The percentage availability of ascorbic acid, ER_{max} and T_{max}, were statistically analyzed to determine any differences among the dosage forms examined. These data were analyzed according to a 4 × 4 Latin square design (15). Variance ratios were calculated for comparisons among dosage forms, subjects, and sequence of administration. Scheffe's test (16) was also employed to contrast these parameters.

RESULTS AND DISCUSSION

Standard curves for ascorbic acid in urine were linear and reproducible over the concentration range of 2–40 μg/ml. By repetitively assaying urine containing a known concentration of ascorbic acid (with 4% metaphosphoric acid and stored in a refrigerator) it was determined that the vitamin was stable for at least 4 days.

The mean assayed contents of ascorbic acid determined from 20 samples of the oral dosage forms were (expressed as percent of label claim): powder, 99.9%; tablet, 107.8%; chewable tablet, 101.2%; and timed-released capsule, 104.3%. The injectable solution contained 108.7% of the label claim based on the assay of three vials. The urinary excretion data were corrected for these values of actual ascorbic acid content.

The results of the intravenous experiments were previously reported elsewhere (17). Figure 1 is a representative graph of ascorbic acid excretion rate as a function of time after intravenous administration to one subject. The data appear to be consistent with a two-compartment model. The average elimination $t_{1/2}$ associated with the log-linear terminal exponential phase (β-phase) was 3.5 hr (range, 2.7–4.3 hr). The percentage of the intravenous dose recovered in the urine averaged 84.7% (range, 81.3–87.3%) as shown in Table I. Figures 2–4 are representative graphs of ascorbic acid excretion rate as a function of time after the oral ingestion of the various dosage forms studied. For comparison, the data obtained from the oral solution are included in each graph. The excretion rate–time profiles are similar for the oral solution, tablets, and chewable tablets. A comparable pattern is not seen, however, for the timed-release preparation. In the latter case, the rate of absorption and ER_{max} are considerably smaller compared with the other oral dosage forms.

The bioavailability of the vitamin from these dosage forms is summarized in Table I. The solution, tablet, and chewable tablet are absorbed to approximately the same extent (~30% of the dose) although there is considerable intersubject variation in the percentage of the dose recov-

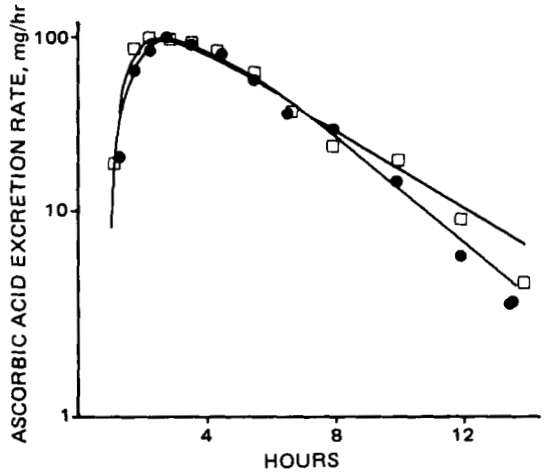

Figure 3—*Urinary excretion rate of ascorbic acid as a function of time in one subject after the ingestion of 1 g of ascorbic acid as a solution (●) or as a chewable tablet (□). The solid lines represent the best fit of the data.*

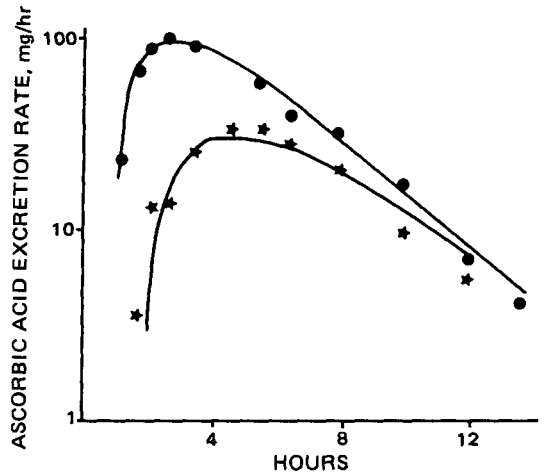

Figure 4—*Urinary excretion rate of ascorbic acid as a function of time in one subject after the ingestion of 1 g of ascorbic acid as a solution (●) or as a timed-release capsule (★). The solid lines represent the best fit of the data.*

ered. Absorption from the timed-release capsule is considerably less than from the other dosage forms (~14% of the dose). Based on analysis of variance there is a statistically significant difference among subjects with respect to the percentage of the oral dose recovered ($p < 0.01$) but there was not a statistical difference with respect to sequence of administration ($p > 0.25$). Percentage recoveries among the oral dosage forms were not statistically different ($0.05 < p < 0.10$), probably as a result of the large variation in these values among the subjects. Since the urinary recovery data suggested that the timed-release capsule was considerably different from the other oral dosage forms, Scheffe's test (16) was used to compare the means obtained from the timed-release capsule *versus* the other forms. As with the analysis of variance, the difference was close to but did not reach statistical significance.

A comparison of maximum ascorbic acid excretion rate (ER_{max}) among the different dosage forms is presented in Table II. These values have been normalized for the assayed content of ascorbic acid in each form. Analysis of variance indicated significant differences among the products ($p < 0.01$) and among subjects ($p < 0.01$), while there was no significant difference with respect to sequence of administration ($p > 0.25$). The timed-release capsule had a substantially lower ER_{max} value compared to the other oral dosage forms.

Table III summarizes the times needed to achieve maximum excretion rates (T_{max}). Consistent with a slower absorption rate noted for the timed-release capsule, T_{max} for this form was significantly prolonged ($p < 0.01$) compared with the other oral dosage forms. There were no statistically significant differences among subjects or as a result of administration sequence.

Prior to the evaluation of ascorbic acid absorption from the various dosage forms examined, all subjects were shown to be saturated with the vitamin. This approach is necessary in evaluating the absorption of the vitamin from urinary excretion data, since the retention of the vitamin in the body is influenced by the nutritional status of the individual (18–20).

The urinary recovery values of the vitamin were very similar among the subjects after intravenous administration. An average of 85% of the dose was ultimately recovered in the urine. The remainder of the dose may be accounted for by other minor metabolites of the vitamin not detected by the assay method (*e.g.*, oxalic acid and ascorbate-2-sulfate) (21, 22) or a portion of the dose may remain in the ascorbate pool.

In contrast to the intravenous data, there was considerable variation in the urinary recovery of the vitamin after oral ingestion (Table I). With any given oral dosage form there is large variation in the excretion of the vitamin among the subjects. There appeared to be a trend in this variation in that subject 1 consistently excreted less vitamin and subject 4 consistently excreted more vitamin than the other subjects. While the conclusions presented here are necessarily limited by the number of subjects that participated, the data suggest that there may be "poor" and "good" absorbers of ascorbic acid. This trend is best supported by the oral solution data where there are no dosage form effects (*e.g.*, disintegration and dissolution processes) to mask the inherent ability to absorb the vitamin. When dissolved in water the vitamin is presented to absorption sites of the GI tract in a form optimal for absorption.

Table III—Time of Maximum Ascorbic Acid Excretion Rate (T_{max}) from Various Dosage forms

	Time of Maximum Excretion Rate, hr			
	Dosage Form			
Subject	Solution	Tablet	Chewable Tablet	Timed-Release Capsule
1	3.1	2.3	2.6	4.9
2	2.3	3.8	2.4	3.8
3	2.1	2.5	3.1	3.5
4	3.0	2.7	2.5	4.5
Mean	2.6	2.9	2.7	4.2
±*SD*	0.5	0.6	0.3	0.6

It was suggested that ascorbic acid is absorbed in humans by a specialized transport mechanism (11, 12). Differences among individuals in the values of the parameters associated with this transport process may partially account for the variation noted in the extent of absorption. Furthermore, differences in physiological variables along the gut (*e.g.* gastric emptying rate) may contribute to this intersubject variation. The absolute absorption of the vitamin from oral solution may be calculated by the ratio of urinary recoveries from the solution to the intravenous dose. Approximately 40% of the dose ingested as a solution is absorbed (range, 20–62%). Compounds transported by specialized processes are generally absorbed only at certain sites along the GI tract. This has been shown, for example, for riboflavin where absorption proceeds from the upper regions of the small intestine (23). The same observation is likely to apply to ascorbic acid. As a result, factors altering gastric emptying and intestinal transit rates (*e.g.*, food and drugs) may influence the efficiency of absorption from the oral dosage form. This effect was adequately illustrated for riboflavin (23, 24) and appears to be the case for ascorbic acid as well (25).

The urinary recovery data indicated that the vitamin was absorbed to approximately the same extent from the solution, tablet, and chewable tablet. The timed-release capsule, however, was absorbed to a much smaller extent compared with the other oral forms. The absolute percentage of the dose absorbed from this capsule was ~17%, which is less than one-half the amount absorbed from the solution (~40%). Several reasons may be suggested to account for the poor absorption of the vitamin from the timed-release capsule. The vitamin may be incompletely released from the formulation resulting in reduced absorption compared with a solution. An additional explanation may be that, to be well absorbed, the vitamin must be released from the formulation and be in solution before the vitamin passes its sites of maximal absorption. Since timed-release formulations are designed to release a compound slowly over an extended period of time, a substantial portion of the dose of the vitamin may not have been released before passing this site. This would be particularly true if, as it appears (26), the major site for absorption is in the upper region of the small intestine.

Further insight into the absorption of ascorbic acid may be obtained by reference to Tables II and III. While the ER_{max} values are similar among the solution, tablet, and chewable tablet forms, the timed-release capsule provides considerably smaller values (Table II). These smaller values for the capsule indicate slower and less complete absorption of the vitamin. The slower and prolonged rate of absorption in contrast to the solution is illustrated in Fig. 4. Also consistent with this slower rate of absorption is the fact that it takes longer for the timed-release capsule to achieve the maximum excretion rate compared with the other oral forms (Table III and Fig. 4). The average value of T_{max} for the timed-release product (4.2 hr) is similar to the value of 4.9 hr reported (27) for a different timed-release formulation of ascorbic acid. Consistent with this discussion are the differences in the apparent first-order absorption rate constant among the dosage forms. The apparent absorption rate constants for the solution (1.4 hr^{-1}), tablet (1.4 hr^{-1}), and chewable tablet (1.3 hr^{-1}) forms are about three times larger than that for the timed-release product (0.4 hr^{-1}).

The results of this study are consistent with the findings of Richards *et al.* (28) who reported greater ascorbic acid plasma concentrations after oral administration of a nonsustained-release product compared with those achieved with a sustained-release product. Similar results were reported by Allen (29) who examined the same timed-release product used in this study. In that study, however, there was no crossover among subjects and the body store of the vitamin was relatively low. The latter point is supported by the small recovery of the vitamin in urine (~3% of the dose for the regular capsule and 1% for the timed-release product). The present findings disagree, however, with those of Zetler *et al.* (27) who measured ascorbic acid blood concentrations and urinary excretion

after oral ingestion of a capsule and a sustained-release product. Their results indicated that the extent of absorption from the sustained-release product was almost twice that from a regular capsule. In addition, ~98% of the sustained-release dose was absorbed compared to an intravenous dose. The latter value is unusually high and we are not aware of any study where an oral dose of ascorbic acid is virtually completely absorbed. Another discrepancy is that the ascorbic acid half-life was determined (27) to be ~11 hr prior to saturation and 29 hr after saturation. These values are considerably greater than those reported for the half-life of the vitamin after exogenous administration (11, 17, 26, 30). The reason for the substantial differences in half-life and availability from the timed-release products reported here and by Zetler *et al.* (27) is not known.

The results of this study indicate that ascorbic acid absorption is incomplete after oral ingestion and that there is considerable intersubject variation in the extent of absorption. In addition, absorption of the vitamin is considerably less efficient from the timed-release capsule examined here compared with the other oral forms. These findings have several implications. From a practical point of view, efficient oral therapy with the vitamin can be achieved by dissolving powdered ascorbic acid in water. In addition, for the specific manufacturers' products examined in this study, tablets and chewable tablets appear comparable to a solution of the vitamin. This conclusion may not apply to tablets made by all manufacturers but that can only be determined from the evaluation of other products in a manner used in the present study. The timed-release capsule examined here appears to be a more expensive and less reliable means of providing oral vitamin therapy compared with other more conventional dosage forms. This conclusion may apply to similar dosage forms which attempt to delay or sustain the release of the vitamin; therefore, bioavailability studies for such forms are essential.

A question that remains to be answered is to what extent does variation in ascorbic acid absorption influence the results of large-scale trials designed to examine the clinical effects of the vitamin? To the authors' knowledge no consideration has been given to absorption as a parameter potentially influencing the findings of such studies. Investigators pursuing such trials should give some consideration to the possible influence of variation in ascorbic acid absorption on clinical outcome.

Mass Spectral Fragmentation of 24,24-Diphenyl-23-ene Derivatives of Cholic Acid

JERRY RAY DIAS

Received December 8, 1980, from the *Department of Chemistry, University of Missouri–Kansas City, Kansas City, MO 64110.* Accepted for publication June 30, 1981.

Abstract □ After electron impact in the mass spectrometer, 24,24-diphenyl-23-ene derivatives of cholic acid ejected the 17-sidechain as an ionized 1,1-diphenyl-butadiene derivative, and the 12α-acetoxy group activated this loss. This contrasts markedly with the mass spectrometric fragmentation of typical sterols having unsaturated 17-sidechains that are also devoid of functionality on the C-ring.

Keyphrases □ Mass spectra—fragmentation of 24, 24-diphenyl-23-ene derivatives of cholic acid □ Cholic acid—24, 24-diphenyl-23-ene derivatives, fragmentation by mass spectra □ Derivatives—24, 24-diphenyl-23-ene derivatives of cholic acid, mass spectral fragmentation

During the course of other investigations (1), a number of 24,24-diphenyl-23-ene derivatives of cholic acid having structural similarities to known biologically active compounds were prepared. Since the Barbier–Wieland 17-sidechain degradation is used extensively in steroid-terpenoid synthesis (2, 3) and electron impact induced loss of the 17-sidechain is of both fundamental and diagnostic importance (4–6), the observations concerning mass spectral cleavage processes of the Barbier–Wieland modified 17-sidechain of steroids and terpenoids are summarized.

RESULTS AND DISCUSSION

The preparation of the compounds in this study was unexceptional. However, isolation of pure diene (IV*a*–IV*d*) was difficult because unreacted monoene was invariably present. Also, it is likely that *E* and *Z*

Mass Spectral Fragmentation of 24,24-Diphenyl-23-ene Derivatives of Cholic Acid

JERRY RAY DIAS

Received December 8, 1980, from the *Department of Chemistry, University of Missouri–Kansas City, Kansas City, MO 64110.* Accepted for publication June 30, 1981.

Abstract □ After electron impact in the mass spectrometer, 24,24-diphenyl-23-ene derivatives of cholic acid ejected the 17-sidechain as an ionized 1,1-diphenyl-butadiene derivative, and the 12α-acetoxy group activated this loss. This contrasts markedly with the mass spectrometric fragmentation of typical sterols having unsaturated 17-sidechains that are also devoid of functionality on the C-ring.

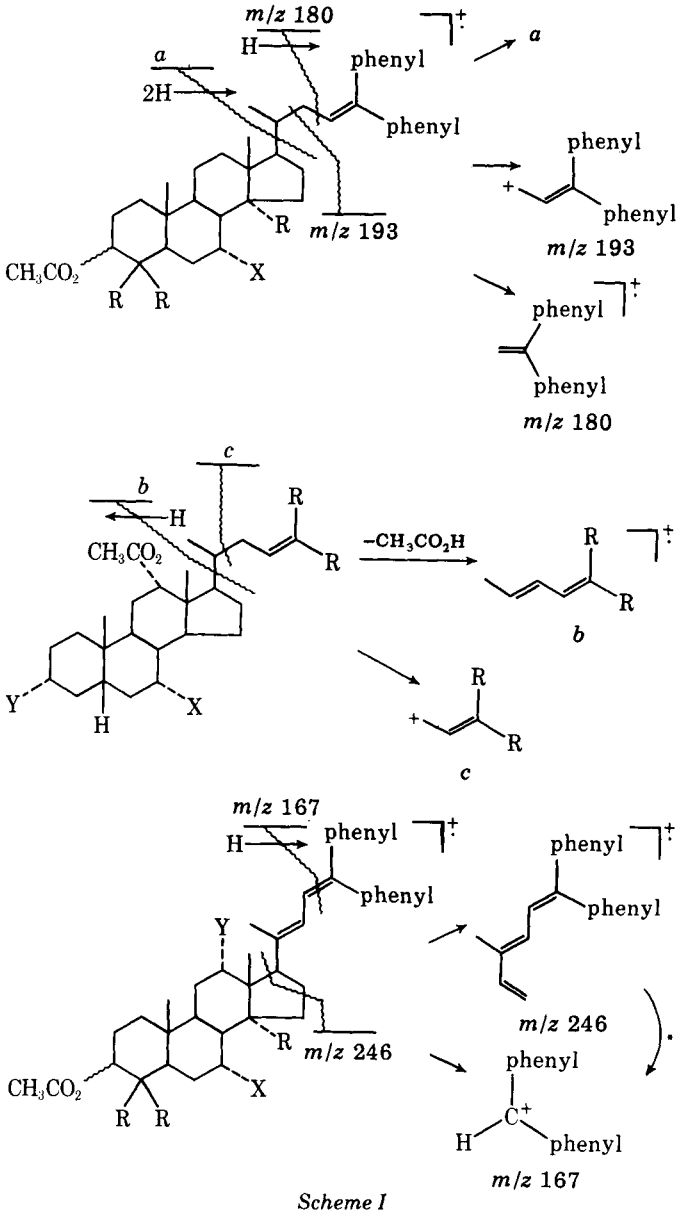
Keyphrases □ Mass spectra—fragmentation of 24, 24-diphenyl-23-ene derivatives of cholic acid □ Cholic acid—24, 24-diphenyl-23-ene derivatives, fragmentation by mass spectra □ Derivatives—24, 24-diphenyl-23-ene derivatives of cholic acid, mass spectral fragmentation

During the course of other investigations (1), a number of 24,24-diphenyl-23-ene derivatives of cholic acid having structural similarities to known biologically active compounds were prepared. Since the Barbier–Wieland 17-sidechain degradation is used extensively in steroid-terpenoid synthesis (2, 3) and electron impact induced loss of the 17-sidechain is of both fundamental and diagnostic importance (4–6), the observations concerning mass spectral cleavage processes of the Barbier–Wieland modified 17-sidechain of steroids and terpenoids are summarized.

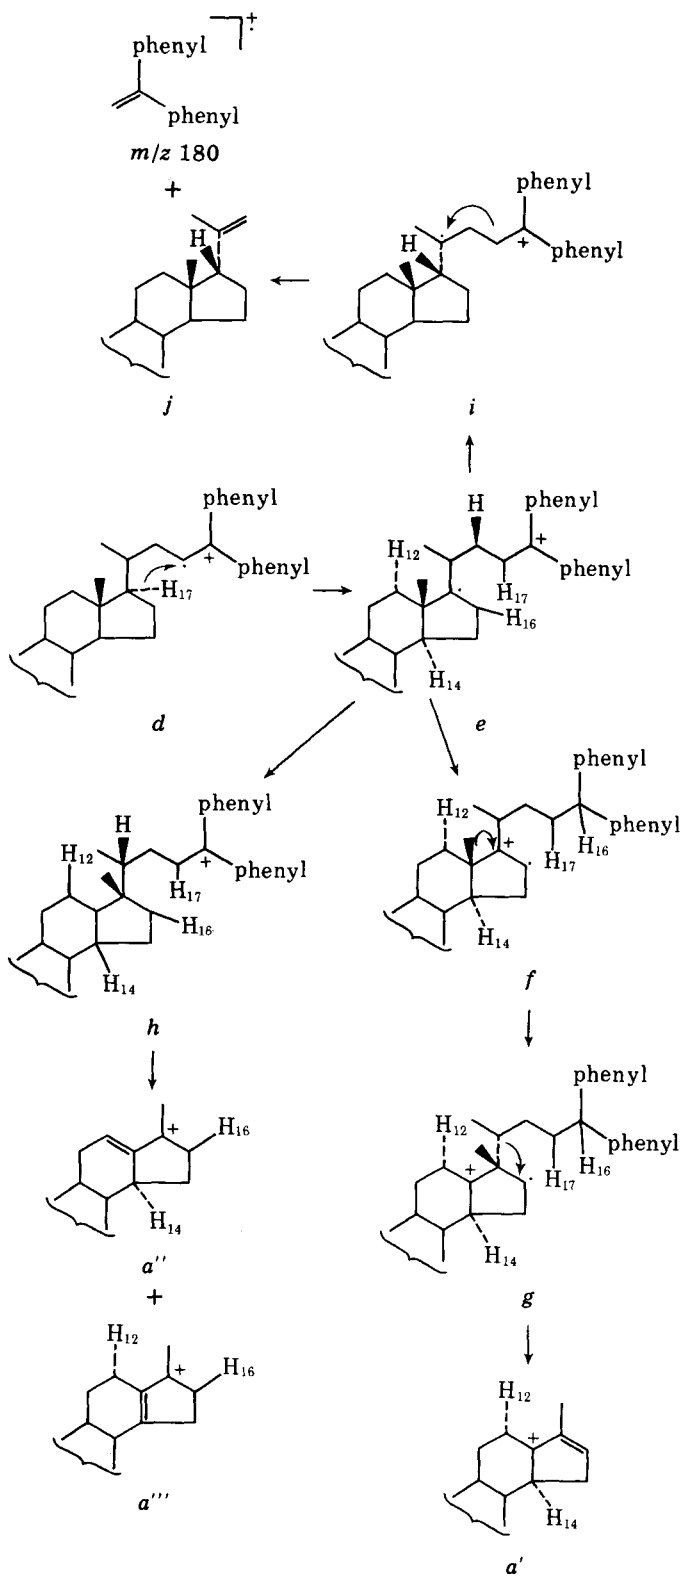
RESULTS AND DISCUSSION

The preparation of the compounds in this study was unexceptional. However, isolation of pure diene (IV*a*–IV*d*) was difficult because unreacted monoene was invariably present. Also, it is likely that *E* and *Z*

0022-3549/82/0300-0285$01.00/0



Scheme I



Scheme II

17-sidechain diene isomers may be coproducts, but this could not be verified experimentally. The propensity for acid catalyzed elimination of the 7α-acetoxy group as acetic acid for both the monoenes and dienes has been previously noted (1, 3). Table I summarizes the mass spectral data for compounds I–VIII.

Scheme I summarizes the characteristic fragmentations of 24,24-diphenyl-23-ene derivatives of cholic acid. If no functionality exists on the C-ring of the monoene, then ion *a*, the allyl carbocation (*m/z* 193), and ionized α,α-stilbene are the predominant ions observed in the mass spectra. The genesis of ion *a* was previously elucidated (4). Typical sterols having no B-ring or C-ring functionality and either a saturated or unsaturated 17-sidechain exhibit 17-sidechain and D-ring cleavage processes in which there is a drift of hydrogen atoms from the steroid skeleton to the departing neutral fragment (7). Placing functionality on the B- or C-rings (*e.g.*, an oxo group at positions 6 or 12) reverses the direction of hydrogen atom drift so that hydrogen moves from the 17-sidechain toward the steroid skeleton. The former process results in increased unsaturation in the steroid framework and corresponding charge residence in that unit upon scission, whereas the latter process produces increased unsaturation in the 17-sidechain unit and frequently results in greater charge residence in that fragment. Thus, ion *a* in Scheme I emanates from hydrogen migration to the 17-sidechain from the steroid skeleton followed by scission at the 17–20 bond; ion *b* emanates from hydrogen migration from the 17-sidechain to the steroid skeleton followed by 17–20 bond scission, where the reversal of hydrogen migration in the latter is induced by the presence of the 12α-acetoxy group. Otherwise, the process not regulated by hydrogen migration, simple allylic scission (*m/z* 193 and ion *c*), appears to be relatively unaltered in 24,24-diphenyl-23-enes either possessing or not possessing C-ring functionalization by the 12α-acetoxy group.

The specific mechanism for the genesis of ion *a* is presented in Scheme II. Charge localization on the olefinic 17-sidechain triggers site specific C-17 hydrogen transfer through a 5-membered ring to give the highly stable ion-radical *e* (4). The second itinerant hydrogen originated from positions C-12, C-14, and C-16 (4). Direct transfer of C-16 hydrogen to C-24 gives ion *f* which can undergo a 1,2-methyl shift to give ion *g*. Simple

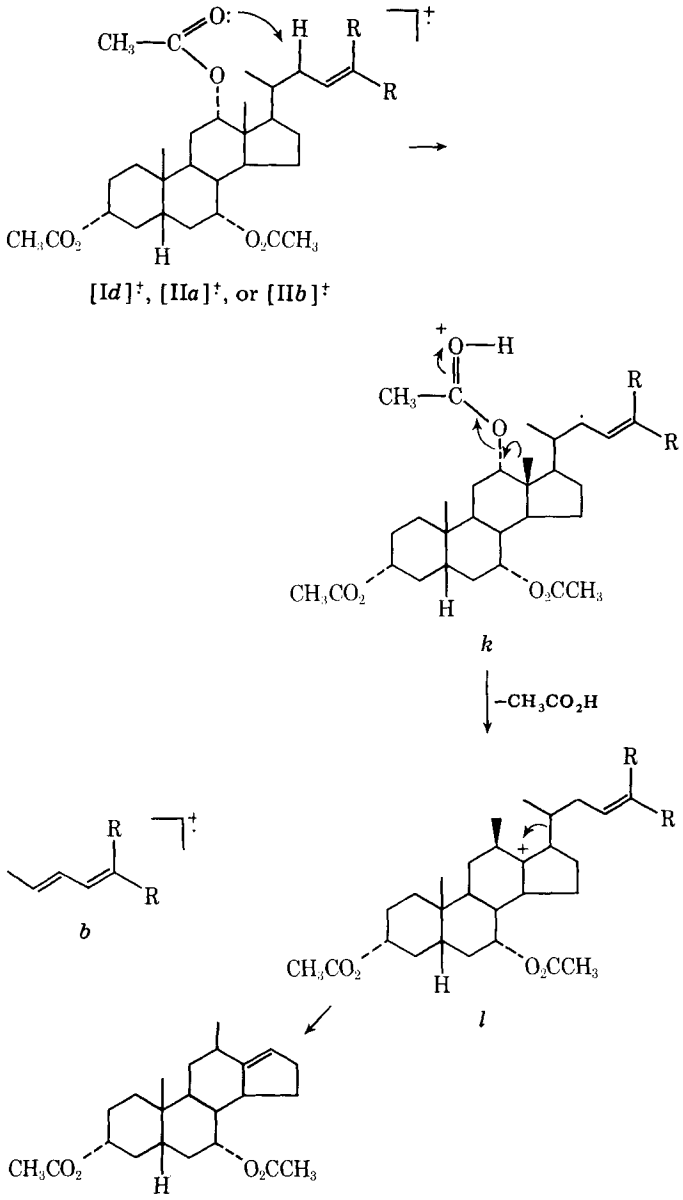
[a] Add one more CH_3CO_2H loss to column heading. [b] Replace one CH_3CO_2H by H_2O in column heading. [c] Delete one CH_3CO_2H in column heading. [d] Subtract or add a CH_2 group to the column heading.

scission of ion *g* leads to the allylic carbocation *a'*. Alternatively, a 1,2-methyl shift in ion *e* gives ion *h* where the tertiary radical at C-12 activates α-hydrogens at both the C-12 and C-14 positions, and their transfer to C-24 followed by simple scission at 17–20 leads to allylic ions *a''* and *a'''*, respectively. An ion analogous to the *m/z* 180 ion was not observed, and no doubt its presence in the spectra of Ib, V, and VII results from the stabilizing effects of the phenyl groups. A 1,2-hydrogen shift from C-20 to C-17 converts ion *e* into ion *i*, which can undergo simple scission to give olefin *j* and the *m/z* 180 ion.

The introduction of a 12α-acetoxy group into the C-ring of 24,24-diphenyl-23-enes results in a dramatic alteration of their mass spectral breakdown and is emphasized by comparing the mass spectra of Ia *versus*

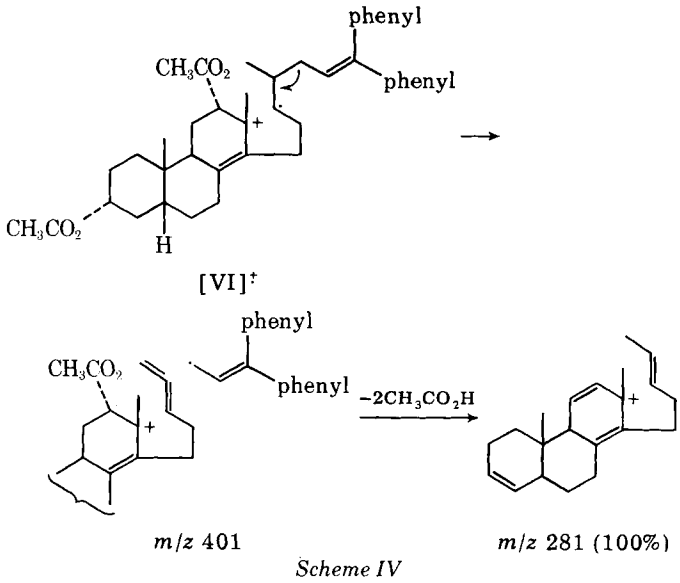


Scheme III

Ib. By selectively labeling with acetate-d_3, prior work demonstrated that in the consecutive loss of three acetic acid molecules from the molecular ion of methyl 3α,7α,12α-triacetoxy-5β-cholan-23-oate, that the first loss of acetate comes from the 12α-acetoxy group, the second from the 7α-acetoxy, and the third from the 3α-acetoxy group (8). A plausible mechanism for the formation of 1,1-biphenyl-1,3-butadiene ions (*b*) from the 17-sidechain in the mass spectra of Ia, Id, IIa, IIb, III, and VI could involve prior elimination of acetic acid from the 12α-acetoxy group to produce an 11–12 double bond which then triggers this process. However, Dreiding models suggests that it is sterically possible to transfer the activated C-22 hydrogen directly to the 12α-acetoxy carbonyl (Scheme III) through a nine-membered ring (an eight-membered ring for III) to generate the resonance stabilized ion *k*. Precedence for long-range activated hydrogen transfer to the 12α-acetoxy group in other cholic acid derivatives after electron impact has been provided (9). Extrusion of acetate from ion *k* simultaneous to 1,2-methyl shift would produce the tertiary carbocation *l* which can decompose *via* simple scission to give ion *b*.

Loss of the allyl radical ($\cdot CH_2CH{=}CR_2$) from the 17-sidechain was observed in all the monoenes and indicates that some charge localization occurs at the 12–17 bond. This is probably responsible for the 281 base peak in the mass specrum of VI, since the 8–14 double bond should activate ionization of this bond

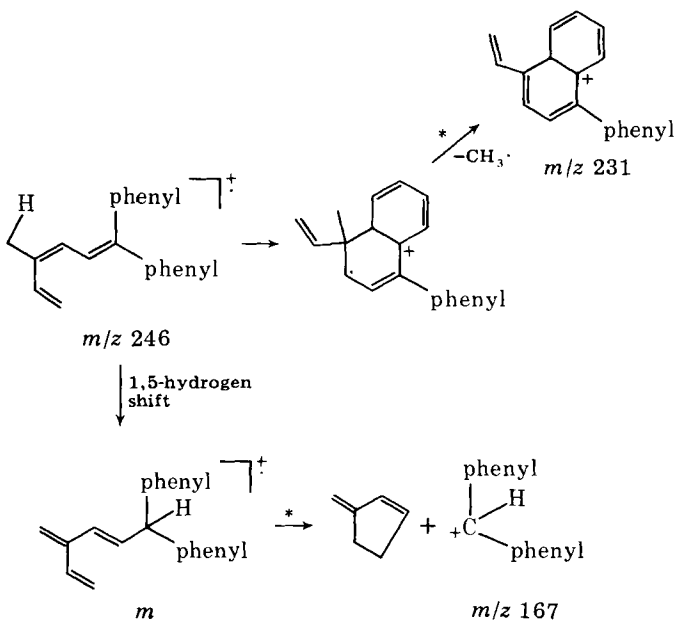
$$[(VI)^{+} \rightarrow m/z\ 401 \xrightarrow{-CH_3CO_2H} m/z\ 341 \xrightarrow{-CH_3CO_2H} m/z\ 281].$$



Scheme IV

Prior mass spectral work established that the dominant consecutive loss of one, two, and three acetic acid molecules from the 12α, 7α, and 3α-acetoxy groups of methyl cholate triacetate after electron impact led to increasingly more stable daughter ions since the relative intensities of the $[M\text{-}CH_3CO_2H]^{+}$, $[M\text{-}2CH_3CO_2H]^{+}$, and $[M\text{-}3CH_3CO_2H]^{+}$ ion peaks dramatically increased in that order (8). This observation permitted tracing of the probable movement of positive charge from the region of the D-ring to that of the A-ring. The fact that the mass spectral ions $[M\text{-}CH_3CO_2H]^{+}$, $[M\text{-}2CH_3CO_2H]^{+}$, and $[M\text{-}3CH_3CO_2H]^{+}$ are of low intensity and decrease in that order in relative intensity for Id, IIa, and IIb (Table I) provides evidence for extensive localization of charge on or near the 24,24-diphenyl-23-ene moiety. Since the critical energy for bond cleavage in a mass spectral ion is lower in the vicinity of positive charge and because there is a quasi-equilibrium fluctuation of excitation energy over the total charged molecule, it was observed that fragmentation in these compounds (I–VIII) is dominated by hydrogen migration and bond scission in the region of the 17-sidechain, which is the site of charge localization.

Simple D-ring scission of dienes IVa to IVd and VIII led to an *m/z* 246 hexatriene ion of obvious stability. Metastable peaks (Table I) corresponding to the degradation of the *m/z* 246 ion to *m/z* 167 (m* 113.5) were observed in the spectra of IVb and VIII. A plausible mechanism (Scheme V) for the formation of the dominant *m/z* 167 ion involves an orbital symmetry allowed 1,5-hydrogen shift to form ion *m* which decomposes



Scheme V

to m/z 167. The m/z 167 related ions in the spectra of the monoenes have a nominal relative abundance and no doubt have an alternate genesis.

Unidirectional migration of two hydrogens from the unsubstituted C- and D-rings of the steroid skeleton to the unsaturated 17-sidechain where charge is initially localized precedes the loss of the 17-sidechain as a neutral radical. In the presence of a 12α-acetate group, this process is superseded by the migration of a hydrogen from the ion-radical containing 17-sidechain to the C-ring acetate substituted steroid system producing an ionized butadiene derivative. Simple scission fragmentation processes occurring near the site of charge localization and not involving hydrogen migration in steroid systems should be less affected (than processes involving hydrogen migration) by the presence of local ring substituents that do not significantly alter the charge distribution in the ion.

EXPERIMENTAL

IR data, reported in inverse centimeters (cm^{-1}), were obtained as chloroform solutions; ^{1}H-NMR data[1], reported in ppm (δ) from tetramethylsilane, were obtained in chloroform-*d*. Mass spectra[2] were obtained at an ionization voltage of 12 and 70 ev (Table I), source temperature of 180°, and a trap current of 10 μamp.

Column chromatography was performed using silica gel[3], and TLC was performed on silica gel HF_{254}[3]. The latter was usually developed with 4:1 hexane–ethyl acetate. TLC was visualized by viewing under a UV lamp and charring by brief heating after spraying the TLC plate with 2% ceric sulfate in 2 *N* sulfuric acid. All reactions were monitored by TLC. In general, the dienes had slightly smaller R_f values than the corresponding monoenes and the deoxycholate analogs had larger R_f values than the corresponding chenodeoxycholate analogs. The order of decreasing R_f value for the monoenes coincided with the order of increasing electron density in the phenyl moiety; *p*-chlorophenyl II *a* (largest R_f), diphenyl I*d*, and *p*-methoxyphenyl II*b* (smallest R_f, gives characteristic red color upon brief charring with ceric sulfate).

The synthesis of compounds I*a*, I*b*, I*d*, IV*b*, V, VI, VII, and VIII have already been described (1, 3, 10).

3α,7α-Diacetoxy-12-oxo-24,24-diphenyl-5β-chol-23-ene(I*c*)—Saponification of 3α,7α,12α-triacetoxy-24,24-diphenyl-5β-chol-23-ene (5 g) was achieved by heating at reflux with potassium hydroxide (10 g) and methanol (165 ml) for 2 hr. This was diluted with water and extracted with ether. The ether extract was washed with 5% HCl and concentrated on a rotary evaporator. The dry residue of triol (4 g) was selectively acetylated to the 3α,7α-diacetate by dissolving it in benzene (20 ml) and pyridine (5 ml) and reacting at room temperature with acetic anhydride (5 ml) for 12 hr. The isolated 3α,7α-diacetoxy-12α-ol (4.2 g) was dissolved in acetone (150 ml), cooled on an ice bath, and oxidized dropwise with Jones reagent. Chromatography of the isolated 3α,7α-diacetoxy-12-one I*c* yielded 83% of pure product: mp 186–188° (melts at 115° and solidifies again and then melts at 186–188°); ^{1}H-NMR: δ 7.23 (s, 10H, phenyl H), 6.15 (t, 1H, C-23), 4.97 (peak, 1H, 7β-H), 4.57 (hump, 1H, 3β-H), 2.00 (s, 6H, 3α,7α-acetates), and 1.02 (s, 6H, C-18, and C-19).

3α,7α,12α-Triacetoxy-24,24-di(*p*-chlorophenyl)-5β-chol-23-ene(II*a*)—A Grignard reagent of 4-bromochlorobenzene (45 g) and magnesium (5.8 g) was prepared in dry ether (100 ml). Methyl cholate (10 g) dissolved in dry tetrahydrofuran (100 ml) was added dropwise to the Grignard reagent. After heating at reflux for 48 hr, the contents of the reaction were poured into ice (400 g) containing 36% HCl (70 ml), the organic layer was separated, and the aqueous phase was extracted with ether. The combined ether extracts were dried over anhydrous sodium sulfate and concentrated on a rotary evaporator to yield 15.7 g of crude tetraol. This tetraol was heated at reflux in a mixture of acetic anhydride (50 ml) and acetic acid (100 ml) for 6 hr, and then the acetic acid/anhydride solvent was slowly distilled off until the volume was reduced to 30 ml. The residue was steam distilled to remove the biphenyl side-product, and the isolated product was chromatographed through silica by gradient elution with hexane–ethyl acetate to yield 11 g of II*a*:mp 180–182°; $\bar{\nu}_{max}$ 2960 (strong, C-H stret), 1730 and 1250 (strong, acetate), and 1590 (weak, olefin stret); ^{1}H-NMR δ 6.94 (4 peak multiplet, 8 H, aromatic H), 4.53 (hump, 1 H, 3β-H), 2.10 (s, 3H, 12α-acetate), 2.05 (s, 3H, 7α-acetate), 2.03 (s, 3H, 3α-acetate), 0.92 (s, 3H, C-10), and 0.73 (s, 3H, C-18).

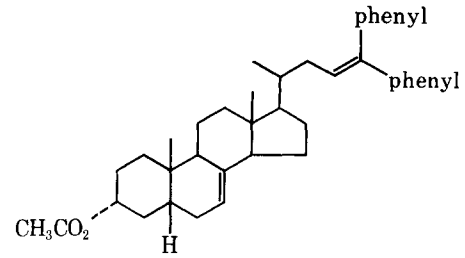
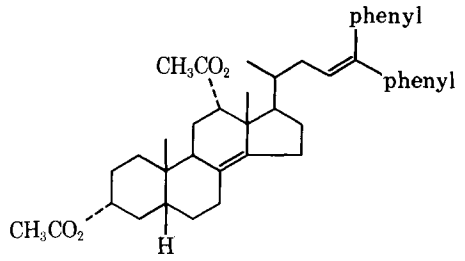
3α,7α,12α-Triacetoxy-24,24-di(*p*-methoxyphenyl)-5β-chol-23-ene (II*b*)—A solution of 4-methoxyphenylmagnesium bromide was prepared from *p*-bromophenol (100 g), magnesium (913 g), and dry tetrahydrofuran (300 ml). Methyl cholate (23 g) in dry benzene (150 ml) was added dropwise to the red-colored Grignard. After heating the reaction mixture at reflux for 24 hr, the reaction was halted, worked up, and purged of 4,4′-bismethoxybiphenyl by steam distillation. The 60 g of carbinol product thus obtained was heated at reflux in acetic anhydride/acetic acid (1:2, 400 ml) for 6 hr. Then the acetic anhydride/acetic acid solution was slowly distilled to a volume of 100 ml. The isolated product was column chromatographed through silica gel to yield 36 g of a glassy solid which refused to crystallize but was pure by TLC: ^{1}H-NMR δ 7.0 (m, 8H, phenyl H, 5.90 (t, 1H, C-23), 5.05 (peak, 1H, 12β-H), 4.98 (peak, 1H, 7β-H), 4.54 (hump, 1H, 3β-H), 3.81 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 2.11 (s, 3H, 12α- acetate), 2.07 (s, 3H, 7α-acetate), 2.02 (s, 3H, 7α-acetate), 0.92 (s, 3H, C-19), and 0.73 (s, 3H, C-18).

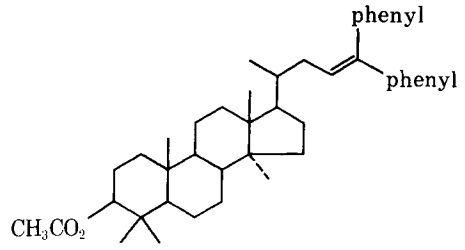
3α,7α,12α-Triacetoxy-23,23-diphenyl-24-nor-5β-chol-22-ene (III)—Methyl norcholate (2.0 g) dissolved in dry benzene (10 ml) was added dropwise to phenylmagnesium bromide (10 equivalents) in ether (25 ml), and tetrahydrofuran (10 ml). After heating at reflux for 24 hr, the reaction mixture was poured into ice (100 g) containing 36% HCl (5



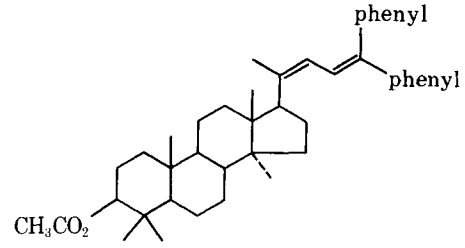
V



VI



VII



VIII

ml). This aqueous mixture was steam distilled to remove the biphenyl side product. The isolated carbinol (3.1 g) was heated at reflux with acetic anhydride (26 ml) and acetic acid (52 ml) for 3 hr, and then the volume of the acetic anhydride/acetic acid was reduced to 20 ml by slow distillation. Column chromatography of the crude triacetate through silica gel with hexane–ethyl acetate yielded 1.8 g of desired product: mp 109–111°; ^{1}H-NMR δ 7.20 (s, 10H, phenyl H), 5.80 (d, J = 10 Hz, 1H, C-22), 4.98 (peak, 1H, 12β-H), 4.88 (peak, 1H, 7β-H), 4.53 (hump, 1H, 3β-H), 2.15 (s, 3H, 12α-acetate), 2.07 (s, 3H, 7α-acetate), 2.02 (s, 3H, 3α-acetate), 0.95 (d, J = 6 Hz, 3H, C-20), 0.88 (s, 3H, C-19), and 0.52 (s, 3H, C-18).

3α,7α-Diacetoxy-12α-hydroxy-24,24-diphenyl-5β-chola-20(22),23-diene (IV*d*)—3α,7α,12α-Triacetoxy-24,24-diphenyl-5β-chola-20(22),23-diene was saponified and selectively acetylated to yield the title compound (IV*d*) after chromatography: mp 164–166°; ^{1}H-NMR δ 7.28 (s, 10H, phenyl H), 6.97 (d, J = 11 Hz, 1H, C-23), 6.03 (d, J = 11 Hz, 1H, C-22), 4.9 (peak, 1H, 7β-H), 4.53 (hump, 1H, 3β-H), 3.60 (peak, 1H, 12β-H), 2.03 (s, 3H, 7α-acetate), 2.02 (s, 3H, 3α-acetate), 1.95 (s, 3H, C-21), 0.92 (s, 3H, C-19), and 0.56 (s, 3H, C-18).

3α-Acetoxy-12-oxo-24,24-diphenyl-5β-chola-20(22),23-diene (IV*c*)—Monoene I*a* was synthesized by a published method [^{1}H-NMR δ 7.18 (s, 10H, phenyl H), 6.06 (t, 1H, C-23), 5.06 (peak 1H, 12β-H), 4.67 (hump, 1H, 3β-H), 2.07 (s, 3H, 12α-acetate), 2.01 (s, 3H, 3α-acetate), 0.91 (s, 3H, C-19), and 0.72 (s, 3H, C-18)]. The volume of a mixture of monoene I*a* (10.5 g) and carbon tetrachloride (400 ml) was reduced to 300 ml by distillation, *N*-bromosuccinimide (4.1 g) was added, and the mixture was photolyzed with a sun lamp (100 watts)while heating at reflux for 1 hr. The resulting mixture was filtered and heated at reflux for an additional 3 hr to complete the hydrogen bromide elimination. Column chromatography of the crude product through silica gel by gradient elution with hexane–ethyl acetate yielded 10 g of material that contained some unreacted monoene (<10% by NMR) but mainly comprised of diene IV*a*: ^{1}H-NMR δ 7.22 (s, 10H, phenyl H), 6.88 (d, J = 11 Hz, 1H, C-23), 5.92 (d, J = 11 Hz, 1H, C-22), 4.82 (peak, 1H, 7β-H), 4.57 (hump, 1H, 3β-H), 2.14 (s, 3H, 7α-acetate), 2.02 (s, 3H, 3α-acetate), 1.92 (s, 3H, C-23), 0.90 (s, 3H, C-19), and 0.60 (s, 3H, C-18). Saponification of IV*a* was achieved by heating at reflux with potassium hydroxide (10 g) and methanol (200 ml) for 3 hr. The reaction mixture was poured into ice (600 g) and the solid was collected by filtration. The dry solid was selectively acetylated by reacting with acetic anhydride (25 ml) and pyridine (25 ml) in benzene (125 ml) for 24 hr. Column chromatography produced 8 g of 3α-acetoxy-12α-hydroxy-24,24-diphenyl-5β-chola-20(22),23-diene: ^{1}H-NMR δ 7.30 (s, 10H, phenyl H), 6.98 (d, J = 11 Hz, 1H, C-23), 6.05 (d, J = 11 Hz, 1H, C-22), 4.75 (hump, 1H, 3β-H), 3.78 (peak, 1H, 12β-H), 2.02 (s, 3H, 3α-acetate), 1.97 (s, 3H, C-21), 0.93 (s, 3H, C-19), and 0.57 (s, 3H, C-18). Jones oxidation of this product was carried out in cold (5°) acetone (800 ml) to yield 4.0 g of IV*c*: mp 190–192°; $\bar{\nu}_{max}$ 1730 and 1240 (acetate), 1705 (12-oxo), and 1630 cm^{-1} (weak C=C stret); ^{1}H-NMR δ 7.23 (s, 10H, phenyl H), 6.90 (d, J = 11 Hz, 1H, C-23), 6.04 (d, J = 11 Hz, 1H, C-22), 4.67 (hump, 1H, 3β-H), 1.99 (s, 6H, 3α-acetate and C-20), 1.01 (s, 3H, C-18), and 0.88 (s, 3H, C-19).

Also, 0.8 g of 3,12-dioxo-24,24-diphenyl-5β-chola-20(22),23-diene [^{1}H-NMR δ 7.28 (s, 10H, phenyl H), 6.94 (d, J = 11 Hz, 1H, C-23), 6.07 (d, J = 11 Hz, 1H, C-22), 2.02 (s, 3H, C-21), 1.10 (s, 3H, C-18), and 0.92 (s, 3H, C-19)], and 1.2 g of 3α-acetoxy-12-oxo-5β-pregnan-20-one [^{1}H-NMR δ 4.68 (hump, 1H, 3β-H), 3.32 (t, 1H, 17α-H), 2.25 (s, 3H, C-21), 2.00 (s, 3H, 3α-acetate), 1.03 (s, 3H, C-18), and 0.95 (s, 3H, C-19)] were obtained.

3α,12α-Diacetoxy-24,24-diphenyl-5β-chol-23-ene (1*a*)—The synthesis of I*a* has been described (10); mass spectrum (12 ev), *m/z* (%): 596 (1, $[M]^+$), 536 (11, $[M-CH_3CO_2H]^+$), 476 (5, $[M-2CH_3CO_2H]^+$), 461 (1, $[M-2CH_3CO_2H-CH_3]^+$), 283 (6, $[M-2CH_3CO_2H-C_{15}H_{13}]^+$), 256 (9, $[M-CH_3CO_2H-C_{14}H_{12}]^+$), 246[3], 220 (100, $[C_{15}H_{13}]^+$), 205 (10, $[220-CH_3]^+$)*, 193 (10, $[C_{15}H_{13}]^+$), 180 (5, $[C_{14}H_{12}]^+$), and 167 (3, $[C_{13}H_{11}]^+$).

3α,7α-Diacetoxy-24,24-diphenyl-5β-chol-23-ene (1*b*)(1)—Mass spectrum (12 ev), *m/z* (%): 569 (1, $[M]^+$), 536 (7, $[M-CH_3CO_2H]^+$), 476 (3, $[M-2CH_3CO_2H]^+$), 343 (5, $[M-CH_3CO_2H-C_{15}H_{13}]^+$), 314[28], 313 (23, $[M-CH_3CO_2H-C_{17}H_{19}]^+$), 253 (100, $[M-2CH_3CO_2H-C_{17}H_{19}]^+$), 193 (33, $[C_{15}H_{13}]^+$), 180 (56, $[C_{14}H_{12}]^+$), and 149 [73].

3β-Acetoxy-24,24-diphenyl-5α-lanost-23-ene (VII)—Mass spectrum (12 ev), *m/z* (%): 580 (2, $[M]^+$), 565 (1, $[M-CH_3]^+$), 387 (2, $[M-C_{15}H_{13}]^+$), 357 (36, $[M-C_{17}H_{19}]^+$), 343[15], 327 (33, $[M-C_{15}H_{13}-CH_3CO_2H]^+$), 297 (6, $[M-C_{17}H_{19}-CH_3CO_2H]^+$), 283[3], 259[2], 231[3], 222[15], 217[15], 193 (22, $[C_{15}H_{13}]^+$), 180 (100, $[C_{14}H_{12}]^+$), 163[5], 149[4], 135[4], and 122[5].

ACKNOWLEDGMENTS

This work was partially supported by the UMKC Research Council.

The author thanks Mr. Rickey Barbarash and Barbara J. Dias for their technical assistance. Also, the author expresses his appreciation to Professor G. R. Pettit for supplying a sample of compounds VII and VIII. The author thanks Dr. Marvin J. Karten, Contraceptive Development Branch, CPR, NICHD, National Institutes of Health, Bethesda, Md., for providing the biological assays.

A preliminary account of this work was presented at the 14th Midwest Regional Meeting of the ACS, Fayetteville, Ark., Oct. 26–27, 1978.

The Synthesis and Analgesic Activities of Some Spiro[indan-1,3′-pyrrolidine] Derivatives Designed as Rigid Analogs of Profadol

P. A. CROOKS *x and **R. SOMMERVILLE**

Received February 18, 1981, from the *Department of Pharmacy, University of Manchester, Manchester M13 9PL, England.* Accepted for publication July 17, 1981. * Present address: College of Pharmacy, University of Kentucky, Lexington, KY 40506.

Abstract □ Aromatic hydroxylated derivatives of spiro[indan-1,3′-pyrrolidine], designed as conformationally restricted analogs of profadol, were synthesized and pharmacologically evaluated in mice for analgesia and other central nervous system activities. None of the compounds synthesized were as potent as profadol in writhing and hot plate tests, but the 4-hydroxy derivative exhibited codeine-level analgesia in the tests.

Keyphrases □ Profadol—rigid analogs, spiro[indan-1,3′-pyrrolidine] derivatives, synthesis and analgesic activity □ Analgesic activity—evaluation of some spiro[indan-1,3′-pyrrolidine] derivatives, synthesis □ Spiro[indan-1,3′-pyrrolidine] derivatives—synthesis and evaluation for analgesic activity

As part of this laboratory's interest in the use of spiro-compounds as analgesic receptor probes (1–3), a series of spiro[tetralin-1,3′-pyrrolidine] (I) derivatives, designed as conformationally and rotationally restricted analogs of the analgesic drug, profadol (II), were synthesized recently and their analgesic activities determined. The present report describes the synthesis and analgesic activities of some structurally related spiro[indan-1,3′-pyrrolidine] (III) derivatives in which conformational flexibility is restricted more than in I.

EXPERIMENTAL[1]

Chemistry—*Ethyl 4-Methoxy-indanylidenecyanoacetate* (*IV*b)—A mixture of 4-methoxy-1-indanone (16.2 g, 0.1 mole), ethyl cyanoacetate (12.43 g, 0.11 mole), ammonium acetate (15.4 g, 0.2 mole), and acetic acid (48 g, 0.8 mole) in benzene (100 ml) was heated under reflux with a Dean and Stark water trap for 24 hr. The cooled reaction mixture was washed with water (3 × 100 ml), the washings extracted with benzene (2 × 50 ml) and the combined benzene liquors dried (magnesium sulfate) and concentrated to give crude product. Recrystallization from ethanol gave an analytical sample (Table I); NMR (dimethyl sulfoxide-d_6): δ 1.38 (t, 3H, OCH_2CH_3), 2.98 (m, 2H, indan-3 protons), 3.52 (m, indan-2 protons), 3.86 (s, 3H, OCH_3), 4.32 (q, 2H, OCH_2CH_3), 7.00 (1H, m, indan-5 proton), 7.29 (1H, m, indan-6 proton), and 8.26 (1H, m, indan-7 proton) ppm; IR: 2215 (C≡N) and 1720 (C=O) cm^{-1}.

Compounds IV*a*, IV*c*, and IV*d* were prepared similarly from the appropriately substituted 1-indanone[2] (Table I). The IR and NMR spectra were consistent with their assigned structures.

4-Methoxy-1-cyano-1-cyanomethylindane (*IVf*)—A solution of potassium cyanide (16.2 g, 0.25 mole) in water (50 ml) was added to a stirred solution of IV*b* (24.5 g, 0.1 mole) in absolute ethanol (200 ml) and the contents stirred at 65° for 16 hr. The mixture was then evaporated to dryness *in vacuo*, the residue suspended in water (200 ml) and extracted with ether (3 × 200 ml). The ether extracts were washed with water (2 × 50 ml), dried (magnesium sulfate), and the solvent evaporated to give a brown oil. This oil was vacuum distilled to give IV*f*, a colorless oil that crystallized on standing. Recrystallization from ethanol gave an analytical sample (Table I); NMR (deuterochloroform): δ 2.40 (m, 2H, indan-2 protons), 2.86 (s, 2H, CH_2CN), 2.97 (m, 2H, indan-3 protons), 3.80 (s, 3H, OCH_3), 6.83 (m, 1H, indan-5 proton), 7.12 (m, 1H, indan-6 proton), and 7.33 (m, 1H, indan-7 proton) ppm; IR: 2255 and 2240 (both C≡N) cm^{-1}.

Compounds IV*e*, IV*g*, and IV*h* were prepared similarly from IV*a*, IV*c*, and IV*d*, respectively. IR and NMR spectra were consistent with the assigned structures.

4-Methoxy spiro[indan-1,3′-pyrrolidine-2′,5′-dione] (*IVj*)—A suspension of IV*f* (21.2 g, 0.1 mole) in acetic acid (50 ml) and 78% (v/v) sulfuric acid (20 ml) was heated in an oil bath at 125° for 1 hr. The acetic acid was removed by *in vacuo* distillation and the resulting mass was suspended in water (50 ml) and extracted with ethyl acetate (3 × 300 ml). The organic phase was washed with saturated sodium bicarbonate solution (2 × 200 ml) and water (100 ml) and then dried (magnesium sul-

fate). Evaporation of the solvent gave the crude product which was recrystallized from absolute ethanol to give an analytical sample (Table I); NMR (dimethyl sulfoxide-d_6): δ 1.87–2.80 (m, 2H, indan-2 protons), 2.89–3.26 (m, 2H, indan-3 protons), 2.03 (s, 2H, pyrrolidine-4′ protons), 3.79 (s, 3H, OCH_3), 6.68 (m, 1H, indan-5 proton), 6.74 (m, 1H, indan-7 proton), 7.21 (m, 1H, indan-6 proton), and 8.50 (broad s, 1H, exchangeable with deuterium oxide, −NH) ppm; IR: 3190, 3075, 1780, 1725, and 1695 cm^{-1}.

Compounds IV*i*, IV*k*, and IV*l* were prepared similarly from IV*e*, IV*g*, and IV*h*, respectively; IR and NMR spectra were consistent with the assigned structures.

4-Methoxy spiro[indan-1,3′-pyrrolidine] (*III*c)—Finely divided IV*j* (23.1 g, 0.1 mole) was added slowly to a stirred suspension of aluminum lithium hydride (11.25 g, 0.3 mole) in dry tetrahydrofuran and the mixture refluxed for 24 hr. The excess aluminum lithium hydride was decomposed by careful addition of water, anhydrous magnesium sulfate was added, and the suspension was filtered. The filtrate was evaporated *in vacuo* to give a pale yellow oil which was distilled *in vacuo* to give III*c;* NMR (deuterochloroform): δ 1.78–2.22 (m, 4H, indan C-2 and C-4′ protons), 2.05 (s, 1H, exchangeable with deuterium oxide, NH), 2.69–2.97 (m, 2H, C-3 protons), 2.90 (s, 2H, C-2′ protons), 2.07–3.29 (m, 2H, C-5′ protons), 3.76 (s, 3H, OCH_3), 6.66 (m, 1H, C-5 proton), 6.80 (m, 1H, C-7 proton), and 7.17 (m, 1H, C-6 proton) ppm. The base was converted to the fumarate salt which was recrystallized from ethanol–ether to give an analytical sample (Table II).

Compounds III*a*, III*c*, and III*g* were prepared in a similar manner from IV*i*, IV*k*, and IV*l*, respectively and converted to the hydrochloride or fumarate salts (Table II). IR and NMR spectra were consistent with the assigned structures.

*4-Methoxy-*N*-methyl spiro[indan-1,3′-pyrrolidine]* (*III*d)—A solution of III*c* (2.0 g, 0.01 mole) in formic acid (2.3 g, 0.05 mole) and 40% formaldehyde solution (2 ml, 0.02 mole) was heated with stirring at 95° for 24 hr. The reaction mixture was diluted with 5% hydrochloric acid (5 ml) and extracted with ether (2 × 10 ml). The aqueous phase was made basic with concentrated ammonia solution, and extracted with ether (3 × 20 ml). The combined layers were washed with water (10 ml), dried (magnesium sulfate), and the solvent evaporated. The resulting oil was distilled *in vacuo* to give pure III*d;* NMR (deuterochloroform): δ 1.88–2.30 (m, 4H, C-2 and C-4′ protons), 2.35 (s, 3H, N—CH_3), 2.50–2.98 (m, 4H, C-3 and C-5′ protons), 2.64 (s, 2H, C-2′ protons), 3.77 (s, 3H, OCH_3), 6.64 (m, 1H, C-5 proton), 6.90 (m, 1H, C-7 proton), and 7.20 (m, 1H, C-6 proton) ppm. The base was converted to the fumarate salt which was recrystallized from ethanol–ether to give an analytical sample (Table II).

Compounds III*b*, III*f*, and III*h* were prepared in a similar manner from III*a*, III*e*, and III*g*, respectively, and converted to either their hydrochloride or fumarate salts (Table II). Their IR and NMR spectra were consistent with the assigned structures.

4-Hydroxy spiro[indan-1,3′-pyrrolidine]hydrobromide (*III*i)—A solution of III*c* (2.0 g, 0.01 mole) in 48% aqueous hydrobromic acid (25 ml) was refluxed under nitrogen for 1.5 hr. The yellow-brown solution was chilled to give buff crystals of III*i* which were recrystallized from ethanol–ether, giving an analytical sample (Table II); NMR (deuterium oxide): δ 1.80–2.20 (m, 4H, C-2 and C-4′ protons), 2.55–2.90 (m, 2H, C-3 protons), 3.21 (s, 2H, C-2′ protons), 3.24–3.68 (m, 2H, C-5′ protons), 6.51 (m, 1H,C-5 proton), 6.69 (m, 1H, C-7 proton), and 7.02 (m, 1H, C-6 proton) ppm; IR: 3210 (–OH), 2720 (NH) cm^{-1}.

Compounds III*j*–III*n* were prepared similarly from the appropriately substituted spiro[indan-1,3′-pyrrolidine]. Their IR and NMR spectra were all consistent with the assigned structures (Table II).

Pharmacology—Analgesia was determined by the acetic acid writhing test (6) in groups of six mice. Each group was dosed orally with either vehicle[3] or the compound under test and injected intraperitoneally 30 min later with dilute acetic acid (0.4 ml, 0.25%). Compounds showing analgesia at 50 mg/kg in that test were also tested for analgesia by the hot-plate method (7) (Table II).

Locomotor activity was determined using a battery of photobeam cages (30 × 12 × 9-cm) traversed by a beam of light. Interruptions of the beam were counted automatically. Groups of 10 mice were dosed and placed singly in the cages. After 45 min the total number of interruptions recorded and the percentage of inhibition or increase in movement relative to controls were determined.

Reversal of reserpine-induced hypothermia was assessed in groups of

[3] The testing vehicle used was "Dispersol," ICI Ltd., Pharmaceuticals Division, Macclesfield, UK, which consists of Lissapol NX (Ex ICI Dyestuffs Division, nonylphenol–ethylene oxide concentrate) (0.1%), "Lissapol" C** (sodium salt of sulfated cetyl/oleyl alcohol mixture) (0.1%), "Dispersol" OG** (polyglyceryl ricinoleate) (0.1%), and water (99.7%).

[a] Confidence limits in parentheses. [b] Effective at 30 mg/kg in reversing pentylenetetrazol-induced convulsions in mice. [c] Failed to exhibit a normal dose-response curve in the hot-plate test. [d] Not active at 50 mg/kg po in hot-plate test. [e] Exhibited central stimulant activity at 30 mg/kg in mice. [f] ED_{50} = 16.8 (11.6–25.3) mg/kg po in hot-plate test. [g] Caused a 90% reduction in motility at 30 mg/kg in mice. [h] ED_{50} = 3.8 (2.2–6.5) mg/kg po in hot-plate test. *NA* Not active at 100 mg/kg.

six mice as described previously (8) and based on the method of Askew (9).

Anticonvulsant activity was measured in groups of six mice subjected to the application of maximal electroshock (20 mamp for 0.22 sec *via* aural clip electrodes) or administration of the chemical convulsant, pentylenetetrazol (160 mg/kg subcutaneously). In each case, tonic extensor spasm was used as the end-point.

Impairment of motor coordination was assessed by measuring the ability of groups of six mice to balance on a stationary 1.3-cm diameter metal rod. Individual animals were placed on the rod and observed throughout the subsequent 20 sec. The time each mouse remained upon the rod was recorded and converted to a score. If the mouse balanced for the entire 20 sec, a score of 0 was given; if the mouse fell off after T sec, a score of $20 - T$ was given. Mice that fell off the rod on their first attempt were replaced for three more trials, providing a maximum possible score of 80. The mean score per mouse was determined and compared by standard statistical procedures with corresponding values obtained for groups treated with vehicle alone.

RESULTS

Chemistry—The syntheses of compounds IV*a*–IV*l* and III*a*–III*h* were carried out using procedures similar to those described previously for the preparation of the spiro[tetralin-1,3′-pyrrolidine] derivatives (3), but utilizing the appropriately substituted 1-indanone in place of the corresponding 1-tetralone. The appropriate 1-tetralone was condensed with ethylcyanoacetate to give the 1-indanylidenecyanoacetate derivative (IV*a*–IV*d*), which was reacted with potassium cyanide to give the corresponding 1-cyano-1-(cyanomethyl)indane (IV*e*–IV*h*). Treatment of compounds IV*e*–IV*h* with an acetic acid–sulfuric acid mixture gave the corresponding spiro[indan-1,3′-pyrrolidine-2′,5′-dione] derivatives (IV*i*–IV*l*). These compounds were then reduced with aluminum lithium hydride in tetrahydrofuran to give the appropriately substituted spiro[indan-1,3′-pyrrolidine] (III). *O*-Demethylation of compounds III*c*–III*h* was carried out under nitrogen in refluxing 48% hydrobromic acid containing 1% phosphoric acid. *N*-Methylation of compounds III*a*, III*c*, III*e*, and III*g* was accomplished in formic acid–formaldehyde solution (Tables I and II).

Pharmacology—Compounds III*b* and III*i* were the most active compounds in the series, exhibiting codeine-level analgesia, whereas compound III*j* showed no analgesic activity. None of the other hydroxylated derivative (III*k*–III*n*) showed any significant analgesic activity, although compound III*l* caused marked reduction in motility in mice at a 30-mg/kg dose, whereas compound III*g* exhibited central stimulant properties at 30 mg/kg in mice. Compound III*b* protected mice against pentylenetetrazol induced convulsions at 30 mg/kg. Compounds III*a*–III*n* were inactive in the maximal electroshock test, in reserpine antagonism tests, and did not produce any impairment of coordination in the stationary rod test.

DISCUSSION

An important feature of profadol (II) structure is the rotational freedom present in the molecule which allows a number of rotameric forms as the aromatic ring is rotated about the C1–C3′ bond. Thus, the weak analgesic activity exhibited by compounds of structure I possibly results from these compounds adopting conformations that are noncomplimentary with the receptor. Spiro[indan-1,3′-pyrrolidine] (III) derivatives may be regarded as profadol analogs, which are more conformationally rigid than the spiro system (I), since aromatic ring rotation is severely

restricted in III as a result of the reduction of ring B to a five-membered ring. Thus, compounds III*j*, III*l*, and III*n* represent interesting rigid analogs of II. Furthermore, molecular model examination of III*j* and morphine shows the phenolic and tertiary amino groups, and the aromatic ring in both compounds to be almost stereosuperimposable. In addition, it was of interest to find a patent describing some 3-hydroxyspiro[indan-1,3'-pyrrolidine] derivatives as orally active analgesics (10). Profadol is thought to interact with the analgesic receptor in the half-chair conformation (11).

Although the spiro systems I and III represent structural analogs in which the profadol molecule is fixed in a conformation related to the morphine molecule, these compounds exhibit only weak or insignificant analgesic properties. Thus, other structural features appear to be important in profadol-receptor interaction. The inability of these spiro analogs to enhance or maintain the analgesic properties of profadol may be related to a decreased fit of these compounds at the receptor due to the rigid orientation of the B ring in these compounds, which represents a fixed, and perhaps undesirable, conformation of the 3-propyl group in II.

Quantitation of Hydroxyprogesterone Caproate, Medroxyprogesterone Acetate, and Progesterone by Reversed-Phase High-Pressure Liquid Chromatography

V. DAS GUPTA

Received March 20, 1981, from the *University of Houston, College of Pharmacy, Houston, TX 77030.* Accepted for publication June 29, 1981.

Abstract □ A high-pressure liquid chromatographic method for the quantitation of hydroxyprogesterone caproate, medroxyprogesterone acetate, and progesterone in pharmaceutical dosage forms was developed. The method gave accurate, precise, and reproducible results. The excipients present in the dosage forms did not interfere with the assay procedure except benzyl benzoate in progesterone injection. The percent relative standard deviations based on six injections were 1.6, 2.5, and 2.7% for hydroxyprogesterone caproate, medroxyprogesterone acetate, and progesterone, respectively. The stability of progesterone in ethanol–propylene glycol–water (10:50:40) was studied. The loss in potency of progesterone, even after 487 days of storage at 50°, was <10%.

Keyphrases □ Hydroxyprogesterone caproate—quantitation by reversed-phase high-pressure liquid chromatography □ Medroxyprogesterone acetate—quantitation by reversed-phase high-pressure liquid chromatography □ Progesterone—quantitation by reversed-phase high-pressure liquid chromatography □ High-pressure liquid chromatography—quantitation of hydroxyprogesterone caproate, medroxyprogesterone acetate, and progesterone

The pharmaceutical dosage forms of hydroxyprogesterone caproate (I), medroxyprogesterone acetate (II), and progesterone (III) are used extensively. The USP method (1) for the quantitative determination of I in dosage forms is based on a reaction with isoniazid. The color produced is measured spectrophotometrically.

For dosage forms of II, the USP method (2) requires normal phase high-pressure liquid chromatography (HPLC) with a porous silica column. The quantitation of III requires reversed-phase chromatography (3). The 1-m column for this procedure has to be packed with octadecylsilane chemically bonded to silica gel. The USP method (3) appears to be a modification of a procedure recommended previously (4).

This investigation attempted to develop a reversed-phase HPLC method (with prepacked column) suitable for the quantitation of I, II, and III in pharmaceutical dosage forms. The stability of III in some aqueous systems was also determined.

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were ACS, USP, or NF grade and were used as received. 17-Hydroxyprogesterone[1], hydroxyprogesterone caproate[1], medroxyprogesterone acetate[2], and progesterone[3] were used without further purification.

Apparatus—The chromatograph[4] was connected to a multiple-wavelength detector[5], a recorder[6], and an integrator[7]. All pH values were determined using a pH meter[8].

Column—The column[9] (30 cm × 4-mm i.d.) was of a semipolar material consisting of a monomolecular layer of cyanopropylsilane permanently bonded by silicone–carbon bonds.

Chromatographic Conditions—The mobile phase contained 30%

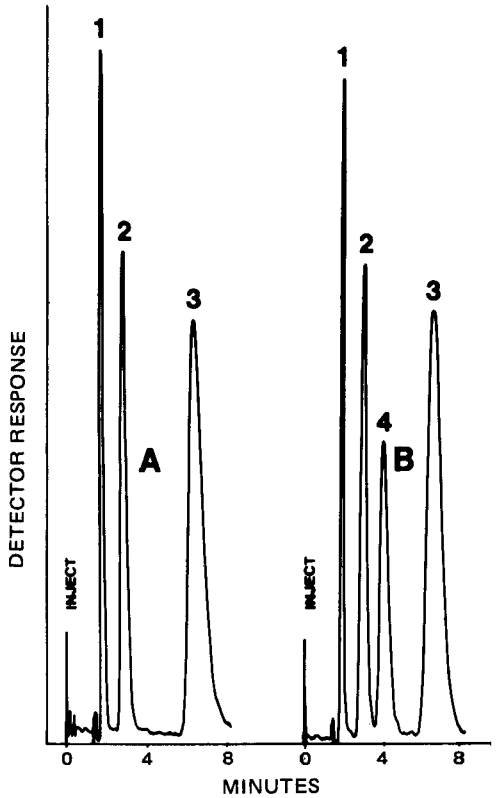

Figure 1—*Sample chromatograms. Peaks 1–3 are from the solvent, internal standard (17-hydroxyprogesterone) and I, respectively. Peak 4 in chromatogram B is from benzyl benzoate. Key: A, standard solution; and B, injection of I. The chromatographic conditions are given in the text.*

by volume (40% by volume for I) of methanol in 0.02 *M* aqueous solution of monobasic potassium phosphate. The temperature was ambient and the flow rate was 2.0 ml/min. The detector was set at 0.04 (254 nm) and the chart speed was 30.5 cm/hr.

Solution Preparation—The stock solutions of I, II, and III were prepared by dissolving 100.0 mg of the compound in enough ethanol to make 100.0 ml. The standard solutions were prepared as needed by diluting the stock solutions either with ethanol or dilute ethanol (50% by volume in water). Before final dilution, an appropriate quantity of the internal standard (17-hydroxyprogesterone for I and hydrocortisone for II and III) was added. The final concentration of the internal standard was always 20 μg/ml. The stock solutions of internal standards were also prepared by dissolving 100.0 mg of the substance in enough ethanol to make 100.0 ml.

Preparation of Progesterone Solutions for Stability Studies—A 10.0-ml quantity of the III solution (10.0 mg/ml in ethanol) was mixed with 50.0 ml of propylene glycol and the mixture was brought to volume (100.0 ml) with either water or a 0.125 *M* phosphate buffer of an appropriate pH value.

After the initial assays, the solutions were divided into two parts and stored in amber bottles[10] (60-ml capacity) at 25 and 50°.

Assay Solutions—One milliliter of the commercially available hydroxyprogesterone caproate injection (250 mg/ml) was diluted to 100.0 ml with ethanol. In addition to I, the injection also contained 46% of benzyl benzoate and castor oil *q.s.*; a 1.2 ml of this solution was mixed with 1.0 ml of the internal standard (a 1.0 mg/ml solution of 17-hydroxyprogesterone in ethanol) and the mixture was brought to volume (50.0 ml) with ethanol.

Medroxyprogesterone Acetate Suspension (400 mg/ml)—A 2.0-ml quantity of the well-shaken suspension was diluted to 1000.0 ml (to 250 ml when the concentration of II in suspension was 100 mg/ml) with ethanol. Then 2.5 ml of the clear mixture was further diluted to 50.0 ml (before diluting, 1.0 ml of the internal standard was added) with ethanol. In addition to II, the suspension contained (per milliliter) polyethylene glycol 4000, 20.3 mg; sodium sulfate anhydrous, 11 mg; and myristyl-γ-picolinium chloride, 1.7 mg.

Suspension (different lot)	II	99.2	—[b]
Tablets	II	99.1	—[b]
Tablets (different lot)	II	100.7	—[b]
Injection	III	132.8[c]	—[b]
Suspension	III	95.6	—[b]
Suspension (different lot)	III	96.3	—[b]
Synthetic mixture similar to above suspension	III	99.7	—[b]

[a] Average of three assays. Reproducibility on different days was within ±1.5%. [b] Not assayed using USP–NF method which is also based on HPLC. [c] Results are high because of interference from benzyl benzoate with the assay procedure.

Medroxyprogesterone Acetate Tablets (10 mg/Tablet)—Ten tablets were ground to a fine powder and stirred with ~50 ml of ethanol. The mixture was transferred to a 100-ml volumetric flask and more ethanol rinses were added to bring it to volume. The mixture was filtered[11], 20 ml of the filtrate was rejected and then 2.0 ml of the filtrate was mixed with 1.0 of the internal standard (hydrocortisone solution in

[a] For samples stored at 50°. The results of samples stored at 25° did not indicate any decomposition, even in 487 days. [b] All other solutions were diluted with 0.125 *M* KH_2PO_4 solution of an appropriate pH value except solution 1, which was diluted with water. [c] pH values of the solutions.

ethanol, 1 mg/ml), and the mixture was brought to volume (50.0 ml) with ethanol. The list of the excipients was not disclosed on the label.

Progesterone Aqueous Suspension (50 mg/ml)—The suspension was shaken well, and 2.0 ml was transferred to a 100-ml volumetric flask and brought to volume with ethanol. The mixture was filtered[11] if necessary, and 2.0 ml of the clear solution was mixed with 1.0 ml of the internal standard (1 mg/ml solution of hydrocortisone in ethanol) and brought to volume (50.0 ml) with ethanol. In addition to III, the suspension contained (per milliliter) sodium carboxymethylcellulose, 2 mg; methylcellulose, 0.3 mg; dioctyl sodium sulfosuccinate, 0.15 mg; and thimerosal, 0.08 mg.

Progesterone Injection (50 mg/ml)—A 2.0-ml quantity of the injection was extracted with ethanol (85% by volume in water) according to the procedure recommended by King *et al.* (4), and the extracts were brought to volume (100.0 ml) with 85% ethanol. A 2.0-ml quantity of the clear solution was further diluted to 50.0 ml with dilute ethanol (50% by volume in water). Before diluting, 1.0 ml of the internal standard was added as already described. In addition to III, the injection contained 20% benzyl benzoate, 0.5% phenol, and peanut oil *q.s.*

Progesterone Solutions for Stability Studies—A 2.0-ml quantity of the solution was mixed with 1.0 ml of the internal standard and the mixture was brought to volume (50.0 ml) with dilute ethanol.

Assay Procedure—A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the appropriate standard solution was injected after the assay solution eluted. The standard solutions contained identical concentrations of the drug (based on label claim of the assay) and the internal standard and were diluted using the identical solvent (ethanol or dilute ethanol).

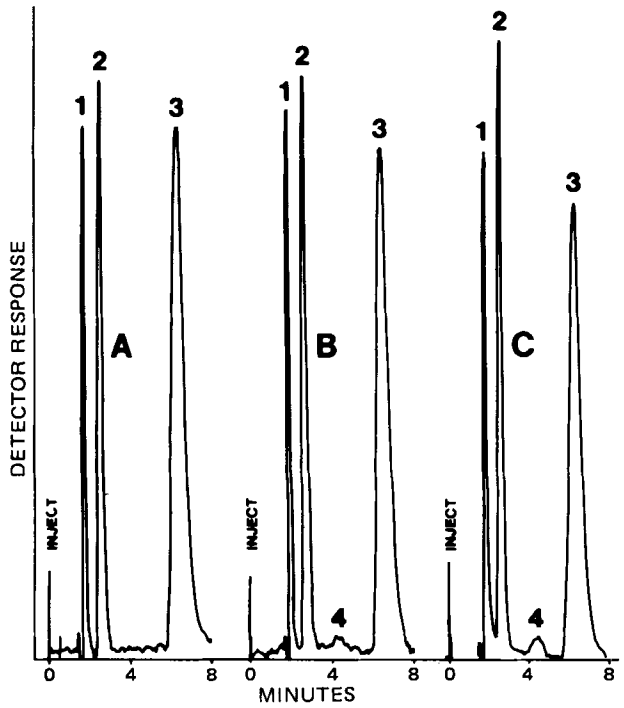

Figure 3—*Sample chromatograms. Peaks 1–3 are from the solvent, hydrocortisone (internal standard), and III, respectively. Peak 4 in chromatograms B and C is from the decomposition product of III. Key: A, standard solution of III in 50% ethanol; B, solution 3 (Table II) after 487 days of storage at 50°; and C, solution of III after boiling with 1* N *NaOH. The chromatographic conditions are given in the text.*

Preliminary studies were conducted to determine the interferences from the excipients with the assay procedure. No interference was found except from benzyl benzoate present in progesterone injection.

Calculations—Since preliminary investigations indicated that peak heights (also the peak areas) were directly related to the concentrations (ranges tested were 0.4–1.6 μg for I and 0.4–1.2 μg for II and III), the results were calculated using

$$\text{percent of label claim} = \frac{(R_{ph})_a}{(R_{ph})_s} \times 100 \qquad \text{(Eq. 1)}$$

where $(R_{ph})_a$ is the ratio of the peak heights of the drug in the assay solution and the internal standard and $(R_{ph})_s$ for the standard solution of identical concentrations. The results are presented in Tables I and II and Figs. 1–3.

Other Experiments—A 2.0-ml quantity of the stock solution of III was mixed with either 2.0 ml of ~0.1 *N* NaOH or 0.1 *N* HCl solution and allowed to stand for 24 hr. The internal standard was then added, and the mixture was brought to volume (50.0 ml) with dilute ethanol and assayed.

In another experiment, 2.0 ml of the stock solution of III was mixed with 1.0 ml of ~1 *N* NaOH solution and 20 ml of dilute ethanol. The mixture was boiled for ~5 min on a hot plate and cooled to room temperature. The internal standard was then added, and the mixture was brought to volume and assayed. The result is presented in Fig. 3C.

RESULTS AND DISCUSSION

Hydroxyprogesterone Caproate—The assay results (Table I) indicate that the proposed HPLC method can be adopted for the quantitative determination of I in injectables. The castor oil and benzyl benzoate present in the injection did not interfere with the assay procedure. Benzyl benzoate gave a separate peak between the internal standard and the drug (peak 2 in Fig. 1B).

No preliminary procedure to extract I from the injectable solution was required. The percent relative standard deviation based on six injections was 1.6. The method was reproducible.

Medroxyprogesterone Acetate—The assay results (Table I) indicate that HPLC is a reliable method for the quantitation of II in suspension and tablets. A very simple procedure was required to extract II from the tablets, while the suspension did not require preliminary extraction. None of the excipients present in suspension (polyethylene glycol 4000, sodium sulfate, and myristyl-γ-picolinium chloride) interfered with the assay procedure (Fig. 2A). The chromatogram obtained from tablets was similar to Fig. 2A.

The percent relative standard deviation based on six injections was 2.5% and the assay method was reproducible.

Progesterone—The assay results of suspensions (Table I) indicate that the HPLC method can be used for the quantitation of III in suspension. However, in the case of injection, the benzyl benzoate interfered. It had the same retention time as of III; therefore, the assay results were high (Table I).

The excipients present in the suspension (sodium carboxymethylcellulose, methylcellulose, dioctyl sodium sulfosuccinate, and thimerosal) did not interfere with assay procedure (Fig. 2C). The percent relative standard deviation based on six injections was 2.7% and the method was reproducible.

The stability results (Table II) indicate that progesterone is a very stable compound in the vehicle (ethanol, 10%; propylene glycol, 50%; and water, 40%) studied. Even in 487 days of storage at 50°, the decomposition in all the solutions was <10%. This is equal to at least 5 years of storage at room temperature. The samples which were stored at room temperature did not decompose at all, even in 487 days.

In other experiments, the progesterone did not decompose in 24 hr on treating with 0.1 *N* HCl and with 0.1 *N* NaOH, the loss in potency was ~4%. On boiling with 1 *N* NaOH for 5 min, the sample lost slightly more than 16% of the potency. An additional peak between the peaks of the

internal standard (hydrocortisone) and III was obtained (Fig. 3C) in the chromatogram.

A Time-Lag Model for Pharmacokinetics of Drugs Subject to Enterohepatic Circulation

JEAN-LOUIS STEIMER*x, YVES PLUSQUELLEC‡, ANNE GUILLAUME*, and JEAN-FRANÇOIS BOISVIEUX*

Received August 1, 1980, from the **INSERM U 194, Département de Biomathématiques, 91, Bd de l'Hôpital, F-75634 Paris Cedex 13, France and the ‡Laboratorie d'Algèbre, Département de Mathématiques, Université Paul-Sabatier, F-31000 Toulouse, France.* Accepted for publication June 29, 1981.

Abstract □ A two-compartment model with time lag is proposed to describe the pharmacokinetics of drugs subject to enterohepatic circulation. The basic model, including two compartments for body and GI tract, respectively, with elimination occurring from both compartments, was previously proposed. The assumption that the reabsorption of a drug molecule is delayed after its biliary excretion is expressed by the addition of a time lag in the transfer from the first to the second compartment. Computer simulation of the model for intravenous bolus injection and oral intake of the drug was performed through first-order numerical integration. Several qualitative results concerning changes in pharmacokinetics due to modifications in biliary excretion, in reabsorption, or in elimination are identical with predictions using the basic model. However, several qualitative and quantitative results were significantly different. The pharmacokinetics, though remaining linear, are no longer biexponential. Initial decay after intravenous injection was not affected by modifications in reabsorption or elimination from intestine. Predictions based on the time-delay model agree with existing experimental evidence concerning pharmacokinetics of substances undergoing enterohepatic cycling. Delayed recirculation may lead to rebounds in plasma level profiles as well as after intravenous and oral administration. The half-life of the drug is significantly prolonged even when the kinetic processes involved in recirculation remain unchanged.

Keyphrases □ Pharmacokinetics—time-lag model, enterohepatic drug circulation □ Models, pharmacokinetic—enterohepatic drug circulation, time-lag model □ Enterohepatic circulation—drugs, pharmacokinetics, time-lag model

When a substance is taken up by the liver and excreted into the bile, it may be either eliminated through the GI tract or reabsorbed and carried to the liver *via* the portal blood stream. This second process is known as enterohepatic cycling. This phenomenon affects both endogenous and exogenous substances.

BACKGROUND

A two-compartment model was previously developed (1) representing the body and the GI tract. Qualitative modifications in pharmacokinetic time-profiles and parameters for drugs subject to enterohepatic cycling due to changes in biliary excretion and reabsorption rates are well depicted by this model.

Predictions of the two-compartment model agree with previous experimental results (1, 2). However, some discrepancies, such as the evidence of a secondary peak in the time course of serum concentrations, remain. Such a secondary peak was reported (3) appearing after intravenous, oral, and intraportal administration of morphine in rats. An eight-compartment model for morphine pharmacokinetics was proposed. The GI tract compartment of Harrison and Gibaldi (1) is split into a catenary system of three compartments forming a loop connected with the central compartment. Experimental evidence for a secondary peak in plasma radioactivity time profiles, as well as subsequent very slow elimination kinetics exist for labeled vitamin D_3 in humans (4) and rats (5). The main active metabolite of vitamin D_3 undergoes enterohepatic cycling (6).

A modification of the two-compartment enterohepatic recirculation model is proposed to take into account these previous experimental findings. The basic assumption is that a time-delay exists between the excretion of a given molecule of the substance into bile and its reabsorption from the intestine. This time lag may be due to delayed biotransformation in the liver, to the storage of the substance in the gallbladder (*e.g.*, in humans), or simply to its transport in bile, at a limited flow-rate, from the site of excretion to the site of reabsorption. The corresponding time-delay model proposed here exhibits qualitative agreement with the two basic observations on pharmacokinetics of drugs subject to enterohepatic circulation: first, the occurrence of "rebounds" in serum level profiles after intravenous and oral administration of drug; and second, the slow terminal kinetics of the drug when recirculation occurs, even when the processes of deconjugation and reabsorption are not rate-limiting.

When a substance is taken up by the liver and excreted into the bile, it may be either eliminated through the GI tract or reabsorbed and carried to the liver *via* the portal blood stream. This second process is known as enterohepatic cycling. This phenomenon affects both endogenous and exogenous substances.

BACKGROUND

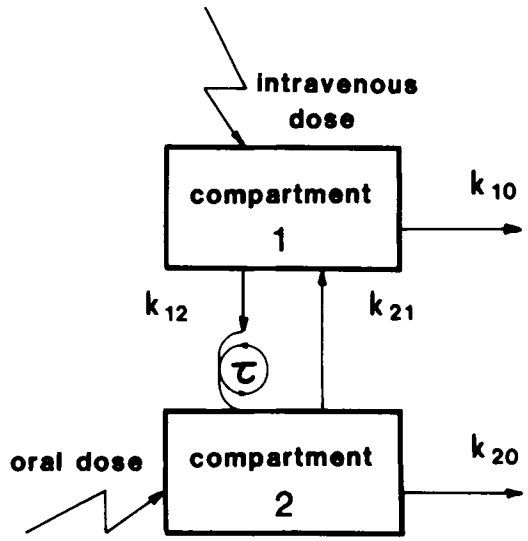
A two-compartment model was previously developed (1) representing the body and the GI tract. Qualitative modifications in pharmacokinetic time-profiles and parameters for drugs subject to enterohepatic cycling due to changes in biliary excretion and reabsorption rates are well depicted by this model.

Predictions of the two-compartment model agree with previous experimental results (1, 2). However, some discrepancies, such as the evidence of a secondary peak in the time course of serum concentrations, remain. Such a secondary peak was reported (3) appearing after intravenous, oral, and intraportal administration of morphine in rats. An eight-compartment model for morphine pharmacokinetics was proposed. The GI tract compartment of Harrison and Gibaldi (1) is split into a catenary system of three compartments forming a loop connected with the central compartment. Experimental evidence for a secondary peak in plasma radioactivity time profiles, as well as subsequent very slow elimination kinetics exist for labeled vitamin D_3 in humans (4) and rats (5). The main active metabolite of vitamin D_3 undergoes enterohepatic cycling (6).

A modification of the two-compartment enterohepatic recirculation model is proposed to take into account these previous experimental findings. The basic assumption is that a time-delay exists between the excretion of a given molecule of the substance into bile and its reabsorption from the intestine. This time lag may be due to delayed biotransformation in the liver, to the storage of the substance in the gallbladder (*e.g.*, in humans), or simply to its transport in bile, at a limited flow-rate, from the site of excretion to the site of reabsorption. The corresponding time-delay model proposed here exhibits qualitative agreement with the two basic observations on pharmacokinetics of drugs subject to enterohepatic circulation: first, the occurrence of "rebounds" in serum level profiles after intravenous and oral administration of drug; and second, the slow terminal kinetics of the drug when recirculation occurs, even when the processes of deconjugation and reabsorption are not rate-limiting.

THEORETICAL

Mathematical Formulation—The model presented in Scheme I is a two-compartment system differing from the basic model of Harrison



Scheme I—Time-lag pharmacokinetic model for a drug subject to enterohepatic circulation. Compartment 1 represents the body including the liver. Compartment 2 represents the GI tract. Existence of a time delay is assumed after biliary excretion, before reabsorption can occur.

0022-3549/82/0300-0297$01.00/0

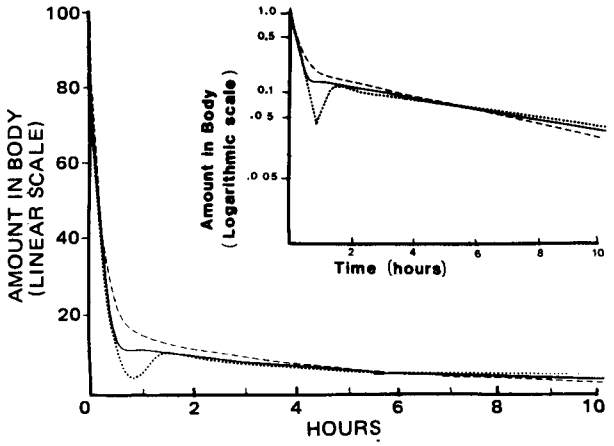


Figure 1—*Effect of time lag on pharmacokinetic profile after intravenous injection. For all curves,* $k_{12} = 3.0$, $k_{10} = 1.0$, $k_{21} = 1.0$, *and* $k_{20} = 0.0\ hr^{-1}$. *Key: - - -,* $\tau = 0$ *(no time lag);* ——, $\tau = 0.4$ *hr; and . . .,* $\tau = 0.8$ *hr.*

and Gibaldi (1) by the addition of a time lag on the transfer pathway from compartment 1 to compartment 2. In this model, compartment 1 represents the whole body, including the liver, while compartment 2 describes the GI tract.

The transfer processes are supposed to be governed by first-order kinetics and are denoted respectively by k_{10} for the nonbiliary elimination process, k_{20} for the biotransformation in the GI tract and the fecal excretion, and k_{21} for the reabsorption process.

The important characteristic of the model lies in the addition of a time delay occurring in series with the conventional k_{12} coefficient, thus implying that the drug leaving compartment 1 at time t enters compartment 2 at time $t + \tau$.

The corresponding mathematical formulation is:

$$\frac{dA_1(t)}{dt} = -(k_{10} + k_{12})A_1(t) + k_{21}A_2(t) \qquad \text{(Eq. 1}a\text{)}$$

$$\frac{dA_2(t)}{dt} = -(k_{20} + k_{21})A_2(t) + k_{12}A_1(t - \tau) \qquad \text{(Eq. 1}b\text{)}$$

Due to the existence of this time delay, the initial conditions take a special form; to calculate the solutions of Eqs. 1*a* and 1*b* starting from arbitrary time t_0, one has to define:

$$A_1(t) \text{ for } t_0 - \tau \leq t \leq t_0 \qquad \text{(Eq. 2}a\text{)}$$

and

$$A_2(t) \text{ for } t = t_0 \qquad \text{(Eq. 2}b\text{)}$$

To be more general, it is also possible to account for any input either in compartment 1 or compartment 2 or both by adding appropriate terms in Eqs. 1*a* and 1*b*. In the present study the single intravenous injection of a given dose D of drug, and the single oral intake of the same dose are considered.

In both cases, the mathematical formulation is described by Eqs. 1*a* and 1*b* with the corresponding initial conditions. For intravenous administration:

$$\begin{gathered} A_1(0) = D \\ A_1(t) = 0 \quad \text{for } -\tau \leq t < 0 \\ A_2(0) = 0 \end{gathered} \qquad \text{(Eq. 3)}$$

and for oral administration:

$$\begin{gathered} A_1(t) = 0 \quad \text{for } -\tau \leq t \leq 0 \\ A_2(0) = D \end{gathered} \qquad \text{(Eq. 4)}$$

Simulation of the Model—Two models were studied: model I corresponds to an intravenous single dose and is described by Eqs. 1*a*, 1*b*, and 3; model II corresponds to an oral single dose and is described by Eqs. 1*a*, 1*b*, and 4.

In both cases, the explicit analytical solutions can only be derived in a recurrent manner on successive time intervals. The results obtained for the models on the first two intervals of duration τ are given in the *Appendix*. It must be emphasized that the derived expressions increase in complexity when t gets larger in such a way that they rapidly become intractable in practice.

The simulation of the models, and more generally of Eqs. 1*a* and 1*b* with appropriate input and initial conditions, has to be carried out through numerical integration.

The method proposed in this study is the first-order Euler method, which calculates the values of $A_1(t)$ and $A_2(t)$ at discrete times $t_j = jh$, where h is a small time increment and j is any positive integer; the time lag should also be a multiple integer of h. The corresponding recursive equations are given by:

$$A_1(t_{j+1}) = (1 - hK_1)A_1(t_j) + hk_{21}A_2(t_j) \qquad \text{(Eq. 5}a\text{)}$$

$$A_2(t_{j+1}) = (1 - hK_2)A_2(t_j) + hk_{12}A_1(t_j - \tau) \qquad \text{(Eq. 5}b\text{)}$$

where

$$K_1 = k_{10} + k_{12} \text{ and } K_2 = k_{20} + k_{21}.$$

Sensitivity Study—Theoretical sensitivity analysis of the whole pharmacokinetic profile through partial differentiation of $A_1(t)$ with respect to the parameters is difficult in the present case, since no explicit analytical expression is available for the complete solution. The study of the influence of modifications in the microconstants k_{12}, k_{21}, k_{10}, and k_{20} and in the time lag τ was performed numerically using repeated computer simulations.

The reference parameter values are those used by Harrison and Gibaldi (1), *i.e.*, $k_{12} = 3.0$, $k_{21} = 1.0$, and $k_{20} = 0.0\ hr^{-1}$. Modified values of the microconstants and values of τ, from 0.0 to 1.0 hr, are indicated for each computer simulation under the corresponding figure or in the text.

With respect to terminal kinetics, general algebraic results can be given. Assuming the final phase of the decay is exponential, the terminal rate constant β' is the solution of the following equation, whose derivation is given in the *Appendix:*

$$(\beta')^2 - \beta'(k_{12} + k_{10} + k_{21} + k_{20}) + (k_{12} + k_{10})(k_{21} + k_{20}) - k_{12}k_{21}\exp(\beta'\tau) = 0 \qquad \text{(Eq. 6)}$$

Because of the term $\exp(\beta'\tau)$, Eq. 6 cannot be solved explicitly for β'. Accordingly, values of β' and of the terminal half-life ($T^{\beta'}_{1/2}$) were obtained numerically for each computer-simulated pharmacokinetic profile. Nevertheless, the equation can be used to investigate the dependency of β' on the microconstants and the time lag. Analytical sensitivity study of β' is explained in the *Appendix*.

Note also that for $\tau = 0$, Eq. 6 reduces to the customary equation for determination of α and β for the basic two-compartment open model for enterohepatic circulation without time delay (1, 2). Furthermore, if k_{12} is interchanged with k_{21}, and k_{10} is interchanged with k_{20} at the same time, the equation remains identical. Hence, the value of β' is not modified.

RESULTS

The case where there is no time delay between biliary excretion and drug reabsorption has been studied extensively (1, 2). This presentation is therefore restricted to the case where the time lag is of the same order of magnitude as the time constants of the first-order kinetics accounting for distribution and elimination.

Modifications in the serum level profile due to changes in the time lag τ (all microconstants being unchanged) are presented in Fig. 1. When τ is zero, the amount in the body shows biexponential monotonic decrease. When τ becomes larger, a plateau ($\tau = 0.4$) is obtained first, and for greater values ($\tau = 0.8$) a significant rebound appears in the time profile. Three periods may be distinguished on the pharmacokinetic profile:

1. From zero to τ, the amount in the body decreases monoexponentially (by analogy with conventional notation, the term α'-phase is proposed).
2. When distribution is achieved, the amount in the body again decreases exponentially with constant β' (the β'-phase).
3. Between these two extreme periods, there exists a transient phase where the influence of the time lag is most apparent (τ-phase).

Although the simulated curves displayed in Fig. 1 correspond to maximum enterohepatic cycling ($k_{20} = 0$), the qualitative results remain the same even when the drug is partly eliminated through the intestine ($k_{20} \neq 0$). When a time lag is present, the entire pharmacokinetic profile is modified, in the so-called initial distribution phase as well as in the terminal elimination phase. Further increase in τ gives rise to other peaks in the drug level profile so that the duration of the transient phase becomes longer. Hence, the whole distribution phase (including the α'-phase

and the τ-phase) is time-lag sensitive with respect to its profile and also to its duration. Furthermore, the hybrid constant β', which describes the terminal phase, decreases when τ is enhanced (*Appendix*) regardless of the combination of microconstants. Figure 1 shows how terminal kinetics slow down when the time lag increases. For example, values of $T_{1/2}^{\beta'}$ for $\tau = 0$, $\tau = 0.4$, and $\tau = 0.8$ hr (Fig. 1) are respectively 3.3, 4.2, and 5.1 hr; there is a 50% increase in terminal half-life between the two extreme cases.

The effects of modifications in biliary excretion on the pharmacokinetics of drugs subject to enterohepatic cycling when the basic model ($\tau = 0$) is considered have been described previously (1, 2). Existence of a significant time delay between excretion and reabsorption slightly modifies the conclusions. The decay in the initial phase is slower when k_{12} is reduced, regardless of other parameter values. The influence of modifications in k_{12} on β', and therefore on the terminal half-life $T_{1/2}^{\beta'}$, are less simple. If $k_{20} < k_{10}$, *i.e.*, when nonbiliary elimination from the body is predominant, a decrease in biliary excretion leads to an increase in β', and therefore shortens the half-life of the drug. For the curves displayed in Fig. 2 ($k_{10} = 0.5$, $k_{20} = 0.2$ hr^{-1}), the half-lives are 4.5, 3.1, and 2.2 hr for k_{12} values of 3.0, 1.0, and 0.33 hr^{-1}, respectively. More precisely, an increase in k_{12} will always decrease β' if $k_{20} < k_{10} + \Delta_1$, where Δ_1 (a quantity depending on k_{10}, k_{21}, and τ) is zero for the basic model and strictly positive when a time lag exists (*Appendix*). On the other hand, if $k_{20} > k_{10} + \Delta_1$, *i.e.*, when the intestine plays the dominant role in elimination, the opposite results are obtained. In this case, the reduction in k_{12} leads to the reduction in β'. However, this effect is markedly less than in the first case ($k_{20} < k_{10}$). For the same set of k_{12} values, the values computed for $T_{1/2}^{\beta'}$ when $k_{10} = 0.2$ and $k_{20} = 0.5$ hr^{-1} are 3.0, 3.1, and 3.3 hr, respectively. Regardless of the relative magnitudes of k_{10} and k_{20}, the pharmacokinetic profile becomes increasingly smooth when k_{12} decreases (Fig. 2). However, note that the initial decrease is strictly monoexponential for the duration of the time delay (1.0 hr for these simulations), even when no rebound is apparent.

The influence of reabsorption on drug disposition was analytically studied by Chen and Gross (2). They showed that enhancement in reabsorption (increase in k_{21}) produces the same effects on terminal kinetics as reduction in biliary excretion (decrease in k_{12}); the effect may be an increase or a decrease of the half-life, depending on which of the parameters, k_{10} or k_{20}, is the greatest. Predictions of the time-lag model are identical with those of the basic model when either $k_{10} < k_{20}$ or $k_{10} > k_{20} + \Delta_2$, where $\Delta_2 > 0$ if $\tau > 0$ (*Appendix*). Enhancement of the reabsorption rate k_{21} will increase the half-life in the first case and reduce $T_{1/2}^{\beta'}$ in the second case. However, if k_{10} is such that $k_{20} < k_{10} < k_{20} + \Delta_2$, increased reabsorption will produce a longer, not shorter, half-life. The curves shown in Fig. 3 are associated with parameter values such that the double inequality holds. Terminal half-lives $T_{1/2}^{\beta'}$ are 3.0, 3.1, and 3.3 hr when k_{21} is set equal to 0.33, 1.0, and 3.0 hr^{-1}, respectively. Predictions based on the time-lag model also differ from those of Chen and Gross (2) when the initial decay is considered. The three simulated curves displayed in Fig. 3 are superimposed during the 1st hr. When a time lag is present, the pharmacokinetics after intravenous injection are insensitive to modifications in reabsorption until τ has elapsed. Influence of reabsorption is only apparent in the transient and terminal phase of the pharmacokinetic profile.

Existence of the rebound is independent of the relative magnitude of rate constants k_{12} and k_{21}. It may be observed either with high biliary excretion and moderate reabsorption ($k_{12} = 3.0$, $k_{21} = 1.0$; Fig. 2) or with moderate biliary excretion and high reabsorption ($k_{12} = 1.0$, $k_{21} = 3.0$; Fig. 3). A slight decrease in either k_{12} or k_{21} implies reduction in the amplitude of the peak; further decrease leads to complete disappearance of this peak.

The influence of both elimination processes (*e.g.*, through the kidney and the intestine) was studied through modifications in rate constants k_{10} and k_{20} (Fig. 4). The first extreme case appears when enterohepatic recirculation is complete ($k_{20} = 0$). When k_{10} varies, both α' and β' vary accordingly; however, the transient τ-phase is modified to a lesser extent. The semi-logarithmic diagram (Fig. 4*a*) does not give an entirely satisfactory description of the time process. Although the minimum (A_1 min) and the peak (A_1 max) both occur when k_{10} is reduced, the magnitude of the gap between these two values remains almost constant and is even slightly increased when k_{10} decreases. The second extreme case is when the substance is not subject to nonbiliary elimination from the body ($k_{10} = 0$). When k_{20} varies, the initial decay remains the same; the α'-phase is insensitive to modifications in k_{20} as well as in k_{21} (Fig. 4*b*). In any case, the terminal half-life $T_{1/2}^{\beta'}$ is longer when either k_{10} or k_{20} is reduced, regardless of the other parameters' values (*Appendix*). If elimination occurs through both the kidney and the intestine, the corresponding pharmacokinetic profile is intermediate between the two extremes.

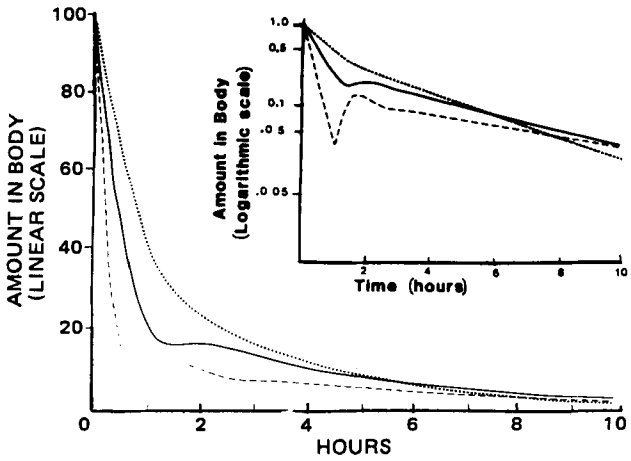

Figure 2—*Effect of biliary excretion on pharmacokinetic profile without modification in time lag. For all curves,* $k_{10} = 0.5$, $k_{21} = 1.0$, $k_{20} = 0.2$ hr^{-1}, *and* $\tau = 1.0$ hr ($k_{20} < k_{10} + \Delta_1$). *Key:* - - -, $k_{12} = 3.0$ hr^{-1}; —, $k_{12} = 1.0$ hr^{-1}; *and* . . ., $k_{12} = 0.33$ hr^{-1}.

The time-delay model may also reveal what happens after oral intake of the drug. The relationship between pharmacokinetic profiles after intravenous and oral administration of a substance is shown in Fig. 5 for the basic model of enterohepatic circulation (1) and the model with time lag ($k_{20} = 0$, $k_{12} > k_{21}$). The oral profile is smoother than the intravenous in both cases. How the increase in time lag affects the pharmacokinetic profile is further depicted in Fig. 6, where $k_{21} > k_{12}$. When the reabsorption rate is greater than the biliary excretion rate, somewhat sharper time profiles (Fig. 6) than in the reverse case are observed. Nevertheless, the conclusions are the same whenever $k_{12} > k_{21}$ (Fig. 5) or $k_{12} < k_{21}$ (Fig. 6). When the delay is present in the enterohepatic cycle, the terminal half-life is prolonged. When τ increases, the τ-phase becomes first apparent ($\tau = 0.4$) and evident afterward ($\tau = 0.8$), although the gap between the local minimum and the secondary peak is less than in the corresponding intravenous case. Furthermore, the customary first peak, though occurring sooner, is of lesser magnitude than in the standard case where no time delay is present.

DISCUSSION

The influence of a delay for drugs subject to enterohepatic circulation was investigated through computer simulation. The time-lag model is a modification of a two-compartment model first proposed by Harrison and Gibaldi (1). Predictions of the time-lag model on the influence of cholestasis on pharmacokinetics show qualitative agreement with results obtained through an analytical parameter sensitivity study of the basic model (2). However, changes in reabsorption or in intestinal elimination lead to different results. The basic model predicts that the α-phase is

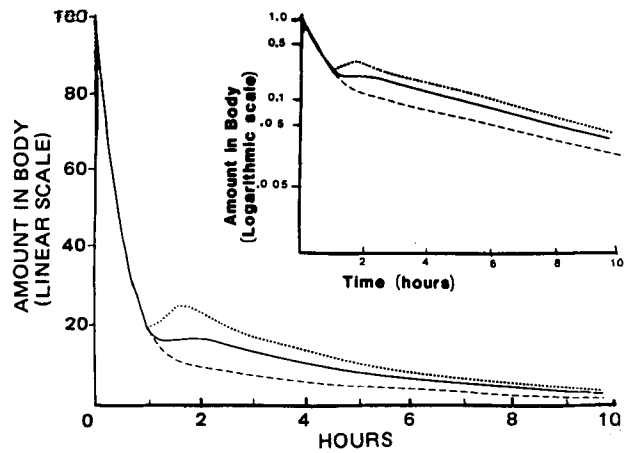

Figure 3—*Effect of reabsorption on pharmacokinetic profile without modification in time lag. For all curves,* $k_{12} = 3.0$, $k_{10} = 0.5$, $k_{20} = 0.2$ hr^{-1}, *and* $\tau = 1.0$ hr ($k_{20} < k_{10} < k_{20} + \Delta_2$). *Key:* . . ., $k_{21} = 3.0$ hr^{-1}; —, $k_{21} = 1.0$ hr^{-1}; *and* - - -, $k_{21} = 0.33$ hr^{-1}.

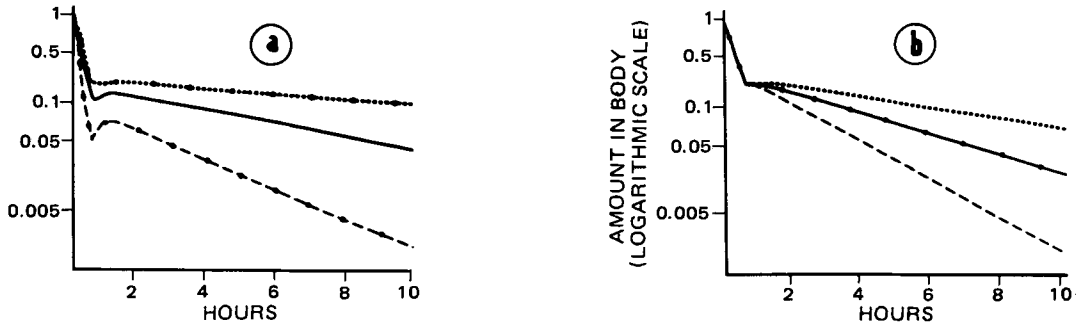

Figure 4—*Effect of both elimination processes on pharmacokinetic profile without modification in time lag. Parameters* k_{12}, k_{21}, *and* τ *are identical for all simulations* ($k_{12} = 3.0$, $k_{21} = 1.0\ hr^{-1}$; *and* $\tau = 0.5\ hr$). *(a) Nonbiliary elimination only* ($k_{20} = 0.0\ hr^{-1}$). *Key:* · ● ·; $k_{10} = 0.33\ hr^{-1}$; —, $k_{10} = 1.0\ hr^{-1}$; *and* –●–, $k_{10} = 3.0\ hr^{-1}$. *(b) Elimination from intestine only* ($k_{10} = 0.0\ hr^{-1}$). *Key:* . . ., $k_{20} = 0.25\ hr^{-1}$, —●—, $k_{20} = 0.50\ hr^{-1}$; *and* - - -, $k_{20} = 1.0\ hr^{-1}$.

modified when either the reabsorption rate k_{21} or the intestinal elimination rate k_{20} changes. Instead, when a significant delay is present in the enterohepatic cycling process, modifications in reabsorption or in intestinal elimination do not affect the initial decay of the plasma level after intravenous injection of the drug.

Further basic differences between both models become apparent when pharmacokinetic profiles are considered after intravenous injection as well as after oral intake of the drug. When a time lag is present, the time profile is not biexponential. For the same values of the microconstants, the time-lag model exhibits both a more rapid decay in the initial phase and a slower disappearance rate for the terminal phase than the basic model. An increase of ~50% in the terminal half-life value is not uncommon for the range of values of microconstants and time lag studied here. In addition to monoexponential initial and terminal kinetics, the time-lag model shows specific behavior in the transient phase. Delayed reabsorption may lead to uncommon patterns such as rebounds, or secondary peaks in plasma level profiles after intravenous injection or oral intake of the drug. Although apparently uncharacteristic, phenomenon of this kind were described for substances undergoing enterohepatic circulation such as morphine (3) and the main metabolite of vitamin D_3 (4–6). The eight-compartment model devised previously to describe morphine pharmacokinetics gives an adequate description of the data (3). It accounts for both rebounds in the measured levels and slow terminal kinetics, two basic features often connected with significant enterohepatic circulation. The overall rate-limiting step in the model (3) is morphine reabsorption from the GI tract; this result may be specific for that drug. In spite of its relative complexity as compared with the eight-compartment model, the time-lag model may produce slow terminal kinetics even when the overall rate-limiting step does not belong to the enterohepatic cycling loop. Existence of a time delay in recirculation prolongs the terminal half-life of the drug by much more than the time lag itself.

Nevertheless, the time-lag model is certainly a rough approximation of the underlying process. A representation of all complex physiological processes involved in enterohepatic circulation of a substance by two first-order rate constants with an additional time lag (presumably due to transport delay) is an oversimplification.

Furthermore, the assumption that the time lag is constant for the duration of the pharmacokinetic experiment may also be an approximation. The delay may be a function of time following slight modifications in bile flow, or may show discontinuous variations in some species due to sudden emptying of the gallbladder. Furthermore, the successive steps of hepatic conjugation, biliary excretion of the metabolite, deconjugation in the GI tract, and reabsorption of the parent drug have been summarized by means of only two first-order rate constants. Although the two-compartment time-lag model is a simplification, it seems to be a reasonable compromise, since it exhibits satisfactory qualitative agreement with existing data.

Enterohepatic recirculation is not the only pharmacokinetic process where time-lag models have been shown to be valuable. Evidence for time-delayed response also exists for various drugs after oral intake. However, pharmacokinetic analysis is somewhat simpler in the latter case because the absorption phase (as opposed to the distribution phase) is affected. Nevertheless, time-lag models may be useful for pharmacokinetic interpretation and substitutes for conventional standard compartment models that fail to describe the data. However, even when a significant time-delay exists, evidence for it may be difficult to demonstrate. Secondary peaks in plasma level profiles may not be observable on all pharmacokinetic data in a series of experiments. Sensitivity analysis of the time-lag model has shown that moderate changes in microconstants and time lag among the sample subjects may lead to important variations in the shapes of time profiles. Predefined standard sampling, a basic requirement in most experimental protocols may be, in some cases, inappropriate for detection of kinetic peculiarities. A combination of uncertainties resulting from interindividual variability, sampling, and measurement errors frequently makes it a difficult task, in practice. To decide whether a given uncommon feature is an artifact or a relevant kinetic pattern, inspection of data may not be sufficient. Additional arguments based on physiological knowledge should exist for the introduction of a time lag in a mathematical model for drug pharmacokinetics.

A present theoretical limitation should be stressed. Computer simulation is a basic requirement for investigation, analysis, fitting to data, and predictive use of the pharmacokinetic model when time lags are present in disposition kinetics. Less analytical results can be obtained in linear time-lag pharmacokinetics, as in nonlinear pharmacokinetics. While powerful numerical integration methods exist for the latter case (7), algorithms higher than first order for simulation of time-lag differential equations are not commonly available. The development of appropriate numerical methods is, therefore, a primary condition for routine use of time-lag models in pharmacokinetic analysis.

APPENDIX

Explicit Solutions of Model I and II for Initial Phase—These results are obtained through straightforward integration of models I and II on successive intervals of duration τ. In each interval, $A_1(t - \tau)$ is considered the forcing term of Eqs. 1*a* and 1*b* submitted to the appropriate initial conditions. For this reason, the complexity of the solution increases rapidly and explicit solutions are presented only for the first two τ intervals.

Model I: Single Intravenous Injection of a Dose (D)—Denoting $K_1 = k_{10} + k_{12}$ and $K_2 = k_{20} + k_{21}$ for $0 \leq t \leq \tau$:

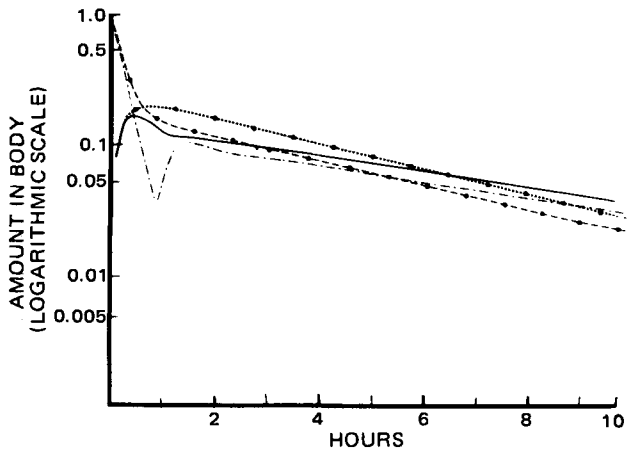

Figure 5—*Pharmacokinetic profiles after intravenous dose and oral dose. For all curves,* $k_{12} = 3.0$, $k_{10} = 1.0$, $k_{21} = 1.0$, *and* $k_{20} = 0.0\ hr^{-1}$. *Key: Without time lag* ($\tau = 0$): –●–, *intravenous; and* · ● ·, *oral. With time lag* ($\tau = 0.8\ hr$): - - -, *intravenous; and* —, *oral.*

$$A_1(t) = D\exp(-K_1 t) \quad \text{(Eq. A1}a\text{)}$$

$$A_2(t) = 0 \quad \text{(Eq. A1}b\text{)}$$

For $\tau \leq t \leq 2\tau$:

$$A_1(t) = D\exp(-K_1 t) + D\frac{k_{12}k_{21}}{K_2 - K_1}\left[\left(t - \tau - \frac{1}{K_2 - K_1}\right) \times \exp[-K_1(t-\tau)] + \frac{1}{K_2 - K_1}\exp[-K_2(t-\tau)]\right] \quad \text{(Eq. A2}a\text{)}$$

$$A_2(t) = D\frac{k_{12}}{K_2 - K_1}\left[\exp[-K_1(t-\tau)] - \exp[-K_2(t-\tau)]\right] \quad \text{(Eq. A2}b\text{)}$$

Model II: Single Oral Intake of a Dose (D)—For $0 \leq t \leq \tau$:

$$A_1(t) = D\frac{k_{21}}{K_2 - K_1}\left[\exp(-K_1 t) - \exp(-K_2 t)\right] \quad \text{(Eq. A3}a\text{)}$$

$$A_2(t) = D\exp(-K_2 t) \quad \text{(Eq. A3}b\text{)}$$

and for $\tau \leq t \leq 2\tau$:

$$A_1(t) = D\frac{k_{21}}{K_2 - K_1}[\exp(-K_1 t) - \exp(-K_2 t)] + D\frac{k_{12}(k_{21})^2}{(K_2 - K_1)^2}\left[\left(t - \tau - \frac{2}{K_2 - K_1}\right)\exp[-K_1(t-\tau)] + \left(t - \tau + \frac{2}{K_2 - K_1}\right)\exp[-K_2(t-\tau)]\right] \quad \text{(Eq. A4}a\text{)}$$

$$A_2(t) = D\exp(-K_2 t) + D\frac{k_{12}k_{21}}{K_2 - K_1}\left[\frac{1}{K_2 - K_1}\exp[-K_1(t-\tau)] - \left(t - \tau + \frac{1}{K_2 - K_1}\right)\exp[-K_2(t-\tau)]\right] \quad \text{(Eq. A4}b\text{)}$$

These expressions are especially useful to validate the numerical approximations to be used on the time interval $[0, 2\tau]$.

Approximation of the Solution of Models I and II for Large Time Values—In the range of the parameter values used in the different simulations, it has been observed that for t greater than a given time t^* which depends on the time-lag τ, the decrease of amount of drug in body is monoexponential. For $t > t^*$:

$$A_1(t) = A_1^* \exp(-\beta' t) \quad \text{(Eq. A5}a\text{)}$$

and

$$A_2(t) = A_2^* \exp(-\beta' t) \quad \text{(Eq. A5}b\text{)}$$

From Eqs. A5a and A5b are derived:

$$\ln[A_1(t)] = \ln A_1^* - \beta' t \quad \text{(Eq. A6}a\text{)}$$

$$\ln[A_2(t)] = \ln A_2^* - \beta' t \quad \text{(Eq. A6}b\text{)}$$

Division of both state equations (Eqs. 1a and 1b) by $A_1(t)$ and $A_2(t)$, respectively, leads to:

$$\frac{dA_1(t)}{A_1(t)dt} = -(k_{10} + k_{12}) + k_{21}\frac{A_2(t)}{A_1(t)} \quad \text{(Eq. A7}a\text{)}$$

$$\frac{dA_2(t)}{A_2(t)dt} = -(k_{20} + k_{21}) + k_{12}\frac{A_1(t-\tau)}{A_2(t)} \quad \text{(Eq. A7}b\text{)}$$

Equations A7a and A7b may be rewritten as:

$$\frac{d[\ln A_1(t)]}{dt} = -(k_{10} + k_{12}) + k_{21}\frac{A_2^*}{A_1^*} \quad \text{(Eq. A8}a\text{)}$$

and:

$$\frac{d[\ln A_2(t)]}{dt} = -(k_{20} + k_{21}) + k_{12}\frac{A_1^*}{A_2^*}\exp(\beta'\tau) \quad \text{(Eq. A8}b\text{)}$$

Therefore:

$$-\beta' = -(k_{10} + k_{12}) + k_{21}\frac{A_2^*}{A_1^*} \quad \text{(Eq. A9}a\text{)}$$

and:

$$-\beta' = -(k_{20} + k_{21}) + k_{12}\exp(\beta'\tau)\frac{A_1^*}{A_2^*} \quad \text{(Eq. A9}b\text{)}$$

Elimination of the ratio A_2^*/A_1^* from Eqs. A9a and A9b leads to the algebraic equation to be solved for β':

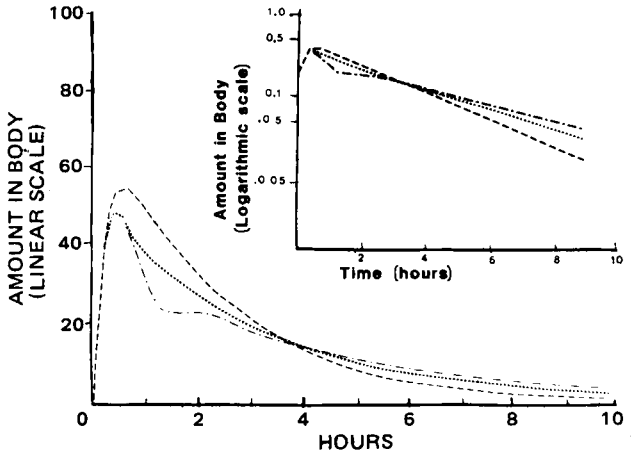

Figure 6—*Effect of time lag on pharmacokinetic profile after oral intake of the drug. For all curves,* $k_{12} = 1.0$, $k_{10} = 0.5$, $k_{21} = 3.0$, *and* $k_{20} = 0.2\ hr^{-1}$. *Key: ---,* $\tau = 0$ *hr; . . .,* $\tau = 0.5$ *hr; and -·-,* $\tau = 1.0$ *hr.*

$$(\beta')^2 - \beta'(k_{12} + k_{10} + k_{21} + k_{20}) + (k_{12} + k_{10})(k_{21} + k_{20}) - k_{12}k_{21}\exp(\beta'\tau) = 0 \quad \text{(Eq. A10)}$$

With $K_1 = k_{10} + k_{12}$ and $K_2 = k_{20} + k_{21}$, Eq. A10 can be rewritten as:

$$f(\beta') \triangleq (\beta' - K_1)(\beta' - K_2) - k_{12}k_{21}\exp(\beta'\tau) = 0 \quad \text{(Eq. A11)}$$

Function f is positive for $\beta' = 0$ and negative for $\beta' = K_1$ and $\beta' = K_2$. Furthermore, its derivative is negative for β' less than the minimum of K_1 and K_2. So f has one unique root on [0, min (K_1, K_2)]. This is the smallest root for β' and the relevant one for large time values.

Sensitivity Analysis of β'—*Sensitivity* versus *the Time Lag* (τ)—Assuming all microconstants to be kept at a fixed value, the partial derivative of β' with respect to τ is deduced from the differentiation of f. Hence:

$$(2\beta' - K_1 - K_2)\frac{\partial\beta'}{\partial\tau} - k_{12}k_{21}\exp(\beta'\tau)\left(\tau\frac{\partial\beta'}{\partial\tau} + \beta'\right) = 0 \quad \text{(Eq. A12).}$$

and:

$$\frac{\partial\beta'}{\partial\tau}[2\beta' - K_1 - K_2 - k_{12}k_{21}\tau\exp(\beta'\tau)] = \beta' k_{12}k_{21}\exp(\beta'\tau) \quad \text{(Eq. A13)}$$

If $\beta' < K_1$ and $\beta' < K_2$, the coefficient of $\partial\beta'/\partial\tau$ is negative. Furthermore, the second member of (Eq. A13) is positive. Therefore:

$$\frac{\partial\beta'}{\partial\tau} < 0 \quad \text{(Eq. A14)}$$

For any value of the microconstants, β' decreases when τ increases and vice versa. Accordingly, the half-life increases when the time lag is enhanced, regardless of the combination of microconstants.

Sensitivity versus *the Transfer Rate Constants* k_{12} *and* k_{21}—When partial differentiation of β' with respect to k_{12} is considered, an equation similar to Eq. A13 is obtained. In the present case, the second member is equal to $\beta' - K_2 + k_{21}\exp(\beta'\tau)$. The sign of $\partial\beta'/\partial k_{12}$ is the opposite sign of the previous expression. In abbreviated form:

$$\text{sign}(\partial\beta'/\partial k_{12}) = -\text{sign}[\beta' - K_2 + k_{21}\exp(\beta'\tau)] \quad \text{(Eq. A15)}$$

After replacement of $k_{21}\exp(\beta'\tau)$ according to Eq. A11, multiplication by k_{12} (positive) and division by $(\beta' - K_2)$ (negative), it follows that:

$$\text{sign}\left(\frac{\partial\beta'}{\partial k_{12}}\right) = \text{sign}(\beta' - k_{10}) \quad \text{(Eq. A16)}$$

According to the definition of function f (Eq. A11) and to its properties on the interval [0, min (K_1, K_2)], the sign of $(\beta' - k_{10})$ verifies:

$$\beta' - k_{10} > 0 \Leftrightarrow f(k_{10}) > 0 \quad \text{(Eq. A17}a\text{)}$$

$$\beta' - k_{10} < 0 \Leftrightarrow f(k_{10}) < 0 \quad \text{(Eq. A17}b\text{)}$$

As:

$$f(k_{10}) = k_{12}k_{21}[1 - \exp(k_{10}\tau)] + k_{12}(k_{20} - k_{10}) \quad \text{(Eq. A18)}$$

We get the following results for $\partial\beta'/\partial k_{12}$:

$$\frac{\partial\beta'}{\partial k_{12}} < 0 \text{ if } k_{20} < k_{10} + \Delta_1 \quad \text{(Eq. A19a)}$$

$$\frac{\partial\beta'}{\partial k_{12}} = 0 \text{ if } k_{20} = k_{10} + \Delta_1 \quad \text{(Eq. A19b)}$$

$$\frac{\partial\beta'}{\partial k_{12}} > 0 \text{ if } k_{20} > k_{10} + \Delta_1 \quad \text{(Eq. A19c)}$$

where $\Delta_1 = k_{21}[\exp(k_{10}\,\tau) - 1]$.

Note that the test condition does not depend on k_{12} itself. Sensitivity analysis of β' *versus* k_{21} relies on similar algebraic manipulations. Therefore:

$$\frac{\partial\beta'}{\partial k_{21}} < 0 \text{ if } k_{10} < k_{20} + \Delta_2 \quad \text{(Eq. A20a)}$$

$$\frac{\partial\beta'}{\partial k_{21}} = 0 \text{ if } k_{10} = k_{20} + \Delta_2 \quad \text{(Eq. A20b)}$$

$$\frac{\partial\beta'}{\partial k_{21}} > 0 \text{ if } k_{10} > k_{20} + \Delta_2 \quad \text{(Eq. A20c)}$$

where $\Delta_2 = k_{12}[\exp(k_{20}\tau) - 1]$.

Clear-cut results can be given in some cases. If $k_{20} < k_{10}$, $\partial\beta'/\partial k_{12}$ is always negative and if $k_{20} > k_{10}$, the same is true for $\partial\beta'/\partial k_{21}$, regardless of the combination of other parameters. For other cases, the test condition should be computed and applied.

Sensitivity versus *the Elimination Rate Constants* k_{10} *and* k_{20}—Differentiation of f with respect to β' and k_{10} leads to:

$$\frac{\partial\beta'}{\partial k_{10}}[2\beta' - K_1 - K_2 - k_{12}k_{21}\,\tau\exp(\beta'\tau)] = \beta' - K_2 \quad \text{(Eq. A21)}$$

As β' is less than K_2, the second member is negative in the present case. Hence:

$$\frac{\partial\beta'}{\partial k_{10}} > 0 \quad \text{(Eq. A22)}$$

Similarly it can be shown that:

$$\frac{\partial\beta'}{\partial k_{20}} > 0 \quad \text{(Eq. A23)}$$

Therefore, an increase in elimination processes, through either k_{10} or k_{20} will always increase β' and shorten the half-life $T^{\beta'}_{1/2}$.

Combined Water-Soluble Carriers for Coprecipitates of Tolbutamide

M. J. MIRALLES, J. W. McGINTY, and A. MARTIN ˣ

Received January 19, 1981, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication July 23, 1981.

Abstract □ A study was conducted on the influence of single and combined carriers on the dissolution rate of tolbutamide from its coprecipitates. All of the water-soluble carriers investigated enhanced the dissolution rate of tolbutamide, but the combination of 40% polyethylene glycol 6000–60% dextrose as the carrier for a 1:1 coprecipitate yielded the most rapid dissolution of tolbutamide. Other carriers used were polyethylene glycol 6000, polyethylene glycol 4000, dextrose, and mannitol, alone or combined in various proportions.

Keyphrases □ Tolbutamide—coprecipitates, combined water-soluble carriers, dissolution □ Solubility—combined water-soluble carriers for coprecipitates of tolbutamide, dissolution □ Dissolution—effect of combined water-soluble carriers, coprecipitates of tolbutamide

The rate at which a drug dissolves from its intact or disintegrated and deaggregated form in the GI tract is often responsible for the rate at which the drug appears in the blood, *i.e.*, the absorption rate of the drug. When this is the case, dissolution is said to be the rate-limiting process.

BACKGROUND

The sulfonylurea compounds employed as oral hypoglycemic compounds are considered to be poorly water soluble. Variation in the dissolution rates of these compounds has been reported (1). The influence of *in vitro* dissolution rates on the rate of decline of blood sugar levels has also been studied (2). Varley (3) investigated two formulations of tolbutamide, both generically equivalent in terms of chemical content and USP specifications; he found they were not equivalent as measured by availability of drug to the patient (serum drug levels) or on the basis of therapeutic efficacy (hypoglycemic response). Levy (4) found marked variation in the dissolution rates of two brands of tolbutamide tablets and recommended that patients should not change the brand of the drug they were taking unless the dose of the new brand was established. Another report (5) showed a correlation between percentage of the tolbutamide dose excreted in the urine as its metabolite and the surface area of tolbutamide in the dosage form.

The influence of povidone and polyethylene glycol 6000 on the dissolution rate of tolbutamide was studied (6). It was found that both carriers favorably increased the dissolution rate of the drug and that a complex formed between the drug and povidone but not between tolbutamide and polyethylene glycol. Later it was found (7) that the solid dispersion of

0022-3549/82/0300-0302$01.00/0

We get the following results for $\partial\beta'/\partial k_{12}$:

$$\frac{\partial\beta'}{\partial k_{12}} < 0 \text{ if } k_{20} < k_{10} + \Delta_1 \quad \text{(Eq. A19a)}$$

$$\frac{\partial\beta'}{\partial k_{12}} = 0 \text{ if } k_{20} = k_{10} + \Delta_1 \quad \text{(Eq. A19b)}$$

$$\frac{\partial\beta'}{\partial k_{12}} > 0 \text{ if } k_{20} > k_{10} + \Delta_1 \quad \text{(Eq. A19c)}$$

where $\Delta_1 = k_{21}[\exp(k_{10}\,\tau) - 1]$.

Note that the test condition does not depend on k_{12} itself. Sensitivity analysis of β' *versus* k_{21} relies on similar algebraic manipulations. Therefore:

$$\frac{\partial\beta'}{\partial k_{21}} < 0 \text{ if } k_{10} < k_{20} + \Delta_2 \quad \text{(Eq. A20a)}$$

$$\frac{\partial\beta'}{\partial k_{21}} = 0 \text{ if } k_{10} = k_{20} + \Delta_2 \quad \text{(Eq. A20b)}$$

$$\frac{\partial\beta'}{\partial k_{21}} > 0 \text{ if } k_{10} > k_{20} + \Delta_2 \quad \text{(Eq. A20c)}$$

where $\Delta_2 = k_{12}[\exp(k_{20}\tau) - 1]$.

Clear-cut results can be given in some cases. If $k_{20} < k_{10}$, $\partial\beta'/\partial k_{12}$ is always negative and if $k_{20} > k_{10}$, the same is true for $\partial\beta'/\partial k_{21}$, regardless of the combination of other parameters. For other cases, the test condition should be computed and applied.

Sensitivity versus *the Elimination Rate Constants* k_{10} *and* k_{20}—Differentiation of f with respect to β' and k_{10} leads to:

$$\frac{\partial\beta'}{\partial k_{10}}[2\beta' - K_1 - K_2 - k_{12}k_{21}\,\tau\exp(\beta'\tau)] = \beta' - K_2 \quad \text{(Eq. A21)}$$

As β' is less than K_2, the second member is negative in the present case. Hence:

$$\frac{\partial\beta'}{\partial k_{10}} > 0 \quad \text{(Eq. A22)}$$

Similarly it can be shown that:

$$\frac{\partial\beta'}{\partial k_{20}} > 0 \quad \text{(Eq. A23)}$$

Therefore, an increase in elimination processes, through either k_{10} or k_{20} will always increase β' and shorten the half-life $T^{\beta'}_{1/2}$.

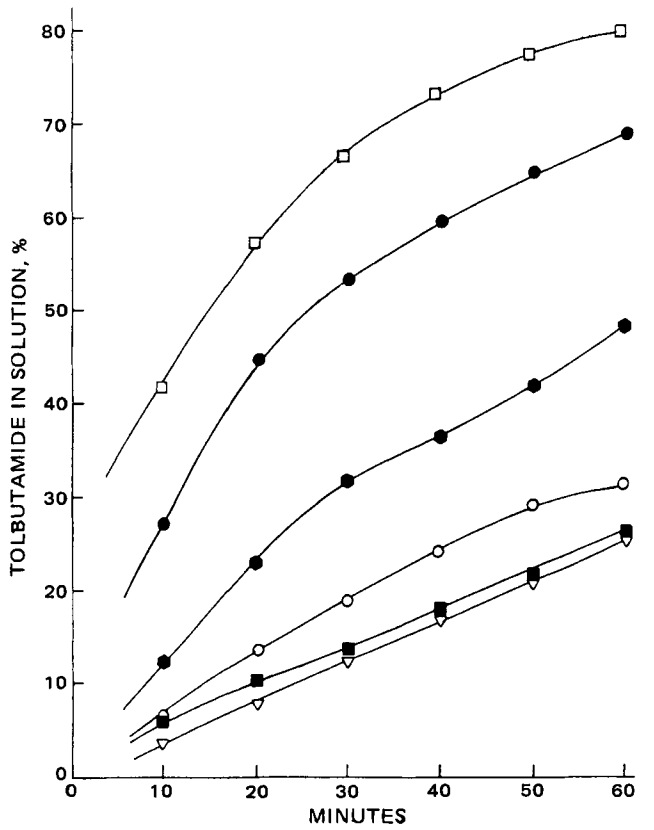

Figure 1—*Dissolution profiles of tolbutamide from its coprecipitates using single carriers. Total amount of tolbutamide: 62.5 mg. Key: ▽, tolbutamide recrystallized from methanol; ■, tolbutamide USP; ○, tolbutamide with mannitol; ●, tolbutamide with dextrose; ●, tolbutamide with polyethylene glycol 6000; and □, tolbutamide with polyethylene glycol 4000.*

tolbutamide in polyethylene glycol and in povidone increased the absorption of the drug and shortened its peak time from 3 hr to <1 hr. Recent reports (8, 9) compared the effect of polyethylene glycol and polyoxyethylene stearate on the dissolution rate and solution properties of tolbutamide from solid dispersions. Sugar combinations have been employed to increase the dissolution rates of hydrocortisone and prednisone (10).

In the present study, the coprecipitation technique was applied to enhance the dissolution rate of tolbutamide. Single and combined water-soluble carriers were utilized and their effects on dissolution rates were compared.

EXPERIMENTAL

Materials—Tolbutamide[1], polyethylene glycol 6000[2], polyethylene glycol 4000[2], dextrose anhydrous[3], and mannitol[3] were obtained commercially.

Preparation of Tolbutamide Coprecipitates—Quantities to make 1:1 coprecipitates of tolbutamide and carrier(s) were weighed accurately and dissolved in a sufficient volume of methanol[4]. The temperature was raised to 37°, and the solvent was allowed to evaporate under the hood, stirring continuously. When evaporation was almost complete, the resulting coprecipitate was removed from the container using a spatula, and placed *in vacuo* for 24 hr. The coprecipitates were sieved and the 100–200 mesh fraction was separated and kept in a desiccator for analysis and dissolution studies. The tolbutamide coprecipitate compositions are shown in Table I.

Dissolution Profiles of Tolbutamide and Tolbutamide Coprecipitates—The dissolution rate studies of tolbutamide and its coprecipitates were done in a dissolution apparatus[5] at 25 ± 0.5°. Nine-hundred

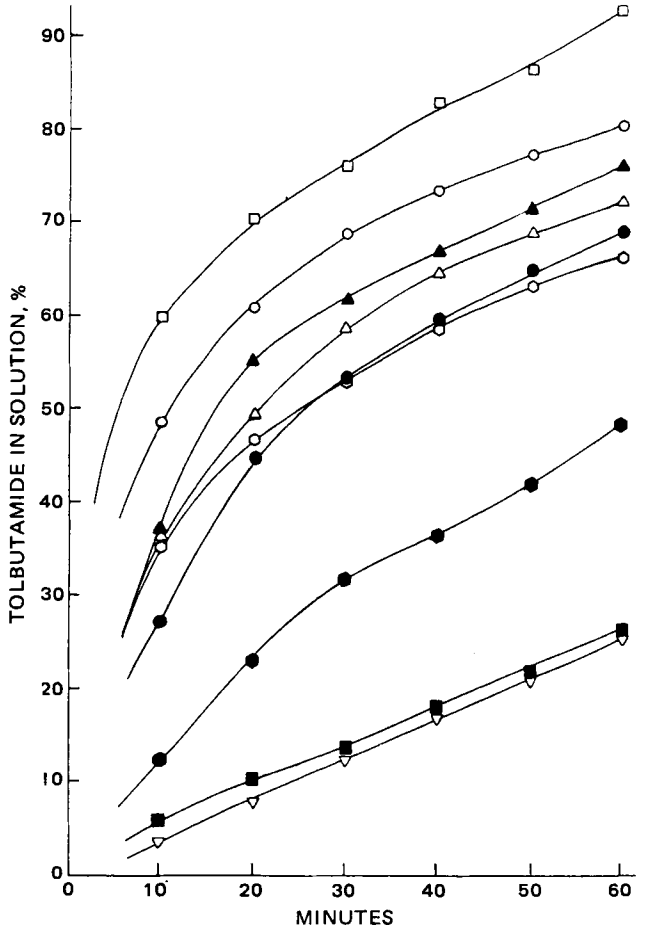

Figure 2—*Dissolution profiles of tolbutamide from its coprecipitates in polyethylene glycol 6000–dextrose carrier systems. Total amount of tolbutamide: 62.5 mg. Key: ▽, tolbutamide recrystallized from methanol; ■, tolbutamide USP; ●, tolbutamide with dextrose; ○, tolbutamide with 20% polyethylene glycol 6000–80% dextrose; ●, tolbutamide with polyethylene glycol 6000; △, tolbutamide with 60% polyethylene glycol 6000–40% dextrose; ▲, tolbutamide with 70% polyethylene glycol 6000–30% dextrose; ○, tolbutamide with 80% polyethylene glycol 6000–20% dextrose; and □, tolbutamide with 40% polyethylene glycol 6000–60% dextrose.*

milliliters of deionized water was placed in the vessels, the paddle stirring speed was set at 150 rpm, and 125 mg of the coprecipitate or 62.5 mg of the drug were added to the medium after the temperature was reached. The paddle was placed 2.5 cm from the bottom of the vessel. A glass filter[6] was attached to a 3-way stopcock[7] and this was attached to a glass syringe. One milliliter of filtrate was removed every 10 min and diluted to 10 ml with deionized water. The volume in the vessel was replaced with deionized water after each sample was taken. The absorbances of the solutions were measured in a spectrophotometer[8] at 230 nm using deionized water as the blank. None of the carriers interfered with the measurement of the absorbances at this wavelength.

RESULTS AND DISCUSSION

Tolbutamide Content of the Coprecipitates—The tolbutamide coprecipitates were assayed by spectrophotometry at λ_{max} = 230 nm using a 5% (v/v) dilution of methanol in deionized water as the blank. The drug content of the tolbutamide coprecipitates was within the 48.9–51.9% (w/w) range.

Dissolution Profiles of Tolbutamide Alone and from Its Coprecipitates—The dissolution profiles of tolbutamide alone, (100/200 mesh, and tolbutamide recrystallized from methanol and sieved to a 100/200 mesh) and with tolbutamide coprecipitates containing single carriers,

are shown in Fig. 1. The dissolution profiles of tolbutamide from the two combination carrier systems (polyethylene glycol 6000–dextrose and polyethylene glycol 4000–mannitol) are shown in Figs. 2 and 3, respectively. Each point in these plots corresponds to the average of six determinations. The dissolution studies of tolbutamide from its coprecipitates showed that the presence of the water-soluble carrier enhanced the dissolution rate of the drug in all cases as compared with plain and recrystallized tolbutamide. From Fig. 1 it can be seen that the increase in the dissolution rate of tolbutamide was more pronounced when polyethylene glycol 4000 was used as the carrier than when polyethylene glycol 6000 was the drug vehicle. Dextrose alone and mannitol alone produced little increase in dissolution rate, but the combination of these carriers with polyethylene glycol 6000 and polyethylene glycol 4000 produced a large increase in dissolution rate of the drug in all proportions studied. The combination of 40% polyethylene glycol 6000–60% dextrose produced the highest dissolution rate of tolbutamide from its coprecipitates. If single carriers were desired, polyethylene glycol 4000 would be the carrier of choice with 44% of drug released after 10 min of the dissolution test. When carrier combinations were studied, ~60% of the drug was dissolved after 10 min for a coprecipitate of the drug in 40% polyethylene glycol 6000–60% dextrose. Approximately the same results were obtained when 50% polyethylene glycol 4000–50% mannitol was employed. It can be seen from Figs. 1–3 that the amount of the drug dissolved increased more than 15 times during the first 10 min of the dissolution study as compared with the dissolution of recrystallized tolbutamide; it was ~3 times higher after 1 hr when the drug was dispersed in a 40% polyethylene glycol 6000–60% dextrose mixture. When mannitol was the carrier, the amount dissolved increased only ~1.5 times indicating that mannitol, in the ratio of drug to carrier investigated (1:1), was a poor carrier for tolbutamide. Polyethylene glycol 6000 has been extensively used as a water-soluble carrier for slightly soluble drugs and has been claimed as a universal carrier. However, in this case the amount of drug dissolved increased only ~5 times as compared with the dissolution of recrystallized tolbutamide.

It is important to point out that only the 1:1 coprecipitates were investigated and that the enhancement of dissolution rates of tolbutamide from its coprecipitates would be expected to increase when the ratio of drug to carrier is diminished.

CONCLUSIONS

The 100–200 mesh fraction of the 1:1 coprecipitates of tolbutamide with dextrose, mannitol, polyethylene glycol 6000, polyethylene glycol 4000, and combinations of polyethylene glycol 6000–dextrose and polyethylene glycol 4000–mannitol in different proportions showed a faster dissolution *in vivo* than plain tolbutamide or tolbutamide recrystallized from methanol.

The use of combined carriers in the preparation of the coprecipitates of tolbutamide constituted an advantage over the formulation of the solid dispersions in a single carrier. The carrier combination consisting of 40% polyethylene glycol 6000–60% dextrose provided the fastest dissolution of the drug from its coprecipitate. Since polyethylene glycol 4000 alone produced a faster dissolution of tolbutamide than polyethylene glycol 6000 alone, and dextrose alone gave a faster dissolution of the drug than did mannitol alone, it is probable that combinations of polyethylene glycol 4000–dextrose would result in a better carrier system for tolbutamide. Further investigation is needed to support this suggestion.

Synthesis and Characterization of Iodoazidobenzylpindolol

ABBAS RASHIDBAIGI and ARNOLD E. RUOHO ˣ

Received April 13, 1981, from the *Department of Pharmacology, University of Wisconsin Medical School, Madison, WI 53706.* Accepted for publication July 15, 1981.

Abstract □ A high affinity β-adrenergic ligand, iodoazidobenzylpindolol, was synthesized and characterized. The absorption spectrum of this compound changed markedly upon photolysis, consistent with decomposition of the azide group. This compound has a K_D of 5–7 × 10^{-10} *M* for the duck erythrocyte ghost β-adrenergic receptor when measured in a competitive binding assay.

Keyphrases □ Iodoazidobenzylpindolol—synthesis and characterization, β-adrenergic receptor competitive binding assay □ β-Adrenergic blocking agents—iodoazidobenzylpindolol, synthesis and characterization □ Photoaffinity labeling—iodoazidobenzylpindolol label for β-adrenergic receptor binding sites

To identify the polypeptides that comprise the catecholamine receptor, suitable derivatives of β-receptor ligands must be available for forming covalent bonds in the binding site. This method for specifically tagging a binding site in an otherwise heterogeneous mixture of binding sites utilizing chemically reactive site-directed ligands has been described as affinity labeling (1–3) or the more recently used method of "photoaffinity labeling" (4–7).

The present study describes the synthesis and characterization of a potent β-adrenergic ligand containing an azide functional group. This compound, which is called iodoazidobenzylpindolol (VI), has been used as a photoaffinity label for β-adrenergic receptor binding site(s) (8).

EXPERIMENTAL[1]

Materials—2-Nitropropane[2], *p*-nitrobenzylchloride[2], thallium trichloride[3], nitromethane[4], *m*-nitrophenol[5], L-alprenolol-D-tartrate[5], and DL-propranolol hydrochloride[5] were all pure grade. DL-[^{125}I]Iodohydroxybenzylpindolol was synthesized according to a slightly modified method of Brown (9) from hydroxybenzylpindolol[6].

Instruments—Photolysis was performed with a high-pressure mercury lamp[7]. Melting points were determined on a capillary melting-point apparatus[8]. The IR spectra were obtained on a grating spectrophotometer[9] as potassium bromide disks. NMR spectra were determined on a 90 MHz Fourier transform spectrometer[10]. The chemical shifts reported are relative to an internal tetramethylsilane standard. Mass spectra were run on a spectrometer[11] at 70 ev.

Synthesis of 4-(2,3-Epoxypropoxy)indole (II)—6-Nitrosalicylaldehyde was prepared from *m*-nitrophenol according to the method of Ando and Emoto (10), with an overall yield of 7.2%. 5-Nitro-1,3-benzodioxane was purified by vacuum distillation (instead of column chromatography) at 1-mm Hg followed by crystallization in ethanol. In the process, 7-nitro-1,3-benzodioxane was removed and discarded.

4-Hydroxyindole (I)—Compound I was prepared from 6-nitrosalicylaldehyde according to the method of Beer *et al.* (11), with an overall yield of 26.0%.

4-(2,3-Epoxypropoxy)indole (II)—4-Hydroxyindole (I) (722 mg, 5.43 mmoles) was added to a solution of sodium hydroxide (216 mg, 5.40 mmoles) in 5 ml of water. Freshly distilled epichlorhydrin, 0.54 ml, was then added under nitrogen, and the reaction was stirred for 22 hr at ambient temperature. The mixture was extracted with ether, decolorized with activated charcoal, and dried over anhydrous sodium sulfate. The ether extract was evaporated to give 570 mg (55.5%) of an oily product. This compound was purified further using a silica gel column[5] (60–200 mesh) equilibrated with petroleum ether. The product was eluted from the column with increasing amounts of chloroform to give a white solid material (II); mp 64–65° [lit. (12), 65–67°]; NMR (deuterochloroform): δ 8.60–8.35 (s, 1H, indole-NH), 7.0–6.3 (m, 5H, aromatic H), and 4.3–2.5 (m, 5H, CH_2, epoxide-H) ppm; mass spectrum: *m/z* 189 (M^+).

Anal.—Calc. for $C_{11}H_{11}NO_2$: C, 69.84; H, 5.82; N, 7.41. Found: C, 70.00; H, 6.02; N, 7.45.

Synthesis of 1-(*p*-Azido-*m*-iodophenyl)-2-methyl-2-propylamine (V)—2-Methyl-2-nitro-1-(*p*-nitrophenyl)propane was prepared according to the method of Hass *et al.* (13), with an overall yield of 47%.

1-(p-Aminophenyl)-2-methyl-2-propylamine (III)—2-Methyl-2-nitro-1-(*p*-nitrophenyl)propane (10 g, 44.6 mmoles) was dissolved in 150 ml of 50% ethanol–water. Zinc powder (42.5 g, 654 mmoles) was mixed with the above solution. While heating the mixture very slowly with fast mechanical stirring, hydrochloric acid (25 ml of 37% mixed with 40 ml of 50% ethanol–water) was added dropwise. The mixture was refluxed for 1 hr after addition of hydrochloric acid and stirring continued during refluxing. After cooling the mixture, a yellow solution was separated from the zinc and was adjusted to pH 9.0 using 2 *N* potassium hydroxide. The amino compound, 1-(*p*-aminophenyl)-2-methyl-2-propylamine (III), was extracted with ether. The ether solution was dried under anhydrous sodium sulfate followed by evaporation of ether and distillation of the compound under vacuum. A yellow solid, 3.45 g (48%), was collected; mp 81–82° [lit. (13), 84–85°]; R_f 0.17 on silica gel plates[12] in chloroform–methanol (70:30); IR (potassium bromide): 3500, 3350, and 3200 cm^{-1} (NH_2); NMR (deuterochloroform): δ 6.7 (d, 2H, aromatic H, *J* = 3 Hz), 6.4 (d, 2H, aromatic H, *J* = 3 Hz), 2.45 (s, 2H, CH_2), and 1.0 (s, 6H, CH_3); mass spectrum: *m/z* 164 (M^+). The dihydrochloride salt of this compound was prepared by passing hydrogen chloride gas through an ether solution.

1-(p-Amino-m-iodophenyl)-2-methyl-2-propylamine (IV)—1-(*p*-Amino-phenyl)-2-methyl-2-propylamine dihydrochloride (III) (1.66 g, 7.0 mmoles) was dissolved in 200 ml of sodium acetate buffer (pH 4.0, 0.1 *M*). To this solution was added sodium iodide (1.05 g, 7.0 mmoles). Thallium trichloride (2.6 g, 7.0 mmoles) in 50 ml of distilled water was slowly added to the above solution under nitrogen. The mixture was heated on a steam bath for 1 hr under nitrogen, then sodium sulfite (0.88 g, 7.0 mmoles) in 20 ml of water was added. The reaction mixture was made alkaline using sodium bicarbonate and extracted with ether. The compound (IV), 0.76 g (37%), was purified using a silicic acid (325 mesh) column, eluting with increasing concentrations of methanol in chloroform. The compound was oily with a brownish color and an R_f of 0.30 on silica gel plate in chloroform–methanol (70:30). NMR (deuterochloroform): δ 7.4 (d, 1H, aromatic H *ortho* to I), 7.0–6.6 (m, 2H, aromatic H), 2.5 (s, 2H, CH_2), 1.1 (s, 6H, CH_3) ppm, and NH exchangeable with deuterium oxide; mass spectrum: *m/z* 290 (M^+).

Anal.—Calc. for $C_{10}H_{15}IN_2$: C, 41.38; H, 5.17, N, 9.66. Found: C, 41.16; H, 5.31, N, 9.42.

1-(p-Azido-m-iodophenyl)-2-methyl-2-propylamine (V)—1-(*p*-Amino-*m*-iodophenyl)-2-methyl-2-propylamine (IV) (220 mg, 0.758 mmoles) was dissolved in 6.2 ml of water containing 0.207 ml of 96% sulfuric acid. The mixture was cooled in crushed ice, and sodium nitrite (58 mg, 0.840 mmoles) in 8 ml of water was added dropwise while stirring the mixture. When the addition was completed, the reaction was allowed to proceed for 15 min, then sodium azide (54 mg, 0.83 mmoles) in 1 ml of water was added. After another 15 min, the mixture was made alkaline

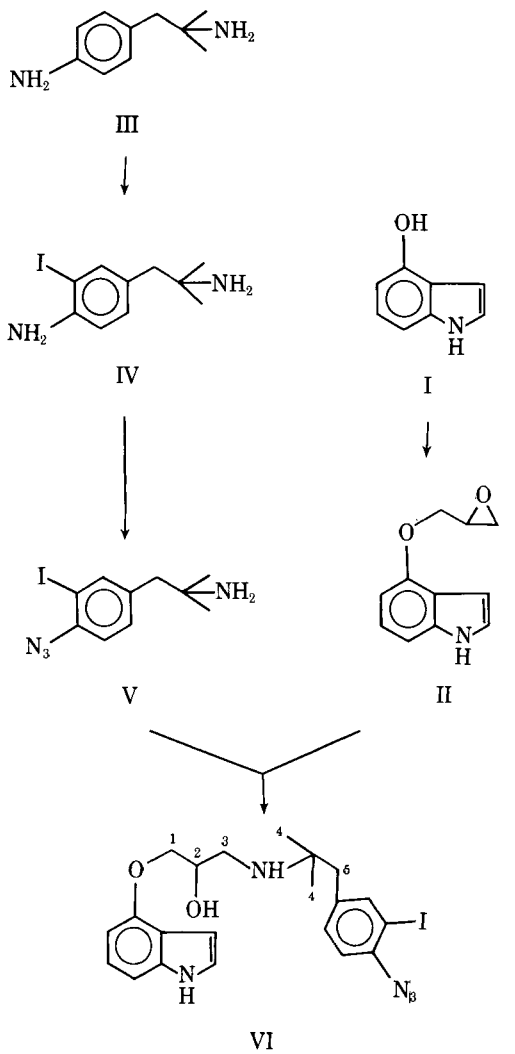

Scheme I—Synthetic scheme for iodoazidobenzylpindolol (VI).

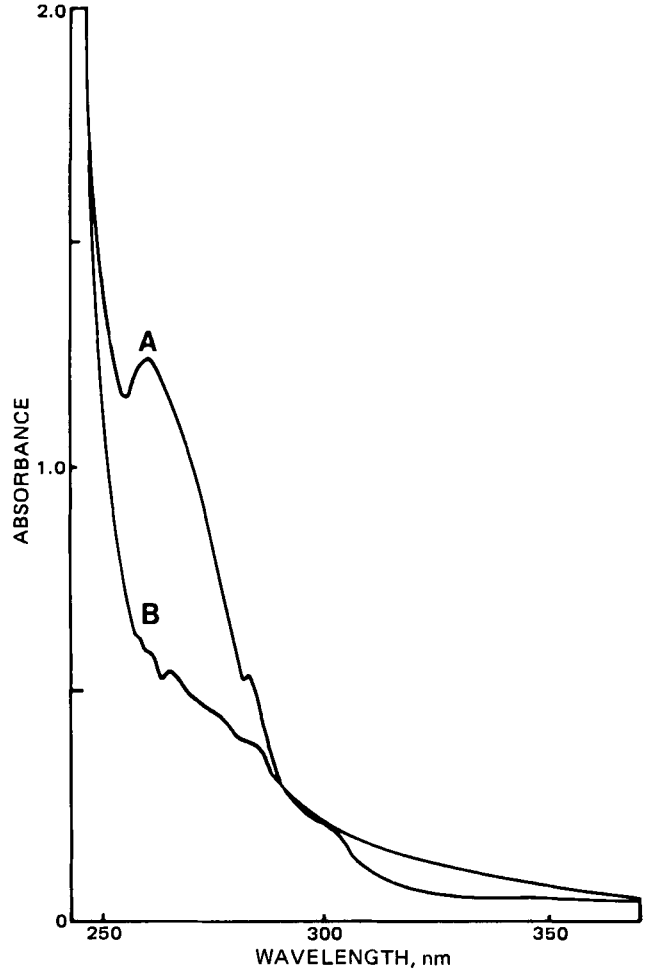

Figure 1—*Ultraviolet spectra for iodoazidobenzylpindolol (VI) before and after photolysis. A, VI (5.7×10^{-5} M) in ethanol; B, VI (5.7×10^{-5} M) photolyzed for 5 sec in ethanol using a high-pressure mercury lamp.*

using sodium bicarbonate and extracted with ether. All reactions were performed in the dark, and 72 mg (30%) of the oily product was purified by preparative TLC using silica gel in chloroform–methanol (70:30) with an R_f of 0.59; IR (potassium bromide): 2150 cm^{-1} (N_3); NMR (deuterochloroform): δ 7.60 (d, 1H, aromatic H *ortho* to I), 7.26–6.97 (m, 2H, aromatic H), 2.5 (s, 2H, CH_2), and 1.1 (s, 6H, CH_3) ppm.

Synthesis of DL-1-(Indol-4-yloxy)-3-[1-*p*-(azido-*m*-iodophenyl)-2-methyl-2-propylamine]-2-propanol (Iodoazidobenzylpindolol, VI)—4-(2,3-Epoxypropoxy)indole (II) (56 mg, 0.296 mmoles) and 1-(*p*-azido-*m*-iodophenyl)-2-methyl-2-propylamine (V) (35 mg, 0.110 mmoles) were dissolved in 1.5 ml of absolute ethanol. The reaction was heated in a sealed tube at 60° in the dark for 7 days. The products of the reaction mixture were separated on preparative silica gel plates with benzene–acetonitrile–triethylamine (100:75:1) to yield 44 mg (78.8%) of a solid compound (VI) with an R_f of 0.39 and a mp of 70–73° (dec. at 140–150°); IR (potassium bromide): 2150 cm^{-1} (N_3); NMR (deuterochloroform): δ 8.9 (s, 1H, indole-NH), 7.78 (d, 1H, aromatic H *ortho* to I), 7.57–6.45 (m, 7H, aromatic H), 4.20 [m, 5H, NH, OH, CH_2(1), CH(2)]; deuterium oxide exchange: 4.10 [m, 3H, CH_2(1), CH(2)], 3.01 [m, 2H, CH_2(3)], 2.70 [s, 2H, CH_2(5)], and 1.12 [s, 6H, CH_3(4)] ppm; UV (ethanol): 300, 288, and 262 nm (Fig. 1A) with ϵ262 = 19,000 and ϵ288 = 6920 M^{-1} cm^{-1}.

Anal.—Calc. for $C_{21}H_{24}IN_5O_2$: C, 49.90; H, 4.75; N, 13.86. Found: C, 50.03; H, 5.24; N, 13.10.

The %H and %N values differ by 0.5 and 0.7%, respectively, from the calculated values. This is probably due to decomposition that occurred before analysis, resulting from exposure of the compound to light.

Preparation of Duck Erythrocyte Ghosts—All steps were performed at 4°. Heparinized whole duck blood was diluted in an equal volume of washing buffer (145 m*M* NaCl, 10 m*M* tromethamine[5], 20 m*M* glucose, pH 7.4). The cells were centrifuged at 500×*g* and the supernate and buffy coat were removed. The packed cells were washed twice more in washing buffer and then lysed by stirring in lysis buffer (10 m*M* tromethamine, 4 m*M* magnesium chloride, pH 7.4). The resulting lysate was centrifuged at 20,000×*g* and the supernate was removed. The ghosts were stored at −80° at a concentration of ~15 mg/ml. The protein content of the ghosts was determined by the Lowry method (14) using bovine serum albumin as a standard.

[^{125}I]Iodohydroxybenzylpindolol Competitive Binding Assay—Nucleated duck ghosts were diluted to a protein concentration of 3–4 mg/ml with 50 m*M* tromethamine buffer, pH 7.4, containing 10 m*M* magnesium chloride. Each condition in the incubation contained ~0.2 mg of nucleated ghosts in 0.1 ml of total incubation volume, various concentrations of the competitive ligands, and 0.6 n*M* [^{125}I]iodohydroxybenzylpindolol. Incubation proceeded for 30 min at 32°. The binding was terminated by diluting 35-μl aliquots in duplicate into 10 ml of lysis buffer at 35°, filtering quickly (10 sec) through a glass fiber filter paper[13] under vacuum, and washing with an additional 10 ml of lysis buffer (5 sec) at 27°. The filter papers were counted using a gamma counter[14] with 70% efficiency, and the amount of bound [^{125}I]iodohydroxybenzylpindolol was determined.

The amount of nonspecific binding in all experiments was determined by incubating membranes and [^{125}I]iodohydroxybenzylpindolol in the presence of 1 μ*M* (L)-alprenolol. Nonspecific binding was generally 5–10% of the total binding and was subtracted from all experimental values. The K_D for each ligand was calculated from the equation (15):

$$K_D = IC_{50}/(1 + L/K_L) \qquad \text{(Eq. 1)}$$

where IC_{50} is the concentration of nonradioactive ligand which half maximally inhibits [^{125}I]iodohydroxybenzylpindolol binding, L is the concentration of [^{125}I]iodohydroxybenzylpindolol in the incubation, and

K_L is the equilibrium dissociation constant of [125I]iodohydroxybenzylpindolol determined from Scatchard analysis (16) (5×10^{-10} *M*).

RESULTS

Synthesis of Iodoazidobenzylpindolol (VI)—The synthetic scheme for the compound is summarized in Scheme I. The indole-containing epoxide (II) was prepared in a straightforward manner from 4-hydroxyindole (I). The epoxide was reacted with a primary amine to generate the final product (VI). The primary amine that was used in this synthesis contained an aralkyl structure, since it is known that affinity for the β-receptor is increased by increasing the size of substituents on the amino nitrogen (17). This final product, VI, has several structural features that are noteworthy: (*a*) the compound contains an indole ring structure which is characteristic of pindolol (12, 18); (*b*) the propanolamine structure which is characteristic of adrenergic compounds; and (*c*) an alkyl chain terminating with an aromatic group. Iodoazidobenzylpindolol (VI) is an analogue of iodohydroxybenzylpindolol (19), in which the phenolic hydroxyl on the aralkyl chain is replaced by an azido group and an iodine atom is *ortho* to the azido group rather than on the indole ring. An important synthetic reaction to generate 1-(*p*-amino-*m*-iodophenyl)-2-methyl-2-propylamine (IV) was the use of thallium trichloride and sodium iodide to incorporate iodine covalently. This type of reaction was reported previously for the preparation of iodinated polynucleotides (20) and nucleotides (21). In these cases, covalent iodine incorporation was followed by using carrier-free [125I]sodium iodide. This reaction demonstrated that the iodine-containing nucleotides could substitute for the parent nucleotides in polymers synthesized by either DNA or RNA polymerase (21). Chemical characterization of the reaction products was not performed.

Iodoazidobenzylpindolol (VI) has three absorption maxima (262, 288, and 300 nm). The main absorption occurs at 262 nm, whereas the 288 and 300 nm absorbances are secondary peaks (Fig. 1A). The photosensitivity of VI is shown in Fig. 1. After a 5-sec photolysis of VI in ethanol using a 1 kw mercury lamp, the ultraviolet absorption at 262, 288, and 300 nm were all reduced in a manner consistent with the decomposition of the azide group (Fig. 1B).

Biological Characterization of Iodoazidobenzylpindolol (VI)—To determine the binding characteristics of VI to the β-adrenergic receptor, intact duck erythrocyte ghosts were utilized. The β-receptor in this system has been thoroughly characterized for [3H]-L-dihydroalprenolol binding and has been partially purified 5000–10,000-fold over detergent extracts[15]. The apparent equilibrium dissociation constants (K_D) were determined by a previous method (15) utilizing competitive inhibition of [125I]iodohydroxybenzylpindolol binding. Iodoazidobenzylpindolol (VI) and hydroxybenzylpindolol possess the same affinity for the duck erythrocyte β-receptor with an apparent K_D calculated to be 0.5–0.7 n*M* (Fig. 2). From Scatchard analysis (16), it was found that the K_D for [125I]iodohydroxybenzylpindolol is 0.5 n*M* under the same conditions (data not shown). DL-Propranolol inhibited [125I]iodohydroxybenzylpindolol binding with a calculated K_D of 12.5 n*M* (Fig. 2), the same as previously reported for other β-adrenergic receptor systems (22).

DISCUSSION

The successful chemical synthesis of an azide derivative of pindolol, a potent β-adrenergic ligand, was performed. The compound was synthesized from 4-(2,3-epoxypropoxy)indole (II), which was prepared in good yield from *m*-nitrophenol. Thallium trichloride and sodium iodide were used to produce 1-(*p*-amino-*m*-iodophenyl)-2-methyl-2-propylamine (IV). This reaction allowed covalent incorporation of iodine into the phenyl ring *ortho* to the amine functional group which could then be readily converted to the azide derivative of V.

Iodoazidobenzylpindolol (VI) has as high an affinity as hydroxybenzylpindolol for the duck erythrocyte β-adrenergic receptor, and contains an azide functional group which can be incorporated into the β-adrenergic receptor binding site(s) upon photolysis (8). To minimize photodestruction of the biological samples and release of iodine, the majority of the light of wavelength <300 nm was filtered out. Successful photoincorporation of 4-[125I]iodobenzene-1-azide (23) and 5-[125I]iodonapthyl-1-azide (24) have also been reported for probing the lipid bilayer of biological membrane and labeling of the α-subunit of the sodium–potassium adenosinetriphosphatase (25).

Phosphorus–Nitrogen Compounds XXIII: Oncolytic Phosphorylated Imines

LINDLEY A. CATES ˣ and VEN-SHUN LI

Received March 18, 1981, from the *Department of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication July 22, 1981.

Abstract □ A series of 15 amidine, iminopiperidine, iso(thio)urea, and guanidine derivatives and six 2,5-dihydro-1,3,5,2-triazaphosphorines were synthesized. Most of the compounds were tested for ability to react with L-cysteine and for antitumor activity against sarcoma 180 and P-388 murine tumor systems. Three acyclic phosphorylated imines and one triazaphosphorine showed activity in the former model to indicate that the P(O)N=C grouping serves as an oncolytic moiety. All agents condensed with L-cysteine with the active antitumor compounds displaying a tendency for relatively higher reactivity with this amino acid.

Keyphrases □ Phosphorus–nitrogen compounds—oncolytic phosphorylated imines □ Antitumor agents, potential—phosphorylated imines □ Phosphorylated imines—amidine, iminopiperidine, iso(thio)-urea, and guanidine derivatives, synthesis and screening for anticancer activity

A number of synthetic and naturally occurring products possessing α,β-unsaturated carbonyl moieties or their congeners are reported to produce an oncolytic effect *via* a type of Michael-condensation with biologically important nucleophiles. Since compounds that contain a P(O)-N=C grouping would be expected to undergo a similar reaction, a series of cyclic and acyclic phosphorylated imines were synthesized and tested for their ability to condense with L-cysteine and for anticancer activity.

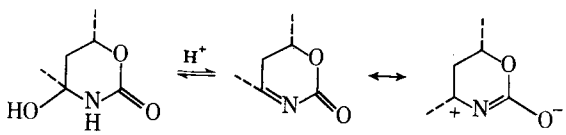
BACKGROUND

Recently, there have been several investigations of conjugated systems that possess anticancer properties. Among those reported are phenyl nonenones (1, 2), styryl ketones (3–6), α-methylene lactams and lactones (7–9), and cyclopentenones (10, 11). Each compound contains a carbonyl function with a lateral overlap between two π-bond systems to produce a molecular orbital encompassing all four atoms. A valence bond representation of the system is $^{+}C—C=C—O^{-}$ where the β-carbon bond carries a positive charge and is subject to nucleophilic attack.

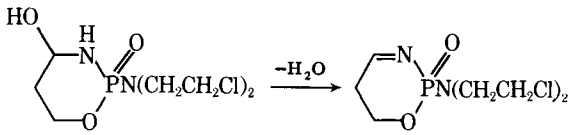
A related system contains an azomethine lactone grouping (IV) arising from the dehydration of carbinolamide derivatives (III) which were synthesized during an investigation of the "eastern zone" of maytansine (12). The dehydration rate of these tertiary alcohols to the conjugated system correlated with their ability to react with DNA bases and to show antineoplastic activity. The carbinolamides also undergo 1,4-addition with alcohols and ethanethiol in the presence of trace acid (13).

The only reported α,β-unsaturated system containing a phosphorus atom and concerned with anticancer activity is a proposed metabolite of cyclophosphamide (14). Iminophosphamide(VI) is thought to arise from the dehydration of 4-hydroxycyclophosphamide(V), providing an alternative explanation for the presence of 4-ethoxycyclophosphamide in microsomal incubation mixtures of V treated with ethanol.

Cyclophosphamide remains the most used and investigated chemotherapeutic of this chemical type. Studies, including those involving metabolism, have not completely accounted for this superior effectiveness. It can be speculated that the P(O)N=C moiety of VI may provide alkylating properties in addition to those of the nitrogen mustard group.



III IV



V VI

This functionality may permit the *in vivo* formation of substituted derivatives as stable, and less toxic transport forms. Support for this latter hypothesis is given by studies with 4(*S,R*) sulfido cyclophosphamide derivatives as stabilized forms of activated V (15).

The biological nucleophile most frequently associated with 1,4-addition to α,β-unsaturated system is L-cysteine, alone or as part of a protein molecule (16). However, correlation between L-cysteine and cytotoxicity was not observed in certain sesquiterpene lactones (17) and α-methylene lactones (9).

With this in mind, a series of acyclic(I) and cyclic(II) phosphorylated imines were synthesized for an investigation of their antitumor and L-cysteine addition properties (Table I).

EXPERIMENTAL

All solvents used were spectranalyzed or reagent grade. Melting points were determined by the capillary method (oil bath) and are corrected to reference standards. IR[1] (potassium bromide or neat for Ic), UV[2], and mass[3] spectra were recorded. ^{1}H-NMR[4] (in deuterochloroform) and ^{13}C-NMR[5] (in dimethylsulfoxide-d_6) spectra were measured in parts per million with tetramethylsilane as the internal standard. Elemental microanalyses were performed[6]. Silica gel 60 (70–230 mesh) was used for column chromatography and silica gel GHLF[7] was used for TLC.

Seven compounds [Ie, If, Ij, Ik (18), Ig, Ih (19), and In (20)] were prepared using literature methods employing the usual reaction of phosphoro(di)chloridates with compounds possessing imino groups or their salts. The catalytic hydrogenolysis of Ij gave Ia (18). Compounds Ib, Ii, Il, and Im were synthesized from *N*-methyl-1-chloro-*N'*-(dichlorophosphinyl)formamidine according to the procedure of Derkach and Narbut (21), while the triazaphosphorines IIa–IId were prepared by a novel reaction involving an intramolecular cyclization of bis imides (20). Compound Ic was prepared previously (22) from triethylphosphite and ethyl *N*-chloroacetamidine and isolated by vacuum distillation (bp 49–50°, 0.08 mm Hg). Compound Ic was synthesized using 4.7 g (0.05 mole) of acetamidine hydrochloride and 8.6 g (0.05 mole) of diethyl phosphorochloridate in the presence of 11.1 g (0.11 mole) of triethylamine and the product purified by chromatography. A solution of the chloridate in 50 ml of methylene chloride was added dropwise with stirring under nitrogen to the amidine salt and triethylamine in methylene chloride (100

ml) at 0°. The reaction mixture was stirred to room temperature over a 2-hr period and refluxed for 12 hr. The mixture was filtered, spin evaporated, and the residue dried under vacuum. This material was extracted with benzene, filtered, and the residue dried under vacuum. The crude product was chromatographed with 10% methanol in chloroform to yield the pure material; IR: 3380, 3180 (NH_2), 1658 (N=C), and 1200 (P=O) cm^{-1}; ^{1}H-NMR: 1.32 (t, 6H, $2CH_3$), 2.15 (s, 3H, CH_3), 4.05 (m, 4H, $2CH_2$), and 7.12, 7.40 (2bs, 2H, NH_2) ppm; mass spectrum: *m/z*, 194 (M^+) (36.8%) and 195 (M^{+1})(6.0%).

***N*-(Diethoxyphosphinyl)phenylbenzamidine (I*d*)**—To a solution of 4.9 g (0.1 mole) of *N*-phenylbenzamidine and 10.1 g (0.1 mole) of triethylamine in 250 ml of ether was added a solution of 4.3 g (0.025 mole) of diethyl phosphorochloridate in 50 ml of ether, dropwise with stirring. The mixture was refluxed for 4 hr and filtered. The filtrate was concentrated by spin evaporation to yield, after drying in a vacuum desiccator, an analytically pure product; ^{1}H-NMR: 6.69–7.69 (m, 10H, aromatic), 3.59–4.28 (p, J = 7 Hz, 4H, $2CH_2$), and 1.20 (t, J = 7 Hz, 6H, $2CH_3$).

Anal.—Calc. for $C_{13}H_{14}N_3O_3P$: C, 61.34; H, 6.37; N, 8.43. Found: C, 61.43; H, 6.39; N, 8.42.

***N*-(Diphenoxyphosphinyl)-3-iminopiperidine (I*o*)**—A solution of 26.9 g (0.1 mole) of diphenyl phosphorochloridate in 100 ml of benzene was added dropwise with stirring at 5–10° to a solution of 13.4 g (0.01 mole) of 2-iminopiperidine hydrochloride and 30.3 g (0.3 mole) of triethylamine in 150 ml of benzene. The mixture was refluxed for 3 hr, at which time only two spots developed on a TLC plate (50% benzene in chloroform) at the origin (I_2 vapor) and at R_f 0.41 (UV and I_2 vapor). The mixture was cooled and filtered. Recrystallization of the residue from benzene produced a pure product. ^{13}C-NMR: pyridine carbons, 17.8 and 19.8 (C-4 and C-5), 28.1 (J = 7.1 Hz, C-3), 42.3 (C-6), and 169.3 (J = 4.6 Hz, C-1), 125.4 (C-4), 129.9 (C-3), and 150.0 (J = 7.3 Hz, C-1).

Anal.—Calc. for $C_{17}H_{19}N_2O_3P$: C, 61.81; H, 5.80; N, 8.48. Found: C, 61.89; H, 5.81; N, 8.47.

2-(Bis-*n*-butylaminophosphinyl)-1-*n*-butyl-3-methylguanidine (I*l*)—To a solution of 6.67 g (0.066 mole) of triethylamine and 4.82 g (0.066 mole) of *n*-butylamine in 20 ml of benzene, precooled to −10° and under a nitrogen atmosphere, was slowly added a solution of 4.10 g (0.02 mole) of *N*-methyl-1-chloro-*N'*-(dichlorophosphinyl)formamidine (21) in 60 ml of benzene. The reaction mixture was stirred at room temperature for 12 hr, filtered, the filtrate washed three times with water, and the benzene layer dried over anhydrous potassium carbonate. The benzene was removed under reduced pressure to yield a glassy solid. The crude product was purified by column chromatography using chloroform–ether (9:1) as the eluent. Recrystallization from methylene chloride–ether gave a white solid; IR: 3280 (NH), 1630 (C=N), and 1120, 1090 (P=O) cm^{-1}; ^{1}H-NMR: 0.65–1.60 (m, 21H, 3 $CH_3CH_2CH_2$), 1.80–2.40 (m, 2H, 2 NHP=O), 2.40–3.30 (m, 9H, CH_3N and 3 CH_2N), and 5.30–6.25 (bd, 2H, 2 NHC=N) ppm; mass spectrum: *m/z*, 247 (100), 191 (48), 149 (44), and 319 (M^+, 41).

Anal.—Calc. for $C_{14}H_{34}N_5OP$: C, 52.62; H, 10.73; N, 21.92. Found: C, 52.56; H, 10.72; N, 21.88.

2-Bis(2-chloroethyl)amino-4,6-dimethyl-2,5-dihydro-1,3,5,2-triazaphosphorine-2-oxide (II*e*)—To a mixture of 4.7 g (0.05 mole) of acetamidine hydrochloride and 1.1 g (0.11 mole) of triethylamine in 250 ml of methylene chloride was added, with stirring, cooling at 5–10°, and under a nitrogen atmosphere, 6.5 g (0.025 mole) of *N*-bis(2-chloroethyl)phosphoramidic dichloride. The reaction mixture was refluxed for 18 hr and filtered. The filtrate was spin evaporated and the residue dried under vacuum. The remaining material was extracted with acetone, the solvent removed by spin evaporation, and the crude product chromatographed with 20% methanol in chloroform to give a crystalline solid. This material was recrystallized from chloroform to yield the pure product; IR: 3260 (NH), 1630, 1660 (C=N), and 1210 (P=O) cm^{-1}; ^{1}H-NMR: 2.16 (s, 6H, $2CH_3$) and 2.95–3.75 (m, 8H, $4CH_2$) ppm; mass spectrum: *m/z*, 284 (M^+, 1.9) and 286 (M^{+2}, 1.0).

Anal.—Calc. for $C_8H_{15}Cl_2N_4OP$: C, 33.79; H, 5.32; N, 19.71. Found: C, 33.63; H, 5.39; N, 19.64.

2-Bis(2-chloroethyl)amino-4,6,diphenyl-2,5-dihydro-1,3,5,2-triazaphosphorine-2-oxide (II*f*)—The method employed was the same as for II*e* with the use of 7.8 g (0.05 mole) of benzamidine hydrochloride instead of acetamidine hydrochloride and except for the chromatographic and recrystallization procedures. The first elution was stepwise with 100 ml of chloroform followed by 2, 5, and 10% of methanol in chloroform. Recrystallization from methylene chloride gave the pure product; IR: 1610, 1630 (C=N), 1580 (C=C), and 1200 (P=O) cm^{-1}; ^{1}H-NMR: 3.0–3.7 (m, 8H, $4CH_2$), 7.2–8.9 (m, 10H, aromatic), and 11.5 (bs, 1H, NH) ppm; mass spectrum: *m/z*, 408 (M^+, 1.8) and 410 (M^{+2}, 0.8).

Anal.—Calc. for $C_{18}H_{19}Cl_2N_4OP$: C, 52.80; H, 4.68; N, 13.69. Found: C, 52.76; H, 4.73; N, 13.66.

An improved method for the preparation of *N*-bis(2-chloroethyl)-phosphoramidic dichloride for use in the synthesis of II*e* and II*f* was devised. A previous procedure (23) employed vacuum distillation to get this product, whereas a slightly higher yield was obtained using recrystallization for the purification step. A suspension of 50.0 g (0.28 mole) of bis(2-chloroethyl)amine hydrochloride, purified by washing with acetone, in 213.8 g (1.37 moles) of freshly distilled phosphorus oxychloride was refluxed at 135–140° in an oil bath for 15 hr or until a clear mixture was obtained. Excess phosphorus oxychloride was removed under vacuum. The residue was dissolved in warm acetone, filtered, the filtrate spin

[a] Performed by contractors of the National Cancer Institute, National Institutes of Health, according to general screening procedures; Ref. 24. In each case the results from the highest, nontoxic dose are shown. [b] Average survival time (treated/control) × 100. [c] 1 cure/6 mice. [d] Administered five times, every other day, beginning with Day 1. [e] Administered nine times, each day, beginning with Day 1. [f] Results of the repeat study. [g] Administered three times, four days apart, beginning with Day 1. [h] Administered once on Day 1.

evaporated, and the residue dried under vacuum. This material (71.0 g) was refluxed for 0.5 hr with 400 ml of ether, the suspension filtered to remove ether insoluble substances, and the filtrate concentrated to give two crops of pure product totaling 60.8 g (83.8%) melting at 53–55° [lit. (23) mp 54–56°].

A modified procedure of Cassady *et al.* (9) was employed for the measurement of L-cysteine addition. To 2.0 ml of 1.25×10^{-4} *M* L-cysteine in 0.05 *M* phosphate buffer (pH 7.4) under nitrogen atmosphere in a 1-cm cell was added 50 μl of a 10^{-2} *M* solution of the test compound or cyclopentenone in tetrahydrofuran. The reference cell contained 2.0 ml of the L-cysteine solution and 50 μl of tetrahydrofuran. After 4 min, 0.1 ml of 10^{-2} *M* 2,2′-dithiopyridine in tetrahydrofuran was added to each cell, the cells inverted to affect mixing, and the absorbance read at 343 nm. The method was done in triplicate, the values averaged, and the deviations between the three values were calculated. The absorbances of the test compounds were converted to values relative to cyclopentenone, arbitrarily set at 100.

Pharmacological Testing—Groups of six female Swiss albino mice weighing 20 ± 2 g were injected intraperitoneally with 0.1 ml of ascites fluid from donor mice bearing 7-day tumor growths and containing ~7.5×10^6 Sarcoma 180 cells. After 24 hr (Day 1) the control group was intraperitoneally administered 0.2 ml of vehicle consisting of 2% polyoxyethylene (20) sorbitan monooleate in normal saline, and test groups were similarly dosed with 0.2-ml solutions or suspensions of the compounds in vehicle. The injections were repeated every other day for a total of five doses. Animals surviving 30 days from Day 1 were considered to be cured and were calculated as 30-day survivors in the calculation of average survival times (treated/controls × 100). Control groups survived an average of 15.4 ± 2.7 (first study) and 16.5 ± 3.2 (second study) days. Prior to tumor testing the maximum nontoxic dose of each compound, up to 400 mg/kg, was estimated by similar injections of female albino mice with the above preparations.

RESULTS AND DISCUSSION

The only chemistry deemed appropriate for discussion concerns compound Io. Although it was assumed that phosphorylation occurs at the more basic imino nitrogen of 2-iminopiperidine, this starting material also possesses a secondary amine nitrogen capable of substitution. The only product isolated was converted to the hydrochloride salt and both it and 2-iminopiperidine hydrochloride were subjected to ^{13}C-NMR spectral analysis. The pertinent chemical shifts and couplings occurred as singlets at 25.3 and 116.5 ppm, which were assigned to C-2 and C-3 of the piperidine ring, respectively, for the starting material and as doublets at 28.1 and 169.3 ppm for the same carbon atoms in the product. If the piperidino nitrogen were phosphorylated, additional splitting of the ring carbon atoms at the 5- and 6-positions would be expected.

The effect of the compounds on the survival times of mice bearing Sarcoma 180 and P-388 ascites cells is shown in Table II. The Sarcoma 180 testing was done in two sets of experiments, while the P-388 screening was done periodically over a 1-year period. The initial Sarcoma 180 study involved Id, Ig–Ii, and Ik–Im. Four compounds, Id, Ii, Il, and Im possessed bulky substituents on the imino carbon atom. The inactivity of these agents led to speculation that adverse steric or solubility factors were involved. However, Ig and Il, whose toxicity required reduction to a lower dose, also gave negative results. The positive effect of Ih and the initial presumptive activity of If against P-388 (which was not confirmed in later testing) prompted the synthesis of compounds possessing methyl or methoxy and amino or methylamino groups as the two imino carbon substituents. Subsequently, the remaining derivatives, principally those with the aforementioned substituents and several with increased hydrophilicity, were synthesized and tested. Activity was found with IIe > Ia > Ic > Ih and borderline effects with Io and IIa, based on T/C % values. Each of these four active compounds possess methyl, methoxy and amino, or NH grouping on the imino, or comparable, carbon atom. Of the three active imido derivatives, the highest activity was found in those with the greatest hydrophilicity, Ia and Ic. Compound IIe, bearing a nitrogen mustard moiety had the greatest activity, but the effects produced by Ia, Ic, and Ih establish the P(O)N=C system as a new oncolytic grouping, probably acting through an alkylating mechanism. Although seven and ten different atoms or groups were used for R1 and attached to the imino carbon atom, respectively, it is believed that substituents providing optimum electronic, steric, and solubility characteristics leading to the most active derivatives of this nature have yet to be found.

Table III—L-Cysteine Addition

Compound	Relative Reactivity
Cyclopentenone	100.0 ± 8.1
I *g*	79.4 ± 3.6
I *a*	77.3 ± 1.1
II *a*	77.1 ± 5.1
I *k*	74.0 ± 2.2
I *n*	74.0 ± 2.2
I *f*	65.0 ± 6.7
I *c*	64.5 ± 3.3
I *o*	61.7 ± 1.1
I *l*	59.2 ± 3.9
II *e*	54.9 ± 1.1
I *j*	50.4 ± 1.1
II *d*	50.4 ± 1.1
II *b*	49.3 ± 4.5
I *i*	47.1 ± 6.7
I *h*	47.1 ± 2.3
I *e*	40.4 ± 4.5
I *d*	33.6 ± 6.7

Seventeen compounds were also investigated for ability to condense with L-cysteine (Table III). Some derivatives, *e.g.* Im, were not sufficiently soluble for use in the procedure. Of the antitumor agents tested, Ia, IIa, and Ic were among the seven compounds possessing the highest degree of reactivity with the amino acid while Ih gave anomalous results. Based on this evidence, there is no precise correlation between biological and chemical activities but there appears to be some relationship between these effects.

Synthesis and Antimicrobial Activity of Triorganotin 5-Nitro-2-furoates

EUGENE J. KUPCHIK *x, MICHAEL A. PISANO ‡, STEPHEN M. WHALEN *, and JOSEPH LYNCH ‡

Received June 29, 1981, from the **Department of Chemistry and the ‡Department of Biological Sciences, St. John's University, New York, NY 11439.* Accepted for publication July 27, 1981.

Abstract □ Five triorganotin 5-nitro-2-furoates were synthesized by reacting 5-nitro-2-furoic acid with either the corresponding bis(triorganotin) oxide or the corresponding triorganotin hydroxide. The IR spectrum of each compound was obtained over the 4000–200-cm^{-1} range, and some of the bands were assigned. One compound, tri-*n*-butyltin 5-nitro-2-furoate, was an excellent antifungal agent, completely inhibiting the growth of six of ten test fungi at a concentration of 1 μg/ml. The new compounds were also investigated for antibacterial activity and were especially inhibitory toward Gram-positive species. Two of the compounds completely inhibited the Gram-negative bacterium *Escherichia coli* at a concentration of 100 μg/ml.

Keyphrases □ Organometallics—triorganotin compounds, synthesis, tested for antifungal and antibacterial activity □ Tin—triorganotin compounds, synthesis and evaluation as antifungal and antibacterial agents □ Antifungal agents, potential—triorganotin compounds, synthesis □ Antibacterials, potential—triorganotin compounds, synthesis

Many biocidal applications have been found or suggested for organotin compounds (1, 2). The specific organotin compounds currently used in agriculture were reviewed recently (3–5). Their use in agriculture as fungicides and pesticides is of special interest because they degrade to nontoxic inorganic compounds and, therefore, appear to pose little threat to the environment (6–10). Recently, a series of diorganotin dihalide complexes was shown to exhibit antitumor activity (11).

It was reported previously that *N*-substituted *N*-(triphenylstannyl)cyanamides (I) are better antifungal agents than *N*-substituted *N'*-cyano-*S*-(triphenylstannyl)isothioureas (II) and *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas (III) (12). The I compounds were similar in activity to ethyl *N*-aryl-*S*-(triphenylstannyl)isothiocarbamates (IV). Triethylammonium (organocyanoamino)chlorotriphenylstannates (V), which are the triethylammonium chloride complexes of the I compounds, reportedly exhibit higher antifungal activity than the I compounds (12). Although all of the compounds mentioned inhibited Gram-positive bacteria, they showed little inhibitory activity toward Gram-negative bacteria. In this respect, they resemble numerous other organotin compounds (13–16). One purpose of the present study was to synthesize some organotin compounds that might inhibit both Gram-positive and Gram-negative bacteria. Since 5-nitro-2-substituted furans are known to inhibit both Gram-positive and Gram-negative bacteria (17–19), the antibacterial activity of some triorganotin 5-nitro-2-furoates (VI) was studied. The antifungal activity of these

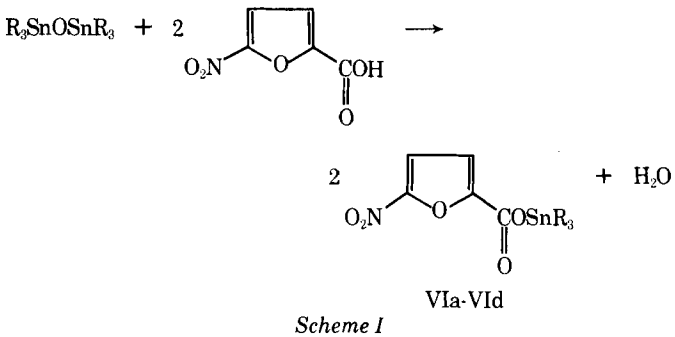
VI*e*	1615s[e]	1345s	558m	510w

[a] Values are expressed in centimeters^{-1}; s = strong, m = medium, and w = weak. The data for 4000–400 cm^{-1} were obtained using potassim bromide pellets. The data for 400–200 cm^{-1} were obtained using mineral oil. [b] Refs. 22 and 23. [c] Refs. 24 and 25. [d] A strong band was present at 280 cm^{-1}. [e] A strong band was present at 1630 cm^{-1}.



Scheme I

compounds was compared also to that of the I–V compounds.

RESULTS AND DISCUSSION

Synthesis—Compounds VI*a*–VI*e* (Table I) were prepared by reacting 5-nitro-2-furoic acid with either the corresponding bis(triorganotin) oxide (VI*a*–VI*d*) (Scheme I) or the corresponding triorganotin hydroxide (VI*e*) (Scheme II). The compounds were identified by elemental analysis (Table I) and IR (Table II). Their IR spectra are considerably different from those of organic esters. Whereas the C=O stretching vibration of normal saturated organic esters occurs in the range 1750–1730 cm^{-1} (20), the C=O stretching vibration of the organotin esters in Table II occurs in the range 1630–1610 cm^{-1}. This shift to lower frequency may be due to intermolecular or intramolecular coordination between the carbonyl oxygen and the tin atom. Interestingly, this shift occurred even for compound VI*d*, which has bulky neophyl groups around the tin atom. The organotin esters contained both the ν_{as}(SnC) and the ν_a(SnC) bands indicating that the triorganotin groups may be nonplanar in these compounds (21).

Biological Results—Compound VI*b* was the best antifungal agent of the VI compounds (Table III), completely inhibiting the growth of six of the ten test fungi at 1 μg/ml and all of the test fungi at 10 μg/ml. Compound VI*b* was the best antifungal agent of the I–VI compound series. Compound VI*a* was the second best antifungal agent of the VI

VIe

Scheme II

compounds, partially inhibiting the growth of all of the test fungi, except *Saccharomyces cerevisiae*, at 1 μg/ml and completely inhibiting the growth of five of the ten test fungi at 10 μg/ml. Compound VI*e* was a generally better antifungal agent than compound VI*c*. Compound VI*e* completely inhibited the growth of *Cladosporium carpophilum* at 10 μg/ml and *Penicillium notatum* at 100 μg/ml. Compound V*c*, on the other hand, inhibited completely the growth of only one fungus (*Penicillium notatum*) at 100 μg/ml. Compounds VI*e* and VI*c* were inactive toward *Saccharomyces cerevisiae* at all concentrations. The poorest antifungal agent of the VI compound series was VI*d*, which was completely inactive toward six of the ten test fungi at all concentrations. The inactivity of VI*d* may be due to the bulky neophyl groups attached to the tin atom in this compound.

The antibacterial activity of the VI compounds is shown in Table IV. Compounds VI*a* and VI*b* both completely inhibited the Gram-positive bacteria *Bacillus megaterium* and *Staphylococcus aureus* at the minimum concentration of organotin compound (1 μg/ml). The activity of compounds VI*a* and VI*b* towards *S. aureus* was identical to that previously observed for the II, IV, and V compounds. The one previously tested III compound, on the other hand, could only completely inhibit this bacterium at 100 μg/ml. Compound VI*e* was the least active of the VI compounds toward the two Gram-positive bacteria. Compound VI*e* was the least active of the II–VI compounds toward *S. aureus*. Compounds VI*b* and VI*e* were the only series VI compounds to show activity toward the Gram-negative bacteria *Pseudomonas aerusginosa* and *Escherichia coli*. Compounds VI*b* and VI*e* both completely inhibited *E. coli* at 100 μg/ml. The one previously tested III compound was inactive toward this bacterium at 100 μg/ml. The II, IV, and V compounds only inhibited growth of this bacterium partially at 100 μg/ml. Compound VI*e* was able to completely inhibit *P. aeruginosa* at 100 μg/ml, while compound VI*b* could only partially inhibit this bacterium at 100 μg/ml.

EXPERIMENTAL[1]

Triphenyltin 5-Nitro-2-furoate (VI*a*)—A mixture of bis(triphenyltin) oxide (11.38 g, 0.01589 mole), 5-nitro-2-furoic acid (5.00 g, 0.0318 mole), and benzene (100 ml) was refluxed for 19 hr. The mixture was filtered, and the benzene was evaporated from the filtrate to give 14.41 g (90%) of VI*a*, mp 111–132°. Four recrystallizations from heptane–benzene (7:5) gave the analytical sample, mp 111.8–112.5°.

Tri-*n*-butyltin 5-Nitro-2-furoate (VI*b*)—A mixture of bis(tri-*n*-butyltin) oxide (10.43 g, 0.01750 mole), 5-nitro-2-furoic acid (5.50 g, 0.0350 mole), and benzene (100 ml) was refluxed for 19 hr. The mixture was filtered, and the benzene was evaporated from the filtrate to give 15.18 g (97%) of VI*b*, mp 62.0–67.0°. Four recrystallizations from heptane gave the analytical sample, mp 68–69.7°.

Tricyclohexyltin 5-Nitro-2-furoate (VI*c*)—A mixture of bis(tricyclohexyltin) oxide (26) (11.96 g, 0.1590 mole), 5-nitro-2-furoic acid (5.00 g, 0.0318 mole), and benzene (100 ml) was refluxed for 16 hr. The mixture was filtered, and the benzene was evaporated from the filtrate to give 16.09 g (97%) of VI*c*, mp 147–155.5°. Four recrystallizations from heptane gave the analytical sample, mp 154.8–156°.

Trineophyltin 5-Nitro-2-furoate (VI*d*)—A mixture of bis(trineophyltin) oxide (27) (2.63 g, 0.00250 mole), 5-nitro-2-furoic acid (0.78 g, 0.0050 mole), and benzene (25 ml) was refluxed for 26.5 hr. The mixture was filtered, and the benzene was evaporated from the filtrate to give 3.14 g (93%) of VI*d*, mp 74–78°. Three recrystallizations from heptane gave the analytical sample, mp 79.3–80°.

Trimethyltin 5-Nitro-2-furoate (VI*e*)—A mixture of trimethyltin hydroxide (9.20 g, 0.0509 mole), 5-nitro-2-furoic acid (8.00 g, 0.0509 mole), and benzene (75 ml) was refluxed for 19 hr. The precipitate was collected on a filter paper and dried to give 15.30 g (94%) of VI*e*, mp 188.2–195.5°. Three recrystallizations from benzene gave the analytical sample, mp 190–192°.

Biological Methods—The compounds were individually dissolved in tetrahydrofuran. The preparation of sterile solutions of the compounds, the fungi employed, the antifungal testing procedures, and the determination of growth inhibition were reported previously (28).

The compounds were also investigated for antibacterial activity according to the procedure reported earlier (28).

[1] Melting points were determined with a Mel-Temp capillary melting point apparatus and are uncorrected. IR data were obtained with a Perkin-Elmer model 283 spectrophotometer. The far IR data were obtained with a Perkin-Elmer model FIS-3 spectrophotometer. The benzene used as a solvent in the synthesis of the organotin esters was dried over sodium ribbon. The water produced in the reactions was removed with the aid of a Dean-Stark trap. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N.Y.

Morphine Pharmacokinetics: GLC Assay *versus* Radioimmunoassay

DONALD R. STANSKI *x, LENNART PAALZOW ‡, and PER OLOF EDLUND ‡

Received April 22, 1981, from the **Department of Anesthesiology and Medicine, Clinical Pharmacology, Stanford University School of Medicine, Stanford, CA 94305*, and the ‡*Department of Pharmacology, Central Research and Control Laboratory, National Corporation of Swedish Pharmacies, Solna, Sweden.* Accepted for publication July 15, 1981.

Abstract □ The validity of a radioimmunoassay (RIA) for research on the pharmacokinetics of morphine has been questioned because of the possible measurement of cross-reactive metabolites. An RIA using antiserum derived from the 3-*O*-carboxymethylmorphine hapten was compared with a specific GLC assay in the measurement of plasma morphine concentrations in humans. The ratio of values for morphine concentrations measured using RIA and those measured using GLC was determined. The RIA values resulted in a 27% overestimation of this ratio. This overestimation did not significantly affect the values for terminal elimination half-life, volume of distribution at steady state, or total body clearance that were derived using results from each assay and model-independent pharmacokinetic techniques.

Keyphrases □ Morphine—pharmacokinetic determination from radioimmunoassay and GLC assay compared □ Pharmacokinetics—morphine, determination from radioimmunoassay and GLC assay compared □ Radioimmunoassay—morphine, comparison with GLC assay, pharmacokinetics □ GLC—morphine, comparison with radioimmunoassay, pharmacokinetics

The radioimmunoassay (RIA) for morphine, first described by Spector *et al.* (1, 2), has been used to characterize the pharmacokinetic profile of morphine (3, 4). A major concern in using any immunoassay for pharmacokinetic research is its accuracy in measuring the true drug concentration. For antibody generated in one laboratory (at morphine concentrations of 20 ng/ml), at least eight times more morphine-3-glucuronide than morphine was required to produce equivalent displacement of the labeled dihydromorphine (5). At 40 ng/ml, more than 32 times more morphine-3-glucuronide was required for an equivalent displacement. Similar results were obtained when relatively high morphine concentrations (1.8–3.1 μg/ml) were measured in rats using the RIA and a specific fluorometric assay (6). This concentration range markedly exceeds that occurring after therapeutic doses in humans. Catlin (7) questioned the validity of RIA for pharmacokinetic analysis, demonstrating a variability in the specificity of the antibody and interference from morphine metabolites that can result in discrepant interpretations.

Because of the limited sensitivity of currently available analytical methods for measuring morphine, it previously has not been possible to validate the accuracy of RIA for morphine in humans because of the low plasma concentrations (1–50 ng/ml) of morphine attained following pharmacological doses of morphine (0.15 mg/kg). A new specific and sensitive GLC assay was used to reevaluate plasma samples of morphine obtained in a previous pharmacokinetic study that were originally analyzed by RIA. The morphine concentrations measured by the different assays were then compared.

EXPERIMENTAL

Plasma Analysis—Plasma samples that were analyzed in a previous study on morphine pharmacokinetics using RIA were reevaluated using a specific GLC morphine assay. The analysis was undertaken on five of the six subjects who had received 10 mg of intravenous morphine sulfate and on four of the five subjects who had received 10 mg of intramuscular morphine sulfate. All samples had remained frozen at −30° until the time of assay. The GLC assays were performed ~2 years after the RIA measurements. There was no evidence of sample deterioration during this time. Demographic characteristics of the patient population and the drug administration protocol were described earlier (4).

Morphine concentrations in plasma were quantitated using RIA and rabbit antimorphine antisera[1] as described previously (4). The detection limit of this assay was 1 ng/ml, and the pooled coefficient of variation was 8.3% for a series of two to three identical samples containing known concentrations of morphine ranging from 1.0 to 45 ng/ml. Although the specificity of the antisera was not assessed, previous reports of antisera from the same source described its relative affinity for morphine, morphine metabolites, and other opiate alkaloids (5). Morphine concentrations in plasma were also determined using the GLC method described by Edlund (8). The detection limit of the assay was 1 ng/ml. The coefficient of variation of the assay was 4 and 10% at 62 and 0.8 ng/ml, respectively.

Data Analysis—Three analyses were performed on the data to determine differences between the two assays and the consequences of these differences on the derived pharmacokinetic values for morphine. The first analysis used linear regression through the origin (9) to compare the morphine concentrations measured with the two assays. Only plasma morphine concentrations <60 ng/ml were used, which included 118 of 138 possible data pairs. The distribution of the 20 data points in the 70–350-ng/ml concentration range was not sufficiently uniform for accurate regression analysis. The excluded data points represented the high morphine concentrations that occurred immediately after the 2-min rapid intravenous infusion. To determine the possible influence of metabolites on the RIA at low concentrations, linear regression through the origin was performed on only those concentrations measured 1 hr after drug administration. In both regression analyses, the 95% confidence interval of the slope was computed to determine if the slope differed significantly from 1.

In the second data analysis, the relative precision and bias of the RIA, as compared with the GLC morphine assay, were determined using approaches suggested previously (10). Relative precision measures the deviation or prediction error of the morphine concentration determined using the RIA compared to the value measured by GLC. This prediction error may have a systematic component called relative bias. The relative bias is the degree to which the typical RIA prediction is either too high

Morphine Pharmacokinetics: GLC Assay *versus* Radioimmunoassay

DONALD R. STANSKI *x, LENNART PAALZOW ‡, and PER OLOF EDLUND ‡

Received April 22, 1981, from the **Department of Anesthesiology and Medicine, Clinical Pharmacology, Stanford University School of Medicine, Stanford, CA 94305*, and the ‡*Department of Pharmacology, Central Research and Control Laboratory, National Corporation of Swedish Pharmacies, Solna, Sweden.* Accepted for publication July 15, 1981.

Abstract □ The validity of a radioimmunoassay (RIA) for research on the pharmacokinetics of morphine has been questioned because of the possible measurement of cross-reactive metabolites. An RIA using antiserum derived from the 3-*O*-carboxymethylmorphine hapten was compared with a specific GLC assay in the measurement of plasma morphine concentrations in humans. The ratio of values for morphine concentrations measured using RIA and those measured using GLC was determined. The RIA values resulted in a 27% overestimation of this ratio. This overestimation did not significantly affect the values for terminal elimination half-life, volume of distribution at steady state, or total body clearance that were derived using results from each assay and model-independent pharmacokinetic techniques.

Keyphrases □ Morphine—pharmacokinetic determination from radioimmunoassay and GLC assay compared □ Pharmacokinetics—morphine, determination from radioimmunoassay and GLC assay compared □ Radioimmunoassay—morphine, comparison with GLC assay, pharmacokinetics □ GLC—morphine, comparison with radioimmunoassay, pharmacokinetics

The radioimmunoassay (RIA) for morphine, first described by Spector *et al.* (1, 2), has been used to characterize the pharmacokinetic profile of morphine (3, 4). A major concern in using any immunoassay for pharmacokinetic research is its accuracy in measuring the true drug concentration. For antibody generated in one laboratory (at morphine concentrations of 20 ng/ml), at least eight times more morphine-3-glucuronide than morphine was required to produce equivalent displacement of the labeled dihydromorphine (5). At 40 ng/ml, more than 32 times more morphine-3-glucuronide was required for an equivalent displacement. Similar results were obtained when relatively high morphine concentrations (1.8–3.1 μg/ml) were measured in rats using the RIA and a specific fluorometric assay (6). This concentration range markedly exceeds that occurring after therapeutic doses in humans. Catlin (7) questioned the validity of RIA for pharmacokinetic analysis, demonstrating a variability in the specificity of the antibody and interference from morphine metabolites that can result in discrepant interpretations.

Because of the limited sensitivity of currently available analytical methods for measuring morphine, it previously has not been possible to validate the accuracy of RIA for morphine in humans because of the low plasma concentrations (1–50 ng/ml) of morphine attained following pharmacological doses of morphine (0.15 mg/kg). A new specific and sensitive GLC assay was used to reevaluate plasma samples of morphine obtained in a previous pharmacokinetic study that were originally analyzed by RIA. The morphine concentrations measured by the different assays were then compared.

EXPERIMENTAL

Plasma Analysis—Plasma samples that were analyzed in a previous study on morphine pharmacokinetics using RIA were reevaluated using a specific GLC morphine assay. The analysis was undertaken on five of the six subjects who had received 10 mg of intravenous morphine sulfate and on four of the five subjects who had received 10 mg of intramuscular morphine sulfate. All samples had remained frozen at −30° until the time of assay. The GLC assays were performed ~2 years after the RIA measurements. There was no evidence of sample deterioration during this time. Demographic characteristics of the patient population and the drug administration protocol were described earlier (4).

Morphine concentrations in plasma were quantitated using RIA and rabbit antimorphine antisera[1] as described previously (4). The detection limit of this assay was 1 ng/ml, and the pooled coefficient of variation was 8.3% for a series of two to three identical samples containing known concentrations of morphine ranging from 1.0 to 45 ng/ml. Although the specificity of the antisera was not assessed, previous reports of antisera from the same source described its relative affinity for morphine, morphine metabolites, and other opiate alkaloids (5). Morphine concentrations in plasma were also determined using the GLC method described by Edlund (8). The detection limit of the assay was 1 ng/ml. The coefficient of variation of the assay was 4 and 10% at 62 and 0.8 ng/ml, respectively.

Data Analysis—Three analyses were performed on the data to determine differences between the two assays and the consequences of these differences on the derived pharmacokinetic values for morphine. The first analysis used linear regression through the origin (9) to compare the morphine concentrations measured with the two assays. Only plasma morphine concentrations <60 ng/ml were used, which included 118 of 138 possible data pairs. The distribution of the 20 data points in the 70–350-ng/ml concentration range was not sufficiently uniform for accurate regression analysis. The excluded data points represented the high morphine concentrations that occurred immediately after the 2-min rapid intravenous infusion. To determine the possible influence of metabolites on the RIA at low concentrations, linear regression through the origin was performed on only those concentrations measured 1 hr after drug administration. In both regression analyses, the 95% confidence interval of the slope was computed to determine if the slope differed significantly from 1.

In the second data analysis, the relative precision and bias of the RIA, as compared with the GLC morphine assay, were determined using approaches suggested previously (10). Relative precision measures the deviation or prediction error of the morphine concentration determined using the RIA compared to the value measured by GLC. This prediction error may have a systematic component called relative bias. The relative bias is the degree to which the typical RIA prediction is either too high

0022-3549/82/0300-0314$01.00/0

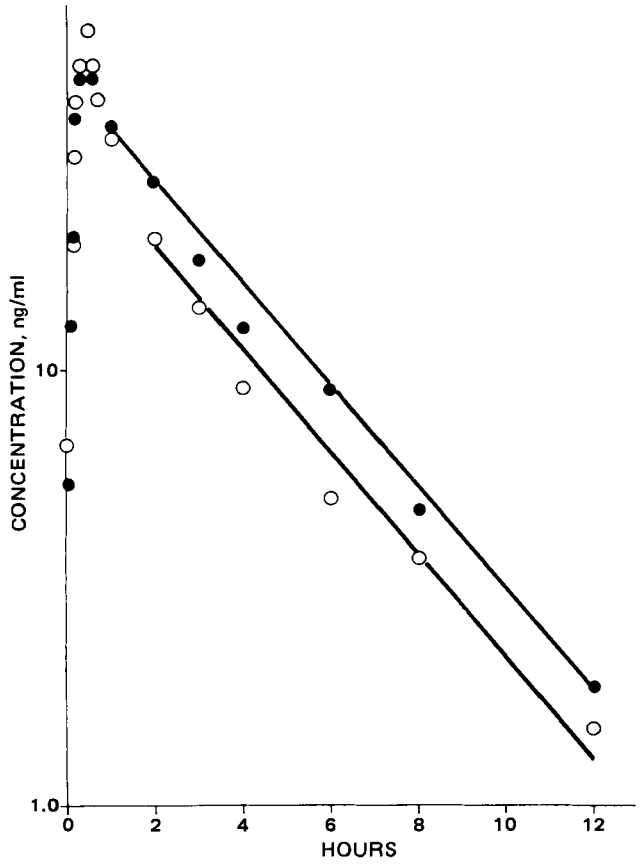

Figure 1—*Plasma concentration data determined by RIA (●) and GLC (○) versus time, for one subject receiving morphine sulfate 10 mg intramuscularly. Lines represent the terminal elimination phases characterized by linear regression.*

or too low. A measure of relative precision is the mean squared prediction error (*MSE*):

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(\text{RIA} - \text{GLC})^2 \qquad \text{(Eq. 1)}$$

where n is the number of data points.

A measure of relative bias is the sample mean prediction error (*ME*):

$$ME = \frac{1}{n}\sum_{i=1}^{n}(\text{RIA} - \text{GLC}) \qquad \text{(Eq. 2)}$$

In the following relationship, the *MSE* is composed of bias (*ME*) and random, nonsystematic error:

$$MSE = ME^2 + \frac{1}{n}\sum_{i=1}^{n}[(\text{RIA} - \text{GLC}) - ME]^2 \qquad \text{(Eq. 3)}$$

in which the last term of the equation is an estimate of the variance of the prediction error and thus a measure of the random error. The relative precision (*MSE*), bias (*ME*), and their 95% confidence interval, along with the proportion of the precision that was bias and random error, were determined using all the values for morphine plasma concentrations that were <60 ng/ml and all the values for 1 hr after drug administration.

In the third data analysis, pharmacokinetic parameters for each individual patient were computed. Model-independent approaches were

Relative precession (*MSE*), ng/ml	27.8	20.4
95% confidence bounds	18.1–37.5	13.6–27.2
Relative bias (*ME*), ng/ml	1.97	3.21
95% confidence bounds	1.02–2.92	2.41–4.01
Components of the *MSE*		
Relative bias, %	14	50
Random error, %	86	50

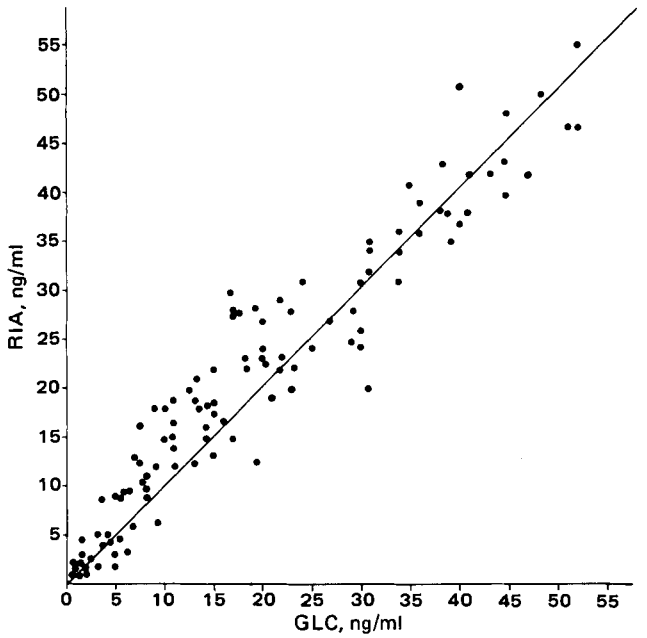

Figure 2—*Regression through the origin using all the morphine concentrations below 60 ng/ml as determined by RIA and GLC. The line represents linear regression.*

applied to the morphine concentration data derived from the two assays. Linear regression of the log plasma concentration *versus* time data was used to determine the apparent terminal elimination half-life. The plasma concentration values that occurred 1 hr after drug administration (*i.e.*, when distribution or absorption was complete) were used. Total body clearance was determined by dividing the dose by the area under the plasma concentration *versus* time curve, determined by the linear trapezoid rule. Complete bioavailability was assumed for intramuscular administration of morphine on the basis of a previous study (4) that demonstrated comparable area under the curves from intravenous and intramuscular administration in the same subject. A model-independent estimate of the volume of distribution at steady state was determined

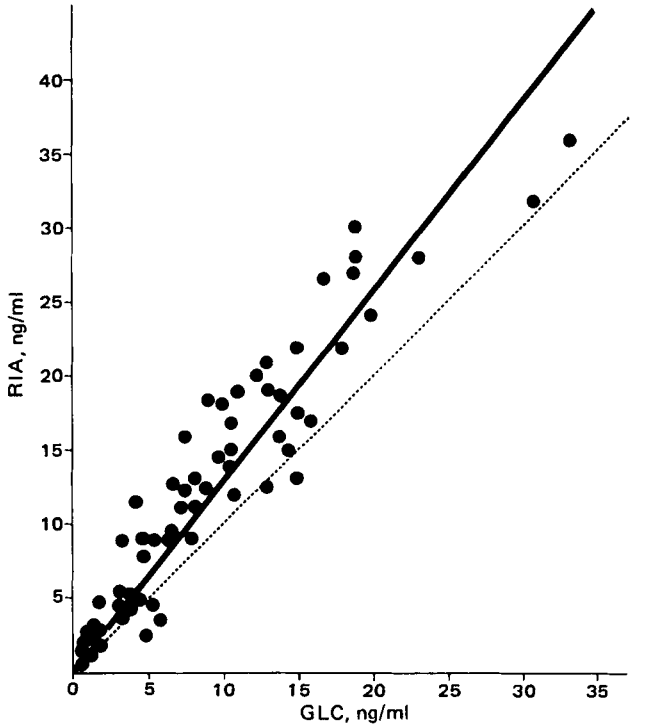

Figure 3—*Regression through the origin of the morphine concentrations as determined by RIA and GLC. Only the values obtained 1 hr after drug administration were used. Linear regression (—) and identity (- - - -) are also shown.*

Table II—Pharmacokinetic Parameters Derived from RIA and GLC Assays

using the first statistical moment described by Benet and Galeazzi (11). An appropriate correction for the intramuscular absorption phase was made in the calculation of the volume of distribution at steady state. A paired Student *t* test was used to determine if there was a significant ($p \leq 0.05$) difference in the pharmacokinetic parameters derived from the RIA and GLC assays.

RESULTS AND DISCUSSION

Examining the individual curves of plasma morphine concentration *versus* time in four of five subjects receiving intravenous morphine, and in three of the four receiving intramuscular morphine, the RIA gave consistently higher plasma concentrations than the GLC assay for time periods 1 hr after drug administration. Figure 1 represents the plasma morphine concentrations determined by the two assays in a subject who received intramuscular morphine.

In the first data analysis, when all plasma concentrations <60 ng/ml were compared (118 data pairs) using regression through the origin, the slope of the regression line was 1.03 and the 95% confidence interval was 0.993–1.064 (Fig. 2). This indicates that the ratio of RIA/GLC morphine concentrations did not differ significantly from 1 when measured with the two assays. When only the data after 1 hr were evaluated (66 data pairs), the slope of the regression through the origin was 1.27 and the 95% confidence interval was 1.23–1.30, indicating that the ratio of RIA/GLC plasma concentrations differs significantly from 1 (Fig. 3). This results in a 27% overestimation of the true morphine concentration by RIA.

In the second data analysis (Table I), the measures of RIA *versus* GLC assay relative precision (*MSE*) and bias (*ME*) are given. The relative biases differ significantly from zero for all plasma morphine concentrations <60 ng/ml and for plasma morphine concentrations 1 hr after drug administration. The plasma concentration data 1 hr after drug administration represents a greater portion of the *MSE* than can be attributed to bias relative to all the plasma morphine concentration data <60 ng/ml.

From the third data analysis, Table II shows the individual pharmacokinetic parameters derived by model-independent techniques for each patient and assay. The GLC assay resulted in a longer mean apparent elimination half-life, higher mean total plasma clearance, and a larger mean apparent volume of distribution at steady state. These differences were not statistically significant when evaluated with a paired *t* test.

Comparison of the morphine concentration determined by RIA and GLC demonstrated a 27% overestimation of the true morphine concentration by RIA at time intervals 1 hr after drug administration. The RIA was significantly less precise than the GLC assay, and had a greater systematic bias for morphine concentrations obtained 1 hr after drug administration. While the morphine antiserum samples have less affinity for morphine metabolites (specifically the main metabolite, morphine-3-glucuronide), they can affect the accurate measurement of morphine with the RIA in several ways. The standard curves for morphine and morphine-3-glucuronide are not parallel, resulting in dose-dependent inhibition ratios of morphine to morphine-3-glucuronide (7). In addition, there is also evidence that the elimination half-life of morphine-3-glucuronide is longer than that of the parent drug in rabbits (7) and humans (3). A previous report (12) showed that morphine metabolites present at concentrations 8–12 times higher than the true morphine concentration 1 hr after drug administration. Overestimation of the true morphine concentration 1 hr after drug administration probably results from cross-reaction of morphine-3-glucuronide with the antiserum samples when true morphine concentrations are lower than the metabolite concentrations.

Overestimation of plasma morphine concentrations by the RIA did not affect derived pharmacokinetic values. The elimination half-life calculated using the values from the GLC assay did not differ markedly from that determined using RIA values. The higher clearance and larger volume of distribution of morphine calculated using the results of the GLC assay reflect the lower plasma concentrations measured by GLC. While statistical differences were not present for the morphine elimination half-lives, clearances, and volumes of distribution derived from the two assays, the variability (standard deviation) of the mean of differences between individual pharmacokinetic values derived from each assay was large and the sample size was small. Both variability and sample size contribute to the probability of detecting a difference in the statistical analysis.

The major mechanism by which morphine is removed from the body is hepatic metabolism. Morphine's high hepatic extraction ratio (13, 14) indicates that clearance is very dependent on hepatic blood flow. The difference in mean total morphine clearance between the two assays (12.9 *versus* 15.3 ml/kg/min) was relatively small given the variability in hepatic perfusion that can exist in humans. The difference in mean volume of distribution between the two assays (2.76 *versus* 3.25 liters/kg) was also small. The differences in derived values for pharmacokinetics between the two assays was minimal and does not affect the interpretation of the fate of morphine in the human body.

Overestimation of the morphine concentration by RIA can be minimized by use of antiserum samples that exhibit minimal cross-reactivity with morphine-3-glucuronide (15, 16).

Peak Homogeneity Determination for the Validation of High-Performance Liquid Chromatographic Assay Methods

G. T. CARTER ˣ, R. E. SCHIESSWOHL, H. BURKE, and R. YANG

Received April 10, 1981, from the *Physical and Analytical Chemistry Department, Ciba-Geigy Corporation, Suffern, NY 10901.* Accepted for publication July 27, 1981.

Abstract □ To validate high-performance liquid chromatographic assay procedures with regard to specificity, methods were developed to determine the homogeneity of the chromatographic peaks. These methods employed a rapid-scanning UV-visible spectrophotometer to monitor the chromatographic effluent. The absorption data were processed to nullify the signal due to the drug substance specifically, while allowing the detection of coincident impurities. Results from three model systems indicated the ability of these methods to detect as little as 0.1% of a coincident impurity.

Keyphrases □ High-performance liquid chromatography—validity, determination of peak homogeneity □ Impurities—high-performance liquid chromatography, determination by measurement of peak homogeneity □ UV spectrometry—use in determination of peak homogeneity of high-performance liquid chromatographic assays

The use of high-performance liquid chromatography (HPLC) for quantitative analyses of pharmaceuticals has been increasing rapidly (1). HPLC offers excellent sensitivity, accuracy, and precision, as well as convenience. Perhaps the most significant advantage of HPLC is the specificity obtained, since the drug substance is assayed following separation from any impurities. It is this specificity which has led to the acceptance of HPLC methods for stability-indicating assays. Naturally, the validity of such procedures is dependent on the homogeneity of the chromatographic peak of interest. In ordinary practice, a procedure is considered sound in this regard if the chromatographic peak representing the drug-substance is resolved from all known or theoretical synthetic impurities as well as decomposition products (2). Such indirect methods do not actually examine the homogeneity of the peak and are limited in scope to compounds previously identified as potential impurities. However, homogeneity, within specified limits, can be shown for any chromatographic technique, if it can be demonstrated that a critical physical property of the peak in question does not change with time. For example, GC peak homogeneity can be shown by using rapid-scanning mass spectrometers as specific detectors to demonstrate the constancy of the mass spectrum of the eluting peak with time (3, 4).

This report presents a similar method which evaluates the homogeneity of HPLC peaks directly, by monitoring the constancy of the UV–visible (UV/VIS) absorption spectrum of the moving eluting substance without the use of a stopped-flow apparatus, which examines only a small portion of the peak of interest. Specifically, it is the ratio between absorbances at specified wavelengths in the absorption spectrum of the eluted peak which is examined. Homogeneity is demonstrated by the fact that for sufficiently dilute solutions of a pure substance, the ratio of absorbances should remain constant, regardless of concentration throughout the chromatographic peak. To accomplish this, a rapid-scanning, microcomputer controlled UV/VIS spectrophotometer was employed to examine the chromatographic effluent. Several reports have appeared (5–9) concerning the use of rapid-scanning spectrophotometers as detectors for HPLC. This report represents the first application of these detectors for HPLC method validation in pharmaceutical analysis. Results obtained for three model systems are described; each of these systems contains a drug substance: carbamazepine (I), desipramine (II), or estrone (III), plus a representative impurity designed to coelute.

Peak Homogeneity Determination for the Validation of High-Performance Liquid Chromatographic Assay Methods

G. T. CARTER ˣ, R. E. SCHIESSWOHL, H. BURKE, and R. YANG

Received April 10, 1981, from the *Physical and Analytical Chemistry Department, Ciba-Geigy Corporation, Suffern, NY 10901.* Accepted for publication July 27, 1981.

Abstract □ To validate high-performance liquid chromatographic assay procedures with regard to specificity, methods were developed to determine the homogeneity of the chromatographic peaks. These methods employed a rapid-scanning UV-visible spectrophotometer to monitor the chromatographic effluent. The absorption data were processed to nullify the signal due to the drug substance specifically, while allowing the detection of coincident impurities. Results from three model systems indicated the ability of these methods to detect as little as 0.1% of a coincident impurity.

Keyphrases □ High-performance liquid chromatography—validity, determination of peak homogeneity □ Impurities—high-performance liquid chromatography, determination by measurement of peak homogeneity □ UV spectrometry—use in determination of peak homogeneity of high-performance liquid chromatographic assays

The use of high-performance liquid chromatography (HPLC) for quantitative analyses of pharmaceuticals has been increasing rapidly (1). HPLC offers excellent sensitivity, accuracy, and precision, as well as convenience. Perhaps the most significant advantage of HPLC is the specificity obtained, since the drug substance is assayed following separation from any impurities. It is this specificity which has led to the acceptance of HPLC methods for stability-indicating assays. Naturally, the validity of such procedures is dependent on the homogeneity of the chromatographic peak of interest. In ordinary practice, a procedure is considered sound in this regard if the chromatographic peak representing the drug-substance is resolved from all known or theoretical synthetic impurities as well as decomposition products (2). Such indirect methods do not actually examine the homogeneity of the peak and are limited in scope to compounds previously identified as potential impurities. However, homogeneity, within specified limits, can be shown for any chromatographic technique, if it can be demonstrated that a critical physical property of the peak in question does not change with time. For example, GC peak homogeneity can be shown by using rapid-scanning mass spectrometers as specific detectors to demonstrate the constancy of the mass spectrum of the eluting peak with time (3, 4).

This report presents a similar method which evaluates the homogeneity of HPLC peaks directly, by monitoring the constancy of the UV–visible (UV/VIS) absorption spectrum of the moving eluting substance without the use of a stopped-flow apparatus, which examines only a small portion of the peak of interest. Specifically, it is the ratio between absorbances at specified wavelengths in the absorption spectrum of the eluted peak which is examined. Homogeneity is demonstrated by the fact that for sufficiently dilute solutions of a pure substance, the ratio of absorbances should remain constant, regardless of concentration throughout the chromatographic peak. To accomplish this, a rapid-scanning, microcomputer controlled UV/VIS spectrophotometer was employed to examine the chromatographic effluent. Several reports have appeared (5–9) concerning the use of rapid-scanning spectrophotometers as detectors for HPLC. This report represents the first application of these detectors for HPLC method validation in pharmaceutical analysis. Results obtained for three model systems are described; each of these systems contains a drug substance: carbamazepine (I), desipramine (II), or estrone (III), plus a representative impurity designed to coelute.

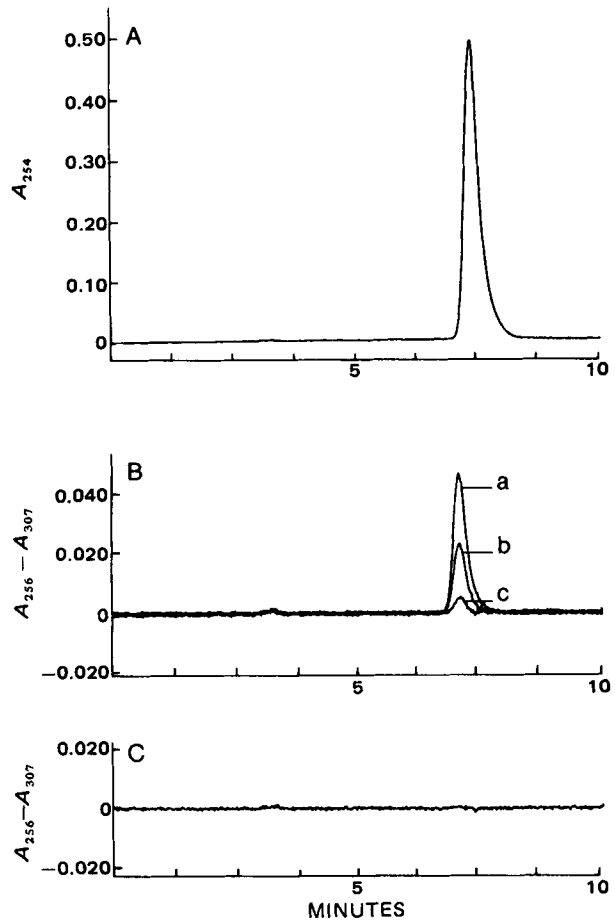

Figure 1—*A) Chromatogram of carbamazepine containing 1% acridone; B) chromatograms of carbamazepine containing (a) 1% acridone, (b) 0.5% acridone, and (c) 0.1% acridone; C) baseline chromatogram obtained for pure carbamazepine. Approximately 5 μg of carbamazepine was injected in 2.5 μl of mobile phase in all cases.*

EXPERIMENTAL

Materials—Carbamazepine[1] (I), acridone[1] (IV), desipramine[1] (II), 5-(3-methylaminopropyl)-5*H*-dibenz[*b*,*f*]azepine[1] (V), estrone[2] (III), and equilenin[2] (VI) were used in the model systems. Spectrophotometric grade solvents[3] were used in all mobile phases. The ion-pairing reagent was prepared by dissolving 5.5 g of sodium heptane sulfonate[4] in 50 ml of distilled water and diluting to 100 ml with glacial acetic acid. All mobile phases were passed through membrane filters[5] prior to use.

Apparatus—All analyses were performed using a high-performance liquid chromatograph[6] equipped with a standard injector, a 3.9 mm × 30-cm reversed-phase column and a fixed wavelength UV absorption detector. The outlet line from the detector was connected *via* a low dead-volume coupling to a quartz micro flow cell[7] (volume, 8 μl, light path, 1 cm) mounted on the optical bench of the rapid-scanning UV/VIS spectrophotometer[8]. The spectrophotometer's built-in microcomputer (16-bit word, 32K words of memory) processed the spectral data in real time. Full-range spectra (200–800 nm) were recorded *versus* air as the blank on the chromatographic effluent, computations were made, and the resultant data were plotted[9] every second to generate the chromatograms shown.

Peak Homogeneity—The methods employed to detect inhomogeneities in chromatographic peaks are designed to specifically nullify the signal due to the drug substance, while allowing the detection of other

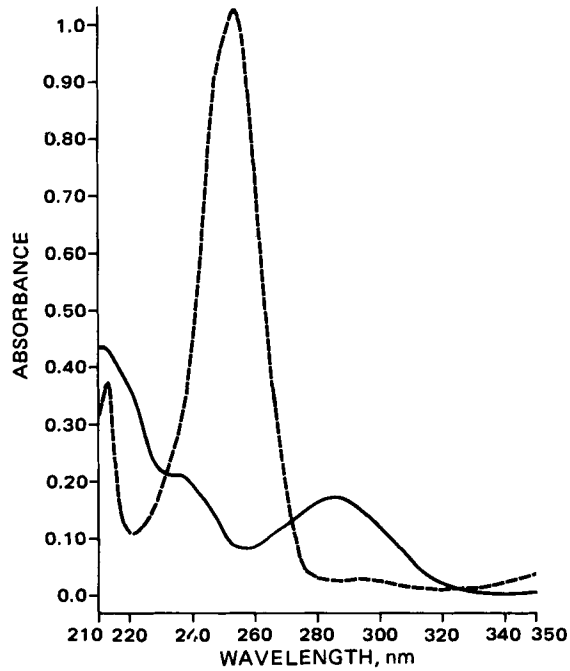

Figure 2—*UV absorption spectra of carbamazepine (—) and acridone (- - - -) obtained as 10 μg/ml solutions in mobile phase.*

compounds. The strict proportionality between absorbances at two wavelengths in the absorption spectrum of the pure drug substance was used, as given:

$$\frac{A_{\lambda_1}}{A_{\lambda_2}} = k_{1,2} \qquad \text{(Eq. 1)}$$

This equation can also be expressed as the null relationship of Eq. 2:

$$A_{\lambda_1} - k_{1,2}A_{\lambda_2} = 0 \qquad \text{(Eq. 2)}$$

which provides a basis for eliminating the response due to the drug-substance. By recording this difference *versus* retention time, a chromatogram which is void of any signal resulting from the elution of the drug substance is obtained. In the simplest case, two wavelengths of equal absorbance (*i.e.* when $k_{1,2} = 1.0$) have been chosen from the absorption spectrum of the drug substance.

In some cases it was advantageous to compare the average absorbance over two or more wavelengths with the absorbance at another single wavelength. The average absorbance over two wavelengths, λ_1 and λ_2, is related to the absorbance at a third wavelength, λ_3. The proportional relationships between the individual wavelengths obtained from Eq. 1 are:

$$A_{\lambda_1} = k_{1,3}A_{\lambda_3} \qquad \text{(Eq. 3)}$$

and

$$A_{\lambda_2} = k_{2,3}A_{\lambda_3} \qquad \text{(Eq. 4)}$$

Addition of these two equations and dividing by 2 gives an expression for the average absorbance at λ_1 and λ_2, $\overline{A}_{\lambda_{1,2}}$:

$$\overline{A}_{\lambda_{1,2}} = \frac{A_{\lambda_1} + A_{\lambda_2}}{2} = A_{\lambda_3}\frac{(k_{1,3} + k_{2,3})}{2} \qquad \text{(Eq. 5}a\text{)}$$

This is more simply written as:

$$\overline{A}_{\lambda_{1,2}} = k'A_{\lambda_3} \qquad \text{(Eq. 5}b\text{)}$$

where $k' = (k_{1,3} + k_{2,3})/2$. Equation 5*b* is then rearranged to give a null relationship similar to Eq. 2.

Comparison of average absorbances of two or more sets of wavelengths is a useful technique. In the simplest case, the average absorbance at λ_1 and λ_2, $\overline{A}_{\lambda_{1,2}}$, is related to the average absorbance at λ_3 and λ_4, $\overline{A}_{\lambda_{3,4}}$. Two equations relate $\overline{A}_{\lambda_{1,2}}$ to the absorbances at the individual wavelengths λ_3 and λ_4:

$$\overline{A}_{\lambda_{1,2}} = k'A_{\lambda_3} = k''A_{\lambda_4} \qquad \text{(Eq. 6)}$$

where $k'' = (k_{1,4} + k_{2,4})/2$. Addition of these equations and division by

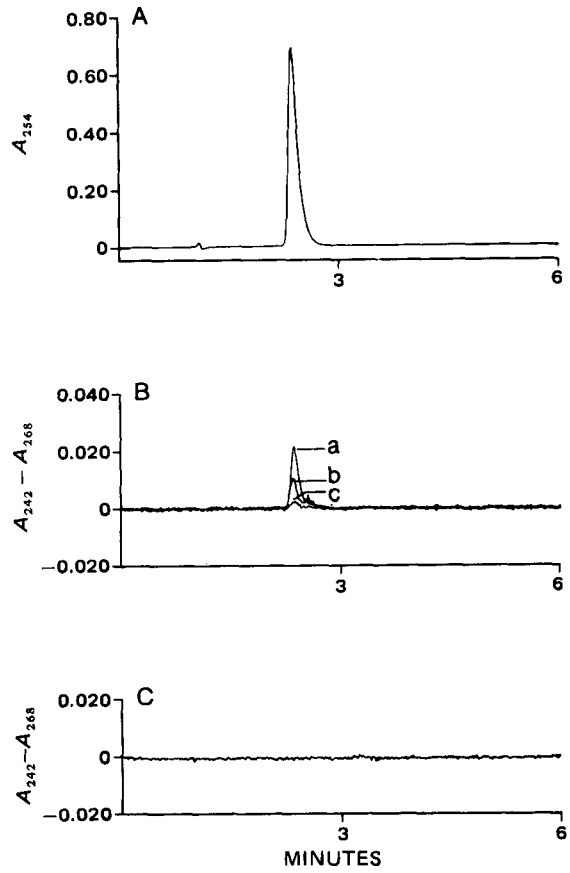

Figure 3—*A) Chromatogram of desipramine containing 1% V; B) chromatograms of desipramine containing (a) 1% V, (b) 0.5% V, and (c) 0.1% V; C) baseline chromatogram obtained for pure desipramine. Approximately 10 μg of desipramine was injected in 5 μl of mobile phase in all cases.*

2 gives Eq. 7, which expresses $\overline{A}_{\lambda_{1,2}}$ as a function of A_{λ_3} and A_{λ_4}:

$$\overline{A}_{\lambda_{1,2}} = \frac{k'A_{\lambda_3} + k''A_{\lambda_4}}{2} \qquad \text{(Eq. 7)}$$

As seen from Eq. 7, $\overline{A}_{\lambda_{1,2}}$ is directly proportional to $\overline{A}_{\lambda_{3,4}}$ only when $k' = k''$:

$$\overline{A}_{\lambda_{1,2}} = k'\frac{(A_{\lambda_3} + A_{\lambda_4})}{2} = k'\overline{A}_{\lambda_{3,4}} \qquad \text{(Eq. 8)}$$

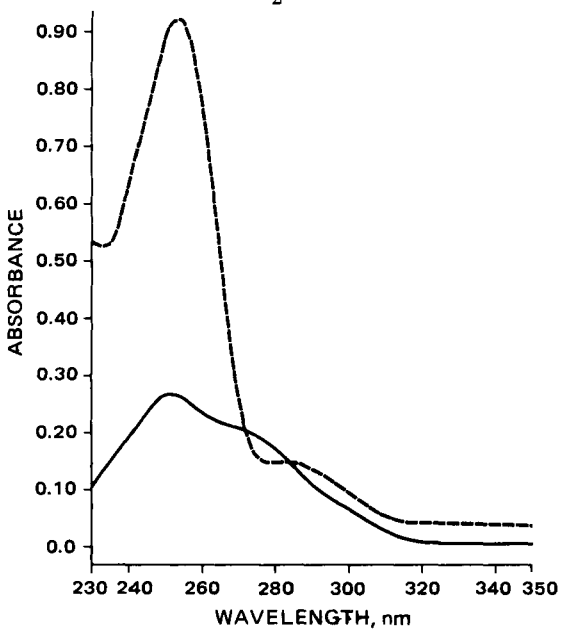

Figure 4—*UV absorption spectra of desipramine(—) and V (- - - -) obtained as 10 μg/ml solutions in mobile phase.*

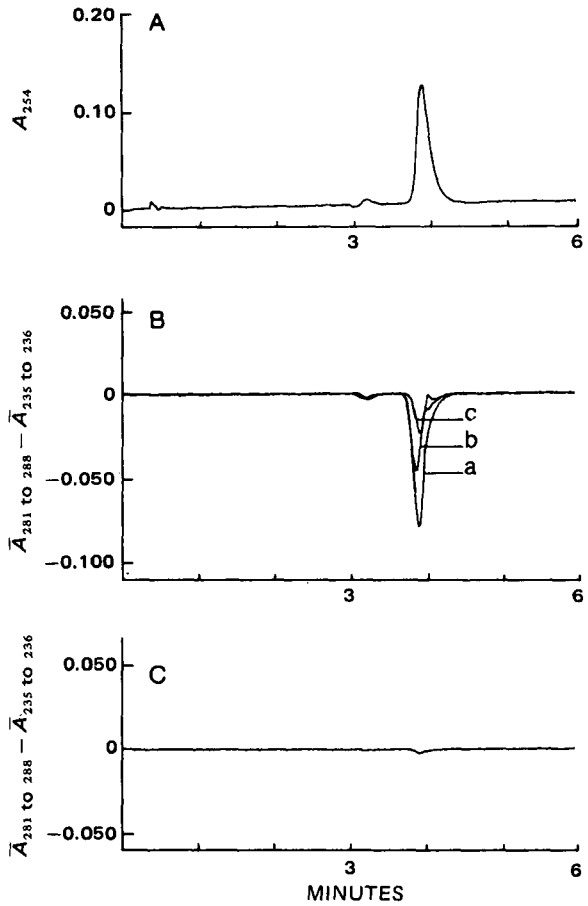

Figure 5—*A) Chromatogram of estrone containing 1% equilenin; B) chromatograms of estrone containing (a) 1% equilenin, (b) 0.5% equilenin, and (c) 0.1% equilenin; C) baseline chromatogram obtained for pure estrone. Approximately 20 μg of estrone was injected in 10 μl mobile phase in all cases.*

Rearrangement of this equation gives the null relationship:

$$\overline{A}_{\lambda_{1,2}} - k'\overline{A}_{\lambda_{3,4}} = 0 \qquad \text{(Eq. 9)}$$

when $k' = k''$. The implication of the requirement that $k' = k''$ in Eq. 9 is that the absorbances at λ_3 and λ_4 must be equal. In practice, this requirement is not a major limitation due to the broad nature of the UV/VIS absorption spectra of most organic compounds. Thus, a range of wavelengths at absorption maxima or minima have essentially equal absorbances, and on all but the steepest curves adjacent wavelengths (within 1–2 nm) have absorbances close enough to be considered equal in these comparisons.

When null relationships are applied to the absorption data obtained as the drug substance elutes from the column, inhomogeneities in the peak result in positive or negative deviations from the baseline. Homogeneity is indicated by a flat baseline.

RESULTS AND DISCUSSION

Carbamazepine—A standard chromatogram (absorbance at 254 nm *versus* time) of carbamazepine containing 1% (w/w) of acridone (IV), a potential impurity, is shown in Fig. 1A. The composition of the mobile phase [methanol–water (55:45); flow rate, 1.0 ml/min] was adjusted to cause the two materials to overlap at a retention time of 7.4 min, since they are readily separable in other mobile phases. Under these conditions, no indication of inhomogeneity in the carbamazepine peak was observed. To detect the acridone, the response derived from the carbamazepine was removed by manipulation of the spectral data. The UV spectrum of carbamazepine (Fig. 2) contains two points of equal absorbance at 256 and 307 nm. To nullify the signal of carbamazepine, the difference in absorbance at these two wavelengths is plotted *versus* time. The resulting chromatogram for pure carbamazepine is shown in Fig. 1C, which reveals a flat baseline. Examination of the UV spectrum of acridone (Fig. 2) shows a strong absorbance at 256 nm and essentially no absorbance at 307 nm,

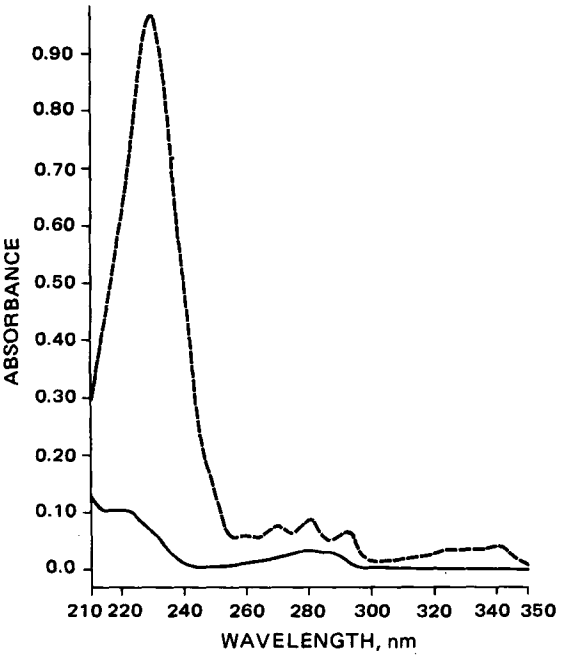

Figure 6—*UV absorption spectra of estrone (—) and equilenin (- - - -) obtained as 4 μg/ml solutions in mobile phase.*

which indicates a positive response should be observed for acridone when this absorbance difference is monitored. The 1% solution used to generate the chromatogram of Fig. 1A gives chromatogram *a* in Fig. 1B. Chromatograms *b* and *c* of Fig. 1B result from the analyses of carbamazepine solutions containing 0.5 and 0.1% acridone, respectively.

Desipramine—A completely analogous method was used to evaluate the homogeneity of the desipramine chromatographic peak in conjunction with its potential by-product (10) 5-(3-methylaminopropyl)-5*H*-dibenz[*b*,*f*]azepine (V). As shown in Fig. 3A, both materials chromatograph with a retention time of 2.5 min under the conditions chosen [mobile phase, acetonitrile/water/ion-pairing reagent/triethylamine (500:500:20:2); flow rate, 2.5 ml/min]. Referring to the UV spectrum of desipramine (Fig. 4), approximately equal absorbances were noted at 242 and 268 nm. Subtraction of the absorbances at these two wavelengths effectively eliminates the response from desipramine, as shown in the chromatogram of Fig. 3C. Samples of desipramine spiked with V at levels of 1.0, 0.5, and 0.1% gave the chromatograms shown in Fig. 3B. The positive signal results from the greater absorbance exhibited by V at 242 nm as compared with 268 nm (Fig. 4).

Estrone—Estrone preparations commonly contain the estrogen equilenin (VI) (11). Using a mobile phase of methanol and water (85:15) and a flow rate of 1.0 ml/min both substances elute at 3.9 min as shown in Fig. 5A. In this case, the relationship of Eq. 9 was applied, as the average absorbance from 235 to 236 nm was subtracted from the average absorbance between 281 and 288 nm (refer to the UV spectrum in Fig. 6) to give the baseline shown in Fig. 5C. When the spiked samples (1.0, 0.5, and 0.1% equilenin) are measured, negative peaks are observed (Fig. 5B), as equilenin has a greater absorbance in the low wavelength range (Fig. 6).

In each of the three systems, the lack of homogeneity created by the addition of low levels of a coeluting substance is apparent. Comparison of the chromatograms for the three 1% mixtures shown in Figs. 1B, 3B, and 5B reveals a range of responses from ~0.02*A* to 0.08*A*. These differences in intensity are related to the absorption characteristics of the particular impurity, the detection method employed and the amount of sample analyzed. The effect of the detection method can be appreciated by considering desipramine. Greater sensitivity for V could be obtained by using Eq. 10 as the null relationship since 255 nm is the absorption maximum of this impurity (Fig. 4):

$$A_{255\text{ nm}} - kA_{280\text{ nm}} = 0 \qquad \text{(Eq. 10)}$$

where:

$$k = \frac{A_{255\text{ nm}}\text{ (desipramine)}}{A_{280\text{ nm}}\text{ (desipramine)}} \qquad \text{(Eq. 11)}$$

The results obtained for these model systems illustrate the potential of the technique for the rapid determination of the homogeneity of HPLC

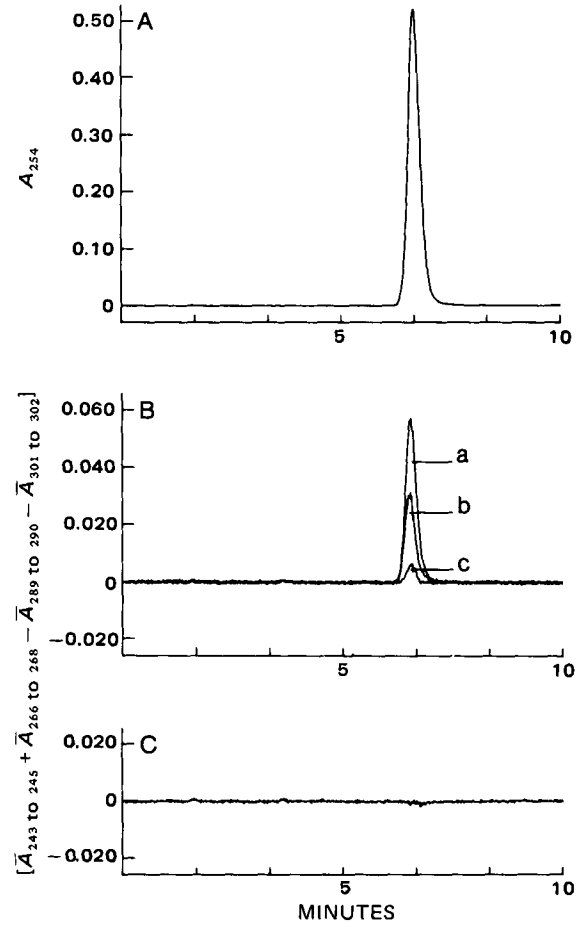

Figure 7—*A) Chromatogram of carbamazepine containing 1% acridone; B) chromatograms of carbamazepine containing (a) 1% acridone, (b) 0.5% acridone, and (c) 0.1% acridone; C) baseline chromatogram obtained for pure carbamazepine. Approximately 5 μg of carbamazepine was injected in 2.5 μl of mobile phase in all cases.*

peaks. Application of these principles to validate HPLC assay procedures is straightforward. The UV/VIS absorption spectrum of the drug substance is measured in the appropriate mobile phase in the flow cell as the material is chromatographed, to eliminate interference from any resolved contaminants. From these data, the nullifying relationship is constructed. The drug-substance is then rechromatographed and the null relationship is monitored *versus* retention time. Homogeneity is indicated if no significant deviation from zero is observed as the drug substance elutes. Hence, from the standpoint of specificity, the chromatographic method is valid.

An erroneous indication of peak homogeneity is possible in the described test if an exactly coincident impurity gives rise to a signal equal in half-width to that of the drug substance. In this case, the contribution from the impurity's absorbance to the total absorbance is proportionally the same throughout the peak. This situation is unlikely in pharmaceutical analysis. Although chromatographic theory (12) predicts equal band widths for substances of identical retention time, impurities typically are present in such small amounts relative to the drug substance (*i.e.*, less than 1%) that they have much narrower effective band widths. The presence of the narrow peak under the envelope of the drug substance is detected readily by these methods.

To bolster the initial indication of peak homogeneity, additional comparison studies should be done. These experiments use the null relationship generated on the original sample to examine the homogeneity of other samples of the drug substance containing increased levels of impurities (and those containing lower levels, if available). Such samples could be derived from purification steps (mother liquors, chromatographic fractions, *etc.*) or as products of accelerated decomposition experiments. These studies are particularly important for stability-indicating assays. Any deviation in the baseline as the drug substance elutes signifies a potential problem in the HPLC method. An invariant baseline represents further evidence of peak homogeneity and essentially eliminates the possibility of a coincident impurity of equal half-width in the

original sample.

Although the method outlined is an independent one, which does not require prior knowledge of possible interfering substances, care must be taken to ensure its generality. The inclusion of just two wavelengths in the detection method, as in Eq. 2, ignores absorbances from contaminants at all other wavelengths. A material which has the same ratio of absorbances at these two wavelengths as the drug-substance (or zero absorbance at each) would not be detected, regardless of the nature of its absorbances at other wavelengths. To enable the detection of the widest range of interfering substances, absorption values across the entire spectral region of interest should be compared. This can be accomplished by either sequential application of the simple relationship of Eq. 2, varying the wavelengths each time, or by using an extended expression which includes the absorbances at several wavelengths.

The latter approach is illustrated in Fig. 7 for the carbamazepine system. Figure 7A shows the unresolved chromatographic peak due to carbamazepine and acridone (1%). To detect the acridone, the multiwavelength expression of Eq. 12 was plotted *versus* retention time:

$$\overline{A}_{243\text{ nm}-245\text{ nm}} + \overline{A}_{266\text{ nm}-268\text{ nm}} - \overline{A}_{289\text{ nm}-290\text{ nm}} - \overline{A}_{301\text{ nm}-302\text{ nm}} = 0 \quad \text{(Eq. 12)}$$

For simplicity, wavelength ranges were chosen whose absorbance values will cancel without the use of proportionality constants. As shown in Fig. 7B, the results are comparable in terms of sensitivity to those given in Fig. 1, and the cancellation of the response due to pure carbamazepine is equally complete (Fig. 7C). The major benefit of this approach is in the generality obtained in one operation. A standard method, which includes sufficient wavelengths to be of wide scope, would be the use of absorbances at 20 nm intervals across a broad spectral region (~200 nm).

One concern is the degree of homogeneity indicated in these methods by a flat baseline. Two limitations imposed by the apparatus described under *Experimental*, are the experimentally determined response threshold of ±0.001*A* and the photometric linearity constraint. This latter restriction requires maximum absorbance values of ~1.0 *A* for wavelengths used in the null relationship, to preserve optimum photometric linearity. Thus, the maximum amount of drug substance analyzed, which governs the relative level of impurities found, is determined by this photometric limitation and by the chromatographic constraint against overloading the column. Given these instrumental restrictions, there are three principal factors which affect the response level of a given impurity: the intensity of its absorption (molar absorptivity), the degree of similarity between its absorption spectrum and that of the drug substance, and the detection method (null relationship) employed. In the case of unknown materials, absorption characteristics are unknown quantities, and the detection method cannot be tailored to attain the maximum response. Because of this, the use of multiple expressions containing data obtained at several wavelengths is recommended. An *a priori* detection limit cannot be stated for all possible impurities. However, these methods can ensure >99% homogeneity in most cases.

Kinetics and Stability of a Multicomponent Organophosphate Antidote Formulation in Glass and Plastic

PETER ZVIRBLIS and ROBERT I. ELLIN[x]

Received March 17, 1980, from the *U.S. Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.* Accepted for publication July 20, 1981.

Abstract □ An aqueous solution of trimedoxime bromide, atropine, and benactyzine hydrochloride was formulated to have maximum stability as an antidote in organophosphorus poisoning. The stability of the mixture in glass and plastic cartridges was determined. Glass cartridges were more desirable than plastic; there was less vapor loss, color formation, and anomolous reaction. Trimedoxime was stable, losing 1.4% of its potency after 1 year at 25° and atropine was more stable than trimedoxime. Considerable degradation of benactyzine occurred; 20% of its potency was lost after 1 year at 25°. Equations for predicting the shelf life of each ingredient at selected temperatures are presented.

Keyphrases □ Benactyzine—in formulation, kinetics and stability in glass and plastic □ Atropine—in formulation, kinetics and stability in glass and plastic □ Trimedoxime—in formulation, kinetics and stability in glass and plastic

The administration of atropine with and without oxime is a common therapy for poisoning by organophosphorus anticholinesterase pesticides such as parathion[1] and malathion[1], and for other organophosphorus compounds such as isopropylmethylphosphonofluoridate (sarin) and pinacolyl methylphosphonofluoridate (soman). Atropine is used to overcome cholinergic stimulation from the anticholinesterases, and oxime reactivates and restores the activity of the enzyme. A recent report claims that the effectiveness of a therapy could be enhanced significantly by simultaneous administration of the cholinolytic drugs,

[1] Parathion, *O,O*-diethyl-*O*-(4-nitrophenyl)phosphorothioate; malathion, *O,O*-dimethyl-*S*-(1,2-dicarbethoxyethyl)phosphorodithioate; trimedoxime bromide, pyridinium-1,1′-(1,3-propanediyl)bis(4-(hydroxyimino)methyl)-dibromide; and benactyzine, α-hydroxy-α-penylbenzeneacetic acid 2-(diethylamino)ethyl ester.

original sample.

Although the method outlined is an independent one, which does not require prior knowledge of possible interfering substances, care must be taken to ensure its generality. The inclusion of just two wavelengths in the detection method, as in Eq. 2, ignores absorbances from contaminants at all other wavelengths. A material which has the same ratio of absorbances at these two wavelengths as the drug-substance (or zero absorbance at each) would not be detected, regardless of the nature of its absorbances at other wavelengths. To enable the detection of the widest range of interfering substances, absorption values across the entire spectral region of interest should be compared. This can be accomplished by either sequential application of the simple relationship of Eq. 2, varying the wavelengths each time, or by using an extended expression which includes the absorbances at several wavelengths.

The latter approach is illustrated in Fig. 7 for the carbamazepine system. Figure 7A shows the unresolved chromatographic peak due to carbamazepine and acridone (1%). To detect the acridone, the multiwavelength expression of Eq. 12 was plotted *versus* retention time:

$$\overline{A}_{243\text{ nm}-245\text{ nm}} + \overline{A}_{266\text{ nm}-268\text{ nm}} - \overline{A}_{289\text{ nm}-290\text{ nm}} - \overline{A}_{301\text{ nm}-302\text{ nm}} = 0 \quad \text{(Eq. 12)}$$

For simplicity, wavelength ranges were chosen whose absorbance values will cancel without the use of proportionality constants. As shown in Fig. 7B, the results are comparable in terms of sensitivity to those given in Fig. 1, and the cancellation of the response due to pure carbamazepine is equally complete (Fig. 7C). The major benefit of this approach is in the generality obtained in one operation. A standard method, which includes sufficient wavelengths to be of wide scope, would be the use of absorbances at 20 nm intervals across a broad spectral region (~200 nm).

One concern is the degree of homogeneity indicated in these methods by a flat baseline. Two limitations imposed by the apparatus described under *Experimental*, are the experimentally determined response threshold of ±0.001*A* and the photometric linearity constraint. This latter restriction requires maximum absorbance values of ~1.0 *A* for wavelengths used in the null relationship, to preserve optimum photometric linearity. Thus, the maximum amount of drug substance analyzed, which governs the relative level of impurities found, is determined by this photometric limitation and by the chromatographic constraint against overloading the column. Given these instrumental restrictions, there are three principal factors which affect the response level of a given impurity: the intensity of its absorption (molar absorptivity), the degree of similarity between its absorption spectrum and that of the drug substance, and the detection method (null relationship) employed. In the case of unknown materials, absorption characteristics are unknown quantities, and the detection method cannot be tailored to attain the maximum response. Because of this, the use of multiple expressions containing data obtained at several wavelengths is recommended. An *a priori* detection limit cannot be stated for all possible impurities. However, these methods can ensure >99% homogeneity in most cases.

Kinetics and Stability of a Multicomponent Organophosphate Antidote Formulation in Glass and Plastic

PETER ZVIRBLIS and ROBERT I. ELLIN[x]

Received March 17, 1980, from the *U.S. Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.* Accepted for publication July 20, 1981.

Abstract □ An aqueous solution of trimedoxime bromide, atropine, and benactyzine hydrochloride was formulated to have maximum stability as an antidote in organophosphorus poisoning. The stability of the mixture in glass and plastic cartridges was determined. Glass cartridges were more desirable than plastic; there was less vapor loss, color formation, and anomolous reaction. Trimedoxime was stable, losing 1.4% of its potency after 1 year at 25° and atropine was more stable than trimedoxime. Considerable degradation of benactyzine occurred; 20% of its potency was lost after 1 year at 25°. Equations for predicting the shelf life of each ingredient at selected temperatures are presented.

Keyphrases □ Benactyzine—in formulation, kinetics and stability in glass and plastic □ Atropine—in formulation, kinetics and stability in glass and plastic □ Trimedoxime—in formulation, kinetics and stability in glass and plastic

The administration of atropine with and without oxime is a common therapy for poisoning by organophosphorus anticholinesterase pesticides such as parathion[1] and malathion[1], and for other organophosphorus compounds such as isopropylmethylphosphonofluoridate (sarin) and pinacolyl methylphosphonofluoridate (soman). Atropine is used to overcome cholinergic stimulation from the anticholinesterases, and oxime reactivates and restores the activity of the enzyme. A recent report claims that the effectiveness of a therapy could be enhanced significantly by simultaneous administration of the cholinolytic drugs,

[1] Parathion, *O,O*-diethyl-*O*-(4-nitrophenyl)phosphorothioate; malathion, *O,O*-dimethyl-*S*-(1,2-dicarbethoxyethyl)phosphorodithioate; trimedoxime bromide, pyridinium-1,1′-(1,3-propanediyl)bis(4-(hydroxyimino)methyl)-dibromide; and benactyzine, α-hydroxy-α-penylbenzeneacetic acid 2-(diethylamino)ethyl ester.

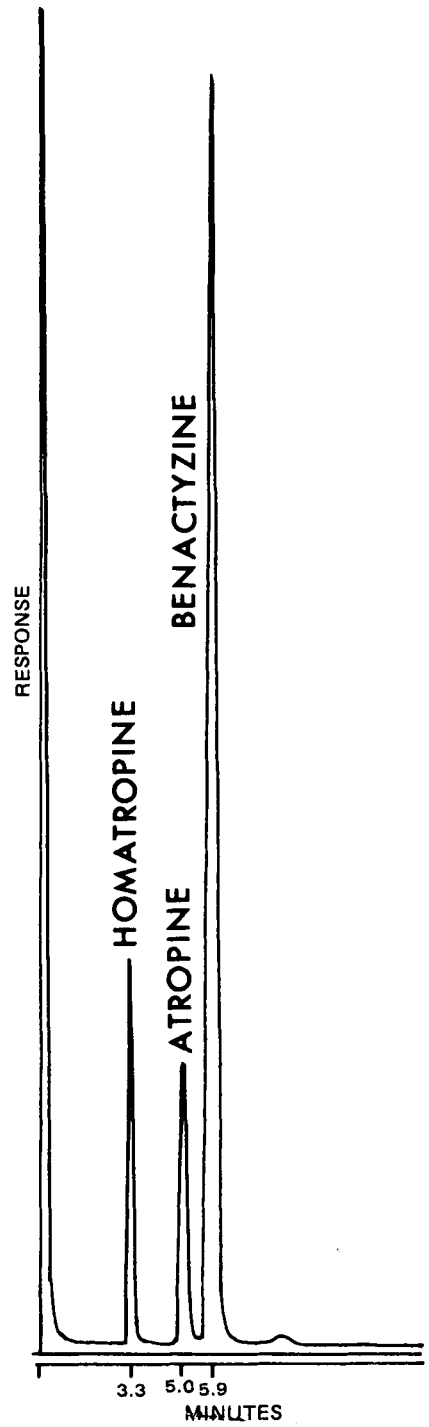

Figure 1—*Chromatogram of atropine and benactyzine with the internal standard, homatropine.*

atropine, and benactyzine[1] (1). This investigation was initiated in answer to the need of the United States Defense Forces for a stable and ready-for-use antidote that would be effective against a variety of organophosphorus compounds. Studies were conducted with a three-drug combination containing trimedoxime bromide[1], atropine sulfate, and benactyzine hydrochloride. The stability of aqueous solutions of the multicomponent mixture, in prefilled glass or plastic cartridges for a semiautomatic injector device, was studied.

The kinetics of hydrolysis of atropine and trimedoxime bromide in dilute aqueous solution in the pH range 0.5–

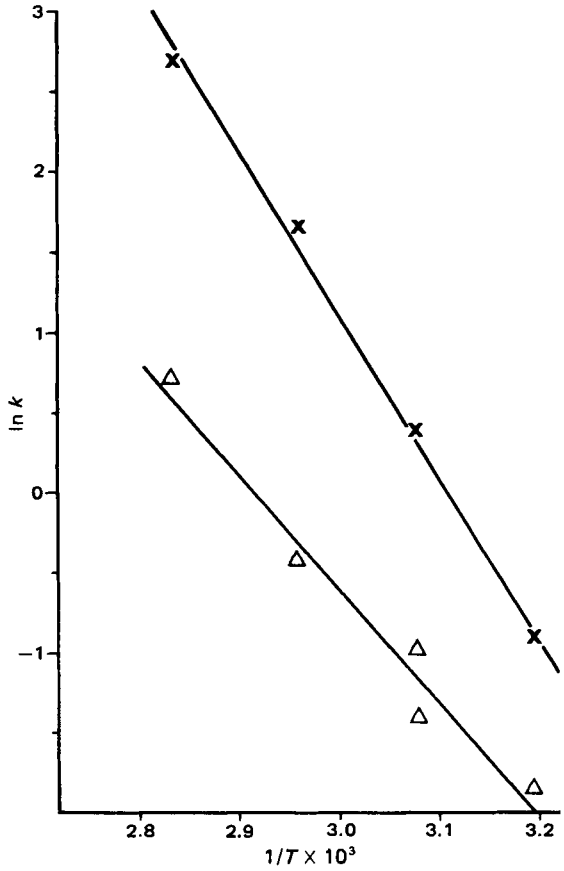

Figure 2—*Effect of temperature on net weight loss. Key: △, glass cartridges; ×, plastic cartridges.*

13.0 and at various temperatures were reported previously (2–4). Another report (5) studied the stability of benactyzine in the pH range 2.1–6.3 at 37°. A mixture of the three drugs (trimedoxime bromide, atropine sulfate, and benactyzine hydrochloride) was prepared at pH 2.8 to maximize the overall stability of the active ingredients of the multicomponent formulation.

EXPERIMENTAL

Materials—Cartridges were either glass (USP type 1) or polypropylene resins. Cartridge seals were butyl rubber.

The ingredients in the cartridge were: trimedoxime bromide, 20 mg/ml; atropine sulfate USP, 0.5 mg/ml; benactyzine hydrochloride, 2.05 mg/ml; methylparaben USP, 0.5 mg/ml; and propylparaben, 0.05 mg/ml[2]. All ingredients are dissolved in USP Water for Injection. Dilute hydrochloric acid USP, ~0.5 ml/liter, was used to adjust the pH to 2.8. Each cartridge was filled to 2.0 ml. The open ends of the cylindrical cartridges were stoppered with tight-fitting gray butyl rubber plugs.

Storage—The glass and plastic cartridge assemblies were wrapped individually in aluminum foil. They were then placed in a horizontal position in constant temperature ovens at either 80° for 3 weeks, 65° for 7 weeks, 52° for 3 months; in a water-jacketed incubator at 40° for 4 months; or in a refrigerator at 5° for 4 months. Some assemblies stored at 65° were placed vertically to determine whether the storage position had any influence. The physical appearance of the assembly cartridges, the net weight of the contents, pH, and the concentrations of benactyzine, trimedoxime, and atropine were studied. Samples were removed from storage at intervals for assessment and analysis. Differences found between glass and plastic cartridges were evaluated using a t test to determine significance at 95% confidence limits (6). The data for both types

[2] Reference standards of trimedoxime bromide and benactyzine hydrochloride are available upon request to Contracting Officer, Defense Personnel Support Center, Directorate of Medical Material, 2800 South 20th Street, Philadelphia, PA 19401.

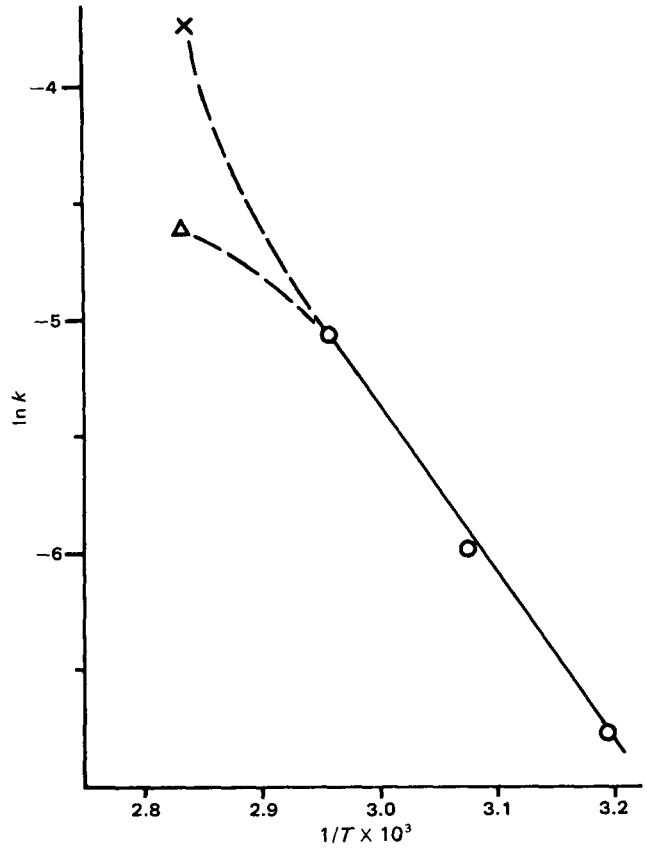

Figure 3—*Influence of temperature on pH decrease. Key: △, glass cartridges; ×, plastic cartridges. Values at 80° deviate significantly from the Arrhenius plot.*

of cartridges were combined where no statistically significant difference was shown.

Assay—*Benactyzine Hydrochloride and Atropine Sulfate*—One milliliter of each antidote mixture was pipetted into 10-ml glass tubes with polytef-lined screw caps. Internal standard[3] (1.0 ml), chloroform (1.0 ml), and 7% sodium carbonate (1.0 ml) were added successively. The tubes were capped immediately, shaken vigorously for 2 min, and the layers were allowed to separate. Approximately 2–3 μl of the chloroform layer was injected into the chromatograph.

The gas chromatographic analysis was done on a 1.2 m × 4-mm i.d. glass column with a 100/120-mesh Gas Chrom Q with 3% OV-17 column support and coating. The column temperature was 200° isothermal, the injection port temperature 190°, and the detector temperature 220°. The carrier gas was helium at a flow rate of 80 ml/min. The detector had an 80 ml/min hydrogen flow, and a 450 ml/min air flow. A typical chromatogram is shown in Fig. 1.

Trimedoxime Bromide (*4*)—Fifty microliters of the cartridge solution was added to 14.0 ml of deionized water; 100 μl of this dilution was added to 10.0 ml of 0.05 *N* NaOH and the resulting mixture was scanned between 400 and 300 nm. The absorbance at the peak near 346 nm was compared to that of a standard solution and the trimedoxime concentration was determined. In a series of samples, a blank and a standard solution were run at the beginning and end of the series. In larger groups, a standard solution was also interspersed between every 8–10 samples. The standard solution was 20 mg of trimedoxime/ml, 0.05% methylparaben, and 0.005% propylparaben in 10^{-3} *M* HCl. This solution was filtered through a 0.22 μm filter and stored at 5°.

RESULTS

The cartridges stored at 5° were assumed to yield baseline values. Over the period of the study there were no changes in the concentrations of trimedoxime, atropine, and benactyzine at 5°. The solutions from these cartridges were clear and faintly yellow, a color characteristic of trimedoxime solutions. No statistically significant differences between the glass and plastic cartridges were demonstrated at this temperature for any of

[3] Homotropine hydrobromide USP, 0.5 ng/ml in 10^{-3} *N* hydrochloric acid.

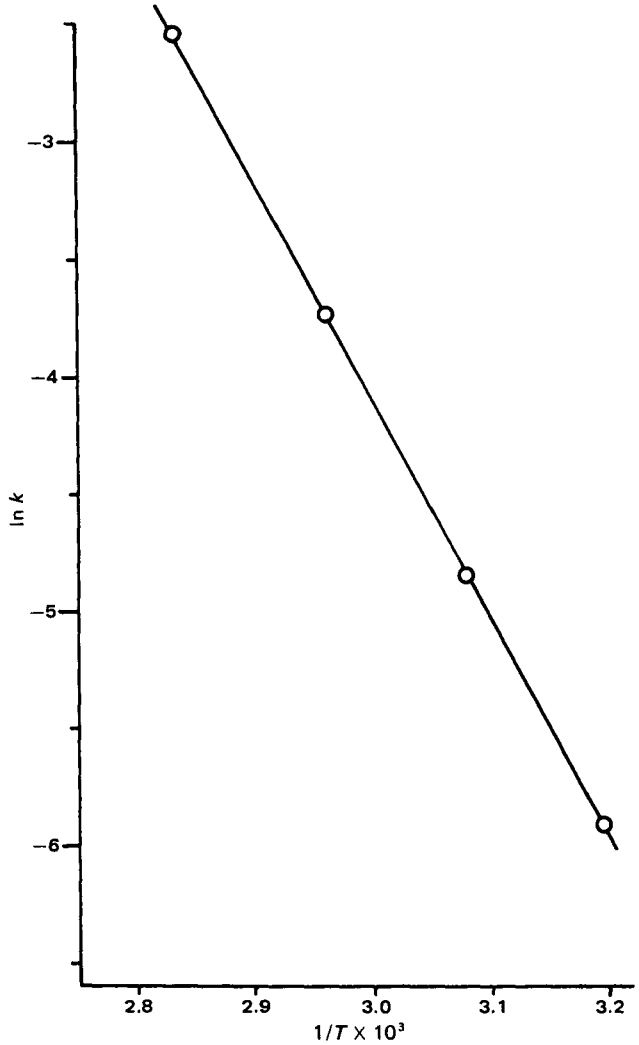

Figure 4—*Influence of temperature on the degradation rates of benactyzine.*

the factors studied except net weight. The average weight of the ejected contents for the plastic cartridge was 14 mg less than that for the glass cartridge at 5°.

The solutions stored at elevated temperatures in both the glass and the plastic cartridges remained clear throughout the study. Solutions in glass cartridges developed a trace of yellow color at 80°. Solutions in the plastic cartridge developed color much faster. At the end of each storage period the solutions were bright yellow at 80°, moderately yellow at 65°, light yellow at 52°, and at 40° contained a trace of yellow. One sample at 40° was very dark yellow, and had a pH of 2.5, (~0.2 units lower than expected).

No physical change was observed in glass cartridges throughout the study. In several plastic cartridges stored at 80°, the pressure generated was sufficient to move the rubber plunger toward the open end of the cartridge. The plastic cartridges became stained with a narrow brown ring at the interface of the plunger and the solution. In the cartridges where the plunger had moved, the stain was diffused over the path of the plunger movement. The stain was apparent in less than 1 week at 80 and 65°, in ~1 month at 52°, and in ~4 months at 40°.

No significant differences were demonstrated when the cartridges were stored in a vertical position (either end up) at 65° when compared with those stored in a horizontal position.

Reaction velocities of the various stability-related factors are influenced by temperature. This is expressed by the Arrhenius equation in its integrated form:

$$\ln k = A - E/RT \qquad \text{(Eq. 1)}$$

where k is the specific rate constant; E is the energy of activation; R is the gas constant (1.987 cal/deg mole); T is the absolute temperature; and A is a frequency factor.

The data were used to determine the best value of k at each tempera-

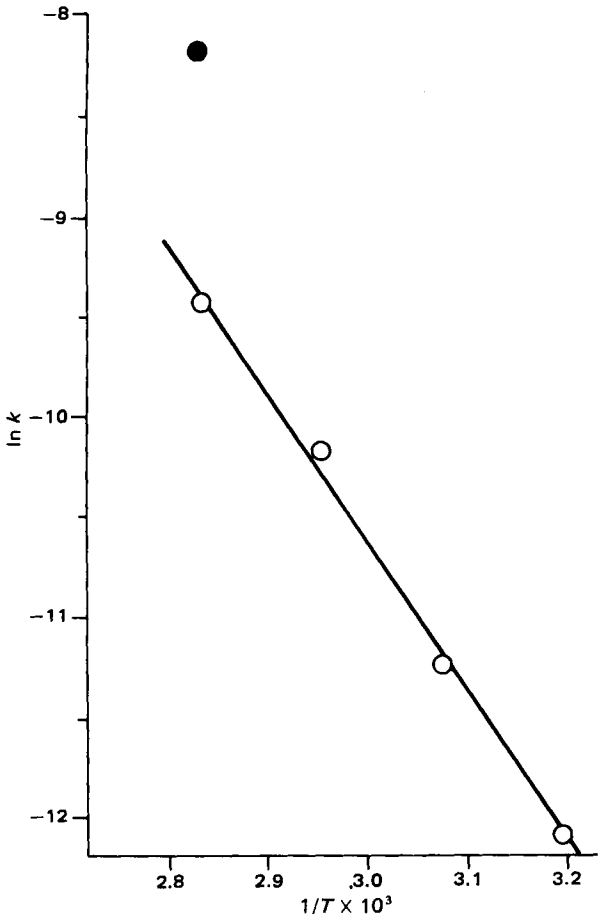

Figure 5—*Influence of temperature on the degradation rates of trimedoxime. The value for plastic cartridges at 80° (●) deviates significantly from the Arrhenius plot.*

ture. The best line of ln k *versus* $1/T$ was fitted by the least-squares method and the intercept (A) and the slope ($-E/R$) were determined.

Weight Loss—Loss of water from the solution in the cartridges, presumably occurring through the rubber closures and the walls of the plastic cartridge, would be reflected in a change in volume. Since the loss was small, measuring the change in weight was considered a more sensitive method of determining the loss than measuring the volume differences. The rate of weight loss in the glass and plastic cartridges was determined at each temperature, using the equation:

$$w = w_0 - kt \qquad \text{(Eq. 2)}$$

where w_0 is the weight in milligrams at the zero intercept, k is the rate of weight loss in milligrams per day[4]; and t is the time in days.

The effect of temperature on weight loss was significantly different between the two types of cartridges. The activation energies for the weight loss in the glass and plastic containers were 14.1 ± 1.6 (SE) and 20.1 ± 0.9 (SE) kcal, respectively. The Arrhenius plot for the glass and plastic cartridges is shown in Fig. 2.

Change in pH—The pH of the solutions in the cartridges decreased with storage time and can be expressed by the equation:

$$\text{pH} = \text{pH}_0 - kt \qquad \text{(Eq. 3)}$$

where pH_0 is the pH at time zero; k is in pH units per day; and t is time in days.

The rate of decrease in pH was significantly different between the glass and plastic cartridges at 80°. At this temperature the rate was lower for the glass cartridge than would be predicted from the other three temperature points, and higher for the plastic cartridge. No significant pH differences between glass and plastic cartridges were found at the lower temperatures. The best values for k are plotted in Fig. 3 and are expressed by the equation:

[4] The unit for k is generally expressed in concentration rather than weight. The authors feel that by expressing water loss in weight, rather than concentration, the data would be more meaningful.

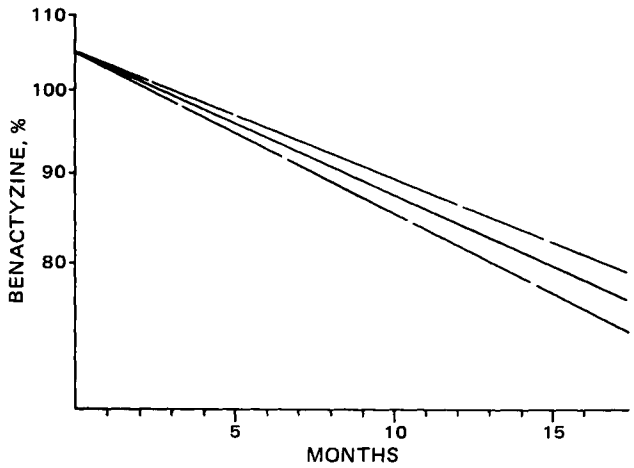

Figure 6—*Predicted disappearance of benactyzine hydrochloride at 25°. The solid line is the predicted thermal degradation rate of benactyzine in the injector at 105% fill. The dashed lines encompass the 95% confidence limits of the predicted rate.*

$$\ln k = 16.1455 - 14{,}300/RT \qquad \text{(Eq. 4)}$$

where the units for k are pH units/day. The standard error for the energy of activation is 690 calories.

Active Ingredients—*Benactyzine Hydrochloride*—The degradation of benactyzine in the mixture can be described adequately by the first-order rate equation:

$$\ln C = \ln C_0 - kt \qquad \text{(Eq. 5)}$$

where C is in milligrams per milliliter, C_0 is concentration at zero time, and t is time in days. There were no statistically significant differences between the glass and plastic cartridges for either C_0 or k.

The effect of temperature on the degradation rate is illustrated in Fig. 4, where the equation is expressed by:

$$\ln k = 23.7461 - 18{,}460/RT \qquad \text{(Eq. 6)}$$

where the unit of k is day^{-1} and the standard error for the activation energy is 150 calories.

Atropine Sulfate—No statistically significant disappearance of atropine sulfate in either glass or plastic cartridges could be demonstrated at any temperature during the term of this study.

Trimedoxime Bromide—The decrease in trimedoxime concentration is expressed by the zero-order equation:

$$C = C_0 - kt \qquad \text{(Eq. 7)}$$

where C is in moles per liter, C_0 is the concentration at zero time, k is in milligrams per day, and t is time in days.

A significant difference between the k values for glass and plastic

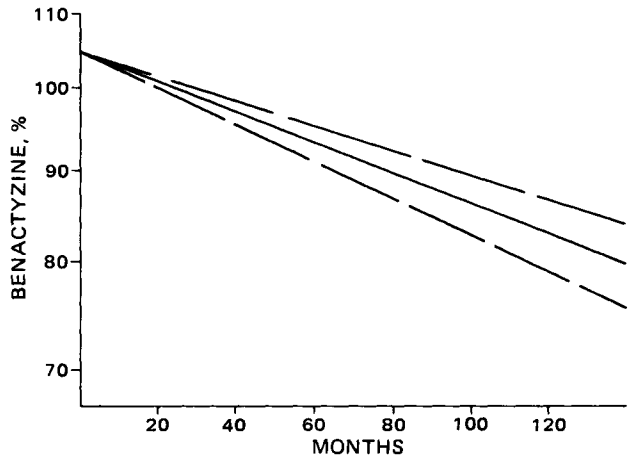

Figure 7—*Predicted disappearance of benactyzine hydrochloride at 5°. The solid line is the predicted thermal degradation rate of benactyzine in the injector at 105% fill. The dashed lines encompass the 95% confidence limits of the predicted rate.*

Table I—Predicted Shelf Life of Benactyzine in Multicomponent Formulation

Temperature	90% Shelf Life	75% Shelf Life
5°	4.5 years	12.3 years
15°	1.4 years	3.9 years
25°	5.9 months	1.3 years
40°	1.3 months	3.6 months
60°	0.2 months	0.6 months

cartridges was found only at 80°. No significant differences were found with regard to k or C_0 at other temperatures. The data for plastic cartridges at 80° were excluded in calculating the regression equation in Fig. 5. The line is expressed by

$$\ln k = 18.0100 - 14{,}900/RT \qquad \text{(Eq. 8)}$$

where k is in moles per liter-day. The standard error for the activation energy is 880 calories.

DISCUSSION

Glass cartridges were found to be more suitable than plastic as containers for trimedoxime, atropine, and benactyzine formulations. Benactyzine is the least stable of the active ingredients in the antidote formulation. Results of this study show that benactyzine degrades ~20% after 1 year at 25° in either plastic or glass. The usefulness of the injector could be prolonged by storage at 5°, where the predicted decrease in benactyzine is 10% after 5 years. Figures 6 and 7 illustrate the enhanced shelf life of benactyzine when filled at 105% of label and stored at 25 or 5°. Predicted shelf life at various temperatures is presented in Table I.

The trimedoxime in the injector is very stable; about 1.4% degradation would occur after 1 year at 25°. Solutions of trimedoxime can exist in equilibrium with its hydrolysis products (7, 8). The degradation rate of trimedoxime in plastic cartridges at 80° was faster then expected. The unusual drop in pH at 80° (Fig. 3), greater than expected based on temperature studies, could shift the equilibrium of trimedoxime and consequently account for the increased degradation rate in plastic.

Atropine sulfate in the medication is quite stable. According to kinetic studies of atropine in solution at pH 2.8, its half-life would be about 200 years at 25° and about 2 years at 80° (2, 3).

The pH values in glass were homogeneous at all temperatures. There was some heterogeneity of pH in the plastic cartridge; *i.e.*, 2 of 23 samples stored at 5° had a pH of about 2.95; one sample at 80° had a pH of 3.01, 0.5 units more than expected. A sample at 40° had a pH of 2.51, 0.2 units lower than expected. The decrease in pH with storage time was consistent with temperatures of 65° and below. At 80°, the decrease in pH was slower than expected, suggesting abstraction of hydrogen ion by the rubber in the cartridge. In the plastic cartridge, the pH decreased at a considerably faster rate than expected; this observation suggests a reaction caused by some material in plastic at this temperature. At 25° the drop in pH, probably due to the formation of benzilic acid, is predicted to be less than 0.15 units after 1 year of storage.

Vapor transmission from the cartridges at ambient temperature is low; it is estimated that water loss would be about 1%/year for the glass cartridge and about 2%/year for the plastic cartridge at 25°.

Factors Influencing the Apparent Protein Binding of Quinidine

THEODOR W. GUENTERT * and SVEIN ØIE ‡

Received September 26, 1980, from the *Department of Pharmacy, School of Pharmacy, University of California at San Francisco, Medical Center, San Francisco, CA 94143.* Accepted for publication July 8, 1981.

*Present address: Pharmazeutisches Institut, Universitaet Basel, Totengaesslein 3, CH-4051 Basel, Switzerland.

Abstract □ Various factors influencing the apparent protein binding of quinidine were examined. Different binding values in rabbit plasma were obtained by equilibrium dialysis techniques employing three commonly used buffers. Binding values comparable to those found by ultrafiltration were achieved after dialysis against isotonic phosphate buffer for ~4 hr. Dialysis beyond 8 hr gave an increased free fraction with time. The reported effect of *in vitro* added heparin on plasma protein binding could be prevented by reducing the final concentration in blood from 20 to 5 U/ml, a concentration still sufficient to prevent clotting of the blood sample. Daily freezing and thawing of plasma samples over 1 week did not alter the binding of quinidine. The samples were stable for at least 2 months at −20°.

Keyphrases □ Binding, protein—quinidine, factors influencing binding, rabbit plasma □ Quinidine—factors influencing protein binding, rabbit plasma □ Plasma protein binding—quinidine, factors influencing binding, rabbits

A wide range of protein binding values for quinidine have been reported. Mean unbound fractions of 0.10–0.29 were observed in normal volunteers (1–5), while mean values of 0.19–0.42 were found for patients with cirrhosis (2, 3). Although interindividual differences in binding properties may contribute significantly to the variability in these results, differences in the blood collection method and in the binding determination could be important contributing factors. Ultrafiltration and equilibrium dialysis have been used previously for quinidine binding determinations. In equilibrium dialysis, various investigators have used different temperatures, equilibrium

Keyphrases □ Binding, protein—quinidine, factors influencing binding, rabbit plasma □ Quinidine—factors influencing protein binding, rabbit plasma □ Plasma protein binding—quinidine, factors influencing binding, rabbits

A wide range of protein binding values for quinidine have been reported. Mean unbound fractions of 0.10–0.29 were observed in normal volunteers (1–5), while mean values of 0.19–0.42 were found for patients with cirrhosis (2, 3). Although interindividual differences in binding properties may contribute significantly to the variability in these results, differences in the blood collection method and in the binding determination could be important contributing factors. Ultrafiltration and equilibrium dialysis have been used previously for quinidine binding determinations. In equilibrium dialysis, various investigators have used different temperatures, equilibrium

0022-3549/82/0300-0325$01.00/0

times, and buffers in their studies (1, 4, 6–9). A significant influence of the ionic composition of the buffer on the extent of apparent protein binding determined by dialysis has been found (10, 11). Woo and Greenblatt (9) demonstrated higher binding at room temperature than at body temperature which could explain differences in results obtained by different investigators. However, no information is available on the time course of equilibrium or whether the dialysis time affects the quinidine binding. Recent studies suggest that the addition of heparin to blood samples may alter the plasma protein binding of quinidine (11).

To determine the influence of the dialysis medium and the equilibrium time on the apparent protein binding of quinidine, the protein binding in rabbit plasma was measured by dialyzing the plasma against various buffers. The influence of heparin *in vitro* at two different concentration levels and *in vivo* was established. Furthermore, the stability of a spiked rabbit plasma sample under conditions of repeated freezing and thawing was tested over 2 months.

EXPERIMENTAL

Assay—Quinidine concentrations in plasma and buffer from equilibrium dialysis were determined using a modification of a previously reported specific high-pressure liquid chromatography (HPLC) method (12). A 50-μl sample of plasma or a 200-μl sample of buffer was mixed with 200 μl (plasma) or 100 μl (buffer) of methanol containing 193 ng of hydroquinine[1]/ml as internal standard. Plasma samples were centrifuged in a microhematocrit centrifuge[2] at ~12,000×*g*. A 20-μl aliquot of the sample was then injected onto a C_{18} μBondapak column[3] of 30-cm length and 3.9-mm bore, connected to an HPLC pump[4]. The mobile phase consisted of methanol[5]–water–phosphoric acid[5] 85% (27.0:72.95:0.05) at a flow rate of 2 ml/min. Quantitation was achieved by means of fluorescence detection[6] with excitation at 245 nm and emission at 440 nm (cutoff filter). Standard curves were prepared daily using peak height ratios of various quinidine[7] concentrations in plasma or buffer prepared as above.

Equilibrium Dialysis—Aliquots (700 μl) of plasma or serum were dialyzed against 700 μl of buffer in a 1-ml dialysis cell[8]. A dialysis membrane[9] with an average pore radius of 24 Å, pretreated by soaking in distilled water (10 min), ethanol (15 min), and buffer (120 min), was used in these studies. The cells were incubated in a shaker bath[10] at 37° during the dialysis. At the end of the planned equilibrium time (6 hr ± 20 min, when not otherwise stated) the plasma or serum and buffer were removed from the half-cells and assayed for quinidine within 24 hr (stored at 4° until assayed). The ratio of quinidine concentrations in the buffer to the plasma or serum was taken as the free fraction of drug in the biological sample.

A blank serum or plasma sample was dialyzed in each binding experiment to assess the presence of endogenous or exogenous compounds that might interfere with the quinidine measurement.

Ultrafiltration—Protein determination using ultrafiltration was carried out with 3 ml of plasma or serum in a stirred cell[11] using an ultrafiltration filter with a molecular weight cutoff of 25,000[12]. The filtration was accomplished using a positive pressure of 3.5 atm with a gas mixture of 1.4% CO_2 in nitrogen at 37° in an incubator. The filtrate was collected in a polyethylene tubing[13]. Volumes of 100-μl aliquots were sampled from the tubing and assayed for quinidine immediately. Filtration was continued until subsequent aliquots of filtrate contained comparable amounts of drug.

Table I—Influence of Storage with Frequent Freezing and Thawing on Plasma Protein Binding of Quinidine

Sample	Free Fraction of Drug, Day 0	Day 2	Day 4	Day 7	Day 60
1	0.20	0.21	0.21	0.17	0.17
2	0.21	0.23	0.22	0.21	0.17
3	0.19	0.21	0.22	0.21	0.20
4	0.18	0.21	0.22	0.18	—
Mean	0.20	0.22	0.22	0.19	0.18
CV[a]	6.6	4.7	2.3	10.7	9.6

[a] Coefficient of variation in percent.

Sample Stability—To determine the influence of storage at −20° with frequent freezing and thawing on the protein binding, a large sample of rabbit plasma was spiked with quinidine[7] at a concentration of 2 μg/ml. A blank sample was kept separate but treated identically to the spiked portion. The samples were stored frozen with daily thawing and freezing for the first week. Protein binding was determined in 700-μl aliquots (quadruplicate) of the spiked sample by equilibrium dialysis [Krebs–Ringer bicarbonate buffer (14)] immediately after drawing the blood from the animal and again after 2, 4, and 7 days. An additional determination was made after 2 months.

Influence of Buffer Composition and Equilibration Time—The dependence of the apparent protein binding value determined by equilibrium dialysis on buffer composition and equilibrium time was evaluated in three experiments. A large sample of freshly drawn pooled rabbit plasma (stabilized with 5 U of heparin/ml) was spiked with 1 μg of quinidine/ml. Aliquots (700 μl) were dialyzed using 12 separate cells for each buffer. The cells were removed after 1, 2 (duplicates), 3, 4, 6 (duplicates), 8, 12, 18, and 24 (duplicates) hr and analyzed by HPLC. The buffers used were Krebs–Ringer bicarbonate and phosphate buffer pH 7.4, both prepared according to Umbreit *et al.* (14) and isotonic phosphate buffer pH 7.4 (0.107 *M* Na_2HPO_4, 0.024 *M* KH_2PO_4 in double-distilled water). The samples containing Krebs–Ringer bicarbonate solutions were dialyzed in a 5% CO_2–95% O_2 atmosphere, the other in a normal atmosphere.

Quinidine binding in the sample was also determined by ultrafiltration ($n = 6$). The first 200 μl of ultrafiltrate was discarded and the unbound concentration was determined in the subsequent aliquots. The concentration in these subsequent aliquots varied less than 2%.

Influence of Heparin—Blank rabbit serum was spiked with quinidine to a concentration of 0.4 μg/ml and with heparin[14] to final concentrations of 0, 5, and 20 U/ml. Protein binding was determined in triplicate by equilibrium dialysis and the values found in the heparinized samples were compared to those found in the nonheparinized samples (Student *t* test).

To test for an indirect effect of heparin *in vivo*, 450 U/kg was injected into a rabbit. Blood samples (3 ml) were collected immediately before injection and after 5, 10, 30, 60, and 180 min. Only the 0- and 180-min samples coagulated within 2 hr and allowed collection of serum; in the other samples the clear supernate after centrifugation was taken for analysis. All samples collected were spiked with 1 μg of quinidine/ml and protein binding was determined using equilibrium dialysis (duplicates) with the Krebs–Ringer bicarbonate buffer.

Concentration Dependence—Rabbit serum was spiked with quinidine at concentration of 250, 750, 1875, and 3000 ng/ml. Protein binding was determined in the samples (triplicates) using equilibrium dialysis with the Krebs–Ringer bicarbonate buffer.

RESULTS AND DISCUSSION

The assay used for quinidine measurements was fast and precise. The number of samples that can be analyzed in 1 day is only limited by the retention time of the compounds on the HPLC column (quinidine, 3.6 min; hydroquinine, 6.0 min). Because no extraction step was involved in the sample preparation there was little variability in repeated determinations of the same sample. For quinidine in plasma or serum the coefficient of variation (*CV*) in duplicated determinations was between 0.18 and 3.9% ($n = 6$) at 0.5 μg/ml and between 0.76 and 1.2% ($n = 2$) at

1 μg/ml. Similar low variability was also observed in duplicate determinations of buffer samples: 0.94–6.3% (n = 4) at 50 ng/ml and 1.7–4.3% (n = 5) at 100 ng/ml. Standard curves were prepared daily by spiking blank plasma or water with various amounts of quinidine. The curves were linear with a CV for concentration-normalized peak height ratios of 4.5–7.5% in plasma and 2.0–5.8% in water.

A great deal of attention has been directed to the stability of biological samples when protein binding is to be measured. Denaturation of a major binding component under the storage conditions could influence the apparent free fraction of drug in the samples. Because freezing of biological fluids collected in pharmacokinetic studies is the most common form of storage, the influence of frequent freezing and thawing on the protein binding of quinidine in rabbit plasma was determined. Table I summarizes the result of a 2-month stability test. There was no significant change or trend in the free fraction of quinidine over a 1-week period with daily freezing and thawing of the sample, and no difference in the extent of binding could be detected after storage of the plasma in the freezer over a 2-month period. These results are in agreement with other findings (9).

The apparent free fraction of quinidine in a test sample was compared using equilibrium dialysis with three different buffers. Because little information exists regarding the time course of the equilibration process of quinidine, studies for each buffer were established. Samples equilibrated for 2, 6, and 24 hr were run in duplicate to allow estimation of the variability in the protein binding determination. Ultrafiltration of the same spiked plasma sample provided an independent estimate of the unbound drug concentration and yielded a value for the free fraction of 0.11.

In the dialysis experiments (Fig. 1), no clear equilibrium was reached for any one of the buffers even after 18–24 hr of dialysis. The values of the free fraction measured at these times exceeded the value of 0.11 determined by ultrafiltration and the samples showed turbidity. However, there appeared to be a temporary plateau discernible in the binding

Table II—Unbound Fraction of Quinidine in Plasma at Various Concentration Levels

Total Quinidine Concentration, ng/ml	Unbound Fraction[a]
250	0.11 (2.8%)
750	0.14 (5.1%)
1875	0.11 (14%)
3000	0.13 (3.2%)

[a] Mean (coefficient of variation).

curves between ~4 and 8 hr with unbound fraction similar to those obtained by ultrafiltration. Therefore, it can be concluded that equilibrium between the free quinidine concentration in plasma and in buffer was established after 4–6 hr, and that a second event causing displacement of drug from the protein or a particularly noticeable reduction of the binding capacity took place when dialysis extended beyond 8 hr. A second, much higher plateau in the equilibration curve was seemingly approached after 18–24 hr.

To further verify the use of the plateau at 4–8 hr as being representative of quinidine binding in plasma, the equilibrium time experiment was repeated using Krebs–Ringer phosphate buffer. However, in this instance the buffer side and not the plasma side was spiked. The result is shown in Fig. 1. After an initial rapid decline in the apparent drug free fraction, a trough value was attained after 8 hr at which time the apparent free fraction increased again, identically to the experiment using spiked plasma samples. The same plateau values were not attained as when the plasma side was spiked and only approached after 8 hr. This is readily explained by the general phenomenon that spiked buffer samples approach equilibrium at a slower rate than spiked plasma samples (15).

These experiments strongly indicate that under the given conditions the equilibrium is reached after 4–6 hr, and beyond 8 hr secondary effects occur that decrease the binding. Special care should be taken when using extended equilibrium times, particularly if the buffer side is spiked when assessing the binding. For example, in a study of demethylchlorimipramine protein binding (16), no apparent equilibrium was found even after 19 hr of dialysis when spiking the buffer side. However, a trough level was observed after 6 hr, after which the apparent free fraction started to increase again. It is possible that the 6-hr trough levels better represent the true unbound levels than the 19-hr dialysis values.

The reason for this phenomenon is not clear. Due to the increasing turbidity of the buffer samples, it is felt that microbiological growth took place, causing either drug displacement or binding protein degradation. This phenomenon is being investigated further.

Krebs–Ringer bicarbonate and Krebs–Ringer phosphate buffers gave higher unbound fraction values than isotonic phosphate buffer after 6 hr. This is consistent with previous findings (10, 11) that chloride displaces quinidine from plasma proteins. The Krebs–Ringer buffers contain chloride (128 mmoles/liter) while isotonic phosphate buffer does not. Because the Krebs–Ringer buffers contain a chloride concentration close to *in vivo* plasma levels, the use of these buffers would be expected to give values close to the *in vivo* unbound levels. However, the ultrafiltration values are closer to the values obtained by use of the isotonic phosphate buffer and therefore do not confirm this assumption.

Figure 1 shows that the increase in the apparent free fraction beyond 8 hr is less pronounced using the isotonic phosphate buffer. For practical reasons it may be more advantageous to use the isotonic phosphate buffer in binding determinations by equilibrium dialysis rather than Krebs–Ringer buffers, although the latter should be the buffer of choice on a theoretical basis.

Heparin is widely used clinically as an anticoagulant, *in vitro* for plasma collection methods, and *in vivo* for blood exchange techniques and for patients undergoing cardiopulmonary bypass or cardiac catheterization. It also has been shown to influence the protein binding or binding determination of various drugs including quinidine (1, 17, 18). The binding of quinidine to serum proteins was unaffected by a heparin concentration of 5 U/ml ($p > 0.10$) but significantly decreased in the presence of 20 U of heparin/ml ($p < 0.05$). Because 5 U of heparin/ml is sufficient to prevent coagulation *in vitro*, the influence of anticoagulant on protein binding could be prevented merely by reducing its concentration.

The effect of injected heparin was immediate with the strongest increase in the free fraction of drug in the first sample (collected at 5 min) and an exponential decline thereafter. Even after 3 hr, the binding of quinidine to proteins had not yet reached the pre-experimental value.

Although the amount of heparin injected may not be large compared to therapeutically administered doses, it is much more than would reach the general circulation by using indwelling heparinized catheters. The effect of lower amounts should be carefully assessed prior to studies using such catheters not only if protein binding determinations are planned, but in kinetic studies in general. This is important because altered protein binding can have a profound effect on kinetic parameters such as clearance (19) and apparent volume of distribution (20) or the interpretation of such data.

An earlier report (12) raised the possibility that protein binding of quinidine, at least in rabbits, might be capacity limited. However, Table II shows that there is no such effect discernible over the concentration range of 250–3000 ng/ml. Similarly, a previous study (9) found no concentration-dependence in the binding of quinidine to human serum over the clinically relevant range.

Antineoplastic Effects of N^6-(Δ^2-Isopentenyl)adenosine against L-1210 Mouse Lymphocytic Leukemic Cells Using a Polymeric Delivery System

YUNIK CHANG ˣ **and BRUCE HACKER**

Received May 27, 1981, from the *Departments of Pharmaceutics and Pharmacology, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication July 24, 1981.

Abstract □ N^6-(Δ^2-Isopentenyl)adenosine (I), a nucleoside previously shown to be cytotoxic against several types of tumor cells, was impregnated in silicone polymer monolithic disc devices for release *in vitro* against lymphocytic mouse leukemia cells. Plotting the cumulative amount of N^6-(Δ^2-isopentenyl)adenosine released per unit area of the device *versus* the square root of time revealed a linear relationship. However, the higher loading dose tended to rapidly release any drug deposited on the polymer surface. The optimum loading dose of the device for the most effective antileukemic activity in 24 hr was calculated based on a plot of the release rate *versus* the square root of an initial loading dose. The silicone polymer–I delivery system enabled a sustained and controllable release of additional agent. It was thus possible to achieve virtually total inhibition of leukemic cell replication using the polymeric delivery system. Increased concentrations of I, without the use of the polymeric system, resulted in maximum 24 hr inhibition of only ~81%, followed by a decline in overall antileukemic activity. It is possible to achieve a more predictable release rate of N^6-(Δ^2-isopentenyl)adenosine and corresponding antileukemic activity using a polymeric delivery system against L-1210 mouse leukemic cells *in vitro*. The relative data indicate the ED_{50} concentrations to be considerably less using the polymeric delivery system.

Keyphrases □ Delivery systems—impregnated silicone polymer, N^6-(Δ^2-isopentenyl)adenosine □ Release rates—impregnated silicone polymer delivery system, N^6-(Δ^2-isopentenyl)adenosine □ N^6-(Δ^2-Isopentenyl)adenosine—antineoplastic, improved delivery using impregnated silicone polymer

N^6-(Δ^2-Isopentenyl)adenosine (I), a nucleoside previously shown to be both an inhibitor and cytotoxic to human leukemic myeloblast and sarcoma-180 cells (1), was prepared entrapped in the polymeric delivery form of a silicone polymer[1] monolithic disk to evaluate its relative antineoplastic properties.

Earlier studies demonstrated that I, found also in several isoaccepting species of tRNA, can interfere with the transport of unmodified nucleosides through the cytoplasmic membrane of mouse embryo cells at the level of the transmembrane translocation function (2). This membrane transport inhibition is believed to be responsible for its ability to alter RNA synthesis in phytohemagglutinin-stimulated mouse spleen lymphocytes as well as to be immunosuppressive in nature (3). In the latter context, it was possible to prepare an antibody with serologic specificity for I (4). Previous studies (5) demonstrated that L-1210 mouse leukemic cells possess the necessary

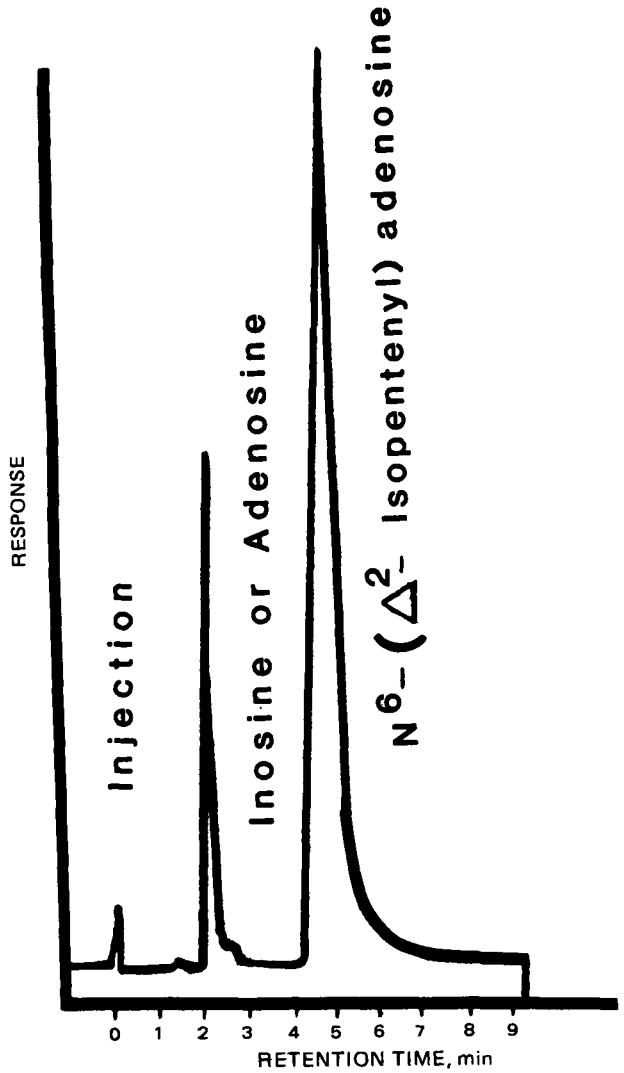

Figure 1—*High-pressure liquid chromatogram of a sample prepared by adding inosine or adenosine to the cultured sample containing 182 μg of I/ml.*

enzyme systems to phosphorylate I to the nucleotide level *in vitro*. It is not yet certain whether this biotransformation is a prerequisite for its antileukemic property.

The chemical reactions, biosynthesis, and metabolism of I, as well as its structural and functional role with respect to tRNA has been extensively reviewed (6). The importance of the intact allylic double bond moiety of the side chain of the purine, in addition to the ribose group of the nucleoside I, is generally recognized as being essential for antileukemic activity.

Table I—Preliminary Determination of Optimum Concentration of N^6-(Δ^2-Isopentenyl)adenosine (without Silicone Polymer) Required to Inhibit the Growth of Cultured L-1210 Mouse Leukemic Cells

Experimental Series[a]	Time after Addition of I to Culture Medium: Concentration of I in Culture Medium[b], μg/ml (4 hr)	Change in Total Cell Number[c], % (4 hr)	Concentration of I in Culture Medium, μg/ml (24 hr)	Change in Total Cell Number, % (24 hr)
A (control)	0	+24.3	0	+141.3
B (182 μg I/ml)	143	−25.1	140	−67.2
C (320 μg I/ml)	253	−61.3	250	−81.2

[a] Each T-flask contained 5 ml of growth medium containing RPMI 1640 plus 10% FCS, L-1210 cells and initial concentrations of I as indicated; cultures were conducted in triplicate. [b] Performed using HPLC. [c] Initial numbers of cells in control and treated cultures were $2 \times 10^5 \pm 6\%$ per ml of growth medium.

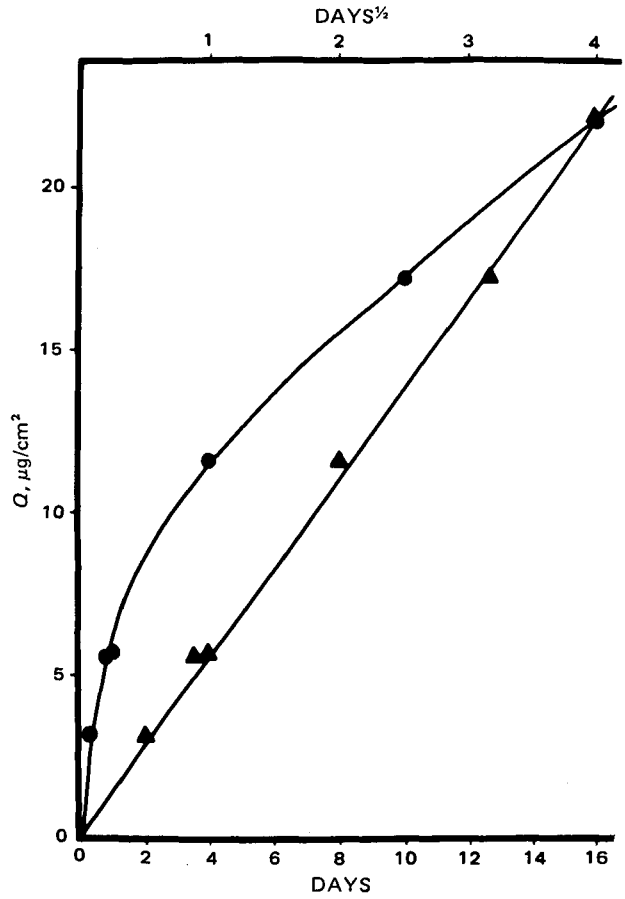

Figure 2—*Release of I in phosphate buffered saline solution from silicone polymer sheet containing 3% (w/w) I (points indicate the average of two experiments). Key:* ●, Q versus t; *and* ▲, Q versus $t^{1/2}$.

Although I has antineoplastic and cytotoxic effects against leukemic cells when administered to humans, it is known to be susceptible to enzyme degradation. Chheda *et al.* (7) showed that the biological half-life of I after intravenous administration was 4 hr. Other results (8) indicated that adenosine deaminase catalyzes conversion of I to inosine. It was also reported (9) that elevated adenosine deaminase activity in human blood significantly facilitates I degradation.

The present study developed a polymeric delivery system capable of releasing the optimum amount of I in a given interval of time required for most effective antileukemic activity.

EXPERIMENTAL

Preparation of N^6-(Δ^2-Isopentenyl)adenosine—I was prepared according to procedures described previously (2, 4, 5). Samples for analytical comparison using enzymatic and chromatographic techniques were described earlier (5).

Isolation and Propagation of L-1210 Mouse Leukemic Cells—Lymphocytic mouse leukemias were first described by Law *et al.* (10). Drug-sensitive and certain resistant sublines were propagated and cryopreserved (11) for *in vivo* and cell culture experiments. Parent lines were initially provided by other institutes[2,3]. Parent L-1210 mouse leukemic cells were grown to various densities as suspension cultures in tissue

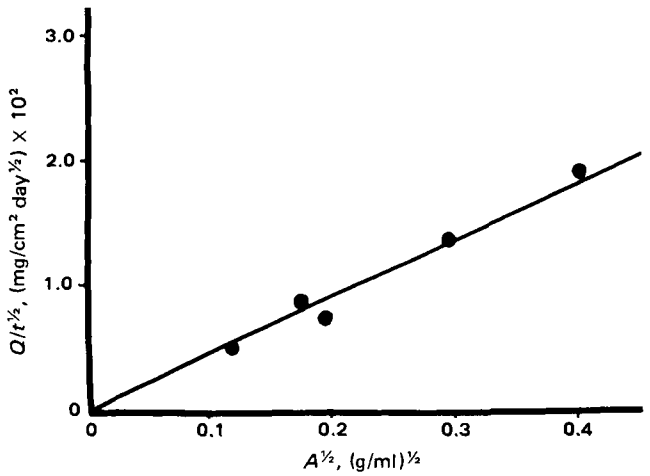

Figure 3—*Effect of the square root loading dose ($A^{1/2}$) in the silicone polymer sheet on the release rate of I ($Q/t^{1/2}$).*

culture flasks[4] containing 5.0 ml of growth medium[5]. Incubations were done at 37° under controlled conditions using a digital incubator[6] containing a 5% carbon dioxide–air atmosphere with a 98% relative humidity. Cells were visually monitored daily to assess general growth characteristics and to ensure the absence of contaminants using an inverted microscope–video system designed and interfaced in this laboratory and described elsewhere (12). Cell number and viability values were determined using Turk's solution and trypan blue exclusion methods, respectively, in hemocytometer cells (11).

Preparation of Isopentenyl Adenosine–Silicone Polymer Monolithic Sheets—N^6-(Δ^2-Isopentenyl)adenosine–silicone polymer sheets were prepared by mixing the required amounts of I into the silicone polymer and polymerizing with catalyst[7]. The mixture was then spread in a thin film on a glass plate and left overnight before the release study. The concentration of I in the polymeric delivery devices was calculated based on the weight-ratio of the drug and polymer used. Sheets of I–silicone for the cell culture media were sterilized using ethylene oxide sterilization[8]. Before use, each preparation was left at room temperature at atmospheric conditions overnight to eliminate residual ethylene oxide effects on the culture medium. Preliminary experiments indicated that equivalent quantities of the silicone polymer without I were not cytotoxic to normal growth of L-1210 cells.

Determination of Antineoplastic Activity of I against L-1210 Lymphocytic Leukemic Cells—Mouse L-1210 leukemic cells were grown in supplemented growth medium at several initial cell concentrations. Aliquots were removed using aseptic techniques for the determinations of cell number, and for centrifugation–filtration to obtain filtrates for assessing I concentration by high-pressure liquid chromatography (HPLC). Cell numbers in each culture flask were determined initially and after the introduction of I–silicone preparations or sterile-filtered solutions of I. These solutions were prepared by dissolving various quantities of solid I in 0.1–0.5-ml volumes of growth medium, and sterile-filtered using individual microunits[9]. After introducing small-volume aliquots of I solutions or I–silicone, aliquots of cell suspensions were removed during continuous incubation conditions and subjected to centrifugation–filtration. The latter consisted of using a centrifugal microfilter device fitted with 0.2-μm regenerated cellulose filters[10] to centrifuge and filter cell suspensions to get a cell-free filtrate.

Determination of I Released from the Polymer Sheet—Polymer sheets of known sizes were suspended on a chrome wire in 100-ml portions of phosphate-buffered saline solution, pH 7.4. The solution was covered to minimize evaporation. Throughout the diffusion experiment, the solution was stirred constantly to reduce boundary-layer effects. Fresh portions of phosphate-buffered saline solution replaced spent medium at each sampling time. For the quantitation of I released, aliquots (30 μl) of the eluting solution were applied onto a high-pressure liquid chromatograph[11]. All determinations of release rates were performed at least in duplicate.

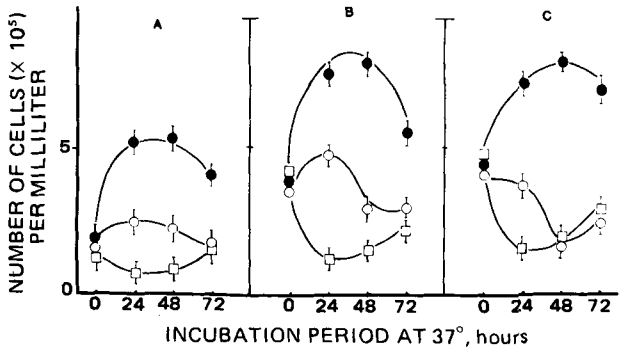

Figure 4—*The antileukemic effect of I using a silicone polymeric delivery system and varying numbers of cultured L-1210 mouse leukemia cells (A, 0.01 ml; B, 0.02 ml; C, 0.03 ml of 24-hr cell stock). Key: ●, control cultures; ○, I–silicone (5 mg I per 200-mg silicone polymer sheet); □, I (40 μg/ml).*

High-Pressure Liquid Chromatographic Procedure—The HPLC separation was performed using a reversed-phase column[12] with a flow rate of 1.0 ml/min using methanol[13]–water (3:2) as the mobile phase. Column effluent was pumped through a variable wavelength detector[14] monitored at 269 nm at ambient temperature. The detector sensitivity for phosphate buffer saline sample and cell culture sample was set at 0.05 and 0.5 aufs respectively. All quantitative determinations were made based on the standard curve obtained by plotting the peak height or electronic integrator response against the concentration of I.

RESULTS AND DISCUSSION

Monolithic sheet devices of I–silicone polymer were prepared that release I at the concentration range for >95% destruction of leukemic cells in the culture medium within 24 hr. The pattern of antileukemic activities of intact I and the I–silicone polymer system were compared.

High-Pressure Liquid Chromatography System—HPLC analysis of I in diffusion samples of phosphate buffered saline solution or cell culture medium was sensitive enough for the diffusion study and provided rapid, quantitative results. The results shown in Fig. 1 show a typical HPLC chromatogram of I in diffusion sample. Retention time of I was 5.0 min. Injection with several possible degradation products such as inosine, xanthine, or hypoxanthine showed no interference with I. These possible degradation products had retention times <5.0 min.

The released concentration of I in 100 ml of phosphate buffered saline solution was ~1–3 μg/ml. The standard curve for I was linear over the concentration range of 0.2–30 μg/ml. The correlation coefficient for the standard curve was 0.99 (n = 7). Standard solution injected at each time of diffusion sample assay showed no significant deviation from the standard curve during a set of experiments.

Since the total volume of cell culture medium was 5.0 ml, the concentration of I in the sample was high enough to change the detector sensitivity 0.5 aufs. The cell culture sample was filtered through cellulose filters before the injection on the HPLC column. The loss of I due to the filtration procedure was found to be negligible. The residual culture base peaks appeared close to the solvent.

Release of I from Silicone Polymer Matrix—Release time profiles of I were obtained with different loading doses on the same size silicone polymer sheets, each having an exposed surface area of 12.0 cm² and 0.35 ± 0.05 mm thick. All the experimental data were analyzed according to Eq. 1 (13, 14) on the basis of the diffusion controlled transport in a polymer matrix:

$$Q = [D(2A - C_s)C_s t]^{1/2} \qquad \text{(Eq. 1)}$$

where Q is the cumulative amount of drug released per unit area of devices (g/cm²) at time t, A is the amount of drug dispersed in a unit volume of device (g/cm³), D is the diffusivity of the drug in the matrix, and C_s is the solubility of the drug in the matrix phase. Based on Eq. 1, the cumulative amount of drug released (Q) from unit area should increase linearly with the square root of time.

C (92 mg I./470-mg silicone device; 16 cm^2)	325	−56.1	456	−98.1

[a] Each T-flask contained 5 ml of growth medium containing RPMI 1640 plus 10% FCS, L-1210 cells, and I–silicone polymer; cultures were conducted in duplicate. [b] Performed using HPLC. [c] Initial numbers of cells were $2 \times 10^5 \pm 5\%$ per ml of growth medium.

Figure 2 shows the plots of Q *versus* t and Q *versus* $t^{1/2}$ obtained from I–silicone sheet containing 3% I. The release rate of drug decreased with time. The linear relationship between Q and $t^{1/2}$ was observed as expected. All other systems showed this type of release pattern. However, at the high loading dose, the Q *versus* $t^{1/2}$ plot showed intercept values on Q axis. The intercept value increased with increased loading dose. This may be due to the rapid release of drug deposited on the surface of the devices. Such a rapid initial drug release was reported previously (15).

The prediction of optimum loading dose in silicone polymer devices to get the effective minimum concentration of I in culture medium was attempted. The slope of Q *versus* $t^{1/2}$ is defined as:

$$Q/t^{1/2} = [D(2A - C_s)C_s]^{1/2} \quad \text{(Eq. 2)}$$

In the case where $2A \gg C_s$, Eq. 2 may be written as:

$$Q/t^{1/2} = (2D\,C_s)^{1/2}\,A^{1/2} \quad \text{(Eq. 3)}$$

indicating the linear relationship of $Q/t^{1/2}$ *versus* $A^{1/2}$. Experimentally, this linear relationship was observed as shown in Fig. 3. The slope, $(2D\,C_s)^{1/2}$ was calculated as 0.0482 with a linear coefficient of 0.986. The ratio of the matrix device volume to its weight was 0.85 ± 0.05. By relating this factor to Fig. 3, the approximate loading dose for the optimum concentrations of I to be released from a device was calculated.

Antineoplastic Effects of I Against L-1210 Mouse Lymphocytic Leukemic Cells—In preliminary experiments to assess the effectiveness of the silicone polymeric delivery system for releasing low concentrations of I certain salient features were uncovered. The I–silicone device initially containing 5 mg of I gave approximately the same concentration after 24 hr as adding I directly; the I–silicone system showed ~38% inhibition compared to ~65% for the direct addition method. On the other hand, the cytotoxic effects of the I–silicone system against L-1210 cells was comparable within 48–72 hr. At 72 hr, at the highest concentration of cells used (Fig. 4C), the pattern was reversed, with the I–silicone system becoming the more inhibitory of the two. In these experiments (and those depicted in Tables I and II), inhibition of cells in fresh medium appeared to be more permanent or irreversible for cells in cultures where I was introduced in the form of I–silicone. In contrast, those cells surviving the direct addition of I allowed for the recovery of viable cells when propagated in fresh medium. This suggested that the exposure time of L-1210 cells to I, which is limited directly to the timing of its release, is important with respect to the permanency of inhibition. This conclusion was supported by data presented in Tables I and II where at higher I–silicone concentration (92 mg/470 mg), inhibition was virtually complete (98.1%). The few surviving cells were deformed, did not exclude trypan blue dye, and did not transfer successfully to fresh medium. This inhibition level was not achievable with any concentration of I using the direct addition method. Recently, the National Cancer Institute group concluded that the pharmacokinetics of drug release and exposure time is important for another adenosine analog, sangivamycin, against Sarcoma-180 (16).

These data suggest that although comparable concentrations of I may be achieved using direct addition, the I–silicone delivery technique appears to produce a timed, controllable, and sustained release which optimizes inhibition by I against L-1210 lymphocytic leukemia. The use of the polymeric delivery systems with other antitumor agents, especially where enzyme degradation or inactivation of the drug is possible, may offer a better means of administering labile drug agents.

Viscosity Change after Dilution with Solutions of Water–Oil–Water Emulsions and Solute Permeability Through the Oil Layer

MINORU TOMITA *, YOSHIRO ABE *, and TAMOTSU KONDO ‡x

Received November 6, 1980, from the **Department of Applied Chemistry, Faculty of Engineering, Keio University, Kohoku-ku, Yokohama, Japan 223* and the ‡*Faculty of Pharmaceutical Sciences, Science University of Tokyo, Shinjuku-ku, Tokyo, Japan 162.* Accepted for publication July 22, 1981.

Abstract □ A water-in-oil-in-water (W/O/W) multiple phase emulsion was prepared by a two-step emulsification procedure. The oil phase consisted of paraffin oil and sorbitan monooleate. The inner aqueous phase and the outer aqueous phase were 0.5% glucose solution and 3% polysorbate 80 solution, respectively. Viscosity measurements were carried out on the W/O/W emulsion after diluting it with a number of solutions. A given sequence for the solutes that would increase the emulsion viscosity after dilution was determined. This sequence was identical with that obtained with the solutes in an independent permeability experiment using a planar membrane composed of sorbitan monooleate alone. As a result, it was suggested that solutes as well as water can permeate the oil layer of vesicles of the emulsion to change the vesicle volume, thereby causing a change in the emulsion viscosity.

Keyphrases □ Emulsions—water–oil–water, viscosity change after dilution with solutions, permeability through the oil layer □ Permeability—solutes, through oil layer of water–oil–water emulsions □ Viscosity—changes, water–oil–water emulsions after dilution with solutions

Recently, a great deal of work has been done on preparation methods and applications of water-in-oil-in-water type multiple phase emulsions (denoted hereafter as W/O/W emulsions). Matsumoto *et al.* (1–3) reported a systematic procedure for the preparation of W/O/W emulsions. It was shown that an anticancer agent is localized at the cancer site for prolonged periods when administered in the form of a W/O/W emulsion, with the drug dissolved in inner aqueous phase (4–8). The application of W/O/W emulsions in foods (9) and cosmetics (10) also has been described.

In the application of W/O/W emulsions, it is necessary to estimate their stability experimentally. Viscosity has been claimed as a convenient method to determine stability (11). Although the viscosity of W/O/W emulsions is affected by a number of factors, the most important is the osmotic pressure gradient between the inner aqueous phase and the outer aqueous phase. This may produce changes in the volume of the inner aqueous phase due to the migration of water and/or solutes through the oil layer. In fact, the initial viscosity rise of some W/O/W emulsions on aging was explained by assuming the permeation of water containing a solute through the oil layer, from the outer aqueous phase to the inner aqueous phase due to the osmotic pressure gradient between the two phases (12). The present study will try to show that the viscosity change of W/O/W emulsions after dilution with solutions is interpreted more reasonably by assuming that solutes as well as water can permeate the oil layer.

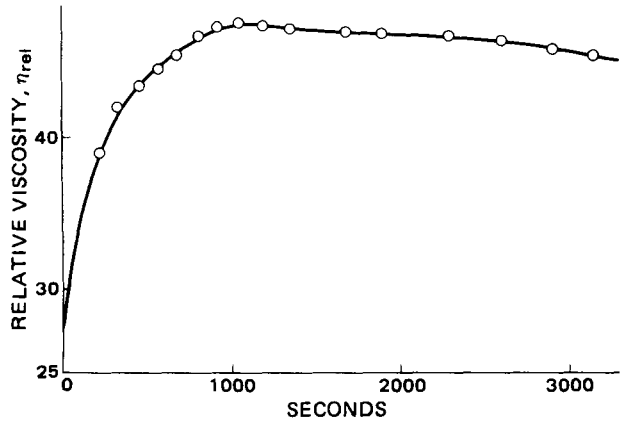

Figure 1—*Viscosity change of W/O/W emulsion after dilution with water.*

EXPERIMENTAL

Preparation of W/O/W Emulsions—The W/O/W emulsion was prepared by a two-step emulsification procedure according to Matsumoto *et al.* (1). Sorbitan monooleate[1] (8 g) and liquid paraffin[2] (10 g) were mixed thoroughly in a 100-ml beaker with a pin-mixer[3]. The stirring bar of the mixer was two six-pin blades which were fixed in a pile with a stainless steel bar. The rotation speed was maintained at 196 rpm by a constant speed stirrer[4]. As the mixture was being stirred, 30 ml of 0.5% (w/v) aqueous glucose solution was added slowly into the beaker at a constant rate. Addition of the glucose solution was controlled at a 3 ml/min rate by a pump[5]. The W/O emulsion formed was then stirred for 10 more min. It took 100 min for the first emulsification.

Thirty-five grams of the newly prepared W/O emulsion was dispersed into 35 ml of 3% aqueous solution of polysorbate 80 [6] using a homogenizer. The blade was a part of another homogenizer[7], and consisted of a fixed outer blade and an inner rotatable blade. The viscous W/O emulsion was torn and dispersed when passed through the narrow gap between the

blades. The blade was connected to the constant speed stirrer used in the first emulsification since slow rotation was necessary. The rotation speed was set at 324 rpm and it took ~10 min to complete the second emulsification. The W/O/W emulsion prepared was denoted Sample A.

Viscometry of W/O/W Emulsion—The viscosity of W/O/W emulsions was measured with a capillary viscometer[8] in a constant temperature water bath maintained at 25 ± 0.1°. The time course was started at the time of Sample A dilution with water or an aqueous solution. The measurement time was taken as the average of the start and finish time of each liquid addition. All diluents were kept at 25° beforehand. As the ratio of diluent volume to Sample A weight was not constant for all runs, it is noted where necessary.

Planar Membrane Experiment—To determine if solutes can migrate through the oil layer, the following planar membrane experiment was done using an apparatus consisting of two acrylic chambers separated by a millipore filter[9] to which sorbitan monooleate was applied. Sorbitan monooleate acts not only as a W/O emulsifying agent, but as water solubilizer in oil. Liquid paraffin was omitted because it made the applied liquid easy to detach from the millipore filter. The millipore filter was compatible with the surfactant without swelling or dissolving. Its thickness was measured as 150 μm. The diameter of the diaphragm was 2.5 cm, and therefore the membrane area was 4.91 cm^2. Water and a solution (200 ml each), were placed in the two cells, respectively, and the whole apparatus was immersed in a thermostated water bath (30°). Since the cells were clear and transparent after each run, sorbitan monooleate was probably not removed from the millipore filter.

Fluxes for electrolytes were measured with a conductance meter equipped with platinum electrodes immersed in the water in one of the cells. In the conductometry, it was necessary to keep room temperature at 19 ± 1° throughout the measurement to obtain reproducible data. Measurements were taken every 30 min. Conventional colorimetric methods were employed for determining the fluxes of nonelectrolytes. Every hour, 3 ml of sample was withdrawn and then an equal volume of water previously kept at 30° was added to the cell to prevent hydrostatic pressure differences from being created.

RESULTS AND DISCUSSION

Figure 1 shows the viscosity change with time for a W/O/W emulsion after dilution with water, in which the ratio of Sample A weight to diluent volume was 1:1.

The viscosity increased with time to a maximum and then decreased monotonically. A similar viscosity change was obtained even with the original emulsion. Matsumoto and Kohda (2) also reported this type of viscosity change for their W/O/W emulsions, the inner and outer aqueous phases of which were glucose solution and water, respectively. This viscosity change was ascribed to the volume change of vesicles in the W/O/W emulsions (2). To deal with this phenomenon quantitatively, an appropriate equation which correlates the relative viscosity to the volume fraction of vesicles should be known. However, it is impossible to determine an equation that would be appropriate, since the volume fraction changes on aging from the time of preparation and also changes on dilution. Hence, the volume change of vesicles in W/O/W emulsions can only be estimated qualitatively by means of viscometry, light scattering measurement, photomicroscopy, etc. For example, vesicle swelling after dilution of the original sample was confirmed by photomicroscopy. Similar observations were reported for a water/*n*-heptane/water emulsion (13).

Figures 2–4 show viscosity changes caused by dilution with aqueous potassium chloride, sucrose, and glucose solutions of various concentrations, respectively. In these cases the ratio of Sample A weight to diluent volume was 1:4.

The rate of viscosity change decreases with increasing concentration of solute in the diluent, and the viscosity falls even below its initial value when the emulsion is diluted with 10^{-2} *M* potassium chloride. These findings may be explained by the osmotic pressure difference between the inner aqueous phase and the outer aqueous phase as suggested previously (12, 14). The oil layer of vesicles in the W/O/W emulsion has a permeability to water, and the amount and direction of water movement depend on the osmotic pressure gradient. Figure 5 shows the viscosity change produced by dilution with a variety of aqueous solutions which have identical π values in the equation:

$$\pi = zcRT \qquad \text{(Eq. 1)}$$

where π is osmotic pressure, c is the concentration of solute, R and T are the usual gas constants, and z is an integer which is 1 for nonelectrolytes, 2 for uni-univalent electrolytes, and 3 for calcium chloride. The ratio of Sample A weight to diluent volume is 1:4. The equation gives the osmotic pressure of the outer aqueous phase when the oil layer has ideal semipermeability to the solute.

Urea and potassium thiocyanate increase viscosity, while potassium chloride, glucose, and calcium chloride decrease it. This suggests that solutes which produce a greater increase in viscosity contribute to a smaller degree to the osmotic pressure of the outer phase. In other words, these latter solutes can more or less permeate the oil layer. Therefore, the permeability sequence for the solutes is: urea > potassium thiocyanate > potassium chloride > glucose > calcium chloride.

Tanaka and coworkers[10] found a dependency of W/O/W emulsion

[10] Personal communication.

Table I—Permeability Coefficients Evaluated from Planar Membrane Experiments

Solute	Permeability Coefficient (30°), cm/sec × 10^9
Urea	440
Potassium thiocyanate	21.9
Cesium chloride	3.76
Rubidium chloride	2.84
Potassium chloride	2.37
Sodium chloride	2.19
Lithium chloride	1.77

viscosity at the time of preparation on the species of solute enclosed in the inner aqueous phase. For example, potassium chloride shows a much higher viscosity than potassium thiocyanate. Although it was suggested[10] that potassium thiocyanate prevents formation of W/O/W to give a lower viscosity, this can also be explained in terms of the permeability difference between the two salts. Since potassium thiocyanate, which is more permeable than potassium chloride, would contribute to the osmotic pressure of the inner aqueous phase less than potassium chloride, there would be less movement of water from the outer to the inner aqueous phase, thus giving a lower viscosity.

Table I lists the permeability coefficients calculated for some solutes from the fluxes determined in the planar membrane experiment. The sequence of permeability coefficient values in the table is identical with that obtained in the viscometry of the W/O/W emulsion. Furthermore, the absolute values of the permeability coefficient for sodium chloride and urea are in good agreement with those obtained with phospholipid bilayer membranes (15, 16). The sequence for alkali chlorides is also identical with that obtained with the lipid bilayers (15).

It would be reasonable to conclude that solutes can permeate the oil layer of vesicles in the W/O/W emulsion, probably due to a large total surface area of the vesicles, even though there is a considerable difference in composition between the oil layer and the planar membrane. Water would act as the carrier of solutes across the oil layer, presumably in the solubilized form.

Matsumoto *et al.* (1) proposed to measure the yield of W/O/W emulsion by a dialysis method. That is, when the emulsion containing a solute in the inner aqueous phase is dialyzed against distilled water, the concentration of the solute in the water should correspond to the yield. However, if the solute can permeate the oil layer of vesicles in the emulsion, there is no way to distinguish the solute diffused from the inner aqueous phase from the solute that leaked out as a result of vesicle destruction. The dialysis method cannot give correct yield. Moreover, if a high solute concentration in the water and a low emulsion viscosity are found (as in the case where a highly permeable solute is used) it could be incorrectly concluded that the solute has prevented the formation of a W/O/W emulsion.

Ion Chromatographic Determination of the Principal Inorganic Ion in Bulk Antibiotic Salts

J. W. WHITTAKER * and P. R. LEMKE ˣ

Received May 13, 1981, from *Pfizer Inc., Quality Control Division, Groton, CT 06340.* Accepted for publication July 28, 1981. *Present address: IBM Instrument Inc., Orchard Park, P.O. Box 332, Danbury, CT 06810.

Abstract □ Two ion-chromatographic procedures were developed for determining the principal inorganic ions in bulk antibiotic salts. The anion system enables sulfate determination in sulfate salts of polymyxin, neomycin, streptomycin, and dihydrostreptomycin, with typical analysis times of 8 min/sample and a relative precision of ±2% (95% confidence interval). The cation system is applicable to sodium or potassium analysis in the respective penicillin salts in 9–16 min with a relative precision of ±2.5%. These methods offer speed, specificity, and easy sample preparation compared with traditional assays.

Keyphrases □ Ion chromatography—determination of inorganic ion in bulk antibiotic salts □ Antibiotics—determination of inorganic ion in salts using ion chromatography □ Inorganic ion—determination in salts of various antibiotics by ion chromatography

Bulk antibiotic salts can be characterized by the determination of their principal components for the purposes of quality assurance. An accurate assay is required for both the pharmacologically active organic ion and the inorganic counterion. For the organic moiety, many specific chromatographic assays (1) are applicable to bulks. However,

viscosity at the time of preparation on the species of solute enclosed in the inner aqueous phase. For example, potassium chloride shows a much higher viscosity than potassium thiocyanate. Although it was suggested[10] that potassium thiocyanate prevents formation of W/O/W to give a lower viscosity, this can also be explained in terms of the permeability difference between the two salts. Since potassium thiocyanate, which is more permeable than potassium chloride, would contribute to the osmotic pressure of the inner aqueous phase less than potassium chloride, there would be less movement of water from the outer to the inner aqueous phase, thus giving a lower viscosity.

Table I lists the permeability coefficients calculated for some solutes from the fluxes determined in the planar membrane experiment. The sequence of permeability coefficient values in the table is identical with that obtained in the viscometry of the W/O/W emulsion. Furthermore, the absolute values of the permeability coefficient for sodium chloride and urea are in good agreement with those obtained with phospholipid bilayer membranes (15, 16). The sequence for alkali chlorides is also identical with that obtained with the lipid bilayers (15).

It would be reasonable to conclude that solutes can permeate the oil layer of vesicles in the W/O/W emulsion, probably due to a large total surface area of the vesicles, even though there is a considerable difference in composition between the oil layer and the planar membrane. Water would act as the carrier of solutes across the oil layer, presumably in the solubilized form.

Matsumoto *et al.* (1) proposed to measure the yield of W/O/W emulsion by a dialysis method. That is, when the emulsion containing a solute in the inner aqueous phase is dialyzed against distilled water, the concentration of the solute in the water should correspond to the yield. However, if the solute can permeate the oil layer of vesicles in the emulsion, there is no way to distinguish the solute diffused from the inner aqueous phase from the solute that leaked out as a result of vesicle destruction. The dialysis method cannot give correct yield. Moreover, if a high solute concentration in the water and a low emulsion viscosity are found (as in the case where a highly permeable solute is used) it could be incorrectly concluded that the solute has prevented the formation of a W/O/W emulsion.

Ion Chromatographic Determination of the Principal Inorganic Ion in Bulk Antibiotic Salts

J. W. WHITTAKER * and P. R. LEMKE ˣ

Received May 13, 1981, from *Pfizer Inc., Quality Control Division, Groton, CT 06340.* Accepted for publication July 28, 1981. *Present address: IBM Instrument Inc., Orchard Park, P.O. Box 332, Danbury, CT 06810.

Abstract □ Two ion-chromatographic procedures were developed for determining the principal inorganic ions in bulk antibiotic salts. The anion system enables sulfate determination in sulfate salts of polymyxin, neomycin, streptomycin, and dihydrostreptomycin, with typical analysis times of 8 min/sample and a relative precision of ±2% (95% confidence interval). The cation system is applicable to sodium or potassium analysis in the respective penicillin salts in 9–16 min with a relative precision of ±2.5%. These methods offer speed, specificity, and easy sample preparation compared with traditional assays.

Keyphrases □ Ion chromatography—determination of inorganic ion in bulk antibiotic salts □ Antibiotics—determination of inorganic ion in salts using ion chromatography □ Inorganic ion—determination in salts of various antibiotics by ion chromatography

Bulk antibiotic salts can be characterized by the determination of their principal components for the purposes of quality assurance. An accurate assay is required for both the pharmacologically active organic ion and the inorganic counterion. For the organic moiety, many specific chromatographic assays (1) are applicable to bulks. However,

Table I—Instrument Conditions for the Ion Chromatographic Analysis of Antibiotic Bulks

	Anion System	Cation System
Columns	3 × 150-mm anion separator	3 × 150-mm cation precolumn
		6 × 250-mm cation separator
	6 × 250-mm anion suppressor	9 × 250-mm cation suppressor
Mobile phase	0.003 *M* $NaHCO_3$/0.0024 *M* Na_2CO_3	0.005 *N* HNO_3
Flow rate	2.25 ml/min	3.0 ml/min
Pressure	400–600 psi	360–580 psi
Detector sensitivity	100 μMHO	10 μMHO
Regeneration solution	1 *N* H_2SO_4	1 *N* NaOH
Regeneration flow rate	2.25 ml/min	2.25 ml/min

Table II—Sample Preparation for Inorganic Ion Analysis

Ion	Antibiotic	Target Weight, mg	Sample Concentration Injected, g/ml	Typical Ion Concentrations, g/ml
K^+	Potassium benzyl penicillin	950	285	30
	Potassium phenoxymethyl penicillin	990	297	30
Na^+	Monosodium indanyl carbenicillin monohydrate	1000	200	9
	Sodium carbenicillin	1000	200	11
SO_4^{2-}	Neomycin sulfate	25	30	7
	Dihydrostreptomycin sulfate	50	60	12
	Streptomycin sulfate	50	60	12
	Polymyxin sulfate	50	60	10

for the inorganic ion portion of the salt, only the traditional volumetric, gravimetric, or colorimetric methods are available (2). The classical assays are generally time consuming, cumbersome, and lack specificity.

The present study reports a rapid and specific inorganic analysis technique which is applicable to a variety of antibiotic salts. The technique was termed ion chromatography by Small (3), in reporting the use of a mobile phase suppressor column as part of an ion-exchange system with conductivity detection. A comparison between suppressed and nonsuppressed ion chromatography and the development of ion chromatography were discussed in a recent review (4). Suppressed ion chromatography was chosen for bulk antibiotic analysis because the conductivity detector response is independent of the counterion species. A standard set of conditions applies to the analysis of various anions or cations and to a variety of sample types. Ion chromatography is specific for the ion of interest, and sample preparation only involves dissolving the salt in the mobile phase. Analysis times are generally shorter than those of traditional assays, and the methodology can be automated.

Table III—Reproducibility of Sulfate Analysis by Ion Chromatography

Antibiotic	SO_4^{2-}, %[a]	Relative Precision, %[b] Manual	Automated
Polymyxin sulfate	17.12 ± 0.10	1.6	2.5
Streptomycin sulfate	18.12 ± 0.04	0.6	2.3
Dihydrostreptomycin sulfate	18.79 ± 0.07	1.0	0.8
Neomycin sulfate	27.73 ± 0.17	0.6	3.0

[a] Confidence interval, 1 *SD*. [b] Confidence interval, 95%.

Table IV—Reproducibility of Cation Analysis by Ion Chromatography

Cation	Anion	Cation, %[a]
K^+	Benzyl penicillin	10.53 ± 0.26
K^+	Phenoxymethyl penicillin	10.20 ± 0.24
Na^+	Indanyl carbenicillin	4.57 ± 0.12
Na^+	Carbenicillin monohydrate	5.40 ± 0.14

[a] Confidence interval, 95%.

EXPERIMENTAL

Apparatus—A commercially available ion chromatograph[1] containing a 100-μl loop-type injector and conductivity detector with a dual pen strip chart recorder[2] or computing integrator[3] was used. The autosampler[4] employed a 50-μl injector loop connected after the manual injection loop and before the first separator column. The prepacked chromatographic columns were obtained commercially[5], and 0.22-μm disposable filters were used to treat sample solutions[6].

Materials—Reagent grade inorganic salts were sufficiently pure to be used as obtained. All water was passed through a mixed bed deionizer and an activated carbon unit[7].

Method—The analysis conditions and instrument settings are shown in Table I. The bulk antibiotic was dried, and a sample weighing approximately the amount specified in Table II was dissolved and diluted with mobile phase to prepare the sample stock solutions. A working solution was prepared by diluting the stock solution with mobile phase to obtain the final sample concentrations (Table II).

The chromatographic system required equilibration for ~1 hr, until

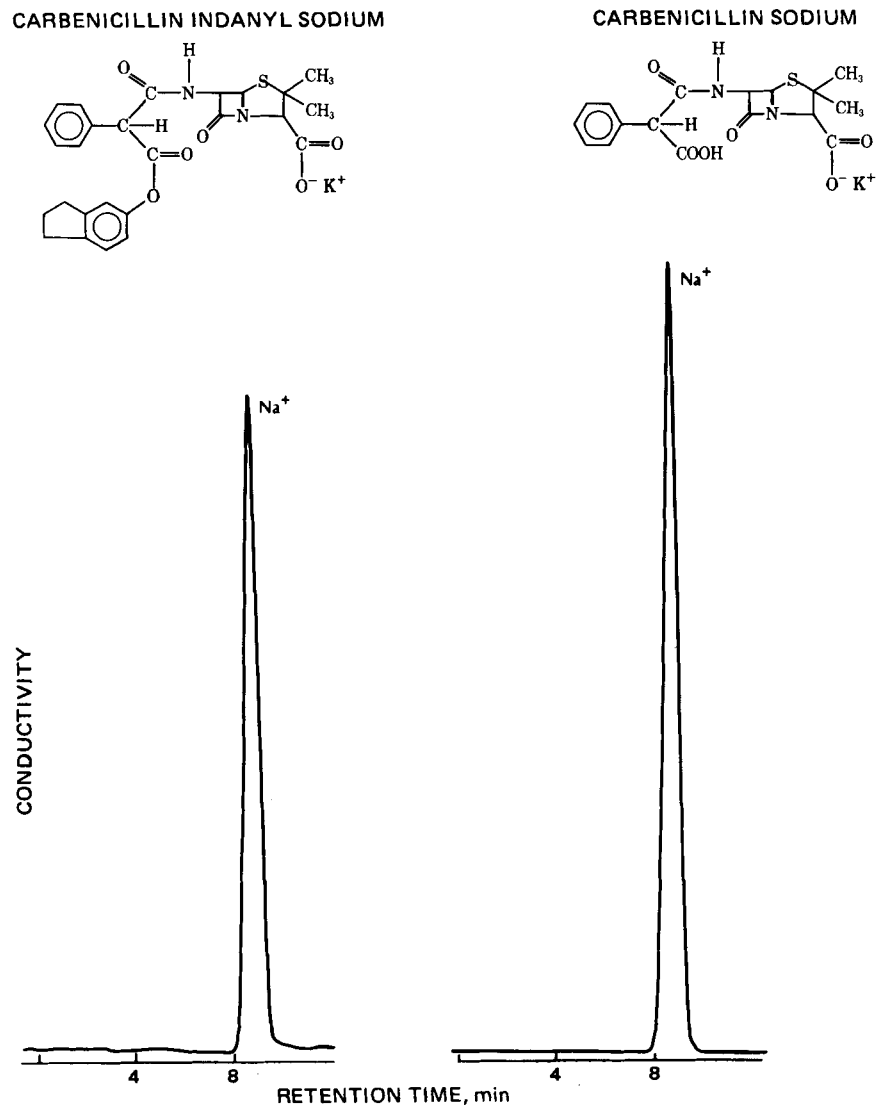

Figure 4—*Chromatograms demonstrating sodium determination in monosodium indanyl carbenicillin (MIC) and monosodium carbenicillin (MSC).*

a stable baseline was obtained. Duplicate injections of the working standard were made, and the peak retention time and response reproducibility were compared with previously determined values in order to check the suitability of the instrument system.

Sample solutions were injected through the disposable filter into the ion chromatograph or autosampler vial. For the autosampler, sample and rinse solutions were alternately injected.

After 5–6 samples were injected, the system was recalibrated by reinjecting the working standard. The sample concentrations can be calculated using either peak height or peak area measurement techniques.

RESULTS AND DISCUSSION

Anion Analysis—The anion system was identical with the systems generally recommended for common anion analysis, (5, 6) except that a short (3 × 150 mm) separator anion exchange column was employed. This short separator column enabled rapid analysis with adequate resolution (Fig. 1). In bulk antibiotic salts, potentially interfering ions are present in only small amounts, thereby minimizing the need for large separator columns and long analysis times.

In the event that simultaneous analyses of the major ion and some trace ion are desired, a longer separator column could be employed. For example, a system that can analyze both 0.1–0.4% bisulfite and 13–38% sulfate in a sulfate salt was developed using both a 3 × 150-mm and a 3 × 500-mm separator column. The bisulfite eluted with a relative retention time of 0.75 (9 min) to sulfate (12 min). Glycerin (1%) was used to stabilize the bisulfite; the glycerin had no effect on the chromatography.

Typical chromatograms (Fig. 2) obtained during sulfate analysis show that the sulfate peak in the antibiotic salt was indistinguishable from that of the sodium sulfate standard.

Linearity—Standards containing 5–20 μg/ml sulfate gave a linear response by both peak height and peak area computation. This range encompasses the theoretical sulfate content for the antibiotic salts, which are 26.9% for neomycin, 19.7% for streptomycin, 19.7% for dihydrostreptomycin, and 16.6% for polymyxin.

Reproducibility—The assay precision was determined by 5–6 replicate analyses of the same antibiotic lot. The precision values (Table III) include variations due to weighing and sample preparation. The manual analyses exhibited better precision than the automated analyses; although the precision of the automated method was adequate, no attempt was made to improve its precision. The precision of the automated method became unacceptable if a sample rinse was not employed to prevent carry over of the sulfate from the previous injection. The automated ion chromatograph was successfully employed for the analysis of all of the sulfated antibiotics in overnight runs.

Equivalency—Two classical methods for sulfate determination can be applied to sulfate analysis in antibiotics: the traditional barium gravimetric method (7) and a volumetric (8) method. The latter has been proposed for incorporation into the *European Pharmacopeia* monograph for polymyxin sulfate. To compare these methods and the ion chromatography technique, various lots of polymyxin sulfate were assayed by both the classical and ion chromatographic methods. For eight lots assayed by both gravimetric and ion chromatography, the average relative difference was −0.6 ±1.1% (confidence interval: 1 *SD*). Similarly, for 14 lots examined by the volumetric and ion chromatographic methods, the difference was −0.3 ±2.7%. The data indicate no apparent bias between

the methods. In both cases, the ion chromatographic method is more rapid and involves less sample manipulation than the traditional assays.

Cation Analysis—An ion chromatographic method, similar to the method reported for the determination of cations in ambient air aerosols (9), was successfully applied to the analysis of various penicillins (Figs. 3 and 4). The cation system, like the anion system, is independent of the nature of the counter-ion.

Linearity—Standards containing 5–15 μg/ml sodium and 10–40 μg/ml potassium gave linear responses by both peak height and peak area computation (Figs. 3 and 4). These ranges encompass the theoretical cation content for the antibiotic salts. The stoichiometric potassium level is 10.07% in penicillin V potassium (potassium phenoxymethyl penicillin) and 10.50% in penicillin G (potassium benzyl penicillin). Theoretical sodium levels in the sodium salts are 4.45% in carbenicillin indanyl sodium and 5.49% in carbenicillin sodium monohydrate. The sample concentrations (Table II) were chosen to give a similar response for both cations so that samples could be batched.

Reproducibility—Typical precisions of the ion chromatographic cation determination are shown in Table IV. These experiments include the complete replicate analysis of the same bulk lot.

Equivalency—No compendial requirement exists for the potassium content of the penicillins; however, both assays agreed well with the theoretical values.

The ion chromatographic sodium analysis was compared with sodium content determined by ashing six different antibiotic lots in the presence of sulfuric acid and measuring the remaining sodium sulfate gravimetrically. For carbenicillin sodium monohydrate, the relative difference was $-1.0 \pm 3.3\%$ (confidence interval: 1 *SD*). Carbenicillin indanyl sodium by ion chromatography was $3.9 \pm 4.3\%$ greater than the analysis by the residue on ignition method. Since both differences are smaller than the confidence interval, there was no apparent bias between methods.

Antitumor Agents XLV: Bisbrusatolyl and Brusatolyl Esters and Related Compounds as Novel Potent Antileukemic Agents

KUO-HSIUNG LEE *x, MASAYOSHI OKANO *, IRIS H. HALL *, DAVID A. BRENT ‡, and BERND SOLTMANN ‡

Received April 6, 1981, from the **Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514* and the ‡Wellcome Research Laboratories, Burroughs Wellcome Co., Research Triangle Park, NC 27709. Accepted for publication July 15, 1981.

Abstract □ A series of new bisbrusatolyl and brusatolyl esters and related compounds were synthesized and tested for *in vivo* antileukemic activity against a quassinoid sensitive strain of P-388 lymphocytic leukemia in BDF_1 mice. The bisbrusatolyl malonate, succinate, glutarate, adipate, and sebacate were as active or more active than brusatol. The C-3 esters of brusatol and bruceantin were also found to be as active or more active than brusatol or bruceantin in general. The free hydroxyl groups at C-11 and C-12 as well as the enone double bond in ring A of both bisbrusatolyl and brusatolyl esters are required for antileukemic activity. The presence of a double bond in the ester side chain contributes to the enhanced activity of these esters.

Keyphrases □ Brusatol—bisbrusatolyl and bisbrusatolyl esters, synthesis, potential antileukemic agents □ Antitumor agents—potential, bisbrusatolyl and bisbrusatolyl esters, synthesis □ Antileukemic agents—potential, bisbrusatolyl and bisbrusatolyl esters, synthesis, tested against P-388 lymphocytic leukemia

The structural requirements for antineoplastic activity (particularly in the P-388 mouse lymphocytic leukemic system) of quassinoids bruceantin (I), holacanthone, glaucarubolone, 6α-senecioyloxychaparrinone, and related compounds have recently been reviewed (1–6). It was concluded that the Δ^3-2-oxo moiety in ring A, the lactone moiety in ring D, the ester groups at either C-6 or C-15, the methyleneoxy bridge, and the hydroxyl moieties at either C-1 or C-3, and at C-12 are required for biological activity.

The isolation of novel antileukemic glycosides bruceoside-A and bruceoside-B, as well as their subsequent hydrolysis product brusatol (II) (7, 8) provided the opportunity for developing brusatol related compounds into future clinically active anticancer agents. Brusatol is structurally identical to bruceantin (I) [currently in the Phase II clinical trial as an anticancer agent by the National Cancer Institute (9)] except for a slight difference in the C-15 ester side chain. The C-15 ester moiety in I is important for its potent antileukemic activity and probably serves as a carrier group in processes such as membrane transport of the drug into intact cells or complex formation as previously suggested (2, 6, 10). The importance of the ester group which contributes to the enhanced antileukemic activity is also seen in other naturally oc-

0022-3549/82/0300-0338$01.00/0

the methods. In both cases, the ion chromatographic method is more rapid and involves less sample manipulation than the traditional assays.

curring antitumor agents (11).

In view of the overall structural requirements for the antileukemic activity of I, any major degradation of the intact I molecule might thus lead to the less active or inactive compounds. However, a minor modification by combining two intact active quassinoids *via* a diester linkage (such as I or II) might yield highly active antileukemic agents with reduced toxicity as observed with bishelenalinyl malonate and related esters (1, 11). An initial examination of the antileukemic activity of bisbrusatolyl malonate (III) and bisbrusatolyl succinate (IV) against a quassinoid-sensitive strain of P-388 lymphocytic leukemia indicated that III and IV were more potent and less toxic than brusatol (11). For example, the optimal T/C % value for III was 272 at 0.6 mg/kg, while for II it was 158 at 0.125 mg/kg. The synthesis and antileukemic activity of bisbrusatolyl and brusatolyl esters and related compounds are now reported.

CHEMISTRY

Bisbrusatolyl esters III–VII were prepared by reacting brusatol II with malonic dichloride, succinic dichloride, glutaric dichloride, adipic dichloride, and sebacic dichloride, respectively, in pyridine–benzene or pyridine–chloroform mixed solvent at room temperature. The monoacetates (VIII–X) of the bisbrusatolyl esters IV–VI were prepared by acetylation using acetic anhydride–pyridine and worked up as usual. Catalytic hydrogenation of the C-15 ester side chain of III and V with palladium-on-carbon in ethanol gave rise to the corresponding bis-dihydro derivatives XI and XII, respectively. The bistetrahydrobrusatolyl succinate (XIII) was prepared by esterification of tetrahydrobrusatol (XXXV), obtained by catalytic hydrogenation of II, with succinic dichloride.

Encouraged by the potent antileukemic activity and reduced toxicity demonstrated by the bisbrusatolyl esters (III–VII) resulting from esterification of the C-3 hydroxyl group of the diosphenol ring A, it was decided to further investigate the C-3 esters of brusatol (II). Thus, various C-3 esters, such as senecioate (XIV), valerate (XV), ethyl succinate (XVI), 3,4-dimethyl-2-pentenoate (XVII), 3′,4′,5′-trimethoxybenzoate (XVIII), and cinnamate (XIX), were prepared by esterification of II with a corresponding acyl chloride in pyridine–benzene or pyridine–chloroform mixed solvent at room temperature. Esterification of II with cinnamoyl chloride under these conditions yielded a C-3, C-11 dicinnamate (XXXI) in addition to the C-3 cinnamate (XIX). Esterification of bruceantin (I)

in an analogous manner afforded its C-3, 3,4-dimethyl-2-pentenoate ester (XXXIII).

Esterification of C-3, C-11, and C-12 hydroxyl groups is greatly affected by the reaction temperature and time. The C-11 hydroxyl group is sterically hindered and resistant to esterification under mild reaction conditions like those for the selective esterification of C-3. In general, it is required to heat the reaction mixture up to ~60° for esterification of C-11 and C-12 hydroxyl groups other than those involving acetylation. However, for esterification of the C-3 hydroxyl group, the reaction may be run at room temperature. The introduction of a C-3 ester was confirmed by examining the UV spectrum which should show the disappearance of a diosphenol chromophore at λ_{max} 278 nm. Confirmation of the presence of ester moieties at C-11 and C-12 was achieved by observing the downfield shift of H-11 and H-12 resulting from such esterification.

The mono- (XX–XXIV), di- (XXV–XXIX), and tri- (XXX) acetates of II were prepared by acetylation of the corresponding esters XIV–XIX with acetic anhydride in pyridine. The tri-ester (XXXII) was prepared by treating II with 3,4-dimethyl-2-pentenoyl chloride in dry benzene under reflux for 24 hr. The dihydro- (XXXIV) and tetrahydro- (XXXV) brusatol were prepared by catalytic hydrogenation of II with palladium-on-carbon. Sodium borohydride reduction of XXXV gave rise to the lactol (XXXVI). Spectral data (Table I) of all compounds (II–XXXIV) were in accord with the assigned structures.

DISCUSSION

The preliminary evaluations of the antileukemic activity of compounds II–XXXVI were carried out in a quassinoid sensitive strain of P-388 lymphocytic leukemia in BDF_1 mice which were described previously (11). A comparison of the T/C % values for the antileukemic activity of the compounds listed in Table II disclosed that the bisbrusatolyl esters (III–VII) possessed equal or more potent activity than brusatol at 0.6 mg/kg (compare T/C% of 272, 217, 176, 176, and 143 for III, IV, V, VI, and VII, respectively, to 149 for II). Compound III followed a dose response curve and demonstrated potent antileukemic activity (T/C = 213, 272, and 215% at doses of 1.0 mg, 0.6 mg, and 0.3 mg/kg/day, respectively). At comparable dose levels, brusatol was either much less active or more toxic. Monoacetylation of the 12- and 12′-hydroxyl groups of the bisesters (IV–VI) resulted in less active or inactive compounds (VIII–X), suggesting that the presence of such hydroxyl groups at the 12- and 12′-positions are required for antileukemic activity. Reduction of the senecioate ester double bonds of III and V afforded the corresponding bisdihydro derivatives XI and XII, in which XI (T/C = 132%) and XII (T/C = 147%) were less active than III and V. Saturation of the diosphenol double bond, as in the case of bistetrahydrobrusatolyl succinate (XIII), gave rise to an inactive compound.

Compounds XIV–XIX were various C-3 esters of brusatol (II). Again it was observed that the esters were more active or as active as II at 0.6 mg/kg/day (compare T/C of 185–130% of XIV–XIX to 149% of II). Similarly, the C-3, 3,4-dimethyl-2-pentenoate ester of bruceantin (*i.e.*, XXXIII), demonstrated a T/C of 194% at the same testing dose. Acetylation of compounds XIV–XIX either at the 12-hydroxyl moiety or at both the 11- and 12-hydroxyl groups yielded compounds XX–XXIV and XXV–XXIX, respectively, which showed no activity. The 11,12-diacetates of 3-cinnamoyl brusatol (XXIX) and of 3-acetyl brusatol (XXX), as well as the 3,11,12-tri-3,4-dimethyl-2-pentenoyl brusatol (XXXII) were all found to be inactive. However, the 3,11-dicinnamoyl brusatol (XXXI) in which the 12-hydroxyl group was free was found to give a T/C of 133% indicating the importance of a free hydroxyl group at position 12 for significant antileukemic activity. Reduction of the ester double bond of II yielded dihydrobrusatol (XXXIV), which did not decrease the activity. However, destruction of the enone system in ring A gave rise to XXXV which was much less active. Further reduction of the carbonyl at C-2 and C-16 yielded the inactive lactol (XXXVI).

EXPERIMENTAL[1]

Brusatol (II)—A solution of bruceoside-A (7, 8) (101 g, 0.148 mole) in 3 *N* sulfuric acid–methanol (1:1, 2000 ml) was stirred at 65° for 20 hr. The hydrolyzed product was extracted with chloroform to give a brown resinous substance (76.9 g). Column chromatography of this substance on silica gel yielded crude brusatol (67.7 g, 86%), which was further recrystallized from acetone to give II as colorless crystals: mp 274–277°.

[1] Unless otherwise specified, melting points were determined on a Thomas–Hoover melting point apparatus and were uncorrected. IR spectra were recorded on a Perkin-Elmer 257 grating spectrophotometer. PMR spectra were measured with a Varian XL-100 instrument (tetramethylsilane). Electron impact mass spectra were determined on an AEI MS-902 instrument at 70 eV using a direct inlet system. The field desorption mass spectra were obtained on a Varian MAT 731 mass spectrometer interfaced to a VG 2200 Datasystem (13). All spectra were run in a cyclic scanning mode with a steady increase of the emitter current from 0–50 mA. The sample was coated on the field desorption wire using the dipping technique. The solution used for dipping contained 5–10 μg of sample/μl of acetone. All samples desorbed at emitter currents between 22 and 26 mA. Compounds XIV–XXXII gave intense $[M]^+$ and/or $[M + H]^+$ ions. The esters of the dicarboxylic acids gave no molecular ions. Rather, these compounds were protonated on the ester oxygen and gave an ion due to simple cleavage, *e.g.* $[a + H]^+$. Some showed only ions which were produced by the net loss of water from this simple cleavage ion. Silica gel for column chromatography refers to Mallinckrodt Silica AR CC7-Special; silica gel for preparative TLC refers to Merck precoated silica gel GF-254 (0.25 mm, 5 × 20 cm) developed with suitable solvent systems and visualized by spraying with 1% cesium sulfate—10% sulfuric acid solution followed by heating or by use of an UV lamp. Pyridine and chloroform used as solvents for reactions were predried on molecular sieve and anhydrous calcium chloride, respectively. Elemental analyses were performed by Integral Microlab, Inc., Raleigh, N.C. All compounds (II–XXXVI) reported gave either satisfactory elemental or mass spectral (high resolution electron impact or field desorption) analyses (Table III). Also, all new compounds have been rigorously purified to homogeneity by TLC in at least three solvent systems. High resolution mass spectrometry was used in lieu of combustion elemental analysis in many cases due to the limited supply of natural brusatol.

[a] Run in $CDCl_3$ at 100 MHz, and values are parts per million. Multiplicities are indicated by the usual symbols: d, doublet; t, triplet; m, multiple whose center is given; bs, slightly broadened singlet. Figures in parentheses are coupling constants in hertz. [b] Overlapped signals.

The identity of II as brusatol was confirmed by a direct comparison (mixed melting point, TLC, and IR, PMR, and mass spectra) with an authentic sample.

Synthesis of III–VII—3,3-Bisbrusatolyl malonate (III), succinate (IV), glutarate (V), adipate (VI), and sebacate (VII) were synthesized. Esterification was accomplished by treating II (~0.2 mmole) in dry pyridine (2 ml) with a solution of the corresponding malonyl (0.348 mmole), succinyl (0.738 mmole), glutaryl (0.74 mmole), adipyl (0.74 mmole), and sebacyl (0.215 mmole) dichlorides in dry chloroform (2 ml) and cooling with ice. After the mixture was stirred at room temperature for 19, 19, 40, 20, and 20 hr, respectively, it was shaken with dilute sulfuric acid to remove pyridine. The product was extracted with chloroform and purified by preparative TLC (chloroform–acetone 1:1).

III: pale blue crystals (19% yield); mp 191–193°; UV (ethyl alcohol) 221 nm (log ϵ 4.38); IR (potassium bromide) 3450 (OH), 1730, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1645 (C=C) cm^{-1}.

IV: colorless crystals (61% yield); mp 248–250°; UV (ethyl alcohol) 221 nm (log ϵ 4.45); IR (potassium bromide) 3480 (OH), 1730, 1710 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1645 (C=C) cm^{-1}.

V: colorless crystals (39% yield); mp 166–168°; UV (ethyl alcohol) 221 nm (log ϵ 4.45); IR (potassium bromide) 3440 (OH), 1740, 1715 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

VI: colorless crystals (53% yield); mp 239–241°; IR (potassium bromide) 3480 (OH), 1725 (ester and lactone CO), 1675 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

5-Fluorouracil	12.5	15.7/9.5	166

[a] A compound is active if it exhibits a T/C $\geq$ 125% (12).

VII: colorless crystals (79% yield); mp 173–175°; UV (ethyl alcohol) 220 nm (log ϵ 4.60); IR (potassium bromide) 3450 (OH), 1730, 1715 (ester and lactone CO), and 1650 (C=C) cm^{-1}.

General Method for the Synthesis VIII–X—12,12′-Diacetoxy-3,3′-bisbrusatolyl succinate (VIII), glutarate (IX), and adipate (X) were synthesized. These 12,12′-diacetates were prepared by acetylation of the corresponding IV–VI with dry pyridine–acetic anhydride (1:1) for 18–24 hr at room temperature with stirring followed by workup with preparative TLC (chloroform–acetone 1:1) purification.

VIII: colorless crystals (42% yield); mp 204–206°; IR (potassium bromide) 3480 (OH), 1735 (ester and lactone CO), 1685 (α,β-unsaturated CO), 1640 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

IX: colorless crystals (85% yield); mp 213–215°; IR (potassium bromide) 3440 (OH), 1740 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

X: colorless crystals (44% yield); mp 248–250°; IR (potassium bromide) 3490 (OH), 1730 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), and 1215 ($OCOCH_3$) cm^{-1}.

General Method for the Synthesis of XI and XII—3,3′-Bis-22,23-dihydrobrusatolyl malonate (XI) and glutarate (XII) were synthesized. A solution of III (36.7 mg, 0.0331 mmole) and V (30 mg, 0.0264 mmole) in absolute ethanol (3 and 2 ml, respectively) was hydrogenated in the presence of prereduced 10% palladium-on-charcoal (48 and 47 mg, respectively and at 65 and 70° for 8 and 48 hr, respectively). Compounds XI and XII were obtained by eluting the reaction mixture with ethanol through a column containing anhydrous magnesium sulfate.

XI: colorless crystals (48% yield); mp 208–210°; IR (potassium bromide) 3480 (OH), 1740 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

XII: colorless crystals (83% yield); mp 223–225°; IR (potassium bromide) 3420 (OH), 1730, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

Synthesis of XIII—3,3′-Bis-3,4,22,23-tetrahydrobrusatolyl succinate (XIII) was synthesized. A solution of IV (32.65 mg, 0.0291 mmole) in ethanol (2 ml) was hydrogenated in the presence of prereduced 10% palladium-on-charcoal (58 mg) at 60° for 44 hr until the disappearance of UV absorption at λ_{max} ~220 nm. The product was purified directly by preparative TLC (chloroform–acetone 1:1) to yield XIII as colorless crystals (21.65 mg, 66%): mp 280° (dec.); IR (potassium bromide) 3430 (OH), 1735, and 1725 (ester and lactone CO) cm^{-1}.

General Method for the Synthesis of XIV–XIX and XXXI—Brusatol-3-yl senecioate (XIV), valerate (XV), ethyl succinate (XVI), 3,4-dimethyl-2-pentenoate (XVII), 3′,4′,5′-trimethoxybenzoate (XVIII), cinnamoate (XIX), and brusatol-3,11-diyl dicinnamoate (XXXI) were synthesized. These esters were prepared by treatment of II (105 mg, ~0.2 mmole) in dry pyridine (2 ml) with a solution of the corresponding senecioyl (171 mg, 1.44 mmoles), valeryl (170 mg, 1.41 mmoles), ethyl succinyl (64 mg, 0.43 mmole), 3,4-dimethyl-2-pentenoyl (106.4 mg, 0.726 mmole), 3′,4′,5′-trimethoxybenzoyl (154 mg, 0.67 mmole, in 10 ml of dry benzene), and cinnamoyl (166.6 mg, 1.00 mmole) chlorides in dry chloroform (2 ml) under cooling with ice. After the mixture was stirred at room temperature for 2, 24, 20, 28, 50, and 24 hr, respectively, and worked up in a manner analogous to the synthesis of III–VII, it was subjected to preparative TLC using chloroform–acetone 10:1 for XIV, XVII, XIX, and XXXI, and chloroform–acetone 1:1 for XV, XVI, and XVIII.

XIV: colorless crystals (83 mg, 66% yield); mp 143–145°; IR (potassium bromide) 3400 (OH), 1725, 1710 (ester and lactone CO), 1675 (α,β-unsaturated CO), and 1635 (C=C) cm^{-1}.

XV: colorless crystals (81 mg, 64% yield); mp 156–158°; IR (potassium bromide) 3480 (OH), 1740 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

XVI: colorless crystals (115 mg, 90% yield); mp 198–200°; IR (potassium bromide) 3460 (OH), 1730, 1715 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

XVII: colorless crystals (83 mg, 65% yield); mp 145–147°; IR (potassium bromide) 3400 (OH), 1720, 1710 (ester and lactone CO), 1670 (α,β-unsaturated CO), and 1635 (C=C) cm^{-1}.

XVIII: colorless crystals (124 mg, 82% yield); mp 147–149°; IR (potassium bromide) 3460 (OH), 1730, 1710 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1640 (C=C) cm^{-1}.

XIX: colorless crystals (103 mg, 80% yield); mp 253–255°; IR (potassium bromide) 3400 (OH), 1730, 1710 (ester and lactone CO), 1690 (α,β-unsaturated CO), and 1630 (C=C) cm^{-1}.

XXXI: colorless crystals (16.4 mg, 11% yield); mp 168–170°; IR (potassium bromide) 3400 (OH), 1730, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), and 1630 (C=C) cm^{-1}.

General Method for Synthesis of XX–XXX—12-Acetoxybrusatol-

[a] The most intense ion is reported.

3-yl senecioate (XX), 11,12-diacetoxybrusatol-3-yl senecioate (XXV), 12-acetoxybrusatol-3-yl valerate (XXI), 11,12-diacetoxybrusatol-3-yl valerate (XXVI), 12-acetoxy-brusatol-3-yl ethyl succinate (XXII), 11,12-diacetoxybrusatol-3-yl ethyl succinate (XXVII), 12-acetoxybrusatol-3-yl 3,4-dimethyl-2-pentenoate (XXIII), 11,12-diacetoxybrusatol-3-yl 3,4-dimethyl-2-pentenoate (XXVIII), 12-acetoxybrusatol-3-yl 3′,4′,5′-trimethoxybenzoate (XXIV), 11,12-diacetoxybrusatol-3-yl cinnamoate (XXIX), and 11,12-diacetoxybrusatol-3-yl acetate (XXX) were synthesized. Acetylation of XIV (58.8 mg, 0.098 mmole), XV (49 mg, 0.081 mmole), XVI (69 mg, 0.106 mmole), XVII (84 mg, 0.133 mmole), and XVIII (25 mg, 0.0342 mmole) with 2 ml of dry pyridine–acetic anhydride (1:1) at room temperature for 21–24 hr yielded the corresponding 12 mono- and 11,12 diacetates XX, XXV, XXI, XXVI, XXII, XXVII, XXIII, XXVIII, and XXIV, respectively. Similar acetylation of XIX (50 mg, 0.0769 mmole) for 68 hr gave XXIX. Compound XXX was prepared according to a literature method (14). All of these acetates (XX–XXIX) were purified by preparative TLC using 1:1 chloroform–acetone for XX, XXV, XXII, XXVII, XXIII, and XXVIII, and 10:1 chloroform–acetone for XXI, XXVI, XXIV, and XXIX.

XX: colorless crystals (26.7 mg, 42% yield); mp 180–182°; IR (potassium bromide) 3440 (OH), 1740, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1635 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

XXV: colorless crystals (9.1 mg, 14% yield); mp 126–128°; IR (potassium bromide) 1730, 1710 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1635 (C=C), and 1215 ($OCOCH_3$) cm^{-1}.

XXI: colorless crystals (31 mg, 59% yield); mp 116–118°; IR (potassium bromide) 3480 (OH), 1735 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), and 1222 ($OCOCH_3$) cm^{-1}.

XXVI: colorless crystals (15 mg, 27% yield); mp 169–170°; IR (potassium bromide) 1740 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), 1220, and 1135 ($OCOCH_3$) cm^{-1}.

XXII: colorless crystals (52.2 mg, 71% yield); mp 170–172°; IR (potassium bromide) 3440 (OH), 1730, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1635 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

XXVII: colorless crystals (22.85 mg, 29% yield); mp 218–220°; IR (potassium bromide) 1730 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1645 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

XXIII: colorless crystals (46.2 mg, 52% yield); mp 178–180°; IR (potassium bromide) 3440 (OH), 1735, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1635 (C=C), and 1225 ($OCOCH_3$) cm^{-1}.

XXVIII: colorless crystals (14.8 mg, 16% yield); mp 160–162°; IR (potassium bromide) 1750, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

XXIV: colorless crystals (8.1 mg, 31% yield); mp 178–180°; IR (potassium bromide) 3440 (OH), 1730, 1720 (ester and lactone CO), 1680 (α,β-unsaturated CO), 1640 (C=C), and 1210 ($OCOCH_3$) cm^{-1}.

XXIX: colorless crystals (27.1 mg, 48% yield); mp 268–270° (dec.); IR (potassium bromide) 1735, 1720 (ester and lactone CO), 1690 (α,β-unsaturated CO), 1630 (C=C), and 1220 ($OCOCH_3$) cm^{-1}.

General Synthesis of XXXII—Brusatol-3,11,12-triyl 3,4-dimethyl-2-pentenoate (XXXII) was synthesized. To a solution of 3,4-dimethyl-2-pentenoic acid chloride (107 mg, 0.728 mmole) in dry benzene (10 ml) was added II (104 mg, 0.20 mmole). The mixture was refluxed for 24 hr and purified by preparative TLC (chloroform–acetone, 10:1).

XXXII: colorless crystals (159.5 mg, 94% yield); mp 98–101°; IR (potassium bromide) 1720 (ester and lactone CO), 1685 (α,β-unsaturated CO), and 1635 (C=C) cm^{-1}.

Bruceantin-3-yl 3,4-Dimethyl-2-pentenoate (XXXIII)—Compound XXXIII was prepared according to the method of Okano and Lee (15).

22,23-Dihydrobrusatol (XXXIV)—This was prepared according to the method of Sim *et al.* (14).

Synthesis of XXXV—A solution of XXXIV (190 mg) in absolute ethanol (10 ml) was shaken with hydrogen at 65° and atmospheric pressure for 48 hr with 10% palladium-on-charcoal (200 mg). The filtered solution was evaporated to yield colorless crystals of 3,4,22,23-tetrahydrobrusatol (XXXV) after purification by preparative TLC.

XXXV: mp 252–253°; IR (potassium bromide) 3440 (OH), and 1715

(ester and lactone CO) cm^{-1}. PMR ($CDCl_3$) δ 0.99 (d, J = 6 Hz, 9H, CH_3-4 and two CH_3-23), 1.40 (s, CH_3-10), 3.86 (s, $COOCH_3$), and 6.40 (d, J = 13 Hz, H-15).

Anal.—Calc. for $C_{26}H_{36}O_{11}$: *m/z* 524.2255 (M^+). Found: *m/z* 524.2259.

Compound XXXV could also be prepared by hydrogenation of II (504 mg) in 90% ethanol (100 ml) with platinum oxide (50 mg) in water at room temperature and atmospheric pressure. The reaction mixture was filtered by use of a silica gel column. The filtered solution was evaporated to yield colorless XXXV (498 mg).

Synthesis of XXXVI—To a solution of XXXV (66 mg) in methyl alcohol (10 ml) was added a solution of sodium borohydride (2 mg) in water (5 ml). The mixture was stirred at room temperature for 23 hr and then subjected to preparative TLC (chloroform-acetone 1:1) to give 2-hydroxy-2-deoxytetrahydrobrusatol lactol (XXXVI) as colorless crystals (31.6 mg).

XXXVI: mp 121–123°; IR (potassium bromide) 3440 (OH), 1715 (ester CO), 1040 (cyclic *sec*-OH); PMR ($CDCl_3$) δ 0.91 (d, J = 6 Hz, 9H, CH_3-4 and two CH_3-23), 1.50 (s, CH_3-10), 3.81 (s, $COOCH_3$), 4.13 (m, H-12), 4.20 (m, H-11), 4.60 (m, H-2 and H-3) and 5.52 (m, H-15 and H-16).

Anal.—Calc. for $C_{26}H_{40}O_{11}$: *m/z* 528.2571 (M^+). Found: *m/z* 528.2573.

Antitumor Agents XLVI: *In Vitro* Effects of Esters of Brusatol, Bisbrusatol, and Related Compounds on Nucleic Acid and Protein Synthesis of P-388 Lymphocytic Leukemia Cells

IRIS H. HALL ˣ, Y. F. LIOU, M. OKANO, and K. H. LEE

Received February 19, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, NC 27514.* Accepted for publication July 15, 1981.

Abstract □ A series of esters of brusatol, bisbrusatol, and bruceantin were shown to have potent antileukemic activity. Antineoplastic activity was correlated with the ability of the compounds to suppress DNA and protein synthesis in P-388 lymphocytic leukemia cells. Compounds with high T/C% values successfully inhibited DNA polymerase activity and purine synthesis. The ability to inhibit protein synthesis during the elongation process also correlated positively with high antileukemic activity in this series of quassinoids. Dihydrofolate reductase activity and basal and adenosine diphosphate stimulated respiration of P-388 cells were also inhibited.

Keyphrases □ Brusatol—esters, *in vitro* effects on nucleic acid and protein synthesis, P-388 lymphocytic leukemia cells □ Bisbrusatol—esters, *in vitro* effects on nucleic acid and protein synthesis, P-388 lymphocytic leukemia cells □ Antitumor agents—*in vitro* effects of brusatol, bisbrusatol, and related compounds on nucleic acid and protein synthesis, P-388 lymphocytic leukemia cells

Bruceantin was first isolated from *Brucea antidysenterica* (1, 2) and is currently in Phase II clinical trials as an antineoplastic agent (3, 4). Brusatol, a derivative of bruceantin, was prepared by Lee *et al.* (5, 6) and shown to be active against P-388 lymphocytic leukemia cell growth (7). This laboratory demonstrated that bruceantin and brusatol reduced nucleic acid and protein synthesis (7, 8), purine synthesis (7), and oxidative phosphorylation processes (8) of P-388 cells. Based on the observation that a number of potent antileukemic agents have an ester in their structure, a series of brusatol related esters as well

(ester and lactone CO) cm^{-1}. PMR ($CDCl_3$) δ 0.99 (d, J = 6 Hz, 9H, CH_3-4 and two CH_3-23), 1.40 (s, CH_3-10), 3.86 (s, $COOCH_3$), and 6.40 (d, J = 13 Hz, H-15).

Anal.—Calc. for $C_{26}H_{36}O_{11}$: *m/z* 524.2255 (M^+). Found: *m/z* 524.2259.

Compound XXXV could also be prepared by hydrogenation of II (504 mg) in 90% ethanol (100 ml) with platinum oxide (50 mg) in water at room temperature and atmospheric pressure. The reaction mixture was filtered by use of a silica gel column. The filtered solution was evaporated to yield colorless XXXV (498 mg).

Synthesis of XXXVI—To a solution of XXXV (66 mg) in methyl alcohol (10 ml) was added a solution of sodium borohydride (2 mg) in water (5 ml). The mixture was stirred at room temperature for 23 hr and then subjected to preparative TLC (chloroform-acetone 1:1) to give 2-hydroxy-2-deoxytetrahydrobrusatol lactol (XXXVI) as colorless crystals (31.6 mg).

XXXVI: mp 121–123°; IR (potassium bromide) 3440 (OH), 1715 (ester CO), 1040 (cyclic *sec*-OH); PMR ($CDCl_3$) δ 0.91 (d, J = 6 Hz, 9H, CH_3-4 and two CH_3-23), 1.50 (s, CH_3-10), 3.81 (s, $COOCH_3$), 4.13 (m, H-12), 4.20 (m, H-11), 4.60 (m, H-2 and H-3) and 5.52 (m, H-15 and H-16).

Anal.—Calc. for $C_{26}H_{40}O_{11}$: *m/z* 528.2571 (M^+). Found: *m/z* 528.2573.

Antitumor Agents XLVI: *In Vitro* Effects of Esters of Brusatol, Bisbrusatol, and Related Compounds on Nucleic Acid and Protein Synthesis of P-388 Lymphocytic Leukemia Cells

IRIS H. HALL ˣ, Y. F. LIOU, M. OKANO, and K. H. LEE

Received February 19, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, NC 27514.* Accepted for publication July 15, 1981.

Abstract □ A series of esters of brusatol, bisbrusatol, and bruceantin were shown to have potent antileukemic activity. Antineoplastic activity was correlated with the ability of the compounds to suppress DNA and protein synthesis in P-388 lymphocytic leukemia cells. Compounds with high T/C% values successfully inhibited DNA polymerase activity and purine synthesis. The ability to inhibit protein synthesis during the elongation process also correlated positively with high antileukemic activity in this series of quassinoids. Dihydrofolate reductase activity and basal and adenosine diphosphate stimulated respiration of P-388 cells were also inhibited.

as bisbrusatolyl esters and related moieties were synthesized. These compounds were tested for antineoplastic activity and were active against P-388 lymphocytic leukemia growth (10). These ester derivatives of brusatol were examined for their *in vitro* effects on nucleic acid and protein synthesis of P-388 cells and the results are now reported.

EXPERIMENTAL

The compound bruceoside-A (I) was originally isolated from *Brucea javanica* (5). Brusatol (II) was obtained by treating bruceoside-A with 3*N* H_2SO_4–methanol (1:1) to hydrolyze the glycosidic linkage (5, 6). Bruceantin (III) was obtained from bruceoside-A by synthetic methods (11). The chemical synthesis, purification, and physical characterization

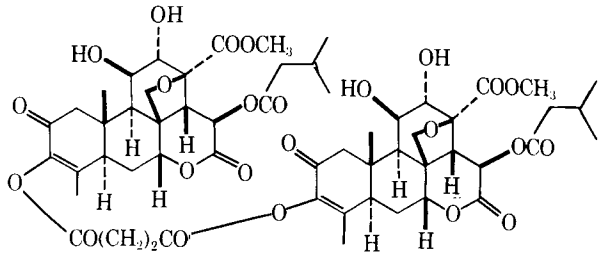
XIV: Bisbrusatolyl malonate: $R_1 = R_2 = H$, n = 1



XV: Bisdihydrobrusatolyl succinate

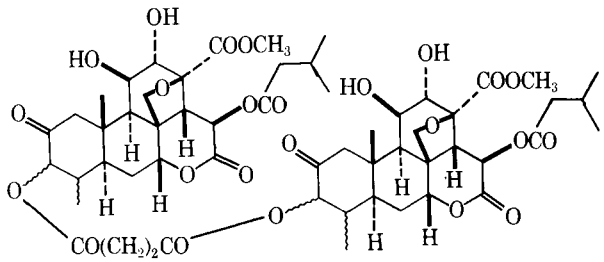
of compounds IV–XIX, *i.e.*, brusatol esters, bisbrusatolyl esters, and related derivatives, were reported recently by this laboratory (10, 11).

Antileukemic Screen—The UNC P-388 lymphocytic leukemia tumor line was maintained in DBA/2 male mice (~20 g) by inoculation with 10^6 P-388 cells on day 0, intraperitoneally. The tumor was transferred on day 8 to BDF_1 male mice (~18 g) for the testing of new agents. Test drugs were suspended by homogenization in 0.05% polysorbate 80 and administered 0.6 mg/kg intraperitoneally on days 1–14, utilizing 5-fluorouracil as a standard (12).

***In Vitro* Incorporation Studies**—BDF_1 ($C_{57}B1/6 \times DBA/j$) male mice were inoculated with 10^6 tumor cells as previously described. On day 9, the P-388 ascites cells were collected from the peritoneal cavity. *In vitro* incorporation studies (8) were carried out using 10^6 P-388 cells in minimum essential medium in 10% fetal calf serum and either 1 μCi of [6-^{3}H] thymidine (21.8 Ci/mmole), [6-^{3}H]uridine (22.4 Ci/mmole) or [4,5-^{3}H(N)]-L-leucine (56.5 Ci/mmole) in a total volume of 1 ml and incubated for 90 min at 37°. The final concentration of I–XIX was 10 μ*M*. Thymidine incorporation into DNA was terminated with perchloric acid containing pyrophosphate which was filtered on glass fiber paper by vacuum suction. The control value was 137,346 dpm/10^6 cells/90 min. RNA and protein incorporation assays were terminated with trichloroacetic acid and the macromolecule was collected on nitrocellulose membrane filter paper. The acid insoluble precipitates on the filter papers were placed in scintillation vials and counted in a toluene–oxtoxynol scintillation fluid. The control value for uridine incorporation was 36,442 dpm/10^6 cells/90 min and for leucine incorporation into protein the value was 8477 dpm/10^6 cells/90 min. Nuclear DNA polymerase activity was determined on isolated P-388 lymphocytic leukemia cell nuclei. The incubation medium was that used by Sawada *et al.* (13) except that [^{14}C]thymidine triphosphate (78.1 Ci/mmole) was used; the insoluble nucleic acids were collected on glass fiber paper discs[1], resulting in a control value of 24,568 dpm/mg nucleic protein. [^{14}C]Formic acid incorporation into purines was measured using 0.5 μCi of [^{14}C]formic acid (4.95 mCi/mmole) (14). The reaction medium was spotted on silica gel TLC plates and eluted with *n*-butanol–acetic acid–water (4:1:5). Using adenosine and guanosine as standards, the plates were scraped and the radioactivity determined. The control value was 10,621 dpm/mg of protein. Dihydrofolate reductase was determined by a spectrophotometric method (15) based on the rate of disappearance of 0.1 μmole of reduced NADP. The control resulted in an absorbance difference of 0.760 o.d. unit/hr/mg of protein using a 600×*g* (10 min) supernate.

Utilizing a test system (7) that differentiates between initiation and elongation inhibitors of protein synthesis, P-388 tumor cells were homogenized and incubated in tromethamine buffer (pH 7.6) containing KCl, $MgCl_2$, adenosine triphosphate, guanosine triphosphate, phosphoenolpyruvate, pyruvate kinase, dithiothreitol, the 19 basic amino acids, and [^{3}H]leucine (56.5 Ci/mmol) for 0–14 min at 37°. Test drugs were added at 10 μ*M* concentration to the incubation medium 90 sec after initiating the experiment. Samples were taken from the assay medium at 1 min intervals and spotted on filter paper[2]. The reaction was terminated with trichloroacetic acid and the protein extracted and counted. The test drugs were compared to the standards pyrocatechol violet, an initiator inhibitor, and emetine, an elongation inhibitor of protein synthesis at 75 μmoles. Oxidative phosphorylation studies were carried out on 9 day P-388 cells (9). Oxygen consumption was measured with an oxygen electrode[3] connected to an oxygraph. The reaction vessel contained 55 μmoles of sucrose, 22 μmoles of monobasic potassium phosphate, 22 μmoles of potassium chloride, 90 μmoles of succinate or 60 μmoles of α-ketoglutarate as substrate, and 22 μmoles of adenosine triphosphate. Test drugs were present in a final concentration of 10 μ*M*. After the basal metabolic level (state 4) was obtained, 0.257 μmole of

[1] GF/F.
[2] Whatman No. 3.
[3] Clark.

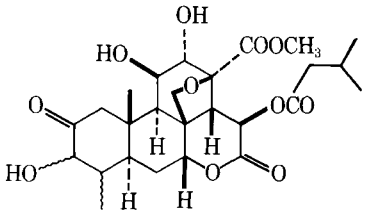


XVI: Bistetrahydrobrusatolyl succinate

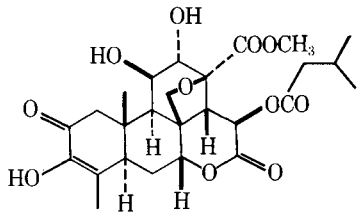
adenosine diphosphate was added to the vessel to obtain the adenosine diphosphate-stimulated respiration rate (state 3). The control values for states 4 and 3 respiration were 11.44 and 20.76 μl of oxygen consumed/min/mg of protein, respectively, using succinate as substrate. When α-ketoglutarate was used as substrate, states 4 and 3 respiration were 10.01 and 19.17 μl of oxygen consumed/min/mg of protein.

RESULTS

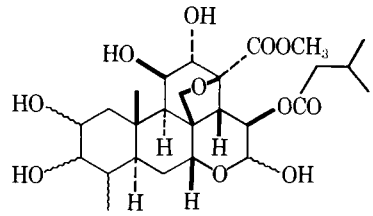
Using a dose of 0.6 mg/kg/day, compounds II, III, V–VII, IX, XI–XV, and XVIII demonstrated significant inhibitory activity against P-388 lymphocytic leukemia cell growth in BDF_1 mice. The bisbrusatolyl esters (XI–XIV) were in general more potent than brusatol (II), especially the succinate (XIII) and the malonate (XIV) with T/C = 217 and 272%, respectively. Reduction of the C-15 ester double bond did not decrease the activity (compare XV to XIII and XVIII to III). However, saturation of the diosphenol double bond gave either less active or inactive compounds



XVII: Tetrahydrobrusatol



XVIII: Dihydrobrusatol



XIX: 2-Hydroxy-2-deoxotetrahydrobrusatol lactol

(XVI, XVII, and XIX). Esterification of II at C-3 afforded VII and IX which were more active than II. Acetylation of hydroxyl groups at C-11 and C-12 gave compounds (IV, VIII, and X) which were either less active or inactive, indicating the importance of these hydroxyl groups for enhanced antileukemic activity.

Examination of the *in vitro* incorporation studies in P-388 lymphocytic leukemia cells demonstrated that compounds II, III, VII, IX, XI–XIV, and XVIII suppressed thymidine incorporation into DNA 41–59%. These same compounds inhibited uridine incorporation into RNA 16–59%. L-Leucine incorporation into protein was suppressed more than 70% by XIV and VIII and more than 50% by II and IX. Compounds III, V, VII, XI, XII, XV, and XVIII caused at least 40% inhibition of protein synthesis of P-388 cells.

Detailed examination of a number of enzymatic activities which are known to be suppressed by quassinoids subsequently followed. Nucleic DNA polymerase activity in P-388 was inhibited at least 50% by compounds XI, XII, and XIV and at least 40% by compounds II, III, VII, and IX. Purine synthesis was inhibited more than 50% by compounds III, VII, IX, and XIII–XV and more than 40% by II, X, XI, and XII. Dihydrofolate reductase activity was suppressed at least 40% by compounds I, III, IV, XI, XIII, XIV, and XV. The elongation process of protein synthesis compared with the emetine standard was inhibited greater than 60% by II, VII, XI, XIII, XIV, IX, and XII at 10 μ*M*. The quassinoids inhibited ongoing polypeptide synthesis. Oxidative phosphorylation processes were not inhibited as significantly as other metabolic events. However, state 4 (basal) respiration with succinate as the substrate was inhibited greater than 15% by compounds II, III, V–VII, IX, XI–XIII, XV, and XVIII. With α-ketoglutarate as the substrate, compounds II, III, VI, VII, IX–XV, XVII, and XVIII caused 15% state 4 inhibition. Adenosine diphosphate-stimulated respiration was inhibited 15% using succinate as substrate by compounds II, III, V, IX, XI, XII, XIV, and XVIII and by compounds II, III, VII, IX, XI–XV, XVII, and XVIII using α-ketoglutarate as substrate.

DISCUSSION

The quassinoids demonstrated that protein and nucleic acid metabolism were inhibited in a manner which correlated positively with their antileukemic activity when tested against P-388 lymphoid leukemia growth. Compounds with the higher T/C % values had a greater ability

to suppress protein synthesis (compounds XIII, XIV, XV, XI, and VII). The elongation step of translocation appeared to be affected preferentially over initiation events of protein synthesis. This observation is consistent with previous data for compound II on rabbit reticulocyte protein synthesis and compound III on yeast. The inhibition of DNA and RNA was also positively correlated with antineoplastic activity although DNA synthesis was suppressed slightly less than the inhibition of protein synthesis. Nuclear DNA polymerase activity was inhibited ~50% by compounds with T/C % >150 although there were exceptions. Purine synthesis inhibition correlated more positively with inhibition of nucleic acid synthesis and antineoplastic activity than inhibition of DNA polymerase activity by these quassinoids. Dihydrofolate reductase activity was affected in a similar manner although the regulatory enzyme of purine synthesis, phosphoribosyl pyrophosphate aminotransferase, was identified as being inhibited when these drugs are administered *in vivo*. However, only marginal inhibitory effects were observed after *in vitro* (6) incubation of the quassinoids with this regulatory enzyme. Surprisingly, 3-(3,4-dimethyl-2-pentonyl) bruceantin (VII) inhibited purine synthesis 83%, apparently at some site other than dihydrofolate reductase. The inhibition of purine synthesis by VII probably contributes significantly to the T/C % = 194. Previously, data indicated that quassinoids affected anaerobic and aerobic respiration of P-388 cells and that state 4 and state 3 respiration were inhibited ~50% by quassinoids at 0.015 mM. However, at 0.010 mM concentrations, the effect on oxidative phosphorylation was not as dramatic. Basal and coupled oxidative phosphorylation was inhibited ~15% by those compounds possessing a T/C % ≥125 in the antineoplastic screen. Reduction of oxidative phosphorylation processes would reduce the available energy for macromolecular synthesis in rapidly dividing cells, thus possibly indirectly affecting nucleic acid and protein synthetic pathways. Hence, it may be concluded that the optimum structural requirements for potent antileukemic activity and metabolic inhibition of P-388 cells are (*a*) bis-esters of brusatol with an ester carbon chain length of one or two and (*b*) a C-3, C-15 disenecioate or di-3,4-dimethyl-2-pentenoate side chain of bruceolide. Both types of structure require an enone system in ring A and a free hydroxyl group at positions C-11 and C-12.

Fluorescence Stability of Human Albumin Solutions

D. L. PARSONS

Received June 24, 1981, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication July 23, 1981. Present address: School of Pharmacy, Auburn University, Auburn, AL 36849.

Abstract □ The fluorescence stability on aging of three types of human albumin solutions was investigated. For the first 8 hr after preparation, the magnitude of the fluorescence of the albumin solutions examined did not undergo the large fluctuations with time that had been previously observed for bovine albumin solutions. The fluorescence intensity of each of the human albumin solutions examined appeared to undergo a small but consistent decrease with time for the length of each study. Based on these results, the practice of preparing human albumin solutions several hours prior to use simply to achieve fluorescence stability is unnecessary.

Keyphrases □ Fluorescence, stability—human albumin solutions □ Human albumin—evaluation of fluorescence stability □ Stability, fluorescence—human albumin solutions

The quenching of the intrinsic fluorescence of serum albumin and other proteins upon the binding of a ligand has been used for many years to study ligand–macromolecule interactions (1). In such studies it is important to correct the collected data for variations in fluorescence intensity that are due to factors other than the ligand–macromolecule interaction, such as the inner filter effect. Another factor that may affect the magnitude of the intrinsic fluorescence of a protein molecule is the age of the protein solution. The magnitude of the fluorescence of freshly prepared solutions of crystallized bovine serum albumin at pH 7.45 varies regularly as a function of time until the solutions are ~5-hr old (2). Fluorescence values for one bovine serum albumin solution varied from an initial value of ~72–65 after 2 hr, and to 85 after 3 hr before stabilizing at a value of 78 after 5 hr. To avoid these time-dependent fluctuations in fluorescence intensity, solutions of bovine serum albumin were not used for ligand binding studies until they were 5–6-hr old. It was suggested that these fluctuations in fluorescence intensity may be the result of a slow obtainment of equilibrium among various conformational species of this protein or to hydration of the bovine serum albumin molecules followed by a rearrangement to native structures. Similar events, which were termed conformational oscillations, were observed for other protein macromolecules (3).

BACKGROUND

In most ligand binding studies utilizing quenching of intrinsic fluorescence of human serum albumin, the possible effect of time was not discussed. However, the results of the study of the fluorescence stability of bovine serum albumin (2) have been applied to studies utilizing human serum albumin. In one binding study, solutions of both bovine and human serum albumin were not used for fluorescence quenching studies until the solutions were at least 6-hr old (4). In another study, measurements of the fluorescence of human serum albumin solutions were not taken until the solutions were 2–3-hr old (5), even though this is the time period when bovine serum albumin appears to undergo the greatest fluctuations in fluorescence (2). A different approach to the problem of fluorescence stability was used in another binding study (6). A reference solution of human albumin was used to correct the fluorometer for drifts in instrument response and for variations in intrinsic protein fluorescence during the titration of a second cell of human albumin with ligand. The magnitude of any variation observed in the fluorescence of these albumin solutions with time was not given. Of course, any variation observed in the magnitude of fluorescence in this study could be the result of instrument drift and/or photodecomposition rather than, or in addition to, the variation in intrinsic albumin fluorescence. In addition, if serum albumin undergoes large fluctuations in fluorescence with time as a result of a time-dependent obtainment of an equilibrium conformation, the binding of ligand could also be time dependent.

Since most ligand binding studies are currently conducted utilizing human, rather than bovine, serum albumin, the stability of the magnitude of fluorescence of human albumin solutions was investigated. The fluorescence stability of three types of human albumin was investigated, since any observed fluctuations in fluorescence could be the result of a time-dependent obtainment of an equilibrium conformation. The time required to obtain this equilibrium conformation could possibly depend on the method used to purify the protein.

EXPERIMENTAL

Materials—Fraction V[1], crystalline[2], and fatty acid-free fraction V[3] human albumin, and propranolol hydrochloride[4] were used as received. Human albumin solutions were prepared using 0.1 *M* phosphate buffer (pH 7.4). The buffer was prepared from analytical grade dibasic sodium phosphate[5], monobasic potassium phosphate[5], and water purified by reverse osmosis followed by distillation.

Methods—Measurements of the magnitude of fluorescence of 2×10^{-6} *M* solutions of human albumin were made at various time intervals after preparation on a spectrofluorometer[6] at excitation and emission wavelengths of 283 and 351 nm, respectively. Excitation and emission slit widths of 2 and 10 nm, respectively, were used for all fluorescence measurements. The fluorescence sample cells had a pathlength of 1 cm and were oriented in the same direction in the cell holder for each fluorescence measurement during an experiment. The zero time point was set as the time at which the human albumin was first brought into contact with the buffer solution. No fluorescence measurements were made for the following 30 min to ensure complete dissolution of the protein.

Fluorescence measurements were made at ambient temperature (23.4 ± 0.6°). However, the temperature of the cell compartment of the spectrofluorometer was found to increase steadily for the first 2 hr after the instrument was turned on. Therefore, an instrument warm-up time of at least 2 hr was used before any fluorescent measurements were taken. After temperature equilibration, the cell compartment temperature was ~4° higher than room temperature. A time of 5 min was found to be sufficient for the temperature equilibration of samples placed inside the cell compartment. The effect of fluctuations in ambient temperature was apparently less than random error, since changes in the magnitude of fluorescence did not follow the variations in temperature observed during these studies.

A solution of propranolol hydrochloride (1.3 μg/ml) in 0.01 *N* HCl was used as a reference solution for each fluorescence measurement to correct for drifts in spectrofluorometer response and to correct for variations in

Fraction V[a]	0.464	63.7	-3.18×10^{-3}	-1.67×10^{-3} to -4.69×10^{-3}

[a] Based on the data of Fig. 2.

the fluorescence sample cells used. No detectable change in the magnitude of the fluorescence of the reference solution occurred after 3 hr of continuous irradiation at the wavelength and slit width of excitation used in this study. The total irradiation time of the reference solution was not more than 15 min in subsequent experiments.

To prevent photodecomposition of the protein solutions, aliquots of the same solution of human albumin were irradiated in the spectrofluorometer only once for the few seconds required for a fluorescence measurement. Except as otherwise noted, fluorescence sample cells were rinsed six times with water followed by two rinses in spectrophotometric grade acetone between each use.

RESULTS AND DISCUSSION

The fluorescence intensities of human albumin solutions were determined at various times for 480 min after preparation. The results obtained for fraction V, crystalline, and fatty acid-free fraction V human albumin are presented in Fig. 1. The three data points obtained at each time point were obtained for three different protein solutions. To allow sufficient drying time after rinsing, two different fluorescence sample cells had to be used for each albumin solution when fluorescence measurements were made every 15 min for crystalline and fatty acid-free fraction V human albumin. In an attempt to decrease data variability, fluorescence measurements were only made every 30 min using the same fluorescence sample cell for each solution of fraction V human albumin.

The three types of human albumin were quite different with respect to the magnitude of their fluorescence. The magnitude of the fluorescence of each type of albumin was not corrected for differences in moisture content and purity. The greater fluorescence of fraction V as compared to the crystalline form of human albumin was observed previously for bovine serum albumin (4). The fatty acid-free fraction V human albumin exhibited the smallest fluorescence intensity of the human albumins examined. This decrease in fluorescence intensity may not be related to the decrease in the fatty acid content of the preparation. The fluorescence intensities of two crystalline human albumin preparations were found to differ, but the preparation containing the lowest content of fatty acid was more fluorescent (7). The difference in the emission spectra for three different crystalline human albumin samples which had equal absorbance values at the wavelength of excitation was apparently due to impurities other than fatty acids (8).

The magnitude of the fluorescence of the three types of human albumin examined in this study did not undergo the large fluctuations with time that had been previously observed for a bovine albumin solution (2). Therefore, it is not necessary to prepare these albumin solutions several hours prior to fluorescence measurements to allow the intrinsic protein fluorescence to stabilize. Of course, the proteins examined could have undergone conformational changes during this time period which were not reflected by changes in fluorescence intensity.

While large fluctuations in fluorescence intensity with time were not observed with the human albumin solutions used in this study, the magnitude of the fluorescence of the solutions appeared to undergo a small but continuous decrease with time for the length of each study. Much of the variability in the data for each type of protein was due to differences between the individual protein solutions used. For each type of human albumin at each time point, one albumin solution consistently had the highest fluorescence intensity while another albumin solution consistently had the lowest fluorescence. The apparent decrease in the magnitude of the fluorescence of each human albumin solution observed 480 min after preparation is not much greater than the experimental

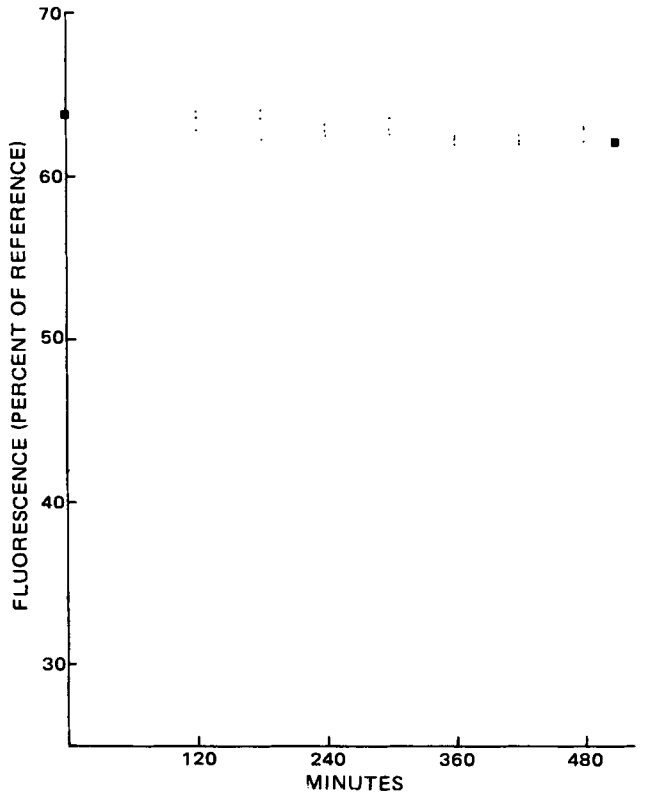

Figure 2—*The magnitude of fluorescence of fraction V human albumin solutions upon aging when fluorescence sample cells are cleaned with sulfuric acid–dichromate solution between measurements. Key: ■, the linear regression line of the data.*

variability observed in the fluorescence intensity of the different albumin solutions at each time point.

The results of linear regression analysis of the data for each type of human albumin are presented in Table I. While the r^2 value for each set of data is very low, the slope of each set of data does have a small negative value and zero is not included in the 95% confidence interval of the slope. The points at $t = 0$ and $t = 510$ min in Fig. 1 represent the linear least-squares fit of the experimental data. The actual lines were not drawn so that the experimental data could be examined without obstruction.

To determine if the small decrease in fluorescence intensity with time was due to inadequate washing of fluorescence sample cells between sample measurements, the experiment with fraction V human albumin was repeated. In this second study, fluorescence measurements were taken every hour to decrease the use of each sample cell. After each fluorescence measurement the cells were rinsed once with water, filled with sulfuric acid–dichromate cleaning solution for 15 min and rinsed using the procedure used in the previous experiments. The results are presented in Fig. 2. The fluorescence intensities of the solutions again appeared to undergo a small decrease with time. The results of linear regression analysis of the data are presented in Table I. The slope has a small negative value which is within the 95% confidence interval of the slope previously obtained for fraction V human albumin. As observed previously, zero is not within the 95% confidence interval of the slope. Thus, this different method of sample cell treatment between fluorescence measurements had no significant effect on the apparent decrease in fluorescence intensity of these protein solutions with time.

In conclusion, the intrinsic fluorescence intensity of each of the solutions of human albumin examined in this study was very stable for the first 8 hr after preparation. Based on these results, the practice of preparing solutions of human albumin several hours prior to use simply to achieve fluorescence stability is unnecessary. Since the fluorescence intensity of each of the albumin solutions examined underwent a small, consistent decrease with time, it may be advisable to use a reference solution of human albumin, as described previously (6), to correct binding data obtained from the quenching of intrinsic human albumin fluorescence by ligand.

Separation of Penicillin and Its Major Degradation Products by Ion-Pair Reversed-Phase High-Pressure Liquid Chromatography

ISAAC GHEBRE-SELLASSIE *, STANLEY L. HEM ‡, and ADELBERT M. KNEVEL *x

Received March 12, 1981, from the **Department of Medicinal Chemistry and Pharmacognosy and the ‡Department of Industrial and Physical Pharmacy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication June 11, 1981.

Abstract □ An ion-pair reversed-phase high-pressure liquid chromatographic technique capable of separating penicillin and its major degradation products within 8 min was developed. The influence of pH, counterion concentration, buffer concentration, and organic modifier content was studied and the observed behavior of the compounds during the chromatographic process was discussed.

Keyphrases □ Penicillin—major degradation products, separation by ion-pair reversed-phase high-pressure liquid chromatography □ High-pressure liquid chromatography—ion-pair reversed-phase, separation of penicillin and its major degradation products □ Degradation products—penicillin, separation by ion-pair reversed-phase high-pressure liquid chromatography

Various analytical methods for the detection, separation, and/or quantification of penicillin in the presence of its degradation products have been reported (1–7). The most recent papers deal with anion-exchange chromatography (5), reversed-phase chromatography (6), and NMR spectroscopy (7). NMR generally lacks sensitivity while the chromatographic approaches result in relatively long analysis times. However, the availability of small-particle size packings for reversed-phase chromatography suggests that very high chromatographic efficiencies and shorter analysis times can be expected with this procedure (8, 9). The present paper describes a high-pressure liquid chromatographic (HPLC) method that utilizes an ion-pair reversed-phase technique to separate penicillin and its three major degradation products: penillic acid, penicilloic acid, and penilloic acid in <8 min.

EXPERIMENTAL

Chemicals and Reagents—Penicillin G potassium[1] and tetrabutylammonium chloride[2] were obtained commercially and used without further treatment. Penillic acid, penicilloic acid, and penilloic acid were synthesized by standard methods (10). Acetonitrile was HPLC grade[3] while all other chemicals were either USP or reagent grade. Double-distilled water was used to prepare buffer solutions.

Apparatus—A liquid chromatograph[4] equipped with a fixed-wavelength UV absorbance detector set at 254 nm was used. A commercial stainless steel column[5] (150-mm × 4.6-mm i.d.) prepacked with 5-μm particles, with the silanol groups chemically bonded to a monomolecular layer of octadecylsilane, was used. A strip-chart recorder[6] recorded the detector output.

Chromatographic Conditions—The mobile phase was composed of acetonitrile, phosphate buffer, and a counterion. The ion-pair reagent, tetrabutylammonium chloride, was dissolved in the phosphate buffer

variability observed in the fluorescence intensity of the different albumin solutions at each time point.

The results of linear regression analysis of the data for each type of human albumin are presented in Table I. While the r^2 value for each set of data is very low, the slope of each set of data does have a small negative value and zero is not included in the 95% confidence interval of the slope. The points at $t = 0$ and $t = 510$ min in Fig. 1 represent the linear least-squares fit of the experimental data. The actual lines were not drawn so that the experimental data could be examined without obstruction.

To determine if the small decrease in fluorescence intensity with time was due to inadequate washing of fluorescence sample cells between sample measurements, the experiment with fraction V human albumin was repeated. In this second study, fluorescence measurements were taken every hour to decrease the use of each sample cell. After each fluorescence measurement the cells were rinsed once with water, filled with sulfuric acid–dichromate cleaning solution for 15 min and rinsed using the procedure used in the previous experiments. The results are presented in Fig. 2. The fluorescence intensities of the solutions again appeared to undergo a small decrease with time. The results of linear regression analysis of the data are presented in Table I. The slope has a small negative value which is within the 95% confidence interval of the slope previously obtained for fraction V human albumin. As observed previously, zero is not within the 95% confidence interval of the slope. Thus, this different method of sample cell treatment between fluorescence measurements had no significant effect on the apparent decrease in fluorescence intensity of these protein solutions with time.

In conclusion, the intrinsic fluorescence intensity of each of the solutions of human albumin examined in this study was very stable for the first 8 hr after preparation. Based on these results, the practice of preparing solutions of human albumin several hours prior to use simply to achieve fluorescence stability is unnecessary. Since the fluorescence intensity of each of the albumin solutions examined underwent a small, consistent decrease with time, it may be advisable to use a reference solution of human albumin, as described previously (6), to correct binding data obtained from the quenching of intrinsic human albumin fluorescence by ligand.

and the pH was adjusted with 1 *M* phosphoric acid before the required volume of acetonitrile was added. The mixture was filtered through a 0.45-μm filter[7] and degassed prior to use. The column was operated at ambient temperatures. Samples were introduced *via* an injection port[8] fitted with a 20-μl loop. The flow rate and the chart speed were 1.5 ml/min and 0.51 cm/min, respectively. The sensitivity range of the detector was set at 0.16 aufs.

RESULTS AND DISCUSSION

Penicillin and its major degradation products contain carboxylic acid functional groups with pH-dependent ionic states. Consequently, in the past, anion-exchange chromatography was usually used for the separation

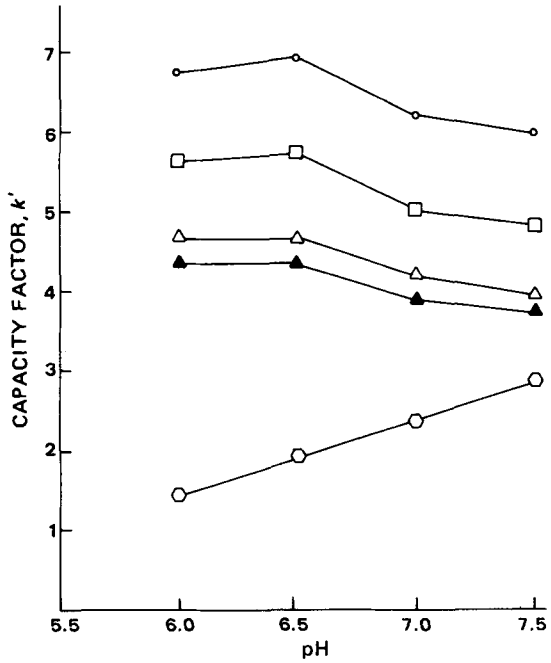

Figure 2—*Plots of the capacity factor* versus *the mobile phase pH. Key:* ○, *penicillin;* □, *penicilloic acid;* △,▲, *penilloic acid; and* ○, *penillic acid.*

of these compounds. A reversed-phase mode utilizing an ion-suppression technique also was employed to achieve separation. However, in addition to having long analysis times, both methods use mobile phases with pH values less than optimum with respect to the stabilities of the compounds being analyzed.

The ion-pair reversed-phase technique reported here combines the advantages of both methods and also utilizes mobile phases with pH values compatible with the chemical stabilities of the solutes (10, 11). The pH range selected (6.0–7.5) satisfies the requirement that bonded-phase columns not be used at high pH while also maximizing the ionization of the solutes, despite the reported rise in pKa values as organic modifiers are added to aqueous solutions (12).

The effects of pH, counterion concentration, acetonitrile content, and phosphate buffer concentration on the capacity factors (k') and separation selectivities were studied (Figs. 1–4). The k' values of penicillin and its major decomposition products were affected substantially by a change in the percent composition of acetonitrile in the mobile phase (Fig. 1).

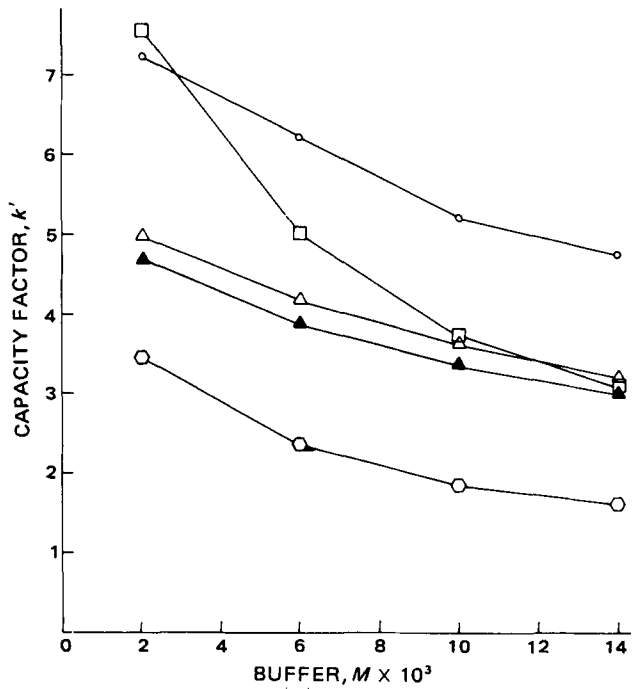

Figure 4—*Plots of the capacity factor* versus *the phosphate buffer concentration in the mobile phase. Key:* ○, *penicillin;* □, *penicilloic acid;* △,▲, *penilloic acids; and* ○, *penillic acid.*

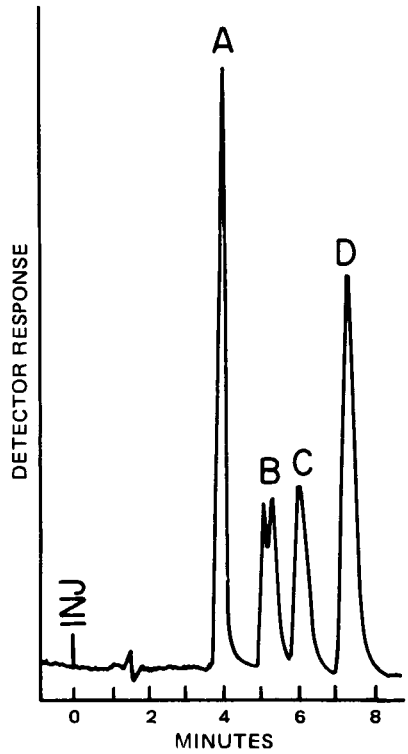

Figure 5—*Ion-pair reversed-phase high-pressure liquid chromatogram of penicillin and its major degradation products. Key: A, penillic acid; B, penilloic acid; C, penicilloic acid; and D, penicillin.*

At high acetonitrile concentrations, all four compounds gave sharp and symmetrical peaks; however, the capacity factors were so close to each other that the resolution was inadequate. Lowering the acetonitrile content improved the resolution significantly. Even the single peak of penilloic acid was partially resolved into two peaks which presumably represent the 5*R* and 5*S*, diastereoisomers of the compound (7).

Maximum k' values for penicillin, penicilloic acid, and penilloic acid were obtained between pH 6.0 and 6.5, when the compounds were completely ionized and ion-pair formation was at a maximum (Fig. 2). As the pH of the mobile phase increased, the k' values of the three anionic compounds decreased, presumably because hydroxyl ions compete with them and reduce the number of ion-pairs that would be formed (13). Although the penillic acid pK_1 and pK_2 values were similar to the ionization constants of the other three compounds (14), its capacity factor increased proportionally with an increase in pH.

Initially, the k' values of the sample molecules increased as the concentration of the ion-pair reagent was raised, but leveled off at higher concentrations (Fig. 3). This was expected because, once all sample anions form ion-pairs, the excess counterions would have no direct effect on retention. However, the ionic strength of the mobile phase increases and, in turn, varies the capacity factors. At low concentrations of ion-pair reagent, the retention times of the compounds are greatly reduced since the number of counterions available is insufficient for maximum ion-pair formation.

Furthermore, an increase in buffer concentration in the mobile phase led to a significant decrease in k' values of penicillin and its degradation products (Fig. 4). This was thought to be due mainly to the phosphate ions tying up the counterions, which would otherwise form ion-pairs with sample molecules. The simultaneous increase in ionic strength also influences the k' values of sample anions.

Logarithmic plots of the capacity factors and the four parameters studied showed linear relationships with correlation coefficients >0.99. The slopes of the curves in each graph were not always the same, clearly indicating the array of selectivities offered by the chromatographic system.

The composition of the mobile phase used to develop the chromatogram in Fig. 5 was determined by these studies. A pH of 7.5 was chosen because the peaks of the compounds were significantly removed from the solvent front and the compounds that eluted last had the lowest k' value compared to those at other pH values. Both 0.008 and 0.012 *M* tetrabutylammonium chloride yielded excellent resolution of the four compounds, but the former concentration was selected because it gave better resolution between the penicillin and penicilloic acid peaks, thus reducing the probability of overlap that might occur at high penicillin concentrations. A 0.006 *M* buffer concentration in the mobile phase offered the best selectivity and was taken as the optimum value. A 30% acetonitrile concentration was used since it provided maximum separation and reasonable analysis time.

The described chromatographic method could be extended to include other degradation products of penicillin. The four compounds studied were selected primarily for two reasons: (*a*) penicilloic acid, penillic acid, and penilloic acid are of prime importance in stability studies since they are major decomposition products of penicillin in acidic and basic media, and (*b*) since penicillin and penilloic acid are monocarboxylic acids, and penicilloic and penillic acids are dicarboxylic acids, a detailed study of their behavior in ion-pair reversed-phase chromatography could assist in the application of this analytical method for other degradation products of penicillin and similar compounds of pharmaceutical interest.

Interaction of Theobromine with Sodium Benzoate

JUZIRO NISHIJO ˣ and IKUKO YONETANI

Received March 30, 1981, from the *Kobe Women's College of Pharmacy, Motoyama-Kitamachi, Higashinada-ku, Kobe 658, Japan.* Accepted for publication June 22, 1981.

Abstract □ The interaction of theobromine with sodium benzoate was investigated by PMR spectroscopy. The interaction of theobromine with pentadeuterated benzoic acid (benzoic acid-d_5) was examined in the same manner but to a lesser degree. Chemical shifts of theobromine protons were determined as a function of sodium benzoate concentration in deuterium oxide at 30 and 15°. Signals of both methyl groups of theobromine underwent significant upfield shifts when sodium benzoate was added to a theobromine solution. This fact suggests that a complex is formed by vertical stacking or plane-to-plane stacking. The same results were obtained for benzoic acid-d_5.

Keyphrases □ Theobromine—interaction with sodium benzoate □ Sodium benzoate—interaction with theobromine □ Diuretics—theobromine, interaction with sodium benzoate

Xanthine derivatives such as theophylline and caffeine form a 1:1 complex with sodium benzoate in aqueous solution. The physicochemical properties relating to this complex formation were studied by various methods including calorimetry (1), a solubility method (2), and by PMR spectroscopy (^{1}H-NMR) (3, 4). In the present study, the interaction of theobromine(I), a xanthine derivative, with either sodium benzoate(II) or pentadeuterated benzoic acid (benzoic acid-d_5)(III) was studied by ^{1}H-NMR in deuterium oxide.

EXPERIMENTAL

Materials—Reagent grade theobromine[1] and sodium benzoate JP were used without further purification. Benzoic acid-d_5 (>99.0% pure) and deuterium oxide (99.8%) were used as received[2].

Methods—To examine whether self-association of theobromine takes place, 1.9×10^{-4}–2.6×10^{-3} *M* theobromine was prepared. The concentration of theobromine was maintained constant while that of benzoic acid-d_5 was varied from 1.0×10^{-3} to 3.0×10^{-2} *M* and that of sodium benzoate varied from zero to 1 *M*. ^{1}H-NMR spectra were recorded[3] in duplicate at probe temperatures of 30 ± 0.5° or 15 ± 0.5°. External tetramethylsilane was used as the reference and as the source of a lock signal[4].

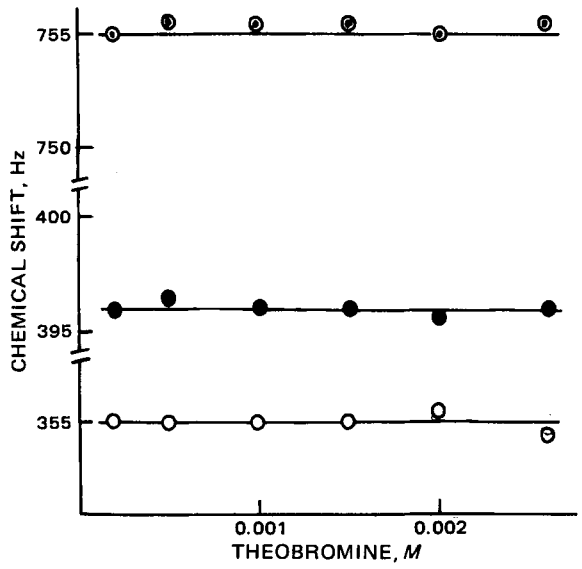

Figure 1—*Concentration dependence of theobromine proton chemical shifts. Key:* ⊙, *8-H;* ●, *7-CH_3; and* ○, *3-CH_3.*

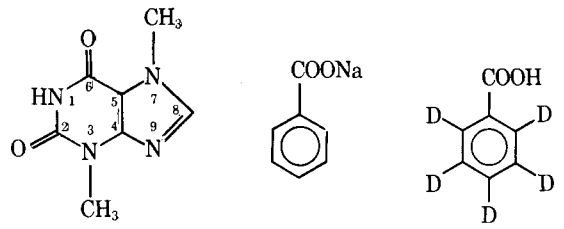

I II III

Bulk susceptibility corrections were tried, but it was found that they were not necessary. In the theobromine-sodium benzoate system, the corrections were too small in comparison with the large induced chemical shift changes due to complexation (4) and in the theobromine-benzoic acid-d_5 system and the study of theobromine self-asasociation, the volume magnetic susceptibilities of the samples were equal to deuterium oxide for the low concentrations of theobromine and benzoic acid-d_5. Chemical shifts were reproducible to better than 0.5 Hz.

RESULTS AND DISCUSSION

The ^{1}H-NMR spectrum of the 1.5×10^{-3} *M* deuterium oxide solution of theobromine has three signals of relative intensities 1:3:3, at 8.36, 4.40, and 3.94 ppm (from external tetramethylsilane), corresponding to the proton at C-8 and to the 7- and 3-methyl protons, respectively, at 30°. The self-associations of theophylline (5) and caffeine (6) in aqueous solution is known, but theobromine self-association has not been reported.

Initially, ^{1}H-NMR spectra of theobromine in deuterium oxide were recorded at 30°. The results (Fig. 1), show that none of the theobromine proton chemical shifts changed regardless of the theobromine concentration and, therefore, no theobromine self-association appears to occur

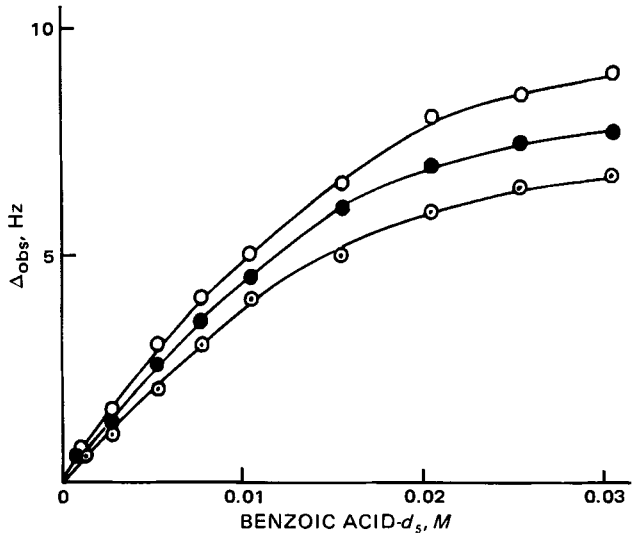

Figure 2—*Induced chemical shift changes for theobromine protons as a function of benzoic acid-*d_5. *Key:* ○, *3-CH_3;* ●, *7-CH_3; and* ⊙, *8-H.*

within the concentration range examined. Because of poor theobromine solubility in water, it is thought that theobromine molecules exist mostly in a monomer state.

^{1}H-NMR spectra of the solution containing both theobromine in a fixed concentration of 1.5×10^{-3} *M* benzoic acid-d_5 at various concentrations were recorded at 30°. Signals for the proton at C-8, and the 7- and 3-methyl protons of theobromine, shifted upfield with an increase in the benzoic acid-d_5 concentration. The extent of the upfield shift of the 3-methyl protons was larger than that of the 7-methyl protons and that of the 7-methyl protons was larger than that of the proton at C-8 (Fig. 2).

The upfield shifts of the 3- and 7-methyl signal, and the proton signal at C-8 in the presence of benzoic acid-d_5 suggest that theobromine and benzoic acid form a complex in which the 3- and 7-methyl groups, and the C-8 proton in the theobromine molecule are located over the benzene ring of benzoic acid. The relative small upfield shift of the C-8 proton signal may be caused by compensation with a downfield shift, resulting from the addition of a proton arising from benzoic acid-d_5 to nitrogen at the 9 position of theobromine. However, the addition of a proton seems to occur very sparingly because benzoic acid is weakly acidic with a pKa of 4.19 (7) at 25°. The pKa assigned to nitrogen at the 9-position of theobromine is 0.45 (8) at 18°.

To confirm this theory, the pH of an aqueous solution of 1.5×10^{-3} *M* theobromine was measured at 18° in the presence of 2.0×10^{-2} *M* benzoic acid. Using this value (pH 3.05), theobromine and protonated theobromine were in a molar ratio of 500:1 and the theory was proven valid. Consequently, the 3-methyl protons are nearer the axis of the benzene ring than the 7-methyl protons, which in turn are nearer the axis than the C-8 proton.

^{1}H-NMR spectra of the solution containing both 1.5×10^{-3} *M* theobromine and sodium benzoate at various concentrations were measured (Fig. 3). The signals of the 3- and 7-methyl protons shifted upfield with an increase in the sodium benzoate concentration, the extent of the upfield shift of the 3-methyl protons being slightly larger than that of the 7-methyl protons. The signal of the proton at C-8 could not be measured because of the overlap with the signals of benzene protons of sodium benzoate. These results suggest that the formation of a complex between theoxyline and benzoic acid or sodium benzoate involves vertical stacking or plane-to-plane stacking. It was similarly reported (4) that theobromine interacts with sodium benzoate to form a complex by vertical stacking or plane-to-plane stacking.

Table I—Apparent Thermodynamic Parameters for Complex Formation of Theobromine with Sodium Benzoate in Deuterium Oxide

Parameter	15°		30°
K, M^{-1}	2.6[a]		1.4[a]
ΔG, kcal/mole	−0.55		−0.20
ΔH, kcal/mole		−7.1	
ΔS, kcal/mole degree	0.023		0.023

[a] Average value calculated from 3-CH_3 and 7-CH_3 of theobromine.

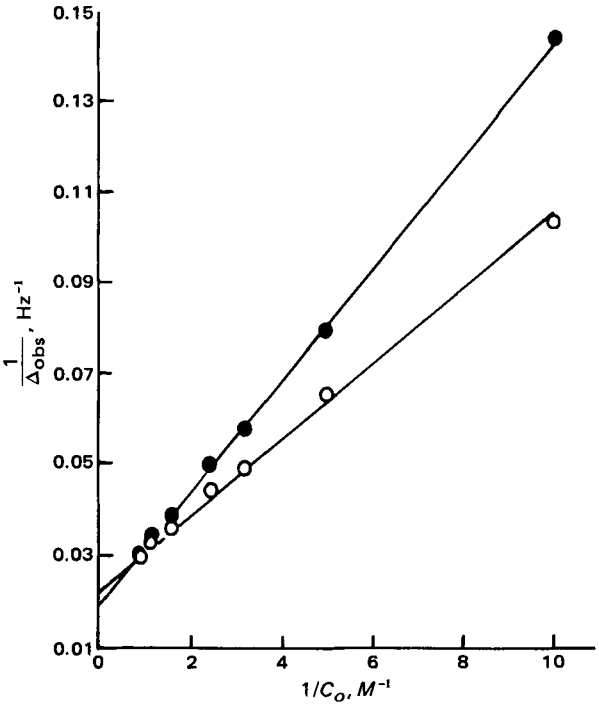

Figure 4—*Plots of theobromine 7-CH_3 versus $C_b{}^{-1}$ of sodium benzoate. Key: ●, 30°; and ○, 15°.*

Following an earlier procedure (9), the apparent formation constant *K* was calculated using Eq. 1, assuming a 1:1 complex:

When $C_b \gg C_a$

$$\frac{1}{\Delta_{obs}} = \frac{1}{K(\delta_c - \delta_a)} + \frac{1}{\delta_c - \delta_a} \qquad \text{(Eq. 1)}$$

where:

K = apparent formation constant
C_a = theobromine concentration
C_b = sodium benzoate concentration
δ_c = chemical shift of theobromine proton in the complex form
δ_a = chemical shift of theobromine proton in the uncomplex form
Δ_{obs} = the difference between the observed chemical shift and δa

The results are shown in Fig. 4 and the apparent formation constant is listed in Table I. The results of the interaction of theobromine with sodium benzoate at 15 and 30° are shown in Figs. 3 and 4 and Table I. As the apparent formation constant *K* was varied depending on temperature, the enthalpy change of complex formation (ΔH), the free energy change (ΔG), and the entropy change (ΔS) were calculated (Table I).

It was concluded that the complex formation of theobromine with sodium benzoate is an exothermic reaction accompanied by reduction of entropy.

Antileukemic Activity of Tetrazole Analogs of Phenylalanine Derivatives

C. M. DARLING

Received February 18, 1981, from the *Auburn University School of Pharmacy, Department of Pharmacal Sciences, Auburn, AL 36849.* Accepted for publication June 9, 1981.

Abstract □ Eleven tetrazole analogs of substituted phenylalanines were prepared and tested for antitumor activity using P-388 lymphocytic leukemia cells in mice. None of the compounds exhibited significant activity (T/C %, < 125).

Keyphrases □ Antileukemic activity—tetrazole analogs of substituted phenylalanines against P-388 lymphocytic leukemia □ Phenylalanines, substituted—tetrazole analogs, preparation and screening for antileukemic activity □ Tetrazole—analogs of substituted phenylalanines, preparation and screening for antileukemic activity

The demand for nutrients differs between tumor cells and normal cells (1). Since rapidly proliferating cancer cells take up nutrients more rapidly, they may be selectively "starved" by substituting nonfunctional amino acid derivatives for the normal substrate. *N*-Chloroacetyl derivatives of *para*-substituted phenylalanines were reported (2) to have significant growth inhibitory activity in a microbial antitumor prescreen.

Recent reviews (3, 4) indicated that no reports have appeared for testing tetrazole analogs of amino acids for antineoplastic activity. Studies of the biological activity of 5-substituted tetrazoles have been prompted by a close similarity between the acidity of the tetrazole group and the carboxylic acid group, and the fact that the tetrazole function appears to be metabolically more stable (3).

The chemically similar tetrazole ring system (5) has been used to replace the carboxyl group in several amino acids (6–8). These *in vitro* studies suggested that the tetrazole analog may serve as substrate inhibitor of the respective amino acid in certain enzymatic reactions. The purpose of this study was to determine whether tetrazole analogs of certain phenylalanine derivatives would exhibit antileukemic action in mice.

EXPERIMENTAL[1]

Aryl-substituted Ethyl 2-Acetamido-2-cyano-3-phenylpropanoates (I–VII)—A previously reported method (6) was used to prepare intermediates I–VII. Physical and chemical data are shown in Table I.

NMR data agreed with the proposed structures. The NMR spectra (dimethyl sulfoxide-d_6, tetramethylsilane internal standard) showed the following common absorption peaks: δ 1.00–1.20 (t, 3H, CCH_3), 1.90–2.10 (s, 3H, $COCH_3$), 3.35–3.55 (s, 2H, aryl CH_2C), 4.00–4.20 (q, 2H, OCH_2C), and 7.10–7.90 (4H, the pattern varied depending on the ring substituent) ppm. Each spectrum integrated for the correct number of protons. The spectra of V and VI exhibited an additional absorption peak at δ 3.70 (s, 3H, OCH_3). The isopropyl ester of II showed absorption peaks for isopropyl at δ 1.10 [m, 6H, $C(CH_3)_2$] and 4.90 (m, 1H, CH) ppm.

Aryl-substituted Ethyl 1-Acetamido-1-tetrazol-5-yl-2-phenylpropanoates (VIII–XIV)—Intermediates VIII–XIV were prepared

[1] Elemental analyses were performed by Atlantic Microlab, Atlanta, Ga. NMR data were recorded on a Varian T-60A spectrophotometer. Melting points were taken in open capillary tubes and are uncorrected.

using a previous procedure (6) and Table II lists their physical and chemical data.

In agreement with the proposed structures, the NMR data exhibited the common absorption peaks (dimethyl sulfoxide-d_6, tetramethylsilane internal standard): δ 1.10–1.20 (t, 3H, CCH_3), 1.90–2.00 (s, 3H, $COCH_3$), 3.65–3.85 (s, 2H, aryl CH_2C), 4.10–4.20 (q, 2H, OCH_2C), and 6.80–7.30 (m,4H, aromatic) ppm. The spectra of XII and XIII showed a singlet at δ 3.60 ppm that integrated for 5 protons (aryl CH_2 and aryl OCH_3).

Aryl-substituted 5-(1-Amino-2-phenylethyl)tetrazoles XV–XXII)—Compounds XV–XX and XXII were prepared by a previously reported method (6). Compound XXI was prepared by modification of a previously reported method (9). A mixture of compound XX (3.0 g, 0.014 mole) in 48% hydrogen bromide (50 ml) was heated at reflux under nitrogen for 4 hr. The mixture was concentrated under reduced pressure. The residue was dissolved in distilled water and the pH was adjusted to 7 with concentrated ammonium hydroxide. After standing at room temperature for 12 hr, the product was filtered, air dried, and recrystallized from *N,N*-dimethylformamide, 2.2 g (76.6%), mp 290° dec. Table III contains physical and chemical data for XV–XXII.

Assignments of the common NMR absorption peaks are (10% sodium deuteroxide): δ 2.95–3.10 (m, 2H, aryl CH_2), 4.30–4.50 (m, 1H, CCH), and 6.70–7.20 (m, 4H, aromatic) ppm. There was an additional absorption peak for XIX and XX at δ 3.40 (s, 3H, aryl OCH_3) ppm.

Anticancer Screening—The tetrazole analogs of substituted phenylalanines were screened for anticancer activity[2] using P-388 lymphocytic leukemia cells in mice of either sex. On day zero, mice were inoculated intraperitoneally with 10^6 leukemic cells. Twenty-four hours later, a test compound was administered intraperitoneally once daily for the first 9 days or in three injections on every 4th day (XVI, XXIII). The test results were recorded on the 30th day.

[2] Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, Silver Spring, MD 20910.

RESULTS AND DISCUSSIONS

All compounds were tested for antileukemic activity at doses of 25, 50, 100, and 200 mg/kg (some in triplicate). For compounds XVI, XVIII, and XIX, the T/C% was near or greater than 125. For all other compounds, the T/C% was < 125 (all mice died when compounds XX and XXIII were administered at 200 mg/kg). Compounds XVI, XVIII, and XIX were retested at 400 mg/kg (in duplicate) and exhibited a T/C% < 125. None of the compounds exhibited significant antileukemic activity.

Analysis of Commercial Pilocarpine Preparations by High-Performance Liquid Chromatography

MICHAEL V. DRAKE ˣ, JAMES J. O'DONNELL, and ROBERT P. SANDMAN

Received May 11, 1981, from the *Department of Ophthalmology, University of California, San Francisco, CA 94143.* Accepted for publication July 15, 1981.

Abstract □ Pilocarpine, isopilocarpine, pilocarpic acid, and isopilocarpic acid can be measured effectively by high-performance liquid chromatography (HPLC). Previous reports have differed on the degree of contamination of commercial pilocarpine preparations with isopilocarpine and pilocarpic acid. This report describes a study of commercial pilocarpine in which no significant contamination was found.

Keyphrases □ Pilocarpine—analysis of commercial preparations by high-performance liquid chromatography □ High-performance liquid chromatography—analysis of commercial pilocarpine □ Ocular agents—pilocarpine, analysis by high-performance liquid chromatography

Several assays have been reported for pilocarpine, isopilocarpine, pilocarpic acid, and isopilocarpic acid using high-pressure liquid chromatography (HPLC) (1–4). The earliest of these reports includes the results of a study done on commercial pilocarpine samples, which showed that in one case, contamination with isopilocarpine was as high as 25% (1). An effort to corroborate this study failed, due to technical difficulties (2). Modifications of the original HPLC method were used in a recent study of commercial pilocarpine preparations and no significant contamination with the isopilocarpine isomer or the degradation products, pilocarpic acid or isopilocarpic acid, was found (5). The present report describes a similar study.

EXPERIMENTAL

Each locally available commercial pilocarpine preparation was obtained through prescription from a retail pharmacy. Letters were sent to all other manufacturers[1] of pilocarpine asking for a 1% sample of their product to be used for animal experimentation. Nine fresh samples of pilocarpine were obtained. Each sample was diluted with HPLC grade water to a concentration of 0.10%. Pilocarpine hydrochloride[2] and isopilocarpine hydrochloride[3] standards were obtained commercially in powder form. Pilocarpic acid and isopilocarpic acid were prepared by the hydrolysis of pilocarpine and isopilocarpine in 0.1 *N* NaOH, respectively. These were diluted to make 0.10% standard solutions.

The mobile phase was prepared by dissolving 50 g of monobasic potassium phosphate in a solution of 900 ml of water and 30 ml of methanol. The solution pH was adjusted to 2.5 with 85% phosphoric acid, and the total volume was brought to 1 liter with water. Separation was achieved by isocratic reversed-phase chromatography[4] on an RP-C18 10μm column[5], (flow rate 1.5 ml/min) at ambient temperature. Detection was by optical absorbance at 216 nm[6]. Peak heights of standard preparations were compared with peak heights of the unknown commercial prepara-

Table I—Commercial Pilocarpine Samples (1%) Compared with a Fresh Pilocarpine Standard

Sample	Percent of Labeled Amount of Pilocarpine Actually Found	Percent Isopilocarpine Found
1	100	1.1
2	99	2.6
3	100	5.5
4	95	5.7
5	101	4.9
6	105	4.0
7	104	1.1
8	102	0.9
9	98	—

tions. There was slight peak tailing; the minimum amount of isopilocarpine detectable in the presence of pilocarpine was 1 part in 100.

RESULTS AND DISCUSSION

Isopilocarpine eluted first at ~10 min followed by pilocarpine, pilocarpic acid, and isopilocarpic acid. The entire process was complete in 20 min. The concentration of pilocarpine found by HPLC analysis was within 5% of the concentration stated by the manufacturer on the label in all cases. The amount of isopilocarpine present ranged from 0.0 to 5.7% of the pilocarpine present (Table I). Pilocarpic acid or isopilocarpic acid were not found in significant quantities in any sample. These results agree with a recent study (5) and are in contrast to another report (1).

There are several possible explanations for the disagreement between this study and the earlier study (1). The official USP method for determining the purity of pilocarpine preparations at the time of the previous report did not effectively distinguish between pilocarpine and isopilocarpine (7). It is possible that pharmaceutical industry standards for purity of pilocarpine preparations have been modified such that they now exceed standards. Another possible explanation is that fresh samples of pilocarpine were used, and degradation products which would have appeared after prolonged storage were not present in these samples.

The results of this study and the study by Noordam *et al.* (5) illustrate the effectiveness of HPLC for pilocarpine assay. Because these newer methods are capable of providing more accurate analysis of pilocarpine than the current official USP method, it is reasonable to consider modifying the USP to reflect more current technology.

Novel Method of Derivatization of an Amidinourea (Lidamidine) for GLC Analysis

C. M. WON ˣ, J. J. ZALIPSKY, D. M. PATEL, and W. M. GRIM

Received February 20, 1981, from the *Analytical & Physical Chemistry Department, Research & Development Division, William H. Rorer, Inc., Fort Washington, PA 19034.* Accepted for publication June 9, 1981.

Abstract □ A new quantitative GLC method for analysis of lidamidine hydrochloride (I) was developed. The method was based on derivatization of I to 1-(2,6-dimethylphenyl)-4-methylamino-dihydro-1,3,5-triazin-2-one (II) using dimethylformamide dimethylacetal reagent. Compound II was synthesized and characterized by IR, NMR, mass spectrometry, and elemental analysis. The assigned structure was in agreement with characterization analyses. Cyclization of I to a triazinone using dimethylformamide dimethylacetal reagent presented a new route for the preparation of II.

Keyphrases □ Lidamidine—derivatization to a triazinone for GLC analysis □ GLC—derivatization of lidamidine to a triazinone for GLC analysis □ Triazinones—derivatization of lidamidine for GLC analysis

The arylamidinoureas are a family of compounds pharmacologically active on the GI tract, and the cardiovascular and central nervous systems. They also demonstrate local anesthetic activity[1]. Among a series of substituted arylamidinoureas, lidamidine hydrochloride, *N*-(2,6 - dimethylphenyl) - *N'* - [imino(methylamino)methyl]urea hydrochloride (I), exhibited promising antidiarrheal activity. Extensive pharmacological, toxicological, and biochemical studies of I have been reported (1–6). The chemical synthesis (7), the hydrolysis kinetics, and the physical and chemical parameters of I were also reported (8).

Stability-indicating high-performance liquid chromatographic (HPLC) methods[1] were developed to analyze I quantitatively in the presence of impurities or hydrolysis products. A direct GLC method to quantitate I failed because of its low volatility and/or thermal instability. The separation of amidinoureas by the GLC method required derivatization of the functional groups. Derivatization attempts by conventional silylation and acylation methods were unsuccessful.

For the derivatization of primary amines, dimethylformamide dimethylacetal reagent is used to form the *N*-dimethylaminoethylene derivative (9). When substituted guanidines were derivatized by dimethylformamide dimethylacetal, the resultant *N*-dimethylaminoethylene derivative underwent further cyclization reactions to form

triazine derivatives (10). Biguanides are also known to undergo similar cyclization reactions on derivatization by trifluoroacetic anhydride (11) and *p*-nitrobenzoyl chloride (12).

Dimethylformamide dimethylacetal was used to derivatize I with the hope that a similar reaction would occur and a stable derivative could be formed. The resultant derivative was a triazinone-type compound, which involved cyclization of I during the derivatization.

EXPERIMENTAL

Materials—*N*,*N*-Dimethylformamide dimethylacetal[2], *N*,*N*-dimethylformamide[3], triphenylethylene[4], and tetraphenylethylene[4] were used without further purification.

Instrumentation—A gas chromatograph[5] and an electronic integrator[6] equipped with a flame-ionization detector were used. The 183-cm × 4-mm i.d. glass column was packed with 10% methyl silicone gum[7] on 80–100 mesh diatomaceous earth[8]. The injection port, column, and detector temperatures were maintained isothermally at 270, 250, and 270°, respectively. Nitrogen was used as the carrier gas at a flow rate of 45 ml/min.

Derivatization—Approximately 10 mg of I and 3 mg of an internal standard (triphenylethylene or tetraphenylethylene) were weighed accurately and placed into a 1-ml hypodermic vial and dissolved in 1 ml of *N*,*N*-dimethylformamide. Using a syringe, 0.1 ml of *N*,*N*-dimethylformamide dimethylacetal reagent was added to the vial. The vial was sealed with a silicone rubber septum, shaken, and put in an oven at 110° for 20 min. An aliquot (2 μl) was injected into a gas chromatograph.

Isolation of the Derivative (II)—The derivative was prepared in larger quantity for isolation and characterization. Approximately 200 mg of I was placed in a hypodermic vial and dissolved in 1 ml of acetonitrile. To the solution was added 0.2 ml of *N*,*N*-dimethylformamide dimethylacetal reagent. The vial was sealed and heated at 105° for 15 min in an oven. Seven identical preparations in the separate vials were made. The contents of the vials were pooled and placed in a round-bottom flask and evaporated to dryness under reduced pressure. The resultant solid residue was dissolved in a mixture of 30 ml of chloroform and 20 ml of water in a 60-ml separator and shaken vigorously. The aqueous layer was discarded and the chloroform layer was washed with another 20 ml of water. To the chloroform solution was added 10 g of anhydrous sodium sulfate. The solution was swirled, decanted into a flask, and evaporated to dryness. The white solid residue was recrystallized from 2-pentanone and dried in a desiccator over phosphorus pentoxide under vacuum for 1 hr.

Characterization of the Derivative (II)—The IR spectrum of a potassium bromide dispersion of II was obtained using an IR spectrophotometer[9]. The NMR spectrum[10] was obtained in deuterated chloroform solution with tetramethylsilane as an internal standard. The chemical-ionization mass spectrum[11] was obtained with methane as a reagent gas.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram of II and the internal standards. To establish optimum derivatization time and temperature, a sample containing I and triphenylethylene, an internal standard, was mixed with *N*,*N*-dimethylformamide dimethylacetal and the peak area ratio of II to the internal standard was followed for 3 hr at room temperature. However, the derivatization was not complete during this time period at room temperature. The same experiment at an elevated temperature (110°) showed that the derivatization was complete within 16 min. Dimethylformamide was chosen as the solvent because it is a relatively good solvent for both I and triphenylethylene or tetraphenylethylene and has a high boiling point.

To evaluate the response linearity of the GLC process, I was derivatized at various concentrations (0.9, 1.8, 2.7, and 3.6 mg) in the presence of triphenylethylene (0.7 mg) and then injected into the GLC. A plot of the peak area ratio of II to the internal standard against the concentration of I showed a linear relationship. The linear plot showed a negative intercept indicating column adsorption of II.

Scheme I shows the most probable pathway in the preparation of II. The structure of II was elucidated from IR, NMR, and mass spectrometric analyses. In addition, elemental analysis was performed on the sample.

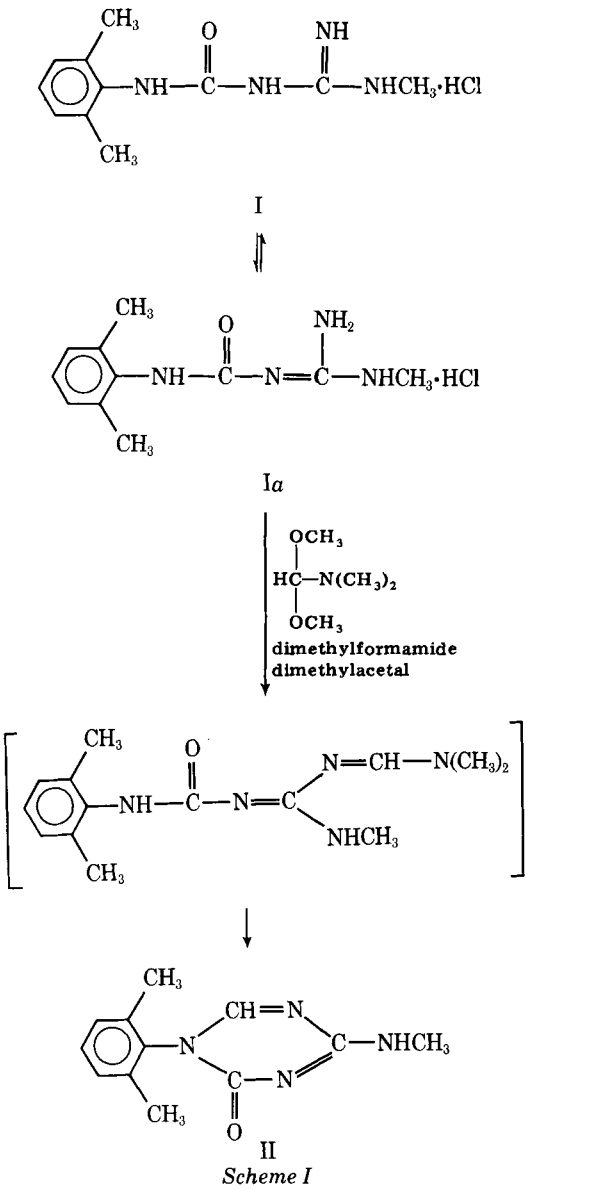

Scheme I

The IR spectrum of II showed a band at 3300 cm^{-1} representing —NH stretch of a secondary amine, a strong band at 1620 cm^{-1}, and a doublet at 1700 cm^{-1}, indicating carbonyl and —C=N stretches.

The NMR spectrum of II showed six protons of two methyl groups on the aromatic ring at 2.20 ppm (singlet), three protons of the methyl group (NH—CH_3) at 3.10 ppm (doublet), three protons of the aromatic ring at 7.26 ppm (singlet), and one proton (—N=CH—N=) at 7.75 ppm (singlet). The spectrum also reveals additional small signals at 3.15 ppm (doublet) and at 7.95 ppm (singlet). The appearance of the additional signals indicates that II can exhibit tautomerism causing protons of the NH—CH_3 and —N=CH—N= groups to be magnetically nonequivalent and therefore in different environments.

The chemical-ionization mass spectrum of II showed mass peaks at *m/z* 231 (M + 1), 259 (M + 29) and 271 (M + 41) which are characteristic peaks formed with methane as a reagent gas. The spectrum confirmed the molecular weight of the derivative as 230.

Based on the spectral data, the structure of the derivative is 1-(2,6-dimethylphenyl)-4-methylamino-dihydro-1,3,5-triazine-2-one. The elemental analysis of the derivative was in agreement with the chemical composition.

Anal.—Calc. for $C_{12}H_{14}N_4O$: C, 62.59; H, 6.13; N, 24.33. Found: C, 62.54; H, 6.14; N, 24.28.

The derivatization process is shown in Scheme I. The amidinourea moiety of I can be drawn in many tautomeric configurations, one of which is Ia. The tautomer would react with *N,N*-dimethylformamide dimethylacetal to form the *N*-dimethylaminoethylene derivative, an intermediate, which imparts structural stability by ring closure to form II. The cyclization of I to a triazinone using *N,N*-dimethylformamide dimethylacetal reagent presents a new route for the preparation of II (13).

Evaluation of ^{99m}Tc-Labeled Iminodiacetic Acid Derivatives of Substituted 2-Aminopyrroles as Hepatobiliary Imaging Agents in Rats II

BERNARD W. GRAHAM ˣ, CARL M. DEJULIIS, RONALD J. MATTSON, and J. WALTER SOWELL, SR.

Received March 20, 1981, from the *College of Pharmacy, University of South Carolina, Columbia SC 29208.* Accepted for publication July 28, 1981.

Abstract □ The synthesis and biodistribution properties of ^{99m}Tc-labeled 5-substituted *N*-(3-cyano-4-methyl-2-pyrrylcarbamoylmethyl)iminodiacetic acids and a similar series of N^1-methyl analogs are described. These compounds were compared with ^{99m}Tc-labeled *N*-(2,6-dimethylphenylcarbamoylmethyl)iminodiacetic acid for hepatobiliary activity in the rat. The effects of structural modifications on biological activity are also reported.

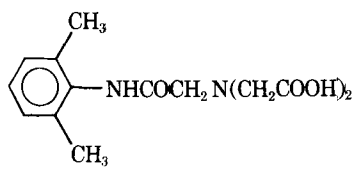
Keyphrases □ Imaging agents—^{99m}Tc-labeled iminodiacetic acid derivatives of substituted 2-aminopyrroles, rats □ Iminodiacetic acid—^{99m}Tc labeled derivatives of 2-substituted aminopyrroles, as hepatobiliary imaging agents in rats □ 2-Aminopyrroles—substituted, ^{99m}Tc-labeled derivatives, as hepatobiliary imaging agents in rats

Diseases of the gall bladder and biliary tract are a major health problem. Visualization of the hepatobiliary system in humans can be used in the differential diagnosis of these diseases. The use of radiopharmaceuticals as diagnostic tools for the dynamic evaluation of the hepatobiliary system was initiated by Taplin *et al.* (1) when they introduced the rose bengal sodium iodine 131 test.

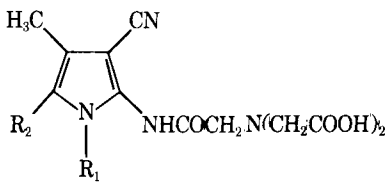
BACKGROUND

Rose bengal sodium iodine 131 has many drawbacks because of the physical characteristics of the iodine 131 label. Recently, many technetium 99*m* complexes have been produced and studied as possible replacements for rose bengal sodium iodine 131. These technetium 99*m* complexes include penicillamine (2), dihydrothioctic acid (3), tetracycline (4), mercaptoisobutyric acid (5), and pyridoxalamine acids (6). Among the most promising of the agents are the iminodiacetic acid derivatives (7), such as *N*-(2,6-dimethylphenylcarbamoylmethyl)iminodiacetic acid (I). Many analogs of I have been synthesized by altering the lipophilic substituent on the benzene ring and many of these analogs are being investigated clinically in humans. To date, however, no ideal hepatobiliary agent has been introduced because all of these complexes are adversely affected by elevated serum bilirubin levels.

To make a more effective hepatobiliary agent more needs to be known about the structure–activity relationship. It was reported previously (8) that a chelate must have a molecular weight between 300 and 1000, exist as an organic anion, contain at least two aromatic rings, and bind to albumin to be effective as a hepatobiliary scintigraphic agent. Another report (9) proposed a bichelate structure for ^{99m}Tc–I with a molecular weight of the lidocaine derivative that favors biliary excretion. One of the first attempts at indicating a structure–activity relationship of the lidocaine analogs (10) reported a linear relationship between the biliary excretion in mice and the natural logarithm of the absolute value of the molecular weight of the technetium 99*m* chelate divided by the net charge on the chelate.



I



II: R_1 = H
III: R_1 = CH_3

Recently, the synthesis and the biodistribution properties of ^{99m}Tc-labeled 2-aminopyrrole analogs of I were reported (11). The activity exhibited by these compounds prompted the synthesis and evaluation of other 5-substituted *N*-(3-cyano-4-methyl-2-pyrrylcarbamoylmethyl)-iminodiacetic acids (II) and a similar series of N^1-methyl analogs (III). All of the derivatives were labeled with technetium 99*m* and compared with ^{99m}Tc–I for hepatobiliary activity in rats. The effects of N^1-methylation and the effects of C-5 substitution on biological activity are reported (Table I).

EXPERIMENTAL[1]

Chemistry—*N-(3-Cyano-1,4,5-trimethyl-2-pyrrylcarbamoylmethyl)-iminodiacetic Acid (IIIa)*—The procedure for the synthesis of IIIa is given as a general method for II*a–e* and III*b–f*. A modified procedure of Callery *et al.* (12) was used. A solution of 2-chloroacetamido-3-cyano-1,4,5-trimethylpyrrole (6.77 g, 0.03 mole) (13), disodium iminodiacetic acid monohydrate (5.85 g, 0.03 mole), and sodium hydroxide (1.2 g, 0.03 mole) in 100 ml methanol–water (3:1) was refluxed with stirring for 3 hr. The solution was stirred at ambient temperature overnight, diluted with water (100 ml), and the methanol removed *in vacuo*. The resulting suspension was diluted with additional water (50 ml), warmed gently, and filtered. After acidification of the filtrate to pH 3 by dropwise addition of concentrated hydrochloric acid, the precipitate was collected and dried. The crude product (7.25 g, 75.0%) was recrystallized from water to yield a light lavender powder (homogeneous on TLC, methanol, R_f 0.57), mp 184–185° dec., IR (KBr): 3300, 3020, 2860, 2210, 1680 (broad), 1560, 1410, 1350, and 970 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 2.00 (s, 3H, CH_3 at C_4), 2.07 (s, 3H, CH_3 at C_5), 3.27 (s, 3H, CH_3 at N_1), 3.53 (s, 6H, —CH_2—alpha to amino group), 7.80–9.20 (broad s, 3H, amide NH and COOH) ppm.

N-(2,6-Dimethylphenylcarbamoylmethyl)iminodiacetic acid (I)—A solution of 1-chloroacetamido-2,6-dimethylbenzene (5.93 g, 0.03 mole), disodium iminodiacetic acid monohydrate (5.85 g, 0.03 mole), and sodium hydroxide (1.2 g 0.03, mole) in 100 ml of methanol–water (3:1) was refluxed with stirring for 4.5 hr. The methanol was removed *in vacuo* and the crude product (5.5 g, 69%) was isolated according to the procedure described for III*a*. The product was recrystallized from water to yield white crystals, mp 216–217° [lit. mp 215–216° (4)]; IR (KBr): 3180, 1750, 1610, 1530, 1215, 1155, and 770 cm^{-1}.

Anal.—Calc. for $C_{14}H_{18}N_2O_5$: C, 57.13; H, 6.16; N, 9.52. Found: C, 57.16; H, 6.18; N, 9.51.

Labeling with Technetium 99*m*—The iminodiacetic acid derivatives (I, II*a–e*, III*a–f*) were labeled by a stannous chloride reduction of sodium (^{99m}Tc) pertechnetate (IV) eluate from a molybdenum 99–technetium

[1] IR spectral data were determined on a Beckman Acculab 4 Spectrophotometer using the potassium bromide technique. NMR spectra were determined on a Hitachi-Perkin-Elmer R24 high-resolution spectrometer with tetramethylsilane as the internal reference. Melting points were obtained using a Thomas-Hoover capillary apparatus and are uncorrected. TLC was performed using Eastman Chromatogram sheets, type 6060 (silica gel), and the sheets were developed in an iodine chamber. Carbon, hydrogen, and nitrogen values were obtained from analysis performed by Atlantic Microlabs, Inc., Atlanta, Ga.

[a] Standard error in parentheses. [b] Data previously reported in ref. 11.

99*m* generator[2] in an aqueous solution. Ten milligrams of each compound were dissolved in minimal amounts of sodium hydroxide (1 *N*). This solution was back titrated with hydrochloric acid (0.05 *N*) to pH 7. Seven millicuries of IV in 0.2 ml was added and the resulting solution was purged with nitrogen for 5 min. After purging, 0.1 ml of freshly prepared stannous chloride solution[3] (1 mg/ml) was added and the solution was kept at room temperature for 20 min. The molar ratio of ligand to tin varied from 52:1 to 77:1. The final solution was passed through a millipore filter into a sterile evacuated vial.

The radiochemical purities of technetium 99*m* labeled IIc, IIe, IIIa, and IIIc compounds were determined using instant TLC[4] with a chloroform–acetone (70:30) solvent system. The radiochemical purities of 99*m* Tc-labeled I, IIa, IIb, IId, IIId, IIIe, and IIIf compounds were determined using instant TLC with methyl–ethyl ketone, 85% methanol, and saline solvent systems. Examination of the chromatographic strips revealed the bound fraction to be 95% or greater for all of the radiopharmaceuticals.

***In Vivo* Studies**—Fasting, nonhydrated, male Sprague-Dawley[5] rats, 175–250 g, were used. The left jugular vein was exposed and cannulated for each animal after anesthetizing with pentobarbital sodium (30 mg/kg). The animal was then positioned over a rectilinear scanner[6] modified to record the counts arising from the cardiac pool. Following the injection of 0.25 mCi of the ^{99m}Tc-labeled compound into the cannula, sequential counts were obtained for the duration of the study. These counts were used to model the disappearance of the radioactivity from the blood.

Each animal was sacrificed 1 hr after injection of the radiopharmaceutical by overanesthesia with ether. Selected organs were removed from the animal and assayed for radioactivity. The results are reported as the percentage of the total injected radioactivity.

RESULTS

The disappearance of the radioactivity from the blood is described by a two-compartment open model. The computer-fitted equation[7] used to describe the data is:

$$C_B = A \exp(-\alpha t) + B \exp(-\beta t) \qquad \text{(Eq. 1)}$$

where C_B refers to the fraction of the dose retained in the blood (biological) and t is time (min). The parameters for Eq. 1 and the correlation

[a] Standard error in parentheses. [b] Data previously reported in reference 11.

coefficient (R^2) for each parameter are listed in Table II. The data represents the combined data for three rats for each compound.

Table III shows the distribution of technetium 99*m* in selected organs and tissues of the rat 1 hr after intravenous injection. The data are expressed as a percentage of the injected dose and represent the average of three rats for each compound. The carcass values represent the remainder after the removal of the other organs and include the bladder, which accounted for much of the activity.

This experiment was a completely randomized block design which permitted the calculation of differences between the ^{99m}Tc-labeled pyrrole derivatives IIa–*e*, IIIa–*f*, and ^{99m}Tc–I. Differences were tested by two-sided Student *t* tests at a 90% confidence level. Student *t* statistics between ^{99m}Tc–I and the ^{99m}Tc-labeled iminodiacetic acid derivatives of 5-substituted 2-aminopyrroles were computed for the β phases of the blood curves, the percentage of injected radioactivity in the GI tracts, carcasses, livers, and kidneys.

The results show that ^{99m}Tc–IIa, ^{99m}Tc–II*d*, and ^{99m}Tc–IIIa are different from ^{99m}Tc–I. When ^{99m}Tc–IIa and ^{99m}Tc–IIIa were compared with ^{99m}Tc–I, these complexes showed less of the radioactivity accumulating in the GI tract and more remaining in the carcass at 1 hr after injection. A comparison between ^{99m}Tc–II*d* and ^{99m}Tc–I showed that ^{99m}Tc–II*d* had less radioactivity remaining in the carcass and more accumulating in the GI tract.

The experimental design allowed testing of the effects of N^1-methylation and C-5 substitution on the pyrrole ring by a two-way analysis of variance. The analysis of variance was performed on the β phase rate constants and on the percentages of radioactivity in the carcass, GI tract, liver, and kidneys.

The results show that N^1-methylation significantly decreased the rate constant, increased the accumulation of radioactivity in the carcass and kidneys, and decreased the accumulation of technetium 99*m* in the GI tract. One possible explanation for these results is that these chelates are in the structure proposed by Loberg and Fields (9) and that the technetium 99*m* labeled compounds IIa–*e* can undergo intramolecular hydrogen bonding between the N^1 hydrogen and the carbonyl group at position 2. The N^1-methyl series (IIIa–*f*) cannot undergo this intramolecular hydrogen bonding. Therefore, the free carbonyl group of compounds IIIa–*f* can interact with water to a greater extent through intermolecular hydrogen bonding which reduces protein binding and biliary excretion.

The two-way analysis of variance also revealed that the C-5 substitution effect was significant for the rate constant and the percentages of radioactivity in the carcass, GI tract, and kidneys.

Since the C-5 substitution was significant for these measured parameters, correlation analysis between the molecular weight of the C-5 substituent and the amount of radioactivity found in the GI tract was performed.

The correlation analysis revealed that when the C-5 substituent of either the N^1-H series (II) or the N^1-methyl series was aliphatic, increasing the molecular weight of the technetium 99*m* complex increased biliary excretion. The correlation coefficient for the N^1-H aliphatic series is 0.86; for the N^1-methyl series it is 0.77. When the C-5 substituent was aromatic, an increase in molecular weight of the technetium 99*m* complex decreased biliary excretion. For the N^1-H series, the correlation coefficient is −0.90; for the N^1-methyl series it is −0.62.

Antibacterial N-[ω,ω'-Bis(alicyclic and aryl)-*sec*-alkyl]-1,3-diamino-2-propanol Dihydrochloride Salts

NATHANIEL GRIER ˣ, RICHARD A. DYBAS, ROBERT A. STRELITZ, BRUCE E. WITZEL, and EUGENE L. DULANEY

Received February 9, 1981, from the *Merck Sharp & Dohme Research Laboratories, Rahway NJ 07065.* Accepted for publication July 27, 1981.

Abstract □ A series of 14 antibacterial N-[ω,ω'-bis(cycloalkyl, bicyclo[2.2.1]heptyl, and substituted phenyl)-*sec*-alkyl]-1,3-diamino-2-propanol dihydrochloride salts were synthesized as potential topical antiseptics and disinfectants. Four derivatives which were particularly effective against *Pseudomonas aeruginosa* encompassed the three diverse ring-type substituents and an 8-n-pentadecyl moiety. The calculated Hansch hydrophobic parameter (π) for the N-substituents of the more efficient compounds were in the range 7.0–9.0 and correlated with minimal inhibitory activity as a parabola for all of the products under the assay conditions. The potencies against Gram-positive and other Gram-negative bacteria were comparable to benzalkonium chloride and chlorhexidine.

Keyphrases □ Antibacterials—potential, N-[ω,ω'-Bis(alicyclic and aryl)-*sec*-alkyl]-1,3-diamino-2-propanol dihydrochloride salts □ *Pseudomonas aeruginosa*—effect of potential antiseptics and disinfectants □ Hansch hydrophobic parameter—correlation with efficiencies of potential antibacterials

Antimicrobial agents have been sought from among N-mono-(1), N,N'-bis(mono)- (2, 3), and disubstituted 1,3-diamino-2-propanol salt derivatives (4). The present report describes the synthesis of N-substituted *sec*-alkyl compounds of the first type, the *in vitro* antibacterial assay, and a potential structure–activity relationship. This study is part of an effort to develop antiseptics and disinfectants especially effective against *Pseudomonas aeruginosa* (5). The cell envelope of Gram-negative bacteria presents a permeability barrier which includes high lipid content, anionic lipopolysaccharides, and proteins (porins) apparently able to form molecular size-limiting channels trans-outer membrane (6). Variation of the *sec*-alkyl group by symmetrical substitution of the ω,ω' carbon atoms with alicyclic or aryl moieties provided products with differences in lipophilicity, geometry, and surfaces with proton or electron enrichment. Interestingly, a recent report noted that single methyl branching introduced on a long-chain alkyl group in several tertiary amines, caused a loss of inhibitory action for Gram-negative bacteria but not toward Gram-positive bacteria (7).

RESULTS AND DISCUSSION

Syntheses—The dihydrochloride salts I*a*–I*n* were prepared by condensation of the requisite symmetrical alkanone and 1,3-diamino-2-propanol to form the Schiff base, followed by reduction of the carbon–nitrogen double bond by catalytic hydrogenation or with sodium borohydride, and neutralization with hydrogen chloride in diethyl ether, 2-propanol, or binary mixtures (2, 8, 9). Yields were 40–90%. Compounds I*d* (5) and I*l* (9) were reported previously. The ketone-starting materials for I*a*, I*b*, and I*f* were purchased[1] or were obtained from earlier N-substituted triamine and tetramine syntheses (5), for I*c–e*, I*h–l*, and were known for I*m* (10). The preparation of ketones required for I*g* and I*n* is described under *Experimental.*

Microbiology—The minimal inhibitory concentrations of the compounds were determined by an agar dilution method. Stock solutions of the 14 compounds containing 1 or 10 mg/ml in dimethyl sulfoxide were added to melted sterile nutrient agar[2] to give the desired final concentrations, and 10 ml was pipetted into Petri plates. The concentrations tested were 200, 100, 80, 60, 50, 40, 30, 20, 10, 8, 6, 4, 2, and 1 μg/ml (5, 11). The dimethyl sulfoxide had no inhibitory effect on the test bacteria. The test bacteria were shaken at 220 rpm for 20 hr at 37° in 10 ml of brain–heart broth[2], diluted to 10^{-3} in fresh brain–heart broth, and spot inoculated onto the surfaces of the agar plates containing the test compounds. The number of colony-forming units in each inoculated spot was $\sim 10^5$. The plates were scored after a 20-hr incubation at 37°. The minimum inhibitory concentration is the lowest concentration of compound that completely inhibited growth by macroscopic examination. All assays were run in duplicate. The results are shown in Tables I and II.

The more potent pseudomonad inhibitors of the series (Table I) represented practically all substituent variations; namely, linear alkyl (I*b*), alicyclic (I*d* and I*e*), and electron-donor substituted aryl (I*i*). The efficiency, comparable to chlorhexidine, could be linked to the lipid–water partition property and apparently was not sensitive to steric, electronic, and bulk factors. However, no attempt was made to analyze structure–activity relationships by molecular connectivity (12) or polarizability parameters (13).

Structure–Activity—The calculated hydrophobic parameter, π, (14) for the $[R(CH_2)_n]^2$ groups of the best inhibitors was in the range 7–9. Regression analysis using the least-squares method indicated, within 95% confidence limits, a parabolic relationship with minimal inhibitory concentration for both pseudomonad strains and provided the predicted curves: minimum inhibitory concentration (μg/ml) = 1340.68 (±279.13) − 343.39 (±78.11) π + 22.40 (±5.25) π^2 for strain MB418 (n = 14, r = 0.8048, and s = 55.65) (Fig. 1); minimum inhibitory concentration (μg/ml) = 1343.55 (±285.83) − 346.38 (±79.99) π + 22.69 (±5.38) π^2 for strain MB2245 (n = 14, r = 0.7985, and s = 56.90); where n is the number of assayed compounds used, r is the correlation coefficient, and s the standard deviation from the regression line.

Use of a lipid group-calculated π for correlation purposes (the polar base moiety remaining constant in the series) avoided problems associated with whether the active molecular species was neutral, ionic (15), or metal chelated (16).

The broad spectrum assay (Table II) showed a similar ordering in which compounds with high inhibitory potency for Gram-negative bacteria (*e.g., Escherichia coli*) were comprised of diverse substituent groups.

[a] Salts were crystallized or recrystallized from isopropanol except as otherwise noted. [b] Hansch hydrophobic parameter (14). [c] Purified by column chromatography of the base on silica gel (1 g:75 g) with methylene chloride–methanol–ammonium hydroxide (35:4:1), conversion to the dihydrochloride in ether with dry HCl in 2-propanol (29% w/w), and isolation upon precipitation or by solvent removal. [d] Recrystallized from ether–2-propanol. [e] Ethanol.

Several of the most lipophilic salts were highly effective against the nine genera; I*j* at ≤6 μg/ml and I*k* exhibited similar patterns, but they were only moderately active for the two *Pseudomonas* strains, suggesting a more critical partitioning requirement.

Many examples of antibacterial activity–lipophilicity parabolic findings have been reported previously for homologs of inhibitors (17). Several explanations have been proposed. Highly hydrophilic compounds in a series cannot penetrate a cell envelope lipid barrier, whereas the more hydrophobic members remain entrapped in the lipid phase and fail to reach target sites. These postulates may account for each low activity side of the parabolic curve, with molecule size and colloidal associations as other possible contributors. More recent studies using quaternary ammonium salts of increasing alkyl chain length, in a simple salts test medium with and without varying sensitivity mutants of *Ps. aeruginosa*, indicate a positive linear correlation between lipophilicity and antimicrobial activity (18). However, the probable test medium imposed artifactual results of the present work may better anticipate activities under conditions of potential use. Preliminary *in vitro* and *in vivo* antibacterial studies on skin (excised and intact cow udder) with Table I derivatives appear to confirm the findings[3].

[3] To be published elsewhere.

EXPERIMENTAL

Melting points were taken in open capillary tubes[4] and are uncorrected. IR spectra for solids were run as mulls in mineral oil[5]. NMR spectra[6] (60 MHz) were obtained in dimethyl sulfoxide-d_6 with tetramethylsilane as an internal standard. Spectral data for all reported compounds appeared consistent with assigned structures. TLC was performed on precoated gel GF glass plates (250 μm)[7], using dioxane–methanol–ammonium hydroxide (15:4:1) as the developing solvent for the diamine hydrochloride salts and ether–petroleum ether (1:1) or hexane–ethyl acetate (1:1) mixtures for ketones (iodine staining). The amine salts were colorless solids, easily hydrated, and were dried for 4 hr at 60–80° (0.05 mm) before analysis. All hydrogenations were run at 20–25° and 2.8–3.5 kg/cm^2 until theoretical hydrogen uptake, requiring from 1 to 4 hr. After catalyst removal by filtration, the solvent was distilled *in vacuo*.

Ketones—1,5-Bis(aryl)-1,4-pentadien-3-ones were prepared by literature methods.

(15.2 g, 0.11 mole) and acetone (3.1 g, 0.05 mole) in 60 ml of ethanol was added dropwise (15 min) to a solution of sodium hydroxide (12 g, 0.3 mole) in 120 ml of water diluted with 100 ml of ethanol. The temperature during addition was maintained at 10–13° and then at 20–25° for 4 hr. The precipitated solids were filtered, washed with water, and air dried. Recrystallization of 0.2 g of the yellow product (13.5 g, 83%) from benzene gave pure bis(4-chlorobenzal)acetone (0.14 g); mp 191–193° [lit. (19) mp 193–194°].

1,5-Bis(4-chlorophenyl)-3-pentanone—A mixture of the di-unsaturated ketone (6 g, 0.02 mole) and 2.5 g of Raney nickel in 100 ml of ethanol was shaken at 20° under 3.5 kg/cm^2 hydrogen for 2 hr until near theoretical uptake was observed. The catalyst was filtered and the solvent was removed by distillation. The residual oil was dissolved in 400 ml of methylene chloride and chromatographed on a column containing 450 g of silica gel. The product was obtained in fractions four and five (400 ml each) as a solid (4 g, 75%) after solvent removal. One gram was recrystallized from 5 ml of 2-propanol to yield colorless plates (0.7 g); mp 65–67°, IR: 1690 (C=O) cm^{-2}.

Anal.—Calc. for $C_{17}H_{16}Cl_2O$: C, 66.46; H, 5.25; Cl, 23.08. Found: C, 66.58; H, 5.20; Cl, 23.02.

***N*-(ω,ω'-Disubstituted *sec*-alkyl)-1,3-diamino-2-propanol Dihydrochlorides (I*a*–I*n*)**—Schiff bases were obtained by condensation of ω,ω'-disubstituted alkanones with 1,3-diamino-2-propanol in refluxing toluene and azeotropic water removal (5), or by reaction in ethanol without water separation. The carbon–nitrogen double bond was reduced catalytically with hydrogen or with sodium borohydride. Both procedures are exemplified with the preparations, I*i* and I*m*. Table I lists the physical and analytical data.

1-Amino -3- {[3-[4-(1-methylethyl)phenyl] -1- [2-[4-(1-methylethyl)phenyl]ethyl]-propyl}amino}-2-propanol Dihydrochloride (I*i*)—A solution of 1,5-bis[4-(1-methylethyl)-phenyl]-3-pentanone (6.4 g, 0.02 mole) in 20 ml of ethanol was added dropwise (45 min) to a stirred solution of 1,3-diamino-2-propanol (10.8 g, 0.12 mole) in 80 ml of ethanol maintained at 90°. The resulting solution was heated at 90° for 12 hr, diluted with 50 ml of ethanol and cooled to 5°. Sodium borohydride (1.2 g, 0.03 mole) was added portionwise (10 min), and the reaction mixture, after 2 hr at 5°, was stirred for 2 hr at 20°. The solvent was removed *in vacuo* and the residual oil partitioned between 75 ml of ether and 75 ml of water. The ether solution was washed with 75 ml of brine, dried over sodium sulfate and concentrated *in vacuo*. The residual base was dissolved in 15 ml of 2-propanol, the solution cooled to 5° and mixed with 25 ml of 2-propanol saturated with hydrogen chloride. The solids, after mixing at 5° for 6 hr, were filtered and recrystallized from 35 ml of 95% 2-propanol to yield 6.9 g of Ic; NMR (dimethyl sulfoxide-d_6): δ 3.47 ppm [quintet, 1H of *sec*-alkyl(—CH_2)$_2$C*H*—NH—].

1-Amino -3- [3-(4-methoxyphenyl) -1- [2-(4-methoxyphenyl)ethyl]propylamino]-2-propanol Dihydrochloride (I*m*)—Powdered 1,5-bis(4-methoxyphenyl)-3-pentanone (6.0 g, 0.02 mole) was added slowly (30 min) to a stirred solution of 1,3-diamino-2-propanol (9.0 g, 0.1 mole) in 100 ml of ethanol maintained at 90°. After 12 hr the solution was cooled to 20°, diluted with 50 ml of ethanol, and mixed with 0.75 g of platinum oxide. Hydrogenation was run at 20–25° and 3.5 kg/cm^2 hydrogen. Within 2.5 hr, theoretical uptake was observed, and the reaction mixture was shaken an additional 0.5 hr. The catalyst was removed by filtration and the solvent distilled *in vacuo*. The residual oil was dissolved in 100 ml of ether. The product precipitated when mixed with 5 ml of 2-propanol which was previously saturated with hydrogen chloride. After 3 hr of mixing, the salt was filtered to yield 7.9 g (89%) of I*n* which was recrystallized from 2-propanol; NMR (dimethyl sulfoxide-d_6): δ 3.24 ppm [quintet, 1 H of *sec*-alkyl(—CH_2)$_2$C*H*—NH—].

Intraocular Penetration of Topically Applied [^{14}C]Fosfonet Sodium in Rabbits

BARBARA A. BOPP,[x] WALTER W. HUNTER, and DAVID J. ANDERSON

Received February 2, 1981, from the *Drug Metabolism Department, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication July 30, 1981.

Abstract □ The intraocular penetration of [^{14}C]fosfonet was studied following topical application of 25 mg of an ointment containing 5% [^{14}C]fosfonet sodium onto the intact and abraded eyes of New Zealand white rabbits. Radioactivity penetrated rapidly through the abraded cornea and entered the anterior chamber. The concentration of fosfonet in the aqueous humor peaked at 7.2 μg/ml by 90 min. Assuming an aqueous humor volume of 300 μl, this level would correspond to approximately 0.2% of the applied dose. The highest concentration of fosfonet found in the abraded cornea was 0.3 μg/mg, or 0.4% of the applied dose. The half-lives for the elimination of fosfonet from the aqueous humor and cornea were about 2.5 and 2.7 hr, respectively. The fosfonet levels in the iris were extremely low throughout the 6-hr period. The penetration of [^{14}C]fosfonet through the intact cornea was considerably less than that found in the abraded eye. The peak concentrations of fosfonet in the aqueous humor and cornea of the intact eye were 0.26 μg/ml and 0.02 μg/mg, respectively, and occurred within 10 min of application of the ointment.

Keyphrases □ [^{14}C]Fosfonet sodium—intraocular penetration □ Ocular agents—[^{14}C]fosfonet, aqueous humor, ophthalmic bioavailability, rabbit eye □ Antiherpetic agent—effect of [^{14}C]fosfonet on rabbit cornea

Shipkowitz *et al.* (1) first reported that fosfonet sodium (disodium phosphonoacetate) inhibited the replication of herpes viruses both in tissue cultures and in experimental animal models. Fosfonet was effective in reducing the severity of the corneal lesions in rabbits when applied topically in concentrations of 0.5 to 5% starting 2 hr after virus inoculation. Subsequent studies demonstrated that 5% fosfonet, either as a solution or an ointment, was as effective as 0.5% idoxuridine in the treatment of established herpetic keratitis in rabbits (2–4) and was superior to idoxuridine in inhibiting the replication of the virus (3). Furthermore, it was found (4) that fosfonet was also effective against idoxuridine-resistant keratitis when applied topically on rabbit eyes and against herpetic iritis when administered to rabbits either intravenously or subconjunctively but not topically.

Fosfonet is relatively nontoxic to rabbit eyes. It was reported (4) that 5% fosfonet was not toxic to the corneal epithelium of rabbits when applied 6 times a day for 5 days. Similarly, rabbit eyes were treated with a 5% fosfonet ointment 4 times a day for 42 days and no evidence of toxicity in clinical and histopathological studies was found (3). Although fine punctate lesions of the superficial corneal epithelium were observed (2) when a 5% fosfonet solution was applied to normal rabbit eyes 8 times a day for 3 days, the lesions disappeared within 48 hr after treatment was stopped and were no more severe than those encountered with idoxuridine.

Because of its potential usefulness in treating herpetic keratitis, this study was performed to investigate the intraocular penetration of [^{14}C]fosfonet after topical application of an ointment containing 5% fosfonet sodium onto the intact or abraded eyes of rabbits. Since removal of the corneal epithelium frequently enhances the intraocular penetration of drugs and the integrity of the corneal epithelium may be disrupted in ocular herpes infections, it was of special interest to study the intraocular penetration of fosfonet in eyes with corneal abrasions.

[a] Mean ± standard error of 10–12 determinations, based on total radioactivity and expressed as micrograms of fosfonet, assuming a 25-mg dose of the ointment corresponding to 1250 μg of fosfonet sodium or 950 μg of fosfonet. Concentrations expressed per milliliter aqueous humor or milligram dry weight of cornea or iris. The percentage in aqueous humor was calculated from the %/ml, assuming a total aqueous humor volume of 0.30 ml.

EXPERIMENTAL

Materials—Fosfonet sodium was labeled with carbon 14 in the carboxylic position. Radiochemical and chemical purity was established by thin layer and anion exchange chromatography and mass spectrometry. A lanolin–petrolatum based ointment[1] containing 5% [^{14}C]fosfonet sodium was prepared and had a final activity of 0.16 μCi/mg ointment.

Animals—Male New Zealand white rabbits, weighing 2.3–4.0 kg, were used. Prior to use, the animals were maintained in standard laboratory animal cages and allowed food and water *ad libitum*. During the study, the rabbits were placed in restraining cages which held them in a normal upright position. All animals were acclimated to these conditions by being placed in the restrainers for successively longer periods of time twice a day for 3 days.

Corneal abrasions were made by anesthetizing the eye with 0.5% tetracaine hydrochloride[2] and then gently scraping the cornea with a scalpel blade to remove the epithelial surface. Fluorescein staining was performed in preliminary studies to assess the abrading technique. Extreme care was exercised to avoid damaging the corneal stroma or the conjunctiva, and any animal that had visible signs of damage (*e.g.*, bleeding) was not used in the study. About 1.5–2 hr elapsed between abrading and dosing the eye.

While holding the eyelids open and after the nictitating membrane had receded, the ointment (~25 mg) was applied onto the corneal surface and into the pocket formed by the lower lid and the globe. The eyelids were

[a] Mean ± standard error of six determinations, based on total radioactivity and expressed as micrograms of fosfonet, assuming a 25-mg dose of the ointment corresponding to 1250 μg of fosfonet sodium or 950 μg of fosfonet. Concentrations expressed per milliliter aqueous humor or milligram dry weight of cornea. The percentage in aqueous humor was calculated from the %/ml, assuming a total aqueous humor volume of 0.30 ml.

then released and gently manipulated to spread the ointment over the cornea. Generally both eyes of each rabbit were used, but the dosing schedule was adjusted so that the eyes represented two different, but not successive, time points. At selected times after dosing, the rabbits were sacrificed by injecting an overdose of a solution[3] containing sodium pentobarbital, sodium secobarbital, and mephenesin into the marginal ear vein. The cornea and sclera were thoroughly rinsed with physiological saline[4] and gently wiped dry with a tissue. An aqueous humor sample (0.1–0.2 ml) was withdrawn from the anterior chamber. The optic nerve and blood vessels were then clamped with a hemostat, and the corneal surface was again rinsed with saline. The cornea and iris were removed by cutting around the corneal-scleral limbus, and the iris was separated from the cornea. Both tissues were thoroughly rinsed in saline, allowed to dry for several days at room temperature, and weighed.

In some animals, ointment was applied to both eyes at the same time, and blood samples were withdrawn from the central artery of an ear at selected times after dosing. The heparinized blood samples were centrifuged and the plasma was saved for radioassay.

Radioassay—An aliquot of the aqueous humor samples was applied to an absorbant paper disc[5] encased in a cellophane combustion envelope[6]. The tissue and plasma samples were placed in combustion cones[7] containing cellulose powder[8]. All samples were then burned in a sample oxidizer[9], and radioassay was accomplished by liquid scintillation spectrometry[10]. Correction for quenching was made by automatic external standardization. All levels were based on total radioactivity and were expressed as micrograms of fosfonet. To correct for the small and statistically insignificant differences in the milligrams of ointment applied, the results were expressed as adjusted concentrations based on a 25.0-mg dose.

RESULTS

The drug concentrations in the aqueous humor, cornea, and iris at various times after topical application of the [^{14}C]fosfonet sodium ointment onto the abraded eyes of New Zealand white rabbits are presented in Table I. The radioactivity appeared to penetrate rapidly through the abraded cornea and enter the aqueous humor. The concentration of fosfonet in the aqueous humor ~2.9 μg/ml by 10 min, reached 6.6 μg/ml by 40 min, and peaked at 7.2 μg/ml by 90 min. Thereafter, the levels in the aqueous humor declined slowly, with a half-life of ~2.5 hr, as determined by linear regression analysis. The peak concentration of fosfonet in the abraded cornea was ~0.3 μg/mg dry weight and remained relatively constant through at least 40 min. The half-life for the disappearance of radioactivity from the cornea was ~2.7 hr. The levels of fosfonet in the iris were very low throughout the study, never exceeding 0.02 μg/mg.

The penetration of fosfonet through the intact cornea (Table II) was considerably less than that found in the abraded eyes. The peak levels in both the aqueous humor and cornea of the intact eyes were reached by 10 min but were only 0.26 μg/ml and 0.02 μg/mg, respectively. The concentrations in the iris were consistently less than 0.01 μg/mg.

The systemic absorption of fosfonet appeared to be quite limited. In rabbits with an intact corneal epithelium, the plasma concentrations at times ranging from 10 min to 24 hr never reached 0.01 μg/ml, while the levels in the rabbits with abraded corneas averaged 0.01–0.02 μg/ml.

DISCUSSION

The results of this study were based on total radioactivity but were expressed as micrograms of fosfonet. Since previous studies[11] in these laboratories had indicated that intravenously administered [^{14}C]fosfonet was excreted unchanged in the urine of rabbits, it is reasonable to assume that most of the radioactivity did represent the parent drug. It was also assumed that the radioactivity found in each eye came from transcorneal penetration and not from the systemic circulation. The low plasma levels of radioactivity suggested that this assumption was also valid. The plasma levels appeared to be slightly higher in the rabbits with abraded corneas than those with an intact corneal epithelium, possibly due to the greater penetration of fosfonet into the abraded eye. However, it was more striking that the drug levels in the systemic circulation were exceedingly low.

Generally, less than 1% of the instilled dose of most drugs crosses the cornea and enters the anterior chamber (5). For example, it was reported (6) that ~0.1–0.2% of an instilled dose of a tritiated pilocarpine nitrate solution was found in the aqueous humor of intact rabbit eyes. If the total volume of aqueous humor in a rabbit eye is assumed to be 300 μl (7, 8), then ~0.23% of the applied fosfonet dose would be present in the aqueous humor of the abraded eyes at the time of the peak concentration (1.5 hr). In contrast, less than 0.01% of the dose would have penetrated through the intact cornea and entered the aqueous humor. Comparison of the areas under the aqueous humor concentration–time curves indicated that the amount of drug penetrating through the intact cornea was only about 3% of that found in the aqueous humor of the abraded eyes. Removal of the corneal epithelium enhances the rate and degree of penetration, especially with water soluble or polar compounds (9). Therefore, the marked difference in the penetration of fosfonet through the intact and abraded corneas is not surprising. However, it should be noted that the integrity of the corneal epithelium is one factor that might markedly affect the intraocular penetration and possibly the therapeutic efficacy of fosfonet.

Most drugs achieve peak concentrations in the cornea and aqueous humor in a short time, thus appearing to penetrate rapidly into the ocular tissues. However, recent studies with pilocarpine nitrate have shown that the short time required to reach the peak concentrations is primarily dependent on the rapid parallel elimination of the drug from the precorneal area and that the actual absorption rates for the cornea and aqueous humor are lower than expected from the concentration–time profiles (10–13). With fosfonet, the peak concentrations in both the intact and abraded corneas were reached within 10 min, the shortest time interval studied. The peak concentration in the aqueous humor of the intact eye was also reached within 10 min, but there was considerable fluctuation in the aqueous humor levels during the first two hr. In contrast, the aqueous humor concentrations in the abraded eye peaked considerably later (1.5 hr). The reasons for the difference in the peak concentration times are not known. More work is required to determine fosfonet pharmacokinetics in intact and abraded eyes and to assess other factors that might influence the time needed to reach peak concentrations.

It was found (4) that fosfonet was effective in treating experimental herpetic iritis in rabbits when administered systemically or subconjunctively but not topically. The low fosfonet levels in the iris were consistent with the lack of beneficial effects of topically applied fosfonet in herpetic iritis in rabbits. However, stromal disease and iritis are difficult to treat effectively with the topical application of most other antiviral agents as well (14).

Unusual Cholesterol Solubility in Water/Glyceryl-1-monooctanoate Solutions

Keyphrases □ Cholesterol—unusual solubility in water/glyceryl-1-monooctanoate solutions □ Glyceryl-1-monooctanoate—aqueous solutions, unusual solubilities of cholesterol □ Gallstones—cholesterol, solubility in water/glyceryl-1-monooctanoate solutions

To the Editor:

Glyceryl-1-monooctanoate (monooctanoin) (I) has been recently used in humans for dissolution of cholesterol gallstones in the common bile duct (1, 2). The solvent is slowly infused into the bile duct for several days, usually *via* a T-tube left in place following cholecystectomy. The high cholesterol solubility in I, 11.7% (w/v) at 37°, was reported in a systematic study of cholesterol solubility in organic solvents by Flynn *et al.* (3). Optimum cholesterol solubility appeared to occur when the solvent (*n*-alkanols or fatty acid ethyl esters) had a total carbon chain length of about seven atoms.

The present study was initiated to determine if cholesterol was involved in formation of liquid crystalline phases in aqueous I solutions. Larsson found that highly purified I and water formed a lamellar liquid crystalline phase at 37° when the water content was between 8 and 45% (4). Such equilibria could be important in gallstone dissolution since I would be in contact with bile during the infusion procedure and with moisture during handling. But when water/I mixtures were prepared with the same type of I used in the reported gallstone dissolution studies[1], only isotropic phases were observed by polarizing microscopy[2]. This apparent discrepancy is thought to be caused by the presence of about 30% of the corresponding diglyceride in the commercial material (1, 5). Diglycerides or triglycerides are more hydrophobic and do not form lyotropic mesophases (4). The solubility of water in the commercial sample of I was determined visually to be ~18–20% (w/w) at 37°. An exact value is not meaningful, since each batch will vary somewhat in its fatty acid distribution and diglyceride content. Above this concentration simple emulsions were formed rather than liquid crystalline phases.

Cholesterol is known to crystallize in anhydrous and monohydrate forms (6) and the anhydrous form is ~50% more soluble in aqueous bile salt solutions (7). Since either of these crystalline forms could possibly exist in aqueous I solutions, the cholesterol solubility in such solvent mixtures was determined (Fig. 1). Suspensions of anhydrous cholesterol[3] or cholesterol monohydrate (recrystallized from aqueous ethanol) were prepared in aqueous I solutions and equilibrated using a vibratory mixer[4] in a constant-temperature bath. The suspensions at equilibrium were observed with the polarizing microscope and quickly filtered through 0.45 μm membranes[5] which had been equilibrated at the test temperature. The two crystal forms were microscopically identified by their characteristic habits (6). The filtrates were analyzed for cholesterol by HPLC (8) with detection at 205 nm and for water content by Karl Fischer titrimetry[6].

Cholesterol solubility increased to a maximum and then decreased over the range of water concentration studied. The solubility was independent of the sampling time and crystal form initially present, indicating that equilibrium had been attained. An explanation cannot be offered for the higher solubility found in the present investigation compared to previous reports (3).

Immediate microscopic inspection of the suspensions showed that at water concentrations below the apparent

This apparent discrepancy is thought to be caused by the presence of about 30% of the corresponding diglyceride in the commercial material (1, 5). Diglycerides or triglycerides are more hydrophobic and do not form lyotropic mesophases (4). The solubility of water in the commercial sample of I was determined visually to be ~18–20% (w/w) at 37°. An exact value is not meaningful, since each batch will vary somewhat in its fatty acid distribution and diglyceride content. Above this concentration simple emulsions were formed rather than liquid crystalline phases.

Cholesterol is known to crystallize in anhydrous and monohydrate forms (6) and the anhydrous form is ~50% more soluble in aqueous bile salt solutions (7). Since either of these crystalline forms could possibly exist in aqueous I solutions, the cholesterol solubility in such solvent mixtures was determined (Fig. 1). Suspensions of anhydrous cholesterol[3] or cholesterol monohydrate (recrystallized from aqueous ethanol) were prepared in aqueous I solutions and equilibrated using a vibratory mixer[4] in a constant-temperature bath. The suspensions at equilibrium were observed with the polarizing microscope and quickly filtered through 0.45 μm membranes[5] which had been equilibrated at the test temperature. The two crystal forms were microscopically identified by their characteristic habits (6). The filtrates were analyzed for cholesterol by HPLC (8) with detection at 205 nm and for water content by Karl Fischer titrimetry[6].

Cholesterol solubility increased to a maximum and then decreased over the range of water concentration studied. The solubility was independent of the sampling time and crystal form initially present, indicating that equilibrium had been attained. An explanation cannot be offered for the higher solubility found in the present investigation compared to previous reports (3).

Immediate microscopic inspection of the suspensions showed that at water concentrations below the apparent

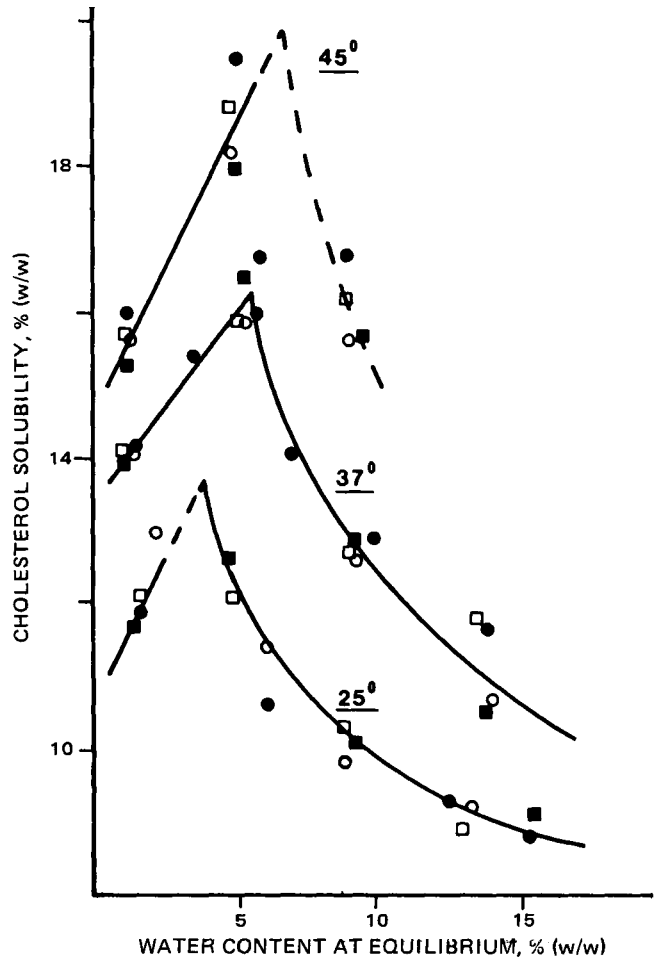

Figure 1—*Solubility of cholesterol in aqueous I solutions at 25, 37, and 45°. Key: Circles, initial solid phase was cholesterol monohydrate; squares, initial solid was anhydrous cholesterol; open symbols, 5 days; closed symbols, 7 days equilibration.*

solubility maxima, anhydrous cholesterol was present. Conversely, cholesterol monohydrate was present at water concentrations above the solubility maxima. In samples at 37° with 5.2% water, both forms were simultaneously observed. The maxima at 25 and 45° were not directly observed and the profiles are indicated by dashed lines.

When suspensions initially containing anhydrous cholesterol and about 5% water at 37 or 45° were cooled to room temperature, cholesterol monohydrate crystallized. The conversion process took place slowly on the microscope slide for several days until the anhydrous crystals were completely eliminated. Suspensions containing 1–2% water, however, remained as the anhydrous form when treated identically.

The concentration units used in this study may be misleading. A concentration of 5% (w/w) water would correspond to ~2.8 *M* and cholesterol concentrations of 14–16% are 0.36–0.41 *M*. The mole fractions for a system containing 5% water and 16% cholesterol are 0.44 and 0.07, respectively. The comparisons show that on a mole fraction basis the systems contain more water than indicated by simple concentration units.

The progression of the apparent maxima to higher water concentrations with increasing temperature (Fig. 1) is related to the heats of solution of the two crystalline forms. The ΔH^s_{anh} = 2.8 kcal/mole for the anhydrous form was estimated from the average of the slopes of ln (solubility) *versus* T^{-1} plots at water concentrations of 0 (extrapolated), 1.0, and 3.0% according to the van't Hoff relationship. For cholesterol monohydrate ΔH^s_{hydr} = 4.1 kcal/mole was estimated from the data at 9% water. The difference in these values represents the enthalpy of hydration of the crystalline anhydrous form to the monohydrate in aqueous I:

$$\text{anhydrous} + H_2O \rightleftharpoons \text{hydrate}, \Delta H = -1.3 \text{ kcal/mole}$$

This value is consistent with literature data for enthalpies of hydration which range from 1–4 kcal/mole for monohydrates (9–11). Therefore, the solubility of the monohydrate is more sensitive to temperature than is that of the anhydrous form.

The maximum cholesterol concentration occurs at the unique point at which the solubilities of the two forms are equal. As temperature increases, more added water is necessary to compensate for the greater effect of temperature on the monohydrate solubility. In this way the solubility maxima occur at higher water concentrations as temperature increases. This process is illustrated by a suspension of the two forms at 25° (solubility = 13.4%, water ≃3.5%) that is warmed to 37°. If excess solid is present and the forms behave independently, the solubility of the monohydrate should increase to 17.5%, the anhydrous form would increase to 16.1%, and the concentration of water would be slightly higher. Dissolution of the monohydrate causes the cholesterol concentration to be above the solubility of the anhydrous form and crystallization occurs. This process continues until the solid monohydrate is exhausted and the system is a suspension of anhydrous cholesterol. Addition of water to the anhydrous cholesterol suspension would cause solubility to increase slightly until the water causes crystallization of the monohydrate. The system would then be at the solubility maximum at 37°. Conversely, cooling of a suspension of both forms from 37 to 25° would result in a suspension containing only cholesterol monohydrate.

Igimi and Carey (7) reported solubility–temperature data for the two forms of cholesterol in aqueous sodium chenodeoxycholate solutions. From van't Hoff plots of these data, ΔH^s_{anh} (0.71 kcal/mole), ΔH^s_{hydr} (1.04 kcal/mole), and a difference (heat of hydration) of −0.33 kcal/mole were calculated. The poor agreement between the data in water/I and chenodeoxycholate solutions can not be explained at present, although the enthalpies for the bile salt solutions appear to be unusually low.

These preliminary data show that the maxima of cholesterol solubility in aqueous I solutions and its temperature dependence are due to the thermodynamics of interconversion of anhydrous and monohydrate crystalline forms. However, the reason for the increase in solubility of anhydrous cholesterol by small amounts of added water is not known. Addition of water to solutions containing cholesterol generally would be expected to *decrease* solubility. Further studies are in progress to investigate this behavior and determine the effect of water on dissolution rates of cholesterol and gallstones in aqueous I solutions.

Noncompartmental Determination of the Steady-State Volume of Distribution for Any Mode of Administration

Keyphrases □ Pharmacokinetics—noncompartmental determination of the steady-state volume of distribution for any mode of administration □ Volume of distribution—steady-state, noncompartmental determination for any mode of administration

To the Editor:

The analysis of concentration–time data by pharmacokinetic methods traditionally involves the use of compartmental models. The interpretation of this analysis, represented by a linear equation in the form of a sum of coefficient and exponential terms, provides useful insight into drug disposition. In recent years, however, there has been a move away from the traditional approach to an alternative method referred to as model-independent data analysis. There are reasons to recommend the latter approach; there is no need to ascribe the data to a specific model, and as a result it is not necessary to have a sophisticated computer and nonlinear regression programs available. The model-independent approach assumes only that all dispositional processes may be described by first-order kinetics with elimination occurring from the rapidly equilibrating or central compartment. This approach may also be termed an area analysis, since the useful parameters of clearance and volumes of distribution (V_{ss} and V_β or V_{area}) are based on determination of the total area under the plasma concentration–time curve (AUC) and total area under the first moment of the plasma concentration–time curve ($AUMC$). The areas generally are determined using the linear or logarithmic trapezoidal rule and extrapolation techniques. The elimination rate constant and half-life are determined from linear regression of the terminal (*i.e.*, post-absorption, post-distribution) concentration–time data.

Benet and Galeazzi (1) applied techniques of tracer kinetics, and used moment analysis (2, 3) to obtain the volume of distribution at steady state, V_{ss}, following an intravenous bolus injection. The purpose of this communication is to extend their analysis to permit calculation of V_{ss} for any mode of administration.

The mean transit time for a drug in the body, $\bar{t}_b$, is a function of the mean transit time for the response to the input (in), usually measured as plasma concentration, $\bar{t}_{b+in}$, and the mean transit time of the input, $\bar{t}_{in}$ (4):

$$\bar{t}_b = \bar{t}_{b+in} - \bar{t}_{in} \qquad \text{(Eq. 1)}$$

Mean transit or residence time for the response to the input, *i.e.*, plasma concentration, is given by:

$$\bar{t}_{b+in} = \int_0^\infty tC\,dt \Big/ \int_0^\infty C\,dt = AUMC/AUC \qquad \text{(Eq. 2)}$$

while the mean transit time for the input is given by (5):

$$\bar{t}_{in} = \int_0^\infty X\,dt/\text{dose} \qquad \text{(Eq. 3)}$$

where dose is the dose administered, and $\int_0^\infty X\,dt$ is the total area under the amount *versus* time curve for the input. For example, if a drug is administered as a zero-order infusion:

$$X = \text{dose} - k_0 t \qquad \text{(Eq. 4)}$$

In Eq. 4, X is the amount remaining to be infused at time t, and k_0 is the zero-order infusion rate. Administration by a first-order process (*e.g.*, extravascular administration) results in the following expression for X, the amount remaining to be administered:

$$X = F\,\text{dose}\,e^{-k_a t} \qquad \text{(Eq. 5)}$$

where k_a is an apparent first-order rate constant, and F is the fraction of the administered dose ultimately reaching the systemic circulation. Integration of Eqs. 4 and 5 yields:

$$\int_0^T X\,dt = k_0 T^2/2 \qquad \text{(Eq. 6)}$$

and

$$\int_0^\infty X\,dt = F\,\text{dose}/k_a \qquad \text{(Eq. 7)}$$

respectively. In Eq. 6, T is the duration of the infusion and is the upper limit of the integral, *i.e.*, T is equivalent to infinity.

Substitution for $\bar{t}_{b+in}$ and $\bar{t}_{in}$, according to Eqs. 2 and 3, respectively, in Eq. 1 gives the following expression for drug transit time in the body:

$$\bar{t}_b = AUMC/AUC - \int_0^\infty X\,dt/\text{dose} \qquad \text{(Eq. 8)}$$

Since V_{ss} is equal to the product of clearance (dose/AUC) and transit time (1), that is:

$$V_{ss} = \frac{\text{dose}}{AUC}\bar{t}_b \qquad \text{(Eq. 9)}$$

Equations 8 and 9 can be readily used to calculate V_{ss} following any mode of administration. Where there is a single mode of administration, Eqs. 8 and 9 can be readily solved for V_{ss}. For the case where drug is administered as a single bolus, $\int_0^\infty X\,dt = 0$,

$$V_{ss} = \frac{\text{dose}}{AUC}\bar{t}_b = \frac{\text{dose}}{AUC}\left(\frac{AUMC}{AUC}\right) = \text{dose}\,\frac{AUMC}{AUC^2} \qquad \text{(Eq. 10)}$$

This is the same equation as derived by Benet and Galeazzi

Noncompartmental Determination of the Steady-State Volume of Distribution for Any Mode of Administration

Keyphrases □ Pharmacokinetics—noncompartmental determination of the steady-state volume of distribution for any mode of administration □ Volume of distribution—steady-state, noncompartmental determination for any mode of administration

To the Editor:

The analysis of concentration–time data by pharmacokinetic methods traditionally involves the use of compartmental models. The interpretation of this analysis, represented by a linear equation in the form of a sum of coefficient and exponential terms, provides useful insight into drug disposition. In recent years, however, there has been a move away from the traditional approach to an alternative method referred to as model-independent data analysis. There are reasons to recommend the latter approach; there is no need to ascribe the data to a specific model, and as a result it is not necessary to have a sophisticated computer and nonlinear regression programs available. The model-independent approach assumes only that all dispositional processes may be described by first-order kinetics with elimination occurring from the rapidly equilibrating or central compartment. This approach may also be termed an area analysis, since the useful parameters of clearance and volumes of distribution (V_{ss} and V_β or V_{area}) are based on determination of the total area under the plasma concentration–time curve (AUC) and total area under the first moment of the plasma concentration–time curve ($AUMC$). The areas generally are determined using the linear or logarithmic trapezoidal rule and extrapolation techniques. The elimination rate constant and half-life are determined from linear regression of the terminal (*i.e.*, post-absorption, post-distribution) concentration–time data.

Benet and Galeazzi (1) applied techniques of tracer kinetics, and used moment analysis (2, 3) to obtain the volume of distribution at steady state, V_{ss}, following an intravenous bolus injection. The purpose of this communication is to extend their analysis to permit calculation of V_{ss} for any mode of administration.

The mean transit time for a drug in the body, $\bar{t}_b$, is a function of the mean transit time for the response to the input (in), usually measured as plasma concentration, $\bar{t}_{b+in}$, and the mean transit time of the input, $\bar{t}_{in}$ (4):

$$\bar{t}_b = \bar{t}_{b+in} - \bar{t}_{in} \qquad \text{(Eq. 1)}$$

Mean transit or residence time for the response to the input, *i.e.*, plasma concentration, is given by:

$$\bar{t}_{b+in} = \int_0^\infty tC\,dt \Big/ \int_0^\infty C\,dt = AUMC/AUC \qquad \text{(Eq. 2)}$$

while the mean transit time for the input is given by (5):

$$\bar{t}_{in} = \int_0^\infty X\,dt/\text{dose} \qquad \text{(Eq. 3)}$$

where dose is the dose administered, and $\int_0^\infty X\,dt$ is the total area under the amount *versus* time curve for the input. For example, if a drug is administered as a zero-order infusion:

$$X = \text{dose} - k_0 t \qquad \text{(Eq. 4)}$$

In Eq. 4, X is the amount remaining to be infused at time t, and k_0 is the zero-order infusion rate. Administration by a first-order process (*e.g.*, extravascular administration) results in the following expression for X, the amount remaining to be administered:

$$X = F\,\text{dose}\,e^{-k_a t} \qquad \text{(Eq. 5)}$$

where k_a is an apparent first-order rate constant, and F is the fraction of the administered dose ultimately reaching the systemic circulation. Integration of Eqs. 4 and 5 yields:

$$\int_0^T X\,dt = k_0 T^2/2 \qquad \text{(Eq. 6)}$$

and

$$\int_0^\infty X\,dt = F\,\text{dose}/k_a \qquad \text{(Eq. 7)}$$

respectively. In Eq. 6, T is the duration of the infusion and is the upper limit of the integral, *i.e.*, T is equivalent to infinity.

Substitution for $\bar{t}_{b+in}$ and $\bar{t}_{in}$, according to Eqs. 2 and 3, respectively, in Eq. 1 gives the following expression for drug transit time in the body:

$$\bar{t}_b = AUMC/AUC - \int_0^\infty X\,dt/\text{dose} \qquad \text{(Eq. 8)}$$

Since V_{ss} is equal to the product of clearance (dose/AUC) and transit time (1), that is:

$$V_{ss} = \frac{\text{dose}}{AUC}\bar{t}_b \qquad \text{(Eq. 9)}$$

Equations 8 and 9 can be readily used to calculate V_{ss} following any mode of administration. Where there is a single mode of administration, Eqs. 8 and 9 can be readily solved for V_{ss}. For the case where drug is administered as a single bolus, $\int_0^\infty X\,dt = 0$,

$$V_{ss} = \frac{\text{dose}}{AUC}\bar{t}_b = \frac{\text{dose}}{AUC}\left(\frac{AUMC}{AUC}\right) = \text{dose}\,\frac{AUMC}{AUC^2} \qquad \text{(Eq. 10)}$$

This is the same equation as derived by Benet and Galeazzi

0022-3549/82/0300-0372$01.00/0

Table I—Equations for $\int_0^\infty X\,dt$ and $\int_0^\infty X\,dt$/Dose for Various Modes of Drug Administration

Mode of Administration	$\int_0^\infty X\,dt$	$\int_0^\infty X\,dt$/dose
Intravenous bolus	0	0
Intravenous infusion	$k_0T^2/2$[a]	$T/2$
First-order input	F dose/k_a[b]	$1/k_a$
Simultaneous bolus plus infusion	$k_0t^2/2$	$k_0T^2/2(k_0T + \text{dose}_{iv})$[c]
Two consecutive infusions	$(k_0T^2/2)_1 + (k_0T^2/2)_2$[d]	$\frac{(k_0T^2/2)_1 + (k_0T^2/2)_2}{(k_0T)_1 + (k_0T)_2}$[c]

[a] See Eqs. 4 and 6. [b] See Eqs. 5 and 7. [c] See Eq. 13. [d] Subscript 1 refers to the first infusion, and subscript 2 refers to the second infusion.

(1). Substitution of $k_0T^2/2$ for $\int_0^\infty Xdt$ (see Eq. 6) in Eq. 8, and recognizing that k_0T equals dose, yields the following equation for V_{ss} for infusion data (6):

$$V_{ss} = \frac{\text{dose}}{AUC}\left(\frac{AUMC}{AUC} - \frac{T}{2}\right) = \text{dose}\,\frac{AUMC}{AUC^2} - \frac{T\ \text{dose}}{2\,AUC} \quad \text{(Eq. 11)}$$

If a case were to arise where input was first-order:

$$V_{ss} = \frac{F\ \text{dose}}{AUC}\left(\frac{AUMC}{AUC} - \frac{1}{k_a}\right) = F\ \text{dose}\,\frac{AUMC}{AUC^2} - \frac{F\ \text{dose}}{k_a\,AUC} \quad \text{(Eq. 12)}$$

If a value of F is not available, V_{ss}/F rather than V_{ss} would be calculated. As is apparent, information other than areas is required to determine V_{ss} where input is other than a bolus.

Administration of drug by multiple modes, for example, a simultaneous bolus plus an infusion, or consecutive infusions, may yield concentration–time data from which it may be desirable to estimate V_{ss}. Equation 9 in conjunction with a more general form of Eq. 8 may be used:

$$\bar{t}_b = \frac{AUMC}{AUC} - \frac{\sum \int_0^\infty X dt}{\sum \text{dose}} \quad \text{(Eq. 13)}$$

Table II—Calculation of V_{ss} for Various Modes of Administration[a]

Mode of Administration	AUC, (μg/ml) hr	$AUMC$, (μg/ml) hr^2	$\frac{AUMC}{AUC}$[b] hr	$\frac{\sum \int_0^\infty X\,dt}{\sum \text{dose}}$ hr	V_{ss}[c] L
IV bolus, 500 mg	1000.0[d]	25002.5[e]	25.0	0	25.0
IV infusion, 250 mg/hr over 2 hr	1000.0	26002.5[f]	26.0	1.0	25.0
First-order administration, 500 mg, $F = 1$, $k_a = 1.4\ \text{hr}^{-1}$	1000.0	25716.8[g]	25.7	0.7	25.0
Bolus plus infusion, 500 mg bolus plus 250 mg/hr over 2 hr	2000.0	51005.0[h]	25.5	0.5	25.0
Two consecutive infusions, 250 mg/hr over 2 hr followed by 41.67 mg/hr over 6 hr	1500.0	40003.7[i]	26.7	1.7	25.0

[a] Calculations based on equation, $C = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$, where $A_1 = 60.9545$ μg/ml, $\lambda_1 = 5.0605\ \text{hr}^{-1}$, $A_2 = 39.0459$ μg/ml and $\lambda_2 = 0.03952\ \text{hr}^{-1}$ following a 500-mg bolus dose. [b] See Table I. [c] See Eq. 13. [d] $AUC = \sum_{i=1}^{n} A_i/\lambda_i$. [e] $AUMC = \sum_{i=1}^{n} A_i/\lambda_i^2$. [f] $AUMC = \sum_{i=1}^{n} A_1/\lambda_i^2 + T\,AUC/2$. [g] $AUMC = N/k_a^2 + k_aA_1/\lambda_1^2(k_a - \lambda_1) + k_aA_2/\lambda_2^2(k_a - \lambda_2)$, where $N = k_a$ dose $(k_{21} - k_a)/V_c(\lambda_1 - k_a)(\lambda_2 - k_a)$. [h] Equals c plus d. [i] Use c for two different infusion rates, and add the resulting numbers. Note that only one-half the dose was given on the second infusion.

In Eq. 13, *AUMC* and *AUC* are the total areas under the resulting t C *versus* time and C *versus* time curves, and can be determined in the same manner as outlined for intravenous bolus data (1). The second term on the right hand side of Eq. 13 can be readily solved as the numerator is simply the sum of the $\int_0^\infty Xdt$ values for each mode of administration, and the denominator is the total dose administered by all modes of administration. Examples are illustrated in Table I.

The V_{ss} was determined for the various modes of administration outlined in Table I, utilizing the same data as employed by Benet and Galeazzi (1). All calculations were performed from explicit equations and are presented in Table II. Explicit equations were used to illustrate the validity of the relationships presented here. Estimation of the areas, *AUC* and *AUMC*, from time zero to the first point of the postabsorption and/or postdistribution phase with the linear or logarithmic trapezoidal rule, and from this latter point to time infinity using explicit equations (1) would yield values which vary from the theoretical values. Such variability is primarily due to inherent errors in the methods used to estimate the areas. However, the values obtained would be as reliable as those calculated using traditional methods of data analysis.

Albumin Does Not Mediate the Removal of Taurocholate by the Rat Liver

Keyphrases □ Albumin—effect on removal of taurocholate from liver □ Taurocholate—removal from liver not mediated by albumin

To the Editor:

In a recent article by Forker and Luxon (1), the authors discuss what they refer to as a contradiction in liver extraction as a function of albumin concentration and taurocholate free concentration. The authors have failed to relate their experimental observations to a fundamental clearance concept (2):

0022-3549/82/0300-0373$01.00/0

Table I—Equations for $\int_0^\infty X\,dt$ and $\int_0^\infty X\,dt$/Dose for Various Modes of Drug Administration

Mode of Administration	$\int_0^\infty X\,dt$	$\int_0^\infty X\,dt$/dose
Intravenous bolus	0	0
Intravenous infusion	$k_0T^2/2$[a]	$T/2$
First-order input	F dose/k_a[b]	$1/k_a$
Simultaneous bolus plus infusion	$k_0t^2/2$	$k_0T^2/2(k_0T + \text{dose}_{iv})$[c]
Two consecutive infusions	$(k_0T^2/2)_1 + (k_0T^2/2)_2$[d]	$\frac{(k_0T^2/2)_1 + (k_0T^2/2)_2}{(k_0T)_1 + (k_0T)_2}$[c]

[a] See Eqs. 4 and 6. [b] See Eqs. 5 and 7. [c] See Eq. 13. [d] Subscript 1 refers to the first infusion, and subscript 2 refers to the second infusion.

(1). Substitution of $k_0T^2/2$ for $\int_0^\infty Xdt$ (see Eq. 6) in Eq. 8, and recognizing that k_0T equals dose, yields the following equation for V_{ss} for infusion data (6):

$$V_{ss} = \frac{\text{dose}}{AUC}\left(\frac{AUMC}{AUC} - \frac{T}{2}\right) = \text{dose}\,\frac{AUMC}{AUC^2} - \frac{T\ \text{dose}}{2\,AUC} \quad \text{(Eq. 11)}$$

If a case were to arise where input was first-order:

$$V_{ss} = \frac{F\ \text{dose}}{AUC}\left(\frac{AUMC}{AUC} - \frac{1}{k_a}\right) = F\ \text{dose}\,\frac{AUMC}{AUC^2} - \frac{F\ \text{dose}}{k_a\,AUC} \quad \text{(Eq. 12)}$$

If a value of F is not available, V_{ss}/F rather than V_{ss} would be calculated. As is apparent, information other than areas is required to determine V_{ss} where input is other than a bolus.

Administration of drug by multiple modes, for example, a simultaneous bolus plus an infusion, or consecutive infusions, may yield concentration–time data from which it may be desirable to estimate V_{ss}. Equation 9 in conjunction with a more general form of Eq. 8 may be used:

$$\bar{t}_b = \frac{AUMC}{AUC} - \frac{\sum \int_0^\infty X dt}{\sum \text{dose}} \quad \text{(Eq. 13)}$$

Table II—Calculation of V_{ss} for Various Modes of Administration[a]

Mode of Administration	AUC, (μg/ml) hr	$AUMC$, (μg/ml) hr^2	$\frac{AUMC}{AUC}$[b] hr	$\frac{\sum \int_0^\infty X\,dt}{\sum \text{dose}}$ hr	V_{ss}[c] L
IV bolus, 500 mg	1000.0[d]	25002.5[e]	25.0	0	25.0
IV infusion, 250 mg/hr over 2 hr	1000.0	26002.5[f]	26.0	1.0	25.0
First-order administration, 500 mg, $F = 1$, $k_a = 1.4\ \text{hr}^{-1}$	1000.0	25716.8[g]	25.7	0.7	25.0
Bolus plus infusion, 500 mg bolus plus 250 mg/hr over 2 hr	2000.0	51005.0[h]	25.5	0.5	25.0
Two consecutive infusions, 250 mg/hr over 2 hr followed by 41.67 mg/hr over 6 hr	1500.0	40003.7[i]	26.7	1.7	25.0

[a] Calculations based on equation, $C = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$, where $A_1 = 60.9545$ μg/ml, $\lambda_1 = 5.0605\ \text{hr}^{-1}$, $A_2 = 39.0459$ μg/ml and $\lambda_2 = 0.03952\ \text{hr}^{-1}$ following a 500-mg bolus dose. [b] See Table I. [c] See Eq. 13. [d] $AUC = \sum_{i=1}^{n} A_i/\lambda_i$. [e] $AUMC = \sum_{i=1}^{n} A_i/\lambda_i^2$. [f] $AUMC = \sum_{i=1}^{n} A_1/\lambda_i^2 + T\,AUC/2$. [g] $AUMC = N/k_a^2 + k_aA_1/\lambda_1^2(k_a - \lambda_1) + k_aA_2/\lambda_2^2(k_a - \lambda_2)$, where $N = k_a$ dose $(k_{21} - k_a)/V_c(\lambda_1 - k_a)(\lambda_2 - k_a)$. [h] Equals c plus d. [i] Use c for two different infusion rates, and add the resulting numbers. Note that only one-half the dose was given on the second infusion.

In Eq. 13, *AUMC* and *AUC* are the total areas under the resulting t C *versus* time and C *versus* time curves, and can be determined in the same manner as outlined for intravenous bolus data (1). The second term on the right hand side of Eq. 13 can be readily solved as the numerator is simply the sum of the $\int_0^\infty Xdt$ values for each mode of administration, and the denominator is the total dose administered by all modes of administration. Examples are illustrated in Table I.

The V_{ss} was determined for the various modes of administration outlined in Table I, utilizing the same data as employed by Benet and Galeazzi (1). All calculations were performed from explicit equations and are presented in Table II. Explicit equations were used to illustrate the validity of the relationships presented here. Estimation of the areas, *AUC* and *AUMC*, from time zero to the first point of the postabsorption and/or postdistribution phase with the linear or logarithmic trapezoidal rule, and from this latter point to time infinity using explicit equations (1) would yield values which vary from the theoretical values. Such variability is primarily due to inherent errors in the methods used to estimate the areas. However, the values obtained would be as reliable as those calculated using traditional methods of data analysis.

Albumin Does Not Mediate the Removal of Taurocholate by the Rat Liver

Keyphrases □ Albumin—effect on removal of taurocholate from liver □ Taurocholate—removal from liver not mediated by albumin

To the Editor:

In a recent article by Forker and Luxon (1), the authors discuss what they refer to as a contradiction in liver extraction as a function of albumin concentration and taurocholate free concentration. The authors have failed to relate their experimental observations to a fundamental clearance concept (2):

0022-3549/82/0300-0373$01.00/0

$$E = \frac{F_f Cl_I}{Q + F_f Cl_I} \quad \text{(Eq. 1)}$$

Equation 1 can be rearranged to yield:

$$Cl_I = \frac{E\,Q}{F_f\,(1 - E)} \quad \text{(Eq. 2)}$$

where F_f is the free fraction (rather than free concentration) of drug in perfusate, E is the extraction ratio, Q is perfusate flow, and Cl_I is intrinsic clearance by the perfused organ. Using Eq. 2 and the mean data presented by the authors in Tables I and II of their paper (1), (*e.g.*, Q = 4.81 ml/min/g when F_f = 0.57 and E = 0.97 and Q = 4.55 ml/min/g when F_f = 0.11 and E = 0.86), it is apparent that the intrinsic organ clearances are comparable, *i.e.*, Cl_I = 273 and 254 ml/min/g, respectively. The similarity of these intrinsic clearance values indicates that the data generated by Forker and Luxon are consistent with, rather than divergent from, conventional pharmacokinetic theory and that liver uptake can be predicted using free fraction in perfusate and Eq. 2. Therefore, it is apparent that albumin does not mediate the removal of taurocholate by rat liver.

Effect of Plasma Protein Binding on Clearance of Drugs Metabolized by Michaelis–Menten Kinetics

Keyphrases □ Plasma protein binding—effect on clearance of drugs metabolized by Michaelis–Menten kinetics □ Michaelis–Menten kinetics—drug metabolism, effect of plasma protein binding

To the Editor:

It is generally known that restrictively bound drugs exhibit increasing clearances as the unbound concentration increases (1–3). However, the applicability of this concept to restrictively bound drugs which are subject to Michaelis–Menten rather than first-order kinetics has not received much attention. Consider a drug cleared exclusively by the liver. If the enzymes mediating its metabolism are saturable and metabolism is further limited by availability of unbound drug, the intrinsic clearance of unbound drug can be described as (4):

$$Cl'_{int} = \frac{V_{max}}{K_m + \alpha \overline{C}_{ss}} \quad \text{(Eq. 1)}$$

where Cl'_{int} is intrinsic clearance of unbound drug, V_{max} is the maximum velocity of the drug metabolizing enzyme, K_m is the concentration of unbound drug in plasma when the rate of metabolism is $V_{max}/2$, $\overline{C}_{ss}$ is the average steady-state plasma concentration of total drug, and α is the unbound fraction[1]. Equation 1 can be rewritten as follows:

$$Cl'_{int} = \frac{V_{max}}{\alpha\left[\frac{K_m}{\alpha} + \overline{C}_{ss}\right]} \quad \text{(Eq. 2)}$$

For a restrictively bound drug eliminated by a single clearing organ, organ clearance and total clearance can be defined in terms of intrinsic organ clearance and the unbound fraction of drug (5) as follows:

$$Cl_{tot} = Cl'_{int}\,\alpha \quad \text{(Eq. 3)}$$

Equation 2 can be rewritten in terms of Cl_{tot} as follows:

$$Cl_{tot} = \frac{V_{max}\alpha}{\alpha\left[\frac{K_m}{\alpha} + \overline{C}_{ss}\right]} \quad \text{(Eq. 4)}$$

which simplifies to:

$$Cl_{tot} = \frac{V_{max}}{\frac{K_m}{\alpha} + \overline{C}_{ss}} \quad \text{(Eq. 5)}$$

Equation 5 shows that Cl_{tot} will increase as α increases, but the magnitude of the increase depends on the values of V_{max}, K_m, and $\overline{C}_{ss}$. Moreover, for a drug such as phenytoin which is restrictively bound and metabolized by a saturable oxidase, the reported values for K_m (6) are really apparent K_m values rather than true K_m values, since they are calculated on the basis of total rather than unbound concentrations. Actual K_m would be given by:

$$K_m = K_{m\ app}\alpha \quad \text{(Eq. 6)}$$

where $K_{m\ app}$ is the apparent K_m. Thus, it should be noted that for a restrictively bound drug:

$$Cl_{tot} = \frac{V_{max}}{K_{m\ app} + \overline{C}_{ss}} \quad \text{(Eq. 7)}$$

The impact of changes in α on Cl_{tot} become more pronounced as K_m increases as shown in Fig. 1. The relationship between Cl'_{tot}/Cl_{tot} *versus* α is unaffected by changes in V_{max}.

Several investigators have shown increased clearances for phenytoin corresponding to increases in the free fraction of the drug. Shand *et al.* (7) perfused phenytoin through isolated rat liver, varying the albumin concentration of the perfusate and consequently the unbound fraction. Their data show a relationship between Cl_{tot} and α similar to that in Fig. 2. Gugler and coworkers (8) reported a doubling of the free fraction and Cl_{tot} in six hypoalbuminemic nephrotic patients compared with six control subjects. However, average steady-state concentrations of total drug were 6.8 and 2.9 mg/liter for controls and nephrotics, respectively, well below the concentrations necessary to saturate the phenytoin oxidase. When $\overline{C}_{ss} \ll K_m/\alpha$, Eq. 7 simplifies to:

$$Cl_{tot} = \alpha\frac{V_{max}}{K_m} \quad \text{(Eq. 8)}$$

If plasma levels are sufficiently high so that metabolism

[1] Cl'_{int} is intrinsic clearance of unbound drug as defined by Wilkinson and Shand [G. Wilkinson and D. Shand, *Clin. Pharmacol. Ther.* 18, 377 (1975)], and is equivalent to Cl_{int} of Rowland *et al.* (4).

0022-3549/82/0300-0374$01.00/0

$$E = \frac{F_f Cl_I}{Q + F_f Cl_I} \quad \text{(Eq. 1)}$$

Equation 1 can be rearranged to yield:

$$Cl_I = \frac{E\,Q}{F_f\,(1 - E)} \quad \text{(Eq. 2)}$$

where F_f is the free fraction (rather than free concentration) of drug in perfusate, E is the extraction ratio, Q is perfusate flow, and Cl_I is intrinsic clearance by the perfused organ. Using Eq. 2 and the mean data presented by the authors in Tables I and II of their paper (1), (*e.g.*, Q = 4.81 ml/min/g when F_f = 0.57 and E = 0.97 and Q = 4.55 ml/min/g when F_f = 0.11 and E = 0.86), it is apparent that the intrinsic organ clearances are comparable, *i.e.*, Cl_I = 273 and 254 ml/min/g, respectively. Effect of Plasma Protein Binding on Clearance of Drugs Metabolized by Michaelis–Menten Kinetics

Keyphrases □ Plasma protein binding—effect on clearance of drugs metabolized by Michaelis–Menten kinetics □ Michaelis–Menten kinetics—drug metabolism, effect of plasma protein binding

To the Editor:

It is generally known that restrictively bound drugs exhibit increasing clearances as the unbound concentration increases (1–3). However, the applicability of this concept to restrictively bound drugs which are subject to Michaelis–Menten rather than first-order kinetics has not received much attention. Consider a drug cleared exclusively by the liver. If the enzymes mediating its metabolism are saturable and metabolism is further limited by availability of unbound drug, the intrinsic clearance of unbound drug can be described as (4):

$$Cl'_{int} = \frac{V_{max}}{K_m + \alpha \overline{C}_{ss}} \quad \text{(Eq. 1)}$$

where Cl'_{int} is intrinsic clearance of unbound drug, V_{max} is the maximum velocity of the drug metabolizing enzyme, K_m is the concentration of unbound drug in plasma when the rate of metabolism is $V_{max}/2$, $\overline{C}_{ss}$ is the average steady-state plasma concentration of total drug, and α is the unbound fraction[1]. Equation 1 can be rewritten as follows:

$$Cl'_{int} = \frac{V_{max}}{\alpha\left[\frac{K_m}{\alpha} + \overline{C}_{ss}\right]} \quad \text{(Eq. 2)}$$

For a restrictively bound drug eliminated by a single clearing organ, organ clearance and total clearance can be defined in terms of intrinsic organ clearance and the unbound fraction of drug (5) as follows:

$$Cl_{tot} = Cl'_{int}\,\alpha \quad \text{(Eq. 3)}$$

Equation 2 can be rewritten in terms of Cl_{tot} as follows:

$$Cl_{tot} = \frac{V_{max}\alpha}{\alpha\left[\frac{K_m}{\alpha} + \overline{C}_{ss}\right]} \quad \text{(Eq. 4)}$$

which simplifies to:

$$Cl_{tot} = \frac{V_{max}}{\frac{K_m}{\alpha} + \overline{C}_{ss}} \quad \text{(Eq. 5)}$$

Equation 5 shows that Cl_{tot} will increase as α increases, but the magnitude of the increase depends on the values of V_{max}, K_m, and $\overline{C}_{ss}$. Moreover, for a drug such as phenytoin which is restrictively bound and metabolized by a saturable oxidase, the reported values for K_m (6) are really apparent K_m values rather than true K_m values, since they are calculated on the basis of total rather than unbound concentrations. Actual K_m would be given by:

$$K_m = K_{m\ app}\alpha \quad \text{(Eq. 6)}$$

where $K_{m\ app}$ is the apparent K_m. Thus, it should be noted that for a restrictively bound drug:

$$Cl_{tot} = \frac{V_{max}}{K_{m\ app} + \overline{C}_{ss}} \quad \text{(Eq. 7)}$$

The impact of changes in α on Cl_{tot} become more pronounced as K_m increases as shown in Fig. 1. The relationship between Cl'_{tot}/Cl_{tot} *versus* α is unaffected by changes in V_{max}.

Several investigators have shown increased clearances for phenytoin corresponding to increases in the free fraction of the drug. Shand *et al.* (7) perfused phenytoin through isolated rat liver, varying the albumin concentration of the perfusate and consequently the unbound fraction. Their data show a relationship between Cl_{tot} and α similar to that in Fig. 2. Gugler and coworkers (8) reported a doubling of the free fraction and Cl_{tot} in six hypoalbuminemic nephrotic patients compared with six control subjects. However, average steady-state concentrations of total drug were 6.8 and 2.9 mg/liter for controls and nephrotics, respectively, well below the concentrations necessary to saturate the phenytoin oxidase. When $\overline{C}_{ss} \ll K_m/\alpha$, Eq. 7 simplifies to:

$$Cl_{tot} = \alpha\frac{V_{max}}{K_m} \quad \text{(Eq. 8)}$$

If plasma levels are sufficiently high so that metabolism

[1] Cl'_{int} is intrinsic clearance of unbound drug as defined by Wilkinson and Shand [G. Wilkinson and D. Shand, *Clin. Pharmacol. Ther.* 18, 377 (1975)], and is equivalent to Cl_{int} of Rowland *et al.* (4).

0022-3549/82/0300-0374$01.00/0

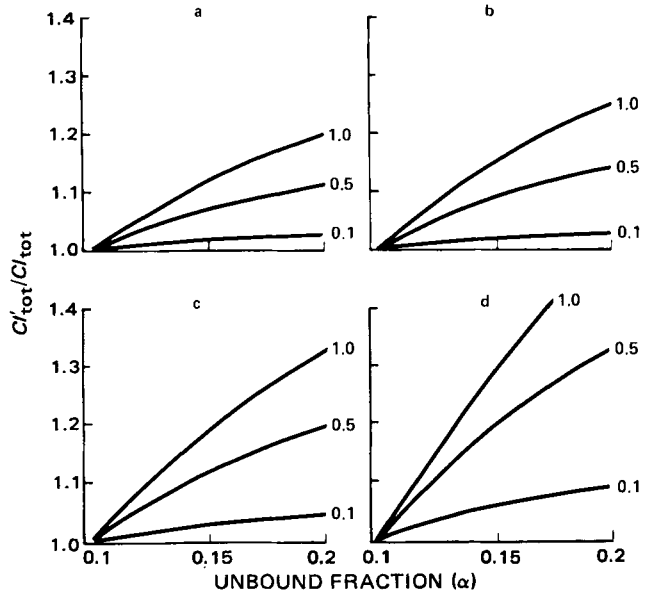

Figure 1—*Impact of α on the clearance of a restrictively bound drug metabolized by Michaelis–Menten kinetics.* Cl'_{tot} *is clearance when* $\alpha > 0.1$. Cl_{tot} *is clearance at* $\alpha = 0.1$. *Actual* K_m *values are shown for each curve.* $\bar{C}_{ss}$ *is 20, 15, 10, and 5 mg/liters for graphs a, b, c, and d, respectively.*

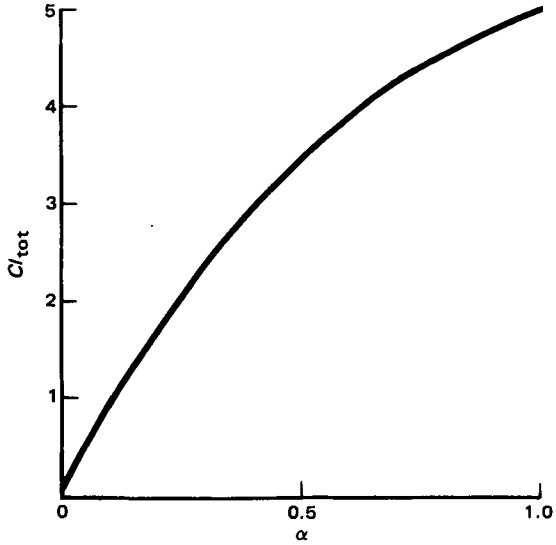

Figure 2—*Relationship between steady-state clearance and magnitude of unbound fraction for a restrictively bound drug metabolized by Michaelis–Menten kinetics.* $\bar{C}_{ss} = 1$ *mg/liter,* $V_{max} = 10$ *mg/hr, and* $K_m = 1$ mg/liter.

is no longer operating by apparent first-order kinetics, the changes in Cl_{tot} will no longer be directly proportional to α. As shown in Fig. 1, a doubling of α will only increase Cl_{tot} slightly, and the extent of the increase will also depend on the actual value of K_m and $\bar{C}_{ss}$.

While clearance changes in a complex manner with altered protein binding, the changes in total and unbound drug concentration are simple. The rate of drug administration required to achieve a targeted average steady-state plasma level is:

$$R_{in} = \frac{V_{max}\bar{C}_{ss}}{\frac{K_m}{\alpha} + \bar{C}_{ss}} \qquad \text{(Eq. 9)}$$

where R_{in} represents the rate of drug administration. If, for example, protein binding were altered by hepatitis, cirrhosis, uremia, heparinization, or drug interaction such that α increased while the rate of administration remained unchanged, the relationship between the total steady-state plasma concentration of drug before and after the change in binding would be:

$$\bar{C}'_{ss} = \frac{\bar{C}_{ss}}{a} \qquad \text{(Eq. 10)}$$

where a is the ratio of altered α to original α, $\bar{C}_{ss}$ is the total plasma concentration before the change, and $\bar{C}'_{ss}$ is the total plasma concentration after the change in binding. From Eq. 10 it is apparent that the average steady-state concentration of free drug is not altered by the change in binding.

The recommendations for adjusting the doses of restrictively bound drugs that are cleared by hepatic metabolism apply to drugs metabolized by either apparent first-order or Michaelis–Menten kinetics when binding is decreased. Though clearance increases, the average steady-state concentration of unbound drug does not. Decreasing the dose and the dosing interval so that the dosing rate remains constant will help to contain peak and trough levels of unbound drug within therapeutic limits.

REVIEWS

Physical Chemical Properties of Drugs. By SAMUEL H. YALKOWSKY, ANTHONY A. SINKULA, and SHRI C. VALVANI. Dekker, 270 Madison Ave., New York, NY 10016. 1980. 361 pp. 14 × 23 cm. Price $45.00 (20% higher outside U.S. and Canada).

An understanding of the chemical properties of a drug is necessary for understanding its activity since covalent bonding at the reaction site sometimes is (and metabolism always is) an important consideration. However, over the past two decades more sophisticated analytical tools, *e.g.*, NMR and X-ray crystallography, have focused our attention on the fact that it is the wide variety of weaker physicochemical forces that nature uses to define a drug for a very specific purpose. Therefore, there recently has been a concerted effort to measure and report these physical constants.

Actual application of appropriate constants to drug design has been limited by two factors: measurement of these constants has not kept pace with the need, and application methodology has lagged behind in certain areas. This volume does a great deal to remedy both shortcomings. Chapters 1, 5, 8, 9, and 10 describe calculation procedures for pKa, partition coefficient (octanol/water), solubility parameter, molecular connectivity, and molecular surface areas, respectively. Chapters 2, 3, 6, and 7 focus on the more effective use of pKa, hydrophobicity, solubility, and thermodynamic considerations in drug improvement. Chapter 4 points out important limitations in the Hansch approach to structure–activity relationships.

This book does not in any important way duplicate others presently available in this field. It can be highly recommended to anyone with a strong commitment in drug design, as well as to students in advanced courses in that discipline. This book should be very valuable to anyone involved in modeling environmental transport and fate.

Pharmaceutical Dosage Forms: Tablets Vol. 2. Edited by HERBERT A. LIEBERMAN and LEON LACHMAN. Dekker, 270 Madison Avenue, New York, NY 10016, 1981. 520 pp. 18 × 25.5 cm Price $59.75. (A special student price of $24.50 for five or more copies through a college or university bookstore in the United States or Canada.)

The second volume of this set lives up to the promise of the first. Whereas the first volume emphasizes the distinction between the types of tablets with details on the manufacturing of each, this volume discusses each unit process completely. As before, each chapter develops without a dependency on the nuances of other sections.

The first four chapters cover mixing, drying, size reduction, and compression. Chapter five is really two chapters, one on the characterization of granulations, and the other on the evaluation of finished tablets. The final chapter is a review of tablet press tooling. The types of punches, terminology, control, and problem solving are all discussed in excellent detail.

Chapter six, "Bioavailability in Tablet Technology," is over one-third of this volume. This does seem excessive. Most relevant background biopharmaceutic and pharmacokinetic concepts are reviewed in detail from the everted gut technique, pH partition, dissolution, and compartmental modeling, to multiple dosing kinetics. There are excellent sections of dissolution evaluation and bioavailability assessment, with liberal referencing to the Federal Register. Examples are given of virtually everything discussed, and yet there is no discussion of the FDA's statistical criteria of bioavailability of bioequivalence or of their criteria for the setting of a dissolution specification for generic bioavailability. These were needed more than some portions of the existing chapter when considering where this chapter is presented.

Nevertheless, this set, when completed, will probably be the state-of-the-art for many years to come.

Fulfilling Member Expectations

For a number of reasons, most of which are not really pertinent to this editorial and which would be very complex to explain in the limited space available here, the American Pharmaceutical Association is in the initial process of assessing and reassessing the products and services that it provides to its membership. Essentially, the Association is attempting to ascertain how well its present activities, projects, and products meet the desires and needs of today's pharmacists and of APhA members in particular.

Moreover, this is not always an all-or-none matter. Perhaps it is just a case that shifting interests or membership orientation calls for expanding a certain activity or project; alternatively, for the same reasons, the budget and resources involving another area may need to be cut back from current levels. But in the case of some projects, it may be concluded that a partial reduction is not a suitable remedy, and total elimination may be the only logical solution.

As an illustration, the huge costs associated with updating the data base for APhA's Drug Interactions Evaluation Program and the skyrocketing costs of paper and printing—coupled with less in the way of clinically significant new information and diminishing practitioner interest—led the APhA Board of Trustees recently to decide against the publication of a complete new edition of its *Evaluations of Drug Interactions*. At the same time, however, the Board also directed staff to continue to explore other communication approaches for drug interactions information, including computerized systems that might be more economically viable.

This incident is not an isolated example of APhA changing its approach in providing some member service. During the past 10 years, there have been any number of such modifications, to wit: in the publications area, the Association's newsletter was doubled in frequency to become a weekly, thereby making it a speedier communications vehicle; several different approaches were tried with regard to supplying news of the Annual Meeting and disseminating the Association's Annual Report; mid-year, regional, and specialized meetings of each of the Association's three subdivisions have been sponsored in addition to the traditional APhA Annual Meeting; innovative poster sessions, audiovisual learning programs, scientific exhibits, and assorted other departures from conventional meeting formats have been experimented with and largely implemented; and books, journals, and meetings have all been condensed and either severely edited or restructured to make them more concise in an effort to save time and money for all concerned. Many of these experiments have proven to be highly successful; on the other hand, in a few cases the reception has been dismal despite every reason to have expected an enthusiastic member reaction.

Nor has APhA been alone in such efforts and their outcome. Other professional, technical, and scientific membership societies have been likewise searching for new and alternative ways to meet contemporary membership needs and expectations. Although few such groups have attempted as many innovations and have been quite as daring as APhA in departures from the conventional "tried and true," we believe that each organization in its own way strives to satisfy the perceived desires of its members.

And, as Shakespeare would have put it, therein lies the rub! No survey, no questionnaire, no Gallup poll, or whatever, really can tell the organization anything, or give it any meaningful guidance, unless the membership has a pretty clear idea of what it wants, what it will use, and what it is willing to support and pay for.

Just this past week, this writer received a questionnaire from the American Chemical Society, an organization in which we have long maintained personal membership. Over the years, the ACS has done a conscientious job of trying to be responsive to its membership, and this latest questionnaire was largely devoted to exploring member preferences in ACS's continuing education programs.

In completing the questionnaire, we were struck by our own ambivalent feelings and reactions. When the question was asked about our interest in, or desire for, a CE program in a new computerized format, we impulsively wanted to express our positive reaction. But yet, our own working experience in conducting such surveys gave us pause to stop and critically ask ourselves the question, "In all honesty, would we *really* order it, pay for it, and use it?" And in this case we concluded that our answer was, "No, we really wouldn't."

The message of this editorial is to suggest that all of us need to reflect in a similar fashion when we are asked for our opinions by our professional organizations.

We know for a fact that the officers and staff of APhA, as well as its Academy of Pharmaceutical Sciences and the other APhA subdivisions, all are making a sincere effort to provide meaningful membership services in the most cost-effective manner. But they can only be responsive in direct proportion to the accuracy with which the membership articulates its true desires and its willingness to utilize and pay for those services when they are subsequently offered.

The best chef in the world can do little to please the diner's palate unless and until the diner selects from the menu a specific dish that will appeal to that particular diner.

Keyphrases □ Liposomes—as drug carriers, cancer therapeutics, literature survey □ Albumin—magnetically responsive microspheres, cancer therapeutics, literature survey □ Cancer therapeutics—experimental methods, literature survey

CONTENTS

During the last 10 years, the search for methods of selectively targeting antineoplastic agents has increased significantly. Because of the lack of tumor specificity of systemically administered antitumor drugs, toxic side effects are common, often resulting in greater harm to the host tissue than to the neoplastic process. Currently, the therapeutic index of most antineoplastic agents used in systemic therapy remains marginal, despite efforts to achieve tumor specificity. Despite various chemical modifications of chemotherapeutic agents (e.g., altering their partition coefficient, attaching immunologic ligands, or altering charge density), only variable success has been achieved in increasing specificity. An alternative approach for increasing the effectiveness of antitumor drugs is to alter their distribution in the body by incorporating them into particulate carriers, which theoretically can be concentrated at the tumor site. In this way, the toxicity of the drug for the tumor might be enhanced while the systemic toxicity is minimized.

Two major approaches for achieving this goal are discussed in this article. The first consists of new types of liposomes which impart an element of selectivity to desired target sites; the second consists of magnetically responsive drug-carrying microspheres which are capable of being targeted to tissue sites by use of an external magnetic field. A detailed comparison of all the various methods of drug delivery has been reviewed elsewhere (1).

BACKGROUND

The goal of any drug delivery system involves the altering of the pharmacokinetics and physiological disposition of the drug in question in order to obtain a higher therapeutic index. This can be accomplished either by decreasing the toxicity of the drug or by increasing its efficacy. In treating neoplastic disease, these concentrations become essential. Since the biochemical differences between normal and transformed cells are minimal and are difficult to exploit (2), the chemical synthesis of more efficacious drugs has not been entirely fruitful. Cancer therapy currently involves the administration of toxic drugs with a relatively small safety margin. Any drug delivery system that could significantly increase the therapeutic index of an antitumor drug would have a major impact in cancer treatment.

Many approaches have been tried in attempts to design a "magic bullet" for cancer. Implanted drug reservoirs give a more uniform dosage rate of the entrapped drug. The pharmacokinetics of the drug and its eventual disposition, however, remain identical to those of the free drug administered *via* normal methods. Covalently attaching antitumor agents to antibodies specific for the tumor has been suggested as a method of achieving tumor specificity. The results so far are only suggestive of potential applicability (3, 4). This approach is limited further by the extent that the attachment of the drug to the antibody de-

0022-3549/82/0400-0379$01.00/0

creases the immunological specificity of the antibody. The most encouraging prospect of increasing the therapeutic index of antitumor drugs is to encapsulate them inside macromolecular carriers that can circulate within the body. In theory, macromolecular carriers can be localized at the tumor site with high specificity, thereby increasing the therapeutic index of the encapsulated drug. Two such macromolecular carriers have been exploited recently in the targeting of drugs. The first, the liposome, is an assembly of phospholipids held together by noncovalent forces. The other carrier is the magnetically responsive albumin microsphere which can be targeted to tissue sites *via* external magnetic fields. We will critically evaluate the current experimental data for both of these systems and then speculate on their future clinical use in treating cancer.

LIPOSOMES

Liposomes form spontaneously when dry phospholipids are hydrated with an aqueous solution. These structures, which are held together by noncovalent forces, consist of concentric bilayers of phospholipids that are separated by an aqueous space (5, 6). Within this aqueous space, water soluble compounds such as antitumor drugs can be stored. Drug-containing lipsosomes can be separated from nonsequestered drug by centrifugation of the liposomes or by gel filtration. However, all phospholipids do not form liposomes; in fact only very few naturally occurring phospholipids form liposomes that are stable under physiological conditions. Phosphatidylcholine, the most abundant natural phospholipid, readily forms stable liposomes, whereas phosphatidylethanolamine, the second most abundant natural phospholipid, does not. Furthermore, phospholipid liposomes only form if they are hydrated above a temperature that corresponds to the physical transition of the phospholipid from a crystal-like (*i.e.*, gel) state to a liquid crystalline state. This temperature, which is dependent on the fatty acid composition of the phospholipid, is known as the transition temperature. Liposomes formed under these conditions are multilamellar bilayers that range from 1 to 5 μm in diameter. Upon sonication, these multilamellar bilayers are reduced in size to 0.02 μm in diameter. Other size ranges between these two extremes are possible *via* polycarbonate filter extrusion techniques (5).

The potential use of liposomes as drug delivery systems for antineoplastic agents has been summarized in many articles (6–10). This review will attempt to update and critically evaluate recent experimental results using liposomes in treating neoplastic disease and to anticipate potential new approaches in this area that may be useful in the future.

Physiological Fate of Liposomes—It is now appreciated that the simple encapsulation of an antitumor drug in unsonicated dispersions of phosphatidylcholine is a relatively naive approach to greater *in vivo* drug specificity. This is partly due to the complexity of the interaction of both the plasma and the reticuloendothelial system with liposomes. In the former case, the drug is released from the liposome so that its fate becomes that of the free drug. In the latter, the rapid removal of liposomes and their associated antitumor drug by fixed macrophages of the liver and spleen limits the number of liposomes capable of reaching a target site.

In the rush to demonstrate the ability of liposomes to treat neoplastic disease, few controlled studies have been conducted into the physiological fate of systemically injected liposomes. Such studies would require having liposomes of defined size and composition. Without this definition, relatively simple experiments such as *in vitro* exchange of cholesterol between sonicated phosphatidylcholine vesicles, can be misinterpreted (11). Rigorous studies on the physiological fate of liposomes require the use of radioactive phospholipids rather than easily obtained commercial radioactive markers such as cholesterol or cholesteryl esters. Such markers exchange readily with blood components (12) or are metabolized in the plasma to components that can exchange easily (13) resulting in an erroneous interpretation of carrier distribution. It is also essential to determine whether actual mass transfer of the phospholipid from the liposome is observed or simply the exchange of radioactive phospholipid equivalents with other blood components. Finally, the structural integrity of the liposome and the associated antitumor drug in the systemic circulation should be verified. Due to the complexity of such experiments, few studies exist that fulfill these criteria. The most complete work is that of Tall (14) in which all of these experimental parameters are examined. This particular study is important in that it gives insight into the molecular modification of liposomes by the lipoprotein apoproteins.

A wide variety of lipoproteins circulate in the plasma. Lipoprotein particles are responsible for transporting highly insoluble lipids such as triglycerides and cholesteryl esters to their site of utilization. The protein moieties of the lipoproteins, known as apoproteins, appear to play a role in the structural integrity of the lipoprotein particle as well as functioning as a recognition signal for various receptors in the body.

Apoproteins, especially apo A, can leave their respective lipoprotein particles and associate with phospholipid liposomes. With apo A, this association can eventually lead to the disruption of liposomal integrity (15–17) and the release of the associated water soluble antitumor agent. It has become clear that the inclusion of cholesterol in the liposome bilayer minimizes the interaction of apo A with phospholipid liposomes *in vitro* (18). However, the inclusion of cholesterol may not significantly alter the physiological fate of most of the liposomes *in vivo* (14).

The effect of another apoprotein, apo E, on phospholipid liposomes is often unappreciated. Apo E is associated with the uptake of chylomicron and very low density lipoprotein (VLDL) remnants in the liver (19, 20). Its association with phospholipids either as liposomes (21) or as phospholipid–triglyceride emulsions (22) is well documented. One hypothesis is that apo E may have a higher affinity for cholesterol-rich liposomes than for cholesterol-poor liposomes. If so, the cholesterol rich liposomes *in vivo* would be taken up by the hepatic receptor that recognizes apo E. Tall indicates that this may be the case (14). Therefore, the physiological fate of most cholesterol rich liposomes *in vivo* may be the liver, even though the fractional amount of the liposomes that remains in the plasma may appear to be structurally intact (18).

It is also well documented that the inclusion of choles-

terol in a liposome will reduce the rate of leakage of entrapped drugs. The reduction in the rate of loss of an antitumor agent from such cholesterol rich liposomes can be beneficial to the efficacy of cell cycle sensitive drugs such as cytarabine (23–25). Cytarabine entrapped within liposomes is sequestered from the plasma and is not subject to rapid metabolism; hence, the liposome acts as a long-lived depot for the drug. For other noncell cycle-dependent drugs, however, large increases in the efficacy of encapsulated drug regardless of the composition of the liposome, has not been observed (26), probably because most of the drug is removed to distant sites before the tumor can be reached. Thus, the inclusion of cholesterol in the liposome only decreases the permeability of the drug from a liposome and does not appear to significantly alter liposome tissue distribution.

The unresolved basic problem is how to gain greater target specificity for the drug. The most exploited way is to reduce the size of the liposome to that of a small unilamellar vesicle with a diameter of ~200 Å. This size reduction increases the plasma lifetime of the liposome compared to unsonicated dispersions (27), thereby increasing the possibility that greater tumor localization can be achieved compared to larger liposomes. The reduction in size of the liposome, however, also decreases the amount of interior aqueous space, thereby limiting the amount of water soluble antitumor drug that can be encapsulated. Moreover, the *in vitro* stability of small unilamellar vesicles is less than that of larger liposomes, either as large unilamellar vesicles or as unsonicated dispersions. The reduction in the size of the liposome while increasing plasma circulation time does not appear to alter extensively the physiological fate of the liposome (*i.e.*, localization primarily in the liver and the spleen).

Incorporation of Glycolipids—One new approach to alter the tissue distribution of liposomes is the inclusion of natural and synthetic glycolipids into the liposomes. Taking advantage of the asialo galactose receptor in the liver, vesicles containing an exposed galactose moiety accumulated to an even greater extent in the liver than liposomes without such glycolipids (28). On the other hand, the presence of a sialic acid group on the glycolipid slightly retards the accumulation of the such liposomes in the liver (29). Using a variety of synthetic glycolipids, such as amino mannose derivatives, Baldeschwieler and coworkers have shown that enhancement of vesicle stability can occur along with a highly altered tissue distribution, especially to the lung (30, 31). More recent studies have indicated that the same amino mannose derivatives enhance the uptake of liposomes by macrophages (32). Whether or not such altered stability and different tissue location have any beneficial effects for cancer chemotherapy remains to be tested. These results indicate that suitable modifications of the liposomal surface can dramatically alter *in vivo* characteristics.

Incorporation of Immunoglobulins—Another new methodology that has received much attention is the use of immunoglobulins to direct liposomes and the associated antitumor drug to a specific site. In theory, suitable tumor-specific antibodies can be bound to the liposomal surface and then can impart the necessary tissue specificity so that targeting can be achieved. An early study indicated that specificity could be achieved *in vitro* (33). Although internalization of the liposome and its associated antitumor drug was demonstrated, the studies were done with highly phagocytic cells. As attractive as this potential may be, there are factors that must be critically assessed. First, as shown by Weinstein and coworkers, the increased binding of a liposome containing the appropriate hapten to a cell, mediated by the $F(ab)_2$ fragment of an IgG specific antibody, does not ensure internalization of the liposome and its associated antitumor drug into nonphagocytic cells (34). Even the localization of liposomes containing methotrexate near tumor cells *in vitro* does not enhance the cytotoxic behavior of methotrexate (34). Recent studies have indicated that sonicated vesicles containing methotrexate and a surface-oriented hapten can be internalized into highly phagocytic cells having an F_c receptor by prior reaction of the lysosomes with antihapten IgG antibody (35). However, the therapeutic uses of this technique may be limited to highly phagocytic cells. Moreover, many normal cells also have F_c receptors that appear to be needed for carrier internalization (35).

Other workers have shown that IgG or $F(ab)_2$ fragments can be covalently linked to liposomes *via* oxidized glycolipids present in the bilayer of the liposome (36). Using $F(ab)_2$ fragments specific for red cells, a high degree of binding to red cells has been observed (37). Likewise, monoclonal antibodies can be rendered hydrophobic and linked to the liposome with subsequent *in vitro* specificity (38) or can be covalently linked *via* phosphatidylethanolamine in the liposome (39). Nonetheless, the mere increased binding to the target cell does not ensure greater efficacy of the associated antitumor drug, even *in vitro* (34). Therapeutic uses of antibody-directed liposomes must also be considered based on work demonstrating the physiological fate of purified ^{131}I-labeled anticarcinoembryonic antigen administered to patients with colorectal carcinomas. It has been shown that although diagnostic specificity (*i.e.*, higher radioactivity in tumor tissue compared to normal adjacent tissue) is observed, only 0.1% of the injected antibody localizes in the resected tumor (40). Such low absolute specificity raises a question for the potential use of antibodies as a way of targeting liposomes and their associated antitumor drugs to a tumor, since the carcinoembryonic antigen is one of the most characterized tumor markers. Also, since solid tumors are known to shed their antigens into the plasma, much of the liposome–antibody complex would most likely bind with circulating antigens, severely limiting the number of liposomes capable of binding to antigens on the tumor surface (40). Finally, there remains the problem of whether the liposome–antibody complex can leave the plasma compartment and enter into the extravascular compartment. If the liposome complex is being simply removed from the circulation by the fixed macrophages of the liver and spleen, then there is little liklihood that the liposome will encounter the bulk of the tumor. On the other hand, if the liposome–antibody complex can leave the vascular system at the tumor site, or enter the lymphatic circulation, then the possibility exists that the complex can interact with the tumor. The problem of the cellular uptake of the liposome and its associated antitumor drug *in vivo* remains the same as discussed for the *in vitro* studies.

Use of Biological Factors—A more novel approach to the problem of tissue specificity is the use of biological

factors to stimulate the body's immune system to attack tumor sites. The use of interferon as an immuno-modulating agent has received much attention, but its use has failed to produce uniformly positive results (41). Attempts have been made to restrict biological response modifiers selectively at the site of tumors. One example of this approach is the encapsulation of lymphokines within phospholipid liposomes (42). Liposomes, composed of phosphatidylcholine and phosphatidylserine, were shown to localize in the lung after intravenous injection. Such localization allowed the alveolar macrophages to phagocytose the liposomes and their associated macrophage activating factor. Thus, by activating the alveolar macrophages, metastases, which have migrated to the lung from a primary tumor, can be attacked with high efficiency, but only if the primary tumor had been excised from the animal (43). Further experiments indicated that macrophage activating factor can be replaced by the synthetic immuno-potentiating compound muramyl dipeptide with similar results (44). This approach indicates that if one can localize biological response modifiers such as macrophage activating factor and muramyl dipeptide to macrophages in the lung, substantial efficacy can be observed under certain conditions (*i.e.*, removal of the primary tumor). In a similar approach, immune RNA has been encapsulated in liposomes coated with antilymphocyte antibody studies. The phagocytosis of these liposomes by lymphocytes *in vitro* resulted in enhanced cytotoxicity to tumor cells (45). The *in vivo* utility of a system using antibodies to target liposomes to lymphocytes to enhance chemotherapy, has the same limitations as outlined previously.

Thus far, most attempts at targeting liposomes to selected tissues *in vivo* has relied on size, glycolipids, or antibodies. Even if successful, unless the tumor cells in the target tissue are highly endocytic, the contents of the liposome are unlikely to enter the target cell unless they leak from the liposome. That is to say, the free drug must still enter the target cell. Another novel approach is the localization of the free antitumor drug at a desired site by using the physical parameters of the liposome phospholipid composition to increase the permeability of the drug.

Use of Transition Temperature—It has been shown that at the transition temperature, when the phospholipids of a liposome undergo a physical transition from the gel to liquid crystalline state, there is a dramatic increase in the permeability of the liposomal membrane (46). An encapsulated drug will leak out more rapidly at this transition temperature than at temperatures slightly higher or lower. Liposomes with entrapped methotrexate have been designed to have a transition temperature near 42° (47). Localized heating of the target tissue can raise the internal tissue temperature high enough to reach 42°, causing a large efflux of the encapsulated methotrexate from the liposome as the carrier enters the heated tissue. As the liposome is removed from the target site *via* the circulatory system, the permeability of the drug from the liposomes decreases rapidly due to the decrease in local temperature. Recent experimental results indicated that high density lipoproteins are necessary to destabilize the liposomes at the phase transition temperature (48). Theoretically this process can be repeated during every circulatory pass of the liposome thereby delivering the drug at high localized concentrations at the target site. A variation of this approach is to incorporate *N*-palmitoyl homocysteine into liposomes. By adjusting the composition of the liposome, one can increase the permeability of an encapsulated drug with decreasing external pH (49). This approach assumes that the pH near the tumor site will be sufficiently lower than that of normal tissue, hence giving a selective release of the drug at that site. Such a theoretical concept remains to be demonstrated *in vivo*. In both approaches, this type of targeting is a transient phenomenon, and while it does not localize the drug in high concentrations at the desired site, it does give greater concentration of the free drug at the target site than can be achieved with conventional administration. With the heat sensitive liposomes, some therapeutic benefit has been observed (47).

Current experimental evidence indicates there is much to accomplish in order to demonstrate the necessary increased efficacy of antitumor agents in liposomes before contemplating potential clinical use. Nonetheless, there are a number of theoretical factors that should be part of an ideal lipid-based drug delivery system. It must be stable *in vivo*; *i.e.*, it should be resistant to the interaction of apoproteins of the plasma lipoproteins on the vesicle surface, resulting in structural destabilization or hepatic localization (especially *via* apo E). The carrier should have a small size (less than 300 Å) in order to penetrate into the extravascular space or lymphatic circulation, thereby giving the drug and carrier maximum opportunity to interact with tumor cells. Furthermore, this small size will enhance the possibility of endocytosis of the lipid-based carrier in a similar fashion to low-density lipoproteins, especially by cells that are not highly phagocytic (50). Finally, the carrier should be able to be localized with high specificity to any desired part of the organism *in vivo*. It is unlikely that immunological means will be able to accomplish this final goal.

MAGNETICALLY RESPONSIVE ALBUMIN MICROSPHERES

By using magnetically responsive albumin microspheres as a drug carrier, an entirely different approach to drug targeting can be considered (51). Microspheres composed of a denatured human serum albumin matrix serve as the vehicle in which a chemotherapeutic agent and ultrafine particles of magnetite (Fe_3O_4), are entrapped. Because of the magnetic material within the microspheres, they are susceptible to the effects of a magnetic field.

Albumin microspheres alone have some of the major problems discussed previously regarding liposomes; namely, clearance by the fixed macrophages of the liver and spleen and the lack of target site specificity. However, magnetically responsive drug-carrying microspheres infused into an artery supplying a tumor can be retained within the capillaries of tumor by an external magnet over the tumor site. Retention of the microspheres in the microvasculature can be achieved by taking advantage of the difference in the linear flow velocity of blood in a large artery (15–30 cm/sec) *versus* that in capillaries (0.05 cm/sec). Since the linear flow velocity of the microspheres is much slower within the capillaries, a much smaller magnetic field is sufficient to retain them within these vessels. By targeting the microspheres in this manner, they can be focused to a desired site with high specificity with

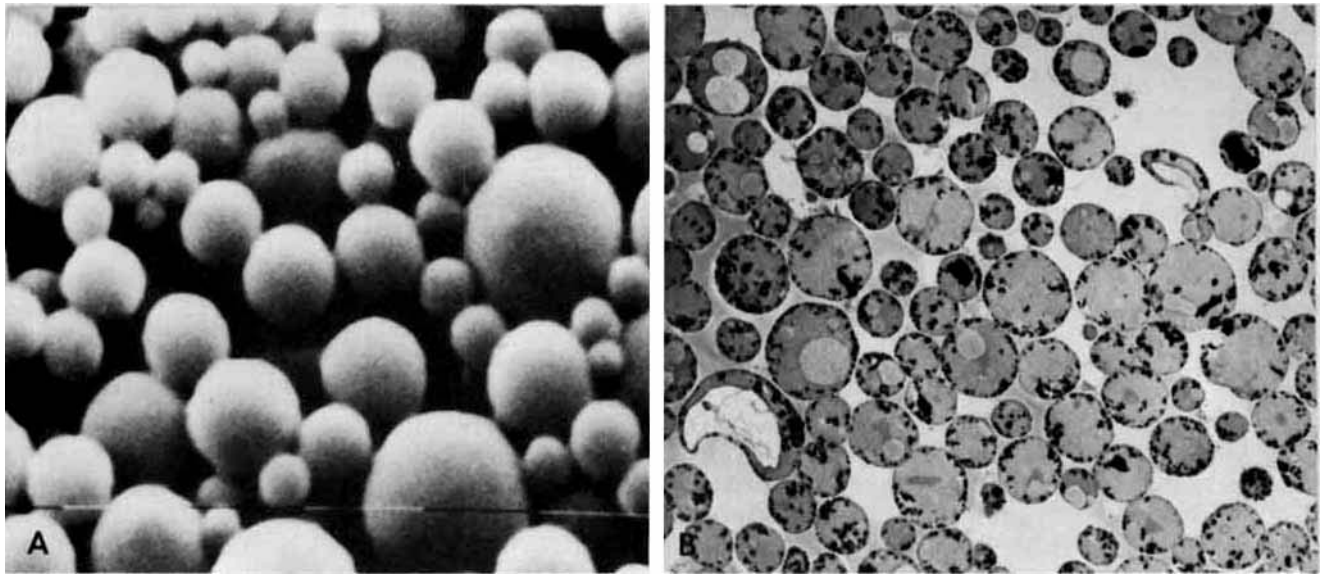

Figure 1—*Scanning electron photomicrograph (A) of microspheres showing an average diameter of ~1 μm. The largest sphere in the photomicrograph is 1.5 μm. Calibration bars represent 1 μm (×15,000). Transmission electron microscopy (B) reveals albumin microspheres containing clusters of Fe_3O_4 in a peripheral orientation (×8500). Drug is entrapped within the albumin matrix.*

subsequent decrease in clearance by mononuclear phagocytes. Restriction of the microspheres within the capillary circulation is essential for two reasons. First, drug diffusion occurs maximally in capillaries and venules; second, the microspheres from the microvasculature must transit into the extravascular space. By doing so, an extra-vascular depot would be created for sustained drug release within the target area. The drug released from the microspheres would saturate the tumor environment with a high local drug concentration. In addition, there is the possibility that the microspheres could be internalized by adjacent tumor cells as a result of increased tumor cell phagocytic activity (52, 53). By this mechanism, cytotoxic drugs released from microspheres would do so intracellularly and in high concentration resulting in cell death. Problems of drug resistance due to the inability of the drug to be transported across the cell membrane may be surmounted.

Preparation—Magnetically responsive albumin microspheres are prepared by a water-in-oil phase separation emulsion polymerization (54). Essentially, this consists of forming, in a small aqueous volume, a solution of albumin and water soluble chemotherapeutic agent (*e.g.*, adriamycin) to which an aqueous suspension of magnetite (Fe_3O_4) is added. This aqueous suspension is then added to a larger volume of oil and the mixture homogenized to generate proteinaceous spheres. These spheres are hardened either by heating the oil above 100° or by adding hydrophobic cross-linking agents to the emulsion. Microspheres are isolated by sequential washings in ether to remove residual oil and are stored as a powder at 4°.

Microspheres range in size from 0.2 to 1.35 μm in diameter with an average of 1.0 μm (Fig. 1A). By transmission electron microscopy it was determined that each albumin sphere contains clumps of Fe_3O_4 distributed largely around the periphery of the spheres (Fig. 1B).

Adriamycin was used in early studies of this approach because of its range of efficacy against a variety of tumors but was limited clinically due to its cardiotoxicity. It must be stressed, however, that virtually any water soluble chemotherapeutic agent may be successfully entrapped within the microspheres, giving them a broad potential range of utility.

Since optimal drug delivery *in vivo* necessitates predominantly capillary-level retention of the targeted microspheres, an *in vitro* system capable of simulating linear flow velocities of blood in various sized vessels was used to study the retention of microspheres using various magnetic parameters (55). Results (Fig. 2) demonstrated, at a magnetic field strength of 8000 Oe and using linear flow velocities comparable to those found in the microvasculature (*i.e.*, 0.05 cm/sec), virtually 100% of microspheres were magnetically retained, while microspheres in flow velocities comparable to those in medium sized arteries were not influenced by the magnetic field. Curve B illustrates the shift in the retention curve obtained when more magnetic material was entrapped within the microspheres. Studies on the effect matrix stabilization (chemical cross linking *versus* heating) indicated that the slow release of adriamycin could be manipulated without extensive loss

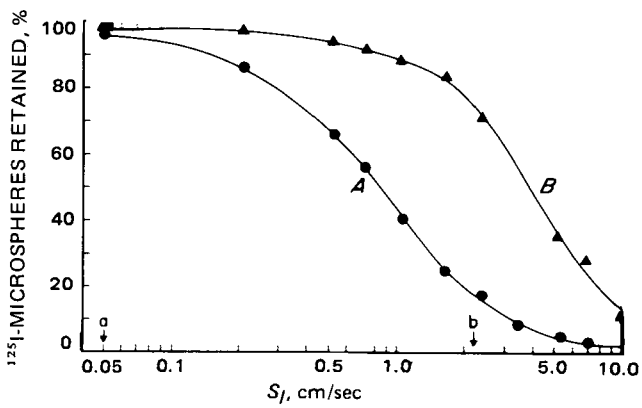

Figure 2—*Magnetic retention of heat-stabilized ^{125}I-microspheres suspended in 0.15 N NaCl at various rates of laminar flow (S_l = linear flow velocity). Curve A represents microspheres containing 20% Fe_3O_4 (w/w); curve B represents microspheres containing 50% Fe_3O_4. Increased microsphere iron content causes the retention curve to shift to the right. Physiological rates of blood flow are indicated for capillaries (a) and medium-sized arteries (b).*

Table I—*In Vivo* Localization of ^{125}I-Labeled Magnetic Albumin

Magnetic Field Strength, Oersteds	Number of Animals	Distribution Percentages								
		Tail Segment Number				Organ				
		1	2	3	4	Liver	Spleen	Kidney	Lung	Heart
0 (control)	10	0	0	0	0	76–85	3–9	<1	6–19	<1

of drug activity (56).

***In Vivo* Testing**—After determining optimal *in vitro* characteristics, *in vivo* testing was undertaken to assess the validity of magnetic targeting. Initially, attempts were made to target microspheres to normal cutaneous and subcutaneous tissue in the tail of Sprague-Dawley rats (51). For experimental purposes, the tail was demarcated into four approximately equal segments with segment 1 being proximal. A permanent bipolar magnet was placed adjacent to tail segment 3, which was regarded as the target site. The ventral caudal artery was exposed by a cut-down procedure at the base of the tail (segment 1) and a polyethylene catheter was inserted 1.5 cm proximal to the target site. Microspheres labeled with iodine 125 were infused at a rate that corresponded to the rate of blood flow in this artery. After 30 min with the magnet in place, rats were sacrificed and organs counted for iodine 125 gamma radiation. The tail was cut into the designated segments and each was counted individually. In separate experiments animals were sacrificed 24 hr after magnetic localization.

Results of these experiments are shown in Table I. Increasing magnetic field strength resulted in increased retention of the drug carrier selectively in tail segment 3, the target site. Using an 8000 Oe magnetic field, ~50% of the infused microspheres were selectively retained in tail segment 3. Animals sacrificed 24 hr after targeting of microspheres demonstrated a similar 50% retention of injected carrier at the target site. No necrosis or evidence of obstructed blood flow was observed in these animals prior to sacrifice. Electron microscopy performed on skin from tail segment 3 demonstrated microspheres within endothelial cells as well as lodged between adjacent endothelial cells (51). Thus, ultrastructural evidence indicated that some targeted microspheres were able to exit from the vascular compartment to set up a potential extravascular drug depot.

The amount of adriamycin at the target site was evaluated in the same rat model system (57). Experimental animals were sacrificed at various time intervals after exposure of the target site to an 8000 Oe magnetic field.

Table II—*In Vivo* Distribution of Carrier-Delivered and Free Adriamycin

Form of Drug	Dose mg/kg	Magnetic Field[a]	Tissue Concentrations, μg/gm[b]	
			Target Tail Skin	Pooled Organs[c]
Carrier-delivered	0.05	0	<1	<1
	0.05	+	3.9	<1
Free	0.05	0	<1	<1
	5.00	0	5.5	15.0

[a] A magnetic field of 8000 Oe was placed over tail segment 3 (target area) for 5 min. [b] Limits of detection, ≤1 μg of drug/g of tissue (wet weight). [c] Organs consisted of liver, spleen, kidneys, lungs, and heart. Adriamycin was found predominantly in the liver.

Adriamycin was solubilized from tail skin and organs and assessed quantitatively by spectrophotofluorometry. In animals sacrificed 5 min after carrier infusion, 3.9 μg of adriamycin/g of tissue was localized in the target tail skin. No drug was detectable in the nontarget tail segments or in the liver. By contrast, a 100-fold higher dose of systemically administered unencapsulated adriamycin was required to obtain comparable local tissue concentrations (Table II). In similar experiments where animals were sacrificed 60 min after carrier infusion, an equivalent adriamycin concentration of 3.7 μg/g was found at the target site with no detectable levels of drug found in adjacent tail segments or in any of the visceral organs examined. In animals receiving 100 times the adriamycin dose (5 mg/kg, iv), the amount of adriamycin at the target site 60 min after administration was only 50% of that delivered by the microspheres. Thus, after 60 min, using 0.1% of the free intravenous dose, adriamycin targeted *via* magnetic microspheres yielded approximately twice the local adriamycin concentration at the preselected site with no detectable systemic distribution as compared to the intravenously administered drug.

The microspheres were next tested for efficacy in the treatment of established rat tumors (58). The ascites form of Yoshida rat sarcoma was chosen due to its known sensitivity to adriamycin and because of its aggressive biological behavior. The solid form of the tumor can be obtained by inoculating tumor cells subcutaneously. Tumor nodules appeared ~3 days after implantation. Average time of death of untreated animals was found to be 16 days post-tumor inoculation.

Prior to microsphere experiments, animals were inoculated with tumor cells in the lateral aspect of the tail and treated with adriamycin intravenously to assess tumor sensitivity to the drug. Animals received either intravenous normal saline, 0.5 mg of adriamycin/kg, or 5.0 mg of adriamycin/kg on days 1, 5, and 9 postinoculation of the tumor. Animals were assessed for tumor size, weight change, and life span.

Only animals receiving the multiple high-dose regimen (5 mg/kg) showed any evidence of tumor sensitivity to the drug as demonstrated by reduction of tumor growth. Furthermore, animals receiving the 5 mg/kg dosage regimen, had an average weight loss of 12 g, demonstrating evidence of systemic toxicity. It should be noted, however, that no difference in life span was noted between any treatment group. In summary, animals receiving multiple doses of adriamycin at 5 mg/kg demonstrated some inhibition of tumor growth; however, these animals also demonstrated evidence of systemic toxicity and no enhancement of life span was noted.

Once tumor sensitivity had been established, experiments were designed to treat the Yoshida sarcoma with adriamycin targeted *via* magnetic microspheres. Again,

Table III—Effect of Magnetic Microspheres Containing Adriamycin on Yoshida Sarcoma-Bearing Rats

	Untreated Control	Adriamycin, 5 mg/kg iv	Adriamycin, 5 mg/kg ia	Adriamycin 0.5 mg/kg, ia	Placebo Microspheres with Magnet	Microspheres Bearing 0.5 mg/kg Adriamycin No Magnet	Microspheres Bearing 0.5 mg/kg Adriamycin With Magnet
Initial tumor size, mm	36.2	19.4	26.8	25.7	29.3	27.8	28.7

Metastases, %	89	100	80	100	80	100	0

animals were inoculated with the tumor cells into the lateral aspect of the tail, but unlike sensitivity experiments, animals were used for experiments 6–8 days *after* tumor implantation. By the time of experimental use, tumors were not only measurable, but occasionally, showed evidence of necrosis. Regardless of the type of therapy given, animals received only single-dose treatment 6–8 days after tumor inoculation.

The experimental group consisted of 12 animals which received drug-bearing microspheres at a dose of 0.5 mg of adriamycin/kg with the tumor exposure to the magnetic field for 30 min. The method of microsphere infusion into the ventral caudal artery was identical to that described previously. The following groups of animals constituted the control groups: 10 animals received placebo microspheres (without drug) infused in the same manner with exposure of the tumor to the magnetic field; another group received drug-bearing microspheres, but no magnetic field was applied. Finally, free adriamycin was administered intra-arterially (*via* the ventral caudal artery) at 0.5 and 5 mg/kg and intravenously at 5 mg/kg. Animals were observed for weight change, tumor size, and death. All animals were sacrificed 29 days after treatment. Complete autopsies were performed and organs were examined both grossly and microscopically for evidence of tumor.

Results of single-dose therapy with magnetically responsive microspheres are presented in Table III. Tumor size increased markedly in all animals treated with free adriamycin, regardless of the administration route or the dose. Control animals receiving either no treatment, placebo microspheres, or drug-bearing microspheres without localization, also demonstrated a significant increase in tumor size. In contrast, there was a significant (92%) decrease in tumor size in animals receiving adriamycin containing microspheres (0.5 mg/kg) with the magnet placed adjacent to the tumor. The weights of all control animals increased during the course of the experiments, indicating no evidence of systemic toxicity. Animals receiving targeted therapy also showed an increase in weight.

In all groups of animals, except those receiving magnetically localized adriamycin microspheres, there was an 80–100% mortality rate and an 80–100% incidence of distant metastases during the 29 days the animals were observed. In contrast, no deaths or metastases occurred in animals treated with the single dose of magnetically targeted microspheres containing adriamycin. Moreover, 75% of the animals in this group had complete tumor remission as confirmed by microscopic examination of the tissues. An additional 17% had significant tumor regression. The remaining animal showed no change in tumor size and was alive at the end of the experimental period. In comparison, there were no remissions in any control group with the exception of a slight decrease in tumor size in one animal from the untreated control group.

In prior experiments performed to assess tumor susceptibility to adriamycin, it was found that the tumor would respond only when the therapeutic regimen consisted of multiple dose intravenous adriamycin (5 mg/kg) given on days 1, 5, and 9 after tumor inoculation. Animals thus treated showed some evidence of tumor regression. However, these animals also experienced weight loss suggestive of toxicity due to the drug. More importantly, survival was not enhanced in animals treated in this fashion compared with untreated controls. In contrast, a single dose of adriamycin, when administered in magnetically responsive microspheres and targeted to the tumor site, achieved 75% total remissions with no deaths or histologic evidence of metastases in experimental animals. These animals were treated after tumor load was evident (6–8 days after tumor inoculation) and with only a single dose of 0.5 mg of adriamycin/kg as compared to multiple-dose therapy. Evidence of tumor necrosis was histologically evident as early as 3 days after treatment.

It is important to note that none of the rats treated with targeted therapy had any histological evidence of metastatic disease. This was perhaps related to the timing of the therapy, though tumor nodules were large and rapidly growing at the time of experimental use. The metastatic potential of the tumor at the time of treatment, however, may well have been limited. It is believed that the spread of metastases begins ~7–8 days after tumor inoculation, with tumor neovascularization beginning at day 2–3[1]. Alternatively, destruction of the tumor cells by adriamycin, along with subsequent decrease in tumor load and inhibited secretion of soluble low molecular weight tumor product inhibitors (59) may have tilted the immunological balance toward an active host response.

Thus, the potential of magnetic microspheres to enhance the therapeutic index of an antineoplastic agent has been demonstrated. The increase in the therapeutic index appears to come from both decreased toxicity and increased efficacy. Nonetheless, several questions remain to be resolved before the advent of clinical use. The first and foremost involves the external magnetic field used in targeting. The magnetic microspheres are held in place by the magnetic field gradient and not just the strength of the magnetic field. Magnetic field gradients drop off dramatically from the magnet pole face. The localization of microspheres to a tumor present subcutaneously allows maximum magnetic field gradients to be imposed on the

[1] Dr. Judah Folkman, personal communication.

target site. Other target sites may be too distant to allow the retention of the magnetic microspheres to take place. The theoretical problem of focusing magnetic field gradients at sites external to the magnet face is formidable. This problem must be solved if widespread clinical use is to be expected.

The second problem is that the magnetic microsphere must be administered intra-arterially as opposed to intravenously. An intravenous administration would result in the clearance of the microspheres by mononuclear phagocytes before reaching the target site. Intra-arterial administration involves a necessary cut-down, and hence some morbidity. This problem may possibly be overcome by altering the surface characteristics of the microspheres to allow them to bypass the phagocytic cells upon intravenous administration. Results in this area would be applicable to liposomes. Finally, this carrier may be applicable only for water soluble antitumor drugs. This problem is relatively minor, since currently, most antitumor drugs are water soluble.

Nonetheless, given the above limitations, the magnetic microspheres have given the most dramatic demonstration to date of the ability to direct antitumor drugs to a target site resulting in increased efficacy of the incorporated drug.

CONCLUSIONS

Drug carriers offer significant promise for the selective delivery of toxic chemotherapeutic agents in the treatment of cancer. Liposomes have been explored to a considerable degree for use as drug carriers in the treatment of neoplasms. Though some interesting results have been obtained in this area, liposomes generally have failed to perform as a practical method for drug delivery *in vivo*. Their usefulness is restricted, mainly due to a lack of target site specificity and their rapid clearance by mononuclear phagocytes in the liver and spleen. Approaches that take advantage of specific cell receptors *via* antibodies or glycolipids show some potential for achieving specificity; however, major obstacles remain in the application of these approaches. In contrast, a magnetically responsive drug delivery system is capable of a significant degree of *in vivo* targeting as well as a controllable release of drug at the microvascular level.

It is the authors' view that magnetically responsive drug carriers, either as a lipid or protein base, may have significant clinical relevance in the treatment of neoplastic disease. Each type of magnetically responsive carrier would have certain advantages. Protein microspheres would be useful for water-soluble drugs and can serve as long-lived localized drug depots. Magnetically responsive lipid base systems would be most applicable to water insoluble antitumor drugs. They may also have a smaller size than the protein microspheres, and hence a longer circulatory lifetime. Whichever type of magnetically responsive carrier is developed, the potential for targeting *via* external magnetic fields offers a new approach to a longstanding challenge in cancer chemotherapy. Although problems remain to be solved, the experimental results to date justify optimism.

RESEARCH ARTICLES

Properties, Stability, Assay, and Preliminary Pharmacokinetics of the Immunomodulatory 1,2-*O*-Isopropylidene-3-*O*-3′(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose Hydrochloride

EDWARD R. GARRETT ˣ, ACHIEL VAN PEER, HELMY MAHROUS, and WALDTRAUT SCHUERMANN

Received May 14, 1981, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication August 14, 1981.

Abstract □ 1,2-*O*-Isopropylidene-3-*O*-3′(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride (I) is a new agent with claimed immunomodulatory action and antiviral activity. Thin-layer chromatographic procedures and identifying tests were developed to separate the drug, its synthetic precursors, and solvolytic products, and were applied to stability studies. It is stable in 0.1 *N* NaOH at 60° where its acid solvolysis product, 3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucose is readily degraded. The partition coefficient of I (pK_a = 9.28) between chloroform and plasma was 6.4 ± 0.2 *SEM* between pH 10.5 and 11.0. Plasma and urine (0.5 ml) adjusted to pH 11.0 were extracted with 10 ml of chloroform and the extract evaporated. The reconstituted residue in 50 μl of benzene, with the diisopropylaminoethyl analog of I as an internal standard, was derivatized with 50 μl of heptafluorobutyric anhydride at 60° for 45 min and was evaporated and reconstituted in 100 μl of benzene to be assayed for I by GLC with electron capture detection with a sensitivity of 5 ng/0.5 ml of biological fluid. The procedure was applied to pharmacokinetics in the dog and a two-compartment body model was observed with a terminal half-life of 103–130 min. At the 40-mg dose, 60–64% was excreted renally unchanged and 20–34% as unidentified metabolities. At the 200-mg dose 82–85% was excreted renally unchanged and 15–17% as unidentified metabolites. The respective renal clearances of I were 135 and 163 ml/min. The respective total clearances of I were 204 and 191 ml/min. These metabolites were apparently unextracted with chloroform from biological fluids at pH 11 and the liquid scintillation counting (LSC) assay of extracted radiolabeled I appeared synonomous with the GLC assay of I in such fluids.

Keyphrases □ Pharmacokinetics—new immunomodulatory and antiviral agent, dogs □ GLC, electron capture—pharmacokinetics of a new immunomodulatory and antiviral agent, dogs □ Immunomodulatory agent—pharmacokinetics of a new immunomodulatory and antiviral agent, dogs

It has been shown (1–7) that 1,2-*O*-isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino - *n* - propyl)-D-glucofuranose hydrochloride, I, exhibits immunomodulatory action and antiviral activity and that it possesses pro host action in which cellular immune response is augmented and macrophages are activated (8, 9). The advantageous therapeutic action is to potentiate protective responses of the immune system(6) without the inhibition of vital cell actions with their concomitant toxicities (4).

Compound I is a substituted monosaccharide of low toxicity, widely different in structure than the clinically used nonsteroidal anti-inflammatory agents with high incidences of toxicity. An interesting argument for this possible activity of the 3-substituted monosaccharide (1–8) is that it mimics the immunological activity of the cell walls of mycobacteria with its positive cyclic guanosine monophosphate action and without its negative cyclic adenosine monophosphate effect on proliferation.

The procedure for the synthesis of I, is outlined in Scheme I. The diisopropylidene derivative of D-glucose, IV, is prepared by the addition of acetone. It is subsequently conjugated with *N*′,*N*′-dimethylamino propanol, II, in the 3 position. Compound I is then prepared by selective acid hydrolysis of the 5,6-*O*-isopropylidene group.

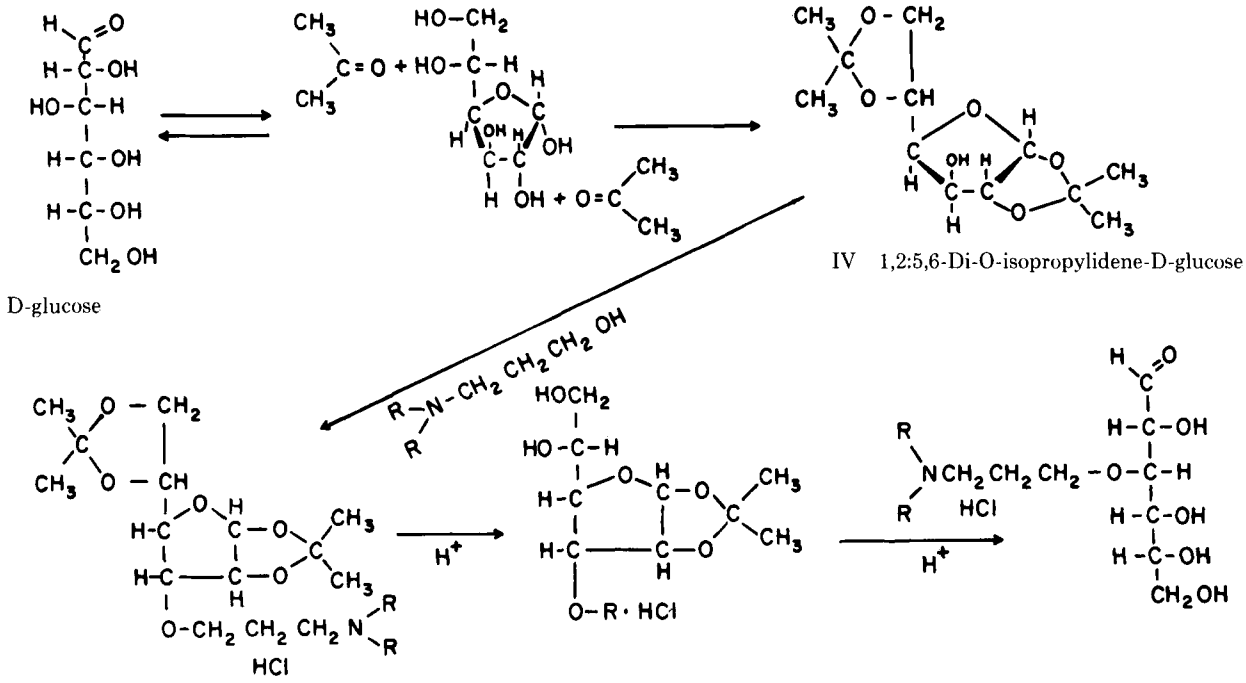
Compound I is a substituted monosaccharide of low toxicity, widely different in structure than the clinically used nonsteroidal anti-inflammatory agents with high incidences of toxicity. An interesting argument for this possible activity of the 3-substituted monosaccharide (1–8) is that it mimics the immunological activity of the cell walls of mycobacteria with its positive cyclic guanosine monophosphate action and without its negative cyclic adenosine monophosphate effect on proliferation.

The procedure for the synthesis of I, is outlined in Scheme I. The diisopropylidene derivative of D-glucose, IV, is prepared by the addition of acetone. It is subsequently conjugated with *N*′,*N*′-dimethylamino propanol, II, in the 3 position. Compound I is then prepared by selective acid hydrolysis of the 5,6-*O*-isopropylidene group.

0022-3549/82/0400-0387$01.00/0



D-glucose

IV 1,2:5,6-Di-O-isopropylidene-D-glucose

II 1,2:5,6-Di-O-isopropylidene-3-O-3′-(N′,N′-dimethylamino-n-propyl)-D-glucofuranose (R = CH_3)

I R = $-CH_2CH_2CH_2-N(CH_3)_2$ 1,2-O-isopropylidene-3-O-3′(N′,N′-dimethylamino-n-propyl)-D-glucofuranose hydrochloride

V di-isopropylaminoethyl analog of I R = $-CH_2-CH_2-N(i-C_3H_7)_2$ (internal standard)

III 3-O-3′-N′,N′-dimethylamino-n-propyl)-D-glucose hydrochloride R = CH_3

Scheme I—Synthesis and Hydrolysis of I

Excessive acid hydrolysis could give the dimethylaminopropylglucose, III. The radiolabeled compound I was prepared with randomly labeled [^{14}C]D-glucose.

These studies present thin-layer chromatographic (TLC) procedures to separate I from its synthetic precursors and its solvolysis products. They were applied to studies of the acid-base stabilities of these compounds. Dissociation constants and partition coefficients as functions of pH were determined. A sensitive GLC method was developed for the assay of I where the heptafluorobutyryl derivative was detected by electron capture. This procedure was applied to preliminary pharmacokinetic studies of intravenously administered I in the dog and compared to the assay of radiolabeled I in the monitored biological fluids.

EXPERIMENTAL

Materials—The following analytical grade materials were used: acetic acid[1], sodium acetate[1], sodium phosphate dibasic[1], potassium phosphate monobasic[1], sodium carbonate[1], sodium bicarbonate[1], ammonium hydroxide[1], phosphoric acid[2], sulfuric acid[1], volumetric concentrates of sodium hydroxide[3] and hydrochloric acid[3], nanograde benzene[1], *n*-butyl alcohol[1], chloroform suitable for GC[4], methylene chloride[1], absolute alcohol[5], ethyl acetate[4], nanograde hexane[1], isopentyl alcohol[6], methanol[4], *n*-propanol[2], heptafluorobutyric anhydride[7], and a silylating agent[8].

Precoated silica gel plates[9] were used for TLC separation. The following spray reagents were used: 1% ninhydrin[8] in alcohol, 4% 2,3,5-triphenyl-2H-tetrazolium chloride[10] in methanol, 3.5% *p*-anisidine hydrochloride[10] in *n*-butyl alcohol–alcohol–water (4:1:1), 3% copper acetate[2] in 18% phosphoric acid. TLC plates were also placed in tanks containing resublimed iodine[11].

1,2-*O*-Isopropylidene- 3 -*O*-3′(*N*′-*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride (I), the diethylaminoisopropyl analog of I, [1,2-*O*-isopropylidene-3-*O*-3′(*N*′,*N*′-diethylaminoisopropyl)-D-glucofuranose hydrochloride] (VI), and the GLC internal standard diisopropylaminoethyl analog of I, [1,2-*O*-isopropylidene-3-*O*-3′(*N*′,*N*′-diisopropylaminoethyl)-D-glucofuranose hydrochloride] (V) were received as hydrochlorides[12]. Diisopropylidene glucose[12], IV (mp 106°) (1,2,5,6-di-*O*-isopropylidene-D-glucose), monoisopropylidene glucose[12] [VII (mp 154–155°) 1,2-*O*-isopropylidene-D-glucose], dimethylamino-*n*-propyl-D-glucose hydrochloride[12] [III (mp 131–133°), 3-*O*-3′(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucose hydrochloride], glucose[2], and lactose[13] were also used as standards for TLC.

Radiolabeled I, randomly ^{14}C-labeled in the glucose component[14] (324.0 mCi/mmole), was used to prepare doses for the pharmacokinetic study. [^{14}C]Urea[15] (55 mCi/mmole) was the internal standard for the radioactive assay. A toluene-based scintillation cocktail[16] was used in the radioactive assays.

Apparatus—A gas chromatograph[17] equipped with a ^{63}Ni-electron capture detector was used. Silylated 1.83-m glass columns were packed with 4% SE 30 and 6% OV 210 on 100/120 chromosorb W-HP[7]. The column temperature was maintained at 190°; injector temperature was 230°, and detector temperature 300°. The flow rate of the carrier gas (95%

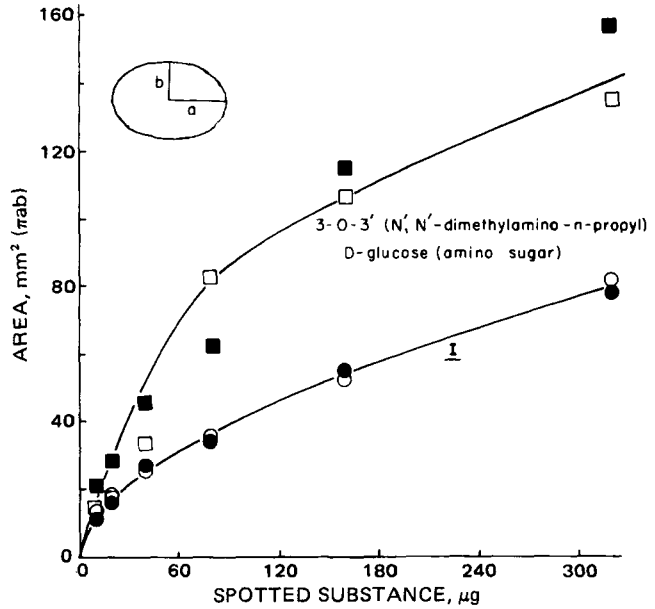

Figure 1—*Quantitative TLC analyses, Area = πab versus μg, of I (○, ●), and 3-O-3′(N′,N′-dimethylamino-n-propyl)D-glucose hydrochloride, III (□, ■) as developed in n-propanol–ethyl acetate–water–NH_4OH (6:1:4:1). Key: open symbols are for the areas of the elliptical spots determined from the product of the orthogonal radii, a × b and π from ninhydrin visualization; closed symbols are from visualization after charring with 50% H_2SO_4. Various volumes of 10-μg/μl materials were spotted at the origin with successive application and drying.*

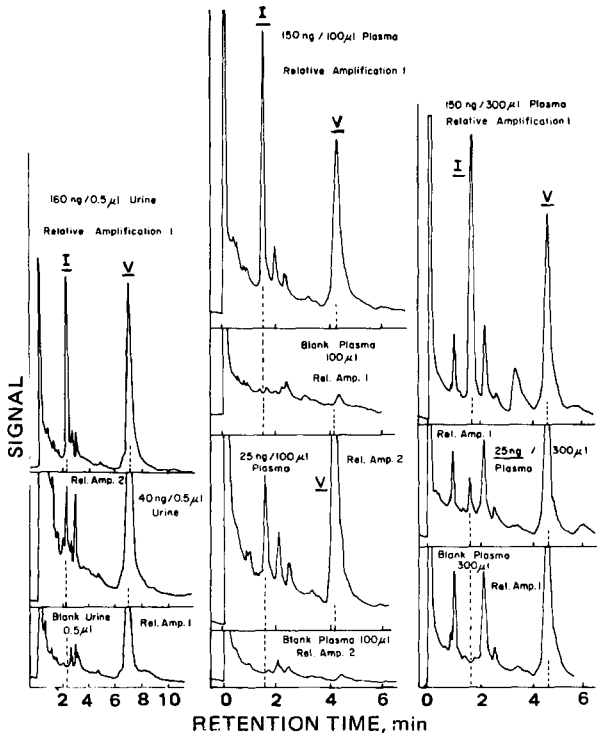

Figure 2—*Typical GLC chromatograms of heptafluorobutyrylated I, and the internal standard diisopropylaminoethyl analog of I, (V) in plasma and urine as well as derivatized blank urine and plasma samples, detected by electron capture. The signals are labeled as to their relative amplification for comparison. The vertical dashed lines represent the retention times of derivatized I and internal standard. The amounts and volumes of biological samples assayed are given.*

argon–5% methane) was 30 ml/min.

Radioactivity of samples was determined with a liquid scintillation counter[18].

GLC Assay of I—A solution (0.05 ml) of internal standard [10 μg diisopropylaminoethyl analog of I hydrochloride (V)/ml of distilled water] was added to an aliquot (<0.5 ml) of urine or plasma, which was diluted to 0.5 ml with distilled water. After adjustment to pH 11.0 with 0.1 *N* NaOH (>50 μl), the solution was extracted with 5 ml of water-saturated chloroform. The samples were shaken for 15 min and centrifuged[19] at 3000 rpm for 15 min.

The aqueous phase was removed by aspiration and 4 ml of the chloroform phase was transferred into 5-ml silylated reaction vials[7] and evaporated to dryness under a nitrogen stream[20] at room temperature. Benzene (50 μl) and heptafluorobutyric anhydride (50 μl) were added to derivatize the extracted I and the diisopropylaminoethyl analog, V, with shaking for 45 min at 60° in heating blocks[21]. The cooled reaction vials contents were evaporated (30 min) under a nitrogen stream at room temperature. The residue was reconstituted in 100 μl benzene and 1 μl was injected into the gas chromatograph.

Calibration curves were prepared using the same amounts of blank urine or plasma spiked with 0, 20, 40, 60, 80, 100, 120, 140, and 160 ng of I.

Thin-Layer Chromatography (TLC)—Glass plates coated with silica gel were used to separate the following materials (50 μg) using the system *n*-propanol–ethyl acetate–water–NH_4OH, 6:1:4:1. The following R_f values were obtained: diisopropylidene glucose (IV), 0.83; I (0.58); monoisopropylidene glucose (VII), 0.54; glucose, 0.32; diethylaminoisopropyl analog of I, (VI), 0.27; dimethylaminopropylglucose (III), 0.20; and lactose, 0.20. Compounds I and III could be detected by iodine vapor on the plate. Compound I could be detected as a purple spot when the plate was sprayed with 1% ninhydrin in ethanol, and VI and III gave burnt yellow colors after heating the plates 10–15 min at 110°. The compounds IV and VII, could not be detected with this reagent although the glucose spot gave a yellow coloration. Glucose compounds III and VI gave an orange spot when sprayed with 4% tetrazolium hydrochloride in methanol after heating 5 min at 110° or a brown spot when sprayed with 3.5% *p*-anisidine in *n*-butanol–ethanol–water (4:1:1) after heating 10 min at 110°, while I gave no coloration.

All spots could be visualized with 3% copper acetate in 18% phosphoric acid after heating for 30 min at 110° or after charring with 50% sulfuric acid for 10–15 min at 120°.

Preliminary Studies of Extractability by TLC—Several organic solvents (5 ml) were used to extract 10 mg of I from 3 ml of pH 10 aqueous solution and 10 mg of III from 2 ml of pH 10 aqueous solution. The mixtures were vortexed for 30 sec and centrifuged for 5 min at 2000 rpm. Aliquots of the organic layer (100 μl) were spotted on the silica gel plates and the developed spots at the R_f of I were visualized by charring with 50% sulfuric acid spray and compared with developed spots after the application of standard I and dimethylaminopropylglucose solutions.

Hexane and hexane with 2% isopentyl alcohol extracts showed no detectable spots at the R_f of I, whereas benzene and hexane with 10 and 20% isopentyl alcohol showed small faint spots of I. The chloroform and methylene chloride extracts of I gave spots of the same size and intensity as the developed standard. Benzene extracts of I gave spots but at less intensity than with chloroform. Compound III was apparently not significantly extracted in any of these solvents as no spot was apparent from the organic extracts at the R_f of standard III.

Quantitative Analysis by TLC—Amounts (1–32 μl, 10–320 μg) of I and III were spotted on several TLC plates and developed in the system. One plate was visualized with ninhydrin (purple for I, orange for III) and one plate was visualized after spraying with 50% sulfuric acid and charring. The areas were estimated from the product of the horizontal and vertical radii times π. Plots of these areas *versus* spotted amounts for the two visualizations are given in Fig. 1.

Stability Estimates by TLC—Solutions (10 mg/ml) of I and III were prepared in water, 0.1 and 1.0 *N* NaOH, and 0.1 and 1.0 *N* HCl and maintained at 30 and 60°. Aliquots (20 μl) of these solutions were spotted on the TLC plates at intervals, and the developed spots visualized after spraying with ninhydrin and/or by charring with 50% sulfuric acid. The samples in alkali were neutralized with acid before spotting.

Potentiometric Titrations of I—Compound I (29 mg, 0.08486 meq) was dissolved in 20 ml water which contained 200 μl of 1.839 *N* NaOH and potentiometrically titrated with 1.967 *N* HCl with a microburette. Similar solutions without I were titrated similarly and the pH was plotted against the difference in milliliters necessary to achieve the same pH values. A typical potentiometric titration curve by this method (10) was

11.0	5.0	1.0	6.7	
11.0	5.0	1.0	6.2	
			Average 6.35 ± 0.16 *SEM*	

[a] $k = (1 + 10^{-pH}/K'_a)\,k'$ where $K'_a = 5.25 \times 10^{-10}$. [b] Omitted from average.

obtained. The pH at half titration between the two inflection points gave pK'_a values of 9.20 and 9.28 and the apparent equivalent weight of the titrated I was 380 (theoretical, 342).

Partition Coefficient—A stock solution of the base of I was prepared in chloroform by the extraction of 0.20 ml of a sodium carbonate buffer solution (pH 10) containing 100 μg of I with 10 ml of chloroform. This 10 μg/ml solution of free base (as I equivalent) was diluted 10-fold to give a stock solution of 1.00 μg of I as the free base in 1.00 ml of chloroform.

Partition studies between appropriate volume ratios of water-saturated chloroform and buffer solutions of various pH values were effected by shaking the mixture for 15 min and then centrifuging. Higher relative volumes of the organic phase were used at the lower pH values and of the aqueous phase at higher pH values (Table I). Aliquots (0.9 of the respective volumes) of the aqueous and organic phases were taken. The organic phase was evaporated to dryness under nitrogen, derivatized, assayed by the GLC method, and the peak height ratio (PHR_{org}) to the internal standard diisopropylaminoethyl analog of I, (V) determined. The volume of aqueous phase taken was adjusted to pH 11.0 with NaOH and extracted with 10 ml chloroform and 9 ml of $CHCl_3$, taken to dryness, derivatized, assayed by the GLC method, and the peak height ratio (PHR_{aq1}) to V determined. The extracted aqueous phase was re-extracted with chloroform and the reclaimed I was assayed (PHR_{aq2}).

Preparation of the Pharmacokinetic Dose—A volume of 2.8 ml of the I-[^{14}C]glucose solution, containing 1.5 mg of I-[^{14}C]glucose hydrochloride with a labeled specific activity of 324.0 mCi/mmol, was mixed with 58.5 mg of I for the 40-mg dose, or with 298.5 mg of I for the 200-mg dose, and with 12.2 ml of sterile isotonic saline. Aliquots (10.00 ml) were injected as intravenous bolus over 20 sec into the dog. The theoretical specific activity was 8.10 mCi/mmol of I for the 40-mg dose and 1.62 mCi/mmole of the 200-mg dose.

The experimental specific activity was determined by mixing 10.00 μl of the prepared dosing solution with 10 ml of liquid scintillation fluid. The capped vials[22] were adapted to the dark for at least 6 hr before counting in the liquid scintillation counter. Experimental specific activities were 7.82 ± 0.03 (*SEM*) mCi/mmole and 1.554 ± 0.004 (*SEM*) mCi/mmole for the 40- and 200-mg dosing, respectively, and were used in the assays.

Counting Efficiencies—Counting efficiency in samples was estimated by the internal standard method. Selected samples of blank and drug-affected plasma or urine and samples of aqueous and organic phase after extraction of plasma and urine were counted before and after the addition of 22,000 dpm of internal standard [^{14}C]urea with a specific activity of 55 mCi/mmole. All capped vials[22] were dark-adapted for at least 6 hr before counting in the liquid scintillation counter. The counting efficiencies in the systems approached 100%, 99.0 ± 0.6 (*SEM*) % in blank and in drug-containing biological fluids. There were no significant quenching effects of 10–200 μl of dog urine or dog plasma when such amounts were added to 10 ml of liquid scintillation fluid.

Total Radioactivity—The total radioactivity of a plasma or urine sample was determined from the addition of 0.01–0.2 ml of plasma or urine to 10 ml of liquid scintillation fluid. The capped vials were dark-adapted for at least 6 hr before counting in the liquid scintillation counter.

The values (counts per minute) were converted to disintegrations per minute (dpm) by dividing by the counting efficiency after subtracting background. The total concentration of radio-labeled substances as I equivalents was calculated by dividing the dpm values by the specific activity and by taking into account the volume of plasma or urine assayed.

Determination of Radiolabeled Substances After Extraction of Plasma or Urine—Plasma (0.025–0.5 ml) or urine (0.005–0.5 ml) was transferred into a 15-ml silylated centrifuging tube. Distilled water was added to a volume of 0.5 ml, and the pH was adjusted to ~11.5 with sodium hydroxide solution (0.1 *N* or 1 *N*). The mixture was extracted with 5 ml of water-saturated chloroform by shaking for 10 min. The phases were separated by centrifugation at 3000 rpm for 10 min. An aliquot of the aqueous phase (0.3 ml) was transferred into a scintillation vial and liquid scintillation fluid (10 ml) was added. The counting efficiency of the aqueous phase was 99.0 ± 0.4 (*SEM*)% for plasma and 93.1 ± 0.5 (*SEM*)% for urine. An aliquot of the organic phase (4 ml) was evaporated in a scintillation vial under nitrogen at room temperature. Liquid scintillation fluid (10 ml) was added to the residue. The capped vials were dark-adapted and counted. The counting efficiency was calculated by the internal standard method already described. The counting efficiency was 96.7 ± 0.4 (*SEM*)% for the organic extract of plasma and 93.8 ± 0.8 (*SEM*)% for that of urine.

Concentrations, C_I^{LSC}, of I in biological fluids were calculated from liquid scintillation counting (LSC) by dividing the disintegrations per minute per milliliter of organic extract by the extraction efficiency (f_1 = 0.984) and by the experimentally determined specific activity of I (f_2), which was 50,304 dpm/μg for the 40-mg dose and 9995 dpm/μg for the 200-mg dose. Thus, when the ratio, r, of milliliters of organic phase to milliliters of biological fluid is known, C_I^{LSC} can be determined as follows:

C_I^{LSC} = concentration of I as hydrochloride in biological fluid

$$= \frac{\text{dpm/ml organic phase}}{f_1 \times f_2} \times r \quad \text{(Eq. 1)}$$

There are two methods to calculate the concentrations of radiolabeled substances in plasma or urine which cannot be assigned to I *per se*, presumably the metabolite concentration, C_M. This is the concentration in the aqueous phase of compounds that are not I expressed in equivalents of I as the hydrochloride after extraction of I from plasma or urine. The direct method for calculation, C_M^{direct}, is to divide the disintegrations per minute per milliliter of the aqueous phase after extraction by the specific activity of I (f_2) and to subtract the unextracted concentration of I that remained in the aqueous phase:

C_M^{direct} = apparent metabolite concentration as equivalents of the hydrochloride of I in biological sample

$$= \frac{\text{dpm/ml of extracted aqueous phase}}{f_2} - (1 - f_1)C_I^{LSC} \quad \text{(Eq. 2)}$$

[22] Kimble, Division of Owens-Illinois, Toledo, OH 43668.

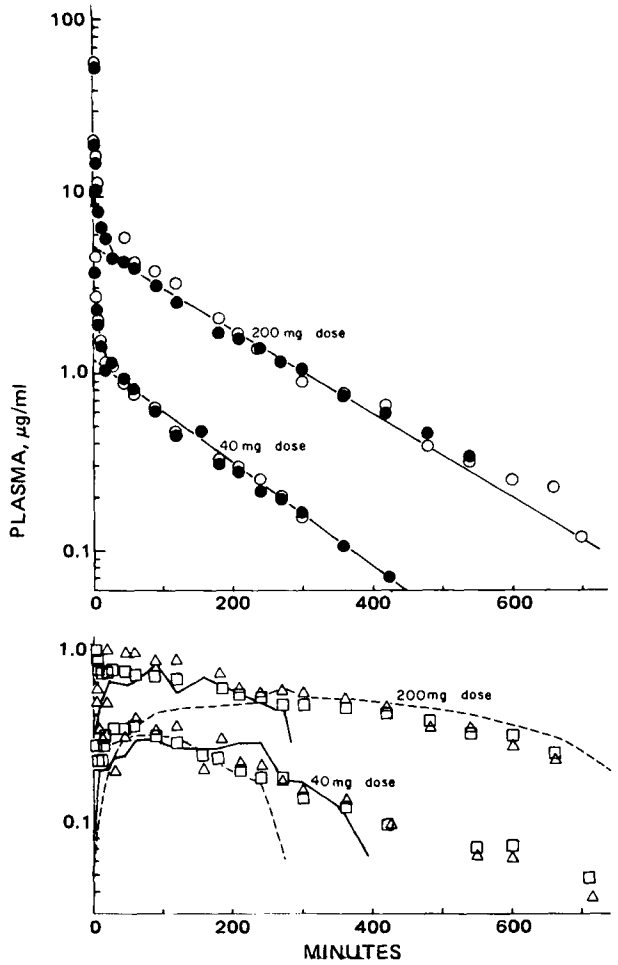

Figure 3—*Semilogarithmic plots of plasma levels of I (○, ●) and apparent total metabolite (□, △) in equivalents of I as the hydrochloride* versus *time for the 40- and 200-mg intravenous doses in the same dog. The symbols represent the GLC assayed I concentrations (C_I^{GLC}, ○) and the LSC assayed I concentrations (C_I^{LSC}, Eq. 1, ●) obtained from radioactivity measurement of the organic extract. The lines, $C = \Sigma A_i e^{-\alpha_i t}$, drawn through the I data were calculated from the parameters given in Table II. The plotted apparent plasma metabolite concentrations were obtained by direct LSC assay of the extracted plasma (C_M^{direct}, Eq. 2, □) and from the difference between the total plasma radioactivity count and that due to I concentrations in plasma (C_M^{diff}, Eq. 3, △). The solid lines drawn through the data were calculated apparent plasma metabolite level values based on the direct LSC assay of the previously extracted urine samples (Eq. 2) in accordance with Eq. 14 using $Cl_{met}^{tot} - Cl_x = 30.4$ and 18.5 ml/min, and $V_M = 4037$ and 3728 ml for the data of the 40- and 200-mg doses, respectively. The dashed line through the 200-mg dose data was also based on this direct LSC assay of previously extracted urine (Eq. 2) but used $Cl_{met}^{tot} - Cl_x = 27.3$ ml/min with $V_M = 16{,}852$ ml in Eq. 14. The dashed line through the 40-mg dose data was based on the urine assays conducted by taking the differences between total radioactivity and that due to I (Eq. 3) where $Cl_{met}^{tot} - Cl_x = 42.2$ ml/min and $V_M = 4078$ ml.*

The alternative difference method for estimating C_M^{diff} is to subtract the concentration, C_I^{LSC}, of I calculated from Eq. 1 from the apparent concentration, C_{tot}, estimated from the liquid scintillation counting of unextracted urine or plasma:

$$C_M^{diff} = \text{apparent metabolite concentration as I (hydrochloride) equivalents in biological sample} = \frac{\text{dpm/ml of unextracted plasma or urine}}{f_2} - C_I^{LSC} \quad \text{(Eq. 3)}$$

Pharmacokinetic Studies in the Dog—The selected dog had physiological values in the normal range: white cell count, 19,900 cells/mm^3; sedimentation rate, 5 min/hr; and packed cell volume, 43%. Tests for microfilaria were negative. The pharmacokinetics of ^{14}C-radiolabeled I in this dog were studied with intravenous bolus doses of 40- and then 200-mg after a 2-month interval.

Table II—Pharmacokinetics of Intravenous I in a 20-kg Dog

[a] Parameters estimated from best fit of [I] (as hydrochloride) in plasma against time (Fig. 3) in accordance with $[I] = Ae^{-\alpha t} + Be^{-\beta t}$. [b] Estimated from Σ^- plot of $\log(\Sigma U_\infty^I - \Sigma U^I) = -\beta/2.303\, t + \log \Sigma U_\infty^I$ (Fig. 4). [c] Total clearance of I, Dose/AUC_∞, where AUC_∞ is the total area under I plasma level–time plot. [d] Renal clearance of I (or total metabolite) consistent with $\Sigma U = Cl_{ren} AUC$ (Fig. 5) where AUC is the area under I (or metabolite) plasma level–time plot for the time when the cumulative amount of I (or metabolite) in the urine, ΣU, was measured. The values for I were consistent with the renal clearance plots of Fig. 6. [e] The total metabolic clearance is the difference between the total and renal clearances of I, $Cl_{tot}^I - Cl_{ren}^I$. [f] Determined from intercept and slope of linear plots in accordance with Eq. 13, $\Sigma U^M/AUC^I = -V_M[M]/AUC^I + Cl_{met}^{tot} - Cl_x$ (Fig. 7). [g] From plots in Figs. 5 and 7 for ΣU^M data based on urinary amounts of metabolite calculated from the differences between total urine radioactivity count and that due I in urine (Eq. 3). [h] From plots in Figs. 5 and 7 for ΣU^M data based on urinary amounts of metabolite calculated from the direct LSC assay of I-extracted urine (Eq. 2). [i] Data from linear fitting in Fig. 7 of 200-mg dose data between 27 and 250 min. [j] Data from linear fitting in Fig. 7 of 200-mg dose data between 250 and 850 min. [k] Clearance of I by processes other than renal or the metabolic process that produced metabolites into the circulating body fluids to be subsequently renally excreted as metabolite. [l] Referenced to total concentrations in plasma. [m] Apparent volume of central compartment for I, Dose/$(A + B)$. [n] Apparent overall volume of distribution for I, Cl_{tot}^I/β. [o] Apparent extrapolated distribution volume for I on presumption of one-compartment body model, Dose/B. [p] Apparent overall distribution volume for metabolite. [q] Estimated from asymptotes of ΣU *versus* time plots of Fig. 5. [r] Based on GLC assay of urine. [s] Based on LSC assay of organic extract of urine (Eq. 1).

The dog was trained for several days before the experiments. He was placed on a table in a standing position and was restrained by separate straps around the forelegs and hindlegs and fixed to a horizontal bar above.

The day before the experiment the dog was weighed. Body weight was 18.6 kg at the first 40-mg dose and 20.9 kg at the 200-mg dose.

After intramuscular administration of 0.75 ml of ketamine hydrochloride[23] equivalent to 100 mg/ml ketamine, one external jugular vein of the neck was exposed and cannulated under sterile conditions with 30 cm of a catheter[24]. At least 20 cm was inserted into the vein. The incision was closed after the patency of the cannula was verified and it was filled with heparinized saline. Heparinized saline (100 units/ml) was prepared by adding 3 ml of heparin[25] (1000 units/ml) to 30 ml of bacteriostatic sodium chloride solution[26]. The dog was transferred to a metabolism cage and fasted overnight with water, *ad libitum*.

On the following day the dog was restrained on the table in the standing position. The dog was water-loaded orally 30 to 60 min before drug administration with 150 ml of tap water and was continuously infused with 0.9% NaCl solution (1 ml/min)[27] *via* a three-way stopcock[28] into the

catheterized jugular vein. A transurethral catheter[29] was placed under sterile conditions to collect bladder urine.

The saline drip was halted before the drug administration and a 10-ml blank blood sample was withdrawn from the jugular catheter *via* the three-way stopcock into a sterile, disposable syringe[30] after the dead space of the catheter (0.5 ml) had been filled with undiluted blood. The saline drip was reconnected. The blood samples taken at intervals were transferred immediately to 15-ml tubes[31] containing 143 USP units of sodium heparin and were carefully mixed and centrifuged[32] at 1500 rpm for 10 min. The plasma was transferred to a 15-ml tube[31] without additive with a Pasteur pipet and the tube was stoppered and frozen.

Urine was collected before and after the drug administration at intervals *via* the transurethral catheter using a sterile 20-ml syringe[30].

A ^{14}C-labeled I solution of a known amount and specific activity was injected into the jugular vein catheter over 20 sec. The dosing syringe and catheter were flushed with 10 ml of sterile saline into the jugular.

Blood was sampled at 1, 3, 5, 8, 13, 20, 30, 45, 60, 90, 120, 150, 180, 210, 240, 270, 300, 360, 420, 480, 540, 600, 660, 750, 840, 1360, 1590, 1800, 2040, 2270, and 2840 min. Adequate volumes of blood were withdrawn: 2 ml for the first 30 min samples, 3 ml for samples between 30 and 150 min, 4 ml for samples between 150 and 300 min, and 5 ml for all subsequent samples. Hematocrits were determined using a microhematocrit centrifuge and reader[33] on selected blood samples prior to centrifugation. An aliquot of plasma was removed to measure total carbon 14. The remaining plasma was stored in the freezer.

Urine was collected from the transurethral catheter at approximately 15, 30, 45, 60, 90, 120, 190, 250, 310, 370, 430, 490, 540, 610, 730, 850, 1380, 1590, 1800, 2040, 2280, and 2800 min. The volume and pH of each thoroughly mixed urine collect were measured immediately after the withdrawal from the catheter. An aliquot of the fresh urine was transferred to a 15-ml tube and was diluted in a ratio of 1:10, 1:20, 1:50, or 1:100 with distilled water, dependent on the sample time and the volume of each urine collected. Appropriate volumes of undiluted and diluted urine were removed to determine total carbon 14. The remaining urine collections were divided into 10-ml portions and stored in the freezer.

The dog was returned to the metabolism cage 14 hr after the drug administration.

RESULTS AND DISCUSSION

Properties of I—Compound I as the hydrochloride is a white crystalline solid, mp 181–183°, mw 341.74, mass spectrum: m/z 305 (m^+).

Anal—Calc % for $C_{14}H_{28}O_6ClN$: C = 49.19; H, 8.19; N, 4.09; Cl, 10.39; O, 28.11. Found: C, 49.31; H, 8.38; N, 3.06; Cl, 10.50; O, 27.9%.

It is highly soluble in water and soluble in methanol and hot ethanol. It is recrystallized from methanol. The free amine from aqueous solutions of I buffered at pH 10 was determined by TLC of the organic extracts to be highly extracted in chloroform and methylene chloride, less efficiently extracted in benzene, and relatively nonextracted in hexane; although, hexane plus 10 and 20% isopentyl alcohol showed small faint spots of I. The dimethylaminopropylglucose, III, was not significantly extracted

by any of these solvents. Compound I has an apparent pK'_a of 9.28 by potentiometric titration, and the optical rotation of a 10% aqueous solution at pH 7 is $-24.5 \pm 0.5°$ and an index of refraction of $n_D^{23°} = 1.3465$. The optical rotation of III is $+37.0 \pm 0.5°$. The infrared spectrum of I (KBr disc) shows the presence of a split OH-band in the 3400 cm^{-1} region and characteristic bands in 1000–1400 cm^{-1} for isopropylidene groups. It cannot be readily differentiated from II and IV, although IV can be removed from acid solutions of I by chloroform extraction.

The compounds I, III, IV, and V can be separated from each other by TLC by the system *n*-propanol–ethyl acetate–water–NH_4OH, 6:1:4:1.

Stability Estimates by TLC—Compound I gave the same spot with the same developed color intensity as the standard on being subjected to 0.1 and 1.0 *N* NaOH at both 30 and 60° for 3, 24, 50, and 400 hr. The dimethylaminopropylglucose, III, $R_f = 0.20$, produced two additional spots at R_f values of 0.13 and 0.37 on being subjected to 0.1 *N* NaOH at 30° for 3 hr whereas, in 1.0 *N* NaOH, most of the amino sugar spot of 0.20 had been transformed to that at $R_f = 0.37$ at 3 hr. The developed spot assigned to compound III had disappeared at 24 hr in both 0.1 and 1.0 *N* NaOH at 30°.

Compound III gave the same spot with the same developed color intensity as the standard on being subjected to 0.1 and 1.0 *N* HCl at both 30 and 60° for 3, 24, 50, and 400 hr. Compound I ($R_f = 0.52$) produced a considerable quantity of the open chain dimethylaminopropylglucose (III) in 1 hr at 30° in 0.1 *N* HCl and was completely transformed to III in 1 hr at 60 and 30° in 1.0 *N* HCl.

Thus, compound I has high stability in 0.1 and 1 *N* NaOH, whereas III is rapidly degraded. I is rapidly degraded in 0.1 and 1 *N* HCl to stable III by splitting of the ether linkages to liberate acetone. The alkaline degradation products of III showed compounds with high UV spectrophotometric absorbances at <550 nm whereas undegraded III had no absorbance down to 210 nm.

Partition Coefficients and Extraction Efficiency of I from Aqueous Solutions and Plasma by Chloroform—The apparent partition coefficients, k', was calculated for chloroform extraction of the aqueous phase at a given pH value by:

$$k' = \frac{[I]_{org}}{[I]_{aq}} = \frac{(PHR)_{org} \times 1/\gamma_1}{[(PHR)_{aq_1} + (PHR)_{aq_2}] \times 1/\gamma_2 \times 1/\gamma_3} \times \frac{V_{aq}}{V_{org}} \quad \text{(Eq. 4)}$$

where the peak height ratios determined for I relative to V were PHR_{org} for the assay of a γ_1 fraction of the volume of the organic phase, and PHR_{aq} for the assay of a γ_3 fraction of the volume of chloroform used to extract a γ_2 fraction of the volume of the aqueous phase. The PHR_{aq_1} and PHR_{aq_2} were the peak height ratios for the first and second extractions of the previously equilibrated aqueous phase. These two extractions accounted for practically all of the I partitioned into the buffer or plasma when a volume of V_{aq} milliliters of buffer or plasma were initially equilibrated with V_{org} milliliters of chloroform (Table I).

This apparent partition coefficient can be defined as:

$$k' = \frac{[I]_{org}}{[I]_{aq}} = \frac{[\text{I as base}]_{org}}{[\text{I as base}]_{aq} + [\text{protonated I}]_{aq}} \quad \text{(Eq. 5)}$$

Since:

$$1/k' = \frac{[\text{I as base}]_{aq}}{[\text{I as base}]_{org}} + \frac{[\text{protonated I}]_{aq}}{[\text{I as base}]_{org}} = 1/k + \frac{[\text{protonated I}]_{aq}}{[\text{I as base}]_{org}} \quad \text{(Eq. 6)}$$

where k is the intrinsic partition coefficient for the free base of I between the organic and aqueous phases, and:

$$[\text{protonated I}]_{aq} = [\text{I as base}]_{aq} [H^+]/K'_a \quad \text{(Eq. 7)}$$

where $K'_a = 5.25 \times 10^{-10}$ is the apparent dissociation constant of I ($pK'_a = 9.28$) and $[H^+] = 10^{-pH}$ is the activity of the hydrogen ion in the extracted buffer solution or plasma. Then by substitution of Eq. 7 into Eq. 6,

$$1/k' = 1/k + \frac{[\text{I as base}]_{aq} [H^+]}{[\text{I as base}]_{org} K'_a} = 1/k + \frac{[H^+]}{kK'_a} \quad \text{(Eq. 8)}$$

It follows that the intrinsic partition coefficient is

$$k = (1 + [H^+]/K'_a)k' \quad \text{(Eq. 9)}$$

and these calculated values are given in Table I.

The standard assay of I in plasma or urine extracts 0.5 ml with 5 ml of chloroform at pH 11.5. Thus, for partition coefficients of 5.63–6.35, 98.4% of I is extracted into the organic phase.

GLC Assay of I—Typical chromatograms of I, and the internal standard diisopropylaminoethyl I are given in Fig. 2 and, for the specified conditions, had retention times of 1.6 and 4.3 min, respectively. The limit of detection was 5–10 ng of I. The regression analysis of the assayed amounts of I in 0.5 ml of plasma or urine against the PHR were effected in accordance with:

$$C \pm s_{C\ PHR} = (m \pm s_m)\text{PHR} + (b \pm s_b) \quad \text{(Eq. 10)}$$

where C is the concentration of I in 0.5 ml of aqueous fluid, PHR is the peak height ratio of I to the internal standard (500 ng of diisopropylaminoethyl analog of I in 0.5 ml of the extracted aqueous phase), m is the slope, b is the intercept, $s_{C\ PHR}$ is the standard error of estimate of concentration/0.5 ml on the PHR, s_m is the standard error of the regression coefficient m, and s_b is the standard error of the intercept b.

The intercepts of such calibration curves were not significantly different from zero. The standard errors of estimates of the concentrations from these calibration curves ranged between 4.9 and 6.3 ng/0.5 ml of assayed fluid.

A typical calibration curve for GLC–electron capture detection of derivatized I with 500 ng of the diisopropylaminoethyl analog of I (V), as the internal standard gave the following regression equation for amounts (A) in 0.5 μl of urine:

$$A \pm 6.34 \text{ ng} = (144.6 \pm 7.1)\ \text{PHR} - 4.6 \pm 5.2 \quad \text{(Eq. 11)}$$

For amounts in 100 μl of plasma,

$$A \pm 4.87 \text{ ng} = (162.0 \pm 6.1)\ \text{PHR} - 10.0 \pm 4.2 \quad \text{(Eq. 12)}$$

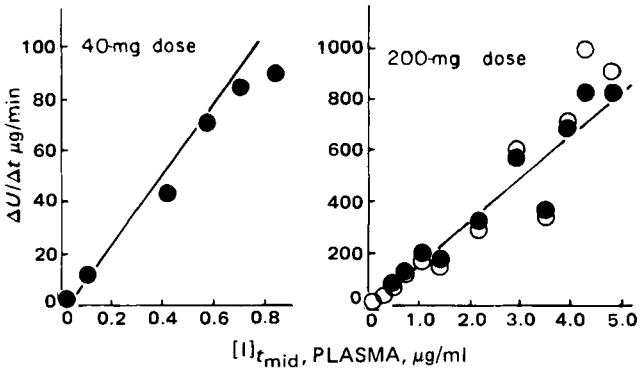

Figure 6—*Renal clearance plots of μg/min of I excreted into the urine versus the plasma levels of I, $[I]_{t_{mid}}$ at the mid-time of the collected interval. Key: (○) data obtained by GLC assay of urine; (●) data from LSC assay of the organic phase of extracted urine (Eq. 1). The lines drawn through the plots are for renal clearances of 135 and 163 ml/min for the 40- and 200-mg I doses, respectively.*

Comparison of GLC and LSC assays—When radiolabeled I was extracted from 0.5 ml of water, plasma, or urine that had been adjusted to pH 11.5 with 5 ml of chloroform, reextraction of the separated aqueous phase with the same amount of chloroform showed less than 2% of the original radioactivity in the second extract. This was consistent with the 1.6% that had been estimated from the measured partition coefficients to be nonextracted under these conditions. The paired assay values of I by GLC and LSC, were highly correlated with a correlation coefficient of $r = 0.995$ for the 40-mg dose for plasma values between 0.15 and 2.6 μg of I/ml of plasma. The paired values were challenged by the Student t test ($t = 1.12$; $df = 13$) and the null hypothesis that the values were the same from both assays could not be rejected. Similarly, the correlation coefficient was 0.991 for the 200-mg dose for plasma values between 0.3 and 4.0 μg I/ml of plasma. The null hypothesis of no difference between the LSC and GLC assays of I in plasma could not be rejected ($t = 1.73$; $df = 9$). The correlation can be observed from Fig. 3.

The correlation coefficients for the paired GLC and LSC urine assays of I were 0.995 and 0.986 at the 40- and 200-mg doses, respectively. The t values for the 40-mg dose were 0.16, $df = 6$, and 1.85, $df = 12$, for the amounts in the urine fractions collected in the interval 0–193 min and 0–732 min, respectively. The t values for the 200-mg dose were 0.25, $df = 11$ and 0.60, $df = 16$, for the amounts in the urine fractions collected between 0–546 min and 0–747 min, respectively.

Thus, it can be concluded that the LSC assay of the radiolabeled I in the chloroform extract of plasma and urine of dogs administered ^{14}C-labeled I intravenously does not give significantly different results than the GLC assay of the extract. Thus, any radiolabeled metabolites that

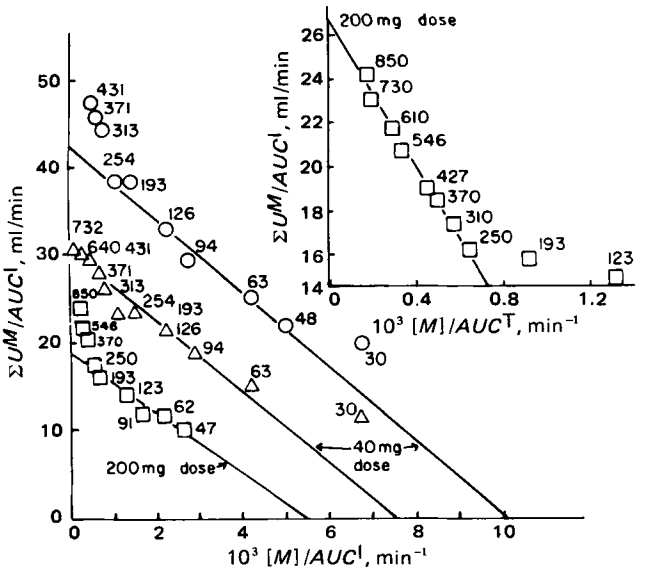

Figure 7—*Plots in accordance with Eq. 13:* $\Sigma U^M/AUC^I = -V_M[M]/AUC^I + Cl^{tot}_{met} - Cl_x$ *where the intercepts of* $Cl^{tot}_{met} - Cl_x$ *and the negative slopes of* V_M, *respectively, were for the 40-mg dose; 42.4 ml/min and 4078 ml when the urinary amounts of metabolite,* U^M, *were calculated from the difference between total urine radioactivity count and that due I in urine (Eq. 3, ⊙); 30.4 ml/min and 4037 ml when the urinary amounts of metabolite,* U^M, *were calculated from the direct LSC assay of I-extracted urine (Eq. 2, △). The respective values for the 200-mg dose when the urinary amounts of metabolite,* U^M, *were calculated from the direct LSC assay of I-extracted urine (Eq. 2, ⊡) were 27.3 ml/min and 3278 ml when the data between 47 and 250 min were fitted linearly and 18.5 ml/min and 16,850 ml when the data between 250 and 850 min were fitted linearly (see insert).*

may exist in the plasma or urine are not readily or significantly extracted into chloroform under the conditions used.

Preliminary Pharmacokinetics of I in the Dog—The pharmacokinetic parameters are listed in Table II. Details of their calculations and the definitions of the symbols have been given in other publications (11, 12). These preliminary studies indicate that the plasma level–time curve of intravenously administered I in the dog conforms to a two-compartment body model (Fig. 3) which can be characterized by the sum of two exponentials. The respective half-lives of the two phases are 3.6–4.3 and 104–127 min. The respective estimated terminal half-lives from the urine sigma minus plot (Fig. 4) and the plasma level–time curves (Fig. 3) were the same (Table II). These limited studies do not permit the definitive conclusion that I may have dose dependent kinetics and a potentially saturable elimination process even though the higher dose had a longer half-life.

The apparent distribution volumes of I, in reference to total concentration in plasma for the central compartment (V_C) and equilibrated tissues (V_d), were 8.7–11.9 and 31–35 liters, respectively.

Clearances—The total clearances of I were similar for both the 40- and 200-mg doses, 204 and 191 ml/min (Table II). The renal clearances for these respective doses were 135 and 163 ml/min (Figs. 5 and 6) indicative of excess tubular secretion in addition to glomerular filtration, since a 12-kg dog has an inulin (glomerular filtration) clearance of 51 ± 12 ml/min (13). The possibility of saturable tubular reabsorption could explain the apparent variation of renal clearance with dose if it were substantiated by further studies.

The extra-renal clearances, Cl^{tot}_{met}, are thus estimable from the differences between the total and renal clearances and are 69.4 and 28.2 ml/min at the 40- and 200-mg doses, respectively, and do indicate a possible saturable metabolism with dose-dependent pharmacokinetics.

Urinary Recoveries—The urinary recovery of unchanged I was 60–64 and 82–85% at the 40- and 200-mg doses, respectively. This was consistent with the fact of higher renal clearance of I at the higher dose. Whereas the calculated total amounts of radiolabeled metabolites excreted in the urine at the higher 200-mg dose, *i.e.*, radiolabeled amounts not extractable into chloroform at pH 11.5, were reasonably the same when calculated from both the direct assay of extracted urine 15% (Eq. 2); and the differences between total urine radioactivity and that due I 17% (Eq. 3). This was not true for the 40-mg dose. The respective values at this dose were 18 and 34%. The only explanation other than technological for this discrepancy would be that some radiolabeled metabolite was extracted into the organic phase in sufficiently small amounts so that statistics of identity between the GLC and LSC analyses of I in this phase were not significantly perturbed.

The total urine recovery of I and its metabolite was 100 ± 2% at the 200-mg dose. It was 96 ± 2 and 80 ± 2% for the 40-mg dose when the difference (Eq. 2) and direct (Eq. 3) assays for metabolites were used, respectively.

Attempted Estimates of Pharmacokinetic Properties of Metabolites—If only one metabolite, M, were produced from I, and if this metabolite in the systemic circulation were only renally excreted, the following equation would be valid for constant clearances (12):

$$\Sigma U^M/AUC^I = -V_M[M]/AUC^I + Cl^{tot}_{met} - Cl_x \qquad \text{(Eq. 13)}$$

where [M] and ΣU^M are the respective plasma concentrations of metabolite and the cumulative amount of metabolite excreted into the urine at time, t, corresponding to the area under the plasma level-time curve of I, AUC^I, to that time; where V_M is the estimated overall apparent distribution volume of the metabolite; and where $C^{tot}_{met} - Cl_x$ is the clearance of I to systematically circulating metabolite.

The V_M and $Cl^{tot}_{met} - Cl_x$ values can be estimated from the slope and intercept, respectively, of plots of the quotients in Eq. 13 (Fig. 7). The discrepancy in the estimates of ΣU^M by the direct and difference methods of radiolabeled metabolites in urine for the 40-mg dose gave different values for $Cl^{tot}_{met} - Cl_x$ of 30.4 and 42.4 ml/min, respectively; even though the apparent distribution volumes, V_M, for the metabolite were the same, 4.0 liters. As a consequence, the residual clearances of I, $Cl_x = Cl^{tot}_{met} - (Cl^{tot}_{met} - Cl_x)$, which could be due to metabolite partitioning or I excretion into the bile, differed also (Table II). The estimated values of these parameters for the 200-mg dose depended on where the data were presumed to be linear (Fig. 7). The assumption of validity for the early time data (<250 min) gave a V_M value of 3.3 liters nearest that obtained for the same time range of data for the 40-mg dose. The assumption of validity of the terminal data (>250 min) in Fig. 7 gave an extremely high apparent volume of distribution for the metabolite, a V_M of 18.5 liters.

Rearrangement of Eq. 13 and use of these estimated parameters permit the estimation of theoretical plasma levels of a possible metabolite in accordance with:

$$[M]_{calc} = \frac{(Cl^{tot}_{met} - Cl_x)AUC_I - \sum U^M}{V_M} \qquad \text{(Eq. 14)}$$

and the lines drawn through the experimental plasma concentrations of apparent metabolite were calculated on these premises (Fig. 3). The fact that the parameters chosen from Fig. 7 for the early time intervals gave reasonable fits for the early time, but not the latter (also compare the two fits of metabolite plasma levels at the 200-mg dose), is a strong indication that either the simple hypothesis of a single metabolite being formed from I is invalid or that the formed metabolite is partitioned into bile and undergoes an enterohepatic recirculation which elevates its terminal plasma levels above the theoretical value calculated from Eq. 14.

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test II: Effects of Deviations in Vessel Curvature from That of a Sphere

DON C. COX*x, CLYDE E. WELLS*, WILLIAM B. FURMAN*, THOMAS S. SAVAGE‡, and ALFRED C. KING§

Received April 16, 1981, from the *Food and Drug Administration: *National Center for Drug Analysis, St. Louis, MO 63101; ‡Los Angeles, CA 90015; and §Winchester Engineering and Analytical Center, Winchester, MA 01890.* Accepted for publication July 23, 1981.

Abstract □ Dissolution vessels made from glass or plastic are recognized by the USP as being suitable for dissolution testing. Glass vessels with a bottom inside curvature flatter than that of a sphere can cause a high bias in dissolution results; vessels with a steeper curvature can cause a low bias. The inside bottom curvature of plastic vessels adhered closely to the curvature of a sphere. The plastic vessels are preferable for use if the drug is not adsorbed and the vessel is not attacked by the dissolution medium. Bias in results between individual positions of a dissolution apparatus was traced to two shafts which were not vertical.

Keyphrases □ Dissolution—systematic error associated with USP dissolution Apparatus 2 □ USP—error associated with dissolution Apparatus 2 □ Apparatus—systematic error associated with USP dissolution Apparatus 2

Only one manufacturer[1] produces a glass, round-bottom vessel (1) suitable for the multiple-spindle drive equipment used for the USP dissolution test (2). The manufacturing process was changed in 1978 in an attempt to improve the vessel. The vessel was formed manually in the older process by using a mold to which the outside of the vessel could conform. These molded vessels vary considerably with respect to weight, inside cylindrical diameter, and inside bottom curvature. In the newer process the vessel is made from large-bore glass tubing, and the bottom of the vessel is shaped manually from the outside. The tubing-produced vessels examined compare closely with respect to weight and inside cylindrical diameter. However, the inside bottom curvature varies from one vessel to the next. Vessels made from the tubing process are in widespread use. Many vessels made from the older process do not pass the USP requirement that the inside diameter be 10.0–10.5 cm.

A plastic vessel[2] formed by injection molding has been available since 1979. The variation in physical dimensions (including bottom curvature) of individual plastic vessels is less than that of glass vessels because of the manner in which they are produced. Both types of vessels are currently recognized by the USP as being suitable for dissolution testing.

The effect of variations in physical dimensions of the vessels on dissolution results was studied. The study of the molded glass vessels was conducted under the test conditions described in the Fourth Supplement to USP XIX (3); *i.e.*, the stirring element consisted of a shaft with a detachable paddle blade positioned on the side of the shaft. The tubing-produced glass vessels and plastic vessels were studied with the currently official stirring element (4). The tubing-produced glass vessels and plastic vessels are compared for their suitability for use in the USP dissolution test for prednisone tablets.

EXPERIMENTAL

A commercial sample of 5-mg prednisone tablets was used to check the performance of dissolution equipment. Dissolution results from these tablets were reported recently (5). The tablets are reasonably uniform in total drug content. A randomly selected 60-tablet subsample gave an overall average result of 97.2% of label claim with a coefficient of variation (CV) of 2.88% in a content-uniformity assay (6). The average weight of the tablets was 143 mg. This tablet sample was referred to as Tablet 1 (7).

In 1979 a commercial sample of 10-mg prednisone tablets, referred to as Tablet 2, was characterized (the supply of Tablet 1 was running low). This second performance standard gave an average result of 100.0% of label claim with a CV of 1.5% when 20 tablets were subjected to content-uniformity assay. The average tablet weight was 225 mg. Both Tablet 1 and Tablet 2 disintegrate within 2 min into coarse, insoluble granules which stay on the bottom of the vessel throughout the test. The granules from three disintegrated units of Tablet 1 visually appear to occupy about the same volume in the bottom of the vessel as the granules from one disintegrated unit of Tablet 2.

Evaluation of Molded Glass Vessels—Three laboratories[3], each using a commercially available six-spindle dissolution apparatus[4], compared dissolution results from four sets of six molded glass vessels. Tablet 1 was used by all three laboratories. The data from this experiment were collected prior to the modification of the apparatus; *i.e.*, the apparatus described in the Fourth Supplement to USP XIX was used. All other experimental data reported in this paper were collected using the current apparatus.

Evaluation of Glass Tubing-Produced Vessels—An apparatus described previously (7) was selected for this experiment. The apparatus

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test II: Effects of Deviations in Vessel Curvature from That of a Sphere

DON C. COX*x, CLYDE E. WELLS*, WILLIAM B. FURMAN*, THOMAS S. SAVAGE‡, and ALFRED C. KING§

Received April 16, 1981, from the *Food and Drug Administration: *National Center for Drug Analysis, St. Louis, MO 63101; ‡Los Angeles, CA 90015; and §Winchester Engineering and Analytical Center, Winchester, MA 01890.* Accepted for publication July 23, 1981.

Abstract □ Dissolution vessels made from glass or plastic are recognized by the USP as being suitable for dissolution testing. Glass vessels with a bottom inside curvature flatter than that of a sphere can cause a high bias in dissolution results; vessels with a steeper curvature can cause a low bias. The inside bottom curvature of plastic vessels adhered closely to the curvature of a sphere. The plastic vessels are preferable for use if the drug is not adsorbed and the vessel is not attacked by the dissolution medium. Bias in results between individual positions of a dissolution apparatus was traced to two shafts which were not vertical.

Keyphrases □ Dissolution—systematic error associated with USP dissolution Apparatus 2 □ USP—error associated with dissolution Apparatus 2 □ Apparatus—systematic error associated with USP dissolution Apparatus 2

Only one manufacturer[1] produces a glass, round-bottom vessel (1) suitable for the multiple-spindle drive equipment used for the USP dissolution test (2). The manufacturing process was changed in 1978 in an attempt to improve the vessel. The vessel was formed manually in the older process by using a mold to which the outside of the vessel could conform. These molded vessels vary considerably with respect to weight, inside cylindrical diameter, and inside bottom curvature. In the newer process the vessel is made from large-bore glass tubing, and the bottom of the vessel is shaped manually from the outside. The tubing-produced vessels examined compare closely with respect to weight and inside cylindrical diameter. However, the inside bottom curvature varies from one vessel to the next. Vessels made from the tubing process are in widespread use. Many vessels made from the older process do not pass the USP requirement that the inside diameter be 10.0–10.5 cm.

A plastic vessel[2] formed by injection molding has been available since 1979. The variation in physical dimensions (including bottom curvature) of individual plastic vessels is less than that of glass vessels because of the manner in which they are produced. Both types of vessels are currently recognized by the USP as being suitable for dissolution testing.

The effect of variations in physical dimensions of the vessels on dissolution results was studied. The study of the molded glass vessels was conducted under the test conditions described in the Fourth Supplement to USP XIX (3); *i.e.*, the stirring element consisted of a shaft with a detachable paddle blade positioned on the side of the shaft. The tubing-produced glass vessels and plastic vessels were studied with the currently official stirring element (4). The tubing-produced glass vessels and plastic vessels are compared for their suitability for use in the USP dissolution test for prednisone tablets.

EXPERIMENTAL

A commercial sample of 5-mg prednisone tablets was used to check the performance of dissolution equipment. Dissolution results from these tablets were reported recently (5). The tablets are reasonably uniform in total drug content. A randomly selected 60-tablet subsample gave an overall average result of 97.2% of label claim with a coefficient of variation (CV) of 2.88% in a content-uniformity assay (6). The average weight of the tablets was 143 mg. This tablet sample was referred to as Tablet 1 (7).

In 1979 a commercial sample of 10-mg prednisone tablets, referred to as Tablet 2, was characterized (the supply of Tablet 1 was running low). This second performance standard gave an average result of 100.0% of label claim with a CV of 1.5% when 20 tablets were subjected to content-uniformity assay. The average tablet weight was 225 mg. Both Tablet 1 and Tablet 2 disintegrate within 2 min into coarse, insoluble granules which stay on the bottom of the vessel throughout the test. The granules from three disintegrated units of Tablet 1 visually appear to occupy about the same volume in the bottom of the vessel as the granules from one disintegrated unit of Tablet 2.

Evaluation of Molded Glass Vessels—Three laboratories[3], each using a commercially available six-spindle dissolution apparatus[4], compared dissolution results from four sets of six molded glass vessels. Tablet 1 was used by all three laboratories. can be aligned to conform to USP specifications, but shafts 4 and 6 are not parallel with the other four shafts. Six glass tubing-produced vessels, purchased specifically for this experiment, were numbered one through six and placed in the apparatus. Two sets of six tablets each were subjected to the dissolution test (one tablet per vessel for each set of tablets). The vessels were then moved one position in a clockwise direction, and two more sets of six tablets each were subjected to the test. This procedure was continued until each vessel had been tested twice in each position of the apparatus. A total of 72 tablets was subjected to the test. Twelve dissolution results were associated with each vessel, which had been sequentially placed in all six positions. Likewise, 12 results were associated with each position in which all six vessels had been sequentially placed. The experiment was conducted with Tablet 1 and then with Tablet 2.

Evaluation of Plastic Vessels—The plastic vessels were evaluated in the same manner as the glass tubing-produced vessels; the same apparatus was used. The experiment was conducted with Tablet 1 and then Tablet 2.

Evaluation of Inside Bottom Curvature of Vessels—The water was removed from the bath used with the dissolution apparatus. The empty vessels were placed in position in the base of the apparatus. A slurry of 60 g of plaster of Paris and 50 ml of water was poured into each vessel and allowed to set for 1–2 hr. The vessels were removed from the apparatus, and the plaster casts were removed. The casts retained the exact shape of the bottom inside curvature of the vessels.

RESULTS AND DISCUSSION

The data obtained from different sets of molded glass vessels are given in Table I. With different sets of vessels, a mean difference of 8.8% of label claim was obtained between laboratories B and C for Tablet 1. When the same vessels were used to analyze Tablet 1 in both laboratories, the mean difference between laboratories dropped to 3.2%. When two sets of vessels were exchanged between laboratories A and B, mean results of 52.4 and 49.3% of label claim, respectively, were obtained using one set, and 37.5 and 42.7% of label claim were obtained for laboratories A and B, respectively, using the other set of vessels.

The data indicate that there are significant differences between laboratories, even when the same vessels are used. The bias in results between the laboratories was reduced considerably when the same sets of vessels were available to each laboratory. These vessels vary considerably with respect to flange thickness, inside diameter, and inside bottom curvature. A correlation between the physical dimensions of the vessels and the dissolution data is difficult to make because of this lack of uniformity in all three critical areas. However, when plaster casts were made of the bottom of the vessels originally used by laboratory A, the impressed curvatures came to a distinct blunted point at what would be the bottom of the vessel. These curvatures were steeper than that of a sphere with a diameter equal to the width of the vessel. These vessels also gave the lowest results for Tablet 1.

The data collected in the evaluation of the plastic and glass tubing-

[a] Percent of label claim dissolved at 30 min. [b] Mean and standard deviation of 12 individual tablets.

produced vessels were analyzed by a two-way analysis of variance (ANOVA) (8). The data collected from the test runs[5], rearranged for the ANOVA, are shown in Tables II–V. The data in the rows are for the individual vessels and the data in the columns are for the individual positions on the apparatus. (For example, the data in row one are the dissolution results from vessel one after it had been placed in all six positions; the data in column one are the dissolution results from position one after all six vessels had been rotated to position one.) Table VI shows the results of the ANOVA for each combination of tablet and vessel.

Table VI shows the difference between the mean dissolution results for 72 tablets of Tablet 1 with the glass tubing-produced vessels and with the plastic vessels. Ideally the results should compare closely if both types of vessels are equivalent for use with Apparatus 2. However, the glass vessels give results that are higher by 13.5% of label claim.

Tablet 2 responded in a similar manner, but the overall difference in results is smaller (5.1%). The difference between the mean squares of the data from these two sets of vessels is more pronounced. The total mean square for the Tablet 2 results collected from the glass vessels is over five times that of the plastic vessels.

Each of the mean squares listed in Table VI for Tablet 1 or 2 is an independent estimate of the variance of that particular tablet. These independent estimates differ widely from each other in most instances. The smallest variance is the within-groups mean square, which is the pooled variance of the tablets taken under the most repeatable conditions for each experiment, *i.e.*, the mean of the variances derived from the duplicate results. The square root of the within-groups mean square gives the best estimate of the inherent standard deviation of the tablets. The standard deviation of Tablet 1 is 1.1% of label claim in the glass vessels and 2.0% of label claim in the plastic vessels. The standard deviation of Tablet 2 is 5.5% of label claim in the glass vessels and 2.7% of label claim in the plastic vessels. The overall standard deviations, derived from taking the square root of the respective total mean squares, are 3.6, 5.1, 10.4, and 4.6% of label claim. Thus, Apparatus 2 is not measuring the variation of the tablets. Instead, the tablets are measuring the variations in Apparatus 2.

[5] The data, in the original order taken, are available from the authors upon request.

The within-groups mean square was divided into mean squares associated with the vessels, apparatus position, and the interaction between vessels and apparatus position to obtain the F ratios shown in Table VI. The magnitudes of the F ratios indicate that there are statistically significant differences in the mean dissolution results associated with the individual vessels and apparatus positions. Tablet 1 showed differences between the individual glass vessels and between the individual plastic vessels. Tablet 2 showed differences only between the individual glass vessels. Both tablets showed differences between the apparatus positions. Finally, Tablet 1 revealed a significant interaction between the glass vessels and the apparatus positions.

Tables II–V clearly show where the major sources of the variations are located. The mean results of 12 tablets associated with a position on the dissolution apparatus (the column means) show that positions 4 and 6 give higher results than positions 1, 2, 3, and 5 for each combination of tablet and vessel type. It was established previously (7) that the paddle shafts in positions 4 and 6 were not parallel with the other four shafts. If the other four shafts were made vertical, shafts 4 and 6 would each be misaligned in relation to the vertical axis of the respective vessel. Though misaligned, the shafts still meet the USP specification because each is within 0.2 cm of the vertical axis of its vessel at all points along the shaft. The manufacturers of dissolution equipment must take special care in the design and manufacture of their equipment if this source of variation is to be reduced.

The mean results of 12 tablets associated with the glass vessels in Tables II and IV show that vessel 4 gives the lowest mean and vessels 5 and 6 the highest means for both Tablet 1 and Tablet 2. The rank correlation from the vessel giving the lowest results to the vessel giving the highest results is the same for both samples (vessels 4, 3, 2, 1, 5, 6). The mean results for the plastic vessels from Tablet 1 (Table III) showed statistically significant differences; however, the mean results from Tablet 2 (Table V) were not significantly different. These findings indicate that Tablet 1 is being affected by a characteristic of the plastic vessels to which Tablet 2 does not respond.

Plaster casts were made of the lower bottom curvatures of both sets of vessels. Visual inspection of the casts showed that all six of the glass vessels had a flattened area on the bottom. The flattened area was not uniform from one glass vessel to the next. Vessels 1, 2, and 3, although

exhibiting a flattened area, possessed some curvature over this area. Vessels 5 and 6 had areas of ~1 cm in diameter that were almost completely flat. Vessel 4 exhibited a curvature similar to vessels 5 and 6, except that there was a small indentation in the middle of the flattened area.

Plaster casts revealed that all six plastic vessels had uniform bottom curvatures which were considerably greater than the curvatures of the glass vessels. The bottom curvatures of the plastic vessels did not vary from one vessel to the next as determined by visual comparison of the plaster casts.

It is known that dissolution rate depends on the surface area of the dissolving substance in contact with the dissolution medium and the velocity of the liquid passing over the substance (9). A tablet which disintegrates fairly rapidly into granules of sufficient specific gravity will appear as a rotating cone-shaped mass of particles on the bottom of the dissolution vessel shortly after being introduced to Apparatus 2 (Fig. 1). If the inner surface of the vessel is symmetrical around the center axis of the paddle, liquid flow in a vessel with a small indentation in the bottom or with a steeper curvature will gather the particles into a more compact mass than in a vessel with a flatter curvature. If the inner surface of the vessel is not symmetrical around the center axis of the paddle, the liquid flow in the vessel will not be symmetrical; the tablet particles will be more agitated, and the conical shape of the mass of particles may be disrupted as the asymmetrical flow of liquid buffets the particles. Asymmetrical liquid flow can be generated by a misaligned paddle, *i.e.*, a paddle whose center axis does not coincide with the cylindrical axis of the vessel, as well as by a vessel that is not symmetrical.

These hypotheses may explain the differences between the tablet results associated with the glass vessels and with apparatus positions. They may also explain the fact that significant interactions exist between the glass vessels and the apparatus positions for Tablet 1. If the individual vessel curvature and paddle misalignment are unique, the liquid flow pattern, and thus the tablet results, will be unique for that combination.

Tablet 1 revealed significant differences which were associated with the plastic vessels. Table III shows that vessel 6 gave higher results than the other five vessels. No physical difference was observed which would account for the higher results in vessel 6. Vessel 6 was obtained at a later time to replace one of the original vessels that was broken before any testing was conducted. As the manufacturing history of none of the vessels is known, this observation may be meaningless; on the other hand, it may point to a subtle difference in manufacture of the plastic vessels.

Since the plastic vessels are physically more uniform than the glass vessels, the plastic vessels are preferable for dissolution testing. The chance for bias in dissolution results between laboratories is less if the plastic vessels are used. The USP specifies that the inside bottom curvature for the dissolution vessels be spherical. Thus, a quantitative determination of vessel curvature for comparison to that of a sphere is required before a conclusion can be reached about the suitability of the vessels for use in the USP dissolution test.

The following relationship exists between the diameter of a circle and a chord parallel to the diameter:

$$D = (L^2/4h) + h \qquad \text{(Eq. 1)}$$

where D is the diameter, L is the chord length, and h is the perpendicular distance from the center of the chord to the circumference of the circle.

A diameter was calculated from the equation for each vessel by determining the values of h and L. A mechanic's depth gauge[6] was used for

[a] All measurements in mm. Chord length (L) was 66.6 mm in all vessels. [b] Perpendicular distance from center of chord to circumference of circle.

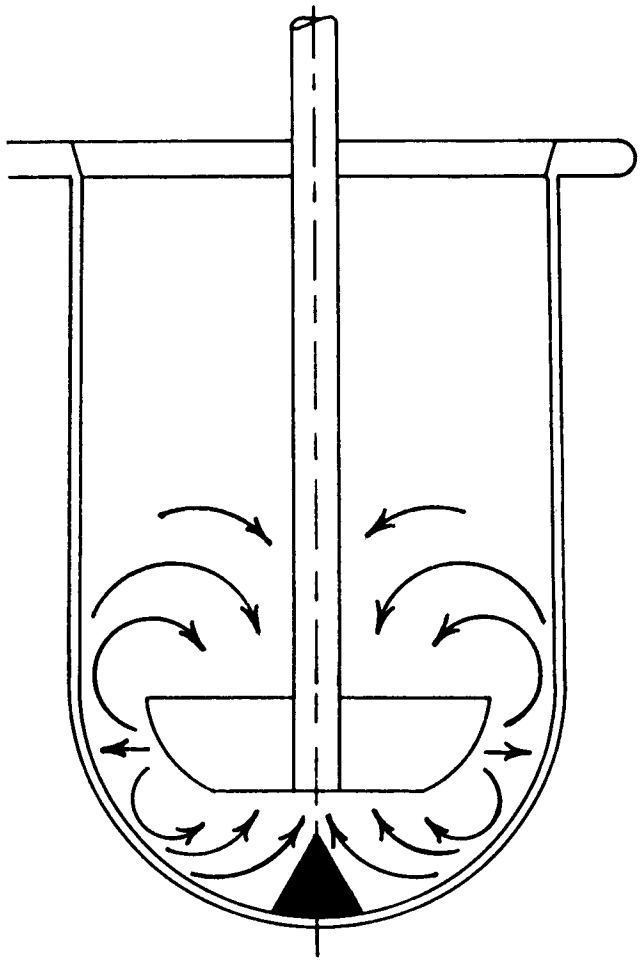

Figure 1—*Vertical cross-sectional view of USP Apparatus 2 illustrating formation of cone-shaped mass of particles due to a symmetrical liquid flow.*

[6] Combination depth and angle gauge, No. 236, L. S. Starrett Co., Athol, MA 01331.

this purpose. The base of the gauge was measured for the chord length (L). The gauge was then set inside the vessel with the ends of the gauge base resting on the curved surface of the vessel. The distance (h) between the base and the bottom of the vessel was taken from the gauge rule. The cylindrical diameter of the vessel was then taken 2 to 3 cm above opposite points where a tangent to the curved bottom of the vessel coincides with the vessel wall. Inside calipers were used for this purpose.

Table VII shows the measurements taken from the vessels and the comparison of the theoretical diameters calculated from these measurements with the actual diameters. The glass vessels possess a flatter curvature than a sphere of the same diameter. The curvature of the plastic vessels closely approximates a sphere of the same diameter. When the results from plastic vessels differ from those obtained from glass vessels, the results from the plastic vessels are more correct, because the plastic vessels conform more closely to the USP specifications.

CONCLUSIONS

Differences in the bottom curvature of dissolution vessels can cause bias in the dissolution results obtained from prednisone tablets. Vessels with a curvature which is less (flatter) than that of a sphere cause a high bias. Vessels with a curvature that is greater (steeper) than that of a sphere cause a low bias. The plastic vessels are more uniform than glass vessels and possess a curvature that more closely approximates the curvature specified in the USP. As such, they are preferable to the glass vessels for use in the dissolution test when the drug is not adsorbed and the vessel is not attacked by the dissolution medium.

The dissolution rate is controlled by the velocity of the liquid passing over the tablet. The liquid velocity at any point in a stirred vessel is controlled by the stirring rate and the geometry of the system. An idealized geometry is defined in the USP. Minor variations from this idealized geometry, such as those discussed in this paper and previously (7), change the liquid velocity in the vicinity of the tablet and, thus, the dissolution results. If the reproducibility of the test is to be improved, equipment must be made available which allows the analyst to adhere to this idealized geometry as closely as possible.

HPLC Determination of D and L Moxalactam in Human Serum and Urine

J. A. ZIEMNIAK *‡, D. A. CHIARMONTE ‡, D. J. MINER §, and J. J. SCHENTAG *‡x

Received March 25, 1981, from the **Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo;* the ‡*Clinical Pharmacokinetics Laboratory, Millard Fillmore Hospital, Buffalo, N.Y. 14209* and the §*Lilly Research Laboratories, Indianapolis, IN 46285.* Accepted for publication July 24, 1981

ABSTRACT □ A high-pressure liquid chromatographic procedure was developed to determine the D and L isomers of moxalactam in human plasma and urine. After protein precipitation with hydrochloric acid the sample was extracted with ethyl acetate. It was then back extracted into tromethamine buffer (pH 8.0) and washed with octanol. Extraction recovery from plasma ranged from 73–81%. An aliquot of the tromethamine buffer was then injected onto a C_{18}-μBondapak column. The mobile phase was 3% acetonitrile in 0.05 *M* ammonium acetate pH 6.5 buffer. Samples were quantitated by UV detection at 275 nm and 0.01 aufs. The lower limit of detection was 0.5 μg/ml for each isomer. Preliminary stability studies were performed to assess proper sample handling and storage conditions. The procedure was evaluated in a clinical setting to demonstrate its applicability to the study of moxalactam pharmacokinetics in critically ill patients.

Keyphrases □ Moxalactam—determination in human plasma and urine by high-pressure liquid chromatography, D and L isomers □ High-pressure liquid chromatography—determination of moxalactam in human plasma and urine, D and L isomers □ Anti-infectives—moxalactam, high-pressure liquid chromatographic determination, D and L isomers

Moxalactam is a new oxycephalosporin derivative undergoing clinical trials in the United States and Europe. *In vitro* experiments have demonstrated that moxalactam is active against a broad spectrum of microorganisms, including resistant Gram-negative bacteria such as *Pseudomonas aeruginosa* and *Bacteroides fragilis*, some indole-positive *Proteus* species (1), β-lactamase-producing strains of *Enterobacteriaceae* (2), and clinical isolates shown to be cephalosporin resistant (3). Its expanded spectrum of activity compared to conventional β-lactam antibiotics is attributed to replacement of the thio group at the 1 position of the dihydrothiazine nucleus with an oxygen moiety (4).

The pharmacokinetics of moxalactam elimination usually have been evaluated employing standard microbiological techniques (5, 6). However, a more specific analytical procedure was required for pharmacokinetic studies of this compound in critically ill patients. A high-pressure liquid chromatographic (HPLC) assay developed recently, although more specific than microbiological techniques, had limited applicability in the critical care setting[1]. A more specific HPLC analysis was required for studies in seriously ill patients. The present report describes a suitable HPLC procedure for the quantitation of both moxalactam isomers in patient plasma and urine.

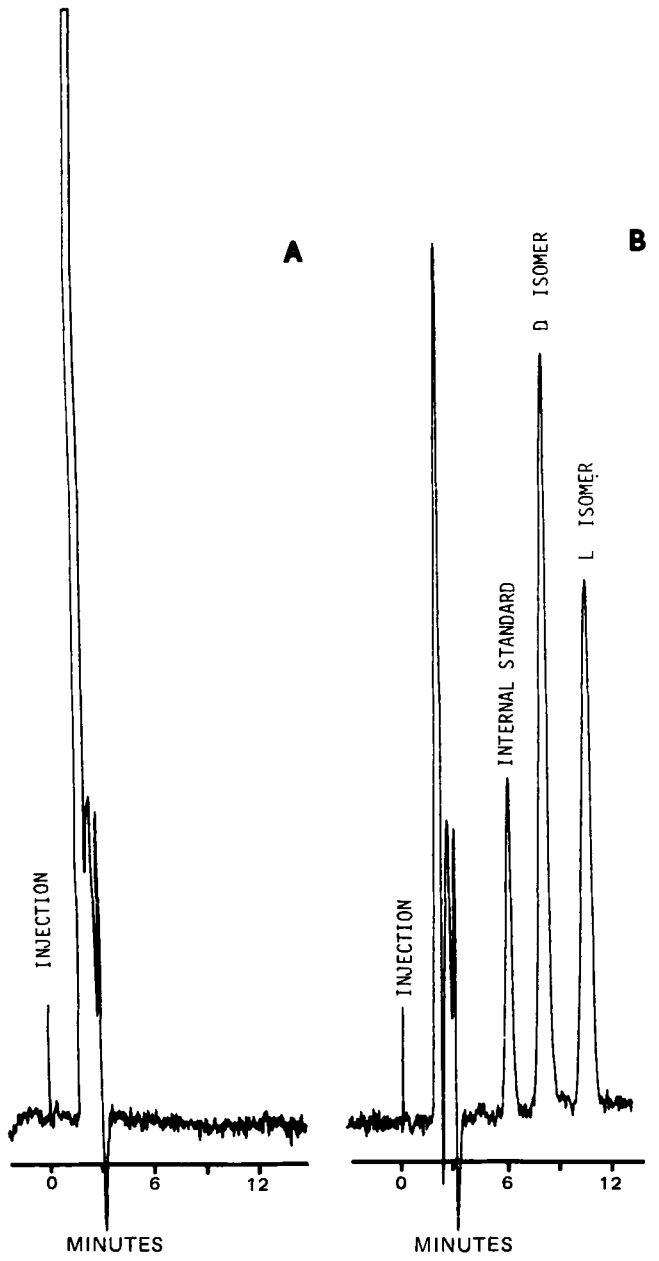

Figure 1—*Chromatograms obtained after extracting 0.5 ml of a blank patient plasma (A) and a moxalactam plasma standard (B). The peak heights of each isomer correspond to a plasma concentration of 10 μg/ml.*

EXPERIMENTAL

Reagents—All chemicals and reagents were analytical grade unless otherwise indicated. Moxalactam was supplied as a lyophylized powder containing a 1:1 mixture of D and L isomers[2]. Allopurinol[3], ammonium acetate, potassium chloride, acetic acid, hydrochloric acid, sodium hydroxide, octanol, tromethamine, glass-distilled acetonitrile[4], methanol, and ethyl acetate[5] were used as received.

Preparation of Stock Solutions—Initial stock solutions of moxalactam were prepared in water and subsequent dilutions made with blank human plasma. Due to the poor aqueous solubility of the internal standard (allopurinol), the drug was first dissolved in 0.1 *N* NaOH and then diluted with water to a final working concentration of 1.5 mg/ml.

Ammonium acetate buffer (0.05 *M*) was adjusted to pH 6.5 with acetic acid. Tromethamine–HCl pH 8.0 and KCl–HCl pH 1.0 buffers (0.05 *M*) were prepared as standard laboratory reagents (7). All buffers were stored at 5° and allowed to reach ambient temperature prior to use.

Extraction Procedure—Two hundred microliters of concentrated hydrochloric acid was added to 0.5 ml of plasma or dilute urine (typically 1:100) containing 0.1 ml of the internal standard solution (allopurinol, 1.5 mg/ml). The mixture was then vortexed, resulting in precipitation of almost all protein present in the sample. After centrifuging at 5000 rpm for 5 min[6], a 0.6-ml portion of the clear supernate was transferred to a 12 × 75-mm polypropylene tube containing 0.5 ml of KCl–HCl pH 1.0 buffer. Three milliliters of HPLC grade ethyl acetate was then added, and the solution was vortexed for 60 sec. After centrifuging[7] at 3000 rpm for 5 min, a 2.9 ml aliquot of the upper ethyl acetate phase was transferred to a second tube containing 0.5 ml of tromethamine–HCl pH 8.0 buffer. This mixture was vortexed for 30 sec, and then centrifuged. The upper organic phase was aspirated and discarded. A 0.4-ml aliquot of the lower aqueous phase was transferred to another tube and washed with 3 ml of octanol by rotation[8] for 1 min. The upper organic phase was discarded after centrifugation, and a 50-μl portion of the lower aqueous phase was used for HPLC analysis. When necessary, the aqueous phase could be stored at 5° for as long as 24 hr prior to HPLC quantitation.

HPLC Conditions—A high-pressure liquid chromatograph[9] equipped with a variable wavelength UV detector[10] and a 10-mv recorder[11] were used. Separation occurred on a C_{18} reverse phase column[12] with a 3% acetonitrile/0.05 *M* ammonium acetate mobile phase at a flow rate of 1.5 ml/min. The column effluent was monitored at 275 nm, and an attenuation of 0.01 aufs was used in all chromatographic procedures.

Recovery Studies—Recovery experiments were performed by adding equivalent amounts of moxalactam to blank plasma and to a solution of mobile phase. Samples were extracted according to the described procedure, except that the internal standard was introduced just prior to injection according to the external standardization method. Recovery was calculated by comparing moxalactam peak-height ratios for the extracted plasma samples with those obtained from direct injection of the mobile phase standard.

Recovery studies were carried out at two concentrations, with five replicate determinations at each concentration. Within- and between-day variation was evaluated at 10 and 80 μg of moxalactam/ml. To assess within-day variation, five aliquots of a single plasma sample were extracted at each concentration. Additional samples were assayed daily over 13 days to assess between-day variation.

Stability Studies—To determine the effects of temperature on the stability of D and L moxalactam, 1.0-ml aliquots of spiked plasma were incubated at −30, 5, 25, and 38°. Samples were periodically assayed for each isomer for up to 40 days. Semilogarithmic plots of each isomer

Table I—Analytical Recovery of D and L Moxalactam from Human Plasma

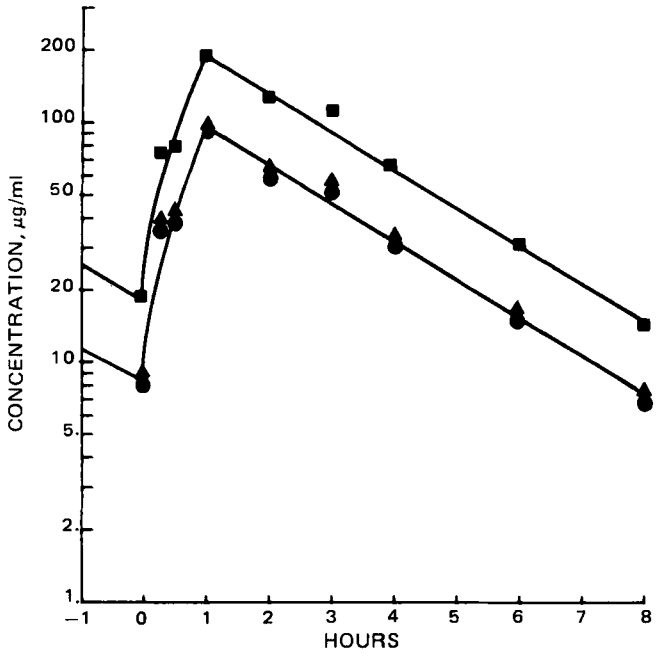

Figure 2—*Plasma concentration versus time profiles for moxalactam (■), its D isomer (▲), and L isomer (●) after intravenous infusion of moxalactam.*

concentration *versus* time were constructed to determine the rate and order of moxalactam degradation. The data were evaluated by means of an Arrhenius plot, and the line of best fit was determined by linear regression analysis.

Pharmacokinetic Study—After getting informed consent, a 10-day course of moxalactam therapy was started in a 60-year old female patient diagnosed as having an abdominal abscess secondary to invasive large bowel cancer. The pathogens involved included *Escherichia coli* and enterococcus, both of which were susceptible to moxalactam *in vitro*. This patient had normal hepatic and renal function, and therefore was given 2 g of intravenous moxalactam every 8 hr. The pharmacokinetic study was conducted on day 6 of therapy to allow steady-state concentrations to be achieved. Plasma and urine samples were obtained throughout a dosing interval and stored at −30° prior to quantitation of D and L moxalactam. The serum concentration *versus* time profiles for moxalactam and each isomer were evaluated by means of nonlinear regression analysis.

RESULTS

Chromatography—Representative chromatograms for a blank patient sample (A) and a spiked plasma standard (B) are presented in Fig. 1. No other peaks were evident in the blank plasma chromatogram even though the patient was receiving numerous medications. Chromatogram B was obtained after extracting 0.5 ml of plasma containing a total moxalactam concentration of 20 μg/ml. A 50-μl aliquot of the final buffer solution was injected onto the column. Allopurinol, the internal standard, had a retention time of 6.0 min, while the D and L isomers of moxalactam had retention times of 7.8 and 10.5 min, respectively. The lower limit of detection for each isomer was 0.5 μg/ml when a 50-μl aliquot of the final buffer phase was injected onto the column.

Calibration curves for each individual isomer were prepared daily by plotting peak-height ratio (isomer/internal standard) *versus* concentration for series of prepared plasma or urine standards. These plots were linear over the 2.5–50-μg/ml concentration range. Samples that exceeded the range of standards were diluted prior to extraction.

Recovery Experiments—The results of the recovery experiments are given in Table I. The overall recovery for both isomers ranged from 73 to 81% over an approximate 10-fold increase in concentration. Although these values are less than quantitative, the recovery was adequate for routine analysis of patient samples. When increased sensitivity was required, the volume ultimately injected onto the column can be increased to as much as 150 μl without deviation from linearity.

Both isomers demonstrate low between- and within-day variation at each of the concentrations evaluated (Table II). The coefficient of variation ranged from 2.8 to 3.9% for the within-day experiments, while the between-day studies yielded coefficients of variation ranging from 1.5 to 4.7%.

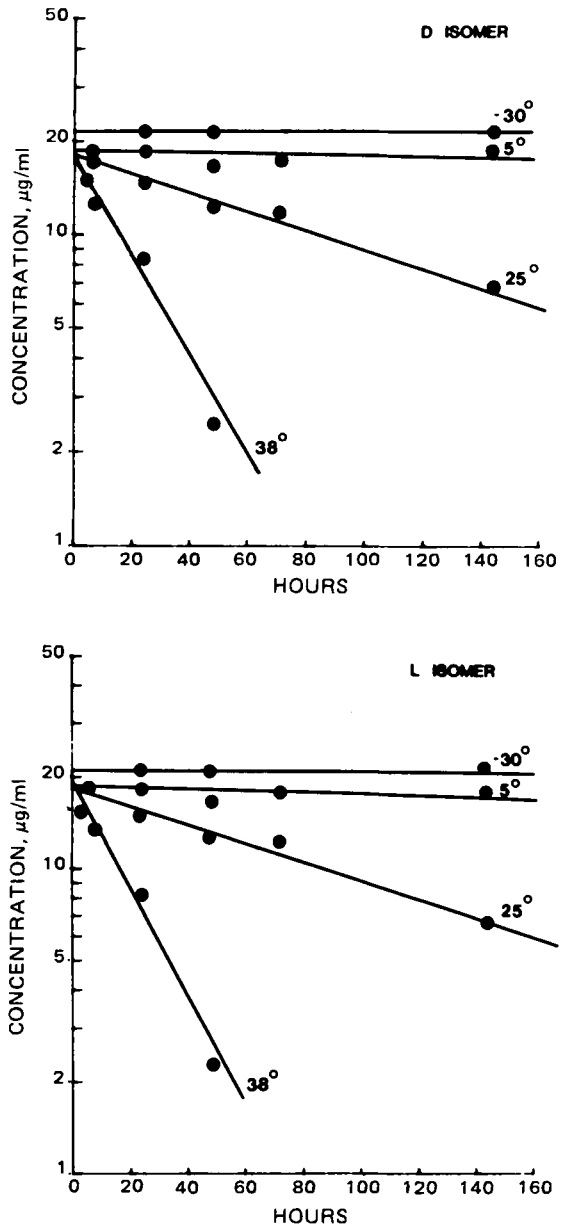

Figure 3—*Effects of temperature on the degradation of D and L moxalactam in human plasma.*

Pharmacokinetic Analysis—Figure 2 is the serum concentration *versus* time profile for moxalactam and its individual isomers in the patient. The subject received 2.0 g of moxalactam by intravenous infusion over 1 hr. The moxalactam concentration is given as the sum of the D and L isomers. The zero plasma sample was obtained immediately before the start of the infusion. The peak concentrations of 95 μg/ml for both isomers were noted at the completion of the infusion period, and concentrations decreased monoexponentially to a minimum of 7 μg/ml. There were no discernible differences in the concentration profile of each isomer.

The data for moxalactam and its isomers were fitted to a one-compartment model with zero order input, by means of nonlinear least-squares regression analysis. Total body clearance of moxalactam calculated as dose/*AUC* was 55.3 ml/min. Total moxalactam and the separate isomers showed similar elimination rates, with half-lives of 1.86, 1.9, and 1.85 hr, respectively.

Stability Studies—Moxalactam is a relatively unstable compound subject to degradation *in vitro*. To assess proper sample handling and storage conditions, the effect of temperature on the degradation rate was evaluated. Figure 3 shows the effect of temperature on the stability of each moxalactam isomer. No differences were observed in the degradation rate for the individual isomers from the two figures. The degradation rate

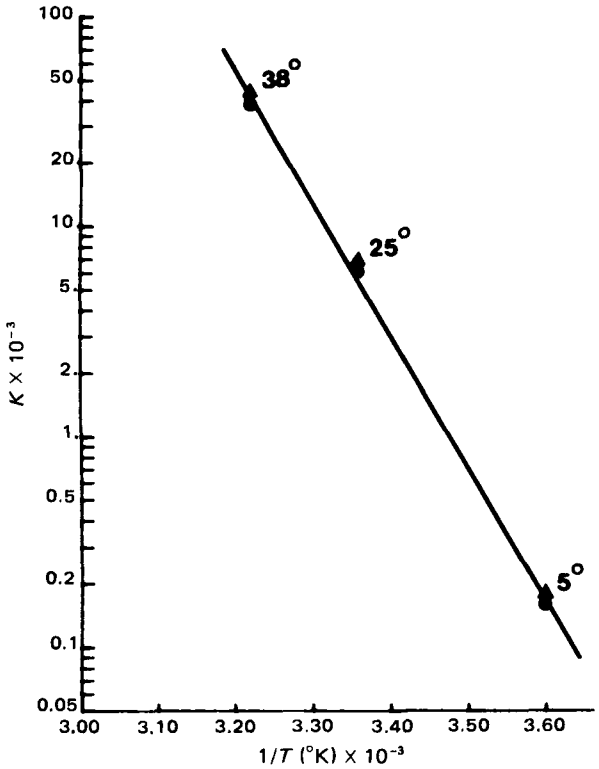

Figure 4—*Arrhenius plot of moxalactam degradation in human plasma. Key:* ▲ *D isomer;* ●, *L isomer.*

is consistent with an apparent first-order process, with the most rapid rate observed at the elevated temperature. Plasma samples were stable over the 40-day test period if frozen at −30°.

An Arrhenius plot was constructed by plotting the apparent first-order rate constant for 10% degradation (K) as a function of the reciprocal of temperature. The data for each isomer are presented in Fig. 4. The relationship was linear over the temperature range of 5–38°, with the slope yielding an activation energy of 29.1 kcal/mole, a value consistent with hydrolysis reactions.

DISCUSSION

Serum moxalactam concentrations have been routinely determined in healthy volunteers using standard microbiological assays (5, 6). The limitation of these assays in a clinical setting is well known, with the most frequently encountered problem being assay interferences from concurrent medications. Additional interferences may arise due to metabolic and/or degradative products of many drugs, or from endogenous substances possessing antibacterial activity. These procedures also cannot measure the individual isomers of moxalactam, whose quantitation may be clinically relevant, as was the case with warfarin (8) and propranolol (9).

An HPLC procedure was reported recently for the determination of D and L moxalactam in serum and urine[1]. This procedure has several short-comings. The extraction procedure, although adequate for samples obtained from select healthy volunteers, was unable to remove interfering substances in samples from critically ill patients. In most instances, extraneous peaks and interferences made quantitation of moxalactam impossible. This method also lacks a suitable internal standard; thus, reproducibility and precision are difficult to achieve. Finally, the previous method requires a separate chromatographic procedure utilizing PIC[13] reagents for the determination of moxalactam in urine.

The present procedure has advantages over existing techniques in that it is more specific than previous methods as well as useful for quantitating both the D and the L isomers of moxalactam. It was tested rigorously during the course of a clinical trial in critically ill patients hospitalized for a variety of disease states including renal and hepatic failure. These patients were receiving numerous concurrent medications and no interferences were seen in any of these samples. Some compounds that were specifically tested and found not to interfere were: cephalothin, cefamandole, cefazolin, cephapirin, cephalexin, caffeine, cimetidine, theophylline, tobramycin, clindamycin, furosemide, dicloxacillin, methicillin, amoxicillin, ampicillin, penicillin G, nafcillin, and trimethoprim.

The effect of disease state on the preferential elimination of one of the isomeric forms of some compounds, such as warfarin and propranolol, is well known. Although the clinical significance of discriminating moxalactam D and L isomers is unknown, this procedure is capable of addressing the question in the course of moxalactam clinical trials.

Carbenicillin Prodrugs: Kinetics of Intestinal Absorption Competing Degradation of the α-Esters of Carbenicillin and Prediction of Prodrug Absorbability from Quantitative Structure–Absorption Rate Relationship

AKIRA TSUJI *×, ETSUKO MIYAMOTO §, TETSUYA TERASAKI *, and TSUKINAKA YAMANA ‡

Received June 8, 1981, from the *Faculty of Pharmaceutical Sciences,‡ Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan, and the §School of Pharmacy, Hokuriku University, Kanagawa-machi, Kanazawa 920-11, Japan. Accepted for publication July 17, 1981.

Abstract □ The intestinal absorption of α-esters of carbenicillin disodium, carbenicillin phenyl sodium, and carbenicillin indanyl sodium was investigated using the *in situ* rat intestinal recirculating method. In the *in situ* intestinal lumen at pH 7, two prodrugs were rapidly converted to poorly absorbable carbenicillin, possibly by the action of intestinal nonspecific esterase in competition with the slow absorption of prodrugs. At pH 5, the reduced action of esterase and the increased absorption rate after 3 hr resulted in 50 and 60% absorption of carbenicillin phenyl sodium and carbenicillin indanyl sodium, respectively. The absorption rate constants determined for both prodrugs were in good agreement with the prediction from the quantitative structure–absorption rate relationship derived from the two-compartment aqueous diffusion model.

Keyphrases □ Carbenicillin—prodrugs, kinetics of intestinal absorption, α-esters □ Prodrugs—carbenicillin, kinetics of intestinal absorption, α-esters □ Absorption, intestinal—carbenicillin prodrugs, kinetics

Carbenicillin (II) is very acid unstable and has low lipid solubility; thus, it is poorly absorbed by the GI tract after oral administration and its use is limited to parenteral administration. A series of α-carboxyl esters (I) of carbenicillin was synthesized in an attempt to overcome these disadvantages in the physicochemical properties of II and to increase oral bioavailability. These esters are designed to hydrolyze in the body to liberate II (1). The *in vitro* degradation kinetics of therapeutically useful derivatives of I, phenyl ester (carfecillin, I*a*) and indanyl ester (carindacillin, I*b*), in a wide pH range at 35° and ionic strength of 0.5 were reported previously (2). Bundgaard (3) showed the acid degradation kinetics of the same compounds at 60°. These kinetic data predicted that the β-lactam moiety of both prodrugs is six times more stable than that of II at pH 2.0 and the half-lives of the ester hydrolysis *in vitro* are 8.5 hr for I*a* and 17 hr for I*b* at pH 7.0 and 37° (2).

The present study was undertaken to evaluate the relative importance of parallel rate processes, absorption, and both chemical and enzymatic degradations (possibly proceeding at the absorption sites after oral administration of these esters) by utilizing the *in situ* rat intestinal recirculating method. The physicochemical properties of carbenicillin prodrugs were also evaluated in order to improve the GI absorption rate of the parent antibiotic by application of the structure–absorption rate relationship established previously for β-lactam antibiotics (4).

EXPERIMENTAL

Materials and Reagents—The materials, reagents, and equipment used in this study were, unless otherwise stated, the same as those used previously (2, 4). All isotonic buffer solutions were prepared with the highest reagent grade chemicals available.

Intestinal Absorption Experiments—Male albino rats (Wistar strain) weighing ~200 g, were fasted over a 20-hr period prior to the experiments, but water was given freely. The rats were anesthetized with urethan, 1.3 g/kg ip.

The intestinal recirculating absorption procedure was reported previously (4). The *in situ* loop absorption method was essentially the same as that of Perrier and Gibaldi (5) except for the use of the duodenum and for the ligation of the bile duct.

Each antibiotic solution was prepared with an isotonic buffer of pH 5 or 7 to make a final concentration of 1–4 mg/ml. Aliquots (0.1 ml) of the samples were withdrawn at appropriate intervals, diluted with distilled water, filtered through a 0.45-μm filter[1] to remove any solid materials, and analyzed.

Analytical Procedure—Samples were analyzed by UV spectrometry developed previously to quantify I and II simultaneously in a solution (2).

Table I—Percentage Residue of Carfecillin (Ia) and Carbenicillin (II) in the *In Situ* Rat Small Intestinal Loop [a]

Rat No.	Residual Ia, %	Residual II, %	Disappearance of Total Antibiotics, %
1	38.6	38.2	22.2
2	0.0	80.4	19.6
3	28.8	47.6	23.6
Mean	22.5	55.4	21.8
SD	20.1	22.2	2.0

[a] All experiments were over 1 hr. I*a* was dissolved in isotonic phosphate buffer (pH 7) and injected in a volume of 1 ml (1 mg/ml) into a 5-cm intestinal loop (duodenum).

RESULTS AND DISCUSSION

Disappearance of Prodrugs from *In Situ* Rat Intestinal Loop—It was suggested that I*a* and I*b* are both well absorbed by the GI tract and can be converted rapidly to II during absorption through the mucous membrane and/or in the blood by a nonspecific esterase (1).

The percentage of the residual I*a* and II produced after 1 hr in the *in situ* rat intestinal loop at pH 7 is shown in Table I. From previous kinetic data (2), the rate constant for the ester hydrolysis of I*a* was evaluated at 1.5×10^{-3} min^{-1} for the isotonic and 0.066 *M* phosphate buffer solution (pH 7.0) used in this study. The 55.4 ± 22.2% of *in situ* formation of II at the end of 1 hr was about six times greater than that predicted from the chemical hydrolysis rate of the phenyl ester. Because the percentage disappearance of the total antibiotics (I*a* + II) was 21.8 ± 2.0%, the result suggests that the prodrug I*a* may be absorbed as well as converted to II by the chemical hydrolysis and enzymatic action of nonspecific esterase in the intestinal fluid and/or mucosal surface of the intestine.

Kinetics of Absorption and Metabolism of Prodrugs by the *In Situ* Rat Intestine—To clarify the GI absorption of I from its kinetics, the intestinal absorption experiments were performed using the recirculating perfusion technique. The pH of the perfusion solution was maintained

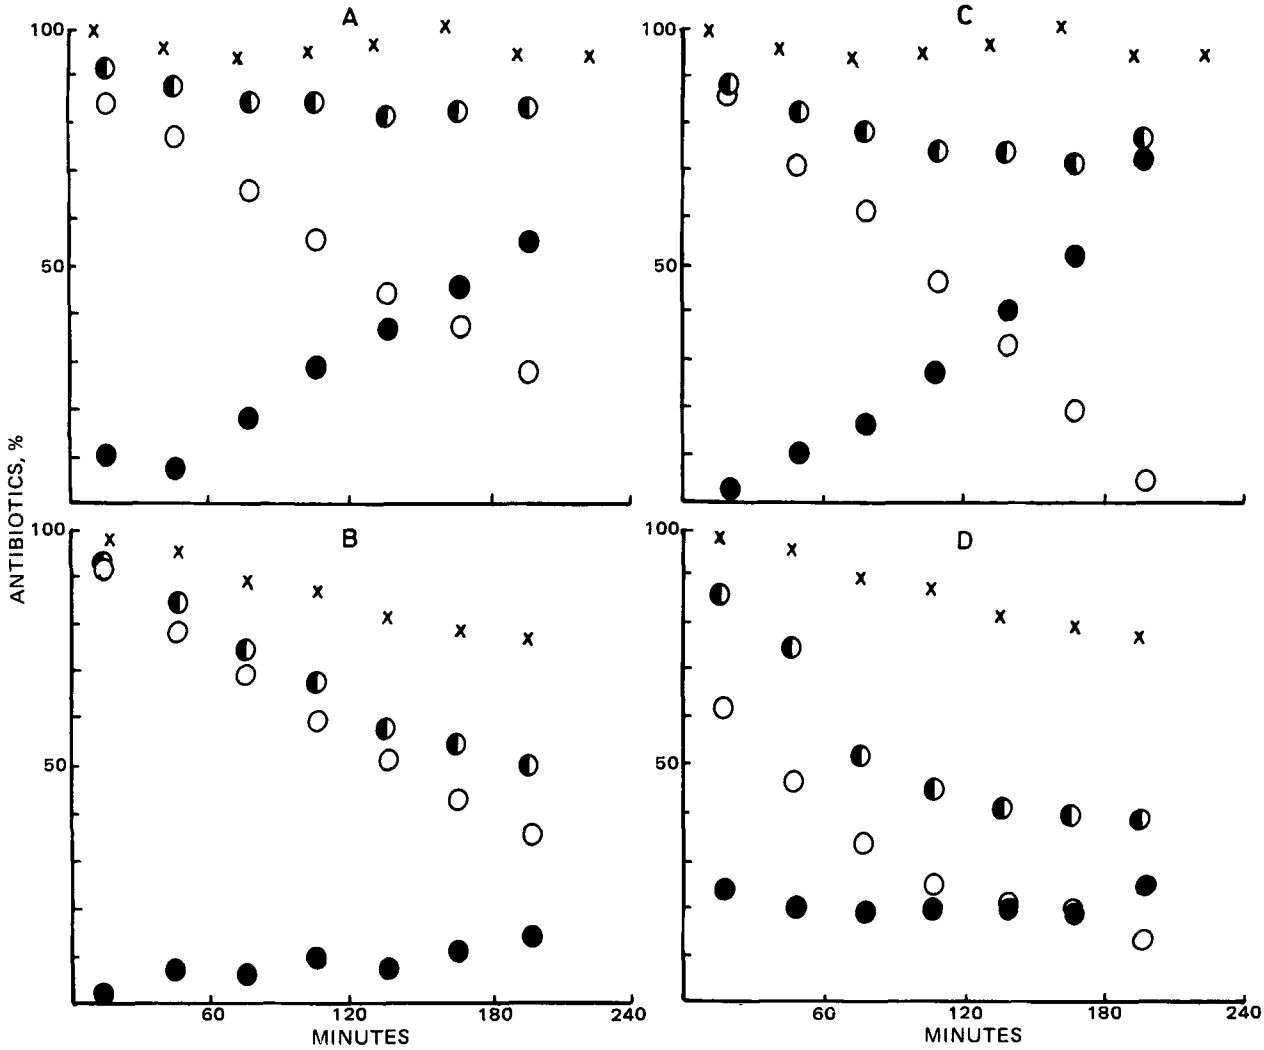

Figure 1—*Time course of absorption and metabolism of carfecillin (Ia) (A and B) and carindacillin (Ib) (C and D) during* in situ *recirculation through the rat small intestine at pH 7.0 (A and C) and pH 5.0 (B and D). Perfusion volume, 15 ml; initial concentration, 4 mg/ml (A and B), 2 mg/ml (C), and 1 mg/ml (D); flow rate, 2 ml/min. Key:* ◐, *total antibiotics;* ○, *prodrug (I); and* ●, *carbenicillin (II). The symbol* (x) *shows the experimental points for II under the same conditions.*

at a constant of pH 5.0 or 7.0 by use of a pH-stat during the absorption experiments.

Results of the lumen content analysis are shown in Fig. 1, indicating that disappearance of I at pH 7.0 proceeds to a similar extent for Ia and Ib, accompanying an increase of II up to ~50–60% after 3 hr in 15-ml of lumen perfusion solution (Figs. 1A and 1C). Interestingly the rates for total loss of I and the formation of II depend markedly on the volume of the perfusion solution. The loss of total antibiotic from 15-ml lumen solution was about 20% for Ib after 3 hr. The disappearance of II was only ~6% after 3 hr under the same condition (Fig. 1A and 1C). The decrease in the total antibiotic may be attributed mostly to the absorption of intact I. However, in the experiments with 40–50 ml of lumen solution, about 35–40% of I loss corresponded to the formation of II; the absorption of the antibiotics was negligible.

At pH 5, on the other hand, absorption was 50% for Ia and 60% for Ib but only 20% for the parent antibiotic II after 3 hr for the 15-ml solution (Figs. 1B and 1D). Under this condition, a relatively small amount (10–20%) of II was produced, probably due to the reduced action of nonspecific esterase.

From these results, the kinetic model for the absorption and metabolism of I may be derived as reported previously (6). I is absorbed by the intestine in an intact form but is partially degraded by two possible processes as shown in Scheme I. One process is a nonenzymatic degradation of β-lactam moiety to produce the penicilloic acid (III) of I and the other is both a nonenzymatic and enzymatic hydrolysis of ester linkage to form the poorly absorbable II. Compound II is also degraded to its penicilloic acid (IV) similarly to form III from I along with the slow absorption by the intestine.

If it is assumed (not being influenced by the volume change of the perfusion solution) that the absorption kinetics obey Fick's law, that enzymatic ester hydrolysis is described by Michaelis–Menten kinetics, and that all β-lactam cleavages obey apparent first-order kinetics, then the rate of each species can be written:

$$\frac{d[\mathrm{I}]}{dt} = -[k_a/V + (k_d)_1 + (k_d)_2][\mathrm{I}] - \frac{k_e(A_e/V)\,[\mathrm{I}]}{K_m + [\mathrm{I}]} \qquad \text{(Eq. 1)}$$

$$\frac{d[\mathrm{II}]}{dt} = (k_d)_1[\mathrm{I}] - [k_a'/V + (k_d)_3]\,[\mathrm{II}] + \frac{k_e(A_e/V)\,[\mathrm{I}]}{K_m + [\mathrm{I}]} \qquad \text{(Eq. 2)}$$

where [I] and [II] represent the concentration of I and II, respectively, at time t, K_m is the Michaelis constant, A_e represents the amount of enzyme, k_e is the degradation rate constant for the formation of II from the drug–enzyme complex, $(k_d)_1$ is the first-order rate constant for the nonenzymatic ester hydrolysis to produce II, $(k_d)_2$ and $(k_d)_3$ are the first-order rate constants for the nonenzymatic β-lactam cleavage reactions of I and II, respectively, k_a and k_a' are the absorption clearance (ml/time) of I and II, and V is the volume of perfusion solution. From Eqs. 1 and 2, Eqs. 3 and 4 can easily be derived (6):

$$k_{app} = k_a/V + (k_d)_2 \qquad \text{(Eq. 3)}$$

$$k_{app} = \frac{[\mathrm{I}]_{t_1} - [\mathrm{I}]_{t_2} + [\mathrm{II}]_{t_1} - [\mathrm{II}]_{t_2} - [k_a'/V + (k_d)_3]\int_{t_1}^{t_2}[\mathrm{II}]dt}{\int_{t_1}^{t_2}[\mathrm{I}]dt} \qquad \text{(Eq. 4)}$$

where subscripts t_1 and t_2 represent the sampling times. The values of

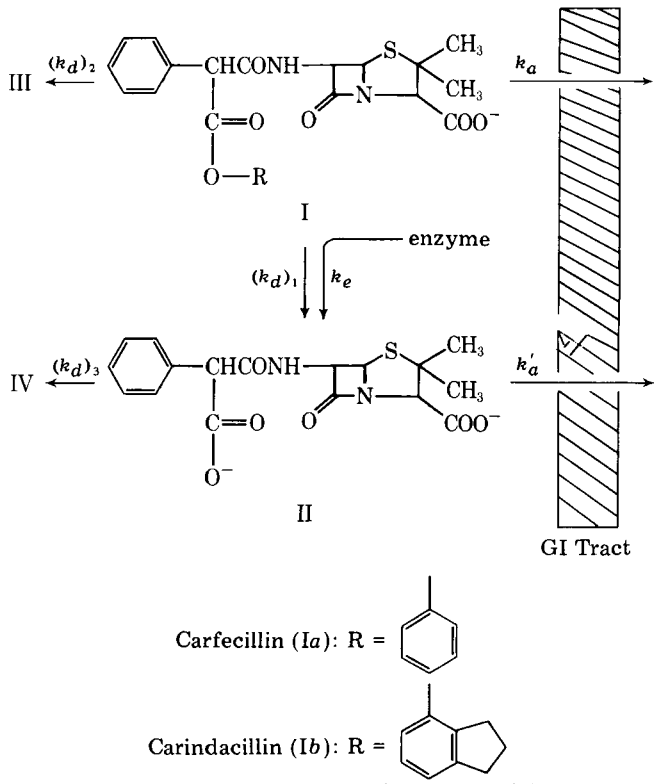
the integrals, which should be equal to the areas under the respective concentration–time curves of I and II, were calculated by the trapezoidal rule.

As shown in Fig. 2, the plots of k_{app} *versus* $1/V$ for both prodrugs gave reasonably straight lines[2]. Absorption clearances at pH 7.0 calculated from the slopes were 0.017 and 0.023 ml/min for I*a* and I*b*, respectively. Despite the 50-fold difference at maximum in the oil–water partition coefficient of the ionized species of I and the other β-lactam antibiotics (7, 8), the absorption clearance of I was very close to that (average 0.012 ml/min) of other monobasic penicillins (4). This supports the fact that the intestinal absorption rate of ionic species of monobasic β-lactam antibiotics is almost independent of their lipophilicity (4).

At pH 5, the absorption clearances were calculated to be 0.066 and 0.135 ml/min for I*a* and I*b*, respectively, according to Eqs. 3 and 4. *In vitro* degradation rate constants of $(k_d)_2 = 9.7 \times 10^{-5}$ min^{-1} and 8.9×10^{-5} min^{-1} for I*a* and I*b* and $(k_d)_3 = 4.3 \times 10^{-4}$ min^{-1}, which were evaluated at 37° and pH 5.0 from the kinetic data (2, 3, 9, 10) were used in the calculations. The absorption clearance of II, k'_a, was determined to be 0.015 ml/min (Fig. 1). The prodrug absorbabilities were ~4 times larger for I*a* and 9 times larger for I*b* than that of the parent drug, II. The increased absorption rate at pH 5 with the increased lipophilicity of I may be due to the enhanced lipoidal membrane transport of undissociated species of I across the aqueous diffusion layer adjacent to the mucosal surface (11).



Scheme I—Pathways of simultaneous absorption and degradation of carbenicillin prodrug (I) in the GI.

Prediction of Penicillin Prodrug Absorbability from Quantitative Structure–Absorption Rate Relationship—A previous report (4) established that the theoretical absorption clearance, k_{theor}, for monobasic β-lactam antibiotics was generalized by the sum of the absorption clearances, $k_u + k_i$, for the undissociated and ionized species of the drug as:

$$k_{theor}\ (\text{ml/min}) = \frac{\alpha}{\sqrt{MW}}\left(\frac{f_u P_u}{\beta + f_u P_u}\right) + k_i \qquad \text{(Eq. 5)}$$

where MW is the molecular weight of the undissociated form of antibiotics, P_u is the partition coefficient of the undissociated drug between oil (*e.g.*, octanol) and water, α, and β are constants, and f_u is the fraction of undissociated species as a function of pH expressed as:

$$f_u = \frac{a_H^+}{K_a + a_H^+} \qquad \text{(Eq. 6)}$$

where a_H^+ is the hydrogen-ion activity of perfusion solution and K_a is the dissociation constant of drug. Thus, $f_u P_u$ represents the apparent partition coefficient, P_{app}, as a function of the solution pH:

$$P_{app} = f_u P_u \qquad \text{(Eq. 7)}$$

The first term in Eq. 5 was derived for k_u from the kinetic model of membrane permeation across the lipoidal barrier for the undissociated penicillin species transported through the aqueous diffusion layer adjacent to the GI membrane surface (11). With the parameters[3] α (4.62), β (35.9), and k_i (0.0115) evaluated from the absorption rates (three phenoxy derivatives and four isoxazole derivatives of penicillins) in the same experiments (4), the theoretical absorption clearances of I*a*, I*b*, and II were calculated according to Eqs. 5 and 6 as a function of lumen solution pH[4]. The results are shown in Fig. 3.

In Fig. 3, the k_a–pH profiles for penicillin V, propicillin, and dicloxacillin (4) are redrawn by conversion of the first-order absorption rate constant to its clearance using the volume (9 ml) of the perfusion solution used. The predicted values are in fairly good agreement with the experimental data for carbenicillin prodrugs and the parent drug, as well as

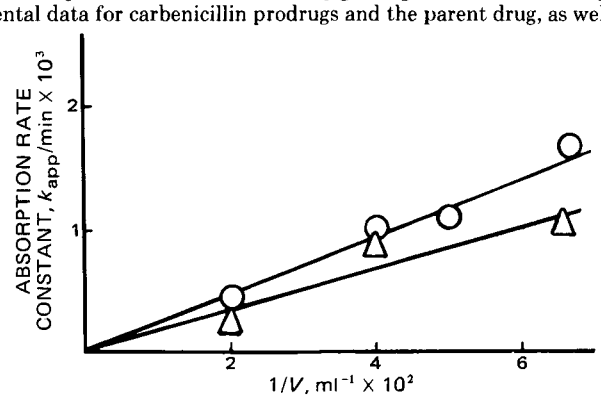


Figure 2—*Effect of the volume of perfusion solution on the absorption rates of carfecillin (Ia, △) and carindacillin (Ib, ○) from the* in situ *rat intestine at pH 7.0 under the same conditions as in Fig. 1.*

[2] For I*b*, k_{app} was reevaluated according to Eqs. 3 and 4 because the calculation in the previous paper (5) neglected the absorption rate of II.

[3] These values were evaluated from Eqs. 6, 12, 14 in Ref. 4 by changing the perfusion solution volume to 9 ml.

[4] The parameters based on these calculations are listed in Table II.

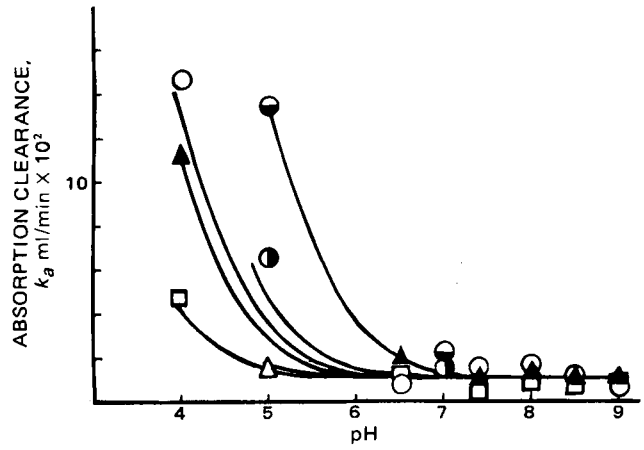

Figure 3—*Plots of the* in situ *rat intestinal absorption clearance,* k_{obs}, *of penicillins* versus *pH of the perfusion solution at 37°. The curves were generated from Eq. 5 with the corresponding parameters listed in Table II and from Ref. 4. Data for dicloxacillin, propicillin, and penicillin V were taken from Ref. 4.*

for other antibiotics. The results indicate that the prodrugs, Ia and Ib, are sufficiently lipophilic to be absorbed rapidly from the GI tract by crossing the first barrier of the aqueous diffusion layer in front of the GI membrane surface and the second barrier of the lipid membrane.

The two prodrug chemical modifications of carbenicillin increase both the GI absorption rate and the acid-stability and exhibit sufficient chemical stability of the ester bond in the GI lumen. However, the results suggest that since the ester moieties of Ia and Ib are easily subject to the intestinal enzymatic metabolism, both ester prodrugs may liberate the poorly absorbable II as a result of nonspecific esterase action accompanied by absorption to reduce both bioavailabilities. After oral dosage in humans, 15–30% for Ia and 35–40% for Ib are recovered as II in urine compared with 75–100% after II intravenously (12). The relatively low recovery for I may be attributed to incomplete absorption and/or a first-pass effect. But II itself can not achieve a large urinary recovery after an oral dose.

A Dissolution Anomaly Involving Ticrynafen in Simulated Intestinal Fluid without Enzyme

ELISABETH S. RATTIE, JOSEPH G. BALDINUS, LOUIS J. RAVIN ˣ, INA B. SNOW, and MIRZA M. A. BEG

Received March 2, 1981, from the *Research and Development Division, Smith, Kline & French Laboratories, Philadelphia, PA 19101.* Accepted for publication July 20, 1981.

Abstract □ Data are presented showing that the anomalous dissolution behavior of ticrynafen in simulated intestinal fluid without enzyme is due to the presence of potassium ions in the dissolution medium. Solubility studies indicate that an insoluble 1:1 complex is formed between ticrynafen and its potassium salt. This complex apparently creates an insoluble barrier that prevents complete dissolution of ticrynafen. To determine whether this might also occur in clinical use, a three-way cross-over study in 12 subjects was done. Data from this investigation show that concomitant administration of ticrynafen tablets and potassium in the form of a commercial supplement does not adversely affect bioavailability.

Keyphrases □ Ticrynafen—dissolution anomaly in simulated intestinal fluid without enzyme, potassium ions □ Potassium ions—complex with ticrynafen, dissolution anomaly in simulated intestinal fluid without enzyme □ Dissolution—anomaly, ticrynafen in simulated intestinal fluid without enzyme

Considerable effort has been devoted to the development of *in vitro* dissolution test methods that attempt to characterize the *in vitro* dissolution rate-controlled absorption of drugs administered in solid dosage forms. Unfortunately, the lack of understanding surrounding the many variables that can influence the *in vivo* dissolution, and possibly the subsequent absorption, make predictions based on *in vitro* data alone extremely difficult. The nature of the dissolution media can sometimes influence *in vitro* dissolution behavior dramatically and be misleading with regard to *in vivo* performance. The present study shows how the presence of potassium ions in simulated intestinal fluid without enzyme retarded drug dissolution without affecting the *in vivo* performance of ticrynafen[1].

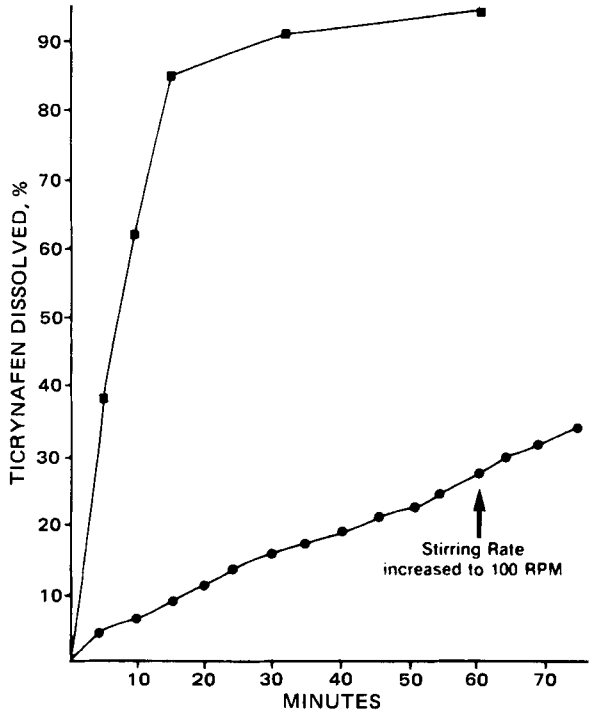

Figure 1—*Effect of stirring rate on the dissolution behavior of 500-mg ticrynafen tablets in simulated intestinal fluid without enzyme. Key: ●, 50 rpm; ■, 100 rpm.*

Dissolution Media—The following dissolution media were used in the dissolution studies: simulated intestinal fluid without enzyme USP (0.05 *M*), 0.05 *M* potassium phosphate buffer (pH 7.5), 0.05 *M* sodium phosphate buffer (pH 7.5), 0.05 *M* tromethamine buffer (pH 7.6). Buffers were freshly prepared prior to all dissolution studies.

Dissolution Methodology—The tablet dissolution profiles were determined in various buffer systems using Method II as described in the official compendia (1). The amount of drug dissolved with time was monitored by circulating the filtered dissolution media through a flow cell in a recording spectrophotometer[3] at 355 nm and returning it to the vessel. The ticrynafen absorbance *versus* time represents the dissolution profile of the tablet. The fractional amount of drug released as a function of time was determined by dividing the absorbance at any particular time by the absorbance after complete dissolution. A standard solution of ticrynafen (500 mg in 900 ml of dissolution medium) was utilized in the flow-cell apparatus to determine the absorbance when the tablet dissolution was complete.

Complexation Studies—A solubility method described previously (2) was utilized. Excess amounts of ticrynafen were placed in screw-capped glass vials. A 10-ml aliquot of various known concentrations of potassium ticrynafen was added to the vials. The samples were rotated overnight in a constant temperature bath at 25 ± 0.5°. An aliquot was removed from the vials, diluted with the appropriate solvent, and analyzed spectrophotometrically at 355 nm.

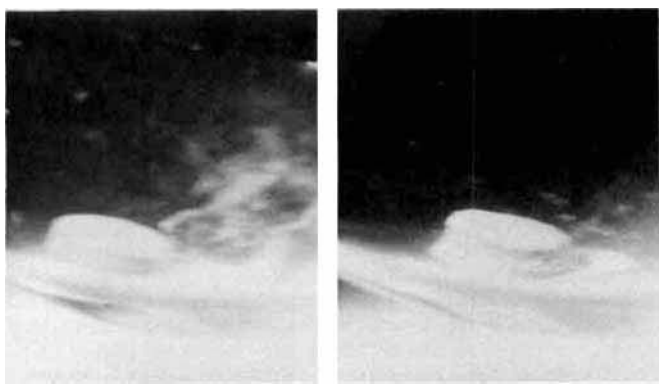

Figure 2—*Ticrynafen tablet (500 mg), initially and after 60 min in simulated intestinal fluid without enzyme.*

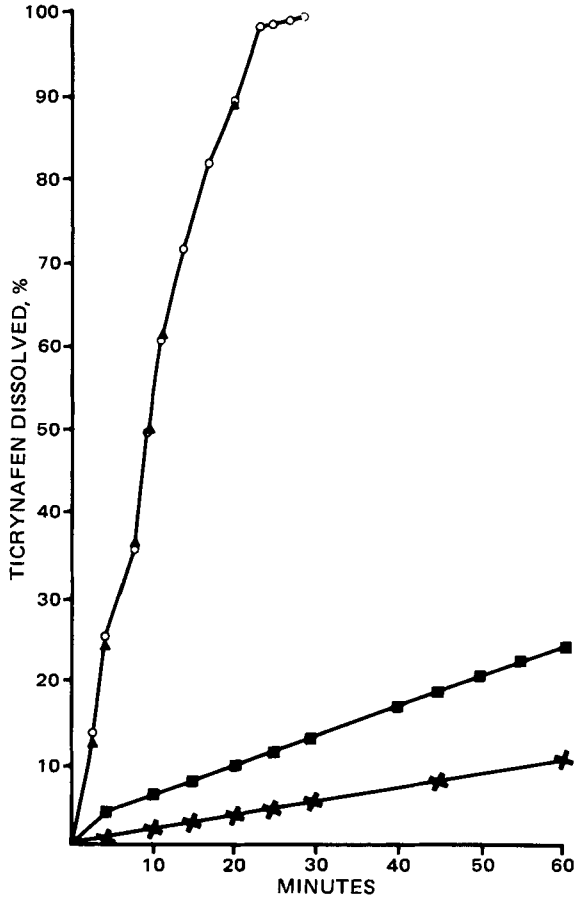

Figure 3—*Dissolution behavior of 500-mg ticrynafen tablets in simulated intestinal fluid without enzyme (■), 0.05 M potassium phosphate solution (×), 0.05 M sodium phosphate solution (○), and 0.05 M tromethamine solution (▲).*

RESULTS AND DISCUSSION

Dissolution Studies—Figure 1 shows the results of dissolution studies conducted with 500-mg ticrynafen tablets by USP Method II in simulated intestinal fluid without enzyme at 37° at 50 and 100 rpm, respectively. There appears to be a marked dependency on agitation. Physical observations during the dissolution test indicate that the tablet appeared to develop a crusty layer at the surface at 50 rpm. This effect is shown in Fig. 2. Since the ticrynafen tablets showed poor dissolution behavior at 50 rpm and developed the crust-like surface, it was thought that something in the system might be causing an interaction that resulted in poor dissolution. The effect also seemed dependent on agitation intensity, since complete tablet dissolution was achieved in 30 min at 100 rpm. In addition, increased agitation intensity had little, if any, effect on the dissolution behavior after the apparent interaction took place.

Additional dissolution studies were then conducted with several alternate buffer systems. Figure 3 shows the results of dissolution studies with 500-mg ticrynafen tablets in 0.05 *M* potassium phosphate, sodium phosphate, and tromethamine buffers and simulated intestinal fluid without enzyme, respectively. It is apparent that the presence of potassium ions in the dissolution media had a significant effect on the dissolution behavior of ticrynafen.

Since ticrynafen is usually administered to patients on concomitant potassium therapy, experiments were conducted to determine what effect

Table I—Summary of Blood Level and Urinary Excretion Data

Regimen	Blood Level *AUC*	Percentages Excreted
Tablet	173.67	30.20
Solution	170.16	30.49
Tablet with 20 meq potassium	165.83	31.55

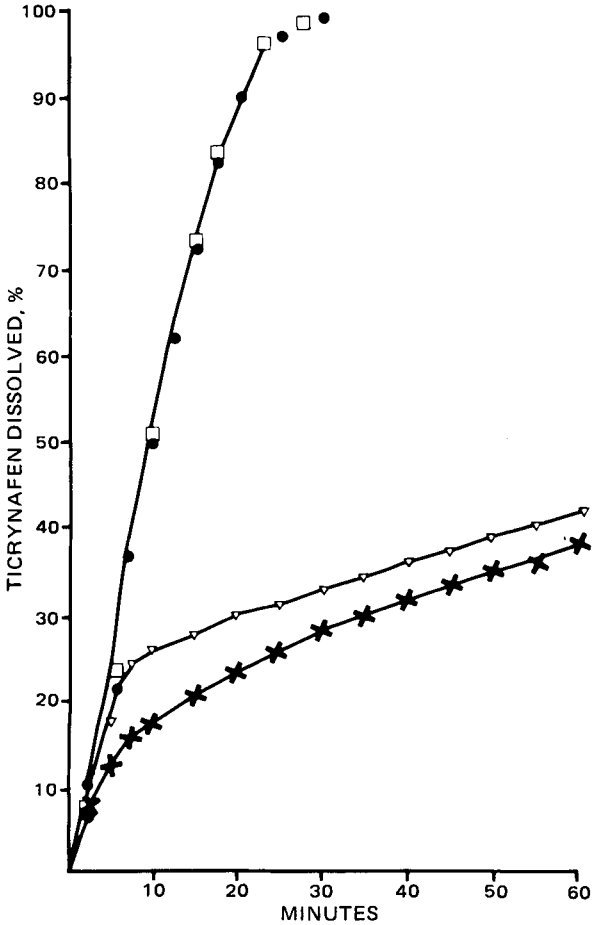

Figure 4—*Effect of the addition of potassium and sodium ions on the dissolution behavior of 500-mg ticrynafen tablets in 0.05* M *tromethamine solution (□), 0.05* M *tromethamine solution with 20 meq potassium added initially (×), 0.05* M *tromethamine solution with 20 meq potassium added after 5 min (▽), 0.05* M *tromethamine solution with 20 meq sodium added after 5 min (●).*

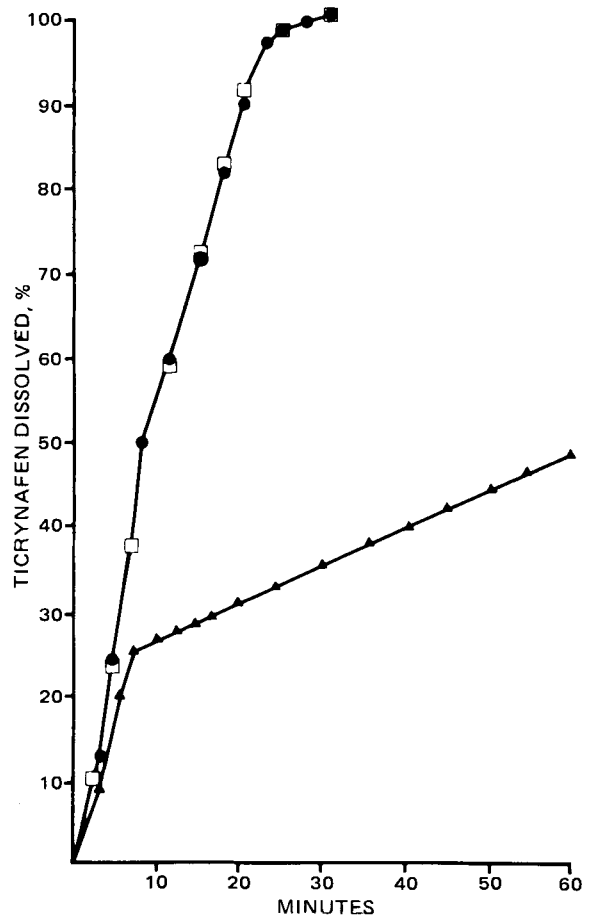

Figure 5—*Effect of the addition of potassium and sodium ions on the dissolution behavior of ticrynafen tablets (500 mg) in 0.05* M *sodium phosphate solution (●), 0.05* M *sodium phosphate solution with 20 meq potassium added after 5 min (▲), 0.05* M *sodium phosphate solution with 20 meq sodium added after 5 min (□).*

the addition of potassium to the tromethamine and sodium phosphate buffer solutions would have immediately and after 5 min on the dissolution behavior of ticrynafen. Sodium ions were also added in a separate experiment. Figures 4 and 5 show the results of these studies. The data indicate that the addition of 20 meq of potassium has a significant effect on the dissolution behavior of ticrynafen and appears to be more pronounced when the potassium ions are added immediately. The addition of 20 meq of sodium has no apparent effect.

To determine if this physicochemical phenomenon was reversible, dissolution studies were done in which 500-mg ticrynafen tablets were placed in 0.05 *M* potassium phosphate buffer. After 15 min the buffer solution was replaced carefully with 0.05 *M* tromethamine buffer solution and the dissolution test was continued for 1 hr. The results of these studies are shown in Fig. 6. It is apparent that this effect is not completely reversible. After changing the medium, dissolution did not proceed at the rate observed in tromethamine buffer. Figure 6 also includes a dissolution study in which the tablet was accidentally disturbed during the transfer of dissolution medium. This apparently created a fresh surface of drug which resulted in increased dissolution. In the case where the tablet was not disturbed the effect was less dramatic. However, in both cases the dissolution of the tablet after the exchange of media did not approach its dissolution in 0.05 *M* tromethamine buffer.

Complexation Studies—Previous reports showed that organic acids can interact with their alkali salts to form soluble and insoluble complex species (3, 4). Since the presence of potassium ions in the dissolution media had such a dramatic effect on the dissolution behavior of ticrynafen it was thought that complex formation might be responsible. Solubility studies were conducted to detect this interaction (Fig. 7). Initially, solubility increased which suggested an interaction had taken place. As more complex formed, the system became saturated with respect to the complex, and precipitated from solution. This is shown by the plateau region in Fig. 7. The pH of the system in this plateau region remained constant even with the continued addition of potassium ticrynafen solution. Since the slope of the initial solubility curve is 2, a complex having a stoichiometry of 1:1 is formed. If no complex was formed this initial slope should be 1, since the appearance of ticrynafen in solution was followed spectrophotometrically.

Samples of the complex were isolated from the saturated solution and analyzed for potassium by atomic absorption spectroscopy. A potassium content of 4.54% was found, which compares favorably with the theoretical potassium content of 4.5% calculated on the basis of a 1:1 complex.

The solubility increases at ~0.01 *M* potassium ticrynafen concentration indicating that the complex is probably soluble in an excess of the potassium ticrynafen solution. This apparently explains the dissolution behavior. During the dissolution of ticrynafen in systems containing potassium ions, a conversion of the free acid to the potassium salt takes place. Apparently, under the conditions of the study, the complex forms at 50 rpm more readily, creating an insoluble barrier which further retards dissolution. However, at 100 rpm the conditions are such that the optimum concentration for the formation of the complex is exceeded rapidly, due to the rapid dissolution of the drug at this agitation intensity.

Bioavailability Studies—Bioavailability studies were conducted to determine the effect of concomitant potassium therapy on the availability of ticrynafen from 500-mg ticrynafen tablets. A three-way cross-over study with a 1-week wash-out period between regimens was conducted in 12 normal, randomly selected adults. The following regimens were tested: (*a*) a 500-mg ticrynafen tablet, (*b*) a solution containing 500 mg of ticrynafen, (*c*) a 500-mg ticrynafen tablet with 20 meq of potassium administered simultaneously (15 ml of a 10% potassium elixir). Blood samples were collected at 0.5, 1, 2, 3, 4, 6, 8, 12, and 24 hr after the administered dose. Urine was collected for 24 hr before and 24 after dosing. Fractional urine collections after administration of the regimens were obtained at 0–4, 4–6, 8–12, and 12–24 hr. The concentration of ticrynafen in plasma and urine samples was determined by an automated high-

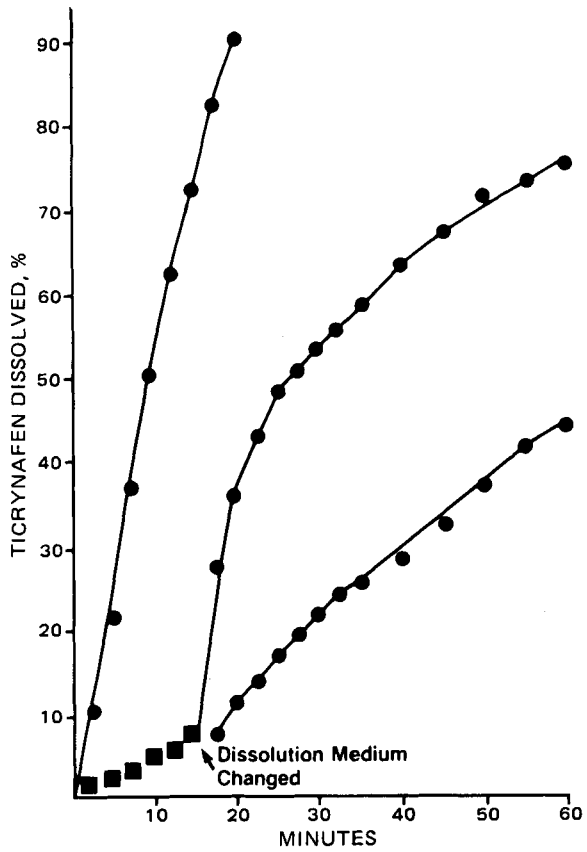

Figure 6—*Effect of media exchange on the dissolution behavior of ticrynafen tablets (500 mg) in 0.05* M *tromethamine solution (●), 0.05 M potassium phosphate solution for 15 min then replaced with 0.05* M *tromethamine solution (■).*

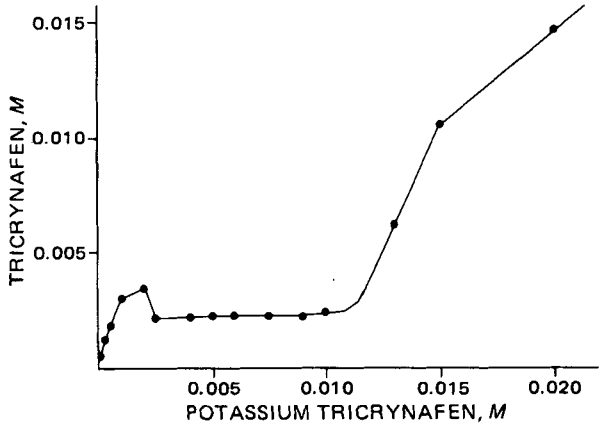

Figure 7—*Effect of potassium ticrynafen on the equilibrium solubility of ticrynafen.*

pressure liquid chromatographic procedure (5). The extraction and analysis of plasma and urine were accomplished in a completely automated fashion using an automatic HPLC system[4]. Figure 8 illustrates the blood level profiles obtained for the various dosage regimens. The area under the blood level curves and the urinary excretion were used as a measure of bioavailability (Table 1). There were no statistically significant differences between the regimen means for the area under the blood level curves or the percentage excreted in the urine when a t test was applied at the 95% confidence interval. Thus, the concomitant use of potassium supplements should not affect the bioavailability of ticrynafen in clinical use.

Metronidazole Phosphate—A Water-Soluble Prodrug for Parenteral Solutions of Metronidazole

M. J. CHO ˣ, R. R. KURTZ, C. LEWIS, S. M. MACHKOVECH, and D. J. HOUSER

Received January 12, 1981, from the *Pharmaceutical Research and Development Division, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication July 29, 1981.

Abstract □ To develop a parenteral solution of relatively water-insoluble metronidazole (2-methyl-5-nitro-1*H*-imidazole-1-ethanol), its phosphate ester was synthesized *via* two routes. One route utilized 2-cyanoethyl phosphate and the other utilized pyrophosphoryl tetrachloride. The first method used dicyclohexylcarbodiimide as a coupling agent and the cyanoethyl group was removed under mild alkaline conditions. The second method was a one-step procedure in which free acid of metronidazole phosphate was isolated as a crystalline solid. The solubility of metronidazole in various solvents was determined at 25°. From the pH-dependence of its aqueous solubility, the pKa of the conjugate acid of metronidazole was estimated to be 2.62, which agreed well with the pKa values of other nitroimidazoles. Metronidazole phosphate behaved as a zwitterionic compound in an acidic medium with a minimum solubility at pH 2.0. At pH 7, its solubility was ~50 times that of metronidazole. The phosphate ester was so soluble at pH higher than 7 that it was difficult to measure the solubility accurately. In human serum, the hydrolysis of metronidazole phosphate followed zero-order kinetics at an initial concentration of 0.25 mg/ml or higher, presumably due to enzyme saturation (0.035 mg/ml/hr at 37°). A reversed-phase HPLC procedure was adopted to monitor the appearance of metronidazole and the disappearance of metronidazole phosphate. Subcutaneous administration of metronidazole phosphate to rats produced a blood level of bioactivity comparable to that observed after administration of metronidazole.

Keyphrases □ Metronidazole phosphate—a water-soluble prodrug for parenteral solutions of metronidazole □ Prodrugs—water-soluble, metronidazole phosphate for parenteral solutions of metronidazole □ Solubility—metronidazole phosphate, water-soluble prodrug for metronidazole

Although metronidazole is associated with some controversy regarding its carcinogenicity in rodents and mutagenicity in bacteria (1–6), it is often the drug of choice for the treatment of certain anaerobic infections, particularly *Trichomonas vaginalis* (7–21). Presently, the drug is available in the U.S. only in an oral dosage form (22). Parenteral dosage forms for a single injection are not available, presumably because of the relatively low solubility of metronidazole in water (~10 mg/ml at 25°). Sterile solutions for infusion are, however, available in other countries[1]. These preparations usually call for infusion of 100.0 ml of a 5 mg/ml solution. To overcome the solubility problem in formulating a parenteral solution, a prodrug approach was adopted in the present report. A water-soluble derivative was prepared and administered, which can be quantitatively converted to metronidazole by specific and/or nonspecific hydrolytic enzymes present in the body.

BACKGROUND

For some drugs with alcoholic functional groups, hemiesters of dicarboxylic acids are derivatives with desirable aqueous solubility and facile enzymatic cleavage in the blood. Parenteral dosage forms of hydrocortisone[2], methylprednisolone[2], and chloramphenicol[3] are all hemiester products. In the case of metronidazole, the monosuccinate ester is in the patent literature (23). One disadvantage associated with such monoesters of dicarboxylic acids is that they are not stable enough in aqueous solutions to provide a satisfactory shelflife for a parenteral solution (less than 10% decomposition within 2 years). Even without catalytic species from buffers, spontaneous hydrolysis of a simple ester prevents formulation in aqueous media. In the case of monosuccinates, hydrolysis is expected to be even faster because of the intramolecular catalysis from the remaining carboxylic acid and/or carboxylate anion (24).

The monophosphate of a drug with an alcoholic group carries two phosphoric acid functions with pKa values in the range of 2 and 6.5, and is freely soluble at physiological pH 7.4. In the past, phosphate esters have been used in preparing parenteral dosage forms of certain drug compounds (25) such as clindamycin, lincomycin, diethylstilbestrol, carboxybenzylpenicillin, hydroxysteroids, and trichloroethanol. Since these phosphate esters were found to be active *in vivo*, it was hoped that metronidazole phosphate also would be bioequivalent to or as bioavailable as the parent drug compound. The serum hydrolysis of metronidazole phosphate was studied to confirm that it regenerates metronidazole in the blood stream after intramuscular or intravenous injection within a reasonable period of time. Since phosphate esters are generally quite stable at neutral pH (26), metronidazole phosphate was expected to be stable enough to be prepared as a parenteral solution with an acceptable shelflife at an ambient temperature. The bioavailability of metronidazole from the phosphate ester prodrug was determined in rats.

EXPERIMENTAL

Solubility of Metronidazole and Metronidazole Phosphate—A large excess of metronidazole was added to a series of 7-ml vials containing 5.0 ml of various solvents. They were shaken continuously for 24 hrs in a waterbath at 25 ± 0.2°, and filtered through disposable pipets with tips that were tightly packed with glass wool. An aliquot of the filtrate was evaporated under a nitrogen stream. The residue was redissolved in water and after proper dilution the concentration was determined from the absorbance[4] at 320 nm.

The apparent aqueous solubilities of metronidazole and its monophosphate also were determined at various pH valves in a similar manner. In the latter case, the phosphate ester free acid was used; hence, at higher pH values, a downward pH drift was noted as the solubility equilibrium was attained. In such a case, the desired pH was maintained by intermittently titrating the sample with concentrated sodium hydroxide solution. In both cases, the concentration of solutes was determined by an

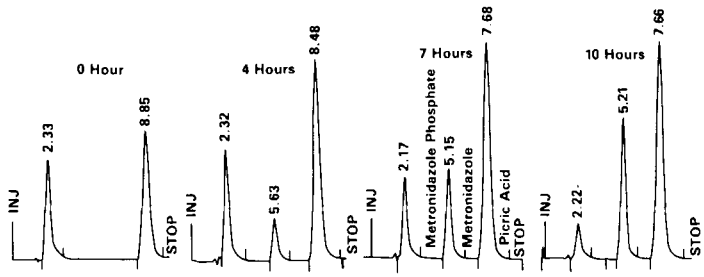

Figure 1—*Reversed-phase HPLC analysis for the serum hydrolysis of metronidazole phosphate to metronidazole at 37°. The samples were obtained after 0, 4, 7, and 10 hr of hydrolysis at an initial concentration 0.50 mg/ml. Numbers by the peaks are the retention times in minutes. Picric acid served as an internal standard.*

HPLC procedure. Buffers used in this series of experiments were hydrochloric acid, chloroacetate, acetate, and phosphate systems.

Synthesis of Metronidazole Phosphate (Method A)—This method essentially followed the literature procedure in which 2-cyanoethyl phosphate was used in preparing phosphate esters (27). The barium salt of 2-cyanoethyl phosphates (16.16 g, 0.05 mole) was added to a suspension of a cationic exchanger[5] (70 ml in 150 ml water), and stirred until the solution was completed. The entire suspension was poured into a column containing the same resin (50 ml), and the column was eluted with water (300 ml). The eluent plus pyridine (~30 ml) was evaporated under vacuum at 40°, and the residue was dried further by evaporation with anhydrous pyridine. Finally the residue was dissolved in 50 ml of dry pyridine.

Metronidazole (3.42 g, 0.02 mole) and the 2-cyanoethyl phosphate stock solution (40 ml, 0.04 mole) were mixed and concentrated under vacuum. After being dried completely, dicyclohexylcarbodiimide (20.6 g, 0.1 mole)[5] in pyridine (180 ml) was added, and the reaction mixture was kept in the dark at room temperature for 2 days. Water (350 ml) was added and dicyclohexylurea was filtered off 2 hr later. The filtrate was taken up into a cationic exchanger suspension[6] (60 ml), stirred for 20 min, and filtered. After concentration, the filtrate was subject to a silica gel liquid chromatographic separation[7] using methanol–water–acetic acid (100:2:1) as the mobile phase. UV absorption of the eluent was continuously monitored at 320 nm. The fraction between 1.3 and 2.0 liter was combined and concentrated to 20 ml.

The solution was then titrated with ~31 ml of 1.0 *N* KOH over 30 min

at 45° maintaining the pH at ~10–11. After another 45 min at 45°, the solution was neutralized with 1.0 *N* HCl. After evaporation, the solid residue was triturated with methanol and filtered. The filtrate was again evaporated to the crude product, which was recrystallized twice from 95% ethanol (3.23 g; 50% yield), mp >180°; NMR (methanol-d_4): δ 7.85 (s, 1H, C-4), 4.5 and 3.9 (t, 2H each, —CH_2—CH_2— at N-1), and 2.5 (s, 3H, C-2) ppm; IR (Nujol) ν_{max}: 3200 (H_2O), 1525 (—NO_2), 1250 (phosphate), and 980 (phosphate) cm^{-1}; Karl Fischer water 6.91%.

Anal.—Calc. for $C_6H_8N_3O_6K_2P \cdot 1.35\ H_2O$: C, 20.50; H, 3.07; N, 11.95; O, 33.45; K, 22.24; P, 8.81. Found: C, 20.07; H, 3.14; N, 10.76; K, 23.04.

Synthesis of Metronidazole Phosphate (Method B)—Pyrophosphoryl tetrachloride was prepared following a literature procedure (28). Metronidazole (5 g, 0.029 mole) was dissolved in tetrahydrofuran (375 ml), stirred, and cooled to −25°. The pyrophosphoryl tetrachloride (12 ml) was then added, and the resulting mixture was stirred at −25° for 1 hr. The mixture was then poured into ice water (200 ml), stirred well, and the solvent was evaporated under vacuum. The resulting oil was triturated with acetonitrile, then seeded and stirred with 95% ethanol (200 ml) to crystallize 6.0 g of metronidazole monophosphate free acid (82% yield), mp 237–238°; IR (Nujol) C_{max}: 3130, 2620, 2300, 1140, 1070, 945, and 865; equivalent weight 125 by titration.

Anal.—Calc. for $C_6H_{10}N_3O_6P$: C, 28.69; H, 4.01; N, 16.73; P, 12.34. Found: C, 28.70; H, 4.20; N, 17.04; P, 12.04.

Metronidazole monophosphate free acid (4.35 g; 0.017 mole) was dissolved in water (40 ml) and titrated with 1.0 *N* KOH to pH 7.20. The resulting solution was freeze-dried to give 6.2 g white powder, which was recrystallized from 95% ethanol to give dipotassium salt hydrate.

Anal.—Calc. for $C_6H_8N_3O_6K_2P \cdot 4H_2O$: C, 17.98; H, 4.50; N, 10.48; P, 7.72. Found: C, 17.99; H, 4.06; N, 11.06; P, 7.88.

Serum Hydrolysis of Metronidazole Phosphate—To each of three 15-ml test tubes with a screw cap were added 0.50, 0.25, or 0.10 ml of a metronidazole phosphate stock solution in water (10.0 mg/ml) and 9.50, 9.75, or 9.90 ml human serum at 37°, respectively. The tubes were shaken immediately and kept at 37 ± 0.2°. At proper intervals, 0.50-ml aliquots were transferred to a series of 10-ml centrifuge tubes containing 2.0 ml of methanol. After being shaken thoroughly, samples were kept at −20° until analysis. Just prior to analysis, 0.05 or 0.20 ml of a picric acid stock solution in water (1.56 mg/ml) was added, mixed thoroughly, and centrifuged. The supernate was analyzed directly by HPLC. A typical res-

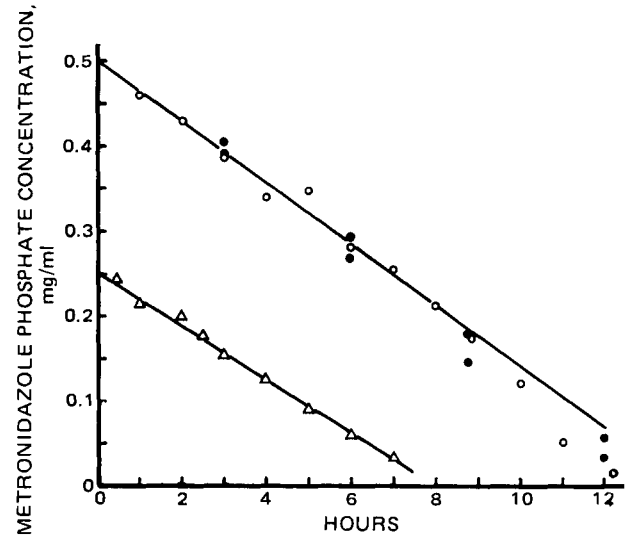

Figure 3—*Serum hydrolysis of metronidazole phosphate at 37° at two initial concentrations. Data obtained from the human serum of two volunteers are represented as open and closed symbols, respectively.*

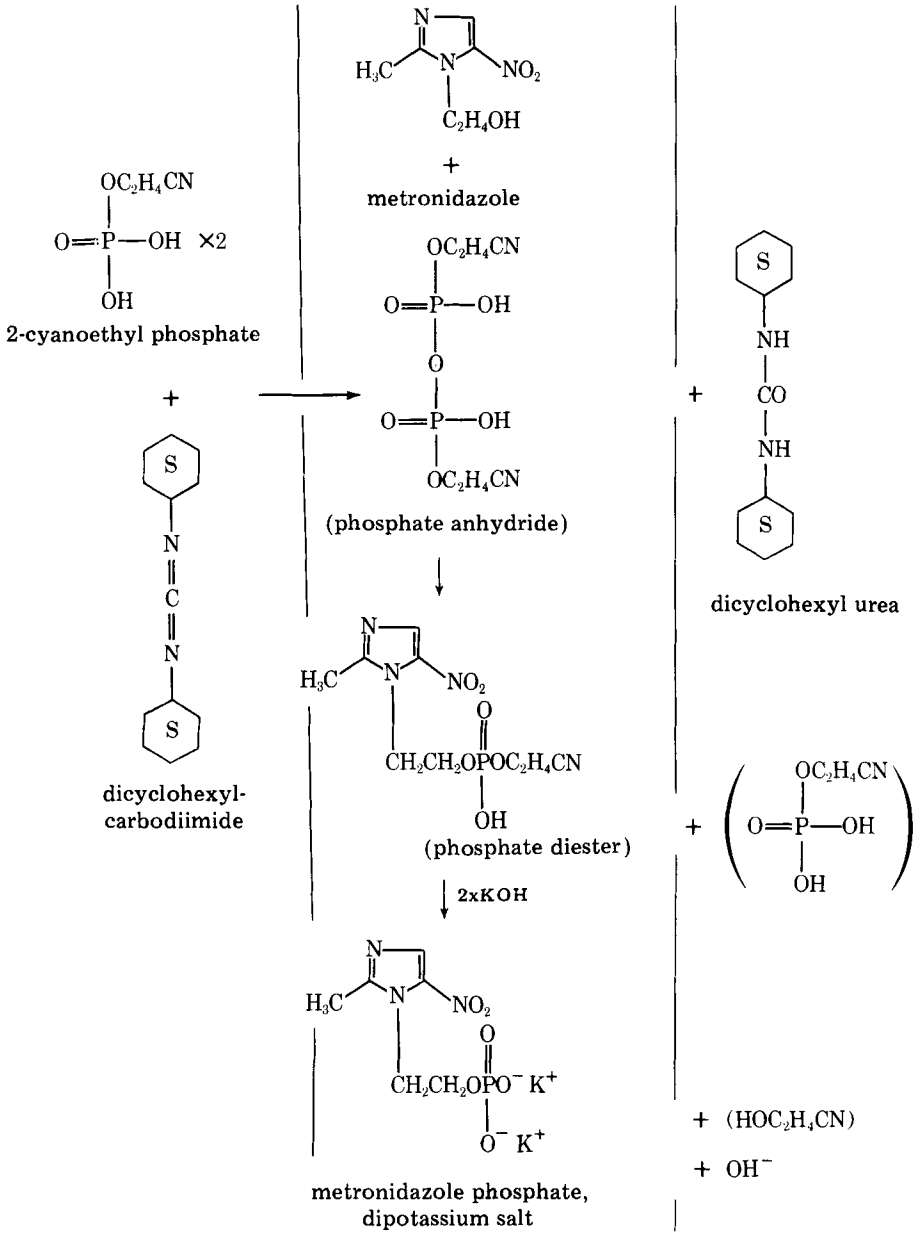

Scheme I—Synthesis of metronidazole phosphate.

olution of metronidazole phosphate and metronidazole is shown in Fig. 1. The following chromatographic conditions were used with a commercially obtained column and equipment[8]: mobile phase, 0.10 *M* phosphate buffer (pH 7.0) and methanol (90:10); pressure, 1500 psi; flow rate, 0.50 ml/min; column temperature 50°; λ, 317 nm; attenuation, 0.08–0.16 absorbance unit; sample size, 5–9 μl.

Bioavailability Studies in Rats—A single 40 mg/kg dose of metronidazole phosphate dipotassium salt was administered subcutaneously to each of three male rats weighing 190–210 g. These animals were fasted (except for water) for 24 hr prior to and during the experiments. Similarly, the parent compound, metronidazole, was administered to three rats. In both cases, the drugs were dissolved in 10% aqueous dimethylformamide.

At a given time after the drug administration, blood was withdrawn by clipping a portion of the tail. Microbiological assay disks[9] were saturated with the blood sample, placed on *C. perfringens*[10] seeded assay agar, and incubated anaerobically at 37°. The size of the inhibition zone was then measured to the nearest millimeter and the metronidazole concentration was determined from a standard curve. The area under a curve on the plot of blood concentration *versus* time was calculated by the trapezoidal rule using a digital computer.

RESULTS AND DISCUSSION

Physical Properties of Metronidazole and Metronidazole Phosphate—The solubility of metronidazole in various solvents is listed in Table I; the average of duplicate determinations is reported. In general, basic polar solvents such as tetrahydrofuran and dioxane dissolve metronidazole well, presumably through hydrogen binding. On the other hand, metronidazole phosphate was found to be freely soluble in water. Its dipotassium salt is also soluble in methanol and hot ethanol.

The pH dependence of the solubility of metronidazole at 25 ± 0.2° is shown in Fig. 2, from which the apparent pKa of metronidazole was estimated as follows: from $S = S_0[1 + K_a/(H^+)]$, in which S and S_0 are the pH dependent apparent and intrinsic solubilities, respectively, $S = 2S_0$ when $(H^+) = K_a$ (30). A value of 2.62 was obtained for the pKa of the protonated N-1. Compared with imidazole (pKa ~7), metronidazole is a much weaker base. This is because of the adjacent —NO_2 group at C-5. Table II lists the pKa values of some structurally related compounds reported in the literature (31). As expected, electron-donating alkyl groups at N-1 or C-2 position of imidazole increase the pKa value but this effect is overridden by the adjacent —NO_2 group (*e.g.*, 1-methyl-5-ni-

[8] DuPont Model 830 HPLC unit was equipped with a DuPont Model 837 spectrophotometer, a Hewlett-Packard Model 3380A integrator, and an automatic injector valve described elsewhere (29). The column used was a Zorbax ODS column from DuPont (2.1 mm i.d. × 30 cm).

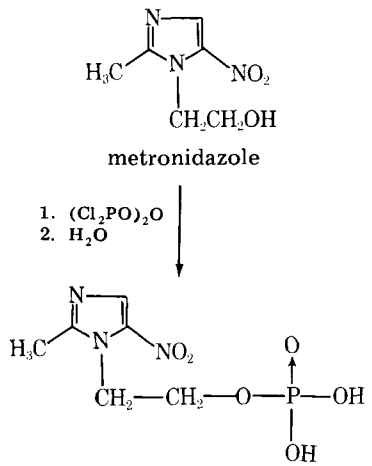
troimidazole). Interestingly, the electron-withdrawing effect through an induction effect appears less significantly than through a resonance interaction (*e.g.*, 1-methyl-4- and 5-nitroimidazole).

Since the first pKa of the two remaining phosphoric acid functions should be close to 2 and since that of protonated N-1 is in the range of 2.5, metronidazole phosphate should predominantly exist as a zwitterion at pH ~2.5. Accordingly, the apparent solubility of the prodrug shows its minimum at pH 2 (Fig. 2). Note, however, that the solubility of the prodrug exceeds 730 mg/ml, equivalent to 500 mg of metronidazole/ml, at pH 7.0, approximately 50 times the metronidazole solubility. As pH increases further, the solubility of metronidazole phosphate increases again as the second phosphoric acid undergoes ionization. Thus, it was possible to formulate the prodrug at a concentration of metronidazole desired in clinical studies, in a desired volume, at a physiologically acceptable pH.

During the measurement of the melting point of metronidazole phosphate dipotassium salts, it was noted that the compound undergoes dehydration at ~90°. This process was seen clearly when a sample suspended in silicone oil was heated. Under microscope, the formation of a distinctive water phase from the dehydration was observed as the temperature approached 90°. Thermal gravimetric analysis, differential scanning calorimetry, and Karl Fischer titration were adopted for further characterization. After dehydration, the compound decomposed at ~180°. Such thermal behavior, dehydration of nonstoichiometric amount of water, and gradual decomposition, is commonly found among other salts of phosphate esters (32).

Synthesis of Metronidazole Phosphate—Method A described earlier employed that 2-cyanoethyl phosphate route in which dicyclohexylcarbodiimide was used as a dehydrative coupling reagent (Scheme I). The procedure is well established in the area of nucleotides (27) and was



Scheme II—Synthesis of metronidazole phosphate

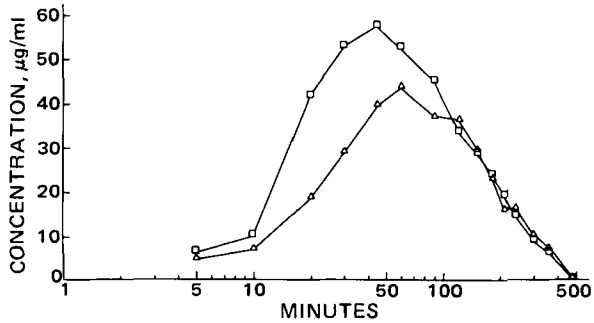


Figure 5—*Blood levels in rats following subcutaneous administration of metronidazole (□) or metronidazole phosphate (△).*

adopted in the synthesis of lincomycin phosphate (32). The procedure was adopted initially in the synthesis of metronidazole phosphate primarily for a feasibility study. Method B, on the other hand, utilizes the high reactivity of pyrophosphoryl tetrachloride (28). This procedure (Scheme II) is simpler and more convenient than Method A.

Biological Properties of Metronidazole Phosphate—The hydrolysis rate of metronidazole phosphate to metronidazole, catalyzed by a number of enzymes, was determined by monitoring the appearance of the latter and the disappearance of the former in whole human serum at 37°. Throughout kinetic experiments, the mass balance was well observed.

As shown in Fig. 3, the disappearance of metronidazole phosphate in serum at 37° follows zero-order kinetics at two initial concentrations, 0.50 and 0.25 mg/ml, with rate constants 0.036 and 0.031 mg/ml/hr (1.10 and 0.95×10^{-4} *M* hr^{-1}), respectively. For a sample with an initial concentration 0.10 mg/ml, no metronidazole phosphate was detected after 3 hr. Limited data obtained within the initial 3 hr appeared to follow first-order kinetics, but this remains to be confirmed.

Serum used for three runs of experiments and with an initial concentration of 0.50 mg/ml was obtained from the two healthy male volunteers. An identical rate constant appears to satisfy both series of data, indicating that the *total* enzyme activity towards metronidazole phosphate does not vary significantly between the two volunteers. Experiments with an initial concentration of 0.25 mg/ml produced a rate constant virtually identical to that obtained with an initial concentration of 0.50 mg/ml, leading to a conclusion that phosphatases and possibly other enzymes that cause the bioconversion are most likely saturated with the substrate at such high substrate concentration. Figure 4, where the appearance of metronidazole in three series of experiments is presented as a function of time, also produces a single zero-order rate constant, 0.037 mg/ml/hr (1.13×10^{-4} *M* hr^{-1}) for the disappearance of the phosphate. This rate constant corresponds to 0.019 mg/ml/hr (1.13×10^{-4} *M* hr^{-1}) in terms of the appearance of metronidazole. The ratio of molecular weight of metronidazole to that of the phosphate is 0.523. The average of three rate constants for the hydrolysis of the phosphate ester reported above, 0.035 mg/ml hr (1.06×10^{-4} *M* hr^{-1}), represents the maximum velocity in the apparent Michaelis–Menten kinetics (33).

As shown in Fig. 5, metronidazole phosphate produced blood levels of bioactivity in rats given 40 mg/kg subcutaneously (metronidazole equivalent) that were comparable to those produced by metronidazole when administered at the same dosage level. The maximum blood level produced by the phosphate ester was 43.3 μg/ml while that produced by metronidazole was 57.4 μg/ml, which occurred 60 and 45 min after administration, respectively. The corresponding ratio of total area under a curve was found to be 0.88:1.00. No conclusive explanation for the slightly (but significant at 95% confidence level) less area under a curve obtained from the phosphate ester than from metronidazole are given in the present report, although it is possible that the phosphate prodrug, being a highly ionic compound, may be readily eliminated intact through the kidney prior to or during the enzymatic conversion to the parent compound. In this aspect, it is interesting to note that the difference in bioavailability occurs during the initial 100 min and that the assumed elimination phase is nearly identical in both cases.

Dose-Dependent Pharmacokinetics of the Antihypertensive 2,3,4,4a-Tetrahydro-1*H*-pyrazino[1,2a]quinoxalin-5-(6*H*)-one in Dogs and Rats

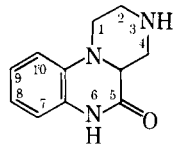
ROGER T. SCHILLINGS *ˣ, SOONG T. CHIANG ‡, and SAMUEL F. SISENWINE *

Received August 5, 1980, from the **Drug Metabolism Subdivision*, ‡*Biostatistics Section, Wyeth Laboratories, Inc., Radnor, PA 19087.* Accepted for publication July 22, 1981.

Abstract □ A sensitive and reproducible GLC assay was developed for determining 2,3,4,4a-tetrahydro-1*H*-pyrazino[1,2a]quinoxalin-5(6*H*)-one (I) in biological fluids, utilizing the electron-capturing capability of the heptafluorobutyryl derivative. After single 2.5- and 10-mg/kg oral and intravenous doses to three dogs, plasma concentration–time data for I were fitted to a biexponential equation and pharmacokinetic parameters were calculated. A dose-dependency for certain parameters, most notably total body clearance (Cl_T), was indicated. The difference in Cl_T for the low and high dose was statistically significant. After single 5-, 25-, and 50-mg/kg intragastric doses were given to rats, the decline in plasma concentrations of I with time followed a monoexponential equation. As with dogs, there was a disproportionate change in kinetic parameters with increasing dose for rats. While simple Michaelis–Menten kinetics were not evident, nonlinearity in biotransformation (intrinsic clearance) appeared to be the cause for the dose-dependent pharmacokinetics.

Keyphrases □ 2,3,4,4a-Tetrahydro-1*H*-pyrazino[1,2a]quinoxalin-5(6*H*)-one—dose-dependent pharmacokinetics, dogs and rats □ Antihypertensive agents — 2,3,4,4a-tetrahydro-1*H*-pyrazino[1,2a]quinoxalin-5(6*H*)-one, dose-dependent pharmacokinetics, dogs and rats □ Pharmacokinetics—dose-dependent, 2,3,4,4a-tetrahydro-1*H*-pyrazino [1,2a]quinoxalin-5(6*H*)-one, dogs and rats

The compound 2,3,4,4a-tetrahydro-1*H*-pyrazino[1,2a]-quinoxalin-5(6*H*)-one (I) is an antihypertensive agent that is effective in lowering blood pressure in hypertensive dogs, cats, and rats[1]. Its synthesis has been described previously (1).



I

For metabolic disposition studies, single intravenous and oral doses of 2.5 and 10 mg/kg were given to normotensive male dogs and intragastric doses of 5, 25, and 50 mg/kg to normotensive male rats. From the resulting data, estimates of pharmacokinetic parameters were determined and the effect of dose on pharmacokinetics was investigated.

EXPERIMENTAL

The hydrochloride salt and free base of I were used and 8-fluoro-2,3,4,4a-tetrahydro-1*H*-pyrazino[1,2a]quinoxalin-5(6*H*)-one hydro-

chloride (II) was the internal standard in the GLC assay. Concentrations of I and II are expressed as free base. Solvents were obtained commercially[2] and were distilled in glass by the manufacturer. Methylene chloride was washed successively with 1 *N* HCl, 1 *N* NaOH, and three times with water before using. Heptafluorobutyrylimidazole[3] (III) was obtained in 1-g ampuls and was used without further purification.

Drug Administration and Sample Collection—Three normotensive, purebred, male beagle dogs (10–14 kg) were used for the study. The dogs were fasted 16 hr prior to each dosing, and feeding was resumed 6 hr after dosing. Compound I was given orally (2.5 or 10 mg/kg) in capsule form and intravenously (2.5 or 10 mg/kg) in saline. Plasma specimens from heparinized whole blood were obtained after each dose at 0.25, 0.50, 1, 2, 4, 6, 8, 12, 24, and 48 hr, and also at 0.08 hr after each intravenous dose. The animals were kept in individual metabolism cages and urine was collected at 0–4, 4–8, 8–12, 12–24, 24–36, 36–48, 48–72, and 72–96 hr after dosing. Plasma and urine were frozen until analysis. Intervals of at least 4 weeks separated each dose.

Male albino rats[4] (250–300 g) were randomly assigned to three treatment groups of 45 animals each, fasted for 16 hr, and given either 5, 25, or 50 mg/kg of I in sterile water by gastric intubation. The animals were fasted except for those to be sacrificed at 24 and 48 hr. At intervals of 0.5, 1, 2, 4, 6, 8, 12, 24, and 48 hr, five animals from each dose group were anesthetized with ether, blood was drawn from the inferior vena cava into heparinized tubes, and the plasma separated by centrifugation. Urine was collected at 0–24 and 24–48 hr after dosing from the five animals who remained in metabolism cages until sacrifice at 48 hr. Plasma and urine were frozen until analysis.

Analytical Procedures—To disposable 16- × 125-mm glass culture tubes[5] (with plastic-lined screw cap) containing a plasma sample (1.0 ml) were added 100 ng of II in 0.05 ml of water and 0.025 ml 1 *N* NH_4OH. Plasma samples less than 1 ml were adjusted to 1 ml with drug-free dog plasma, and water was added to bring the total volume to 2 ml. Ethyl acetate (5 ml) was added to each tube, the tubes were shaken for 5 min on a mechanical rocker-type shaker[6], and centrifuged for 5 min. The organic layer was transferred to another 16- × 125-mm culture tube, and the extraction of the aqueous phase was repeated with 4 ml of ethyl acetate. The combined extracts were mixed[7] with 1 ml of 0.1 *N* H_2SO_4 for 30 sec and centrifuged.

The organic layer was aspirated, and the aqueous phase was washed with 1.5 ml of methylene chloride. Methylene chloride (5 ml) and 1 *N* NH_4OH (0.3 ml) were added to the aqueous phase, and the contents were mixed for 30 sec and centrifuged. The aqueous phase was aspirated, and the organic phase was evaporated to dryness in a 37° water bath under a nitrogen stream. The residue was dissolved in 0.7 ml of toluene, and 50 μl of III was added. The contents were heated at 55° for 15 min and then washed with successive 1 ml portions of 1 *N* NH_4OH, 0.2 *N* H_2SO_4, and water. The washed toluene phase was transferred to a 12- × 75-mm test tube and stored at −20° until analysis by GLC.

A 1 μl volume was injected into the chromatograph. For each analysis, calibration standards were prepared by adding varying amounts (25–400 ng) of I in 0.05–0.1 ml of water to a series of tubes containing 1 ml of drug-free dog plasma. Internal standard, alkali, and water were added to these tubes in the same way as for the plasma samples of unknown concentration.

Aliquots of urine were diluted to 1 ml with water and processed in a manner similar to that for the plasma samples. The calibration standards contained 100–800 ng of I and 200 ng of internal standard in 0.1 ml of control urine. Additional water was added to adjust the total volume to 1 ml.

The samples containing the heptafluorobutyryl derivatives of I and II were chromatographed on a gas chromatograph[8] equipped with a nickel 63 electron-capture detector and a 122- × 0.2-cm glass column packed with 1% Silar 10CP on 100/20 mesh chromosorb W-HP[9]. The column temperature was 240°, the injection port was 250°, and the detector was 350°; the flow of carrier gas (95% argon, 5% methane) was maintained at 26 ml/min.

A calibration curve was constructed daily by plotting the ratio of peak heights for derivatized I to derivatized internal standard *versus* the concentration of the I standard. Unknown concentrations of I were determined from the calibration curve.

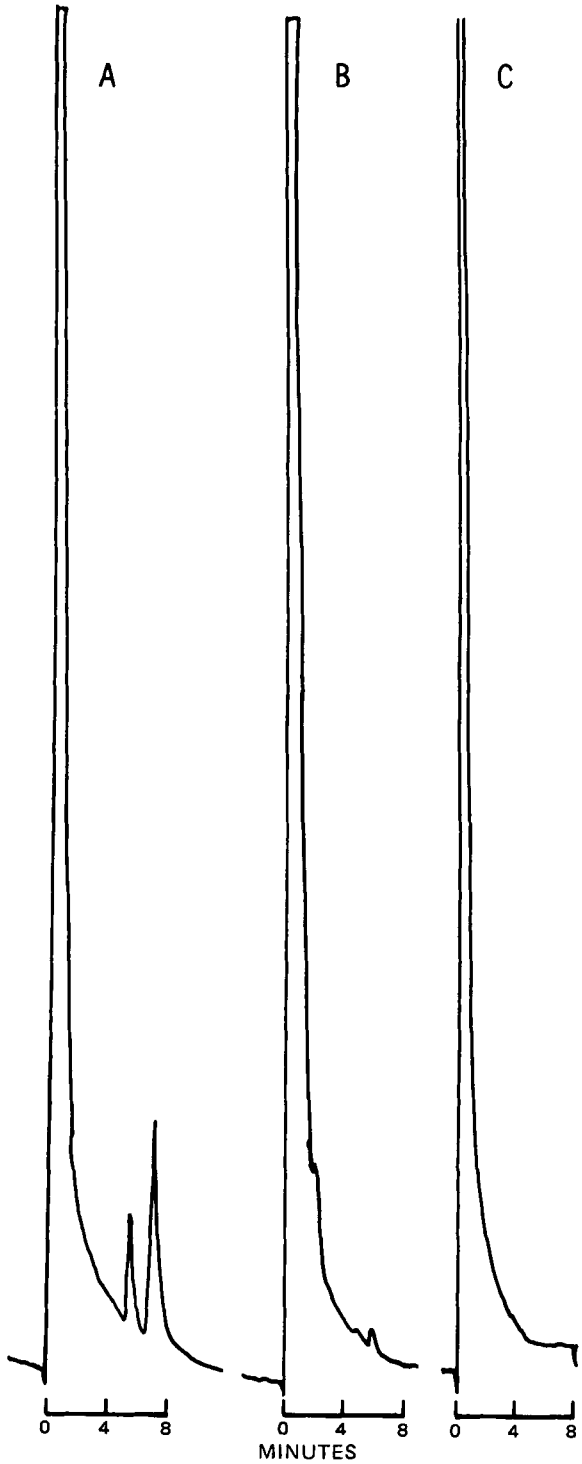

Figure 1—*Gas–liquid chromatograms. Key: A, 50 ng of I (as derivative, t_r = 5.5 min) and 100 ng of II (as derivative, t_r = 7.2 min) in dog plasma extract; B, blank dog plasma extract, 1 ml; C, blank dog urine extract (1 ml).*

Pharmacokinetic Analysis—A two-compartment model was applied to fit simultaneously the intravenous and oral plasma data from each dog at a given dose level according to the equations:

$$C_{iv} = \frac{\text{dose}}{V_c}\left(\frac{k_{21}-\alpha}{\beta-\alpha}e^{-\alpha t} + \frac{k_{21}-\beta}{\alpha-\beta}e^{-\beta t}\right) \quad \text{(Eq. 1)}$$

$$C_{po} = \frac{F\ \text{dose}\ k_a}{V_c}\left[\frac{k_{21}-k_a}{(\beta-k_a)(\alpha-k_a)}e^{-k_a t} + \frac{k_{21}-\alpha}{(k_a-\alpha)(\beta-\alpha)}e^{-\alpha t} + \frac{k_{21}-\beta}{(\alpha-\beta)(k_a-\beta)}e^{-\beta t}\right] \quad \text{(Eq. 2)}$$

[a] Coefficient of variation.

where C is the plasma concentration at time t, k_a, α, and β are the first-order absorption, distribution, and elimination rate constants, respectively, V_c is the distribution volume of the central compartment, F is the systemic availability of the oral dose, and k_{21} is the intercompartmental distribution rate constant (2).

The initial values of model parameters were estimated using the AUTOAN computer program (3). F was estimated by:

$$AUC_{po} \times \text{body weight}_{iv}/AUC_{iv} \times \text{body weight}_{po} \qquad \text{(Eq. 3)}$$

where AUC is the area under the plasma concentration–time curve between zero and infinity. Equations 1 and 2 were then applied to fit the intravenous and oral plasma data from each dog simultaneously with the aid of the NONLIN computer program (4). The statistical weighting factor in the least-squares procedure was the inverse of the observed plasma concentration and the overall goodness of fit was assessed by the coefficient of determination (r^2). Other parameters calculated were the total body clearance (Cl_T), the volume of distribution at steady state (Vd_{ss}), and after distribution equilibrium (Vd_β), the renal clearance (Cl_R), and the intercepts A and B (2). The fraction of the intravenous dose eliminated as unchanged I in urine was designated as f_{iv}.

The plasma concentration–time data from intragastrically dosed rats were fitted by a one-compartment model according to the equation:

$$C = \frac{FDk_a}{V(k_a - K)}(e^{-Kt} - e^{-k_a t}) \qquad \text{(Eq. 4)}$$

Synthesis of Heptafluorobutyramides—Compound I as free base (200 mg) in 2 ml of ethyl acetate was reacted with 0.5 ml of III at 55°. After completion of the reaction (0.5 hr), the reaction mixture was washed once with 2 ml of 0.2 N H_2SO_4, twice with 2 ml of water, and evaporated to dryness at 55° under a nitrogen stream. The residue was recrystallized from ethanol and gave 150 mg of 3-(2′,2′,3′,3′,4′,4′,4′-heptafluorobutyryl)-2,4,4a-trihydro-1H-pyrazino[1,2a]quinoxalin-5-(6H)-one (IV), mp 188°.

Anal.—Calc. for $C_{15}H_{12}N_3O_2F_7$: C, 45.12; H, 3.03; N, 10.53. Found: C, 45.23; H, 3.14; N, 10.22.

The free base of II was extracted with ethyl acetate from an alkalinized solution of the hydrochloride and then derivatized and crystallized by the described method to give 8-fluoro-3-(2′,2′,3′,3′,4′,4′,4′-heptafluorobutyryl)-2,4,4a-trihydro-1H-pyrazino[1,2 a]quinoxalin-5(6H)-one(V), mp 190°.

Anal.—Calc. for $C_{15}H_{11}N_3O_2F_8$: C, 43.18; H, 2.66; N, 10.07. Found: C, 43.13; H, 2.69; N, 10.07.

Mass Spectrometry—Samples were examined by direct introduction with the mass spectrometer[10] in the electron-impact mode. Source temperature was 150–200° and ionizing potential 70 ev.

Differential Scanning Calorimetry (DSC)—DSC curves were obtained using a differential scanning calorimeter[11]. Samples (1 mg) were heated at the rate of 10°/min in a nitrogen atmosphere.

RESULTS

Analytical—The elemental analysis of IV indicated that a monoheptafluorobutyryl derivative of I was formed. Consistent with the elemental analysis, the mass spectrum of IV exhibited a molecular ion at m/z 399 (base peak) and a major ion at m/z 202 from the loss of the acyl group (C_4F_7O). The thermogram for IV from the differential scanning calorimeter (DSC) showed a single sharp peak at the melting point (188°) of the derivative and no decomposition up to 260°. The DSC curve confirmed the purity of the product and demonstrated the stability of the derivative at the GLC operating conditions.

The retention times (t_r) of IV and V were 5.5 and 7.2 min, respectively. A representative chromatogram from an analysis of 50 ng of I and 100 ng of II in 1 ml of dog plasma is illustrated in Fig. 1A. Chromatograms of blank dog plasma and urine (1 ml each) carried through the GLC assay are shown in Figs. 1B and 1C, respectively. No metabolites of I interfered with the chromatographic detection of IV and V. To determine reproducibility, the mean ratio of the peak heights of IV to V (n = 5) and its coefficient of variation (CV) at concentrations ranging from 25 to 400 ng/ml were determined during two analyses on separate days (Table I). The peak height ratio varied with a CV <7%. The mean ratio was linearly related to I concentration with a correlation coefficient of 0.999 between these two analyses. The recoveries of the drug at each concentration varied from 37 to 39% (CV = 2–13%). A minimum of 12 ng/ml could be quantified using a 2-ml plasma sample.

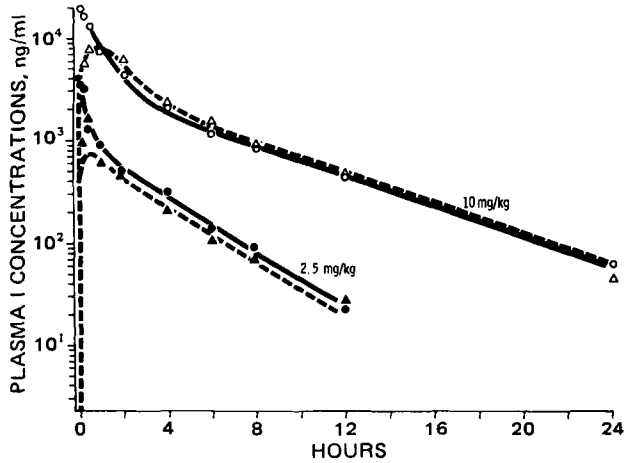

Figure 2—*Mean concentrations of I in the plasma of dogs given intravenous (○) and oral (△) doses of 2.5 and 10 mg/kg.*

Pharmacokinetics of I in Dogs—Concentrations of I in dog plasma after 2.5 and 10 mg/kg iv and oral doses are illustrated in Fig. 2 and the derived pharmacokinetic parameters are listed in Table II. The decline in plasma concentrations followed the biexponential equation for a two-compartment model. After oral administration, observed peak plasma concentrations and standard deviations (C_{max}) were 1667 ± 651 and 7710 ± 6858 ng/ml for the 2.5- and 10-mg/kg doses, respectively, and occurred at 0.5 hr for each dose.

The mean drug recoveries in urine and their standard deviations after

[a] The overall goodness of fit of measured plasma data to the generated curves (Fig. 2) was r^2 = 0.93. [b] Paired t test; degrees of freedom = 2. [c] For statistical analysis, these parameters were normalized by dose.

[10] AEI-MS902 equipped with a Data General Nova 3 computer and DS-50s software.

[11] Model 2, Perkin-Elmer Corp.

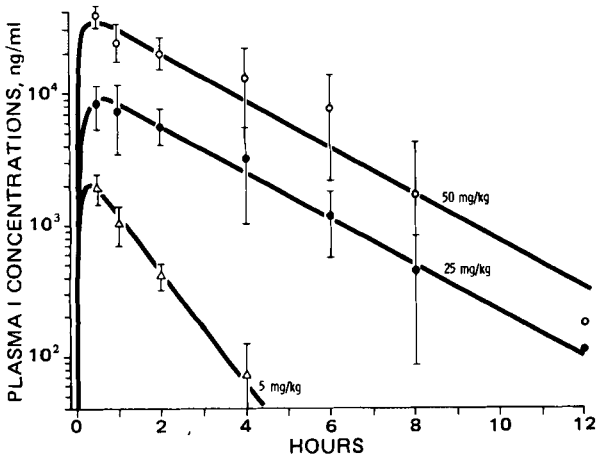

Figure 3—*Mean concentrations of I (±SD) in the plasma of rats given intragastric doses of 5 mg/kg (△), 25 mg/kg (○), and 50 mg/kg (●).*

the 2.5-mg/kg iv and oral doses were 5.0 ± 0.3 and 1.8 ± 0.8 % of the administered dose, respectively. After the 10-mg/kg iv and oral doses 13.4 ± 4.4 and 5.4 ± 0.5% of the administered doses were recovered, respectively.

Pharmacokinetics of I in Rats—Concentrations of I in rat plasma after intragastric administration of 5, 25, and 50 mg/kg are shown in Fig. 3; the estimated pharmacokinetic parameters are listed in Table III. The decline in plasma concentrations after 5, 25, and 50 mg/kg was apparently monoexponential. In the order of increasing dose, the observed peak plasma concentrations ($C_{max} \pm SD$) were 1966 ± 529, 8609 ± 3176, and 38,999 ± 5896 ng/ml and occurred at 0.5 hr for each dose. The mean drug recoveries in urine after the 5, 25, and 50 mg/kg doses were 1.3 ± 0.4, 4.0 ± 2.0, and 6.9 ± 3.7% of the administered dose, respectively.

DISCUSSION

The described GLC assay is highly sensitive and reproducible. The minimum quantifiable concentration was 25 ng/ml for a 1-ml specimen, while a minimum of 12 ng/ml could be quantified in plasma using 2-ml samples.

In dogs, I was quickly absorbed with a Vd_{ss} (1.6 liter/kg) which is 2–3 times larger than the reported total body water of the dog [0.5–0.8 liter/kg (5)]. The calculated availability (F) was high (73% for a 2.5-mg/kg dose and 95% for a 10-mg/kg dose) and increased with increasing dose (Table II). The compound was eliminated rapidly from plasma and was excreted to a small extent into urine, but appears to be eliminated mainly by metabolism. The elimination half-lives in the rat (Table III) were less than those calculated for the dog (Table II), and similar plasma levels of the compound in rats and dogs were observed only when rats received higher doses. This species difference in disposition may account for a longer duration of the compound's hypotensive effect in the dog.[1]

Although linear pharmacokinetic models were used to fit the plasma data for both dogs and rats, the disproportionate increases in AUC with increasing dose indicate that dose-dependent kinetics are in effect. For example, total body clearance in dogs is almost reduced by one-half at the higher dose. However, the elimination of I from plasma does not appear to follow simple Michaelis–Menten kinetics since the elimination is slower after the higher doses than the lower doses in the same concentration range. This pattern suggests product inhibition as pointed out by Perrier *et al.* (6). Thus, the model employed to fit the data yields dose-average pharmacokinetic parameters at each dosage level which may not be operative as a function of specific plasma concentrations. Although the differences in β, $t_{1/2\beta}$, and F at the two doses were below statistical significance (Table II) these differences were assumed to be connected with the statistically significant change in Cl_T. The lack of visible nonlinearity and Michaelis–Menten characteristics precluded fitting the data with a specific nonlinear function. However, the NONLIN-fitted least-square value of Cl_T agreed well with the time-average value obtained from the quotient Dose/AUC_{iv}.

The factor responsible for the nonlinear disposition of I can be assessed further by considering first-pass concepts (7). If complete availability from the dosage form is assumed, then the apparent intrinsic clearance of I can be estimated as:

$$Cl'_{int} = \frac{(1 - f_{iv})_{Dose}}{AUC_{po}} \qquad \text{(Eq. 5)}$$

Table III—Pharmacokinetic Parameters of I in Rats following Single Intragastric Doses

Parameter	Dose, mg/kg 5	25	50
C_{max}, μg/ml	2.0	8.6	39.0
t_{max}, hr	0.5	0.5	0.5

Table IV—Comparison of Apparent Intrinsic Clearance (Cl'_{int}) and Systemic Availability (F) of I after Oral and Intravenous Doses in Dogs

Dose, mg/kg	Oral Cl'_{int}, ml/min/kg	Oral F^a	Intravenous Cl'_{int}, ml/min/kg	Intravenous F^a
2.5	13.0 ± 1.4	0.76 ± 0.02	11.3 ± 1.1	0.78 ± 0.02
10.0	4.4 ± 1.2	0.90 ± 0.02	4.5 ± 0.6	0.90 ± 0.01

[a] Calculated from Cl'_{int} and Q_H as discussed in text.

where f_{iv} is the fraction of the intravenous dose excreted as unchanged I. Protein binding was not measured so these equations do not yield the true $Cl_{int} = V_{max}/K_m$. The intravenous doses give the body clearance (Cl_T):

$$Cl_T(1 - f_{iv}) = \frac{Q_H\, Cl'_{int}}{Q_H + Cl'_{int}} \qquad \text{(Eq. 6)}$$

where Q_H is hepatic blood flow.

Equation 6 can be rearranged to:

$$Cl'_{int} = \frac{Cl_T(1 - f_{iv})Q_H}{Q_H - Cl_T(1 - f_{iv})}$$

Table IV shows calculated values of Cl'_{int} obtained by both methods. Hepatic blood flow in the dog was assumed to be 40 ml/min/kg (8). The good agreement and diminishment with dose indicates that nonlinearity in I disposition is probably due to a dose-dependent decrease in biotransformation rate. The Cl'_{int} values can be used to estimate values of F, as shown in Table IV, since:

$$F = \frac{Q_H}{Q_H + Cl'_{int}} \qquad \text{(Eq. 7)}$$

The larger F with increasing dose is consistent with the nonlinear Cl'_{int}. The significant decrease in Vd_β with increasing dose could result from changes in elimination (9).

Phenethylamine Inhibitors of Partially Purified Rat and Human Pancreatic Lipase

KAREN COMAI ˣ and ANN C. SULLIVAN

Received March 18, 1981, from the *Department of Pharmacology, Hoffmann–La Roche, Nutley, NJ 07110.* Accepted for publication July 23, 1981

Abstract □ Methodology for the preparation of rat and human pancreatic lipase (EC 3.1.1.3) is described, which resulted in good yield of partially purified, stable enzyme useful for kinetic studies. Apparent K_m values for the rat (6.5 m*M*) and human (3.5 m*M*) enzyme were determined with triolein as the substrate. Several compounds of the phenethylamine class were found to be inhibitors of both rat and human pancreatic lipase. The structural feature in the phenethylamine series tested, which appeared to be necessary for lipase inhibition, was a halogenated substituent on the 3 or 4 position of the aromatic ring as in flutiorex, fenfluramine, *N*-benzyl-β-methoxy-3-(trifluoromethyl)phenethylamine (I), chlorphentermine and *p*-chloroamphetamine. A chloro group at the 2 position was ineffective (chlortermine). Alterations in the ethylamine portion of the molecule did not cause significant changes in the inhibitory properties of the active phenethylamines.

Keyphrases □ Phenethylamines—inhibition of pancreatic lipase, rats and humans □ Kinetics—competitive inhibition of pancreatic lipase, rats and humans □ Pancreatic lipase—inhibition by phenethylamines, rats and humans

The anorectic effect of many compounds of the phenethylamine class has been recognized for almost 40 years (1). In addition to anorexia, some phenethylamines show marked effects on lipid metabolism. Amphetamine and fenfluramine have been shown to decrease the postprandial rise in plasma triglycerides in corn oil loaded rats (2–4) and in humans (5), and to elevate plasma free fatty acid concentration (5, 6). Fenfluramine also was reported to inhibit hepatic lipogenesis (2), reduce intestinal motility (4), and interfere with postabsorptive reesterification by inhibiting rat intestinal palmitolyl CoA monolein transferase activity (7). Furthermore, fenfluramine and an analog, benfluorex, were reported to inhibit pancreatic lipase (2, 8, 9). Although these activities were postulated previously (4, 10) to explain (in part) weight reduction by fenfluramine through decreased dietary triglyceride absorption, a study in healthy humans revealed that fenfluramine did not alter fat absorption (11).

In addition to phenethylamines, several chemically unrelated compounds which inhibit the release of free fatty acids from adipose tissue reportedly interfere with postprandial lipemia (12, 13). Barboriak, *et al.* (12) demonstrated that 3,5-dimethylpyrazole, salicylic acid, and nicotinic acid inhibit plasma triglyceride rise in rats given corn oil. In these studies, reduced fat absorption was observed in animals receiving salicylic acid. Another report (13) demonstrated the antilipolytic activity of two α-blockers, phentolamine and phenoxybenzamine. These studies were furthered by examination of inhibitory effect of phentolamine and phenoxybenzamine on rat epididymal fat and pancreatic lipases (14). The epididymal fat lipase appeared to be inhibited by both α-blockers; pancreatic lipase was inhibited by phenoxybenzamine but stimulated by phentolamine.

The present study reports the effectiveness of various phenethylamines and other antilipolytic agents as inhibitors of rat and human pancreatic lipase. A systematic *in vitro* evaluation of representative compounds was initiated using freshly prepared, partially purified preparations of rat and human pancreatic lipase. The results were compared with those obtained with diethyl-*p*-nitrophenyl phosphate, a known active site inhibitor of hog pancreatic lipase (15).

MATERIALS AND METHODS

Pancreatic Lipase Preparations—Rat pancreatic proteins were prepared by adaptation of a method described for the guinea pig pancreas (16). In a representative experiment, six female Sprague-Dawley rats[1], weighing 180–220 g were fed a 20% corn oil diet *ad libitum* for 8 to 10 weeks. This diet was shown to increase pancreatic lipase levels ~50% (17, 18). Prior to sacrifice the rats were fasted for 24 hr to accumulate zymogen granules in the acinar cells of the pancrease (19). The pancrease was removed quickly after sacrifice and immersed in oxygenated Krebs-Ringer bicarbonate. The pancreatic lobules were prepared as described previously (16). Eight lobules corresponding to ~50 mg wet weight per flask were incubated for 4 hr in 5 ml of the oxygenated Krebs-Ringer bicarbonate containing carbachol (10^{-5} *M*), soybean trypsin inhibitor (10 μg/ml), benzamidine (10 m*M*), and phenylmethylsulfonyl fluoride (5 m*M*). After incubation the flask contents were centrifuged at 100,000×*g* for 30 min. The resulting juice was frozen immediately in liquid nitrogen and stored at −70°.

Human pancreatic juice was obtained from a patient with acute pancreatitis whose pancreatic duct had been cannulated. Benzamidine (8.2 m*M*) and soybean trypsin inhibitor (0.5 mg/ml) were added to the collection vessels to deter enzymatic degradation of the lipase. The juice was stored at −70°.

Rat and human pancreatic juices were purified by gel filtration chromatography[2] (2.5 × 100 cm) using 0.05 *M* tromethamine[3] buffer, pH 8 at 25°. Protein profiles were monitored at 280 nm[4]. Active fractions were combined, concentrated[5], and stored in 1-ml aliquots at −70°. These preparations remained fully active for over 6 months and were the source of enzymes for all experiments.

Pancreatic Lipase Assays—Two methods were utilized for the pancreatic lipase assay. The first was developed for use in screening large numbers of compounds and was based on the method of Krauss *et al.* (20). Glycerol tri[1-^{14}C]oleate (32 m*M*) was emulsified in 0.2 *M* tromethamine, pH 8 at 36° containing 0.15 *M* NaCl, bovine serum albumin (15 mg/ml, fatty acid free), and sodium taurocholate (1.4 m*M*) by sonication for three 1-min intervals at 80 watts[6]. The final assay volume was 1.0 ml. The reaction was initiated by the addition of enzyme and was allowed to proceed for 10 min. Under these conditions the reaction was linear for up to 20 min. The liberated free fatty acids were extracted and quantitated in a liquid scintillation counter[7]. The second method used was the titrimetric assay described by Maylie *et al.* (15). An olive oil–sodium taurocholate (1.4 m*M*) emulsion stabilized in 2% gum arabic was the substrate. The molecular weight of triolein (885 g) was used to calculate the substrate concentration. The final assay volume was 3.0 ml. The reaction was initiated by the addition of enzyme. The long-chain fatty acids released at 25° (pH 8) were continuously titrated with the aid of a recording pH-stat[8]. The lipase activity was determined directly from the slope of the linear portion of the curve.

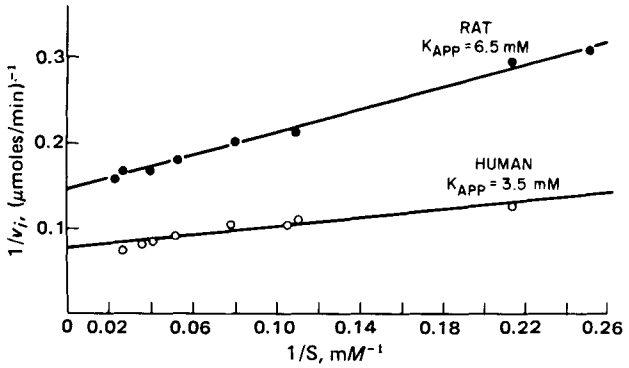

Figure 1—*Lineweaver–Burke plot of rat and human G-200 lipase activity. Assays were run using the described pH-stat method. Key: ●, rat G-200 lipase (protein concentration, 8.6 μg/ml); and ○, human G-200 lipase (protein concentration, 9.2 μg/ml).*

Inhibitors were added to the assays as solutions in either 90% ethanol or water, pH 8; 90% ethanol had no effect on pancreatic lipase activity assayed by either method.

Protein determinations were performed using the Lowry method (21).

Materials—Glycerol tri[1-^{14}C]oleate[9] was used without further purification. Sodium taurocholate, norepinephrine, epinephrine, phenylephrine, bovine serum albumin (fatty acid free), dopamine, phenethylamine, phenylpropanolamine, *l*-ephedrine, *d*-ephedrine, tyramine, and diisopropylfluorophosphate were purchased commercially[10]. Hydroxyamphetamine, amphetamine, phenoxybenzamine and *N*-benzyl-β-methoxy-3-(trifluoromethyl)phenethylamine (I) were used as received[11]. Diethylpropion[12], protokylol[12], metaraminol[13], nordefrin[13], tuaminoheptane[14], cyclopentamine[14], methoxyphenamine[15], clortermine[16], phentermine[17], nylidrin[18], metaproterenol[19], benzphetamine[20], phenmetrazine[21], phentolamine[21], chlorphentermine[22], fenfluramine[23], flutiorex[24], *p*-chloroamphetamine[25], and diethyl-*p*-nitrophenylphosphate[26] were used without further purification.

RESULTS

Characterization of Pancreatic Lipase Activities—Gel filtration of rat and human pancreatic juices by chromatography resulted in partial purification of both enzymes. The enzyme activities emerged 2.2 void volumes for rat lipase and 2.0 void volumes for human lipase resulting in a twofold purification of rat lipase and a sevenfold purification of human lipase.

Molecular weights were determined on the chromatographic column by comparing the elution of the lipases to standard proteins. The rat lipase appeared to have a molecular weight near 37,000; the human lipase molecular weight was ~48,000 (22).

The kinetics of the lipolytic reactions of the two lipase preparations were analyzed using the Michaelis–Menten formula as has been done for hog lipase (23) and phospholipases (24–26). The effects of varying substrate concentration on the initial velocity are shown in Fig. 1. Apparent K_m values obtained for rat and human G-200 lipase were of the order of 6.5 m*M* and 3.5 m*M*, respectively. It is not known whether the similar apparent K_m values are due to enzyme similarities or the physical characteristics of the emulsion assay system.

To determine whether the G-200 preparations contained colipase, purified hog colipase was incubated for 10 min at 37° with both the rat and human G-200 preparations at a ratio of 2 moles pure colipase to 1 mole of enzyme. The enzymic activities were assessed from initial velocity measurements using the pH-stat assay. As seen in Figs. 2A and 2B, there was no enhancement of either rat or human lipase activity after addition of exogenous colipase, indicating the G-200 lipase preparations were saturated with colipase. However, the additional colipase provided some protection of enzymic activity at high taurocholate concentrations (5–14 m*M*).

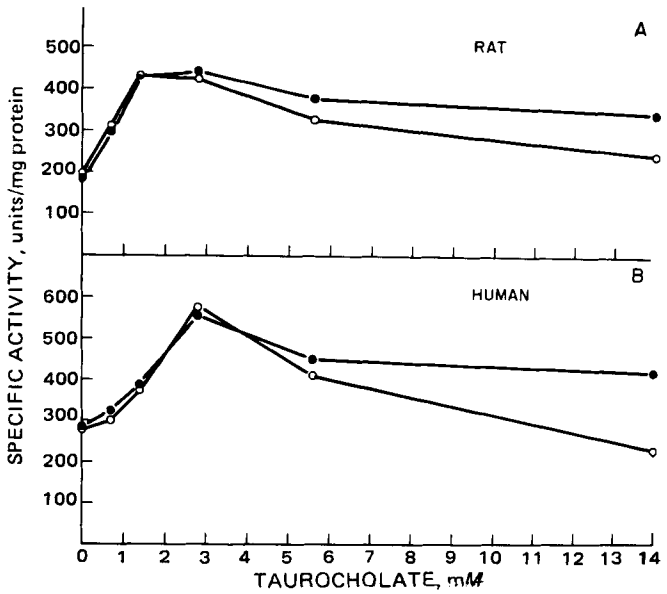

Figure 2—*Effect of added colipase on rat and human G-200 lipase. Two moles of pure colipase per mole of lipase were incubated with lipase for 10 min at 37°. An aliquot of the incubated enzyme–colipase mixture was added to the assay medium and the initial velocity recorded using the pH-stat assay. Key: ○, minus colipase; and ●, added colipase. (A), rat G-200 lipase; and (B), human G-200 lipase.*

Inhibition of Rat G-200 Pancreatic Lipase—Many phenethylamines with central nervous system effects were inactive as inhibitors of pancreatic lipase. Table I shows the results of a structure–activity profile of the phenethylamine series evaluated in the carbon 14 and pH-stat titrimetric assays. All compounds were tested either to 20 m*M* or 100% inhibition. The catecholamines were either ineffective or slightly stimulatory toward rat pancreatic lipase. Interestingly, the five compounds in this series, which exhibited good inhibition, were the compounds related to amphetamine but with halogenated substituents on the 3 or 4 position of the aromatic ring. Inhibition constants summarized in Table I, as determined by a graphical method (27), were calculated for the five active phenethylamines from initial velocity data recorded during the titrimetric assay at 6 and 28 m*M* substrate concentrations. The lines were determined from linear regression analyses of the initial velocity data points which appeared to lie along a straight line. Cooperative and competitive inhibitory phenomena were observed for flutiorex, fenfluramine, and chlorphentermine. Using this method chlorphentermine, flutiorex, fenfluramine, *p*-chloroamphetamine, and I gave K_i values of 1.9, 3.0, 3.3, 6.2, and 11 m*M*, respectively. Analysis of the carbon 14 assay data resulted in K_i values of 9.6 m*M* for chlorphentermine, 6 m*M* for *p*-chloroamphetamine, 3.5 m*M* for flutiorex, 9.0 m*M* for fenfluramine, and 11 m*M* for I (Table I). Variation in the initial velocity was observed at the low substrate concentrations (6 m*M* triolein). However, this was <10% variation in the resulting K_i values. Interestingly, chlortermine, a phenylamine having a chlorine in the 2 position of the benzene ring, was not an inhibitor of rat pancreatic lipase, whereas the 4-chloro derivatives were inhibitors.

Two α-blockers were examined as inhibitors of rat G-200 pancreatic lipase and compared with diethyl-*p*-nitrophenylphosphate. The data were obtained and analyzed in the same manner as was done for the phenethylamines. The results are given in Table II. Phenoxybenzamine, which appeared to be a very strong inhibitor in the carbon 14 screen (0.9 m*M*), was a much weaker inhibitor when evaluated in the titrimetric assay (10 m*M*). This discrepancy was due to the fact that phenoxybenzamine delayed the initial velocity reaction for up to 6 min. However, after the initial lag time the enzymatic reaction proceeded and required relatively high phenoxybenzamine concentrations for inhibition.

Phentolamine was inhibitory in both the carbon 14 and titrimetric

assay. Inhibition constants of 5.8 mM for the former assay and 1.6 mM for the titrimetric assay were determined from Dixon plots (27). Diethyl-p-nitrophenylphosphate, an active site inhibitor of hog lipase (15), gave comparable K_i values for rat G-200 lipase in both the carbon 14 assay (0.1 mM) and the titrimetric assay (0.1 mM). Diisopropylfluorophosphate, an inhibitor of enzymes having an essential serine residue in the active site, produced no inhibition of rat G-200 lipase at 20 mM. This agrees with data obtained with hog lipase (15).

Inhibition of Human G-200 Pancreatic Lipase—The active inhibitors of rat G-200 pancreatic lipase were tested as inhibitors of human G-200 pancreatic lipase using the pH-stat titrimetric assay. Except for minor variations, the inhibitors of rat G-200 lipase were also effective as inhibitors of human G-200 lipase (Table III).

Diethyl-p-nitrophenylphosphate was the most effective inhibitor of both rat and human G-200 lipase giving identical inhibition constants of 0.1 mM. p-Chloroamphetamine was a stronger inhibitor of human G-200 lipase with an inhibition constant of 3.5 mM compared with rat G-200 lipase, 6.2 mM. The other active compounds gave inhibition constants for human G-200 lipase that were comparable or identical to the inhibition constants obtained for rat G-200 lipase.

DISCUSSION

Based on the reported specific activities for purified rat lipase and purified human lipase (28–30), the present preparations of rat and human G-200 lipases were 47 and 65% pure, respectively. A molecular weight of 37,000 was calculated for the rat lipase and agreed with the reported value of 36,000 (28). The human lipase had a calculated molecular weight of 48,000, slightly higher than the reported values of 45,000 (30) and 46,000 (29).

The fact that gel filtration did not appear to separate lipase from colipase was a major advantage of the present preparations. The presence of sufficient colipase for maximum activity with rat or human lipase was demonstrated in the experiments where high taurocholate concentrations (14 mM) did not inhibit significantly and added colipase did not stimulate significantly (Fig. 2).

The reversal of bile salt inhibition of lipase by colipase is most notable using the nonphysiological bile salt, taurodeoxycholate (28, 31, 32) and the nonphysiological substrate, tributyrin (23, 28). With a more physiological substrate (33), taurocholate at concentrations of 1–3 mM stimulated lipase hydrolysis of olive oil whether or not exogeneous colipase was added (Fig. 2). In the absence of exogeneous colipase, taurocholate at concentrations >6 mM produced similar decreases in rat and human lipase activity in agreement with previous results (34). Exogenous colipase protected the activity from this mild inhibition.

The results from conventional kinetic analysis were valuable despite difficulties due to the complex nature of the enzyme systems. The apparent K_m values calculated for rat (6.5 mM) and human (3.5 mM) lipases (Fig. 1) were on the same order as reported by Maylie, *et al.* for hog lipase using olive oil as substrate (23). In that communication, the reported K_m values were 2 mM in the presence and 3.5 mM in the absence of colipase, with 1.6 and 0.4 mM taurodeoxycholate, respectively. These K_m values do not represent the affinity between lipase and triglyceride as would be interpreted in aqueous systems. However, as suggested in another report (35) the K_m values do reflect the affinity of the enzyme molecule for the emulsion interface and could be considered the enzyme–interface dissociation constant, thereby lending a physical concept to the value.

The evaluation of compounds as inhibitors of lipase was validated by the agreement between the two lipase assays. The single-time point carbon 14 assay was valuable since a large number of compounds could be evaluated quickly. However, it did not have the ability to distinguish compounds which delayed the initial velocity from the true enzyme inhibitors. The pH-stat assay, which recorded initial velocities, could distinguish easily between the two types of compounds. Phenoxybenzamine was an inhibitor that caused a long delay in the initial velocity of rat G-200 lipase. Previous studies which indicated that phenoxybenzamine was a potent inhibitor of pancreatic lipase (1 mM resulting in 80% inhibition),

Table II—Inhibition Constants of Non-Phenethylamine Inhibitors of Rat Pancreatic Lipase

Compound	Pancreatic Lipase: Assay Carbon 14 K_i (mM)	Pancreatic Lipase: Titrimetric Assay K_i (mM)
Diethyl-*p*-nitrophenylphosphate	0.1	0.2
Phenoxybenzamine	0.9	10.2
Phentolamine	5.8	1.6
Diisopropylfluorophosphate	No inhibition at 20 mM	

Table III—Comparison of Inhibition Constants of Inhibitors of Rat and Human Pancreatic Lipase

Compound	Pancreatic Lipase: Rat K_i (mM)	Pancreatic Lipase: Human K_i (mM)
Diethyl-*p*-nitrophenylphosphate	0.1	0.1
Phentolamine	1.6	1.1
Chlorphentermine	1.9	2.1
Flutiorex	3.1	2.6
Fenfluramine	3.3	3.8
p-Chloroamphetamine	6.2	3.5
Phenoxybenzamine	10.0	8.9
N-Benzyl-β-methoxy-3-(trifluoromethyl)phenethylamine	11.0	12.0

utilized a single-time point assay and eliminated bile salt from the assay medium (36). Either condition might be responsible for the discrepancy between the present results and those published previously. Because of the complexity of the lipase system, phenoxybenzamine and the other inhibitors may interfere with an organization step in the enzyme–colipase–substrate–bile salt complex, thereby causing the lag time and/or inhibition of the initial velocity. A disruption of the lipase–colipase interaction by fenfluramine has been reported recently (37).

The utility of classical kinetics in studying the competitive inhibitors of lipase was evident in the use of the Dixon plot and resulting K_i values for ranking the efficacy of lipase inhibitors. Cooperative and competitive inhibitory properties were observed for fenfluramine, flutiorex, chlorophentermine, and phentolamine at concentrations >10 mM. A halogenated substituent on the 3 or 4 position of the aromatic ring (flutiorex, fenfluramine, I, chlorphentermine, *p*-chloroamphetamine) appeared to be necessary for lipase inhibition in the phenethylamine series tested (Table I). A chloro group at the 2 position was ineffective (chlortermine). Alterations in the ethylamine portion of the molecule did not cause significant changes in the inhibitory properties of the active phenethylamines. These data confirm the inhibitory effect of fenfluramine on pancreatic lipase (2, 8) and extended the observation to include a structure–activity profile of a number of phenethylamines.

Effects of Phenobarbital on the Distribution Pharmacokinetics and Biological Half-Lives of Model Nonmicrosomal Enzyme Metabolizable Sulfonamides in Rats

JANARDAN B. NAGWEKAR ˣ **and SUBHAS KUNDU** *

Received August 6, 1980, from the *Pharmaceutics Division, College of Pharmacy and Allied Health Professions, Wayne State University, Detroit, MI 48202.* Accepted for publication July 6, 1981. * Present address: Syntex Labs, Inc., Palo Alto, CA 94304.

Abstract □ The pharmacokinetics of sulfisoxazole and sulfanilamide were studied in control rats and in rats treated for 5 days with a daily 100 mg/kg ip dose of phenobarbital. These drugs represent the organic anionic and nonionized drugs, respectively, whose nonmicrosomal enzymatic metabolisms were unstimulated by phenobarbital. Sulfisoxazole showed the characteristics of a two-compartment open model. However, its biological half-life and the apparent distribution volume of the central compartment were significantly lower and the intercompartmental transport rate constants and the urinary excretion rate constant were significantly greater, in phenobarbital treated rats than in control rats. The apparent steady-state distribution volume of sulfisoxazole was smaller in the phenobarbital treated rats at the 90% confidence level. Sulfanilamide showed characteristics of a one-compartment model in both the control and phenobarbital treated rats, but none of the pharmacokinetic parameters of the compound in the phenobarbital treated rats were significantly different from those in the control rats.

Keyphrases □ Phenobarbital—effect on pharmacokinetics of sulfisoxazole and sulfanilamide □ Pharmacokinetics—effect of phenobarbital on sulfisoxazole and sulfanilamide □ Sulfisoxazole—effect of phenobarbital on pharmacokinetics □ Sulfanilamide—effect of phenobarbital on pharmacokinetics □ Sulfonamides—effect of phenobarbital on the pharmacokinetics of sulfisoxazole and sulfanilamide

In a previous paper (1), it was reported that phenobarbital treatment in rats caused a decrease in the apparent distribution volumes of nonmetabolizable model organic anions which gave the body characteristics of multicompartment open models. Regardless of the model followed by the body (one-compartment or multicompartment model), the half-lives of these compounds were shorter in phenobarbital treated rats than in control rats.

BACKGROUND

It is recognized that all drugs do not possess the ideal properties described for the organic anions previously reported (1). Drugs usually are subject to metabolism and binding to plasma proteins and remain in the blood in the ionized and/or nonionized forms. Therefore, the influences of phenobarbital treatment on the distribution volumes of organic anionic drugs which are metabolized and bound to plasma proteins were investigated. However, as an extension of previous work (1), the effect of phenobarbital treatment on the apparent distribution volumes and biological half-lives of drugs, which are metabolized and bound to plasma proteins but whose metabolism and extent of protein binding will not be affected by the microsomal enzymes induced by phenobarbital, were studied. The organic anionic drug chosen was sulfisoxazole (pKa 5.1) and the nonionized drug chosen was sulfanilamide (pKa 10.1). Sulfisoxazole and sulfanilamide are metabolized mainly by acetylation by the nonmicrosomal enzymes (2), which apparently are not induced by phenobarbital treatment. Both the drugs and their metabolites are excreted by the kidney, thereby avoiding the possible influence of increased biliary flow brought about by phenobarbital treatment (3). The protein binding of sulfisoxazole is not affected by phenobarbital treatment (4). Furthermore, while sulfisoxazole is involved in renal tubular secretion, sulfanilamide is excreted in the urine due to glomerular filtration (5).

It was stated previously (1) that the apparent distribution volumes of organic anions, which give the body the characteristics of a multicompartment open model, are likely to be lower in phenobarbital treated rats than in control rats, possibly due to reduction in the aqueous pore size of tissue cell membranes brought about by phenobarbital. It was also postulated that, if the biological half-lives of compounds are shortened in treated rats due to the stimulatory effect of phenobarbital on the renal tubular secretion mechanism (1), then such effects would be expected only for compounds involved in renal tubular secretion and not those excreted in the urine due to glomerular filtration. Therefore, the apparent distribution volume(s) and biological half-life of sulfisoxazole should be reduced in the phenobarbital treated rats but not those of sulfanilamide.

EXPERIMENTAL

Materials—Sulfanilamide[1] (mp 166°), sulfisoxazole[2] (mp 198°), and phenobarbital sodium[1] were USP grade. The other chemical agents used were analytical reagent grade.

Methodology—Male Sprague-Dawley rats weighing between 175 and 210 g (most weighed ~200 g) were used in the study.

Overall urinary excretion studies of the sulfonamides were conducted to determine the effect of phenobarbital treatment on the extent of their metabolism and to select the phenobarbital pretreatment regimen. For the urinary excretion studies of sulfanilamide, 20, 50, and 100-mg/kg ip doses were tried; a given dose was administered to each rat daily for 5–10 consecutive days. The intraperitoneal doses of phenobarbital were dissolved in 5 ml of normal saline. Each control rat was treated with 5 ml normal saline for similar periods of time as the phenobarbital treated rats. Twenty-four hours after the last treatment dose of phenobarbital or normal saline, each rat received a 10-mg iv dose of sulfanilamide *via* the tail vein. The intravenous solution of sulfanilamide (2 ml) was prepared by dissolving 10 mg of the drug in water for injection, adjusting the pH of the solution to 7.4 with sodium hydroxide, and rendering the solution isotonic with sodium chloride. Food was withheld from the rats for 12–14 hr prior to the intravenous administration of the drug and during the study. The rats were anesthetized with ether for ~2 min when the drug was administered. After administering the drug, rats are transferred to urine collection cages described previously (6). Urine samples were carefully collected over the periods of 0–8 and 8–35 hr. These urine samples were analyzed for intact sulfanilamide and its metabolites. The phenobarbital treatment schedule selected was a daily 100-mg/kg ip dose for 5 consecutive days.

Overall urinary excretion studies were also conducted for sulfisoxazole in control rats and rats treated with a daily dose of 100 mg/kg of phenobarbital for 5 consecutive days. The 2 ml of pH 7.4, isotonic solution containing 7 mg of sulfisoxazole was injected intravenously *via* the tail vein to each rat 24 hr after the last dose of phenobarbital or normal saline. Urine samples were collected over a period of 0–10 and 10–52 hr and analyzed for intact sulfisoxazole and its metabolites.

In the sulfanilamide pharmacokinetic study, three sets of studies were carried out on three different days. The first two sets of studies involved six control rats and six phenobarbital treated rats, and the third set involved only 6 phenobarbital treated rats. The third study was carried out to reinforce the finding of the first two sets of studies. In each set, only one blood sample was obtained from a given rat following decapitation at the predetermined time after intravenous administration of sulfanilamide. Blood samples were collected at 0.25, 0.5, 1, 2, 3, and 4 hr from both control and phenobarbital treated rats. The procedure of obtaining one

blood sample per rat was described previously for other compounds (1).

In the sulfisoxazole pharmacokinetic study, two sets of studies were carried out on two different days, each set involving 12 control and 12 phenobarbital treated rats. In each set, only one blood sample was obtained from a given rat after decapitation at the predetermined time after the intravenous administration of sulfisoxazole. Blood samples were collected at 0.083, 0.166, 0.25, 0.5, 0.75, 1, 2, 3, 4, 5, 6, and 8 hr from both control and phenobarbital treated rats.

The reason multiple concentration values of a sulfonamide were obtained at a given time period was to further ascertain the assumption of the regression model: each concentration variate corresponding to the given value of time is a sample from a population of independently and normally distributed variates and that the samples along the regression line have a common variance (7).

After decapitation the blood sample from a rat was collected in a 30-ml beaker coated with 0.2 ml (40 U) of heparin to prevent coagulation. Blood samples were analyzed for the intact and total (intact plus metabolites) sulfonamide on the same day they were collected.

Assay of Sulfanilamide and Sulfisoxazole—A general method used for the analysis of a sulfonamide, first developed by Bratton and Marshall (8), was to quantitate intact sulfanilamide or sulfisoxazole and the total (intact plus metabolites) sulfanilamide or sulfisoxazole present in the urine or blood samples with minor modifications. The absorbance of the complex formed between free sulfonamide and Bratton–Marshall reagent was measured on a spectrophotometer[3] at 540 nm for sulfanilamide and 545 nm for sulfisoxazole.

An accurately measured blood sample (1.0–1.5 ml) was transferred to a 150-ml beaker, diluted with 30 ml of water, stirred for 1 min, and the proteins and blood cells precipitated by dropwise addition of 8 ml of 15% trichloroacetic acid. The precipitate was allowed to settle for 2 min and 5 ml of the supernate was transferred to a 10-ml test tube. Sodium nitrite solution (1 ml, 0.1% w/v) was added, and the contents were mixed for 2 sec. Then 1 ml of 0.5% (w/v) sulfamic acid solution was added to the mixture and stirred for 10 sec. Following this, 1 ml of a 0.1% (w/v) Marshall reagent solution was added to the mixture, and it was stirred again for 10 sec. After allowing this mixture (total volume 8.5 ml) to stand for 5 min, the colored solution was filtered and the absorbance of the complex

[a] Expressed as the equivalent amount of sulfisoxazole. [b] Not significantly different from the corresponding values of the control.

of the sulfonamide formed was measured at the appropriate wavelength.

The amounts of intact sulfanilamide or sulfisoxazole excreted in the urine samples were determined by the procedure described for blood samples, except that protein precipitation was unnecessary for the urine samples.

The total (intact plus metabolites) amount of sulfanilamide or sulfisoxazole excreted in the urine samples was determined after hydrolyzing the conjugated metabolites of the sulfonamide by heating the samples in the boiling water bath for 2 hr with 4 *N* HCl. The total sulfonamide was then analyzed according to the procedure described above for the intact sulfonamide.

The amount of free sulfonamide present in the unhydrolyzed urine or blood sample or the hydrolyzed urine sample was calculated with a calibration curve prepared for the respective sulfonamide. To prepare a calibration curve, known quantities of a sulfonamide were added to 1-ml volumes of blood obtained from rats not treated with a sulfonamide. The standard blood samples were treated in the same way as the actual blood samples, and their absorbance values were measured on a spectrophotometer at appropriate wavelength.

The absorbance for a given amount of sulfonamide contained in 1 ml of blood or 1 ml of water was identical after treatment by the Bratton–Marshall procedure, indicating that the residual amount of the blood constituents present in the supernate of the blood samples did not contribute to the absorbance. Therefore, the calibration curve of a sulfonamide was prepared from its aqueous solution without involving blood.

The main metabolite of sulfanilamide or sulfisoxazole was reported to be the acetylated form (9, 10). The amount of metabolite (in terms of the equivalent amount of intact sulfonamide) was calculated by subtracting the amount of free sulfonamide in the unhydrolyzed urine samples from the total amount of free sulfonamide in the hydrolyzed urine samples.

pH Determination of Cumulative Urine Samples—Each of four rats was treated with 5 ml normal saline for 5 days, and each of eight rats was treated with a 100-mg/kg ip dose of phenobarbital (in 5 ml normal saline) for 5 days. Each rat received 2 ml of pH 7.4 normal saline solution *via* the tail vein 24 hr after the last treatment dose of phenobarbital or normal saline. Cumulative urine samples were then collected separately from each rat for 7 hr. The pH of each cumulative urine sample was measured with a laboratory pH-meter. The urine pH of control rats varied from 6.35 to 6.50 and that of phenobarbital treated rats varied from 6.28 to 6.45.

RESULTS

Urinary Excretion Data for Sulfanilamide and Sulfisoxazole—The overall urinary excretion data obtained following the intravenous dose of sulfanilamide to the control and phenobarbital treated rats are shown in Table I. Virtually the entire dose of sulfanilamide was recovered in the urine in the intact and the metabolic forms in 35 hours for both the control and phenobarbital treated rats. All excretable intact compound was excreted in the urine in 8 hr and all excretable metabolite(s) were

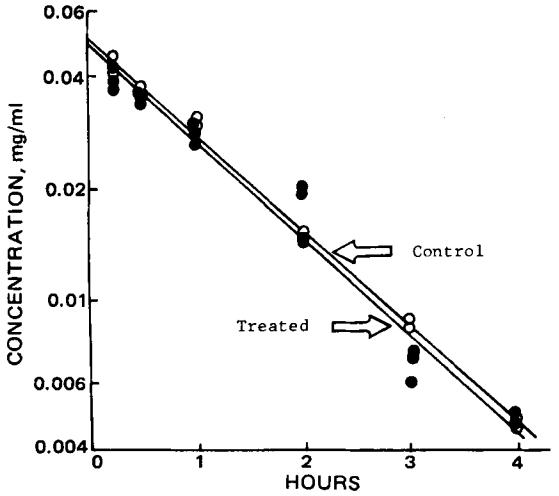

Figure 1—*Monoexponential semilogarithmic plots of blood concentrations of sulfanilamide obtained in control (○) and phenobarbital treated (●) rats. The solid lines are least-squares regression lines for the data of respective groups of rats.*

excreted in the urine in 35 hr. Of the total amount of the metabolites excreted, 80 to 85% was excreted in 8 hr.

To select the daily intraperitoneal dose of phenobarbital and the number of days to pretreat rats with this dose, the data in Table I were considered. The extent of metabolism of the compound in rats treated with a daily phenobarbital dose of 20 mg/kg for 5 days, 20 mg/kg for 10 days, 50 mg/kg for 5 days, or 100 mg/kg for 5 days was practically the same. Therefore, the regimen of phenobarbital treatment adopted in the pharmacokinetic study was a 100-mg/kg ip dose per day for 5 consecutive days. This was 5 times greater than the dose used in a previous study (1). The selection of the high phenobarbital dose was considered advisable since the compounds used in the present study are metabolized and bound to plasma proteins, unlike the nonmetabolized and nonprotein bound compounds used in a previous study (1). It was thought that, if the effects of phenobarbital treatment on sulfonamide distribution pharmacokinetics and biological half-lives were marginal at daily 20-mg/kg doses, more pronounced effects might be seen at daily 100-mg/kg doses. However, no pharmacokinetic studies were carried out at a daily 20-mg/kg dose of phenobarbital to determine if phenobarbital effects at the lower dose were less pronounced than those seen at a daily 100-mg/kg dose.

The overall urinary excretion data obtained following intravenous administration of 7 mg of sulfisoxazole to each control or phenobarbital treated rat are shown in Table II. Practically the entire administered dose of sulfisoxazole was recovered in the urine in intact and metabolic forms for the control and phenobarbital treated rats. There was no significant difference in the amounts of intact drug or metabolites recovered in the urine of the control and phenobarbital treated rats. The fractions of sulfisoxazole recovered in the intact (f_I) and metabolic (f_m) forms, based on the total amount recovered in 52 hr, are also listed in Table II. Of the total amount of sulfisoxazole recovered in the urine during the initial 10-hr period, 80–86% was in the intact form and 9–11% in the metabolic forms in the control and phenobarbital treated rats.

From the data in Tables I and II, a subject-to-subject variation among the control and phenobarbital treated rats in the extent of metabolism of the sulfonamides was minimum.

Pharmacokinetics of Sulfanilamide—The semilogarithmic plots of concentration *versus* time obtained for sulfanilamide in both the control and phenobarbital treated rats were monoexponential (Fig. 1). Therefore, the data were analyzed according to a one-compartment open model.

$$C = C_0 e^{-K_{el}t} \qquad \text{(Eq. 1)}$$

where C is the concentration of intact sulfanilamide at time t, C_0 is the concentration of intact sulfanilamide at time zero, and K_{el} is the apparent first-order rate constant of elimination of the drug. The drug concentrations plotted in Fig. 1 are normalized on the basis of a 10-mg iv dose of the drug per 200 g rat weight. The values of C_0 for the drug were determined from the intercepts obtained by extrapolating the respective least-squares line to time zero (Fig. 1). Values of K_{el} were calculated from the respective slope ($-K_{el}/2.303$) of the least-squares line. The apparent

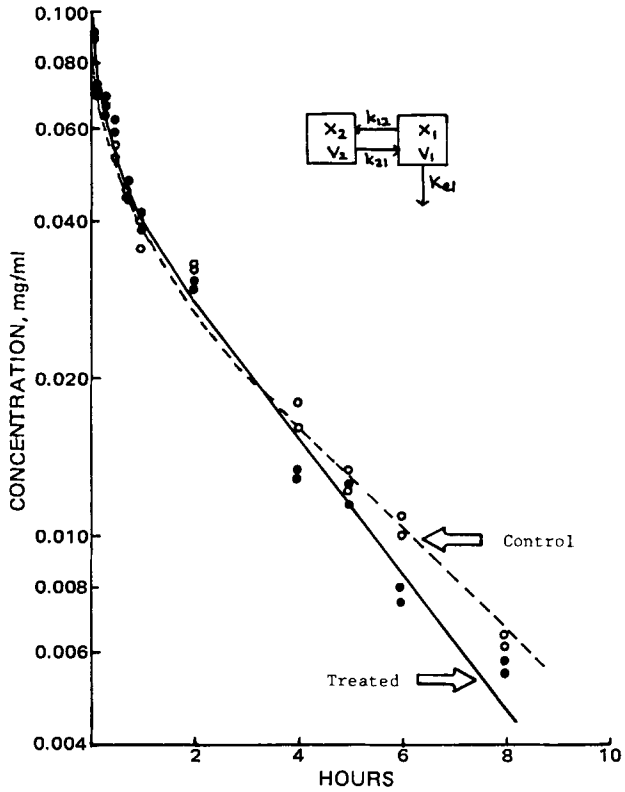

Figure 2—*Biexponential semilogarithmic plots of blood concentrations of sulfisoxazole obtained in control (○) and phenobarbital (●) treated rats. The solid and dotted lines are NONLIN least-squares regression lines for the data of respective group of rats. Insert is Scheme I.*

distribution volumes (V_d) and biological half-lives ($t_{1/2}$) of the drug were calculated in the usual manner (1). The pharmacokinetic parameters determined from these studies are listed in Table III. The standard deviations of all pharmacokinetic parameters were estimated by procedures described previously (1). The values of the parameters determined for the phenobarbital treated rats were not significantly different from those determined for the control rats. In fact, the values of all pharmacokinetic parameters observed are almost identical in the phenobarbital treated rats and the control rats, indicating that phenobarbital treatment had no effect on the distribution and elimination kinetics of sulfanilamide.

Pharmacokinetics of Sulfisoxazole—The semilogarithmic plots of concentration *versus* time for sulfisoxazole in both the control and phenobarbital treated rats indicated biexponential decline of the drug concentration in blood (Fig. 2). Therefore, the data were analyzed according to a two-compartment open model (Scheme I, Fig. 3) with elimination of the drug occurring from the central compartment:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

where C is the concentration of intact sulfisoxazole in the blood at time t and other terms in the equation (and in Scheme I) are described in previous papers (1, 11). The drug concentrations plotted in Fig. 2 are normalized on the basis of a 7-mg iv dose of the drug per 200 g rat weight. Preliminary estimates of the intercepts (A and B) and slopes ($-\alpha/2.303$ and $-\beta/2.303$) for the two linear exponential segments (resolved by the method of residuals) were obtained by a least-squares method described previously (1). Using the preliminary estimates of A, B, α, and β, the initial estimates of V_1, k_{12}, k_{21}, and K_{el} were obtained in the manner described previously (1). Refined estimates of V_1, k_{12}, k_{21}, and K_{el} with their standard deviations, and those of α and β without their standard deviations, were obtained by analyzing the data using the NONLIN least-squares program (12). Using the computer estimated values of these parameters, estimates of V_2, V_{ss}, elimination phase ($t_{1/2}$), and body clearance ($K_{el}V_1$) were calculated as shown previously (1). The estimated and derived parameters are listed in Table IV. Standard deviation values of V_1, k_{12}, k_{21}, and K_{el} are computer estimated values and those of other parameters were estimated by the procedures described previously (1). The values of all pharmacokinetic parameters, except V_2, V_{ss}, and $K_{el}V_1$, determined for sulfisoxazole in phenobarbital treated rats were significantly different from those determined in control rats.

Table III—One-Compartment Model Pharmacokinetic Parameters of Sulfanilamide Determined in Control and Phenobarbital Treated Rats

Parameter	Control	Phenobarbital Treated	Statistical Significance of Difference (p)
C_0, mg/ml	0.054 ± 0.002	0.053 ± 0.003	*NS*[a]
K_{el}, hr^{-1}	0.598 ± 0.020	0.615 ± 0.030	*NS*
$t_{1/2}$, hr	1.16 ± 0.04	1.13 ± 0.06	*NS*

r	0.996	0.980	

[a] No significant difference.

Rate Constants of Urinary Excretion and Metabolism of Sulfisoxazole—In Scheme I (Fig. 2), K_{el} is the sum of the apparent first-order rate constants of urinary excretion (k_{ex}) and metabolism (k_m) of sulfisoxazole. The values of k_{ex} and k_m can be calculated using the following equations (13):

$$k_{ex} = K_{el} f_I \quad \text{(Eq. 3)}$$

$$k_m = K_{el} f_m \quad \text{(Eq. 4)}$$

$$f_I = \frac{S_{e\infty}}{S_{e\infty} + M_{e\infty}} \quad \text{(Eq. 5)}$$

$$f_m = \frac{M_{e\infty}}{S_{e\infty} + M_{e\infty}} \quad \text{(Eq. 6)}$$

where $S_{e\infty}$ is the amount of sulfisoxazole excreted in the urine in infinite time and $M_{e\infty}$ is the equivalent amount of sulfisoxazole excreted in the urine as metabolite(s) in infinite time (Table II). Using the corresponding values of f_I and f_m from Table II and those of K_{el} in Table IV, the values of k_{ex} and k_m were calculated for control and phenobarbital treated rats (Table V). The standard deviation of k_{ex} and k_m were estimated according to the formulas (14):

$$k_{ex} = [\{(\sigma k_{ex}/k_{ex})^2 + (\sigma f_I/f_I)^2\}(k_{ex})^2]^{1/2} \quad \text{(Eq. 7)}$$

$$k_m = [\{(\sigma k_m/k_m)^2 + (\sigma f_m/f_m)^2\}(k_m)^2]^{1/2} \quad \text{(Eq. 8)}$$

As noted in Table V, according to the t test statistics, k_{ex}, but not k_m, was significantly greater in the phenobarbital treated rats than in the control rats.

DISCUSSION

Phenobarbital treatment did not affect the extent of nonmicrosomal enzymatic metabolism (Table II) or protein binding (4) of sulfisoxazole (which is excreted mainly by the kidney in rats). The significant decrease in the apparent distribution volume of the central compartment and the biological half-life of sulfisoxazole in the phenobarbital treated rats cannot be attributed to the increased hepatic blood flow, microsomal enzyme concentration, and biliary flow usually brought about by chronic phenobarbital treatment. The possibility of a decrease in the biological half-life of sulfisoxazole (pKa 5.1) due to a posssible increase in urine pH of rats was also evaluated. The normal pH of luminal fluids in the proximal tubules of rats was reported to be 6.82 (15). In this study, the pH of the cumulative urine samples collected separately from four control rats for 7 hr varied from 6.35 to 6.5, with an average pH of 6.42. Similarly, the pH of the cumulative urine samples collected separately from eight phenobarbital treated rats for 7 hr varied from 6.28 to 6.45, with an average pH of 6.36. Thus, the urine pH in phenobarbital treated rats was similar to that in the control rats. In the pH ranges measured, sulfisoxazole remains 94–96% in the anionic form. Therefore, the slight variation in urine pH was not expected to influence the half-life of sulfisoxazole in these rats.

Distribution Kinetics—The reduction in the distribution volume of the central compartment of sulfisoxazole in phenobarbital treated rats may be due to a possible decrease in the rate of diffusion of the anionic form of sulfisoxazole through the aqueous pores of the cell membranes of central compartment tissues. This was previously proposed (1) for the anions of mandelic acid, which also displayed the characteristics of a two-compartment model. As observed with mandelic acid, there was a tendency for V_2 and V_{ss} of sulfisoxazole to be lower in the phenobarbital treated rats, but the values of these parameters were not significantly different at the 95% confidence level from those in the control rats. However, V_{ss} of sulfisoxazole in the phenobarbital treated rats was different from that in the control rats at a 90% confidence level.

Table IV—Two-Compartment Model Pharmacokinetic Parameters of Sulfisoxazole Determined in Control and Phenobarbital Treated Rats

Parameter	Control	Phenobarbital Treated	Statistical Significance of Difference (p)

As rationalized previously (1) for model organic anions, the transmembrane transport of sulfisoxazole anions is assumed to occur through the aqueous pores of cell membranes of the central and tissue compartments. It is likely that the possible increase in protein and phospholipid concentration brought about by phenobarbital pretreatment (1), probably causes a decrease in the pore size of (especially) the small size pores of cell membranes of the central and tissue compartments. This may cause a greater interaction of diffusing sulfisoxazole molecules with the proteins and phospholipids of the aqueous pore lining by intermolecular forces such as hydrogen bonding, hydrophobic bonding, and electrostatic interaction.

Interestingly, k_{12} and k_{21} for the intercompartmental transport of sulfisoxazole and mandelic acid in a previous study (1) were significantly greater in the phenobarbital treated rats than in the control rats, although the rate and extent of penetration of these anions into the deeper regions of the tissues was decreased in the phenobarbital treated rats. This may be rationalized by recognizing that k_{12} and k_{21} are the hybrid overall rate constants of anions which penetrate the tissues by diffusing through aqueous pores of small and large sizes, experiencing a greater transport barrier through the small size aqueous pores. If the very small size aqueous pores have narrowed sufficiently due to phenobarbital treatment and blocked penetration of anions through them in the deeper regions of tissues and decreased the apparent distribution volumes of accessible tissues, the remaining pores are the relatively large size aqueous pores whose resistance to penetration of the anions is not substantially affected. This situation would give a relatively rapid attainment of equilibrium of the reversible intercompartmental transport of the anions, leading to apparent increases in k_{12} and k_{21} values in phenobarbital treated rats.

Elimination Kinetics—The elimination rate constant (K_{el}) of sulfisoxazole, which is involved in renal tubular secretion (4), is increased by the phenobarbital treatment, as were the elimination rate constants of model organic anions (1) involved in renal tubular secretion in rats. Since the model organic anions were not metabolized and were eliminated from the body due to urinary excretion, K_{el} of these compounds were essentially the urinary excretion rate constants (k_{ex}). The increase in k_{ex} of model organic anions was attributed to the possible stimulatory effect of phenobarbital on the renal tubular secretory process (1). The rate constant of elimination of sulfisoxazole (K_{el}) represents the sum of k_{ex} and k_m, and, as noted in Table V, the increase in K_{el} is due to the significant increase in k_{ex} of sulfisoxazole in the phenobarbital treated rats. The increase in k_{ex} of sulfisoxazole anions may also be due to a stimulatory effect of phenobarbital on its renal tubular secretion process. This effect was shown for p-amino hippurate in phenobarbital treated rats (16).

Sulfanilamide—It was proposed (1) that a decrease in the apparent distribution volumes may be observed in phenobarbital treated rats for compounds which exist in the blood in the ionized form, exhibit multicompartment characteristics, and distribute between the compartments mainly by diffusion through the aqueous pores of the tissue cell membranes. It was also postulated (1) that such changes in the apparent distribution volumes are unlikely to be observed for compounds that exist in the blood in the nonionized form and may even display multicompartment characteristics, since they generally have greater membrane solubility and diffuse through the entire membrane surface of which aqueous pores constitute only a fractional surface area. It was further proposed that the increase in the elimination rate constants may be observed in the phenobarbital treated rats even for organic anions whose metabolic process is not stimulated by phenobarbital, but are secreted

Table V—Apparent First-Order Rate Constants of Urinary Excretion (k_{ex}) and Metabolism (k_m) of Sulfisoxazole Calculated for Control and Phenobarbital Treated Rats

	Control	Phenobarbital Treated	Statistical Significance of Difference (p)
k_{ex}, hr^{-1}	0.3838 ± 0.0204	0.4582 ± 0.0260	<0.05
k_m, hr^{-1}	0.0398 ± 0.0130	0.0601 ± 0.0156	*NS*

by the renal tubules, due to the possible stimulatory effect of phenobarbital on the renal tubular secretory mechanism of organic anions such as *p*-amino hippurate (16). As a corollary to this, it was postulated that the elimination rate constants of compounds whose metabolic process if not stimulated by phenobarbital will not be influenced in phenobarbital treated rats if the compounds are excreted in the urine by glomerular filtration.

The results (Table III) obtained for sulfanilamide are supportive of these hypotheses. The apparent distribution volume of sulfanilamide, which not only exists in the blood in the nonionized form but also shows characteristic one-compartment behavior, was not affected by the phenobarbital treatment. Also, K_{el} or $t_{1/2}$ of sulfanilamide, which is not involved in renal tubular secretion but is excreted by glomerular filtration in the urine, is not affected by the phenobarbital treatment.

CONCLUSIONS

The previous (1) and present studies demonstrate that, besides its known drug metabolizing enzyme induction effect, phenobarbital treatment may produce two additional effects on the pharmacokinetics of organic anions displaying multicompartment model characteristics. One effect is the changes in distribution space and rates reflected in such pharmacokinetic parameters as k_{12}, k_{21}, V_1, and V_{ss} of two-compartment model compounds. The other effect is on the renal tubular secretion process, reflected in such pharmacokinetic parameters as k_{ex} and K_{el} of the compounds. The fact that these pharmacokinetic parameters of drugs are independent of their elimination rate constants was pointed out previously (17).

The biological half-lives of multicompartment model compounds are derived from the disposition rate constants of the compounds and are, therefore, a function of both distribution and/or elimination (11). Therefore, the change in the biological half-lives of compounds brought about by phenobarbital treatment reflect the changes in distribution and/or elimination of the compounds.

Although the results of the previous (1) and present studies are consistent with the mechanism conceived previously (1) for the effects of phenobarbital, direct evidence of the increase in the protein and phospholipid concentration of certain target peripheral tissue cell membranes has not been obtained at this time. However, regardless of whether such direct evidence is obtained in the future, further evidence of the effects of phenobarbital treatment on the distribution and elimination pharmacokinetic parameters of other suitable organic anionic drugs should be gathered.

A Comparison of Frozen and Reconstituted Cattle and Human Skin as Barriers to Drug Penetration

IAN H. PITMAN ˣ **and SUSAN J. ROSTAS**

Received March 6, 1981, from the *School of Pharmaceutics, Victorian College of Pharmacy, Parkville, Victoria, Australia 3052.* Accepted for publication August 3, 1981.

Abstract □ An *in vitro* study of the permeabilities of frozen and reconstituted cattle skin and human skin to levamisole was done. Cattle skin was 400 times more permeable to levamisole from an organic solvent (largely 2-ethoxyethanol) than was human skin. The diffusion coefficient value of levamisole in cattle skin and the partition coefficient value of levamisole from the organic solvent into the skin suggested that a relatively large amount of drug passed through skin appendages such as hair follicles or sweat/sebaceous ducts. Transcellular transport across the stratum corneum was rate-determining in human skin penetration.

Keyphrases □ Permeability—frozen and reconstituted cattle and human skin *in vitro*, levamisole □ Levamisole—*in vitro* permeability through frozen and reconstituted cattle and human skin □ Dosage forms, topical—levamisole, *in vitro* permeability through frozen and reconstituted cattle and human skin

The use of topical dosage forms for the systemic delivery of drugs to domestic animals was foreshadowed by Rogoff and Kohler (1) when they showed that cattle grubs could be controlled by applying a small volume of a concentrated crufomate solution to a cow's skin. Such dosage forms, which are known as pour-ons or spot-ons, have subsequently been proposed for the systemic delivery of a variety of drugs to sheep and cattle (2–6).

The present report concerns the rate and mechanism by which the anthelmintic levamisole is transported across samples of excised cattle skin that were frozen and reconstituted.

The work was undertaken as part of a program to develop an *in vitro* screen for pour-on formulations. The development of topical drug delivery systems for humans has been greatly facilitated by the use of *in vitro* screens which are based on the realization that strong qualitative agreement exists between the rate at which drugs penetrate excised human skin in *in vitro* experiments and *in vivo* penetration (7). In addition, it was established (8) that it does not matter whether the skin used in the *in vitro* experiments is fresh or frozen or whether stratum corneum, epidermis, or whole skin is used.

EXPERIMENTAL

Preparation of Cattle Skins—Skin was harvested in mid-March (*i.e.*, early fall in Australia) from an 8-month old Hereford calf. As soon as the animal had been sacrificed its hair was clipped[1] as close as possible to the skin without damaging it. Strips of skin were removed from the dorsal thoraco-lumbar region using a dermatome[2] set at 1.1 mm. The strips of skin were immediately labeled, wrapped, and placed on ice. Within 3 hr the skins were placed in a freezer at −30° until required for an experiment. The permeability of skin handled in this way did not change appreciably after at least 12 months storage.

Before starting a skin permeability experiment, a sample was thawed at room temperature in a sealed jar containing paper that was soaked in normal saline. This procedure was adopted to minimize skin dehydration.

Preparation of Human Skin—Skin, and its accompanying subcutaneous fat, was obtained from the upper thigh of humans following leg amputations or from breasts following cosmetic surgery. The skin was frozen, stored, and thawed in the manner described for cattle skin. When the human skin had thawed, the subcutaneous fat and the lower section of the dermis were removed with a scalpel.

Materials—Levamisole[3], mp 61°, was used without further purification. the solvents used in the levamisole formulations were an aqueous borate solution (pH 8.9 buffer) and an organic solvent (solvent A) containing nonaromatic hydrocarbons (15%), polyoxypropylene 15-stearyl ether (12%), and ethoxyethanol (73%). The receptor phase was normal saline.

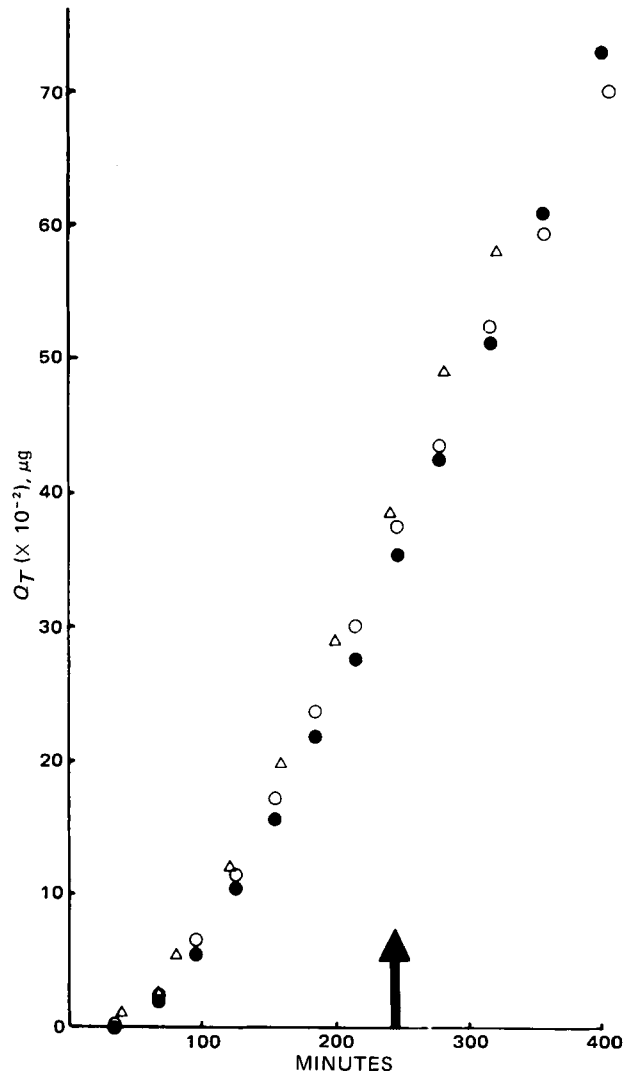

Figure 1—*The quantity of levamisole penetrating 1.45 3 cm² of cattle skin from a 10% solution in solvent A* versus *time using a constant stirring rate throughout (△), a constant stirring rate for 245 min and then half the rate (●), and a constant stirring rate for 245 min and then no stirring except for 4 min prior to taking a reading (○).*

[a] r = skin thickness and number in parentheses is the spread; [b] k_p = permeability constant; [c] L = lag time; [d] D = diffusion coefficient; [e] PC = partition coefficient; [f] Q_{200} = quantity crossing 1.453 cm^2 in 200 min.

Measurement of Skin Permeability and Calculation of Permeability Constants—The method used for measuring skin permeability and the chemical assay of levamisole have been described previously (9). Skin thickness was measured at the conclusion of an experiment with a tension micrometer. These measuresments were made at the end of an experiment rather than at the beginning to avoid causing mechanical damage to the skin prior to making permeability measurements. The average of five readings taken over the entire surface was recorded.

The permeability constant, k_p (cm/min), was calculated using:

$$k_p = \frac{S \times V}{1.453 \times C} \qquad \text{(Eq. 1)}$$

where S (μg/ml/min) is the slope of the steady-state plot of drug concentration in the receptor compartment *versus* time, V (cm^3) is the volume of the receptor compartment, 1.453 cm^2 is the surface area of the skin, and C (μg/ml) is the concentration of drug applied to the skin surface.

The lag time, L (min), was taken as the intercept on the x-axis of the steady-state plot of drug concentration in the receptor compartment *versus* time.

RESULTS AND DISCUSSION

Permeability of Cattle Skin to Levamisole—*Effect of Rate of Stirring of Receptor Phase*—Figure 1 shows the amounts of levamisole that had penetrated samples of cattle skin (Q_T) from a 10% solution in solvent A. The stirring rate of the receptor phase was different in each experiment. In one experiment, a constant stirring rate was maintained from start to finish. In subsequent experiments, the same rate was maintained for 245 min, and then the stirring rate was either halved or stopped (except for 4 min immediately prior to the removal of an aliquot for assay).

The results of Fig. 1 indicate that the rate of appearance of levamisole in the receptor phase was independent of the stirring rate. This result suggests that transport of levamisole through the skin is the *in vitro* rate-determining process rather than clearance from the skin into the receptor phase (10). Increasing the agitation rate of the receptor phase would decrease the thickness of the unstirred layer of receptor phase adjacent to the skin and would increase the rate of appearance of levamisole in the receptor phase if this were the rate-determining process.

The value of the present report to an understanding of the *in vivo* topical absorption process in domestic animals depends on whether penetration of drug through the skin rather than clearance into a receptor phase is the rate-determining step in both *in vitro* and *in vivo* situations. If this were not the case, the difference in character between stirred normal saline (*in vitro* experiments) and flowing blood (*in vivo* experiments) as receptor phases would reduce the likelihood of correlation between the results of the two types of experiment.

Effect of Skin Sample Thickness—The skin samples from the calf consisted of the epidermis together with varying thicknesses of dermis.

Table II—Permeability of Human Skin to Levamisole from a 0.85% Solution in an Aqueous Buffer at pH 8.9

Donor	$10 \times r^a$, cm	$10^6 \times k_p{}^b$, cm/min	L^c, min	$10^{-2} \times Q_{200}{}^d$, μg
6	1.28 ± 0.04	131	83	2.2
6	1.23 ± 0.06	145	84	2.4
6	0.98 ± 0.19	117	98	1.7
9	1.09 ± 0.18	161	75	1.7
9	0.99 ± 0.08	135	98	2.0
8	0.91 ± 0.05	101	107	1.3
8	0.81 ± 0.01	118	150	0.9

[a] r = skin thickness. [b] k_p = permeability constant. [c] L = lag time. [d] Q_{200} = quantity crossing 1.453 cm^2 in 200 min.

Studies of the penetration of levamisole from its 10% solution in solvent A indicated that steady-state penetration was achieved by 100 min in all cases and was maintained for at least 5–6 hr. Table I shows the permeability constants, lag times, and quantity of levamisole which had penetrated in 200 min through samples of cattle skin 0.65–1.69 mm thick.

There was a strong negative correlation between skin thickness and permeability constant ($\gamma = -0.95$; $0.01\% > P$) and a positive correlation between skin thickness and lag time ($\gamma = +0.90$; $0.01\% > P$). Furthermore, the product of permeability constant and total skin thickness ($k_p r$) was essentially constant for skins whose thickness varied from 0.65–1.1 mm.

These results suggest that the outer 1 mm or so of skin acts like a homogeneous barrier to levamisole penetration. For diffusion of molecules through a homogeneous barrier, the values of k_p and L are related to the skin thickness, r, in the following manner (11):

$$k_p = \frac{D(PC)}{r} \qquad \text{(Eq. 2)}$$

$$L = \frac{r^2}{6D} \qquad \text{(Eq. 3)}$$

where D (cm^2/min) is the diffusion coefficient of the diffusing molecule in the barrier, and PC is the partition coefficeint for the diffusing substance between the barrier and the solvent.

Under conditions where Eqs. 2 and 3 apply, values of the terms $k_p r$ [$= D(PC)$] and $r^2/6L$ ($=D$) should be constant. Values of these terms are included in Table I.

While values of $k_p r$ and $r^2/6L$ do vary with r when it is changed from 1.69 to 0.8 mm, it appears that these terms are essentially constant for skin specimens <1.1 mm thick. This suggests that the portion of the skin from the surface of the stratum corneum down to a depth of ~1 mm can be considered to be a homogeneous barrier when considering levamisole penetration. The mean value of the term $r^2/6L$ throughout this thickness range, 2.1×10^{-5} cm^2/min, is the apparent diffusion coefficient of levamisole in the homogeneous barrier.

The mean value of the term $k_p r$ [$D(PC)$] throughout the barrier with a thickness 0.8–1.09 mm was 17.2×10^{-6} cm^2/min. Thus, on the basis that D was 2.1×10^{-5} cm^2/min, the apparent value of PC between the barrier and the solvent A was 0.84.

Permeability of Human Skin to Levamisole—It has been established (11, 12) that the stratum corneum is the rate-determining barrier to penetration of human skin by most nonelectrolytes of small to medium size molecular weights. This was confirmed for levamisole penetration in human skin by considering the effect of skin sample thickness and the removal of the stratum corneum on permeability.

Table II contains the calculated permeability constants and lag times for penetration of human skin at 37° by levamisole from its 0.85% solution in an aqueous buffer, pH 8.9.

Table III—Effect of Removal of Stratum Corneum on Human Skin Permeability to Levamisole from a 0.85% Solution in an Aqueous Buffer at pH 8.9

Donor	$10 \times r^a$, cm	Treatment	$10^6 \times k_p{}^e$, cm/min	L^f, min	$10^{-2} \times Q_{200}{}^g$, μg
9	1.09	*b*	161	75	1.7
9	0.97	*c*	108	92	1.7
9	0.93	*d*	720	33	17.5
9	0.91	*d*	692	46	15.5

[a] r = skin thickness. [b] treated as in Table II. [c] heated at 60° for 2 min and cooled. [d] as in *c* but stratum corneum peeled off. [e] k_p = permeability constant. [f] L = lag time. [g] Q_{200} = quantity penetrating 1.453 cm^2 in 200 min.

Figure 2—*Micrograph (×80) of a vertical section of calf skin stained with hemotoxylin and eosin.*

The aqueous buffer was used in these experiments instead of solvent A because levamisole only penetrated human skin very slowly from the latter solvent. This is in marked contrast to the situation with cattle skin penetration. Whereas 4180 μg of levamisole penetrated a 0.8 mm thick sample of calf skin in 200 min from solvent A, only 10 μg penetrated through a 0.81-mm sample of human skin in the same time. Only 121 μg of levamisole had penetrated the human skin in 12 hr. Steady-state penetration from the aqueous solution was achieved within 100 min in most cases and was maintained for at least 5 hr.

One problem encountered in interpreting the data in Table II arose because only limited amounts of skin could be obtained from each donor. Hence, in contrast to the situation with cattle skin penetration, insufficient data to permit a statistical analysis of the effect of skin thickness was obtained on skin from a single donor. However, the data suggest that no strong correlation with a negative correlation coefficient exists between human skin thickness and the permeability constant when the former is varied between 0.81 and 1.28 mm. The small amount of data on skin from each donor is more consistent with the conclusion that permeability constants and lag times for diffusion are independent of skin sample thickness. This is in contrast to the cattle skin permeability and is consistent with the proposal that the stratum corneum (*i.e.*, the outer 10 μm of the epidermis) is the rate-determining barrier to penetration.

Table III supports this conclusion. The data relate to the permeability of a skin sample that was heated in 60° water for 2 min prior to the penetration experiment and a similarly treated skin sample whose stratum corneum was peeled off after heating and prior to the permeability experiment.

The results show that heating the skin to 60° and cooling prior to a permeability experiment did not significantly effect the skin permeability. However, removal of the stratum corneum led to a dramatic increase in permeability which confirmed the postulate that this layer is rate determining for penetration of levamisole through human skin which has been frozen and reconstituted.

An estimate of the diffusion coefficient of levamisole in human stratum corneum, D (cm^2/min), and of the partition coefficient of levamisole between water at pH 8.9 and human stratum corneum can be made using Eqs. 1 and 2, a value of 10^{-3} cm for the thickness of the stratum corneum, and values of k_p (cm/min) and L (min) in Table II. For the purpose of this exercise, the data in Table II that were obtained on skin sample 6 were used, *i.e.*, $k_p = 131 \pm 14 \times 10^{-6}$ cm/min and $L = 88 \pm 10$ min. This led to values of $D = 1.9 \times 10^{-9}$ cm^2/min and $PC = 69$.

The value of D is similar to the values that have been reported (11) for water and low molecular weight nonelectrolytes ($3–4 \times 10^{-8}$ cm^2/min) in human stratum corneum.

Levamisole has a pKa value of 7.94 at 37° (9) and, thus, exists to the extent of 90% as a neutral molecule at pH 8.9. The calculated value of PC(69) suggests that the stratum corneum has a much lower polarity than water and is a better solvent for levamisole than water.

Mechanism of Absorption of Levamisole across Cattle Skin—The apparent constancy of the product $k_p r$ for levamisole absorption across cattle skin samples with a thickness of 0.65–1.1 mm suggests that this total skin thickness, rather than the 30 μm stratum corneum (13), is the rate-determining barrier. Values of $k_p r$ tended to decrease when skin with a thickness >1.1 mm was used. It will be argued subsequently that the first 1.1 mm of skin is richly supplied with blood and that drug molecules that penetrate into it would be rapidly absorbed into the blood. Consequently, it is proposed that controlling the rate at which drug molecules pass through the first 1.1 mm will result in control of the rate at which they enter the blood in the *in vivo* situation.

It may be argued that the stratum corneum was removed from the skin samples investigated by either the method of the skin preparation or by solvent A. The first possibility is considered unlikely since fine clipping of hair was shown (14) to remove no more than 4 of 30 layers of bovine stratum corneum. The second possibility is discounted because $k_p r$ was also constant for levamisole penetration through cattle skin from aqueous solutions.

It is proposed that the first 1.0–1.1 mm of the cattle skin used in these experiments is made up of the epidermis with its stratum corneum (60 μm thick) (13) and the highly vascular papillary layer of the dermis.

Histological studies of a variety of cattle skins revealed (15) that the first 1 mm is usually epidermis plus papillary layer of the dermis, and the lower 6 mm is the collagenous reticular layer of the dermis. McEwan-Jenkinson (16) has suggested that the papillary and reticular layers of the dermis of bovine skin meets in the area of the sebaceous gland. Confirmation of this proposition comes from inspection of the micrograph of a dehydrated, paraffin-embedded section of cattle skin (Fig. 2). This section, which is typical of the skin studied, shows that the first 1 mm of skin contains most of the hair follicle and the sebaceous gland associated with it.

It is not clear whether the bulk of the drug is transported through the first 1 mm or so of skin *via* the cells (*i.e.*, transcellular) as in human skin penetration (11) (although in this case it is only the stratum corneum which is rate determining) or *via* the appendages such as the hair follicle, sweat duct or sebaceous duct.

The value of the diffusion coefficient for levamisole in the first 1.0 mm of cattle skin (2.1×10^{-5} cm^2/min) is much closer to those of water and low molecular weight nonelectrolytes through human hair follicles ($0.3–1.2 \times 10^{-5}$ cm^2/min) or sweat ducts ($6.0–12.0 \times 10^{-5}$ cm^2/min) than to the value calculated for levamisole passing through human stratum corneum cells (1.9×10^{-9} cm^2/min). Consequently, it is tempting to postulate that most of the drug is transported *via* the skin appendages in transport across cattle skin.

A major reason why transport *via* skin appendages has only been assigned a minor role in human skin transport is because their density per unit area of skin is very low (40–70 cm^{-2} for hair follicles and 200–250 cm^{-2} for sweat glands) (11). Thus, it would be reasonable to predict that this route would be more favorable in cattle skin penetration because the density of hair follicles is higher ($\simeq$890 cm^{-2}) (17), and each follicle has a sweat gland, sebaceous gland, and the ducts associated with it. However, the greater density of hair follicles in cattle (~15 times the density in human skin) cannot on its own account for the 400-fold increase in the rate at which levamisole crosses cattle skin as compared to human skin. It is possible that penetration *via* the cattle skin appendages is facilitated by the emulsified sebum that is associated with them (18). This emulsion may be a better solvent for levamisole than the sebum which is associated with human hair follicles or the sweat associated with human sweat glands. Studies concerning the role that emulsified sebum plays in cattle skin penetration are currently underway.

If the above postulate is correct, it is likely that the drug would rapidly enter the systemic circulation in live animals because the appendages are richly supplied with blood vessels.

CONCLUSIONS

The first 1 mm or so of frozen and reconstituted cattleskin[4] acts as a homogeneous barrier to penetration of the skin by chemicals. The diffusion coefficient of levamisole in this barrier is close to its expected value in hair follicles or sweat ducts. The results of the present study suggest that polar molecules such as levamisole will penetrate cattle skin much more rapidly than human skin.

[4] It should be noted that freezing the skin could very well alter its cellular geography to such an extent that the results of this study may not reflect properties of intact fresh skin. If this is true, then the value of the present results to *in vivo* behavior will only be realized when *in vivo* experiments are completed. However, the results clearly indicate that frozen and reconstituted cattle skin has very different barrier properties to similarly treated human skin and that the stratum corneum of the former skin does not appear to be the rate-determining barrier to penetration.

Antitumor Agents XLVIII: Structure–Activity Relationships of Quassinoids as *In Vitro* Protein Synthesis Inhibitors of P-388 Lymphocytic Leukemia Tumor Cell Metabolism

Y. F. LIOU, I. H. HALL ˣ, M. OKANO, K. H. LEE, and S. G. CHANEY *

Received April 6, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, and the *Department of Biochemistry, School of Medicine, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication August 4, 1981.

Abstract □ A series of brusatol, bisbrusatol, and bruceantin esters were examined for their ability to inhibit protein synthesis in P-388 lymphocytic leukemia cells. Compounds which produced high T/C % values (170–272) resulted in ID_{50} of 5.4–15.5 μM for inhibition of whole cell protein synthesis, ID_{50} of 1.3–13 μM for inhibition of endogenous protein synthesis in cell homogenates, and ID_{50} of 1.9–6 μM for inhibition of polyuridine directed polyphenylalanine synthesis using "runoff" ribosomes and a "pH 5" enzyme preparation. The polyuridine directed polyphenylalanine synthesis requires neither initiation nor termination factors, suggesting that quassinoids are exclusively elongation inhibitors. Bruceantin, brusatol, and bisbrusatolyl malonate allowed a runoff of the polyribosomes to 80S free ribosomes. However, formation of the ternary complex and 80S initiation complex were not inhibited by the quassinoids. Thus, these agents do not affect the individual steps leading to the formation of a stable 80S initiation complex in P-388 cells. Brusatol, bruceantin, and bisbrusatolyl malonate inhibited the formation of the first peptide bond between puromycin and [^{3}H]methionyl-transfer RNA bound to the initiation complex, indicating peptidyl transferase activity is inhibited by the quassinoids in P-388 cells. These studies also suggest that the free 80S ribosome is the site of binding by the quassinoid. Ribosomes actively conducting protein synthesis will continue protein synthesis and terminate before the quassinoids bind. This proves quassinoids are elongation inhibitors of tumor cells. A strong correlation was observed between potent antileukemic activity and the ability to inhibit protein synthesis in P-388 lymphocytic leukemia cells.

Bruceantin, a quassinoid now in phase II clinical trials, was first isolated from *Brucea antidysenterica* (1, 2). Subsequently, bruceoside A was isolated from *Brucea javanica* (3) and brusatol was derived chemically from bruceoside A. It was demonstrated (4) that bruceantin inhibited protein synthesis in HeLa cells by 90% at 2 μM, whereas DNA and RNA synthesis were inhibited 60 and 15%, respectively. Protein synthesis was inhibited 79% in rabbit reticulocytes by bruceantin at 0.1 μM (4). Liao (4) postulated that bruceantin was an initiation inhibitor of

0022-3549/82/0400-0430$01.00/0

protein synthesis. However, it was shown (5), using the yeast organism *Saccharomyces cereviseae*, that bruceantin blocks the peptidyl transferase site of the ribosome and inhibits the peptide chain elongation reaction. Interestingly, the drug binds to the free ribosome as opposed to the ribosome actively engaged in protein synthesis (5).

Brusatol has been observed to inhibit DNA, RNA, and protein synthesis of P-388 lymphocytic leukemia cells at 0.015 m*M* concentration resulting in 84, 62, and 86% inhibition, respectively. At 0.005 m*M* the inhibitions are 38, 44, and 60%, respectively (6). Brusatol was shown to be an elongation inhibitor by using the rabbit reticulocyte pro-

tein synthesis system. Brusatol probably inhibits peptidyl transferase activity (7). Bruceantin and brusatol are active against P-388 lymphocytic leukemia growth *in vivo* between 100 μg/kg to 1 mg/kg depending on the host strain of mice used (8). A series of brusatol esters and bisbrusatolyl esters were synthesized and characterized previously (9).

The present study reports the structure–activity relationships between the antileukemic activity and the ability to suppress protein synthesis elongation processes.

RESULTS AND DISCUSSION

Potent antileukemic activity against P-388-UNC lymphocytic leukemia was observed with compounds VII, IX, XIII, XIV, and XV giving T/C % ≧ 180 at 0.6 mg/kg/day in BDF_1 male mice. The results are comparable with the standard, fluorouracil, at 25 mg/kg/day. Moderate activity (T/C % ≧ 140–176) was observed with compounds II, III, XI, XII, and VIII. The bisbrusatolyl esters (XI–XIV) were more potent than brusatol (II) or bruceoside A (I), respectively, the succinate (XIII) and malonate (XIV) esters with T/C % of 217 and 272, respectively. Reduction of the C_{15} ester double bond did not decrease the antileukemic activity significantly (compare XV to XIII and XVIII to III). However, saturation of the diosphenol double bond resulted in either less activity or an inactive compound (XVI, XVII, and XIX). Esterification of II at the C-3 position gave VII and IX which were more active than II. Compounds formed by acetylation of the hydroxyl groups at C-11 and C-12 possessed little antileukemic activity (IV, VIII, and X).

Whole cell protein synthesis of P-388 cells was inhibited maximally (92%) by compound XIV (Table I) followed by compounds II, IX, and XIII (78–69%) and compounds I, III, V, VII, XII, XV, and XVIII (60–53%) at 15 μ*M* final concentration. The quassinoids followed a dose response from 5–15 μ*M*. Examination of the lysate protein synthesis assay demonstrated that compounds II, IX, XIII, XIV, and XV caused >80% inhibition, whereas compounds VII, XI, and XII resulted in >70% inhibition of protein synthesis (Table II).

Compounds II and III have been previously demonstrated to be elongation inhibitors in normal rabbit reticulocytes and compound XIV in the P-388 tumor line. For this reason a series of experiments were conducted to establish the inhibition mechanism by compounds II and III in the P-388 leukemia cells. A comparison of Fig. 2 with Fig. 1 shows that compounds II, III, and XIV all allow accumulation of the 80S ribosome peak similar to pyrocatechol violet rather than emetine. The result suggests the quassinoids allow completion of the already initiated polypeptide chain synthesis and release of the free 80S ribosome from the polyribosome before totally inhibiting protein synthesis. The quassinoids had little or no effect on the formation of either the ternary complex[1] or the 80S initiation complex[2] (Table III). The quassinoids II, III, and XIV behaved in these assays more like emetine than pyrocatechol violet indicating that they did not inhibit initiation events of polypeptide chain synthesis.

In an additional study, the formation of the 80S initiation complex[2] and peptide bond formation was examined by treating P-388 cell lysates with the elongation inhibitor chlortetracycline, which specifically inhibited binding of the aminoacyl-transfer RNA to the ribosome A site but did not inhibit the peptidyl transferase reaction. When [^{3}H]methionyl-transfer RNA was added to the system, most of the radioactivity was found associated with the 80S initiation complex. Addition of poly-adenosine-uridine-guanosine to the chlortetracycline treated lysate allowed formation of an 80S initiation complex (Fig. 3). The complex then reacted with puromycin followed by the puromycin-induced release of [^{3}H]methionine from the 80S complex (Fig. 4). The quassinoids II, III, and XIV did not appear to inhibit the formation of the 80S initiation complex, but did inhibit puromycin release of methionine indicating that the quassinoids inhibit P-388 peptide bond formation. Examination of the formation of aminoacyl-transfer RNA with phenylalanine, leucine, or methionine indicated that these agents had no effect on the activation of amino acid for incorporation into polypeptides. These studies suggest that the quassinoids are elongation inhibitors of protein synthesis, probably inhibiting peptidyl transferase activity. The quassinoids do not inhibit the synthesis of ongoing polypeptide synthesis but rather appear to bind to free P-388 80S ribosomes. The 80S peak which accumulates in the presence of the quassinoids is actually an 80S initiation complex

rather than true runoff ribosomes. The acceleration of 80S initiation complex has been reported previously with bruceantin in yeast, brusatol in rabbit reticulocytes, and bisbrusatolyl malonate in P-388 cells. Table IV demonstrates that the quassinoids inhibit polyuridine directed synthesis of polyphenylalanine, a study carried out on purified runoff ribosomes isolated from 10-day P-388 cells. Polyuridine directed polyphenylalanine synthesis does not require the normal initiation and termination reactions; consequently, this inhibition is of the elongation type exclusively. Table IV shows that compound XIV caused 92% inhibition at 15 μM. Compounds VII and XIII result in greater than 80% inhibition of polyphenylalanine synthesis, whereas compounds II, IX, XI, and XII caused greater than 75% inhibition at 15 μM.

The structural rquirements for inhibition of protein synthesis of P-388 leukemia cells are bis-esters of brusatol with an alkyl side chain of the ester of 1 or 2 carbons, or a C-3 or C-15 disenecioate or di-3,4-dimethyl-2-pentenoate side chain of bruceolide. Those compounds which demonstrated potent activity possessed an enone system in ring A and free hydroxy groups at C-11 and C-12. The same structural requirements are needed for antileukemic activity and *in vitro* inhibition of protein synthesis of P-388 cells. Analysis of the inhibition of polyuridine directed polyphenylalanine synthesis in Table IV and T/C % values obtained in the antileukemic screen indicated that there was a negative correlation coefficient of 0.84, *i.e.*, the higher the T/C % value obtained for the esters, the greater the degree of inhibition of protein synthesis in P-388 lymphocytic leukemic cells.

EXPERIMENTAL

Source of Compounds—Bruceoside A (1) originally was isolated from *Brucea javanica* (1, 2). Brusatol (II) was obtained by treating bruceoside A with 3 N H_2SO_4–methanol (1:1) to hydrolyze the glycosidic linkage (3). Bruceantin (III) was obtained from bruceoside A by the synthetic method (20). The chemical synthesis, purification, and physical characteristics of compounds IV–XIX, *i.e.*, brusatol esters, bisbrusatolyl esters, and related derivatives, were reported elsewhere (9).

P-388 Lymphocytic Leukemia Antitumor Screen—The P-388 lymphocytic leukemia cell line was maintained in DBA/2 male mice (~20 g). For the antineoplastic screen, 10^6 cells were injected intraperitoneally into BDF_1 male mice (~20 g) on day 0. Test compounds were homogenized in 0.05% polysorbate 80–water and administered on days 1–14. The average number of days survived for each group was determined and T/C % values were calculated (10). Fluorouracil was used as a positive standard.

Studies of the effects of quassinoid esters on protein synthesis were conducted on P-388 cells harvested on day 10. P-388 lymphocytic leukemia lysates were prepared by the method of Kruh *et al.* (11). The following were isolated from P-388 lysates by literature techniques: runoff ribosomes (12), "pH 5" enzyme (11), and uncharged transfer RNA (13). The P-388 lymphocytic leukemia cell initiation factors for protein synthesis were prepared as decribed previously (14). [^{3}H]Methionyl-transfer RNA was prepared from P-388 cell transfer RNA by the method of Takeishi *et al.* (15). The effects of the brusatol esters on endogenous protein synthesis (4) of P-388 lysates were carried out in a reaction

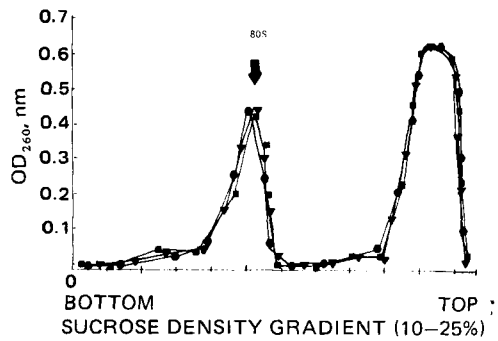

Figure 2—*Effects of brusatol, bruceantin, and bisbrusatolyl malonate on the P-388 ribosomal profile. Key:* ■, *brusatol;* ●, *bruceantin; and* ▼, *bisbrusatolyl malonate.*

Table III—Effects of Bisbrusatolyl Malonate on Ternary and 80S Complex Formation

XIV. + Bisbrusatolyl malonate	25	1.51	83

mixture (0.5 ml) containing 10 mM tromethamine (pH 7.6), 76 mM KCl, 1 mM adenosine triphosphate, 0.2 mM guanosine triphosphate, 15 mM creatine phosphate, 2 mM $MgCl_2$, 1 mM dithiothreitol, 0.1 mM of each of the essential amino acids, 0.9 mg/ml creatine phosphokinase, and 20 μCi [^{3}H]leucine (56.6 Ci/mmole). An aliquot of the reaction mixture was incubated at 30°. After 90 sec of incubation, test drugs or the standards (pyrocatechol violet or emetine) were added to a final concentration of 1, 10, and 100 μM. At 1-min intervals, 50-μl aliquots were removed from the reaction tubes and spotted on filter papers[3] which were treated for 10 min in boiling 5% trichloroacetic acid, followed by 10 min in cold 5% trichloroacetic acid and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1), and ether. The filter papers were dried and counted in scintillation fluid.

The effects of bruceantin, brusatol, bisbrusatolyl malonate, pyrocatechol violet, and emetine on the ribosome profile (4) of P-388 cell lysates were assayed using the reaction medium described previously (500 μl). Following drug addition to a 100-μM final concentration, the reaction was incubated for 4 min at 37°. The reaction was terminated in ice and gradient buffer consisting of 1 ml of tromethamine (pH 7.6), 10 mM KCl, and 1.5 mM $MgCl_2$-$6H_2O$ was added. The mixture was layered over 36 ml of 10–25% linear sucrose gradient (4), prepared in gradient buffer, and centrifuged for 165 min at 25,000 rpm in a swinging bucket rotor[4] at 4°. The absorbance profile at 260 nm was determined with a flow cell (light path 0.2 cm) attached to a spectrophotometer[5].

The reaction medium for the polyuridine (poly U) directed polyphenylalanine synthesis (16) contained 50 mM tromethamine (pH 7.6), 12.5 mM magnesium acetate, 80 mM KCl, 5 mM creatine phosphate, 0.05 mg/ml creatine phosphokinase, 0.36 mg/ml polyuridine[6] (A_{280}/A_{260} = 0.34), 0.5 μCi [^{14}C]phenylalanine (536 mCi/mmole), 75 μg uncharged P-388 cell transfer RNA, 70 μg of P-388 "pH 5" enzyme preparation, and 0.9 A_{260} of P-388 cell runoff ribosomes. Test drugs I–XIX were present in 5-, 10-, and 15-μM concentrations. Incubation was for 20 min at 30°,

after which a 35-μl aliquot was spotted on filter paper[3] and processed as indicated previously.

The reaction medium (200 μl) used to measure the formation of the 80S initiation complex and the methionyl puromycin reaction (17) contained 15 mM tromethamine (pH 7.6), 80 mM KCl, 1 mM adenosine triphosphate, 0.5 mM guanosine triphosphate, 20 mM creatine phosphokinase, 3 mM magnesium acetate, 0.1 mM edetic acid, 1 mM dithiothreitol, 0.1 mM each of the 19 essential amino acids, 3 mg of P-388 cell lysates, 100 μg/ml chlortetracycline[7] 3 × 105 cpm [^{3}H]methionyl-transfer RNA, and 20 μg/ml (polyadenosine–uridine–guanosine); and 5 μl of bruceantin, brusatol, and bisbrusatolyl malonate (25 μmoles). The incubation was carried out at 23° and aliquots were withdrawn after 2 min to analyze for 80S complex formation. Puromycin (10 μg/ml) was then added to the reaction medium. The incubation was continued for another 6 min and aliquots were withdrawn to analyze for reaction of the 80S complex with puromycin. All aliquots (50 μl) were diluted to 250 μl with 20 mM tromethamine (pH 7.6), 80 mM KCl, 3 mM magnesium acetate, 1 mM dithiothreitol, and 0.1 mM edetic acid, layered on 11.8 ml of a 15–30% linear sucrose gradient, and centrifuged for 3 hr at 36,000 rpm in a swinging bucket rotor[8]. Fractions (0.4 ml) were collected and precipitated with 10% trichloroacetic acid on filter papers and counted.

The reaction mixtures (75 μl) for the ternary complex formation[1] (18) contained 21.4 mM tromethamime (pH 8.0), 80 mM KCl, 0.26 mM gua-

nosine triphosphate, 2.14 mM dithiothreitol, 10 μg of bovine serum albumin, 5 pmoles of P-388 cell [^{3}H]methionine-transfer RNA (Met-tRNA$_f$, 1×10^4 cpm), 100 A_{260}/ml of crude P-388 cell initiation factors and 10 μl of drug or standard. The incubation was conducted for 5 min at 37° and terminated by addition of 3 ml of cold buffer [21.4 tromethamine (pH 8.0), 80 mM KCl, and 2.14 mM dithiothreitol]. The samples were filtered through 0.45-μm filters, washed twice in buffer, and counted.

The reaction mixture (75 μl) for the 80S initiation complex[2] (18) formation contained, in addition to the components necessary for the ternary complex formation reaction, 1.9 mM magnesium acetate, 5 A_{260}/ml polyadenosine–uridine–guanosine[7], and 100 A_{260}/ml of 80S P-388 cell ribosomes. Incubation was 10 min at 37° which was then cooled to 4° and titrated to 5 mM with magnesium acetate. After 5 min at 4°, the samples were diluted with cold buffer [21.4 mM tromethamine (pH 8.0), 80 mM KCl, 5 mM magnesium acetate, and 2.14 mM dithiothreitol] and filtered as indicated for the ternary complex formation experiment.

Amino acid transfer RNA activation steps were determined by the method of Moldave (19). The reaction medium contained 0.1 mM tromethamine (pH 7.4), 0.2 mM adenosine triphosphate, 0.3 mg/ml "pH 5" enzyme from P-388 cells, and 2.5 μCi/ml of [^{14}C]phenylalanine (536 mCi/mmole), [^{3}H]leucine (56.5 Ci/mmole), or [^{3}H]methionine (80.0 Ci/mmole) in a total volume of 1 ml. After incubation at 37° for 20 min, 2 ml of ice cold 10% trichloroacetic acid was added and the activated amino acid-transfer RNA was collected on nitrocellulose filters.

An Isocratic High-Pressure Liquid Chromatographic Determination of Naproxen and Desmethylnaproxen in Human Plasma

J. L. SHIMEK, N. G. S. RAO, and S. K. WAHBA KHALIL ˣ

Received April 24, 1981, from the *College of Pharmacy, North Dakota State University, Fargo, ND 58105.* Accepted for publication August 14, 1981.

Abstract □ An isocratic high-pressure liquid chromatographic method for the determination of naproxen and its desmethyl metabolite in human plasma is presented. A reversed-phase octadecylsilane column was utilized with a mobile phase consisting of 55% methanol and 45% 0.10 *M* acetate buffer, pH 5.0. A spectrofluorometric detector with an excitation wavelength of 253 nm and a band pass filter provided high sensitivity with no interference from normal plasma constituents. The reproducibility and precision of the method were shown by analysis of spiked samples containing 2.5–70 μg/ml of plasma.

Keyphrases □ Naproxen—determination by isocratic high-pressure liquid chromatography, human plasma □ High-pressure liquid chromatography—isocratic, determination of naproxen and desmethylnaproxen in human plasma □ Metabolites—determination of naproxen and its desmethyl metabolite in human plasma, high-pressure liquid chromatography

Naproxen is a nonsteroidal anti-inflammatory drug commonly used for the treatment of arthritis, dysmenorrhea, and for the relief of mild to moderate pain (1). Drugs in this class share many side effects such as GI (2, 3) and renal toxicity (4). Due to the high incidence of side effects, there is interest in the use of patient monitoring as a method of minimizing adverse reactions.

A direct spectrophotometric method lacking specificity due to interference from metabolites and salicylic acid has been reported (5). Several GLC methods also have been reported, all of which require derivation and a minimum 0.5-ml plasma sample (6–10). Quantitation has been performed by high-pressure liquid chromatography (HPLC) (11–14), and methods have been described involving precipitation of plasma protein followed by injection of the supernate (11) and the direct injection of diluted samples (12). The use of ion-pairing has also been described (12). An HPLC method for screening solid dosage forms using dual UV detectors was reported recently (15). Methods capable of determining the metabolite require a 0.5-ml plasma sample (10, 13).

The present report describes a method for the rapid determination of naproxen and its desmethyl metabolite using an isocratic HPLC separation and fluorometric detection. Conditions for the extraction, separation, and detection of naproxen and desmethylnaproxen in a sample size of 0.1-ml plasma are discussed. The applicability of this model was demonstrated by the analysis of plasma from patients receiving oral naproxen.

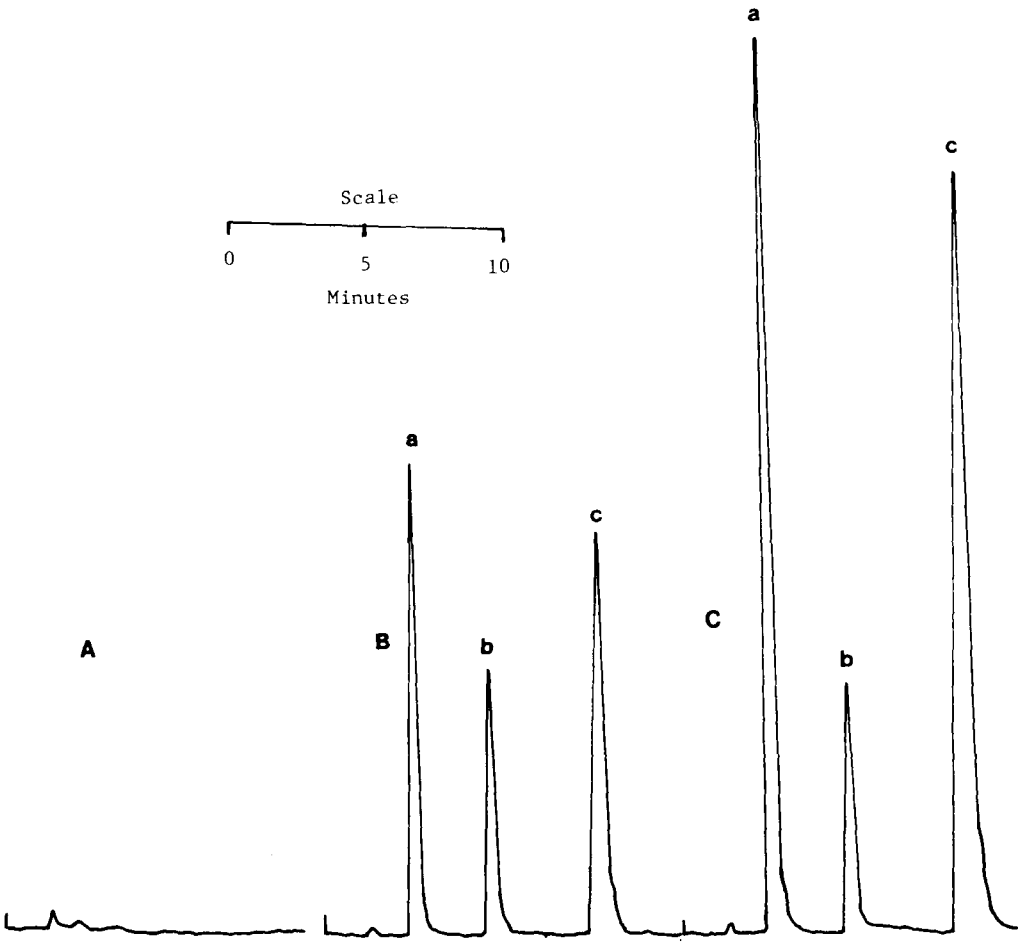

Figure 3—*Typical chromatograms of desmethylnaproxen (a), diphenylacetic acid (b), and naproxen (c) from plasma. Key: A, plasma blank; B, 15 μg drug and metabolite/1.0 ml plasma; and C, 30 μg drug and metabolite/1.0 ml plasma.*

(25 cm × 4.6-mm i.d.). The degassed mobile phase was pumped through the column at 1.5 ml/min (3200–3400 psi) at ambient temperature until a stable baseline was obtained. The fluorometer was set at an excitation wavelength of 253 nm and a band pass filter (230–420 nm) was used.

Chemicals and Reagents—Sodium acetate, sodium phosphate, acetic acid, phosphoric acid, methylene chloride, hexane, chloroform, ethyl acetate, ether, isopropanol, and diphenylacetic acid were reagent grade. HPLC grade methanol was used. Naproxen and desmethylnaproxen were obtained from the manufacturer[4].

Mobile Phases—To study the effect of ionic concentration and pH on retention time, methanol with pH 4 and 5 sodium acetate buffers (0.01, 0.02, 0.03, 0.04, 0.06, 0.08, 0.10, 0.12, and 0.15 *M*) or acetic acid solutions (0.01, 0.02, and 0.3 *M*) were used as mobile phases. All mobile phases were degassed under vacuum.

Extraction Conditions—Plasma containing naproxen and desmethylnaproxen was acidified with one of the following: 1.0 *M* phosphoric acid, 1.0 *M* sulfuric acid, 0.1 *M* phosphate buffer (pH 4), 0.1 *M* phosphate buffer (pH 3), or 0.1 *M* acetate buffer (pH 4). The acidified plasma was extracted with hexane, methylene chloride, chloroform containing 5% isopropanol, ether, or ethyl acetate.

Standard Stock Solution—A solution containing 10 mg each of naproxen and its desmethyl metabolite in 10 ml of methanol was prepared.

Extraction Solution—A solution of 120 mg of the internal standard, diphenylacetic acid, in 250 ml of methylene chloride was prepared (2.4 mg/5 ml).

Analytical Procedure—Spiked plasma standards were prepared by adding an appropriate aliquot of the standard stock solution to 1 ml of heparinized plasma. The spiked plasma was vortexed and 0.1-ml portions were placed in 15-ml screw-capped centrifuge tubes. The plasma was acidified with 0.3 ml of 1.0 *M* phosphoric acid, and 5-ml extraction solution containing the internal standard was added. The tubes were vortexed for 10 sec and centrifuged for 5 min at 3500 rpm. A 4-ml volume of the organic phase was transferred to a concentration tube[5] and evaporated to dryness at ambient temperature under a gentle nitrogen stream. The residue was dissolved in 0.5 ml of methanol and 10 μl was injected[6]. The mobile phase used for the analysis was 55:45 methanol and acetate buffer (pH 5, 0.10 *M*).

Quantitation—A standard curve was constructed by injecting plasma extracts simulating concentrations of the drug and metabolite. The chromatograms were recorded[7] at a chart speed of 0.5 cm/min. The ratios of peak heights (drug or metabolite to internal standard) were calculated and plotted *versus* the concentration in micrograms per milliliter plasma.

Interference—The possible interference of normal plasma constituents was tested by the analysis of blank plasma. The interference of other drugs was tested by direct injection of methanolic drug solution or by the analysis of extracts of plasma samples containing therapeutic concentrations.

Recovery—For the recovery study, plasma standards were prepared as described previously. After evaporation the residue was dissolved in 0.5 ml of methanol containing 360 ng of naproxen or desmethylnaproxen. A 10-μl aliquot containing 7.2 ng was injected onto the column.

Patient Sample Preparation and Analysis—Heparinized plasma samples from patients receiving oral naproxen were processed in duplicate as described previously. The amount of drug and metabolite was calculated by comparison with standards prepared daily.

RESULTS AND DISCUSSION

Increasing buffer molarity had a complex effect on the capacity factors of naproxen, desmethylnaproxen, and the internal standard (Fig. 1). The capacity factor was increased by decreasing pH (Fig. 2). Moreover, at low pH the compounds have a high capacity factor causing very long retention times and band broadening.

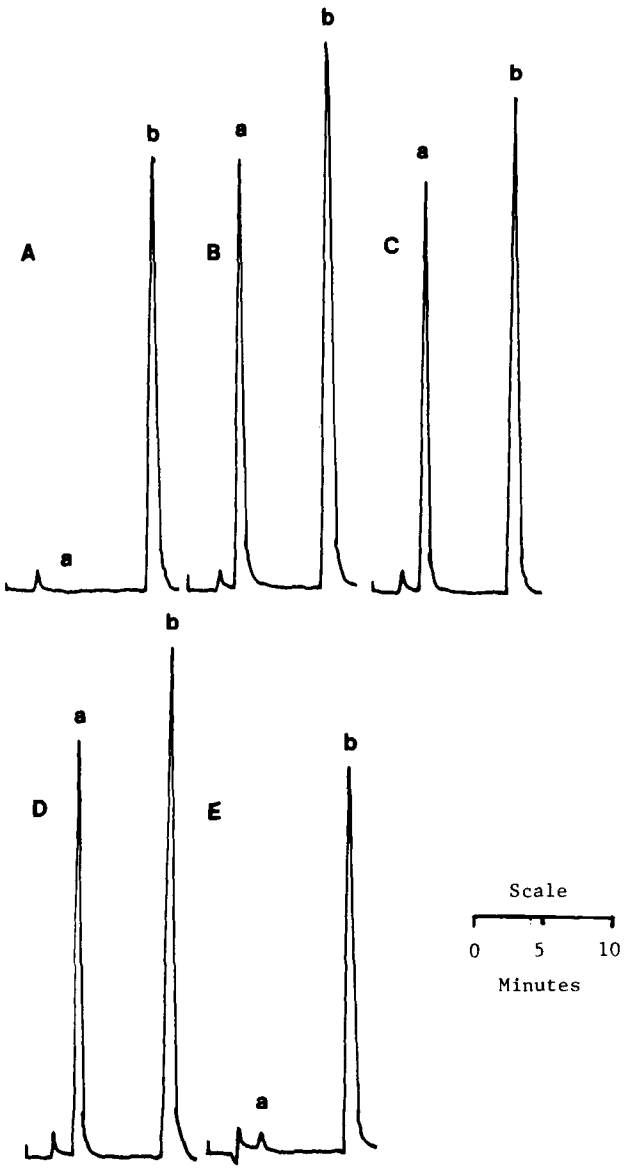

Figure 4—*Chromatograms of plasma extracts containing desmethylnaproxen (40 μg/ml) (a) and naproxen (40 μg/ml) (b). Key: A, hexane; B, methylene dichloride; C, chloroform containing 5% isopropanol; D, ether; and E, ethyl acetate.*

The choice of diphenylacetic acid as internal standard was based on coextractability with the drug and metabolite and an ideal relative retention time. A mobile phase of 55% methanol and 45% acetate buffer (pH 5, 0.10 *M*) gave well resolved, sharp peaks for naproxen, its metabolite and the internal standard, with retention times of 10.0, 3.3, and 5.9 min, respectively (Fig. 3). Under the described conditions 0.5 μg of naproxen or its desmethyl metabolite per milliliter of plasma could be quantitated.

Naproxen can be extracted readily from acidified plasma using organic solvents with a wide range of polarities; however, its desmethyl metabolite cannot be extracted with hexane or ethyl acetate (Fig. 4). The choice of acid or buffer for acidification of plasma can be used to optimize recovery and to minimize interference from plasma constituents, but due to the small sample size required and the small aliquot injected onto the column,

Table I—Statistical Analysis of Linear Regression

Parameter	Naproxen	Metabolite
Range of standards, μg/ml plasma	2.5–70	2.5–70
Correlation coefficient	0.9913	0.9922
Slope	0.1021 ± 0.0029	0.1247 ± 0.0046
Intercept	−0.0327 ± 0.0480	−0.0714 ± 0.0760

Table II—Assay Precision[a]

Theoretical, μg/ml plasma	Naproxen % Found	Naproxen *SE*	Metabolite % Found	Metabolite *SE*
2.5	113.6	0.09	113.6	0.22

Table III—Possible Interferences Under Assay Conditions

Drug or Metabolite	Fluorescence at Assay Conditions	Retention Time, min
Acetaminophen	No	—
Caffeine	No	—
Carbamazepine	No	—
Fenoprofen	Yes	>15
Ibuprofen	Yes	>15
Indomethacin	No	—
Des(chlorobenzoyl) metabolite	Yes	Solvent front
Desmethyl metabolite	No	—
Phenobarbital	No	—
Phenytoin	No	—
Primidone	No	—
Quinidine	No	—
Salicylic acid	Yes	Solvent front
Sulindac	No	—
Sulfide metabolite	No	—
Sulfone metabolite	No	—
Theophylline	No	—
Tolmetin	No	—
Metabolite	No	—
Valproic acid	No	—

there was no interference from plasma constituents with any of the acids or buffers tested. Optimum recovery of naproxen (66.6%) and desmethylnaproxen (62.4%) from spiked plasma samples was obtained using 1.0 *M* phosphoric acid to acidify plasma prior to extraction with methylene chloride.

The ratio of peak height of naproxin or its metabolite to the peak height of the internal standard was plotted *versus* concentration. Statistical analysis indicated excellent linearity (Table I) and reproducibility (Table II).

Plasma levels of patients receiving 250-mg doses, two or three times daily were 21.5–65.1 μg/ml. The metabolite was not present in significant amounts since it is not expected to significantly accumulate unless the patient's renal function is compromised (12).

Aspirin and other commonly used drugs did not interfere with the analysis (Table III).

The described method is simple and rapid. Both naproxen and its desmethyl metabolite can be determined in a single isocratic assay with no interference from many commonly used drugs. This method can be recommended for routine patient monitoring and for pharmacokinetic studies.

Extended Hildebrand Solubility Approach: Solubility of Tolbutamide, Acetohexamide, and Sulfisomidine in Binary Solvent Mixtures

A. MARTIN ˣ and M. J. MIRALLES

Received March 12, 1981, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication August 6, 1981.

Abstract □ The extended Hildebrand approach for predicting solubilities of crystalline compounds in solvent mixtures was tested using tolbutamide, acetohexamide, and sulfisomidine in mixed solvents consisting of hexane–absolute ethanol and 95% (v/v) ethyl alcohol–aqueous buffer. The solubility of these drugs was determined at 25 ± 0.2° and then back-calculated using the adhesive energy term, W, to account for solute–solvent interaction. Solubilities were predicted within 13% for tolbutamide, 31% for acetohexamide, and 43% for sulfisomidine, and with considerably better accuracy in most solvent mixtures.

Keyphrases □ Hildebrand solubility approach, extended—tolbutamide, acetohexamide, and sulfisomidine in binary solvent mixtures □ Tolbutamide—solubility in binary solvent mixtures, extended Hildebrand approach □ Acetohexamide—solubility in binary solvent mixtures, extended Hildebrand approach □ Sulfisomidine—solubility in binary solvent mixtures, extended Hildebrand approach

The Hildebrand–Scatchard theory (1) for crystalline solids in regular solution is expressed by:

$$-\log X_2 \simeq \frac{\Delta H_m^f}{2.303\,RT}\left(\frac{T_m - T}{T_m}\right) + \frac{V_2\,(\phi_1)^2}{2.303\,RT}(\delta_1 - \delta_2)^2 \quad \text{(Eq. 1)}$$

where X_2 is the mole fraction solubility, ΔH_m^f is the heat of fusion, T_m is the melting point of the solute expressed in absolute degrees, T is the absolute temperature of the solution, R is the gas constant expressed in cal/°Kmole, V_2 is the molar volume of the solute as a hypothetical supercooled liquid, δ_1 and δ_2 are the solubility parameters of the solvent and the solute, respectively, and ϕ_1 is the volume fraction of the solvent.

An approach (2) was suggested recently to extend regular solution theory to semipolar drugs in pure solvents and in polar binary solvent mixtures (2–4). The extended Hildebrand solubility equation may be written as:

$$-\log X_2 = -\log X_2^i + \frac{V_2\,(\phi_1)^2}{2.303\,RT}(\delta_1^2 + \delta_2^2 - 2W_{calc}) \quad \text{(Eq. 2)}$$

where X_2^i is the ideal solubility of the solute expressed in mole fraction, W_{calc} is the potential energy of solute–solvent interaction, and all other terms are identical with those in Eq. 1. The square of the solubility parameters are referred to as cohesive energy densities, and W may be referred to as an adhesive energy density since it involves both solute and solvent. The units of energy densities are calories per cubic centimeter (cal/cm^3) and for solubility parameters they are the square root of the same unit [(cal/cm^3)$^{1/2}$]. The ideal solubility term, $-\log X_2^i$, constitutes the first right-hand term of Eq. 1. Log X_2^i may be taken as roughly equal to $-\Delta H_m^f/2.303\,RT\,[(T_m - T)/T_m]$ as seen in Eq. 1, or as $\Delta S_m^f/R\,[\log (T/T_m)]$ as used in earlier studies (2–4). Although it has not been established which is more correct, either form provides satisfactory results

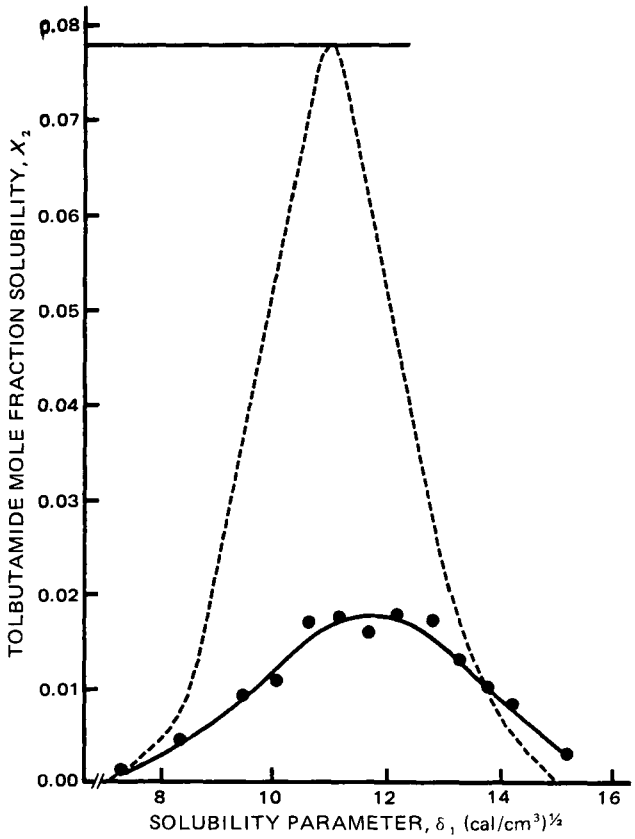

Figure 1—*Solubility profile of tolbutamide in* n*-hexane–absolute ethanol and 95% ethanol–aqueous buffer systems at 25°; δ_2 = 10.98, X_2^i = 0.07218. Key: (- - -) regular solution (Eq. 1); (—) calculated solubility (Eqs. 3*a *and* b*). The horizontal line intersecting the regular solution curve at its peak is the ideal solubility, X_2^i = 0.07218.*

[a] $X_2^i = 0.07218$; $V_2 = 209.9$; $\delta_2 = 10.98$.

in the back-calculation method of the extended solubility approach.

To further test the extended solubility approach for drugs in mixed solvents, solubilities of the hypoglycemic agents, tolbutamide (I) and acetohexamide (II), and a structurally related compound, sulfisomidine (III), were determined in mixtures of *n*-hexane–absolute ethanol, and 95% (v/v) ethanol in an aqueous buffer. The W values of the extended solubility equation are obtained from experimental X_2 using Eq. 2, and then W_{calc} is obtained by regressing W on δ_1 for the solvent mixture in a second degree or higher power series. Log α_2/A may also be regressed against δ_1 to obtain logα_2/A_{calc}.

EXPERIMENTAL

Materials—Tolbutamide[1], acetohexamide[2], sulfisomidine[3], *n*-hexane[4], absolute ethanol[5], 95% ethanol[6], sodium hydroxide[6], and methanol[6] were tested for identity and purity, and otherwise used as received.

Solubility Determination—The solubility of I (δ_2 = 10.98) and II (δ_2 = 11.64) was determined in mixed solvents consisting of *n*-hexane (δ_{1a} = 7.30) and absolute ethanol (δ_{1b} = 12.76), and in 95% ethanol (δ_{1c} = 13.24) mixed with aqueous buffer (δ_{1d} = 22.77, pH = 2.59) in different proportions. The solubility of III (δ_2 = 12.80) was determined in mixed solvents consisting of *n*-hexane and absolute ethanol, and 95% ethanol–aqueous buffer (δ_{1c} = 22.34, pH = 4.9).

About 20 ml of the pure solvent or solvent mixture was introduced into screw-capped vials containing an excess of the drug being studied. The vials were agitated for ~72 hr in a shaker bath maintained at 25 ± 0.2°. After equilibrium was obtained, a filtered aliquot was pipetted, using an automatic micropipette, into a volumetric flask and appropriately diluted with methanol. The solutions were analyzed in a spectrophotometer[7] at 264 nm for I, 247 nm for II, and 281.5 nm for III. The densities of the saturated solutions and solvent mixtures were determined at 25 ± 0.2° using a 10-ml pycnometer. All determinations were made in triplicate.

Water Content—The water content of absolute ethanol and ethanol labeled 95% (v/v) was determined by direct titration[8].

Aqueous Buffer Preparation—The pH of the distilled water used in the preparation of the solvent mixtures was adjusted so that the drugs existed predominantly in their nonionized form; thus, solubility as the ion was not involved. The pH of the buffer solution was measured after preparation and at several intervals to be sure that changes in pH did not occur in the solutions alone or after the drug was added.

Heat of Fusion of I, II, and III—A differential scanning calorimeter[9] was used to determine the heats of fusion of the drugs. The technique and equations utilized in the determination were reported earlier (3).

Solubility Parameter and Molar Volume—The solubility parameters and molar volumes of I, II, and III were calculated using the functional group contribution method of Fedors (5). The solubility parameters of the solutes were verified using the data from solubility studies of the drugs in binary systems (4). The solubility parameter (δ_2) was obtained at peak solubility and was assumed to be equal to the solubility parameter of the solvent mixture (δ_1). In polar solvent mixtures this procedure yields somewhat different solubility parameters depending on the solvent system used.

Other quantities required in predicting the solubility of a drug in solvent mixtures (molar volumes, V; volume fraction of the solvent mixtures, ϕ_1; mole fraction solubility of the solute, X_2; ideal solubility of the solute expressed in mole fraction, X_2^i; solute activity coefficients, α_2; and the adhesive energy density, W) were calculated as described previously (3). The solubility parameters and the molecular weights of absolute ethanol

Table III—Regression Equations of W_{calc} and log α_2/A_{calc} for I, II, and III in Hexane–Absolute Ethanol and 95% Ethanol–Aqueous Buffer Systems at 25°. [a]

Compound	Equations	
Tolbutamide (I)	$W_{calc} = 32.9064\ (\pm 0.8420) + 4.3342\ (\pm 0.1528)\ \delta_1 + 0.3137\ (\pm 0.0067)\ \delta_1^2$	(Eq. 3a)
	$n = 13 \quad R^2 = 0.999 \quad s = 0.12663 \quad F = 265172 \quad F_{(2,10,0.01)} = 7.56$	
	$\log \alpha_2/A_{calc} = 54.7567\ (\pm 1.6842) - 8.6700\ (\pm 0.3056)\ \delta_1 + 0.3726\ (\pm 0.0135)\ \delta_1^2$	(Eq. 3b)
	$n = 13 \quad R^2 = 0.988 \quad s = 0.25330 \quad F = 420 \quad F_{(2,10,0.01)} = 7.56$	
Acetohexamide (II)	$W_{calc} = 43.0479\ (\pm 1.8180) + 3.7634\ (\pm 0.3300)\ \delta_1 + 0.3460\ (\pm 0.0146)\ \delta_1^2$	(Eq. 4a)
	$n = 10 \quad R^2 = 0.999 \quad s = 0.25268 \quad F = 53040 \quad F_{(2,7,0.01)} = 9.55$	
	$\log \alpha_2/A_{calc} = 49.4027\ (\pm 3.6367) - 7.5282\ (\pm 0.6601)\ \delta_1 + 0.3081\ (\pm 0.0291)\ \delta_1^2$	(Eq. 4b)
	$n = 10 \quad R^2 = 0.962 \quad s = 0.50544 \quad F = 90 \quad F_{(2,7,0.01)} = 9.55$	
Sulfisomidine (III)	$W_{calc} = 93.8825\ (\pm 6.5207) - 5.7575\ (\pm 1.6683)\ \delta_1 + 1.1189\ (\pm 0.1366)\ \delta_1^2 - 0.0186\ (\pm 0.0036)\ \delta_1^3$	(Eq. 5a)
	$n = 12 \quad R^2 = 0.999 \quad s = 0.33165 \quad F = 49488 \quad F_{(3,8,0.01)} = 7.59$	
	$\log \alpha_2/A_{calc} = -23.9294\ (\pm 13.0437) + 11.5170\ (\pm 3.3371)\ \delta_1 - 1.2380\ (\pm 0.2732)\ \delta_1^2 + 0.0371\ (\pm 0.0072)\ \delta_1^3$	(Eq. 5b)
	$n = 12 \quad R^2 = 0.984 \quad s = 0.66342 \quad F = 166 \quad F_{(3,8,0.01)} = 7.59$	

[a] The statistical parameters under each regression equation are n, the number of solvent mixtures used; R^2, the squared multiple correlation coefficient; s, the standard deviation of the sample; F, the Fisher F ratio, which is followed by the tabular value of F with degrees of freedom k and $n - k - 1$ at the 99% level. The value k is the number of independent variables in the equation.

and 95% ethanol were corrected relative to their water content [0.57% (v/v) for absolute ethanol and 5.06% (v/v) for ethanol labeled 95%].

RESULTS AND DISCUSSION

Experimental melting points (T_m), obtained with a capillary apparatus[10], heat of fusion (ΔH_m^f), ideal solubilities (X_2^i), solubility parameters, and molar volumes for I, II, and III are reported in Table I.

The values of observed and calculated solubilities (Eq. 2) of I in hexane–absolute ethanol and 95% ethanol–aqueous buffer are compared in Table II. Solution densities are included to allow calculations of solubilities in mole/liter or gram/cm^3. The experimental solubilities of I, II, and III, expressed as mole fraction *versus* the solubility parameters of the solvent mixtures, are plotted in Figs. 1–3. The ideal solubilities, X_2^i, and the regular solution curve obtained using Eq. 1 are also shown. The regression equations and statistics for W_{calc} and log α_2/A_{calc} are shown in Table III. Earlier studies (3, 4) employed 20–30 data points for regression analysis. The present study shows that about 12 points are adequate for back-calculating the solubility curve.

The regular solution curves of Figs. 1, 2, and 3, do not coincide with the experimentally determined solubilities, indicating that the mixtures do not follow regular solution theory. In contrast, the lines obtained by using the extended Hildebrand approach for the drugs investigated reproduced the solubility of I, II, and III in the solvent mixtures satisfactorily (Figs. 1, 2, and 3). The ideal solubilities of I and II are higher than the peak solubility in mixtures of *n*-hexane–absolute ethanol and 95% ethanol–aqueous buffer. For III the ideal solubility is lower than the experimental solubility in aqueous ethanol, presumably because of solvation of the drug by the mixed solvent.

At the maximum of the solubility curve, the experimental points for II fall below the predicted solubility using the extended Hildebrand approach, but the discrepancy is not great. This may be explained by the presence of small peaks and valleys in the solubility profile of II that the empirical expression for W cannot be expected to reproduce. The presence of peaks and valleys around the maximum solubility is not an uncommon occurrence; prominent peaks were first observed by Paruta and Irani (6) in the solubility of caffeine in a mixture of dioxane and water.

The solubility parameters for I, II, and III were used to position the maxima of the regular solution lines of Figs. 1–3. The maxima do not coincide exactly with the peaks of the experimental curves. Although an accurate knowledge of the solubility parameters of the drugs is important for an understanding of physicochemical properties, the extended solubility method—being a back-calculation procedure—does not depend on absolute values of δ_2 for its success. As reported earlier (3) the method may, in fact, bypass W and δ_2 and yield X_{2calc} by regression of logα_2/A on δ_1, as shown in Table III. In the present study, the results obtained using the Fedors method (5) were accepted as a first approximation as the solubility parameters of the three drugs.

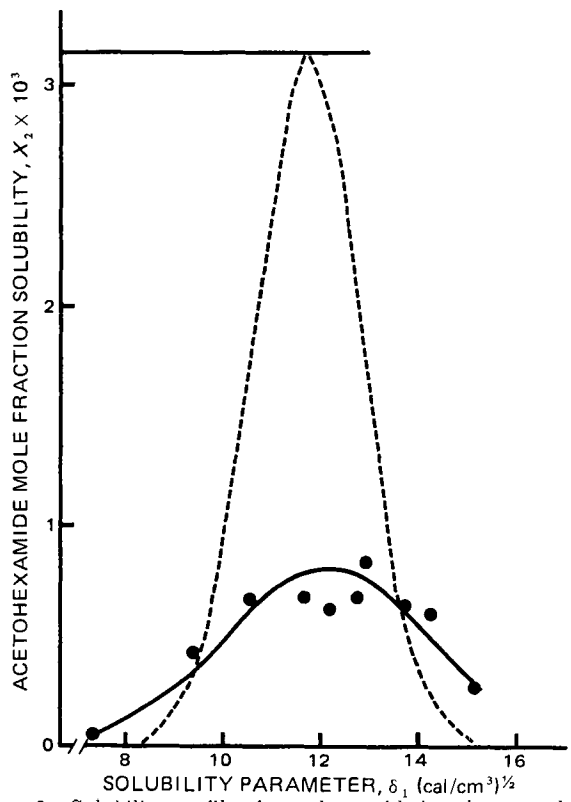

Figure 2—*Solubility profile of acetohexamide in* n*-hexane–absolute ethanol and 95% ethanol–aqueous buffer at 25°; $\delta_2 = 11.64$, $X_2^i = 0.00314$. Key: (- - -) regular solution (Eq. 1); (—) calculated solubility (Eqs. 4a and b). The horizontal line intersecting the regular solution curve at its peak is the ideal solubility, $X_2^i = 0.00314$.*

[10] Thomas Hoover capillary melting point apparatus, A. H. Thomas Co.

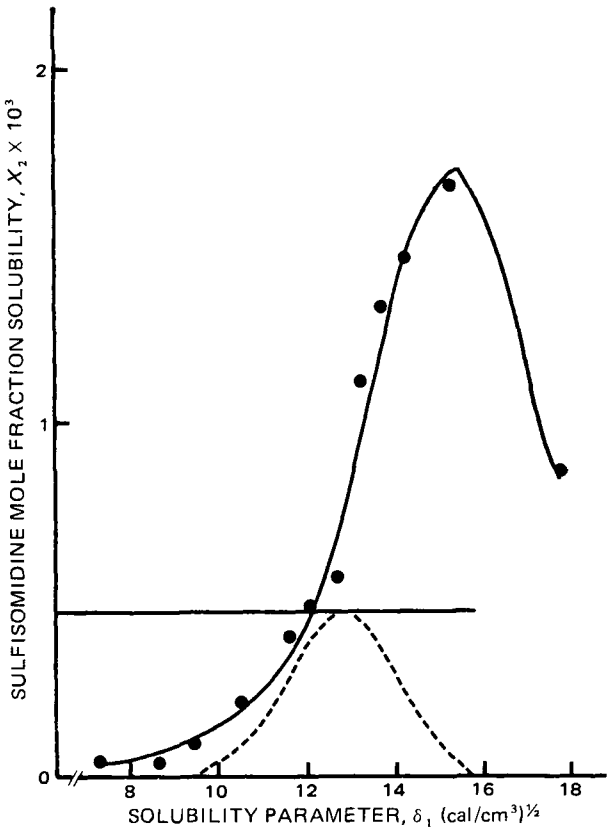

Figure 3—*Solubility profile of sulfisomidine in n-hexane–absolute ethanol and 95% ethanol–aqueous buffer systems at 25°; δ_2 = 12.80. Key: (- - -) regular solubility (Eq. 1); (—) calculated solubility (Eqs. 5a and b). The horizontal line intersecting the peak of the regular solution curve signifies the ideal mole fraction solubility, $X_2^i = 0.463 \times 10^{-3}$.*

CONCLUSIONS

The extended Hildebrand solubility approach (1–3) was tested for its ability to reproduce solubilities of tolbutamide, acetohexamide, and sulfisomidine in mixtures of *n*-hexane–absolute ethanol and 95% ethanol–aqueous buffer. Power series regression (quadratic for I and II and cubic for III) in δ_1 was used to back-calculate W, and from W to calculate solubilities.

Workers in various industries, including the pharmaceutical and cosmetic sciences, have not been able to rely on the Hildebrand equation (Eq. 1) for estimating solubilities in polar solvent systems. According to regular solution theory the solubility of I is predicted to be much larger than actual solubility at $\delta_1 = \delta_2 = 10.98$ (Fig. 1). Conversely, for III the solubility predicted by the Hildebrand approach is grossly underestimated (Fig. 3). The Hildebrand theory provides reasonable, although not always accurate, estimates of solubility in nonpolar solvents but is not successful for polar systems.

The extended Hildebrand solubility approach, replacing the geometric mean $\delta_1\delta_2$ by an adhesive energy density W, and regressing W against the solvent solubility parameter to obtain back-calculated values of solubility, shows one reason why the Hildebrand method (Eq. 1) fails in binary mixtures of polar solvents. Surprisingly, small differences between W and $\delta_1\delta_2$ result in large differences between actual and ideal solubility. For I at $\delta_1 = 11.12$, $\delta_1\delta_2 = 122.0976$, and $W = 119.8957$; $X_2 = 0.017380$, and $X_2^i = 0.072180$. The difference of as little as 1.8% between W of the extended approach and $\delta_1\delta_2$ of the Hildebrand theory yields a 315% solubility difference between experimental solubility and that calculated by the Hildebrand method. In the same mixed solvent, 30% hexane in ethanol, the extended Hildebrand solubility method calculates the correct solubility, $X_{2calc} = 0.01738$ (0.0% error).

Both the Hildebrand and its extended method yield unsatisfactory estimates for solubilities of crystalline drugs in single polar solvents. Unlike binary mixtures, individual solvents show wide differences in molar volume, acid–base characteristics, and other properties. It will be necessary to devise new approaches, such as that suggested by the Hansen partial solubility parameters (7), in order to describe complex drug molecules in single solvents of high, low, and intermediate polarity.

O-Methylhydroxylamine as a New Trapping Reagent for Quantitative Studies of 4-Hydroxycyclophosphamide and Aldophosphamide

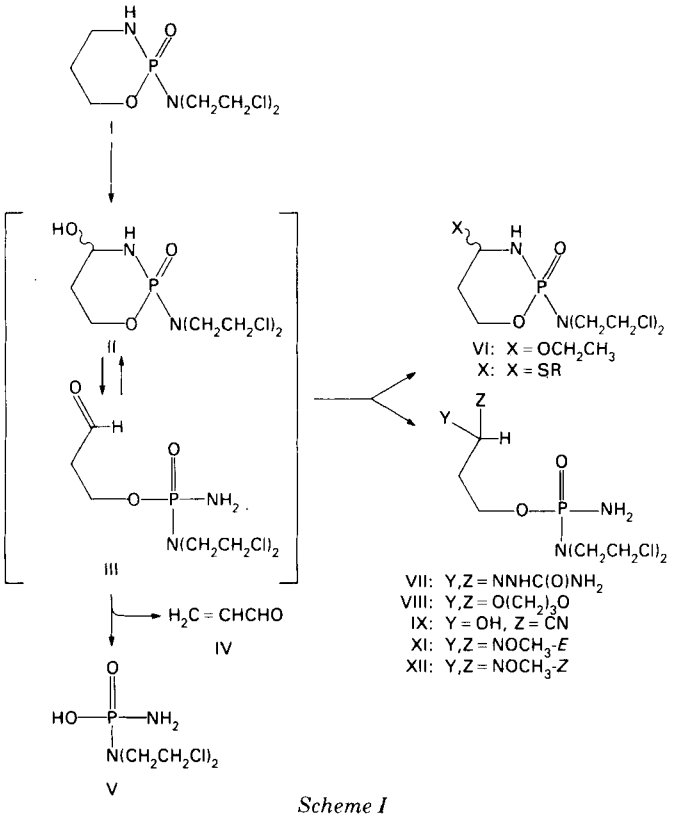
GERALD ZON *x, SUSAN MARIE LUDEMAN *, EDWARD M. SWEET *, WILLIAM EGAN ‡, and LAWRENCE R. PHILLIPS ‡

Received June 19, 1981, from the **Department of Chemistry, The Catholic University of America, Washington, DC 20064*, and the ‡*Bureau of Biologics, Food and Drug Administration, Bethesda, MD 20205.* Accepted for publication August 14, 1981.

Abstract □ ^{31}P- and ^{1}H-NMR spectroscopy were used to demonstrate that the primary metabolites of the anticancer drug cyclophosphamide (4-hydroxycyclophosphamide and its acyclic tautomer, aldophosphamide) are quantitatively converted by *O*-methylhydroxylamine, at pH 7.4 and 37°, into the *E* and *Z* isomers of aldophosphamide *O*-methyl oxime. These trapping products are readily extracted from aqueous media with either chloroform or ethyl acetate, are stable at pH 6–8 toward oxime hydrolysis and elimination of phosphoramide mustard (a secondary metabolite of cyclophosphamide), and showed no evidence for transoximination with either ketone or aldehyde acceptors. All of these features support the use of aldophosphamide *O*-methyl oxime in quantitative studies related to cyclophosphamide metabolism.

Keyphrases □ Cyclophosphamide—metabolites, 4-hydroxycyclophosphamide, aldophosphamide, trapping with *O*-methylhydroxylamine □ Aldophosphamide—*O*-methyloxime derivative, *E* and *Z* isomers, ^{1}H-NMR identification □ NMR Spectroscopy—^{1}H analysis aldophosphamide *O*-methyloxime identification, ^{31}P analysis, decomposition kinetics

There is considerable interest in the organic chemistry and quantitative analysis of 4-hydroxycyclophosphamide (II) and aldophosphamide (III) (Scheme I), as these primary metabolites of cyclophosphamide (I) are generally believed to play pivotal roles in the oncostatic selectivity of this widely used anticancer prodrug (1, 2). The presence of a hemiaminal moiety in II allows for facile tautomerization with III, which can fragment into acrolein (IV) and phosphoramide mustard (V). The combined alkylating activity of II, III, and V can be quantified using 4-(*p*-nitrobenzyl)pyridine (3), whereas the combined cytotoxicity of low levels of all lethal cyclophosphamide metabolites is measurable [*e.g.*, by an *in vitro* assay employing Walker 256 rat carcinosarcoma cells (4)]. One method for selectively measuring the total concentration of metabolites II and III is their conversion to a relatively stable derivative using reaction conditions which preempt loss of II and III by fragmentation. Reported examples of such trapping products (Scheme I) include 4-ethoxycyclophosphamide (VI) (5), aldophosphamide semicarbazone (VII) (6), aldophosphamide propanediol-1,3-acetal (VIII) (7), and aldophosphamide cyanohydrin (IX) (8). In contrast to these compounds, analytical utilization of 4-sulfidocyclophosphamides (X) must contend with their hydrolytic instability (9). Pulse Fourier-transform NMR spectroscopy is an alternative methodology which offers the unique advantages of providing direct quantitative measurements of II and III as individual solution components.



Scheme I

During the NMR kinetic studies of II and III, *O*-methylhydroxylamine, which serves as a derivatizing agent for GC–mass spectrometric analyses of aldoses (10), was conducive to this study because of (*a*) its super-nucleophilicity due to lone-pair repulsion; (*b*) the thermal (GC, GC–mass spectrometric) stability of *O*-methyl oximes; (*c*) the resistance of *O*-methyl oximes toward hydrolytic reversion to aldehydes; (*d*) the availability of *O*-methylhydroxylamine hydrochloride in various stable isotope-enriched (^{2}H, ^{13}C, ^{15}N) and radioactive (^{3}H, ^{14}C) forms; and (*e*) the possibility for chemically induced reformation of aldehyde III. Since all of these features are not applicable to VI–IX, this study reports the formation and characterization of the trapping products derived from the reaction of II/III with *O*-methylhydroxylamine, namely, the *E* (XI) and *Z* (XII) isomers of aldophosphamide *O*-methyl oxime.

EXPERIMENTAL

Hydroxyphosphamide (8), 4-ketocyclophosphamide (XIV) (11), and compound XV (12) were synthesized and compound XIII was prepared and purified by Colvin's[1] method. ^{31}P-Fourier-transform NMR spectra at 40.25 MHz[2] were obtained using 10-mm sample tubes, a 5-kHz spectral window, 8192 data points zero-filled to 16,384, a $\pi/2$ pulse of 18 μsec, low-power ^{1}H-decoupling, and a 2-sec pulse repetition time. Spectra were

broadened by 1 Hz due to exponential multiplication prior to Fourier-transform. ^{31}P-Fourier-transform NMR spectra at 121.5 MHz[3] were recorded in a similar manner except for the use of a 20-μsec $\pi/2$ pulse, a 1.4-sec pulse repetition time, and 2.5 Hz of line-broadening. ^{1}H-Fourier-transform NMR spectra at 300 MHz[3] were recorded using 5-mm sample tubes, a 6-kHz spectral window, a 2-μsec $\pi/2$ pulse, a 5.4-sec pulse repetition time, and 0.2 Hz of line-broadening. ^{1}H-NMR spectra at 220 MHz[4] were recorded in the continuous-wave mode. Unless specified otherwise, ^{31}P-chemical shifts (δ, ppm) refer to deuterium oxide solvent and are relative to external 25% H_3PO_4. ^{1}H-Chemical shifts are relative to internal tetramethylsilane. NMR sample temperatures were measured by immersion of a precalibrated copper-constantan thermocouple. Values of pH measured[5] in deuterated water were not corrected for isotope effects (13). Electron-impact mass spectra[6] were scanned from samples introduced *via* a solids' inlet probe; the probe temperature was maintained at 20° for a 2-min period and was then elevated at 120°/min to a final temperature of 325°. Chemical-ionization mass spectra obtained with isobutane were scanned from samples similarly introduced. The ion-source temperature was 180°, the ionizing potential was 70 eV (150 eV for chemical-ionization), the ion-source pressure was 5×10^{-6} torr (10^{-3} torr for chemical ionization), and the ionizing current was 50 μamp.

4-(*tert*-Butylperoxy)cyclophosphamide (XVI)[7]—A solution of cyclophosphamide monohydrate[8] (2.048 g, 7.34 mmole) and *tert*-butyl hydroperoxide (1.0 ml, 70% aqueous solution) in 34 ml of acetone–water 1:2 was cooled with an ice bath, and ozone[9] (25–50 mg/min) was then bubbled into this solution through a glass frit. More acetone (5 ml) was added at 30-min intervals, and more *tert*-butyl hydroperoxide (1 ml) was added at 1.0-hr intervals during the course of the reaction (3 hr). Acetone was removed *in vacuo* on a rotary evaporator at room temperature and the remaining aqueous solution was extracted with methylene chloride (5×25 ml). The combined extracts were dried over anhydrous magnesium sulfate and solvent was then removed *in vacuo* without heating. The residual oil was chromatographed at 6° on a column (2.2×26-cm) of silica gel[10] using acetone–chloroform (2:1) and a flow rate of 8 ml/hr. Product [R_f 0.80, 250-μm silica gel, acetone–chloroform (2:1), iodine visualization] contaminated with *tert*-butyl hydroperoxide (R_f 0.95) and XIV (R_f 0.60) eluted in fractions 7–9 (8 ml/fraction), which were combined and concentrated *in vacuo* to give material (380 mg) for rechromatography in hexane–acetone–chloroform (3:2:1). The two diastereomers of XVI were detected in fractions 12–16 as overlapping TLC components [R_f 0.58 and 0.52, 250-μm silica gel, hexane–acetone–chloroform (3:2:1)]. Removal of solvent from these fractions afforded a pure sample (144 mg) of the faster eluting diastereomer and a mixture (113 mg) of the faster and slower eluting diastereomers; total yield 10% (257 mg). ^{31}P-NMR (40.25 MHz, deuterochloroform) of faster eluting XVI: δ 6.04; for slower eluting XVI, δ 6.44. ^{1}H-NMR (220 MHz, deuterochloroform) of faster eluting XVI: 5.09 (d, J_{HP} = 25 Hz of q, J_{HH} = 3 Hz, 1H, C_4—H), 4.64 (m, 1H, 1-C_6—H), 4.09 (m, 1H, 1-C_6—H), 3.82 (broad s, 1H, NH), 3.59 (t, J_{HH} = 7 Hz, 4H, 2-NCH_2CH_2Cl), 3.41 (m, 4H, 2-NCH_2CH_2Cl), 2.02 (m, 2H, 2-C_5—H), and 1.23 [s, 9H, $C(CH_3)_3$] ppm; electron-impact mass spectrum: *m/z* 57 (55%) $[(CH_3)_3C]^+$, 73 (2%) $[(CH_3)_3CO]^+$, 92 (70%) $(^{35}ClCH_2CH_2NHCH_2)^+$, and 142 (4%) $[(^{35}ClCH_2CH_2)_2NH_2]^+$; chemical-ionization—mass spectrum: *m/z* 93 (38%) $(^{35}ClCH_2CH_2NHCH_2 + 1)^+$, and 143 (100%) $[(^{35}ClCH_2CH_2)_2N + 3]^+$; 349 $(M + 1)^+$ not observed.

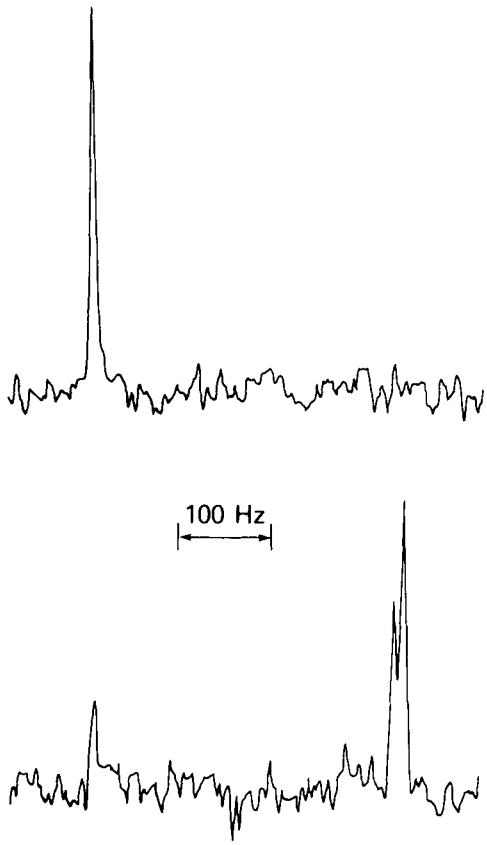

Figure 1—*^{31}P-NMR (40.25 MHz) spectra recorded in 0.05* M *lutidine buffer at 37°; bottom:* cis- *and* trans-*II (δ 12.62, 12.93) and III (δ 20.83); top: ~10 min after reaction with* O*-methylhydroxylamine to form* O*-methyl oximes XI/XII (δ 20.83).*

Reaction of II/III with *O*-Methylhydroxylamine—After recording the ^{31}P-NMR (40.25 MHz) spectrum of a solution of *cis*-XIII (10 mg, 0.034 mmole) in deuterochloroform (2 ml) at 25°, triphenylphosphine (12.5 mg, 0.048 mmole, 1.4 equivalents) was added and the spectrum was recorded after 5 min. The original signal for *cis*-XIII (δ 11.07) was replaced by that of *cis*-II (δ 10.89), and residual triphenylphosphine (δ −6.70) was detected in addition to the triphenylphosphine oxide (δ 27.42) by-product. Solvent was removed *in vacuo* on a rotary evaporator without heating, and the residue was then sonicated for 10 min with lutidine buffer (2 ml of 0.05 *M*, pH 7.4, 5 v/v% deuterium oxide). The filtered solution was clarified by centrifugation and was then analyzed by ^{31}P-NMR before and after (10 min) addition of *O*-methylhydroxylamine hydrochloride (14 mg, 0.170 mmole, 5 equivalents; sample pH adjusted to 7.4 with 1 *N* sodium hydroxide); spectra are shown in Fig. 1. The solution was saturated with sodium chloride and then extracted with deuterochloroform (2×1 ml) for ^{1}H- and ^{31}P-NMR analyses, which showed the presence of XI/XII as a single phosphorus resonance (δ 14.13); XI/XII were not detectable (^{31}P-NMR) in the remaining aqueous layer. Similar results were obtained by ethyl acetate extraction of a duplicate reaction mixture.

Preparative-Scale Isolation of XI/XII, Decomposition of XIII in the Presence of *O*-Methylhydroxylamine—A sample of crude XIII (175 mg, ~0.5 mmole), which contained ~20 moles % XIV by ^{31}P-NMR, was dissolved in water (10 ml) and was then treated with an alkaline solution of *O*-methylhydroxylamine that had been prepared from its hydrochloride salt (100 mg, 1.2 mmoles in 6.2 ml of 0.2 *M* sodium hydroxide). After 24 hr at room temperature, the sodium chloride-saturated

reaction mixture was extracted with chloroform (3 × 15 ml) and the combined extract was then dried with anhydrous magnesium sulfate. Removal of chloroform *in vacuo* gave a residue (54 mg) which was subjected to TLC (1000-μm silica gel, acetone–chloroform 1:1) and afforded two overlapping components (R_f 0.1–0.2) identified as a 62:38 mixture of *E* (XI) and *Z* (XII) *O*-methyl oximes of III (17 mg of oil, 12% corrected yield); ^{1}H-NMR (300 MHz, acetone-d_6) for XI and XII, respectively (Fig. 2): δ 7.40 and 6.79 (2-t, J_{HH} = 5.8 and 5.1 Hz, 61:39, 1H total, nonequivalent CH_2CH=N), 4.07 (m, 2H, CH_2O), 3.74 and 3.80 (2-s, 63:37, 3H total, nonequivalent OCH_3), 3.90 (broad s, 2H, NH_2), 3.69 (t, *J* = 7.2 Hz, 4H, 2-NCH_2CH_2Cl), 3.31 (m, 4H, 2-NCH_2CH_2Cl), 2.50 and 2.62 (2-q, J_{HH} = 6.2 and 5.9 Hz, respectively, 61:39, 2H total, nonequivalent CH_2CH=N) ppm; electron-impact–mass spectrum: *m/z* 274 (0.8%) and 276 (0.4%) $(M-CH_3O)^+$, 165 (70%) $[M-(ClCH_2CH_2)_2N]^+$, 142 (3%) $[(^{35}ClCH_2CH_2)_2NH_2]^+$, 92 (87%) $(^{35}ClCH_2CH_2NHCH_2)^+$, and 86 (69%) $(CH_3ON{=}CHCH_2CH_2)^+$; chemical-ionization–mass spectrum: 87 (100%) $(CH_3ON{=}CHCH_2CH_2+1)^+$, 93 (26%) $(^{35}ClCH_2CH_2NHCH_2+1)^+$, 143 (58%) $[(^{35}ClCH_2CH_2)_2N+3]^+$, 308 (39%) and 310 (25%) $(M+3)^+$. Upon standing in a freezer, the initial oily sample of XI/XII crystallized, mp 72–75°.

Anal.—Calc. for $C_8H_{18}N_3O_3PCl_2$: C, 31.38; H, 5.94; N, 13.73. Found: C, 31.34; H, 5.89; N, 13.64.

Decomposition of XV in the Presence of *O*-Methylhydroxylamine—A solution of lutidine buffer (1.75 ml of 0.05 *M*, 5 v/v% deuterium oxide) and *O*-methylhydroxylamine hydrochloride (20 mg, 0.24 mmole), adjusted to pH 7.4 with 1 *N* sodium hydroxide, was sonicated with crystalline XV (10 mg, 0.018 mmole) to achieve rapid dissolution. The sample was placed in the ^{31}P-NMR (121.5 MHz) probe at 37°, and after 10 min of temperature equilibration, the free-induction decay signal for each spectrum (320 pulses, 7.56 min) was automatically accumulated and stored. The average concentration of XV in each frequency-domain spectrum was measured as a relative percentage, using the peak height of XV (δ 12.60) and all other reaction components: XI/XII (δ 20.83), XIII (δ 13.43), and XIV (δ 9.93). A plot of $\ln([XV]_0/[XV]_t)$ *versus* time (*t*) using eight data points was linear over the monitored decomposition period (75%) and gave $\tau_{1/2}$ = 0.5 hr.

Decomposition of XVI in the Presence of *O*-Methylhydroxylamine—The procedure with the faster eluting diastereomer of XVI (15 mg, 0.043 mmole) was the same as that described above for compound XV, except for the use of pyridine buffer (1.30 ml of 0.1 *M*, 5 v/v% deuterium oxide). From the ^{31}P-NMR peak heights of XVI (δ 11.57), XIII (δ 12.84), and XI/XII (δ 20.80) in eight spectra (300 pulses, 10.00 min/spectrum) obtained over 9 hr of monitoring (67% decomposition), a linear plot of $\ln([XVI]_0/[XVI]_t)$ *versus t* gave $\tau_{1/2}$ = 5.2 hr.

Stability Studies with XI/XII—All buffers refer to 0.05 *M* aqueous solutions. An aliquot (0.10 ml) of a stock solution of XI/XII (0.073 *M*) in methanol was added to potassium dihydrogen phosphate (1 ml) at pH 6.00, 7.03, and 8.03, and lutidine (1 ml) at pH 7.01. A standard solution of the oximes was similarly prepared in chloroform (1 ml). Each solution was magnetically stirred at room temperature and was analyzed as a function of time using TLC [250-μm silica gel, acetone–chloroform (3:1)], XI/XII R_f = 0.62. There was no detectable oxime decomposition after 6 days.

An aliquot (25 μl) of a stock solution of XI/XII (0.146 *M*) in methanol was added to both the phosphate buffer at pH 7.03 and the lutidine buffer at pH 7.01, giving an oxime concentration of 7.0 m*M*. The former solution was combined with acetone (15 μl, 0.2 mmole, 55-fold molar excess), while the latter solution was treated with acetaldehyde (10 μl, 0.18 mmole, 48-fold molar excess). Daily TLC monitoring as described showed no evidence of reaction after 6 days at room temperature.

The initial oxime solutions in phosphate buffer at pH 6.00, 7.03, and 8.03, and lutidine buffer at pH 7.01, were each combined after 6 days with aqueous formaldehyde (6 μl of 37 w/w %, 0.073 mmole, 10-fold molar excess) and were stirred at room temperature. TLC analysis showed no detectable oxime decomposition after 4 days.

RESULTS AND DISCUSSION

Triphenylphosphine deoxygenation of 4-hydroperoxycyclophosphamide (XIII) is commonly employed for synthetic entry to *cis*-II, *trans*-II, and III, which give rise to ^{1}H-decoupled, ^{31}P-NMR singlet absorptions at δ 12.63, 12.93, and 20.83, respectively, in 0.05 *M* lutidine buffer at 37° (Fig. 1)[11]. Hydroxyphosphamide (δ 21.01), which is the 3-hydroxypropyl analog of aldophosphamide (III), is a good chemical shift model for ^{31}P-NMR identification of III; however, it should be noted that the proportion of free aldehyde in III *versus* its hydrate (15) has not been established. The absolute and relative signal intensities for *cis*-II, *trans*-II, and III vary (not shown) during the course of their gradual tautomerization and fragmentation of III to give IV and V, which is relatively short-lived and was previously studied by ^{31}P-NMR (16). In contrast to these spectral changes, addition of a 5-fold molar excess of *O*-methylhydroxylamine hydrochloride leads to rapid (<10 min) consumption of II/III with formation of a single resonance (δ 20.83) due to the *E* and *Z* aldophosphamide *O*-methyl oxime (XI and XII) trapping products (Fig. 1)[12]. ^{1}H-NMR analysis of an analytically pure oxime sample, which was obtained from spontaneous decomposition of XIII in the presence of *O*-methylhydroxylamine followed by extraction and TLC, showed resonance doubling (Fig. 2) for three types of protons: CH_3O (singlets), CH_2CH_2CH=N (quartets), and CH_2CH_2CH=N (triplets). Other investigators (17, 18) have compared the ^{1}H-NMR spectra of nine *E/Z* pairs of *O*-methyl oximes, and have concluded that the imino proton (CH=N) in the *E* isomer generally exhibits an ~0.6–0.9 ppm downfield shift relative to the corresponding resonance from the *Z* form. On this basis, the triplets at δ 7.40 and 6.79 (Δδ = 0.61 ppm) are respectively assigned to the *E* (XI) and *Z* (XII) *O*-methyl oximes of III, while averaged signal integrations gave a 62:38 (±1%) *E/Z* product ratio. Selective irradiation of each imino proton triplet led to the observation of a triplet for the corresponding CH_2CH_2CH=N nuclei, while irradiation of the overlapping absorptions for the CH_2O protons led to simultaneous collapse of both CH_2CH_2CH=N quartets into doublets, thus confirming the internal spectral assignments.

The utility of *O*-methylhydroxylamine in simplifying kinetic studies of 4-peroxy derivatives of I and its analogs (2) was exemplified by the spontaneous decomposition of 4-peroxycyclophosphamide (XV) in lutidine buffer (0.05 *M*) containing a 13-fold molar excess of this trapping reagent. ^{31}P-NMR spectra recorded as a function of time at 37° show the gradual disappearance of XV (δ 12.60) with the transient intermediacy of XIII (δ 13.43) and the steady accumulation of XI/XII (δ 20.83), together with the formation of 4-ketocyclophosphamide (XIV, δ 9.93) as a minor by-product (18%). The disappearance of XV obeys a first-order rate law, with $\tau_{1/2}$ = 0.5 hr, whereas other investigators (19), who monitored the time-course for release of acrolein from XV, reported an initial lag phase and postulated a coupled set of homolytic reactions. While the mechanistic origins for these kinetic differences require further investigation, the competing production of XIV is tentatively ascribed to free-radical cage reactions prior to formation of II and then III, which is finally intercepted as XI/XII. Analogous kinetic measurements with diastereomerically pure 4-(*tert*-butylperoxy)cyclophosphamide (XVI) revealed an ~10-fold increase in stability ($\tau_{1/2}$ = 5.2 hr), relative to XV ($\tau_{1/2}$ = 0.5 hr), and the absence of XIV (<1%) during formation of XI/XII. The contrasting results obtained for XV and XVI clearly reveal that the details for spontaneous decomposition of 4-peroxy derivatives of I are more complex than anticipated, *a priori*.

The stability of XI/XII toward either hydrolytic reversion to II/III or fragmentation into IV and V was demonstrated by TLC monitoring of the *O*-methyl oximes in buffered solutions at pH 6, 7, and 8, which showed no evidence of either oxime disappearance or formation of acrolein (IV) after 6 days at room temperature. Treatment of these solutions at pH 7 with excess acetone (55 equivalents), acetaldehyde (48 equivalents), or formaldehyde (10 equivalents) gave no TLC evidence for transoximination.

[11] The ^{31}P-NMR chemical shifts of I and its metabolites in aqueous solution are dependent upon pH, temperature, and the type of buffer (14).

[12] TLC and ^{1}H-NMR analyses of a deuterochloroform extract confirmed the presence of oximes XI and XII, thus ruling out the possibility of catalyzed conversion of II into III, which happens to have the same chemical shift as XI/XII under the stated reaction conditions.

CONCLUSIONS

O-Methylhydroxylamine rapidly reacts with tautomers II and III at neutral pH to quantitatively produce an ~60:40 mixture of the *E* and *Z* isomers of aldophosphamide *O*-methyl oxime, XI and XII. Assuming that oxime formation occurs by condensation of the amine with aldehyde III, it follows that the rate of ring-opening of *cis*- and *trans*-II to give III must be relatively fast, since ^{31}P-NMR analysis of the reaction mixture showed that these hemiaminals are no longer detectable after ~10 min at 37°. The *O*-methyl oximes of III are resistant toward hydrolysis of the oxime functionality, fragmentation into IV and V, and transoximination with either acetone, acetaldehyde, or formaldehyde. In concert, these features lend themselves to the use of *O*-methylhydroxylamine as an effective trapping agent for studies of cyclophosphamide metabolites II and III. Investigations of enzymatic and chemical regeneration of III from XI/XII in the design of new anticancer prodrugs will be reported in another study.

High-Performance Liquid Chromatographic Analysis of Hydrocortisone Drug Substance, Tablets, and Enema

MILDA J. WALTERS ˣ **and WALTER E. DUNBAR**

Received January 28, 1981, from the *Food and Drug Administration, Department of Health and Human Services, Detroit, MI 48207.* Accepted for publication August 10, 1981.

Abstract □ Methods for the analysis of hydrocortisone drug substance, tablets, and enema were developed using adsorption high-performance liquid chromatography (HPLC). This HPLC system was shown to be capable of isolating hydrocortisone from its degradation products, synthesis precursor, and related corticosteroids. The accuracy, precision, and linearity of the HPLC assay methods and their applicability to commercial products has been demonstrated.

Keyphrases □ High-performance liquid chromatography—analysis of hydrocortisone drug substance, tablets, and enema □ Hydrocortisone—analysis of drug substance, tablets, and enema using high-performance liquid chromatography □ Degradation products—separation from hydrocortisone, high-performance liquid chromatography

The majority of reported analytical methods for corticosteroids utilize blue tetrazolium (1–10), isoniazid (11), or phenylhydrazine (12, 13) reactions, UV spectrophotometry (14), or high-performance liquid chromatography (HPLC)[1] (15–22).

The methods for determining hydrocortisone products in the last four revisions of the United States Pharmacopeia (USP) (2, 23–25) have employed the blue tetrazolium reaction as the final determinative step. This is preceded by extraction or thin layer chromatographic (TLC) isolation of the active ingredient. Interferences and critical parameters of the reaction have been reported (6–9, 26).

HPLC is rapidly becoming the method of choice for the analysis of many drugs, and numerous applications of this technique to hydrocortisone are reported in the literature. The majority of published methods utilize reversed-phase systems (15–20). Recent reports, however, demonstrate that normal-phase adsorption chromatography offers greater selectivity for closely related corticosteroid structures[2] (21–22).

This study was undertaken to develop an HPLC system suitable for the analysis of hydrocortisone products and to compare the relative advantages of the USP and HPLC methods. Accuracy, precision, specificity, indication of

High-Performance Liquid Chromatographic Analysis of Hydrocortisone Drug Substance, Tablets, and Enema

MILDA J. WALTERS ˣ **and WALTER E. DUNBAR**

Received January 28, 1981, from the *Food and Drug Administration, Department of Health and Human Services, Detroit, MI 48207.* Accepted for publication August 10, 1981.

Abstract □ Methods for the analysis of hydrocortisone drug substance, tablets, and enema were developed using adsorption high-performance liquid chromatography (HPLC). This HPLC system was shown to be capable of isolating hydrocortisone from its degradation products, synthesis precursor, and related corticosteroids. The accuracy, precision, and linearity of the HPLC assay methods and their applicability to commercial products has been demonstrated.

Keyphrases □ High-performance liquid chromatography—analysis of hydrocortisone drug substance, tablets, and enema □ Hydrocortisone—analysis of drug substance, tablets, and enema using high-performance liquid chromatography □ Degradation products—separation from hydrocortisone, high-performance liquid chromatography

The majority of reported analytical methods for corticosteroids utilize blue tetrazolium (1–10), isoniazid (11), or phenylhydrazine (12, 13) reactions, UV spectrophotometry (14), or high-performance liquid chromatography (HPLC)[1] (15–22).

The methods for determining hydrocortisone products in the last four revisions of the United States Pharmacopeia (USP) (2, 23–25) have employed the blue tetrazolium reaction as the final determinative step. This is preceded by extraction or thin layer chromatographic (TLC) isolation of the active ingredient. Interferences and critical parameters of the reaction have been reported (6–9, 26).

HPLC is rapidly becoming the method of choice for the analysis of many drugs, and numerous applications of this technique to hydrocortisone are reported in the literature. The majority of published methods utilize reversed-phase systems (15–20). Recent reports, however, demonstrate that normal-phase adsorption chromatography offers greater selectivity for closely related corticosteroid structures[2] (21–22).

This study was undertaken to develop an HPLC system suitable for the analysis of hydrocortisone products and to compare the relative advantages of the USP and HPLC methods. Accuracy, precision, specificity, indication of

0022-3549/82/0400-0446$01.00/0

product stability, and applicability to most products on the commercial market were the criteria considered necessary for a suitable HPLC method. Of particular concern was the separation of hydrocortisone (I) from the major degradation products 11β,17-dihydroxyandrost-4-ene-3-one-20-oic acid (II) and 11β-hydroxyandrost-4-ene-3,17-dione (III) (6, 27–29), the common synthesis precursor, hydrocortisone acetate (IV), and the other closely related steroids, cortisone acetate (V), cortisone (VI), prednisone (VII), and prednisolone (VIII).

A silica microparticulate column with a mobile phase of ethylene dichloride containing methanol as modifier with small, controlled amounts of water and acetic acid met all of the listed requirements for an HPLC system. This system was incorporated into the assay procedures developed for hydrocortisone drug substance, tablets, and enema.

EXPERIMENTAL

Reagents and Materials—All solvents used were HPLC grade[3,4]. Glacial acetic acid was analytical reagent grade[5]. USP Reference Standard I, the degradation products II and III[6], acetaminophen[7], and corticosteroids[8] were used without further treatment. The TLC plates were purchased precoated with a 250-μm layer of silica gel with a fluorescent indicator[9]. Polytetrafluoroethylene 0.5-μm porosity membrane filters[10] were used to filter HPLC solvents and samples.

HPLC Determination of I—*Internal Standard Solution*—Two hundred milligrams of acetaminophen (IX) was dissolved in 4 ml of methanol and diluted to 200 ml with ethylene dichloride. The solution was kept in a tightly stoppered flask protected from light.

Standard Solutions—Solution A was prepared by accurately weighing and dissolving ~10 mg of I in 2 ml of methanol in a 50-ml volumetric flask. The internal standard solution (4 ml) was added, and the solution was diluted to volume with methylene chloride.

Solution B was prepared by accurately weighing and dissolving ~8 mg of I in 4 ml of methanol in a 100-ml volumetric flask. Internal standard solution (2 ml) was added and the solution was diluted to volume with chloroform. Solution A was used in the drug substance and tablet assays. Solution B was used to assay the enema.

HPLC System—The liquid chromatograph[11] was equipped with an automatic injector[12] having a 10-μl loop, a 25-cm × 4.6-mm i.d. column packed with spherical, 5–6 μm diameter, porous silica microparticles[13], a 254-nm UV detector[14], and a 10-mv span recorder[15]. The HPLC system was interfaced with a data system[16] for tracking peak areas and performing calculations. The detector was set at 0.5 absorbance units full scale (aufs) which produced peak heights of ~50% of full scale for both I and the internal standard in a 10-μl injection of standard solution A. Mobile solvent A was prepared by mixing 55 ml of a 5% water in methanol solution with 1.0 ml of acetic acid and diluting to 1 liter with ethylene dichloride. The flow rate was 1.5 ml/min and the methanol content was adjusted when needed to obtain a retention time of ~7.5 min for I. An alternate mobile solvent B consisted of 45 ml of 5% water in methanol solution mixed with 1.0 ml of acetic acid and diluted to 1 liter with methylene chloride.

System Suitability Test—The HPLC system was equilibrated by passing mobile solvent through the column for ~0.5 hr. Portions of the standard solution (10 μl) were then introduced. The system was considered suitable when (*a*) the retention times for I and IX were ~7.5 and ~10 min, respectively; (*b*) the resolution[17] R between I and IX was not less than 2.5, the column efficiency[18] N calculated using the I peak was not less than 5000 theoretical plates; and (*c*) the relative standard deviation of the response ratios of the I peak relative to the internal standard IX peak for six consecutive injections did not exceed 1%.

Table I—HPLC Retention of Hydrocortisone and Related Compounds

Compound	Retention Volume, ml	Capacity Factor, k'
Carbon tetrachloride	2.85	0
Benzene	2.85	0
Propylparaben	4.37	0.53
Methylparaben	4.67	0.61
11β-Hydroxyandrost-4-ene-3,17-dione	4.82	0.69
Cortisone acetate	4.88	0.71
Hydrocortisone acetate	5.55	0.95
Methylprednisolone acetate	6.02	1.11
Prednisolone acetate	6.32	1.22
Triamcinolone acetonide	6.89	1.42
Cortisone	6.96	1.44
Prednisone	7.74	1.72
Dexamethasone	10.28	2.60
Hydrocortisone	11.07	2.88
Methylprednisolone	12.84	3.51
Prednisolone	13.58	3.76
Acetaminophen	14.10	3.95
11β,17-Dihydroxyandrost-4-ene-3-one-20-oic acid	15.17	4.32
Triamcinolone	18.42	5.46

Sample Preparation—*Drug Substance*—Approximately 50 mg of sample, previously dried for 3 hr at 105°, was weighed into a 250-ml volumetric flask. Ten milliliters of methanol and 20.0 ml of internal standard solution were added and the solution was diluted to volume with methylene chloride.

Tablet Composite Assay—An accurately weighed portion of a 20-tablet composite equivalent to one tablet was transferred to a volumetric flask of an appropriate size to yield a final I concentration of ~0.2 mg/ml. Two milliliters of methanol per 10 mg of declared I was added and the flask placed in an ultrasonic bath for 2 min. Methylene chloride was then added until the flask was about half full and the flask was returned to the ultrasonic bath for 1 min. An accurately measured volume of internal standard solution equivalent to 4 ml/10 mg of declared I was added. The sample was diluted to volume with methylene chloride and a portion was filtered for HPLC assay.

Tablet Content Uniformity Determination—Each tablet was placed in an Erlenmeyer or volumetric flask of a size selected to yield a final I concentration of ~0.2 mg/ml. The tablet was softened by placing 100 μl of water/10 mg of declared I directly on the tablet and allowing it to soak in for 0.5 hr. Methanol (2 ml/10 mg of declared I) was added and the flask was placed in an ultrasonic bath for 10 min or until the tablet disintegrated. The procedure for tablet composite assay was then followed.

Enema—A sample equivalent to 8 mg of I was accurately weighed by difference into a separatory funnel and I was extracted with four 20-ml portions of chloroform, each portion filtered through chloroform-washed cotton into a 100-ml volumetric flask.

Methanol (4 ml) and internal standard solution (2 ml) were added, the sample was diluted to volume with chloroform, and a portion was filtered for HPLC assay.

Procedure—The HPLC system was allowed to equilibrate by passing the mobile solvent through the column for ~0.5 hr. Standard solution (10-μl portions) were introduced and the response ratios (R_s) of the I peak relative to the internal standard IX were calculated. When the R_s for three consecutive injections agreed within 1%, 10 μl of the sample preparation was injected. The quantity of I in the portion of the sample taken was calculated by the formula I (mg) = $V_u W_s R_u / V_s R_s$, where W_s is milligrams of I in the standard solution, V_s and V_u are the volumes (ml) of internal standard solution in the standard and sample solutions, respectively, and R_u is the response ratio of the peaks (I/IX) in the sample chromatogram.

Validation of HPLC Procedures—*Specificity*—Test solutions

Key: I, hydrocortisone; V, cortisone acetate; IV, hydrocortisone acetate; VI, cortisone; VII, prednisone; VIII, prednisolone; column 1, 25 cm × 4.6-mm i.d. packed with 5–6 μm diameter spherical silica particles; column 2, 25 cm × 4.6-mm i.d. packed with 5 μm irregular shaped silica; column 3, 30 cm × 3.9-mm i.d. packed with 10 μm, irregular shaped silica; column 4, 10 cm × 8-mm i.d. pressurized cartridge packed with 10 μm diameter, spherical silica particles. All chromatograms were obtained using the same mixture of compounds; the order of elution was the same for all columns.*

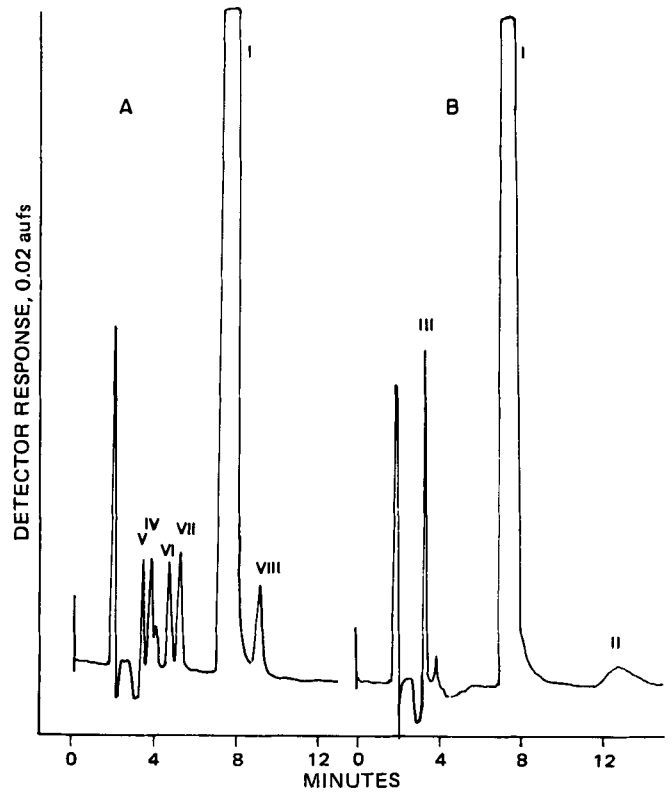

Figure 2—*Chromatograms of hydrocortisone (I) with added (0.5% of each) corticosteroids IV–VIII(A) and degradation products II and III (B).*

containing 0.04–0.2 mg/ml of the compounds listed in Table I, prepared in methylene chloride–methanol (98:2), were introduced into the HPLC system and their respective capacity factors[19] (k') were calculated. A model mixture containing 0.1 mg/ml each of I and IV–VIII in methylene chloride–methanol (98:2) was used to compare the performance of HPLC columns, mobile solvents, and HPLC to TLC.

Precision—Precision of the HPLC system was tested by injecting 36 portions of standard solution A, determining the R_s values for the peaks (I/IX) based on areas as well as heights, and calculating the relative standard deviation. The precision of the respective assay methods was tested by subjecting 10 portions of each of the appropriate sample composites to the entire assay procedure and determining the relative standard deviation of the results.

Accuracy—The accuracy of the assay procedures was tested using synthetic samples. The product formulations were categorized by excipient formulation. Typical formulations were selected for five tablet and two enema products, and placebo mixtures were prepared by combining all ingredients except I. Five portions of each placebo were taken and an accurately weighed amount of I, equivalent to the declared product potency, was added to each portion. These were analyzed by the appropriate HPLC assay procedures and the recovery of I was calculated.

Confirmation of Impurities—(*A*) *Separation of II–VII from I*—Drug substance I (~80 μg) was spotted on a TLC plate previously impregnated with 15% formamide in acetone (30). The chromatogram was developed three times using chloroform as the mobile solvent. The spots were detected by examining in short wavelength (254 nm) UV light followed by spraying with 25% H_2SO_4 in methanol, heating 5 min at 120°, and observing characteristically colored corticosteroid spots in long wavelength (366 nm) UV light. Compound I with added II–VIII at a level of 0.5% each was spotted and developed using the above system. Compounds II–VII were resolved and detected, while VIII was not separated from I at this level.

(*B*) *Separation of VIII from I*—Concentrated solutions (10 mg/ml) of I samples suspected to contain VIII were injected into the HPLC system and eluate portions corresponding to VIII retention were collected. After concentrating by evaporation, the eluate was spotted on a TLC plate and developed with methylene chloride–methanol–water (180:15:1) mobile solvent (2). Prednisolone was detected as in the TLC system described in A.

RESULTS AND DISCUSSION

The USP (2) single steroid assay (included in the I drug substance and tablet monographs) requires a TLC separation, quantitative transfer of portions of the silica layer, extraction, and final quantitation by the blue tetrazolium colorimetric procedure. The USP assay for hydrocortisone enema (2) involves a chloroform extraction followed by blue tetrazolium quantitation. This reaction is not specific for I and because I is not isolated from related steroids in the enema assay the results would include total corticosteroids as well as other compounds which react with this reagent (26). The USP methods for hydrocortisone were found to be tedious and time-consuming, and presented difficulties with the sample preparation of some commercial products[23]. Therefore, it was considered advantageous to develop alternate methods capable of providing equal specificity without these limitations.

HPLC was selected as the technique offering the greatest potential with respect to specificity, speed, and convenience. Adsorption HPLC was utilized due to its capabilities to separate closely related structures. The desired separation of I from its degradation products, precursor (IV), and related steroids (V–VIII) was achieved on a silica column with two equivalent mobile solvent systems (A and B). Though both mobile solvents have the same retention and selectivity for I–VIII, A is less volatile

[19] $k' = (t_r - t_0)/t_0$, where t_0 is the time required to elute unretained component through the system.

Table II—Analysis of Hydrocortisone Drug Substance

Sample	Hydrocortisone Found, %		Impurities Found, %[b]			
	HPLC[a]	USP[a]	Cortisone	Prednisolone	Hydrocortisone Acetate	Unidentified
22	98.6 (0.0)	98.2 (1.3)	0.13	—	—	Trace
23	98.5 (0.4)	98.2 (0.9)	0.26	0.53	0.1	Trace
24	98.8 (0.3)	98.7 (0.4)	0.13	0.57	0.1	Trace
25	97.2 (0.2)	98.2 (1.2)	0.20	—	—	Trace
26	99.1 (0.0)	102.4 (1.1)	0.16	0.31	—	Trace

[a] % by weight on dried basis, average of two determinations (% difference between duplicates). [b] % by weight, trace was estimated to be less than 0.1% based on UV response equivalent to cortisone.

Table III—HPLC Analysis of Synthetic Samples

Product	Formulation Type	HPLC Assay				
		Number of Determinations	Added I, mg[a]	Added I found, %		
				Average	Range	$RSD^{\dagger}$
Tablets	A	5	20	99.4	98.6–98.8	0.48
Tablets	B	5	20	99.0	98.6–99.4	0.30
Tablets	C	5	10	99.7	99.1–100.6	0.56

Average				99.5		

[a] Approximate amount of accurately weighed hydrocortisone (I) added to each portion of placebo.

resulting in a more rugged system and was therefore incorporated into the assay procedures. The selectivity of this HPLC system is illustrated in Table I, which shows the capacity factors (k') for compounds of interest. A good separation was obtained for corticosteroid pairs I and VIII, and VI and VII, which are difficult to resolve by reversed-phase systems (20). Corticosteroid acetates, which eluted close together when mobile solvent A was used, were found to have higher k' values and better resolution when the methanol content of the mobile solvent was decreased to 3.5%. Thus, the same column with slight modifications in the mobile solvent shows a potential for application to corticosteroid products other than those reported here.

A model mixture of I and IV–VIII was used to investigate four silica columns, using resolution (R) between VI and VII as well as efficiency (N) (calculated as theoretical plates based on the I peak) as the criteria for comparison. Columns 1 and 2 were both 25 cm × 4.6-mm i.d. in size. Column 1 was packed with 5–6 μm diameter, spherical silica[13], while column 2 contained irregular-shaped 5-μm silica particles[20]. Column 3 was 30 cm × 3.9-mm i.d. in size packed with 10-μm, irregular-shaped silica[21]. Column 4 was packed with 10-μm spherical silica particles in a 10 cm × 8-mm i.d. plastic cartridge[22] maintained under pressure. The test compounds eluted in the same order through all four columns. Differences were observed in the total elution times and resolution (Fig. 1). The highest efficiency (N = 8300) and resolution (R = 1.56) were obtained with column 1. The performance of column 2 was very similar to 1, while the differences were more apparent with columns 3 and 4 which had 3400 and 3700 theoretical plates, respectively. Compound I was completely resolved on all four columns. Column 1 was used for all analyses reported in this paper.

The six-steroid model mixture was also used to compare the specificity of HPLC to that of the TLC system used in the USP single steroid assay, and Fig. 1 shows that HPLC provides equal or better selectivity for related steroids. Figure 2 demonstrates the system's capability to separate I from its major degradation products, II and III, as well as from its immediate synthesis precursor, IV.

Acetaminophen (IX) was incorporated into the procedures as an internal standard to compensate for possible injection variability and solution volume changes. The relative standard deviation of the response ratios (R_s) for the peaks (I/IX) of 36 replicate injections of standard solution was found to be 0.19% based on peak areas and 0.60% using manually measured peak heights. While the computerized area calculations are preferred due to better precision and a savings of time and effort, manual peak height calculations also gave acceptable results.

The response for I was found to be linear in the tested range of 0.8–3.4 μg, equivalent to 40–170% of the injection amount specified in the method. The internal standard (IX) produced a linear response as did the response ratios for the I peak relative to the internal standard peak over the range of 50–150% of the specified concentrations.

The HPLC assay results for five I drug substance samples (Table II) show reasonable agreement with those obtained by the USP assay. Duplicate assays by the HPLC method agree within <0.5% (average = 0.2%) while the USP duplicates range from 0.4 to 1.3% (average = 1%). An additional portion from each sample was prepared and chromatographed

without the internal standard, and none of the chromatograms showed interfering peaks at the retention corresponding to the internal standard. These solutions were also used to test for the presence of impurities by increasing the detector sensitivity 25-fold, from 0.5 to 0.02 aufs. Chromatograms of reference standard I with degradation products II, III, and the related steroids IV–VIII, each added at a level of 0.5% of I, showed that these impurities are detectable at this level by this procedure (Fig 2). An estimated 0.1–0.3% of cortisone was found in all five samples and 0.3–0.6% of prednisolone was found in three samples of I drug substance (Table II). The presence of cortisone and prednisolone was confirmed by TLC, the latter after subjecting concentrated solutions to HPLC, collecting, and concentrating the appropriate portions of the eluate. Traces of hydrocortisone acetate and unidentified impurities were also detected. No degradation products were found. The total amount of detected impurities was <1% in all samples.

The HPLC system was applied to the analysis of I tablets by introducing a sample preparation step and performing additional validation experiments. The dilutions specified in the sample preparation for tablets result in the same final concentration of I regardless of the dosage level, which ranges from 5 to 20 mg/tablet. Thus, the same standard solution and detector sensitivity can be used.

The recovery of I through the method and the influence of excipients was checked by the synthetic sample approach. Five typical product formulations prepared in the laboratory were assayed. The recovery results (Table III) ranged from 98.6 to 101.8% and the overall mean for a total of 25 determinations was 99.9% with a relative standard deviation of 0.91%. No bias in the method is indicated. The precision for commercial products was checked by assaying 10 composite portions for each of five samples. The results showed good precision with the relative standard deviation for the five samples ranging from 0.27 to 0.78%.

The tablet content uniformity procedure is essentially identical to the assay, the only difference being in the initial sample preparation required to disintegrate the intact tablet. A small amount of water was needed to soften the tablet and enhance the disintegration. The volumes of water and methanol were limited to the specified low levels in order to maintain the equilibrium of the chromatographic system.

Twenty-one commercial tablet products manufactured by 12 different firms were subjected to the HPLC assay and content uniformity procedures. The results are summarized in Table IV along with those obtained by the USP assay. While all the results are within USP limits, 14 of the 21 USP assay results are lower than the HPLC assay with an average difference of 1.45%, suggesting a negative bias in the USP assay. The average difference between results of duplicate determinations was 1.1% for the USP method and 0.49% for the HPLC assay method. The HPLC composite assay results show good agreement with the respective average content uniformity results for 10 individual tablets.

A typical chromatogram is shown in Fig. 3A. A portion of each composite chromatographed without internal standard showed no interferences at the retention volume of IX.

The same HPLC system was applied to the assay of hydrocortisone enema after introducing an appropriate sample preparation step. Since the adsorption HPLC system requires that the water content be maintained at a low and closely controlled level, aqueous enema samples could not be introduced without eliminating the water. An extraction of I into chloroform was found to overcome this problem. Methyl- and propylparabens, present as preservatives, were also extracted into chloroform but were well resolved from I by HPLC (Fig. 3B).

The average recovery for 10 portions of I through the enema assay was 100.2% with a relative standard deviation of 0.65%. The average of 10 recoveries for two synthetic enema formulations was 99.9 and 99.1% with a relative standard deviation of 0.38 and 0.24%, respectively (Table III). Replicate determinations of two commercial enema products resulted in a relative standard deviation of 1.0% in both cases, showing acceptable precision. One of the products was found to have satisfactory potency with good agreement between the HPLC and blue tetrazolium assays, 99.8 and 101.0%, respectively. The second product showed only 82.7% of the labeled I content by HPLC and 86.5% by blue tetrazolium. Since the blue tetrazolium reaction is not specific, it is possible that an impurity in the product may have caused false high results. This suspicion was further reinforced when a small peak at 5.6 min was observed in the sample chromatograms. This peak did not appear in the standard, synthetic sample or the other enema product chromatograms; did not correspond to I–IX; and remains unidentified. The low HPLC assay result was confirmed by subjecting the sample to a reversed-phase HPLC assay using an octyl–silane bonded column and a methanol–water (60:40) mobile solvent.

The presented HPLC methods for the analysis of I drug substance tablets and enema have been shown to be accurate, precise, specific, and applicable to products on the commercial market. It is anticipated that with appropriate sample preparation the same HPLC system will be applicable to other hydrocortisone products.

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test I: Effects of Physical Alignment of the Dissolution Apparatus

DON C. COX[x] and WILLIAM B. FURMAN

Received April 17, 1981, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication July 23, 1981.

Abstract □ The physical alignment of the paddle and the vessel is critical in obtaining reproducible results from the USP dissolution test with Apparatus 2. Large variations in dissolution results were traced to minor variations in alignment of different apparatuses.

Keyphrases □ Dissolution—USP Apparatus 2, reproducibility of results □ USP—dissolution Apparatus 2, reproducibility of results □ Apparatus—USP dissolution Apparatus 2, reproducibility of results

This laboratory has been recently studying the systematic error associated with Apparatus 2 of the USP dissolution test (1). Collaborative studies conducted by the Academy of Pharmaceutical Sciences[1] and by the Food and Drug Administration (2) showed a wide variation in test results reported by different laboratories. The present report is the first of a series of papers describing sources of systematic error associated with the dissolution test.

The test method first appeared in the Fourth Supplement to USP XIX and NF XIV (3). The stirring element consisted of a shaft with a detachable paddle blade positioned on its side. In the Fifth Supplement of USP XIX and NF XIV, the stirring element was modified to its present configuration: the blade is now rigidly mounted through the diameter of the shaft. The data reported in this paper were collected prior to the modification of the apparatus.

[1] Unpublished data, Dissolution Technology Committee, APhA Academy of Pharmaceutical Sciences.

EXPERIMENTAL

Two commercial samples of 5-mg prednisone tablets (referred to as Tablet 0 and Tablet 1) were used for the evaluation of six dissolution apparatuses. Dissolution data for the two samples from each apparatus were collected using a single set of six glass dissolution vessels[2] and uniform analytical technique. Two appartuses, designated A and B, were designed and built by the Food and Drug Administration. Four apparatuses, designated C, D, E, and F, were commercially available[3]. Each apparatus could test six tablets simultaneously.

The dissolution and analytical methodology is described in the Fourth Supplement to USP XIX and NF XIV (4).

RESULTS AND DISCUSSION

The data collected from the two samples with each apparatus are shown in Table I. The results for apparatuses E and F are considerably higher than those for the other four apparatuses. These discrepancies were traced to minor variations in the vertical alignment of the paddle shafts. The experiment pointed out two deficiencies in the dissolution methodology.

The first deficiency was that the equipment operator could not be certain that the USP alignment specifications were being met: the paddle shaft must be aligned so that its axis is not more than 0.2 cm from the vertical axis of the vessel at any point. Devices adequate to measure and adjust the equipment to meet this requirement were not available initially. Although the apparatus was adjusted to make the drive head parallel with the base, no conscientious effort was made to improve the precision with which a vessel was centered around its shaft.

The second deficiency lay in the design of the apparatus. The support

The dissolution and analytical methodology is described in the Fourth Supplement to USP XIX and NF XIV (4).

RESULTS AND DISCUSSION

The data collected from the two samples with each apparatus are shown in Table I. The results for apparatuses E and F are considerably higher than those for the other four apparatuses. These discrepancies were traced to minor variations in the vertical alignment of the paddle shafts. The experiment pointed out two deficiencies in the dissolution methodology.

The first deficiency was that the equipment operator could not be certain that the USP alignment specifications were being met: the paddle shaft must be aligned so that its axis is not more than 0.2 cm from the vertical axis of the vessel at any point. Devices adequate to measure and adjust the equipment to meet this requirement were not available initially. Although the apparatus was adjusted to make the drive head parallel with the base, no conscientious effort was made to improve the precision with which a vessel was centered around its shaft.

The second deficiency lay in the design of the apparatus. The support

for the dissolution drive for apparatuses D, E, and F consisted of a keyed center post. The drive could be moved vertically on the post and pivoted up and out of the way to facilitate the changing of vessels between tests. Because of this design the dissolution drives of apparatuses D, E, and F were held less rigidly and precisely over the holes in the base of the apparatus than the dissolution drive of apparatus C.

Alignment procedures were developed for the apparatus. A centering tool, a paddle depth gauge, and a means of holding the vessel in a position centered around the paddle shaft were developed. These procedures and tools (5) were used to realign apparatuses E and F. The dissolution test was repeated on Tablet 0 and Tablet 1. Realignment improved the test results for apparatuses E and F (Table II), which were in closer agreement with the Table I results for the other four apparatuses than before realignment.

Data collected from Tablet 1 after alignment of a commercial apparatus[4] are shown in Table III. The shafts were then tilted ~0.5 degree by raising one side of the drive base by 3 mm. Additional data were collected. The shafts were readjusted to a vertical position, and the test was repeated a third time. The data (Table III) show that the effect of tilting the shafts from a vertical position by only 0.5 degree is substantial and reproducible.

The shafts in a six-spindle apparatus can all be made vertical only if the chucks hold the shafts parallel to each other. The shafts of one of the commercial apparatuses showed small deviations from parallelism. Vernier calipers, capable of measurement to the nearest 0.02 mm, were used to measure the distances between shafts. Measurements were taken in a horizontal plane near the chucks and in a horizontal plane 17 cm below the chucks. The differences in the measurements (Fig. 1) are small but significant. If shafts 1, 2, 3, and 5 are made vertical, shafts 4 and 6 will not be vertical. Shaft 4 in particular will be displaced about 0.5 degree

[4] Model 72RL, Hanson Research Corp.

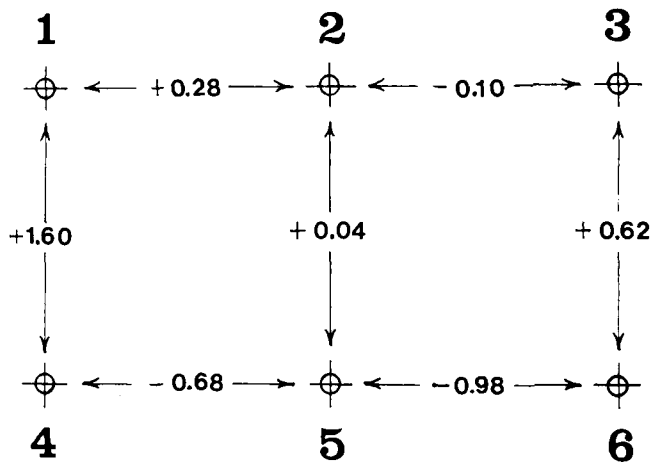

Figure 1—*Deviations (in millimeters) from parallelism of shafts of one commercial apparatus. Measurements were taken where the shafts come out of the chucks and compared to measurements taken 17 cm below the chucks. A positive sign indicates the two shafts are divergent. A negative sign indicates the two shafts are convergent.*

from a vertical position. When Tablet 1 was examined with this apparatus, the data from shafts 4 and 6 were markedly different from those from shafts 1, 2, 3, and 5, and the differences were of the same magnitude as the differences in averages reported in Table III.

Experience has since indicated that an analyst who is new to the dissolution test may interpret the USP requirement for paddle shaft alignment as a requirement to center the tops of the vessels around the shafts to within 0.2 cm. It is equally important that the shafts are precisely vertical. Despite the fact that the top of each vessel was centered around its shaft, minor vertical deviations of shafts caused large changes in the test results from Table 1.

CONCLUSIONS

The liquid flow rates generated in different sections of the vessel are controlled by the location of the paddle in the vessel as well as the rotational rate of the paddle. Dissolution results obtained prior to modification of the paddle blade can differ from results obtained after modification. The system geometry of both paddle designs must be precisely controlled if results from either are to be reproducible. To minimize error resulting from minor variations in the system geometry of Apparatus 2, the base of the apparatus must be horizontal, the shafts must be vertical, each shaft must be positioned along the vertical axis of each vessel, and the paddles must be set at a standarized depth in the vessels. These alignments must be made as precisely as current technology will allow.

Reduced Hydrolytic Lability of Epoprostenol in the Presence of Cationic Micelles

M. J. CHO

Received January 12, 1981, from the *Upjohn Co., Kalamazoo, MI 49001.* Accepted for publication July 24, 1981.

Abstract □ The rapid hydrolysis of epoprostenol to 6-keto-prostaglandin $F_{1\alpha}$ is hydronium ion-catalyzed even at pH 10 or higher. In the presence of 1.0% hexadecyltrimethylammonium chloride, the rate was reduced significantly (1580-fold at pH 2 and 283-fold at a physiological pH). This decrease in the hydrolysis rate is attributed to two causes: favorable partitioning of epoprostenol in the micellar phase and electrostatic repulsion between the hydronium ion and the cationic micellar surface.

Keyphrases □ Prostaglandins—epoprostenol, reduced hydrolytic lability in the presence of cationic micelles □ Micelles—reduction of hydrolytic lability of epoprostenol □ Epoprostenol—reduced hydrolytic lability in the presence of cationic micelles

The antiplatelet (anti- and deaggregatory) and vasodilator actions of epoprostenol (I) has brought about not only some potential clinical applications but also "a direct impact on research dealing with the mode of antiaggregatory cyclic AMP activity" (1). Being a vinyl ether, however, I is extremely unstable in aqueous media; half-life ($t_{1/2}$) of its hydrolysis is only several minutes at a physiological pH and 25° (2). Subsequently it was found that the compound is unusually reactive even as a vinyl ether and that the hydronium ion-catalyzed hydrolytic lability of the carboxylate anion is nearly two orders of magnitude greater than that of the free acid or methyl ester (Fig. 1) (3). The instability of this endogenous hormone-like substance has hampered the progress of clinical applications and in the basic research area. The present study reports that in the presence of cationic micelles the hydrolysis rate can be retarded by a factor of 1.5×10^3 at pH 2 and 10^2 at a physiological pH.

EXPERIMENTAL

A UV spectrophotometric[1] procedure was used to follow the hydrolysis of I (2). Essentially, the absorbance change at 235 or 240 nm was monitored continuously immediately after the sodium salt of I (~4 mg) was dissolved in a non-UV absorbing buffer solution (~3 ml) of 0.5 *M* ionic strength in a cell. When the spectral change was scanned continuously, an isosbestic point was observed at 256 nm throughout a kinetic run over the pH range studied. Hexadecyltrimethylammonium chloride[2], was used as received.

RESULTS AND DISCUSSION

Negative micellar catalysis has not been subject to numerous applications in the area of drug formulation development, although stabilization of a drug compound can be achieved in aqueous media (4). This is surprising since micelle-catalyzed organic reactions in aqueous media have been studied extensively as model systems of enzymatic reactions.

Aqueous solutions containing a surface-active agent form molecular aggregates known as micelles when the total concentration reaches a certain value, which is referred to as the critical micellar concentration (CMC). The CMC of hexadecyltrimethylammonium chloride $[(CH_3)_3N^+(CH_2)_{15}CH_3 \cdot Cl^-]$ is $\sim 1.3 \times 10^{-3} M$(5), and hence in a 1.0% $(3.12 \times 10^{-2} M)$ solution (in which the stability of I was investigated), most of the surfactant molecules are engaged in micelles. Since the polarity of the micellar phase can be much lower than that of the bulk aqueous phase, I free acid is expected to partition favorably into the micellar phase. However, as pH increases the apparent fractional concentration of I found inside the micellar phase will decrease because the dynamic equilibrium becomes more favorable for the anion to exist in an aqueous environment.

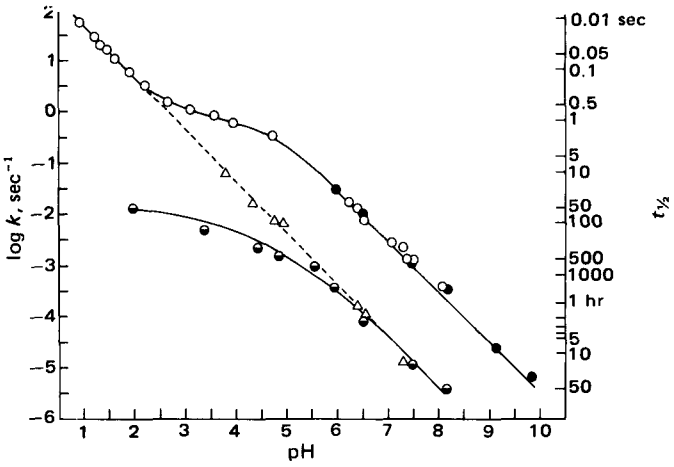

Figure 1—*pH dependence of the hydrolysis rate of I (closed circles from Ref. 2 and open circles from Ref. 3), I methyl ester (triangles from Ref. 3), and in the presence of 1.0% hexadecyltrimethylammonium chloride (half-circles), all at 25°. The former two are the rate constants at zero buffer concentration, and the last one was at 0.5* M *ionic strength.*

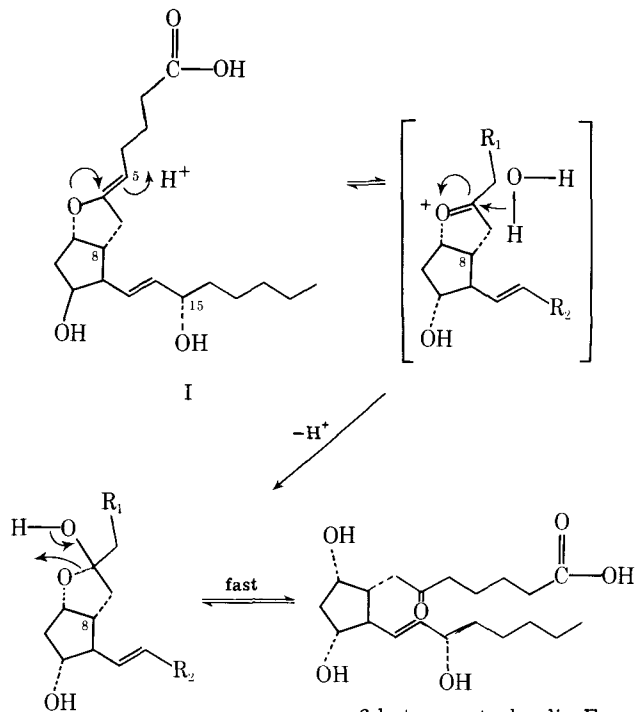
From this pH-dependence of the partitioning behavior of I and from



Scheme I—Reaction pathway of I hydrolysis.

the general belief that the thermodynamic activities of water (reactant) and hydronium ion (catalyst) can be extremely low inside the micellar phase, one would expect the pH-profile of log k_{obs} shown in Fig. 1 (half-filled circles). Note that the overall rate-determining step in the hydrolysis of I is the protonation at C-5, which makes the Δ^5 bond polarized and susceptible to the subsequent water attack (Scheme I) (3). That is, if an intrinsic reactivity is assigned to the free acid present inside the micellar phase, regardless of the pH of the bulk phase, then the pH-profile of the observed rate constant should resemble that of the apparent partition coefficient. This analysis is consistent with what was observed.

In the presence of 1.0% hexadecyltrimethylammonium chloride, the apparent hydrolysis rate at pH below 3 is $\sim 1.5 \times 10^3$ fold slower than in the absence of the surfactant (Fig. 1). At neutral pH values, however, such a comparison can be made only after taking the general acid catalysis by buffer components into consideration. At pH 7.45, for instance, if the data shown in Fig. 1 are compared, only a 62-fold decrease in the rate is obtained. However, the hydrolysis rate shown in Fig. 1 in the absence of the surfactant is the rate extrapolated to zero buffer concentration, whereas that in the presence of the surfactant was obtained in a 0.165 *M* phosphate buffer of 0.50 *M* ionic strength. In an identical buffer system without the surfactant, it was found previously that the hydrolysis is ~4.56 faster than at zero buffer concentration (2). The net effect of 1.0% hexadecyltrimethylammonium chloride is, therefore, a reduction of the hydrolysis rate of ~280-fold; $t_{1/2}$ from 3.5 min to 16.5 hr.

Finally, one should not attempt to interpret the coincidental overlap of the rate constants for the hydrolysis of methyl ester (triangles in Fig. 1) and I in the presence of the surfactant at pH above 6. As discussed previously (4), the latter is a function of the concentration of both substrate and the surfactant present in a given system.

Determination of Tissue to Blood Partition Coefficients in Physiologically-Based Pharmacokinetic Studies

GILBERT LAM *, MEI-LING CHEN, and WIN L. CHIOU ˣ

Received May 18, 1981, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60680.* Accepted for publication August 10, 1981. * Present address: Stine Laboratory, E.I. du Pont Nemours and Co., Inc., Newark, DE 19711.

Abstract □ The partition coefficient between tissue and blood used in physiologically-based pharmacokinetic modeling analysis was investigated using the concept of clearance. New equations were derived and compared with previously reported equations in constant intravenous infusion and bolus injection methods. The importance of differentiating arterial from venous blood is discussed.

Keyphrases □ Partition coefficient—tissue to blood, physiologically-based pharmacokinetics □ Pharmacokinetics—determination of tissue to blood partition coefficients in physiologically-based pharmacokinetic studies □ Blood sampling—differences between arterial and venous blood, physiologically-based pharmacokinetic studies

The formulation of a physiologically-based pharmacokinetic model requires an accurate determination of physiological parameters such as blood flow, organ volume, partition coefficient, and clearance (1). The estimation of the tissue to blood partition coefficients for a compound is of special interest to pharmacokineticists because it can be directly measured in the laboratory. Recently, Chen and Gross (2) pointed out different methods by which tissue to plasma partition coefficients can be determined under specific experimental conditions. The following equations were used in constant infusion and bolus injection studies, respectively:

$$R = \left(1 + \frac{K}{Q}\right)\frac{C_t^\infty}{C_p^\infty} \qquad \text{(Eq. 1)}$$

$$R = \frac{(Q + K)C_t^0}{(QC_p^0 + \alpha V_t C_t^0)} \qquad \text{(Eq. 2)}$$

where R is the partition coefficient of drug between organ tissue and plasma, K was defined as the first-order elimination rate constant [but was used as organ clearance in their calculations (2)], Q is the flow rate of plasma in the organ, C_t^∞ and C_p^∞ are the concentrations of drug in tissue and plasma at steady state, C_t^0 and C_p^0 are the concentrations of drug in tissue and plasma at time zero extrapolated from the terminal phase, α is the terminal rate constant, and V_t is the volume of the organ or tissue. The present study examined Eqs. 1 and 2 from the concept of physiological clearance and derived new equations for the determination of R in constant infusion and bolus injection studies. Flow and concentration in terms of blood were dealt with instead of plasma.

THEORETICAL

The concept of clearance and its applications are well defined in the pharmacokinetic literature (3–7). In an eliminating organ or tissue, it describes the volume of incoming blood completely cleared of drug by the organ per unit time. Conventionally, it is expressed as the organ clearance, CL_s, and is defined as:

$$CL_s = \frac{r}{C_i} \qquad \text{(Eq. 3)}$$

where r is the rate at which the drug is removed from the organ and C_i is the drug concentration in the incoming blood. However, it has been observed that CL_s might be dependent on the blood flow through the organ and the use of intrinsic clearance, CL_i, was proposed to correct for the influence of blood flow (3). CL_i is defined as:

$$CL_i = \frac{r}{C_0} \qquad \text{(Eq. 4)}$$

where C_0 is the effluent venous blood concentration which is in equilibrium with the eliminating organ. It measures the maximum capacity of the organ to eliminate the drug. An important relation obtained from the above clearance equation is:

$$r = CL_s C_i = CL_i C_0 \qquad \text{(Eq. 5)}$$

0022-3549/82/0400-0454$01.00/0

the general belief that the thermodynamic activities of water (reactant) and hydronium ion (catalyst) can be extremely low inside the micellar phase, one would expect the pH-profile of log k_{obs} shown in Fig. 1 (half-filled circles). Note that the overall rate-determining step in the hydrolysis of I is the protonation at C-5, which makes the Δ^5 bond polarized and susceptible to the subsequent water attack (Scheme I) (3). That is, if an intrinsic reactivity is assigned to the free acid present inside the micellar phase, regardless of the pH of the bulk phase, then the pH-profile of the observed rate constant should resemble that of the apparent partition coefficient. Determination of Tissue to Blood Partition Coefficients in Physiologically-Based Pharmacokinetic Studies

GILBERT LAM *, MEI-LING CHEN, and WIN L. CHIOU ˣ

Received May 18, 1981, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60680.* Accepted for publication August 10, 1981. * Present address: Stine Laboratory, E.I. du Pont Nemours and Co., Inc., Newark, DE 19711.

Abstract □ The partition coefficient between tissue and blood used in physiologically-based pharmacokinetic modeling analysis was investigated using the concept of clearance. New equations were derived and compared with previously reported equations in constant intravenous infusion and bolus injection methods. The importance of differentiating arterial from venous blood is discussed.

Keyphrases □ Partition coefficient—tissue to blood, physiologically-based pharmacokinetics □ Pharmacokinetics—determination of tissue to blood partition coefficients in physiologically-based pharmacokinetic studies □ Blood sampling—differences between arterial and venous blood, physiologically-based pharmacokinetic studies

The formulation of a physiologically-based pharmacokinetic model requires an accurate determination of physiological parameters such as blood flow, organ volume, partition coefficient, and clearance (1). The estimation of the tissue to blood partition coefficients for a compound is of special interest to pharmacokineticists because it can be directly measured in the laboratory. Recently, Chen and Gross (2) pointed out different methods by which tissue to plasma partition coefficients can be determined under specific experimental conditions. The following equations were used in constant infusion and bolus injection studies, respectively:

$$R = \left(1 + \frac{K}{Q}\right)\frac{C_t^\infty}{C_p^\infty} \qquad \text{(Eq. 1)}$$

$$R = \frac{(Q + K)C_t^0}{(QC_p^0 + \alpha V_t C_t^0)} \qquad \text{(Eq. 2)}$$

where R is the partition coefficient of drug between organ tissue and plasma, K was defined as the first-order elimination rate constant [but was used as organ clearance in their calculations (2)], Q is the flow rate of plasma in the organ, C_t^∞ and C_p^∞ are the concentrations of drug in tissue and plasma at steady state, C_t^0 and C_p^0 are the concentrations of drug in tissue and plasma at time zero extrapolated from the terminal phase, α is the terminal rate constant, and V_t is the volume of the organ or tissue. The present study examined Eqs. 1 and 2 from the concept of physiological clearance and derived new equations for the determination of R in constant infusion and bolus injection studies. Flow and concentration in terms of blood were dealt with instead of plasma.

THEORETICAL

The concept of clearance and its applications are well defined in the pharmacokinetic literature (3–7). In an eliminating organ or tissue, it describes the volume of incoming blood completely cleared of drug by the organ per unit time. Conventionally, it is expressed as the organ clearance, CL_s, and is defined as:

$$CL_s = \frac{r}{C_i} \qquad \text{(Eq. 3)}$$

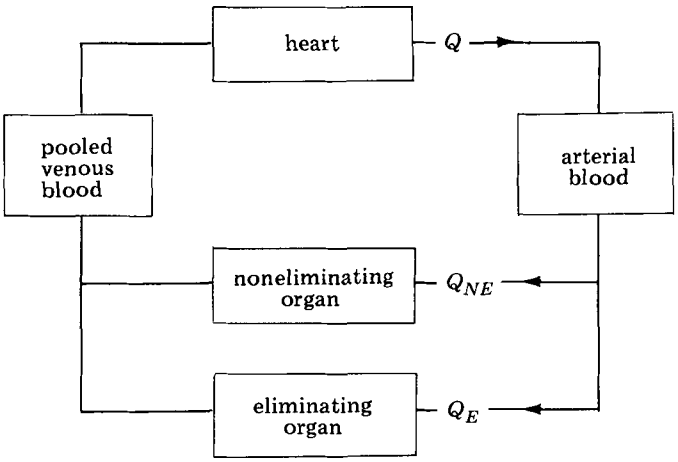
where r is the rate at which the drug is removed from the organ and C_i is the drug concentration in the incoming blood. However, it has been observed that CL_s might be dependent on the blood flow through the organ and the use of intrinsic clearance, CL_i, was proposed to correct for the influence of blood flow (3). CL_i is defined as:

$$CL_i = \frac{r}{C_0} \qquad \text{(Eq. 4)}$$

where C_0 is the effluent venous blood concentration which is in equilibrium with the eliminating organ. It measures the maximum capacity of the organ to eliminate the drug. An important relation obtained from the above clearance equation is:

$$r = CL_s C_i = CL_i C_0 \qquad \text{(Eq. 5)}$$

0022-3549/82/0400-0454$01.00/0



Scheme I—A simplified physiologically-based pharmacokinetic model in mammals.

This relationship describes the rate of removal of the drug from the eliminating organ in terms of either the influent arterial or effluent venous blood concentration. A simplified physiological model (Scheme I) is depicted for discussion purposes. Conventionally, the eliminating organs are the liver and kidney, while the noneliminating organs are the heart, muscle, adipose tissue, bone, etc. The lung is also considered as an eliminating organ for many drugs (8, 9), but due to its anatomical arrangement, it is treated separately. Nevertheless, the same reasoning could be applied to its treatment.

From the mass balance principle, the rate of drug accumulation in any organ can be described by the following equation:

$$V_t \frac{dC_t}{dt} = QC_i - QC_0 - CL_sC_i \qquad \text{(Eq. 6)}$$

In a well-stirred model, one generally assumes rapid equilibrium between organ tissue and its emerging venous blood (3, 10). The partition coefficient between tissue and blood is then defined as the ratio of the amount of drug per gram of the extravascular tissue (C_t) to the concentration of drug in the effluent venous blood:

$$R = \frac{C_t}{C_0} \qquad \text{(Eq. 7)}$$

Substituting into Eq. 6 yields:

$$V_t \frac{dC_t}{dt} = QC_i - \frac{QC_t}{R} - CL_sC_i \qquad \text{(Eq. 8)}$$

Partition coefficients can be estimated based on the conditions imposed by the method of administration, namely, constant infusion, intravenous bolus injection, and first-order absorption (2). Only the first two methods will be examined here.

Constant Infusion—It is apparent that at steady state, the differential term in Eq. 8 will become zero and:

$$R = \frac{QC_t^\infty}{(Q - CL_s)C_i^\infty} \qquad \text{(Eq. 9)}$$

Since $CL_s = QE$, and $C_i^\infty = C_0^\infty/(1 - E)$, where E is the extraction ratio of the organ, Eq. 9 will be reduced to:

$$R = \frac{C_t^\infty}{C_0^\infty} = \frac{C_t^\infty}{C_i^\infty(1 - E)} \qquad \text{(Eq. 10)}$$

In the case of a noneliminating organ, the concentration of the influent blood will be the same as the effluent blood at the steady state (7, 11) and the applicability of Eq. 10 is evident.

Bolus Intravenous Injection—For a linear multicompartmental system, the concentration in each compartment will decay at the same rate after the attainment of pseudo-distribution equilibrium. Both the arterial and the venous blood concentration will be of the form:

$$C = C^0e^{-\alpha t} \qquad \text{(Eq. 11)}$$

at the terminal phase; C^0 and α are the same as defined previously. Substitution of Eq. 11 and its derivative into Eq. 8 yields:

$$-\alpha V_tC_t^0e^{-\alpha t} = QC_i^0e^{-\alpha t} - \frac{QC_t^0}{R}e^{-\alpha t} - CL_sC_i^0e^{-\alpha t} \qquad \text{(Eq. 12)}$$

so that:

$$R = \frac{QC_t^0}{(Q - CL_s)C_t^0 + \alpha V_tC_t^0} \qquad \text{(Eq. 13)}$$

RESULTS AND DISCUSSION

The derived equations provide the theoretical basis for estimating the partition coefficient of drugs between tissue and blood. It is obvious that Eqs. 9 and 13 are different from Eqs. 1 and 2. If CL_iC_0 is in the place of CL_sC_i in Eq. 6, and knowing that $CL_s = CL_iQ/(CL_i + Q)$, the same conclusion can be drawn. The discrepancy between the newly derived and the reported equations lies in the definition of the clearance in the mass balance equation. The effluent concentration, C_0 or C_t/R, in the elimination rate in Eq. 6 should only be used with CL_i.

For constant infusion studies, R can be calculated by simply taking the ratio of the drug concentration in the tissue to the effluent venous blood as indicated in Eq. 10. The arterial blood concentration can also be used if the extraction ratio of the compound by the organ is known. Either arterial or venous blood concentration can be used interchangeably for the R determination of a noneliminating organ.

Equation 13, on the other hand, offers the tool to estimate R from bolus injection data. Its limitation, however, is quite severe because all of the physiological and clearance parameters must be known before applying the equation. It also requires the exclusive use of arterial blood concentration in its application. In the case of a noneliminating organ, Eq. 13 could be reduced to:

$$R = \frac{C_t^0}{C_0^o} = \frac{C_t}{C_0} \qquad \text{(Eq. 14)}$$

By recognizing the fact that $QC_i + \alpha V_tC_t = QC_0$ and $CL_s = 0$. The use of effluent venous blood concentration would then be most appropriate. It is of interest to note that for such an organ, venous blood sampling avoids the cumbersome restrictions dictated by Eq. 13. It also avoids the use of literature physiological parameter values, since errors in them may be compounded in the determination of R.

The previous discussions suggest the importance of the source of blood sampling. As indicated in Eqs. 10 and 14, venous blood concentration can be used for determining R; however, venous blood must be obtained from the outflow of the organ of interest. Since the venous concentrations can vary among organs (11) many venous samples might have to be taken from different organs to satisfy the conditions prescribed by the equations. In reality, venous blood is often obtained from one peripheral vein or the pooled venous blood (such as studies in mice or rats); the validity of such practices appears questionable in light of the arguments presented. In addition, many tissues and blood (plasma) flow parameters are often pooled and scaled accordingly, making the possibility of obtaining venous blood for these tissues almost impossible.

Systemic arterial blood, on the other hand, is generally regarded as homogeneous in the body (7, 11). Sampling it from any site could closely reflect the influent arterial blood concentration in all other organs except for the lung (7, 8). Because of its association with CL_s in Eq. 6, literature clearance data can be used readily without any modifications, since organ clearance is estimated routinely by the quotient of the total amount of drug eliminated from a particular route and the total area under the blood (plasma) level–time curve. In addition, sampling of arterial blood is relatively easy in experimental animals and the advantage of this approach is obvious.

The source of blood sampling is not only important in the determination of R, but may also be significant in the overall successfulness of a physiologically-based pharmacokinetic model. From a mathematical standpoint, the predicted blood (plasma) levels from the system of first-order differential equations are, in fact, those of the arterial blood (12–17). Therefore, it seems only logical to sample arterial blood for comparison with the predicted levels. A brief review of the literature, however, revealed that the source of blood sample could be any one of the following: arterial[lidocaine (12) and procaine (13)], jugular venous [sulfobromophthalein (14) and digoxin (15)], peripheral venous [adriamycin (16)], and total pooled plasma [methotrexate (17)]. It is apparent that no general rule has been adopted in this area. Arterial sampling certainly is justifiable physiologically and should be used. This is particularly true in view of a recent study which showed significant arteriovenous plasma concentration difference for six compounds after intravenous administration to dogs and rabbits (11).

Conductivity Studies of Suspension Systems in Different States of Aggregation

BERNARD ECANOW ˣ, JUDY M. WEBSTER, and MARTIN I. BLAKE

Received February 8, 1980, from the *College of Pharmacy, Department of Pharmacy, University of Illinois at the Medical Center, Chicago, IL, 60612.* Accepted for publication July 29, 1981.

Abstract □ The electrical conductivity effects of dispersed, coagulated, and flocculated systems were investigated using sulfamerazine powder, an insoluble, hydrophobic drug to prepare the suspension systems. For the dispersed systems, a peak in conductivity was observed at a drug concentration between 5 and 15%. The critical coagulating concentration was defined as the concentration of drug at which a maximum in specific conductance was observed. At this concentration, a maximum number of charged particles were in the system. Coagulated suspensions showed higher conductance values than the dispersed systems at equivalent concentrations; however, the critical coagulating concentration value appeared to be the same. For flocculated suspensions there was an increase in conductance with drug concentration with no perceptible peak conductance value.

Keyphrases □ Conductivity—use in studies of suspension systems in different states of aggregation □ Aggregation states—electrical conductivity effects on dispersed, coagulated, and flocculated systems □ Suspension systems—electrical conductivity effects on dispersed, coagulated, and flocculated systems

As defined in the United States Pharmacopeia (1), suspensions are preparations of finely divided, undissolved drugs in liquid vehicles. Insoluble particles dispersed in a liquid medium have large specific surface areas which render the suspension system thermodynamically unstable. The particles tend to settle and form aggregates which have a reduced surface area and, thus, a decreased surface free energy. This results in a system of greater thermodynamic stability. Two types of aggregation are identified: coagulation and flocculation. Unfortunately, these terms are used frequently in the literature in a way that confuses the nature of the systems being described (2).

Here, a dispersed system in water is described as consisting of primary particles acting as independent entities in the bulk water polar medium. The settling process, in general, is relatively slow with each particle settling separately.

In a coagulated system the aggregated particles, including adsorbed surface films, are in surface contact with each other and each aggregate of particles (coagula) acts as a unit. The particles are held together by film–film bonds. The interstitial water is structured and exhibits nonpolar behavior. Coagulated suspensions tend to form caked systems which can be difficult, if not impossible, to redisperse.

In a flocculated system the aggregated particles are held together by one of several mechanisms: adsorption bridging, chemical bridging, or long-range Van der Waals forces (secondary minimums). The particles settle out as a "floc," a loosely packed aggregate having a network-like structure. A hard cake does not form and the sediment is readily redispersed to the original suspension form. The water medium is bulk polar water.

The classification of these systems was first reported by Ecanow *et al.* (3) and has since been referred to by others (4). The properties of dispersed, coagulated, and flocculated systems have been compared in terms of caking (5), sedimentation rate (6), rheology (3), gas adsorption (7), and filtration rates (8). In the present study, the electrical conductivity effects of these systems were investigated. Sulfamerazine powder, a hydrophobic drug, was used to prepare the suspensions, and docusate sodium (I), an anionic surfactant, rendered the drug particles hydrophilic in the formation of the dispersed and the coagulated systems. Compound I and aluminum chloride were used to form the flocculated systems (9) of sulfamerazine particles.

EXPERIMENTAL

Materials—Sulfamerazine[1] was USP grade and ranged in particle size from 5 to 20 μm. Docusate sodium[2] USP was employed as the surfactant, and aluminum chloride[3] NF served as the flocculating agent. All other chemicals were reagent grade and were used without further treatment.

Conductivity Studies of Suspension Systems in Different States of Aggregation

BERNARD ECANOW ˣ, JUDY M. WEBSTER, and MARTIN I. BLAKE

Received February 8, 1980, from the *College of Pharmacy, Department of Pharmacy, University of Illinois at the Medical Center, Chicago, IL, 60612.* Accepted for publication July 29, 1981.

Abstract □ The electrical conductivity effects of dispersed, coagulated, and flocculated systems were investigated using sulfamerazine powder, an insoluble, hydrophobic drug to prepare the suspension systems. For the dispersed systems, a peak in conductivity was observed at a drug concentration between 5 and 15%. The critical coagulating concentration was defined as the concentration of drug at which a maximum in specific conductance was observed. At this concentration, a maximum number of charged particles were in the system. Coagulated suspensions showed higher conductance values than the dispersed systems at equivalent concentrations; however, the critical coagulating concentration value appeared to be the same. For flocculated suspensions there was an increase in conductance with drug concentration with no perceptible peak conductance value.

Keyphrases □ Conductivity—use in studies of suspension systems in different states of aggregation □ Aggregation states—electrical conductivity effects on dispersed, coagulated, and flocculated systems □ Suspension systems—electrical conductivity effects on dispersed, coagulated, and flocculated systems

As defined in the United States Pharmacopeia (1), suspensions are preparations of finely divided, undissolved drugs in liquid vehicles. Insoluble particles dispersed in a liquid medium have large specific surface areas which render the suspension system thermodynamically unstable. The particles tend to settle and form aggregates which have a reduced surface area and, thus, a decreased surface free energy. This results in a system of greater thermodynamic stability. Two types of aggregation are identified: coagulation and flocculation. Unfortunately, these terms are used frequently in the literature in a way that confuses the nature of the systems being described (2).

Here, a dispersed system in water is described as consisting of primary particles acting as independent entities in the bulk water polar medium. The settling process, in general, is relatively slow with each particle settling separately.

In a coagulated system the aggregated particles, including adsorbed surface films, are in surface contact with each other and each aggregate of particles (coagula) acts as a unit. The particles are held together by film–film bonds. The interstitial water is structured and exhibits nonpolar behavior. Coagulated suspensions tend to form caked systems which can be difficult, if not impossible, to redisperse.

In a flocculated system the aggregated particles are held together by one of several mechanisms: adsorption bridging, chemical bridging, or long-range Van der Waals forces (secondary minimums). The particles settle out as a "floc," a loosely packed aggregate having a network-like structure. A hard cake does not form and the sediment is readily redispersed to the original suspension form. The water medium is bulk polar water.

The classification of these systems was first reported by Ecanow *et al.* (3) and has since been referred to by others (4). The properties of dispersed, coagulated, and flocculated systems have been compared in terms of caking (5), sedimentation rate (6), rheology (3), gas adsorption (7), and filtration rates (8). In the present study, the electrical conductivity effects of these systems were investigated. Sulfamerazine powder, a hydrophobic drug, was used to prepare the suspensions, and docusate sodium (I), an anionic surfactant, rendered the drug particles hydrophilic in the formation of the dispersed and the coagulated systems. Compound I and aluminum chloride were used to form the flocculated systems (9) of sulfamerazine particles.

EXPERIMENTAL

Materials—Sulfamerazine[1] was USP grade and ranged in particle size from 5 to 20 μm. Docusate sodium[2] USP was employed as the surfactant, and aluminum chloride[3] NF served as the flocculating agent. All other chemicals were reagent grade and were used without further treatment.

35	0.31 ± 0.017	0.37 ± 0.014	9.00 ± 0.000

[a] Mean value based on at least four determinations ± *SD*.

Apparatus—A conductivity apparatus[4] designed for testing suspension systems was used to measure the specific conductances of the suspension systems.

Suspension Systems—Sulfamerazine dispersed suspensions and coagulated systems contained 2, 5, 10, 15, 20, 25, 30, 35% (w/v) sulfamerazine. In each system the concentration of I was one-tenth the sulfamerazine content.

In the flocculated systems the concentrations of sulfamerazine and I were the same as in the previous systems, but, in addition, the concentration of aluminum chloride in each system was equal to 5% that of the sulfamerazine content.

The suspensions were prepared by weighing out the calculated amount of sulfamerazine powder and transferring the powder to a glass mortar. The appropriate volume of a 5% solution of I was added to the mortar and the mixture was triturated until a smooth slurry was formed. The slurry was then transferred to a 100-ml graduated cylinder with additional rinsings of the mortar using distilled water. Sufficient water was added to bring the volume to the 100-ml mark. For the preparation of the flocculated suspensions, the same procedure was followed except that the appropriate volume of a 20% aluminum chloride solution was added to the cylinder prior to filling to the mark with distilled water. The cylinder was then capped with a glass stopper, inverted, and agitated sufficiently to ensure both thorough mixing and the formation of a uniform initial suspension of the powder.

The conductance of the initial suspensions (dispersed systems) was measured immediately by immersing the conductivity cell into each suspension system. The systems were then allowed to settle for 48 ± 2 hr before additional conductivity data were obtained. During the settling period, aggregation took place resulting in the formation of a coagulated system. Before the conductance reading was taken, the cylinder containing the coagulated system was agitated sufficiently to ensure dispersion of the coagula. The conductivity of the dispersed system was then measured immediately. The flocculated systems were treated in the same manner as the coagulated systems. Conductivity readings were measured after thoroughly agitating the system to ensure redispersion of the flocules.

RESULTS AND DISCUSSION

Conductance data for all of the suspension systems are shown in Table I. The data for dispersed systems were analyzed statistically by the Student t test. The t value was 4.131 corresponding to a p value of < 0.005, indicating that conductance is dependent on concentration. Analysis of the data for the coagulated systems by the Student t test produced a t value of 4.102, which corresponds to a p value <0.005. The t value obtained for the flocculated suspensions by comparing concentration with the mean conductance value was 2.837, which corresponded to a p value <0.01.

It was the purpose of this study to observe the electrical conductivity properties associated with different states of suspension aggregation and to note the effect of variable concentration of an insoluble drug on the electrical conductivity of each suspension system. Specific conductance, rather than equivalent conductance, was determined since it is a measure of conductance capacity of all ions present in a unit volume of solution and thus, varies with concentration.

[4] Solu Bridge Soil Tester, Beckman Instruments, Inc., Model RD-B15, Ser. 21034.

The system can be described as follows: The sulfamerazine powder is in the paracolloid particle size range (5–20 μm). Compound I, an anionic surfactant, acts by coating the insoluble drug particles and converting them to hydrophilic particles (9). Therefore, each particle has a negative charge and is surrounded by its own ionic atmosphere. Closely associated with the hydrophilic particles are water molecules from the suspension medium. Sodium ions of I balance the negatively charged particles. Compound I molecules are present in the system as individual ionic species and as micelles, since the critical micelle concentration for I is about 0.07% at 25°. This concentration was exceeded in all suspensions prepared in this study.

It is evident that, for the dispersed suspension system, the conductivity increases with drug concentration at low concentrations of drug. This is expected because the number of charged particles in the system has increased. However, at some concentration between 5 and 15%, a peak in conductance is reached after which the conductance values decrease with increasing drug concentration. This may be explained by the fact that after a peak value is reached, the charged particles begin to aggregate by forming associated particles, or coagula, which results in fewer, but larger, charged species. Because the actual number of charged particles is decreased, the specific conductance will be lower. The concentration of drug in a dispersed or coagulated system at which the specific conductance is a maximum is the critical coagulating concentration. At this concentration there is a maximum number of charged particles in the system which accounts for the maximum in specific conductance.

The coagulated suspensions behaved similarly to that of the dispersed systems. The conductance values for the coagulated systems were consistently higher than the corresponding dispersed systems (Table I). Since the coagulated suspensions consist of fewer and larger charged particles, it would be expected that the specific conductance would be lower than in the dispersed systems (as noted previously in connection with the effect of drug concentration on the conductivity in the dispersed systems). One possible explanation of this behavior is that because the water in the film–film bonds of the coagula is highly structured (nonpolar) (10), electrolytes are squeezed out of the films, thus increasing the concentration of charged species in the polar aqueous medium of the supernate. This, in effect, produces higher conductance values for the coagulated systems.

The data for the flocculated systems show an almost direct linear relationship between conductance and drug concentration. This is in contradistinction to that observed for the dispersed and coagulated systems. In a separate study, a similar relationship was observed with only aluminum chloride and I (the sulfamerazine was excluded). Apparently, the aggregation state of the suspended particles does not affect the conductance of the flocculated system. In this system each suspended drug particle behaves independently. The precise nature of aluminum ion participation in the flocculation process was reported previously (9) and first identified as a chemical bridging reaction.

Presystemic Elimination of Drugs: Theoretical Considerations for Quantifying the Relative Contribution of Gut and Liver

R. F. MINCHIN *x and K. F. ILETT

Received November 19, 1980 from the *Department of Pharmacology, University of Western Australia, Nedlands, Western Australia, 6009.* Accepted for publication July 30, 1981. * Present address: National Cancer Institute, Bethesda, MD 20205.

Abstract □ From a consideration of the basic processes involved in drug elimination, the fraction of drug cleared by the gut and by the liver were described as functions of availability and hepatic clearance. For a drug given orally, a plot of the fraction of drug cleared by the gut or liver against α, a proportionality constant relating gut elimination following intravenous administration to that following oral administration, allowed an estimate of the possible contribution of gut and liver to presystemic elimination. This method was dependent only on the measurement of peripheral blood drug concentrations and urine levels. Application of the theory to published data for several drugs known to have a reduced availability after oral administration was used to illustrate the procedure.

Keyphrases □ Liver—relative contribution to presystemic elimination □ Gut—relative contribution to presystemic elimination □ Presystemic elimination—quantification of contribution of gut and liver, theoretical considerations

When given orally, many drugs undergo significant presystemic metabolism in the gut and liver, reducing their pharmacological activity by decreasing systemic availability (1). In experimental animals, the relative contribution of the liver and gut to presystemic elimination can be quantified by measuring portal and peripheral blood drug concentrations following oral and intravenous administration (2–4). However, as pointed out by Routledge and Shand (1), such procedures cannot be readily carried out in humans because of technical and ethical limitations and, therefore it has not been possible to demonstrate which site of metabolism is more important during presystemic elimination in humans. In the present study, a theoretical approach to quantifying the contribution of gut and liver to presystemic elimination was considered and equations derived which, for drugs obeying certain criteria, allowed calculation of the fraction of drug cleared in the gut or liver using clearance and availability estimates obtained by measurement of drug concentrations in systemic blood.

THEORY

The presystemic elimination of a drug in a linear system was considered. Availability (F) can be estimated by:

$$F = \frac{AUC_{oral}\, D_{iv}}{AUC_{iv}\, D_{oral}} = (1 - f_G)(1 - f_L) \qquad \text{(Eq. 1)}$$

where AUC_{oral} and AUC_{iv} are the areas under the blood drug concentration–time curves following an oral (D_{oral}) and an intravenous (D_{iv}) dose respectively, f_G is the fraction of dose cleared in gut, and f_L is the fraction of dose reaching the portal blood system which is cleared by the liver.

When such a drug is given intravenously, elimination may occur in the liver or in the gut if significant diffusion of the drug from the portal blood into the gut wall occurs. The rate of drug elimination in the liver (dE_L/dt) can be described by:

$$\frac{dE_L}{dt} = (Q_L - Q_G)f_L C_1 + Q_G f_L C_G \qquad \text{(Eq. 2)}$$

where Q_L is the total hepatic blood flow, Q_G is the intestinal blood flow, C_1 is the peripheral blood concentration, and C_G is the concentration of drug entering the liver *via* the portal system. The rate of drug elimination in the gut wall following intravenous administration (dE_G/dt) is given by:

$$\frac{dE_G}{dt} = \alpha Q_G f_G C_1 \qquad \text{(Eq. 3)}$$

where $1 \geq \alpha \geq 0$. The proportionality constant, α, allows for the fact that the fraction of drug cleared after entering the gut from the general circulation may not be equal to that cleared after entering the gut from the lumen. Total elimination rate from the splanchnic circulation (dE/dt) can be described by the addition of Eq. 2 and 3.

$$\frac{dE}{dt} = (Q_L - Q_G)f_L C_1 + Q_G f_L C_G + \alpha Q_G f_G C_1 \qquad \text{(Eq. 4)}$$

Since $C_G = (1 - \alpha f_G)C_1$, then:

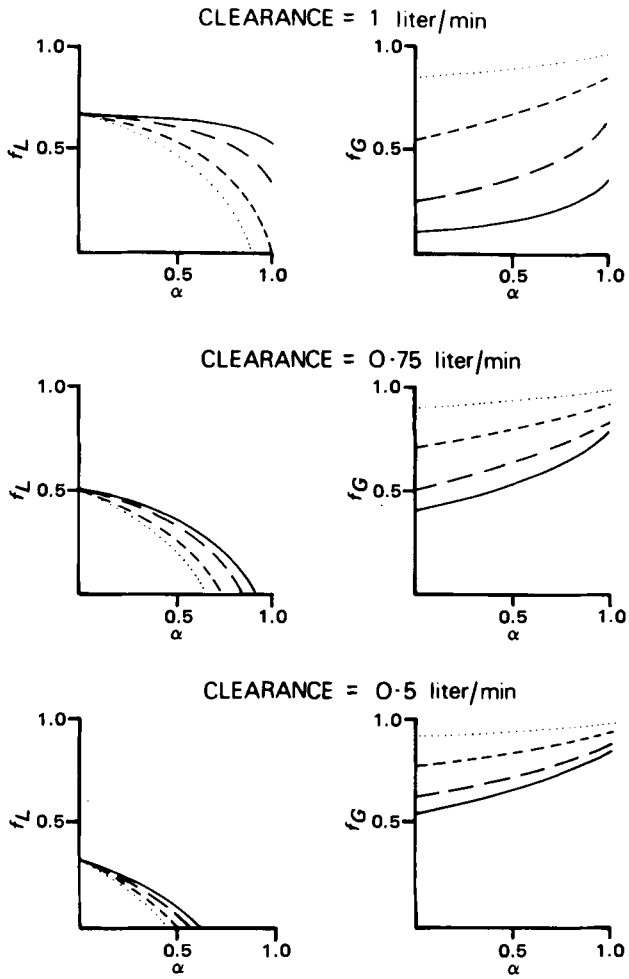

Figure 1—*Dependence of* f_L *and* f_G *on availability, clearance, and* α. *Assuming* Q_L *and* Q_G *to be 1.5 and 1.2 liters/min, respectively,* f_L *and* f_G *were calculated according to Eqs. 8 and 9. Key: Availability = 0.3 (——), 0.25 (— —), 0.15 (– – –), and 0.05 (. . .).*

Table I—Kinetic Data for Drugs Known to Undergo Significant Presystemic Elimination

Drug	Availability	Plasma Clearance, liter/min	Blood-Plasma Distribution Ratio	Fraction Excreted in Urine	Hepatic Blood Clearance[a], liters/min	Reference
Imipramine	0.47	1.05	1.34	0.0	0.784	8
Propranolol	0.36	0.702	0.78	0.0	0.90	9
Quinidine	0.795	0.256	0.66	0.276	0.281	10
Pentazocine	0.184	1.38	1.07	0.154	1.09	11
Oxprenolol	0.462	0.372	0.80	0.03	0.457	12
Nortriptyline	0.505	0.527	1.49	0.02	0.347	13
Lidocaine						
Healthy subjects	0.37	0.77	0.83	0.01	0.918	14
Epileptics	0.15	0.85	0.83	0.01	1.014	14
Phenacetin[b]						
Controls	0.452	0.00276	1.06	0.0	0.0026	15
Induced	0.058	0.01763	1.06	0.0	0.0166	15

[a] Calculated as $[1-f_R]Cl_T/\lambda$ where f_R = fraction of drug excreted in urine, Cl_T = total plasma clearance, and λ = blood to plasma distribution ratio. [b] Study undertaken in rats, controls were pretreated with saline, while induced were pretreated with 3-methylcholanthrene; Q_L = 21 ml/min, Q_G = 16.8 ml/min.

$$\frac{dE}{dt} = (Q_L - Q_G)f_L C_1 + Q_G f_L(1 - \alpha f_G)C_1 + \alpha Q_G f_G C_1 \quad \text{(Eq. 5)}$$

Equation 5 simplifies to:

$$\frac{dE}{dt} = C_1[Q_L f_L + \alpha Q_G f_G(1 - f_L)] \quad \text{(Eq. 6)}$$

The term enclosed by the square brackets is equivalent to the classical hepatic clearance constant (Cl_H) where gut and liver are considered as a single functional unit. Thus:

$$Cl_H = Q_L f_L + \alpha Q_G f_G(1 - f_L) \quad \text{(Eq. 7)}$$

From Eq. 1:

$$f_G = 1 - [F/(1 - f_L)] \quad \text{(Eq. 8)}$$

Substituting Eq. 8 into Eq. 7 and rearranging:

$$f_L = \frac{Cl_H - \alpha Q_G(1 - F)}{(Q_L - \alpha Q_G)} \quad \text{(Eq 9)}$$

Exact solutions of f_L, f_G, and α are not possible from the above equations, since the three parameters are described by only two independent equations (Eqs. 8 and 9). However, a plot of f_L and f_G *versus* α for $1 \geq \alpha \geq 0$ may allow some conclusions concerning the overall contribution of gut and liver to the presystemic elimination of a drug to be made.

RESULTS AND DISCUSSION

The proportionality constant α in Eq. 9 relates gut elimination following oral to that following intravenous drug administration. The role of the GI tract in drug metabolism, particularly after intravenous administration, has not been comprehensively investigated. Theoretically, α is equal to unity when the gut contributes equally to the elimination of a drug after its oral and intravenous administration. During absorption, a drug must cross the mucosal epithelium, basement membrane, and the capillary endothelium. Movement of drug in the opposite direction may be equal to or less than the corresponding rate of absorption depending on its physicochemical properties, the pH gradient across the gut wall, the blood flow rate, and the degree of drug binding to blood constituents. All these factors may cause α to be less than unity. For some drugs such as isoproterenol (5, 6) and pentazocine (7) which have been shown to undergo significant biotransformation in the gut following oral administration but not after infusion into the mesenteric arterial blood supply, α is equal to zero.

Using Eqs. 8 and 9, f_L and f_G have been computed at various clearance and availability values for $1 \geq \alpha \geq 0$, Q_L = 1.5 liters/min, and Q_G = 1.2 liters/min (Fig. 1). For a given oral availability, the importance of the liver to overall presystemic elimination decreases, while that for gut increases as clearance is reduced. Furthermore, regardless of the value of α, the gut becomes increasingly more important as availability is reduced at a constant clearance. In general, the liver is the site of greater elimination in systems of relatively high clearance and high availability, whereas the gut is dominant in systems of relatively low clearance and low availability.

Using kinetic data (Table I) obtained from the literature (8–15), curves of *f versus* α were constructed to determine the contribution of gut and

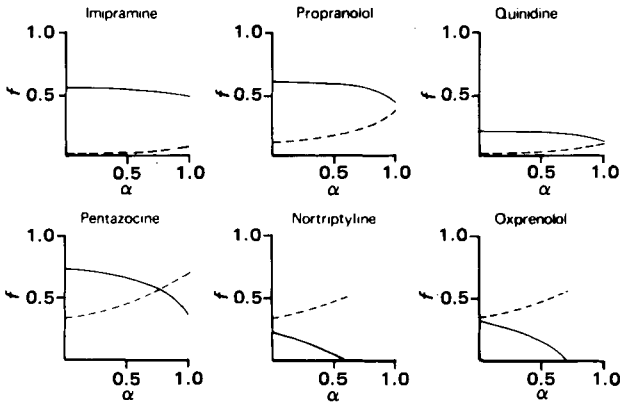

Figure 2—*The* f *versus* α *curves for several drugs known to undergo significant presystemic elimination (see Table I). Key:* —— f_L; *and* — — — f_G.

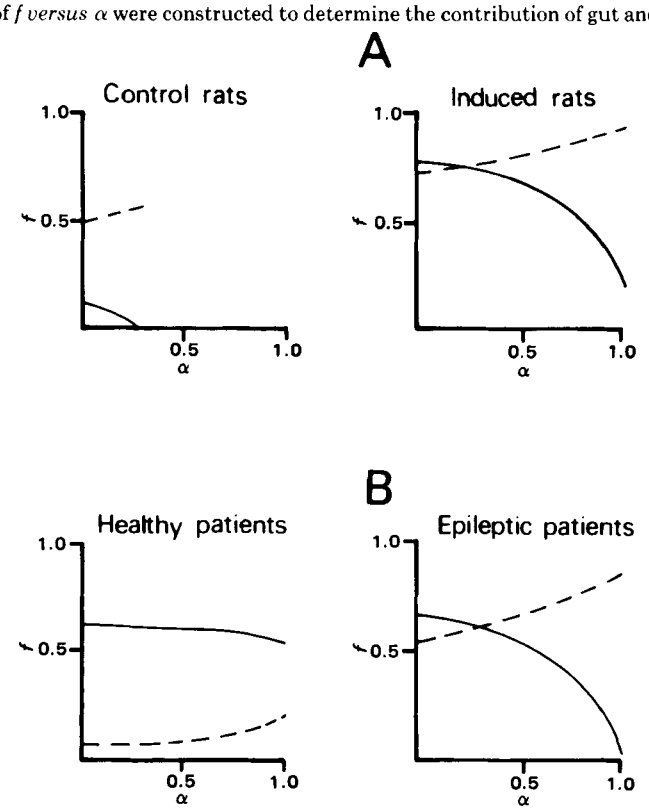

Figure 3—*Effect of induction on the* f versus α *curves for phenacetin (A) and lidocaine (B). For phenacetin, rats were pretreated with saline (controls) or 3-methylcholanthrene (induced) before receiving an oral or intravenous dose of phenacetin. For lidocaine, data were collected from healthy subjects and also from epileptic patients who were receiving enzyme-inducing drugs such as phenobarbital. Key:* —— f_L, *and* — — — f_G.

liver to the presystemic elimination of a number of drugs. Total hepatic clearance was calculated as $(1 - f_R)Cl_T/\lambda$ where f_R is the fraction of drug eliminated unchanged in the urine, Cl_T is the total plasma clearance, and λ is the blood to plasma distribution ratio. For all drugs considered, it was assumed that significant elimination occurred only in gut, liver, and kidney. Total hepatic and intestinal blood flows were assumed to be 1.5 and 1.2 liters/min, respectively (16). For the phenacetin data that were obtained from experiments in rats, Q_L and Q_G were taken to be 21.0 and 16.8 ml/min, respectively, assuming a body weight of 240 g (17).

The contribution of the liver to presystemic elimination was greater than that of the gut for imipramine, propranolol, and quinidine regardless of the value of α (Fig. 2). However, with oxprenolol and nortriptyline, the gut was generally more important. For both these drugs, the boundaries of α were reduced to $0.708 \geq \alpha \geq 0$ and $0.584 \geq \alpha \geq 0$, respectively, since, by definition, $1 \geq f_L \geq 0$ and $1 \geq f_G \geq 0$. Because of the nature of Eqs. 8 and 9, it is possible that plotting f_L and f_G *versus* α will produce curves which suggest that the gut is more important than the liver at one extremity of α ($\alpha \rightarrow 1$), while the reverse is true at the other extremity ($\alpha \rightarrow 0$). This is exemplified by the f *versus* α curves for pentazocine Fig. 2) where the gut eliminated 33% of an oral dose if $\alpha = 0$, but 71% if $\alpha = 1$. In such a case, plotting f_L and f_G against α would not assist in assessing the relative contribution of gut and liver to the reduced availability, and information concerning the magnitude of α would have to be obtained from isolated human gut loops, experiments in patients undergoing portocaval anastomosis, or by extrapolation from animal data.

The use of f *versus* α curves also may reveal how induction or inhibition of enzymatic systems can affect availability. In Fig. 3, the change in f_L and f_G for phenacetin in rats and lidocaine in humans was illustrated before and after induction. For control rats, it could be calculated that at least 88% of the total dose eliminated before reaching the systemic circulation was due to clearance in the gut. After pretreatment with 3-methylcholanthrene, there was a small increase in f_G, but a far more marked increase in f_L for all values of α suggesting that the decrease in availability in induced animals was due to a greater contribution from the liver. However, the change in lidocaine availability from 37% in healthy subjects to only 15% in epileptic patients was primarily due to an increase in gut elimination. It should be noted that f_G may be a function of a number of factors such as gut lumen metabolism, gut wall metabolism, or incomplete absorption. The greater contribution of gut to the presystemic elimination of lidocaine in epileptic patients was also reflected in the lack of any change in plasma half-life (14) which should have been reduced by a significant increase in liver metabolism since f_L was much less than 1 in healthy subjects, (greatest value of f_L was 0.612 for $\alpha = 0$).

Finally, it should be noted that the use of this method in humans is dependent on reliable estimates of Q_L and Q_G. While numerous studies have shown relatively constant estimates for these values in healthy subjects, both may be markedly altered in patients with cardiovascular, hepatic, or renal disease, or by the drug under investigation. For example, the f *versus* α curves for propranolol, oxprenolol, quinidine, and lidocaine should be interpreted cautiously considering the known hemodynamic effects of these drugs. This limitation could be avoided by individual measurement of Q_L and Q_G. Hepatic blood flows may be estimated using well-established invasive techniques (18, 19) which usually involve direct infusion of a radiolabeled inert gas such as xenon or krypton into the liver.

Pharmacokinetics of Rosoxacin in Human Volunteers

G. B. PARK, J. SANESKI, T. WENG, and J. EDELSON ˣ

Received June 8, 1981, from the *Departments of Drug Metabolism and Disposition, and Biometry, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication August 12, 1981.

Abstract □ Reversed-phase liquid chromatography was used to determine plasma rosoxacin concentrations in normal, healthy males, each of whom received one 300 mg capsule of rosoxacin. The plasma data for each subject were described by an open one-compartment body model with first-order absorption, and the pharmacokinetic parameters were determined. The mean (±*SE*) apparent first-order terminal elimination rate constant was 0.203 ± 0.015 hr^{-1} (N = 16), the mean apparent volume of distribution was 0.644 ± 0.050 liters/kg, and the mean apparent plasma clearance was 2.08 ± 0.15 ml/min/kg.

Keyphrases □ Rosoxacin—pharmacokinetics, normal, healthy males □ Pharmacokinetics—rosoxacin, one-compartment body model, oral absorption, normal, healthy males □ Absorption—first-order with open one-compartment body model, pharmacokinetics of rosoxacin, normal, healthy males

Rosoxacin[1], 1-ethyl-1,4-dihydro-4-oxo-7-(4-pyridyl)-3-quinolinecarboxylic acid, is a member of the class of orally active antimicrobial agents which includes nalidixic acid. The metabolic fate and assay methods for this class of compounds has been reviewed (1).

Rosoxacin is effective *in vitro* against a variety of microorganisms (2–5) and has been used clinically for the treatment of gonorrhea (6). Concentrations of rosoxacin, which were higher than the minimum inhibitory concentrations for most Enterobacteriaceae, were found in renal hilar lymph, renal interstitial fluid, prostatic interstitial fluid, prostatic secretion, vaginal and urethral secretions, and cerebrospinal fluid from dogs treated with this compound (7, 8).

The present report describes the results of a pharmacokinetic study in a group of normal, male, human subjects receiving 300 mg of rosoxacin.

EXPERIMENTAL

Human Volunteers—Appropriate institutional review and approval were obtained from the subjects, none of whom had clinical or laboratory findings indicative of renal, hepatic, or cardiac dysfunction. The mean (±*SE*) age of these volunteers was 29.4 ± 1.9 yr; the mean weight was 71.7 ± 1.6 kg and the mean height was 174 ± 1.7 cm. Each of the 16 volunteers received a single 300-mg capsule of rosoxacin. Blood samples were collected before medication and 0.33, 0.67, 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0, 6.0, 8.0, 10, 12, 15, and 24 hr after treatment. The blood was centrifuged, and the plasma was separated and frozen until assayed.

Assay Procedure—Plasma samples were analyzed by a high-performance liquid chromatographic (HPLC) method developed previously (9). Plasma standards, prepared in control human plasma, were extracted and analyzed with each set of plasma samples from the volunteers. Plasma rosoxacin concentrations were determined by inverse prediction on the linear regression of peak height ratios obtained from plasma and internal standards. The minimum quantifiable level of the assay was estimated as the concentration whose lower 80% confidence limit just encompassed zero[2], and was ~0.13 μg of rosoxacin/ml of plasma.

Three separate modular HPLC systems were used for the analyses. Each consisted of an automatic injector, a pump, a column[3], and a UV detector monitoring the column effluent at 280 nm.

Pharmacokinetic Calculations—The data obtained from the analysis of the human plasma samples were described by a one-compartment open model with first-order absorption by means of an unweighted nonlinear regression procedure (10). This model is described by the equation:

$$C = A[e^{-k_e(t-t_0)} - e^{-k_a(t-t_0)}] \quad \text{(Eq. 1)}$$

where C is the plasma concentration at time t, t_0 is the lag time (before absorption begins), A is a constant, and k_a and k_e are apparent first-order rate constants for absorption and elimination, respectively. The volume of distribution of rosoxacin, V, was calculated by:

$$V = \frac{FDk_a}{A(k_a - k_e)} \quad \text{(Eq. 2)}$$

where F is the fraction of the administered dose (D) which is available to the systemic circulation; the other terms are as defined previously. The total area under the plasma concentration *versus* time curve [AUC_0^∞], time to maximum concentration (t_{max}), maximum concentration (C_{max}), and plasma clearance (Cl_p) for each subject were calculated from:

$$t_{max} = t_0 + \frac{\ln(k_a/k_e)}{k_a - k_e} \quad \text{(Eq. 3)}$$

$$C_{max} = A[e^{-k_e(t_{max}-t_0)} - e^{-k_a(t_{max}-t_0)}] \quad \text{(Eq. 4)}$$

$$AUC_0^\infty = \frac{A(k_a - k_e)}{k_a k_e} \quad \text{(Eq. 5)}$$

$$Cl_p = \frac{FD}{AUC_0^\infty} \quad \text{(Eq. 6)}$$

In addition to the regression-dependent parameters defined previously, the plasma concentration data were analyzed with respect to the following model-independent parameters: the maximum observed plasma concentration (C_{max}^{obs}), the time at which the maximum plasma concentration was observed (t_{max}^{obs}), and the area under the plasma concentration *versus* time curve, 0–24 hr, AUC_0^{24}. The latter was calculated by trapezoidal rule, using all data for the 24-hr study period.

RESULTS AND DISCUSSION

The mean observed plasma rosoxacin concentration data are shown in Fig. 1. Plasma levels declined exponentially with time suggesting a one-compartment body model. Pharmacokinetic parameters for each subject were estimated after computer-fitting of the data by an iterative nonlinear least-squares regression technique (10). For subjects 1 and 6 it was necessary to adjust the lag time such that it corresponded to the

[a] No meaningful value; the lag time is that time at which the observed plasma concentration first exceeded the minimum quantifiable level.

first time point with measurable rosoxacin concentration, to obtain a reasonable fit of the data. In the other 14 subjects, no adjustment was necessary (Table I). Using the mean parameters, the plasma rosoxacin concentration, C (μg/ml) at time t (hr), is given by:

$$C = 10.5\,[e^{-0.203(t-0.41)} - e^{-1.20(t-0.41)}] \qquad \text{(Eq. 7)}$$

The mean apparent first-order terminal elimination half-life for rosoxacin was ~3.4 hr.

The mean observed concentration data were also described by the model, and a comparison of the observed and predicted concentrations is shown in Fig. 1. The observed, model-independent, parameters are in reasonable agreement with those calculated from the open one-compartment body model with oral absorption, Table I.

The mean apparent volume of distribution was 0.644 liters/kg. This suggests that rosoxacin is distributed into the total body water, which may be responsible for the membrane permeability and relatively high levels of rosoxacin found in tissues (7, 8). This hypothesis will be tested in future studies.

An earlier study of the pharmacokinetics of rosoxacin in the dog (9) reported an apparent first-order terminal elimination half-life of 2 hr and a plasma clearance, corrected for body weight, of 8.6 ml/min/kg. In humans the elimination half-life is longer, ~3.4 hr, and the plasma clearance of rosoxacin, corrected for weight, is slower, 2.08 ml/min/kg.

Toxicity of *Gonyaulax tamarensis* var. *excavata* Cells to the Brine Shrimp *Artemia salina* L.

JOSEPH M. BETZ * ˣ and WALTER J. BLOGOSLAWSKI ‡

Received February 25, 1981, from the **Department of Biology, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104* and the *‡ National Marine Fisheries Service, Northeast Fisheries Center, Milford Laboratory, Milford, CT 06460.* Accepted for publication August 21, 1981.

Abstract □ Brine shrimp (*Artemia salina* L.) were exposed to concentrations of live *Gonyaulax tamarensis* var. *excavata* cells ranging from 0 to 13,400 cells/ml in unialgal culture. The shrimp ingested the dinoflagellate cells and an LD_{50} determination was made. The shrimp had a 72-hr LD_{50} of 1258 *G. tamarensis* cells/ml, which was calculated to correspond to 73,385 μg/kg of body weight. This figure can be compared with an oral LD_{50} value of 2100 μg/kg for the mouse. Since it requires one-tenth as much toxin to kill a mouse (LD_{50} approximately 0.04 mg) as to kill an *Artemia* (LD_{50} approximately 0.4 mg), the whole cell *G. tamarensis* bioassay is a poor alternative to the current mouse assay.

Keyphrases □ Paralytic shellfish poisoning—toxicity of *Gonyaulax tamarensis* var. *excavata* cells to brine shrimp □ Brine shrimp—toxicity of *Gonyaulax tamarensis* var. *excavata*, potential bioassay for paralytic shellfish poisoning □ Bioassay—potential, toxicity of *Gonyaulax tamarensis* var. *excavata* to brine shrimp, paralytic shellfish poisoning

Paralytic shellfish poisoning is a potentially fatal form of food poisoning caused by ingestion of shellfish that have been feeding on blooms of toxic dinoflagellates (1). Mollusks feeding on the dinoflagellates appear unaffected, the immunity apparently related to a lack of sensitivity of the nerves of bivalve mollusks to the action-potential blocking effects of the toxins (2). Isolated crayfish (*Procambarus clarkii*) (3), spider crab (*Maia squinado*) (4), and American lobster (*Homarus americanus*) (5) nerves have been found to be highly susceptible to the toxins. Controlled feeding of highly toxic clams to lobsters has, however, failed to demonstrate any toxicity to the intact animal (6).

The present study attempted to develop an inexpensive bioassay for paralytic shellfish poison to replace the costly mouse assay, and to determine the LD_{50} value of the gonyautoxins present in the Atlantic dinoflagellate *Gonyaulax tamarensis* var. *excavata*, to a crustacean (*Artemia salina* L.). This was a preliminary step in the investigation of the immunity mechanism of crustaceans to the toxins.

EXPERIMENTAL

Culture of Organisms and Confirmation of Dinoflagellate Toxicity—Experimental media for culture of *Gonyaulax* (*Gonyaulax* medium) were prepared from salt well water[1] and supplemented with 100 mg of KNO_3, 10 mg of K_2HPO_4, 1 mg of $FeCl_3$, and 0.05 mg of Na_2SiO_3/liter. The pH was adjusted to 8.6 with 1 *N* NaOH (7). This solution was sterilized by autoclaving for 15 min at 15 psi. Traces of cyanocobalamin and thiamine solutions which had been filtered through a sterile membrane filter unit were added to the medium aseptically (8).

The culture was initiated by inoculating 1 liter of medium with 1 ml of stock *Gonyaulax tamarensis* var. *excavata*, (Strain IB-72)[2] culture containing 20,000 cells/ml and was then incubated at 20° for 30 days in 3-liter Fernbach flasks. All cultures were incubated under continuous illumination in an environmental chamber. *G. tamarensis* cells in the culture were counted with a hemacytometer slide using appropriate dilutions to count 1-ml samples (6). The toxicity of this *G. tamarensis* strain was confirmed by mouse assay of an extract of the dinoflagellate. Three liters of 25-day *G. tamarensis* culture containing 2500 cells/ml were membrane filtered. The filter pads were then placed into 100 ml of 0.1 *N* HCl to lyse the cells. The clear yellow-green solution was refiltered to remove cellular debris, and the solution assayed using female white mice (9). *Dunaliella salina*[3] (a nontoxic marine phytoflagellate) was extracted and assayed as described. Brine shrimp (*Artemia salina* L.) eggs[4] were hatched and raised to the adult state (10) with *Dunaliella salina* as an additional food source.

Brine Shrimp Assay—The experimental vessels for the study of *G. tamarensis* toxicity to brine shrimp were 125-ml Erlenmeyer flasks which had been loosely stoppered with nonabsorbent cotton and autoclaved at 15 psi for 15 min. The dinoflagellate source was a 29-day *G. tamarensis* culture with an original concentration of 13,400 cells/ml. The experiment was performed using five different dinoflagellate concentrations (13,400, 6700, 3400, 1300, and 135 cells/ml) and a control containing no cells. Each flask was prepared by removing a portion of the stock culture with a sterile pipet and placing the calculated volume containing the appropriate number of cells into an aliquot of diluent (sterile *Gonyaulax* medium) in one of the experimental flasks. Five brine shrimp were then added to each flask, and five flasks were used for each concentration of dinoflagellate cells. The experiment was repeated four times for a total of 100 shrimp at each concentration of cells. After restoppering the flask with its cotton plug, it was examined for cessation of *Artemia* swimming motions at intervals of 20 min, 1, 8, 24, and 72 hr.

Two controls for this portion of the experiment were sterile *Gonyaulax* medium to which no inoculum had been added, and medium from an active culture of *G. tamarensis* (13,400 cells/ml) from which the cells had been removed by membrane filtration. Bioassay data on *G. tamarensis* were used to calculate LD_{50} values by transforming the curve for percent mortality *versus* log dose of toxin (cells/ml) to a straight line by probit

analysis (11), using a computer program written specifically for the purpose[5].

RESULTS AND DISCUSSION

Confirmation of Toxicity of *G. tamarensis* Culture—The solution obtained from extraction of the dinoflagellate was found to be toxic to mice (Table I). Concentration of toxin as determined by mouse assay was 109 μg/1000 ml of extract. This is 1 μg of saxitoxin equivalent/2294 cells. In the *Dunaliella* control solution, all mice survived.

Brine Shrimp Assay—The two control groups using *Gonyaulax* medium (uninoculated and inoculated with cells removed) gave negligible mortality and a pronounced mortality of 19%, respectively (Table II). This second mortality was taken into account when calculating the LD_{50}.

Mortality in the control group followed a pattern similar to that seen in the experimental group and was probably caused by toxins released into the medium by dinoflagellate cells (12). Brine shrimp added to *G. tamarensis* cells became intoxicated and died. Microscopic examination of the *Artemia* disclosed the presence of dinoflagellate cells within their digestive tracts (Fig. 1). The computer program used for statistical analysis of the data took into account the 19% control mortality (11). Thus, the rate at which *Artemia* were killed (according to this model) depended on the concentration of *G. tamarensis* cells rather than on the rate of dinoflagellate ingestion by the brine shrimp. Further studies on the rate of dinoflagellate ingestion should provide more accurate estimates of oral LD_{50}. Upon intoxication, the *Artemia* underwent a period of hyperactivity during which they evinced a series of contractions (anterior–posterior curling and uncurling motions). This lasted for 1–2 hr and then ceased. Soon after, the shrimp lost their ability to remain near the surface of the medium and sank to the bottom of the container. The vigor of swimming motions decreased gradually and the organism ceased all movements.

The LD_{50} for 72 hr was 1258 cells/ml in 50 ml of medium (Table II). This value was converted to a microgram per kilogram lethal dose by taking the value of 1 μg of toxin/2294 cells and multiplying it by the 20% toxin reduction expected between the 25th and 29th days of culture (13). The corrected value for toxin content per dinoflagellate cells is 1 μg of toxin/2868 cells. This figure yields a toxin content of 0.00035 μg/*G. tamarensis* cell. When this concentration is multiplied by the number of cells per lethal dose (Table II), it is found that the LD_{50} in terms of amount of toxin is 0.4403 mg/*Artemia*.

Since the culture was unialgal but not axenic, decomposition of *Artemia* proceeded rapidly after death, and attempts to obtain shrimp weights were futile unless performed immediately after death. An average *Artemia* weight of 6 mg was used in determining microgram per kilogram LD_{50} values (14). Thus, the toxicity of gonyautoxins to *Artemia salina* L. is ~73,385 μg/kg of body weight. This figure is almost 150 times larger than the oral LD_{50} of 500 μg/kg for man, and 18 times larger than the 4000 μg/kg for the most resistant recorded mammal, a monkey (15). Mice, which are the current assay organisms and are somewhat closer in size to *Artemia* than either of the aforementioned animals, have an oral LD_{50} value of 2100 μg/kg of body weight (15). Thus, one-tenth as much toxin is required to kill a mouse as to kill a brine shrimp (LD_{50} 0.04 mg and 0.4 mg/animal, respectively). This fact, coupled with the 72 hr duration of the test (compared to the 15 min required for the Association of Official Analytical Chemists mouse assay) make the whole cell assay of *G. tamarensis* by *Artemia* a poor alternative to the mouse assay for purposes of routine monitoring of shellfish toxicity.

Attempts to assay both homogenized cells and shellfish extract which had been proven toxic by mouse assay failed due to rapid fungal overgrowth of the test solution. *Artemia* subjected to overgrown extract died rapidly in the presence or absence of paralytic shellfish poison. Concomitant administration of an antifungal agent not only added another variable to the experiment, but also did not sufficiently control fungal growth over the 72 hr required for the test.

The cause of death in cases of saxitoxin intoxication is paralysis of muscular contraction by inhibition of nerve conduction (blockade of Na^+ influx) resulting in a peripheral paralysis of respiratory muscles (16), as opposed to a nonspecific cytolytic factor which physically destroys gill surfaces (as is the case with *Gymnodinium breve* toxin) (13). Absorption of the gonyautoxins is necessary for their activity, detoxification occurring in either the absorptive or metabolic phase of digestion.

Organic extraction procedures similar to those employed for brine shrimp assay of ciguatera toxins (17) were beyond the scope of this study but will be examined in future experiments.

1,4-Bis(4-guanylphenylethyl)benzenes as Potential Antitrypanosomal Agents

BIJAN P. DAS, VERA B. ZALKOW, MARGRET L. FORRESTER, FRANK F. MOLOCK, and DAVID W. BOYKIN ˣ

Received July 13, 1981, from the *Department of Chemistry, Georgia State University, Atlanta, GA 30303.* Accepted for publication August 14, 1981.

Abstract □ A series of 1,4-bis(4-guanylphenylethyl)benzenes, including masked amidines in which the guanyl function is incorporated into a heterocyclic ring, were prepared for screening as potential antitrypanosomal agents. Some of these compounds were active against *Trypanosoma rhodesiense* in mice. The diamidines were prepared by standard methods from 1,4-bis(4-cyanophenylethyl)benzene which was obtained from 1,4-bis(4-cyanostyryl)benzene by diimide reduction. The latter compound was prepared by the Wittig reaction between 4-cyanobenzylphosphonium ylide and terephthaldicarboxaldehyde.

Keyphrases □ Antitrypanosomal agents—potential, 1,4-bis(4-guanylphenylethyl)benzenes □ *Trypanosoma rhodesiense*—1,4-bis(4-guanylphenylethyl)benzenes, activity as antitrypanosomal agents □ Structure–activity relationships—1,4-bis(4-guanylphenylethyl)benzenes as potential antitrypanosomal agents

Aryl diamidines have been known to be useful antitrypanosomal agents for many years (1, 2). The aryl diamidines reported to exhibit antitrypanosomal activity fall into two general, apparently arbitrary, sets: those that have their guanyl functions separated by approximately 12Å and those that are separated by approximately 20Å (3). It is not known if this observation has any significance regarding the interaction of these compounds with their bioreceptor(s). A number of quite active aryl diamidines have been reported which fall into the category of the 12Å set (3–5) and this report describes efforts to synthesize compounds that fall into the 20Å class. Pentamidine (1), congocidin (1), and the terephthanilide amidines (6) are notable examples of the antitrypanosomal compounds that fall into the latter structural class. While pentamidine and the terephthanilide amidines have similar separation of the guanyl functions, they differ in that terephthanilide amidines probably exist in a planar conformation, whereas this is unlikely for pentamidine. The present study attempted to determine the effect on antitrypanosomal activity and binding to the bioreceptor for the terephthanilide amidine types which are conformationally more flexible. To test this point, 1,4-bis(4-guanylphenylethyl)benzene was synthesized along with related compounds in which the conformationally rigid carboxamido groups of the terephthanilide amidines were replaced by the conformationally flexible $-CH_2CH_2-$ units.

RESULTS AND DISCUSSION

The synthesis of the target diamidines was achieved by employing a conventional synthetic approach (Scheme I). The first step involves a Wittig reaction between the 4-cyanobenzylphosphonium ylide and terephthaldicarboxaldehyde to yield a bis-1,4-(4-cyanostyryl)benzene (I), the stereochemistry of which was not determined. The bis styryl

VII[g]	5		5		5		5		5		5		5	5	4	4

[a] See Ref. 8. Antitrypanosomal testing was done at the Leo Rane Laboratory of the University of Miami under the direction of Dr. A. L. Ager, Jr. [b] A cure is defined as a 30-day increase in survival time of the treated animals over the controls. Five mice were used at each dosage level; hence, five is the maximum number of cures. [c] ΔMST is the increase in mean survival time of test animals *versus* controls in days. ΔMST is differentiated from cures by the use of *D*; *i.e.*, 1.3*D* = 1.6 days. [d] Dosage is in milligrams of compound per kilogram of body weight of the test animal (mice). [e] T = toxic death. [f] Pentamidine. [g] 2,5-Bis(guanylphenyl)furan.

compound I was subjected to a diimide-type reduction by the method of Dewey and Van Tamelen (7) and produced 1,4-bis(4-cyanophenylethyl)benzene (II). The bis-nitrile was converted into the corresponding imidate ester which was used directly to prepare the guanyl derivatives.

The target compounds (III–V) were screened against *Trypanosoma rhodensiense* in mice (8), and the results are shown in Table I. Included for comparison in Table I are test results from the same screening program for pentamidine and 2,5-bis(4-guanylphenyl)furan, a very effective 12Å-type compound reported previously (3). The bis-guanyl compound (III) showed good activity, providing cures down to a dosage level of 26 mg/kg. Its activity was significantly lower than that of pentamidine or the furan derivative included in Table I. Interestingly, the two masked amidines showed markedly different activities. The imidazolinyl compound (IV) was essentially devoid of activity; however, the related pyrimidinyl (V), while toxic at high dosages, was slightly more active than the parent compound III at low dosage levels. In a large number of 12Å types (3–5), the masked amidines have generally shown limited activity.

EXPERIMENTAL[1]

Melting points reported under 300° were taken using an oil-bath melting point apparatus; the melting points of compounds melting above 300° were obtained using a solid block apparatus and all melting points are uncorrected. Satisfactory IR spectra were reported for all new compounds; the expected PMR spectra were recorded on all new compounds in [^{2}H]chloroform or [^{2}H]dimethylsulfoxide (tetramethylsilane standard).

1,4-Bis(*p*-cyanostyryl)benzene (I)—4-Cyanobenzyl triphenylphosphonium bromide (10 g, 0.02 mole) was added, under a nitrogen atmosphere, to a solution containing 0.03 mole of freshly prepared sodium ethoxide in 180 ml of ethanol. The solution was stirred for ~5 min and terephthaldicarboxaldehyde (1.4 g, 0.01 mole) dissolved in 100 ml of ethanol was added dropwise. After addition was complete the reaction mixture was stirred for 3.5 hr under a nitrogen atmosphere during which time crystals appeared. The solid (1.1 g, 17%) was filtered and recrystallized from ethanol mp 280–282°.

Anal.—Calc. for $C_{24}H_{16}N_2$: C, 86.74; H, 4.81. Found: C, 86.66; H, 4.95.

1,4-Bis(*p*-cyanophenylethyl)benzene (II)—*p*-Toluenesulfonylhydrazide (9) (4.0 g, 0.02 mole) in 50 ml of ethylene glycol monomethylether was added in portions to a refluxing suspension of the bis-styryl compound (3.3 g, 0.01 mole) in 100 ml of ethylene glycol monomethylether, under a nitrogen atmosphere. After addition was complete, the mixture was refluxed for 16 hr. The volume of solvent was reduced to ~30 ml and 2.8 g (83%) was obtained on cooling. The product was dissolved in methylene chloride, passed through a short alumina column, and the solvent was evaporated. Recrystallization from chloroform and dimethylsulfoxide gave a solid which melted 208–211°.

Anal.—Calc. for $C_{24}H_{20}N_2$: C, 85.68; H, 5.99; N, 8.33. Found: C, 85.56; H, 5.99; N, 8.27.

1,4-Bis(4′-guanylphenylethyl)benzene Dihydrochloride (III)—The bis-nitrile (1.4 g, 0.004 mole) was dissolved in 100 ml of dioxane and 25 ml of ethanol, cooled in an ice bath, and hydrogen chloride gas was passed through it until the solution was saturated. The mixture was placed in a pressure bottle and shaken for 3 days at room temperature. The solid (imidate ester hydrochloride) that formed was filtered, dried under vacuum, and checked for unreacted starting material by examining the nitrile region of its IR spectra. A suspension of 1.5 g of imidate ester in 100 ml of absolute ethanol was prepared and dry ammonia was passed through the cold suspension until it was saturated. The mixture was shaken at room temperature for 3 days in a pressure bottle. The yellow solid that formed was dissolved in absolute ethanol saturated with hydrogen chloride gas; concentration of the solution gave 1.1 g (63%) of yellow solid which was recrystallized from ethanol, mp 345–346° (dec).

Anal.—Calc. for: $C_{24}H_{28}Cl_2N_4$: C, 65.01; H, 6.32; N, 12.64. Found: C, 64.81; H, 6.37; N, 12.53.

1,4-Bis[4-(2-imidazolinyl)phenylethyl]benzene (IV)—The imidate ester hydrochloride (2.9 g, 0.0054 mole) was suspended in 75 ml ethanol, ethylene diamine (0.65 g, 0.11 mole) was added, and the mixture was refluxed for 16 hr. The solid product was filtered, washed with ethanol, and dried. The solid was dissolved in absolute ethanol and the solution was saturated with dry hydrogen chloride gas. The solution was filtered and then concentrated until crystals began to appear; 1.9 g (78%), mp 298–303° (dec).

Anal.—Calc. for $C_{28}H_{32}Cl_2N_4$: C, 67.87; H, 6.46; N, 11.31. Found: C, 67.41; H, 6.56; N, 11.02.

1,4-Bis[4-(1,4,5,6-tetrahydro-2-pyrimidinyl)phenylethyl]benzene (V)—The imidate ester hydrochloride (1.9 g, 0.0043 mole) was suspended in 75 ml of ethanol and 1,3-propanediamine (0.64 g, 0.009 mole) was added and the mixture was refluxed overnight during which time a solid formed. The solid was washed with ethanol and dried. It was then dissolved in absolute ethanol and the solution was saturated with dry hydrogen chloride gas. The solution was filtered and concentrated until crystals formed; 1.4 g (61%), mp 345–350° (dec.).

Anal.—Calc. for $C_{30}H_{36}Cl_2N_4(0.5)H_2O$: C, 67.66; H, 7.00; N, 10.52. Found: C, 67.55; H, 6.83; N, 10.32.

The Interaction of Granaticin with Nucleic Acids and Pyruvate Decarboxylase

GAIL GIBSON-CLAY, STEPHEN R. BYRN, and PETER HEINSTEIN ˣ

Received November 14, 1979, from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication August 5, 1981.

Abstract □ The interaction of granaticin with two different yeast ribonucleic acids, dialyzed transfer RNA and calf thymus DNA was studied. Contrary to previous reports, no binding of granaticin to DNA or RNA was observed. The visible spectrum of granaticin on direct mixing or equilibrium dialysis of granaticin with RNA or DNA was unchanged. Furthermore, granaticin did not displace acridine orange from DNA in competitive binding studies using fluorescence polarization. However, granaticin was shown to inhibit pyruvate decarboxylase. From the K_i for granaticin (3.8 m*M*) it was concluded that granaticin is as efficient as other 1,4-naphthoquinones in inhibiting pyruvate decarboxylase.

Keyphrases □ Granaticin A—absence of interaction with DNA and RNA, interaction with proteins from the inhibition of pyruvate decarboxylase □ DNA—interaction with granaticin A □ RNA—interaction with granaticin A □ Pyruvate decarboxylase—inhibition by granaticin A in the interaction between granaticin A and protein

Granaticin, isolated from *Streptomyces olivaceus* (1), is a quinone antibiotic which is active against Gram-positive bacteria (2). Also known as litmomycin (3), granaticin has been studied for its interaction with various biochemical species. Previous work proposed that granaticin (*a*) interferes with the charging process of transfer RNA, thereby inhibiting the synthesis of leucyl transfer RNA (4), (*b*) interferes with leucyl transfer RNA synthetase (5), (*c*) inhibits the synthesis of RNA or the function of RNA polymerase, which is not DNA dependent (6), (*d*) inhibits reverse transcriptase by binding to the template RNA (7), and (*e*) appears to inhibit maturation of ribosomal RNA (8). These biological effects of granaticin could be due to the interaction of granaticin with template macromolecules (*i.e.*, DNA and RNA) or with catalytic macromolecules, (*i.e.* proteins).

The inhibition of the reverse transcriptase was attributed to the interaction of granaticin with the RNA template (7). Inhibition of leucyl transfer RNA formation (4) and maturation of RNA may have been due to binding of granaticin to the RNA or to the reaction of granaticin with a protein factor required in the formation of RNA (8).

The purpose of this study was to investigate the binding of granaticin to two different RNA preparations and DNA and to measure the effect of granaticin on enzyme activity.

EXPERIMENTAL

Binding Studies—A stock solution of granaticin A[1] (27.9 μM) was prepared in 0.005 *M* phosphate buffer, pH 7.2, by stirring in the dark for 3 days at 2–37°. The solution was gravity filtered before use. Yeast transfer RNA type III (19.0 mg)[2] (9) was dissolved in 250 ml of 0.005 *M* phosphate buffer, pH 7.2. A fixed amount of granaticin stock solution (15 ml) was directly mixed with varying amounts of RNA solution (2, 5, 8, 10, 15, and 20 ml) and diluted to 100 ml with phosphate buffer. Visible spectra of these samples were recorded[3] scanning from 625–460 nm. The baseline was established by using phosphate buffer in both the sample and reference cells. Control absorption curves were generated using granaticin stock solution (15 ml) diluted to 100 ml with phosphate buffer and RNA solution (2–20 ml, as described above) diluted to 100 ml with phosphate buffer. The same procedure was used to test the interaction of granaticin with RNA type XI[2] (a mixture of messenger and ribosomal RNA) and calf thymus DNA[2].

In a slightly different experimental approach, 1 and 2 ml of an RNA solution (type XI and type III)[2] containing 20 mg of RNA in 10 ml of 0.005 *M* phosphate buffer, pH 7.2, was placed in a dialysis bag[4], sealed, and immersed in 50 ml of a granaticin solution (27.9 μM) in phosphate buffer. The solution was stirred in the dark for 72 hr at 2–37°. Thereafter, visible spectra (625–460 nm) of the RNA–granaticin solution inside the dialysis bag and the granaticin solution outside the dialysis bag were recorded[3]. In control incubations, phosphate buffer replaced the RNA solutions inside the dialysis bag, and in a second incubation the granaticin solution outside the dialysis tubing was replaced with phosphate buffer. Controls were treated the same as the samples.

Competitive Binding Studies[5]—Granaticin, 0.025–25 μg/ml in 0.01 *M* cacodylate[2] buffer, pH 6.7, was used in the competitive binding assay inhibiting the binding of acridine orange[2] to calf thymus DNA type I[2]. This binding is accompanied by an increase in fluorescence polarization. Granaticin and acridine orange (100 μl of a 10-μM solution) were mixed in a cell, and the initial fluorescence polarization (P_0) was measured[6] using excitation and emission filters at 492 and 520 nm, respectively. DNA (equivalent to 35% saturation) was then added to the cell and the final polarization (P) was determined after mixing. Results were expressed as a percentage of maximum binding; maximum binding was expressed as the P–P_0 obtained without granaticin (11).

Enzyme Assays—Pyruvate decarboxylase[2] (2-oxo acid carboxyl-lyase, EC 4.1.1.1, 13 U/mg protein) was assayed in a coupled assay with alcohol dehydrogenase[2] (alcohol:NAD$^+$ oxidoreductase EC 1.1.1.1, 300 U/mg protein) by measuring the oxidation of reduced nadide[2] at 340 nm (12). A typical incubation mixture contained reduced nadide (1.2 μmoles), alcohol dehydrogenase (0.3 U), pyruvate[2] (0–150 μmoles), pyruvate decarboxylase (0.29 U), and granaticin (0, 0.33, 0.42, and 0.52 μmoles) in a total volume of 3.0 ml of 0.2 *M* citrate[2] buffer, pH 6.0. Granaticin was dissolved in 0.2 *M* citrate buffer, pH 6.0 by stirring in the dark for 4 days at 2°. The reagents, except pyruvate decarboxylase, were mixed in a cell and the base line was recorded from 300–380 nm. The spectrophotometer[3] was then set at 340 nm and pyruvate decarboxylase was added, rapidly mixed, and the change in absorbance at 340 nm recorded. Temperature was maintained at 30°.

To ensure that the observed effect of granaticin in the enzyme assay was not due to the inhibition of alcohol dehydrogenase by granaticin, this enzyme was assayed with or without granaticin and without pyruvate decarboxylase. The reaction mixture contained reduced nadide (1.2 μmoles), acetaldehyde[2] (0–114 μmoles), granaticin (0, 0.33, 0.42 and 0.52 μmole, solution prepared as described previously), and alcohol dehydrogenase (0.3 U) in a total volume of 3.0 ml and 0.2 *M* citrate buffer, pH 6.0. The reagents, except the enzyme, were mixed in a cell and the base line recorded from 300–380 nm. The reaction was started by adding alcohol dehydrogenase and the change in absorbance at 340 nm was recorded. Temperature was maintained at 30°.

RESULTS AND DISCUSSION

It was proposed that granaticin binds to transfer RNA (4) and to the template RNA in the reverse transcriptase assay (7); however, these results were based on indirect observations. Therefore, binding of granaticin

to yeast transfer RNA type III and a mixture of ribosomal RNA and messenger RNA type XI through direct addition and dialysis experiments was attempted. In neither experiment did the absorption spectrum of granaticin exhibit any changes on addition of the RNA. Part of the visible absorption spectrum of granaticin is shown in Fig. 1 (curve a). Neither the peak at 580 nm, nor the shoulder at 550 nm in the granaticin spectrum were changed significantly on addition of RNA. The same results were obtained when granaticin and RNA were mixed or dialyzed for up to 3 days at temperatures that varied from 2 to 37° in different experiments. These results indicate that granaticin does not bind to RNA molecules *in vitro*.

In identical experiments where calf thymus DNA was substituted for RNA, no *in vitro* binding of granaticin to DNA was observed.

The inability of granaticin to interact *in vitro* with nucleic acids is supported by the results of the competitive binding assay (11). Granaticin showed no evidence of displacement of acridine orange from DNA.

Since the inhibitory action of granaticin on reverse transcriptase (7) and on the charging of transfer RNA (4) might be due to the interaction with proteins involved in these processes, and no interaction between RNA or DNA with granaticin was observed, the possibility that granaticin binds to protein (potential nucleophilic reactants) was investigated. The enzyme selected for these experiments was pyruvate decarboxylase, since compounds similar in structure to granaticin, naphthoquinone, and anthraquinone, inhibit this enzyme (13). Pyruvate decarboxylase was assayed at optimum conditions (12) and was coupled to the reduction of acetaldehyde, the product of the pyruvate decarboxylase reaction, by alcohol dehydrogenase resulting in the oxidation of reduced nadide.

Lineweaver–Burk plots ($1/V$ *versus* $1/[S]$) yielded parallel lines which indicated that granaticin is an uncompetitive inhibitor of pyruvate decarboxylase. In a control experiment where only alcohol dehydrogenase was assayed, granaticin had no effect on the enzyme. The K_i for granaticin was calculated to be 3.8 mM. Granaticin is, therefore, as good an inhibitor of pyruvate decarboxylase as 1,4-naphthoquinone (k_i = 4.2 mM) (12), whereas anthraquinone, at twice the concentration, did not inhibit pyruvate decarboxylase (13). Interestingly, granaticin had a half-wave potential of −0.685v (14) compared with a half-wave potential of −0.603v for naphthoquinone (15), but different from the half-wave potential of −0.85v for anthraquinone (16). These values would indicate a bioreductive alkylation (17) of a nucleophilic center in a protein. Additional experiments are required to prove this hypothesis.

It appears that at least one of the inhibiting actions of granaticin on living cells is the interaction of granaticin with proteins and not with RNA or DNA as reported previously (4, 7). However, it should be emphasized that the experimental procedures used in the present report utilized direct binding studies, whereas previous reports (4, 7) used indirect biochemical measurements to conclude that granaticin interacted with RNA and DNA.

Distribution Volume Related to Body Weight and Protein Binding

Keyphrases □ Volume of distribution—related to body weight and protein binding □ Pharmacokinetics—distribution volume related to body weight and protein binding

To the Editor:

The physiological approach to drug distribution volume proposed by Gillette (1) has proven very useful for characterizing the dual effects of body size and plasma and tissue binding on steady-state volume of distribution (V_{ss}). Gillette's equation has commonly appeared as:

$$V_{ss} = V_p + \frac{f_{up}}{f_{ut}} V_t \qquad \text{(Eq. 1)}$$

where V_p is plasma volume, V_t is remaining body volume or mass accessible to drug, and f_{up} and f_{ut} are the fractions of unbound drug in plasma and tissues, respectively, which are assumed to be concentration-independent parameters.

Related conceptual models have been proposed by Wagner (2), Øie and Tozer (3), and others (reviewed in Ref. 4) with the assumptions that unbound drug diffusion serves as the equilibrating mechanism throughout body spaces, linear conditions exist, and the drug is bound and/or partitions into various tissue spaces. Equation 1 has been particularly helpful in pharmacokinetics as it rationalizes the meaning and calculation of V_{ss} as an essential "model-independent" parameter (5) and provides a means for estimating tissue binding of drugs. In the latter regard, Gibaldi and McNamara (6) revised Eq. 1 to yield a relationship which allowed calculation of f_{ut} based on assumption of reasonable values of V_p and V_t:

$$f_{ut} = \frac{V_t f_{up}}{V_{ss} - V_p} \qquad \text{(Eq. 2)}$$

The purpose of this communication is to further consider Eq. 1 in terms of the practice of normalizing V_{ss} for body weight and for f_{up}.

The adjustment of V_{ss} for total body weight (TBW) has been proposed as a means of expressing drug distribution in terms of an apparent tissue–plasma distribution or partition coefficient (5, 7):

$$K_D = V_{ss}/\text{TBW} \qquad \text{(Eq. 3)}$$

While further division of V_{ss}/TBW by f_{up} appears logical, the usefulness of the resulting parameter has not been ascertained. For oral dose clearance data, the analogous computation of Dose/f_{up} × AUC yields the intrinsic clearance of unbound drug, a parameter indicative of the V_{max}/K_m ratio for a biotransformation process (8, 9). It would be helpful if V_{ss}/f_{up} had a similar, direct physiological interpretation.

Equation 1 can be rearranged to the following expression upon division by f_{up} and substitution of TBW − V_t for V_p:

$$\frac{V_{ss}}{f_{up}} = \frac{\text{TBW}\, f_{ut} + V_t(f_{up} - f_{ut})}{f_{up} f_{ut}} \qquad \text{(Eq. 4)}$$

Since V_p is small compared to TBW, the approximation can be made that $V_t \simeq$ TBW and Eq. 4 simplifies and rearranges to:

$$K_D^u = V_{ss}\,\text{TBW}^{-1} f_{up}^{-1} = f_{ub}^{-1} \qquad \text{(Eq. 5)}$$

Thus, the calculation of V_{ss}, normalized both for body weight[1] and plasma binding, should yield a reasonable value for the reciprocal of f_{ub}, an estimate of the unbound fraction of drug in the body. This "intrinsic volume" should help in examining factors such as the effects of disease states on plasma and tissue binding of drugs.

While f_{ut} has been viewed (6) as "the average fraction of unbound drug in the extravascular water space weighted for tissue mass" according to Eq. 2, it serves in Eq. 5 as "the average fraction of unbound drug in the body weighted for tissue mass." Neither parameter can be considered more correct without direct quantitation of tissue binding. However, Eq. 5 is proposed for use because of several advantages. It obviates the need to estimate V_p and V_t in different persons or animals as body water spaces. The assumption that drugs are localized only in body water spaces is thereby removed, but the influences of lipid partitioning, active transport, ion trapping caused by pH differences among tissues, and binding to body solids become implicitly included (3, 4). As experimental capabilities for estimating tissue drug binding *in vitro* (4, 10) improve, the value of f_{ub} should prove easier to measure and calculate per unit of total tissue mass than per unit of tissue water.

One major value of Eq 5 is that calculation of K_D^u directly from free drug concentrations in plasma has been rationalized as having intrinsic merit. Equation 1 is difficult to employ when plasma protein binding is nonlinear. For prednisolone (which exhibits marked concentration-dependent binding to transcortin and albumin in plasma) the model-independent calculation of V_{ss} from plasma clearance (Cl) and mean transit time ($\bar{t}$):

$$V_{ss} = Cl\bar{t}/\text{TBW} \qquad \text{(Eq. 6)}$$

yields dose and time-average values of V_{ss} which vary with dose (11). Similar calculations can be made using free drug concentrations (C_u) and area–moment analysis (12) to yield:

$$K_D^u = \frac{\text{dose} \int_0^\infty t C_u dt}{\left(\int_0^\infty C_u dt\right)^2 \text{TBW}} = f_{ub}^{-1} \qquad \text{(Eq. 7)}$$

This approach served as the basis for comparing prednisolone pharmacokinetics in humans and rabbits. As shown in Fig. 1, both species yielded K_D^u values (time and dose average) which centered about 2 liters/kg. Extending the interpretation using Eqs. 5 and 7, the average body binding of the corticosteroid would be ~50%.

A second demonstration of the use of Eqs. 2 and 5 for estimation of drug binding is shown in Table I. Oxaprozin

[1] While K_D^u has units of liters/kg, it can be altered to a dimensionless number more equivalent to f_{ub}^{-1} by converting body weight to volume. Weight is retained here for simplicity.

Table I—Protein Binding and Distribution Properties of Oxaprozin in Normal and Azotemic Subjects

Subjects	V_{ss}/TBW, liters/kg	f_{up}, %	K_D^u, liters/kg	f_{ut}, % Eq. 2[a]	f_{ub}, % Eq. 5
Normal	0.15 (0.01)	0.078 (0.003)	193 (11)	0.42 (0.03)	0.52 (0.03)
Renal impairment	0.18 (0.01)	0.177 (0.016)	103 (13)	0.79 (0.11)	1.03 (0.12)
Dialysis	0.21 (0.02)	0.283 (0.036)	79 (13)	1.05 (0.21)	1.43 (0.25)

[a] Assumes V_t = extravascular water space (554 ml/kg) and V_p = 46 ml/kg.

pharmacokinetics and binding were examined in subjects with normal and impaired renal function[2]. Direct plasma protein binding studies showed altered binding in plasma in the azotemic patients. The values of f_{ut} and f_{ub} were estimated by the two equations. The proposed equation did not obscure the apparent occurrence of impaired tissue binding in azotemic patients.

It is becoming common practice to calculate intrinsic clearance and the unbound volume of distribution directly from C_u *versus* time data. It is helpful to be able to interpret the resultant value in terms of overall drug binding. The necessary assumption that passive diffusion of unbound drug accounts for equilibration between tissues is retained. These arguments for simplified calculation of K_D^u, however, should not preclude the application of more specific tissue binding models when based on appropriate experimental data.

Trace Decomposition of Choline

Keyphrases □ Choline—trace decomposition after exposure to high humidity or in unbuffered solutions □ Decomposition—trace, of choline after exposure to high humidity or in unbuffered solutions

To the Editor:

Decomposition of pharmaceuticals to the extent of parts per thousand, or less, usually is considered negligible. Such trace decomposition cannot be ignored where it affects the acceptability of drug products, *i.e.*, where it is manifested as insoluble matter in an injection, as discoloration, or by odor formation. The origin of a characteristic fishy odor in oxtriphylline (choline theophyllinate) exposed to high humidity for protracted periods or in unbuffered solutions led to the studies reported here. This odor, which is characteristic of many choline salts, can be attributed to trace decomposition; trace, because the presence of an odor has no measurable effect on physicochemical properties and decomposition, since quaternary ammonium salts are nonvolatile and would be expected to be odorless on that account.

A decomposition study of choline, measuring intact quaternary ammonium function, showed that it proceeded very slowly in solution at 100°. On heating choline has been reported (1) to yield 85–90% trimethylamine, 5% dimethylamine, 25% ethylene glycol, 4% acetaldehyde, and 10–15% acetylene on a molar basis with excess concentrated potassium hydroxide. The nature of the neutral reaction products would be expected to vary with reaction conditions, but it was assumed in this study that trimethylamine would constitute the bulk of the basic products. Because the amounts of trimethylamine formed were extremely low, a method was developed using microdiffusion to iso-

To the Editor:

Decomposition of pharmaceuticals to the extent of parts per thousand, or less, usually is considered negligible. Such trace decomposition cannot be ignored where it affects the acceptability of drug products, *i.e.*, where it is manifested as insoluble matter in an injection, as discoloration, or by odor formation. The origin of a characteristic fishy odor in oxtriphylline (choline theophyllinate) exposed to high humidity for protracted periods or in unbuffered solutions led to the studies reported here. This odor, which is characteristic of many choline salts, can be attributed to trace decomposition; trace, because the presence of an odor has no measurable effect on physicochemical properties and decomposition, since quaternary ammonium salts are nonvolatile and would be expected to be odorless on that account.

A decomposition study of choline, measuring intact quaternary ammonium function, showed that it proceeded very slowly in solution at 100°. On heating choline has been reported (1) to yield 85–90% trimethylamine, 5% dimethylamine, 25% ethylene glycol, 4% acetaldehyde, and 10–15% acetylene on a molar basis with excess concentrated potassium hydroxide. The nature of the neutral reaction products would be expected to vary with reaction conditions, but it was assumed in this study that trimethylamine would constitute the bulk of the basic products. Because the amounts of trimethylamine formed were extremely low, a method was developed using microdiffusion to iso-

0022-3549/82/0400-0470$01.00/0

late the amine and gas chromatography with a nitrogen-specific detector to quantify it. Heating solutions of choline in 1 *N* sodium hydroxide at 60° for 14 days produced decomposition products in quantities of parts per million measured as trimethylamine. The rate and extent of decomposition appear to vary directly with the hydroxyl ion concentration of the medium.

Solutions of choline chloride, 2 mg/ml, were prepared in water with 0.01, 0.1, and 1.0 *N* sodium hydroxide. They were filled into 10-ml glass ampuls and sealed, then heated at steam bath temperature, ~100°, for 21 days. Intact choline was estimated by a modification of the Reinecke salt colorimetric method (2), the modification consisting of sparging the solutions with nitrogen gas to remove volatile amines. Three-milliliter portions of the ampule contents were acidified with sulfuric acid, 10 ml of 1% aqueous ammonium reineckate was added to each solution with stirring, and the mixtures were allowed to stand for 10 min. They were chilled in ice water and filtered through fine-frit sintered-glass crucibles. The precipitates were washed with ice water, then dissolved and made up to 10 ml with acetone. Absorbance of the solutions was determined in 1-cm cells at 523 nm, and the choline concentrations were calculated by reference to a standard curve constructed by carrying scalar amounts of choline chloride through the colorimetric procedure. The results support the hypothesis that degradation increases with increase in hydroxyl ion concentration; 96.0% of intact choline remained with water as the medium, 92.9% with 0.01 *N*, 89.8% with 0.1 *N*, and 80.4% in 1.0 *N* alkali.

Although drug decomposition at pH extremes generally is of little practical significance, it is important in this instance, for the pH of a saturated solution of oxtriphylline is >13. In a moist environment, oxtriphylline particles or granulation may be visualized as surrounded with a thin film of saturated solution. In support of this concept, it was found that adjustment of oxtriphylline granulations to a lower degree of alkalinity resulted in an odorless product. (Since the pKa of theophylline is ~8.8, a pH of 11 would afford all of the drug in the anionic form, yet the 100-fold reduction in hydroxyl ion concentration represented by the change from pH 13 to 11 minimizes the extent of decomposition.)

Solutions of choline chloride containing 50 mg/ml were prepared in water with 0.01, 0.1, and 1 *N* sodium hydroxide solutions. Aliquots of 2 ml were pipetted into the outer chamber of microdiffusion cells[1] and 2 ml of 1 *M* citric acid was pipetted into the inner chamber. The cells were sealed with a fine-ground flat glass plate using a minimum amount of stopcock grease and placed in an oven maintained at 60°. They were removed at intervals and allowed to cool to room temperature. A 1-ml portion of the citric acid solution from the inner chamber was pipetted into a 15-ml glass-stoppered centrifuge tube, then 3 ml of 30% chloroform in hexane and 5 ml of 1 *N* sodium hydroxide were added, the tube was stoppered and shaken for 5 min, and then centrifuged to obtain clear, immiscible phases. A 4-μl portion of the upper layer was injected into a gas chromatograph[2] fitted with a nitrogen-specific detector, using a 3.66-m × 2-mm i.d. glass column[3]. Temperatures were 110° for the column, 100° for the injection port, and 150° for the detector. Hydrogen pressure was 3 psi and attenuation × 8. The retention time for authentic trimethylamine was ~2 min and its detection limit ~5 ng on-column. Standard solutions of trimethylamine were prepared by serial dilutions of a 25% aqueous solution. Concentrations of 13.3–266 ng on-column, in 6 increments (3.3–66.5 μg/ml), provided a rectilinear plot of concentration *versus* peak area.

No time-dependent data were obtained for the solution in water or the lower alkali concentrations over a 24-day period; the amount of trimethylamine that diffused into the citric acid solution was ~6 μg (or 12 ng on-column), close to the limit of detection. Losses due to adsorption on glass surfaces or dissolution in the grease seal may be significant at this level. In 1 *N* NaOH, however, the trimethylamine determined was 43 μg after 2 days at 60° and 78 μg after 14 days, when the experiment was terminated. These data, with intermediate points obtained at 4, 7, and 10 days, gave a pseudo first-order rate constant of 7.14×10^{-5} day^{-1}. The amount of trimethylamine determined after 2 weeks at 60° represented <4 ppm of decomposed choline on a molar basis.

Changes in Plasma Protein Binding of Drugs after Blood Collection from Pregnant Rats

Keyphrases □ Protein binding—plasma, changes after blood collection from pregnant rats □ *In vitro–in vivo* correlation—plasma protein binding changes after blood collection from pregnant rats

To the Editor:

Determinations of drug–protein binding in plasma are associated with a number of potential methodological and technical difficulties. It is, therefore, desirable to confirm the suitability of *in vitro* protein binding measurement procedures by *in vivo* studies, if possible. The steady-state concentration of phenytoin in cerebrospinal fluid is essentially identical to the concentration of free (unbound) phenytoin in plasma so that the ratio of phenytoin concentration in cerebrospinal fluid to the total (free plus bound) concentration of phenytoin in plasma gives an *in vivo* estimate of the free fraction of phenytoin in plasma (1). We have recently used this method in rats to demon-

0022-3549/82/0400-0471$01.00/0

strate that the apparent decrease of phenytoin binding in plasma after heparin administration is an *in vitro* artifact (1) apparently due to increased nonesterified fatty acid concentrations caused by lipolysis in plasma after blood collection (2). On the other hand, there was excellent agreement between the *in vivo* free fraction of phenytoin in the serum of rats who received that drug alone or together with the competitive binding inhibitor salicylic acid, and the *in vitro* free fraction measurements by equilibrium dialysis (1).

More recent studies on pregnant rats yielded *in vivo* plasma free fraction estimates for phenytoin that were considerably lower than the free fraction values determined by *in vitro* equilibrium dialysis. Therefore, experiments were designed to assess these differences. Wistar-Lewis rats, 20 days pregnant and weighing ~320 g, received 14.7 mg/kg phenytoin through a jugular vein cannula by rapid injection followed immediately by an infusion of 195 μg/min/kg for 2 hr. The animals were then anesthetized with ether, and cerebrospinal fluid and 10 ml of blood from the aorta were obtained. The blood was collected in a plastic syringe containing 200 U of heparin. Plasma was separated immediately (10 min centrifugation at 1500×*g*). About 2 ml of plasma was placed in cellophane tubing which was mounted in stoppered plastic centrifuge tubes. They were centrifuged at 750×*g* for 30 min at about 37° in a controlled temperature centrifuge, whose head had been preheated to 37°, and about 0.1 ml ultrafiltrate (tested with trichloroacetic acid for absence of protein) was collected. The time interval between blood collection and the end of the ultrafiltration procedure was ~50 min. Another portion of plasma was placed in a closed glass vial which was rotated in a water-bath at 37° for 6 hr. That plasma was then subjected to ultrafiltration. A third portion of plasma was placed in a dialysis cell and dialyzed for 6 hr (sufficient to reach equilibrium in the case of plasma from normal animals) at 37° against an equal volume of pH 7.4 phosphate buffer (1). All samples were assayed for phenytoin by high-performance liquid chromatography (HPLC) as described previously (1).

Results obtained from studies on nine animals are summarized in Table I. The free fraction values determined by immediate ultrafiltration were similar (~32% higher, on the average) to the *in vivo* estimates. These *in vitro* and *in vivo* free fraction values were strongly correlated ($r = 0.79$, $p < 0.02$). On the other hand, the free fraction values obtained by ultrafiltration after 6 hr were ~133% higher than the *in vivo* estimates and the free fraction values obtained by dialysis were ~63% higher. Clearly, a pronounced decrease in protein binding of phenytoin occurred in plasma from the pregnant rats during 6 hr after blood collection. Additional ultrafiltration studies with plasma incubated at 37° for 4 and 9 hr, respectively, showed that the maximum change in binding had occurred by 4 hr. This change was not prevented by the addition of antibiotics (mixture of penicillin G, streptomycin, and polymyxin B) to the plasma.

Table I—Protein Binding of Phenytoin in Plasma from Pregnant Rats [a]

Total phenytoin in plasma, μg/ml	12.9 ± 2.1
Cerebrospinal fluid/plasma concentration ratio	0.200 ± 0.029
Free fraction by immediate ultrafiltration	0.263 ± 0.027
Free fraction by ultrafiltration after 6 hr at 37°	0.461 ± 0.044
Free fraction by dialysis for 6 hr at 37°	0.322 ± 0.028

[a] Mean ± *SD*, $n = 9$.

Table II—Protein Binding of Salicylate in Plasma from Pregnant and Nonpregnant Rats [a]

	Pregnant Rats	Nonpregnant Rats
Total salicylate in plasma, μg/ml	234 ± 18	295 ± 33
Free fraction by immediate ultrafiltration	0.560 ± 0.081	0.435 ± 0.036
Free fraction by ultrafiltration after 4 hr at 37°	0.763 ± 0.118	0.468 ± 0.037
Free fraction by dialysis for 4 hr at 37°	0.733 ± 0.165	0.385 ± 0.029
Ratio of free fractions by ultrafiltration[b], 4 hr/immediate	1.36 ± 0.09	1.08 ± 0.04
Ratio of free fractions[b], dialysis/immediate ultrafiltration	1.30 ± 0.17	0.886 ± 0.040

[a] Mean ± *SD*, $n = 5$ per group. [b] These ratios are reported because one of the pregnant rats had an unusually low free fraction value in all determinations, thereby causing a relatively large coefficient of variation of the mean free fraction values.

The results of these studies do not mean that *in vivo* drug–protein binding alterations do not occur during pregnancy. The phenytoin concentration ratio, cerebrospinal fluid/plasma, in the pregnant rats is significantly larger than that ratio in nonpregnant rats from the same group of animals studied concurrently[1].

Additional protein binding studies were carried out with salicylic acid, but cerebrospinal fluid–plasma concentration ratios were not obtained because salicylate in cerebrospinal fluid, unlike phenytoin, does not equilibrate with free salicylate in plasma due to the active transport of salicylate from cerebrospinal fluid to blood (1). Twenty-days pregnant Wistar-Lewis rats and nonpregnant female rats (200–250 g) received a rapid intravenous injection of sodium salicylate, 100 mg/kg, and blood was collected 30 min later. Plasma was ultrafiltered immediately and after 4 hr of incubation at 37°, and another portion of plasma was subjected to equilibrium dialysis at 37° for 4 hr as described previously. All assays were carried out by HPLC (1). The results of these studies are summarized in Table II. There were only very small differences between free fraction values obtained by ultrafiltration immediately and 4 hr after blood collection, and between the 4 hr ultrafiltration and equilibrium dialysis free fraction values, in nonpregnant rats. On the other hand, there were considerably larger differences between free fraction values obtained immediately by ultrafiltration as compared with values obtained 4 hr later by ultrafiltration or equilibrium dialysis in plasma from pregnant rats. Results obtained by ultrafiltration at 4 hr and by equilibrium dialysis were essentially identical. These observations also indicate that drug–protein binding in plasma from pregnant animals decreases *in vitro* with time and that the magnitude of such changes in plasma from nonpregnant animals is much smaller.

In summary, drug–protein binding in plasma obtained from pregnant rats can undergo rapid changes (decreases) *in vitro* after blood collection. Similar changes may occur in plasma of other species, including humans, and in plasma from animals with other pathophysiological conditions associated with alterations in drug–protein binding,

[1] Results to be published.

but the rates and magnitudes of these changes may be different. Careful attention will have to be given to the methodology of *in vitro* drug–protein binding determinations if artifactual results are to be avoided.

The Loss of Nitroglycerin from Intravenous Administration Sets during Infusion: A Theoretical Treatment

Keyphrases □ Nitroglycerin—loss from intravenous administration sets during infusion □ Administration sets—loss of nitroglycerin during infusion

To the Editor:

In a recent report (1), a model was proposed to explain the loss of nitroglycerin from solution into a plastic bag. Under static conditions, the kinetics describing the loss of drug was biexponential and expressed as:

$$A = \beta e^{-k_3 t} + (A_0 - \beta)e^{-k_1 t} \quad \text{(Eq. 1)}$$

where A is the amount of drug in solution, k is the rate of drug absorption onto the surface of the plastic, k_3 is the diffusion of drug into the plastic, A_0 the initial amount of drug in solution, and β is a constant. With plastic bags, Eq. 1 showed an excellent fit to the experimental data.

During the infusion therapy, the above principles apply to large volume parenteral therapy. However, a dynamic situation exists in the infusion set due to the constant flow of solution through the plastic tubing. A model depicting the loss of nitroglycerin from solution when drug is diluted in a glass bottle (no absorption) and allowed to flow through the infusion set is shown in Scheme I.

In addition, because of the large amount of drug in the bottle, the tubing could become saturated. Thus, the amount of drug lost from solution is also dependent on the amount of drug present in the tubing. (It was assumed that the rate of absorption is not dependent on the amount remaining to be absorbed, $C_0 - C_T$, but on the amount present, C_T. The results appear to support this assumption.) The differential equations, therefore, describing the rate of change of C_0, C_I, C_S, and C_T are:

$$\frac{dC_T}{dt} = k_2 C_T \quad \text{(Eq. 2)}$$

$$\frac{dC_S}{dt} = k_1 C_I - k_{-1} C_S - k_2 C_T \quad \text{(Eq. 3)}$$

$$\frac{dC_I}{dt} = k_0 C_0 - k_1 C_I - k_3 C_I + k_{-1} C_S \quad \text{(Eq. 4)}$$

$$\frac{dC_0}{dt} = 0 \quad \text{(Eq. 5)}$$

To solve for this model, it must be assumed that the supply of drug in the bottle is infinite, and that the amount of drug and solution delivered through the infusion set is insignificant compared to what remains in the bottle. Solving for Eq. 2, then:

$$C_T = C_{T_0} e^{-k_2 t} \quad \text{(Eq. 6)}$$

where C_{T_0} is the saturation concentration in the tubing. To solve Eq. 3, one needs to consider the total mass balance of drug (D) in that:

$$D_0 = D_I + D_B + D_S + D_T \quad \text{(Eq. 7)}$$

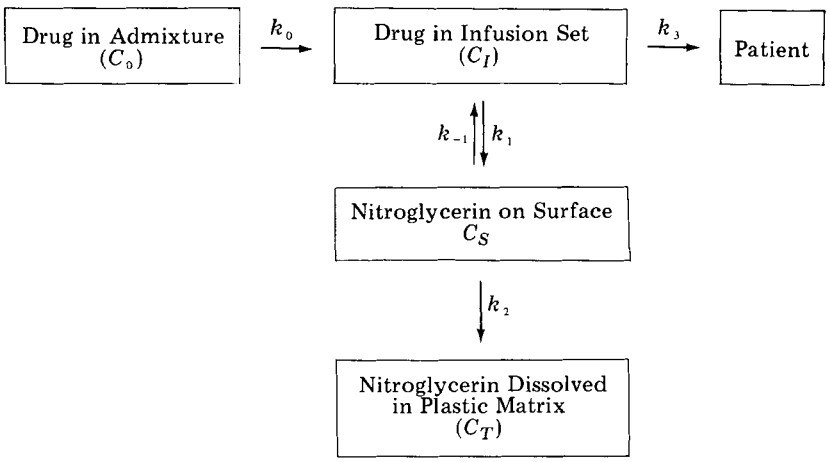
where D_0 is the total amount of drug, D_I is the drug in the infusion set (which includes the amount delivered), D_B is the drug in the bottle, D_S is the drug on the surface of the set, and D_T is the amount of drug in the plastic. Since the assumption was made that the amount of drug in the bottle is in infinite supply, then $D_0 \approx D_B$. Since D is the concentration (C) × volume (V), Eq. 7 can be approximated to be:

$$C_I = -\frac{V_S}{V_T} C_S - \frac{V_T}{V_I} C_T \quad \text{(Eq. 8)}$$

Substituting Eqs. 8 and 6 into Eq. 3, and solving for C_S, one obtains the following solution for C_S:

$$C_S = Ae^{-at} - Ae^{-k_2 t} \quad \text{(Eq. 9)}$$

where



Scheme I

0022-3549/82/0400-0473$01.00/0

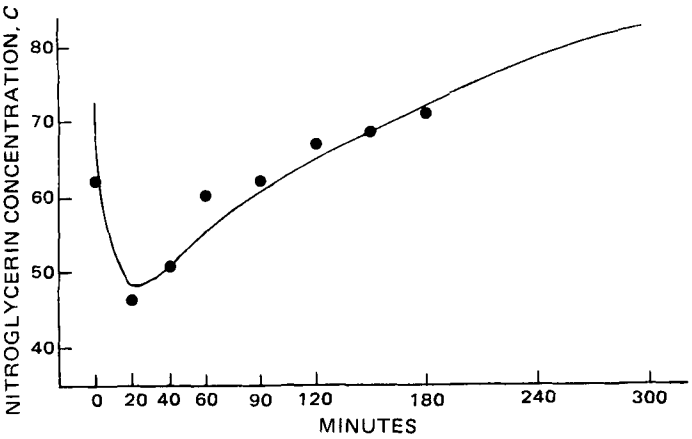


Figure 1—*Nitroglycerin loss: concentration in bottle = 100 μg/ml, flow rate = 1.0 ml/min. Equation describing loss:* $1 - (C/C_0) = 0.327e^{-0.0036t} - 0.270e^{-0.049t} + 1.08e^{-0.91t}$, *where ● is actual data and the smooth curve is computer-fitted data.*

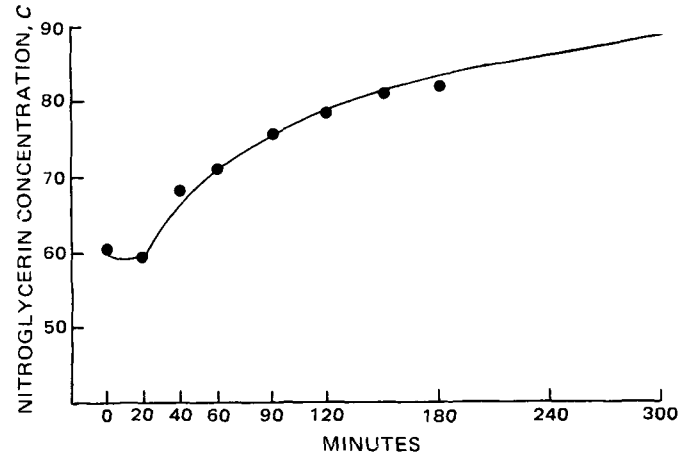

Figure 2—*Nitroglycerin loss: concentration in bottle = 100 μg/ml, flow rate = 0.5 ml/min. Equation describing loss:* $1 - (C/C_0) = 0.201e^{-0.068t} - 0.57e^{-0.004t} + 0.59e^{-0.118t}$, *where ● is actual data and smooth line is computer-fitted data.*

$$A = \frac{k_1 \frac{V_T}{V_I} C_{T_0} + k_2 C_{T_0}}{k_2 - k_{-1} - k_1 \frac{V_S}{V_I}} \qquad \text{(Eq. 10)}$$

and

$$a = k_1 \frac{V_S}{V_I} + k_{-1} \qquad \text{(Eq. 11)}$$

Finally, substituting Eq. 9 into Eq. 4 and solving for C_I:

$$C_I = \frac{k_0 C_0}{k_1 + k_3} - \left(\frac{k_0 C_0}{k_1 + k_3} - \alpha + \beta\right) e^{-(k_1 + k_3)t} + \alpha e^{-at} - \beta e^{-k_2 t} \qquad \text{(Eq. 12)}$$

where

$$\alpha = \frac{k_1 A}{a - k_1 - k_3} \qquad \text{(Eq. 13)}$$

and

$$\beta = \frac{k_1 A}{k_2 - k_1 - k_3} \qquad \text{(Eq. 14)}$$

To further simplify Eq. 12 at the initial phase, prior to adsorption of nitroglycerin, $k_1 = 0$, $k_3 = k_0$, and rearranging Eq. 12:

$$1 - \frac{C_I}{C_0} = \left(\frac{k_0}{k_1 + k_3} - \frac{\alpha + \beta}{C_0}\right) e^{-(k_1 + k_3)t} - \frac{\alpha}{C_0} e^{-at} + \frac{\beta}{C_0} e^{-k_2 t} \qquad \text{(Eq. 15)}$$

The results of the treatment of the infusion data using Eq. 15 is shown in Figs. 1 and 2, using different flow rate conditions. The data were listed using back projection (stripping) technique (2). As predicted by the model, a triexponential loss of nitroglycerin is seen. The model shows that the initial loss is due to adsorption and loss due to infusion, followed by equilibration on the inside surface of the infusion set and, consequently, the rate-limiting adsorption of nitroglycerin by the plastic. The model also shows that when no adsorption/absorption occurs, the concentration of drug delivered is the same as the concentration in the bottle.

All factors affecting nitroglycerin loss have been documented previously for static conditions (1). All these factors apply here, in addition to the loss also being dependent on the flow rate.

General Derivation of the Equation for Time to Reach a Certain Fraction of Steady State

Keyphrases □ Pharmacokinetics—derivation of the equation for time to reach a certain fraction of steady state □ Equations—for time to reach a certain fraction of steady state, derivation

To the Editor:

The time to reach a certain fraction of a given steady-state plasma concentration for a drug which exhibits multiexponential characteristics is not a simple function of the terminal disposition rate constant or half-life. Rather, it is a complex function of all coefficients and disposition rate constants in the equation describing the concentration–time curve. A given fraction of steady state is reached sooner with a drug that demonstrates multiexponential behavior than one that demonstrates monoexponential behavior. Recently, Chiou (1, 2) developed a general equation that permits the estimation of fraction of steady state from area ratios. The derivations were based on the superposition principle, or assume constant rate input of drug into the body. The following appears to be a more general approach for the derivation of the area equation.

0022-3549/82/0400-0474$01.00/0

but the rates and magnitudes of these changes may be different. Careful attention will have to be given to the methodology of *in vitro* drug–protein binding determinations if artifactual results are to be avoided.

The Loss of Nitroglycerin from Intravenous Administration Sets during Infusion: A Theoretical Treatment

Keyphrases □ Nitroglycerin—loss from intravenous administration sets during infusion □ Administration sets—loss of nitroglycerin during infusion

To the Editor:

In a recent report (1), a model was proposed to explain the loss of nitroglycerin from solution into a plastic bag. Under static conditions, the kinetics describing the loss of drug was biexponential and expressed as:

$$A = \beta e^{-k_3 t} + (A_0 - \beta)e^{-k_1 t} \quad \text{(Eq. 1)}$$

where A is the amount of drug in solution, k is the rate of drug absorption onto the surface of the plastic, k_3 is the diffusion of drug into the plastic, A_0 the initial amount of drug in solution, and β is a constant. With plastic bags, Eq. 1 showed an excellent fit to the experimental data.

During the infusion therapy, the above principles apply to large volume parenteral therapy. However, a dynamic situation exists in the infusion set due to the constant flow of solution through the plastic tubing. A model depicting the loss of nitroglycerin from solution when drug is diluted in a glass bottle (no absorption) and allowed to flow through the infusion set is shown in Scheme I.

In addition, because of the large amount of drug in the bottle, the tubing could become saturated. Thus, the amount of drug lost from solution is also dependent on the amount of drug present in the tubing. (It was assumed that the rate of absorption is not dependent on the amount remaining to be absorbed, $C_0 - C_T$, but on the amount present, C_T. The results appear to support this assumption.) The differential equations, therefore, describing the rate of change of C_0, C_I, C_S, and C_T are:

$$\frac{dC_T}{dt} = k_2 C_T \quad \text{(Eq. 2)}$$

$$\frac{dC_S}{dt} = k_1 C_I - k_{-1} C_S - k_2 C_T \quad \text{(Eq. 3)}$$

$$\frac{dC_I}{dt} = k_0 C_0 - k_1 C_I - k_3 C_I + k_{-1} C_S \quad \text{(Eq. 4)}$$

$$\frac{dC_0}{dt} = 0 \quad \text{(Eq. 5)}$$

To solve for this model, it must be assumed that the supply of drug in the bottle is infinite, and that the amount of drug and solution delivered through the infusion set is insignificant compared to what remains in the bottle. Solving for Eq. 2, then:

$$C_T = C_{T_0} e^{-k_2 t} \quad \text{(Eq. 6)}$$

where C_{T_0} is the saturation concentration in the tubing. To solve Eq. 3, one needs to consider the total mass balance of drug (D) in that:

$$D_0 = D_I + D_B + D_S + D_T \quad \text{(Eq. 7)}$$

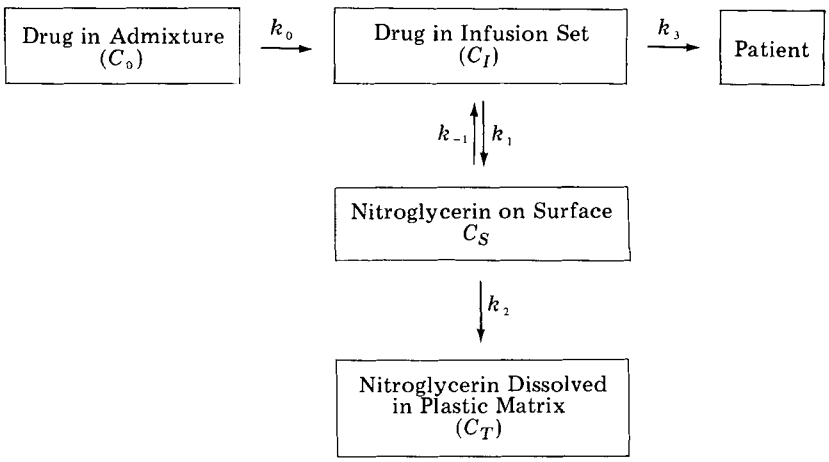
where D_0 is the total amount of drug, D_I is the drug in the infusion set (which includes the amount delivered), D_B is the drug in the bottle, D_S is the drug on the surface of the set, and D_T is the amount of drug in the plastic. Since the assumption was made that the amount of drug in the bottle is in infinite supply, then $D_0 \approx D_B$. Since D is the concentration (C) × volume (V), Eq. 7 can be approximated to be:

$$C_I = -\frac{V_S}{V_T} C_S - \frac{V_T}{V_I} C_T \quad \text{(Eq. 8)}$$

Substituting Eqs. 8 and 6 into Eq. 3, and solving for C_S, one obtains the following solution for C_S:

$$C_S = Ae^{-at} - Ae^{-k_2 t} \quad \text{(Eq. 9)}$$

where



Scheme I

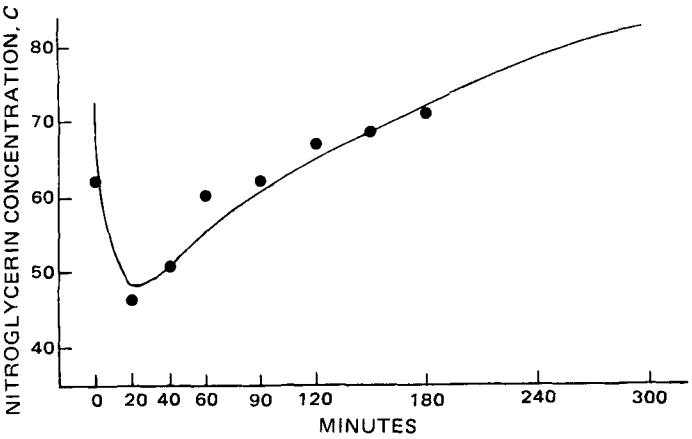

Figure 1—*Nitroglycerin loss: concentration in bottle = 100 μg/ml, flow rate = 1.0 ml/min. Equation describing loss:* $1 - (C/C_0) = 0.327e^{-0.0036t} - 0.270e^{-0.049t} + 1.08e^{-0.91t}$, *where ● is actual data and the smooth curve is computer-fitted data.*

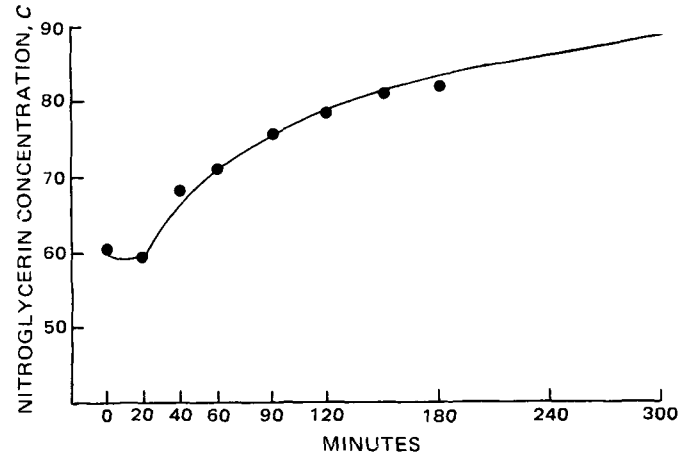

Figure 2—*Nitroglycerin loss: concentration in bottle = 100 μg/ml, flow rate = 0.5 ml/min. Equation describing loss:* $1 - (C/C_0) = 0.201e^{-0.068t} - 0.57e^{-0.004t} + 0.59e^{-0.118t}$, *where ● is actual data and smooth line is computer-fitted data.*

$$A = \frac{k_1 \frac{V_T}{V_I} C_{T_0} + k_2 C_{T_0}}{k_2 - k_{-1} - k_1 \frac{V_S}{V_I}} \qquad \text{(Eq. 10)}$$

and

$$a = k_1 \frac{V_S}{V_I} + k_{-1} \qquad \text{(Eq. 11)}$$

Finally, substituting Eq. 9 into Eq. 4 and solving for C_I:

$$C_I = \frac{k_0 C_0}{k_1 + k_3} - \left(\frac{k_0 C_0}{k_1 + k_3} - \alpha + \beta\right) e^{-(k_1 + k_3)t} + \alpha e^{-at} - \beta e^{-k_2 t} \qquad \text{(Eq. 12)}$$

where

$$\alpha = \frac{k_1 A}{a - k_1 - k_3} \qquad \text{(Eq. 13)}$$

and

$$\beta = \frac{k_1 A}{k_2 - k_1 - k_3} \qquad \text{(Eq. 14)}$$

To further simplify Eq. 12 at the initial phase, prior to adsorption of nitroglycerin, $k_1 = 0$, $k_3 = k_0$, and rearranging Eq. 12:

$$1 - \frac{C_I}{C_0} = \left(\frac{k_0}{k_1 + k_3} - \frac{\alpha + \beta}{C_0}\right) e^{-(k_1 + k_3)t} - \frac{\alpha}{C_0} e^{-at} + \frac{\beta}{C_0} e^{-k_2 t} \qquad \text{(Eq. 15)}$$

The results of the treatment of the infusion data using Eq. 15 is shown in Figs. 1 and 2, using different flow rate conditions. The data were listed using back projection (stripping) technique (2). As predicted by the model, a triexponential loss of nitroglycerin is seen. The model shows that the initial loss is due to adsorption and loss due to infusion, followed by equilibration on the inside surface of the infusion set and, consequently, the rate-limiting adsorption of nitroglycerin by the plastic. The model also shows that when no adsorption/absorption occurs, the concentration of drug delivered is the same as the concentration in the bottle.

All factors affecting nitroglycerin loss have been documented previously for static conditions (1). All these factors apply here, in addition to the loss also being dependent on the flow rate.

General Derivation of the Equation for Time to Reach a Certain Fraction of Steady State

Keyphrases □ Pharmacokinetics—derivation of the equation for time to reach a certain fraction of steady state □ Equations—for time to reach a certain fraction of steady state, derivation

To the Editor:

The time to reach a certain fraction of a given steady-state plasma concentration for a drug which exhibits multiexponential characteristics is not a simple function of the terminal disposition rate constant or half-life. Rather, it is a complex function of all coefficients and disposition rate constants in the equation describing the concentration–time curve. A given fraction of steady state is reached sooner with a drug that demonstrates multiexponential behavior than one that demonstrates monoexponential behavior. Recently, Chiou (1, 2) developed a general equation that permits the estimation of fraction of steady state from area ratios. The derivations were based on the superposition principle, or assume constant rate input of drug into the body. The following appears to be a more general approach for the derivation of the area equation.

General Derivation of the Equation for Time to Reach a Certain Fraction of Steady State

Keyphrases □ Pharmacokinetics—derivation of the equation for time to reach a certain fraction of steady state □ Equations—for time to reach a certain fraction of steady state, derivation

To the Editor:

The time to reach a certain fraction of a given steady-state plasma concentration for a drug which exhibits multiexponential characteristics is not a simple function of the terminal disposition rate constant or half-life. Rather, it is a complex function of all coefficients and disposition rate constants in the equation describing the concentration–time curve. A given fraction of steady state is reached sooner with a drug that demonstrates multiexponential behavior than one that demonstrates monoexponential behavior. Recently, Chiou (1, 2) developed a general equation that permits the estimation of fraction of steady state from area ratios. The derivations were based on the superposition principle, or assume constant rate input of drug into the body. The following appears to be a more general approach for the derivation of the area equation.

0022-3549/82/0400-0474$01.00/0

The plasma concentration (C) *versus* time (t) curve for a drug obeying linear kinetics can be described by:

$$C = \sum_{l=1}^{n} A_l e^{-\lambda_l t} \quad \text{(Eq. 1)}$$

following a single dose, or by:

$$C_N = \sum_{l=1}^{n} A_l \left(\frac{1 - e^{-N\lambda_l \tau}}{1 - e^{-\lambda_l \tau}}\right) e^{-\lambda_l t} \quad \text{(Eq. 2)}$$

following the administration of multiple doses at a fixed time interval of τ. In Eq. 2, C_N is the plasma concentration during a dosing interval at any time following the Nth dose. Once steady state is achieved, the concentration (C_{ss}) is given by:

$$C_{ss} = \sum_{l=1}^{n} A_l \left(\frac{1}{1 - e^{-\lambda_l \tau}}\right) e^{-\lambda_l t} \quad \text{(Eq. 3)}$$

The fraction of the steady-state concentration (f_{ss}) can be defined as the ratio of the average plasma concentration during the Nth dosing interval ($\overline{C}_N$) to the average plasma concentration at steady state ($\overline{C}$), that is:

$$f_{ss} = \overline{C}_N / \overline{C} \quad \text{(Eq. 4)}$$

where

$$\overline{C}_N = AUC_N / \tau \quad \text{(Eq. 5)}$$

and

$$\overline{C} = AUC / \tau \quad \text{(Eq. 6)}$$

AUC_N and AUC are the areas under the plasma concentration–time curves during the Nth dosing interval and at steady state, *i.e.* $\int_0^\tau C_N\,dt$ and $\int_0^\tau C_{ss}\,dt$, respectively. Integrating Eqs. 2 and 3 from time zero to τ, substituting these values for AUC_N and AUC in Eqs. 5 and 6, and solving for f_{ss} in Eq. 4 using the resulting values for $\overline{C}_N$ and $\overline{C}$ yields:

$$f_{ss} = \frac{\sum_{l=1}^{n} A_l (1 - e^{-N\lambda_l \tau})/\lambda_l}{\sum_{l=1}^{n} A_l/\lambda_l} \quad \text{(Eq. 7)}$$

This relationship for f_{ss} can be expanded to give

$$f_{ss} = \frac{\sum_{l=1}^{n} A_l/\lambda_l - \sum_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l}{\sum_{l=1}^{n} A_l/\lambda_l} \quad \text{(Eq. 8)}$$

The total area under a plasma concentration *versus* time curve following a single dose of a drug equals $\Sigma_{l=1}^{n} A_l/\lambda_l$ (*i.e.*, the integral of Eq. 1), therefore,

$$f_{ss} = \frac{AUC - \sum_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l}{AUC} \quad \text{(Eq. 9)}$$

Furthermore, the integral of Eq. 1 from time t to ∞ provides an expression for the area under a plasma concentration *versus* time curve following a single dose from time t to ∞, AUC_t^∞:

$$AUC_t^\infty \sum_{l=1}^{n} A_l e^{-\lambda_l t}/\lambda_l \quad \text{(Eq. 10)}$$

Because $N\tau$ in Eq. 9 equals the time since the beginning of dosing, *i.e.*, t, AUC_t^∞ can be substituted for $\Sigma_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l$ in Eq. 9 to yield:

$$f_{ss} = \frac{AUC - AUC_t^\infty}{AUC} = \frac{AUC_0^t}{AUC} \quad \text{(Eq. 11)}$$

Therefore, the fraction of steady state reached at time t after initiation of a multiple dosing regimen can be determined by knowing the areas, AUC and AUC_t^∞ or AUC_0^t obtained from a single dose of the drug. No model has to be assumed to permit the use of Eq. 11 for determining f_{ss}.

Hypotensive Activity of *Cecropia obtusifolia*

Keyphrases □ *Cecropia obtusifolia*—ethanol extract, hypotensive activity □ Hypotensive activity—effect of *Cecropia obtusifolia*, ethanol extract

To the Editor:

Cecropia obtusifolia Bertol is a medium-sized tree of the Moraceae family which grows wild in the tropical areas of Mexico. In the traditional medicine of tropical America, different species of *Cecropia* have been credited with a variety of therapeutic properties, such as antitussive, anti-inflammatory, and antidiarrhetic. Since the beneficial effects of extracts of *Cecropia* leaves in the treatment of heart failure were documented in a clinical study (1), it seemed of interest to determine the cardiovascular effects of *C. obtusifolia* in view of its widespread distribution in Mexico.

The material investigated[1] was collected in the area of the botanical station of Los Tuxtlas operated by the Institute of Biology of the University of Mexico and located in the Gulf coast state of Veracruz. Two kilograms of the leaves were ground and extracted with hexane in a Soxhlet apparatus. The residue was then treated with ethanol and the resulting extract dried by lyophilization. One portion of the 104-g extract was used for pharmacological studies; the other for further extraction [shown previously (2)]. The results of this work, which led to the isolation and identification of two compounds, will be reported elsewhere.

The cardiovascular activity of the extract was determined in male Wistar rats anesthetized with a 1.8 g/kg ip dose of urethane. Blood pressure and heart rate were recorded continuously, the former with a transducer connected to a cannulated femoral artery and the latter with a tachograph triggered by the pressure pulse. The extract was dissolved in propylene glycol and diluted with isotonic saline to a final concentration of 10 mg/ml, resulting in a

[1] The plant material used in this investigation was identified as *Cecropia obtusifolia* Bertol (Moraceae) by J. I. Calzada, Institute of Biology, National University of Mexico. A specimen (Number MEXU-237314) representing material collected for this investigation is available for inspection at the Herbarium of the Institute of Biology, National University of Mexico.

The plasma concentration (C) *versus* time (t) curve for a drug obeying linear kinetics can be described by:

$$C = \sum_{l=1}^{n} A_l e^{-\lambda_l t} \quad \text{(Eq. 1)}$$

following a single dose, or by:

$$C_N = \sum_{l=1}^{n} A_l \left(\frac{1 - e^{-N\lambda_l \tau}}{1 - e^{-\lambda_l \tau}}\right) e^{-\lambda_l t} \quad \text{(Eq. 2)}$$

following the administration of multiple doses at a fixed time interval of τ. In Eq. 2, C_N is the plasma concentration during a dosing interval at any time following the Nth dose. Once steady state is achieved, the concentration (C_{ss}) is given by:

$$C_{ss} = \sum_{l=1}^{n} A_l \left(\frac{1}{1 - e^{-\lambda_l \tau}}\right) e^{-\lambda_l t} \quad \text{(Eq. 3)}$$

The fraction of the steady-state concentration (f_{ss}) can be defined as the ratio of the average plasma concentration during the Nth dosing interval ($\overline{C}_N$) to the average plasma concentration at steady state ($\overline{C}$), that is:

$$f_{ss} = \overline{C}_N / \overline{C} \quad \text{(Eq. 4)}$$

where

$$\overline{C}_N = AUC_N / \tau \quad \text{(Eq. 5)}$$

and

$$\overline{C} = AUC / \tau \quad \text{(Eq. 6)}$$

AUC_N and AUC are the areas under the plasma concentration–time curves during the Nth dosing interval and at steady state, *i.e.* $\int_0^\tau C_N\,dt$ and $\int_0^\tau C_{ss}\,dt$, respectively. Integrating Eqs. 2 and 3 from time zero to τ, substituting these values for AUC_N and AUC in Eqs. 5 and 6, and solving for f_{ss} in Eq. 4 using the resulting values for $\overline{C}_N$ and $\overline{C}$ yields:

$$f_{ss} = \frac{\sum_{l=1}^{n} A_l (1 - e^{-N\lambda_l \tau})/\lambda_l}{\sum_{l=1}^{n} A_l/\lambda_l} \quad \text{(Eq. 7)}$$

This relationship for f_{ss} can be expanded to give

$$f_{ss} = \frac{\sum_{l=1}^{n} A_l/\lambda_l - \sum_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l}{\sum_{l=1}^{n} A_l/\lambda_l} \quad \text{(Eq. 8)}$$

The total area under a plasma concentration *versus* time curve following a single dose of a drug equals $\Sigma_{l=1}^{n} A_l/\lambda_l$ (*i.e.*, the integral of Eq. 1), therefore,

$$f_{ss} = \frac{AUC - \sum_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l}{AUC} \quad \text{(Eq. 9)}$$

Furthermore, the integral of Eq. 1 from time t to ∞ provides an expression for the area under a plasma concentration *versus* time curve following a single dose from time t to ∞, AUC_t^∞:

$$AUC_t^\infty \sum_{l=1}^{n} A_l e^{-\lambda_l t}/\lambda_l \quad \text{(Eq. 10)}$$

Because $N\tau$ in Eq. 9 equals the time since the beginning of dosing, *i.e.*, t, AUC_t^∞ can be substituted for $\Sigma_{l=1}^{n} A_l e^{-N\lambda_l \tau}/\lambda_l$ in Eq. 9 to yield:

$$f_{ss} = \frac{AUC - AUC_t^\infty}{AUC} = \frac{AUC_0^t}{AUC} \quad \text{(Eq. 11)}$$

Therefore, the fraction of steady state reached at time t after initiation of a multiple dosing regimen can be determined by knowing the areas, AUC and AUC_t^∞ or AUC_0^t obtained from a single dose of the drug. No model has to be assumed to permit the use of Eq. 11 for determining f_{ss}.

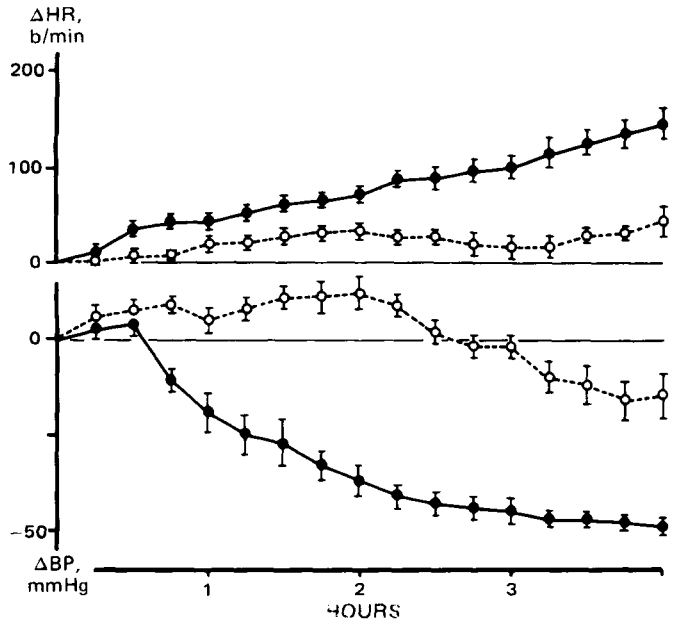

Figure 1—*Influence of a lyophilized ethanol extract of leaves of* Cecropia obtusifolia *on the blood pressure and heart rate of anesthetized rats. Also shown are the changes in these parameters observed in animals receiving the vehicle (15% propylene glycol). Circles correspond to means of six experiments; vertical lines denote standard errors. Key: (●—●) extract, 10 mg/kg; (○- - -○) vehicle.*

propylene glycol concentration of 15%. Groups of six rats received the extract at intravenous doses of 3.1, 10, or 31 mg/kg; an additional group received the vehicle.

The dose of 10 mg/kg produced a slowly developing fall in blood pressure, which began 45 min after injection and reached a maximum at ~3 hr (Fig. 1). This was accompanied by a progressive increase in heart rate. Rats receiving the vehicle showed a slight tachycardia and a decrease in blood pressure toward the end of the 4-hr observation period. The 31-mg/kg dose (not shown) produced a virtually identical hypotensive response and a smaller rise in heart rate; the 3.1-mg/kg dose (not shown) elicited changes similar to those seen in the vehicle-treated animals.

The blood pressure-lowering effect of relatively low doses of lyophilized ethanol extracts of *C. obtusifolia* leaves is interesting in view of its delayed onset and long duration. Such characteristics are theoretically desirable in an agent potentially useful in the treatment of arterial hypertension. Studies are continuing to confirm this effect in more suitable models of hypertension and to identify the active principle involved.

Effect of Propylene Glycol on Subcutaneous Absorption of a Benzimidazole Hydrochloride

Keyphrases □ Propylene glycol—effect on subcutaneous absorption of a benzimidazole hydrochloride □ Absorption, subcutaneous—effect of propylene glycol on subcutaneous absorption of a benzimidazole hydrochloride □ Pharmacokinetics—effect of propylene glycol on subcutaneous absorption of a benzimidazole hydrochloride

To the Editor:

In the field of parenteral preparations, several water-miscible nonaqueous solvents are known to enhance either the stability or solubility of certain drugs. Reviews on the subject are available (1, 2). A third use of these nonaqueous solvents is to alter the absorption rate of the drug from the injection site. Absorption rates of several intramuscularly administered drugs were shown to decrease when the ethanol content of each preparation increased (3). This inhibitory effect was attributed to the combined effects of an increased viscosity of the vehicle and a decreased connective tissue permeability in the presence of ethanol (3). In systems involving propylene glycol, glycerin, or polyethylene glycol 400 as a cosolvent, the viscosity increased was found to be solely responsible for absorption rate reduction of intramuscularly administered isonicotinamide (4). A similar viscosity effect was revealed from a comparison of the duration of action of a prostaglandin administered subcutaneously to beagles in polyethylene glycol 400 and in water (5). However, these past studies investigated only nonionic drugs. Yet, many parenteral drugs are soluble salts of weak acids or weak bases. Very little is known about how the water-miscible nonaqueous solvents might affect the absorption rate of a drug delivered in a salt form. This communication reports the effect of propylene glycol on the subcutaneous absorption of a benzimidazole hydrochloride, 5(6)-isobutylsulfinyl-2-carbomethoxyaminobenzimidazole hydrochloride (I).

An aqueous solution and a propylene glycol–water (1:1) solution of 2-^{14}C-I (1.01 μCi/mg) were made with distilled water and propylene glycol, USP, at 100 mg/ml equivalent to the free base of I. The propylene glycol solutions of 2-^{14}C-I were made at 50 and 75 mg/ml. These solutions were administered subcutaneously to six heifers at 5 mg/kg free base equivalent. The two propylene glycol solutions, 50 and 75 mg/ml, were administered to groups 1 and 2, three heifers in each group, respectively. On the eighth day postinjection, the same groups 1 and 2 were administered the propylene glycol–water solution and the aqueous solution, respectively. In all cases, blood was drawn periodically into heparinized tubes following each administration. Plasma was obtained immediately after collection and frozen until analyzed. Total radioactivity in the plasma was determined by liquid scintillation counting[1]. The results are reported as free base equivalents (Fig. 1). Each point represents a mean plasma concentration of three animals. Vertical bars represent the standard error of each mean.

Figure 1 exhibits an apparent trend of relative absorption rate in the decreasing order for the four injections tested: 75 mg/ml propylene glycol solution >50 mg/ml

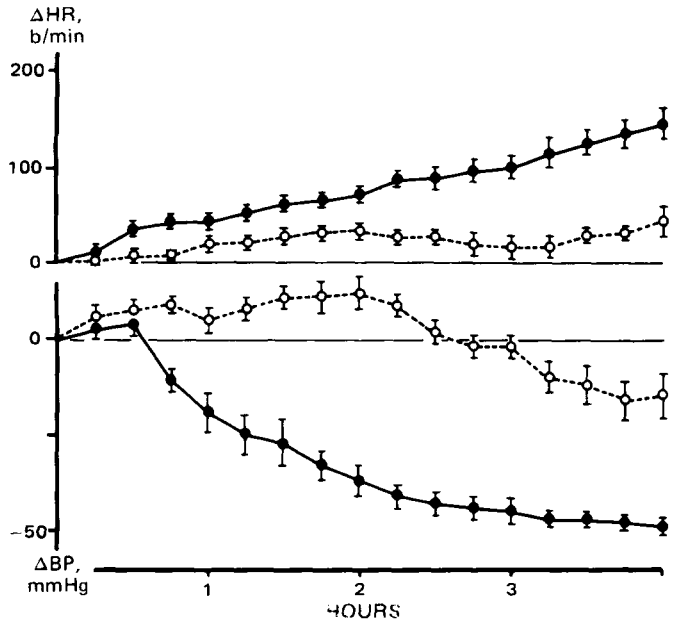

Figure 1—*Influence of a lyophilized ethanol extract of leaves of* Cecropia obtusifolia *on the blood pressure and heart rate of anesthetized rats. Also shown are the changes in these parameters observed in animals receiving the vehicle (15% propylene glycol). Circles correspond to means of six experiments; vertical lines denote standard errors. Key: (●—●) extract, 10 mg/kg; (○- - -○) vehicle.*

propylene glycol concentration of 15%. Groups of six rats received the extract at intravenous doses of 3.1, 10, or 31 mg/kg; an additional group received the vehicle.

The dose of 10 mg/kg produced a slowly developing fall in blood pressure, which began 45 min after injection and reached a maximum at ~3 hr (Fig. 1). This was accompanied by a progressive increase in heart rate. Rats receiving the vehicle showed a slight tachycardia and a decrease in blood pressure toward the end of the 4-hr observation period. The 31-mg/kg dose (not shown) produced a virtually identical hypotensive response and a smaller rise in heart rate; the 3.1-mg/kg dose (not shown) elicited changes similar to those seen in the vehicle-treated animals.

The blood pressure-lowering effect of relatively low doses of lyophilized ethanol extracts of *C. obtusifolia* leaves is interesting in view of its delayed onset and long duration. Such characteristics are theoretically desirable in an agent potentially useful in the treatment of arterial hypertension. Studies are continuing to confirm this effect in more suitable models of hypertension and to identify the active principle involved.

Effect of Propylene Glycol on Subcutaneous Absorption of a Benzimidazole Hydrochloride

Keyphrases □ Propylene glycol—effect on subcutaneous absorption of a benzimidazole hydrochloride □ Absorption, subcutaneous—effect of propylene glycol on subcutaneous absorption of a benzimidazole hydrochloride □ Pharmacokinetics—effect of propylene glycol on subcutaneous absorption of a benzimidazole hydrochloride

To the Editor:

In the field of parenteral preparations, several water-miscible nonaqueous solvents are known to enhance either the stability or solubility of certain drugs. Reviews on the subject are available (1, 2). A third use of these nonaqueous solvents is to alter the absorption rate of the drug from the injection site. Absorption rates of several intramuscularly administered drugs were shown to decrease when the ethanol content of each preparation increased (3). This inhibitory effect was attributed to the combined effects of an increased viscosity of the vehicle and a decreased connective tissue permeability in the presence of ethanol (3). In systems involving propylene glycol, glycerin, or polyethylene glycol 400 as a cosolvent, the viscosity increased was found to be solely responsible for absorption rate reduction of intramuscularly administered isonicotinamide (4). A similar viscosity effect was revealed from a comparison of the duration of action of a prostaglandin administered subcutaneously to beagles in polyethylene glycol 400 and in water (5). However, these past studies investigated only nonionic drugs. Yet, many parenteral drugs are soluble salts of weak acids or weak bases. Very little is known about how the water-miscible nonaqueous solvents might affect the absorption rate of a drug delivered in a salt form. This communication reports the effect of propylene glycol on the subcutaneous absorption of a benzimidazole hydrochloride, 5(6)-isobutylsulfinyl-2-carbomethoxyaminobenzimidazole hydrochloride (I).

An aqueous solution and a propylene glycol–water (1:1) solution of 2-^{14}C-I (1.01 μCi/mg) were made with distilled water and propylene glycol, USP, at 100 mg/ml equivalent to the free base of I. The propylene glycol solutions of 2-^{14}C-I were made at 50 and 75 mg/ml. These solutions were administered subcutaneously to six heifers at 5 mg/kg free base equivalent. The two propylene glycol solutions, 50 and 75 mg/ml, were administered to groups 1 and 2, three heifers in each group, respectively. On the eighth day postinjection, the same groups 1 and 2 were administered the propylene glycol–water solution and the aqueous solution, respectively. In all cases, blood was drawn periodically into heparinized tubes following each administration. Plasma was obtained immediately after collection and frozen until analyzed. Total radioactivity in the plasma was determined by liquid scintillation counting[1]. The results are reported as free base equivalents (Fig. 1). Each point represents a mean plasma concentration of three animals. Vertical bars represent the standard error of each mean.

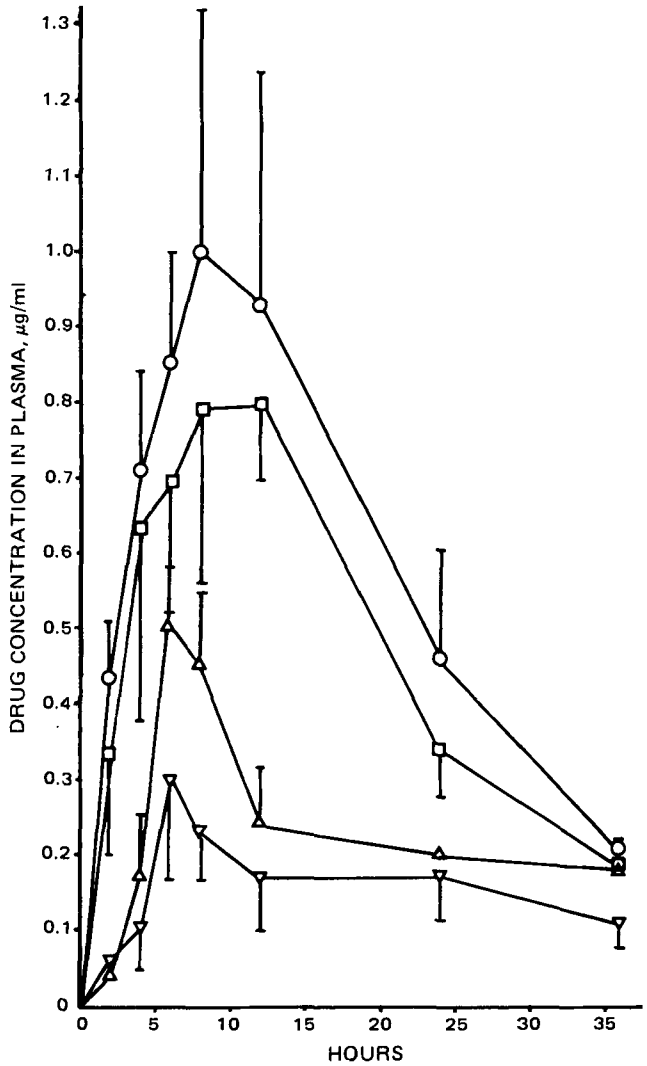

Figure 1—*Plasma concentration of I in heifers. Key: ○, 75 mg/ml propylene glycol solution; □, 50 mg/ml propylene glycol solution; △, 100 mg/ml propylene glycol–water (1:1) solution; and ▽, 100 mg/ml aqueous solution.*

propylene glycol solution >100 mg/ml propylene glycol–water (1:1) solution >100 mg/ml aqueous solution. The absorption rate difference between the two propylene glycol solutions revealed that concentration and/or injection volume had some effect on the subcutaneous absorption of I. Since the dose was kept constant, the injection volume varied inversely with the concentration. For a given increase in the injection volume, there exists a disproportionate ratio between increase in surface area and the increased volume. Therefore, from the passive diffusion standpoint, the smaller the injection volume, the faster the absorption. Atropine (6), sodium ion (7), sugars (8), testosterone (9), and aminoglycosides (10) were all found to be absorbed more rapidly when the compounds were administered in smaller injection volumes. This injection volume effect has been reviewed previously in review articles on intramuscular and subcutaneous injections (11, 12). The injection volume effect appears to be responsible for the rate difference between the absorption of I from the two propylene glycol solutions. However, the effect is ambiguous when the dose volume is relatively small. It was reported (4, 13, 14) that the intramuscular

Table I—Pharmacokinetic and Physicochemical Parameters of the Solutions Investigated

Solutions[a]	C_{max}, μg/ml	AUC, μg/ml hr	1/Viscosity,[b] cp^{-1}	Solubilities, mg/ml I	Solubilities, mg/ml Free Base
A	1.03 ± 0.30	21.29 ± 5.71	0.04	89.9	21.7
B	0.89 ± 0.19	17.10 ± 3.25	0.04	89.9	21.7
C	0.50 ± 0.14	8.60 ± 2.34	0.25	130.0	4.17
D	0.30 ± 0.08	5.61 ± 2.15	1.45	v. soluble	0.44

[a] A = 75 mg/ml propylene glycol solution of I; B = 50 mg/ml propylene glycol solution of I; C = 100 mg/ml propylene glycol-water (1:1) solution of I; D = 100 mg/ml aqueous solution of I. [b] From ref. 4.

absorption of isonicotinamide was independent of the injection volume which ranged from 5 to 20 μl. It was postulated that the effective absorption area might not vary in the case of small injection volume ranging from 5 to 20 μl. In yet another case, a reversed relationship between the injection volume and the absorption rate of I was observed in rabbits that were injected subcutaneously 0.5, 1.0, and 2.0 ml of a propylene glycol solution of I (15). The authors attributed this deviation from the result predicted by diffusion controlled absorption to the precipitation of I at the interface of the injected solution and surrounding tissue.

From the plasma concentration curves shown in Fig. 1, the following can be observed: the drug is absorbed faster from the propylene glycol solution than from the aqueous solution, the absorption rate of I from the propylene glycol–water solution is intermediate between those from the propylene glycol and the aqueous solution. These results at first may seem paradoxical to the previous finding (4) that propylene glycol, *via* its contribution to vehicle viscosity, inhibits intramuscular absorption. One could speculate that factors affecting intramuscular absorption might not be applicable to subcutaneous absorption. Nevertheless, the viscosity effect on subcutaneous absorption was shown to be operative for polyethylene glycol 400 solution of a prostaglandin (5). The paradox might be explained by the following analysis. Table I summarizes the maximum plasma concentration (C_{max}) and the area under the concentration–time curve (AUC) for the curves shown in Fig. 1. Also listed are solubilities of I and its free base in the respective vehicles. From Table I it appears that both C_{max} and AUC can be correlated to the free base solubility. Because the pKa and the aqueous solubility of I are low (3.4 and 0.44 mg/ml, respectively), it is likely that I is converted to its free base and precipitated to some degree at the injection site due to the infiltration of tissue fluid that has a pH of 6.0 (12). Consequently, the higher the free base solubility in the vehicle, the more available the drug for absorption. In the case of propylene glycol injection, the ionized drug concentration will decrease due to neutralization; however, the free base species would be maintained because of the relatively high solubility of the free base in propylene glycol. In the case of the aqueous injection, both the salt species and the free base species would decrease because of neutralization and precipitation. The change in drug solubility is apparently the predominant factor governing the absorption rate of I in the present study. Therefore, absorption of I by subcutaneous injection is enhanced, rather than inhibited, by propylene glycol.

Antitumor Agents Based on Natural Product Models. Edited by JOHN M. CASSADY and JOHN D. DOUROS. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 500 pp. 15 × 23 cm.

This text is volume 16 of *Medicinal Chemistry, A Series of Monographs*. The emphasis of the book is on lead or novel antineoplastic agents, structure–activity relationships, modes of action, and toxicology of natural products. The choice of agents which is discussed in the monograph is rational and appropriate for the scope of the text. The book serves the purpose of assimilating diverse topics on natural product antineoplastic agents of clinical importance. In general, the text is well-written, concise and well-referenced, and includes pertinent structures, synthetic schemes, and biological data. The text is written with emphasis on the current development or status of a given group of agents and states scientific areas where further development is required.

The book is divided in the following contributions by individual authors:

Chapter 1, "The Development of New Antitumor Anthracyclines" (F. Arcamone), details the basic chemical modifications at the C-9, C-13, and C-14 of the amino sugar residue and of the chromophore of anthraquinone comparing the antitumor activity against HeLa cell, L-1210, P-388, and gross leukemia growth.

Chapter 2, "Trichothecanes" (T. W. Doyle and W. T. Bradner), discusses the history, mechanism of action, toxicity, metabolism, bioassay, cytotoxicity, and structure–activity relationships for antitumor activity in the P-388, L-1210, and B-16 tumor models.

Chapter 3, "Nucleosides" (M. Ohno), summarizes the structure–activity relationships of C- and N-pyrimidine nucleosides required to block the growth of tumors, bacteria, and viruses as evaluated by several investigators.

Chapter 4, "Mitomycins" (W. A. Remers), relates the history, chemical properties, mode of action, and structure–activity relationships for antibacterial and antitumor activity in the L-1210 and P-388 tumors, and the newly synthetic analogues of mitomycin.

Chapter 5, "Recent Progress in Bleomycin Studies" (H. Umezawa), deals with the chemistry and biosynthesis of bleomycin and phleomycin, including a revised structure of bleomycin, copper and iron complexes of bleomycin, the mechanism of action against squamous cell carcinomas, and other therapeutic uses of the agents.

Chapter 6, "Streptozocin" (P. F. Wiley), reviews the fermentation and isolation processes of streptozocin from bacterial cultures, its pharmacology, toxicology, carcinogenicity, mutagenicity, antibacterial, and antineoplastic modes of action, chemical studies, and the structure–activity relationships of several analogues.

Chapter 7, "Terpenoid Antitumor Agents" (J. M. Cassady and M. Suffness), correlates the structures, possible modes of action, and structure–activity relationships in the KB cytotoxicity screen of NCI of mono- and sesquiterpenes, diterpenes, bufadienolides, cardenolides, with anolides, cucurbitacins, and quassinoids.

Chapter 8, "Dimeric Catharanthus Alkaloids" (K. Gerzon), surveys the history, clinical observations, assay methods, mode of action, toxicity, polarity, and structure–activity relationships of vinblastine and vincristine, including a discussion of chemical modification of vinblastine.

Chapter 9, "Podophyllotoxins" (I. Jardine), discusses the history, clinical aspects, structures and chemical synthesis, and modes of action of podophyllotoxins, VM26, VP16-213, and steganacin against the P-815 mastocytoma and L-1210 leukemia cell growth.

Chapter 10, "Maytansinoids" (Y. Komoda and T. Kishi), reviews the isolation of natural and chemical synthesis of novel derivatives of maytansinoids and antitumor activity, toxicity, and effects on cellular growth and biochemical parameters.

Chapter 11, "Harringtonine and Related Cephalotaxine Esters" (C. R. Smith, Jr., K. L. Mikolajczak, and R. G. Powell), relates the characteristics, configuration, and antineoplastic activity of cephalotaxine and its esters. Total synthesis of cephalotaxine, chemical conversion to its naturally occurring esters, biosynthesis of ester analogues and structure–activity relationship against P-388 and L-1210 tumor growth are reviewed.

Chapter 12, "Camptothecin" (M. E. Wall and M. C. Wani), covers the naturally occurring, total and semisynthesized camptothecin analogues, antitumor activity, effects on RNA and DNA components of the cell, and structure–activity relationships.

Chapter 13, "Microbial Transformation as an Approach to Analogue Development" (J. P. Rosazza), offers a general discussion of the use of microorganisms to transform metabolic compounds to new, highly active antitumor agents. Examples used for transformation include bacterial and plant natural products and miscellaneous agents.

Chapter 14, "Miscellaneous Natural Products With Antitumor Activity" (M. Suffness and J. Douros), surveys a series of antitumor agents

Terpenoids and Steroids, Vol. 10. Senior Reporter, J. R. HANSON. The Royal Society of Chemistry, Burlington House, London W1V 0BN, England. 1981. 284 pp. 15 × 22 cm. (Available from: Special Issues Sales, American Chemical Society, 1155 16th Street, N.W., Washington, DC 20036.)

This is the 10th volume on terpenoids and steroids in the valuable series first published 11 years ago. The aim of the series is to provide systematic, comprehensive, and critical reviews of progress in the major areas of chemical research. This volume reviews literature published between September 1978 and August 1979.

Volume 10 does not contain a subject index but is organized in a systematic manner that facilitates the location of information. There is also an extensive author index which is helpful to those following the research of a given individual. The book contains 1700 chemical structures and is documented with 1900 references, conveniently listed on the page of each chapter where first noted.

Part I, which covers the terpenoids, is divided into chapters that include sesquiterpenoids, diterpenoids, triterpenoids, and carotenoids and polyterpenoids. Chapters on monoterpenoids and the biosynthesis of terpenoids and steroids, unlike many of the earlier volumes, are not included. The chapter on monoterpenoids will be included in the next volume.

Part II, which covers the steroids, is divided into two chapters. The chapter on physical methods includes sections on structure and conformation, NMR spectroscopy, chiroptical phenomenon, mass spectrometry, miscellaneous physical properties, and analytical methods. The chapter on steroid reactions and partial syntheses contains sections devoted to each of these topics.

The first section is divided topically according to the more common functional groups and such important subjects as molecular rearrangements, functionalization of nonactivated positions, and photochemical reactions. The second section on partial syntheses, covers cholestane derivatives, vitamin D and its metabolites, pregnanes, androstanes and oestranes, cardenolides, heterocyclic steroids, and microbiological oxidations.

An unusual variety of terpenoid structures, particularly from insect and marine sources, has been included in this volume. The sharp increase in the use of high-field ^{1}H-NMR and ^{13}C-NMR is evident in this review.

The six reporters who prepared this volume are to be commended for maintaining the high standards set by the previous volumes in this series. Everyone interested in the chemistry of terpenoids and/or steroids should have access to this volume and the others in the series.

Lexikon der Hilfsstoffe für Pharmazie, Kosmetik und angrenzende Gebiete. By HERBERT P. FIEDLER, Editio Cantor Aulendorf, D-7960 Aulendorf, West Germany, 2 Volumes, 1081 pp., 17 × 24 cm., 1981, Price: 245 DM.

In view of the scarcity of textbooks dealing exclusively with excipients, the revised and expanded edition of the Lexikon der Hilfsstoffe is a timely contribution to the reference libraries of pharmaceutical companies, regulatory agencies, and schools of pharmacy. Comparison of the contents with the original one-volume edition published in 1970 demonstrates the evolution of a broader and more critical attitude toward available technical information on excipients.

The author has provided a series of tables listing specific physical properties of excipients, types of surfactants used in pharmaceutical or cosmetic preparations, HLB values, MAC (maximum workplace concentration) values, colorants suitable for cosmetic preparations, and a table of the German and English titles of selected excipients together with their Merck Index and Chemical Abstracts Registry Numbers where appropriate.

The main body of the text lists excipients in alphabetical order with information on their physical, chemical, and biological properties. There is considerable variation in coverage between excipients, which reflects the author's judgment or the extent of information available to him. It is clear that Dr. Fiedler has made a special effort to make these volumes useful to English-speaking pharmaceutical scientists. However, the construction of some of the interminable German sentences may create impatience in readers with a limited knowledge of the language.

As far as this reviewer knows, no similarly detailed encyclopedia of excipients has appeared in the English language. Until this gap is properly filled, the *Lexikon der Hilfsstoffe* will remain a valuable source book for pharmaceutical scientists engaged in dosage form design, production, and control.

USAN and the USP Dictionary of Drug Names 1982. United States Pharmacopeial Convention, 12601 Twinbrook Parkway, Rockville, MD 20852. 1981. 614 pp. 21 × 28 cm. Price $25.00 (Foreign: $40.00 AO rate, $27.00 surface rate).

The 1982 edition of *USAN and the USP Dictionary of Drug Names* has been updated in some subtle but important ways. The entry format and familiar orange cover are the same but the book itself is 104 pages longer than last year. There are 96 new adopted names in this edition, inclusive to June 15, 1981. Many International Nonproprietary Names and graphic formulas from the World Health Organization's listings have been added as well as the molecular weights of compounds where appropriate.

There are over 17,000 entries and 2043 adopted names in this issue. The three appendixes and five lists that appear in the back of the book are the same as last year.

USAN is the officially recognized source of drug names for the USP, the National Formulary, and the major source used by the FDA in referring to drug substances. Consequently, this book is an invaluable reference to those in the drug trade and health professionals.

Terpenoids and Steroids, Vol. 10. Senior Reporter, J. R. HANSON. The Royal Society of Chemistry, Burlington House, London W1V 0BN, England. 1981. 284 pp. 15 × 22 cm. (Available from: Special Issues Sales, American Chemical Society, 1155 16th Street, N.W., Washington, DC 20036.)

This is the 10th volume on terpenoids and steroids in the valuable series first published 11 years ago. The aim of the series is to provide systematic, comprehensive, and critical reviews of progress in the major areas of chemical research. This volume reviews literature published between September 1978 and August 1979.

Volume 10 does not contain a subject index but is organized in a systematic manner that facilitates the location of information. There is also an extensive author index which is helpful to those following the research of a given individual. The book contains 1700 chemical structures and is documented with 1900 references, conveniently listed on the page of each chapter where first noted.

Part I, which covers the terpenoids, is divided into chapters that include sesquiterpenoids, diterpenoids, triterpenoids, and carotenoids and polyterpenoids. Chapters on monoterpenoids and the biosynthesis of terpenoids and steroids, unlike many of the earlier volumes, are not included. The chapter on monoterpenoids will be included in the next volume.

Part II, which covers the steroids, is divided into two chapters. The chapter on physical methods includes sections on structure and conformation, NMR spectroscopy, chiroptical phenomenon, mass spectrometry, miscellaneous physical properties, and analytical methods. The chapter on steroid reactions and partial syntheses contains sections devoted to each of these topics.

The first section is divided topically according to the more common functional groups and such important subjects as molecular rearrangements, functionalization of nonactivated positions, and photochemical reactions. The second section on partial syntheses, covers cholestane derivatives, vitamin D and its metabolites, pregnanes, androstanes and oestranes, cardenolides, heterocyclic steroids, and microbiological oxidations.

An unusual variety of terpenoid structures, particularly from insect and marine sources, has been included in this volume. The sharp increase in the use of high-field ^{1}H-NMR and ^{13}C-NMR is evident in this review.

The six reporters who prepared this volume are to be commended for maintaining the high standards set by the previous volumes in this series. Everyone interested in the chemistry of terpenoids and/or steroids should have access to this volume and the others in the series.

Lexikon der Hilfsstoffe für Pharmazie, Kosmetik und angrenzende Gebiete. By HERBERT P. FIEDLER, Editio Cantor Aulendorf, D-7960 Aulendorf, West Germany, 2 Volumes, 1081 pp., 17 × 24 cm., 1981, Price: 245 DM.

In view of the scarcity of textbooks dealing exclusively with excipients, the revised and expanded edition of the Lexikon der Hilfsstoffe is a timely contribution to the reference libraries of pharmaceutical companies, regulatory agencies, and schools of pharmacy. Comparison of the contents with the original one-volume edition published in 1970 demonstrates the evolution of a broader and more critical attitude toward available technical information on excipients.

The author has provided a series of tables listing specific physical properties of excipients, types of surfactants used in pharmaceutical or cosmetic preparations, HLB values, MAC (maximum workplace concentration) values, colorants suitable for cosmetic preparations, and a table of the German and English titles of selected excipients together with their Merck Index and Chemical Abstracts Registry Numbers where appropriate.

The main body of the text lists excipients in alphabetical order with information on their physical, chemical, and biological properties. There is considerable variation in coverage between excipients, which reflects the author's judgment or the extent of information available to him. It is clear that Dr. Fiedler has made a special effort to make these volumes useful to English-speaking pharmaceutical scientists. However, the construction of some of the interminable German sentences may create impatience in readers with a limited knowledge of the language.

As far as this reviewer knows, no similarly detailed encyclopedia of excipients has appeared in the English language. Until this gap is properly filled, the *Lexikon der Hilfsstoffe* will remain a valuable source book for pharmaceutical scientists engaged in dosage form design, production, and control.

Synthesis with Stable Isotopes of Carbon, Nitrogen, and Oxygen. By DONALD G. OTT. Wiley, 605 Third Ave., New York, NY 10016. 1981. 224 pp. 16 × 24 cm. Price $28.50.

This book is designed for chemists who are confronted with the need to prepare a compound with a stable isotope of carbon, nitrogen, or oxygen. It is intended to be useful for individuals actively involved in labeled compound synthesis as well as for chemists just entering the field.

Although compounds are presented in chapters according to functional groups, not all compounds appear in designated chapters. However, the text contains an index that lists all labeled compounds. The compounds are cited in the index as a product of synthetic procedures or as a reactant. Unfortunately, the index does not indicate information other than the compounds.

In many cases, the synthesis of a compound is provided in detail, but sometimes the reader is referred to a reference. References are used liberally throughout the text. The author indicates that the text does not contain all syntheses that have been developed for stable isotopes considered in the book, and states that the preparations presented represent types of reaction methods and techniques that may be applicable to many products other than those shown in the text. The efficient synthesis of key intermediates has been considered to be particularly important.

The text is concise, unique, and useful for individuals wishing to synthesize labeled compounds with stable isotopes and should be beneficial to all chemists involved in this area of research.

Anionic Polymeric Drugs. Edited by L. G. DONARUMA, R. M. OTTENBRITE, and O. VOGL. Wiley, 605 Third Ave. New York, NY 10016. 1980. 356 pp. 15×23 cm. Price $39.50.

This work is written as a first volume in a series to be published under the heading "Polymers in Biology and Medicine." The series is aimed at integrating knowledge in polymer sciences; it deals with endogenous polymers on one hand, and synthetic polymers used in biological and medical applications on the other.

The book is written by a number of experts, each contributing in their field. The work presents an overview of polymers as drugs, drug carriers, drug delivery systems, and as biopolymers in medicine. The structure and biological activity of polysaccharides and polycarboxylic acids are reviewed, with a discussion of the synthesis, characterization, and chelating properties of polycarboxylic acids.

An extensive review is provided of the divinyl ether–maleic anhydride copolymers (Pyran copolymer) and related structures. The discussion ranges from a captivating historical background through an in-depth discussion on a range of biological activities as they relate to structure, including the effects of polymers on the immune system. Subsequently the work expands on antiviral activity, effect on mixed-function oxidases, interferon induction, and antitumor activity.

The monograph represents a thorough and broad review of the chemistry, physics, charcterization, pharmacological, and physiological effects of polyanions with emphasis on the so-called Pyran polymers which have been studied most extensively. The editors have succeeded in bridging the gap between polymer science, biology, and medicine by providing a balanced mix that brings the reader up to date with the frontier of this fundamental research.

Foreign Compound Metabolism in Mammals, Vol. 6. A Specialist Periodical Report. Senior Reporter D. E. HATHWAY. The Royal Society of Chemistry, Burlington House, London, W1V OBN, England, 1981. 390 pp. 13 × 22 cm. Price $138.00.

This book is the latest in a series of literature reviews on the titled subject which are compiled by Dr. Hathway and associates every two years. For the most part, the organization of the book follows the format introduced in the previous volume. With the exception of the first chapter on pharmacokinetics, the emphasis is on papers published during 1978 and 1979 pertaining to the biotransformation of xenobiotics. Although most of the book is devoted to drugs, there are chapters on "Industrial Chemicals and Miscellaneous Organic Compounds," "Agricultural Chemicals," and "Food Additives."

This series represents the closest thing available to a systematic, periodic review of both the conceptual and compound-oriented aspects of the drug metabolism literature. Although the reviewed literature is 2–3 years old, a search of the *Science Citation Index* for the cited references can bring anyone up to date in the areas of drug metabolism covered in a relatively short time. The material presented appears adequately indexed to allow this volume to be used for reference purposes. In contrast to the previous volume, an author index has been omitted. This is not a serious loss because most workers are more interested in following a particular subject or compound rather than an author (other than themselves). The table of contents is as sufficiently detailed as a subject index whereas the "Index of Compounds and Metabolites" at the back of the book lists specific compounds discussed.

Despite a few lapses found, *e.g.*, misspelling my name, eliminating three coauthors (reference 43 on p. 205) and misplacing reference 60 on p. 207, the authors appear to have succeeded in producing a valuable (and expensive) contribution to the practice of drug metabolism.

Steroid Analysis by HPLC: Recent Applications (Chromatographic Science Series, Volume 16). Edited by MARIE P. KAUTSKY, Dekker, Inc., 270 Madison Avenue, New York, New York 10016, 1981. 397 pages bound and illustrated. 15 × 23 cm. $45 (Price is 15% higher outside the U.S. and Canada).

This book is divided into 11 major sections on: Bile acids, cardiac glycosides and related steroids, progestins, synthetic adrenocorticosteroids in pharmaceutical preparations and biological fluids, estrogens, D vitamins, determination of sterol intermediates in cholesterol biosynthesis, steroid hormones in adrenal and testicular cells, enzymatic steroid epimers, and analysis of natural and synthetic hormones in foods and feeds.

This volume is a collection of reviews by practicing chromatographers who describe their own work in detail and review in less detail work done by numerous others. Some 1980 references are cited but most are from 1979 or before. Recent reviews are included in the 654 references cited in the eleven sections. However, the editor states that the volume makes no attempt to include all of the recent applications of HPLC to steroid analysis.

The book is written for practicing analytical chemists, presenting laboratory tested approaches to problems in steroid separation and quantitation. Sufficient details are included to enable the analyst to quickly set up a system that would give satisfactory chromatography for routine analyses. This book would be a good source for information for any chromatographer who may be faced with an analysis in the steroid field for the first time. It could also be used for the purpose of reviewing any topic in the subject areas for developing new ideas, and for identifying key references. However, anyone using this book for the latter purpose should also supplement the information by surveying the current literature, since the publication rate of recent advances in the steroid area has been growing rapidly.

Food Chemicals Codex, Third Edition. Prepared by the Committee on Codex Specifications, Food and Nutrition Board, Division of Biological Sciences, Assembly of Life Sciences, National Research Council, National Academy of Sciences, 2101 Constitution Ave., N.W., Washington, D.C. 20418. 1981. 735 pp. Price $45.00.

The *Food Chemicals Codex* is the definitive source of information on food additives and processing aids. This new edition has been extensively revised and updated since the second edition, published in 1972. Over 800 food ingredients and processing materials are included in 776 monographs, 113 of which are new. A series of 400 IR spectra for many

In many cases, the synthesis of a compound is provided in detail, but sometimes the reader is referred to a reference. References are used liberally throughout the text. The author indicates that the text does not contain all syntheses that have been developed for stable isotopes considered in the book, and states that the preparations presented represent types of reaction methods and techniques that may be applicable to many products other than those shown in the text. The efficient synthesis of key intermediates has been considered to be particularly important.

The text is concise, unique, and useful for individuals wishing to synthesize labeled compounds with stable isotopes and should be beneficial to all chemists involved in this area of research.

Anionic Polymeric Drugs. Edited by L. G. DONARUMA, R. M. OTTENBRITE, and O. VOGL. Wiley, 605 Third Ave. New York, NY 10016. 1980. 356 pp. 15×23 cm. Price $39.50.

This work is written as a first volume in a series to be published under the heading "Polymers in Biology and Medicine." The series is aimed at integrating knowledge in polymer sciences; it deals with endogenous polymers on one hand, and synthetic polymers used in biological and medical applications on the other.

The book is written by a number of experts, each contributing in their field. The work presents an overview of polymers as drugs, drug carriers, drug delivery systems, and as biopolymers in medicine. The structure and biological activity of polysaccharides and polycarboxylic acids are reviewed, with a discussion of the synthesis, characterization, and chelating properties of polycarboxylic acids.

An extensive review is provided of the divinyl ether–maleic anhydride copolymers (Pyran copolymer) and related structures. The discussion ranges from a captivating historical background through an in-depth discussion on a range of biological activities as they relate to structure, including the effects of polymers on the immune system. Subsequently the work expands on antiviral activity, effect on mixed-function oxidases, interferon induction, and antitumor activity.

The monograph represents a thorough and broad review of the chemistry, physics, charcterization, pharmacological, and physiological effects of polyanions with emphasis on the so-called Pyran polymers which have been studied most extensively. The editors have succeeded in bridging the gap between polymer science, biology, and medicine by providing a balanced mix that brings the reader up to date with the frontier of this fundamental research.

Foreign Compound Metabolism in Mammals, Vol. 6. A Specialist Periodical Report. Senior Reporter D. E. HATHWAY. The Royal Society of Chemistry, Burlington House, London, W1V OBN, England, 1981. 390 pp. 13 × 22 cm. Price $138.00.

This book is the latest in a series of literature reviews on the titled subject which are compiled by Dr. Hathway and associates every two years. For the most part, the organization of the book follows the format introduced in the previous volume. With the exception of the first chapter on pharmacokinetics, the emphasis is on papers published during 1978 and 1979 pertaining to the biotransformation of xenobiotics. Although most of the book is devoted to drugs, there are chapters on "Industrial Chemicals and Miscellaneous Organic Compounds," "Agricultural Chemicals," and "Food Additives."

This series represents the closest thing available to a systematic, periodic review of both the conceptual and compound-oriented aspects of the drug metabolism literature. Although the reviewed literature is 2–3 years old, a search of the *Science Citation Index* for the cited references can bring anyone up to date in the areas of drug metabolism covered in a relatively short time. The material presented appears adequately indexed to allow this volume to be used for reference purposes. In contrast to the previous volume, an author index has been omitted. This is not a serious loss because most workers are more interested in following a particular subject or compound rather than an author (other than themselves). Food Chemicals Codex, Third Edition. Prepared by the Committee on Codex Specifications, Food and Nutrition Board, Division of Biological Sciences, Assembly of Life Sciences, National Research Council, National Academy of Sciences, 2101 Constitution Ave., N.W., Washington, D.C. 20418. 1981. 735 pp. Price $45.00.

The *Food Chemicals Codex* is the definitive source of information on food additives and processing aids. This new edition has been extensively revised and updated since the second edition, published in 1972. Over 800 food ingredients and processing materials are included in 776 monographs, 113 of which are new. A series of 400 IR spectra for many

essential oils and flavoring compounds is also new to this edition. Specifications for flavor aromatics and isolates are now given in clear tabular form.

In the area of policy, the new edition contains a set of guidelines for "good manufacturing practice" developed by the Committee on Codex Specifications.

Officially, the Codex is recognized by the Food and Drug Administration which adopted certain Codex specifications in 1971.

This book is essential to anyone working in the areas of food science and technology, quality control, and good research. More than 600 scientists from a variety of disciplines contributed to this work as well as many trade associations and professional societies.

Purchasers of this edition are entitled to receive three supplements to the Codex, included in the purchase price.

Staff Review

Textbook of Biopharmaceutic Analysis. By R. V. SMITH and J. T. STEWART. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1981. 308 pp. 18 × 25 cm. Price $25.00 (Canada $30.00)

To better prepare the practitioner for anticipated new roles in the delivery of health care, pharmaceutical education has evolved from a product oriented emphasis to a clinically oriented one. This change has given rise to such courses as biopharmaceutics, clinical pharmacy, and clinically oriented clerkships and externships. In addition, it often has necessitated the restructuring of the traditional basic science courses in order to provide a more adequate background for the clinical sciences. This textbook treats those aspects of analytical chemistry, analytical microbiology and biochemistry, and drug assay that concern the development and application of procedures for the determination of drugs and their metabolites in the biological fluids. This volume appears to be the first attempt to provide such a body of knowledge in textbook form for utilization in the pharmacy curriculum.

This book is divided into three sections: "Defining the Problem," "The Separation Step," and "The Measurement Step." This sequence is based on the approach that one would presumably follow in developing a methodology for the determination of a drug or its metabolites in biological fluids. The first section presents relevant background material, covers the development of methods for determining trace levels of medicaments in biological fluids, and deals with the procurement and characterization of reference standards. While three sources of reference standards are mentioned, unfortunately, the United States Pharmacopeial Convention has been overlooked.

The second section reviews the major separation and purification techniques including liquid–solid extraction, liquid–liquid extraction, partition coefficient, ion-pairing procedures, and the major chromatographic methods, *i.e.*, TLC, GC, HPLC, gel permeation, and ion-exchange chromatography.

The third section covers techniques for measurement and encompasses 10 chapters. Separate chapters are devoted to the following topics: statistical treatment of data, treatment of chromatographic data, UV-visible absorption and emission spectrophotometry, fluorimetry and phosphorimetry, electroanalytical methods, radiochemical methods, immunoassay techniques (RIA, EMIT, HI, SLFIA, and spin immunoassay), microbiological assay methods, enzymatic analysis, and a very brief concluding chapter on the method of selecting the appropriate analytical procedure for a particular situation. An array of pertinent literature references is provided at the end of each chapter along with a series of learning objectives to assist the student in reviewing the chapter content. Additional recommended readings are presented for more advanced students.

This text is written in a lucid manner, is well-organized, and the information is presented in a logical format. While the content of this book may be presented as a separate course offering, the subject matter may be more appropriately covered as segments in those courses where the basic concepts are taught, or it may possibly be included as a component of one of the clinical science courses. This material is important and serves well as a bridge between the clinical sciences and the basic pharmaceutical sciences. It merits consideration in the pharmaceutical curriculum.

Pharmacognosy, 8th edition. VARRO E. TYLER, LYNN R. BRADY, and JAMES E. ROBBERS. Lea & Febiger, Philadelphia, PA 19106. 1981. 520 pp. 18 × 25 cm. Illustrated with Numerous chemical structures, figures and photographs. Price: $31.50 U.S., $37.75 Canada.

This modern pharmacognosy text is all-inclusive and deals with drugs of natural origin that make up close to 50% of all medicinals currently employed. It has been the standard textbook of pharmacognosy in the U.S. for a number of years, and is the only one which has been periodically updated. It provides a systematic and comprehensive review of plant and animal drugs in a biochemical classification system. Major chapter titles include, general introduction, carbohydrates and related compounds, glycosides and tannins, lipids, volatile oils, resins, steroids, alkaloids, peptide hormones, enzymes, vitamins, antibiotics, biologicals, allergens and allergenic preparations, poisonous plants, and a new section entitled, herbs and "health foods". Several obsolete drugs and references have been deleted and new materials added where appropriate. Many of the chemical structures have been redrawn to reflect appropriate steric configurations. New prescription products as examples of the various drugs have been added as required.

In general, the new edition has retained the flavor of the previous ones with much updating. The chapter on herbs and "health foods" is a welcome addition to a subject that has gained popularity in recent years. This chapter has wisely divided the literature references into two groups, *e.g.*, authoritative and advocacy literature. This will help the pharmacist and others who use it, to determine whether the references their patients use are good or bad since self medication with herbs and teas has become common. However, several excellent recent references on the hazards of herbal teas and ginsing tea analysis have been omitted, and should be included in the next edition. As a constructive criticism, more recent key journal articles and reviews also should be included in the chapter references. This edition is really top-heavy with text references. Since text references tend to be dated by publication time, this policy detracts from access to recent literature and the usefulness of the book. This text is a must for all pharmacists.

Biochemistry of Antimicrobial Action. 3rd ed. By T. J. FRANKLIN and G. A. SNOW. Methuen, Inc. 733 Third Avenue, New York, NY 10017. 1981. 217 pp. 15 × 24 cm. Price $35.00 (hardcover), $17.95 (paperback).

Biopharmazie. Theorie und Praxis der Pharmakokinetik. By HERAUSGEGEBEN von J. MEIER, H. RETTIG and H. HESS. George Thieme Verlag, Stuttgart, West Germany. 1981. 473 pp. 17 × 24 cm. (German).

Coca and Cocaine, Vol. 3, issues 2–3 of the Journal of Ethno-Pharmacology. Edited by L. RIVIER, J. G. BRUHN. Elsevier, P. O. Box 211, 1000 AE Amsterdam, The Netherlands. 1981. 379 pp. 16 × 24 cm.

essential oils and flavoring compounds is also new to this edition. Specifications for flavor aromatics and isolates are now given in clear tabular form.

In the area of policy, the new edition contains a set of guidelines for "good manufacturing practice" developed by the Committee on Codex Specifications.

Officially, the Codex is recognized by the Food and Drug Administration which adopted certain Codex specifications in 1971.

This book is essential to anyone working in the areas of food science and technology, quality control, and good research. More than 600 scientists from a variety of disciplines contributed to this work as well as many trade associations and professional societies.

Purchasers of this edition are entitled to receive three supplements to the Codex, included in the purchase price.

Staff Review

Textbook of Biopharmaceutic Analysis. By R. V. SMITH and J. T. STEWART. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1981. 308 pp. 18 × 25 cm. Price $25.00 (Canada $30.00)

To better prepare the practitioner for anticipated new roles in the delivery of health care, pharmaceutical education has evolved from a product oriented emphasis to a clinically oriented one. This change has given rise to such courses as biopharmaceutics, clinical pharmacy, and clinically oriented clerkships and externships. In addition, it often has necessitated the restructuring of the traditional basic science courses in order to provide a more adequate background for the clinical sciences. This textbook treats those aspects of analytical chemistry, analytical microbiology and biochemistry, and drug assay that concern the development and application of procedures for the determination of drugs and their metabolites in the biological fluids. This volume appears to be the first attempt to provide such a body of knowledge in textbook form for utilization in the pharmacy curriculum.

An Updated Review of the "Drug Lag"

At the time this editorial is being written—and which, due to the lead-time necessitated by the *Journal's* production schedule, is long before our subscribers will have an opportunity to read it—the public press and broadcast media are filled with widely contradictory assessments as to whether the United States or the Soviet Union currently enjoys overall military superiority.

In many respects, this debate reminds us of a similar one in the health care field which has raged on with comparable intensity and, seemingly, for as lengthy a period of time. We refer to the so-called "drug lag"—a highly controversial subject which we have addressed in editorials on several previous occasions and most particularly in the April 1978 issue of this journal.

All sorts of data, statistics, and "evidence" are paraded out by those on each side of the question in an attempt to prove their claim that either (*a*) in this country, drugs are approved much more slowly than in other developed nations, with the result that the American public is deprived of significant public health benefits, or (*b*) there really is little, if any, difference in the speed of U.S. drug approvals when compared across the board with other major nations.

Furthermore, it cannot be claimed that the issue has suffered from lack of attention or study. Indeed, at least four separate analyses have either just been completed or are about to be so.

These include: (*a*) a study by the FDA's Office of Planning and Evaluation, which was released in mid-March 1982; (*b*) another study conducted at George Washington University under a contract from FDA's New Drug Evaluation Division, which also was released in mid-March 1982; (*c*) an analysis being conducted by the FDA Commissioner's Task Force on New Drug Review, which is soon to submit its report through Health and Human Services Secretary Richard S. Schweiker; and (*d*) the findings and recommendations of the Federal Drug Approval Process Commission, a body sponsored by the U.S. Congress and serving under the chairmanship of F. Gilbert McMahon of Tulane University. At the time of our writing, this latter body was circulating a "final draft" version of its recommendations, and the formal report itself was due to be released almost any day.

Hopefully, each of these studies in its own way will contribute to an understanding of the process and to improvements in its operation.

But even while these studies were still under way, we noted a number of new drug approvals that were announced with accompanying FDA statements that the approval was processed in some sort of expedited manner. Two of the most recent "fast-track" drug approvals included the antiviral herpes agent, acyclovir, which cleared FDA in less than 9 months, and the calcium channel blocker, verapamil, which completed all its FDA processing in just over a year from first filing.

These examples—and several similar ones—demonstrate that, given the right set of circumstances, FDA drug approval can be quite swift.

Finally, we were especially impressed with an FDA year-end report released in early January of this year, in which it was claimed that over twice as many new drug entities were approved during 1981 (27 in all) as compared with 1980 (12 in all). Furthermore, the FDA's statistics showed that the average period from submission of application to final approval for marketing of new chemical entities has dropped from 37.5 months in 1979 to 31.2 months in 1981. With respect to the "fast-track" drugs, the decline was even more dramatic: from 17 months in 1976–78 to just 10 months in the 1979–81 period.

Even the General Accounting Office—not known for handing out very many good "report cards"—issued a conclusion to an investigation it completed in late 1981, which stated that the FDA, since 1978, has "approved more drugs in less time than before, despite an increased workload."

All of this suggests to us that if truly there ever was a drug lag, it no longer exists—or is at least of manageable proportions and susceptible to administrative remedies within the regulatory agency. Consequently, new legislation or major changes in the pertinent existing regulations would now appear to be of doubtful value.

Indeed, legislative or regulatory tinkering could actually prove to be more disruptive than beneficial, insofar as expediting the judicious approval of new drugs. With those thoughts in mind, we personally would recommend that, for the immediate future anyway, Congress "cool it" with respect to amending the present drug approval provisions of the Federal Food, Drug, and Cosmetic Act.

Kinetics and Mechanism of Hydroxy Group Acetylations Catalyzed by *N*-Methylimidazole

NIVEDITA K. PANDIT * **and KENNETH A. CONNORS** ˣ

Received July 6, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication September 4, 1981. * Present address: Boehringer-Ingelheim, Ridgefield, CT 06877.

Abstract □ The kinetics of acetylation of alcohols by acetyl chloride and acetic anhydride, with *N*-methylimidazole as the catalyst, were studied in acetonitrile solution at 25°; some measurements were also made with 4-dimethylaminopyridine as the catalyst. The acetic anhydride–*N*-methylimidazole system proceeds entirely by a general base catalysis, whereas the acetyl chloride–*N*-methylimidazole system reacts entirely *via* a nucleophilic route, with the intermediate formation of the *N*-acylated catalyst. The reaction of this intermediate with the alcohol is general base catalyzed. The acetyl chloride–4-dimethylaminopyridine system also reacts *via* the nucleophilic route. In the acetic anhydride–4-dimethylaminopyridine system a small fraction of the intermediate was detected. The acetic anhydride–*N*-methylimidazole system was studied in *n*-propanol–acetonitrile solvent mixtures; no spectral evidence for intermediate formation was seen. However, the hydrolysis reaction in acetic anhydride–*N*-methylimidazole, studied over a wide range of water–acetonitrile mixtures, revealed a change in mechanism from general base in dry acetonitrile to a solely nucleophilic route at high water concentrations.

Keyphrases □ Acetylation—kinetics and mechanism, hydroxy groups catalyzed by *N*-Methylimidazole □ Kinetics—mechanism of hydroxy group acetylations, catalyzed by *N*-Methylimidazole □ *N*-Methylimidazole—kinetics and mechanism of hydroxy group acetylations, catalyst □ 4-Dimethylaminopyridine, acetylation catalyst.

Acetylations of hydroxy compounds are usually carried out with acetic anhydride or acetyl chloride as the acylating agent. Pyridine is commonly used as a catalyst. Several catalysts more powerful than pyridine are now available, most notably 4-dimethylaminopyridine, which was developed by Steglich and Höfle (1–3) as a catalyst for synthetic acetylations, and has since been applied to analytical acetylations (4–7). This study introduced *N*-methylimidazole as an analytical acylation catalyst (8–11). The relative catalytic effectiveness of pyridine–*N*-methylimidazole–4-dimethylaminopyridine is about $1:3 \times 10^2:1.7 \times 10^4$, respectively (12), in aprotic solvents.

Although the mechanisms of acyl transfer reactions have been well studied, most investigations have been of acyl transfer to water, that is, of the hydrolysis of carboxylic acid derivatives in aqueous solution. These kinetic and mechanistic results, therefore, may not be applicable to acylation reactions carried out in aprotic solvents. Because synthetic and analytical acylations usually employ nonaqueous media, it is important to understand the course of the reactions and the role of the catalyst in these systems, and several laboratories have described studies of the newer catalysts (particularly of 4-dimethylaminopyridine) in aprotic solvents. The mechanism of the catalysis is not well understood, and there is disagreement among the interpretations of reactivity data for these systems; these viewpoints are cited in the later discussion.

To achieve an understanding of the mode of catalysis by *N*-methylimidazole, the present study was designed to allow systematic kinetic measurements to be made over a wide range of conditions. The reaction systems are relatively simple but represent practical situations. Acetic anhydride and acetyl chloride are the two acylating agents studied. *N*-methylimidazole is the catalyst, though some observations were also made on 4-dimethylaminopyridine because of its importance; hence, four separate combinations of acylating agent and catalyst were studied. The acyl acceptor was an alcohol or water, and the solvent was acetonitrile, modified in some cases by the addition of alcohol or water.

EXPERIMENTAL

Materials—Acetyl chloride and acetic anhydride, analytical reagent grade[1], were used directly. *N*-Methylimidazole[2] was distilled at 10–12 mm Hg pressure; atmospheric bp 199°. 4-Dimethylaminopyridine[2] was recrystallized from *n*-hexane; mp 113°. The alcohols were of analytical reagent quality and were used directly; their purities were checked by gas chromatography.

0022-3549/82/0500-0485$01.00/0

Acetonitrile, technical grade[2], was refluxed over phosphorus pentoxide for 1 hr, then distilled from phosphorus pentoxide at 80–81°. The water content of this product was ~0.003% as determined by visual Karl Fischer titration.

Kinetic Procedure—A typical kinetic run was carried out as follows: Solutions of appropriate concentrations of the acetylating agent, the catalyst, and the hydroxy compound were prepared in acetonitrile and equilibrated at 25 ± 0.1°. Acetonitrile (4.0 ml), 3.0 ml of the catalyst solution, and 1.0 ml of the acetylating agent solution were added to a 10-ml volumetric flask. The reaction was initiated by adding 2.0 ml of the solution of hydroxy compound. The well-mixed solution was transferred to a 1-cm spectrophotometer cell, and the absorbance was monitored at a selected wavelength as a function of time[3]. The absorbance at the completion of reaction (A_∞) was measured after the lapse of ~10 half-lives.

All measurements were made at 25.0 ± 0.1°.

RESULTS AND DISCUSSION

Kinetic Scheme—The design and interpretation of the kinetic experiments were based on the model represented by Scheme I:

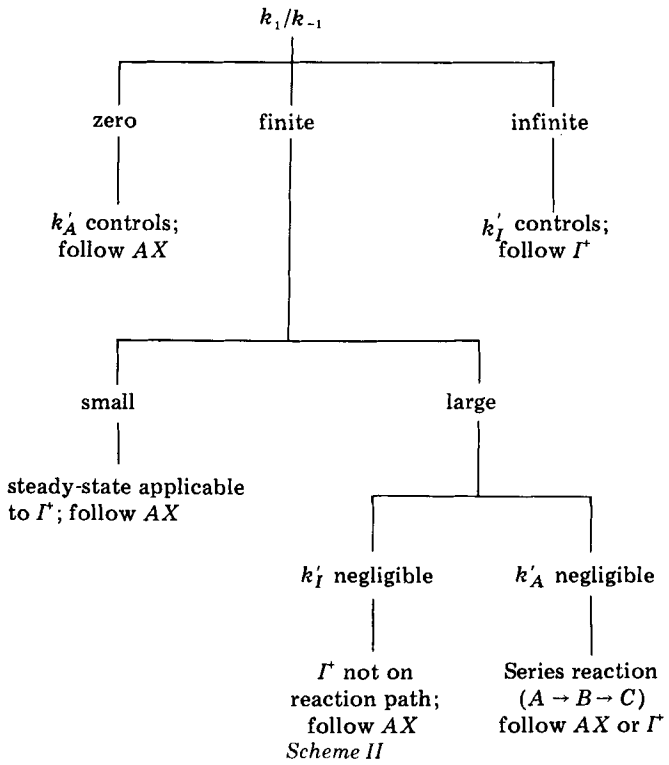
$$AX + N \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} I^+ + X^-$$

$$\downarrow k'_A[\mathrm{ROH}] \qquad \downarrow k'_I[\mathrm{ROH}]$$

$$AOR + HX \qquad AOR + NH^+$$

Scheme I

where AX is the acetyl compound (acetyl chloride or acetic anhydride), N is the catalyst (N-methylimidazole or 4-dimethylaminopyridine), I^+ is an intermediate acetylammonium ion, X^- is the counterion (chloride or acetate), and ROH is the acetyl acceptor (alcohol or water). Although a single general rate equation is too complex to be useful, several important cases arise from the operation of: (*a*) the ratio k_1/k_{-1}; (*b*) the detailed nature of k'_A and k'_I; (*c*) the relative magnitudes of k'_A and k'_I; (*d*) the relative concentrations of the reactants; (*e*) the method of observation; (*f*) the nature of ROH. The experiments were designed to evaluate the validity of Scheme I and to obtain estimates of the parameters. Scheme II outlines some of the possible cases:



Scheme II

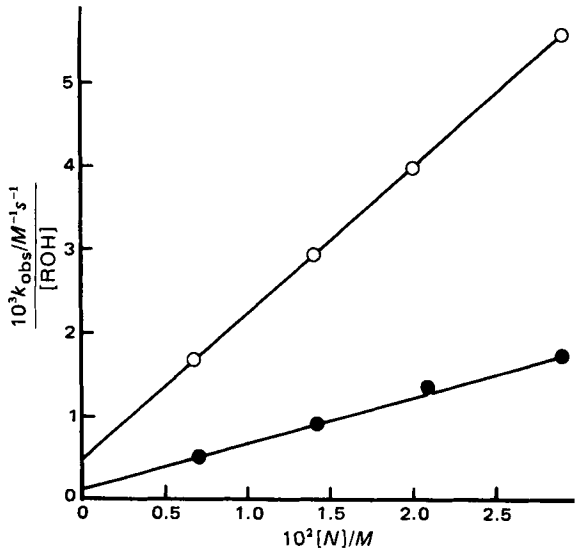

Figure 1—*Plot according to Eq. 3 for the acetylchloride–*N*-methylimidazole system. Key: (○), sec-butanol; (●), isopropanol.*

In this study the reactions were followed spectrophotometrically by monitoring the loss of AX or I^+ with time. The initial concentration of hydroxy compound usually was at least 50 times that of the acetylating agent, and in most cases good first-order behavior was observed, the apparent first-order rate constant k_{obs} being evaluated from a plot of log $(A_t - A_\infty)$ *versus* time. The precision of k_{obs} was ~2%. Deviations from first-order behavior are pointed out as appropriate.

Acetyl Chloride–*N*-Methylimidazole–Alcohols—When acetonitrile solutions of acetyl chloride and N-methylimidazole are mixed, the absorbance of the resulting solution is much greater than that calculated for the mixture of reactants. It is inferred that a very fast and quantitative formation of N-acetyl-N'-methylimidazolium ion occurs; this is the intermediate I^+ in Scheme I. At a given concentration of catalyst and varying concentrations of acetyl chloride, the same absorbance was produced as long as $[AX]_0 > [N]_0$ and *vice versa*, showing that the formation of I^+ was quantitative. The spectrum of the intermediate showed λ_{max} = 245 nm, log ϵ_{max} = 3.51. Since N-methylimidazole shows λ_{min} = 245 nm, log ϵ_{min} = 0.2, the reaction was followed at 245 nm, with initial condition $[AX]_0 < [N]_0$. In a typical reaction $[AX]_0 = 8 \times 10^{-4}$ M and $[\mathrm{ROH}]_0 = 0.5$ M.

This system therefore appears to be a case in which k_1/k_{-1} is essentially infinite (Scheme II), the observed reaction being (Scheme III):

$$I^+ + \mathrm{ROH} \xrightarrow{k'_I} \mathrm{ROAc} + NH^+$$

Scheme III

In Scheme III ROAc represents the acetylated alcohol.

It is anticipated that k'_I is given by Eq. 1, which is a testable assumption.

$$k'_I = k_I + k_{IN}[N] \qquad \text{(Eq. 1)}$$

The hypothetical rate equation is, therefore:

$$\frac{-d[I^+]}{dt} = (k_I + k_{IN}[N])[I^+][\mathrm{ROH}] \qquad \text{(Eq. 2)}$$

The experimental rate equation was found to be $-d[I^+]/dt = k_{obs}[I^+]$, the plots being linear over the course of the reactions. Therefore:

$$\frac{k_{obs}}{[\mathrm{ROH}]} = k_I + k_{IN}[N] \qquad \text{(Eq. 3)}$$

Table I—Rate Constants for the Acetyl Chloride–*N*-Methylimidazole System in Acetonitrile at 25° [a]

Alcohol	$10^3 k_I/M^{-1}s^{-1}$	$k_{IN}/M^{-2}s^{-2}$	$10^3 k_A/M^{-1}s^{-1}$
n-Propanol	0.16 (0.025)	0.50 (0.007)	4.61 (0.021)
n-Butanol	0.36 (0.026)	0.98 (0.006)	4.49 (0.032)
Isopropanol	0.15 (0.030)	0.053 (0.002)	1.49 (0.036)
sec-Butanol	0.49 (0.024)	0.17 (0.001)	3.32 (0.025)

[a] Standard deviation in parentheses, evaluated from the least-squares fit to the appropriate linear equation.

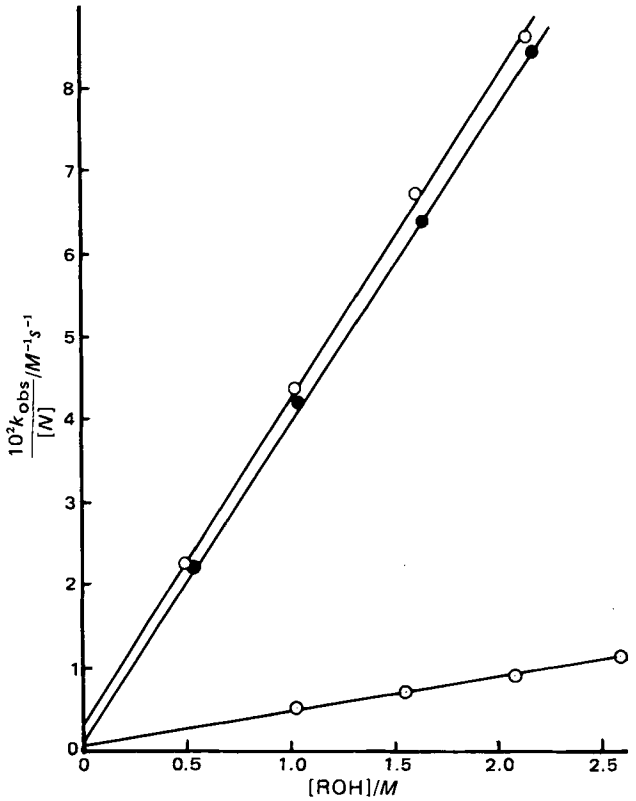

Figure 2—*Plot according to Eq. 9 for the acetic anhydride–*N*-methylimidazole system. Lines from top to bottom:* n-*propanol,* n-*butanol, isopropanol.*

Equation 3 suggests that a plot of $k_{obs}/[ROH]$ *versus* $[N]$ will be linear, where $[N]$ represents free *N*-methylimidazole. Since it was shown that conversion to the intermediate is quantitative, $[N]$ is given by:

$$[N] = [N]_0 - [AX]_0 \qquad \text{(Eq. 4)}$$

Moreover, $[N]$ should remain constant at this value throughout the course of the reaction, because each *N*-methylimidazole released from I^+ upon reaction with ROH accepts a proton, since it is the strongest base in the system.

Figure 1 shows a plot according to Eq. 3 for *sec*-butanol and isopropanol. Similar behavior was observed for *n*-propanol and *n*-butanol, and the resulting estimates of k_I and k_{IN} are listed in Table I.

To evaluate k'_A, the acetylation of these four alcohols by acetyl chloride was examined in the absence of *N*-methylimidazole. The first-order plots were linear for ~1 half-life, perhaps as a consequence of the proton release accompanying the acetylation. If k'_A is given by:

$$k'_A = k_A + k_{AN}[N] \qquad \text{(Eq. 5)}$$

evidently the rate equation in the absence of *N*-methylimidazole is $-d[AX]/dt = k_A[AX][ROH]$, or $k_{obs}/[ROH] = k_A$, where k_{obs} is evaluated from the initial linear portion of the plots. The k_A estimates obtained in this way are given in Table I.

It is evidently impossible to determine k_{AN} for this system, because acetyl chloride and *N*-methylimidazole cannot coexist in significant concentrations.

Acetic Anhydride–*N*-Methylimidazole–Alcohols—When acetonitrile solutions of acetic anhydride and *N*-methylimidazole are mixed, the resulting spectrum can be quantitatively accounted for as the sum of the spectra of these two solutes; thus, there is no spectral evidence for intermediate formation. Since the counterion should have little effect on the spectrum of the cation, and the intermediate in the acetyl chloride–*N*-methylimidazole system exhibited an intense absorption at 245 nm, it is inferred that in the present case k_1/k_{-1} is close to zero. The acetylating agent is acetic anhydride (λ_{max} = 240 nm, log ϵ_{max} = 2.0). The reaction was monitored at 245 nm, corresponding to a minimum in the spectrum of the catalyst. The apparent first-order plots were linear for at least 4 half-lives. The initial concentrations were: acetic anhydride, 0.02 *M*; alcohols, 0.5–2.6 *M*; *N*-methylimidazole, 0.011–0.11 *M*.

Table II—Rate Constants for the Acetic Anhydride–*N*-Methylimidazole System in Acetonitrile at 25° [a]

Alcohol	$10^3 k_1/M^{-1}s^{-1}$	$10^5 k_A/M^{-1}s^{-1}$	$10^2 k_{AN}/M^{-2}s^{-1}$
n-Propanol	0.70 (1.05)	2.4 (3.7)	4.03 (0.05)
n-Butanol	1.20 (1.42)	8.3 (10.2)	3.80 (0.06)
Isopropanol	0.007 (0.011)	0.15 (0.11)	0.413 (0.002)

[a] Standard deviation in parentheses.

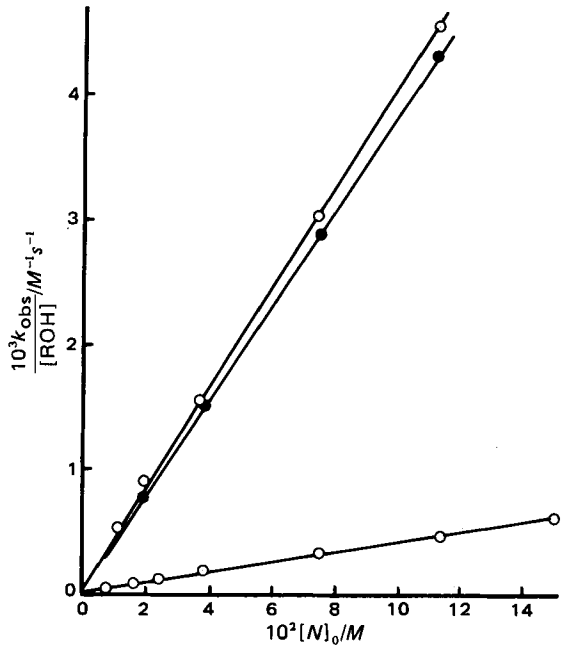

Figure 3—*Plot according to Eq. 10 for the acetic anhydride–*N*-methylimidazole system. Lines from top to bottom:* n-*propanol,* n-*butanol, isopropanol.*

Although the intermediate could not be detected spectrally, its possible presence is admitted in the rate equation for the loss of anhydride:

$$-\frac{d[AX]}{dt} = k_1[AX][N] + k'_A[AX][ROH] - k_{-1}[I^+][X^-] \qquad \text{(Eq. 6)}$$

The assumption is made that all of the H^+ produced in the acetylation is accepted by X^- (acetate); then $[X^-] = 0$, so Eq. 6 becomes:

$$-\frac{d[AX]}{dt} = k_1[AX][N] + k'_A[AX][ROH] \qquad \text{(Eq. 7)}$$

This assumption is justified in the later discussion. By hypothesis, $k'_A = k_A + k_{AN}[N]$. The experimental rate equation is $-d[AX]/dt = k_{obs}[AX]$, so:

$$k_{obs} = k_1[N] + k_A[ROH] + k_{AN}[ROH][N] \qquad \text{(Eq. 8)}$$

If in a series of experiments the catalyst concentration is held constant while the alcohol concentration is varied, the plotting form of Eq. 9 is used:

$$\frac{k_{obs}}{[N]} = k_1 + \left(\frac{k_A}{[N]} + k_{AN}\right)[ROH] \qquad \text{(Eq. 9)}$$

whereas, if [ROH] is kept constant and $[N]$ is varied, Eq. 10 can be used.

$$\frac{k_{obs}}{[ROH]} = k_A + \left(\frac{k_1}{[ROH]} + k_{AN}\right)[N] \qquad \text{(Eq. 10)}$$

Thus, from the slopes and intercepts of these two plots, the constants k_1, k_A, and k_{AN} can be evaluated.

Figure 2 is the plot according to Eq. 9, and Fig. 3 shows Eq. 10 plotted for three alcohols in the acetic anhydride–*N*-methylimidazole system. The rate constants estimated by this treatment are given in Table II; the k_1 and k_A values are not significantly different from zero.

This system was used to investigate the medium effect of the alcohol on the rate and mechanism. The reaction was studied in *n*-propanol–acetonitrile mixtures, with the results shown in Table III. Good first-order kinetics were observed, but at an alcohol concentration of 80%, sharp deviations from first-order kinetics were seen. The dependence of k_{obs}

Table III—Dependence of Rate Constant on Solvent Composition for the Acetic Anhydride–*N*-Methylimidazole System in *n*-Propanol–Acetonitrile Mixtures [a]

Concentration of *n*-Propanol		
Volume, %	Molarity	$10^3 k_{obs}/s^{-1}$
20	2.67	3.93
30	4.00	5.92
40	5.34	8.08
50	6.68	9.81
60	8.02	12.0
70	9.35	14.4

[a] $[AX]_0 = 2.95 \times 10^{-3}\ M$; $[N]_0 = 3.76 \times 10^{-2}\ M$; temp. = 25°.

upon [ROH] is linear, and no spectral evidence was seen for intermediate formation, indicating that there is no mechanism change over this range of solvent composition. The alcohol is functioning as a reactant, and has no kinetically significant medium effect over the range reported in Table III.

Acetic Anhydride–*N*-Methylimidazole–Water—In one stage of this study, the water was treated as an instance of a hydroxy compound, in relatively low concentration, undergoing acetylation in acetonitrile solution; another stage involved the hydrolysis in water–acetonitrile mixtures over a wide range of composition.

This system behaved dramatically differently from the corresponding anhydride–alcohol system, in that when water was present a strong UV absorption was observed, similar to that ascribed to intermediate formation in acetyl chloride solutions. At low water concentrations the initial absorbance was proportional to the water concentration. It is inferred that water alters the polarity of the medium, making the formation of the *N*-acetyl-*N'*-methylimidazolium intermediate possible. With this hypothesis the following kinetic treatment, based on Scheme I, describes the system. Since reaction may take place *via* both AX and I^+ (at a given water concentration both species may be present), and the change in absorbance may receive contributions from both routes, the rate $-d([AX] + [I^+])/dt = -d[AX]/dt - d[I^+]/dt$ is needed. From the kinetic scheme:

$$-\frac{d[AX]}{dt} = k_1[AX][N] + k'_A[AX][H_2O] - k_{-1}[I^+][X^-] \quad \text{(Eq. 11)}$$

$$-\frac{d[I^+]}{dt} = k_{-1}[I^+][X^-] + k'_I[I^+][H_2O] - k_1[AX][N] \quad \text{(Eq. 12)}$$

Therefore,

$$-\frac{d([AX] + [I^+])}{dt} = k'_A[AX][H_2O] + k'_I[I^+][H_2O] \quad \text{(Eq. 13)}$$

The concentrations $[AX]$ and $[I^+]$ are related by Eq. 14, where the nature of R′ is examined later:

$$[AX] = R'[I^+] \quad \text{(Eq. 14)}$$

Therefore, $-d[AX]/dt = -R'(d[I^+]/dt)$, or:

$$-\frac{d([AX] + [I^+])}{dt} = -(1 + R')\frac{d[I^+]}{dt} \quad \text{(Eq. 15)}$$

Substituting Eq. 14 into 13:

$$-\frac{d([AX] + [I^+])}{dt} = (k'_I + R'k'_A)[I^+][H_2O] \quad \text{(Eq. 16)}$$

Equations 15 and 16 are combined to give:

$$-\frac{d[I^+]}{dt} = \left(\frac{k'_I + R'k'_A}{1 + R'}\right)[I^+][H_2O] \quad \text{(Eq. 17)}$$

An alternative development in terms of AX yields:

$$-\frac{d[AX]}{dt} = \left(\frac{k'_I + R'k'_A}{1 + R'}\right)[AX][H_2O] \quad \text{(Eq. 18)}$$

It follows that:

$$-\frac{d([AX] + [I^+])}{dt} = \left(\frac{k'_I + R'k'_A}{1 + R'}\right)[H_2O]([AX] + [I^+]) \quad \text{(Eq. 19)}$$

If R′ is invariant with time, Eq. 19 has a first-order form, with the observed rate constant given by:

$$k_{obs} = \left(\frac{k'_I + R'k'_A}{1 + R'}\right)[H_2O] \quad \text{(Eq. 20)}$$

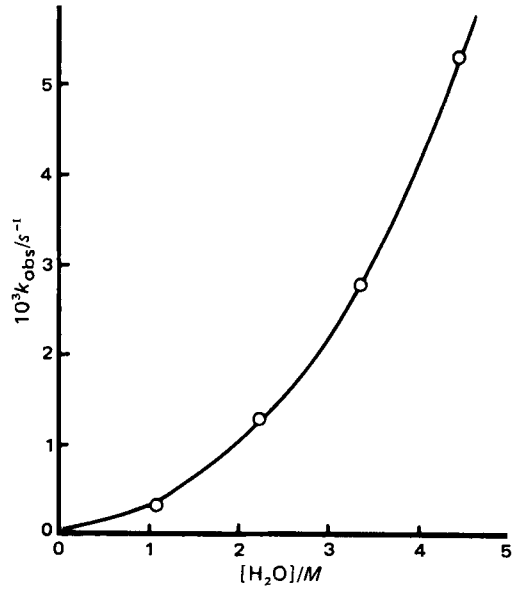

Figure 4—*Dependence of* k_{obs} *on water concentration in the acetic anhydride–*N*-methylimidazole system;* $[N]_0 = 1.5 \times 10^{-3}$ M.

It can be shown that Eq. 20 applies also when the total absorbance of the solution is followed.

The nature of R′ is now investigated. The concentrations $[AX]$ and $[I^+]$ might be controlled by the equilibrium relation:

$$K = \frac{k_1}{k_{-1}} = \frac{[I^+][X^-]}{[AX][N]} \quad \text{(Eq. 21)}$$

or $[AX] = R[I^+]$, where $R = [X^-]/K[N]$. Another possibility is that the steady-state approximation may be applied to $[I^+]$, giving:

$$[AX] = \left(\frac{k_{-1}[X^-] + k'_I[H_2O]}{k_1[N]}\right)[I^+] \quad \text{(Eq. 22)}$$

Comparison with Eq. 14 gives:

$$R' = \frac{[X^-]}{K[N]} + \frac{k'_I[H_2O]}{k_1[N]} \quad \text{(Eq. 23)}$$

The quantity R′ is therefore a function of water concentration through $[H_2O]$, k_1, and K, all of which increase as the water content of the medium increases. As $[H_2O]$ increases, R′ will approach zero and k_{obs} will approach $k'_I[H_2O]$. At very low $[H_2O]$, R′ will become large and k_{obs} will approach $k'_A[H_2O]$. Equations 22 and 23 include equilibrium control as a special case.

In general, R′ is also a function of time (at given water concentration), so first-order kinetics may not be observed when R′ is finite. This means that deviations from first-order kinetics are most likely to be observed at water concentrations where R′ is making a significant contribution to k_{obs}, that is, where both k'_A and k'_I are contributing.

Deviations from first-order kinetics were seen at water concentrations <20% v/v (4.45 *M*); above this concentration good first-order plots were obtained. Figures 4 and 5 show the dependence of k_{obs} on water concentration in the low and high water concentration regions. From the slope at high water concentration, k'_I is found to be $1.05 \times 10^{-3}\ M^{-1}\ s^{-1}$ (at $[N]_0 = 3.76 \times 10^{-4}\ M$). An estimate of the slope at $[H_2O] = 0$ gives $k'_A \approx 2 \times 10^{-4}\ M^{-1}\ s^{-1}$ ($[N]_0 = 1.50 \times 10^{-3}\ M$).

The dependence of k_{obs} on $[N]$ can be investigated by combining Eq. 20 with the detailed expressions for k'_A, k'_I, and R′, but the results are complex and difficult to interpret (13). The experimental observation is that k_{obs} shows positive curvature as a function of $[N]_0$ at low water concentration and negative curvature at high water concentration.

The linear portion of Fig. 5 suggests that R′ becomes negligible above ~5–10 *M* water; presumably above this value the medium is polar enough to support the extensive formation of the intermediate. Below 5–10 *M* water the reaction proceeds *via* both the anhydride and the intermediate.

The acetyl chloride–*N*-methylimidazole system was also studied in the presence of water, but very complicated kinetics were observed. This is thought to be a consequence of the unanticipated production of acetic anhydride in the system, which can occur in this way. Acetyl chloride hydrolyzes (*via* the intermediate) to give acetic acid, which transfers a proton to *N*-methylimidazole yielding acetate ion. At low water con-

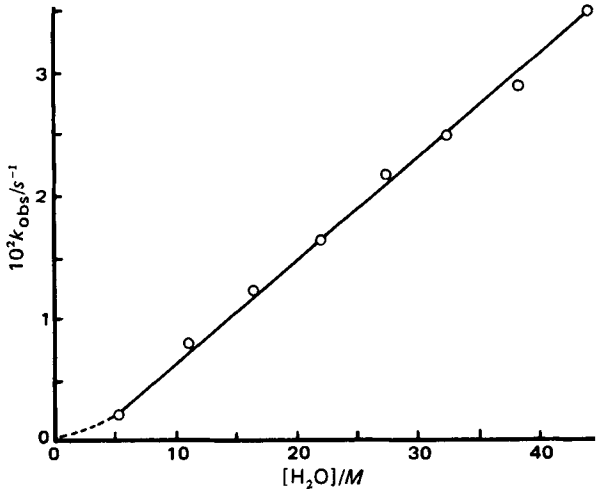

Figure 5—*Dependence of* k_{obs} *on water concentration for the acetic anhydride–N-methylimidazole systems;* $[N]_0 = 3.76 \times 10^{-4}$ M. *The dashed line represents the behavior seen in Fig. 4, but the two figures were obtained at different catalyst concentrations.*

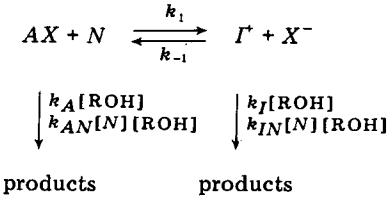
centrations, acetate will react with the intermediate I^+ to generate acetic anhydride, according to Scheme I. Further study of this complex system did not seem warranted.

Catalysis by 4-Dimethylaminopyridine—A mixture of acetyl chloride and 4-dimethylaminopyridine in acetonitrile shows a rapid and quantitative conversion to the intermediate, with λ_{max} = 315 nm, log ϵ_{max} = 4.5. The acetylation of isopropanol was followed at 315 nm. The reactions did not exhibit good first-order kinetic behavior; the reason is unknown. By estimating rate constants from the initial stage of the reaction, data treatment according to the method described for the acetyl chloride–*N*-methylimidazole system yielded the approximate estimates $k_I = 6.4 \times 10^{-4}\ M^{-1}\ s^{-1}$ and $k_{IN} = 1.3\ M^{-2}\ s^{-1}$.

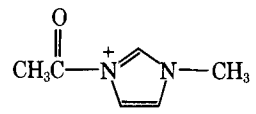
When acetonitrile solutions of acetic anhydride and 4-dimethylaminopyridine are mixed, a rapid but small absorbance increase is obtained at λ_{max} = 315 nm. This is attributed to intermediate formation. Using the molar absorptivity found in the acetyl chloride–dimethylaminopyridine system, it is estimated that 5–10% conversion to the intermediate occurs. The acetylation of isopropanol was studied, the loss of anhydride being followed. Deviations from first-order kinetics were observed, though the deviations were less pronounced than in the acetyl chloride system. Estimates of k_{obs} from the initial portions of the plots led to the estimates $k_A \simeq 0$ and $k_{AN} \simeq 0.5\ M^{-2}\ s^{-1}$. The estimate of k_{AN} may include a contribution from the k_{IN} route.

Mechanism of *N*-Methylimidazole Catalysis—This study has shown that catalysis of acetylations by *N*-methylimidazole can be accounted for in terms of Scheme IV. The intermediate I^+ is the *N*-acetyl-*N'*-methylimidazolium ion (I). The rate constants can be described as follows: k_A = the uncatalyzed reaction; k_{AN} = general base catalysis; k_I = the nucleophilic route; and k_{IN} = general base catalysis of the nucleophilic route.

When *AX* is acetyl chloride, k_1/k_{-1} is very large, the reaction occurs essentially only *via* the I^+ route. When *AX* is acetic anhydride, k_1/k_{-1}

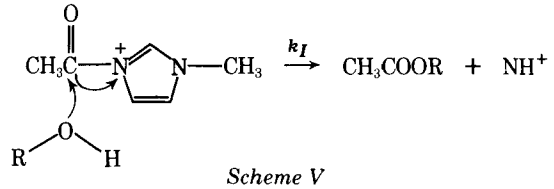


Scheme IV

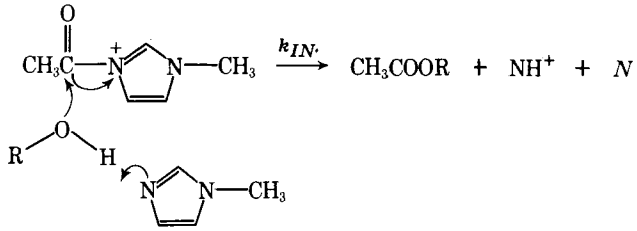


I

is zero, and the reaction occurs entirely *via* the *AX* route. The k_I and k_{IN} reactions are conjectured to occur as shown in Schemes V and VI, where *N* represents *N*-methylimidazole:



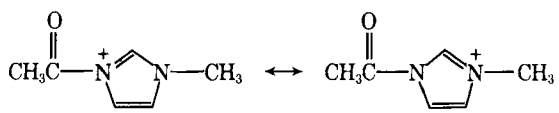
Scheme V



Scheme VI

The mechanisms for acetyl chloride and acetic anhydride are different because chloride is a better leaving group than acetate. When *N*-methylimidazole is replaced by the more powerful catalyst 4-dimethylaminopyridine, some intermediate formation is detected even in the acetic anhydride system. When water is added to the acetonitrile medium, intermediate formation occurs in the acetic anhydride–*N*-methylimidazole system, which constitutes a case in which the mechanism changes from the pure *AX* route (in dry acetonitrile) to the pure I^+ route (in acetonitrile containing $\geq$10 *M* water). This effect can be ascribed to the increase in the polarity in the medium, which will promote formation of the polar intermediate. The dielectric constant of acetonitrile is 36 and that of water is 78. In contrast, incorporation of *n*-propanol into acetonitrile led to no detectable intermediate formation. This is consistent with the view that alcohol–acetonitrile mixtures are not more polar than pure acetonitrile; the dielectric constant of *n*-propanol is 20.5. Besides the spectral and kinetic evidence described here, these mechanistic conclusions are supported by other results. *N*-acetyl-*N'*-methylimidazolium acetate could not be synthesized in acetonitrile, but in a previous report it was found that the chloride salt could be prepared (14). The rate of acetylation of isopropanol by acetic anhydride–*N*-methylimidazole has been investigated in a series of aprotic solvents, with a very small solvent effect being observed (15). This is consistent with the general base (k_{AN}) route but not with the formation of the polar intermediate. It may be noted that the third-order rate constants determined titrimetrically for acetic anhydride–*N*-methylimidazole acetylations in earlier work (8, 15) may now be identified as k_{AN} in Scheme IV.

Comparison of k_A and k_I for the acetyl chloride–*N*-methylimidazole system (Table I) shows that $k_A > k_I$ for each alcohol studied. This means that diversion through the unassisted nucleophilic route (k_I) actually inhibits the reaction relative to the uncatalyzed (k_A) process, possibly because of stabilization of the intermediate by electron delocalization as indicated in II. (Similar delocalization can occur in the 4-dimethylaminopyridine intermediate.)



II

Table IV—Rate Constants for Acetylation of Isopropyl Alcohol in Acetonitrile at 25° [a]

	Acetyl Chloride				Acetic Anhydride			
	k_A	k_{AN}	k_I	k_{IN}	k_A	k_{AN}	k_I	k_{IN}
N-Methylimidazole	0.0015	—	0.00015	0.053	0	0.0041	—	—
4-Dimethylaminopyridine	—	—	0.00064	1.3	0	0.5	—	—

[a] Units of rate constants as in Tables I and II.

Although it has not been possible to measure both k_{AN} and k_{IN} for the same system, Table IV gathers rate constants that have been obtained for both acetylating agents and both catalysts with isopropanol. Analogy with the k_A/k_I ratio suggests that k_{AN} may be $>k_{IN}$, whereas Table IV indicates that $k_{IN} > k_{AN}$ (although these data are not for precisely the same system).

These observations may account for the puzzling report (3) that 1-ethynylcyclohexanol is acetylated faster by acetic anhydride than by acetyl chloride in the presence of 4-dimethylaminopyridine (in $CDCl_3$ solution). If the mechanisms are as described here, the intermediate is quantitatively formed from acetyl chloride, with the concomitant consumption of an equimolar amount of 4-dimethylaminopyridine; thus, the concentration of free catalyst is depleted and is very low under the conditions described. The reaction occurs by the k_I and k_{IN} routes. In the acetic anhydride system, on the other hand, no intermediate is formed, with the result that the catalyst concentration remains high, and the reaction proceeds *via* the k_{AN} route. Under the reported conditions (3), using the rate constants in Table IV, it is calculated that the rate in the anhydride system is greater than the rate in the acetyl chloride system.

Effect of the Solvent—The rates and mechanisms of acylation reactions can be affected by the reaction medium through the operation of several effects.

The Ratio k_1/k_{-1}—This ratio describes the formation of the polar final state ($I^+ + X^-$) from the less polar initial state ($AX + N$). An increase in solvent polarity should increase k_1/k_{-1}; this effect was seen in the system acetic anhydride–*N*-methylimidazole–water, in which k_1/k_{-1} changes from practically zero at low water concentration to very large in substantial water concentrations. The mechanism is changed as a consequence. In the intermediate range where k_1/k_{-1} is finite, both reaction routes are accessible and the kinetics are complex.

Since much prior kinetic study of acylation mechanisms has emphasized fully aqueous systems, the nucleophilic route has often been implicated for those reactions, as in the pyridine-catalyzed hydrolysis of acetic anhydride (16). As the present study shows, however, the extent of *N*-acylammonium intermediate formation can be very sensitive to the solvent.

The Rate Constants k_A, k_{AN}, k_I, *and* k_{IN}—These will be expected to respond to solvent polarity in accord with the postulate that increased solvent polarity will increase the rate if the transition state is more polar than the initial state and *vice versa*. For example, the k_{AN} route will involve some charge separation in the transition state, so k_{AN} may increase slightly as the solvent is made more polar.

The initial state for the k_I and k_{IN} routes is highly polar, being I^+ or the ion-pair I^+X^-. The effect of the solvent will depend upon the relative polarity of the transition state. Greater acylation rates in nonpolar solvents, in terms of a favored breakdown of the charged intermediate to neutral products, has been accounted for (17). This requires the following reaction (in the symbols of Scheme IV): $I^+X^- + ROH \rightarrow AOR + N + HX$. The proton transfer must also be part of (or take place prior to) the rate determining step. If the reaction is $I^+ + ROH \rightarrow AOR + NH^+$, the solvent effect should be modest. In interpreting a solvent effect in these terms, the concurrent behavior of k_1/k_{-1}, which may alter the route of the reaction, must be taken into account.

The Basicity of the Catalyst (N) *and the Counterion* (X^-)—Upon this property depend the proton-accepting abilities of these bases, the effectiveness of X^- as a leaving group, and the nucleophilicity of *N*. As the solvent is changed, the relative basicity of a pair of bases may change.

Acetonitrile is a weaker base than water, so acids are weaker in acetonitrile than in water (as measured by their acid dissociation constants). For carboxylic acids, the relationship between pKa in acetonitrile and water is (18):

$$\text{pKa (acetonitrile)} = \text{pKa (water)} + 4.4$$

whereas for the conjugate acids of amines it is:

$$\text{pKa (acetonitrile)} = 0.47\ \text{pKa (water)} + 2.2$$

The different behavior for acids RCOOH and RNH_3^+ is a consequence of the lower dielectric constant of acetonitrile and its poor anion-solvating capability. The base strengths of acetate and *N*-methylimidazole in acetonitrile, as calculated with these relationships, are:

Acetic acid: pKa (acetonitrile) = 9.15, pKa (water) = 4.75

N-Methylimidazole: pKa (acetonitrile) = 5.5, pKa (water) = 7.0

In water, *N*-methylimidazole is a stronger base than acetate, but in acetonitrile, acetate is the stronger base. This conclusion was used in the derivation of Eq. 7.

The possibility of nucleophilic catalysis is largely determined by the relative basicities of the leaving group (X^-) and the attacking nucleophile (*N*). If pKa (NH^+) > pKa (HX), then the nucleophile is a stronger base than the leaving group, and the nucleophilic route (*via* formation of the *N*-acylated nucleophile) is favored, whereas if pKa (HX) > pKa (NH^+) the nucleophilic route is not favored, and the direct general base route is more probable. As described previously, acetate is a much stronger base than is *N*-methylimidazole in acetonitrile, hence, formation of *N*-acetyl-*N'*-methylimidazolium acetate is not probable from acetic anhydride. The observation of reaction solely *via* the k_{AN} route is consistent with this description. In the acetyl chloride case, however, *N*-methylimidazole is a stronger base than chloride in acetonitrile [chloride is solvated in acetonitrile, whereas larger anions are not (19)], so the nucleophilic route predominates.

Since 4-dimethylaminopyridine is a stronger base than is *N*-methylimidazole, it would be expected to form the acyl intermediate to a greater extent (with a given AX). This behavior was observed: with acetic anhydride, *N*-methylimidazole gave no detectable intermediate, whereas 4-dimethylaminopyridine gave 5–10% conversion to the intermediate.

Molecular Aggregation—In solvents of low dielectric constant, ion-pairs and higher ionic aggregates can be detected. The reactivity of an ion-pair will in general differ from that of a dissociated ion, so ion-pair formation may have kinetic consequences. Acetonitrile is a solvent of moderate polarity, and ion-pairing will not be as extensive as in solvents of much lower dielectric constant. It has not been found necessary to invoke the ion-pair I^+X^- in the present kinetic treatment. Greater reactivity of acetic anhydride than of acetyl chloride (with 4-dimethylaminopyridine catalyst) in nonpolar solvents by postulating the I^+X^- ion-pair has been reported (3), the explanation being that the I^+Cl^- ion-pair is tightly bound and therefore less reactive than the more loosely bound I^+OAc^- ion-pair. An alternative explanation for these results was given previously.

A recent study (20) questioned whether the intermediate I^+ is on the reaction path in 4-dimethylaminopyridine-catalyzed acetylations, and proposed a mechanism in which the catalyst attacks a molecular complex of anhydride and alcohol formed in a pre-equilibrium, giving a solvated ion-pair. No kinetic evidence for this mechanism was presented. The presence of molecular complexes is very likely in these systems, hydrogen-bonded complexes of alcohols with H-bond acceptors being probable in nonpolar solvents. In highly aqueous systems, complex formation of the hydrophobic type can occur. The *N*-methylimidazole systems studied here did not require the mechanistic presence of complexes. It is possible that such species may be responsible for some of the anomalous kinetic behavior seen with 4-dimethylaminopyridine, but this was not investigated[4].

Unusual rate equations for the reaction of anilines with acetyl halides in the presence of *N*-methylimidazole, in nonpolar solvents has been reported (21). Rate terms included the quantities $[I^+X^-]^2$ and $[I^+X^-][AX]$. Such terms may arise because of the presence of ion-pairs and molecular complexes.

Metabolism of Tocainide in the Rat

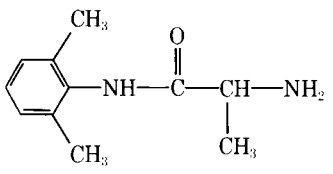
RAMAN VENKATARAMANAN *, FRANK S. ABBOTT, and JAMES E. AXELSON ˣ

Received June 24, 1981, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada V6T IW5.* Accepted for publication August 28, 1981. * Present address: University of Pittsburgh, 3501 Terrace Street, Pittsburgh, PA 15261.

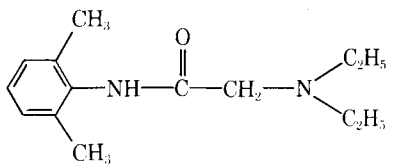
Abstract □ The metabolism of tocainide, an oral antiarrhythmic agent, was studied in male Wistar rats following oral administration of 15 mg/kg of tocainide hydrochloride. Qualitative and quantitative identification of the metabolites in urine was carried out by GC–mass spectrometry and electron capture detector gas chromatography. About 15–20% of the dose administered was excreted as intact drug in the urine. An additional 20% of the dose was present as acid hydrolysable conjugates. Enzymatic hydrolysis (β-glucuronidase) revealed half of the acid hydrolysable conjugates to be a glucuronide. The enzyme mediated hydrolysis was blocked by its specific inhibitor saccharo-1,4-lactone. *N*-acetyl tocainide, an oxidatively deaminated tocainide, an aldehyde adduct of tocainide, and a cyclic hydantoin derivative of tocainide were also identified as metabolites in the urine samples.

Keyphrases □ Tocainide—oral antiarrhythmic agent, study of metabolism, rats □ Metabolism—of tocainide, after oral administration in rats □ GC–mass spectrometry—determination of metabolism of tocainide, rats

Tocainide, 2-amino-2′,6′-propionoxylidide (I), a structural analog of lidocaine (II), is an experimental antiarrhythmic agent, presently undergoing clinical trials (1–4). In humans, tocainide is completely absorbed following oral administration (5), and most of the orally or intraperitoneally administered dose, up to 15 mg/kg, of tocainide is absorbed in rats (6). Kinetic studies carried out in rats revealed the presence of dose dependent elimination of tocainide ≥20 mg/kg (6). Identification of the pathways contributing to the nonlinearity was not possible previously due to the lack of information on the metabolism of tocainide in rats. The present report describes the metabolic fate of tocainide in male Wistar rats.



I



II

EXPERIMENTAL

Animal Experimentation—Adult male Wistar rats with an average weight of 200 g (190–210 g) were used in the present study (animals were obtained from the University of British Columbia animal care unit). The animals were maintained in 0.41- × 0.34- × 0.18-m metallic cages (6 rats/cage) in a controlled environment (24°) for at least 3 days prior to experimentation. Wooden shavings were used as bedding under elevated cages (18 cm from the bottom of the cages). The photoperiod was controlled to provide a dark cycle from 8 pm to 6 am and a light cycle from 6 am to 8 pm. The animals had access *ad libitum* to food (rat chow) and water during this period. The animals were fasted for 8–10 hours prior to and during the experiments; however, water was allowed *ad libitum*.

An aqueous solution of tocainide hydrochloride[1] or 3′,4′,5′-trideuterated tocainide hydrochloride was given orally (stomach tube) to animals under light ether anesthesia. Dosed animals were housed in separate stainless steel metabolic cages (24.5 × 17.5 × 18 cm) with facilities for collecting urine samples free of fecal contamination, into an amber-colored bottle. Twenty-four hours postdose, the sides of the cage and the collecting funnel were washed three times with distilled water to recover all excretory products. The urine samples were stored in the freezer until analyzed.

Analytical Methods—Measurement of intact tocainide in urine samples was carried out by using an electron capture detector gas chromatographic method previously reported (7).

The presence of conjugated tocainide in urine samples was determined by acidic and enzymatic hydrolysis. For the acid hydrolysis, 1 ml of urine was incubated with 1 ml of 1 *N* HCl in a sealed glass ampul for 1 hr at 100°. An aliquot of this solution was used for the analysis of tocainide.

Preliminary studies with enzymes from different sources suggested maximal hydrolysis of the conjugates to occur when bovine liver β-glucuronidase was used. The enzymatic hydrolysis involved the addition of 1 ml of 1 *M* acetate buffer (pH 5.0) and 0.2 ml of β-glucuronidase[2] to 1 ml of urine and incubation of the mixture at 37° for 24 hr. At the end of the incubation period the samples were analyzed for intact tocainide. Additional experiments were also carried out to determine the effect of saccharo-1,4-lactone[3], 0.1 m*M* final concentration, on the enzyme mediated hydrolysis of tocainide conjugates.

Multiple extraction of the urine samples (25–30 ml), without any pH adjustments or at pH 9.0 (ammonium hydroxide and ammonium carbonate) or at pH 9.0 and 12.0 using sodium hydroxide, was carried out

in a separatory funnel with an equal volume of methylene chloride[4]. In another experiment the urine samples (25 ml) were freeze-dried and the residue was dissolved in methanol (5 ml). The methanolic solution was then filtered and concentrated to ~1 ml under nitrogen at room temperature. Methylene chloride and methanolic extracts of urine were analyzed by GC–mass spectrometry[5] to determine the presence of other metabolites of tocainide. The GC component of the GC–mass spectrometric system was equipped with a 1.8-m × 2-mm i.d. coiled glass column packed with Silar 10 C[6] coated on ChromoSorb W–HP (100–120 mesh). The injection port temperature was 170° and the oven temperature was programmed from 100 to 250° at 10°/min. The temperature was held at 250° until the end of the analysis. Helium was used as a carrier gas at a flow rate of 30 ml/min. The temperature of the separator was 280°. The ionization energy was 70 eV and the accelerating voltage was 820 V. The mass spectrometer was operated in the scanning mode and the mass spectra were recorded continuously at 5-sec intervals during an entire run.

Methylation of the extracted samples was carried out by the addition of 100 μl of trimethylanilinium hydroxide[7] and subsequent incubation at 100° for ~10 min.

RESULTS

The results of the acid hydrolysis studies are summarized in Fig. 1. Incubation of the urine samples with hydrochloric acid liberated tocainide corresponding to >15% of the dose administered. Control experiments carried out in the absence of any acid revealed nearly a 20% loss of tocainide during the experimental process following 1 hr of hydrolysis. This would imply that the actual amount of tocainide present as conjugate would be >20% of the administered dose. Longer periods of incubation (2 hr) resulted in further reduction in the recovery of tocainide from the conjugates. This could be due to the breakdown of tocainide under the conditions of hydrolysis employed in this study.

Enzymatic hydrolysis (β-glucuronidase) of the urine, revealed the presence of nearly 7% of the dose administered as a glucuronide conjugate. The enzymatic hydrolysis mediated by β-glucuronidase was blocked by its specific inhibitor saccharo-1,4-lactone, thus confirming the conjugate to be a glucuronide. The percent of dose recovered as intact tocainide in untreated urine, β-glucuronidase treated urine, and urine treated with β-glucuronidase and saccharo-1,4-lactone were 17.5 ± 1.1 (n = 3), 24.0 ± 0.7 (n = 3), and 17.0–17.7 (n = 2).

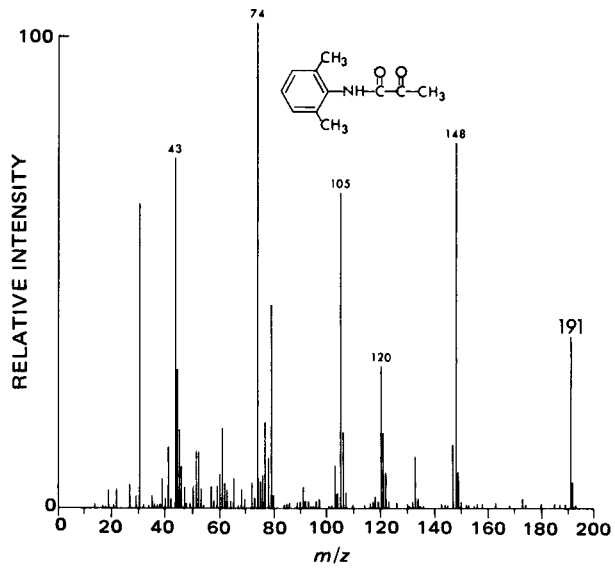

Figure 4—*Mass spectrum and the postulated structure of a metabolite of tocainide (IV). This compound corresponds to peak B of Fig. 2.*

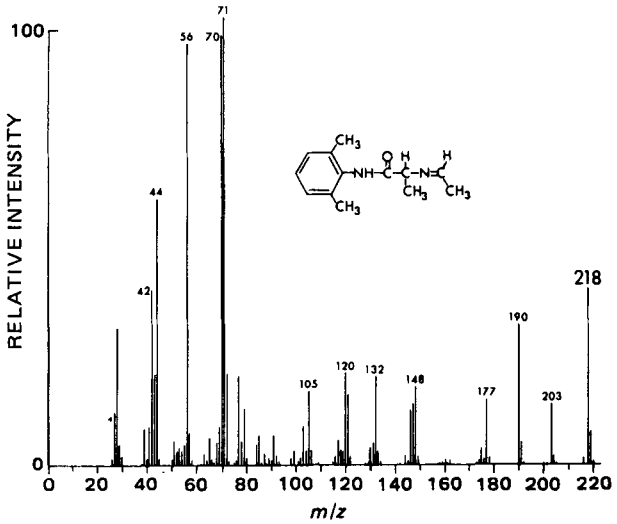

Figure 5—*Mass spectrum and the postulated structure of a metabolite of tocainide (V). This compound corresponds to peak C of Fig. 2.*

Other Metabolites of Tocainide—The chromatogram obtained following injection of the methylene chloride extract of tocainide onto a Silar 10 C column of the GC–mass spectrometer is shown in Fig. 2. Confirmation as to the origin of peaks A, B, C, D, and E were obtained from studies using trideuterated tocainide. The presence of molecular ions at *m/z* values of (M ± 3) following analysis of the urine of rats administered trideuterated tocainide pointed to tocainide as the source of these peaks. Since all three deuterium labels were present in all of these peaks, it was inferred that these peaks result from modification of the structure by metabolism at the side chain. The other peaks present in the chromatogram were from endogenous materials in the urine.

Peak A—Peak A appeared in the methylene chloride extract of urine samples at pH 9.0 as well as in the methanolic extract of the freeze-dried urine samples with a retention time of ~5 min. The mass spectrum and the postulated structure of the compound (III) are shown in Fig. 3. The molecular ion was at *m/z* 121 (124) and the base peak was at *m/z* 106 (109). The compound, however, seems to account for <5% of the dose administered.

Peak B—Peak B was present in the methylene chloride and the methanolic extract of the urine samples. The molecular ion at *m/z* 191 corresponds to a composition of $C_{11}H_{13}NO_2$ (Fig. 4). The presence of peaks at *m/z* 105, 120, and 148 suggested intactness of the carboxy-xylidide moiety of tocainide. The abundant peak at *m/z* 43 corresponded to C_2H_3O. This compound (IV) eluted at about 10 min in the chromatogram and was also present in small quantities in the urine samples.

Peak C—Peak C was present in the following extracts of rat urine: (*a*) direct extraction of urine with methylene chloride; (*b*) extracts of urine at pH 9.0 (ammonium carbonate and ammonium hydroxide) with

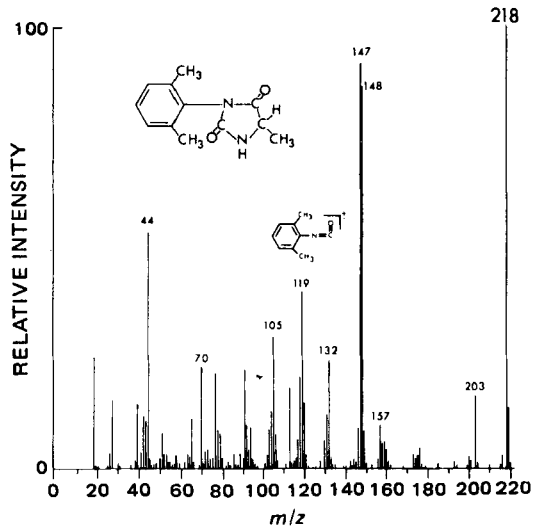

Figure 6—*Mass spectrum of the cyclic compound VI.*

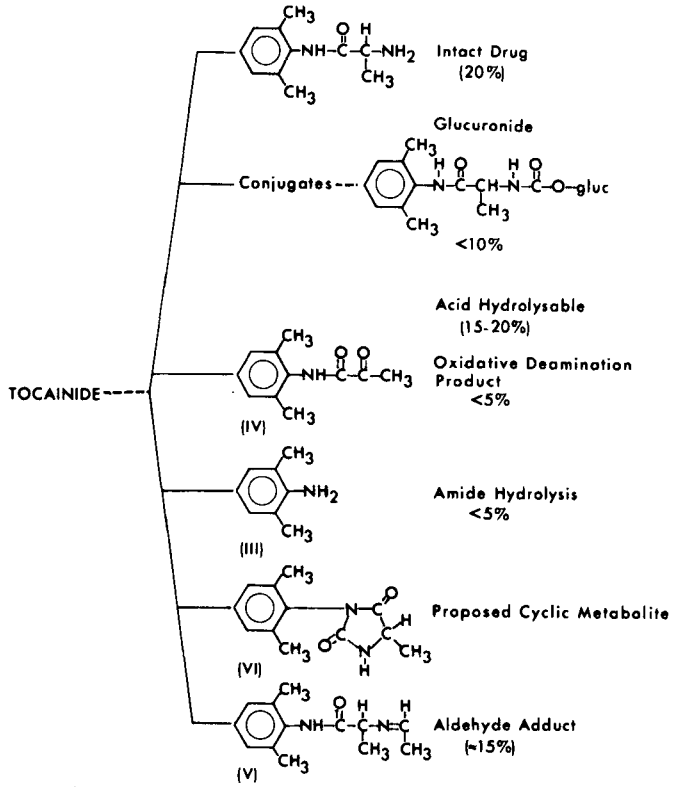

Scheme I—Proposed metabolic products of tocainide. The structures and the relative amounts of the proposed metabolites of tocainide. The percentage values are the percent of dose excreted as a particular metabolite.

methylene chloride; (*c*) extracts of acid hydrolyzed urine extracted with methylene chloride at pH 9.0 (ammonium carbonate and ammonium hydroxide); (*d*) methanolic extracts of freeze-dried urine.

When subjected to mass spectral analysis, this compound revealed a molecular ion at *m/z* 218 suggesting the addition of 26 mass units to the parent compound (Fig. 5). The presence of *m/z* 221 in studies using the trideuterated tocainide suggested that all three deuterium atoms are present in this compound. The persistence of the deuterium atoms in the aromatic ring was also evident from the presence of the following peaks: *m/z* 105 (108), 120 (123), 132 (135), 148 (151), 177 (180), 190 (193), and 203 (206). The presence of ions of the following composition: C_8H_9 (105), $C_8H_{10}N$ (120), $C_9H_{10}NO$ (148), $C_{11}H_{15}NO$ (177), and $C_{11}H_{14}N_2O$ (190) indicated the intactness of the major skeleton to tocainide. The peak at *m/z* 203 (M −15) suggested the presence of a methyl group as part of the structural modification. Ions of *m/z* 28 (C_2H_4), 42 (C_2H_4N), and 70 (C_4H_8N) in samples obtained following administration of tocainide or trideuterated tocainide indicated that these fragments must arise from the side chain. The fragmentation, thus observed, corresponds to an aldehyde adduct (V) of tocainide. The adduct appears to be one of the major metabolic pathways of tocainide in rats. Preliminary estimates show nearly 15% or more of the dose of tocainide to be eliminated *via* this metabolic pathway.

Peak D—Peak D in Fig. 2 corresponded to intact tocainide. Nearly 20% of the dose administered appeared in the urine as intact drug in the 24-hr period following drug administration.

Peak E—Direct extraction of the urine samples with methylene chloride or extraction, following adjustment of the urine pH to 9.0 with ammonium carbonate and ammonium hydroxide or sodium hydroxide, resulted in peak E which eluted at ~23 min.

The parent ion at *m/z* 218 (221) suggested this compound to be a product from tocainide with the addition of 26 mass units (Fig. 6). Ions of the composition C_8H_9 (105) and C_8H_9N (122) indicate the xylidine moiety of tocainide to be intact. The presence of a peak at *m/z* 119 (122) and not at 120 (123) indicates the xylidine nitrogen to be tertiary. The abundance of *m/z* at 147 (150) indicates that the carboxylidine moiety of tocainide is also intact but for the loss of one hydrogen atom, further suggesting that the amide nitrogen is tertiary and possibly part of a cyclic system. The presence of a methyl group is indicated by *m/z* at 203 (M −15). The compound could be methylated (implying the presence of a replaceable hydrogen) but failed to form any derivative with heptafluo-

robutyric anhydride[7]. The mass fragmentation pattern of this compound was identical with the fragmentation pattern of 3-(2,6-xylyl)-5-methyl hydantoin (VI)[1].

The relative amounts of VI in the methanolic extract was quite high as compared to the methylene chloride extract. This could be due to the generation of the cyclic compound from the glucuronide conjugate that was dissolved in methanol.

DISCUSSION

The metabolic products of tocainide are summarized in Scheme I. Following oral, intravenous, or intraperitoneal administration of tocainide (15 mg/kg) to rats, ~15–20% of the dose is excreted as intact drug over a 24-hr period (6). Nearly 44% of an oral dose was excreted as free tocainide in humans while an acid or β-glucuronidase hydrolyzable metabolite accounted for nearly 23% of the tocainide dose administered (8). A novel biotransformation pathway was put forth to explain the disposition of tocainide in humans (8). The proposed structure of this metabolite was tocainide carbamoyl O-β-D-glucuronide. During preliminary work in rats, the authors identified the presence of a similar conjugate of tocainide in rat urine. Acid hydrolysis (nonspecific) as well as enzyme (β-glucuronidase) hydrolysis (specific for glucuronide conjugate) of the urine samples were carried out to determine the nature of the conjugates.

Use of β-glucuronidase corresponding to 1000 U of enzyme resulted in maximal release of tocainide from its conjugates. Addition of trace quantities (10 μl) of chloroform as suggested previously (9) did not result in any increase in the yield of tocainide from the conjugates. Under the conditions of the enzymatic hydrolysis (24 hr at 37°), no detectable degradation of tocainide was observed. Enzymatic hydrolysis resulted in the liberation of tocainide, equivalent to ~7–10% of the dose administered. Addition of saccharo-1,4-lactone into the incubation medium prevented the enzyme mediated hydrolysis of the conjugate, thus indicating the conjugate to be a glucuronide.

Acid hydrolysis of the urine sample resulted in the liberation of tocainide corresponding to ~20% of the administered dose. Simultaneous experiments showed that there is a loss of nearly 20% of tocainide in the control samples (urine sample–distilled water instead of 1 *N* HCl). This suggested that one is probably underestimating the amount of acid hydrolysable conjugates by the method used, due to the degradation of tocainide at the pH and temperature used for acid hydrolysis. Further proof for this hypothesis came about from the stability studies of tocainide carried out at different temperatures and in the presence of acid of different strength. An increase in the strength of the acid (1 *N* to 12 *N*) as well as the time of incubation resulted in a progressive reduction in the amount of tocainide remaining in an aqueous solution of the drug at 100°. Consistent with this observation, incubation of the urine samples for a longer period of time (>2 hr) or with acids of higher normality (2 *N*, 6 *N*, or 12 *N*) provided decreased estimates of the conjugates present in urine. The use of higher temperatures (autoclaving of the urine sample with water for 35 min) also degraded tocainide, but to a greater extent than that seen at 100°.

During these experiments tocainide was observed to degrade at a faster rate in the presence of urine. To determine the possible role of urea in this degradation, tocainide was incubated with 8 *M* urea for 1 hr at 100°. At these higher concentrations of urea marked degradation of tocainide was observed. It is possible that the degradation of tocainide at higher temperature is to some extent related to the urea in the urine sample. Hence, it should be noted that the estimates of the acid hydrolysable conjugates carried out in the present study are only an approximation of the actual amount present in the urine.

Experiments carried out under optimal conditions for the enzymatic hydrolysis of the glucuronide conjugates of tocainide did not account for all of the conjugates observed following acid hydrolysis. It would appear that there are other conjugates of tocainide which also yield tocainide following acid hydrolysis. Acetylation is a known metabolic pathway for the elimination of primary amines (10). GC–mass spectrometric analysis has identified the presence of small quantities of *N*-acetyl derivative of tocainide in the rat urine. It is also possible that tocainide is eliminated by an as yet unidentified conjugation pathway.

Cleavage of the amide group (amide hydrolysis) has been shown to be a metabolic pathway for the elimination of a number of lidocaine analogs (11–14). In the present study, small quantities of 2,6-dimethylaniline were observed as a metabolite of tocainide (Fig. 3).

Condensation of a metabolite of lidocaine with acetaldehyde generates N^1-ethyl-2-methyl-N^3-(2,6-dimethylphenyl)-4-imidazolidinone (14). Such condensation reactions can occur under very mild reaction conditions (14). An aldehyde adduct of tocainide was observed in relatively large quantities (nearly 15% of the dose administered in the present study). The adduct was present in the methylene chloride and the ether extract of the urine samples.

A small quantity of oxidatively deaminated tocainide was also proposed to be present as a metabolite in rats (Fig. 4).

In addition to being formed from an unstable metabolite of tocainide, the cyclic compound was also present in small quantities in the urine sample as inferred by its presence in the methylene chloride extract of the urine sample at pH < 9.0 (15). The presence of a cyclic hydantoin metabolite of etidocaine in humans was reported previously (11). This hydantoin metabolite was a close structural analog of the cyclic metabolite observed in the present study.

Thus, the metabolic pathway shown in Scheme I accounts for nearly 60–70% of the dose of tocainide. Even though not identified in the present study, hydroxylation of the aromatic ring is a possible additional pathway of elimination of tocainide.

Studies on the Absorption of Practically Water-Insoluble Drugs following Injection V: Subcutaneous Absorption in Rats from Solutions in Water Immiscible Oils

KOICHIRO HIRANO ˣ, TERUHISA ICHIHASHI, and HIDEO YAMADA

Received March 2, 1981, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka, 553, Japan.* Accepted for publication September 2, 1981.

Abstract □ To elucidate the kinetics and mechanisms of subcutaneous absorption of practically water-insoluble drugs in oily solutions, the absorption behaviors of select azo dyes and other prototype agents were investigated by a local clearance method in the dorsum in intact rats. The absorption of the drug components appeared to be first-order. The first-order rate constant (k) was inversely proportional to the cube root of the injection volume. In more limited studies, essentially the same behavior was observed in the rat abdomen, and the difference in k between the dorsal and abdominal injections was slight. The comparison of k of a given compound from different oily vehicles showed that k was governed predominantly by the distribution coefficient (K) between the oily vehicle and the aqueous subcutaneous medium and depended little on the viscosity of the vehicle. This distributioning relationship was shown through correlation of the rate constants with *in vitro* distribution coefficients. A plot of log k *versus* log K for all the compounds tested was linear with a slope of ~−0.7. This linear relationship allows adequate prediction of absorption rates of other drugs from oily vehicles. The observed subcutaneous absorption rates and behaviors are compared with previous results involving the intramuscular route.

Keyphrases □ Absorption, subcutaneous—from solutions in water immiscible oils, rats □ Water-insoluble drugs—subcutaneous absorption from solutions in water immiscible oils, rats □ Drug clearance—local clearance method following subcutaneous injection of practically water-insoluble drugs, drug absorption kinetics from oily solution, rats.

A previous study (1) investigated the intramuscular absorption characteristics of practically water-insoluble drugs in oily solutions in rats and considered the major factors governing the absorption kinetics. In parenteral drug administration, the subcutaneous route is as useful and important as the intramuscular route for early screening and preclinical testing of drugs in laboratory animals. The extensiveness of the subcutaneous tissue and its porosity and loose attachment allow injections of larger volumes than can be easily given intramuscularly. Thus, subcutaneous administration is applicable for dose–response experiments and multiple dosing experiments in small animals.

Since the publication of Schou's review (2) of drug absorption from subcutaneous connective tissue, there has been an increasing interest in quantitatively evaluating the subcutaneous absorption rate of drugs (3–6). However, very little work has been done on the absorption characteristics of marginally water-soluble drugs relative to highly water-soluble drugs in aqueous solution. The absorption rate and the resulting pharmacological responses of hydrophobic drugs are dependent primarily on the dosage form or physicochemical state of the preparation, and thus, it is very important to clarify the relationship of the kinetics of release of such drugs to the physical form in which they were administered.

The present study was undertaken to clarify the absorption mechanisms and kinetics attending subcutaneous injection of practically water-insoluble drugs in oily solutions and to compare them with intramuscular injection. Several azo compounds and testosterone were used as model drugs and a variety of water-immiscible oils were used as model vehicles. Subcutaneous absorption rates of these model drugs were measured in intact rats by a local clearance method first reported by Secher-Hansen *et al.* (3). Rates were compared across diverse experimental systems and conditions to evaluate the contribution of physicochemical factors to the kinetic process.

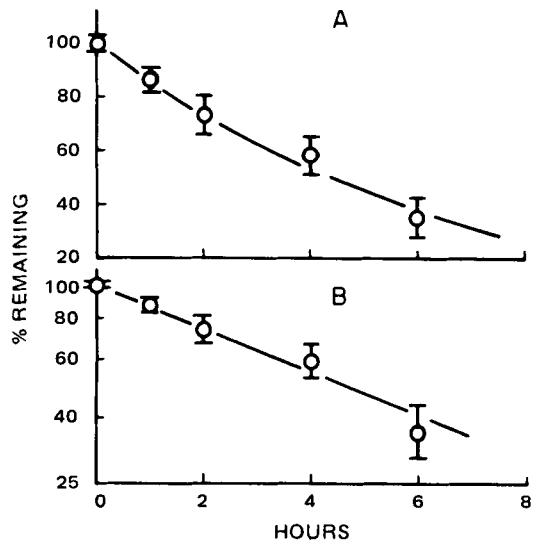

Figure 1—*Absorption time course of* p-*hydroxyazobenzene in sesame oil solution after subcutaneous injection into the intact rat. Initial drug concentration (C_0), 1 mg/ml; injection volume (V_0), 0.5 ml. Each data point represents the mean of four or five experiments and the vertical bar indicates the standard deviation.*

EXPERIMENTAL

Materials—Azo dyes (*p*-hydroxyazobenzene[1], *p*-aminoazobenzene[2], *o*-aminoazotoluene[3], 1-phenylazo-2-naphthylamine[2]), and testosterone[2] were selected as model compounds. These compounds are unionized under physiological conditions and are the same as used in a previous study (1). Sesame oil[4], medium-chain (C_8–C_{12}) triglycerides[5], isopropyl myristate[6], diethyl sebacate[6], and simethicone[7] were selected for their wide ranging viscosities and solubilizing powers. Other than simethicone, the oils were the same as used previously (1). All other chemicals used in this study were of analytical or reagent grade.

Preparation of Test Solutions—Test injection solutions for the absorption studies were prepared by dissolving the drugs in the oily media and then clarifying the media by passing the solutions through membrane filters (1). All test solutions of the azo dyes and testosterone were ascer-

tained to be chemically and physically stable over the experimental period.

Procedure for Subcutaneous Absorption—Male Wistar albino rats (260–280 g) were used in all absorption experiments. Prior to an experiment, the hair in the center region (area, 5 × 5 cm^2) of the dorsum (or abdomen) of the rat was removed with an electric clipper[8]. With the rats under light anesthesia with ether, a given volume of test solution was injected into the subcutaneous space near the center of the shorn area using a calibrated syringe connected to a 0.50 × 25-mm needle[9] at an injection speed between 0.04 and 0.4 ml/sec. Immediately after withdrawal of the needle, a rapidly drying adhesive[10] was applied to the insertion site to prevent leakage. During an absorption experiment, each rat was housed in a cage and allowed freedom of movement and easy access to water and food. At various intervals postinjection, each rat was decapitated and bled, and the tissues around the injection site containing the oily depot were excised as completely as possible and then minced. Drug remaining at the injection site was extracted from the minced tissues with 20 ml of ethyl acetate, and the amount of drug was determined. Most of the test compounds recovered from the tissue were within the oily deposits and there appeared to be little drug recovered from the surrounding tissues. Decomposition and metabolism of the model compounds at the injection site were presumed to be negligible; thus, their clearance in the absorption experiments is mainly attributed to removal by blood and lymphatic flows. Three to five rats were used for each time interval in all the absorption experiments.

Measurement of Absolute Viscosity—The kinematic viscosity of each oily solvent was determined with a viscometer[11] and converted into the absolute viscosity using its density, which was measured with a calibrated flask[12]. These determinations were done at 37°.

Determination of the Distribution Coefficient—The distribution coefficient (K) of a model compound between an oily solvent and 0.9% (w/v) NaCl in water (saline) was determined by equilibrating an oily solution with saline and computing K from the equilibrium saline concentration and the initial concentration in the oil phase (1).

Analytical Method—In the absorption experiments extracts containing the azo dyes were adequately diluted with ethyl acetate and analyzed colorimetrically (1). Extracted testosterone was assayed by a gas chromatographic method (1). Three-milliliter samples were shaken with 0.6 g of Al_2O_3–silica gel (1:1) to remove interfering substances. The mixture was centrifuged for 5 min at 3000 rpm and 1 ml of the supernatant liquid was mixed with 0.1 ml of the internal standard (3β-acetoxy-5α-androstan) in ethyl acetate. Two microliters of these solutions was injected using the same instrument settings reported previously (1). For determination of the distribution coefficients, test compounds in saline equilibrated with oily solutions of known initial concentration were assayed by direct spectrophotometric methods (1).

RESULTS

Time Course of Drug Absorption and Effect of Initial Drug Concentration—It was reported (5) that benzyl alcohol, which is relatively hydrophobic, was absorbed from an aqueous medium in the rat subcutaneous region according to first-order kinetics. However, the kinetic process for subcutaneous absorption of practically water-insoluble drugs from oily solutions has not been explored.

The time course of subcutaneous absorption in a typical experiment is illustrated in Fig. 1, which shows the profile for *p*-hydroxyazobenzene absorbed from a sesame oil solution. The initial drug concentration (C_0) and the injection volume (V_0) are given in the legend. The fraction (percent) of *p*-hydroxyazobenzene remaining at the injection site was plotted against time on arithmetic and logarithmic scales. The linear relationship shown in Fig. 1B indicates this compound is absorbed according to first-order kinetics. To verify this, the effect of the initial drug concentration (C_0) on the absorption rate was examined. Figure 2 shows the absorption time courses of *p*-hydroxyazobenzene from solutions initially of 1, 5, and 20 mg/ml on a semilogarithmic scale. All three profiles are approximately linear with the same slope. Similar results were obtained with other compounds such as *p*-aminoazobenzene and *o*-aminoazotoluene. These findings suggest that subcutaneous absorption of practically water-insoluble and unionized drugs from oily solutions behaves as a first-order process.

Effect of Injection Volume—It has been noted that the injection volume of aqueous (7, 8) or oily (9) solutions might be an important factor influencing intramuscular absorption rates of drugs. A previous report (1) revealed the quantitative relationship between the absorption rate constant and the injection volume for intramuscular administration of practically water-insoluble drugs administered as oily solutions. However, for subcutaneous administration, the effect of the injection volume has not always been clear (10, 11).

Figure 3 compares the absorption time courses of *p*-hydroxyazobenzene injected in different volumes on a semilogarithmic scale. Each absorption profile is linear and the slopes decrease with increased injection volume. Figure 4 demonstrates the relation between the observed first-

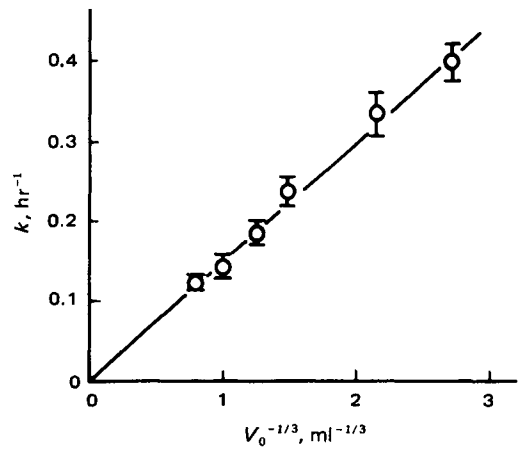

Figure 4—*Relationship between the first-order absorption rate constant (k) and injection volume (V_0). The values of* k *were estimated from the data shown in Fig. 3 by the least-squares method and are plotted together with their standard errors.*

order absorption rate constant (k) and injection volume (V_0). It was evident from this figure that k was inversely proportional to the cube root of V_0.

Comparison of Absorption Rates between Dorsal and Abdominal Subcutaneous Injections—A significant difference in the absorption half-life of ^{131}I-labeled insulin injected subcutaneously into the human arm and thigh was noted (12). Given this difference, and considering the fact that subcutaneous drug injections to animals are not always limited to the dorsal site, the abdomen was selected as a second subcutaneous injection site to draw site-to-site comparisons. Drug absorption time courses from this site with different injection volumes were evaluated, and again first-order absorption rate constants were obtained from semilogarithmic plots. The values are compared in Fig. 5 with those obtained for the dorsal injections. The relationship between the rate constant of absorption and the volume of material injected found by dorsal subcutaneous injection also held for the subcutaneous abdominal injections. Remarkably, differences in the absorption rate constants between these two injection sites were negligible. These findings showed that, at least with these substances and under these experimental conditions, absorption behaviors of the two sites are virtually identical.

Comparison of Absorption Rates from Various Oily Solvents—Up to this point, sesame oil was used as the oily solvent since it is commonly used as a parenteral solvent. To clarify possible influences of the oily medium on absorption kinetics, the absorption time courses from different oily vehicles were evaluated. Figure 6 shows absorption time profiles of *p*-hydroxyazobenzene from six oily vehicles, diethyl sebacate, medium chain triglycerides[5], isopropyl myristate, sesame oil, and two isopropyl myristate–simethicone systems (40:60 and 20:80, v/v), all administered at the same volume. The semilogarithmic plots are linear but each has a different slope. Similar results were obtained for *p*-aminoazobenzene and *o*-aminoazotoluene. The first-order absorption rate constants obtained from these experiments are summarized in Table I along with the viscosities (η) of the oil solvents and the distribution coefficients (K, oily vehicle/saline). Clearly, the distribution coefficient is the predominant factor controlling the absorption rates from these oily vehicles.

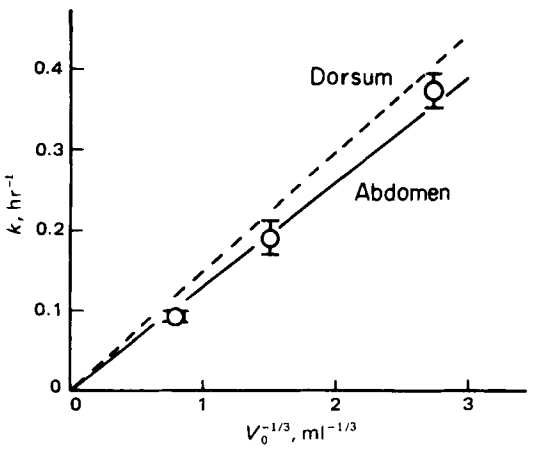

Figure 5—*Comparison of the subcutaneous absorption rate constants (k) of p-hydroxyazobenzene in sesame oil at various injection volumes (V_0) between injection sites on the dorsum and abdomen of rat (C_0, 5 mg/ml). The k values were estimated by the least-squares method and plotted together with their standard errors. Key: (—○—) abdomen; (- - -) dorsum (same as shown in Fig. 4).*

DISCUSSION

Shape of Depot and Drug Absorption Kinetics—It is observed that when a given volume of water-immiscible oil is injected subcutaneously, the major part of it is confined to the injection site by the connective tissues and possibly other surrounding tissues. Also the depot formed in such a manner tends to take the shape of a flattened oblate or prolate spheroid. These observations are similar to those described previously (13), where w/o emulsions containing radioactive substances were used to define the local distribution. The shape of the oily depot, which determines the surface area of the oily phase exposed to the body fluids, is thought to be a critical factor affecting drug absorption. The geometry of the oily depot may depend on the injection volume, the fluidity of the oily solution, hydrodynamic factors such as the injection speed, the available space at the injection site, and/or body movements. The deposit configuration is undoubtedly time-dependent. Visual observation confirmed geometrical change of the depots caused by spreading. These were initially abrupt but became very slight after a short time. Water-immiscible oils such as sesame oil apparently disappear much more slowly from the subcutaneous site than do the drug components they contain (14). A previous study (1) showed that sesame oil was also very slowly absorbed from the m. gastrocnemius of the rat during the first several hours after injection. Therefore, it seems reasonable to regard the surface area of the oily depot as a constant during the absorption process except for a short period immediately after injection. The state of the oily depots and the first-order absorption characteristic of the rate process strongly suggest that the absorption behavior of drugs in oily solutions deposited subcutaneously is very similar to that of the intramuscular route (1). Therefore, the kinetic treatment previously proposed for intramuscular absorption (1) seems equally applicable to the subcutaneous situation.

The kinetics of absorption from an intramuscular, oil deposit were developed for a physical model in which mass transfer was strictly controlled by diffusion through the interface of the depot with the tissue.

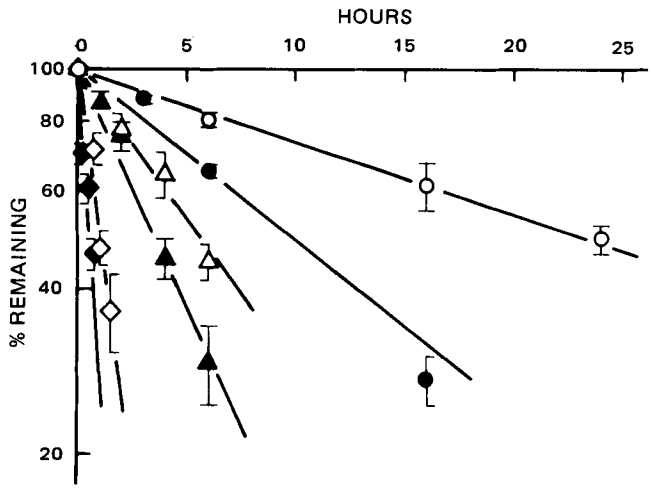

Figure 6—*Time courses of the subcutaneous absorption of p-hydroxyazobenzene from various oily vehicles (C_0, 0.5–5 mg/ml; V_0, 0.5 ml). Each data point represents the mean of at least three experiments and the vertical bar indicates the standard deviation. Key: (○) diethyl sebacate; (●) medium chain triglycerides; (△) isopropyl myristate; (▲) sesame oil; (◇) isopropyl myristate–simethicone (40:60, v/v); (◆) isopropyl myristate–simethicone (20:80, v/v).*

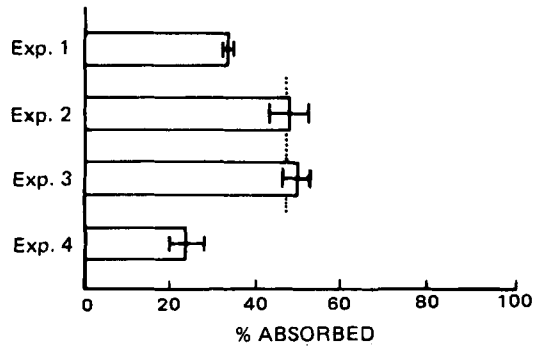

Figure 7—*Comparison of the subcutaneous absorption of* p-*aminoazobenzene among various injection methods at a constant dose. The dotted line shows the value for Exps. 2 and 3 predicted from the results of Exp. 1. Each data point shows the mean of at least four experiments. Key: Exp. 1, 4 mg/ml–0.5 ml; Exp. 2, 20 mg/ml–0.1 ml; Exp. 3, 4 mg/ml–0.1 ml, 5 injections at different points; Exp. 4, 4 mg/ml–0.5 ml (o/w emulsion).*

The interface was seen as a series barrier, possibly with significant diffusional resistances on each side of the interface, *i.e.*, in the boundary layer in the depot and in the tissue immediately in contact with the depot. Mass transfer coefficients (permeability coefficients) k_o and k_a describe the diffusive velocities in the depot's boundary and the tissue, respectively. It is implicit that the depot acts as a well-stirred phase everywhere except at its interface. It was also assumed in developing the model that: (*a*) over the full course of drug release the depot's interfaces and surface area remain essentially constant; (*b*) the distribution coefficient of a drug between the depot and the tissue fluids strictly governs the relative concentrations on each side of the interface; (*c*) the depot acts as a reservoir for the drug; (*d*) the body of the animal acts as a diffusional sink; and (*e*) there is no assimilation of the oily vehicle by the body over the course of drug release. With these assumptions the release process becomes a first-order depletion of a reservoir into a sink by means of diffusion across an oil–water boundary. The following equations were derived for the quasi-steady-state (period after establishment of the gradient across the boundary):

$$\ln (W/W_0) = -kt \qquad \text{(Eq. 1)}$$

and

$$k = \frac{k_o A}{V_0\left(1 + \frac{k_o}{k_a} K_i\right)} \qquad \text{(Eq. 2)}$$

where W_0 and W represent the dose and the remaining amount of the drug at any time t, respectively; V_0 and A are the injection volume and the surface area of the oily depot, respectively; k_o and k_a are the diffusive velocities of the drug in the oily and aqueous tissue boundaries, respectively; K_i is the distribution coefficient at the interface; and k is the first-order absorption rate constant (1). Equation 1 describes the expected first-order behavior, while Eq. 2 characterizes the rate constant for the series barrier situation.

Comparison of Absorption Rates among Various Injection Methods—Equation 2 contains the ratio, A/V_0, which describes the geometrical aspects of the absorption process. The dependency of drug-release rate on the injected volume centers around the interdependency of area and volume. When the shape of the injected mass is spherical or near spherical, the area–volume ratio is simply $3/r$ or three times the reciprocal radius of the equivalent sphere. This is directly proportional to the reciprocal cube root of the volume[13]. Therefore, for an injection acting as a near spherical (or spheroidal) mass, it is expected that the absorption rate constant of an incorporated drug will be proportional to the $V_0^{-1/3}$, a dependency on volume which was closely followed in the subcutaneous administrations as evidenced in Figs. 4 and 5.

[13] When the injected mass takes the shape of a spheroid or a near spheroid and retains the same shape (dimensions) for alterations in injection volume, the same cube root volume dependency can also be derived mathematically as follows:

Spheroid 
$$\frac{A}{V} = \left\{\frac{3}{2\beta}\left(\frac{3}{4\pi\beta}\right)^{-\frac{1}{3}}\left(1 + \frac{\beta^2}{2\sqrt{1-\beta^2}} \log \frac{1+\sqrt{1-\beta^2}}{1-\sqrt{1-\beta^2}}\right)\right\} V^{-\frac{1}{3}}$$

$(a > b,\ b/a = \beta)$

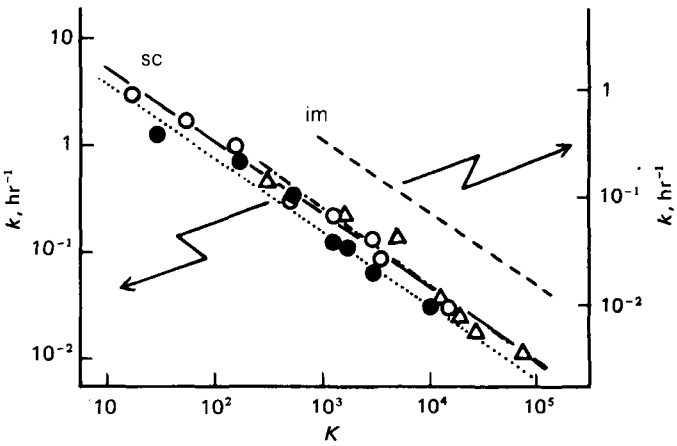

Figure 8—*Plots of* k versus K *on log–log scale for three model compounds. Key: (—○—) p-hydroxyazobenzene; (·····●·····) p-aminoazobenzene; (-·-▵-·-) o-aminoazotoluene; (sc) data for subcutaneous injection at* C_0 = *0.5–5 mg/ml and* V_0 = *0.5 ml; (im) data for intramuscular injection m. gastrocnemius) at* C_0 = *5 mg/ml and* V_0 = *0.05 ml reported previously (1).*

The preceding discussion indicates that the absorption rate constant is dependent on injection volume and not on the initial drug concentration. This means that the absorption rate can be manipulated by the injection method even if the drug, solvent, and dose are fixed. This was demonstrated experimentally using *p*-aminoazobenzene in sesame oil solution. Figure 7 shows the percentage of this drug absorbed 3 hr after injection of a fixed dose, 2 mg/rat, by four differing injection protocols. In Exp. 1 a single, 0.5-ml injection of solution containing 4 mg/ml was given; in Exp. 2 a single, 0.1-ml injection of solution containing 20 mg/ml was given; in Exp. 3 five injections were given at different sites, each with 0.1 ml of solution containing 4 mg/ml; and in Exp. 4 a single, 0.5-ml injection of an o/w emulsion [equal volumes of sesame oil containing 8 mg/ml of *p*-aminoazobenzene and saline containing 2% (w/v) polysorbate 80; emulsion particle diameter, 2–10 μm] was given. The theory was tested as follows. The first-order absorption rate constant (k_1) was determined in Exp. 1. Using this k_1 value, the value of the percentage absorbed for Exp. 2 can be estimated by the following equation derived from Eq. 1 and the cube root volume dependency:

$$\text{Percent absorbed} = 100\{1 - \exp[-k_1(V_1/V_2)^{1/3}t]\} \qquad \text{(Eq. 3)}$$

The dotted line in Fig. 7 shows the value estimated by substitution of the calculated value, 0.12 (hr^{-1}), for k_1, of 5 for V_1/V_2 (the actual injection volume ratio), and of 3 (hr) for t in Eq. 3. In Exp. 3 the absorption at each injection site will proceed independently and to the same extent; thus, the dotted line also shows the estimate for the third case as the injection volume at each injection point is equal to that in Exp. 2. The value calculated from the results of Exp. 1 agrees well with the observed values of Exps. 2 and 3. Accordingly, it is concluded that the reciprocal cube root volume dependency expressed in Eq. 3 will be generally applicable. These findings imply that faster absorption occurs when the injection volume per one site is minimized either by increasing the number of injections or by using more concentrated solutions.

Addition of surface-active agents and emulsifiers to injected oily solutions of drugs has been reported to enhance the absorption of the oily vehicle (9) or practically water-insoluble drugs contained therein (15). Recently, emulsion systems have been promoted as novel drug delivery systems for some anticancer agents (16). Figure 7 shows that the absorption of *p*-aminoazobenzene from the emulsion system (Exp. 4) would be slower than that from oily solution (Exp. 1). However, so many new variables are introduced when the administration system is changed to an emulsion that it is impossible to even qualitatively interpret this result.

Correlation among the Absorption Rate Constant, Viscosity, and the Distribution Coefficient—It was shown previously (17) that a certain correlation exists between the viscosity of vaccines (aluminum monostearate paraffin gels) injected subcutaneously into rabbits and guinea pigs and the degree of enhancement and prolongation of the antitoxin levels. However, as is evident from Table I, no distinguishable relationship was observed between the viscosity (η) of the vehicle and the absorption rate constant (k) under our experimental conditions (η, 3.6–35 cps). This difference is not surprising when it is realized that the

Table II—Predicted and Observed Subcutaneous Absorption Rate Constants (k) [a]

Test Compound	M.W.[b]	K[c]	k, hr^{-1} Predicted[d]	k, hr^{-1} Observed (SE)
Testosterone	288	1.30×10^2	0.79	0.64 (0.09)
1-Phenylazo-2-naphthylamine	247	3.82×10^5	0.0035	0.0053 (0.0003)

[a] Sesame oil solution; C_0, 2.5 mg/ml for testosterone and 5 mg/ml for 1-phenylazo-2-naphthylamine; V_0, 0.5 ml. [b] Molecular weight. [c] Distribution coefficient (sesame oil/saline) at 37°. [d] Calculated using the regression equation obtained from all sc data in Fig. 8: $\log k = -0.68 \log K + 1.33$

gelled systems of Coles *et al.* (17) could hardly act as well-stirred phases. Moreover, smaller mass transfer coefficients (k_o) due to the increased viscosity are expected to elevate the role in rate control played by the vehicle's boundary layer.

If the term $(k_o/k_a)K_i$ in Eq. 2 is $\ll 1$, Eq. 2 is approximated by:

$$k = Ak_o/V_0 \qquad \text{(Eq. 4)}$$

This equation signifies that diffusion in the oily phase is the rate limiting process in drug absorption as appears to be the case for the gels of Coles *et al.* (17). However, this relationship does not appear representative of the behavior of the present systems as k, according to Eq. 4, depends upon k_o, which in turn depends on viscosity of the oily vehicle, but not on K_i. On the other hand, when the term $(k_o/k_a)K_i$ is $\gg 1$, which seems very likely due to the large distribution coefficients (K_i) of the drugs between the phases considered here, Eq. 2 is approximated by:

$$k = Ak_a/(V_0K_i) \qquad \text{(Eq. 5)}$$

This equation signifies that k is independent of k_o; that is, independent of the viscosity of the oily vehicle and dependent on K_i. Given the partitioning dependency of the process (Table I), the present results seem to favor the relationship as written in Eq. 5 on two counts. Partitioning and diffusion across a tissue boundary also appear to control rates of intramuscular absorption (1).

Taking the logarithm of both sides of Eq. 5 gives:

$$\log k = \log (Ak_a/V_0) - \log K_i \qquad \text{(Eq. 6)}$$

The term $\log (Ak_a/V_0)$ in this equation is governed by the injection volume and the permeability of the drug in the connective tissues adjacent to the oily depot. According to Eq. 6, a plot of $\log k$ *versus* $\log K_i$ should give a single straight line with a slope of -1 for compounds having a similar tissue permeability as long as the injection volume is maintained constant. Figure 8 shows this plot for the three compounds presented in Table I, all of which have similar molecular weights. In this plot the *in vitro* bulk distribution coefficient (K, oily solvent/saline) is used instead of the *in vivo* distribution coefficient (K_i) which is not measurable. The plot indicates linear relationships over a wide range of K values for all three compounds. The regression equations ($x = \log K$, $y = \log k$) and their correlation coefficient (r) for the individual compounds are as follows: for *p*-hydroxyazobenzene, $y = -0.686x + 1.398$ ($r = -0.994$); for *p*-aminoazobenzene, $y = -0.689x + 1.256$ ($r = -0.982$); for *o*-aminoazotoluene, $y = -0.733x + 1.594$ ($r = -0.974$). From these separate results, the following experimental equation relating the rate constant to the *in vitro* distribution coefficient is evident:

$$\log k = \log (Ak_a/V_0) - \delta \log K \qquad \text{(Eq. 7)}$$

The resultant values for δ are of the order of -0.7, whereas perfect *in vivo–in vitro* distributioning correlation would yield a value of -1.0. This slight deviation might be attributable to fundamental, systematic differences in partitioning sensitivities between the *in vivo* and *in vitro* systems, to a not totally negligible diffusional resistance in the vehicle's boundary layer, which itself precludes exact adherence to Eq. 5, or to the coexistence of another absorption mechanism not accounted for in Eq. 2, *i.e.*, absorption of the drug as the result of assimilation of the injected medium by the body. In any case, the experimental equation can be put in the following, general phenomenological form:

$$k = \gamma/V_0{}^mK^\delta \qquad \text{(Eq. 8)}$$

where γ is a coefficient lumping together all intangible experimental parameters. This relationship seems to have practical value for the estimation of absorption rates of diverse drugs from diverse oily vehicles.

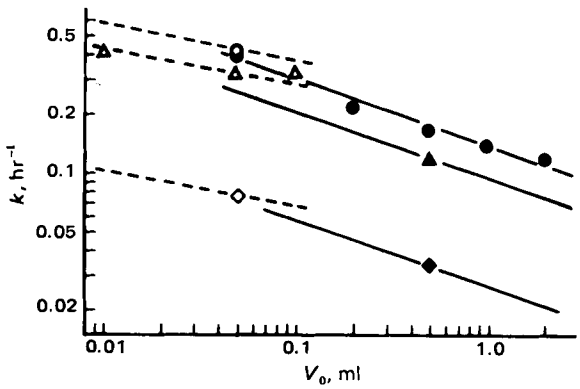

Figure 9—*Comparison of the absorption rate constants (k) at various injection volumes (V_0) between subcutaneous (dorsum) and intramuscular (m. gastrocnemius) injections in intact rats. The straight lines for subcutaneous injection of* p-aminoazobenzene *and* o-aminoazotoluene, *and those for intramuscular injection of* p-hydroxyazobenzene *and* o-aminoazotoluene *are depicted to pass through one data point with a slope of −0.33 and −0.14, respectively. The subcutaneous data are shown elsewhere in this paper and those for intramuscular injection are quoted from a previous work (1). Key: (—●—) (sc), (---○---) (im),* p-hydroxyazobenzene; *(—▲—) (sc), (---△---) (im),* p-aminoazobenzene; *(—◇—) (sc), (---◇---) (im),* o-aminoazotoluene.

Figure 8 also shows with a broken line the corresponding regression line for the intramuscular absorptions of the same three compounds (1). The parallelism of the regression lines suggests a strong similarity in distributioning behavior at the injection's interface between the subcutaneous and intramuscular routes.

Prediction of Absorption Rates of Other Drugs—Figure 8 shows the regression lines of three separate compounds to be essentially inseparable when the injection volume was fixed. Their composite regression equation is: $\log k = -0.68 \log K + 1.33$ ($r = -0.98$). It was anticipated through this colinearity that this relationship might provide a means of estimating absorption rate constants (k) of other drugs simply from the K values determined in the *in vitro* saline system. To examine this possibility, testosterone and 1-phenylazo-2-naphthylamine, compounds with molecular weights similar to the three compounds presented in Fig. 8, were selected as additional test substances. Absorption rate constants predicted from their respective K values and the above regression equation were compared with experimental values. The results appear in Table II. For these compounds, the predicted values agree well with the observed values. This satisfactory result suggests the absorption behaviors of other drugs may be similarly predicted.

Comparison of Absorption Rates between Subcutaneous and Intramuscular Routes in Rats—It was found (12) that no significant difference in the absorption rates of ^{131}I-labeled insulin[14] (insulin suspensions) from subcutaneous and intramuscular tissues exists at either the thigh or arm region in humans. No such comparison between sites exists for a drug presented in oily solution. In the present and a previous (1) report, the quantitative relationships between the absorption rate constant (k) and the injection volume (V_0) for subcutaneous and intramuscular routes has been elucidated in rats. By both routes the value of k was proportional to $V_0{}^m$. However, the experimental m values for subcutaneous (dorsum) and intramuscular (m. gastrocnemius) injections in intact rats are apparently different and are -0.33 and -0.14, respectively.

In Fig. 9, k values in intact rats obtained by the subcutaneous route (dorsum) for the three test compounds at various injection volumes (V_0) are compared with those by the intramuscular route (1). Although the data points available for direct comparison are few in this figure, it appears that the values by the two routes may be quantitatively compatible. If this is true, then a change in volume dependency (m) is apparent as the injected volume goes from the very small volumes given intramuscularly to the relatively large subcutaneous volumes.

Studies on the Absorption of Practically Water-Insoluble Drugs Following Injection VI: Subcutaneous Absorption from Aqueous Suspensions in Rats

KOICHIRO HIRANO ˣ and HIDEO YAMADA

Received April 8, 1981, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka, 553, Japan.* Accepted for publication May 20, 1981.

Abstract □ The absorption characteristics and kinetics of practically water-insoluble drugs following subcutaneous injection of their aqueous suspensions were investigated in intact rats by the local clearance method and compared with those following intramuscular injection reported previously. The plot of the cube root of the residual fraction of the drug in the injection site *versus* time gave a good linear relationship under various experimental conditions. The absorption rate constant (j) increased with decreasing particle size. This increase was remarkable in the region of mean particle diameter <2–3 μm, while it was gradual or slight in the region above this. This phenomenon was explained by the fact that the *in vivo* spreading of particles of more than ~3 μm was still more limited by the network of the fibrous tissues. Between j and the initial drug concentration (C_0) or injection volume (V_0), the practically important relationship $j \propto C_0^g V_0^h$ ($g = -0.66$ and $h = -0.32$) could approximately be derived from the experimental results. Comparison of j values among various compounds with different solubility (C_s') in saline but with similar colloidal properties (particle size distribution and sedimentation volume) showed that a log j *versus* log C_s' plot gave a nearly straight line with a slope of ~0.5. All the results observed for the subcutaneous absorption were similar to those for intramuscular absorption and could reasonably be explained by the kinetic model proposed for intramuscular absorption.

Keyphrases □ Absorption, subcutaneous—from aqueous suspensions of practically water-insoluble drugs, rats □ Water-insoluble drugs—subcutaneous absorption from aqueous suspensions, rats □ Aqueous suspensions—subcutaneous absorption of practically water-insoluble drugs, rats

Although subcutaneous administration of aqueous suspensions is very popular for practically water-insoluble drugs in preclinical animal experiments, little has been studied on their absorption mechanisms and kinetics except for the particle-size effect on pharmacological responses (1). Previously investigated (2, 3) were the absorption behaviors of subcutaneously implanted solid drugs (sphere, disk, and cylindrical shapes) and the absorption kinetic process was clarified. The intramuscular absorption characteristics of practically water-insoluble drugs from aqueous suspension were investigated in detail, and a kinetic equation was proposed for the drug absorption, which was obtained empirically and was very useful (4).

In the present work, similar investigations for the subcutaneous route were done with the local clearance method in intact rats. The purpose of the present study was to clarify the relationship between the absorption rate and physicochemical properties (particle size, initial drug concentration, injection volume, drug solubility, *etc.*), to express this relationship in appropriate mathematical terms, and to compare the results with those for the intramuscular route reported previously (4).

The findings obtained in this study will offer a novel and useful guide for more detailed screening and preclinical testing in laboratory animals of new drugs under development.

EXPERIMENTAL

Materials—Azo dyes (*p*-aminoazobenzene, *p*-hydroxyazobenzene, *o*-aminoazotoluene, and 1-phenylazo-2-naphthylamine), sulfa drugs (N^1-acetylsulfamethoxazole and sulfamethoxazole), and a steroid (betamethasone dipropionate[1]) were used as models for practically water-insoluble drugs. These azo dyes and sulfa drugs were the same as those used in a previous study (4). Betamethasone dipropionate was of medicinal grade and its purity was ascertained to be satisfactory through elementary analysis, melting point measurement, and TLC. Methylcellulose[2] and polysorbate 80[3], used as dispersing agents for preparations, were the same as those reported previously (4). All other chemicals were of analytical or reagent grade.

To compare the spreading area of injected particles, the following standard particles of different sizes were also used: two polystyrene latexes (0.721 and 1.305 μm in mean diameter based on number size distribution)[4], polyvinyltoluene latex (2.956 μm)[4], spores (4.94 μm)[5], di-

Materials—Azo dyes (*p*-aminoazobenzene, *p*-hydroxyazobenzene, *o*-aminoazotoluene, and 1-phenylazo-2-naphthylamine), sulfa drugs (N^1-acetylsulfamethoxazole and sulfamethoxazole), and a steroid (betamethasone dipropionate[1]) were used as models for practically water-insoluble drugs. These azo dyes and sulfa drugs were the same as those used in a previous study (4). Betamethasone dipropionate was of medicinal grade and its purity was ascertained to be satisfactory through elementary analysis, melting point measurement, and TLC. Methylcellulose[2] and polysorbate 80[3], used as dispersing agents for preparations, were the same as those reported previously (4). All other chemicals were of analytical or reagent grade.

To compare the spreading area of injected particles, the following standard particles of different sizes were also used: two polystyrene latexes (0.721 and 1.305 μm in mean diameter based on number size distribution)[4], polyvinyltoluene latex (2.956 μm)[4], spores (4.94 μm)[5], di-

p-Hydroxyazobenzene	3.6–4.1	2.5–2.7	2.8–3.1
o-Aminoazotoluene	3.9	2.7	2.4
1-Phenylazo-2-naphthylamine	4.0	2.5	2.2

[a] Mean particle diameter obtained from Rosin-Rammler plot. [b] This value (obtained from Rosin-Rammler plot) shows the degree of narrowness of particle size distribution. The larger the value, the narrower the particle size distribution.

vinylbenzene latex (8.99 μm)[4], and ragweed pollen (17.95 μm)[5]. These are nearly spherical and commonly used as size calibrators for particle size measurements.

Preparation of Test Suspensions—Unless otherwise mentioned, the vehicle composed of 0.5% (w/v) of methylcellulose, 0.005% of polysorbate 80, and 0.9% NaCl was used as a dispersion medium for the same reason mentioned previously (4). This vehicle was presaturated with the drug to be dispersed and filtered through a membrane filter[6], then used for making the various preparations. To regulate particle size, all test aqueous suspensions were prepared by fractionation techniques using natural or centrifugal sedimentation. The suspensions formulated according to the controlled preparation method in which they were intended to contain particles of ~4 μm in average diameter, described in the previous report (4), were used unless otherwise mentioned. Hereafter, these suspensions are referred to as controlled suspensions. Colloidal properties such as mean particle diameters (D_{ss}), distribution constants (n), and sedimentation volumes (V_{sed}) of the test suspensions prepared by this method appear in Table I. The suspensions other than the controlled ones were prepared by similar methods with appropriate modifications. After adjustment of the drug concentration in a test suspension, it was stored at 25° until use. The syringeability for all the suspensions was good in the same needle (25G × 2.54 cm)[7] and syringe used in the absorption experiment.

Procedure of Absorption Experiment—Male Wistar albino rats (250–290 g) were used in all absorption experiments. The subcutaneous region near the center of the dorsum of intact rat was selected as a model injection site and the same local clearance method described in the previous paper (5) was employed for the present investigations. Since almost all of the drug remaining in the injection site was undissolved and unchanged, the absorption experiment adopted was considered to be appropriate for understanding the true absorption phenomena from the systems of interest.

Measurement of Physicochemical Properties of Test Compounds and Suspensions—For the solubilities of model drugs in 0.9% (w/v) NaCl (saline) or in pH 7.25 phosphate buffer (0.067 *M* Na_2HPO_4–KH_2PO_4) isotonized with NaCl, previously obtained data (4) were used. The solubilities in 2% (w/v) bovine serum albumin[8] in pH 7.25 isotonic phosphate buffer were determined according to a method similar to that described in the previous paper (4). The density (ρ) of the model compound, and the sedimentation volume (V_{sed}) and particle size distribution (D_{ss} and n) of each test suspension were also measured by the methods described in the previous report (4).

Analytical Method—*Samples from Absorption Experiments*—The amounts of test compounds other than betamethasone dipropionate remaining in the injection site were determined colorimetrically as described previously (4). Betamethasone dipropionate was analyzed by the HPLC method under the following conditions: HPLC apparatus[9]; UV detector (254 nm); column[10], 25 cm × 2.1-mm ϕ; mobile phase, *n*-hexane–isopropyl ether–ethanol–H_2O (5:20:1.5:10, v/v, upper layer); flow rate (pressure), 0.43–0.46 ml/min (84 kg/cm²).

Samples from Other Experiments—The concentrations of model compounds other than betamethasone dipropionate in test suspensions were analyzed spectrophotometrically as described in the previous paper (4). For the analysis of betamethasone dipropionate, the optical density was read at 243 nm after dilution with ethanol–H_2O (1:1, v/v). The sample solutions (filtrate or supernate) for the determination of the solubilities of azo compounds in 2% bovine serum albumin solution were assayed by a colorimetric method similar to that reported previously (4). Those of sulfa drugs were assayed as follows: One milliliter of the sample solution was thoroughly mixed with 5 ml of pH 4.7 buffer [1 *N* HCl–1 *N* CH_3COONa, 3:7 (v/v)] and from this mixture the sulfa drug was extracted with 10 ml of ethyl acetate. A portion of this extract was freed of the solvent *in vacuo* then assayed colorimetrically after diazotization according to the method described in the previous paper (4).

RESULTS AND DISCUSSION

State of the Depot and Drug Absorption Kinetics—Although the subcutaneous region is composed of networks of loosely cross-linked fibrous tissues, injected solutions form a pool (depot) with lateral spread (6, 7). This was also observed in experiments using aqueous suspensions of some dyes and uniform latexes. In addition, the suspension particles were confined to such networks and their spreading was not so extensive as that of the aqueous dispersion medium (vehicle) after injection. For example, even in the case of a 1-ml injection of 0.5% (w/v) of uniform latex of 0.7 μm in diameter (this size seems to be the approximate lower limit for common preparations) into the dorsal subcutaneous region of rats, the resulting lateral spreading area of the particles did not exceed ~30% of that of the aqueous vehicle. This spreading area became smaller with increasing particle size. These findings clearly indicated that the subcutaneously injected particles were loosely agglomerated at the injection site.

In common cases, a drug in aqueous suspension injected subcutaneously must first become dissolved in the tissue fluids surrounding the particle agglomerate, diffuse into the intercellular space (or intracellular region) of the connective tissues, and then permeate the vascular membranes until it enters the blood or lymph stream. The participation of direct absorption of the fine particles by phagocytosis or some other mechanisms can not be completely denied (8, 9). However, their contribution to the drug absorption may be much smaller than that of the above mentioned mechanism *via* the dissolution process except for exceedingly fine particles of water-insoluble drugs (10).

It was indicated previously (11) that the connective tissue ground substance formed a diffusion barrier to the subcutaneous absorption of carbohydrates with different molecular weights in aqueous solution. The relationship between the absorption rates of a variety of compounds subcutaneously implanted in rats and their physicochemical properties

were studied (2). It was concluded that the absorption from this system was solution rate limited. Visual observations of present experimental systems supported this conclusion, since the tissue fluid colored by the dissolution of a dye was almost limited to the narrow region close to the surface of the particles or their agglomerate except for a short period immediately after injection.

On the basis of the above findings, it is assumed that the absorption is controlled by diffusion from the surface of the agglomerate. The process of this absorption seems to have a resemblance to that observed after intramuscular injection. Thus, the absorption model proposed for the intramuscular injection in a previous study (4) is expected to be applicable to the subcutaneous injection as well. From that model the following kinetic equations could be derived to describe the intramuscular absorption process (4). The fraction of the drug amount (W) remaining at the injection site to the dose (W_0) was given as a function of time (t):

$$(W/W_0)^{1/3} = 1 - jt \qquad \text{(Eq. 1)}$$

where j was defined as an absorption rate constant. This j could be related to the *in vivo* solubility (C_s), density of the drug crystal (ρ), *in vivo* dissolution rate constant (k), and the dose (W_0), using a correction parameter (ϵ) for the effective surface area of the particle agglomerate for the *in vivo* dissolution:

$$j = k\epsilon C_s \rho^{-2/3} W_0^{-1/3}/3 \qquad \text{(Eq. 2)}$$

In this equation the parameter ϵ was assumed to be an unknown function of the effective particle size (D), initial volume concentration (C_0/ρ) of the suspended drug, injection volume (V_0), and other factors (U) containing hydrodynamic factors (injection speed and pressure) and the histological and physiological factors in the injection site:

$$\epsilon = F(D, C_0/\rho, V_0, U) \qquad \text{(Eq. 3)}$$

The relationship between ϵ (or j) and C_0, V_0, or D was investigated experimentally (4).

In the present study, the above kinetic relationships proposed for the intramuscular absorption were checked to ascertain their applicability for the subcutaneous absorption and then developed to gain greater understanding of its phenomena.

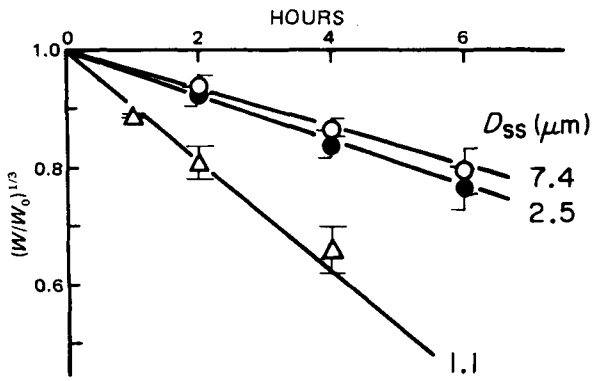

Figure 2—*Effect of particle size on subcutaneous absorption of* p-*hydroxyazobenzene. Each point represents the mean of at least three experiments; vertical bar indicates the standard deviation.* C_0 = *5 mg/ml;* V_0 = *0.5 ml.*

Time Course of Drug Absorption—First, the validity of Eq. 1 was checked experimentally. Figure 1 shows a plot of the residual fraction (W/W_0) or its cube root of the drug remaining in the injection site against time after dorsal subcutaneous administration of the controlled aqueous suspension of *p*-hydroxyazobenzene into intact rats. The initial drug concentration (C_0) and injection volume (V_0) are given in the legend. The cube root plot (B) gave a good linear relationship while the other (A) showed an upward curvature. This tendency was common throughout the following absorption experiments of different conditions, and the correlation coefficient obtained by the least-squares linear regression from the cube root plot was always larger than that from the linear plot. These results suggest that Eq. 1 is appropriate for describing the time course of the subcutaneous drug absorption from aqueous suspensions. In addition, the moderate magnitude of the standard deviations shown in Fig. 1 demonstrated that the other factors (U) in the parameter ϵ might be well-controlled under the experimental conditions in this study.

Effect of Particle Size on Absorption—The particle size of a suspension is an important factor for intramuscular (12–14) and subcutaneous absorption (1) as well as for absorptions from other routes (15). If the suspension particles are dispersed at the injection site too extensively to aggregate with each other, and, hence, the drug transport from the surface of each particle takes place independently, the particle size effect on the absorption may appear most strongly. In such a case, theoretically, $\epsilon = 6(W_0/\rho)^{1/3}/D$ for monodispersed spherical particles (diameter, D) and therefore is inversely proportional to the particle size (4). However, this is expected to be rare in practice because of the agglomerate formation in the injection site, except in an exceedingly dilute suspension with very fine particles. Thus, the relationship between the drug absorption

rate and particle size seems to be very complicated. A previous study on the intramuscular absorption showed that the increase in the absorption rate constant (j) with decreasing mean particle diameter (D_{ss}) was remarkable in the region of D_{ss} smaller than 2–3 μm, while it was gradual or slight in the region above this (4).

Figure 2 compares subcutaneous absorption time profiles of *p*-hydroxyazobenzene from three preparations with different mean particle diameters (D_{ss}) but with similar distribution constants (n) and sedimentation volumes (V_{sed}): D_{ss} (n), 7.4 μm (2.5), 2.5 μm (2.8), and 1.1 μm (2.9); V_{sed}, 2.8–3.2 cm^3/g. The absorption rate constant (j) was obtained from the slope of each linear relationship in this figure and then plotted against D_{ss} in Fig. 3. For comparison, the results from similar experiments of the intramuscular route (m. gastrocnemius) are also shown. Figure 3 suggests that the relationship between j and D_{ss} for the subcutaneous route is qualitatively similar to that for the intramuscular route. The particles smaller than 2–3 μm in diameter seem to pass more easily through the network of the fibrous tissues accompanying the spreading of the dispersion medium during injection. This may cause a looser agglomeration of the particles and result in the abrupt change in j below this particle size.

Figure 4 shows the effect of particle size on the lateral spreading of the particle agglomerate. Here, six water-insoluble standard particles with different mean diameters ($\bar{D}$, obtained from the number size distribution curve) were used for comparison. The similarity of the form of this curve to those in Fig. 3 may support the above speculation. The participation of direct absorption mechanisms involving phagocytosis must be also considered but their contributions seem to be relatively small under the present experimental conditions. In any event, the tendency of the particle size effect appears to have a very important practical meaning.

Effect of Initial Drug Concentration and Injection Volume—If the injected particles form no agglomerate and the drug transport from each particle proceeds independently, and if this process is a rate-determining step, the absorption rate constant (j) does not depend on the dose and is inversely proportional to the particle size as mentioned previously. However, this was not the case for the subcutaneous injection of ordinary aqueous suspensions. The absorption rate constant (j), given by Eq. 2, is a function of the dose W_0 and the parameter ϵ. The term W_0 is the product of the initial drug concentration (C_0) and injection volume (V_0). The parameter ϵ is assumed to depend on C_0 and V_0, but their relationship is not known. Therefore, the quantitative relationship between j and C_0 or V_0 is also not clear.

To elucidate this relationship, the absorption time courses of the controlled suspensions of *p*-hydroxyazobenzene with different C_0 and V_0 were followed, then their absorption rate constants (j) were obtained from the same plot as Fig. 1B. In Fig. 5 j is plotted against C_0 at fixed V_0 (0.5 ml) or against V_0 at fixed C_0 (5 mg/ml) on a log–log scale. The linear relationships of both plots allow the following tentative and approximate representation:

$$j = fC_0^g V_0^h \qquad \text{(Eq. 4)}$$

where f is a constant that depends on the drug and its suspension preparation.

Thus, the experimental values of g and h were estimated by multiple regression analysis from 12 sets of data for the controlled suspensions of *p*-hydroxyazobenzene. The original data used for this estimation and resulting g and h values are summarized in Table II. Next, to ascertain the applicability of these experimental values ($g = -0.66$ and $h = -0.32$), additional examinations were done using aqueous suspensions of betamethasone dipropionate. Employing Eq. 4 and the g and h values determined above, the ratio of $j(i)$ at $C_0(i)$ and $V_0(i)$ to $j(1)$ at $C_0(1)$ and $V_0(1)$ for suspensions with the same drug and similar colloidal properties can be represented as:

$$j(i)/j(1) = [C_0(i)/C_0(1)]^{-0.66}\,[V_0(i)/V_0(1)]^{-0.32} \qquad \text{(Eq. 5)}$$

Table III compares the calculated and experimental ratios $j(i)/j(1)$ for the case where $C_0(i)/C_0(1) = 10$ or $V_0(i)/V_0(1) = 10$. These comparisons showed good mutual agreements, despite the fact that the vehicle and the colloidal properties of the suspensions tested here differed considerably from those of the controlled suspension of *p*-hydroxyazobenzene used for the estimation of g and h values. Therefore, Eq. 5, obtained ex-

perimentally, is expected to be generally applicable for aqueous suspensions other than the model ones tested here.

Using the above results, the relationship between the parameter ϵ and C_0 or V_0 can be clarified empirically in the following manner:

$$j = fC_0^{-0.66}V_0^{-0.32} \quad \text{(Eq. 6)}$$

Employing the relationship $W_0 = C_0V_0$, Eq. 2 can be rewritten as:

$$j = kC_s\rho^{-2/3}\epsilon C_0^{-1/3}V_0^{-1/3}/3 \quad \text{(Eq. 7)}$$

From the equivalency of Eqs. 6 and 7, the parameter ϵ must satisfy the following relationship:

$$\epsilon = F(D, C_0/\rho, V_0, U) = \delta(C_0/\rho)^{-0.33}V_0^{0.01} \quad \text{(Eq. 8)}$$

where δ is a term that depends on the remaining factors D and U. Equation 8 means that the parameter ϵ depends little on the injection volume (V_0) but decreases by increasing initial drug concentration (C_0). This also implies that the degree of agglomeration may tend to increase with an increase in C_0. Substitution of Eq. 8 for ϵ in Eq. 7 yields:

$$j = (kC_s\delta/3)\rho^{-0.34}C_0^{-0.66}V_0^{-0.32} \quad \text{(Eq. 9)}$$

The above empirical equation obtained for the subcutaneous route demonstrates a great similarity to that for the intramuscular route, which was given by the following equation (4):

$$j_m = (k_mC_s\delta_m/3)\rho^{-0.45}C_0^{-0.55}V_0^{-0.32} \quad \text{(Eq. 10)}$$

It should be noted that the correlation between the absorption rate constant and injection volume is identical for the two routes.

Although Eqs. 9 and 10 are derived empirically, they should be very important and useful since they give relationships between the dose and absorption rate constant which have been unknown until now.

Comparison of Absorption Rate among Various Compounds—Equation 9 shows that the absorption rate constants (j) of different compounds depend upon the values of k, C_s, and ρ when the preparation-dependent parameters (δ) are the same. As defined previously, ρ, k, and C_s represent the density of the drug, the *in vivo* dissolution rate constant, and *in vivo* solubility in the injection site, respectively. Of these factors, only the value of ρ can be determined by an *in vitro* experiment; the other two (k and C_s) cannot be completely estimated from such an experiment. From a practical point of view, an attempt was made to clarify the quantitative relationship between j and the above three factors (or their first approximations).

Figure 6 compares the subcutaneous absorption time profiles of six test compounds. In this comparison, the controlled suspensions with similar colloidal properties (Table I) were used to minimize the variation in δ in Eq. 9. All the compounds gave good linear relationships with different slopes. Their observed absorption rate constants (j) are summarized in Table IV with their physicochemical factors such as *in vitro* solubilities in saline and 2% (w/v) bovine serum albumin (C_s' and C_s'', respectively).

As discussed previously, the absorption is inferred to be a diffusion-controlled process. Diffusion coefficients of compounds having low molecular weight (MW) are known to be inversely proportional to the square root of MW (16). The *in vivo* dissolution rate constant (k) in Eq. 9 is considered to be proportional to the diffusion coefficient, like that *in vitro* (2, 17). Therefore, Eq. 9 can be converted to

$$j = (\theta\delta/3)\mathrm{MW}^{-0.5}\rho^{-0.34}C_sC_0^{-0.66}V_0^{-0.32} \quad \text{(Eq. 11)}$$

where θ is a constant. Thus, the values of $\mathrm{MW}^{-0.5}\rho^{-0.34}$ for model drugs were calculated and are in Table IV as the correction term. However, these values were similar to each other for the compounds tested here. In contrast, the *in vitro* solubility was a more dominant factor and had a positive relation with the absorption rate constant.

Equation 11 means that the plot of j (or $j_{corr} = j\mathrm{MW}^{0.5}\rho^{0.34}$, if the correction for MW and ρ is necessary) against *in vivo* solubility (C_s) on a log–log scale gives a straight line with a slope of unity at the constant initial drug concentration (C_0) and injection volume (V_0). The closed circles in Fig. 7 show this plot using *in vitro* solubility (C_s') in Table IV instead of *in vivo* solubility (C_s). This gave a nearly straight line with a slope of 0.53 (regression equation, $\log j = 0.525 \log C_s' - 0.578$; correlation coefficient, $r = 0.956$). Using j_{corr} in place of j, a similar relationship was also obtained ($\log j_{corr} = 0.534 \log C_s' + 0.660$, $r = 0.953$).

In Fig. 7, similar data for the intramuscular administration (m. gastrocnemius), cited from a previous study (4), are also plotted with open circles. Remarkably, the slopes of these plots for the two routes were almost identical. This shows a strong similarity in the absorption mechanism between the two routes. The deviation of the slope from unity observed in Fig. 7 may be attributed mainly to a gradual increase in the ratio C_s/C_s' with decreasing C_s' caused by the relatively larger solubilization effect of the protein components in the body fluid for the drug having a smaller solubility. The comparison of C_s' and C_s'' in Table IV supports this explanation.

The good linear relationship between $\log j$ (or $\log j_{corr}$) and $\log C_s'$ mentioned previously is expected to be applicable for predicting the subcutaneous absorption rates of other compounds in the controlled suspensions from C_s'. For instance, the prediction (from the regression equation, $\log j_{corr} = 0.534 \log C_s' + 0.660$) for the test material, betamethasone dipropionate (MW = 504; $\rho = 1.23$ g/cm^3; $C_s' = 0.002$ mg/ml) gave a value of 0.007 hr^{-1} for j (at $C_0 = 5$ mg/ml and $V_0 = 0.5$ ml), which almost agreed with the experimental value of 0.0096 ($\pm$0.0011) hr^{-1} observed using the following controlled suspension: $D_{ss} = 4.3$ μm; $n = 2.6$. This satisfactory result suggests that similar prediction will be possible for other drugs.

Comparison of Absorption Rates between Subcutaneous and Intramuscular Routes—Hitherto, drug absorption kinetics and mechanisms from aqueous suspensions in the subcutaneous route have been clarified, and their strong similarity to those by the intramuscular route, discussed previously (4), have been pointed out. A direct comparison of absorption rates between the two routes seems to be usable but there has been little available data (18). Table V shows this com-

[a] Controlled suspension. C_0, 5 mg/ml; V_0, 0.05 ml. [b] Estimated by extrapolation of data shown in Table IV using Eq. 5. [c] Experimental data (with standard error) cited from the previous report (4). [d] Experimental value (with standard error).

parison using five controlled suspensions. To compare at the same drug concentration (C_0) and injection volume (V_0), the values estimated by extrapolation of the data shown in Table IV using Eq. 5 were used for the absorption rate constants (j) in the subcutaneous route. This comparison shows that the absorption rate from the subcutaneous route is slower than that from the intramuscular route for all the test suspensions. A similar tendency was previously observed for injections of drug-oil solutions (5). The relationship between j and C_0 in the subcutaneous route differed slightly from that in the intramuscular route (Eqs. 9 and 10). Therefore, it should be noted that the difference in j shown in Table V may increase with increasing C_0.

Dissolution and Bioavailability Studies of Whole and Halved Sustained-Release Theophylline Tablets

KEITH J. SIMONS **, EVELYN M. FRITH ‡, and F. ESTELLE R. SIMONS ‡

Received July 24, 1980, from the **Faculty of Pharmacy, and* ‡ *Section of Allergy and Clinical Immunology, Department of Pediatrics, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, Canada, R3T 2N2.* Accepted for publication August 5, 1981.

Abstract □ In dissolution studies of whole and halved 100-mg sustained-release theophylline tablets, drug release from halved tablets was significantly higher. These differences were not reflected in the bioavailability studies. The area under the curve (AUC) mean absorption time and fraction-of-dose recovered in urine at 24 hr were not significantly different following the ingestion of whole or halved 100-mg tablets. The elimination rate constant, half-life, volume of distribution, plasma, and renal clearance values were consistent with values reported previously. Discrepancies were found in the 24-hr metabolite distribution as compared to literature values and may be accounted for by the age and health of the subjects and the frequency of dosing.

Keyphrases □ Dissolution—whole and halved sustained-release theophylline tablets □ Sustained-release system—dissolution of whole and halved theophylline tablets □ Bioavailability—whole and halved sustained-release theophylline tablets □ Theophylline—bioavailability and dissolution study of whole and halved sustained-release tablets

Breaking sustained-release theophylline tablets in half is commonly practiced to achieve more accurate milligrams per kilogram dosing in children. The extent to which this affects dissolution and bioavailability is unknown.

In this investigation, 100-mg sustained-release theophylline tablets[1] were used to study the effect of halving tablets on dissolution and bioavailability. No published information about the dissolution of these tablets was available. After oral administration of the 100-mg tablet, however, 90% of the dose was absorbed within 14 hr and almost 100% was absorbed by 28 hr (1). When 300-mg tablets were dissolved, 50% of the dose entered solution by 2 hr and > 90% of the dose entered solution by 6 hr (1).

EXPERIMENTAL

Dissolution—The official USP dissolution apparatus was used (2). Simulated gastric and intestinal fluids were used as dissolution media (2).

Simulated gastric fluid, USP (2), was prepared by dissolving 2 g of sodium chloride and 3.2 g of pepsin in 7 ml of HCl and diluting the solution to 1000 ml with distilled water. This test solution had a pH of 1.2.

Simulated intestinal fluid, USP (2), was prepared by dissolving 6.8 g

7			70.1 ± 7.2	61.0 ± 6.6
8			73.8 ± 8.5	64.5 ± 6.9
9			76.8 ± 7.6	67.7 ± 7.5
10			78.6 ± 6.5	72.0 ± 7.2
11			82.3 ± 8.4	75.2 ± 8.6
12			84.4 ± 6.7	78.4 ± 7.9
25			91.2 ± 3.5	95.1 ± 7.6

of potassium phosphate (KH_2PO_4) in 250 ml of distilled water. To this solution was added 190 ml of 0.2 *N* sodium hydroxide and 400 ml of distilled water. Ten grams of pancreatin were then added and the resulting solution adjusted to pH 7.5 ± 0.1 with 0.2 *N* sodium hydroxide. This solution was diluted to 1000 ml with distilled water.

The 100-mg sustained-release theophylline tablets, as whole or halved tablets, were tested up to six times in each dissolution medium. The tablet, or tablet halves, were placed in the gold-plated basket and immersed in 900 ml of dissolution medium at 37° in the dissolution apparatus. The basket was rotated at 100 ± 5 rpm. Samples were withdrawn at 1, 2, 3, 4, 5, and 6 hr in gastric fluid and at 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, and 25 hr in intestinal fluid under sink conditions.

Bioavailability—Relative bioavailability studies were carried out in seven normal adult volunteers, four female and three male, on 2 study days, 1 week apart, after informed consent was obtained. Their mean age was 30 ± 7 yr (range: 21–39 yr) and their mean weight was 72 ± 21 kg (range: 54–100 kg). As determined by a comprehensive medical history they were in excellent health, were nonsmokers, and were not taking any medication at the time of the study. All volunteers had normal complete blood counts and normal screening tests for renal and hepatic function.

All subjects refrained from the ingestion of tea, coffee, chocolate, and cola for 48 hr before and during the 2 separate study days. On each study day, after an overnight fast with ingestion of no more than 480 ml of water, a heparin lock was inserted, a control blood sample was withdrawn, and a control urine specimen collected. Each subject received a mean 5.20 ± 0.24 mg/kg (range: 4.9–4.6 mg/kg) dose of theophylline to the nearest whole 100-mg sustained-release tablet. Tablets were administered whole or halved along with 120 ml of water. Subjects were assigned by random choice into Study Group 1 or Study Group 2. Study Group 1 received whole tablets the first week and halved tablets the second week. Study Group 2 received the halved tablets the first week and whole tablets the second week.

Blood samples were withdrawn at 0.25, 0.5, 0.75, 1.0, 1.25, 1.5, 2, 3, 4, 6, 8, 10, 12, 14, 18, and 24 hr. Serum was separated and frozen along with an aliquot of accurately measured pooled 24-hr urine until analysis for theophylline content could be performed. Subjects ate meals of uniform composition 4 and 8 hr after ingestion of the dose.

Assay Procedure—There are many methods for measuring theophylline concentrations and these have been adequately reviewed (3). Reversed-phase high-pressure liquid chromatography (HPLC) appears to be the method of choice and was used in this study[2]. Although direct injection methods are available for both theophylline (4–7) and its metabolites (8), the chromatograms obtained using these methods were not satisfactory. Since theophylline is bound to plasma proteins (9) some of these methods only measured unbound drug. The procedures developed and used were based on older methods (10) involving extraction.

Theophylline Extraction Procedure—To 50 μl of dissolution medium, urine, or serum in a 10 × 75-mm test tube was added 50 μl of aqueous solution of β-hydroxyethyltheophylline (15 μg/ml) as internal standard. A 25-μl aliquot of 20% trichloroacetic acid was added and the solution was vortexed and centrifuged. The supernate was transferred into a clean 13 × 100-mm test tube. After buffering with 300 μl of 2.5 *M* acetate buffer (pH 6.4) the solution was extracted with 2 ml of chloroform–isopropanol (20:1) by vortexing and centrifugation. The aqueous supernate was aspirated and the organic layer evaporated to dryness using low heat and a stream of dry nitrogen. The sample was redissolved in 50–100 μl of mobile phase and a 25 μl aliquot was injected directly onto the column. Theophylline concentration was calculated from a calibration curve of the peak height ratio of theophylline to the internal standard *versus* concentration.

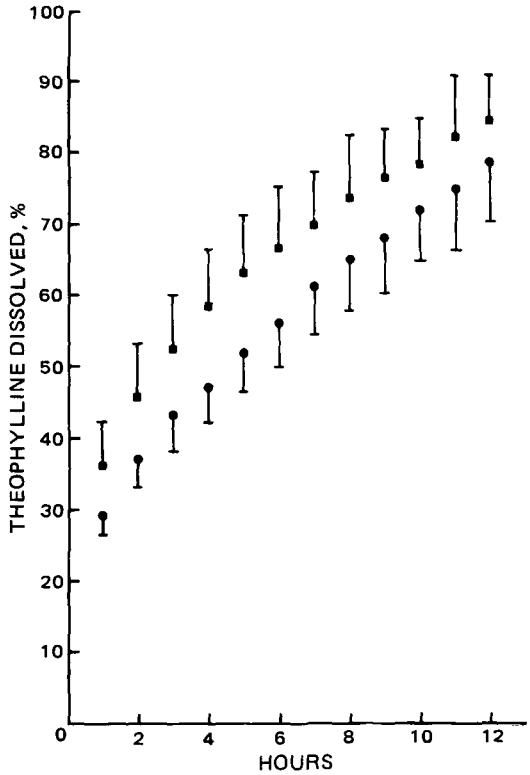

Figure 1—*Percent theophylline dissolved in simulated intestinal fluid* versus *time, from whole, (●) or halved (■) 100-mg sustained-release tablets.*

Theophylline Metabolite Extraction Procedure—To 200 μl of urine, test sample, or standards in solution in urine was added 50 μl of aqueous solution of theobromine (150 μg/ml). After buffering with 150 μl of 2.5 *M* acetate buffer (pH 6.4), the solution was extracted with 4 ml of chloroform–isopropanol (20:1) by vortexing and centrifugation.

The supernate was transferred to a clean test tube with a Pasteur pipet, and 50 μl was diluted with 200 μl filtered, distilled water to yield a final dilution of 1:10 of the urine sample. Exactly 25 μl of the diluted supernate was injected into the HPLC. The concentration of 1-methyluric acid was calculated from a calibration curve in which absolute peak heights *versus* concentration were plotted.

The organic layer from the sample was transferred to a clean, dry test tube and evaporated to dryness in a water bath at 60° with dry nitrogen. The sample was redissolved in 500 μl of mobile phase, and 25 μl was injected onto the chromatograph. The concentrations of 3-methylxanthine and 1,3-dimethyluric acid were calculated from calibration curves constructed by plotting the peak height ratios of the two metabolites to theobromine *versus* concentration of the metabolites.

HPLC Conditions—A 30-cm × 3.9-mm i.d. stainless steel column[3] was used in all assay procedures.

The mobile phase for theophylline was 9% acetonitrile in 0.01 *M* acetate buffer (pH 4.0). At a flow rate of 2 ml/min and an operating pressure of 1500–2000 psi, theophylline and β-hydroxyethyltheophylline had retention times of 4.9 and 6.2 min, respectively.

The mobile phase for 1-methyluric acid was 5% methanol in 0.05 *M* phosphate buffer (pH 4.75). At a flow rate of 2.0 ml/min the 1-methyluric acid had a retention time of 4.0 min.

The mobile phase for the other two theophylline metabolites was 11% methanol in 0.05 *M* phosphate buffer (pH 4.75). At a flow rate of 2 ml/min, 3-methylxanthine, 1,3-dimethyluric acid, and theobromine had retention times of 2.9, 4.2, and 5.1 min, respectively.

[2] The HPLC system consisted of a Model U6K injector, a Model 6000A high-pressure pump, and a Model 440 absorbance detector, all from Waters Associates, Milford, Mass. A 10 mv Omniscribe recorder from Houston Instrument, Austin, Tex. completed the system.

[3] μ Bondapak C_{18}, Waters Associates, Milford, MA 01757

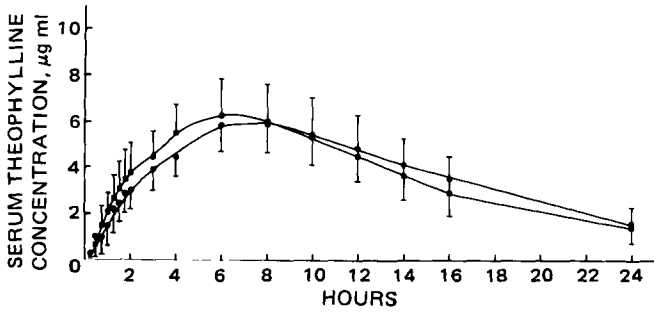

Figure 2—*Mean serum theophylline concentration* versus *time curves from seven normal volunteers who ingested a 5-mg/kg dose as whole (●) or halved (■) 100-mg sustained-release tablets.*

Data Analysis—The theophylline concentration *versus* time curve data from halved and whole 100-mg sustained-release tablets in simulated gastric and intestinal fluid were analyzed by plotting the cumulative percent dissolved *versus* time.

From each of the seven subjects who ingested a mean 5.2 mg/kg dose of theophylline as whole or halved 100-mg tablets, the log serum theophylline concentrations *versus* time curve was plotted. From the terminal linear portion of the curve, the first-order elimination rate constant (K_e) was calculated by:

$$\log Cp = \log Cp_0 - \frac{K_e}{2.303} t \qquad \text{(Eq. 1)}$$

where Cp is the serum theophylline concentration at any time t, and Cp_0 is the extrapolated serum theophylline concentration at zero time, *i.e.*, the y intercept. Elimination half-life values ($t_{1/2}$) were calculated by:

$$t_{1/2} = \frac{0.693}{K_e} \qquad \text{(Eq. 2)}$$

The fraction of the dose absorbed (f) at any time t was calculated by the formula:

$$f = \frac{(Xa)^t}{(Xa)^\infty} = \frac{Cp + K_e \int_0^t Cp\, dt}{K_e \int_0^\infty Cp\, dt} \qquad \text{(Eq. 3)}$$

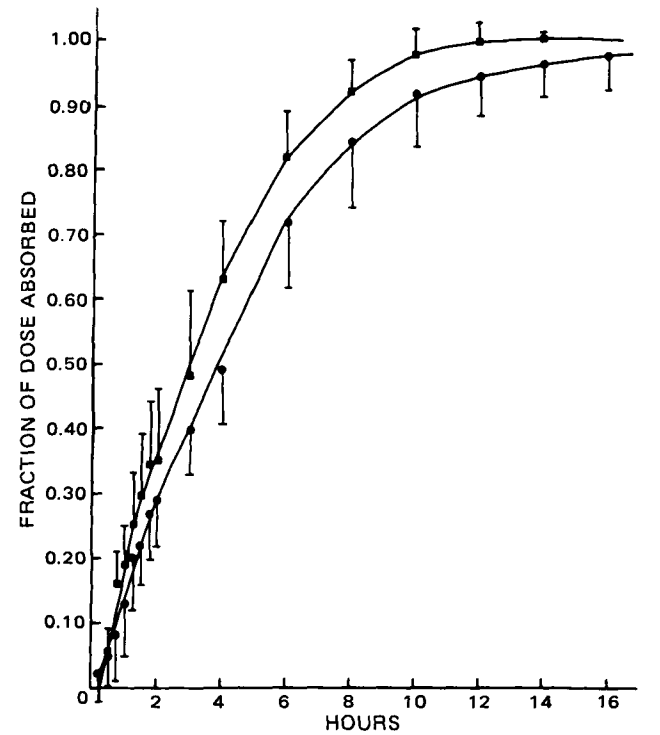

Figure 3—*Mean fractions of a 5-mg/kg dose of theophylline absorbed* versus *time in seven normal volunteers who ingested whole (●) or halved (■) 100-mg sustained-release tablets.*

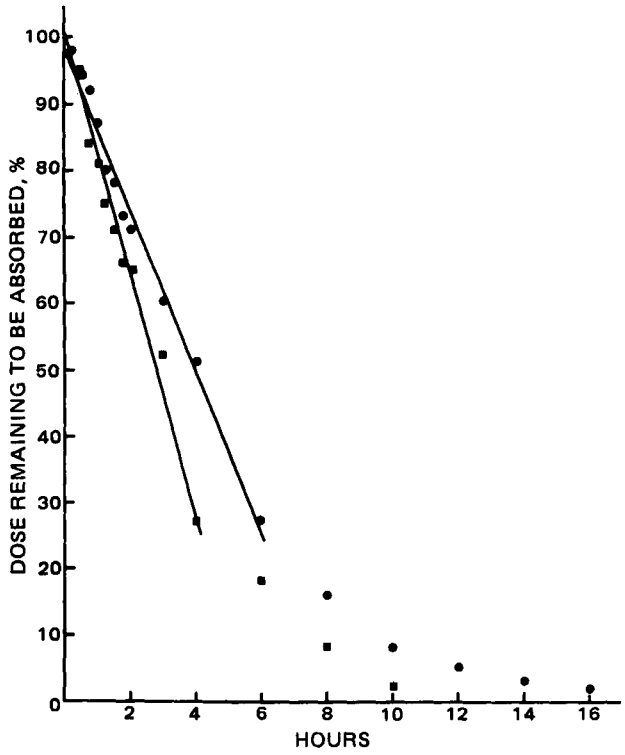

Figure 4—*Mean percentages of a 5-mg/kg dose of theophylline remaining to be absorbed* versus *time in seven normal volunteers who ingested whole (●) or halved (■) 100-mg sustained-release tablets.*

where $\int_0^t Cp\,dt$ and $\int_0^\infty Cp\,dt$ are the areas under the serum concentration *versus* time curves for time 0 to any time t and time 0 to infinity (*i.e.*, total amount absorbed), respectively. The areas $\int_0^t Cp\,dt$ and $\int_0^{t_n} Cp\,dt$ were calculated using the trapezoid method to time t_n. The area $t_n \int^\infty Cp\,dt$ was calculated using Eq. 4 and added to the area $\int_0^{t_n} Cp\,dt$ (11).

$$\int_{t_n}^{\infty} Cp\,dt = \frac{Cp_n}{K_e} \qquad \text{(Eq. 4)}$$

The mean absorption time (MAT) was calculated by (12):

$$\text{MAT} = \frac{\int_0^\infty Cpt\,dt}{\int_0^\infty Cp\,dt} - \frac{1}{K_e} \qquad \text{(Eq. 5)}$$

Plasma clearance (Cl) of theophylline was given by:

$$Cl = \frac{\text{dose}}{\int_0^\infty Cp\,dt} \qquad \text{(Eq. 6)}$$

where $\int_0^\infty Cp\,dt$ is the area under the serum concentration *versus* time curve for time zero to infinity as calculated in Eq. 3.

The apparent volume of distribution for theophylline (V_d) was calculated from:

$$V_d = \frac{Cl}{K_e} \qquad \text{(Eq. 7)}$$

The renal clearance of theophylline (Cl_R) was calculated by the formula:

$$Cl_R = f_e Cl \qquad \text{(Eq. 8)}$$

where f_e is the fraction of the total amount of the dose in 24 hr urine excreted as theophylline (11).

RESULTS

The mean cumulative percentage of theophylline dissolved from the whole and halved 100-mg sustained-release tablets at each sample time in simulated gastric and intestinal fluids is tabulated in Table I. The mean cumulative percent of theophylline dissolved from the whole and halved 100-mg tablets in intestinal fluid *versus* time is shown in Fig. 1.

Serum theophylline concentrations from the seven subjects following the administration of a mean theophylline dose of 5.2 mg/kg theophylline as whole or halved 100-mg tablets are listed in Table II. The mean serum theophylline concentration *versus* time plots for the two doses are shown in Fig. 2.

The fractions of the dose of theophylline absorbed (f) at each time interval for each subject following the dose as whole and halved tablets are shown in Table III. The mean values following each dose *versus* time is shown in Fig. 3. The pharmacokinetic parameters, AUC, MAT, K_e, $t_{1/2}$, V_d, Cl_1, and Cl_R for each subject, following both doses, are listed in Table IV. The mean percentage of the dose to be absorbed following the ingestion of whole or halved 100-mg tablets *versus* time is given in Fig. 4. The amounts of the dose recovered in 24 hr in the urine as unchanged theophylline and the various metabolites are shown in Table V. In Table VI the metabolites and theophylline recovery is reported as percentages of theophylline equivalents of the 24-hr urine recovery.

DISCUSSION

The only reference to dissolution data in the literature was from the manufacturer as reported by one group of investigators (1). From the 300-mg sustained-release tablets, 50% of the dose was reported to be in solution by 2 hr and > 90% was in solution by 6 hr. No specifications were reported. In the present study, in gastric fluid, 46.1 ± 2.5 and 65.8 ± 4.7% of the dose was in solution at 6 hr from whole and halved 100-mg tablets, respectively (Table I). The stomach mean emptying time for enteric-coated tablets has been reported to be 3.61 ± 1.47 hr (13); therefore, dissolution studies in gastric fluid were stopped at 6 hr.

In intestinal fluid, 52.7 ± 7.8% of the dose was released in 3 hr by halved 100-mg tablets, and 52.3 ± 5.5% was released in 5 hr by whole 100-mg tablets. After 12 hr, 84.4 ± 6.7% of the dose was in solution from halved tablets and 78.4 ± 7.9% of the dose in 10 hr from whole tablets (Table I). With the paucity of information available in the literature (1), it was not possible to compare previously reported results with the results from the present study.

These sustained-release theophylline tablets are reported to release theophylline by a zero-order rate, *i.e.*, equivalent to an infusion; therefore, plots of percentage released *versus* time should be linear. It was possible to fit a straight line by linear regression ($r = 0.99$) to the terminal portion of the percentage released *versus* time curve. However, the lines did not pass through the origin (Fig. 1). From these data it would appear that the first portion of any dose is probably released by first-order diffusion.

Table V—Fraction of a 5-mg/kg Dose of Theophylline Excreted as Unchanged Drug or Metabolites in 24 hr following the Ingestion of Whole or Halved 100-mg Sustained-Release Tablets by Normal Volunteers

A fraction of each dose in these tablets is contained in uncoated granules. As the tablets do not readily disintegrate, the availability of this portion of the dose by pore diffusion would account for the nonlinear 2–3 hr first-order release of drug. The remaining fraction of the dose is contained in coated pellets. As the tablet begins to disintegrate and the portion of the dose in these pellets is released, the rate of drug availability begins to approximate a zero-order infusion release. This ultimately causes the terminal portion of the curve to approach linearity as shown in Fig. 1. Fractions of the dose released from halved tablets were significantly higher than from whole tablets at all times ($p < 0.05$). This is probably due to the increased surface area exposed by breaking the tablets.

In this bioavailability study in normal subjects of whole and halved 100-mg sustained-release theophylline tablets, relative bioavailability was assessed by comparing the areas (time zero to infinity) under the serum concentration *versus* time curves (*AUC*) (Fig. 2). For halved 100-mg tablets, the *AUC* was 103.52 ± 39.16 μg/ml/hr and for whole tablets 108.36 ± 35.83 μg/ml/hr (Table IV). These were not significantly different ($p = 0.05$). In addition, although the mean serum theophylline concentrations following the ingestion of the halved tablets were numerically higher than the values obtained for the whole tablets up to 8 hr, none of the values were significantly different ($p = 0.05$) (Table II).

The fraction of the dose absorbed at any time (f) was calculated using Eq. 3. All subjects absorbed 50% of the dose from either whole or halved 100-mg sustained-release tablets in the 3–4 hr period (Table III, Fig. 3). Except for subject F, following the ingestion of the whole tablets, all other subjects absorbed 90–100% of the dose in the 8–12 hr period. This is consistent with previous reports (1).

The mean percentage of the dose remaining to be absorbed *versus* time is shown in Fig. 4. The initial portion of the graph is linear. These results can be used to confirm the results of dissolution data that there is apparent zero-order release of theophylline from these tablets. The terminal nonlinear portion of the curve is probably due to the fact that the fraction absorbed calculated using Eq. 3 is approaching the asymptote. Theophylline absorption is rapid and complete once the drug is in solution (14).

The mean absorption times (MAT) calculated from Eq. 5 are shown in Table IV. The average MAT of 3.60 ± 0.82 hr following ingestion of the halved tablet was not significantly different ($p = 0.05$) from the value of 4.71 ± 1.00 hr obtained from the whole tablets. In addition, these values are not significantly different ($p = 0.05$) from previously reported values (15) of 5.67 ± 1.40 and 4.20 ± 1.48 hr following the ingestion of whole and halved 300-mg sustained-release tablets, respectively.

The mean theophylline elimination half-life values in these seven subjects following ingestion of these 100-mg sustained-release tablets were 8.50 ± 6.64 hr for whole tablets and 6.29 ± 2.48 hr for halved tablets. These values are not significantly different ($p = 0.05$) and are comparable to literature values of 3.6–12.8 hr in normal, healthy adults (16). Subject F had an extremely long half-life of 23 hr (Table IV) following ingestion of the whole tablets.This is probably not the true half-life, but a value distorted by continued absorption from the sustained-release dosage form. The half-life in this subject following the halved tablet was 7.70 hr.

The apparent volume of distribution for theophylline following ingestion of whole 100-mg tablets was 0.56 ± 0.27 liter/kg. This was not significantly different ($p = 0.05$) from 0.46 ± 0.08 liter/kg obtained from the halved 100-mg tablets. Both values were comparable to those reported in the literature (16).

Total body clearance of theophylline was found to be 0.90 ± 0.36 and 1.02 ± 0.57 ml/min/kg following ingestion of whole and halved 100-mg sustained-release theophylline tablets, respectively. These clearances were not significantly different ($p = 0.05$) from each other or from values reported in the literature (16). Renal clearance of theophylline has been shown to be dependent upon the urine flow rate (17). However, the values found in this study of 0.14 ± 0.05 and 0.15 ± 0.06 ml/min/kg following the ingestion of whole and halved 100-mg tablets, respectively, were not significantly different ($p = 0.05$) from each other or from values previously reported in the literature (17, 18).

The quantities of theophylline and its metabolites, 1-methyluric acid, 3-methylxanthine, and 1,3-dimethyluric acid, recovered in 24-hr urine following ingestion of ~5-mg/kg dose as whole or halved 100-mg tablets are shown in Table V. The metabolite recovery values were converted to theophylline equivalents and reported along with theophylline as total xanthines. This permitted the calculation of the percentage of the dose recovered in the urine as unchanged drug and metabolites during the 24 hr period. Mean recoveries of 66.11 ± 16.47 and 65.50 ± 20.97% following ingestion of whole and halved tablets, respectively, were not significantly different ($p = 0.05$).

The distribution of the various metabolites following the whole or halved tablet doses (Table VI) were not significantly different ($p = 0.05$). This is not surprising since the other parameters such as *AUC*, MAT, K_e, $t_{1/2}$, V_d, Cl and Cl_R were not significantly affected by halving the tablets. However, when compared to other values in the literature, some differences were observed. In a study where 15 older patients were given sustained-release tablets (19), theophylline recovery was 7.7 ± 6.1%, whereas in the present study 17.89 ± 9.27% was found. The recovery of 3-methylxanthine (19) was 36.2 ± 7.3%, while only 14.86 ± 1.85% was recovered in this study. The recoveries of 16.5 ± 3.3% and 39.6 ± 4.5% for 1-methyluric acid and 1,3-dimethyluric acid, respectively (19), were not significantly different ($p = 0.05$) from the present study.

In the previously reported study (19), middle-aged to elderly patients were used, whereas the present study used healthy, young subjects. The older patients were at steady state and 116 ± 36% of the 24-hr dose was recovered in the urine. The younger subjects only received a single dose and only 66.11 ± 47% of the dose was recovered in the 24-hr urine. These differences may account for the discrepancies.

In summary the theophylline elimination parameters such as half-life ($t_{1/2}$), elimination rate constant (K_e), apparent volume of distribution (V_d), clearance (Cl), and renal clearance (Cl_R) were not significantly different from literature values obtained in similar subjects. The metabolite excretion pattern differed from that previously reported but the differences in subject age and in the dosage regimen may have accounted for these discrepancies. In conclusion, halving the sustained-release 100-mg theophylline tablets to achieve more accurate mg/kg doses should not affect drug therapy in patients.

Determination of Related Compounds in Aspirin by Liquid Chromatography

C. D. PFEIFFER and J. W. PANKEY ˣ

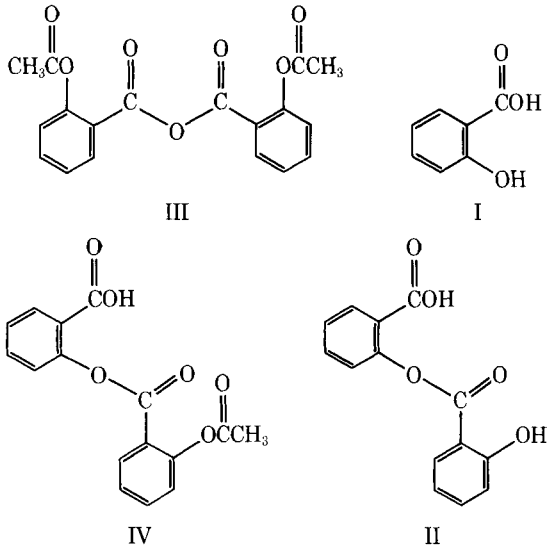
Received May 22, 1981, from the *Analytical Laboratories, The Dow Chemical Company, Midland, MI 48640.* Accepted for publication July 15, 1981.

Abstract □ A rapid liquid chromatographic procedure has been validated for the determination of salicylic acid, salsalate, acetylsalicylsalicylic acid, and acetylsalicylic anhydride in aspirin. Samples are dissolved in methylene chloride and analyzed directly by adsorption chromatography in a 7-min separation using an isocratic mobile phase. Recoveries averaged 99% over a 200–10,000 ppm concentration range with standard deviations of <4% for the four compounds of interest. Detection limits ranged from 5 to 36 ppm. Compared to a recently published reversed-phase liquid chromatographic procedure for analyzing aspirin, this method is twice as fast, more sensitive, and avoids the use of hydroxylic solvents which lead to degradation of aspirin and acetylsalicylic anhydride.

Keyphrases □ Aspirin—determination of salicylic acid and related compounds by liquid chromatography □ Liquid chromatography—determination of salicylic acid and related compounds in aspirin □ Salicylic acid—determination in aspirin by liquid chromatography, related compounds

Several recent papers (1–5) have discussed the possible immunological response to the presence of low levels of related compounds in aspirin. Methods, too numerous to discuss, employing gas chromatography, spectrophotometry, liquid chromatography, *etc.*, have been published describing the determination of salicylic acid (I), salsalate (II), acetylsalicylic anhydride (III), and acetylsalicylsalicylic acid (IV) in aspirin. Liquid chromatography (LC) appears to be the most useful approach with respect to specificity, speed, and sensitivity. Various LC methods have appeared in the literature employing adsorption, polar bonded phase, as well as reversed-phase column packings.

After considering the various LC methods, it appeared that the methods employing adsorption chromatography are most appropriate for the determination of related compounds in aspirin on a routine basis. Reversed-phase methods are not desirable because III and aspirin are not stable in the mixed aqueous–organic eluents used in that



form of LC (5). In addition, the selectivity of the reversed-phase system is such that I elutes from the column immediately following aspirin and a poor detection limit is found for I because the larger aspirin peak tails into the peak for I. This difficulty can be avoided by using fluorescence detection (6) to selectively detect I, but this requires the use of dual detectors which increases the cost and complexity of the LC system.

Several normal-phase LC systems have been published for these analyses. A silica gel support containing perchloric acid as a stationary phase for the determination of I, III, and IV in aspirin has been used (7). In another study (8) a polar bonded phase[1] column has been used for the separation of II, III, IV, and other compounds. However,

the separation on silica gel described previously (9) appears to be the most practical for use on a routine basis, and modification of this approach was used in this current work.

EXPERIMENTAL

Reagents—Hexane, chloroform, and methylene chloride of distilled-in-glass quality were used[2,3]. Glacial acetic acid of reagent grade[4] and 2,2-dimethoxypropane (98%)[5] were used as purchased.

Standards—Salicylic acid[6], salsalate[7], and acetylsalicylic anhydride[8] were used as purchased. The acetylsalicylsalicylic acid was synthesized[9] and characterized utilizing spectroscopic and chromatographic techniques to confirm its identity and purity.

A standard solution containing I, II, III, and IV was accurately prepared by weight in methylene chloride with each component at ~800 μg/ml. This concentrated standard solution was accurately diluted to yield a standard at the ~40-μg/ml level, and was used to calibrate the LC system. It was observed that the standard solutions were somewhat unstable and, therefore, all standards were prepared fresh whenever the system was recalibrated.

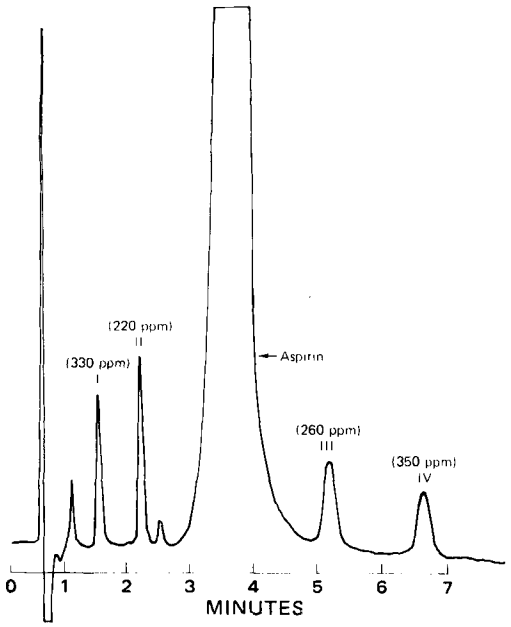

Figure 1—*Analysis of spiked aspirin. Column, 4.6 × 150 mm, Zorbax-SIL; flow rate, 3.0 ml/min; injection, 10 μl; detector, 0.016 aufs at 254 nm; mobile phase, hexane–chloroform–acetic acid (80:19:3).*

[9] Dow Chemical Co.

Apparatus—The liquid chromatograph was a modular system consisting of a pump[10], sample injection valve[11], and a single wavelength (254 nm) UV detector[12]. A computing integrator[13] was used for measuring peak areas and calculating results of analyses.

The microparticulate silica gel column[14] (4.6 × 150 mm) was purchased prepacked from the supplier. Prior to use, the column was activated using 2,2-dimethoxypropane (10). Ten column volumes of a solution consisting of methylene chloride–acetic acid–2,2-dimethoxypropane, 96:2:2 (v/v/v) were pumped through the column at a flow rate of 3.0 ml/min to condition and activate the packing. The column was then equilibrated by pumping mobile phase, hexane–chloroform–acetic acid, 80:19:3 (v/v/v), at a flow rate of 3.0 ml/min until a flat base line was obtained, ~15 min. The specific LC conditions used for the analysis were: mobile phase—hexane–chloroform–acetic acid, 80:19:3 (v/v/v); temperature ambient; detector wavelength, 254 nm, 0.016 aufs; injection, 10 μl.

Sample Preparation—Samples of aspirin crystals were dissolved in methylene chloride (20 mg/ml) and analyzed directly by LC. The sample solutions were injected as soon as dissolution had occurred because it was observed that aspirin hydrolyzed to I in methylene chloride solution. Therefore, artificially high results were obtained for I unless sample solutions were analyzed immediately.

Samples of aspirin tablets were finely ground and dissolved in methylene chloride (20 mg/ml). The resulting solutions were rapidly filtered[15] to remove insoluble materials, and the clear filtrate was immediately analyzed by LC. This entire dissolution–filtering operation was completed in less than 2 min to minimize formation of I.

RESULTS AND DISCUSSION

Validation—A typical chromatogram of a spiked aspirin sample is shown in Fig. 1. The linearity of the LC system was demonstrated by

chromatographing a series of standard solutions containing varying levels of the four compounds of interest. Plots of peak area against concentration yield straight lines going through the origin for up to the equivalent of 1% of each of the related compounds in the samples. The peak height response was also linear up to 1200 ppm at 0.016 aufs.

For the recovery study, a sample of aspirin was analyzed in triplicate using the external standard technique to determine the native levels of the related compounds. Recovery data were generated by spiking the control sample at levels in a 200–10,000 ppm range with the components of interest and analyzing those components by the external standard technique. The results were corrected for native levels of each component before calculating the recovery values. The results are summarized in Table I. The data demonstrated that relative standard deviations of 4% were obtained for the four compounds of interest.

Precision data were generated by analyzing a single sample of aspirin 5 times on each of two consecutive days. The results are summarized in Table II. The precision obtained would have been predicted from the recovery study, further demonstrating the validity of the method.

The detection limits of the method for the four components of interest for both peak area and peak height are summarized in Table III. The minimum detectable quantity was defined as a peak <2.5 times the short-term peak-to-peak baseline noise. The retention times for several other aspirin related compounds on this LC system are listed in Table IV. Chromatograms of typical bulk aspirin samples are shown in Fig. 2; results are summarized in Table V.

F	540	700	ND	4500

[a] Measured in parts per million. [b] Not detected at a detection limit of 6 ppm. [c] Not detected at a detection limit of 5 ppm.

Mobile Phase—During this investigation, it was found that the aspirin separation was somewhat dependent on the particular brand of chloroform used. Various suppliers use different preservatives to inhibit degradation, and it was found in particular that ethanol used as a preservative had a significant effect on retention times.

The separation between III and aspirin is most critically affected. Using a ratio of hexane–chloroform–acetic acid of 80:19:3 (v/v/v), with a nonpolar hydrocarbon stabilizer in the chloroform, the relative retention of III to aspirin was 1.59. With 80:19:3 and 1% ethanol in the chloroform, the relative retention was 1.36. Thus, when ethanol is used as a preservative in chloroform, the relative amount of chloroform in the mobile phase should be reduced to adequately resolve III and aspirin.

Analysis of Tablets—While this method was developed and validated for the specific determination of related compounds in bulk aspirin, it is also applicable to the analysis of aspirin tablets. A complicating factor in the analysis of tablets is the presence of starch and other insoluble excipients in the sample matrix which must be removed prior to the LC separation. However, this was readily accomplished *via* filtration using the filter described previously. A small, 4.6 × 50-mm guard column packed with pellicular silica gel[16] was used to protect the analytical column when analyzing tablets.

The method was not formally validated for the analysis of tablets. However, the LC separation was evaluated for this application by analyzing six commercial brands of tablets. A typical chromatogram is shown in Fig. 3 and the results are summarized in Table VI. It is interesting to note that no III was detected in any of the samples analyzed. At this time, it is not known whether these particular brands were formulated from bulk aspirin not containing III, or if III is not stable in the starch matrix since the starch may contain up to 14% water.

CONCLUSIONS

A new, rapid method has been validated for the determination of related compounds in bulk aspirin. Recoveries averaged 99% with a standard deviation of <4% for the four compounds of interest over a 200–10,000 ppm concentration range. For a single determination, results may be expected to be <7.7% relative error at the 95% confidence level.

This method has three significant advantages compared to the re-

[16] Corasil II, Waters Associates, Milford, Mass.

versed-phase LC procedure recently published by the United States Food and Drug Administration (11, 12). In addition to being twice as fast, the selectivity of the adsorption LC system is such that I and II elute prior to aspirin, permitting a low limit of detection for I. The normal phase LC method avoids the use of hydroxylic solvents, which lead to degradation of aspirin and III preventing accurate determination of III by reversed-phase LC. This method uses an inexpensive fixed wavelength (254 nm) UV detector and has a lower limit of detection than any previously published normal phase LC procedure.

Soft Drugs V: Thiazolidine-Type Derivatives of Progesterone and Testosterone

NICHOLAS BODOR *x and KENNETH B. SLOAN ‡

Received April 8, 1981, from the **Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610* and the ‡*Inter$_x$ Research Corporation, Lawrence, KS 66044.* Accepted for publication August 5, 1981.

Abstract □ Progesterone and testosterone are natural soft drugs, but to be used as drugs, their fast and facile metabolism must be prevented and their delivery controlled. A prodrug–soft drug combination can serve this purpose. Thiazolidines of testosterone, testosterone 17-propionate and progesterone were synthesized from the reaction of cysteine alkyl esters, *N*-methylaminoethanethiol, and mercaptamine and their hydrochlorides with the appropriate steroids. The thiazolidines function as bioreversible derivatives of the parent steroids.

Keyphrases □ Soft drugs—thiazolidine-type derivatives of progesterone and testosterone □ Prodrugs—thiazolidine-type derivatives of progesterone and testosterone □ Progesterone—thiazolidine-type derivatives, prodrugs □ Testosterone—thiazolidine-type derivatives, prodrugs

Oral contraception is accomplished currently by products containing synthetic hormones, mostly as fixed combinations of synthetic estrogens and progestins (1). The contraceptive action of these products is mediated primarily by inhibition of ovulation through specific macromolecular receptors for each hormone. It is clear that if the natural hormones, *e.g.*, progesterone and estradiol, were delivered to the receptors, they would elicit the same contraceptive effect as the synthetic analogs. The advantage of this method is that the natural hormone might decrease or eliminate the side effects accompanying synthetic contraceptive agents. Some of these side effects are the result of oxidative metabolism (2), such as the one involving the 17α-ethinyl group in norethindrone (17β-hydroxy-19-nor-17α-pregn-4-en-20-yn-3-one) or norgestrel (13-ethyl-17β-hydroxy-18,19-dinor-17α-pregn-4-en-20-yn-3-one), which leads to destruction of cytochrome P-450 (3).

Natural hormones such as progesterone, estradiol, and testosterone are natural soft drugs (4, 5); that is, due to their efficient and nontoxic metabolic disposition, they will not cause unexpected toxicity at concentrations close to their natural levels. On the other hand, natural hormones administered as drugs suffer from low physiological availability because, as natural substances, the body has developed efficient mechanisms for their metabolism and excretion. For example, the α,β-unsaturated ketone and the 20-ketone in progesterone are reduced in the liver to give pregnane-3α,20-diol, which can then be conjugated and excreted (1). In addition, the natural hormones are virtually insoluble in water which precludes their efficient dissolution and absorption from most formulations. Thus, to utilize progesterone as a contraceptive drug component, solutions to the problems of slow dissolution (water solubility) and rapid metabolism must be found.

In the case of hydrocortisone (4), the preferred approach to solving the described problems is through chemical modification, *i.e.*, a prodrug. However, progesterone is a difficult candidate for such an approach because the only functional groups available for reversible modification are the 3- and 20-ketones. Therefore, an extension of the spirothiazolidine approach (4) seemed the most attractive, as thiazolidines are unique examples of a bioreversible steroidal ketone derivative. The spontaneous S_N1 cleavage of the thiazolidine (6) to a β-thioethylene imine is followed by hydrolysis of the imine [possibly through a hydration–disassociation mechanism (7)] to regenerate the parent carbonyl compound (4). In addition to their potential bioreversibility, thiazolidines were attractive as prodrugs because they could be prepared from cysteine. Consequently, the hydrolysis products (steroid and cysteine) of the prodrugs would not present any unusual metabolic burden to the body. The carboxylic group of cysteine could also be easily esterified, thus providing a convenient method for changing the lipophilicity/hydrophilicity of the derivatives. In addition to progesterone, testosterone thiazolidines were also investigated[1].

Soft Drugs V: Thiazolidine-Type Derivatives of Progesterone and Testosterone

NICHOLAS BODOR *x and KENNETH B. SLOAN ‡

Received April 8, 1981, from the **Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610* and the ‡*Inter$_x$ Research Corporation, Lawrence, KS 66044.* Accepted for publication August 5, 1981.

Abstract □ Progesterone and testosterone are natural soft drugs, but to be used as drugs, their fast and facile metabolism must be prevented and their delivery controlled. A prodrug–soft drug combination can serve this purpose. Thiazolidines of testosterone, testosterone 17-propionate and progesterone were synthesized from the reaction of cysteine alkyl esters, *N*-methylaminoethanethiol, and mercaptamine and their hydrochlorides with the appropriate steroids. The thiazolidines function as bioreversible derivatives of the parent steroids.

Keyphrases □ Soft drugs—thiazolidine-type derivatives of progesterone and testosterone □ Prodrugs—thiazolidine-type derivatives of progesterone and testosterone □ Progesterone—thiazolidine-type derivatives, prodrugs □ Testosterone—thiazolidine-type derivatives, prodrugs

Oral contraception is accomplished currently by products containing synthetic hormones, mostly as fixed combinations of synthetic estrogens and progestins (1). The contraceptive action of these products is mediated primarily by inhibition of ovulation through specific macromolecular receptors for each hormone. It is clear that if the natural hormones, *e.g.*, progesterone and estradiol, were delivered to the receptors, they would elicit the same contraceptive effect as the synthetic analogs. The advantage of this method is that the natural hormone might decrease or eliminate the side effects accompanying synthetic contraceptive agents. Some of these side effects are the result of oxidative metabolism (2), such as the one involving the 17α-ethinyl group in norethindrone (17β-hydroxy-19-nor-17α-pregn-4-en-20-yn-3-one) or norgestrel (13-ethyl-17β-hydroxy-18,19-dinor-17α-pregn-4-en-20-yn-3-one), which leads to destruction of cytochrome P-450 (3).

Natural hormones such as progesterone, estradiol, and testosterone are natural soft drugs (4, 5); that is, due to their efficient and nontoxic metabolic disposition, they will not cause unexpected toxicity at concentrations close to their natural levels. On the other hand, natural hormones administered as drugs suffer from low physiological availability because, as natural substances, the body has developed efficient mechanisms for their metabolism and excretion. For example, the α,β-unsaturated ketone and the 20-ketone in progesterone are reduced in the liver to give pregnane-3α,20-diol, which can then be conjugated and excreted (1). In addition, the natural hormones are virtually insoluble in water which precludes their efficient dissolution and absorption from most formulations. Thus, to utilize progesterone as a contraceptive drug component, solutions to the problems of slow dissolution (water solubility) and rapid metabolism must be found.

In the case of hydrocortisone (4), the preferred approach to solving the described problems is through chemical modification, *i.e.*, a prodrug. However, progesterone is a difficult candidate for such an approach because the only functional groups available for reversible modification are the 3- and 20-ketones. Therefore, an extension of the spirothiazolidine approach (4) seemed the most attractive, as thiazolidines are unique examples of a bioreversible steroidal ketone derivative. The spontaneous S_N1 cleavage of the thiazolidine (6) to a β-thioethylene imine is followed by hydrolysis of the imine [possibly through a hydration–disassociation mechanism (7)] to regenerate the parent carbonyl compound (4). In addition to their potential bioreversibility, thiazolidines were attractive as prodrugs because they could be prepared from cysteine. Consequently, the hydrolysis products (steroid and cysteine) of the prodrugs would not present any unusual metabolic burden to the body. The carboxylic group of cysteine could also be easily esterified, thus providing a convenient method for changing the lipophilicity/hydrophilicity of the derivatives. In addition to progesterone, testosterone thiazolidines were also investigated[1].

EXPERIMENTAL[2]

Biological—*In vivo* animal tests used standard procedures for the Clauberg and seminal vesicle and ventral prostate weight tests.

Plasma Hydrolysis Studies of Thiazolidines—Whole blood was drawn from female beagles immediately before the hydrolysis study. The whole blood was treated with edetate disodium as an anticoagulant. The blood was centrifuged at 2000 rpm for 10 min. The plasma was removed from the red blood cells and filtered through a 0.2-μm methylcellulose membrane filter. Concentrated spiking solutions of the thiazolidines (Table I) were prepared in dimethylformamide. Small volumes of these solutions (20 μl/ml of plasma) were added to the plasma to give the appropriate concentrations. Methyl testosterone (0.020 mg/ml) was added as an internal standard for chromatography. The samples were mixed thoroughly and placed in a water bath at 37°, equipped with a shaking mechanism. Samples (5 μl) were withdrawn at ~12-hr intervals for injection onto the high-pressure liquid chromatograph. The mobile phase was tetrahydrofuran–methanol–water (1:1:2) at a 2.0-ml/min flow rate. The eluate was monitored at 254 nm for progesterone. The progesterone concentration was determined by comparison of the peak areas of the sample and standard solutions, and corrected using the internal standard. Hydrolysis rates were determined by the rate of appearance of progesterone. Straight lines were determined using a least-squares fit.

Pharmacokinetics of XI in Dogs—Female beagle dogs were used for the study which included a crossover experiment. The dogs were placed in separate stainless steel cages 24 hr prior to administration of the drug. Water was available at all times and normal feeding schedules were maintained. The dogs were dosed with 2.5 μCi of drug by intravenous injection in the front leg over a 30 sec period. The ^{14}C-labeled progesterone was 1 μCi/mg. The ^{14}C-labeled XI was 0.446 μCi/mg. All drugs were dissolved in 100 μl of benzyl alcohol. Blood samples (~4 ml) were drawn from the jugular vein of the dog using tubes containing edetate disodium as an anticoagulant preservative. Blood samples were taken at 5, 10, 15, 30, 45, 60, and 90 min, 2, 4, 6, 8, 12, 24, 32, and 48 hr, and at other appropriate times after injection. The blood (3.5 ml) was transferred to a tared 25-ml heavy duty centrifuge tube with a polytef-lined screw cap. The samples were weighed accurately before extraction. Extractions were performed by shaking for 10 min with 10 ml of 10% ethylene dichloride in ether (v/v) on a wrist-shaker, centrifuging for 15 min at 2000 rpm, and transferring the organic phase to new liquid scintillation vials. Samples were extracted twice and the organic phases from each extraction were combined. The organic solvent was evaporated to dryness in a 50° water bath under dry nitrogen stream. The extracts were dissolved in 15 ml of scintillation cocktail and mixed thoroughly. The samples were stored overnight at 4° prior to counting to reduce chemiluminescence.

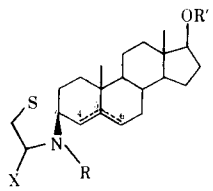
Urine samples from each dog were collected at 24 and 48 hr after dosing. Both samples were frozen separately until all the studies were completed and all samples were prepared at once. The urine was thawed and the total volumes measured. A small amount of well mixed urine from each sample was centrifuged to remove particulate matter. One milliliter of each sample was quantitatively transferred to a liquid scintillation vial containing 0.5 ml of 0.5 *N* hydrochloric acid and mixed. Fifteen milliliters of scintillation cocktail was added to each vial and mixed. Samples were then counted.

Recovery experiments were conducted using radioactive labeled drugs at three blood levels for each of the three compounds in whole dog blood. Extraction efficiencies for each compound at each blood level were determined using 10% ethylene dichloride in ether as a solvent. For each compound, studies were conducted at blood levels of 0.001, 0.0001, and 0.00005 μCi/3 ml of blood. For each blood level, 18 ml of blood was transferred to a tared, heavy-duty centrifuge tube and weighed accurately. Each pool of blood was spiked at the appropriate concentration using either 30 or 60 μl of a spiking solution (methanol). The spiked blood was shaken for 30 min to reach equilibrium. Five replicate 3-ml samples were drawn from each pool and transferred to tared 25-ml heavy-duty centrifuge tubes equipped with polytef-lined screw caps and weighed accurately.

Each sample was extracted twice by shaking for 15 min on a wrist-shaker with 10 ml of 10% ethylene dichloride in ether, centrifuging for 10 min at 2200 rpm, and transferring the supernate to a liquid scintillation vial. Combined extracts were evaporated to dryness under a dry nitrogen stream at 55°. The residues were dissolved in 15 ml of scintillation cocktail. Samples were stored overnight at 4° to reduce chemiluminescence and then counted.

Distribution Studies in Rats—Approximately 1 μCi/mmole of progesterone, XI, and VIII*a* in 5 ml of benzyl alcohol were injected intravenously in the tail veins of six female rats (90–120 g). They were then placed in a clean metabolism cage and their urine and feces were collected.

Table I—Thiazolidines of Testosterone and Testosterone 17β-Propionate



Compound	X	R	Δ	R′

[2] Radiolabeled counting was performed on a Beckman LS-100C Scintillation Counter. TLC were run on Brinkman Polygram Sil G/UV 254. Melting points (uncorrected) were taken with a Thomas–Hoover capillary apparatus. NMR spectra were recorded on a Varian T-60 (^1H spectra) or on a Bruker WP-80 (^{13}C spectra) spectrophotometer. Infrared spectra were obtained on a Beckman Acculab 4 infrared spectrophotometer, while UV spectra were determined on a Carey Model 14 spectrophotometer. Optical rotations were obtained using a Perkin Elmer 141 polarimeter. HPLC analyses were run on a Waters 6000A solvent delivery system U6K universal injector and a 440 Dual Channel UV detector. Microanalyses were performed by Midwest Microlab, Ltd, Indianapolis, Ind. Progesterone, testosterone, testosterone propionate, cysteine methyl, and ethyl ester hydrochlorides were obtained from Sigma. 2-Aminoethanethiol hydrochloride was obtained from Aldrich, the scintillation cocktails were Aquasol or Biofluor from New England Nuclear, the protein solubilizer was Protosol from New England Nuclear, while all other reagents were obtained from Mallinckrodt unless otherwise specified. The cysteine glycerol, butyl, hexyl, and decyl esters were prepared according to Voullie (8) *et al.*, and the *N*-acyl-thiazolidines were prepared according to Sloan *et al.*[3] The hairless mice (SKH-hr-1) were obtained from the Temple University Skin and Cancer Hospital. *In vivo* animal tests were conducted at the National Institutes of Health.

[3] K. B. Sloan, N. Bodor, and J. Zupan, *Tetrahedron*, in press.

Sixty minutes after injection each rat was anesthetized with ether, and its blood was collected in a preweighed test tube containing 4 drops of 15% edetate disodium. Each rat was then sacrificed with more ether and dissected. The fat deposits, spleen, kidneys, ovaries, liver, lungs, heart, brain, intestinal walls, GI contents, and the tail were all removed and each one placed in a preweighed test tube.

After each organ (except the tail) was weighed, it was homogenized with a known amount of water in a glass tissue grinder. The tail was wrapped in aluminum foil, frozen in liquid nitrogen, shattered with a hammer, and mixed thoroughly with a known volume of water. The feces were diluted with water and mixed thoroughly. Samples (0.5 ml) of the homogenates or suspensions and 1.0 ml of a protein solubilizer–ethanol mixture were placed in liquid scintillation counting vials. The vials containing the samples were heated at 55° for 60 min, and if necessary, the samples were decolorized by heating with 0.1–0.5 ml of 30% hydrogen peroxide. After the samples were cooled, 15.0 ml of scintillation cocktail and 0.5 ml of 0.5 *N* HCl were added to the samples, and they were counted. A quenching curve was obtained using tissue samples, protein solubilizer, hydrogen peroxide, and scintillation cocktail. The urine from each rat was collected directly in a scintillation vial, and counted in 15.0 ml of scintillation cocktail.

Percutaneous Distribution in Mice—For the percutaneous delivery study, the thiazolidine VIII*a* and progesterone were dissolved in ethanol–isopropyl myristate (90:10) and applied to the backs of six hairless mice using a bandage to form an occlusive application. The mice were then placed in metabolism cages for 24 hr and then sacrificed. The bandages were then removed and the surface of the skins were washed three times with 5 ml of ethanol. The washes were combined with the patches and counted. An epidermal plug, 2 cm in diameter, was taken from each carcass from directly beneath where the patches (3 cm^2) had been with a leather punch. The epidermal plugs, the remainder of the carcasses, the urine, and feces were processed as described for the rat distribution study.

Reaction of Testosterone 17β-propionate with Cysteine Ethyl Ester Hydrochloride—To a mixture of testosterone 17β-propionate (1.0 g, 0.0029 mole) and cysteine ethyl ester hydrochloride (3.70 g, 0.02 mole) was added 10 ml of pyridine. The solution was allowed to sit at room temperature overnight under a nitrogen atmosphere in a tightly closed flask. The solution was then partitioned using methylene chloride–water (100:100) and the methylene chloride layer was separated, dried over sodium sulfate, and concentrated to give a solid residue. The residue was crystallized from 10 ml of hot ethanol to give 0.35 g (mp 144–147°, 26% yield) of 5-androstene-17β-propionyloxy-3-spiro-2′-(4′-ethoxycarbonyl-1′,3′-thiazolidine), I*a*: TLC (silica gel, ether) R_f 0.45; IR (KBr): 1735 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): δ 5.53–5.2 (m, 1, C*H*=C), 4.6 (t, *J* = 8 Hz, 1, C*H*O_2C), 4.21 (q, *J* = 7 Hz, 2, CH_3CH_2O), 4.2–3.8 (m, 1, O_2CC*H*N), 3.4–2.7 (m, 2, CH_2S), 1.29 (t, *J* = 7 Hz, 3, CH_3CH_2O), 1.01 (s, 3, CH_3—C), 0.8 (s, 3, CH_3—C), and 2.7–1.0 (m, 24, N*H*, CH_2 and C*H*); ^{13}C-NMR ($CDCl_3$): δ 174.7, 171.9 (CO_2), 140.7 (C-5), and 122.4 (C-6); $[\alpha]_D^{25}$ −55° (*C* = 0.55, ethanol).

Anal.—Calc. for $C_{27}H_{41}NO_4S$: C, 68.17; H, 8.69; N, 2.95. Found: C, 68.46; H, 8.78; N, 2.70.

The mother liquor was concentrated to 5 ml and allowed to crystallize further. This gave 0.51 g (mp 100–104°, 37% yield) of a mixture containing primarily 4-androstene-17β-propionyloxy-3-spiro-2′-(4′-ethoxycarbonyl-1′,3′-thiazolidine), I*b*, but with some I*a* (ratio ~9:1, I*b*:I*a*). TLC and IR were the same as for I*a*. The ^{1}H-NMR spectrum was the same except that the major (90%) C*H*=C absorption was a singlet as δ 5.3; ^{13}C-NMR ($CDCl_3$): δ 174.7, 171.9 (CO_2), 148.7 (C-5), and 123.0 (C-4); $[\alpha]_D^{25}$ = +10 (*C* = 0.49, ethanol).

Anal.—Calc. for $C_{27}H_{41}NO_4S$: C, 68.17; H, 8.69; N, 2.95. Found: C, 68.28; H, 8.79; N, 2.75.

Compounds II*a*, II*b*, III, and IV were prepared in a similar manner and had NMR and IR spectra consistent with the assigned structures.

5- and 4-Androstene-17β-ol-3-spiro-2′-(4′-ethoxycarboxyl-1′,3′-thiazolidine)—These are II*a* and II*b*, respectively.

II*a*: mp 136–140° from ethanol, 32% yield; $[\alpha]_D^{25}$ = −60° (*C* = 0.47, $CHCl_3$).

Anal.—Calc. for $C_{24}H_{37}NO_3S$: C, 68.69; H, 8.89; N, 3.34. Found: C, 68.58; H, 8.79; N, 3.18.

II*b*: An amorphous powder from water; $[\alpha]_D^{25}$ = +2° (*C* = 0.45, $CHCl_3$).

Anal.—Calc. for $C_{24}H_{37}NO_3S$: C, 68.69; H, 8.89; N, 3.34. Found: C, 67.87; H, 8.79; N, 3.54.

The 4-androstene-3-thiazolidine could be crystallized from 1 ml of ethanol to give a light yellow fibrous solid (0.28 g, mp 67–75°), which was identical in all respects with the crude product and gave a low carbon analysis also.

5-Androstene-17β-propionyloxy-3-spiro-2′-(4′-β-hydroxyethoxycarbonyl-1′,3′-thiazolidine)—III: mp 127–130° from ether; $[\alpha]_D^{25}$ = −49° (*C* = 0.5, $CHCl_3$).

Anal.—Calc. for $C_{27}H_{41}NO_5S$: C, 66.00; H, 8.34, N, 2.84; S, 6.52. Found: C, 65.90; H, 8.55; N, 2.68; S, 6.69.

5-Androstene-17β-ol-3-spiro-2′-(4′-β-hydroxyethoxycarbonyl-1′,3′-thiazolidine)—IV: mp 135–140° from ether.

Anal.—Calc. for $C_{24}H_{37}NO_4S$: C, 66.22; H, 8.50, N, 3.21; S, 7.36. Found: C, 66.16; H, 8.77; N, 3.39; S, 7.48.

Reaction of Progesterone with Cysteine Ethyl Ester Hydrochloride—Progesterone (1.0 g, 0.0032 mole) was mixed with increasing amounts of cysteine ethyl ester hydrochloride (0.65 g, 0.0035 mole, one equivalent; 1.30 g, 0.0070 mole, two equivalents; 2.60 g, 0.014 mole, four equivalents; 3.90 g, 0.021 mole, six equivalents) and dissolved in pyridine (10 ml) in four separate reactions. The reactants were kept at room temperature overnight under nitrogen in a tightly closed flask. Each reaction was then concentrated *in vacuo* (0.1 mm, 1 hr, 45°) to give a gummy solid which was suspended in 50 ml of ethylene dichloride. The ethylene dichloride suspensions were extracted with 10 ml of water, dried over sodium sulfate and concentrated *in vacuo* to give yellow solids which were analyzed by TLC and NMR spectroscopy. Only the reaction with six equivalents of cysteine ethyl ester hydrochloride appeared to give a homogeneous product. All of the reaction products were suspended in 25 ml of boiling ethanol and filtered. In the case of the reactions with four and six equivalents, there was a considerable amount of the ethanol insoluble material. The ethanol insoluble fraction from the reaction with four equivalents of cysteine ethyl ester hydrochloride was a mixture, but that from six equivalents was homogeneous and it was identified as 17β-(4″-ethoxycarbonyl-2″-methyl-1″,3″-thiazolidine-2″-yl)-5-androstene-3-spiro-2′-(4′-ethoxycarbonyl-1′,3′-thiazolidine)VIII*a* (1.2 g, mp 167–170°, 67% yield); IR (KBr): 1735 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): δ 5.6–5.2 (m, 1, C*H*=C), 4.20 (q, *J* = 7 Hz, 4, OCH_2CH_3), 4.1–3.65 (m, 2, O_2CC*H*—N), 3.5–2.6 (m, 4, CH_2—S), 1.57 (s, 3, CH_3—C(N)—S), 1.03 (s, 3, CH_3—C), 0.85 (s, 3, CH_3—C), 1.3 (t, *J* = 7 Hz, 6, CH_3CH_2O), 2.6–0.6 (m, 19, CH_2 and C*H*); ^{13}C-NMR ($CDCl_3$): δ 171.9 (CO_2), 140.6 (C-5) and 122.6 (C-4); $[\alpha]_D^{25}$ = −92° (*C* = 0.56, $CHCl_3$); TLC (silica gel, ether) R_f 0.42.

Anal.—Calc. for $C_{31}H_{48}N_2O_4S_2$: C, 64.54; H, 8.39; N, 4.86. Found: C, 64.61; H, 8.44; N, 4.63.

The crystals obtained from the 25-ml ethanol solutions contained mixtures except for the product from the reaction of progesterone with one equivalent of cysteine ethyl ester hydrochloride. Those crystals were identified as 5-pregnene-20-one-3-spiro-2′-(4′-ethoxycarbonyl-1′,3′-thiazolidine) (IX*a*) with about 10% of the 4-pregnene IX*b* as a contaminant (0.45 g, mp 127–134°, 33% yield); IR (KBr): 1735 and 1700 cm^{-1} (s) (C=O); ^{1}H-NMR ($CDCl_3$): δ 5.6–5.2 (m, 1, C*H*=C), 4.26 (q, *J* = 7 Hz, 2, CH_3CH_2O), 4.2–3.8 (m, 1, O_2CC*H*N), 3.6–2.8 (m, 2, CH_2S), 2.11 (s, 3, CH_3—C=O), 1.02 (s, 3, CH_3—C), 0.63 (s, 3, CH_3—C), 1.3 (t, *J* = 7 Hz, 3, CH_3CH_2O), 2.8–0.6 (m, 19, CH_2 and C*H*); ^{13}C-NMR ($CDCl_3$): δ 209.7 (C-20 = O), 171.9 (CO_2), 140.6 (C-5) and 122.5 (C-6); $[\alpha]_D^{25}$ = +11° (*C* = 0.58, $CHCl_3$); TLC (silica gel, ether) R_f 0.34.

Anal.—Calc. for $C_{26}H_{39}NO_3S$: C, 70.07; H, 8.82; N, 3.14. Found: C, 69.84; H, 8.80; N, 3.05.

In the case where six equivalents of cysteine ethyl ester hydrochloride was used, a precipitate formed after the reaction was allowed to run overnight. In a separate reaction, that precipitate was filtered to give VIII*a* (mp 164–170, 61% yield).

The following were prepared in a similar manner. Their NMR and IR spectra were consistent with the assigned structures.

17β-(4″-Butoxycarbonyl-2″-methyl-1″,3″-thiazolidine-2″-yl)-4-androstene-3-spiro-2′-(4′-butoxycarbonyl-1′,3′-thiazolidine)— mp 149–150°, from ethanol; $[\alpha]_D^{25}$ = −38° (*C* = 0.58, $CHCl_3$).

Anal.—Calc. for $C_{35}H_{50}N_2O_4S_2$: C, 66.42; H, 8.92; N, 4.43. Found: C, 66.90; H, 9.20; N, 4.30.

17β-(4″-Hexoxycarbonyl-2″-methyl - 1″,3″ - thiazolidine-2″-yl)-4- and 5-androstene-3-spiro-2′-(4′-hexoxycarbonyl-1′,3′-thiazolidine) (*XI*)—mp 113–115°, from ethanol; $[\alpha]_D^{25}$ = −25° (*C* = 0.51, $CHCl_3$).

Anal.—Calc. for $C_{39}H_{64}N_2O_4S_2$: C, 67.98; H, 9.36; N, 4.07. Found: C, 68.40; H, 9.48; N, 3.90.

17β-(4″-Decoxycarbonyl-2″-methyl-1″,3″-thiazolidine-2″-yl)-4-androstene-3-spiro-2′-(4′-decoxycarbonyl-1′,3′-thiazolidine) (*XII*) —mp 100–102°, from ethanol.

Anal.—Calc. for $C_{47}H_{80}N_2O_4S_2$: C, 70.45; H, 10.66; N, 3.50. Found: C, 70.62; H, 10.20; N, 3.40.

Preparation of 17β-(4″-Ethoxycarbonyl-2″-methyl-1″,3″-thiazolidine-2″-yl)-4-androstene-3-spiro-2′-(4′ - ethoxycarbonyl - 1′,3′-

Table II—Hydrolyses of Thiazolidines [a]

	$t_{1/2}$ [b], hr
Mono-thiazolidines

[a] Time for one-half the theoretical amount of progesterone to form. [b] Concentration of thiazolidines in plasma was 0.040 mg/ml.

thiazolidine) (VIII*b*)—Cysteine ethyl ester hydrochloride (11.2 g, 0.06 mole) was suspended in 40 ml of triethylamine with vigorous stirring for 1 hr at room temperature. The triethylamine hydrochloride was filtered and the filtrate was concentrated to give cysteine ethyl ester as an oil. The oil was dissolved in 30 ml of pyridine and allowed to react with 3.2 g (0.01 mole) of progesterone at room temperature for 3.5 days. The suspension that resulted was filtered and crystallized from ethyl acetate to give 2.7 g (mp 162–165°, 47% yield) of the desired product: IR (KBr): 1740 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): δ 5.23 (s, 1, C*H*=C), 4.2 (q, *J* = 7 Hz, 4, CH_3CH_2O), 4.2–3.6 (m, 2, O_2CCHN), 3.50–2.65 (m, 4, CH_2S), 1.55 (s, 3, CH_3—C(N)S), 1.3 (t, *J* = 7 Hz, 6, CH_3CH_2O), 1.03 (s, 3, CH_3—C), 0.85 (s, 3, CH_3—C), 2.6–0.6 (m, 19, CH_2 and C*H*); ^{13}C-NMR ($CDCl_3$): δ 171.9 and 172.0 (CO_2), 148.9 (C-5) and 122.9 (C-4); $[\alpha]_D^{25} = -24°$ (*C* = 0.63, $CHCl_3$).

Anal.—Calc. for $C_{31}H_{48}N_2O_4S_2$: C, 64.54; H, 8.39; N, 4.86. Found: C, 64.59; H, 8.46; N, 4.88.

Preparation of 4-Pregnene-20-one-3-spiro-2′-(4′-ethoxycarbonyl-1′,3′-thiazolidine) (IX*b*)—Compound VIII*a* (1.0 g) was heated in 25 ml of 80% acetic acid at 65° for 3.5 min then quickly neutralized with 400 ml of ice cold water containing 25 g of sodium bicarbonate. The suspension that resulted was filtered and dried to give 0.41 g of a white solid which was about 65% pure. The solid was crystallized from ethanol (7 ml) to give 0.22 g (mp 131–135°, 28% yield) of the desired product; IR (KBr): 1735 and 1700 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): δ 5.30 (s, 1, C*H*=C), 4.23 (q, *J* = 7 Hz, 2, CH_3CH_2O), 4.4–3.9 (m, 1, O_2CCHN), 3.6–2.8 (m, 2, CH_2S), 2.15 (s, 3, CH_3—C=O), 1.3 (t, 3, *J* = 7 Hz, CH_3CH_2O), 1.03 (s, 3, CH_3—C), 0.63 (s, 3, CH_3—C), 2.8–0.6 (m, 19, CH_2 and C*H*); ^{13}C-NMR ($CDCl_3$): δ 209.7 (C-20), 171.9 (CO_2), 148.7 (C-5), and 123.1 (C-6); $[\alpha]_D^{25}$ = +98° (*C* = 0.47, $CHCl_3$).

Anal.—Calc. for $C_{26}H_{39}NO_3S$: C, 70.07; H, 8.82; N, 3.14. Found: C, 70.00; H, 8.89; N, 2.55.

Preparation of 5-Andostrene-17β-ol-3-spiro-2′-(3′-methyl-1′,3′-thiazolidine) (VII)—*N*-Methylaminoethanethiol (1.3 g, 0.014 mole) was warmed to its melting point, 2.0 g (0.0069 mole) of testosterone was added, and the mixture was heated at ~130° for 40 min. The mixture was dissolved in methylene chloride (80 ml), and the solution was washed with water (40 ml), separated, dried over sodium sulfate, and concentrated to give an orange gum. The gum was extracted with 50 ml of refluxing cyclohexane. The cyclohexane was concentrated to 15 ml and cooled to give 0.67 g (mp 112–123°, 27% yield) of the desired thiazolidine: TLC (silica gel, ether) R_f 0.30; IR (KBr): 3400 cm^{-1} (m, OH); ^{1}H-NMR ($CDCl_3$): δ 5.5–5.3 (m, 1, C*H*=C), 3.67 (t, 1, *J* = 7 Hz, C*H*—OH), 3.5–3.17 (m, 2, CH_2—N), 3.17–3.77 (m, 2, CH_2—S), 2.37 (s, 3, CH_3—N), 1.05 (s, 3, CH_3—C), 0.78 (s, 3, CH_3—C), and 2.7–0.8 (m, 20, O*H*, CH_2— and C*H*); ^{13}C-NMR ($CDCl_3$): δ 140.6 (C-5) and 122.5 (C-6).

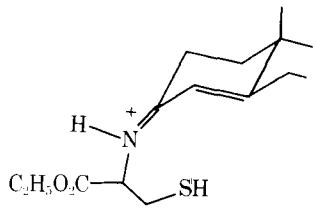
Anal.—Calc. for $C_{22}H_{35}NOS$: C, 73.07; H, 9.75; N, 3.87. Found: C, 73.19; H, 9.41; N, 3.88.

The filtrate was concentrated to 5 ml, the cyclohexane was decanted from some gum that precipitated, and the cyclohexane was concentrated to dryness to give an additional 0.80 g (32% yield) of the desired product as a foam which was identical with the crystalline material by TLC, NMR, and IR.

5-Pregnene-20-one-3-spiro-2′-(3′-methyl-1′,3′-thiazolidine) (XVII) was prepared in a similar manner (mp 149–151°, from hexane, 25% yield); IR (KBr): 1710 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): δ 5.5–5.2 (m, 1, C*H*=C), 2.8–3.5 (m, 4, CH_2—N), 2.33 (s, 3, CH_3—N), 2.13 (s, 3, CH_3CO), 1.03 (s, 3, CH_3—C), and 0.63 (s, 3, CH_3C).

Anal.—Calc. for $C_{24}H_{37}NOS$: C, 74.36; H, 9.62; N, 3.61. Found: C, 74.60; H, 9.80; H, 3.45.

Preparation of 5-Pregnene-20-one-3-spiro-2′-(1′,2′-thiazolidine) (XIII)—A mixture of 3.14 g (0.01 mole) of progesterone and 6.7 g (0.06 mole) of 2-aminoethanethiol hydrochloride was suspended in 20 ml of pyridine overnight at room temperature under a nitrogen atmosphere.



XVIII

The suspension was concentrated *in vacuo*. The residue that resulted was partitioned between methylene chloride–water (100:150 ml). The methylene chloride layer was dried over sodium sulfate, concentrated, and the residue triturated with 10 ml of warm methanol. Almost all of the residue went into solution. After the suspension had cooled, it was filtered to give 1.72 g (mp 127–136°, 46% yield) of the desired compound: TLC (silica gel, ether) R_f 0.20; IR (KBr): 3300 (w, N—H), and 1700 cm^{-1} (s, C=O); ^{1}H-NMR ($CDCl_3$): 5.5–5.2 (m, 1, C*H*=C), 3.6–2.9 (m, 4, SCH_2—CH_2—N), 2.11 (s, 3, CH_3C=O), 1.03 (s, 3, CH_3—C), 0.63 (s, 3, CH_3—C) and 2.9–0.6 (m, 21, CH_2, C*H* and N*H*); $[\alpha]_D^{25}$ = +104° (*C* = 0.51, $CHCl_3$).

Anal.—Calc. for $C_{23}H_{35}NOS$: C, 73.94; H, 9.44; N, 3.75. Found: C, 73.69; H, 9.80; N, 4.00.

Compounds V and VI were prepared in a similar manner. Their NMR and IR spectra were consistent with the assigned structures.

5-Androstene-17β-ol-3-spiro-2′-(1′,3′-thiazolidine) (VI)—TLC (silica gel, ether) R_f 0.24; $[\alpha]_D^{25}$ = +83° (*C* = 0.57, $CHCl_3$).

Anal.—Calc. for $C_{21}H_{33}NOS$: C, 72.57; H, 9.57; N, 4.03. Found: C, 72.56; H, 9.23; N, 4.03.

5-Androstene - 17β-propionyloxy-3-spiro-2′-(1′,3′-thiazolidine):V—mp 152–157° (from methanol, 71% yield); TLC (silica gel, ether) R_f 0.16; $[\alpha]_D^{25}$ = +69° (*C* = 0.52, $CHCl_3$).

Anal.—Calc. for $C_{24}H_{37}NO_2S$: C, 71.41; H, 9.24; N, 3.47. Found: C, 71.32; H, 9.38; N, 3.15.

Preparation of [4-^{14}C]-VIII*a* and XI—[4-^{14}C]Progesterone (100 mg, 100 μCi) was mixed with 1 g of cysteine ethyl or hexyl ester hydrochloride in 2 ml of pyridine. The systems were purged with nitrogen and then stirred overnight under nitrogen. The reaction mixtures were dissolved in 50 ml of ether and extracted with 25 ml of water. The water layers were extracted with an additional 50 ml of ether. The two ether layers were combined, dried over magnesium sulfate and evaporated. Methanol (10 ml) was added to each residue and after they were cooled the solutions gave 47 mg of VIII*a* from the reaction with the ethyl ester and 114 mg of XI from the reaction with hexyl ester. Both thiazolidines were analyzed by radiochromatograph and found to be homogeneous (VIII*a*, R_f = 0.8; XI, R_f = 0.7) using silica gel and ether.

RESULTS AND DISCUSSION

Chemistry—The synthesis and biological activity of the thiazolidines of hydrocortisone and hydrocortisone derivatives have been described recently (4). Similar reaction conditions were used in this study except for the preparation of the *N*-methylthiazolidines and the 4,5-double bond isomers of the mono- and dithiazolidines of progesterone, where special reaction conditions were necessary. As in the hydrocortisone series, the product from the reaction of cysteine with the steroids could not be isolated. However, as opposed to the hydrocortisone series where only one thiazolidine isomer was obtained from the reaction with the cysteine esters or an aminoethanethiol, testosterone and progesterone gave two series of thiazolidine isomers. The simplest case was the testosterone series. The reaction between testosterone 17β-propionate and cysteine ethyl ester hydrochloride gave two isomers, I*a* and I*b* (Table I) which were separated by fractional crystalization from ethanol. The elucidation of the structures of these isomers was reported recently[4], and it was shown that the isomers are the 4,5- and 5,6-double bond isomers as indicated by their optical rotations and ^{1}H- and ^{13}C-NMR spectra when compared with known 4,5- and 5,6-double bond isomers of 3-ethylene ketals and with each other. Although testosterone also gave two double bond isomers from its reaction with cysteine ethyl ester hydrochloride, only the 5,6-double bond isomer II*a* could be isolated in pure form.

Similar reactions of progesterone could be directed to give either the 5,6-double bond mono-3-thiazolidine IX*a* or di-3,20-thiazolidine VIII*a* by using either one or six equivalents, respectively, of cysteine ester hy-

drochloride. No significant amounts of the 4,5-double bond isomers VIII*b* and IX*b* were observed in these crude reaction mixtures based on an analysis of the shape and position of the C*H*=C absorption in the ^{1}H-NMR spectra. Since the thiazolidines decomposed on TLC plates and during column chromatography, analysis of the ^{1}H-NMR spectra of the isomers was the only reliable means of qualitatively determining the extent of the reactions and ratio of isomers. On the other hand, when butyl, hexyl, or decyl cysteine ester hydrochlorides were used instead of the ethyl ester, mixtures of the double bond isomers were isolated, or the 4,5-double bond isomer was the predominant isomer in the mixture (X, XI, and XII, Table I).

The preparation of the 4,5-double bond isomer VIII*b* from the reaction of cysteine ethyl ester with progesterone was accomplished without an acid catalyst necessary for the 4,5 → 5,6 migration by using the free base rather than the hydrochloride of cysteine ethyl ester.

In the second case (IX*b*), the successful synthesis was based on the observation of the iminium ion XVIII (9) as an intermediate in the UV monitored hydrolyses of the 4,5-double bond thiazolidines (4). This suggested that generation of the iminium ion followed by quenching of the reaction with base would result in recyclization of the imine to the thiazolidine, without concomitant reisomerization of the double bond to the 5,6-position. Indeed, when VIII*a* was treated with aqueous acetic acid at 65° for 3.5 min, then with cold aqueous bicarbonate, a mixture of progesterone and IX*b* was obtained from which IX*b* was easily isolated by crystallization from ethanol.

The success of the partial hydrolysis reaction to generate IX*b* was based in part on the observation that the 20-ketone thiazolidine hydrolyzed faster than the 3-ketone thiazolidine. This was not surprising since in addition to suggesting that the thiazolidine of α,β-unsaturated steroidal ketones could not be isolated, a previous report (10) suggested that thiazolidines of 17- and 20-steroidal ketones could not be obtained from the base catalyzed reaction of cysteine with the steroid. Thus, it was expected that both ketones would be difficult to derivatize for progesterone. In addition, the formation of the iminium ion XVIII from the 5,6-double bond isomer VIII*a* obviously could not be instantaneous because the double bond had to isomerize to the 4,5-position. Hence, the reaction time of 3.5 min was not only essential to ensure the complete conversion of VIII*a* to XVIII, but it also allowed more time for the complete hydrolysis of the 20-ketone thiazolidine to take place.

Since the 4′-ethoxycarboxyl group is electron withdrawing, the 4′ unsubstituted thiazolidines were prepared in an attempt to improve the hydrophilicity of the thiazolidines by increasing the pKa of the amine group, thus increasing the concentration of the conjugate acid of the thiazolidine at any pH. Since the rate of hydrolysis of thiazolidines is directly related to the pKa of the amine group (11), a 4′-unsubstituted thiazolidine (*e.g.*, XIII) was expected to be more easily hydrolyzed than the 4′-alkoxycarbonyl thiazolidines (*e.g.*, IX*a*). However, it was also expected that if the 4′-position was left unsubstituted, and an alkyl group was introduced into the 3′-position of the thiazolidine, it would be as soluble as the 4′-unsubstituted thiazolidine, and would also be more stable (11).

The 4′-unsubstituted thiazolidine XIII was prepared from the reaction of progesterone with six equivalents of aminoethanethiol hydrochloride in pyridine. Only the monothiazolidine was obtained even when 12 equivalents of the aminoethanethiol was used. Inspection of the positions of the 18-CH_3 and 19-CH_3 absorptions in the NMR spectra of the crude reaction mixtures showed that XIII was the only product present, even before work-up. The 18-CH_3 absorption shifted from 40 to 38 to 51 Hz in going from progesterone to the 3-mono IX*a* to the 3,20-dithiazolidine VIII*a* while the 19-CH_3 absorption shifted from 71 to 62 Hz in going from progesterone to the mono-3-IX*a* and the di-3,20-thiazolidine VIII*a*. Thus, the position of the 18- and 19-CH_3 absorptions at 38 and 62 Hz and the 20-CH_3 at 127 Hz in the NMR spectrum of XIII indicated only mono-3-thiazolidine formation.

Use of the aminoethanethiol rather than the hydrochloride in the reaction did not result in the preferential formation of the 4,5-double bond isomer. In fact, it was difficult to determine that XIII was the 5,6-double bond isomer. Because of the large number of scans necessary to obtain the ^{13}C-NMR spectra, deuterochloroform samples of XIII decomposed significantly before a satisfactory spectrum could be obtained. The structure of XIII was established from its ^{1}H-NMR spectrum, which showed the broad multiplet expected for 5,6-double bond isomers[4], and from the ^{13}C-NMR spectrum of its *N*-acyl derivative (XV: 141.0, C-5; 121.7, C-6)[3]. Although it is conceivable that XIII was actually the 4,5-double bond isomer which then underwent isomerization upon acylation, none of the 4′-substituted or unsubstituted 4,5-double bond thiazolidine isomers gave any *N*-acylthiazolidine (only hydrolysis products)[3] suggesting that XIII was not the 4,5-double bond isomer. It was also possible that XIII was a mixture of the two isomers and that the 4,5-double bond isomer hydrolyzed and the 5,6-double bond isomer was acylated. This would explain the rather low yields of the *N*-acylthiazolidine from these reactions. However, the ^{1}H-NMR spectrum of XIII is consistent with the presence of only the 5,6-double bond isomer.

The testosterone and testosterone 17β-propionate 4′-unsubstituted thiazolidines were prepared in the same manner as the progesterone analogs. The structures of the testosterone and testosterone propionate derivatives were determined from their ^{1}H-NMR spectra and the ^{13}C-NMR spectra of their *N*-acyl derivatives[3].

Attempts to prepare the *N*-methyl thiazolidines of progesterone and testosterone using the conditions previously used to prepare the other thiazolidines[1,4] were unsuccessful. In addition, although azeotropic distillation using *p*-toluenesulfonic acid in benzene as a catalyst was partially successful, an acid catalyst failed to drive the reaction between the steroid and *N*-methylaminoethanethiol (12) to completion. Furthermore, it was impossible to separate the unreacted starting material from the thiazolidine by crystallization or chromatography since excessive decomposition of the thiazolidine occurred in both cases. Finally, it was discovered that the reaction could be driven to completion by heating a mixture of the steroid with *N*-methylaminoethanethiol (two equivalents) at about 130° for 30 or 40 min. The products could then be conveniently isolated by crystallization. As in the other 4′-unsubstituted case, the only isomer obtained was the 5,6-double bond isomer VII, determined by comparison of its ^{13}C-NMR spectrum (carbon absorptions at δ 140.6 and 122.5) with that of other 5,6-double bond isomers[4]. The ^{1}H-NMR spectrum of the crude reaction product was identical to that of the pure product.

The preparation of the *N*-acyl thiazolidines XIV, XV and XVI *via* direct acylation has been described separately[3]. Thiazolidines III, IV, X, XI, and XII were prepared by substituting the appropriate cysteine ester for cysteine ethyl hydrochloride in the usual reaction conditions.

Although the hydrolysis of thiazolidines in buffers has been carefully studied already (11), their hydrolysis in plasma has not been reported. Table II shows the hydrolysis rates of some selected thiazolidines. The rates were obtained by following the appearance of progesterone so the values are qualitative, especially when considering the dithiazolidines VIII*a*, VIII*b*, and XI, where two separate rates corresponding to the hydrolyses of the 3- and 20- thiazolidines are involved. However, the data does show that the 4,5-double bond isomers release progesterone 2.5 to 3.5 times faster than the 5,6-double bond isomers and the 4′-unsubsti-

tuted thiazolidine about 5 times faster than the 4′-ethoxycarbonyl thiazolidine.

The low solubility of the thiazolidines in water was very difficult to determine accurately. An approximate value was obtained by dissolving the thiazolidines in acetonitrile and adding the acetonitrile solution to a pH 7.4 buffer solution until turbidity was produced. The suspension was then filtered through a millipore 0.2-μm filter and the filtrates were decomposed with acid and analyzed by UV for progesterone. No measurable water solubility was observed for the 3,20-dithiazolidines using this technique. The mono-3-thiazolidine XIII was about as soluble as progesterone (5 mg/liter) and the mono-3-thiazolidine IX*b* was about one-third as soluble.

Biology—Preliminary pharmacokinetic studies on the thiazolidines were concerned with determining their bioavailability and their distribution. 4-^{14}C-Labeled VIII*a* and XI were synthesized for this purpose from [4-^{14}C]progesterone. Initially, XI was given intravenously as a benzyl alcohol solution (0.1 ml) to two female beagle dogs in a crossover study. The results are shown in Tables III and IV. Table III shows that the level of [4-^{14}C]steroid found in the dog's blood after administration of progesterone itself was usually at least one order of magnitude higher than that after administration of [4-^{14}C]-XI in the first few minutes after injection. Samples that were taken over several days after injection showed little consistent variation in the level of radiolabeled steroid from either progesterone or XI. Moreover, Table IV shows that the higher blood levels of [4-^{14}C]steroid obtained from progesterone compared to XI resulted in higher levels (about one order of magnitude) of excreted [4-^{14}C]steroid.

Obviously, the pattern of distribution of XI and its parent compound were very much different. Consequently, whole animal distribution studies were run to determine where the labeled steroid was going. Table V shows the distribution results in rats ($n = 6$) from intravenous tail injections of labeled progesterone VIII*a* and XI as benzyl alcohol solutions; benzyl alcohol was used as a vehicle to be consistent with the dog study. Only the data for the four major distribution sites are given in Table V, but the total recovery of labeled material was 66% for progesterone, 75% for VIII*a*, and 100% for XI.

Table VI—Androgenic Test [a]

Compound	Total Dose, mg	Seminal Vesicle Weight, mg	Ventral Prostate Weight, mg
Testosterone	16.0	14.0 ± 2.0	38.5 ± 2.5
	32.0	13.4 ± 1.2[b]	45.7 ± 2.0
	64.0	28.9 ± 3.2	67.1 ± 2.5
VII	4.0	8.2 ± 0.4	39.9 ± 1.9
	8.0	9.9 ± 0.6	45.7 ± 2.5
	16.0	15.8 ± 0.8	50.9 ± 3.4
Vehicle		6.4 ± 0.3	8.3 ± 0.5

[a] The compounds were given orally as a suspension in sesame oil daily for 10 days starting on day of castration using 10 rats/dose. [b] Unusually low value compared to data at same concentration in all other control experiments (17.0 ± 1.7 mg).

The finding of extremely high concentrations in the lung when the thiazolidines were injected is rather surprising. It did not seem to be an artifact and, if real, might have specific importance in site-specific drug delivery. The reason for the high concentration can be related to the fact that it was found that in a number of species (rabbit, rat, hamster); the mixed function oxygenase activity is at least one order of magnitude higher in the lung than in the liver (13). On the other hand, the importance of cysteine residue (14) in some slow reacting substance of anaphylaxis implies its more complex involvement in drug binding (through its —SH function) than originally believed.

None of the progesterone derivatives which were given orally or subcutaneously had even one-tenth the activity of a subcutaneous dose of progesterone in the Clauberg test. Although some of the testosterone thiazolidines had marginal activity in androgenic tests, their dose response curves were not parallel with those of the standard (*e.g.*, the parent steroid), so no estimation of their potency was possible. However, one derivative, VII, the *N*-methylthiazolidine of testosterone, was definitely more active than its parent steroid. The data for VII are presented in Table VI. It is representative of the data for the other thiazolidines in that it shows that the two dose response curves are not parallel.

Compound VIII*a* also was applied topically to hairless mice to see what effect the thiazolidine had on the residence time of the steroid in a biological membrane, as progesterone was found to show activity in controlling acne (15). Thus, a stronger binding pro-progesterone would have longer effect and reduced systemic activity. The results of the comparative percutaneous absorption and distribution of labeled steroid from doses of VIII*a* and progesterone are shown in Table VII. Those results show a remarkable tendency of the thiazolidine VIII*a* to increase the relative amount of labeled steroid in the skin. Whether this tendency is due to the greater lipophilicity of the thiazolidines or to the possible formation of disulfide bonds from the interaction of the ring-opened

[a] 75 μl of a solution of 0.9 mg in 675 μl in ethanol–isopropylmyristate (90:10). [b] 75 μl of a solution of 1.85 mg in 675 μl ethanol–isopropylmyristate (90:10). [c] $n = 6$. [d] 2-cm diameter plug of epidermis taken directly under the bandage patch (3 cm^2). [e] Includes the contents of an ethanolic wash of the skin circle after the bandage patch was removed.

thiazolidine with thiol groups in the skin cannot be determined at this time.

Thus, a series of thiazolidine derivatives of progesterone and testosterone were prepared and characterized. Except for VII the thiazolidines were found to be inactive or less active than their parent steroids in animal models. This lack of activity can be explained by the rapid distribution of the thiazolidines out of blood followed by a slow release of the parent, such that the biological concentration of steroid is always too low to be biologically effective.

High-Performance Liquid Chromatographic Assay for Bumetanide in Plasma and Urine

DAVID E. SMITH

Received May 26, 1981, from the *University of Michigan, College of Pharmacy, Ann Arbor, MI 48109.* Accepted for publication August 20, 1981.

Abstract □ A new high-performance liquid chromatographic (HPLC) method was developed for the analysis of bumetanide in plasma and urine. A reversed-phase column was fitted to the instrument and fluorescent (excitation λ = 338 nm, emission λ = 433 nm) and UV (254 nm) detectors were utilized to monitor simultaneously bumetanide and the internal standard, acetophenone, respectively. The assay is rapid, sensitive, and specific. Plasma bumetanide concentrations can be detected as low as 5 ng/ml using a 0.20-ml sample. Time-consuming extraction and/or derivatization steps are not required. The only clean-up procedure involved is the precipitation of plasma proteins with acetonitrile.

Keyphrases □ Bumetanide—high-performance liquid chromatographic determination in plasma and urine □ High-performance liquid chromatography—determination of bumetanide in plasma and urine □ Diuretics—bumetanide, determination in plasma and urine by high-performance liquid chromatography

Bumetanide (3-*n*-butylamino-4-phenoxy-5-sulfamoylbenzoic acid) is a new, high-ceiling diuretic with a pharmacological action similar to furosemide (1–4). However, on a molecular weight basis, bumetanide is 40–60 times more potent (1–4). Studies describing the pharmacokinetics and disposition of bumetanide have been sparse due to the lack of a sensitive and specific assay method. Fluorimetric (1), GLC (5), radioactive (6, 7), radioimmune (8), and high-performance liquid chromatographic (HPLC) (9) assays currently are available for the determination of bumetanide in biological fluids. However, all of these methods have inherent disadvantages, including time-consuming extraction, derivatization, or incubation steps (1, 5–9), large sample requirements (1, 5–7, 9), poor sensitivity (1, 5), or lack of specificity (1, 8).

Therefore, a rapid, sensitive, and specific HPLC assay was developed, without requiring prior extraction and/or derivatization, for the measurement of bumetanide in plasma and urine. The analytical method is suitable for bioavailability and pharmacokinetic studies in dogs and human subjects.

EXPERIMENTAL

Chemicals—Bumetanide[1], acetophenone[2], acetic acid[3], and phosphoric acid[4] were used as received. The methanol[3], acetonitrile[5] (glass-distilled), and deionized water[6] were filtered and degassed prior to use.

Standard Solutions—Bumetanide (4.12 mg) was dissolved in 50% acetonitrile–distilled water to yield a stock solution of 41.2 μg/ml. This stock solution was diluted 20- (2.06 μg/ml) and 100-fold (0.412 μg/ml) to give the working standard solutions for urine and plasma, respectively. Acetophenone was diluted in 50% acetonitrile–distilled water to yield a 0.50 mg/ml stock solution for urine and a 0.25 mg/ml stock solution for plasma.

Instrumentation—Samples were analyzed using a high-performance liquid chromatograph[7] equipped with a U6-K universal injector[8], a flu-

[a] Standard curves were constructed on five different days over a 12-day period. [b] 11-day period.

orescence spectrophotometer[9], and a variable wavelength UV absorbance detector[10]. A reversed-phase column[11] (25 cm × 4.6-mm i.d.) was fitted to the instrument and a dual-pen recorder[12] was used at a chart speed of 20 cm/hr. Fluorescent (excitation λ = 338 nm, emission λ = 433 nm) and UV (254 nm) detection were used to monitor simultaneously bumetanide and the internal standard, respectively.

Plasma Assay of Bumetanide—Bumetanide stock solution (0.412 μg/ml) was added in volumes of 0, 2.5, 5, 15, 30, 50, 75, and 100 μl to 0.20 ml of blank plasma to provide calibration standards of 0 (no bumetanide added), 5.2, 10.3, 30.9, 61.8, 103, 154, and 206 ng/ml. A 50-μl aliquot of the internal standard (0.25 mg/ml) was added to the mixture which was then shaken on a vortex mixer[13]. Precipitation of plasma proteins was accomplished by addition of 0.40 ml of acetonitrile. The mixture was shaken again on a vortex mixer and then sonicated[14] for ~2 min. After 10 min of centrifugation[15] (0.75 speed), the supernate was transferred to a clean test tube. An appropriate aliquot was then injected directly into the loop injector. Plasma samples were prepared in an identical manner except for the addition of bumetanide stock solution.

The mobile phase consisted of methanol–water–acetic acid (70:30:1), pumped isocratically at a flow rate of 1.5 ml/min, at ambient temperature.

Urine Assay of Bumetanide—Bumetanide stock solution (2.06 μg/ml) was added in volumes of 0, 2, 5, 15, 30, 50, 75, and 100 μl to 0.10 ml of blank urine and 0.10 ml distilled water to provide calibration standards of 0 (no bumetanide added), 0.0412, 0.103, 0.309, 0.618, 1.03, 1.54, and 2.06 μg/ml. A 50-μl aliquot of the internal standard (0.50 mg/ml)

was added to the mixture which was then shaken on a vortex mixer. An appropriate volume was injected directly into the loop injector. Urine samples were prepared in an identical manner except for the addition of bumetanide stock solution.

The mobile phase consisted of 50% acetonitrile in 0.015 *M* phosphoric acid aqueous solution, pumped isocratically at a flow rate of 2.0 ml/min, at ambient temperature.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram for the analysis of bumetanide in plasma. Using the appropriate mobile phase, as described previously, the retention times for bumetanide and acetophenone were 5.5 and 4.0 min, respectively. A representative standard curve of the bumetanide–acetophenone peak height ratio over the bumetanide plasma concentration range 5.2–206 ng/ml resulted in the following linear least-squares regression equation: $Y = 0.0235X + 0.0075$; $r^2 = 0.9998$. With fluorescence detection, concentrations as low as 5 ng/ml were measured for bumetanide (peak to noise ratio ≥5) using 0.20-ml plasma samples.

Figure 2 shows a typical chromatogram for the analysis of bumetanide in urine. A different mobile phase than that used for the plasma assay was necessary for the analysis of bumetanide in urine, due to the presence

of endogenous interference peaks. With the appropriate solvent system, as described previously, bumetanide and acetophenone had retention times in urine of 6.5 and 4.5 min, respectively. A representative standard curve of bumetanide–acetophenone peak height ratio over the bumetanide urine concentration range 0.0412–2.06 μg/ml resulted in the following linear least-squares regression equation: $Y = 1.674X + 0.014$; $r^2 = 0.9997$.

Both the plasma and urine assays were specific with respect to possible metabolite interference. Several metabolites of bumetanide (2′-alcohol, 3′-alcohol, 4′-alcohol, and 3′-acid), which have been reported recently in healthy volunteers (6), were obtained[1] and found to elute in the void volume prior to the elution of the compounds of interest (bumetanide and acetophenone). The desbutyl derivative was not available but should also elute in the void volume.

Standard curves of bumetanide in plasma (5.2–206 ng/ml) were constructed on 5 different days to determine the variability of the slopes and intercepts (Table I). The results show little day-to-day variability of slope and intercept as well as good linearity ($r^2 > 0.999$) over the plasma concentration range studied. The coefficient of variation for the slope was 3.8%. Standard curves of bumetanide in urine (0.0412–2.06 μg/ml) were also constructed (Table I). The coefficient of variation for the slope was 5.0% and all five curves showed good linearity ($r^2 > 0.999$) over the urine concentration range studied.

Table II shows the intra- and interday precision and accuracy for the plasma assay of bumetanide, assessed at three concentrations. The precision of the assay, as determined by the coefficient of variation, was ≤4.2% intraday as well as interday. In addition, the assay was quite accurate even at plasma concentrations as low as 5.2 ng/ml (bias = 7.7%). Other plasma concentrations had a bias ≤1.8%. A similar comparison was made for the urine assay of bumetanide as shown in Table III. The method was found to be precise (CV ≤5.2%) and accurate (bias ≤3.9%) intraday as well as interday.

The recovery of bumetanide from plasma proteins was assessed by comparing the bumetanide–acetophenone peak height ratio in plasma samples *versus* samples prepared in water. Five comparisons at three different concentrations were made. As shown in Table IV, the recovery of bumetanide from plasma was essentially complete at all concentrations.

Stability studies of plasma spiked with bumetanide (12.0, 50.0, and

Table V—Stability of Bumetanide in Plasma

Added Concentration, ng/ml	Measured Concentration/Added Concentration, % Days					
	0	1	3	8	21	31
12.0	96.7	100.0	—	104.0	108.0	97.5
50.0	104.0	98.4	97.6	99.6	96.2	95.0
140.0	102.0	99.3	97.1	99.3	100.0	101.0

140 ng/ml) were performed over a 31-day period (Table V). Plasma samples were stored in the freezer at −20° until the time of analysis. The results demonstrate that bumetanide can be stored frozen in plasma for at least 1 month without degradation.

Figure 3 shows a urinary excretion rate *versus* midpoint time plot of unchanged bumetanide after oral administration of 1.0 mg of bumetanide to a healthy volunteer. The biological half-life, as determined by linear regression using the last four data points from the log-linear terminal portion of the curve, was 84.5 min. The fraction of the oral dose excreted unchanged in the urine was 0.445. Both of these parameters are in agreement with values from other studies (5, 6–8, 10).

Application of the Ammonia Gas-Sensing Electrode: Determination of Drugs Having a Carboxyamide Group by Decomposition with Acid

SHOICHIRO TAGAMI ˣ and MASAKO FUJITA

Received June 8, 1981, from the *Toyama Medical and Pharmaceutical University, Sugitani, Toyama, Japan.* Accepted for publication August 19, 1981.

Abstract □ A simple potentiometric method for the determination of drugs having a carboxyamide group is described. Ethenzamide, niacinamide, pyrazinamide, or salicylamide was refluxed with 20% HCl and the carboxyamide was hydrolyzed. The ammonia evolved at a pH >11 and was determined without separation from the decomposition solution using an ammonia gas-sensing electrode. A linear calibration plot was obtained with drugs in the range of 2×10^{-5}–1×10^{-2} *M*. This method was applied to the analysis of injection and powder-containing auxiliary compounds.

Keyphrases □ Ammonia gas-sensing electrode—analysis of drugs with a carboxyamide group by decomposition with acid □ Potentiometry—determination of ammonia using an ammonia gas-sensing electrode □ Carboxyamide groups—determination of carboxyamide moiety using ammonia gas-sensing electrode analysis

Methods for the determination of drugs having a carboxyamide group are based on the determination of ammonia liberated by refluxing the carboxyamide compounds in alkaline solution. The ammonia is distilled and determined by titration. The methods described in the United States (1), British (2), and Japanese (3) Pharmacopoeias are based on these principles. Spectrophotometric methods of analysis for the determination of carboxyamide having a pyridine ring are based on the König reaction (4) of pyridine derivatives with cyanogen bromide. These methods are sensitive and relatively free from interference; however, they have the disadvantage of using the extremely toxic cyanogen bromide. Polarographic and microbiological methods (5) have also been employed, but they are tedious and time consuming. The gas-permeable membrane electrode is advantageous because of its simplicity, accuracy of assay, and lower cost compared with the conventional methods. However, its applications to drug analysis have not been widely reported in the literature, although the analysis of *N*-unsubstituted carbamates and meprobamate has been studied (6).

This paper describes a potentiometric method for the determination of drugs having a carboxyamide group. Assay methods for ethenzamide (o-ethoxybenzamide), salicylamide, niacin (nicotinamide), and pyrazinamide were developed. The samples were refluxed with 20% HCl and the carboxyamide was hydrolyzed, liberating an equivalent amount of ammonium ion. After alkalinization, the ammonia was determined with an ammonia gas-sensing electrode.

EXPERIMENTAL

Apparatus—The ammonia gas-sensing electrode[1] consisted of an ammonia gas-permeable membrane, a pH glass-electrode, and a silver–silver chloride reference electrode. The potential measurement system consisted of a pH/mV meter[2] and recorder[3].

All measurements were carried out at 20° in an 80-ml cell equipped with a magnetic stirrer.

Reagents—Ethenzamide[4], salicylamide[4], and pyrazinamide[4] were purified twice by recrystallization from water and then dried *in vacuo* at room temperature for 5 hr. Niacinamide[5] was dried *in vacuo* at room temperature for 4 hr. Other chemicals used were reagent grade.

A stock solution of 0.1 *M* NH_4Cl was prepared for testing the ammonia response of the electrode, and 5 *M* NaOH was employed to adjust the pH of the solution to within the operating range of the electrode.

140 ng/ml) were performed over a 31-day period (Table V). Plasma samples were stored in the freezer at −20° until the time of analysis. The results demonstrate that bumetanide can be stored frozen in plasma for at least 1 month without degradation.

Figure 3 shows a urinary excretion rate *versus* midpoint time plot of unchanged bumetanide after oral administration of 1.0 mg of bumetanide to a healthy volunteer. The biological half-life, as determined by linear regression using the last four data points from the log-linear terminal portion of the curve, was 84.5 min. The fraction of the oral dose excreted unchanged in the urine was 0.445. Both of these parameters are in agreement with values from other studies (5, 6–8, 10).

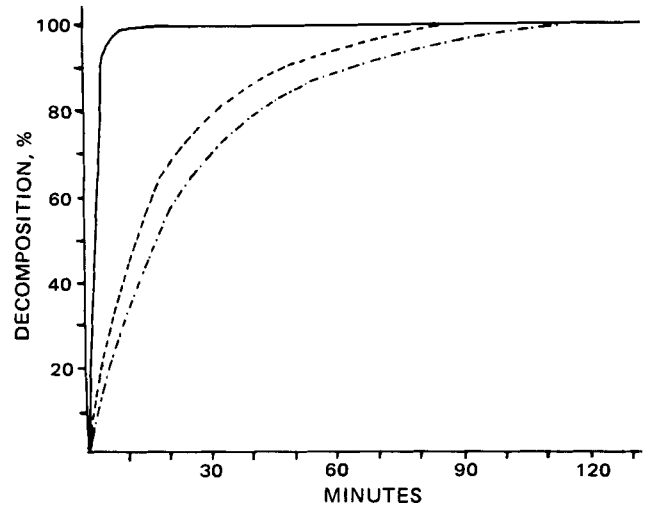

Figure 1—*Effect of 20% HCl concentration on drug decomposition. Key: —, pyrazinamide, niacinamide; - - -, ethenzamide; and — · —, Salicylamide.*

The internal filling solution supplied with the ammonia electrode was used.

An electrode storage solution of 0.01 *M* NH_4Cl for storage overnight or a weekend was prepared and the electrode tip was immersed in this solution. In 10^{-5}–10^{-4} *M* ammonia measurements, the use of the electrode immersed in 0.01 *M* NH_4Cl led to erroneous results because the gas-permeable membrane absorbed ammonium chloride and did not regenerate when washed with water. The electrode tip was therefore immersed in a buffer solution[6], pH 4, between measurements.

Standard Drug Solutions—A mixture of 307.78 mg (2.50×10^{-3} moles) of pyrazinamide and 50 ml of 20% HCl was placed in a 100- ml round-bottom flask and boiled gently in an oil bath for 20 min. The flask was then cooled, the solution poured into a 250-ml beaker, and diluted with ~150 ml of water. A drop of methyl orange was added and, while cooling the beaker continuously, the acid was carefully neutralized with 10 *N* NaOH solution until the indicator began to change color. Using a pH meter, the solution was adjusted to pH 6.5 with diluted sodium hydroxide solution, and the solution was poured into a 250-ml volumetric flask and diluted to full volume with water. The concentration of the final pyrazinamide solution was 1×10^{-2} *M*, corresponding to 1×10^{-2} *M* ammonia. Standard solutions for calibration were obtained by diluting this stock solution with water.

Other standard solutions of ethenzamide, salicylamide, and niacinamide were prepared in a similar manner as described previously according to the corresponding drug decomposition time shown in Fig. 1.

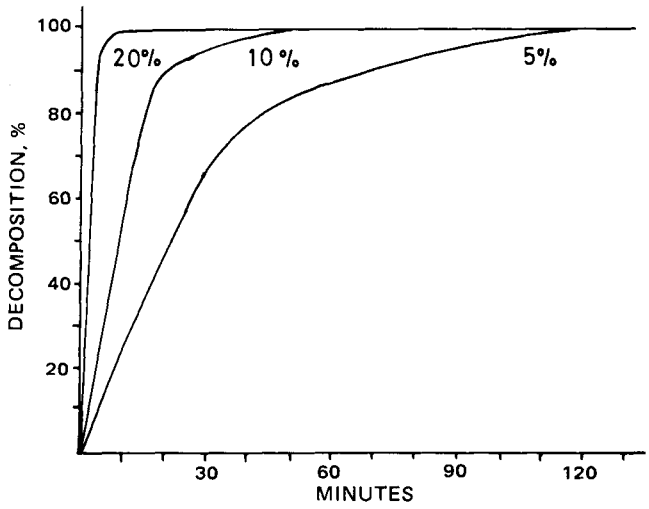

Figure 2—*Effect of various HCl concentrations on niacinamide decomposition.*

			± *SD*	0.62

Assay Procedure—A mixture of 123 mg (~1×10^{-3} mole) of pyrazinamide and 20 ml of 20% HCl was boiled for 20 min. The resultant solution was adjusted to pH 6.5, diluted to 100 ml in a volumetric flask, and then 20 ml of this solution was diluted to 100 ml with water. A 50-ml portion of the sample was transferred to an ~80-ml cell (3.5 × 9-cm), 1 ml of 5 *M* NaOH was added, and the mixture was incubated for 30 min at 20°. Finally, the ammonia electrode was immersed in the solution, and the potential measurements were carried out. The ammonia concentration in the sample solution was determined from the calibration curve.

Assay procedures of ethenzamide, salicylamide, and niacinamide were carried out in a similar manner. The ammonia concentration was determined from the calibration curve prepared from the corresponding standard drug solutions.

Because of the temperature dependence of the ammonia electrode, the sample solution was maintained at 20 ± 0.1° and stirred during the measurement. Since the potential may vary as a result of changes in the internal filling solution, the solution was replaced with fresh solution before subsequent use.

Assay of Niacinamide Injection—A mixture of 3 ml (equivalent to 150 mg of niacinamide) of the injection and 25 ml of 20% HCl was boiled for 30 min. The resultant solution was poured into a 250-ml volumetric flask and diluted to full volume with water. The ammonia concentration in the 50-ml portion of the sample was determined using an ammonia gas-sensing electrode.

Assay of 10% Niacinamide Powder—A portion of the powder (equivalent to ~153 mg of niacinamide) was accurately weighed out, and 25 ml of acetone was added. The solution was swirled for 5 min to extract the niacinamide and allowed to stand for ~3 min. The supernatant acetone solution was removed and 25 ml of acetone was added to the residue. The extraction procedure was carried out four times and the solution was finally filtered through a dry filter into a dry flask. The collected acetone fractions were evaporated to dryness. The residue was then refluxed for 30 min with 25 ml of 20% HCl. The same procedure as described previously was followed.

RESULTS AND DISCUSSION

The dissolved ammonia in the sample solution diffused through the hydrophobic gas-permeable membrane and dissolved in the internal filling solution. The resulting pH change was then measured.

A mixture of ethenzamide, salicylamide, niacinamide, or pyrazinamide,

and 20% HCl was boiled gently and the resultant ammonia in the decomposition solution was determined at various boiling times. In the case of ethenzamide and salicylamide, the electrode potentials reached a maximum at boiling times of 90 and 120 min, respectively. However, the electrode potentials of pyrazinamide and niacinamide reached a maximum at the same boiling times of 10 min. In the case of decomposition with 10 and 5% HCl, the electrode potentials of niacinamide reached a maximum at boiling times of 60 and 90 min, respectively (Figs. 1 and 2).

In the potential measurements, the level of ions in the decomposition solution (osmotic strength) is not equal to that of the internal filling solution. Water vapor as well as ammonia can move across the gas-permeable membrane, modifying the concentration of the internal filling solution. Since such changes lead to errors in potential measurements, standards and samples should have approximately the same level of ions in solution (7). Therefore, the standard solution of drug used the corresponding pure drug instead of ammonium chloride.

When the potential *versus* the logarithm of drug concentration was plotted, a linear calibration plot was obtained in the drug concentration range of 2×10^{-5}–1×10^{-2} *M*.

The amount of drug was determined in the pure drug powder. According to the Pharmaceopoeia, ethenzamide (8), salicylamide (9), and niacinamide (10, 11) determined on a dry weight basis should be over 98, 98, and 98.5% pure, respectively. Pyrazinamide (1) contains not less than 99% and not more than 101.0%. The recoveries of the drugs are given in Table I. The amounts of ethenzamide, salicylamide, niacinamide, and pyrazinamide can be determined with average errors of 0.15, 0.27, 0.08, and 0.22%, respectively.

The determination of commercially available niacinamide injection was carried out on six 3-ml samples (equivalent to ~150 mg niacinamide) of niacinamide injection, which is a sterile solution of niacinamide in water. A mixture of 3 ml of niacinamide injection and 25 ml of 20% HCl was boiled for 20 min and the potential measurements were carried out as described previously. According to the United States (10) and Japanese (11) Pharmacopoeias, niacinamide injection contains not less than 95% and not more than 110% of the labeled amount of $C_6H_6N_2O$. The recoveries of niacinamide injection are given in Table II. The mean recovery was 107.5 ± 0.31%. The accuracy of the proposed method was checked by the König method. The recoveries of niacinamide injection from four samples were 107.3, 106.4, 106.4, and 108.7%, respectively; the mean value was 107.2 ± 1.09%.

In determining other commercially available 10% niacinamide powders, a suitable extraction was sought. (Extraction of niacinamide is necessary to avoid interference from auxiliary compounds.) Niacinamide is very soluble in water (1 g in 1 ml) as are the auxiliary compounds; however, methanol does not dissolve the auxiliary compounds and separation of the extract from the powder is difficult. Niacinamide powder (10%) was extracted with acetone, since acetone does not inhibit the assay of pure niacinamide powder. After dissolution in acetone, the supernate was removed. The extraction was carried out four times and the extract filtered from the powder. The auxiliary compound was very hygroscopic, and it is thought that the niacinamide in the auxiliary compound was not homogeneous. Therefore, the recovery of the assay varied from 98 to >100%. The 10% niacinamide powder was mixed thoroughly in a mortar with a pestle and was dried *in vacuo* at room temperature for 24 hr (Table III). The mean recovery was 116.0 ± 0.24%. According to the Japanese Pharmacopoeia, niacinamide tablets contain not less than 95.0 and not more than 115.0% of the labeled amount of $C_6H_6N_2O$, but the description as a percentage of niacinamide powder is not noted. The accuracy of the proposed method was checked using the König method. The assay was performed on three samples of the 10% powder. The recoveries were 115.7, 118.5, and 115.3%, respectively, with a mean value of 116.5%.

CONCLUSIONS

In the Pharmacopoeial assay methods for ethenzamide, pyrazinamide, and salicylamide, the ammonia gas liberated by decomposition with sodium hydroxide is determined by acid titration (1, 8, 9). Using this method, the separation of the ammonia gas is difficult and tedious. The following procedures have been described previously for the analysis of niacinamide: (*a*) the sodium hydroxide decomposition method, (*b*) the nonaqueous titration method (12), (*c*) the colorimetric method for pure powder (10, 11), and the König method for injections. The sodium hydroxide decompositon method is identical to the method discussed. In the nonaqueous titration method, the normality factor is unstable. The colorimetric method is nonspecific, and the König method is adopted for the determination of injections in Japanese Pharmacopoeia IX (11) and USP XIX (13). The latter method is influenced by the experimental conditions (14, 15) and has the disadvantage of using extremely toxic cyanogen bromide. The present method using an ammonia gas-sensing electrode, beside being simple, has high specificity and precision.

Liquid Membrane Phenomena in Haloperidol Action

S. B. BHISE, P. R. MARWADI, S. S. MATHUR, and R. C. SRIVASTAVA ˣ

Received May 27, 1981, from the *Birla Institute of Technology and Science, Pilani-333031, India.* Accepted for publication August 20, 1981.

Abstract □ Haloperidol, a surface-active neuroleptic drug, was shown to generate a liquid membrane on a supporting membrane. Transport of adrenalin, noradrenalin, dopamine, serotonin, histamine, glutamic acid, γ-aminobutyric acid, and sodium, potassium, and calcium ions through the haloperidol liquid membrane was studied. The data indicate that the phenomenon of a liquid membrane plays a significant role in the mechanism of action of haloperidol.

Keyphrases □ Liquid membrane phenomena—effect on haloperidol action □ Haloperidol—liquid membrane phenomena, effect on mechanism of action □ Surface-active drugs—haloperidol, effect of liquid membrane phenomena

A wide variety of biologically active agents have been shown to be surface active (1–4). This does not appear to be a coincidence. In a number of cases a definite correlation between surface activity and biological effects has been demonstrated (1, 3, 4). Most of the potent neuroleptics are known to behave like powerful surface-active agents (2) and the surface activities of neuroleptic drugs also correlate with their clinical potencies (1). Palm *et al.* (5) concluded that regardless of the chemical structure, mainly the surface activity of psychotropic drugs determines their potencies toward all kinds of membranes, especially that of catecholamine-storing particles. Surface-active agents have been shown (6–8) to generate liquid membranes which completely cover the interface at or above the critical micelle concentration of the surfactants when added to water or aqueous solutions. Therefore, it is likely that the liquid membrane phenomena may have an important role in the mechanism of action of such drugs, and deserves a systematic investigation. Haloperidol is a neuroleptic drug belonging to the class of butyrophenones and is known to be surface active in nature (2).

Haloperidol acts by modifying the permeabilities of catecholamines and a few neurotransmitter amino acids in biological cells (2). To date, this effect has been explained solely on the basis of specific drug interaction with the receptors. No serious attempt has been made to assess the contribution of the liquid membrane to the mechanism of its action. Experiments were designed to demonstrate the existence of a haloperidol liquid membrane at the interface. Data on the transport of endogenous amines, neurotransmitter amino acids, and sodium, potassium, and calcium ions through the haloperidol liquid membrane were obtained. A cellulose acetate membrane–water interface was chosen as a site for the formation of the liquid membrane. In this way, any active and specific interaction of the drug with the membrane that alters the permeabilities of relevant permeants was ruled out and only data on passive transport was obtained.

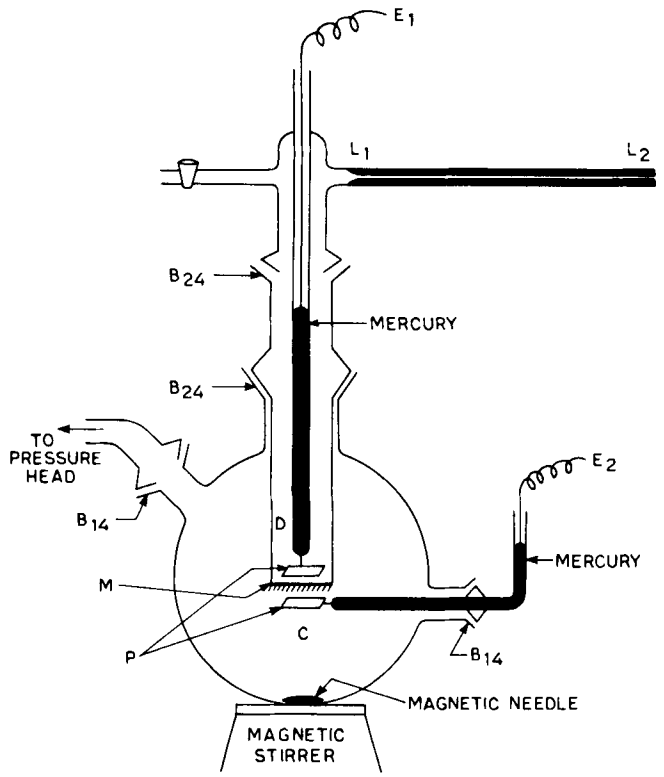

Figure 1—*The transport cell. Key: M, supporting membrane (cellulose acetate millipore filter); P, bright platinum electrodes; L_1L_2, 17-cm capillary tube with 1.33 × 10^{-1} cm diameter and E_1 and E_2, electrode terminals. Volume of Compartments C and D are 590 and 50 ml, respectively.*

EXPERIMENTAL

Materials—Haloperidol[1], dopamine chlorhydrate[2], adrenalin hydrogen tartrate[2], L-noradrenalin[3], serotonin creatinine sulfate[4], histamine acid phosphate[5], L-glutamic acid[5], γ-aminobutyric acid[5] (I), sodium chloride[6], potassium chloride[6], calcium chloride[6], and water glass-distilled over potassium permanganate were used.

Methods—The critical micelle concentration (CMC) of aqueous haloperidol was determined from the plots of surface tension *versus* concentration at 37 ± 0.1°. The surface tensions were measured using the method of capillary rise. The CMC value found for aqueous solutions of haloperidol, was 1.064 × 10^{-6} *M*. To prepare the aqueous solutions of haloperidol, the weight of drug necessary to attain the desired concentration was dissolved in ethanol and added with constant stirring to the aqueous phase. The stirring was continued for ~12 hr. In the aqueous solutions of haloperidol thus prepared, the final concentration of ethanol was never allowed to exceed 0.1% (v/v) because a control experiment showed that 0.1% (v/v) solution of ethanol in water did not lower the surface tension of water to any measurable extent.

The all-glass cell described earlier (8) was used for the transport studies (Fig. 1). The transport cell was separated into two compartments by a cellulose acetate millipore filter[7] which acted as a support for the liquid membrane.

For measurements of hydraulic permeability, aqueous haloperidol solutions of various concentrations ranging from 0 to 1.064 × 10^{-5} *M* were filled in Compartment C of the transport cell (Fig. 1), while Compartment D was filled with distilled water. The concentration range was selected

to get data on both the lower and higher sides of the CMC of haloperidol. Known pressures were applied on Compartment C by adjusting the pressure head and the resulting volume flux was measured by noting the rate of advancement of the liquid meniscus in capillary L_1L_2 with a cathetometer reading up to 0.001 cm and a stopwatch reading up to 0.1 sec. The magnitude of the applied pressures also was measured by noting the position of the pressure head, with a cathetometer reading up to 0.001 cm. During the volume flux measurements the solution in Compartment C was well stirred and electrodes E_1 and E_2 were short circuited so that the electro-osmotic back flow that developed due to streaming potentials did not interfere with the observations.

To measure permeability of endogenous amines, amino acids, and sodium, potassium, and calcium ions, two sets of experiments were performed. In the first set of experiments, Compartment C of the transport cell was filled with the respective permeants, prepared in 4.256×10^{-6} *M* aqueous solution of haloperidol and Compartment D was filled with distilled water. In the second set of experiments Compartment D was filled with 4.256×10^{-6} *M* solution of haloperidol and Compartment C was filled with aqueous solutions of the permeants. No haloperidol was used in the control experiments. The initial concentrations chosen for the endogenous amines, amino acids, and cations were comparable to their concentrations in the vicinity of nervous tissue. The condition of no net volume flux ($J_v = 0$) was attained by adjusting the pressure head attached to Compartment C of the transport cell so that the liquid meniscus in capillary L_1L_2 remained stationary. After a known period of time, the concentration of the permeant in the other compartment was measured. The amount of permeant gained by Compartment D divided by the time and the area of the membrane gave the value of solute flux (J_s). The value of solute permeability was estimated using the definition (9, 10):

$$\left(\frac{J_s}{\Delta\pi}\right)_{Ju=0} = \omega \qquad \text{(Eq. 1)}$$

where $\Delta\pi$ is the osmotic pressure difference. The value of $\Delta\pi$ used in the calculation of ω was the average of the $\Delta\pi$ values at the beginning ($t = 0$) and end of the experiment. During the permeability measurements, the solution in Compartment C was kept well stirred. All measurements were made at constant temperature by placing the transport cell (Fig. 1) in a thermostat set at 37 ± 0.1°.

Estimations—The amounts of the various permeants transported to Compartment D were estimated as follows:

Endogenous Amines—The amounts of the catecholamines, namely dopamine, noradrenalin, and adrenalin, were estimated fluorometrically at 325 nm (11). Though the fluorescence maximum of serotonin is reported to be 330 nm (12), it was measured at 325 nm since a quartz cell was used. Histamine was estimated by measuring the fluorophor derived from its reaction with *o*-phthalaldehyde[8] (11, 13) at 450 nm. A UV-visible–near IR spectrophotometer[9] with fluorescence attachment was used for fluorescence measurements.

Amino Acids—The amounts of glutamic acid and γ-aminobutyric acid were estimated by spectrophotometric[10] determination of their reaction products with ninhydrin[5] (14) at 570 nm.

Cations—The amounts of sodium, potassium, and calcium ions were determined using an atomic absorption spectrophotometer[11] using emission mode.

The estimations were carried out using the following lines: sodium, 589.6 nm; potassium, 766.5 nm; and calcium, 422.7 nm.

RESULTS AND DISCUSSION

Liquid Membrane Formation—From the hydraulic permeability data at various haloperidol concentrations (Fig. 2), it is obvious that the linear relationship is obeyed in all cases:

$$J_v = L\,\Delta P \qquad \text{(Eq. 2)}$$

where J_v represents the volume flux per unit area of the membrane, ΔP is the applied pressure difference, and L is the hydraulic conductivity coefficient. The values of L show (Table I) a progressive decrease as the haloperidol concentration is increased from 0 to its CMC value, *i.e.*, 1.064×10^{-6} *M*. When the haloperidol concentration is increased further, the value of L also decreases, but much less than the decrease observed up to the CMC value of haloperidol. This trend is in keeping with Kesting's

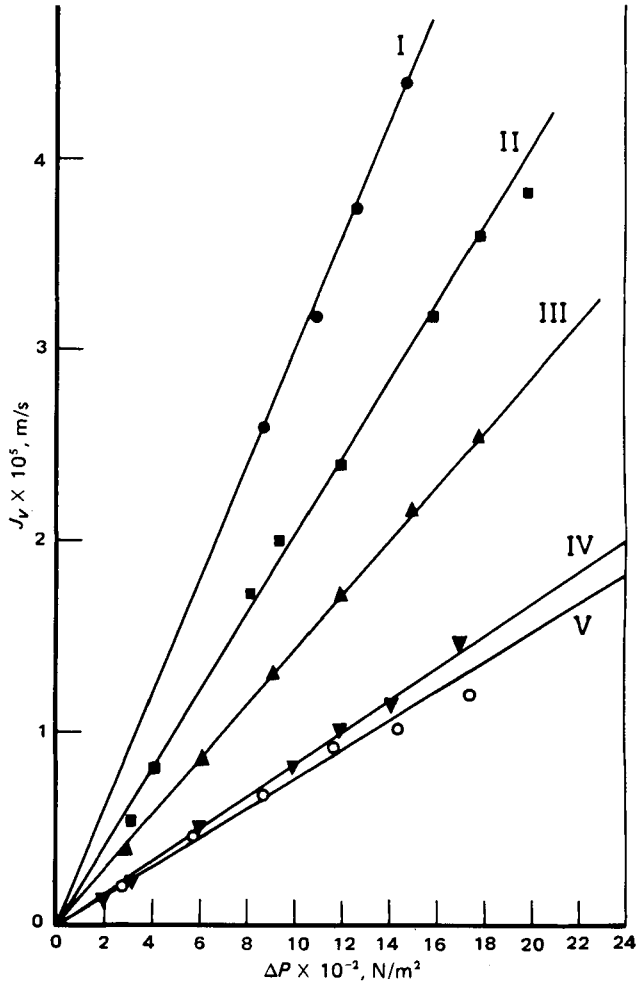

Figure 2—*Hydraulic permeability data. Curves I, II, III, IV, and V are for 0, 1.064×10^{-7}, 5.32×10^{-7}, 1.064×10^{-6}, and 1.064×10^{-5} M haloperidol concentrations, respectively.*

liquid membrane hypothesis (6–8), where the surfactant concentration is increased, the supporting membrane gets progressively covered with the surfactant layer liquid membrane. Then, at the CMC, the supporting membrane is completely covered with the liquid membrane. The decrease in the value of L beyond the CMC of haloperidol, could possibly be due to densing of the liquid membrane (6).

In light of the mosaic membrane model (15–17) analysis of the flow data (Fig. 2, Table I) supports the existence of the liquid membrane in series with the supporting membrane. At concentrations lower than the CMC, the supporting membrane is only partially covered with the liquid membrane. The equation for the volume flux of water for such a case can be written as:

$$J_v = \left[L^c\left(\frac{A^c}{A^c + A^s}\right) + L^s\left(\frac{A^s}{A^c + A^s}\right)\right]\Delta P \qquad \text{(Eq. 3)}$$

where A represents area of the membrane denoted by the superscripts, and superscripts c and s represent the bare supporting membrane and the supporting membrane covered with the liquid membrane, respectively. In the present case L^c represents the value of the hydraulic conductivity when no haloperidol was used, and L^s represents the value of the hydraulic conductivity when the haloperidol concentration equals its CMC. At half the CMC, the fraction of the total area covered with the liquid membrane will be halved and, therefore, the value of L should be equal to $(L^c + L^s/2)$. Similarly, for 0.1 CMC of haloperidol, the value of L should equal $(0.9\,L^c + 0.1\,L^s)$. The values of L were computed in this way, corresponding to the two haloperidol concentrations given in Table I. These values match the experimentally determined values well.

Solute Permeability in the Presence of Haloperidol—The value of ω for endogenous amines, amino acids, and cations are given in Table II. To make sure that the supporting membrane of the transport cell was completely covered with the haloperidol liquid membrane, the concentration of haloperidol chosen for the present study was 4.256×10^{-6} *M*, which is much higher than its critical micelle concentration. being surface active, has both hydrophobic and hydrophilic parts in its structure. The orientation of its molecules will, therefore, be significant when it forms a liquid membrane. The hydrophobic ends of the haloperidol molecules would be preferentially oriented toward the hydrophobic supporting membrane and their hydrophilic ends will face outwards, away from the supporting membrane. When haloperidol is in compartment C of the transport cell (first set of experiments) the haloperidol liquid membrane will present a polar surface to the permeant present in the same compartment. In the second set of experiments, however, where haloperidol is in Compartment D of the transport cell and the aqueous solution of the permeant is in Compartment C, the haloperidol liquid membrane would present a hydrophobic surface to the permeant. Therefore, the orientation of haloperidol molecules with respect to approaching permeant would be different in the two sets of experiments.

The values of ω given in Table II indicate that when the hydrophobic surface of the haloperidol liquid membrane faces the approaching permeant (second experiment), a marked decrease in their permeability is observed. The haloperidol liquid membrane, thus, offers resistance to the transport of these permeants in this specific orientation. This reduction in the passive transport of biogenic amines, amino acids, and cations is likely to be accompanied by a reduction in their active transport. This occurs because the access of these permeants to the active carrier site of the biological membrane is likely to be effectively reduced due to the resistance of the haloperidol liquid membrane. The results also indicate that this specific orientation of haloperidol molecules with hydrophobic ends facing the catecholamines and amino acids, would be necessary for the liquid membrane to resist the flow of these species. In the first set of experiments, where haloperidol orients its hydrophilic ends toward the catecholamines or amino acids, the permeability of these substances is increased in the presence of haloperidol. This indicates that the orientation of haloperidol with its hydrophobic ends facing the permeants would be necessary even in biological cells.

In cells, haloperidol reduces the permeability of catecholamines (2). Despite the fact that the present experiments were carried out using a cellulose acetate membrane, the results are similar to those observed in biological cells. This indicates that the liquid membrane generated by haloperidol contributes to the resistance of the flow of catecholamines.

The haloperidol liquid membrane also resists the flow of glutamic acid and γ-aminobutyric acid (Table II). The antiemetic and antipsychotic actions of haloperidol are explained on the basis of reduced permeability of dopamine to biological cells, which is under the influence of the γ-aminobutyric acid–glutamic acid system (2). To investigate whether a similar trend is observed on nonspecific membranes, the dopamine permeability was measured in the presence of γ-aminobutyric acid. Interestingly, the present set of experiments also indicates that the presence

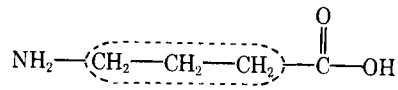
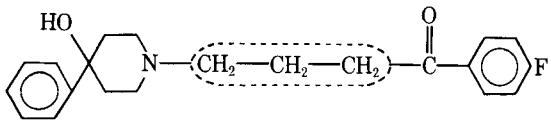
hydrophobic



γ-aminobutyric acid



haloperidol

of γ-aminobutyric acid increases resistance to the transport of dopamine through haloperidol liquid membrane (Table II). This can be explained by a strengthening of the hydrophobic core of haloperidol liquid membrane by γ-aminobutyric acid, which is obvious from the similarity of the hydrophobic components of their structures.

It is tempting to suggest that increased passive resistance to the flow of dopamine in the presence of γ-aminobutyric acid, coupled with the resistance to the flow of glutamic acid by the haloperidol liquid membrane, is likely to contribute to the mechanism of action of haloperidol.

It was reported (18) that haloperidol is considerably more potent on a milligram basis than chlorpromazine *in vivo*. The formation of liquid membrane phenomena might explain this. Because haloperidol exhibits greater surface activity than chlorpromazine (1, 2), the former will form liquid membranes at a lesser concentration, making it pharmacologically effective even at a comparatively lower concentration.

The present study shows that haloperidol reduces the permeability of serotonin (Table II). This agrees with the observations reported on biological cells (19). The extrapyramidal effects of antipsychotic drugs like haloperidol reportedly are resistant to levodopa therapy (20). Since reduced concentration of serotonin in cerebrospinal fluid has also been linked with a defect of extrapyramidal function (21, 22), the reduced permeability of serotonin in the presence of antipsychotic drugs like haloperidol offers a clue to the causation of extrapyramidal symptoms.

The observation of increased permeability of histamine in the presence of haloperidol, and its biological implication, if any, remains to be explained.

The resistance offered by haloperidol liquid membrane to the flow of sodium, potassium, and calcium cations is probably due to hydrophilicity of the ions. Unlike the observation in the case of endogeneous amines and amino acids, even when the hydrophilic ends of haloperidol are facing the approaching cations, the permeability of these ions is reduced (Table II). This may be because the ions are more hydrophilic and experience more resistance to their flow. This observation may have some biological implications relative to nerve conduction.

High-Pressure Liquid Chromatographic Determination of Promethazine Plasma Levels in the Dog After Oral, Intramuscular, and Intravenous Dosage

RAJNI B. PATEL AND PETER G. WELLING ˣ

Received July 6, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication August 27, 1981.

Abstract □ Plasma levels of promethazine were determined using a high-pressure liquid chromatographic procedure incorporating a fixed wavelength (254 nm) UV detector, following single 50-mg intravenous, intramuscular, and oral doses to two male dogs. Initial plasma promethazine concentrations following intravenous doses were 556 and 535 ng/ml in the two dogs. The subsequent decline in drug levels were satisfactorily described by a triexponential function. Peak promethazine levels of 76 and 64 ng/ml were obtained 0.5 hr following intramuscular doses. Peak levels for the oral doses were 10.6 and 11.0 ng/ml occurring 2 hr after dosing. The apparent biological half-life of promethazine, obtained from only 2–3 data points, varied from 8.5 to 27.7 hr. Areas under the promethazine plasma curves, compared to values obtained from intravenous doses between 0 and 24 hr, indicated that systemic availability of intact drug was 55–73% following intramuscular injection and 8.3–9.5% following oral administration.

Keyphrases □ High-pressure liquid chromatography—determination of promethazine plasma levels after oral, intramuscular, and intravenous dosage, dogs □ Promethazine—high-pressure liquid chromatographic determination of plasma levels after oral, intramuscular, and intravenous dosage, dogs □ Pharmacokinetics—high-pressure liquid chromatographic determination of promethazine plasma levels after oral, intramuscular, and intravenous dosage, dogs

Promethazine has been used extensively for the control of allergy and as a sedative and antiemetic; however, little information is available on its bioavailability from oral dosage forms or on its pharmacokinetics. This has been due to the absence of suitable methods for determining promethazine in body fluids.

Gas chromatographic procedures have been used to measure promethazine (1, 2) and other phenothiazines (3, 4), but these methods lack sensitivity and require extensive sample preparation before chromatography. Studies in this laboratory showed that unless promethazine is separated from its various metabolites prior to gas chromatography, spurious results may result from on-column reduction of oxidized metabolites to the parent compound (5).

High-pressure liquid chromatographic (HPLC) procedures for promethazine have been reported recently (6–8). Two of the procedures (6, 7) require either large samples or prior derivatization, while the other (8) requires the use of electrochemical detection. The lack of assays suitable for routine use is the major cause for the scarcity of information on the pharmacokinetics of promethazine in animals (2, 9) and humans (1, 10) in the literature.

The use of a specific and sensitive HPLC assay to measure plasma promethazine levels following single oral, intramuscular, and intravenous doses to male dogs is described. Preliminary details of the liquid chromatographic procedure and comparisons with a gas chromatographic assay have been described elsewhere (5).

EXPERIMENTAL

Assay for Promethazine in Plasma—To 2 ml of plasma were added 200 μl of a 0.56-μg/ml aqueous solution of chlorpromazine hydrochloride (equivalent to 0.5 μg/ml of chlorpromazine) as internal standard, 0.5 ml of 1.0 *N* sodium hydroxide, and 8 ml of methylene chloride. After shaking for 15 min at low speed on a horizontal shaker and centrifuging at 3000×*g* for 5 min, the upper aqueous phase was discarded by aspiration. The organic phase was transferred to a clean tube and evaporated to dryness under nitrogen at room temperature. The tube was rinsed with 1 ml of methylene chloride and was again evaporated to dryness. The residue was reconstituted in 60 μl of the chromatographic mobile phase by vortexing, centrifuged at 3000×*g* for 1 min, and 20 μl of the supernate was injected into the chromatograph.

The HPLC consisted of a solvent pump[1]; a fixed-volume (20 μl) injection valve[2]; a 10-μm particle size, reversed-phase octadecyl column[3]

(4.6 mm × 25 cm); a precolumn[4]; and a fixed wavelength (254 nm) detector[5]. Chromatograms were recorded on a chart recorder[6] with 10-mV input and 20-cm/hr chart speed. The mobile phase consisted of 42% acetonitrile and 3% *n*-nonylamine in 0.02 *M* phosphate buffer, pH 2.5. The flow rate was 2 ml/min at a pump pressure of 2.0×10^3 psi.

Dog Study—Two 3-year-old, mixed-breed, beagle-type dogs weighing 16 and 17 kg were fasted overnight before receiving 50-mg doses of promethazine orally[7], and by intramuscular[8] and intravenous[8] injection on three separate occasions at least 1 week apart. (Doses were administered at 8 am.)

During each experiment the dog was placed in a restraining sling, designed so that the dog could stand or rest comfortably but could not displace indwelling catheters which were placed into leg veins. To familiarize the dogs with this procedure, they were placed in the apparatus for 6 hr during each of the 3 days preceding the study.

Tablet doses (2 × 25 mg) were placed on the back of the dogs' tongues, so that the tablets were not fractured or chewed before being swallowed. This was immediately followed by 50 ml of water administered *via* an irrigating syringe[9]. Intramuscular doses were administered in 1 ml of physiological saline into a hind-leg thigh muscle. Intravenous doses were administered in 1 ml of physiological saline into a hind-leg vein over a 30-sec period.

Following the oral dose, blood samples (7–8 ml) were taken immediately before, at 30 min, and at 1, 2, 3, 4, 6, 8, 12, and 24 hr after dosing. An additional blood sample was drawn 15 min after the intramuscular dose, while additional samples were drawn at 5, 10, 15, and 45 min following the intravenous dose. During the initial 6-hr sampling period, blood samples were obtained *via* a vein infusion set[10] positioned in the front leg. The infusion set was kept patent by means of an intravenous drip (4 drops/min) of normal saline[11] containing 1 U/ml of sodium heparin[12]. At each sampling time 2 ml of residual fluid were withdrawn from the infusion set before drawing a 7–8-ml blood sample into a clean syringe[13]. The sets were removed after 6 hr and the dogs were released from the

Promazine	4.5
Chlorpromazine	7.2
Triflupromazine	9.0
Thioridazine	10.5

apparatus. Subsequent blood samples were obtained in heparinized tubes[14]. The samples were drawn immediately, and before the blood came into contact with the rubber tube stoppers, they were replaced by cork stoppers wrapped in aluminum foil. Plasma was separated from blood by centrifugation and stored at −20° until assayed. All samples were assayed within 2 weeks of collection.

Reagents—Human plasma for assay development was purchased[15]. Dog plasma for assay validation in this species was obtained from dogs in the School of Pharmacy animal care facility. Promethazine hydrochloride[16], promethazine-5-sulfoxide hydrochloride[16], and chlorpromazine hydrochloride[17], of reference standard quality; acetonitrile[18], methylene chloride[18], toluene[19], potassium phosphate monobasic[19], of analytical grade quality; and n-nonylamine (98%)[20] and hexamethyldisilazane[21], as supplied were used. All glassware was silanized with 5% hexamethyldisilazane in toluene prior to use.

RESULTS

Assay for Promethazine in Plasma—Typical chromatograms obtained from dog plasma containing no added compounds and from plasma containing promethazine and chlorpromazine (internal standard) are shown in Fig. 1. Retention times for promethazine and chlorpromazine were 4.5 and 7.0 min, respectively. Assay response was linear for promethazine concentrations between 1 and 250 ng/ml. The coefficient of variation in assay response was 11% for a promethazine concentration of 1 ng/ml, and was <10% for all other concentrations. The linear regression of the promethazine–chlorpromazine peak height ratios against promethazine concentrations from repeated determinations was $y = 0.013 + 0.053\,x$, $r = 0.999$, $n = 100$. The day-to-day reproducibility of the procedure, determined during the assay of actual plasma samples, is shown in Table I. The extraction efficiency for promethazine was 94.5 ± 5.6% (n = 5). Substituting dog plasma for human plasma did not affect the assay results.

The use of n-nonylamine in the liquid chromatographic mobile phase has the effect of reducing compound retention time and improving the peak shape on chromatograms (11). This modification improves assay sensitivity. Promethazine-5-sulfoxide, a major metabolite of promethazine, has a retention time of 2.5 min under the chromatographic conditions used, and any peak resulting from the presence of this metabolite was obscured by endogenous plasma components (5). The retention times of some phenothiazines in the system are shown in Table II.

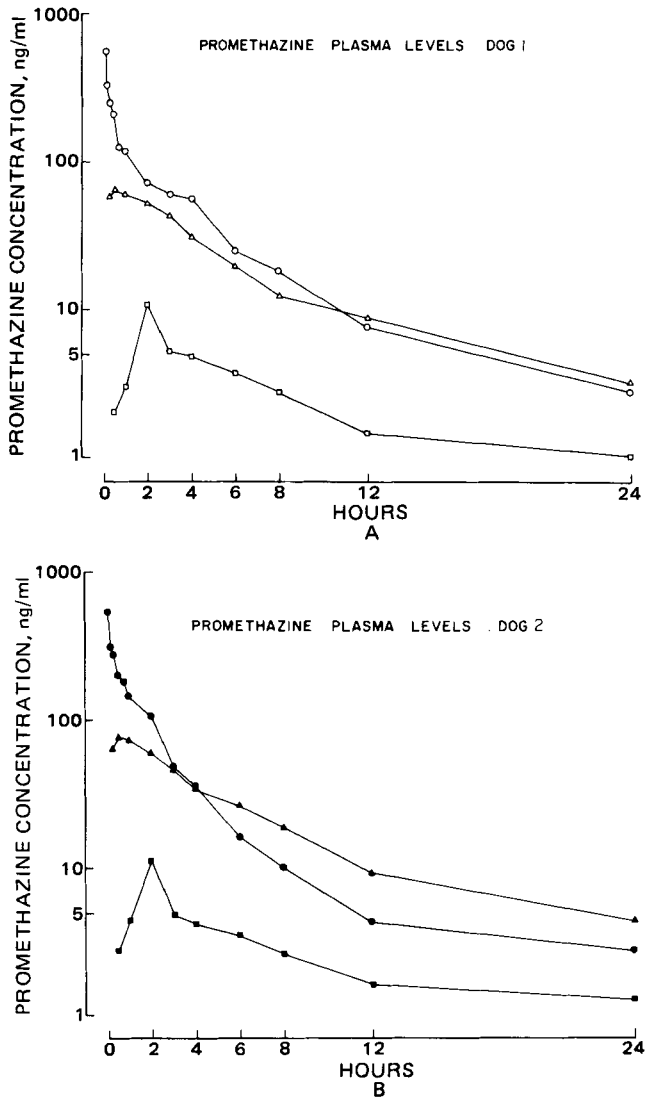

Figure 3—*Promethazine plasma levels following (A) single 50-mg intravenous (○), intramuscular (△), and oral (□) doses to Dog 1; and (B) single 50-mg intravenous (●), intramuscular (▲), and oral (■) doses to Dog 2.*

Pharmacokinetic Study in Dogs—Preliminary studies showed that the rubber stoppers, supplied with the evacuated glass tubes[14], reduce the apparent promethazine concentration by 25–30% compared with values obtained when aluminum-wrapped cork stoppers are used. Plasticizers in the rubber stoppers previously have been shown to displace chlorpromazine from plasma protein binding sites with subsequent redistribution of drug from plasma water into erythrocytes (12). Although it has not been shown that a similar phenomenon occurs with promethazine, the good assay results obtained with the aluminum cork stoppers justified their use.

The plasma promethazine profiles following single 50-mg oral, intramuscular, and intravenous doses of promethazine (hydrochloride) are shown in Fig. 2. The profiles obtained from the three dosage routes are combined for each dog for comparison in Fig. 3.

The promethazine plasma levels were similar in the two dogs. Concentrations of 556 and 535 ng/ml were obtained 5 min after the intravenous doses. Plasma levels declined rapidly at first and then more slowly to reach values of 3–4 ng/ml at 24 hr. The decline in plasma levels appeared to be triphasic in nature. Graphical analysis of the individual data sets in terms of a triexponential function gave rise to half-lives of 0.18, 1.9, and 8.3 hr and 0.14, 1.4, and 27.7 hr from the three exponents in Dogs 1 and 2, respectively. The coefficients of determination [$r^2 = (\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2$] between observed and predicted promethazine plasma concentrations using the triexponential function were 0.9996 and 0.9997.

[20] Aldrich Chemical Co., Milwaukee, Wis.
[21] Pierce Chemical Co., Rockford, Ill.

Peak promethazine levels of 76 and 64 ng/ml were obtained at 0.5 hr following the intramuscular doses; levels declined rapidly and then at a slower rate after 8–12 hr. At 24 hr the levels from these were similar to those observed following intravenous injection. The terminal half-lives, which were calculated from 12- and 24-hr data points in one dog, and the 8–24-hr data points in the other, were 8.5 and 11.6 hr.

Two hours following the administration of oral doses, peak promethazine levels of 10.6 and 11.0 ng/ml were obtained. The subsequent decline in drug levels was again nonlinear, and the drug was barely detectable in plasma at 24 hr. The later times of peak promethazine levels after oral doses, compared to intramuscular doses, indicates that absorption is slower *via* the oral route.

The efficiency of drug absorption from intramuscular and oral doses can be calculated by comparison of areas under plasma curves resulting from the different doses. The trapezoidal areas under plasma curves for Dog 1 in a 24-hr period were 714, 391, and 59 ng hr/ml following intravenous, intramuscular, and oral doses, respectively. In Dog 2 the equivalent values were 650, 472, and 62 ng hr/ml. Since the same dosage was given by each route, the absorption efficiency of unchanged promethazine can be obtained by direct comparison of area values. Thus, compared with intravenous values, drug bioavailability was 55 and 73% after intramuscular doses, and after oral doses, 8.3 and 9.5%.

DISCUSSION

The assay for promethazine used in this study is suitable for routine laboratory use. Sample preparation is uncomplicated and compounds are measured using a fixed wavelength UV detector. The method is sufficiently sensitive and specific to monitor plasma promethazine levels in animals and humans during a 24-period following therapeutic doses (5).

The reduction in plasma promethazine levels observed when rubber stoppers were used in blood collection tubes is similar to that reported previously for chlorpromazine (12). Failure to account for this may give rise to considerable assay error. The present data do not establish, however, that the mechanism causing reduced promethazine levels is the same as that for chlorpromazine. As a result, protein-binding characteristics of promethazine and other phenothiazines under different situations are being examined.

The plasma promethazine levels obtained in the two dogs show that the pharmacokinetics of promethazine are complex, and its disposition in the body cannot be described in terms of a simple one- or two-compartment kinetic model. It cannot be determined from these data whether the apparent triphasic decline in plasma levels following intravenous doses is due to differential uptake of drug by deep and shallow tissue compartments or to concentration-dependent changes in drug binding to plasma proteins.

Comparison of the areas under plasma curves from the three dosage routes indicates that the overall bioavailability of intact promethazine is reduced somewhat after intramuscular injection compared to intravenous administration. This is not uncommon (13) and probably results from partial degradation of drug at the intramuscular injection site and from slow release of some drug from the site at later, postsampling times.

The marked reduction in promethazine plasma levels following oral doses, compared to intravenous and intramuscular doses, indicates inefficient absorption by this dosage route. The degree of reduction is greater than that previously reported in rabbits (9), where systemic drug availability was calculated to be 50%, but appears to be similar to that reported in a single human volunteer following 12.5-mg intravenous and oral doses (14).

Although extensive first-pass metabolism of oral promethazine has been inferred (10, 14), the data currently available from this and previous studies is insufficient to determine the relative contributions of limited absorption and first-pass metabolism to the poor systemic availability of oral promethazine.

As the availability of poorly absorbed drugs is likely to be more variable, and more easily influenced by other factors, than that of efficiently absorbed compounds, the results obtained in this study confirm that promethazine is a compound with potential bioequivalence problems (15). The data presented here and elsewhere (10, 14) indicate that the dog may be a suitable animal model for promethazine bioavailability studies.

Relative Bioavailability of Chlorthalidone in Humans: Adverse Influence of Polyethylene Glycol

ROGER L. WILLIAMS ˣ, CHERYL D. BLUME, EMIL T. LIN, NICHOLAS H. G. HOLFORD, and LESLIE Z. BENET

Received May 1, 1981, from the *Drug Studies Unit, the School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication August 27, 1981.

Abstract □ The bioavailability of two commercial preparations of chlorthalidone was studied in healthy male subjects. Reference solutions/suspensions for the two products were chlorthalidone dissolved in a solution of water–polyethylene glycol and a solution/suspension of chlorthalidone. Bioavailability of the chlorthalidone in water–polyethylene glycol solution was significantly reduced in comparison to one of the commercial preparations, and trends in the data suggested that it was less well absorbed than either the chlorthalidone in water solution/suspension or the other commercial preparation of chlorthalidone. These data, together with previous reports indicating that polyethylene glycol may retard the absorption of some drugs *in vitro*, suggest that this compound should not be used to aid dissolution of drug in a reference standard for bioavailability investigations.

Keyphrases □ Chlorthalidone—relative bioavailability in humans, adverse influence of polyethylene glycol □ Bioavailability—chlorthalidone in humans, adverse influence of polyethylene glycol □ Polyethylene glycol—adverse influence on relative bioavailability of chlorthalidone, humans

Chlorthalidone[1] [2-chloro-5-(1-hydroxy-3-oxo-1-isoindolinyl)benzene-sulfonamide] is a diuretic agent with a relatively long half-life (~45 hr), correspondingly long duration of effect, and a low incidence of adverse effects. Because it is now possible for several manufacturers to market the drug in the United States, studies will be performed to assess the bioequivalence of different formulations of chlorthalidone. Guidelines issued by the U.S. Food and Drug Administration (FDA) for the performance of these investigations recommend that bioequivalency studies of chlorthalidone be performed against a standard reference solution of chlorthalidone in at least 20 individuals in a two-way crossover design (1).

Because chlorthalidone is poorly soluble in water (12 mg/100 ml water at 20°) (2), FDA guidelines recommend a solution of chlorthalidone in polyethylene glycol (I) as the reference standard for bioavailability because polyethylene glycol aids the dissolution of the drug in water. Preliminary studies, however, have suggested that chlorthalidone in a water–polyethylene glycol solution is less well absorbed than a tablet formulation. To assess this possibility and to evaluate a generic preparation of chlorthalidone in accordance with FDA guidelines, a crossover investigation was designed to determine the relative bioavailability of different formulations of chlorthalidone.

EXPERIMENTAL

Clinical Study—The study was performed in the clinical facilities of the Drug Studies Unit, University of California, San Francisco. Subjects were healthy male volunteers between the ages of 21 and 40 and within 10% of standard weight for height and body frame size (3). Information about the study was given to each participant prior to entry and each subject signed a consent form indicating they were informed of the purpose and procedures of the study. The study lasted 12 weeks, during which the participants were administered a single dose of each of four preparations of chlorthalidone with a 3-week wash-out period between each dose.

Table I—Measurement of Blood Concentration–Time Curves in 12 Healthy Male Subjects After a Single 50-mg Dose of Chlorthalidone (Treatment A)

Cl/F^b, liter/hr	0.180 ± 0.046
Cl_{renal}, liter/hr	0.080 ± 0.018

[a] Calculated using computer fitted parameters. [b] Calculated using measured *AUC* values.

The following four formulations of chlorthalidone were administered as a single oral dose in the study: Two 25-mg chlorthalidone tablets[2] taken with 180 ml of water (Treatment A); chlorthalidone[3], two 25-mg tablets taken with 180 ml of water (Treatment B); chlorthalidone in water–polyethylene glycol solution, 50 mg/100 ml followed by an 80-ml water rinse of the dosing container (Treatment C); and chlorthalidone in solution/suspension, 50 mg/100 ml water, followed by an 80-ml water rinse of the dosing container (Treatment D). Chlorthalidone in solution or solution/suspension was prepared according to the following procedures. For treatment C, 10% water–polyethylene glycol 4000 solution was heated to 37° and added to chlorthalidone powder to give, after filtration, 50 mg of drug/100 ml of solution. Assay of solution, using the same assay as for blood, for Treatment C confirmed that the content of chlorthalidone was appropriate. For Treatment D, 50 mg of chlorthalidone was stirred in 100 ml of water prior to dosing.

Dose Administration—Twenty-two healthy males participated in the study. Twelve of the 22 subjects received all four formulations of chlorthalidone according to a balanced 4 × 4 Latin square design. Three subjects were assigned to each of four treatment sequences. An additional 10 subjects received only the formulation of chlorthalidone used in Treatment B and chlorthalidone in water–polyethylene glycol solution. Five of these subjects were randomly assigned to one of the two possible treatment sequences (product used in Treatment B followed by water–polyethylene glycol solution of drug) and five were assigned to the reverse procedure. Postexperiment analysis of the data indicated no sequence, period, or crossover effects in the 12 individuals receiving all four treatments. The data for Treatment B and for chlorthalidone in water–polyethylene glycol solution (Treatment C) from these 12 individuals were, therefore, combined with the data in the additional 10 subjects receiving these treatments to give 22 individuals who received both Treatments B and C. These data provided bioequivalency data for chlorthalidone tablets required by FDA for premarketing approval.

Dosing of chlorthalidone occurred at 8 am on a treatment day, followed by blood and urine collections for a period of 120 hr. Beginning with the 8 am dose, blood was collected at the following time periods: 0, 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 48, 72, 96, and 120 hr. Urine was collected at the following time periods, beginning with the 8 am dose: 0–2, 2–4, 4–6, 6–8, 8–12,

12–24, 24–48, 48–72, 72–96, and 96–120 hr. Aliquots of urine were taken after volume measurement and both blood and urine samples were stored at −20° until analysis. Subjects fasted overnight (10 hr) prior to dosing and continued fasting until a standard lunch was administered 4 hr after dosing. They were ambulatory during the study but did not engage in strenuous exertion.

Drug Analysis—Chlorthalidone concentrations in whole blood and urine were assayed with high-pressure liquid chromatography (HPLC). Whole blood assay was performed because chlorthalidone is known to concentrate in red blood cells, whereas the concentrations in plasma are low. The method of assay is summarized here; however, details of the method will be presented in a separate publication.

Whole blood (0.2 ml) was mixed with an equal volume of distilled water, sonicated for 5 min, and mixed with acetonitrile containing phentolamine hydrochloride (internal standard). After mixing and centrifugation, the supernate was transferred to a clean tube and evaporated under nitrogen until ~0.4 ml of the solution remained. A portion of this sample was injected into the loop injector of the high-pressure liquid chromatograph. Urine was handled as blood with the exceptions that the sonication and centrifugation steps were not included and the urine internal standard was pentobarbital sodium. Chromatography was performed on a high-performance liquid chromatograph[4] equipped with a variable wavelength spectrophotometric detector[5]. The UV detector was set at 210 nm for blood and 250 nm for urine samples. The lower limit of sensitivity of the assay in blood was 200 ng/ml with a coefficient of variation of 5.0% and 750 ng/ml in urine with a coefficient of variation of 6.6%.

Pharmacokinetic and Statistical Analysis—To obtain the absorption and elimination rate constants, the blood concentration–time data were fitted to a two-compartment body model with first-order input and lag time. Due to the prolonged peak time, the absorption half-time was assumed to be longer than that for the fast disposition constant, α. This is consistent with values obtained previously (4) following intravenous dosing. Weighting of each data point was performed by squaring the value of the reciprocal of the observation. Parameter estimates were obtained using a nonlinear least-square computer program (3). The area under the plasma concentration curve (AUC) for chlorthalidone in blood was calculated by trapezoidal rule to C_{peak} and log-trapezoidal rule thereafter. $AUC_{120\ hr-\infty}$ was estimated from the concentration of chlorthalidone in blood at 120 hr divided by the terminal rate constant of elimination obtained from the fitting procedure. This area was added to the $AUC_{0-120\ hr}$ to give $AUC_{0-\infty}$. C_{peak} and T_{peak} represent the points of the highest concentration of chlorthalidone observed in blood and the time this concentration occurred. As verification of the fitting procedure, chlorthalidone clearance/F was also calculated using the noncompartmental method of dividing dose by $AUC_{0-\infty}$, where F is the fraction of the oral dose available to the systemic circulation. Renal clearance was determined by dividing the amount of drug excreted into the urine at 120 hr by the $AUC_{0-120\ hr}$.

The following parameters were analyzed statistically: absorption and elimination rate constants, $AUC_{0-\infty}$, amount of drug excreted in the urine in 120 hr, and C_{peak} and T_{peak} (5). Significant differences between treatments were identified using the Newman-Keuls test.

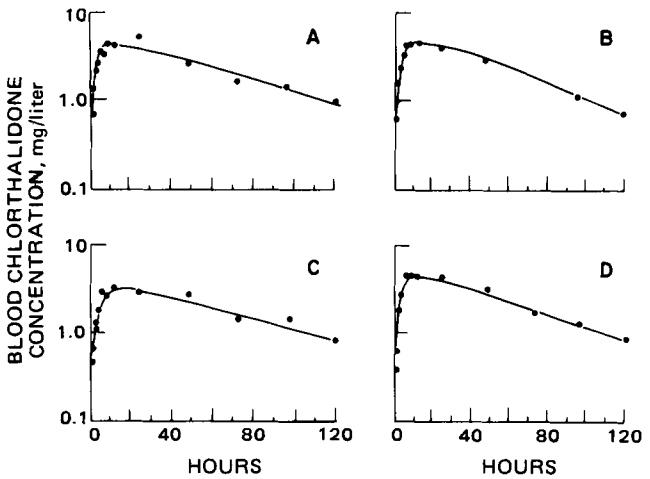

Figure 1—*Blood chlorthalidone concentration–time curves in a single individual (Subject 1) following administration of Treatment A, Treatment B, chlorthalidone in water/polyethylene glycol solution (Treatment C), and chlorthalidone in water solution/suspension (Treatment D).*

[5] Schoeffel, model SP 770.

RESULTS AND DISCUSSION

Representative blood concentration–time curves observed in a single individual (Subject 1) after each of the four treatments are shown in Fig. 1. Pharmacokinetic parameters derived from the curves in the 12 individuals receiving Treatment A are shown in Table I. Variables assessing bioequivalence in the 12 subjects who received all four treatments are shown in Table II and in the 22 subjects who received Treatments B and C in Table III. Table II also contains the results of the Newman-Keuls analysis that tested which of the four treatments differed. Table IV shows the comparison of values in all four preparations for the amount of drug excreted in the urine in 120 hr and the $AUC_{0-\infty}$. Because urine was collected for only approximately three half-lives of chlorthalidone, this measurement is probably less valuable in assessing chlorthalidone bioavailability than $AUC_{0-\infty}$.

The data in Table I correspond well with previous reports of chlorthalidone pharmacokinetics following an oral dose of the drug. Fleuren *et al.*, (4) reported a plasma clearance/F of 9.55 liter/hr for chlorthalidone (Treatment A) after a single dose of the drug. Using the Reiss *et al.* (6) value of 0.0138 for the plasma to blood ratio of chlorthalidone, this plasma clearance may be converted to a blood clearance of 0.132 liter/hr. This corresponds to the value of 0.184 liter/hr observed in this study for Treatment A, given the apparent variability in plasma to blood ratio of chlorthalidone over concentrations exhibited following clinical doses of the drug. This variability occurs as a consequence of saturable binding

Table III—Variables Assessing Bioequivalence Between Two Formulations of Chlorthalidone in 22 Subjects

of drug to erythrocytes (7). Fleuren *et al.* (4) reported a terminal half-life of 44.1 hr, whereas a value of 46.7 hr was obtained in this study. Although absolute bioavailability could not be assessed in this study, Fleuren and coworkers reported that the fraction of drug absorbed into the systemic circulation after an oral dose is ~0.60. Multiplying the clearance/*F* values by 0.60 yields a blood chlorthalidone clearance of ~0.110 liter/hr (1.84 ml/min). Slightly less than three-quarters of the chlorthalidone clearance is represented by renal elimination of unchanged drug, while the remainder presumably occurs as a result of hepatic biotransformation and biliary excretion. With a low distribution volume and a relatively long terminal half-life, chlorthalidone belongs to the category of drugs that are poorly extracted from the blood.

The data in Table III demonstrate a statistically significant difference between Treatments B and C for several parameters, apparently because of the larger number of individuals studied. From this study, Treatment B is absorbed more rapidly, attains a higher concentration of chlorthalidone in the blood, produces a greater $AUC_{0-\infty}$, and results in a greater amount of drug excreted in the urine by 120 hr in comparison with the drug in the water–polyethylene glycol solution. The data in this table also indicate that for $AUC_{0-\infty}$, Treatment B differs from Treatment C (as does Treatment A) according to the 75:75 rule (FDA), in which 75% of the individuals must demonstrate a test value within 75% of the value for the reference solution.

Previous investigations have suggested that polyethylene glycol can retard drug absorption. In 1966 it was demonstrated in two different *in vitro* systems that polyethylene glycol retarded the dissolution and absorption of phenobarbital (8). It was suggested that this effect probably occurred as a consequence of complexation of phenobarbital with polyethylene glycol. This particular phenomenon was observed only for phenobarbital, however, and not for pentobarbital, barbital, or barbituric acid. It was demonstrated more recently using the *in situ* rat gut technique, that both polyethylene glycol 4000 and 6000 retarded the rate of disappearance of salicylic acid from the gut (9). The clinical data in this report corroborate these *in vitro* observations on the potential influence of polyethylene glycol on drug dissolution and/or absorption.

Polyethylene glycol 4000 is one of several polyethylene glycols produced by reacting ethylene oxide with ethylene glycol or water; they bear the general formula of $H(CH_2CH_2)_nOH$. Used as demulcents, polyethylene glycols are found in water-soluble ointment bases, as ingredients of lotions and suppositories, and as tablet coatings. Although polyethylene glycol 4000 results in improved solubility of chlorthalidone in water, the data in this investigation, as well as previous reports (8, 9), indicate that it is not an appropriate constituent for use in chlorthalidone bioavailability studies. Its use in bioequivalency investigations for other drugs should probably be discouraged until it can be shown to be inert in the test system employed.

The data in Tables II and IV suggest also that Treatment B may be slightly more bioavailable than a water solution/suspension of chlorthalidone or the currently marketed preparation of the drug, Treatment A. Whatever differences exist between the treatments in this study, however, are not likely to be of clinical significance. These observations raise the following issue: As pharmaceutical technology advances, generic formulations of marketed drugs may be produced that are substantially more bioavailable than the innovators' products. In such circumstances, the FDA may be in the unenviable position of requesting that generic manufacturers either design a product with lower bioavailability characteristics or alter the drug content of their formulation. As an alternative, the FDA may ask the innovator to reformulate. Whatever the final decision, the results of this study emphasize the importance of including the innovator's formulation in assessing the bioequivalence of a generic product.

GLC Method for Iminodibenzyl and Desipramine Impurities in Imipramine Hydrochloride and Its Formulated Products

DON W. THOMPSON

Received December 12, 1980, from the *Food and Drug Administration, Atlanta, GA 30309.* Accepted for publication August 26, 1981.

Abstract □ A GLC method is described for the determination of iminodibenzyl and desipramine impurities in imipramine hydrochloride and its formulated products. These impurities were extracted from an alkaline solution with a mixture of 30% methylene chloride in hexane for chromatography on a 3% OV-17 GLC column. Iminodibenzyl was determined using anthracene as an internal standard and desipramine was determined (after derivatization) using nortriptyline as an internal standard. Based on spiked excipient mixtures typically used to compound imipramine tablets, recoveries were 93–109% for iminodibenzyl and 93–107% for desipramine at 0.2–0.4% of the labeled claim of imipramine. Minimum detection levels were ~0.02% for each impurity, and procedural standards gave coefficients of variation of <1% for each impurity. The method was linear in the 0.05–0.5 μg range and typically gave correlation coefficients ≥0.999.

Keyphrases □ Imipramine—GLC method for determining iminodibenzyl and desipramine impurities, drug substance and formulated products □ GLC—determination of iminodibenzyl and desipramine impurities in imipramine and its formulated products □ Antidepressants—GLC determination of iminodibenzyl and desipramine impurities in imipramine and its formulated products □ Desipramine—as an impurity in imipramine, determined by GLC

A determination of the kinds and amounts of organic impurities in drugs and drug formulations is a measure of both product stability and good manufacturing practices. Impurities may be present as by-products of synthesis, inadequate purification after synthesis, or from decomposition due to improper storage and handling.

It would be highly impractical to analyze for all of the possible organic impurities that might be present in imipramine and its formulated products. The present study determined which imipramine impurities might be indicators of both product stability and good manufacturing practices and developed an analytical system capable of measuring one or more of these impurities.

Several investigators have reported analytical procedures for imipramine and its related compounds using techniques such as GLC (1–6), GC–mass spectrometry (7–10), TLC (11–15), HPLC (16–20), and spectrophotometric methods (21–24). However, these reports primarily applied to the analysis of imipramine and its biological metabolites rather than the analysis of impurities in the drug substance.

Other investigators have reported impurities in imipramine and its formulated products by TLC. Adank and Hammerschmidt (25) reported the presence of eight impurities in commercial imipramine drug substance with total impurities < 0.2% and no single entity > 0.05%. The presence of similar amounts and kinds of impurities in commercial clomipramine (a compound structurally related to imipramine) was also reported (26). McErlane *et al.* (27) performed a study on impurities in imipramine, desipramine, and their formulations. When 19 lots of imipramine tablets from seven manufacturers were tested, five impurities were detected. Two of the major impurities were iminodibenzyl and desipramine at levels of up to 0.3% of the labeled claim of the drug.

A recent study (28) reported relatively high levels of impurities in imipramine samples taken from a hospital pharmacy in Richmond, Virginia. Iminodibenzyl levels of up to 2.8% and desipramine levels of up to 3.2% by GC–mass spectrometry techniques were reported. These results appear high when compared with this and previous studies (25–27).

The present report describes a GLC procedure for the quantitative determination of two major imipramine impurities, iminodibenzyl and desipramine, which appear to be indicators of product stability and good manufacturing practices.

EXPERIMENTAL

Materials—Desipramine hydrochloride, nortriptyline hydrochloride, and iminodibenzyl were the respective USP or NF reference standards. Reagent grade anthracene[1] was used as received. All other reagents and solvents were analytical reagent grade.

Apparatus—Analyses were performed on a gas chromatograph[2] equipped with a flame ionization detector and a strip chart recorder[3]. Air and hydrogen flow rates were set to maximize the detector response. The amplifier sensitivity settings were generally 3–6 × 10^{-10} amps full scale.

Column—A 1.8-m (6 ft) × 2-mm glass column packed with 3% OV-17 on 100–120 mesh Gas Chrom Q was conditioned overnight at 260° with nitrogen flow. The column temperature was maintained at 190° for the iminodibenzyl determination and 240° for the desipramine determination. The injection port and detector temperatures were held at 250°. Nitrogen was used as the carrier gas at 40 ml/min.

Edetate Disodium Solution—Four grams of ACS edetate disodium was dissolved in 50 ml of 1.5 *N* NaOH.

Internal Standard Solution—Approximately 4 mg of USP nortriptyline hydrochloride reference standard and ~2.5 mg of reagent grade anthracene were dissolved in 60 ml of methylene chloride. This was diluted to 200 ml with hexane and mixed thoroughly.

Standard Preparation—Approximately 2.5 mg each of USP reference iminodibenzyl and desipramine standards (accurately weighed) were dissolved in methanol and diluted to volume in a 5-ml volumetric flask (prepare fresh daily). Aliquots (100, 200, and 300 μl) of the standard preparation were then transferred to separate 15-ml test tubes fitted with polytef-lined screw caps. Each was evaporated to dryness using a nitrogen stream and gentle heat.

Procedure—A portion of imipramine hydrochloride drug substance, tablets or injection, equivalent to ~50 mg of imipramine hydrochloride was accurately weighed and transferred to a 15-ml test tube with a polytef-lined screw cap. The internal standard solution (5 ml) and 5 ml of the edetate disodium solution were added (for the injection, substitute 2 ml of 10% NaOH plus 400 mg of edetate disodium). The solution was shaken vigorously for 5 min and centrifuged until the upper organic layer was clear. A 4–4.5 ml portion of the upper layer was transferred to a tapered 15-ml centrifuge tube and evaporated to 0.5–1 ml using nitrogen and gentle heat. To equilibrate the system, 1–2 μl of this sample extract was injected into the gas chromatograph three or more times prior to quantitation.

[a] Excipient mixtures typically used to compound imipramine tablets.

The peak height ratios of iminodibenzyl to anthracene internal standard *versus* concentration for the calibration curve was plotted.

After the iminodibenzyl determination, 0.5 ml of methylene chloride and 5–7 drops of reagent grade acetic anhydride were added to the sample and standard extracts. This solution was mixed thoroughly and allowed to stand at room temperature for ~5 min. Then, 0.5 ml of methanol was added, mixed, and evaporated to dryness using a nitrogen stream and moderate heat (steam bath). The residue was dissolved in ~1 ml of 30% methylene chloride in hexane.

The GC column was maintained at 240° for the desipramine calibration curve, as previously described for iminodibenzyl, using peak height ratios of desipramine to nortriptyline internal standard.

RESULTS AND DISCUSSION

The TLC systems reported previously for imipramine and its impurities (25–27) showed good separations and adequate sensitivities for all the compounds when applied to an examination of imipramine drug substance and some commercial products. Eight impurities were detected at levels of ≤0.3% based on spot size and intensity. The predominant impurities were shown to be iminodibenzyl and desipramine. Additional examination of some commercial products by TLC, GLC, and GC–mass spectrometry in this laboratory did not reveal any impurities other than those reported previously.

Preliminary decomposition studies were conducted to determine the conditions necessary for the formation of iminodibenzyl and desipramine impurities in imipramine drug substance. Imipramine was heated at 100° in 0.1 *N* HCl for 3 hr with a current of air flowing over the surface. This treatment was followed by a 15-min exposure to long-wave UV light. TLC examination of the treated imipramine drug substance, compared to a nontreated sample, revealed a significant increase in both iminodibenzyl and desipramine content based on R_f values and spot intensity. The chromatogram of the treated sample was similar to that of a nontreated commercial imipramine tablet in that at least eight different known decomposition products were observed.

In another decomposition study, pure (by TLC) imipramine free base was exposed to normal laboratory fluorescent lighting and/or air for 72 hr on a silica gel TLC plate. At the end of this exposure period, the imipramine was extracted with methanol to be rechromatographed. The

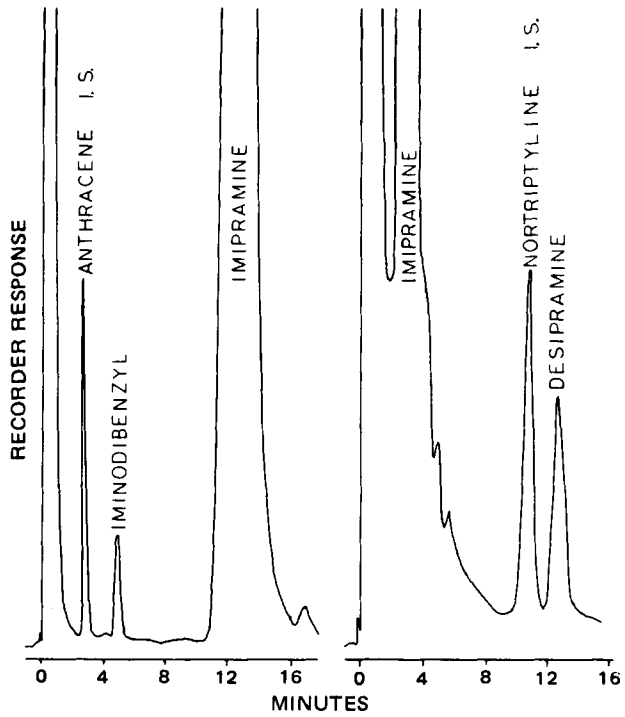

Figure 1—*Gas chromatogram of a commercial imipramine hydrochloride tablet extract at a column temperature of 190° prior to derivatization (left). The chromatogram on the right is the same extract at a column temperature of 240° after derivatization.*

imipramine exposed only to fluorescent light showed no discoloration and indicated only a trace of an impurity at the same R_f value as that of desipramine. The imipramine exposed to both the fluorescent lighting and air showed considerable discoloration and five additional spots on TLC. The predominant spots were those corresponding in R_f value to iminodibenzyl and desipramine. Although the presence of both iminodibenzyl and desipramine was confirmed by GC–mass spectrometry, the predominant compound present at the R_f value for iminodibenzyl had a molecular weight of 240 and is currently unidentified. Because chromatographically pure imipramine free base was used, it would appear that the unidentified compound is definitely related to imipramine. Interestingly, no compound with a molecular weight of 240 was detected in any of the commercial products examined in this study.

The decomposition studies indicated that there is a probability of some type of decomposition occurring in imipramine if adequate control of heat, light, air, and moisture is not used during commercial product formulation. In addition, iminodibenzyl and possibly desipramine may be present as part of these decomposition products.

The GLC procedure used offers comparable sensitivity to TLC (~0.02–0.04% impurities based on the labeled claim of imipramine) and considerable improvement over TLC in accuracy and precision. The method is linear in the 0.05–0.5 μg range and standard curves typically give correlation coefficients of ≥0.999. Procedural standards gave coefficients of variation of <1% for each impurity. The uncertainty of quantitation of impurities by TLC using spot size and intensity was estimated to be ±30%.

Two commercial tablet products were encountered which consistently gave low iminodibenzyl and desipramine recoveries. Further study revealed that calcium salts were present as high percentage excipients in the two products in question. Additional recovery studies using only iminodibenzyl and desipramine standards and the calcium salts revealed that calcium was indeed interfering with the assay. Several techniques such as multiple extractions, pH adjustments, and salting out were all used without success. Edetate disodium was finally added to complex the calcium and this provided successful assay results.

Excipient mixtures used to compound imipramine tablets from five different manufacturers were spiked with iminodibenzyl and desipramine at three concentration levels (Table I) and assayed in quintuplicate as a measure of precision and accuracy. Recoveries for iminodibenzyl ranged from 93 to 109% with a mean of 99.8% and a standard deviation of 3.4%. Recoveries for desipramine ranged from 93 to 107% with a mean of 102.7% and a standard deviation of 3.4%. A typical chromatogram of a com-

[a] Product a, tablet; product b, injection; and product c, drug substance.

mercial tablet extract shown in Fig. 1 demonstrates that adequate separation is achieved for all compounds. The increased retention time of the desipramine derivative is apparent from the relative locations of imipramine in each chromatogram.

The reactions of desipramine and nortriptyline with acetic anhydride to form their respective derivatives appear to be quantitative within 5 min based on the absence of underivatized desipramine and nortriptyline peaks in the gas chromatogram. Iminodibenzyl does not form the derivative under the conditions used in the method, nor with moderate heat (~100°).

No interfering GLC peaks were detected in any commercial products at the retention times of the anthracene and nortriptyline internal standards.

A tabulation of iminodibenzyl and desipramine levels found in some commercial products is shown in Table II. Wide variations in impurity levels were found for the various products and manufacturers. There are currently no USP limits for either iminodibenzyl or desipramine in tablets or injections and only a limit of 0.1% of iminodibenzyl in imipramine drug substance USP. Since imipramine USP was used in the manufacturing of the products studied, some decomposition must have occurred either in the manufacturing process or because of instability of the finished product. Interestingly, product C was found to contain more iminodibenzyl (0.37%) 3 years prior to its expiration date, whereas product A (50 mg) contained only a small amount of iminodibenzyl (0.08%) within 3 months of its expiration date.

Bioavailability, Pharmacokinetics, and Analgesic Activity of Ketamine in Humans

J. A. CLEMENTS *x, **W. S. NIMMO** ‡, **and I. S. GRANT** ‡§

Received May 14, 1981, from the *Heriot-Watt University, Department of Pharmacy, Edinburgh, EH1 2JH, Scotland, and the ‡Departments of Anaesthesia, Western Infirmary, Glasgow, G11 6NT, Scotland. Accepted for publication August 26, 1981. §Present address: Department of Anaesthesia, Ninewells Hospital, Dundee, Scotland.

Abstract □ The pharmacokinetics of ketamine in analgesic doses after intravenous, intramuscular, and oral administration was investigated in healthy volunteers. Plasma ketamine concentration–time curves were fitted by a two-compartment open model with a terminal half-life of 186 min. Absorption after intramuscular injection was rapid and the bioavailability was 93%. However, only 17% of an oral dose was absorbed because of extensive first-pass metabolism. Simultaneous measurements of the elevation of pain threshold in an ischemic exercise test showed a marked effect for 15–60 min after intramuscular injection, but little or no effect after the oral solution. Pain threshold elevation occurred at plasma ketamine concentrations above 160 ng/ml.

Keyphrases □ Ketamine—bioavailability, pharmacokinetics, and analgesic activity in humans, intravenous, intramuscular, and oral administration compared □ Pharmacokinetics—ketamine, intravenous, intramuscular, and oral dosage forms compared □ Anesthetics—ketamine, bioavailability, pharmacokinetics, and analgesic activity in humans

Ketamine [2-*o*-chlorophenyl-2-(methylamino)cyclohexanone] is an anesthetic induction agent which produces sleep rapidly after intravenous injection of 1–2 mg/kg (1). It may also be given by intramuscular injection (6–10 mg/kg) and this route is used extensively in children. The oral route has not been used, although a self-administration of 300 mg and loss of consciousness has been reported (2).

Wieber *et al.* (3) reported the pharmacokinetics of intravenous ketamine (2.5 mg/kg) in five patients to be in accordance with a two-compartment model with a mean terminal half-life of 2.52 hr. Idvall *et al.* (4) found the mean half-life in 31 patients to be 79 min after an intravenous infusion.

In lower doses, ketamine also has analgesic properties (5, 6) and has been used in post-operative pain relief (7–9), but the pharmacokinetics have not been reported.

This paper reports the pharmacokinetics of ketamine in healthy volunteers who received analgesic doses by intravenous and intramuscular injection and as an oral solution. Simultaneous measurements were made of the elevation of the pain threshold in an ischemic exercise test (10).

EXPERIMENTAL

Procedure—In the first study, ketamine hydrochloride[1] was administered by intravenous injection (0.25 or 0.125 mg of base/kg body weight) on separate occasions to five healthy, fasting adult volunteers [age: 33.8 ± 1.4 (*SE*) years; weight: 74.8 ± 2.1 kg]. On a third occasion, an injection of normal saline was given.

In the second study, normal saline or ketamine (0.5 mg/kg) was given to six healthy, fasting adult volunteers [age: 31.8 ± 2.0 (*SE*) years; weight: 70.7 ± 4.4 kg] by intramuscular injection or as an oral solution on separate occasions. On each occasion, the subject drank 50 ml of orange juice with or without ketamine in solution and simultaneously received an intramuscular injection of ketamine or normal saline into the triceps muscle of the dominant arm.

Each study was a crossover design, the order of administration was randomized, and the subject and the person recording pain scores were not aware of the nature of the administered solution. Samples of venous blood (8 ml) were removed from the dominant arm at 0 (blank), 3, 5, 10, 15, 20, 30, and 45 min and at 1, 2, 4, and 7 hr.

Pain Measurements—The method was a modification of the ischemic exercise test of Harrison and Bigelow (10) and was described previously (11). The test was carried out during a 30-min control period before, and at 0, 5, 10, 15, 20, 30, 40, 50, and 60 min (first study) or at 0, 15, 30, 45, 60, 75, 90, and 120 min (second study) after administration of ketamine or normal saline.

Elevation of pain threshold was indicated by a reduction of the "pain score" or an increase in the time to reach intolerable pain, or both, when compared with corresponding values in the subject on the same day during the control period.

Analysis of Blood Samples—Immediately after collection in heparinized tubes, plasma was separated and stored at −20° until as-

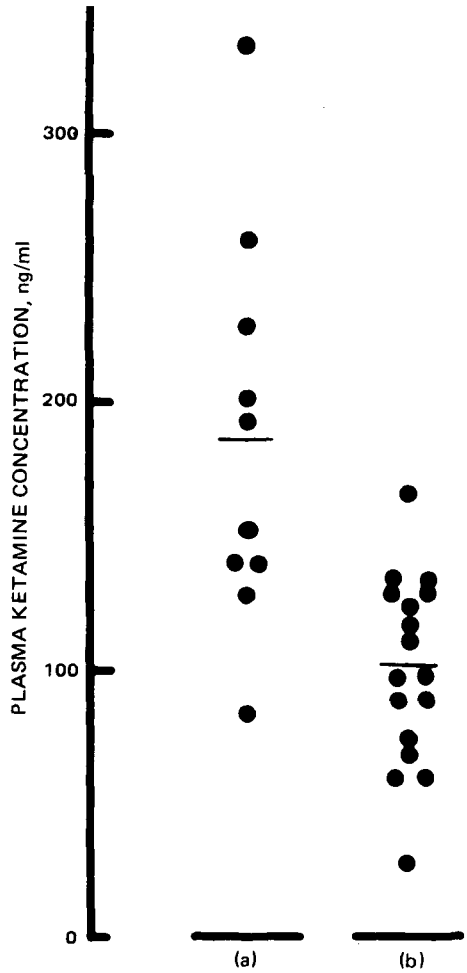

Figure 1—*Distribution of plasma ketamine concentration (ng/ml) that corresponds to pain scores after 75 to 105-sec ischemic exercise of (a) "none" or "mild" or (b) "moderate" or "severe," after intramuscular ketamine (0.5 mg/kg) in six subjects.*

sayed. Plasma samples were analyzed in duplicate or triplicate for ketamine and norketamine (metabolite 1) as their heptafluorobutyryl derivatives on a gas chromatograph with electron-capture detection (12–14). Dehydronorketamine (metabolite 2) consistently gave two peaks on the chromatogram; this was observed previously by White *et al.* (15).

Pharmacokinetic Analysis—Plasma ketamine concentrations were fitted to a two-compartment model by nonlinear regression with a simplex algorithm (16, 17); individual data points were weighted as recommended by Ottaway (18).

Preliminary estimates of the apparent volume of the central compartment, the absorption rate constant (second study), and transfer microconstants were obtained using an analog computer. Goodness of fit criteria used were the run test and the number test on the signs of the residuals (19) and a test statistic for serial correlation between residuals (20). Both of these criteria indicated a satisfactory fit in all cases.

The bioavailability (F_{area}) was calculated from the ratio of the trapezoidal area (with correction for the area beyond the last data point and adjustment for dose) after intramuscular or oral administration to that after intravenous injection in the same subject. Apparent distribution volumes of the central compartment (V_1), at steady-state ($V_{d_{ss}}$), and during the terminal phase (V_{d_β}) and total body clearance values (TBC) (21), were not corrected for bioavailability. Estimates of the absorption rate constant were also obtained by the method of Loo and Riegelman (22).

The fraction of the dose lost by first-pass metabolism (F) was calculated from:

$$F = 1 - \frac{TBC}{Q_1} \qquad \text{(Eq. 1)}$$

where TBC is the clearance value for ketamine after intravenous injection and Q_1, the hepatic blood flow, was taken as 1.53 liters/min (23), and from:

$$F = \frac{Q_1}{Q_1 + X_0/(AUC)_{oral}} \qquad \text{(Eq. 2)}$$

where $(AUC)_{oral}$ is the area under the plasma ketamine concentration–time curve after oral administration of the dose X_0 (21).

The Student t test was used in tests of statistical significance.

RESULTS

Pharmacokinetics—Immediately after intravenous injection, plasma ketamine concentrations fell rapidly, and the data were fitted by a two-compartment open model with a mean terminal half-life of 186 ± 10 min. The concentration y (ng/ml) at time t(min) after injection was given by:

$$y = 82\exp(-0.044t) + 22\exp(-0.0039t)$$

after a 0.125 mg/kg dose (Eq. 3)

and by:

$$y = 108\exp(-0.039t) + 40\exp(-0.0038t)$$

after a 0.25 mg/kg dose (Eq. 4)

There were no significant differences in the values of α, β, apparent distribution volumes, or clearance for the two doses.

Ketamine was rapidly absorbed after intramuscular injection with apparent absorption half-times of 2–17 min. The estimated interval between the injection and the appearance of ketamine in the plasma (lag time) was less than 4 min and the bioavailability was 93% (Table I). Apparent peak concentrations (C_{max}) of between 100 and 425 ng/ml occurred at 5–30 min (t_{max}) after injection. Absorption rate constants calculated by the Loo–Riegelman method agreed well with those from nonlinear regression, except in one subject in whom absorption was very rapid. The mean (±SE) terminal plasma half-life (155 ± 12 min) did not differ significantly from that after intravenous injection (186 ± 10 min) and no difference was observed in the clearance values (23.2 and 19.1 ml/min/kg, respectively) (Table II).

After oral administration, ketamine absorption was incomplete, with only 16.6% of the dose reaching the systemic circulation. The lag time was between 4 and 13 min (mean 8.0 min). The mean apparent peak concentration of 44 ng/ml (range 15–80 ng/ml) was much lower than the value (243 ng/ml) after intramuscular injection (Table II). The fractions of the oral dose available to the systemic circulation, as calculated from Eq. 2, were in close agreement with observed values; however, the fractions predicted from clearance values after intravenous injection (Eq. 1) agreed well in only two of the four subjects (Table I).

Norketamine was found in measurable concentrations after each route of administration. After intravenous injections of 0.125 and 0.25 mg/kg, apparent peak concentrations of 15–30 ng/ml and 20–60 ng/ml, respectively, occurred at 15–60 min. Areas under the plasma norketamine concentration–time curves (corrected for dose) did not differ significantly. Although the mean peak norketamine concentration after oral admin-

istration was higher than after intramuscular injection, the areas were similar and neither differed significantly from that after intravenous injection (Table II).

Pain Measurements—In the control period, before administration of ketamine or normal saline, severe pain was observed after 75–105 sec of exercise and was reproducible in each individual on each occasion. The pain became intolerable after a further 7 sec (range 1–13 sec). The pain threshold was considered to have been raised when the pain was graded as "none" or "mild" at these times, or when the time to reach intolerable pain was significantly prolonged, or both.

After intravenous injection of ketamine, the pain threshold elevation lasted for less than 10 min after 0.25 mg/kg and less than 5 min after 0.125 mg/kg (14). At 15 and 30 min after intramuscular injection of ketamine, the period of ischemic exercise before pain became intolerable was significantly prolonged, by 24 and 21 sec, respectively. At later times, and also after injection of normal saline, the period was not prolonged (11).

Elevation of pain threshold after intramuscular injection occurred in all individuals for up to 1 hr; the corresponding plasma ketamine concentrations were between 85 and 330 ng/ml. Concentrations that corresponded to a pain score of "none" or "mild" after 75–105 sec of ischemic exercise were significantly higher (186 ± 23 ng/ml) than those when pain scores were "moderate" or "severe" (101 ± 8 ng/ml) (Fig. 1). There was a significant correlation between the plasma ketamine concentrations and the increase in time taken to reach intolerable pain (Fig. 2) in the hour after injection, but no significant correlation was found for norketamine concentrations.

After oral administration, pain thresholds were not markedly elevated, and subjects experienced moderate or severe pain after 75–105 sec of ischemic exercise. The mean increase in exercise time before intolerable pain was reached was not significant except at 30 min after administration when the increase (9 sec) reached significance ($0.05 > p > 0.025$). Plasma ketamine concentrations were between 17 and 65 ng/ml. Norketamine concentrations were higher, in the range 80–390 ng/ml. No significant correlations were observed between plasma ketamine or plasma norketamine concentrations and the increase in time to reach intolerable pain.

DISCUSSION

The pharmacokinetics of intravenous ketamine in the analgesic doses used in this study are similar to those previously reported for anesthetic doses (3). Plasma concentration–time data were adequately fitted by a two-compartment open model, and apparent distribution volumes, terminal plasma half-lives, and clearance values after analgesic doses (0.125 or 0.25 mg/kg) in volunteers did not differ significantly from those reported for anesthetic doses (2.5 mg/kg) in patients (14). Mean terminal plasma half-lives after anesthetic and analgesic doses were 151 and 186 min, respectively. Both times are much longer than the value (79 min) reported for patients at the end of an intravenous infusion (4). This difference is attributed to the relatively short sampling period (2–2.5 hr) used in the latter study, since early termination of sample leads to underestimation of the half-life (24). Analysis of data for this period after intravenous injection of ketamine gave an apparent half-life of 105 min.

The low plasma ketamine concentrations after oral administration could have been due to incomplete absorption from the GI tract or to extensive metabolism during the first-pass through the liver. The relatively high concentrations of the metabolite norketamine suggest that liver metabolism is largely responsible. Where the liver is the sole site of metabolism, the area under the curve of concentration of metabolite *versus* time is independent of route of administration (25). Since the area under the norketamine concentration–time curves after oral administration was similar to that after intravenous injection (after correction for dose), the low plasma ketamine concentrations can be attributed solely to the extensive first-pass metabolism. Also, the fraction of the oral dose reaching the systemic circulation, as calculated from Eq. 2 on the assumption that absorption from the gut lumen was complete, was in good agreement with F_{area}, the fraction calculated from area analysis.

Estimation of the fraction of an oral dose reaching system circulation from areas after intravenous injection, using Eq. 1, gave good agreement in two subjects but underestimated the values in two.

Since elevation of pain threshold was previously reported to be associated with plasma ketamine concentrations above 100–150 ng/ml (11, 14), the absence of any marked effect after oral administration may be explained by the low concentrations of ketamine as these did not exceed 80 ng/ml. Norketamine has been shown to have pharmacological activity, including analgesic properties, in the rat (15) but its effects in humans are not known. As high norketamine concentrations, up to 390 ng/ml, were found in some subjects after oral administration of ketamine, it is possible that this metabolite, either alone or in combination with ketamine, was responsible for the small increase in time taken to reach intolerable pain during ischemic exercise. However, no correlation was observed between the increase in time to reach intolerable pain and plasma norketamine concentration. The activity of other metabolites formed by hydroxylation of the cyclohexanone ring (Metabolites 3 and 4) is not known and these are not measured in the assay. In view of the extensive first-pass metabolism, oral administration of ketamine in a dose of 0.5 mg/kg is not satisfactory for producing analgesia.

After intramuscular injection, ketamine was rapidly and almost completely absorbed, and the fall in the terminal plasma concentrations represented the elimination phase, since the half-life did not differ from that observed after intravenous injection.

Intramuscular injection of ketamine produced a marked elevation of pain threshold for between 15 and 60 min. Using the criterion of a pain score of "none" or "mild," after 75 to 105 sec of ischemic exercise or an increase of 20 sec or more in the time to intolerable pain, it was found that elevation of pain occurred consistently at plasma ketamine concentrations exceeding 160 ng/ml, but not at concentrations below 80 ng/ml (Fig. 1). These data make it possible to design dosage regimens and may increase the usefulness of ketamine as an analgesic agent.

Synthesis, Hydrolytic Reactivity, and Anticancer Evaluation of *N*- and *O*-Triorganosilylated Compounds as New Types of Potential Prodrugs

FANG-TING CHIU, YOUNG HWAN CHANG, GÜNAY ÖZKAN, GERALD ZON ×, KENNETH C. FICHTER *, and LAWRENCE R. PHILLIPS ‡

Received April 24, 1981, from the *Department of Chemistry, The Catholic University of America, Washington, DC 20064*, the **Mid-Atlantic Research Institute, Bethesda, MD 20014*, and the ‡*Bureau of Biologics, Food and Drug Administration, Bethesda, MD 20205.* Accepted for publication August 6, 1981.

Abstract □ *N*- and *O*-Triorganosilylated compounds related to various anticancer agents were synthesized for evaluation as potential anticancer prodrugs. ^{1}H-NMR and UV kinetic measurements of hydrolytic desilylation were used to correlate relative rates of structural unmasking with steric bulk about the silicon reaction center. The *tert*-butyldimethylsilyl ester of chlorambucil and a number of *O*-triorganosilylated carbamate derivatives of nor-nitrogen mustard showed significant activity against P-388 lymphocytic leukemia in mice.

Keyphrases □ Prodrugs—*N*- and *O*-triorganosilylated compounds, synthesis, potential anticancer prodrug □ Anticancer agents—synthesis of *N*- and *O*-triorganosilylated compounds, potential anticancer prodrugs □ Triorganosilylated compounds—synthesis and evaluation of potential anticancer prodrugs

In an earlier investigation of potential anticancer prodrugs (1), it was found that *O*-aryl-*N*,*N*-bis(2-chloroethyl)phosphorodiamidates are resistant toward chemical activation involving P-OAr hydrolysis and failed to provide evidence for *in vivo* formation of phosphoramide mustards, which are usually cytotoxic and may exhibit anticancer activity (2). The hydrolytic lability (3) of Si—N and Si—O bonds suggested that strategically triorganosilylated derivatives of known oncostatic agents might constitute a class of compounds which are, for kinetic reasons, more suitable candidates for anticancer prodrugs. The possibility of controlling drug unmasking rates (desilylation) by manipulating the nature of the silicon reaction center represents an interesting feature of these hypothetical compounds. The expected hydrolysis byproducts, namely triorganosilanols and disiloxanes, are generally nontoxic (4). Derivatization with a triorganosilyl group increases lipophilicity; consequently, triorganosilyl prodrugs might eventually prove to be useful against central nervous system cancers, which apparently require somewhat more lipophilic chemotherapeutic agents for effective penetration of the blood–brain barrier (5).

In view of the widespread interest in the design of anticancer prodrugs (6, 7) and the development of organosilicon compounds as medicinal agents (8), the aforementioned proposal is unique in that it encompasses both of these growing research areas. This report is the first of a series of exploratory investigations of hydrolytically labile *N*- and *O*-triorganosilyl prodrugs having potential anticancer activity. These studies include the synthesis of several new classes of nitrogen mustards, measurement of hydrolytic desilylation rates by a combination of ^{1}H-NMR and UV methods, examination of the hydrolysis mechanisms by Hammett-type kinetic studies and ^{18}O-labeling, and the comparison of screening results obtained with experimental cancers in mice.

EXPERIMENTAL

NMR refers to ^{1}H-NMR at 60 MHz, except as noted; chemical shifts refer to deuterochloroform and are relative to internal tetramethylsilane, unless specified otherwise. ^{31}P-NMR spectra were recorded at 40.25 MHz using a $\pi/2$ pulse (13 μsec) and a 2-sec repetition time. All organosilicon starting materials were commercially available and were checked for purity by NMR; if necessary, further purification was achieved by either conventional distillation or recrystallization. All handling and reactions of organosilicon compounds were performed under an atmosphere of dry nitrogen; all reagents and solvents were anhydrous. Satisfactory elemental analyses were not always possible, due to hydrolytic reactivity. However, each product was reliably characterized by NMR as well as IR (9–11) and/or mass spectroscopy. In all cases, NMR signal integrations established that product purity was >90%. Electron-impact mass spectra were scanned from samples introduced *via* a solids' direct probe inlet. The probe, when loaded with a sample and properly positioned with respect to the ion source, was heated at 100°/min from ambient temperature to a final temperature of 320°. The ion source temperature was 180°, the ionizing potential was 70 eV, and the ionizing current was 50 μA. Analytical thin-layer chromatography (TLC) employed 2.5 × 10-cm plates coated with a 250-μm layer of silica gel containing a fluorescent indicator; component visualization was achieved with iodine vapor and/or a short wavelength UV lamp. Column chromatography utilized 60–200 mesh silica gel, which was dried by heating at 150° for 24 hr and then cooling to room temperature under nitrogen.

All compounds having a bis(2-chloroethyl)amino functionality are potentially toxic and/or mutagenic and should be handled with extreme care.

***O,O*-Dimethyl-*N,N*-bis(2-chloroethyl)phosphoramidate (III)** —Lithium methoxide was prepared fresh by slowly adding a benzene solution (10 ml) of methanol (6.5 ml) to a mixture of benzene (10 ml) and sliced lithium wire (15 cm, 6.11 mmoles/cm) at 25°. In an earlier investigation of potential anticancer prodrugs (1), it was found that *O*-aryl-*N*,*N*-bis(2-chloroethyl)phosphorodiamidates are resistant toward chemical activation involving P-OAr hydrolysis and failed to provide evidence for *in vivo* formation of phosphoramide mustards, which are usually cytotoxic and may exhibit anticancer activity (2). The hydrolytic lability (3) of Si—N and Si—O bonds suggested that strategically triorganosilylated derivatives of known oncostatic agents might constitute a class of compounds which are, for kinetic reasons, more suitable candidates for anticancer prodrugs. The possibility of controlling drug unmasking rates (desilylation) by manipulating the nature of the silicon reaction center represents an interesting feature of these hypothetical compounds. The expected hydrolysis byproducts, namely triorganosilanols and disiloxanes, are generally nontoxic (4). Derivatization with a triorganosilyl group increases lipophilicity; consequently, triorganosilyl prodrugs might eventually prove to be useful against central nervous system cancers, which apparently require somewhat more lipophilic chemotherapeutic agents for effective penetration of the blood–brain barrier (5).

In view of the widespread interest in the design of anticancer prodrugs (6, 7) and the development of organosilicon compounds as medicinal agents (8), the aforementioned proposal is unique in that it encompasses both of these growing research areas. This report is the first of a series of exploratory investigations of hydrolytically labile *N*- and *O*-triorganosilyl prodrugs having potential anticancer activity. These studies include the synthesis of several new classes of nitrogen mustards, measurement of hydrolytic desilylation rates by a combination of ^{1}H-NMR and UV methods, examination of the hydrolysis mechanisms by Hammett-type kinetic studies and ^{18}O-labeling, and the comparison of screening results obtained with experimental cancers in mice.

EXPERIMENTAL

NMR refers to ^{1}H-NMR at 60 MHz, except as noted; chemical shifts refer to deuterochloroform and are relative to internal tetramethylsilane, unless specified otherwise. ^{31}P-NMR spectra were recorded at 40.25 MHz using a $\pi/2$ pulse (13 μsec) and a 2-sec repetition time. All organosilicon starting materials were commercially available and were checked for purity by NMR; if necessary, further purification was achieved by either conventional distillation or recrystallization. All handling and reactions of organosilicon compounds were performed under an atmosphere of dry nitrogen; all reagents and solvents were anhydrous. Satisfactory elemental analyses were not always possible, due to hydrolytic reactivity. However, each product was reliably characterized by NMR as well as IR (9–11) and/or mass spectroscopy. In all cases, NMR signal integrations established that product purity was >90%. Electron-impact mass spectra were scanned from samples introduced *via* a solids' direct probe inlet. The probe, when loaded with a sample and properly positioned with respect to the ion source, was heated at 100°/min from ambient temperature to a final temperature of 320°. The ion source temperature was 180°, the ionizing potential was 70 eV, and the ionizing current was 50 μA. Analytical thin-layer chromatography (TLC) employed 2.5 × 10-cm plates coated with a 250-μm layer of silica gel containing a fluorescent indicator; component visualization was achieved with iodine vapor and/or a short wavelength UV lamp. Column chromatography utilized 60–200 mesh silica gel, which was dried by heating at 150° for 24 hr and then cooling to room temperature under nitrogen.

All compounds having a bis(2-chloroethyl)amino functionality are potentially toxic and/or mutagenic and should be handled with extreme care.

***O,O*-Dimethyl-*N,N*-bis(2-chloroethyl)phosphoramidate (III)** —Lithium methoxide was prepared fresh by slowly adding a benzene solution (10 ml) of methanol (6.5 ml) to a mixture of benzene (10 ml) and sliced lithium wire (15 cm, 6.11 mmoles/cm) at 25°. After an additional 3 hr of stirring, a solution of I (12) (10.4 g, 40 mmoles) in benzene (40 ml)

0022-3549/82/0500-0542$01.00/0

was added over a 30-min period. 2,3,11,12-Dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene (0.3 g) was added and stirring was continued overnight at 25°. After separation of lithium chloride by suction filtration and evaporation of solvent from the filtrate, the yellow residue was chromatographed on a column (40 × 4 cm) of dry silica gel using chloroform–methanol (24:1) as eluent; R_f = 0.60. Evaporation of solvent gave III as a pale yellow oil (75%) which was used without further purification. NMR: δ 3.82 (d, 6H, 2-CH_3) and 3.52 (m, 8H, 4-CH_2) ppm; mass spectrum: *m/z* 249 (M^+, 2-Cl).

***O,O*-Bis(trimethylsilyl)- *N,N*- bis(2-chloroethyl)phosphoramidate (IV)**—A mixture of III (0.26 g, 1 mmole), sodium iodide (0.45 g, 3 mmoles), and acetonitrile (5 ml) was treated dropwise with a solution of trimethylchlorosilane (0.35 g) in acetonitrile (3 ml) over 20 min. After 3 hr of continued stirring, followed by solvent evaporation, the residue was extracted with carbon tetrachloride (5 ml) to give IV (85%), which is extremely sensitive to atmospheric moisture and hydrolyzes to give hexamethyldisiloxane. NMR: δ 3.43 (m, 8H, 4-CH_2) and 0.28 [s, 18H, 2-Si(CH_3)$_3$] ppm.

***O,O*-Bis(*tert*-butyldimethylsilyl) -*N,N*- bis(2-chloroethyl)-phosphoramidate (V)**—Reaction of III and *tert*-butyldimethylchlorosilane in the presence of sodium iodide according to the identical procedure described for IV gave product V (56%) as a pale yellow oil. Attempts to decolorize this material by either preparative TLC or column chromatography on dry silica gel led to hydrolysis of the *tert*-butyldimethylsilyl groups, as evidenced by isolation of the corresponding triorganosilanol. NMR: δ 3.42 (m, 8H, 4-CH_2), 0.90 [s, 18H, 2-C(CH_3)$_3$], and 0.23 [s, 12H, 2-Si(CH_3)$_2$] ppm. For V (45 mg, 0.1 mmole) and tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium (156 mg, 0.13 mmole) in deuterochloroform (1 ml), the expected resonance doubling of enantiotopic groups (13) was observed and diastereotopic methyl groups in V were resolved: δ 2.37 [s, 9H, C(CH_3)$_3$], 2.09 [s, 9H, C(CH_3)$_3$], 1.97 (s, 3H, SiCH_3), 1.87 (s, 3H, SiCH_3), 1.52 (s, 3H, SiCH_3), and 1.35 (s, 3H, SiCH_3) ppm. IR (neat): 2950, 2900, and 2875 (C—H), 1366 [C(CH_3)$_3$], 1250 (P=O), and 1045 (Si—O) cm^{-1}.

***O,O*-Bis(diphenylmethylsilyl) -*N,N*- bis(2-chloroethyl)phosphoramidate (VI)**—Compound VI was synthesized (60%) from diphenylmethylchlorosilane and III by the same procedure described for IV. Purification of the crude product was achieved by rapid elution from dry silica gel using carbon tetrachloride eluent to remove 1,3-dimethyl-1,1,3,3-tetraphenyldisiloxane (R_f = 0.5, carbon tetrachloride) and then ether to collect VI (R_f = 0.85, ether) as a colorless oil. NMR: δ 7.44 (m, 20H, 4-C_6H_5), 3.15 (m, 8H, 4-CH_2), and 0.67 (s, 6H, 2-SiCH_3) ppm. For VI (0.1 *M*) and tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium (0.13 *M*) in deuterochloroform, the expected resonance doubling of enantiotopic groups was observed: δ 0.95 (s, 3H, SiCH_3) and 0.82 (s, 3H, SiCH_3) ppm. IR (neat): 3090, 3060, and 3035 (C_6H_5), 2950 (C—H), 1270 (P=O), 1050 (Si—O), and 760 and 700 (C_6H_5) cm^{-1}.

***O,O*-Bis(*tert*-butyldiphenylsilyl) -*N,N*- bis(2-chloroethyl)-phosphoramidate (VII)**—Reaction of *tert*-butyldiphenylchlorosilane and III in a manner identical to that described above for the preparation of IV was followed by column chromatography using dry silica gel, eluting first with carbon tetrachloride to remove *tert*-butyldiphenylsilanol (R_f = 0.3, carbon tetrachloride), and then with ether to remove VII (90%, R_f = 0.81, ether). NMR: δ 7.56 (m, 20H, 4-C_6H_5), 3.06 (m, 8H, 4-CH_2), and 1.14 [s, 18H, 2-C(CH_3)$_3$] ppm. For VII (0.1 *M*) and tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium (0.13 *M*) in deuterochloroform, the expected resonance doubling of enantiotopic groups was observed: δ 1.33 [s, 9H, C(CH_3)$_3$] and 0.95 [s, 9H, C(CH_3)$_3$] ppm. IR (neat): 3055 (C_6H_5), 2950 and 2850 (C—H), 1375 [C(CH_3)$_3$], 1255 (P=O), 1130 (Si—O), and 740 and 700 (C_6H_5) cm^{-1}.

***O* - Methyl -*N,N* - bis(2 - chloroethyl)phosphorodiamidate (VIII)**—A solution of methanol (1 ml, 24.7 mmoles) in benzene (5 ml) was added (20 min) to a stirred suspension of sliced lithium wire (3.6 cm, 22 mmoles) in benzene (5 ml) at 25°, and after 4 hr it appeared that all of the metal had reacted. The resultant suspension of lithium methoxide was added dropwise by syringe to a chilled mixture of I (5.2 g, 20 mmoles) and 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene (0.1 g) in benzene (30 ml). After 5 hr of stirring at 25°, lithium chloride was removed by suction filtration and the filtrate containing intermediate II was diluted with benzene (18 ml). Dry ammonia was bubbled through the stirred filtrate at 5° until precipitation of ammonium chloride was complete. After separation of the precipitate and removal of solvent *in vacuo*, the residue was chromatographed on a dry silica gel column (40 × 4 cm) using methanol–chloroform (5:95, 250 ml). The concentrated eluate was dissolved in benzene (8 ml) and diluted with low-boiling petroleum ether until turbid. Refrigeration afforded pure VIII (51%), mp 75–78°. NMR: δ 3.84 [d ^3J(PH) = 11 Hz, 3H, CH_3], 3.80–3.35 (m, 8H, 4-CH_2), and 3.00 (broad, 2H, NH_2) ppm. IR (mull): 3403 and 3268 (NH_2), 1362 (OCH_3), and 1218 (P=O) cm^{-1}.

Anal.—Calc. for $C_5H_{13}N_2O_2PCl_2$: C, 25.55; H, 5.58; N, 11.92. Found: C, 25.49; H, 5.64; N, 11.91.

***O*-(*tert*-Butyldimethylsilyl) -*N,N*- bis(2-chloroethyl)phosphorodiamidate (X)**—A stirred mixture of VIII (0.94 g, 4 mmoles), sodium iodide (0.9 g, 6 mmoles), 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene (0.15 g), and acetonitrile (15 ml) at 25° was treated dropwise (30 min) with a solution of *tert*-butyldimethylchlorosilane (1.1 g, 7 mmoles) in acetonitrile (10 ml). After 5 hr, solvent was removed *in vacuo* and the residue was extracted with carbon tetrachloride (15 ml). Removal of carbon tetrachloride *in vacuo* gave X as a viscous pale yellow oil (70%). Attempts to further purify X by flash chromatography on dry silica gel led to hydrolysis of the *tert*-butyldimethylsilyl group, as evidenced by isolation of the corresponding silanol. NMR: δ 3.56 (m, 8H, 4-CH_2), 3.40 (d, 2H, NH_2), 0.92 [s, 9H, C(CH_3)$_3$], and 0.25 [s, 6H, Si(CH_3)$_2$] ppm. IR (neat): 3350 (NH_2), 2980 and 2950 (C—H), 1351 [C(CH_3)$_3$], 1260 (P=O), and 1100 (Si—O) cm^{-1}.

***O*-Trimethylsilyl-*N,N*-bis(2 - chloroethyl)phosphorodiamidate (IX)**—The synthetic procedure was analogous to that described above for X, and yielded IX as a colorless oil (87%). Compound IX is extremely sensitive to atmospheric moisture and rapidly hydrolyzes to give hexamethyldisiloxane, which was identified in partially decomposed samples of IX by chemical shift comparisons with authentic material. NMR: δ 3.55 (m, 8H, 4-CH_2), 3.39 (d, 2H, NH_2), and 0.30 [s, 9H, Si(CH_3)$_3$] ppm. IR (neat): 3324 (NH_2), 2975, 2932, and 2872 (C—H), 1238 (P=O), and 1121 (Si—O) cm^{-1}.

***O*-(*tert*-Butyldiphenylsilyl) -*N,N*- bis(2-chloroethyl)phosphorodiamidate (XI)**—Reaction of VIII and *tert*-butyldiphenylchlorosilane in exactly the same manner as that described above for the synthesis of X afforded crude material, which was chromatographed on a column (40 × 2 cm) of dry silica gel using carbon tetrachloride (100 ml) to first remove *tert*-butyldiphenylsilanol (R_f = 0.3, carbon tetrachloride). Compound XI (65%) was then eluted with ether (150 ml); R_f = 0.78, ether. NMR: δ 7.57 (m, 10H, 2-C_6H_5), 3.49 (m, 8H, 4-CH_2), 3.29 (d, 2H, NH_2), and 1.12 [s, 9H, C(CH_3)$_3$] ppm. IR (neat): 3447 and 3278 (NH_2), 3094 and 3075 (C_6H_5), 2981 and 2895 (C—H), 1372 [C(CH_3)$_3$], 1230 (P=O), 1111 (Si—O), and 743 and 698 (C_6H_5) cm^{-1}.

Bis(2-chloroethyl)amine (nor-nitrogen mustard)—A stirred mixture of bis(2-chloroethyl)amine hydrochloride (35.7 g, 0.2 mole) in ice-water (100 ml) and ether (100 ml) was titrated rapidly with aqueous sodium hydroxide (1 *N*), using phenolphthalein indicator. The ether layer was separated and the aqueous layer was extracted quickly three times with ether (80 ml). The combined ether layer and washings were dried with magnesium sulfate (4 g) at 5° and then carefully concentrated on a rotary evaporator. Rapid Kugelrohr distillation of the residue gave (94%) bis(2-chloroethyl)amine[1] as a colorless oil, bp 46–50° (3 mm). NMR: δ 3.44 (t, 4H, 2-CH_2Cl), 2.77 (t, 4H, 2-NCH_2), and 1.82 (s, 1H, NH) ppm. IR (neat): 3348 (NH) cm^{-1}.

***N*-Trimethylsilyl-*N,N*-bis(2-chloroethyl)amine (XII)**—A solution of trimethylchlorosilane (30 ml, 125 mmoles) in ether (30 ml) was added dropwise (30 min) to a stirred solution of bis(2-chloroethyl)amine (7.1 g, 50 mmoles) and triethylamine (8.4 ml, 55 mmoles) in ether (150 ml) at 5°. After stirring for 15 hr at 25° and then removal of solvent *in vacuo*, triethylamine hydrochloride was separated by suction filtration. Fractional distillation of the filtrate gave (90%) XII as a colorless oil, bp 45–47° (1 mm). Compound XII decomposes relatively slowly at room temperature, but is extremely reactive toward hydrolysis of the trimethylsilyl group to give hexamethyldisiloxane. The presence of this disiloxane in partially hydrolyzed samples of XII is evidenced by chemical shift comparisons with authentic material. NMR δ 3.65 (m, 8H, 4-CH_2) and −0.06 [s, 9H, Si(CH_3)$_3$] ppm. IR (neat): 2980 and 2893 (C—H), 1262 (SiCH_3), and 980 (Si—N) cm^{-1}.

***N*-(*tert*-Butyldimethylsilyl) -*N,N*- bis(2-chloroethyl)amine (XIII)**—Bis(2-chloroethyl)amine (7.1 g, 50 mmoles), *tert*-butyldimethylchlorosilane (9.0 g, 60 mmoles), and triethylamine (9.2 ml) were refluxed in ether (150 ml) for 5 hr. After cooling, triethylamine hydrochloride was removed by suction filtration and fractional distillation of the filtrate led to isolation (83%) of XIII as a colorless oil, bp 58–60° (2 mm), which is best stored at low temperatures with complete exclusion of moisture. NMR: δ 3.95 (t, 4H, 2-CH_2Cl), 3.29 (t, 4H, 2-NCH_2), 1.20 [s, 9H, C(CH_3)$_3$], and 0.03 [s, 6H, Si(CH_3)$_2$] ppm. IR (neat): 2980, 2946, and 2863 (C—H), and 960 (Si—N) cm^{-1}.

[1] Bis(2-chloroethyl)amine undergoes rapid intramolecular alkylation in polar solvents such as water, but may be stored in ether at low temperatures for short periods of time.

Table I—Hydrolysis Kinetic Data [a]

Compound	Initial Concentration, *M*	pH[b]	Method[c]	k'[d], sec^{-1}	$\tau_{1/2}$[e], min
V	1.8×10^{-2}	7.4	NMR	3.00×10^{-3}	3.8
X	1.5×10^{-2}	7.4	NMR	4.02×10^{-4}	28.6

	3.0×10^{-3}	7.4	NMR	1.07×10^{-4}	1.08
	3.0×10^{-3}	8.4	NMR	1.1×10^{-4}	1.14

[a] Compound V was studied in a dioxane–0.05 *M* lutidine buffer (pH 7.4) mixture (60:40), all other NMR studies were similarly carried out using a tromethamine buffer component. All UV studies refer to a dioxane–0.10 *M* tromethamine buffer mixture (50:50). In all cases the temperature was 27 ± 1°. [b] The indicated pH value refers to the aqueous buffer component prior to mixing with dioxane. [c] See text and Experimental section for details. [d] Pseudo first-order rate constant for desilylation, except as noted. [e] $\tau_{1/2} = \ln 2/k'$. [f] Refers to carbonate production following desilylation. [g] Not determined; the reaction was too fast to monitor by the NMR method.

***N*-Aryldimethylsilyl-*N*,*N*-bis(2-chloroethyl)amines**—The procedure described above for compound XII was applied to a series of aryldimethylchlorosilanes and afforded (80–90%) the following products, which were purified by fractional vacuum distillation and identified by NMR (CCl_4): *p*-methoxyphenyl (45–46°, 2 mm), δ 7.20 (broad s, 4H, C_6H_4), 3.60 (s, 3H, OCH_3), 3.50 (m, 8H, 4-CH_2), and 0.13 [s, 6H, $Si(CH_3)_2$]; *p*-tolyl (43–44°, 2 mm), δ 7.40 (broad s, 4H, C_6H_4), 3.60 (m, 8H, 4-CH_2), 2.50 (s, 3H, CH_3), and 0.13 [s, 6H, $Si(CH_3)_2$]; phenyl (40–42°, 2 mm), δ 7.30 (m, 5H, C_6H_5), 3.40 (m, 8H, 4-CH_2), and 0.08 [s, 6H, $Si(CH_3)_2$], *p*-fluorophenyl (41–43°, 2 mm), δ 7.30 (m, 4H, C_6H_4), 3.50 (m, 8H, 4-CH_2), and 0.07 [s, 6H, $Si(CH_3)_2$]; and *p*-chlorophenyl (45–46°, 2 mm), δ 7.40 (m, 4H, C_6H_4), 3.50 (m, 8H, 4-CH_2), and 0.06 [m, 6H, $Si(CH_3)_2$] ppm.

***O*-Trimethylsilyl-*N*,*N*-bis(2-chloroethyl)carbamate (XIV)**—A cold (−10°) solution of XII (2 g, 11 mmoles) in ether (10 ml) and pentane (35 ml) containing bis(2-chloroethyl)amine (0.16 g) as a required catalyst was reacted with anhydrous carbon dioxide gas for 4 hr. The progress of the reaction was monitored by IR with diminishing intensity of the Si—N absorption at 980 cm^{-1} and concomitant increase of the C=O absorption at 1748 cm^{-1} indicating the extent of product formation. Precipitated material was removed by suction filtration, and fractional distillation of the filtrate gave (90%) XIV as a colorless oil, bp 56–57° (1 mm). NMR: δ 3.30 (m, 8H 4-CH_2) and 0.03 [s, 9H, $Si(CH_3)_3$] ppm. IR (neat): 2970, 2933, and 2872 (C—H), 1748 (C=O), 1270 ($SiCH_3$), and 1160 (Si—O) cm^{-1}.

***O*-(*tert*-Butyldimethylsilyl)-*N*,*N*-bis(2-chloroethyl)carbamate (XV)**—Compound XV, bp 82–84° (2 mm), was prepared and isolated (65%) in a manner identical to that described above for XIV. Attempted distillation of XV at somewhat higher pressure and temperature (~100°) led to violent decomposition. NMR: δ 3.55 (broad s, 8H, 4-CH_2), 0.92 [s, 9H, $C(CH_3)_3$], and 0.22 [s, 6H, $Si(CH_3)_2$] ppm. IR (neat): 2981, 2950, and 2880 (C—H), 1750 (C=O), 1380 [$C(CH_3)_3$], 1258 ($SiCH_3$), and 1161 (Si—O) cm^{-1}.

***O*-(*tert*-Butyldiphenylsilyl)-*N*,*N*-bis(2-chloroethyl)carbamate (XVII)**—A solution of *tert*-butyldiphenylchlorosilane (27.5 g, 0.1 mole) in ether (30 ml) was added dropwise (30 min) to a cold (5°) solution of bis(2-chloroethyl)amine (12.6 g, 0.11 mole) and triethylamine (16.8 ml) in ether (270 ml). After 3 hr of stirring at 25°, the reaction mixture was cooled to −10° and (without filtration) anhydrous carbon dioxide was bubbled through it for 4 hr. Precipitated material was separated by suction filtration and ether was removed from the filtrate by fractional distillation. The residue obtained by further concentration *in vacuo* (25°, 0.1 mm, 18 hr) was extracted with benzene (25 ml), leaving undissolved material that was removed by suction filtration. Low-boiling petroleum ether was added to the filtrate until turbidity was apparent, and the solution was then stored in a freezer. Compound XVII was isolated either as an oil or a low-melting solid, mp 40–45°. NMR: δ 7.63 (m, 10H, 2-C_6H_5), 3.76 (m, 8H, 4-CH_2), and 1.22 [s, 9H, $C(CH_3)_3$] ppm. IR (neat): 3106 and 3071 (C_6H_5), 2993, 2951, and 2891 (C—H), 1715 (C=O), 1391 [$C(CH_3)_3$], 1255 ($SiCH_3$), 1121 (Si—O), and 744 and 702 (C_6H_5) cm^{-1}.

***O*-Diphenylmethylsilyl-*N*,*N*-(2-chloroethyl)carbamate(XVI)**—The same procedure described above for the synthesis of XVII gave (75%) XVI as a colorless oil, which was isolated upon cooling the benzene–petroleum ether solution of the crude product. NMR: δ 7.42 (m, 10H, 2-C_6H_5), 3.40 (t, 4H, 2-CH_2Cl), 2.70 (t, 4H, 2-NCH_2), and 0.45 (s, 3H, $SiCH_3$) ppm. IR (neat): 3092, 3075, and 3030 (C_6H_5), 1748 (C=O), 1254 ($SiCH_3$), 1122 (Si—O), and 732 and 698 (C_6H_5) cm^{-1}.

***O*-Tribenzylsilyl-*N*,*N*-bis(2-chloroethyl)carbamate XVIII**—Compound XVIII was synthesized according to essentially the same procedure as that described above for XVI, except that the reaction mixture was treated with gaseous carbon dioxide for 7 hr at −10°. Crystallization of the crude product from benzene–petroleum ether gave pale yellow crystals, mp 106–108°. NMR: δ 6.95 (m, 15H, 3-C_6H_5), 3.51 (m, 8H, 4-CH_2), and 2.00 (s, 6H, 3-$SiCH_2$) ppm. IR (mull): 3070 (C_6H_5), 1716 (C=O), 1155 (Si—O), and 722 and 685 (C_6H_5) cm^{-1}.

***O*-Triethoxysilyl-*N*,*N*-bis(2-chloroethyl)carbamate (XIX)**—The synthetic procedure described above for compound XVII yielded (75%) XIX as a colorless oil, which was isolated upon cooling the benzene–petroleum ether solution of the crude product. NMR: δ 4.06–3.55 (m, 14H, 2-NCH_2CH_2Cl and 3-OCH_2) and 1.25 (t, 9H, 3-CH_3) ppm. IR (neat): 2995 and 2896 (C—H), 1685 (C=O), and 1162 (Si—O) cm^{-1}.

***O*-Aryldimethylsilyl-*N*,*N*-bis(2-chloroethyl)carbamates**—The same procedure described above for compound XIV was applied to each member of the series of *N*-aryl-*N*,*N*-bis(2-chloroethyl)amines and afforded (50–80%) the following products, which were purified by fractional vacuum distillation and identified by NMR (CCl_4): *p*-methoxyphenyl (40–41°, 0.3 mm), δ 6.80 (m, 4H, C_6H_4), 3.80 (s, 3H, OCH_3), 3.30 (m, 8H, 4-CH_2), and 0.35 [s, 6H, $Si(CH_3)_2$]; *p*-tolyl (55–56°, 1 mm), δ 7.20 (broad s, 4H, C_6H_4), 3.20 (m, 8H, 4-CH_2), 2.30 (s, 3H, CH_3), and 0.32 [s, 6H, $Si(CH_3)_2$]; phenyl (53–54°, 1 mm), δ 7.30 (broad s, 5H, C_6H_5), 3.3 (m, 8H, 4-CH_2), and 0.30 [s, 6H, $Si(CH_3)_2$]; *p*-fluorophenyl (42–43°, 0.5 mm), δ 7.40 (m, 4H, C_6H_4), 3.2 (m, 8H, 4-CH_2), and 0.29 [s, 6H, $Si(CH_3)_2$]; *p*-chlorophenyl (50–51°, 0.5 mm), δ 7.50 (m, 4H, C_6H_4), 3.30 (m, 8H, 4-CH_2), and 0.28 [s, 6H, $Si(CH_3)_2$] ppm.

Bis-carbamoyldisiloxane (XX)—A stirred solution of bis(2-chloroethyl)amine (13.1 g, 0.12 mole) and triethylamine (17.6 ml) in ether (250 ml) at 5° was treated dropwise (1 hr) with a solution of 1,3-dichloro-1,1,3,3-tetramethyldisiloxane (10 ml, 0.052 mole) in ether (20 ml). After stirring for 2 hr at 25°, triethylamine hydrochloride was removed by suction filtration and the filtrate was reacted with gaseous anhydrous carbon dioxide for 6 hr at −10°. Further processing as described above for compound XVII led to isolation of XX as a pale yellow oil, which was isolated upon cooling the benzene–petroleum ether solution of crude product. NMR: δ 3.81 (broad s, 16H, 4-NCH_2CH_2Cl), 0.41 [broad s, 6H, 2-$Si(CH_3)_2$] and 0.23 [d, 6H, 2-$Si(CH_3)_2$] ppm. IR (neat): 2940 and 2885 (C—H), 1711 (C=O), 1269 ($SiCH_3$), and 1100 (Si—O) cm^{-1}.

***O*-(*tert*-Butyldimethylsilyl)-*N*-(2-chloroethyl)carbamate (XXI)**—A mixture of *tert*-butyldimethylsilanol (0.8 g, 6 mmoles) and 2-chloroethylisocyanate (3.6 g, 34 mmoles) was heated at 110° for 3 hr, after which time IR analysis indicated the absence of isocyanate starting material (2275 cm^{-1}) and the presence of product (1710 cm^{-1}). Volatiles were removed *in vacuo* (0.1 mm) at 25° and pentane (10 ml) soluble material was then extracted from the residue. Removal of pentane yielded (25%) crude XXI, mp 54–55°, which contained 20% isocyanate starting material and was used without further purification; compound XXI undergoes extensive fragmentation giving silanol and isocyanate when stored at 5° for 2–3 weeks. NMR: δ 5.16 (broad s, 1H, NH), 3.75–3.40 (m, 4H, NCH_2CH_2Cl), 1.03 [s, 9H, $C(CH_3)_3$], and 0.20 [s, 6H, $Si(CH_3)_2$]; integrations corrected for 20% $ClCH_2CH_2NCO$, δ 3.85 (s) ppm, mass spectrum: no M^+; base peak *m/z* 180 (M^+, −57), loss of $C(CH_3)_3$.

***O*-(*tert*-Butyldimethylsilyl)-*N*-{*p*-[*N'*,*N'*-bis(2-chloroethyl)-amino]}phenylcarbamate (XXII)**—A mixture of *p*-isocyanatophenyl mustard (1.09 g, 4.2 mmoles), *tert*-butyldimethylsilanol (0.39 g, 3

Table II—Screening Data for *In Vivo* Anticancer Activity against L-1210 Lymphoid Leukemia and P-388 Lymphocytic Leukemia in Mice

Compound	Vehicle[a]	Dose/Inj., mg/kg	Total Inj.	Treatment Schedule[b]	Screen[c]	max T/C, %[d]

XXVII	C	200	5	1 × 5	L 1210	131

[a] A = mixture of distilled water and polyoxyethylene sorbitan monooleate; B = hydroxypropylcellulose; C = mixture of saline and polyoxyethylene sorbitan monooleate; D = saline. Samples for injection were prepared immediately prior to use. [b] For example, 4 × 3 indicates a 4-day interval between treatments repeated three times; all injections were given ip. [c] For L-1210, the inoculum was 10^5 cells; for P-388, the inoculum was 10^6 cells. [d] Maximum T/C evaluation parameter which was obtained, where T/C % = (treated survivors/control survivors) × 100. A value of ≥125% indicates activity. In all cases, the max T/C % was obtained without drug-associated mortality.

mmoles), and toluene (15 ml) was refluxed until the isocyanate IR absorption (2268 cm^{-1}) was no longer detected (24 hr). Concentration *in vacuo* (0.1 mm) at 25° gave a pale yellow oil, which was extracted three times with low-boiling petroleum ether (45 ml). The combined petroleum ether extracts were concentrated to half-volume and then kept at −10° for 15 hr to afford (60%) product XXII, mp 58–60°. NMR (220 MHz): δ 7.40–6.50 (AA′BB′ q, 4H, C_6H_4), 3.64 (m, 8H, 4-CH_2), 0.85 [s, 9H, $C(CH_3)_3$], and 0.21 [s, 6H, $Si(CH_3)_2$] ppm. IR (neat melt): 3348 (NH), 3085 (C_6H_5), 2982 and 2880 (C—H), 1715 (C=O), 1260 ($SiCH_3$), 1120 (Si—O), and 837 (C_6H_4-*p*) cm^{-1}.

Anal.—Calc. for $C_{17}H_{28}N_2O_2SiCl_2$: C, 52.17; H, 7.16; N, 7.16. Found: C, 52.13; H, 7.12; N, 7.28.

***O*-(*tert*-Butyldimethylsilyl)chlorambucil (XXIII)**—A solution of chlorambucil[2] (0.92 g, 3 mmoles) in benzene (10 ml) was added dropwise (20 min) to a stirred suspension of sodium hydride (96 mg, 4 mmoles) in benzene (3 ml) at 25°. After continued stirring for 3 hr, a solution of *tert*-butyldimethylchlorosilane (0.76 g, 5 mmoles) in benzene (5 ml) was slowly added (20 min), and the mixture was refluxed for 3 hr. The reaction mixture was cooled to 25° and solid materials were removed by suction filtration. The filtrate was concentrated and further removal of volatile *in vacuo* (0.1 mm) at 25° yielded (77%) XXIII as a viscous pale yellow syrup. NMR (carbon tetrachloride): δ 6.65 (AA′BB′ q, 4H, C_6H_4), 3.56 (broad s, 8H, 2-NCH_2CH_2Cl), 2.75–1.65 (m, 6H, $CH_2CH_2CH_2$), 0.86 [s, 9H, $C(CH_3)_3$], and 0.15 [s, 6H, $Si(CH_3)_2$] ppm. IR (neat): 3030 (C_6H_4), 2975 and 2875 (C—H), 1722 (C=O), 1371 [$C(CH_3)_3$], 1200 ($SiCH_3$), 1155 (Si—O), and 832 (C_6H_4-*p*) cm^{-1}.

***O*-(*tert*-Butyldiphenylsilyl)chlorambucil (XXIV)**—Chlorambucil (0.92 g, 3 mmoles), sodium hydride (96 mg, 4 mmoles), and *tert*-butyldiphenylchlorosilane (0.83 g, 3 mmoles) were used to prepare XXIV in a manner identical to that described above for XXIII. The product was isolated (77%) as a viscous oil, which showed no evidence (NMR) of significant contamination by either the starting chlorosilane or its corresponding silanol. NMR: δ 7.90–7.15 (m, 10H, 2-C_6H_5), 7.15–6.35 (AA′BB′ q, 4H, C_6H_4), 3.55 (broad s, 8H, 2-NCH_2CH_2Cl), 2.75–1.40 (m, 6H, $CH_2CH_2CH_2$), and 1.13 [s, 9H, $C(CH_3)_3$] ppm.

***N*-(*tert*-Butyldimethylsilyl)cyclophosphamide (XXV)**—A solution of *tert*-butyldimethylchlorosilane (0.75 g, 5 mmoles) in ether (10 ml) was added slowly (30 min) to a stirred solution of anhydrous cyclophosphamide[3] (0.79 g, 3 mmoles) and triethylamine (0.5 ml) in ether (20 ml) at 5°. After continuous stirring for 24 hr at 25°, the reaction mixture was cooled to −78° and solid materials were collected at that temperature by suction filtration under a nitrogen atmosphere. The solids were immediately extracted with tetrahydrofuran, and this solvent was then removed on a rotary evaporator. The residue was chromatographed on a column (40 × 4 cm) of dry silica gel, using chloroform as the eluent, and the concentrated eluate gave XXV as low-melting crystals, mp 45–47°. NMR (220 MHz): δ 4.46–4.15 (m, 2H, OCH_2) 3.70 (t, 4H, 2-CH_2Cl), 3.45–3.20 (m, 6H, 3-NCH_2), 2.20–1.64 (m, 2H, $CH_2CH_2CH_2$), 1.09 [s, 9H, $C(CH_3)_3$], 0.37 (s, 3H, $SiCH_3$), and 0.22 (s, 3H, $SiCH_3$). The observation of resonance doubling for the $Si(CH_3)_2$ moiety is due to the chirality at phosphorus in XXV (diastereotopic CH_3 groups), and unambiguously establishes that the *tert*-butyldimethylsilyl group is bonded to the cyclophosphamide ring system. ^{31}P-NMR (deuterochloroform, 25% H_3PO_4 external reference): δ 13.82 *versus* 10.78 for cyclophosphamide ppm, mass spectrum: no M^+; *m/z* 317 (M^+, −57), loss of $C(CH_3)_3$, 2-Cl isotope cluster.

***O,O*-Bis(*tert*-butyldimethylsilyl)fluorouracil (XXVI)**—A stirred mixture of fluorouracil (1.30 g, 10 mmoles) and *tert*-butyldimethylchlorosilane (3.3 g, 22 mmoles) in benzene (20 ml) was brought to reflux, and a solution of triethylamine (3.4 ml, 22 mmoles) in benzene (8 ml) was then added dropwise over a 1-hr period. The mixture was refluxed for an additional 15 hr, and then cooled to 25° for separation of triethylamine hydrochloride and unreacted fluorouracil by suction filtration. Volatile materials were removed first on a rotary evaporator and then under high vacuum (0.1 mm) at 25° for 24 hr. The residual material was dissolved in ether (15 ml) decolorized with dry activated charcoal, and then reconcentrated to afford XXVI (67%) as a colorless oil, which crystallized upon standing at −10°, mp ~30°. Contamination of XXVI by fluorouracil was excluded by NMR and IR analyses, which showed no detectable absorptions due to the amido functionalities. Compound XXVI is extremely reactive toward moisture. NMR: δ 7.88 (d, 1H, vinylic H), 0.99 [two overlapping s, 18H, 2-$C(CH_3)_3$], 0.33 [s, 6H, $Si(CH_3)_2$], and 0.21 [s, 6H, $Si(CH_3)_2$] ppm.

***tert*-Butyldimethylsilylftorafur (XXVII)**—A stirred mixture of ftorafur (2 g, 9.8 mmoles) and *tert*-butyldimethylchlorosilane (3 g, 20 mmoles) in benzene (35 ml) was brought to reflux, and a solution of triethylamine (2 ml) in benzene (10 ml) was then added dropwise over a period of 1 hr. The mixture was further reacted and processed as described above for XXVI to afford (56%) product XXVII, mp 149–150°, which was recrystallized from carbon tetrachloride. NMR: δ 7.52 (d, $^3J_{FH}$ = 6 Hz, 1H, vinyl), 6.10 (m, 1H, methine), 4.50–3.80 (m, 2H, CH_2O), 2.70–1.85 (m, 4H, CH_2CH_2O), 0.95 [s, 9H, $SiC(CH_3)_3$], and 0.15 [s, 6H, $Si(CH_3)_2$] ppm.

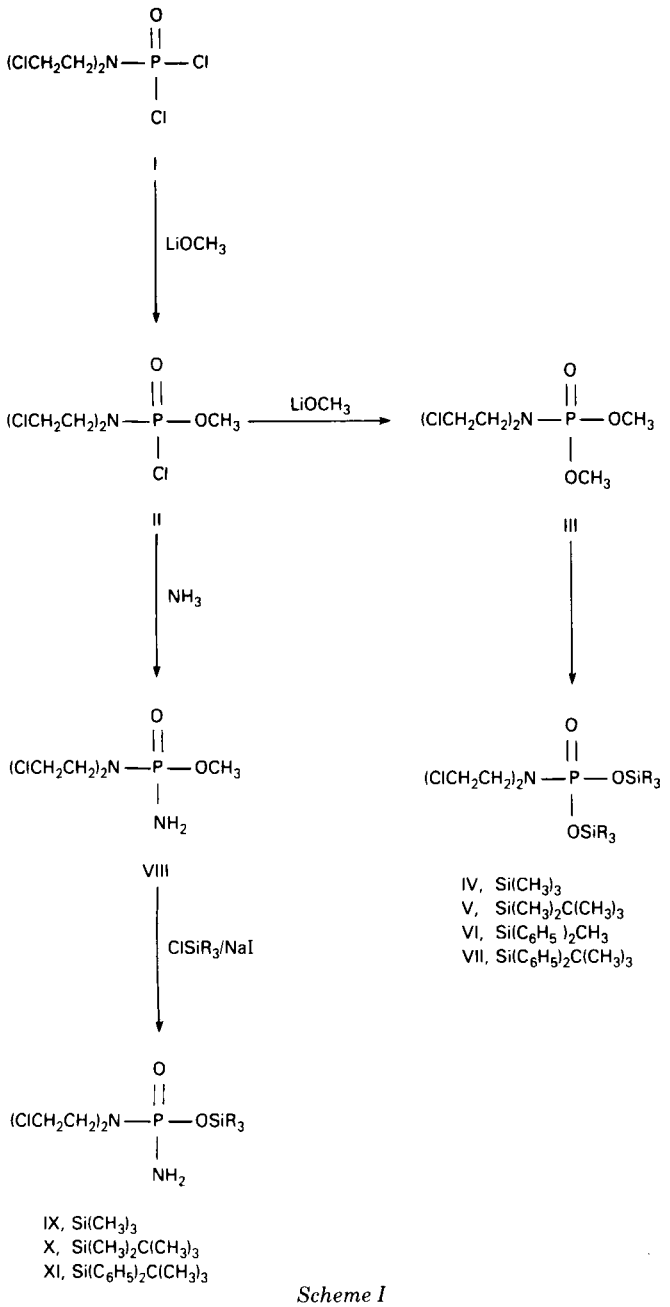
***O*-Trimethylsilylbenzohydroxamic Acid (XXVIII)**[4]—A solution of benzohydroxamic acid (1.37 g, 10 mmoles), trimethylchlorosilane (1.27 ml, 10 mmoles), and triethylamine (1.5 ml, 10 mmoles) in tetrahydrofuran (15 ml) was stirred for 3 days at 25°, and triethylamine hydrochloride was then removed from the reaction mixture by suction filtration. After initial concentration of the filtrate on a rotary evaporator, the residue was kept under high vacuum (0.1 mm) for 2 days at 25°. The crude crystalline product (~100%), mp 96–99°, was used without further purification (25% starting material) due to its hydrolytic reactivity. For XXVIII, NMR: δ 8.00 (broad s, 1H, NH), 7.80–7.42 (m, 2H, *ortho* H), 7.40–7.18 (m, 3H, *meta* and *para* H), and 0.15 [s, 9H, $Si(CH_3)_3$].

***O*-(*tert*-Butyldimethylsilyl)benzohydroxamic Acid (XXIX)**—The synthetic procedure described above for compound XXVIII was applied

[2] Chlorambucil (NSC-3088) was obtained from the Drug Synthesis and Chemistry Branch of the National Cancer Institute.

[3] Cyclophosphamide monohydrate (NSC 26271) was obtained from the Drug Synthesis and Chemistry Branch of the National Cancer Institute. Water of hydration was removed *in vacuo* over phosphorus pentoxide (0.1 mm, 25°, ≥48 hr).

[4] For the preparation of *N,O*-bis(trimethylsilyl)benzohydroxamic acid and its *para*-substituted derivatives, see Ref. 14.



Scheme I

to the reaction of benzohydroxamic acid (1.37 g, 10 mmoles) with equimolar amounts of *tert*-butyldimethylchlorosilane and triethylamine. The resultant product (~100%), mp 127–129°, was found by NMR analysis to be free of detectable contamination by its bistriorganosilylated analog. NMR: δ 8.23 (broad s, 1H, NH), 8.00–7.67 (m, 2H, *ortho* H), 7.67–7.27 (m, 3H, *meta* and *para* H), 1.00 [s, 9H, $C(CH_3)_3$], and 0.25 [s, 6H, $Si(CH_3)_2$].

Anal.—Calc. for $C_{13}H_{21}NO_2Si$: C, 62.11; H, 8.42; N, 5.57. Found: C, 62.12; H, 8.37; N, 5.81.

***N,O*-Bis(*tert*-butyldimethylsilyl)hydroxyurea (XXX)**—A solution of *tert*-butyldimethylchlorosilane (3.8 g, 25 mmoles) in ether (15 ml) was added dropwise (50 min) to a stirred solution of hydroxyurea (1.52 g, 20 mmoles) and triethylamine (3.06 ml, 20 mmoles) in ether (25 ml) at 5°, and the mixture was stirred at 25° for 18 hr. Triethylamine hydrochloride was removed by suction filtration, and the filtrate was concentrated on a rotary evaporator. The residue was extracted with ether (25 ml) and XXX was then obtained (25%) as a microcrystalline solid (mp 92.5–110°) by removal of solvent *in vacuo* (18 hr, 0.1 mm, 20°). NMR: δ 5.80 (broad s, 1H, NHO), 5.30 (broad s, 1H, NH), 0.93 [s, 18H, 2-$C(CH_3)_3$], 0.25 [s, 6H, $OSi(CH_3)_2$], and 0.17 [s, 6H, $NSi(CH_3)_2$]. Mass spectrum: *m/z* 304 (M^+), <1%; 247 (M^+, −57), 36%, loss of $C(CH_3)_3$.

Prodrug Hydrolysis Kinetics by NMR—The compound (15–23 mmoles) to be studied was placed in an NMR tube and then dissolved in dioxane (0.60 ml). Either tromethamine or lutidine buffer (0.40 ml, 0.05 *M*, pH 7.4) was added, and after rapid mixing the spectral region from δ 0.7–0 was repeatedly recorded as a function of time using a fixed-sweep rate. Total peak height for starting material and the triorganosilanol hydrolysis product remained constant and was equated with the initial concentration of starting material, C_0. The decreasing peak height for starting material was equated with the concentration of starting material at time *t*, C_t. Linear least-squares fits of $\ln(C_0/C_t)$ *versus* *t* gave the pseudo first-order rate constants (*k'*) and half-life ($\tau_{1/2}$) values listed in Table I. The NMR probe temperature (27 ± 1°) was measured using the chemical shift difference between methyl and hydroxyl protons in methanol (15).

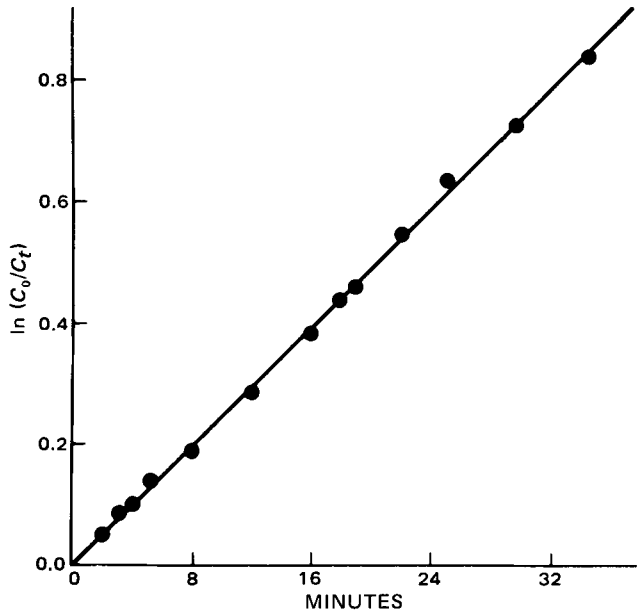


Figure 1—*Pseudo first-order kinetic plot for hydrolysis of X (1.5 × 10^{-2} M) in dioxane–0.05 M tromethamine buffer (pH 7.4) mixture (60:40) at 27°. Substrate concentration terms C_0 and C_t were determined by NMR (see text for details).*

Prodrug Hydrolysis Kinetics by UV—Stock solutions of each compound were prepared in dioxane at concentrations of 6.0 × 10^{-4}–5.4 × 10^{-2} *M*. An aliquot (1.5 ml) was rapidly mixed with an equal volume of tromethamine buffer (0.1 *M*, pH 7.4–8.4), and the reaction mixture was monitored continuously as a function of time *t*, using a fixed wave-

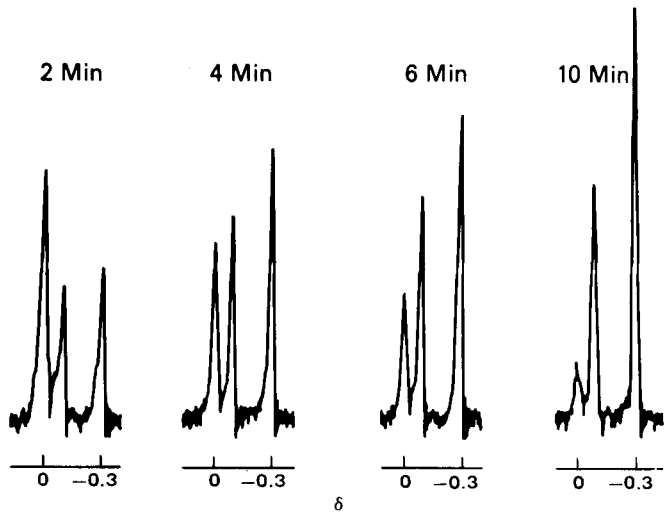

Figure 2—*Variation in the dimethylsilyl NMR (60 MHz) spectral region for V (1.8 × 10^{-2} M) as a function of time (min) in dioxane–0.05 M lutidine buffer (pH 7.4) mixture (60:40) at 27°. Chemical shifts are relative to V (0 δ); the absorption signal at −0.08 δ is assigned to the monoester derived from partial hydrolysis of V, while the* tert*-butyldimethylsilanol signal is at −0.30 δ.*

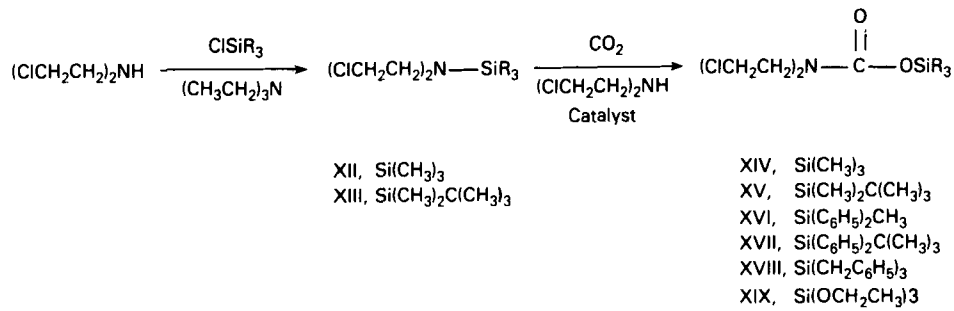
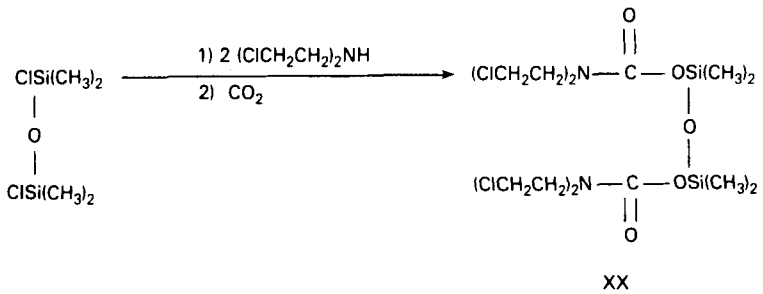
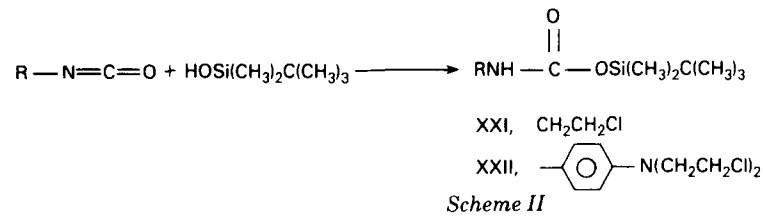




XX



Scheme II

length (Table I) and a reference sample containing the dioxane–buffer mixture (50:50). The initial absorbance was equated with A_0 and the final absorbance after 4 hr was equated with A_∞. Linear least-squares fits of $\ln [(A_\infty - A_0)/(A_\infty - A)]$ *versus* t gave the pseudo first-order rate constants (k') and half-life ($\tau_{1/2}$) values listed in Table I. The temperature (27 ± 1°) of the UV samples after equilibration in the spectrophotometer was measured with a small thermometer.

NMR Kinetic Measurements with Aryldimethylsilyl Compounds—Each of the five *N*-aryldimethylsilyl-*N*,*N*-bis(2-chloroethyl)-amines (2.5×10^{-2} mmoles) was dissolved in deuterochloroform (0.5 ml) and was then reacted with a large excess of absolute ethanol (0.5 ml) using NMR to monitor the reaction rate at a spectrometer probe temperature of 27 ± 1°. The relative concentrations of each starting material and its corresponding ethoxysilane product were determined from dimethylsilyl absorption intensities at $\delta \sim 0.15$ and ~0.08, respectively, using scale-expansion, low RF-power, and a fast sweep rate. Linear least-squares fits of $\ln(C_0/C_t)$ *versus* t had an average slope-error of ± ~5%, and gave the following pseudo first-order rate constants: p-OCH_3, 1.14×10^{-3} sec^{-1} ($\tau_{1/2}$ 10.1 min); p-CH_3, 1.43×10^{-1} sec^{-1} ($\tau_{1/2}$ 8.1 min); p-H, 2.73×10^{-3} sec^{-1} ($\tau_{1/2}$ 4.2 min); p-F, 6.86×10^{-3} sec^{-1} ($\tau_{1/2}$ 1.7 min); and p-Cl, 1.04×10^{-2} sec^{-1} ($\tau_{1/2}$ 1.1 min). The previously described NMR method for
