blood volumes.

Efficiency—The efficiency of extraction of I from hemolyzed whole blood into the organic phase was determined by spiking 1.0-ml aliquots of blood with ^{14}C-I, and determining the amounts of ^{14}C-I in the evaporated hexane–*n*-butanol extract by liquid scintillation counting. The extraction procedure was identical to that in the other parts of the study. Concentrations of 20, 50, 100, and 200 ng of ^{14}C-I/ml were extracted in duplicate. Results obtained as counts per minute were converted to disintegrations per minute using the external standard method. These values were compared with those obtained by adding the same amounts of labeled I directly to scintillation fluid, and the resulting ratios were expressed as the percent extraction.

Recovery—Aliquots (1 ml) of hemolyzed whole blood were spiked with known tricyclic quantities (50 and 200 ng/ml, five replicates for each concentration). After the samples were extracted and chromatographed as described, the peak heights for I and its metabolites were compared with the peak heights obtained when the same amount of each component in a standard solution was injected directly onto the column.

RESULTS

Chromatography—The retention times for I, its metabolites, and the internal standard are shown in Fig. 2. Occasional day-to-day adjustment of the methanol concentration (±0.1%) was necessary to obtain optimal separation between II and III. Column temperature was also a critical factor in maintaining this separation. Since room temperature fluctuated daily between 22 and 32°, the use of a column water-jacket maintained at 22° greatly improved baseline stability and peak resolution. In some samples from human subjects, a broad contaminant peak appeared between III and IV; careful manipulation of the methanol concentration was required to prevent it from eluting with one of the peaks of interest.

Calibration—A typical calibration curve relating peak height ratio to concentration was linear for all species over the concentration range studied. The *CV* for the estimation of I averaged 5.2%; corresponding values for the metabolites ranged from 3.6 to 10.2%. A standard curve was assayed with each set of unknowns. The limits of detection of an extracted standard, defined as five times the baseline noise, were 2 ng/ml for I and II, 6 ng/ml for IV, and 16 ng/ml for V and VI.

For the standards prepared in plasma, plots of concentration *versus* peak height ratio were linear with *CV* values of 1.8% for I, and 2.2–10.8% for the metabolites.

Reproducibility—Data showing the reproducibility of the assay are summarized in Table I. All species extracted consistently at three different concentrations from 1.0 ml of hemolyzed whole blood. The averaged normalized peak height values showed no trend with increasing concentration.

For any given sample size, extraction of all components was highly reproducible. There was a trend towards a lower percentage of extraction for all species with increasing sample size. This was probably due to a change in the volume ratio of aqueous to organic phase.

Efficiency and Recovery—Extraction efficiency was compared with overall recovery as described. For 20–200 ng/ml concentrations of ^{14}C-I, the amount of labeled drug partitioning into the organic phase varied from 96 to 100%. The total amount of I recovered from the assay procedure was 61% of an original 50 ng/ml concentration, and 53.5% for 200 ng/ml. Recovery of the metabolites was also consistent (46–69%).

DISCUSSION

Previously reported high-pressure liquid chromatographic assays for I have been unable to separate all of the metabolites of interest using a single procedure. As such, they were inadequate for studying the disposition of I in humans, since the metabolites are pharmacologically active, and are often present at concentrations comparable to those of the unchanged drug. To analyze blood samples from subjects participating in a single-dose pharmacokinetic study, it was necessary to develop a simple and rapid procedure which could resolve the parent drug from its demethylated and 10-hydroxylated metabolites. Since unchanged I was the major component of interest in the separation, a normal-phase chromatographic procedure was developed which would elute I first (as the most nonpolar species), giving maximum sensitivity for quantitation. It was possible, to separate I, II, IV, V, and VI in a total run time of 15 min by careful adjustment of the methanol concentration.

Propranolol was chosen as the internal standard, since it did not interfere chromatographically with any of these compounds. However, zymelidine, which eluted at 14 min under the described conditions, could have been used for samples in which VI was not present. Aqueous ammonium hydroxide was used at a low concentration in the mobile phase to decrease chemisorption on the silica column, which leads to peak tailing.

Although this paper describes chromatography on 5-μm packing material, acceptable peak resolution can be obtained using 10-μm silica with slight modifications of the chromatographic conditions. In this laboratory, a 250 × 2.0-mm i.d. column packed with 10-μm silica[15] was used for

II	1.53 ± 0.06	1.57 ± 0.06	1.53 ± 0.03	1.56 ± 0.05	1.47 ± 0.03	1.38 ± 0.06
IV	0.56 ± 0.06	0.61 ± 0.02	0.64 ± 0.01	0.65 ± 0.01	0.55 ± 0.03	0.48 ± 0.02
V	0.18 ± 0.02	0.15 ± 0.01	0.16 ± 0.004	0.18 ± 0.005	0.14 ± 0.004	0.13 ± 0.007
VI	0.21 ± 0.02	0.20 ± 0.01	0.23 ± 0.03	0.23 ± 0.005	0.19 ± 0.01	0.18 ± 0.01

[a] Mean ± *SD*, $n = 5$ for columns 1–3, $n = 4$ for columns 4–6. [b] Amount of I and metabolites added to 1.0 ml of blank, hemolyzed whole blood. [c] Volumes of blank, hemolyzed whole blood to which 100 ng of each component was added.

several months for quantitation of I and all of its metabolites. The use of a water-jacket to maintain column eqilibrium should not be necessary if laboratory ambient temperature fluctuates 3° or less daily.

Plasma samples can be analyzed satisfactorily using the same procedure as that followed for blood samples. As evidenced by the reproducibility of the normalized peak height values of I and the fact that there was no trend in these values with concentration, adsorption to glassware, if it occurred, did not present a problem with the calibration of the assay. This is in contrast to other extraction procedures where adsorption to glassware has resulted in erratic recoveries (7). Butanol was added to the extracting solvent to prevent emulsification and to improve extraction of the more polar metabolites and the internal standard. It is likely that this short-chain alcohol acts like isoamyl alcohol in decreasing adsorption of basic drugs to glass. When standard solutions were assayed, all methanol was evaporated off before the addition of whole blood, as it otherwise affected the cleanliness of the extract. Maximum recovery depended on careful attention to every step of the extraction, particularly the pooling of the organic phase, evaporation, and final vortexing.

Although the addition of bases to mobile phases used with silica columns is known to decrease column life (8), the low concentration of aqueous ammonium hydroxide used in this procedure caused little deterioration of the packing material. A greater problem arose from column contamination by sample extracts, resulting in broadening or even splitting of the peaks. This condition was rectified periodically by removing the top few millimeters of packing material and replacing it with glass microbeads. The use of a guard column packed with pellicular silica should circumvent this problem.

The present method offers several advantages over some previously published procedures. The extraction is simple and rapid, the chromatography is short (15 min), yet allows good separation of I and its known active metabolites. The sensitivity is good, which should allow pharmacokinetic studies to be carried out; the procedure can be applied to either whole blood or plasma. For high-clearance compounds such as I, whole blood measurements may be preferable, obviating the need for determining the red cell to plasma partition coefficient, which may be concentration-dependent.

NOTES

Analysis of Conjugated Estrogens in a Vaginal Cream Formulation by Capillary Gas Chromatography

G. K. PILLAI and K. M. McERLANE ˣ

Received June 9, 1981, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia, V6T 1W5, Canada.* Accepted for publication August 26, 1981.

Abstract □ A capillary gas-chromatographic method is described for the quantitative analysis of nine equine estrogens in a vaginal cream formulation. The sodium sulfate ethers of the estrogens were selectively extracted from the formulation, subjected to enzyme hydrolysis, and derivatized to their oxime-trimethylsilyl esters. Resolution of the resulting derivatives was achieved on a short (15 m) capillary column, wall-coated with cyanopropylmethyl silicon stationary phase.

Keyphrases □ Estrogens—conjugated, analysis of a vaginal cream formulation by capillary gas chromatography □ GC—capillary, analysis of conjugated estrogens in a vaginal cream formulation □ Vaginal cream formulation—conjugated estrogens, analysis by capillary gas chromatography

The pharmaceutical product known as conjugated estrogens, is a mixture of nine or more equine estrogens isolated from the urine of pregnant mares (1). As their sodium sulfate salts, they have been used in tablet, injectable, and cream formulations for relieving symptoms associated with menopause. Application of the vaginal cream

Analysis of Conjugated Estrogens in a Vaginal Cream Formulation by Capillary Gas Chromatography

G. K. PILLAI and K. M. McERLANE ˣ

Received June 9, 1981, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia, V6T 1W5, Canada.* Accepted for publication August 26, 1981.

Abstract □ A capillary gas-chromatographic method is described for the quantitative analysis of nine equine estrogens in a vaginal cream formulation. The sodium sulfate ethers of the estrogens were selectively extracted from the formulation, subjected to enzyme hydrolysis, and derivatized to their oxime-trimethylsilyl esters. Resolution of the resulting derivatives was achieved on a short (15 m) capillary column, wall-coated with cyanopropylmethyl silicon stationary phase.

Keyphrases □ Estrogens—conjugated, analysis of a vaginal cream formulation by capillary gas chromatography □ GC—capillary, analysis of conjugated estrogens in a vaginal cream formulation □ Vaginal cream formulation—conjugated estrogens, analysis by capillary gas chromatography

The pharmaceutical product known as conjugated estrogens, is a mixture of nine or more equine estrogens isolated from the urine of pregnant mares (1). As their sodium sulfate salts, they have been used in tablet, injectable, and cream formulations for relieving symptoms associated with menopause. Application of the vaginal cream

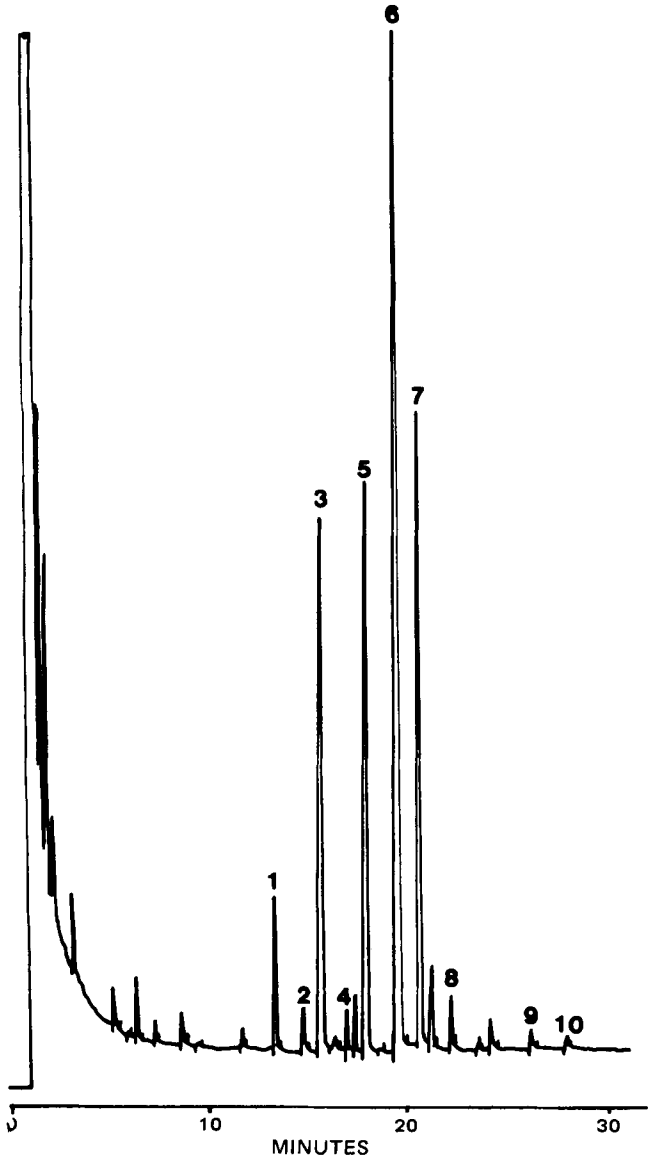

Figure 1—*Chromatogram of equine estrogens as their oxime–trimethylsilyl derivatives derived from a vaginal cream formulation. Key: 1, 17α-estradiol; 2, 17β-estradiol; 3, 17α-dihydroequilin; 4, 17β-dihydroequilin; 5, ethinyl estradiol (internal standard); 6, estrone; 7, equilin; 8, 17α-dihydroequilenin; 9, 17β-dihydroequilenin; and 10, equilenin.*

has been shown to produce a marked improvement in vaginal and vasomotor symptoms (2), and it has been noted that estradiol and estrone plasma levels significantly increased after a single dose. Since estrogens are readily absorbed into the bloodstream after local application, an accurate and selective method for quality assessment of the cream is as essential as one for the tablet and injectable formulations.

At the present time, the assay contained in the United States Pharmacopeia (3) is a colorimetric procedure that quantifies only the two major steroids, estrone and equilin. A gas chromatographic (GC) procedure is specified only for identification of the steroid mixture. Monographs in USP relate to the tablet formulation only. More selective packed column (4, 5) and capillary column (6) GC methods have been reported for the quantitative analysis of the individual steroids in conjugated estrogens. However, these methods have been suitable only for tablet and injectable formulations.

Table I—Analysis of Vaginal Cream Formulation [a]

Component	Potency[a]	Percentage
17α-Estradiol	0.0196	3.14
17β-Estradiol	0.0054	0.86
17α-Dihydroequilin	0.0941	15.07
17β-Dihydroequilin	0.0074	1.18
Estrone	0.3122	49.99
Equilin	0.1497	23.97
17α-Dihydroequilenin	0.0113	1.81
17β-Dihydroequilenin	0.0015	0.24
Equilenin	0.0233	3.73
Total	0.6245	99.92

[a] Expressed as milligrams of the sodium sulfate salts in each gram of cream (label claim: 0.625 mg/g). Average of two assays.

The quantitative method described herein is a modification of a capillary GC assay described previously (6) for tablet and injectable formulations.

EXPERIMENTAL

A capillary gas chromatograph[1] operated in the split mode was used with a flame ionization detector and a data terminal[2] for all measurements. A commercial 15 m × 0.25-mm borosilicate column[3], wall-coated with cyanopropylmethyl silicon liquid phase (Silar 10C), was used with a helium carrier gas flow of 0.8 ml/min through the column and a split vent flow of 40 ml/min. The column inlet pressure was 10 psi. The injector and detector temperatures were 250° and the oven was programmed from 170° for 7 min to 220° at 2.3°/min and was maintained at the upper temperature until elution of the last peak (equilenin).

Materials and Supplies—Methylene chloride, chloroform, acetic acid, sodium acetate, and sodium chloride were reagent grade quality. *N,O*-Bis(trimethylsilyl)trifluoroacetamide and pyridine were silylation grade[4]. Sulfatase enzyme[5], ethinyl estradiol[6], hydroxylamine hydrochloride[7], and equine estrogens[8] were used without further purification.

Sample Preparation—An accurately weighed sample of the vaginal cream, equivalent to ~1 mg of conjugated estrogens, was transferred directly into a 50-ml screw-capped centrifuge tube. Ten milliliters of a 10% solution of sodium chloride in water were added and the tube was shaken thoroughly. The suspended cream was washed twice with 25-ml portions of methylene chloride and the organic phase was discarded after centrifugation.

Nitrogen was bubbled through the aqueous phase to remove any residual methylene chloride until its odor was no longer apparent. To the aqueous extract was added 15 ml of acetate buffer (pH 5.2, 0.02 *M*), 2000 U of sulfatase enzyme, and the mixture was incubated for 30 min at 45°. Following hydrolysis of the sodium sulfate esters, a 0.2-ml aliquot of the internal standard, ethinyl estradiol (1.0 mg/ml), in chloroform was added and the mixture was shaken for 15 min on a rotary tube tumbler[9]. After centrifuging, the chloroform layer was separated and evaporated under a gentle nitrogen stream. The equine estrogens were then converted to their oxime–trimethylsilyl derivatives by the addition of 200 μl of hydroxylamine hydrochloride in pyridine (2.0%) and heating the solution in a screw-capped conical vial[10] for 30 min at 70°. After conversion of the keto-steroids to their oxime derivatives, the remaining hydroxy functions were silylated by the addition of 150 μl of *N,O*-bis(trimethylsilyl)trifluoroacetamide and further heating the vials for 10 min at 70°. A 2-μl aliquot was used for analysis.

RESULTS AND DISCUSSION

The chromatogram shown in Fig. 1 is representative of the steroid profile obtained from the analysis of a vaginal cream formulation. The identity of each steroid was established previously (6) by comparison with authentic equine estrogens. The resolution of the capillary column is sufficient to separate all the estrogen steroids along with the internal standard in ~28 min.

[9] RotoRack, Fisher Scientific Co. Ltd., Vancouver, B.C., Canada.
[10] Reacti-Vial, Pierce Chemical Co., Rockford, Ill.

The quantitation of each of the equine estrogens separated in this fashion was accomplished by using the relative response ratios of each estrogen as compared to the internal standard, ethinyl estradiol. For such determinations, the response ratio and linearity of response were determined by injection of six aliquots of each individual steroid at levels bracketing the anticipated quantity in the mixture with a constant amount of internal standard. For all such measurements, the correlation between peak area ratios and concentrations was 0.998 or better.

Extraction of the water soluble sodium sulfate salts of the equine estrogens required the addition of sodium chloride to suppress emulsion formation. The methylene chloride extraction effectively removed lipid soluble formulation excipients as evidenced by a chromatogram that was essentially devoid of extraneous peaks other than those of the equine estrogens. Subsequent hydrolysis of the sulfate conjugates with 2000 U of sulfatase enzyme had earlier been reported (5) as sufficient for hydrolysis of 1 mg of the conjugates, even in the presence of small amounts of phosphates.

The quantitative assay data obtained from the analysis of two aliquots of a vaginal cream formulation is given in Table I. The quantities of estrone and equilin are within the limits specified for conjugated estrogens in the United States Pharmacopeia (3). The total potency determined indicates that the product was 99.9% of labeled claim.

In summary, this method represents the first quantitative procedure for the total analysis of the steroid composition in an estrogen vaginal cream formulation.

Effect of Some Formulation Adjuncts on the Stability of Benzoyl Peroxide

V. DAS GUPTA

Received June 8, 1981, from the *University of Houston, College of Pharmacy, Department of Pharmaceutics, Houston, TX 77030.* Accepted for publication August 26, 1981.

Abstract □ The stability of benzoyl peroxide in polyethylene glycol ointment base and some liquid vehicles (acetone, ethanol, propylene glycol, and their mixtures) was studied. Some solutions also contained an additional ingredient (acetanilide, benzoic acid, chlorhydroxyquinoline, and hydroxyquinoline) as a possible stabilizer. Benzoyl peroxide decomposed very fast (first-order K value 0.028 day^{-1} at 24°) in polyethylene glycol ointment base. At 50°, the potency of benzoyl peroxide in polyethylene glycol ointment base decreased to <1% in 5 days. Decomposition in solutions is complex. Considering acetone as a standard vehicle, ethanol improved the stability of benzoyl peroxide and propylene glycol had an adverse effect on the stability. Of the stabilizers studied, only chlorhydroxyquinoline improved the stability.

Keyphrases □ Benzoyl peroxide—stability, effect of some formulation adjuncts □ Formulations—benzoyl peroxide, effect of some formulation adjuncts on stability □ Keratolytics—benzoyl peroxide, effects of some formulation adjuncts on stability

Benzoyl peroxide formulations are used extensively for the treatment of acne; however the literature on the stability of benzoyl peroxide is scarce. Gruber *et al.* (1) studied the stability of some commercial lotions containing I but the formulations' excipients were not reported. According to that report, benzoyl peroxide usually decomposes to benzoic acid and carbon dioxide.

The stability of benzoyl peroxide in pharmaceutical gels was reported by Bollinger *et al.* (2). These authors recommended the use of sodium hydroxide over triethanolamine as a neutralizing agent. Moreover, gels containing some acetone were reported to be very stable (even at higher temperature) *versus* ethanol which had an adverse effect on the stability of benzoyl peroxide. These studies used a selective titrimetric analysis method (3).

A stability-indicating assay method using high-pressure liquid chromatography (HPLC) was reported recently (4). The report questioned the accuracy of the titrimetric method (3) which is also official in the USP (5). The latest USP–NF edition (6) recommends the same titrimetric method of analysis for both hydrous benzoyl peroxide and its lotion.

The purpose of these investigations was to study the effect of some formulation adjuncts, polyethylene glycol ointment USP (7), some liquid vehicles, and some possible stabilizers, on the stability of benzoyl peroxide.

EXPERIMENTAL

Chemicals and Reagents—All the chemicals and reagents were either USP, NF, or ACS grade and were used without further purification. Benzoyl peroxide granules[1] and hydrous benzoyl peroxide granules[2] were used as received.

Apparatus—The HPLC[3] was equipped with a multiple wavelength detector[4], a recorder[5], and a digital integrator[6].

Column—A nonpolar column[7] (30 cm × 4-cm i.d.) was used.

Chromatographic Conditions—The mobile phase contained 60% (v/v) of acetonitrile and 0.8% (v/v) of glacial acetic acid in water. The flow rate was 2.5 ml/min and the temperature was ambient. The sensitivity was set at 0.04 (254 nm) and the chart speed was 30.5 cm/hr.

Preparation of Ointments for Stability Studies—A 2.0% (w/w)

Effect of Some Formulation Adjuncts on the Stability of Benzoyl Peroxide

V. DAS GUPTA

Received June 8, 1981, from the *University of Houston, College of Pharmacy, Department of Pharmaceutics, Houston, TX 77030.* Accepted for publication August 26, 1981.

Abstract □ The stability of benzoyl peroxide in polyethylene glycol ointment base and some liquid vehicles (acetone, ethanol, propylene glycol, and their mixtures) was studied. Some solutions also contained an additional ingredient (acetanilide, benzoic acid, chlorhydroxyquinoline, and hydroxyquinoline) as a possible stabilizer. Benzoyl peroxide decomposed very fast (first-order K value 0.028 day^{-1} at 24°) in polyethylene glycol ointment base. At 50°, the potency of benzoyl peroxide in polyethylene glycol ointment base decreased to <1% in 5 days. Decomposition in solutions is complex. Considering acetone as a standard vehicle, ethanol improved the stability of benzoyl peroxide and propylene glycol had an adverse effect on the stability. Of the stabilizers studied, only chlorhydroxyquinoline improved the stability.

Keyphrases □ Benzoyl peroxide—stability, effect of some formulation adjuncts □ Formulations—benzoyl peroxide, effect of some formulation adjuncts on stability □ Keratolytics—benzoyl peroxide, effects of some formulation adjuncts on stability

Benzoyl peroxide formulations are used extensively for the treatment of acne; however the literature on the stability of benzoyl peroxide is scarce. Gruber *et al.* (1) studied the stability of some commercial lotions containing I but the formulations' excipients were not reported. According to that report, benzoyl peroxide usually decomposes to benzoic acid and carbon dioxide.

The stability of benzoyl peroxide in pharmaceutical gels was reported by Bollinger *et al.* (2). These authors recommended the use of sodium hydroxide over triethanolamine as a neutralizing agent. Moreover, gels containing some acetone were reported to be very stable (even at higher temperature) *versus* ethanol which had an adverse effect on the stability of benzoyl peroxide. These studies used a selective titrimetric analysis method (3).

A stability-indicating assay method using high-pressure liquid chromatography (HPLC) was reported recently (4). The report questioned the accuracy of the titrimetric method (3) which is also official in the USP (5). The latest USP–NF edition (6) recommends the same titrimetric method of analysis for both hydrous benzoyl peroxide and its lotion.

The purpose of these investigations was to study the effect of some formulation adjuncts, polyethylene glycol ointment USP (7), some liquid vehicles, and some possible stabilizers, on the stability of benzoyl peroxide.

EXPERIMENTAL

Chemicals and Reagents—All the chemicals and reagents were either USP, NF, or ACS grade and were used without further purification. Benzoyl peroxide granules[1] and hydrous benzoyl peroxide granules[2] were used as received.

Apparatus—The HPLC[3] was equipped with a multiple wavelength detector[4], a recorder[5], and a digital integrator[6].

Column—A nonpolar column[7] (30 cm × 4-cm i.d.) was used.

Chromatographic Conditions—The mobile phase contained 60% (v/v) of acetonitrile and 0.8% (v/v) of glacial acetic acid in water. The flow rate was 2.5 ml/min and the temperature was ambient. The sensitivity was set at 0.04 (254 nm) and the chart speed was 30.5 cm/hr.

Table I—Solutions Prepared For Stability Studies

Solution Number	Concentration of Benzoyl Peroxide	Vehicle, % v/v	Other Ingredient
1	0.1	Acetone	—
2	0.1	Acetone 75 Ethanol 25	—
3	0.1	Acetone 50 Ethanol 50	—
4	0.1	Acetone 25 Ethanol 75	—
5	0.1	Acetone 75 Propylene glycol 25	—
6	0.1	Acetone 50 Propylene glycol 50	—
7	0.1	Acetone 25 Propylene glycol 75	—
8	0.1	Acetone 50 Ethanol 50	0.01% of 8-hydroxyquinoline
9	0.1	Acetone 25 Propylene glycol 75	0.01% of 8-hydroxyquinoline
10	0.1	Acetone 25 Propylene glycol 75	0.01% of acetanilide
11	0.1	Acetone 25 Propylene glycol 75	0.01% of benzoic acid
12	1.0	Acetone 50 Propylene glycol 50	—
13	1.0	Acetone 50 Propylene glycol 50	0.1% of 8-hydroxyquinoline sulfate
14	1.0	Acetone 50 Propylene glycol 50	0.1% of 5-chloro-8-hydroxyquinoline

benzoyl peroxide ointment was prepared by mixing 612.0 mg of benzoyl peroxide granules with 6 ml of acetone and then incorporating this mixture with enough polyethylene glycol ointment USP (7) to make 30 g of ointment. Separate lots of ointments containing 0.01% (w/w) of acetanilide or benzoic acid in addition to 2% (w/w) of benzoyl peroxide were also prepared. After the initial assays, the ointments were divided into two portions and transferred to 30-g opal ointment jars[8]. One portion was stored at 50°; the other portion at room temperature (24°).

Preparation of Solutions for Stability Studies—Solutions containing 0.1% of benzoyl peroxide in various vehicles (acetone, ethanol, propylene glycol, or mixtures of two) were prepared using a simple solution method. Benzoyl peroxide granules were always dissolved in acetone. Some of the solutions also contained an additional ingredient (Table I). After the initial assays, the solutions were transferred to amber-colored, 120-ml glass bottles[8] and stored at 24°.

Another set of solutions containing 1.0% of benzoyl peroxide were prepared from hydrous benzoyl peroxide granules. The vehicle and additional ingredients added are listed in Table I. These solutions were also stored in amber-colored glass bottles at 24°.

Assay Procedure—The HPLC analysis used is similar to one reported previously (4). The internal standard was hydroxyprogesterone caproate. The stock solutions of benzoyl peroxide and the internal standard in methanol (1.0 mg/ml each) were prepared fresh daily. The standard solution was prepared by mixing 2.0 ml of the stock solution of benzoyl peroxide with 4.0 ml of the internal standard stock solution and then bringing the volume to 50.0 ml with methanol.

Preparation of Assay Solutions from Ointments—An appropriate quantity of the ointment containing 2.0 mg of benzoyl peroxide was weighed accurately and dissolved in 30 ml of methanol. A 4.0-ml portion of the internal standard stock solution was added and the mixture brought to volume (50.0 ml) with methanol.

[8] Brockway Glass Co., Brockway, Pa.

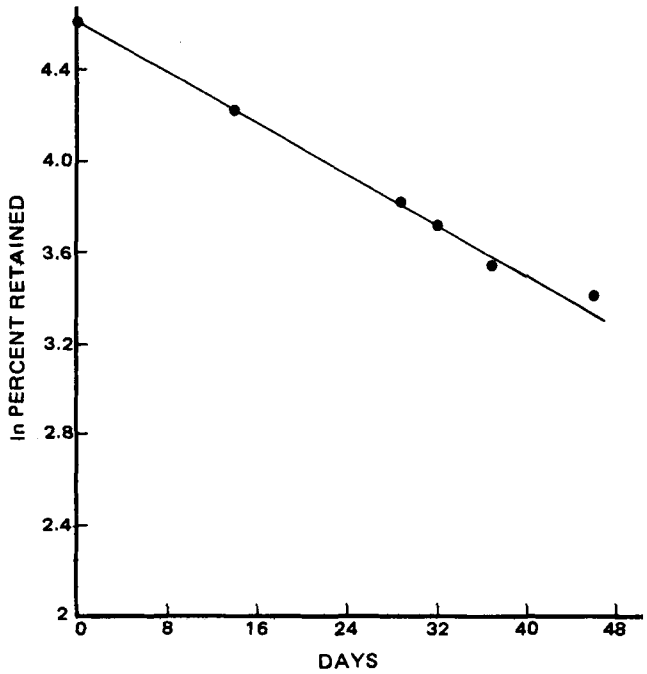

Figure 1—*First-order plot of decomposition (at 24°) of benzoyl peroxide in polyethylene glycol ointment base USP. The results of ointments containing an additional ingredient (acetanilide or benzoic acid) were similar.*

All the solutions studied were diluted with methanol to a concentration (based on the label claim) of 40.0 μg/ml of benzoyl peroxide. Before final dilution, enough of the internal standard stock solution was added to contain 80.0 μg/ml in the final solution.

Injections—A 20.0-μl aliquot of the assay solution was injected into the chromatograph at the conditions described. For comparison, an identical volume of the standard solution was injected after the assay eluted.

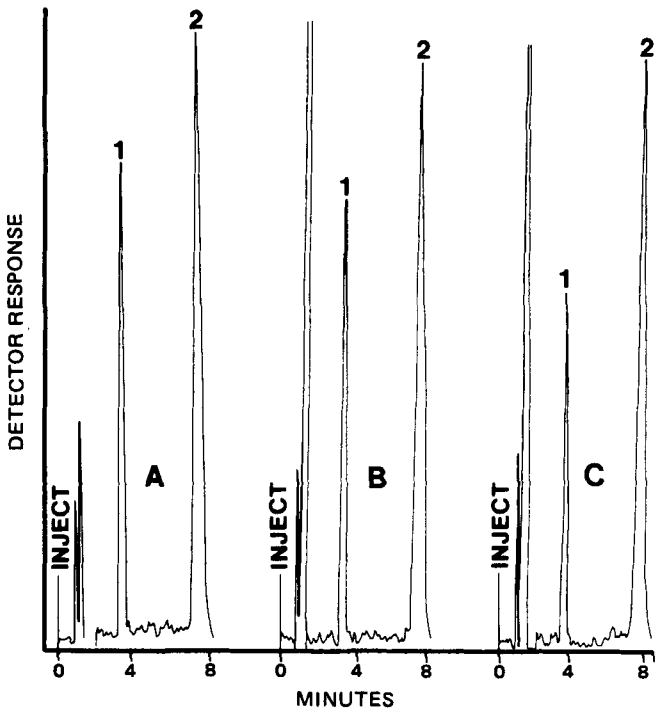

Figure 2—*Sample chromatograms. Peaks 1 and 2 are from benzoyl peroxide and hydroxyprogesterone caproate (internal standard), respectively. The long peak (out of scale) after injection in chromatograms B and C is from acetone. Chromatogram A is from a standard solution (see text) and B and C from 97-days-old solutions (Numbers 4 and 7, Table I), respectively.*

Table II—Assay Results of Solutions [a]

Solution Number[b]	Percent Retained					
	0 day	10 days	46 days	50 days	60 days	97 days
1	101.3	101.4	97.7	—	—	85.2
2	101.8	100.8	98.2	—	—	85.6
3	101.3	101.1	100.2	—	—	89.5
4	102.2	101.8	100.7	—	—	90.9
5	101.1	98.3	96.5	—	—	82.8
6	102.0	98.3	94.2	—	—	81.7
7	100.9	95.6	90.3	—	—	74.7
8	100.0	100.8	99.2	—	—	86.4
9	99.8	97.7	93.3	—	—	72.6
10	100.6	98.2	92.5	—	—	73.2
11	100.6	99.1	95.1	—	—	76.8
12	101.2	97.7	—	81.8	76.9	—
13	100.7	100.1	—	83.1[c]	78.3[c]	—
14	100.1	98.7	—	94.2[c]	87.1[c]	—

[a] For results of ointments stored at 24°, see Fig. 1. Almost all benzoyl peroxide decomposed in 5 days in ointments stored at 50°. [b] For composition of the solutions, see Table 1. [c] These solutions had discolored to light yellow due to oxidation of hydroxyquinoline/chlorhydroxyquinoline.

Calculations—Since the ratios of peak heights were directly related to concentrations, the results were calculated using the equation:

$$100 \times \frac{R_{pha}}{R_{phs}} = \text{percent of the label claim} \qquad \text{(Eq. 1)}$$

where R_{pha} is the ratio of the peak heights of benzoyl peroxide and hydroxyprogesterone caproate of the assay solution and R_{phs} is that of the standard solution.

After the initial assays, the ointments and solutions were reassayed after appropriate time intervals.

RESULTS AND DISCUSSION

The results (Fig. 1, and footnote *a* in Table II) indicate that benzoyl peroxide decomposes quickly when mixed with polyethylene glycol ointment base. The K value at room temperature was 0.028/day. It has been postulated (2) that OH groups in the vehicle had an adverse effect on the stability of benzoyl peroxide. At 50°, almost all of the benzoyl peroxide in polyethylene glycol ointment base decomposed in 5 days. The addition of acetanilide (a commonly used stabilizer for hydrogen peroxide) and benzoic acid (a major decomposition product of benzoyl peroxide) did not improve the stability of benzoyl peroxide. The lag period, which was prominent in solutions, almost disappeared in 2% (w/w) ointment of benzoyl peroxide in polyethylene glycol base.

After the lag period, the solutions decomposed slowly without following any particular order of reaction. However, the following observations might be made from the data (Table I, and Figs. 1 and 2):

1. Ethanol improves the stability of benzoyl peroxide when substituted for acetone (Solutions 3 and 4 *versus* 1, Table II).
2. Propylene glycol hastens the degradation when substituted for acetone (solutions 5–7 *versus* 1, Table II). An attempt to substitute glycerin for acetone (50% v/v) was unsuccessful. There was a problem preparing a single homogeneous phase.
3. The addition of acetanilide, benzoic acid, and hydroxyquinoline did not improve the stability (Solutions 9–11 *versus* 7, Table II). 8-Hydroxyquinoline (oxine) has been reported (8) to improve the stability of hydrogen peroxide in certain pharmaceutical gels.
4. Chlorhydroxyquinoline improved the stability of benzoyl peroxide (solution 14 *versus* 12–13, Table II). This is probably the reason why commercial formulations contain this compound (9).
5. The decomposition of benzoyl peroxide appears to be concentration dependent (solution 6 *versus* 12, Table II). Solution 12 was prepared from hydrous benzoyl peroxide (71%) *versus* Solution 6 which was prepared from benzoyl peroxide (98%). Another solution similar to 12 was prepared using benzoyl peroxide (98%) and this solution was slightly more stable than Solution 12. All commercial formulations are prepared from hydrous benzoyl peroxide to prevent explosion.

In brief, the decomposition of benzoyl peroxide is complex and susceptible to many factors, some of them still unknown. Furthermore, the benefits of adding stabilizer(s) are themselves controversial (2). It has been suggested (2) that addition of chelating agents (citric acid or edetate disodium) might have an adverse effect on the stability of benzoyl peroxide. Yet some commercial products (9) add these chelating agents to improve the stability.

The effect of small traces of impurities in benzoyl peroxide, the vehicles, and additives is still not well understood. The stability of benzoyl peroxide needs to be thoroughly investigated. Further work is in progress in this laboratory.

Common Ion Equilibria of Hydrochloride Salts and the Setschenow Equation

JOSEPH B. BOGARDUS

Received July 21, 1981, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication September 3, 1981.

Abstract □ A simple equation was derived to describe the relationship between the aqueous solubility of sparingly soluble salts (S_0) and the empirical Setschenow salting-out constant (k): $k = 0.217/S_0$. This relationship and the Setschenow equation were found to be valid only at low concentrations of added salt. This equation agreed with recently published data when compared for the effect of the chloride ion on the solubility of a series of drug hydrochloride salts. The theoretical treatment also predicts the curvature which has been reported in literature Setschenow plots at higher salt concentrations. As the concentration of added salt increases, the apparent k value is not constant but is dependent on solubility and the rate of change of solubility with added salt concentration. It was concluded that the Setschenow treatment is generally inappropriate for description and analysis of common ion equilibria.

Keyphrases □ Hydrochloride salts—relationship of aqueous solubility and Setschenow constant □ Setschenow equation—relationship between solubility of hydrochloride salts □ Common ion equilibria—of hydrochloride salts and Setschenow equation

In several studies the empirical Setschenow equation has been used to describe the effect of the chloride ion on the solubility of drug hydrochloride salts (1–5). Although this equation was originally proposed to describe salting-out phenomena of nonelectrolytes (6), it appeared to adequately describe suppression of solubility by the common ion effect. In other investigations the principles of solubility product equilibrium were used for describing the solubility of drug salts (7, 8). The solubility product treatment was essential in studying the solubility of doxycycline hydrochloride since self-association to form a dimer dominated the aqueous solubility (8).

The present study was initiated to examine the relationship between the empirical Setschenow equation and rigorous solubility product equilibrium theory. The mathematical treatment shows that the apparent Setschenow salting-out constant (k) is not a physical chemical constant. It is related to solubility or the solubility product constant only at low concentrations of added salt. Due to these limitations and the difficulty in detecting self-association of drug, rigorous solubility product relationships should be used to describe common ion equilibria of hydrochloride salts.

THEORY

The solubility product constant (K_{sp}) for the hydrochloride salt of a weak base is defined as:

$$K_{sp} = S\,[Cl^-] \qquad \text{(Eq. 1)}$$

where S is the concentration of the protonated base and $[Cl^-]$ is the chloride ion concentration at equilibrium. The chloride ion concentration is expressed as the sum:

$$[Cl^-] = S + [NaCl] \qquad \text{(Eq. 2)}$$

where [NaCl] is the concentration of added salt (8).

When [NaCl] = 0, $S = S_0 = [Cl^-]$ and the solubility product constant is:

$$K_{sp} = S_0^2 \qquad \text{(Eq. 3)}$$

This equation is valid only when self-association of drug is negligible (8). The Setschenow equation can be written:

$$\log \frac{S_0}{S} = k[NaCl] \qquad \text{(Eq. 4)}$$

where k is the apparent salting-out constant. It is assumed that the salting-out behavior is due only to chloride ion, and specific cation effects are negligible. Literature data using ammonium or sodium chlorides indicate that this assumption is valid (4, 8). The salting-out constant is the slope of a plot of log S_0/S *versus* [NaCl]:

$$k = \frac{d \log \frac{S_0}{S}}{d\,[NaCl]} = \frac{-\frac{dS}{d\,[NaCl]}}{2.303\,S} \qquad \text{(Eq. 5)}$$

This equation indicates that the apparent salting-out constant depends on the solubility and the rate of change of solubility with added salt concentration. The limiting slope at low added salt concentration is:

$$\lim_{[NaCl]\to 0} k = \frac{-\lim_{[NaCl]\to 0}\left(\frac{dS}{d\,[NaCl]}\right)}{2.303\,S_0} \qquad \text{(Eq. 6)}$$

since, as [NaCl] → 0, $S \to S_0$.

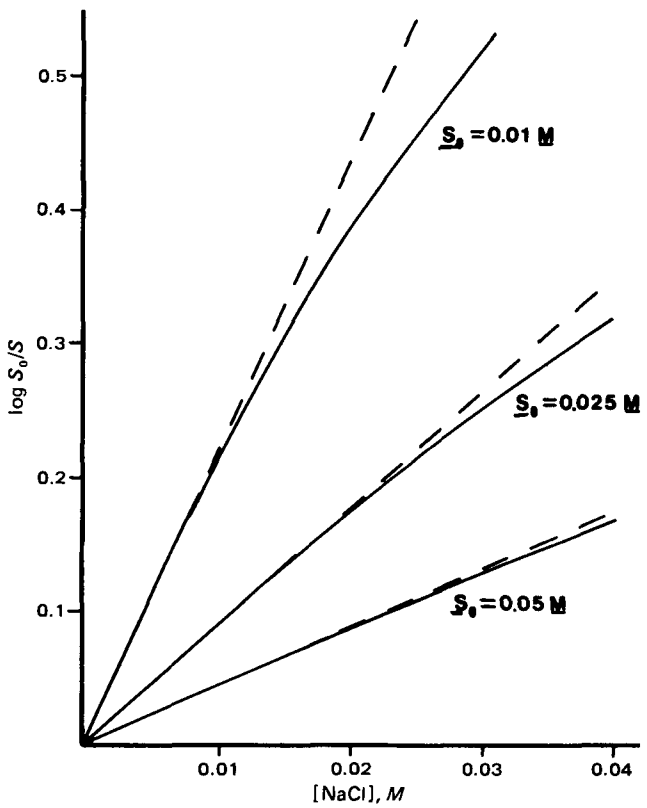

Figure 1—*Hypothetical Setschenow plots at three* S_0 *values according to Eqs. 3 and 7 (—). The initial slopes (- - -) were calculated using Eq. 10.*

0022-3549/82/0500-0588$01.00/0

Table I—Comparison of Experimental and Calculated Salting-out Constants

Hydrochloride Salt	25°		37°	
	k^a_{exp}	k^b_{calc}	k^a_{exp}	k^b_{calc}
Phenazopyridine	18.06	16.5	11.57	11.5
Cyproheptadine	21.18	20.9	14.80	13.7
Bromhexine	20.00	21.3	16.78	16.8
Trihexyphenidyl	8.24	12.6	5.66	5.8
Isoxsuprine	6.32	7.4	6.30	5.6
Chlortetracycline	9.60	9.7	6.52	8.9
Methacycline	8.24	5.7	6.36	4.9
Papaverine	5.09	2.3	3.60	1.8
Demeclocycline	3.73	3.1	2.68	2.4
Doxycycline	5.3[c]	1.8[b], 5.1[d]	—	—

[a] From Ref. 1 except as noted. [b] Calculated using Eq. 10. [c] Calculated from the data in Ref. 8. [d] Calculated using Eq. 12 and $K_{sp} = 1.8 \times 10^{-3}\ M^2$ (8).

From Eqs. 1 and 2 and the quadratic formula, the following expression for S is obtained:

$$S = \frac{-[\mathrm{NaCl}] \pm ([\mathrm{NaCl}]^2 + 4K_{sp})^{1/2}}{2} \qquad \text{(Eq. 7)}$$

The derivative with respect to [NaCl] is:

$$\frac{dS}{d\,[\mathrm{NaCl}]} = \frac{-1 \pm [\mathrm{NaCl}]([\mathrm{NaCl}]^2 + 4K_{sp})^{-1/2}}{2} \qquad \text{(Eq. 8)}$$

and the limit of this differential is:

$$\lim_{[\mathrm{NaCl}]\to 0} \left(\frac{dS}{d[\mathrm{NaCl}]}\right) = -1/2 \qquad \text{(Eq. 9)}$$

Therefore, from Eqs. 6 and 9, the limiting value of the salting-out constant has a simple relationship with solubility:

$$k_l = \lim_{[\mathrm{NaCl}]\to 0} k = \frac{1}{4.606\,S_0} = \frac{0.217}{S_0} \qquad \text{(Eq. 10)}$$

or in log form:

$$\log k_l = -\log S_0 - 0.664 \qquad \text{(Eq. 11)}$$

In the absence of self-association, S_0 and K_{sp} are related by Eq. 3, and the limiting value of the salting-out constant can also be written as:

$$k_l = \frac{0.217}{K_{sp}^{1/2}} \qquad \text{(Eq. 12)}$$

DISCUSSION

Figure 1 contains hypothetical Setschenow plots which were generated at solubilities of 0.01, 0.025, and 0.05 M using Eqs. 3 and 7. The range of S_0 and salt concentration were chosen to be similar to that reported previously (1) for several drug salts. At each concentration the lines show downward curvature with increasing salt concentration. With decreasing drug salt solubility the deviations from the initial slope based on Eq. 10 begin to appear at progressively lower concentrations of added salt. Curved Setschenow plots of this type were reported for the hydrochloride salts of phenazopyridine, cyproheptadine, and bromhexine (1). These compounds have solubilities of ~0.01 M, which is consistent with the theoretically generated data. More soluble drug salts, as expected, showed lower slopes and essentially linear relationships.

The experimental salting-out constants at 25 and 37° for several compounds are compared in Table I with values calculated from their solubilities. Good agreement was obtained in most cases with the largest differences appearing with the most soluble salts which have the smallest slopes. Papaverine was approximately two times more sensitive to salt than would be predicted from its solubility. The calculated and experimental values for methacycline differ by 30–40%.

The k_{exp} for doxycycline shows poor agreement with the value calculated from S_0 using Eq. 10. This is not unexpected, since doxycycline is known to form a dimer and higher order complexes in aqueous solution (8). These equilibria cause the apparent solubility product calculated from Eq. 3 ($13.1 \times 10^{-3}\ M^2$) to be larger than the limiting K_{sp} ($1.8 \times 10^{-3}\ M^2$), which was determined under conditions where self-association was negligible. Thus, the k_{calc} from Eq. 10 is incorrect because of the solubility-increasing effect of self-association. Calculations of k using the limiting K_{sp}, which is not influenced by self-association, provides a value similar to the experimental constant.

In view of the known self-association of doxycycline, it is surprising that k_{exp} is so similar to k_{calc}. This appears to be due to compensation of S_0 and dS/d[NaCl] in Eq. 5. The approximately three-fold higher solubility ($S_0/K_{sp}^{1/2}$) caused by self-association is compensated by a three-fold higher salting-out rate estimated from the slope of the plot of S *versus* [NaCl]. The added salt may be decreasing the stability of the associated species.

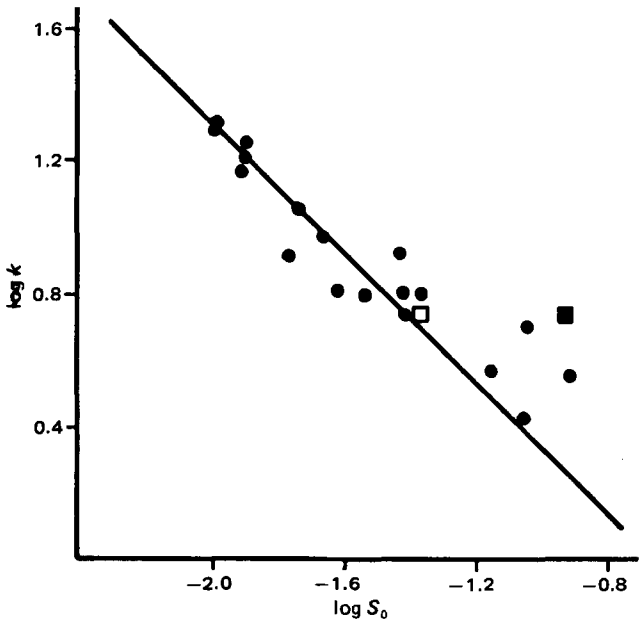

Figure 2—*Relationship between salting-out constant and solubility. Key: (—) Eq. 11; (●) 25 and 37°, data from (1), for the drugs in Table I; (■) observed data for doxycycline hydrochloride; (□) experimental* k *value and* S_0 *calculated from the limiting* K_{sp} *using Eq. 3.*

Since the initial slope is most important in a Setschenow plot, and this region is most susceptible to the effects of self-association, the use of this method may lead to erroneous results. A probable explanation for the poor agreement with papaverine and methacycline hydrochlorides is that the solubilities (S_0) are anomalously high due to self-association. This would be especially likely for methacycline, which is structurally similar to doxycycline. Based on the limited doxycycline data, self-association appears to have a stronger effect on solubility than it does on the apparent salting-out constant.

The solubility product constant is inversely proportional to the square of the salting-out constant (Eq. 12). A doubling in the slope of a Setschenow plot corresponds to a four-fold decrease in K_{sp}. Thus, K_{sp} is a more sensitive indicator of common ion effects than the salting-out constant. A major disadvantage of the use of Setschenow plots is that self-association of the drug cannot be detected. This is not a problem when the data are analyzed according to the principles of solubility product equilibrium since the apparent K_{sp}, calculated as the product of solubility and chloride concentrations, will not be constant (8).

The existence of a linear correlation between log k and log S_0 has been shown (1). More soluble drug salts were found to have smaller salting-out constants. These observations are theoretically predicted by Eq. 11. In Fig. 2 the salting-out constant and solubility of the drug salts in Table I are plotted according to Eq. 11. The experimental data show good agreement with the theoretical line of slope = −1.0. Points for doxycycline, papaverine, and methacycline lie above the line, which is consistent with the proposed self-association of these compounds.

Few of the drugs deviate negatively from the theoretically predicted relationship. Trihexyphenidyl at 25° and chlortetracycline at 37° are below the line, but at the other temperature these compounds show satisfactory agreement. These apparent deviations cannot be explained at present.

The results of this study indicate that the Setschenow treatment, originally proposed to describe salting-out of nonelectrolytes, is inappropriate for description of common ion equilibria of hydrochloride salts. Data analysis based on solubility product equilibrium theory is a more satisfactory approach.

High-Pressure Liquid Chromatographic Determination of Cimetidine in Plasma and Urine

G. W. MIHALY ˣ, S. COCKBAIN, D. B. JONES, R. G. HANSON, and R. A. SMALLWOOD

Received April 22, 1981, from the *Gastroenterology Unit, Department of Medicine, University of Melbourne, Austin Hospital, Heidelberg, 3084, Victoria, Australia.* Accepted for publication August 26, 1981.

Abstract □ An assay is described for the determination of the H_2-receptor antagonist, cimetidine, in human plasma and urine. Alkalinized plasma or urine was extracted with methylene chloride, the organic phase was evaporated, and the reconstituted residue was analysed by high-pressure liquid chromatography (HPLC) using a reversed-phase prepacked plastic column housed in a radial compression module. The metabolite, cimetidine sulfoxide, was identified but could not be quantitated due to interference from the solvent front. The sensitivity limit of the assay was 25 ng/ml. The assay was applied to the measurement of plasma and urine samples in a pilot pharmacokinetic study. Cimetidine was substantially absorbed and rapidly eliminated (plasma elimination half-life of 112–130 min). Plasma cimetidine concentrations could be measured to 12 hr after a 200-mg dose (iv or oral), but they were below the sensitivity of the assay by 24 hr. Urinary excretion of unmetabolized cimetidine accounted for 40–50% of the administered dose in the first 12 hr. This assay is simpler and more sensitive than those previously described, and it is suitable for the measurement of cimetidine in plasma and urine of subjects receiving doses appropriate for clinical use.

Keyphrases □ Cimetidine—high-pressure liquid chromatographic analysis in plasma and urine □ High-pressure liquid chromatography—analysis, cimetidine, human plasma and urine □ H_2-Receptor antagonists—cimetidine, high-pressure liquid chromatographic analysis in plasma and urine

The H_2-receptor antagonist, cimetidine, profoundly inhibits gastric acid secretion and is effective in the treatment of gastric and duodenal ulcers (1). Studies have shown that the degree of inhibition of gastric acid secretion is related to cimetidine plasma level measurements (2).

Chromatographic assays for the measurement of blood, plasma, and urine concentrations of cimetidine have been published. The sample treatment in these methods is complex and involves multiple extraction steps (3, 4). Moreover, samples are chromatographed on silica-based column packing which is likely to limit the column's efficiency and life under alkaline conditions. A simple micromethod for the estimation of plasma cimetidine has also been reported (5). This method exhibited low precision and sensitivity, as well as lengthy chromatography.

A more sensitive liquid chromatographic method for measuring cimetidine in plasma and urine, using a simple, single extraction step in sample treatment, is reported. Chromatography is rapid and conducted on a column system[1,2] which recently has become commercially available. These columns operate under conditions that produce greater column efficiency and allow longer column life. This method has been applied to a pilot study on a patient with a gastric ulcer, in which the influence of a 6-week course of cimetidine (1 g/day) on its own disposition and elimination is investigated.

EXPERIMENTAL

Instrumentation—A constant flow high-pressure liquid chromatograph[3] was used for all assays. This consisted of a solvent delivery system[4], a universal injector[5], and a variable wavelength UV absorbance detector[6] operating at 228 nm. The plastic column was obtained prepacked[1] (100 mm × 8-mm i.d.) and was housed in a radial compression module[2] which maintained external column pressure at ~2500 psi.

Reagents—Pure samples of cimetidine, cimetidine sulfoxide, and the internal standard, burimamide, were obtained[7]. The HPLC mobile phase contained UV grade acetonitrile[8], triethylamine[9], phosphoric acid[10], and glass-distilled water.

Calibration Standards—A pool of drug-free plasma was spiked with pure cimetidine to a concentration of 5000 ng/ml. By a series of quantitative double dilutions with additional drug-free plasma, standards of 2500, 1250, 625, and 312.5 ng/ml were prepared and stored at −20°. Similarly, drug-free urine was spiked with pure cimetidine to a concentration of 200 μg/ml and diluted to prepare standards of 100, 50, and 25 μg/ml. Calibration curves were prepared by plotting the relationship between the peak height ratios of cimetidine–burimamide and the cimetidine concentration in each sample.

Recoveries of cimetidine and burimamide from plasma or urine were estimated by comparing the peak height of cimetidine obtained after extraction, against that obtained when the same amount of cimetidine from an aqueous stock solution was chromatographed.

Extraction of Plasma—Burimamide (internal standard, 10 μg/ml, 200 μl), NaOH (2 *M*, 0.5 ml), and methylene chloride (20 ml) were added to 1.0 ml of plasma in a 30-ml glass tube. After vortex mixing (60 sec) and centrifugation (3000 rpm, 10 min), the organic layer was carefully transferred into a second tube and evaporated under a gentle stream of

High-Pressure Liquid Chromatographic Determination of Cimetidine in Plasma and Urine

G. W. MIHALY ˣ, S. COCKBAIN, D. B. JONES, R. G. HANSON, and R. A. SMALLWOOD

Received April 22, 1981, from the *Gastroenterology Unit, Department of Medicine, University of Melbourne, Austin Hospital, Heidelberg, 3084, Victoria, Australia.* Accepted for publication August 26, 1981.

Abstract □ An assay is described for the determination of the H_2-receptor antagonist, cimetidine, in human plasma and urine. Alkalinized plasma or urine was extracted with methylene chloride, the organic phase was evaporated, and the reconstituted residue was analysed by high-pressure liquid chromatography (HPLC) using a reversed-phase prepacked plastic column housed in a radial compression module. The metabolite, cimetidine sulfoxide, was identified but could not be quantitated due to interference from the solvent front. The sensitivity limit of the assay was 25 ng/ml. The assay was applied to the measurement of plasma and urine samples in a pilot pharmacokinetic study. Cimetidine was substantially absorbed and rapidly eliminated (plasma elimination half-life of 112–130 min). Plasma cimetidine concentrations could be measured to 12 hr after a 200-mg dose (iv or oral), but they were below the sensitivity of the assay by 24 hr. Urinary excretion of unmetabolized cimetidine accounted for 40–50% of the administered dose in the first 12 hr. This assay is simpler and more sensitive than those previously described, and it is suitable for the measurement of cimetidine in plasma and urine of subjects receiving doses appropriate for clinical use.

Table I—Pharmacokinetic Parameters and Cumulative Urinary Excretion Data for Cimetidine [a]

Pharmacokinetic Parameters	Study Number I	II	III	IV
Dose, mg	200	200	200	200
Route	iv	oral	oral	iv
$AUC_{0\to\infty}$, ng min/ml × 10^{-3}	350.2	308.0	315.8	487.3
$t_{1/2\beta}$, min	129.7	122.8	114.8	112.6
Cl_s, ml/min	563.6	563.6	406.8	406.8
Vd_β, liters	105.5	99.9	67.4	66.1
F, × 10^2	—	89.3	65.8	—
Cumulative percent of dose excreted in urine:				
4 hr	35.2	29.0	26.7	31.2
8 hr	46.8	37.4	36.0	36.0
12 hr	49.1	41.1	38.8	38.0
24 hr	50.1	44.4	40.4	38.8

[a] Studies I and II were undertaken before a 6-week course of cimetidine (1 g/day), while III and IV were undertaken immediately after the course of therapy. ($AUC_{0\to\infty}$ = area under the plasma concentration–time curve; $t_{1/2\beta}$ = terminal elimination phase half-life; Cl_s = systemic clearance; Vd_β = volume of distribution; F = bioavailability fraction.)

nitrogen at 45°. The residue was reconstituted in 100 μl of the chromatographic mobile phase and 40 μl was injected onto the liquid chromatograph.

Extraction of Urine—Burimamide (1 mg/ml, 25 μl), NaOH (2 *M*, 100 μl), and methylene chloride (5 ml) were added to 250 μl of urine in a 30-ml glass tube, and the sample was treated as described for the plasma. Only 20 μl of the reconstituted residue was injected onto the chromatograph.

Chromatography—The mobile phase was 1% triethylamine and 5% acetonitrile in water, adjusted to pH 3 with phosphoric acid (85% v/v). The flow rate was 3 ml/min at a back pressure of 1500 psi. The retention times of burimamide and cimetidine were 2.4 and 3.8 min, respectively. Under these conditions the peaks were resolved completely to baseline.

Patient Sampling—The effect of a course of cimetidine on drug disposition was assessed in a pilot study of a female patient with a gastric ulcer (age, 49 years; weight, 59 kg). The patient underwent intravenous and oral pharmacokinetic studies before and after a 6-week course of cimetidine. After an overnight fast, the patient received a 200-mg/15-ml dose *iv* of cimetidine over 5 min (Table I, Study I). Venous blood samples (10 ml) were withdrawn before the cimetidine dose and at intervals to 24 hr. Urine was also collected predose and over a 24-hr period. At 48 hr, after an overnight fast, a 200-mg tablet of cimetidine was administered with 150 ml of water (Table I, Study II). Blood and urine were again collected over a 24-hr period. The patient then began a 6-week course of cimetidine (200 mg three times daily and 400 mg at night). Twenty four hours after the final dose, the oral and intravenous pharmacokinetic studies were repeated (Table I, Studies III and IV). In all studies food was withheld for the first 3 hr. Thereafter a standard meal was supplied, and free access to water was allowed.

Calculations—Pharmacokinetic parameters were derived from the plasma cimetidine concentration *versus* time data, using the nonlinear least squares regression program, AUTOAN (6), and standard pharmacokinetic formula (7).

RESULTS AND DISCUSSION

Column effluent was monitored at 228 nm, since this corresponds to the wavelength of maximum UV absorbance of cimetidine. For the chromatographic separation of cimetidine, the radial compression column system offers several advantages over the stainless steel, packed reversed-phase columns. Chromatography is faster and more efficient, enhancing sensitivity. The columns are less expensive and more robust, and the use of an acidified mobile phase (pH 3) containing triethylamine gives longer column life.

Single step extraction with methylene chloride results in simple sample preparation. Figure 1 (A and B) shows the chromatograms of a blank predose plasma extract and a plasma extract obtained after a single oral dose of cimetidine. Plasma from the patient receiving cimetidine showed a distinct peak at 3.8 min, which represented 801 ng/ml of cimetidine. No peaks corresponding to the cimetidine sulfoxide metabolite were present. Figure 1(C) shows the chromatogram of 100 ng of each of the reference compounds, cimetidine sulfoxide, burimamide, and cimetidine, injected as an aqueous solution. There is satisfactory separation of cimetidine from both the internal standard and the sulfoxide metabolite.

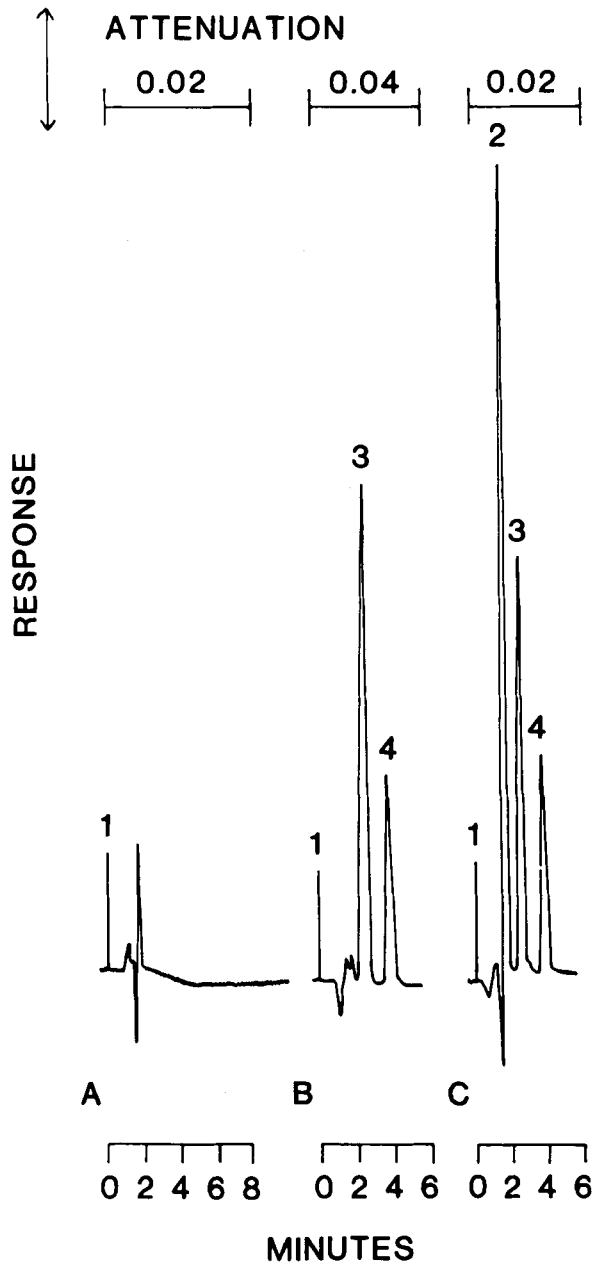

Figure 1—*High-pressure liquid chromatograms for a blank plasma extract (A); an extract of a plasma sample obtained from a patient who received a single dose of cimetidine (cimetidine concentration = 801 ng/ml) (B); and reference compounds showing the injection event (1), cimetidine sulfoxide (2), the internal standard, burimamide (3), and cimetidine (4), for which 100 ng of each compound was injected as a mixed solution in the mobile phase (C).*

In the chromatograms of some patients' plasma samples, a single broad peak eluted at 32 min. This peak was attributed to a cimetidine metabolite because it was absent from predose sample chromatograms. However, it could not be identified, since appropriate pure metabolite standards were unavailable.

Chromatograms of blank urine and a urine specimen collected after a single intravenous dose of cimetidine are shown in Fig. 2. Due to the much higher concentrations of cimetidine in urine, the detector attenuation was reduced. The late-eluting component seen in some plasma chromatograms was not seen in any urine chromatograms, suggesting that this presumed metabolite is not excreted in urine in significant amounts.

Cimetidine sulfoxide, which has been identified as a major metabolite of cimetidine (8), did not interfere with the assay. Although this metabolite appeared in the chromatogram of an aqueous stock solution at a retention time of 1.7 min (Fig. 1C), it was not possible to quantitate it due to interference from the solvent front.

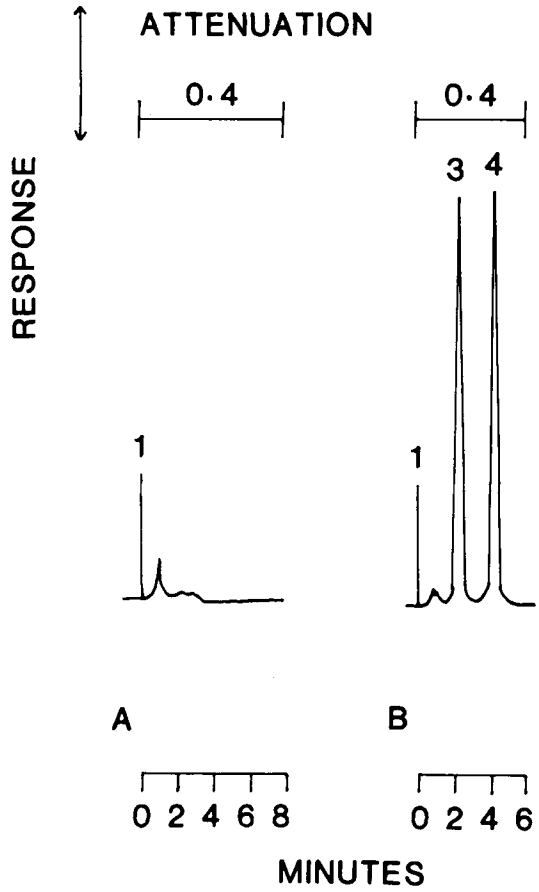

Figure 2—*High-pressure liquid chromatograms for a blank urine extract (A); and an extract of urine sample obtained from a patient who had received a single dose of cimetidine (cimetidine concentration = 156 μg/ml) (B). The peaks are the injection event (1); the internal standard, burimamide (3); and cimetidine (4).*

Methylene chloride was chosen as the extraction solvent because it gave optimal recovery of cimetidine with minimal extraction of endogenous components that might have interfered with quantitation. Analytical recoveries of cimetidine and burimamide were 60 and 31%, respectively. The limit of detection for both cimetidine and burimamide in plasma was 25 ng/ml, which gave peaks four times that of the baseline noise at the highest detector sensitivity. Ranitidine and oxmetidine, two other H_2-receptor antagonists under clinical evaluation, did not interfere with the assay.

The precision of the assay was assessed by replicate assays of aliquots of the same sample spiked with pure cimetidine. The coefficient of variation for same-day assays of plasma cimetidine levels was 4.6% at 1000 ng/ml (n = 6); for urine it was 0.4% at 55 μg/ml (n = 7). The coefficient of variation of day-to-day assays of plasma cimetidine levels over 4 weeks was 6.6% at 960 ng/ml (n = 9). The value for urine over the same period was 3% at 54 μg/ml (n = 5). The accuracy of cimetidine determination was not influenced by dried methylene chloride-extracted residue, stored for up to 5 days at 20°.

This method can be readily extended to the assay of burimamide, although this H_2-receptor antagonist is now only used in animal experiments. For burimamide assays, cimetidine is used as the internal standard. This approach has been successfully applied to the analysis of burimamide in samples obtained from animal studies.

The assay was applied to the measurement of plasma samples obtained from a pilot pharmacokinetic study. Figure 3 shows the semilogarithmic plot of plasma cimetidine concentrations following intravenous and oral doses, which were administered before (Table I, Studies I and II) and after (Table I, Studies III and IV) a 6-week course of cimetidine. The resultant pharmacokinetic and urinary excretion data for this patient are presented in Table I.

In all studies, plasma cimetidine could be estimated only to 12 hr, since by 24 hr, concentrations were below the sensitivity of the assay (25 ng/ml). The pharmacokinetic results agree with earlier studies (9, 10) and show that oral cimetidine is substantially absorbed and that both oral and intravenous cimetidine undergo rapid elimination. The urinary excretion

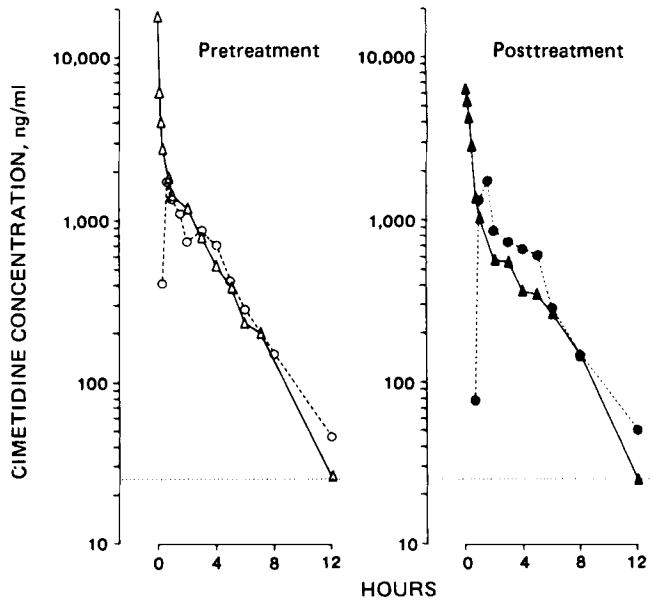

Figure 3—*Semilogarithmic plot of the mean plasma cimetidine concentration* versus *time following intravenous and oral administration of cimetidine to a patient before and after a 6-week course of treatment with cimetidine. Key: Pretreatment: (△) 200 mg, iv; (○) 200 mg, oral. Posttreatment: (▲) 200 mg, iv; (●) 200 mg, oral.*

data (Table I) confirm that renal clearance of unmetabolized drug is an important route of elimination. Approximately 40–50% of an administered dose is excreted unchanged in urine within the first 12 hr.

In contrast to an earlier study (10), the 6-week course of treatment in the patient appeared to alter the disposition of cimetidine (Table I). However, no firm conclusions can be drawn from this pilot study in one patient, and further studies are now under way.

Advantages of this assay over earlier published methods are increased precision and sensitivity (2–4-fold) resulting from improved chromatographic conditions. In addition, sample treatment has been kept simple. From the pilot pharmacokinetic study, it is apparent that the proposed method is sufficiently sensitive and specific for cimetidine quantitation in both plasma and urine, when clinically used doses are administered.

Enhanced Rectal Bioavailability of Polypeptides Using Sodium 5-Methoxysalicylate as an Absorption Promoter

SUMIE YOSHIOKA *§, **LARRY CALDWELL** ‡, **and TAKERU HIGUCHI** *‡ x

Received June 24, 1981, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045, and the ‡INTERx Research Corporation, Lawrence, KS 66044. Accepted for publication October 16, 1981. §Present address: National Institute of Hygienic Sciences, 18-1, Kamiyoga 1-chome, Setagaya-ku, Tokyo 158, Japan.

Abstract □ The absorption-promoting effect of sodium 5-methoxysalicylate was studied in the rat with respect to rectal delivery of pentagastrin and gastrin. Rectal bioavailability was quantitated by direct comparison of pharmacological effect with intravenous dose response. Coadministration of the absorption adjuvant greatly enhanced the rectal bioavailability of the model polypeptides. Sodium 5-methoxysalicylate, therefore, is representative of a new type of absorption promoter which appears to facilitate rectal absorption of polypeptide drug entities.

Keyphrases □ Bioavailability—rectal, absorption of small polypeptides, rats □ Polypeptides—pentagastrin and gastrin, rectal bioavailability, rats □ Adjuvant—absorption effect of sodium 5-methoxysalicylate, rats

Parenteral injection has long been the only reliable method to administer polypeptide drugs. Successful oral dosage forms of biologically active polypeptides have traditionally been elusive (1). However, there has been some limited success using the rectal delivery route as an alternative to the parenteral route.

Surface-active agents have been shown to increase rectal absorption of water-soluble polypeptides such as insulin (2). More recently, enhanced rectal delivery of theophylline and lidocaine using sodium salicylate as an absorption promoter was reported (3, 4), and enhanced rectal delivery of insulin in rats using 5-methoxysalicylate as an absorption adjuvant has been demonstrated (5). The use of salicylates as rectal absorption adjuvants represents a divergence from the traditional surfactant-enhanced delivery of poorly absorbed drugs. Furthermore, nontoxic salt forms of salicylate appear to be less tissue damaging than surfactant-type absorption adjuvants (3, 6).

The present study was designed to evaluate the feasibility of rectal delivery of small polypeptides using 5-methoxysalicylate as an absorption promoter.

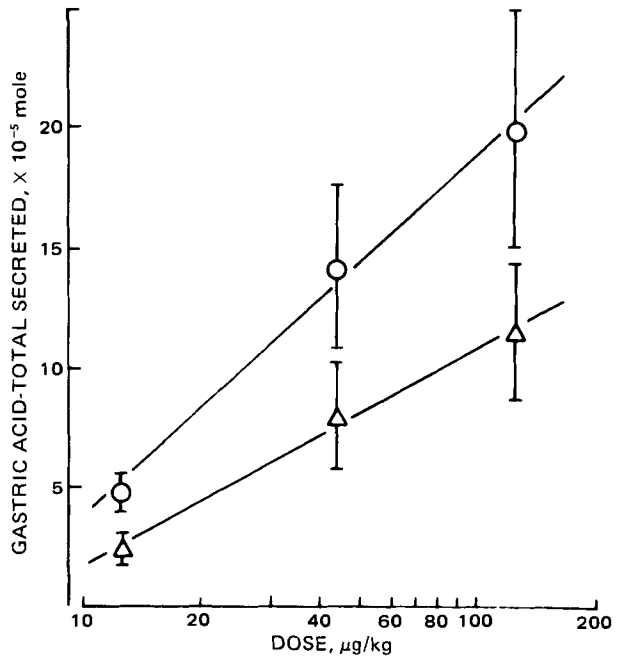

Figure 1—*Intravenous dose response of total gastric acid secretion following intravenous administration of gastrin (△) and pentagastrin (○) to anesthetized rats. The drug dosages were 12.5, 44.0, and 125 μg/kg. The error bars represent standard deviations with n=6.*

EXPERIMENTAL

Male Long-Evans rats, 230–290 g, were fasted 36 hr prior to experimentation. Rats were anesthetized with pentobarbital sodium (50 mg/kg ip) and surgically prepared for gastric perfusion according to the method of Ghosh and Schild (7). The stomachs were rinsed and ultimately perfused with 20 ml of physiological saline solution. The perfusion rate was 2 ml/min provided by a peristaltic pump. Perfusate and rat body temperature were held constant at 38° and the pH of the perfusate was held constant at 4.0[1] with 0.05 *N* NaOH as the titrant. Stomach acid output was continuously monitored by recording the amount of titrant required to maintain a constant pH with respect to time.

The target polypeptides for rectal delivery were pentagastrin[2] (5 residues) and gastrin[3] (17 residues). Aqueous polypeptide solutions were made up and adjusted to pH 8.0 using ammonium hydroxide and the ionic strength was adjusted to $\mu = 0.15$ with sodium chloride. Polypeptide concentration in these solutions was 250 μg/ml. Both pentagastrin and gastrin were administered intravenously (external jugular) to obtain dose–response curves.

Identical drug solutions were also administered rectally as microenema formulations (0.5 ml/kg) with or without the addition of 50 mg/ml of

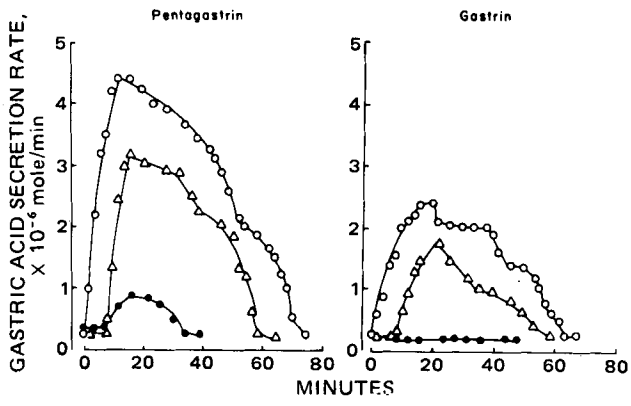

Figure 2—*Typical, single animal profiles of gastric acid secretion following administration of pentagastrin and gastrin to anesthetized rats. The solutions were administered: intravenous with 125 μg polypeptide/kg in saline (○); rectally with 125 μg polypeptide/kg in saline, pH 8.0 (●); and rectally with 125 μg polypeptide/kg rat and 25 mg 5-methoxysalicylate/kg rat in saline, pH 8.0 (△).*

sodium 5-methoxysalicylate. After the addition of the sodium 5-methoxysalicylate as a potential absorption adjuvant, the microenema was readjusted to pH 8.0 before administration. As a separate control, a solution of 5-methoxysalicylate without the polypeptides was administered.

RESULTS AND DISCUSSION

Gastrin-like compounds were chosen for this study for several reasons. Gastric acid secretion is relatively easy to monitor in a test animal and at the same time is particularly sensitive to circulating hormone levels. The relationship between pharmacological response and the logarithm of the intravenous dose is relatively linear over a significant dosage range (Fig. 1)[4]. This allows for a reasonable bioavailability assessment of the rectally administered aqueous polypeptide solutions by comparing the pharmacological effect with the intravenous dose–response curve.

Figure 2 shows typical, single animal plots of gastric acid secretion rate after intravenous or rectal administration of both pentagastrin and gastrin at doses of 125 μg/kg. The area under the curve represents the total amount of gastric acid secretion in response to administration of either pentagastrin or gastrin in the presence or absence of adjuvant. The time course of the pharmacological response following intravenous administration did not decline in an apparent zero-order fashion and, therefore, may not directly represent the logarithm of the drug–plasma concentration. Nevertheless, the response profiles are similar regardless of administration route and should allow for a reasonable rectal bioavailability assessment based on the intravenous dose response.

Rectal administration of 125 μg/kg of pentagastrin resulted in only 6 ± 4% bioavailability relative to intravenous dose response (uncertainties are expressed as standard deviations) (Table I). The addition of 5 mg of sodium 5-methoxysalicylate to the microenema resulted in a bioavailability of 33 ± 10%, a five-fold increase in drug delivery to the active site. The rectal administration of 125 μg/kg of gastrin without the absorption adjuvant resulted in no detecetable response (Table II). However, the addition of the absorption adjuvant to the microenema resulted in 18 ± 7% drug delivery.

In a separate series of experiments, the concentration of absorption adjuvant in the microenema formulations was lowered from 5 to 1% (w/v). In these experiments the bioavailability of rectally administered gastrin was only 8%, suggesting a dose-response relationship between adjuvant concentration and the absorption promoting effect.

The microenema formulations containing 5% sodium 5-methoxysalicylate are hyperosmotic. In control experiments in which an osmolar equivalent of sodium chloride was substituted for the adjuvant, no enhancement of rectal absorption was seen due to an osmolarity effect. Additional control experiments in which 5-methoxysalicylate was administered rectally without the polypeptide hormone produced no change in stomach acid output. Thus, the observed improvement in rectal polypeptide delivery must be attributed to the adjuvant, which appears to effect a temporary change in the normal mucosal permeability of the rectal compartment.

From this study, it is apparent that sodium 5-methoxysalicylate is representative of a new type of absorption promoter which facilitates nonparenteral polypeptide drug delivery. As nonparenteral alternatives, rectal dosage forms such as microenemas and suppositories may offer a convenient means of expanding polypeptide drug therapy beyond the clinical setting.

[4] The response to higher dosage appears to be more variable than the response in the lower dosage range.

Decreases in Ciliary Beat Frequency Due to Intranasal Administration of Propranolol

H. J. M. van de DONK ˣ and F. W. H. M. MERKUS

Received May 28, 1981, from *The Department of Biopharmaceutics, Faculty of Pharmacy and Faculty of Medicine, Plantage Muidergracht 14, 1018 TV Amsterdam, The Netherlands.* Accepted for publication September 2, 1981.

Abstract □ Recently the intranasal application of 5% propranolol was proposed in order to prevent the extensive first-pass metabolism of this drug. The ciliary epithelium in the nose affects the removal of dust, allergens, and microorganisms. The decreasing effect of propranolol on the ciliary beat frequency of human adenoid tissue and chicken embryo tracheas was measured with a photoelectric registration device. After nasal application of 5% propranolol, the drop is diluted by the nasal mucus. It was found that even 0.1% propranolol had a deleterious effect on the cilia of chicken and human tissue. Ciliary movement was arrested irreversibly within 20 min.

Keyphrases □ Propranolol—decrease in ciliary beat frequency due to intranasal administration □ Intranasal administration—propranolol, decrease in ciliary beat frequency □ Ciliary movement—decrease due to intranasal administration of propranolol

The extensive use of nasal drops necessitated the investigation of the effects of nasal medication on the ciliary beat frequency. The nasal ciliary epithelium effects the removal of dust, allergens, and microorganisms that are precipitated after inhalation. This nasal clearance is a physiological defense mechanism which should not be disturbed. A method has been developed to investigate the influence of drugs on the ciliary beat frequency (1). With this method the ciliary beat frequency of chicken embryo tracheas is measured with a photoelectric registration device. The effects of preservatives (2) and nasal drops (3) have been investigated previously. A good correlation has been found between the ciliary beat frequency of ciliary epithelium of human adenoids and of chicken embryo tracheas (4). Recently, the intranasal application of propranolol has been suggested in order to prevent the first-pass effect of this drug after oral administration (5). As propranolol is used in chronic therapies, the effects of intranasal application on the ciliary beat frequency may be important. Therefore, the effect of propranolol on the ciliary beat frequency of chicken embryo tracheas and human adenoid tissue was investigated.

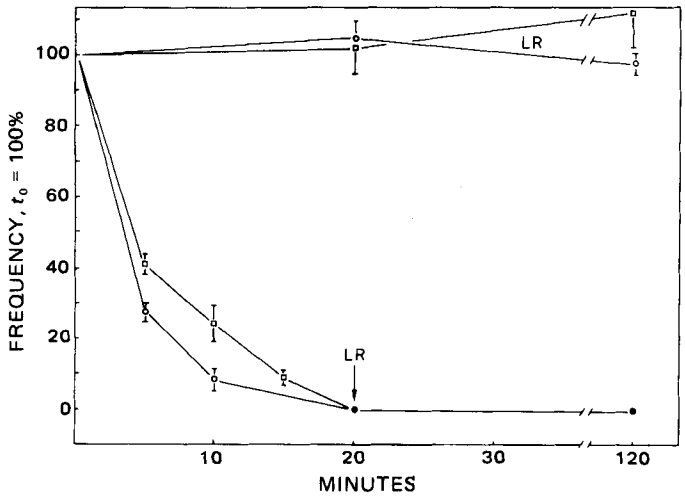

Figure 1—*Time* versus *ciliary beat frequency plot: effect of 0.1% propranolol hydrochloride on the cilia of human adenoids and chicken embryo tracheas. Locke-Ringer (LR) solution was used as a reference. Key: (□), human; (○), chicken; (●), Locke-Ringer.*

Table I—The Decreasing Effect of Propranolol on the Ciliary Beat Frequency of Chicken Embryo Tracheal Epithelium and Human Adenoid Epithelium

Compound	Frequency[a], % Time 2 min	10 min	20 min	Species
Propranolol hydrochloride, 1%	0	0	0	Chicken
Propranolol hydrochloride, 0.1%	70	8	0	Chicken
Propranolol hydrochloride, 0.1%	77	25	0	Human

[a] Frequency as a percentage of the initial frequency.

EXPERIMENTAL

The effects of a solution containing 1% propranolol hydrochloride[1], made isotonic with sodium chloride and of a 10-fold dilution of this solution in Locke-Ringer, were investigated. Both solutions were adjusted to pH 7.4. The effects on the ciliary beat frequency were assessed on six different tracheas for each concentration and for the reference (Locke-Ringer) and on pieces of six different human adenoids for the 10-fold dilution and the reference.

RESULTS

The effects of 1 and 0.1% propranolol are demonstrated in Table I. Frequencies are listed as a percentage of the frequency just before the start of the experiments. The solution containing 1% propranolol arrested ciliary movement of chicken embryo tracheas within 2 min. The 10-fold dilution arrested the ciliary movement of both human adenoids and chicken embryo tracheas within 20 min. This effect was irreversible: rinsing with Locke-Ringer solution after a 20-min contact with 0.1% propranolol did not restore ciliary movement within 2 hr.

The effects of 0.1% propranolol are shown in more detail in Fig. 1 with *SEM* values indicated by vertical bars.

DISCUSSION

The use of a nasal drop containing 5% propranolol has been suggested (5). This nasal drop is diluted by the nasal mucus after application, therefore, the investigation began with 1% propranolol which had a deleterious effect on ciliary movement of chicken embryo tracheas. Propranolol (0.1%) also irreversibly arrested the ciliary movement of chicken and human cilia within 20 min. It is not likely that the nasal drop will be diluted more than 50 times in 20 min, especially since it interferes with the nasal clearance.

For repeated intranasal administration of propranolol, its ciliotoxicity should be taken into account.

Influence of Ethylene Oxide Exposure on the Extraction of Indomethacin from Dimethicone Polymeric Rods

P. R. HURST ˣ, P. V. PEPLOW, and P. von DADELSZEN

Received June 30, 1981 from the *Department of Anatomy, University of Otago Medical School, Dunedin, New Zealand.* Accepted for publication September 2, 1981.

ABSTRACT □ Dimethicone polymeric rods were made to contain 0.3, 2.0, or 3.3% by weight of indomethacin. For each different loading of indomethacin, some of the rods were treated with ethylene oxide at 55° for 1 hr, while others were not exposed to the gas. Treated and untreated rods were sliced, placed in ethanol to extract the indomethacin, and the concentrations of indomethacin in the extracts determined by fluorometry and high-performance liquid chromatography (HPLC). After ethylene oxide treatment, the quantity of indomethacin in the extracts was significantly reduced in rods containing 0.3 and 2.0% indomethacin. For the rods containing 3.3% indomethacin, the recovery of the drug from treated rods was not significantly different from those not exposed.

Keyphrases □ Ethylene oxide—extraction of indomethacin from dimethicone polymeric rods □ Indomethacin—dimethicone polymeric rods, influence of ethylene oxide exposure □ Polymeric rods—dimethicone, ethylene oxide exposure on extraction of indomethacin □ Fluorometry—determination of influence of ethylene oxide exposure on the extraction of indomethacin from dimethicone polymeric rods □ High-performance liquid chromatography—determination of influence of ethylene oxide exposure on the extraction of indomethacin from dimethicone polymer rods

The development of simple systems or devices for drug delivery over extended periods has potentially wide usage, especially for delivery of compounds to selected sites in the body. In this regard, experiments have been performed with a system which can provide a sustained release of nonsteroidal anti-inflammatory drugs such as indomethacin or naproxen from dimethicone polymeric rods (1). In these and other studies (2, 3) the quantity of drug released *in vivo* is determined by measuring the residual amount of drug in the rods at various time periods and subtracting it from values from similar rods prepared in an identical manner but which were not placed in the body. The measurements are performed on ethanolic or methanolic extracts of the rods.

Before being fitted into the body, such rods must be sterilized. Since autoclaving and chemical methods (such as placing in aqueous ethanol) appear unsuitable for this system, ethylene oxide gas treatment has been used.

The present study indicates that by using this method of sterilization, there is a decrease in the percentage of indomethacin that can be extracted into ethanol from rods containing the drug at low concentrations (<3% w/w).

EXPERIMENTAL

Indomethacin[1] was recrystallized, dried, and either 0, 10, 60, or 100 mg was thoroughly mixed with 3 g of dimethicone[2]. Following the addition of catalyst (15 mg) the different mixtures were forced into vinyl tubing (french gauge 5, 1-mm i.d.)[3] and allowed to polymerize. Rods of 1-cm length were cut and weighed and either stored at room temperature or subjected to ethylene oxide exposure (1.2–1.4 g/liter) in a stainless steel sterilizer[4]. In this apparatus the gas was released from ampuls into a chamber initially evacuated to 150 mm Hg. Following exposure to the gas for 1 hr at 55°, the rods were aerated for at least 12 hr and left for 2 days at room temperature.

Rods containing indomethacin were weighed, cut into thin slices, and the drug extracted with ethanol (2 ml/day for 4 days). The amounts of indomethacin in the extracts were determined by fluorometry and HPLC with standard solutions of indomethacin prepared from the recrystallized compound. For the fluorometric analysis, samples were assayed in duplicate using a spectrophotofluorometer[5] with an excitation wavelength of 295 nm and an emission wavelength of 361 nm. Continuous scan recordings over an emission range of 300 to 450 nm (constant excitation wavelength of 295 nm) were also made of certain extracts of the gassed and nongassed rods. For HPLC, 10 μl samples were injected into a C18 μ Bondapak column[6] with a mobile phase of methanol–50 m*M* KH_2PO_4 (3:1), pH 6.72, and a flow rate of 2 ml/min. The UV absorbance at 230 nm of the column eluate was continuously recorded with a variable wavelength UV detector[6]. Heights of the peaks corresponding in position to the indomethacin standards were measured to determine the amounts of indomethacin in the extracts. These amounts, compared with those determined to be present initially on the basis of the quantity of indomethacin in the mixture and the weight of each rod, were used to calculate percentage recoveries.

RESULTS

For the rods not subjected to ethylene oxide exposure, over 90% of the incorporated indomethacin was recovered into ethanol when measurements on the extracts were made by fluorometry (Fig. 1). This was confirmed by HPLC of the extracts of rods made from the 60 and 100 mg/mixture. (The HPLC system used did not allow a reliable measurement of indomethacin in the extracts obtained from the 10 mg/mixture rods as the peaks assigned to indomethacin were not sufficiently large to be accurately quantitated.) Following ethylene oxide treatment, however, the recovery of indomethacin into alcohol was significantly reduced for

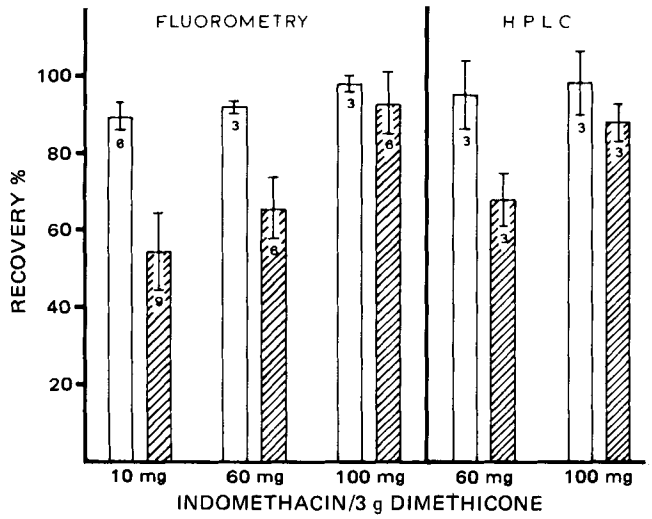

Figure 1—*Mean percentage recovery of indomethacin from dimethicone rods at different concentrations following ethylene oxide treatment (hatched bars). Standard deviations and the number of rods extracted in each group are shown. Results of gassed and ungassed rods at each indomethacin concentration were compared by t test analysis. This revealed no significant difference for the rods containing 100 mg of indomethacin/mixture. For the 60- and 10-mg/mixture groups, however, p values were <0.01 and <0.001, respectively.*

the 10 and 60 mg/mixture rods (Fig. 1). There was also a slight reduction in the recoveries for the 100 mg/mixture rods, but this difference was not significant, as determined by *t* test analysis, from the ungassed rods.

Continuous scan recording by the fluorometer showed no change in the shape of the curves obtained from the analysis of extracts of gassed rods, and no additional peaks were seen in the trace recordings of the HPLC analysis.

DISCUSSION

These results provide evidence that ethylene oxide treatment reduces the extraction into alcohol of a common nonsteroidal anti-inflammatory drug incorporated into a dimethicone delivery system. This effect was dependent upon the concentration of the drug, with the lower doses (10 and 60 mg/mixture) being most affected. For the rods made from 100 mg indomethacin/mixture, over 90% of the drug was recovered after gassing, indicating that rods made to contain the drug at this concentration would be suitable for studies of indomethacin release rates from dimethicone rods placed in the body. The similarity in profiles of the extracts from the gassed and nongassed rods (continuous fluorometric scan and HPLC tracings) suggest that no alteration in the qualitative composition of the extracts occurred. The reasons for the reduced recoveries of indomethacin at the two lowest concentrations were not investigated here. One possibility is that at low drug concentrations, a greater matrix volume would be unoccupied by the drug and is available to be taken up by the gas. This, in turn, might alter the diffusion properties of the matrix or chemically interfere with the drug, thereby reducing its extraction into alcohol.

It would be valuable to know if other nonsteroidal anti-inflammatory drugs, and those steroids that are currently being used in conjunction with dimethicone systems (4, 5, 6), are affected by ethylene oxide gassing.

Model-Independent Steady-State Volume of Distribution

Keyphrases □ Pharmacokinetics—evaluation of model-independent steady-state volume of distribution □ Drug disposition—first-order disposition rates, evaluation of model-independent steady-state volume of distribution □ Models, pharmacokinetic—methods to evaluate model-independent steady-state volume of distribution

To The Editor:

Recently, pharmacokinetic methods have been proposed to evaluate model-independent input and disposition parameters for drugs exhibiting first-order disposition rates (1–4). The use of these statistical moment parameters is appealing, not only because of the relatively simple calculations involved, but also because the parameters determined are independent of any modeling assumptions, which greatly facilitates cross-study comparison of drug disposition. For example, Benet and Sheiner (5) have compiled volume of distribution steady-state (Vd_{ss}) data for numerous drugs using statistical moment analysis. However, as proposed (4), the method is valid only for single dose instantaneous input data and will result in an overestimation of Vd_{ss} when applied to data obtained after infusion or multiple dose input. The purpose of this communication is to report a simple method to obtain Vd_{ss} values from multiple intravenous bolus and/or infusion data.

For a drug administered by bolus injection, a single distribution–elimination rate parameter, the mean residence time (MRT_{iv}), can be evaluated using statistical moment analysis (1). The MRT_{iv} describes the average time a drug molecule spends in the body and is determined

0022-3549/82/0500-0597$01.00/0

by dividing the area under the concentration multiplied by time–time curve [area under the moment curve ($AUMC$)] by the area under the concentration–time curve (AUC):

$$MRT_{iv} = \frac{AUMC_{iv}}{AUC_{iv}} \quad \text{(Eq. 1)}$$

As shown previously by Benet and Galeazzi (4), a model independent distribution volume (Vd_{ss}) may be determined from the dose (D), MRT_{iv}, and AUC_{iv} as follows:

$$Vd_{ss} = \frac{D(MRT_{iv})}{AUC_{iv}} = \frac{D(AUMC_{iv})}{(AUC_{iv})^2} \quad \text{(Eq. 2)}$$

If the same dose (D) is administered as an infusion over a time (t') or is divided into increments ($D_1, D_2, \ldots D_n$) and administered as a combination of infusions and/or boluses at different times ($T_1, T_2, \ldots T_n$), the area under the curve (AUC_{total}) will equal the AUC_{iv}; but the $AUMC_{total}$ will be greater than the $AUMC_{iv}$, resulting in an overestimation of Vd_{ss} if $AUMC_{total}$ is used in Eq. 2. For a case where the drug is administered as a single infusion rather than a bolus, the MRT_{total} and the $AUMC_{total}$ are easily corrected, since the infusion will increase the MRT_{iv} by $0.5t'$ (6), and:

$$AUMC_{iv} = AUMC_{total} - AUC_{iv}(0.5t') \quad \text{(Eq. 3)}$$

When multiple dosing occurs, the correction is somewhat more complex, since there is a delay (T) in the input of a fraction of the dose. Assuming there is no previous dosing, the delay time will increase the MRT_{iv} by T if administered as a bolus and by $0.5t' + T$ if administered as an infusion, and:

$$AUMC_{iv} = AUMC_{total} - AUC_{iv}(0.5t' + T) \quad \text{(Eq. 4)}$$

The general form for n bolus and/or infusion doses then becomes:

$$AUMC_{iv} = \sum_{i=1}^{n} AUMC_i - \sum_{i=1}^{n} AUC_i(0.5t_i' + T_i) \quad \text{(Eq. 5)}$$

where: $t_i' = 0$ for a bolus dose and $T_1 = 0$.

Dividing both sides of Eq. 5 by AUC_{iv} (the total AUC calculated), and recognizing the ratio of the individual AUC_i's to AUC_{iv} is the fraction of the total dose administered (F_i), one obtains:

$$MRT_{iv} = MRT_{total} - \sum_{i=1}^{n} F_i(0.5t_i' + T_i) \quad \text{(Eq. 6)}$$

Equation 6 may be used to correct total moment data for use in Eq. 2, even when a bolus is administered during an infusion. Although it is not valid if residual drug is present prior to characterization of the concentration–time curve, corrections for the residual drug are possible in certain instances. One may be tempted to correct for oral dosing by adding $1/K_a$ to the summation term in Eq. 6, but the fraction of the oral dose absorbed must be known as well as K_a. Finally, calculation of $AUMC_{total}$ and AUC_{total} are subject to extrapolation errors as described previously (3, 4), so it is advisable to obtain data which will allow excellent characterization of the terminal elimination rate constant after the last dose increment is administered, or to collect samples until the concentration of drug is essentially zero.

Tampon Leachable Substances: Acute Toxicity

Keyphrases □ Tampons—leachable substances, acute toxicity □ Toxicity, acute—tampon leachable substances, intramuscular implantation in rabbits □ Inhibition of cell growth—acute toxicity of tampon leachable substances □ Dehydration—tissue response, acute toxicity of tampon leachable substances

To the Editor:

The use of tampons for the control of menstrual flow has been associated with the induction of vaginal ulcerations, mucosal changes, and toxic shock syndrome. The evidence for those clinical phenomena has been reviewed recently (1), emphasizing the role of dehydration and alteration of calcium levels in the vaginal tissue as important mechanisms in the induction of vaginal ulceration. Since we are not aware of any reports on the potential toxicity of leachable substances of tampons, two acute toxicity tests were performed on regular and superabsorbant tampons available commercially. The tests performed were: a tissue culture inhibition of cell growth test on aqueous extracts (23°) of whole tampons (Table I); and a 7-day intramuscular implantation test in rabbits using (*a*) the absorbant material of the tampons (excluding the casing and fibrous material), (*b*) partially hydrated absorbant material, and (*c*) fibrous material (excluding casing and absorbant material (Table II).

The decrease in the gross rating of the muscle implant of the partially hydrated tampon material as compared to the dry material implant was consistent with the generally accepted conclusion that dehydration is a major factor in the initiation of vaginal ulceration. Also, the soluble, leachable components of the tampons tested have a significant cellular toxicity at concentrations well below that which might be expected in vaginal secretions adjacent to a tampon. The tissue culture test covers a period of time (72 hr) of usual tampon usage, and several tampons are frequently used in that period. It should also be noted that there was a significant concentration-dependent response for both extracts and that the highest concentration tested was 50% with respect to the original extract.

40	38	57
45	47	62
50	48	64

[a] Undiluted Extract = 100%. [b] Regular tampon: extracted with 95 ml of distilled water. [c] Superabsorbant tampon: extracted with 75 ml of distilled water.

Table II—Intramuscular Implantation: Tampon Material

Implanted Material	Gross Rating[a]	Histopathologic Rating[a]
Absorbant material[b]	3	4
Absorbant material[c]	3	4
Partially hydrated absorbant material	0	4
Fibrous material[b]	0	4
Fibrous material[c]	0	4

[a] Ratings: 0, equivalent to negative control; 3, marked positive response; 4, equivalent to positive control. [b] Regular tampon. [c] Superabsorbant tampon.

Muscle tissue reaction (necrotic and inflammatory) to the absorbant and fibrous materials of tampons were the most severe of any materials tested in this laboratory, actually exceeding the positive control response in some cases. The isolated fibrous material which has lower absorbancy than the absorbant material did not show a positive gross response but had a histopathologic rating equivalent to the absorbant material, suggesting that the response was not totally due to dehydration. Fibrous material has been reported to be present in biopsies of vaginal lesions (1). Although the rabbit muscle response can not be considered to be identical to the response of vaginal tissue, the presence of fibrous material in vaginal lesions indicates that tampon material comes into intimate contact with vaginal tissue. Tissue dehydration has been demonstrated to alter calcium levels of vaginal tissue, facilitates contact of tampon material with the tissue, and undoubtedly alters cellular response to leachable toxic components of tampons. The inhibition of cell growth reported in Table I was observed in normal liquid tissue culture medium where dehydration is not a factor. The effect of leachable, soluble components of tampons on cells partially impaired or altered by dehydration is not known. The potential for the exacerbation of the ulcerative process by leachable substances of tampons is apparent.

Simplified Method to Study Stability of Pharmaceutical Systems

Keyphrases □ Decomposition—determination of shelf-life using analytic methodologies □ Kinetics—decomposition, determination of shelf-life using analytic methodologies □ Stability—simplified method of study in pharmaceutical systems

To the Editor:

In a previous report (1), shelf-life, defined as the time for 10% decomposition at 25°, was estimated by a simplified method. The method involved carrying out a number of kinetic tests at different temperatures followed by linear regression of the logarithm of $t_{0.9}$ (the time required for the drug to decompose to 90% of its original value) on the reciprocal of absolute temperature. Simulated data were used initially to test the linearity of such plots. Since it had been reported previously (2) that it was not possible to distinguish between first-, zero-, and simple second-order kinetics when the decomposition was <10%, it was believed the plots of ln ($t_{0.9}$) *versus* $1/T$ would be linear.

In a subsequent criticism of a previous study (1), it was stated that the use of this Arrhenius approach for all orders of reaction was erroneous and that the slope of the line would be highly dependent on the initial concentration (3). For this reason, and because of analytical difficulties when decomposition is <10%, it was concluded that this method was of little use.

The problem arises because $t_{0.9}$ was defined with respect to the original concentration. It was tacitly assumed (1) that all test samples would have the same initial concentration, whereas it was implied (3) that this would not be the case necessarily.

The purpose of this communication is to point out that plots of $\ln(t_\alpha)$ (where t_α is the time to decompose from concentration C_1 to C_2) *versus* $1/T$ will be linear for all reaction orders irrespective of the α value chosen. If C_1 equals the initial concentration (C_0), and it is the same for all experiments, and C_2 is 90% of C_0, then $t_\alpha = t_{0.9}$.

Assuming the usual rate expression:

$$dC/dt = -kf(C) \qquad \text{(Eq. 1)}$$

where $f(C)$ is some function of concentration, then integrating between the limits t_2 and t_1 ($t_2 - t_1 = t_\alpha$):

$$g(C_2) - g(C_1) = -kt_\alpha \qquad \text{(Eq. 2)}$$

where $g(C)$ is the integrated form of $f(C)$. If a number of kinetic experiments are performed at different temperatures, each starting with approximately the same initial concentration, and C_1 and C_2 are chosen the same for all experiments, then $g(C_2) - g(C_1)$ is constant (G). Substituting this into Eq. 2, assuming the Arrhenius equation is applicable:

$$G = -k_a \exp[-E(1/T - 1/T_a)/R]t_\alpha \qquad \text{(Eq. 3)}$$

where k_a is the rate constant at the arbitrarily chosen temperature, T_a, and E is the activation energy. Rearranging and taking logarithms:

$$\ln(t_\alpha) = \ln(-G/k_a) + E(1/T - 1/T_a)/R \qquad \text{(Eq. 4)}$$

Thus a plot of $\ln(t_\alpha)$ *versus* $(1/T - 1/T_a)$ will be linear with slope E/R and intercept $\ln(-G/k_a)$. If C_1 is chosen

Simplified Method to Study Stability of Pharmaceutical Systems

Keyphrases □ Decomposition—determination of shelf-life using analytic methodologies □ Kinetics—decomposition, determination of shelf-life using analytic methodologies □ Stability—simplified method of study in pharmaceutical systems

To the Editor:

In a previous report (1), shelf-life, defined as the time for 10% decomposition at 25°, was estimated by a simplified method. The method involved carrying out a number of kinetic tests at different temperatures followed by linear regression of the logarithm of $t_{0.9}$ (the time required for the drug to decompose to 90% of its original value) on the reciprocal of absolute temperature. Simulated data were used initially to test the linearity of such plots. Since it had been reported previously (2) that it was not possible to distinguish between first-, zero-, and simple second-order kinetics when the decomposition was <10%, it was believed the plots of ln ($t_{0.9}$) *versus* $1/T$ would be linear.

In a subsequent criticism of a previous study (1), it was stated that the use of this Arrhenius approach for all orders of reaction was erroneous and that the slope of the line would be highly dependent on the initial concentration (3). For this reason, and because of analytical difficulties when decomposition is <10%, it was concluded that this method was of little use.

The problem arises because $t_{0.9}$ was defined with respect to the original concentration. It was tacitly assumed (1) that all test samples would have the same initial concentration, whereas it was implied (3) that this would not be the case necessarily.

The purpose of this communication is to point out that plots of $\ln(t_\alpha)$ (where t_α is the time to decompose from concentration C_1 to C_2) *versus* $1/T$ will be linear for all reaction orders irrespective of the α value chosen. If C_1 equals the initial concentration (C_0), and it is the same for all experiments, and C_2 is 90% of C_0, then $t_\alpha = t_{0.9}$.

Assuming the usual rate expression:

$$dC/dt = -kf(C) \qquad \text{(Eq. 1)}$$

where $f(C)$ is some function of concentration, then integrating between the limits t_2 and t_1 ($t_2 - t_1 = t_\alpha$):

$$g(C_2) - g(C_1) = -kt_\alpha \qquad \text{(Eq. 2)}$$

where $g(C)$ is the integrated form of $f(C)$. If a number of kinetic experiments are performed at different temperatures, each starting with approximately the same initial concentration, and C_1 and C_2 are chosen the same for all experiments, then $g(C_2) - g(C_1)$ is constant (G). Substituting this into Eq. 2, assuming the Arrhenius equation is applicable:

$$G = -k_a \exp[-E(1/T - 1/T_a)/R]t_\alpha \qquad \text{(Eq. 3)}$$

where k_a is the rate constant at the arbitrarily chosen temperature, T_a, and E is the activation energy. Rearranging and taking logarithms:

$$\ln(t_\alpha) = \ln(-G/k_a) + E(1/T - 1/T_a)/R \qquad \text{(Eq. 4)}$$

Thus a plot of $\ln(t_\alpha)$ *versus* $(1/T - 1/T_a)$ will be linear with slope E/R and intercept $\ln(-G/k_a)$. If C_1 is chosen

as the labeled concentration and C_2 = 90% of this, then $-G/k_a$ is the shelf-life at temperature T_a (assuming no overage in the product).

An advantage of this method is that the activation energy and shelf-life can be estimated without assuming a particular reaction order. An average value for E can be estimated by appropriately grouping data into sets with each set having a different α value, then solving them simultaneously by weighted nonlinear regression to estimate an average E across sets and a $-G/k_a$ for each set.

An analogous technique has been used in thermogravimetric analysis (4–6), in which a number of nonisothermal experiments were performed at different linear heating rates. The logarithm of the reaction rate at a selected percentage decomposition *versus* $1/T$ was plotted using this technique. The reaction rate at a specific fraction of decomposition was estimated by linear interpolation. In the method suggested previously, t_α can be estimated similarly by linear interpolation, by alternative methods (*e.g.*, cubic splines, polynomial regression), or by assuming knowledge of the functional relationship [$f(C)$] as was done previoulsy (1).

Simplified Method to Study Stability of Pharmaceutical Systems: A Response

Keyphrases □ Decomposition—determination of shelf-life using analytic methodologies, response □ Kinetics—decomposition, determination of shelf-life using analytic methodologies, response □ Stability—simplified method of study in pharmaceutical systems, response

To the Editor:

The preceding paper (1) discusses my earlier criticism, based on pragmatic reasons, of the paper (2) published by Amirjahed (3). It was suggested by Amirjahed (3) that if only 10% decomposition of a product is monitored, it is possible to ascertain the shelf-life, while using less than sophisticated analytic methodologies such as may be available in small institutional settings. My criticism that the initial concentration of the sample is important is still valid regardless of how the kinetic equation is manipulated such as reported by Tucker (1):

$$\ln(t_\alpha) = \ln(-G/k_a) + E\,(1/T - 1/T_a)/R \qquad \text{(Eq. 1)}$$

where t_α is the time to decompose from concentration C_1 to C_2, and $-G/k_a$ becomes the shelf-life at temperature T_a for a 10% concentration change. However, the assumptions involved here are self-defeating. It assumes that all preparations have similar initial concentrations and that there is no overage in the product (1). It should be reiterated that a ±5% variation in the content is routinely acceptable. This alone will discard the calculations that require identical starting concentrations. Furthermore, obtaining sufficient data points during 10% decomposition of the product (which may have several excipients) is a difficult, but not impossible, task and requires sophisticated analytic technology. Together, these arguments make such exercises as reported by Amirjahed (3) and Tucker (1) of merely academic interest and could be misleading if their use is suggested in those instances where operators may not be fully aware of these pitfalls. I would highly recommend that the authors (1, 3) use these equations with actual data collected in the laboratory and show their validity. It is only when such studies are reported that the validity of the interesting concept reported by Amirjahed (3) can be ascertained.

Use of Unbound Drug Concentration in Blood to Discriminate Between Two Models of Hepatic Drug Elimination

Keyphrases □ Plasma protein binding—effect on systemic unbound blood drug concentration of orally administered drug □ Hepatic drug clearance—discrimination between two models, venous equilibrium model, sinusoidal perfusion model

To the Editor:

Two well-defined models have been proposed to describe the hepatic elimination of drugs and other compounds. These models differ in their basic hypotheses and in some of their quantitative predictions, *e.g.*, concerning the influence of blood flow, protein binding, and drug metabolizing activity on extraction ratio and hepatic clearance.

Model 1 (the equilibrium or well-stirred model) assumes that the liver is a single, well-stirred compartment, and that the concentration of unbound drug in hepatic venous blood is in equilibrium with unbound drug throughout the liver (1). Model 2 (the sinusoidal perfusion or parallel tube model) assumes that at any point along the hepatic sinusoid, the concentration of drug in the liver cell will equal

0022-3549/82/0500-0600$01.00/0

as the labeled concentration and C_2 = 90% of this, then $-G/k_a$ is the shelf-life at temperature T_a (assuming no overage in the product).

An advantage of this method is that the activation energy and shelf-life can be estimated without assuming a particular reaction order. An average value for E can be estimated by appropriately grouping data into sets with each set having a different α value, then solving them simultaneously by weighted nonlinear regression to estimate an average E across sets and a $-G/k_a$ for each set.

An analogous technique has been used in thermogravimetric analysis (4–6), in which a number of nonisothermal experiments were performed at different linear heating rates. The logarithm of the reaction rate at a selected percentage decomposition *versus* $1/T$ was plotted using this technique. The reaction rate at a specific fraction of decomposition was estimated by linear interpolation. In the method suggested previously, t_α can be estimated similarly by linear interpolation, by alternative methods (*e.g.*, cubic splines, polynomial regression), or by assuming knowledge of the functional relationship [$f(C)$] as was done previoulsy (1).

Simplified Method to Study Stability of Pharmaceutical Systems: A Response

Keyphrases □ Decomposition—determination of shelf-life using analytic methodologies, response □ Kinetics—decomposition, determination of shelf-life using analytic methodologies, response □ Stability—simplified method of study in pharmaceutical systems, response

To the Editor:

The preceding paper (1) discusses my earlier criticism, based on pragmatic reasons, of the paper (2) published by Amirjahed (3). It was suggested by Amirjahed (3) that if only 10% decomposition of a product is monitored, it is possible to ascertain the shelf-life, while using less than sophisticated analytic methodologies such as may be available in small institutional settings. My criticism that the initial concentration of the sample is important is still valid regardless of how the kinetic equation is manipulated such as reported by Tucker (1):

$$\ln(t_\alpha) = \ln(-G/k_a) + E\,(1/T - 1/T_a)/R \qquad \text{(Eq. 1)}$$

where t_α is the time to decompose from concentration C_1 to C_2, and $-G/k_a$ becomes the shelf-life at temperature T_a for a 10% concentration change. However, the assumptions involved here are self-defeating. It assumes that all preparations have similar initial concentrations and that there is no overage in the product (1). It should be reiterated that a ±5% variation in the content is routinely acceptable. This alone will discard the calculations that require identical starting concentrations. Furthermore, obtaining sufficient data points during 10% decomposition of the product (which may have several excipients) is a difficult, but not impossible, task and requires sophisticated analytic technology. Together, these arguments make such exercises as reported by Amirjahed (3) and Tucker (1) of merely academic interest and could be misleading if their use is suggested in those instances where operators may not be fully aware of these pitfalls. I would highly recommend that the authors (1, 3) use these equations with actual data collected in the laboratory and show their validity. It is only when such studies are reported that the validity of the interesting concept reported by Amirjahed (3) can be ascertained.

Use of Unbound Drug Concentration in Blood to Discriminate Between Two Models of Hepatic Drug Elimination

Keyphrases □ Plasma protein binding—effect on systemic unbound blood drug concentration of orally administered drug □ Hepatic drug clearance—discrimination between two models, venous equilibrium model, sinusoidal perfusion model

To the Editor:

Two well-defined models have been proposed to describe the hepatic elimination of drugs and other compounds. These models differ in their basic hypotheses and in some of their quantitative predictions, *e.g.*, concerning the influence of blood flow, protein binding, and drug metabolizing activity on extraction ratio and hepatic clearance.

Model 1 (the equilibrium or well-stirred model) assumes that the liver is a single, well-stirred compartment, and that the concentration of unbound drug in hepatic venous blood is in equilibrium with unbound drug throughout the liver (1). Model 2 (the sinusoidal perfusion or parallel tube model) assumes that at any point along the hepatic sinusoid, the concentration of drug in the liver cell will equal

0022-3549/82/0500-0600$01.00/0

as the labeled concentration and C_2 = 90% of this, then $-G/k_a$ is the shelf-life at temperature T_a (assuming no overage in the product).

An advantage of this method is that the activation energy and shelf-life can be estimated without assuming a particular reaction order. Use of Unbound Drug Concentration in Blood to Discriminate Between Two Models of Hepatic Drug Elimination

Keyphrases □ Plasma protein binding—effect on systemic unbound blood drug concentration of orally administered drug □ Hepatic drug clearance—discrimination between two models, venous equilibrium model, sinusoidal perfusion model

To the Editor:

Two well-defined models have been proposed to describe the hepatic elimination of drugs and other compounds. These models differ in their basic hypotheses and in some of their quantitative predictions, *e.g.*, concerning the influence of blood flow, protein binding, and drug metabolizing activity on extraction ratio and hepatic clearance.

Model 1 (the equilibrium or well-stirred model) assumes that the liver is a single, well-stirred compartment, and that the concentration of unbound drug in hepatic venous blood is in equilibrium with unbound drug throughout the liver (1). Model 2 (the sinusoidal perfusion or parallel tube model) assumes that at any point along the hepatic sinusoid, the concentration of drug in the liver cell will equal

0022-3549/82/0500-0600$01.00/0

that in the sinusoid but that this concentration will fall as blood traverses the sinusoid (2).

Determination of which of the two models is the more appropriate to describe hepatic drug elimination is at present in dispute (3, 4). One of the important practical applications of these models is the calculation of intrinsic hepatic drug clearance, which measures the ability of the liver to remove drug irreversibly from liver water; for many compounds it can be regarded as an index of the activity of the drug metabolizing enzymes (5). The method of calculating intrinsic hepatic clearance differs between the two models, so that the same pharmacokinetic data may lead to two quite different answers. This is particularly true of high-clearance drugs (5, 6). Clearly, there is a need for an accurate and unambiguous method of measurement of hepatic drug metabolizing function for these high-clearance drugs, which is applicable to the intact animal rather than only to isolated liver enzyme preparations.

An extensive theoretical comparison of the two models showed that the greatest discrepancies between the predictions of the two models occur when the following parameters:

1. availability
2. steady-state drug concentration in hepatic venous blood
3. area under the blood drug concentration–time curve following a single oral dose
4. steady-state drug concentration in blood following constant oral drug administration for a highly extracted drug are examined under perturbations of either hepatic blood flow or of the degree of binding within the blood (7).

However, to date there are few experimental data available, and the evidence that is available does not single out one model as being more appropriate. For example, studies with lidocaine (3) from one laboratory using the isolated perfused rat liver preparation support the venous equilibrium model, whereas similar studies with galactose (8) from a second laboratory support the sinusoidal perfusion model. So far, experiments designed to discriminate between the two models of hepatic drug elimination have only involved examination of the effect of hepatic blood flow on the steady-state output concentration of highly cleared drugs in the perfused rat liver preparation. This is because hepatic blood flow is easily monitored and controlled in this preparation.

As a result of a series of computer simulations we have performed, relating intrinsic clearance to various pharmacokinetic indexes, another discriminant between Models 1 and 2 has emerged. The equations relating the area under the blood drug concentration–time curve following a single oral dose with the determinants of hepatic drug elimination (7) are for the venous equilibrium model (model 1):

$$AUC_{po} = \frac{D_{po}}{fu_b\, CLu_{int}} \qquad \text{(Eq. 1)}$$

and for the sinusoidal perfusion model (model 2):

$$AUC_{po} = \frac{D_{po}\,(e^{-fu_b\, CLu_{int}/Q_H})}{Q_H(1 - e^{-fu_b\, CLu_{int}/Q_H})} \qquad \text{(Eq. 2)}$$

where:

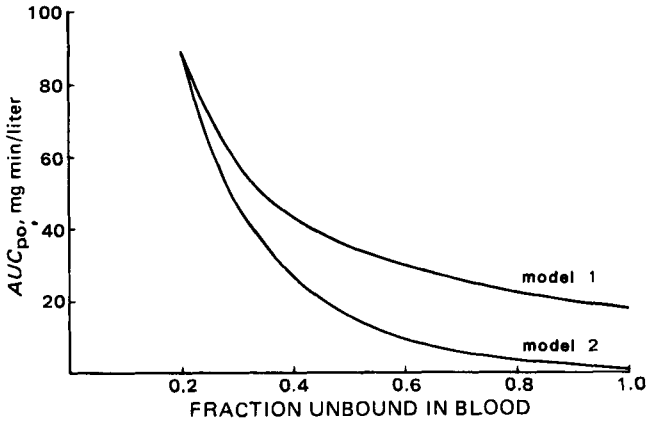

Figure 1—*Effect of fraction of unbound drug in blood on* AUC_{po} *for 200 mg of meperidine administered orally.*

D_{po} = dose administered by the oral route,
fu_b = fraction of unbound drug in blood,
CLu_{int} = intrinsic hepatic clearance of unbound drug, and
Q_H = hepatic blood flow.

From these equations, expressions can be derived which relate the area under the unbound blood drug concentration–time curve following a single oral dose ($AUCu_{po}$) with the determinants of hepatic drug elimination for model 1:

$$AUCu_{po} = fu_b\, AUC_{po} = \frac{D_{po}}{CLu_{int}} \qquad \text{(Eq. 3)}$$

and for model 2:

$$AUCu_{po} = fu_b\, AUC_{po} = \frac{fu_b\, D_{po}\,(e^{-fu_b\, CLu_{int}/Q_H})}{Q_H(1 - e^{-fu_b\, CLu_{int}/Q_H})} \qquad \text{(Eq. 4)}$$

Simulations of Eqs. 1–4 were performed for the drug meperidine and the following parameters were used:

Q_H = 1.5 liter/min
D_{po} = 200 mg
fu_b = 0.2
CLu_{int} = 11.25 liter/min (model 1)
CLu_{int} = 6.872 liter/min (model 2)

The systemic blood clearance of meperidine is ~0.9 liter/min (9), which corresponds to an hepatic extraction ratio of 0.6. Systemic blood clearance is a model-independent variable, whereas intrinsic clearance is model-dependent, *i.e.*, the value calculated depends on whether model 1 or 2 is invoked. Hence, two different values are given for intrinsic hepatic clearance of meperidine. Figure 1 shows the relationship between the fraction free in blood and AUC_{po}, according to Eqs. 1 and 2. The results are consistent with those described previously (7), in that a greater dependence of AUC_{po} on free fraction is predicted by model 2. Figure 2 shows the relationship between the fraction free in blood and area under the unbound blood drug concentration–time curve following a single oral dose, according to Eqs. 3 and 4. The $AUCu_{po}$ appears to be a much better discriminator between the two models than AUC_{po}, because $AUCu_{po}$ should be independent of free fraction in blood according to model 1 but not to model 2. These simulations present another and potentially more powerful method of discriminating between the two models using

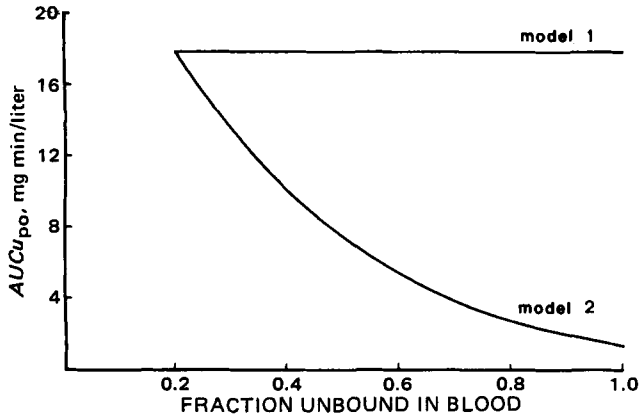

Figure 2—*Effect of fraction of unbound drug in blood on* AUC *of unbound drug concentration (*$AUCu_{po}$*) versus time for 200 mg of meperidine administered orally.*

the isolated perfused rat liver preparation. It is theoretically possible to vary the fraction of unbound drug in the perfusate by at least 10-fold for a highly bound drug, whereas the hepatic perfusion rate may only reasonably be varied by less than twofold (3). A preliminary investigation of the plasma protein binding of propranolol has been carried out using equilibrium dialysis. The results of this investigation show that it is possible to achieve a 10-fold variation of the fraction of unbound drug by varying the concentration of bovine serum albumin and α_1-acidglycoprotein in the perfusate[1].

The predictions of models 1 and 2 for the relationship between free fraction in blood and the steady-state unbound drug concentration in the reservoir of the isolated perfused rat liver preparation (Cu_{ss}) following constant-rate drug administration into the portal vein are analogous to those described for $AUCu_{po}$. The equations relating fraction of unbound drug in blood with Cu_{ss} can be derived from the equations presented by Pang and Rowland (7) and for model 1:

$$Cu_{ss} = \frac{R}{CLu_{int}} \qquad \text{(Eq. 5)}$$

and for model 2:

$$Cu_{ss} = \frac{fu_b\, Re^{(-fu_b\, CLu_{int}/Q_H)}}{Q_H[1 - e^{(-fu_b\, CLu_{int}/Q_H)}]} \qquad \text{(Eq. 6)}$$

where R is the infusion rate of drug into the portal vein.

Hence, the effect of changing free fraction of drug in perfusate on the steady-state unbound drug concentration in the reservoir following constant-rate drug administration into the portal vein in the isolated perfused rat liver preparation may also be used to discriminate between the two models.

Filter-Probe Extractor: A Tool for the Rapid Determination of Oil–Water Partition Coefficients

Keyphrases □ Filter-probe extractor—tool for rapid determination of oil–water partition coefficients □ Oil–water partition coefficients—rapid determination using filter-probe extractor □ Thermodynamics—filter-probe extractor use for rapid determination of oil–water partition coefficients

To the Editor:

The distribution of solutes between water and oil has been the subject of hundreds of studies since the end of the last century (1). The oil–water partition coefficient [or liquid–liquid distribution constant, as recommended (2) by IUPAC] is of use in separation science as it indicates the extent of extraction in a two-phase system. Also, since the partition coefficient is taken (3) as a measure of solute hydrophobicity, it is an often used parameter in, for example, preformulation and drug design (QSAR) studies. Partition coefficients have been determined by a large number of methods, including shake flask, counter-current distribution (4), and various automated methods including the AKUFVE (5) and SEGSPLIT (6) approaches.

Recently, we published a study (7) on the thermodynamics of solute oil–water partitioning, where use was made of a modification of a rapid solvent extraction method described by Cantwell and Mohammed (8) for photometric acid-base titrations in the presence of an immiscible solvent. Using various data manipulations, these workers have been able to demonstrate (9, 10) that their method provides ion-pair distribution coefficients and is of consequent use in drug analysis. Here we wish to communicate some of our experiences with a modified filter-probe for measuring oil–water partition coefficients of molecules of pharmaceutical interest, and to draw attention to the fact that the method has particular use for the examination of the effect of a large number of variables on the distribution process. It is emphasized that the apparatus here described is similar to, but not the same as, that developed by Cantwell and Mohammed.

Filter-Probe Extractor: A Tool for the Rapid Determination of Oil–Water Partition Coefficients

Keyphrases □ Filter-probe extractor—tool for rapid determination of oil–water partition coefficients □ Oil–water partition coefficients—rapid determination using filter-probe extractor □ Thermodynamics—filter-probe extractor use for rapid determination of oil–water partition coefficients

To the Editor:

The distribution of solutes between water and oil has been the subject of hundreds of studies since the end of the last century (1). The oil–water partition coefficient [or liquid–liquid distribution constant, as recommended (2) by IUPAC] is of use in separation science as it indicates the extent of extraction in a two-phase system. Also, since the partition coefficient is taken (3) as a measure of solute hydrophobicity, it is an often used parameter in, for example, preformulation and drug design (QSAR) studies. Partition coefficients have been determined by a large number of methods, including shake flask, counter-current distribution (4), and various automated methods including the AKUFVE (5) and SEGSPLIT (6) approaches.

Recently, we published a study (7) on the thermodynamics of solute oil–water partitioning, where use was made of a modification of a rapid solvent extraction method described by Cantwell and Mohammed (8) for photometric acid-base titrations in the presence of an immiscible solvent. Using various data manipulations, these workers have been able to demonstrate (9, 10) that their method provides ion-pair distribution coefficients and is of consequent use in drug analysis. Here we wish to communicate some of our experiences with a modified filter-probe for measuring oil–water partition coefficients of molecules of pharmaceutical interest, and to draw attention to the fact that the method has particular use for the examination of the effect of a large number of variables on the distribution process. It is emphasized that the apparatus here described is similar to, but not the same as, that developed by Cantwell and Mohammed.

0022-3549/82/0500-0602$01.00/0

The apparatus consists of an efficient mixing chamber (fitted with vortex spoilers and a well-sealed lid), one or two filter probes immersed in the mixed phases, and a pumping system that pumps the probed phase(s) through a spectrophotometric flow-through cell and back to the mixing chamber (see refs. 7 and 8 for schematics). The mixing chamber is thermostated and can have a volume from 50 to 1000 ml. Figure 1 gives the design of our modified filter probe, which is machined out of a stainless steel block. There is almost zero contact between the phases and the protective polytef spacer, compared to the polytef mesh (8) and wafer (10) that Cantwell and Mohammed place behind their filter material (to increase flow).

With our earlier experiments on the partitioning of hydrophobic drugs, it was found that using the latter configurations adsorption of drug onto the polytef was a problem. With the modified probe, postfiltration flow is improved by 20 radial channels (0.2-mm depth) cut into the surface of the cylindrical stainless steel block. Adsorption to polytef was such an early problem that all connecting tubing is now constructed of an HPLC-grade 1.0-mm bore stainless steel tube. In addition, HPLC pumps are used to effect flow, since these give no adsorption problems (unlike peristaltic pumps) and can be readily used with volatile solvents.

For our studies, a cellulose filter paper[1] was used for the probing of the aqueous phase and a polytef film[2] for probing of the oil. (Any hard cellulose filter paper should suffice for the hydrophilic filter probe.) We prefer to monitor the aqueous phase, and as a general procedure add only aqueous phase to the system, pump, adjust recorder baseline, add solute in a volume of the aqueous phase; after further equilibration (given by constant recorder reading), add a volume of oil, equilibrate, add an equal volume of oil, equilibrate, add a third equal volume of oil, and equilibrate. Since it takes between 0.5 and 15 min to reach equilibration (depending on pumping rates, phase volumes, and partition coefficient), one can very quickly determine from these experiments the effect of solute concentration on distribution. One can then go on to study the effect of various variables on the partitioning process; *e.g.*, temperature can be altered if the thermodynamics are to be studied, or a pH stat can be employed to obtain the pH–partition profile of a compound and hence determine the pKa.

Since the method is rapid, it can be used to determine the partition characteristics of relatively unstable compounds. Phase volume ratios of 1000:1 are possible, though the probed phase must have a volume greater than that of the pumping circuit. The range of partition coefficients that can be measured is $\sim +5.3$ to -5.3 log units, though this is dependent on the sensitivity of the analytical method. Generally, a pumping rate of between 1.0 and 1.5 ml/min is used: greater speeds result in overloading of the filter system.

There are three potential disadvantages to the procedure: One is evaporation of solute. This was found for benzene in our original experiments, and has since been described[3] as a problem common to all conventional methods for determining the partition coefficient of benzene, but which should be circumvented by the use of a closed system. The second, more serious problem, is that of adsorption. This has been circumvented in our system by employing stainless steel fittings and tubing and HPLC pumps, but it could still be a problem for some very polar compounds. Adsorption is very clearly seen in the step before addition of oil by a continuing fall in recorder reading, which is seen to be reversible during washing. Another problem encountered is the use of silicon-based filters as hydrophobic probes when cyclohexane and 2,2,4-trimethylpentane are used. Here it is found that after a short time the filters become permeable to the aqueous phase, due to a stripping of the filter material.

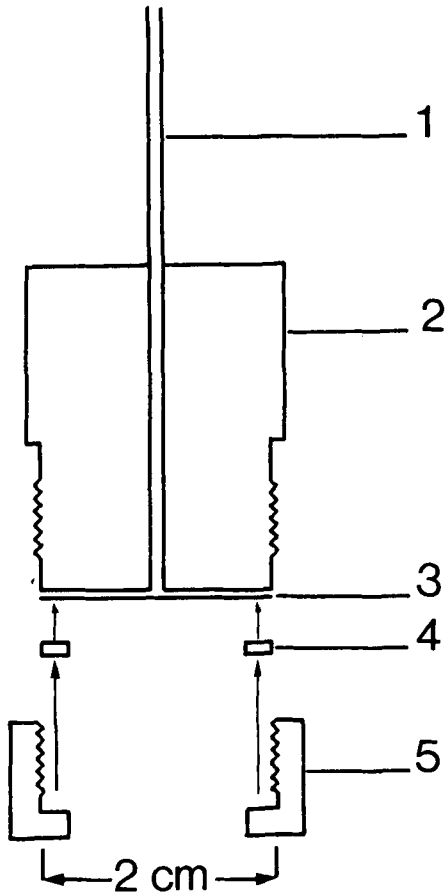

Figure 1—*Filter-probe extractor. 1, 1.0-mm bore stainless steel tube; 2, cylindrical stainless steel block; 3, filter material; 4, polytef o-ring spacer; and 5, screw-on stainless steel cap.*

To date, this modified filter probe system has been used in our laboratory for a number of studies including the aforementioned thermodynamics study and the determination of the partitioning of unstable compounds, peptides, and various hydrophilic and hydrophobic neutral drugs. Cyclohexane, 2,2,4-trimethylpentane, 1-octanol, and chloroform have all been successfully employed as oil phases. Table I illustrates the close agreement between partition coefficients determined by both conventional shakeflask and the described filter-probe methods (7). The filter probe system can be described as a simple and convenient tool for not only determining ion-pair equilibria (8–10), but also, as discussed here, both for "one-off" determination of solute oil–water partition coefficients, and

BOOKS

Applied Pharmacokinetics: Principles of Therapeutic Drug Monitoring. Edited by WILLIAM E. EVANS, JEROME J. SCHENTAG, and WILLIAM J. JUSKO. Applied Therapeutics, P.O. Box 31-747, San Francisco, CA 94131. 1980. 708 pp. 15 × 23 cm. Price $34.00.

As noted in the preface, this text is intended as a "source of the objective criteria and systematic approaches necessary for rational application of pharmacokinetics in clinical practice." The editors and authors have achieved that goal admirably. The text is primarily a compilation of information on specific drugs amenable to therapeutic monitoring and for which there is sufficient literature to permit a critical review. A particularly attractive approach is the inclusion of "counterpoint" discussions which accompany several chapters. These are intended to present another author's perspective when a consensus of opinion did not exist on that topic.

An introductory chapter is followed by a discussion (and a counterpoint presentation) of clinical pharmacokinetic consultation services and three chapters dealing with pharmacokinetics in renal and liver disease and in neonates. The remaining chapters are devoted to specific drugs and include: theophylline, aminoglycosides, cephalosporins, phenytoin, digoxin, lidocaine, procainamide, quinidine, propranolol, salicylates, methotrexate, tricyclic antidepressants, lithium, and heparin. Counterpoint discussions accompany the sections on theophylline, aminoglycosides, phenytoin, and lidocaine. The final chapter is concerned with guidelines for collection and the pharmacokinetic analysis of data.

Each chapter dealing with a specific drug contains the following major topics: introduction/background, absorption, distribution, elimination, concentration *versus* response and toxicity, clinical application of pharmacokinetic data, assay methods, and summary. Adhering to a common format enhances the readability of the text and permits the reader easy access to specific desired information. The chapters are concise, written well, and are replete with summary tables and figures. Each chapter has a substantial reference list and literature citations are current.

This book is unquestionably the best text of this type currently available. The editors by necessity have assumed a basic understanding in pharmacokinetics and as a result there are few expositions on fundamental principles and relatively few equations are employed. The reviewer believes this to be an advantage of the text.

A difficulty with publishing a compilation of this type is the fact that much of the material will become rapidly dated as a result of the literature explosion in the area of clinical pharmacokinetics. The editors are certainly aware of this and mention in the preface that this is the first edition. One presumes that others will follow. In subsequent revisions, the editors are encouraged to employ the approach for compiling clinical pharmacokinetic data as suggested by Sheiner *et al.* [*J. Pharmacokinet. Biopharm.*, **9**, 59 (1981)]. The text might also benefit from a table of symbols to be used uniformly throughout (and with common units, if possible).

The reviewer has no hesitation in recommending this text to pharmacy and medical practitioners who are involved in drug therapy and who are interested in improving theory. Pharmacy students in advanced courses, all Pharm.D. students, and clinical pharmacology fellows should consider this a most useful text.

Training Pharmacists for Today—Not Yesterday

Approximately 10 years ago, the National Pharmaceutical Council and the Student American Pharmaceutical Association established a cooperative activity known as the Pharmaceutical Industry Summer Internship Program.

From its inception, the program has flourished; it has been well-supported by various major drug companies, and each year the number of student applicants has exceeded the total positions annually available. To date, about 1,000 students have had an opportunity to participate in the program.

In theory, the program sounded as if it would be a terrific learning experience. As described, the student would have a meaningful opportunity to add to that student's overall knowledge of pharmacy, with emphasis on its industrial aspects. Training would be offered within the industry setting which would supplement that received in traditional types of pharmacy practice.

But cynics had their doubts. All too often in the past, pharmacists have been taken in by the industry. Beneath the attractive surface glitter of other drug industry programs or projects, there have been too many instances of an ulterior motive.

Consequently, many pharmacy leaders suspected that the NPC-SAPhA Summer Internship Program would turn out in actuality to be either: (a) a clever way to get cheap help as laboratory glassware washers or for other routine "floor sweeper" type jobs; or (b) an ingenious scheme to "brainwash" selected student leaders regarding the industry's position on various pharmaceutically related policy matters or political issues.

But it didn't turn out that way at all! In fact, all the students, with whom we have talked after they participated in the program, have enthusiastically related how much they learned, how they were given exposure to a broad spectrum of industry operations, and how much immediate attention and instruction they received from the highly committed and well-qualified professionals who served as their preceptors.

The typical industry program is of about 12-weeks duration on a full-time basis; this is equivalent to about one-fourth of the one-year pharmacy internship required by most states. Generally, the internship is of a broad general nature, with the student spending the entire summer at a single drug company, but with rotating assignments in several different departments or divisions, such as quality control, marketing, manufacturing, formulation development, and so on. All those assigned any responsibility for the interns emphasize learning over productivity and, by training, they usually are pharmacists themselves.

The program did not turn out this well by pure accident. The NPC wisely drew up a document entitled "Guidelines for Pharmaceutical Industry Internships" which gives direction to each individual company in operating its respective program in a way that will provide reasonable uniformity and consistency from one firm to another. Furthermore, to its credit, the NPC has consistently shown good judgment in organizing and operating the program. For example, when initially established, considerable constructive input was provided by the SAPhA leadership, and ever since its inception, the entire program has been regularly monitored by a joint NPC-SAPhA committee.

In light of the beneficial nature of this internship learning experience, efforts have been made to get individual state boards of pharmacy to award credit for participation in such programs. This credit—to a maximum of 500 hours of the total 1,500 hours typically specified—would partially fulfill the experimental training requirements of state boards of pharmacy as one of the requisites for pharmacy licensure. To date, some 32 state boards of pharmacy either will allow, or will consider, various amounts of time in nontraditional practice experience as counting toward the total internship requirement.

Regrettably, however, the remaining states have refused to give credit for participation in either the NPC-SAPhA industry program, or for various other equally commendable, nontraditional practice experiences. The latter include the Veterans Administration Hospital Pharmacy Undergraduate Training Programs, the U.S. Public Health Service COSTEP Training Program, national or state pharmaceutical association internships, or a host of other programs conducted under the auspices of colleges, governmental agencies, or drug companies.

Both the SAPhA House of Delegates and the National Association of Boards of Pharmacy adopted resolutions at their 1981 Annual Meetings calling on individual state pharmacy boards to recognize and credit nontraditional practice experience. Recognition and credit would be conditioned upon a determination that a particular program met established criteria including preceptor orientation and written reports.

At its recently concluded 1982 Annual Meeting, the APhA House of Delegates considered the adoption of a similar policy position for the Association.

Hopefully, the 20 reluctant boards of pharmacy will give due consideration to this matter. Pharmacy today is not practiced as it was 50 years ago; as a result, it makes little sense that the only practice experience that will be accepted toward licensure should be exclusively oriented toward the way pharmacy was practiced in 1932 rather than in 1982.

Factors Influencing Axial and Radial Tensile Strengths of Tablets

PAUL J. JAROSZ * and EUGENE L. PARROTT ˣ

Received June 8, 1981, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication October 13, 1981. *Present address: Ortho Pharmaceutical Corp., Raritan, NJ 08869.

Abstract □ The axial and radial tensile strengths of compressed tablets have been measured by a tensiometer. A comparison of these strengths is indicative of the bonding strength in two directions and may be related to the tendency toward capping. The influence of compressional force, concentration of binder, and time on the tensile strengths of several materials is presented.

Keyphrases □ Tensile strength—factors influencing axial and radial tensile strengths in tablets □ Tablets—factors influencing axial and radial tensile strengths □ Compressional force—factors influencing axial and radial tensile strengths of tablets

Tablets must possess sufficient strength to withstand mechanical handling and transport. Various types of tests (abrasion, bending, indentation hardness, diametral crushing) have been used to express strength (1); however, the data from these tests seldom can be correlated in a precise manner. Even the most common strength test of diametral crushing may cause failure of the tablet by more than one type of force (2, 3). If the test method is designed so that tablet failure is a result of the application of tensile strength only, strength may be expressed precisely in terms of kilograms per square centimeter (4–7).

Most pharmaceutical tablets are anisotropic and nonhomogeneous, with the values of their properties (*e.g.*, density and strength) varying in different directions. The purpose of this investigation was to measure the axial and radial tensile strengths of tablets as influenced by compressional force, concentration of binder, and aging.

EXPERIMENTAL

Preparation of Tablets—Powders to be granulated were blended in a planetary mixer[1]. The appropriate amount of granulating solution was added and mixed for 5 min. The mass was passed through an oscillating granulator[2], collected on drying trays, and dried overnight in a forced-air oven at ambient temperature. A 16/20-mesh size fraction of the dried granulation was separated by standard sieves. Directly compressible materials were separated by standard sieves into a 60/80-mesh size fraction. An appropriate weight of the material to produce tablets from 0.3 to 0.5 cm thick was compressed by means of 1.275-cm flat-faced punches and the die fitted to a hydraulic press[3] for 5 sec at the desired compressional force. The die wall was prelubricated with 5% magnesium stearate in acetone. At least 72 hr elapsed between tablet compression and measurement of tablet strength to allow for any stress relaxation. The weight and thickness of 10 tablets were determined.

Measurement of Radial Tensile Strength—The radial tensile strength of the tablet was measured by a diametral compression test. The tensiometer[4] was modified for compression by the use of a compression device used for calibration of the mercury manometer of the tensiometer. Steel bolt heads served as platens for the radial compression test. To ensure that the tablet failed in tension, a padding, consisting of three layers of manila computer cards 1 mm thick, was used (5, 6, 8). The length of each paper strip was sufficient to extend over the edge of the bolt head. The pad was replaced after ~200 tablets had been fractured. The tablet was strained at the rate of 0.299 cm/min. The maximum force for tablet failure resulting from tensile stress (3, 4) was determined, and the force–displacement profile was recorded. The maximum tensile failure force F_σ of 10 tablets was determined, and the average was used to calculate the radial tensile strength (σ_x) by the relationship:

$$\sigma_x = \frac{2F_\sigma}{\pi Dt} \qquad \text{(Eq. 1)}$$

where D is the diameter (1.275 cm) and t is the thickness of the tablet (9).

Measurement of Axial Tensile Strength—The tablet was linearly aligned and fixed between the machined heads of two 1.275 × 2.54-cm steel bolts by means of a cyanoacrylate resin adhesive[5]. The adhesive was cured at room temperature for at least 36 hr prior to testing. By use of a pair of adapters, the bolt–tablet–bolt assemblage was fitted horizontally into the tensiometer. The tablet was strained at the rate of 0.229 cm/min. The tensiometer allowed the recording of the stress component against the extension, proportional to the distance moved by the crosshead beam. The distance traveled by the crosshead beam was magnified 16 times and recorded on the drum chart paper. The value of the maximum force was recorded only if failure was due to tension stresses. Tablet failure occurred in the body of the tablet and not near the tablet–bolt interface. The av-

erage maximum force of axial tensile failure of 10 tablets was used to calculate the axial tensile strength by the relationship (10):

$$\sigma_z = \frac{4F_a}{D^2} \qquad \text{(Eq. 2)}$$

Measurement of Density—The densities of the materials and granulations were determined by pycnometry using *n*-heptane at 25° and are given in Table I. The measured dimensions and weight of each cylindrical tablet were used to calculate the apparent density of the tablet. The relative density used in the Heckel plot is the quotient of the apparent density of the tablet and the density of the material. The values of porosity used in the Ryshkewitch relationship were calculated from the relationship:

$$\text{porosity} = (1 - \rho_{\text{apparent}}/\rho) \qquad \text{(Eq. 3)}$$

Conservation curves, rather than tables of the dimensions and calculations, are presented for each tablet.

RESULTS AND DISCUSSION

The consolidation of a powder to form a tablet proceeds through several stages during compression (11, 12). As a force is applied to a powder, interparticular rearrangement causes consolidation to the closest packing. Additional compressional force results in deformation of the particles by brittle fragmentation; plastic, nonrecoverable conformation changes; and/or elastic, recoverable conformation changes. Eventually, maximum consolidation is attained at which an increase in compressional force no longer reduces the relative volume of the tablet. It has been shown (13), in terms of density, that the distribution of compressional pressure within a tablet exists. It was previously demonstrated that the bond formation is greater in a region where, because of compressional pressure, distribution is more intense (14).

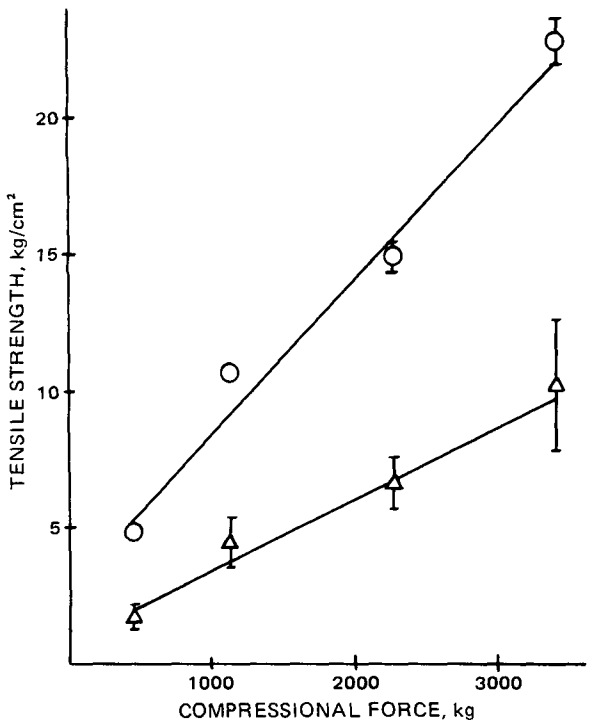

Figure 1—*The influence of compressional force on tensile strengths of tablets compressed of 60/80-mesh size dibasic calcium phosphate dihydrate*[6]. *Key: (△) axial; (○) radial.*

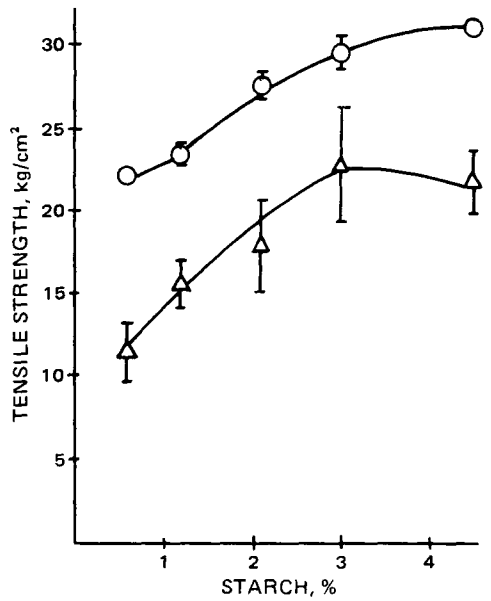

Figure 2—*The influence of starch on the tensile strengths of tablets of dibasic calcium phosphate dihydrate*[6] *compressed at 2268 kg. Key: (△) axial; (○) radial.*

For an isotropic, homogeneous tablet, the radial and axial tensile strengths should be equal. The distribution of compressional force, differences in density within a tablet, and the mixture of materials contribute to the nonhomogeneity of the tablet and to the nonuniformity of tensile strengths. To demonstrate this, the axial and radial tensile strengths were measured experimentally. Typical results for several materials are given in Table II in which there is a difference in the axial and radial tensile strengths for each material.

As shown in Table II, the variance of radial tensile strength is less than the variance of the axial tensile strength. The experimental conditions

of the diametral compression (radial) test are specifically controlled to ensure tablet failure only because of tension stresses. The axial test has the disadvantage of requiring the adapter–bolt–tablet assemblage to be placed horizontally in the tensiometer. Bending stress due to the mass of the adapter and the torsion stress due to loading are present in each sample. These additional stresses add to the deviation in applied tension stress required to cause failure of the tablet. A similar set of experimental values using another apparatus has been reported (15).

The radial tensile strength is greater than the axial tensile strength with a brittle material (dibasic calcium phosphate dihydrate[6]). The difference may be a reflection of the number of clean particle bonds and of original particle bonds oriented in the axial and radial direction. In brittle fracture, clean surfaces are formed during compression, and two fresh, clean surfaces bond to form the strongest bond. A newly formed surface may bond to an original surface of another particle, whereas two original surfaces, which bond during compression, probably form the weakest bond.

When a brittle material is compressed along the vertical (axial) axis, the stress upon each particle does not necessarily compress the particle along the axial direction because of the random packing and alignment of the particles toward each other during the stages of compression; however, a greater potential exists for vertical stress on the particles during the relocation and fragmentation stages due to the movement of the punch. The overall result is that more clean surfaces are created when they are normal to the radial than to the axial direction. As the compressional force is increased, a brittle fracture results in a stronger, radial tensile strength than axial tensile strength (Fig. 1). The slope (0.00577, $r = 0.990$) of the radial tensile strength–force line is twice that of the slope (0.00275, $r = 0.993$) of the axial tensile strength–force line.

The Griffith fracture theory (16) proposes that failure results from the existence of flaws or cracks within the sample. If more bonds are formed in the radial direction, the potential for the presence of a flaw or crack is greater in the axial than the radial direction. This concept appears to be supported by the results shown in Fig. 1.

Influence of Compressional Force and Concentration of Binder—In tableting technology, a blend of pharmaceutical powders is commonly granulated with a granulating or binding solution. The incorporation of the binder increases the adhesiveness of the formulation. As shown in Fig. 2, the radial tensile strength of tablets compressed at 2268 kg of force from dibasic calcium phosphate dihydrate[6] granulated with starch paste is increased as the concentration of starch is increased. The axial tensile strength is increased to its greatest value at 3% starch and is not increased by an additional increase in the starch concentration.

The effect of compressional force on the tensile strength of tablets compressed from dibasic calcium phosphate dihydrate[6] with 1.2% starch is shown in Fig. 3. For the given concentration of binder, the axial tensile strength is increased to a maximum value at 4536 kg of force and is not increased at greater compressional forces.

The tensile strengths of tablets compressed from dibasic calcium

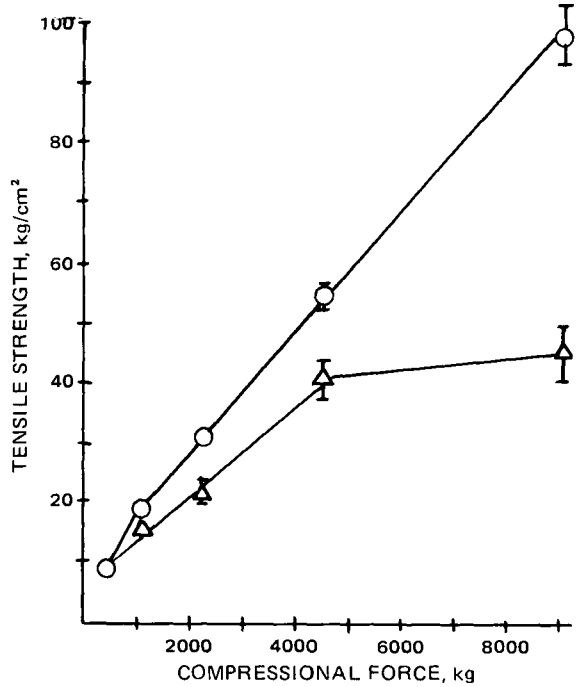

Figure 4—*The influence of compressional force on the tensile strengths of tablets compressed of dibasic calcium phosphate dihydrate[6] granulated with 4.5% starch. Key: (△) axial; (○) radial.*

[6] Emcompress, Edward Mendell Co., Carmel, N.Y.

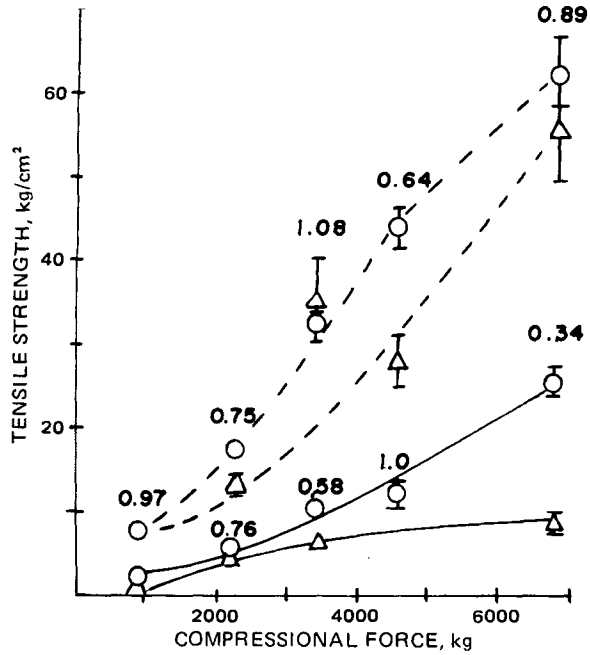

Figure 6—*The influence of compressional force on the tensile strengths of tablets of dicalcium phosphate dihydrate granulated with 1.0 (—) and with 7.0% (- - - -) povidone. At each compression force the value is given for σ_z/σ_x. Key: (△) axial; (○) radial.*

phosphate dihydrate[6] with 4.5% starch are shown in Fig. 4. The rate of increase of radial tensile strength with an increase in compressional force is essentially the same as that of the tablet containing 1.2% starch. The maximum axial tensile strength is attained at the same compressional force as for the tablet containing 1.2% starch, but there is no decrease in axial strength as the compressional force is increased further. This difference in the axial and radial tensile strength–force profiles indicates that consolidation is not uniform throughout the entire tablet mass.

Similarly, for tablets compressed at 2268 and 4536 kg of force from dibasic calcium phosphate dihydrate[7] granulated with povidone, the tensile strengths are increased as the concentration of povidone is increased (Fig. 5). The influence of compressional force on tensile strength of tablets of dibasic calcium phosphate dihydrate[7] and povidone is illustrated in Fig. 6. As the compressional force is increased, the slope of the radial tensile strength *versus* percent of binder increases more rapidly than the slope of the axial tensile strength. A maximum axial tensile strength is attained at 5–6% povidone when compressed at 4536 kg.

The influence of compressional force on the tensile strengths of tablets

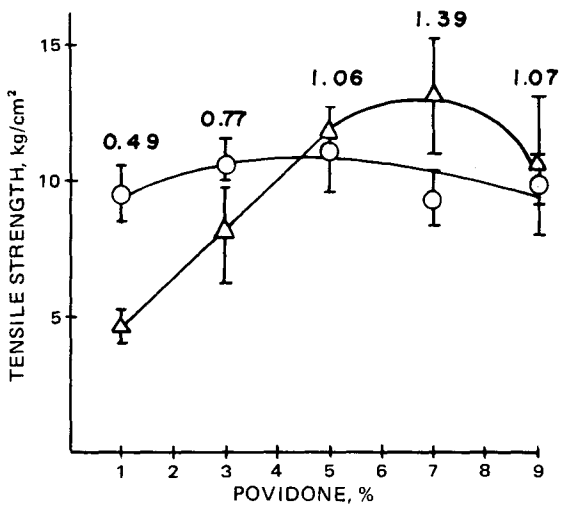

Figure 7—*The initial influence of povidone on the tensile strengths of tablets of hydrous lactose compressed at 1134 kg. At each compressional force the value is given for σ_z/σ_x. Key: (△) axial; (○) radial.*

[7] Ruger Chemical Co., Irvington, N.J.

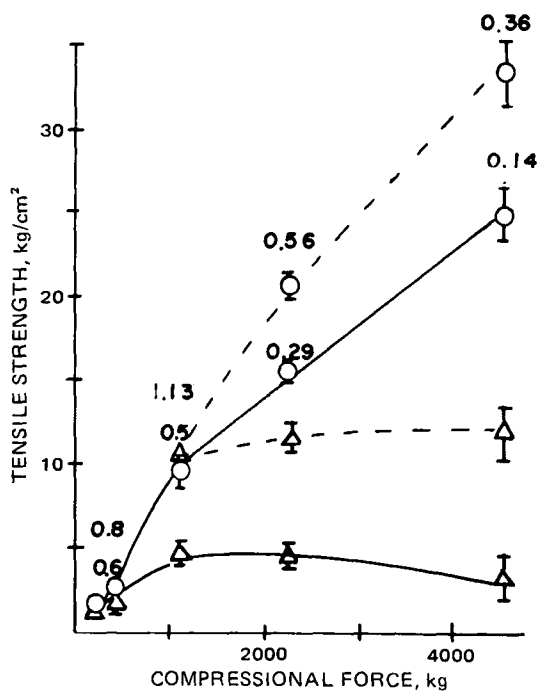

Figure 8—*The influence of compressional force on the tensile strengths of tablets of hydrous lactose granulated with 1 (—) and 9.0% (- - - -) povidone. At each compressional force the value is given for σ_z/σ_x. Key: (△) axial; (○) radial.*

of dibasic calcium phosphate dihydrate[7] granulated with 1.0 and 7.0% povidone is shown in Fig. 6. The strength of tablets compressed from dibasic calcium phosphate dihydrate[6] is increased only moderately with an increase in compressional force. At low concentrations of binder, the effect of compressional force on dibasic calcium phosphate dihydrate[7] is moderate, but at high concentrations, 7% of binder, the tensile strength is significantly increased with an increase in compressional force (Fig. 6).

The influence of povidone concentration on the tensile strength of hydrous lactose tablets compressed at 1134 kg of force is shown in Fig. 7. The concentration of povidone has little effect on the radial tensile strength. As the concentration of povidone is increased, the axial tensile strength is increased rapidly to values that exceed the radial tensile strength. Thus, povidone axially strengthens a tablet of hydrous lactose to a greater extent than a tablet of dibasic calcium phosphate dihydrate.

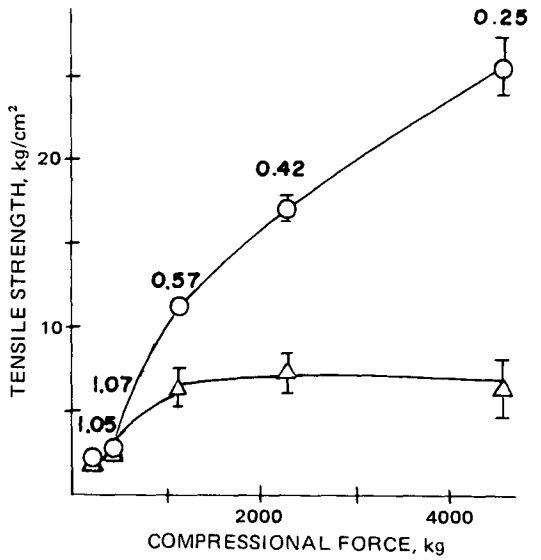

Figure 9—*The influence of compressional force on tensile strengths of tablets of hydrous lactose granulated with 1.9% starch. At each compressional force the value is given for σ_z/σ_x. Key: (△) axial; (○) radial.*

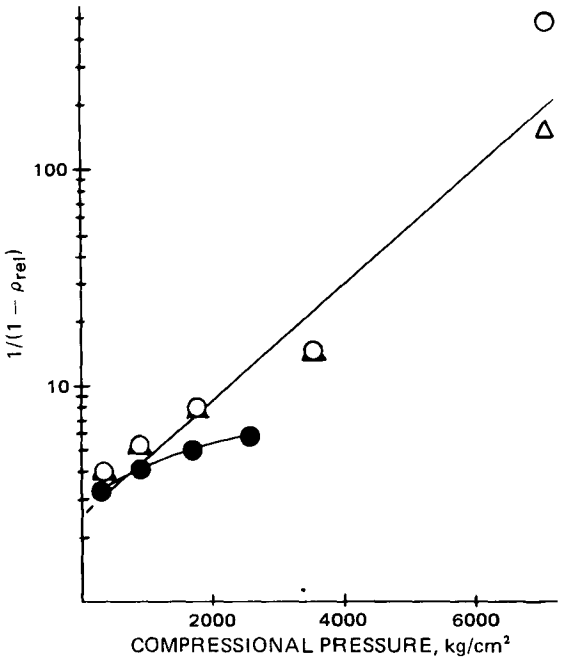

Figure 10—*Density–compressional pressure relationship according to Heckel plot. Key: (●) dibasic calcium phosphate dihydrate[6]; (○) with 1.2% starch; (△) with 4.5% starch.*

Since the granulating solvent was water, in which lactose is soluble, the lactose may have partially dissolved at the surface of the granules and upon drying formed bridges, which mechanically strengthened the tablet (17, 18).

The influence of compressional force on the tensile strengths of tablets composed of hydrous lactose with 1.0 and 9.0% povidone is shown in Fig. 8. There is a maximum axial tensile strength attained at a low concentration of binder with an observed tendency for capping at high compressional forces. Lactose behaves as a Mohr body (19) and is known to be prone to capping (20). A similar result is shown in Fig. 9 for tablets of hydrous lactose granulated with 1.9% starch.

Behavior of Material—Heckel (21, 22) characterized the behavior of materials during compression by the relationship:

$$\log \frac{1}{1-\rho_{rel}} = \frac{KP}{2.303} + A \qquad \text{(Eq. 4)}$$

where ρ_{rel} is the relative density, P is the compressional pressure, and K and A are constants. The slope (K) has been related to the reciprocal of the mean yield pressure, which is the minimum pressure required to cause

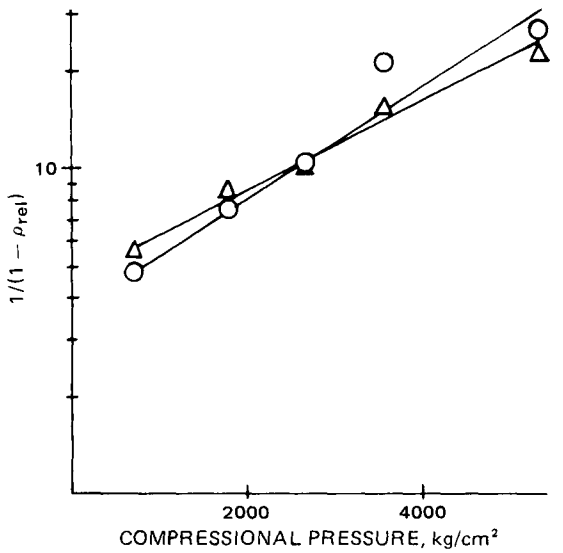

Figure 11—*Density–compressional pressure relationship according to Heckel plot for dibasic calcium phosphate dihydrate[7] granulated with povidone. Key: (△) 1.0% povidone; (○) 7.0% povidone.*

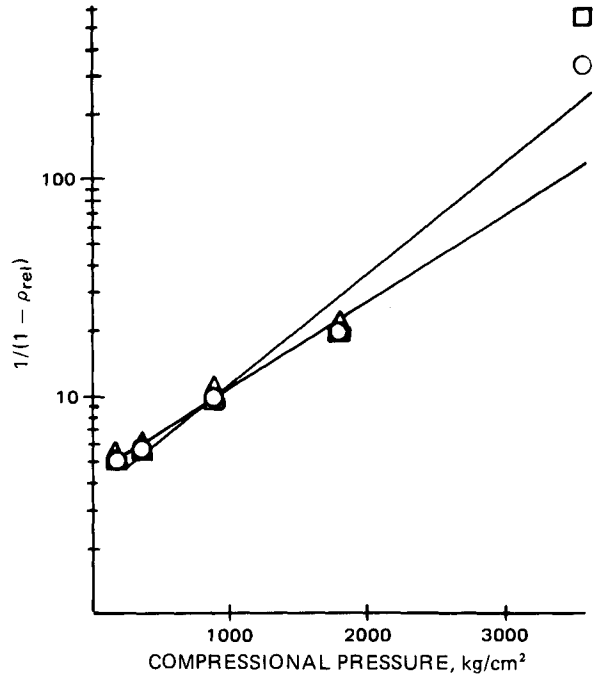

Figure 12—*Density–compressional pressure relationship according to Heckel plot of hydrous lactose granulated with povidone and starch. Key: (△) 1.0% povidone; (○) 9.0% povidone; (□) 1.9% starch.*

deformation of the material undergoing compression (23). The intercept of the curved portion of the curve at low pressure represents a value due to densification by particle rearrangement. The intercept obtained from the slope of the upper portion of the Heckel plot is a reflection of the densification obtained during consolidation. A large value of the slope indicates the onset of plastic deformation at relatively low pressures (24). A Heckel plot for tablets of dibasic calcium phosphate dihydrate[6] is shown in Fig. 10. The small value of the slope indicates consolidation of dibasic calcium phosphate dihydrate is not by plastic deformation but primarily by brittle fracture (25).

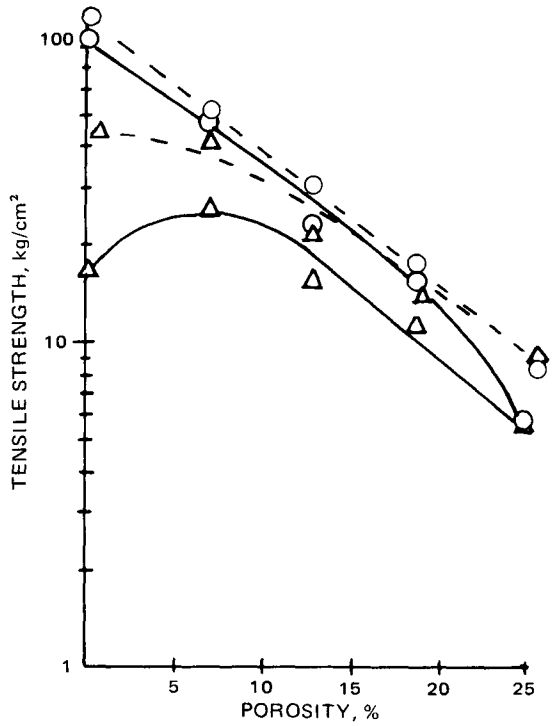

Figure 13—*Tensile strengths–porosity relationship of logarithmic form of the Ryshkewitch equation for dibasic calcium phosphate dihydrate[6] granulated with 1.2 (——) and 4.5% (- - - -) starch. Key: (△) axial; (○) radial.*

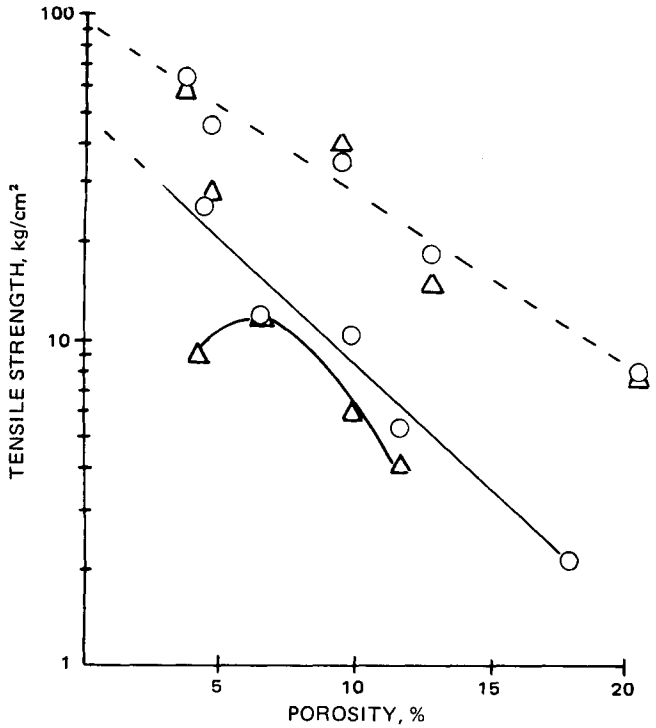

Figure 14—*Tensile strengths–porosity relationship of logarithmic form of Ryshkewitch equation for dibasic calcium phosphate dihydrate[7] granulated with 1.0 (—) and 7.0% (- - - -) povidone. Key: (△) axial; (○) radial.*

The effect of the addition of starch to dibasic calcium phosphate dihydrate[6] is shown in Fig. 10. The lower mean yield pressures (1442 and 1904 kg/cm^2 with 1.2 and 4.5% binder, respectively) for dibasic calcium phosphate[6] granulated with starch, than the mean yield pressure (4303 kg/cm^2) for dibasic calcium phosphate dihydrate indicate that the addition of starch confers some plastic property to the mass. The density–compressional pressure relationship of dibasic calcium phosphate dihydrate[7] granulated with povidone is plotted in Fig. 11. The lower mean yield pressure (2535 kg/cm^2) for dibasic calcium phosphate dihydrate[7] granulated with 7.0% povidone than the mean yield pressure (3282 kg/cm^2) with 1.0% povidone indicates the onset of plastic deformation with an increase in concentration of the binder.

The Heckel plots for lactose granulated with povidone and for lactose granulated with starch are shown in Fig. 12. The mean yield pressure is

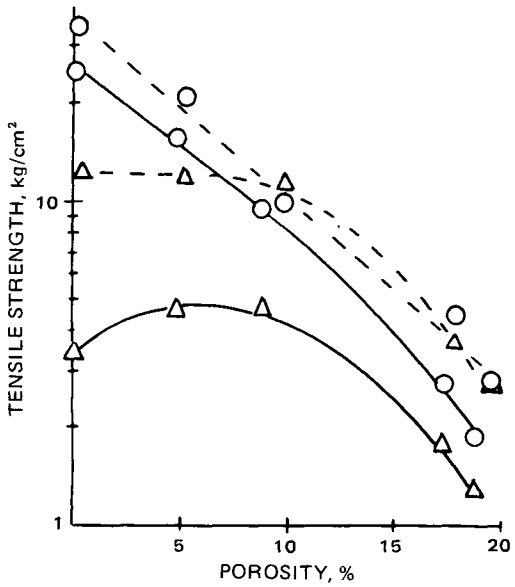

Figure 15—*Tensile strengths–porosity relationship of logarithmic form of the Ryshkewitch equation for hydrous lactose granulated with 1.0 (—) and 9% (- - - -) povidone. Key: (△) axial; (○) radial.*

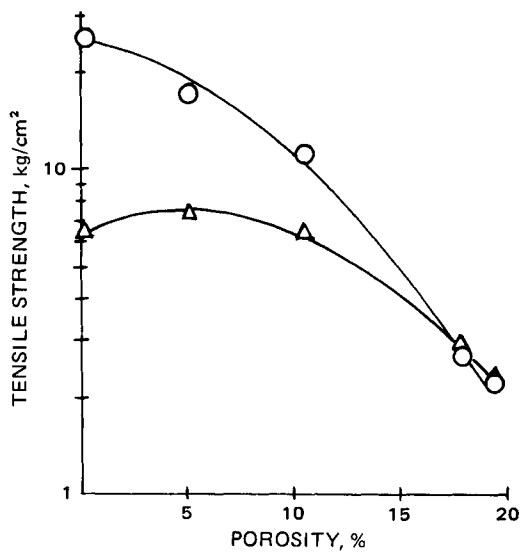

Figure 16—*Tensile strengths–porosity relationship of logarithmic form of Ryshkewitch equation for hydrous lactose granulated with 1.9% starch. Key: (△) axial; (○) radial.*

decreased as the concentration of plastically deformed povidone is increased. The addition of a plastic binder to an excipient tends to confer some plasticity to the excipient.

Ryshkewitch (26) observed that:

$$\log \sigma_x = \log \sigma_{max} - bp \qquad \text{(Eq. 5)}$$

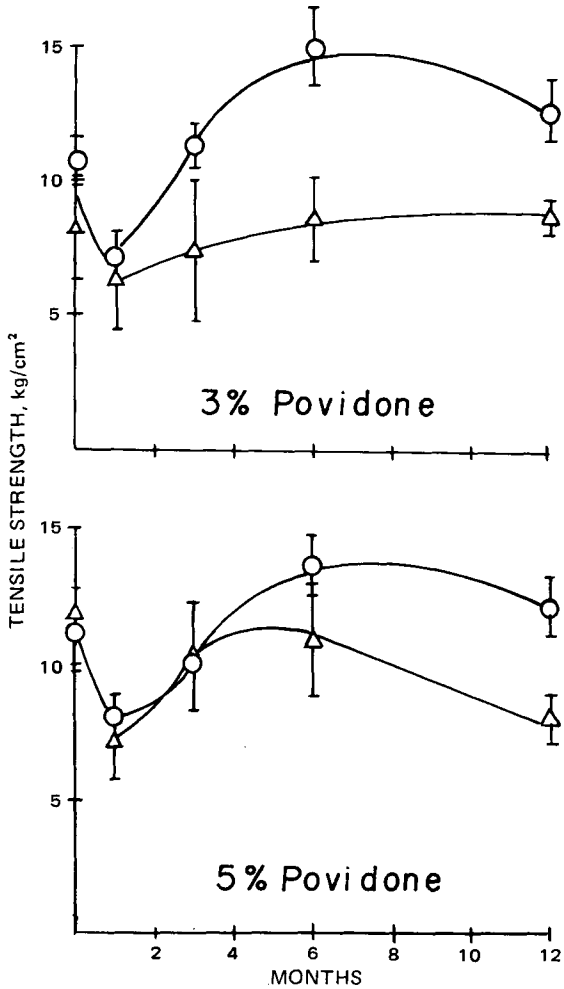

Figure 17—*The influence of time on the tensile strength of tablets of hydrous lactose granulated with 3 and 5% povidone. Key: (△) axial; (○) radial.*

Table III—Values of Constants b and σ_{max} of the Ryshkewitch Equation

	b	σ_{max}	r
Lactose granulated with 1.9% starch	5.7	31.8	0.981
Lactose granulated with 1.0% povidone[a]	5.5	27.4	0.996
Lactose granulated with 9.0% povidone	5.3	36.1	0.996
Dibasic calcium phosphate dihydrate[b] granulated with 1.0% povidone	7.6	48.2	0.979
Dibasic calcium phosphate dihydrate[b] granulated with 7.0% povidone	5.1	89.3	0.991
Dibasic calcium phosphate dihydrate[c] granulated with 1.2% starch	4.6	95.4	0.993
Dibasic calcium phosphate dihydrate[c]	4.1	106.6	0.999

[a] Regression of four points only. [b] Ruger Chemical Co. [c] Emcompress, Edward Mendell Co.

where σ_x is the radial tensile strength, σ_{max} is the theoretical radial tensile strength at zero void, b is a constant, and p is porosity.

In Fig. 13 the logarithms of tensile strengths are plotted against the porosity of tablets compressed from dibasic calcium phosphate dihydrate[6] granulated with 1.2 and 4.5% starch, and the increase in starch increases the radial tensile strength 47%, even though the porosity remains at 25%. The increase in starch increases the radial tensile strength only 12% as zero void is approached.

The Ryshkewitch relationship of tensile strength to the porosity of dibasic calcium phosphate dihydrate[7] granulated with 1.0 and 7.0% povidone is shown in Fig. 14. The maximum axial tensile strength occurs at 6–7% porosity, which is the same porosity as for dibasic calcium phosphate dihydrate[6,7] and starch.

Similarly, the Ryshkewitch relationships for hydrous lactose with 1.0 and 9.0% povidone are plotted in Fig. 15. A nine-fold increase in concentration of povidone causes a 58% increase in radial tensile strength near 20% porosity and only a 34% increase near zero void. The Ryshkewitch relationship for hydrous lactose with starch is shown in Fig. 16. Values for the constants of the Ryshkewitch equation are given in Table III.

It appears that the concentration of the binder has a greater influence in more porous tablets than in those approaching zero void. As compressional force is increased and the porosity of the tablet is decreased, the interparticular distances through which adhesive forces operate are shorter. Thus, the adhesive forces of the material are stronger at lower porosity, and a lesser amount of binder would be required to produce a tablet of the desired strength.

Index of Capping—The elastic property of a material is responsible for the capping or failure of a tablet perpendicular to its compressional axis. When the compressional force is removed, shear deformation occurs as the elastic material rebounds (27). Strains are magnified about regions of low density, and upon release of the force, there may be a mechanical failure.

Binders are added to materials having poor adhesive property to strengthen intergranular binding and, thus, reduce the tendency to cap. For elastic materials the elastic energy released, when the punch pressure is relieved, overcomes the bonds present between particles in that region and capping occurs. Binders are plastic materials, and under compression these materials undergo plastic deformation. The total energy of compression is dissipated throughout the entire material being compressed. A greater part of the total energy of compression is absorbed by the binder at greater concentrations, and less energy is stored elastically by the elastic deformation of the other materials of the formulation. Upon removal of the compressional force, there is less elastic recovery and a reduced tendency toward capping.

A weak axial tensile strength has been associated with capping (1, 10, 28). A comparison of Figs. 3 and 4 shows that the maximum axial tensile strength for a tablet of dibasic calcium phosphate dihydrate[6] containing 4.5% starch is reached at the same compressional force as for a tablet containing 1.2% starch, but there is no decrease in axial strength after reaching the maximum value for the tablet containing 4.5% starch. The slopes of the radial tensile strength–force curves are nearly identical. The difference in axial and radial tensile strengths indicates that the tablet is not as strongly bonded in the axial direction as in the radial direction. As the axial and radial tensile strengths are measures of bonding, it appears that the ratio σ_z/σ_x could be used as an index of capping. The ratio would be unity for a homogeneous tablet and would decrease toward zero as the homogeneity became progressively less.

The data presented in Fig. 6 for the tablets of dibasic calcium phosphate dihydrate[7] with 1.0 and 7.0% povidone support the statement that an increase in concentration of binder reduces capping. At the highest compressional force (6804 kg) the ratio σ_z/σ_x is 0.34 and 0.89 for 1.0 and 7.0% povidone, respectively. Capping does not occur as the dibasic calcium phosphate dihydrate is a brittle material, and fragmentation occurs and is the mode of consolidation.

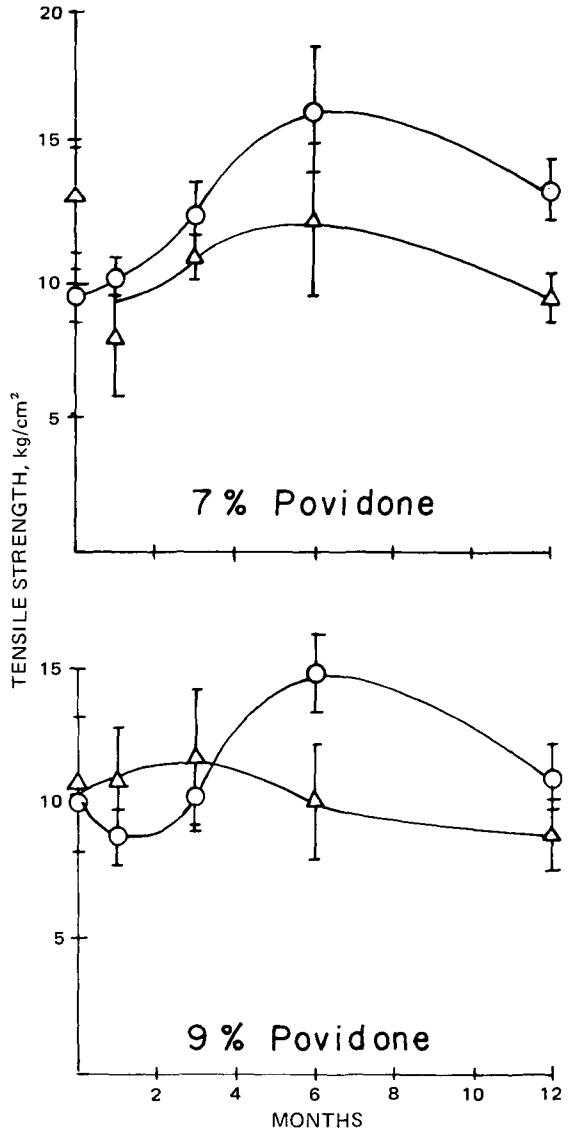

Figure 18—*The influence of time on the tensile strength of tablets of hydrous lactose granulated with 7 and 9% povidone. Key: (△) axial; (○) radial.*

With nonbrittle materials, considerable consolidation may be due to elastic bonding. As elastic rebound will occur when the compressional force is removed, the tablet will have a capping tendency. For such materials, a low value for σ_z/σ_x indicates that capping is likely. To properly evaluate the probability of capping, the mechanism of bonding or consolidation and the ratio of the axial and radial tensile strengths must be considered. Hydrous lactose with povidone attains a maximum axial tensile strength at a low concentration of binder with a tendency for capping at high compressional forces. At the highest compressional force (4536 kg) for hydrous lactose tablets, containing 1.0 and 9.0% povidone, the ratio σ_z/σ_x is 0.14 and 0.36, respectively.

Aging—Changes in strength of tablets have been reported to be a function of strain recovery (29), time (30), and loss of moisture (31, 32). Five formulations of tablets weighing 800 mg were prepared by compression at 1134 kg of force for hydrous lactose containing from 1.0 to 9.0% povidone. The tablets were stored in tightly closed glass containers at 43% relative humidity and ambient temperature. The axial and radial tensile strengths measured initially and at 1, 3, 6, and 12 months are shown in Fig. 17 for hydrous lactose with 3.0 and 5.0% povidone. Similar plots are shown in Fig. 18 for hydrous lactose tablets with 7.0 and 9.0% povidone. The implication is that the tensile strength did not change to a significant extent after 1 year in storage. A report (33) that the hardness

of hydrochlorothiazide tablets composed of lactose and povidone did not change after 1 year at room temperature supports this implication.

Determination of Octanol–Water Equivalent Partition Coefficients of Indolizine and Substituted 2-Phenylindolizines by Reversed-Phase High-Pressure Liquid Chromatography and Fragmentation Values

CLAUDIO L. K. LINS, JOHN H. BLOCK ˣ, ROBERT F. DOERGE, and GERARD J. BARNES

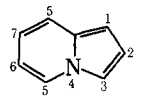
Received May 19, 1980, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97331.* Accepted for publication July 27, 1981.

Abstract □ Octanol–water partition values were calculated using fragmentation values and measured rapidly by high-pressure liquid chromatography (HPLC) on bonded octadecylsilane supports. Log *P* for indolizine, π, and fragment (*f*) values for the indolizinyl substituents were determined using both methods. Good agreement was obtained for all three values.

Keyphrases □ Partition coefficient—indolizine and 2-phenylindolizines, determination by high-pressure liquid chromatography and fragmentation values □ Indolizine—substituted 2-phenylindolizines, partition coefficients determined by high-pressure liquid chromatography and fragmentation values □ High-pressure liquid chromatography—determination of partition coefficients of indolizine and 2-phenylindolizines □ Fragmentation values—determination of partition coefficients of indolizine and 2-phenylindolizine

There is considerable interest in partition coefficient determination in the area of rational drug design (1). The partition coefficient, log *P*, represents the distribution of a substance between an organic and aqueous phase. Several methods may be used to determine partition coefficients including the shake-flask method, liquid–liquid chromatography on liquid impregnated plate technique, and high-pressure liquid chromatography (HPLC).

No studies have been done on the log *P* of indolizines. Indolizine (I) is a 10π aromatic heterocyclic compound with the nitrogen at the bridge head position. It is nearly electrically neutral and weakly basic with a pKa value of 3.94 (2).



I

For the normal shake-flask method, octanol and water have been used previously as the biological lipid and aqueous phases, respectively, in partition determination (3). Due to the instability of the indolizine nucleus, measuring log *P* values of this compound by this technique has proven difficult. The shake-flask procedure (4) is a tedious, time-consuming process and subject to purity, stability, and mass-balance problems from the compounds being measured.

BACKGROUND

Liquid chromatography on paper or lipid-impregnated plates has been used as an alternative to octanol–water partition. Martin (5) derived Eq. 1 for thin-layer or paper chromatography (TLC):

0022-3549/82/0600-0614$01.00/0

of hydrochlorothiazide tablets composed of lactose and povidone did not change after 1 year at room temperature supports this implication.

Benzophenone	1.49	3.18	3.15
Indolizine (I)	0.894	—	2.49 ± 0.02[c]

[a] Reference 18. [b] Equation 3. [c] Standard error of the estimate from Eq. 3.

$$\log P = \log K + R_m \qquad \text{(Eq. 1)}$$

where K is a constant for the system, $R_m \approx \log [(1/R_f) - 1]$ where R_f has the usual meaning.

Reversed-phase HPLC has been used to measure the lipophilicity of several compounds. In HPLC, the capacity factor k' replaces R_m and is defined as:

$$k' = \frac{(t_r - t_0)}{t_0} = \frac{(V_r - V_0)}{V_0} = \frac{(d_r - d_0)}{d_0} \qquad \text{(Eq. 2)}$$

where:

t_r = retention time of the compound
t_0 = retention time of the solvent
V_r = retention volume of the compound
V_0 = retention volume of the solvent or dead volume
d_r = distance between the peak of the compound and peak of the solvent front
d_0 = distance between the point of injection and the peak of the solvent front.

Haggerty and Murrill (6) measured log *P* values for a family of nitrosoureas using a column packed with octadecylsilane bonded to silica[1] and eluted with 30% acetonitrile in pH 7.41 buffer solution. Another study (7) obtained good correlation between log *k'* and log *P* of some substituted phenol and aniline derivatives using bonded[2] columns with various mixtures of distilled water and acetone as the eluent. Exhaustive silylation of octadecylsilane reversed-phase columns were reported to give a better correlation between *k'* and log *P* than the untreated packing material (8). The rationale is that exhaustive silylation eliminates adsorption phenomena due to free SiOH sites.

The lipophilicities of 1,4-benzodiazepine derivatives were determined using oleyl alcohol supported on a porous silica[3] as an HPLC procedure and the results were compared with reversed-phase TLC techniques (9). Similar work was done (10) using 1-octanol supported on diatomaceous earth[4] with octanol-saturated water as the eluent.

Various HPLC techniques were compared (11) using three different columns: one reversed-phase[1], one unmodified absorption system[5], and one nonbonded porous silica[6] coated with 1-octanol or squalene. Several good correlations between log *k'* and log of biological activity were reported. Investigators using these techniques were warned to be careful in interpreting these correlations. Unger *et al.* (12) had near perfect agreement between shake-flask and reversed-phase HPLC procedures over a log *P* range of 3.5 units, using octanol-saturated pH 7.00 (0.01 *M*) phosphate buffer as the mobile phase, and silylated octadecyl-bonded silica[1] as the stationary phase.

The latter HPLC procedure (12) was used in the present study to determine the log *P* of unstable indolizine. Then, a modified HPLC method was developed to measure partition coefficients of 3.5 to 5.0. Using this method, the π and fragment values for the indolizinyl substituent were also determined.

EXPERIMENTAL

Solvents were analytical reagent quality, and the 1-octanol for chromatographic purposes was purified according to reported procedures (13). Standards were obtained from commercial sources. Indolizine and 2-phenylindolizines were synthesized by the Boekelheide (14) method and *via* the Chichibabin-Stepanow (15, 16) route, respectively.

Samples were dissolved in water-saturated octanol and/or a minimal amount of methanol. Sodium nitrate in octanol-saturated water was used as a suitable nonretained compound to define dead volume, V_0. Sample concentrations were adjusted so that the relative peak areas remained approximately constant.

The high-pressure liquid chromatograph[7] consisted of a pump[8] and injector[9]. A UV–visible spectrophotometer[10] with low dead volume flow cells was used as detector. Standards and indolizines were analyzed at 260 nm. Peaks were measured on a 25-cm dual pen recorder[11]. The column packing of silica particles (37–50 μm) with an octadecylsilane-bonded coating[1] was persilated by McCall's method (8). Stainless steel columns (2-mm i.d.) in lengths of 5, 10, 30, and 60 cm were packed using published "tap-fill" procedures (17), and then mounted onto the liquid chromatograph.

Two methods were used to determine log *P*. One system followed Unger's procedure (12). The second procedure was patterned after reported methods (6–8) using persilated octadecylsilane columns[1] with 40% (v/v) acetonitrile in water as the mobile phase to determine large log *P* values (range 3.5 to 5.0) of standards and 2-phenylindolizines. Samples were dissolved in acetonitrile and/or a minimal amount of methanol. For both procedures, all solutions containing solute were first filtered[12] to reduce contamination or column clogging. All experiments were performed at ambient temperature (25°).

Log *P* values for unknowns obtained from HPLC data were determined by calculation using regression analysis derived from literature log *P* values (18) *versus* their log *k'* obtained experimentally. Daily standards were run with excellent reproducibility. Statistical analyses were performed using a statistical package[13].

RESULTS AND DISCUSSION

Log *P* Determination of Indolizine by HPLC—Due to the instability of indolizine, its log *P* value was estimated using HPLC techniques. Compounds possessing physical properties similar to those of indolizine were selected. These reference compounds (the first six compounds in Table I) were electrically neutral and had partition coefficients close to the estimated value for indolizine (log *P* 2.45 calculated by the fragment method). These compounds were chromatographed on a silylated column[1] coated with octanol. The mobile phase was octanol-saturated water

Table II—Estimated Log *P* Values on HPLC Using 40% (v/v) Acetonitrile in Water

Compound	Log *k'*	Log *P*	
		Literature[a]	HPLC[b]
o-Dibromobenzene	0.580	3.64	3.60
m-Dibromobenzene	0.732	3.75	3.93
Dibenzofuran	0.748	4.12	3.96
Fluorene	0.857	4.18	4.21
Diphenylacetylene	1.10	4.78	4.76

[a] Reference 18. [b] Equation 4.

using a 10-cm column. A linear relationship between log *P* values and their log *k'* values (Fig. 1) is given by:

$$\log P = 1.516\ (\pm\ 0.059) + 1.094\ (\pm\ 0.057) \log k' \qquad \text{(Eq. 3)}$$

$$n = 6, s = 0.0453, r^2 = 0.9893, F_{1,4} = 370$$

The values in parentheses are the standard errors, *n* is the number of compounds, *s* is the standard error of the corrleation, r^2 is the coefficient of determination, and *F* is the overall significance parameter with the indicated degrees of freedom.

Unger *et al.* (12) showed that nitrogenous compounds capable of hydrogen bonding with nonsilated silanol sites deviated from the calculated regression line. Pyridine and certain substituted pyridines deviated the most. Quinoline did not deviate as much. Acridine, 2,6-lutidine, and *N,N*-dimethylaniline fit the regression model. It appears that as the pKa of an amine decreases and steric hindrance about the nitrogen increases the ability to adsorb onto an open silanol site decreases. Indolizine has a reported pKa of 3.94 (2), far lower than that for pyridine (5.19) or quinoline (4.90). Furthermore, protonation of indolizine occurs on carbons 1 and 3, not on the nitrogen atom (19). The ring nitrogen is sterically hindered. Finally, in some unreported earlier work[14] the use of shift reagents was investigated in an attempt to simplify the proton NMR spectrum of indolizines. No noticeable change in the chemical shifts of any of the protons was obtained, which is strong evidence of a very weakly basic and/or sterically hindered nitrogen (20). For these reasons, reference compounds containing nitrogen capable of hydrogen bonding to silanol sites on the HPLC column were omitted.

The log *k'* value for indolizine (0.894) was measured under the same conditions used for the standards (Table I) and a log *P* value of 2.49 was calculated using Eq. 3.

Determination of π Value of the Indolizinyl Moiety by HPLC—Because the 2-phenylindolizines are more stable than indolizine their log *P* determinations using the traditional shake-flask procedure (4) were attempted without success. These compounds degrade in solution with changes detectable in the UV spectrum within 1 hr. Undoubtedly agitation in the octanol–water system hastened this degradation. Thus, an HPLC procedure was devised.

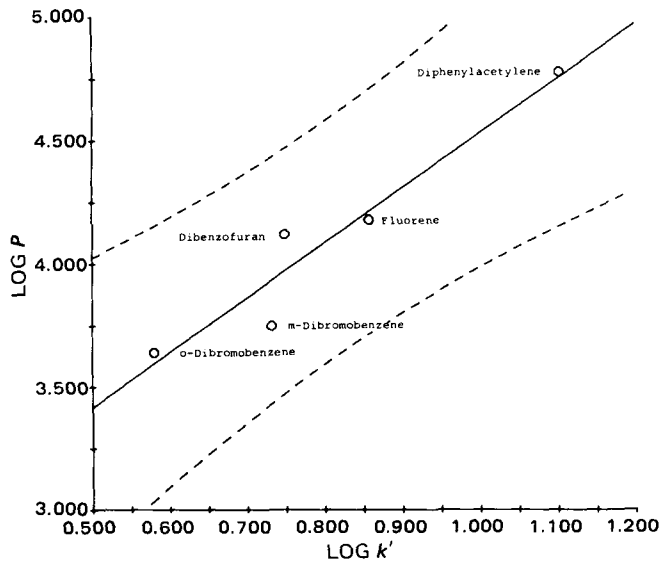

Figure 2—*Literature log* P *value* versus *log* k' *determined by 10-cm column*[1] *using 40% (v/v) acetonitrile in water as the mobile phase. Key: (- - -) the 95% confidence limits of the predicted line; (○) standards are from Table II.*

Table III—Estimated Log *P* on HPLC of 2-Phenylindolizines

Compound	X	Y	Log *k'*[a]	Log *P* HPLC[b]
II*a*	H	H	0.892	4.29 (±0.07)
II*b*	OCH_3	H	0.851	4.20 (±0.07)
II*c*	H	OCH_3	0.826	4.14 (±0.06)
II*d*	CH_3	H	1.19	4.96 (±0.16)
II*e*	H	CH_3	1.15	4.87 (±0.14)
II*f*	Cl	H	1.30	5.20 (±0.19)
II*g*	H	Cl	1.27	5.14 (±0.18)
II*h*	Br	H	1.40	5.43 (±0.23)
II*i*	H	Br	1.35	5.31 (±0.21)

[a] Values measured on a persilated column[1] (10 cm) using 40% (v/v) acetonitrile as the eluant. [b] Equation 4; numbers within the parentheses are the standard error of the estimate.

The octanol–water HPLC system is limited to compounds having a log *P* of 3.15 which is the log *P* of octanol itself (18). Any compound with a greater log *P* would, in theory, remain on the HPLC column indefinitely. Using either the π or fragment approach of calculating log *P* values, the log *P* values for the 2-phenyl substituted indolizines were estimated to be in the range of 4–5.

Selected standards (Table II) with known log *P* values (18) in this range were chromatographed using several different solvent systems. These consisted of a reversed-phase persilated column[1] with different column lengths and different concentrations of acetonitrile in water as the mobile phase. Columns[1] varied in length from 5 to 10 cm and the solvent system consisted of acetonitrile concentrations in the range of 35–50%. Good linear relationships (Fig. 2) were found in a system using 40% acetonitrile in a 10-cm column[1]. The results are displayed in Table II and represented by:

$$\log P = 2.300\ (\pm\ 0.2967) + 2.234\ (\pm\ 0.360) \log k' \qquad \text{(Eq. 4)}$$

$$n = 5, s = 0.1416, r^2 = 0.9251, F_{1,3} = 37.0$$

A variety of 2-phenylindolizine analogs with widely different lipophilicities were prepared (Table III). These compounds have different substituents in the *para* and *meta* positions on the 2-phenyl groups. These substituted 2-phenylindolizines were chromatographed under conditions identical to those in Table II. Their log *k'* values were used to calculate their log *P* values using Eq. 4 (Table III).

π Value Correlation from HPLC Data—An investigation was conducted to determine whether the retention times of substituted 2-phenylindolizines using a persilated column[1] were proportional to their Hansch π constants (17). The previously described mobile phase of 40% acetonitrile in water using a 10-cm column was used. An excellent linear relationship was found between the log *P* values of the 2-phenyl substituents and log *k'*. The results are represented by:

$$\text{Log } P_{\text{substituent}} = 0.696\ (\pm\ 0.027) + 1.674\ (\pm 0.072) \log k' \qquad \text{(Eq. 5)}$$

$$n = 9, s = 0.0452, r^2 = 0.9874, F_{1,7} = 548.2$$

There is no complete set of π values for substituted phenyl compounds. That is, there are π values for CH_3, CH_3O, Cl, Br, and C_6H_5, but not tolyl, anisyl, *etc.* Since π_H is defined as zero, the log *P* values of the intact molecule (toluene, anisole, *etc.*) were used as an estimate of π to obtain Eq. 5.

The $\pi_{\text{indolizinyl}}$ values were calculated by subtracting the log *P* of the complete molecule, which represents the substituent (21) from the log *P* of the substituted indolizine (Table IV):

$$\pi_{\text{indolizinyl}} = \log P_{\text{substituted indolizine}} - \log P_{\text{substituent}} \qquad \text{(Eq. 6)}$$

The calculated $\pi_{\text{indolizinyl}}$ values vary from 2.03 and 2.44 with a mean of 2.41, a standard error of ±0.045, and a coefficient of variation of 6.0%.

Examination of the $\pi_{\text{indolizinyl}}$ results in Table IV shows that they can be placed into two groups. Compounds II*a*–II*e* compose one group with a mean of 2.14 and II*f*–II*i* have a mean of 2.36. The latter group contains the halogens. Hansch and Leo[15] have found that halogen adds about 0.2 units to π and fragment values. Correcting for the halogen effect, the mean $\pi_{\text{indolizinyl}}$ value becomes 2.15 (±0.024) with a coefficient of variation of 3.4%.

[15] A. Leo and C. Hansch, personal communications.

Table IV—$\pi_{indolizinyl}$ and $f_{indolizinyl}$ Values Using HPLC, 2-Phenyl Substituent [a]

Compound	Log $P_{substituent}$ [b]	$\pi_{indolizinyl}$ [c]	$f_{substituent}$ [d]	$f_{indolizinyl}$ [e]
IIa	2.13	2.16	1.90	2.39
IIb	2.11	2.09	1.88	2.32
IIc	2.11	2.03	1.88	2.26
IId	2.69	2.26	2.46	2.49
IIe	2.69	2.17	2.46	2.39
IIf	2.84	2.36 (2.16)	2.61	2.59 (2.39)
IIg	2.84	2.30 (2.10)	2.61	2.53 (2.33)
IIh	2.99	2.44 (2.24)	2.76	2.67 (2.47)
IIi	2.99	2.32 (2.12)	2.76	2.55 (2.35)

[a] See Table II for log k' and log P results obtained by chromatography. [b] Reference 18. [c] Equation 6; values within the parentheses are corrected for the presence of a halogen. [d] Reference 21; obtained by subtracting f_H (0.23) from log P of the 2-phenyl substituent. [e] Equation 8; values within the parentheses are corrected for the presence of a halogen.

Log P of Indolizine Calculated by the Fragment Method—The log P of the indolizine nucleus can be also calculated by the fragment method using values from model systems (18).

For example, for the fused aromatic ring model, the aromatic carbon (f_{CH}) has a value of 0.35 and the bridgehead carbon next to a heteroatom (f_C^*) is 0.44. For the nitrogen, several values can be used depending on the specific location of the atom in the molecule. According to a previous report (21), the fragment constant for the nitrogen in a ring system such as indole or pyrrole (−0.67) lies between the values of the nitrogen attached to one aromatic ring (−1.03), and two aromatic rings (−0.03). The fragment value for N-phenyl pyrrole is −0.56. Indolizine (I) is a special case because the nitrogen is located at the bridgehead position of the molecule. The nitrogen in this system is more lipophilic than the usual heterocyclic nitrogen because the unshared electrons on the nitrogen resonate among all the atoms of the ring (22). The low pKa (3.94) and the fact that protonation occurs on carbons 1 and 3 is further evidence of the special nature of this nitrogen. For this reason, a fragment value of −0.44 was used as an approximation of the nitrogen constant for indolizine[15]. This value represents a nitrogen in an aromatic system attached to two aromatic rings. The addition of all these fragment values is illustrated below:

$$\log P = 7 f_{(CH)} + f_{(C)}^* + f\text{—}\underset{\phi}{\overset{|}{\underset{\phi}{N}}}\text{—}\phi \qquad \text{(Eq. 7)}$$

$$= 7\,(0.35) + (0.44) + (-0.44)$$

$$= 2.45$$

In a similar manner, the fragment substituents of 2-phenylindolizines were calculated by the fragment method (20) and listed in Table IV. Indolizinyl fragment values were calculated by subtracting fragment substituent values from log P values:

$$f_{indolizinyl} = \log P - f_{substituent} \qquad \text{(Eq. 8)}$$

The average indolizinyl fragment value is 2.47 with a sample standard error of ±0.044. The fragment values vary from 2.26 to 2.67 with a coefficient of variation of 5.4%.

As was done with the π determination, the fragment results in Table IV can be divided into two groups with the methyl and methoxy substituted compounds IIa–IIe in the first group and the halogen substituted compounds IIf–IIi in the second. The average fragment value for the nonhalogenated indolizines is 2.37 and for the halogenated indolizines is 2.59. Applying a correction of 0.2 for the halogenated compounds, the average decreases to 2.39. The average $f_{indolizinyl}$ for all 11 compounds then becomes 2.38(±0.024) with a coefficient of variation of 3.0%.

Both the fragment and π approach to calculating log P values assumes that partial partition coefficients are additive. They also assume that each substituent behaves independently in terms of any effect on lipophilicity; this is not true. To correct for interactions, the fragment approach uses correction terms or different fragment substituent values dependent on the type of parent molecule containing the substituent. Nevertheless, neither method differentiates between a *meta* and *para* substituent in terms of resonance *versus* inductive effects on lipophilicity. Furthermore, both approaches ignore any resonance or inductive effect that the indolizine ring might have on the phenyl ring.

In both the fragment and π approaches, the individual substituent values are derived from known compounds whose partition coefficients were obtained by the classical shake-flask procedures. There have been no reported studies on the partitioning behavior of indolizine. It is difficult to extrapolate this heteroaromatic to other heteroaromatic systems for the reasons already stated. Nevertheless, the results obtained for indolizine by the different methods described in this paper show good consistency and can be considered a measure of lipophilicity for future quantitative structure–activity relationship (QSAR) studies involving indolizine.

The authors thank Professors Corwin Hansch and Albert Leo for supplying a value for the halogen effect and an estimate for the fragment value for the indolizine nitrogen.

Quantitative Structure–Activity Relationships of Purines II: Prediction of Activity against Adenocarcinoma CA755 and Toxicity in Mice

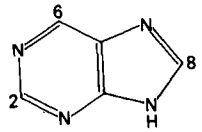
ZOHAR NEIMAN and FRANK R. QUINN ˣ

Received June 11, 1981, from the *Laboratory of Medicinal Chemistry and Biology, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication September 16, 1981.

Abstract □ Quantitative structure–activity relationships (QSAR) were derived for a number of 2,6-mono- and disubstituted purines. The derived equations relate the anticancer activity in murine Adenocarcinoma CA755 to the molar refractivity of substituents at position 2 and electron-withdrawing effects of substituents at position 6. A QSAR was also derived for the acute toxicity (LD_{50}) of substituents at position 6. The results suggest that toxicity is relatively independent of the nature of the substituent.

Keyphrases □ Anticancer activity—of purines, prediction of activity against Adenocarcinoma CA755 and toxicity in mice □ Purines—anticancer activity, prediction of activity against Adenocarcinoma CA755 and toxicity in mice, structure–activity relationship □ Structure–activity relationships—of purines, prediction of activity against Adenocarcinoma CA755 and toxicity in mice

Purine (I) and purine nucleosides comprise a very important class of potential anticancer agents (1). Many hundreds of purine analogs have been synthesized (2) and tested for their anticancer properties. Of the purine bases, only mercaptopurine and thioguanine have found general usage in the clinical treatment of cancer (3).



In a previous study (4) it was demonstrated that quantitative structure–activity relationships (QSAR) were possible with purines in spite of the fact that the purine ring system is not typically aromatic (5). In the present study quantitative structure–activity correlations were derived for the *in vivo* activity and toxicity of a number of 2- and 6-substituted purines against the murine solid tumor Adenocarcinoma 755(CA755).

It has been pointed out (6) that CA755 is a test system that is artificially sensitive to purines. Under the protocols for testing drugs against CA755 (7) many purines prove to be impressively carcinostatic and sometimes carcinolytic. However, these test conditions, in which the drug is administered 24 hr after tumor implantation, reflect treatment during early stages of the disease. It has been shown (6) that, if treatment is delayed until the disease is well-advanced, a situation more typical of that encountered in humans, these purines are not as effective. The principal value in using data from a sensitive system such as CA755 is that the effect of subtle structural changes on the activity may be easily discerned. The ultimate effectiveness of any analog against other animal or human tumors would still have to be determined.

EXPERIMENTAL

The substituted constants employed in this study included the hydrophobic parameter π and the Swain-Lupton field and resonance constants $\mathcal{F}$ and $\mathcal{R}$ (8). The molar refractivity (MR) was used as a measure of steric bulk (8). The physicochemical parameters which appear in the correlations are given in Table I. Substituent constants were taken from the recent literature (9). Values of π not available from the literature were calculated by the additive method (10); MR values were calculated from Vogel's bond refraction values (11).

It should be noted that the π values used in this study were determined in an aromatic system, *i.e.*, from benzene derivatives. Purine, on the other hand, is a nitrogen heterocycle and substituents on the purine ring may undergo various perturbations due to inter- and intramolecular associations with the ring nitrogens. It is quite possible that π values for purine substituents would differ considerably from those of their benzene analogs. The major deviations from standard π values would be expected for substituents at positions 2 and 8, both of which are adjacent to two-ring nitrogen atoms. The 6 position, on the other hand, may be similarly af-

[a] *C* is the concentration (moles/kg) which produced a tumor weight regression = 80%. [b] From Eq. 1.

fected but to a lesser extent since substituents are α to only one-ring nitrogen. This effect was tested by examining the π values of a number of 2-substituted pyridines in comparison with normal π values. Substituents were CN, Cl, Br, $COCH_3$, CH_3, C_2H_5, CH_3O, NH_2, $NHCOCH_3$ and NO_2. The following relationship was found:

$$\pi \text{ pyridines} = 0.38(\pm 0.17) + 0.49(\pm 0.22)\ \pi \text{ aromatics}$$

$$n = 10;\ r = 0.876;\ s = 0.227;\ F_{1,9} = 27.06\ (p < 0.001)$$

This relationship which was derived for some widely diverse substituents suggests that normal aromatic π values may be employed at position 6 with relative safety.

Antitumor data (Table II) were collected by the Drug Evaluation Branch, National Cancer Institute (NCI), according to the protocols (7) mentioned previously. A tumor fragment was implanted subcutaneously and treatment was initiated 24 hr later. The drug was administered daily for 11 consecutive days (QD1–11). On the twelfth day the animals were sacrificed and the tumor was excised and weighed. A compound is considered active in this system if it produces a tumor weight regression >58% (T/C ≤42%) compared to controls.

In the present study, a computer search was made of the NCI biological database for active 2-, 6-, and 8-substituted purines. 8-Substituted purines do not appear in the final correlation because there were too few active compounds to warrant their inclusion. Compounds containing SH or OH groups were excluded because these drugs exist as tautomers and no true substituent constants are available. Admittedly, this may narrow the conclusions somewhat. It has been shown, however, that one of the active forms of mercaptopurine and thioguanosine is the 6-methylthio derivative of each of those compounds obtained by *in vivo S*-methylation (12), and these analogs have been included in this study. Aminopurines, which have been shown to exist mainly in the NH_2 form (13), were included. Dose response plots were generated and the standard biological response was taken at T/C = 20%. C is the dose (moles/kg) that produces this response.

The toxicity correlation was restricted to 6-monosubstituted purines, since these comprise the major portion of purine bases tested by the NCI. The biological database was searched for those compounds for which a dose–response curve could be constructed and which showed reproducible toxicity. The LD_{50} (Table III), in moles/kg, was calculated by the probit method (14) from toxicity day (Day 11) survivors (15).

RESULTS AND DISCUSSION

Equation 1 was generated from the data in Tables I and II. The development of Eq. 1 is given in Table IV.

Table III—Observed and Predicted Toxicities of 6-Substituted Purines

[a] From Eq. 3. [b] Azathioprine.

$$\log(1/C) = 4.26(\pm 0.24) - 0.47(\pm 0.37)\ \text{MR}(2) + 1.18(\pm 0.55)\ \mathcal{R} \quad (6)$$

$$n = 22;\ r = 0.815;\ s = 0.372 \quad \text{(Eq. 1)}$$

Equation 1 relates the CA755 antitumor potency of 2,6-mono- and disubstituted purines to the molar refractivity of substituents at position 2 and the resonance constant $\mathcal{R}$ at position 6. The negative coefficient of the MR (2) term indicates that bulky substituents at position 2 are to be avoided for maximum potency in this tumor system. The larger positive coefficient of the $\mathcal{R}$ term suggests that potency in CA755 is predominantly influenced by the resonance effect of groups at position 6. Strong electron-withdrawing groups would be expected to increase potency. This is consistent with the observation that the 6-methylthio derivative ($\mathcal{R} = -0.11$) routinely produced complete tumor regression (T/C = 0%) at doses of 20 mg/kg. The 6-methoxy derivative ($\mathcal{R} = -0.51$), by comparison, requires ~10 times as much drug (250 mg/kg) to produce the same effect.

The 6-halo analogs (6-Cl, 6-Br, and 6-I) have about the same $\mathcal{R}$ values (−0.15, −0.17, and −0.19) as the 6-methylthio derivative and exhibit about the same potency as the latter. The 6-thiocyanate derivative ($\mathcal{R}$ = +0.19) was an outlier and was not included in Eq. 1. It was, however, one of the most potent compounds tested by the NCI, producing complete tumor regression at ~7 mg/kg. This analog may be, as suggested previously (16), a masked form of mercaptopurine, which may be produced by *in vivo* reduction.

The correlation coefficient of Eq. 1 is quite reasonable, considering the inherent variability in tumor weigh measurements. It accounts for ~66% of the variance in the biological data ($r^2 = 0.664$).

Equation 2, a toxicity correlation, was derived from the data in Tables I and III and includes only 6-thiopurines:

Table IV—Development of Equation 1

Intercept	MR (2)	$\mathcal{R}$ (6)	r	s	$F_{1,x}$	p	Equation
4.03	−0.72	—	0.560	0.519	$F_{1,21}$ = 9.16	<0.01	A
4.13	—	1.39	0.736	0.424	$F_{1,21}$ = 23.63	<0.001	B
4.26	−0.47	1.18	0.815	0.372	$F_{1,20}$ = 6.92[a]	<0.025	C

[a] This F value was obtained in comparison with Eq. B.

Table V—Development of Equation 3

Intercept	π(6)	MR (6)	r	s	$F_{1,x}$	p	Equation
3.30	−0.05	—	0.342	0.202	$F_{1,35}$ = 4.49	<0.05	A
3.04	—	0.08	0.452	0.192	$F_{1,35}$ = 8.73	<0.01	B
2.89	−0.15	0.19	0.908	0.092	$F_{1,34}$ = 116.06[a]	<0.001	C

[a] This F value of Eq. C is obtained in comparison with Eq. B.

$$\log(1/LD_{50}) = 2.95(\pm0.12) - 0.14(\pm0.02)\pi\ (6) + 0.17(\pm0.04)\text{MR}\ (6)$$
$$n = 29;\ r = 0.911;\ s = 0.076 \qquad \text{(Eq. 2)}$$

Equation 2 indicates that toxicity of 6-substituted thiopurines is influenced to about the same extent by the lipophilicity and bulkiness of groups at position 6. Toxicity would be expected to decrease with increasing lipophilicity. Bulky groups would be expected to increase the toxicity. To ensure that this was not a phenomenon peculiar to 6-thiopurines, seven additional compounds without sulfur bonds (II–IV, XXIX–XXXII) were included in the following:

$$\log(1/LD_{50}) = 2.89(\pm0.08) - 0.15(\pm0.03)\pi\ (6) + 0.19(\pm0.03)\ \text{MR}\ (6)$$
$$n = 36;\ r = 0.908;\ s = 0.092 \qquad \text{(Eq. 3)}$$

The development of Eq. 3 is given in Table V. Equation 3 is identical to Eq. 2 and appears to express a general structure–activity relationship for 6-substituted purines. In Eq. 3, the positive effect of increasing π (6) in order to decrease toxicity is offset by the toxicity-increasing effect of MR (6). This phenomenon has been observed in other systems[1], but the biochemical implications are not at all clear. There is some intercorrelation between MR (6) and π (6) (arc cos 0.38 = 68°) (17) as might be expected.

Equation 3 reflects the rather limited range of toxicities of 6-monosubstituted purines (Table III). Viewed together with Eq. 3, Eq. 1 suggests that, other things being equal, the development of more potent 6-substituted purines is not likely to result in a substantial increase in toxicity.

Few cancer QSAR studies have been published to date (18). This may be due both to the complexity of the problem and the nature of the data. Nevertheless, those studies that have been published show that cancer data will yield reasonable structure–activity correlations (15, 19, 20). In the present study, an attempt has been made to employ tumor weight inhibition data and standard physicochemical parameters in order to derive QSAR for an important class of antitumor agents. The correlations presented are reasonable and consistent with the data. The results suggest that other biological data obtained from the study of purines (enzyme inhibition data, *in vivo* survival data, *etc.*) may yield satisfactory correlations as well.

Rectal Absorption of Nitroglycerin in the Rat: Avoidance of First-Pass Metabolism as a Function of Rectal Length Exposure

A. KAMIYA, H. OGATA*, and HO-LEUNG FUNG ˣ

Received June 8, 1981, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication September 2, 1981. * Present address: National Institute of Hygienic Sciences, Tokyo, Japan.

Abstract □ Nitroglycerin administered orally undergoes substantial presystemic elimination. It was shown recently that first-pass hepatic metabolism of high clearance drugs can be substantially avoided *via* rectal administration. In applying this concept to nitroglycerin in rats, it was found that unrestricted rectal instillation of nitroglycerin (at 3.5-mg/kg dose) gave a mean ±*SD* bioavailability of 26.7 ± 7.0% (n = 6) compared to 1.8 ± 0.9% (n = 5) from oral dosing. This mode of dosing did not lead to complete avoidance of first-pass metabolism of nitroglycerin in rats. When the rectal exposure length to nitroglycerin was restricted to 3.5 cm from the anus, the mean ±*SD* bioavailability increased to 83.5 ± 74.5% (n = 14). However, the variability in bioavailability was extremely large. When the rectal exposure length was restricted to 2.0 cm from the anus (at 1.75-mg/kg dose), nitroglycerin bioavailability was estimated at 91.2 ± 30.4% (n = 6). The plasma nitroglycerin concentrations (>5 min) obtained after this mode of administration were similar to those achieved after intravenous dosing. The data showed that substantial avoidance of presystemic nitroglycerin metabolism can be achieved *via* rectal administration. This avoidance can be nearly complete if nitroglycerin is limited in exposure to only the lower rat rectum. It was also demonstrated that sustained (at least 24 hr) nitroglycerin delivery *via* the rat rectal route was feasible with an experimental osmotic minipump. This delivery system also produced nearly complete bioavailability for nitroglycerin in the rat.

Keyphrases □ Nitroglycerin—rectal absorption, avoidance of first-pass metabolism as a function of rectal length exposure, rats □ Absorption, rectal—nitroglycerin, avoidance of first-pass metabolism as a function of rectal length exposure, rats □ First-pass metabolism—avoidance as a function of rectal length exposure, nitroglycerin, rats

Nitroglycerin undergoes extensive and variable first-pass metabolism when administered orally in rats (1–3) and in humans (4). Recent studies showed that rectal administration of lidocaine, propranolol, and salicylamide in rats led to substantial avoidance of first-pass metabolism of these drugs (5–7). The possibility of similar improvement in bioavailability of nitroglycerin, another high-clearance drug, through the rectal route has been suggested (5). This hypothesis, however, has not been tested.

The studies reported here were designed, therefore, to determine the bioavailability of nitroglycerin after rectal administration in rats. Since drug spreading in the colon and rectum may lead to reduction of avoidance of first-pass metabolism (5), rectal dosing of nitroglycerin was carried out with three different lengths of rectal exposure to examine this effect. Finally, an experimental rectal delivery system was tested to explore whether sustained and complete absorption of nitroglycerin was feasible *via* the rectal route.

BACKGROUND

Since its introduction into clinical practice by Murrell (8) about 100 years ago, nitroglycerin has been the drug of choice for the acute relief and prophylaxis of angina pectoris. Interest in nitroglycerin has increased substantially in the past few years because new important clinical use for this drug has been documented. For example, nitroglycerin improved hemodynamics in patients with congestive heart failure (9), myocardial infarction (10), and unstable angina (11). Recently, this drug has been also used for the induction of hypotension during anesthesia and surgery (12). In spite of the long history of use and the increasing therapeutic scope of nitroglycerin, however, many basic aspects of the pharmacokinetics of this drug have not been investigated. The recent availability of sensitive analytical methods (13, 14) have made initiation of these studies (1–4) possible.

Oral sustained-release dosage forms of nitroglycerin are used clinically for prophylaxis of angina. The effectiveness of these dosage forms, and indeed the oral route itself, have been a subject of considerable debate in the literature (15). The pioneering work of Needleman *et al.* (1) showed that oral dosing of nitroglycerin in rats gave negligible blood concentrations of intact drug compared to those found for metabolites. Since human liver biopsy samples were shown to have an enzyme capacity similar to that found in rats, these authors concluded that there is no rational basis for oral nitroglycerin use. However, this suggestion had been refuted by clinical experience (16) and also by a well-conducted clinical study (17) which showed oral nitroglycerin to have significant benefits in controlling angina. Recent pharmacokinetic data (4, 18) also showed that intact nitroglycerin could be detected in plasma after oral admin-

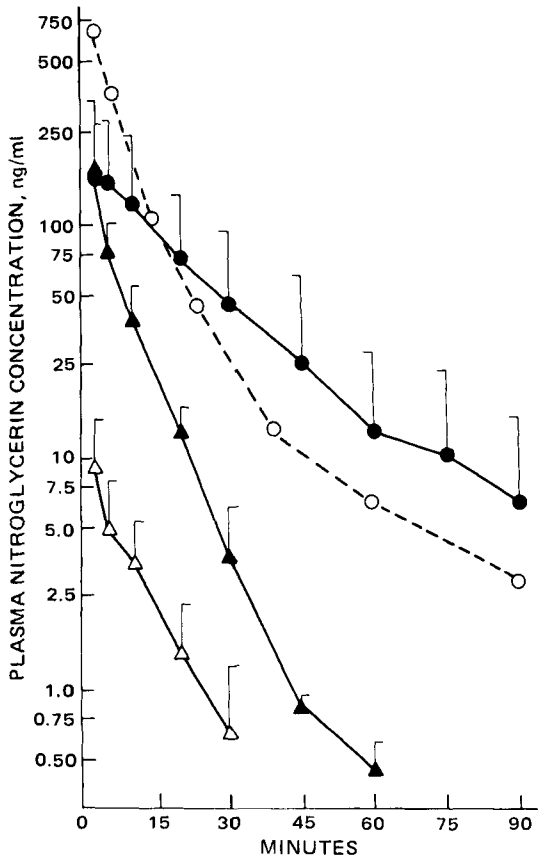

Figure 1—*Plasma nitroglycerin concentrations following different routes of administration at 3.50 mg/kg. Data represent mean ± SD of restricted rectal (3.5 cm) (●); unrestricted rectal (▲); and oral (△) administration. Plasma concentration curve after intravenous dosing (○) represents the predicted mean values calculated from a 1.75-mg/kg nitroglycerin dose*[8].

Table I—Bioavailability of Nitroglycerin following Different Routes of Administration

Route of Administration	Dose, mg/kg	Number of Animals	Peak Plasma Concentration[a], ng/ml	*AUC*[b], ng min/ml	Apparent Bioavailability[c], %
Oral	3.50	5	9 ± 5*	0.09 ± 0.04*	1.8 ± 0.9**
Unrestricted rectal	3.50	6	170 ± 58	1.28 ± 0.34	26.7 ± 7.0+
Restricted rectal (3.5 cm)	3.50	14	189 ± 181	4.02 ± 3.57	83.8 ± 74.5
Restricted rectal (2.0 cm)	1.75	6	129 ± 56	2.19 ± 0.73	91.2 ± 30.4

[a] Mean ± *SD*. [b] Area under plasma concentration *versus* time curve. [c] See *Experimental*. Symbols indicate significant difference from all other groups (*); from 100% and all other groups (**); and from 100% and restricted rectal (2.0 cm) dosing group (+).

istration of sustained-release capsules in humans. A report has appeared which suggests the bioavailability of a retard capsule to be ~20% of an equivalent dose of a sublingual tablet (4). In rats, the bioavailability of an oral nitroglycerin dose in aqueous solution was ~2% after a nitroglycerin dose of 7 mg/kg of body weight (2). Interanimal variability in oral bioavailability was also large. This variation has been found to be primarily due to the difference in the intrinsic activity of liver organic nitrate reductase in each individual animal (3). The composite evidence to date suggests, therefore, that although oral nitroglycerin may be bioavailable in part, first-pass metabolism (primarily hepatic in nature) is both extensive and variable.

A recent study has shown that the first-pass hepatic metabolism of lidocaine, another high clearance drug, could be avoided *via* rectal administration. This avoidance was partial in humans (5) but almost complete in rats (6). Nitroglycerin may exhibit a similar dependency. It was pointed out (7) that at least two sets of rectal veins (upper and lower) carry blood from the rat rectum: the upper rectal vein feeds into the portal vein, while the lower rectal vein empties into the inferior vena cava directly without first passing through the liver. Thus, drugs absorbed rectally and carried into the body *via* the upper rectal vein can be, in principle, subjected to first-pass elimination, while drug carried through the lower rectal vein is not. It is therefore anticipated that avoidance of first-pass metabolism may be dependent on the length of the rectum which is exposed to the drug solution. It is believed that there has not been any documentation of this phenomenon in the literature. Therefore, the bioavailability of rectally administered nitroglycerin as a function of rectal length exposure was examined to determine whether this hypothesis can be substantiated.

A major disadvantage of rectal delivery of drugs is that the bioavailability is highly variable. This variability may be caused by the difference in the time elapsed between rectal drug administration and bowel movement in individual subjects (19). If a rectal delivery device can be fabricated which produces ideal zero-order release at all times, then removal of the device for bowel movement and reinsertion of the same device (or for aesthetic reasons, a fresh one) afterwards will potentially allow the drug to be delivered at the same rate before and after bowel movement. For nitroglycerin, which has an extremely short half-life ($t_{1/2}$ = ~2–3 min) (2, 20, 21), zero-order delivery through the appropriate part of the rectum may also produce sustained plasma drug concentrations leading to potential prolongation of the therapeutic effects of the drug. The last part of this report deals with studies that explored the possibility of using an experimental osmotic pump system to produce sustained delivery and improved bioavailability of nitroglycerin in the rat.

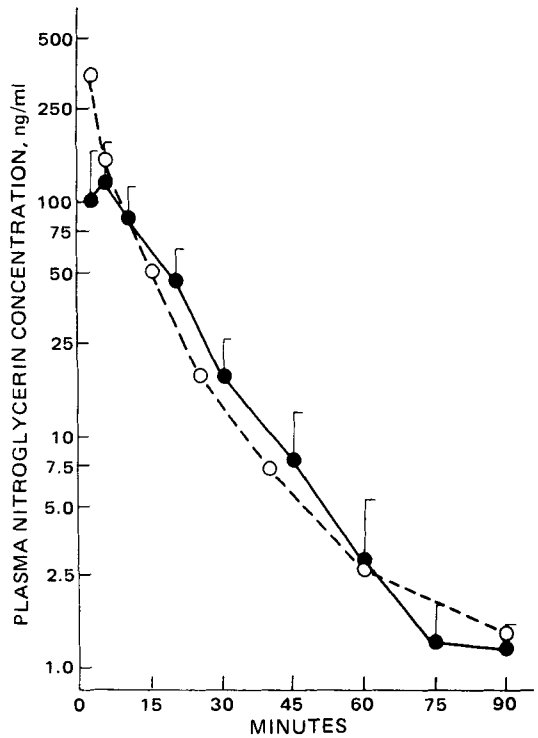

Figure 2—*Plasma nitroglycerin concentrations following restricted rectal (2.0 cm) administration at 1.75 mg/kg. Data represent mean ± SD after restricted rectal (2.0 cm) administration, (●); and mean after intravenous dosing*[8] (○).

EXPERIMENTAL

Materials—Nitroglycerin and isosorbide dinitrate solutions in hexane were prepared according to a previous report (14). A commercial 10% (w/w) nitroglycerin–lactose adsorbate[1] was used to prepare the aqueous and propylene glycol nitroglycerin solutions. To obtain the lactose-free nitroglycerin, an aqueous solution of the powder was extracted with ether, which was then evaporated under a gentle nitrogen stream. The resultant oil was dissolved in distilled water or propylene glycol to yield the appropriate concentration, which was then confirmed by gas chromatographic assay (14).

Animals—Male Sprague-Dawley rats[2] (300—360 g) were used. The right jugular vein was cannulated chronically (22). Animals were used after at least 16 hr of fasting prior to nitroglycerin administration and allowed free movement in a metabolic cage after dosing. Blood (~0.5 ml) was withdrawn *via* the jugular vein cannula at appropriate times.

Bolus Administration Studies—Nitroglycerin in normal saline solution (1.22 mg/ml) was used. For unrestricted rectal dosing, a septum plug[3] was affixed to the anus with glue[4]. Nitroglycerin was then injected into the rectum with a syringe through the septum. For restricted rectal

dosing, a device was constructed which connected two septum plugs at a fixed distance (either 2.0 or 3.5 cm) with a stainless steel wire. This device was inserted into the rectum from the anus while the animal was under slight ether anesthesia. The upper septum plug[5] was used to avoid upward spreading of nitroglycerin solution. The lower septum plug[3] was glued to the anus. Drug solution was injected into the rectum following the withdrawal of a volume of air from the rectum identical to that of the rectal drug solution. For oral administration, nitroglycerin solution was introduced by intubation to rats under slight ether anesthesia. Nitroglycerin doses were 3.50 mg/kg for unrestricted rectal dosing, restricted rectal dosing at 3.5-cm rectal length exposure, and oral dosing; and 1.75 mg/kg for restricted rectal dosing at 2.0-cm rectal length exposure. The lower dose was used in the last case because of limitations in the aqueous solubility of nitroglycerin and in the volume of dosing solution which could be injected at that specified rectal length exposure.

Sustained Rectal Delivery Studies—Osmotic pumps[6] were used as possible drug delivery systems for sustained rectal delivery of nitroglycerin. Nitroglycerin was dissolved in propylene glycol at 89.0 mg/ml. Each minipump was filled with ~0.25 ml of drug solution. The pump was placed at the bottom of a round-bottom flask in 200 ml of normal saline at 37°. The solution was stirred at 60 rpm and sampled from 12 to 36 hr (0.5 ml/sample) to determine the *in vitro* nitroglycerin release rate.

After this *in vitro* experiment, the minipump was washed with saline, blotted dry, and inserted into the rat. The osmotic pump was inserted into the rectum either in the upright (release hole pointing toward the intestine) or inverted position under slight ether anesthesia. For upright placement, the bottom of the osmotic pump was glued directly in place at the anus. For inverted placement, the neck plug of the pump was connected to a septum[3] by a stiff wire. This delivery system was inserted into the rectum and the septum was secured at the anus with glue. Blood samples were withdrawn up to 24 hr after insertion of these devices.

Assay of Nitroglycerin—After collection, blood samples were immediately transferred to chilled centrifuge tubes and centrifuged. Aliquots of plasma (0.2 ml) were mixed with 10 μl of 1 *N* silver nitrate and stored at −20° until assay. In the *in vitro* release experiment, 0.1-ml aliquots were assayed. The samples were extracted with hexane and nitroglycerin concentrations were determined by a previously reported gas chromatograph procedure (14) using isosorbide dinitrate as the internal standard.

The glue and septum plugs used were shown not to produce any interference in the assay of nitroglycerin. Sham experiments conducted using these devices showed also that the apparent clearance of nitroglycerin after intravenous injection was unaltered.

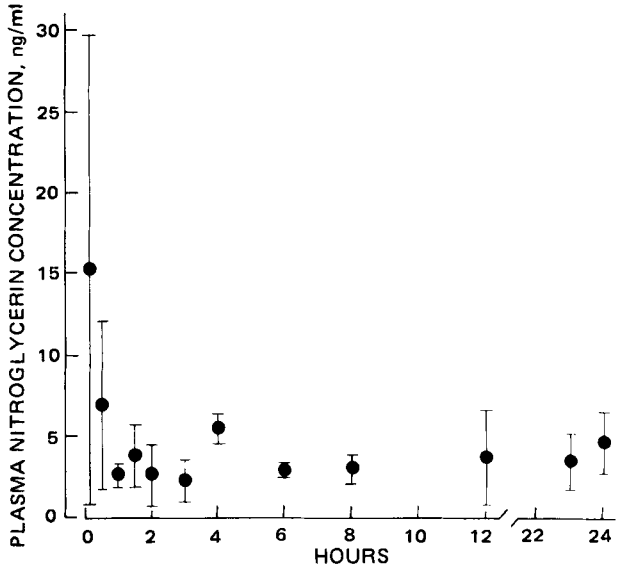

Figure 5—In vivo *nitroglycerin rectal delivery* via *osmotic minipump (inverted placement). Data represent mean* ± SD.

Calculation of Statistics—The area under the plasma concentration *versus* time curve (*AUC*) was computed using the spline method from a commercially available program with a desk top computer[7]. Residual area of *AUC* ($AUC_{t\to\infty}$) was estimated by C_t/k, where k was the first-order kinetic rate constant derived from linear least-square regression using the last three plasma concentrations of each experiment and C_t was the plasma nitroglycerin concentration at the last sampling time. The apparent bioavailability (F) after oral or rectal dosing was estimated by the traditional method of comparing the $AUC_{0\to\infty}$ to that of an equivalent intravenous dose. It is assumed here that the systemic clearance is independent of the route of administration. The apparent systemic clearance after intravenous bolus administration in rats has been found to be independent of dose from 0.15 to 2.5 mg/kg and has a value of 730 ± 241 ml/min/kg (mean ±*SD*, n = 26)[8].

Statistical analysis was performed using the unpaired t test and $p < 0.05$ was employed to establish statistical significance.

RESULTS AND DISCUSSION

Plasma nitroglycerin concentrations observed at various times after oral, rectal, and intravenous administration are shown in Fig. 1 (3.50-mg/kg dose) and Fig. 2 (1.75-mg/kg dose). Intravenous bolus doses of nitroglycerin at 3.50 mg/kg were found to be toxic to the animals, many of which exhibited immediate severe convulsions, presumably because of the extremely high initial concentrations. The intravenous curve shown in Fig. 1 was constructed, therefore, from the mean data of 1.75 mg/kg iv dose after correction for dose. It will be shown elsewhere[8] that the systemic intravenous nitroglycerin clearance in the rat is essentially concentration independent below its toxic dose.

Oral bioavailability of nitroglycerin at 3.50 mg/kg in aqueous solution was shown to be poor (Fig. 1). The apparent bioavailability was found to be ~2% at this dose (Table I), which agrees with data obtained previously at 7 mg/kg (2).

Three rectal lengths of exposure were used to determine the degree of avoidance of first-pass metabolism of nitroglycerin in the rat. In the first case, only one septum was affixed at the anus and the administered drug was allowed to spread unrestricted into the lower and upper intestines. In a preliminary experiment using a dye as a marker, it was noted that this mode of administration led to significant upward spreading of the rectal dose, presumably due to peristaltic movement of the GI tract. When nitroglycerin was given in this manner, the bioavailability was found to be 26.7 ± 7.0% (Table I) of a comparable intravenous dose. This bioavailability was ~15 times that of an oral dose, indicating that rectal dosing led to some avoidance of first-pass metabolism.

When the rectal dosing solution was restricted to a region no further than 3.5 cm from the anus, absorption of nitroglycerin was considerably improved but rather variable (Fig. 1). The terminal half-life obtained

after this mode of administration (16.5 ± 8.4 min, mean ± *SD*) appeared larger than, though not statistically different from, those observed after unrestricted rectal ($t_{1/2}$ = 10.1 ± 3.2 min) and intravenous administration (18.3 ± 6.1 min). Since the plasma clearance of nitroglycerin was shown to be independent of intravenous dose[8], it is unlikely that the systemic clearance of nitroglycerin has been altered with this mode of dosing. Any potential divergence in apparent plasma half-life in the present case might have arisen instead from differences in absorption rates among the treatments, since flip-flop kinetics might be operative after nonintravenous administration (2). Using these assumptions, the apparent bioavailability of nitroglycerin from this mode of rectal dosing (restricted, 3.5 cm) could be estimated as 83.8 ± 74.5% (Table I), which was ~3 times higher than that found in the case where the rectal solution was unrestricted.

Figure 2 shows the case in which the dose was restricted to the lowest 2.0 cm of the rectum. It is apparent that, except for the first time point, the rectal dose yielded similar plasma nitroglycerin concentrations compared to an equivalent intravenous dose. Indeed, the *AUC*'s calculated for these two routes of administration were not statistically different ($p > 0.05$). The bioavailability of this rectal mode of dosing was estimated at 91.2 ± 30.4% (Table I). The interanimal variability was noticeably smaller here than in the previous case where rectal exposure was set at 3.5 cm.

It is quite clear, then, that rectal administration of nitroglycerin in the rat leads to substantial avoidance of the first-pass metabolism of nitroglycerin. Consistent with anatomical prediction, this avoidance decreases when the rectal dose is exposed to the upper rectal area where drug can be adsorbed through the upper rectal veins and transported *via* the portal vein to the liver. It is believed that this is the first instance in which this suspected relationship of drug rectal length exposure to avoidance of first-pass metabolism has been clearly demonstrated.

A previous study has shown that instillation of lidocaine into the unrestricted rectum of rats led to near complete bioavailability of this drug (6). As far as can be determined, the present experimental procedure in the unrestricted rectum case was similar to that used by these authors, with the possibly important difference in the volume of rectal solution used. This study (6) used an instillation volume of 0.4 ml, whereas a volume of ~1.0 ml was used in the present study. The smaller volume used in the lidocaine study might permit less upward spreading of the dose, thus allowing more complete avoidance of first-pass metabolism. It is also possible that this apparent discrepancy may have arisen from the difference in the permeability and metabolic properties of the drugs themselves.

The osmotic minipump has been reported to produce sustained zero-order drug delivery *in vivo* (23). This particular experimental device was tested to explore whether rectal delivery of nitroglycerin can produce almost complete bioavailability as well as sustained plasma drug concentrations over a 24-hr period. When these minipumps were filled with a propylene glycol solution of nitroglycerin (an aqueous solution was impossible because of solubility limitations), the *in vitro* release was shown to be zero-order in nature (Fig. 3). Preliminary trials of these minipumps inserted into the animal in the upright position showed them to be ineffective in producing sustained plasma nitroglycerin concentrations (Fig. 4). Since zero-order delivery of drugs from the osmotic minipump depends, among other factors, on an unobstructed aperture in the pump itself, fecal materials which might have been deposited on the aperture could interfere with drug delivery. When the osmotic minipump was inverted so that the pump aperture now pointed toward the anus (which was sealed with a septum), the desired pharmacokinetic release profile was observed. Figure 5 shows the mean (±*SD*) plasma concentrations of nitroglycerin over 24 hr after insertion of the rectal osmotic minipumps in the inverted position in four rats. Although these pumps had been pre-equilibrated in saline at 37° for at least 36 hr (during which time the *in vitro* release rate was determined), an initial burst of nitroglycerin release was observed upon insertion of those devices. However, the plasma nitroglycerin concentrations from 1 to 24 hr after rectal pump insertion were quite stable (Fig. 5 and Table II).

It was noted that the *in vitro* drug release rate of the minipumps was quite variable. The reasons for this variability are not known presently. The *in vivo* release rate of each minipump could not be measured directly but could be approximated by the equation $k_0 = C_{ss}Cl$ where C_{ss} is the measured mean steady-state plasma nitroglycerin concentration in each animal and Cl is the systemic clearance of nitroglycerin (which averages 241 ml/min/300-g rat). Based on the mean values (Table II) the estimated *in vivo* release rates for the osmotic pumps appeared similar to the measured *in vitro* rates. This agreement suggests that near complete bioavailability can be achieved with this mode of rectal dosing. It would appear then that the experimental osmotic pump, when placed in the inverted position, can provide both sustained and complete delivery of nitroglycerin *via* the rectal route.

CONCLUSIONS

The present studies showed that rectal dosing of nitroglycerin in rats can lead to substantial avoidance of first-pass metabolism. If the nitroglycerin dose can be restricted to the lower rectum, this avoidance can be made complete. It has been shown that an experimental osmotic pump is capable of producing sustained and apparent zero-order release of nitroglycerin over a 24-hr period. Since the degree of avoidance of first-pass metabolism from rectal administration is somewhat less in humans when compared to the rat (5, 6), the applicability of the present findings to rectal absorption of nitroglycerin in humans has to be validated.

A GLC–Nitrogen Phosphorous Detector Assay for Trifluoperazine in Plasma

R. M. H. ROSCOE, J. K. COOPER, E. M. HAWES, and K. K. MIDHA ˣ

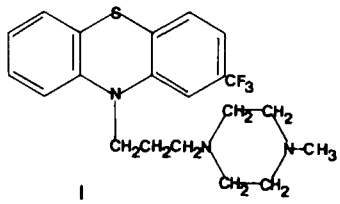
Received May 29, 1981, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0, Canada.* Accepted for publication September 11, 1981.

Abstract □ A GLC–nitrogen phosphorous detector (NPD) method for the quantitative determination of trifluoperazine in plasma is described. It depends on an organic extraction of trifluoperazine and the internal standard prochlorperazine from basified plasma. Following the extraction, the organic solvent is evaporated to dryness and the residue is reconstituted in a small volume of methyl alcohol. GLC analysis of aliquots of the methanolic solution using a NPD permitted the determination of 0.5 ng/ml of trifluoperazine in plasma. Standard curves for trifluoperazine over a concentration range of 0.5 to 15 ng/ml of plasma were linear with an overall variation coefficient of 5.3%. In isolated samples obtained from a normal healthy volunteer, application of this method to plasma concentration determinations after oral administration of a 5-mg trifluoperazine tablet, is demonstrated and compared with the concentrations obtained by GLC–mass spectrometry and radioimmunoassay procedures.

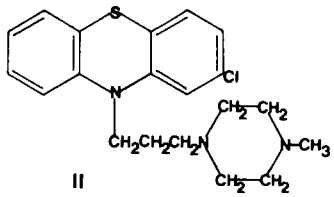
Keyphrases □ Trifluoperazine—GLC–nitrogen phosphorous detector analysis in human plasma □ Prochlorperazine—GLC–nitrogen phosphorous detector analysis of trifluoperazine in human plasma □ GLC–Nitrogen phosphorous detector—analysis of prochlorperazine in human plasma

Since the introduction of the major tranquilizers in the early 1950's, the phenothiazines with the piperazine ring system have been widely used. Over the past 25 years, several publications (1–5) have been concerned with the quantitation of chlorpromazine in biological fluids; however, the analysis of piperazine containing phenothiazines has been more difficult. Being therapeutically more potent, these antipsychotic drugs are administered in much smaller doses than chlorpromazine. Like chlorpromazine, these agents undergo extensive metabolism leading to numerous metabolites, several of which are pharmacologically active. These drugs are also subject to extensive first-pass (gut wall and/or hepatic) biotransformation. Other properties of these drugs include large interindividual variations in plasma levels following identical doses to volunteers or patients, extensive binding to multiple sites, large volumes of distribution, and their extreme instability in all stages of handling during analysis (4–7). Published reports indicate that the plasma concentrations of these piperazinyl phenothiazines in patients are much lower than those encountered with chlorpromazine. Thus, sensitivity requirements for these drugs are more stringent than those for the assay of chlorpromazine (8–10).

The techniques which may have the sensitivity for the quantitation of chlorpromazine and other antipsychotics include GLC–nitrogen phosphorous detector (NPD), GLC–electron capture detector (ECD), GLC–mass spectrometry (MS), HPLC–UV, HPLC–spectrofluorometric detector (SPF), and other procedures such as radioimmuno- and radioreceptor assays. For the orally administered antipsychotic agent, trifluoperazine, only the radioimmunoassay and GLC–MS methods of Midha *et al.* (11, 12) have demonstrated the necessary sensitivity to follow plasma concentration–time profiles following the



I



II

administration of single 5-mg doses of trifluoperazine in healthy human volunteers. These procedures are capable of quantitating plasma trifluoperazine concentrations in specimens collected as late as 24 hr postadministration of trifluoperazine.

A new GLC method for trifluoperazine (I) based on an organic extraction of basified plasma and quantitation using a more conventional NPD system with prochlorperazine (II) (the 7-chloro analog of trifluoperazine) as internal standard is described. Trifluoperazine in the concentration range 0.5–15 ng/ml of plasma can be quantitated in this method with an overall variation coefficient of 5.3%.

EXPERIMENTAL

Materials—Trifluoperazine dihydrochloride[1], *N*-desmethyltrifluoperazine dimaleate[1], trifluoperazine sulfoxide[1], 7-hydroxytrifluoperazine[1], and prochlorperazine dimaleate[2] were generously donated.

Heparinized evacuated tubes[3] were commercially obtained. All solvents used were HPLC grade, and all other chemicals were commercial analytical grade, used without further purification.

The assay was done in subdued light. Standard solutions of trifluoperazine, trifluoperazine metabolites, and prochlorperazine were prepared by dilution in ethanol and/or double distilled water. Appropriate dilutions of the standard solutions were made in outdated human plasma[4].

Plasma Level Study—A normal, healthy male volunteer (57 kg) fasted overnight was given a single 5-mg commercial trifluoperazine tablet orally[5]. Blood samples (10 ml) were withdrawn from the cubital vein into heparinized evacuated tubes, centrifuged, and separated plasma was stored at −4° for a maximum period of 7 days. During blood sample collection, care was taken to avoid contact of the blood with the rubber stopper of the evacuated tube.

Extraction of Trifluoperazine—One milliliter of aqueous internal

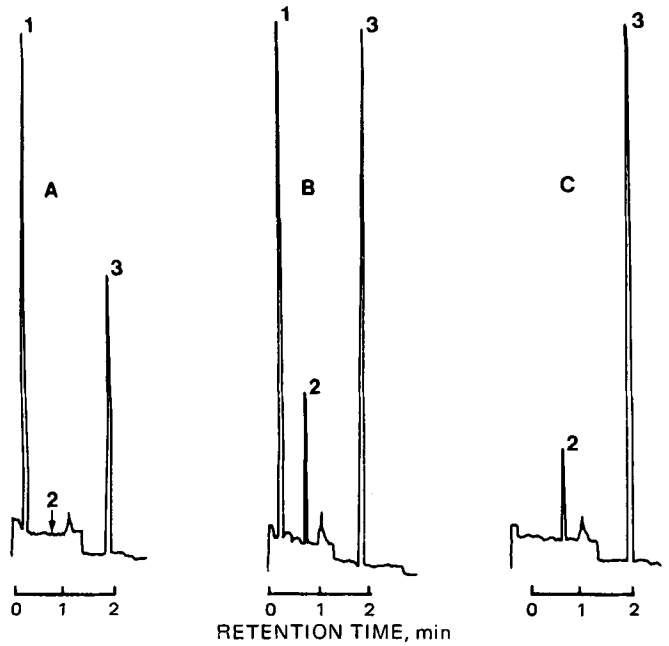

Figure 1—*GLC–NPD chromatogram of: (A), extracted blank human plasma; (B), extracted human plasma spiked with 2.5 ng/ml of trifluoperazine; (C), extracted plasma obtained from human volunteer 2.0 hr following the administration of 5 mg of trifluoperazine. (1, caffeine; 2, trifluoperazine; 3, prochlorperazine.)*

standard solution of prochlorperazine (100 ng/ml) and 0.5 ml of 10 *N* NaOH were added to a 2-ml plasma sample (spiked or from dosed volunteer) in a 10-ml polytef-lined screw-capped test tube. The sample was gently mixed[6] and 5 ml of *n*-pentane–isopropyl alcohol (50:1) was added. The tube was tightly capped and the drug and the internal standard were extracted from plasma by first mixing[7] for 15 min and then centrifuging[8] for 15 min at room temperature at 1720×*g*. Following centrifugation, ~4 ml of the upper organic layer was transferred with the aid of a disposable Pasteur pipet to a fresh tube, taking extreme care not to contact the organic–aqueous interface. The organic extract was evaporated[9] almost to dryness at 55°. The sides of the tube were washed down with ~1 ml of the extracting solvent and the contents re-evaporated[9] to dryness. The residue was then reconstituted in the same tube with 25 μl of methyl alcohol by mixing[6] and aliquots of 2–4 μl were injected into the gas chromatograph.

GLC—The gas chromatograph[10] was equipped with a nitrogen phosphorous detector. The column was a coiled glass tube[11], 1.8 m long × 2-mm i.d., packed with 3% phenyl methyl silicon[12] coated on acid-washed, dimethylchlorosilane-treated 100–120 mesh high-performance, flux-calcined diatomite support[13].

The column was conditioned at 335° for 12–24 hr with a low helium flow. For plasma analysis, the injection port, detector block, and column oven temperatures were 300, 300, and 310°, respectively. Helium was used as a carrier gas at a flow rate of 30 ml/min. Hydrogen and air flow rates and NPD bead voltages were optimized for maximum response at electrometer settings of 3 or 4.

Calculations—Peak height ratios were calculated by dividing the height of the peak due to trifluoperazine (0.89 min) by that of prochlorperazine, the internal standard (1.90 min). Calibration curves were constructed by plotting the spiked control plasma peak height ratios against the concentrations of trifluoperazine (nanograms per milliliter of plasma).

RESULTS AND DISCUSSION

Under the chromatographic conditions described previously, trifluoperazine and the internal standard prochlorperazine gave sharp and symmetrical peaks with retention times of 0.89 and 1.90 min, respectively. Figure 1A shows a typical chromatogram obtained by processing control blank plasma which contained 50 ng/ml of the internal standard, prochlorperazine. No extraneous peak at the retention time of trifluoperazine was observed. A chromatogram obtained when the method was applied to spiked human plasma containing 2.5 ng/ml of trifluoperazine and 50 ng/ml of the internal standard is shown in Fig. 1B. In the blank and spiked plasma (Fig. 1A, 1B) a sharp peak which had an identical retention time to caffeine was obtained. Caffeine was extracted in the procedure used, and because of the presence of four nitrogen atoms it gave a good response to the NPD.

Figure 1C shows a chromatogram of the plasma sample (2 ml) from blood withdrawn from a male volunteer (57 kg) at 2.0 hr after oral administration of a 5-mg commercial tablet. This sample was estimated to contain 1.45 ng/ml of trifluoperazine. There was no peak due to caffeine, since the subject was asked to withdraw from caffeine-containing beverages and food. A chromatographic analysis time of ~2 min was required for each sample.

The use of a mixed organic solvent system of *n*-pentane and isopropyl alcohol provided quantitative extraction of the drug and the internal standard in one step from basified plasma. The overall recoveries of trifluoperazine and prochlorperazine were of the order of 102.3 ± 3.6 and 90.7 ● 2.8%, respectively, as reported earlier (12). The use of isopropyl alcohol not only provides the necessary polarity needed for the quantitative extraction of the drug and the internal standard, it also retards the adsorption of these basic drugs onto the glass surface during extraction. It was also found useful to keep the concentration of the internal standard high, as the prochlorperazine competes with the drug for the adsorption sites on the glassware used for extraction. This type of observation has been made earlier with the structurally similar drug chlorpromazine (13), where it was found necessary to use very high concentrations of the internal standard mesoridazine.

The important metabolites of trifluoperazine, which are extracted under the conditions described previously, did not interfere in this procedure. These metabolites elute with retention times different from that of the drug and the internal standard. Figure 2 shows the chromatographic separation of these metabolites, *i.e.*, *N*-desmethyltrifluoperazine, 7-hydroxytrifluoperazine, and trifluoperazine sulfoxide, from trifluoperazine and the internal standard prochlorperazine. Trifluoperazine sulfone also did not interfere, as it was found to elute after the trifluoperazine sulfoxide.

After repeated injections into the gas chromatograph, an uneven response from the NPD was observed, which led to reduced sensitivity as well as the ratios of peak heights of the drug and the internal standard becoming irreproducible. This generally required readjustment of the NPD bead voltage or installation of a new bead.

An interesting problem of interference with respect to trifluoperazine was observed in the present GLC–NPD assay. If the plasma samples were prepared from blood collected in the heparinized brand of evacuated tubes[3], an interfering peak with nearly the same retention time as trifluoperazine was observed in the chromatograms. The interference, often observed as a double peak was small but significant. This was overcome by employing a different brand of evacuated tubes[14]. Some additional experimentation revealed that the interfering material was alkaline and aqueous soluble; however, positive chemical identification attempts by mass spectrometry were not successful. It should be noted that although the plasticizer effect (14) with trifluoperazine is not as significant as with other phenothiazines, care must be exercised during the collection of blood by evacuated tubes to see that the blood does not come in contact with the rubber stopper.

The accuracy and precision of the GLC–NPD assay are demonstrated in Table I. Results are based on six determinations of each concentration of trifluoperazine, ranging from 0.5 to 15 ng/ml of plasma. The overall variation coefficient was 5.3%. The calibration curve obtained by plotting the peak height ratio of the trifluoperazine and prochlorperazine *versus* the concentration of trifluoperazine was linear over the 0.5–15.0-ng range of the drug/ml of plasma. A mean slope value of $0.1003x + 0.0035$ ($r^2 = 0.9996$) was obtained.

The application of the present method to plasma concentration determinations is shown in Table II, where the values obtained by the present method are given along with those obtained by GLC–MS and radioimmunoassay procedures. Because of the sensitivity limitations of the GLC–NPD assay, only concentrations around the peak times are shown from one volunteer. The GLC–NPD values compare well with the GLC–MS method; however, the radioimmunoassay gives values that are slightly higher than those obtained with the chemical methods. This is probably due to the cross-reactivity of the antiserum to the 7-hydroxy and *N*-desmethyl metabolites of trifluoperazine (11).

Table II—Comparison of Plasma Trifluoperazine Concentrations Determined by Three Different Methods

Subject Plasma Sample, hr	Trifluoperazine Plasma Concentration		
	GLC-NPD, ng/ml	Radioimmunoassay, ng/ml	GLC–MS, ng/ml
2.0	0.88	1.00	0.80
3.0	0.91	1.09	0.93
4.5	0.73	1.13	0.71

In conclusion, the described procedure is simple and specific for trifluoperazine. It may not have the sensitivity for single-dose pharmacokinetics and bioavailability studies for the drug, however, steady-state monitoring can be easily carried out. This procedure can also be easily adopted for the quantitative determination of prochlorperazine by using trifluoperazine as the internal standard. The other phenothiazine drugs which have been tested for plasma extraction and sensitivity are promazine, chlorpromazine, butaperazine, and promethazine. Thus, the described procedure has the potential for its applicability in the quantitative analysis of these drugs.

Pectin–Gelatin Complex Coacervates I: Determinants of Microglobule Size, Morphology, and Recovery as Water-Dispersible Powders

JEAN N. McMULLEN *x, DAVID W. NEWTON ‡, and CHARLES H. BECKER §

Received March 9, 1981, from the **Faculty of Pharmacy, University of Montreal, Montreal, Canada H3C 3J7;* the ‡*Department of Pharmaceutics, College of Pharmacy, University of Nebraska Medical Center, Omaha NE 68105;* and the § *College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication September 3, 1981.

Abstract □ The pectin–gelatin complex coacervate system was evaluated and characterized. The effects of final pH, mixing pH, colloid ratio, and solution concentration were investigated. A recovery procedure yielding microglobules of a controlled and uniform size in dry powder form which were readily revertible in water to a polydispersed suspension was developed. The effect of various conditions and additives on the recovery morphology and size of the microglobules was evaluated.

Keyphrases □ Coacervate system—pectin–gelatin complex, final pH, mixing pH, colloid ratio, solution concentration □ Microglobules—pectin–gelatin, suspension in water, dry powder recovery system □ Pectin–gelatin system—microglobules, effects of final pH, mixing pH, colloid ratio, solution concentration

The complex ionic relations of the gelatin–acacia coacervate system have been established and reported previously (1–3) and have been used successfully in the microencapsulation of solids as well as liquids (4–10). Until recently (9), it was difficult to control the morphological characteristics of and recover a free-flowing powder of unagglomerated microglobules which were spontaneously dispersible in aqueous solutions. Therefore, it seemed desirable to develop a complex coacervate system from pectin and gelatin capable of yielding spherical globules of a uniform size that could be controlled for possible application as a pharmaceutical delivery system in parenteral or other products.

Although complex coacervation of the gelatin–pectin system was initially reported by Bungenberg de Jong (1) and employed as the basis of one patent in 1966 (11), the system has apparently received no further attention until this study. Studies of pectin–albumin (12) and pectin–polyethylenimine (13) have, however, been reported. This study was, therefore, undertaken to evaluate and characterize the fundamental complex ionic relations between the amphoteric protein, type A gelatin, and the low equivalent weight anionic colloid, pectin, with special emphasis on the effects of pH of coacervation (pH_c), mixing pH (pH_m), colloid ratio, and solution concentration on microglobule morphology, size, percent yield, and recovery technique yielding a free-flowing powder which was redispersible in water.

EXPERIMENTAL

Materials—Type A gelatin[1] and pectin, NF[2], were used in solutions containing 1% (w/w) benzyl alcohol for preservation. Formaldehyde solution, USP, glycerin, 99.6%, and isopropyl alcohol, 99%, were used in the recovery of microglobules in dry powder form. These and other reagents were of analytical reagent grade and were used as received.

Preparation and Recovery of Coacervates—Coacervates were prepared at 45° from 40.0-g batches stirred by means of a magnetic stirrer and polytef-coated bar at a speed sufficient to produce a vortex without entrainment of air bubbles. Stock pectin and gelatin solutions of the same weight concentration were prepared by dispersing the colloids in cold water, stirring for 30 min in a water bath at 45° and storing at 5° for no more than 24 hr before use. Appropriate weights of stock solutions of the same concentration were individually adjusted[3,4] to the mixing pH with 1.0 *N* NaOH at 45° to give the desired pectin to gelatin ratio. The gelatin solution was added to the pectin solution with stirring, and after 2 min the pH was lowered by fast addition of 0.5 *N* HCl to pH 5, then by slower addition of 0.5 *N* HCl until the desired pH_c was reached. The batch was stirred for 30 min then 5 ml of 37% (w/w) HCHO was added with stirring. After 30 min of stirring under ambient conditions, the batch was covered with paraffin film and allowed to stand for 15–20 hr. The batch was then

Table I—Effect of pH_m on Diameter of Spherical Microglobules Produced from Isovolumetric Coacervates of 2% (w/w) Pectin (20 ml) and Gelatin (20 ml) Solutions Adjusted to pH_c 3.8 at 45°

pH_m	Diameter of Microglobules, ≤μm
3.80	0.5
5.85	1.1
6.51	1.4
6.98	2.0
8.06	3.9
9.01	5.4
9.49	7.3
10.04	10.0

stirred to resuspend any sedimented microglobules, and 40 g of the suspension was centrifuged at 1000–2000 rpm for 15–60 min, depending on microglobule size and morphology. The supernate was then decanted. The microglobules were resuspended in 5 ml of glycerin with a vortex mixer and 35 ml of isopropyl alcohol or other flocculating agent was slowly added while mixing. The flocculated microglobules were then filtered using a Buchner funnel and filter paper[5], washed with two 100-ml portions of isopropyl alcohol and dried for 15–20 hr in an oven at 36 ±1°.

Effect of Colloid Concentration—Pectin and gelatin solutions of 1.0, 1.5, 2.0, 2.5, and 3.0% (w/w) concentration were used. Batches were prepared by combining 20-g portions of each solution in order to give a colloid ratio of 1:1 (w/w). Coacervation was carried out for three pH_m values, 8.0, 9.0, and 10.0, over a pH_c range of 5.0–2.6, and evaluated for weight percent yield and microglobule morphology at 1000× under a microscope.

Effect of Colloid Ratio—Pectin to gelatin colloid ratios >1:1 were not studied because the average size of microglobules produced was <1 μm and, consequently, difficult to recover in dry form. The pectin–gelatin ratios studied, at a 2% (w/w) total colloid concentration, were 15, 25, 30, 33, 40, and 50% pectin fractions of total colloid. Coacervation was carried out according to the pH_m and pH_c conditions listed above. Microglobule morphology and weight percent yield were evaluated.

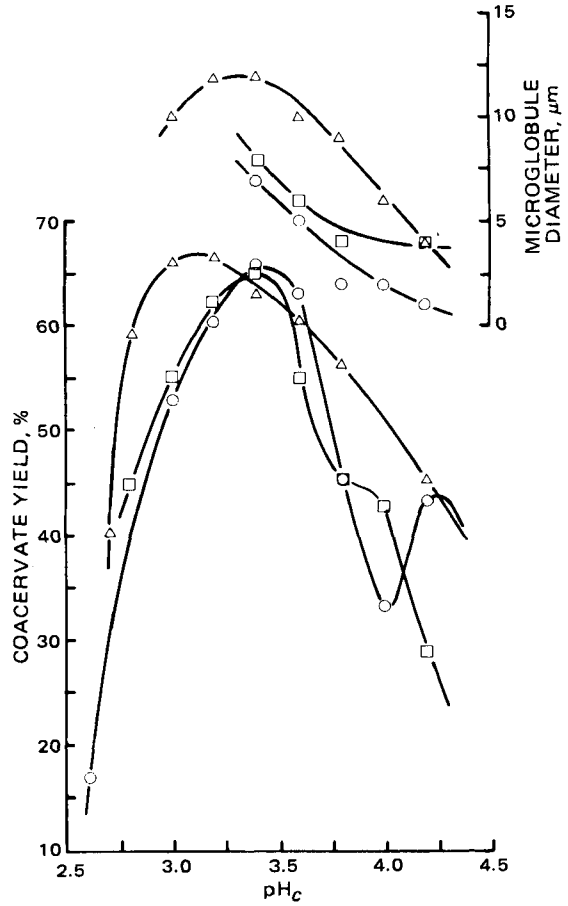

Figure 3—*Coacervate yield (left ordinate) and microglobule diameter (right ordinate)* versus *pH_c for isogravimetric (20 g) 2% (w/w) gelatin and pectin solutions adjusted to pH_m values of 8.0, 9.0, and 10.0. Key: ○, pH_m = 8.0; □, pH_m = 9.0; △, pH_m = 10.0.*

Effect of Additives on Recovery—Batches weighing 40.0 g were prepared from 2.0% (w/w) solutions to give a pectin–gelatin mixing ratio of 33:67%, and adjusted to a pH_m of 10.0 and pH_c of 4.5.

Glycerin volumes of 5, 10, 15, 20, 25, and 30 ml were slowly added to individual batches while mixing, with stirring at 45° after achieving pH_c 4.5.

Volumes of 37% (w/w) HCHO (adjusted to pH 5.0) of 2.5, 5.0, 7.5, 10.0, 12.5, and 15.0 ml were added to individual batches at 20° after achieving pH_c 4.5. The effect of formaldehyde treatment time was determined by adding 15 ml of 37% (w/w) HCHO and stirring for 1, 3, 7, 9, 12, 24, 36, and 54 hr.

Glycerin, propylene glycol, polyethylene glycol, 50% (v/v) isopropyl alcohol in distilled water, and distilled water were evaluated as redispersing media. Volumes of 5 ml of each were added to individual batches after centrifugation and decantation of the supernate.

The effect of various water miscible flocculating agents was determined by adding to individual batches 35 ml of isopropyl alcohol, 1-propanol, ethanol, methanol, and acetone.

All batches studied for the effect of additives on recovery were evaluated as to their dry product characteristics, such as coherence and friability, and redispersibility in distilled water.

RESULTS AND DISCUSSION

Until the effect of pH_m was elucidated, previously reported complex coacervation procedures, particularly for the gelatin–acacia system, were applied to the gelatin–pectin system with little success. Some results of this exploratory phase are summarized in Table I. As reported previously (14), mixing of isohydric solutions (pH 3–4) does not change the system pH significantly, a fact demonstrated in this study but also one that

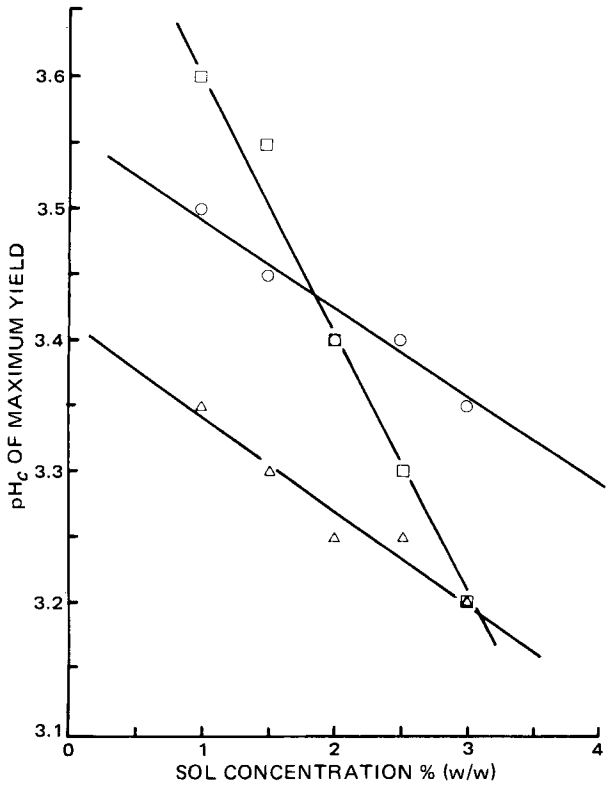

Figure 4—*pH_c of maximum microglobule yield* versus *total colloid concentration in pectin–gelatin (1:1) coacervates prepared from solutions adjusted to pH_m values of 8.0, 9.0, and 10.0. Key: ○, pH_m = 8.0; □, pH_m = 9.0; △ pH_m = 10.0.*

yielded such small globules as to be hardly resolvable under the microscope at 1000×. The method of Luzzi (4), mixing of isohydric (pH 6.5), isovolumetric solutions then adjusting the pH of the mixture with acid to the desired endpoint (pH 3.8), resulted in a marked increase in globule diameter to ~1 μm. The method of Newton (9), mixing of isovolumetric solutions, gelatin (pH 10) and pectin (pH 3.6), then adjusting the pH of the mixture with acid to the desired endpoint (pH 3.8), gave comparable results. These results suggested the possible involvement of the mixing pH in the control of microglobule size which was confirmed in a series of experiments where isohydric, isovolumetric solutions were adjusted to pH 7.0, 8.0, 9.0, 9.5, and 10.0 before mixing and coacervation to pH 3.8. The mean globule size increased from 2 to 10 μm as the mixing pH was increased from 7–10 (Table I).

Volume measurements of coacervate phases were impractical due to the noncoalescence of the globules into a continuous phase. A comparison of sediment volume of microglobules after centrifugation with yield based on dry weight as a function of pH_c is given in Fig. 1. The increasing sediment volume at pH_c <3.4 is attributed to a change in morphology from globular to elliptical particles having a lower packed density and greater hydration. Therefore, dry weight recovery was adopted to measure microglobule yields in all subsequent experiments.

Effect of Colloid Concentration—The results of studies to determine the effects of total colloid concentration on coacervate yield for solutions having equal concentrations of pectin and gelatin showed that maximum yield was obtained at a total colloid concentration of ~2% (w/w) for the mixing of isohydric, isogravimetric solutions coacervated to pH_c 3.5 (Fig. 2). The increasing efficiency of coacervation with increasing total colloid concentration up to a maximum of ~2.0% probably resulted from increased reactivity of the gelatin and pectin linear molecules as the forces of intramolecular aggregation limiting their movement were minimal. Above 2% (w/w) of total colloids, the decreasing efficiency of coacervation arises from an increasing salt or gegenion (*e.g.*, Na^+, Ca^{2+}, Cl^-) concentration which insulates the oppositely charged colloids, suppressing coacervation and increasing the mutual solubilities of the coacervate and equilibrium solution phases (14).

Figure 3 shows the relationship for the 2% colloid concentration between percent yield[6] and microglobule morphology as a function of pH_c

[6] Expressed as percent (w/w) of the total mass of pectin and gelatin in the coacervate system.

Table II—Effect of Glycerin on the Morphology and Powder Characteristics of Pectin–Gelatin Microglobules Recovered from Coacervate Systems Prepared from 2% (w/w) Pectin–Gelatin (33:67) at pH_m 10.0 and pH_c 4.5

for pH_m values of 8.0, 9.0, and 10.0. Microglobule size increased as the pH_c decreased, until the maximum yield was reached, at which point the shape was transformed from spherical to ellipsoidal or amorphous.

The dependence of microglobule size on pH_c at fixed pH_m likely arises from the fact that as the pH_c is lowered, the relative ratio of pectin to gelatin increases in the coacervate. Furthermore, the more intense complex ionic relations of the pectin–gelatin *versus* the acacia–gelatin system would cause a greater coacervate reduction in the water content of the coacervate and a total coacervate colloid concentration >10%, a value reported for the gelatin–acacia system (15), thereby affecting droplet size and solubility[7].

As the system is adjusted to lower pH_c, the number of anionic charges on pectin decreases while the number of cationic charges increases on gelatin, resulting in more and more pectin being required for an equivalent union with gelatin. Therefore, at high pH_c values, the combination of both a high total colloid concentration and a low pectin–gelatin ratio in the coacervate resulted in stabilization of the coacervate drops as a result of a high viscosity and partial gelling of the microglobules precluding their coalescence. As the pH_c was lowered, the pectin–gelatin

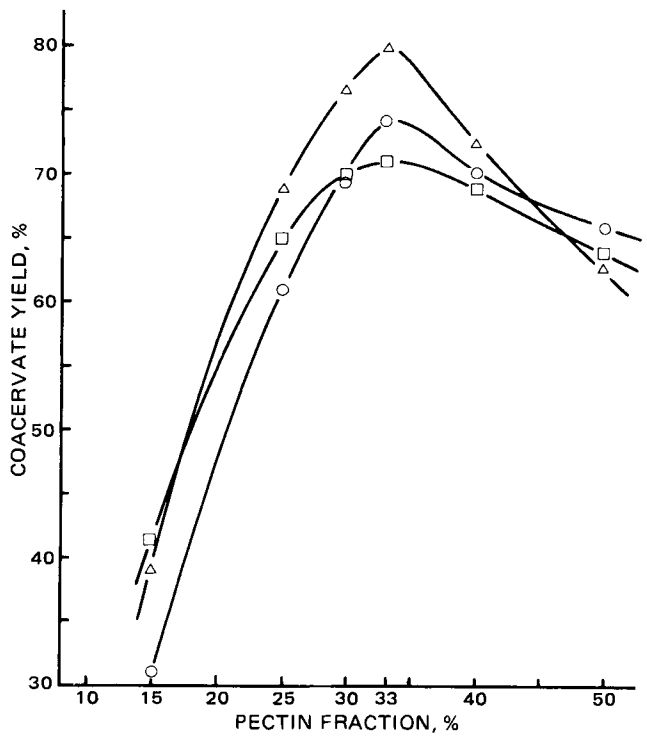

Figure 5—*Coacervate yield* versus *pectin–gelatin and pectin solutions adjusted to pH_m values of 8.0, 9.0, and 10.0 and coacervated to pH_c 3.5. Key: ○, pH_m = 8.0; □, pH_m = 9.0; △, pH_m = 10.0.*

[7] The lower the equivalent weight of anionic colloid the higher is its charge density and, thus, the stronger are its complex ionic relations with cationic gelatin. The equivalent weights of acacia and pectin (pectate) are 1200 and 200, respectively (1, 15).

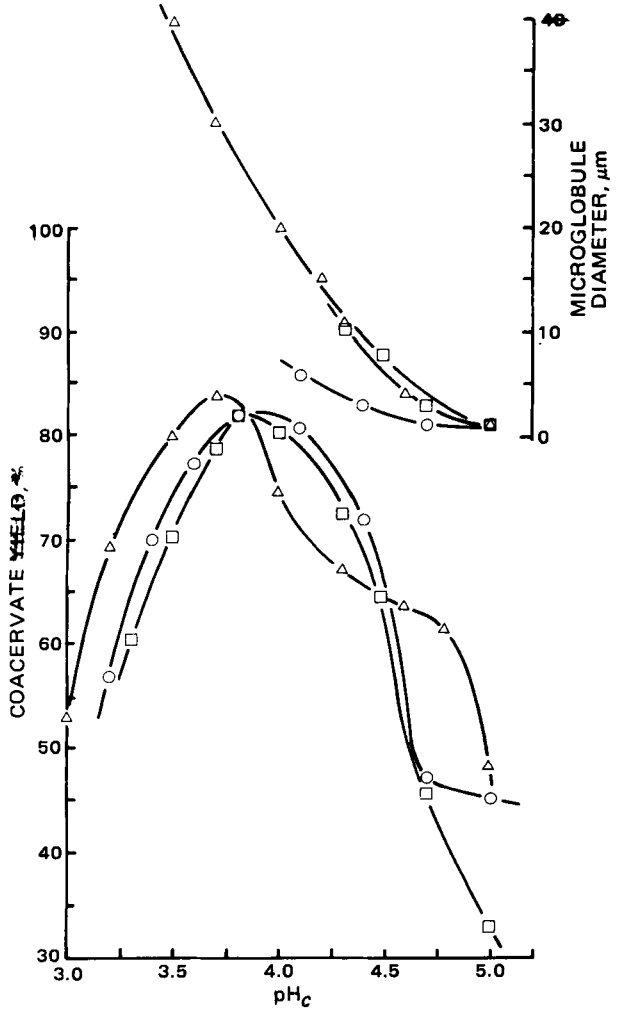

Figure 6—*Coacervate yield (left ordinate) and microglobule diameter (right ordinate)* versus *pH_c for coacervate systems prepared from a 33:67 gravimetric ratio of 2% (w/w) pectin and gelatin solutions, respectively, adjusted to pH_m values of 8.0, 9.0 and 10.0. Key: ○, pH_m = 8.0; □, pH_m = 9.0; △, pH_m = 10.0.*

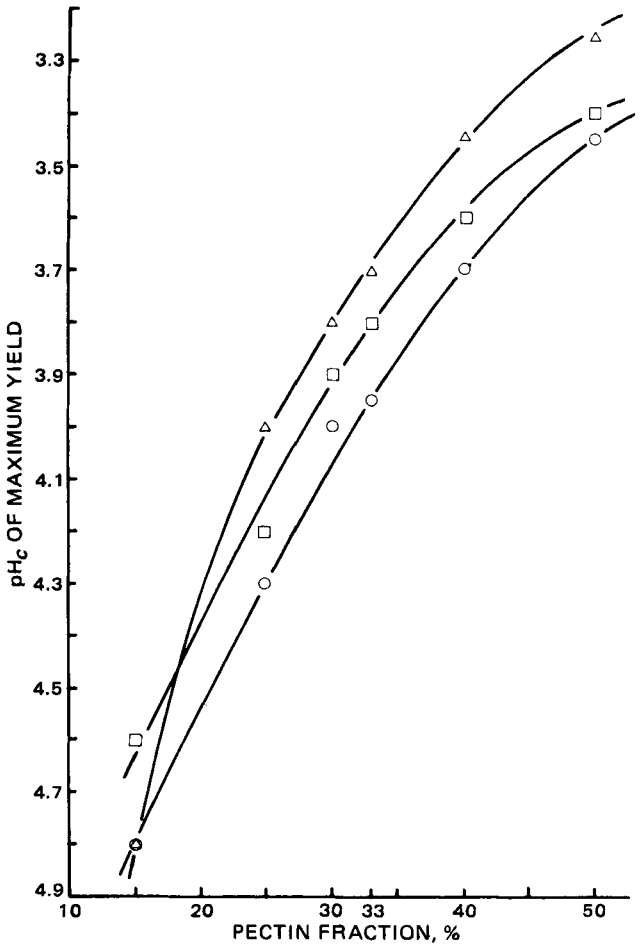

Figure 7—*pH_c of maximum yield* versus *pectin weight fraction of total colloid in coacervates prepared from 2% (w/w) gelatin and pectin solutions adjusted to pH_m values of 8.0, 9.0, and 10.0. Key: ○, pH_m = 8.0; □, pH_m = 9.0; △, pH_m = 10.0.*

ratio in the coacervate increased allowing microglobule growth to proceed further before an equilibrium sphere occurred at a higher equilibrium size.

Microglobule size increases with decreasing pH_c and with increasing pectin–gelatin ratio in the coacervate, probably as a result of increasing coacervate viscosity until the stabilizing forces become too weak to prevent deformation of the microglobules by the stirring forces. This results in ellipsoidal particles which cannot readily return to the spherical state because of their very viscous and gel-like state and finally amorphous particles as a result of agglomeration and partial coalescence of ellipsoidal particles. The microglobules are further stabilized from coalescing into a single phase by the anionic charge they acquire as they form above the optimum pH_c. As for the gelatin–acacia system (16), as the PH_c is lowered, the net charge on the microglobules remains negative because of the predominance of dissociated carboxylate groups on pectin and gelatin as opposed to cationic amino groups on gelatin.

The pronounced effect of pH_m on microglobule morphology is probably related to the pectin–gelatin ratio in the coacervate and the gegenion concentration. It has been reported that pectin molecules in solution exist in a high state of aggregation in solutions >0.1%, as a result of suppressed ionization of carboxyl groups (17). It was found through titration and pH *versus* viscosity studies of 2% solutions at 45° that some carboxyl groups are not readily ionizable until pH 7.5, above which such solutions show a sharp decrease in viscosity, which can be attributed to increased repulsive forces tending to further lower the degree of aggregation. Therefore at pH_m 8.0 in 2% (w/w) solutions, the reactivity of pectin with gelatin is limited by the higher degree in intramolecular aggregation as compared to that at higher pH_m, *i.e.*, 9.0 or 10.0. Subsequently, this results in a lower pectin–gelatin ratio at pH_c. As the pH_m is raised >8, deaggregation of pectin increases, permitting more pectin molecules to react with gelatin molecules and microglobules and higher yields.

Figure 4 indicates that as the solution concentration increases, the pH_c of maximum coacervation decreases; an observation also made previously (14) for gelatin–acacia coacervates. Again, as the concentration of solutions increases, so does that of the accompanying gegenions which suppress coacervation. Hence, pH_c must be lowered to increase the cationic charge on gelatin, while causing a smaller decrease in the anionic charges on both pectin and gelatin.

As expected, there was a linear relationship between the volume of 0.5 *N* HCl added and pH_c, verifying that the complex ionic relations between pectin and gelatin were stoichiometric and rapid (9, 18).

Effect of Colloid Ratio—On the basis of results obtained in studies of the optimum total colloid concentration to maximize microglobule yield, 2% (w/w) was used in evaluating the effect of varying pectin–gelatin ratios of 15:85, 25:75, 33:67, 40:60, and 50:50. Figure 5 indicates that the maximum yield was obtained at a colloid ratio of pectin–gelatin (33:67)

Table III—Flocculation Rates by Four Alcohols and Acetone of Coacervate Microglobules Prepared from 2% (w/w) Pectin–Gelatin (33:67) at pH_m 10.0 and pH_c 4.5

Flocculating Agent	Relative Flocculation Rate[a]	Product Characteristics[b]

Isopropyl alcohol	4	C, D
Ethanol	3	G, N
Methanol	2	F, N
Acetone	1	F, N

[a] Rate increases from 5 to 1. [b] C, coarse powder; D, spontaneously dispersible to individual spheres in water; G, granular powder; N, not dispersible as individual spheres in water; F, fused filter cake mass.

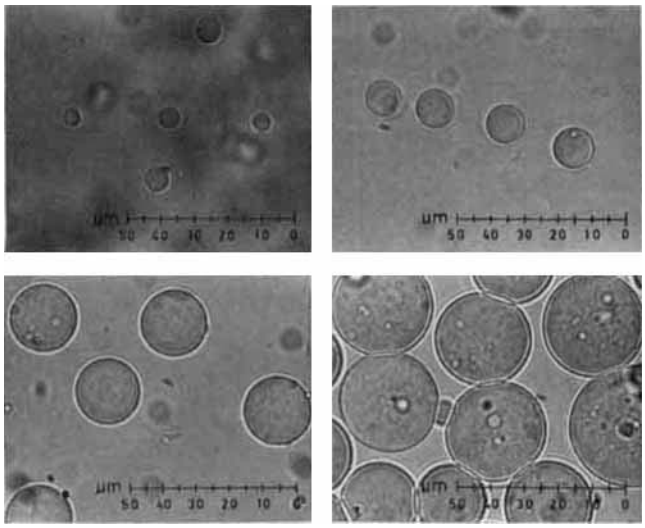

Figure 8—*Pectin–gelatin microglobules having nominal diameters of 5, 10, 20, and 30 μm.*

for the mixing of isohydric solutions coacervated to a pH_c of 3.5. The percent yields of microglobules ranged from ~70–80% of total colloids available, indicating a high reactivity in the complex coacervate system.

The fact that at a 15% pectin fraction the maximum yield was higher than expected is misleading because the microglobules or amorphous particles obtained were highly vacuolated, containing uncoacervated colloid-rich liquid, referred to as hollow spheres (19).

Figure 6 demonstrates the relationship for 2% (w/w) solutions between percent yield, microglobule diameter, and pH_c for pectin–gelatin colloid ratios of 33:67 at pH_m values of 8.0, 9.0, and 10.0. The microglobule diameter increased by ~3.3 μm/0.1 pH unit decrement, *i.e.*, from 20–40 μm as pH_c was lowered from 4.0 to 3.6 at pH_m 10.0. Microglobule diameter increased proportional to increasing pH_m and decreasing pH_c probably for the same reasons previously discussed. At $pH < pH_c$ of maximum yield, the globules became elliptical and amorphous.

Figure 7 shows that as the pectin fraction increased in coacervate systems of 2% (w/w) colloid concentration, the pH_c of maximum coacervation decreased from pH_m 8.0, 9.0, and 10.0.

Figure 8 shows typical microglobules having nominal diameters of 5, 10, 20, and 30 μm demonstrating control of microglobule size and the ability of spontaneously reverting to a polydisperse system like that of the gelatin–acacia microglobules in a figure from a study published previously (9).

Effect of Additives on Recovery—The effect of glycerin added to coacervate systems at 45° after achieving pH_c is shown in Table II. With the addition of ≥49% (w/w) glycerin, ellipsoidal particles were obtained, a possible result of partial dehydration of the pectin and gelatin molecules in the coacervate and of increased intramolecular association, resulting from the decreasing dielectric constant of the system. A similar result was found with gelatin–acacia coacervates where from 23 to 41% (v/v) of glycerin yielded nonvacuolated, spherical microglobules, but ≥44% (v/v) glycerin resulted in vacuolated ellipsoids (20). In the pectin–gelatin system, glycerin improved the fineness of the dry recovered powder, but had no apparent effect on the dispersibility of the microglobules in water.

The results of formaldehyde treatment of the microglobules showed that at least 10 ml of 37% HCHO, preferably 15 ml, per 40-g batch prepared from 2% (w/w) pectin–gelatin solutions (33:67) was required to obtain microglobules in dry powdered form spontaneously revertible to a dispersed suspension in water. This result was comparable to that for gelatin–acacia microglobules (9). A minimum formaldehyde treatment time of 9 hr was required to obtain redispersible microglobules prepared by the previously mentioned conditions.

Glycerin, propylene glycol, and polyethylene glycol were equally satisfactory as redispersing media for the formaldehyde treated, unflocculated, sedimented microglobules. Water and 50% (v/v) isopropyl alcohol yielded a finer dry powder, but the rate of filtration of the centrifuged sediments was unacceptably lengthened.

The flocculation rates of the microglobules, by 35-ml portions of four aliphatic alcohols and acetone added to the centrifuged sediments of microglobules (~3–4 ml, Fig. 1) resuspended in 5 ml of glycerin after preparation from 2% (w/w) pectin and gelatin solutions according to previously specified conditions, are described in Table III. Flocculation by only 1-propanol and isopropyl alcohol elicited microglobules spontaneously dispersible in aqueous suspension, whereas ethanol, methanol, and acetone resulted in filter cakes which were not revertible to suspensions of individual microglobules in water. Although these results corroborate those for gelatin–acacia (9) and gelatin (21) coacervate products, there is no readily discernible relationship, *e.g.*, with dielectric constant, ε[8]. The greater dehydration of pectin and some remaining hydrophilic groups on gelatin[9] by ethanol, methanol, and acetone, resulting from their stronger hydrogen bonding affinity for water, could explain the apparent intramolecular–intermolecular colloid aggregation and the failure of the microglobules to disperse as individual units upon suspension in water.

CONCLUSIONS

Based on these studies, it was possible to recover microglobules of controlled and uniform diameter from complex coacervates of pectin–gelatin by regulating the concentrations of pectin and gelatin solutions, pH_m, pH_c, and the pectin–gelatin ratio as well as certain additives. The spherical microglobules so obtained are spontaneously revertible to a dispersed system upon suspension of the powdered products in aqueous solutions.

Pharmacokinetic Profile of Progabide, a New γ-Aminobutyric Acid-Mimetic Drug, in Rhesus Monkey

IKUO JOHNO, B. TERI LUDWICK, and RENÉ H. LEVY ˣ

Received March 30, 1981, from the *Departments of Pharmaceutics and Neurological Surgery, Schools of Pharmacy and Medicine, University of Washington, Seattle, WA. 98195.* Accepted for publication September 10, 1981.

Abstract □ The pharmacokinetic profile of progabide was investigated in five chronically catheterized male rhesus monkeys. The experimental design included single-dose intravenous bolus and oral administration at two dose levels (50 and 100 mg) and zero-order intravenous infusion for 7 days. Plasma samples were analyzed by electron-capture–GLC. Protein binding of the drug was determined by equilibrium dialysis (4°). A one-compartment open model with monoexponential decay was proposed to describe the pharmacokinetics. The mean parameters (±*SEM*) of the 50- and 100-mg iv bolus were: total body clearance, 2.09 (±0.15) and 1.53 (±0.18) liter/hr/kg; half-life, 0.656 (±0.054) and 0.789 (±0.079) hr; distribution volume, 1.97 (±0.08) and 1.79 (±0.21) liter/kg. Progabide was highly bound to plasma proteins and also to erythrocytes. The drug was rapidly absorbed (T_{max} < 1 hr at both doses). The mean bioavailability was attributed principally to a first-pass effect. In the constant rate infusion study, systemic clearance was larger than that of the single dose studies.

Keyphrases □ Progabide—pharmacokinetics in rhesus monkeys, plasma bioavailability □ Bioavailability—pharmacokinetics of progabide in plasma of rhesus monkeys □ Pharmacokinetics—bioavailability of progabide in plasma of rhesus monkeys □ Electron-capture–GLC—determination of progabide in rhesus monkey blood plasma, bioavailability, pharmacokinetics

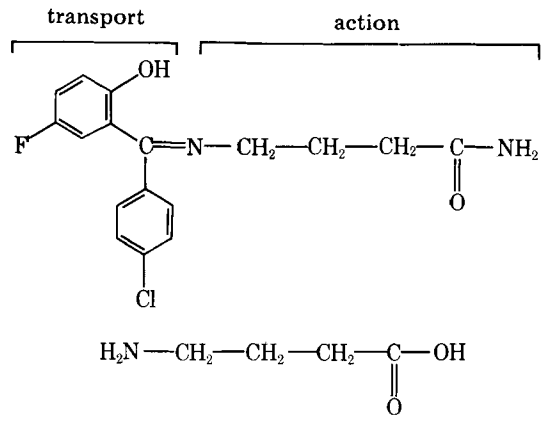
Progabide[1] is a new γ-aminobutyric acid-mimetic drug with a broad spectrum of anticonvulsant activity (1–6). Progabide was designed to be a carrier of γ-aminobutyramide into the central nervous system where it would be broken down and release γ-aminobutyramide.

The present study was undertaken to characterize the pharmacokinetic behavior of progabide in the rhesus monkey in view of its efficacy testing in the chronic epileptic monkey model.

EXPERIMENTAL

Five healthy male rhesus monkeys (*Macaca mulatta*) (2.7–3.8 kg) were used in this study. The monkeys were maintained on fresh fruits and monkey chow and chaired for the duration of the study. Each monkey had two chronic catheters, one for drug administration (femoral vein) and one for blood sampling (jugular vein). The experimental design included single-dose and chronic administration studies. In the single-dose studies, each monkey received 50 or 100 mg of the drug intravenously and orally in a randomized fashion. The drug was dissolved in 100% polyethylene glycol 400[2] at concentrations of 25 and 50 mg/ml. Two milliliters of this solution was injected over 5 min through the femoral vein or administered by intranasal gastric intubation. Fourteen (50-mg dose) or 15 (100-mg dose) blood samples were collected over a 5–6-hr period. Ethylenediaminetetraacetic acid tripotassium salt was used as an anticoagulant, and the blood samples were stored in ice. They were centrifuged at 4° and the separated plasma was frozen immediately. The samples were kept frozen until assayed. Some blood samples were also frozen to determine the blood level of the drug and the total blood clearance in each monkey.

I



I

The chronic administration studies consisted of constant rate intravenous infusion for 7 days. The drug was dissolved in 80% polyethylene glycol 400 at a concentration of about 3 mg/ml (1.91–3.84 mg/ml), and the infusion rate was 1 ml/hr. Blood samples were collected during the accession to steady state (0–6 hr), on a daily basis during steady state, and during the post steady-state decay phase.

Protein binding of progabide was measured by equilibrium dialysis at 4° to minimize the degradation of drug in plasma. A volume of 0.7 ml of pooled monkey plasma, and an equal volume of isotonic phosphate buffer system (pH 7.4), were used. The dialyzing system consisting of plexiglass cells was rotated at a rate of 10 rev/min for 12 hr. The dialysis was carried out with spiked plasma samples with concentrations ranging from 0.4 to 34.6 μg/ml (determined postdialysis). The drug on both sides of the membrane was analyzed by electron-capture–GLC.

Progabide concentrations were determined by the method of Gillet and Dring[3] using a GLC equipped with electron-capture detector[4]. The column consisted of 3% OV-17 on Chromosorb W-HP (column length was 184.3 cm and 2-mm i.d.). Temperatures of detector, injection port, and oven were 300, 250, and 240°, respectively. An analog of progabide, [α-(chloro-4′-phenyl)chloro -5- hydroxy-2-benzylideneamino]-4-butyramide, was used as the internal standard.

Areas under intravenous and oral curves were calculated by the trapezoidal method (with extrapolation to infinite time). Systemic clearance was determined by dose–area ratio. Oral bioavailability was calculated by ratio of oral and intravenous areas.

RESULTS AND DISCUSSION

Single-Dose Intravenous Studies—Representative semilog plasma concentration–time curves obtained for the two intravenous bolus doses in monkeys 574A and 706A are shown in Figs. 1 and 2. The continuous lines were obtained by nonlinear least-squares fitting of experimental data points to a monoexponential equation. A summary of the pharmacokinetic parameters obtained from intravenous bolus administration is presented in Table I.

Progabide has a large systemic clearance, large distribution volume, and short biological half-life. The total body clearance at the 50- and 100-mg doses ranged from 1.60 to 2.50, and 1.09 to 1.92 liter/hr/kg, respectively. The distribution volume at the same doses ranged from 1.81 to 2.27 and 1.42 to 2.33 liter/kg, respectively. The apparent half-life at the 50-mg dose ranged from 0.53 to 0.82 hr and, at the 100-mg dose, from 0.56 to 0.90 hr. Although progabide clearance decreased with dose in all four monkeys, statistical comparison showed no significant difference ($p = 0.088$). There was also no apparent dose dependency in distribution volume or elimination half-life.

The progabide blood–plasma ratio was calculated in four monkeys and the mean value (±*SEM*) was 0.700 ± 0.019. Hematocrit was also measured in three monkeys with a mean of 36% yielding a mean red blood cell–plasma ratio of 0.17. If the free fractions found *in vitro* are applicable *in vivo*, it would suggest that progabide binds to erythrocytes.

Urinary excretion of unchanged drug was negligible during 24 hr. The large plasma clearance and low blood–plasma ratio of progabide suggest that progabide has a medium to high extraction ratio in rhesus monkeys (assuming all metabolism is hepatic and nonrenal elimination of progabide is negligible).

Single-Dose Oral Studies—Figures 3 and 4 show the plasma concentration–time profiles and bioavailability obtained following two single

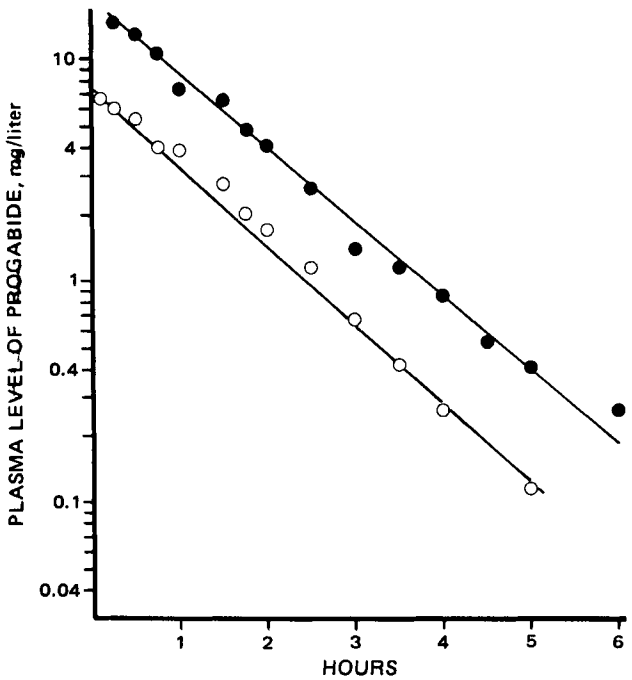

Figure 1—*Semilog plasma–time curve after intravenous bolus administration of progabide (50 mg, ○; 100 mg, ●) in monkey 574A.*

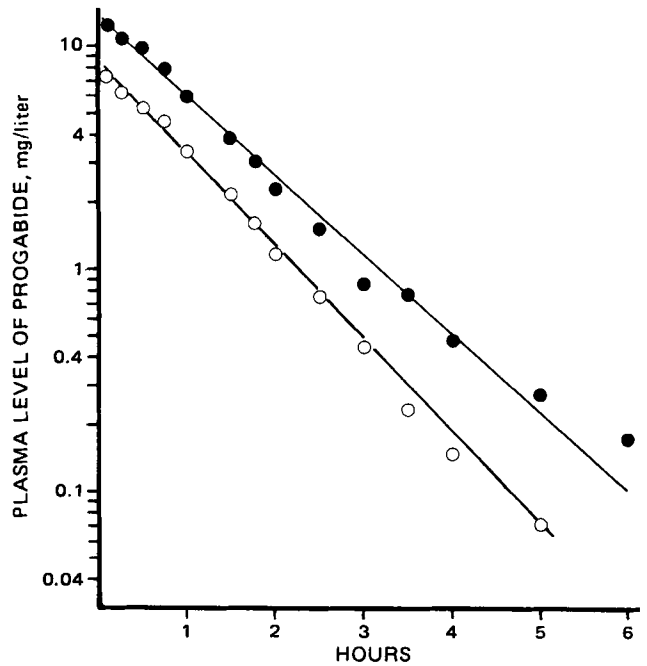

Figure 2—*Semilog plasma–time curve after intravenous bolus administration of progabide (50 mg, ○; 100 mg, ●) in monkey 706A.*

Table IV—Pharmacokinetic Parameters of Progabide Derived from Constant Rate Infusion Studies

Monkey Number	Infusion Rate, mg/hr	Steady-State Plasma Concentration, mg/liter	Systemic Plasma Clearance, liter/hr/kg	Postinfusion Half-Life, hr
514A	2.03	0.237	2.47	0.831
706A	1.92	0.314	2.31	1.028
574A	1.62	0.236	2.21	0.666
020	2.84	0.292	2.76	—
Mean	2.10	0.270	2.44[a]	0.842[b]
(±*SEM*)	(0.26)	(0.020)	(0.12)	(0.09)

[a] Using a two-way ANOVA, the levels of significance for the pairwise comparisons of infusion clearances to those of single dose studies were $p = 0.071$ for infusion *versus* 50-mg dose and $p = 0.0023$ for infusion *versus* 100-mg dose. [b] $p > 0.05$ when compared with single intravenous bolus studies using ANOVA.

oral and intravenous bolus doses in one monkey. Plasma half-life and bioavailability are tabulated in Table II. Progabide was absorbed rapidly and typically reached maximum plasma levels ~1 hr postdose. The bioavailability was between 29 and 69% with a mean (±*SEM*) of 46.8 (±6.6)% for the 50-mg dose and between 22 and 87% with a mean (±*SEM*) of 43.6 (±14.7)% for the 100-mg dose. There was no significant difference between the bioavailabilities of both doses ($p > 0.05$). The incomplete bioavailability is probably due to a first-pass effect and not to poor absorption. Based on a mean extraction ratio, the mean bioavailability was calculated to be 34%, which is in agreement with experimental findings. This calculation assumed complete metabolism in the liver with a hepatic blood flow of 13 liter/hr (7, 8).

Postabsorption half-lives ranged between 0.6 and 0.8 hr at the low dose, and between 0.6 and 1.0 hr at the high dose. These are in agreement with the corresponding intravenous data.

Protein Binding Studies—Protein binding of progabide was determined *in vitro* with plasma concentrations ranging from 0.4 to 34.6 μg/ml. Free fractions ranged between 0.020 and 0.051 (Table III) showing that progabide is highly bound to plasma proteins. Binding appeared concentration-dependent in this plasma level range.

Chronic Dosing Studies—A 7-day continuous zero-order infusion study was performed to test for the presence of any time dependency. A representative plasma concentration–time plot is shown in Fig. 5 and a summary of the pharmacokinetic parameters in four monkeys is given in Table IV. Steady state was achieved in a few hours as predicted from the single-dose studies. Steady-state plasma concentrations ranged between 0.24 and 0.31 mg/liter with infusion rates of 1.6–2.8 mg/hr. Systemic clearance values, ranging from 2.21 to 2.76 liter/hr/kg, were larger than those obtained in single-dose studies. These differences reached

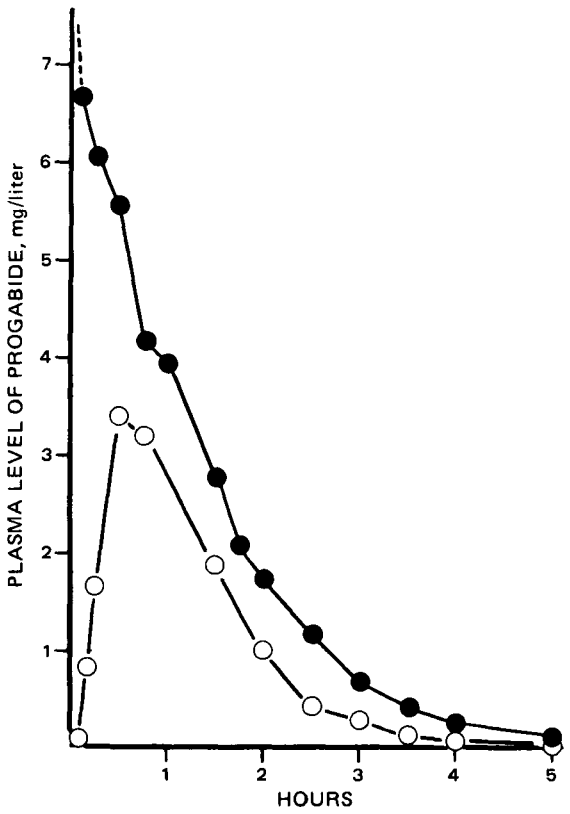

Figure 3—*Plasma concentration–time curve after the intravenous bolus (●) and oral (○) administration of 50 mg of progabide.*

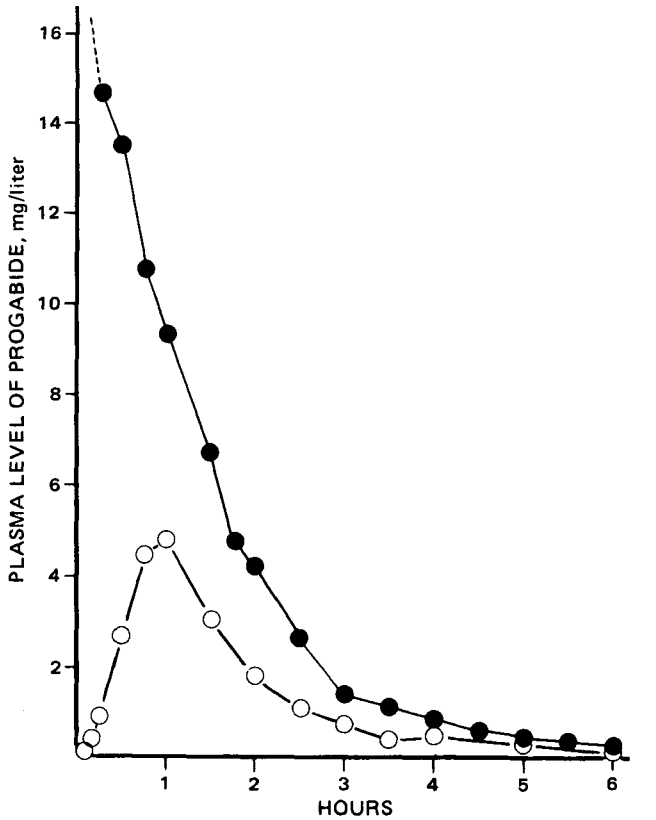

Figure 4—*Plasma concentration–time curve after the intravenous bolus (●) and oral (○) administration of 100 mg of progabide.*

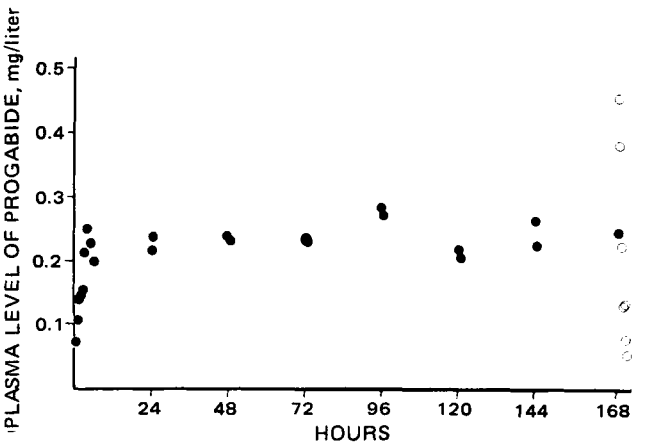

Figure 5—*Plasma concentration during (●) and after (○) the intravenous infusion of progabide in monkey 514A.*

significance for the comparison of the infusion values with the 100-mg dose. Post steady-state disappearance half-lives ranging from 0.67 to 1.03 hr were not different from the single-dose data, (the increase in the postinfusion plasma concentration seen in Fig. 5 was due to flushing of the catheter with saline at the time the infusion was stopped). No time-dependent change in clearance or half-life was exhibited over the 1-week period of the study.

In the rhesus monkey, progabide behaves as a medium extraction ratio drug with incomplete bioavailability and first-order disappearance kinetics. It exhibits nonlinearity in plasma binding *in vitro*. There was a tendency for systemic clearance to decrease within a two-fold dose range. Progabide exhibited no evidence of time dependency in clearance during chronic infusion.

Determination of Ethinyl Estradiol in Solid Dosage Forms by High-Performance Liquid Chromatography

SUZANNE H. STRUSIAK, JOHN G. HOOGERHEIDE ˣ, and MAUREEN S. GARDNER

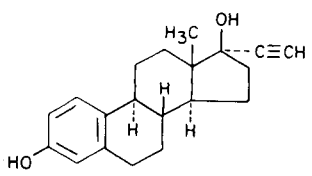
Received July 16, 1981, from the *Schering Corporation, Bloomfield, NJ 07003.* Accepted for publication September 17, 1981.

Abstract □ A rapid, reproducible high-performance liquid chromatographic system for the determination of ethinyl estradiol in solid dosage forms consisting of a reversed-phase column with a mobile phase of 0.05 *M* aqueous KH_2PO_4–methyl alcohol (2:3) and fluorescence detection has been developed. This stability-indicating method is applicable to tablets containing ethinyl estradiol alone or in combination with methyltestosterone and progesterones. The procedure has been used for the determination of ethinyl estradiol in single tablets, stability samples, and dissolution medium. Recovery of drug substance added to placebo was from 97.3 to 101.5% in stability and single-tablet assays, and 95.4 to 102.2% in dissolution assays. Reproducibility studies gave relative standard deviations of 0.4–2.2%.

Keyphrases □ Ethinyl estradiol—high-performance liquid chromatographic analysis, stability, content uniformity and dissolution assays □ High-performance liquid chromatography—analysis, ethinyl estradiol, fluorescence detection □ Estrogens—ethinyl estradiol, high-performance liquid chromatography, analysis of solid dosage forms

Ethinyl estradiol (I), a well known estrogen, is used in hormonal therapy, contraception, and certain cancer treatments. The steroid may be prescribed either alone, as in treatment of estrogen deficiency, or in combination with a progesterone in contraceptive formulations.

Current methods for the analysis of ethinyl estradiol include both wet chemical (1–4) and chromatographic methods. Among the latter are gas chromatography (GC) (5) and high-performance liquid chromatography (HPLC) with UV detection (6–10).



(I)

Determination of ethinyl estradiol by HPLC has been hampered by low sensitivity, as the administered dosages may be as low as 10 μg/tablet. To counter this lack of sensitivity, several investigators have proposed analyzing composite samples of up to 10 tablets (7, 8). While useful for stability assays, this approach is not suitable for either content uniformity or dissolution assays. Other investigators have increased detection sensitivity by using precolumn derivatization with dansyl chloride and fluorescence detection (11, 12). A much simpler approach is to use the native fluorescence of the phenolic ring of the steroid; this method has been used for normal phase HPLC of estrogens (13) and of ethinyl estradiol in cosmetics (14, 15).

A reversed-phase HPLC system with native fluorescence detection for the determination of ethinyl estradiol in solid dosage forms is described. The proposed method, which requires minimal sample preparation, is not only stability-indicating but also sensitive enough for use in content uniformity and dissolution assays.

EXPERIMENTAL

Materials—HPLC grade methyl alcohol[1], *o*-phenylphenol[2], and potassium phosphate monobasic crystals[2] (KH_2PO_4) were obtained from commercial sources. Ultrapure water was prepared by deionization, treatment for removal of organic compounds, and filtering[3].

Apparatus—The high-performance liquid chromatograph was equipped with a constant flow pump[4], an automatic injector[5], a fluores-

significance for the comparison of the infusion values with the 100-mg dose. Post steady-state disappearance half-lives ranging from 0.67 to 1.03 hr were not different from the single-dose data, (the increase in the postinfusion plasma concentration seen in Fig. 5 was due to flushing of the catheter with saline at the time the infusion was stopped). No time-dependent change in clearance or half-life was exhibited over the 1-week period of the study.

In the rhesus monkey, progabide behaves as a medium extraction ratio drug with incomplete bioavailability and first-order disappearance kinetics. It exhibits nonlinearity in plasma binding *in vitro*. There was a tendency for systemic clearance to decrease within a two-fold dose range. Progabide exhibited no evidence of time dependency in clearance during chronic infusion.

Determination of Ethinyl Estradiol in Solid Dosage Forms by High-Performance Liquid Chromatography

SUZANNE H. STRUSIAK, JOHN G. HOOGERHEIDE ˣ, and MAUREEN S. GARDNER

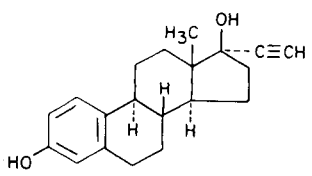
Received July 16, 1981, from the *Schering Corporation, Bloomfield, NJ 07003.* Accepted for publication September 17, 1981.

Abstract □ A rapid, reproducible high-performance liquid chromatographic system for the determination of ethinyl estradiol in solid dosage forms consisting of a reversed-phase column with a mobile phase of 0.05 *M* aqueous KH_2PO_4–methyl alcohol (2:3) and fluorescence detection has been developed. This stability-indicating method is applicable to tablets containing ethinyl estradiol alone or in combination with methyltestosterone and progesterones. The procedure has been used for the determination of ethinyl estradiol in single tablets, stability samples, and dissolution medium. Recovery of drug substance added to placebo was from 97.3 to 101.5% in stability and single-tablet assays, and 95.4 to 102.2% in dissolution assays. Reproducibility studies gave relative standard deviations of 0.4–2.2%.

Keyphrases □ Ethinyl estradiol—high-performance liquid chromatographic analysis, stability, content uniformity and dissolution assays □ High-performance liquid chromatography—analysis, ethinyl estradiol, fluorescence detection □ Estrogens—ethinyl estradiol, high-performance liquid chromatography, analysis of solid dosage forms

Ethinyl estradiol (I), a well known estrogen, is used in hormonal therapy, contraception, and certain cancer treatments. The steroid may be prescribed either alone, as in treatment of estrogen deficiency, or in combination with a progesterone in contraceptive formulations.

Current methods for the analysis of ethinyl estradiol include both wet chemical (1–4) and chromatographic methods. Among the latter are gas chromatography (GC) (5) and high-performance liquid chromatography (HPLC) with UV detection (6–10).



(I)

Determination of ethinyl estradiol by HPLC has been hampered by low sensitivity, as the administered dosages may be as low as 10 μg/tablet. To counter this lack of sensitivity, several investigators have proposed analyzing composite samples of up to 10 tablets (7, 8). While useful for stability assays, this approach is not suitable for either content uniformity or dissolution assays. Other investigators have increased detection sensitivity by using precolumn derivatization with dansyl chloride and fluorescence detection (11, 12). A much simpler approach is to use the native fluorescence of the phenolic ring of the steroid; this method has been used for normal phase HPLC of estrogens (13) and of ethinyl estradiol in cosmetics (14, 15).

A reversed-phase HPLC system with native fluorescence detection for the determination of ethinyl estradiol in solid dosage forms is described. The proposed method, which requires minimal sample preparation, is not only stability-indicating but also sensitive enough for use in content uniformity and dissolution assays.

EXPERIMENTAL

Materials—HPLC grade methyl alcohol[1], *o*-phenylphenol[2], and potassium phosphate monobasic crystals[2] (KH_2PO_4) were obtained from commercial sources. Ultrapure water was prepared by deionization, treatment for removal of organic compounds, and filtering[3].

Apparatus—The high-performance liquid chromatograph was equipped with a constant flow pump[4], an automatic injector[5], a fluores-

cence detector (excitation at 280 nm, emission at 330 nm) containing a xenon lamp source[6], and a chart recorder[7]. The stainless steel column (25 cm × 4.6-mm i.d.) was packed with 10-μm, irregularly shaped, totally porous silica particles bonded with a C-8 hydrocarbon phase[8]. A 2.0-μm filter[9] was placed in-line before the column. A data acquisition system[10] was used for peak processing.

Chromatographic Conditions—The mobile phase was 0.05 *M* aqueous KH_2PO_4, filtered through a 0.45-μm filter[11]–methyl alcohol (2:3) and degassed for 20 min by using an ultrasonic water bath. The flow rate through the HPLC system was 2.0 ml/min. Helium was bubbled through the mobile phase constantly while the system was running.

Internal Standard Solution—A 0.1-mg/ml solution of *o*-phenylphenol was prepared in mobile phase. This solution was diluted to 1.0 μg/ml with mobile phase.

Standard Solution—Approximately 25 mg of ethinyl estradiol standard was accurately weighed, transferred to a 100-ml volumetric flask, and dissolved and diluted to 100 ml with methyl alcohol. This solution was diluted exactly 5:50 in methyl alcohol. A 2.00-ml aliquot of this solution and 5.00 ml of a 1.0-μg/ml internal standard solution were added to a 50-ml volumetric flask. Approximately 23 ml of methyl alcohol was added to the flask and diluted to volume with 0.05 *M* aqueous KH_2PO_4 to a final concentration of 1 μg/ml of ethinyl estradiol and 0.1 μg/ml of internal standard. A 50-μl aliquot was injected into the liquid chromatograph.

Determination of Ethinyl Estradiol in Solid Dosage Forms—Tablets containing 0.02 mg of ethinyl estradiol were assayed by adding single tablets to individual 50-ml centrifuge tubes containing 4.00 ml of aqueous 0.05 *M* KH_2PO_4. The sample was rotated for 15 min. A 2.00-ml aliquot of internal standard and 4 ml of methyl alcohol were added to the sample, which was again rotated for 15 min and centrifuged. The super-

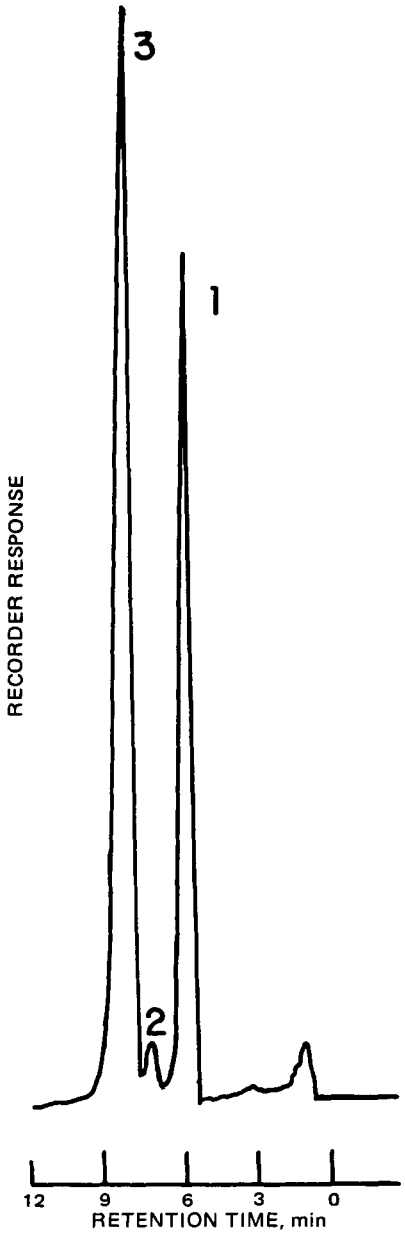

Figure 2—*High-performance liquid chromatogram of ethinyl estradiol tablet extract. Key: 1, o-phenylphenol; 2, butylparaben; 3, ethinyl estradiol.*

nate was transferred to a 25-ml volumetric flask. The samples were extracted two more times with ~5 ml of mobile phase and a 10-min rotation. The supernates were combined and a 50-μl aliquot injected into the liquid chromatograph. The ethinyl estradiol content was calculated as follows:

mg of ethinyl estradiol/tablet =

$$(R_{sam}/R_{std}) \times (W_{std}) \times (V_{sam}/V_o) \qquad \text{(Eq. 1)}$$

where:

R_{sam} = ratio of ethinyl estradiol to *o*-phenylphenol peak heights in the sample chromatogram;
R_{std} = peak height ratio in the standard chromatogram;
W_{std} = weight of ethinyl estradiol in the reference standard solution;
V_{sam} = total volume of sample solution;
V_o = total volume of *o*-phenylphenol in the sample solution.

This sample preparation allows for the determination of ethinyl estradiol in higher strength dosage forms. Tablets containing up to 0.5 mg of ethinyl estradiol may be assayed by adjusting extraction volumes and internal standard concentration to give final assay concentrations of 1 μg/ml of ethinyl estradiol and 0.1 μg/ml of internal standard.

Accelerated Degradation Studies—Accelerated degradation studies were conducted by heating the ethinyl estradiol drug substance at 178° for 16 hr as described previously (16), and heating the ethinyl estradiol tablets for 2 weeks at 75°.

Dissolution Assay Studies—A solution of 2 μg/ml of *o*-phenylphenol was prepared in methyl alcohol as the internal standard solution.

Approximately 25 mg of ethinyl estradiol standard was accurately weighed, transferred to a 50-ml volumetric flask, and dissolved and diluted to volume with methyl alcohol. This standard solution was diluted exactly 2:50 in methyl alcohol. A 1.00-ml aliquot of this solution and 1.00 ml of the 2 μg/ml internal standard were added to 900 ml of ultrapure water[3].

Determination of Ethinyl Estradiol in Dissolution Medium—Single tablets containing 0.02 mg of ethinyl estradiol were placed in 900 ml of ultrapure water[3] along with 1.00 ml of 2 μg/ml of the internal standard solution. Dissolution of the tablet was conducted at 37° for 1 hr. The samples and standards were then treated identically. The standard solutions and dissolution medium were filtered through a 1.2-μm filter[12], the filtrates equilibrated to room temperature, and the entire contents of each filtrate concentrated onto an activated C-18 cartridge[13] by using a vacuum to draw the solution through the cartridges. The cartridge was eluted with 20-ml 0.05 *M* aqueous KH_2PO_4–methyl alcohol (2:3) and a volume of 50 μl injected into the liquid chromatograph. The ethinyl estradiol content was calculated from Eq. 1.

This sample preparation also allows for the determination of higher levels of ethinyl estradiol in dissolution medium. Tablets containing up

RSD, %	1.0	1.6	1.8

to 0.5 mg of ethinyl estradiol were assayed by adjusting the internal standard concentration and dilutions to give approximate concentrations of 1 μg/ml of ethinyl estradiol and 0.1 μg/ml of the internal standard.

RESULTS AND DISCUSSION

Content Uniformity and Stability Assays—To develop a rapid, reproducible HPLC method for the determination of ethinyl estradiol, sample preparation was kept as simple as possible. In this method the tablet matrix is disintegrated by mixing with aqueous buffer, after which methyl alcohol is added to solubilize the drug substance; the final extracting solution has the same solvent composition as the mobile phase. Under these conditions, two extractions are sufficient to remove more than 99% of both active and internal standard from the tablet matrix; however, a third extraction was added to ensure quantitative recoveries.

To simplify the assay methods, ethinyl estradiol was detected by its native fluorescence rather than by precolumn fluorescence labeling. Both ethinyl estradiol and the internal standard, *o*-phenylphenol, have UV absorption maxima around 280 nm as well as from 200 to 220 nm. Excitation at either of these maxima produces broad ethinyl estradiol emission at 310 nm and *o*-phenylphenol emission at 340 and 420 nm. Adequate sensitivity and selectivity was maintained for these compounds by monitoring emission at 330 nm with a 20-nm spectral band width. While excitation can be done at either 220 or 280 nm, excitation at 220 nm leads to interferences of two types. First, more compounds absorb at 220 than at 280 nm, leading to a loss in detection specificity. Second, impurities in the mobile phase fluoresce to give a significant background. Large amounts of UV absorbing material, such as the methyltestosterone encountered in some formulations, absorb enough radiation to decrease the background, giving negative peaks which are potential chromatographic interferences. Both of the above detection interferences are of significantly lower magnitude when using excitation at 280 rather than 220 nm.

Due to the low levels of ethinyl estradiol and high detection sensitivity, care must be taken to avoid interferences due to fluorescent impurities. Glassware must be thoroughly cleaned and dried, avoiding any surfactants which could leave residues of fluorescing compounds on the glass. In the course of this work, it was also noted that spurious peaks arose from the use of latex dropper bulbs; particulate matter from the bulbs caused severe chromatographic interferences.

In the described method, ethinyl estradiol elutes with a retention time of 9 min and the internal standard elutes at 6 min (Fig. 1). Butylparaben, a tablet-coating excipient, chromatographs at 8 min and does not interfere with the assay. A sample chromatogram is shown in Fig. 2.

Ethinyl estradiol, when subjected to the extreme temperature conditions of 178° for 16 hr used in a previous study (16), degraded ~25%. The degradation products are separated from both ethinyl estradiol and the internal standard as shown in Fig. 3. A discussion of the degradation of ethinyl estradiol has been previously reported (16).

The linearity of the chromatographic system was demonstrated within the range of 0.61–1.42 μg/ml of ethinyl estradiol standard. Response *versus* concentration data gave a correlation coefficient of 0.9995 and an estimated relative standard deviation of linearity of 1.4%. Linearity of the sample preparation was tested over the range of 60–140% of the assay sample size for tablets containing 0.02 mg of ethinyl estradiol and yielded a correlation coefficient of 0.9999 and an estimated relative standard deviation of linearity of 0.64%. Linearity of the sample preparation was also demonstrated for high strength dosage forms of ethinyl estradiol tablets. The correlation coefficients obtained from these experiments were no less than 0.9994. No statistically significant bias was observed in any of the linearity experiments when extrapolated to zero sample size.

The accuracy of the content uniformity–stability method was demonstrated by the addition of ethinyl estradiol to varying amounts of placebo. As seen in Table I, recovery of ethinyl estradiol from the placebo is excellent, ranging from 97.3 to 101.5%.

The precision of the method was tested by performing replicate assays on several sample batches over a period of several days (Table II). The relative standard deviations of the assays were <2% for all normal batches, but increased slightly for heated samples.

Table V—Retention Times for Compounds Commonly Found in Combination with Ethinyl Estradiol

Compound	Relative Retention Time
Ethinyl Estradiol	1.00
Norethindrone	1.00
Norgestrel	1.49
Methyltestosterone	1.57
Norethindrone acetate	2.15
Ethynodiol diacetate	[a]

[a] No peak observed.

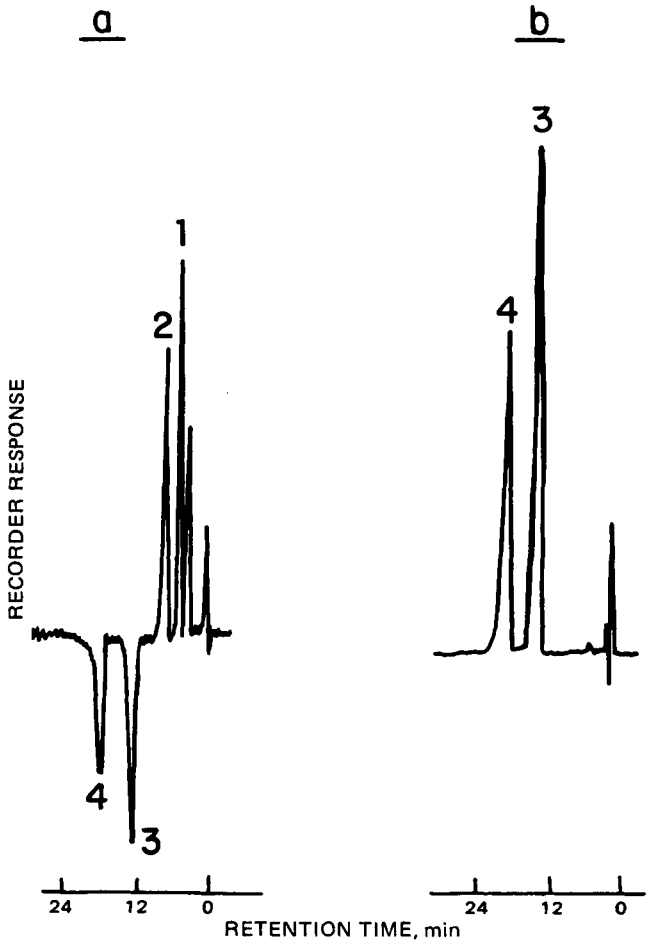

Figure 4—*High-performance liquid chromatogram of tablets containing both ethinyl estradiol and methyltestosterone, (a) fluorescence; (b) ultraviolet. Key: 1, o-phenylphenol; 2, ethinyl estradiol; 3, methyltestosterone; 4, progesterone (internal standard).*

Table VI—Reproducibility of Ethinyl Estradiol Determinations in the Presence of Methyltestosterone

Sample	Assay, % Label		
	Lot A[a]	Lot B[a]	Lot C[b]

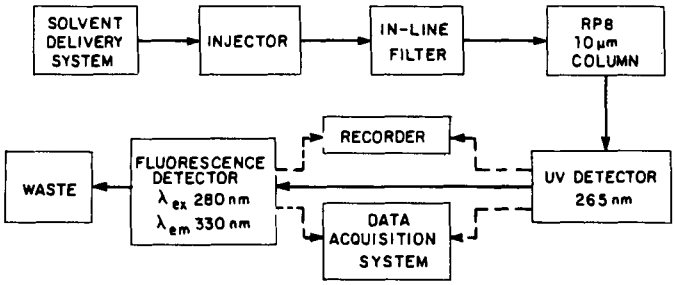
$\bar{X}$	110.6	106.1	104.2
RSD, %	1.3	1.7	—

[a] 0.04 mg of ethinyl estradiol, 10 mg of methyltestosterone/tablet. [b] 0.02 mg of ethinyl estradiol, 5 mg of methyltestosterone/tablet.



Scheme A—High-performance liquid chromatographic system for simultaneous determination of ethinyl estradiol and methyltestosterone.

Dissolution Assays—The medium chosen for the dissolution assays was ultrapure distilled water, from which ions and organic compounds had been removed[3]. Ultrapure water must be used to prevent concentration of any fluorescent impurities onto the cartridge[13].

Precision of ethinyl estradiol recovery from dissolution assay medium was demonstrated by preparing eight standard solutions as described previously and assaying these according to the HPLC method described. These eight standards produced a relative standard deviation of 2.1%.

Since relatively large volumes of liquid were passed through the cartridges[13], some breakthrough of ethinyl estradiol and internal standard was expected. Standard solutions were concentrated onto cartridges[13] series so that any breakthrough from one cartridge would be concentrated onto a second cartridge. The breakthrough observed was 5.7% for ethinyl estradiol and 6.6% for the internal standard. These losses were considered acceptable since both standard and sample solutions are concentrated onto the cartridges and lose equal amounts of material. The breakthrough percentage is constant over a wide range of sample size as demonstrated by recovery studies of ethinyl estradiol and internal standard from dissolution medium. Over the range of 10–500 ng/ml of ethinyl estradiol, peak height ratios were obtained with a relative standard deviation of 1.0%.

The accuracy of the method was demonstrated by the addition of varying amounts of ethinyl estradiol to a constant amount of placebo. The recovery of ethinyl estradiol for three different tablet strengths is seen in Table III. The recovery of ethinyl estradiol ranged from 95.4 to 102.2% with no statistically significant bias when extrapolated to zero sample size.

To avoid the differences of tablet-to-tablet variations, precision of the recovery of ethinyl estradiol from dissolution media was tested on single tablet equivalents of tablet grinds. The largest relative standard deviation observed is 1.8% (Table IV).

Separation of Ethinyl Estradiol from Other Drug Substances—This HPLC method is also applicable to the analysis of ethinyl estradiol in the presence of other drug substances. Various drug substances commonly found in combination with ethinyl estradiol were chromatographed by using the proposed HPLC system with UV detection at 220 nm. As the relative retention times in Table V indicate, norgestrel, methyltestosterone, and norethindrone acetate are all well separated from ethinyl estradiol; norethindrone coeluted with ethinyl estradiol and ethynodiol diacetate did not appear to elute from the column.

Assays for ethinyl estradiol were performed on tablets containing both ethinyl estradiol (0.04 mg/tablet) and methyltestosterone (10 mg/tablet). The chromatographic system for this analysis is given in Scheme A. The relative standard deviation of the determination of ethinyl estradiol in the presence of methyltestosterone was not greater than 1.9%, as shown in Table VI for replicate sample preparations. Figure 4 indicates that methyltestosterone causes no chromatographic interference in the assay for ethinyl estradiol.

Use of Dipole Moment as a Parameter in Drug–Receptor Interaction and Quantitative Structure–Activity Relationship Studies

ERIC J. LIEN ˣ, ZONG-RU GUO, REN-LI LI, and CHING-TANG SU

Received June 11, 1981 from the *Section of Biomedicinal Chemistry, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication July 31, 1981.

Abstract □ The theoretical basis for using dipole moment as a free-energy related parameter in studying drug–receptor interaction and quantitative structure–activity relationship (QSAR) is presented. Over 300 group dipole moments for aromatic substituents were compiled using the dipole moments of monosubstituted benzene derivatives. Examples in the literature of using dipole moment in QSAR studies are also presented.

Keyphrases □ Dipole moment—parameter in drug–receptor interaction and quantitative structure–activity relationships, list of 300 for aromatic substituents □ Quantitative structure–activity relationships—dipole moment as a parameter, 300 dipole moments listed for aromatic substituents □ Drug–receptor interaction—dipole moment as a parameter, list of 300 dipole moments for aromatic substituents

It is generally accepted that most interactions between drugs and receptors are physicochemical processes. When an equilibrium between a drug–receptor complex (DR), a free drug (D), and unoccupied receptor (R) is established, the reversible process can be expressed as:

$$D + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} DR \qquad \text{(Eq. 1)}$$

Under equilibrium conditions the following holds:

$$\log K = -\Delta G°/2.303RT \qquad \text{(Eq. 2)}$$

where $K = (k_1/k_2)$ is the association constant of the complex DR, $\Delta G°$ is the change in standard free energy during the formation of DR, T is the absolute temperature, and R is the gas constant.

The ability of each member of a series of drugs to bind to the receptor is dependent on the difference in the standard free energy change ($\Delta G°$) under the same condition. Factors contributing to this variation in $\Delta G°$ can be divided into three major categories: lipophilic, electronic, and steric.

THEORETICAL

Based on linear free-energy relationships, Hansch and Fujita (1, 2) developed a general model to quantitatively describe the relationships between biological activities and molecular structures:

$$\log (1/C) = -a\pi^2 + b\pi + \rho\sigma + dE_s + c \qquad \text{(Eq. 3)}$$

where $\log (1/C)$ is the negative logarithm of the concentration or dosage of a drug producing a standard biological response, π is the hydrophobic constant of the substituent, σ is the Hammett substituent, and E_s is the steric constant.

This model was later extended to include differences in degree of ionization, molecular size, and dipole moment, as well as branching (3–5):

$$\log \text{biological response} = -a(\log P)^2 + b \log P + c\,(\text{pKa} - \text{pH}) + d \log MW + e\,\mu + f\,\chi + g \qquad \text{(Eq. 4)}$$

where pKa − pH equals the log (undissociated/dissociated) for acids, μ is the dipole moment, and χ is the branching or other steric factors.

The electronic effects in drug–receptor interactions are represented by the electric dipole moment, μ.

All forces between atoms or drug molecules and receptors or biomacromolecules are electrostatic in origin. Several types of noncovalent interactions between drugs and receptors can be described as interactions between charges (long-range force), between charge and a dipole, and between dipoles (short-range forces).

The potential energy of interaction of two oppositely charged ions relative to the magnitudes of the charges q_1 and q_2 and the distance between them r, is given by Coulomb's law:

$$E = \frac{-q_1 q_2}{Dr} \qquad \text{(Eq. 5)}$$

where D is the dielectric constant through which the charges interact. The energy of interactions between charges and receptors is much larger than that of noncharged electronic effects, hydrophobic effects, and others. A charged species also has quite different transport properties than a noncharged species. Therefore, the ionic member in a series of compounds often does not fit the regression line obtained from the series of noncharged compounds and is usually excluded from the series in quantitative structure–activity relationship (QSAR) analysis.

The energy of interaction between an ion and a dipole is given by the following (6):

$$E = \frac{-N_a e\,\mu\cos\theta}{D(r^2 - d^2)} \qquad \text{(Eq. 6)}$$

where N_a is Avogadro's number, e is the magnitude of the charge, θ is the angle between the line joining the charge and the middle of the dipole and the line between the ends of the dipole, D is the dielectric constant, r is the distance between the charge and the middle of the dipole, and d is the length of the dipole. It is obvious from this equation that the extent to which an ion and a dipole interact is related to the dipole orientation.

The energy of interaction between two dipoles in the most favorable alignment is given by:

$$E = \frac{-2\mu_a\mu_b}{Dr^3} \qquad \text{(Eq. 7)}$$

where μ_a and μ_b stand for the dipole moments (6):

The average interaction for all orientations is given by:

$$E = \frac{-2\mu_a^2\mu_b^2}{3\,KTDr^6} \qquad \text{(Eq. 8)}$$

The energy of dipole-induced dipole interactions (Debye forces) is:

$$E = \frac{-\mu_a^2\alpha_b + \mu_b^2\alpha_a}{D^2r^6} \qquad \text{(Eq. 9)}$$

where α_a and α_b are the polarizabilities.

The dispersion interactions (London forces) are governed by:

$$E = \frac{-3\alpha_a\alpha_b[I_aI_b/(I_a + I_b)]}{2r^6} \qquad \text{(Eq. 10)}$$

where I_a and I_b stand for the ionization potentials.

Note that the dipole–dipole (Keesom) interactions are not only dependent on the orientation of the dipoles but also inversely proportional to the third power of distance (Eq. 7) or the sixth power of distance for all orientations (Eq. 8).

In QSAR studies it it assumed that the receptor remains unchanged; therefore, only the properties of the drug molecule need to be considered (μ_a, α_a, I_a, *etc.*).

In most of the published QSAR studies, the electronic parameters most commonly used are the Hammett σ constant and Taft polar constant σ^*. The Hammett σ constants result from the comparison of the pKa of a series of substituted benzoic acids to that of benzoic acid. They describe the magnitude of electronic effects of substituents on the reactive center attached to the benzene ring, *i.e.*, the dissociation constants of substituted

0022-3549/82/0600-0641$01.00/0

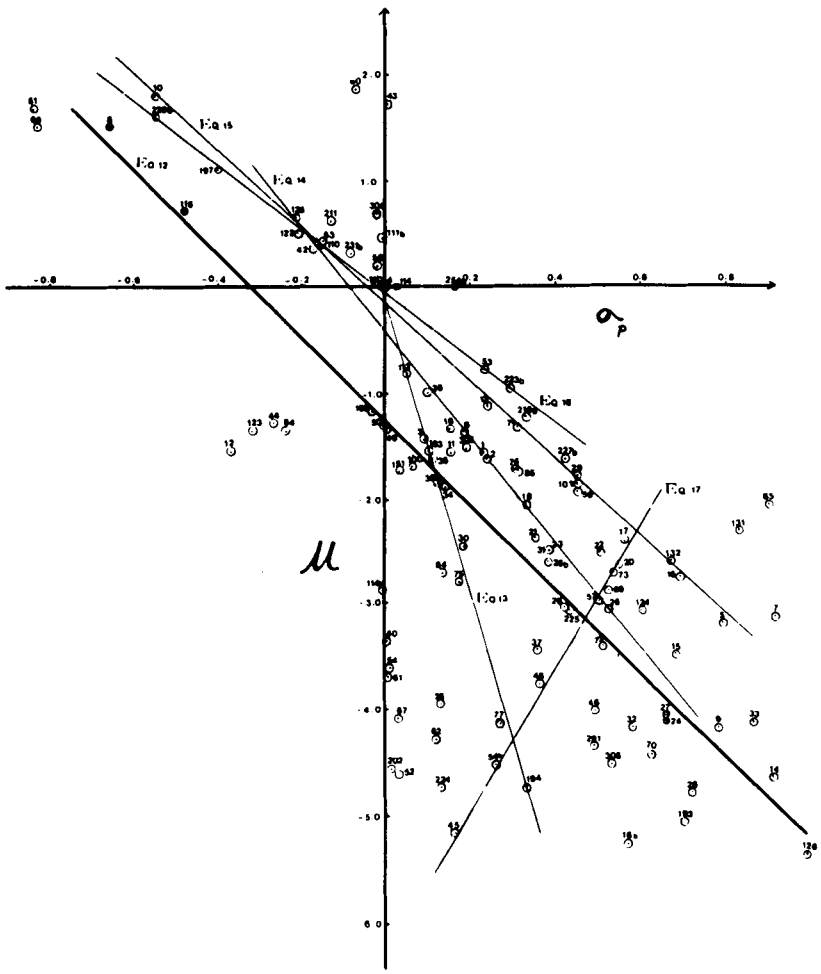

Figure 1—*A plot of* μ versus σ_p. *Note the scattering of the points, and the quite different slopes and intercepts for equations derived from various subsets.*

benzoic acids. In other words, σ constants are a measurement of substituent electronic effects on the reactivity of other parts of the same molecule. It is known that in using σ constants, the orientation and the rate or equilibrium of reactions can be predicted when aromatic compounds are substituted by various functional groups.

If interactions between drugs and receptors are controlled by the electronic nature of the substituents on the benzene ring, σ constants are suitable descriptors of electronic effects for QSAR analysis. However, not all the electronic effects of a series of drugs in drug–receptor complexes work by varying the electronic properties of another reactive center. Different substituents in a series of drugs may directly interact with receptors, *i.e.*, *via* charge–dipole, dipole–dipole, dipole–induced dipole, and induced dipole–induced dipole interactions between the substituent of a drug and a part of receptor. These interactions could affect the binding force of the drug with the receptor. Therefore, dipole moments, which are the quantitative measurements of separation of charge, should be useful in describing direct drug–receptor interactions through noncovalent bonding.

Group dipole moments of substituents are thermodynamically linear free-energy related functions. They are vectors with additive and constitutive properties. For congeneric series of compounds, dipole moments have been frequently found to correlate well with σ or other linear free-energy related parameters. For example, the dipole moments of substituted anilines have been correlated with the melting points, N–H stretching frequency in infrared spectra, as well as σ_p constants (7). Colinese *et al.*, also have found linear correlation between the dipole moments and $\nu_{(O-H)}$ of a series of 4′-substituted-4-hydroxyazobenzenes (8). It was also reported that for *N*-(4-substituted benzylidene)-4-hydroxyanilines that $\nu_{(O-H)}$ and $\mu_{(O-H)}$ are linearly related to Hammett's σ constant (9). A linear relationship between $\mu_{(O-H)}$ and the relative frequency shift ($\Delta\nu$) in dioxane has been used as an evidence of the dependence of $\mu_{(O-H)}$ on the strength of hydrogen bonding (9). Van Beek (10) also reported some linear relationships between dipole moments and σ constants in a few disubstituted benzene systems. Apparent correlation has also been reported between the N–H chemical shift and the dipole moment of lactams and thiolactams (11).

Despite successful correlation within limited series, the correlation between μ and σ may vary drastically or fail completely if noncongeneric groups are lumped together (Figs. 1 and 2).

Since Hammett's substituent constants (σ) are more readily available for a wide variety of substituents (12, 13) than dipole moments, the use of dipole moments in QSAR has only been reported by a few groups in spite of the direct relationship with interaction energy. The present report reviews the reported cases of QSAR using dipole moment as an independent electronic parameter, and compiles a table of group dipole moments for future use.

Method—More than 300 group dipole moments were collected (Appendix I), most of which were taken from McClellan's book (14). The magnitudes of the group dipole moments of substituents are equal to those of the corresponding monosubstituted benzene. The sign is taken by comparison of the electronegativities between the substituent and the aromatic carbon to which the group is connected. A negative sign stands for a negative end pointing away from the benzene ring.

A total of 114 substituent groups (for which both μ and σ are available) were analyzed to examine the interrelationship between μ and σ. Hammett's σ constants were taken from Hansch and Leo's book (13). All the regression lines were derived by computer[1] *via* the method of nonweighted least-squares fit.

RESULTS AND DISCUSSION

The overall correlations between Hammett σ constants and the group dipole moments of 114 substituents are shown in Eqs. 11 and 12:

$$\mu = -5.99\,\sigma_m - 0.53 \qquad \text{(Eq. 11)}$$
$$n = 114,\ r = 0.749,\ s = 1.279$$

[1] IBM 370/185 computer.

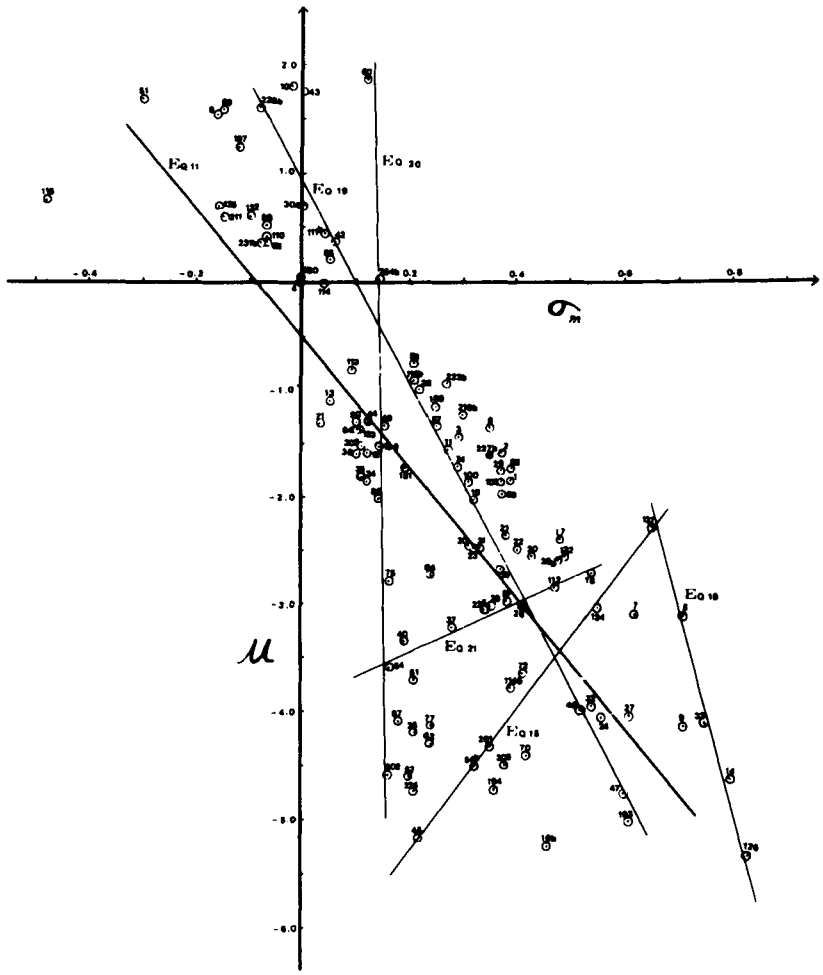

Figure 2—*A plot of* μ versus σ_m. *Note the scattering of the points, and the quite different slopes and intercepts for equations derived from various subsets.*

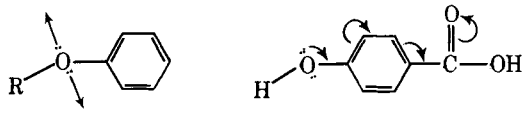
$$\mu = -3.65\,\sigma_p - 1.27$$
$$n = 114, r = 0.706, s = 1.367 \qquad \text{(Eq. 12)}$$

where μ is the group dipole moment of the substituent, and σ_m and σ_p are *meta*- and *para*-substituent constants, respectively.

Equations 11 and 12 indicate that the correlations between σ constants and dipole moments are not very good, and only 56 and 50%, respectively, ($r^2 \times 100$) of the variance in the data can be explained by these equations. In other words, about half of the variance in the data cannot be accounted for by these linear relationships. Comparison of Eqs. 11 and 12 shows that the correlation between σ_m and μ is better than that of σ_p and μ. This is probably due to the delocalization of π electrons between *para*-substituents and the benzene ring. The σ_m value is mainly a measure of inductive effect of the substituent and hence is more comparable to the group dipole moment.

The signs of the dipole moments of hydroxy and alkoxy groups are negative, *i.e.*, the oxygen atom is at the negative end of the dipoles in phenol and alkoxybenzene molecules. This can be explained in terms of the high electronegativity of oxygen in spite of the resonance effect in benzoic acid:



By dividing 11 substituents into subgroups graphically, there are quite different equations correlating dipole moments and σ constants as shown in Table I. In each subgroup no distinct structural relationship is found. The slopes range from −161 to +6.62, while the intercept ranges from +17.46 to −6.63.

Table I—Correlations Between Group Dipole Moment and σ Constants for Selected Subgroups from Table I, Showing Different Slopes and Intercepts [a]

	n	*r*	*SD*	*Equation*

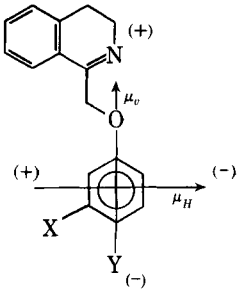
$\mu = 6.62\,\sigma_m - 6.63$	5	0.999	0.041	(22)

[a] n = number of data points; r = correlation coefficient; and SD = standard deviation.

Although the application of dipole moment in QSAR is not as common as that of σ constants, in some cases it can play an important role in drug–receptor interactions. For example, Tute's results (15) on the inhibition of viral neuraminidase by 1-phenoxymethyl-3,4-dihydroquinolidines was reexamined. Using group dipole moment values instead of the components along the vertical axis μ_v, Eq. 23 was derived, which is slightly better than Tute's result using μ_v (Eq. 24):



$$\log 1/C = 0.258\pi + 0.094\mu + 0.034\mu^2 + 2.596$$
$$n = 16, r = 0.956, s = 0.062 \qquad \text{(Eq. 23)}$$

Table II—Examples of the Application of Dipole Moment and Polarizability in QSAR [a]

Compounds	Biological Activity and Correlations Reported	Reference
1-Decylnipecotamides	Chlorinesterase inhibition. Inhibitory activity parallels the increase in dipole moment	16
Local anesthetics	Minimum blocking concentration (MBC) is a function of polarizability and ionization potential I_p $\log MBC = -a\alpha I_p + b$	17
Chloramphenicol analogs	Antimicrobial activity is a function of electronic polarization (P_e) $k_I = 2.76\,P_e - 6.55$ $n = 10, r = 0.991$	18
Cyclic ureas and thioureas	Respiratory stimulant activity is dependent on the dipole moment of three series of the compounds, while the acute lethal toxicity is a function of molecular weight	19
1-Decyl-3-carbamoylpiperidines	Butyrylcholinesterase $pI_{50} = -0.058\pi^2 + 0.923\pi - 0.456\mu + 5.589$ $n = 6, r^2 = 0.998$ (more data needed)	20
Anticonvulsants	Antielectroshock in mice $\log 1/C = 0.720 \log P - 0.396\mu + 3.144$ $n = 11, r = 0.967, SD = 0.189$	21
Sulfonamides	Antimicrobial activity measured as minimum inhibitory concentration (MIC) $\log 1/MIC = -0.11\ pKa + 0.041\mu^2 + 5.31$ $n = 10, r^2 = 0.91, SD = 0.18$	22
Nitroanilines	Sweetening potency $\log$ relative sweetness $= 1.31\pi - 1.08\sigma_0 + 0.45\mu^2 + 0.052(\alpha_R - \alpha_H) + 1.66$ $n = 9, r^2 = 0.976, SD = 0.149$ (too many parameters for too few data points)	22
Miscellaneous anticonvulsants	Antielectroshock activity $\log 1/C = -0.222(\log P)^2 + 1.153 \log P - 0.368\mu + 2.994$ $n = 18, r = 0.092, SD = 0.24$	23
Barbiturates, hydantoins, and imides	Antipentylenetetrazol seizures $\log 1/C = -0.123(\log P)^2 + 0.588 \log P - 0.597\mu + 0.825$ $n = 10, r = 0.99, SD = 0.12$	23
	Acute lethal toxicity $\log 1/C = -0.226(\log P)^2 + 0.800 \log P - 0.361\mu + 0.175$ $n = 10, r = 0.99, SD = 0.11$	2
Convulsants (lactams, thiolactams, ureas, and thioureas)	Acute lethal toxicity $\log 1/C = -0.364(\log P)^2 + 1.005 \log P + 0.247\mu + 1.298$ $n = 20, r = 0.89, SD = 0.24$	23
7-Substituted-1,4-benzodiazepinones	Antipentylenetetrazol seizures $\log 1/C = -0.301(\log P)^2 + 0.852 \log P - 0.629\mu + 4.139$ $n = 12, r = 0.915, SD = 0.227$	24
	Rotorod Ataxia log 1/C = 15.939 log Molecular Weight − 0.972 log P + 0.549μ − 33.187 $n = 16, r = 0.933, SD = 0.388$	24
Carbamates and aromatic compounds	Acetylcholinesterase inhibition $\log 1/K_d = -1.340 \log MR - 2.340\Sigma\pi + 2.404\Sigma\sigma - 0.478\,D + 0.338\mu + 4.818$ $n = 32, r = 0.945, SD = 0.594$	25
Quaternary ammonium compounds	Affinity for Acetylcholine Receptors $\log K = 0.784\pi_R - 0.353\,(\pi^{\oplus}_{-N\equiv})^2 - 0.171\,\pi^{\oplus}_{-N\equiv} + 0.736\mu_R + 2.309\,n_{OH} + 2.173$ $n = 128, r = 0.961, SD = 0.441$	26
N–$SCCl_3$ containing fungicides	Inhibition of spore germination *versus Stemphylium sarcinaeforme* $\log 1/C = -0.314\,(\log P)^2 + 2.385 \log P + 0.683\mu - 1.666$ $n = 14, r = 0.951, SD = 0.411$	27

[a] n = number of data points used in the regression, r = correlation coefficient, SD = standard deviation.

$$\log 1/C = 0.271\pi + 0.062\mu_v + 0.030\mu_v^2 + 2.552 \quad n = 16, r = 0.937, s = 0.074 \qquad \text{(Eq. 24)}$$

It seems that the substituent effect in the drug–receptor interaction depends more directly on the separation of charge μ than on the electronic distribution of the benzene ring (σ). Although the difference in the regressions obtained is small, this example illustrates the usefulness of the aromatic group dipole moment in QSAR.

Other examples of QSAR using dipole moment as an independent variable are shown in Table II. The examples presented and the theoretical relationships between dipole moment and intermolecular interaction energies with receptors, strongly suggest that dipole moment may be a parameter worth considering in QSAR, especially if σ or other electronic parameters fail to give meaningful correlation.

McFarland (22) has reported that in some cases μ^2 gives better correlation than μ; this may be due to the relatively narrow range of μ examined. When μ^2 is used, a wider range of values and a better correlation are obtained. Another report (28) found high degrees of intercorrelation between log molar refraction ($MR = P_e$) and log molar volume (MV), and between log molar refraction and log molecular mass (M):

$$\log MR = -0.290 + 0.981 \log MV \quad n = 213, r = 0.943, s = 0.086 \qquad \text{(Eq. 25)}$$

$$\log MR = -0.358 + 0.884 \log M \quad n = 213, r = 0.917, s = 0.104 \qquad \text{(Eq. 26)}$$

This is easily understandable from the following equations:

$$MR = \frac{n^2 - 1}{n^2 + 2}\frac{M}{d} \qquad \text{(Eq. 27)}$$

$$MV = \frac{M}{d} \qquad \text{(Eq. 28)}$$

The only substituent groups which will not fit Eqs. 27 and 28 are the ones with unusually high densities (d), such as heavy metals and polyhalogenated groups (28).

Furthermore, because of the interrelationship between MR (P_e) (29) and α, one would also expect similar relationship between α and M:

$$MR = P_e, P_e = (4/3)\pi N_a \alpha \qquad \text{(Eq. 29)}$$

where N_a is Avogadro's number.

It was recently reported (25) that charge-transfer effects of various carbamates and aromatic compounds can be separated into steric, electronic (μ and σ), and indicator variables (the number of lone pair electrons). They have also shown that the binding of these acetylcholinesterase inhibitors to the enzyme is well correlated with substituent constants like log MR, $\Sigma\pi$, $\Sigma\sigma$, and D (indicator variable, Table II).

The affinity constants of 128 quarternary ammonium compounds were correlated linearly with the hydrophobicity constant of the side chain (π_R), the dipole moment (μ_R), and the number of hydroxy group (n_{OH}). The dependence on the hydrophobicity constant of the quaternary ammonium head (π-$^{+}_{N\equiv}$) is parabolic (26).

The dipole moment of the heterocyclic ring bearing N-$SCCl_3$ group has also been shown to be important in determining the antifungal activity of these fungicides (27). This is true in the spore germination test against a single organism *S. sarcinaeforme* in QSAR as well as in a test using mixed organisms. In the latter case, discriminant analysis has indicated the important roles of both μ and log P (27).

It is hoped that the compilation of Table I will make it easier for medicinal chemists to use dipole moment as an independent electronic parameter in future QSAR work.

ACKNOWLEDGMENTS

This paper is dedicated to the late Warren D. Kumler for his pioneering work in electric dipole moments and acid–base dissociation constants.

The authors express their sincere thanks to Professor Corwin Hansch of Pomona College for his suggestions and encouragements, and to Dr. Albert Leo for his assistance in assigning the WLN to many of the groups listed.

Determination of Cyclobenzaprine in Tablets by High-Performance Liquid Chromatography

MAXINE L. HEINITZ

Received July 23, 1981, from the *Food and Drug Administration, Minneapolis, MN 55401.* Accepted for publication September 8, 1981.

Abstract □ A convenient high-performance liquid chromatographic method for the quantitative determination of cyclobenzaprine hydrochloride in tablets is described. Samples were dissolved in 0.05 *N* sulfuric acid and diluted with methanol. The cyclobenzaprine hydrochloride was chromatographed using an octylsilane column and the eluent acetonitrile–0.6% dibasic potassium phosphate aqueous buffer (pH 3.0) (75:25) at a flow rate of 1.5 ml/min. Naphazoline hydrochloride was used as an internal standard. The UV detector response at 254 nm was linear for cyclobenzaprine hydrochloride in the 0.005–0.03 mg/ml range under conditions of the analysis.

Keyphrases □ Cyclobenzaprine hydrochloride—determination in tablets by high-performance liquid chromatography □ High-performance liquid chromatography—determination of amount of cyclobenzaprine in tablets □ Naphazoline hydrochloride—internal standard in high-performance liquid chromatographic test for cyclobenzaprine hydrochloride in tablets

The pharmacopeial determination of the skeletal muscle relaxant cyclobenzaprine hydrochloride is tedious and time consuming. The procedure (1) consists of extraction of the chloride ion pair into methylene chloride, followed by back extraction into dilute sulfuric acid and quantitative measurement by UV spectrophotometry. As any degradation product would be expected to exhibit UV absorbance, the USP procedure will not be indicative of stability.

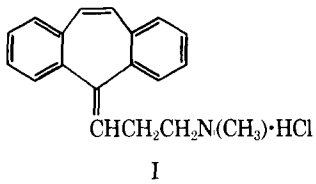
A number of procedures have been reported for the measurement of tricyclic antidepressant drugs in serum or in tablets by HPLC (2–11). Many of these methods use adsorption chromatography (2–6). Of those chromatographic systems utilizing reversed phases (7–11), the use of pentanesulfonic acid (10), sodium lauryl sulfate (11), or aliphatic amines (5) in the mobile phase was avoided. Premature deterioration of the column has been experienced in this laboratory when these reagents are used over an extended period of time. An eluent described previously (9) was adapted to the determination of cyclobenzaprine using an octyl-bonded silica column.

The procedure described was developed for the routine analysis of cyclobenzaprine hydrochloride in tablets. The method employs naphazoline hydrochloride as an internal standard and is readily adaptable to semi-automated analysis with equipment available in most laboratories.

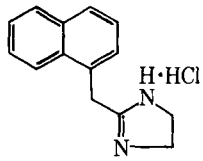
EXPERIMENTAL

Chemicals—Cyclobenzaprine hydrochloride[1] raw material was assayed (100.5%) and its purity confirmed before use by the USP (1) monograph procedures. Naphazoline hydrochloride[2], amitriptyline hydrochloride[1], and desipramine hydrochloride[3] were used without further purification or analysis. All other reagents were commercial analytical reagent grade. Solvents[4] were glass distilled except for distilled water which was deionized and distilled.

Apparatus—The liquid chromatograph consisted of a pump and a fixed wavelength UV detector[5] (254 nm). Solutions were injected by an automated sample processor[6] set to inject 20 μl. The chromatograms were recorded and results calculated by a reporting integrator[7]. UV spectra were recorded on a recording spectrophotometer[8].



I



II

Chromatographic Conditions—The mobile phase consisted of acetonitrile–0.6% KH_2PO_4 aqueous buffer (pH 3.0) (75:25). A flow rate of 1.50 ml/min was maintained. Ambient temperature was used throughout these experiments. A 25 × 0.46-cm i.d. column containing an octyl-bonded phase on silica packing[9] was used. Following each day of use, the column was flushed with acetonitrile–water (75:25), followed by methanol at 1 ml/min and stored in methanol.

Reagents—The pH 3.0 buffer was prepared by dissolving 12 g of potassium phosphate, monobasic in 1800 ml and adjusting to pH 3.0 with phosphoric acid (1:3) using a calibrated pH meter and diluting to 2 liters. Naphazoline hydrochloride prepared as a 1-mg/ml solution in methanol was present as the internal standard at a final concentration of 0.05 mg/ml in the sample solution. The standard solution contained 0.01 mg/ml of cyclobenzaprine hydrochloride and 0.05 mg/ml of naphazoline hydrochloride.

Assay and Calculations—Twenty tablets[10] were accurately weighed and finely powdered to pass a 60-mesh sieve. The equivalent of 1 tablet mass was transferred to a 100-ml volumetric flask, 25 ml of 0.05 *N* sulfuric acid in water was added and the flask was shaken for 1 hr. Methanol was added to a volume of ~85 ml, the flask contents were swirled, and allowed to equilibrate to room temperature. (The mixing of these solvents resulted in a warm solution.) The flask was diluted to volume and mixed. A 10.0-ml aliquot of each sample and 5.00 ml of a 1 mg/ml internal standard were diluted with water to 100 ml, and an aliquot was filtered[11]. For individual tablet analyses, each tablet was dissolved and diluted as described previously.

Duplicate 20-μl aliquots of composite solutions and single 20-μl aliquots of individual tablet solutions were chromatographed. Measurement was by peak area ratio of sample and reference standard to the internal standard using an average of two standard injections. Calculations were done by the reporting integrator.

RESULTS AND DISCUSSION

A typical chromatogram of cyclobenzaprine in the presence of naphazoline is shown in Fig. 1. Linearity of response was demonstrated by chromatographing standard solutions. The graph of response to variation in the concentration over the 0.005–0.030 mg/ml range of cyclobenzaprine hydrochloride with a constant naphazoline hydrochloride concentration (0.050 mg/ml) was linear and passed through the origin.

To determine the precision of this method as compared to the official USP assay, six replicate composites from each of four different commercial lots of cyclobenzaprine tablets were assayed. The results are tabulated in Table I. The coefficient of variation averaged 1.57% by HPLC and 1.00% by the USP method. The devised procedure was con-

[a] Thirty tablets from each sample were assayed. [b] Declaration of 10 mg of cyclobenzaprine hydrochloride/tablet.

Table III—Relationship of the Retention Time to the Phosphate Content in the Aqueous Portion of the Mobile Phase [a]

% KH_2PO_4 [b]	Retention Time, min		
	Cyclobenzaprine Hydrochloride	Amitriptyline Hydrochloride	Desipramine Hydrochloride
0.4	8.18	8.42	6.35
0.5	7.95	8.26	6.21
0.6	6.79	6.95	5.28

[a] The mobile phase consisted of acetonitrile–aqueous potassium phosphate pH 3.0 buffer (75:25); a 25 × 0.46-cm octyl-bonded phase on a silica column was used. [b] The phosphate content is expressed as the amount of monobasic potassium phosphate used to prepare the aqueous pH 3.0 buffer.

Table IV—Ultraviolet Absorption of Cyclobenzaprine Hydrochloride and Naphazoline Hydrochloride at Selected Wavelengths [a]

Compound	Wavelength, nm	$E^b \times 10^3$
Cyclobenzaprine hydrochloride	290	10.79 (max)
	254	10.26
Naphazoline hydrochloride	290	4.52 (sh)
	254	2.31

[a] Spectra recorded in water. [b] E = molar absorptivity.

the mobile phase were tried. The retention time of the cyclobenzaprine varied inversely with the acetonitrile content of the mobile phase. The proposed chromatographic system elutes cyclobenzaprine in ~7 min; but if the acetonitrile is reduced from 75:25 to 65:35, the retention time increases to 12 min. Substitution of methanol increases the retention time and magnifies the tailing.

The relationship of the phosphate content in the mobile phase to the retention time of cyclobenzaprine and two structurally related compounds is shown in Table III. As the concentration of phosphate decreases, the retention time increases.

Initially, only methanol was used to dissolve the tablet material. Choice of this solvent led to ~10% lower results by HPLC than by the USP procedure, even though measurement by UV spectrophotometry of the solution injected showed that the cyclobenzaprine was there at the expected level. Changing the solvent to water did not improve this disparity. When a small amount of acid was added to the solvent used to dissolve the tablet material, the HPLC results correlated well with those of the USP procedure. This problem may be caused by one of the tablet excipients. Examination of the chromatograms of solutions exhibiting low results did now show any evidence of band broadening. Some of the materials used in the tablet may be complexing with the cyclobenzaprine to either render the species immobile on the column, or in some other way interfere with the chromatography.

The use of a completely aqueous solvent for the tablet material was appealing because it would have eliminated the problem of heat formation on mixing the aqueous 0.05 *N* sulfuric acid with methanol. However, an entirely aqueous solvent, or acetonitrile and water, carry into solution most of the tablet excipients, which would then be injected on the column. By the use of methanol, many of the excipients can be removed by filtration prior to chromatography.

Naphazoline hydrochloride was selected for the internal standard for this study because it produced a symmetrical peak shape with good retention characteristics. The molecule possesses a large π-electron system with a good UV chromaphore.

The detector wavelength used throughout this study was 254 nm. More specificity would be gained by the use of the detector wavelength at 290 nm. The UV spectral parameters of cyclobenzaprine and naphazoline at these wavelengths are tabulated in Table IV. At 290 nm half the amount of naphazoline hydrochloride would give a detector response comparable to the response observed at 254 nm.

The HPLC assay procedure is rapid, precise, and specific for the analysis of cyclobenzaprine hydrochloride in tablets and represents a more convenient assay method than that of the USP.

Derivatization of Chiral Amines with (*S*,*S*)-*N*-Trifluoroacetylproline Anhydride for GC Estimation of Enantiomeric Composition

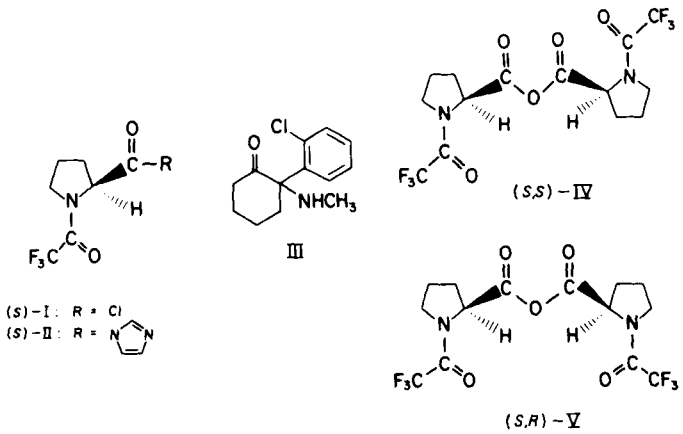
JAMES D. ADAMS, Jr. *§ˣ, THOMAS F. WOOLF ‡, ANTHONY J. TREVOR *, LYALL R. WILLIAMS ‡, and NEAL CASTAGNOLI, Jr. ‡

Received June 8, 1981, from the * *Department of Pharmacology and the* ‡ *Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143.* Accepted for publication September 16, 1981. § Present address: Department of Internal Medicine, Baylor College of Medicine, Texas Medical Center, Houston, TX 77030.

Abstract □ The reaction characteristics of (*S*,*S*)-*N*-trifluoroacetylproline anhydride were examined in an attempt to develop a quantitative GC assay of the enantiomers of the sterically hindered, chiral amine ketamine. With the aid of the individual enantiomers of ketamine and the corresponding synthetic *N*-trifluoroacetylprolyl amides, it was found that the derivatization reaction proceeds stereoselectively, in poor yield, and with some degree of racemization of the acylating reagent. The results indicate that care must be exercised when prolyl derivatizing reagents are chosen for assaying chiral amines.

Keyphrases □ (*S*,*S*)-*N*-Trifluoroacetylproline anhydride—derivatization of ketamine, GC estimation of enantiomeric composition □ GC analysis—detection of enantiomers of chiral amines with (*S*,*S*)-*N*-trifluoroacetylproline anhydride □ Enantiomers—derivatization of chiral amines with (*S*,*S*)-*N*-trifluoroacetylproline anhydride for GC estimation of enantiomeric composition

It is important to examine the extent to which chiral xenobiotics may undergo enantioselective metabolic transformations in an effort to characterize the effects which such processes may have on the pharmacological and toxicological properties of these substances (1, 2). In the case of chiral amines, quantitative estimations of enantiomeric composition have been achieved through GC analysis of the diastereomeric amides formed by derivatization with (*S*)-*N*-trifluoroacetylprolyl chloride [(*S*)-I] (3). Although commercially available as a solution in chloroform, this reagent is difficult to obtain in pure form and is susceptible to racemization (4). The corresponding imidazolide, compound (*S*)-II, is a relatively stable, crystalline solid (5). However, it was observed that this derivative reacts sluggishly with sterically hindered amines such as ketamine (III) (6). In an attempt to obtain a derivatizing reagent that can be prepared in crystalline form and that might react more readily with ketamine, the synthesis of (*S*,*S*)-*N*-trifluoroacetylproline anhydride [(*S*,*S*)-IV] was attempted. An attractive feature of (*S*,*S*)-IV is that inversion about one of the two chiral centers present in this molecule leads to the *meso*-diastereomeric species (*S*,*R*)-V which, in theory, should be separable from (*S*,*S*)-IV.



RESULTS AND DISCUSSION

The synthesis of (*S*,*S*)-IV from (*S*)-proline and trifluoroacetic anhydride was reported originally by Weygand (7). Attempts to repeat this synthesis initially led to the isolation of a species (mp 114–115°) which proved to be an isomer of the Weygand compound; longer reaction times however provided the Weygand compound (mp 138–140°). The electron impact mass spectra and NMR spectra of these products were essentially identical, which suggested that the two compounds were diastereomerically related. Since the high-melting isomer did not rotate plane polarized light, whereas the low-melting isomer was strongly levorotatory, the low-melting isomer was tentatively assigned the asymmetric structure (*S*,*S*)-IV and the Weygand compound the *meso*-structure, (*S*,*R*)-V.

Consistent with these assignments, reaction of (*S*,*S*)-IV with (*S*)-

The HPLC assay procedure is rapid, precise, and specific for the analysis of cyclobenzaprine hydrochloride in tablets and represents a more convenient assay method than that of the USP.

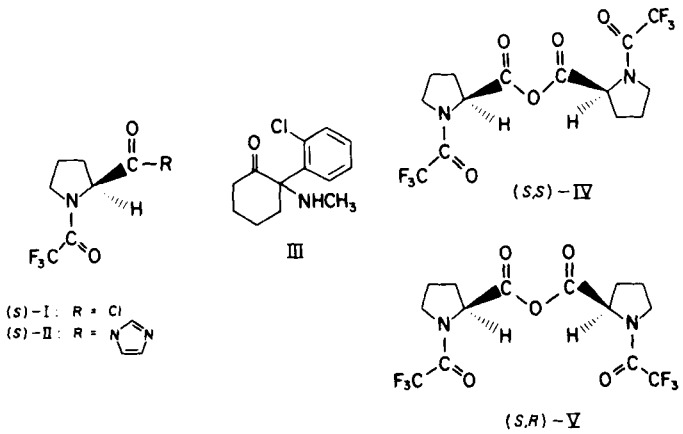
Abstract □ The reaction characteristics of (*S*,*S*)-*N*-trifluoroacetylproline anhydride were examined in an attempt to develop a quantitative GC assay of the enantiomers of the sterically hindered, chiral amine ketamine. With the aid of the individual enantiomers of ketamine and the corresponding synthetic *N*-trifluoroacetylprolyl amides, it was found that the derivatization reaction proceeds stereoselectively, in poor yield, and with some degree of racemization of the acylating reagent. The results indicate that care must be exercised when prolyl derivatizing reagents are chosen for assaying chiral amines.

Keyphrases □ (*S*,*S*)-*N*-Trifluoroacetylproline anhydride—derivatization of ketamine, GC estimation of enantiomeric composition □ GC analysis—detection of enantiomers of chiral amines with (*S*,*S*)-*N*-trifluoroacetylproline anhydride □ Enantiomers—derivatization of chiral amines with (*S*,*S*)-*N*-trifluoroacetylproline anhydride for GC estimation of enantiomeric composition

It is important to examine the extent to which chiral xenobiotics may undergo enantioselective metabolic transformations in an effort to characterize the effects which such processes may have on the pharmacological and toxicological properties of these substances (1, 2). In the case of chiral amines, quantitative estimations of enantiomeric composition have been achieved through GC analysis of the diastereomeric amides formed by derivatization with (*S*)-*N*-trifluoroacetylprolyl chloride [(*S*)-I] (3). Although commercially available as a solution in chloroform, this reagent is difficult to obtain in pure form and is susceptible to racemization (4). The corresponding imidazolide, compound (*S*)-II, is a relatively stable, crystalline solid (5). However, it was observed that this derivative reacts sluggishly with sterically hindered amines such as ketamine (III) (6). In an attempt to obtain a derivatizing reagent that can be prepared in crystalline form and that might react more readily with ketamine, the synthesis of (*S*,*S*)-*N*-trifluoroacetylproline anhydride [(*S*,*S*)-IV] was attempted. An attractive feature of (*S*,*S*)-IV is that inversion about one of the two chiral centers present in this molecule leads to the *meso*-diastereomeric species (*S*,*R*)-V which, in theory, should be separable from (*S*,*S*)-IV.



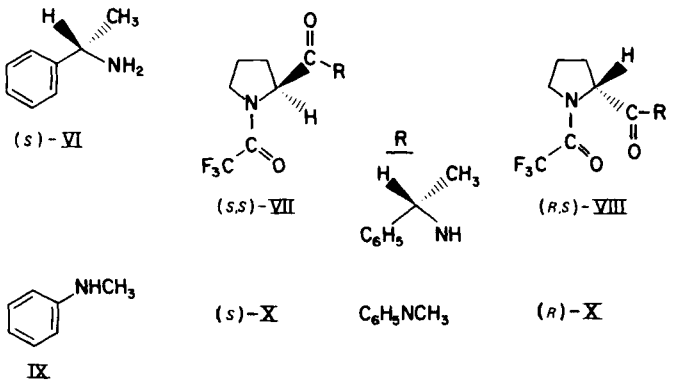
RESULTS AND DISCUSSION

The synthesis of (*S*,*S*)-IV from (*S*)-proline and trifluoroacetic anhydride was reported originally by Weygand (7). Attempts to repeat this synthesis initially led to the isolation of a species (mp 114–115°) which proved to be an isomer of the Weygand compound; longer reaction times however provided the Weygand compound (mp 138–140°). The electron impact mass spectra and NMR spectra of these products were essentially identical, which suggested that the two compounds were diastereomerically related. Since the high-melting isomer did not rotate plane polarized light, whereas the low-melting isomer was strongly levorotatory, the low-melting isomer was tentatively assigned the asymmetric structure (*S*,*S*)-IV and the Weygand compound the *meso*-structure, (*S*,*R*)-V.

Consistent with these assignments, reaction of (*S*,*S*)-IV with (*S*)-

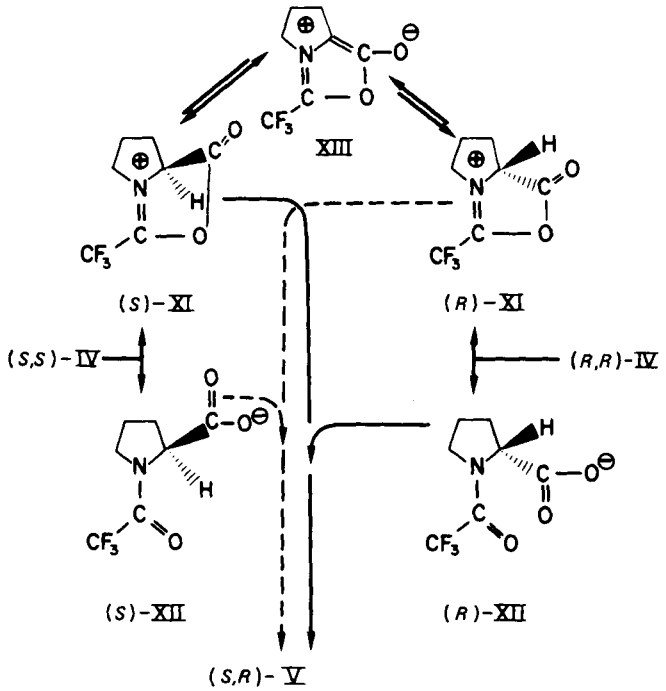
0022-3549/82/0600-0658$01.00/0

α-methylbenzylamine [(S)-VI] yielded a product that displayed a single GC peak and that presumably corresponds to structure (S,S)-VII. Reaction of (S)-VI with (S,R)-V, on the other hand, yielded a product displaying two equally intense GC peaks corresponding to (S,S)-VII and (R,S)-VIII[1]. Additionally, reaction of (S,S)-IV with N-methylaniline (IX) yielded a levorotatory anilide [(S)-X], while the corresponding reaction with compound (S,R)-V yielded a racemic mixture of (S)-X and (R)-X.



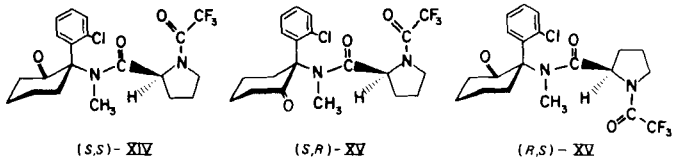
The experimental evidence described previously is sufficient to assign unambiguously the structure of the low-melting isomer. Parallel experimental results have led to the same conclusions (8). The data supporting the structure assignment of (S,R)-V, however, are also consistent with a racemic mixture of (S,S)-IV and (R,R)-IV. As has been reported with related systems, the ability to distinguish between such species is often not a trivial task (9). Therefore, the preparation of the racemate of IV was attempted by mixing equal amounts of (R,R)-IV [prepared from (R)-proline and trifluoroacetic anhydride] and (S,S)-IV. The product obtained after crystallization proved to be identical in every way to the high-melting isomer. The IR spectra of the presumed racemate and the high-melting isomer obtained from the Weygand procedure also were identical but were different from that of (S,S)-IV. Based on these results and the facile interchange which is reported to occur with mixtures of acetic anhydride and trifluoroacetic anhydride (10), it is possible that upon recrystallization, the racemic mixture of IV undergoes disproportionation to yield the thermodynamically more stable *meso*-isomer (S,R)-V.

The pathway leading to the formation of the *meso*-compound is likely to involve the oxazolinium intermediate (XI) (Scheme I). Recombination of the (R)-N-trifluoroacetylprolyl anion [(R)-XII] with (S)-XI leads to (S,R)-V. Compound (S,R)-V may also be formed from (S)-XII and (R)-XI. It seems reasonable to speculate that the formation of compound (S,R)-V from (S)-proline and trifluoroacetic anhydride also proceeds through XI, which may undergo inversion to (R)-XI through reversible tautomerism to the symmetric mesoionic species (XIII). A similar process has been proposed for the racemization of (S)-N-p-nitrobenzoylproline in the presence of acetic anhydride and a trace of acid (11).



Scheme I

The utility of (S,S)-IV for the quantitative estimation of the enantiomeric composition of ketamine was examined next. GC analysis of the reaction product obtained between (S,S)-IV and racemic ketamine in the presence of triethylamine gave a pair of sharp peaks with baseline separation and mass spectra consistent with the expected amide structures (S,S)-XIV and (S,R)-XV[2]. With the aid of the pure ketamine enantiomers, the diastereomer with the shorter retention time was shown to be the (S)-N-trifluoroacetylprolyl amide of (S)-ketamine. Under a variety of reaction conditions, however, product formation appeared to favor the diastereomer having the longer retention time, *i.e.*, (S,R)-XV. For reasons to be discussed, reaction of racemic ketamine with (S,S)-IV also may yield significant amounts of the enantiomeric species (R,S)-XV.



The two N-trifluoroacetylprolyl diastereomeric amides of (R)- and (S)-ketamine were obtained in analytically pure form from the reaction of (S)-N-trifluoroacetylprolyl chloride and individual ketamine enantiomers. Although the reaction with (R)-ketamine proceeded smoothly, attempts to prepare the corresponding amide of (S)-ketamine were accompanied by extensive inversion of the derivatizing reagent. The main product obtained in this reaction was the diastereomeric (R)-N-trifluoroacetylprolyl amide of (S)-ketamine, *i.e.*, (R,S)-XV. The N-trifluoroacetylproline recovered from the reaction mixture proved to be racemic, which indicates that racemization of the prolyl reagent during the reaction with (S)-ketamine is extensive.

GC analysis of the two diastereomers showed that the detector responses of these compounds were essentially identical. Consequently, the different peak heights observed in the analysis of racemic ketamine must be due to the stereoselective formation of the (S)-N-trifluoroacetylprolyl amide of (R)-ketamine and/or the (R)-N-trifluoroacetylprolyl amide of (S)-ketamine.

An additional frustration encountered in the attempts to develop a ketamine assay with (S,S)-IV was the low yields realized in these reactions. Based on peak heights found with the synthetic N-trifluoroacetylprolyl amides, the maximum combined yield of the two diastereomeric amides obtained upon reaction of racemic ketamine with (S,S)-IV was only 17% (Table I). The use of a large excess of the anhydride or introduction of additional anhydride during the course of the reaction did not influence the overall yield. Although somewhat better yields were obtained with (S)-I, the derivatization of ketamine with (S)-I was more stereoselective (Table I).

A pathway to account for these results would involve cleavage of the anhydride to the (S)-oxazolinium species [(S)-XI] and (S)-N-trifluoroacetylproline anion [(S)-XII]. Conversion of (S)-XI to XIII would deplete the acylating reagent and also generate 1 mole of acid. Although a 5:1 *M* ratio of triethylamine to ketamine was used, the large excess of (S,S)-IV could result in adequate acid production to protonate (and hence inactivate) the ketamine. The yellow color which developed during the course of the reaction is consistent with the report that XIII is yellow (12).

Analytical scale reactions with the individual isomers of ketamine again demonstrated the poor reactivity of (S)-ketamine with both (S,S)-IV and (S)-I (Table I). Extensive racemization occurred during these reactions. Since the chiral center of ketamine is tetrasubstituted, and therefore unlikely to racemize, the formation of the undesired diastereomer is attributed to inversion of the prolyl moiety. The reactions of (S,S)-IV and (S)-I with (R)-III proceeded in reasonable yields and were accompanied by only a limited amount of inversion (Table I). If it is assumed that the transition state energy for the formation of the prolyl

[1] For all such designations, the first symbol refers to the chirality of the N-trifluoroacetylprolyl moiety and the second symbol to the chirality of the amine.

[2] The absolute stereochemistry of ketamine-free base has been found to be R(+) and S(−). These data will be published in the near future.

Table I—GC Analysis of Ketamine following Derivatization with *N*-Trifluoroacetylpropyl Reagents[a]

Reactant	Reagent	Temperature (Time, hr)	Peak Areas[b] (*S,S*)-/(*R,S*)-XIV	Peak Areas[b] (*S,R*)-/(*R,S*)-XV	Yield, %[c]
(*R,S*)-III	(*S,S*)-IV	75° (2)	3	6	2
(*R,S*)-III	(*S,S*)-IV	75° (2)	3	8	2
(*R,S*)-III	(*S,S*)-IV	100° (1)	14	68	16
(*R,S*)-III	(*S,S*)-IV	100° (2)	21	63	17
(*R,S*)-III	(*S,S*)-IV	100° (4)	20	58	16
(*S*)-III	(*S,S*)-IV	75° (2)	2	0	1
(*S*)-III	(*S,S*)-IV	100° (2)	49	14	25
(*R*)-III	(*S,S*)-IV	75° (2)	0	6	3
(*R*)-III	(*S,S*)-IV	100° (2)	12	86	39
(*R,S*)-III	(*S*)-I	75° (2)	33	206	48
(*R,S*)-III	(*S*)-I	75° (4)	32	196	46
(*R,S*)-III	(*S*)-I	100° (1)	49	211	52
(*R,S*)-III	(*S*)-I	100° (2)	29	134	33
(*S*)-III	(*S*)-I	75° (2)	27	19	18
(*R*)-III	(*S*)-I	75° (2)	18	208	90

[a] The assays were performed according to the procedure described in the Experimental section. [b] Since (*S,S*)-IV and (*S*)-I are susceptible to inversion, the peak areas reported for reactions involving racemic ketamine represent the sum of the responses of the enantiomeric prolyl amides. [c] Yields were calculated on the basis of detector responses obtained with pure (*S,S*)-XIV and (*R,S*)-XV. Note that the individual enantiomers were run at one-half the concentration of racemic ketamine.

amide with (*S*)-ketamine is greater than with (*R*)-ketamine, the competing reaction pathway (Scheme I) leading to isomerization of (*S,S*)-IV and (*S*)-I would proceed to a greater extent in the reaction with (*S*)-ketamine than with (*R*)-ketamine. Once inversion has occurred, the energetically more favored reaction of (*S*)-ketamine with the (*R*)-prolyl reagent could occur preferentially.

The results obtained in this study clearly point to a number of difficulties with prolyl derivatizing reagents to which researchers should be alerted. Whenever possible, quantitative estimations based on GC analysis of reaction mixtures should be based on detector responses measured with the pure synthetic diastereomeric amides. Secondly, the possibility of stereoselective reactions with chiral amines and prolyl derivatizing reagents should be carefully evaluated. Finally, the stability of the derivatizing reagent with respect to racemization should be examined with the aid of the individual enantiomers of the amine. In the present study it has been found that the reaction of the anhydride reagent (*S,S*)-IV with ketamine proceeds stereoselectively, in poor yield, and is accompanied by inversion. Unfortunately, the corresponding reaction between the commercially available (*S*)-*N*-trifluoroacetylprolyl chloride suffers from similar limitations.

EXPERIMENTAL[3]

(*S,S*)-*N*-Trifluoroacetylproline Anhydride [(*S,S*)-IV]—Trifluoroacetic anhydride (84 g, 0.40 mole) was added dropwise with stirring under nitrogen and external cooling to an ice cold suspension of (*S*)-proline (23 g, 0.20 mole). After 3 hr, the volatile components were removed under vacuum and the residual yellow mass was recrystallized 3 times from ether to yield 22.9 g (0.06 mole, 57%) of white crystals, mp 114–115° [lit. (8) mp 114–115°]; NMR (deuterochloroform): 1.8–2.5 (m, 8H, CH_2), 3.79 (m, 4H, NCH_2), and 4.62 (t, J = 6.2 Hz, 2H, CH) ppm; IR (oil mull): 1822, 1760, 1690, 1460, 1380, 1360, 1350, 960, 940, 930, 910, 878, 840, 815, 795, and 768 cm^{-1}; electron impact mass spectrum (relative intensity): 404 (M^+, 0.4), 376 (0.5), 211 (1.4), 194 (44), 166 (100), 98 (9.8), 96 (35), and 69 (82); $[\alpha]_D^{22} = -98.6°$ (*C*, 0.7 mg/ml; benzene).

Anal.—Calc. for $C_{14}H_{14}N_2O_5F_6$: C, 41.60; H, 3.49; N, 6.93. Found: C, 41.53; H, 3.51; N, 6.83.

[3] Melting points were taken on a Thomas-Hoover apparatus and are uncorrected. IR spectra were obtained using a Beckman Aculab 2 spectrophotometer. NMR spectra were recorded on a Varian FT-80 instrument. Chemical shifts are reported in parts per million (ppm) relative to trimethylsilane. Chemical ionization mass spectra were taken on an Associated Electronics Inc. Model MS-902 double-focus mass spectrometer equipped with a direct inlet system and modified for chemical ionization. The electron impact mass spectra were recorded on a Hitachi model M-52 instrument. Specific rotation measurements were performed on a Perkin-Elmer 141 electronic polarimeter. GC analyses of the derivatized amines were recorded on a Hewlett-Packard 5700A machine equipped with a nickel electron capture detector. The column was a 3 m × 6-mm i.d. glass column packed with 3% SP 2250 coated on 100/120 mesh Supelcoport. Argon–methane carrier gas flow rate was 30 ml/min and the column temperature was 250°. Peak area integration was done automatically by a Hewlett-Packard 3380A integrating recorder. Microanalyses were performed by the Microanalytical Laboratory, University of California at Berkeley.

The corresponding reaction with (*R*)-proline provided the enantiomeric anhydride (*R,R*)-IV, in 36% yield: mp 114–115°; $[\alpha]_D^{22} = +106.5°$ (*C*, 0.7 mg/ml, benzene).

(*S,R*)-*N*-Trifluoroacetylproline Anhydride [(*S,R*)-V]—The reaction of (*S*)-proline (5.75 g, 0.05 mole) and trifluoroacetic anhydride (42.0 g, 0.20 mole) in 20 ml of methylene chloride at room temperature for 48 hr yielded 2.5 g (0.006 mole, 25%) of the *meso*-anhydride, (*S,R*)-V, which was recrystallized from ether: mp 139–140° [lit. (7) mp 138–140°]; NMR and electron impact mass spectrum were indistinguishable from (*S,S*)-IV; $[\alpha]_D^{22} = 0.0°$ (*C*, 0.66 mg/ml; benzene); IR (oil mull): 1822, 1760, 1690, 1465, 1380, 1368, 1355, 940, 930, 914, 874, 812, and 760 cm^{-1}.

Anal.—Calc. for $C_{14}H_{14}N_2O_5F_6$: C, 41.60; H, 3.49; N, 6.93. Found: C, 41.77; H, 3.62; N, 6.96.

(*S*)-*N*-(*N*-Trifluoroacetylprolyl)-*N*-methylaniline [(*S*)-X]—A mixture of (*S,S*)-IV (1.8 g, 4.5 mmoles) and *N*-methylaniline (5 g, 46.7 mmoles) was heated for 2 hr under nitrogen with stirring. The cooled reaction mixture was washed twice with 10 ml of hexane and the residual oil was subjected to a short path distillation under reduced pressure. The distillate was crystallized from chloroform to yield 0.6 g (2.0 mmoles, 22.4%) of a colorless solid: mp 136–138°; NMR (deuterochloroform): 1.5–2.3 (m, 4H, CH_2), 3.28 (s, 3H, CH_3), 3.76 (m, 2H, NCH_2), 4.43 (t, J = 6.3 Hz, 1H, CH), and 7.40 (m, 5H, phenylH) ppm; $[\alpha]_D^{22} = -102.9°$ (*C*, 0.7 mg/ml; benzene).

Anal.—Calc. for $C_{14}H_{15}N_2O_2F_3$: C, 56.00; H, 5.04; N, 9.33. Found: C, 55.65; H, 5.07; N, 9.28.

The same reaction carried out with (*S,R*)-V provided (*S,R*)-X in 17% overall yield: mp 102–104°; $[\alpha]_D^{22} = 0.0°$ (*C*, 0.7 mg/ml, benzene).

Anal.—Calc. for $C_{14}H_{15}N_2O_2F_3$: C, 56.00; H, 5.04; N, 9.33. Found: C, 56.05; H, 5.04; N, 9.31.

(*S,S*)-2-[*N*-(*N*-Trifluoroacetylprolyl)-*N*-methyl]amino-2-*o*-chlorophenylcyclohexanone [(*S*)-*N*-Trifluoroacetylprolyl Amide of (*S*)-Ketamine, (*S,S*)-XIV]—A solution of (*S*)-*N*-trifluoroacetylprolyl chloride (536 mg, 2.33 mmoles in 23 ml of methylene chloride) and (*S*)-III (13) (500 mg, 2.11 mmoles in 10 ml of toluene) was heated at 75° with stirring under nitrogen for 1.5 hr. After cooling, the reaction mixture was stirred with 30 ml of 0.2% NaOH, separated, and washed with 10 ml of 0.5% HCl. After drying with sodium sulfate, hexane was added and the resulting solution was cooled to 5° to produce 300 mg (0.7 mmole, 33.2%) of a solid: $[\alpha]_D^{22} = +41.6°$ (*C*, 0.77 mg/ml; benzene); mp 197–200°. The NMR, electron impact mass spectrum, and GC retention time of the product were identical to the corresponding values for (*S,R*)-XV and therefore, its structure is assigned as (*R,S*)-XV. Treatment of the mother liquor with an additional 5 ml of hexane caused the precipitation of a second solid (45 mg, 0.2 mmole) which proved to be racemic *N*-trifluoroacetylproline: mp 53–55°; $[\alpha]_D^{22} = 0.0°$ (*C*, 0.7 mg/ml; benzene); chemical ionization mass spectrum, 212 (MH^+).

Anal.—Calc. for $C_7H_8NO_3F_3$: C, 39.81; H, 3.79; N, 6.64. Found: C, 39.80; H, 3.88; N, 6.60.

The residue obtained from the mother liquor filtrate was chromatographed on 10 g of silica. Elution with benzene–ethanol (95:5) provided a solid, which after crystallization from toluene–hexane yielded 7 mg (0.016 mmole, 0.8%) of the desired amide (*S,S*)-XIV: mp 184–186°; chemical ionization mass spectrum (*m/z*, relative intensity): 433 and 431 (MH^+, 25, 100), 397 (10), 227 and 225 (50, 100), 211 and 209 (60, 100); GC retention time, 16.8 min.

Anal.—Calc. for $C_{20}H_{22}N_2O_3F_3Cl$: C, 55.75; H, 5.15; N, 6.50. Found: C, 55.56; H, 5.30; N, 6.46.

(*R*)-2-[*N*-(*N*-Trifluoroacetyl-(*S*)-prolyl)-*N*-methyl]amino-2-*o*-chlorophenylcyclohexanone [(*S*)-*N*-Trifluoroacetylprolyl Amide of (*R*)-Ketamine, (*S,R*)-XV]—(*S*)-*N*-Trifluoroacetylprolyl chloride and (*R*)-ketamine were allowed to react under the same conditions as described previously. After treatment with 0.2% NaOH, extraction with 0.5% HCl, and drying with sodium sulfate, addition of hexane and cooling led to the crystallization of 490 mg (1.14 mmoles, 54%) of (*S,R*)-XV: mp 200–202°; NMR (deuterochloroform): 1.5–2.6 (m, 11H, CH_2), 3.24 (s, 3H, NCH_3), 3.3–3.5 (q, 1H, CH), 3.7–3.9 (m, 2H, CH_2), 5.09 (t, 1H, CH), and 7.1–7.5 (m, 4H, phenylH) ppm; $[\alpha]_D^{22} = -41.2°$ (*C*, 0.68 mg/ml; benzene); chemical ionization mass spectrum was identical to (*S,S*)-XIV; GC retention time, 19.2 min.

Anal.—Calc. for $C_{20}H_{22}N_2O_3F_3Cl$: C, 55.75; H, 5.15; N, 6.50. Found: C, 55.70; H, 5.24; N, 6.32.

Amine Derivatization—Derivatizations of racemic ketamine and the individual enantiomers of ketamine for GC analysis were performed under similar conditions except that the concentration of racemic ketamine was twice that of the individual enantiomers. Reactions were carried out in 50 μl of toluene–methylene chloride–triethylamine (95:5:0.02) containing (*R,S*)-ketamine (1.68 m*M*) or the ketamine enantio-

mers (0.84 mM), and in each case a 30 M excess of (S,S)-IV or (S)-I. The reactions were performed in screw cap sealed, polytef-lined reaction vials which were heated to 75–100° for 1–4 hr in a block heater. At the end of the reaction, the mixtures were washed with 0.2% NaOH (50 μl) followed by 0.5% HCl (50 μl) and then dried over sodium sulfate. The solutions were carefully transferred with the aid of a Pasteur pipet to a second reaction vial and the solvent removed under a stream of dry nitrogen. The residues were dissolved in 100 μl of toluene, and 1 μl of the resulting solution was analyzed by GC. Retention times for (S,S)-XIV and (S,R)/(R,S)-XV were 16.8 and 19.2 min, respectively. Derivatization of (S)-α-methylbenzylamine with (S,S)-IV and (R,S)-V proceeded in a similar fashion. GC retention times for (S,S)-VII and (S,R)-VIII were 15.5 and 13.3 min, respectively, using the same conditions as for the ketamine analyses.

Abstract □ The sweet compounds 2-methyl- and 3-methylcyclohexyl- and 2-cyclohexenylsulfamates were fed to Wistar albino rats. The urine (and feces in the case of 2-cyclohexenylsulfamate) was examined for possible amine, ketone, and alcohol metabolites. The total percent of metabolites formed was low and the hexenyl compound gave a particularly small quantity of metabolite. The results with these compounds are compared with those obtained from earlier *in vivo* studies with cyclamate and other sulfamates. In complementary *in vitro* studies, the four sweetest sulfamates, namely, cyclamate, cycloheptyl-, cyclooctyl-, and cyclopentylsulfamates were incubated with the cell-free extract of bacteria isolated from the feces of cyclamate fed rats. Some correlation was apparent between these *in vitro* experiments and previous *in vivo* studies. Preliminary mutagenicity testing (the Ames test) of some amines (corresponding to the sulfamates studied) has been carried out.

Keyphrases □ Sulfamate sweeteners—*in vivo* and *in vitro* studies of amine, ketone, and alcohol metabolites □ Metabolism—amine ketone, and alcohol metabolites of sulfamate sweeteners □ Cyclamates—*in vivo* and *in vitro* studies of amine, ketone, and alcohol metabolites

The controversial ban on the use of cyclohexylsulfamate (cyclamate) salts as nonnutritive sweeteners has provided a strong impetus for wide and varied toxicity studies of these compounds and their metabolites (1). Though at least some other sulfamates have a sweetness potency similar to the banned parent compound (2), and it has been suggested that certain of these sulfamates might be less readily metabolized than is cyclamate (3), nevertheless toxicological studies have been carried out on just a few such compounds (4). In the present work, *in vivo* animal feeding studies employed three other sweet sulfamates: 2- and 3-methylcyclohexyl- and 2-cyclohexenylsulfamates. In a complementary *in vitro* study, some of the sweetest known sulfamates have been incubated in cell-free extracts of the microorganisms responsible for the metabolism of cyclamate. Some work has been carried out on the mutagenicity of the amines to which these sulfamates give rise when metabolized.

EXPERIMENTAL

Reagents and Chemicals—The amines, ketones, and alcohols were commercially available and were used as obtained. The following compounds were synthesized by known literature methods: 2-methylcyclohexanol (5), cyclohexyl- (6), 2-methyl- (6), 3-methyl- (6), 2-cyclohexenyl- (7), *n*-octyl- (8), and phenyl- (9) sulfamates. Cyclopentyl-, cycloheptyl-, and cyclooctylsulfamates were previously prepared (4). All the synthesized sulfamates (as their sodium salts) gave a positive "sulfamate test" (2), satisfactory C, H, and N analysis, and the characteristic IR bands for sulfamates. 2-Cyclohexenylsulfamate gave an additional band in the 1640–1615 cm^{-1} region, which is characteristic of an ethylenic double bond.

***In Vivo* Experiments**—Female Wistar albino rats (200–257 g) were kept on solid food and water in rat metabolism cages[1]. The sodium salts of 2- and 3-methylcyclohexyl- and 2-cyclohexenylsulfamates were administered orally in water (~20 ml) at a level of 1.45 g/kg of body weight to groups of six rats (five in the case of 2-methylcyclohexylsulfamate). Prior to administration of the sulfamates, the rats were deprived of water for 24 hr. Prior to feeding, the urine of each rat was examined for metabolites by GLC. Similarly, the three sulfamates fed were screened for occluded amine, also by GLC. After administration of each sweet compound, the urine (and feces in the case of 2-cyclohexenylsulfamate) was collected for 3 days, bulked, and refrigerated for no more than 1 day when GLC analysis for the metabolites was carried out.

The urine and feces recovered from rats, fed 2-cyclohexenylsulfamate, was not analysed until the eighth day (instead of the customary fourth day), and accordingly, a study of the stabilities of 2-cyclohexenylamine and 2-cyclohexenone in urine and feces over a 7-day period was made.

mers (0.84 mM), and in each case a 30 M excess of (S,S)-IV or (S)-I. The reactions were performed in screw cap sealed, polytef-lined reaction vials which were heated to 75–100° for 1–4 hr in a block heater. At the end of the reaction, the mixtures were washed with 0.2% NaOH (50 μl) followed by 0.5% HCl (50 μl) and then dried over sodium sulfate. The solutions were carefully transferred with the aid of a Pasteur pipet to a second reaction vial and the solvent removed under a stream of dry nitrogen. The residues were dissolved in 100 μl of toluene, and 1 μl of the resulting solution was analyzed by GC. Retention times for (S,S)-XIV and (S,R)/(R,S)-XV were 16.8 and 19.2 min, respectively. Derivatization of (S)-α-methylbenzylamine with (S,S)-IV and (R,S)-V proceeded in a similar fashion. GC retention times for (S,S)-VII and (S,R)-VIII were 15.5 and 13.3 min, respectively, using the same conditions as for the ketamine analyses.

±*SE*	±8.41		±3.38		±5.15

The two metabolites were added individually to samples of rat urine and feces, and these samples were then refrigerated for 7 days, worked-up, and analyzed in the same manner as the actual samples from the feeding experiments.

General Work-Up Procedure, Standardization, and GLC Analysis—The details for other sulfamates have been reported previously (4). Analogous procedures and methods were employed for the three sulfamates. The GLC conditions were as follows. 2-Methylcyclohexylsulfamate metabolites: column temperature, 117°; gas flow rates, nitrogen, 60 ml/min, hydrogen, 60 ml/min, and overall (including air), 500 ml/min; retention times (min), 2-methylcyclohexylamine (4.5), 2-methylcyclohexanone (6.7), 2-methylcyclohexanol (10.1), and 4-methylcyclohexanol (internal standard) (12.6). 3-Methylcyclohexylsulfamate metabolites: column temperature and flow rates, as described previously; retention times (min), *n*-undecane (internal standard) (3.8), 3-methylcyclohexylamine (4.6), 3-methylcyclohexanone (7.2), and *cis*- and *trans*-3-methylcyclohexanols (10.5 and 11.7, respectively). 2-Cyclohexenylsulfamate metabolites: column temperature, 107°; gas flow rates were identical with those described previously; retention times (min), *n*-dodecane (internal standard) (11.0), 2-cyclohexenone (16.5), and 2-cyclohexenylamine (18.6). The lengthy retention times involved in the latter analysis could not be shortened on the column (4). This is because a rise in the temperature tended to cause the cyclohexenyl metabolite peaks to merge. The GLC conditions for analysis of the sulfamate metabolites used in the *in vitro* experiments have been described previously (4), except in the case of *n*-octyl- and phenylsulfamates. The following are the GLC conditions for the determination of the metabolites of these two sulfamates. *n*-Octylsulfamate metabolites: column temperature, 130°; nitrogen gas flow rate, 150 ml/min; retention times (min); *n*-octylamine (6.4), tridecane (internal standard) (9.6), and *n*-octanol (19.5). Phenylsulfamate metabolites: column temperature and nitrogen flow rate as for *n*-octylmetabolites; retention times (min), aniline (3.8), tridecane (internal standard) (9.6), and phenol (31.0).

***In Vitro* Experiments**—*Isolation of Organisms and Preparation of Cell-Free Extracts*—Wistar albino rats were fed cyclohexylsulfamate at the rate of 2 g/week for a 10-week period. The urine was tested for the presence of cyclamate metabolites, *i.e.*, cyclohexylamine, cyclohexanone, and cyclohexanol, using solvent extraction and identification by GLC (10). When a rat was consistently breaking down cyclamate to its metabolites, the feces were then used for the isolation of the microorganisms.

A nutrient broth agar containing 1% cyclohexylsulfamate was inoculated with a sample of fecal material, allowed to grow overnight, and transferred to a larger volume the following day. The bacteria were grown in a shaking incubator for 5 days after which they were harvested by centrifugation. The pellets were resuspended in a small volume of tromethamine-hydrochloride buffer, pH 7.2, and lysed by sonication.

Incubation Procedure and Analysis for Metabolites—Two milliliters of cell-free extract were incubated with 200 μmoles of test sulfamate in 2 ml of 0.1 *M* phosphate buffer, pH 6.8, for 2 hr at 50°. The reaction was stopped by adding 1 ml of 10 *N* NaOH followed by 4 ml of 20% sulfosalicylic acid.

The incubation mixture was extracted three times with 20-ml volumes of methylene chloride. The methylene chloride extracts were bulked and evaporated to dryness and the residue reconstituted with 1 ml of methylene chloride. Analysis for metabolites was then carried out using the procedure described previously. The incubation studies were carried out over a 2-hr period at 50°, pH 6.8, and were the conditions under which the enzymes present in the cell-free extract displayed maximum activity. The variations of enzyme activities with temperature, pH, and incubation time were determined in separate experiments.

Mutagenicity Testing—Amines were tested for their ability to cause base-pair substitution mutations using the mutant strain of *Salmonella typhimurium* TA 1535, according to the method described previously (11). Fifteen micrograms of the test substance contained in 0.1 ml of water was used in each case and 2-aminofluorene was used as a standard.

The mixed oxidase S-9 mixture was not used because the compounds under test were already presumed metabolites.

RESULTS AND DISCUSSION

In the present paper the three compounds, 2-methyl- and 3-methylcyclohexyl- and 2-cyclohexenylsulfamates, were administered as their sodium salts to rats. These studies extended previous studies in which sulfamates other than the "parent" sweet sulfamate, cyclohexylsulfamate (cyclamate), were fed to animals and the urine examined for breakdown products (4). Prior to administration of the three compounds in the present study, standard curves and percent recoveries of likely metabolites were determined using procedures established in earlier work (4). In Tables I–III, percent recoveries for metabolites of 2-methyl- and 3-methylcyclohexyl- and 2-cyclohexenylsulfamates are seen to be satisfactory. It should be noted that in general the quantities in micrograms used in the determination of the percent recoveries are in the same range as the amounts of metabolites found in the feeding experiments.

In other preliminary experiments, the sulfamates given to the animals were screened for small occluded amounts of metabolite(s) and the urine (feces in one instance) of the rats to be fed was screened for metabolites. Since it was not possible to examine the urine/feces of the rats that were fed 2-cyclohexenylsulfamate for 7 days after administering the sweetener, a study of the stabilities of 2-cyclohexenylamine and 2-cyclohexenone in urine/feces was made over a 7-day period. The stabilities of the two compounds, reported as percent survival, is excellent (Table IV). Samples of 2-cyclohexenols were not available but it appears unlikely that they were products of the metabolic cleavage of 2-cyclohexenylsulfamate.

The aim of the *in vivo* study was to examine the effect of introducing a substituent or double bond on metabolic breakdown of cyclohexylsulfamate. If metabolic breakdown was decreased, then the risks associated with cyclamate ingestion should be reduced. The first compound administered was 2-methylcyclohexylsulfamate. Table V shows that this compound was broken down by all rats to the metabolites 2-methylcyclohexylamine and/or 2-methylcyclohexanone. None of the rats in this group gave alcohol metabolites. In this work, as previously (4), the percent conversion to a particular metabolite is defined as the amount of metabolite found (milligrams) divided by the amount of sulfamate fed (milligrams) multiplied by a hundred times the ratio of the molecular weight of the sulfamate to that of the particular metabolite. In this instance, the mean percent conversions to amine and ketone are 0.00013 and 0.00067, respectively. In the case of the study with 3-methylcyclohexylsulfamate, the mean percent of 3-methylcyclohexylamine, 3-methylcyclohexanone, and 3-methylcyclohexanol formed were 0.014, 0.0002, and 0.0098, respectively (Table VI). After administration of 2-cyclohexenylsulfamate, only two rats in the group of six were found to be converters, and interestingly, these two rats gave amine only (mean percent, 0.00017) with no metabolites in their feces (Table VII). It was not possible to check positively for the presence of 2-cyclohexenols, since these compounds were not available. However, from experience it was felt that the retention time(s) of this alcohol(s) should be fairly close to that of the corresponding amine and ketone, but no traces were obtained in the vicinities of the peaks due to these metabolites, nor did any traces appear when the chromatograph was run 29 min, *i.e.*, 10 min after the appearance of the last peak.

Table VIII gives the mean percent and the percent total metabolites found in *in vivo* studies with the three sulfamates of the present study, five sulfamates previously administered to rats and, for comparison, some typical data for cyclohexylsulfamate.

[a] Rat 1 received approximately half the amount of sulfamate.

Table VIII shows that the degree of metabolic cleavage by rats of various types of sulfamates is low, being generally <0.1%. Since the number of rats involved in each of the feeding studies was small, *i.e.*, five or six, any deductions made from the results in Table VIII regarding the relative stability of sulfamates would be tenuous. However, it seems that cyclooctylsulfamate, which gives rise to all three metabolites, is cleaved to a somewhat greater extent than the other sulfamates. On the other hand, the introduction of a double bond into the cyclohexyl system, *i.e.*, in 2-cyclohexenylsulfamate, appears to reduce metabolic breakdown considerably. This latter compound has a comparable level of sweetness to cyclamate (7). Interestingly, when the closely related and sweet 3-cyclohexenylsulfamate was administered intraduodenally for 2 weeks to rats at a dosage of 1 g/kg of body weight, no pathological changes in the main organs or tissues could be detected (7).

One of the sulfamates in Table VIII is not sweet; however, on the basis of a previous cursory examination, it was taken to be sweet (4). On careful examination it was classified as being bitter (13). Unterhalt and Böschemeyer (14), who first made this compound, also reported it as being nonsweet.

Complementary to the *in vivo* studies, a series of *in vitro* experiments have been carried out. In this study, the microorganisms responsible for the metabolism of cyclamate were isolated from the feces of rats fed cyclamate. A cell-free extract of these organisms was then incubated with the four sweetest known sulfamates and two standards to ascertain the extent to which these compounds were broken down to potentially toxic metabolites.

Earlier work (15) showed that dogs and humans fed on cyclamate

[a] Results for feces. [b] The mean was obtained by dividing the summation of the percent of metabolite in the urine by 6.

Table VIII—Metabolism of Sulfamates in Rats

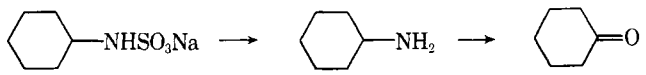
Cyclic Sulfamate	Percent Metabolites[a]			Total Metabolites, %	Reference
	Amine	Ketone	Alcohol		
Octyl	0.127	0.08	0.092	0.297	4
Heptyl	0.0514	0.0088	0.0034	0.064	2[b]
Hexyl[c]	0.0096	0.00095	0.004	0.0146	12
2-Methylhexyl	0.00013	0.00067	0	0.00037	This work
3-Methylhexyl	0.014	0.0002	0.0098	0.0242	This work
4-Methylhexyl	0.0073	0.0013	0	0.0085	4
2-Hexenyl	0.00017	0	0	0.00017	This work
Pentyl	0.057	0.016	0.0087	0.083	1[d]
Pentylmethyl	0.007	—[e]	0.007	0.0144	3[f]

[a] These percents were calculated by summing the percent metabolite for each rat, summing the totals, and dividing by the number of rats in each study. [b] Reference 2 in (4). [c] The figures for hexyl were obtained from data on six rats (2 groups of 3). The percent total metabolites represents the total for amine, ketone, and alcohol. In Ref. 12 the authors also detected "conjugated" cyclohexanol as a metabolite, so their total differs slightly. [d] Reference 1 in (4). [e] A ketone metabolite is not possible for this compound. [f] Reference 3 in (4).

produced large quantities of a metabolite, cyclohexylamine, in their urine. It was considered that this compound was the carcinogen, and it seemed likely that the conversion from cyclohexylsulfamate to cyclohexylamine was carried out by processing enzymes in the liver. Attempts to verify this *in vitro* study, however, met with little success (16).

The formation of cyclohexylamine and cyclohexanone from cyclamate by microorganisms isolated from guinea pig feces was demonstrated previously (17). This work was followed up by carrying out a partial purification of the enzyme involved, cyclohexylsulfamatase (18). The substrate specificity of the partially purified enzyme using several other sulfamates, which were generally not sweet, was also examined.

These studies subsequently partially purified and examined the properties of cyclohexylamine oxidase, which is the next enzyme in the metabolic sequence (19):



cyclohexylsulfamate cyclohexylamine cyclohexanone

Biochemical tests for Gram-negative enteric bacteria were first carried out on the bacteria whose cell-free extract carried out the sulfamatase function. These tests included indole production; hydrogen sulfide production; liquefaction of gelatin; cleavage of sugars, alcohols, and glucosides; and methyl red Voges Proskauer tests. The results of these tests indicated the presence of *Escherichia coli*, *Enterobacter hafniae*, and *Proteus mirabilis*. Pure cultures of these organisms were grown and cell-free extracts incubated with cyclohexylsulfamate, but it was found that greater activity was observed when a mixed culture was used.

A series of investigations was carried out to determine the optimum conditions for assay of enzyme activity. The variation in crude enzyme activity in relation to temperature, pH, and time of incubation was investigated and as a result, it was decided to adopt the incubation conditions as outlined previously: pH 6.8 for 2 hr at 50°.

Partial purification of the enzyme by ammonium sulfate fractionation (18) resulted in greatly reduced activity. Therefore, it was decided to conduct the studies using the crude enzyme extract. It has also been reported (18) that heat treatment of the crude enzyme extract (60° for 10 min) inactivates heat labile enzymes which are responsible for further degradation of cyclohexylamine, while leaving the heat stable sulfamatase unaffected. However, experience showed that the sulfamatase itself is largely inactivated by this procedure so it was not adopted. Consequently, the crude enzyme extract was used in the incubation studies.

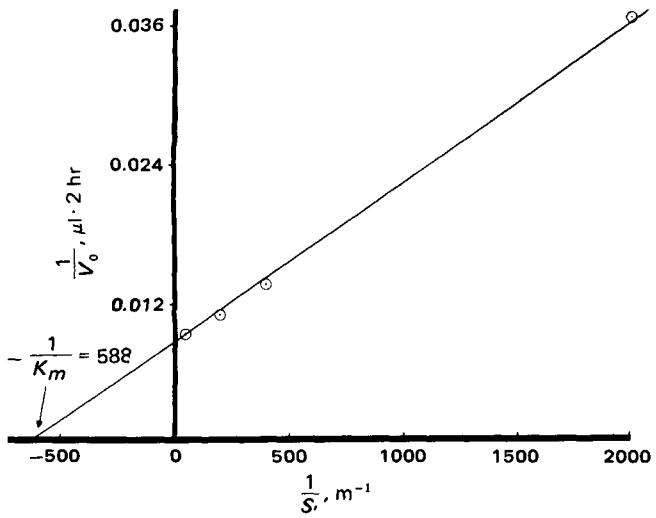


Figure 1—*Lineweaver-Burk plot for cyclohexylsulfamate.*

Table IX—Sulfamate Specificity of the Enzyme Extract and Mutagenicity (Ames Test) of the Corresponding Amines

N-Substituted Sulfamate	Relative Activity	Relative Sweetness[b]	Mutagenicity of Parent Amine[c]
Cyclohexyl	1[a]	1	0.02
Phenyl	5.3	—	—[d]
n-Octyl	6.4	—	—[d]
Cycloheptyl	0.52	0.83	—[d]
Cyclopentyl	0.50	0.24	0.006
Cyclooctyl	0	0.67	—[d]

[a] Total breakdown was 0.5%. [b] Data taken from Ref. 2; no values indicate not sweet. [c] Compared to standard 2-aminofluorene which is equal to one. [d] Zero or negligible.

In Table IX the results of incubation of various sulfamates with this enzyme extract are shown relative to cyclohexylsulfamate. The activities are computed as the sum of metabolites, *i.e.*, amine, alcohol, and ketone. Since it was found that *n*-octylsulfamate (which is not sweet) was the most labile substrate examined (18), this compound was included in the present study to assess the activity of the enzyme extract. As can be seen from Table IX, the enzyme extract was also highly active against this substrate, giving a relative activity of 6.4 as compared to cyclohexylsulfamate.

Phenylsulfamate was also included as another standard and it was found that it too was quite labile, in contrast to previous results, which indicated that the enzyme had only a very weak or uncertain activity on this substrate. It was confirmed that this breakdown was not due to impurities in the sulfamate and/or nonenzymatic hydrolysis. This was done by incubating the buffered substrate in the absence of the enzyme extract when no aniline or phenol was detected.

A variety of sulfamates was incubated previously (18), but apart from cyclohexylsulfamate, only two faintly sweet sulfamates, *n*-propyl- (2) and *ac*-tetrahydro-β-naphthyl (6) sulfamates, were included in the study. For the current incubation experiments, the four sweetest known sulfamates, cyclohexyl-, cycloheptyl-, cyclooctyl-, and cyclopentyl-, were incubated. Relative to cyclohexylsulfamate, all three had less activity. There was a partial correlation between the *in vivo* results in Table VIII for these four compounds and the *in vitro* results for the sulfamates in Table IX. Thus, in both types of experiments the heptyl- and pentyl-compounds were metabolized ~50% that of cyclohexylsulfamate. In the case of cyclooctylsulfamate, the results from the *in vivo* and *in vitro* studies contradict each other. The Michaelis constant (Km) for the enzyme with cyclohexylsulfamate was determined using a Lineweaver-Burk plot (Fig. 1) and was found to be 1.7×10^{-3} *M*. This indicates a three times greater affinity between enzyme and substrate than that reported previously (18).

In Table IX, preliminary studies on the mutagenicity of the amines of the sulfamates which were incubated are reported. The amines of all the sulfamates reported in Table IX show zero or negligible mutagenic activity [in the case of aniline this result was already established (20)]. The amines, isobutylamine and isoamylamine, both of whose sulfamates are moderately sweet (compared to cyclamate) (2), also show negligible mutagenicity, but *n*-butylamine, whose sulfamate is faintly sweet (2),

appeared to be mutagenic (60 revertants/15 μg). It should be stressed, however, that these are preliminary studies and would have to be confirmed using other tester strains of *Salmonella typhimurium*.

Plasma Levels of a Novel Antidysrhythmic Agent, Meobentine Sulfate, in Humans as Determined by Radioimmunoassay

JAMES T. WARREN *, GEOFFREY G. COKER ‡, RICHARD M. WELCH *, ARTHUR S. E. FOWLE ‡, and JOHN W. A. FINDLAY *x

Received July 27, 1981, from the * *Wellcome Research Laboratories, Research Triangle Park, NC 27709;* and the ‡ *Wellcome Research Laboratories, Beckenham, Kent BR3 3BS, U.K.* Accepted for publication September 21,1981.

Abstract □ A radioimmunoassay for the quantitation of meobentine sulfate, a novel antidysrhythmic and antifibrillatory agent in biological fluids, is described. Antisera were raised in rabbits in response to immunization with a conjugate of bovine serum albumin and a meobentine analog with a propionic acid sidechain *ortho* to the methoxyl group. These antisera have low affinities for *N*- and *O*-desmethylmeobentine metabolites, which show less than 5% cross-reaction in radioimmunoassay procedures employing either tritiated or radioiodinated radioligands. The radioimmunoassay using [^{125}I]meobentine was capable of detecting <0.4 ng/ml (40-pg mass) of meobentine. This assay was used to demonstrate the absorption of meobentine in humans after oral administration and also permitted studies of meobentine sulfate disposition in human plasma following two (2.5 and 5 mg/kg) oral doses. Mean peak meobentine concentrations in plasma occurred 3 hr postdose in both cases and were 230 and 451 ng/ml following the 2.5- and 5-mg/kg doses, respectively. The approximate mean terminal half-life after all treatments was 12 hr.

Keyphrases □ Meobentine sulfate—plasma levels in humans, radioimmunoassay □ Bioavailability—plasma levels of meobentine sulfate in humans determined by radioimmunoassay □ Radioimmunoassay—plasma levels of meobentine sulfate in humans

Meobentine sulfate [bis-(*N*-4-methoxybenzyl-*N'*-*N''*,dimethylguanidinium)sulfate] possesses marked antidysrhythmic properties against arrhythmias induced by ouabain and those induced by coronary artery ligation in dogs (1). It has been demonstrated that meobentine causes a significant incidence of spontaneous recovery from electrically induced fibrillation in the dog[1]. The electrophysiological properties of meobentine have been studied (2). Although very close in structure to the hypotensive agent, bethanidine (3), meobentine is not a neuronal blocking agent and thus, does not decrease blood pressure in animals when administered intravenously at effective antidysrhythmic doses (1). In this respect, meobentine also appears to be superior to the quaternary ammonium compound bretylium tosylate, which is indicated only for treatment of life-threatening ventricular arrhythmias (4) due to its severe hypotensive side effects.

The clinical safety and efficacy of meobentine sulfate when administered to humans by oral and parenteral routes are currently under study. Pharmacokinetic studies of meobentine in animals and humans, which are needed to facilitate the evaluation of meobentine in current clinical trials, require adequately sensitive and specific procedures for the determination of the drug in body fluids. Earlier gas and thin-layer chromatographic techniques lacked sensitivity, while administration and quantitation of radiolabeled meobentine is impractical for extensive pharmacokinetic studies in humans.

Radioimmunoassay methods have been applied increasingly to the quantitation of drugs (5, 6). This report describes the development of sensitive and specific radioimmunoassay procedures for meobentine, employing tritium or radioiodine ligands. The sensitivity limit for the procedure using the ^{125}I-labeled meobentine was <0.4 ng/ml (40-pg mass), while interference with desmethyl metabolites of the drug was minor. These analytical procedures were used to demonstrate the absorption of meobentine after oral administration to healthy subjects and to explore the relationship of plasma concentrations and relative oral bioavailability to the oral dose administered.

EXPERIMENTAL

Chemicals—Thin-layer chromatography (TLC) employed micropolyamide on a nylon support[2] or silica gel[3] on a glass support[4]. Radiochemical purities were determined by scanning thin-layer plates on a radiochromatogram scanner[5]. Bovine serum albumin[6] isobutyl chloroformate[6], Freund's complete adjuvant[7], [^{125}I]sodium iodide[8], and polyethylene glycol 6000[9] were obtained commercially. Methyl isothiocyanate, 4-hydroxybenzaldehyde, and 5% palladium on charcoal were obtained from a single supplier[10], as were chloramine-T and *N*-nitrosomethyl urea[11]. Beta-emitting radionuclides (^{3}H and ^{14}C) were quantitated in scintillation fluid[12] in a scintillation counter[13]. Gamma radiation was quantitated in a spectrometer[14]. *N*-Desmethylmeobentine was a gift[15], as also were guanethidine[16], clonidine[17], guanabenz[18], propranolol[19], isoproterenol[20], and procainamide[21].

Immunogen Preparation—*3-(5-Cyano-2-methoxyphenyl)-propionic Acid (II)*—A mixture of 10 g of 3-(5-bromo-2-methoxyphenyl)propionic acid (I) (7), cuprous cyanide (15 g), and pyridine (20 ml) was heated with stirring in a bath at 200° for 4 hr. The cooled material was triturated with water (150 ml) and filtered, and the solid mass of copper salts was extracted with warm dilute sodium hydroxide solution (2 × 100 ml). Acidification of the combined aqueous filtrates gave 7 g of the crude acid (II) mp 142–146°. Recrystallization from aqueous ethanol and then from benzene raised the mp to 147–148° (4.7 g).

Anal.—Calc. for $C_{11}H_{11}NO_3$: C, 64.39; H, 5.37; N, 6.83. Found: C, 63.53; H, 5.23; N, 6.32.

3-(5-Aminomethyl-2-methoxyphenyl)propionic Acid (III)—A mixture of 4.5 g of the cyano-acid (II) in ammonium hydroxide solution (35%; 30 ml) containing a nickel catalyst[22] (~2 g) was stirred under hydrogen at 10^7 N/m^2 and 100° for 4 hr. The mixture was filtered and the filtrate was evaporated to dryness. The resulting greenish solid was extracted with warm water (3 × 10 ml) and the extracts were freed from nickel salts by passage of H_2S followed by filtration. The amino acid (III), isolated by evaporation *in vacuo*, crystallized from aqueous ethanol in colorless platelets (2.5 g) mp 218–219° (dec).

Anal.—Calc. for $C_{11}H_{15}NO_3$: C, 63.2; H, 7.2; N, 6.7. Found: C, 63.09; H, 7.32; N, 6.78.

3-[2-Methoxy-5-(N′,N″-dimethylguanidinomethyl)phenyl]-propionic Acid (VI)—Methyl isothiocyanate (0.92 g) in ethanol (40 ml) was added to a solution of 2.4 g of the amino acid (III) in 1 *M* NaOH solution (12 ml). Sulfuric acid (0.5 *M*, 12 ml) was added 24 hr later, followed by acetone (100 ml). The solution was filtered from inorganic material and treated with methyl iodide (10 ml). After 1 hr the mixture was evaporated *in vacuo* and the residue was treated with 30% aqueous methylamine solution (40 ml). Gentle warming on a steam bath for 1 hr followed by evaporation to dryness yielded the product as a waxy solid. Recrystallization from isopropyl alcohol and then from water afforded colorless needles, mp 201–204° (0.9 g).

Anal.—Calc. for $C_{14}H_{21}N_3O_3$: C, 56.56; H, 7.80; N, 14.14; $1H_2O$, 6.06. Found: C, 56.23; H, 8.13; N, 13.87; loss at 100°/VAC 6.06.

3-[2-Methoxy-5-(N′,N″-dimethylguanidinomethyl)phenyl]propionic Acid Bovine Serum Albumin-Conjugate—A solution of the guanidino–propionic acid (VI) (0.05 g, 0.168 m*M*) in a warm, 20-ml mixture of dimethyl sulfoxide–dimethylformamide (2:1) was cooled to 0°. Triethylamine (0.035 liter, 0.252 m*M*) and isobutyl chloroformate (0.025 liter, 0.190 m*M*) were added and the solution was stirred for 1 hr at 0°. This cold (0°) solution of the mixed anhydride was added dropwise to a solution of bovine serum albumin (0.080 g, 0.065 m*M* ϵ-amino lysine residues) in 160 ml of a 0.1 *M* sodium bicarbonate solution at 0° and the mixture was stirred overnight at 4°. After filtering insoluble material, the solution was pressure dialysed through a membrane-containing filter unit[23] (50 psi, 2 liter H_2O), and finally lyophilized, yielding an amorphous powder (0.075 g).

Synthesis of Radiolabeled Compounds—*[^{3}H]bis(N-4-methoxybenzyl-N′,N″-dimethylguanidinium)sulfate*—This compound was prepared by a supplier under contract, using general tritium exchange procedures. The specific activity of this compound was estimated to be 0.8 Ci/m*M*.

Bis[N-(3-iodo-125-4-methoxybenzyl)-N′,N″-dimethylguanidinium]-sulfate (VIII).

N-4-Hydroxybenzyl-N′,N″-dimethylguanidinium iodide (VII)—Prepared as described previously (8).

Bis[N-(3-iodo-125,4-hydroxybenzyl)-N′,N″-dimethylguanidinium]sulfate (VIII)—To VII sulfate (2.7 μg, 11.2 n*M*) in phosphate buffer (70 μl, 0.5 *M*, pH 7.7) contained in a small test tube was added carrier-free [^{125}I]sodium iodide (1.12 n*M*, 2 mCi) in 20 μl of dilute sodium hydroxide followed by a freshly prepared solution of chloramine-T (47.25 μg, 0.168 μ*M*) in phosphate buffer (25 μl, 0.05 *M*, pH 7.7). After 1 min of agitation, a freshly prepared solution of sodium metabisulfite (0.64 mg, 3.36 μ*M*) in phosphate buffer (100 μl, 0.05 *M*, pH 7.7) was added to stop the reaction. The entire reaction mixture was then applied to the origin of a micropolyamide TLC plate (0.1 mm, 20 × 20 cm) and allowed to dry.

Bis[N-(3-iodo-125,4-methoxybenzyl)-N′,N″-dimethylguanidinium]-sulfate (IX)—To the origin of the TLC plate containing the iodinated phenolic guanidine VIII was repeatedly applied an ether solution of diazomethane prepared from *N*-nitrosomethyl urea (5 g) (9). The plate was then developed in the system H_2O–triethylamine (100:1) and then allowed to expose an X-ray film. Radioiodine-containing material remaining at the origin was eluted with methanol (3 × 5 ml) and the solution was stored at −80°. The specific activity of the material obtained (1 mCi) was estimated to be 179 Ci/m*M*. Radiochemical purity was established by TLC on silica gel in the system *n*-butanol–methanol–water–acetic acid (4:20:20:10) in which the R_f (0.6) of the iodinated product was identical to that of unlabeled meobentine sulfate.

Immunization Procedures—Male New Zealand white rabbits received a primary immunization of bovine serum albumin-drug conjugate (1 mg) in 0.9% saline (1 ml) emulsified with Freund's complete adjuvant (1 ml) as two intramuscular (vastus lateralis) and eight subcutaneous injections (along each side of the dorsal column) of 0.2 ml each. At intervals of 2, 4, and 6 weeks following the primary immunization, and at monthly intervals thereafter, booster immunizations of immunogen (0.5 mg) in saline (0.5 ml), emulsified with Freund's complete adjuvant (0.5 ml), were administered at multiple subcutaneous sites. Following the second and all subsequent booster immunizations, blood samples were collected from the central ear artery and the serum was separated and stored at −80°.

Clinical Studies—Six healthy subjects (three male and three female) each took 2.5 mg/kg of meobentine sulfate and then 5.0 mg/kg 1 week later. (One male subject did not complete the study at the higher dose.) The drug was administered in 100 ml of water. Plasma was sampled beforehand and at 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, 24, 32, 48, and 56 hr afterwards. Samples were taken by collecting 5-ml venous blood into a lithium heparin tube which was immediately centrifuged. The separated plasma was then immediately removed and stored at −20° until assayed.

Radioimmunoassay Procedures—The assay buffer used throughout these studies was 0.05 *M* Na_2HPO_4, 0.15 *M* NaCl, and 0.01 *M* edetic acid,

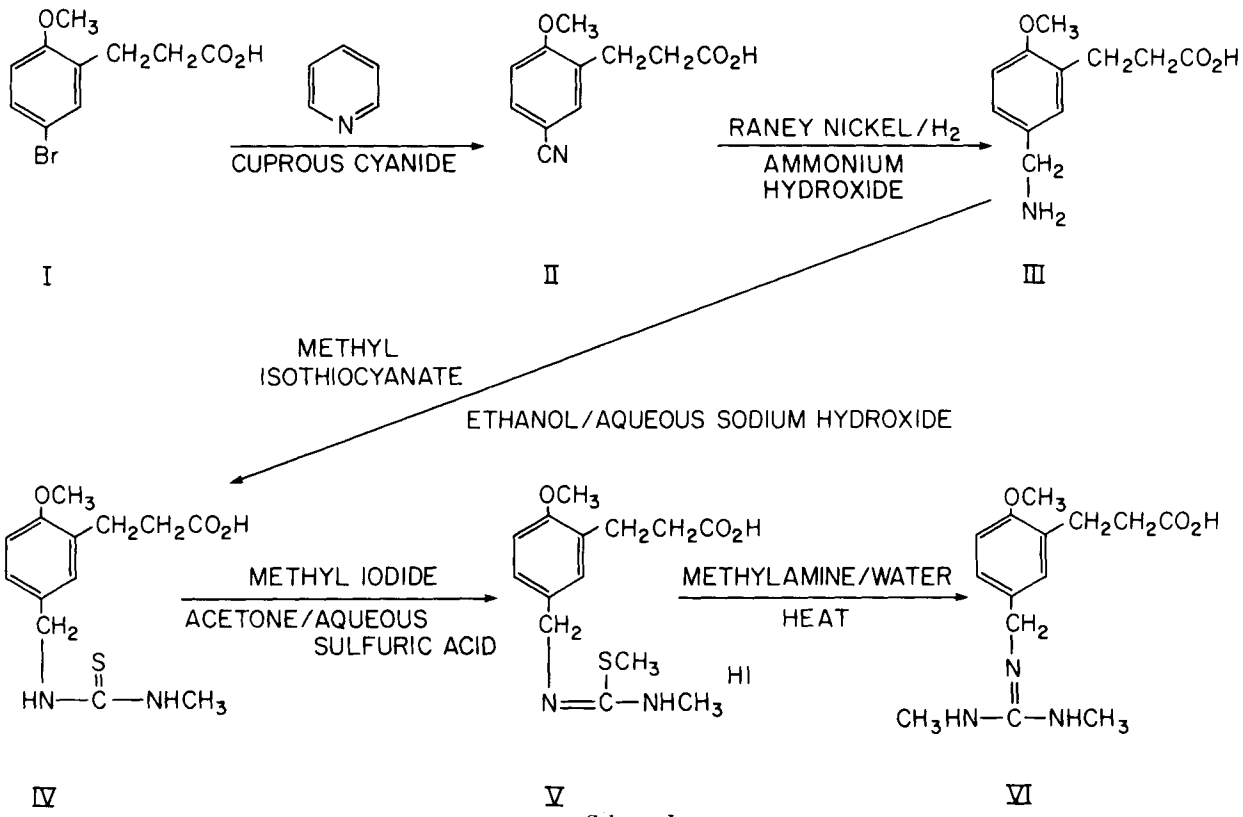
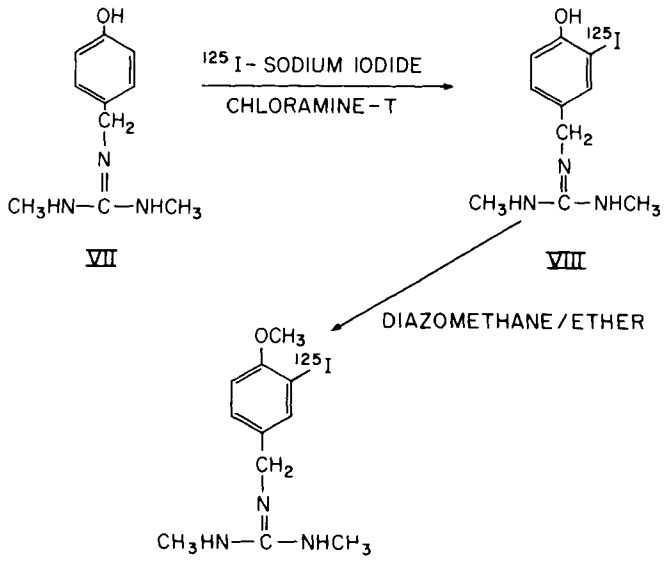


Scheme I

pH 7.0, containing 0.02% bovine serum albumin. Antibody-bound and free radioligand were separated by addition of polyethylene glycol 6000 at a concentration of 130 g/liter in assay buffer. After incubating with the polyethylene glycol 6000 for 30 min at 0°, the immunoglobulins were pelleted by centrifugation (4000×*g*) for 30 min at 4° and the supernate, containing free radioligand, was decanted. For assays employing the tritium label, the immunoglobulin pellet was redissolved in assay buffer (0.3 ml), scintillation fluid was added (3 ml), and the vials capped, mixed, and placed in specially prepared vials for liquid scintillation counting. For assays employing the radioiodine label, the tubes containing the immunoglobulin pellets were placed into a gamma counter. All assay points were established in duplicate. Raw scintillation counter data were automatically entered and stored in a computer file for later processing by computer program. All meobentine concentrations determined by radioimmunoassay are expressed as meobentine-free base, while doses administered are expressed as meobentine sulfate.



Scheme II

Antiserum Titrations—Varying dilutions of antiserum in assay buffer (0.5 ml) and normal blank plasma (0.1 ml; dog, rat, or human) were incubated with [^{3}H]meobentine (2 ng, 12,000 dpm) in buffer (0.5 ml) or [^{125}I]iodomeobentine (0.25 ng, 40,000 dpm) in buffer (0.5 ml) overnight at 4°. Background-binding tubes contained only radioligand and buffer. Aliquots of polyethylene glycol 6000 solution in assay buffer (1.1 ml) were added to the ice-cold incubation tubes, and the contents were vortex-mixed, incubated at 0° for 30 min, and centrifuged (4000×*g*, 30 min). After decanting the supernates, the immunoglobulin pellets were prepared for either liquid scintillation or gamma counting as described previously. The antiserum titer chosen for use in the radioimmunoassay was defined as that dilution which bound 40% of the total radioligand added.

Antisera Specificity—To determine the specificity of the antisera,

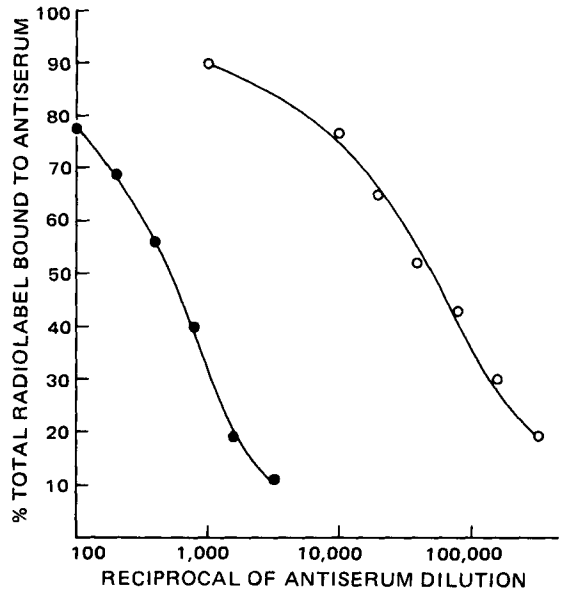


Figure 1—*Titration curves for meobentine antiserum used in the present experiments. Key:* ●, *[^{3}H]meobentine;* ○, *[^{125}I]iodomeobentine.*

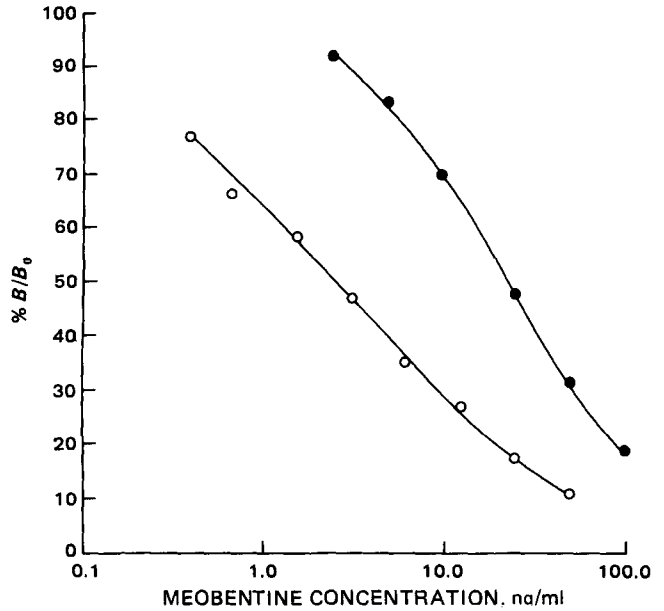

Figure 2—*Meobentine standard curves for tritium and radioiodine radioimmunoassays: mean of 8 curves in each case. Key: ●, [^{3}H]meobentine; ○, [^{125}I]iodomeobentine.*

the 0.1 ml of normal blank plasma added in the previously described procedure was replaced by 0.1 ml of increasing concentrations of meobentine, known metabolites, structurally related compounds, or various cardiovascular drugs in normal blank plasma. Incubation with radioligand and predetermined titer of antisera in assay buffer followed by isolation of the antibody-bound radioligand proceeded as described previously. Standard curves were expressed as percent B/B_0 *versus* log meobentine free base concentration, where B_0 represents the amount (cpm) of labeled meobentine (^{3}H or ^{125}I) bound in the absence of any unlabeled meobentine, and B is the amount bound in the presence of a given drug concentration (corrected for nonspecific binding). The cross-reactivity of each related compound was defined as the percentage ratio of the IC_{50} for meobentine to that of the compound studied, where IC_{50} is the concentration of each respective compound required to inhibit binding of radioligand to antiserum by 50% (10).

Radioimmunoassay of Unknown Plasma Samples—A series of meobentine standard solutions (2.5–250 ng/ml free base equivalents for ^{3}H-radioimmunoassay or 0.39–100 ng/ml for ^{125}I-radioimmunoassay) in normal blank plasma (0.1 ml) was incubated with [^{3}H]meobentine or [^{125}I]iodomeobentine and appropriately diluted antiserum as described previously. Spiked control samples of meobentine in blank plasma (0.1 ml) or unknown plasma samples appropriately diluted with normal blank plasma to enter the assay range were also incubated with radioligand and antiserum. Most unknown samples were assayed at two dilutions. Standard curves were linearized by a logit–log computer transformation of B/B_0 *versus* meobentine concentration data and unknown concentrations were determined by interpolation.

RESULTS

Immunogen Synthesis—A propionic acid analog (VI) of meobentine, with the acid chain attached to the phenyl ring *ortho* to the methoxyl group, was prepared from 3-(5-bromo-2-methoxyphenyl)propionic acid (I) by displacing bromine with cuprous cyanide to give the 5-cyano derivative (II) which was catalytically reduced to the benzylamine (III). The general method of Maxwell and Walton (8) was employed to convert the benzylamine derivative to IV, *via* the intermediates, IV and V. The synthetic scheme is shown in Scheme I. Elemental and spectral analysis established the identity of the hapten, which was coupled to bovine serum albumin by the mixed anhydride approach, described previously (11). No attempt to quantitate the extent of hapten incorporation to the immunogen was made.

NT—not tested.

Radioligand Syntheses—[^{3}*H*]*Meobentine*—This compound was obtained from meobentine by catalytic exchange of tritium for hydrogen with subsequent removal of labile tritium. The resulting, generally tritiated radioligand had a relatively low specific activity (0.8 Ci/m*M*). This feature limits the usefulness of the radioimmunoassay employing [^{3}H]-meobentine due to low sensitivity and lengthy scintillation counter times.

[^{125}*I*]*Iodomeobentine* (*IX*)—The need for a radioligand with much higher specific activity to enable the development of a more efficient and sensitive radioimmunoassay for meobentine necessitated the synthesis of a meobentine analog containing iodine 125 (Scheme II). An analog (and

metabolite) of meobentine, VII, was synthesized from 4-hydroxybenzylamine (8). The phenol (VII) was *ortho*-iodinated with [^{125}I]sodium iodide by the method of Hunter and Greenwood (12). *In situ* methylation of the iodophenol with diazomethane followed by TLC purification afforded iodomeobentine of high specific activity.

Antisera Production—Two out of three rabbits immunized with the hapten produced useful antisera, detectable within 1 month and steadily increasing in titer with time. The highest titer elicited from the best rabbit was selected for further studies. Excess antibody bound > 90% of either radioligand and the working titers were 1/4000 and 1/100,000 for [^{3}H]-meobentine and [^{125}I]iodomeobentine, respectively (Fig. 1).

Assay Sensitivity and Precision—The sensitivity limit of the radioimmunoassay for meobentine sulfate employing a tritium or radioiodine label (defined as the concentration of unlabeled meobentine producing 10% inhibition of maximal [^{3}H]meobentine or [^{125}I]iodomeobentine binding) was 2.5 or 0.39 ng/ml, respectively. Typical mean standard curves for the two assay procedures are shown in Fig. 2; the coefficient of variation around each standard concentration point was <10%. Further confirmation of interassay precision was provided by the low coefficient of variation around means of assayed spiked plasma controls varying across the range of assay sensitivity (Table I).

Assay Specificity—Specificity data of this antiserum for meobentine, some known metabolites, and structurally related compounds are summarized in Table II for both tritiated and radioiodinated meobentine radioligands. Cross-reactivities with the two known metabolites, *O*-desmethyl and *N*-desmethylmeobentine, were low, being 2–5% in both assays. The desmethoxy analog, bethanidine, also showed relatively low cross-reactivity (5%) while the *para* methyl derivative, *N*-4-methylbenzyl-*N'*,*N''*-dimethylguanidine, was recognized much better by the antiserum, resulting in a higher (40%) cross-reactivity. As expected, the propionic acid hapten derivative (VI) used for the production of the immunizing conjugate was recognized by the antiserum more effectively than meobentine itself. A variety of other structurally related guanidines with (guanethidine, guanabenz, and clonidine) and without (guanidine and dimethylguanidine) substituents on the imino nitrogen atom showed little cross-reactivity. A number of drugs (procaine, procainamide, lidocaine, propranolol, isoproterenol, and morphine), which might be administered to patients concurrently with meobentine sulfate, had cross-reactivities of <0.001% in the radioimmunoassay.

Correlation of Tritiated and Radioiodinated Assay Methods—Since both assay methods were used in the analysis of different phases of the human disposition studies, it was imperative to demonstrate that analysis of given samples by both methods gave the same results. To this end, a number of plasma samples obtained from humans, dogs, and rats after meobentine treatment were analyzed by both methods. The results are shown in Table III. The slope and linear regression coefficient approach unity, indicating good agreement between results from tritiated and radioiodinated methods.

Disposition Studies in Humans—The radioimmunoassay employing [^{3}H]meobentine was used to assay plasma samples from humans who received two separate oral doses (2.5 and 5 mg/kg) of meobentine sulfate in water. Mean plasma levels of meobentine in these subjects are shown in Fig. 3. No detailed pharmacokinetic analysis was performed on these data, but some model-independent mean kinetic parameters are collated in Table IV. Mean observed maximum plasma concentrations were 239 and 451 ng/ml following 2.5 and 5.0-mg/kg doses, respectively (Table IV). The mean area under the plasma concentration–time curve (*AUC*) values increased ~1.8-fold on increasing the dose from 2.5 to 5 mg/kg. Thus, similar trends are evident in C_{max} and *AUC* values. The mean times to observed peak plasma concentration (T_{max}) were 3.3 and 3 hr after each of the 2.5 and 5-mg/kg doses, respectively. Meobentine half-life, as estimated from the limited number of points in the terminal disposition phase, ranged from 9 to 20 hr between individual subjects, while mean values following treatments were ~ 14 and 11 hr.

Table IV—Model-Independent Pharmacokinetic Parameters for Meobentine Sulfate (Mean ± *SD*)

Parameter	Oral Dose Administered	
	2.5 mg/kg (n = 6)	5.0 mg/kg (n = 5)

T_{max}, hr	3.3 ± 0.5	3.0 ± 0.7
AUC, hr ng/ml	1890 ± 526	3358 ± 1294
TBC/F, liter/hr[a]	78.6 ± 14.9	95.1 ± 29.6

[a] Total body clearance/fraction dose absorbed = dose/area under the curve (*AUC*).

DISCUSSION

Previous investigations have demonstrated the need for conjugation of drugs to macromolecules in order to render them immunogenic (5, 6, 13). In the present study, meobentine was coupled *via* a propionic acid sidechain to bovine serum albumin by a mixed anhydride procedure. Attachment of the 3-carbon bridge was *ortho* to the methoxyl group of meobentine, as shown in Scheme I. Antibodies formed in response to repeated immunization with this substance were used to develop two radioimmunoassay procedures for meobentine. One assay, employing a generally labeled [^{3}H]meobentine ligand, was precise and accurate and showed a sensitivity limit of 2.5 ng/ml (250 pg, actual mass). The use of [^{125}I]iodomeobentine (Scheme II), which had much greater specific activity, considerably increased efficiency and lowered sensitivity limits to <0.4 ng/ml (40 pg, actual mass) while retaining precision and accuracy (Fig. 2 and Table I). Plasma meobentine levels in the rat, dog, and humans following intravenous and oral administration, assayed by the two different procedures, agreed well (Table III). These radioimmunoassay procedures represent a significant advance in sensitivity and convenience over previously available methods for determination of meobentine in plasma. The sensitivity of the procedure using the iodinated radioligand, which is currently in use for analysis of meobentine disposition studies, exceeds that of analytical procedures reported for the related drugs, bethanidine (14) and bretylium (15, 16).

The ability of drug antisera to discern changes in molecular architecture normally is greatest for structural changes at sites distant from the site of attachment of the drug to macromolecular carrier in the immunizing conjugate. The applicability of this statement to the case of meobentine is not complete, as the data in Table II indicate. Thus, 4-methylbethanidine cross-reacts extensively, as expected for a relatively minor structural change close to the site of attachment of hapten to protein. However, the cross-reactivities of bethanidine (4.7%) and *O*-desmethylmeobentine (2.3–4.7%), which also involve relatively minor structural changes at the *para* position, are much lower. It is fortunate that the cross-reactivity of *O*-desmethylmeobentine is low, since this compound appears to be a major metabolite in the rat and dog (17), although the most likely circulating species, the *O*-glucuronide of *O*-desmethylmeobentine, would be expected to cross-react even less. *N*-Desmethylmeobentine, a lesser metabolite in the rat and dog (17), has lower cross-reactivity. The *O*-desmethoxy analog, bethanidine, while undergoing significant *N*-dealkylation in the rat and dog, has been reported to be excreted largely unchanged by humans (18). Bethanidine is not well recognized by the antiserum, while the 4-methyl analog binds strongly to the antibodies, indicating the sensitivity to changes in molecular charge localization and lipophilicity. A wide range of structurally similar guanidines and other cardiovascular drugs and potentially concurrently administered medications did not cross-react.

The applicability of the present radioimmunoassay techniques to pharmacokinetic studies is shown by the data in Fig. 3. Plasma levels 56 hr after a single oral dose could still be measured reliably by the [^{3}H]-meobentine assay, which was used for analysis of plasma samples in the

human studies described in this paper. The higher sensitivity and greater convenience of the [^{125}I]-based assay have resulted in its use in current meobentine studies. The plasma profile in the subjects studied indicated that meobentine kinetics are multicompartmental in nature with a long terminal half-life (11–14 hr). A long terminal half-life has also been seen with bethanidine (18) and bretylium (19) in humans. Mean peak meobentine plasma levels in the same group of volunteers essentially doubled from 239 to 451 ng/ml with an increase in dose from 2.5 to 5.0 mg/kg. Mean area under the curve also approximately doubled from 1890 to 3358 ng hr/ml over this dose range. These observations suggest linear kinetics for meobentine in the 2.5–5-mg/kg dose range. Clearance (TBC/F) did not change significantly with increasing dose. The extent of absorption and bioavailability of meobentine are currently under investigation in animals and humans. The related guanidine, bethanidine, has been reported to be well absorbed by humans (18).

Currently, these radioimmunoassay procedures are being applied to detailed studies of the disposition of meobentine sulfate in animals and humans. Studies of the absolute oral bioavailability and pharmacokinetics of meobentine sulfate will be presented elsewhere in the near future.

Automated Sampling of *In Vitro* Dissolution Medium: Effect of Sampling Probes on Dissolution Rate of Prednisone Tablets

THOMAS S. SAVAGE *x and CLYDE E. WELLS ‡

Received June 8, 1981, from the **Food and Drug Administration, Los Angeles, CA 90015*, and the ‡*National Center for Drug Analysis, St. Louis, MO 63101.* Accepted for publication September 18, 1981.

Abstract □ The effect of sampling probe size and location on the *in vitro* dissolution rate of prednisone tablets was examined. Using USP XX Apparatus 2 with an automated sampling system, dissolution rates were determined using two types of large filter-tipped probes and a small capillary probe. Each probe was tested at three locations within the kettle. The large probes caused hydrodynamic changes which, when compared with results obtained through manual sampling, resulted in significant changes in dissolution rates at each location. These changes were less evident when the capillary probe was used, with an insignificant difference between results of automated and manual sampling when the capillary probe was placed midway between the paddle shaft and the kettle wall.

Keyphrases □ Dissolution rates—effect of sampling probe size and location on dissolution rate of prednisone tablets □ Hydrodynamics—dissolution rates affected by sampling probe size and location, USP paddle method □ Prednisone—tablets in dissolution rate testing with effects of sampling probe size

Automated sampling and analysis of *in vitro* dissolution aliquots can be a useful, timesaving procedure. Several automated sampling systems are commercially available in which aliquots of the dissolution fluid, taken at specified times, travel into sample cups or into an automated analytical system. Results of such a system are not generally considered acceptable, however, unless they agree with those obtained by manual sampling.

A large number of dissolution testing variables have been identified (1). These need to be strictly controlled if reproducible results are to be obtained. Changes in any of these variables can have a significant effect on the dissolution rate of a dosage form. A previous study (2) showed that the dissolution rate is affected by the effects of various dissolution parameters on the hydrodynamics of the dissolution fluid. Another study (3) showed that the hydrodynamic disturbance caused by insertion of a relatively large object, such as a thermometer, into the dissolution fluid may cause a change in dissolution rate, and that the location of such an object can also have a significant effect.

With most automated sampling systems now in use, a relatively large filter-tipped probe is immersed in the dissolution fluid. The above studies imply that a large probe can affect the system hydrodynamics, and therefore the dissolution rate of some dosage forms, thereby causing results which differ from those obtained by manual sampling, and that a smaller probe may have less effect on the

0022-3549/82/0600-0670$01.00/0

human studies described in this paper. The higher sensitivity and greater convenience of the [^{125}I]-based assay have resulted in its use in current meobentine studies. The plasma profile in the subjects studied indicated that meobentine kinetics are multicompartmental in nature with a long terminal half-life (11–14 hr). A long terminal half-life has also been seen with bethanidine (18) and bretylium (19) in humans. Mean peak meobentine plasma levels in the same group of volunteers essentially doubled from 239 to 451 ng/ml with an increase in dose from 2.5 to 5.0 mg/kg. Mean area under the curve also approximately doubled from 1890 to 3358 ng hr/ml over this dose range. These observations suggest linear kinetics for meobentine in the 2.5–5-mg/kg dose range. Clearance (TBC/F) did not change significantly with increasing dose. The extent of absorption and bioavailability of meobentine are currently under investigation in animals and humans. The related guanidine, bethanidine, has been reported to be well absorbed by humans (18).

Currently, these radioimmunoassay procedures are being applied to detailed studies of the disposition of meobentine sulfate in animals and humans. Studies of the absolute oral bioavailability and pharmacokinetics of meobentine sulfate will be presented elsewhere in the near future.

Automated Sampling of *In Vitro* Dissolution Medium: Effect of Sampling Probes on Dissolution Rate of Prednisone Tablets

THOMAS S. SAVAGE *x and CLYDE E. WELLS ‡

Received June 8, 1981, from the **Food and Drug Administration, Los Angeles, CA 90015*, and the ‡*National Center for Drug Analysis, St. Louis, MO 63101.* Accepted for publication September 18, 1981.

Abstract □ The effect of sampling probe size and location on the *in vitro* dissolution rate of prednisone tablets was examined. Using USP XX Apparatus 2 with an automated sampling system, dissolution rates were determined using two types of large filter-tipped probes and a small capillary probe. Each probe was tested at three locations within the kettle. The large probes caused hydrodynamic changes which, when compared with results obtained through manual sampling, resulted in significant changes in dissolution rates at each location. These changes were less evident when the capillary probe was used, with an insignificant difference between results of automated and manual sampling when the capillary probe was placed midway between the paddle shaft and the kettle wall.

Keyphrases □ Dissolution rates—effect of sampling probe size and location on dissolution rate of prednisone tablets □ Hydrodynamics—dissolution rates affected by sampling probe size and location, USP paddle method □ Prednisone—tablets in dissolution rate testing with effects of sampling probe size

Automated sampling and analysis of *in vitro* dissolution aliquots can be a useful, timesaving procedure. Several automated sampling systems are commercially available in which aliquots of the dissolution fluid, taken at specified times, travel into sample cups or into an automated analytical system. Results of such a system are not generally considered acceptable, however, unless they agree with those obtained by manual sampling.

A large number of dissolution testing variables have been identified (1). These need to be strictly controlled if reproducible results are to be obtained. Changes in any of these variables can have a significant effect on the dissolution rate of a dosage form. A previous study (2) showed that the dissolution rate is affected by the effects of various dissolution parameters on the hydrodynamics of the dissolution fluid. Another study (3) showed that the hydrodynamic disturbance caused by insertion of a relatively large object, such as a thermometer, into the dissolution fluid may cause a change in dissolution rate, and that the location of such an object can also have a significant effect.

With most automated sampling systems now in use, a relatively large filter-tipped probe is immersed in the dissolution fluid. The above studies imply that a large probe can affect the system hydrodynamics, and therefore the dissolution rate of some dosage forms, thereby causing results which differ from those obtained by manual sampling, and that a smaller probe may have less effect on the

dissolution rate. A previous study (4) confirmed this implication by showing that manual aliquots taken while a large probe was suspended in the dissolution fluid gave higher results than those obtained when a small capillary probe or no probe was present.

In the work described in this paper, the effect of sampling probe size and probe location within the dissolution kettle were investigated by using an automated sampling system to collect aliquots through probes of several sizes and by comparing these results with those obtained by manual sampling.

EXPERIMENTAL

Principles—Dissolution testing was performed using the USP (5) method on a sample of 10-mg prednisone tablets which had been shown to be sensitive to changes in dissolution testing parameters[1]. Using an automated sampling system, samples were withdrawn at 30 min, sequentially diluted with water, and passed through a spectrophotometer flowcell, with absorbance measured at 242 nm. For comparison, manual samples were taken from separate dissolution runs, filtered, and determined spectrophotometrically.

The dissolution apparatus[2] was USP XX Apparatus 2 (6). Paddle rotation speed was maintained at 50 rpm with a gear plate. Temperature was maintained at 37.0 ± 0.5° using a heater-circulator[3] immersed in the water bath.

The automated sampling and analysis system[4] consisted of a multichannel peristaltic valve; plattered manifold for storage; and sequential analysis of sampled aliquots, tape programmer, peristaltic pump, spectrophotometer (set at 242 nm) with a 15-mm flowcell, and recorder. The apparatus was programmed according to Table I. This program allowed for sampling from each dissolution kettle at 30 min, with each aliquot being stored in a separate holding coil. A portion of standard solution was then introduced to the analytical system followed by sequential introduction of the contents of each sample storage coil. The schematic diagram in Fig. 1 shows the postsampling analytical system.

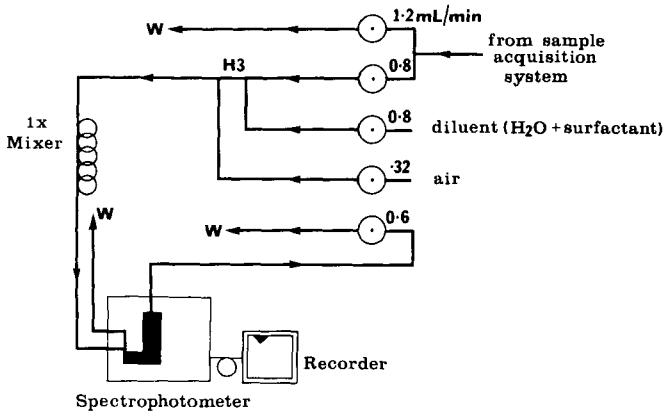

Figure 1—*Flow diagram for postsampling analytical system. All pump tubes are Tygon; all transmission tubing is trifluoroethylene, 1.0-mm i.d.; W indicates flow to waste reservoir.*

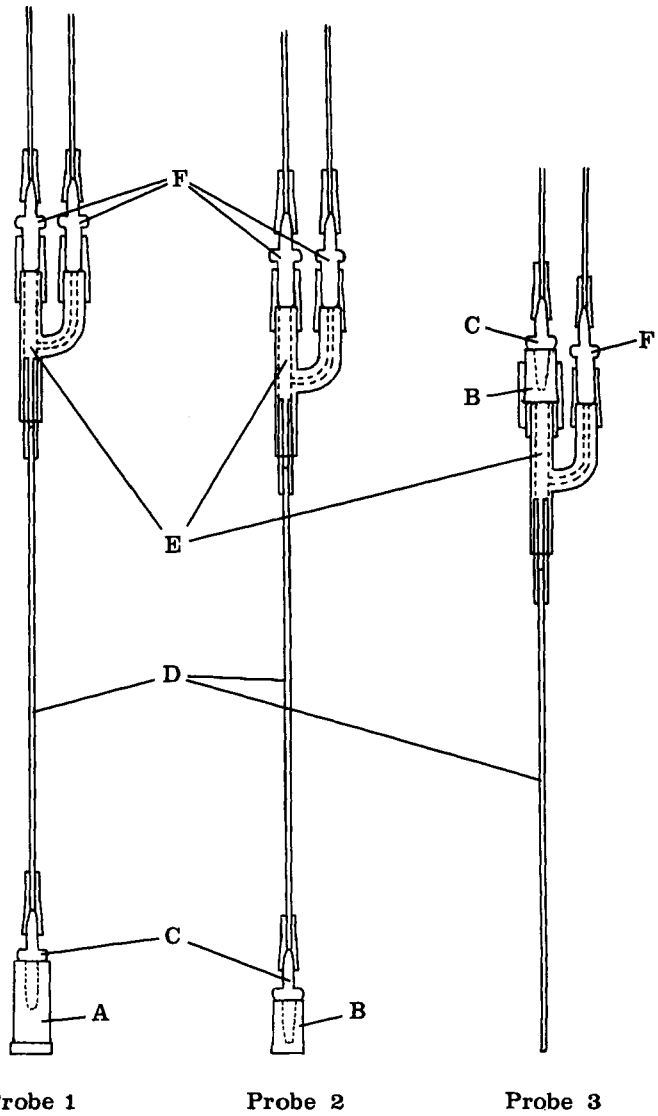

Figure 2—*Three types of probes used in automated sampling. Key: A, filter; B, filter; C, N7 nipple connector; D, glass capillary tube, size 0.8–1.10 × 100 mm; E, D1 "h"-connector; F, N5 nipple connector. Parts are connected to each other with sleeves of rubber tubing.*

The three types of sampling probes used with the automated sampling system are shown in Fig. 2. In Probes 1 and 2, commercially available filters[5,6] were attached to glass stalks connected to the "h"-connectors in the automated sampling system. The filters and stalks were suspended in the dissolution fluid throughout the dissolution run. In Probe 3, the glass stalk connected to the "h"-connector was extended into the dissolution fluid. The filter was attached "downstream" from the connector. Maximum immersed diameters for Probes 1, 2, and 3 were 8.0, 7.2, and 1.5 mm, respectively. Displacements of the immersed portions of the three probes were 1.1, 0.7, and 0.1 ml, respectively.

Manual sampling was performed using 50-ml syringes with 14-gauge needles. Aliquots were filtered through p 0.8-μm porosity membrane filters[7] and analyzed spectrophotometrically.

Reagents and Standards—Distilled water, deaerated by stirring under reduced pressure for 2 hr was used as the dissolution fluid.

[a] Number of aliquots taken. [b] Not tested.

The diluent used in the automated analysis was prepared by adding 1 ml of surfactant[8] to 1 liter of water.

The standard stock solution was prepared by dissolving 25 mg of prednisone USP Reference Standard in 20 ml of ethyl alcohol and diluting to 500 ml with water. A working standard was prepared daily by diluting a 10-ml standard stock solution to 100 ml with water.

Procedure—Before the automated sampling system was used, all lines and coils were filled with their respective solutions, and the system was allowed to equilibrate by running in the "wash" position for ~30 min. To start the dissolution run, the peristaltic valve was set in Position 1, and the dissolution apparatus was turned on. With all paddles rotating and sampling probes in the proper positions within the kettle, tablets were dropped simultaneously into all kettles and the programmer was turned on. After the 30-min sample aliquot collection (with the peristaltic valve in Position 3), the probes were removed from the kettles and placed in a beaker of water until the end of the analysis.

Dissolution testing was performed with samples withdrawn either manually or by automation from one of the three positions shown in Fig. 3. Position A is 0–1 cm from the wall of the vessel, Position B is midway between the kettle wall and the paddle shaft, ±0.5 cm, and Position C is 0–1 cm from the paddle shaft. The vertical location of all three probe positions is midway between the surface of the dissolution fluid and the level of the top of the paddle blade. Position B is the generally accepted position for manual sampling (1).

RESULTS AND DISCUSSION

Accuracy and reproducibility of the automated system were tested by running the system with the probes immersed in standard solution concentration of 7.08 μg/ml, equivalent to 35.4% of the declared tablet content dissolved. Each set of sampling probes was tested in this manner, with two runs of 6 aliquots/run made for each probe. Recoveries were 102.6, 101.7, and 101.4%, with coefficients of variation of 0.408, 0.554, and 0.796 for Probes 1, 2, and 3, respectively. Linearity was tested by aspirating standard solutions of 1.6, 3.2, 4.8, 6.4, 7.8, and 9.6 μg/ml, equivalent to 8.0–48.0% of the declared tablet content dissolved, using each of the three types of sampling probes. The response was linear throughout this range for each type of probe.

Dissolution testing of prednisone tablets was performed, with aliquots taken from each of the three kettle locations. Sampling was done automatically, using the three automated sampling probes, and manually. Results are summarized in Table II.

Statistical comparisons of dissolution results using each of the automated sampling probes with results obtained by manual sampling indicated a significant effect of the size of the probe. When aliquots were taken from the generally recommended Position B, each of the larger probes (Probes 1 and 2) gave significantly higher results than those of manual sampling when the t criterion was used at the 1% level of significance. The difference between the results using the smaller Probe 3 and the manual results was insignificant. In Position A, automated sampling with all probes gave significantly higher results than manual sampling, although the results with the larger probes were much higher than with the smaller. A different hydrodynamic effect was seen, however, when automated sample probes were suspended in Position C. Automated results from this position were lower than those obtained by manual sampling, with the lowering effect being more pronounced with the larger probes.

By subjecting the manual sampling data for the three sampling positions to a two-way analysis of variance at the 2% level of significance, it was shown that there was no significant difference among the three mean percentages dissolved, thereby indicating that no significant horizontal concentration gradient existed within the kettle. The observed changes in dissolution rates obtained by automated sampling were, therefore, caused by interference by the sampling probes with the hydrodynamic flow within the kettle. The degree of interference was directly related to the size of the probe as well as to its location.

The hydrodynamic change caused by insertion of the large probes was confirmed by visual observation. The normal disintegration of the prednisone tablets within the dissolution kettle formed a regular cone-shaped pile of undissolved tablet material, with a small amount of material dispersed throughout the medium. Extension of the large Sampling Probe 1 into the medium at Position B caused an immediate shifting of the conical pile to one side, followed by the dispersal of considerably more tablet material throughout the medium. This dispersal would account for the higher dissolution results obtained. The effect was more pronounced when the probe was extended into Position A. With the large probe in Position C, the conical pile became taller and narrower, with an apparent decrease in the amount of dispersed material accounting for the lower dissolution results. The insertion of the capillary probe into any of the three positions caused little or no visible disturbance of the undissolved tablet material.

CONCLUSIONS

The large sampling probes provided with several commercially available automated dissolution sampling systems were shown to cause significant hydrodynamic disturbances, resulting in changes in the dissolution rate of a sample of prednisone tablets. The disturbances were reduced through the use of a small capillary probe. Probe location within the kettle was also shown to require careful control. While only one type of tablet was used in this study, the changes in dissolution hydrodynamics caused by the sampling probe could be expected to affect the dissolution

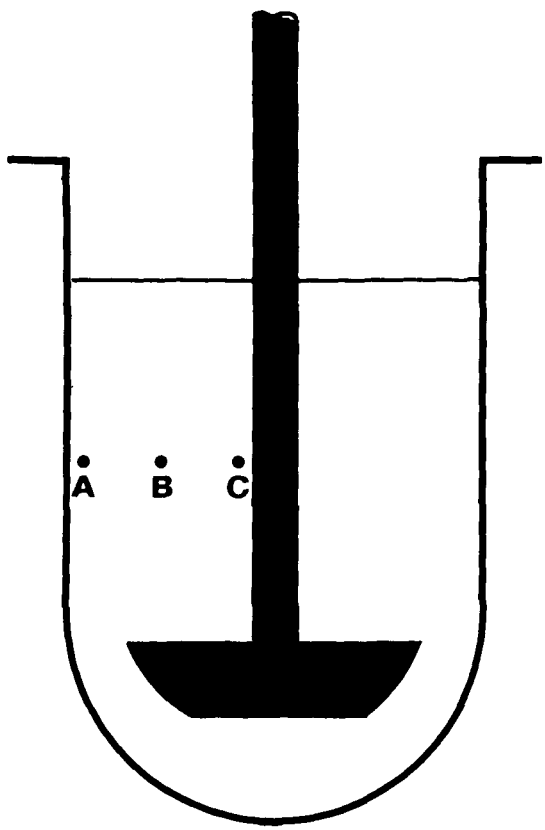

Figure 3—*Three probe locations used in dissolution sampling.*

rate of other types of dosage forms. It is therefore recommended that the sampling probes used with automated sampling systems be made as small as possible, and that the horizontal sampling position be carefully maintained halfway between the paddle shaft and the kettle wall.

Sequential Organ First-Pass Effects: Simple Methods for Constructing Compartmental Pharmacokinetic Models from Physiological Models of Drug Disposition by Several Organs

JAMES R. GILLETTE

Received April 22, 1981, from the *Laboratory of Chemical Pharmacology, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication September 22, 1981.

Abstract □ The relationships between organ clearances derived from physiological pharmacokinetic models and the first-order rate constants in compartmental pharmacokinetic models are frequently difficult to visualize when drugs are eliminated simultaneously by several organs. Two simple methods for showing these relationships are illustrated in this paper.

Keyphrases □ Pharmacokinetics—construction of compartmental models from physiological models of drug disposition, first-pass effects □ First-pass effects—construction of compartmental pharmacokinetic models from physiological models of drug disposition □ Compartmental models—construction of pharmacokinetic models from physiological models of drug disposition, first-pass effects

Changes in the blood concentrations of drugs after their oral administration are frequently fitted to a pharmacokinetic equation representing a three-compartment model in which it is assumed that all eliminating organs are within the central compartment. In such a model, a first-order rate constant (k_{31}) is frequently used to represent the absorption of a drug from the GI tract into a central compartment and first-order microconstants (k_{12}, k_{21}) are frequently used to represent the passage of the drug between the central and peripheral compartments. The elimination of the drug from the body is represented by a first-order microconstant (k_{10}) emanating solely from the central compartment. This model would be identical to that pictured in Fig. 1 except that k_{13}, k_{20}, and k_{30} would be zero.

Despite the simplicity of this model, it adequately describes the major events in the absorption and disposition of most drugs and, thus, has gained wide acceptance. But it is invalid in many situations, particularly those in which drugs are very rapidly cleared by enzymes in the GI mucosa, liver, and lung (the first-pass organs) and those situations in which the drug passes into the GI tract by reversible diffusion from mucosal blood into the lumen of the GI tract or by biliary excretion. Moreover, the model also fails to describe adequately the pharmacokinetics of metabolites that are rapidly cleared by various organs. In these situations it is necessary to consider physiological models.

Several years ago, Bischoff and Dedrick (1) developed a physiological approach in which Fick's Principle is applied to individual organs. In this approach, each organ comprises three homogeneous compartments: the blood, the interstitial fluid, and an intracellular compartment. Since a differential equation is required to express the rate of change in the amount of drug in these subcompartments of each organ, the number of equations required to describe changes in the disposition of the drug in the body at any given time can be quite large; frequently as many as 15–20 equations are used. It is possible to integrate a set of such equations by means of LaPlace transforms. Unfortunately, the pharmacokinetic constants obtained by integration of the simultaneous equations or from measurements of drug concentrations in blood are virtually impossible to interpret in physiological terms.

The present paper describes a general approach for developing pharmacokinetic models that combine some of the complexities that can occur during rapid simultaneous elimination of drugs by several organs with the simplicity of the linear three-compartment model. The approach is essentially intuitive and, thus, requires very little mathematical ability. It is illustrated by a model in which a drug is rapidly cleared by the GI mucosa, the liver, the lungs, and the kidneys.

THEORY

As in the three-compartment model, it is assumed that after rapid injection into the aorta, a drug is almost instantaneously distributed into a central compartment that includes most of the organs of elimination such as the kidneys, the GI mucosa, the liver, and the lungs. Thus, by the time the arterial concentration of the drug is estimated, the ratios of the intracellular concentrations of the drug in the organs included within the central compartment to the drug concentration in arterial blood have reached constant values. (This is usually estimated indirectly by measuring the drug concentration in systemic venous blood: draining a nonelimination organ such as an arm.) Under these quasi steady-state

0022-3549/82/0600-0673$01.00/0

rate of other types of dosage forms. It is therefore recommended that the sampling probes used with automated sampling systems be made as small as possible, and that the horizontal sampling position be carefully maintained halfway between the paddle shaft and the kettle wall.

Sequential Organ First-Pass Effects: Simple Methods for Constructing Compartmental Pharmacokinetic Models from Physiological Models of Drug Disposition by Several Organs

JAMES R. GILLETTE

Received April 22, 1981, from the *Laboratory of Chemical Pharmacology, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication September 22, 1981.

Abstract □ The relationships between organ clearances derived from physiological pharmacokinetic models and the first-order rate constants in compartmental pharmacokinetic models are frequently difficult to visualize when drugs are eliminated simultaneously by several organs. Two simple methods for showing these relationships are illustrated in this paper.

Keyphrases □ Pharmacokinetics—construction of compartmental models from physiological models of drug disposition, first-pass effects □ First-pass effects—construction of compartmental pharmacokinetic models from physiological models of drug disposition □ Compartmental models—construction of pharmacokinetic models from physiological models of drug disposition, first-pass effects

Changes in the blood concentrations of drugs after their oral administration are frequently fitted to a pharmacokinetic equation representing a three-compartment model in which it is assumed that all eliminating organs are within the central compartment. In such a model, a first-order rate constant (k_{31}) is frequently used to represent the absorption of a drug from the GI tract into a central compartment and first-order microconstants (k_{12}, k_{21}) are frequently used to represent the passage of the drug between the central and peripheral compartments. The elimination of the drug from the body is represented by a first-order microconstant (k_{10}) emanating solely from the central compartment. This model would be identical to that pictured in Fig. 1 except that k_{13}, k_{20}, and k_{30} would be zero.

Despite the simplicity of this model, it adequately describes the major events in the absorption and disposition of most drugs and, thus, has gained wide acceptance. But it is invalid in many situations, particularly those in which drugs are very rapidly cleared by enzymes in the GI mucosa, liver, and lung (the first-pass organs) and those situations in which the drug passes into the GI tract by reversible diffusion from mucosal blood into the lumen of the GI tract or by biliary excretion. Moreover, the model also fails to describe adequately the pharmacokinetics of metabolites that are rapidly cleared by various organs. In these situations it is necessary to consider physiological models.

Several years ago, Bischoff and Dedrick (1) developed a physiological approach in which Fick's Principle is applied to individual organs. In this approach, each organ comprises three homogeneous compartments: the blood, the interstitial fluid, and an intracellular compartment. Since a differential equation is required to express the rate of change in the amount of drug in these subcompartments of each organ, the number of equations required to describe changes in the disposition of the drug in the body at any given time can be quite large; frequently as many as 15–20 equations are used. It is possible to integrate a set of such equations by means of LaPlace transforms. Unfortunately, the pharmacokinetic constants obtained by integration of the simultaneous equations or from measurements of drug concentrations in blood are virtually impossible to interpret in physiological terms.

The present paper describes a general approach for developing pharmacokinetic models that combine some of the complexities that can occur during rapid simultaneous elimination of drugs by several organs with the simplicity of the linear three-compartment model. The approach is essentially intuitive and, thus, requires very little mathematical ability. It is illustrated by a model in which a drug is rapidly cleared by the GI mucosa, the liver, the lungs, and the kidneys.

THEORY

As in the three-compartment model, it is assumed that after rapid injection into the aorta, a drug is almost instantaneously distributed into a central compartment that includes most of the organs of elimination such as the kidneys, the GI mucosa, the liver, and the lungs. Thus, by the time the arterial concentration of the drug is estimated, the ratios of the intracellular concentrations of the drug in the organs included within the central compartment to the drug concentration in arterial blood have reached constant values. (This is usually estimated indirectly by measuring the drug concentration in systemic venous blood: draining a nonelimination organ such as an arm.) Under these quasi steady-state

0022-3549/82/0600-0673$01.00/0

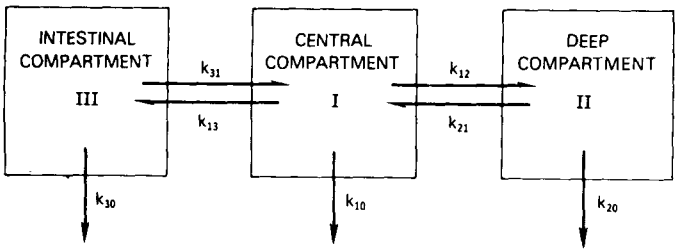

Figure 1—*Three-compartment pharmacokinetic model.*

conditions, virtually all of the drug entering a given organ in the central compartment leaves the organ by the venous blood and by excretion and metabolism; the rate of change in the amount of drug retained by the organ is negligible. When the drug is eliminated from the central compartment by a single organ, the rate of elimination under steady-state conditions may be described by the equivalent terms shown in Table I. In these terms Q_{organ} is the blood flow rate through the organ of elimination, C_{art} is the drug concentration in the arterial blood, and C_{out} is the drug concentration in the systemic blood leaving the organ. The organ availability of the drug (F_{organ}) equals C_{out}/C_{art} for that organ. As will be shown, it is also important to realize that Q_{organ}/C_{art} is the rate, expressed in amount per time, at which the drug enters the organ under steady-state conditions; *i.e.*, rate into organ. Moreover, F_{organ} may also be expressed as the rate out of organ/rate into organ. Thus, the clearance (Cl_{organ}) may be expressed by the equivalent terms shown in Table I.

When a drug is eliminated from the body by several organs, the total clearance from the central compartment is sometimes difficult to visualize. When all of the organs of elimination are perfused solely by arterial blood, the total clearances of elimination from the central compartment is the sum of the clearances of the individual organs. But some organs (notably the liver and the lungs) are perfused by venous blood as well as by arterial blood, and thus, the calculation of the total clearance of elimination from the central compartment depends on whether the drug is eliminated from the body by several organs in sequence. If the drug is eliminated by two or more organs in sequence, the total clearance of elimination from the central compartment contributed by organs is less than the sum of the individual organ clearances as calculated from the equation shown in Table I.

One approach that may be used to derive the equations for multiorgan clearances is to write the differential equations for the organs comprising the central compartment as in the Bischoff-Dedrick approach. The equations may then be set to zero, because the rate of change in the amount of drug present in the organs under the stated steady-state conditions is virtually negligible. The solution of the set of equations, however, is laborious and requires considerable mathematical skill. Moreover, the concept of organ clearances is lost, and the resulting equations are model dependent, in that each organ is assumed to be a well-stirred compartment (2).

For the present paper, two much simpler methods for the derivation of total clearance of elimination from the central compartment have been developed. In both methods a clearance term is defined as the rate of elimination of the drug divided by the concentration of the drug in a reference compartment, namely the systemic arterial blood.

In the first method, the partitioned blood flow method (Method A), the cardiac output is partitioned according to the arterial flow rates through the individual organs in the central compartment. One then visualizes the organs that a given blood supply must pass through before it reenters the systemic arterial circulation. For example, the blood serving the intestinal mucosa must also pass through the liver and the lung before it reenters the aorta (Fig. 2). Thus, in accordance with the rate equation in Table I, the rate of elimination of the drug from mucosal blood (G-1 flow) by the mucosa (G-1) may be written:

Table I—Equivalent Equations for the Rate and Clearance of Elimination of Drugs by Single Organs

(Rate of elimination) organ $= Q_{organ}(C_{art} - C_{out})$
$= Q_{organ}C_{art}[1 - (C_{out}/C_{in})] = Q_{organ}C_{art}(1 - F_{organ})$
= (Rate into organ)$(1 - F_{organ})$
$= Q_{organ}C_{art}E_{organ}$ = (Rate into organ) E_{organ}
$Cl_{organ} = Q_{organ}E_{organ}$
$= Q_{organ}(1 - F_{organ})$
= Rate of elimination by organ/C_{art}
= (Rate into organ) $(1 - F_{organ})/C_{art}$
= (Rate into organ) E_{organ}/C_{art}

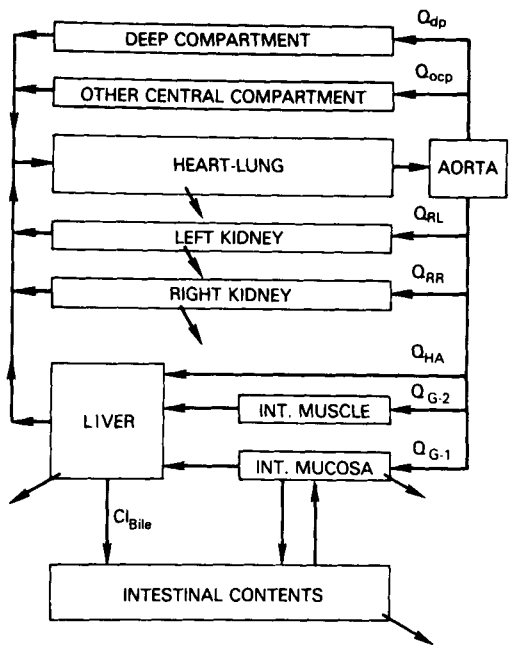

Figure 2—*A physiological pharmacokinetic model.*

rate of elimination from G-1 flow by G-1
$$= (\text{rate into } G\text{-}1 \textit{ via } G\text{-}1 \text{ flow})(1 - F_{G\text{-}1}) = C_{art}\,Q_{G\text{-}1}\,(1 - F_{G\text{-}1}) \quad \text{(Eq. 1)}$$

in which $F_{G\text{-}1}$ is the ratio of the rates at which the drug in amount per minute enters and leaves the capillary bed serving the intestinal mucosa.

The rate of elimination of the drug from the mucosal blood by the liver (H) depends on the concentration of the drug in blood leaving the mucosa and only indirectly on the concentration of the drug in the arteries. Thus:

rate of elimination from G-1 flow by H
$$= (\text{rate into } H \textit{ via } G\text{-}1 \text{ flow})(1 - F_H) = C_{art}Q_{G\text{-}1}F_{G\text{-}1}(1 - F_H) \quad \text{(Eq. 2)}$$

In Eq. 2, F_H is the ratio of the rates at which the drug leaves the liver by the hepatic vein (HV) and enters the liver by both the portal vein and the hepatic artery:

$$F_H = \frac{(Q_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})C_{HV}}{(Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})C_{art}} \quad \text{(Eq. 3)}$$

In Eq. 3 $Q_{G\text{-}2}$ represents the portal venous flow of the blood that does not perfuse the mucosa. In rats this has been estimated to be ~75% of the total intestinal blood flow (3). In addition to intestinal blood, it also includes the gastric and splenic blood.

By the same reasoning, the rate of elimination of the drug in mucosal blood by the lung will depend on the hypothetical concentration that would have been present in the hepatic venous blood if the mucosal blood perfusing the mucosa were the only blood perfusing the liver. Thus:

rate of elimination from G-1 flow by L
$$= (\text{rate into } L \textit{ via } G\text{-}1 \text{ flow})\,(1 - F_L) = C_{art}Q_{G\text{-}1}F_{G\text{-}1}F_H\,(1 - F_L) \quad \text{(Eq. 4)}$$

In Eq. 4, F_L is the rate at which the drug leaves the lung by the pulmonary vein divided by the rate at which it enters the lung by the pulmonary artery. The total rate of elimination of the drug from the mucosal blood, $\text{rate}_{(G\text{-}1\text{ flow})}$ is the sum of the expressions given by Eqs. 1, 2, and 4:

$$\text{rate}_{(G\text{-}1\text{ flow})} = C_{art}Q_{G\text{-}1}(1 - F_{G\text{-}1}) + C_{art}Q_{G\text{-}1}F_{G\text{-}1}\,(1 - F_H) + C_{art}Q_{G\text{-}1}F_{G\text{-}1}F_H\,(1 - F_L) \quad \text{(Eq. 5)}$$

which on expansion and collection of terms becomes:

$$\text{rate}_{(G\text{-}1\text{ flow})} = C_{art}Q_{G\text{-}1}(1 - F_{G\text{-}1}F_HF_L) \quad \text{(Eq. 6)}$$

The mucosal blood clearance of the drug thus becomes:

$$Cl_{(G\text{-}1\text{ flow})} = \frac{\text{rate}_{(G\text{-}1\text{ flow})}}{C_{art}} = Q_{G\text{-}1}(1 - F_{G\text{-}1}F_HF_L) \quad \text{(Eq. 7)}$$

Table II—Poly Input Organ Clearances

Intestinal Mucosa
- metabolic: $Cl_{G\text{-}1(met)} = Q_{G\text{-}1}E_{G\text{-}1}f_{G\text{-}1(met)}$
- diffusion: $Cl_{G\text{-}1(dif)} = Q_{G\text{-}1}E_{G\text{-}1}f_{G\text{-}1(dif)}$
- since, $f_{G\text{-}1(met)} + f_{G\text{-}1(dif)} = 1$,
- total: $Cl_{G\text{-}1} = Q_{G\text{-}1}E_{G\text{-}1}$

Liver
- metabolic: $Cl_{pinH(met)} = (Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})E_Hf_{H(met)}$
- biliary: $Cl_{pinH(biliary)} = (Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})E_Hf_{H(biliary)}$
- since, $f_{H(met)} + f_{H(biliary)} = 1$,
- total: $Cl_{pinH} = (Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})E_H$

Kidney
- left kidney: $Cl_{RL} = Q_{R1}E_{RR}$
- right kidney: $Cl_{RR} = Q_{RR}E_{RR}$
- total: $Cl_R = Q_{RL}E_{RL} + Q_{RR}E_{RR}$

Deep Compartment
- total: $Cl_{dp} = Q_{dp}E_{dp}$

Lung
- metabolism: $Cl_{pinL(met)} = [Q_{G\text{-}1}F_{G\text{-}1}F_H + (Q_{G\text{-}2} + Q_{HA})F_H + Q_{RL}F_{RL} + Q_{RR}F_{RR} + Q_{ocp} + Q_{dp}F_{dp}]E_Lf_{L(met)}$
- diffusion: $Cl_{pinL(dif)} = [Q_{G\text{-}1}F_{G\text{-}1}F_H + (Q_{G\text{-}2} + Q_{HA})F_H + Q_{RL}F_{RL} + Q_{RR}F_{RR} + Q_{ocp} + Q_{dp}F_{dp}]E_Lf_{L(dif)}$
- total: $Cl_{pinL} = [Q_{G\text{-}1}F_{G\text{-}1}F_H + (Q_{G\text{-}2} + Q_{HA})F_H + Q_{RL}F_{RL} + Q_{RR}F_{RR} + Q_{ocp} + Q_{dp}F_{dp}]E_L$

The partitioned blood flow clearance of drug from blood passing through several organs, thus, may be expressed as the partitioned blood flow rate times one minus the mathematical product of the drug availabilities of the organs through which the blood passes.

By similar reasoning, the clearance of the drug from the partitioned blood flow perfusing other organs may be written:

hepatic arterial blood clearance and G-2 arterial blood clearance

$$Cl_{(H\ flow)} + Cl_{(G\text{-}2\ flow)} = (Q_H + Q_{G\text{-}2})(1 - F_HF_L) \quad \text{(Eq. 8)}$$

left (RL) and right (RR) renal arterial blood clearances

$$Cl_{(RL\ flow)} = Q_{RL}(1 - F_{RL}F_L) \quad \text{(Eq. 9)}$$

$$Cl_{(RR\ flow)} = Q_{RR}(1 - F_{RR}F_L) \quad \text{(Eq. 10)}$$

Clearance from blood perfusing the nonelimination organs in the central compartment ($Cl_{ocp\ flow}$) and the deep compartment ($Cl_{dp\ flow}$) is:

$$Cl_{(ocp\ flow)} + Cl_{(dp\ flow)}F_{dp} = (Q_{ocp} + Q_{dp}F_{dp})(1 - F_L) \quad \text{(Eq. 11)}$$

In which F_{dp} is the fraction of the drug in blood perfusing the deep compartment tissues that does not enter the deep compartment, *i.e.*, $(1 - F_{dp})$ equals the rate of diffusion of the drug into the deep compartment divided by $Q_{dp}C_{art}$.

The total clearance of elimination of the drug from the central compartment (Cl_{10}) is, thus, the sum of the individual partitioned blood flow clearances:

$$Cl_{10} = Q_{G\text{-}1}(1 - F_{G\text{-}1}F_HF_L) + (Q_H + Q_{G\text{-}2})(1 - F_HF_L) + Q_{RL}(1 - F_{RL}F_L) + Q_{RR}(1 - F_{RR}F_L) + Q_{ocp}(1 - F_L) + Q_{dp}F_{dp}(1 - F_L) \quad \text{(Eq. 12)}$$

The rate constant of elimination from the central compartment is obtained from the relationship, $k_{10} = Cl_{10}/V_c$ in which V_c is the apparent volume of the central compartment.

Although the partitioned blood flow method (Method A) provides a simple, concise way of expressing Cl_{10}, it will fail when significant amounts of the drug are reabsorbed after the drug enters the lumen of the intestine either by biliary excretion or by passive diffusion from the blood across GI membranes. Method A also provides equations that are difficult to interpret when the various F_{organ} values approach 1.0 or when the investigator wishes to visualize the relative importance of the individual organs in clearing the drug from the body.

Method B was developed to overcome these difficulties. For this method, a general concept of clearance was envisioned, the poly input organ clearance or $Cl_{pin\ organ}$. In this concept, the rate of elimination of the drug by an organ is the difference in the rates at which the drug enters and leaves the organ *via* the blood under steady-state conditions. Thus, $Cl_{pin\ organ}$ may be expressed as:

$$Cl_{pin\ organ} = (\text{total rate in} - \text{total rate out})/C_{art}$$
$$= \text{total rate in}\ (1 - \text{total rate out/total rate in})/C_{art} \quad \text{(Eq. 13)}$$

The term (total rate out/total rate in), however, is the organ availability, F_{organ}. Thus:

$$Cl_{pin\ organ} = \frac{(\Sigma\ Q_iC_i)(1 - F_{organ})}{C_{art}} \quad \text{(Eq. 14)}$$

In turn, $1 - F_{organ}$ may be expressed as the extraction ratio of the drug by the organ, E_{organ}. Thus:

$$Cl_{pin\ organ} = \frac{(\Sigma\ Q_iC_i)E_{organ}}{C_{art}} \quad \text{(Eq. 15)}$$

However the C_i values may be expressed in terms of steady-state arterial concentration of the drug and the mathematical product (Π) of the individual availabilities of the organs through which the blood passes before it reaches the organ under consideration, *i.e.*, $\Pi\ F_{preorgan}$, where $F_{preorgan}$ is the F_{organ} of a given preorgan. Thus:

$$Cl_{pin\ organ} = \frac{C_{art}(\Sigma Q_i \Pi F_{preorgan})E_{organ}}{C_{art}} = (\Sigma Q_i \Pi F_{preorgan})E_{organ} \quad \text{(Eq. 16)}$$

From this general equation, equations may be written (Table II) for the poly input organ clearances in a system in which a drug is eliminated by the intestinal mucosa (both metabolically and by passive diffusion into the intestinal lumen), the liver (both metabolically and by biliary excretion), the lungs (both metabolically and by exhalation), and the kidneys (both metabolically and by excretion) (Fig. 2).

The model also includes an effective shunt in which it is recognized that only ~25% of the intestinal blood perfuses the intestinal mucosa (3); thus, $Q_{G\text{-}1}$ represents the intestinal blood that perfuses the mucosa and $Q_{G\text{-}2}$ represents the portion of the portal blood that has bypassed the mucosa. The equations in Table II also indicate how the poly input organ clearance by any given organ may be distributed between elimination by excretion or metabolism. The metabolic clearance by an organ may be expressed as a fraction, $f_{organ\ (met)}$, of the poly input organ total clearance. For example, the metabolic clearance by the mucosa is $Cl_{G\text{-}1\ (met)} = Cl_{G\text{-}1}f_{G\text{-}1\ (met)}$, in which $f_{G\text{-}1\ (met)}$ is the fraction of the total organ clearance due to metabolism. Similarly, the diffusional clearance may be written as $Cl_{G\text{-}1\ (dif)} = Cl_{G\text{-}1}f_{G\text{-}1\ (dif)}$, in which $f_{G\text{-}1\ (dif)}$ is the fraction of the total mucosal clearance due to diffusion. Thus, $f_{G\text{-}1\ (met)} + f_{G\text{-}1\ (dif)} = 1.0$. The equations may then be expanded to those shown in Table II.

The next step in the development of the compartmental model is to distribute the sequential organ clearances among the rate constants that emanate from the central pool. By *definition, any clearance by which* the drug irreversibly leaves the central compartment is a part of Cl_{10}. Thus, the investigator must decide whether a drug that leaves the central compartment by biliary excretion or passive diffusion across the intestinal mucosa into the intestinal lumen will be reabsorbed from the intestines. If the compound is not reabsorbed the clearances of these processes should be included in Cl_{10}. But if the drug is reabsorbed, the sum of the clearances of these processes equals Cl_{13}, the clearance for the passage of the drug into the GI tract. The investigator also must decide whether the drug that leaves the body by exhalation is reabsorbed. If the animal is in the open air, which contains negligible amounts of the drug, then the effective lung clearance by exhalation of the drug is part of Cl_{10}. But if the animal is placed into a closed chamber in which the drug vapor is at a significant concentration, the chamber becomes a pharmacokinetic compartment, which may be either closed or open. In this situation, the effective lung clearance by exhalation of the drug is not included in Cl_{10}, but is represented by a separate clearance. For the purpose of the present discussion, however, we will assume that the drug is reabsorbed from the GI tract and the animal is in the open air. With these assumptions, the components of Cl_{10}, Cl_{12}, and Cl_{13} are those shown in Table III.

The other microclearances for the three-compartment model may also be written, although some of them may not be immediately obvious. For example, the microclearance representing the passage of the drug from the deep compartment to the central compartment, Cl_{21}, may be visualized as a diffusional clearance, $Cl_{dp(dif)}$, but after leaving the deep compartment the drug must first pass through the lungs before it reenters the arterial circulation and, thus, Cl_{21} equals $Cl_{dp(dif)}F_L$. The drug that is removed by the lungs as it passes from the deep compartment into the arterial blood must also be accounted for. Thus, the microclearance, Cl_{20}, that represents an irreversible removal of the drug from the deep com-

Table III—Relationship between Various Microconstants of the Three-Compartment Model and the Poly Input Organ Clearance

Micro Clearance	Volume Times Microconstants	Components of Micro Clearances	Expanded Version of Micro Clearances
	Central Compartment to Gastrointestinal Tract		
Cl_{13}	V_1k_{13}	$Cl_{G\text{-}1(\text{dif})} + Cl_{\text{pin}H(\text{biliary})}$	$Q_{G\text{-}1}E_{G\text{-}1}f_{G\text{-}1(\text{dif})} + (Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})E_Hf_{H(\text{biliary})}$
	Central Compartment to Deep Compartment		
Cl_{12}	V_1k_{12}	Cl_{dp}	$Q_{\text{dp}}E_{\text{dp}}$
	Central Compartment Irreversible Elimination		
Cl_{10}	V_1k_{10}	$Cl_{G\text{-}1(\text{met})} + Cl_{\text{pin}H(\text{met})} + Cl_{RL} + Cl_{RR} + Cl_{\text{pin}L}$	$Q_{G\text{-}1}E_{G\text{-}1}f_{G\text{-}1(\text{met})}$ $(Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})E_Hf_{H(\text{met})}$ $Q_{RL}E_{RL} + Q_{RR}E_{RR}$ $[(Q_{G\text{-}1}F_{G\text{-}1} + Q_{G\text{-}2} + Q_{HA})F_H + Q_{RL}F_{RL}$ $+ Q_{RR}F_{RR} + Q_{\text{ocp}} + Q_{\text{dp}}F_{\text{dp}}]E_L$
	Deep Compartment to Central Compartment		
Cl_{21}	V_2k_{21}	$Cl_{\text{dp}(\text{dif})}F_L$	$Q_{\text{dp}}E_{\text{dp}}F_L$
	Deep Compartment Irreversible Elimination		
Cl_{20}	V_2k_{20}	$Cl_{\text{dp}(\text{met})} + Cl_{\text{dp}(\text{dif})}E_L$	$Cl_{\text{dp}(\text{met})} + Q_{\text{dp}}F_{\text{dp}}E_L$
	Gastrointestinal Tract to Central Compartment		
Cl_{31}	V_3k_{31}	—	$Cl_{g(\text{dif})}F_{G\text{-}1}F_HF_L$
	Gastrointestinal Tract Irreversible Elimination		
Cl_{30}	V_3k_{30}	—	$Cl_{g(\text{met})} + Cl_{g(\text{dif})}[E_{G\text{-}1}f_{G\text{-}1(\text{met})} + F_{G\text{-}1}E_Hf_{H(\text{met})} + F_{G\text{-}1}F_HE_L]$

partment will include not only the metabolism of the drug that takes place in the deep compartment, $Cl_{\text{dp}(\text{met})}$, but also the drug that is eliminated by the lungs as the drug passes from the deep compartment to the arterial circulation, $Cl_{\text{dp}(\text{dif})}E_L$. For this reason, a three-compartment model in which a drug is rapidly eliminated by the lungs theoretically should always include both Cl_{10} and Cl_{20}.

By a similar line of reasoning, a drug absorbed from the intestinal tract passes through the intestinal mucosa, the liver, and the lungs before it enters the arterial circulation; therefore, Cl_{31} must include not only the clearance of diffusion across the intestinal wall, $Cl_{g(\text{dif})}$, but also the availability of the drug as it passes through the various organs before it reaches the arterial circulation. Thus, Cl_{31} equals $Cl_{g(\text{dif})}F_{G\text{-}1}F_HF_L$. Moreover, Cl_{30} must include not only the drug that is eliminated in the feces or metabolized by intestinal flora, but also the metabolic clearance of the drug as it passes through the intestinal mucosa, the liver, and the lungs. Therefore, as shown in Table III:

$$Cl_{30} = Cl_{g(\text{met})} + Cl_{g(\text{dif})}[E_{G\text{-}1}f_{G\text{-}1(\text{met})} + F_{G\text{-}1}E_Hf_{H(\text{met})} + F_{G\text{-}1}F_HE_Lf_{L(\text{met})}] \quad \text{(Eq. 17)}$$

Thus, any compartmental model in which a drug is rapidly eliminated by the intestinal mucosa, the liver, or the lungs should theoretically always include Cl_{30} as well as Cl_{10}.

Once the microconstants have been written they may be incorporated into the equations derived for the appropriate compartmental models. The equations for the blood concentrations of a drug in the three-compartment model shown in Fig. 1 are given in the *Appendix*.

DISCUSSION

It is interesting that the intestinal mucosa and the liver are simultaneously a part of the intestinal compartment and the central compartment; and that the lung is simultaneously a part of the intestinal compartment, the central compartment, and the deep compartment. What the equations illustrate, however, is the artificiality of compartmental models when applied to complex physiological systems. Therefore, it is evident that the visualization of the body as a set of compartments is fraught with difficulties, not only because the volume of the various compartments is difficult to determine, but also because the clearances by which the drug is transferred from one compartment to another and eliminated from the body are difficult to visualize.

Both methods illustrated in this paper are based solely on the conservation of mass and the anatomy and function of the cardiovascular system. The investigator is at liberty to choose any model he or she wishes, to illustrate the effects of altering blood flow rates or reversible binding of drugs to blood components on the availabilities (F values) and extraction ratios (E values). Indeed, he or she may wish to choose different models for different organs. For example, the investigator may wish to use the well-stirred model (4) [in which $F = Q/(Q + f_B\,Cl^u_{\text{int}})$] and $E = f_B\,Cl^u_{\text{int}}/(Q + f_B\,Cl^u_{\text{int}})$ for the liver and the parallel tube model [in which $F = (\exp - f_B\,Cl^u_{\text{int}}/Q)$] and $E = 1 - [\exp - (f_B\,Cl^u_{\text{int}}/Q)]$ for the kidney (5), where Cl^u_{int} represents the free intrinsic clearance of the organ and f_B is the unbound fraction of drug in the blood.

With the principles for the partitioned blood clearances and the poly input organ clearances in mind, the investigator may construct other models. For example, a separate compartment to represent the gall bladder or blood shunts such as the portal vena cava may be introduced. Alternatively, the investigator may wish to simplify the model by setting the F values equal to one and the E values equal to zero when such simplifications seem warranted. Thus, the methods are not only simple, but also versatile.

With measurements of drug concentrations in blood alone, it is not possible to differentiate between the model described in Fig. 1 from the three-compartment model described by Gibaldi and Perrier (6) in which the drug is eliminated solely from a central compartment. The main purpose of the model described here is to provide the investigator with insights by which he or she may infer possible meanings of the individual microconstants of compartmental models and how changes in them might affect the pharmacokinetics of drugs. The use of these simplified physiological approaches should help investigators to understand the relationship between poly input first-pass effects in physiological systems and the pharmacokinetics as predicted by compartmental models. They also should clarify some of the problems that can arise in the interpretation of such models.

APPENDIX

The solution of the three-compartment model shown in Fig. 1 by La-Place transforms gives the following equations for the drug concentration in blood:

Oral Administration:

$$C = \frac{\text{dose}}{V_1}\left[\frac{k_{31}(k_{20}+k_{21}-\gamma)}{(\alpha-\gamma)(\beta-\gamma)}e^{-\gamma t} + \frac{k_{31}(k_{20}+k_{21}-\alpha)}{(\gamma-\alpha)(\beta-\alpha)}e^{-\alpha t} + \frac{k_{31}(k_{20}+k_{21}-\gamma)}{(\gamma-\beta)(\alpha-\beta)}e^{-\beta t}\right]$$

Intravenous administration:

$$C = \frac{\text{dose } F_L}{V_1}\left[\frac{(k_{30}+k_{31}-\gamma)(k_{20}+k_{21}-\gamma)}{(\alpha-\gamma)(\beta-\gamma)}e^{-\gamma t} + \frac{(k_{30}+k_{31}-\alpha)(k_{20}+k_{21}-\alpha)}{(\gamma-\alpha)(\beta-\alpha)}e^{-\alpha t} + \frac{(k_{30}+k_{31}-\beta)(k_{20}+k_{21}-\beta)}{(\gamma-\beta)(\alpha-\beta)}e^{-\beta t}\right]$$

In these equations, γ, α, and β are the roots[1] of the transformed equation

$$0 = (s+\gamma)(s+\alpha)(s+\beta)$$
$$= (s+k_{30}+k_{31})(s+k_{10}+k_{12}+k_{13})(s+k_{20}+k_{21}) - k_{12}k_{21}(s+k_{30}+k_{31}) - k_{13}k_{31}(s+k_{20}+k_{21})$$

[1] When hypothetical values of the microconstants based on their physiological components are substituted into the transformed equation, the roots may be determined by iteration of synthetic division. Decreasing values of s (0 to $-\infty$) are iterated with a programmable calculator until all three values of s that satisfy the equation, $F(s) = 0$, are found. Unfortunately, the presence of k_{20} and k_{30} in the model precludes the calculation of the microconstants from actual data. In the three-compartment model of Gibaldi and Perrier (6), the elimination of a drug is represented solely by k_{10}. Thus, their method would overestimate the values of k_{31}, k_{21}, and k_{10} and would provide no adequate way of estimating k_{20} or k_{30}. However, simulations are still possible by substituting reasonable numerical values of the various microconstants into the equation.

Biological Effects of Nonalkaloid-Containing Fractions of *Erythroxylon coca*

ERNEST C. HARLAND, JAMES C. MURPHY ˣ, HALA ELSOHLY, DEBORAH GREUBEL, CARLTON E. TURNER, and E. S. WATSON

Received May 18, 1981, from the *Research Institute of Pharmaceutical Sciences, University of Mississippi, University, MS 38677.* Accepted for publication September 24, 1981.

Abstract □ Water soluble nonalkaloid fractions of *Erythroxylon coca* were screened in mice for their effects on oxygen utilization and central nervous system (CNS) activity. The fractions were screened in dogs for cardiovascular, blood glucose, and respiratory changes. No CNS effects were demonstrated in mice; however, there was a reduction in the oxygen utilization rate. Intravenous administration of the extract to dogs produced hyperglycemia, a reduction in heart rate, and a decrease in blood pressure. No substantial change in the respiratory rate and tidal or minute volumes were observed.

Keyphrases □ *Erythroxylon coca*—biological effects of nonalkaloid-containing fractions □ Nonalkaloids—fractions in *Erythroxylon coca*, effects □ Oxygen utilization rate—effects of *Erythroxylon coca* on oxygen utilization rate, mice, dogs □ CNS activity—effect of nonalkaloid-containing fractions of *Erythroxylon coca*

The plant *Erythroxylon coca* has been used in the cultures of many Latin American societies for medicinal, nutritional, and religious purposes for centuries (1). The pharmacological and possible psychological effects of coca have made its use by natives commonplace. It is reported to aid them in performing strenuous work and in coping with the harsh mountain environment. While cocaine is not the only biologically active compound in the coca plant, it is the principal alkaloid and the most studied of the active compounds. Alkaloid free fractions of the coca leaf extracts recently have been shown to reduce food consumption but do not show alterations in locomotor activity (2). Cocaine, at doses ranging from 3.45 to 27.6 mg/kg, produced dose-related increases in locomotor activity and decreases in food consumption (3).

It has been reported that chewing coca leaves causes the Latin American native to be more resistant to cold and fatigue and decreases the need for food and sleep (4, 5). Most of these effects have been considered to be related to cocaine, since cocaine has been shown to increase the heart rate and blood pressure and to elevate blood glucose levels (6).

The present study was undertaken to determine whether cocaine-free extracts would produce changes in oxygen utilization, blood glucose levels, respiration, and/or cardiovascular effects that could be related to the alleged enhancement of physical stamina in humans.

EXPERIMENTAL

Test Compounds—Coca leaves (*Erythroxylon coca*)[1] were obtained from Tingo Maria, Peru, and extracted as described previously (2). Briefly, the crude ethanol extract of coca leaves was partitioned between water (fraction A) and chloroform (fraction B). Fraction A was made cocaine free by dissolving in ammonium hydroxide solution and extracting 10 times with chloroform. Each chloroform fraction was subjected to GLC analysis. These fractions each showed the absence of cocaine peaks. Fraction A was further partitioned between butanol and water yielding two fractions: fraction C, the butanol phase; fraction D, the water phase. The fractions were dried on a rotary evaporator at 40°.

All test solutions were prepared in distilled water from dried fractions immediately prior to testing.

Test Animals—The mice were male ICR Swiss, weighing 26–30 g[2]. They were housed in shoe box caging on pelleted corncobs[3] with food[4] and water freely available. Food was withheld overnight prior to testing. The mice were maintained in an environment of 21 ± 1° and a 12 hr light–dark cycle.

[1] The plant material was obtained through Mr. Ing Alberto Trelles Barnett, Impresa Nacionale de la Coca, Lima, Peru, and through the United States Department of Justice and the United States State Department. It was identified as *Erythroxylon coca* by Dr. M. W. Quimby, Department of Pharmacognosy. Voucher specimens are stored in the drug plant herbarium at the School of Pharmacy, University of Mississippi, University, MS 38677.

The fractions were dried on a rotary evaporator at 40°.

All test solutions were prepared in distilled water from dried fractions immediately prior to testing.

Test Animals—The mice were male ICR Swiss, weighing 26–30 g[2]. They were housed in shoe box caging on pelleted corncobs[3] with food[4] and water freely available. Food was withheld overnight prior to testing. The mice were maintained in an environment of 21 ± 1° and a 12 hr light–dark cycle.

[1] The plant material was obtained through Mr. Ing Alberto Trelles Barnett, Impresa Nacionale de la Coca, Lima, Peru, and through the United States Department of Justice and the United States State Department. It was identified as *Erythroxylon coca* by Dr. M. W. Quimby, Department of Pharmacognosy. Voucher specimens are stored in the drug plant herbarium at the School of Pharmacy, University of Mississippi, University, MS 38677.

The dogs[5] were conditioned, mongrel, adult males weighing 10–12.5 kg; vaccinated against distemper, hepatitis, and leptospirosis[6]; checked for internal parasites; and treated[7] as necessary. All dogs were free of heartworms and had two normal hemograms over the 3-week conditioning period.

Oxygen Utilization Screen—The oxygen utilization apparatus consisted of three widemouth 946 ml jars glued[8] to a 25 × 40 × 1.5-cm aluminum platform. Pelleted corncob bedding was placed in the bottom 2–3 cm of each jar to absorb urine. The platform and jars were placed in a constant temperature water bath[9] with water covering ~75% of the outer jar to maintain the temperature at 25°. This was done to minimize temperature change inside the jar during testing. A 4-cm piece of copper tubing (7-mm o.d.), fitted with a 3-way stopcock, was attached to the lid of the jar. This allowed the addition of air to the jar as well as attachment to a pressure transducer without breaking the jar's seal. A 7 × 7-cm nylon net bag filled with soda lime was suspended from the underside of the lid to absorb the carbon dioxide produced by the mouse. Ten mice were dosed intraperitoneally with either drug or vehicle. Five minutes after dosing, the mice were placed in the jar and the chamber was sealed. Twenty milliliters of air was added to the chamber and the resulting air pressure and the time required to return to baseline were recorded[10]. This allowed the determination of the amount of oxygen per gram per second utilized by the mouse using the following:

$$\text{ml } O_2/\text{g/sec} = \frac{20\ (\text{ml } O_2)}{\text{time (sec)} \times \text{wt of mouse (g)}} \qquad \text{(Eq. 1)}$$

Open Field Locomotor Screen—Locomotor activity was measured in an open field arena which consisted of 1 m^2 box with the floor marked off into 25 squares. The top was open and lighted by an overhead fluorescent lamp for better observation. Open field sessions were 5 min long and began 5 min following intraperitoneal injections. Treated and vehicle controls were run alternately to erase diurnal variation. Activity was measured by counting the number of squares the mouse entered during the test period. Statistical analysis was accomplished using the Mann-Whitney nonparametric test (7).

Respiratory and Cardiovascular Screen—The dogs used in the respiratory, cardiovascular, and blood glucose studies were anesthetized with pentobarbital (30 mg/kg). The femoral artery and vein were cannulated and a tracheotomy performed. Electrocardiograph[10] (ECG) (lead II), femoral arterial blood pressure[10], and respiratory parameters[11] (rate, tidal volume, minute volume, and oxygen uptake) were recorded. Arterial blood pO_2, pCO_2, and pH were measured at 15-min intervals[12].

Blood glucose levels[13] were determined at 15-min intervals on venous blood. Control parameters were recorded, then a single dose of fraction C was administered (200 mg/kg, iv). Blood pressure and heart rate were monitored constantly, while other samples and measurements were taken at 15-min intervals. Statistical evaluation of the data was performed using Student *t* test (8).

RESULTS AND DISCUSSION

In the partitioning of fraction A, ~26% of the starting material is removed in the butanol fraction. Five major and five minor constituents were detected in the butanol fraction by TLC.

The effects of fractions A, C, and D on the rate of oxygen utilization are shown in Fig. 1. Fraction A reduced the rate of oxygen utilization at doses ranging from 400 to 600 mg/kg, while fraction C reduced oxygen utilization at doses ranging from 60 to 800 mg/kg. Fraction D reduced the rate of oxygen utilization at 240 mg/kg, but lower doses were not tested. Partitioning fraction A between butanol and water successfully separated all other pharmacological activity into the butanol phase (fraction C).

Oxygen utilization rates are of interest since South American natives claim that chewing coca improves their ability to perform strenuous work, especially at high altitudes (1). Even though a decreased locomotor ac-

Table I—Effect of Fractions C and D on Open Field Activity in Mice

Compounmd	Dose	Counts/5 min ± *SEM*
Vehicle	0.5 ml	150.45 ± 12.0
Fraction C	200 mg/kg	117.8 ± 8.86[a]
	400 mg/kg	51.0 ± 9.25[b]
	600 mg/kg	42.1 ± 9.99[b]
Vehicle	0.5 ml	129.1 ± 16.1
Fraction D	200 mg/kg	138.2 ± 14.5
	400 mg/kg	175.20 ± 23.44
	600 mg/kg	179.60 ± 25.80

[a] $p < 0.05$. [b] $p < 0.001$.

tivity would decrease oxygen utilization, gross observation (9) of activity showed no difference between animals treated with fraction A and control animals. Additionally, fractions C and D produced a decrease in oxygen utilization (Fig. 1) while only fraction C produced a decrease in activity in the open field experiment (Table I). These data would indicate that the decrease in locomotor activity was not the only cause of decreased oxygen consumption.

A potent hyperglycemic effect was seen both in the anesthetized and conscious dogs treated with 200 mg/kg of fraction C. Blood glucose levels reached their peak 45 min after dosing and began to decline after 60 min (Fig. 2). This could explain a ready energy source which would improve the short-term ability to do work and alleviate hunger. The blood glucose levels begin to decline in 1 hr. This is the approximate length of time that chewing of coca leaves is reported to give stimulatory effects. The increased blood glucose is most likely due to a direct effect on glucose metabolism since no sugars remain in fraction C after extraction and separation. Therefore, it would seem that prolonged use of coca, by people on energy deficient diets, could lead to a rapid loss of the body's energy stores. However, histologically[14] no effect was observed on liver glycogen stores in mice 30 min postdose with 120 mg/kg of fraction C. These same mice showed significantly elevated blood glucose levels.

Since hard work or heavy exercise tends to increase cardiac output and mean arterial pressure, the sustained hypotensive effect and decrease in heart rate could be partially responsible for the enhanced work performance and endurance experienced by natives using coca.

Five minutes after injection of 200 mg/kg of fraction C, the heart rate of anesthetized dogs decreased from a mean of 200 to 125 bpm. The rate had not returned to baseline after a 60-min period (Fig. 3). Mean blood pressure dropped from 160 to 100 mm Hg concomitant with the initial fall in heart rate. Both systolic and diastolic pressures remained 20–30 mm Hg below baseline during the remainder of the test period (Fig. 4). There were no significant changes in oxygen uptake, tidal volume, minute volume, pO_2, pCO_2, or arterial blood pH; however, there was an initial increase in respiratory rate (panting). Electrocardiographic tracings

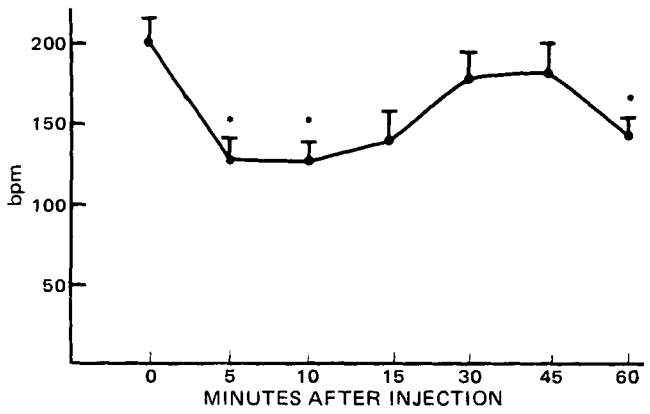

Figure 3—*Change in heart rate (beats per minute, bpm) of anesthetized dogs following a single dose of 200 mg/kg, iv of fraction C (n = 5). Vertical bar represents* SEM. * $p < 0.05$.

frequently showed an inversion of the T wave, which returned to pretreatment polarity 20 min postinjection. Since pO_2 values remained stable during this period, the T wave inversion would not appear to be a hypoxic effect. No other ECG alterations were noted. No autonomic, CNS, hyperglycemic, or cardiovascular effects were obtained with fraction D.

A single 200-mg/kg dose, iv of fraction C given to conscious dogs produced a dramatic effect on the autonomic nervous system. Shallow, rapid panting and increased salivation, swallowing, and defecation began immediately after injection. Cyanosis and inactivity were produced and lasted ~1 hr postdose. These effects, exclusive of defecation, appeared to be masked in the anesthetized animals.

Vomiting, defecation, and inactivity are not problems reported by humans chewing the coca leaf. Chewing would slow intake of the drug and could modify most of the autonomic effects since the fraction would be absorbed over a longer period of time. It also appears that some compounds in the extract may be rapidly bound or metabolized since most effects return to normal levels within 10–30 min following a single injection. However, the increased blood glucose levels, lower blood pressure, and decreased heart rate remain, indicating that other compounds in the extract are longer acting.

The biological effects produced by noncocaine-containing coca fractions are not identical to those seen after cocaine administration. However, these data suggest that noncocaine-containing fractions may contribute to the beneficial effects seen in subjects chewing coca leaves.

Local Anesthetics: 2-*N*,*N*-Dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-butylaminoanilides

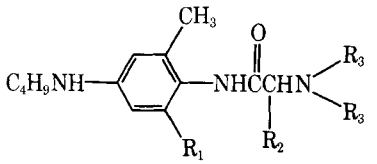
WILLIAM O. FOYE ˣ, CHAUR-MING JAN, and BERTIL H. TAKMAN *

Received June 8, 1981, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115;* and the **Astra Pharmaceutical Products, Inc., Worcester, MA 01606.* Accepted for publication September 29, 1981.

Abstract □ A series of tetracaine analogs based on the lidocaine structure, having a 2′-methyl-(or 2′,6′-dimethyl)-4′-butylaminoanilide moiety with α substitution on the dialkylaminoacyl function, has been synthesized. Local anesthetic activity was found with the *N*-butyl derivatives in both the 2′-methyl and 2′,6′-dimethyl series using both the method of rabbit cornea loss of reflex and spinal anesthesia in sheep. Duration of activity of the compounds was greater than that of lidocaine, but less than that of tetracaine, with comparable dosage levels.

Keyphrases □ Anesthetics—2-*N*,*N*- dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-butylaminoanilides, local anesthetic, rabbits, sheep □ Tetracaine—synthesis of analogs from lidocaine structure □ Lidocaine—tetracaine synthesis

Tetracaine is employed as both an injectable and topical local anesthetic and remains in common use for spinal anesthesia (1). This compound, an ester, is fairly stable but suffers some loss of potency during autoclaving (2). To provide greater stability and possibly lower toxicity, a series of amide analogs based on the lidocaine structure has been synthesized. This series includes both 2-methyl and 2,6-dimethyl substituents in the aromatic ring, as well as alkyl groups on the α position of the aliphatic side chain, giving structures of Type 1:



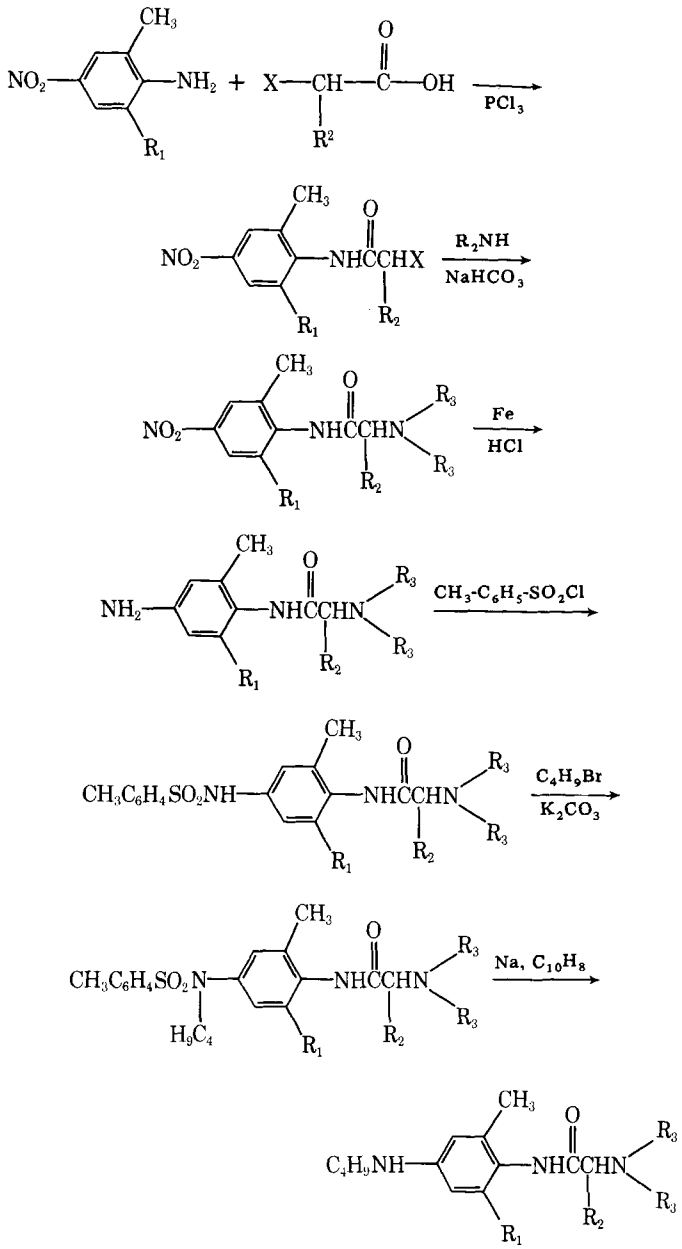
R_1 = H, CH_3
R_2 = H, CH_3, C_2H_5, C_3H_7, C_4H_9
R_3 = CH_3, C_2H_5

A few sterically hindered tetracaine analogs have been prepared previously: several 2-dialkylaminoethyl 4′-butylamino-2′,6′-dimethylbenzoates and two 2-*N*,*N*-dialkylaminoethyl-4′-butylamino-2′,6′-dimethylbenzamides (3). The latter compounds showed a long duration of activity but were appreciably toxic. No 2-*N*,*N*-dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-butylaminoanilides, which comprise true lidocaine-type analogs of tetracaine, have been reported.

RESULTS AND DISCUSSION

Synthesis—The synthetic procedure followed is outlined in Scheme I. The starting material for the synthesis of the 2,6-dimethylanilides, 2,6-dimethyl-4-nitroaniline, was prepared by the method of Wepster (4), which involved the nitration of the *N*-tosyl derivative of 2,6-dimethylaniline. Attempts to nitrate *N*-chloroacetyl-2,6-dimethylanilide failed.

The preparation of some of the *N*-chloroacyl-2′-methyl-4′-nitroanilides was carried out using the procedure of Löfgren (5), using the reaction of chloroacyl chlorides with 2-methyl-4-nitroaniline. When this reaction was applied to 2,6-dimethyl-4-nitroaniline, no amide resulted. For the preparation of the *N*-haloacyl-2′,6′-dimethyl-4′-nitroanilides, or 2′-methyl derivatives where the acid halide was not commercially available,



R_1 = H, CH_3
R_2 = H, CH_3, C_2H_5, C_3H_7, C_4H_9
R_3 = CH_3, C_2H_5

Scheme I

the method of Lemaire *et al.* (6) was successful. This involved the preparation of the acid chloride *in situ* with phosphorus trichloride.

The *N*,*N*-dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-nitroanilides were obtained in conventional fashion from treatment of the α-haloacylanilides with dimethylamine hydrochloride in the presence of anhydrous sodium bicarbonate or from diethylamine. E_2 elimination was observed with the longer chain acyl functions. Physical constants of the haloacyl and dialkylaminoacyl derivatives are listed in Table I.

The reduction of the nitro group was done with iron and hydrochloric acid, according to the method of Clinton *et al.* (7), giving 85–95% yields of amine. The butylation of the 4-amino group was attempted by several procedures. Both direct alkylation with butyl bromide and reductive alkylation procedures using propionaldehyde and reducing agents gave mixtures of mono- and dibutylamino compounds. Monobutylation succeeded by using a modification of the method of Hendrickson and Bergeron (8), in which the amino group is first tosylated and then alkylated with butyl bromide. The alkylations generally required 5–10 days at room temperature. The regeneration of the amine from the *N*-butylsulfonamide was achieved in excellent yield by treatment with sodium naphthalene anion radical in 1,2-dimethoxyethane. The mechanism for this procedure is assumed to be the same as that proposed previously (9) for the sodium–liquid ammonia cleavage of toluenesulfonamides.

Physical constants of the 4′-*N*-tosyl intermediates prepared are listed in Table II, and of the 4′-amino and 4′-butylamino compounds are recorded in Table III.

Local Anesthetic Evaluation—Primary local anesthetic activity was measured by determining loss of reflex of the rabbit cornea (10), using lidocaine for comparison. With this method, both time of onset and duration of action may be determined; testing data are recorded in Table IV. Of the 4′-amino compounds which were not *N*-butylated, none showed significant activity by this procedure. Of the *N*-butyl derivatives, the 2′,6′-dimethyl compounds generally had a longer duration of action than the 2′-methyl substituted compounds. One 2′-methyl derivative, the α-butyl compound, had a comparable time for duration of activity, indicating that a greater extent of alkylation gave greater duration times. This was also the case among the 2′,6′-dimethyl derivatives, where the α-propyl and α-butyl compounds had the longest duration times. Times of onset of action were comparable in both series and were somewhat less than that of lidocaine. Duration times in both series were significantly greater than that for lidocaine.

Determination of the degree of spinal anesthesia in sheep, using the method of Lebeaux (11), was also done with four of the 2′,6′-dimethyl series, including one non-*N*-butyl derivative. Times of onset of activity as well as duration of anal block, digital block, and motor block were

										N 10.20	9.71
										Cl 16.36	16.15

measured and are listed in Table V. With this determination, the non-*N*-butyl derivative tested (number 13) showed activity somewhat greater in duration than that of lidocaine. The three *N*-butyl compounds tested showed greater duration of activity than 13, but were significantly less than that of tetracaine. It is concluded that this series of compounds has local anesthetic potency intermediate between that of lidocaine and tetracaine.

Ionization constants are listed in Table III for the 4′-amino derivatives. No correlation is evident between local anesthetic potency and pKa values. A previous attempt to find a correlation between ionization constants, oil–water partition coefficients, and local anesthetic activity failed to give statistically significant results (12), although some general trends were noted. Also, IR absorption frequencies for carbonyl absorption are listed in Table III. A previous study (13) revealed an optimum absorption frequency range for good anesthetic potency, but no optimum range for carbonyl absorption is evident for the durations of activity reported here. However, a definite effect of the α-substituent on increasing the wavelength at which carbonyl absorption occurs is apparent.

EXPERIMENTAL

Melting points were taken[1] and are uncorrected[2]. Infrared spectra were recorded on a spectrophotometer[3] using KBr pellets. TLC was carried out using silica gel plates, and the products were detected by exposure to iodine vapor or UV light. Organic reagents were supplied[4–6].

***N*-Haloacyl-2′-methyl (or 2′,6′-dimethyl)-4′-nitroanilides**—*Method 1*—Chloroacetyl chloride (14.91 g, 0.132 mole) was added rapidly to a solution of 18.26 g (0.12 mole) of 2-methyl-4-nitroaniline in 100 ml of glacial acetic acid at 15°. A solution of 45.2 g of sodium acetate trihydrate in 200 ml of water at 10° was added quickly. The mixture was shaken for 35 min, and the product was filtered, washed with 50% hydrochloric acid and water and dried. Recrystallization was generally done with ethanol and charcoal.

Method 2—A mixture of 15.22 g (0.1 mole) of 2-methyl-4-nitroaniline, 7 ml (0.084 mole) of phosphorus trichloride, and 0.105 mole of 2-bromocarboxylic acid in 250 ml of dry benzene was refluxed for 3 hr and filtered. The filtrate was evaporated, and the crude product was washed with 50% hydrochloric acid and water and dried. Recrystallization was done with aqueous ethanol and charcoal. Refluxing time for acylation of 2,6-dimethyl-4-nitroaniline was 24–48 hr.

Method 3—2,6-Dimethyl-4-nitroaniline (4) (15.0 g, 0.09 mole) and redistilled triethylamine (10.0 g, 0.1 mole) in 200 ml of anhydrous ether was cooled to 0–5°, and 14.12 g (0.125 mole) of chloroacetyl chloride was added dropwise with vigorous stirring and ice cooling for 1 hr. The mixture was shaken for 6 hr at room temperature and the ether was evaporated under reduced pressure. The crude product was washed with 50% hydrochloric acid and water, dried, and recrystallized from ethanol and charcoal.

2-*N,N*-Dimethylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-nitroanilides—Dimethylamine hydrochloride (16.15 g, 0.198 mole) and anhydrous sodium bicarbonate (16.63 g, 0.198 mole) in 300 ml of anhydrous benzene was stirred for 30 min, and chloroacetyl-2′-methyl-4′-nitroanilide (13.8 g, 0.066 mole) was added. The mixture was refluxed for 30 hr, cooled, and filtered. The benzene filtrate was extracted with four 80-ml portions of 1 *N* HCl, and the combined extracts were brought to pH 10 with 7 *N* NaOH solution. The precipitate was recrystallized from aqueous ethanol. When this method was applied to α-haloacyl 2,6-dimethyl-4-nitroanilines, the refluxing required 4–6 days.

For preparation of the *N,N*-diethyl derivatives, redistilled diethylamine was used.

2-*N,N*-Dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-aminoanilides—To a stirred, boiling mixture of powdered iron (10.35 g, 0.185 mole), ethanol (85 ml), water (25 ml), and concentrated hydrochloric acid (1 ml) was added in 7.0-g portions (0.026 mole) of *N,N*-diethylaminoacetyl-2′-methyl-4′-nitroanilide. The heat source was removed during the addition. The mixture was stirred and boiled gently for 35 min, cautiously treated with 10.0 g of powdered sodium bicarbonate, stirred at boiling for 10 min, and filtered hot. The filter cake was washed with hot alcohol, and the alcohol was removed *in vacuo*. The residue was added to 15 ml of water and extracted three times with ethyl acetate. The extract was

dried ($MgSO_4$) and concentrated to a small volume. The syrupy residue was recrystallized from benzene–commercial hexane[7].

2-*N*,*N*-Dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-(*p*-toluenesulfonamido)anilides—2-Dimethylaminoacetyl-2′-methyl-4′-aminoanilide (4.2 g, 0.021 mole) and redistilled pyridine (1.5 ml) in 40 ml of methylene chloride was cooled to 0°, and 4.46 g (0.023 mole) of *p*-toluenesulfonyl chloride was added slowly with stirring and ice-cooling during 30 min. The mixture was stirred for several hr at 0–5°, methylene chloride was removed *in vacuo*, and the residue was added to 80 ml of water. The pH was adjusted to 10 with dilute sodium hydroxide solution, the solution was extracted with ethyl acetate, and the extract was dried ($MgSO_4$). It was concentrated to a small volume, and the residue was recrystallized from benzene–commercial hexane[7].

2-*N*,*N*-Dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-(*N*′-butyl-*p*-toluenesulfonamido)anilides—2-Dimethylaminoacetyl-2′-methyl-4′-(*p*-toluenesulfonamido)anilide (2.8 g, 0.0078 mole), anhydrous potassium carbonate (4.31 g, 0.031 mole), and redistilled *n*-butyl bromide (9.62 g, 0.0702 mole) in 70 ml of dry acetone was stirred at room temperature for 7 days. The mixture was filtered, and acetone was removed in a rotary evaporator. The residual syrup was crystallized from benzene–or ether–commercial hexane[7].

2-*N*,*N*-Dialkylaminoacyl-2′-methyl (or 2′,6′-dimethyl)-4′-butylaminoanilides—Naphthalene (4.64 g, 0.036 mole) in 30 ml of 1,2-dimethoxyethane was kept under nitrogen, and 0.83 g (0.036 mole) of sodium was added. After 5 min, 2.49 g (0.006 mole) of 2-dimethylaminoacetyl-2′-methyl-4′-(*N*′-butyl-*p*-toluenesulfonamido) anilide in 10 ml of 1,2-dimethoxyethane was added, and the solution was kept at room temperature under nitrogen for 80 min. Water was added to quench the reaction, and the solvent was removed in a rotary evaporator. The residue was added to 50 ml of water, the pH was brought to ~2, and the solution was extracted three times with ether. The aqueous solution was adjusted to pH 10 and extracted with ethyl acetate. The extract was dried ($MgSO_4$) and concentrated, and the residual syrup was crystallized from hexane.

Local Anesthetic Evaluation—Primary local anesthetic testing was done by measuring loss of reflex of the rabbit cornea according to Rose (10). Each compound was tested in sterile 1% aqueous solution, pH 6.7, using 1% lidocaine solution, containing no epinephrine, as standard. The test solution (3–4 drops) was applied to one eye of the rabbit, the other eye being treated with control solution, pH 6.7, containing no anesthetic. Using a soft cotton filament rolled to a fine point, the time at which loss of reflex on touching with the filament was recorded to indicate onset of action. The procedure was continued, and the time at which reflex activity returned was recorded for duration of action.

The extent of spinal anesthesia in the sheep was determined according to the procedure of Lebeaux (11). Sterile solutions (2 ml) of the test compounds at the concentrations indicated in Table V and containing glucose (50 mg/ml) were injected intrathecally between the L6 and S1 vertebra. Onset and duration times for sensory blocks from the anal and digital (hind limb) areas were recorded, and for motor block when the animals were able to stand. Frequency of block was 100% except where indicated. Lidocaine (1.5%) and tetracaine (0.5%) solutions were used as standards and glucose (5.0%) solution as control.

Ionization Constants—Determination of ionization constants was done according to the procedure of Albert and Serjeant (14) using a pH meter[8] with glass and calomel electrodes. Titrations of 0.001 *M* aqueous solutions of the compounds were made with 0.01 *N* KOH in 0.5-ml portions. Each titration yielded 10 pH values, giving 10 values for the pKa's, which were averaged. If pH values fell outside the 5–9 range, corrections were made for hydrogen or hydroxide ion concentrations.

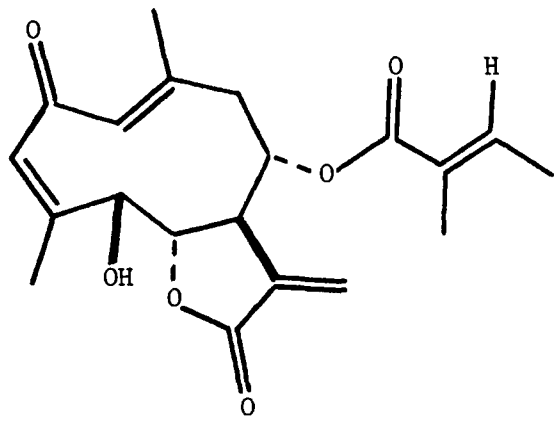
Antitumor Agents LII: The Effects of Molephantinin on Nucleic Acid and Protein Synthesis of Ehrlich Ascites Cells

IRIS H. HALL ˣ, Y. F. LIOU, and K. H. LEE

Received June 19, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, The University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication October 7, 1981.

Abstract □ Molephantinin, a germacranolide, has previously been shown to possess antineoplastic activity in rodents. The principle effect of molephantinin on Ehrlich ascites carcinoma cells was to depress DNA and protein synthesis both *in vivo* and *in vitro*. DNA synthesis was inhibited at the following sites: DNA polymerase, purine synthesis specifically at inosinic acid dehydrogenase and to a lesser degree at dihydrofolate reductase, pyrimidine synthesis at orotidine monophosphate decarboxylase, thymidine kinase, histone phosphorylation, and oxidative phosphorylation processes. The protein synthesis inhibition pattern resembled more an initiation inhibitor as opposed to an elongation inhibitor.

Keyphrases □ Molephantinin—effects on nucleic acid and protein synthesis of Ehrlich ascites cells □ Antitumor agents—effects of molephantinin on nucleic acid and protein synthesis of Ehrlich ascites cells □ DNA—synthesis, effects of molephantinin, Ehrlich ascites cells □ RNA—synthesis, effects of molephantinin, Ehrlich ascites cells □ Protein synthesis—effects of molephantinin, Ehrlich ascites cells



I

Molephantinin (I), a germacranolide, was originally isolated from the winter collection of *Elephantopus mollis*, a member of the herbal Compositae family. Subsequently, molephantinin was shown to be active against Walker 256 carcinosarcoma growth in rats at 2.5 mg/kg/day resulting in a T/C% = 397 (1, 2). Further studies demonstrated that the agent was also active against P-388 lymphocytic leukemia and Ehrlich ascites cell growth (3). *In vitro* DNA polymerase activity and oxidative phosphorylation processes were reported to be inhibited by molephantinin at a relatively high concentration (3). At this time a more detailed examination of the effects of molephantinin on Ehrlich ascites tumor cell metabolism is reported.

EXPERIMENTAL

In vitro incorporation of [^{3}H]thymidine, [^{3}H]uridine, or [^{3}H]leucine was determined using 10^6 Ehrlich ascites cells, 1 μCi of labeled precursor, minimum essential medium, and varying final concentrations of drug from 0.125–2.0 m*M* (4). The tubes were incubated at 37° for 60 min and inactivated by trichloroacetic acid. The insoluble acid, labeled DNA, was collected on glass filter discs[1], and RNA and protein were precipitated on nitrocellulose filters[2] by vacuum suction. Results are expressed as disintegrations per minute of incorporated precursor/hr/10^6 cells. For *in vitro* studies, cells were collected on Day 10 and the drug was incubated at 1.38 m*M*.

Ehrlich ascites cells (10^6) were injected intraperitoneally into CF_1 male mice (~22 g) on day 0. On Days 7, 8, and 9, molephantinin (12.5 mg/kg/day, ip in 0.05% polysorbate 80–water) was injected. Incorporation of thymidine into DNA was determined by the method of Chae *et al.* (5). One hour prior to the animal sacrifice on Day 10, 10 μCi, ip of [6-^{3}H]-thymidine (21.5 Ci/mmole) was injected. The DNA was isolated and the tritium content was determined in a toluene based scintillation fluid[3]. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as a standard. Uridine incorporation into RNA was determined using 10 μCi of [5,6-^{3}H]uridine (22.4 Ci/mmole). RNA was extracted by the method of Wilson *et al.* (6). Using yeast RNA as a standard, the RNA content was assayed by the orcinol reaction. Leucine incorporation into protein was determined by the method of Sartorelli (7) using 10 μCi of [4,5-^{3}H]leucine (52.2 Ci/mmole). Extracted protein was determined by the Lowry procedure (8) using bovine albumin as a standard. *In vitro* and *in vivo* nuclear DNA polymerase activity was determined on isolated Ehrlich ascites cell nuclei (9). The incubation was that described by Sawada *et al.* (10) except that [methyl-^{3}H]deoxythymidine triphosphate (82.4 Ci/mmole) was used. The acid insoluble nucleic acid was collected on filters[1] and counted.

Nuclear RNA polymerase activities were determined on enzymes isolated from nuclei (9). Messenger, ribosomal, and transfer RNA polymerases were isolated using 0.3, 0.04, and 0.0 *M* concentrations of ammonium sulfate in magnesium chloride, respectively. The incubation medium was that of Anderson *et al.* (11) using [^{3}H]uridine triphosphate (23.2 Ci/mmole). The acid insoluble RNA was collected on nitrocellulose filters and counted.

Deoxythymidine as well as deoxythymidylate monophosphate and diphosphate kinase activities were measured spectrophotometrically at 340 nm at 20 min using reduced nadide (0.1 μmole) (12). [6-^{3}H]Thymidine (21.5 Ci/mmole) incorporation into the nucleotides was also measured using the reaction medium of Maley and Ochoa (12) and then plating the ether extracted reaction medium on polyethyleneiminecellulose plates. The plates were eluted with 0.5 *N* formic acid–0.6 *N* LiCl (1:1). After identifying R_f values consistent with the standards, thymidine, thymidylate monophosphate, thymidylate diphosphate, and thymidylate triphosphate, the areas on the plates were scraped and counted. Carbamyl phosphate synthetase activity was determined using the reaction medium of Kalman *et al.* (13) in the presence of ornithine and the enzyme ornithine transcarbamylase. Citrulline formed from ornithine was measured at 490 nm by the method of Archibald (14). Aspartate transcarbamylase activity was assayed using the incubation medium of Kalman *et al.* (13). The colorimetric determination of carbamyl aspartate was conducted by the procedure of Koritz and Cohen (15). Orotidine monophosphate decarboxylase activity was assayed by the method of Appel (16) using 0.1 μCi of [^{14}C]orotidine monophosphate (34.9 mCi/mmole). The [^{14}C]-carbon dioxide generated in 15 min was trapped in 1 *M* methanolic base[4] and counted. Thymidylate synthetase activity was determined using a

postmitochondrial supernate (9000×*g* for 10 min) and 5 μCi of [5-^{3}H]-deoxyuridine monophosphate (14 Ci/mmole) according to the method of Kampf *et al.* (17). [^{14}C]Formate incorporation into purines was determined by the method of Spassova *et al.* (18), using 0.5 μCi of [^{14}C]-formic acid (52.0 mCi/mmole). Purines were separated on silica gel TLC plates eluted with *n*-butanol–acetic acid–water (4:1:5). After identifying R_f values consistent with the standards, adenine and guanine, the plates were scraped and the radioactive content determined. Phosphoribosyl-1-pyrophosphate amidotransferase activity was determined on a supernatant fraction (600×*g* for 10 min) measuring the reduction of 0.6 μmole of nadide at 340 nm for 30 min (19). Inosinic acid dehydrogenase activity was determined spectrophotometrically at 340 nm for 30 min using a supernatant fraction (600×*g* for 10 min). The assay medium was that of Magasanik (20) which contained nadide. Dihydrofolate reductase activity was determined at 340 nm for 30 min as the oxidation of reduced nadide phosphate (21). Ribonucleotide reductase activity was determined by the method of Moore and Hurlbert (22) using [5-^{3}H]cytidine-5-diphosphate (25 Ci/mmole). Ribose and deoxyribose nucleotide were separated on polyethyleneiminecellulose plastic precoated plates eluted with 4% boric acid–4 *M* LiCl (4:3) and scraped at the R_f values consistent with the standard deoxycytidine diphosphate. *In vivo* phosphorylation of histones was determined by injecting 10 μCi of [γ^{32}P]adenosine triphosphate (30.0 Ci/mmole) into mice 1 hr prior to sacrifice. The nuclei were isolated (9), and the histone chromatin protein was extracted by the method of Raineri *et al.* (23). *In vitro* nonhistone protein phosphorylation, dependent on nuclear protein kinase, was determined using 2 n*M* of [γ-^{32}P]adenosine triphosphate (30.0 Ci/mmole) and isolated nuclei chromatin protein was collected on nitrocellulose filters (24). Cyclic 3′,5′-adenosine monophosphate levels were determined by the radioimmunoassay method of Gilman (25) using a commercial kit. An *in vitro* method was used to determine if the drug was an initiation or an elongation protein synthesis inhibitor by comparing with known standards, pyrocatechol violet and emetine, using 1 μCi of [^{3}H]leucine (52.2 Ci/mmole) incubated at 37° for 14 min. Aliquots of the reaction medium were spotted on filter paper[5], chemically extracted, and counted (4).

In vitro oxidative phosphorylation studies (26) were conducted on Ehrlich ascites cells using the substrates, α-ketoglutarate, or succinate. Basal oxygen consumption (State 4) was determined with an oxygen electrode connected to an oxygraph. The adenosine diphosphate was added to obtain State 3, or adenine diphosphate stimulated respiration. The number of microliters of oxygen consumed per hour per milligram of protein for States 3 and 4 was calculated. Protein was determined by the Lowry technique (8).

[5] Whatman No. 3.

Probable (p) significant differences were determined by the Student t test. Data are expressed in Tables I and II as percent of control with standard deviations; n is the number of animals per group.

RESULTS

The *in vitro* effects of molephantinin at 1.38 m*M* concentration are presented in Table I and the *in vivo* effects at 12.5 mg/kg/day are presented in Table II.

In vitro studies for the incorporation of labeled precursors into DNA, RNA, and protein revealed that all three were inhibited in the presence of molephantinin (Fig. 1). Thymidine incorporation into DNA was inhibited significantly with an $ID_{50} \cong 1.22$ m*M*. It may be noted that at the concentration that caused 50% inhibition of DNA synthesis, RNA synthesis was inhibited 30% and protein was inhibited 20% at 1.22 m*M*. The *in vivo* incorporation of thymidine incorporation into DNA was inhibited 81% after dosing for 3 days (Table II). The RNA synthesis was only inhibited 12%, whereas *in vivo* protein synthesis was inhibited 44% after 3 days dosing. The control value for thymidine incorporation was 107,533 dpm/mg of DNA, uridine incorporation was 51,192 dpm/mg of RNA, and leucine incorporation into protein was 19,181 dpm/mg of isolated protein.

Nuclear DNA polymerase activity for the control was 76,528 dpm/hr/mg of nucleoprotein which was suppressed *in vitro* 45% by drug presence (Table I) at 1.38 m*M*, and *in vivo* 62% (Table II) by 3-day administration of drug at 12.5 mg/kg/day. Messenger RNA polymerase activity for the control was 4867 dpm/hr/mg of protein, ribosomal RNA polymerase was 8751 dpm/hr/mg of protein, and transfer RNA polymerase activity was 10,792 dpm/mg of protein. Molephantinin caused little effect on messenger RNA polymerase activity either *in vitro* or after *in vivo* administration. However, ribosomal RNA polymerase activity was inhibited 26% *in vitro* in the presence of drug and 30% after *in vivo* administration of the drug. The transfer RNA polymerase activity was slightly elevated in both *in vitro* and *in vivo* studies.

Ribonucleotide reductase activity for the control was 153,791 dpm/mg of protein which was not affected by molephantinin administration. [^{14}C]Formate incorporation into purines for the control cells was 28,786 dpm/mg of protein which was suppressed 30% in the *in vitro* study and 81% after *in vivo* administration. Phosphoribosyl-pyrophosphate amido transferase activity for the control 10-day Ehrlich ascites cells was observed as an increase of 1.223 optical density unit/hr/mg of protein. *In vitro* presence of drug caused a 23% reduction while *in vivo* administration demonstrated only 13% reduction of enzyme activity. Inosinic acid dehydrogenase activity for the control was 0.358 optical density unit/hr/mg of protein. *In vitro* presence of drug caused 56% inhibition and *in*

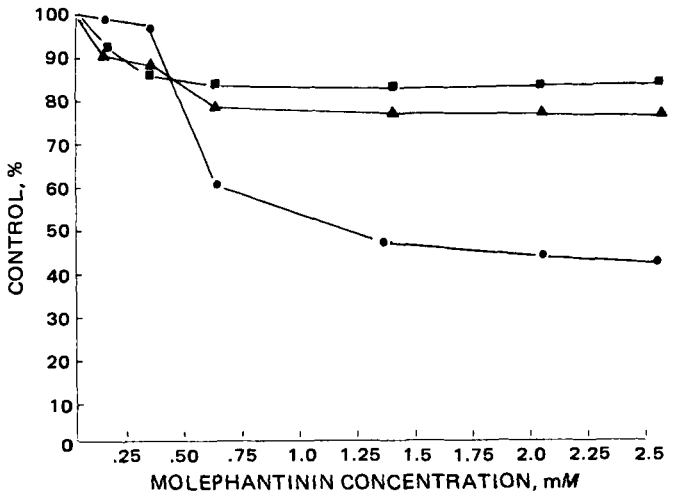

Figure 1—*The* in vitro *effects of molephantinin on nucleic acid and protein synthesis. Key:* ●, *[^{3}H]thymidine → DNA;* ▲, *[^{3}H]uridine → RNA;* ■, *[^{3}H]leucine → protein.*

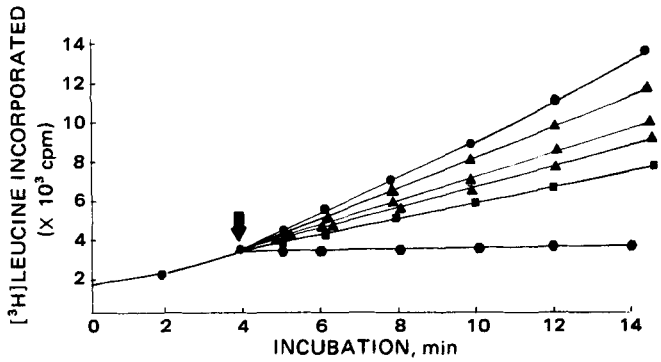

Figure 2—*Effect of pyrocatechol violet, emetine, and molephantinin on the protein synthesis of Ehrlich ascites homogenates using endogenous messenger RNA. Key:* ●, *control;* ▲, *molephantinin (10,100 and 1000 μM);* ■, *pyrocatechol violet (100 μM);* ●, *emetine (100 μM).*

vivo administration of drug resulted in 74% reduction of dehydrogenase activity. Dihydrofolate reductase activity for 10-day Ehrlich ascites cells was 0.514 optical density unit/hr/mg of protein which was unaffected by drug in the *in vitro* studies but was suppressed 33% by 3-day dosing.

Carbamyl phosphate synthetase activity for the control was 0.128 mg of carbamyl phosphate formed/hr/mg of protein. Aspartate carbamyl transferase activity for Day-10 Ehrlich ascites cells was 7.526 mg of carbamyl aspartate formed/hr/mg of protein. Neither of these enzymatic activities was suppressed significantly by molephantinin. Orotidine monophosphate decarboxylase activity for the control was 10,775 dpm of [^{14}C] carbon dioxide regenerated in 15 min/mg of protein. In the *in vitro* studies, there was an 80% reduction in the enzymatic activity, while in the *in vivo* studies there was a 71% reduction of the decarboxylase activity. Thymidylate synthetase activity for the control was 103,328 dpm/mg of protein which was not affected by molephantinin presence. Thymidine kinase activity for the control was 0.531 optical density unit/hr/mg of protein, which was reduced 35% in the *in vitro* studies and 37% in the *in vivo* studies. Thymidylate monophosphate kinase for the control was 0.305 optical density unit/hr/mg of protein which was suppressed 64% by the *in vitro* administration of molephantinin. Thymidylate diphosphate kinase activity in 10-day Ehrlich ascites cells was 0.238 optical density unit/hr/mg of protein which was reduced 16 and 27% in the *in vitro* and *in vivo* studies, respectively. The labeled nucleotide pool levels demonstrated a 54% reduction in the pool level of thymidylate diphosphate and a 58% reduction in thymidylate triphosphate level after 1-hr incubation with drug *in vitro*.

The basal respiration (State 4) of Day-10 Ehrlich ascites tumor cells with succinate as substrate was 5.273 μl of oxygen consumed/hr/mg of protein, while the adenosine diphosphate stimulate respiration (State 3) was 8.752 μl of oxygen consumed/hr/mg of protein. Molephantinin inhibited *in vitro* State 4 respiration by 36% and State 3 respiration by 25%. Using α-ketoglutarate as substrate resulted in a State 4 respiration of 3.569 μl of oxygen consumed/hr/mg of protein and in a State 3 respiration of 5.156 μl of oxygen consumed/hr/mg of protein. Molephantinin inhibited *in vitro* State 4 respiration 31% and State 3 respiration 33%.

Histone phosphorylation of chromatin protein for the control was at a rate of 3650 dpm/mg of isolated chromatin protein which was inhibited 64% by molephantinin administration for 3 days. Nonhistone chromatin phosphorylation for the control was 28,593 dpm/mg of chromatin protein isolation which was reduced 19% by molephantinin administration. Cyclic adenosine monophosphate levels for 10-day Ehrlich ascites cells was 3.65 pmole/10^6 cells. Drug administration for 3 days caused a 17% elevation of cyclic adenosine monophosphate levels of Ehrlich ascites cells. Molephantinin was shown to be a mild initiation inhibitor of protein synthesis (Fig. 2), which compared favorably to pyrocatechol violet, an initiation inhibitor, rather than to emetine, an elongation inhibitor.

DISCUSSION

Molephantinin administration at 12.5 mg/kg/day for 3 days significantly reduced DNA synthesis in Ehrlich ascites cells. The major sites of DNA synthesis inhibition appeared to occur at DNA polymerase, orotidine monophosphate decarboxylase, inosinic acid dehydrogenase, and thymidylate monophosphate kinase. These studies demonstrated that key enzymes in both the purine and pyrimidine pathways were markedly inhibited by molephantinin both *in vitro* and *in vivo*. The observed reduction in the level of either purine or pyrimidine nucleosides would account for the degree of reduction of labeled thymidine incorporation into DNA observed after administration of molephantinin. The germacronolides, eupaformosanin (27) and eupahyssopin (28), as well as the sesquiterpene lactones, helenalin and tenulin (29), have previously been shown to inhibit DNA polymerase activity, and thus, DNA synthesis in Ehrlich ascites cells. Eupaformosanin has been observed to reduce purine synthesis significantly (30). Supposedly, the moiety responsible for this inhibition is the O=CC=CH_2 system which exists both as an α-methylene-γ-lactone and as a C-8 ester side chain in molephantinin. The α-methylene-γ-lactone can undergo a rapid Michaelis-type addition with biological nucleophiles, *e.g.*, sulfhydryl, amino, and carboxyl group (29, 30), and has been shown to play a significant role in antineoplastic activity of sesquiterpene lactones.

Moderate reduction of other enzymes was observed after *in vivo* administration of molephantinin (*e.g.*, ribosomal RNA polymerase, dihydrofolate reductase, and thymidine kinase). *In vitro* administration of molephantinin resulted in a significant reduction in thymidylate diphosphate and triphosphate levels and an accumulation of thymidine. Inhibition of the phosphorylation of histone of the chromosomes was also observed. Inhibition of phosphorous 32 incorporation into histones has been demonstrated by eupaphyssopin, eupaformosanin, and helenalin (27–29). Supposedly, phosphorylation of histones helps to regulate cellular proliferation (31). Energy for this process is supplied by the mitochondrial oxidative phosphorylation process. As can be seen, molephantinin suppressed basal respiration and adenosine diphosphate stimulated respiration, thus reducing available energy sources. Preliminary studies have indicated molephantinin is an initiation inhibitor of protein synthesis in Ehrlich ascites cells. Formation of the initiation complex requires initiation factors which possess an exposed sulfhydryl group which may be alkylated by molephantinin's functional moieties. There appears to be a positive correlation between protein synthesis inhibitors and reduction of oxidative phosphorylation (32).

Molephantinin appears to be one of the more potent germacranolides and is more active than the sesquiterpene lactone, helenalin (27–29). Molephantinin has been shown to have a similar mode of action on the Ehrlich ascites cells as other germacranolides and sesquiterpene lactones.

Herbal Remedies of the Maritime Indians: Sterols and Triterpenes of *Achillea millefolium* L. (Yarrow)

R. F. CHANDLER *x, S. N. HOOPER *, D. L. HOOPER ‡, W. D. JAMIESON §, C. G. FLINN §, and L. M. SAFE *¶

Received July 23, 1981, from the **College of Pharmacy and the* ‡*Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, B3H 3J5*, and the §*Atlantic Research Laboratory, National Research Council, Halifax, Nova Scotia, B3H 3Z1.* Accepted for publication October 1, 1981. ¶ Present address: Department of Chemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1.

Abstract □ As part of ongoing studies of the medicinal aspects of Maritime flora, particularly the herbal remedies of the Micmac and Malecite Indians, the sterols and triterpenes of *Achillea millefolium* L. (Compositae), a widely used herbal remedy known commonly as yarrow, were determined. Using modern techniques, including nuclear magnetic resonance spectroscopy and combined GC–mass spectrometry, β-sitosterol was identified as the major sterol and α-amyrin as the major triterpene of this plant. The sterols stigmasterol, campesterol, and cholesterol and the triterpenes β-amyrin, taraxasterol, and pseudotaraxasterol were also identified. Successful therapeutic application of yarrow may be partly due to the presence of one or more of these compounds since many sterols and triterpenes exhibit a wide range of pharmacological activities. This is the first reported occurrence of cholesterol, campesterol, and the four triterpenes in yarrow.

Keyphrases □ *Achillea millefolium* L.—herbal remedies, extraction of triterpenes and sterols □ Triterpenes—extraction from *Achillea millefolium* L., herbal remedies, sterols □ Sterols—extraction from *Achillea millefolium* L., herbal remedies, triterpenes

Since the Trojan war (~1200 BC), *Achillea millefolium* L. has been used extensively by many cultures on different continents as a herbal remedy for various afflictions (1). While conducting studies on the medicinal aspects of the Maritime flora, particularly the herbal remedies of the Micmac and Malecite Indians (2, 3), it was observed that although *A. millefolium* (yarrow) had been widely used and extensively studied (1), very little had been reported regarding its sterols and triterpenes.

Some early articles and various screening papers have reported sterols, triterpenes (3–5), and saponins (6, 7) present in yarrow, although at least one paper stated that the plant contained no steroids (8). Only two authors have previously attempted to determine the nature of the sterols and triterpenes present in this plant. One of those authors documented the presence of stigmasterol and a sitosterol (9), while another reported the presence of β-sitosterol, its acetate, a phytol, and a diol (10).

Therefore, the examination of yarrow for the presence and nature of these compounds is described.

EXPERIMENTAL

Collection and Extraction—The aerial parts of *A. millefolium* were collected during the flowering stage from an open field near Scots Bay, Kings Co., Nova Scotia in September, 1979[1]. The plant material was dried in a forced-air oven at 60° and ground in a Wiley mill to a coarse powder (0.5 cm). This material (2.09 kg) was placed in a stainless steel tank and

[1] The plant material utilized in this investigation was identified as *Achillea millefolium* (L.) (Compositae) by Dr. M. J. Harvey, Department of Biology, Dalhousie University. Herbarium samples (Number 79-03) representing material collected for this investigation are available for inspection at the College of Pharmacy, Dalhousie University.

[a] In deuterochloroform; number of hydrogens, multiplicity (d = doublet, m = multiplet, q = quartet, s = singlet, t = triplet), J = coupling constant. [b] δ, ppm. [c] J = 6 Hz. [e] J = 7, 11 Hz. [f] J = 3–4 Hz. [g] J = 6 Hz.

macerated in chloroform–methanol (1:1, v/v) for at least 24 hr; the extract was then drained from the tank. This process was repeated 3 times; the extracts were then combined and the solvent removed *in vacuo*, producing a dark green, waxy mass (78.8 g). This material was saponified following a published method (11). The nonsaponifiable portions were extracted with ether and the solvent was removed *in vacuo*, yielding an amber-colored residue (34.2 g).

Thin-Layer Chromatography—The nonsaponifiable portions were fractionated by preparative TLC using plates coated with silica gel[2] (11). Following visualization procedures, the sterols appeared as a red band ($R_f \simeq 0.25$) and the triterpenes as a red-brown band $R_f \simeq 0.40$). The material from these two bands was recovered by extracting the silica gel with ether and chloroform (12).

The triterpene band, converted to acetates (12), was further fractionated using silica gel[2] impregnated with silver nitrate (13). The visualization process, using 2′,7′-dichlorofluorescein (13), indicated that six bands were present; these were numbered according to increasing R_f. Following recovery from the silica gel with ether and chloroform, bands 3, 4, and 5 gave positive Liebermann-Burchard tests (14) for triterpenes. Bands 1, 2, and 6 produced negative tests and were not considered for further study.

Gas–Liquid Chromatography—The sterol fraction was analyzed using SE-30, OV-1, OV-17, and OV-225[3] columns[4], authentic reference standards, and cholestane as an internal standard (15). The triterpenes were similarly analyzed using SE-30, OV-17, and OV-225 columns and respective oven temperatures of 290, 275, and 250°. The acetates (12) of the taraxasterols and their dihydroderivatives were analyzed using OV-1 with an oven temperature of 275° and OV-17 and OV-225 columns.

Nuclear Magnetic Resonance Spectroscopy—All spectra were recorded in dilute solutions in deuterated solvents using tetramethylsilane as the internal reference[5,6].

Gas Chromatography–Mass Spectrometry—GC–mass spectrometry studies[7] were performed on a high-capacity 3% OV-1 flexible quartz capillary column[8] (25 m × 0.3-mm i.d.), which was directly interfaced to the source of the mass spectrometer. Electron impact mass spectra were determined at 70 eV and a source temperature of 260° (indicated). Source temperature was 230° (indicated) for the positive ion chemical ionization mass spectrometric studies. Methane was used as the ionizing gas at a source pressure of 0.02 torr (indicated), and helium was used as the carrier gas (2 ml/min).

Taraxasterol and pseudotaraxasterol acetates were also run on an OV-1 packed column[9] with an oven temperature of 290° and with helium as the carrier gas (35 ml/min).

Hydrogenation—Sufficient samples (2–3 mg) of taraxasterol acetate, pseudotaraxasterol acetate, and α-amyrin acetate fractions were dissolved in ethanol. Each was hydrogenated in a microhydrogenator[10] at room temperature and pressure using palladium–charcoal as the catalyst. After 3 hr, the reaction medium was filtered to remove the catalyst and reduced to dryness *in vacuo*.

Authentic Samples—Authentic samples of cholestane[11], β-sitosterol[11], stigmasterol[11], cholesterol[12], campesterol[13], α- and β-amyrin[14] were purchased; taraxasterol[15] and pseudotaraxasterol acetate[16] were gifts.

RESULTS AND DISCUSSION

Quantitative TLC indicated that sterols and triterpenes represented ~6 and 54%, respectively, of the nonsaponifiable materials in yarrow (11). GLC studies of the TLC fractions demonstrated that β-sitosterol was the major sterol present, representing ~75% of the sterols. Campesterol (10%), cholesterol (5%), stigmasterol (3%), and an unidentified sterol (6%) were also present. Sequential coinjection of the sterol fraction recovered from TLC with each of the authentic sterols produced single, symmetrical peaks, verifying the identity of these four sterols from yarrow.

Similar studies of the triterpene fraction using the SE-30 column indicated that there were four triterpenes in the material recovered from the TLC fractions. The OV-17 column presented a split peak, indicating the presence of at least five triterpenes. Complete separation, achieved on an OV-225 column, established that yarrow contained seven triterpenes. Comparison with authentic material verified that α-amyrin was the major triterpene present, representing ~42% of this fraction; β-amyrin (33%) and taraxasterol (18%) were also identified in this way. A fourth triterpene, tentatively identified as pseudotaraxasterol (4%), and three unidentified triterpenes accounted for the balance of this fraction (3%).

The triterpene fraction was acetylated (12) and subjected to argentation chromatography (13, 16, 17) to obtain sufficient amounts of pseudotaraxasterol to conduct instrumental and chemical analyses. Initially, six bands were obtained, although only bands 3, 4, and 5 produced positive Liebermann-Burchard tests (14) following elution from the silica gel. Bands 3, 4, and 5 were each subjected to further argentation chromatography. In this manner it was possible to obtain a few milligrams of α- and β-amyrin acetates from band 5, pseudotaraxasterol acetate from band 4, and taraxasterol acetate from band 3. Each of these samples was at least 80% pure, and nuclear magnetic resonance (NMR) (Table I) and GC–mass spectrometry (Tables II and III) data were collected for each.

The NMR spectra of α- and β-amyrin acetates and taraxasterol acetate in deuterochloroform and deuterobenzene were in keeping with similar compounds (18, 19).

The electron impact mass spectra of α- and β-amyrin acetate agreed

[a] Methane was the ionizing gas. [b] Molecular ion (M+).

with published data (13), while that of taraxasterol acetate was in keeping with predicted fragmentation patterns (20, 21). The positive chemical ionization mass spectra for these compounds differed only in the relative abundance of the fragment ions. All showed a base peak at *m/z* 109.

Direct comparison with authentic samples by GLC, NMR, and GC–mass spectrometry confirmed the identity of these three triterpene acetates.

The identification of pseudotaraxasterol (ψ-taraxasterol) was the most difficult and frustrating aspect of this research. Previous investigators also encountered this problem. As early as 1938 it was stated (22) that the material Power and Browning (23) had called homotaraxasterol was "a difficultly separable mixture of taraxasterol, ψ-taraxasterol, and possibly other unidentified substances."

The 220-MHz NMR spectrum provided valuable information that helped to identify this compound as pseudotaraxasterol. The spectrum of the acetate contained peaks for the acetate methyl group (2.05 ppm) and for the corresponding methine hydrogen (4.50 ppm) that were in keeping with the spectra described previously.

The spectrum also showed six methyl singlets present between 0.74 and 1.05 ppm. The three resonances that provided the most data, however, were those at 1.04, 1.66, and 5.27 ppm. The first was a three-proton doublet (J = 6 Hz), which corresponded to the features expected of a methyl group at a tertiary carbon. The signal at 1.66 ppm was not clearly defined, but contained a broad three-proton singlet corresponding to a vinylic methyl group. These groups normally appear in this region (1.63–1.80 ppm), and, although usually sharp and well defined (18), they may appear as a broad, less well defined peak at ~ 1.67 ppm (19). Irradiation experiments showed that a methine hydrogen coupled to the olefinic proton at 5.27 ppm also appeared at this resonance. This latter resonance was perhaps the most useful one in the entire spectrum. This one-proton signal appeared as a broad doublet (J = 6 Hz), the broadening presumably caused by additional coupling. The appearance of such a one-proton signal indicated that the other olefinic carbon was quaternary and either at a ring junction or bonded to a methyl group.

To determine the skeletal structure of the triterpene in question, a small amount was hydrogenated and the product was compared with those obtained by hydrogenating taraxasterol acetate and α-amyrin acetate. Of the limited number of compounds (Δ^5, Δ^9, Δ^{12}, Δ^{20}) that would produce the same product of catalytic hydrogenation as taraxasterol [$\Delta^{20(30)}$] and α-amyrin (Δ^{12}), only pseudotaraxasterol (Δ^{20}) fit the additional experimental facts presented by the NMR spectrum and by the mass spectrometry data to be discussed.

The GC–mass spectrometry data were obtained by both electron impact and methane positive chemical ionization. Although the diagnostic peak *m/z* 386 produced from cleavage of ring E (19) was absent in all spectra, a small peak at *m/z* 326 (386-acetic acid, 0.9%) occurred in the spectrum obtained by electron impact–mass spectrometry using a packed column and also at *m/z* 327 (0.4%) and 326 (0.2%) when positive chemical ionization–mass spectrometry and a capillary column were used. These peaks were not observed in the corresponding spectra of taraxasterol acetate. The hydrogenation experiment supplied further proof that the structure of pseudotaraxasterol was the correct assignment. Upon catalytic hydrogenation, both taraxasterol acetate and pseudotaraxasterol acetate produced a common product, dihydrotaraxasterol acetate. GC–mass spectrometry of these two products produced identical electron impact and positive chemical ionization spectra.

Conclusive proof of identity occurred when positive chemical ionization mass spectrometry and GLC on OV-17 and OV-225 columns showed that a sample of pseudotaraxasterol acetate[17] was identical to the pseudotaraxasterol acetate isolated from yarrow.

[17] A gift from Dr. R. V. Madrigal.

The second and smaller GLC peak obtained from the hydrogenation of taraxasterol acetate is believed to be the C-20 isomer (20α-methyl). This material produced a mass spectrum that was essentially identical to that of the other dihydrotaraxasterol acetate.

Thus, using modern instrumental techniques, four sterols and four triterpenes of yarrow were identified. β-Sitosterol was the major sterol and α-amyrin the major triterpene present. Other sterols identified were cholesterol, campesterol, and stigmasterol while the other triterpenes were β-amyrin, taraxasterol, and pseudotaraxasterol. Another study (24) found that pseudotaraxasterol occurred in *Tanacetum vulgare* L. (as did the other compounds) but it was not positively identified at that time due to sample size.

This study confirms that stigmasterol (9) and β-sitosterol (9, 10) are present in yarrow. It is also the first time that cholesterol, campesterol, α- and β-amyrin, taraxasterol, and pseudotaraxasterol have been reported in yarrow, although the presence of sterols and triterpenes have been previously noted (3–5, 10). No diols (10) were identified, although the possibility remains that they may have been the compounds observed with the longer relative retention time.

Much of the time and effort of this project was spent applying modern instrumental techniques to resolve a problem that has plagued chemists for over half a century—how to separate and identify taraxasterol and pseudotaraxasterol (22, 23).

Mathematical Model for *In Vitro* Drug Release from Controlled Release Dosage Forms Applied to Propoxyphene Hydrochloride Pellets

FINN NORRING CHRISTENSEN *, FLEMMING YSSING HANSEN ‡, and HELLE BECHGAARD **

Received December 16, 1980, from the **Controlled Release Division, A/S Alfred Benzon, DK-1700 Copenhagen V, Denmark* and the ‡*Institute of Physical Chemistry, The Technical University of Denmark, DK-2800 Lyngby, Denmark.* Accepted for publication October 1, 1981.

Abstract □ The *in vitro* release of drugs from controlled-release dosage forms has been studied in terms of a diffusion model. The model has been applied to a pellet formulation containing propoxyphene hydrochloride. It is demonstrated that the model may be used to predict the drug release profile adequately, when the pellet size is changed and when the thickness of the coating is varied. The size distribution of pellets in an experiment may be too broad to justify a simulation with just one average pellet size. Therefore, the results for pellets of the same size are generalized to any size distribution of pellets in an experiment. This is only trivial if sink condition exists in the extraction medium, since under that condition, the release from each pellet type is independent of the releases from other pellet types. In that case, the total release may therefore be found as the sum of the individual releases. In the general case considered here, the releases are coupled.

Keyphrases □ Mathematical models—*in vitro* drug release from controlled-release dosage forms, propoxyphene hydrochloride pellets □ Propoxyphene hydrochloride pellets—mathematical model for *in vitro* drug release from controlled-release dosage forms □ Controlled-release dosage forms—mathematical model for *in vitro* drug release, propoxyphene hydrochloride pellets

In a recent paper (1) it was shown that a quasistationary diffusion description of the drug release from controlled release dosage forms formally leads to an expression of the same form as a Rosin-Rammler-Sperling-Weibull distribution when $\beta = 1$, (1–4). The advantage of the diffusion description is that it allows a prediction of the drug release as a function of pellet size and coat thickness once the diffusion coefficient for a given drug in the coat is known. In the present paper, the general solution to the diffusion description without the simplifying assumption about quasistationarity is considered.

THEORETICAL

It is assumed that pellets are spherical and consist of a core containing the drug and a coat which is the rate-limiting element in the release process (5). The radius of the core is b and the radius of the coated pellet is a giving a coat thickness of $(a - b)$.

In practice a dissolution test is done with a large number of pellets. If the pellets have a narrow size distribution, one may use the results for pellets of the given size. In the case of a broad size distribution, it is necessary to take that into account. In the present general solution to the diffusion description, both cases are discussed.

It is evident that the release profile, in general, may not be calculated as a superposition of the profiles from each pellet size since the increase of drug concentration in the extraction medium couples the releases from the pellets. Only in the case of zero concentration in the extraction medium (sink condition) no coupling is present, and a superposition of releases gives the total release.

It is important to note the simplifying assumptions inherent in this description. The initial phase, where dry pellets are introduced into an extraction medium, water penetrates the coat and dissolves the drug in the core, is not included in this description. This model may be applied from the time the drug in the core has been dissolved by the penetrating water. A time lag may be accounted for simply by shifting the zero point on the time axis, corresponding to the duration of the initial phase. Since there are no data available to calculate the initial phase kinetics, it is necessary to rely on experimental evidence for a reasonable assessment of time lag. It is a very important assumption that the pellets do not change dimensions (*e.g.*, due to swelling during the release period). In particular, if the pellet dimensions are determined from dry pellets, it is crucial to check that the dimensions are not changed after introduction into the extraction medium.

Assuming the drug concentration in the extraction medium is uniform at all times, due to effective stirring, the most general boundary condition to be considered is one where the drug concentration in the core gradually decreases as drug is released, while the drug concentration in the extraction medium gradually increases.

In the present paper, modifications of these boundary conditions are also considered. One modification is to assume sink conditions in the extraction medium and another is to assume a constant core concentration. From these examples it will be easy to see how to modify the calculation scheme in order to comply with other boundary conditions.

Pellets of Equal Size—As only radial diffusion is considered, the diffusion equation (6) for the coat is:

$$\frac{\partial[rC(rt)]}{\partial t} = D\frac{\partial^2[rC(rt)]}{\partial r^2} \qquad \text{(Eq. 1)}$$

where D is the diffusion coefficient for the particular drug in the coat, and $C(rt)$ is the drug concentration in the coat at distance r from the center at time t.

Equation 1 is solved with different boundary conditions and with the initial conditions:

$$C_e(t = 0) = 0 \qquad \text{(Eq. 2)}$$

$$C_c(t = 0) = C^0 \qquad \text{(Eq. 3)}$$

$$C(rt = 0) = 0 \qquad b < r < a \qquad \text{(Eq. 4)}$$

$$C(bt = 0) = \frac{C_c(t = 0)}{k_c} = \frac{C^0}{k_c} \text{ [see (Eq. 5)]}$$

where $C_e(t = 0)$ is the initial drug concentration in the extraction medium, and $C_c(t = 0)$ is the initial drug concentration in the core.

Variable Core and Extraction Medium Concentrations—The boundary conditions are sketched in Fig. 1 and may be expressed in the following way:

The Core-Coat Boundary—Assuming local equilibrium at the boundary at any time:

$$C_c(t) = k_c C(bt) \qquad \text{(Eq. 5)}$$

where k_c is the equilibrium constant. The continuity equation at the boundary may be written:

$$4\pi b^2 D\left[\frac{\partial C(rt)}{\partial r}\right]_{r=b} = \frac{4\pi b^3}{3}\frac{\partial C_c(t)}{\partial t} \qquad \text{(Eq. 6)}$$

and with Eq. 5:

$$\left[\frac{\partial C(rt)}{\partial r}\right]_{r=b} = \frac{bk_c}{3D}\frac{\partial C(bt)}{\partial t} \qquad \text{(Eq. 7)}$$

The Coat-Extraction Medium Boundary—The assumption of local equilibrium at the boundary gives:

$$C_e(t) = k_e C(at) \qquad \text{(Eq. 8)}$$

where k_e is the equilibrium constant. If there are n pellets of identical size, the continuity equation at the boundary may be written:

$$-n4\pi a^2 D\left[\frac{\partial C(rt)}{\partial r}\right]_{r=a} = V_e\frac{\partial C_e(t)}{\partial t} \qquad \text{(Eq. 9)}$$

0022-3549/82/0600-0694$01.00/0

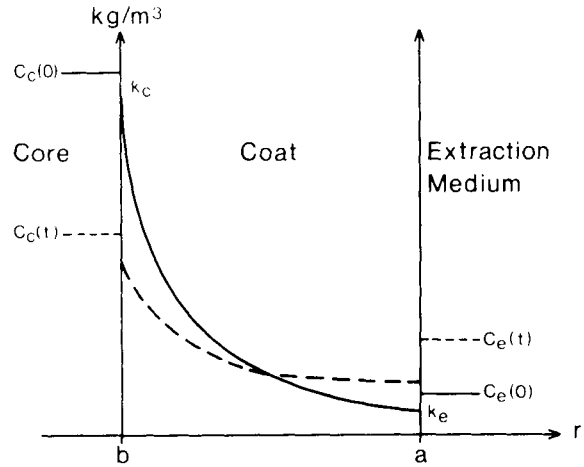

Figure 1—*A sketch of a segment of the core, coat, and extraction medium with boundary conditions corresponding to variable core and extraction medium concentrations. The stationary concentration profiles at time zero and at time* t *are shown. The concentration jumps at the boundaries are governed by the equilibrium constants* k_c *and* k_e.

where V_e is the volume of the extraction medium. Introduction of Eq. 8 into Eq. 9 gives:

$$\left[\frac{\partial C(rt)}{\partial r}\right]_{r=a} = -\frac{V_e k_e}{n4\pi a^2 D}\frac{\partial C(at)}{\partial t} \qquad \text{(Eq. 10)}$$

The time Laplace transform of Eq. 1 with Eq. 4 gives:

$$\frac{\partial^2 \tilde{C}(rs)}{\partial r^2} + \frac{2}{r}\frac{\partial \tilde{C}(rs)}{\partial r} - \frac{s}{D}\tilde{C}(rs) = 0 \qquad \text{(Eq. 11)}$$

where,

$$\tilde{C}(rs) = \int_0^\infty e^{-st} C(rt)\mathrm{d}t \qquad \text{(Eq. 12)}$$

is the Laplace transformed concentration. In the same way Eqs. 7 and 10 are Laplace transformed and give:

$$\left[\frac{\partial \tilde{C}(rs)}{\partial r}\right]_{r=b} = \frac{bk_c}{3D}[s\tilde{C}(bs)] - \frac{b}{3D}C^0 \qquad \text{(Eq. 13)}$$

and;

$$\left[\frac{\partial \tilde{C}(rs)}{\partial r}\right]_{r=a} = -\frac{V_e k_e}{n4\pi a^2 D}s\tilde{C}(as) \qquad \text{(Eq. 14)}$$

Equation 11 is a standard second-order differential equation with the solution

$$\tilde{C}(rs) = \frac{A}{r}\sinh\left(\sqrt{\frac{s}{D}}r\right) + \frac{B}{r}\cosh\left(\sqrt{\frac{s}{D}}r\right) \qquad \text{(Eq. 15)}$$

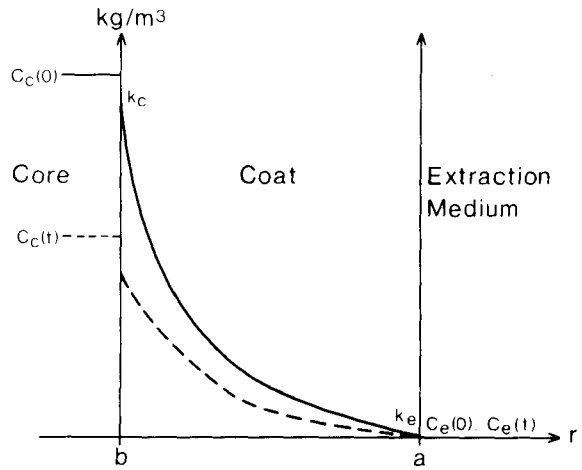

Figure 2—*A sketch of a segment of the core, coat, and extraction medium with boundary conditions corresponding to variable core conditions and sink conditions in the extraction medium. The stationary concentration profiles at time zero and time* t *are shown.*

The integration constants A and B are determined by inserting Eq. 15 into Eqs. 13 and 14. This gives the following system of equations, which in matrix form may be written:

$$\begin{bmatrix}\phi_1 & \phi_2\\ \phi_3 & \phi_4\end{bmatrix}\begin{bmatrix}A\\ B\end{bmatrix} = \begin{bmatrix}-\frac{C^0 b}{3}\\ 0\end{bmatrix} \qquad \text{(Eq. 16)}$$

where:

$$\phi_1 = b\sqrt{sD}\cosh\left(\sqrt{\frac{s}{D}}b\right) - D\sinh\left(\sqrt{\frac{s}{D}}b\right) - \frac{k_c s b^2}{3}\sinh\left(\sqrt{\frac{s}{D}}b\right) \qquad \text{(Eq. 17)}$$

$$\phi_2 = b\sqrt{sD}\sinh\left(\sqrt{\frac{s}{D}}b\right) - D\cosh\left(\sqrt{\frac{s}{D}}b\right) - \frac{k_c s b^2}{3}\cosh\left(\sqrt{\frac{s}{D}}b\right) \qquad \text{(Eq. 18)}$$

$$\phi_3 = a\sqrt{sD}\cosh\left(\sqrt{\frac{s}{D}}a\right) - D\sinh\left(\sqrt{\frac{s}{D}}a\right) + \frac{V_r k_e s a^2}{3}\sinh\left(\sqrt{\frac{s}{D}}a\right) \qquad \text{(Eq. 19)}$$

$$\phi_4 = a\sqrt{sD}\sinh\left(\sqrt{\frac{s}{D}}a\right) - D\cosh\left(\sqrt{\frac{s}{D}}a\right) + \frac{V_r k_e s a^2}{3}\cosh\left(\sqrt{\frac{s}{D}}a\right) \qquad \text{(Eq. 20)}$$

where the relative volume, $V_r = \dfrac{V_e}{\frac{n4\pi a^3}{3}}$

Equation 16 is solved for A and B, and after introduction of A and B in Eq. 15 is found:

$$\tilde{C}(rs) = \frac{-C^0 b^3\phi_4\sinh\left(\sqrt{\frac{s}{D}}r\right) + C^0 b^3\phi_3\cosh\left(\sqrt{\frac{s}{D}}r\right)}{3r(\phi_1\phi_4 - \phi_2\phi_3)} \qquad \text{(Eq. 21)}$$

By a reverse transformation of Eq. 21, $C(rt)$ can be found. This is done by residue calculation (7):

$$C(rt) = \sum_{l=1}^{\infty}\frac{C^0 b^3\left[(\phi_3)_{s_l}\cosh\left(\sqrt{\frac{s_l}{D}}r\right) - (\phi_4)_{s_l}\sinh\left(\sqrt{\frac{s_l}{D}}r\right)\right]e^{s_l t}}{3r\left(\frac{\partial}{\partial s}[\phi_1\phi_4 - \phi_2\phi_3]\right)_{s=s_l}} \qquad \text{(Eq. 22)}$$

Where s_l is the l'th pole of $\tilde{C}(rs)$ in Eq. 21. From Eq. 22 it is clear that $s_l \leq 0$, since $C(rt)$ is final. To find $C_e(t)$, Eq. 8 is used and we obtain from Eq. 22 after lengthy manipulations:

$$C_e(t) = \sum_{l=1}^{\infty}\frac{k_e C^0 b\sqrt{-\frac{s_l}{D}}e^{s_l t}}{N(s_l)} \qquad \text{(Eq. 23)}$$

where:

$$N(s_l) = \left[\sin\left(\sqrt{\frac{s_l}{D}}a\right)\cos\left(\sqrt{-\frac{s_l}{D}}b\right) - \sin\left(\sqrt{-\frac{s_l}{D}}a\right)\times\cos\left(\sqrt{-\frac{s_l}{D}}b\right)\right]\left\{\frac{k_c}{k_e} - \frac{3}{2k_e}\left[1 + \left(\frac{a}{b}\right)^2\right] + V_r\left(\frac{a}{b}\right)^2 - \frac{a^2 s_l}{D}\left[\frac{2}{3}V_r k_c + \frac{k_c}{2k_e}\left(1 - \frac{a}{b}\right) + \frac{V_r}{2}\left(\frac{a}{b} - 1\right)\right]\right\} + \left[\sin\left(\sqrt{-\frac{s_l}{D}}b\right)\sin\left(\sqrt{-\frac{s_l}{D}}a\right) + \cos\left(\sqrt{-\frac{s_l}{D}}a\right)\cos\left(\sqrt{-\frac{s_l}{D}}b\right)\right]a\sqrt{-\frac{s_l}{D}}\left[\frac{k_c}{2k_e}\left(2 + \frac{b}{a}\right) + \frac{V_r}{2}\left(2\frac{a}{b} + \left(\frac{a}{b}\right)^2\right) + \frac{V_r k_c s_l a^2}{6D}\left(1 - \frac{b}{a}\right)\right] \qquad \text{(Eq. 24)}$$

A convenient way of representing the results in Eq. 23 is to plot the release $R(t) = C_e(t)/C_e(t = \infty)$ as a function of time. It is evident that $R(t) \rightarrow 1$ for $t \rightarrow \infty$. The limiting value for $C_e(t)$ is given by the time independent term in Eq. 23, *i.e.*, one of the poles of $\bar{C}(rs)$ in Eq. 21 is zero. Indeed, it is clear from Eqs. 17–20 that $s = 0$ is a pole of $\bar{C}(rs)$. Let $s_1 = 0$, then Eq. 23 may be written:

$$R(t) = 1 + \sum_{l=2}^{\infty} \frac{k_e C^0 b \sqrt{-\frac{s_l}{D}}\, e^{s_l t}}{N(s_l) C_e(t = \infty)} \qquad \text{(Eq. 25a)}$$

where the concentration in the extraction medium at $t = \infty$ is found to be:

$$C_e(t = \infty) = \frac{C^0}{\frac{a^3}{b^3} V_r + \frac{k_c}{k_e} + \frac{1}{k_c}\left(\frac{a^3}{b^3} - 1\right)} \qquad \text{(Eq. 25b)}$$

Sink Condition in Extraction Medium–Variable Core Concentration—With the boundary conditions sketched in Fig. 2, Eq. 8 now changes to:

$$C(at) = 0 \qquad \text{(Eq. 26)}$$

The initial conditions (Eqs. 2–4) and the other boundary conditions (Eqs. 5 and 7) are unchanged. The integration constants A and B in Eq. 15 are now determined by introducing $\bar{C}(rs)$ into Eq. 13 and the Laplace transform of Eq. 26:

$$\bar{C}(as) = 0 \qquad \text{(Eq. 27)}$$

In analogy with Eq. 16, the following system of equations is obtained:

$$\begin{bmatrix} \phi_1 & \phi_2 \\ \phi_3' & \phi_4' \end{bmatrix} \begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} -\frac{C^0 b^3}{3} \\ 0 \end{bmatrix} \qquad \text{(Eq. 28)}$$

where ϕ_1 and ϕ_2 are given in Eqs. 17 and 18 and

$$\phi_3' = \sinh\left(\sqrt{\frac{s}{D}}\, a\right) \qquad \text{(Eq. 29)}$$

$$\phi_4' = \cosh\left(\sqrt{\frac{s}{D}}\, a\right) \qquad \text{(Eq. 30)}$$

Equation 28 is solved for A and B, and it is found, as previously:

$$\bar{C}(rs) = \frac{-C^0 b^3 \phi_4' \sinh\left(\sqrt{\frac{s}{D}}\, r\right) + C^0 b^3 \phi_3' \cosh\left(\sqrt{\frac{s}{D}}\, r\right)}{3r(\phi_1 \phi_4' - \phi_2 \phi_3')} \qquad \text{(Eq. 31)}$$

where:

$$\phi_1 \phi_4' - \phi_2 \phi_3' =$$
$$\left[b\sqrt{sD} \cosh\left(\sqrt{\frac{s}{D}}\, b\right) - D \sinh\left(\sqrt{\frac{s}{D}}\, b\right) - \frac{k_c s b^2}{3} \sinh\left(\sqrt{\frac{s}{D}}\, b\right)\right] \cosh\left(\sqrt{\frac{s}{D}}\, a\right)$$
$$- \left[b\sqrt{sD} \sinh\left(\sqrt{\frac{s}{D}}\right) - D \cosh\left(\sqrt{\frac{s}{D}}\, b\right) - \frac{k_c s b^2}{3} \cosh\left(\sqrt{\frac{s}{D}}\, b\right)\right] \sinh\left(\sqrt{\frac{s}{D}}\, a\right) \qquad \text{(Eq. 32)}$$

By residue calculation (7) Eq. 31 is reversed and it is found that $C(rt)$:

$$C(rt) = \sum_{l=1}^{\infty} \frac{C^0 b^3 \left[(\phi_3')_{s=s_l} \cosh\left(\sqrt{\frac{s_l}{D}}\, r\right) - (\phi_4')_{s=s_l} \sinh\left(\sqrt{\frac{s_l}{D}}\, r\right)\right] e^{s_l t}}{3r\left[\frac{\partial}{\partial s}(\phi_1 \phi_4' - \phi_2 \phi_3')\right]_{s=s_l}} \qquad \text{(Eq. 33)}$$

where s_l is the l'th pole of $\bar{C}(rs)$ in Eq. 31. After lengthy manipulations the following is obtained:

$$C(rt) = \sum_{l=1}^{\infty} \frac{C^0 b}{r N'(s_l)} \left[\sin\left(\sqrt{-\frac{s_l}{D}}\, a\right) \times \cos\left(\sqrt{-\frac{s_l}{D}}\, r\right) - \cos\left(\sqrt{-\frac{s_l}{D}}\, a\right) \sin\left(\sqrt{-\frac{s_l}{D}}\, r\right)\right] e^{s_l t} \qquad \text{(Eq. 34)}$$

where:

$$N'(s_l) = \left[\frac{3}{2}\left(1 - \frac{a}{b}\right) - k_c\right] \left[\sin\left(\sqrt{-\frac{s_l}{D}}\, b\right) \times \cos\left(\sqrt{-\frac{s_l}{D}}\, a\right) - \sin\left(\sqrt{\frac{-s_l}{D}}\, a\right) \cos\left(\sqrt{-\frac{s_l}{D}}\, a\right)\right]$$
$$+ a\sqrt{-\frac{s_l}{D}} \left[\frac{k_c}{2}\left(1 - \frac{b}{a}\right) + \frac{3D}{2 s_l b^2}\right] \left[\sin\left(\sqrt{-\frac{s_l}{D}}\, a\right) \times \sin\left(\sqrt{-\frac{s_l}{D}}\, b\right) + \cos\left(\sqrt{-\frac{s_l}{D}}\, a\right) \cos\left(\sqrt{-\frac{s_l}{D}}\, b\right)\right] \qquad \text{(Eq. 35)}$$

It is clear from Eq. 34 that $C(at) = 0$ at any time t, in accordance with Eq. 26. The flux $dJ(t)/dt$ of drug into the extraction medium is given by:

$$\frac{dJ(t)}{dt} = -4\pi a^2 n D \left(\frac{\partial C(rt)}{\partial r}\right)_{r=a} \qquad \text{(Eq. 36)}$$

and the total amount of drug released at time t is given by:

$$\mathrm{M}(t) = -4\pi a^2 n D \int_0^t \left(\frac{\partial C(rt')}{\partial r}\right)_{r=a} dt' \qquad \text{(Eq. 37)}$$

From Eq. 34 it is found:

$$\left(\frac{\partial C(rt)}{\partial r}\right)_{r=a} = \sum_{l=1}^{\infty} -\frac{C^0 b}{a N'(s_l)} \sqrt{-\frac{s_l}{D}}\, e^{s_l t} \qquad \text{(Eq. 38)}$$

so

$$\mathrm{M}(t) = 4\pi a^2 n D \sum_{l=1}^{\infty} \frac{C^0 b}{a N'(s)} \sqrt{-\frac{1}{s_l D}} (e^{s_l t} - 1) \qquad \text{(Eq. 39)}$$

Divided by the total amount of drug, $M(t = \infty) = 4\pi b^3/3\, NC^0$ (neglecting the capacity of the coat) the release $R'(t)$ is obtained:

$$R'(t) = \frac{\mathrm{M}(t)}{\mathrm{M}(t = \infty)} = \frac{3aD}{b^2} \sum_{l=1}^{\infty} \frac{1}{N'(s_l)\sqrt{-s_l D}} (e^{s_l t} - 1) \qquad \text{(Eq. 40)}$$

Constant Core Concentration–Variable Extraction Medium Concentration—If the solubility of the drug in the core is low, the concentration of dissolved drug remains constant as long as there is undissolved drug in the core. The boundary conditions are sketched in Fig. 3, and Eq. 7 now changes to:

$$C_c(t) = C' = k_c C(bt) \qquad \text{(Eq. 41)}$$

The initial conditions and the other boundary conditions, Eqs. 8 and 10, are unchanged. The integration constants A and B in Eq. 15 are now determined by introducing $\bar{C}(rs)$ into Eq. 14 and the Laplace transform of Eq. 41:

$$\bar{C}(bs) = \frac{C'}{k_c s} \qquad \text{(Eq. 42)}$$

In analogy to Eqs. 16 and 28 the following set of equations is obtained:

$$\begin{bmatrix} \phi_1' & \phi_2' \\ \phi_3 & \phi_4 \end{bmatrix} \begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} -\frac{C' b}{k_c s} \\ 0 \end{bmatrix} \qquad \text{(Eq. 43)}$$

where:

$$\phi_1' = \sinh\left(\sqrt{\frac{s}{D}}\, b\right) \qquad \text{(Eq. 44)}$$

$$\phi_2' = \cosh\left(\sqrt{\frac{s}{D}}\, b\right) \qquad \text{(Eq. 45)}$$

ϕ_3 and ϕ_4 are given by Eqs. 19 and 20, respectively. In analogy with the previous examples, it is now straightforward to derive an equation for the concentration:

$$C(rt) = \sum_{l=1}^{\infty} \frac{C' b e^{s_l t}}{k_c s r} \frac{\left[(\phi_4)_{s=s_l} \sinh\left(\sqrt{\frac{s_l}{D}}\, r\right) - (\phi_3)_{s=s_l} \cosh\left(\sqrt{\frac{s_l}{D}}\, r\right)\right]}{\left[\frac{\partial}{\partial s}(\phi_1' \phi_4 - \phi_2' \phi_3)\right]_{s=s_l}} \qquad \text{(Eq. 46)}$$

and with Eq. 8:

$$C_e(t) = \sum_{l=1}^{\infty} \frac{k_e C' b e^{s_l t}}{k_c s a} \frac{\left[(\phi_4)_{s=s_l} \sinh\left(\sqrt{\frac{s_l}{D}}\, a\right) - (\phi_3)_{s=s_l} \cosh\left(\sqrt{\frac{s_l}{D}}\, a\right)\right]}{\left[\frac{\partial}{\partial s}(\phi_1' \phi_4 - \phi_2' \phi_3)\right]_{s=s_l}} \qquad \text{(Eq. 47)}$$

At the moment when all undissolved drug has disappeared from the core, the concentration will be given by Eq. 23. Thus, the release profile will be given by two different expressions according to the conditions in the core.

Pellets of Different Size—*Variable Core and Extraction Medium Concentrations*—This is a generalization of the results derived for pellets of equal size to a situation where there is a distribution in the size of pellets used. Assuming that there are N different types of pellets involved, differing in size, coat material, *etc.*, for each of the N types of pellets there is an equation like Eq. 15. For the j'th type:

$$\tilde{C}_j(rs) = \frac{A_j}{r}\sinh\left(\sqrt{\frac{s}{D_j}}r\right) + \frac{B_j}{r}\cosh\left(\sqrt{\frac{s}{D_j}}r\right) \qquad \text{(Eq. 48)}$$

also allowing the diffusion coefficients D_j to be different. If the coating material is the same for all types of pellets $D_j = D$ for all j.

The boundary condition at the core-coat boundary is the same as in Eqs. 5 and 7 for each type of pellet, *i.e.*,

$$\left(\frac{\partial\tilde{C}_j(rs)}{\partial r}\right)_{r=b_j} = \frac{b_j k_{jc}}{3D_j}\left[s\tilde{C}_j(rs)\right] - \frac{b_j C_j^0}{3D_j} \qquad \text{(Eq. 49)}$$

The boundary condition at the coat-extraction medium boundary is:

$$V_e\left(\frac{\partial C_e(t)}{\partial t}\right) = \sum_{j=1}^{N} -4\pi a_j^2 n_j D_j\left(\frac{\partial C_j(rt)}{\partial r}\right)_{r=a_j} \qquad \text{(Eq. 50)}$$

with:

$$C_e(t) = k_{1e}C_1(a_1t) = \ldots = k_{je}C_j(a_jt) = \ldots = k_{Ne}C_N(a_Nt) \qquad \text{(Eq. 51)}$$

Time Laplace transformation of Eqs. 50 and 51 gives:

$$s\tilde{C}_e(s) = \sum_{j=1}^{N} -\frac{3}{a_j V_{rj}} D_j\left(\frac{\partial\tilde{C}_j(rs)}{\partial r}\right)_{r=a_j} \qquad \text{(Eq. 52)}$$

and:

$$\tilde{C}_e(s) = k_{1e}\tilde{C}_1(a_1s) = \ldots = k_{je}\tilde{C}_j(a_js) = \ldots = k_{Ne}\tilde{C}_N(a_Ns) \qquad \text{(Eq. 53)}$$

To determine the $2N$ integration constants, A_j and B_j, it is necessary to have $2N$ equations. The first N equations are obtained from Eq. 49 after introduction of $\tilde{C}_j(rs)$ from Eq. 48. The j'th equation has the form:

$$iA_j\left[\frac{1}{b_j}\sqrt{-\frac{s}{D_j}}\cos\left(\sqrt{-\frac{s}{D_j}}b_j\right) - \frac{1}{b_j^2}\sin\left(\sqrt{-\frac{s}{D_j}}b_j\right) - \frac{sk_{je}}{3D_j}\sin\left(\sqrt{-\frac{s}{D_j}}b_j\right)\right] + B_j\left[\frac{1}{b_j}\sqrt{-\frac{s}{D_j}}\sin\left(\sqrt{-\frac{s}{D_j}}b_j\right) - \frac{1}{b_j^2}\cos\left(\sqrt{-\frac{s}{D_j}}b_j\right) - \frac{sk_{jc}}{3D_j}\cos\left(\sqrt{-\frac{s}{D_j}}b_j\right)\right] = -\frac{b_jC_j^0}{3D_j} \qquad \text{(Eq. 54)}$$

The last N equations are obtained from Eqs. 52 and 53 after introduction of Eq. 48. The j'th equation has the form:

$$\sum_{l=1}^{N}\left\{iA_l\left[\sqrt{-\frac{s}{D_l}}\frac{1}{a_l}\cos\left(\sqrt{-\frac{s}{D_l}}a_l\right) - \frac{1}{a_l^2}\sin\left(\sqrt{-\frac{s}{D_l}}a_l\right) + \delta_{lj}\frac{V_{rj}k_{jl}s}{3D_j}\sin\left(\sqrt{-\frac{s}{D_j}}a_j\right)\right] + B_l\left[-\sqrt{-\frac{s}{D_l}}\frac{1}{a_l}\sin\left(\sqrt{-\frac{s}{D_l}}a_l\right) - \frac{1}{a_l^2}\cos\left(\sqrt{-\frac{s}{D_l}}a_l\right) + \delta_{jl}\frac{V_{rj}k_{jl}s}{3D_j}\cos\left(\sqrt{-\frac{s}{D_j}}a_j\right)\right]\right\} = 0 \qquad \text{(Eq. 55)}$$

The results in Eqs. 54 and 55 may conveniently be written in matrix form as

$$EF = G \qquad \text{(Eq. 56)}$$

where:

$$E = \begin{bmatrix} g_1 & 0 & 0 & \ldots & 0 \\ 0 & g_2 & 0 & \ldots & 0 \\ 0 & 0 & g_3 & \ldots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \ldots & g_N \\ (c_1+l_1) & c_2 & c_3 & \ldots & c_N \\ c_1 & (c_2+l_2) & c_3 & \ldots & c_N \\ c_1 & c_2 & (c_3+l_3) & \ldots & c_N \\ \vdots & \vdots & \vdots & & \vdots \\ c_1 & c_2 & c_3 & \ldots & (c_N+l_N) \end{bmatrix} \begin{bmatrix} h_1 & 0 & 0 & \ldots & 0 \\ 0 & h_2 & 0 & \ldots & 0 \\ 0 & 0 & h_3 & \ldots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \ldots & h_N \\ (d_1+f_1) & d_2 & d_3 & \ldots & d_N \\ d_1 & (d_2+f_2) & d_3 & \ldots & d_N \\ d_1 & d_2 & (d_3+f_3) & \ldots & d_N \\ \vdots & \vdots & \vdots & & \vdots \\ d_1 & d_2 & d_3 & \ldots & (d_N+f_N) \end{bmatrix} \qquad \text{(Eq. 57)}$$

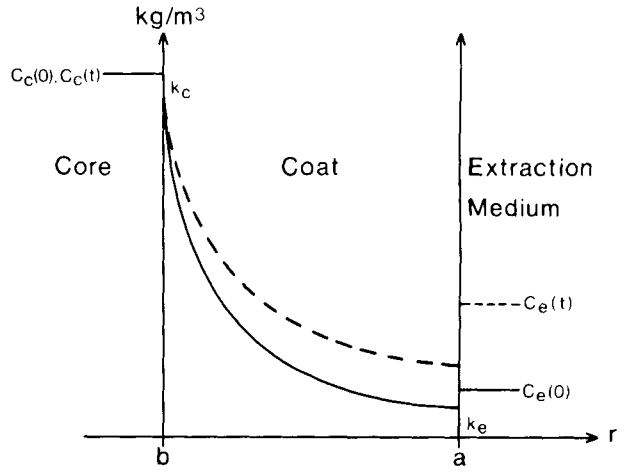

Figure 3—*A sketch of a segment of the core, coat, and extraction medium with boundary conditions corresponding to constant core concentration and variable extraction medium concentration. The stationary concentration profiles at time zero and time t are shown.*

and

$$F = \begin{bmatrix} iA_1 \\ iA_2 \\ \vdots \\ iA_N \\ B_1 \\ B_2 \\ \vdots \\ B_N \end{bmatrix} \quad \text{and} \quad G = \begin{bmatrix} -\frac{b_1C_1^0}{3D_1} \\ \vdots \\ -\frac{b_NC_N^0}{3D_N} \\ 0 \\ \vdots \\ 0 \end{bmatrix} \qquad \text{(Eq. 58)}$$

with:

$$g_i = \sqrt{-\frac{s}{D_i}}\frac{1}{b_i}\cos\left(\sqrt{-\frac{s}{D_i}}b_i\right) - \frac{1}{b_i^2} \times \sin\left(\sqrt{-\frac{s}{D_i}}b_i\right) - \frac{sk_{ic}}{3D_i}\sin\left(\sqrt{-\frac{s}{D_i}}b_i\right) \qquad \text{(Eq. 59)}$$

$$h_i = \sqrt{-\frac{s}{D_i}}\frac{1}{b_i}\sin\left(\sqrt{-\frac{s}{D_i}}b_i\right) - \frac{1}{b_i^2} \times \cos\left(\sqrt{-\frac{s}{D_i}}b_i\right) - \frac{sk_{ic}}{3D_i}\cos\left(\sqrt{-\frac{s}{D_i}}b_i\right) \qquad \text{(Eq. 60)}$$

$$c_i = \sqrt{-\frac{s}{D_i}}\frac{1}{a_i}\cos\left(\sqrt{-\frac{s}{D_i}}a_i\right) - \frac{1}{a_i^2}\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 61)}$$

$$d_i = -\sqrt{-\frac{s}{D_i}}\frac{1}{a_i}\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) - \frac{1}{a_i^2}\cos\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 62)}$$

$$l_i = \frac{V_{ri}k_{ie}s}{3D_i}\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 63)}$$

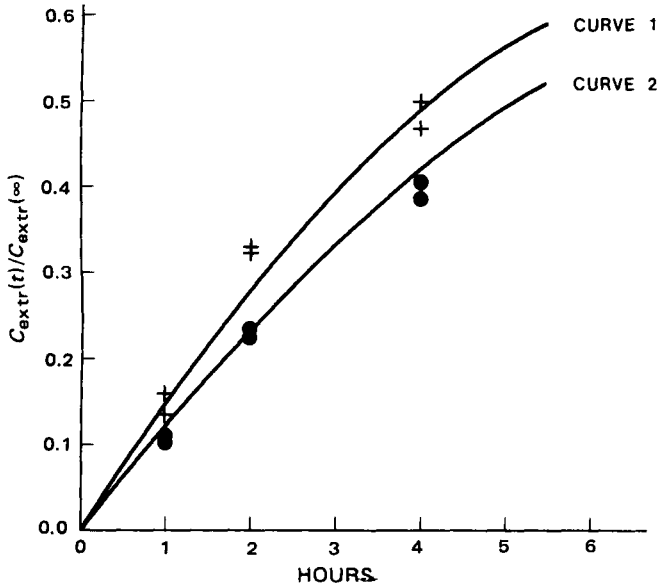

Figure 4—*Curve 1: Release profile calculated from Eq. 25 (or Eq. 56) when* a = *475 μm,* b = *459.2 μm,* V_{ri} = *75,* k_{ic} = k_{ie} = *1 to give the least-squares fit to experimental data. The diffusion coefficient is determined to be* $1.17 \times 10^{-13}\ m^2\ sec^{-1}$. *Curve 2: Predicted release profile of pellets when* a = *478.8 μm,* b = *459.2 μm,* V_{ri} = *75,* k_{ie} = k_{ic} = *1 and* D = $1.17 \times 10^{-9}\ cm^2\ sec^{-1}$.

$$f_i = \frac{V_{ri}k_{ie}s}{3D_i}\cos\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 64)}$$

Equation 56 is solved for iA_j and B_j (j = 1,N) and after introduction of iA_j, B_j into Eq. 49 for the j'th type of pellet, the following expression for $\bar{C}_j(rs)$ is found:

$$\bar{C}_j(rs) = \frac{\chi_j(rs)}{\psi_j(rs)} \qquad \text{(Eq. 65)}$$

where:

$$\chi_j(rs) = |E(j = G)|\sin\left(\sqrt{-\frac{s}{D_j}}r\right) + |E[(N + j) = G]| \times \cos\left(\sqrt{-\frac{s}{D_j}}r\right) \qquad \text{(Eq. 66)}$$

and:

$$\psi_j(rs) = r|E| \qquad \text{(Eq. 67)}$$

$|E|$ is the determinant of the E matrix (Eq. 57) and $|E(j = G)|$ is the determinant of the matrix obtained from E by replacing the j'th column with the vector G. Equation 65 may be reversed in the usual way by residue calculation:

$$C_j(rt) = \sum_{i=1}^{N}\frac{\chi_j(rs_i)e^{s_it}}{\left\{\frac{\partial}{\partial s}[\psi_j(rs)]\right\}_{s=s_i}} \qquad \text{(Eq. 68)}$$

where $\partial\psi/\partial s$ means a differentiation of the determinant $|E|$. This is done by replacing the elements in one row by the same elements differentiated with respect to s. In that way $2N$ new determinants are generated and they are all identical to the original determinant besides one row. Finally the $2N$ determinants are added giving the desired result. Therefore, it is necessary to know:

$$\frac{\partial g_i}{\partial s} = \left(\frac{1}{2D_i} - \frac{k_{ic}}{3D_i}\right)\sin\left(\sqrt{-\frac{s}{D_i}}b_i\right) + \frac{sk_{ic}b_i}{6D_i\sqrt{-sD_i}}\cos\left(\sqrt{-\frac{s}{D_i}}b_i\right) \qquad \text{(Eq. 69)}$$

$$\frac{\partial k_i}{\partial s} = \frac{1}{D_i}\left(\frac{1}{2} - \frac{k_{ic}}{3}\right)\cos\left(\sqrt{-\frac{s}{D_i}}b_i\right) - \frac{sk_{ic}b_i}{6D_i\sqrt{-sD_i}}\sin\left(\sqrt{-\frac{s}{D_i}}b_i\right) \qquad \text{(Eq. 70)}$$

$$\frac{\partial c_i}{\partial s} = \frac{1}{2D_i}\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 71)}$$

$$\frac{\partial d_i}{\partial s} = \frac{1}{2D_i}\cos\left(\sqrt{-\frac{s}{D_i}}a_i\right) \qquad \text{(Eq. 72)}$$

$$\frac{\partial l_i}{\partial s} = \frac{V_{ri}k_{ie}}{3D_i}\left[\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) - \frac{a_i}{2}\sqrt{-\frac{s}{D_i}}\cos\left(\sqrt{-\frac{s}{D_i}}a_i\right)\right] \qquad \text{(Eq. 73)}$$

$$\frac{\partial f_i}{\partial s} = \frac{V_{ri}k_{ie}}{3D_i}\left[\frac{a_i}{2}\sqrt{-\frac{s}{D_i}}\sin\left(\sqrt{-\frac{s}{D_i}}a_i\right) + \cos\left(\sqrt{-\frac{s}{D_i}}a_i\right)\right] \qquad \text{(Eq. 74)}$$

These results can be programmed into a digital computer. The poles of $\bar{C}_j(rs)$ are found as the zero points of the determinant $|E|$, and once they are known, it is straightforward to use Eq. 68 for pellet type j and calculate $C_e(t)$ according to:

$$C_e(t) = k_{ie}C_j(a_jt) \qquad \text{(Eq. 75)}$$

Sink Condition in Extraction Medium–Variable Core Concentration—The boundary condition at the coat-extraction medium is:

$$C_i(a_it) = 0$$

for each type of pellet. That is, there is no coupling between the different types of pellets, which means that the release may be described as a superposition of the release from each type of pellet as given by Eq. 39, for example.

Other Boundary Conditions—It is fairly easy to adapt this calculation scheme to other relevant boundary conditions as discussed under Pellets of Equal Size.

RESULTS AND DISCUSSION

It has been shown that the general solution to the diffusion description of drug release from controlled-release solid dosage forms consisting of either one-size pellets or a broad-size distribution of pellets is straightforward and easy to handle in terms of matrix equations.

The poles s_n of $\bar{C}(rs)$ are found as the zero points of the determinant of the E matrix (Eqs. 56 and 65). The s_n has to be determined numerically, which may be done on computers. Once the poles have been found, either one of the concentrations $C_j(rt)$ and, thus, $C_e(t)$ may be calculated from Eqs. 68 and 75. It is noted that, due to Eq. 51, any one of the concentrations, $C_j(rt)$, may be used to calculate the extraction medium concentration, $C_e(t)$. Finally, it is noted that the one-size pellet case is included as a special case of the general treatment given previously, and in that case, Eq. 56 degenerates to Eq. 16.

As an illustration, the diffusion model has been applied to the prediction of the release profile of pellets with a known diffusion coefficient D and a coat thickness ($a - b$). Two experimental and calculated release profiles of propoxyphene hydrochloride pellets, coated with different amounts of a synthetic coat (5) are shown in Fig. 4. Curve 1 corresponds to pellets with a thin coat (8%) and Curve 2 to pellets with a thick coat (10%). Since the coating material is the same, it is assumed that the diffusion coefficients are identical in both cases which implies that the difference in release profiles is due to a different thickness of the coating. The diffusion model should be able to reproduce this difference if the model reflects essential features of the process. As the pellets had a narrow size distribution, only calculations for pellets of one size were used.

The dimensions of the pellets (a and b) were obtained from microscopy of a series of microtome sections of the pellets. It was found that b = 459.2 μm and a = 475.0 μm and 478.8 μm, respectively. Since there are only one-size pellets in the experiments, the results in Eq. 56 for N = 1 may be used. Adsorption phenomena were considered unimportant, and k_{ic} and k_{ie} were set equal to 1. The relative volume V_{ri} = 75. Equation 56 was then applied to fit data points for pellets with the thin coat (Curve 1) in order to obtain a value for the diffusion coefficient.

The experiments were conducted with the general boundary conditions with varying coat and extraction medium concentrations. It was possible to fit the data points with D = 420 $\mu m^2 h^{-1}$, ~ $1.17 \times 10^{-13}\ m^2\ sec^{-1}$ (Curve 1). Curve 2 was then calculated from Eq. 56 with the relevant b and a, and the predicted release profile is seen to be in good agreement with the experimental data. It is noted that the diffusion coefficient is somewhat different from the one reported earlier (1), where quasistationary conditions were imposed.

APPENDIX

Variable	Units	
β	—	= parameter in the Rosin-Rammler-Sperling-Weibull distribution (See Ref. 1)
b	m	= radius of core
a	m	= radius of coated pellet
r	m	= radial distance from the center of a sphere
t	sec	= time
s	sec^{-1}	= frequency
s_i	sec^{-1}	= poles in Eq. 22
$C(rt)$	kg/m^3	= concentration of drug in coat at position r and at time t
$C_c(t)$	kg/m^3	= concentration of dissolved drug in the core at time t
$C_e(t)$	kg/m^3	= concentration of drug in extraction medium at time t
C^0	kg/m^3	= initial concentration of drug in core
$\bar{C}(rs)$	kgs/m^3	= time Laplace transform of $C(rt)$ at r
C'	kg/m^3	= constant core concentration in case of a sparingly soluble drug
D	m^2/sec	= diffusion coefficient of drug in coat
k_c	—	= distribution coefficient for drug between core and coat
k_e	—	= distribution coefficient for drug between extraction medium and coat
V_e	m^3	= volume of extraction medium
V_r	—	= the ratio of the volume of extraction medium to total volume of pellets
n	—	= number of pellets of identical size
$N(s_i)$	—	= denominator in Eq. 23 defined in Eq. 24
$M(t)$	kg	= total amount of drug released at time t
N	—	= number of different types of pellets in a sample
$J(t)$	$kg/sec\ m^2$	= flux of drug at time t

Stereoselective Disposition and Glucuronidation of Propranolol in Humans

BERNIE SILBER *[x], NICHOLAS H. G. HOLFORD, and SIDNEY RIEGELMAN [†]

Received August 10, 1981, from the *Departments of Pharmaceutical Chemistry and Pharmacy, School of Pharmacy, and Division of Clinical Pharmacology, Department of Medicine, School of Medicine, University of California, San Francisco, California.* Accepted for publication October 5, 1981.

[†] Deceased. * Present address: Department of Pharmaceutics, BG-20, School of Pharmacy, University of Washington, Seattle WA 98195.

Abstract □ Following oral dosing to steady state, the disposition of $S(-)$- and $R(+)$-propranolol and their corresponding glucuronide conjugates was studied in 4 healthy adults using doses from 40 to 320 mg/day of the racemate. Steady-state plasma concentrations of $S(-)$-propranolol and its corresponding glucuronide conjugate were greater than that for $R(+)$-propranolol and its corresponding conjugate. The average steady-state concentration of both enantiomers increased disproportionately to dose. There was a 52 ± 7 (mean ± *SD*) % decrease in the intrinsic clearance (Cl_{int}) of $S(-)$-propranolol and a 65 ± 22% decrease in the Cl_{int} of $R(+)$-propranolol over the dosing range studied. The terminal elimination half-lives of $S(-)$-propranolol and its glucuronide conjugate were longer than for the $R(+)$-enantiomer at all doses. The formation of glucuronide conjugates of $S(-)$- and $R(+)$-propranolol was best described by a saturable process in all subjects. Within individuals, the ratio of V'_{max}/K_m for the glucuronide conjugate of $S(-)$-propranolol was from 2.1- to 4.9-fold greater than for the conjugate of the $R(+)$-enantiomer. These studies demonstrate for the first time, that propranolol undergoes stereoselective disposition in humans.

Keyphrases □ Propranolol—$S(-)$- and $R(+)$-enantiomers and corresponding glucuronide conjugates, stereoselective disposition, humans □ Stereoselectivity—disposition of $S(-)$- and $R(+)$-propranolol, humans □ Glucuronide—conjugates of $S(-)$- and $R(+)$-propranolol in stereoselectivity disposition studies, humans

Propranolol [1-isopropylamino-3-(1-naphthoxy)-2-propanol] is a nonselective beta adrenergic blocking agent used clinically as a racemic mixture of the $S(-)$- and $R(+)$-enantiomers. Because $S(-)$-propranolol is about 100 times more potent as a beta blocker than the $R(+)$-enantiomer, $S(-)$-propranolol is believed to be largely responsible for the clinical effects of racemic drug (1).

Numerous investigators have described the absorption, distribution, metabolism, and elimination of propranolol in humans and animals. Pharmacokinetic studies in healthy volunteers and in patients have demonstrated up to 20-fold variation between individuals in plasma propranolol concentrations after oral doses (2–8). Age (9, 10); cigarette smoking (9, 11); concomitant drug intake (12);

Abstract □ Following oral dosing to steady state, the disposition of $S(-)$- and $R(+)$-propranolol and their corresponding glucuronide conjugates was studied in 4 healthy adults using doses from 40 to 320 mg/day of the racemate. Steady-state plasma concentrations of $S(-)$-propranolol and its corresponding glucuronide conjugate were greater than that for $R(+)$-propranolol and its corresponding conjugate. The average steady-state concentration of both enantiomers increased disproportionately to dose. There was a 52 ± 7 (mean ± *SD*) % decrease in the intrinsic clearance (Cl_{int}) of $S(-)$-propranolol and a 65 ± 22% decrease in the Cl_{int} of $R(+)$-propranolol over the dosing range studied. The terminal elimination half-lives of $S(-)$-propranolol and its glucuronide conjugate were longer than for the $R(+)$-enantiomer at all doses. The formation of glucuronide conjugates of $S(-)$- and $R(+)$-propranolol was best described by a saturable process in all subjects. Within individuals, the ratio of V'_{max}/K_m for the glucuronide conjugate of $S(-)$-propranolol was from 2.1- to 4.9-fold greater than for the conjugate of the $R(+)$-enantiomer. These studies demonstrate for the first time, that propranolol undergoes stereoselective disposition in humans.

Keyphrases □ Propranolol—$S(-)$- and $R(+)$-enantiomers and corresponding glucuronide conjugates, stereoselective disposition, humans □ Stereoselectivity—disposition of $S(-)$- and $R(+)$-propranolol, humans □ Glucuronide—conjugates of $S(-)$- and $R(+)$-propranolol in stereoselectivity disposition studies, humans

Propranolol [1-isopropylamino-3-(1-naphthoxy)-2-propanol] is a nonselective beta adrenergic blocking agent used clinically as a racemic mixture of the $S(-)$- and $R(+)$-enantiomers. Because $S(-)$-propranolol is about 100 times more potent as a beta blocker than the $R(+)$-enantiomer, $S(-)$-propranolol is believed to be largely responsible for the clinical effects of racemic drug (1).

Numerous investigators have described the absorption, distribution, metabolism, and elimination of propranolol in humans and animals. Pharmacokinetic studies in healthy volunteers and in patients have demonstrated up to 20-fold variation between individuals in plasma propranolol concentrations after oral doses (2–8). Age (9, 10); cigarette smoking (9, 11); concomitant drug intake (12);

0022-3549/82/0600-0699$01.00/0

and renal (13), hepatic (14), and thyroid disease (15–17) have all been shown to affect the disposition of the drug. The disposition of propranolol in humans is highly dose dependent and this previously unrecognized observation may explain much of the apparent differences between individuals (18).

To date, pharmacokinetic studies involving propranolol have conclusions based on total [$S(-)$- plus $R(+)$-] propranolol concentrations. However, no information is available describing the pharmacokinetic behavior of each enantiomer measured simultaneously after administration of the racemate.

Racemic mixtures of drugs are commonly employed clinically. However, there may be large differences between enantiomers in their pharmacological activity, metabolism, and elimination. Warfarin enantiomers, for example, have significantly different anticoagulant properties, are metabolized differently, and have different rates of elimination (19–23).

Reports have indicated that the area under the plasma concentration–time curve (AUC) for $S(-)$-propranolol in the dog was 50% less than the AUC for the $R(+)$-enantiomer after administration of a single oral dose of the racemate (24, 25). Both groups found that the $S(-)$-enantiomer was more extensively glucuronidated and the AUC for the glucuronide conjugate of this enantiomer was over 3 times greater than the AUC for the glucuronide conjugate of $R(+)$-propranolol. However, no differences in the terminal elimination half-life of propranolol enantiomers or their glucuronide conjugates were observed.

The purpose of this study was to investigate, over a wide range of doses in humans, any differences in the disposition of $S(-)$- and $R(+)$-propranolol and formation of their corresponding glucuronide conjugates.

EXPERIMENTAL

Subjects were four healthy male volunteers. Informed consent was obtained and the protocol approved by the University of California, San Francisco, Committee on Human Research. All subjects had a medical history, physical examination, electrocardiogram (ECG), complete blood count with differential, urinalysis, and selected blood chemistries done. There was no evidence of renal or hepatic disease by medical history. Each subject had normal values of blood urea nitrogen, serum creatinine, urinalysis and urine culture, serum glutamic oxloacetic transaminase, lactic dehydrogenase, alkaline phosphatase, bilirubin, prothrombin time, and total serum proteins. All were nonsmokers and abstained from alcohol and marijuana and other medications until completion of the study. On each of 4 days/week that propranolol was taken, subjects were interviewed for side effects, had their pulse and blood pressure measured, and had a 1-min ECG rhythm strip taken.

All subjects were given 40, 80, 160, 240, and 320 mg/day of propranolol in divided doses every 6 hr for a total of 13 doses. No dietary restrictions were imposed, but food was withheld for at least 9 hr before and 3 hr after the 13th dose.

Blood samples were obtained at the end of the 8th, 9th, and 12th dosing intervals (trough concentrations) and at 0, 15, 30, 45, 60, and 90 min, and 2, 3, 4, 5, 6, 8, 10, and 12 hr following the 13th dose. Venous blood samples were obtained using an indwelling butterfly catheter whose patency was maintained by flushing with 1 ml of heparinized saline (10 U/ml) after obtaining each blood sample (26); these small doses of heparin do not affect the plasma protein binding or disposition of propranolol (27). After discarding 0.5 ml of blood, a 7-ml blood sample was collected in a sterile 12-ml disposable syringe. The blood sample was immediately transferred to a 16 × 150-mm polytef-lined screw cap test tube to which had been added 100 U of aqueous sodium heparin. After gentle mixing, blood samples were centrifuged at 2000 rpm (500×g) for 10 min. Plasma was transferred with a disposable Pasteur pipet to glass screw cap vials and stored at −20° until assay.

Assay for $S(-)$- and $R(+)$-Propranolol and Their Corresponding Glucuronide Conjugates—The concentrations of $S(-)$- and R(+)-propranolol and their corresponding glucuronide conjugates in plasma were measured in each subject after receiving doses of the racemate by a previously reported method (25). At each dosing rate, plasma concentrations were measured during the 13th dosing interval at steady state. Glucuronide concentrations were determined as the difference between enantiomer concentrations before and after enzymatic hydrolysis (25). One milliliter of plasma was extracted with ether after adding 0.4 ml of 0.2 N KOH by vortexing for 2 min and centrifuging at 2000 rpm (500×g) for 10 min. Ether extracts transferred to conical test tubes were evaporated to dryness under nitrogen. After adding 1 ml of methylene chloride, tubes were placed in a −78° bath. N-trifluoroacetyl-$S(-)$-prolyl chloride (0.3 ml) (the derivatizing agent) and 50 μl of triethylamine were added to the tubes, removed from the bath, and allowed to stand for 15 min. After adding 8 ml of 0.05N NaOH, vortexing for 2 min, and centrifuging at 2000 rpm (500×g) for 10 min, the upper layer was discarded and the lower layer evaporated to dryness under nitrogen after being transferred to culture test tubes. An aliquot of the residue, reconstituted with an equivolume mixture of acetonitrile and water, was injected onto the high-performance liquid chromatograph for analysis.

Data Analysis—The average steady-state concentration ($\overline{C}_{ss}$) of each enantiomer of propranolol and for each of their corresponding glucuronide conjugates during the 13th dosing interval was determined by:

$$\overline{C}_{ss} = \frac{AUC_0}{\tau} \qquad \text{(Eq. 1)}$$

where AUC_0 is the area under the plasma concentration–time curve after the oral dose, and τ is the dosing interval. The AUC of each propranolol enantiomer and for their corresponding glucuronide conjugates was calculated by the trapezoidal rule. The intrinsic clearance (Cl_{int}) of each propranolol enantiomer was calculated by the following (28):

$$Cl_{int} = \frac{D_0}{AUC_0} \qquad \text{(Eq. 2)}$$

where D_0 is the dose of each enantiomer; this is equal to one-half the total dose since the drug is administered as the racemate. This relationship assumes that the drug is totally absorbed and that all blood containing the drug passes through the liver before reaching the systemic circulation. The terminal elimination half-life of each propranolol enantiomer and their corresponding glucuronide conjugates was calculated by 0.693/terminal elimination rate constant (determined by least-squares regression utilizing at least four plasma concentration–time points in the log–linear region).

At steady state, the relationship between the formation of metabolite and its elimination is given by:

$$Cl_{f,M}\, C_{P_{ss}} = Cl_{el,M}\, C_{M_{ss}} \qquad \text{(Eq. 3)}$$

where $Cl_{f,M}$ is the formation clearance and $Cl_{el,M}$ is the elimination clearance for metabolite (M), and $C_{P_{ss}}$ and $C_{M_{ss}}$ are the concentrations of propranolol and metabolite, respectively. Rearrangement of Eq. 3 yields:

$$C_{M_{ss}} = Cl_{f,M}\frac{C_{P_{ss}}}{Cl_{el,M}} \qquad \text{(Eq. 4)}$$

for a first-order process and can be expressed as Eq. 5 for a saturable process:

$$C_{M_{ss}} = \frac{V_{max_M}}{K_{m_M} + C_{P_{ss}}}\frac{C_{P_{ss}}}{Cl_{el,M}} \qquad \text{(Eq. 5)}$$

where V_{max_M} and K_{m_M} are the Michaelis–Menten constants for a saturable metabolic process.

The formation clearance of each glucuronide conjugate (metabolite) can be estimated by substituting steady-state concentrations of propranolol enantiomers, their corresponding glucuronide conjugates, and the elimination clearance for each of the glucuronide conjugates into these equations.

Although the value of $Cl_{el,M}$ for the glucuronide conjugates is not known, in an earlier study (18) the renal clearance (Cl_r) for racemic (total) propranolol glucuronide ($Cl_{r,M}$) has been determined; previous investigators have shown that the clearance of propranolol glucuronide is primarily by the renal route (29). The $Cl_{r,M}$ for racemic propranolol glucuronide was independent of concentration in these same four subjects (18). Therefore, if it is assumed that the renal clearance is equal to the elimination clearance (*i.e.* $Cl_{r,M} = Cl_{el,M}$), then Eqs. 4 and 5 can be rewritten as Eqs. 6 and 7, respectively:

Table I—The Relationship Between the Intrinsic Clearance (Cl_{int}) of Propranolol Enantiomers and the Daily Dose of Racemic Propranolol

Week			3		4		5			
Dose, mg/day; racemate			160		240		320			Percent change in Cl_{int} from week 3 to week 5
Subject	Age, yr	Weight, kg	Cl_{int} of Propranolol Enantiomers (liters/min)[a] $S(-)$	$R(+)$	$S(-)$	$R(+)$	$S(-)$	$R(+)$		$S(-)$ / $R(+)$
MR	25	82	3.69	5.35	3.07	3.89	2.27	3.42		−48 / −46
TB	26	64	3.17	9.74	1.90	3.60	0.89	1.28		−62 / −87
AT	24	68	3.22	5.02	3.00	4.14	1.69	2.65		−48 / −47
TC	28	75	4.25	15.75	2.89	7.44	2.98	3.19		−51 / −80
									$x \pm SD$	-52 ± 7 / -65 ± 22

[a] The intrinsic clearance (Cl_{int}) was calculated according to Eq. 2.

$$C_{M_{ss}} = Cl_{f,M} \frac{C_{P_{ss}}}{Cl_{r,M}} \quad \text{(Eq. 6)}$$

$$C_{M_{ss}} = \frac{V_{max_M}}{K_{m_M} + C_{P_{ss}}} \frac{C_{P_{ss}}}{Cl_{r,M}} \quad \text{(Eq. 7)}$$

Because urinary excretion rate data is available for racemic propranolol glucuronide, the contribution by each glucuronide conjugate to the total renal clearance cannot be precisely estimated. However, the total renal clearance is the sum of the fractional contributions and can be defined by:

$$Cl_{r,M(-)} = \phi_{(-)}\, Cl_{r,M} \quad \text{(Eq. 8)}$$

for the glucuronide conjugate of $S(-)$-propranolol and by:

$$Cl_{r,M(+)} = \phi_{(+)}\, Cl_{r,M} \quad \text{(Eq. 9)}$$

for the glucuronide conjugate of $R(+)$-propranolol. The coefficient, ϕ, may be the same or different for each of the glucuronide conjugates. Therefore, for a saturable metabolic process, the Cl_f can be described by:

$$C_{M_{ss(-)}} = \frac{V_{max_{M(-)}}}{K_{m_{M(-)}} + C_{P_{ss(-)}}} \frac{C_{P_{ss(-)}}}{\phi_{(-)}\, Cl_{r,M}} \quad \text{(Eq. 10)}$$

for the glucuronide conjugate of $S(-)$-propranolol, and by:

$$C_{M_{ss(+)}} = \frac{V_{max_{M(+)}}}{K_{m_{M(+)}} + C_{P_{ss(+)}}} \frac{C_{P_{ss(+)}}}{\phi_{(+)}\, Cl_{r,M}} \quad \text{(Eq. 11)}$$

for the glucuronide conjugate of $R(+)$-propranolol.

To test the hypothesis that the formation of propranolol glucuronide is stereoselective, the predictions of six models were compared: Model 1, same V_{max} and K_m; Model 2, same V_{max}, different K_m; Model 3, different V_{max}, same K_m; Model 4, different V_{max} and K_m; Model 5, similar nonsaturable clearance; Model 6, different nonsaturable clearance.

Because ϕ appears in all equations of Cl_f, the value of V_{max} or Cl_f obtained for saturable or first-order processes, respectively, will have this coefficient incorporated into the estimate.

The formation clearance models listed above were specified (30). The parameters of the models listed previously were estimated by simultaneous unweighted nonlinear least-squares regression (31) of the $C_{M_{ss}}$ for each glucuronide conjugate *versus* the $C_{P_{ss}}$.

Discrimination between the models was made with the Schwarz criterion and Leonard test (32–34).

Mean values are reported with standard deviations; differences between means are evaluated by student's paired t test and are considered to be significant when $p < 0.05$ (35).

RESULTS

The dose-dependent elimination of propranolol and its major metabolites was previously reported in the same four individuals (18). Steady-state conditions were achieved in all subjects at each dosing rate. Steady-state trough concentrations of total [$S(-)$- and $R(+)$-] propranolol were attained at least by the ninth dose and only slight interday variation within subjects was observed.

Because concentrations of propranolol were near the sensitivity limit of the stereospecific assay with doses of 40 and 80 mg/day, enantiomer concentrations were not measured at these dosing rates. Concentrations of $S(-)$- and $R(+)$-propranolol, along with their corresponding glucuronide conjugates, were measured at dosing rates of 160, 240, and 320 mg/day.

Relationship Between the Intrinsic Clearance (Cl_{int}) of Propranolol Enantiomers and the Dosing Rate—The Cl_{int} of $S(-)$- and $R(+)$-propranolol at each dosing rate was determined according to Eq. 2. The Cl_{int} of $S(-)$-propranolol was always lower than the Cl_{int} of the $R(+)$-enantiomer (Table I). On the average, there was a 52 ± 7 (mean $\pm$ SD) % decrease in the Cl_{int} of $S(-)$-propranolol and a 65 ± 22% decrease in the Cl_{int} of $R(+)$-propranolol when the dose was increased from 160 to 320 mg/day.

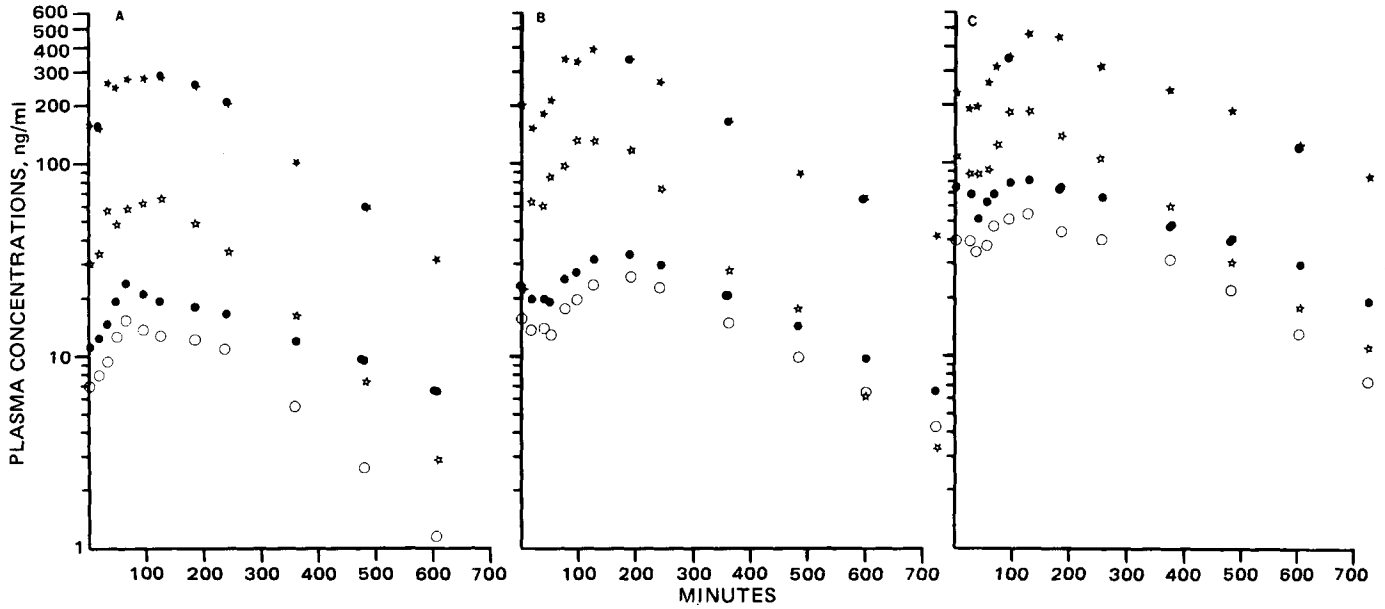

Figure 1—*Plasma concentrations of* S(−)-[●] *and* R(+)-[○] *propranolol and the glucuronide conjugates of* S(−)-[★] *and* R(+)-[*] *propranolol during the 13th dosing interval at steady state after: A, 160; B, 240; and C, 320 mg/day in subject AT. Similar results were seen in the three other subjects studied.*

$x \pm SD$	2.7 ± 0.4	2.0 ± 0.2[a]	3.5 ± 0.3[b]	3.1 ± 0.5[b]	4.5 ± 1.6	3.4 ± 0.9[a,b]

[a] $p < 0.05$ when compared with the value obtained for the $S(-)$-enantiomer at the same dosing rate. [b] $p < 0.05$ when compared with the value obtained for the same enantiomer at 160 mg/day.

Plasma Concentrations of $S(-)$- and $R(+)$-Propranolol and Their Corresponding Glucuronide Conjugates—Concentrations of $S(-)$-propranolol and its glucuronide conjugate were always greater than those for $R(+)$-propranolol and its glucuronide conjugate in all subjects at all dosing rates. Representative data obtained from subject AT is depicted in Fig. 1*A–C*.

The ratio of steady-state concentrations of $S(-)$- : $R(+)$-propranolol during the 13th dosing interval was 2.45 ± 1.12 at 160, 1.78 ± 0.60 at 240, and 1.51 ± 0.05 and 320 mg/day; and the ratio of the steady-state concentrations of the glucuronide conjugates of $S(-)$- : $R(+)$-propranolol was 4.74 ± 0.96 at 160, 3.64 ± 0.41 at 240, and 2.93 ± 0.17 at 320 mg/day.

There was a disproportionate increase in the $\bar{C}_{ss}$ of $S(-)$- and $R(+)$-propranolol in each subject as the daily dose was increased from 160 to 320 mg/day.

Terminal Elimination Half-Lives of Propranolol Enantiomers and Their Corresponding Glucuronide Conjugates—The half-life of $S(-)$-propranolol was 1.5-fold greater than for the $R(+)$-enantiomer at 160 mg/day ($p < 0.05$) and 1.6-fold greater at 320 mg/day ($p < 0.05$). In addition, the half-life of the glucuronide conjugate of $S(-)$-propranolol was 1.4-fold greater than for the conjugate of the $R(+)$-enantiomer at 160 mg/day ($p < 0.05$) and 1.3-fold greater at 320 mg/day ($p < 0.05$) (Table II). The half-life of both enantiomers and for their corresponding glucuronide conjugates increased with increasing dosing rate.

Estimation of the Formation Clearance (Cl_f) for Glucuronide Conjugates of $S(-)$- and $R(+)$-Propranolol—The Cl_f of glucuronide conjugates of $S(-)$- and $R(+)$-propranolol in all four subjects was best described by a saturable process. However, the model best explaining the data varied among the four subjects. The Cl_f for the glucuronide conjugate of $S(-)$-propranolol estimated by V'_{max}/K_m [$V_{max}/(\phi \cdot K_m)$] ranged from 496 to 1831 ml/min, whereas the Cl_f for the conjugate of $R(+)$-propranolol ranged from 202 to 477 ml/min. The summation of the individual Cl_fs for each individual determined in this investigation was compared with the value for the racemate Cl_f determined in the same individual (Table III).

DISCUSSION

A technique for the simultaneous determination of $S(-)$- and $R(+)$-propranolol along with their corresponding glucuronide conjugates after administration of the racemate was recently developed (25). Utilizing this technique, this investigation has shown that in healthy adults, the intrinsic clearance, plasma concentrations, elimination rate, and the formation clearance of glucuronide conjugates of propranolol enantiomers are substantially different.

The half-life of propranolol in humans after oral administration of the $R(+)$-enantiomer alone was reported to be shorter than after a dose of the racemate (36). In a previous report using a radioimmunoassay, the half-life of propranolol in rats after an intravenous dose of the $R(+)$-enantiomer was found to be shorter than after an intravenous dose of the racemate (37), whereas no difference was observed in mice when the same technique was employed (38).

These studies, however, do not predict the disposition of propranolol enantiomers after administration of the racemate, because $R(+)$-propranolol has no influence on liver blood flow, whereas racemic propranolol results in a decrease in liver blood flow. Because propranolol has a high extraction ratio and its clearance is blood flow limited, racemic propranolol would be expected to have a longer elimination half-life when compared with the half-life after $R(+)$-propranolol (39).

In a previous report (25), it was shown that in a patient with angina pectoris taking 200 mg of propranolol every 6 hr, the area under the plasma concentration–time curve for the $S(-)$-propranolol enantiomer was ~1.4 times greater than that for the $R(+)$-enantiomer. In the present investigation, concentrations of $S(-)$-propranolol were greater than those of $R(+)$-propranolol at each dosing rate (Fig. 1); these results confirm earlier findings but are in contrast to those observed in the dog (24, 25). In addition, the average steady-state concentration of each enantiomer increased disproportionately with doses from 160 to 320 mg/day. Similar to results observed in dogs, glucuronide concentrations of $S(-)$-propranolol were substantially greater than those for the glucuronide conjugate of the $R(+)$-enantiomer (24, 25).

The half-life of $S(-)$-propranolol and its glucuronide conjugate was greater than for the $R(+)$-enantiomer and its corresponding conjugate ($p < 0.05$) (Table II). In contrast, half-lives of propranolol enantiomers and their glucuronide conjugates were identical in the dog (24, 25).

Although the AUC for $S(-)$-propranolol was greater than that for the $R(+)$-enantiomer, it would be invalid to draw conclusions about the relative extent of bioavailability (F). Calculations of F for each enantiomer, based solely on AUCs after oral but not intravenous doses, must assume that the systemic clearances (Cl_s) of each enantiomer are identical. Although Cl_s, was not estimated, the intrinsic clearance of each enantiomer differed sharply and decreased with increasing dose (Table I).

In a previous report involving the same four individuals (18), it was shown that at steady state ~55% of an oral dose of propranolol could be accounted for by formation of three major metabolites: propranolol glucuronide, 4-hydroxypropranolol glucuronide, and α-naphthoxylactic acid. These metabolites are formed by different metabolic pathways and are eliminated by the kidneys in the urine (29). The formation of these metabolites was saturable in the dosage range studied.

The formation clearance (Cl_f) for the glucuronide conjugate of $S(-)$-propranolol (estimated by V'_{max}/K_m) was 2.1–4.9-fold greater than the Cl_f for the glucuronide conjugate of the $R(+)$-enantiomer in a given individual (Table III). However, when the sum of these individual Cl_fs was compared with the Cl_f for the racemate estimated from a previous investigation in the same individuals, a large disparity between estimates was observed. Because both V_{max} and ϕ for each glucuronide conjugate are unknown, it cannot be determined precisely whether the observed difference between $Cl_{f,T}$ and $Cl_{f,T'}$ (Table III) is due to a difference in V_{max}, ϕ, or both.

As previously mentioned, steady-state concentrations of $S(-)$-propranolol and its glucuronide conjugate were much higher than those for the $R(+)$-enantiomer and its conjugate in plasma. It is possible that other metabolites are being formed stereoselectively; at least some of these may be preferential for the $R(+)$-enantiomer. Although stereoselectivity in other metabolic pathways for propranolol has not been demonstrated in humans, a previous study (40) has recently shown that in the rat, $S(-)$-propranolol is preferentially hydroxylated to 4-hydroxypropranolol *in vivo* but not *in vitro*. 4-Hydroxypropranolol is equally active as a beta

[a] Renal clearance for racemic propranolol glucuronide; data from Silber *et al.* (18). [b] See data analysis section for description of models and selection criteria. [c] $V'_{max} = V_{max}/\phi$; see data analysis section for explanation. [d] $Cl_{f,T}$ represents the sum of the Cl_f for the glucuronide conjugates of $S(-)$- and $R(+)$-propranolol. [e] Estimated from V_{max}/K_m for racemic propranolol glucuronide; data from Silber *et al.* (18).

adrenergic blocking agent when compared with propranolol (41); presumably, the $S(-)$-enantiomer of 4-hydroxypropranolol is responsible for the beta blocking effects of a racemic mixture of $S(-)$- and $R(+)$-4-hydroxypropranolol.

Extensive deconjugation of propranolol glucuronide back to propranolol has been reported to occur in the dog (42). The occurrence of such a process in humans could be important since results from this study demonstrate that $S(-)$-propranolol is preferentially glucuronidated and that the resulting conjugate has a slower elimination rate when compared with the glucuronide conjugate for the $R(+)$-enantiomer (Table II). These findings may lend support to the theory proposed by Walle *et al.* (42) that propranolol glucuronide in humans serves as a storage pool or depot for the slow release of propranolol. This may be especially significant since deconjugation of propranolol glucuronide in humans should yield primarily $S(-)$-propranolol, the pharmacologically more active enantiomer. This presumes that the rate and extent of deconjugation, if it occurs, is equivalent for each glucuronide conjugate of propranolol.

The mechanism for the slower rate of elimination of the glucuronide conjugate of $S(-)$-propranolol cannot be explained by this investigation. Previous investigators have shown that the clearance of racemic propranolol glucuronide is primarily by the renal route (29). Further studies will need to establish whether the renal clearance of propranolol glucuronides are equivalent or different.

Because these results clearly demonstrate that the disposition and glucuronidation of $S(-)$- and $R(+)$-propranolol are not the same, and because they are essentially two distinct entities pharmacologically, future pharmacokinetic and pharmacodynamic studies involving propranolol should be focused on the pharmacologically more important $S(-)$-propranolol enantiomer rather than on total [$S(-)$- and $R(+)$-] concentrations of the drug.

NOTES

Sterility Testing of Fat Emulsions Using Membrane Filtration and Dimethyl Sulfoxide

A. M. PLACENCIA ˣ, G. S. OXBORROW, and J. W. DANIELSON

Received July 28, 1981, from the *Sterility Research Center, Minneapolis Center for Microbiological Investigations, Food and Drug Administration, Minneapolis, MN 55401.* Accepted for publication September 18, 1981.

Abstract □ A method was described for sterility testing of 10% fat emulsions, which consisted of solubilizing the emulsion in dimethyl sulfoxide and filtering the mixture using a polyester membrane. The procedure was rapid and avoided the problems of turbidity and plugging of the membrane filter encountered with other methods.

Keyphrases □ Dimethyl sulfoxide—sterility testing of 10% fat emulsions using membrane filtration □ Membrane filtration—sterility testing of 10% fat emulsions, dimethyl sulfoxide □ Fat emulsions—sterility testing using membrane filtration and dimethyl sulfoxide

Intravenous fat emulsions are used in peripheral and central vein infusions. Since bacterial contamination might be a problem with this kind of human drug product, a reliable method for sterility testing is necessary to ensure that possible contamination is detected.

The two basic methods for sterility testing (direct inoculation and membrane filtration) described in the USP XX (1) are not suitable to test this product. Direct inoculation of the product into growth media renders the media turbid and makes it impossible to observe microbial growth. To detect growth, various transfers must be made from the original inoculated media to fresh media, thus increasing the possibilities of contamination and extending the analysis time. Only small quantities of the product can be tested with this method. Membrane filtration of the product is difficult because the emulsified fat globules will not pass the commonly used membrane filters, and the filter pores become plugged. The present report describes a method for the sterility testing of fat emulsions in which membrane filtration is combined with the use of a solvent, dimethyl sulfoxide.

As part of the study, dimethyl sulfoxide was tested for bacteriostatic and fungistatic properties because of conflicting reports concerning its antimicrobial effects. It was shown (2) that 10% dimethyl sulfoxide protects and aids in the recovery of heat-shocked *Bacillus subtilis* spores. The high recovery of the bacteria has been linked to the capability of the compound to activate dormant spores (3, 4). At concentrations of 10, 20, and 30% in food transport systems, dimethyl sulfoxide acts as a cryoprotective agent and increases the survival of some bacteria (5). A solution of 10% dimethyl sulfoxide yielded a 100% recovery rate of *B. subtilis* phage after storage of the phage for 25 days at −20° (6). During freezing and thawing of *Aerobacter aerogenes* and red blood cells, 10–20% dimethyl sulfoxide increased the organisms' viability (7, 8). Dimethyl sulfoxide (100%) had no diffusible bacteriostatic activity when tested in disk agar diffusion sensitivity studies with various organisms (9). Normal growth of test organisms was obtained after 15-min exposure to 200,000 ppm (20%) dimethyl sulfoxide (10).

Dimethyl sulfoxide has been classified by other researchers as weakly antibacterial and antifungal (11). Bacterial growth was inhibited when 20% dimethyl sulfoxide was used in media (12, 13). Pottz *et al.* (14) found that 5–10% dimethyl sulfoxide was bacteriostatic and 20–80% bacteriocidal. Dimethyl sulfoxide (25%) was reported to inhibit the growth of bacteria isolated from leukemia and cancer patients (15). Dimethyl sulfoxide affects a wide range of bacteria and fungi in concentrations used in antimicrobial testing programs in the pharmaceutical industry (16).

The described method was designed to test the bacteriostatic and fungistatic capabilities of dimethyl sulfoxide to be used in the sterility testing of fat emulsions. Decimal reduction (D values) were determined using various test organisms.

EXPERIMENTAL

Dimethyl Sulfoxide Preparation—Dimethyl sulfoxide[1] was filter-sterilized using a polyester membrane[2] (0.2-μm pore size, 47-mm diameter) and stored in 25- and 50-ml amounts in sterile glass screw-capped tubes.

Sterility Testing of Fat Emulsions—Aliquots (100 ml) of a 10% intravenous fat emulsion[3] were aseptically transferred to sterile 38 × 200-mm glass screw-capped test tubes. To each tube, 25 ml of dimethyl sulfoxide was added. The mixture was vigorously stirred for 30 sec using a vortex mixer and then filtered through a 0.4-μm polyester membrane[2]. The membrane was rinsed with 100 ml of fluid D (1) and two 100-ml portions of fluid A (1), cut into two sections, transferred to fluid thioglycolate and soybean casein digest broth, and incubated as described in USP XX (1).

lowing ATCC test organisms were used to test dimethyl sulfoxide for bacterio- and fungistasis: *Bacillus subtilis* (6633), *Staphylococcus aureus* (6538), *Candida albicans* (10231), *Pseudomonas aeruginosa* (9027), *Clostridium perfringens* (11437), and *Aspergillus niger* (16404).

Six sets of four tubes each, containing 100 ml of fat emulsion[3], were prepared. Each tube was inoculated with 1 ml of a test organism suspension. Dimethyl sulfoxide (25 ml) was added to two tubes per set, and 50 ml to the remaining two tubes. All tubes were vigorously stirred for 30 sec using a vortex mixer. The mixtures were membrane-filtered using a 0.4-μm polyester membrane[2]. The membranes were washed with 200 ml of fluid A (1) and 100 ml of fluid D (1) and then cut into two sections. One section was transferred to fluid thioglycolate and the other to soybean casein digest broth. The fluid thioglycolate was incubated at 33 ± 2° and soybean casein digest broth at 23 ± 2°, both for 7 days (1).

D Value Determination—D values were determined using *B. subtilis* and *C. albicans*. *C. albicans* was used because the results of the bacteriostatic and fungistatic test showed that it was more sensitive to dimethyl sulfoxide at concentrations of 33%.

Spore stock suspensions containing ~10^9 *B. subtilis* organisms/ml of water were used for inoculum.

Cultures of *C. albicans* were grown in 13 × 100-mm trypticase soy agar slants at 37 ± 2° for 72 hr. The slants were washed with 2 ml of phosphate buffer to a final concentration of 10^9 organisms/ml.

Six 25-ml aliquots of a 10% fat emulsion were transferred to separate glass screw-capped test tubes. Three of the tubes were each inoculated with 0.1 ml of a spore stock suspension of *B. subtilis* and the other three tubes with *C. albicans*. The contents of the tubes were vigorously stirred using a vortex mixer, and 6.25 ml of dimethyl sulfoxide was added to each tube. The tubes were stirred as before, and 5-ml aliquots were taken at 0, 15, 30, 45, and 60 min. Each aliquot was filtered through a 0.4-μm polyester membrane. The membranes were washed with 100 ml of fluid A and transferred to 38 × 200-mm test tubes containing 100 ml of fluid A. The tubes were ultrasonicated for 6 min at 55 kHz and dilutions plated using trypticase soy agar. The plates were incubated at 35 ± 2° for 48 hr.

RESULTS

The results show that 20% dimethyl sulfoxide was not bacteriostatic or fungistatic to the test organisms used in this study. The growth rate of the sample was comparable to that of the control samples. A concentration of 33% dimethyl sulfoxide showed some fungistasis only against *C. albicans* after 7 days incubation at 23 ± 2°.

When 20% dimethyl sulfoxide was used, the D values of *B. subtilis* and *C. albicans* were >60 min.

The polyester membrane had good filtration rates, taking ~4 min to filter dimethyl sulfoxide and the emulsion. No problem was noted in the rinsing of the membrane with fluids A and D. Other membranes tested, such as acetate cellulose, pyroxylin, mixed esters of cellulose, and mixed cellulose acetate pyroxylin, were either dissolved by dimethyl sulfoxide or the pores were plugged by the fat emulsion.

In contrast to the direct inoculation of a product, the entire product could be analyzed in this membrane filtration method, with no problem of the media showing turbidity upon inoculation. The use of dimethyl sulfoxide as a solvent and of polyester membrane filters for the filtration of the product and rinsing fluids provided a rapid method of analysis. Since dimethyl sulfoxide showed no bacteriostasis or fungistasis and the analysis time was short, the probability of obtaining a better bacterial recovery is greatly increased by using the described method.

Tensile Strengths and Hardness of Tablets

PAUL J. JAROSZ * and EUGENE L. PARROTT ˣ

Received June 8, 1981, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication October 13, 1981. *Present address: Ortho Pharmaceutical Corp., Raritan, NJ 08869.

Abstract □ The axial and radial tensile strengths were compared to the hardness of compressed tablets containing various concentrations of lubricants. Since radial tensile strength measurement considers the thickness of a tablet, and only tensile stress and axial tensile strength express the strength in the direction in which capping may occur, the tensile strengths characterize the strength of a tablet more completely than hardness.

Keyphrases □ Tensile strength—axial and radial tensile strengths compared to the hardness of compressed tablets □ Tablets—axial and radial tensile strengths compared to the hardness of compressed tablets

Although the strength of pharmaceutical tablets, which must be sufficient to withstand handling and shipment, may be expressed in a variety of ways, hardness (the force which, when applied diametrically to the tablet, causes fracture) has been the most common expression of strength. Studies of various hardness testers have shown the variations in fracture strength to be due to inaccuracies of instrumental scale values, zero errors, variations in the method of application of the load, physical dimensions, and shape of the tablet (1–4).

Although hardness has been a convenient and useful parameter for in-process control and quality assurance, it

0022-3549/82/0600-0705$01.00/0

lowing ATCC test organisms were used to test dimethyl sulfoxide for bacterio- and fungistasis: *Bacillus subtilis* (6633), *Staphylococcus aureus* (6538), *Candida albicans* (10231), *Pseudomonas aeruginosa* (9027), *Clostridium perfringens* (11437), and *Aspergillus niger* (16404).

Six sets of four tubes each, containing 100 ml of fat emulsion[3], were prepared. Each tube was inoculated with 1 ml of a test organism suspension. Dimethyl sulfoxide (25 ml) was added to two tubes per set, and 50 ml to the remaining two tubes. All tubes were vigorously stirred for 30 sec using a vortex mixer. The mixtures were membrane-filtered using a 0.4-μm polyester membrane[2]. The membranes were washed with 200 ml of fluid A (1) and 100 ml of fluid D (1) and then cut into two sections. One section was transferred to fluid thioglycolate and the other to soybean casein digest broth. The fluid thioglycolate was incubated at 33 ± 2° and soybean casein digest broth at 23 ± 2°, both for 7 days (1).

D Value Determination—D values were determined using *B. subtilis* and *C. albicans*. *C. albicans* was used because the results of the bacteriostatic and fungistatic test showed that it was more sensitive to dimethyl sulfoxide at concentrations of 33%.

Spore stock suspensions containing ~10^9 *B. subtilis* organisms/ml of water were used for inoculum.

Cultures of *C. albicans* were grown in 13 × 100-mm trypticase soy agar slants at 37 ± 2° for 72 hr. The slants were washed with 2 ml of phosphate buffer to a final concentration of 10^9 organisms/ml.

Six 25-ml aliquots of a 10% fat emulsion were transferred to separate glass screw-capped test tubes. Three of the tubes were each inoculated with 0.1 ml of a spore stock suspension of *B. subtilis* and the other three tubes with *C. albicans*. The contents of the tubes were vigorously stirred using a vortex mixer, and 6.25 ml of dimethyl sulfoxide was added to each tube. The tubes were stirred as before, and 5-ml aliquots were taken at 0, 15, 30, 45, and 60 min. Each aliquot was filtered through a 0.4-μm polyester membrane. The membranes were washed with 100 ml of fluid A and transferred to 38 × 200-mm test tubes containing 100 ml of fluid A. The tubes were ultrasonicated for 6 min at 55 kHz and dilutions plated using trypticase soy agar. The plates were incubated at 35 ± 2° for 48 hr.

RESULTS

The results show that 20% dimethyl sulfoxide was not bacteriostatic or fungistatic to the test organisms used in this study. The growth rate of the sample was comparable to that of the control samples. A concentration of 33% dimethyl sulfoxide showed some fungistasis only against *C. albicans* after 7 days incubation at 23 ± 2°.

When 20% dimethyl sulfoxide was used, the D values of *B. subtilis* and *C. albicans* were >60 min.

The polyester membrane had good filtration rates, taking ~4 min to filter dimethyl sulfoxide and the emulsion. No problem was noted in the rinsing of the membrane with fluids A and D. Other membranes tested, such as acetate cellulose, pyroxylin, mixed esters of cellulose, and mixed cellulose acetate pyroxylin, were either dissolved by dimethyl sulfoxide or the pores were plugged by the fat emulsion.

In contrast to the direct inoculation of a product, the entire product could be analyzed in this membrane filtration method, with no problem of the media showing turbidity upon inoculation. The use of dimethyl sulfoxide as a solvent and of polyester membrane filters for the filtration of the product and rinsing fluids provided a rapid method of analysis. Since dimethyl sulfoxide showed no bacteriostasis or fungistasis and the analysis time was short, the probability of obtaining a better bacterial recovery is greatly increased by using the described method.

is an empirical property. Tensile strength is a property of the compressed material, and it is a basic parameter which maintains consistency of property if the size of the tablet is changed (5). In an earlier report (6), the values of axial and radial tensile strengths were reported to present a directional appreciation of the strength of tablets. The purpose of the present report is to suggest that the evaluation of the axial and radial tensile strengths will characterize the strength of a tablet with more validity than hardness.

EXPERIMENTAL

The preparation of tablets and the method of measurement of the axial and radical tensile strengths of tablets by a tensiometer[1] have been reported previously (6). Tablet hardness was measured by diametral compression using a motor-driven hardness tester[2]. The maximum of the scale was 20 kp. Typical data are given in Table I. The mean hardness and the standard deviations plotted in the figures represent data for 10 tablets.

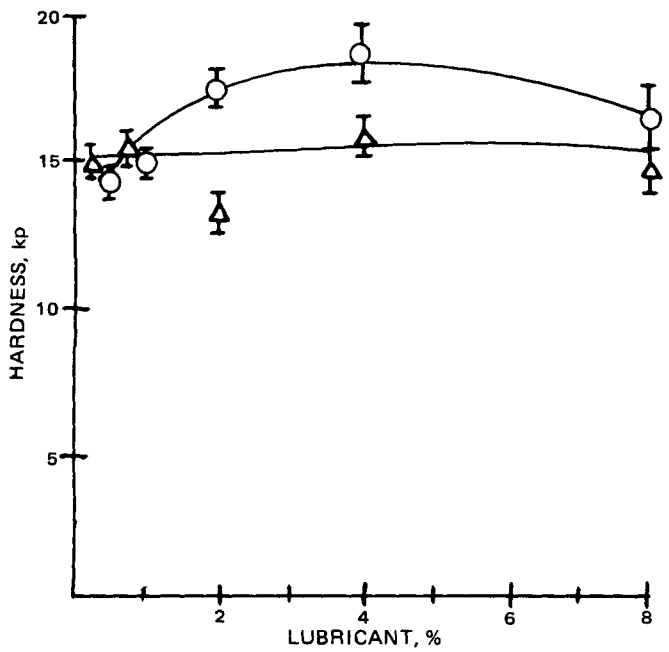

Figure 1—*The influence of the concentration of lubricant on the hardness of dibasic calcium phosphate dihydrate compressed at 2268 kg. Key: (○) hydrogenated vegetable oil; and (△) stearic acid.*

RESULTS AND DISCUSSION

Dibasic calcium phosphate dihydrate[3] and various concentrations of hydrogenated vegetable oil[4] and stearic acid were compressed at 2268 kg of force into flat-faced tablets with a 1.27-cm diameter. The hardness of the tablets was measured and plotted against the concentration of lubricant in Fig. 1. Based on the hardness values obtained by diametral compression, it is concluded that the addition of stearic acid to dibasic calcium phosphate dihydrate has no significant effect on the strength

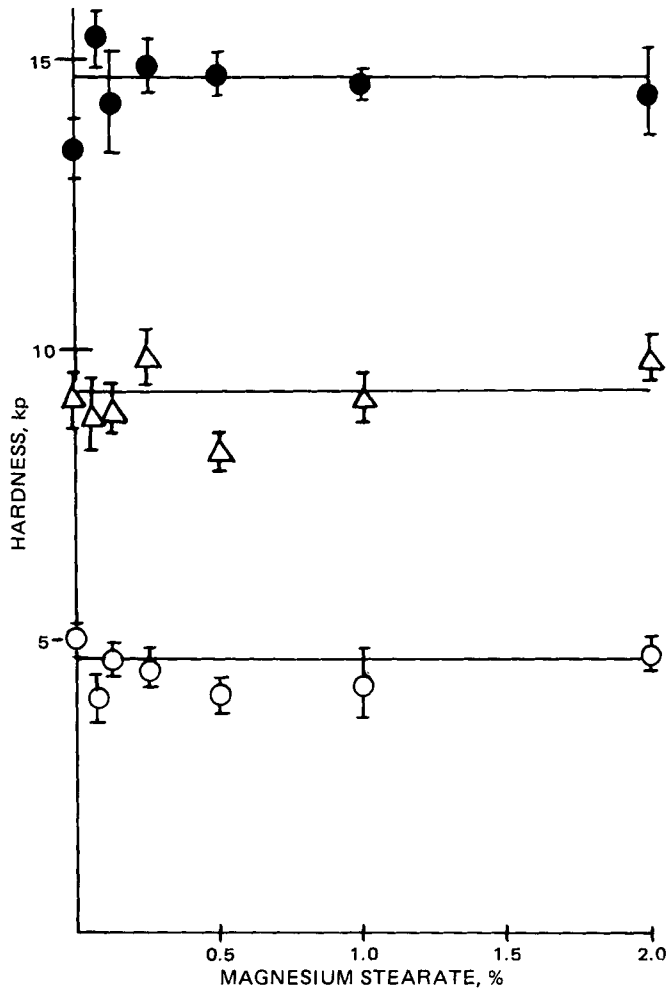

Figure 2—*The influence of the concentration of magnesium stearate on hardness of dibasic calcium phosphate dihydrate compressed at various forces. Key: (○) 454 kg; (△) 1134 kg; and (●) 2268 kg.*

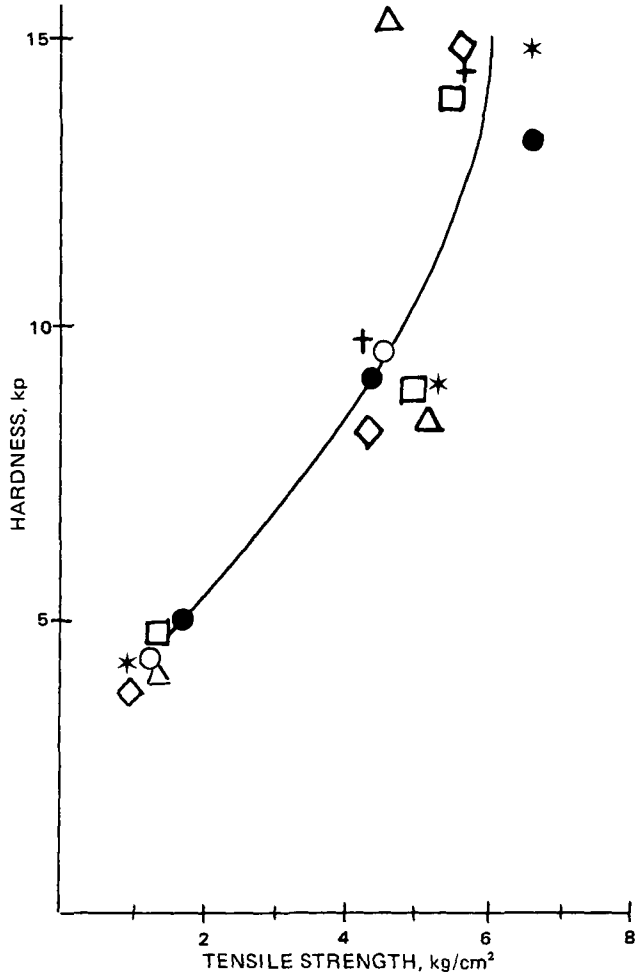

Figure 4—*The relationship of hardness and axial tensile strength for dibasic calcium phosphate dihydrate with various concentrations of magnesium stearate. Key: (●) 0%; (△) 0.075%; (□) 0.125%; (○) 0.25%; (◇) 0.5%; (★) 1.0%; and (+) 2.0%.*

of the tablet. For hydrogenated vegetable oil it appears that, as the concentration is increased to 4%, there is an increase in hardness as the concentration of lubricant is increased. A material that would lubricate and strengthen a tablet would be a useful excipient.

The wide variance in measurement may lead to erroneous conclusions. As illustrated in Fig. 1, for dibasic calcium phosphate dihydrate with hydrogenated vegetable oil, the variance in hardness may be a result of composite stresses (compressive, tensile, and shear) causing failure and minute differences in thickness of the tablets (5). In a tensile strength test, only tensile stress causes failure, and any difference in thickness is considered.

Dibasic calcium phosphate dihydrate and various concentrations of magnesium stearate were compressed at 454, 1134, and 2268 kg of force. The hardness of the tablets was measured and plotted against the concentration of lubricant in Fig. 2. Based on the hardness values obtained by diametral compression, it is concluded that the addition of magnesium stearate to dibasic calcium phosphate dihydrate has no significant effect on the strength of the tablet. As shown in Table I, the majority of the breakage was by a nontension failure. In the hardness tester, weaker tablets failed due to tensile stresses, and stronger tablets failed due to compressive stresses. For low values, the hardness is proportional to the radial tensile strength (Fig. 3).

The relationship of hardness to axial tensile strength is nonlinear as shown in Fig. 4. As the hardness is increased, at higher values of hardness, there is a progressive lessening of the rate of increase of axial tensile strength until a limiting axial tensile strength is attained. Thus, if the strength of a tablet as its hardness is considered, the axial tensile strength could be weak, and the tablet would be likely to laminate and cap under stress. If the axial tensile strength is measured, the strength in the axial direction and its implication in terms of capping are known. It appears that if both axial and radial tensile strengths are known, the strength of a tablet is basically characterized.

Structure–Activity Relationship Study of Anthraquinones: 1,4-Dihydroxy-5,8-bis[[2-(2-hydroxyethoxy)ethyl]amino]-9,10-anthracenedione, an Analog of an Established Antineoplastic Agent

ROBERT K. Y. ZEE-CHENG and C. C. CHENG

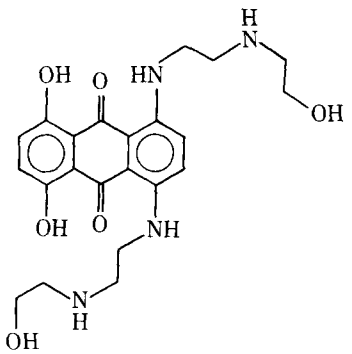
Received March 9, 1981, from the *Drug Development Laboratory, Mid-America Cancer Center, The University of Kansas Medical Center, Kansas City, KS 66103.* Accepted for publication July 20, 1981.

Abstract □ An oxygen analog of the antineoplastic anthraquinone, 1,4-dihydroxy-5,8-bis[[2-(2-hydroxyethyl)amino]ethyl]amino - 9,10 -anthracenedione, was synthesized. This compound, 1,4-dihydroxy-5,8-bis[[2-(2-hydroxyethoxy)ethyl]amino]-9,10-anthracenedione, was found to be inactive against P-388 lymphocytic leukemia. A comparative structure–activity study of these two anthraquinones in terms of previously postulated N—O—O triangulation hypothesis was discussed.

Keyphrases □ Antineoplastic agents—structure–activity relationship, 5,8-bis[[2-(2-hydroxyethoxy)ethyl]amino]-9,10-anthracenedione □ Structure–activity relationships—5,8-bis[[2-(2-hydroxyethoxy)ethyl]-amino]-9,10-anthracenedione □ Anthraquinones—antineoplastic agents, 5,8-bis[[2-(2-hydroxyethoxy)ethyl]amino] - 9,10-anthracenedione, structure–activity relationships

The importance of the nitrogen atom in the center of the side chain of 1,4-dihydroxy-5,8-bis[[2-(2-hydroxyethyl)-amino]ethyl]amino-9,10-anthracenedione (I), an outstanding antineoplastic drug, was noted previously (1, 2). Replacement of this critical nitrogen atom by other atoms, such as sulfur or carbon, resulted in compounds with no inhibitory action against leukemias P-388 or L-1210 in experimental animals (1). Based on the proposed N—O—O triangulation hypothesis (3), the structural and spatial relationship of this nitrogen atom to two oxygen atoms on the dihydroxyanthracenedione ring (I) has been correlated with that of the amino atom of daunosamine to the two oxygen functions on the aglycones of daunorubicin (II*a*) and doxorubicin (II*b*) (4, 5). The reported biological activity profile of these aminoanthraquinones and anthracycline antibiotics also has been found to be similar (5–7).

Interestingly, in recent publications, certain analogs of the anthracycline antibiotics, with the amino function of



I

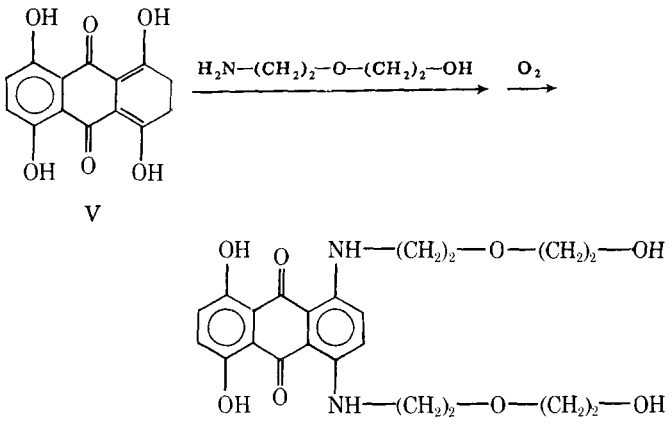
These compounds include 2′-deoxy-di-*O*-acetyl-D-ribopyranosyl-ϵ-rhodomycinone (III) (8), 7-*O*-(2,6-dideoxy-α-L-*lyxo*-hexopyranosyl)daunomycinone (IV*a*), 3′-deamino-3′-hydroxydaunorubicin) and its diacetyl derivative (IV*b*) (9), the corresponding 3′-deamino-3′-hydroxydoxorubicin analog (IV*c*) and its diacetyl derivative (IV*d*) (10), and 2′-deoxy-L-fucopyranosylcarminomycinone (IV*e*) (11). However, the dosages required for activity are generally larger than those for the established antineoplastic agents I, II*a*, and II*b*. Activity displayed by these oxygenated analogs may not always be as potent. In addition, most other glycosides synthesized by these investigators failed to show activity against P-388 or L-1210 leukemia (8–11). Nevertheless, the information suggests that the significance of the nitrogen atom of compound I should be reexamined with respect to the corresponding oxygen atom. Consequently, 1,4-dihydroxy-5,8-bis[[2-(2-hydroxyethoxy)ethyl]amino] - 9,10-anthracenedione (VI) was synthesized.

EXPERIMENTAL

Compound VI was synthesized by placing 2.75 g (0.01 mole) of purified 5,8-dihydroxyleukoquinizarin (V) in a round-bottom flask equipped with a mechanical stirrer and a condenser. To this, 10.5 g (0.1 mole) of 2-(2-aminoethoxy)ethanol was added dropwise, with stirring. The mixture was heated with stirring under nitrogen at 60° in an oil bath for 2 hr, and allowed to stand at room temperature overnight. On the next day, the stirring rod (rinsed with 100 ml of ethanol which was added into the reaction mixture) was replaced by a glass sparge tube. Dry air was bubbled through the tube into the warm (50–60°) mixture for 4 hr, during which time the top of the condenser was connected to a water aspirator so that the entire system was under a slightly reduced pressure. The mixture was chilled and the separated solid product collected by filtration, washed successively with ethanol (10 ml), petroleum ether (20 ml), and diethyl ether (2 × 20 ml), and dried to give 3.66 g (82% yield) of VI. Recrystallization from a mixture of ethanol and petroleum ether (2:1) gave analytically pure VI as dark blue crystals, mp 156–157° (Scheme I). UV: λ_{max} (ethanol) 190 (log ϵ 4.23), 214 (4.35), 232 (4.48), 270 (4.07), 380 (3.69), 512 (3.52), 563 (3.86), 610 (4.31), and 662 (4.34) nm.

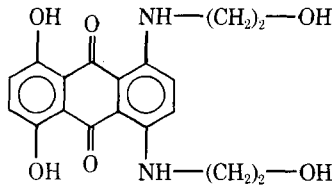


Scheme I

Anal.—Calc. for $C_{22}H_{26}N_2O_8$: C, 59.18; H, 5.87; N, 6.28. Found: C, 59.27; H, 6.03; N, 6.39.

RESULTS AND DISCUSSION

Although compound I has shown consistently outstanding antineoplastic activity in a number of experimental animal systems (1, 2, 5), compound VI was inactive against P-388 leukemia in the National Cancer Institute screening (T/C values at 200, 100, 50, and 25 mg/kg were 113, 110, 103, and 102%, respectively)[1]. This information, and the earlier negative test results of 1,4-dihydroxy-5,8-bis[(2-hydroxyethyl)amino]-9,10-anthracenedione (VII) against L-1210 leukemia (T/C values at 400, 200, and 100 mg/kg were 113, 110, and 103%, respectively), indicated that the oxygen atom (either in the form of —OH or —OR) cannot replace the particular nitrogen atom for antineoplastic activity in the aminoanthraquinone series.



VII

The relevancy of this nitrogen atom to the originally proposed N—O—O triangulation pharmacophore (3) is also reaffirmed.

Gas Chromatographic Determination of Guanabenz in Biological Fluids by Electron-Capture Detection

JOHN A. KNOWLES ˣ, GRACE R. WHITE, CONSTANCE J. KICK, TAYLOR B. SPANGLER, and HANS W. RUELIUS

Received April 16, 1981, from the *Wyeth Laboratories, Inc., Philadelphia, PA 19101.* Accepted for publication September 17, 1981.

Abstract □ A sensitive gas chromatographic method for the determination of guanabenz [(2,6-dichlorobenzylidene)amino]guanidine in urine and plasma was developed. The method depends upon the acid hydrolysis of guanabenz to 2,6-dichlorobenzaldehyde, which has strong electron capturing properties and is volatile enough to be eluted from a gas chromatographic column. Concentrations as low as 0.1 ng of guanabenz/ml can be determined and recovery of the drug from urine and plasma samples is 81.8 ± 5.5% (*SD*). No interferences arising from plasma, urine, or reagents were encountered. Examples of the application of the method are given.

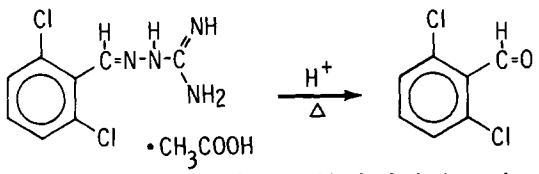
Keyphrases □ Guanabenz—gas chromatographic determination in biological fluids, electron-capture detection □ Electron-capture detection—gas chromatographic determination of guanabenz in biological fluids □ GC determination—guanabenz in biological fluids, electron-capture detection

Guanabenz, [(2,6-dichlorobenzylidene)amino]guanidine, (Scheme I) is a new agent which lowers blood pressure in hypertensive rats (1) and dogs (2), as well as in humans (3–5). When administered orally, the compound is subjected to extensive first-pass metabolism. Extensive metabolism and distribution into tissues resulted in very low concentrations of guanabenz in plasma when single oral doses, in the therapeutic range, were given to hypertensive patients (6). Thus, a highly sensitive method is required for the analysis of the drug in plasma, urine, and tissue samples derived from animal or clinical studies. Such a method, along with its application, is described in this report. Extraction of guanabenz from the sample, followed by acid hydrolysis to a volatile, strongly electron-capturing compound, led to a sensitivity of 0.1 ng/ml with an overall recovery of 81.8 ± 5.5%. No interferences stemming from reagent, urine, or plasma were observed.

EXPERIMENTAL

Materials—Sodium bicarbonate[1], sodium hydroxide[1], ether[1], toluene[1], and sulfuric acid[2] were all analytical reagent grade. The chromatographic standard, 2,6-dichlorobenzaldehyde[3], was recrystallized twice from absolute ethanol.

Extraction and Hydrolysis—The pH of a 1-ml aliquot of plasma or 0.5–3 ml urine (in a 12-ml screw-cap centrifuge tube) was adjusted to 10 by the addition of 2 ml of sodium bicarbonate–sodium hydroxide buffer (pH 10). Ether (5 ml) was added and the tube was sealed, shaken mechanically for 10 min, and then centrifuged for 5 min. Four milliliters of the ether layer was transferred to a clean centrifuge tube and the aqueous phase was re-extracted with an additional 3 ml of ether. After shaking and centrifuging the mixture, 3 ml of the ether layer was combined with the original 4 ml. The aqueous layer was discarded, and the ether extracts were shaken with 2 ml of 0.5 *N* sulfuric acid for 10 min, and centrifuged for 5 min. The ether phase was discarded by aspiration. Any residual ether was dispelled by placing the uncapped tube in a 60° water bath for 3 min prior to the addition of 2 ml of 12 *N* H_2SO_4. The tube was capped and placed in the 60° water bath. After 45 min, the tube was cooled in an ice bath, 0.1 ml of toluene was added, and the mixture was shaken for 10 min and centrifuged for 5 min. The aqueous phase was removed by a syringe aspirator, and after recentrifugation, 2–4 μl of the toluene solution was injected onto the gas chromatographic column.



Scheme I—Structure of guanabenz and its hydrolysis product, 2,6-dichlorobenzaldehyde.

Chromatography—The procedure just described resulted in the acid hydrolysis of guanabenz to 2,6-dichlorobenzaldehyde which was quantitated by electron-capture gas chromatography[4]. The glass column was 6-mm o.d. (2-mm i.d.) × 3 m and packed with 1% neopentylglycol succinate on 60/80 mesh Chromosorb G AW-DMCS[5]. Its temperature was maintained at 200°, and the flow rate of the ultra-high pure helium[6] carrier gas was 20 ml/min. The flow rate of the purge gas (argon–methane, 95:5)[6] was 30 ml/min. The temperature of the injection port was 220° and that of the electron-capture detector was 320°.

Under these conditions, the retention time of 2,6-dichlorobenzaldehyde was 2.5 min (Fig. 1) and injection of a 4-μl aliquot resulting from the extraction and hydrolysis of a 0.2-ng/ml guanabenz standard gave a peak height of 14 mm.

A response curve to check detector linearity and recovery of guanabenz was determined daily by injecting 2–4-μl aliquots of solutions consisting of 2, 5, and 10 ng of 2,6-dichlorobenzaldehyde/ml of toluene into the chromatograph and plotting peak area *versus* concentration of the solution of the aldehyde.

A calibration curve of concentration of guanabenz *versus* detector response was determined daily by adding known amounts of guanabenz (0.1, 0.5, 1.0, 5.0, and 20.0 ng/ml) to control urine or plasma and then processing these standards in the same manner as unknown samples.

RESULTS AND DISCUSSION

Standard curves, constructed daily, were linear from 0.1 to 20 ng of guanabenz/ml, the range usually encountered in clinical studies. The minimal detection limit was 0.1 ng of guanabenz/ml. Recovery of the drug from aqueous solution, spiked human plasma, rhesus monkey plasma, and urine in the 0.1–20 ng/ml range was 81.8 ± 5.5% (*SD*; $n = 154$). This recovery was determined by use of the response curve for 2,6-dichlorobenzaldehyde.

No interfering chromatographic peaks were observed (Fig. 1) after acid hydrolysis of extracts obtained from control samples collected prior to dosing. Figure 2 presents the concentration–time curve of guanabenz in the plasma of a normotensive human subject following administration of a 24-mg oral dose of the drug.

The highly selective, sensitive, and accurate method, developed for the quantitation of guanabenz in biological fluids, depends on the hy-

drolysis of the drug to 2,6-dichlorobenzaldehyde, a volatile compound which has strong electron-capturing properties. No 2,6-dichlorobenzaldehyde was found as a metabolite in plasma samples. If any were present, it would not interfere with the determination of guanabenz as it would be separated from the drug during the back extraction into dilute sulfuric acid.

This procedure is sensitive enough to enable concentrations as low as 0.1 ng/ml to be determined. This sensitivity permitted the determination of the very low drug concentrations in human plasma resulting from therapeutic doses and the calculation of pharmacokinetic parameters from these data (6). Furthermore, guanabenz was measured in rat brain (7) and in urine and plasma of rhesus monkeys (8).

An internal standard was not used in the procedure, because no compound could be found that would have extraction and hydrolysis characteristics similar to those of guanabenz when added to an unknown sample. The day-to-day variation of the method was <7%. No interferences from plasma, urine, or reagents were encountered. For standards containing 0.1 ng of guanabenz/ml, the recovery for 0.1 ng/ml was 82.6 ± 9.2% (*SD*); for 5 ng/ml, 81.6 ± 5.1%; and for 20 ng/ml, 81.1 ± 6.5%. These data, which were calculated from the detector response given by known amounts of 2,6-dichlorobenzaldehyde, demonstrate good recovery of the drug and high precision of the method.

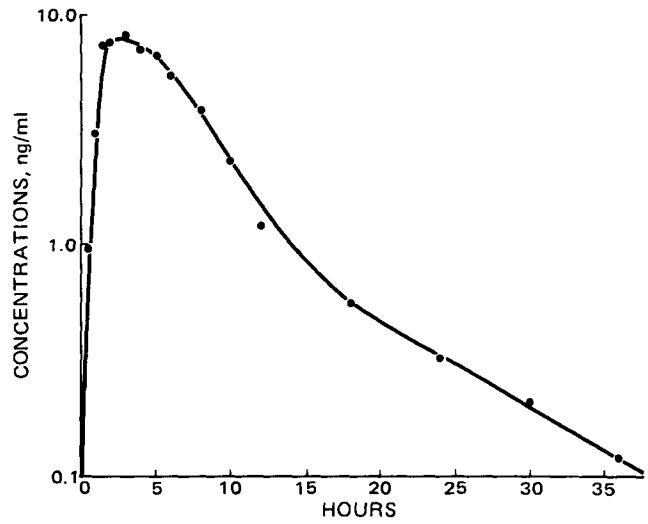

Figure 2—*Concentrations of guanabenz* versus *time in the plasma of a healthy subject after oral administration of 24 mg of guanabenz.*

The Measurement of Theophylline Metabolism in Hepatic Microsomes Using High-Performance Liquid Chromatography

THERESA C. HEMSWORTH and KENNETH W. RENTON ˣ

Received May 11, 1981 from the *Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.* Accepted for publication September 11, 1981.

Abstract □ A method is described to measure the *in vitro* metabolism of theophylline by liver microsomes. The formation of 1-methyluric acid and 1,3-dimethyluric acid in incubation mixtures was determined by high-performance liquid chromatography. The formation of both metabolites was linear with time and the formation of 1-methyluric acid was blocked by allopurinol. This method will be useful in assessing potential drug interactions involving theophylline.

Keyphrases □ Theophylline—metabolism in hepatic microsomes, high-performance liquid chromatographic measurement □ Microsomes, hepatic—measurement of theophylline metabolism, high-performance liquid chromatography □ High-performance liquid chromatography—measurement of theophylline metabolism in hepatic microsomes □ Metabolism—theophylline in hepatic microsomes, high-performance liquid chromatography

Theophylline (1,3-dimethylxanthine) is a widely used antiasthmatic drug which is metabolized by hepatic microsomal enzymes (1). The use of theophylline can be problematic because of the narrow therapeutic range of serum concentrations and because of the large number of factors which can alter its metabolism and ultimate elimination (2). An *in vitro* system to study theophylline metabolism would be a useful technique to examine and define many of the factors which alter the elimination of this drug. Such a method for the study of radiolabeled theophylline has been described previously (3), but this technique was successful only with liver slices or with microsomes from animals previously induced with 3-methylcholanthrene. The present report discusses an improved method for the determination of theophylline metabolism in normal liver microsomes using high-performance liquid chromatography to quantitate the metabolites.

EXPERIMENTAL

Reagents and Chemicals—Theophylline[1], theobromine[1], 1,3-dimethyluric acid[1], 8-chlorotheophylline[1], and 1-methyluric acid[2] were used as received.

Chromatography—A liquid chromatograph[3] with reciprocating dual-piston constant flow rate pump and rotary valve injector[4] was equipped with a 20-μl loop, HPLC reversed-phase column[5], variable wavelength UV detector[6], and recorder[7]. The mobile phase contained 0.01 *M* sodium acetate–1% acetic acid–methanol (64:21:15, v/v/v). The solvent was degassed before use. Mobile phase flow rate was 0.4 ml/min.

Calibration Curves—Standard solutions which contained 0.10–10 μg/ml of 1-methyluric acid or 0.25–25 μg/ml of 1,3-dimethyluric acid and 100 μg/ml of 8-chlorotheophylline or 20 μg/ml of theobromine as internal standard were extracted and chromatographed in an identical manner to the incubation mixtures. Standard curves were linear throughout the range utilized.

Microsomal Biotransformation—Microsomes (3 mg of protein) were incubated in media (3) containing 50 m*M* tromethamine hydrochloride pH 7.5, 5 m*M* $MgCl_2$, 10 m*M* D-glucose-6-phosphate, 1 m*M* triphosphopyridine nucleotide, 10 U glucose-6-phosphate dehydrogenase, and 0.25 m*M* theophylline in a total volume of 3 ml. Incubations were carried out at 37° in a metabolic shaking water bath[8]. After 2 hr of incubation the mixture was placed on ice and 100 μg/ml of 8-chlorotheophylline was added. The incubation mixture was then extracted with 3 ml of chloroform–isopropanol (90:10, v/v) for 30 min to remove unmetabolized theophylline. The aqueous layer was dried in a stream of air and then reconstituted in a 100-μl HPLC mobile phase for chromatography using 295 nm for detection.

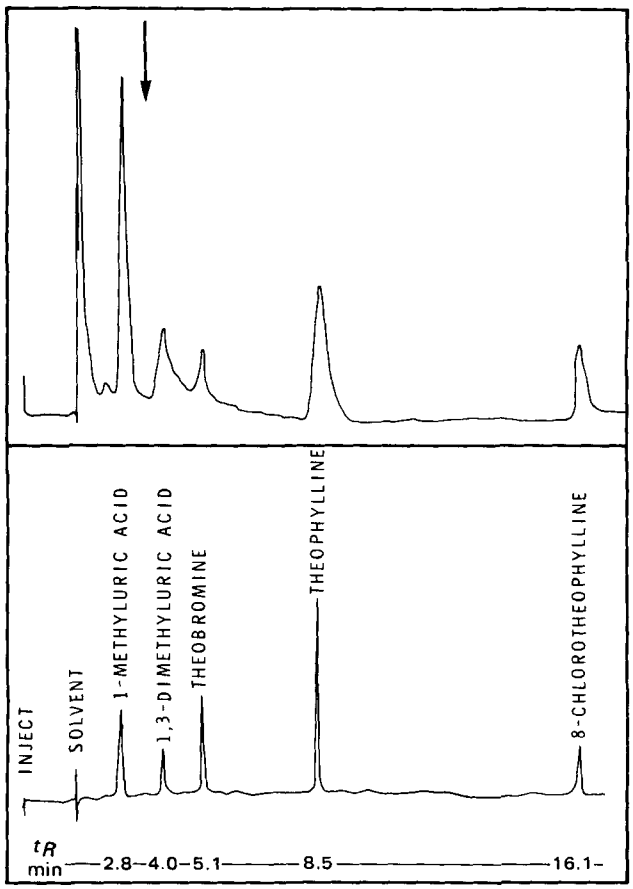

Figure 1—*HPLC for theophylline metabolites and internal standards. HPLC of extracted liver microsomes incubated with theophylline (upper). HPLC of 1-methyluric acid, 1,3-dimethyluric acid, theobromine, theophylline, and 8-chlorotheophylline standards (lower).*

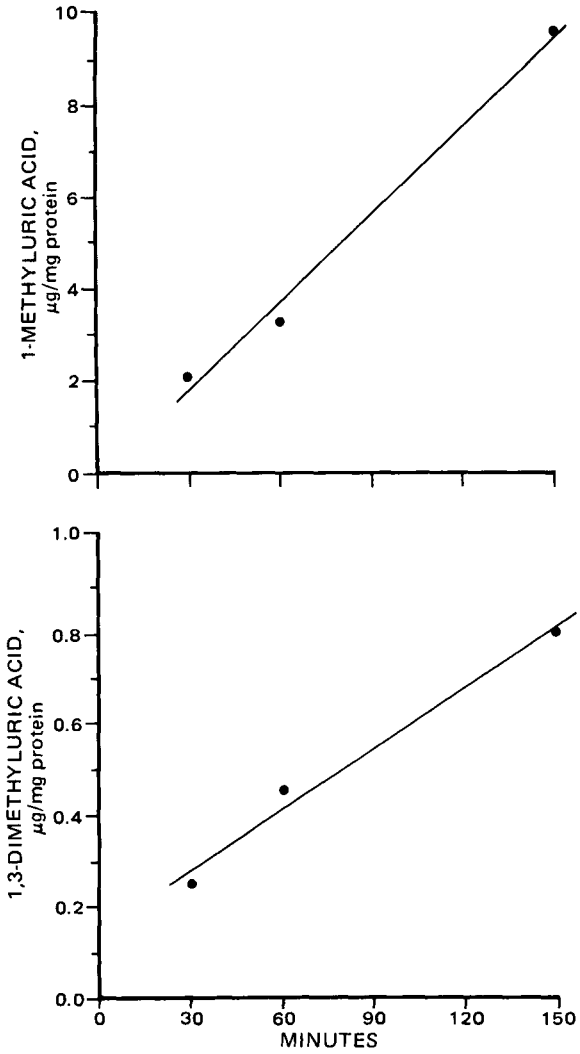

Figure 2—*Effect of increasing incubation time on production of 1-methyluric acid and 1,3-dimethyluric acid. The production of 1-methyluric acid (upper) and 1,3-dimethyluric acid (lower) from theophylline in microsomes prepared from rabbit liver were determined at 30, 60, and 150 min of incubation in a metabolic shaking water bath*[8].

Microsomes—Hepatic microsomes were prepared from rabbits using ultracentrifugation (4). Microsomal protein was determined by the method of Lowry using bovine serum albumin as a standard (5).

RESULTS AND DISCUSSION

A chromatogram of a hepatic microsomal incubation mixture demonstrated a clear separation of peaks for 1-methyluric acid, 1,3-dimethyluric acid, theophylline, theobromine, and 8-chlorotheophylline and is compared to a chromatogram of standards in Fig. 1. The production of 1-methyluric acid and 1,3-dimethyluric acid from theophylline by hepatic microsomes was determined to be linear for at least 150 min of incubation time (Fig. 2). A 2-hr incubation period was determined to give adequate amounts of metabolite for most experimental purposes. The amount of metabolites formed *in vitro* by rabbit liver microsomal enzyme metabolism of theophylline was 0.17 ± 0.04 μg of 1,3-dimethyluric acid/mg of protein/hr and 1.08 ± 0.58 μg of 1-methyluric acid/mg of protein/hr. Each value represents the mean ± standard error of microsomal preparations from four individual animals. The production of 3-methylxanthine from theophylline could not be detected in these incubation mixtures.

Table I—*In Vitro* Effect of Allopurinol[a] on *In Vitro* Theophylline Metabolism in Rabbits

	Control	Allopurinol[a]
1,3-Dimethyluric acid, μg/mg of protein/hr	0.04[b]	0.04
1-Methyluric acid, μg/ml of protein/hr	2.66	Not detectable

[a] 10^{-4} *M* allopurinol was added to microsomal incubation mixture. [b] Each value represents an individual incubation mixture using microsomes from the same control animal.

Allopurinol has been reported to decrease production of 1-methyluric acid from 1-methylxanthine (6, 7) by inhibiting xanthine oxidase. In this preparation, the addition of allopurinol (10^{-4} *M*) to the incubation mixture blocked production of 1-methyluric acid (minimum detectable limit 0.015 μg/mg of protein/hr) while not affecting production of 1,3-dimethyluric acid (Table I). This confirms that in this incubation system, 1-methyluric acid was being produced along the predicted metabolite route.

This method for the measurement of the metabolism of theophylline using an *in vitro* microsomal preparation does not require previous induction of hepatic microsomes and provides a rate of formation of specific major metabolites of theophylline. Use of this method can determine whether a change in theophylline elimination is due to specific changes in metabolite production and will also be useful in the investigation, assessment, and prediction of drug interactions involving alterations of theophylline metabolism.

Batch-Swirl Method for Detoxification of Isopropyl Myristate Used for Sterility Testing of Oils and Ointments: Membrane Selection

A. M. PLACENCIA ˣ, G. S. OXBORROW, and J. W. DANIELSON

Received July 23, 1981, from the *Minneapolis Center for Microbiological Investigations, Food and Drug Administration, Minneapolis, MN 55401.* Accepted for publication September 21, 1981.

Abstract □ A 1-hr batch-swirl method was developed for the preparation of isopropyl myristate to be used in the sterility testing of oils and ointments. The method is simpler and faster than that in *USP XX*. Flow rates of various membrane filters were tested. Cellulose acetate filters increased the filtration rate of oils and ointments and, thus, reduced the exposure time of possible microbial contaminants to the toxicity of isopropyl myristate.

Keyphrases □ Isopropryl myristate—batch-swirl method for detoxification, sterility testing of oils and ointments □ Microbial contamination—batch-swirl method for detoxification of isopropyl myristate used for sterility testing of oils and ointments □ Toxicity—batch-swirl method for detoxification of isopropyl myristate, sterility testing of oils and ointments

Problems are encountered when the *United States Pharmacopeia XX* (USP XX) method is used for the sterility testing of ointments and oils soluble in isopropyl myristate (1). Commercially prepared isopropyl myristate, which is used to dissolve the specimen, is toxic to microorganisms. It was found that the toxicity of isopropyl myristate is partially due to its pH variability, *i.e.*, the higher the pH of isopropyl myristate, the higher the decimal reduction (D value) of *Pseudomonas aeruginosa* (2, 3).

Heated isopropyl myristate has also been shown to be toxic to vegetative microorganisms during prolonged holding temperatures at 47° (3–5). Detoxification of isopropyl myristate by the USP method, which takes more than 8 hr to complete, makes the analysis time-consuming.

USP XX requires rinsing of the membrane with fluids A and D after a sample is filtered. However, after filtration of isopropyl myristate, the mixed cellulose acetate–pyroxylin membrane becomes hydrophobic and the water-based fluids, A and D, are difficult to filter.

Studies have indicated that the D value of *P. aeruginosa* is lower if the microorganisms are filtered through a 0.2-μm membrane rather than through a 0.45-μm membrane. The slower filtration rate of the 0.2-μm filter exposes the microorganisms to the isopropyl myristate for a longer time. Other authors have indicated that the use of the conventional membrane filtration technique may be the cause of low recovery rates of *P. aeruginosa* from oils or ointments (3, 6).

The present report describes a 1-hr batch-swirl method for the detoxification of isopropyl myristate and compares membrane filters used in the analysis of oils and ointments.

EXPERIMENTAL

Three methods for preparation of isopropyl myristate were compared:

Batch-Swirl Method—A 50-g amount of basic alumina (Brockman Activity 1, 80–200 mesh[1]) was weighed in a 1-liter glass beaker, and 500 ml of isopropyl myristate (detyl NF extra-isopropyl myristate NF[2]) was added. The beaker was covered with aluminum foil, and the mixture was swirled at high speed for 1 hr with a magnetic stirrer. The mixture was filter-sterilized through a 0.22-μm filter membrane (mixed cellulose acetate–pyroxylin, 47-mm diameter) and a disk prefilter[3]. Aliquots of 100 ml of filtrate were transferred to sterile 38 × 200-mm screw-capped glass test tubes for toxicity determinations.

USP XX Column-Filtered Method—Basic alumina was added to a 20 mm × 20-cm glass column to a height of 15 cm (54 g), 500 ml of isopropyl myristate was passed through the column, and the eluate was filter-sterilized as in the batch-swirl method.

Untreated Isopropyl Myristate—A 500-ml sample of isopropyl myristate obtained directly from the manufacturer was filter-sterilized as in previous methods.

pH Determination of Isopropyl Myristate—The pH of isopropyl myristate prepared for the three methods was determined after sterilization by the USP XX method, which uses the water rinse technique. A sample containing 100 ml of isopropyl myristate and 10 ml of double distilled water was transferred to a 250-ml container. The mixture was shaken vigorously for 1 hr by a mechanical shaker, then centrifuged for 20 min at 1800 rpm (529×*g*). The water layer was used to determine the pH.

Bacterial Culture Preparation—*Pseudomonas aeruginosa* (ATCC 10145) was used as a test microorganism because of its sensitivity to isopropyl myristate (4, 7). The culture was transferred to a trypticase soy agar slant and incubated for 24 hr at 35°. The slant was washed with sterile phosphate buffer and the final concentration of 10^9 organisms/ml was used as the stock solution for inoculation of isopropyl myristate.

D Value Determinations—Two test tubes, each containing 100 ml of isopropyl myristate, were prepared according to the previously described methods. A control tube of phosphate-buffered water was used to determine the initial bacterial concentration. Tubes were inoculated with 0.1 ml of stock culture solution, and all tubes were vigorously hand-shaken. One tube of isopropyl myristate from each preparation method was placed in a 47° water bath. Ten-milliliter samples were taken from each tube of isopropyl myristate at intervals of 10, 20, 30, 45, and 60 min and at 0-time from the buffered water control tube.

Aliquots were filtered through a 0.22-μm membrane[3], and membranes were transferred to 100 ml of fluid D before sonification for 6 min at 55 kHz. Dilutions were plated on trypticase soy agar and incubated at 35° for 48 hr.

Membrane Filter Evaluation—Time rates to filter the isopropyl myristate and the rinsing fluids, A and D, through various membranes (47-mm diameter, 0.2- and 0.45-μm pore sizes) were determined by placing the membrane in a membrane filtration assembly unit and filtering 100 ml of isopropyl myristate, followed by 200 ml of rinsing fluid D and 100 ml of fluid A.

B	3.7	10.0	<10.0

Table II—Comparison of Flow Rates for Membrane Filters Used in the Filtration of Oils and Ointments

Membranes	Flow Rate, min[a]: Isopropyl Myristate 0.2 μm[b]	Isopropyl Myristate 0.45 μm[b]	Fluids A and D 0.2 μm[b]	Fluids A and D 0.45 μm[b]
Acetate Cellulose	2	1	3	1
Cellulose Nitrate	3	1	>120	20
Polyester	2	1	5	2
Mixed Esters of Cellulose	3	1	83	2
Polycarbonate	4	1	14	3
Mixed Cellulose Acetate–Pyroxylin	3	1	>120	19

[a] Approximate time. [b] Pore size of membrane.

RESULTS

The pH levels of the untreated isopropyl myristate, the USP XX column isopropyl myristate, and the batch-swirled isopropyl myristate are shown in Table I. The D values of *P. aeruginosa* obtained at room temperature and at 47°, which correspond to the three methods of preparation of isopropyl myristate, are also shown.

The approximate time required to filter isopropyl myristate and the rinsing fluids, A and D, through various membranes are given in Table II. The acetate cellulose membrane[4] and the polyester membrane[5] showed the fastest flow rates for the 0.2-μm membrane: 2 min for isopropyl myristate with both filters and 3 and 5 min, respectively, for rinsing fluids A and D. An oily film was noted on the polyester membrane after filtration of the isopropyl myristate and rinsing fluids A and D, regardless of pore size.

The flow rates of both the 0.2-μm mixed cellulose acetate–pyroxylin and the pyroxylin membranes exceeded 2 hr for the rinsing fluids. All of the 0.45-μm membranes had acceptable flow rates for isopropyl myristate. Flow rates for the rinsing fluids (pyroxylin, 20 min and cellulose acetate-pyroxylin, 19 min) were not acceptable.

DISCUSSION

The batch-swirl method for detoxification of isopropyl myristate used in the analysis of oils and ointments was simpler and faster than the USP XX method, *i.e.*, 1 hr *versus* 8 hr for the detoxification process. In the batch-swirl method, filter sterilization immediately followed the stirring, with no need for centrifugation. The pH of the isopropyl myristate prepared by the batch-swirl method met the requirements of the USP XX, and D values of the test organisms were comparable to those obtained by the USP XX method.

Use of cellulose acetate filters rather than 0.22- and 0.45-μm mixed cellulose acetate-pyroxylin membranes reduced the analysis time. Rapid filtration reduced the exposure time of microbial contaminants to the toxicity of isopropyl myristate and, thus, provided greater probability of their detection.

Synthesis and Antitumor Testing of 3-Methenylthiochroman-4-one-1,1-dioxide

MARK H. HOLSHOUSER *x and LARRY J. LOEFFLER

Received July 6, 1981 from the *Division of Medicinal Chemistry, School of Pharmacy, The University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication September 18, 1981.

* Present address: Department of Medicinal Chemistry, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Abstract □ Treatment of thiochroman-4-one-1,1-dioxide (II) with paraformaldehyde and dimethylamine hydrochloride in isopropyl alcohol at reflux afforded directly in 89% yield the dimeric dihydropyran (IV), corresponding to the dimerization of the target compound 3-methenylthiochroman-4-one-1,1-dioxide (III). Neither the monomer III nor the expected Mannich base, 3-dimethylaminomethylthiochroman-4-one-1,1-dioxide, were isolated under conditions of the reaction. The monomer III could be prepared in 55% yield by sublimation of the dimer IV at 230–250°; however, redimerization slowly occurred at room temperature. The dimer IV was also prepared by the use of paraformaldehyde and *N*-methylanilinium trifluoroacetate. The monomer III was found to be marginally active at 10 mg/kg/day *versus* Ehrlich ascites tumor growth in mice.

Keyphrases □ Antitumor agents—3-methenylthiochroman-4-one-1,1-dioxide, synthesis, testing, dimerization, mice □ α-Methenyl carbonyl function—alkylating moiety in some antitumor agents, synthesis of 3-methenylthiochroman-4-one-1,1-dioxide

The presence of a ring system containing an α-methenyl carbonyl function is important as an alkylating moiety in some antitumor agents (1–5). So called quinone methides (1–3), α-methenyl derivatives of quinones, are thought to be active metabolic intermediates in alkylation mechanisms. In general, the stability of the α-methenyl carbonyl

All of the 0.45-μm membranes had acceptable flow rates for isopropyl myristate. Flow rates for the rinsing fluids (pyroxylin, 20 min and cellulose acetate-pyroxylin, 19 min) were not acceptable.

DISCUSSION

The batch-swirl method for detoxification of isopropyl myristate used in the analysis of oils and ointments was simpler and faster than the USP XX method, *i.e.*, 1 hr *versus* 8 hr for the detoxification process. In the batch-swirl method, filter sterilization immediately followed the stirring, with no need for centrifugation. The pH of the isopropyl myristate prepared by the batch-swirl method met the requirements of the USP XX, and D values of the test organisms were comparable to those obtained by the USP XX method.

Use of cellulose acetate filters rather than 0.22- and 0.45-μm mixed cellulose acetate-pyroxylin membranes reduced the analysis time. Rapid filtration reduced the exposure time of microbial contaminants to the toxicity of isopropyl myristate and, thus, provided greater probability of their detection.

Synthesis and Antitumor Testing of 3-Methenylthiochroman-4-one-1,1-dioxide

MARK H. HOLSHOUSER *x and LARRY J. LOEFFLER

Received July 6, 1981 from the *Division of Medicinal Chemistry, School of Pharmacy, The University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication September 18, 1981.

* Present address: Department of Medicinal Chemistry, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

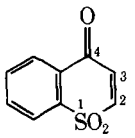
Abstract □ Treatment of thiochroman-4-one-1,1-dioxide (II) with paraformaldehyde and dimethylamine hydrochloride in isopropyl alcohol at reflux afforded directly in 89% yield the dimeric dihydropyran (IV), corresponding to the dimerization of the target compound 3-methenylthiochroman-4-one-1,1-dioxide (III). Neither the monomer III nor the expected Mannich base, 3-dimethylaminomethylthiochroman-4-one-1,1-dioxide, were isolated under conditions of the reaction. The monomer III could be prepared in 55% yield by sublimation of the dimer IV at 230–250°; however, redimerization slowly occurred at room temperature. The dimer IV was also prepared by the use of paraformaldehyde and *N*-methylanilinium trifluoroacetate. The monomer III was found to be marginally active at 10 mg/kg/day *versus* Ehrlich ascites tumor growth in mice.

Keyphrases □ Antitumor agents—3-methenylthiochroman-4-one-1,1-dioxide, synthesis, testing, dimerization, mice □ α-Methenyl carbonyl function—alkylating moiety in some antitumor agents, synthesis of 3-methenylthiochroman-4-one-1,1-dioxide

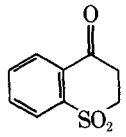
The presence of a ring system containing an α-methenyl carbonyl function is important as an alkylating moiety in some antitumor agents (1–5). So called quinone methides (1–3), α-methenyl derivatives of quinones, are thought to be active metabolic intermediates in alkylation mechanisms. In general, the stability of the α-methenyl carbonyl

0022-3549/82/0600-0715$01.00/0

function is variable, depending on substitution (3). In working with novel compounds containing the thiochromone-1,1-dioxide (I) and thiochroman-4-one-1,1-dioxide (II) ring systems (6), it became desirable to synthesize the 3-methenyl derivative (III) (Scheme I), the sulfone analog of a naphthoquinone methide, as a potential antitumor agent of the alkylating type and a possible active metabolite of previously reported compounds (6). The synthesis, testing, and dimerization of III is the subject of this study.



I



II

EXPERIMENTAL[1]

Sulfone Dimer (IV) (Method A)—Compound IV was formed by a modification of the method of Welch, *et al.* (7). A suspension of 7.76 g (39.6 mmoles) of II, 2.86 g (35.6 mmoles) of dimethylamine hydrochloride, 2.5 g (30 mmoles) of paraformaldehyde, and 0.72 ml of saturated hydrogen chloride–isopropyl alcohol solution in 25 ml of isopropyl alcohol was refluxed for 24 hr at 75°. At the end of this period a fine, white precipitate had formed. The suspension was cooled, filtered, and the solid washed with isopropyl alcohol and ether, then recrystallized from dimethylformamide. A white powder resulted with a melting point of 249–250° (yield 7.5 g, 89%).

Anal.—Calc. for $C_{20}H_{18}O_6S_2$: C, 57.39; H, 4.34. Found: C, 57.45; H, 4.22. IR: 1700 (C=O), 1300 (S=O, antisymmetrical), 1145 (S=O, symmetrical) cm^{-1}; NMR (acetone-d_6): δ 2.52 (s, 2, —C—CH_2—C—), 2.83 (s, 2, —OCH_2—), 4.10 (s, 2, 2′H), 4.39 [s, 2, 2 (II)], 7.57–8.30 (m, 8, 5–8H, 5′–8′H) ppm.

Sulfone Dimer IV (Method B)—Compound IV was also synthesized by a modification of the method of Gras (8). Paraformaldehyde (1.08 g, 12 mmoles), *N*-methylanilinium trifluoracetate (2.25 g, 10 mmoles), and (II) (1.96 g, 10 mmoles) were added to 12 ml of dioxane (dried over potassium hydroxide, then distilled from sodium metal). The mixture was refluxed for 2 hr under nitrogen, cooled, and 1.125 g (5 mmoles) of *N*-methylanilinium trifluoracetate, 0.54 g (6 mmoles) of paraformaldehyde, and 16 ml of dioxane were then added. The mixture was refluxed an additional 2 hr, allowed to cool, then extracted with chloroform, washed with a 2.5% sodium bicarbonate solution, dried over magnesium sulfate, and evaporated. The resulting white powder was dissolved in dimethyl sulfoxide and crystals formed as water was added. The product was collected and dried *in vacuo* at 100°, yielding 500 mg, 30%.

3-Methenylthiochroman-4-one-1,1-dioxide (III)—Compound IV, the dimer, (200 mg, 0.48 mmole) was placed in a sublimation apparatus and sublimed at 230–250° (1 mm Hg). On the condenser appeared a mixture of Compounds III and IV. Compound III could be purified by either repeated sublimation or column chromatography on silica gel eluted with chloroform, the monomer III eluting before the dimer IV. On immediate solvent evaporation and freezing in a desiccator, compound III remains relatively stable; yield: 110 mg (55%) observed mp 248–250°. TLC: silica gel, $CHCl_3$, R_f = 0.26. IR: 1699 (C=O), 1665 (C=C, conjugated), 1300 (S=O, antisymmetrical), 1145 (S=O, symmetrical) cm^{-1}; NMR ($CDCl_3$): δ 4.42 (s, 2,2H), 5.89 (d, 1, J = 1 Hz, =CH_2), 6.65 (d, 1, J = 1 Hz, =CH_2), 7.5–8.32 (m, 4, 5–8H) ppm.

***In Vivo* Ehrlich Ascites Screen**—All test compounds were homogenized in 0.05% polysorbate 80 and administered in doses ranging from 5 to 20 mg/kg/day ip. Tumor cells (2×10^6) were injected into CF_1 male mice (~25 g) on day 0 (n = 6). Test compounds were administered intraperitoneally on days 1–8. On day 9 the mice were sacrificed and peritoneal ascites cell volume and packed cell volume (ascites-crit) were determined by the method of Piantadosi *et al.* (9). Results of this screen are reported as percent inhibition calculated by the following:

$$\% \text{ inhibition} = 100 - \left[\frac{(\text{vol of treated})(\text{ascrit of treated})}{(\text{vol of control})(\text{ascrit of control})}\right] \times 100 \quad \text{(Eq. 1)}$$

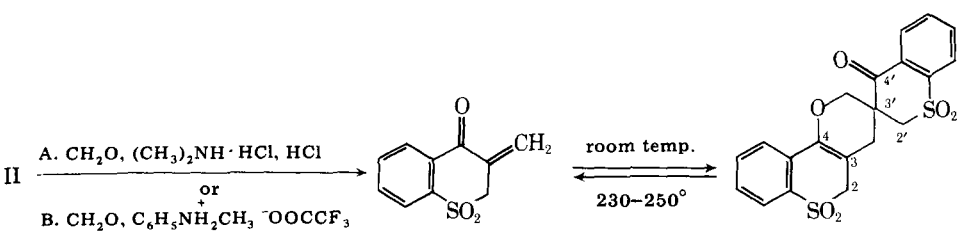
6-Mercaptopurine was used as an internal standard. Six to eight mice were used per test compound, and >80% inhibition was considered significant.

RESULTS AND DISCUSSION

The classical synthetic approach to compound III involves Mannich base formation alpha to the carbonyl of II followed by base-catalyzed amine elimination. However, attempts to form the Mannich base (7) of II using dimethylamine hydrochloride and paraformaldehyde under acidic conditions (*i.e.*, the acid-catalyzed enol of II serving as a nucleophile) afforded an insoluble high-melting neutral product which was identified by NMR as the dihydropyran type dimer, IV (Scheme I). Compound IV resulted from the initially formed III, the desired product, which was formed either by spontaneous amine elimination (7) from the Mannich base or direct reaction with the hydroxycarbenium ion of protonated formaldehyde with no involvement of the amino species (10). Subsequently, a Diels-Alder type 1,4-addition of one molecule of III to the exomethylene group of another molecule of III occurred, forming the dihydropyran ring system of IV. High temperature was required to reverse the dimerization. Formation and subsequent isolation of III was accomplished by sublimation of IV at 230–250° (1 mm Hg), followed by rapid column chromatography of the material appearing on the condenser. Good yields of IV were obtained from II (89%), however, a poorer yield of III (55%) resulted in the reversal step. Furthermore, at room temperature and/or in the presence of solvent, III redimerized completely within 48 hr. The identical observed melting points for III and IV (248–250°) resulted from redimerization of III on slow heating, as indicated by TLC.

Specific reagents for preparing α-methenyl ketones provided an alternate method for the synthesis of III (8, 11, 12). Use of one of these agents, *N*-methylanilinium trifluoracetate (8) afforded IV as well. In anticipation of the same result, no other reagent was tried. It was of interest that this 3-exomethylene derivative of III is isolable in the thiochroman-4-one-1,1-dioxide series. This appeared not to be the case with the naphthoquinone methides previously generated, which required trapping (3). Isolability of such a reactive intermediate as III opens a route to the synthesis of a wide variety of novel 3-substituted thiochroman-4-one-1,1-dioxides *via* Michael, Diels-Alder, or 1,3-dipolar type reactions.

Freshly prepared and analyzed compound III, immediately tested at



Scheme I

[1] All melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. TLC was performed on precoated plates (silica gel 60-F-254, EM reagents) with fluorescent backing. The plates were visualized by UV light. Elemental analyses were done by Atlantic Microlab, Atlanta, Ga., and agreed with theoretical values within ±0.4%.

Infrared spectra were obtained in NUJOL using a Perkin-Elmer Model 297 IR spectrophotometer. Photon NMR spectra were taken on a JEOLCO JNM-FX60 using tetramethylsilane as an internal standard. All IR and NMR spectra were completely consistent with assigned structures. Starting materials were used as received from suppliers unless otherwise indicated.

Table I—Effects of Test Compounds on Ehrlich Ascites Carcinoma[a] Growth

Compound	Dose, mg/kg/day ip	Survival at Day 9	Ascrit[b]	Ascites Volume, Mouse	Inhibition[c], %

IV	10	6/6	21.2	2.2	0.0
6-Mercaptopurine[e]	200	6/6	0.3	0.7	99.6

[a] 2×10^6 cells were injected intraperitoneally into 6 or 8 male CF_1 mice on day 0. The drug was administered from day 1 to 8. On day 9 the mice were sacrificed and the experiment was evaluated. [b] Packed cell volume as a percent. [c] Greater than 80% inhibition is required for significant activity. [d] Compound V is 3-chloromethylthiochromone-1,1-dioxide (6). [e] Sigma Chemical Co.

10 mg/kg/day in mice, *versus* Ehrlich ascites carcinoma tumor growth, was found to be only marginally active (80% inhibition of tumor growth) relative to many other compounds reported previously (6) (Table I). Several of these compounds, such as 3-chloromethylthiochromone-1,1-dioxide (V) (highly active in the test, giving 100% inhibition), could conceivably give rise to compound III *in vivo* by bioreduction and hydrogen chloride elimination (1, 3). The low activity observed with compound III may result from *in vivo* dimerization or other instability such as participation in Michael type reactions. The dimer (IV) was completely inactive in the antitumor test (Table I).

Diazoketone and Chloromethylketone Analogs of Methotrexate as Potential Antitumor Agents

ALEEM GANGJEE *, THOMAS I. KALMAN, and THOMAS J. BARDOS ˣ

Received June 25, 1981, from the *Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260.* Accepted for publication September 24, 1981. *Present address: Department of Pharmaceutical Chemistry and Pharmaceutics, School of Pharmacy, Duquesne University, Pittsburgh, PA 15282.

Abstract □ The synthesis of 4-amino-4-deoxy-N^{10}-methylpteroyl-(6-diazo-5-oxo)-L-norleucine and 4-amino-4-deoxy-N^{10}-methylpteroyl-(6-chloro-5-oxo)-L-norleucine, analogs of methotrexate in which the γ-carboxyl group is replaced by a diazoketone and a chloromethylketone, respectively, was carried out. The analogs inhibited the growth of leukemia L-1210 cells in culture by 50% at 4×10^{-7} *M* and 2×10^{-7} *M*, respectively, and were effective inhibitors of the synthesis of thymidylate in L-1210 cells *in vitro* ($I_{50} = 3 \times 10^{-6}$ *M*), exhibiting significant antifolate activity. The results demonstrated the feasibility of introducing chemically reactive groups at the γ-position of pteroyl glutamates with retention of biological activity. However, in the systems investigated thus far, there was no evidence of covalent bond formation due to these reactive groups at the active sites of the enzymes.

Keyphrases □ Methotrexate—diazoketone and chloromethylketone as potential antitumor agents □ Antitumor agents—potential, diazoketone and chloromethylketone analogs of methotrexate □ Analogs—diazoketone and chloromethylketone, of methotrexate, potential antitumor agents

Many structural analogs of the clinically useful antitumor agent methotrexate (4-amino-4-deoxy-N^{10}-methylpteroyl-L-glutamic acid, amethopterin) (1), modified at the carboxyl groups of its glutamic acid moiety, have been prepared in the past in attempts to alter the membrane transport properties and to improve the tissue distribution and selectivity of the drug, as well as to circumvent drug resistance. This class of methotrexate derivatives includes a variety of α- and γ-monoesters (2), diesters (3), amides (4), and peptides (4, 5) and also analogs in which the carboxyl groups are replaced by hydrogen (6–8), hydroxymethyl, or methyl (9) groups. As was observed for methotrexate analogs modified at other parts of the molecule (8, 10), with the possible exception of 10-deazaaminopterin

Diazoketone and Chloromethylketone Analogs of Methotrexate as Potential Antitumor Agents

ALEEM GANGJEE *, THOMAS I. KALMAN, and THOMAS J. BARDOS ˣ

Received June 25, 1981, from the *Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260.* Accepted for publication September 24, 1981. *Present address: Department of Pharmaceutical Chemistry and Pharmaceutics, School of Pharmacy, Duquesne University, Pittsburgh, PA 15282.

Abstract □ The synthesis of 4-amino-4-deoxy-N^{10}-methylpteroyl-(6-diazo-5-oxo)-L-norleucine and 4-amino-4-deoxy-N^{10}-methylpteroyl-(6-chloro-5-oxo)-L-norleucine, analogs of methotrexate in which the γ-carboxyl group is replaced by a diazoketone and a chloromethylketone, respectively, was carried out. The analogs inhibited the growth of leukemia L-1210 cells in culture by 50% at 4×10^{-7} *M* and 2×10^{-7} *M*, respectively, and were effective inhibitors of the synthesis of thymidylate in L-1210 cells *in vitro* ($I_{50} = 3 \times 10^{-6}$ *M*), exhibiting significant antifolate activity. The results demonstrated the feasibility of introducing chemically reactive groups at the γ-position of pteroyl glutamates with retention of biological activity. However, in the systems investigated thus far, there was no evidence of covalent bond formation due to these reactive groups at the active sites of the enzymes.

Keyphrases □ Methotrexate—diazoketone and chloromethylketone as potential antitumor agents □ Antitumor agents—potential, diazoketone and chloromethylketone analogs of methotrexate □ Analogs—diazoketone and chloromethylketone, of methotrexate, potential antitumor agents

Many structural analogs of the clinically useful antitumor agent methotrexate (4-amino-4-deoxy-N^{10}-methylpteroyl-L-glutamic acid, amethopterin) (1), modified at the carboxyl groups of its glutamic acid moiety, have been prepared in the past in attempts to alter the membrane transport properties and to improve the tissue distribution and selectivity of the drug, as well as to circumvent drug resistance. This class of methotrexate derivatives includes a variety of α- and γ-monoesters (2), diesters (3), amides (4), and peptides (4, 5) and also analogs in which the carboxyl groups are replaced by hydrogen (6–8), hydroxymethyl, or methyl (9) groups. As was observed for methotrexate analogs modified at other parts of the molecule (8, 10), with the possible exception of 10-deazaaminopterin

0022-3549/82/0600-0717$01.00/0

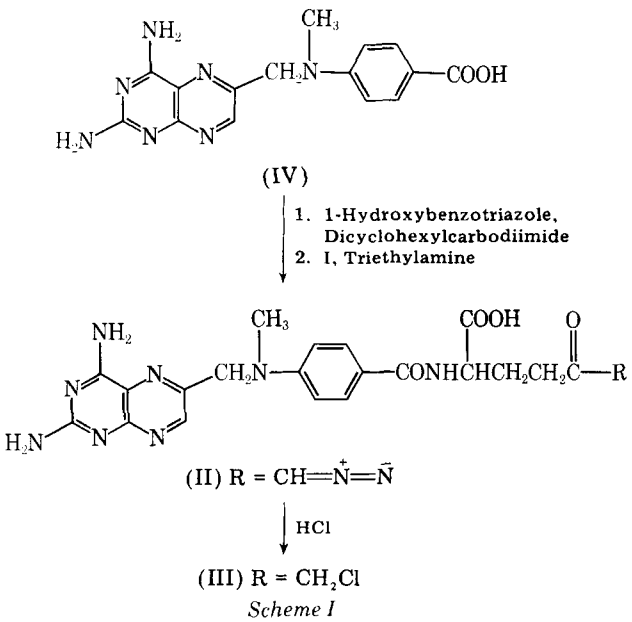
(10), none of these derivatives proved more effective than methotrexate. Modification at the α-position generally led to a marked decrease in biological activity including binding to the primary target dihydrofolate reductase, whereas substitution at the γ-carboxyl was better tolerated (4–10), with enzyme inhibitory activities approaching that of the parent drug.

The feasibility of introducing chemically reactive groups capable of covalent bond formation into the more permissive γ-position of pteroyl glutamates was explored. This type of modification may lead to the development of new active-site directed inhibitors (11) of folate metabolizing enzymes with potential antitumor activity. The replacements of the γ-carboxyl of methotrexate by a diazoketone and a chloromethylketone were chosen as prototypes of this modification. The diazoketone analog of glutamic acid, the antitumor antibiotic 6-diazo-5-oxo-L-norleucine (I) is a potent, irreversible inhibitor of glutamine amidotransferases (12). α-Haloketone analogs of various substrates are widely used for the affinity labeling of enzyme active sites (11–13).

In this report the synthesis and *in vitro* biological activities of the methotrexate analogs 4-amino-4-deoxy-N^{10}-methylpteroyl-(6-diazo-5-oxo)-L-norleucine (II) and 4-amino -4- deoxy-N^{10}-methylpteroyl-(6-chloro-5-oxo)-L-norleucine (III) are described. The results demonstrate that methotrexate can be substituted at the γ-position of its glutamate moiety with diazoketone and chloromethylketone functionalities, and that these modifications permit effective cellular uptake and expression of antifolate activity.

RESULTS AND DISCUSSION

Chemistry—The synthesis of the target compound (II) was accomplished by coupling 4-amino-4-deoxy-N^{10}-methylpteroic acid (14) (IV) with I using dicyclohexylcarbodiimide and 1-hydroxybenzotriazole *via* a modification of the peptide coupling procedure of Konig and Geiger (15, 16) (Scheme I). This coupling procedure, requiring milder conditions, was selected over the mixed anhydride method generally adopted for the coupling of IV with a variety of amino acid esters (6), mainly because of the known instability of I (17) to heat and pH extremes. Compound II displayed strong IR absorption bands at 2106 cm^{-1}, characteristic of the diazo moiety, and at 1633 and 1605 cm^{-1}, indicative of the ketone and amide, respectively. The NMR spectrum was consistent with the assigned structure; it included a singlet at 5.99 ppm associated with the methine proton of the diazoketone and a multiplet, strongly resembling a doublet, at 7.98 ppm assigned to the NH proton of the amide group.



Scheme I

Treatment of II with dry hydrogen chloride afforded the hydrochloride salt of the chloromethylketone analog (III), illustrated in Scheme I. The IR spectrum of III included a strong band at 1725 cm^{-1}, characteristic of chloromethyl ketones, and at 1610 cm^{-1}, assigned to the amide. The NMR spectrum included a singlet at 4.48 ppm, assigned to the methylene protons of the chloromethylketone, in accordance with the assigned structure.

Biological Results—The growth of leukemia L-1210 cells in culture (18) was inhibited 50% by II and III at 4×10^{-7} *M* and 2×10^{-7} *M*, respectively. In L-1210 cells *in vitro*, both compounds showed the same antifolate activity as measured by the *in situ* thymidylate synthetase assay (19) ($I_{50} = 3 \times 10^{-6}$ *M*). The potency of II and III was within an order of magnitude of that of methotrexate. The activity in both assay systems may be attributed to methotrexate-like activity involving inhibition of intracellular dihydrofolate reductase.

In preliminary studies of the effects of II and III in isolated enzyme systems, the thymidylate synthetases of *Lactobacillus casei* (20) and human blast cells (21), dihydrofolate reductase of *L. casei* (22), and folylpolyglutamate synthetase of rat liver (23), no irreversible inactivation was demonstrated. In these systems methotrexate exerted reversible inhibitory activity, with the exception of folylpolyglutamate synthetase, for which methotrexate is a substrate (23). Using various experimental tumor and isolated enzyme systems in comparison with methotrexate, further studies of II and III are in progress.

The synthetic procedures described in this paper are currently being applied with appropriate modifications to the preparations of diazoketone and chloromethylketone analogs of folic acid and its derivatives.

EXPERIMENTAL[1]

4-Amino-4-deoxy-N^{10}-methylpteroyl- (6-diazo-5-oxo) -L-norleucine (II)—To a solution of 4-amino-4-deoxy-N^{10}-methylpteroic acid (IV) (14), (180 mg, 0.5 mmole) in 10 ml of dimethyl sulfoxide–tetrahydrofuran (1:1) cooled to 0° was added 1-hydroxybenzotriazole (67.2 mg, 0.5 mmole) and dicyclohexylcarbodiimide (102.5 mg, 0.5 mmole). The reaction mixture was stirred for 1 hr at 0° and 1 hr at room temperature. To this mixture, kept in the dark, was added a solution of 6-diazo-5-oxo-L-norleucine (86.2 mg, 0.5 mmole) in dimethyl sulfoxide (2 ml) and water (1.5 ml). The reaction coupling time was 3 hr, during which the pH of the reaction mixture was monitored and maintained at 7.9–8.0 by the addition of the required amount of a dilute solution of triethylamine–dimethyl sulfoxide–tetrahydrofuran (2:1:5). After 3 hr, the reaction mixture was cooled to −15° overnight and filtered. Tetrahydrofuran was removed from the filtrate by evaporation which was followed by filtration and evaporation of the filtrate *in vacuo* to dryness. The residue was stirred with *N,N*-dimethylformamide and filtered to afford a clear solution which was concentrated to half of its volume, cooled overnight (−15°), and filtered. The filtrate was evaporated to dryness and triturated with ethyl acetate; subsequent filtration followed by washing with tetrahydrofuran, water, and acetone afforded a yellow solid (II). The compound was homogeneous by TLC (silica gel, dimethylsulfoxide–H_2O, 1:1), yield 53% (71% based on unrecovered IV). IR (KBr): 2106 ($N^+{=}N^-$), 1633 ($COCHN_2$), 1605 (CONH) cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 3.22 (s, 3H, N—CH_3), 4.32 (m, 1H, α—CH), 4.79 (s, 2H, CH_2—N), 5.99 (s, 1H, $CH{=}N^+{=}N^-$), 6.67 (s, 2H, NH_2), 6.83 and 7.72 (2d, 4H, C_6H_4), 7.50 (broad s, 2H, NH_2), 7.98 (m, resembling a doublet, 1H, CONH), and 8.58 (s, 1H, C_7H) ppm.

Anal—Calc. for $C_{21}H_{22}N_{10} \cdot 0.5\ H_2O$: C, 51.74; H, 4.72; N, 28.75. Found: C, 52.04; H, 4.91; N, 27.71. (The low value for nitrogen is not unusual in the elemental analysis of diazo compounds.)

4-Amino-4-deoxy-N^{10}-methylpteroyl- (6-chloro-5-oxo) -L-norleucine hydrochloride (III). Compound II (115 mg, 0.24 mmole) was dissolved in dry *N,N*-dimethylformamide (6.5 ml) and cooled in an ice-water bath. Dry hydrogen chloride was bubbled into the cooled solution for 10 min. The deep brown solution was stirred for 1 hr at 4° and then poured into cold anhydrous diethyl ether (35 ml). The crude product was purified by repeated triturations with cold (4°) anhydrous diethyl ether, and finally with ether–ethanol mixture (10:1), to give a brown oil. Con-

[1] IR spectra were obtained using a Nicolet Model 7000 Fourier transform IR spectrometer on samples prepared in a potassium bromide pellet. NMR spectra were obtained using a Varian FT-80 instrument. Compounds were dissolved in dimethyl sulfoxide-d_6 from commercial sources with tetramethylsilane as the internal standard.

tinued treatment with several portions of cold anhydrous ether, followed by filtration in a dry box under nitrogen, gave III as a pale yellow solid, yield 98%. IR (KBr): 1725 ($COCH_2Cl$), 1610 (CONH) cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 3.26 (s, 3H, N—CH_3), 4.48 (s, 2H, CH_2Cl), 4.88 (broad s, 3H, CH_2 and α—CH), 6.83 and 7.75 (two d, 4H, C_6H_4), 7.95 (s, 2H, CONH), and 8.75 (s, 1H, C_7H) ppm. An analytical sample was obtained by drying over phosphorus pentoxide *in vacuo*.

Anal.—Calc. for $C_{21}H_{23}ClN_8O_4 \cdot HCl \cdot 4H_2O$: C, 42.36; H, 5.42; N, 18.82; Cl, 11.91. Found: C, 42.61; H, 5.47; N, 19.08; Cl, 11.73.

Cell Culture Studies—Growth inhibition of murine leukemia L-1210 cells in culture was determined as described previously (18). The cells were maintained in a medium[2] supplemented with 10% calf serum[3] and antibiotics (penicillin and streptomycin). The cultures were incubated at 37° for 40 hr. During this time, the density in the control cultures increased from 1.5×10^5 to $1.2–1.5 \times 10^6$ cell/ml. Cell viability was determined by the trypan blue dye exclusion technique.

Cellular Thymidylate Synthetase Assay—Studies of the inhibition of intracellular thymidylate synthesis were carried out using murine leukemia L-1210 cells suspended in modified Eagle's media (without folate). The L-1210 cell line was maintained by weekly passage of 10^5 cells into DBA/2HA mice and harvested 6 days after inoculation.

The cellular radioisotopic assay of thymidylate synthetase activity was performed as described previously (19) by measuring the extent of tritium released into water from [5-^{3}H]deoxyuridine[4] (specific activity 22 Ci/mmole). Radioactivity was determined by liquid scintillation counting techniques[5] using a counter and scintillation cocktail[6] with 30–35% counting efficiency.

ACKNOWLEDGMENTS

Presented in part at the 179th National Meeting of the American Chemical Society, Houston, TX, March 27, 1980.

This work was supported by Research Grants CA-06695 and CA-13604 and Training Grant 5-T32-CA-09166 from the National Cancer Institute, National Institutes of Health.

The authors thank Professor M. Bodanszky, Case Western Reserve University, for helpful suggestions, and the Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute for supplying samples of I and 2,4-diamino-6-hydroxymethylpteridine hydrobromide. The authors are grateful to Drs. J. J. McGuire and J. R. Bertino and Dr. Y. C. Cheng for the results with folylpolyglutamate synthetase and human thymidylate synthetase, respectively. The assistance of Mrs. K. Baranski and J. C. Yalowich in performing the cell culture assays is appreciated.

Paradoxical Increase in Aminoglycoside Body Clearance in Renal Disease When Volume of Distribution Increases

Keyphrases □ Pharmacokinetics—aminoglycosides in renal disease, clearance, volume of distribution □ Aminoglycosides—body clearance in renal disease with increased volume of distribution, pharmacokinetics □ Renal disease—aminoglycoside body clearance with increased volume of distribution, pharmacokinetics

To the Editor:

Recent studies in our laboratory on the disposition of gentamicin in dogs (1) and sheep (2) with glomerular disease indicated that gentamicin's volume of distribution (Vd) increased, while the glomerular filtration rate, as measured by endogenous creatinine clearance, decreased. A re-evaluation of these studies to include a comparison of renal clearance parameters demonstrates that body or systemic clearance of gentamicin (Cl_B) paradoxically increases in the face of a decreased glomerular filtration rate (Table I). The purpose of this communication is to explore the nature of this paradox and to assess its significance in predicting drug disposition from clinical estimates of the glomerular filtration rate.

Volume of distribution generally has been shown to remain constant or decrease in renal failure for drugs that are not extensively protein bound (4–6). Often the decrease in Vd is not physiological, but rather is dependent on the pharmacokinetic parameters used to estimate it. Thus, in a two-compartment open model, a decrease in elimination will result in a decrease in Vd_β, Vd_{area}, and Vd_B, but not Vc or Vd_{ss} which are estimates of the physiologic distribution space of the drug (7). Aminoglycoside antibiotics are not appreciably bound to serum proteins. They are distributed essentially in extracellular water, are eliminated unchanged by the kidney, and a decreased glomerular filtration rate decreases their elimination (8). However, Vd_{ss} and Vc of netilmicin (9, 10) and Vd calculated after constant intravenous infusion of gentamicin (11) increased in patients with a decreased glomerular filtration rate, as measured by creatinine and/or inulin clearance. This is similar to the situation seen in our laboratory in animals with glomerulonephropathy. The mechanism of increased Vd is not known and may be specifically related to the pathophysiology of acute glomerulonephropathy. This condition, which has been associated with sodium retention and concommitantly increased exchangeable body sodium (12), could cause fluid retention and thus an increased physiological Vd. Alternatively, the immunological events occurring at the glomerulus could release a vasoactive factor(s) which might increase tissue binding of drug. Since the etiologic diagnosis of the renal disease is often not reported in pharmacokinetic studies, some of the human patients in the studies cited may have had glomerular disease.

Clearance may be calculated from the following:

$$Cl_B = K_{el}Vc \qquad \text{(Eq. 1)}$$

$$Cl_B = \beta Vd_{area} \qquad \text{(Eq. 2)}$$

where K_{el} is the elimination rate constant, Vc is the volume of the central compartment, β is the overall elimination rate constant, and Vd_{area} is the volume of distribution calculated from the area; all are defined in terms of a two-compartment open pharmacokinetic model (7, 13, 14). Body clearance can also be calculated according to the following model-independent technique:

$$Cl_B = \frac{\text{Dose}}{AUC} \qquad \text{(Eq. 3)}$$

where AUC is the area under the plasma concentration *versus* time curve, and dose is the amount of absorbed drug unchanged in the body (13, 14). Incomplete collection of data points may result in spuriously low values for AUC due to low serum concentrations seen with the expanded Vd, the result being increased Cl_B.

An increase in Cl_B could reflect a physiological increase in drug clearance. Gentamicin Cl_B calculated using Eqs. 1 and 3 increased in animals with glomerulonephropathy (Table I). In the human studies cited (9, 11), the ratio of aminoglycoside clearance to the glomerular filtration rate (fractional urinary excretion) also increased with a decreasing glomerular filtration rate and increasing Vd. In one study (11), actual renal gentamicin clearance even exceeded the glomerular filtration rate in some patients. This finding is supported in a recent micropuncture study in rats (15), which demonstrated that expansion of extracellular fluid volume with saline or bicarbonate caused an increase in the fractional urinary excretion of gentamicin exceeding unity in some cases. Similar findings were also noted when furosemide was administered concurrently with gentamicin (16). In this study utilizing rabbits, gentamicin renal clearance exceeded the glomerular filtration rate, as determined by inulin clearance, when furosemide was coadministered. The authors attributed this to in-

Table I—Selected Pharmacokinetic Data [a] of Gentamicin Disposition in Dogs and Sheep with Normal or Decreased Renal Function Secondary to Glomerular Disease

Parameter	Units	Dogs [b]		Sheep [c]	
		Normal (n = 11)	Diseased (n = 4)	Normal (n = 6)	Diseased (n = 2)
GFR [d]	ml/min/kg	3.8 ± 0.9	1.9 ± 0.6	1.7 ± 0.3	0.5 ± 0.2
Cl_B	ml/min/kg	4.1 ± 0.6	5.3 ± 1.2	1.0 ± 0.2	1.4 ± 0.5

0022-3549/82/0600-0720$01.00/0

creased gentamicin excretion by a renal tubular process, an event which was not present in the control animals studied. Finally, when water-deprived and hydrated rats were treated with gentamicin (17), the trend in changes seen in Cl_B and Vd with hydration were of similar nature to the animals with glomerulonephropathy. Extrapolation of these findings to the diseased animal is difficult due to the precisely defined experimental conditions of these studies. This is especially true in micropuncture experiments where small quantities of drug are involved. However, these data provide a physiologic basis for the pharmacokinetic changes detected in the dogs and sheep with acute glomerular disease.

It would appear that certain physiologic conditions and disease states associated with volume expansion and/or increased urine flow might lead to increased gentamicin clearance. This response may be modulated through a mechanism triggered by the abnormal fluid status. The increase in drug clearance may be a reflection of nephron heterogeneity (15) or a result of active tubular secretion, decreased proximal tubular reabsorption, or decreased nonionic back diffusion in the distal nephron (16, 18). Alternatively, glomerular disease may specifically increase the drug's ultrafilterability across the glomerular capillary membrane, normally restricted due to the Donnan Effect (18). This functional lesion would be expected to increase the fractional urinary excretion of gentamicin. Mechanistic studies have not been performed in diseased animals, and thus, further speculation is not warranted. This situation may not be seen in the chronic disease situation where individual nephrons have undergone compensatory hypertrophy. This chronic condition is pathophysiologically distinct and is clinically characterized by a different syndrome than is the acute disease process.

In view of these changes, one must be cautious in predicting Cl_B from the glomerular filtration rate, especially when an increased Vd is present, because these methods assume that this relationship does not change with the underlying disease process. However, certain disease conditions may uncouple this association of Cl_B to the glomerular filtration rate. Actual renal clearances of drug should be determined by measuring urinary drug excretion. Note that serum elimination half-life may remain relatively stable in the above situation because the increasing clearance will offset the increased volume of distribution. Dosage nomograms, which correlate elimination half-life or decreasing Cl_B with decreasing creatinine clearance, must be interpreted differently when Vd is known to have increased. Finally, additional studies relating drug disposition to specific pathophysiologic states of renal disease must be conducted to define the effects of various disease processes on drug clearance and volume of distribution, the two physiologic determinants of drug disposition.

Isosorbide Dinitrate: Pharmacokinetics after Intravenous Administration

Keyphrases □ Pharmacokinetics—intravenous administration of isosorbide dinitrate, bioavailability □ Bioavailability—pharmacokinetics of isosorbide dinitrate after intravenous administration □ Isosorbide dinitrate—pharmacokinetics after intravenous administration, bioavailability

To the Editor:

Isosorbide dinitrate is an organic nitrate found therapeutically useful in its sublingual and oral forms in various cardiovascular diseases such as angina pectoris (1) and congestive heart failure (2). Recently, Distante *et al.* (3) showed that an intravenous infusion of this drug (0.021–0.083 mg/min) was also effective in managing unstable angina. The availability of an intravenous dosage form of isosorbide dinitrate not only affords the opportunity to characterize the pharmacokinetics of this drug after this particular mode of therapy, it also allows the possibility to assess the bioavailability of this drug after other (*e.g.*, oral) routes of administration in patients. This latter subject has been of major controversy since Needleman *et al.* (4) made the assertion that oral nitrate therapy is irrational because of its complete first-pass metabolism.

A preliminary study has appeared which provided some initial information on this important issue. Taylor *et al.* (5) showed that in two normal, young subjects who received

0022-3549/82/0600-0721$01.00/0

creased gentamicin excretion by a renal tubular process, an event which was not present in the control animals studied. Finally, when water-deprived and hydrated rats were treated with gentamicin (17), the trend in changes seen in Cl_B and Vd with hydration were of similar nature to the animals with glomerulonephropathy. Extrapolation of these findings to the diseased animal is difficult due to the precisely defined experimental conditions of these studies. This is especially true in micropuncture experiments where small quantities of drug are involved. However, these data provide a physiologic basis for the pharmacokinetic changes detected in the dogs and sheep with acute glomerular disease.

It would appear that certain physiologic conditions and disease states associated with volume expansion and/or increased urine flow might lead to increased gentamicin clearance. This response may be modulated through a mechanism triggered by the abnormal fluid status. Isosorbide Dinitrate: Pharmacokinetics after Intravenous Administration

Keyphrases □ Pharmacokinetics—intravenous administration of isosorbide dinitrate, bioavailability □ Bioavailability—pharmacokinetics of isosorbide dinitrate after intravenous administration □ Isosorbide dinitrate—pharmacokinetics after intravenous administration, bioavailability

To the Editor:

Isosorbide dinitrate is an organic nitrate found therapeutically useful in its sublingual and oral forms in various cardiovascular diseases such as angina pectoris (1) and congestive heart failure (2). Recently, Distante *et al.* (3) showed that an intravenous infusion of this drug (0.021–0.083 mg/min) was also effective in managing unstable angina. The availability of an intravenous dosage form of isosorbide dinitrate not only affords the opportunity to characterize the pharmacokinetics of this drug after this particular mode of therapy, it also allows the possibility to assess the bioavailability of this drug after other (*e.g.*, oral) routes of administration in patients. This latter subject has been of major controversy since Needleman *et al.* (4) made the assertion that oral nitrate therapy is irrational because of its complete first-pass metabolism.

A preliminary study has appeared which provided some initial information on this important issue. Taylor *et al.* (5) showed that in two normal, young subjects who received

0022-3549/82/0600-0721$01.00/0

intravenous isosorbide dinitrate, the plasma clearance was found to be 0.32 and 0.16 liter/min. Based on these values, these authors concluded that sublingual and oral administration of isosorbide dinitrate are only bioavailable to the extent of 6 and 3%, respectively. If these data can be confirmed in a larger group, they could represent an unusual example of very poor sublingual bioavailability of a small neutral compound given at a relatively low dose. Further, if shown applicable to patients, these data could also have wide-ranging implications regarding the clinical use as well as the regulatory policy of oral and sublingual dosage forms of isosorbide dinitrate. It follows then that there may be a necessity (and perhaps urgency) of further research in identifying the reasons for, and approaches in circumventing, the poor sublingual bioavailability of this drug.

We have expanded on the study of Taylor *et al.* (5) through an examination of the pharmacokinetics of isosorbide dinitrate in 11 cardiac patients after intravenous infusion at two different rates. These data were obtained as part of a comprehensive study which examined the pharmacokinetics of isosorbide dinitrate after intravenous, sublingual, oral, and percutaneous administration. Because the intravenous data are crucial in the strategic planning of further pharmaceutical research of this drug, we present here a preliminary report on this aspect for the interest of workers in this area.

Eleven angina patients were infused intravenously with an isosorbide dinitrate solution[1] which had been suitably diluted such that a total dose of 2 mg in 10 ml was delivered over 15 min (infusion rate = 0.133 mg/min). Two of these patients received isosorbide dinitrate again on another day at a slower infusion rate (0.083 mg/min), one for 1 hr and the other for a 2-hr duration. This latter infusion rate was identical to that used by Taylor *et al.* (5). The strength of the dosing solution, *via* an HPLC analysis developed in this laboratory[2], was determined to be at a mean of 94% of the theoretical value. The concentration of isosorbide dinitrate in the infusion solution emerging from the polyethylene infusion tubing was essentially identical both before and after the experiment, indicting that adsorptive loss to the infusion system was absent. Serial plasma samples were drawn, anticoagulated with sodium citrate, and frozen (−20°) until assayed for isosorbide dinitrate by GC–electron capture detection (6).

The terminal disapearance phase rate constant (β) was obtained by least-square regression of the last four concentration–time points. The area under the plasma concentration *versus* time curve from time zero to the last plasma sample collected (C_t) was determined by Lagrange integration (7). Total area under the curve (AUC) was estimated by addition of the residual area (~15%) which was calculated by dividing C_t by β. The systemic clearance (Cl_{iv}) was calculated by dividing the administered dose by AUC. The apparent volume of distribution (Vd_{area}) was then determined by dividing the systemic clearance by β (8).

Figure 1 shows the plasma concentration of isosorbide dinitrate after intravenous infusion in the patient population studied. Results from the short infusion (2 mg over 15 min) showed that steady-state concentrations were not

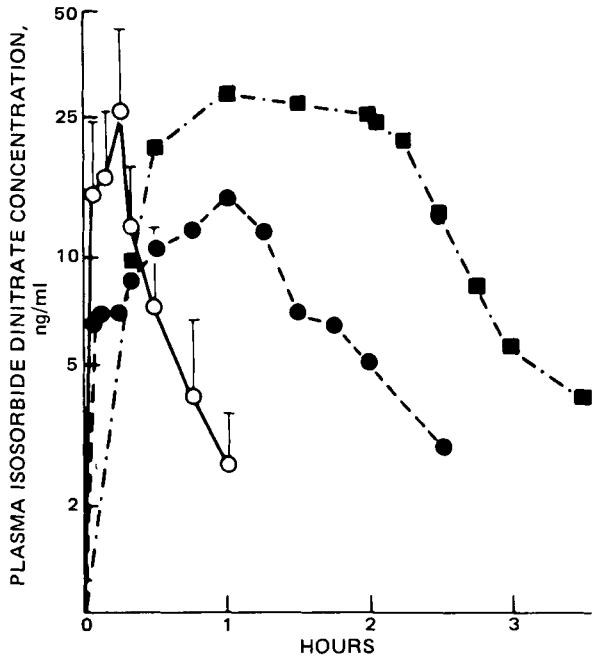

Figure 1—*Plasma isosorbide dinitrate concentrations observed after different rates and duration of intravenous infusion. Key: (○) 0.133 mg/min for 15 min, mean +SD, n = 11, (●) 0.083 mg/min for 1 hr, (■) 0.083 mg/min for 2 hr.*

achieved after this infusion regimen and that decline of plasma drug was apparently biexponential. Unfortunately, the initial rapid distributive phase observed after cessation of the infusion could not be quantitated due to insufficient sampling. The mean half-life of the terminal disappearance phase, however, was found to be 18 ± 7 min (± SD, n = 11), with a range of 10–30 min. The Cl_{iv} value was estimated at 3.4 ± 1.4 liter/min (mean ± SD, n = 11) with a range of 1.8–6.3 liter/min. The mean Vd_{area} (±SD) was estimated to be 101 ± 67 liters (range 46–241 liters). Infusion rate and duration did not appear to affect the pharmacokinetics of isosorbide dinitrate: in one patient, Cl_{iv} was estimated at 4.0 and 4.7 liter/min at infusion rates of 0.083 mg/min for 1 hr and 0.133 mg/min for 15 min, respectively; in a second patient, Cl_{iv} was 2.9 and 2.7 liter/min at infusion rates of 0.083 mg/min for 2 hr and 0.133 mg/min for 15 min, respectively.

If a prolonged elimination phase existed, but was undetected due to assay limitations, the Cl_{iv} values obtained here would be overestimated. However, in the patient infused for 2 hr at 0.083 mg/min, both the time to steady state, and concentration at steady state were consistent with the experimentally observed β and Cl_{iv} values, respectively. Regardless, a doubling of the terminal half-life for residual area calculation would only lead to a 7% decrease in Cl_{iv}. These observations suggest that the Cl_{iv} values obtained here are both internally consistent and reliable.

The clearance values observed in our patient population were, in general, at least 10-fold larger than those obtained by Taylor *et al.* (5) in two normal subjects. The reasons for this discordance are not known; however, a study is in progress which will reassess the validity of the low bioavailability estimates of sublingually and orally administered isosorbide dinitrate reported thus far, particularly to its applicability in cardiac patients.

Time-Dependent Kinetics VIII: Absence of Diurnal Oscillations in Valproic Acid Disposition Following Single Dose Administration to Rhesus Monkey

Keyphrases □ Valproic acid—time-dependent kinetics, absence of diurnal oscillations, disposition following single dose administration to rhesus monkey □ Kinetics, time-dependent—absence of diurnal oscillations in valproic acid disposition following single dose administration to rhesus monkey

To the Editor:

Valproic acid exhibits an unusual pharmacokinetic property in the rhesus monkey, namely, extensive diurnal oscillations in systematic clearance. An initial study in three normal rhesus monkeys showed that during constant rate intravenous infusion, steady-state levels increased at night with maxima 40–140% higher than the corresponding minima (1). In a subsequent study in four normal monkeys, where levels were monitored for 48 hr, it was found that the diurnal fluctuations in steady-state levels were reproducible in 2 consecutive days (2). Furthermore, after reversal of the 12-hr light–12-hr dark cycle, plasma concentrations tended to follow the phase shift with maxima during the reversed dark phase (actual day time) (2). In a later efficacy study in 12 epileptic monkeys, valproic acid was infused at a constat rate to achieve steady-state levels of 46, 97, and 147 μg/ml (3). The diurnal fluctuations in valproate levels were found at all three steady-state concentrations (4).

In each of the studies just described, the diurnal changes in valproate clearance were found under steady-state conditions. In the present study, the objective was to determine whether this phenomenon could be observed with an acute mode of administration. To this effect, valproate was administered at different times of day by intravenous boluses to a group of six rhesus monkeys. In addition, this design would allow a detection of diurnal effects in valproate distribution.

Six chair-adapted male rhesus monkeys (mean body weight 4.1 kg) with two chronic venous catheters (femoral for valproate bolus injection and jugular for blood sampling) were used in this study. Environmental conditions were maintained the same as those described previously (1, 2) (diurnal cycle: light period, 6 am–6 pm; dark period, 6 pm–6 am). Based on the findings of previous studies (valproate plasma levels remained stable or decreased during 10 am–6 pm, increased and reached a maximum during 6 pm–6 am, and tended to decline from 6 am–noon), the following times were selected for drug administration: 2 am, 8 am, 2 pm, and 8 pm. At these times of the day, valproate intravenous bolus injections were administered in a randomized fashion to six monkeys. At least 1 week of rest was allowed between any two injection times. From 2 to 4 replicate studies at each time period were conducted for each of the six monkeys.

At each time period, including replications, each monkey received 63.75 mg of valproic acid equivalent as sodium salt in 0.5 ml of sterile saline as an intravenous bolus injection. An additional 5 ml of saline was used to flush the line after bolus administration. Blood samples (2 ml) were collected in vacuum tubes containing edetic acid at 2, 20, 40, 60, and 100 min following drug administration. Plasma was separated and frozen until assay. Valproate was assayed by GLC using the procedure of Levy *et al.* (5).

The area under the plasma concentration–time curve (extrapolated to infinite time) was calculated by the trapezoidal rule and the systemic or total body clearance was computed from the dose–area relationship. The plasma valproate concentration time data were least-squares fitted to a monoexponential decay equation (BMDX-85), and the volume of distribution was calculated by the ratio of total body clearance and elimination rate constant. The null hypothesis of equal mean values for clearance, volume of distribution, and elimination rate constant among treatments was tested using a one-way ANOVA for repeated measures (BMDP2V). Then Tukey's method for multiple comparisons (6) was used to test for differences between particular pairs of treatments.

Mean plasma valproate concentration–time profiles at 2 am, 8 am, 2 pm, and 8 pm are shown in Fig. 1. Based on the findings of previous studies, which revealed the presence of circadian rhythms in steady-state valproate plasma levels (1–4), lower clearance values would be expected at 2 am and 8 pm than at 2 pm and 8 am. However, no significant difference in valproate clearance was observed between any of the four time periods. Volume of distribution and half-life also did not exhibit any time dependence ($p > 0.05$). Values of clearance, volume of distribu-

Time-Dependent Kinetics VIII: Absence of Diurnal Oscillations in Valproic Acid Disposition Following Single Dose Administration to Rhesus Monkey

Keyphrases □ Valproic acid—time-dependent kinetics, absence of diurnal oscillations, disposition following single dose administration to rhesus monkey □ Kinetics, time-dependent—absence of diurnal oscillations in valproic acid disposition following single dose administration to rhesus monkey

To the Editor:

Valproic acid exhibits an unusual pharmacokinetic property in the rhesus monkey, namely, extensive diurnal oscillations in systematic clearance. An initial study in three normal rhesus monkeys showed that during constant rate intravenous infusion, steady-state levels increased at night with maxima 40–140% higher than the corresponding minima (1). In a subsequent study in four normal monkeys, where levels were monitored for 48 hr, it was found that the diurnal fluctuations in steady-state levels were reproducible in 2 consecutive days (2). Furthermore, after reversal of the 12-hr light–12-hr dark cycle, plasma concentrations tended to follow the phase shift with maxima during the reversed dark phase (actual day time) (2). In a later efficacy study in 12 epileptic monkeys, valproic acid was infused at a constat rate to achieve steady-state levels of 46, 97, and 147 μg/ml (3). The diurnal fluctuations in valproate levels were found at all three steady-state concentrations (4).

In each of the studies just described, the diurnal changes in valproate clearance were found under steady-state conditions. In the present study, the objective was to determine whether this phenomenon could be observed with an acute mode of administration. To this effect, valproate was administered at different times of day by intravenous boluses to a group of six rhesus monkeys. In addition, this design would allow a detection of diurnal effects in valproate distribution.

Six chair-adapted male rhesus monkeys (mean body weight 4.1 kg) with two chronic venous catheters (femoral for valproate bolus injection and jugular for blood sampling) were used in this study. Environmental conditions were maintained the same as those described previously (1, 2) (diurnal cycle: light period, 6 am–6 pm; dark period, 6 pm–6 am). Based on the findings of previous studies (valproate plasma levels remained stable or decreased during 10 am–6 pm, increased and reached a maximum during 6 pm–6 am, and tended to decline from 6 am–noon), the following times were selected for drug administration: 2 am, 8 am, 2 pm, and 8 pm. At these times of the day, valproate intravenous bolus injections were administered in a randomized fashion to six monkeys. At least 1 week of rest was allowed between any two injection times. From 2 to 4 replicate studies at each time period were conducted for each of the six monkeys.

At each time period, including replications, each monkey received 63.75 mg of valproic acid equivalent as sodium salt in 0.5 ml of sterile saline as an intravenous bolus injection. An additional 5 ml of saline was used to flush the line after bolus administration. Blood samples (2 ml) were collected in vacuum tubes containing edetic acid at 2, 20, 40, 60, and 100 min following drug administration. Plasma was separated and frozen until assay. Valproate was assayed by GLC using the procedure of Levy *et al.* (5).

The area under the plasma concentration–time curve (extrapolated to infinite time) was calculated by the trapezoidal rule and the systemic or total body clearance was computed from the dose–area relationship. The plasma valproate concentration time data were least-squares fitted to a monoexponential decay equation (BMDX-85), and the volume of distribution was calculated by the ratio of total body clearance and elimination rate constant. The null hypothesis of equal mean values for clearance, volume of distribution, and elimination rate constant among treatments was tested using a one-way ANOVA for repeated measures (BMDP2V). Then Tukey's method for multiple comparisons (6) was used to test for differences between particular pairs of treatments.

Mean plasma valproate concentration–time profiles at 2 am, 8 am, 2 pm, and 8 pm are shown in Fig. 1. Based on the findings of previous studies, which revealed the presence of circadian rhythms in steady-state valproate plasma levels (1–4), lower clearance values would be expected at 2 am and 8 pm than at 2 pm and 8 am. However, no significant difference in valproate clearance was observed between any of the four time periods. Volume of distribution and half-life also did not exhibit any time dependence ($p > 0.05$). Values of clearance, volume of distribu-

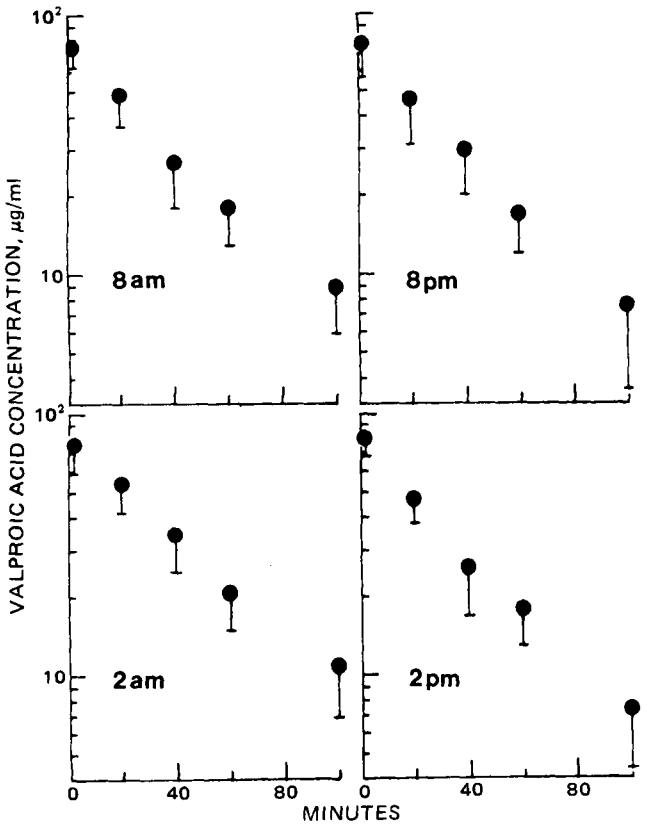

Figure 1—*Mean plasma valproate concentration–time profiles for six rhesus monkeys following four separate drug administrations by intravenous bolus injections.*

Table I—Pharmacokinetic Parameters Following Single Dose Administration of Valproic Acid to Rhesus Monkey

	2 am	8 am	2 pm	8 pm
Clearance, liter/hr^{-1} Mean (*SD*)	1.231 (0.369)	1.150 (0.267)	1.281 (0.390)	1.214 (0.264)
Volume of distribution, liter Mean (*SD*)	0.955 (0.263)	0.765 (0.080)	0.766 (.112)	0.795 (0.146)
Elimination Rate Constant, hour^{-1} Mean (*SD*)	1.312 (0.271)	1.517 (0.266)	1.636 (0.392)	1.573 (0.330)

tion, and half-life (Table I) are very similar to those found previously (1, 3, 7).

A consistent pattern of diurnal fluctuations in systemic clearance was previously found in three separate studies (1–4). The difference in experimental findings between those studies and the present one may be explained by the difference in the nature of the clearance obtained in both instances. In the former studies (1–4), valproate was administered by constant rate intravenous infusion and thus enabled the determination of an instantaneous systemic clearance at steady state. In the present study, however, valproate was administered by single bolus injection and resulted in the determination of an average clearance, a hybrid of the clearances operating during the elimination of the majority of the administered dose. Under steady-state conditions, differences in instantaneous clearance can be measured within a few hours and several (10–12) clearance determinations can be obtained in 24 hr. In contrast, the single dose approach revealed only four 2-hr hybrid samples of the diurnal evolution of drug clearance. Thus, in the case of valproic acid in the rhesus monkey, the single dose clearance represents an insensitive tool in the characterization of the time dependency in clearance.

Also, comparison of steady-state clearances between any two time points of the diurnal cycle involves only intraday variability in clearance. However, since each determination of single-dose clearance required several blood samples, any two clearance determinations (at the same time or at different times) were separated by at least a 1-week period. Appreciable interday variability was present. Table 1 shows that relative standard deviations of replicates at a given time of administration varied between 22 and 30%.

It may be argued that the particular group of six monkeys used in the present study does not exhibit the property of diurnal oscillations in steady-state clearance as was observed in previous studies (1–4). This possibility is eliminated by the fact that, in a later study (of diurnal fluctuations in cerebrospinal fluid valproate levels) four of the present six monkeys exhibited typical diurnal oscillations in steady-state plasma and cerebrospinal fluid levels (unpublished data). An alternative hypothesis to explain the findings of this study could be that chronic exposure to valproic acid is necessary to evoke a circadian rhythm in plasma concentration, *i.e.*, the constant presence of valproate *in vivo* would initiate an endogenous cycle in metabolism. This would be possible if, for example, chronic infusion (as opposed to bolus administration) of valproic acid was associated with depletion of cofactors necessary in the biotransformation of valproate. Such cofactors would then become rate-limiting and, if their synthesis or turnover rate was under diurnal control, valproate clearance would also exhibit a diurnal rhythm. In relation with this hypothesis, it is of interest to note that diurnal oscillations in steady-state levels have been observed with other drugs [ethosuximide (8), carbamazepine (9) and clonazepam (10)] in the rhesus monkey under the same experimental conditions. However, no studies of diurnal variation following single dose administration have been performed with these drugs. Therefore, several *in vivo* and *in vitro* metabolic studies will be necessary before the cofactor depletion hypothesis can be generalized.

Centering Tool for Dissolution Vessels

Keyphrases □ Drug dissolution—testing, centering tool for dissolution vessels □ Centering tool—drug dissolution testing, for basket and paddle methods

To the Editor:

Proper alignment and standardization of equipment is essential to obtain reliable results in drug dissolution testing. The USP XX requires that the shaft in both the basket and paddle methods be positioned so that its axis is not >0.2 cm at any point from the vertical axis of the vessel (1). A centering tool for alignment of the shaft was previously described (2), and several centering tools are commercially available[1,2]. We have designed a centering tool which has been widely used in FDA laboratories and which we believe offers significant advantages over other designs.

The tool is machined from a block of plexiglass (Fig. 1). The sides of the tool are tapered at an angle of 30° from the axis so that the tool can be used with plastic or glass dissolution vessels or to align the base plates that support the dissolution vessels. The main slot is oversized to 10 mm to allow the tool to be used with 9.52-mm diameter shafts.

[1] Hanson Research Corp., Northbridge, CA 91324.
[2] Van-Kel Industries, Chatham, NJ 17928.

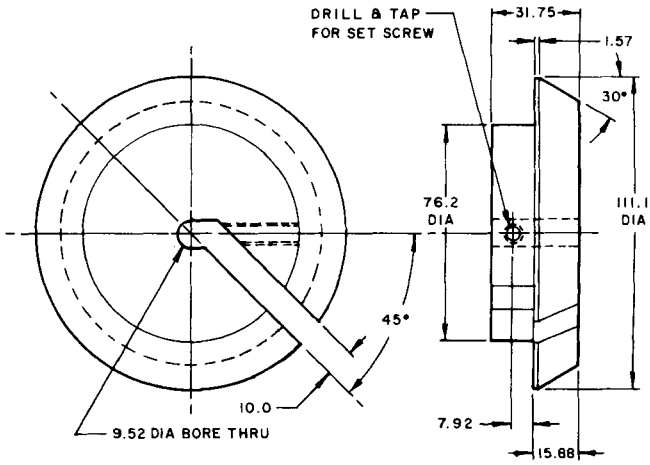

Figure 1—*Dissolution vessel centering tool. The material used was plexiglass and all measurements are in millimeters.*

The center portion of the slot is offset 45° from the main slot, so that the shaft can be accurately butted against the radius of the 9.50-mm center hole with a 6.35-mm screw. Securing the shaft against the center hole radius prevents the tool from accidental tipping when aligning the vessels. The final machining of the tapered edge is done with the device secured by its set screw to an arbor to ensure that the center hole and the tapered portion of the tool will be concentric.

While in use, the tool is slipped down the shaft into the mouth of the vessel, and the vessel is aligned with the tool after tightening the set screw. The design offers these advantages:

1. Locking the tool to the shaft prevents the alignment from changing while adjusting the kettle.
2. The circular design aligns the kettle's total circumference in one operation.
3. Dimension of the tool permits it to be used to align the base plate.

With proper use, most, if not all, of the centering tools previously described should be capable of aligning the shaft within USP specifications.

Concepts in Drug Metabolism (in Two Parts) Part B (Drug and Pharmaceutical Sciences, Vol. 10.) Edited by PETER JENNER and BERNARD TESTA. Dekker, 270 Madison Ave., New York, NY 10016. 1981. 627 pp. 15 × 23 cm. Price $65.00.

Concepts in Drug Metabolism is a two volume, multiauthored collection of essays on major topics in drug metabolism and allied fields. The various chapters reflect the state of knowledge from the viewpoint of each of the respective authors.

The contents of Part B are divided into nine chapters which deal with the following topics: The role of the endoplasmic reticulum in physiological and pathological situations; the hepatic cytochrome P-450 drug metabolizing systems; toxification and detoxification as a result of xenobiotic metabolism; enzyme induction and inhibition related to drug action and interactions; genetic aspects of drug metabolism; some evolutionary considerations regarding drug metabolism and toxicity; *in vivo* assessment of hepatic drug disposition; altered drug disposition in disease states; and is drug metabolism due to necessity, chance, mishap, or none of the above?

Since each chapter has been written by a different author, some overlapping has occurred. However, this demonstrates the relationship and interdependencies of the various topics. The reader will find that most of the chapters in Part B are more factual and less philosophical than some of the chapters found in Part A.

The chapters are well referenced and, although not being all inclusive, reflect a command of the most important research in each area. A drawback is that with few exceptions, Part B represents a review of the literature through 1978. The area of drug metabolism is a rapidly moving field, and many significant contributions have been made in the interval between the time the book was finished and the date of publication. This is a problem which is common to an active area of research.

Concepts in Drug Metabolism is intended for use by postgraduate students and research workers in the fields of biomedicinal chemistry, pharmacology, toxicology, and biochemistry. The two volume set makes an excellent text for a graduate level course in drug metabolism. Unfortunately, the cost of the books tends to prohibit purchase by students. The volume serves as a valuable guide in the area of drug metabolism; however, it is also an important source of new ideas since many of the chapters go beyond the basic facts, providing a conceptual, almost philosophical, approach to some of the topical areas.

Part B of *Concepts in Drug Metabolism* in conjunction with Part A provides an authoritative overview of basic topics and developments in drug metabolism and related areas. The two volume set is highly recommended for persons working in the general area of xenobiotic metabolism.

Pharmaceutical Analysis: Modern Methods, Part A (Drugs and the Pharmaceutical Sciences Series, Vol. 11). Edited by JAMES W. MUNSON. Dekker, 270 Madison Ave., New York, NY 10016. 1981. 504 pp. 15.5 × 23.2 cm. Price $55.00 (Special Student Price $29.75).

As stated in the preface, this text is intended to "provide an intermediate level of coverage ... (it) is designed for the graduate student studying pharmaceutical analysis and for the researcher . . . who wishes to increase his personal awareness and understanding of modern techniques of pharmaceutical analysis."

The first three chapters offer a review of the theory, instrumentation, and applications to pharmaceutical analysis of gas chromatography (GC), pyrolysis GC, and GC–mass spectroscopy. The authors of each chapter have incorporated and harmonized theory and practice and have written three well-integrated chapters. The topics are covered at a depth suitable for a graduate course covering the GC aspects of pharmaceutical analysis.

The last three chapters deal with luminescence (fluorescence and phosphorescence) spectroscopy, liquid scintillation counting, and radioimmunoassays. The chapter authors have done an excellent job of presenting the underlying theory and applications of their individual topics: there is greater detail and breadth of coverage than is usually found in other textbooks devoted to pharmaceutical analysis. However, the interrelationship of these chapters with each other, or with the rest of the text, does not meet the high standard established in the first three chapters. In fact, if there is a fault with this text, it is in the organization and integration of the individual chapter topics with one another. For example, in terms of material, the logical arrangement would have been to incorporate the chapters on high-performance liquid chromatography and quantitative thin-layer chromatography, which are to be covered in Part B, with the chapters on GC found in this volume.

Nevertheless, the presentation and content of material in each chapter is excellent, and taken individually they are well-suited for graduate courses in pharmaceutical analysis. However, the ordering and arrangement of the topic chapters in both Part A and Part B make it ill-suited for courses that may be segregated into spectroscopic and separation techniques.

Antibiotic Certification—An Anachronism

All too often it is human nature to continue to operate in a certain way or to do a certain thing, even though the reasons for performing that action have long ceased to exist. Moreover, in government and bureaucratic circles, the propensity for such behavior is all the more pronounced.

For these reasons, the Food and Drug Administration's current proposal to phase-out its antibiotic certification program comes as a refreshing change. Many of us on the Washington scene have become skeptics because we usually see "business as usual" from the federal government despite campaign promises to the contrary from politicians when they are running for office.

For those readers not familiar with the history of this certification program, a brief review would be appropriate.

When the first several antibiotic drugs initially were marketed in the 1940s, they were extremely crude concentrates of extracts obtained from microbial culture media. At that time, conventional chemical or instrumental methods of drug analysis were not applicable to them; in particular, those analytical procedures could not provide a true measure of the biological potency of the antibiotic test samples.

To meet this immediate problem, between 1945 and 1948, Congress passed legislation providing for the batch certification of the five antibiotics then available. The certification program was conducted by a laboratory within the Food and Drug Administration, and it used microbiological test procedures to measure growth inhibition of various organisms when tested against a relatively purified, standard reference sample of the crude antibiotic.

However, rapid advances in the manufacturing processes of production, synthesis, and purification soon made it possible to produce these antibiotics as essentially pure, homogeneous, crystalline substances with a degree of purity comparable to other fine chemicals.

In light of these modernized production procedures—along with the development of many new analytical techniques—it was not considered necessary to add to the certification program any of the dozens of newer antibiotics which subsequently came onto the market during the 1950s and very early 1960s. Indeed, because of these developments, by 1962 it was difficult to rationalize the continuation of the antibiotic certification program in any form, much less its wholesale expansion to cover all antibiotics as provided for in the 1962 Drug Amendments to the Federal Food, Drug, and Cosmetic Act.

Both APhA and the Pharmaceutical Manufacturers Association—as well as several other groups including the United States Pharmacopeia—testified in opposition to the antibiotic certification provision during 1959–1962 Congressional hearings conducted by Senator Kefauver and Representative Cellar. However, drug industry opposition suddenly evaporated, apparently as the result of a closed-door political compromise in which the industry agreed to accept antibiotic certification as a trade-off for having Congress not disturb the exclusivity of drug patents. At any rate, the bill passed by Congress and signed into law by President Kennedy in October 1962 included the section extending certification to all antibiotics.

Over the years, experience convincingly showed the antibiotic certification program to be a needless and costly exercise, because batch after batch was found to be well within compliance.

In light of this track record, in the late 1970s, the FDA began to exempt certain antibiotic dosage forms from the certification requirement. Then, in a somewhat surprise action, FDA Commissioner Arthur Hull Hayes, Jr., published a sweeping proposal in the Federal Register of May 7, 1982, calling for the elimination of the entire certification program for all antibiotic drugs. In essence, Dr. Hayes was saying that, rather than go through the lengthy and unnecessary process of a gradual phase-out, decisive action was clearly preferable. In our personal view, this action is both administratively logical and scientifically sound. Moreover, it will greatly minimize paperwork and procedural processing.

As an aside, one might properly wonder how the FDA is able to nullify or revoke a program enacted by Congress. It is because of the unique construction of the language used in the Act as it relates to the certification program. Specifically, FDA has the authority to grant exemptions from certification, and any antibiotic drugs so exempted no longer are subject to section 507 of the Act (the special category of antibiotic drugs), but are then automatically covered by section 505 of the Act (the so-called "new drugs" provision which covers drugs generally).

In concert with the FDA's proposed decertification action, the USP is actively preparing and promulgating revised monographs to ensure the continued existence of public standards of quality for these pharmaceutical products. Consequently, even in the absence of the FDA certification program, the combination of (*a*) compendial standards, (*b*) manufacturers' quality control testing, and (*c*) FDA market surveillance and enforcement will ensure the continued high quality of antibiotics in exactly the same manner as with all other pharmaceutical products (except for insulin and biologicals).

In a way, this FDA action makes such good sense that one is inclined simply to say, "fine," and then dismiss it from his or her mind. However, as noted in our opening paragraphs, society generally, and the government in particular, very rarely halts an activity or discards a procedure simply because it has become obsolete and outdated.

Consequently, we feel that Dr. Hayes, the FDA, and the Administration should be commended for this bold and decisive action.

Kinetics and Mechanism of Hydrolysis of Labile Quaternary Ammonium Derivatives of Tertiary Amines

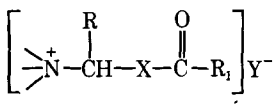
JOSEPH B. BOGARDUS * and TAKERU HIGUCHI ˣ

Received June 29, 1981, from the *Pharmaceutical Chemistry Department, School of Pharmacy, University of Kansas, Lawrence, KS 66044.* Accepted for publication October 22, 1981. *Present Address: College of Pharmacy, University of Kentucky, Lexington, KY 40506.

Abstract □ The kinetics and mechanism of hydrolysis of *N*-(4-hydroxy-3,5-dimethylbenzyl)pyridinium bromide and similar quaternary derivatives of niacinamide, *N*,*N*-dimethylaniline, and trimethylamine were investigated. pH–Rate profiles at 25° for formation of tertiary amine and 4-hydroxymethyl-2,6-dimethylphenol indicated that the zwitterionic quaternary phenoxide was the reactive species in alkaline solution. The apparent rate of hydrolysis was strongly inhibited by addition of small amounts of product tertiary amine, which is consistent with the presence of an intermediate in the reaction pathway. A mechanism was proposed for the hydrolysis and methanolysis of these compounds involving the reversible formation of the quinone methide, 4-methylene-2,6-dimethyl-2,5-cyclohexadien-1-one, followed by a trapping reaction with solvent or nucleophiles. Replacement of the phenolic hydrogen with methyl or acetyl groups greatly stabilized the molecule which is in agreement with the proposed mechanism. For the ester, the rate of amine release was limited by specific base catalyzed hydrolysis of the ester group. Compounds of this type may be useful in prodrug design for tertiary amines. The possibility of quinone methine intermediates in the degradation of structurally similar drugs, such as epinephrine, was discussed.

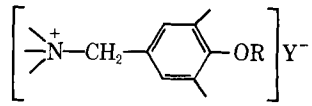
Keyphrases □ Hydrolysis—labile quaternary ammonium derivatives, tertiary amines □ Amines—tertiary, kinetics, mechanism of hydrolysis, labile quaternary ammonium derivatives □ Kinetics—labile quaternary ammonium derivatives, mechanism of hydrolysis, tertiary amines

In recent years a number of approaches have been investigated for preparation of prodrugs (1, 2). Tertiary amines are unusual in that derivatization forms quaternary ammonium compounds. Quaternary salts resulting from simple alkylation, however, are generally chemically stable and therefore are not useful as prodrugs. A class of labile quaternary ammonium salts of the following general type have been investigated previously (3–6):



In this salt R and R_1 are hydrogen, alkyl, or aryl; X is oxygen or sulfur; and Y is a halogen. These compounds hydrolyze to form tertiary amine (>N—), aldehyde (RCHO), carboxylic acid (R_1COXH), and HY. Applications of this approach have included the preparation of soft quaternary germicides, anticholinergic agents, and antitumor agents.

In the present report, the kinetics and mechanism of hydrolysis of a different type of labile quaternary salt were studied. The general structure is:



where R is H, CH_3, or CH_3CO and Y^- is Br^-. Simple tertiary amines were used as model compounds, although the results should be useful in the design of prodrugs. The 4-hydroxybenzyl structure of the quaternizing agent was chosen, since it is known to be a major factor in the instability of drugs such as epinephrine (7, 8). An unstable quinone methide was found to be an intermediate in the hydrolysis of the quaternary salts, and it is likely that the degradation of drugs such as epinephrine proceeds by an analogous mechanism.

EXPERIMENTAL

The following general sequence was used to prepare the quaternary salts *N*-(4-hydroxy-3,5-dimethylbenzyl)pyridinium bromide (I), *N*-(4-hydroxy-3,5-dimethylbenzyl)-3′-carbamoylpyridinium bromide (II), and *N*-(4-hydroxy-3,5-dimethylbenzyl)phenyldimethylammonium bromide (VIII): Formaldehyde and base were used to hydroxymethylate

0022-3549/82/0700-0729$01.00/0

2,6-dimethylphenol. The benzyl bromide was then prepared using hydrobromic acid–acetic acid. This compound was reacted with the corresponding tertiary amine to form the quaternary salt. Satisfactory elemental analyses were obtained on all stable compounds. NMR and IR spectra were run on commercial instruments[1,2]. Melting points were uncorrected.

4-Hydroxymethyl-2,6-dimethylphenol (III)—Equimolar amounts of 2,6-dimethylphenol[3], formaldehyde, and aqueous potassium hydroxide solution were reacted for 24 hr at 5° (9). The product precipitated upon neutralization and was recrystallized from chloroform, mp 101–102° [lit. (9) 105°]. UV (H_2O) 270, 220 nm max; IR (KBr): 3340 cm^{-1}; NMR [$(CD_3)_2SO$]: δ7.98 (s, 1H), 6.80 (s, 2H), 4.90 (s, 1H), and 2.17 (s, 6H) ppm.

4-Bromomethyl-2,6-dimethylphenol—A solution containing 0.5 g of III, 1 ml of 48% hydrobromic acid, and 10 ml of acetic acid was stirred for 0.5 hr at 6°. Cold chloroform (40 ml) and ice water (25 ml) were added, the organic layer was dried with calcium sulfate and rotary evaporated at room temperature. The unstable pink crystals could not be further characterized and were used immediately.

***N*-(4-hydroxy-3,5-dimethylbenzyl)pyridinium bromide (I)**—Immediately upon addition of pyridine to a solution of 4-bromomethyl-2,6-dimethylphenol in chloroform the quaternary compound precipitated, mp 190° dec. UV max (H_2O) 258 nm; IR (KBr): 3360 cm^{-1}; NMR [$(CD_3)_2SO$]: δ 9.25 (d, 2H), 8.35 (m, 4H), 7.24 (s, 2H), 5.77 (s, 2H), and 2.17 (s, 6H) ppm.

***N* - (4-hydroxy-3,5-dimethylbenzyl)-3′-carbamoylpyridinium bromide (II)**—The product precipitated from a solution of 1.6 g of niacinamide and 4-bromomethyl-2,6-dimethylphenol (prepared from 2 g of III) in 3 ml of dry dimethylformamide, mp 202°. NMR [$(CD_3)_2SO$]: δ 9.66 (s, 1H), 9.16 (m, 2H), 8.60 (s, 2H), 8.27 (t, 1H), 7.30 (s, 2H), 5.84 (s, 2H), 3.3 (s, 1H), and 2.22 (s, 6H) ppm.

***N* - (4-hydroxy-3,5-dimethylbenzyl)phenyldimethylammonium bromide (VIII)**—The procedure for I was followed with the substitution of *N*,*N*-dimethylaniline, mp 131–132°. IR (KBr): 3350 cm^{-1}; NMR [$(CD_3)_2SO$]: δ 7.67 (m, 5H), 6.50 (s, 2H), 4.84 (s, 2H), 3.50 (s, 7H), and 2.03 (s, 6H) ppm.

***N*-(4-acetoxy-3,5-dimethylbenzyl)pyridinium bromide (IV)**—A 0.5-g portion of I was acetylated with 1 ml of acetic anhydride in 3 ml of warm pyridine. The product crystallized upon cooling, mp 258°. UV max (H_2O) 258 nm; NMR [$(CD_3)_2SO$]: δ 9.25 (d, 2H), 8.33 (m, 3H), 7.33 (s, 2H), 5.80 (s, 2H), 2.33 (s, 3H), and 2.10 (s, 6H) ppm.

4-Dimethylaminomethyl-2,6-dimethylphenol—Mannich condensation of equimolar amounts of 2,6-dimethylphenol, formaldehyde, and dimethylamine in aqueous solution yielded the product (10). Recrystallization from benzene or ethanol—water gave long needles, mp 112° [lit. (10) 120–122°]. NMR (acetone-d_6): δ 6.83 (s, 2H), 3.22 (s, 2H), 2.19 (s, 6H), and 2.12 (s, 6H) ppm.

4-Hydroxy-3,5-dimethylbenzyltrimethylammonium Iodide (IX)—A literature procedure (10) for the reaction of 4-dimethylaminomethyl-2,6-dimethylphenol with methyl iodide in ether gave significant quantities of two byproducts (11). The water-soluble fraction containing IX and tetramethylammonium iodide was used. NMR (D_2O): δ 7.17 (s, 2H), 4.33 (s, 2H), [3.22 (s, $(CH_3)_4N^+$)], 3.07 (s, 9H), and 2.28 (s, 6H) ppm.

4-Hydroxymethyl-2,6-dimethylanisole—Two milliliters of dimethylsulfate was slowly added to 30 ml of a cold alkaline aqueous solution containing 1.0 g of III. The reaction mixture (two layers) was kept alkaline with 10% aqueous potassium hydroxide. After stirring 2 hr, the mixture was warmed gently and allowed to stand for 1 hr. The product was obtained as a yellow oil by ether extraction and solvent evaporation. NMR (CCl_4): δ 6.80 (s, 2H), 4.30 (s, 2H), 3.90 (s, 1H), 3.58 (s, 3H), and 2.17 (s, 6H) ppm.

4-Bromomethyl-2,6-dimethylanisole—A 0.5-g sample of 4-hydroxymethyl-2,6-dimethylanisole was converted to the bromide in 25 ml of 48% hydrobromic acid containing 1 ml of sulfuric acid. The product was extracted into 60 ml of chloroform, washed with 5% sodium bicarbonate solution, and dried with calcium sulfate. Evaporation of solvent gave a yellow oil. NMR (CCl_4): δ 6.91 (s, 2H), 4.28 (s, 2H), 3.65 (s, 3H), and 2.24 (s, 6H) ppm.

***N*-(4-methoxy-3,5-dimethylbenzyl)pyridinium bromide (VII)**—One milliliter of 4-bromomethyl-2,6-dimethylanisole was reacted with an equal volume of dry pyridine at 60°. Upon cooling, an oil separated which subsequently crystallized. Recrystallization from acetone afforded the pure product, mp 173–174°. UV max (H_2O) 257 nm; NMR (D_2O): δ 8.67 (m, 5H), 7.27 (s, 2H), 5.80 (s, 2H), 3.80 (s, 3H), and 2.34 (s, 6H) ppm.

Rate Studies—Reaction rates were measured in the thermostated cell compartment of a spectrophotometer[4]. Inorganic salts and nucleophiles were reagent grade and water was redistilled from an all-glass apparatus. Pseudo first-order rate constants were calculated[5] from the slopes of $\ln|A_\infty - A_t|$ *versus* time plots using the least-squares method. Correlation coefficients were consistently >0.998 and infinity values were taken after 10 half-lives. The pH of all solutions was measured[6] before and after the reactions and the change was <0.04. The reaction was initiated by injection of a concentrated stock solution into the buffer in the spectrophotometer cell. Wavelengths for the kinetic measurements were: I, 260 nm; II, 265 nm; IV, 250 and 285 nm; VIII, 250 nm; IX, 260 nm.

Reactions with half-lives <10 sec were followed using a stopped-flow spectrophotometer[7]. Transmittance–time data were converted to absorbance and then analyzed as before.

A high-performance liquid chromatograph (HPLC) with 254 nm detector was used[8]. The mobile phase consisting of pH 9.1, 5 m*M* borax buffer was pumped through the strong anion exchange column at 1.0 ml/min resulting in retention times of 3.5 (III) and 8.3 min (VI). Reaction solutions containing III and VI were extracted with 15 ml each of chloroform–ether–chloroform; the combined extracts were evaporated to dryness and reconstituted with 5 ml of methanol. The methanol solution was injected on the HPLC. The relative peak areas for III and VI were measured planimetrically. The aqueous phase from the extraction contained negligible amounts of the two compounds.

RESULTS

pH–Rate Profiles for Hydrolysis of I, II, and IV—In neutral to alkaline aqueous solutions, the quaternary ammonium salts of pyridine (I) and niacinamide (II) rapidly cleave to form the corresponding tertiary amine and III, as shown in Scheme I. The products were identified by UV, NMR, and TLC analyses. Repetitive UV scanning did not indicate the presence of an intermediate during the reaction. The rate was pH-de-

Scheme I

pendent and the spectrophotometrically determined log k_{obs}–pH profiles at 25° are shown in Fig. 1.

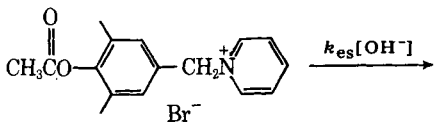
The reaction rates were increased by buffers and the buffer data are shown in Tables I and II. All data in Fig. 1 were extrapolated to zero buffer concentration. The lines for I and II in Fig. 1 were calculated according to:

$$k_{obs} = k_{max}\left(\frac{K_a'}{K_a' + a_H}\right) + k_{OH}K_w/a_H \qquad \text{(Eq. 1)}$$

where k_{obs} is the pseudo first-order rate constant at zero buffer concentration, k_{max} is the rate constant in the plateau region, K_a' is the dissociation constant of the reactant, k_{OH} is the apparent second-order rate constant for the effect of hydroxide on the conjugate base of I or II, K_w is the ion product of water, and a_H is the hydrogen ion activity. The rate of hydrolysis of II at high pH could not be accurately determined using the stopped-flow technique, and thus, k_{OH} could not be determined.

For the hydrolysis of I under conditions of pH < pK_a' and [I] $\simeq 10^{-4}$ *M*, the apparent rate constant became smaller during the reaction. This rate-retarding effect was due to the pyridine produced upon hydrolysis of I, according to the Law of Mass Action. The rate constants reported for this pH region were for the initial portion of the reaction where first-order conditions were well approximated or were obtained with more dilute solutions of I in longer path length UV cells. A study of this effect is reported in the next section.

Also shown in Fig. 1 is the effect of pH on the hydrolysis of IV, the acetate ester of I. As shown in Scheme II, this compound decomposed by consecutive kinetics:



IV

$$CH_3COO^- + I \longrightarrow III + Pyridine$$

Scheme II

After hydrolysis of equal concentrations of I and IV at pH 12.5, the UV spectra of the products were identical. In the pH region studied, the rate of decomposition of I was three- to ten-fold faster than the hydrolysis of the ester. This allowed the rate constant for ester hydrolysis to be determined as the terminal slope of ln $|A_t - A_\infty|$ *versus* time plots.

The second-order rate constant for ester hydrolysis, k_{es}, was calculated from the slope of a plot of k_{obs} *versus* K_w/a_H according to:

$$k_{obs} = k_{es}K_w/a_H \qquad \text{(Eq. 2)}$$

Table I—Reaction Conditions and Buffer Data for the Hydrolysis of I[a]

pH	Buffer Species	Conc. Range, *M*	Number of Concs.	Number of k_{obs}

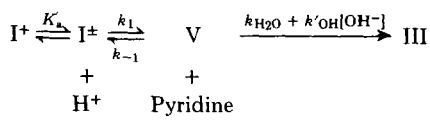
12.05–12.5	Hydroxide	—	—	—

[a] At 25°, μ = 1.0.

This reaction was first order in hydroxide ion, as indicated by the slope of 1.1 in Fig. 1. At pH 12.75 the rates of decomposition of I and IV were equal, *i.e.*, $k_{max} = k_{es}K_w/a_H$.

Effect of Added Pyridine on the Hydrolysis of I—In the pH-independent region for hydrolysis, addition of small amounts of pyridine at constant pH greatly decreased the observed rate constants. Figure 2 shows the kinetic effect of added pyridine at three pH values. The rate-retarding effect of pyridine decreased as pH increased, in the region where the hydrolysis reaction (Fig. 1) was strictly pH-independent. This mass law effect of pyridine was analogous to the common ion effect observed in many S_N1 reactions (12). A possible explanation for these data was a mechanism involving reversible dissociation of I to pyridine plus an intermediate (V). As shown in Scheme III, the intermediate can either react with pyridine to form starting material or with solvent irreversibly to form III:



Scheme III

By applying the steady-state assumption to the intermediate, the rate law for loss of I may be expressed as shown in Eq. 3 where $[I]_T = [I^+] + [I^\pm]$ and [P] is the pyridine concentration:

$$\frac{-d[I]_T}{dt} = \frac{k_1(k_{H_2O} + k'_{OH}K_w/a_H)[I]_T}{k_{-1}[P] + k_{H_2O} + k'_{OH}K_w/a_H}\left(\frac{K_a'}{K_a' + a_H}\right) \qquad \text{(Eq. 3)}$$

The observed rate constant is defined as:

$$k_{obs} = \frac{k_1K_a'}{(K_a' + a_H)\left(1 + \left[\frac{k_{-1}[P]}{k_{H_2O} + k'_{OH}K_w/a_H}\right]\right)} \qquad \text{(Eq. 4)}$$

In the absence of added pyridine, $k_{-1}[P] \ll (k_{H_2O} + k'_{OH}K_w/a_H)$ and the rate constant is given by Eq. 1 with $k_{max} = k_1$ in the pH region where the k_{OH} term is negligible. Inversion and rearrangement of Eq. 4 gives:

$$\frac{1}{k_{obs}} = \left(\frac{k_{-1}[P]}{k_1(k_{H_2O} + k'_{OH}K_w/a_H)} + \frac{1}{k_1}\right)\left(1 + \frac{a_H}{K_a}\right) \qquad \text{(Eq. 5)}$$

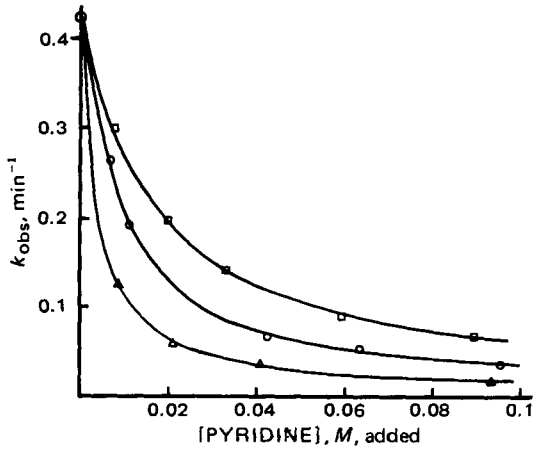


Figure 2—*Effect of added pyridine on the rate constant for hydrolysis of I at three pH values. Key:* (△) *pH 12.15,* (○) *pH 12.45,* (□) *pH 12.74.*

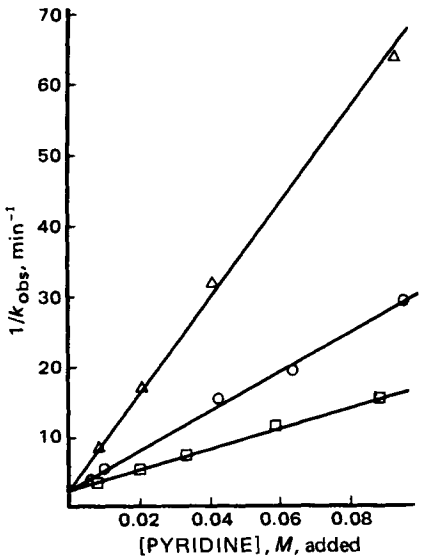

Figure 3—*Inverse rate constant for hydrolysis of I as a function of added pyridine concentration according to Eq. 5. Key:* (△) *pH 12.15,* (○) *pH 12.45,* (□) *pH 12.74.*

Equation 5 predicts a linear pH-dependent relationship between $1/k_{obs}$ and pyridine concentration, with slope = $k_{-1}/[k_1(k_{H_2O} + k'_{OH}K_w/a_H)]$ and intercept $1/k_1$. Figure 3 is an inverse plot according to Eq. 5 for the data in Fig. 2. Division of the intercept in Eq. 5 by the slope allows elimination of k_1 giving a hydroxide-dependent ratio, R:

$$R = \frac{k_{H_2O} + k'_{OH}K_w/a_H}{k_{-1}} \qquad \text{(Eq. 6)}$$

Figure 4 is a plot of R *versus* K_w/a_H with slope equal to $k'_{OH}/k_{-1} = 0.29$ and zero intercept. Thus, the reaction of the intermediate with water (k_{H_2O}) was negligible compared to k_{-1}. The slope of Fig. 3 indicates that the intermediate is 3.4-fold more reactive with pyridine than with hydroxide ion.

Effect of Added Substances on the Hydrolysis of I—The hydrolysis of I exhibited significant salt and solvent effects (Table III). The rate of hydrolysis at pH 12.8 decreased by one-half as ionic strength increased from 0.08 to 1.0. Identical rates of hydrolysis were obtained when potassium chloride–potassium iodide mixtures were used as electrolyte even though iodide is a stronger nucleophile in most displacement reactions. Addition of the polar nonelectrolytes, acetonitrile and dimethylformamide, at ~4 and 7% (v/v), respectively, strongly increased the observed rate at constant ionic strength.

Table IV contains apparent second-order rate constants and experimental conditions for the effect of several nucleophilic substances on the hydrolysis of I. A Brønsted plot of this data (log k_2^{app} *versus* pK'_a) showed a slope of ~0.1 indicating that the reaction was essentially insensitive to changes in basicity. The effect of imidazole was pH-dependent. As pH increased the apparent catalytic constant for imidazole decreased. In Fig. 5a, the apparent second-order rate constants for imidazole have been plotted against K_w/a_H. If the rate effect of imidazole anion was negligible compared to the neutral molecule, a description of the kinetic data gives:

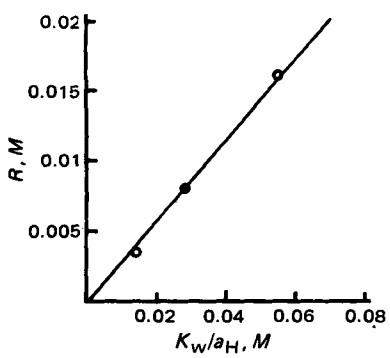

Figure 4—*Dependence of the ratio,* R, *on hydroxide ion concentration according to Eq. 6.*

Table III—Effect of Variations in Salt and Solvent Concentrations on the Hydrolysis of I

Conditions[a]	Ionic Strength	k_{obs}, min^{-1}	$\frac{k_{obs}}{k_{max}}$
0.92 *M* KCl	1.0	0.415	1
0.08 *M* KOH	0.08	0.800	1.9
0.4 *M* KI	1.0	0.414	1.0
0.8 *M* KI	1.0	0.410	0.99
1.15 *M* CH_3CN	1.0	0.611	1.5
1.02 *M* *N*,*N*-dimethylformamide	1.0	1.243	3.0

[a] All solutions contained 0.08 *M* KOH.

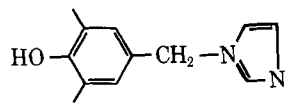
$$k_2^{app} = k_0\left[\frac{a_H}{K'_a + a_H}\right] \qquad \text{(Eq. 7)}$$

where k_0 is the second-order rate constant for the effect of neutral imidazole on the hydrolysis of I, and K'_a is the apparent dissociation constant for imidazole as an acid. Inversion and rearrangement gives:

$$\frac{1}{k_2^{app}} = \frac{1}{k_0} + \frac{K_w}{k_0K'_ba_H} \qquad \text{(Eq. 8)}$$

Equation 8 predicts a linear relationship between reciprocal rate constant and K_w/a_H as shown in Fig. 5b. The second-order rate constant for imidazole in Table IV was calculated from the intercept of Fig. 5b.

Upon hydrolysis of a concentrated solution of I in the presence of imidazole, *N*-(4-hydroxy-3,5-dimethylbenzyl) imidazole (VI) crystallized and was isolated as a product.

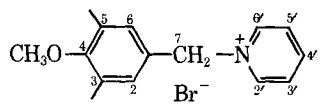


VI

The effect of added imidazole on the product composition for the hydrolysis of I at pH 12.70 was determined by HPLC. Figure 6 shows the effect of imidazole on the molar ratio of imidazole- and hydroxide-substituted products, $[VI]/[III]_\infty$, at the end of the reaction. The kinetic effect of added imidazole at pH 12.70, $k_2^{app} = 0.22\ M^{-1}\ min^{-1}$, can be interpolated from Fig. 5a. Therefore, the ratio of rate constants for the effects of imidazole and hydroxide at this pH was $k_2^{app}/k_{max} = 0.5\ M^{-1}$. Comparison of this value with the slope of Fig. 6, 14 M^{-1}, indicates that 28-fold more imidazole was appearing in the product than could be accounted for by the apparent second-order rate dependency.

The potent nucleophile cyanide ion had no effect on the rate of hydrolysis of I at pH 12.47 (Table IV). The low standard deviation for duplicate runs at each concentration of cyanide ion ($0.446 \pm 0.010\ min^{-1}$) indicated the absence of any effect other than that attributable to salt composition.

Stability of the *O*-methyl Quaternary Salts—No change in absorption spectrum was detectable when *N*-(4-methoxy-3,5-dimethylbenzyl)pyridinium bromide(VII) was dissolved in water, 1.0 *M* KOH, or 1.0 *M* NaCN and scanned with time over a 1-hr period. Replacement of the phenolic hydrogen by a methyl ether completely eliminated the instability of I in solution.



VII

When the NMR spectrum of VII in alkaline deuterium oxide (pD 13.1) was scanned over a 6-day period at room temperature, the benzylic protons (position 7) and the 2′ and 6′ protons of the pyridine ring were completely exchanged. Under these conditions, no decomposition of VII could be detected. Similar exchange has been reported for 1-methyl and 1-oxypyridinium ions (15). The analogous quaternary derivative of niacinamide was also stable in base but formed an apparent cyanide adduct with characteristic absorption maximum at 340 nm (16).

Hydrolysis of Aliphatic Quaternary Compounds—Analogous quaternary derivatives of *N*,*N*-dimethylaniline (VIII) and trimethylamine (IX) hydrolyzed similarly to I and II except that rate inhibition by the product amine was a more serious problem:

Table IV—Apparent Second-Order Rate Constants for the Effect of Nucleophiles on the Hydrolysis of I[a]

Species	pK'_a	k_2^{app}, M^{-1} min^{-1}	pH	Conc. Range, M
Iodide	—	0	12.75	0.4–0.8

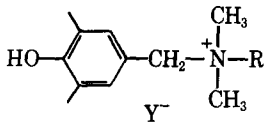
[a] At 25°, μ = 1.0. [b] Reference 13. [c] $(k_{obs} - k_0)/[N]$. [d] Reference 14. [e] pH independent. [f] pK'_a = pH − log[$\alpha_n/(1-\alpha_n)$], where α_n is the fraction of nonionized amine.

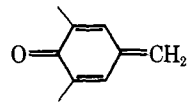


VIII: R = phenyl, Y = Br
IX: R = CH_3, Y = I

Initial rate data for VIII at neutral pH and the highest practicable dilution allowed estimation of k_{max} as shown in Table V. Stopped-flow measurements were not possible due to the instability of VIII in all solvents in which it was soluble. Hydrolysis of the trimethylammonium salt (IX) was studied using 10-cm UV cells in which first-order kinetics were obtained. Constant values of k_{max} were measured at pH 12.5 and 12.9.

Table V summarizes the hydrolysis data for I, II, VIII, and IX as a function of the pK'_a of the tertiary amine leaving group. When these data are plotted as log k_{max} *versus* pK'_a, heterocyclic and aliphatic ammonium compounds appear to fall on separate lines with slope ≃0.8, according to the limited data available. The aliphatic quaternary ammonium compounds are ~250 times more reactive than the pyridinium compounds. More data would be necessary to determine the existence of any possible structure–reactivity relationships.

Reactions in Methanol—The quaternary salts react in methanol to form amine and 4-methoxymethyl-2,6-dimethylphenol, which was identified by TLC comparison with a synthesized sample. In this solvent VIII exhibited unexpectedly high absorptivity, a different λ_{max} (285 nm), and a monoexponential decline in absorbance with $t_{1/2}$ = 17 sec. An identical rate constant and λ_{max} were reported previously (18) for the reaction of the quinone methide, 4-methylene-2,6-dimethyl-2,5-cyclohexadien-1-one (V), with methanol:



V

Apparently VIII completely dissociated to amine and V by the time the spectrophotometric data were obtained. The reaction of I and II was biexponential and showed a broad rise and fall in absorbance with time. An added complication was that the rates of both steps were sensitive to small amounts of water in the methanol. Due to this problem and the kinetic complexity of A ⇌ B → C systems, reactions in methanol were not studied further.

When the quaternary compounds were dissolved in polar aprotic solvents, *e.g.*, acetonitrile, dimethylformamide, or dimethyl sulfoxide, the dissociation equilibrium was again rapidly established. Since the reaction of V with these solvents was not possible, condensation reactions occurred to form dimeric products (19).

DISCUSSION

Mechanism of Hydrolysis—The intermediate in the aqueous reaction of these quaternary compounds was probably the quinone methide (V). A generalized form of Scheme III involving unimolecular dissociation of phenoxide zwitterion to V and tertiary amine, followed by trapping of the intermediate with solvent or nucleophiles, is consistent with the data. A kinetically indistinguishable pathway is possible, involving reaction of hydroxide with the protonated form of the quaternary compounds. If this mechanism were operative, compounds with the phenolic

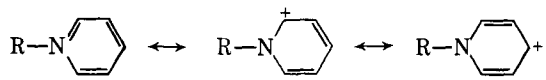
hydrogen replaced by a methyl group should exhibit comparable rates of hydrolysis to the phenolic derivatives. The complete stability of the methoxy compounds under conditions where their phenolic derivatives were quite unstable rules out a mechanism involving nucleophilic attack of hydroxide ion.

Although the proposed quinone methide intermediate (V) was too unstable in water to be observed spectrophotometrically, its presence was essential in explaining the kinetic data. Moreover, spectrophotometric detection of this compound upon methanolysis of the quaternary derivatives strongly suggested that the same intermediate occurred in water.

The mass law effect of added pyridine in the hydrolysis of I supports the proposed unimolecular mechanism. In the absence of added pyridine, the rate of reaction of V with solvent was faster than its reaction with pyridine. The rate-determining step under these conditions was the loss of reactant (k_1) and pH-independent kinetics were observed. Addition of small amounts of pyridine greatly increased the rate of reversion of V to starting material and caused the observed rate constant to exhibit an inverse dependence on pyridine concentration. The approximation that the rate of reaction of quinone methide with hydroxide was much faster than its reaction with pyridine was no longer valid. In this manner addition of pyridine transformed an apparently pH-independent reaction into one which was first-order in hydroxide.

The maximum rate of hydrolysis of the quaternary compounds of this study was quite sensitive to the structure and basicity of the tertiary amine leaving group (Table V). The rate increased with decreasing basicity of the leaving group for structurally similar compounds. Structural influence is demonstrated by the quaternary compounds of dimethylaniline and pyridine reacting at quite different rates, even though the amine leaving groups had similar pK'_a values. The large rate difference between the two structural classes is due to resonance stabilization of the pyridinium derivatives, as opposed to the instability of the aliphatic and aryl-aliphatic amines (20):



Charge delocalization of this type is not possible with salts of aliphatic or aryl-aliphatic amines.

Effect of Additives on the Rate of Hydrolysis—The effect of medium on reaction rates in solution is described by the Brønsted equation:

$$k = k_0 \frac{\gamma_A \gamma_B}{\gamma_\pm} \qquad \text{(Eq. 9)}$$

where k is the observed reaction rate constant, k_0 is the limiting value of the rate constant at zero concentrations of all solutes, and the γ's are the activity coefficients of the reactants and transition state (12). For the unimolecular reactions of the present report, this equation can be expressed as:

$$k = k_0 \frac{\gamma_z}{\gamma_\pm} \qquad \text{(Eq. 10)}$$

with γ_z defined as the activity coefficient of the zwitterionic reactant.

The hydrolysis of I involved a negative salt effect, *i.e.*, the compound was more stable as ionic strength increased. This phenomenon was due to stabilization of the zwitterionic reactant by added salt (a decrease in γ_z) more than the nonpolar transition state. Usually, a unimolecular reaction of an electrically neutral species is insensitive to variations in ionic strength (12). The highly polarized zwitterion of I, however, would be expected to be affected greatly by changes in ionic strength of the medium.

The addition of nonionic solutes at constant ionic strength caused a rate effect opposite to that of added salt. Acetonitrile or dimethylformamide stabilized the nonpolar transition state causing an increase in rate. This effect was exhibited more dramatically by the several thousand-fold increase in rate of decomposition in methanol compared to water. In addition, the reactant in methanol was presumably the nonionized phenol which was essentially unreactive in water.

The presence of several inorganic and organic nucleophilic species increased the rate of hydrolysis of I (Table IV). A Brønsted slope of ~0.1 was found for this data. Charged nucleophiles, *e.g.*, acetate, azide, imidazole anion, glycinate, and hydroxide, exhibited negative deviations compared to neutral substances of similar pK'_a values. The less polar amines, morpholine, and butylamine showed greater than first-order rate dependencies (11) while cyanide of similar basicity had no effect. These data suggest that the nucleophilic substances affect the activity coefficients rather than participating in a general acid–base or nucleophilic reaction with I.

The apparent Brønsted correlation of rate with basicity was probably a kinetic artifact arising from the effects of added solutes on the activity coefficients. The pH dependency of the effect of imidazole on the hydrolysis of I was in accord with this hypothesis. Imidazole anion is generally a much stronger nucleophile than the neutral form, although it was less effective in causing hydrolysis of I. This behavior is consistent with the expected effect of a charged species on the activity coefficients. The lack of kinetic dependency on cyanide ion is also in agreement with this hypothesis. Added sodium cyanide at constant ionic strength should have very little effect on the activity coefficient, although this compound is a strong nucleophile. The k_{OH} term observed in the hydrolysis of I was thought to be due to medium effects of hydroxide ion rather than a nucleophilic or base-catalyzed reaction.

Hydrolysis of the Ester (IV)—When the phenolic group of I was acetylated, the slow step in the overall rate of hydrolysis <pH 12.5 was the hydrolysis of the ester. The rapid hydrolysis of the quaternary compounds can, therefore, be moderated by the choice of a suitable ester function. The second-order rate constant for hydrolysis of IV is ~10-fold smaller than that for hydrolysis of phenyl acetate (13). This value is reasonable considering the rate-retarding steric and electronic effects of the two *ortho* methyl groups (21) and the accelerating effect of the ammonium group.

The results of this preliminary report indicate that quaternization and hydrolysis *via* quinone methides is a possible method for forming useful prodrug derivatives of tertiary amines. The simple amines studied represent a wide range of basicity and structure. Although actual drug molecules were not employed, the results are expected to be easily extrapolated to more complex molecules. Esterification yields a quaternary salt for which the release of the parent drug is controlled by ester hydrolysis. This is desirable since structure–reactivity relationships of esters are well known and the compounds should be substrates for enzymatic cleavage *in vivo*.

Possible Quinone Methide Intermediates in Drug Degradation—The abnormally high reactivity of drugs containing the *o*- or *p*-hydroxybenzyl alcohol structure has been recognized and studied previously (8). In a survey of reactions of several pharmaceuticals with bisulfite, an *o*- or *p*-hydroxyl or amino group was essential for reaction. *meta*-Substituted isomers as well as *o*- or *p*-methoxy derivatives were unreactive with sulfite under the experimental conditions. Substituted benzyl sulfonic acids were determined to be the products in several of the reactions. An explanation for these data would be reversible dehydration to form the quinone methide followed by a rapid reaction with bisulfite to form the sulfonate product.

The reaction of epinephrine with bisulfite also suggests the intermediacy of a quinone methide (7). Below pH 5 the rate of degradation was zero-order in bisulfite concentration indicating a unimolecular mechanism. Additional evidence for a quinone methide intermediate is the specific acid catalyzed racemization of epinephrine observed in the absence of bisulfite (22). The planar intermediate formed by dehydration could react with solvent to form optically inactive epinephrine.

Concentration-Dependent Disappearance of Fluorouracil from Peritoneal Fluid in the Rat: Experimental Observations and Distributed Modeling

JERRY M. COLLINS ˣ, ROBERT L. DEDRICK, MICHAEL F. FLESSNER, and ANTHONY M. GUARINO

Received February 12, 1981, from the *Biomedical Engineering and Instrumentation Branch, Division of Research Services and the Developmental Therapeutics Program, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication October 6, 1981.

Abstract □ The rate of disappearance of fluorouracil from peritoneal fluid has been experimentally measured and mathematically modeled. The experimental data were obtained following the instillation of 50 ml of dialysis fluid which contained an initial fluorouracil concentration ranging from 24 μM to 12 mM. The rate of disappearance was strongly dependent upon concentration. A distributed model has been formulated which incorporates concepts of diffusion with saturable metabolism and nonsaturable capillary uptake in the tissue surrounding the peritoneal fluid. This model successfully describes the experimental observations and also suggests that the effective penetration depth into tissue is highly dependent upon concentration.

Keyphrases □ Fluorouracil—concentration-dependent disappearance from peritoneal fluids, rats □ Pharmacokinetics—concentration-dependent disappearance of fluorouracil from peritoneal fluid, rats □ Peritoneal fluid—concentration-dependent disappearance of fluorouracil, rats

Although intraperitoneal injections are extensively used for the administration of drugs to rodents, there are few studies which examine the kinetic features of this route (1, 2). When drugs are administered in a small volume, it is usually assumed that absorption occurs through pathways which lead to the portal vein. For larger volumes, as used in peritoneal dialysis, nonportal pathways such as the ventral abdominal wall, diaphragm, and retroperitoneal tissues may have a significant role. Lymphatic uptake, although largely unexplored, is assumed to be quantitatively unimportant for substances with small molecular weights.

The rate of disappearance of drugs from peritoneal fluid is primarily a consequence of the concentration gradient established between peritoneal fluid and surrounding tissue. As drug molecules diffuse into this tissue, they can be carried away by capillary blood, metabolized by enzymes in the tissue, or be bound to tissue constituents. Removal by capillary blood is kinetically a first-order process, while metabolism and tissue uptake or binding are potentially saturable since these processes depend upon a finite number of sites.

The intraperitoneal administration of the pyrimidine analog, fluorouracil, is currently undergoing clinical evaluation for the treatment of several cancers which are initially confined to the abdomen (2, 3). Since the clinical range of intraperitoneal fluorouracil concentration is restricted by therapeutic considerations, a previously developed rat model was used for these peritoneal disappearance studies. The metabolism of fluorouracil is saturable (4), and at least some tissues surrounding the peritoneal cavity are sites for this metabolism (5). No tissue binding has been reported.

Data have been collected on the rate of peritoneal disappearance over a wide range of initial concentrations in order to observe metabolism in both linear and nonlinear regions. A distributed model has been formulated which incorporates concepts of diffusion with chemical reaction and capillary uptake in the surrounding tissue. The nonlinear partial differential equation was solved numerically with the appropriate initial and boundary conditions. The solution suggests that the effective penetration depth into the tissue and the rate of removal from the peritoneal cavity are concentration dependent.

Concentration-Dependent Disappearance of Fluorouracil from Peritoneal Fluid in the Rat: Experimental Observations and Distributed Modeling

JERRY M. COLLINS ˣ, ROBERT L. DEDRICK, MICHAEL F. FLESSNER, and ANTHONY M. GUARINO

Received February 12, 1981, from the *Biomedical Engineering and Instrumentation Branch, Division of Research Services and the Developmental Therapeutics Program, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication October 6, 1981.

Abstract □ The rate of disappearance of fluorouracil from peritoneal fluid has been experimentally measured and mathematically modeled. The experimental data were obtained following the instillation of 50 ml of dialysis fluid which contained an initial fluorouracil concentration ranging from 24 μM to 12 mM. The rate of disappearance was strongly dependent upon concentration. A distributed model has been formulated which incorporates concepts of diffusion with saturable metabolism and nonsaturable capillary uptake in the tissue surrounding the peritoneal fluid. This model successfully describes the experimental observations and also suggests that the effective penetration depth into tissue is highly dependent upon concentration.

Keyphrases □ Fluorouracil—concentration-dependent disappearance from peritoneal fluids, rats □ Pharmacokinetics—concentration-dependent disappearance of fluorouracil from peritoneal fluid, rats □ Peritoneal fluid—concentration-dependent disappearance of fluorouracil, rats

Although intraperitoneal injections are extensively used for the administration of drugs to rodents, there are few studies which examine the kinetic features of this route (1, 2). When drugs are administered in a small volume, it is usually assumed that absorption occurs through pathways which lead to the portal vein. For larger volumes, as used in peritoneal dialysis, nonportal pathways such as the ventral abdominal wall, diaphragm, and retroperitoneal tissues may have a significant role. Lymphatic uptake, although largely unexplored, is assumed to be quantitatively unimportant for substances with small molecular weights.

The rate of disappearance of drugs from peritoneal fluid is primarily a consequence of the concentration gradient established between peritoneal fluid and surrounding tissue. As drug molecules diffuse into this tissue, they can be carried away by capillary blood, metabolized by enzymes in the tissue, or be bound to tissue constituents. Removal by capillary blood is kinetically a first-order process, while metabolism and tissue uptake or binding are potentially saturable since these processes depend upon a finite number of sites.

The intraperitoneal administration of the pyrimidine analog, fluorouracil, is currently undergoing clinical evaluation for the treatment of several cancers which are initially confined to the abdomen (2, 3). Since the clinical range of intraperitoneal fluorouracil concentration is restricted by therapeutic considerations, a previously developed rat model was used for these peritoneal disappearance studies. The metabolism of fluorouracil is saturable (4), and at least some tissues surrounding the peritoneal cavity are sites for this metabolism (5). No tissue binding has been reported.

Data have been collected on the rate of peritoneal disappearance over a wide range of initial concentrations in order to observe metabolism in both linear and nonlinear regions. A distributed model has been formulated which incorporates concepts of diffusion with chemical reaction and capillary uptake in the surrounding tissue. The nonlinear partial differential equation was solved numerically with the appropriate initial and boundary conditions. The solution suggests that the effective penetration depth into the tissue and the rate of removal from the peritoneal cavity are concentration dependent.

EXPERIMENTAL

Separation of Fluorouracil from Its Metabolites—Fluorouracil is extensively metabolized by both anabolic and catabolic enzymes. The goal of this separation procedure was to isolate the parent compound, fluorouracil, but not necessarily to identify individual metabolites. A 10–25-μl sample of peritoneal fluid was applied to 250 μm of silica gel G TLC plates[1]. Each plate included a [^{14}C]fluorouracil[2] standard. The plates were developed for 10 cm by the upper phase of the solvent system of Koechlin *et al.* (6): ethyl acetate (60%, v/v), formic acid (5% v/v), and water (35%, v/v). Samples were counted in a liquid scintillation counter with automatic external standardization. In this system, 97% of [^{14}C]-fluorouracil radioactivity was located above R_f 0.45, while all metabolites were below R_f 0.45 ([^{14}C]floxuridine[2], 98%; [^{14}C]urea[3], 99%; [^{14}]fluoro-ureido-propionic acid, 99%). Since dihydrofluorouracil is unstable in this system, it was measured as fluoro-ureido-propionic acid or urea (6). [^{14}C]Fluoro-ureido-propionic acid was isolated by the procedure of Chauduri *et al.* (7) from the urine of rats given [^{14}C]fluorouracil. Urine was placed on anion exchange resin[4] (10 × 1 cm) and eluted with 50 ml of water, 80 ml of 0.05 *M* formic acid, 150 ml of 1.5 *M* formic acid, and finally 50 ml of 0.5 *M* HCl. [^{14}C]Fluoro-ureido-propionic acid was found in the third fraction. [^{14}C]Fluorouracil standard eluted in the second fraction, as validated by TLC.

Experimental Procedures—Female Sprague-Dawley rats[5] (220–240 g) were anesthetized with 50 mg/kg ip pentobarbital. Supplemental doses of 15 mg/kg im were given as required. Fluorouracil[2] was dissolved in peritoneal dialysis solution[6] (major components: 1.5% dextrose; 132 mEq Na; 3.5 mEq Ca; 1.5 mEq Mg; 99 mEq Cl; 35 mEq lactate), and the solution was warmed to 37°. [^{14}C]Fluorouracil was added to yield total fluorouracil concentrations ranging from 24 μM to 12 m*M*. Fifty milliliters of drug solution was injected into the peritoneal space through an 18-G needle. Periodic 100-μl samples were obtained by transcutaneous puncture with a 23-G needle. Rectal temperature was maintained at 37 ± 0.2° by means of a heat lamp and temperature controller[7].

Simulations—Although an analytical solution is not feasible for the model presented in the Appendix, Eqs. 1 and 2 can be integrated numerically, using Eqs. 3*a*, 3*b*, and 3*c* as initial and boundary conditions. The simulations presented in this paper were computed by means of the implicit form of the finite difference method, based on the algorithm of Carnahan *et al.* (8).

RESULTS

Measurements of fluorouracil disappearance from peritoneal fluid are plotted in Fig. 1. Initial fluorouracil concentrations in the peritoneal fluid ranged from 24 μM to 12 m*M*. There is a very strong dependence of disappearance rate on concentration. The rate of disappearance at low concentration is 10-fold greater than at high concentration.

The simulated disappearance curves shown in Fig. 1 were obtained by numerical integration of Eqs. 1–3 from Appendix I. The model parameters are discussed in Appendix II. The *a priori* parameters associated with the simulations in Fig. 1 provide an adequate representation of the data over the five orders of magnitude that drug concentration was measured. Although a statistical best fit was not attempted[8], an example of the ability of the distributed model to match more closely the experimental data is presented in Fig. 2. For these simulations, V_{max} was arbitrarily adjusted to 36 nmole/min/g and K_M to 5 μM, while the other parameters were unchanged.

Solution of Eqs. 1–3 also yields information about the concentration profile of drug in tissue. There are no experimental data for comparison, and these calculations are highly dependent on assumptions about model geometry. Nonetheless, there are some important predictions worthy of consideration. Figure 3 shows that the tissue concentration profile requires 15 min to become fully developed for an initial peritoneal concentration of 12 m*M*. In contrast, Fig. 4 shows that only 1 min is required for profile development when the initial peritoneal concentration is 24 μM. At high concentrations, >600 μm are needed for the tissue concentration to drop to 5% of the tissue fluid interfacial value, while <200 μm are required for the same percentage drop at low concentration. Also, there are qualitative differences in the shape of the profiles. At low concentrations, the fully developed profile is log-linear, since metabolism dominates and is essentially linear in this concentration range. At high concentration, the profile is convex downward as a result of changes in the extent of saturation of metabolism.

DISCUSSION

The strong concentration-dependence of fluorouracil disappearance from peritoneal fluid is a novel observation and a challenge for pharmacokinetic modeling. It is likely that the peritoneal disappearance is

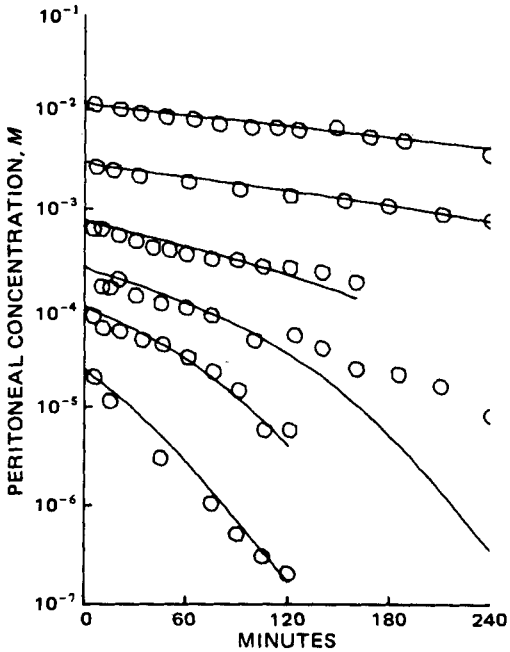

Figure 2—*Disappearance of fluorouracil from peritoneal fluid. Key: experimental data (O) plus simulations (—). Simulation parameters are the same as in Fig. 1, except that* K_M = 5 μM *and* V_{max} = 36 *nmole/min/g.*

[8] Such calculations would have limited usefulness in the absence of experimental data for tissue concentration profiles. These calculations would also be extremely expensive.

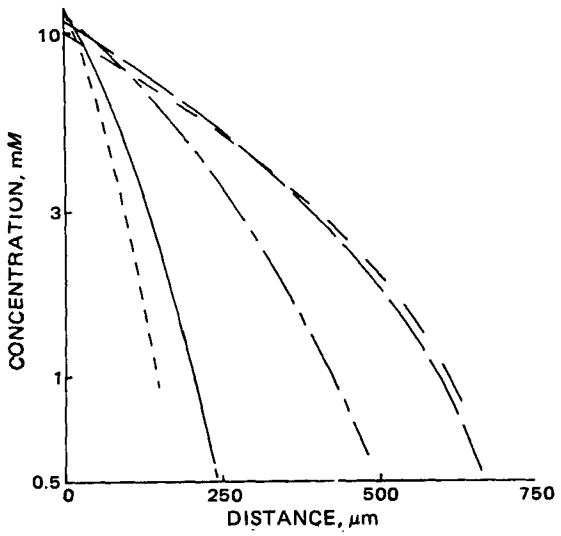

Figure 3—*Simulated time course for development of concentration profile in tissue. Initial concentration at interface is 12 m*M. *Key: (- - -) 30 seconds after dialysis fluid is added; (——) 1 min after; (— –) 5 min; (— —) 15 min; and (– – –) 30 min.*

a consequence of diffusion of drug into the surrounding tissue, where removal of fluorouracil by blood and metabolism by tissue enzymes are competing parallel processes. Although the drug is stable in peritoneal fluid itself, it is quite plausible that cells in the peritoneal membrane, and especially in the surrounding tissues, have sufficient enzyme capacity to account for the observed increase in fluorouracil disappearance at low concentrations. Both catabolic and anabolic enzymes for fluorouracil metabolism are widespread in body tissues, including abdominal organs (7, 9).

The selection of a modeling approach must be justified by the nature of the information obtained from the model. In the analysis of fluorouracil peritoneal disappearance data, there are two major items of interest: the depth to which the drug can penetrate into tissue and the relative role of removal by blood flow compared with metabolic elimination. Compartmental analysis is the major tool used in pharmacokinetic analysis. This approach consolidates areas of the body into regions in which the concentation is a function of time but not of anatomic position. Compartmental analysis cannot provide assistance for the two items outlined previously. Therefore, the next level of pharmacokinetic modeling has been utilized for the analysis of peritoneal uptake data, namely, direct consideration of positional variations in concentration.

Penetration distance is the crucial parameter for two major clinical questions which need to be answered regarding intraperitoneal therapy:

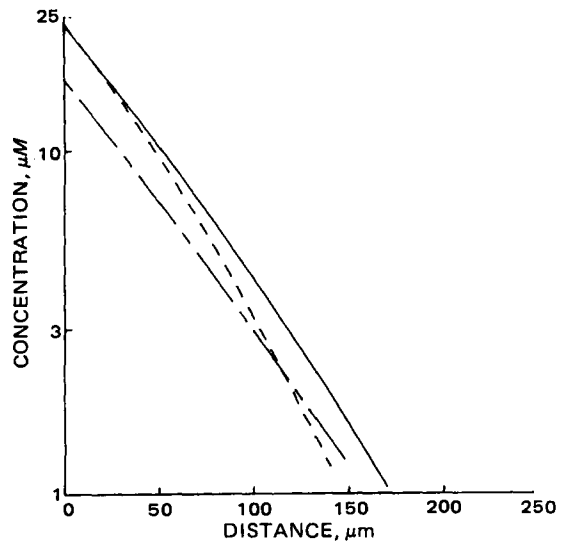

Figure 4—*Simulated time course for development of concentration profile in tissue. Initial concentration at interface is 24 μ*M. *Key: (- - -) 30 sec; (——) 1 min; (— –) 5 min after dialysis fluid is added.*

(a) How large a tumor will be exposed to drug levels which are in excess of those which can be achieved with systemic therapy. (b) Since GI mucosal cells are a major site for drug toxicity, what concentration can be administered safely, *i.e.*, does not cause penetration of high drug levels to these cells.

For comparative purposes, a penetration depth may be defined as the distance at which the tissue concentration has declined to some percentage of the interfacial concentration. As noted previously, the 5% penetration depth is a strong function of concentration: <200 μm for an interfacial concentration of 24 μM and >600 μm for 12 mM. Thus, not only are tissues exposed to higher concentrations as peritoneal fluid concentration is raised, but progressively deeper tissues are exposed. When referred to a typical cell diameter of 10 μm, these penetration distances are equivalent to a depth of 20–60 cells.

The second major question about peritoneal uptake concerns the relative roles for blood and metabolic removal. Fortunately, this question can be addressed without the specification of a particular geometry for tissue uptake. As long as the ratio of blood removal capacity to metabolic capacity is independent of position, some conclusions can be reached about their relative roles, regardless of the exact three-dimensional location of these processes in tissue. The dominant process is simply determined by a comparison of the removal terms in Eq. 2, $V_{max}/(K_M + C)$ *versus* PS/V. For the parameters given in Appendix II, the two removal processes are equally effective when C = 2.4 mM. At the highest concentration used in this study, 12 mM, blood flow removal is 5-fold greater than metabolic removal. However, as fluorouracil penetrates the tissue, its concentration is reduced until the dominant role is shifted to metabolism. In the linear range of metabolism ($K_M \ll C$) the rate of metabolism is 79 times as great as the rate of removal by flowing blood. The specific shape of the tissue concentration profile is dependent on model geometry, but the trends illustrated in Figs. 2 and 3 are generalized properties of distributed modeling.

Distributed models can be very useful in pharmacokinetics in special circumstances such as when there is a need for understanding the positional variation of concentration. Construction of distributed models requires information about kinetic properties as a function of position, and verification of distributed models requires experimental determination of concentration profiles in tissue. This combination of experimental data and distributed modeling is very rare. One excellent study describes the penetration of several anticancer drugs into brain tissue (10). However, there is no study in which a metabolized substance has been quantified. Indeed, the technology for exposing tissue to a rapidly metabolized drug and then quenching the metabolism and assaying for spatial variation in the concentration of the parent within ~200 μm probably does not exist.

Since the profile data are not available for fluorouracil, all quantitative aspects of the proposed model cannot be validated. The principal goal of this modeling effort has been to demonstrate the plausibility of a distributed model for the analysis of pharmacokinetic data. The model structure has been shown to be consistent with the peritoneal disappearance data, but no attempt has been made to choose the best model parameters based on statistical criteria. Despite its limitations, the distributed modeling process has given insight into the mechanisms of disappearance for fluorouracil and has suggested a strong dependence of penetration depth on peritoneal fluid concentration. Further experimental design could be guided by these results.

APPENDIX I

Distributed Model for Peritoneal Disappearance—The rate of disappearance of fluorouracil from peritoneal fluid can be governed by a variety of resistances to mass transport. The model which is described in this section is based on diffusion of fluorouracil through the extracellular space of peritoneal tissue. As will be discussed, there is no transcellular pathway, but intracellular drug is in equilibrium with extracellular concentration.

For a constant peritoneal fluid volume (V_{ip}), the rate of change of drug concentration in the peritoneal fluid (C_{ip}) depends on the diffusivity of the drug in surrounding tissue (D), the area available for transport (A), and the concentration gradient in the tissue at the tissue–fluid interface. The concentration in the surrounding tissue (C, extracellular or diffusible concentration) depends on both anatomic position and time. The diffusion problem has been represented by a one-dimensional model in which constant kinetic properties are assumed throughout the tissue; *i.e.*, diffusivity, capillary permeability (PS/V), maximum metabolic capacity (V_{max}), and half-saturating concentration (K_M). R is the ratio of intracellular to extracellular drug mass.

$$V_{ip}\frac{dC_{ip}}{dt} = -DA\left.\frac{\delta C(x,t)}{\delta x}\right|_{x=0} \quad \text{(Eq. 1)}$$

$$\frac{\delta C}{\delta t} = \frac{D}{R+1}\frac{\delta^2 C(x,t)}{\delta x^2} - \frac{1}{(R+1)}\frac{PS}{V}C(x,t) - \frac{1}{(R+1)}\frac{V_{max}C(x,t)}{K_M + C(x,t)} \quad \text{(Eq. 2)}$$

The term PS/V should be interpreted as effective capillary permeability, since tissue perfusion rate may also limit the rate of capillary removal. Metabolism is referred to extracellular fluorouracil concentration, since that was the basis in the hepatocyte parameter estimation (11).

Initially, the tissue concentration is zero throughout, and there is always some point ($x = x'$) where the gradient has vanished. As will be discussed, resistance to mass transfer posed by the peritoneal fluid is assumed to be negligible. Thus, the initial and boundary conditions are:

$$C_{ip}(0) = C(0,0) = C_0 \quad \text{(Eq. 3a)}$$

$$C(x,0) = 0 \quad \text{(Eq. 3b)}$$

$$\frac{\delta C(x',t)}{\delta x} = 0 \quad \text{(Eq. 3c)}$$

Resistance Within Peritoneal Fluid—The peritoneal fluid drug concentration, which is measured experimentally, is the bulk fluid concentration. The concentration at the interface between peritoneal fluid and tissue will be less than the bulk fluid concentration if the rate of drug transport in fluid is not much faster than the rate capacity of the tissue to take up drug. Resistance to drug transfer in the bulk fluid might be visualized as a stagnant layer adjacent to the tissue. Calculations for intraperitoneal fluorouracil based on stagnant layer thickness reported previously (12) suggest that this resistance is negligible at high concentrations and has a mild influence at low concentrations.

Diffusion Pathways—Drug diffusion through tissue may involve transcellular pathways in addition to extracellular movement. Several possibilities exist: (*a*) extracellular drug movement and very little, if any, intracellular uptake; (*b*) very rapid transcellular movement so that drug effectively moves through both pathways; and (*c*) moderate transcellular movement so that drug moves only extracellularly but equilibrates with intracellular space. The third option was selected based on a comparison of transfer rates through extracellular space, across cells, and across capillaries. A half-time for cellular uptake of fluorouracil of 40 sec or less can be calculated from reports for hepatoma cells (13), Ehrlich ascites cells (14), and L 1210 cells (15). Since the transcapillary exchange half-time of 140 sec, calculated from PS/V, is substantially slower, there is sufficient time for intracellular exchange and option (*a*) can be eliminated. The characteristic time (x^2/D) for extracellular diffusion is only 0.2 sec, based on a half-cell diffusion distance (5 μm) and a fluorouracil diffusivity of 1.2×10^{-6} cm^2/sec. Therefore, option (*b*) was eliminated since extracellular movement is very rapid compared to transcellular movement.

APPENDIX II

Parameter Selection—There are seven parameters in Eqs. 1 and 2. Since V_{ip} was experimentally set to 50 ml, six parameter values must be estimated:

1. Michaelis constant (K_M) was fixed at 30 μM. This value has been reported for fluorouracil metabolism in rat liver cells (11).
2. Maximum metabolic capacity per cubic centimeter of tissue (V_{max}) was fixed at 71 nmole/min/cm^3, a value which has been reported for rat liver tissue (11). Values of V_{max} or K_M for other tissues have not been reported.
3. Area of tissue available for flux (A) was set at 125 cm^2. If the measurements of Esperanca and Collins (16) of peritoneal surface area in human infants and adults are extrapolated using the 0.7 power of body weight to a 200-g rat, ~125 cm^2 is obtained.
4. Diffusivity (D) in tissue was estimated by the method of Schultz and Armstrong (12). First, aqueous diffusivity was estimated to be 10×10^{-6} cm^2/sec, based upon its molecular weight (17). Then the aqueous diffusivity was corrected for extracellular fluid fraction (0.3) and tortuosity (2.5) to yield a value of 1.2×10^{-6} cm^2/sec.
5. Capillary removal rate (PS/V) is the product of capillary permeability (P, cm/sec) and capillary surface per volume of tissue (S/V, cm^2/cm^3). Reported values of PS/V range from 0.004 sec^{-1} for the gastric wall of dogs for a hexose (18) to 7.6×10^{-4} sec^{-1} for glucose in muscle capillaries (19). Since 0.001 sec^{-1} is a reported value for tissue perfusion in rat muscle (20), the effective value for PS/V is limited by perfusion. A value of 5×10^{-4} sec^{-1} is consistent with these observations and provides reasonable agreement between the simulations and the data in the high-concentration concentration region where PS/V dominates.
6. The ratio (R) of intracellular to extracellular fluorouracil amount is calculated from the apparent distribution volume for fluorouracil and the extracellular fluid fraction of tissue. Based on a whole body distribution volume of 60% of body weight (4) and an extracellular fluid fraction of 0.3 (see item 4), an equal amount of drug is in the two spaces: $R = 1$.

Cardiac Stimulant Action of Constituents of *Aloe Saponaria*

AKIRA YAGI *x, SHOJI SHIBATA ‡, ITSUO NISHIOKA *, SHUICHI IWADARE ‡, and YUKISATO ISHIDA ‡

Received November 28, 1980, from the **Faculty of Pharmaceutical Sciences, Kyushu University, Maidashi, Higashi-ku, Fukuoka, Japan* and the ‡*School of Medicine, University of Hawaii, Honolulu, Hawaii.* Accepted for publication October 6, 1981.

Abstract □ A highly potent cardiotonic substance, calcium isocitrate, was isolated from *Aloe saponaria*, using solvent partition, nonionic porous resin, and gel permeation chromatographies. Cardiac stimulant activity of synthesized stereoisomers of calcium isocitrate was demonstrated in isolated guinea pig atria.

Keyphrases □ *Aloe Saponaria*—cardiac stimulation activity of various constituents, calcium isocitrate □ Calcium isocitrate—isolated from *Aloe saponaria*, cardiac stimulation of rabbit and rat, and guinea pig atria □ Stereoisomers—synthesis of calcium isocitrate stereoisomers, cardiac stimulation activity, rats, rabbits, guinea pigs

Aloe is a group of succulent plants native to dry areas, especially southern Africa. The leaves of *Aloe saponaria* have been used widely as folk medicine for various external and internal diseases such as burns, cuts, ulcers, and stomach disorders, *etc.* Aloin has been isolated from the plants as the major component (1) and is used as a purgative. While examining the antibacterial and antitumor activities of *Aloe* extracts (2), the cardioexcitatory effect of the extracts on the isolated atria was recently identified. The present experiments were undertaken to isolate the cardiotonic substances from *A. saponaria* and to evaluate their positive inotropic effects on isolated cardiac muscles.

EXPERIMENTAL

Materials[1]—Nonionic porous resin[2], anion exchange resin[3], dextran gel[4], dextran gel possessing both hydrophilic and lipophilic properties[5], and thin layer chromatography (TLC) aluminum sheets of silica gel[6] were purchased from suppliers. TLC was performed using butanol–ethanol–chloroform–28% ammonium hydroxide (4:5:2:8) and ethyl acetate–butanol–acetic acid–water (6:8:5:8) as solvent systems. Anisaldehyde–sulfuric acid and iodine were used as spraying reagents.

Chromatography—The flow rate for a column of resin[2] (4 × 6 cm) was ~20 ml/hr and for resin[3] (1.5 × 15 cm) was ~20 ml/hr. The gel filtration through dextran gel[4] (2.5 × 36 cm) and gel[5] (1.5 × 40 cm) was performed at room temperature at a flow rate of 21 ml/hr. The chromatography with silica gel[6] was performed through a column (2 × 22 cm).

Bioassay—Bioassay of compounds was performed on isolated atria of rat, rabbit, and guinea pig hearts. The atrium was separated from the rest of the heart and suspended in a 50-ml tissue bath containing Krebs-Ringer bicarbonate solution of the following composition (m*M*): sodium chloride, 120.3; potassium chloride, 4.8; calcium chloride, 1.2; magnesium sulfate, 1.3; potassium biphosphate, 1.2; sodium bicarbonate, 25.2; and glucose 5.5. The solution was continuously bubbled with a gas mixture of 95% oxygen and 5% carbon dioxide and maintained at 30°, pH 7.4. Tension was recorded isometrically through a force displacement transducer[7] and displayed on a polygraph[8]. In some experiments, spontaneously beating right atria were used; in other cases, the left atria were driven by an electrical stimulator[9] at a frequency of 1.0 Hz with square wave pulses of 5 msec at 100% above threshold voltage. The atria were allowed to equilibrate under 0.5-g tension for 60 min prior to beginning the experiment. The changes in contractile force and rate produced by the test agents are expressed as a percentage variation.

Extraction—The fresh leaves of *Aloe saponaria*[10] were harvested from the greenhouse of the herbal garden of Kyushu University. Fresh leaves (20 kg) were cut in half and colorless gelatinous pulp was separated carefully by scraping the green cortical layer which contained yellow phenolics. The homogenized pulp (6 kg) was extracted with distilled water, filtered, and the filtrate centrifuged at 10,000 rpm for 30 min. The supernate was dialyzed by dialysis membrane [11] against distilled water for 48 hr. The dialysate was flash evaporated at ≤50° to dryness (50 g).

Chromatography on Nonionic Porous Resin—The dialysate (4.4 g) suspended in methanol was chromatographed on a column of resin[2] (150 ml). After the methanolic eluate containing sugar moiety was excluded, the cardiac stimulant fraction was eluted with methanol–water (1:5) and water and evaporated to dryness.

Gel Permeation Chromatography—The crude extract dissolved in a small amount of water was reprecipitated by adding methanol to yield a colorless powder *A*. The colorless powder *A* (1 g) was chromatographed over dextran gel[4] (400 ml), using 3 ml of water as a solvent, and fractionated to fraction *A* (tube numbers 1–4) and Fraction *B* (tube numbers 5–10). Each fraction was flash evaporated to dryness and monitored by TLC. Fraction *B* (0.8 g) was further chromatographed over dextran gel[4] (400 ml), using 3 ml of water as a solvent, and fractionated to Fraction *C* (tube numbers 5–9, 0.3 g), and Fraction *D* (tube numbers 10–15, 0.2 g). Each fraction was flash evaporated to dryness and monitored by TLC.

Characterization of Compound I—Fraction *C* was reprecipitated from methanol to give a colorless powder, compound I, mp >290°, which had a strong absorption band due to carboxylate ion on IR spectrum, and presented a positive reaction to calcium ion (calcium oxalate). Compound I (1 g), dissolved in water (10 ml), was put on an anion exchange resin[3] column (20 ml) and eluted with water. The elution was continued until no residue was obtained in the flash evaporation. Then, 10% formic acid was passed through the column and the effluent was evaporated to dryness *in vacuo*. The residue (0.6 g) was chromatographed over dextran gel[5] using methanol as a solvent to give a colorless powder, compound I (free form). PMR (deuterium oxide) δ: 2.72(2H; d; d; J_{gem} = 16; J = 6, 10 Hz; —CH_2—CH_2—), 3.36(1H, m, —CH_2—CH—), 4.40(1H, d, J = 4 Hz, —CHOH—CH—). CMR (deuterium oxide) δ: 34.8(t, —CH_2—), 47.5(d, —CH—), 72.8(d, —CHOH—), 176.0, 179.0(s, COOH × 3). Compound I (free form, 40 mg) dissolved in methanol (10 ml) was methylated with diazomethane under ice cooling for 1 hr, and the reaction mixture was evaporated to dryness to yield a yellow oil (47 mg). The product was chromatographed over silica gel[7] using the solvent, ethyl acetate–chloroform (1:99), to give a colorless oil of the methyl ester (40 mg). $[\alpha]_D^{29}$ + 4.8°(*c*, 2.0 in chloroform). PMR (deuterochloroform) δ: 2.62(1H, d, d, J_{gem} = 18, J = 8 Hz, —CH_2—CH—), 2.90(1H, d, d, J_{gem} = 18, J = 8 Hz, —CH_2—CH—), 3.24(1H, d, J = 6 Hz, —CHOH—), 3.48(1H; sex; J = 8, 3 Hz; —CH—CH—CH_2—), 3.64, 3.66, 3.78($COOCH_3$ × 3), 4.32(1H; q; J = 6, 3 Hz; —CHOH—CH—). CMR (deuterium oxide) δ: 32.11(t, —CH_2—), 44.88(d, —CH—), 51.85, 52.15, 52.73(q, $COOCH_3$), 70.47(d,

[1] IR, PMR (tetramethylsilane as the internal standard), CMR (tetramethylsilane as the internal standard) and mass spectra were recorded using KOKEN DS-301, JEOL PS-100, JEOL FX-100, and JMS D-300, respectively. In the PMR descriptions, s = singlet, d = doublet, d,d = doublet of doublets, t = triplet, q = quartet, sex = sextet, and m = multiplet. Optical rotations were obtained on a JASCO DIP-4 and melting points were determined on a Yanagimoto melting point apparatus and are uncorrected.

Table I—Positive Inotropic Effect of Fractions of *Aloe* Extracts on Isolated Atria

Fraction	Increase, % mean, (n = 2–3)	Concentration, mg/ml	Animal
Dialysate	35.8	0.5	rabbit
Nonionic porous resin[2]			
methanol–water (1:5)	550	1.0	rabbit
water	570	1.0	rabbit
Powder *A*	350	1.0	rat[b]
Fraction *A*[c]	220	1.0	rat
Fraction *C*[a,d]	243	3.0	rat
Fraction *D*[a,e]	88	3.0	rat
Isoproterenol	320	5×10^{-8} *M*	rabbit
Isoproterenol	250	5×10^{-8} *M*	rat

[a] Fraction *C* and *D* increased the heart rate 23.0–55.3%. [b] Tissues were beating spontaneously. Similar results were also observed on the electrically driven atria (1.0 Hz). [c] Fraction *A*: Mixture of calcium isocitrate, malate, succinate, *etc.* [d] Fraction *C*: Calcium isocitrate. [e] Fraction *D*: Calcium malate.

Table II—Positive Inotropic Effect of Various Synthesized Isocitrates on Guinea Pig Atria[a]

Compound[b]	Increase, %[c]	Concentration, mg/ml
(+)-Calcium isocitrate	30 ± 4	5×10^{-2}
	129 ± 16	10^{-1}
(±)-Calcium isocitrate	90 ± 8	5×10^{-2}
	171 ± 18	10^{-1}
(±)-Calcium alloisocitrate	115 ± 15	5×10^{-2}
	148 ± 8	10^{-1}
(+)-Calcium isocitrate[d]	132 ± 10	10^{-1}
Isoproterenol	330 ± 35	5×10^{-8} *M*

[a] Four atria from different animals were used for each experiment, mean ±*SE*. [b] All compounds caused no apparent change in heart rate. [c] Increase of norepinephrine, 10^{-6} mg/ml, 92%. [d] Isolated from *Aloe saponaria*.

—CHOH—), 170.9, 171.8, 172.9(s, $COOCH_3$). Mass spectrum *m/z*: 235($M^+ + 1$), 175($M^+ - 60$), 143($M^+ - 59, -32$), 115($M^+ - 60, -60$). The methyl ester was identified with methyl isocitrate (3, 4) by direct comparison (IR and TLC).

Characterization of Compound II—Fraction *D* (0.4 g) was reprecipitated from methanol to give a colorless powder, compound II, mp >290°, which had a strong absorption band due to a carboxylate ion on IR spectrum and presented a positive reaction to calcium ion (calcium oxalate). Compound II (1 g) dissolved in water (10 ml) was put on an anion exchange resin[3] column (20 ml) and eluted with water. The elution was continued until no residue was obtained in flash evaporation. Then, 10% formic acid was passed through the column and the effluent was evaporated to dryness *in vacuo*. The residue (170 mg) was chromatographed over dextran gel[5] (20 ml) using acetone as a solvent to give a colorless powder, compound II (free form, 50 mg) together with a small amount of Compound III and IV (free form). Compound II (free form) mp 101–102° (ethyl acetate), $[\alpha]_D^{20}$ −6.0° (*C*, 0.4 in acetone). IR (potassium bromide) cm^{-1}: 2800–2600 (hydroxyl), 1700 (carboxylic acid). PMR (deuteroacetone) δ: 2.74(2H; d; q, J_{gem} = 16 Hz; *J* = 8, 4 Hz; —CH_2—CH—), 4.50(1H; d; d; *J* = 8, 4 Hz; —CH—CH_2—), 7–8(3H, OH, COOH). Compound II (free form, 10 mg) dissolved in methanol (10 ml) was methylated with diazomethane under ice cooling for 1 hr, and the reaction product (12 mg) was chromatographed over silica gel[6] using the solvent, *n*-hexane–chloroform (1:1) to yield a colorless oil of methyl ester (10 mg). $[\alpha]_D^{21}$ −2.5° (*C*, 0.4 in chloroform). IR (liquid film) cm^{-1}: 3350 (hydroxyl), 1730(ester), 1440(methylene), 1100. PMR (deuterochloroform) δ: 2.66(1H, d, d, J_{gem} = 16, *J* = 5 Hz, —CH_2—), 3.25(1H, OH), 3.71, 3.81 ($COOCH_3$ × 2), 4.50(1H; d; d; *J* = 5, 5 Hz; —CHOH—CH_2—). CMR (deuterochloroform) δ: 38.38(—CH_2—), 51.91, 52.68($COOCH_3$ × 2), 67.09(CHOH), 170.56, 173.32(COOH × 2). Mass spectrum *m/z*: 163($M^+ + 1$), 103($M^+ - 59$). The methyl ester was identified with methyl malate by direct comparison (IR and TLC).

Characterization of Compound III—Compound III (free form) was obtained from Fraction *D*, which showed a positive reaction to calcium ion (calcium oxalate) by the following procedure for the isolation of Compound I (free form): mp 185° (acetone), IR (potassium bromide) cm^{-1}: 2800–2600(hydroxyl), 1700(carboxylic acid). PMR (deuteromethanol) δ: 2.56(2H, s, —CH_2—). CMR (deuteromethanol) δ: 29.77(—CH_2—), 175.78(COOH). Compound III (free form) was identified with succinic acid by direct comparison (IR and mixed melting point).

Characterization of Compound IV—Compound IV (free form) was obtained from the Fraction *D*, which showed a positive reaction to calcium ion (calcium oxalate) by the following procedure for the isolation of compound I (free form): mp 74–75° (ethyl acetate), $[\alpha]_D^{20}$ −6.8° (*C*, 6.6 in acetone), IR (potassium bromide) cm^{-1}: 2800–2600(hydroxyl), 1725(ester), 1440(methylene). PMR (deuterochloroform) δ: 2.86(2H; d; d; J_{gem} = 16; *J* = 8, 6 Hz; —CH_2—CH—), 2.80(3H, $COOCH_3$), 4.52(1H; q; *J* = 8, 6 Hz; —CH_2—CH—), 6.34(br, s, OH). CMR (deuteromethanol) δ: 38.32(—CH_2—), 52.80($COOCH_3$), 66.97(CHOH), 173.37($COOCH_3$), 174.60(COOH). Mass spectrum *m/z*: 149($M^+ - 17$), 103($M^+ - 45$), 89($M^+ - 59$). Based on the comparative study of CMR spectra the structure of compound IV (free form) was determined to be (−)-2-hydroxybutandiolic acid 4-methyl ester.

Syntheses of (±), (+) or (−)-Calcium Isocitrate and of (±)-Calcium Alloisocitrate—The following compounds were synthesized according to the literature (3):

(±)-*Isocitric Acid Lactone*—mp 156–158°[4] (ethyl acetate), PMR (deuterodimethyl sulfoxide) δ: 2.76(2H, d, *J* = 8 Hz), 3.70(1H; sex; *J* = 7.5, 8 Hz), 5.11(1H, d, *J* = 7.5 Hz), 10.5(2H, br).

(+)-*Isocitric Acid Lactone*—mp 152–153° (ethyl acetate), $[\alpha]_D^{26}$ +59.4° (*C*, 1.3 in water).

(−)-*Isocitric Acid Lactone*—mp 151–153° (ethyl acetate), $[\alpha]_D^{25}$ −53.0° (c, 1.1 in water).

(±)-*Alloisocitric Acid Lactone*—mp 155–157° (ethyl acetate), PMR (deuterodimethyl sulfoxide) δ: 2.75(2H, d, *J* = 7.5 Hz), 3.45(1H, m), 5.05(1H, d, *J* = 4.0 Hz), 9.70(2H, br).

(±)-Isocitric acid lactone (2.0 g) dissolved in 2 *N* NaOH (20 ml) was hydrolyzed at 90° for 3 hr and the reaction mixture was passed through cation exchange resin[12] (70 ml). Saturated calcium hydroxide solution was added to acidic eluate and the pH of the solution was made up to 9.0. After the filtration, the filtrate (200 ml) was concentrated to a 20 ml volume, and from the precipitate (±)-calcium isocitrate (2.78 g) was obtained. IR (potassium bromide) cm^{-1}: 3400, 1635, 1600, 1570, 1400, 1310, 1110, 1070. PMR (deuterium oxide–deuterium chloric acid) δ: 2.79(2H, d, *J* = 6.5 Hz), 3.46(1H, m), 4.50(1H, d, *J* = 3.9 Hz). Quantitative analysis of calcium ion for $(C_6H_5O_7)_2Ca_3 \cdot 5H_2O$: Calc. 20.43%. Found: 20.54%. In the same way as the formation of (±)-calcium isocitrate, (+),(−)-calcium isocitrate and (±)-calcium alloisocitrate were synthesized.

RESULTS AND DISCUSSION

Table I summarizes the cardiac stimulatory action (inotropic) of each fraction of *Aloe saponaria* extract after dialysis and chromatography using resin[2] and dextran gel[4]. The dialysate caused a positive inotropic action on isolated rabbit atria without any change in the diastolic tension. Pretreatment of atria with propranolol (10^{-6} *M*, a β-adrenoreceptor blocking agent) or phentolamine (10^{-6} *M*, an α-adrenoreceptor blocking agent) had no effect on the inotropic response to the dialysate. Thus, it is apparent that the cardiac stimulatory action of the dialysate and other extracts are not mediated through the stimulation of adrenergic receptors.

In the preliminary examinations on cellulose and silica gel chromatographs, using butanol–acetic acid–water (4:1:5) and butanol–ethanol–chloroform–28% ammonium hydroxide (4:5:2:8) as solvents, the inotropic substance in the dialysate was demonstrated to be a hydrophilic substance which is considerably stable for acid, alkaline, and heat treatments. Since the methanol eluate on resin[2] column chromatography failed to cause any inotropic effect, the fraction was completely excluded from active substances. Active components were obtained from the effluent of methanol–water (1:5) and water. Then, the gel filtration using dextran gel[4] was performed to give fractions of *A*, *C*, and *D*. From these fractions compounds I–IV were obtained. Each compound showed a single spot on TLC-2 and was determined to be a calcium salt of organic acid by the positive reaction to calcium ion. On the treatment with anion exchange resin[3], compound I or II provided an organic acid in the free form which did not cause any cardiac stimulation on the isolated rat atria. Thus, it is suggested that compounds I and II have cardiac stimulation action only in the form of calcium salts. The chemical and spectral examinations led to the conclusion that compounds I–IV are calcium salts of (+)-isocitric (3, 4), L-(−)-malic, succinic, and of (−)-2-hydroxybutandiolic acid 4-methyl ester, respectively. Calcium salts of the stereoisomers of isocitric acid were synthesized according to the literature (3) and the cardiotonic effect of these synthetic isomers and compound I on isolated atria were

carried out. As shown in Table II, calcium salts of (+), (±)-isocitric acid and (±)-alloisocitric acid caused a positive inotropic effect on isolated guinea pig atria to the same degree as compound I at a concentration of 10^{-4} g/ml, while no toxic effect such as arrhythmia was observed.

Antitumor Agents LIII: The Effects of Daphnoretin on Nucleic Acid and Protein Synthesis of Ehrlich Ascites Tumor Cells

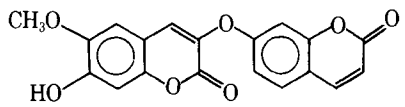
I. H. HALL[x], K. TAGAHARA, and K. H. LEE

Received July 2, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, The University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication October 7, 1981.

Abstract □ Daphnoretin, a dicoumaryl ether, has been shown to inhibit growth of Ehrlich ascites carcinoma cells. Dosing for three days at 6 mg/kg/day reduced the cell number per milliliter by 60%. *In vitro* DNA and protein synthesis studies demonstrated an $ID_{50} \cong 0.194$ m*M* and $ID_{50} \cong 0.340$ m*M*, respectively, for daphnoretin. Subsequently it has been shown that *in vivo* nucleic acid and protein synthesis were inhibited. Major sites in the DNA synthetic pathway inhibited significantly by daphnoretin were dihydrofolate reductase, orotidine monophosphate decarboxylase, thymidylate monophosphate kinase, and ribonucleotide reductase. Reduction of *in vitro* oxidative phosphorylation processes and acid hydrolytic enzymes were also inhibited in the presence of daphnoretin.

Keyphrases □ Daphnoretin—effects on nucleic acid and protein synthesis of Ehrlich ascites tumor cells, antitumor agent □ DNA—effects of daphnoretin, protein synthesis, Ehrlich ascites tumor cells □ Protein synthesis—effects of daphnoretin, DNA, Ehrlich ascites tumor cells □ Antitumor agents—the effects of daphnoretin on nucleic acid and protein synthesis of Ehrlich ascites tumor cells

Daphnoretin has been isolated from the whole plant of *Wikstroemia indica* C. A. Mey (Thymelaeaceae) (1), which is known as "Nan-Ling-Jao-Hua" or "Po-Lun" in Chinese folklore as a herbal remedy for the treatment of human syphilis, arthritis, whooping cough (2), and cancer (3). Daphnoretin was shown to have significant inhibitory activity *in vivo* against the Ehrlich ascites carcinoma growth in mice but did not demonstrate any activity against P-388 lymphocytic leukemia growth (4). A detailed examination of the effects of daphnoretin on nucleic acid and protein synthesis of Ehrlich ascites carcinoma cells is presented.



Daphnoretin

EXPERIMENTAL

CF_1 male mice (~30 g) were implanted with 2×10^6 Ehrlich ascites tumor cells intraperitoneally on day 0. Daphnoretin was suspended by homogenization in 0.05% polysorbate 80–water and 3–12 mg/kg ip was administered for 9 days to determine the inhibition of tumor growth. Mice were sacrificed on day 10, and the ascites fluid was collected from the peritoneal cavity. The volume and ascrit were determined for each animal and the inhibition of tumor growth was calculated (5). For the metabolic studies, mice were treated on days 7–9 with 6 mg/kg ip of daphnoretin. The animal was sacrificed on day 10 and the ascites fluid was harvested. The *in vitro* metabolic studies were performed at 0.340 m*M*.

In vitro incorporation of [^{3}H]thymidine, [^{3}H]uridine, or [^{3}H]leucine was determined using 10^6 Ehrlich ascites cells, 1 μCi labeled precursor, minimum essential medium, and varying final concentrations of drug from 0.035 to 0.35 m*M*. The tubes were incubated at 37° for 60 min and inactivated by trichloroacetic acid. The acid insoluble-labeled DNA was collected on glass filter discs[1], and RNA and protein were precipitated on nitrocellulose filters by vacuum suction (6). Results are expressed as disintegrations per minute of incorporated precursor per hour per 10^6 ascites cells.

For *in vivo* studies, incorporation of thymidine into DNA was determined by the method of Chae *et al.* (7). One hour prior to the animal sacrifice on day 10, 10 μCi of [6-^{3}H]thymidine (21.5 Ci/mmole, ip) were injected. The DNA was isolated and the tritium content was determined in a toluene based scintillation fluid[2]. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as a standard. Uridine incorporation into RNA was determined using 10 μCi of [5,6-^{3}H]uridine (22.4 Ci/mmole). RNA was extracted by the method of Wilson *et al.* (8). Using yeast RNA as a standard, the RNA content was assayed by the orcinol reaction. Leucine incorporation into protein was determined by the method of Sartorelli (9) using 10 μCi of [4,5-^{3}H]leucine (52.2 Ci/mmole). Protein content was determined by the Lowry procedure using bovine serum albumin as a standard.

In vitro and *in vivo* nuclear DNA polymerase activity was determined on isolated Ehrlich ascites cell nuclei (10). The incubation was that described previously (11), except that [methyl-^{3}H]deoxythymidine triphosphate (82.4 Ci/mmole) was used. The acid insoluble nucleic acid was collected on filters and counted. Nuclear RNA polymerase activities were determined on enzymes isolated from nuclei. Messenger, ribosomal, and transfer RNA polymerase enzymes were isolated using 0.3, 0.04, and 0.0 *M* concentrations, respectively, of ammonium sulfate in magnesium chloride. The incubation medium was [^{3}H]uridine triphosphate (23.2 Ci/mmole) (12). The acid insoluble RNA was collected on nitrocellulose filters and counted.

Deoxythymidine, deoxythymidylate monophosphate, and diphosphate kinase activities were measured spectrophotometrically at 340 nm at 20

[1] GF/F glass filter discs.

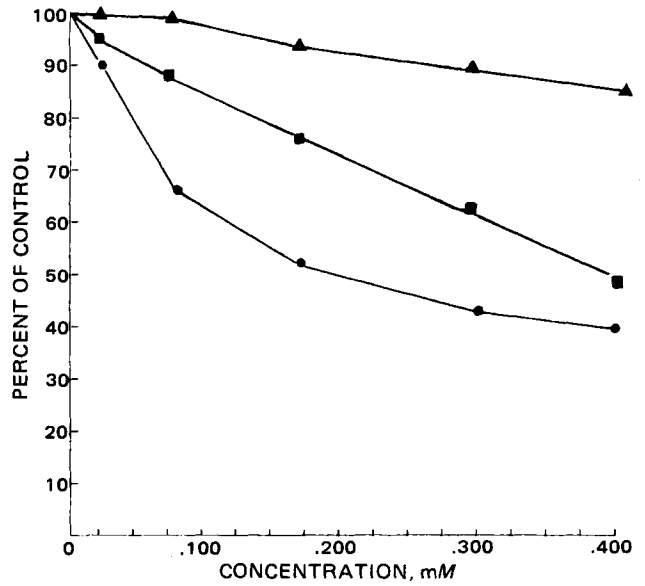

Figure 1—*The in vitro effects of daphnoretin on Ehrlich ascites nucleic acid and protein synthesis. Key: (●), [^{3}H]thymidine → DNA; (▲), [^{3}H]uridine → RNA; (■), [^{3}H]leucine → Protein.*

min using reduced nadide (0.1 μmole) (13). [6-^{3}H]Thymidine incorporation (21.5 Ci/mmole) into nucleotides was measured using the medium of Maley and Ochoa (13). The reaction medium was extracted with ether and the aqueous layer plated on polyethyleneiminecellulose plates and eluted with 0.5 *N* formic acid–0.6 *M* LiCl (1:1). Areas that correlated with the R_f values of thymidylate monophosphate, diphosphate, and triphosphate standards were scraped and counted.

Carbamyl phosphate synthetase activity was determined using the reaction medium of Kalman *et al.* (14) in the presence of ornithine and ornithine transcarbamylase. Citrulline formed from ornithine was measured at 490 nm by the method of Archibald (15). Aspartate transcarbamylase activity was assayed using the incubation medium of Kalman *et al.* (14). Colorimetric determination of carbamyl aspartate was conducted by the procedure of Koritz and Cohen (16). Orotidine monophosphate decarboxylase activity was assayed by the method of Appel (17) using 0.1 μCi of [^{14}C]orotidine monophosphate (34.9 mCi/mmole). The [^{14}C]carbon dioxide generated in 15 min was trapped in 1*M* KOH[3] and counted. Thymidylate synthetase activity was determined using a postmitochondrial supernate (9000×*g* for 10 min) and 5 μCi of [5-^{3}H]-deoxyuridine monophosphate (14 Ci/mmole) according to the method of Kampf *et al.* (18). [^{14}C]Formate incorporation into purines was determined by the method of Spassova *et al.* (19) using 0.5 μCi of [^{14}C]-formic acid (52.0 mCi/mmole). Purines were separated on silica gel TLC plates eluted with *n*-butanol–acetic acid–water (4:1:5).

After identifying R_f values consistent with the standards, adenine and guanine, the plates were scraped and the radioactive content determined. Phosphoribosyl-1-pyrophosphate amidotransferase activity was determined on a supernatant fraction (600×*g* for 10 min) measuring the reduction of 0.6 μmole of nadide at 340 nm for 30 min (20). Inosinic acid dehydrogenase activity was determined spectrophotometrically at 340 nm for 30 min using a supernatant fraction (600×*g* for 10 min). The assay medium was that of Magasanik, (21), which contained nadide. Dihydrofolate reductase activity was determined at 340 nm for 30 min as the oxidation of reduced nadide phosphate (22). Ribonucleotide reductase activity was determined by the method of Moore and Hurlbert (23) using [5-^{3}H]cytidine-5′-diphosphate (25 Ci/mmole). Ribose and deoxyribose nucleotide were separated on polyethyleneiminecellulose plastic precoated TLC plates eluted with 4% boric acid–4*M* LiCl (4:3) and scraped at the R_f values consistent with the standard deoxycytidine diphosphate.

In vivo phosphorylation of histones was determined by injecting 10 μCi of [γ-^{32}P]ATP (30.0 Ci/mmole) into mice 1 hr prior to sacrifice. The nuclei were isolated (10) and the histone chromatin protein was extracted by the method of Raineri *et al.* (24). *In vitro* nonhistone protein phosphorylation dependent on nuclear protein kinase was determined using 2.0 nmoles of [γ-^{32}P]ATP (30.0 Ci/mmole) and isolated nuclei chromatin protein was collected on nitrocellulose filters (25). Cyclic 3′,5′-adenosine monophosphate levels were determined by the radioimmunoassay method of Gilman (26) using a commercial kit.

In vitro oxidative phosphorylation studies (27) were conducted on Ehrlich ascites cells using the substrates, α-ketoglutarate or succinate. Basal oxygen consumption (State 4) was determined with an oxygen electrode connected to an oxygraph. The adenosine diphosphate was added to obtain State 3, or stimulated respiration. The number of microliters of oxygen consumed per hour per milligram of protein for States 3 and 4 were calculated. Deoxyribonuclease activity was measured at pH 5.0 by a modification of the de Duve method (28). Ribonuclease activity and acid cathepsin activity were determined at pH 5.0 by the method of Cho-Chung and Gullino (29). Protein content for the enzymatic assays was determined by the Lowry technique (30). UV studies between 210 and 340 nm for the binding of daphnoretin (20 μg/ml) to DNA (38 μg/ml) were performed in 0.1 *M* phosphate buffer, pH 7.2 (31) for 24 hr at room temperature.

Table I—Antineoplastic Activity of Daphnoretin Against Ehrlich Ascites Tumor Growth

	N	Volume	Ascrit	Inhibition, %
Control	6	4.25	37.5	—
Daphnoretin				
3 mg/kg/day	6	0.08	59.5	97
6 mg/kg/day	6	0.16	35.0	96
12 mg/kg/day	6	0.45	36.2	90
6-Mercaptopurine	6	0.10	2.5	99

RESULTS

Daphnoretin successfully inhibited Ehrlich ascites growth at 3 mg/kg/day by 97%, at 6 mg/kg/day by 96%, and at 12 mg/kg/day by 90%. The normal number of Ehrlich ascites cells per milliliter on day 10 was 226 × 10^6. Daphnoretin treatment on days 7, 8, and 9 reduced the cell count by 60% (Table I).

Preliminary whole cell *in vitro* incorporation studies demonstrated that for DNA synthesis, the $ID_{50} \cong 0.194$ m*M* and for protein synthesis the $ID_{50} \cong 0.340$ m*M*. RNA synthesis was suppressed only marginally by daphnoretin *in vitro* demonstrating only 15% inhibition at 340 μmole (Fig. 1). Results from *in vitro* studies can be found in Table II, and results from *in vivo* studies can be found in Table III.

For the *in vivo* incorporation studies, the control values for 10-day Ehrlich ascites cells for thymidine incorporation into DNA were 107,533 dpm/mg of isolated DNA, 51,193 dpm/mg of isolated RNA for uridine incorporation, and 19,181 dpm/mg of isolated protein for leucine incorporation. After 3 days of dosing with daphnoretin at 6 mg/kg, DNA synthesis was reduced by 46%, RNA synthesis was suppressed by 42%, and protein synthesis was inhibited by 77%.

Nuclear DNA polymerase activity for the control was 76,528 dpm/hr/mg of nucleoprotein which was essentially unaffected by daphnoretin *in vitro* and was reduced by only 16% by *in vivo* administration of drug. Nuclear mRNA polymerase activity for the control was 4867 dpm/hr/mg of nucleoprotein, rRNA polymerase activity was 8751 dpm/hr/mg of protein, and tRNA polymerase activity was 10,792 dpm/mg of protein. Messenger RNA polymerase activity was suppressed by 10% *in vitro* and 17% *in vivo*, rRNA polymerase activity was elevated by 81% *in vitro* and 94% *in vivo*, and tRNA polymerase activity was reduced by 14% *in vitro* and 10% *in vivo*.

Ribonucleotide reductase activity for the control was 153,791 dpm/mg of protein which was suppressed by 31% *in vitro* and 39% *in vivo*. [^{14}C]-Formate incorporation into purines for the 10-day control was 28,786 dpm/mg of protein. Purine synthesis *in vitro* was inhibited by 32% and after drug administration for 3 days was suppressed by 30%. Phosphoribosyl pyrophosphate amidotransferase activity for the control was 0.544 optical density unit/hr/mg of protein. *In vitro* presence of drug resulted in a 39% reduction of enzymatic activity and *in vivo* administration of drug caused 31% suppression. Inosinic acid dehydrogenase activity for the control was 0.358 optical density unit/hr/mg of protein, reduced 19% by *in vivo* administration of drug. Dihydrofolate reductase activity for 10-day Ehrlich ascites cells was 0.514 optical density unit/hr/mg of protein which was inhibited by 53% *in vitro* and 59% *in vivo* by daphnoretin.

Carbamyl phosphate synthetase activity was 0.128 mg of carbamyl phosphate formed/hr/mg of protein for the control. Aspartate carbamyl transferase activity for 10-day Ehrlich ascites cells was 7.526 mg of car-

bamyl aspartate formed/hr/mg of protein. Neither of these enzyme activities was affected by daphnoretin *in vitro* or *in vivo*. Orotidine monophosphate decarboxylase activity for the control was 10,775 dpm of $^{14}CO_2$ generated in 15 min/mg of protein. In the *in vitro* studies, decarboxylase activity was inhibited by 36%, and after drug administration *in vivo* the activity was reduced by 31%. Thymidylate synthetase activity for the control was 103,328 dpm/mg of protein which was unaffected by drug treatment. Thymidine kinase activity for the control was 0.531 optical density units/hr/mg of protein which was suppressed by 25% *in vitro* and 53% *in vivo*. Thymidylate monophosphate kinase activity for the control was 0.305 optical density units/hr/mg of protein inhibited by 74% *in vitro* and by 87% *in vivo*. Thymidylate diphosphate kinase activity for 10-day Ehrlich ascites cells was 0.238 optical density units/hr/mg of protein which was suppressed 17% *in vitro*, but daphnoretin had no effect *in vivo*. Thymidine incorporation studies into nucleotide showed that daphnoretin reduced the thymidylate monophosphate pools by 16%, thymidylate diphosphate pools by 53%, and thymidylate triphosphate levels by 45%. Deoxyribonuclease hydrolytic activity for day 10 Ehrlich ascites cells was 247 μg of DNA hydrolyzed/hr/mg of protein which was inhibited 29% *in vitro* by daphnoretin. Ribonuclease hydrolytic activity for control tumor cells was 43 μg of RNA hydrolyzed/hr/mg of protein which was suppressed 27% in the presence of drug. Cathepsin activity for the control was 869 μg of protein hydrolyzed/hr/mg of protein which was reduced 36% in the presence of daphnoretin.

The basal respiration (State 4) of day 10 Ehrlich ascites tumor cells with succinate as substrate was 5.273 μl of oxygen consumed/hr/mg of protein. Daphnoretin inhibited *in vitro* State 4 respiration 35% at 0.340 mM. Adenosine diphosphate stimulated (State 3) respiration was 8.752 μl of oxygen consumed/hr/mg of protein which was reduced 36% in the presence of daphnoretin. Using α-ketoglutarate as substrate resulted in

a State 4 respiration of 3.569 μl of oxygen consumed/hr/mg of protein and in State 3 respiration of 5.156 μl of oxygen consumed/hr/mg of protein. In the presence of daphnoretin, State 4 respiration was reduced by 38% and State 3 was reduced by 27%. Histone phosphorylation of chromatin proteins for the control was at the rate of 3650 dpm/mg of isolated chromatin protein which was inhibited 36% after *in vivo* administration of daphnoretin. Nonhistone phosphorylation of chromatin proteins for the control was 28,593 dpm/mg of chromatin protein isolated, which was elevated 35% *in vitro* and 106% *in vivo*. Cyclic adenosine monophosphate levels for 10-day Ehrlich ascites cells was 3.65 pmoles/10^6 cells which was elevated 17% after daphnoretin administration for 3 days. The *in vitro* UV studies demonstrated that the spectrum of DNA and daphnoretin when present together caused a hyperchromic shift of DNA. However, there were no new peaks nor any shift to a higher wavelength, which probably suggests nonspecific binding of daphnoretin to DNA.

DISCUSSION

Daphnoretin significantly inhibited Ehrlich ascites tumor growth in CF_1 mice. DNA synthesis was inhibited at a low dose of daphnoretin, whereas protein synthesis was inhibited at a higher concentration. However, protein synthesis was inhibited to a greater degree than DNA synthesis after *in vivo* drug administration. The major enzymatic sites of inhibition by daphnoretin which could reduce DNA synthesis were thymidine kinase, thymidylate monophosphate kinase, ribonucleotide reductase, and dihydrofolate reductase. The reduction in enzymatic activity at any of these biochemical sites would be of sufficient magnitude to account for the degree of suppression of total DNA synthesis. Other minor sites of enzyme reduction are orotidine monophosphate decarboxylase, phosphoribosyl amidotransferase, and inosinic acid dehydrogenase as well as the incorporation of formic acid into purines and phosphorylation of histones. The magnitude of inhibition of the regulatory enzyme phosphoribosyl amido transferase of the purine pathway is of the same magnitude of reduction observed in the formate incorporation.

Daphnoretin also suppressed oxidative phosphorylation processes at 0.340 m*M*. Using the substrate succinate, which is a flavine adenine dinucleotide-linked dehydrogenase, daphnoretin suppressed basal and adenosine diphosphate stimulated respiration. The same was also true when using α-ketoglutarate, a nadide-linked dehydrogenase. Loss of energy from oxidative phosphorylation processes could account for the reduction of kinase activity of tumor cells since kinase reactions require ATP.

Daphnoretin reduced the catalytic enzyme activities responsible for the hydrolysis of nucleic acids and proteins. Elevation of the activities of these acid hydrolytic enzymes by the drug could account for the reduction of incorporation of radiolabeled precursors into nucleic acid or proteins. However, no elevation was observed with daphnoretin.

High cellular proliferation is associated with an increase in histone phosphorylation. As can be seen, daphnoretin reduced phosphorylation of chromatin histones (32). Although daphnoretin caused only a slight increase in cyclic adenosine monophosphate levels, elevated levels are associated with cessation of cellular division and reversal of tumor morphology to a normal state (33). A detailed study on the mechanism of protein synthesis inhibition has been reported (30).

Antitumor Agents LIV: The Effects of Daphnoretin on *In Vitro* Protein Synthesis of Ehrlich Ascites Carcinoma Cells and Other Tissues

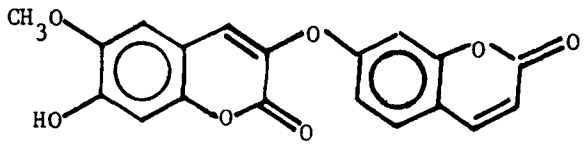
Y. F. LIOU, I. H. HALL ˣ, and K. H. LEE

Received July 2, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication October 7, 1981.

Abstract □ Daphnoretin has been shown to suppress Ehrlich ascites carcinoma growth in mice. One of the modes of action of the drug is to block protein synthesis; however, the inhibition of protein synthesis requires a higher concentration of drug than the inhibition of DNA synthesis. The inhibition of protein synthesis appears to occur during the elongation step with the drug preferentially binding to free ribosomes not engaged in active protein synthesis.

Keyphrases □ Daphnoretin—effects on *in vitro* protein synthesis of Ehrlich ascites carcinoma cells □ Antitumor agents—daphnoretin, effects on *in vitro* protein synthesis of Ehrlich ascites carcinoma cells □ Protein synthesis—effects of daphnoretin on *in vitro* protein synthesis of Ehrlich ascites carcinoma cells

Daphnoretin dicoumaryl ether, has been isolated from *Daphne mezereum* and *Wikstroemia indica* (Thymelaeaceae) (1–4). Daphnoretin, 3 to 12 mg/kg, has been demonstrated to significantly inhibit Ehrlich ascites carcinoma growth. Daphnoretin inhibited leucine incorporation into protein by 77% after administration of the drug at 6 mg/kg/day for 3 days. *In vitro* studies of leucine incorporation into protein of Ehrlich ascites cells demonstrated an $ID_{50} \cong 0.340$ m*M* (5). A more detailed study of the mechanism of protein synthesis inhibition is reported at this time.



Daphnoretin

EXPERIMENTAL

The Ehrlich ascites tumor cell line was maintained in CF_1 male mice (~30 g). The tumor cells were harvested from mice on Day 10, which were inoculated on Day 0 with 2×10^6 Ehrlich ascites cells. The Ehrlich ascites lysates were prepared by an analogous method as outlined by Kruh *et al.* (6). The following were isolated from Ehrlich ascites lysates by literature techniques: runoff ribosomes (7), pH 5.0 enzymes (6), and uncharged transfer RNA (8). The Ehrlich ascites carcinoma initiation factors for protein synthesis were prepared as described by Majumdar *et al.* (9). The [^{3}H]methionyl tRNA was prepared from Ehrlich ascites cell tRNA according to the method of Takeishi *et al.* (10).

The effects of daphnoretin on endogenous protein synthesis of Ehrlich ascites cells (11) was carried out in a reaction medium (0.5 ml) containing 10 m*M* tromethamine (pH 7.6), 76 m*M* KCl, 1 m*M* ATP, 0.2 m*M* guanosine triphosphate, 15 m*M* creatine phosphate, 2 m*M* $MgCl_2$, 1 m*M* dithiothreitol, 0.1 m*M* of each of the 19 essential amino acids, 0.9 mg/ml of creatine phosphokinase, and 20 μCi of [^{3}H]leucine (56.6 Ci/mmole). An aliquot of the reaction mixture was incubated at 30°. After 5 min of incubation, test drugs or the standards, pyrocatechol violet or emetine, were added with a final concentration of 50, 100, and 500 μ*M*. At 1-min intervals, 50-μl aliquots were removed from the reaction tubes and spotted on filter papers[1], which were treated for 10 min in boiling 5% trichloroacetic acid, followed by 10 min in cold 5% trichloroacetic acid and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1), and finally, ether. The filter papers were dried and counted in scintillation fluid[2].

The effects of daphnoretin, pyrocatechol violet, cycloheximide, and emetine on the ribosome profile and leucine incorporation (11) of Ehrlich ascites cell lysates were assayed using a reaction medium (500 μl) described previously. Following drug addition with a 100 μ*M* final concentration, the reaction was incubated for 4 min at 37°. The reaction was terminated by placing the tubes in ice and gradient buffer (1 ml of tromethamine, pH 7.6; 10 m*M* KCl; and 1.5 m*M* $MgCl_2$-$6H_2O$) was added. The mixture was layered over 36 ml of 10–25% linear sucrose gradient (11), prepared in gradient buffer, and centrifuged for 165 min at 25,000 rpm[3] at 4°. The absorbance profile at 260 nm was determined using a flow cell (light path of 0.2 cm) attached to a spectrophotometer[4]. Each gradient was fractionated into 1-ml aliquots. The protein was precipitated by trichloroacetic acid and counted.

The reaction medium for the polyuridine directed polyphenylalanine synthesis (12) contained 50 m*M* tromethamine (pH 7.6), 12.5 m*M* magnesium acetate, 80 m*M* KCl, 5 m*M* creatine phosphate, 0.05 mg/ml of creatine phosphokinase, 0.36 mg/ml of polyuridine[5] ($A_{280}/A_{260} = 0.34$), 0.5 μCi of [^{14}C]phenylalanine (536 mCi/mmole), 75 μg of uncharged Ehrlich ascites cell tRNA, 70 μg of Ehrlich ascites pH 5 enzyme preparation, and 0.9 A_{260} of Ehrlich ascites cell runoff ribosomes. Daphnoretin was present from 0.038–0.570 mmole final concentrations. Incubations were for 20 min at 30° after which a 35-μl aliquot was spotted on filter paper[1] and processed as indicated previously.

The reaction medium (200 μl) used to measure the formation of the 80S initiation complex and the methionyl puromycin reaction (13) contained 15 m*M* tromethamine (pH 7.6), 80 m*M* KCl, 1 m*M* ATP, 0.5 m*M* guanosine triphosphate, 20 m*M* creatine phosphate, 0.2 mg/ml of creatine phosphokinase, 3 m*M* magnesium acetate, 0.1 m*M* edetic acid, 1 m*M* dithiothreitol, 0.1 m*M* of each of the 19 essential amino acids, 3 mg of Ehrlich ascites cell lysates, 100 μg/ml of chlortetracycline[6], 3×10^5 cpm

80S Initiation Complex Formation			
Control	—	0.44	100
+ Aurintricarboxylic Acid	100	.05	11
+ Emetine	100	.44	100
+ Pyrocatechol Violet	100	.15	35
+ Daphnoretin	280	.42	96
+ Daphnoretin	560	.41	94

of methionine tRNA and 20 μg/ml of polyadenosine–uridine–guanosine and daphnoretin (560 μmole). The incubation was carried out at 23° and after 2 min, aliquots were withdrawn to analyze for the 80S complex formation. Puromycin (10 μg/ml) then was added to the reaction medium. The incubation was continued for another 6 min, and aliquots were withdrawn to analyze for the reaction of the 80S complex with puromycin. All aliquots (50 μl) were diluted to 250 μl of buffer (20 mM tromethamine, pH 7.6; 80 mM KCl; 3 mM magnesium acetate; 1 mM dithiothreitol; and 1 mM edetic acid), layered on 11.8 ml of 15–30% linear sucrose gradient and centrifuged for 3 hr at 36,000 rpm[7]. Fractions (0.4 ml) were collected and precipitated with 10% trichloroacetic acid on filter papers and counted.

The reaction mixtures (75 μl) for the ternary complex formation (14) contained 21.4 mM tromethamine (pH 8.0), 80 mM KCl, 0.26 mM guanosine triphosphate, 2.14 mM dithiothreitol, 10 μg of bovine serum albumin, 5 pmoles of Ehrlich ascites cell [^{3}H]methionyl-tRNA (met-tRNA$_f$) (1×10^4 cpm), 100 A_{260}/ml of crude Ehrlich ascites cell initiation factors, and 560 μM of drug or standards. The incubation was conducted for 5 min at 37° and terminated by the addition of 3 ml of cold buffer (21.4 mM tromethamine, pH 8.0, 80 mM KCl, 2.14 mM dithiothreitol). The samples were filtered through 0.45-μm nitrocellulose filters, washed twice in buffer, and counted.

The reaction mixture (75 μl) for the 80S initiation complex formation (14) contained, in addition to the components necessary for the ternary complex formation reaction, 1.9 mM magnesium acetate, 5 A_{260}/ml polyadenosine–uridine–guanosine and 100 A_{260}/ml of 80S Ehrlich ascites ribosomes. Incubations were conducted for 10 min at 37° and were then cooled to 4° and titrated to 5 mM with magnesium acetate. After 5 min at 4°, the samples were diluted with cold buffer (21.4 mM tromethamine, pH 8.0, 80 mM KCl, and 5 mM magnesium acetate and 2.14 mM dithiothreitol), and filtered as indicated for the ternary complex formation experiment.

Amino acid-tRNA activation steps were determined by the method of Moldave (15). The reaction medium contained 0.1 mM tromethamine (pH 7.4), 0.2 mM ATP, 0.3 mg/ml of pH 5 enzyme from Ehrlich ascites cells, and 2.5 μCi of [^{14}C]phenylalanine (536 mCi/mmole), [^{3}H]leucine (56.5 Ci/mmole) or [^{3}H]methionine (80.0 Ci/mmole) in a total volume of 1 ml. After incubation at 37° for 20 min, 2 ml of ice cold 10% trichloroacetic acid was added and the activated amino acid-tRNA were collected on nitrocellulose filters by suction.

P-388 lymphocytic leukemia cells and L-1210 lymphocytic lymphoma cells were obtained from DBA/2 male mice donors (~30 g). B-16 melanoma and Lewis lung tumor cells were obtained from C_{57}B1/6 male mice donors (~30 g). Antineoplastic tumor screens were conducted according to National Institutes of Health protocols (16). The Ehrlich ascites carcinoma tumor was maintained in CF_1 male mice.

Normal tissues (*i.e.*, liver, lung, brain, and kidney) were excised from CF_1 male mice (~30 g) and homogenized in 0.25 M sucrose and 0.001 M edetic acid.

[6-^{3}H]Thymidine (21.5 Ci/mmole) or [4,5-^{3}H]leucine (52.2 Ci/mmole) was incorporated *in vitro* into normal tissues and tumors using 1 μCi of labeled precursor and minimum essential medium with 10% fetal calf serum with drug concentrations varying from 0.042–0.340 mM. The tubes were incubated for 60 min at 37° (11). The acid insoluble DNA was collected on glass filter discs[8] and protein was collected on nitrocellulose filters by vacuum suction. Results are expressed as disintegrations per minute of incorporated precursors per hour per 10^6 cells or 10 mg of wet tissue.

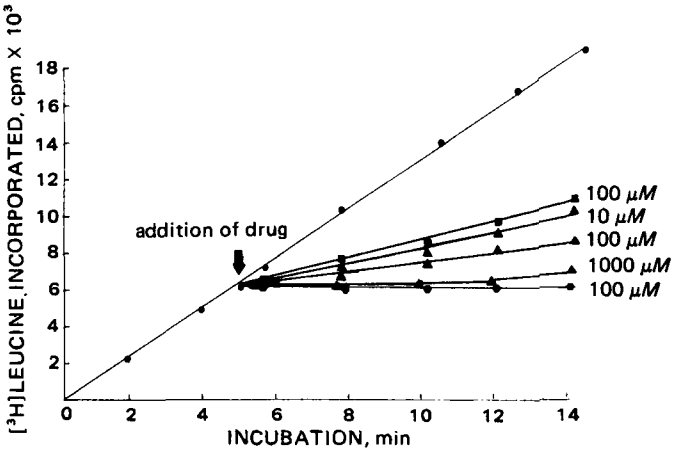

Figure 2—*Effect of pyrocatechol violet, emetine, and daphnoretin on the protein synthesis of Ehrlich ascites homogenates using endogenous messenger RNA. Key: (●) control; (■) pyrocatechol violet; (▲) daphnoretin; (●) emetine.*

RESULTS

The Ehrlich ascites whole-cell incubation studies demonstrated that daphnoretin, after 60 min of incubation, caused 50% inhibition at 240 μM and, after 90 min of incubation, 50% inhibition was achieved at 182 μM (Fig. 1). Twenty-eight percent suppression could be achieved at 560 μM concentration after 90-min incubation. The effect of daphnoretin on protein synthesis was compared to known inhibitors of protein synthesis (pyrocatechol violet is an initiation inhibitor that allows completion of the ongoing round of protein synthesis and causes accumulation of free 80S ribosomes, whereas emetine and cycloheximide are elongation inhibitors which freeze the ribosomes of the mRNA). When daphnoretin (50–500 μM) is added to the Ehrlich ascites lysate actively engaged in protein synthesis, there is a slight lag before inhibition of protein synthesis is effected (Fig. 2). Pyrocatechol violet demonstrated an even longer lag time, whereas emetine caused immediate inhibition of protein synthesis. The effect of daphnoretin, pyrocatechol violet, and cycloheximide on the ribosome profile and leucine incorporation can be seen in Fig. 3. Emetine induces the breakdown of the 80S polysome similar to the control, whereas pyrocatechol violet and daphnoretin allow the accumulation of the 80S ribosomal peak. Daphnoretin at 100 μM after 4-min incubation of lysate caused the release of radioactive peptides from the ribosomes similar to pyrocatechol violet. The results suggest that daphnoretin allows completion of the ongoing chain elongation steps and then causes the release of polypeptides from polyribosomes before it inhibits protein synthesis.

The effect of daphnoretin on the initiation steps of protein synthesis was examined using a fractionated Ehrlich ascites system. Table I shows daphnoretin had little or no effect on either the ternary complex[9] or the 80S initiation complex formation[10]. These studies indicated that daphnoretin was not an initiation inhibitor.

Further studies were performed to determine if daphnoretin was an elongation inhibitor. As can be easily seen in Fig. 4, daphnoretin inhibits polyuridine directed polyphenylalanine synthesis of purified runoff ribosomes from Ehrlich ascites tumor cells. Polyuridine-directed polyphenylalanine synthesis does not require the normal initiation and termination reactions; thus, agents that block this step are exclusively elongation type inhibitors.

In an additional study, the formation of the 80S initiation complex[10] and peptide bond formation was examined by treating Ehrlich ascites lysates with the elongation inhibitor, chlortetracycline, which specifically inhibits binding of the aminoacyl tRNA to the ribosome A site but does not inhibit the peptidyl transferase reaction. Thus, when [^{3}H]methionine-tRNA (met-tRNA$_f$) is added to the system, most of the radioactivity

[8] GF/F.
[9] eIF·GTP[^{3}H]methionyl-tRNA.
[10] 80S·adenosine–uridine–guanosine·eIF·GTP[^{3}H]methionyl-transfer RNA.

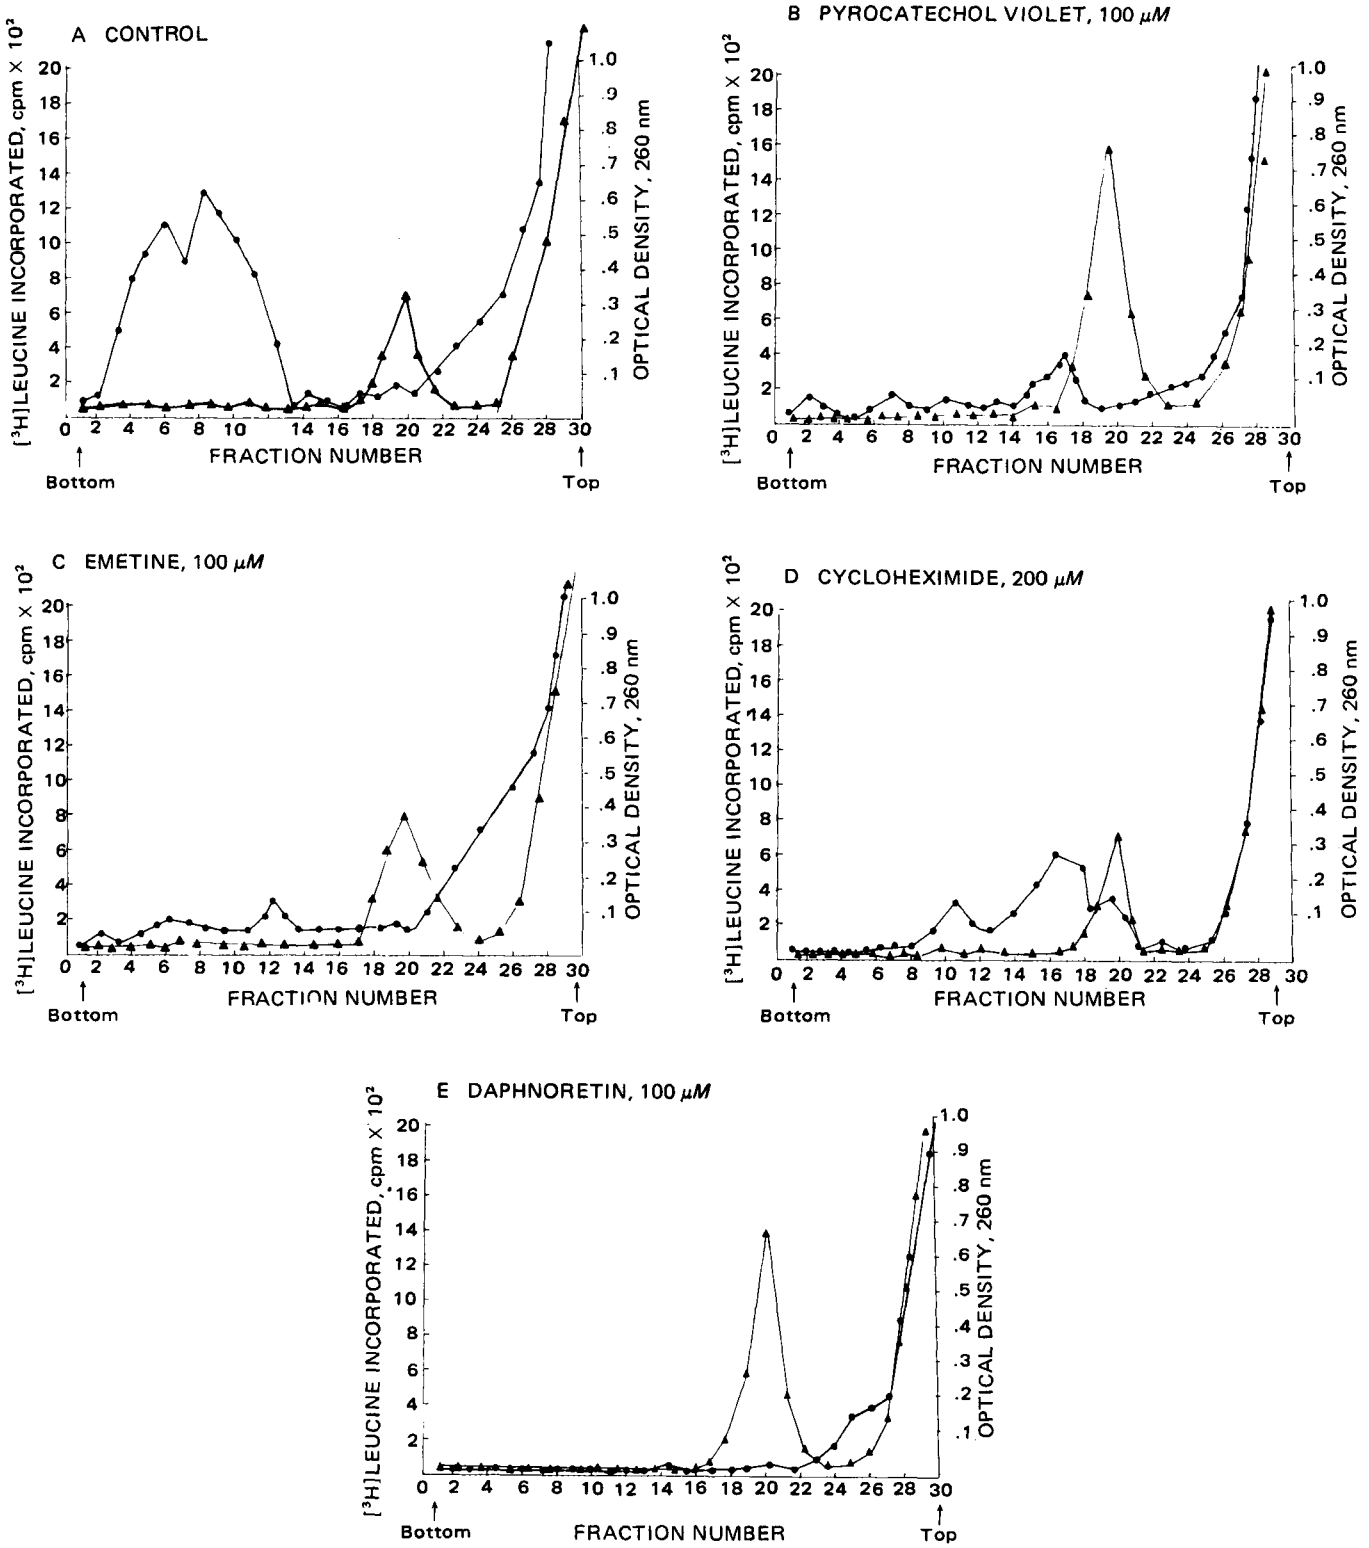

Figure 3—*Fate of nascent protein of protein synthesis in Ehrlich ascites tumor lysate. Key: (●) leucine incorporated; (▲) ribosomal profile.*

is found associated with the 80S initiation complex. Addition of polyadenosine–uridine–guanosine to the chlortetracycline-treated lysate allows formation of an 80S initiation complex (Fig. 5A), which then reacts with puromycin followed by the puromycin-induced release of [^{3}H]-methionine from the 80S complex (Fig. 5B). Daphnoretin (560 μ*M*) does not appear to inhibit the formation of the 80S initiation complex but did inhibit puromycin release of methionine, indicating that daphnoretin inhibits peptide bond formation in Ehrlich ascites ribosomes. Examination (Table II) of the formation of aminoacyl tRNA with phenylalanine, leucine, or methionine indicated that daphnoretin had no effect on the activation of amino acids for incorporation into polypeptides.

Examination of the *in vitro* leucine incorporation into protein for normal tissues of CF_1 male mice demonstrated that daphnoretin at 0.042–0.340 m*M* had no effect on protein synthesis by brain, kidney, or lung but suppressed *in vitro* protein synthesis by liver at low doses (Table III). Concentrations at 0.044 m*M* daphnoretin caused 53% inhibition, at 0.085 m*M* 34% inhibition, 0.177 m*M* 23% inhibition, and 0.340 m*M* 16% inhibition of leucine incorporation into liver proteins. Furthermore, daphnoretin did not suppress the protein synthesis of P-388 lymphocytic leukemia cells, L-1210 lymphocytic lymphomas, B-16

Table II—Effects of Daphnoretin on Amino Acid tRNA Activation in Ehrlich Ascites Cells

Inhibitor	Concentration, μM	Amino Acid Transfer RNA Formation, pmoles	Control, %

Lung (6564 dpm/hr/10 mg)	100 ± 5	113 ± 7[a]	129 ± 8[a]	124 ± 5[a]
Brain (6757 dpm/hr/10 mg)	100 ± 6	156 ± 9[a]	146 ± 8[a]	189 ± 6[a]

[a] $p \leq 0.001$. [b] $p \leq 0.010$.

melanoma and Lewis lung carcinoma as it did Ehrlich ascites carcinoma. Concomitantly, daphnoretin did not possess any antitumor activity in the P-388, L-1210, B-16, or Lewis screen.

Daphnoretin inhibited thymidine incorporation into nucleic acid resulting in an $ID_{50} \cong 0.194$ mM. However, daphnoretin did not suppress *in vitro* DNA synthesis in P-388, L-1210, B-16, and Lewis lung tumor cells. Similarly, daphnoretin had no effect on the *in vitro* thymidine incorporation with DNA of CF_1 mouse liver, lung, kidney, or brain.

DISCUSSION

Daphnoretin has been shown to be an elongation inhibitor of protein synthesis which allows the completion of ongoing polypeptide synthesis and releases the 80S ribosome. These observations suggest that daphnoretin binds to free ribosomes rather than the polyribosomes actively engaged in protein synthesis and similarly to other elongation inhibitors *e.g.* bruceantin, brusatol (17), T-2-toxin (18), verucarin (19), harring-

tonine (20), and fusarenon-X (13). One explanation for this is that peptidyl tRNA or methionyl tRNA lowers affinity binding of drug to ribosome (21). Daphnoretin effectively blocked peptidyl transferase activity of the elongation process. The magnitude of inhibition of protein synthesis is of a sufficient degree to account for the cessation of cell growth. It has been reported previously that daphnoretin suppresses DNA synthesis with an $ID_{50} \cong 0.194$ mM (5). The present studies show that daphnoretin only suppresses protein and DNA synthesis in the Ehrlich ascites carcinoma cells, the only tumor screen in which daphnoretin demonstrated antineoplastic activity at 3–12 mg/kg/day. Protein and DNA synthesis of whole cells was not suppressed in normal mouse tissue, *e.g.*, brain, kidney, and lung; but there was a moderate reduction of protein synthesis in the liver. Daphnoretin was isolated from *Wikstroemia indica* C. A. Mey (Thymelaeaceae), which has been used as a herbal remedy to treat human cancer, arthritis, syphilis, and whooping cough (22, 23). This study of the mode of action of daphnoretin may explain some of the pharmacological properties of the plant.

Square Root of Time Dependence of Matrix Formulations with Low Drug Content

HATEM FESSI, J.-P. MARTY, F. PUISIEUX, and J. T. CARSTENSEN *x

Received July 30, 1980 from the *Faculté de Pharmacie, Université de Paris-Sud, Châtenay-Malabry, 92290 France* and the **School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication September 25, 1981.

Abstract □ One of the conditions of derivation of the Higuchi square root law is that $A/\epsilon > S/2$ where A is drug content per cubic centimeter of matrix tablet, ϵ is the porosity, and S is the solubility of the drug in the dissolution medium. In actuality, A/ϵ should be larger than S. It is shown in this work that a similar square root equation can be derived when $A/\epsilon < S$. Experimental data are presented supporting the equation $Q = A(Dt)^{1/2}$, where Q is the amount of drug released per square centimeter at time t and D is the diffusion coefficient.

Keyphrases □ Matrix formulations—square root of time dependence, with low drug content □ Dissolution—square root of time dependence of matrix formulations with low drug content □ Release rate—square root of time dependence of matrix formulations with low drug content

Many sustained-release products are designed around the principle of imbedding the drug in a porous matrix. Liquid will penetrate and dissolve the drug, which will then diffuse out into the exterior liquid (Fig. 1). In general, for the purpose of derivation, a slab is considered which has a unit cross-section, is infinite to the left (Fig. 1), has a porosity ϵ', contains A grams of drug (of density ρ) per cubic centimeter of matrix, and allows penetration and diffusion through the unit surface only. At time t a depth of h is penetrated.

BACKGROUND

Higuchi (1, 2) was the first to derive the following expression for the amount of material released (Q) through the unit surface. He cautions that "the equation would be essentially valid for systems in which A is greater than the solubility S or ϵS by a factor of three or four. Of course,

Square Root of Time Dependence of Matrix Formulations with Low Drug Content

HATEM FESSI, J.-P. MARTY, F. PUISIEUX, and J. T. CARSTENSEN *x

Received July 30, 1980 from the *Faculté de Pharmacie, Université de Paris-Sud, Châtenay-Malabry, 92290 France* and the **School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication September 25, 1981.

Abstract □ One of the conditions of derivation of the Higuchi square root law is that $A/\epsilon > S/2$ where A is drug content per cubic centimeter of matrix tablet, ϵ is the porosity, and S is the solubility of the drug in the dissolution medium. In actuality, A/ϵ should be larger than S. It is shown in this work that a similar square root equation can be derived when $A/\epsilon < S$. Experimental data are presented supporting the equation $Q = A(Dt)^{1/2}$, where Q is the amount of drug released per square centimeter at time t and D is the diffusion coefficient.

Keyphrases □ Matrix formulations—square root of time dependence, with low drug content □ Dissolution—square root of time dependence of matrix formulations with low drug content □ Release rate—square root of time dependence of matrix formulations with low drug content

Many sustained-release products are designed around the principle of imbedding the drug in a porous matrix. Liquid will penetrate and dissolve the drug, which will then diffuse out into the exterior liquid (Fig. 1). In general, for the purpose of derivation, a slab is considered which has a unit cross-section, is infinite to the left (Fig. 1), has a porosity ϵ', contains A grams of drug (of density ρ) per cubic centimeter of matrix, and allows penetration and diffusion through the unit surface only. At time t a depth of h is penetrated.

BACKGROUND

Higuchi (1, 2) was the first to derive the following expression for the amount of material released (Q) through the unit surface. He cautions that "the equation would be essentially valid for systems in which A is greater than the solubility S or ϵS by a factor of three or four. Of course,

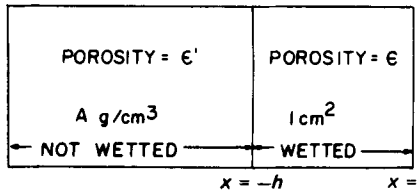

Figure 1—*Schematic of penetration of liquid into a solid matrix. The distance is denoted* x *(cm) and is zero at the surface and* −h *at the border of penetration.*

0022-3549/82/0700-0749$01.00/0

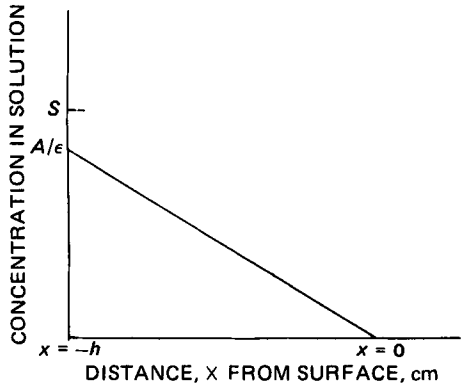

Figure 2—*Assumed concentration profile in the penetrating liquid for the situation in Fig. 1.*

if $A < S$ or ϵS, the drug would no longer be present as a solid and a different equation would apply."

$$Q = [2DS\epsilon(A - 0.5S\epsilon)]^{1/2}t^{1/2} \quad \text{(Eq. 1)}$$

The tortuosity term has been omitted since it does not apply in the following; ϵ is the porosity of the part of the matrix already penetrated by liquid, and S is the solubility (in gram per cubic centimeter) of the drug in the penetrating liquid. The point that A should be greater than S by a factor of three or four has been emphasized previously (3–5). In cases where the above is not the case, *ie.*, when

$$S > A/\epsilon \quad \text{(Eq. 2)}$$

derivations are nevertheless possible. The following sequence follows closely that described previously (1, 2, 5), and the following assumptions are made:

(*a*) sink conditions exist (*i.e.*, $C \sim O$) in the exterior liquid, where C is concentration of drug;

(*b*) the concentration gradient in the liquid in the penetrated space is linear;

(*c*) the diffusion coefficient is concentration independent;

(*d*) the drug content, A, is less than $S\epsilon$;

(*e*) the rate of dissolution is governed by the liquid penetration rate, not the dissolution rate.

The case where both dissolution and penetration rates play a part has been treated elsewhere (6, 7). Because of (*d*) and (*e*), the drug will, in fact, dissolve immediately when reached by liquid and form an unsaturated solution of concentration A/ϵ ($<S$). It is emphasized here that ϵ is the actual porosity in the penetrated space, *i.e.*, the original porosity, ϵ', and that created by dissolution of drug, A/ρ (presuming that an ideal solution forms). In the following, ϵ will be referred to as actual and ϵ' as measured porosity. It follows that:

$$\epsilon = \epsilon' + (A/\rho) \quad \text{(Eq. 3)}$$

The concentration profile shown in Fig. 2 will therefore apply. The

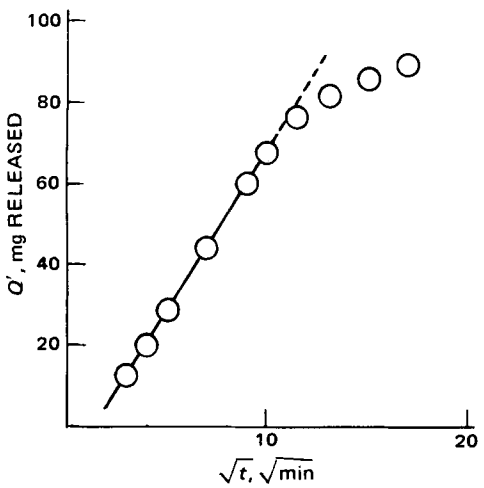

Figure 3—*Release data for Formula II, Table I.*

Table I—Compositions of Formulations Tested

	Formulation Number[a]			
	I	II	III	IV
Diphenhydramine HCl[b]	5	10	15	20
Polyvinyl acetate–polyvinyl chloride copolymer	50	50	50	50
Povidone	1.5	1.5	1.5	1.5
Magnesium stearate	3	3	3	3
Calcium phosphate, tribasic	←a sufficient quantity to 500 mg→			

[a] Percent by weight.
[b] The measured porosities of the formulations were 0.17, 0.16, 0.16, 0.17, and 0.13, respectively, giving drug concentrations on a volume basis of 0.067, 0.142, 0.200, and 0.260, respectively.

amount dissolved at time t is Q grams per square centimeter of surface and is given by:

$$Q = Ah - 0.5(A/\epsilon)h\epsilon = 0.5Ah \quad \text{(Eq. 4)}$$

Ah is the amount present in the matrix in the h-cm thick layer before dissolution started. After penetration to a depth of h, there are ϵ cubic centimeters of liquid per cubic centimeter of matrix and the average concentration is $0.5(A/\epsilon)$, so that the total amount not liberated to the exterior liquid is $h\epsilon(0.5A/\epsilon) = hA/2$.

Differentiation of Eq. 4 with respect to time gives:

$$dQ/dt = (A/2)dh/dt \quad \text{(Eq. 5)}$$

The diffusion of the drug takes place *via* Fick's law:

$$\text{Flux} = -D \times \text{Gradient} \quad \text{(Eq. 6)}$$

The flux is the amount of material passing through a unit cross-section per unit of time (dt). The cross-sectional area available for liquid is ϵ in square centimeters, and the amount of material passing through it is dQ/dt, so that the left hand side of Eq. 6 may be written:

$$\text{Flux} = (1/\epsilon)(dQ/dt) \quad \text{(Eq. 7)}$$

The gradient (dC/dx) is assumed to be constant [condition (*b*)] and drops from $C = A/\epsilon$ at $x = -h$ (Fig. 2) to zero at $x = 0$ [condition (*a*)]. Hence the gradient term in the right hand side of Eq. 6 is:

$$\text{Gradient} = dC/dx = [0 - (A/\epsilon)]/h = -A/(h\epsilon) \quad \text{(Eq. 8)}$$

so that inserting Eqs. 7 and 8 in Eq. 6 gives:

$$(1/\epsilon)dQ/dt = -D\{-[A/(h\epsilon)]\}$$

or

$$dQ/dt = DA/h \quad \text{(Eq. 9)}$$

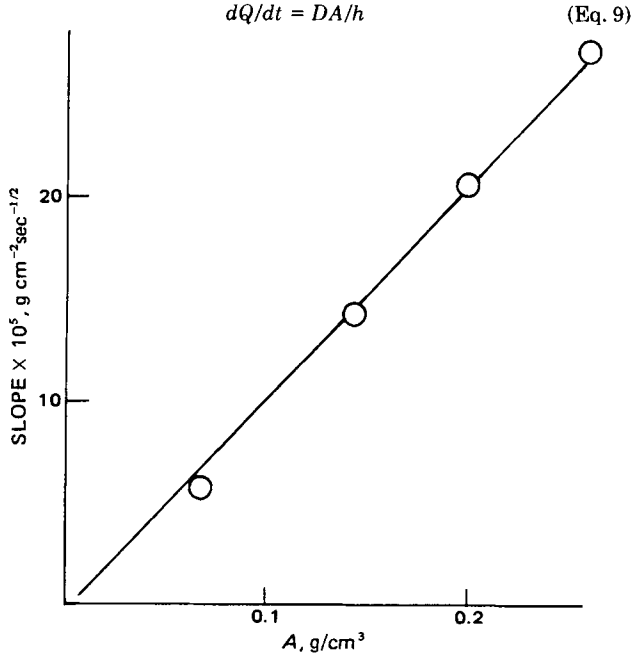

Figure 4—*Slopes of data as shown in Fig. 3 (divided by surface area) as a function of* A, *the drug content (Eq. 13) (data from Table III).*

Table II—Release Rate Data from Matrix Tablets of Four Drug Substances, Using Formula IV from Table I

Theophylline	1.28	0.37	0.73	180

[a] 7-(2,3-dihydroxypropyl)-1,3-dimethylxanthine, $C_{10}H_{14}N_4O_4$.

Combining Eqs. 4 and 9 yields:

$$(A/2)dh/dt = AD/h \qquad \text{(Eq. 10)}$$

or

$$hdh = 2Ddt \qquad \text{(Eq. 11)}$$

which integrates (with the initial condition that $h = 0$ at $t = 0$) to:

$$h^2 = 4Dt \qquad \text{(Eq. 12)}$$

Inserting Eq. 12 into Eq. 4 gives:

$$Q = A(Dt)^{0.5} \qquad \text{(Eq. 13)}$$

Equation 13 predicts that Q, the amount released per square centimeter of tablet surface, is proportional to the square root of time, and that the slope of such a plot is independent of porosity and solubility and is directly proportional to the drug content (per cubic centimeter) of the matrix.

As mentioned earlier, the case of (*d*), *i.e.*, of Eq. 2, is the exception rather than the rule. Only one case was reported in literature with drug concentrations where A may approach a low value close to S (8). These data fit fairly well to Eq. 13, but are difficult to analyze, because due to the lack of porosity data, the independence of Eq. 13 of the porosity cannot be tested in that specific case.

EXPERIMENTAL

Matrix tablets of the composition shown in Table I were produced as described in earlier publications (9–11). The matrix is sufficiently insoluble to consider it as completely insoluble (albeit the 1.5% povidone does dissolve to some extent).

Four drugs were tested (Table II) that have solubilities above and below the solubilities dictated by the Higuchi equation (Eqs. 1 and 2). The solubilities were tested by equilibrating excess of drug substance with water at 37 ± 0.2° in a rotating bottle in a waterbath. The concentrations in the supernate were determined spectrophotometrically at the peaks of the respective adsorption spectra. Densities were determined pycnometrically.

The tablets made were produced at various, controlled compression forces on an instrumented single punch machine (11). The porosities were measured using a mercury intrusion porosimeter[1]. The surface areas and volumes of the tablets were obtained from their dimensions. The dissolution rates were determined using a flow cell as described previously (6, 7, 9).

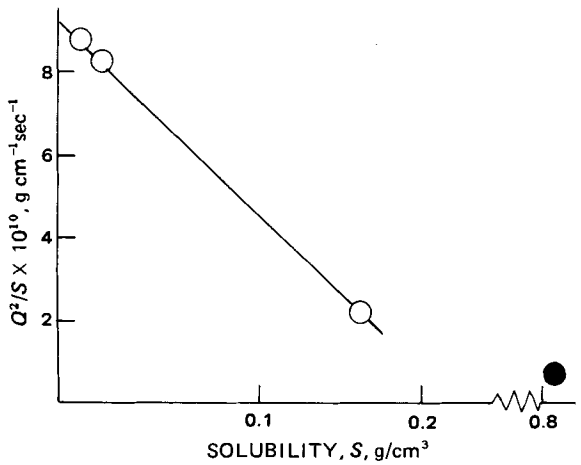

Figure 5—*Data from Table II plotted according to Eq. 18.*

RESULTS AND DISCUSSION

Figure 3 shows an example of dissolution of diphenhydramine hydrochloride from formulas as shown in Table I. It is seen that the amount released is linear in the square root of time up to the critical time (9, 10) when the tablet is completely penetrated by liquid. There is also a slight lag time, also explained in previous publications (9, 10). Slopes from four concentrations of drug are shown in Table III. The data in the last column are obtained by converting the slopes from plots like Fig. 3 to g sec^{-1} cm^{-2}, by multiplying by $10^{-3}/\sqrt{60}$ and dividing by the surface area of the tablet. This latter, in the case cited, is 3.54 cm², as it is in most of the tablets in question. An exception to this is the data leading to the Heckel plot mentioned at a later point[2]. Data of the type in Table III are plotted in Fig. 4, where the specific release rates (in grams per square centimeter sec$^{-0.5}$) are plotted as a function of A. According to Eq. 13 this should be a straight proportionality, which is borne out by the graph. The least squares fit line is:

$$y = 1.13 \times 10^{-3}x - 2 \times 10^{-6} \qquad \text{(Eq. 14)}$$

where $y = Qt^{-0.5}$ (g cm^{-2} sec$^{-1/2}$) and $x = A$ (g cm^{-3}). The intercept does not differ significantly from zero ($p = 0.001$) as predicted by Eq. 13. If this latter case is correct, then the slope of the plot in Fig. 4 should equal $D^{0.5}$, *i.e.*, $D^{0.5} = 1.13 \times 10^{-3}$ cm sec$^{-0.5}$ or $D \cong 10^{-6}$ cm² sec^{-1}, which is

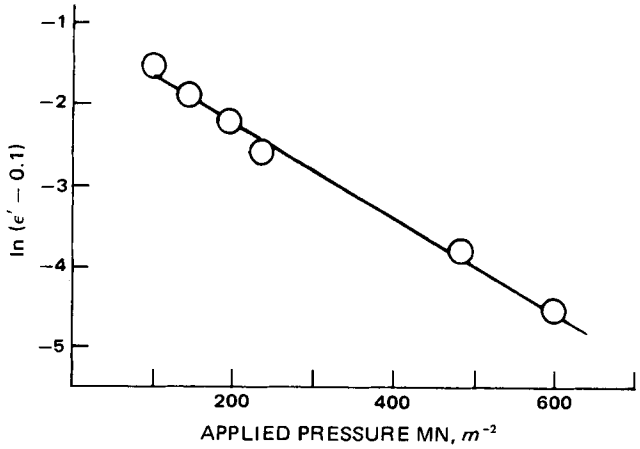

Figure 6—*Data from Table IV plotted as a Heckel function.*

[1] J. T. Carstensen and M. A. Zoglio, *J. Pharm Sci.*, Submitted for publication.
[2] The low porosity points in Table IV have slightly larger surface areas per tablet, due to a larger thickness.

Table III—Data for Diphenhydramine HCl Square Root Dissolution Rate Constants in a Series of Compositions[a]

[a] Porosity has been kept constant.

Table IV—Release Data of Diphenhydramine HCl as a Function of Porosity

Compression Force, MPa	$Q \times 10^5$ $g\ cm^{-2}\ sec^{-0.5}$	ϵ'	ϵ	$\ln(\epsilon' - 0.1)$
98	43	0.302	0.48	−1.600
147	39	0.260	0.45	−1.900
196	27	0.207	0.42	−2.235
234	25	0.169	0.39	−2.674
490	24	0.123	0.35	−3.772
588	24.3	0.111	0.34	−4.510

the right order of magnitude. The formulations listed in Table I all adhere to the inequality in Eq. 2, and they demonstrate the utility of the modification of the Higuchi equation in low concentration regions.

To further test the correctness of the developments described, it is noted that Eq. 1 may be written:

$$Q^2 = aS - bS^2 \qquad \text{(Eq. 15)}$$

where

$$a = 2D\epsilon A \qquad \text{(Eq. 16)}$$

and

$$b = D\epsilon^2 \qquad \text{(Eq. 17)}$$

This solubility dependence of the Higuchi equation has been checked and verified with three drug substances, the latter three listed in Table II. It is noted from the table that the A-values have been kept constant. If D is the same for the three substances, then a plot of Q^2/S *versus* S should give a straight line:

$$Q^2/S = a - bS \qquad \text{(Eq. 18)}$$

The slope and intercept should give the same value for D. It should be noted that according to the Stokes-Einstein equation:

$$D = kT/(6\pi\eta r) \qquad \text{(Eq. 19)}$$

where η is viscosity, k is Boltzmann's constant, T is absolute temperature, and r is the molecular radius. The value r should be proportional (roughly) to the cube root of the molar volume, so that the D-values should vary at the most by a factor of $(254/151)^{1/3} = 1.19$, *i.e.*, ~20%. It is assumed that the D-values of the three compounds are identical.

The data from the last three entries in Table II have been plotted according to Eq. 18, and are shown in Fig. 5; it can be seen that a straight line ensues. The least-squares fit equation is

$$10^{10}Q^2/S = -42{,}000\,S + 9300 \qquad \text{(Eq. 20)}$$

Hence, from the slope:

$$b = D\epsilon^2 = 0.42 \times 10^{-5} \qquad \text{(Eq. 21)}$$

so that setting $\epsilon = 0.38$ (Table III) gives $D = 3 \times 10^{-5}\ cm^2/sec$. From the intercept:

$$a = 9.3 \times 10^{-7} = 2D\epsilon A \qquad \text{(Eq. 22)}$$

so that setting $\epsilon = 0.38$ (Table III) gives $D = 10^{-5}\ cm^2/sec$. This demonstrates that substances adhering to the Higuchi requirements, in the system tested and using the test methods described, adhere to the Higuchi equation and give reasonable parameter values.

From the point of view of the present study, the most important point is that diphenhydramine has a Q^2/S value out of line with the remaining compounds.

An important difference between Eqs. 1 and 13 is that the latter is independent of the porosity, ϵ. This point is difficult to investigate, as shown below. Preparations were made at different preparative porosities, ϵ'. This was accomplished by varying the applied compression force at which the tablets were made.

The data are tabulated in Table IV. The force *versus* porosity data are consistent as demonstrated in the Heckel plot in Fig. 6. Of the preparations, the three made at the low pressures disintegrated, and hence, from a point of view of release, do not fall into the described models. The last three entries in Table IV, however, show that Q is not drastically a function of ϵ: Q is 24–25 $g\ cm^{-2}\ sec^{-0.5}$ over a range of initial porosity values of $\epsilon' = 0.11$–0.17 (*i.e.*, a 60% spread). However, due to the A-contribution to the porosity ϵ, the overall porosity, is 0.34–0.39, which is only at best a 20% variation. It would appear that a 20% variation in actual porosity, ϵ, causes a change of <4% in the slope (Q) of the square root plot, so that the effect of ϵ is small. Experimentally, it would have been desirable to have a wider spread of ϵ-values, but the disintegration is a problem at the lower end and the A-values a problem at the upper end.

It has been shown that when $A < S\epsilon$ the release rate for a matrix should be $Q = AD^{0.5}t^{0.5}$. Release plots of drug in situations where $A < S\epsilon$ have been shown to follow a square root law with slopes that are proportional to A. The proportionality constant gives a reasonable value of D ($2 \times 10^{-6}\ cm^2/sec$). Evidence is presented that the proportionality constant is independent of solubility, S, and porosity, ϵ.

Microencapsulation III: Preparation of Invertase Microcapsules

P. RAMBOURG, J. LÉVY, and M.-C. LÉVY ˣ

Received July 15, 1981, from the *Laboratoire de Pharmacie Galénique, E.R.A. au C.N.R.S. n°319, Faculté de Pharmacie, 51, rue Cognacq-Jay, F51096 REIMS Cédex, France.* Accepted for publication October 5, 1981.

Abstract □ Invertase was incorporated into polyamide microcapsules. The following parameters were studied: pH of the aqueous phase during interfacial polymerization; duration of the polymerization; surfactant concentration; stirring rate; improvements in the isolation procedure; effect of lyophilization. The inactivation of the encapsulated enzyme by pepsin was shown to be related to the acidic incubation medium and prompted incorporation of protective proteins in the microcapsules. This process allowed relative protection of the enzyme. In a second set of experiments, an emulsification–reticulation method was developed, which encapsulated invertase in a cross-linked protein. Various proteins and bifunctional acylating agents were tested. Microcapsules of immobilized invertase were prepared through cross-linking of the enzyme protein itself.

Keyphrases □ Microencapsulation—preparation of invertase microcapsules □ Invertase—preparation of microcapsules □ Emulsification–reticulation—preparation of invertase microcapsules

Invertase (β-D-fructofuranoside-fructohydrolase[1]) is lacking in the intestinal mucosa of some patients with constitutional intolerance to sucrose (1–4).

Accumulation of sucrose in the lumen prompts intense diarrhea, amplified further by microbial fermentation. The palliative treatment consists of adding large doses (~1 g) of yeast invertase to the food. As the excessive amount of the supplemented enzyme is probably related to its partial hydrolysis in the digestive tract, it was decided to microencapsulate invertase. Invertase microencapsulation with a 40% retention of enzymatic activity was recently reported (5).

This report deals with the preparation of such microcapsules through two different procedures (6–8). While in the well-known interfacial polymerization procedure (9), the capsule wall is made of an interfacially prepared polyamide, in the emulsion–reticulation procedure, it is made up of an interfacially prepared cross-linked protein. This second technique was progressively devised, and is reported herein.

Although much research has been devoted to the cross-linking of proteins, only a few authors have used this reaction in the preparation of microcapsules: Chang (9, 10), and more recently Miyawaki (11), reported on the chemical interactions between a protein and the acylating agent used in interfacial polymerization. Apparently, only Chang (12) attempted preparation of microcapsules walled in cross-linked proteins. However, he encountered serious difficulties in obtaining stable preparations.

In the cross-linking experiments, the aim was no longer to prepare therapeutically useful invertase microcapsules, but rather to test the feasability and limits of the method, with invertase used as a tracer.

EXPERIMENTAL

Reagents—Invertase from baker's yeast[2], exhibiting 34 U of activity/mg was used as a suspension (5%, w/v) in distilled water.

A buffer was adjusted to pH 9.8 by adding hydrochloric acid to a 0.45 *M* solution of Na_2CO_3. It was used to prepare a 6.67 g% (w/v) solution of alcalisoluble casein[3] and a 1.2 *M* solution of 1,6-hexamethylenediamine[4] (13.95%, w/v).

The organic solvent was a chloroform–cyclohexane mixture (1:4, v/v), which was used to prepare solutions of sebacoylchloride[4] (1:250, v/v), terephthaloylchloride[4] (0.04 *M* and 0.12 *M*), succinyl chloride[5] (0.04 *M*), toluene diisocyanate[6] (0.14 *M*), and piperazine[6] (1.2 *M*).

The surfactants were sorbitan trioleate[7] (1% solution v/v in the organic solvent) and polysorbate[7] (50% solution v/v in distilled water).

The dye for the permeability studies was erioglaucine A[8].

The proteolytic enzymes used were pepsin[9], pancreatin[10], and pronase[11].

Materials—Stirring was performed with a motor[12] and a 3-bladed screw (each blade was 16 mm long). An homogenizer[13] was used in one experiment. Lyophilization was performed with a freeze dryer[14].

Evaluation of Enzymatic Activity—A qualitative test was made using reactive strips[15]. Quantitative determinations were performed through the automated method of Goldstein and Lampen (13). The ac-

Table I—Effect of the Polymerization pH on the Enzymatic Activity of Invertase Microcapsules

pH		
Buffer	Aqueous Phase	Enzymatic Activity, U/mg
9.8	10.8	19.5
8.4	9.8	6.8
7.2	8.8	6.5

Table II—Effect of the Polymerization Duration on the Enzymatic Activity of Invertase Microcapsules

Duration of the Polymerization Step, min	Enzymatic Activity, U/mg
2	17.4
3	19.5
5	19.5
10	13
20	11.5

tivity of the microcapsules was calculated relative to 1 mg of invertase used in each experiment.

Microencapsulation Procedures—A standard emulsion–polymerization procedure is as follows: In a 100-ml beaker cooled in an ice bath, the casein solution (1.5 ml), the invertase suspension (1 ml, *i.e.*, 50 mg of invertase), the hexamethylene diamine solution (0.5 ml), and the 1% solution of sorbitan trioleate (15 ml) were mixed. The stirrer was set at 650 rpm, and the sebacoyl chloride solution (15 ml) was added.

After a 3-min agitation, the suspension was diluted with the organic solvent (30 ml) and centrifuged (350×*g*, 30 sec).

The sediment was dispersed in 40 ml of the polysorbate solution and then transferred to a 500-ml beaker. Dispersion of the microcapsules was achieved by stirring with a glass rod (30 sec) and then by mechanical stirring (650 rpm, 2 min). Water (120 ml) was added, the suspension was agitated (300 rpm, 3 min), and then diluted further with 300 ml of water. A prolonged sedimentation then allowed isolation of the microcapsules, which were again suspended in distilled water.

Variations were introduced in the pH of the aqueous phase, in the duration of the polymerization steps, surfactant concentration, stirring rate, method of isolation of microcapsules, nature of the polyamide, and nature of the protective protein.

In the emulsion–reticulation experiments, no diamine was used in the emulsification step, while a protein (100–800 mg) was reacted with a bifunctional reagent. Cross-linking of invertase itself was performed with terephthaloylchloride with no diamine and no protein added.

Membrane Permeability Test—The typical emulsion–polymerization procedure was performed with 3 mg of erioglaucine A (MW 1159) added during the emulsification step. Blue microcapsules were obtained and one could microscopically observe their progressive discoloration through washing with water.

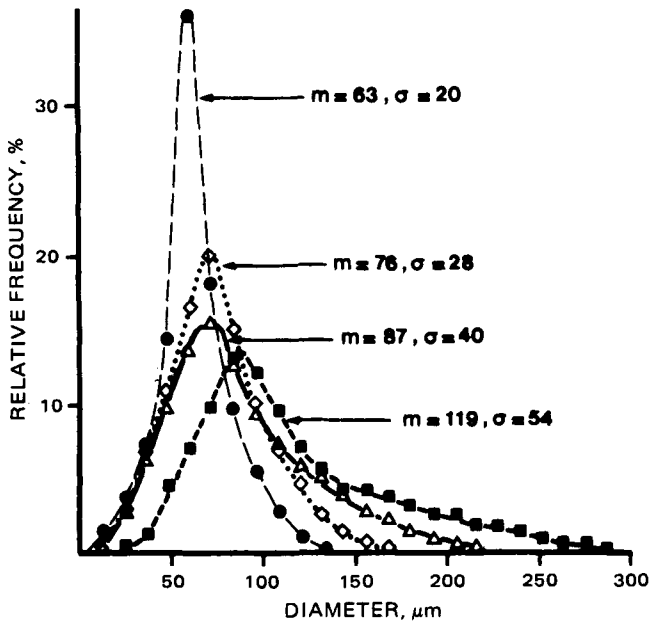

Figure 2—*Effect of the stirring rate on the size of microcapsules. Key: (■), 450 rpm; (△), 650 rpm; (◊), 900 rpm; (●), 1200 rpm.*

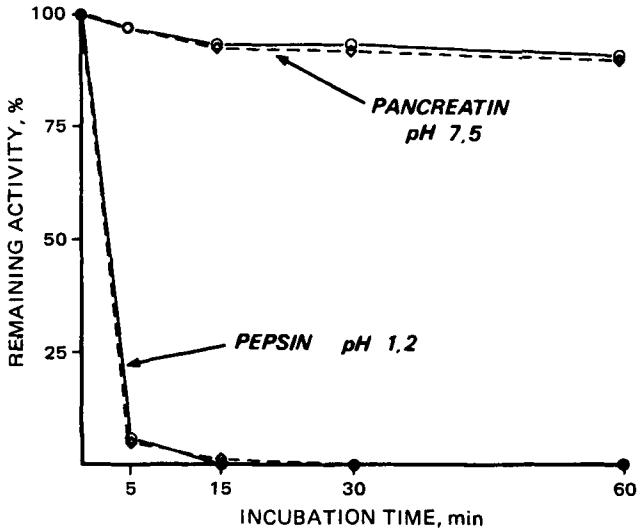

Figure 3—*Effect of proteases on the enzymatic activity of free and encapsulated invertase. Key: (○), free invertase; (◊), encapsulated invertase.*

RESULTS AND DISCUSSION

Interfacial Polymerization—When prepared through the standard procedure, the microcapsules were spherical, with their sizes ranging from 50 to 150 μm. A thin membrane, including insoluble particles of invertase, was to be seen. The permeability test was positive. When washed with water, the capsules became clear; the blue color passed into the surrounding liquid. Their enzymatic activity was 19.5 U/mg used in their preparation, *i.e.*, 57% of the activity (34 U) of free invertase.

Crushing of the microcapsules with an homogenizer[13] resulted only in a slight increase of activity: 22.2 U, *i.e.*, 61% of the activity (36.4 U) of crushed, free invertase. It was then concluded that invertase was lost or inactivated (to an extent of ~40%) during the microencapsulation process.

Lowering the pH of the aqueous phase during polymerization resulted in a loss of activity (Table I). Although the diamine solution increased the pH value, a rather basic medium was necessary for membrane formation.

The optimal duration of the polymerization step was shown (Table II) to be 3–5 min. Shorter time gave unstable capsules; longer time yielded thick membranes and eventually denatured the enzyme. With no surfactant used, no microcapsules were formed.

Increasing the concentration of the surfactant solution from 1 to 2%

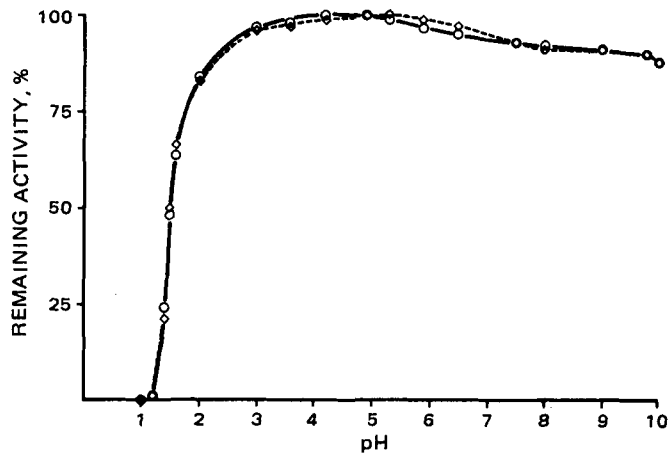

Figure 4—*Remaining activity of invertase (free and microencapsulated) after a 15-min incubation at different pH values. Key: (○), free invertase; (◊), microencapsulated invertase.*

(Fig. 1) had little effect on the average size (87–73 μm) but resulted in a more homogeneous repartition of the diameters. With a 5% solution, however, the membranes were altered and a large amount of invertase escaped microencapsulation.

When the stirring speed was raised from 450 to 1200 rpm, the size of the capsules decreased regularly, while the distribution of their diameter became more and more homogeneous (Fig. 2). Simultaneously, the enzymatic activity rose to a maximum of 21.3 U/mg (63% retention).

Stirring became more efficient when the 3-bladed screw was replaced by a 5-bladed screw (each blade was 20 mm long, 9 mm wide).

The separation and washing of the microcapsules from the reaction medium is the most time-consuming step in the process. Several attempts were unsuccessful (replacement of polysorbate by other surfactants and washing with organic solvents: ethanol, dioxane, and acetone inactivated the enzyme). Another technique afforded an improvement. The sediment from the first centrifugation was suspended in a mixture of glycerin–polysorbate (3:1, v/v, 5–10 ml) and 50 ml of distilled water was added. After agitation and centrifugation (350×*g*, 5 min) the sediment was washed several times with water.

After lyophilization, observation of the dried microcapsules (optical *versus* electron scattering microscopy) showed the integrity of the membranes; they rehydrated instantaneously with no modification of the shape. When held at +4° for 50 days, the aqueous suspension lost 15% of its initial activity, while the lyophilizate completely retained the enzymatic activity.

Evaluation of the Protection of the Enzyme—The protecting effect of the microcapsule wall was evaluated toward proteolytic enzymes. Figure 3 shows that no noticeable differences were observed regarding the protection of the free *versus* microencapsulated invertase toward pancreatin and pepsin. The same result was obtained with pronase since the activity curve was similar to the curve established with pancreatin.

This unsatisfying result was readily explained when the activity of invertase was tested after a short incubation time at different pH values, with no other enzyme added (Fig. 4).

In agreement with literature data (14), invertase (either free or microencapsulated) was irreversibly denatured by standing in acidic medium <pH 3.

Changes in the nature of the wall were studied according to Table III.

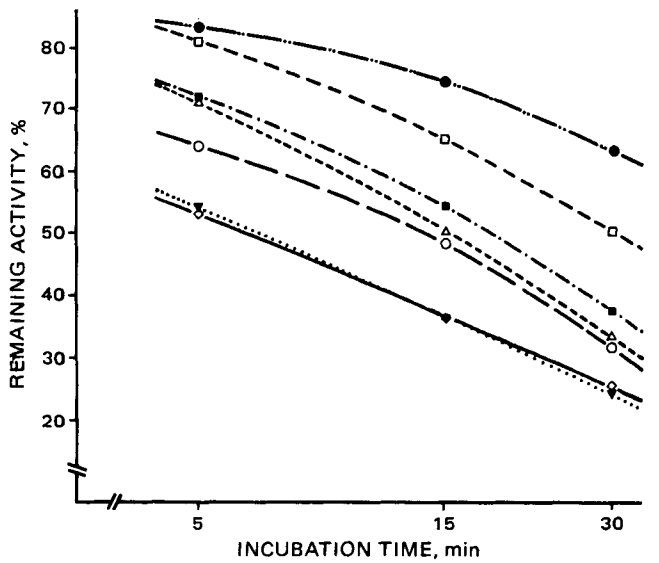

Figure 5—*Remaining activity of different invertase microcapsules after incubation at pH 1.5. [a] Isolation of microcapsules very difficult.

Table VI—Feasability of Microcapsules with Cross-Linked Protein Membrane

Protein–Acylating Agent		Feasability of Microcapsules
Casein–Sebacoyl chloride		Very unstable microcapsules
Casein–Terephthaloylchloride		Unstable but isolable
Albumin–Sebacoyl chloride		No microcapsules (after 3 min)
Albumin–Terephthaloylchloride	Albumin = 200 mg	Unstable but isolable
	Albumin = 400 mg	Stable microcapsules
Ovalbumin–Sebacoylchloride		No microcapsules (after 3 min)
Ovalbumin–Terephthaloylchloride	Ovalbumin = 200 mg	Unstable but isolable
	Ovalbumin = 400 mg	Stable microcapsules
Gelatin–Terephthaloylchloride		Unstable but isolable
Gelatin–Toluene diisocyanate		Stable microcapsules
Gelatin–Hexamethylene diisocyanate		Unstable but isolable
Gelatin–Succinyldichloride		Immediate coagulation after addition of succinyldichloride
Hemoglobin–Sebacoyl chloride		Stable microcapsules
Hemoglobin–Terephthaloylchloride	Hemoglobin = 400 mg	Very unstable microcapsules
	Hemoglobin = 600 mg	Stable microcapsules
Hemoglobin–Succinyldichloride		Stable microcapsules
Hemoglobin–Hexamethylene diisocyanate		Very unstable microcapsules

Stirring was effected by means of a 5-bladed screw at a speed of 1200 rpm.

The surfactant solution was 2% sorbitan trioleate. Isolation and washing of the microcapsules were performed through the glycerin–polysorbate method.

Formation of the microcapsules was satisfactory in every case except for the polymerization of piperazine with 0.04 *M* terephthaloylchloride. The mean size was 50 μm.

According to the improvements in the process, the activity of the microcapsules made from hexamethylene diamine and sebacoyl chloride reached 26 U/mg.

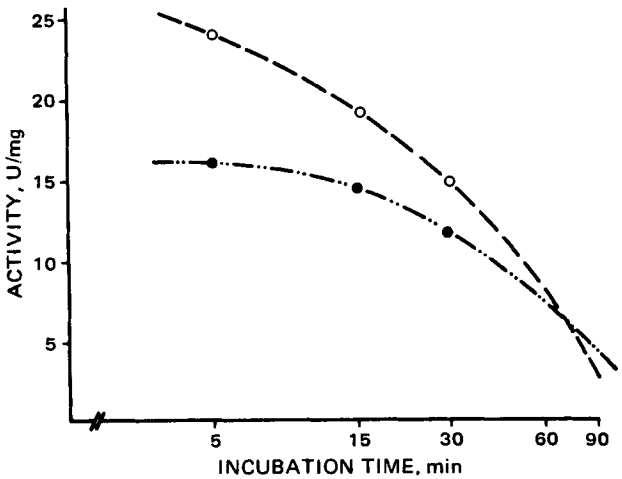

Figure 7—*Invertase microcapsules containing gelatin (nylon 6–10 membrane). Remaining activity after incubation at pH 1.55 as compared with free invertase. Key: (○), microcapsules with gelatin; (●), free invertase.*

These microcapsules were incubated at pH 1.5 for 5–30 min. The results of the activity measurements are plotted in Fig. 5: no radical improvement in the protection of invertase could be noticed. Moreover, the capsules made from hexamethylene diamine and terephthaloylchloride were destroyed by pancreatin, while an increase in the invertase activity was observed (Table IV).

Table VII—Microcapsules with Cross-Linked Protein Membrane: Mean Particle Size

Table IX—Microcapsules of Cross-Linked Invertase (Terephthaloylchloride) Enzymatic Activity

Invertase, mg	Terephthaloylchloride, mg	Activity U/mg	% Activity of the Invertase Used	Total Activity, U Calculated	Measured	Difference
100	375	7.5	22	3400	750	−2650
200	375	16.3	48	6,800	3250	−3550
400	375	25.2	74	13,600	10,050	−3550

Changes in the Nature of the Protective Protein—To protect the microencapsulated invertase from the effect of lower pH values, changes were introduced in the nature and concentration of the accompanying protein (*i.e.*, alcalisoluble casein in the standard procedure). The following proteins were checked: protamine[16], human serum albumin, egg albumin, gelatin, human hemoglobin. These proteins were incorporated as 4% (w/v) solutions in the buffer, pH 9.8. The membrane was made from hexamethylene diamine and sebacoyl chloride (nylon 6-10) as before.

Protamine failed to give well-constituted microcapsules, as a reaction between protamine and the diacylchloride occurred. This observation prompted the development of the reticulation method. The results of successive assays are summarized in Table V.

The initial activity of all microcapsules prepared was in the 20–26 U/mg range. The slight decrease of activity observed with the higher concentrations in proteins may be due to a slowing down of the diffusion rate inside the capsules.

Figure 6 plots for six assays the effect of incubation at pH 1.55 on the enzymatic activity as a percentage of the initial activity of each batch. The good performance of gelatin is better illustrated in Fig. 7, where the invertase activity is now plotted as a percentage of the activity of the invertase used in the preparation. The slopes of the curves indicate that after ~1 hr, the microcapsules retain more enzymatic activity than does an equal amount of free invertase. However, only 6 U/mg (18% of activity) is still available.

Emulsification–Reticulation Procedure—While protamine actually afforded well-defined capsules, this protein rapidly was shown not to be an ideal material. With sebacoyl chloride (whatever the protamine concentration), the reticulation period necessary for gaining solid capsules had to be raised to 30 min. However, the membranes were very thin and vanished in water after 24 hr at +4°. With terephthaloylchloride, the results were somewhat better but the initial activity was low: with 200 mg of protamine and 750 mg of terephthaloylchloride (batch 12), it was 8.5 U (25%); with 400 mg of protamine (batch 13) it was 11 U (32%).

Using other cross-linked proteins gave better results. Table VI reports

on the feasability of various microcapsules while Tables VII and VIII summarize the results on batches 14–25.

The high retention of activity obtained with hemoglobin (94–97%), serum albumin (88–94%), and egg albumin (87%) is of interest.

Batches 15 and 16 (Fig. 8), and especially the microcapsules prepared from hemoglobin (batches 21–25, Fig. 9), were more resistant than the free enzyme toward inactivation caused by standing at pH 1.5.

The membrane was digested by the proteases. The microcapsules were destroyed within 5 (hemoglobin)–15 min (ovalbumin) in pepsin, pancreatin, or pronase. However, in some cases, and especially with hemoglobin (Fig. 10), a significant retention of activity was observed, even after the membrane was no longer visible.

Immobilized Invertase—An attempt was made to acylate invertase with no protein added. The reticulation agent was terephthaloylchloride. The amount of invertase admixed to 375 mg of terephthaloylchloride (2.5% solution (w/v) in the organic solvent) varied from 50 to 400 mg.

Though somewhat unstable, spherical microcapsules were obtained. Washing and transfer to water were only possible with the 100–400-mg capsules. The membranes did not survive a 3–4 day stay in water at +4°.

When evaluated immediately after the preparation, the enzymatic activity was as reported in Table IX. The loss of activity due to acylation tends to be a constant value. Terephthaloylchloride (375 mg) stoichiometrically combines with invertase so as to inhibit 3550 U of activity.

While invertase encapsulated in nylon membranes was irreversibly denatured by incubation in acidic medium, incorporation of various proteins in the capsules allowed relative protection. However, an interaction between the proteins and the bifunctional acylating agent was suspected and prompted the preparation of invertase encapsulated in cross-linked proteins. Invertase itself could be used both as the contents and as the cross-linked membrane. Application of this microencapsulation process to various proteins and polyhydroxylated substrates is under current investigation.

Microencapsulation IV: Cross-Linked Hemoglobin Microcapsules

M.-C. LÉVY *x, P. RAMBOURG *, J. LÉVY *, and G. POTRON ‡

Received July 15, 1981, from the **Laboratoire de Pharmacie Galénique, E.R.A. au C.N.R.S. n° 319, Faculté de Pharmacie, 51, rue Cognacq-Jay, F 51096 REIMS Cédex, France.* and the *‡Laboratoire d'Hématologie, Centre Hospitalier Universitaire, Place Alexis Carrel, F 51092 REIMS Cédex, France.* Accepted for publication October 5, 1981.

Abstract □ Hemoglobin microcapsules were prepared through cross-linking of hemoglobin itself with various acyldichlorides. Variations in the reticulation conditions were performed in order to ameliorate the oxygen dissociation curve, the mean diameter, and the possibility for the microcapsules to be lyophilized. With terephthaloylchloride, as the cross-linking agent, incorporation of inositol hexaphosphate and glucose, followed by stabilization through glutaraldehyde and using a high stirring speed, allowed preparation of stable hemoglobin microcapsules, 5 μm in diameter, which suffered rapid lysis by proteases. They were able to ensure oxygen transfer: the dissociation curve was sigmoidal with a p50 = 13 mm Hg. They retained these properties after lyophilization followed by rehydration.

Keyphrases □ Hemoglobin—preparation of cross-linked microcapsules □ Microencapsulation—preparation of cross-linked hemoglobin microcapsules □ Cross-linking—proteins, microencapsulation of hemoglobin

Human hemoglobin has been subjected to microencapsulation by several authors: Chang (1–4) was the first to prepare hemoglobin microcapsules through interfacial polymerization or coacervation processes. However, the membrane made of nylon, polystyrene, collodion, or silicon rubber (dimethicone membrane[1]) failed to be biodegradable.

More recently, Kondo (5–8) used polyphthaloyl-L-lysine as the wall-constituting polymer and the microcapsules could be digested by proteolytic enzymes.

Vigneron (9, 10) obtained similar results through interfacial polymerization between sebacoyl chloride and hexamethylene diamine with L-lysine admixed.

On the other hand, whereas cross-linking of hemoglobin by various reagents [dialdehydes (11, 12), carbodiimides (13), diepoxides, diisocyanates (14), and unsaturated sulfones (14, 15)] has been extensively studied, application of the procedure to clinical problems has been restricted to the preparation of hemoglobin, modified in order to increase its life-span when used as a blood replacement fluid.

In continuation of microencapsulation experiments through cross-linking of proteins (16–18), this paper deals with the application of this concept to hemoglobin.

EXPERIMENTAL

Reagents—Human hemoglobin was used. Red blood cells were collected from citrated human blood by centrifugation and washed with isotonic sodium chloride solution. After centrifugation, the red cells were subjected to hemolysis. Stromas were eliminated by successive filtration through membranes with porosities of 3 μm then 0.2 μm. The hemoglobin solution (6%, w/v) was added to glucose (2%, w/v) and then lyophilized.

Several buffers were prepared with pH's ranging from 9.8 (0.45 *M* Na_2CO_3; HCl to pH 9.8); [0.5 *M* bis(2-hydroxyethyl)amino-tris(hydroxymethyl) methane(I)[2]; HCl to pH 9.8] to 10.5 (0.45 *M* Na_2CO_3; HCl to pH 10.5); and 11.5 (0.45 *M* Na_2CO_3; HCl to pH 11.5), (2 *M* Na_2CO_3; HCl to pH 11.5).

The organic solvent was chloroform–cyclohexane (1:4, v/v). It was used to prepare solutions of terephthaloylchloride[3] (2.5 and 5 g%, w/v), sebacoyl chloride[3] (2.25 and 4.5 g%, w/v), and succinylchloride[4] (0.25, 0.50, and 1 g%, w/v).

An etheral solution of 12% glutaraldehyde (v/v) was prepared from a 25% aqueous solution[3] (v/v) through extraction with diethyl ether from a sodium chloride-saturated solution.

The surfactants were sorbitan trioleate[5] [2, 5, and 10% solutions (v/v) in the organic solvent] sorbitan monolaurate[5] [5 and 10% solutions (v/v) in the organic solvent], lecithin from soybean[6] [1, 2, 3, and 5% solutions (w/v) in the organic solvent]. Polysorbate[5] was used for the transfer of microcapsules, as a 1:3 mixture (v/v) with glycerin.

The other reagents were inositol hexaphosphate[2], sodium chloride solution 0.9 g% (w/v), and buffered sodium chloride solution, pH 7.3.

Macromolecular solutions (plasma substitutes) were used for resistance assays (dextran[7], modified gelatin[8,9]).

Materials—A stirrer[10], fitted with a 5-bladed screw (maximal speed: 1800 rpm) was first used and later replaced by an homogenizer[11], fitted with a metallic double blade (maximal speed: 23,000 rpm).

The oxygen dissociation curves were recorded with an analyzer[12].

Procedures—The hemoglobin lyophilisate (1.4 g, corresponding to 0.35 g of glucose and 1.05 g of hemoglobin) was dissolved in the buffer (3 ml) and emulsified with 15 ml of 2% surfactant solution (1200 rpm) at 0°.

The acylchloride solution (15 ml) was added and stirred for 3 min. The organic solvent (30 ml) was then mixed into the suspension. After centrifugation (350×*g*, 30 sec), the sediment was resuspended in the glycerin–surfactant mixture (5–10 ml) to which 50 ml of 0.9% aqueous NaCl was then added. The suspension was centrifuged (350×*g*, 5 min) and the sediment washed twice in 0.9% NaCl. Finally, the hemoglobin microcapsules were suspended in 30 ml of buffered sodium chloride solution.

After freezing at −30°, the suspension was easily lyophilized to yield a light brownish powder.

Modifications in the Reticulation Conditions—*Buffer*—Several 0.45 *M* Na_2CO_3 buffers (pH increasing from 9.8 to 11.5) were used during the polymerization step. Other attempts were made with a 2 *M* Na_2CO_3 buffer (pH 11.5) and with a I buffer[2], pH 9.8.

Acylating Agent—Several acyldichlorides were used as acylating agents at different concentrations: terephthaloylchloride, sebacoyl chloride, succinyldichloride, and a dialdehyde:glutaric dialdehyde.

Surfactant—Sorbitan trioleate, sorbitan monolaurate, and soybean lecithin were checked at different concentrations during the polymerization step.

Stirring—Variations of stirring conditions were made by replacement of the stirrer[10] by an homogenizer[11].

Temperature—Microcapsules were prepared at 20, 0, and −10°. Use of a nitrogen atmosphere was attempted to avoid oxidation of hemoglobin.

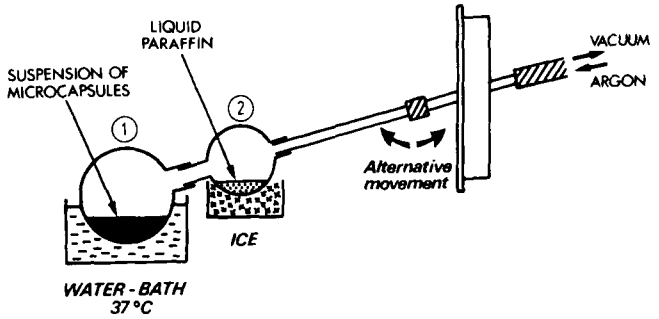

Figure 1—*Scheme of the apparatus used for deoxygenation of microencapsulated hemoglobin.*

glucose was added to the microcapsule suspension, as a hemoglobin protector (19).

Stabilization with Glutaraldehyde—To strengthen the cross-linked wall, microcapsules were prepared according to the following process: Microcapsules were obtained from hemoglobin and terephthaloylchloride at 0° in a pH 9.8 buffer with 5% sorbitan monolaurate (stirring speed: 1800 rpm). The capsules were centrifuged, resuspended in 60 ml of 0.9% NaCl solution, and 0.4 ml of a 25% aqueous glutaraldehyde solution was added. After a 3-min reaction, the capsules were isolated as before.

Incorporation of Inositol hexaphosphate—Inositol hexaphosphate is known to lower the oxygen affinity of hemoglobin (20, 21). Therefore, it was added to the hemoglobin microcapsules, either through incubation (20 hr, 4°) of the microcapsules in the phosphate solution (external phase) or during the preparation of the microcapsules (internal phase).

Assays—*Centrifugation*—Microcapsules were centrifuged for 60 min at 100,000×*g* (4°).

Resistance of Microcapsules to Ultrasound—Evaluation followed a 15-min treatment at 45 kHz.

Resistance to Freezing–Defreezing Cycles—Freezing at −30° followed by melting at 20° was repeated 4 times.

Aging—Suspensions of capsules in water or in 0.9 g% NaCl solution were stored at +4°.

Resistance to Macromolecular Solutions—Microcapsules were suspended in different macromolecular plasma substitutes at 37°.

Degradability Effect of Proteases—Microcapsules were incubated at 37° in different media containing proteases: pepsin (0.32 g %, w/v) in a hydrochloric acid solution (pH 2); pancreatin (1 g %, w/v) in a KH_2PO_4–NaOH buffer (pH 7.5); pronase 4×10^{-3} g % (w/v) in a $Na_2B_4O_7$–KH_2PO_4 buffer (pH 8) with $Ca(CH_3COO)_2$ (0.176 g %, w/v).

Oxygen Transfer Properties—Permeability toward oxygen was studied by using the apparatus depicted in Fig. 1.

A suspension of microcapsules of suitable concentration was prepared in a phosphate buffer (pH 7.5). Flask 1 contained the suspension and was heated to 37°. Flask 2 contained liquid petrolatum[13] and was cooled in an ice bath. The apparatus was continuously agitated and evacuated to 10^{-1}–10^{-2} T, after which argon was introduced. After several cycles, the apparatus was placed in an upright position so as to cover the deoxygenated suspension with liquid petrolatum. The microcapsule suspension was then transfered into the measurement cell of a spectrometer through a syringe containing liquid petrolatum so as to avoid any contact with air.

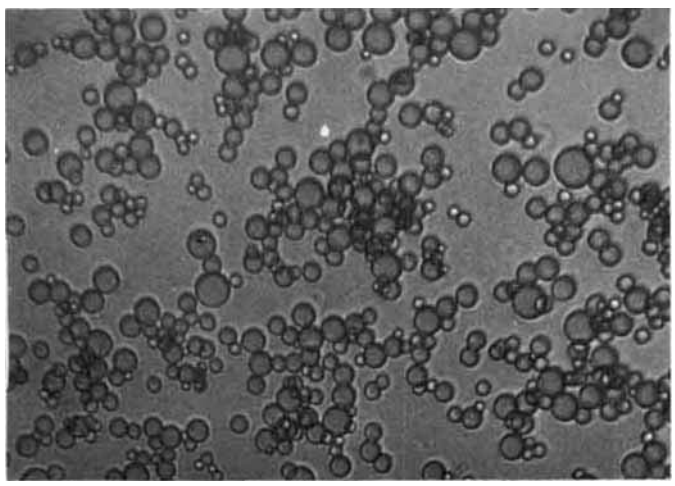

Figure 2—*Photomicrograph of hemoglobin microcapsules with cross-linked hemoglobin membrane (terephthaloylchloride).*

[13] Nujol.

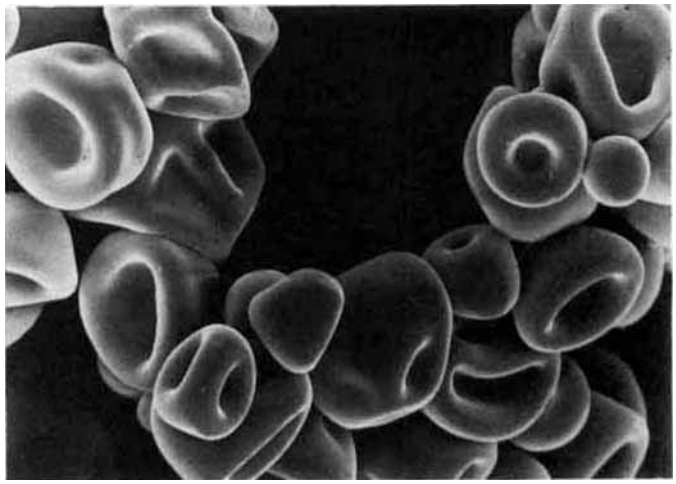

Figure 3—*Scanning electron micrograph of hemoglobin microcapsules with cross-linked hemoglobin membrane (terephthaloylchloride).*

After recording of the initial spectrum of the microcapsules, progressive reoxygenation was performed by bubbling air through the suspension with a syringe (0.5 ml in 15 sec) while the spectra were successively measured.

The saturation curve was recorded by plotting the percentage of oxyhemoglobin *versus* the partial pressure of oxygen.

RESULTS AND DISCUSSION

The initial typical procedure gave reddish spherical microcapsules. Their size was ~60 μm (σ = 23 μm) (Fig. 2).

A scanning electron micrograph of the dehydrated microcapsules is presented in Fig. 3.

Hemoglobin was chemically modified by terephthaloylchloride, which was indicated by examination of the film, isolated at the interface of an aqueous solution of hemoglobin and an organic solution of terephthaloylchloride. The IR spectrum of the film showed significant differences from that of hemoglobin in the fingerprint area (700–1500 nm).

After a 60-min centrifugation at 100,000×*g* (4°), the microcapsules were found mainly unaltered. However, the supernate was slightly colored, indicative of some hemoglobin leak. The microcapsules resisted a 15-min treatment by ultrasound at 45 kHz. Four freezing–defreezing cycles did not affect the microcapsules. Rehydration of the lyophilized microcapsules regenerated their spherical shape; however, a large amount of hemoglobin (20–25% of the total amount of hemoglobin used) was oxidized to methemoglobin during the process. Suspending the capsules in water resulted in turgescence, diffusion of hemoglobin, and, finally, lysis of the membrane. In 0.9% NaCl solution, hemoglobin also slowly diffused into the medium. After suspension in macromolecular solutions, optical microscopic observation showed the membrane to be collapsed, especially in the case of the larger capsules. The original spherical shape was regenerated through resuspension in an isotonic aqueous medium.

Table I—Hemoglobin Microcapsules with a Cross-Linked Hemoglobin Wall (Terephthaloylchloride): Influence of Nature and Concentration of the Lipophilic Surfactant [a]

Surfactant	Concentration, %	Mean diameter, μm	σ, μm
Sorbitan trioleate	2	40.8	18.9
	5	32.6	13.9

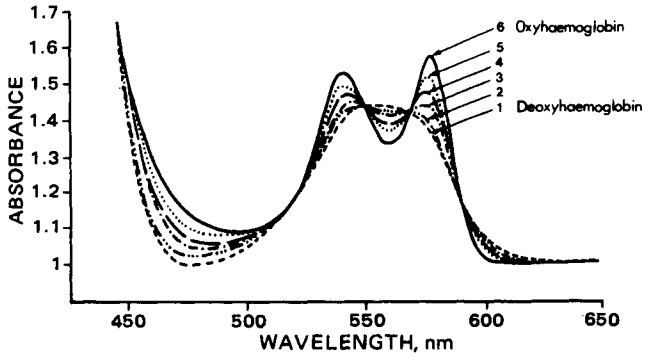

Figure 4a—*Visible absorption spectra of hemoglobin microcapsules: progressive reoxygenation of deoxyhemoglobin (curve 1) to oxyhemoglobin (curve 6).*

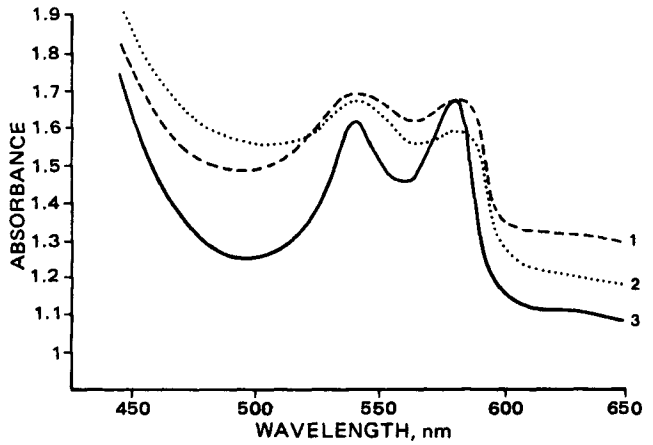

Figure 4b—*Absorption spectra of hemoglobin microcapsules, influence of the cross-linking reagent. Key: curve 1, terephthaloylchloride; curve 2, sebacoyl chloride; curve 3, glutaraldehyde.*

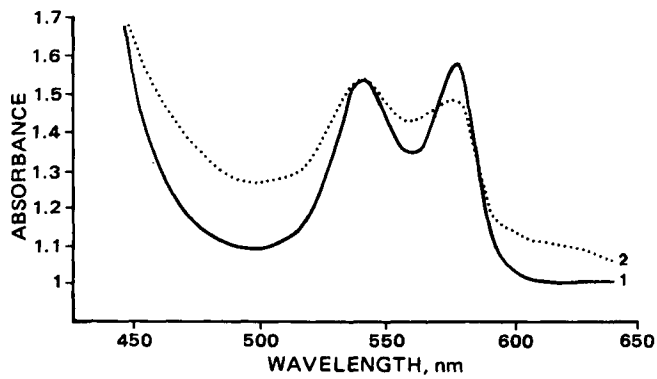

Figure 4c—*Absorption spectra of lyophilized hemoglobin microcapsules (terephthaloylchloride as cross-linking agent). Key: curve 1, glucose added prior to lyophilization; curve 2, without glucose.*

The microcapsules were destroyed after a 2-min incubation in pepsin or pronase, 1-min in pancreatin.

The electronic spectrum of the deoxygenated capsules (Fig. 4a) was characteristic of deoxyhemoglobin and gradually changed to the spectrum of oxyhemoglobin upon oxygenation.

The oxygen dissociation curve (curve 1, Fig. 5a) was not sigmoidal and differed from that of a hemoglobin solution (curve 3) or of normal human blood (curve 4). The p50 was only 6 mm Hg.

The initial procedure then allowed preparation of relatively stable hemoglobin microcapsules, the membranes of which were resistant, biodegradable, and permeable to oxygen.

However, the mean diameter was far too large, presence of methemoglobin had to be avoided, the lyophilization process needed improvements, and the oxygen affinity had to be reduced.

The following results were gained upon modifications of the procedure: Attempts to raise the pH of the 0.45 *M* Na_2CO_3 buffer from 9.8 to 11.5,

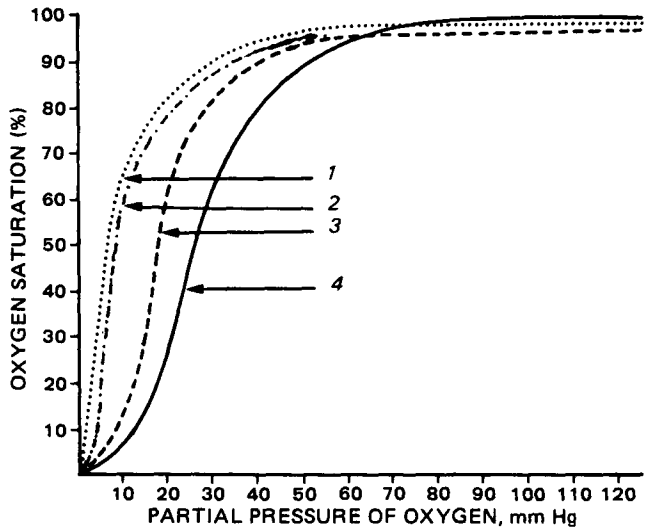

Figure 5a—*Oxygen dissociation curves. Key: curve 1, hemoglobin microcapsules with terephthaloylchloride as cross-linking agent; curve 2, hemoglobin microcapsules with glutaraldehyde as cross-linking agent; curve 3, hemoglobin solution; curve 4, normal human blood.*

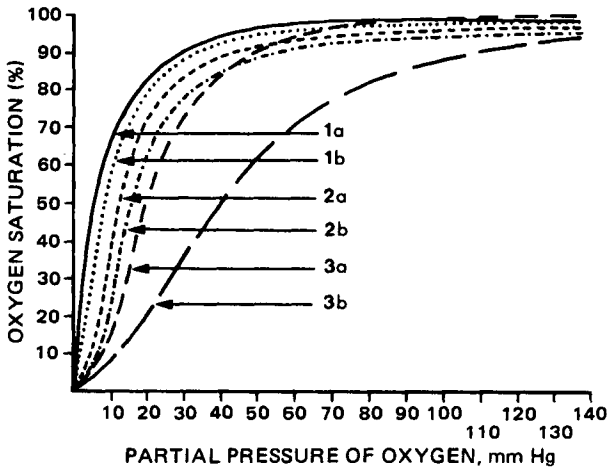

Figure 5b—*Oxygen dissociation curves of hemoglobin microcapsules without subsequent treatment and after stabilization with glutaraldehyde: effect of adding inositol hexaphosphate. Key: 1a, untreated microcapsules (p50 = 6 mm Hg); 1b, untreated microcapsules with inositol hexaphosphate added to the external phase (p50 = 8 mm Hg); 2a, stabilized microcapsules (p50 = 11 mm Hg); 2b, stabilized microcapsules with inositol hexaphosphate incorporated in the internal phase (p50 = 13 mm Hg); 3a, hemoglobin solution (p50 = 18 mm Hg); 3b, hemoglobin solution + inositol hexaphosphate (p50 = 39 mm Hg).*

as well as increasing the molarity to 2 *M* were not useful. However, replacing the sodium carbonate buffer by a 0.5 *M* I buffer, pH 9.8, gave good results. Increasing the concentration of terephthaloylchloride provided partial denaturation of hemoglobin. Sebacoyl chloride and succinylchloride gave poor results: the membranes were tiny and hemoglobin diffused into water, while the absorption spectrum was strongly altered (Fig. 4b, curves 1 and 2). On the contrary, glutaraldehyde yielded nice microcapsules which suffered practically no diffusion of hemoglobin. The absorption spectrum (Fig. 4b, curve 3) was unaltered and the p50 was 7 mm Hg. The oxygen dissociation curve was slightly sigmoidal (Fig. 5a). The microcapsules could be easily lyophilized. They were destroyed within 2 min in pepsin (pH 2) and only 2–3 hr in pancreatin (pH 7.5).

From the various surfactants checked (Table I), 5% sorbitan monolaurate seemed to give the best results regarding the average size and the distribution of diameters. Soybean lecithin also gave interesting results. Variation in the nature and concentration of surfactant did not affect the absorption spectrum nor the affinity curve.

The stirrer[10] used previously allowed only a maximum speed of 1800 rpm, but the use of the homogenizer[11] (metallic double blade) drastically improved the size of capsules (Table II). While graduation 100 of the

Table II—Hemoglobin Microcapsules with a Cross-Linked Hemoglobin Wall (Terephthaloylchloride): Influence of Stirring Conditions

apparatus corresponds to a maximum speed of 23,000 rpm, graduation 40 yielded capsules with a 4.9-μm diameter (σ = 1.2).

With microcapsules prepared at 20°, hemoglobin was altered. At −10°, hemoglobin rapidly diffused from the microcapsules. Again, the best results were gained at 0°. An attempt was made to prepare the microcapsules from deoxyhemoglobin under nitrogen. No improvement in the qualities of the capsules (p50 = 6 mm Hg) could be observed. Adding an amount of glucose equal to the weight of hemoglobin used prevented alteration of the hemoglobin during lyophilization (Fig. 4c).

When the capsules prepared from hemoglobin and terephthaloylchloride were further stabilized with glutaraldehyde they became very resistant. They resisted ultracentrifugation (100,000×g, 60 min, + 4°), freezing, melting cycles, and lyophilization. They were, however, rendered less deformable than previously and showed greater resistance to proteases (pepsin, 2 min; pancreatin, 30 min; pronase 2–3 hr). Diffusion of hemoglobin out of the wall was much slower. Interestingly, their p50 was now 11 mm Hg and the curve became slightly sigmoidal in shape (Fig. 5b).

Incorporation of inositol hexaphosphate induced modifications of the oxygen dissociation curves (Fig. 5b).

With standard microcapsules [not stabilized with glutaraldehyde (p50 = 6 mm Hg)], inositol hexaphosphate was only efficient when added in the external phase (p50 = 8 mm Hg). This result was probably due to inositol hexaphosphate being washed out during the isolation step of microcapsules.

On the contrary, with glutaraldehyde-stabilized capsules (p50 = 11 mm Hg), inositol hexaphosphate was not efficient when added to external phase (p50 unchanged = 11 mm Hg), but raised the p50 to 13 mm when in the internal phase. These last two results show that inositol hexaphosphate did not diffuse through glutaraldehyde-stabilized membranes.

The hemoglobin microcapsules prepared through the emulsion–reticulation method present interesting properties: one could actually obtain stable and biodegradable microcapsules with a 5-μm diameter, with a membrane permeable to oxygen but not to hemoglobin and inositol hexaphosphate, with a sigmoidal saturation curve (p50 = 13 mm Hg), and which could be lyophilized. Complementary work is necessary to evaluate their rheological and biological properties.

Operation of Long-Range Substituent Effects in Rigid Opiates: Protonated and Unprotonated Oxymorphone

STEPHEN D. DARLING *, **VERA M. KOLB** ‡x, **GRETCHEN S. MANDEL** §, and **NEIL S. MANDEL** §

Received January 19, 1981, from the * *Department of Chemistry, The University of Akron, Akron, OH 44325;* the ‡ *Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901;* and the § *Medical College of Wisconsin, Veterans Administration Medical Center, Wood, WI 53193.* Accepted for publication October 6, 1981.

Abstract □ The structure of protonated oxymorphone (amine salt) was determined by an X-ray crystallographic study. Significant differences were found with the previously determined structure of unprotonated oxymorphone (free base). Upon protonation on nitrogen, an elongation of the N—C bond occurred, accompanied by subtle changes in bond lengths and angles distant from the site of protonation. These changes in geometry are interpreted as a reflection of long-range substituent effects.

Keyphrases □ Oxymorphone—protonated and unprotonated, operation of long-range effects in rigid opiates □ Opiates—operation of long-range substituent effects, protonated and unprotonated oxymorphone □ Crystallography, X-ray—determination of structure of protonated and unprotonated oxymorphone

The existence of long-range substituent effects in morphines was proposed in 1979 (1). The anomalous variations in the pKa values of variously substituted morphines (2) were interpreted as the evidence for the existence of these effects. Additional evidence was sought to support the existence of these effects in morphines, including the X-ray evidence which is expected to show that a substituent introduced in the morphine molecule causes changes in bond lengths and angles, not only locally but throughout the entire molecule (1), and the voltammetric evidence, which is expected to demonstrate that the electron transfer from the lone electron pair of the nitrogen of morphines is affected by remote substitution. The data on voltammetric behavior of morphines recently published (3) may constitute the latter evidence[1]. The authors report here the X-ray evidence.

Early X-ray crystallographic studies of morphines were performed on morphine (4) and codeine (5) with the objective of determining their molecular structure and absolute stereochemistry, respectively. More recently, refined structures of morphine (6) and some of its pharmacologically important derivatives, such as naloxone (7) and oxymorphone (8), have been obtained. The latter studies responded to the needs of medicinal chemists who attempted to explain the pharmacological effects of morphine agonists and antagonists in terms of the geometric (9,10) and stereoelectronic (11–18) features of these molecules. After the publication of the refined structures of morphine (6) and naloxone (7), medicinal and quantum chemists started using these structures as an approximation of the structures of other morphine derivatives whose X-ray structures had not been determined (11–13, 15–17). Such approximations were widely used and did not stimulate additional X-ray work in the morphine field.

The approximate geometries were derived from the known geometries using three assumptions: (*a*) The geometry of a morphine does not change upon protonation of nitrogen (12, 15). Thus, the X-ray structure of morphine amine salt was used in place of the structure of the corresponding free base (12). (*b*) In morphines that differ only in the substituent on nitrogen, the geometry of *N*-nor moieties is the same (12, 13, 15–17). For example, the geometry of the *N*-nor moiety of nalorphone was assumed to be the same as that of morphine (12); in the same way, the geometries of the *N*-nor moieties of oxymorphone (13, 16, 17), nalmexone, naltrexone, and nalbuphine (16, 17) were derived from the geometry of naloxone. (*c*) Introduction of the substituent at C-2 and at the phenolic and alcoholic oxygens of morphine does not change its basic geometry (11). Therefore, skeletal structures of 2-amino morphine, codeine, heroin, and 6-acetyl morphine were assumed to be the same (11).

Justification of assumption *a* seems to be difficult when considering the IR data of amines and their salts, which suggests longer N—C bonds in protonated amines (19–21). The validity of these assumptions is challenged by the existence of long-range substituent effects in morphines (1): the introduction of a substituent in a rigid molecule like morphine is likely to cause distortions of bond angles and torsional angles, not only locally, but throughout the entire molecule. The geometry changes caused by long-range substituent effects are typically very small. However, it has been demonstrated recently that even very small differences in geometry significantly influence the results of quantum chemical calculations of oxymorphone (18). These results suggest that the use of exact (X-ray) structures of morphines is preferred to the use of approximate (slightly inaccurate) structures for quantum chemical studies of morphines.

The objective of this study was to test experimentally

[a] The anisotropic temperature factor has the form: $\exp -2\pi(U_{11}h^2a^{*2} + \ldots + 2U_{12}hka^*b^* + \ldots)$. [b] Numbers in parentheses are the estimated *SD* of the last digit.

the validity of assumption *a*: to establish, by an X-ray crystallographic study, whether protonation of nitrogens influences the geometry of morphines. The results of this study would also test the validity of the long-range substituent concept in morphines. Since the X-ray structure of an unprotonated morphine derivative, oxymorphone, has already been reported (8), the protonated oxymorphone (amine salt) was chosen as the subject of the X-ray structure determination.

EXPERIMENTAL

A single crystal of oxymorphone hydrochloride[2] (4,5α-epoxy-3,14-dihydroxy-17-methylmorphinan-6-one hydrochloride), suitable for X-ray analysis, was grown from 95% ethanol after slow evaporation. The size of the crystal used for data collection measured ~0.25 × 0.3 × 0.4 mm. The crystals were clear, colorless prisms.

Weissenberg and precision photographs showed the crystal to be orthorhombic and have systematic extinctions HOO:H=2*n* OKO:K=2*n* OOL:L=2*n* indicating space group $P2_12_12_1$ (number 19). The density was measured by flotation in a mixture of toluene and bromotrichloromethane. The crystal was mounted on a $P2_1$ automatic diffractometer[3] equipped with an incident beam graphite-crystal monochromator. All measurements were made at 25(±2)° using molybdenum K_α radiation. The unit-cell constants and the orientation matrix to be used in data collection were obtained from a least-square refinement of 15 centered general reflections. Crystal data are listed in Table I.

Data Collection—The diffraction data were collected by the θ–2θ scan technique at room temperature with graphite monochromated molybdenum K_α radiation. The scan rate varied from 2 to 10°/min, dependent on the intensity of diffraction maxima (scan width was based on $\Delta\theta = 1.00 + 0.15 \tan\theta$). A decay of ~50% was noted for the three standard reflections ($\bar{4},\bar{2},2;\bar{2},1,2;0,\bar{1},4$) monitored for every 50 reflections over the period of collection.

A total of 2172 reflections was collected, comprising the quadrant of reciprocal space where *h*, *k*, and *l* are each nonnegative. Of the 2172 reflections collected, 1710 were classified as observed for $|F_o|^2 > 3\sigma(|F_o|^2)$, where $|F_o|$ is the observed structure factor amplitude corrected for Lorentz and polarization effects.

Structure Determination and Refinement—The diffractometer data were reduced and corrected for decay using a program from the CRYSP programs (22). The structure was solved by direct methods using the MULTAN 74 program (23). The probable phase set, as determined by statistics and based on three origin and three starting reflections, produced an *E*-map containing 19 of the 27 heavy atoms in the structure. The remaining atoms were located in difference Fourier maps using the program set CRYM (24).

Full matrix least-square refinement on the heavy atom positions minimizing the quantity $\Sigma\omega(F_o^2 - F_c^2)^2$, where $\omega = 1/\sigma^2(F_o^2)$, was followed by the calculation of all hydrogen atom positions except for the hydroxyl hydrogen atoms and methyl hydrogen atoms which were located in difference Fourier maps. At this point, two cycles of isotropic full matrix least-squares resulted in an *R* value, $[= \Sigma(||F_o| - |F_c||)/\Sigma|F_o|]$

0.112. Further full matrix least-square analysis of 245 variables—coordinates and anisotropic temperature factors for 27 heavy atoms, a secondary extinction parameter (25) and a scale factor—led to a final R value of 0.068 and a goodness-of-fit [$= \Sigma\omega(F_o^2 - F_c^2)^2/M - S)^{1/2}$] for $M = 2172$ reflections and $S = 245$ parameters of 9.7. (In this analysis the coordinates and isotropic temperature factors for 27 hydrogen atoms were held constant). The ωR value [$= [\Sigma\omega(F_o^2 - F_c^2)^2/\Sigma\omega F_o^4]^{1/2}$] was 0.117 and the R factor for the 3σ data set was 0.056. The estimated standard deviations were computed from the inverse matrix of the last full matrix, least-squares cycle. All shifts in parameters were less than their estimated standard deviations in the final refinement cycle. The scattering factors and anomalous dispersion terms for chlorine were taken from a published source[4], the scattering factors for hydrogen were taken from Stewart *et al.* (26).

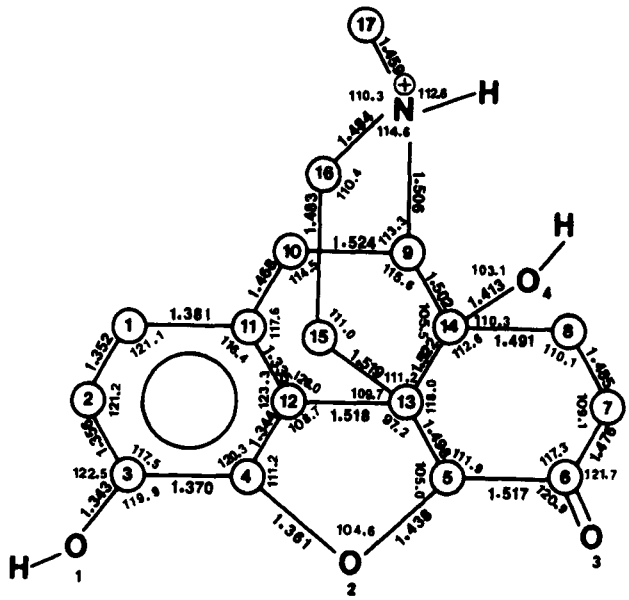

Figure 2—*Bond lengths and bond angles in protonated oxymorphone (oxymorphone·HCl·H_2O·C_2H_5OH). The estimated standard deviations are 0.005–0.006 Å for C—C, C—O, and C—N bonds, and 0.3–0.4° for C—C—(C,O,N) angles.*

[a] Numbers in parentheses are the estimated *SD* of the last digit. [b] Oxymorphone ·HCl·H_2O·C_2H_5OH. [c] Oxymorphone ·H_2O (8). [d] If (a − b)/σ ≥ 5, the difference in torsional angles, a − b, is significant.

Detailed information about the crystal structure of oxymorphone·HCl·H_2O·C_2H_5OH is given in Tables I–VII: crystal data (Table I), coordinates and B_{equiv} for nonhydrogen atoms (Table II), anisotropic thermal parameters (Table III), positional parameters and B_{iso} for hydrogen atoms (Table IV), interatomic distances (Table V), bond angles (Table VI), and torsional angles (Table VII).

The molecular structure of oxymorphone·HCl·H_2O·C_2H_5OH is depicted in Fig. 1, with bond lengths and bond angles shown in Fig. 2. For the purpose of comparison, the geometry of unprotonated oxymorphone (8) is also shown (Fig. 3).

RESULTS AND DISCUSSION

Inspection of Figs. 2 and 3 and Table V reveals some significant[5] differences in bond lengths of protonated and unprotonated oxymorphone. Thus, the N—C-9 is longer by 0.032 (6) Å in protonated oxymorphone (Scheme II) than in the unprotonated analog (Scheme III). The elongation of the N—C bond upon protonation is not unexpected in light of the IR data of amines and their salts[6] and is consistent with the previously described elongation of the N—C bonds of cyclazocine upon protonation (28).

Several C—C bonds are considerably shorter (0.036–0.054 Å) in the protonated than in the unprotonated molecule: C-1–C-2, C-10–C-11, C-5–C-13, C-9–C-14, C-11–C-12, and C-4–C-12. Significant differences in several C—O bonds are also observed. Comparison of bond angles for protonated and unprotonated oxymorphone (Table VI) reveals several small but significant differences of up to ~6 degrees. Similarly, several torsional angles of these two molecules differ for up to ~6 degrees (Table VII).

Observed changes in bond lengths, angles, and torsional angles distant from the site of protonation are interpreted as a reflection of long-range substituent effects in oxymorphone (1). Protonation leads to a formal positive electric charge on nitrogen, which can be transmitted further throughout the molecule *via* long-range inductive and electrostatic field effects (1). The elongation of the N—C bond upon protonation may introduce a local strain and conformational distortion which may be transmitted through the entire molecule by a slight flexing of bond and torsional angles (conformational transmission effect); in this way, the strain is shared by the whole structure (1).

While long-range effects are expected to influence the geometry of the entire molecule, the exact location and magnitude of the geometric changes are difficult to predict; observed changes therefore appear to be erratic. For this reason, extrapolation of the geometric changes observed here, upon protonation of oxymorphone to predictions of geometries of other morphine derivatives, is extremely difficult.

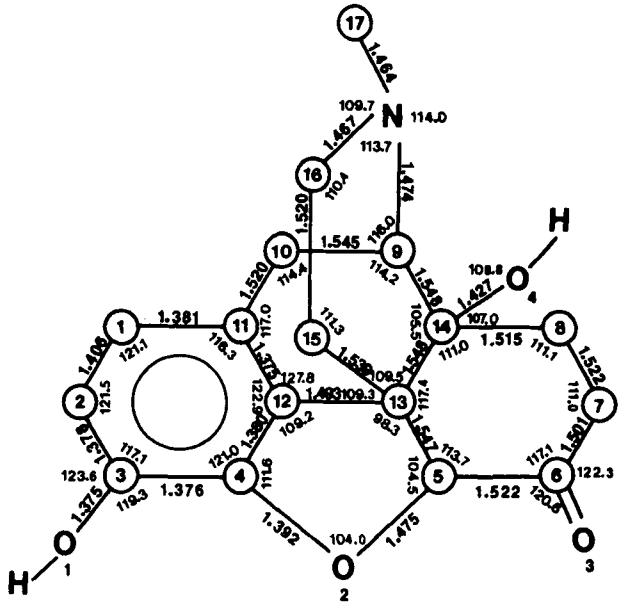

Figure 3—*Bond lengths and bond angles in unprotonated oxymorphone (oxymorphone·H_2O) (8). The estimated standard deviations are 0.004–0.005 Å for C—C, C—O, and C—N bonds, and 0.2–0.3° for C—C—(C,O,N) angles.*

[5] Significant differences are those which are >5σ. $\sigma = (\sigma_a^2 + \sigma_b^2)^{1/2}$, where σ_a and σ_b are standard deviations of the property measured (bond lengths, bond angles, *etc.*) of protonated and unprotonated oxymorphone.

[6] The N—H stretching frequencies of protonated amines (amine salts) are lower than those of their respective free bases (19–21). Since the frequency is directly related to the square root of the force constant of the bond (29), the lower frequency indicates a weaker and probably longer bond.

Medicated Tampons: Intravaginal Sustained Administration of Metronidazole and *In Vitro–In Vivo* Relationships

Y. W. CHIEN *x, J. OPPERMANN ‡, B. NICOLOVA ‡, and H. J. LAMBERT ‡

Received February 27, 1981, from **Rutgers—The State University, College of Pharmacy, Piscataway, NJ 08854* and ‡*Searle Laboratories, G. D. Searle & Co., Skokie, IL 60077.* Accepted for publication September 29, 1981.

Abstract □ The technical feasibility of utilizing tampons as a drug delivery system for prolonged intravaginal drug administrations was studied. Several commercially available brands of tampons were examined. The methodology for the incorporation of various doses of metronidazole, an antitrichomonas agent, in tampons was described. The sustained-release profile of metronidazole from these medicated tampons was characterized. Intravaginal administration of metronidazole *via* the medicated tampons was investigated in rhesus monkeys and human volunteers, and *in vitro–in vivo* correlations were established. The biopharmaceutics of intravaginal absorption of metronidazole *via* medicated tampons was analyzed in comparison with a vaginal solution formulation.

Keyphrases □ Metronidazole—intravaginal sustained administration in medicated tampons, *in vitro–in vivo* relationships □ Tampons—intravaginal sustained administration of metronidazole, *in vitro–in vivo* relationships □ Intravaginal administration—sustained metronidazole in tampons, *in vitro–in vivo* relationships

Tampons are made of cotton and/or cellulose and are commonly used for intravaginal insertion to absorb menstrual discharge (1). Numerous brands of vaginal tampons are commercially available. Their characteristics of high fluid absorbability and retention have been recommended for the absorption of extensive vaginal discharge in trichomonas-infected women.

Metronidazole[1] has been shown to be an effective antiprotozoal agent with a broad spectrum of activity against anaerobes (2–6). It is selectively absorbed by and produces cytotoxicity in anaerobes (6–8). Its efficacy in the treatment of *Trichomonas vaginalis* has been well documented (9). The idea of developing a medicated tampon to combine the therapeutic efficacy of metronidazole and the high fluid absorbability of tampon for trichomonas-infected women is thus generated.

Additionally, a high incidence of toxic shock syndrome was recently reported in menstruating women who used tampons, especially one brand[2] (10). Continuing epidemiological and microbiological studies at the Center for Disease Control have firmly related the pathogenesis of toxic shock syndrome to the infection of *Staphylococcus aureus* isolated from the vaginas of patients who suffered from toxic shock syndrome (98 *versus* 7% in the unmatched controls). On the other hand, no *S. aureus* could be recovered from the unused tampons, including those from tampon boxes used by the patients (10). The incidence of toxic shock syndrome further suggests the need to develop a medicated tampon, which administers an antistaphylococcal agent in the vagina in a controlled manner for a prolonged period of time, to protect the user from *S. aureus* infection.

The objective of this investigation is to evaluate the technical feasibility of using the tampon as an intravaginal drug delivery system. In this report, the methodology for

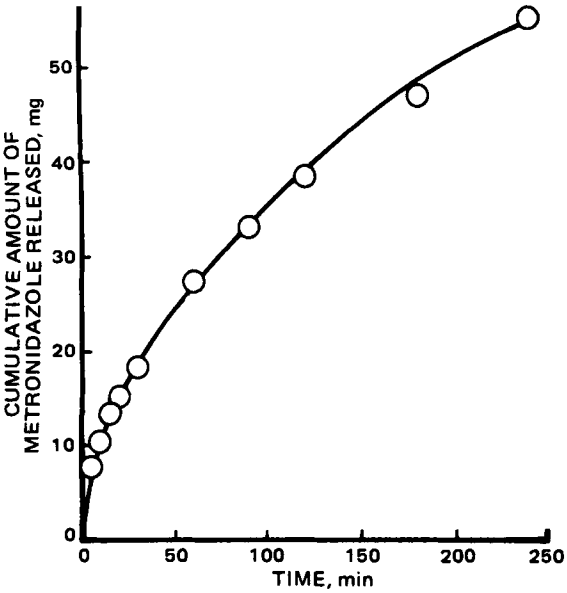

Figure 1—*Time course for the release of metronidazole from medicated Tampon I (A = 20.25 mg/cm³) into 200 ml of simulated vaginal fluid (pH 4.5) at 37° for 4 hr.*

the incorporation of various doses of metronidazole in several well-known brands of tampon is described, and the sustained-release profile of metronidazole from these medicated tampons is characterized. Sustained intravaginal administration of metronidazole *via* the tampon was also examined in both rhesus monkeys and human volunteers. *In vitro–in vivo* correlations were established and the biopharmaceutics of intravaginal absorption of metronidazole was also analyzed.

EXPERIMENTAL

Materials—Both metronidazole[1] and various commercial brands[3–5] of tampon (I–IV) were used as obtained. All the reagents or solvents used were analytical reagent grade.

Impregnation of Tampons with Metronidazole—Impregnation of tampons with metronidazole was achieved by preparing a concentrated metronidazole solution in acetone–methanol combinations and placing an aliquot of this solution onto the tip of the tampons. The solution was allowed to diffuse throughout the tampon body and the solvent was then evaporated under controlled conditions. This process was repeated until the desired amount of metronidazole was impregnated.

***In Vitro* Elution Studies of Medicated Tampons**—A polyethylene tube (6-cm length; 1.6-cm o.d.; 1.5-cm i.d.) with 20 evenly distributed openings (2.5 mm in diameter) was fabricated as the tampon holder for *in vitro* drug elution studies to simulate the constriction produced by the vaginal wall on the tampon *in situ*. All *in vitro* elution studies of medicated tampons were conducted under sink conditions in 200 ml of simulated vaginal fluid (0.026 *M* citric acid and 0.024 *M* sodium citrate in distilled water at pH 4.5) in a 250-ml reagent bottle thermostated at 37° in a waterbath (with a shaking rate of 80 oscillations/min). A 1-ml aliquot was withdrawn at each scheduled interval for up to 4 hr. After appropriate dilution, the concentration of metronidazole in the simulated vaginal fluid was determined spectrophotometrically[6] at its λ_{max} value of 316 nm. Several long-term (*e.g.*, 24 hr) drug elution studies were also carried out to ensure that 100% release of the impregnated metronidazole could be achieved from various brands of tampons.

Intravaginal Release Studies of Medicated Tampons—Five female, mid-cycle rhesus monkeys, weighing 4.7–6.5 kg, were used for crossover intravaginal release studies. Each monkey was tranquilized with 3 mg im of phencyclidine hydrochloride[7]. After tranquilizing, the animal was placed on its stomach on a V-board with the legs hanging freely over the end. The vagina was then sufficiently distended with a speculum to permit the easy insertion of a medicated tampon (1.5 cm in length). After insertion, each animal was placed in a primate chair[8] until the tampon was removed. The tampon was removed at 2, 4, 8, 16.5, or 25.5 hr after insertion by gently pulling on the string (which is attached to the tampon). The residual amount of metronidazole in each tampon was then analyzed spectrophotometrically following a 4-hr extraction with 40 ml of methanol.

Table I—*In Vitro* Release of Metronidazole from Various Brands of Tampon

Brands[a]	Surface Area, cm^2	Volume of Liquid Retained[b], ml/tampon	$Q/t^{1/2}$ [c], $\mu g/cm^2/min^{1/2}$
I	22.93	32.2	79.4
II	21.34	35.5	76.9
III	27.26	30.0	37.4
IV	28.99	24.0	51.6

[a] Each tampon was impregnated with 60 mg of metronidazole. [b] Volume of simulated vaginal fluid absorbed by 10-min soaking of tampon at room temperature. [c] *In vitro* release profile determined in simulated vaginal fluid at 37°.

Pharmacokinetics of Intravaginal Absorption—*[^{14}C]Metronidazole*—[^{14}C]Metronidazole, 1-(2[U-^{14}C]hydroxyethyl)-2-methyl-5-nitroimidazole[9], with a radiochemical purity >98% was used. The labeled drug was diluted with unlabeled metronidazole to yield a specific activity of 1.13 μCi/mg.

[^{14}C]Metronidazole-Tampon—Following the method described earlier, Tampon I was impregnated with 48.3 μCi (42.75 mg) of [^{14}C]-metronidazole.

Intravaginal Absorption of [^{14}C]Metronidazole from Medicated Tampons—One rhesus monkey was selected from the group that was used in the earlier intravaginal release studies. The animal was tranquilized and the [^{14}C]metronidazole-impregnated tampon was inserted in the manner as described previously. A urinary catheter[10] and a venous catheter[11] were also inserted. The patency of the venous catheter was maintained with a slow infusion of saline. The animal was secured in a

Table II—Apparent Diffusivities of Metronidazole and Porosity–Tortuosity Ratio in Various Brands of Tampons

Brands	$(D_m C_s)^{1/2}$ [a], $mg^{1/2}/cm^{1/2}/min^{1/2}$	$D_m \times 10^6$, cm^2/sec	ϵ/θ [b]
I	28.0×10^{-3}	1.03	0.213
II	29.5×10^{-3}	1.14	0.236
III	24.6×10^{-3}	0.79	0.164
IV	33.5×10^{-3}	1.47	0.304

[a] Slope of the linear $Q/t^{1/2}$ *versus* $(2A - C_s)^{1/2}$ plots, where C_s = 12.7 mg/ml. [b] The ratio of porosity over tortuosity as calculated from Eq. 3 using a D value of 4.84×10^{-6} cm^2/sec, which was determined polarographically from the following relationship: $D = [(i_d)/0.605nCm^{2/3}t^{1/2}]^2$. *p*-Nitrophenol ($D = 9.18 \times 10^{-6}$ cm^2/sec) was run simultaneously as reference.

primate chair[8] until the tampon was removed and then transferred to a metabolism cage for continuous urine collections. Two milliliters of blood were collected at 3, 6, 8, 24, 26, 28, 30, 72, 96, and 120 hr. Urine was collected at 24, 48, 72, 96, and 120 hr.

Intravaginal Absorption of [^{14}C]*Metronidazole in Solution*—Three female rhesus monkeys, weighing 4.5–5.0 kg, were tranquilized with 1 mg/kg of phencyclidine hydrochloride[7]. After tranquilizing, catheters were placed in the saphenous vein[11] and urinary bladder[10]. A slow infusion of saline was initiated to maintain patency of the saphenous vein catheter. The animals were then placed on their backs on a V-board with the legs in a vertical (lithotomy) position and the pelvic area was supported and slightly elevated. A solution of 1 mg/kg of [^{14}C]metronidazole in 0.5 ml of distilled water was then quantitatively instilled into the vagina with a micropipet.

The animals were maintained in a tranquilized state by periodic administration of phencyclidine hydrochloride (1 mg/kg/90 min) for the first 5 hr after drug administration. Then, the animals were transferred to primate chairs[8] and remained there until 24 hr after drug administration. At this time the catheters were removed, the vaginal vault was thoroughly rinsed with 50 ml of saline, and the animals were transferred to metabolism cages for continuing urine and plasma collection.

Radioactivity Measurements—Aliquots (100–500 μl) of plasma, urine, or tampon extracts were added to 4 ml of water in scintillation vials. Ten milliliters of liquid scintillation solution[12] was added and the mixture was agitated to form a gel. Each sample was then assayed for carbon 14 content by liquid scintillation spectrometry[13].

RESULTS AND DISCUSSION

***In Vitro* Release Studies of Medicated Tampons**—The release profile of metronidazole from a medicated tampon in simulated vaginal fluid (pH 4.5) under a sink condition is shown in Fig. 1. Mechanistic analyses of this nonlinear drug release profile suggested that the release of metronidazole from tampons is under a matrix-controlled process and follows the same Q *versus* $t^{1/2}$ release pattern as demonstrated earlier in the release of norgestomet from hydrogel-type drug delivery device (11). The linear Q–$t^{1/2}$ relationship observed can be defined mathematically by:

$$Q = [D_m(2A - C_s)C_s t]^{1/2} \quad \text{(Eq. 1)}$$

where Q is the cumulative amount of metronidazole released from a unit surface area of a tampon; D_m is the effective diffusivity of metronidazole in the tampon matrix; A is the initial amount of metronidazole impregnated per unit volume of tampon; C_s is the solubility of metronidazole in the simulated vaginal fluid; and t is the time. As demonstrated in Fig. 2 a Q *versus* $t^{1/2}$ linearity was followed. The slope of this linearity is thus defined as:

$$Q/t^{1/2} = [D_m(2A - C_s)C_s]^{1/2} \quad \text{(Eq. 2)}$$

The $Q/t^{1/2}$ profiles for various brands of tampons are compared in Table I. It is noted that Tampons I and II released metronidazole at very much the same magntiude of $Q/t^{1/2}$, which was slightly more than twice the value of $Q/t^{1/2}$ for Tampon III; and the *in vitro* release of metronidazole from Tampon IV (Tampon III with deodorant) was observed to be 40%

faster than Tampon III. No correlation could be estalished between the values of $Q/t^{1/2}$ and the extent of liquid retention of the tampons.

The effect of the dose of metronidazole initially impregnated in a tampon on the sustained-release profile of metronidazole was also studied. Equation 2 suggests that the magnitude of $Q/t^{1/2}$ values should increase as the drug content (A) in the tampon increases. A dose level ranging from 60 to 360 mg/tampon was investigated. As suggested by Eq. 2, the results confirmed that $Q/t^{1/2}$ values show a linear dependency on the square root of $(2A - C_s)$ values (Fig. 3). These data indicate that the dosage administered intravaginally to a subject can be controlled by incorporating an appropriate amount of metronidazole in the tampon.

The slope of this linear $Q/t^{1/2}$ *versus* $(2A - C_s)^{1/2}$ relationship is defined by $(D_m C_s)^{1/2}$. If the aqueous solubility (C_s) of metronidazole is known or predetermined, the effective diffusivity (D_m) of metronidazole in a tampon matrix can be calculated. A D_m value ranging from 0.79 to 1.47 × 10^{-6} cm^2/sec was determined (Table II). Using the relationship:

$$D_m = D\frac{\epsilon}{\theta} \qquad \text{(Eq. 3)}$$

and the solution diffusivity (D) which was determined independently by dc polarography (12), the ratio of porosity (ϵ) over tortuosity (θ) can be estimated (Table II). It appears that the value of ϵ/θ varies from one brand of tampon to another (ranging from 0.164 to 0.304). The higher values of D_m and ϵ/θ for Tampon IV than for Tampon III are, apparently, due to the addition of deodorant in Tampon IV. The pretreatment by a fragrance (as the deodorant) with an o/w-type surfactant, such as polysorbate 20, should result in the enhancement of wettability of the tampon cotton and/or the reduction of drug–cotton interaction, leading to a higher porosity-tortuosity (ϵ/θ) ratio and, hence, a greater diffusivity (D_m) in the tampon matrix. It is also noticed that a lower liquid retention was obtained for Tampon IV than for Tampon III (Table I).

Intravaginal Release Studies of Medicated Tampons in Rhesus Monkeys—The intravaginal release profile of metronidazole from medicated tampons in rhesus monkeys is illustrated in Fig. 4. As expected from Eq. 1, the results indicated that the intravaginal release profile of

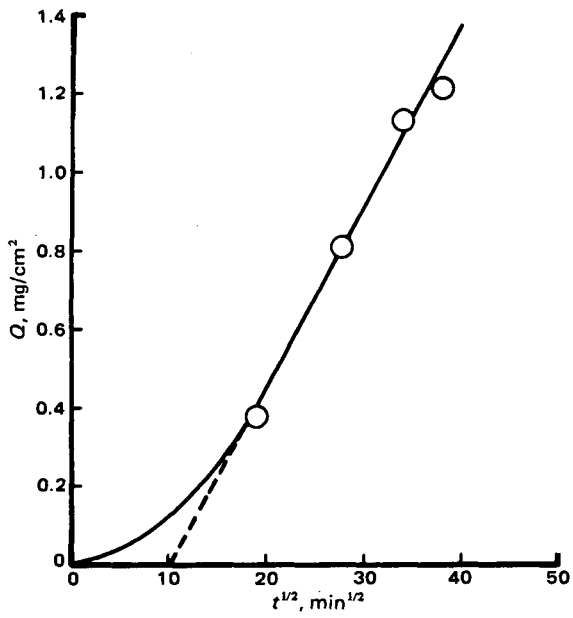

Figure 6—*Intravaginal release of metronidazole from Tampon III (A = 6.59 mg/cm^3) in a human volunteer for up to 24 hr. Q/t$^{1/2}$ = 45.9 μg/cm^2/min$^{1/2}$.*

Table IV—Effect of the Days in Menstrual Cycles on the Sustained Release of Metronidazole [a]

Days[b]	$Q/t^{1/2}$, mg/min$^{1/2}$	
	8 pm → 8 am	8 am → 8 pm
1	0.301	0.595
7	0.215	0.452
14	0.366	0.647
21	0.344	0.444

[a] For each 12-hr insertion, each volunteer receives one tampon (III) impregnated with 60 mg of metronidazole. [b] Days after the termination of menstruation.

metronidazole also follows the linear Q *versus* $t^{1/2}$ relationship. A $Q/t^{1/2}$ value of 74.9 μg/cm^2/min$^{1/2}$ was calculated. This intravaginal release rate of metronidazole (74.9 μg/cm^2/min$^{1/2}$) was found to be very close to the *in vitro* release rate (79.4 μg/cm^2/min$^{1/2}$) determined in the 4-hr drug elution studies (Fig. 2 and Table III).

Tampon I was also impregnated with 3 dosage levels of metronidazole and examined in rhesus monkeys to test the applicability of Eq. 2 to the *in vivo* condition. Results (Fig. 5) were in agreement with the *in vitro* observations (Fig. 3). Assuming that metronidazole has a solubility (C_s) in vaginal secretions similar to that in the simulated vaginal fluid (12.7 mg/ml), the effective diffusivity (D_m) can be calculated from the slope of $Q/t^{1/2}$ *versus* $(2A - C_s)^{1/2}$ plot. A value of 7.21 × 10^{-7} cm^2/sec is the result. It is only slightly lower than the value of 10.3 × 10^{-7} cm^2/sec determined in *in vitro* studies (Table II).

Intravaginal Release Studies of Medicated Tampons in Human Volunteers—The intravaginal release profile of metronidazole from medicated tampons in human volunteers is illustrated in Fig. 6. In this study, Tampon III was medicated and tested in one volunteer for a duration from 6 hr up to 24 hr. An intravaginal release rate of 45.9 μg/cm^2/min$^{1/2}$ was achieved. This release rate was found to be only slightly higher than the 37.4 μg/cm^2/min$^{1/2}$ measured in the 4-hr *in vitro* elution study (Table III).

Considering the cyclic variation in vaginal physiology, the effect of physiological phases in a menstrual cycle on the intravaginal release of metronidazole from medicated tampons was examined in one volunteer. The data in Table IV suggest that the intravaginal release rate of metronidazole first decreases right after menstruation and then increases toward the middle of the cycle just prior to ovulation. This behavior is very similar to the cyclic pattern observed in rhesus monkeys on the intravaginal absorption of hydrophilic and hydrophobic n-alkanols (13).

A higher rate of intravaginal release was also consistently observed in those medicated tampons inserted in daytime (8 am–8 pm) as compared to those inserted at night (8 pm–8 am). The observation may be related to the higher physical activity shown in the daytime, which may give a greater secretion of vaginal fluid.

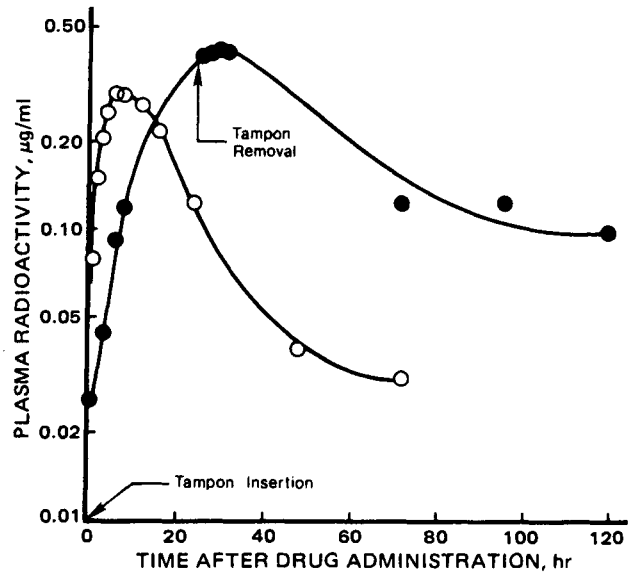

Figure 7—*Comparative plasma profiles of total radioactivity in rhesus monkeys administered with [^{14}C]metronidazole in solution dose (○; 5 mg; n = 3) and via medicated Tampon III (●; 42.75 mg; n = 1), where n is the number of subjects tested. The tampon was inserted for 25 hr while solution was administered for 24 hr.*

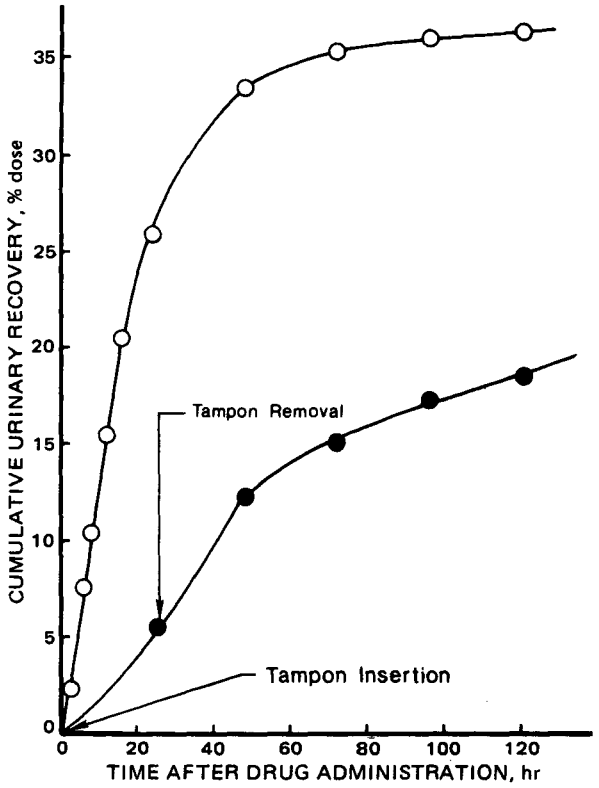

Figure 8—*Cumulative urinary recovery of total radioactivity (percent of the applied dose) after the intravaginal administrations of [^{14}C]-metronidazole in rhesus monkeys through solution dose (○) and medicated Tampon III (●). Conditions are the same as in Fig. 7.*

***In Vitro–In Vivo* Correlations**—The correlations between the *in vitro* data and intravaginal release profiles, as shown in Table III, are very encouraging. The results suggest that the 24-hr intravaginal release of metronidazole from medicated tampons in both rhesus monkeys and human volunteers can be predicted from the 4-hr *in vitro* drug elution study.

Comparative Plasma Profiles of Metronidazole—To study the comparative systemic bioavailability by intravaginal drug administration *via* medicated tampon and solution formulation, one unit of Tampon III was medicated with 48.3 μCi (42.75 mg) of [^{14}C]metronidazole and then inserted into the monkey vagina for 25 hr. Analysis of the ethanol extract of the removed tampon (by double 50-ml extractions) indicated that 10.4 mg of [^{14}C]metronidazole still remained in the tampon. Complete combustion of the extracted tampon to [^{14}C]carbon dioxide and water further demonstrated that an additional 1.2% (0.51 mg) of the original radioactivity was present in the tampon[14]. These results suggest that altogether, 74.5% (31.84 mg) of the [^{14}C]metronidazole incorporated into the tampon was released in the rhesus monkey during the 25-hr insertion period. This result is in agreement with the data obtained from similar experiments conducted with unlabeled metronidazole utilizing a UV spectrophotometric assay technique.

The plasma profile of total radioactivity following the 25-hr intravaginal administration of [^{14}C]metronidazole in the rhesus monkey *via* medicated tampon is compared with that following the intravaginal administration of [^{14}C]metronidazole in a solution formulation for 24 hr (Fig. 7). Results show that the peak plasma carbon 14 concentration occurs at 6 hr during administration of the solution dose, whereas after the vaginal tampon medication the peak is reached at a much later time (30 hr after insertion or 5 hr after tampon removal). These observations suggest a delayed intravaginal uptake of metronidazole by the sustained release mechanism of the medicated tampon as compared to the drug administration in solution dose. On the other hand, 5 hr after the removal of the tampon, the plasma radioactivity eliminates at basically the same rate as that following solution administration. These results suggest that the use of tampons as the intravaginal drug delivery device does not change the elimination kinetics of metronidazole from the body.

Comparing the areas under the plasma carbon 14 concentration curves (0–120 hr, corrected for the difference in the doses applied), it was estimated that the systemic bioavailability of metronidazole administered by the medicated tampon is only 27.2% of the solution dose. The low relative systemic bioavailability (27.2%) may occur if the majority of metronidazole released from the medicated tampon remains in the vaginal tract to exert a localized therapeutic activity. This possibility is confirmed by the observation that the peak plasma carbon 14 concentration is reached at 5 hr after removal of the medicated tampons (Fig. 7).

Comparative Urine Excretion Profiles of Metronidazole—Figure 8 compares the rate and extent of the urinary excretion of radioactivity after intravaginal administration of [^{14}C]metronidazole in solution formulation (5 mg) and medicated tampon (42.75 mg) to rhesus monkeys. Apparently, the rate and extent of urinary recovery of the radioactivity were significantly reduced when [^{14}C]metronidazole was administered *via* the medicated tampon. The observed reduction in the rate of urinary recovery is in agreement with the result observed in the plasma profiles (Fig. 7). This could well be the outcome of the sustained release of metronidazole from the medicated tampon, which prolongs the uptake of drug by the vagina.

Only 18.5% of the released dose was recovered in the urine during the 5-day observation period. [The majority (13%) was excreted in the 4-day period following removal of the tampon.] This is considerably lower than the 36.3% recovered from the solution dose during the same period (Fig. 8). By comparison with the vaginal absorption of the solution dose, it is estimated that the medicated tampon produces a relative systemic bioavailability of 51%, which is almost twice the value (27.2%) calculated from the plasma data (Fig. 7). This difference suggests that metronidazole molecules administered by sustained release medicated tampon may become more locally available *via*, possibly, binding to the vaginal wall. The bound metronidazole is then excreted *via* the perieum venous plexus, which drains the vaginal tissue and rectum, flows into the pudentum vein, and ultimately into the vena cava, resulting in a lower systemic bioavailability (13).

Received July 31, 1981, from the *Department of Basic Pharmaceutial Sciences, College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication October 6, 1981.

Abstract □ A series of even numbered fatty acid esters (C_2–C_{18}) of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol were synthesized and evaluated as to acute toxicity as well as effectiveness against L-1210 mouse leukemia. The acetate through the decanoate derivatives demonstrated toxicity between 2 and 3 times that of phenol mustard in HA/ICR mice. The less soluble laurate, myristate, palmitate, and stearate derivatives were less toxic. Significant survival times in the leukemia studies (T/C% ≥ 125) were observed for all compounds except the acetate and hexanoate derivatives. The myristate derivative produced the greatest significant increase in survival time, 162%. The palmitate and stearate derivatives produced significant survival at five and four dosage levels, respectively. The butyrate and laurate derivatives produced significant survival at three dosage levels and the octanoate, decanoate, and myristate at two dosage levels.

Keyphrases □ Fatty acid esters—synthesis of fatty acids of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, toxicity, effectiveness against L-1210 mouse leukemia □ *p*-[*N*,*N*-Bis(2-chloroethyl)amino]phenol—synthesis of fatty acid esters for toxicity and effectiveness against L-1210 mouse leukemia □ Bioevaluation—synthesis of fatty acid esters of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, toxicity, effectiveness against L-1210 mouse leukemia

Efforts to develop latent forms of phenol mustard, *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, have resulted in the synthesis of various esters of the phenol (1–3), as well as its ether derivatives (4). A previous study (2) on a series of substituted benzoate esters of phenol mustard suggested that the toxicity of those esters was related to their hydrolysis to the phenolic mustard. They also suggested that antitumor activity in Walker 256 tumor paralleled hydrolysis of the esters to phenol mustard. A retrospective QSAR study on a number of derivatives of aniline mustard has been performed (5). That study supports the concept that, in general, antitumor activity parallels hydrolysis to phenol mustard, as well as toxicity. That evaluation of the aforementioned series of benzoate esters of phenol mustard suggests that the hydrolyzed form of the ester is not the principle antitumor agent.

An earlier report from this laboratory compared the antileukemic activity of the acetate, hexanoate, and decanoate esters of phenol mustard (3). Those results indicated a decrease in toxicity and an increase in antileukemic activity was associated with an increase in the length of the fatty acid side chain. In light of these results, it was felt that an expanded series of fatty acid esters would provide additional information with respect to the effect of chain length on toxicity and antileukemic activity. The specific objectives of this report were to: (*a*) synthesize a series of even numbered fatty acid esters (C_2–C_{18}) of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, (*b*) determine the acute toxicity as measured by the LD_{50} for each compound studied, and (*c*) determine the effect of each compound on the prolongation of life of L-1210 leukemic mice.

The compounds evaluated in this project were synthesized using either Method A or Method B as shown in Scheme I.

EXPERIMENTAL

Synthesis of the Fatty Acid Esters of *p*-[*N*,*N*-Bis(2-hydroxyethyl)amino]phenol (IIIa–*i*), Method A—*Step I: Synthesis of the p-Nitrophenyl Esters (Ia–i).*—Ninety milliliters of 1,4-dioxane, 10 ml of pyridine, and 13.9 g (0.1 mole) of *p*-nitrophenol were stirred at room temperature until solution of the *p*-nitrophenol was complete. Then, 0.1 mole of either acetic or butyric anhydride, or the appropriate acid chloride for all other derivatives, was added slowly with stirring. The reaction mixture was stirred at room temperature in a glass-stoppered flask for ~2 hr. The volume of the reaction mixture was then reduced ~50% *in vacuo*. The products separated as a solid with the exception of the butyrate, hexanoate, and octanoate derivatives which were oils. The products were removed by filtration or by use of a separatory funnel and washed 3–5 times with a 5% sodium carbonate solution. After drying in a vacuum desiccator, the solid products were recrystallized from absolute ethanol. The oily products were dried *in vacuo* for 30–60 min and the pure products were characterized by physical data (Table I) and IR spectra and NMR spectra[1].

[1] All IR spectra were obtained using potassium bromide pellets or neat on sodium chloride plates using a Beckman Model IR-20A Spectrophotometer. NMR spectra were obtained from solutions of the derivatives in deuterated chloroform using a Hitachi–Perkin-Elmer Model R-24 high resolution spectrometer with tetramethylsilane as the internal standard. The elemental analyses reported were performed by either Galbraith Laboratories, Knoxville, Tenn. or Atlantic Microlab, Inc., Atlanta, Ga. Melting points reported were obtained using a Thomas Hoover capillary melting point apparatus and are uncorrected. All hydrogenation reactions were carried out in a Parr Low-Pressure Hydrogenation Apparatus.

[a] Temperature/pressure at which fractions used for analysis and subsequent reaction were collected. [b] Characterized using comparative melting or boiling points, IR and NMR spectra. [c] An acceptable elemental analysis could not be obtained, but acceptable products were obtained in the subsequent reaction, Step III, Method A.

Step II: Reduction of the p-*Nitrophenyl Esters*—A solution containing 0.02 mole of the appropriate *p*-nitrophenol ester in 150 ml of absolute ethanol was placed in a reaction bottle. Sixty milligrams (0.0002 mole) of platinum oxide was added and the mixture was shaken under pressure with hydrogen until a pressure drop representing 0.06 mole of hydrogen uptake (4.92 psi) was observed. The catalyst was removed by filtration and the filtrate concentrated *in vacuo*. The product separated from the concentrated solution after cooling to 0°. Recrystallization from absolute ethanol yielded solid derivatives with the exception of the hexanoate ester which was an oil. The pure *p*-aminophenyl esters (II*a–i*) were characterized by physical data (Table I) and IR and NMR spectra.

Step III: Condensation of the p-*Aminophenyl Esters with Ethylene Oxide*—The *p*-[*N,N*-bis(2-hydroxyethyl)amino]phenyl esters (III*a–g*) were formed by dissolving 0.0005 mole of the appropriate *p*-aminophenyl ester in a minimum amount of absolute methanol using a 500-ml round-bottomed reaction flask. Two grams (0.05 mole) of cold ethylene oxide were added to 20 ml of methanol at 0°. The cold ethylene oxide–methanol mixture was added with continuous stirring to the methanol solution of the *p*-aminophenyl ester. The reaction flask was packed in dry ice and allowed to reach room temperature. The methanol and excess ethylene oxide were removed *in vacuo*. The solid products were recrystallized from absolute ethanol. The butyrate and hexanoate derivatives were isolated as semisolids, which gave crystalline solids when recrystallized from acetone–water. Acceptable products were not obtained for the palmitate nor the stearate derivatives (III*h* and III*i*). The pure derivatives were characterized by physical data (Table II) and IR and NMR spectra.

Synthesis of the Fatty Acid Esters of *p*-[*N,N*-Bis(2-hydroxyethyl)amino]phenol (III*a–i*), Method B—The *p*-[*N,N*-bis(2-hydroxyethyl)amino]phenol (V) was prepared using a procedure reported earlier (4). Absolute ethanol (250 ml); powdered KOH (2.8 g); (V) (9.5 g, 0.05 mole); and 0.05 mole of either myristoyl chloride, palmitoyl chloride, or stearoyl chloride were added to a glass 500-ml round bottomed flask, equipped with a magnetic stirrer and a glass stopper. The flask was stoppered and the solution was allowed to stir overnight. The resulting product was removed by filtration, the filtrate reduced *in vacuo*, and the residue dissolved in 100 ml of acetone. To the acetone solution was added 50 ml of water and the suspension was allowed to cool at 5° overnight. The crystals were filtered from the acetone–water solution and combined with the original product. Recrystallization from acetone–water gave analytically pure products (III*g–i*) which were characterized by physical data (Table II) and IR and NMR spectra.

Synthesis of the Fatty Acid Esters of *p*-[*N,N*-Bis(2-chloroethyl)amino]phenol (IV*a–i*)—A solution of 10 ml of chloroform, 0.3 ml of absolute ethanol, and 0.5 ml of thionyl chloride was stirred in a 100-ml round bottomed flask until room temperature was reached. To this solution 0.005–0.01 mole of the appropriate derivative of III was added slowly as the solution was stirred. The reaction flask was fitted with a condensor and a drying tube and packed in dry ice after solution was complete. An additional 1.5 ml of thionyl chloride was added to the cold solution. The reaction mixture was allowed to reach ambient temperature

Table II—Physical Data and Elemental Analysis for the Fatty Acid Esters of *p*-[*N,N*-Bis(2-hydroxyethyl)amino]phenol (III*a–i*) and of *p*-[*N,N*-Bis(2-chloroethyl)amino]phenol (IV*a–i*)

[a] Literature value 82.5°(1). [b] Consistent with literature observation (1). [c] Calculated for the acetate mustard (IV*a*) with one-half mole of water.

and stirred for 24 hr. The mixture was concentrated *in vacuo*. An ether solution of the residue was washed with 5% sodium carbonate or sodium bicarbonate solutions and the ether removed *in vacuo*. The acetate, hexanoate, decanoate, and laurate derivatives were obtained in pure form from absolute ethanol. The acetate (IV*a*) was an oil, the decanoate (IV*e*) a semisolid, and the hexanoate (IV*c*) and laurate (IV*f*) were light brown solids. The butyrate mustard separated from ethyl acetate as a light-brown solid. The octanoate (IV*d*) was isolated as a dark oil from acetone. The myristate (IV*g*), palmitate (IV*h*), and stearate (IV*i*) derivatives were obtained from acetone–water (80:20) as light brown to off-white solids. All pure products were characterized by IR and NMR spectra. Physical data and elemental analysis are given in Table II for all final products.

Biological Evaluation—*Test Animals*—DBA/2 mouse strain[2], BDF_1 mouse strain[2], HA/ICR mouse strain[3], and L-1210 leukemic mice (tumor source)[4] were used.

Instruments—The necessary equipment included an electronic cell counter[5], a channelizer[5], a dilutor[5], an x-y recorder[5], a hemocytometer[6], and a microscope[7].

Materials—Counting diluent[5], red blood cell-lysing reagent[5], crystal violet[8], Giemsa stain[9], isotonic diluting solution[10], trypan blue[11], and Wright's stain[8] were obtained commercially. The ester derivatives of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol were prepared as described in this report, and their physical and analytical data are reported in Table II.

Pharmacological Screen and LD_{50} Evaluation—Five groups of six (HA/ICR) mice each were selected. A gross screen was conducted for acute toxicity, and results were recorded during the 3 hr following injection. The mice were observed and weighed every day for 21 days, and the mortalities were recorded daily. A linear regression and correlation coefficient program (6) and a graphic method (7) were applied to determine the LD_{50} for each drug tested.

Transplantation Procedures and *In Vivo* Determination of Antileukemic Activity Survival Times—Using the procedures described earlier for a series of ethers of phenol mustard (4), the transplantation procedures and *in vivo* determination of antileukemic activity by survival times were conducted. The palmitate (IV*h*) and stearate (IV*i*) derivatives were poorly soluble in propylene glycol; therefore, an equal mixture of polyethylene glycol 400, propylene glycol, and ethanol was used for these two derivatives. This solvent mixture allowed the evaluation of higher dosage levels of IV*h* and IV*i* in the survival studies.

RESULTS AND DISCUSSION

The synthesis of the even numbered fatty acid esters of *p*-[*N*,*N*-bis(2-hydroxyethyl)amino]phenol (III*a–i*) was accomplished *via* either Method A or Method B (Scheme I). The initial synthetic approach (Method A) consisted of an uncomplicated sequence of routine organic synthetic reactions. Using Method A, all of the *p*-nitro intermediates (I*a–i*), all of the *p*-amino intermediates (II*a–i*), and the acetate through the laurate diol intermediates (III*a–f*) were obtained in satisfactory yields. The condensation of ethylene oxide with the *p*-aminophenyl palmitate or stearate led to the isolation of the corresponding *p*-[*N*-(2-hydroxyethyl)amino]phenyl ester. The *p*-aminophenyl myristate gave very poor yields of the diol (≤12%) in addition to the monohydroxy ethyl derivative, when condensed with ethylene oxide. Method B provided an alternate route to intermediates III*g–i*, giving good yields of quality products. Compounds IV*a–i* were obtained following the reaction of thionyl chloride with the diol precursors. Not all of the final products were isolated as crystalline solids but an acceptable elemental analysis was obtained for each compound.

The use of Method A to obtain III*a–f* involved three synthetic steps. Step I, the esterification of *p*-nitrophenol, followed a modification of a procedure reported previously (8) in the synthesis of fatty acid esters of acetaminophen. The replacement of pyridine as a solvent with a mixture of dioxane (90 ml) and pyridine (10 ml) simplified the isolation of the ester products. The yields of the esters (I*a–i*) ranged from 50 to 85% and the observed melting points or boiling points (Table I) were consistent with reported values (9, 10). Step II, the reduction of I*a–i* to II*a–i*, employed the procedure described by Adams and Cohen (11) for the reduction of an aromatic nitro group in the presence of an ester. Yields for Step II ranged from 29 to 93%. The condensation of ethylene oxide with the *p*-aminophenyl esters (II*a–i*), Step III, followed the procedure described by Rao and Price (12) with elimination of the reflux step. This had no effect on the yields, which ranged from 25 to 74% for compounds III*a–f*.

Method B employed a modification of the method described by Wise, *et al.* (4) in the synthesis of a series of alkyl ethers of V. When the myristoyl, palmitoyl, or stearoyl chlorides were added to an alcoholic solution containing the potassium phenolate of Compound V, a quality product was isolated in final yields of 71 to 86% for III*g–i*.

The final nitrogen mustard products (IV*a–i*) were prepared by the method of Benitez *et al.* (13). Although the procedure was conducted at low temperature, tarry crude products were always obtained initially and final yields were relatively low (22–62%). The use of another chlorinating agent, *e.g.*, phosphorus oxychloride or phosphorus pentachloride, proved less satisfactory than thionyl chloride.

Physical data for I*a–i* and II*a–i*, as well as the elemental analyses for II*a–i*, are presented in Table I. The *p*-aminophenyl octanoate failed to yield satisfactory elemental analysis but provided acceptable products from Step III. The physical data and elemental analyses for III*a–i* and the IV*a–i* are shown in Table II. Within each series of compounds there was observed a decrease in the melting points as the chain length of the acid increased to C_6 or C_8, then the melting points increased through the stearate derivative. An exception was noted in the acetate mustard (IV*a*) which was isolated as an oil containing an average of one-half mole of water of hydration. The remainder of the final products (IV*b–i*) followed this melting point trend.

All intermediates and final products were characterized by their IR and NMR spectra. Within each homologous series there were observed the expected characteristic IR and NMR absorptions. The effect of increasing the alkyl chain length produced the only notable spectral differences between members of the same series. The IR spectra of the I*a–i* contained the following characteristic absorptions: aromatic and aliphatic C—H stretching bands between 3100 and 2900 cm^{-1}, a carbonyl absorption band at 1750 cm^{-1}, and an absorption at 875 cm^{-1}, indicating the presence of the nitro group. The C—H stretching bands and the carbonyl band were present in this region for each series of compounds. Reduction of the I*a–i* to II*a–i* resulted in the loss of the nitro group absorption and the appearance of the N—H stretching absorption at ~3400 cm^{-1}. This distinct absorption changed to a broad band in the region of 3400–3200 cm^{-1}, when the II*a–i* were condensed with ethylene oxide, indicating the presence of III*a–i*.

Compounds IV*a–i* were distinguished from the corresponding *p*-bis(2-hydroxyethyl)amino compounds by the absence of the broad —OH band in the IR spectrum. In addition, the final products contained absorption in the region of 650 cm^{-1} that is characteristic for the C—Cl bond. The presence of water was indicated in the acetate mustard by the observation of a broad band from 3500 to 3300 cm^{-1}. Only slight shifts in the carbonyl absorption were observed between the different series of compounds.

The NMR spectra of each series of compounds contained characteristic absorptions for the alkyl side chain. The observed chemical shift values for the alkyl pattern did not demonstrate much difference from one series of compounds to the next. In each series the methyl group of the acetate derivatives appeared as a 3-proton singlet at 2.55. In the butyrate, through the stearate derivatives in each series, the pattern consisted of the following absorptions: 2.45–2.55 δ (t, 2H) for the methylene alpha to the carbonyl; a triplet (3H) centered in the range of 0.85–1.05δ for the terminal methyl group; and a multiplet (which appeared as a singlet for the higher members of each series) centered in the range of 1.5–2.1δ for the remainder of the alkyl chain. The aromatic protons of I*a–i* displayed an AA′XX′ pattern which appeared as two doublets (2H each) centered at 7.25 and 8.2δ. Reduction of I*a–i* to II*a–i* changed the aromatic proton absorption from the AA′XX′ pattern to an AA′BB′ pattern which exhibited two doublets (2H each) centered at 6.5 and 7.0δ. This pattern, which appeared to be a quartet, was essentially the same for the remaining series of compounds (III*a–i* and IV*a–i*). The esters II*a–i* also displayed a singlet at 3.52δ for the two amino protons which disappeared from the spectra of II*a–g* following the condensation with ethylene oxide.

The NH_2 absorption was replaced by the absorption characteristic for the *p*-[*N*,*N*-bis(2-hydroxyethyl)amino] moiety, which in this series includes two triplets (4H each) centered around 3.5 and 3.7δ and the two alcoholic protons, which appeared as a singlet between 3.0 and 4.2δ. The NMR spectra of the products isolated from the condensation with the

[a] Administered in propylene glycol. [b] The T/C% represents the ratio of the sum of the number of days the animals in a treated group survived (T) to the sum of the number of days the animals in the control group survived (C) multiplied by 100. [c] A summary of data reported earlier.

p-aminophenyl palmitate and stearate esters, and one of the products from the *p*-aminophenyl myristate ester, indicated that only 1 mole of ethylene oxide had condensed with the amine. These spectra contained one amino proton and the ethylene triplets integrated for only two protons each. The NMR spectra of the final products (IV*a–i*) demonstrated a loss of the two alcoholic protons present in III*a–i*. In addition, the eight ethylene protons appeared as a sharp singlet in the region of 3.5–3.8δ. The aromatic protons and the alkyl side chain absorptions appeared as described previously. The presence of one-half mole of water of hydration in the acetate mustard (IV*a*) was verified by NMR, as well as IR and elemental analysis.

Biological Evaluation—The LD_{50} values for compounds IV*a* and IV*c–e* were determined using probit analysis and linear regression and are presented in μmoles/kg in Table III (6, 7). The data for the butyrate mustard (IV*b*) indicates that its LD_{50} is <25 mg/kg (82.2 μmoles/kg). Determination of exact LD_{50} values for compounds IV*f–i* was restricted by their limited solubility in propylene glycol. The 100 mg/kg dosage level was the highest that could be administered for those compounds in propylene glycol. Only a few isolated deaths occurred in the LD_{50} studies for IV*f* and IV*g*, and no deaths occurred at any dosage levels for IV*h* and IV*i*. The results of the LD_{50} study indicate that IV*b* and IV*d* have a toxicity slightly less than, but comparable to, IV*a*, IV*c*, and IV*e* reported earlier (3). All of these fatty acid ester derivatives (IV*a–i*) appear to be less toxic than the unhindered benzoate esters of a previous report (2).

The acetate through the decanoate mustards (IV*a–e*) demonstrates acute toxicities comparable to, or greater than, that observed for the parent phenolic mustard, *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol, 74.8 (2)–162.4 μmoles/kg in HA/ICR mice[12]. Compounds IV*a–e* are 2–3 times more toxic than the phenolic mustard when LD_{50} values in HA/ICR mice are compared. These esters are more lipophilic in nature and should be more readily absorbed and distributed in the biologic system than the phenolic mustard. This enhanced distribution, coupled with the possible ester hydrolysis to the free phenol, may account for these observations. The lower toxicities observed for compounds IV*f–i* may be related in part to their lower aqueous solubility. All of Compounds IV*a–i* appear to be much more toxic than the comparable series of even numbered ethers (C_2–C_{14}) of phenolic mustard (LD_{50} range 714–>1395 μmoles/kg) recently reported (4).

The effect of compounds IV*a–i* on the prolongation of life of L-1210 leukemic mice was determined. A comparison of the survival of treated groups (T) to untreated control groups (C) was performed. A calculated T/C ratio ≥125% implied that the drug treatment significantly increased the life span. Table III summarizes the T/C% survivals produced at each dosage level for each compound, the number of animals used per dosage level, and the mean survival for each animal group. The doses producing optimum survival for each compound are summarized in Table IV.

Compound IV*g* produced the highest mean survival time (T/C%) in this series, 162% at a dose of 10 mg/kg (22.5 μmoles/kg). Compounds IV*d*, IV*e*, and IV*g* produced significant survival at two dosage levels and compounds IV*b* and IV*f* at three dosage levels each. Compounds IV*h* and

[12] Unpublished data from these laboratories.

Table IV—Summary: Optimum Dose and Survival Time for the Fatty Acid Esters of *p*-[*N*,*N*-bis(2-chloroethyl)amino]phenol

Compound Number (Derivative)	Optimum Dose		T/C%
	mg/kg	μmoles/kg	
IV*a* (Acetate)	1.5	5.4	115
IV*b* (Butyrate)	2.0	6.6	133
IV*c* (Hexanoate)	1.0	3.0	117
IV*d* (Octanoate)	5.0	13.9	142
IV*e* (Decanoate)	1.82	4.7	150
IV*f* (Laurate)	10.0	24.0	144
IV*g* (Myristate)	10.0	22.5	162
IV*h* (Palmitate)	100.0	211.9	152
IV*i* (Stearate)	200.0	400.0	144

IV*i* produced significant survival at five and four dosage levels, respectively. Compounds IV*a* and IV*c* failed to produce significant T/C% survival at any of the dosage levels investigated.

The enzymatic hydrolysis rates for a series of fatty acid esters of acetaminophen have been determined by Bauguess *et al.* (8). Those results indicate the near complete and rapid hydrolysis of the acetate and butyrate esters and a decrease in the rate of hydrolysis for the hexanoate ester which was more rapidly hydrolyzed than the octanoate ester. The rate and completeness of hydrolysis declined from the decanoate through the myristate esters, and only limited hydrolysis could be obtained for the palmitate and stearate esters of acetaminophen. This work by Bauguess, coupled with the suggestion by Hansch *et al.* (5) that the antitumor activity for esters of phenolic mustard is due primarily to the intact ester rather than the hydrolysis product, phenol mustard, provides some insight into the biologic results reported in this paper.

Compounds IV*h* and IV*i* demonstrated low toxicity in the survival studies as well as the toxicity studies. The results for these two compounds are consistent with the expectation of a slow and limited enzymatic hydrolysis rate *in vivo*. The high doses for these compounds required the use of a different solvent mixture due to their limited solubility in propylene glycol. It is feasible that their poor solubility and hydrolysis properties resulted in a continuous and prolonged absorption from the injection site, thus providing significant survival over a greater range of doses. Both IV*f* and IV*g* demonstrated toxicity at the highest respective doses used in the survival study. These two compounds produced significant survival at the medium dosage levels, while activity dropped off at the lowest dose level (5 mg/kg). The toxicity at the higher dosage levels is consistent with an expected increase in hydrolysis of these two compounds, as well as indicating toxicity differences between the leukemic test mice (BDF_1 strain) and the HA/ICR strain used in the LD_{50} determinations. The optimum survival dose level for both IV*f* and IV*g* of 10 mg/kg was much less than IV*h* and IV*i* but was greater than the lower members of the series, IV*a–e*. Optimum survival was observed at lower dosage levels for IV*c*, IV*d*, and IV*e* (Table IV). This observation is consistent with the higher toxicity observed for these compounds, as well as the expected increase in enzymatic hydrolysis when compared to compounds IV*f–i*.

Compound IV*b* produced optimum survival at a slightly higher dose than IV*c* (6.6 *versus* 3.0 μmoles/kg). If the intact ester derivative of phenolic mustard is the active antileukemic molecule, then a higher dose would be required for IV*b* to achieve optimum activity in order to compensate for its anticipated rapid hydrolysis.

Compound IV*a* produced optimum survival at a dose comparable to the optimum dose of IV*b*. The failure of IV*a* to produce significant survival at any dose level suggests that an effective level of IV*a* could not be sustained long enough to be effective against the leukemia, probably due to very rapid hydrolysis *in vivo*. Compound IV*c* also failed to significantly prolong the life of leukemic mice. This observation cannot be related to the expected hydrolysis within the series. However, in the alkyl ether series studied earlier, the *n*-hexyl derivative produced similar survival results in leukemic mice (4).

The possibility that the 6-carbon ether derivative is of appropriate length to interact with the nitrogen atom when in dilute solution, has been suggested. A similar interaction could occur between the terminal methyl of the hexanoate side chain and the nitrogen atom of the mustard moiety. Such an interaction could sterically hinder the participation of the nitrogen atom in the formation of the aziridinium ion intermediate, thus reducing the reactivity of IV*c*. This in turn could reduce its antileukemic effectiveness.

High-Performance Liquid Chromatographic Analysis of Digoxin Formulations

BELACHEW DESTA and K. M. McERLANE ˣ

Received June 9, 1981, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, BC, Canada V6T 1W5.* Accepted for publication October 2, 1981.

Abstract □ A rapid, selective, and simple high-performance liquid chromatographic (HPLC) assay for digoxin formulations is described. The method utilizes a conventional octadecyl bonded phase column with detection at 220 nm. The analytical procedure has been applied for the quantitation of digoxin in tablets, elixir, and injectable formulations with a resulting relative standard deviation of 1.45, 1.70, and 1.80%, respectively. The method is sufficiently sensitive to monitor content uniformity of individual tablets. Potential impurities or degradation products are resolved from the digoxin peak in a total chromatographic time of <15 min.

Keyphrases □ High-performance liquid chromatography—analysis of digoxin formulations □ Digoxin—high-performance liquid chromatographic analysis, assay of tablet, injectable, and elixir formulations □ Formulations—high-performance liquid chromatographic analysis of digoxin formulations: tablets, elixir, and injectable

Digoxin is a cardioactive glycoside isolated from the leaves of *Digitalis lanata* and is the most frequently used drug in the treatment of congestive heart failure. Its low dosage and narrow therapeutic safety margin require assurance of potency and content uniformity of dosage forms, particularly in tablet formulations. The potential for the presence of degradation products or impurities introduces an additional requirement of assay specificity.

Previous methods for the analysis of digoxin as its drug substance and in formulations have largely been colorimetric (1–7), fluorometric (8–13), or chromatographic. The latter methods have included paper (14, 15), thin-layer (16–18), column (19, 20), gas-liquid (21–25), and high-performance liquid chromatographic (HPLC) methods (26–32). Colorimetric methods are largely nonselective and lack high sensitivity. Fluorometric methods, although more selective and certainly more sensitive, lack specificity, since the acidic fluorogenic reaction required would lead to an identical fluorescent species for digoxin and its potential impurities. GC methods require the preparation of a sufficiently volatile derivative. However, the derivitization procedures cause hydrolysis of the digitoxose sugar residues and, thus, would be inappropriate for the determination of the intact digoxin moiety in the presence of its degradation products. The utilization of HPLC for the determination of digoxin provides a distinct advantage since the digitalis glycoside does not require pretreatment to facilitate chromatographic manipulation. HPLC has been used by several investigators (30, 31) for the quantitative measurement of digoxin drug substance and its degradation products. The methods, although providing an indication of the hydrolysis rate of digoxin drug substance in aqueous media, were not applied to dosage forms.

Therefore, it would appear that there is a need for a method of analysis of digoxin in its dosage forms that is reliable and accurate as well as sufficiently sensitive to facilitate single-tablet assay. Such a method is described in this paper.

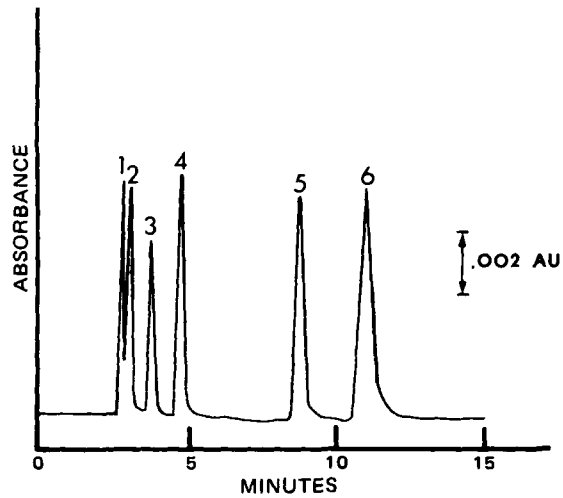

Figure 1—*HPLC of a synthetic mixture of digitalis glycosides. Sequence of elution: 1, digoxigenin; 2, digoxigenin monodigitoxoside; 3, digoxigenin bisdigitoxoside; 4, digoxin; 5, 17α-ethynylestradiol internal standard; 6, gitoxin. Mobile Phase: water–methanol–isopropanol–methylene chloride (47:40:9:4), flow rate: 1.2 ml/min.*

EXPERIMENTAL

Apparatus—A high-performance liquid chromatograph[1] equipped with dual pumps[2], a 20-μl injector[3], and a dynamically stirred mixing chamber[4] were used throughout with a variable wavelength detector[5] and an electronic data processor[6]. All analyses were performed on a 4.6 mm × 250-mm column[7] packed with 5-μm bonded octadecylsilane (C_{18} phase).

Materials—Water, methanol, isopropanol, and methylene chloride were of HPLC grade[8]. Digoxin[9] and 17α-ethynylestradiol[10] were used without further purification.

Preparation of Internal Standard Solutions—An accurately weighed quantity, equivalent to 100 mg of 17α-ethynylestradiol, was dissolved in 100 ml of methanol.

Preparation of Standard Solutions of Digoxin—A stock solution was prepared by dissolving an accurately weighed quantity, equivalent to 20 mg of digoxin, in 80 ml of boiling methanol, cooling the flask to room temperature, and bringing the final volume to 100 ml with methanol. Six aliquots equivalent to 0.1, 0.2, 0.4, 1.0, 2.0, and 2.5 mg of digoxin were added to 100-ml volumetric flasks. A 2.5-ml aliquot of the internal standard was added to each flask, followed by an amount of methanol required to bring the volume to 35 ml. The flasks were then brought to volume with distilled water and thoroughly mixed. Three injections of each of the six standard solutions containing digoxin and 17α-ethynylestradiol were used to establish linearity and response ratios.

Sample Preparation—Not less than 30 tablets were weighed and

triturated to a fine powder. An accurately weighed quantity, equivalent to 1.25 mg of digoxin, was transferred to a 100-ml volumetric flask. Ten milliliters of distilled water was added and the flask was swirled for 2–3 min. Exactly 32.5 ml of methanol was added and the mixture was mechanically shaken for 15 min. The suspension was filtered using filter paper[11], and the residue was washed with three 5-ml portions of distilled water. The combined filtrate and washings were collected in a 100-ml volumetric flask containing a 2.5-ml aliquot of the internal standard solution, and the flask was brought to volume with distilled water and thoroughly mixed. A 20-μl sample, containing 12.5 ng/μl of digoxin and 25 ng/μl of the internal standard, was injected into the liquid chromatograph.

Single Tablet Assay—One tablet was placed in a 100-ml volumetric flask and treated in the same manner as the tablet composite assay.

Injectable Formulation Assay—The contents of 20 ampules were bulked and a 2-ml aliquot was transferred to a 10-ml volumetric flask (in the case of the 0.05 mg/ml injection) or to a 50-ml volumetric flask (in the case of the 0.25 mg/ml injection). Aliquots of 0.25 ml and 1.25 ml of internal standard solution were added to the 10- and 50-ml volumetric flasks, respectively. A volume of 0.25 ml (0.25 mg) of the internal standard solution was added to the 10-ml volumetric flask, and 1.25 ml (1.25 mg) of the internal standard solution was added to the 50-ml volumetric flask. A volume of methanol equivalent to 2.8 and 14.0 ml, was added to the 10- and 50-ml volumetric flasks, respectively. The theoretical final concentration of digoxin and the internal standard were 10 and 25 ng/μl, respectively.

Elixir—A 20-ml aliquot of the elixir was transferred to a 100-ml volumetric flask, followed by 2.5 ml of the internal standard solution and 20 ml of methanol. The flask was brought to volume with distilled water and thoroughly mixed. The theoretical final concentration of digoxin and the internal standard were 10 and 25 ng/μl, respectively.

Precision of Tablet Assay—A total of 40 digoxin tablets were weighed and triturated to a fine powder. Six aliquots, equivalent to 1.25 mg of digoxin, were weighed into six volumetric flasks and treated as described under tablet assay. Three injections were made for each sample.

Recovery of Digoxin from Tablets—Six aliquots of digoxin tablets were prepared as described previously. To each aliquot an accurately weighed[12] quantity of digoxin reference standard[9], equivalent to 0.625 mg, was added, and the samples were treated as described under tablet assay. Three injections were made for each sample.

HPLC Conditions for Tablet and Injectable Formulation Assays—The mobile phase consisted of water–methanol–isopropanol–methylene chloride (47:40:9:4) and was pumped at a flow rate of 1.2 ml/min. The UV detector was set at 220 nm.

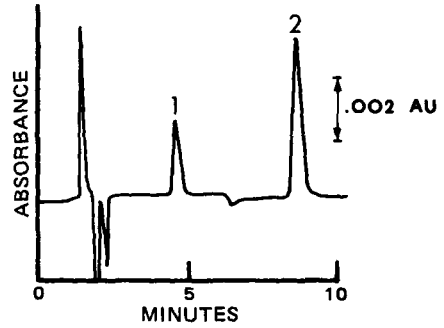

Figure 2—*HPLC of a digoxin tablet formulation. Sequence of elution: 1, digoxin; 2, 17α-ethynyl estradiol. Mobile Phase: refer to Fig. 1.*

[11] Number 1, Whatman Paper, W. and R. Balston Ltd., Eng.
[12] Cahn Electrobalance, Ventron Instruments Corp., Paramount, Calif.

HPLC Conditions for Elixir Formulation Assay—The mobile phase consisted of water–methanol–isopropanol–methylene chloride (51:42:5:2). All other conditions were identical to those described for tablet and injectable formulation assay.

RESULTS AND DISCUSSION

A chromatogram of a standard mixture of digoxin and its potential degradation products, digoxigenin, digoxigenin monodigitoxoside, digoxigenin bisdigitoxoside, as well as a common impurity, gitoxin, and the internal standard, ethynylestradiol, is given in Fig. 1. From this chromatogram it can be ascertained that the common potential impurities would not interfere with the assay of digoxin (Peak 4). In addition, common tablet excipients such as starch, lactose, methylcellulose, and stearate lubricants were subjected to the extraction procedure for the tablet assay and were found to be noninterfering.

The presence of a relatively small amount of methylene chloride in the mobile phase contributes to absorption of radiant energy at 220 nm and therefore raises the baseline. However, the presence of a considerably large amount of water minimizes the absorbance effect of methylene chloride. The problem of miscibility of the two solvents is resolved by the presence of methanol and isopropanol. Moreover, since there is sufficient differential absorbance contributed by digoxin, it has been consistently shown that no problem arises from the presence of methylene chloride. A description of the evolution of the mobile phase has been given (33) where the HPLC separation of a number of cardiac glycosides has been reported using different proportions of the four solvents (water–methanol–isopropanol–methylene chloride).

Calibration curves were constructed, and the relative response ratios of digoxin to the internal standard, 17α-ethynylestradiol, was found to be 1.426 for the analysis of digoxin tablets and injection, and 1.386 for the analysis of digoxin elixir. The relative standard deviation was 2% (n = 6) in both cases. Calibrations were performed for each batch of solvent systems prepared on a daily basis.

The chromatogram depicted in Fig. 2 is representative of a composite assay of a tablet containing 0.25 mg of digoxin. The initial baseline disturbance and the small negative peak at ~6.5 min are due to a solvent effect from the sample injection.

The recovery data for the extraction of digoxin from tablets (0.25 mg) was determined by adding an amount of digoxin reference standard equivalent to half of the amount of digoxin contained in the tablet sample. Analysis of six such samples resulted in recovery values of 99.7, 101.3, 96.8, 102.6, 95.2, and 103.4% of the total quantity expected. The mean and relative standard deviation were found to be 99.8 and 3.2%, respectively, with a 95% confidence limit of (±) 3.4. The precision of the assay was

independently determined on six aliquots of the same tablet lot. The values for the percentage of label claim were: 98.0, 99.4, 98.2, 98.0, 101.4, and 100.5% with a mean value of 99.2% and a relative standard deviation of 1.45%. Therefore, it can be observed from the above data that the assay has satisfactory accuracy and precision.

The application of the HPLC assay to three commercial sources of digoxin tablet formulations provided the data given in Table I. Four aliquots of each of the four tablet lots were independently assayed, and it can be observed that all lots were well within the USP limits of 92–108% (7). The same four lots were assayed by the USP colorimetric method for digoxin tablets and the results are also given in Table I. The respective mean assay values for the four lots compare favorably; however, a significant time benefit of the HPLC assay was noted. The time taken for the total assay of four aliquots of a single tablet lot using the USP method was ~4.5 hr, while the HPLC assay required only 45 min.

The USP monograph for content uniformity of tablets is a long colorimetric procedure requiring repetition of the tablet assay for each of 10 tablets. Consequently, the HPLC procedure developed was applied to a single-tablet assay of 10 randomly selected tablets from two tablet strengths obtained from the same manufacturer. As shown in Table II, the individual assay results for a 0.125-mg tablet fell within 90.0–105.8% and for a 0.25-mg tablet, 92.6–106.0%. The general requirement for content uniformity of tablets in the USP specifies that the potency of all 10 tablets must fall within 85–115% of the label claim. Hence the tablets selected in this determination met the pharmacopeial requirements. The assay time for the HPLC method was significantly shorter.

The analysis of digoxin injection indicated that the peaks due to digoxin and the internal standard are free from interference from formulation excipients. The chromatogram was essentially identical to that shown for a tablet formulation (Fig. 2). The assay results (Table III) for two strengths of injectable formulation obtained from the same manufacturer provided a mean potency of 99.4 and 99.1% with a respective relative standard deviation of 1.7 and 1.6%. The mean potency of the HPLC assay compares favorably with that obtained for the same formulations using the USP assay (Table II).

Due to the presence of excipients in the elixir formulation, the relative composition of mobile phase for this assay was modified slightly. The chromatogram depicted in Fig. 3 is representative of the analysis of a single elixir formulation. Peaks 1–4 and 6 were due to pharmaceutical excipients. Peak 4 was determined to be methylparaben, the remaining excipients, however, were not identified. The assay results obtained from 4 aliquots of this formulation are given in Table III and indicate a mean potency of 99.4%, with a relative standard deviation of 1.8%. The assay results for the elixir formulation as obtained by the USP method (Table III) compare favorably with those obtained from the HPLC assay method. It is significant that the analysis of both the injectable and elixir formulations was achieved by simple dilution of the formulation. The USP, on the other hand, requires a prior solvent extraction for the analysis of the elixir.

In comparison with the long, labor-intensive requirements for the assay of tablet, injectable,and elixir formulations as outlined in the USP, the HPLC method described herein provides a significant advantage in terms of selectivity, simplicity, convenience, and time of analysis.

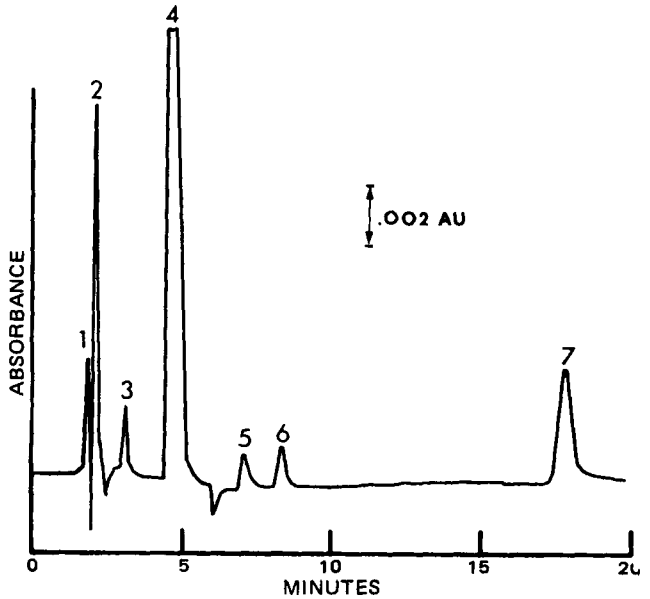

Figure 3—*HPLC of a digoxin elixir formulation. Sequence of elution: 1–3, unknown; 4, methylparaben; 5, digoxin; 6, unknown; 7, 17 α-ethynylestradiol. Mobile Phase: Water–methanol–isopropanol–methylene chloride (51:42:5:2) flow rate: 1.2 ml/min.*

Formation of Hydrotalcite in Mixtures of Aluminum Hydroxycarbonate and Magnesium Hydroxide Gels

ROGER K. VANDERLAAN *, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received June 12, 1981, from the *School of Pharmacy and Pharmacal Sciences*, **Departments of Industrial and Physical Pharmacy, and* ‡*Agronomy Department, Purdue University, West Lafayette, IN 47907.* Accepted for publication October 13, 1981.

Abstract □ IR and X-ray analysis demonstrate that hydrotalcite forms during the aging of aluminum hydroxycarbonate gel and magnesium hydroxide gel mixtures. The formation of hydrotalcite produces a change in the pH-stat titrigram and a sharp increase in the pH of the mixture. Hydrotalcite was noted earlier in mixtures having a high molar ratio of magnesium to aluminum, a high total gel concentration, a high initial pH, or in mixtures stored at elevated temperatures. The addition of sorbitol to the mixtures substantially delayed the appearance of hydrotalcite. Nonacid-reactive hydrotalcite formed when mixtures of chloride-containing aluminum hydroxide gel and magnesium hydroxide gel were aged.

Keyphrases □ Hydrotalcite—formation, mixtures of aluminum hydroxycarbonate and magnesium hydroxide gels, IR and X-ray analysis □ Mixtures—formation of hydrotalcite in mixtures of aluminum hydroxycarbonate and magnesium hydroxide gels □ Gels—aluminum hydroxycarbonate and magnesium hydroxide gels, mixtures, formation of hydrotalcite

It has been reported recently that amorphous aluminum hydroxycarbonate gel forms a coating on magnesium hydroxide particles due to electrostatic attraction (1). This interaction was detected because the rate of acid neutralization of mixtures of aluminum hydroxycarbonate gel and magnesium hydroxide gel was slower than expected, based on individual rates of acid neutralization. The interaction occurred immediately and an additive rate of acid neutralization only occurred when the gels were separately added to the reaction vessel. As the mixtures aged, the rate of acid neutralization decreased further, suggesting that the amorphous aluminum hydroxycarbonate coating was becoming more ordered as the amorphous to crystalline phase transition occurred.

It was noticed, however, that the rate of acid neutralization in some aged mixtures was greater than the initial rate of acid neutralization. Thus, a further reaction appeared to be occurring during the aging of mixtures of aluminum hydroxycarbonate and magnesium hydroxide gels. This interaction is the focus of this study.

EXPERIMENTAL

Magnesium hydroxide gel[1] was obtained commercially as a paste containing the equivalent of 21% (w/w) MgO. Aluminum hydroxycarbonate gel was prepared as described previously (2) by the addition of 0.47 *M* $AlCl_3 \cdot 6H_2O$ to 0.53 *M* $NaHCO_3$ and 0.23 *M* Na_2CO_3 to a final pH of 6.5. Chloride-containing aluminum hydroxide gel was prepared as described previously (2) by the addition of 13% (v/v) strong ammonia solution to 0.29 *M* $AlCl_3 \cdot 6H_2O$ to a final pH of 7.0.

Aluminum and magnesium content were determined by chelatometric titration (3).

Mixtures of aluminum hydroxycarbonate gel or chloride-containing aluminum hydroxide gel and magnesium hydroxide gel were prepared on a weight basis. For example, a 200-g mixture containing a total of 0.6 mmole of metal/g in a magnesium–aluminum molar ratio of 5:1 was prepared by weighing magnesium hydroxide gel and aluminum hydroxycarbonate gel or chloride-containing aluminum hydroxide gel containing 100 mmoles of magnesium and 20 mmoles of aluminum, respectively. A solution containing an excipient was added when necessary. The final weight was adjusted to 200 g with double-distilled water and the mixture was stirred mechanically until uniform. The mixtures were aged in widemouth polyethylene bottles.

The acid neutralization reaction was monitored by an automated[2] pH-stat titrator at pH 3.0, 25° using a sample size which would theoretically neutralize 2.25 mEq (4).

X-ray diffractograms were obtained using air-dried samples in McCreery mounts (5). Diffractograms were recorded from 6 to 40° (2 θ) under the following conditions[3]: CuK_α radiation, 30 kV, 28 mamp, 2°/min.

IR[4] spectra were recorded using potassium bromide disks containing 0.8–2.0 mg of air-dried sample and 300 mg of KBr.

RESULTS AND DISCUSSION

The rate of acid neutralization of a mixture of aluminum hydroxycarbonate gel and magnesium hydroxide containing 0.6 mmole of metal/g in a magnesium–aluminum molar ratio of 5:1 decreased during the first 31 days of aging at 25° (Fig. 1A). A slight decrease in the total acid reac-

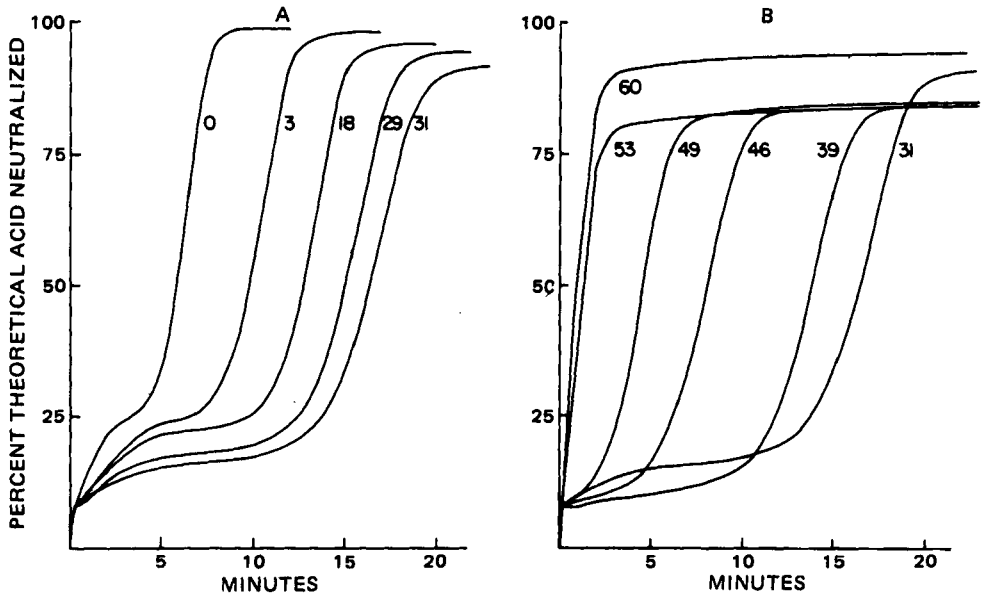

Figure 1—*pH-stat titrigram of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. Each titrigram is labeled with the age of the mixture in days.*

tivity was also noted. After 31 days, a major reversal occurred in the rate of acid neutralization, *i.e.*, the rate of acid neutralization progressively increased until the mixture reacted in a rapid, single-phase reaction (Fig. 1B). With the establishment of a single, highly reactive phase, the total acid reactivity increased to the theoretical value. The acid reactivity of the mixture was monitored for 375 days at 25° but no further significant changes in the pH-stat titrigrams were observed.

Corresponding to the period of a decreasing rate of acid neutralization observed in Fig. 1A, the pH of the mixture (Fig. 2) decreased slightly during the initial aging period, which is consistent with the polymerization of aluminum hydroxide by the formation of double hydroxide bridges (6). After 37 days, the mixture exhibited a drastic change in pH, rising to pH 11.3 after 80 days at 25°. The pH remained at 11.3 until the study was terminated at 500 days.

The hydroxyl-stretching region of the IR spectrum of the freshly prepared mixture is shown in Fig. 3, Curve A. The broad absorption band between 3000 and 3700 cm^{-1} is characteristic of amorphous aluminum hydroxycarbonate gel with hydroxide groups in a continuum of environments, indicative of a highly disordered state (7). The sharp peak at 3698 cm^{-1} is indicative of the rigid environment of the brucite structure of magnesium hydroxide gel (8). After 48 days (Fig. 3, Curve B), the absorption band at 3698 cm^{-1} showed a dramatic decrease, signaling a reduction in the amount of magnesium present as brucite in the mixture. The decrease in the peak at 3698 cm^{-1} continued as the mixture aged, but the position of the brucite peak remained constant (Fig. 3, Curve C). The maximum absorption of the diffuse hydroxyl-stretching band shifted toward higher energy absorption.

Figure 4 shows the region of carbonate absorption in the IR spectrum of the mixture. The large initial split (Fig. 4, Curve A) in the carbonate peaks at 1406 and 1540 cm^{-1} is a result of coordination of carbonate to aluminum in the aluminum hydroxycarbonate gel (9). The shoulder at 1640 cm^{-1} is due in large part to free water adsorbed by the aluminum hydroxycarbonate. The region of carbonate absorption became less well defined after 48 days (Fig. 4, Curve B) while the splitting of the carbonate peaks increased slightly. A major structural change occurred by Day 61 as the peak at 1406 cm^{-1} was reduced to a shoulder and the peak at 1540 cm^{-1} was almost completely replaced by a single strong absorbance at 1463 cm^{-1} with a well-defined shoulder at 1448 cm^{-1}. This shift indicates

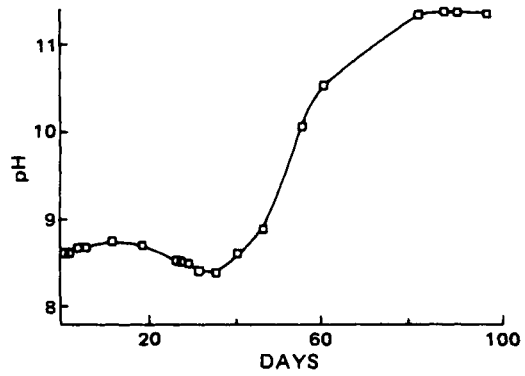

Figure 2—*pH of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°.*

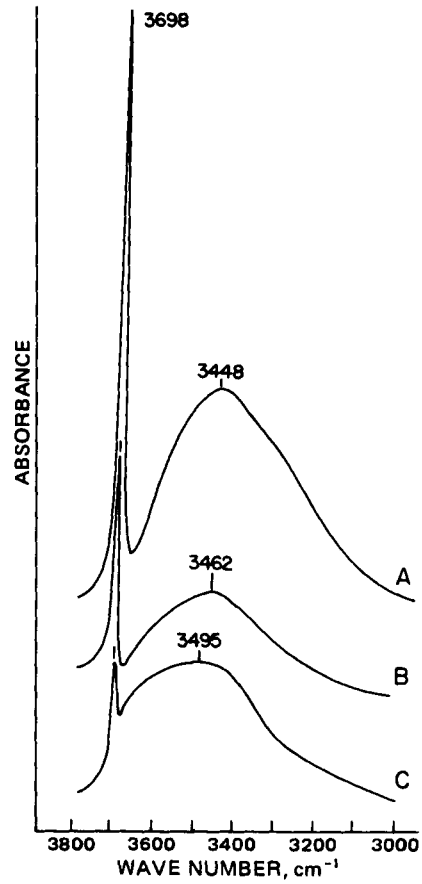

Figure 3—*Hydroxyl-stretching region of the IR spectrum of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. Key: (A) initial; (B) 48 days; (C) 61 days.*

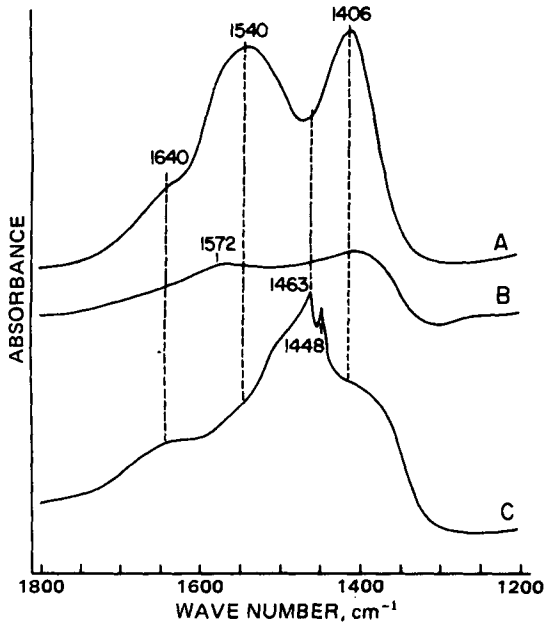

Figure 4—*Carbonate absorption region of the IR spectrum of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. Key: (A) initial; (B) 48 days; (C) 61 days.*

that the carbonate ion is no longer strongly associated with aluminum but is in a less perturbed state. The peak of 1448 cm^{-1} is characteristic of a symmetrical carbonate anion as in sodium carbonate (10). The strong peak at 1463 cm^{-1} may result from the carbonate anion regaining its symmetrical character but being in a slightly different environment compared to sodium carbonate.

Figure 5 shows the 800–1200 cm^{-1} region of the IR spectrum during aging of the mixture at 25°. In the fresh mixture, the broad shoulder at 957 cm^{-1} indicates the disordered hydroxyl environment in the aluminum hydroxycarbonate gel. The peaks at 846 and 1094 cm^{-1} are present only when there is distortion of the carbonate ion, while the peak which appears at 878 cm^{-1} after 48 days is characteristic of unperturbed carbonate ion as found in sodium carbonate (11). The disappearance of the peak at 1094 cm^{-1} and the appearance of the free carbonate band at 878 cm^{-1} suggest that structural changes occurred in the mixture which resulted in a drastic change in environment for the carbonate ion.

X-ray diffractograms of the mixture during aging also suggest that structural changes occurred (Fig. 6). The initial X-ray diffractogram (Table I) had peaks at interplanar spacings of 4.74, 2.369, 1.794, 1.569, and 1.491 Å which corresponded to the peaks for brucite. In addition, there was a diffuse band between 15 and 35° (2 θ) which was attributed to disordered, amorphous aluminum hydroxycarbonate. After 48 days (Fig. 6, Curve B), the brucite peaks had diminished in intensity but remained sharp. In the case of both X-ray and IR observations, the peaks

corresponding to brucite decreased in intensity while maintaining a high degree of sharpness. This indicated a decrease in the total amount of brucite in the mixture but a high degree of crystallinity in the remaining brucite. The brucite peaks did not shift in location, even after 510 days, suggesting that the structure of the remaining brucite was not altered.

After 61 days, the peaks corresponding to brucite had decreased substantially and a new set of moderately sharp peaks appeared (Fig. 6, Curve C). After checking the mineralogical literature, the new peaks were indexed to be virtually identical to those of hydrotalcite, a magnesium aluminum hydroxycarbonate (Table I). The structure of hydrotalcite (Fig. 7) is unique, as it is composed of two layers of brucite in which aluminum replaces some magnesium. The positive charge on the brucite layer which results from the substitution is balanced by carbonate, hydroxyl, and other anions which are sandwiched between the substituted brucite layers (12–19).

The changes in the rate of acid neutralization, pH, IR spectrum, and X-ray diffraction of the magnesium–aluminum (5:1) mixture are consistent with the formation of hydrotalcite. The pH-stat titrigram after

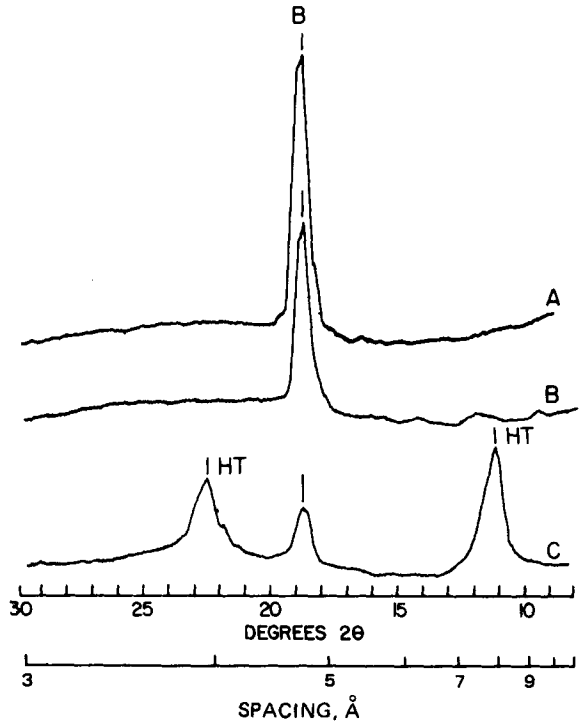

Figure 6—*X-ray diffractogram in the 3–9 Å region of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. Figure 7—*Schematic representation of hydrotalcite (from ref. 8).*

60 days at 25° showed the same rapid, one-phase reaction as is characteristic of magneisum hydroxide. The reaction rate of hydrotalcite would be expected to be similar to magnesium hydroxide as both minerals are based upon the brucite crystal lattice.

The initial pH of the mixture, 8.7, was intermediate between pH 10.35 for the magnesium hydroxide gel, and pH 6.5 for the aluminum hydroxycarbonate gel. The rise in pH associated with the formation of hydrotalcite may be attributed to the presence of carbonate in the interlayer space of hydrotalcite. Carbonate ion neutralizes the positive charge of the substituted brucite layer more efficiently than hydroxyls and will, therefore, displace hydroxyls which cause the bulk pH to rise.

The formation of hydrotalcite in the mixtures was first noted in the IR spectrum by the decrease in the intensity of the brucite peak. The change in the carbonate band from a highly perturbed state, due to coordination to aluminum in aluminum hydroxycarbonate to a virtually unperturbed state (as would occur if carbonate functioned as a counterion between the substituted brucite layers), is consistent with the formation of hydrotalcite during aging of the mixtures. The X-ray diffractograms showed evidence of hydrotalcite at 61 days. Prior to this time, some decrease in the intensity of the brucite peaks was noted, but a sharp decrease in the intensity of the brucite peak occurred with the formation of hydrotalcite. Since the appearance of hydrotalcite in the mixture is sudden rather than gradual, and since no further significant changes were noted, it appears that some threshold condition must be reached after which the rapid formation of hydrotalcite can occur.

The magnesium to aluminum ratio in mixtures of aluminum hydroxycarbonate gel and magnesium hydroxide gel substantially affects the length of time before hydrotalcite is formed in the mixtures. A series of mixtures was prepared where each contained 0.6 mmole of metal/g but the magnesium–aluminum molar ratio was 5:1, 2:1, 1:1, 1:2, and 1:5. X-ray diffraction showed that hydrotalcite formed in the magnesium–aluminum mixture (5:1) after ~30–40 days of aging at 25°. Hydrotalcite was detected in the magnesium–aluminum mixture (2:1) after 200 days. The magnesium–aluminum mixtures (1:1 and 1:2) showed the presence of hydrotalcite before 516 days, while the magnesium–aluminum mixture (1:5) remained free of hydrotalcite through 516 days. Thus, the higher the molar ratio of magnesium to aluminum, the sooner hydrotalcite was formed. This may be due to the higher pH of the mixtures which contain a higher magnesium–aluminum ratio. The solubility of aluminum hydroxycarbonate increases in alkaline medium, thus facilitating the conversion to hydrotalcite.

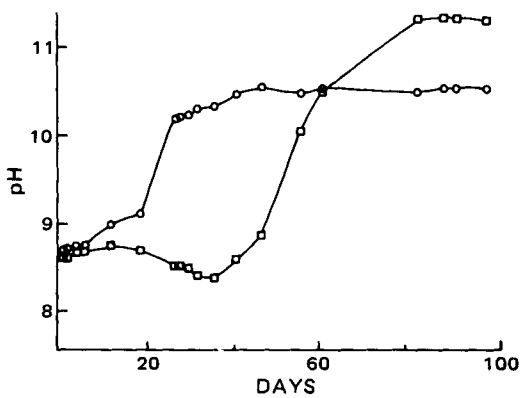

Figure 8—*pH of a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture during aging at 25°. Key: (□) 0.6 mmole of metal/g; (○) 1.2 mmole of metal/g.*

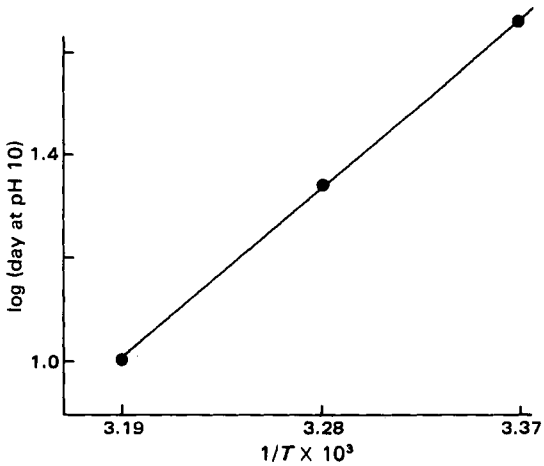

Figure 9—*Relationship of aging temperature to time for pH to increase to 10 for a magnesium–aluminum molar ratio (5:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g.*

Hydrotalcite also appeared more rapidly as the concentration of the mixture was increased. As seen in Fig. 8, the pH of a magnesium–aluminum mixture (5:1) at 1.2 mmoles of metal/g rose sharply after ~20 days at 25°, while the pH of a magnesium–aluminum mixture (5:1) containing 0.6 mmole of metal/g increased after ~40 days at 25°. X-ray diffractograms and changes in the pH-stat titrigrams confirmed that hydrotalcite had formed in these mixtures. The formation of hydrotalcite would be expected to occur sooner in concentrated mixtures if, as suggested earlier, some threshold condition must be reached to initiate its formation.

Higher aging temperatures promoted more rapid formation of hydrotalcite, probably due to increased solubility at higher temperatures. Figure 9 is an Arrhenius-type plot of the log of the time for magnesium–aluminum mixture (5:1) containing 0.6 mmole of metal/g to reach pH 10 *versus* the reciprocal of the aging temperature (T). A linear relationship exists with a heat of activation of ~8.6 kcal/mole.

To observe the effect of initial suspension pH, a magnesium–aluminum mixture (5:1) containing 0.6 mmole of metal/g was divided into six portions. One portion served as the control, while three portions were brought to either pH 9.5, 10.0, or 10.5 with sodium hydroxide. One portion was brought to pH 10 with sodium carbonate to determine if the carbonate anion played a role in initiating the formation of hydrotalcite. The pH of the final portion was not altered, but a small amount of a similar mixture in which hydrotalcite had formed was added to serve as a seed. As seen in Table II, the time required for the pH to rise, indicating hydrotalcite formation, is inversely related to the initial pH of the mixture. The pH of the samples, which had been adjusted to pH 10.5 and 10.0, increased within 1 day, while the sample at pH 9.5 showed evidence of the formation of hydrotalcite within 10 days. The main factor appears to be pH rather than the reagent used to adjust the pH as similar results were obtained when either sodium hydroxide or sodium carbonate was used to adjust the pH. The increased solubility of aluminum hydroxycarbonate at higher pH conditions is believed to be responsible for the pH effect. Seeding the mixture with hydrotalcite had no effect as the pH profile of the seeded sample was similar to the control.

Table II—pH of Magnesium–Aluminum [a] at Different Initial pH

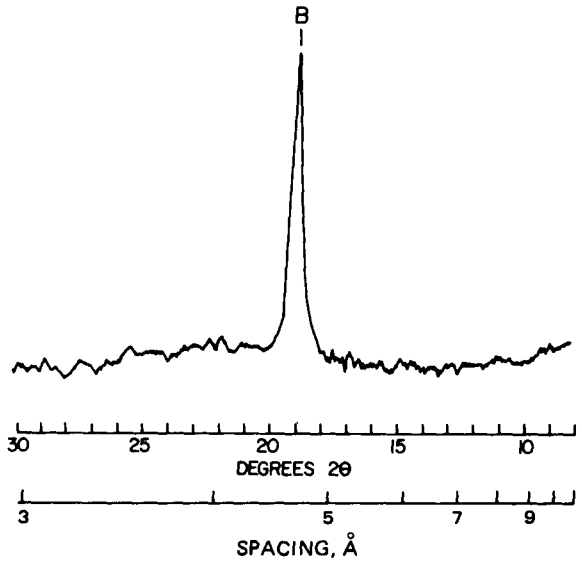

Figure 10—*X-ray diffractogram in the 3–9 Å region of a magnesium–aluminum molar ratio (2:1) of an aluminum hydroxycarbonate gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g and 2% sorbitol after aging for 616 days at 25°. B indicates the peak corresponding to brucite.*

Two experiments were performed to determine if any excipients would act to stabilize the mixture by controlling the formation of hydrotalcite. A magnesium–aluminum mixture (2:1) containing 0.6 mmole of metal/g was divided into four portions. One portion served as the control, while the other three portions contained either 2% sorbitol, 0.5% simethicone, or 1% polysorbate 80. Hydrotalcite was found in the control and the mixtures containing simethicone or polysorbate 80 at approximately the same time, *i.e.*, after 200 days at 25°. As seen in Fig. 10, the X-ray diffractograms of the sample containing 2% sorbitol showed a very sharp brucite peak and no evidence of hydrotalcite after aging for 616 days at 25°.

Various other excipients were compounded with magnesium–aluminum mixtures (5:1) containing 0.9 mmole of metal/g. The mixtures were aged at 32° and the time required to reach pH 10 was recorded. As seen in Table III, all but two of the mixtures reached a pH of at least 10 within 18 days. Five control samples were included in the experiment to give an indication of the variability in the time required for hydrotalcite to form. The average time for the pH of the control to reach 10 was 12.6 days with 1.5 *SD*. Only the higher concentration of sodium citrate (0.5%) and 2% sorbitol were able to prevent the formation of hydrotalcite during the 52 days of the experiment. Sorbitol is known to hydrogen bond with aluminum hydroxycarbonate gel, while citrate anion is a chelating agent for aluminum. Figure 11 compares the pH-stat titrigrams of selected samples. Initial titrigrams of all samples except the sodium citrate-containing samples were identical. Mixtures containing sodium citrate exhibited

a decrease in both rate and extent of acid reactivity in the region of aluminum hydroxycarbonate gel neutralization which was directly related to the concentration of sodium citrate, while the magnesium hydroxide portion of the pH stat titrigram was unaffected (1).

After 52 days at 32°, the pH-stat titrigram of the control and all the mixtures, except those containing 2% sorbital or 0.5% sodium citrate, consisted of a single, highly-reactive phase which is characteristic of the formation of hydrotalcite. The rate of acid neutralization of the sorbitol-containing mixture had decreased but the sample was completely reactive. The sodium citrate-containing sample exhibited both a decreased rate and extent of acid neutralization. Both sorbitol and sodium citrate substantially delayed the formation of hydrotalcite, although the use of citrate anion is not recommended due to its deleterious effect on acid neutralization.

The observations of the factors affecting the formation of hydrotalcite in mixtures of aluminum hydroxycarbonate gel and magnesium hydroxide gel support a previous conclusion (20) that the formation of hy-

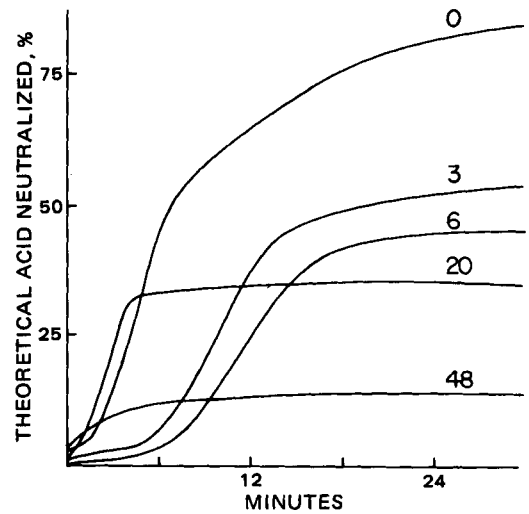

Figure 12—*pH-stat titrigram of magnesium–aluminum molar ratio (1:1) of a chloride-containing aluminum hydroxide gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. Each titrigram is labeled with the age of the mixture in days.*

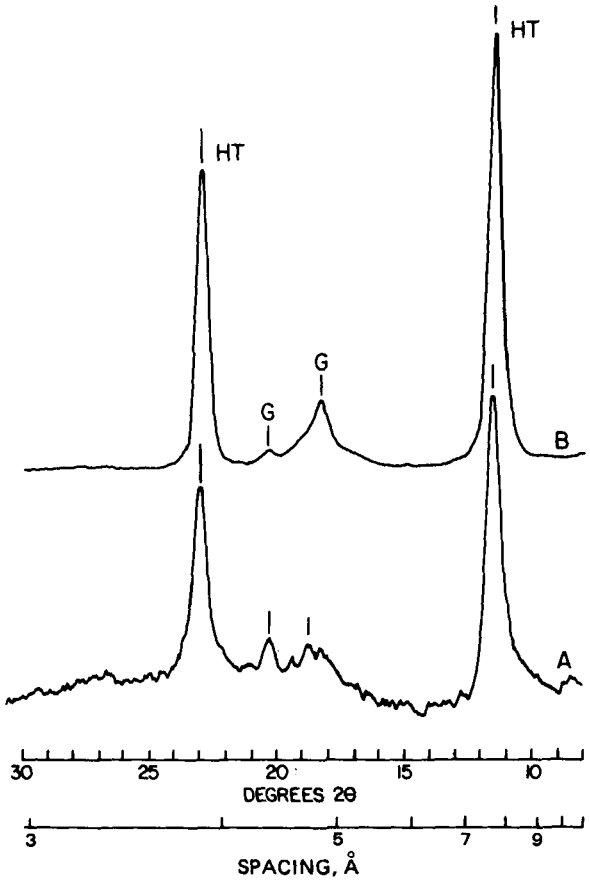

Figure 13—*X-ray diffractogram in the 3–9 Å region of a magnesium–aluminum molar ratio (1:1) of a chloride-containing aluminum hydroxide gel–magnesium hydroxide gel mixture containing 0.6 mmole of metal/g during aging at 25°. HT and G indicate the peaks corresponding to hydrotalcite and gibbsite, respectively. Key: (A) 69 days; (B) 173 days.*

drotalcite is a solution phenomena of the following type:

$$Na^+Al(OH)_4^- + 2[(MgOH)^+Cl^-] \rightarrow [AlMg_2(OH)_6]^+Cl^- + NaCl \quad \text{(Eq. 1)}$$

This conclusion was based on the observation that hydrotalcite formed when separate dialysis sacks containing aluminum hydroxide and magnesium carbonate were suspended in water at 60° for 3–6 months (21). Hydrotalcite (~90%) was found in the sack which initially contained aluminum hydroxide, ~10% was found in the dialysis medium, and virtually none was present in the sack which initially contained magnesium carbonate. Hydrotalcite had been precipitated previously (22) from a solution equimolar in aluminum chloride and magnesium chloride at pH 10 in the presence of 4 *N* Na_2CO_3.

The following sequence of reactions are hypothesized to occur when hydrotalcite forms during the aging of mixtures of aluminum hydroxycarbonate gel and magnesium hydroxide gel. At pH 8–9 magnesium hydroxide will have a relatively high tendency to donate hydroxyls:

$$Mg(OH)_2 \rightarrow MgOH^+ + OH^- \quad \text{(Eq. 2)}$$

Under these conditions aluminum hydroxide will tend to gain hydroxyls to form aluminate:

$$Al(OH)_3 + OH^- \rightarrow Al(OH)_4^- \quad \text{(Eq. 3)}$$

At first the pH of the mixture remains relatively constant due to the balance of Eqs. 2 and 3. After a period of time, the aluminum hydroxide is no longer able to readily assimilate hydroxyls and the suspension pH begins to rise due to the continued dissolution of magnesium hydroxide. The formation of hydrotalcite occurs by the same mechanism as proposed previously (20), *i.e.*, the coalesence of the products of Eqs. 2 and 3 as shown by Eq. 1. This mechanism is consistent with the sudden appearance of hydrotalcite in mixtures and also with the effect of magnesium–aluminum ratio, concentration, pH, and temperature observed in this study.

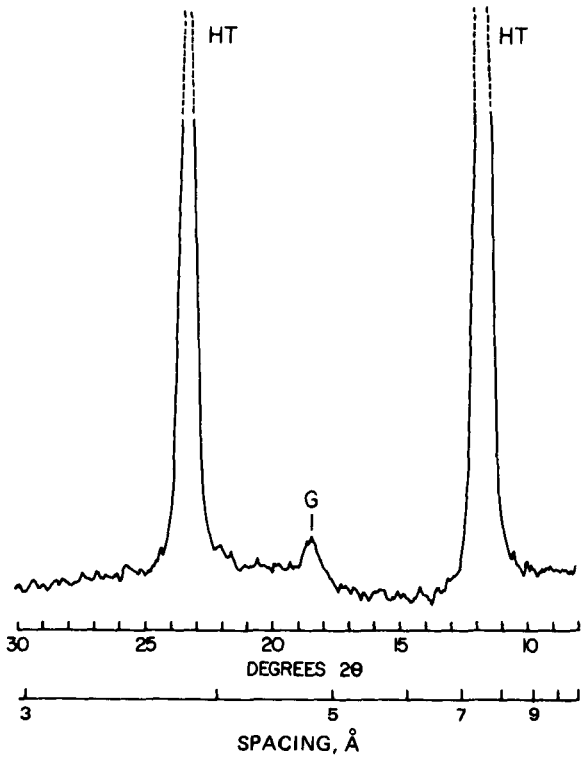

Figure 14—*X-ray diffractogram in the 3–9 Å region of the nonacid-reactive component of a magnesium–aluminum molar ratio (1:1) of a chloride-containing aluminum hydroxide gel and magnesium hydroxide gel containing 0.6 mmole of metal/g after aging for 173 days at 25°. HT and G indicate the peaks corresponding to hydrotalcite and gibbsite, respectively.*

A nonacid-reactive form of hydrotalcite is produced when a mixture of a chloride-containing aluminum hydroxide gel and magnesium hydroxide is aged at 25°. Compared to an aluminum hydroxycarbonate gel, a chloride-containing aluminum hydroxide gel shows a more rapid decrease in the rate of acid neutralization, and the total amount of acid neutralized at pH 3 also decreases (4). The pH of a mixture containing 0.6 mmole of metal/g in a magnesium–aluminum molar ratio of 1:1 increased from 6.6 to 8.5 after 8 days at 25°. The pH-stat titrigram also showed a change in shape at this same time (Fig. 12). However, in contrast to mixtures containing aluminum hydroxycarbonate gel, (Fig. 1) the total amount of acid neutralized decreased to ~15% of the theoretical yield after aging for 48 days. Well-crystallized hydrotalcite peaks were evident in the X-ray diffractograms after 69 days at 25° (Fig. 13, Curve A). No magnesium hydroxide peaks were present in the X-ray diffractogram, but peaks at 4.82 and 4.34 Å indicated the presence of gibbsite, a crystalline polymorph of aluminum hydroxide. An X-ray diffractogram of the mixture after 173 days at 25° (Fig. 13, Curve B) showed a further increase in the crystallinity of hydrotalcite.

The sharp peaks suggested a larger crystallite size for the hydrotalcite formed in the chloride-containing aluminum hydroxide gel and magnesium hydroxide gel mixtures than formed in the aluminum hydroxycarbonate gel and magnesium hydroxide gel mixtures. After 118 days at 25°, the unreactive fraction from the pH-stat test was collected and washed. An X-ray diffractogram (Fig. 14) shows that the nonacid reactive component is chiefly highly crystalline hydrotalcite. Thus, a nonacid-reactive aluminum hydroxide gel quickly gave rise to a nonacid-reactive form of hydrotalcite.

The formation of hydrotalcite during the aging of mixtures of aluminum hydroxide gel and magnesium hydroxide gel is important because the *United States Pharmacopeia* recognizes two mixtures of aluminum hydroxide gel and magnesium hydroxide gel, as well as magaldrate (23) which is a form of hydrotalcite having sulfate as the principal interlayer anion. Alumina and magnesia oral suspension (3) may contain a magnesium–aluminum molar ratio of between 0.4 and 0.8 and a total metal content of between 0.8 and 1.2 mmoles of metal/g. Magnesia and alumina oral suspension (24) may contain a magnesium–aluminum molar ratio of between 1.4 and 2.4 and a total metal content of between 0.9 and 1.2 mmoles of metal/g. These mixtures are within the range of magnesium–

aluminum and total metal concentration of the mixtures in which hydrotalcite was found to form on aging.

The present monographs for these mixtures do not contain any tests which would detect the presence of hydrotalcite, nor do they require the inclusion of sorbitol in the mixtures. Thus, there is the possibility of the formation of hydrotalcite during the aging of official aluminum hydroxide gel and magnesium hydroxide gel mixtures.

Toxicity of Polyalkylcyanoacrylate Nanoparticles I: Free Nanoparticles

B. KANTE *, P. COUVREUR *x, G. DUBOIS-KRACK ‡, C. DE MEESTER ‡, P. GUIOT §, M. ROLAND *, M. MERCIER ‡, and P. SPEISER ¶

Received May 21, 1981 from the **Laboratoire de Pharmacie Galénique and the* ‡*Laboratoire de Chimie Médicale, Toxicologie, et Bromatologie, Université Catholique de Louvain, 1200 Bruxelles, Belgium;* the §*Laboratoire de Chimie Physiologique, Université Catholique de Louvain et International Institute of Cellular and Molecular Pathology, 1200 Bruxelles, Belgium;* and the ¶*School of Pharmacy, Federal Institute of Technology, Zürich, Switzerland.* Accepted for publication October 7, 1981.

Abstract □ The present report describes preliminary results concerning the acute toxicity of placebo polyalkylcyanoacrylate nanoparticles used as drug carrier. It was demonstrated that nanoparticles induced cellular damage only at relatively high concentrations in the cell culture medium. The absence of mutagenicity was shown for both nanoparticles and their degradation products, and the LD_{50} for polybutyl- and polyisobutylcyanoacrylate nanoparticles was also determined.

Keyphrases □ Polyalkylcyanoacrylate—toxicity of nanoparticles □ Nanoparticles—polyalkylcyanoacrylate toxicity □ Toxicity—polyalkylcyanoacrylate nanoparticles □ Drug carrier systems—nanoparticles, toxicity of polyalkylcyanoacrylate

Previous studies have demonstrated the interest of polyalkylcyanoacrylate nanoparticles as a drug carrier (1, 2). The main advantage of these particles is their degradability at a rate depending on the length of the alkyl chain (3). These ultrafine particles (diameter of ~0.2 μm) are able to efficiently adsorb a variety of drugs in a stable and reproducible way (4). It has been shown previously that the binding of cytostatic drugs to nanoparticles modifies their distribution pattern in rat tissues and generally increases the tissue capture of these drugs (5, 6).

Recently, preliminary results of experimental chemotherapy were published (7) using actinomycin D-loaded polymethylcyanoacrylate nanoparticles against the growth of a transplantable soft sarcoma tissue of the rat. The results indicated that the use of polymethylcyanoacrylate nanoparticles as a drug carrier increased the anticancer activity of actinomycin towards subcutaneous sarcoma. Furthermore, these particles could be of interest in the field of long-acting insulin therapy (8).

However, it was important to have information about the toxicity of the carrier to determine if these results did not prohibit the use of nanoparticles in human medicine. The present report describes preliminary results concerning the acute toxicity of nondrug-bound nanoparticles towards cells in culture and the determination of the LD_{50} of the carrier.

EXPERIMENTAL

Polyalkylcyanoacrylate Nanoparticles Preparation—Polymethyl-, polybutyl-, and polyisobutylcyanoacrylate nanoparticles were prepared following previous methods (1, 6), slightly modified. To an

Toxicity of Polyalkylcyanoacrylate Nanoparticles I: Free Nanoparticles

B. KANTE *, P. COUVREUR *x, G. DUBOIS-KRACK ‡, C. DE MEESTER ‡, P. GUIOT §, M. ROLAND *, M. MERCIER ‡, and P. SPEISER ¶

Received May 21, 1981 from the **Laboratoire de Pharmacie Galénique and the* ‡*Laboratoire de Chimie Médicale, Toxicologie, et Bromatologie, Université Catholique de Louvain, 1200 Bruxelles, Belgium;* the §*Laboratoire de Chimie Physiologique, Université Catholique de Louvain et International Institute of Cellular and Molecular Pathology, 1200 Bruxelles, Belgium;* and the ¶*School of Pharmacy, Federal Institute of Technology, Zürich, Switzerland.* Accepted for publication October 7, 1981.

Abstract □ The present report describes preliminary results concerning the acute toxicity of placebo polyalkylcyanoacrylate nanoparticles used as drug carrier. It was demonstrated that nanoparticles induced cellular damage only at relatively high concentrations in the cell culture medium. The absence of mutagenicity was shown for both nanoparticles and their degradation products, and the LD_{50} for polybutyl- and polyisobutylcyanoacrylate nanoparticles was also determined.

Keyphrases □ Polyalkylcyanoacrylate—toxicity of nanoparticles □ Nanoparticles—polyalkylcyanoacrylate toxicity □ Toxicity—polyalkylcyanoacrylate nanoparticles □ Drug carrier systems—nanoparticles, toxicity of polyalkylcyanoacrylate

Previous studies have demonstrated the interest of polyalkylcyanoacrylate nanoparticles as a drug carrier (1, 2). The main advantage of these particles is their degradability at a rate depending on the length of the alkyl chain (3). These ultrafine particles (diameter of ~0.2 μm) are able to efficiently adsorb a variety of drugs in a stable and reproducible way (4). It has been shown previously that the binding of cytostatic drugs to nanoparticles modifies their distribution pattern in rat tissues and generally increases the tissue capture of these drugs (5, 6).

Recently, preliminary results of experimental chemotherapy were published (7) using actinomycin D-loaded polymethylcyanoacrylate nanoparticles against the growth of a transplantable soft sarcoma tissue of the rat. The results indicated that the use of polymethylcyanoacrylate nanoparticles as a drug carrier increased the anticancer activity of actinomycin towards subcutaneous sarcoma. Furthermore, these particles could be of interest in the field of long-acting insulin therapy (8).

However, it was important to have information about the toxicity of the carrier to determine if these results did not prohibit the use of nanoparticles in human medicine. The present report describes preliminary results concerning the acute toxicity of nondrug-bound nanoparticles towards cells in culture and the determination of the LD_{50} of the carrier.

EXPERIMENTAL

Polyalkylcyanoacrylate Nanoparticles Preparation—Polymethyl-, polybutyl-, and polyisobutylcyanoacrylate nanoparticles were prepared following previous methods (1, 6), slightly modified. To an

aqueous solution (10 ml) of 0.01 *M* HCl containing 0.2% of a polysaccharide[1] and 0.8% of a polyoxyethylene–polyoxypropylene surfactant[2], butyl-[3], or isobutylcyanoacrylate[4] monomer (165 μl) was added under mechanical stirring. Polymethylcyanoacrylate nanoparticles were prepared in the same manner by adding the methylic monomer[3] (165 μl) to 10 ml of 0.01 *M* HCl containing 0.5% of polysorbate 20. After polymerization (at least 2 hr), each nanoparticle suspension was buffered at pH 7 using 100 μl of a molar solution of NaOH and 900 μl of a phosphate buffer[5]; NaCl (83 mg) was then added. No filtration was carried out before using, except in the case of the LD_{50} assays, where nanoparticles were filtered through a sintered glass filter (pore size 9–15 μm).

Scanning electron microscopy[6] showed mostly spherical particles with a diameter of ~0.2 μm for the polymethylcyanoacrylate preparations and of ~0.4 μm for the polyisobutyl- and polybutylcyanoacrylate preparations.

Cell Toxicity Procedures Using Placebo Nanoparticles—Hepatocytes were isolated using an *in situ* enzymatic perfusion method in the rat liver (9). Isolated cells were then incubated at 37° in a Waymouth medium supplemented with 10% newborn calf serum (10). Polybutylcyanoacrylate nanoparticles or their polymerization milieu were then added to obtain final concentrations of 0.5 and 1%, which corresponded,

respectively, to 7.5 and 15 mg of nanoparticles in 100 ml of the incubation medium, assuming the density of the polymer was equal to one.

Membrane integrity of the incubated cells was regularly controlled using both the 0.36% erythrosin B exclusion test and the leakage of lactic dehydrogenase, a cytosolic enzyme.

Macrophages were obtained after washing the peritoneal cavity of C 57 black mice three times with a medium[7] containing 0.1 mg/ml of streptomycin and 0.06 mg/ml of penicillin G. The liquid was incubated in plastic petri dishes containing a small glass coverslip. After 2 hr of incubation, the nonadhering cells were washed off with phosphate buffer solution, and the remaining macrophages were then further incubated at 37° in the culture medium[7] (containing 20% calf serum) in a 10% CO_2/90% air atmosphere incubator[8]. Nanoparticles were then added at a concentration of 1% in the culture medium. After 1 hr of incubation, nonadhering nanoparticles were washed off with phosphate buffer solution medium. Fresh medium was added to wash the macrophage monolayer culture. The macrophages were then fixed in glutaraldehyde (2.5% by volume in 0.1 *M* cacodylate buffer, pH 7.4) for 15 min at 37°, washed three times with cacodylate buffer, treated 1 hr at 4° with OsO_4 (1% w/v in 0.17 *M*

barbital acetate buffer, pH 7.4) and washed with barbital acetate buffer.

Finally, the macrophages were washed five times with double distilled water, frozen in liquid nitrogen, and dried by lyophilization for 3 hr. The glass coverslips with the dried macrophages were then attached to metal disks and coated with a thin film of gold in a vacuum evaporator[9]. The specimens were then stored at room temperature until examination under a scanning electron microscope.

Mutagenicity Tests—Mutagenicity tests were performed on polybutyl- and polymethylcyanoacrylate nanoparticles using the *Salmonella typhimurium* method (11). This test was performed with and without metabolic activation[10] on both intact and degraded nanoparticles. A preliminary toxicity test was carried out to determine the maximum noninhibitory doses of nanoparticles.

Determination of Nanoparticle Histotoxicity—A total of 14 male mice[11] (20 g) were injected subcutaneously with 0.2 ml of a polyisobutylcyanoacrylate suspension containing 3 mg of nanoparticles. After 24 hr, six mice were sacrificed under carbon dioxide atmosphere, the skin was turned inside out and macroscopically examined according to a previously described method (12).

Three days later, the remaining animals were rechallenged with the same dose of nanoparticles and were divided into two groups of four mice. The first group was sacrificed 48 hr after the second injection, while the second group received a third injection and was sacrificed 2 days later. All these mice were treated as mentioned previously. Control mice, which received no injection, were treated in the same manner.

Determination of Nanoparticle LD_{50}—Six groups of 10 male NMRI mice (20 g) were treated with nanoparticles by injection in the tail vein. Each group received one of the following doses in a single injection, respectively: 12.5, 17.5, 22.5, 27.5, 32.5, and 40 ml/kg of polybutyl- or polyisobutylcyanoacrylate nanoparticles suspension. Both suspensions contained 9.2 mg of nanoparticles/ml. The same volumes of the polymerization milieu were injected into different groups of mice and the LD_{50} of this milieu was then determined.

RESULTS AND DISCUSSION

Toxicity of Polybutylcyanoacrylate Nanoparticles on Isolated Hepatocytes—At a concentration of 0.5% in the culture medium, neither polybutylcyanoacrylate nanoparticles nor nanoparticle polymerization medium modified the cellular integrity of the hepatocytes; in fact the lactic dehydrogenase leakage and the dye exclusion capacity of the cells remained comparable to the untreated hepatocytes (Fig. 1). In the case of the 1% final concentration, the polybutylcyanoacrylate nanoparticles greatly affected the integrity of the hepatocytes; the polymerization medium, on the other hand, exerted no effect (Fig. 2).

A cytotoxic effect appeared between 0.5 and 1% and seemed to proceed

from the polymer itself rather than from the surfactants present in the nanoparticle polymerization medium. However, the 1% dose corresponded to a high ratio ($\sim 2 \times 10^4$) of particles per hepatocyte.

Scanning Electron Microscopy Studies with Macrophages—This microscopic study was performed to determine the exact morphological cell changes resulting from nanoparticle ingestion. Macrophages were used because of their high phagocytic capacity. It is known that toxicity of the polymer seems to be dependent on the biodegradation half-life which is prolonged with increasing alkylchain length (13). For this reason, it was decided to test polymethyl- and polyisobutylcyanoacrylate nanoparticles.

Scanning electron micrographs revealed marked morphological membrane modifications after incubation of the macrophages for 1 hr in the presence of polymethylcyanoacrylate nanoparticles at a 1% concentration in the culture medium (Fig. 3). The cell membrane appeared to be completely perforated. After incubation of the macrophages with polyisobutylcyanoacrylate nanoparticles under the same experimental conditions (1 hr at a concentration of 1%), no signs of toxicity were observed, and the morphological appearance of the macrophages under the scanning electron microscope seemed to be normal as compared with control (Fig. 4).

Mutagenicity Tests—Table I shows the bacterial survival of the *S. typhimurium* strains after incubation with nanoparticles on nutrient agar plates seeded with $2-7 \times 10^7$ viable cells. Polymethylcyanoacrylate induced an appreciable toxic effect when it was used at the dose of 1500 μg/plate. A slight inhibitory effect was observed with polybutyl- and polymethylcyanoacrylate nanoparticles at a concentration of 300 μg/plate. No toxicity was noted at the 150-μg dose. This dose was then considered the maximum noninhibitory level for the two types of polymer. The results of the Ames test, performed with different doses of nanoparticles and degradation products, are presented in Tables II–V. The assays were made either with or without metabolic activation. No mutagenic effect was observed using both nanoparticles and their degradation products. In all tests carried out, the number of induced revertants as compared with spontaneous revertants was not significantly increased. Furthermore, no dose–response effect was obtained. Although the Ames test was performed only with the polymethyl- and the polybutyl product, from the data obtained, it can be inferred that polyethyl- and polyisobutylcyanoacrylate nanoparticles are unlikely to be mutagenic. Indeed, in a mutagenic assay, the observed effect is closely dependent upon the chemical nature of the product tested, and polyalkylcyanoacrylates are very similar in their chemical structure.

In the Ames test, as in any mutagenicity assay, the observed mutations are related to only a very small part of the genome. Therefore, a negative result does not necessarily mean that the product under study is not mutagenic for humans (14); however, the Ames method is reliable in detecting carcinogens (15, 16). Moreover, cyanoacrylate polymers have been used in surgery for a long time, and until now, no carcinogenic action has been observed with these products (17, 18).

Nanoparticle Histotoxicity and LD_{50}—Twenty four hours after subcutaneous injection of 3 mg of polyisobutylcyanoacrylate nanoparticles, neither necrosis nor tissue irritation was visible. Furthermore, 48 hr after multiple treatments (2 or 3 injections) no hypersensitivity reaction nor granulomatous response was observed. Figure 5 shows the cumulative mortality of the mice after intravenous administration of different nanoparticle suspension volumes (milliliters per kilogram). Brought again to dry polymer weight per kilogram, the LD_{50} was determined to be 196 and 230 mg/kg for polyisobutylcyanoacrylate and polybutylcyanoacrylate nanoparticles, respectively. It should be noted, however, that the polymerization medium alone is not free of toxicity (LD_{50} = 33.4 ml/kg).

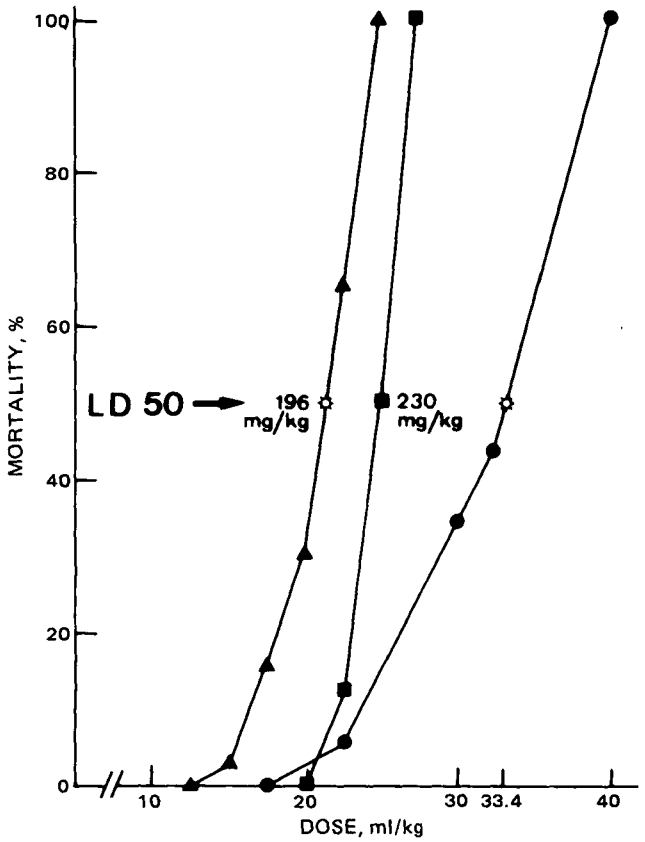

Figure 5—*Cumulative mortality of mice after intravenous administration of various nanoparticle suspension volumes. Key: (▲) polyisobutylcyanoacrylate nanoparticle; (■) polybutylcyanoacrylate nanoparticle; (●) nanoparticles polymerization medium.*

CONCLUSIONS

These first toxicological data obtained at the cellular and whole body animal levels did not demonstrate any acute toxicity susceptible to hinder the use of polyalkylcyanoacrylate nanoparticles in human medicine. Indeed, they induced cellular damage only at a relatively high concentration in the culture medium (1%). This toxicity is probably due to the presence of nanoparticle degradation products in the cytoplasm following their phagocytosis. This consideration could explain the lesser toxicity of the isobutyl product, which is more slowly biodegradable than the methyl derivative. Moreover, LD_{50} values are reasonable, and because of the presence of surfactants in the polymerization medium, it could be possible to reduce considerably the acute toxicity of the particles by washing off the surfactants and eventual remaining monomers. Finally, the absence of histotoxicity and mutagenicity for both nanoparticles and their degradation products are encouraging. These results will be completed by subacute and chronic toxicological studies and we will examine the possibility of decreasing the toxicity of an anticancer agent by its adsorption on polyisobutylcyanoacrylate nanoparticles.

Toxicity of Polyalkylcyanoacrylate Nanoparticles II: Doxorubicin-Loaded Nanoparticles

P. COUVREUR *x, B. KANTE *, L. GRISLAIN *, M. ROLAND *, and P. SPEISER ‡

Received May 21, 1981, from the * *Laboratoire de Pharmacie Galénique, Université Catholique de Louvain, 1200 Bruxelles, Belgium* and the ‡ *School of Pharmacy, Federal Institute of Technology, Zürich, Switzerland.* Accepted for publication October 7, 1981.

Abstract □ The possibility of significantly reducing toxicity of an anticancer drug such as doxorubicin by fixing it on polyisobutylcyanoacrylate nanoparticles was studied. It was shown that, when the drug was adsorbed on nanoparticles, significant reduction of both mortality and weight loss of mice were recorded under various administration schedules. Furthermore, cardiotoxicity was decreased due to the poor uptake by the myocardium.

Keyphrases □ Polyalkylcyanoacrylate—toxicity of doxorubicin-loaded nanoparticles □ Doxorubicin—toxicity of polyalkylcyanoacrylate nanoparticles □ Toxicity—doxorubicin-loaded polyalkylcyanoacrylate nanoparticles □ Drug carrier systems—toxicity of doxorubicin-loaded polyalkylcyanoacrylate nanoparticles

The first toxicological data concerning the polyalkylcyanoacrylate nanoparticles did not demonstrate any distinct toxicity susceptible to hinder their use in human medicine (1). The aim of the present investigation was to reduce considerably the toxicity of an anticancer drug such as doxorubicin by fixing it on nanoparticles. The idea of using doxorubicin in association with a macromolecular carrier such as DNA, to minimize the detrimental effect of this anticancer drug on normal cells, has been previously investigated (2, 3).

Doxorubicin, an anthracycline antibiotic, has produced encouraging results in the treatment of neoplastic diseases (4). However, it is toxic, with its most severe side effects involving the heart (acute and chronic cardiomyopathy), bone marrow, and intestine (5, 6). For these reasons, and because doxorubicin is highly adsorbed on nanoparticles, this cytostatic drug was chosen as the experimental model.

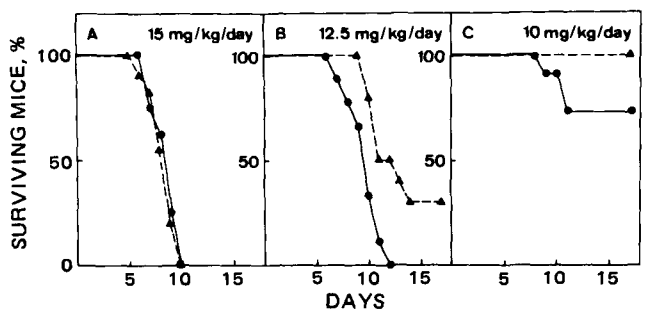

Figure 1—*Percent of surviving mice after intravenous administration on 3 consecutive days of various doses of free (●) and nanoparticle-bound doxorubicin (▲).*

EXPERIMENTAL

Polyalkylcyanoacrylate Nanoparticle Preparation—After dissolution of doxorubicin[1] (10 mg) in 10 ml of aqueous solution containing 100 mg of a polysaccharide[2], 50 mg of citric acid, and 1 mg of calcium chloride, 100 μl of isobutylcyanoacrylate monomer was dispersed under mechanical stirring.

After polymerization (3 hr), the resulting milky suspension was brought to isotonicity with 72 mg of sodium chloride. The size of the particles obtained was then estimated by measuring light scattering, arising from a laser source[3].

Measurement of Doxorubicin Linked to Nanoparticles—A 10-ml nanoparticle suspension was centrifuged[4] at 20,000 rpm for 1 hr. Sediment was then separated and dissolved in 10 ml of dioxane containing 20% water.

The content of doxorubicin was determined in both supernate and sediment by fluorimetric[5] dosage. For this purpose, 200-μl samples were diluted to 10 ml by water (for the supernate) or by dioxane (for the sediment) and measurements were performed using reference solutions of doxorubicin.

Toxicity of Polyalkylcyanoacrylate Nanoparticles II: Doxorubicin-Loaded Nanoparticles

P. COUVREUR *x, B. KANTE *, L. GRISLAIN *, M. ROLAND *, and P. SPEISER ‡

Received May 21, 1981, from the * *Laboratoire de Pharmacie Galénique, Université Catholique de Louvain, 1200 Bruxelles, Belgium* and the ‡ *School of Pharmacy, Federal Institute of Technology, Zürich, Switzerland.* Accepted for publication October 7, 1981.

Abstract □ The possibility of significantly reducing toxicity of an anticancer drug such as doxorubicin by fixing it on polyisobutylcyanoacrylate nanoparticles was studied. It was shown that, when the drug was adsorbed on nanoparticles, significant reduction of both mortality and weight loss of mice were recorded under various administration schedules. Furthermore, cardiotoxicity was decreased due to the poor uptake by the myocardium.

Keyphrases □ Polyalkylcyanoacrylate—toxicity of doxorubicin-loaded nanoparticles □ Doxorubicin—toxicity of polyalkylcyanoacrylate nanoparticles □ Toxicity—doxorubicin-loaded polyalkylcyanoacrylate nanoparticles □ Drug carrier systems—toxicity of doxorubicin-loaded polyalkylcyanoacrylate nanoparticles

The first toxicological data concerning the polyalkylcyanoacrylate nanoparticles did not demonstrate any distinct toxicity susceptible to hinder their use in human medicine (1). The aim of the present investigation was to reduce considerably the toxicity of an anticancer drug such as doxorubicin by fixing it on nanoparticles. The idea of using doxorubicin in association with a macromolecular carrier such as DNA, to minimize the detrimental effect of this anticancer drug on normal cells, has been previously investigated (2, 3).

Doxorubicin, an anthracycline antibiotic, has produced encouraging results in the treatment of neoplastic diseases (4). However, it is toxic, with its most severe side effects involving the heart (acute and chronic cardiomyopathy), bone marrow, and intestine (5, 6). For these reasons, and because doxorubicin is highly adsorbed on nanoparticles, this cytostatic drug was chosen as the experimental model.

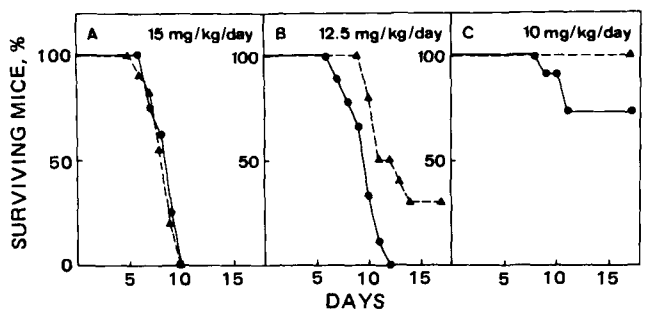

Figure 1—*Percent of surviving mice after intravenous administration on 3 consecutive days of various doses of free (●) and nanoparticle-bound doxorubicin (▲).*

EXPERIMENTAL

Polyalkylcyanoacrylate Nanoparticle Preparation—After dissolution of doxorubicin[1] (10 mg) in 10 ml of aqueous solution containing 100 mg of a polysaccharide[2], 50 mg of citric acid, and 1 mg of calcium chloride, 100 μl of isobutylcyanoacrylate monomer was dispersed under mechanical stirring.

After polymerization (3 hr), the resulting milky suspension was brought to isotonicity with 72 mg of sodium chloride. The size of the particles obtained was then estimated by measuring light scattering, arising from a laser source[3].

Measurement of Doxorubicin Linked to Nanoparticles—A 10-ml nanoparticle suspension was centrifuged[4] at 20,000 rpm for 1 hr. Sediment was then separated and dissolved in 10 ml of dioxane containing 20% water.

The content of doxorubicin was determined in both supernate and sediment by fluorimetric[5] dosage. For this purpose, 200-μl samples were diluted to 10 ml by water (for the supernate) or by dioxane (for the sediment) and measurements were performed using reference solutions of doxorubicin.

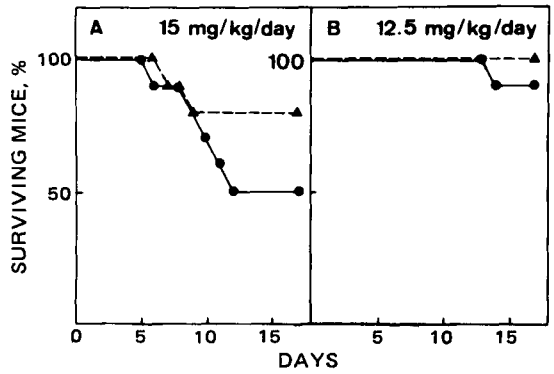

Figure 3—*Percent of surviving mice after intravenous administration on 2 consecutive days of various doses of free (●) and nanoparticle-bound doxorubicin (▲).*

Toxicity Studies—Toxicity of free and nanoparticle bound doxorubicin was determined using female mice[6]. Bound and free drug were given intravenously using various dosages for 5, 3, or 2 consecutive days of administration. During 5 consecutive days, 3, 4, 5, 6, and 8 mg/kg were given; 5, 7.5, 10, 12.5, and 15 mg/kg were given during 3 consecutive days; and 12.5 and 15 mg/kg during 2 consecutive days, respectively.

If the density of the polymer was assumed to be one, the cumulative dose of injected nanoparticles varied between 150 and 450 mg/kg of body weight.

An average of at least 10 mice were used per drug form in each dose series. The lethality was recorded 30 days after administration of the drug, and the weight of the mice was controlled daily.

Tape Sectioning Technique—After ether anesthesia, mice were killed by immersion in liquid nitrogen and embedded in a solution of carboxymethylcellulose. Sagittal sections measuring between 15 and 40

μm were cut through the animals according to a previously described technique of tape-sectioning (7).

Fluorescence Technique—After drying, the sections were examined with an optic microscope[7] under UV light. A yellow filter[8] was used for the examination of doxorubicin fluorescence. Registration on film was taken on a daylight color film[9]. The exposure times were automatically determined using a photoelectric cell incorporated in the camera[10].

RESULTS AND DISCUSSION

The fluorimetric dosage showed that 94% of the doxorubicin employed was fixed by the nanoparticles. That corresponded to 94 mg of drug/g of polymer (confirmed by preliminary, unpublished data obtained by HPLC dosage).

Figure 1 shows the mortality, 15 days after injection, of either free or bound doxorubicin at doses of 15, 12.5, and 10 mg/kg/day. No mortality was recorded when free or bound doxorubicin was given at a dose less than or equal to 7.5 mg/kg/day. Except for a dose of 15 mg/kg/day, which appeared highly toxic in both forms tested (confirming that doxorubicin fixed to nanoparticles remained active), the mortality noted for nanoparticle-treated groups was always less than that recorded for the free drug injected groups. For example, after 12 days at the 12.5-mg/kg/day dose, a 100% mortality rate was observed in the free doxorubicin group, as compared to the 50% mortality rate in the nanoparticle-injected group (Fig. 1B).

These results were completed by controlling the weight of the treated animals (Fig. 2). At the doses of 10, 7.5, and 5 mg/kg/day, the loss of weight in the free doxorubicin group was significantly higher than that noted in the nanoparticles group ($p \geq 0.975$). At the dose of 5 mg/kg/day, the weight loss in the free doxorubicin group was twofold higher than for the groups injected with the bound drug (Fig. 2A). The mortality observed

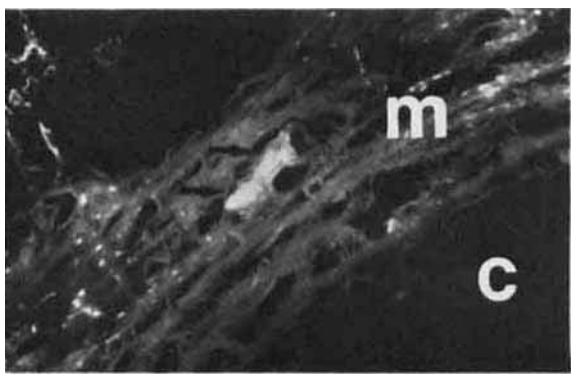

Figure 6—*Detail of a whole body fluorogram showing the heart of a mouse sacrificed 3 hr after the last of three injections of 10 mg/kg of free doxorubicin. There is a high accumulation of doxorubicin in the muscular fibers of the heart (→) (m = muscular myocardic fibers; c = myocardic cavity).*

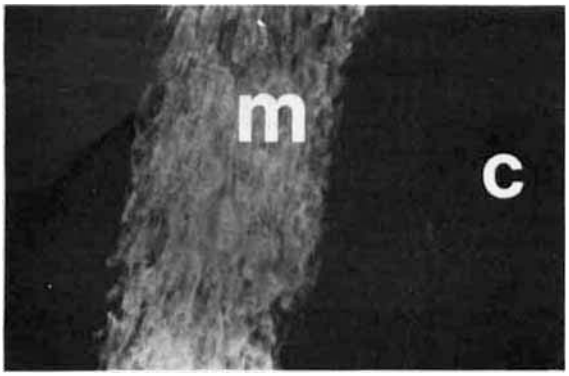

Figure 7—*Whole body fluorogram showing the heart of a mouse sacrificed 3 hr after the last of three injections of 10 mg/kg of doxorubicin bound to nanoparticles. In comparison with Fig. 6, no fluorescence appears in the myocardium (m = muscular myocardic fibers; c = myocardic cavity).*

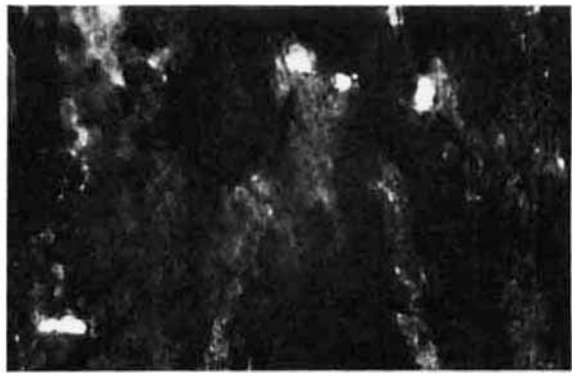

Figure 8—*Detail of whole body fluorogram of a mouse sacrificed 3 hr after the last of three injections of 10 mg/kg of doxorubicin bound to nanoparticles. Inversely to Fig. 6, fluorescence is retained in the lung (→).*

was primarily related to the intestinal toxicity of doxorubicin; the same mechanism was also responsible for the observed weight loss.

Therefore, at a dose of 10 mg/kg/day, the weight difference between mice treated with free doxorubicin and those treated with the bound drug was likely to be underestimated (Fig. 2C). No dead mice were recorded in the latter group, whereas significant mortality was noted in the former group. Dead mice were deleted from the weight loss charts.

When the administration schedules of both free and bound doxorubicin were limited to two successive injections of 12.5 and 15 mg/kg/day similar results were obtained. When the drug was linked to nanoparticles, significant differences in both mortality (Fig. 3) and weight loss (Fig. 4) were again observed. However, at the dose of 15 mg/kg/day, the weight loss difference (Fig. 3B) between the two experimental groups was underestimated for the same reasons mentioned previously.

Figure 5 shows the variance in time of the survival rate of the animals after five consecutive injections of 5 and 8 mg/kg/day of both free and bound doxorubicin, respectively. Three hours after the last of three daily injections of 10 mg/kg of body weight of both free and bound doxorubicin, mice were killed and sectioned. After drying, the sections were examined under a fluorescent microscope to determine which organs presented an orange-red fluorescence due to the presence of doxorubicin. Because a side effect of doxorubicin involved the heart, the investigations concentrated on the cardiac tissue. Figure 6 shows a high amount of cytostatic behavior in the cardiac muscle when free drug was injected into the animal. By contrast, no fluorescence was found in the myocardium after administration of the same dose of doxorubicin bound to the nanoparticles (Fig. 7). Examination of other organs confirmed the high uptake capacity of the nanoparticle adsorbed doxorubicin by the lung (Fig. 8) and liver, while the free drug seemed to show less fluorescence in these tissues. It appears that nanoparticle bound doxorubicin has a preferential distribution for organs such as the liver and lung, with significantly less distribution in the heart.

CONCLUSIONS

These results show a significant decrease of doxorubicin's toxicity when fixed to nanoparticles. This decrease corresponds to both a diminution in weight loss and to a higher survival rate in mice after administration of bound doxorubicin for various doses and administration schedules. In addition, the absence of doxorubicin fluorescence in the cardiac muscle when the drug was adsorbed on the nanoparticles can be of interest, considering the important cardiotoxicity of the drug. However, these observations were made on a limited number of animals and should be completed with a larger number of specimens injected under various administration schedules, dose, and time before sacrifice. It should be noted that the use of polyalkylcyanoacrylate nanoparticles as the drug carrier can reduce considerably the inherent toxicity and side effects of a cytotoxic drug and could be useful in cancer chemotherapy.

Theorems on the Apparent Volume of Distribution of a Linear System

D. P. VAUGHAN

Received April 10, 1981, from the *Department of Pharmaceutics, Faculty of Pharmaceutical Sciences, Sunderland Polytechnic, Sunderland, Tyne and Wear SR1 3SD, U.K.* Accepted for publication October 8, 1981.

Abstract □ If the concentration of drug in one compartment of a linear N-compartment system, without sinks and loss only from the sampled compartment is sampled, then the total apparent volume of distribution can be determined without knowledge of the topology of the system. This apparent volume is identical to the apparent volume of the corresponding closed system.

Keyphrases □ Volume of distribution—apparent, theorems of a linear system □ Linear system—theorems on the apparent volume of distribution □ Theorems—apparent volume of distribution of a linear system

Oppenheimer and others have derived a noncompartmental drug distribution volume (1). This volume is the ratio of the first statistical moment of the blood drug concentration–time function observed after a unit intravenous drug dose to the integral of the function on $(0,\infty)$. Benet and Galeazzi have re-presented Oppenheimer's derivation (2). In both these texts the derivation is not strictly analytical and relies mainly on unsubstantiated statements. However, this expression for a distribution volume has previously been derived, for an N-compartmental system, in a strict analytical fashion by Bright (3).

Bright's derivation is based on the following assumptions:

(*a*) irreversible drug loss from the compartmental system occurs only from the sampled compartment;

(*b*) the eigenvalues of the coefficient matrix are all real and distinct;

(*c*) if Compartment j is connected to Compartment i (i and $j \in 1,2,\ldots N, i \neq j$) by a rate constant, $k_{ji} > 0$, then compartment i is connected to compartment j by a rate constant $k_{ij} > 0$;

(*d*) $k_{ij} = k_{ji}$.

Conditions *c* and *d* define the coefficient matrix of the N-compartmental system as a symmetric matrix which directly implies condition *b*. Conditions *b* and *c*, but not necessarily condition *d*, are obviously realizable for mammillary and caternary compartmental systems (4, 5). However, condition *b* specifically excludes any compartmental system whose matrix has repeated real eigenvalues or has pairs of complex conjugate eigenvalues. Condition *c* excludes systems with nonreversible cycles involving three or more compartments, regardless of the validity of condition *b*.

Compartment systems, that are based on physiological considerations and include specific compartments for the arterial and venous blood, must contain nonreversible drug circulation cycles involving three or more compartments. Consequently, previous derivations (3) are not applicable to such systems.

In the present report, a relationship between the volume of distribution of a compartmental system and the first moment of the sampled function is derived. This derivation does not require conditions on the eigenvalues of the system, the topology of the system, or the intercompartmental rate constants.

THEORY

Consider an arbitrary set of N interconnected compartments in which it is possible for material in Compartment j to reach all other Compartments $i, i \neq j$. Such a system of compartments does not contain any sinks, disjointed sets of compartments, or subsystems (6). For such a system:

$$\begin{pmatrix} \dot{X}_1 \\ \dot{X}_2 \\ \dot{X}_3 \\ \vdots \\ \dot{X}_n \end{pmatrix} = \begin{pmatrix} -E_1 & k_{21} & k_{31} & \cdots & k_{N1} \\ k_{12} & -E_2 & k_{32} & & k_{N2} \\ k_{13} & k_{23} & -E_3 & & k_{N3} \\ \vdots & \vdots & \vdots & & \vdots \\ k_{1N} & k_{2N} & k_{3N} & & k_{N4} \end{pmatrix} \begin{pmatrix} X_1 \\ X_2 \\ X_3 \\ X_4 \end{pmatrix} \equiv \dot{\boldsymbol{X}} = \boldsymbol{AX} \quad \text{(Eq. 1)}$$

where $X_j (j \in 1,2,\ldots N)$ is the amount of drug in compartment j, and $\dot{X}_j$ is the first derivative with respect to time of X_j. Intercompartmental rate constants, k_{ji} and k_{ij}, are for drug transport from Compartment j to Compartment i and from Compartment i to Compartment j, respectively (j and $i \in 1,2,\ldots N, i \neq j$). Both k_{ij} and k_{ji} are ≥ 0. If a particular k_{ij} is zero, the status of k_{ji} cannot be inferred.

The E_j's are defined as:

$$E_j = k_{jo} + \sum_{\substack{i=1 \\ j \neq i}}^{N} k_{ji} \qquad (j \in 1,2,\ldots N) \quad \text{(Eq. 2)}$$

where $k_{jo} (k_{jo} \geq 0)$ is the rate constant for irreversible drug loss from the system *via* Compartment j.

The coefficient matrix $\boldsymbol{A}$ is a dominant diagonal matrix and, since the compartmental system does not contain any sinks or disjointed subsystems, matrix $\boldsymbol{A}$ cannot be reduced to a matrix of the form:

$$\begin{pmatrix} \boldsymbol{P} & \boldsymbol{O} \\ \boldsymbol{U} & \boldsymbol{Q} \end{pmatrix}$$

by some permutation of the rows and columns where $\boldsymbol{P}$ and $\boldsymbol{Q}$ are square matrixes and $\boldsymbol{O}$ consists of zero elements. These row column permutations are equivalent to a renumbering of the compartmental system (6).

Matrix $\boldsymbol{A}$ is irreducible and theorems have been given (7) for irreducible dominant diagonal matrixes of the form specified by matrix $\boldsymbol{A}$; thus, the determinant of matrix $\boldsymbol{A}$ is bound by $|\boldsymbol{A}| \neq 0$ if at least one $k_{jo} \geq 0$, and $|\boldsymbol{A}| = 0$ if all the $k_{jo} = 0$ for $j \in 1,2,\ldots N$.

A special form of matrix $\boldsymbol{A}$ is one in which only one k_{jo} is greater than zero. Considering such a system, and without loss of generality, let $k_{10} > 0$ and $k_{jo} = 0 (j \in 2,3,\ldots N)$. In this case:

$$|\boldsymbol{A}| = -\left(k_{10} + \sum_{j=2}^{N} k_{1j}\right) |\boldsymbol{M}_{11}| + \sum_{j=2}^{N} (-1)^{(j-1)} k_{j1} |\boldsymbol{M}_{1j}| \neq 0 \quad \text{(Eq. 3)}$$

where $\boldsymbol{M}_{11}$ is the principle minor of matrix $\boldsymbol{A}$ obtained by deleting Row 1 and Column 1, and the $\boldsymbol{M}_{1j}$'s are the minors of $\boldsymbol{A}$ obtained by deleting Row 1 and Column $j (j \in 2,3,\ldots N)$.

The minors, $\boldsymbol{M}_{11}$ and $\boldsymbol{M}_{1j}$ are independent of k_{10}. By setting $k_{10} = 0$ in Eq. 3 and utilizing Taussky's theorem, it follows that:

$$-\sum_{j=2}^{N} k_{1j} |\boldsymbol{M}_{11}| + \sum_{j=2}^{N} (-1)^{(j-1)} k_{j1} |\boldsymbol{M}_{1j}| = 0$$

consequently, Eq. 3 becomes:

$$|\boldsymbol{A}| = -k_{10} |\boldsymbol{M}_{11}| \quad \text{(Eq. 4)}$$

Volume of Distribution—Consider a closed irreducible compart-

0022-3549/82/0700-0793$01.00/0

mental system (*i.e.*, $k_{jo} = 0$ for all $j, j\epsilon 1,2,\ldots N$) with a unit drug impulse input, δD, into a particular compartment. Assume the drug concentration–time function, $\hat{C}(t)$, in Compartment 1 is observed. Since the system is closed, the amount of drug in the compartmental system at any time t is D. Also, since the system is irreducible and closed, the system will eventually achieve a state of drug concentration equilibrium. Consequently, the equilibrium drug concentration, $\hat{C}(\infty)$, in Compartment 1 is governed by $\hat{C}(\infty) > 0$. The volume of distribution of the closed system, V, may be defined as the scalar that maps the equilibrium concentration in the sampled compartment to the known amount of drug in the system, where $V = D/\hat{C}(\infty)$.

If the equilibrium concentration in all compartments of the closed system were identical, then V would define the exact volume of the system. However, since the latter condition cannot be assumed to hold for an arbitrarily closed compartmental system, the derived volume must be regarded as an apparent distribution volume. In general, $\hat{C}(\infty)$ will not be constant for all observation points. Consequently, the numerical value of V depends on which particular compartment is sampled.

The apparent volume of an open irreducible compartmental system is the same as the corresponding closed system. When the topology and intercompartmental rate constants of an open system are known, the distribution volume can be calculated readily. However, an analytical method for calculating V, which does not require specified topology or intercompartmental rate constants, would be useful since the calculated V would be model independent.

Theorem 1—For an irreducible compartmental system with irreversible drug loss from one compartment only and sampling from the same compartment, the first moment, $\bar{t}$, of the sample concentration–time function, $C(t)$, after an impulse input, δD, into the sample compartment is related to the apparent volume of distribution, V, of the corresponding closed compartmental system by:

$$\frac{D\bar{t}}{\int_0^\infty C(t)dt} = V$$

where $\bar{t} = \int_0^\infty tC(t)dt / \int_0^\infty C(t)dt$.

Proof—To establish a proof, expressions for $\bar{t}/\int_0^\infty C(t)dt$ of an open compartmental system with sampling and loss from one compartment and the concentration at $t = \infty$ in the corresponding closed system, $\hat{C}(\infty)$, are required. These expressions are derived first and then used to establish the theorem.

Open System—For an impulse input, δD, into Compartment 1, the initial conditions are $X_1(+0) = D$ and $X_j(+0) = 0$ for $j\epsilon 2,3,\ldots N$. With these initial conditions, the Laplace transform $x_1(s)$ of $X_1(t)$ can be expressed by standard methods as:

$$x_1(s) = \frac{D|s\boldsymbol{I} - \boldsymbol{M}_{11}|}{|s\boldsymbol{I} - \boldsymbol{A}|} = \frac{D(s^{N-1} + a_1 s^{N-2} \ldots a_{N-2}s + (-1)^{N-1}|\boldsymbol{M}_{11}|)}{(s^N + b_1 s^{N-1} \ldots b_{N-1}s + (-1)^N|\boldsymbol{A}|)} \quad \text{(Eq. 5)}$$

where b_j and a_j are $(-1)^j$ times the sum of the determinants of all the j-squared principle minors of matrix $\boldsymbol{A}, j\epsilon 1,2,\ldots N-1$, and matrix $\boldsymbol{M}_{11}$, respectively.

Since $\boldsymbol{A}$ and $\boldsymbol{M}_{11}$ are matrixes with real elements, the coefficients a_j and b_j are real. Both $\boldsymbol{A}$ and $\boldsymbol{M}_{11}$ are dominant diagonal matrixes and by the application of Gerschgorins root location theorem (8) both $\boldsymbol{A}$ and $\boldsymbol{M}_{11}$ have eigenvalues with negative real parts. Consequently, the polynomials $|s\boldsymbol{I} - \boldsymbol{A}|$ and $|s\boldsymbol{I} - \boldsymbol{M}_{11}|$ have coefficients that are all of the same sign (9). Since the diagonal elements of $\boldsymbol{A}$ and $\boldsymbol{M}_{11}$ are negative, the coefficients a_1 and b_1 are positive, consequently, $a_j > 0$ and $b_j > 0$ for all $j(j\epsilon 1,2,\ldots N-1)$ and $(-1)^N|\boldsymbol{A}| > 0$ as is $(-1)^{N-1}|\boldsymbol{M}_{11}|$.

By standard Laplace transform theory:

$$-\frac{dx_1(s)}{ds} = \int_0^\infty tX_1(t)dt = \lim_{ts\to 0} \frac{D[b_{N-1}(-1)^{N-1}|\boldsymbol{M}_{11}| - a_{N-2}(-1)^N|\boldsymbol{A}|]}{|\boldsymbol{A}|^2} \quad \text{(Eq. 6)}$$

which on substitution of Eq. 4 into Eq. 6 gives:

$$\int_0^\infty tX_1(t)dt = \frac{D(b_{N-1} - a_{N-2}k_{10})}{(-1)^{N-1}|\boldsymbol{M}_{11}|(k_{10})^2} \quad \text{(Eq. 7)}$$

Also, by standard Laplace transform theory:

$$\lim_{ts\to 0} \frac{x_1(s)}{} = \int_0^\infty X_1(t)dt = \frac{(-1)^{N-1}|\boldsymbol{M}_{11}|D}{(-1)^N|\boldsymbol{A}|} \equiv \frac{D}{k_{10}} \quad \text{(Eq. 8)}$$

The latter identity in Eq. 8 follows from Eq. 4. The limits in Eqs. 6 and 8 are guaranteed by the fact that $X_j, j\epsilon 1,2,\ldots N$, are nonnegative bounded functions such that $X_j(\infty) = 0$(10). The $X_j(t)$ functions are nonnegative since the off diagonal elements of A are ≥ 0 (11), and $X_j(\infty) = 0$ because the eigenvalues of A have negative real parts. Combining Eqs. 7 and 8 and substituting $X_1(t) = V_1C(t)$, where V_1 is the volume of Compartment 1, then:

$$\frac{D\int_0^\infty C(t)dt}{\left(\int_0^\infty C(t)dt\right)^2} = \frac{(b_{N-1} - a_{N-2}k_{10})}{(-1)^{N-1}|\boldsymbol{M}_{11}|}V_1 \quad \text{(Eq. 9)}$$

Closed System—In the arbitrary open system, $k_{10} > 0$ and $k_{jo} = 0$ for $j\epsilon 2,\ldots N$; consequently, the corresponding closed system is obtained by setting $k_{10} = 0$ in $\boldsymbol{A}$. Let the closed system matrix be $\hat{\boldsymbol{A}}$ and let $\hat{\boldsymbol{M}}_{11}$ be the matrix obtained by deleting Row one and Column one from $\hat{\boldsymbol{A}}$; $\hat{\boldsymbol{M}}_{11} = \boldsymbol{M}_{11}$ and from Eq. 4, $|\hat{\boldsymbol{A}}| = 0$. Let $\hat{X}_1(t)$ represent the mass–time function of drug in Compartment 1 after an impulse input, δD, into Compartment 1.

By standard Laplace transform theory:

$$\lim_{ts\to 0} \frac{s\hat{x}_1(s)}{} = X_1(\infty) = \lim_{s\to 0} \frac{ts|s\boldsymbol{I} - \boldsymbol{M}_{11}|}{|s\boldsymbol{I} - \hat{\boldsymbol{A}}|} = \lim_{s\to 0} t\,\frac{Ds(s^{N-1} + a_1 s^{N-2} \ldots a_{N-2}s + (-1)^{N-1}|\boldsymbol{M}_{11}|}{(s^N + \hat{b}_1 s^{N-1} \ldots \hat{b}_{N-1}s + (-1)^N|\hat{\boldsymbol{A}}|)} = \frac{(-1)^{N-1}|\boldsymbol{M}_{11}|D}{\hat{b}_{N-1}} \quad \text{(Eq. 10)}$$

where $\hat{b}_j$ is $(-1)^j$ times the sum of the determinants of all the j-squared principle minors of $\hat{\boldsymbol{A}}$.

Since the volume of distribution, V, is defined by $V = D/\hat{C}(\infty)$, and $V_1\hat{C}(\infty) = \hat{X}_1(\infty)$, then from Eq. 10:

$$V = \frac{\hat{b}_{N-1}}{(-1)^{N-1}|\boldsymbol{M}_{11}|}V_1 \quad \text{(Eq. 11)}$$

The equivalence of Eqs. 9 and 11 is necessary and sufficient for Theorem 1 to hold. Consequently, if:

$$\hat{b}_{N-1} = (b_{N-1} - a_{N-2}k_{10}) \quad \text{(Eq. 12)}$$

then Theorem 1 is established. The latter identity, Eq. 12, can be proved as follows: The coefficients b_{N-1}, $\hat{b}_{N-1}$, and a_{N-2} are given as:

$$b_{N-1} = (-1)^{N-1}\sum_{j=1}^{N}|\hat{\boldsymbol{M}}_{jj}|$$

$$\hat{b}_{N-1} = (-1)^{N-1}\sum_{j=1}^{N}|\hat{\boldsymbol{M}}_{jj}| \quad \text{(Eq. 13)}$$

$$a_{N-2} = (-1)^{N-2}\sum_{j=1}^{N-1}|\hat{\boldsymbol{M}}_{jj}| \quad \text{(Eq. 14)}$$

where M_{jj} and $\hat{M}_{jj}$ are the $(N-1)$ squared principle minors of the N-squared matrixes $\boldsymbol{A}$ and $\hat{\boldsymbol{A}}$, respectively, and the $\overline{M}_{jj}$'s are the $(N-2)$ squared principle minors of the $(N-1)$ squared matrix $\boldsymbol{M}_{11}$. The coefficient b_{N-1} can be expressed as:

$$b_{N-1} = (-1)^{N-1}\left[|\boldsymbol{M}_{11}| + \sum_{j=1}^{N-1}|\boldsymbol{P}_j|\right] \quad \text{(Eq. 15)}$$

where:

$$|\boldsymbol{P}_j| = \begin{vmatrix} -E_1 & \boldsymbol{r}_{j+1} \\ \boldsymbol{c}_{j+1} & \hat{\boldsymbol{M}}_{jj} \end{vmatrix}$$

and where $\boldsymbol{r}_{j+1}(j\epsilon 1,2,\ldots N-1)$ is the row of $N-2$ elements obtained from $(k_{21},k_{31},\ldots k_{N1})$ by striking out the element $k_{j+1,1}$ and $\boldsymbol{c}_{j+1}$ is the column of $N-2$ elements obtained from $(k_{12},k_{13},\ldots k_{1N})^T$ by striking out the element $k_{1,j+1}$. Expanding the determinants $|\boldsymbol{P}_j|(j\epsilon 1,2,\ldots N-1)$ by their first rows, then:

$$b_{N-1} = (-1)^{N-1}\left[|\boldsymbol{M}_{11}| - \left(k_{10} + \sum_{i=2}^{N}k_{1i}\right)\sum_{j=1}^{N-1}|\overline{\boldsymbol{M}}_{jj}| + \sum_{j=1}^{N-1}|Z_j|\right] \quad \text{(Eq. 16)}$$

where $|Z_j|$ is the summation of determinants associated with the expansion of $|\boldsymbol{P}_j|$ along $\boldsymbol{r}_{j+1}$. Since the elimination constant k_{10} does not occur in any $\boldsymbol{r}_{j+1}$ or any $\overline{\boldsymbol{M}}_{jj}$, the determinants $|Z_j|$ are independent of k_{10}. Since $\boldsymbol{M}_{11}$ is also independent of k_{10}, then $\hat{b}_{N-1}$ is directly obtainable from b_{N-1} by setting $k_{10} = 0$ in Eq. 16, thus:

$$\delta_{N-1} = (-1)^{N-1}\left[|\boldsymbol{M}_{11}| - \left[\sum_{i=2}^{N} k_{1i}\right]\sum_{j=1}^{N-1}|\overline{\boldsymbol{M}}_{jj}| + \sum_{j=1}^{N-1}|Z_j|\right] \quad \text{(Eq. 17)}$$

Substitution of Eqs. 16 and 17 into Eq. 12 establishes the identity expressed in Eq. 12 and thus complete the proof of Theorem 1.

Theorem 2—For a known nonnegative and finite drug input function, $\mathrm{In}(t)$, into Compartment 1 of an open irreducible compartmental system, with sample and loss from Compartment 1 only, the volume of distribution of the corresponding closed system, V, is given by:

$$V \equiv \frac{\int_0^\infty tC(t)dt}{\left(\int_0^\infty C(t)dt\right)^2} = \left[\frac{\int_0^\infty t\overline{R}(t)dt}{\int_0^\infty \overline{R}(t)dt} - \frac{\int_0^\infty t\mathrm{In}(t)dt}{\int_0^\infty \mathrm{In}(t)dt}\right]\frac{\int_0^\infty \mathrm{In}(t)dt}{\int_0^\infty \overline{R}(t)dt} \quad \text{(Eq. 18)}$$

where $\overline{R}(t)$ is the observed drug concentration–time function produced by the input function $\mathrm{In}(t)$, and $C(t)$ is the concentration–time function produced by a unit impulse input into Compartment 1. Both $\overline{R}(t)$ and $C(t)$ are observed in Compartment 1.

Proof—By application of standard linear system theory the mass of drug, $R(t)$, in Compartment 1 is:

$$R(t) = \int_0^t \mathrm{In}(\tau)X_1(t-\tau)d\tau \quad \text{(Eq. 19)}$$

where $X_1(t)$ is the mass–time function in Compartment 1 that would result from a unit impulse input into Compartment 1.

By the standard Laplace transform theory:

$$\int_0^\infty tR(t)dt = \frac{dR(s)}{ds} = \operatorname*{Lim}_{ts\to 0} \operatorname*{Lim}_{s\to 0} t\left[-\frac{d\mathrm{In}(s)}{ds}x_1(s) - \frac{dx_1(s)}{ds}\mathrm{In}(s)\right] \quad \text{(Eq. 20)}$$

Since $\mathrm{In}(t)$ is a nonnegative function with $\mathrm{In}(\infty) = 0$ the limit of $\mathrm{In}(s)$ as $s \to 0$ is $\int_0^\infty \mathrm{In}(t)dt$ and the limit of $-d\mathrm{In}(s)/ds$ as $s \to 0$ is $\int_0^\infty t\,\mathrm{In}(t)dt$. Also, since $X_1(t)$ is nonnegative and integrable on $(0,\infty)$ the limit of $x_1(s)$ as $s \to 0$ is $\int_0^\infty X_1(t)dt$, and the limit of $-dx_1(s)/ds$ is $\int_0^\infty tX_1(t)dt$. Applying a known theorem on the limits of products of Laplace transforms (10):

$$\int_0^\infty tR(t)dt = \int_0^\infty t\mathrm{In}(t)dt\int_0^\infty X_1(t)dt + \int_0^\infty tX_1(t)dt\int_0^\infty \mathrm{In}(t)dt \quad \text{(Eq. 21)}$$

Also, applying the known theorem on limits (10) to Eq. 19:

$$\int_0^\infty R(t)dt = \int_0^\infty \mathrm{In}(t)dt\int_0^\infty X_1(t)dt \quad \text{(Eq. 22)}$$

An expression for $\int_0^\infty tX_1(t)dt/\int_0^\infty X_1(t)dt$ is obtainable by a rearranging Eq. 21 and dividing by Eq. 22, which on dividing by $\int_0^\infty X_1(t)dt$ and utilizing Eq. 22 gives:

$$\frac{\int_0^\infty tX_1(t)dt}{\left(\int_0^\infty X_1(t)\right)^2} = \left(\frac{\int_0^\infty tR(t)dt}{\int_0^\infty R(t)dt} - \frac{\int_0^\infty t\mathrm{In}(t)dt}{\int_0^\infty \mathrm{In}(t)dt}\right)\frac{\int_0^\infty \mathrm{In}(t)dt}{\int_0^\infty R(t)dt} \quad \text{(Eq. 23)}$$

Substituting $V_1C(t) = X_1(t)$ and $V_1\overline{R}(t) = R(t)$ into Eq. 23 gives Eq. 18 and completes the proof of Theorem 2.

DISCUSSION

Theorems 1 and 2 state model-independent methods for calculating a drug distribution volume. The expressions are model independent in the sense that no knowledge of the topology of the compartmental system is required. Since no constraints on the topology are applied, then no constraints on either the eigenvalues of the coefficient matrix or on intercompartmental rate constants are applied. Additionally, it is not necessary to specify some functional form (*e.g.*, a summation of exponentials) to apply the equations. However, it is assumed in the derivation that irreversible drug loss from the system occurs only from the sampled compartment. The proofs of Theorems 1 and 2 are strictly analytical and have the advantage of being mainly algebraic. No concepts of clearance or equilibrium elimination are required.

The derived volume is clearly related to the apparent volume of the corresponding closed system.

Although the terms compartments are used in the derivation, their use should not be interpreted literally as circumscribable regions of space where physical translocation of matter takes place. The term is merely a convenience. Matrix $\boldsymbol{A}$ is simply an operator for a stable linear system, and the conditions of nonnegative off-diagonal elements in $\boldsymbol{A}$ are necessary if observations in the system are to be nonnegative functions. Also, the negative diagonal elements are necessary for stability. Consequently, the derivation could have followed equally well the line of considering a stable linear system which would also have yielded Eq. 1 but where the elements of Matrix $\boldsymbol{A}$ would have no meaning in relation to compartmental analysis. These latter concepts have been discussed previously (11).

To apply Theorem 1, it is not necessary to assume any functional form to describe the $C(t)$ data. The numerical values of the required integrals can be obtained by standard numerical methods (2). For Theorem 2, it is necessary to know the functional form of the input function. For example, the input function may be a step input of magnitude k and of duration τ. In this case $\int_0^\infty \mathrm{In}(t)dt = k\tau$ and $\int_0^\infty t\ \mathrm{In}(t)\ dt = k\tau^2/2$. The numerical values of the other integrals in Theorem 2 are obtainable by standard numerical methods.

Synthesis and Hypoglycemic Activity of Benzamidophenyl-alkanoic Acid Derivates: New Inhibitors of Gluconeogenesis

ERICH RAPP and HORST P. O. WOLF ˣ

Received July 21, 1981, from the *Research Laboratories of Byk Gulden Lomberg Pharmaceuticals, D-7750 Konstanz, Federal Republic of Germany.* Accepted for publication October 13, 1981.

Abstract: □ A series of ω-[2-(*N*-alkylbenzamido)-phenyl]-alkanoic acids was synthesized and tested for its effects on blood glucose concentration in fasted rats and on gluconeogenesis from lactate and pyruvate in isolated perfused rat livers. The compounds led to a dose-dependent and reversible inhibition of gluconeogenesis, with 4-[2-(*N*-methyl-3-trifluoromethylbenzamido)-phenyl]-butanoic acid leading to a 50% inhibition at 0.02 m*M*. The compounds lowered blood glucose in fasted rats. No correlation between hypoglycemic effect and inhibition of gluconeogenesis could be detected, however.

Keyphrases □ Benzamidophenyl-alkanoic acid—derivatives, synthesis, hypoglycemic activity □ Gluconeogenesis—inhibited by synthesized benzamidophenyl-alkanoic acid derivatives □ Hypoglycemic activity—benzamidophenyl-alkanoic acid derivatives, new inhibitors of gluconeogenesis

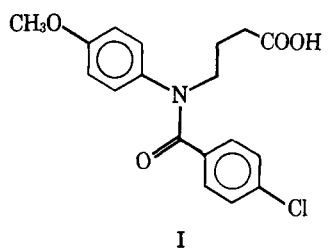
Numerous substances have been reported to lower blood glucose levels by inhibiting gluconeogenesis in mammalian liver; various sites of inhibition have been discussed (1). So far, only biguanides have been used as therapeutic agents in the treatment of diabetes.

Recently, clanobutin [4-[4-chloro-*N*-(4-methoxyphenyl)-benzamido]butanoic acid, (I)[1]] (2) was found to be an inhibitor of gluconeogenesis from the precursors lactate and pyruvate (3). This led to the synthesis of a series of structurally related compounds in order to find more potent inhibitors of gluconeogenesis as potential hypoglycemic drugs.

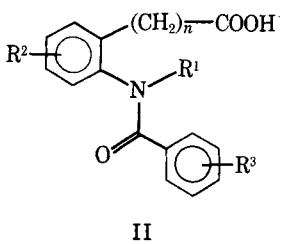
In variation of structure I, the alkanoic acid chain was attached to the aromatic ring *ortho* to the amide nitrogen, which was kept substituted with a methyl or ethyl group. Chain length and substitution pattern were modified (Table I).

EXPERIMENTAL

Chemistry—*3-[2-(N-Methyl-4-chlorobenzamido)-phenyl]propionic Acid (IIb)*—*N*-Methyldihydrocarbostyril (III*b*) 4.84 g (30 mmoles) and 5.6 g (100 mmoles) of potassium hydroxide were dissolved in 20 ml of ethylene glycol monoethyl ether. While stirring, the mixture was refluxed for 3 hr. After cooling to room temperature, the solution was diluted with 200 ml of water and extracted with two portions of ether. The pH of the aqueous phase was brought to 8–8.5 by addition of 2 *N* HCl. A solution of 5.25 g (30 mmoles) of 4-chlorobenzoylchloride (IV*b*) in 50 ml of ether was added slowly, while the pH of the aqueous phase was held at 7.5–8.5 with 1 *N* NaOH. The aqueous layer was separated and washed with ether twice. The resulting acid was precipitated with 2 *N* HCl, washed with water, and dried. Recrystallization from ethyl acetate yielded 6.2 g of II*b*, mp 156–158° (66%). Compounds II*d*, *e*, *g*, *h*, *k*, and *m–u* were synthesized by the same procedure.



I



II

4-[2-(N-Methylbenzamido)phenyl]butanoic Acid (IIh)—2-Aza-2-methyl-benzo[*c*]-cycloheptanone (III*h*) [14.0 g (80 mmoles)], 17.9 g (320 mmoles) of potassium hydroxide, and 50 ml of ethylene glycol monoethyl ether were brought together in a glass pressure vessel and heated to 150° for 6 hr. After cooling to room temperature, the contents were diluted with 200 ml of water and adjusted to pH 9 with glacial acetic acid. After stirring 33.6 g (400 mmoles) of sodium bicarbonate into this solution, 11.8 g (80 mmoles) of benzoyl chloride in 20 ml of ether was added dropwise within 2 hr. Dilution with 800 ml of water was followed by extraction with ether. The aqueous phase was acidified with 2 *N* HCl and extracted three times with ethylene chloride. The organic fractions were collected and concentrated; the residue was recrystallized from ethyl acetate–petroleum ether (1:1) to give 19.6 g of II*h*, mp 102–103° (80%). Compounds II*a*, *b*, *c*, *f*, *i*, *j*, and *l* were prepared according to this method.

6-[2-(N-Methyl-3-trifluoromethylbenzamido)-phenyl]caproic Acid (IIu)—Oxalyl chloride [13.0 g (102 mmoles)] and one drop of dimethyl formamide were given to 12.5 g (34 mmoles) of 4-[2-(*N*-methyl-3-trifluoromethylbenzamido)-phenyl]butanoic acid (III*l*) in 40 ml of toluene. The mixture was stirred for 1.5 hr and then evaporated *in vacuo*. The residue was taken up in 50 ml of dry dioxane and added dropwise to 1.32 g (35 mmoles) of sodium borohydride in 20 ml of dioxane. The mixture was heated to 100° for 4 hr, then cooled to room temperature. Acidifying with 2 *N* HCl and dilution with 20 ml of water was followed by extraction of the product with two portions of ether. Evaporation left an oily residue (10.9 g), which was dissolved in 20 ml of pyridine and 10 ml of toluene and added to a solution of 11.8 g (61.7 mmoles) of *p*-toluenesulfonyl chloride in 40 ml of toluene; stirring at 40° was continued for 20 hr. After filtration, the solution was first washed with 2 *N* HCl and saturated sodium chloride solution, then dried and concentrated *in vacuo*. The tosylate was obtained as a viscous oil, was dissolved in 40 ml of ethanol, and added dropwise to a solution of 2.6 g (14.3 mmoles) of sodium diethyl malonate in 30 ml of ethanol. Refluxing for 24 hr was followed by removing ethanol. The residue, after extractive workup, yielded 4.1 g of a light brown oil. This was treated with potassium hydroxide in methanol–toluene (1:1) at room temperature (stirring for 30 hr). Workup led to 2.0 g of the free substituted malonic acid, which was decarboxylated by heating to 160° for 2.5 hr. After recrystallization from ether, 0.8 g of II*u*, mp 103–104° (2%) was obtained.

Pharmacology—*Hypoglycemic Activity* —Groups of 6–12 male Sprague-Dawley rats[2] (160–200 g) were fasted overnight. Using an oral tube, the substances were administered as aqueous, neutral solutions (10 ml/kg of body weight), with control rats receiving the same volume of 0.9% NaCl. The dosage range was 0.36–1.67 mmoles/kg of body weight. Blood samples were obtained prior to and at 2, 4, and 6 hr after administration by puncturing the retroorbital plexus. Blood glucose was measured by standard enzymatic procedure[3]. The results were expressed as relative change in comparison to the control group on log-transformed intraindividual ratios of treatment *versus* pretreatment. An effective dose, ED_{50} (25%) ± *SD*, was calculated from dose–response relationships by linear or nonlinear regression techniques. An ED_{50} of 25% indicated that 50% of the group showed at least a 25% decrease of blood glucose compared with controls. Intergroup comparison of change due to treatment was performed by ANOVA and subsequent Scheffé-contrasts or pairwise Student-Welch tests (Table I).

[a] All reported compounds show NMR spectra in accordance with expected structures. [b] Melting points are not corrected. [c] Percent decrease of blood glucose compared with controls after oral administration of 0.06 mmole/kg; the values represent the maximum decrease within 6 hr after administration, 6 rats/group. [d] Statistical tests: ANOVA and subsequent Scheffé-contrasts or pairwise Student-Welch tests with $p < 0.05$, two-sided. [e] $p < 0.01$, two-sided. [f] $p < 0.001$, two-sided.

Liver Perfusion—The isolated livers of rats fasted overnight were perfused in a nonrecirculating system (4). Krebs-Henseleit bicarbonate buffer (pH 7.4), saturated with an oxygen–carbon dioxide mixture (95:5) and containing L(+)-lactate[4] (1.6 m*M*) and pyruvate[5] (0.2 m*M*), was used for perfusion. The livers were perfused for 2 hr; the test substances were infused from 32–80 min using three different, increasing concentrations at 16-min intervals.

Analytical Method and Determination of K_i—Samples of the liver perfusion effluent were collected at 1-min intervals and analyzed for glucose. For each experiment, the values observed at 32, 48, 64, 80, and 96 min were obtained by averaging five neighboring values. The slight linear decline found in control experiments was taken into account by using the values at 32 and 96 min as a basis for linear interpolation. The concentration producing a 50% decrease in glucose due to inhibition of gluconeogenesis (K_i) was calculated from these data by linear or log–linear correlation.

Acute Toxicity—Five female mice[6] (22–26 g) were used for every group. The animals received water *ad libitum;* food was reduced to 50 g/kg of body weight 18 hr prior to administration. The test compounds were administered orally. LD_{50} values were calculated according to a previous study (5).

Synthesis—The title compounds were synthesized as follows: According to the known procedures, benzolactams (III) with varying ring size were prepared from substituted anilines (*via* internal Friedel-Crafts alkylation) (6), tetralones, and benzosuberones (*via* Beckmann or Schmidt rearrangement) (7, 8); the resulting lactams were *N*-alkylated to III with dimethyl- or diethylsulfate either directly or by use of phase-transfer catalysis (9). Benzolactams (III) were then hydrolyzed by refluxing with potassium hydroxide in ethylene glycol monoethyl ether; in some cases, glass pressure vessels were used for even higher reaction temperatures. Acylation of the amino group with substituted benzoyl chlorides (IV) and acidic workup led to compounds IIa–*t*. One

[a] *N* = number of animals tested. [b] 1-butylbiguanide hydrochloride.

further example, II*u*, was prepared by extension of the alkyl chain *via* malonic ester synthesis (Scheme I).

RESULTS AND DISCUSSION

Compounds II*a–u* were tested for their ability to lower blood glucose levels in fasted rats and to inhibit gluconeogenesis from lactate and pyruvate in the model isolated perfused liver of fasted rats.

The decrease of blood glucose after a single oral dose of 0.6 mmole/kg in overnight fasted rats was determined. Table I shows the maximum value within 6 hr after administration.

For a number of compounds, dose–response relationships were studied by calculating ED_{50} (25%) values from the corresponding data (dosage range 0.36–1.67 mmoles/kg). A dose–response relationship could not be found in all cases, *i.e.*, the ED_{50} value was not feasible (Table II).

The inhibition of gluconeogenesis from L(+)-lactate (1.6 m*M*) and pyruvate (0.2 m*M*) in the liver perfusion experiment is expressed by the inhibition constant K_i, *i.e.*, the concentration producing a 50% inhibition (Table II).

Acute toxicity data were determined for selected compounds (Table II).

The *in vivo* glucose lowering effects of the reported compounds were found to be in the same order of magnitude as the 1-butylbiguanide hydrochloride[7]. The butanoic acid derivatives (II*i* and *j*) showed the lowest ED_{50} (25%) values: 0.99 and 1.26 mmoles/kg.

Effective inhibitions of gluconeogenesis, however, were demonstrated by most members of the group, the best of which are II*d*, *j*, *l*, *n*, and *t* ($K_i \leq 0.05$ m*M*). Inhibition was fully reversible without delay upon terminating the infusion of the inhibitor substance. This coincides with results obtained on I (3). In comparison, 1-butylbiguanide hydrochloride fails to show a substantial effect upon gluconeogenesis in this model up to 1.0 m*M*.

Neither structure–activity relationships within the group II*a–u* nor any correlation between hypoglycemic activity and K_i values could be found.

Unsubstituted ω-phenylalkanoic acids have been reported to inhibit glucose synthesis from various precursors (10). 4-Phenylbutanoic acid effects a 60% inhibition at 4 m*M*. Structurally closely related to II are some 2-benzamidophenylacetic and -propionic acids, which were found to possess anti-inflammatory and analgesic activity (11).

Other inhibitors reported within the last 10 years include cyclopropanecarboxylic acid (12), phenelzine (13), tryptophan metabolites (14), 3-mercaptopicolinic acid (15), and aminopyrine (4), all effective in the range of 0.1–0.5 m*M*; 0.6 m*M* is reported for 2-bromooctanoate (16), 0.5–1.0 m*M* for pent-4-enoic acid (17), 2 m*M* for phenylpyruvate (18), and 5 m*M* for butylmalonate (19).

CONCLUSION

The data presented in Tables I and II indicate that some of the substituted ω-(2-benzamidophenyl)alkanoic acids of type II lower the blood glucose level *in vivo* significantly, while a larger group of compounds inhibit gluconeogenesis *in vitro*. Although no obvious correlation seems to exist between the two groups, a few substituted butanoic acids are effective in both models, especially II*j*, which, in addition to interesting ED_{50} and K_i values, possesses the lowest toxicity of the compounds measured. The inhibition constants of II*d*, *l*, and *n*, relatively nontoxic substances, belong to the lowest K_i values reported.

Synthesis of ω-(4-Aminophenylsulfonamido)alkyl Disulfides and Thiosulfates and their Activity against Dihydropteroate Synthetase from Sulfanilamide-Resistant *Neisseria gonorrhoeae*

WILLIAM O. FOYE ˣ, JOEL M. KAUFFMAN *, and WICHAI SUTTIMOOL ‡

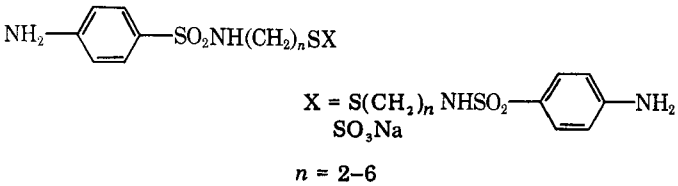
Received June 24, 1981, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication October 19, 1981. Present address: *Department of Chemistry, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104 and the ‡Department of Biochemistry, Chulalongkorn University, Bangkok, Thailand.

Abstract □ A series of ω-(4-aminophenylsulfonamido)alkyl disulfides and ω-(4-aminophenylsulfonamido)alkanethiosulfates was synthesized from the reaction of *p*-acetamidobenzenesulfanilyl chloride and either the aminoalkyl disulfide dihydrobromide or the aminoalkyl bromide hydrobromide followed by sodium thiosulfate. Several of the compounds showed inhibitory activity against dihydropteroate synthetase isolated from a sulfanilamide-resistant strain of *Neisseria gonorrhoeae* of the same order of activity as that of sulfanilamide. An increase in the hydrophobic nature of the sulfanilamide structure did not increase inhibitory activity against this enzyme.

Keyphrases □ ω-(4-Aminophenylsulfonamido)alkyl—disulfides and thiosulfates, synthesis, activity against dihydropteroate synthetase, sulfanilamide-resistant *Neisseria gonorrhoeae* □ *Neisseria gonorrhoeae*—synthesis of ω-(4-aminophenylsulfonamido)alkyl disulfides and thiosulfates, activity against dihydropteroate synthetase, sulfanilamide-resistant □ Dihydropteroate synthetase—synthesis of ω-(4-aminophenylsulfonamido)alkyl disulfides and thiosulfates, sulfanilamide-resistant *Neisseria gonorrhoeae*

The development of bacterial resistance to many of the antibiotics and synthetic antibacterials has reopened the search for synthetic antibacterials, particularly for use against resistant strains of bacteria. The inclusion of a reactive function in the sulfonamide molecule that might lead to an irreversible inhibitor of dihydropteroate synthetase appeared to offer a plausible approach to an agent of this type. The active site of dihydropteroate synthetase is not well defined, but it may be considered, like most enzymes, to contain disulfide bonds between juxtaposed cysteine residues. This provides an accessory receptor site which should bind with functional groups reactive toward disulfides. Accordingly, a series of *N*-sulfonamidoalkyl disulfides and thiosulfates (I) has been synthesized for testing against a drug-resistant organism. A sulfanilamide-resistant strain of *Neisseria gonorrhoeae* was available for this purpose (1). It has been shown (2) that carboxyl groups in the side chains of N_1-substituted sulfanilamides showed relatively high affinities toward a dihydropteroate synthesizing system of *Escherichia coli*, probably by interacting with an accessory area of the enzyme.

It is possible that a sulfonamido disulfide, previously



I

prepared in this laboratory, may have reacted with such an accessory receptor site. Bis[4-(4-acetamidobenzenesulfonamido)phenyl] disulfide was described as curative in mice infected with *Plasmodium berghei* (3). It was considered at the time that this molecule might be acting as a binding agent to DNA, but other related nonsulfonamido containing disulfides with good DNA binding potential showed no antimalarial activity (4).

Previously, other examples of molecules containing both sulfonamide and disulfide functions have been reported: several 4-aminobenzenesulfonamidoaryl disulfides (5) and two 4-aminobenzenesulfonamidoalkyl disulfides, where the alkyl function had two and three methylene units (6). Both series showed some antibacterial properties. No 4-aminobenzenesulfonamidoalkane thiosulfates have been reported as antibacterials.

RESULTS AND DISCUSSION

Chemistry—The synthesis of the 4-aminobenzenesulfonamidoalkyl disulfides is outlined in Scheme I. Reaction of polymethylene dibromides with potassium phthalimide gave the known ω-bromalkylphthalimides, which were separated from byproduct diphthalimides by recrystallization from hexane. Treatment of the bromoalkylphthalimides with sodium thiosulfate gave intermediate thiosulfates which were oxidized *in situ* with iodine to give the disulfides. Although the literature recommends addition of solid iodine (7) for this conversion, a solution of the stoichiometric amount of iodine in methanol was found superior for these compounds.

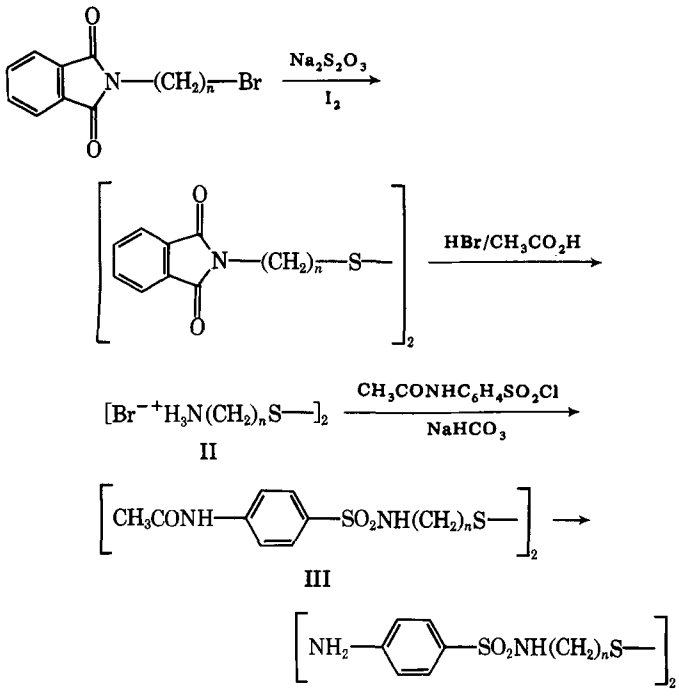
Removal of the phthaloyl groups by hydrazinolysis failed, but the use of hydrobromic acid, mixed with acetic (8) or propionic acid was successful in giving the aminoalkyl disulfide hydrobromides (II).

Sulfonamide formation from *N*-acetylsulfanilyl chloride and amines generally is catalyzed with aqueous sodium hydroxide or carbonate or anhydrous pyridine. Because of the alkali-sensitive disulfide function, these catalysts were unsuitable; the use of sodium bicarbonate gave the desired products. All of the acetamidobenzenesulfonamidoalkyl disulfides (III) were difficult to purify; washing with an aqueous solution of ethanol and acetic acid generally provided good yields of reasonably pure material.

Deacetylation was carried out in a boiling mixture of hydrochloric acid–water–glycol (1:1:2) for 10 min; prolonged heating cleaved the sulfonamide as well. Since the dihydrochlorides of the higher homologs (n = 4–6) were insoluble in hot water, the free amines (IV) were isolated by the action of ammonia on dilute solutions of the dihydrochlorides in hot methanol. With the n = 3 homolog, the free base actually separated from the acid reaction mixture. All of the disulfides had similar IR spectra showing N—H stretching frequencies at 3345–3440 and 3255–3370 cm^{-1}, and S—O stretching at 1322–1406 and 1138–1152 cm^{-1}.

The preparation of the 4-aminobenzenesulfonamidoalkane thiosulfates is outlined in Scheme II. Although the *N*-acetyl derivative of the sulfonamidoethane thiosulfate is known (9), only free amino sulfonamides have shown antifolate activity. Since either acid or basic hydrolysis of the acetyls would decompose the thiosulfate function, the free amino thiosulfates were prepared from the 4-aminobenzenesulfonamidoalkyl

0022-3549/82/0700-0799$01.00/0



n = 2–6

Scheme I

bromides on reaction with sodium thiosulfate. The intermediate amine hydrochloride, where n = 3, was surprisingly insoluble in water. Conversion to the free base gave a water-soluble sodium salt of the desired thiosulfate.

Since the disulfides proved in general to be too insoluble for enzyme inhibition tests, a carboxyl group was introduced for water solubilization by preparing the bis(4-aminobenzenesulfonamido) derivative (V) of L-cystine (10). The melting point of the product (192–194°) agreed with that reported previously (193–194°) (10).

Inhibition of Dihydropteroate Synthetase—Determination of ID_{50} concentrations was carried out for sulfanilamide, sodium *p*-aminobenzenesulfonamidoethane (and -propane) thiosulfate, *N,N'*-bis(sulfanilyl)-L-cystine and *p*-aminobenzenesulfonamidopropyl bromide. The enzyme preparation used was an extract of a sulfanilamide-resistant strain of *N. gonorrhoeae* (1). Results are recorded in Table I.

Results of the inhibition study show that sulfanilamide itself showed the greatest inhibitory activity, although the ID_{50} values for the synthesized compounds fall within the same order of activity. It is possible that the additional bulk of the alkyl functions on the sulfonamide nitrogen reduces the binding ability of the compounds. If this were the case, it would be expected that the disulfide, with a nonlinear carboxyl group, would show the least inhibition. If the inhibition depended on a greater degree of hydrophobicity, then the bromoethyl derivative should have shown a greater inhibitory effect. It is apparent from the results, however, that a disulfide link with enzyme mercapto did not take place.

Since there was very little difference in inhibitory properties between the homologous thiosulfates, and the more hydrophobic bromoethyl derivative had even less activity, it is apparent that additional hydrophobic functions play no significant role in the binding at the receptor site. This finding agrees with a previous report (11) where it was found that inhibition of this enzyme by N_1-phenylsulfonamides was not improved by greater hydrophobicity.

Table I—Inhibition of Dihydropteroate Synthetase

Compound	Concentration range, m*M*	ID_{50}, μM
Sulfanilamide	0–0.6	59
Sodium 4-aminobenzenesulfonamidoethanethiosulfate	0–1.2	106
Sodium 4-aminobenzenesulfonamidopropanethiosulfate	0–1.2	108
N,N'-Bis(sulfanilyl)-L-cystine	0–1.2	160
4-Aminobenzenesulfonamidopropyl bromide	0–1.2	250

Scheme II

EXPERIMENTAL[1]

α-Bromoalkyl-ω-phthalimides—These compounds were prepared esssentially by the method of Klayman *et al.* (12). The crude products were recrystallized from ethyl alcohol, dried, recrystallized from hexane, and cooled at 25° for several hours and then cooled at 3°. Yields of 48–66% were obtained from material which melted at literature values (12).

Bis(ω-Phthalimidoalkyl) Disulfides—The procedure is a modification of that of Dirscherl and Weingarten (7). To a heated solution of water (75 ml), methanol (75 ml), and α-bromoalkyl-ω-phthalimide (0.08 mole) was added 0.08 mole of sodium thiosulfate pentahydrate with stirring. After 1 hr at reflux temperature, the mixture was treated with 10.15 g (0.04 mole) of iodine in 60 ml of methanol during 45 min, followed by 10 min of refluxing. The two-phase system was stirred and cooled; the resulting solid was ground in a mortar, slurried with 150 ml of water for 1 hr, filtered, and dried. Yields of 89–95% were obtained from material whose melting points agreed with literature values (7, 8).

ω,ω'-Dithioalkanamine Dihydrobromides (II)—A mixture of 0.04 mole of the appropriate bis(ω-phthalimidoalkyl) disulfide, 22 ml of 48% hydrobromic acid, and either 22 ml of acetic acid (for n = 3, 4) or 22 ml of propionic acid (for n = 5, 6) was refluxed for 24 hr. The hot orange liquid was poured into 50 ml of water and kept overnight at 25°. Phthalic acid was removed by filtration, and the filtrates were freed from acids by rotary evaporation. The residue was slurried with 40 ml of water and 0.3 g of activated charcoal and filtered, and the filtrate was slurried with 25 ml of water and evaporated to dryness. The residue was dissolved in 50–100 ml of hot ethyl alcohol, cooled to 25°, and treated with 50–200 ml of ether. The isolated solid was washed with ether and dried. Physical constants of products are listed in Table II.

ω-(4-Acetamidophenylsulfonamido)alkyl Disulfides (III)—Purified *N*-acetylsulfanilyl chloride (mp 144–149°) (17.53 g, 0.075 mole) was dissolved in 150 ml of acetone, and a solution of 0.035 mole of the appropriate ω,ω'-dithioalkanamine dihydrobromide in 50 ml of water was added with ice cooling the mixture. A solution of 13.45 g (0.16 mole) of sodium bicarbonate in 170 ml of water was added dropwise with stirring below 10° during 40 min. The resulting mixture was heated at 50° for 20 hr, cooled in an ice bath, filtered, and washed with water. The solid was slurried with a solution of 200 ml of water, 100 ml of ethyl alcohol, and 10 ml of acetic acid for 4 hr and filtered. The product was dried over sodium hydroxide at 25°/0.4–1.0 torr for 16–24 hr. Physical constants of products are listed in Table II.

ω-(4-Aminophenylsulfonamido)alkyl Disulfides (IV)—With magnetic stirring, 0.004 mole of the preceding diacetyl derivative, 5 ml of HCl, 5 ml of water, and 10 ml of ethylene glycol were refluxed for 10 min. A thick precipitate of the dihydrochloride was generally obtained, 40 ml of water was added, and the solid was filtered and dried at 25°/0.5–1.5 T for 18 hr over sodium hydroxide. The solid was dissolved in 250 ml of boiling methanol, treated with 0.3 g of activated carbon, and diluted with 10 ml of 4 *N* ammonium hydroxide and 200 ml of water to precipitate the free base. It was filtered and dried as before. Physical constants of products are listed in Table II.

[1] Melting points were determined in capillaries with a Mel-Temp block and needed no correction. IR spectra were taken in KBr pellets using a Perkin-Elmer 457 grating spectrophotometer. Elemental analyses were done by Dr. F. B. Strauss, Oxford, England or by Instranal Laboratory, Rensselaer, N.Y. TLC was carried out using silica gel plates and exposure to iodine vapor. Organic reagents were supplied by Aldrich Chemical Co. or by Eastman Organic Chemicals. [7-^{14}C]*p*-Aminobenzoic acid (>95% radiochemical purity) was obtained from New England Nuclear Corp., Boston, Mass. Measurement of enzyme inhibition was done with a Packard Liquid Scintillation Spectrometer, model 3320. Frozen cells of sulfanilamide-resistant *Neisseria gonorrhoeae* strain 7134 were supplied by Johnna Ho, Harvard University School of Public Health.

[a] Lit. (6) mp 232°. [b] Lit. (7) mp 240°. [c] Commercially available 2,2′-dithiobisethanamine dihydrochloride was used as reagent instead of the hydrobromide. [d] Lit. (6) mp 194–196.5°. [e] Lit. (6) mp 162–163°. [f] Lit. (6) mp 129°. [g] Lit. (6) mp 154.5–155.5°. [h] Lit. (10) mp 193–194°.

2-(4-Acetamidophenylsulfonamido)ethyl Bromide—This was prepared from *N*-acetylsulfanilyl chloride and 2-bromoethylamine hydrobromide[2] by the same general procedure used for the ω-(4-acetamidophenylsulfonamido)alkyl disulfides. The crude product was slurried with aqueous sodium bicarbonate, filtered, and dried to give a 77% yield of material melting at 168–169° [lit. (13) mp 168–169°].

2-(4-Aminophenylsulfonamido)ethyl Bromide—The previous compound (9.63 g, 0.03 mole), 10 ml of 38% HCl, and 10 ml of 95% ethyl alcohol were refluxed for 30 min and diluted with 125 ml of water. The solution was decolorized with activated carbon and neutralized with sodium bicarbonate; the free base was filtered, slurried with 100 ml of water, filtered, and dried at 25°/0.8 torr for 20 hr to give an 84% yield of tan solid, mp 87.5–88.5° [lit. (14) mp 90–91°].

Sodium 2-(4-Aminophenylsulfonamido)ethanethiosulfate—A mixture of 5.97 g (0.024 mole) of sodium thiosulfate pentahydrate, 6.72 g (0.024 mole) of the previous product, 25 ml of methanol, and 25 ml of water was refluxed for 30 min and cooled to 25°. Solvent was removed by rotary evaporation, and the resulting solid was dried further by evaporation of 2 × 25 ml of absolute ethanol. The residue was shaken with 15 ml of dimethylformamide, cooled overnight, and the insoluble sodium bromide was removed. The filtrate was diluted with 50 ml of acetone, filtered after several hours, and the residue was dried at 20°/0.3 torr for 16 hr to give 8.81 g of crude solid, mp 178–182°. Recrystallization from 95% ethyl alcohol at −20° gave a 44% yield of colorless solid, mp 207.5–209°(dec), which gave a negative test for halogen.

Anal.—Calc. for $C_8H_{11}N_2NaO_5S_3$: C, 28.73; H, 3.32; N, 8.38; S, 28.77. Found: C, 28.76; H, 3.17; N, 8.39; S, 28.39.

3-(4-Acetamidophenylsulfonamido)propyl Bromide—This compound was prepared by the same method used for 2-(4-acetamidophenylsulfonamido)ethyl bromide, from *N*-acetylsulfanilyl chloride and 3-bromopropylamine (8). After heating, the solution was decolorized with activated carbon, diluted with 200 ml of water, and cooled to 3° before filtration to give a crude product that was recrystallized from 50% ethyl alcohol to give a 64% yield of tan prisms, mp 104–105.5°.

Anal.—Calc. for $C_{11}H_{15}BrN_2O_3S$: C, 39.41; H, 4.51; Br, 23.84. Found: C, 39.61; H, 4.20; Br, 24.10.

3-(4-Aminophenylsulfonamido)propyl Bromide—The previous compound (16.00 g, 0.048 mole), 20 ml of 38% HCl, and 20 ml of 95% ethyl alcohol were refluxed for 30 min, and the solid mass was transferred to a beaker with 100 ml each of water and 95% ethyl alcohol. After being heated, the solution was decolorized with activated carbon, cooled to 25°, and neutralized with sodium bicarbonate. The free base was filtered, slurried with 100 ml of water, and dried at 23°/0.2 torr for 16 hr to give 9.45 g (68%) of shiny, white prisms, mp 106–106.2°.

Anal.—Calc. for $C_9H_{13}BrN_2O_2S$: C, 36.86; H, 4.47; Br, 27.26; S, 10.94. Found: C, 37.05; H, 4.43; Br, 27.54; S, 10.75.

Sodium 3-(4-Aminophenylsulfonamido)propanethiosulfate—A mixture of 1.29 g (0.0052 mole) of sodium thiosulfate pentahydrate, 1.52 g (0.0052 mole) of the previous product, 5 ml of methanol, and 5 ml of water was refluxed for 25 min, cooled, and freed of solvent by rotary evaporation. After further evaporation with 5 ml of absolute ethanol, the remaining gum was leached with 20 ml of 97.5% ethyl alcohol and cooled overnight. The solid sodium bromide was removed, and the filtrate was diluted with 30 ml of 1-propanol and cooled to −20° to give 0.9 g of white solid, which was recrystallized from 18 ml of 95% ethyl alcohol at −20° to give 0.6 g (33%) of white prisms, mp 212.5–213.5°.

Anal.—Calc. for $C_9H_{13}N_2NaO_5S_3$: C, 31.02; H, 3.78; N, 8.04. Found: C, 31.29; H, 3.64; N, 8.05.

Determination of Enzyme Inhibition—ID_{50} values for the inhibition of dihydropteroate synthesis using a cell-free extract of dihydropteroate synthetase from *N. gonorrhoeae* (1) were determined for the test compounds using six inhibitor concentrations in duplicate experiments. The ID_{50} value was taken from the plot of the percent inhibition against the logarithm of the inhibitor concentration.

Solutions of the test compounds were made to contain the following components in a 200-μl volume: tris(hydroxymethyl)aminomethane hydrochloric acid buffer (140 m*M*, pH 5.8), dihydropteridine pyrophosphate (7 μ*M*) (15), [7-^{14}C]*p*-aminobenzoic acid (15 μ*M*), magnesium chloride hexahydrate (5 m*M*), 2-mercaptoethanol (0.1 *M*), test compound (0–1.2 m*M*), and enzyme (0.14 mg of protein). The reaction mixture without dihydropteridine pyrophosphate served as blank. After the mixture was incubated at 37° for 20 min, the reaction was stopped by the addition of 2-mercaptoethanol (20 μl). The amount of labeled dihydropteroate was measured as follows.

A portion (100 μl) of the reaction mixture was spotted on 3-mm chromatographic paper[3] (22.86 × 29.21 cm). The chromatogram was developed in descending fashion by immersing the lower margin of the paper in potassium phosphate buffer (0.1 *M*, pH 7.0) inside a chamber at room temperature. After the solvent front had moved 15 cm from the origin, the paper was removed and dried. Neither the labeled dihydropteroate nor the labeled pteroate moved under these conditions, whereas unreacted [7-^{14}C]*p*-aminobenzoic acid migrated with an R_f of 0.78. An area (3 × 3 cm) of the paper around the origin was cut into small pieces and put into a counting vial containing 10 ml of scintillation fluid consisting

of the following in a volume of 1 liter: naphthalene (150 g), 2,5-diphenyloxazole (8 g), 1,4-bis(4-methyl-5-phenyl-oxazol-2-yl)benzene (0.6 g), ethylene glycol (20 ml), 2-ethoxyethanol (100 ml), and toluene to make 1 liter. The radioactivity was measured in the liquid scintillation counter with an 18% gain setting. Each vial was counted twice, and the data represent the average of two counts. Results are shown in Table I.

Optical Purity Determination by NMR: Use of Chiral Lanthanide Shift Reagents and a Base Line Technique

G. H. DEWAR *x, J. K. KWAKYE *§, R. T. PARFITT *‡, and R. SIBSON ‡

Received June 10, 1981, from the **School of Pharmacy and Pharmacology* and ‡*School of Mathematics, University of Bath, Claverton Down, Bath, England BA2 7AY.* Accepted for publication October 6, 1981.

§ Present address: Faculty of Pharmacy, University of Science and Technology, Kumasi, Ghana, West Africa.

Abstract □ A method for optical purity determination of a range of chiral drug molecules by NMR spectroscopy is reported. This technique involves the use of optically active lanthanide shift reagents and a newly developed base line analysis. Its applicability was demonstrated for a variety of drugs including nonsteroidal antiinflammatory agents and some adrenergic agents. It is established that successful application of the method depends on a constant shift reagent to sample molar ratio, constant instrumental conditions for all solutions, and the use of a calibration curve derived from solutions containing the same total concentration of the two enantiomers. For the examples cited, the correlation coefficient is not <0.97, and a mathematical treatment is included which supports the basis of the method.

Keyphrases □ Optical purity determination—by NMR spectroscopy, use of chiral lanthanide shift reagents and a base line technique □ Chiral lanthanide shift reagents—determination of optical purity by NMR spectroscopy, base line technique □ NMR spectroscopy—determination of optical purity, use of chiral lanthanide shift reagents and a base line technique

The application of NMR spectroscopy to the quantitative analysis of pharmaceuticals has become widespread (1, 2) since the publication of Hollis (3) on the determination of aspirin, phenacetin, and caffeine mixtures. Provided that careful consideration is given to solvent, internal standard, and instrumental conditions (including spinning sidebands and carbon 13 satellites), mixtures, often of some complexity, can be analyzed with a high degree of accuracy. Optical purity determination is another aspect of the analysis of any drug presented in a resolved form (enantiomer) or the racemate of a particular diastereoisomer. Apart from polarimetry, which has been extensively employed despite its drawbacks, optical purity determination has been achieved by chromatographic methods such as GLC (4, 5) and HPLC (6, 7), isotope dilution (8), kinetic resolution (9), and NMR. Even before the discovery of chiral lanthanide shift reagents, the NMR method was used for optical purity measurement either by diastereoisomer formation (10, 11) or the application of chiral solvents (12, 13). Since the publication of Whitesides and Lewis (14) on the relatively large frequency differences between corresponding resonances of enan-

tiomeric amines in the presence of 3-(*tert*-butylhydroxymethylene)-*d*-camphorato europium, much attention has been given to the use of the method in routine optical purity determination (15). The problem with this approach is the difficulty in achieving complete separation of corresponding resonances of the enantiomers before serious line broadening occurs. The purpose of this report is to describe a method of optical purity determination which does not require complete separation of resonance indicative of each enantiomer in a mixture.

EXPERIMENTAL[1]

Materials—Hydrochloride or sulfate salts of (±)-, (+)-, and (−)-ephedrine[2] and (−)-ephedrine base[2] were used, as well as (±)-, (+)-, and (−)-propranolol hydrochloride[3]; (±)-, *S*(+)-, and *R*(−)-albuterol sulfate[4]; (±)-, (+)-, and (−)-ibuprofen[5]; (±)-, (+)-, and (−)-naproxen[6]; (±)- and (+)-ketoprofen[7]; and (±)- and (−)-fenoprofen calcium[8].

The lanthanide shift reagents tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium (I)[9], tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)praseodymium (II)[9], tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato], europium (111) derivative (III)[9], and tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato], praseodymium (111) derivative (IV)[9] were stored over phosphorus pentoxide in a desiccator.

NMR: Determination of Lanthanide Induced Shifts[10]—A solution (~0.2–0.4 *M*) of the racemic compound in the appropriate solvent (0.7 ml) was prepared and the NMR spectrum recorded. Compound I or II in quantities of 10–20 mg was added incrementally and the spectrum recorded after each addition.

Optical Purity Determination[10]—Different quantities of (+)- and (−)-isomers, or alternatively the racemate and either pure isomer or suitable derivatives, were mixed to give differing optical purities, but approximately the same final concentration of total drug when dissolved in the appropriate solvent (0.7 ml). The quantity of chiral lanthanide shift reagent necessary to give the desired shift reagent: drug molar ratio was added (see text and Tables II, III, and V–VIII for explanation and data) and the NMR spectrum of the various solutions recorded under identical instrumental conditions.

Derivatives[11]—*Ketoprofen Methyl Ester*—(±)-Ketoprofen (50 mg) in a mixture of methanol (20 ml) and concentrated hydrochloric acid (1 ml) was refluxed for 1 hr. Evaporation to dryness *in vacuo* gave an oil sufficiently pure for use in subsequent NMR analyses. IR (ν_{max}): 1740, 1690, 1590, and 1500 cm^{-1}; NMR ($CDCl_3$): δ 1.40 (3H, d, C—CH_3), 3.60 (3H, s, $COOCH_3$), 3.62 (1H, q, CH—CH_3), and 7.20–7.90 (9H, m, Ar—*H*) ppm.

Fenoprofen Methyl Ester—(±)-Fenoprofen calcium salt (0.5 g) was dissolved in warm methanol (40 ml), and concentrated hydrochloric acid (1 ml) was added. Concentration of the solution *in vacuo* and extraction with ether (3 × 15 ml) gave the ester as an oil. IR (ν_{max}): 1735, 1590, and 1500 cm^{-1}; NMR ($CDCl_3$): δ 1.48 (3H, d, CH—CH_3), 3.61 (3H, s,

[1] All NMR spectra were recorded on a Perkin-Elmer R12B instrument operating at 60 MHZ with a probe temperature of 37 ± 1°. Unless otherwise stated, tetramethylsilane was employed as internal standard. Abbreviations used in the experimental section to describe resonance appearance are as follows: s, singlet; d, doublet; dd, double doublet; q, quartet; m, multiplet. Solvents were dried over molecular sieve type 4A. IR spectra, obtained as liquid films or as potassium chloride discs (for solids), were recorded on a Pye Unicam SP200 instrument. Low resolution mass spectra were obtained from an automatic electron impact mass spectrometer 12 instrument at 70 eV.

[10] Ephedrine and propranolol proton salts were converted to the corresponding free amine by basifying an aqueous solution of the salt with 5 *M* NaOH. Ether or chloroform extraction was performed rapidly in the usual way. Final drying of samples was achieved *in vacuo* at 50°.

[11] The corresponding derivatives of optically pure material were similarly prepared.

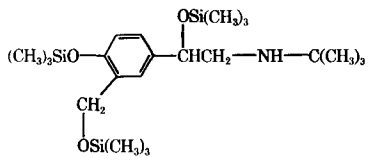
Table III—Application of the Base Line Technique to Ephedrine [a] of Varying Optical Purity

Optical Purity[b], %	Separation[c], mm	$\left(1 - \frac{\text{optical purity}}{100}\right)$
0.0	4.70	1.00
25.6	3.80	0.74
47.3	2.71	0.53
76.0	1.48	0.24

[a] Ephedrine concentration of 0.30 *M* and shift reagent IV–drug molar ratio of 0.216 in deuterated benzene. [b] An optical purity of 0.00 refers to the racemate. The difference between the percentage of the two isomers in a mixture is the percent optical purity. Thus, a sample containing 99% (+)- and 1% (−)-isomer is 98% optically pure. If the percent optical purity is X, then that isomer enriched in the mixture has a percentage given by (X + 100)/2. [c] Using C—CH_3 signal at δ −1.0–−1.5 ppm.

$COOCH_3$), 3.62 (1H, q, CH—CH_3), and 6.72–7.53 (9H, m, Ar—*H*) ppm.

Albuterol Tri(trimethylsilyl)ether (*V*)—(±)-Albuterol (60 mg) was



V

heated with *N,N*-bis-trimethylsilyltrifluoroacetamide (VI; 0.4 ml) at 130° for 15 min. The excess of VI and trifluoroacetamide were removed *in vacuo* at 50° to leave V as an oil. IR (ν_{max}): 3000, 1620, and 1508 cm^{-1}; NMR [$CDCl_3$; most shielded $(CH_3)_3Si$ 9H singlet resonance taken as δO]: δ 0.11 [9H, s, $(CH_3)_3Si$], 0.25 [9H, s, $(CH_3)_3Si$], 1.05 [9H, s, $—C(CH_3)_3$], 2.41–2.76 (3H, m, N*H* + CH_2N—, deuterated water reduces to 2H), 4.61–4.76 (3H, m, O—CH_2Ar + $ArCH$—), and 6.60–7.47 (3H, m, Ar—*H*) ppm. Distillation of the oil gave a fraction, bp 140–142°/0.8 mm Hg, of analytical purity; mass spectrum: *m/z* (%), 457 (2), 442 (5.7), 370 (34), 368 (98), 192 (3.4), 148 (18), and 147 (100).

Anal.—Calc. for $C_{22}H_{45}NO_3Si_3$: C, 58.3; H, 9.9; N, 3.1; Si, 18.5. Found[12]: C, 57.9; H, 9.9; N, 3.7; Si, 18.0.

***N*-Acetylpropranolol**—Freshly distilled acetic anhydride (0.3 ml) was added to (±)-propranolol (0.85 g) in tetrahydrofuran (5 ml) and the mixture stirred for 15 hr. The solvent was removed *in vacuo* and the residue dissolved in chloroform (20 ml). The organic layer was washed with 0.1 *M* HCl (10 ml), 0.1 *M* NaOH (10 ml), and then evaporated in the usual way. The residual oil crystallized from petroleum ether (40–60)–ether (1:3) as colorless needles of (±)-*N*-acetylpropranolol. Recrystallization from the same solvent mixture gave a sample (0.45 g; 46%) mp 104°[13], suitable for analysis. IR (ν_{max}): 2950, 1690, 1603, and 1470 cm^{-1}; NMR ($CDCl_3$): δ 1.11–1.42 (6H, overlapping dd, $—CH(CH_3)_2$) 2.07 (3H, s, $COCH_3$), 3.41–4.27 (7H, m, $ArOCH_2$ + $CH(OH)$ + CH_2NCO + $CONCH$), and 6.73–8.34 (7H, m, Ar—*H*) ppm.

RESULTS AND DISCUSSION

It was routine practice in this work to study the influence of the nonchiral shift reagents of I and II[9] on the NMR resonances of racemic molecules, before attempting to use the much more expensive chiral shift reagents, III and IV. Table I shows the lanthanide induced shift for 0.45 *M* (±)-ephedrine in deuterated benzene at varying II–ephedrine and I–ephedrine ratios. By this means it was possible to demonstrate the susceptibility of quantitatively important groups such as C—CH_3 and N—CH_3, which show sharp lines, to the shifting influence of the lanthanide agents. The absence of serious line broadening of the various

[12] Elemental analyses were performed by Butterworth Laboratories Ltd., Teddington, Middlesex, U.K.

[13] Melting points, which are uncorrected, were obtained on a Gallenkamp melting point apparatus Number 889339, supplied by Gallenkamp, Birmingham, U.K.

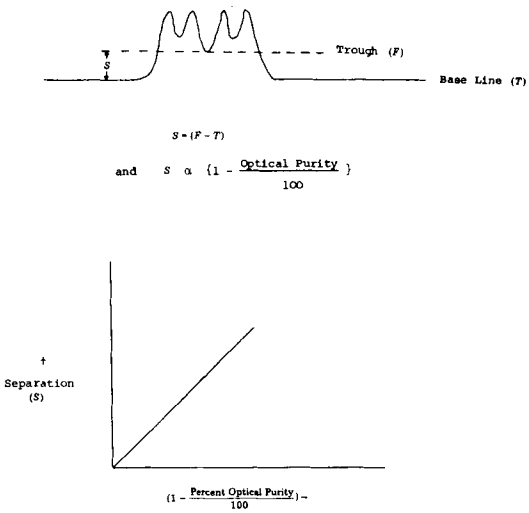


Figure 2—*The base line technique.*

resonances of (±)-ephedrine even at I–drug molar ratio of 0.292, was also observed. A plot of lanthanide induced shift (ppm) against lanthanide agent–ephedrine molar ratio for both nonchiral shift agents yields a linear standard curve for the important C—CH_3 and N—CH_3 groups in the concentration range studied (Table I). The magnitude of observed shifts for N—CH_3 and C—CH_3 in ephedrine, particularly with agent II, indicated their potential use in experiments with chiral lanthanide compounds.

Table II gives data for shifts and differential shifts of the (+)- and (−)-isomers of ephedrine in deuterated benzene in the presence of IV and III. The change in spectral appearance in the δ 1.75–2.10 (N—CH_3) region for 0.4 *M* (±)-ephedrine in deuterated benzene by addition of increasing quantities of III is shown in Fig. 1. Thus, the complexation of the optically active shift reagent with (+)- and (−)-ephedrine gives diastereoisomeric species with slightly different chemical shifts for corresponding groups within the drug molecule. In this case, the relatively large ΔΔv value of 0.33 for the overlapping C—CH_3 doublets at a molar ratio of 0.212 IV–drug, even though line broadening was slightly greater than with III, made IV the shift reagent of choice. It has been observed that for ephedrine, studied under the conditions shown in Table III and in the examples subsequently cited, the distance between the true base line (*T*, Fig. 2) and the trough between the overlapping resonances associated with corresponding groups in the two isomers (*F*, Fig. 2) is proportional to (1 − percent optical purity/100). The distance (*F* − *T*) is *S*, the separation. The principles of this base line technique are outlined, as applied to the analysis of the overlapping C—CH_3 doublets of ephedrine, in Fig. 2. An appropriate calibration curve then allows a sample of unknown optical purity to be determined.

The successful application of the method depends on three important factors:

1. The use of solutions containing a constant shift reagent–drug molar ratio once that ratio has been selected.
2. Determination under constant instrumental conditions for all solutions.
3. The use of a standard total concentration of the two isomers in the

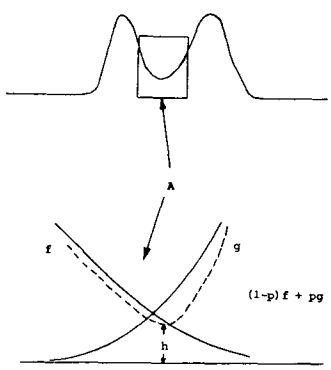

Figure 3—*Mathematical analysis of the overlapping portion of curves similar to the response appearance obtained in the base line technique.*

mixture for the calibration curve. In practice the concentration need not be the same for all solutions studied, provided that appropriate conversion to the standard concentration is effected for purposes of calibration.

It is considered that the relaxation phenomena associated with corresponding groups in such a diastereoisomeric complex need not necessarily be identical, and consequently, a mathematical analysis has been applied to similar overlapping curves. This is presented to support the basis of the method (Fig. 3):

In the region of the minimum (A), suppose that the left hand curve is $f(x)$, the right hand curve is $g(x)$; when it is assumed that $f' < 0, g' > 0$, $f'' > 0, g'' > 0$, and f, g such that for all relevant p, $(1 - p)f + pg$ has a minimum.

Suppose the minimum is at z, with a minimal value, h. The consequence of perturbing p to $(p + \delta p)$ is then considered. Write $\phi(x)$ for $(1 - p)f(x) + pg(x)$. Thus, z is governed by $\phi'(z) = 0$. Therefore:

$$(1 - p)f'(z) + pg'(z) = 0 \qquad \text{(Eq. 1)}$$

Thus, to find δz:

$$(1 - p - \delta p)f'(z + \delta z) + (p + \delta p)g'(z + \delta z) = 0 \qquad \text{(Eq. 2)}$$

where:

$$\phi'(z + \delta z) + \delta p[g'(z + \delta z) - f'(z + \delta z)] = 0 \qquad \text{(Eq. 3)}$$

And on expanding and using $\phi'(z) = 0$

$$\phi''(z)\delta z + 0(\delta z^2) + \delta p[g'(z) - f'(z) + 0(\delta z)] = 0 \qquad \text{(Eq. 4)}$$

Table V—Shift Data for (+)- and (−)-*N*-Acetylpropranolol[a] Using Reagent III

Molar Ratio	(+)-isomer δ	(+)-isomer Δν	(−)-isomer δ	(−)-isomer Δν	ΔΔ[b], ppm
0.000	2.10	0.00	2.10	0.00	0.00
0.183	3.07	0.97	2.92	0.82	0.15
0.276	3.64	1.54	3.42	1.32	0.22
0.367	4.15	2.05	3.87	1.77	0.28
0.521	4.70	2.60	4.39	2.29	0.31

[a] Concentration of 0.25 M acetylated drug in carbon tetrachloride, using $COCH_3$ signal. [b] Using the same shift reagent, the ΔΔν values in deuterated benzene and deuterated chloroform at ~0.5 molar ratios were 0.15 and 0.02 ppm, respectively.

Table VI—Application of the Base Line Technique to *N*-Acetylpropranolol[a] of Varying Optical Purity

Optical Purity, %	S[b], mm	$\left(1 - \frac{\text{optical purity}}{100}\right)$
0.0	4.90	1.00
24.9	3.90	0.75
50.4	2.80	0.50
75.4	1.40	0.25
100.0	0.20	0.00

[a] Concentration of 0.248 M in carbon tetrachloride, using agent III–acetylated drug molar ratio of 0.40. [b] Resonance of $COCH_3$ at δ3.9–4.2 ppm employed in the analysis.

where:

$$\delta z = \frac{-[g'(z) - f'(z)]}{\phi''(z)}\delta p + 0(\delta p^2) \qquad \text{(Eq. 5)}$$

Therefore:

$$h + \delta h = (1 - p - \delta p)f(z + \delta z) + (p + \delta p)g(z + \delta z)$$
$$= \phi(z + \delta z) + \delta p[g(z + \delta z) - f(z + \delta z)] \qquad \text{(Eq. 6)}$$

and:

$$\delta h = \phi'(z)\delta z + \tfrac{1}{2}\phi''(z)\delta z^2 + 0(\delta z^3) + \delta p\{[g(z) - f(z)] + [g'(z) - f'(z)]\,\delta z + 0(\delta z^2)\}$$
$$= \{\phi'(z)\delta z + [g(z) - f(z)]\delta p\} + \tfrac{1}{2}\phi''(z)\delta z^2 + [g'(z) - f'(z)]\delta p\delta z + 0(\delta p\delta z^2\delta z^3)\}$$
$$= [g(z) - f(z)\delta p] + \left\{\tfrac{1}{2}\phi''(z)\frac{[g'(z) - f'(z)]^2}{\phi''(z)^2} + [g'(z) - f'(z)]\frac{-g'(z) - f'(z)]}{\phi''(z)}\right\}\delta p^2 + 0(\delta p^3)$$
$$= [g(z) - f(z)]\delta p - \tfrac{1}{2}\frac{[g'(z) - f'(z)]^2}{\phi''(z)}(\delta p)^2 + 0(\delta p^3)$$

[note that $\phi'(z) = 0$] (Eq. 7)

Thus, δh is approximately linearly related to δp, with coefficient $g(z) - f(z)$, but the quadratic term does not vanish, and indeed the coefficient:

$$-\frac{[g'(z) - f'(z)]^2}{\phi''(z)}$$

need not even be particularly small; it is known that $g' < 0$ and $f' < 0$.

Results for the application of the base line technique to ephedrine of varying optical purity are shown in Table III and the corresponding calibration plot[S *versus* (optical purity/100)] yields a standard linear curve.

In accordance with previous work (16), the lanthanide induced shift produced by nonchiral and chiral shift reagents was found to be altered by dilution of prepared samples with more solvent. For a fixed shift reagent–ephedrine molar ratio, incremental addition of deuterated benzene caused a downfield shift proportional to the amount of solvent added.

Table VII—Application of the Base Line Technique to V[a]

Optical Purity, %	S[b], mm	$\left(1 - \frac{\text{optical purity}}{100}\right)$
0.0	7.00	1.00
25.0	5.20	0.75
50.0	3.70	0.50
75.3	1.80	0.25
100.0	0.15	0.00

[a] Concentration of 0.188 M in carbon tetrachloride employing III–derivatized drug molar ratio of 1.20. [b] ΔΔν (ppm) values of 7.8, 4.8, and 6.5 were obtained at III–drug derivative molar ratios of 1.20 in carbon tetrachloride, deuterated chloroform, and deuterated benzene, respectively. The analytical peak was that for $ArCH_2OSi\leqslant$ in all three cases, but least line broadening occurred in carbon tetrachloride.

Table VIII—Application of the Base Line Technique to Various Nonsteroidal Anti-inflammatory Agents or Their Derivatives

	Optical Purity, %	S, cm	$\left(1 - \frac{\text{optical purity}}{100}\right)$
Ibuprofen[a]	0.0	0.59	1.00

	70.1	0.79	0.30
	100.0	0.40	0.00
Ketoprofen methyl ester[c]	0.0	0.90	1.00
	20.0	0.72	0.80
	45.0	0.48	0.55
	70.0	0.27	0.30
	78.0	0.19	0.22
Fenoprofen methyl ester[d]	0.0	1.80	1.00
	20.0	1.45	0.80
	55.0	0.86	0.45
	80.0	0.46	0.20

[a] Concentration of drug used was 0.23 *M* in carbon tetrachloride, using III–drug molar ratio of 0.366. The analytical peak was $ArCHCH_3$ in the region δ3.14–3.52 ppm. [b] Drug concentration was 0.29 *M* in deuterated chloroform–carbon tetrachloride (3:4), using III–drug molar ratio of 0.355. The analytical peak was at δ1.80–2.60 ppm ($ArCHCH_3$). [c] Drug derivative concentration was 0.30 *M* in carbon tetrachloride, using III–ester molar ratio of 0.406. The analytical peak was $ArCHCH_3$ in the region δ1.90–2.15. [d] Concentration of derivatized drug was 0.215 *M* in carbon tetrachloride using III–ester molar ratio of 0.919. The analytical peak was the $COOCH_3$ resonance in the δ5.20–5.30 region.

Higher molar ratios produced greater downfield shifts. Table IV shows results for two different molar ratios, using I as shift reagent, on successive addition of 0.1 ml volumes of deuterated benzene to a mixture prepared in 0.7 ml of the same solvent.

Data obtained on application of the base line technique to *N*-acetylpropranolol, compound V, ibuprofen, naproxen, ketoprofen methyl ester, and fenoprofen methyl ester are presented in Tables V–VIII and the corresponding calibration curves, when plotted, are linear. Appropriate derivatization was required in those cases of poor solubility of the parent drug in the solvents available, or where the number of points of complexation with the shift reagent was large, with consequent line broadening.

If authentic, optically pure samples of a drug are available, this method offers a useful means of routine optical purity determination up to ~90% optical purity. The susceptibility of a molecule to pseudocontact shifting influences of a lathanide agent can be quickly established using a nonchiral compound, and the appropriate shift reagent–drug molar ratio necessary in a given case found from incremental addition of the shift reagent (Table II).

It has also been observed that, in certain cases, the peak height difference (δh) of overlapping resonances from corresponding groups of optical isomers in the presence of a chiral shift reagent bears a linear relationship to optical purity up to levels of ~50%. However, there was little success in establishing optical purity at levels >50%. The instrumental and other conditions necessary for successful application of the base line technique similarly apply to the peak height difference method.

Liposome Dialysis for Improved Size Distributions

MARK E. BOSWORTH, C. ANTHONY HUNT ˣ, and DOUGLAS PRATT

Received May 22, 1981 from the *School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 13, 1981.

Abstract □ A technique is described which allows reproducible preparation of liposomes with improved size–frequency distributions. The recent procedure of extrusion of crude liposome dispersions through controlled-pore polycarbonate membranes is used to control the upper limit of liposome diameter. Subsequent dialysis, using the same type of membrane, can remove the majority of liposomes smaller than a predetermined size. The pattern of dialysis of a liposome preparation is a function of the size–frequency distribution (as well as the membrane pore size) and can be used to approximate the distribution and/or used to monitor the reproducibility of liposome preparations.

Keyphrases □ Liposomes—dialysis for improved size–frequency distribution □ Polycarbonate membranes—dialysis of liposomes, size–frequency distribution □ Dialysis—liposomes, improved size–frequency distribution □ Distribution—size–frequency, liposome dialysis

It is recognized that liposome properties, both as model membranes and drug carrier systems, are dependent on their size (1–4). The differences in the plasma time course and tissue distribution seen between large multilamellar and small unilamellar vesicles are now well established (5), and even different size classes of large multilamellar vesicles can have significantly different pharmacokinetics (6). Unfortunately, the size distribution of the original multilamellar preparation previously described (7) is very heterogeneous and poorly reproducible. The use of this

Liposome Dialysis for Improved Size Distributions

MARK E. BOSWORTH, C. ANTHONY HUNT ˣ, and DOUGLAS PRATT

Received May 22, 1981 from the *School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 13, 1981.

Abstract □ A technique is described which allows reproducible preparation of liposomes with improved size–frequency distributions. The recent procedure of extrusion of crude liposome dispersions through controlled-pore polycarbonate membranes is used to control the upper limit of liposome diameter. Subsequent dialysis, using the same type of membrane, can remove the majority of liposomes smaller than a predetermined size. The pattern of dialysis of a liposome preparation is a function of the size–frequency distribution (as well as the membrane pore size) and can be used to approximate the distribution and/or used to monitor the reproducibility of liposome preparations.

Keyphrases □ Liposomes—dialysis for improved size–frequency distribution □ Polycarbonate membranes—dialysis of liposomes, size–frequency distribution □ Dialysis—liposomes, improved size–frequency distribution □ Distribution—size–frequency, liposome dialysis

It is recognized that liposome properties, both as model membranes and drug carrier systems, are dependent on their size (1–4). The differences in the plasma time course and tissue distribution seen between large multilamellar and small unilamellar vesicles are now well established (5), and even different size classes of large multilamellar vesicles can have significantly different pharmacokinetics (6). Unfortunately, the size distribution of the original multilamellar preparation previously described (7) is very heterogeneous and poorly reproducible. The use of this

0022-3549/82/0700-0806$01.00/0

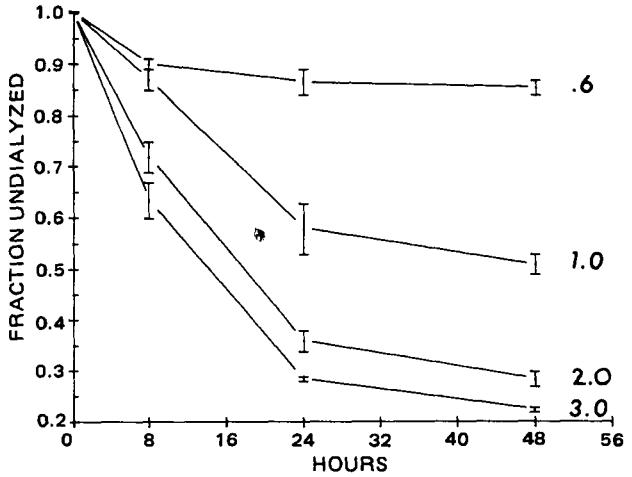

Figure 1—*The fraction of liposomes remaining in the dialysis cells is plotted* versus *time for a suspension [10 μmoles (total lipid)/ml] of mechanically dispersed liposomes dialyzed against either a 0.6-, 1.0-, 2.0-, or 3.0-μm pore-size membrane. Liposomes were quantified by measuring [^{14}C]cholesterol included in the membrane. The vertical bars give the range for duplicate runs using one preparation.*

preparation for *in vivo* tissue distribution studies may mask some differential effects of size. Indeed, complex blood level time courses have been attributed by some investigators to the heterogeneous size distribution of the administered liposomes (4).

Several procedures have attempted to improve the size distribution or encapsulation efficiency of the liposome preparation: sonication and centrifugation (8, 9), detergent dialysis (10–12), injection methods (13–15), French pressure cell (16, 17), reversed-phase evaporation (18), and others (19–21). All suffer from at least one of three faults: (*a*) the resulting size range is too wide or unpredictable; (*b*) the method produces liposomes in only one size range; or (*c*) there are restrictions on composition or specific solutes. However, a significant improvement in size distribution can be obtained by extrusion of a heterogeneous population through straight bore pore polycarbonate membranes of defined pore size (22, 23); this technique defines the upper size limit for the population but does not

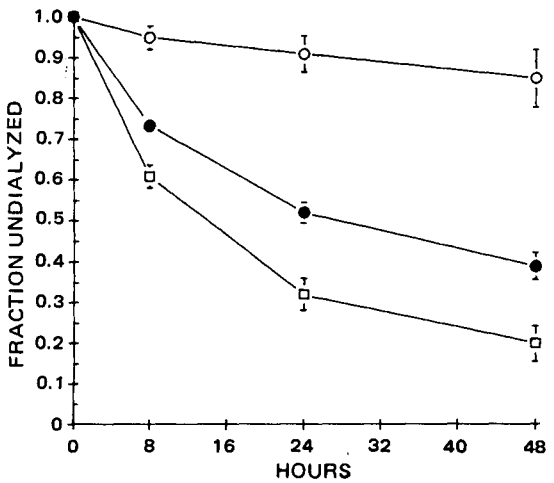

Figure 2—*The fraction of liposomes remaining in the dialysis cells is plotted* versus *time for a suspension [10 μmoles (total lipid)/ml] of small unilamellar French press liposomes dialyzed against either a 0.05 (○), 0.1 (●), or 0.2 (□) μm pore-size membrane. Liposomes were quantified as described in Fig. 1. The values are the means ± 1 SD for four preparations.*

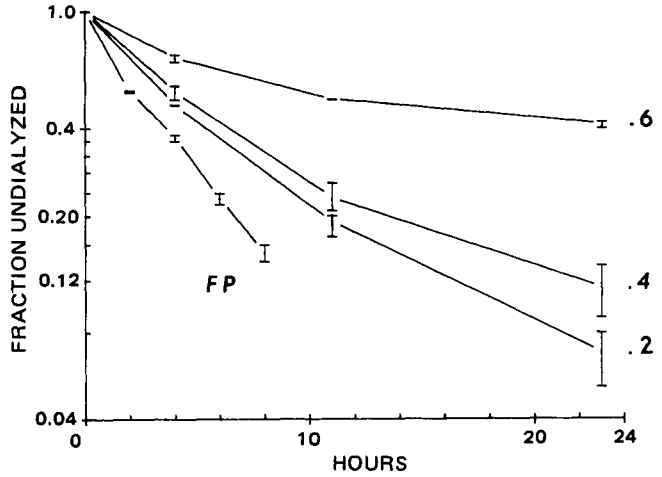

Figure 3—*The fraction of liposomes remaining in the dialysis cells is plotted* versus *time for four different batches of liposomes dialyzed against a 0.8-μm membrane. Liposome concentration and quantitation were as described in Fig. 1. The three upper curves are for liposomes prepared by two extrusions (see text) of mechanically dispersed liposomes through 0.6-, 0.4-, and 0.2-μm membranes. The lower curve is for French press liposomes. The vertical bars give the range for two preparations.*

affect the lower half of the distribution (control of the smaller size may be critical if liposome pharmacokinetics depend in part on the surface area or number of injected liposomes). In this report an improvement on the extrusion technique is described in which the extruded liposomes are subsequently dialyzed with the same type membrane with the object of removing a fraction of the smaller liposomes, thus narrowing the size distribution from its lower end.

EXPERIMENTAL

Chemicals—Purified egg yolk phosphatidylcholine (I), sodium dipalmitoyl phosphatidate (II), cholesterol (III), and α-tocopherol (IV) were chromatographic grade[1], as were sucrose [U-^{14}C] and cholesterol [4-^{14}C][2]. A universal scintillation reagent[3] was used. All other chemicals were

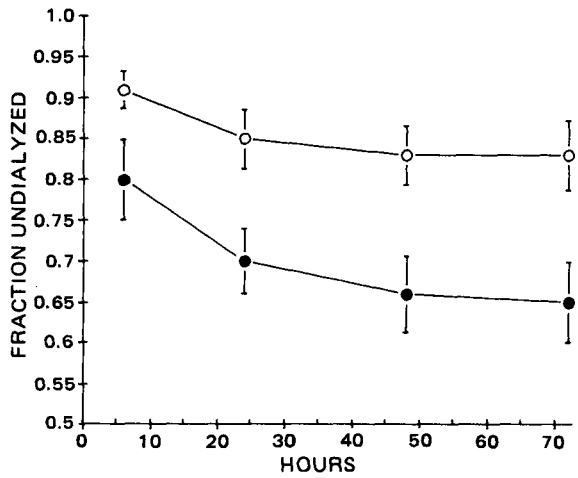

Figure 4—*The undialyzed fraction is plotted* versus *time for 1.0-μm extruded liposomes previously dialyzed against a 0.8-μm membrane. These values are for the previously described liposomes following 20 hr of dialysis against a 0.05-μm membrane (○) (essentially no dialysis of small liposomes), or following 20 hr of dialysis against a 0.8-μm membrane (●). Liposome concentration and quantitation were as described in Fig. 1. The values are the means ± 1 SD for nine preparations.*

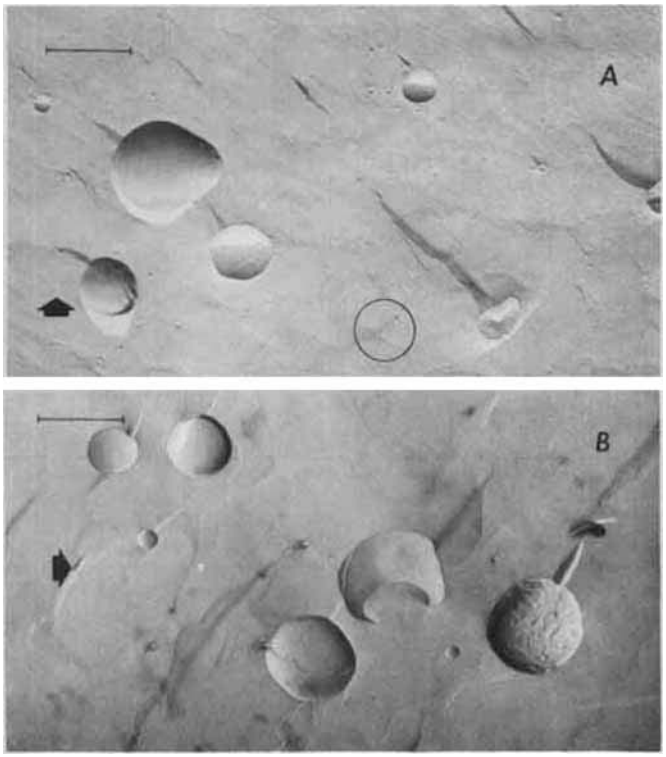

Figure 5—*Freeze-fracture electron micrographs of a mixture of liposomes before (A) and after (B) dialysis. The lipid in the original mixture (A) was from two sources: 70% consisted of a preparation of 1.0-μm extruded liposomes, the larger liposomes (Fig. 6), and 30% consisted of French press liposomes, the smaller liposomes (Fig. 2). Preparation is described in the text, and the mixture is described in Table I; in this mixture liposomes ≤80 nm in diameter account for ~99% of the total number (Fig. 8), ~58% of the total surface area (Fig. 9) and only 7% of the total liposome volume. Frame B shows the same mixture after 21 hr of dialysis against a 1.0-μm membrane; most of the small liposomes were removed. The bar in the upper left of each frame shows 1.0 μm. Within the circle in frame A are five of the small French press liposomes ranging in diameter from 16 to 57 nm.*

analytical reagent grade or better. The buffer, phosphate-buffered saline, contained 92 m*M* NaCl, 23 m*M* dibasic sodium phosphate, and 11 m*M* monobasic sodium phosphate. Prior to use, phosphatidic acid was obtained by chloroform extraction of an aqueous 0.4 *N* HCl solution of sodium phosphatidate containing 20% methanol.

Preparation of Liposomes—Multilamellar liposomes were prepared essentially as previously described (6, 22) and were composed of I–II–III–IV in the molar ratios 4:1:4.5:0.05 or 4:1:1:0.05. The α-tocopherol was added to retard autoxidation and improve stability (24). The lipids were dissolved in chloroform, mixed in a round-bottom flask, and subsequently evaporated to dryness under vacuum. An aliquot of buffer was added to the dried lipid; the mixture was then agitated by hand (at 20° after nitrogen purging) until all lipid was suspended, giving a final concentration of 10 μmoles of lipid/ml. In most cases a small amount of [^{14}C]cholesterol, as a liposomal membrane marker, was included with the other lipids. In other cases, 5 m*M* [^{14}C]sucrose, as an aqueous space marker, was included in the buffer used to disperse the lipids. This hand dispersal system results in the heterogeneous multilamellar population designated as being mechanically dispersed. The 1.0-μm extruded liposomes were prepared by placing the crude mechanically dispersed preparation in a 25-mm stirred ultrafiltration cell[4] fitted with a 1.0-μm pore-size polycarbonate membrane[5] and extruding it with positive nitrogen pressure at 10 ml/min. These liposomes could then be sequentially extruded through 0.8-, 0.6-, 0.4-, and 0.2-μm pore-size membranes to further reduce the size.

In selected cases the suspension was extruded twice through each membrane. The liposome size type was then designated by the smallest membrane size through which the suspension was extruded. The lipid recovery at each extrusion step was 100%, except at or below the 0.2-μm level; the extrusion was always done twice through the final membrane.

French press liposomes were prepared as previously described (16). A multilamellar liposome preparation was placed in a French pressure cell[6] and extruded three times at room temperature (flow rate ~15 ml/min) at 20,000 psi. The French press liposomes were then centrifuged at low speed to remove rubber particles sheared from the cells' O-rings during the extrusion.

Liposomes were dialyzed against the selected polycarbonate membrane as follows: 1 ml (or larger) dialysis cells (actual capacity 1.3 ml/side) were fitted with 25-mm membranes, and 1.0 ml of liposome suspension was placed in the sample chamber and 1.0 ml of buffer was placed in the second compartment. The cells were shaken at 5° on a horizontal shaker at 1.5–2 cycles/sec with a 5-cm amplitude. The dialysate side was replaced frequently with fresh buffer so as to maintain sink conditions. The total counts per minute of carbon on the sample side was monitored with time using scintillation-counting techniques. In the case where [^{14}C]sucrose was used as the liposomal marker, the nonentrapped sucrose was removed prior to the polycarbonate membrane dialysis by overnight dialysis *versus* excess buffer at 5° in a dialysis bag with a molecular weight cutoff of 10,000.

The corrected data are shown in Fig. 6.*

quots of the liposome suspensions were diluted twofold with a 25% (v/v) solution of glycerin in buffer and kept at room temperature for 2 hr. The samples were then quickly frozen in liquid freon at ~−155° and stored at −190° in liquid nitrogen. Stored samples were transferred to the specimen stage of a freeze-fracture device[7], fractured at −115°, and then platinum-carbon coated. The replicas then were cleaned in dilute (1%) hypochlorite solution overnight, and rinsed for 10 min in several successive distilled water baths. A final 30-sec acetone rinse removed any remaining lipid. Replicas were then transferred to flamed 200-mesh grids and viewed at 80 kV. Magnification was determined using a carbon calibration grid.

RESULTS

Dialysis of Liposomes—Figure 1 shows results when mechanically dispersed liposomes were dialyzed against several different pore-size membranes. The initial rate and extent of dialysis increases with increasing pore size. The results suggest that the majority of liposomes are between 0.6 and 3.0 μm in diameter. When the French press liposomes, averaging 28 nm in diameter, were dialyzed against 0.05-, 0.1-, and 0.2-μm pore-size membranes (Fig. 2), the half-life of dialysis increased, as the ratio of the pore size to mean liposome diameter increased.

Figure 3 shows the results of a study in which 0.6, 0.4, and 0.2 μm extruded and French press liposomes were dialyzed against 0.8-μm membranes. There is a clear trend of more rapid and extensive dialysis as the liposome size decreases relative to membrane pore size. A first-order dialysis was seen only for the French press liposomes, where the membrane pore size is significantly larger than the largest liposomes in the suspension. Figure 4 shows the combined results of three separate studies in which 1.0-μm extruded liposomes were made and treated as follows: half of the batch was dialyzed for 20 hr against 0.8-μm membranes, the other half against 0.05-μm membranes. Both subbatches were subsequently dialyzed a second time against 0.8-μm membranes for 72 hr. There is a significant difference in dialysis patterns because a fraction of the smaller liposomes dialyzed across the 0.8-μm membrane, whereas no significant dialysis across the 0.05-μm membrane was detected. Aliquots of both subbatches, taken after the first dialysis step, were used to construct size frequency distributions.

The effects of dialysis on a heterogeneous population, consisting of 1.0-μm extruded liposomes and French press liposomes (70 and 30%, respectively, of the total lipid), pictured in Fig. 5, were dramatic. This mixture was selected to represent a worse-case example (it is similar in size composition to those resulting from sonication of mechanically dispersed liposomes for short periods of time). A sample of this heterogeneous batch was saved and the rest was dialyzed for 21 hr using 1.0-μm membranes. Electron microscopy was then done on the dialyzed and undialyzed samples

Control Studies—The effect of the dialysis system on liposome stability was assessed as follows: aliquots of 0.8-μm extruded liposomes of either the I–II–III–IV = 4:1:1:0.05 or 4:1:4.5:0.01 composition, containing [^{14}C]sucrose, were dialyzed against 0.05-μm membranes following the same procedures used in other studies; these two compositions (differing in cholesterol content) were chosen as medium- and low-permeability liposomes (1). It was previously established that these same liposome types, when labeled with [^{14}C]cholesterol, would not dialyze across 0.05-μm membranes, so the appearance of [^{14}C]sucrose on the dialysate side would be evidence of liposome instability. After 24 hr a maximum of 3% had leaked from the more permeable liposomes, whereas no leakage was detected from the less permeable liposomes. For the case where the label did dialyze, it was important to know if the liposomes dialyzed across intact. To answer this question, 0.4-μm extruded liposomes of the I–II–III–IV = 4:1:4.5:0.05 composition containing [^{14}C]sucrose were dialyzed to equilibrium against 3.0-μm membranes (the size distribution of these liposomes is such that all are small enough to dialyze). Samples of the dialysate side were chromatographed on a sepharose gel column[8], and all of the radioactivity appeared in the void volume, indicating that the liposomes had dialyzed across intact.

The rate and extent of liposome dialysis was found to be a function of several system variables. The dialyses were concentration-dependent; that is, with all other variables held constant (*e.g.*, liposome size, mem-

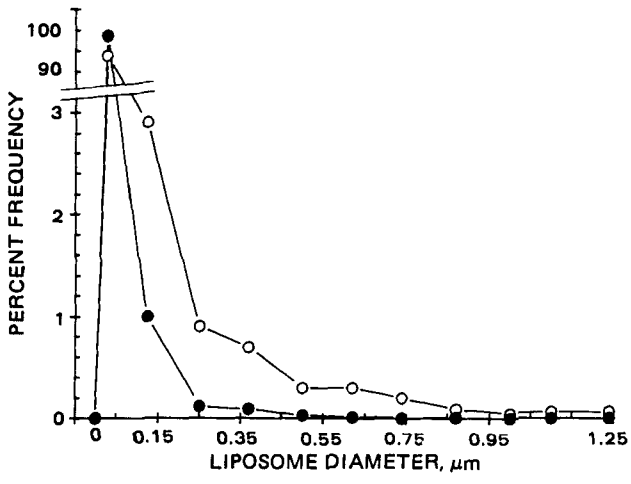

Figure 8—*The corrected percent of liposomes within equal diameter ranges is plotted* versus *the midpoint of the range for the liposome preparation consisting of a 1.0-μm-extruded (70% of total lipid) and French press liposomes (30% of total lipid) before (●) and after (○) dialysis for 20 hr against a 1.0-μm membrane. The original frequencies (not shown) were corrected to the observed frequencies using the Wicksell method (25).*

brane size), samples with higher lipid concentration dialyzed more slowly than more dilute samples. The agitation rate and the cell fill-volume were important. Three different modes of agitation rates (*i.e.*, motionless, gentle test tube inverter, and the horizontal shaker described previously) gave dialysis rates that covered a sixfold range. It was necessary to leave a small head space of air (~300 μl) when filling the cells, so that the dialyzing solution had the opportunity to agitate sufficiently. When these variables were held constant, the dialyses were reproducible.

Electron Microscopy and Liposome Sizing—Size–frequency distributions are obtained directly from diameter measurements on freeze-fracture electron micrographs. Figure 5 shows the mixture of 1-μm extruded and French press liposomes. A large number of small liposomes (Fig. 5A) were seen before dialysis, but were rare after dialysis (Fig. 5B).

Size distributions were constructed by assigning each liposome (on the photomicrograph) to size categories of 1-mm width (*e.g.*, 1–2 mm, 2–3 mm, *etc.*). Diameters of liposomes with oblong shape were calculated by averaging the values for their long and short axes. Diameter measurements were made for the above mixture from 8070× micrographs, except for the smallest liposomes, which were measured on 26,090× blow-ups of regions on the same 8070× micrographs. The ratio of smaller to larger liposomes found on each blowup was assumed to hold constant on the small scale micrograph. On the 26,090× micrographs all liposomes with diameters 0–3.3 mm were counted and measured; on the 8070× micrographs all liposomes >1.0 mm were counted and measured. After all liposomes had been counted and measured, the appropriate scaling correction was made to yield actual diameters. The total number of liposome profiles measured and counted in each experiment is shown in Table I.

There are certain inherent biases in the previously described method of sizing. A given fracture plane may not make an equatorial cut through a specific liposome, and it is more probable that a large liposome will be cut than a smaller one; this has the effect of making the apparent average diameter larger than the actual average diameter. The magnitude of the overall bias depends on factors such as the population range and the shape of the actual distribution. These biases are correctable using the mathematical approach developed by Wicksell (25), and the cumulative surface area or cumulative total liposome volume was plotted *versus* diameter and their parameters tabulated in Table I.

The corrected and uncorrected frequency plots for dialyzed (*i.e.*, those remaining after dialysis) and undialyzed 1.0-μm extruded liposomes are shown in Figs. 6 and 7. It can be seen that the correction procedure shifts the size distribution to smaller sizes. Nevertheless, there is a clear upward shift in average size for the dialyzed liposomes, with a doubling in average corrected diameter (from 0.156 to 0.3 μm, Table I). The corrected cumulative surface area and volume curves, not shown, also exhibit dramatic shifts toward larger diameters, which is reflected in the changes in the diameters of the liposomes with the average surface area and volume (Table I).

The data in Figs. 8–10 for the mixture of 1-μm extruded and French press liposomes illustrates an extreme case but serves as an example for a number of points. The corrected frequency *versus* size curve before

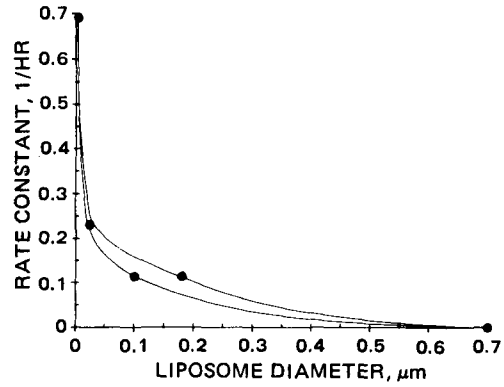

Figure 11—*The apparent first-order rate constant for various size liposomes against a 0.8-μm membrane is plotted* versus *their diameter. From left to right: (a) the rate constant for [^{14}C]inulin, assumed to be the upper limit for rate constants under the conditions used; (b) French press liposomes; (c) 0.2-μm extruded liposomes having an average diameter of 0.1 μm; (d) 0.2-μm extruded liposomes having an average diameter of 0.18 μm; (e) 0.7-μm extruded liposomes assuming negligible dialysis. The curves are arbitrary and drawn to approximate the actual underlying relationship.*

dialysis (Fig. 8) shows that ~99% of the liposomes are in the smallest size class, although French press liposomes comprised only 30% of the liposomal lipid; this class accounted for 58% of the total surface area, but only 7% of total liposome volume. Following dialysis the number of liposomes in the smallest size class decreased dramatically, but still accounted for ~95% of the total number (liposome dialysis was not limited to this size class; liposomes in the next few larger classes also dialyzed but to a lesser extent). Although dialysis of this mixture did not greatly increase the average diameter of the liposomes (Table I), it did produce a large increase in the diameter of the lipsomes with the average surface area and the average volume (Table I).

All differences noted between dialyzed and undialyzed preparations were significant; in the case where the fewest number of liposomes was measured (n = 195, Table I), the difference between mean diameters for the uncorrected dialyzed and undialyzed distributions was significant at the p <0.01 level (1-tailed t test using frequency *versus* log diameter distributions). For the corrected distributions (Fig. 5A) the level of significance between mean diameters before and after dialysis was greater.

Dialysis Simulations—The dialysis data for the French press liposomes (Fig. 2) indicates that when the preparation is homogeneous, dialysis is first order. Thus, the dialysis of a heterogeneous population may be simulated by a sum of first-order processes (or exponentials), one for each narrow size class as given by:

$$N_T = \sum_{i=1}^{n} N_{0,i}e^{-k_i t} + M \qquad \text{(Eq. 1)}$$

where N_T is the total number of liposomes remaining in the dialysis cell at time t, $N_{0,i}$ is the number in the ith narrow size class (*e.g.*, Fig. 5), k_i is the apparent first-order rate constant for dialysis of the ith class across a specific membrane, and M is the number of liposomes which cannot dialyze across that pore-size membrane. When a dialysis cleanup is complete, or after some time t, when dialysis is terminated, the fraction of liposomes in each size class will be:

$$N_{t,i}/N_T, N_{t,2}/N_T \ldots N/N_T \qquad \text{(Eq. 2)}$$

where

$$N_{t,i} = N_{0,i}e^{-k_i t} \qquad \text{(Eq. 3)}$$

Thus, if estimates of k_i can be obtained and the predialysis size–frequency distribution is known or can be approximated, the postdialysis size–frequency distribution can be determined. (If size–frequency distributions are not available, demonstrating the reproducibility of the dialysis pattern should ensure reproducibility of the final size–frequency distribution.) For example, the relationship between dialysis rate constant and diameter for the 0.8-μm membrane system described previously can be approximated (see Fig. 11). The maximum value of k_i is set equal to that obtained for a solution of [^{14}C]inulin. A rate constant of zero is assigned to liposomes >0.7-μm diameter, which were shown not to dialyze to any significant extent in this system over a 24-hr period. Additional rate constants are shown for French press liposomes of known mean diameter

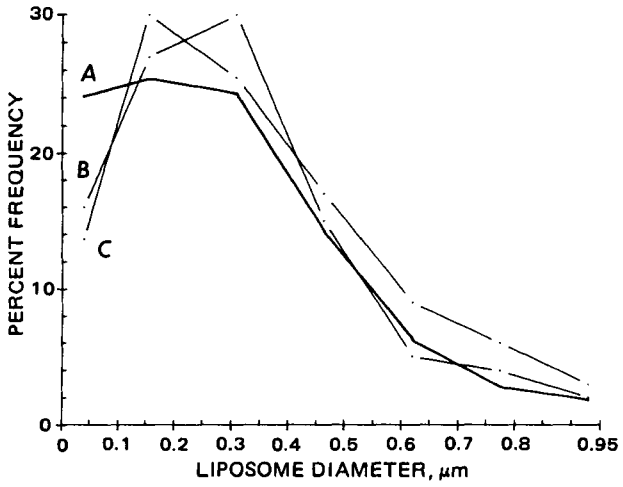

Figure 12—*Frequency, as percent of total, is plotted* versus *diameter. Curve* A *is replotted from Fig. 6 and is for 1.0-μm extruded liposomes following dialysis. Curves* B *and* C *are estimates of curve* A *calculated using Eq. 3, the undialyzed data in Fig. 6, and apparent dialysis rate constants interpolated from Fig. 10 as described in the text.*

and 0.2-μm extruded liposomes with mean diameters of 0.1 and 0.18 μm.

No attempt was made to fit the data in Fig. 11 to any specific function, rather the points were connected by two arbitrary curves to approximate the actual underlying pattern. Two sets of approximate rate constants were interpolated from this curve for the medium size of the seven smallest size categories used for construction of Fig. 6. Values of $N_{0,i}$ and M, obtained from the predialysis data in Fig. 6, along with seven estimates of k_i taken from each of the two curves in Fig. 11, were substituted into Eq. 1 to calculate the postdialysis in size–frequency distribution. The solid curve in Fig. 12 is the actual postdialysis size–frequency distribution. The broken curves are the two estimated size–frequency distributions and are reasonable given the limitations of both the method of calculation and the dialysis system: (*a*) the pores are not uniform in diameter; the manufacturer states that maximum pore size is 0—20% of the rated pore size; (*b*) pore size itself has a size–frequency distribution; (*c*) the technique for estimating the dialysis rate constants is crude; (*d*) the potential exists for large liposomes to block pores, thus reducing the effective dialysis rate constant for each size class.

DISCUSSION

A prerequisite for understanding the *in vivo* properties of liposomes is the availability of techniques to reproducibly prepare liposomes with defined size properties. With the exception of small unilamellar liposomes produced by prolonged sonication or carefully prepared French press liposomes, it is difficult to compare results between or within laboratories because the number, average size, size–frequency pattern, or surface area of the liposome dose rarely is known.

Because each liposome preparation has a characteristic dialysis profile for a given membrane and set of dialysis conditions (Figs. 1–4), dialysis data can be used as a means to compare the similarity of preparations and as a measure of their reproducibility. From the data presented (Figs. 1–4), the relative reproducibility of these preparations can be compared. Although the described technique is unsophisticated and simple, it does allow one to narrow the size–frequency distribution of any liposome batch while improving the reproducibility of preparation. Membrane extrusion under controlled conditions allows one to define and control the upper limit of liposome size anywhere between ~0.1 and 3.0 μm in diameter. This dialysis procedure allows control of the lower end of the size–frequency distributions.

Other techniques can be used to minimize the fraction of smaller liposomes in a preparation, but each has limitations. Separation of larger from smaller liposomes by centrifugation poorly discriminates between adjacent size classes and is further limited because liposomes of the same diameter may have different densities (*i.e.*, number of lamellae) and *vice versa*. Separation by filtration is possible in some cases when there is minimal interaction between liposomes and membranes (fiber types), but even at low pressure, some extrusion (22) occurs for all fluid-phase liposomes with the membranes used here. Filtration is more reliable when the process is carried out at a temperature below the phase transition temperature of the liposomal lipids (26, 27). Gel exclusion chromatography can be successfully used to obtain relatively narrow size distributions of small liposomes between ~20 and 80 nm in diameter and can also be used to control the lower end of the size–frequency distribution of larger liposomes when the adsorption of liposomal lipid onto the column can be minimized (this depends on liposome composition and column). Sedimentation field flow fractionation (28) is specifically designed for separation and analysis of particles in the liposome size range but is not designed for large-scale preparation; as the technique becomes more widely available it will, however, provide a technique to characterize the size–frequency distribution of liposome suspensions.

Control of liposome size may be critical when liposomes are designed for use as *in vivo* drug carriers. When *in vivo* fate is being followed using an aqueous space or liposomal membrane marker, the pharmacokinetic pattern seen will be a function primarily of the larger liposomes (Fig. 10), *i.e.*, the volume adjusted average size (29). Yet, the actual mechanisms governing liposome disposition are expected to be a function of the number of liposomes used and/or their total surface area, as well as diameter, when composition is held constant.

A combination of extrusion followed by dialysis, both using controlled-pored membranes, allows reproducible preparation of liposomes having a variety of definable size–frequency distributions. Subsequent use of dialysis rates can be used to obtain information about the size–frequency distribution and may be useful as a quality control technique.

Disposition of Quinidine in the Rabbit

THEODOR W. GUENTERT *, JIN-DING HUANG, and SVEIN ØIE ˣ

Received June 18, 1981, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 15, 1981. *Present address: Pharmazeutisches Institut, Universität Basel, Totengässlein 3, CH-4051 Basel, Switzerland.

Abstract □ Quinidine shows two-compartment characteristics in rabbits with a terminal half-life of 67 min for total drug and 58 min for unbound drug. Statistically, the values are not significantly different from each other ($p > 0.05$). The clearances for total and unbound drug are 52 and 464 ml/min/kg, respectively, and the total and unbound apparent volumes of distribution at steady state are 4.2 and 27.3 liters/kg, respectively. The unbound clearance and unbound apparent volume of distribution were inversely related to the unbound fraction of quinidine in plasma. The total clearance and apparent volume of distribution showed no relationship to the binding. Approximately 0.5% of the dose was excreted as unchanged quinidine. Six identifiable metabolites were found in the urine, accounting for ~14% of the dose. Two unknown metabolites were also observed in the urine. With the exception of 2′-quinidinone, these metabolites were formed in the rate-limiting step in the metabolite kinetics. The quinidine unbound fraction ranged from 0.06 to 0.23 in the eight rabbits studied. The binding of the metabolites was less pronounced, and only 3-hydroxyquinidine showed a significant correlation with quinidine binding.

Keyphrases □ Quinidine—disposition in rabbits, metabolites, binding □ Metabolites—binding, quinidine disposition, rabbits □ Binding—quinidine disposition, metabolites, rabbits □ Pharmacokinetics—disposition of quinidine, rabbits

Very little information exists regarding quinidine disposition in the rabbit, especially when unbound quinidine and metabolite concentrations are considered. The rabbit is, however, an attractive animal model for quinidine studies because it allows for sampling of sufficiently large blood volumes to determine both total and unbound concentrations; blood and urine sampling is simple; and if drug responses are desired, the response, measured as EKG changes, can be readily obtained (1).

As part of a long-term study of the disposition and response interrelationship between binding of quinidine to plasma proteins the pharmacokinetic picture of quinidine was evaluated in the rabbit.

EXPERIMENTAL

Quinidine Administration—Eight male New Zealand white rabbits (2.0–3.3 kg) were injected with 5.2 mg/kg of quinidine base as the gluconate salt[1] dissolved in 1 ml of saline into an ear vein over 2 min. Blood samples of 3-ml volume were obtained from the marginal vein in the other ear before the injections and again at 4, 8, 20, 40, 60, 90, 120, 150, 195, and 240 min after the injections. The blood was heparinized[2] to a final concentration of 5 U/ml. The blood was centrifuged and the plasma was stored at −20° until assayed. In addition, a 300-μl whole blood aliquot from the 4- and 150-min sampling time was also stored frozen until assayed. The red blood cells from the samples obtained at 20 min and at later time points were suspended in an equal volume of 6% dextran 75 in isotonic saline and reinfused within 10 min of sampling.

The urethra of each animal was cannulated with a catheter[3]. To ensure complete urine collection over the 4-hr study period, the bladder was rinsed twice with normal saline at the end of the study. The total urine collected was stored frozen until assayed.

Hepatic Blood Flow Determination—The hepatic blood flow was estimated in the individual animals 20–40 min after the end of the quinidine experiment by determining the indocyanine green blood clearance. Indocyanine green[4] (1 mg/kg) was infused over 30 sec into a marginal ear vein. Blood was collected from the marginal ear vein in the other ear by continuous withdrawal at a speed of 0.36 ml/min over a 12-min period, starting at the time of indocyanine green infusion.

The indocyanine green concentration in plasma of the withdrawn blood (C_{ICG}) was determined spectrophotometrically at 800 nm. Because the half-life of indocyanine green is 1 min and it does not enter the red blood

Disposition of Quinidine in the Rabbit

THEODOR W. GUENTERT *, JIN-DING HUANG, and SVEIN ØIE ˣ

Received June 18, 1981, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication October 15, 1981. *Present address: Pharmazeutisches Institut, Universität Basel, Totengässlein 3, CH-4051 Basel, Switzerland.

Abstract □ Quinidine shows two-compartment characteristics in rabbits with a terminal half-life of 67 min for total drug and 58 min for unbound drug. Statistically, the values are not significantly different from each other ($p > 0.05$). The clearances for total and unbound drug are 52 and 464 ml/min/kg, respectively, and the total and unbound apparent volumes of distribution at steady state are 4.2 and 27.3 liters/kg, respectively. The unbound clearance and unbound apparent volume of distribution were inversely related to the unbound fraction of quinidine in plasma. The total clearance and apparent volume of distribution showed no relationship to the binding. Approximately 0.5% of the dose was excreted as unchanged quinidine. Six identifiable metabolites were found in the urine, accounting for ~14% of the dose. Two unknown metabolites were also observed in the urine. With the exception of 2′-quinidinone, these metabolites were formed in the rate-limiting step in the metabolite kinetics. The quinidine unbound fraction ranged from 0.06 to 0.23 in the eight rabbits studied. The binding of the metabolites was less pronounced, and only 3-hydroxyquinidine showed a significant correlation with quinidine binding.

Keyphrases □ Quinidine—disposition in rabbits, metabolites, binding □ Metabolites—binding, quinidine disposition, rabbits □ Binding—quinidine disposition, metabolites, rabbits □ Pharmacokinetics—disposition of quinidine, rabbits

Very little information exists regarding quinidine disposition in the rabbit, especially when unbound quinidine and metabolite concentrations are considered. The rabbit is, however, an attractive animal model for quinidine studies because it allows for sampling of sufficiently large blood volumes to determine both total and unbound concentrations; blood and urine sampling is simple; and if drug responses are desired, the response, measured as EKG changes, can be readily obtained (1).

As part of a long-term study of the disposition and response interrelationship between binding of quinidine to plasma proteins the pharmacokinetic picture of quinidine was evaluated in the rabbit.

EXPERIMENTAL

Quinidine Administration—Eight male New Zealand white rabbits (2.0–3.3 kg) were injected with 5.2 mg/kg of quinidine base as the gluconate salt[1] dissolved in 1 ml of saline into an ear vein over 2 min. Blood samples of 3-ml volume were obtained from the marginal vein in the other ear before the injections and again at 4, 8, 20, 40, 60, 90, 120, 150, 195, and 240 min after the injections. The blood was heparinized[2] to a final concentration of 5 U/ml. The blood was centrifuged and the plasma was stored at −20° until assayed. In addition, a 300-μl whole blood aliquot from the 4- and 150-min sampling time was also stored frozen until assayed. The red blood cells from the samples obtained at 20 min and at later time points were suspended in an equal volume of 6% dextran 75 in isotonic saline and reinfused within 10 min of sampling.

The urethra of each animal was cannulated with a catheter[3]. To ensure complete urine collection over the 4-hr study period, the bladder was rinsed twice with normal saline at the end of the study. The total urine collected was stored frozen until assayed.

Hepatic Blood Flow Determination—The hepatic blood flow was estimated in the individual animals 20–40 min after the end of the quinidine experiment by determining the indocyanine green blood clearance. Indocyanine green[4] (1 mg/kg) was infused over 30 sec into a marginal ear vein. Blood was collected from the marginal ear vein in the other ear by continuous withdrawal at a speed of 0.36 ml/min over a 12-min period, starting at the time of indocyanine green infusion.

The indocyanine green concentration in plasma of the withdrawn blood (C_{ICG}) was determined spectrophotometrically at 800 nm. Because the half-life of indocyanine green is 1 min and it does not enter the red blood

cells, the blood clearance of indocyanine green (Cl_{ICG}) can be determined by:

$$Cl_{ICG} = \frac{\text{Amount infused}}{C_{ICG}\,\tau\,(1-H)}$$

where τ is the time of withdrawal and H is the hematocrit value.

Protein Binding—Protein binding was determined in each plasma sample using an equilibrium dialysis technique (2): A 700-μl volume of freshly obtained plasma and of Krebs–Ringer bicarbonate buffer (pH 7.4) (3) was placed into the two half-cells of a 1-ml dialysis cell[5], separated by a dialysis membrane[6] (average pore radius 24 Å). The membrane was pretreated by soaking in water (10 min), ethanol (15 min), and buffer (120 min) before use. The cells were equilibrated in a shaker bath[7] at 37° for 6 hr ± 20 min. The plasma and buffer were then removed and assayed immediately, or frozen until assayed for quinidine and metabolite content.

Plasma Protein Concentration—The total plasma protein concentration was determined before the injection of quinidine and again 30 min after concluding the study. Plasma (100 μl) was mixed with 5 ml of biuret reagent[8], and the absorbance at 540 nm was determined within 1 hr. An aqueous solution containing 80 g/liter of total protein was used as a standard[9].

Quinidine Assays—Quinidine and quinidine metabolites in plasma, whole blood, or buffer from equilibrium dialysis were determined using a specific reversed-phase high-pressure liquid chromatographic method. A 100-μl sample to be analyzed was mixed with 200 μl of a methanolic solution containing 170 ng/ml of dihydroquinidine internal standard (quinidine-free). Plasma and blood samples were centrifuged in a microhematocrit centrifuge[10] at 12,000×*g* for 2 min. A 20-μl aliquot of the sample was then injected into a C-18 μBondapak column of 30-cm length and 3.9-mm bore[11], connected to an HPLC pump[12]. Methanol–water–phosphoric acid 85% (27:72.95:0.05, v/v/v) was used as the mobile phase at a flow rate of 1.0 ml/min. Detection was achieved using a fluorescence detector[13] with excitation at 245 nm and emission at 440 nm (cutoff filter). Correction of dihydroquinidine contamination in the injection contributing to the internal standard peak was made from injection of the samples prepared as described previously, without addition of the internal standard. All samples were analyzed within 1 week of collection. However, the frozen samples have been found to be stable for up to 12 months without change in analyzed concentration.

Quinidine and quinidine metabolites in urine were assayed by a method described by Guentert *et al.* (4): Urine (200 μl) or 500 μl of urine hydrolysate was mixed with 150 μl of aqueous solution of 34 μg/ml pronetalol (internal standard), and 1.5 ml of 1 *M* borate buffer (pH 9.4). The mixture was extracted into 10 ml of methylene chloride–isopropanol (4:1, v/v). The organic phase was removed and extracted with 1 ml of 0.1 *N* sulfuric acid. The aqueous phase was then alkalinized with 1.5 ml of 1 *M* borate buffer (pH 9.4) and extracted with 8 ml of methylene chloride–isopropanol (4:1, v/v). The organic layer was evaporated to dryness and the residue reconsitituted in 200 μl of eluent. A 50-μl aliquot was injected

[a] Not detected. [b] Only trace concentration was detected.

onto a μBondapak-phenyl column[11]. The mobile phase was acetonitrile–tetrahydrofuran–0.05 *M* phosphate buffer (pH 4.75) (15:6:79, v/v/v). The eluent was monitored using a variable wavelength detector[14] set at 230 nm. Quantitation of the compounds was achieved by using standard curves of quinidine and metabolites (5–8). The unknown metabolites were assumed to have identical spectroscopic behavior to quinidine. All standards were made from spiked blank plasma or urine samples and treated as described previously.

Hydrolysis of Urine—Urine (200 μl) was adjusted to pH 5.0 by addition of acetic acid. One milliliter of β-glucuronidase[8] (5000 Fishman U/ml) was added to the urine and incubated at 37° for 12 hr. The hydrolysate was analyzed for quinidine and metabolites as described previously. This method was at several instances compared to results obtained by hydrolysis with 0.1 ml of sulfatase[8] (2970 U/ml), containing 92,000 Fishman U/ml β-glucuronidase activity, and with incubation of 1 ml of denaturated β-glucuronidase (denatured by heating over steam bath for 5 min). Furthermore, the results were also compared to results from urine that had been refluxed with 2 *N* HCl at 100° for 1 hr. As the other two modes of hydrolysis did not give different results from β-glucuronidase, only the β-glucuronidase hydrolysis results are reported here. Incubation with denatured β-glucuronidase gave no significant alteration of the original urine concentration of quinidine and its metabolites. Standards made from spiked urine were treated identically to that described previously.

Pharmacokinetic Analysis—An open two-compartment model with a short-term, zero-order input was found suitable to describe the observed total and unbound quindine plasma concentration with time in all animals studied.

The metabolite concentrations could adequately be described by an apparent one-compartment model with a first-order rate of formation. The values of the rate constants were obtained using a fitting procedure (9) available through a computer system (10). Plasma concentrations were weighted by their inverse value squared. The clearance was determined using the dose and area under the plasma concentration–time curve, and the apparent volume of distribution at steady state was obtained by the area under the moment curve as described previously (11).

RESULTS

The log-averaged plasma concentrations of total and unbound quinidine in the eight animals as a function of time are given in Fig. 1. The various pharmacokinetic parameters for total and unchanged drug are given in Table I.

From three to six metabolites could be detected in plasma of the different rabbits. Only in rabbit No. 5 could six different metabolites be distinguished (Fig. 2). Five of these metabolites represent known metabolites [quinidine-10,11-dihydrodiol (8), 3-hydroxyquinidine (5, 12), 6′-desmethylquinidine (7), quinidine-*N*-oxide (6), 2′-quinidinone (13)]. Metabolite number 4 is unknown. Rate constants for the various metabolites are given in Table II.

Urine was found to contain at least eight metabolites of quinidine, of which five could be associated with known metabolic products (5–8, 12, 13). In Fig. 3 a chromatogram from urine of rabbit No. 1 is presented. Metabolite number 1, quinidine-10,11-dihydrodiol, appears to have a shoulder on many of the chromatograms, possibly indicative of the two diastereoisomers of this compound. In addition to the metabolites shown, the 6′-desmethylquinidine peak substantially increased upon hydrolysis of urine with β-glucuronidase, indicative of a 6′-desmethylquinidine conjugate (probably a glucuronide).

The fraction of the dose recovered as unchanged quinidine in urine ranged between 0.001 and 0.010. The fraction of the dose recovered as known quinidine metabolites, including the 6′-desmethylquinidine conjugate, ranged between 0.110 and 0.202 for the six rabbits where the urine collection was complete (Table III).

The blood to plasma ratio of quinidine in the rabbits was 1.05 ± 0.08, which is not statistically significantly different from 1.

The indocyanine green clearance, indicative of liver blood flow, was found to be 58 ± 12 ml/mg/kg.

The unbound fraction of quinidine in plasma varied between 0.06 and 0.23 in the eight rabbits (Table I). Of the known quinidine metabolites, only quinidine-10,11-dihydrodiol and 3-hydroxyquinidine could be evaluated for their binding to plasma protein. The unbound fraction in the eight rabbits varied between 0.26 and 0.46, with an average value of 0.34 and a *SD* of 0.06 for quinidine-10,11-dihydrodiol. In six of the rabbits, where 3-hydroxyquinidine was detected, the unbound fraction for this metabolite ranged between 0.16 and 0.32, with an average value of 0.25 and a *SD* of 0.06. The unknown metabolite (4), showed negligible binding, with an average ±*SD* of 0.74 ± 0.09. Of these metabolites, only 3-hydroxyquinidine showed a statistically significant correlation with the binding of quinidine ($r^2 = 0.84$, $p < 0.01$).

DISCUSSION

The disposition of both total and unbound quinidine in the rabbit can be described by a two-compartment model. Statistically, the fast disposition half-lives for total and unbound drug were not significantly different from each other and were found to be 5.8 and 3.1 min, respectively, indicating fast distribution. The slow disposition half-life for total drug at 67 min was not significantly different from that reported for unbound drug, 58 min ($0.10 > p > 0.05$). However, in two of the animals, No. 1 and 8, the terminal slope and half-life for total drug was significantly different from that of the unbound drug. This suggests that the rate constants of total and unbound drug for individual animals cannot be assumed to be interchangeable, even though the average population values show no differences. The observed half-life is much longer than the average half-life of 29 min previously reported in rabbits (1). However, these studies were carried out for only 50 min after an intravenous injection and for 60 min after the termination of an infusion over 90 min. This short collection time and the use of Cramer and Isaksson's assay method for quinidine (14), which has been shown to be nonspecific for quinidine (15), could be contributing factors to this discrepancy. Ueda and Nichols (16) found a slow disposition half-life for total drug that was much longer than that of this study. In a 3-hr study they observed a terminal half-life of 132 min, almost twice the value in this study. Except for using much larger and presumably older animals than those in this study, no significant differences in the experimental protocol can be found to explain this difference. Similarly, Ueda and Nichols also reported a much smaller clearance of quinidine than that reported in this study (16.8 ml/min/kg *versus* 52 ml/min/kg).

The fraction of quinidine excreted unchanged in the urine is very low (Table III). Provided the extrarenal clearance is predominantly hepatic, quinidine shows a high extraction ratio in the rabbit liver. The metabolic clearance of quinidine (52 ml/min/kg) approaches the value of hepatic blood flow (58 ml/min/kg). According to theoretical considerations, the total drug clearance of quinidine in this case should be independent of

the unbound fraction, and the unbound clearance inversely related to the unbound fraction (17). In accordance with this principle, the total clearance showed no statistically significant correlation with the unbound fraction ($p > 0.70$). The unbound clearance was strongly correlated with the inverse of the unbound fraction of quinidine in plasma ($p < 0.001$). These data confirm and support the previous observation in rabbits where the binding was altered by a bleeding procedure (18).

The apparent steady-state volume of distribution for total drug in this study, 4.2 liters/kg, was similar to the value calculated from the study of Ueda and Nichols (16). It showed no correlation with the unbound fraction in plasma ($p > 0.20$). The unbound apparent steady-state volume of distribution, however, showed a negative correlation with the unbound fraction ($p < 0.005$). This is the opposite to what could theoretically be expected for a compound with a large apparent volume of distribution (19) and is indicative of a correlation between tissue and plasma protein binding in individual animals.

Using the assay method described, the total recovery of the six identifiable metabolites and quinidine in the urine accounts for only 14% of the administered dose. Other primary or secondary metabolites must, therefore, account for the elimination of quinidine. However, only one conjugate of quinidine metabolites could be identified *via* enzymatic or acid hydrolysis of the urine.

Based on the fast elimination of unchanged quinidine in the rabbit, urine was collected for only 4 hr in this study. The terminal half-life of five of the metabolites in plasma was ~1 hr, suggesting that most of these compounds were eliminated in the collection period. The terminal half-lives of these metabolites are similar to that of quinidine, indicating that their formation is the rate-limiting step in their pharmacokinetic profile.

Accumulation of these metabolites after multiple doses will, therefore, only occur to a small degree. The sixth metabolite, 2′-quinidinone, exhibited a much slower elimination, with an apparent terminal half-life of 8 hr. The urinary recovery of this metabolite, with a study period of only 4 hr, therefore, was seriously underestimated and could possibly contribute to the overall low recovery of quinidine and metabolites in the urine. Because the observed half-life is greater than the study period, there is also little confidence in the estimated value of the half-life.

The protein binding of quinidine is variable; an unbound fraction varying from 0.06 to 0.23 was observed. Although two of the eight animals showed a statistically significant positive correlation between concentration and unbound fraction of quinidine in plasma, there was no difference in the terminal half-life between the total and unbound drug, suggesting that concentration-dependent binding is not a general phenomenon.

Because quinidine metabolites reportedly contribute to the pharmacologic activity (20), it may be of importance to note that all the metabolites for which protein binding was measured exhibited a lower binding than the parent compound. Of these metabolites for which binding could be evaluated, 3-hydroxyquinidine was the only one to show a statistically significant correlation with quinidine binding. This might suggest a common binding site and possible mutual displacement at high concentration.

Simultaneous Determination of Corticosterone, Hydrocortisone, and Dexamethasone in Dog Plasma Using High Performance Liquid Chromatography

M. ALVINERIE ˣ and P. L. TOUTAIN

Received May 22, 1981, from the *Station de Pharmacologie-Toxicologie, 180 chemin de Tournefeuille, 31300 Toulouse, France.* Accepted for publication October 13, 1981.

Abstract □ A sensitive, specific and reproducible high-performance liquid chromatographic procedure, using the normal phase and radial compression system, is described for the simultaneous determination of corticosterone, hydrocortisone, and dexamethasone in plasma, with prednisolone as the internal standard. Samples were extracted with methylene chloride and chromatographed on a microparticulate silica gel column using a radial compression system with UV detection at 254 nm. The assay has been applied in pharmacokinetic studies, and a typical plasma concentration–time profile for the three corticosteroids (all with 2 ng/ml sensitivity) is presented for dogs receiving dexamethasone.

Keyphrases □ Corticosterone—high-performance liquid chromatographic determination in dog plasma □ Hydrocortisone—high-performance liquid chromatographic determination in dog plasma □ Dexamethasone—high-performance liquid chromatographic determination in dog plasma □ High-performance liquid chromatography—determination of hydrocortisone, corticosterone, and dexamethasone in dog plasma □ Pharmacokinetics—high-performance liquid chromatographic determination of corticosteroids

Many methods for the determination of corticosteroids in plasma have been described, but many of them lack specificity or are too time-consuming for routine use.

Fluorometric techniques (1, 2) measure different steroids that fluoresce with varying intensity, but overestimate the true amounts of hydrocortisone and corticosterone. Analysis using GC (3) is complicated, because steroids with a C_{17} hydroxyacetone side chain undergo thermal degradation at the temperature employed. The assay of corticosteroids by GC would also seem to require the prior formation of a stable derivative. In competitive protein binding methods, the unknown and radiolabeled hydrocortisone compete for a hydrocortisone-binding protein such as transcortin (4–6). However, endogeneous substances with significant cross reactivity confound the assay performance. Radioimmunoassay is a competitive protein binding technique using an antibody to hydrocortisone as the binding protein. If the antibody is specific and binds hydrocortisone with high affinity, a sensitive assay can be made, although separation of hydrocortisone and corticosterone is crucial to obtaining a good specificity (7, 8). All these procedures are time-consuming and difficult to automate for use in a routine pharmacokinetic study.

The recent emergence of commercial high-pressure liquid chromatographic (HPLC) equipment (coupled with a sensitive UV detector), having the advantages of simple preliminary treatment of the sample, has attracted the attention of workers studying the analysis of corticosteroids in plasma.

Separation of corticosteroids by HPLC in humans has been documented by several authors (9, 10). However, in the dog, levels of endogeneous corticoids are lower than in humans, and techniques already described are not sensitive enough to be applied in this species.

The purpose of the present study was to report the use of a new radial compression system to determine simultaneously the plasma levels of endogenous and synthetic corticoids with a sensitivity level of ~2 ng/ml.

EXPERIMENTAL

Apparatus—The apparatus used in the extraction procedure was constant shaker[1] and a refrigerated centrifuge[2]. A constant volume high pressure liquid chromatograph[3] was equipped with a single wavelength 254 nm detector[4]. The column (10 × 0.8-cm i.d.) was packed with a 10-μm nominal normal phase[5] and was included in a radial compression system[6].

Reagents—Hydrocortisone, corticosterone, dexamethasone, and prednisolone reference standards[7] were used as received. Methylene chloride[8] and acetic acid[8] (analytical grade solvents) were used without further purification.

Mobile Phase—The mobile phase was prepared by mixing exact volumes of methylene chloride, methanol, and glacial acetic acid. The solution was strained and the gas removed. The ratio of methylene chloride, methanol, and acetic acid was 96:4:0.4 (v/v/v).

Operating Conditions—The UV detector was fixed at 254 nm, with a sensitivity of 0.005 aufs. A constant flow rate of 1.5 ml/min was maintained. The radial compression pressure was 1500 psi, and the inlet pressure was 200 psi. Chart speed was 0.5 cm/min.

Preparation of Standard Solutions—Each steroid was dissolved in methanol at a concentration of 1 mg/ml. The operating standard mixture was prepared by a 1:100 dilution in the elution solvent. Prednisolone was used as an internal standard at a concentration range of 1 mg/ml in methanol; a working solution was prepared by a 1:10 dilution in the same solvent.

Extraction Procedure—One milliliter of plasma sample, 1 ml of 0.1 *N* NaOH, and 10 ml of methylene chloride were added to a 30-ml tube[9]. The tubes were shaken for 10 min and centrifuged at 8400×*g* for 10 min at 4°. The methylene chloride layer was aspirated and evaporated at 40° under a nitrogen gas stream to prevent oxidation. The residue was dissolved in 100 μl of elution solvent and then injected into the column.

Calibration and Reproducibility—Pooled plasma of the dog was spiked with corticosterone and hydrocortisone (10–100 ng/ml) and with dexamethasone (10–1000 ng/ml). A constant amount of 100 ng of prednisolone as the internal standard was added to each sample (10 μl of a solution containing 10 μg/ml). Pooled plasma was extracted and was performed as outlined previously.

Calibration curves were constructed by calculating the ratio of the peak height of each compound to that of the internal standard, plotting the ratio against the amount of compound added to the sample. Peak heights of hydrocortisone and corticosterone were corrected for blank plasma response representing an endogenous serum component. The corrected peak height was used as the response.

Least-squares linear regression analysis was used to determine the slope, *y* intercept, and correlation coefficients.

The response of the HPLC system was linear in the concentration range

Table I—Retention Times and Capacity Factor of Selected Glucocorticoids

Compound	Capacity Factor (K′)	Retention Time, min
Corticosterone	1.3	4.0
Dexamethasone	2	5.0
Hydrocortisone	2.5	6.0
Prednisolone	3.3	7.5

of 10–100 ng/ml for corticosterone and hydrocortisone and 10–100 ng for dexamethasone.

The analytical recovery of the compounds was measured by comparing the chromatographic peak heights from the analysis of biological samples, spiked with 100 ng of each compound and the peak height resulting from a direct injection of methanol standards.

Recovery of all compounds from plasma was 80–85% when ~85–90% of the methylene chloride layer was available for evaporation.

Assay precision was determined with successive sampling of pooled dog plasma. Ten successive samplings gave coefficients of variation <5% for all compounds: 3.39 for corticosterone, 4.90 for hydrocortisone, and 1.92 for dexamethasone.

Calculations—The concentration of corticosterone, hydrocortisone, and dexamethasone in the sample was determined from the following expression:

$$C_p: \frac{R}{a} + b \qquad \text{(Eq. 1)}$$

where C_p is the concentration of the substance in plasma (ng/ml), R is the peak height ratio (drug:internal standard), a is the slope of the calibration curve, and b is the y intercept.

Retention Time and Selectivity (Table I)—Normal-phase liquid chromatography using radial compression showed a high selectivity in the separation of corticosteroids. A good separation of the four compounds was obtained in 8 min.

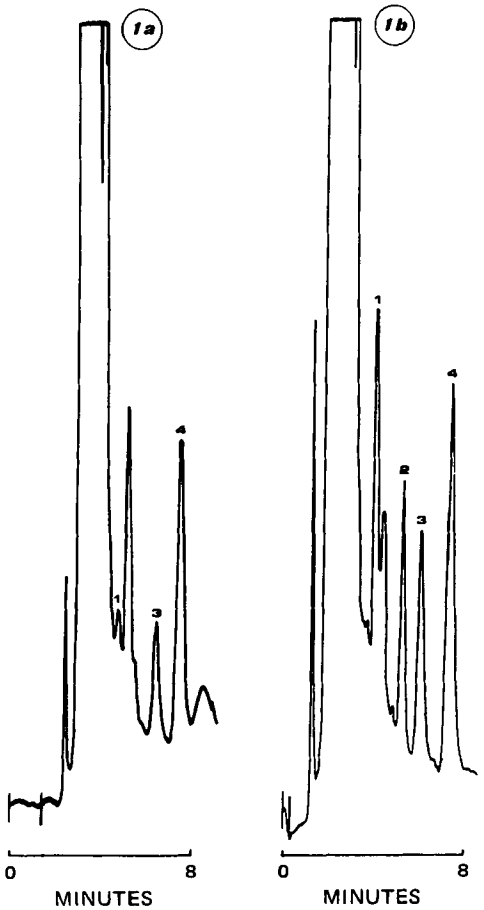

Figure 1—*Chromatogram of extracted blank dog plasma containing only internal standard (1a); chromatogram of extracted dog serum spiked with hydrocortisone, corticosterone, and dexamethasone (1b). 1, Corticosterone; 2, dexamethasone; 3, hydrocortisone; 4, prednisolone.*

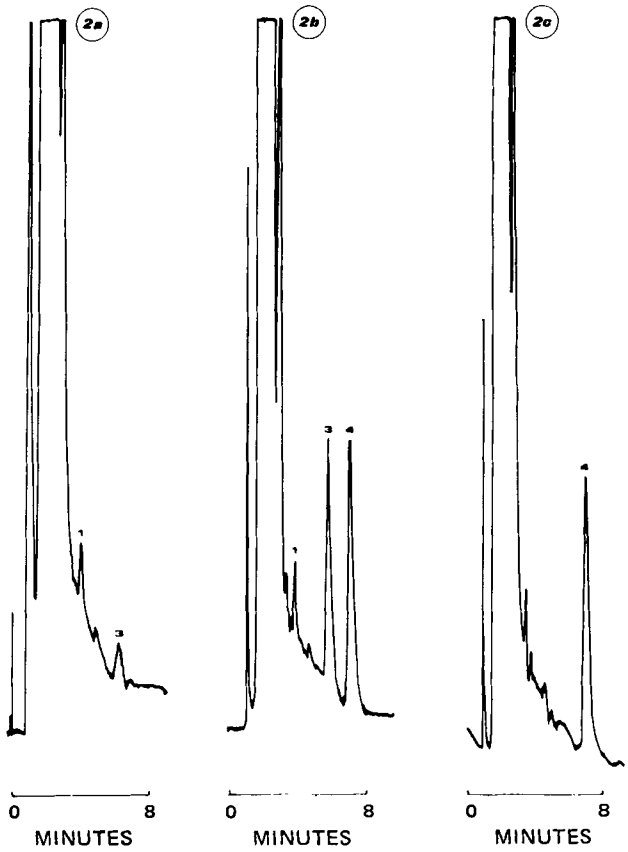

Figure 2—*Chromatogram of a plasma sample taken from a dog before the administration of corticotropin (2a); chromatogram of plasma 2 hr after the dose of corticotropin (2b); and chromatogram of extracted plasma after the injection of dexamethasone (2c). 1, Corticosterone; 3, hydrocortisone; 4 prednisolone.*

Drug Disposition Study—To test the ability of this method to detect endogenous corticosteroids, corticotropin[10] was administered intramuscularly (20 IU) into two dogs (11–12 kg; 4–5 years of age). To prove that exogenous corticoid could be detected, dexamethasone[11] was injected intravenously (1 mg/kg). Blood was withdrawn *via* the jugular vein at 15 and 30 min and 1, 2, 4, 8, and 24 hr after the treatment and placed in tubes containing 10 U of heparin. The plasma was separated immediately and stored at −20° until analysis.

RESULTS AND DISCUSSION

A chromatogram of a blank dog plasma extract and a chromatogram of plasma spiked with 40 ng of hydrocortisone, corticosterone, and dexamethasone are shown in Fig. 1. These chromatograms illustrate the response of the chromatographic system to 40 ng of corticosteroids/ml of plasma and to 100 ng of prednisolone which was used as the internal standard.

Figure 2*a* illustrates the chromatogram of a plasma sample taken from a dog before the administration of corticotropin. In addition, Fig. 2*b* illustrates the steroid concentration 2 hr after the dose of corticotropin; hydrocortisone concentrations were much greater in contrast to the small increase in corticosterone.

Figure 2*c* shows the effect of an injection of dexamethasone 12 hr postadministration. This chromatogram indicates that dexamethasone suppressed plasma corticosterone and hydrocortisone so that concentrations were no longer detectable. At this time, concentrations of dexamethasone were not detected.

Figure 3 presents a typical plasma concentration–time profile of dexamethasone after intravenous administration and the simultaneous evolution of the endogenous corticosteroids.

The simultaneous determination of corticosterone, hydrocortisone, dexamethasone, and prednisolone by this HPLC method proves to be

[10] ACTH-Choay, Choay, Paris, France.

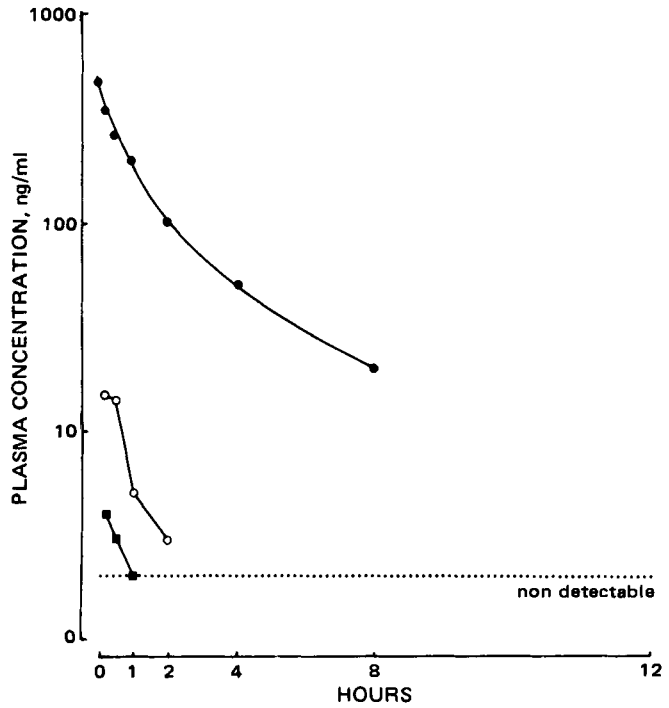

Figure 3—*Plasma concentration–time curve in the dog given a 1 mg/kg iv dose of dexamethasone. Key: (●), dexamethasone; (○), hydrocortisone; (■), corticosterone.*

efficient, precise, sensitive, and selective. It also allows the examination of the effects of dexamethasone on circulating hydrocortisone and corticosterone concentrations.

The selectivity of the extraction procedure and chromatographic system is demonstrated by the chromatogram from the blank plasma (Fig. 1*a*). Analysis of the figure indicates that there is no significant interference from endogenous compounds. It should be noted that one source of interference was encountered when the methylene chloride layer was recovered by filtration on phase-separating paper. One large interfering peak eluted at a retention time of 5 min and was labeled as an endogenous biological sample.

This chromatographic procedure differs from those previously described (11–19), as a new radial compression separation system was used. In this system a strong radial compression is applied to a soft column, thus diminishing the dead volume and the formation of preferential ways inside the column. This results in higher efficacy, with a lower pressure and increased flow rate. Moreover, it is possible to attain the same separation in 2 min with a flow rate of 6 ml/min and with only a 10% decrease in response.

Responses were considered significant when the signal to noise ratio was >1.5. In such conditions, using a detector sensitivity of 0.005 aufs, levels as low as 2 ng/ml, giving 0.5-cm peaks, could be quantitated.

In conclusion, the described method offers a simple, rapid, and reliable determination of corticosteroids for use in pharmacokinetic studies.

Received July 6, 1981, from the *Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication September 25, 1981.

Abstract □ A rapid enzymatic method for the preparation of [1-^{14}C]D-leucine is described. [1-^{14}C]D-Leucine was obtained from [1-^{14}C]DL-leucine by oxidative deamination of the L-isomer using immobilized L-amino acid oxidase. The total preparation (including ion exchange purification) was accomplished in 40 min with an 83% yield. The methodology is applicable to the production of [1-^{11}C]D-leucine, a potential imaging agent for tumor localization.

Keyphrases □ [^{14}C]D-leucine—rapid enzymatic preparation for tumor localization □ Enzymatic preparation—D-leucine isomers, [^{11}C]D-leucine production for tumor localization

Amino acids labeled with gamma-emitting radionuclides (carbon 11 or nitrogen 13) have been investigated for tumor localization, pancreatic scanning, and the study of normal physiological processes. Rapid Enzymatic Preparation of [^{14}C]D-Leucine from [^{14}C]DL-Leucine

GEORGE A. DIGENIS ˣ, RENSUKE GOTO, JAMES E. CHANEY, and OSAMU TAMEMASA

Received July 6, 1981, from the *Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication September 25, 1981.

Abstract □ A rapid enzymatic method for the preparation of [1-^{14}C]D-leucine is described. [1-^{14}C]D-Leucine was obtained from [1-^{14}C]DL-leucine by oxidative deamination of the L-isomer using immobilized L-amino acid oxidase. The total preparation (including ion exchange purification) was accomplished in 40 min with an 83% yield. The methodology is applicable to the production of [1-^{11}C]D-leucine, a potential imaging agent for tumor localization.

Keyphrases □ [^{14}C]D-leucine—rapid enzymatic preparation for tumor localization □ Enzymatic preparation—D-leucine isomers, [^{11}C]D-leucine production for tumor localization

Amino acids labeled with gamma-emitting radionuclides (carbon 11 or nitrogen 13) have been investigated for tumor localization, pancreatic scanning, and the study of normal physiological processes. Several ^{13}N-labeled L-amino acids have been synthesized enzymatically and their tissue distribution and pancreatic uptake studied in animals

0022-3549/82/0700-0818$01.00/0

(1–3). Transplanted tumors in rats have been detected by external scintigraphy using [^{11}C]carboxyl-labeled 1-aminocyclopentanecarboxylic acid (4). A modified synthesis[1] has been successfully utilized for the production of [^{11}C]carboxyl-labeled amino acids (5, 6). On the basis of data obtained from animal experiments and studies with humans it has been suggested that [^{11}C]carboxyl-labeled DL-tryptophan (7, 8) and DL-valine (9), when used in conjunction with positron computerized transaxial tomography, have significant potential as clinical pancreas-imaging agents.

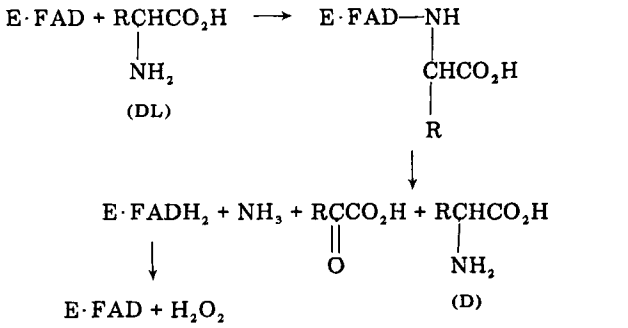
Recent studies suggest that optically active isomers of ^{11}C-labeled amino acids would be biologically more interesting than the racemic amino acids. For example, it has been previously demonstrated (10) that ^{14}C-labeled D-isomers of some amino acids showed greater affinity for tumors in mice than did the L-isomers. More specifically, ^{14}C-labeled D-leucine has been shown to exhibit a preferential incorporation into tumor cells of nude mice bearing human colon and thyroid cancer[2].

The present report describes the methodology for the rapid preparation of D-leucine which makes possible the availability of this amino acid in its ^{11}C-labeled form as a potential diagnostic reagent for tumors.

EXPERIMENTAL

Immobilization of L-Amino Acid Oxidase—Snake venom L-amino acid oxidase[3] (50 mg) was dissolved in 30 ml of 0.1 *M* sodium pyrophosphate buffer, pH 8.3. Cyanogen bromide-activated sepharose-4B beads[3] (2.5 g) were washed and swollen by treating with 400 ml of 1×10^{-3} *N* HCl. The beads were recovered by filtration using a coarse sintered glass funnel and were immediately added to the buffered enzyme solution in a 50-ml round-bottom flask. The mixture was stoppered and gently mixed with a wrist action shaker at 4–5° for 30 hr. After immobilization, the beads were washed several times on a coarse sintered glass funnel using 0.1 *M* sodium pyrophosphate, pH 8.3, to remove the soluble enzyme. Subsequently, the immobilized enzyme was alternately washed twice with 0.1 *M* pyrophosphate buffer (pH 8.3) and 0.1 *M* acetate buffer (pH 5.6) and finally twice more with 0.1 *M* pyrophosphate buffer (pH 8.3). The resulting L-amino acid oxidase on sepharose-4B was stored at 5–7° in 50–100 ml of 0.1 *M* pyrophosphate buffer at pH 8.3.

Preparation of [1-^{14}C]D-Leucine—[1-^{14}C]DL-Leucine[4] (1.25 μCi) (specific activity: 59 mCi/mmole; concentration: 50 μCi/ml) and 2.5 g sepharose-immobilized L-amino acid oxidase were added to a 50-ml solution of 1×10^{-3} *M* DL-leucine[3] in 0.1 *M* sodium phosphate buffer (pH 8.3). The preparation was described previously. The resulting mixture was gently agitated on a gyratory shaker bath at 37° for 10 min with concomitant passage of oxygen through the reaction mixture at the rate of 0.5 liters/min using a gas dispersion tube.



Scheme I—*Resolution of DL-leucine by oxidative deamination. FAD = flavin adenine dinucleotide, E = immobilized L-amino acid oxidase (L-AAO), and R = $CH_2CH(CH_3)_2$.*

The immobilized enzyme was removed from the reaction mixture by use of a sintered glass filter funnel and an aspirator vacuum. The filtrate was acidified with 1 ml of concentrated HCl and added to a cation exchange column (10 × 15 mm)[5]. The column was washed with two 50-ml portions of distilled water. (Insignificant amounts of radioactivity were found in the second wash.) The total radioactivity in these washings was 0.54 μCi. To recover the D-leucine the cation exchange column was eluted with 100 ml of 0.2 *N* NaOH which resulted in 0.52 μCi of radioactivity. The pH of the eluted [1-^{14}C]D-leucine solution was adjusted to 7.0, the resulting solution was concentrated to 1 ml, and an aliquot was applied to a silica gel TLC plate[6] (20 × 20 cm).

After two-dimensional chromatography [butanol[7]–acetic acid[8]–water (4:1:2) followed by phenol[9]–water, (75:25)] the plate was monitored by autoradiography[10]. The respective R_f values were 0.55 and 0.74. The position of the radioactive spot corresponded to the colored spot obtained prior to X-ray film exposure upon spraying with ninhydrin[3]. This spot corresponded to that of authentic leucine.

Optical Rotary Dispersion Spectropolarimetric Determination of the Production of D-Leucine—A solution of nonradioactive DL-leucine (1×10^{-3} *M*) was incubated with immobilized L-amino acid oxidase as described previously. The pH of the amino acid solution in 100 ml of 0.2 *N* NaOH recovered from the cation exchange column was adjusted to 7.0 and taken to dryness at 40° using a rotary evaporator. The residue was reconstituted into a 15-ml aqueous HCl solution (final pH 1.0). The optical rotary dispersion curve was determined in a 5-cm cell using an optical rotary dispersion spectropolarimeter[11]. The optical rotary dispersion spectrum was scanned in the wavelength region of 300 nm to 200 nm at a sensitivity setting of 350 millidegrees. The maximum absorbance was found at 224 nm. For comparison of the optical rotary dispersion spectrum to that of authentic D-leucine[3], a 0.25 m*M* solution of D-leucine in 0.2 *N* NaOH was prepared, dried, and reconstituted as for the previous solution. Also, a solution of D-leucine (0.5 m*M*) in 50 ml of 0.1*M* sodium pyrophosphate buffer was subsequently treated as the enzymatically produced D-leucine except for the enzyme exposure and the optical rotary dispersion was run.

Keto Acid Assay—The enzyme reaction was carried out as described previously using nonradioactive DL-leucine. 2,4-Dinitrophenylhydrazine[12] (0.5 ml, 0.1%) dissolved in 2 *N* HCl was added to vials containing 0.5 ml of the 50-ml filtrate. The mixtures were allowed to stand at 25° for 10 min, followed by the addition of 5 ml of 1.25 *N* NaOH. The optical densities at 440 nm using a spectrophotometer[13] were determined. A standard calibration curve was plotted and found to be linear at concentrations of keto acid (4-methyl-2-oxopentanoic acid[14]) ranging from 0.0625×10^{-3} *M* to 0.5×10^{-3} *M*.

RESULTS AND DISCUSSION

Resolution of [1-^{14}C]DL-leucine was accomplished by oxidative deamination as outlined in Scheme I. [1-^{14}C]D-Leucine was obtained from [1-^{14}C]DL-leucine by destruction of the L-isomer by the action of sepharose-immobilized L-amino acid oxidase at pH 8.3. When the reaction was complete (10 min) the mixture was acidified and passed through a cation exchange column to remove the keto acid. The column was washed with water until the eluate was practically free of radioactivity. Of the original activity in the starting [^{14}C]DL-leucine, 43% was found in these washings in the form of 4-methyl-2-oxopentanoic acid. This 43% recovery represents a yield of 86% for the keto acid. The [1-^{14}C]D-leucine was eluted from the column with 0.2 *N* NaOH in an 83.2% yield (41.6% of original radioactivity). These yields are an average of five experiments. An additional 11% of the unaccounted radioactivity (15%) was recovered by washing the enzyme two times with 50 ml of water. Two-dimensional TLC of the leucine recovered from the cation exchange column revealed that the product was pure and it chromatographed identically to authentic leucine as determined by spraying the plate with ninhydrin and finding that the ninhydrin positive spot coincided with the position of

the radioactivity detected by autoradiography. The total resolution time including the ion exchange purification step was 40 min.

A nonradioactive resolution was analysed by optical rotary dispersion polarimetry in the range of 300–200 nm (Fig. 1). The optical rotary dispersion curve (Curve C) of the resolved D-leucine gave an optical rotation at 224 nm practically identical to that (Curve B) obtained by starting with half the amount of authentic D-leucine relative to the weight of DL-leucine used in the resolution and submitting it to the same ion exchange and reconstitution treatment applied to the resolved product.

The oxidative deamination of L-leucine in DL-leucine to the corresponding 4-methyl-2-oxopentanoic acid also was confirmed in the developmental work using nonradioactive DL-leucine by reacting aliquots of the reaction mixture with 2,4-dinitrophenylhydrazine yielding the 2,4-dinitrophenylhydrazone derivative which was monitored colorimetrically (440 nm) against standard 2,4-dinitrophenylhydrazone solutions. The keto acid yield was 84%. It was shown in this keto acid assay that the amino acid does not interfere with the analysis for the keto acid, making it unnecessary to separate the keto acid from the D-leucine.

Advantages of the oxidative deamination method for resolution are that it requires simple materials, is easily adaptable to hot cell conditions, and produces each of the enantiomers depending on the amino acid oxidase used.

Correction of Perfusate Concentration for Sample Removal

WILLIAM L. HAYTON ˣ and TINA CHEN

Received August 17, 1981, from the *College of Pharmacy, Washington State University, Pullman, WA 99164-6510.* Accepted for publication October 13, 1981.

Abstract □ Repeated sampling of a drug solution that is recirculated through a perfused body increases the rate of drug disappearance from the perfusate. When the volume of the drug solution (V_T) is maintained constant by addition of drug-free perfusate after sampling, the measured drug concentration (C_i) can be corrected for drug removed in previous samples by using the equation $C_i' = C_i V_T C_{i-1}'/(V_T - V_S)C_{i-1}$, where C_i' is the corrected drug concentration in the ith sample, V_S is the volume of the sample, and $C_1' = C_1$. An error in any particular C_i is not transmitted to a subsequent C_i' value. The method can be used when the time interval between samples and when V_S vary from sample to sample, but return of the drug from the perfused body to the perfusate after sampling may cause C_i' to be overestimated.

Keyphrases □ Perfusates—correction of perfusate concentration for sample removal □ Drug concentration—correction of perfusate concentration for sample removal □ Correction methods—perfusate concentrations for sample removal

Several experimental techniques involve the perfusion of a tissue, an organ, or an entire organism with a drug solution (perfusate); *e.g.*, muscle (1), kidney (2), placenta (3), liver (4), intestine (5), and fish (6). Samples of the perfusate are periodically removed for determination of drug concentration. One experimental approach involves sampling the perfusate after it is passed once through the perfused body. An alternative approach is to recirculate the perfusate, usually by pumping it from a reservoir, through the perfused body, and back to the reservoir. Using the once-through approach, correction for sampling is unnecessary. When samples are removed repeatedly from recirculated perfusate, however, the concentration of drug is reduced, as a result of sample removal, in all samples but the first. Sample removal thereby biases the concentration–time relationship and confounds a kinetic analysis of the data.

If the ratio of the total sample volume to the perfusate volume is small, the bias is small and may be ignored. This ratio can be reduced by reducing the sample volume, reducing the number of samples, or increasing the volume

Correction of Perfusate Concentration for Sample Removal

WILLIAM L. HAYTON ˣ and TINA CHEN

Received August 17, 1981, from the *College of Pharmacy, Washington State University, Pullman, WA 99164-6510.* Accepted for publication October 13, 1981.

Abstract □ Repeated sampling of a drug solution that is recirculated through a perfused body increases the rate of drug disappearance from the perfusate. When the volume of the drug solution (V_T) is maintained constant by addition of drug-free perfusate after sampling, the measured drug concentration (C_i) can be corrected for drug removed in previous samples by using the equation $C_i' = C_i V_T C_{i-1}'/(V_T - V_S)C_{i-1}$, where C_i' is the corrected drug concentration in the ith sample, V_S is the volume of the sample, and $C_1' = C_1$. An error in any particular C_i is not transmitted to a subsequent C_i' value. The method can be used when the time interval between samples and when V_S vary from sample to sample, but return of the drug from the perfused body to the perfusate after sampling may cause C_i' to be overestimated.

Keyphrases □ Perfusates—correction of perfusate concentration for sample removal □ Drug concentration—correction of perfusate concentration for sample removal □ Correction methods—perfusate concentrations for sample removal

Several experimental techniques involve the perfusion of a tissue, an organ, or an entire organism with a drug solution (perfusate); *e.g.*, muscle (1), kidney (2), placenta (3), liver (4), intestine (5), and fish (6). Samples of the perfusate are periodically removed for determination of drug concentration. One experimental approach involves sampling the perfusate after it is passed once through the perfused body. An alternative approach is to recirculate the perfusate, usually by pumping it from a reservoir, through the perfused body, and back to the reservoir. Using the once-through approach, correction for sampling is unnecessary. When samples are removed repeatedly from recirculated perfusate, however, the concentration of drug is reduced, as a result of sample removal, in all samples but the first. Sample removal thereby biases the concentration–time relationship and confounds a kinetic analysis of the data.

If the ratio of the total sample volume to the perfusate volume is small, the bias is small and may be ignored. This ratio can be reduced by reducing the sample volume, reducing the number of samples, or increasing the volume

0022-3549/82/0700-0820$01.00/0

of the perfusate. Reduction of the sample volume is limited by the sensitivity of the drug assay. Reducing the number of samples and increasing the perfusate volume are not good strategies as either one tends to obscure the kinetic behavior of the drug. In most cases the optimum approach is to remove a relatively large number of samples and to maintain the volume of the perfusate in the reservoir as small as is conveniently possible. To do this, the sampling-induced bias in the concentration–time data must be removed.

Two techniques for correction of perfusate concentration for sample removal have been described (4, 7). Both techniques require the assumption of a particular kinetic model before the correction can be made. The present report describes a relatively simple technique for correction of measured concentrations for previously removed samples. The correction is exact if no back transfer of drug occurs from the body to the perfusate after sampling. In many cases when back transfer does occur, the method introduces an acceptable error and may still be used.

EXPERIMENTAL

The perfusion system was the perfused body, an external reservoir, and a pump that recirculated perfusate between the reservoir and perfused body. Samples of perfusate were removed periodically from the reservoir and the concentration of drug in each perfusate sample was determined. The volume of the perfusate was maintained constant by addition of drug-free perfusate to the reservoir after a sample was removed. Because the sampling process removes drug from the perfusate, the concentration of drug in the sampled perfusate declined more rapidly than it would have if sampling had not occurred. If the perfused body eliminated drug from the perfusate by a zero-order process, the measured drug concentration would be corrected by adding the total amount of drug removed in previous samples divided by the volume of the perfusate.

Usually, however, the drug elimination rate is proportional to the drug concentration in the perfusate. In this case it is not correct to add the amount removed in samples to subsequently determined concentrations, since part of the drug removed as a sample would have been consumed if the sample had not been removed. The problem then is to determine how much of the drug that was removed in each sample to add to each subsequently measured concentration.

Assume that the drug concentration in the perfusate declines exponentially, and let C_i represent the measured drug concentration in the ith sample. The concentration of drug in the reservoir after removal of the first sample and addition of drug-free perfusate would be $C_1(V_T - V_S)/V_T$, where V_T and V_S are the volumes of the perfusate and the sample, respectively. The measured concentration of drug in the perfusate at the time that the second sample was removed can be corrected for drug removed in the first sample as follows:

$$C'_2 = C_2 V_T/(V_T - V_S) \qquad \text{(Eq. 1)}$$

C'_2 is the corrected drug concentration, *i.e.*, the concentration that would have been measured if the first sample had not been removed. In making the correction, it was assumed that the concentration of drug in the sample declined at the same rate as did the concentration of drug in the perfusate between the first and second samples. The measured concentration in the third sample can be corrected for drug removed in the first two samples:

$$C'_3 = C_3\left(\frac{V_T}{V_T - V_S}\right)\left(\frac{C'_2}{C_2}\right) \qquad \text{(Eq. 2)}$$

The term $V_T/(V_T - V_S)$ corrects for drug removed in the second sample, and the term C'_2/C_2 corrects for drug removed in the first sample. Correction of the fourth and subsequent samples is similar to the correction for the third sample:

$$C'_n = C_n\left(\frac{V_T}{V_T - V_S}\right)\left(\frac{C'_{n-1}}{C_{n-1}}\right) \qquad \text{(Eq. 3)}$$

RESULTS AND DISCUSSION

The validity of the method was explored by using it to correct calculated drug concentrations, assuming some probable cases for drug disappearance kinetics. The proposed method was exact when drug was eliminated monoexponentially from the perfusate by apparent first-order kinetics. The method permits flexibility in that the time interval between samples and the volume of each sample can be varied from sample to sample. In addition, an error in the concentration determined for a particular sample is not transmitted by the method to subsequent samples. When the drug concentration was assumed to decline according to a biexponential equation, the correction was also exact. However, a biexponential concentration–time relationship usually indicates that drug distributes between the perfused body and the perfusate. Simulations using the model described previously (7), a two-compartment model with drug distribution between perfusate and perfused body followed by drug elimination from the perfused body, showed that the method is not exact when drug returns from the perfused body as a result of an instantaneous decrease in the drug concentration in the perfusate. The corrected concentration in the sampled perfusate was higher than the corresponding concentration in unsampled perfusate from the third to the final sample. The percentage error increased with the sample number, and it depended on the amount of drug that returned to the perfusate after sampling, compared to the amount of drug in the perfusate. The error in the final corrected concentration increased with the number of samples, the sample volume, the apparent volume of distribution of the perfused body relative to the volume of perfusate, and as drug clearance from the perfused body increased relative to the reversible clearance between the perfusate and the perfused body. If the method is used when a distributive phase in the perfusate concentration–time data is apparent, simulation with the model described previously (7) is recommended to select a sampling regimen that does not introduce unacceptable error. In some cases the correction method described previously (7) may be required.

Thiazides IV: Comparison of Dissolution with Bioavailability of Chlorothiazide Tablets

VINOD P. SHAH [x], **PATRICK KNIGHT, VADLAMANI K. PRASAD, and BERNARD E. CABANA**

Received Jan 26, 1981, from the *Division of Biopharmaceutics, Bureau of Drugs, Food and Drug Administration, Washington, DC 20204.* Accepted for publication October 6, 1981.

Abstract □ Based on the initial dissolution rate profiles in water, a slow-dissolving, an intermediate-dissolving, and a fast-dissolving chlorothiazide 250-mg tablet were selected for the bioavailability and bioequivalence study. In addition, two marketed 500-mg chlorothiazide tablets were studied. The three 250-mg tablets were bioequivalent, as were the two 500-mg tablets. Therefore, the dissolution test conditions were modified to associate *in vitro* dissolution with *in vivo* performance of the product. Based on these results, it was concluded that a dissolution of 75% in 60 min by paddle method at 75 rpm in pH 7.4 phosphate buffer can be used as a quality assurance test for 250- and 500-mg chlorothiazide tablets.

Keyphrases □ Thiazides—dissolution–bioavailability comparison, chlorothiazide tablets □ Bioavailability—comparison to dissolution, thiazides, chlorothiazide tablets □ Dissolution—comparison to bioavailability, thiazides, chlorothiazide tablets □ Chlorothiazide—tablets, bioavailability–dissolution comparison, thiazides

A drug product such as a tablet or capsule consists of the active ingredient, the drug itself, and the inactive ingredients such as fillers, binding agents, lubricants, and other substances which, along with the process factors, influence the products' dissolution and its performance. The dissolution test has emerged as the single most important *in vitro* test for ensuring the quality of the solid oral dosage forms (tablets and capsules) and in many instances predicts the bioavailability of the product. In instances where the dissolution test results have been correlated with *in vivo* performance of the product, *in vitro* dissolution test criteria are used as part of bioequivalence requirements by the Food and Drug Administration. In the absence of *in vivo*-correlated *in vitro* results, the dissolution test can be used to ensure the characteristic of the batch.

The steps necessary to arrive at a meaningful correlation between *in vitro* dissolution and *in vivo* performance of a product include: (*a*) a dissolution survey of marketed multisource drug products by a method, (*b*) selection of drug products with a wide range of dissolution profiles for bioavailability study, (*c*) determination of apparent *in vitro–in vivo* correlation, and (*d*) refinement (if necessary) of the dissolution tests to reflect *in vivo* product performance and optimize the *in vitro–in vivo* correlation.

An *in vitro* dissolution test is reported for marketed chlorothiazide tablets which is associated with *in vivo* performance, and which could be utilized as a quality assurance test.

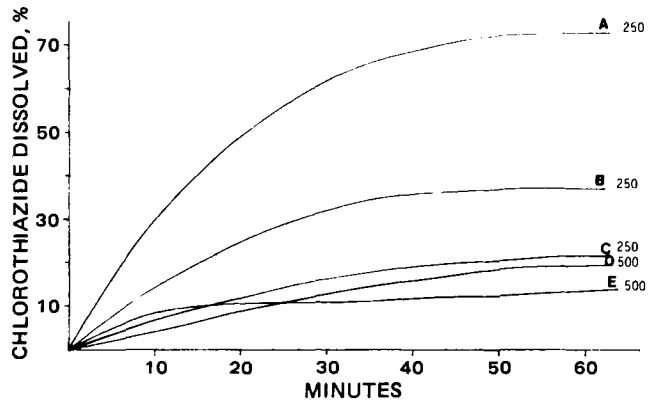

Figure 1—*Dissolution profiles of 250- and 500-mg chlorothiazide tablets in water by USP paddle method at 50 rpm.*

EXPERIMENTAL

Materials—The chlorothiazide tablets for the study were obtained directly from the manufacturers. The following products were used: 250 mg A, 250 mg B, 250 mg C, 500 mg D and 500 mg E[1].

***In Vitro* Dissolution Test**—The dissolution test was carried out by the procedure described in USP XX using the compendial Method II (paddle method) (1). Agitation speeds of 50, 75, and 100 rpm were used. The dissolution medium was distilled water, pH 7.4 or pH 8.0 phosphate buffer at 37 ± 0.2°.

***In Vivo* Tests**—The *in vivo* tests were carried out in 12 normal, healthy volunteers using a complete crossover Latin-square design. The urine samples were collected at intervals over a 72-hr period and were analyzed by a specific and sensitive HPLC method. The details of the study and the results are described elsewhere (2, 3).

RESULTS AND DISCUSSION

At present there is no dissolution test requirement for chlorothiazide 250- and 500-mg tablets in the compendia. The survey of dissolution profiles of marketed 250- and 500-mg tablets was carried out using a paddle method (USP XX, Method II) in water at 50 rpm. Several lots of the innovator's product were screened. The results of the survey (Table I, Fig. 1) suggest a wide variation in dissolution profiles under the test conditions. For 250-mg tablets, the dissolution varied from 15 to 81% in 30 min and from 21 to 88% in 60 min. Based on these results, three products with a wide range in dissolution profiles—slow dissolving product C, intermediate dissolving product B, and fast dissolving product A—were selected for the bioavailability–bioequivalence study. There are only two approved 500-mg chlorothiazide tablets on the market, and both showed very poor dissolution profiles. They were also used in the bioavailability–bioequivalence study.

The bioavailability–bioequivalence study was carried out in 12 healthy volunteers in a crossover fashion using 250-mg A, B, and C products. In another crossover study with 12 volunteers, 500-mg D and E products were used. The urine samples were collected at intervals over a 72-hr period and analyzed by a specific and sensitive HPLC method. The cumulative amount of drug excreted in 72 hr was calculated and used as a measure of the bioavailability of the product (Table II). The details of the *in vivo* studies are described elsewhere (2, 3).

From a 250-mg tablet, a mean of 42, 52, and 45 mg of chlorothiazide was recovered in 72 hr from C, B, and A tablets, respectively (Table II). The total amount of drug excreted in 72 hr was not significantly different between tablets. All products were bioequivalent.

In vitro dissolution results by the paddle method at 50 rpm in water could not be correlated with *in vivo* results because all the products showed approximately the same amount of drug elimination (absorption) in 72 hr and were bioequivalent. This suggests that the preliminary dis-

[a] Data represents mean dissolution of six tablets. [b] The standard deviation is given in parenthesis.

solution method for chlorothiazide tablets in water was overly discriminative. Therefore, this *in vitro* dissolution test was modified in order to arrive at a meaningful *in vitro* test.

Two types of *in vivo–in vitro* relationships are possible. The first type of relationship is where different *in vitro* dissolution results can be correlated with differences in observed *in vivo* parameters such as *AUC*, *Ae*, C_{max}, *etc.* The second type of relationship is where all products tested are bioequivalent, and *in vitro* dissolution data is associated with a minimum dissolution rate. In the case of chlorothiazide, where all three 250-mg products tested are bioequivalent (*i.e.*, no difference in amount of chlorothiazide recovered from urine in 72 hr), an attempt was made to obtain the latter type of *in vitro–in vivo* relationship. From the latter type of *in vitro–in vivo* relationship, and in the absence of any bioinequivalent product, the *in vitro* dissolution method will at least serve as a quality assurance test. Since several formulations made by different manufacturers were used in this study, one can be reasonably assured that a new product meeting this *in vitro* test will be bioequivalent with existing products.

Using USP Method II, the dissolution of 250-mg chlorothiazide tablets was carried out in pH 7.4 and 8.0 phosphate buffer at 50, 75, and 100 rpm (Table I). The dissolution results at 50 rpm were found to be slow and highly discriminative, whereas the agitation at 100 rpm was found to be so drastic and indiscriminative that it may not differentiate between the currently marketed bioequivalent products and a possible poorly bioavailable future generic product. The agitation at 75 rpm in pH 7.4 phosphate buffer was found to be appropriate and reasonable for all bioequivalent 250-mg products. Using pH 7.4 phosphate buffer medium and 75 rpm agitation, a dissolution of 70–94% in 30 min and 82–97% in 60 min was observed (Table II).

There are only two approved 500-mg chlorothiazide tablets on the market, and both showed poor dissolution in water at 50 rpm (Table I).

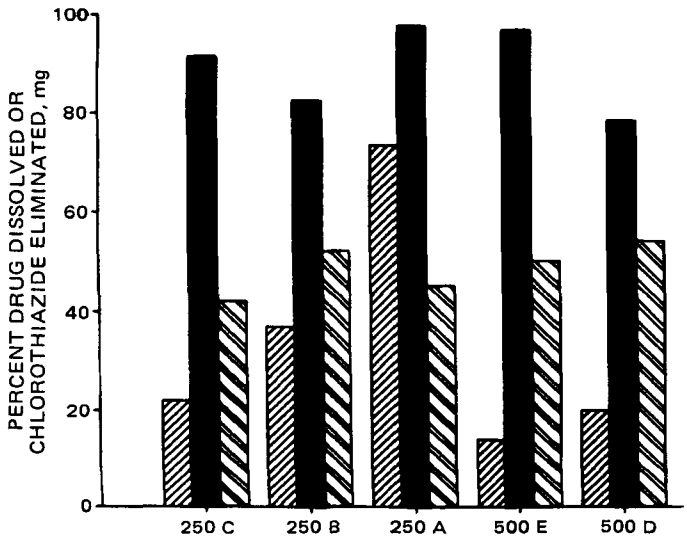

Figure 2—In vitro *dissolution (percent dissolved in 60 min) and* in vivo *cumulative elimination (milligrams in 72 hr) for 250- and 500-mg chlorothiazide tablets. Key: (▨) percent dissolved in water; (■) % dissolved in pH 7.4 phosphate buffer; and (▧) chlorothiazide eliminated in urine.*

Table II—Relationship Between *In Vitro–In Vivo* Parameters for Chlorothiazide Tablets

Product	*In Vitro* Dissolution Data[a]				*In Vivo* Cumulative[b] Excretion Data, mg mean ± *SD*	
	Water		pH 7.4 buffer			
	20 min	60 min	30 min	60 min		
250 mg C	16	22	73	91	42	15
250 mg B	32	37	71	82	52	25
250 mg A	62	73	94	97	45	19
500 mg E	11	14	79	96	50	13
500 mg D	13	20	56	78	54	15

[a] *In vitro* dissolution data obtained by paddle method in water at 50 rpm and pH 7.4 phosphate buffer at 75 rpm. [b] Represents mean cumulative excretion in 12 subjects.

Both products showed the same extent of absorption and elimination, and were bioequivalent. The dissolution of these two 500-mg products was studied under various test conditions. A dissolution of 56–79% in 30 min and 78–96% in 60 min was achieved by the paddle method at 75 rpm in pH 7.4 phosphate buffer.

As seen in Table II, approximately the same amount of drug was eliminated in urine in 72 hr from both 250- and 500-mg chlorothiazide tablets. There is no statistical difference in the bioavailability of these two products in normal healthy volunteers. The implications of this bioavailability finding are discussed separately (2–4). Both 250- and 500-mg tablets achieved approximately the same percent of dissolution in pH 7.4 phosphate buffer by the paddle method at 75 rpm. Figure 2 shows the relationship between *in vivo* and *in vitro* data. For comparison, *in vitro* dissolution data in water are also included. The figure clearly shows that the amount of drug eliminated in urine and the amount of drug dissolved in phosphate buffer are nearly the same in all five formulations studied.

In order to evaluate the appropriateness of the dissolution method and the acceptance limits as a routine quality control test, additional batches of chlorothiazide tablets were tested. These products[2] represented four manufacturers and were different from those that were used in the bioequivalency study. The results showed that all products dissolved >75% in 60 min, thus suggesting that these products would be bioequivalent.

A dissolution test which will ensure the quality of chlorothiazide tablets has been established. The product should dissolve not less than 75% in 60 min when the dissolution test is carried out by USP paddle method in 900 ml of pH 7.4 phosphate buffer at 37° and agitation of 75 rpm. On the basis of these findings, it is reasonable to expect that a product meeting such a dissolution criterion will be bioequivalent to the marketed product.

Effect of Skin Binding on Percutaneous Transport of Benzocaine from Aqueous Suspensions and Solutions

U. G. DALVI * and J. L. ZATZ ˣ

Received March 27, 1981, from the *Rutgers College of Pharmacy, Piscataway, NJ 08854.* Accepted for publication October 7, 1981.
* Present Address: E. R. Squibb & Sons, Inc., New Brunswick, NJ 08903.

Abstract □ Various aqueous suspensions of benzocaine containing nonionic surfactants exhibited the same rate of *in vitro* penetration through hairless mouse skin. Saturated solutions yielded a lower rate of benzocaine penetration due to depletion of drug from the donor portion of the diffusion cell. Extensive skin binding was responsible.

Keyphrases □ Benzocaine—effect of skin binding on percutaneous transport from aqueous suspensions and solutions □ Skin binding—effect on percutaneous transport of benzocaine from aqueous suspensions and solutions □ Percutaneous transport—effect of skin binding, of benzocaine from aqueous suspensions and solutions

The effect of surfactants on drug penetration through skin is an important aspect of formulation of topical drug products. The influence of these additives depends on the rate-limiting step in penetration, so that the type of preparation and conditions of application to the skin are important considerations. Penetration from aqueous solutions containing a fixed benzocaine concentration depended on the extent of benzocaine solubilization by surfactant included in the formula (1). Penetration flux was directly proportional to the unbound benzocaine concentration. A series of surfactant solutions saturated with benzocaine had the same rate of benzocaine penetration. No alteration of membrane permeability was found. This work was extended to aqueous gel suspensions to determine the rate limiting step in penetration and the influence of nonionic surfactants in these systems. The suspensions were similar to those utilized in previous studies of benzocaine release (2, 3).

EXPERIMENTAL

Materials and apparatus used for the *in vitro* penetration experiments were reported previously (1). Surfactants used in the formulations were commercially available polyoxyethylene nonylphenols[1]. The membrane was whole hairless mouse skin. The receptor solution (normal saline containing 0.25% chlorobutanol) was maintained at 37° and stirred at 500 rpm. The donor compartment was not stirred. Further details concerning experimental procedure appeared previously (1). All donor systems were studied in triplicate.

All the suspensions were prepared on a w/v basis. Accurately measured surfactant stock solution was transferred to a wide mouth glass jar containing a magnetic stirring bar. To that solution, the required amount of benzocaine was added and stirring was continued for ~15 min until all lumps were broken. A preweighed quantity of gelling agent was sprinkled on the top and stirring was continued for ~3 hr to yield a smooth homogeneous suspension. A control suspension without the drug was prepared for every formulation. All the suspensions were analyzed for benzocaine content and were stored at 30° until needed.

[1] Igepal CO series, GAF Corp., N.Y.

RESULTS AND DISCUSSION

Details of the suspension formulations are listed in Table I. In the case of all the formulations studied, when the cumulative amount of benzocaine in the receptor compartment was plotted against time, a linear relationship with a small lag time was observed. A typical plot is shown in Fig. 1. The gradual rise in penetration rate (Fig. 1) until steady state was achieved is typical of membrane controlled diffusion. When transport through the vehicle is rate limiting, the flux is initially high and then gradually decreases with time. A second indication that diffusion across the stratum corneum was the slow step in benzocaine transport is high flux values obtained from the suspension formulations, which will be discussed.

The flux values were calculated for all formulations (Table I). ANOVA showed that drug concentration, gelling agent, and surfactant concentration had no statistically significant effect on flux. No influence of the surfactants on skin membrane integrity was evident.

These results are similar to those with saturated benzocaine solutions (1). However, there is a surprising difference in the magnitude of the penetration values when saturated solutions are compared to suspensions. Mean benzocaine flux from saturated solutions was ~60 $\mu g\ hr^{-1}\ cm^{-2}$ (1), whereas the average flux for suspensions was 101 $\mu g\ hr^{-1}\ cm^{-2}$. This difference was unexpected since the free benzocaine concentration, which provides the driving force for diffusion, should have been the same in both types of preparation.

In penetration experiments, the amount of drug transported during the course of an experiment is usually small enough to justify the assumption that the donor concentration is constant. In conducting experiments on benzocaine solutions, there had been no reason to question the validity of this basic assumption. However, in view of the difference in benzocaine flux from saturated solutions as compared to suspensions, it was hypothesized that depletion of drug from the donor must have been taking place in the solution systems during the course of the penetration experiments.

Table I—Skin Penetration of Benzocaine from Aqueous Suspensions

Formulation	Benzocaine Concentration, % w/v	Gelling Agent, % w/v: Hydroxypropyl Cellulose	Gelling Agent, % w/v: Xanthan Gum	Surfactant Concentration $M \times 10^3$: $n = 50$	Surfactant Concentration $M \times 10^3$: $n = 15$	Flux ± *SD*, mg hr^{-1} $cm^{-2} \times 10^3$
A	1	2	—	—	22.7	97.3 ± 6.5
B	5	2	—	—	22.7	109.8 ± 4.3
C	10	2	—	—	22.7	98.6 ± 8.1
D	1	—	0.4	—	22.7	88.9 ± 7.3
E	5	—	0.4	—	22.7	97.3 ± 8.7
F	5	—	0.4	22.7	—	108.6 ± 6.3
G	5	—	0.4	—	2.27	107.8 ± 6.2

To test this hypothesis, a set of skin penetration experiments was conducted using a saturated aqueous benzocaine solution as donor, and at regular intervals the donor and receptor solutions were sampled and analyzed for benzocaine content. Figure 2 shows the results of these experiments. From the start, drug concentration in the donor dropped rapidly. The rate of drug transport to the receptor under sink conditions dropped during the 24-hr period for which data were collected. However, for the first 8–10 hr, the usual time allotted to previous experiments, the penetration rate was pseudo zero-order.

Assuming that the drug is distributed between donor, receptor, and skin at any given time, the donor and receptor were analyzed and the amount of benzocaine present in skin as a function of time was calculated by difference. Results are plotted in Fig. 2. There was significant uptake of benzocaine by the membrane. At the end of 24 hr, the skin contained 1.2 mg of benzocaine, while only 0.65 mg of benzocaine was left in the donor compartment.

To confirm the fact that a significant amount of benzocaine was actually retained in the skin, a new set of experiments was performed. A saturated aqueous solution was placed on hairless mouse skin and left undisturbed for 24 hr. At the end of 24 hr, the donor and receptor solutions were completely removed from the diffusion cell and analyzed for benzocaine content. The amount of benzocaine retained in the skin was estimated as the difference between the original quantity in the donor and that found in the analyses. The donor solution was then replaced by distilled water and the experiment was continued with regular withdrawal and replacement of receptor solution. The results are plotted in Fig. 3. Benzocaine release continued for the duration of the experiment (144 hr). Approximately 70% of the benzocaine estimated to be in the skin was removed during this period. These data confirm that a significant quantity of benzocaine was bound by the skin.

The mineral oil–water partition coefficient of benzocaine is ~0.9. Based on the relative volumes of the skin and donor compartments, the apparent skin–donor partition coefficient is many times higher than this value. Apparently, proteinaceous material in the skin is responsible for benzocaine uptake. Although no data on protein binding of benzocaine was found, other anilide local anesthetics such as lidocaine, mepivacaine, and bupivacaine are bound by proteins (4). Investigation of skin binding of drugs has not been extensive. *In vitro* binding of testosterone and benzyl alcohol to human dermis was reported previously (5, 6).

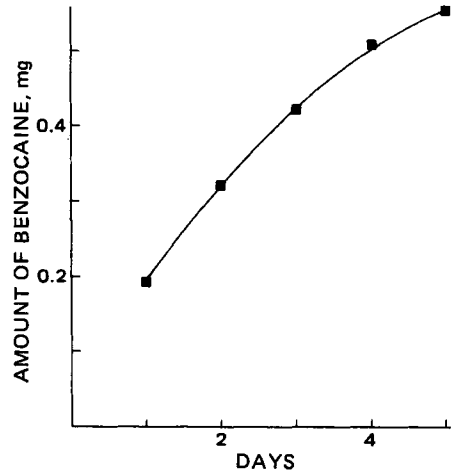

Figure 3—*Benzocaine release from the skin after complete withdrawal of donor solution.*

A dual sorption model was used (7) to explain the sorption and skin penetration behavior of aqueous scopolamine solutions. The same model is in qualitative agreement with the findings on benzocaine transport through hairless mouse skin. A significant portion of the benzocaine that enters the stratum corneum is immobilized there without contributing to the flux. This material, together with the benzocaine that partitions in the membrane and diffuses into the receptor, causes loss of benzocaine from the donor. If the donor is a suspension, the solid particles act as a reservoir to replenish lost benzocaine and maintain a constant concentration. Sorbed benzocaine equilibrates with nonimmobilized drug, the system eventually reaches diffusional steady state and the sorption of benzocaine by the membrane has no effect on the penetration flux. However, with benzocaine solutions, drug that is lost from the donor by penetration and sorption is not replaced and the driving force for penetration is reduced. The result is a decrease in the apparent steady-state

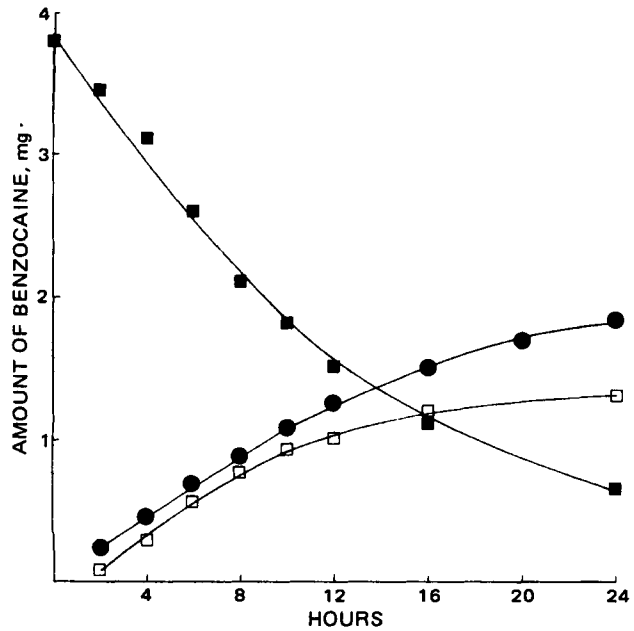

Figure 2—*Skin penetration of benzocaine from saturated aqueous solution. Key: (■) donor; (●) receptor; (□) skin.*

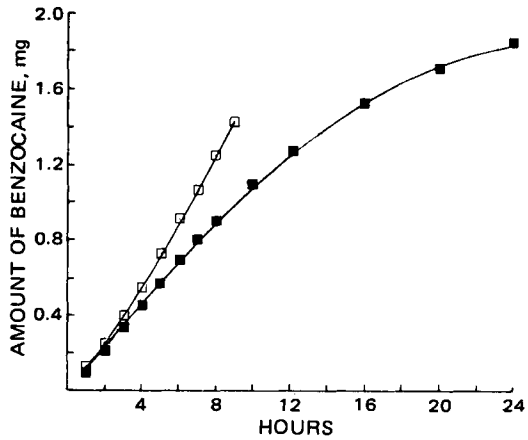

Figure 4—*Skin penetration of benzocaine from saturated aqueous solution. Key: (■) saturated solution; (□) saturated solution with 1 mg/ml of excess drug.*

flux value, in comparison to suspensions, as well as a continuing reduction in flux with time.

As a final test of this explanation, and to ensure that the surfactant used in the suspension formulations did not influence the results, experiments were performed using a saturated solution of benzocaine in water to which excess benzocaine (1 mg/ml) was added.

The results are plotted in Fig. 4 for the penetration profiles with and without excess drug in donor. It is evident that the slopes for the two curves are different. The flux for the donor with excess drug (100×10^{-3} mg hr^{-1} cm^{-2}) was very close to the values obtained for the suspension systems (Table I).

Degradation of Melphalan in Aqueous Solutions—Influence of Human Albumin Binding

HANS EHRSSON ˣ **and ULLA LÖNROTH**

Received April 28, 1981, from the *Karolinska Apoteket, S-104 01 Stockholm, Sweden.* Accepted for publication September 28, 1981.

Abstract □ The protein binding and degradation rate of melphalan in human albumin solutions and plasma have been investigated. In plasma, melphalan is bound 69.0 ± 3.4% (25°, melphalan concentration 25 μg/ml). The stability of melphalan when bound to albumin is about three times higher ($k = 3.07 \times 10^{-2} \pm 0.48 \times 10^{-2}$ hr^{-1}) than unbound in solution ($k = 1.14 \times 10^{-1} \pm 0.01$ hr^{-1}).

Keyphrases □ Melphalan—degradation studies in aqueous solutions, influence of human albumin binding □ Binding—human albumin to melphalan, degradation of melphalan in aqueous solutions □ Albumin, human—influence in binding with melphalan, degradation in aqueous solutions

Melphalan, an alkylating agent of the nitrogen mustard type, can be bound to plasma proteins as a result of a chemical reaction with the protein molecules as well as by a process of reversible adsorption (1). At least 60% of melphalan was bound to serum proteins (26°) as studied by an equilibrium dialysis technique (2). However, the quantitative determinations were performed using an unselective technique, and it is unclear to what extent the results are affected by a codetermination of degradation products of melphalan formed during the dialysis procedure. Melphalan (30%) was observed previously to be undialyzable in human plasma (4°), the quantitative determinations being performed by high-performance liquid chromatography (1). In the present study the reversible protein binding of melphalan in albumin solutions and human plasma has been determined by a modified ultrafiltration technique (3). Since the binding of melphalan to albumin might have a profound effect on its stability *in vivo* (4), the rate constants for the degradation of protein-bound and free melphalan have been evaluated.

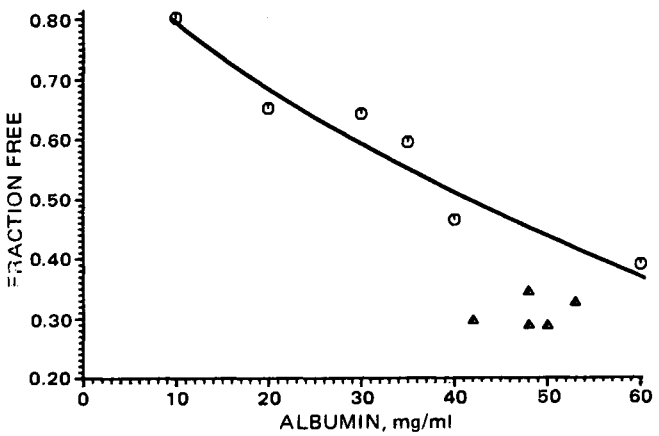

Figure 1—*Influence of albumin concentration on fraction free melphalan (25°; melphalan concentration: 25 μg/ml). The fraction free melphalan is a mean of four determinations. Key: (○) albumin solutions; (▲) plasma samples.*

EXPERIMENTAL

Degradation Studies—Melphalan[1], dissolved in 0.1 *M* HCl, was diluted 100 times with a solution of human albumin[2] in isotonic phosphate buffer pH 7.35 (NaCl concentration 0.095 *M*) or plasma[3] to a final melphalan concentration of 25 μg/ml. The mixture was incubated at 25.0 ± 0.1° and at appropriate times aliquots were analyzed by liquid chromatography.

Protein-Binding Studies—The protein binding was determined using a modified ultrafiltration technique (3). The studies were carried out at 25 ± 2° using albumin or plasma solutions containing 25 μg/ml of melphalan, unless otherwise stated. The degradation of melphalan in the ultrafiltrate was minimized by collecting it in albumin solutions containing the same concentration of albumin as the solution inside the dialysis tubing. No binding of melphalan to the dialysis membrane could be observed as studied by ultrafiltration of melphalan dissolved in isotonic phosphate buffer pH 7.35.

Quantitative Analysis—The quantitative determinations of melphalan were performed by liquid chromatography according to previous

flux value, in comparison to suspensions, as well as a continuing reduction in flux with time.

As a final test of this explanation, and to ensure that the surfactant used in the suspension formulations did not influence the results, experiments were performed using a saturated solution of benzocaine in water to which excess benzocaine (1 mg/ml) was added.

The results are plotted in Fig. 4 for the penetration profiles with and without excess drug in donor. It is evident that the slopes for the two curves are different. The flux for the donor with excess drug (100×10^{-3} mg hr^{-1} cm^{-2}) was very close to the values obtained for the suspension systems (Table I).

Degradation of Melphalan in Aqueous Solutions—Influence of Human Albumin Binding

HANS EHRSSON ˣ **and ULLA LÖNROTH**

Received April 28, 1981, from the *Karolinska Apoteket, S-104 01 Stockholm, Sweden.* Accepted for publication September 28, 1981.

Abstract □ The protein binding and degradation rate of melphalan in human albumin solutions and plasma have been investigated. In plasma, melphalan is bound 69.0 ± 3.4% (25°, melphalan concentration 25 μg/ml). The stability of melphalan when bound to albumin is about three times higher ($k = 3.07 \times 10^{-2} \pm 0.48 \times 10^{-2}$ hr^{-1}) than unbound in solution ($k = 1.14 \times 10^{-1} \pm 0.01$ hr^{-1}).

Keyphrases □ Melphalan—degradation studies in aqueous solutions, influence of human albumin binding □ Binding—human albumin to melphalan, degradation of melphalan in aqueous solutions □ Albumin, human—influence in binding with melphalan, degradation in aqueous solutions

Melphalan, an alkylating agent of the nitrogen mustard type, can be bound to plasma proteins as a result of a chemical reaction with the protein molecules as well as by a process of reversible adsorption (1). At least 60% of melphalan was bound to serum proteins (26°) as studied by an equilibrium dialysis technique (2). However, the quantitative determinations were performed using an unselective technique, and it is unclear to what extent the results are affected by a codetermination of degradation products of melphalan formed during the dialysis procedure. Melphalan (30%) was observed previously to be undialyzable in human plasma (4°), the quantitative determinations being performed by high-performance liquid chromatography (1). In the present study the reversible protein binding of melphalan in albumin solutions and human plasma has been determined by a modified ultrafiltration technique (3). Since the binding of melphalan to albumin might have a profound effect on its stability *in vivo* (4), the rate constants for the degradation of protein-bound and free melphalan have been evaluated.

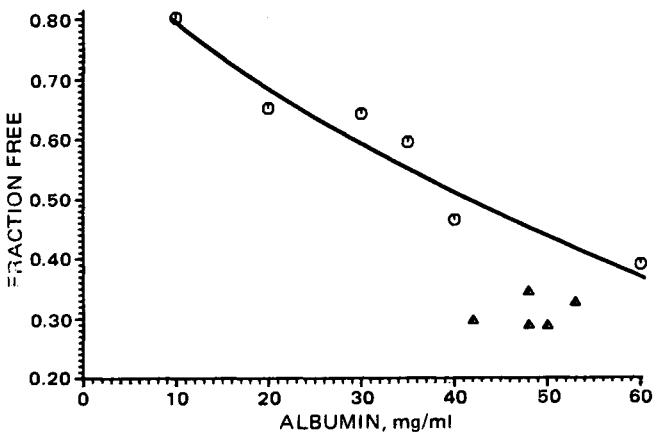

Figure 1—*Influence of albumin concentration on fraction free melphalan (25°; melphalan concentration: 25 μg/ml). The fraction free melphalan is a mean of four determinations. Key: (○) albumin solutions; (▲) plasma samples.*

EXPERIMENTAL

Degradation Studies—Melphalan[1], dissolved in 0.1 *M* HCl, was diluted 100 times with a solution of human albumin[2] in isotonic phosphate buffer pH 7.35 (NaCl concentration 0.095 *M*) or plasma[3] to a final melphalan concentration of 25 μg/ml. The mixture was incubated at 25.0 ± 0.1° and at appropriate times aliquots were analyzed by liquid chromatography.

Protein-Binding Studies—The protein binding was determined using a modified ultrafiltration technique (3). The studies were carried out at 25 ± 2° using albumin or plasma solutions containing 25 μg/ml of melphalan, unless otherwise stated. The degradation of melphalan in the ultrafiltrate was minimized by collecting it in albumin solutions containing the same concentration of albumin as the solution inside the dialysis tubing. No binding of melphalan to the dialysis membrane could be observed as studied by ultrafiltration of melphalan dissolved in isotonic phosphate buffer pH 7.35.

Quantitative Analysis—The quantitative determinations of melphalan were performed by liquid chromatography according to previous

principles (1), using the same equipment as described previously (3). The results were evaluated using a standard curve prepared by adding known amounts of melphalan to albumin solutions and plasma.

RESULTS AND DISCUSSION

The protein binding of melphalan (25 μg/ml) was 69.0 ± 3.4% in plasma obtained from five donors, the mean albumin concentration being 48 mg/ml. No significant change in the degree of protein binding was observed in the concentration range 5–50 μg/ml of melphalan. The protein binding in albumin solutions was lower than in plasma containing comparable albumin concentrations (Fig. 1). The protein binding was 53.5 ± 1.7% at an albumin concentration of 40 mg/ml.

The influence of albumin concentration on the pseudo first-order rate constant for the degradation of melphalan is given in Fig. 2. The half-life for the degradation of melphalan is 9.88 ± 0.24 hr ($n = 10$, $r = 0.998$) at an albumin concentration of 40 mg/ml. The stability in plasma obtained from five donors is higher ($t_{1/2} = 12.80 \pm 0.52$ hr) than in albumin solutions containing comparable albumin concentrations.

The rate constant for the degradation of melphalan in albumin solutions (k_{obs}) can be expressed by (3):

$$k_{obs} = k_1 + f_{free}(k_2 - k_1)$$

where k_1 and k_2 are pseudo first-order rate constants for the degradation of protein-bound and free melphalan, respectively, and f_{free} is the fraction of free melphalan in solution. A plot of k_{obs} *versus* f_{free} in albumin solutions and plasma is given in Fig. 3. The fraction free melphalan in the albumin solutions was changed by the use of different albumin concentrations (10–60 mg/ml) at a constant ligand concentration (25 μg/ml). Evaluation of the rate constants by linear regression analysis using the data obtained in albumin solutions gave $k_1 = 3.07 \times 10^{-2} \pm 0.48 \times 10^{-2}$ hr^{-1} and $k_2 = 1.15 \times 10^{-1} \pm 0.09 \times 10^{-1}$ hr^{-1} ($r = 0.916$, $n = 24$). The rate constant for free melphalan obtained from the plot is in good agreement with the value obtained from degradation studies in albumin-free isotonic phosphate buffer pH 7.35 ($k_{obs} = 1.14 \times 10^{-1} \pm 0.01 \times 10^{-1}$ hr^{-1}, $n = 14$, $r = 0.999$). Thus, the stability of melphalan bound to albumin is about three times higher than unbound in solution.

Since the degradation rate of nitrogen mustards is increased markedly with increasing dielectric constant of the solvent (5), it can be concluded that the nitrogen mustard group of melphalan when bound to albumin is in a chemical environment with solvating properties different from those in pure aqueous solution. It has been shown previously (3) that the nitrogen mustard drug, chlorambucil, was efficiently protected from degradation when bound to albumin, the rate constant for the bound form being ~100 times lower than for chlorambucil being free in solution. This indicates that melphalan is bound to albumin in a different way than chlorambucil. Furthermore, it can be observed (Fig. 3) that the data obtained for melphalan in plasma fall on the line obtained from studies in pure albumin solutions. The increased stability for melphalan observed in plasma must, therefore, be due to a more excessive binding to albumin or to other plasma ligand(s) which bind the nitrogen mustard group in a similar way as albumin.

HPLC Analysis of Indomethacin and Its Impurities in Capsule and Suppository Formulations

E. KWONG, G. K. PILLAI, and K. M. McERLANE ˣ

Received June 30, 1981, from the *Faculty of Pharmaceutical Sciences, The University of British Columbia, Vancouver, BC, V6T 1W5, Canada.* Accepted for publication October 5, 1981.

Abstract □ Indomethacin and its impurities in suppository and capsule formulations were quantitatively determined by HPLC using a reversed-phase, octadecyl column and a mobile phase of methanol–water–acetonitrile–acetic acid (55:35:10:1). Analysis of the suppository formulations provided a mean potency for indomethacin of 103.8%. The same formulation was found to contain 4-chlorobenzoic acid (0.02%), 5-methoxy-2-methyl-3-indoleacetic acid (0.07%), 4-chlorobenzoic acid-α-monoglyceride (0.39%), and indomethacin-α-monoglyceride (0.9%) as impurities. The latter two impurities were a result of the interaction of indomethacin and 4-chlorobenzoic acid with glycerin used in the suppository base. Capsule formulations were likewise assayed with an average potency of 99.9 and 101.5% for 25- and 50-mg dosage forms, respectively. Only one of the two capsule formulations examined contained detectable quantities of 4-chlorobenzoic acid (0.05%).

Keyphrases □ Indomethacin—HPLC analysis, impurities in capsule and suppository formulations □ HPLC—indomethacin, impurities in capsule and suppository formulations □ Formulations—indomethacin, impurities in capsule and suppositories, HPLC analysis

Indomethacin is an anti-inflammatory and analgesic agent used in the treatment of rheumatoid arthritis, gout, degenerative joint disease, and other inflammatory conditions that do not respond to salicylates. Indomethacin may be synthesized by several routes (1–5), but these are generally modifications of the original method (1). The USP XX (6) contains monographs for the drug substance and capsule formulations, and the BP 1973 (7) includes monographs for these, as well as suppository formulations. The official pharmacopeias do not specify tests for impurities, and the hydrolytic, titrimetric assay procedure would not be indicative of purity if substances with structural similarities were present.

It has been reported that indomethacin is subject to hydrolysis in basic solutions (8) and in the presence of polysorbates (9). However, in only one instance has the presence of impurities in untreated capsule and suppository formulations been noted (10). Previous HPLC assay methods reported for the analysis of indomethacin in plasma (11) or capsule formulations (12) were not concerned with the detection or determination of impurities. The present method offers a rapid and simple HPLC procedure for the simultaneous quantitation of indomethacin and its major impurities in capsule and suppository formulations.

EXPERIMENTAL

Materials—All indomethacin (I) capsule and suppository formulations were obtained directly from the manufacturer[1]. Testosterone[2], 4-chlorobenzoic acid[3] (II), 5-methoxy-2-methyl-3-indoleacetic acid[4] (III), glycerin[5], and I drug substance[2] were used without further purification.

Methanol, water, and acetonitrile were HPLC quality[6], and acetic acid[7] and ether[8] were reagent grade. TLC plates[9] were precoated with silica gel G-25 UV (254) (20 × 20 cm, 0.25 mm). Solvents used for TLC were reagent grade[8].

HPLC System—An isocratic HPLC[10] equipped with a single piston pump[11], 20-μl loop injector[12], fixed wavelength detector[13] (254 nm), electronic data system printer/plotter[14], and a 5-μ reversed-phase (C-18) column (4.6 mm × 25 cm)[15] were used throughout. The mobile phase consisted of methanol–water–acetonitrile–acetic acid (55:35:10:1) and was pumped at 1 ml/min.

Synthesis of 4-Chlorobenzoic acid-α-monoglyceride (IV)—In a

50-ml screw-capped culture tube, 1 g of II was heated with 30 ml of glycerin at 60° for 96 hr. During this period II went into solution. The glycerin solution was dissolved in water (50 ml) and extracted with three 50-ml portions of ether. The combined ether extracts were evaporated under vacuum and the residue was dissolved in a minimum volume of ether, diluted with petroleum ether (bp 60–80°)[5] and left at 4° until crystals separated. The crystalline material was recrystallized from ether–petroleum ether to a constant melting point (88–89°). The product was analyzed by HPLC to determine the absence of starting material or other impurities, and its structure was confirmed by PMR, IR, and mass spectrometric analysis. The compound exhibited identical characteristics to that reported earlier (10).

Table I—Slope of the Calibration Curves for Indomethacin and its Impurities Determined at 254 nm

Compound	Slope	Intercept	Correlation Coefficient[a]
Indomethacin (I)	1.05	0.17	0.999
4-Chlorobenzoic Acid (II)	1.008	0.0	0.999
5-Methoxy-2-methyl-3-indoleacetic acid (III)	0.380	−0.008	0.999
4-Chlorobenzoic acid-α-monoglyceride (IV)	0.834	−0.003	0.996

[a] $n = 4$.

Table II—Recovery of Indomethacin from Capsule and Suppository Formulations

Form and Dosage	Drug Weight in Formulation, mg	Amount of Drug Added, mg	Recovery mg	Recovery (%)
Suppository, 100 mg	50.06	20.12	69.52	99.1
Capsule, 50 mg	49.15	21.58	68.81	98.1
Capsule, 25 mg	25.08	15.20	40.10	99.6

Isolation and Identification of Indomethacin-α-monoglyceride (V)—A 100-mg suppository was crushed, suspended in 5 ml of water, and extracted with three 50-ml portions of ether. The combined ether extracts were evaporated under vacuum, the residue was taken up in 4 ml of ether, and applied in a narrow band to four TLC plates precoated with silica gel G-25 UV. The plates were eluted with ether–acetic acid (100:1) for a distance of 15 cm. The major impurity band corresponding to V (R_f 0.25) was removed from the four plates and extracted from the silica gel with 100 ml of chloroform. The subsequent identity of this material was confirmed by PMR, IR, and mass spectrometric analysis and was identical to that reported earlier (10).

Standard Solutions—Stock solutions of I (175 mg/50 ml), II (0.5 mg/100 ml), III (1 mg/100 ml), and IV (2 mg/25 ml) were prepared in methanol. Two working solutions of the internal standard, testosterone, were prepared in ether (50 mg/50 ml) and methanol (50 mg/50 ml).

Determination of Linearity and Calibration Curves—*Impurities*—To four 10-ml screw-capped culture tubes were added 0.25, 0.50, 1.0, and 1.5 ml of each of the stock solutions of II, III, and IV, along with 1 ml of the internal standard in methanol. The volume of each tube was brought to 10 ml with methanol and 20 μl was used for analysis of each sample.

Indomethacin—To four 10-ml screw-capped culture tubes were added 0.5, 1, 2, 3, 4, and 8 ml of the stock solutions of I, along with 1 ml of the internal standard in methanol. The volume of each tube was brought to 10 ml with methanol, and 20 μl was used for analysis of each sample.

Extraction of Capsule and Suppository Formulations—*Capsules*—The contents of four capsules (25- or 50-mg dose) were removed, weighed, and combined. Two aliquots equivalent to 50 mg of I were transferred to two 50-ml screw-capped culture tubes. A 3-ml aliquot of the internal standard in ether was added to each tube along with 15 ml of water and 25 ml of ether. The tubes were tightly capped and tumbled for 20 min. The ether layer was removed, dried, and evaporated under a stream of clean, dry nitrogen. The residue was dissolved in 30 ml of methanol and 20 μl was used for analysis.

Suppositories—Four suppositories (100 mg of I/dose) were weighed and crushed. Five aliquots equivalent to 50 mg were placed in five 50-ml screw-capped culture tubes and treated as described previously.

Recovery of Indomethacin from Formulations—An amount of I, equivalent to half the amount of I contained in a suppository formulation (~50 mg), was placed in a screw-capped tube. An aliquot of 3 ml of the internal standard in ether, 15 ml of water, and 25 ml of ether were added, and the mixture was treated as described previously. A similar recovery experiment was conducted on capsule formulations.

RESULTS AND DISCUSSION

A previous publication (10) reported the degradation of indomethacin and its interaction with glycerin used in a suppository base (Scheme I). To more precisely analyze indomethacin and its impurities, an HPLC

Table III—Quantitation of Indomethacin and its Impurities in Capsule and Suppository Formulations

Compound	Dosage Forms[a], % 100-mg[b] Suppository	50-mg[c] Capsule	25-mg[c] Capsule
Indomethacin (I)	103.800 ± 2.160	101.50	99.85
4-Chlorobenzoic Acid (II)	0.020 ± 0.002	0.05	None
5-Methoxy-2-methyl-3-indole-acetic acid (III)	0.070 ± 0.007		
4-Chlorobenzoic acid-α-monoglyceride (IV)	0.390 ± 0.023		
Indomethacin-α-mono-glyceride (V)	0.919 ± 0.067		

[a] All dosage forms were obtained from the same manufacturer. [b] Values are the mean of five determinations and are presented as the percentage based on labeled claim of indomethacin (±SD). [c] Values for capsules were taken from the average of two determinations.

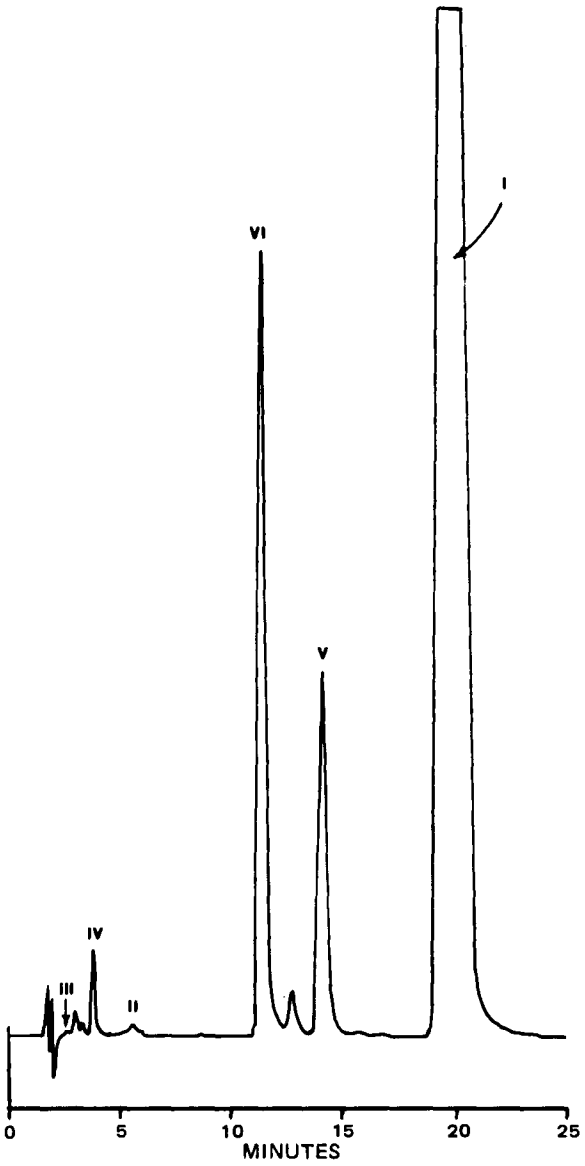

Figure 2—*HPLC of extract of indomethacin suppository formulation. Peaks: (I) indomethacin; (II) 4-chlorobenzoic acid; (III) 5-methoxy-2-methyl-3-indoleacetic acid; (IV) 4-chlorobenzoic acid-α-monoglyceride; (V) indomethacin-α-monoglyceride; (VI) the internal standard, testosterone.*

method was investigated. The chromatogram shown in Fig. 1 was obtained for a standard mixture of I and its impurities II–IV. Impurity V could not be included in this chromatogram due to lack of sufficient quantities of pure material. Calibration curves for I and the impurities II–IV were determined by dissolution in methanol containing the internal standard, testosterone. It was not possible to isolate a sufficiently pure crystalline form of V; therefore, the response factor for this impurity was equated to that of I. This was considered sufficiently accurate, as little difference in the UV absorptivity at 254 nm would be expected for these two compounds, due to the identical nature of the basic chromophore portion of both molecules. To establish the reliability of the calibration curves determined by dissolution in methanol, a single mixture of I and the impurities II–IV were likewise partitioned between the water–ether mixture used to extract the formulations. The recoveries of the drug and impurities from the aqueous phase into ether were quantitative. The response factors and correlation coefficients for I–IV are given in Table I.

The extraction of I from capsule and suppository formulations was determined by analysis of an aliquot of the formulation to which a quantity of indomethacin, equivalent to half of the theoretical amount of indomethacin, was added. The extraction efficiencies thus determined are summarized in Table II. The apparent high recovery indicates that the formulation excipients do not interfere with such a simple, single extraction.

The results obtained for the analysis of I and its impurities II–V in both capsule and suppository formulations are given in Table III. A representative chromatogram for a suppository formulation is shown in Fig. 2. Impurities II–V account for a total of 1.4% of the amount of indomethacin in the suppository formulation, while only small quantities of 4-chlorobenzoic acid were detected in one of the two capsule formulations.

Examination of the chromatogram of a suppository formulation (Fig. 2) reveals an impurity at 12.5 min following the internal standard. Several attempts to isolate and identify this material were unsuccessful. No attempt was made to isolate the minor components appearing between impurities III and IV. However, the remaining impurities II–V were confirmed by comparison of their retention times with authentic samples.

All formulations analyzed by the HPLC procedure described fall within the limits specified for capsule and suppository formulations in the USP (6) and BP (7). The presence of impurities, particularly in the suppository formulations represents a distinct example of the interaction of a drug with an excipient, glycerin. Although the amount of the α-monoglyceride impurities were less than 1.4% of the amount of indomethacin, these levels could be increased several-fold by holding the suppository at its melting point. Since all formulations were obtained fresh from the manufacturers, the rate of this reaction under normal storage conditions could not be determined, and accelerated stability studies were not considered due to the relatively low softening temperature of the suppository base.

Correlation of Antitumor Activity and Electron Deficiency of Nitrofuranylhydrazone Compounds

ROBERT A. NEWMAN ˣ, MICHAEL J. STRAUSS, and RICHARD RENFROW

Received June 12, 1981, from the *Vermont Regional Cancer Center and Departments of Pharmacology and Chemistry, University of Vermont, Burlington, VT 05405.* Accepted for publication October 22, 1981.

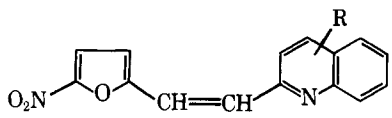
Abstract □ Phenylhydrazone derivatives of 5-nitro-2-furaldehyde were tested for antitumor activity against L-1210 murine leukemia *in vitro*. A substantial increase in antitumor activity was observed in these series of compounds as the electron deficiency of the six-membered aromatic ring was increased. A possible mechanism of action involving drug reduction as well as antibacterial and antitumor efficacy is discussed.

Keyphrases □ Nitrofuranylhydrazones—correlation, antitumor activity, electron deficiency □ Electron deficiency—correlation of antitumor activity, nitrofuranylhydrazone compounds □ Antitumor activity—electron deficiency, nitrofuranylhydrazone compounds

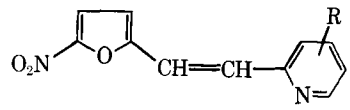
Nitrofuran compounds exhibit a wide range of useful pharmacologic activity. Nitrofurazone, for example, is a broad spectrum topical antibacterial agent used primarily in the treatment of mixed infections of wounds and diseases of the skin. Nitrofurantoin, a chemically related compound, is a urinary tract antiseptic quite active against many strains of common urinary pathogens. In addition to their current use as antibiotics, nitrofuran compounds have in the past been considered useful against selected neoplasias. *cis*-Dichlorodiammine platinum and bleomycin are currently considered two of the drugs of choice for the treatment of testicular carcinomas (1). However, the use of nitrofurazone and nitrofurantoin in testicular tumor therapy has been reported frequently during the past three decades (2–6).

Although there are a few reports of structure–activity relationships for nitrofurans as antitumor agents (7–10), this area has not been fully explored. This is especially true for simple phenylhydrazone derivatives of 5-nitro-2-furaldehyde. There still exists, therefore, potential for the development of new drugs in this class for the treatment of testicular or other tumor types.

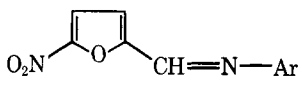
The most thorough synthetic and pharmacologic studies on new types of antineoplastic nitrofuran derivatives are those of Ujiie and Miura *et al.* (7, 8, 10). These authors have prepared a series of compounds like Compounds I, II, and III, and have screened these in a variety of experimental tumor systems. Certain derivatives of Compounds I and II were found to completely cure Ehrlich ascites carcinoma in mice. The compounds are relatively nontoxic and doses of up to 1000 mg/kg did not cause any drug-related deaths. Moderate antitumor activity was also seen with Schiff base derivatives like Compound III.



I



II



III

The present study describes the *in vitro* antitumor activity of a new series of phenylhydrazone derivatives of 5-nitro-2-furaldehyde. An examination was made of the correlation of electron withdrawing potential of each compound as a contributing factor to the possible mechanism of antibacterial and antitumor activity of this series of drugs.

EXPERIMENTAL

Cell Culture—Mouse leukemic L-1210 cells[1] were maintained in medium containing 10% fetal calf serum[2]. Stock cultures of cells were diluted with the medium to give final concentrations of 5×10^5 cells/ml. The compounds were dissolved in dimethyl sulfoxide and diluted to a concentration 500 times greater than the experimental level desired, so the 10 μl of the compound solution could be added to 5 ml of the inoculated growth medium. No precipitation occurred during this addition. This amount of compound in solution yielded a final dimethyl sulfoxide concentration of 0.2%, which itself had no effect on cell growth.

Each ID_{50} experiment (i.e., the determination of that dose which results in 50% inhibition of L-1210 growth) was run four times. Cell cultures were incubated at 37° in a 95% O_2–5% CO_2 humidified atmosphere and were counted after 96 hr. All cell counts were done by diluting the cell culture 1:40 and then counting with an electronic cell counter. The concentration of cells in the control tubes of L-1210 after 96 hr was ~2.5×10^6/ml.

Hydrazone Syntheses—The hydrazones were prepared from commercially available hydrazines and 5-nitrofurancarboxaldehyde by heating an ethanolic solution of these precursors containing a small portion of glacial acetic acid. The hydrazones that precipitated were recrystallized from ethanol and all had satisfactory elemental analyses. Elemental analyses and melting point data are listed in Table I.

RESULTS AND DISCUSSION

The series of nitrofuranylhydrazones like Compound IV clearly show a substantial and significant increase in antitumor activity as the electron deficiency of the six-membered aromatic ring increases.

The *in vitro* L-1210 screening data for the various compounds, the sum of σ values for the six-membered ring substituents, as well as pertinent ^{1}H-NMR shifts, are represented in Table II.

The metabolic reaction first occurring with most nitrofurans in animals involves reduction of the furanyl nitro group to a hydroxylamine (12). This is followed by further reduction to the amine and finally ring opening and fragmentation (13). Hydrolysis of the azomethine linkage can also
