JOURNAL OF PHARMACEUTICAL SCIENCES

A publication of the American Pharmaceutical Association

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C. and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $75; educational institutions $75; individuals *for personal use only* $40; single copies $10. APhA and SAPhA members may subscribe to *J. Pharm. Sci.* for $20.00 per year. All foreign subscriptions add $10 for postage. Subscription rates are subject to change without notice.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., 21 Congress St., Salem, MA 01970. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

Scientists Respond to Tylenol Crisis

Surely, all of the writers who prepare "year-end wrap-up articles," in which they list and summarize the big news stories of 1982, will include the Tylenol incident and related product tampering as one of the most notorious events of the year.

The episode constituted a major "happening" just in itself. But beyond the effect it had on the victims and their families and friends, the tragic incident has had a profound impact that is far broader. For example, it is little exaggeration to say that (*a*) it has affected human behavior for many, if not most, Americans; (*b*) it has shaken public confidence in the quality and reliability of many common products; and (*c*) it has revolutionized the packaging of consumer products and particularly nonprescription drug products.

Consequently, considerable attention has been devoted to the reaction and performance of the health care professions in the days and weeks following the initial Tylenol news reports.

Almost without exception, all those involved—from individual practitioners to the overall drug industry—behaved admirably. Virtually everyone kept "calm, cool, and collected," as per the standard recommendation for dealing with emergencies. Suitable advice, in keeping with the degree of information available at the time, was generally given by pharmacists and other practitioners. Panic was avoided despite the fertile conditions that prevailed.

The American Pharmaceutical Association issued a statement entitled "The Tylenol Issue in Perspective," and it seemed to go a long way toward helping to generate rational thinking and sensible reaction. Many other organizations undertook comparable or analogous efforts.

But what about scientists? Where were they? What did they do? And how well did they perform?

To date, we have not heard nor read of any effort to analyze or assess such performance by the scientists involved. Hence, it seems timely and appropriate to do so in this column.

Initially, it was medical scientists who made the diagnosis and clinical laboratory scientists who confirmed cyanide as the causative agent. Unquestionably, this prompt detective work was instrumental in holding down the number of deaths by enabling the authorities to issue bulletins and warnings expeditiously and for the press and broadcast media to communicate that alarming information so quickly on a nationwide basis.

Secondly, scientists effectively participated in the testing and analytical phases of the massive screening and monitoring program to assess the extent of the tampering in terms of geography, product line, manufacturers involved, and so on. No drug, cosmetic, or packaged food distributor could feel secure in those early days of the tragedy, and the responsibility for decisions as to what testing was needed, as well as the burden of conducting the testing itself, fell squarely on scientists in industry. Similarly, comparable decisions and follow-up testing were expeditiously handled by regulatory scientists in government service.

Thirdly, scientists quickly and correctly pointed out that any effort to make products "tamper-proof," or to require such product packaging through legislation, was doomed to failure. They convincingly explained that it is impossible to achieve such a result in any way that approaches being pragmatic.

Finally, scientists and engineers have quickly come up with workable designs and the necessary technology to implement them, whereby millions upon millions of individual packages can be made tamper-resistant—and at an extremely high level of reliability.

Hence, scientists not only participated and responded in this time of crisis, but they have made critical contributions in minimizing the tragedy itself as well as in proceeding toward workable, prompt, and effective solutions to avoid the possibility of any reoccurrences.

Indeed, through it all, we are aware of only one disappointing action on the part of the scientific community.

A prominent toxicologist sent off a letter calling "for legislation restricting and controlling the availability of potent poisons." But since (*a*) the letter was personally addressed to U.S. President Ronald Reagan, (*b*) it urged the President "to appoint a Presidential Task Force to study the situation and recommend appropriate restrictive legislation," and (*c*) it was publicly distributed with a news release to the press, we suspect that it was done more as a grandstand publicity play than as a serious recommendation.

Cyanide salts alone are widely used in many industrial processes, as well as in medical, scientific, and manufacturing laboratories. And beyond cyanide, there are numerous poisonous substances used to produce common, everyday, important products; in many instances, these poisonous substances may be an ingredient or even the sole ingredient of those products. Household cleaners—such as bleach, ammonia, and drain cleaners containing sodium hydroxide—are just a few examples. Garden products such as pesticides, herbicides, and fertilizers; and fuels such as gasoline, kerosene, and methyl alcohol are several others.

Obviously, it is totally impractical to restrict and control all poisons. The approach being implemented by the Food and Drug Administration with regard to requiring tamper-resistant packaging seems to be well conceived and carefully balanced. And again, it was scientists—this time government regulatory scientists—who assisted the legal people in drafting the proposed regulations.

The bottom line is that all scientists can be proud of the contributions their scientific colleagues have made in resolving one of the major crises of recent times.

Literature Survey

Physical and Biological Properties of Pyrilamine

THOMAS J. HALEY

Received December 7, 1981, from the *Department of Health and Human Services, Food and Drug Administration, National Center for Toxicological Research, National Toxicology Program, Jefferson, AR 72079.*

Keyphrases □ Pyrilamine—antihistamine, chemistry, pharmacology, metabolism, toxicology, mutagenicity, teratogenicity, carcinogenicity, literature survey □ Antihistamine—pyrilamine, chemistry, pharmacology, metabolism, toxicology, mutagenicity, teratogenicity, carcinogenicity, literature survey □ Structure–activity relationships—pyrilamine, chemistry, pharmacology, metabolism, toxicology, mutagenicity, teratogenicity, carcinogenicity, literature survey

When metapyrilene was found to be an animal carcinogen a search was begun to obtain another drug for use in nonprescription sleeping aids (1). It appeared that a related compound, pyrilamine, an antihistamine with sedative properties, could be used (2). This resulted in pyrilamine, which is structurally related to methapyrilene, being nominated for a National Toxicology Program carcinogenesis bioassay. As a result the chemistry, pharmacology, metabolism, toxicology, mutagenicity, teratogenicity, and carcinogenicity of pyrilamine was reviewed.

CHEMISTRY

Background—Production of antihistamines in the United States in 1976 was 217.2×10^3 kg, but data on pyrilamine production is unknown (3).

Pyrilamine has not been found in U.S. drinking water supplies (4), industrial effluents (5), or European water supplies (6).

It has been used as an antihistamine in treatment of allergies (7).

Synthesis—Table I (2, 8–10) gives the structure and physical and chemical properties of pyrilamine. This chemical is prepared by condensing 2-(*N*-*p*-methoxybenzyl)aminopyridine with dimethylaminoethyl chloride or by condensing *N*,*N*-dimethylaminoethyl-α-aminopyridine with *p*-methoxybenzyl chloride in the presence of sodamide or lithamide (11–14).

Analysis—Pyrilamine was separated by TLC on silica gel G plates using benzene–dioxane–diethylamine–absolute ethanol (50:40:5:5) as a solvent system, and several identifying agents (15). It was determined using silica gel G plates, 18 different solvent systems, and 8 chromogenic reagents (5). Another technique used the following solvent systems containing 0.1 *M* NaBr: methanol–butanol (60:40); chloroform–methanol (90:10); and ethyl acetate–cyclohexane–methanol (70:15:5). The use of these ion-paired adsorption systems gave improved, more reproducible separations (16). Celite columns acidified with tosic acid, 0.1 or 1.0 *M* HCl, 10.0 *M* H_2SO_4, or 1.0 *M* H_3PO_4 were used in ion-pair extraction followed by partition chromatography to separate pyrilamine and codeine (17). Other inorganic ions such as Cl^-, Br^-, I^-, NO_3^-, ClO_4^-, SCN^-, and SO_4^{2-} were also used (18).

Chromatographic columns[1] were used as anion and cation exchangers to separate pyrilamine from other amines (19). Thin-layer plates composed of silica $60F_{254}$[2], silica $60F_{254}$[2] sprayed with 0.1 *N* NaOH, silica G-25, alumina[2] $F_{254}E$, and cellulose type F[2] sprayed with 5% sodium dihydrogen citrate were used to separate pyrilamine from other amines and to determine recovery percentages (20). TLC was systematized by relating R_f values and solvent systems of five to seven test substances and coding the results into tables for rapid identification (21). This approach was applied to 76 prescription drugs (22) and other therapeutically significant organic bases (23).

TLC using plates[3] and extraction with 1,2-dichloroethane was used to identify 32 basic poisons (24). Pyrilamine was identified using nine color reagents (25), silica gel microfiber sheets[4] and the following solvent systems:

[1] Sephadex SPC 25 or QAE 25.
[2] Merck.
[3] Keiselgel.
[4] ITLC type SA.

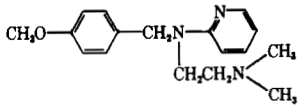
Table I—Structure and Physical and Chemical Properties of Pyrilamine[a]



Physical State	Oily liquid
Boiling Point	201°(5 mm); 168–172°(0.06 mm)
Solubility	Soluble in acids
Refractive Index	n_D^{25} 1.5760–1.5765
CAS Number	91849
Molecular Weight	285.58
Spectroscopic Data	IR spectra 2940, 2780, 1590, 1520, 1490, 1450, 1350, 1320, 1250 1180, 1040, 980, 760, 730; UV spectra 310, 247; pH 0.1 316, 238; pH 1.0 314, 238; pH 4.1 308, 239; pH 5.7 306, 244 nm.
Volatility	Slightly volatile
Stability	Turns brown on exposure to light
Reactivity	Reacts with acids to form salts
Synonyms	*N*-[(4-methoxyphenyl)methyl]-*N'*,*N'*-dimethyl-*N*-2-pyridinyl-1,2-ethanediamine; 2[(2-dimethylaminoethyl-*p*-methoxybenzyl)amine] pyridine; *N*-*p*-methoxybenzyl-*N'*,*N'*-dimethyl-*N*-α-pyridylethylenediamine; Mepyramine; Pyranisamine; Neo-Antergan.

ethyl acetate–cyclohexane–ammonia–methanol–water (70:15:2:7:0.5); ethyl acetate–cyclohexane–methanol–ammonia, (50:40:0.7:0.4); ethyl acetate–cyclohexane–methanol–ammonia (70:15:10:5); ethyl acetate–cyclohexane–ammonia (50:40:0.1). Correlations between R_f values from five systems and chemical groups indicated that steric hindrance around the group responsible for the bonding to silica in a particular system, compound basicity, and the presence or absence of a pyridyl group influenced the R_f values to the greatest extent (26).

Carboxylmethylcellulose ion exchange paper (CM82) and the solvent system of water–acetone–formamide (10:1:1) easily separated pyrilamine from other antihistamines (27). Thin-layer electrophoresis on silica gel G plates was used to separate 23 basic drugs (28). Using chromatographic sheets[5] pyrilamine was separated with methanol and identified with Dragendorff's reagent or 0.3% aqueous sodium nitrate (29). Separation on silica gel $60F_{254}$ plates was reported (30) using the following solvent systems: chloroform–methanol (9:1); methanol–concentrated ammonium hydroxide (100:1.5); and chloroform–acetone (9:1); and identified under UV light (254 nm) followed by spraying with either iodine in methanol, modified Ludy–Tenger reagent, or iodine in methanol and copper chloride. Colorimetric determination of pyrilamine was performed using the pyrocatechol violet method (31). The drug was allowed to react with aniline and cyanogen bromide reagent and then was determined at 410 nm (32). Pyrilamine has been spectrophotometrically determined using the Δpi method at 236 nm with an accuracy of 100.2 ±0.8% (33). Various pharmaceutical preparations were analyzed by UV spectrophotometry to determine the pyrilamine content (34). After separation on a cation-exchange resin, alginic acid, pyrilamine was determined by UV spectrometry with an accuracy of 98.97% (35). Difference spectrophotometry at 320 nm (36) and by GC using a column[6] with a flame ionization detector were used in another study (37). Pyrilamine was determined by GC using columns of 20% GESF-96 on 45–60 mesh Chromosorb P and 5% SE-30 on 80–100 mesh Chromosorb A with cyclohexanedimethanol succinate and a thermoconductive detector (38).

A column of 1% cyclohexanedimethanol succinate on 100–120 mesh silanized GC P and a flame ionization detector were also used to determine pyrilamine after acetone–ether extraction of blood (39). A column of 200 mg of cyclohexanedimethanol succinate and 2.0 g of methylphenyl silicone on 80–100 mesh diatomaceous earth was used (40) and columns of OV-1 and OV-17 were employed under isothermal conditions (41). Retention indexes for 230 chemicals including pyrilamine were reported for analyses on SE-30, OV-1, and OV-17 columns under isothermal conditions at 180° (42). Discriminating power analysis for GC showed that columns of either SE-30 or OV-17 possessed the highest discriminating powers for separation and determination of 62 basic drugs (43). GC analysis using a column of 3% OV-17 on high-performance Chromosorb W was used to separate pyrilamine from other street drugs (44).

Columns of either 2.1 or 4.1 g of Dexsil 300 on 18 g of 80–100 mesh Chromosorb W (HP) with a flame ionization detector and an automatic sample injector were used to determine pyrilamine in pharmaceutical preparations (45). Detection in blood from cases of overdosage was possible using columns of 3% OV-17 on 100–200 mesh screens or 1% SP-1000 on 100–200 mesh screens[7] using a nitrogen–phosphorus detector (46).

GC analysis of stored blood samples indicated that the drug was stable for at least 7 months (47). Gas chromatography–mass spectrometry (GC–MS), was used to detect pyrilamine in blood plasma (48), and it was found (49) for pyrilamine and its deuterated analogs that single-ion monitoring at *m/z* 121 gave more precise ratios than multiple-ion monitoring at *m/z* 121 and 124 (49).

Direct thin-layer chromatography–mass spectrometry (TLC–MS) was applied to pyrilamine and 30 μg was detected (50). Isocratic multi-column HPLC with a variable wavelength UV detector was found useful to characterize pyrilamine eluted from columns of silica, silica treated with 3-mercaptopropyltrimethoxysilane, or a strong aliphatic cation exchange (51). A phenyl column[8], using a UV detector set at 254 nm, could detect 18 ng of pyrilamine (52). Use of a column consisting of a monomolecular layer of octadecyltrichlorosilane permanently bonded to Si—C, and a UV detector set at 254 nm, enabled the HPLC separation of pyrilamine from various other drugs (53). HPLC was used to separate pyrilamine from pentobarbital in polyethylene glycol-based suppositories (54).

After testing 15 HPLC systems, it was found that the best separations were obtained with acetonitrile–water–propylamine[9] (90:10:0.01) and CN-10, heptane–methylene chloride–acetonitrile–propylamine (50:50:25:0.1) using commercially available columns[10] (55).

METABOLISM AND STRUCTURE-ACTIVITY RELATIONSHIPS

Metabolism and Metabolic Products—One study suggested that pyrilamine can be *N*-demethylated but that

[5] Eastman 6061.
[6] 15% Dexsil 300 on Chromosorb W.
[7] Supelcocort.
[8] μBondapak.
[9] Micropak CN-10.
[10] Micropak CN-10.

more information is needed on cellular distribution, metabolism, and excretion (56). Intravenous injection of pyrilamine in rabbits did not increase the urinary excretion of histamine but did significantly increase the excretion of histamine metabolites (57). Pyrilamine increased brain histamine by blockade of central histaminergic receptors and the inhibition of histamine-*N*-methyltransferase (58) but was ineffective in decreasing histamine uptake in the heart and stomach of rats (59).

In rats, intraventricular injection of histamine affected dopamine metabolism by increasing the amount of homovanillic acid in the striatum. This effect was blocked by pyrilamine (60). Pyrilamine inhibited the activity of histamine-*N*-methyltransferase in the brain, ileum, atrium and stomach of the guinea pig *in vivo* and *in vitro* (61). Histamine-*N*-methyltransferase from pig atrium was inhibited by pyrilamine when the substrate was histamine but not when the substrate was *N'*-methylhistamine (62). Purified guinea pig histamine-*N*-methyltransferase was inhibited by pyrilamine (63). It inhibited rat liver phosphatidate phosphohydrolyase but had no effect on glycerol phosphate acyltransferase or diacylglycerol acyltransferase (64).

In another study, pyrilamine inhibited rat liver phosphatidate cytidylyltransferase, glycerol phosphate acyltransferase, and phosphatidate phosphohydrolyase (65). This inhibition had a marked effect on lipid metabolism (66). Pyrilamine blocked guinea pig adenylcyclase activity induced by tolazoline and to a lesser extent that induced by histamine (67).

Structure–Activity Relationships—Pyrilamine is a derivative of ethylenediamine and modifications in this moiety can cause extreme changes in antihistaminic potency. The terminal nitrogen atom must be tertiary; replacement of the dimethyl group with a diethyl group decreased potency as did quaternization; the chain between the nitrogen atoms must be two carbon atoms and it should not be branched; the replacement of the pyridyl group with pyrimidyl or halogenated phenyl groups did not affect potency, but substituting an additional pyridyl group for the benzyl group decreased potency, while substituting a *para*-methoxy group increased potency (68).

Pharmacodynamics and Kinetics—Pyrilamine blocked the hypotensive action of both histamine and 5-hydroxytryptamine in the rat (69). It markedly potentiated the depressor response of isoproterenol in the dog, had no effect on the isolated rat seminal vesicle preparation but antagonized epinephrine and norepinephrine, reduced the inhibitory effects of these latter drugs on the guinea pig tracheal chain, and relaxed the isolated rabbit ileum. Pyrilamine had no effect on the hind limb preparation of the rat and potentiated the positive inotropic and chronotropic effects of isoproterenol on the rabbit heart *in situ* (70). Pyrilamine was shown to be a noncompetitive antagonist to epinephrine and norepinephrine when tested on the rabbit aortic strip, rat seminal vesicle, and dog blood pressure. It reduced the response of the dog retractor penis muscle and the rat fundal strip to catecholamines (71). When applied topically (72), pyrilamine was a potent constrictor of the mammalian capillary bed of the rat. Pyrilamine significantly attenuated the baroreceptor reflex vasoconstrictor and the vasoconstrictor effect of intra-arterial histamine, but had no effect on such responses induced by intra-arterial norepinephrine in the isolated, perfused gracilis muscle of the dog (73).

Pyrilamine blocked the pressor response and potentiated the depressor response in rabbits given intravenous histamine (74). It also blocked the constrictor response of the isolated rabbit ear artery but had no effect on the perfused human temporal artery (75). Intra-arterial histamine caused a dose-dependent vasodilatation in the carotid vascular bed of the dog which was only partially blocked by pyrilamine (76, 77). In monkeys, pyrilamine only partially blocked the histamine response in the external carotid circulation but had a greater effect on the internal carotid circulation (78). The histamine depressor response in the monkey was partially blocked (79). Increases in blood flow in the left circumflex coronary artery of the dog induced by histamine infusion were only partially blocked by pyrilamine (80). Perfusion of pyrilamine from the lateral ventricle to the cisterna magna in dogs gave a hypertensive followed by a hypotensive response (81). Pyrilamine did not block the hypotension induced by venom from the green mamba (*Dendroaspis angusticeps*) in the cat, dog, rat, and guinea pig (82). Injection of histamine into the pulmonary artery circulation of the isolated perfused guinea pig lung caused increases in pulmonary perfusion pressure which were converted into decreases upon injection of pyrilamine (83, 84). Pyrilamine added to the perfusion fluid used in isolated cat lung perfusions prevented histamine and anoxia pressor responses but greatly increased the resistance of the lungs to air flow (85). Pyrilamine noncompetitively inhibited the positive ionotropic effect of histamine on the isolated guinea pig papillary muscle (86). Using the isolated spontaneously beating rabbit atria, pyrilamine was shown to have antimuscarinic and antinicotinic effects and to have a cocaine-like effect unrelated to local anesthesia (87). Pyrilamine blocked the typical cardiovascular responses, hyperkalemia and hyperglycemia, induced by histamine (88).

Pyrilamine reversed the airway constriction of the isolated guinea pig trachea and bronchus induced by histamine and honey bee venom (89), but relaxation of isolated cat tracheal rings caused by histamine was only partially inhibited (90). Pyrilamine prevented the bronchoconstrictor effect of histamine and increased bronchial motility in the gallamine paralyzed unanesthetized rabbit (91). It had no effect on the preconvulsion time in guinea pigs exposed to aerosolized propranolol (92), but it elevated the total blood carbon dioxide and decreased the blood pH in dogs (93). Histamine-induced modifications of airway resistance, respiratory frequency, pulmonary blood volume, alveolar tensio-active substances for pulmonary compliance, P_aO_2, P_aCO_2, blood pressure, and pulmonary compliance for respiratory frequency in dogs and guinea pigs were all blocked by pyrilamine (94). In the isolated perfused guinea pig lung preparation, pyrilamine inhibited the pressor response to histamine but not that of prostaglandin $F_2\alpha$, and it blocked the histamine induced contraction of guinea pig pulmonary artery strips (95). Aerosolized pyrilamine attenuated the histamine induced nasal airway resistance in the dog (96), but aerosolized histamine or sulfur dioxide inhalation increased airway resistance in humans and only the former was blocked by pyrilamine (97).

Rhythmic contractions in the isolated vas deferans of the guinea pig and rat with or without intact intramural nerves (98) were induced by pyrilamine, and it blocked the responses of the neonatal rabbit ileum to histamine (99). The acetylcholine induced contraction of the isolated toad rectus abdominalis muscle was blocked by pyrilamine (100). While the drug had no effect on the synthesis of prostaglandin E_2 from arachidonic acid by bull seminal vesicle homogenates (101), it blocked the peristaltic reflex induced by increasing the intraluminal pressure in the isolated frog stomach and guinea pig ileum (102). It did not antagonize the acid secretion induced by histamine in the isolated guinea pig gastric fundus (103), but it inhibited the responses in the fundus and antrum of isolated guinea pig stomach to histamine, cholecystokinin, and gastrin and partially inhibited the antral response to acetylcholine (104).

Pyrilamine did not antagonize gastric acid secretion induced in rats and guinea pigs by gastrin, bethanechol, and histamine (105), failed to inhibit histamine stimulation, but did suppress aminopyrine accumulation in histamine stimulated isolated rabbit gastric glands (106). Pyrilamine counteracted the inhibitory effect of supramaximal doses of histamine on gastric acid secretion in conscious gastric fistula cats (107), but failed to protect guinea pigs from histamine induced duodenal ulceration (108). In pylorus ligated rats, pyrilamine failed to prevent aspirin plus hydrochloric acid gastric ulcerations (109). It prevented the fall in diastolic blood pressure but did not prevent gastric secretion induced by histamine in dogs (110).

Histamine stimulation of gastric acid secretion and mucosal blood flow in dogs was not prevented (111), production of gastric lesions by stress in rats was inhibited (112), and gastric lesions produced by cold-restraint stress in rats were not antagonized by the drug (113). The activation of adenylate cyclase in broken-cell preparations of guinea pig gastric mucosa by histamine, sodium fluoride, or 5-guanylylimidophosphate was inhibited by pyrilamine (114). It was shown that pyrilamine had no real effect in treating gastric hyperacidity and peptic ulcers in humans (115).

Pyrilamine blocked the histamine mediated vascular exudation response to mild but not strong cold injury to rat skin (116). Intramuscular injection in sheep prevented the vascular permeability produced by intradermal injection of histamine, hyaluronidase, adenosine, guanosine, inosine, or xanthosine (117). It was reported to release histamine and as a result increased the permeability of sheep skin (118). Compound 48/80 was used to deplete histamine stores in sheep but resulted in a biphasic response in which the first phase could be blocked by pyrilamine (119). Pyrilamine blocked the vascular permeability evoked in sheep by histamine and 5-hydroxytryptamine but not that evoked by bradykinin (120). Pulmonary exudation and histamine release was induced in rats by intrapleural injection of turpentine, silver nitrate, or carrageen, and pyrilamine decreased both parameters for turpentine and silver nitrate but had an irregular effect on carrageen (121). Pyrilamine had no influence on rat mast cell histamine release mediated by cyclic adenosine phosphate or cyclic 5′-guanylic acid (122), however, it released 5-hydroxytryptamine from rat peritoneal mast cells (123) as well as from cow enterochromaffin granules *in vitro* (124). It caused a large release of histamine and stimulation of salivary secretion in the submaxillary gland of the dog (125).

Pyrilamine was used to identify two histamine binding sites in the isolated guinea pig ileum (126), and was identified as an H_1-receptor antagonist through its histamine blocking effects on guinea pig atria and ileum *in vitro* and on rat stomach contractions *in vivo* (127). It only partially antagonized the effects of histamine on the isolated cat tracheal rings and did not affect isolated sheep bronchial strips indicating very few H_1-receptors in the former and none in the latter (128). It was used to identify the histamine H_1-receptors in the cardiovascular system of the chicken (129). One study showed that pyrilamine had no effect on the microcirculation of the dog's synovial membrane, which indicated a lack of histamine H_1-receptors (130).

Pyrilamine appears to have a pseudo-dualist effect on the histamine H_1-receptors of the guinea pig ileum and trachea *in vitro* (131). [^{3}H]Pyrilamine was shown to bind specifically to guinea ilial histamine H_1-receptors *in vitro* (132). Brain membranes from rats, calves, and guinea pigs specifically bind [^{3}H]pyrilamine *in vitro* indicating the presence of histamine H_1-receptors (133), which has been confirmed in the guinea pig brain (134).

Pyrilamine did not bind to γ-aminobutyric acid receptors in the rat brain synaptosomal membrane (135), but it did bind to the histamine H_1-receptors in cultured mouse neuroblastoma cells (136). Pyrilamine was used to block H_1-receptors and had a slight immunosuppressive effect when combined with an H_2-receptor blocker in rat heart allografting (137). [^{3}H]Pyrilamine binds with high affinity to brain membranes from humans, rats, guinea pigs, rabbits, and mice indicating an association with H_1-receptors (138). Differences in [^{3}H]pyrilamine binding in guinea pig and rat brains has been attributed to an actual difference between the H_1-receptors or the presence of a relatively large number of secondary binding sites in the rat (139). Pyrilamine exhibited a noncompetitive binding to the histamine H_1-receptors in the rabbit coronary artery (140) but was only weakly bound to the tricyclic antidepressant binding sites in the rat brain (141). The binding sites in the guinea pig brain have been localized by autoradiography (142). Specific and nonspecific binding of [^{3}H]pyrilamine was studied in the brain, lung, adrenal, heart, aorta, and ileum of the guinea pig, rat, and rabbit and in the lung of the mouse and monkey. There were significant differences in the number of high affinity binding sites in the lung and adrenal gland depending upon species.

In the bovine adrenal gland, it was shown that binding was more abundant and had a higher affinity in the medulla than in the cortex (143). The H_1-receptor involved in hypotension is only partially attenuated by pyrilamine in the dog (144). [^{3}H]Pyrilamine was used to label the H_1-histamine receptors in the hypothalamus, midbrain, cortex, brain stem, cerebellum, striatum, and hippocampus of the mouse *in vivo* (145). The potencies of H_1-antihistamines in reducing [^{3}H]pyrilamine binding *in vivo* corresponded with their pharmacological activities and their affinities for [^{3}H]pyrilamine binding sites in isolated brain membranes (146). The positive inotropic effects of histamine in the dog were unmasked by injection of both H_1-

and H_2-histamine receptor antagonists (147).

Pyrilamine had an inhibitory effect on human platelet aggregation and adhesiveness *in vitro* (148), but had no effect on rubidium-86 uptake by erythrocytes (149). Pyrilamine caused red cell agglutination *in vitro* (150), but had no influence on digitalis toxicity in cats and guinea pigs (151). Histamine-induced sleepiness in chicks was counteracted by pyrilamine (152), and it inhibited development of physical dependence but not tolerance to morphine, in mice (153). Histamine potentiates the sedative action of chloral hydrate in mice and pyrilamine counteracted this effect (154). Pyrilamine had no effect on the *in vitro* hydroxylation of protocollagen by protocollagen proline hydroxylase (155) but antagonized the release of Ca^{2+} from skeletal muscle induced by scorpion venom (156). When administered alone the drug had no effect on the lipolysis of rat adipose tissue *in vitro*, but in the presence of epinephrine, it stimulated or inhibited lipolysis depending upon dose (157). Whereas pyrilamine suppressed turpentine induced pleural exudate in adult rats, it had little effect in 7-day-old rats (158).

Pyrilamine blocked the decrease in patency in the eustachian tube of the dog caused by topical or intra-arterial histamine (159), accelerated wound healing in the rat when given in conjunction with a histamine liberator, 48/80 (160), but did not antagonize reserpine induced hypothermia in mice (161). It antagonized the hypothermia produced in mice by oxotremorine, but when administered in a high dose also produced hypothermia (162). Pyrilamine antagonized posthistamine catalepsy in rats (163). Pyrilamine reduced the mortality from tourniquet shock in rats from 75 to 35% (164), but only partially reduced the edema and vascular permeability changes produced by prostaglandin E, in the rat paw (165). The binding of spleen cells[11] to beads[12] was inhibited *in vitro* (166). It did not modify the pituitary production of prolactin in patients with Parkinson's disease (167), but did reduce the tremor (168).

No information is available on the pharmacokinetics of pyrilamine (169).

TOXICOLOGY

Acute Toxicity in Animals—The acute LD_{50} in the mouse is 30 mg/kg iv; 102 ± 11 mg/kg ip (68); 150 mg/kg sc (170); 36 mg/kg orally in the rat. Symptoms of acute toxicity include generalized tremor, increased activity, incoordination of movement, Straub tail phenomenon, squeaking, restlessness, chronic convulsions, and death by asphyxia (68). Pyrilamine did not counteract lantana poisoning in buffalo calves (171). Pyrilamine and antischistosomal agents released histamine from the rat's mesentary (172). It only partially counteracted the hypotension produced by quinuronium in sheep (173), did not prevent brain edema in rats induced by intra-arterial injection of ^{85}S-microspheres (174), and not only did not protect against paracetamol-induced hepatic necrosis in rats but actually increased mortality (175).

Chronic Toxicity in Animals—Subcutaneous injection of 35 mg/kg of pyrilamine twice daily in rats arrested growth by the 7th day and normal growth ensued when the drug was discontinued. Daily subcutaneous injections of 20 mg/kg had no effect on weight gain in weanling mice. Rats receiving 10 mg/kg daily for 6 months or 200 mg/kg daily for 32 days showed no signs of chronic toxicity nor was there any evidence of gross or histological abnormalities due to the drug. Similar results were obtained in dogs receiving 20 mg/kg five times weekly for 6 months, and in monkeys receiving 50 mg/kg daily for 35 days (68). Pyrilamine, 50 mg/kg sc daily, caused leukocytosis after 14–23 days, and rupture and enlargement of the gall bladder and common duct in guinea pigs (176).

Acute Toxicity in Humans—Subcutaneous injections of pyrilamine in humans produced a 6–12-fold increase in blood histamine levels for 24 hr. Symptoms of acute toxicity included dizziness, jitteriness, somnolence, dry nose, nausea, weakness, palpitation, insomnia, abdominal cramping, numbness, cold extremities, fatigue, tendency to hemorrhage, chloroform taste, faintness, acute hysterical reaction, mydriasis, narcolepsy, sore tongue, hot flushes, early menses, and dermatitis medicamentosa (68).

Immunotoxicology—Pyrilamine completely blocked the acute inflammatory response induced in the rat skin by histamine but only partially blocked that induced by bradykinin, 5-hydroxytryptamine, and prostaglandin E_1 (177). The acute pinnal inflammation induced in mice by intravenous dextran was blocked (178). It did not inhibit the inflammatory response in hairless mice induced by photosensitization (179). The passive cutaneous anaphylactic reaction evoked in mice and rats by injection of immunoglobulin antibody was only partially blocked (180). The estradiol induced edematous response in the immature rat uterus was not inhibited (181) but pressure induced edema in the rat foot was reduced by 13% (182). It inhibited the paw edema elicited in rats and guinea pigs by local injection of histamine (183), and blocked the 4-hr passive cutaneous anaphylactic reaction in rats injected with rabbit antirat mast cell antiserum (184).

The drug inhibited the active bronchial anaphylactic response in the rat elicited by reagin-type antibodies (185), and completely antagonized the histamine released when carrageenin was injected into the rat's paw and prevented the inflammatory response (186). It reduced the volume of the rat's paw induced by injection of Freund's complete adjuvant only between days 1 and 4 (187). Pyrilamine protected rats against anaphylactic shock evoked by sensitization to egg albumin (188), but had no effect on the direct Arthus reaction elicited in the hind paw of the rat (189). Rats were not protected from horse serum induced anaphylactic shock at 10 days and only protected 20% at 20 days (190). Pyrilamine blockade of histamine's effect on the guinea pig tracheobronchial muscle and ileum *in vitro* was abolished by slow reacting substance of anaphylaxis (191). It protected against the liberation of histamine *in vivo* and *in vitro* by chloroplatinate (192), but did not inhibit the response to ovalbumin in tracheal strips from sensitized guinea pigs (193). Histamine, inhibited by pyrilamine, evoked contractions of ovalbumin sensitized guinea pig lung parenchymal strips, but was only weakly active against ovalbumin (194). The antigen–antibody reaction of the isolated guinea pig ileum was not inhibited by pyrilamine (195), and there was no effect on the rise of cyclic adenosine phosphate and 5′-guanylic acid in the

[11] BALB/c.
[12] HRS.

sensitized guinea pig lung stimulated with antigen (196). Cyclic adenosine phosphate release was suppressed in normal and sensitized guinea pig lung slices when stimulated by either histamine or antigen (197). These results have been confirmed (198).

Anaphylactic response in sensitized guinea pigs is not modified by the drug (199). Pretreatment of guinea pigs with pyrilamine and papaverine to prevent death from anaphylactic shock showed that the histaminolytic activity of the liver and plasma increased under such conditions (200). Pretreatment with pyrilamine prevented anaphylactic death in guinea pigs and increased the time before the appearance of dyspnea and cough (201). Pyrilamine suppressed the histamine-induced bronchoconstrictor component of the anaphylactic response in sensitized guinea pigs (202), but had no effect on slow-reacting substance of anaphylaxis induced bronchoconstriction in the sensitized guinea pig (203). It inhibited the increase in potassium in the blood of guinea pigs in histamine shock and anaphylaxis but not in Forssman shock (204). It prevented death in guinea pigs from anaphylatoxin and histamine and at high doses from anaphylactic shock, and also inhibited bronchoconstriction and emphysema formation from antigen (206–207).

In isolated perfused hearts of sensitized guinea pigs, pyrilamine did not affect the coronary dilating, heart stimulating, and antianaphylactic effects of released histamine or prevent anaphylaxis (208). It reduced cardiac output in the heart–lung preparation of guinea pigs and histamine, injected or antigen released, counteracts this effect (209). Pyrilamine had little effect on anaphylactic bronchospasm in the guinea pig heart–lung preparation or on the increased pulmonary vascular resistance. However, when histamine caused the above effects, pyrilamine completely counteracted them (210). In the isolated perfused sensitized guinea pig lung, pyrilamine was effective in counteracting the bronchospastic effect of antigen (211).

Pyrilamine prevented early shock death in acute anaphylaxis in guinea pigs and this effect could be abolished by propranolol (212). It significantly reduced the lipid-mobilization and hyperlipoproteinemia induced in rabbits by endotoxin (213). In horse serum sensitized rabbits, it antagonized the vasoconstrictor action of histamine on the pulmonary vessels and the right ventricular vasoconstriction caused by the administration of antigen (214). It counteracted the increased vascular permeability produced by histamine in the monkey but had no effect against prostaglandin E vascular effects (215).

Pyrilamine inhibited the skin reaction to histamine in the monkey but had no effect on the *Ascaris* antigen reaction (216). It had only a small effect against the capillary damaging effects of passive cutaneous anaphylaxis in sheep (217) and did not prevent the changes in the lymph nodes, spleen, and intestinal lymphoid tissues of sensitized sheep injected with antigen (218). Pyrilamine selectively inhibited responses to histamine and raised the threshold antibody required to elicit a passive cutaneous anaphylactic response in calves (219). It incompletely blocked depressor changes in carotid blood pressure elicited in calves by histamine and anaphylaxis (220). Pyrilamine had no effect in blocking the photobiologic increase in blood content of the pig skin sensitized to anthracene and long-wave UV radiation but inhibited the increased vascular permeability to [^{125}I]albumin (221).

Pyrilamine had little effect in causing histamine release from human leukocytes *in vitro* and little activity against antigen induced histamine release (222). It relaxed human bronchial muscle contracted by histamine or antigen *in vitro* (223). Histamine release induced by antigen in sensitized human lung mince *in vitro* was inhibited by pyrilamine (224). Intradermal injection inhibited the histamine evoked wheal and flare reaction in human skin (225). The drug had no protective effect in fog provocation of bronchoconstriction in bronchitis patients but had some protective effect against inhaled allergen in asthmatics (226).

Chloroplatinate exposure gives rise to pruritis, erythema, urticaria, eczema, mild lymphocytosis, cough, dyspnea, conjunctival vasodilatation, and asthma. All of these symptoms were successfully treated with pyrilamine, aminophylline, and corticoid therapy (227). The wheal and flare reaction induced by histamine and kallikrein were reduced (228). Pyrilamine inhibited the histamine skin reaction induced by pollen in skin testing for allergies (229).

Neurotoxicology—Injection of histamine into the endonerium of the rat sciatic nerve resulted in a markedly increased permeability of the endoneural blood vessels. This effect was blocked by pretreatment with pyrilamine. The permeability changes caused by compound 48/80, a histamine liberator, could be only partially inhibited by pyrilamine (230). Histamine caused both stimulation and inhibition of the spontaneous electrical activity of neurons in the isolated brain of the snail (*Helix asperse*) and both actions were blocked by the drug (231). Pyrilamine blockade of the motor action of histamine on the guinea pig plexus containing longitudinal muscle preparations from the ileum could still be electrically stimulated into tetanic spasms which were inhibited by histamine (232). Pyrilamine reduced potassium ion permeability in the sartorius muscle of *Rana pipiens* in a chlorine ion-free medium and increased the electrical potential change (233).

The drug did not abolish neuromuscular transmission or decrease the lingui-mandibular reflex in dogs treated with cannabis resin, tetrahydrocannabinol, or parahexyl (234). When injected into the preoptic/anterior hypothalamic nuclei, the lateral ventricle, or the third ventricle it did not block the hypothermic response elicited by systemic injection of histamine in rats (235). It reduced the contractions of the stomach of *Rana temporaria* induced by vagal stimulation (236) and the uptake of [^{3}H]γ-amino-*n*-butyric acid by the rat cerebral cortex *in vitro* (237). The postganglionic action potential of the isolated rabbit superior cervical ganglion *in vitro* was depressed in the presence of histamine and further depressed by the addition of pyrilamine (238). Pyrilamine blocked the calcium ion-related hyperpolarization of *Amphiuma* erythrocyte membrane (239).

Pyrilamine blocked the atropine-resistant responses elicited by electrical stimulation of an area located ventrally in the anterior hypothalamus and rising dorsally toward the optic tegmentum (240). Intraventrical injection of pyrilamine in cats blocked the pressor response induced by intraventricular histamine. Pyrilamine alone produced

a depressor response and blocked both reflex as well as direct excitability of the medullary vasomotor center (241), but had no effect on toothpulp nociceptive thresholds in conscious dogs (242). Pyrilamine had no effect on the biphasic response evoked by transmural stimulation of the guinea pig distal colon *in vitro* (243).

CARCINOGENICITY

Animal Carcinogenicity—No information is available on short term tests on the carcinogenicity of pyrilamine (169), but it is scheduled for a National Toxicology Program carcinogenesis bioassay (244).

Human Carcinogenicity—No epidemiological studies or case reports relating pyrilamine to human neoplasia were found in the literature (169).

MUTAGENICITY

Pyrilamine caused unscheduled DNA synthesis in primary adult rat hepatocytes in culture (245). Mitosis was inhibited 68% by histamine in human keratinocytes in culture, pyrilamine blocked this effect (246). No information is available on *in vivo* mutagenesis (247).

TERATOGENICITY

Pregnant mice given pyrilamine in their drinking water produced resorptions, abortions, premature parturitions, decreased weight of the neonates, decrease in survival rate at 44 days, alterations in skin and fur, delayed eye opening, pneumoperitoneum, and delayed opening of the external auditory meatus and vagina (248). Pyrilamine was not teratogenic in the rat (249). It caused stromal edema to be inhibited but increased the number of blastocytes recovered from the uterus of the pregnant rat on day 5 (250). Injection of histamine into the right ventricle of the rat brain produced hypokinesis and catalepsy, and pyrilamine reduced these effects (251). Pyrilamine significantly decreases motor activity in mice (252). No information is available concerning pyrilamine with the production of human malformations (253).

CONCLUSIONS

The chemistry, metabolism, structure–activity relationships, pharmacology, toxicology, mutagenicity, teratogenicity, and carcinogenicity of pyrilamine have been reviewed. More mutagenic studies using cells in culture are required to establish the drug's mutagenicity potential. Teratogenic and three generation studies employing both mice and rats are necessary to understand pyrilamine's effects on the reproductive process. A chronic toxicology study is necessary to determine the long-term effects of pyrilamine. A pharmacokinetic study coupled with *in vitro* metabolism would assist in showing the exact metabolic pathways used in biotransformation of pyrilamine.

RESEARCH ARTICLES

Diffusion of Phenol in the Presence of a Complexing Agent, Tetrahydrofuran

J. B. DRESSMAN *§, K. J. HIMMELSTEIN *‡§x, and T. HIGUCHI *

Received October 29, 1981, from the **Department of Pharmaceutical Chemistry* and the ‡*Department of Chemical and Petroleum Engineering, The University of Kansas, Lawrence, KS 66045.* Accepted for publication February 19, 1982. §Present address: Inter$_x$ Research Corporation, Lawrence, KS 66044.

Abstract □ The effect of a complexing agent, tetrahydrofuran, on the diffusion of phenol across a stagnant fluid layer has been studied. At a given activity of free phenol, the steady-state flux of phenol appearing in an acceptor phase was greatly enhanced. However, as the fraction of phenol associated with the complexing agent increased, the flux of phenol decreased, since the transport was then controlled by the diffusion of the complex, a larger structure. A mathematical model of simultaneous association and diffusion was derived to determine whether the diffusional behavior of two associating species could be accounted for in terms of the association equilibrium constant and Fick's second law. Experimental results supported the model. It was concluded that the presence of a complexing agent tends to reduce the rate of diffusion, the effect being more pronounced at high concentrations of complexing agent.

Keyphrases □ Phenol—diffusion in a complexing agent, tetrahydrofuran □ Diffusion—phenol in a complexing agent, tetrahydrofuran □

The purpose of this study was to investigate the influence of complexing agents on the diffusional behavior of drugs. The ability of most drugs to undergo association interactions is intrinsically related to their activity, since most drugs exert their action by complexing to a receptor site. Some dosage forms are designed to take advantage of this associative tendency by using a complexing agent to increase the solubility of the drug in the formulation (1, 2). In other cases, complexing agents are used to modify the dissolution rate of a drug at the site of administration (3, 4), as it is known that the dissolution rate can be greatly affected by association in the diffusion layer (5).

In a previous study (6), the importance of associative interaction on mass transport of drugs was exemplified by the case of simultaneous self-association and diffusion of phenol through an immobilized layer of isooctane. The results of this analysis showed that the self-association of phenol can significantly alter the rate of transport of phenol. The case of simultaneous complexation and diffusion has also been investigated (7). However, those results relied on accurate determination of the forward and reverse rate constants for the associative interaction, parameters which may prove difficult to obtain. It was also assumed that for association equilibrium to be attained within the diffusion layer, it was necessary for the con-

Abstract □ The effect of a complexing agent, tetrahydrofuran, on the diffusion of phenol across a stagnant fluid layer has been studied. At a given activity of free phenol, the steady-state flux of phenol appearing in an acceptor phase was greatly enhanced. However, as the fraction of phenol associated with the complexing agent increased, the flux of phenol decreased, since the transport was then controlled by the diffusion of the complex, a larger structure. A mathematical model of simultaneous association and diffusion was derived to determine whether the diffusional behavior of two associating species could be accounted for in terms of the association equilibrium constant and Fick's second law. Experimental results supported the model. It was concluded that the presence of a complexing agent tends to reduce the rate of diffusion, the effect being more pronounced at high concentrations of complexing agent.

Keyphrases □ Phenol—diffusion in a complexing agent, tetrahydrofuran □ Diffusion—phenol in a complexing agent, tetrahydrofuran □

The purpose of this study was to investigate the influence of complexing agents on the diffusional behavior of drugs. The ability of most drugs to undergo association interactions is intrinsically related to their activity, since most drugs exert their action by complexing to a receptor site. Some dosage forms are designed to take advantage of this associative tendency by using a complexing agent to increase the solubility of the drug in the formulation (1, 2). In other cases, complexing agents are used to modify the dissolution rate of a drug at the site of administration (3, 4), as it is known that the dissolution rate can be greatly affected by association in the diffusion layer (5).

In a previous study (6), the importance of associative interaction on mass transport of drugs was exemplified by the case of simultaneous self-association and diffusion of phenol through an immobilized layer of isooctane. The results of this analysis showed that the self-association of phenol can significantly alter the rate of transport of phenol. The case of simultaneous complexation and diffusion has also been investigated (7). However, those results relied on accurate determination of the forward and reverse rate constants for the associative interaction, parameters which may prove difficult to obtain. It was also assumed that for association equilibrium to be attained within the diffusion layer, it was necessary for the con-

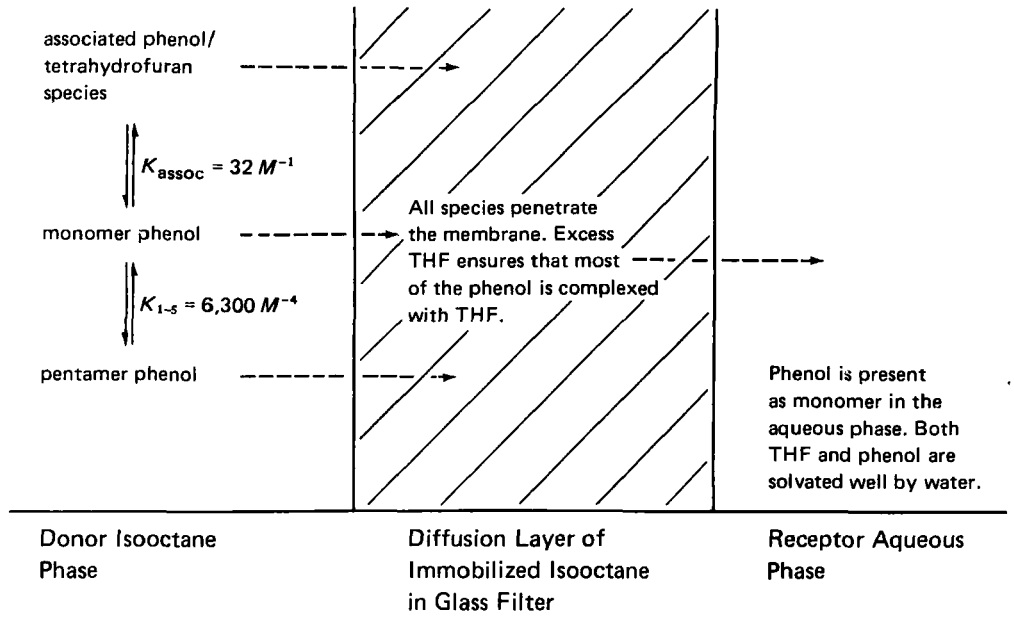

Figure 1—*The influence of tetrahydrofuran on the diffusion of phenol through an unstirred layer of isooctane.*

centration of the complexing agent to be the same at all points in the system.

In the present study, the model system used was the diffusion of phenol from a donor phase solution in isooctane, through a diffusion layer consisting of immobilized isooctane, into an aqueous receptor phase (Fig. 1). The complexing agent used was tetrahydrofuran which, as a cyclic ether, was capable of associating strongly with phenol *via* hydrogen bond formation. A mathematical model of this system was derived to determine whether the experimental diffusional behavior of the two associating species could be accounted for in terms of their association equilibrium constant and Fick's second law. The derivation was based on the following assumptions: (*a*) coupling of the fluxes of free phenol, free tetrahydrofuran, and the complex occurs; (*b*) equilibrium is rapidly attained compared with the rate of diffusion; and (*c*) diffusion of each kind of species is governed by Fick's laws.

THEORETICAL

A silanized sintered glass filter was used in the experimental portion of the present investigation to create an immobilized layer of isooctane between the donor isooctane phase and the receptor aqueous phase, a procedure described previously (6). The immobilized isooctane layer thus formed a stagnant diffusion layer. This arrangement allowed both the phenol and the tetrahydrofuran in the donor isooctane phase to diffuse across the diffusion layer. The association equilibria which occur in the donor phase and the diffusion layer are shown in Fig. 1.

The self-association of phenol in isooctane can be described by the equilibrium (8):

$$5P_m \rightleftharpoons P_5 \text{ with } K_{1-5} \approx 6{,}300\ M^{-4} \text{ at } 25° \qquad \text{(Eq. 1)}$$

where P_m is the concentration of free (monomer) phenol, P_5 is the concentration of self-associated (pentamer) phenol, and K_{1-5} is the equilibrium constant for self-association. The equilibrium governing the association between phenol and tetrahydrofuran is given by:

$$P_m + T \rightleftharpoons [P - T] \text{ with } K_{assoc} = 32\ M^{-1} \text{ at } 25° \qquad \text{(Eq. 2)}$$

where $[P - T]$ is the concentration of associated phenol–tetrahydrofuran species and K_{assoc} is the equilibrium constant for association of phenol and tetrahydrofuran in isooctane. The total concentration of phenol in the presence of tetrahydrofuran is represented by:

$$P_T = P_m + [P - T] + 5P_5 \qquad \text{(Eq. 3)}$$

The total concentration of tetrahydrofuran is given by:

$$T_T = T + [P - T] \qquad \text{(Eq. 4)}$$

where T_T is the total concentration of tetrahydrofuran, similarly expressed. Association in the aqueous phase is assumed to be negligible, since the concentrations of both phenol and tetrahydrofuran in the aqueous phase remained low over the duration of the experiment. Under these conditions, self-association also appears to be negligible[1]. Applying Fick's second law:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2}$$

to each species of phenol present, one obtains:

$$\frac{\partial P_T}{\partial t} = D_M\frac{\partial^2 P_m}{\partial x^2} + 5D_5\frac{\partial^2 P_5}{\partial x^2} + D_{P-T}\frac{\partial^2[P - T]}{\partial x^2} \qquad \text{(Eq. 5)}$$

where D is diffusivity, t is time, C is the concentration of a given species, x is equal to distance, D_m is the diffusivity of free phenol, D_5 is the diffusivity of pentamer phenol, and P_T is expressed as molarity of monomeric phenol.

Assuming that the association equilibria are established quickly compared with the rate of diffusion, P_5 and $[P - T]$ can be substituted in Eq. 3 by the equilibrium expressions:

$$P_5 = K_{1-5}P_m{}^5 \qquad \text{(Eq. 6)}$$

$$[P - T] = K_{assoc}TP_m \qquad \text{(Eq. 7)}$$

resulting in:

$$\frac{\partial P_T}{\partial t} = D_M\frac{\partial^2 P_m}{\partial x^2} + 5D_5K_{1-5}\frac{\partial^2 P_m{}^5}{\partial x^2} + D_{P-T}K_{assoc}\frac{\partial^2(TP_m)}{\partial x^2} \qquad \text{(Eq. 8)}$$

The second term in Eq. 8 can be reexpressed as:

$$\frac{\partial^2(P_m{}^5)}{\partial x^2} = 5P_m{}^4\frac{\partial^2 P_m}{\partial x^2} + 20\,P_m{}^3\left(\frac{\partial P_m}{\partial x}\right)^2 \qquad \text{(Eq. 9)}$$

The third term in Eq. 8 can be reexpressed as:

$$\frac{\partial(TP_m)}{\partial x^2} = P_m\frac{\partial^2 T}{\partial x^2} + T\frac{\partial^2 P_m}{\partial x^2} + 2\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x} \qquad \text{(Eq. 10)}$$

Also, by substituting Eqs. 6 and 7 into Eq. 3:

$$P_T = P_m + 25K_{1-5}P_m{}^5 + K_{assoc}TP_m \qquad \text{(Eq. 11)}$$

Taking the derivative of both sides with respect to time one obtains the expression:

$$\frac{\partial P_T}{\partial t} = \frac{\partial P_m}{\partial t} + 25K_{1-5}P_m{}^4\frac{\partial P_m}{\partial t} + K_{assoc}T\frac{\partial P_m}{\partial t} + K_{assoc}P_m\frac{\partial T}{\partial t}$$

[1] Personal communication, M. Tobin.

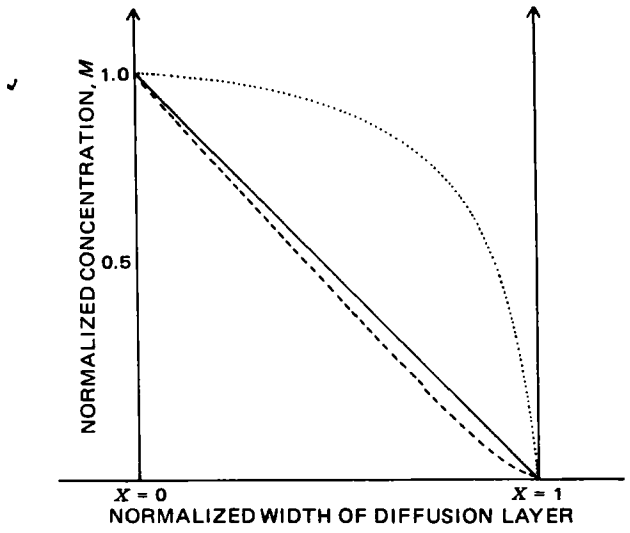

Figure 2—*Normalized steady-state concentration profiles in the diffusion layer, at total phenol concentration of 0.1403* M *and total tetrahydrofuran concentration of 4.76% (v/v) in the donor phase. Key: (——) free tetrahydrofuran concentration scaled up by a factor of 2.194; (- - - - -) associated phenol concentration scaled up by a factor of 7.616; (. . . . .) concentration of free phenol scaled up by a factor of 111.11.*

This expression can be rearranged to give:

$$\frac{\partial P_T}{\partial t} = \frac{\partial P_m}{\partial t}(1 + 25K_{1\text{-}5}P_m^4 + K_{assoc}T) + K_{assoc}P_m\frac{\partial T}{\partial t} \quad \text{(Eq. 12)}$$

By substituting Eqs. 9, 10, and 12 into Eq. 8 the following is derived:

$$\frac{\partial P_m}{\partial t}[1 + 25K_{1\text{-}5}P_m^4 + K_{assoc}T] = D_M\frac{\partial^2 P_m}{\partial x^2} + D_5K_{1\text{-}5}5P_m^4\frac{\partial^2 P_m}{\partial x^2} + 20P_m^3\left(\frac{\partial P_m}{\partial x}\right)^2 + P_m\frac{^2T}{\partial x^2} + T\frac{\partial^2 P_m}{\partial x^2} + 2\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x}D_{P\text{-}T}K_{assoc} - K_{assoc}P_m\frac{\partial T}{\partial t} \quad \text{(Eq. 13)}$$

Equation 13 can be rearranged to produce the following in terms of monomer phenol only:

$$\frac{\partial P_m}{\partial t} = \frac{\left[D_M\frac{\partial^2 P_m}{\partial x^2} + D_5K_{1\text{-}5}5P_m^4\frac{\partial^2 P_m}{\partial x^2} + 20P_m^3\left(\frac{\partial P_m}{\partial x}\right)^2 - K_{assoc}P_m\frac{\partial T}{\partial t} + D_{P\text{-}T}K_{assoc}P_m\frac{\partial^2 T}{\partial x^2} + T\frac{\partial^2 P_m}{\partial x^2} + 2\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x}\right]}{[1 + 25K_{1\text{-}5}P_m^4 + K_{assoc}T]} \quad \text{(Eq. 14)}$$

An expression for diffusion of tetrahydrofuran can be derived in a similar manner. The concentration of tetrahydrofuran in associated form can be calculated using Eq. 15:

$$[P - T] = K_{assoc}TP_m \quad \text{(Eq. 15)}$$

By applying Fick's second law to the species of tetrahydrofuran present, an expression for flux of tetrahydrofuran across a small distance within the diffusion layer can be obtained:

$$\frac{\partial T_T}{\partial t} = D_T\frac{\partial^2 T}{\partial x^2} + D_{P\text{-}T}\frac{\partial^2[P - T]}{\partial x^2} \quad \text{(Eq. 16)}$$

By appropriate substitution and rearrangement, the following expression is derived:

$$\frac{\partial T}{\partial t} = \frac{\left[\frac{\partial^2 T}{\partial x^2}[D_T + D_{P\text{-}T}K_{assoc}P_m] + D_{P\text{-}T}K_{assoc}T\frac{\partial^2 P_m}{\partial x^2} + 2\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x} - K_{assoc}T\frac{\partial P_m}{\partial t}\right]}{[1 + K_{assoc}P_m]} \quad \text{(Eq. 17)}$$

In view of the great excess of tetrahydrofuran present in all experiments

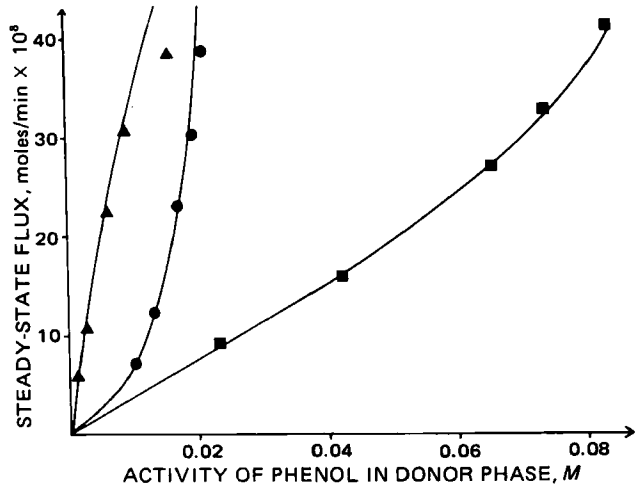

Figure 3—*Steady-state flux* versus *activity of phenol (free concentration) in the donor phase. Solid lines represent computer-generated results. Key: (▲) data from experiments in which 4.76% (v/v) tetrahydrofuran was used; (●) data from experiments in which an approximately 2:1 ratio of tetrahydrofuran to phenol was used; (■) control experiments in which no tetrahydrofuran was used.*

in which this complexing agent was used and also the magnitude of the association constant between phenol and tetrahydrofuran, it is reasonable to assume that the self-association of phenol was negligible in these experiments. For example, at $T_T = 0.5872\ M$ and $P_T = 0.1403\ M$, $[P_5] = 3.7 \times 10^{-7}\ M$.

Neglecting the contribution of the pentamer allowed the terms for diffusion of the self-associated species to be omitted. Eq. 13 is then simplified to give the following expression:

$$\frac{\partial P_m}{\partial t} = \frac{\left[\frac{\partial^2 P_m}{\partial x^2}[D_P + D_{P\text{-}T}K_{assoc}T] + D_{P\text{-}T}K_{assoc}P_m\frac{\partial^2 T}{\partial x^2} + 2\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x} - K_{assoc}P_m\frac{\partial T}{\partial t}\right]}{[1 + K_{assoc}T]} \quad \text{(Eq. 18)}$$

Since Eq. 18 is in the same form as Eq. 17, these two interdependent equations can then be solved simultaneously to determine the concentration profiles of phenol and tetrahydrofuran in the diffusion layer at a given time. Owing to the complexity of the equations involved, it was convenient to use numerical methods to obtain the required solutions. The computer program, based on the approaches described previously (9), used an implicit method of solution of differential equations of similar form. Approximate algebraic expressions, written on the $(n + 1)$ time step, were found by applying the central difference approximation to the derivative term which were thus converted to finite difference expressions. Equations 17 and 18 are nonlinear and coupled equations. To linearize and effectively decouple the equations, the following approximations were used for Eq. 17:

$$T\frac{\partial^2 P_m}{\partial x^2} = \frac{P_{n,i-1} - 2P_{n,i} + P_{n,i+1}}{\Delta x^2}T_{n+1,i}$$

$$\frac{\partial P_m}{\partial x}\frac{\partial T}{\partial x} = \frac{P_{n,i} - P_{n,i-1}}{\Delta x}\frac{T_{n+1,i} - T_{n+1,i-1}}{\Delta x}$$

$$T\frac{\partial P_m}{\partial t} = T_{n+1,i}\frac{P_{n,i} - P_{n-1,i}}{\Delta t}$$

Analogous approximations were made for the equivalent expressions in the equation governing phenol transport (Eq. 18). Since the tetrahydrofuran concentration profile was solved first for a given time step, the current values of $T_{n,i}$ were retained rather than substituting those from the previous time step:

$$P\frac{\partial T}{\partial t} = P_{n+1,i}\frac{T_{n+1,i} - T_{n,i}}{\Delta t}$$

From these expressions, it can be seen that the dependent variable on which the equation was written, *e.g.*, T in Eq. 17, was always taken to be the variable on which the terms were written implicitly. This effectively decoupled Eqs. 17 and 18, allowing them to be solved separately as sets of linear algebraic expressions to give the concentration profiles for phenol and tetrahydrofuran in the diffusion layer at a given time.

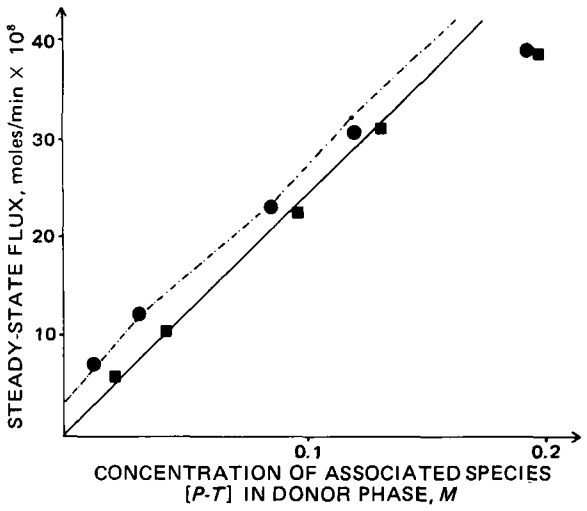

Figure 4—*Steady-state flux* versus *concentration of associated phenol in the donor phase for experiments in which 4.76% (v/v) tetrahydrofuran was used. Figure 5—*Burst time* versus *concentration of phenol in the donor phase, for experiments in which 4.76% (v/v) tetrahydrofuran was used. Key: (——) computer-generated results; (■) average values observed; (⊥) ranges observed.*

It should be noted that the sets of linearized decoupled equations for Eqs. 17 and 18 can be solved iteratively for T_{n+1}^{j+1} and P_{n+1}^{j+1} such that the jth solution of the two sets of equations allows for the more accurate approximations of the nonlinear portions of the expressions. However, by choosing sufficiently small values of t, the assumed and calculated values of the derivatives differed only by a tolerably small amount after the first iteration, and therefore, iterative solutions were not required.

The coefficients of the set of linear equations for tetrahydrofuran were arranged in a matrix and solved by a method equivalent to Gaussian elimination using the subroutine TRIDAG (9) to give the current diffusion layer concentration profile of tetrahydrofuran. The same method was then applied to determine current concentrations of phenol in the diffusion layer.

From the gradients of phenol and tetrahydrofuran concentrations at the interface between the immobilized isooctane layer and the aqueous phase, the flux into the aqueous phase and subsequently the cumulative concentration in the aqueous phase was determined for each species at successive times. Since the concentrations in the aqueous phase remained consistently low, sink conditions were applied at the isooctane–aqueous phase interface for the purpose of calculating flux into the aqueous phase. This assumption may have introduced some error into the calculated steady-state flux predictions, especially at the higher donor phase concentration of phenol, and into the burst time calculations.

Typical computer-generated concentration profiles within the membrane at steady state are shown in Fig. 2 for donor phase concentrations of 0.1043 M phenol and 0.5872 M tetrahydrofuran. The gradient of the free tetrahydrofuran is linear due to the large excess of tetrahydrofuran present, but the profiles of both the associated and free phenol are nonlinear owing to the association equilibrium with tetrahydrofuran.

EXPERIMENTAL

Materials—Commercially obtained analytical reagent grade phenol[2] was fractionally distilled under vacuum to remove the preservative and other contaminants and then stored under nitrogen in a desiccator.

Tetrahydrofuran[3], containing 0.025% butylated hydroxytoluene as a preservative, was distilled from benzophenone and sodium under nitrogen, and then collected over activated 4-Å molecular sieves[4]. Batches were discarded 4 days after distillation.

Certified ACS isooctane (2,2,4-trimethylpentane)[3] was used without further purification.

Diffusion Apparatus and Study—The diffusion apparatus and the analytical procedure for phenol were described in a previous paper (6). The cutoff point for tetrahydrofuran in the UV region was 220 nm. It did not interfere with the assay of samples for phenol. Three different solution compositions were used at each concentration of phenol studied:

1. Fifty milliliters of the phenol in isooctane solution plus 2.5 ml of isooctane were used. Experiments in which solutions of this composition were used provided control data for comparison with diffusion data from experiments in which tetrahydrofuran was used.
2. Fifty milliliters of the phenol in isooctane solution, sufficient tetrahydrofuran to provide a ratio of ~ 2:1 tetrahydrofuran to phenol, and 2.5 ml (less the volume of tetrahydrofuran used) of isooctane were used.
3. Fifty milliliters of the phenol in isooctane solution plus 2.5 ml of tetrahydrofuran were used. The concentration of tetrahydrofuran present in these solutions was 0.5872 M (4.76% v/v).

The solutions required were prepared and added immediately to the tube containing the silanized sintered glass filter. Each solution was allowed to equilibrate with the filter for 3 min, enabling an immobilized layer of solution to be established within the filter. At the end of 3 min, the lower face of the filter was carefully wiped dry and the tube lowered into the jacketed beaker containing the aqueous phase, the temperature of which was maintained at 25°. When overhead and aqueous phase stirrers were turned on, the study was begun. Samples were taken from the aqueous phase at convenient times, replacing the volume removed with distilled, deoxygenated water. At the conclusion of the experiment the samples were analyzed for phenol. Further experimental details were presented in a previous study (6).

RESULTS AND DISCUSSION

Diffusion of phenol from the donor isooctane phase, through an immobilized layer of isooctane within the silanized sintered glass filter, into an aqueous receptor phase was followed by determination of the cumulative concentration of phenol in the aqueous phase at times ≤300 min. When tetrahydrofuran was used, it was present initially in both the donor phase solution and the diffusion layer. It was assumed that the association equilibrium between phenol and tetrahydrofuran was established in both the diffusion layer and the donor phase and that all species were capable of diffusing through the immobilized isooctane layer into the aqueous phase. For each type of experiment, four runs were made at each of the five phenol concentrations studied. Steady-state flux was calculated from the slope of the concentration *versus* time plot using vaues obtained at times of 100 min or longer. Runs were rejected if the linear regression correlation coefficient for the data used to calculate the slope fell below 0.999, to minimize variation in the steady-state flux and burst time values.

Steady-State Flux—When simultaneous association and diffusion occur, the rate of diffusion may increase, decrease, or remain the same. The change in the diffusion rate depends on the size of the associated species formed, its ability to penetrate or partition into the diffusion layer, and the extent to which complexation occurs.

Figure 3 shows a plot of steady-state flux *versus* concentration of free phenol (defined as activity) present in the donor phase. In the control experiments, there was a positive deviation from linearity at high phenol activities. This was accounted for by the contribution of the diffusion of

the self-associated pentameric phenol to the overall rate of flux. In the presence of tetrahydrofuran, the steady-state flux at a given activity of phenol was greatly enhanced. The effect was more pronounced when 4.76% (v/v) tetrahydrofuran was present than when a 2:1 ratio of tetrahydrofuran to phenol was added. In both cases the increase in steady-state flux could be attributed to diffusion of the phenol–tetrahydrofuran-associated species. When 4.76% (v/v) tetrahydrofuran was used, the extent of association was greater owing to the larger excess of complexing agent present. This led to a greater enhancement of the steady-state flux values than observed for the 2:1 excess experiments, in which a significant proportion of phenol present remained unassociated.

In the 4.76% (v/v) tetrahydrofuran experiments, almost all of the phenol was expected to be associated with tetrahydrofuran (Table I). Therefore, the steady-state flux was expected to have an approximately linear relationship to the concentration of associated species present as shown in Fig. 4. Except at the highest concentration of phenol, the 4.76% (v/v) tetrahydrofuran data fall along a straight line within experimental error. This deviation at the higher donor phase phenol concentrations may arise from changes in the composition of the neighborhood of molecules surrounding each molecule. Since the theoretical development does not account for changes in the activity coefficient of the free phenol, a deviation of this nature is not surprising.

For a given concentration of associated phenol, a higher steady-state flux was predicted and observed when a 2:1 ratio of tetrahydrofuran to phenol was used than when 4.76% (v/v) tetrahydrofuran was present. This result was accounted for by the following model. In the 4.76% (v/v) tetrahydrofuran experiments virtually all flux was due to diffusion of the associated species. However, in the 2:1 ratio experiments, a significant proportion of phenol was present as free phenol. Since free phenol was able to diffuse across the immobilized isooctane layer at a faster rate than that of the larger associated species, it was able to contribute significantly to the overall flux into the aqueous phase. This resulted in a larger steady-state flux than would be predicted by considering only the contribution of the associated phenol. The differences in the steady-state flux data were most pronounced at low total concentrations of phenol. At those concentrations, the disparity in percentage of phenol present in unassociated form was also greatest (Table I), supporting the arguments derived from the model.

Overall, the steady-state flux results showed that for a system in which the associated species can penetrate the diffusion layer, the flux for a given total concentration of drug decreases as the concentration of complexing agent present increases. This is accounted for by the lower diffusivity of the larger associated species.

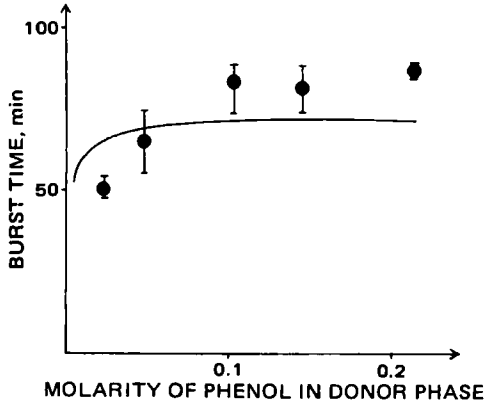

Figure 6—*Burst time* versus *concentration of phenol in the donor phase for experiments in which an approximate 2:1 ratio of tetrahydrofuran of phenol was used. Key: (——) computer-generated results; (●) experimentally observed results; (⊥) ranges.*

Transient Behavior (Burst Time)—As for the more commonly reported time lag, the burst time is inversely proportional to the diffusivity of the diffusing species. When diffusion of one species accounts for the entire flux observed, the burst time is related to the diffusivity of that species. In such cases, the burst time is independent of the donor phase concentration of the diffusing species.

Figure 5 shows the plot of burst time *versus* concentration of phenol in the donor phase in the presence of 4.76% (v/v) tetrahydrofuran. Burst time was calculated by extrapolating the steady-state portion of the concentration *versus* time plot back to zero concentration. Although there is considerable scatter in the results, the burst time was essentially independent of concentration, indicating that one species accounted for most of the mass transport observed. The excess of tetrahydrofuran was large enough in these experiments to ensure that virtually all phenol (93–98%) present was associated with tetrahydrofuran. It was proposed, therefore, that the diffusion of the associated species accounted for the greater fraction of the flux. The large value for the burst time observed in the 4.76% tetrahydrofuran experiments supported this proposal. Since large molecules have lower diffusivities, burst time tends to increase with molecular size. The average burst time observed in these experiments was ~90 min. This time was much greater than the burst time of ~35 min which was calculated for a diffusion system in which only monomer phenol was present (6).

Figure 6 depicts the burst time *versus* the donor phase concentration data for experiments in which a 2:1 ratio of tetrahydrofuran to phenol was used. The theory predicted that the burst time would be shorter at low donor phase phenol concentrations, since in those cases the percentage of phenol in the associated form was considerably lower than at high phenol concentrations (Table I). The smaller free phenol molecules were able to diffuse faster than the associated species so that when free phenol was present in significant quantities, the system came to steady state more rapidly and exhibited a shorter burst time. The observed burst times were similar to the predicted relationship. However, the effects were magnified somewhat.

The failure of the numerical solution of the derived equations to predict exactly the overall burst time was probably due partly to the boundary condition used for the aqueous phase–diffusion layer interface in the computer program (*i.e.*, sink conditions) and partly to an artifact of the experimental method. As in the phenol experiments described previously (7), small amounts of phenol on the lower face of the sintered glass filter may have been released immediately upon contact with the aqueous phase. This would result in high values for cumulative concentration in the aqueous phase and higher burst times than predicted. Build-up of tetrahydrofuran in the aqueous phase may also have affected partitioning of phenol between the diffusion layer and the aqueous phase, which would again alter the concentration of phenol attained in the aqueous phase.

Despite the great reduction in activity of phenol caused by the addition of a complexing agent, the overall transport rate of phenol for a given total concentration of phenol was almost as fast as in a complexing agent-free system. This consistency in transport rates was attributed to the ability of the associated tetrahydrofuran–phenol complex to form in and diffuse through the diffusion layer. A set of equations derived in terms of readily obtainable parameters were found to adequately account for all the data except that obtained at high concentration of phenol. Thus, it was possible to explain the seemingly complicated relationship between steady-state flux diffusional behavior and donor-phase concentration of phenol in the presence of a codiffusing species using the familiar concept of associative interactions.

In the system studied, all species formed were capable of penetrating the diffusion layer. Comparing the results of the 4.76% (v/v) tetrahydrofuran and the twofold excess tetrahydrofuran experiments, it appears

that the excessive use of an excipient capable of complexing with a drug could result in a markedly reduced rate of delivery of that drug by simultaneously lowering the drug's activity and apparent diffusivity. Although such an effect is undesirable in most circumstances, it may be possible to use this effect to advantage in the design of slow-release preparations.

Abstract □ Theoretical and experimental analyses demonstrate that a hemispheric polymer–drug matrix laminated with an impermeable coating, except for an exposed cavity in the center face, can be used to achieve zero-order release kinetics. Hemispheric systems for low molecular weight drugs were prepared by heating and compressing polyethylene and drug (sodium salicylate) in a brass mold. Hemispheric systems for high molecular weight drugs were prepared by casting ethylene–vinyl acetate copolymer and protein in a hemispheric mold at −80°, followed by a two-step drying procedure (−20 and 20°). In both systems, cavities were made in the center face of the hemispheres and the remainder of the matrices coated with an impermeable material. Zero-order release for 60 days at a rate of 0.5 mg/day was achieved from polymer matrices containing bovine serum albumin (mol. wt. 68,000).

Keyphrases □ Drug delivery system—zero-order controlled-release polymer matrices, micro- and macromolecules □ Controlled-release delivery—zero-order, polymer matrices, micro- and macromolecules □ Polymers—matrices, zero-order controlled-release, micro- and macromolecules □ Sustained-release delivery—zero-order controlled-release polymer matrices, micro- and macromolecules

Diffusion-controlled matrix devices have been among the most widely used drug delivery systems, but a disadvantage frequently cited is their inability to achieve zero-order release kinetics (1–3). Most matrix devices have been designed in the form of a rectangular slab, and it has been observed that the cumulative release of drug is inversely proportional to the square root of time (4–8).

One possible means of altering release kinetics from matrix systems is to vary the matrix geometry. The influence of shape on kinetics of drug release from matrix tablets in spherical, cylindrical, and biconvex shapes has been evaluated (9, 10). It was predicted (11) that a matrix in the shape of a sector of a right circular cylinder would release drug at a zero-order rate. This analysis was more critically evaluated, and it was found that true zero-order kinetics were not achieved in practical cases but that this shape resulted in release rates that were initially high and then began to approach, but not achieve, linearity (12). A limitation cited in both studies was the need for effective procedures to fabricate these delivery systems and the requirement for further experimental testing.

In a previous study, a theoretical analysis suggested that a hemisphere with all portions laminated with an impermeable coating, except for a small cavity cut into the center of the flat surface, could achieve zero-order release kinetics (13).

In the present study, experimental results have been obtained that provide support for the theoretical analysis. Two types of fabrication procedures are presented here to demonstrate that the hemisphere design is universally suitable for either low or high molecular weight drugs.

THEORETICAL

Assuming that the drug is released from a solid matrix device by diffusion, a steady-state condition exists, and the area for mass transport,

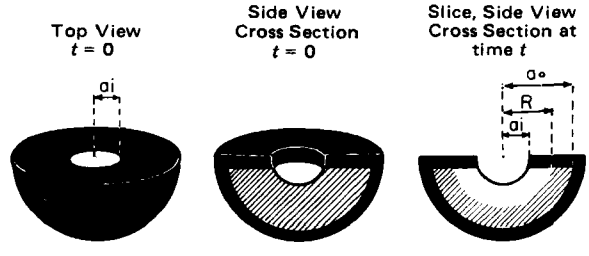

Figure 1—*Diagram of an inwardly-releasing hemisphere;* a_i *is the inner radius,* a_o *is the outer radius, and* R *is the distance to the interface between the dissolved region (white area) and the dispersed zone (diagonal lines). Black represents laminated regions through which release cannot occur.*

that the excessive use of an excipient capable of complexing with a drug could result in a markedly reduced rate of delivery of that drug by simultaneously lowering the drug's activity and apparent diffusivity. Although such an effect is undesirable in most circumstances, it may be possible to use this effect to advantage in the design of slow-release preparations.

Diffusion-controlled matrix devices have been among the most widely used drug delivery systems, but a disadvantage frequently cited is their inability to achieve zero-order release kinetics (1–3). Most matrix devices have been designed in the form of a rectangular slab, and it has been observed that the cumulative release of drug is inversely proportional to the square root of time (4–8).

One possible means of altering release kinetics from matrix systems is to vary the matrix geometry. The influence of shape on kinetics of drug release from matrix tablets in spherical, cylindrical, and biconvex shapes has been evaluated (9, 10). It was predicted (11) that a matrix in the shape of a sector of a right circular cylinder would release drug at a zero-order rate. This analysis was more critically evaluated, and it was found that true zero-order kinetics were not achieved in practical cases but that this shape resulted in release rates that were initially high and then began to approach, but not achieve, linearity (12). A limitation cited in both studies was the need for effective procedures to fabricate these delivery systems and the requirement for further experimental testing.

In a previous study, a theoretical analysis suggested that a hemisphere with all portions laminated with an impermeable coating, except for a small cavity cut into the center of the flat surface, could achieve zero-order release kinetics (13).

In the present study, experimental results have been obtained that provide support for the theoretical analysis. Two types of fabrication procedures are presented here to demonstrate that the hemisphere design is universally suitable for either low or high molecular weight drugs.

THEORETICAL

Assuming that the drug is released from a solid matrix device by diffusion, a steady-state condition exists, and the area for mass transport,

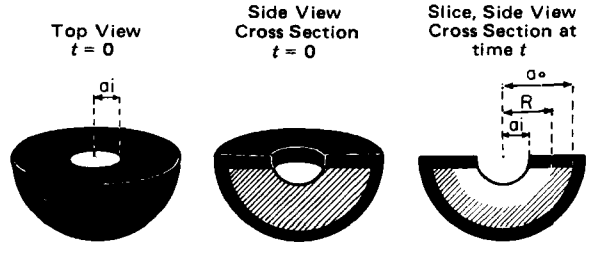

Figure 1—*Diagram of an inwardly-releasing hemisphere;* a_i *is the inner radius,* a_o *is the outer radius, and* R *is the distance to the interface between the dissolved region (white area) and the dispersed zone (diagonal lines). Black represents laminated regions through which release cannot occur.*

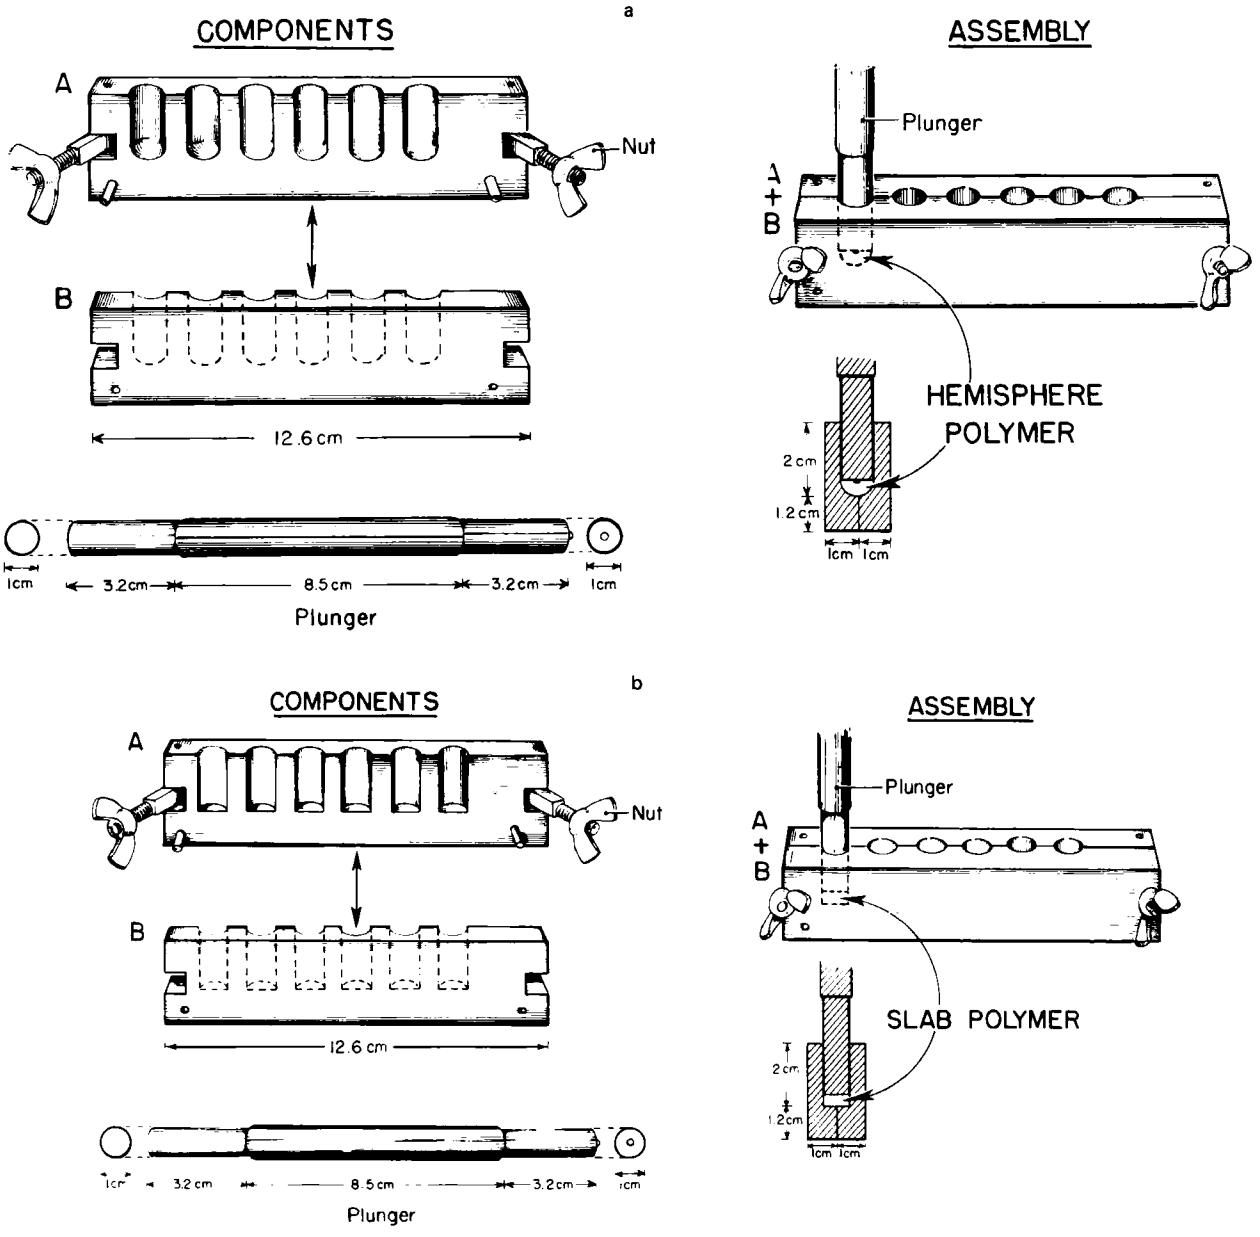

Figure 2—*Diagram of brass molds and plungers for making hemispheres and slabs containing low molecular weight drugs. (a) The brass mold (12.6 × 3.2 × 2 cm) had two halves (components A and B) fastened together with wing nuts (assembly). The mold had six hollowed cylinders (1-cm diameter and 11.4-cm length) with hemispheric bottoms (1-cm diameter). The brass plunger (1-cm diameter × 14.9-cm length) had two ends: one end was flat and the other end was press-fitted with a 2-mm (diameter) steel bead in the center in such a way that one-half of the bead was exposed and the other half was buried within the plunger. The plunger end containing the bead was used for making hemispheres. (b) The brass mold, with the same dimensions as those shown in Fig. 2a, had six hollowed cylinders with flat bottoms. The same plunger in Fig. 2a was used; however, this time the flat end was used for slabs.*

A, and drug diffusion coefficient, D, remain constant, then Fick's law of diffusion can be applied and is represented by:

$$\frac{dQ}{dt} = -DA\frac{dc}{dr} \qquad \text{(Eq. 1)}$$

where Q is the mass of drug being transferred, t is the time, c is the drug concentration, and r is the distance from the diffusion source to the release surface. From Eq. 1 it can be seen that the release rate decreases as the distance r increases; that is, the release rate is inversely proportional to the distance which the drug must travel from within the matrix to the matrix surface. The purpose of altering matrix geometry is to increase the available area of drug so as to compensate for the increase in diffusion distance of drug transport.

In a previous study (13), a theoretical analysis was conducted to derive release equations for a hemispheric device in which release only occurs through a cavity in the flat surface; all other surfaces would be laminated with an impermeable coating (Fig. 1). In the theoretical analysis (13), it was assumed as in a previous study (4) that the amount of drug present per unit volume, C_0, is substantially greater than the solubility of drug per unit volume of the vehicle, C_s. It was further assumed, as previously (4), that the solid drug dissolves from the surface layer of the device first; when this layer is depleted of drug, the next layer begins to be depleted. The interface between the region containing dissolved drug and dispersed drug moves into the interior as a front. Infinite sink conditions, no boundary layer effects, as well as other assumptions originally made (4) were considered applicable. The following notation is used:

a_i = inner radius or radius of the cavity
a_o = outer radius of device
R = radial distance to interface between dissolved and dispersed drug within the matrix (Fig. 1)
C_s = drug solubility in the release media [this also equals the concentration of drug at the interface between dissolved and dispersed drug (4)]
$Q(t)$ = drug released (wt) from the pellet at time t
D = diffusion coefficient of drug in matrix

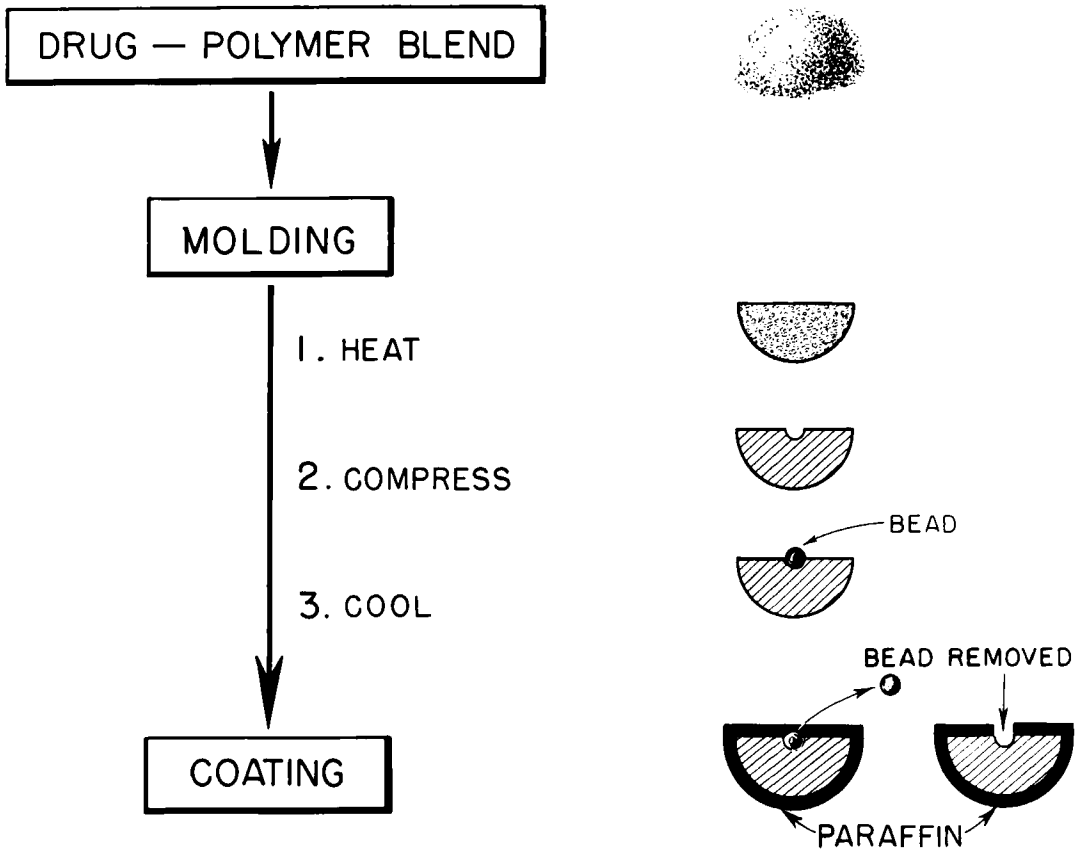

Figure 3—*Flow chart for preparing hemisphere-shaped devices for the release of small molecules. (Detailed procedures were recorded in the text.)*

Then, the release rate for the hemisphere can be derived as described previously (13) resulting in:

$$\frac{dQ}{dt} = 2\P C_s D a_i \left(\frac{R}{R - a_i}\right) \qquad \text{(Eq. 2)}$$

The approach to zero-order kinetics can be observed by examination of Eq. 2. In this equation, when $R \gg a_i$, $R - a_i$ becomes equal to R and:

$$\frac{dQ}{dt} = 2\P D C_s a_i \qquad \text{(Eq. 3)}$$

Each of the terms in Eq. 3 is a constant. Thus, for a hemispheric device with small a_i, release rates will be essentially constant. It can be calculated that for hemispheric devices designed so that the outer radius (a_o) is at least three times greater than the inner radius (a_i) zero-order kinetics will be achieved after a short burst and maintained for the duration of release (13).

Release rate expressions have been derived for several different shaped devices (13). In comparing such devices, the following statement provides a useful guideline: The hemisphere will more closely approximate zero-order release than other shapes (*e.g.*, a cylinder sector), if the inner radii (a_i) of both shapes are similar; if, however, the inner radius of the other device is much smaller than that of the hemisphere, the second device will more closely approximate zero-order release.

EXPERIMENTAL

To experimentally test the zero-order release concept for hemispheres, a polyethylene–sodium salicylate matrix was used. This matrix has been shown to follow the Higuchi model (6). For reference, release kinetics from a slab (in the present report any shape that has cross sections which were identical throughout the matrix was considered a slab) were also studied. In these studies a drug–polymer blend was molded into the different shapes; however, both the hemisphere and the slab were designed with dimensions such that similar apparatuses could be used and so that each would release approximately the same quantity of drug after the same time period.

Materials Used for Matrices Containing Low Molecular Weight Compounds—Sodium salicylate[1] and polyethylene[2] were passed through a 60-mesh screen[3] separately. These ingredients (30% sodium salicylate and 70% polyethylene) were then mixed together in a cube blender[4] for 5 min. The brass[5] mold[6] (Fig. 2) had two halves fastened together with wing nuts. The molds had six hollow cylinders (1-cm diameter, 11.4-cm long) that were either round-bottomed (with a 0.5-cm radius) for making hemispheres (Fig. 2a) or flat-bottomed for making slabs (Fig. 2b).

Hemisphere-Shaped Systems for Low Molecular Weight Compounds—A summary of the steps involved in the fabrication procedure for making hemispheres is shown in Fig. 3 and described in detail as follows. In the first step, each hollow cylinder mold (Fig. 2a) was loaded with 220 mg of a sodium salicylate–polyethylene blend and placed into a preheated oven[7] at 150° for 30 min. After heating, a brass plunger[6] (1-cm diameter) was forcefully inserted into each cylinder. Compression was complete within 30 sec. This plunger was flat-bottomed except for a central depression into which a 2-mm (diameter) steel bead[8] was press-fitted (press-fitting involves molding one metal object to another so that they are permanently attached) in such a way that half of the bead was exposed and the other half was buried within the plunger (Fig. 2a). By using this type of plunger to compress the polymer–drug matrix, a small cavity in the face of the hemisphere was formed. After compression the plunger was immediately removed. The mold containing hemispheric pellets was cooled at room temperature for 20 min. Then, the mold was disassembled. The hemispheric polymer–drug pellets were removed from the mold and trimmed with a scalpel[9] containing a surgical blade[10] to eliminate any irregular edges. The average weight of the hemisphere after trimming was 208 ± 3 mg.

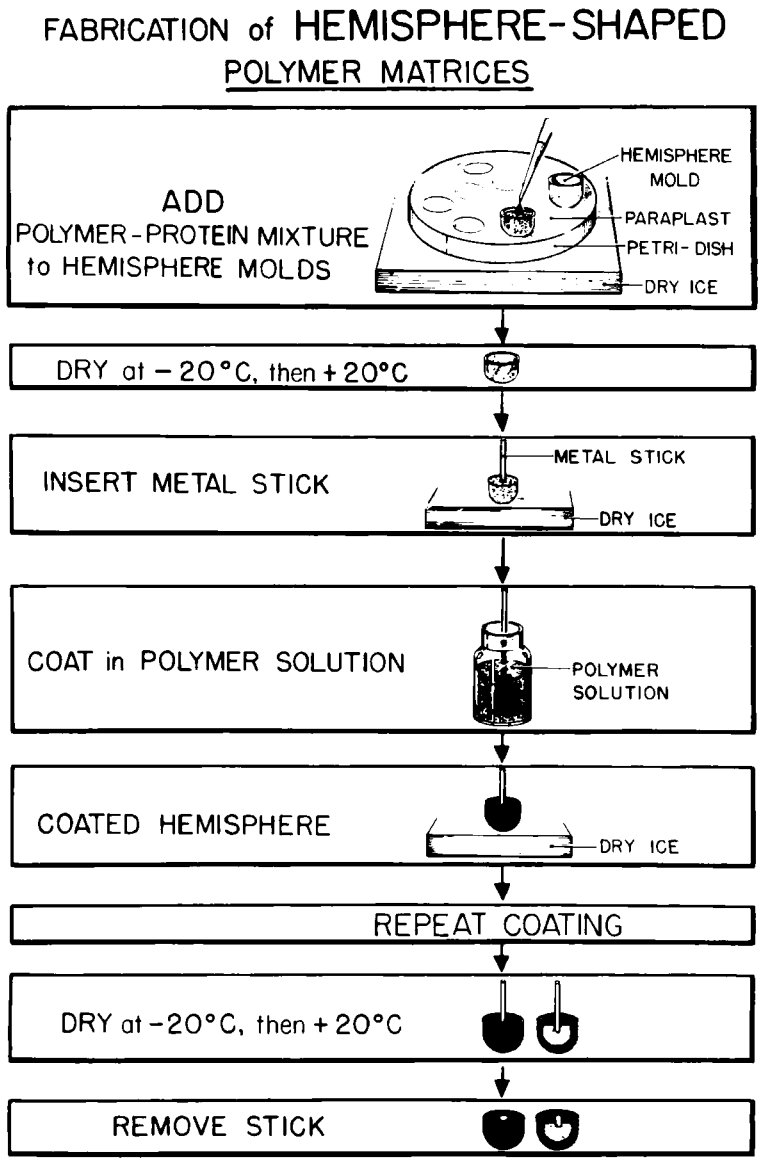

Figure 4—*Flow sheet for preparing hemisphere-shaped devices for the release of macromolecules. (Detailed procedures were recorded in the text.) In the last two blocks of the flow sheet, both the top view and a cross-sectional view of the same hemisphere device are shown.*

To protect the cavity within the hemisphere pellet during coating, a steel bead[8], 2 mm in diameter, was inserted (Fig. 3) into it with forceps[11]. The flat face of the hemisphere pellet containing the steel bead was then placed face down against a lid of a petri dish[12]. A total of nine pellets was placed in each dish. To coat the matrix, paraffin[13] was first melted in a glass beaker on a hot plate[14] until the temperature[15] of the paraffin was 50 ± 2°. Approximately 15 ml of melted paraffin was pipeted[16] onto the petri dish surrounding the pellets. This resulted in a block of paraffin[13] containing nine pellets. This block was removed with a laboratory spatula[11] and cut into nine pieces with a scalpel blade; each piece thus contained one hemisphere pellet. A drop of the melted paraffin was then layered over the flat surface of each of the hemisphere pellets, causing the pellets to be completely coated.

The final step in achieving the hemispheric design (Fig. 1) was to expose the cavity, yet leave the remainder of the pellet coated. This was accomplished by gently scraping off the paraffin covering the steel bead and removing the bead with a pair of forceps[11].

Slab Systems for Low Molecular Weight Compounds—The procedures to fabricate slabs followed methods similar to those described above. A sodium salicylate–polyethylene blend (800 mg) was loaded in the flat-bottomed brass mold[6], followed by heating in the oven and compressing with the flattened part of the plunger[6] (Fig. 2b). After compression, the resultant cylinder was cut lengthwise into two halves and trimmed to lengths of 7.4 ± 0.2 mm. The average weight was 210 ± 5 mg. The resultant pellet was placed with one of its flat faces down on the surface of a petri dish[12] and coated with melted paraffin. About 15 ml of the melted paraffin was poured over 10 pellets. The resultant slabs thus were coated on all sides except the flat faces. Each face had an exposed area of ~56 mm^2.

Hemisphere-Shaped Systems for Macromolecules—The molds used for fabricating hemisphere-shaped systems for macromolecules were composed of glass and had hemispheric bottoms[17] (13-mm diameter × 11-mm height). To prevent these molds from falling over, an embedding platform was made. This platform was constructed by pouring 15 ml of molten paraffin[13] into a bacterial petri dish[12], and then placing empty glass molds[17] into the paraffin so that they touched the bottom. After allowing the paraffin to harden, the molds were removed and the indentations left behind in the paraffin could be used to subsequently support the molds.

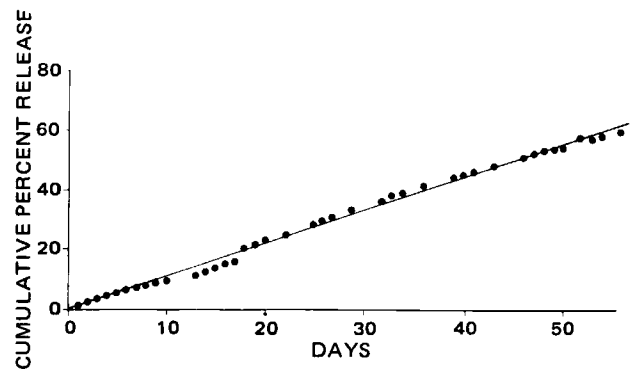

Figure 6—*Cumulative release of bovine serum albumin* versus *time. The matrix was made of ethylene–vinyl acetate copolymer and bovine serum albumin. Standard error of the mean of the cumulative release at each time point was within 12%.*

To make the hemisphere polymer systems, earlier methods of preparing polymer–macromolecule slabs (8) were adapted. The procedure is illustrated in Fig. 4 and described in detail as follows. First, empty glass molds were positioned in the indentations in the paraffin-embedding platform. Then, 6 ml of 20% ethylene–vinyl acetate copolymer[18] solution in methylene chloride[19] and 514 mg of bovine serum albumin[20] powder [particle size range (8) from 150 to 180 μm] were mixed in a glass vial at room temperature and vortexed[21] for 1 min to yield a uniform suspension. Into each hemispheric glass mold[17], 0.8 ml of the protein–polymer dispersion was pipeted[22]. The petri dish containing these samples was then transferred onto a block of dry ice for 10 min. The samples gelled within 1 min. The petri dish containing the samples was then dried first at −20° for 2 days and then at 20° for another 2 days as reported previously (8).

The hemisphere pellets were coated twice with 20% ethylene–vinyl acetate copolymer solution (containing no macromolecules) to form an impermeable barrier. The coating procedure is described as follows: (*a*) The tip of a cylindrical metal stick[23] (1.8-mm diameter × 30-mm length) was inserted into the center of the flat surface of each hemisphere pellet to a depth of ~3 mm. (*b*) Using the uninserted portion of the stick as a handle, the hemisphere pellets were placed directly on the surface of a block of dry ice for 10 min. (The round bottoms of the pellets were touching the dry ice.) (*c*) Again using the metal stick as a handle, the cooled hemisphere then was immersed into 20% ethylene–vinyl acetate copolymer solution at 20° for 10 sec, removed, and then placed immediately on the same dry ice for 10 min. (*d*) A second layer of coating was done in the same manner as described above. (*e*) The hemispheres were then put in the freezer[24] (−20°) for 2 days followed by further drying at 20° for 2 days in a desiccator[25] under a houseline vacuum (600 mtorr) to remove residual solvent (8). (*f*) Finally, to create the exposed cavity in the face of the hemisphere pellet, the metal stick[23] was removed by gently encircling the polymer surface immediately surrounding the stick with a scalpel blade.

Kinetic Studies—Studies were conducted to measure the release of salicylate into saline from polymer matrices. For these studies, each matrix was immersed in a scintillation vial[26] containing 10 ml of saline solution (0.154 *M* NaCl[27]). Each matrix was weighted down with five 9-mm stainless steel standard wound clips[28] stuck onto the wax coating. Any bubbles present on the uncoated, releasing surface were removed by aspiration with a pasteur pipet. The vials were placed on a shaker[29] at 20°. (Preliminary experiments have shown no significant difference between the release rates obtained with this mild shaking and those obtained using vigorous stirring.) At each time point, the matrices were transferred using a pair of forceps into 10-ml fresh saline-containing vials. During these transfers, excess solution on the matrix surface was removed by gentle blotting on a tissue. The released sodium salicylate concentration was determined spectrophotometrically[30] by measuring absorbance at 294 nm.

As controls, hemispheres of pure polyethylene were prepared uncoated and completely coated (including the cavity). Similarly, uncoated and completely coated hemispheres with the 30% salicylate–polyethylene blend were prepared. Identical controls were conducted for the ethylene–vinyl acetate copolymer system. All of these controls were tested for release kinetics.

The kinetics of albumin release from the hemisphere-shaped systems were followed by methods described previously (8). Albumin concentrations were measured spectrophotometrically[30] by determining absorbance at 280 or 220 nm (8).

RESULTS

The cumulative percentage release of sodium salicylate *versus* time from polyethylene matrices of these hemispheres and slabs is compared in Fig. 5. The hemisphere-shaped device closely approximates zero-order release. Standard error of the mean of cumulative release at each time point was within 2% for slabs and 4% for hemispheric devices.

Control matrices of coated and uncoated pure polyethylene hemispheres, as well as the completely coated sodium salicylate–polyethylene hemispheres, showed no material exhibiting spectrophotometric absorbance in the saline solution. The uncoated hemisphere-shaped device containing sodium salicylate prepared in the same manner as those used in the above study showed a rapid, nonlinear release and was nearly exhausted of its drug within 3 days.

To determine if the hemispheric design was applicable to macromolecules such as proteins as well as low molecular weight drugs, ethylene–vinyl acetate copolymer matrices containing bovine serum albumin were tested. Figure 6 shows the release kinetics of albumin from the hemisphere-shaped systems. Each point represented eight samples. A linear relationship between cumulative percentage release and the time of release was observed for 60 days. The release rate was ~0.5 mg of albumin/day. Standard error of the mean of cumulative release at each time point was within 12%. Control hemisphere-shaped devices completely coated twice with 20% ethylene–vinyl acetate copolymer solution did not release any protein. The media collected in the release experiments of the control hemisphere-shaped devices prepared from pure ethylene–vinyl acetate copolymer solution (without albumin) showed no spectrophotometric absorbance.

DISCUSSION

These studies demonstrate that hemispheric matrices can act as constant release systems for both low molecular weight drugs (Fig. 5) and high molecular weight compounds (Fig. 6). The fabrication procedures for these systems are relatively simple and can be performed without expensive apparatus. To fabricate the hemisphere-shaped devices, two different methods were employed: the fusion of polyethylene and drug

[18] Ethylene–vinyl acetate copolymer beads (Elvax 40, 40% vinyl acetate content w/w) manufactured by DuPont Chemical Co., Wilmington, Del., and extracted with hot water if the beads were clay coated.

by heating (14), and the gelation of ethylene–vinyl acetate copolymer by freezing at −80° (8). The selection of the fabrication procedure depended on the nature of the drugs. For example, the gelation of polymer at low temperature is more suitable for proteins or peptides because they may be denatured at high temperature.

It should be noted that reservoir systems, in which a core of drug is surrounded by a membrane, can also be used as a zero-order release system. In these systems, if the drug is loaded above its solubility, the drug concentration at the inside of the membrane wall will be a constant (*i.e.*, the drug solubility); furthermore, the drug will always traverse the same diffusion distance (*i.e.*, the membrane thickness). Thus, the release rate will be constant. However, such systems have disadvantages such as expense, undesirable release properties for large molecular weight drugs, and danger in the case of leaks (1–3). The reservoir system principle also was applied to polymer matrices (15), where the rectangular matrices of polymer–drug were coated with pure polymer. Under appropriate conditions, the rate-limiting step for release was diffusion through the pure polymer coating rather than through the polymer–drug matrix, and constant release was observed. To ensure that the constant release rates observed for the experimental devices in this report were not due to a similar effect (caused perhaps by drug sedimentation towards the center of the matrix during fabrication leaving a film of pure polymer at the surface), a microscopic examination of the drug–polyethylene hemisphere was conducted. In this case, a colored compound, bromcresol green[1], was incorporated into the matrix, due to its ease of optical examination under a light microscope. The matrix was sectioned using a scalpel blade. The examination of the sections confirmed the assumption that the drug particles were evenly distributed in the polyethylene matrix. A similar microscopic examination was conducted for the ethylene–vinyl acetate copolymer–protein system using previously described methods (16). These matrices also showed a uniform drug distribution. Both tests ruled out the possibility that these matrices could act in any way as a reservoir type device.

In *Theoretical*, it was assumed that no boundary layer effects were present and that infinite sink conditions prevailed. In practice there may be significant drug concentration gradients between the matrix release surface and the surrounding media. However, the resultant bulk flow has been shown to bring the release kinetics even closer to zero order (12).

In matrix systems, the factors controlling release rates can be classified into two groups: the matrix parameters such as porosity and tortuosity and the properties of drugs such as solubility and diffusion coefficient. The former are closely related to the loadings and drug particle sizes; the latter are the inherent properties of the incorporated drugs and polymers. Higuchi (4, 5) was the first to design a mathematical model to predict the release kinetics for low molecular weight drugs from a matrix system; the theoretical predictions were proven (6) by measuring the porosity and tortuosity of the matrix from a model system consisting of polyethylene and sodium salicylate. It was also found that the porosity and tortuosity of the matrix were affected by the loading and particle size of the incorporated drugs (6). In a hemisphere-shaped matrix system, it is conceivable that release rates can be varied by a similar manipulation of these fabrication parameters. Additionally, the size of the opening is another governing factor. In situations where Eq. 3 applies, it can be seen that the release rate is directly proportional to the radius of the cavity, a_i.

The release rate of macromolecules or proteins, such as bovine serum albumin, from ethylene–vinyl acetate copolymer matrix slabs can be varied by as much as 2000-fold by manipulating three fabrication parameters, (*i.e.*, drug loadings, aggregate sizes, and matrix coating) (8). The release rate of macromolecules from a hemisphere-shaped device conceivably can be changed by manipulating the same fabrication parameters and the size of the opening. Although the hemisphere design resulted in zero-order release kinetics for macromolecules such as albumin, the release mechanism for these systems has not yet been fully established. However, evidence continues to indicate that the release of macromolecules from polymeric matrices occurs *via* diffusion through interconnecting pores (16). The present study is consistent with such a mechanism. However, a mathematical model that can be used to predict release kinetics from macromolecular release systems has not yet been developed.

Although only bovine serum albumin was used as a model macromolecule in the present study, initial results have also indicated that zero-order release rates were obtained for over 1 month for lysozyme and β-lactoglobulin when they were incorporated into hemispheric matrices. The hemisphere systems have not yet been tested *in vivo*. However, initial studies have demonstrated good correlation between *in vivo* and *in vitro* release rates of macromolecules from ethylene–vinyl acetate copolymer slabs (17).

The major problems encountered in the fabrication procedures in the present study are the techniques of both coating the matrix and opening the cavity uniformly. Paraffin was used to coat the hemispheres for small molecules; however, it may not be suitable as a coating material for an *in vivo* implant because of its brittleness and incompatibility with the tissue. A search is being conducted to find an appropriate coating material to replace paraffin. On the other hand, the ethylene–vinyl acetate copolymer system used for macromolecules has been shown to be highly biocompatible (18). The development of a technique for opening the hole on the flat face of the hemisphere is very critical to achieve reproducibility. Besides the methods practiced in these studies, improved techniques to create holes on the flat face of the hemisphere-shaped device should be explored. Techniques such as computer-aided drilling may prove useful in future studies.

In summary, both theoretical and experimental analyses have demonstrated that a hemisphere can act as a zero-order release system for both micro- and macromolecules. The achievement of constant release rates for macromolecules is particularly significant, since other approaches (*e.g.*, reservoir systems) have not yet been able to release macromolecules in a controlled fashion. This study appears to be the first demonstration that macromolecules can be released at a zero-order rate for long time periods from controlled-release polymer systems.

^{60}Co-Irradiation as an Alternate Method for Sterilization of Penicillin G, Neomycin, Novobiocin, and Dihydrostreptomycin

KIYOSHI TSUJI [x], PAUL D. RAHN, and KATHY A. STEINDLER

Received August 26, 1981, from *Control Analytical Research and Development, The Upjohn Co., Kalamazoo, MI 49001.* Accepted for publication February 26, 1982.

Abstract □ The effects of the use of ^{60}Co-irradiation to sterilize antibiotics were evaluated. The antibiotic powders were only occasionally contaminated with microorganisms. The *D*-values of the products and environmental isolates were 0.028, 0.027, 0.015, 0.046, 0.15, 0.018, and 0.19 Mrads for *Aspergillus* species (UC 7297, 7298), *A. fumigatus* (UC 7299), *Rhodotorula* species (UC 7300), *Penicillium oxalicum* (UC 7269), *Pseudomonas maltophilia* (UC 6855), and a biological indicator microorganism, *Bacillus pumilus* spores (ATCC 27142). An irradiation dose of 1.14 Mrads, therefore, was sufficient to achieve a six-log cycle destruction of *B. pumilus* spores. Based on the bioburden data, a minimum irradiation dose of 1.05 Mrads was calculated to be sufficient to obtain a 10^{-6} probability of sterilizing the most radioresistant isolate, *Pen. oxalicum*. To determine the radiolytic degradation scheme and the stability of the antibiotics following irradiation, high-performance liquid chromatographic (HPLC) methods were developed. The resulting rates of degradation for the antibiotics were 0.6, 1.2, 2.3, and 0.95%/Mrad for penicillin G, neomycin, novobiocin, and dihydrostreptomycin, respectively. Furthermore, radiolytic degradation pathways for the antibiotics were identified and found to be similar to those commonly encountered when antibiotics are subjected to acidic, basic, hydrolytic, or oxidative treatments. No radiolytic compounds unique to ^{60}Co-irradiation were found.

Keyphrases □ Irradiation—cobalt-60, alternate method for antibiotic sterilization □ Antibiotics—^{60}Co-irradiation as an alternate method for sterilization □ Sterilization—use of ^{60}Co-irradiation as an alternate method □ High-performance liquid chromatography—determination of radiolytic degradation scheme and stability of antibiotics following irradiation

The majority of pharmaceutical compounds are thermolabile. Sterilization of these compounds, therefore, is performed with the use of an ethylene oxide treatment. However, such a process has a low sterility assurance (1) and is quite costly. Moreover, the efficiency and safety of ethylene oxide as a sterilization agent are being questioned by both the Food and Drug Administration (FDA) (2) and the Environmental Protection Agency (3). ^{60}Co-Irradiation has been recognized as the preferred method for sterilization of medical devices and has been accepted for terminal sterilization of ophthalmic ointment (4). In many countries, products irradiated at 2.5 Mrads can be released for marketing as sterile without final sterility testing.

Recently the FDA proposed a guideline to regulate the irradiation of foods for human consumption (5). This proposal is based on a quantitative estimate of the projected daily human consumption of unique radiolytic compounds in irradiated foods (6). The daily dose of pharmaceutical products is substantially less than the amount of food intake. Thus, the feasibility of ^{60}Co-irradiation for the sterilization of antibiotics has been examined by assessing the resistance of product and environmental isolates to ^{60}Co-irradiation, determining stability, and identifying radiolytic compounds of ^{60}Co-treated antibiotics.

EXPERIMENTAL

^{60}Co-Irradiation—All irradiations were carried out[1], by raising the irradiation source, consisting of several rods containing ^{60}Co-pellets mounted on a plaque, from a pool of water into a stationary position for irradiation. Samples were placed in totes on two tiers surrounding the cobalt-60 source. A shuffle–dwell system averaged the radiation gradient around the source by periodically shifting the tote horizontally and vertically. Other samples were stationed at calibrated points where the radiation intensity was more precisely known.

Absorbed irradiation doses were measured potentiometrically using a ceric-cerous dosimeter[2] (7, 8) and spectrophotometrically using a red perspex dosimeter[3].

High-Performance Liquid Chromatography—The modular liquid chromatographic system consisted of a variable wavelength UV monitor[4] or a fixed wavelength UV monitor[5], a high pressure pump[6], a 20-μl fixed-loop injector[7], or a sample processor[8].

Chromatographic Conditions—*Penicillin G*—The chromatographic conditions were as described previously (9) using a reversed-phase column[9] with a mobile phase of acetonitrile, water, and 0.2 *M* ammonium acetate (50:40:10) at pH 4.0. The column effluent was monitored at 254 nm.

Neomycin—The chromatographic conditions were as described previously (10), which consisted of a precolumn derivatization of neomycin with 1-fluoro-2,4-dinitrobenzene at 100° for 40 min, followed by chromatography using a silica column[10] with a mobile phase of chloroform, tetrahydrofuran, methanol, and acetic acid (598:392:8:2). The column effluent was monitored at 254 nm.

Table I—Destruction of Microorganisms by ^{60}Co-Irradiation

Microorganism	*D*-Value, Mrads
Aspergillus species	
UC 7297	0.028
UC 7298	0.027
A. fumigatus (UC 7299)	0.015
Rhodotorula species (UC 7300)	0.046
Pen. oxalicum (UC 7269)	0.15
Pseud. maltophilia (UC 1885)	0.018
B. pumilus spore (ATCC 27142)	0.19

Novobiocin—The HPLC methods were as described previously (11). The normal-phase chromatography employed a silica column[10] with a mobile phase of 50% water-saturated butyl chloride, tetrahydrofuran, methanol, and acetic acid (88:5:4:3). A C_{18} column[11] was used for reversed-phase chromatography with 0.005 *M* 1-heptanesulfonate in methanol–water (80:20). The column effluent was monitored at 254 and 340 nm.

Dihydrostreptomycin—A reversed-phase RP-8 column[12] was maintained at 30°. A linear gradient elution program changed from mobile phase A to B in 30 min. Mobile phase A was 6% methanol; mobile phase B was 20% methanol, both contained hexanesulfonic acid, sodium sulfate, and acetic acid. The postcolumn oxidation and derivatization with hypochlorite and orthophthaldehyde (12) was applied for fluorometric detection of dihydrostreptomycin. A fluorometer[13] was used to monitor the column effluent.

Microbial Resistance to ^{60}Co-Irradiation—The resistance of microorganisms, isolated from the products and environment, to ^{60}Co-irradiation was investigated. The microorganisms examined were: *Aspergillus* species (UC 7297, 7298), *A. fumigatus* (UC 7299), *Rhodotorula* species (UC 7300), *Penicillium oxalicum* (UC 7269), and *Pseudomonas maltophilia* (UC 6888). Spores of *Bacillus pumilus* (ATCC 27142) were also used as biological indicator microorganisms.

0	682.2	88.6
0.9	675.1	81.7
2.3	661.0	81.7
3.2	654.9	82.7
4.1	649.0	82.7
4.5	643.7	81.2

Table III—Stability of Penicillin G Procaine to ^{60}Co-Irradiation

Irradiation Dose, Mrads	Potency, Units
0	110.800
1.5	108.800
2.5	107.000
4.0	108.600

B. pumilus received doses of 0.0, 0.15, 0.3, 0.5, 0.7, and 0.93 Mrads, while all other microorganisms received 0, 0.02, 0.04, 0.06, and 0.08 Mrads of irradiation.

***D*-Value Determination**—Microbial resistance to ^{60}Co-irradiation was determined by the *D*-value, the irradiation dose in megarads required to achieve 90% reduction in the microbial population. The *D*-value was calculated using:

$$D = \frac{U}{\log a - \log b} \qquad \text{(Eq. 1)}$$

where *U* is the radiation in megarads, *a* is the initial microbial population prior to radiation treatment, and *b* is the microbial population surviving after treatment with *U* amount of radiation.

To determine the number of microorganisms surviving after receiving *U* amount of radiation, the samples were serially diluted, and 1.0 ml of the appropriate dilutions were plated in duplicate in trypticase soy agar[14].

RESULTS AND DISCUSSION

Microbial Resistance to ^{60}Co-Irradiation—Environmental and occasional microbial contaminants were isolated and used to examine resistance to ^{60}Co-irradiation. The survival curves of microorganisms irradiated followed first-order kinetics: when the log of survivors are plotted against the absorbed dose, a straight line is obtained. A typical

Table IV—Effect of ^{60}Co-Irradiation on Stability of Sodium Novobiocin and Dihydrostreptomycin Sulfate Powder

Irradiation Dose, Mrads	Novobiocin, %	Dihydrostreptomycin, %
0	100	100
0.6	96.2	98.2
1.8	93.0	97.6
2.9	91.5	95.0
3.5	90.3	95.6
4.8	88.3	96.0
5.9	88.8	93.4

survival curve of an isolate, *Aspergillus* species (UC 7298), is shown in Fig. 1. Table I summarizes the *D*-values for *Aspergillus* species (UC 7297, 7298), *A. fumigatus* (UC 7299), *Rhodotorula* species (UC 7300), *Pen. oxalicum* (UC 7269), *Pseud. maltophilia* (UC 6888), and a biological indicator, *B. pumilus* (ATCC 27142) spores. The *D*-values of these microorganisms do not differ significantly from those values appearing in the literature (13–15).

Minimum Irradiation Dose (MID)—The highest *D*-value obtained in this study was 0.19 Mrads for the biological indicator microorganism, *B. pumilus*. Thus, 1.14 Mrads is sufficient to achieve a six-log cycle destruction of *B. pumilus* spores (0.19 × 6).

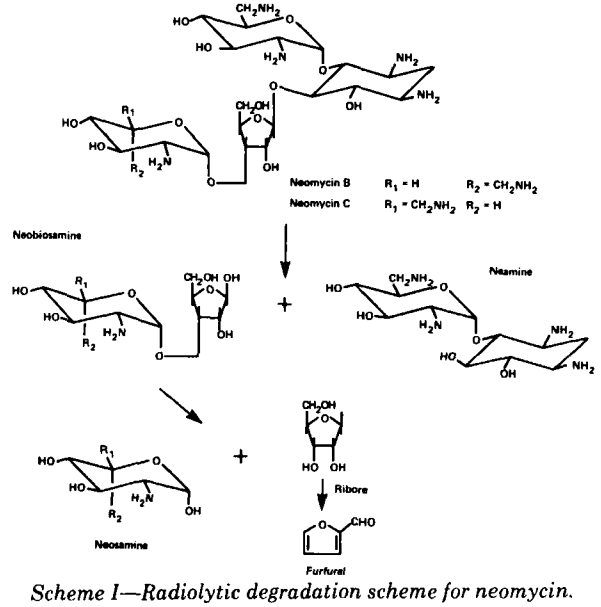
Bioburden data accumulated for 2 years indicated that <25% of a product contained >10 microorganisms/g of powder. The detection limit of the test is $\sim 10^1$ cells/g of sample. The MID required to achieve a 10^{-6} probability of sterility assurance was calculated by:

$$\text{MID} = D \times (6+1) \qquad \text{(Eq. 2)}$$

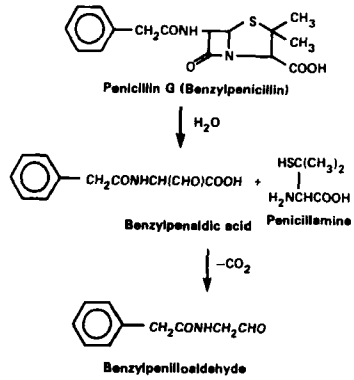
The most resistant isolate was *Pen. oxalicum* with a *D*-value of 0.15 Mrads (Table I). The MID for the product thus was calculated to be 1.05 Mrads. The 2.5-Mrads irradiation dose preferred by many countries for sterilization would result in an ~17-log cycle destruction of the most resistant isolate.

Stability of Antibiotics to ^{60}Co-Irradiation—To determine the feasibility of ^{60}Co-irradiation for the sterilization of antibiotics, stability to ^{60}Co-irradiation must be demonstrated and any unique radiolytic compounds identified.

The stability of neomycin sulfate, penicillin G procaine, sodium novobiocin, and dihydrostreptomycin following irradiation with cobalt 60 was examined by HPLC (Tables II–IV). The correlation between the HPLC and microbiological assay data was well established (9–11). The rates of degradation of penicillin G, neomycin, novobiocin, and dihydrostreptomycin by cobalt-60 were 0.6, 1.2, 2.3, and 0.95%/Mrad, respectively. If the ratio of maximum to minimum irradiation dose levels of a product is 1.3 (14), then the maximum irradiation dose that a product receives would be 1.37 Mrads (1.05 × 1.3), since the MID is 1.05. At 1.37 Mrads of irradiation, the expected percentages of degradation for penicillin G, neomycin, novobiocin, and dihydrostreptomycin are 0.8, 1.6, 3.2, and 1.3%, respectively. The rates of degradation for neomycins B and C were not statistically different (Table II).



Scheme I—Radiolytic degradation scheme for neomycin.



Scheme II—Radiolytic degradation scheme for penicillin G.

Identification of Radiolytic Degradation Compounds—Irradiated antibiotic powders were analyzed by stability-indicating HPLC to isolate, identify, and quantify radiolytic degradation compounds.

For positive identification, samples containing radiolytic compounds were extracted with solvents to enrich the compounds. Compounds were then purified using semipreparative scale HPLCs. The column effluents corresponding to the radiolytic compounds were collected and freeze dried. The identification of the radiolytic compounds was confirmed by a comparison of their mass spectra with those of authentic samples.

Neomycin—A nonirradiated sample and one irradiated at 5.0 Mrads were analyzed by HPLC. The nonirradiated sample contained 39.3 mg of total neomycin (neomycins B and C)/g of a product, while the 5.0-Mrads irradiated sample contained 34.8 mg/g: a decrease of 4.5 mg of neomycin/g. An inspection of HPLC chromatograms indicated an increase in the neamine peak (Fig. 2). The nonirradiated sample contained 0.8 mg of neamine/g of the product, while the irradiated sample contained 3.3 mg/g: a difference of 2.5 mg of neamine/g. A degradation of 4.5 mg of

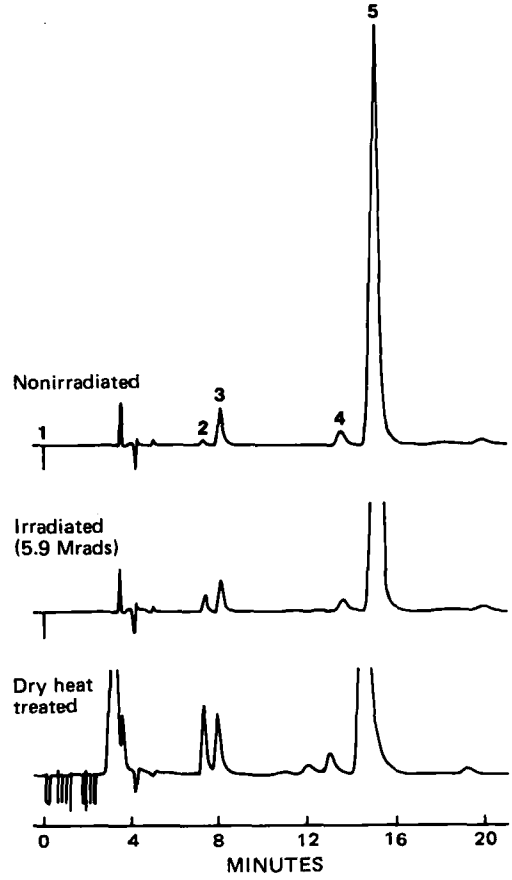


Figure 3—*Normal phase HPLC of novobiocin. Key: (1) injection; (2) radiolytic compound; (3) descarbamyl novobiocin; (4) isonovobiocin; (5) novobiocin.*

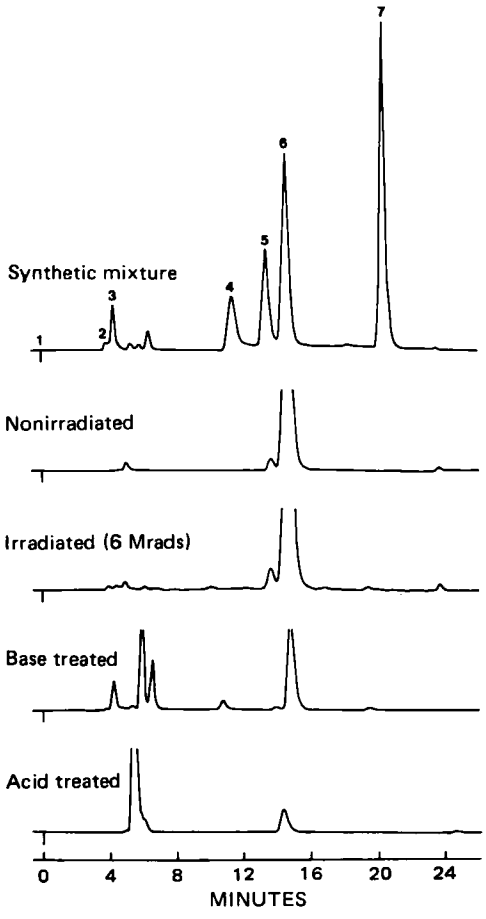

Figure 4—*HPLC of dihydrostreptomycin treated with irradiation, base, and acid. Peak identification: (1) injection; (2) streptamine; (3) D-glucosamine; (4) streptomycin; (5) dideguanyldihydrostreptomycin; (6) dihydrostreptomycin; (7) β-methyldihydrostreptobiosaminide.*

neomycin theoretically yields 2.4 mg of neamine. This calculated quantity of neamine is not statistically different from the observed value of 2.5 mg. Furthermore, a peak corresponding to neosamine increased, but no significant increase of the neobiosamine peak was observed. Thus, it may be concluded that neomycin, upon irradiation, undergoes hydrolytic cleavage at a glycosidic bond to form neamine and neobiosamine. Neobiosamine further degrades to neosamine and ribose; the latter likely yields furfural. A postulated radiolytic degradation scheme is shown in Scheme I. This is the common, hydrolytic degradation pathway for neomycin (16).

Penicillin G—The radiolytic degradation scheme for penicillin G was similarly identified and is shown in Scheme II (9). Penicillin G underwent hydrolytic cleavage to form benzylpenillic acid and benzylpenicilaldehyde. These degradation compounds may also be formed through alkaline treatment (17). Benzylpenicilloic acid, benzylpenilloic acid, and hydroxybenzylpenicillin, reported to form when penicillin G is irradiated in an aqueous solution (18), were not detected.

Novobiocin—Upon examination of the HPLC chromatogram of irradiated and nonirradiated novobiocin powder (Fig. 3), it became evident that one peak, which was originally present in the bulk powder, increased upon irradiation. This degradation compound can easily form upon dry heat treatment of novobiocin powder (Fig. 3). No new peak unique to ^{60}Co-irradiation was detected. Relative chromatographic retention of this peak (0.50) is close to but not identical to that of novobiocic acid (0.44); moreover this peak lacks absorptivity at 340 nm. Novobiocic acid strongly absorbs at 340 nm. The column fraction corresponding to this unknown peak was collected and analyzed by mass spectrometry. The mass spectrometric data clearly identified the unknown compound as the ring A amide (11). The site of the radiolytic cleavage of the novobiocin molecule is shown in the structure of novobiocin.

Dihydrostreptomycin—Identification of degradation compounds and the radiolytic pathway for dihydrostreptomycin are in progress. However, as shown in Fig. 4, the compounds that increase by irradiation were either inherently present in commercially available, nonirradiated lots or can easily be formed by acidic or basic treatment. No new compounds peculiar to irradiation were found.

^{60}Co-Irradiation has been shown to be an effective means of sterilizing antibiotics. The minimum irradiation dose required to achieve 10^{-6} probability of sterilizing the most resistant isolate, *Pen. oxalicum*, is 1.05 Mrads, degradation of antibiotics from ^{60}Co-irradiation is minimal, and the radiolytic degradation schemes are similar to those commonly encountered when antibiotics are subjected to acidic, basic, hydrolytic, or oxidative treatment. No radiolytic compounds unique to irradiation have been found.

Morphine Radioimmunoassay Specificity Before and After Extraction of Plasma and Cerebrospinal Fluid

PATRICIA Y. GRABINSKI *, ROBERT F. KAIKO *x, T. D. WALSH §, KATHLEEN M. FOLEY ‡, and RAYMOND W. HOUDE *

Received December 2, 1981, from the *Analgesic Studies Section, Sloan-Kettering Institute for Cancer Research and ‡Department of Neurology, Pain Service, Memorial Hospital, New York, NY 10021 and §St. Christopher's Hospice, Sydenham, England. Accepted for publication March 1, 1982.

Abstract □ Currently available morphine radioimmunoassays, using antiserum to 3-*O*-carboxymethylmorphine, lack sufficient specificity for clinical pharmacokinetic studies following repeated oral doses due to the relatively high plasma concentrations of cross-reacting metabolites. A procedure is described for the recovery of the drug and removal of its polar metabolites. The single-step solvent extraction recovered 97% (*CV* 6.9%) morphine and none of the major inactive metabolite, morphine-3-glucuronide. Extracted and nonextracted morphine radioimmunoassay standard curves had comparable slopes, precision, and I_{50} values. Cross reactivity between morphine-3-glucuronide and the antiserum was eliminated when the radioimmunoassay was preceded by extraction. Without prior extraction, the apparent plasma morphine concentration following repeated oral doses was dilution dependent. In contrast, concentration was dilution independent when the radioimmunoassay was preceded by extraction. The plasma morphine concentration in 23 cancer patients at 4 hr following their previous dose (calculated to 10 mg of base) was 26 ng/ml (95% confidence interval (CI), 20–33 ng/ml) with prior extraction, as compared with the apparent concentration of 80 ng/ml (95% CI, 64–96 ng/ml) without extraction. These data indicate that by combining prior extraction with radioimmunoassay, specific, steady-state plasma morphine levels can be obtained following repeated oral doses. However, no significant differences were observed between extracted and nonextracted morphine concentrations in ventricular cerebrospinal fluid from four patients who had received a single intravenous dose. The extraction procedure, prior to radioimmunoassay, provides the specificity required for the measurement of morphine in biofluids that contain relatively high concentrations of cross-reacting metabolites.

Keyphrases □ Morphine—radioimmunoassay specificity before and after extraction of plasma and cerebrospinal fluid □ Radioimmunoassay—morphine, specificity before and after extraction of plasma and cerebrospinal fluid

While the development of a sensitive morphine radioimmunoassay (1) has allowed measurement of clinical pharmacokinetic parameters following single parenteral morphine dosing (2–9), there is limited pharmacokinetic information available following repeated and oral dosing (10). Morphine-3-glucuronide, the major biotransformation product, cross reacts with morphine antisera (1, 11–13). Cross reactivity does not appear to be a significant factor following single parenteral dosing due to the limited amount of metabolite present in plasma and to its relatively low affinity for morphine antisera (3). However, with repeated and oral dosing, the ratio of plasma morphine-3-glucuronide to morphine is likely to be much higher due to the first-pass effect (14) and consequent accumulation of the inactive metabolite. Under these circumstances, most currently available morphine radioimmunoassays are lacking in specificity. While there are other methods available for the measurement of morphine, such as those employing derivatization followed by GLC (15, 16) and that employing extraction followed by scintillation counting of radiolabeled drug (14), an appropriately specific radioimmunoassay would be desirable to many investigators for further studies of the clinical pharmacokinetics of morphine.

The objective of the studies reported here was to demonstrate that an extraction procedure, preceding an otherwise nonspecific radioimmunoassay, provides the specificity required for the measurement of unconjugated morphine in plasma following repeated oral dosing. The utility of the method is demonstrated by the measurement of extracted and nonextracted steady-state plasma morphine concentrations in hospice patients who had been receiving oral morphine doses for the relief of pain due to advanced cancer. These results are contrasted with those obtained by the morphine radioimmunoassay of extracted and nonextracted serial samples of cerebrospinal fluid from cancer patients with chronic pain who had received single intravenous injections of morphine.

EXPERIMENTAL

The extraction procedure is a modification of the first step in a previously reported multistep procedure (17).

Solutions—Glassware for morphine extraction and for storage of morphine standard solutions was siliconized[1]. Morphine standards[2] were added to control plasma in concentrations of 0.31, 0.62, 1.2, 2.5, 5.0, 10, and 20 ng of free base/ml. The extraction buffer, pH 8.6–8.7, contained 40% (w/v) K_2HPO_4 and was sodium chloride saturated. The extraction organic solvent was chloroform–2-propanol (3:1). The extract was reconstituted with 0.1% (w/v) gelatin[3] in 0.01 *M* phosphate-buffered saline, pH 7.3 (assay buffer).

Procedure—An aliquot (0.5 ml) of each plasma standard and of the patient's plasma (up to 0.5 ml) was added to distilled water (1.0 ml) and extraction buffer (1.0 ml) in 15-ml screw-top centrifuge tubes. The varied volumes of the patients' plasma were adjusted to a common volume (0.5 ml) by the addition of control plasma. Each tube was vortexed. The organic solvent (6 ml) was added, and the tubes were capped and shaken for 10 min. The tubes were then centrifuged for 5 min at 300×*g*. The upper aqueous phase and the lipid interphase were aspirated off, and an aliquot (3.0 ml) of the lower organic phase was transferred to a 12-ml conical centrifuge tube. The organic phase was evaporated to dryness in a water bath at 83°. The dry extract was reconstituted with assay buffer (0.5 ml). The tubes were vortexed, and the reconstituted extract was frozen until radioimmunoassay.

Morphine and Morphine-3-glucuronide Recovery Studies—[6-^{3}H]morphine[4] (1.0, 2.0, 4.0, 5.0, 8.0, and 25 ng) was added to control plasma and extracted. Results from scintillation[5] counting of these samples at full tritium window were compared with those of identical amounts of tritiated morphine which had been added directly to the organic phase (3 ml, which had been previously shaken with buffered control plasma and water), evaporated to dryness, and reconstituted. Extracted and nonextracted [^{14}C]morphine-3-glucuronide[6] (40 μg) was also treated as described above.

The radioimmunoassay is a modification of a previously reported procedure (1, 3).

Solutions—A suspension of 0.1% (w/v) dextran[7] and 1.0% (w/v)

Table I—Influence of Morphine-3-glucuronide Cross Reactivity on the Measurement of Unconjugated Morphine

Parts Morphine-3-glucuronide: Morphine Added to Control Plasma		Ratio of Morphine Equivalents Measured by Radioimmunossay to Morphine Added	
Parts	N	Extracted	Nonextracted
0:1	9	1.00 ± 0.03	1.01 ± 0.05
10:1	9	1.08 ± 0.07	1.79 ± 0.11
40:1	9	1.02 ± 0.06	2.51 ± 0.21

charcoal[8] in assay buffer was used for the adsorption of unbound morphine. The radioligand, [7,8-^{3}H]dihydromorphine[9] with a specific activity of 49 Ci/mmole at a concentration of 1.0 mCi/ml of ethanol, was diluted (1:2000) in ethanol to obtain ~20,000 cpm/50 μl. Morphine antiserum[10] was prepared from the blood of New Zealand white rabbits immunized by the administration of 3-carboxymethyl-morphine–bovine serum albumin every 2–3 months for 1 year (18). Antibody dilution studies resulted in 50% binding of the radioligand at an antibody dilution of 1:6000 in 0.01 *M* phosphate-buffered saline (pH 7.3) when 100 μl of diluted antibody was incubated in a final assay volume of 450 μl.

Procedure—Diluted antiserum (100 μl) was added to assay tubes (10 × 75-mm disposable culture tubes) containing the reconstituted plasma extract (200 μl of the original 0.50 ml for standards and 50–200 μl of the original 0.50 ml for patients' samples), radioligand (50 μl), and control plasma (100 μl) to yield a final volume of 450 μl. If necessary for patients' samples, assay buffer was added to yield the 450-μl final volume. Two sets of duplicate background tubes containing no antibody or unlabeled morphine and two sets of triplicate maximum-binding tubes containing no unlabeled morphine were included. Standards and unknowns were assayed in duplicate. The tubes were incubated at room temperature for 1 hr. After incubation, the dextran–charcoal suspension (0.50 ml), which was kept stirring in an ice bath, was added to each tube. The tubes were vortexed and placed in an ice bath for 10 min. The tubes were then centrifuged at 4° and 1500×*g* for 15 min. An aliquot (0.50 ml) of the supernatant was removed from each tube for scintillation counting. A logit-log transformation[11] was used for the linearization of the standard curve and the calculation of the amount of morphine in patients' samples.

Nonextracted radioimmunoassay conditions were identical to those described above for the extracted radioimmunoassay except that 100-μl aliquots of the plasma morphine standards were added to the assay buffer (200 μl) along with the usual amounts of radioligand and antibody solutions. Patients' plasma samples were added in 10–100-μl volumes with any volume differences adjusted by the addition of control plasma to yield a final plasma volume of 100 μl and a final incubation volume of 450 μl as in the extracted radioimmunoassay. Morphine concentrations in cerebrospinal fluid were determined by radioimmunoassays before and following extraction as described for plasma.

Specificity Studies—*Morphine-3-glucuronide Affinity Study*—A morphine-3-glucuronide[12] standard curve was generated by the substitution of the metabolite for morphine in plasma standards which were prepared in 10 times the concentrations (weight basis) as the morphine plasma standards. Conditions of the radioimmunoassay were identical to those described above for the nonextracted morphine standard curve.

Morphine-3-glucuronide Cross Reactivity Study—Three different sets of standards in control plasma were prepared as follows: set I, morphine standards in concentrations of 0.62, 5, and 20 ng/ml; set II, morphine standards as in set I with 10-fold amounts of morphine-3-glucuronide added; set III, morphine standards as in set I with 40-fold amounts of morphine-3-glucuronide added. Triplicates of each standard were assayed before and after extraction as described above for patients' plasma.

Variable Dilutions Study—Plasma samples from two hospice patients (described in the following section) were assayed prior to extraction in graded dilutions of 1:10, 1:50, and 1:250 and following extraction in graded dilutions of none, 1:5, and 1:25.

	1:25	18.6	1:250	226

Applications—Extracted and nonextracted radioimmunoassay procedures were applied to the measurement of morphine equivalents in two sets of biofluids: a set of plasma samples in which the ratio of morphine-3-glucuronide to morphine might be expected to be relatively high and a set of cerebrospinal fluid samples in which the ratio would be expected to be considerably lower.

Plasma Morphine after Repeated Oral Dosing—The patients[13] (Group I) were being treated with morphine for relief of pain due to advanced cancer. There were 23 patients (10 men and 13 women) ranging in age from 42 to 84 years. They had been receiving oral doses of either 5, 10, 20, 30, 45, or 60 mg of morphine sulfate every 4 hr for at least 48 hr and had been receiving oral morphine for at least 1 week before being stabilized at their given doses. Blood samples were obtained at 4 hr following their previous medication. The plasma was recovered and assayed for morphine equivalents prior to and following extraction.

Cerebrospinal Morphine after a Single Intravenous Dose—The patients[14] (Group II) were being treated for the relief of chronic pain. There were four men (34, 45, 56, and 67 years old) who had received a single intravenous injection of 10 mg of morphine sulfate. An indwelling intraventricular catheter and Ommaya reservoir had been implanted in these patients for the introduction of chemotherapeutic agents as part of their treatment for cancer. This allowed the collection of ventricular cerebrospinal fluid samples (5, 10, 15, and 30 min and 1, 2, 4, 8, and 24 hr postdrug). Samples were assayed for morphine prior to and following extraction. The results of an initial nonextracted assay of these samples were previously reported (19).

RESULTS AND DISCUSSION

The extraction of added radiolabeled morphine (1.0–25 ng) to plasma resulted in a mean recovery of 97% (range, 88–104%; *CV*, 6.9%), with no indication of any trend between the amount of morphine added to plasma and the amount recovered. The extraction of 40 μg of radiolabeled morphine-3-glucuronide from plasma resulted in a consistent recovery of 0%. These data indicate that the extraction procedure effectively eliminates the metabolite while recovering the parent drug with acceptable loss and variation. The consistency of morphine recovery is more important than the absolute percentage recovery, since the assay is designed to treat the standards and unknowns in the same manner. Any losses of morphine in the extraction procedure would be reflected in the standards and unknowns to the same extent. High and consistent recovery is achieved, however, with thorough siliconization of the extraction tubes.

Assuming 100% recovery of extracted morphine and taking aliquot losses into consideration, the assays had been designed to yield the same amounts of morphine in each of the standard curves (0.031, 0.062, 0.12, 0.25, 0.50, 1.0, and 2.0 ng). Extracted and nonextracted standard curves were comparable with respective mean slopes of 2.4 ± 3.3% (*CV* from day to day) and 2.6 ± 6.7%, regression correlation coefficients of 0.996 ± 0.3% and 0.997 ± 0.1%, and amounts of morphine which inhibit 50% of radioligand binding equivalent to 0.16 ng ± 3.0% and 0.18 ng ± 14%. The intra-assay variation (*CV*) for duplicate standards was 4.5 and 2.8% for extracted and nonextracted assays, respectively. These data demonstrate that the assays are quite reproducible with acceptable variations in the various parameters for both standard curves. In addition, the data for extracted assays support the consistency of extraction recovery results obtained with radiolabeled morphine standards.

When morphine-3-glucuronide was substituted for morphine in the nonextracted standard curve, a slope of 1.2 was obtained as compared with the slope of 2.6 for morphine. At 25, 50, and 75% displacement of

24 hr	2	0.4 ± 0.3	1.1 ± 0.4

radioligand binding, 9.4, 28, and 84 times as much glucuronide as morphine (weight basis) was required. Thus, the ratio of metabolite to parent drug which displaces equivalent amounts of radioligand from the antibody is dependent on the total extent of radioligand displacement. It has previously been reported that standard curves for morphine and its major metabolite (when substituted for morphine in a morphine radioimmunoassay) are not parallel (13), and that the commonly used index of cross reactivity, the ratio of the amounts of two compounds at I_{50}, can be misleading (13).

A more direct approach to examining the cross reactivity of two compounds is to assay varying combinations of them. When morphine-3-glucuronide was added to selected plasma morphine standards in 10- and 40-fold amounts, significantly higher morphine equivalents were obtained as compared with when no metabolite was added in the assays not preceded by extraction (Table I). Ten- and 40-fold amounts of the metabolite resulted in overestimates of 1.8 and 2.5 times as much morphine, respectively. The degrees of overestimation of morphine, when graded amounts of metabolite are added and assayed without prior extraction, are reasonably consistent with what would be predicted on the basis of the ratio of amounts of compounds at I_{50} derived from separate standard curves. However, when the assay was preceded by extraction of duplicate samples of the above, no significant differences were observed among morphine equivalents. These data indicate that the extraction effectively removes morphine-3-glucuronide and are consistent with the results of the recovery study.

One of the methods employed for the validation of the specificity of a radioimmunoassay is the demonstration that the final concentration of the component being measured in a particular sample is independent of the dilution at which it is assayed (20). Table II illustrates that this criterion is fulfilled when the assay is preceded by extraction, but that this is not the case when the assay is performed without prior extraction. These data indicate that the extraction removes morphine metabolites from plasma which cross react with the morphine antibody. The higher dilutions resulted in higher morphine equivalents in the nonextracted assay. This is consistent with the greater degree of cross reactivity between morphine and its metabolite at lower degrees of label displacement observed in the comparison of their standard curves.

The mean morphine concentration (calculated as a common dose of 10 mg of base) in the 23 hospice patients' plasma was 26 ng/ml (95% confidence internal (CI), 20–33 ng/ml) when assayed following extraction as compared to 80 ng/ml (95% CI, 64–96 ng/ml) when assayed without extraction (Table III). Nonextracted morphine equivalents ranged from ~1 to 10 times the extracted levels, but since these ratios are highly dependent upon the dilution of nonextracted plasma, which varied, they cannot be taken as an estimation of the actual ratios of metabolite to parent drug. Nevertheless, the average threefold difference ($p < 0.001$) indicates considerable cross-reacting metabolite(s) in plasma as compared with unconjugated morphine. These data are consistent with the significant first-pass effect for oral morphine, which results in 20–33% bioavailability (14). A molar ratio of glucuronide to unconjugated morphine of 1.8 has been reported at 4 hr following a single intravenous dose of morphine (3).

Steady-state 4-hr trough plasma levels of morphine in a comparable patient group receiving morphine according to a comparable dosing regimen have been reported to be 34 ng/ml (95% CI, 21–48 ng/ml) when adjusted to a common dose of 10 mg of morphine base (10). A nonextracted radioimmunoassay was employed in these latter studies. The mean morphine concentration was significantly ($p < 0.05$) higher (31%) than the concentration reported here. The earlier report used morphine antiserum which had been raised against 6-succinyl morphine–bovine serum albumin, rather than against a 3-position antigen. Thus, the antiserum would have a lower affinity for morphine-3-glucuronide as compared with the antiserum used in this study. While they reported a cross-reactivity of <10% in their radioimmunoassay, even this degree of specificity would not be acceptable for situations in which there is a high ratio of glucuronide to free morphine.

Table III details the results of the radioimmunoassay of extracted and nonextracted cerebrospinal fluid samples which had been obtained from four cancer patients with chronic pain following the intravenous injection of 10 mg of morphine sulfate. In contrast to the extracted and nonextracted plasma levels of patients receiving repeated oral morphine doses, there is no significant ($p > 0.3$; n, 32; paired t test) difference (5.9%) between extracted and nonextracted morphine equivalents in the cerebrospinal fluid following a single intravenous dose. These data are consistent with reports of the limited access of morphine metabolites to the cerebrospinal fluid (21).

A most specific morphine antiserum, raised against *N*-carboxymethylmorphine, has a morphine-3-glucuronide–morphine ratio of ~350–I_{50} (22). This antiserum, however, is not readily available. But even the same antigen in the same individual animal can result in batches of morphine antisera of widely differing specificity (13). Thus, short of the generation of a readily available monoclonal antibody specific for morphine, it is not likely that the numerous investigators of the clinical pharmacokinetics of morphine will be able to employ a common antiserum. While radioimmunoassays may be sufficient for accurate determination of plasma morphine following single parenteral doses, studies of the clinical pharmacokinetics of morphine following repeated and/or oral dosing should incorporate more specific methodology. Because the sensitivity and relative ease of carrying out the radioimmunoassay has made this method more acceptable to many investigators than the use of other methods, the single-step extraction procedure, prior to radioimmunoassay, provides an alternative to the adaptation of other methods for morphine measurement in human biofluids.

Radiolytic Degradation Scheme for ^{60}Co-Irradiated Corticosteroids

MICHAEL P. KANE and KIYOSHI TSUJI ˣ

Received August 26, 1981, from *Control Analytical Research and Development, The Upjohn Co., Kalamazoo, MI 49001.* Accepted for publication February 26, 1982.

Abstract □ The cobalt 60 radiolytic degradation products have been identified in the following corticosteroids: cortisone, cortisone acetate, hydrocortisone, hydrocortisone acetate, hydrocortisone sodium succinate, isoflupredone acetate, methylprednisolone, methylprednisolone acetate, prednisolone, prednisolone acetate, and prednisone. Two major types of degradation processes have been identified: loss of the corticoid side chain on the D-ring to produce the C-17 ketone and conversion of the C-11 alcohol, if present, to the C-11 ketone. Minor degradation products derived from other changes affecting the side chain are also identified in several corticosteroids. These compounds are frequently associated in corticosteroids as process impurities or degradation compounds. No new radiolytic compounds unique to ^{60}Co-irradiation have been found. The majority of corticosteroids have been shown to be stable to ^{60}Co-irradiation. The rates of radiolytic degradation ranged from 0.2 to 1.4%/Mrad.

Keyphrases □ Corticosteroids—^{60}Co-irradiated, radiolytic degradation scheme □ Degradation—scheme for ^{60}Co-irradiated corticosteroids □ Irradiation—radiolytic degradation of corticosteroids

The U.S. Food and Drug Administration (FDA) has proposed strict limits on allowable residual quantities of ethylene oxide and its major reaction products in drugs because of possible mutagenic and carcinogenic properties of ethylene oxide (1). Faced with the possibility of increased regulatory pressure, the replacement of ethylene oxide with steam or ^{60}Co-irradiation is a major goal of a sterilization alternative program. One phase of this program is to conduct the experimental work required to demonstrate the feasibility of sterilizing bulk drugs and formulated products with ^{60}Co-irradiation.

Recently, the FDA published a proposal regulating irradiated foods for human consumption (2). The proposal permits irradiation of any food at a dose not >100 Krads without the additional safety data. The proposal also permits irradiation of foods at a dose of ≤5 Mrads if the foods comprise only a minor portion (NMT 0.01%) of the daily diet. The proposal includes guidelines for toxicological testing of other foods irradiated at a dose >100 Krads. The proposal is based on projected daily human consumption of radiolytic degradation compounds (3).

The daily dose of pharmaceutical products is substantially less than the amount of foods consumed. Information determining the rate of degradation and identifying degradation compounds unique to irradiation, therefore, should be sufficient to examine the feasibility of ^{60}Co-irradiation as an alternate method for sterilizing pharmaceutical materials and products. The present report provides such information for corticosteroids.

EXPERIMENTAL

^{60}Co-Irradiation—The irradiation source[1], consisting of several rods containing ^{60}Co-pellets mounted on a plaque, was raised from a pool of water into a stationary position for irradiation. Samples were placed in totes on two tiers surrounding the cobalt 60 source. A shuffle–dwell system averaged the radiation gradient around the source by periodically shifting the tote horizontally and vertically. Other samples were stationed at calibrated points where the radiation intensity was more precisely known.

Absorbed irradiation doses were measured potentiometrically using a ceric-cerous dosimeter[2] (4, 5) and spectrophotometrically using a red perspex dosimeter[3].

High-Performance Liquid Chromatography (HPLC) Appara-

The present report provides such information for corticosteroids.

EXPERIMENTAL

^{60}Co-Irradiation—The irradiation source[1], consisting of several rods containing ^{60}Co-pellets mounted on a plaque, was raised from a pool of water into a stationary position for irradiation. Samples were placed in totes on two tiers surrounding the cobalt 60 source. A shuffle–dwell system averaged the radiation gradient around the source by periodically shifting the tote horizontally and vertically. Other samples were stationed at calibrated points where the radiation intensity was more precisely known.

Absorbed irradiation doses were measured potentiometrically using a ceric-cerous dosimeter[2] (4, 5) and spectrophotometrically using a red perspex dosimeter[3].

Relative Change, %		−1.5	+0.4	+0.8	+0.1

[a] Methylprednisolone is USP micronized, and peak response is in area per milligram. [b] An equimolar response was assumed for 11β,17α-dihydroxy-6α-methyl-1,4-androstadiene-3-one due to lack of an authentic sample.

tus—The modular liquid chromatographic system consisted of a fixed wavelength UV monitor[4], a high pressure pump[5], and a 20-μl fixed-loop injector[6] or a sample processor[7].

Chromatographic Conditions—The normal-phase chromatographic conditions used for the HPLC analysis of corticosteroids were similar to those described in another report (6). The mobile phase consisted of butyl chloride (50% water saturated)–tetrahydrofuran–methanol–glacial acetic acid (970:70:35:30) for the C-21 alcohols and 880:25:25:25 for the C-21 acetates of corticosteroids. A silica column[8] was used to chromatograph corticosteroids.

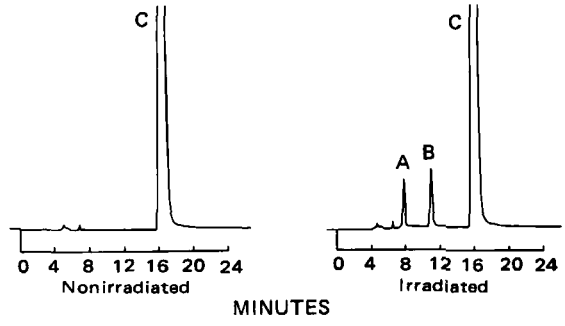

Figure 2—*HPLC chromatograms of nonirradiated and irradiated (2.5 Mrads) hydrocortisone. Mobile phase: butyl chloride (50% water saturated)–tetrahydrofuran–methanol–glacial acetic acid (950:70:35:30). Column: Brownlee SI-100. Peak identification: (A) 11β-hydroxy-4-androstene-3,17-dione; (B) cortisone; (C) hydrocortisone.*

To ensure that all major degradation products were separated, the samples were also analyzed by reversed-phase HPLC using various mixtures of acetonitrile or methanol with water on an octadecylsilane column[9]. Reversed-phase chromatographic methods for analysis of steroids have been reported (7, 8). Normal-phase conditions proved inadequate in only two cases. In hydrocortisone acetate, two degradation compounds eluted at the same retention time, but they were easily separated by reversed-phase chromatography using methanol and water (55:45) as the mobile phase. No degradation product could be eluted by normal phase HPLC for prednisone, but it was detected by reversed-

phase chromatography using acetonitrile–water (40:60) as the mobile phase.

The semipreparative scale HPLC methods used to purify the radiolytic degradation compounds for identification are listed in Table I.

Corticosteroids—The following corticosteroids were examined: cortisone, cortisone acetate, hydrocortisone, hydrocortisone acetate, hydrocortisone sodium succinate, isoflupredone acetate, methylprednisolone, methylprednisolone acetate, prednisolone, prednisolone acetate, and prednisone. 17α-Hydroxyprogesterone was also examined.

RESULTS AND DISCUSSION

Identification of Radiolytic Degradation Compounds—The identities of the radiolytic degradation products are based in part on the comparison of the HPLC retention times by both normal- and reversed-phase HPLC of the degradation products with the retention times of the reference standards or authentic samples.

The identities of the degradation products were confirmed by comparison of the mass spectra (electron impact at 250°) of samples of the degradation products obtained by preparative HPLC with the mass spectra of the reference standards or authentic samples. The degradation products were isolated by preparative HPLC from enriched samples. In most cases samples could be enriched by refluxing in butyl chloride or methylene chloride. This process is, in principle, the same as recrystallization, where the mother liquor hopefully contains the impurities. For example, the degradation products of prednisolone were enriched by refluxing 2.5 g of irradiated corticosteroid in 10 ml of methylene chloride for 30 min. The methylene chloride was collected by filtration and evaporated to dryness. In the case of hydrocortisone sodium succinate, the sample was first hydrolyzed by treating a solution of 5 g in 10 ml of water with one drop of 40% NaOH. The hydrolysis products, which precipitated within minutes as the reaction proceeded, were collected by filtration and air dried prior to enrichment by refluxing in methylene chloride. The residues obtained after evaporation were then dissolved in ~20 ml of the appropriate mobile phase and chromatographed either by a normal-[7] or reversed-phase column[8]. Between 10 and 20 100-μl injections normally were made. The mobile phase was removed from the collected fractions by freeze drying.

Although this process was successful in enriching the C-11 and C-17 ketone degradation products in methylprednisolone acetate, the process failed to enrich the third minor product. An enriched sample containing this component was obtained from a normal-phase chromatographic column[10] using butyl chloride (50% water saturated)–tetrahydrofuran–methanol–glacial acetic acid (950:70:35:30). A 2-g solution of the irradiated corticosteroid was dissolved in 10 ml of acetonitrile; twelve 280-μl injections were made. Fractions containing the third component of interest were combined and freeze dried. The freeze-dried material was dissolved in 2 ml of mobile phase and rechromatographed.

The choice of whether to use a normal- or reversed-phase for preparative chromatography was made on the basis of which system provided the best separation from existing process impurities. The chromatographic conditions used in the isolation of the degradation products of each corticosteroid are listed in Table I.

Authentic samples were available for HPLC and mass spectra comparison with all degradation products isolated except the C-17 ketone derived from isoflupredone acetate and the C-17α alcohol derived from methylprednisolone. In the former case, the mass spectrum shows the expected molecular parent ion and is sufficiently similar to related compounds to establish the identification. In the latter case, the C-17β epimer was available for comparison purposes. Although the HPLC retention times of the two epimers were clearly distinctive, the mass spectra

were nearly identical. It is not unusual for stereoisomers, especially epimers, to have indistinguishable mass spectra.

As examples, HPLC chromatograms of irradiated and nonirradiated cortisone, hydrocortisone, and isoflupredone acetate are shown in Figs. 1–3. The mass spectrum of a radiolytic compound in cortisone used to positively identify it as 4-androstene-3,11,17-trione is shown in Fig. 4.

Mass Balances—The mass balances were determined for the majority of the corticosteroids investigated to ascertain how much of the total degradation could be accounted for by the observed degradation process. The mass balances were obtained by comparing samples irradiated at high dose (2.5 or 6 Mrads) with nonirradiated or low dose (0.5 Mrads) samples. Using carefully dried and accurately weighed samples, the dif-

ferences in peak response (are per weight ratio) were determined for the corticosteroid and each degradation product. The differences in peak response for the degradation products were then corrected for differences in relative molar absorptivity and are reported on a percentage basis relative to the response of the corticosteroid in the nonirradiated or low-dose sample. An equimolar response was assumed when an authentic sample was not available for determination of relative molar absorptivity. As an example, the mass balance data for methylprednisolone is shown in Table II. The data support the conclusion that all of the degradation by ^{60}Co-irradiation has been accounted for.

Major Cobalt 60 Radiolytic Degradation Products—The major cobalt 60 radiolytic degradation products were identified in the following corticosteroids: cortisone, cortisone acetate, hydrocortisone, hydrocortisone acetate, hydrocortisone sodium succinate, isoflupredone acetate, methylprednisolone, methylprednisolone acetate, prednisolone, prednisolone acetate, and prednisone. Radiolytic degradation of corticosteroids are shown in Schemes I–XI. A structurally related steroid, 17α-hydroxyprogesterone, was also examined (Scheme XII).

Two major types of degradation processes were found to occur by ^{60}Co-irradiation: loss of the C-17 side chain to produce the C-17 ketone and oxidation of the C-11 alcohol, if present, to the C-11 ketone. Several degradation processes have been reported to occur in corticosteroids without irradiation: they include air oxidation of the C-11 alcohol to the C-11 ketone (9, 10), stepwise air oxidation of the D-ring corticoid side chain to the C-17 ketone, hydrolysis of C-21 esters, acyl migration of C-21 hemisuccinate to C-17 hemisuccinate, and loss of the corticoid side chain to produce the C-17 ketone by thermal treatment (11). Thus, the radiolytic degradation products were found to be identical to existing process impurities or known degradation products. A similar loss of the C-17 acyl side chain in 17α-hydroxyprogesterone to produce the C-17 ketone was also found to occur.

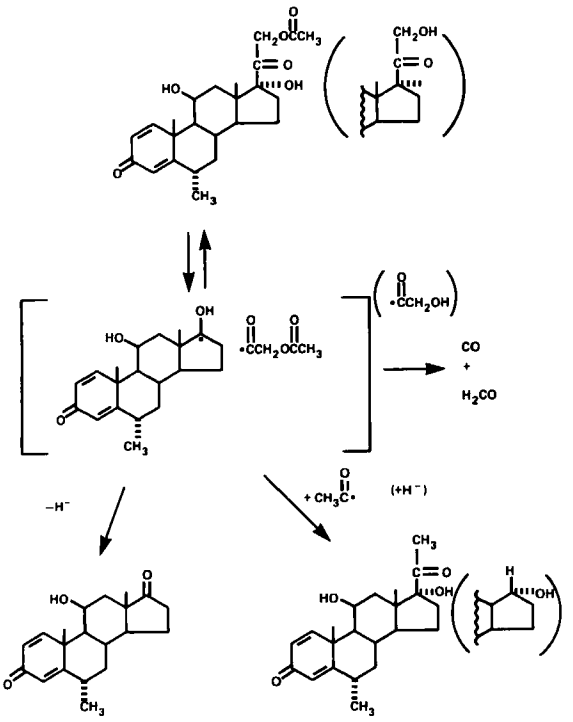
Table III—Rate of Radiolytic Degradation for Corticosteroids

Corticosteroids	Radiolytic Degradation, %/Mrad
Cortisone acetate	0.6
Hydrocortisone	1.0
Hydrocortisone acetate	0.3
Hydrocortisone sodium succinate	1.4
Isoflupredone acetate	0.4
Methylprednisolone	0.7
Methylprednisolone acetate	0.6
Prednisolone	0.7
Prednisolone acetate	0.4
Prednisone	0.2

Minor Cobalt 60 Radiolytic Degradation Products—Additional minor degradation products derived from processes affecting the C-17 side chain were identified in methylprednisolone and methylprednisolone acetate (Schemes VII, VIII). Loss of the C-17 side chain in methylprednisolone was also found to result in formation of the C-17α alcohol (11β,17α-dihydroxy-6α-methyl-1,4-androstadiene-3-one) in addition to the C-17 ketone. The C-21 desoxy derivative (11β,17α-dihydroxy-6α-methyl-1,4-pregnadiene-3,20-dione) was produced in methylprednisolone acetate. Hydrocortisone was identified as an additional degradation product of hydrocortisone sodium succinate (Scheme V). Sufficient water is present in the formulation to allow some hydrolysis to occur during irradiation.

Although similar minor degradation products derived from the C-17 side chain were not observed in the other corticosteroids investigated, the possibility of their formation below the detection limit of HPLC methods cannot be ruled out. The minor degradation products detected in methylprednisolone acetate and methylprednisolone were only present at 0.1 and 0.2%, respectively, at 6 Mrads.

Mechanism of Degradation—Two major types of radiolytic degradation processes for corticosteroids have been identified to occur: loss of the C-17 side chain to form the C-17 ketone and oxidation of the C-11 alcohol to form the C-11 ketone. When considering a mechanism to explain these degradation processes, the fact that the reactions involved occur in the solid state must be considered. Molecular packing within the crystal lattice and the amount of surface area could have an influence on degradation. One possible mechanism that accounts for the formation of C-17 ketones as well as the minor products derived from changes in



Scheme 13—Postulated mechanism for cobalt 60 radiolytic degradation of C-17 side chain of corticosteroids (example: methylprednisolone and methylprednisolone acetate).

the C-17 side chain of methylprednisolone and methylprednisolone acetate is shown in Scheme XIII. By this mechanism, reaction is initiated by homolytic cleavage between C-17 and C-20. Subsequent loss of a proton from the steroidal fragment would lead to the C-17 ketone. Recombination of the initially formed radicals could also occur. Alternatively, further disintegration of the side chain radical could lead to other radicals. Recombination with any of these radicals could also occur. For example, the C-21 acetate substituted side chain in methylprednisolone acetate could produce carbon monoxide, formaldehyde, and an acetyl radical. Recombination would generate the C-21 desoxy derivative. By a similar process, the side chain in methylprednisolone would produce a radical. Recombination in that case would form the C-21α alcohol. Preservation of the original stereochemistry at C-21 in these degradation products is attributed to the crystal lattice structure which would trap the radical intermediates in close proximity. In addition to formation of carbon monoxide and formaldehyde, other possible products derived from the C-17 side chain include methanol, methyl acetate, acetaldehyde, methane, and hydrogen. Formation of C-11 ketones could proceed by a similar mechanism initiated by loss of the C-11 proton with hydrogen produced as the other product.

Rate of Degradation—The rates of radiolytic degradation for corticosteroids were determined by analyzing irradiated and nonirradiated steroid powders using HPLC methods. The rates of degradation, expressed as percentage per megrad, are shown in Table III. The rates of degradation ranged from 0.2 to 1.4%/Mrad, thus, the majority of corticosteroids are stable to ^{60}Co-irradiation.

Difficulties in Applying the Scatchard Model of Ligand Binding to Proteins—Proposal of New Mathematical Tools—Application to Salicylates

C. MONOT *x, P. NETTER ‡, M. C. STALARS ‡, J. MARTIN *, R. J. ROYER ‡, A. GAUCHER §

Received December 21, 1981, from the **Inserm U 115*, ‡*Laboratoire de Pharmacologie* and the §*Clinique Rhumatologique, Université de Nancy 1 France.* Accepted for publication February 26, 1982.

Abstract □ Ill-considered use of the Scatchard model often leads to unjustified deductions. Since the main difficulty of this model is its number of parameters, new models are proposed that have only two parameters. After checking the models on simulated data, they were applied to real data on the binding of salicylates to albumin.

Keyphrases □ Scatchard model—difficulties in application to ligand binding to proteins, new mathematical tools, application to salicylates □ Salicylates—application of Scatchard model, difficulties in application to ligand binding to proteins, new mathematical tools □ Binding—ligand to proteins, difficulties in applying the Scatchard model, new mathematical tools, application to salicylates □ Proteins—ligand binding, difficulties in applying the Scatchard model, new mathematical tools, application to salicylates

The binding of ligands to proteins is most often analyzed in terms of the model proposed by Scatchard (1), in which proteins are considered to possess binding sites divided into independent classes according to their affinities. From estimations of the free and bound fractions of the ligand, it is in principle possible to determine the number of

classes, the number of sites in each class, and the affinity constant of each class. Before computers became available, graphical methods of solving the nonlinear equations introduced by this problem were proposed (2–4). Discrepancies in the results could be attributed to the imprecisions of graphical methods, and the emergence of computers should then have caused the results to become more consistent. The results of various graphical methods were compared (4) with the results obtained by computer methods, while taking care not to adopt the algorithm of these graphical methods for the computer. Despite the extremely powerful methods available in large computing centers (5–11) difficulties remained. It was shown (8) that the results for binding of dicumarol to albumin were doubtful when errors became as large as 2%, even when based on 50 experimental measurements, and that the results obtained from 200 experimental measurements with a precision of 5% had no significance. In addition, 50 publications were reviewed (12) that contained various errors of graphical construction. However, many authors continue to use this model and to calculate the classical parameters (universally called n_i, K_i, and m).

This model is habitually used since most scientists accept it as a good representation of the real phenomenon. A study of the discussions of the independence and the initial existence of all the sites (the basic hypothesis of Scatchard), and the introduction of an interaction between sites (13–20) may provide an understanding of how efficiently this model represents reality.

Problems are encountered in the study of this model. If available experimental data do not allow determination of all parameters of the model, it becomes simply a mathematical tool whose parameters have no significance. If the experimental data do not allow an accurate determination of the parameters, then a question arises as to whether the use of other mathematical functions would provide better results.

An attempt was made in this study to solve these problems using the binding of salicylate to albumin. Other models are proposed using simulated and real data.

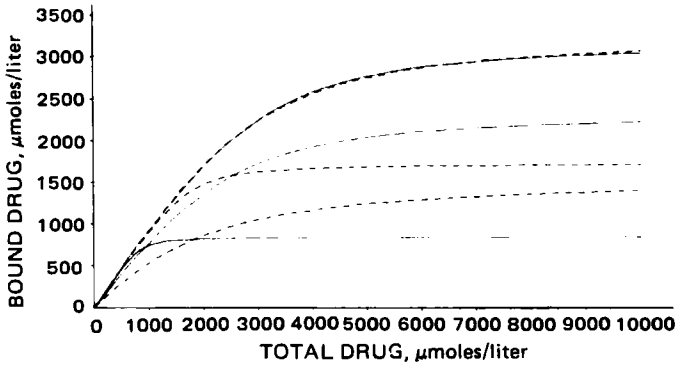

Figure 1—*Scatchard model with two classes of sites: curve of ligand binding to each class and to both classes taken as a whole, with two different combinations of parameters. Key: (—)* $K_1 = 0.00210$ *μmole/liter,* $K_2 = 0.02840$ *μmoles/liter,* $n_1 = 4.10$, $n_2 = 1.46$; *(- - - -)* $K_1 = 0.00109$ *μmoles/liter,* $K_2 = 0.01103$ *μmoles/liter,* $n_1 = 2.68$, $n_2 = 3.00$.

EXPERIMENTAL

To analyze and test different models, simulated and real data are used. Simulated data are the values of a published example on the binding of salicylate to albumin (21, 22). Real data are obtained *in vitro* by equilibrium dialysis on an apparatus[1], equipped with membranes[2] (with a molecular weight cutoff of 14,000), separating two 1.0-ml cells. The dialysis cells were placed in a water bath thermostated at 37°. Salicylate was estimated by spectrofluorimetry (excitation at 300 nm, emission at 410 nm).

Classical Scatchard Model—This model is deduced from the law of mass action and from the probability of binding to a carrier protein (1). It is based on a classification of independent sites of binding to the protein:

$$\frac{B}{P} = \sum_{i=1}^{m} \frac{n_i K_i F}{1 + K_i F} \qquad \text{(Eq. 1)}$$

where B is the concentration of the bound substance, F is the concentration of the unbound substance, P is the concentration of the protein, m is the number of classes of sites, and K_i and n_i are, respectively, the affinity constant and the number of sites of the ith class of sites.

Proposed Models—These are mathematical functions that must have the same shape as the amount of ligand bound at equilibrium expressed as a function of the total ligand concentration present. These functions have only two parameters:

$$\text{trigonometric model: } B = a_1 \arctan(a_2 T) \qquad \text{(Eq. 2)}$$

$$\text{exponential model: } B = b_1[1 - \exp(-b_2 T)] \qquad \text{(Eq. 3)}$$

where T is the total concentration of the ligand present, B is the concentration of the bound fraction at equilibrium, and a_1 and a_2, b_1 and b_2 are the two parameters of the models that are determined from the experimental data. These parameters are not totally meaningless, since in each case a_1 and b_1 are directly related to the saturating values B_∞ of the quantity of ligand bound to the protein:

$$B_\infty = a_1 \frac{\pi}{2} \qquad \text{(Eq. 4)}$$

$$B_\infty = b_1 \qquad \text{(Eq. 5)}$$

The two models proposed make it possible to study the equilibrium binding of the ligand either to binding proteins, where the protein concentration must be specified, or per unit concentration of binding protein:

$$\frac{B}{P} = \frac{a_1}{P} \arctan(a_2 T) \qquad \text{(Eq. 6)}$$

$$\frac{B}{P} = \frac{b_1}{P}[1 - \exp(-b_2 T)] \qquad \text{(Eq. 7)}$$

In this case the parameters a_1 and b_1 are divided by the protein concentration P, whereas other parameters, a_2 and b_2, are independent of the protein concentration.

The Scatchard model, when limited to a single class of sites, can be used in certain cases and more precisely when the zone being studied is more limited (in the case of therapeutic or toxic doses of salicylates, up to or exceeding 400 μg/ml.)

The model (Eq. 1) is then written:

$$B = \frac{nPKF}{1 + KF} \quad \text{or} \quad B = \frac{nPK(T - F)}{1 + K(T - F)} \qquad \text{(Eq. 8)}$$

This model has only two parameters and occasionally gives good results, but it is disadvantageous because it is also a mere mathematical tool requiring solution of a nonlinear equation.

RESULTS AND DISCUSSION

General Applications of the Model—The usual procedure is to use a computer (or graph paper) to determine the parameters n_i, K_i, and sometimes m starting from the experimental data that has been obtained.

There are, however, problems encountered with this procedure. The study of the binding phenomenon itself, while assuming that the model is a true reflection of reality, is one problem. It must be possible to determine the parameters m, n_i, and K_i, and each must have a unique value. Other problems encountered are the study of the influence of a pathological condition on the quantity of ligand bound (which leads to a comparison of groups) and the study of a particular region of the curve of binding to a protein, such as therapeutic or toxic doses, or the saturation value of binding.

Difficulties Encountered—Difficulties are not related to the theoretical model itself but are related to the number of unknown parameters whose estimation is often incompatible with the quantity and quality of the experimental data (8). The determination of these parameters is considered from simulated data, thus eliminating experimental errors, taking as an example published data on the binding of salicylate (^{14}C-labeled COOH-salicylic acid) to albumin (21, 22).

It is essential to know the number (m) of classes of sites if one wishes the model to reflect the real phenomenon. The number m, determined only from estimations of the concentrations at equilibrium of free and bound ligand as a function of the total ligand concentration, is in reality only the minimum possible number of classes compatible with the experimental data.

As an example, Table I represents the concentrations of salicylate bound at equilibrium throughout the whole concentration range (0–10 mg/ml). The results were obtained by simulation for three cases. The first case (Table I, column 1) assumed two classes of sites (m = 2); using the values of the parameters for the binding of salicylate generally accepted in published sources. The second and third cases assumed three classes

of sites ($m = 3$) (Table I, columns 2 and 3), with two combinations of the six parameters n_i and K_i. However, in practice there is an infinite number of these combinations, since they were obtained by simple identification of the parameters K_i. The values of n_i were chosen arbitrarily as:

$$(n_1 + n_2 + n_3)_{m=3} = (n_1 + n_2)_{m=2} \qquad \text{(Eq. 9)}$$

so that the bound fractions reached the same limit at saturation (Eq. 1).

The exact number of classes of sites may be confused with the minimum number compatible with the available experimental results. This does not matter if the model is used simply as a mathematical tool (for example for smoothing), but it becomes a problem if the phenomenon itself is to be used and a real significance is to be given to the parameters.

Suppose that the number of classes of sites is known (or is accepted to be equal to the minimum number defined above). Difficulties have already been reported with the determination of other parameters such as n_i and K_i from the results of equilibrium estimations (4) as shown in Table II. Again the data used are the 12 values of the bound fraction simulated from published parameters (21, 22) for the binding of salicylate to albumin (Table II, column 1). The parameters (n_i and K_i are calculated in several cases: For the four parameters, n_1, n_2, K_1, and K_2, even starting the iterations from remote initial values, the results are not much different from the correct values (Table II, column 2); for the three parameters, n_1, K_1, and K_2, to the fourth parameter (n_2) we attribute the values 1, 2, 3, 4, and 5, successively (Table II, columns 3–7). The results yield combinations for the values of the parameters that are naturally very different; the quantity of ligand bound, however, remains similar from one of these groups of values to another. Figure 1 represents this phenomenon. The curves represented correspond to the two combinations:

$$K_1 = 0.00109\ K_2 = 0.01103\ n_1 = 2.6833\ n_2 = 3.0000$$
$$\text{and } K_1 = 0.0021\ K_2 = 0.0284\ n_1 = 4.1000\ n_2 = 1.4600 \qquad \text{(Eq. 10)}$$

where K_1 and K_2 are given in micromoles per liter.

In both cases the curves drawn represent the quantity bound to each site and the overall quantity for the whole of the two sites, respectively. These two curves, representing the total quantity bound to albumin, are practically identical (Fig. 1), which shows that it cannot be determined how much ligand is bound to each site; that is, the four parameters n_1, n_2, K_1, and K_2 cannot be determined.

Conclusions About Current Application of the Scatchard Model—The difficulties encountered at the various stages of the application of the model to simulated cases have been shown, in the total absence of experimental errors, for the determination of the various parameters of binding to proteins. The problem of the number of classes of sites alone destroys any significance of the parameters.

Therefore, this model should not at present be used except as a mathematical tool. It requires that a nonlinear equation be solved at each point; this drawback, which was the reason for the various graphical methods, makes it difficult to use. The large number of these parameters that cause this practical indetermination that has been reviewed previously prohibits any direct interpretation of the results (such as comparison of the parameters from two groups of patients). One solution is to arbitrarily fix the values of certain parameters (for example n_1 and n_2), as suggested previously (8). Other mathematical models are proposed here as mathematical tools but they are easier to manipulate, and have

been used during a study of the variation of the binding of salicylate in rheumatoid arthritis.

Application of the Proposed Models—In the current state of interpretation, no physiological significance should be sought in the calculated parameters. The models proposed are merely mathematical tools. They are the trigonometric model in Eq. 2 and the exponential model in Eq. 3. These equations make it possible to represent the variation in the quantity of ligand bound at equilibrium as a function of a total quantity present, while using the minimum number of parameters. The choice is not exhaustive, but the models have been tested in various circumstances: a broad-range study of the phenomenon, a detailed study of therapeutic doses over a narrowed region of study, and a study of high doses with an attempt to determine the saturating value of the quantity of ligand bound. These models can also be used to compare groups of patients.

Checking Models with Simulated Data—Simulated input data values of the equilibrium fraction of salicylate bound to albumin (Table III), derived from the Scatchard model (Eq. 1) were used for two classes of sites whose parameters have the published values (21, 22):

$$m = 2 \quad n_1 = 1.46 \quad K_1 = 0.0284\ \mu\text{moles/liter}$$
$$n_2 = 4.10 \quad K_2 = 0.0021\ \mu\text{moles/liter} \qquad \text{(Eq. 11)}$$

These data were approached as closely as possible by adjusting the parameters a_1, a_2, b_1, b_2, and perhaps n and K of the various models proposed (Eqs. 2, 3, and 8).

The proposed models were tested at equilibrium in three zones of total concentration of ligand; <1250 μg/ml (9060 μmoles/liter); <350 μg/ml (therapeutic doses); and >400 μg/ml (high concentrations).

Doses <1250 μg/ml (i.e., 9060 μmoles/liter)—This is the concentration generally studied because it covers therapeutic doses, and also approaches the limit of saturation of binding. It is more difficult to approximate a function while minimizing the number of parameters to be adjusted over a wide range of a variable (0–1250 μg/ml) than over a narrow range. However, the differences between the theoretical curve (4-Parameter Scatchard model) and the curves from the proposed models (with two parameters) remain small and less than the experimental errors encountered (Fig. 2, and Table III). The values obtained for the parameters of the two models were:

trigonometric model (Eq. 2): $a_1 = 2370.00$ μmoles/liter and $a_2 = 0.00044979$ liter/μmoles

exponential model (Eq. 3): $b_1 = 3210.57$ μmoles/liter and $b_2 = 0.00038606$ liter/μmoles (Eq. 12)

The last line of Table III represents the sum of squares of the differences between the results from the Scatchard model and from the proposed models:

$$W = \sum_{i=1}^{p} (B1_i - B2_i)^2 \qquad \text{(Eq. 13)}$$

where $B1_i$ and $B2_i$ are the fractions of ligand bound at point i at equilibrium from, respectively, the Scatchard model with two classes of sites (Eqs. 1 and 11, the input data) and one of the proposed models, p is the number of data points.

Comparison of the values obtained for W with each of the two proposed models shows that the trigonometric model gives the better results. The exponential model is a poor fit at low salicylate concentrations (of the order of 50–100 μg/ml)—at the first two points it gives an unacceptable

[a] Comparison of the trigonometric model, the exponential model, the Scatchard model with one class of sites, and the reference Scatchard model with two classes of sites.

value for the bound fraction, greater than the total concentration. The Scatchard model with a single class of sites is inapplicable over this wide range of variation of total salicylate concentration.

Therapeutic Zone of Concentrations <350 μg/ml (2500 μmoles/liter)—Over this limited zone the approximation is easier. Table IV and the curves in Fig. 3 represent the results obtained from the 14 data points from the first two columns of the table. The values of the parameters obtained with the two proposed models are:

trigonometric model (Eq. 2):

$$a_1 = 2783.6\ \mu\text{moles/liter} \quad a_2 = 0.000347\ \text{liter}/\mu\text{mole}$$

exponential model (Eq. 3):

$$b_1 = 3858.4\ \mu\text{moles/liter} \quad b_2 = 0.000285\ \text{liter}/\mu\text{mole} \quad \text{(Eq. 14)}$$

Here again the trigonometric model gives better results than does the exponential model, which has three unacceptable points where more than the total salicylate concentration is bound. A weighting of the first points in the computation remedied this disadvantage, but the differences then became greater at the points for higher concentrations.

The Scatchard model with one class of sites (Eq. 8) is applicable over this region (Fig. 3 and Table IV) and gave good results with the values $K = 0.006972$ μmoles/liter and $n = 4.3964$.

High Concentrations >400 μg/ml, 2900 μmoles/liter—The 11 points lying between 400 and 5000 μg/ml in Table V were used. The exponential model gave better results than the trigonometric model (Table V and Fig. 4):

trigonometric model (Eq. 2):

$$a_1 = 2124.92\ \mu\text{moles/liter} \quad a_2 = 0.000682\ \text{liter}/\mu\text{mole}$$

exponential model (Eq. 3):

$$b_1 = 3161.30\ \mu\text{moles/liter} \quad b_2 = 0.000421\ \text{liter}/\mu\text{mole} \quad \text{(Eq. 15)}$$

However, for high concentrations the best results were obtained with the Scatchard model limited to a single class of sites (Eq. 8). The corresponding curve was then similar to the curve from the model with two classes of sites used as data (Fig. 4 and Table V). The parameters obtained had the values $n = 5.536$ and $K = 0.003104$ μmole/liter.

Application of the Proposed Models to Real Data—The models were applied to experimental results on the binding of sodium salicylate to albumin and studied over the various zones mentioned.

Total Salicylate Concentration Lying Between 0 and 1200 μg/ml—Table VI and Fig. 5 show the bound fraction at equilibrium obtained with the trigonometric model having parameters a_1 (2865 μmoles/liter) and a_2 (0.000284 liter/μmole) and with the exponential model having parameter b_1 (3910 μmoles/liter) and b_2 (0.000240 liter/μmole).

This first zone is too broad for application of the Scatchard model limited to a single class of sites (Eq. 8).

Note that the two curves are almost identical (Fig. 5). This figure shows also that the saturation limit was still not reached and any extrapolation to estimate the value of this limit would be dangerous, whatever model is used.

Therapeutic Concentrations <350 μg/ml—Table VII and Fig. 6 show the results obtained with the trigonometric model with a_1 (1720.68 μmoles/liter) and a_2 (0.0005654 liter/μmole), and with the exponential model with b_1 (3142.97 μmoles/liter) and b_2 (0.000317 liter/μmole). Over this relatively narrow zone the single-class Scatchard model (Eq. 8) can be applied with n equal to 3.4784 and K equal to 0.00910 μmole/liter. Of the three models, the trigonometric model gave the best results (Table VII).

High Concentrations (from 400–500 μg/ml)—This zone can be of interest for example in studies of toxic doses or to estimate the saturation limit of bound fraction of substance (the plateau of the curve). The coefficients, a_1 and b_1, here have an important role since they are directly related to the value of this limit (Eqs. 4 and 5). But the experimental

396.30	2477	1829	1851	1805	1892
537.04	3356	2338	2223	2199	2373
703.70	4398	2546	2534	2557	2780
2305.83	14,411	3823	3425	3553	3591
3286.90	20,543	3586	3557	3606	3658
4214.90	26,343	2687	3626	3615	3689
5619.05	35,119	7744	3688	3618	3715
W			17.10^6	18.10^6	17.10^6

difficulties are greater at high concentrations; there are problems of dilution and precision of the measurements. The curves in Fig. 7 represent our first results in this zone (Table VIII). They were obtained with the following parameter values:

trigonometric model:

$$a_1 = 2466.2\ \mu\text{moles/liter} \quad a_2 = 0.000377\ \text{liter}/\mu\text{mole}$$

exponential model:

$$b_1 = 3618.2\ \mu\text{moles/liter} \quad b_2 = 0.000279\ \text{liter}/\mu\text{mole}$$

single-class Scatchard model: $K = 0.00171\ \mu\text{moles/liter} \quad n = 6.0$ (Eq. 16)

The basis of the Scatchard model is not questioned, but rather its quasi-automatic application in studies of the binding of a substrate to a protein. Even if this model is an accurate reflection of a real biochemical phenomenon, there may be insufficient experimental data to determine the values of the parameters unambiguously. The indistinguishability of the true number of binding classes and the minimum number of classes compatible with experimental data is sufficient to show that this model can be used only as a mathematical tool, for example, to interpolate data, or to calculate derivatives of curves or areas under them. This tool is difficult to manipulate, since it requires that a nonlinear equation be solved at each point. In addition, the practical indeterminacy of these parameters prevents them from being used separately as elements of reference for comparing groups of patients. Therefore, other models with only two parameters that have been used to study the influence of a pathological condition on the binding of a substance to a protein have been proposed.

Evaluation of Basket and Paddle Dissolution Methods Using Different Performance Standards

VADLAMANI K. PRASAD ˣ, VINOD P. SHAH, JOHN HUNT, EDWARD PURICH, PATRICK KNIGHT, and BERNARD E. CABANA

Received January 6, 1982, from the *Division of Biopharmaceutics, Bureau of Drugs, Food and Drug Administration, Washington, DC 20204.* Accepted for publication March 2, 1982.

Abstract □ Dissolution studies using both basket and paddle methods were carried out to evaluate two prednisone standards. Results of the experiments showed that the USP prednisone calibrator is sensitive to perturbations by the basket method but not to perturbations by the paddle method. However, the National Center for Drug Analysis (NCDA) prednisone performance standard is sensitive to perturbations by the paddle method but not to perturbations by the basket method. These results suggest that no single standard can predict the suitability of the dissolution equipment by the basket and paddle methods.

Keyphrases □ Dissolution—evaluation of basket and paddle methods using different performance standards, prednisone □ Prednisone—evaluation of basket and paddle dissolution methods using different performance standards □ Basket dissolution method—prednisone, evaluation using different performance standards □ Paddle dissolution method—prednisone evaluation using different performance standards

Dissolution analysis of pharmaceutical solid dosage forms has emerged as the single most important test that will ensure the quality of the product when carried out appropriately. In several instances, the dissolution results have been correlated with the bioavailability of the product, in which case the dissolution test can also ensure the bioavailability of the product between batches that meet the dissolution criteria. The dissolution test is generally carried out by either the basket or paddle method, both of which are official in USP XX, and are referred to as USP methods I and II (1). Important variables that play a major role in the dissolution methodology include dissolution medium and intensity of agitation. In addition, before the methodology can be used, it is imperative that the instrument be properly aligned and tuned to achieve reproducible and reliable dissolution results. A system suitability test is carried out using USP prednisone and salicylic acid calibrators to check alignment and fine tuning of the dissolution unit. Deficiencies in the equipment, such as the looseness of the chain, tilt of the stirring motor (tilt), misalignment of the flasks with respect to the stirring rod (off-centering), *etc.*, have been shown (2) to be easily detectable from the dissolution results of the basket method using the USP prednisone calibrator. The results obtained using the paddle method under the same conditions did not show significant differences in the dissolution results, although the equipment was judged as being not in good operating condition. These observations led to the conclusion that the basket method was superior to the paddle method. These are worthy conclusions, yet they do not lend support to the superiority of the basket method because of the lack of reproducibility (3, 4) and problems identified with mixing (5–8).

The National Center for Drug Analysis[1] (NCDA) has identified a prednisone tablet (NCDA prednisone performance standard II) that is highly sensitive to the aberrations of the equipment when the dissolution studies are carried out by the paddle method (9). However, no systematic study has been carried out to evaluate these two standards (USP prednisone calibrator and NCDA prednisone performance standard II) using the basket as well as paddle methods.

The purpose of this report is to evaluate the basket and paddle methods using both the USP calibrator and NCDA performance standard II, and to study the influence of various perturbations of the apparatus on the results.

EXPERIMENTAL

Method—The studies were carried out using commercially available dissolution equipment[2] and employing the basket method at 100 rpm and the paddle method at 50 rpm as previously described (1). The experimental directions provided with the official calibrator were followed in performing the study.

Instrument Operating Conditions—*Normal*—The instrument was aligned properly, finely tuned, and standardized according to a previous procedure (10).

Perturbed—The following perturbations were made to the dissolution apparatus, and the dissolution test was carried out under these conditions:

1. Tilt: The dissolution head (stirring motor) was tilted by raising the back rest of the unit. This produced deviations in shaft perpendicularity. The tilt produced was accurately measured by a universal protractor[3] at 1.5°.
2. Off-center: The dissolution head was moved to one side to displace the paddle or the basket from the exact center in the vessel by 3 mm.
3. Tilt with off-centering: A 1.5° tilt was produced with 3 mm off-centering.

Standards—Two prednisone standards, USP[4] 50-mg prednisone calibrator and NCDA 10-mg prednisone performance standard II, were used in this study.

Dissolution tests were carried out in deaerated water. Six tablets were used for each dissolution run. For the USP prednisone calibrator, 900 ml of the dissolution medium was used, and for the NCDA performance standard, 500 ml of the dissolution medium was used. The amount of the drug dissolved in 30 min was determined by comparing the absorbance of the sample with the USP prednisone reference standard at 242 nm in a spectrophotometer[5].

RESULTS AND DISCUSSION

The dissolution study results obtained by the basket and paddle methods, using a USP prednisone calibrator and an NCDA prednisone performance standard under normal standardized conditions and different perturbations, are summarized in Tables I–IV.

In the dissolution studies using the basket method, an agitation of 100 rpm was used. This agitation speed was used previously in different collaborative studies (4, 11). It was also used in a study where the influence of different perturbations on the dissolution characteristics of the

USP prednisone calibrator were examined (2). For normal conditions, the instrument was aligned, and all precautions were taken as described previously (10).

The basket method using the USP prednisone calibrator under normal conditions gave mean dissolution results of 68% (Table I). It is important to note that this value is very nearly identical to the normal mean value for the USP prednisone calibrator using the paddle method (4). However, when the equipment is perturbed, such as tilting the gear plate by 1.5°, the results are decreased to 40%. This is a substantial decrease. The off-centering of the basket (*i.e.*, from the center of the dissolution vessel) also produced a reduction in the mean dissolution value to 47%, which was similar to tilting. Both tilt and off-centering decreased the dissolution to ~37%, which although lower, did not suggest that these effects were additive.

This dramatic influence (*i.e.*, drop in the dissolution value, from 68 to 37% between normal and perturbed conditions) on the results of the basket method substantiates the findings reported earlier (2). The reason for the substantial decrease may partly be attributed to the decrease in the effective stirring of the dissolution medium under these perturbed conditions. The particles of the disintegrated tablet (USP prednisone calibrator) were observed to drop and collect at the center of the flask. Under tilt and off-center conditions, the particles are not sufficiently agitated because the rotating basket is not directly above the particles. These perturbed conditions, therefore, effectively lower the intensity of agitation resulting in lower dissolution value.

The intensity of agitation should not be confused with mixing, *i.e.*, uniform mixing. It was clearly established (12) that the basket method produces uniform mixing of the dissolution medium. This conclusion was based on the observation that samples drawn from different positions in the flask gave very similar results. In the cement investigation under tilt condition, the basket is positioned such that one side of the basket is close to the wall of the dissolution flask, whereas the other side is at the most distant position. Dissolution samples drawn from either side of the basket, at the same time using two probes, resulted in identical dissolution values, further indicating that there is no problem with mixing in the basket method.

The dissolution results using the USP prednisone calibrator and paddle method under normal and perturbed conditions are nearly the same (~70%, Table II). These results indicate that the paddle method cannot differentiate between the normal and perturbed conditions when the USP prednisone calibrator is used. A plausible explanation for the insensitivity of the USP prednisone calibrator to the perturbations in the paddle method is that the intensity of agitation (effective stirring) is adequate to disperse the tablet fragments throughout the medium under normal,

tilt, and off-center conditions, thus overcoming the inadequacies noticed in the basket method.

The results from several collaborative studies (3, 4, 11) indicate that the basket method always results in a wide range of dissolution values, where the paddle method has a narrow range of dissolution values. To establish the ruggedness and sensitivity of the paddle method, NCDA has identified a prednisone product (NCDA prednisone performance standard II) that can detect perturbations in the paddle method and that can be used for system suitability tests (9).

The dissolution results using the NCDA performance standard by the paddle method under normal and perturbed conditions are summarized in Table III. Under normal conditions, the dissolution results are ~40%, whereas under perturbed conditions they are ~ 50%. These values are significantly different when compared to normal conditions. The results thus indicate that the paddle method is sensitive to minor perturbations in the system and can differentiate between equipment that has been properly set up (normal) as opposed to a system that is improperly aligned, tilted, *etc.*, (perturbed) when NCDA performance standard II is used. The results of the NCDA performance standard using the paddle method were influenced by perturbations, and the reason might have been that after rapid disintegration, the particles are not very well dispersed, but form a mount (or cone) in the bottom of the flask. Because the particles are dense and settle down, the drug diffuses from the mound and not by dispersion throughout the medium.

NCDA prednisone performance standard II using the basket method resulted in a mean dissolution of 74% under normal conditions (Table IV). The dissolution results under perturbed conditions are also shown in Table IV. Different perturbations do not influence the results of NCDA performance standard II when the basket method is used. The tablet components of this standard, after disintegration, remained inside the basket longer, whereas the USP prednisone calibrator rapidly disintegrated and settled to the bottom of the flask. These observations partly explain the anomaly observed in the results of these two prednisone tablets when tested by the basket method. If one notices the USP calibrator results by the basket procedure, the differences between the normal and perturbed conditions are dramatic. Thus, one can reasonably conclude that the USP prednisone calibrator is sensitive to perturbations in the basket procedure, whereas the NCDA prednisone performance standard II is insensitive to any unanticipated aberrations in the equipment. The differences in the physical state of the deaggregated tablet matrix as well as the differences in the density of the particles (as observed in the flask) can, at the present time, explain these differences in the results.

The dissolution data on both standards using both methods are summarized in Fig. 1. It is interesting to note that identical perturbations

Table IV—NCDA Prednisone Performance Standard (Basket Method) Dissolution in 500 ml of Water at 100 rpm

Unit Operating Condition[a]	Mean ($N = 6$)	$\pm SD$	Range
Normal	77.4	2.6	74.7–80.5
	72.1	6.1	65.4–78.2
Tilt	81.5	3.1	77.6–85.9
	80.3	2.6	77.0–84.7

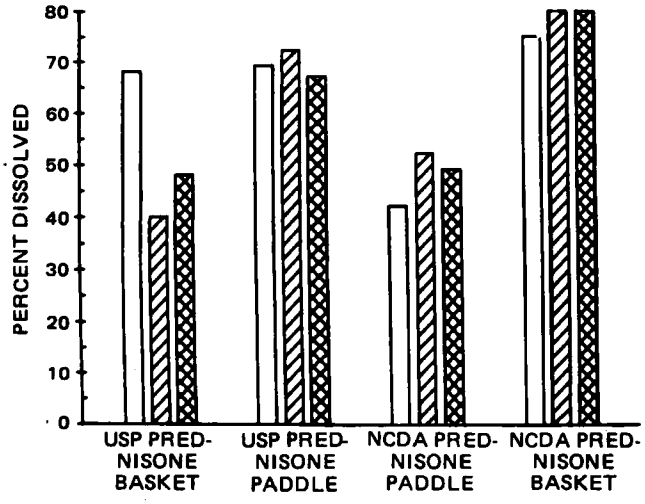

Figure 1—*Evaluation of the basket and paddle method using the USP prednisone calibrator and the NCDA prednisone performance standard. Key = (□) Normal; (▨) Tilt; (▩) Off-center.*

result in increased dissolution of the NCDA performance standard by the paddle method but decreased dissolution of USP prednisone calibrator by the basket method. The conclusion that one method (basket or paddle) is better than the other is, therefore, largely dependent on the standard product used in the system suitability test. At the present time neither the USP prednisone calibrator nor NCDA prednisone performance standard II alone can predict the suitability of a dissolution system when both the basket and paddle methods as described in the USP, are to be used.

All the dissolution results were statistically analyzed using ANOVA and Duncan's Multiple Range Test. The statistical results indicate that the dissolution results of the basket method using the USP prednisone calibrator and the dissolution results by paddle method using NCDA performance standard II under normal conditions were significantly different from the results obtained under perturbed conditions. It is therefore concluded that the USP prednisone calibrator is sensitive to perturbations by the basket method, and can be used as a calibrator in the system suitability test by the basket method only. Similarly, NCDA prednisone performance standard II is sensitive to perturbations by the paddle method and can be used as a calibrator for the system suitability test of the paddle method only. From the ANOVA it is also concluded that the USP prednisone calibrator is insensitive to perturbations by the paddle method, and NCDA performance standard II is insensitive to perturbations by the basket method. These results are summrized in Table V and indicate the necessity of an official calibrator similar to NCDA prednisone performance standard II to perform the system suitability test when the paddle method is used.

Table V—Statistical Analysis of Dissolution Data between Methods, Conditions, and Calibrators

Method	Calibrator	ANOVA[a]
Basket	USP Prednisone	$p = 0.0008$
	NCDA Prednisone	Not Significant
Paddle	USP Prednisone	Not Significant
	NCDA Prednisone	$p = 0.0001$

Potential Broad Spectrum Anthelmintics IV: Design, Synthesis, and Antiparasitic Screening of Certain 3,6-Disubstituted-(7*H*)-*s*-triazolo-[3,4-*b*][1,3,4]thiadiazine Derivatives

M. A. El-DAWY *, A.-MOHSEN M. E. OMAR ‡x, ABLA M. ISMAIL *, and A. A. B. HAZZAA ‡

Received December 4, 1980, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmacy, *University of Tanta and ‡University of Alexandria, Egypt.* Accepted for publication December 29, 1981.

Abstract □ A series of 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]-thiadiazine derivatives were prepared. The compounds were designed to obtain structural similarities and/or bear isosteric relation with certain fused systems encountered in some well-known antiparasitic drugs. The substituents in all products were selected according to the Topliss scheme. Preliminary screening for antiparasitic activity, using *Ascaris vitulorum*, showed that the 6-substituted derivatives were generally more active than the 3-substituted ones and that the π effect is more pronounced than the σ effect.

Keyphrases □ Anthelmintics—potential broad spectrum, design, synthesis, antiparasitic screening of certain 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]thiadiazine derivatives □ Antiparasitic screening—potential broad spectrum anthelmintics, design, synthesis of certain 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]thiadiazine derivatives □ Thiadiazine, derivatives—potential broad spectrum, design, synthesis, antiparasitic screening of certain 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]thiadiazine derivatives

In the past few years, studies have been concerned with the design, synthesis, and screening for anthelmintic activity of several fused systems bearing structural and isosteric relationships with (±) 6-phenyl-2,3,5,6-tetrahydroimidazo[2,1-*b*]thiazone (tetramisole) (1), the well-known broad spectrum anthelmintic. As a result, a variety of compounds derived from imidazo[1,2-*b*]thiazole (2, 3), imidazo[1,2-*b*][1,3,4]thiadiazole, thiazolo[2,3-*b*]thiadiazole (4), thiazolo[2,3-*c*]tetrazole (5) as well as their open-ring counterparts were developed.

In view of the recently reported antiparasitic activity of some derivatives of triazole (6, 7), a novel series of potential anthelmintics were prepared in which the triazole is a part of the fused heterocyclic system. The compounds of interest, namely 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*]-[1,3,4]thiadiazines (III–XLIV), Scheme I, were designed to contain various substituents selected according to the Topliss scheme (8). The purpose was to study the effect of the different possible variations of π and σ on the biological activity of the parent compound.

RESULTS AND DISCUSSION

Chemistry—Compounds III–XLIV were prepared in accordance with the sequence of reactions presented in Scheme I. The potassium salts of N^1-acyl-N^2-dithiocarbazates (I), synthesized from the reaction of the corresponding acylhydrazines (9–13) with carbon disulfide and potassium hydroxide, were treated with hydrazine hydrate in refluxing ethanol to give the 3-substituted-4-amino-*s*-triazolo-5-thiones (II) (14). The IR spectra of these triazoles indicated their existence in thione form *A* rather than in thiol form *B*. Condensation of the triazoles (II) with the appropriately substituted phenacylbromides (15, 16) in refluxing ethanol gave the required 3,6-disubstituted-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]thiadiazines (III–XLIV). The yields and physical constants of the products are recorded in Table I.

Unlike earlier claims (18, 19), the trials to synthesize the noncyclic analogs of compounds III–XLIV, namely the 3-(4-substituted aryl)-4-amino -5- [*S*-(4-substituted-phenacyl)mercapto]-(4*H*)-1,3,4-triazoles (XLV), which bear the same spatial arrangement as the triazolothiadiazines (III–XLIV), were fruitless. The reactions, even under the mildest conditions, always yielded the cyclized products.

The IR spectra of the products (III–XLIV) were compatible with the structures assigned. In particular, the thioureido (I, II, III, and IV) bands located for the C=S and —NH mixed vibrational coupling in the triazole (II) were greatly affected. The bands contributing to the —NH moiety of the —CSNH function at 1515 and 1090 cm^{-1} completely disappeared while those at 1315 and 950 cm^{-1}, characteristic for the C=S function (20), became weaker in intensity. The absence of the carbonyl absorbance at 1660–1630 cm^{-1} has also confirmed the cyclic structures. The PMR spectra showed the signals at the expected chemical shifts. The compounds containing the methyl groups in the aryl substituents showed a singlet in the region of 2.37–2.50 ppm, while those containing the methoxy functions showed the singlet at 3.73–3.87 ppm. The C_7-methylinic protons appeared as a singlet in the region of 4.42–4.43 ppm. The chemical shifts of the aromatic protons of the 3- and 6-aryl functions were dependent on the nature of the *p*-substituents in these groups.

For more concerted evidence, the mass spectra of compounds XXVII and XXX, as representative examples, were run, and the structure of the ions formed, under electron impact, was assigned. The spectrum of 3-*p*-methoxyphenyl-6-*p*-bromophenyl-(7*H*)-*s*-triazolo[3,4-*b*][1,3,4]thiadiazine (XXX) showed the molecular ion peak at *m/z* 400 (402 for M+2). Its

[a] Time in minutes for 100% deaths or relaxation. [b] The compound is reported in Ref. 18. [c] D = Death. [d] R = Relaxation. [e] Reference 17.

fragmentation as shown in Scheme II followed four different pathways. In accordance with pathway 1, the molecule eliminated sulfur giving ion *A* at *m/z* 368 (370). In pathway 2, a *p*-bromophenyl ion was removed from compound XXX giving ion *B*, *m/z* 245, which on elimination of a nitrogen molecule and a cyanide group yielded ion *C* at *m/z* 191. This ion in turn eliminated cyanide and methylene fragments to give the phenoxyethylenesulfide ion *D* at *m/z* 151, or underwent successive cleavage of carbon monosulfide, methylene, cyanide, methyl, carbon monoxide moieties, and hydrogen producing ions *E* and *F* at *m/z* 133 and 63, respectively. The *p*-methoxyphenylcyanide ion *E* was shown as the base peak. In alternative fragmentation pathway 3, the product cleaved ion *E* and nitrogen to produce *p*-bromophenylthiazole ion *G* at *m/z* 241 (243). This on further elimination of carbon monosulfide, methylene, and cyanide fragments gave *p*-bromophenylcyanide ion *H* at *m/z* 181 (183) and *p*-bromophenyl ion *I* at *m/z* 155 (157). In pathway 4, however, the molecule eliminated ions *H* and *E* leading to ion *J* at *m/z* 219 and ion *N* at *m/z* 90. Ion *J* either eliminated a hydrogen sulfide and a methyl group giving ion *M* at *m/z* 158 or cleaved a methylene and accepted two hydrogens to produce ion *K* at *m/z* 207. Further cleavage of a *p*-methoxyphenyl ion or ion *E* from ion *K* gave ion *L* at *m/z* 102 and the pseudothiourea ion at *m/z* 75. The mass spectrum of compound XXVII showed the molecular ion peak at *m/z* 322 and the ion at 133, corresponding to *p*-methoxyphenylcyanide, as the base peak. The additional ions shown were indicative that the fragmentation of the compound followed the fragmentation pattern proposed for compound XXX.

Antiparasitic Screening—The effect of the synthesized compounds III–XLIV on *Ascaris vitulorum* worms was evaluated in accordance with a method developed previously (21). As shown in Table I, the products containing substituted phenyl groups in the 3 position were generally less active than those having the same type of substituents at the 6 position. In addition, due to increased π effect, the biological activity was higher for compounds containing 4-chloro and 4-bromophenyl substituents relative to the nonsubstituted ones.

The tolyl derivatives were found to be less potent compared with the phenyl derivatives. This finding, as well as the fact that compounds containing the nitro group ($\sigma = 0.78$) or the methoxyl group ($\sigma = 0.27$) were less active than the substituted derivatives, led to the assumption that the π effect is more predominating in this series of compounds. Moreover, the equipotent activity of the products containing 4-pyridyl and phenyl functions has been attributed to the isostericity of both functional groups.

EXPERIMENTAL[1]

Potassium Salts of 3-Aroyl Dithiocarbazates (I)—Compound I was prepared, as reported (14), starting from the corresponding acid hydrazides. They were obtained in nearly quantitative yield and employed in the following reactions without further purification.

3-Substituted-4-amino-5-mercapto-(4*H*)-1,2,4-triazoles (II)—Compound II was prepared by reaction of potassium salts of 3-aroyl dithiocarbazates with 98% hydrazine hydrate according to the reported method (14).

3,6-Disubstituted - (7*H*)-*s*-triazolo[3,4 - *b*][1,3,4]thiadiazines (III–XLIV)—Equimolar amounts of the triazoles (II) and the appropriate phenacyl bromide derivative in anhydrous ethanol were heated under reflux for 2 hr. After cooling, the mixtures were neutralized with ammonium hydroxide to separate the free base. Filtration, washing with water, and crystallization from boiling ethanol separated the products as white or pale yellow crystals. The physical constants of the products are recorded in Table I. Mass spectra for compound XXVII, *m/z* (relative abundance percent): M^+ at 322 (97), 293 (3), 290 (4), 288 (2), 245 (2), 219 (8), 191 (4), 177 (4), 161 (40), 158 (8), 151 (7), 145 (16), 133 (97), 132 (26), 130 (7), 118 (10), 117 (16), 103 (100), 90 (29), 77 (48), 63 (13), 58 (36), 51 (2); and for compound XXX: 402 (M+2) and 400 (M^+) (63), 370 (13), 368 (13), 245 (3), 241 (5), 239 (5), 219 (10), 207 (10), 197 (8), 195 (6), 191 (4), 183 (31), 181 (36), 161 (39), 158 (8), 157 (8), 155 (8), 151 (5), 145 (13), 133 (100), 118 (8), 116 (8), 103 (26), 102 (49), 90 (27), 76 (3), 75 (21), 63 (13), 58 (36), 51 (17), 50 (17).

3-Substituted-4-amino-5-[*S*-(substituted phenacyl)mercapto]-(4*H*)-1,2,4-triazole (XLV) (Attempted Preparation)—A solution of 3-(4-methoxyphenyl)-4-amino-5-mercapto-*s*-triazole (0.1 mole) in 1 *N* methanolic potassium hydroxide (20 ml) was stirred while cooling in an

[1] All melting points were uncorrected. IR spectra were measured for Nujol Mulls on a Beckmann 4210 IR Spectrophotometer. PMR spectra were measured for dimethyl sulfoxide-d_6 solutions on a high resolution T-60A Varian NMR Spectrometer. The mass spectra were taken to 70 eV on an AEIMS 902 Mass Spectrometer attached to an AEIDS 30 data system.

ice bath until a precipitate developed. This was dissolved by addition of methanol and the solution was treated by a dropwise addition of a solution of 4-chlorophenacyl bromide (0.2 mole) in methanol (20 ml) while maintaining the pH at 7–7.5 by 1 *N* methanolic potassium hydroxide. The final mixture was stirred for 1 hr while cooling in ice and for an additional hour at room temperature. Dilution with cold water (60 ml) caused complete separation of the product, which was found to be the cyclized product (XXIX) as evidenced by mixed melting point determination and superimposability of IR. Repeating the reaction for a shorter period of time (15 min) in aqueous methanol again gave the cyclized product (XXIX).

Influence of Environment and Substituents on the Stability of the Radical Cations of Several Phenothiazine Derivatives

A. ORTIZ[x], I. POYATO, and J. I. FERNANDEZ-ALONSO

Received December 24, 1980, from the *Departamento de Química-Física y Química Cuántica, Centro Coordinador CSIC-UAM, Facultad de Ciencias C-XIV, Cantoblanco, Madrid 34, Spain.* Accepted for publication March 1, 1982.

Abstract □ The UV decay spectra of the radical cations of several phenothiazine derivatives in different environments was studied. The influence of the substituents on the reference spectrum could be seen, as well as a relationship between the stability of such radicals and the acidity of the environment. There is also an influence of the substituents on the stability of the radicals in the different environments studied. The instability of the radicals in solution has been studied to relate to the pharmacological activity of neuroleptics.

Keyphrases □ Phenothiazine—derivatives, influence of environment and substituents on the stability of the radical cation □ Neuroleptics—phenothiazine derivatives, influence of environment and substituents on the stability of the radical cations □ Radical cations—influence of environment and substituents on stability, phenothiazine derivatives

The physicochemical study of phenothiazines has increased in recent years. One of the most common properties of phenothiazine and its derivatives is that they are oxidized easily (1–3). The fact that various oxidized compounds were found (4) among metabolic degradation products suggested that the phenothiazines could act in humans in their oxidized form or produce a redox reaction. Based on this, it was proposed (5) that certain products could act in humans by means of an energy or electron transfer. The phenothiazines, then, can act as electron donors if there are adequate acceptors. Evidence has been presented that the drugs interact with dopamine receptors, and a good correlation has been found between drug potency and the strength of this interaction (6, 7). Several investigators have proposed that the cation radical formed by the oxidation of a phenothiazine derivative (8) such as chlorpromazine, could be an intermediate of the metabolism of the drug and may be the active pharmacological entity (8, 9).

In the present report a study of the kinetics of decay of the first oxidation product of several phenothiazine derivatives in different environments is described, and their instability is related to the substituents and their pharmacological activity.

BACKGROUND

The influence of the R_2 substituents and the structure of the R_{10} side chain on the antipsychotic activity of phenothiazines has been studied (10). However, information about substituent effects on the radical cation behavior is less prevalent due to the difficulty in studying the reactive cation radicals; therefore, it is useful to investigate the behavior of the radicals as a function of structure, given the possible involvement of the radicals in the metabolism of the drugs and in their activity.

The cation radicals of phenothiazine were first obtained in 1913 (11). It was stated that the phenothiazine oxidation proceeds by two steps (12):

Keyphrases □ Phenothiazine—derivatives, influence of environment and substituents on the stability of the radical cation □ Neuroleptics—phenothiazine derivatives, influence of environment and substituents on the stability of the radical cations □ Radical cations—influence of environment and substituents on stability, phenothiazine derivatives

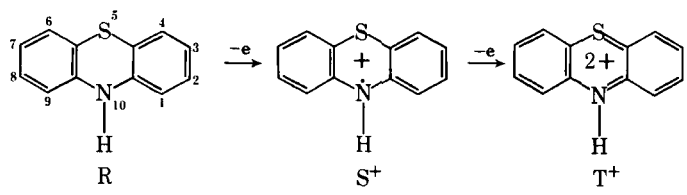
The physicochemical study of phenothiazines has increased in recent years. One of the most common properties of phenothiazine and its derivatives is that they are oxidized easily (1–3). The fact that various oxidized compounds were found (4) among metabolic degradation products suggested that the phenothiazines could act in humans in their oxidized form or produce a redox reaction. Based on this, it was proposed (5) that certain products could act in humans by means of an energy or electron transfer. The phenothiazines, then, can act as electron donors if there are adequate acceptors. Evidence has been presented that the drugs interact with dopamine receptors, and a good correlation has been found between drug potency and the strength of this interaction (6, 7). Several investigators have proposed that the cation radical formed by the oxidation of a phenothiazine derivative (8) such as chlorpromazine, could be an intermediate of the metabolism of the drug and may be the active pharmacological entity (8, 9).

In the present report a study of the kinetics of decay of the first oxidation product of several phenothiazine derivatives in different environments is described, and their instability is related to the substituents and their pharmacological activity.

BACKGROUND

The influence of the R_2 substituents and the structure of the R_{10} side chain on the antipsychotic activity of phenothiazines has been studied (10). However, information about substituent effects on the radical cation behavior is less prevalent due to the difficulty in studying the reactive cation radicals; therefore, it is useful to investigate the behavior of the radicals as a function of structure, given the possible involvement of the radicals in the metabolism of the drugs and in their activity.

The cation radicals of phenothiazine were first obtained in 1913 (11). It was stated that the phenothiazine oxidation proceeds by two steps (12):

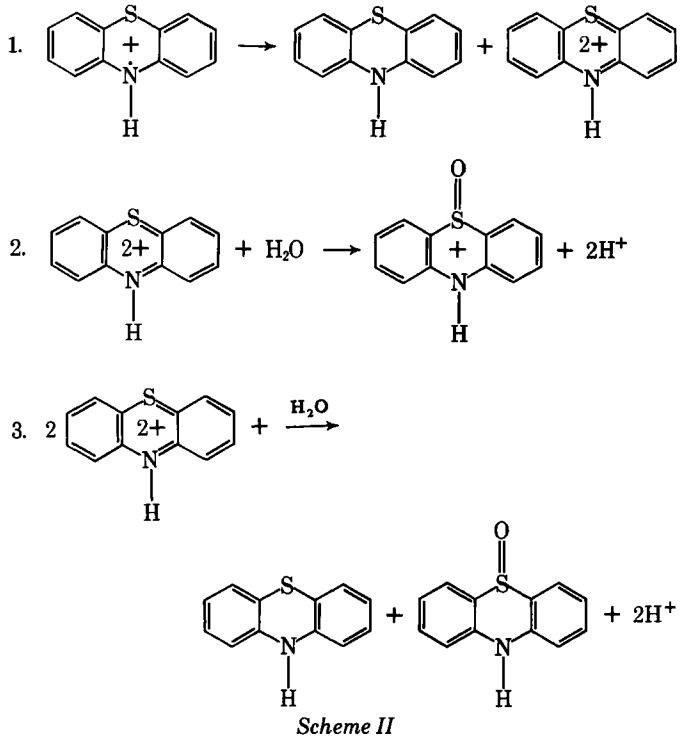


Scheme I

0022-3549/83/0100-0050$01.00/0

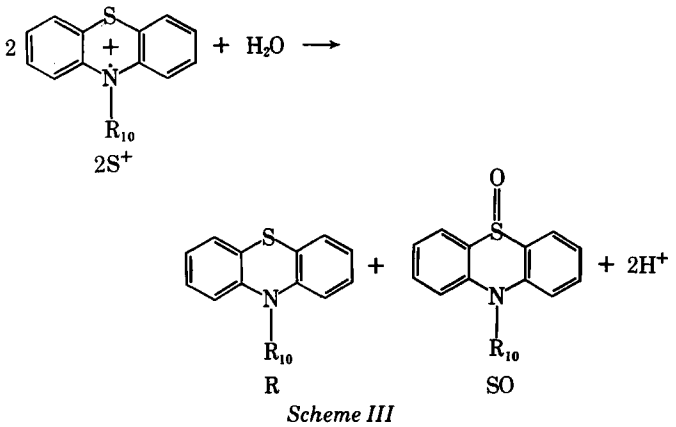
where R produces an uncolored solution, S^+ produces a colored solution, and T^+ an intense red solution.

The radical in solution is stable only in a concentrated acid environment, otherwise disproportionation occurs in three steps:



Scheme II

The first and second steps can be eliminated by acidifying the environment. The third step does not occur in the case of substituted R_{10} derivatives. Therefore, the reaction ends at step 2 and it can be expressed (13):



Scheme III

While the S^+ produces a colored solution, the R and sulfoxide solution are decolorized.

EXPERIMENTAL

Materials—Phenothiazine derivatives with R_2 and R_{10} substituents were used (Table I). The products were pharmacologically pure and were used without further purification. Perchloric acid (70%) was the oxidizing agent.

The solvents were bidistilled water, sulfuric acid (9 *N* and 2 *N*), and solutions with different pH values (pH 1, 2.2, and 3.5). UV and visible spectrophotometers were used to obtain the spectra to which the kinetic decay of the radicals in solution adjust.

Method—A method reported previously was used to obtain the cation radicals in the solid state (14). Analysis for phenothiazine derivative radical perchlorates were calculated.

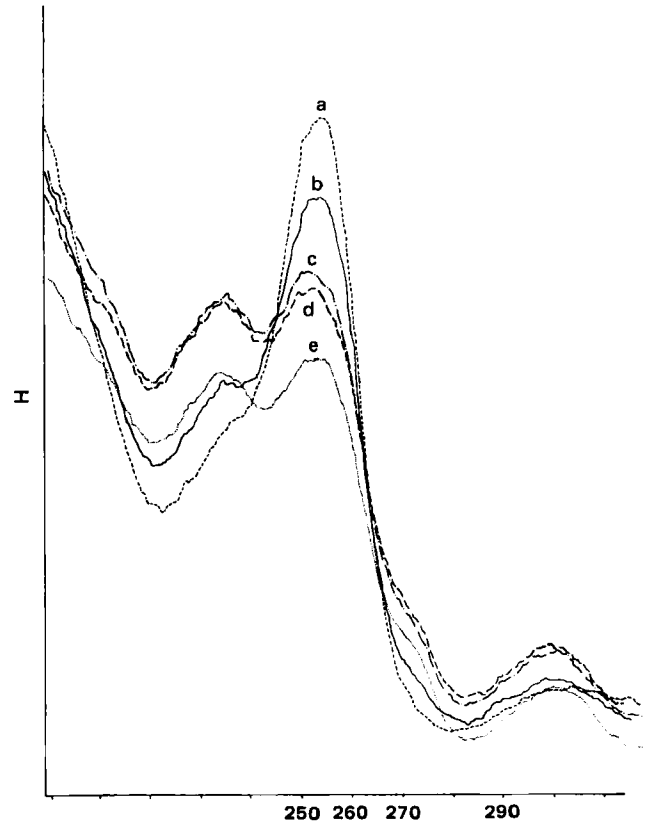


Figure 1—*Decay of the trifluoperazine radical cation in the following solutions (350–200 nm* versus *absorption) (a) water; (b) sulfuric acid pH 3.5; (c) sulfuric acid, pH 2.2; (d) sulfuric acid, pH 1; (e) 2 N sulfuric acid.*

Perazine—Anal.—Calc.: C, 43.80; H, 4.96; S, 5.84; N, 7.66; Cl, 12.93. Found: C, 43.14; H, 4.91; S, 5.92; N, 7.66; Cl, 12.91.

Trifluoperazine—Anal.—Calc.: C, 40.88; H, 4.25; N, 6.81; S, 5.20; Cl, 11.50; F, 9.24. Found: C, 40.28; H, 4.21; N, 7.05; S, 5.29; Cl, 11.6; F, 9.38.

Prochlorperazine—Anal.—Calc.: C, 41.21; H, 4.49; N, 7.20; S, 5.50; Cl, 18.25. Found: C, 41.21; H, 4.43; N, 7.35; S, 5.18; Cl, 17.84.

Thiethylperazine—Anal.—Calc.: C, 43.42; H, 5.05; N, 6.90; S, 10.53; Cl, 11.65. Found: C, 43.7; H, 5.20; N, 7.01; S, 11.0; Cl, 10.92.

Promazine—Anal.—Calc.: C, 41.38; H, 4.49; S, 6.49; N, 5.67; Cl, 14.37. Found: C, 41.15; H, 4.35; S, 6.53; N, 5.61; Cl, 14.52.

These values agreed with the proposed formula given in an earlier report for chlorpromazine perchlorate (14): (phenothiazine derivative) + $ClO_4^-.ClO_4H.\frac{1}{2}H_2O$. The melting points of these compounds ranged from 170 to 224°.

RESULTS AND DISCUSSION

The radicals dissolved in all solvents used. An intense coloration appeared which corresponded to the oxidized form. The radicals remained indefinitely stable only in 9 *N* sulfuric acid solution because of its high acidity. Disproportionation of the cation radicals occurred in all other solvents employed, with the characteristic coloration of the cation radical disappearing.

To study the kinetics of these compounds, the cation radical perchlorates were used as the oxidized form in the solid state. For each radical a control in 9 *N* sulfuric acid solution, the acid-stabilized solution, was used as a comparison standard of fixed concentration.

To determine the concentration of the radical, electron-spin resonance (ESR) spectroscopy was employed. As a reference, a benzene solution of 1,1-diphenyl-2-picrylhydrazyl, as free radical standard was used. An acid-stabilized control sample of each compound with *concentrations* of 10^{-2}–10^{-3} *M* served as the reference.

The characteristic superfine structure of the molecular structure of phenothiazine was suppressed; consequently, the ESR spectra of the radical cations consisted of a single line. The proportion of the ESR signal height with respect to the radical concentration gave a concentration measurement accurate to 3%. The comparison with the free radical

Table I—UV Spectra Data for the Radical Cations of the Phenothiazine Derivatives in 9 *N* Sulfuric Acid

Compounds[a]	R_2	Concentration	λ_{max}, nm (log ϵ)	λ_{max}, nm (log ϵ)	λ_{max}, nm (log ϵ)
I Perazine[b]	—H	4×10^{-4} mole/liter	271(3.50)	265(3.48)	212(3.25)
II Promazine[c]	—H	4×10^{-4} mole/liter	271(3.51)	265(3.48)	212(3.25)
III Thiethylperazine[d]	$-SC_2H_5$	6×10^{-4} mole/liter	296(3.29)	267(3.12) 245–236(2.98)	205(2.95)
IV Prochlorperazine[e]	—Cl	5.14×10^{-4} mole/liter	275(3.39)	268(3.37)	216(3.20)
V Trifluoperazine[f]	$-CF_3$	4×10^{-4} mole/liter	271(3.60)	—	213(3.24)

[a] For I, III–V R_{10} = $-CH_2-CH_2-CH_2-N\langle(H)\rangle N-CH_3$; for II R_{10} = $-CH_2-CH_2-CH_2-N-(CH_3)_2$. [b] Rhodia. [c] Promonta. [d] Upjohn. [e] Sandoz. [f] Squibb.

standard showed that, within the accuracy of the method, the acid-stabilized control was entirely in the free radical cation form.

The promazine and perazine cation radicals decayed slowly enough so that successive passes through the UV region (350–200 nm) could be made, and it was possible to study the entire spectrum with respect to time. For the other products, only the λ_{max}, which refers to the oxidized form, were taken, and the time dependence of the absorbance was recorded.

Influence of the Substituents of the Radical Cations in 9 *N* Sulfuric Acid Solution—Table I presents the transitions corresponding to the cation radicals in 9 *N* sulfuric acid solution (15). The reference used to study the substituent effects was perazine.

Perazine (I) and promazine (II) generate no change from the reference spectrum with R_2 = H and different substituents at R_{10}.

The radical cations with different substituents at R_2 and the same at R_{10} give different changes. Thus, the —Cl and $-SCH_2CH_3$ substituents show a resonance effect upon the π structure of the nucleus of the phenothiazine derivative which manifests itself in bathochromic shifts of the peaks (16). However, R_2= $-CF_3$, with a strong electron-withdrawing effect, seems not to affect the transitions corresponding to the radical cation.

In the perazine spectrum, it can be seen that the —Cl substituent shows a bathochromic shift in all bands.

The $-SCH_2CH_3$ caused an intense bathochromic shift in the first band, the second remained at 265 nm, and a transition peak appeared at 245–228 nm, which represents a vibratory structure. This transition peak could be caused by the sulfur atom in the R_2 substituent [the same transitions also appeared at the same wavelength in the spectra of an identical neutral compound (17)].

The $-CF_3$ derivative produces no shift in the bands; however, the second maximum at 265 nm disappeared.

Through log ϵ, a relationship can also be established between the intensity of the bands of each radical cation and the substituents. Thus, the R_{10} substituent does not exert any influence on the intensity of the bands; with perazine, however, derivatives with R_2 substituents such as —Cl or $-SC_2H_5$ seem to exert a negative influence on such bands showing a hypochromic effect. On the contrary, the $-CF_3$ substituent affects the π electronic structure of the tricyclic nucleus producing hyperchromic shifts on its maxima (16).

Decay of the Radicals—Figures 1 and 2 show the final spectra of the decay of the radical cation in the different solutions used. The corresponding λ_{max} and log ϵ values are given in Table II. The values of λ for the sulfoxide are on the right side of the table and the values for λ corresponding to neutral phenothiazine derivatives are on the left. The neutral form and sulfoxide of each radical cation were identified from earlier reports (18–20).

From these spectra the following can be seen. (*a*) The radical cations stay stable only in 9 *N* sulfuric acid; (*b*) The radicals are not stable in 2

Table II—UV Spectra of the Phenothiazine Derivatives in Sulfuric Acid Solutions of Different Acidity

Product (concentration)	Solvent	Neutral form λ_{max} (log ϵ)	Sulfoxide λ_{max} (log ϵ)
Promazine (4×10^{-4} mole/liter)	2 *N* H_2SO_4	250 (3.21) 298s (2.72)	270 (2.91) 235s (3.14) 222s (3.09)

	distilled water	250 (3.15) 300s (2.54)	240 (3.05)

[a] There is an intense overlap of the bands corresponding to the sulfoxide and to the neutral derivative.

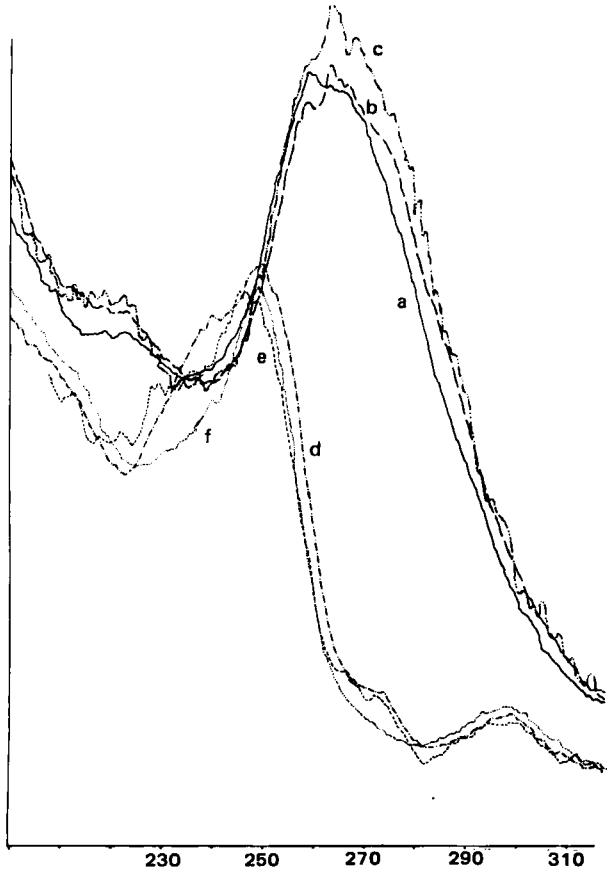

Figure 2—*Final decay spectra of prochlorperazine and thiethylperazine radical cations in the following solutions: 350–200 nm* versus *absorption) thiethylperazine in (a) 2* N *sulfuric acid; (b) water; (c) sulfuric acid, pH 1. Prochlorperazine in (d) 2* N *sulfuric acid; (e) pH 1 sulfuric acid; (f) water.*

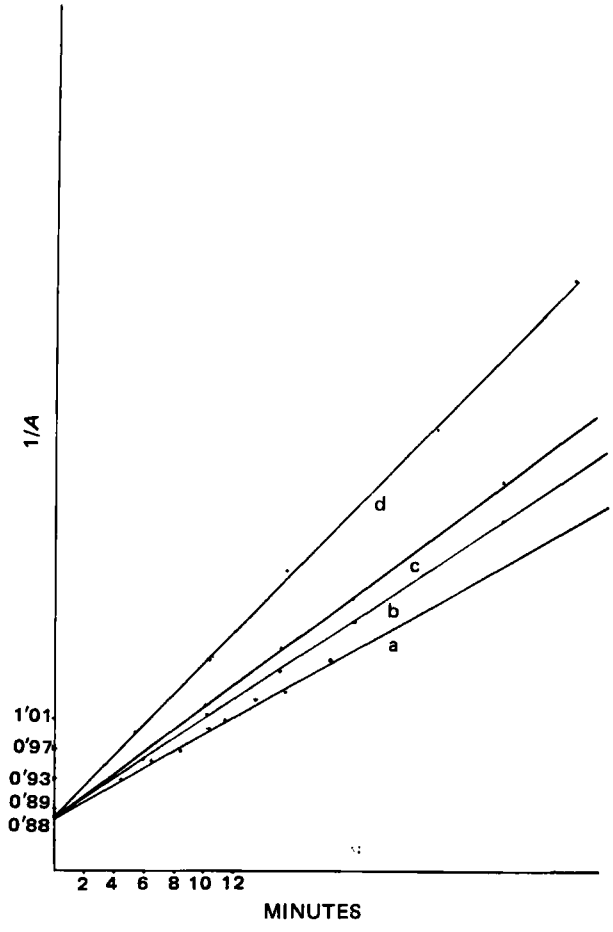

Figure 3—*1/*A versus *time (minutes) for promazine acid; in (a) 2* N *sulfuric acid; (b) pH 1 sulfuric acid; (c) pH 3.5 sulfuric acid; (d) water.*

N sulfuric acid, decoloration occurs, and new bands appear, which are different from those of the radical cation. The sulfoxide coexists with the neutral form, with the sulfoxide being more important. (*c*) In solutions of pH 1 and 3.5 decoloration goes fast, and it can be seen that the band corresponding to the neutral phenothiazine derivative is of a stronger intensity than the one corresponding to the sulfoxide. (*d*) In solutions in distilled water, the decay is almost simultaneous and decoloration is practically immediate. There is a strong prevalence of the band corresponding to the neutral phenothiazine derivative over the one corresponding to the sulfoxide. However, upon observing the spectra, an overlapping of some bands can be noticed (Fig. 2). Nevertheless, the decay of the radical cations depends upon the acidity concentration of the environment and substituents R_2 and R_{10}.

There is a correlation between the bands characteristic of each compound with the environment. Thus, in solutions with higher acidity, the sulfoxide dominates; in solutions with lower acidity, the neutral derivative dominates; and in solutions at pH 2.2 and 3.5, the proportion between these two forms is similar.

Kinetics—The decay velocity of the radicals in each solution studied was obtained from spectral data on the assumption that the absorbance was linearly related to the free radical concentration, representing $1/A$ *versus* time. In this way the initial absorbance was computed from the intercept of zero time with $1/A$. The velocity constant was obtained from:

$$K = (1/t)\,(1/A - 1/A_0) \qquad \text{(Eq. 1)}$$

where A_0 is the initial, extrapolated absorbance, A is the absorbance at time t, and t is time in minutes.

In all cases the data produced a straight line (Figs. 3 and 4) indicating a second-order decay of the semiquinone or oxidated form S^+, which agrees with 2 S+ - - - - R + SO, as proposed in other reports (13, 21).

Since the oxidized form is unstable in insufficiently acidic solutions, the initial concentration is no longer 100% but is lower from the beginning. This makes it necessary to extrapolate at time 0 to calculate A_0, which can be compared with the absorbance of the coresponding radical in 9 *N* sulfuric acid, taken as the reference, in which the concentration is 100%, because the radical stays stable indefinitely. Thus, in 2 *N* sulfuric acid the calculated initial concentration of the radicals studied are between 85 and 100% of the same compound in 9 *N* sulfuric acid.

In the less acidic solutions, the measurements are even less accurate because of the speed of the radical decay, and at lower pHs, the extrapolated initial concentrations were still lower than for 2 *N* sulfuric acid. However, it can be considered sufficient for obtaining relative reaction rates on the disproportionation of the radicals.

Effect of the Environment pH on K Decay—Least-square fits were made to obtain constants for K, experimental errors, ϵ, coefficients of regression, R^2, and $1/A_0$ data for every compound in the different media employed (Table III).

In Fig. 3 it can be seen that, as for any of the compounds studied, K increases as the acidity of the solvent decreases.

Compounds I and II with R_2 = H and a Side Chain at R_{10}—Compounds I and II differ by their R_{10} substituents and from the values obtained it could be pointed out that the chain of I, which is longer than that of II, is capable of producing a more stable radical.

It can be seen from Table III that for compound I the K decay values are very similar, in spite of the different solutions employed. This appears to indicate that acidity has little influence on the stability of this radical in solution.

However, for II, K-values depend more on the solutions used, and the relation of the K decay of these two compounds in water is double for II than for I, that is, II decays two times faster than I in water.

Effects of R_2 Substituents—A clear influence of R_2 on K is observed; thus, it can be seen that the K-values for the same solution, 2 *N* sulfuric acid, (Fig. 4) or distilled water, follow the sequence: —H < —SCH_2CH_3 < —Cl < —CF_3. Similar to the first case with R_2 = H, the K-values increase as the acidity of the solution decreases; however, this K increase is stronger for compounds with $R_2 \neq$ H.

The strongest increase of the decay constant of the radicals can be seen in the product with the electron-withdrawing substituent, R_2 = —CF_3.

The introduction of an R_2 substituent, activated or deactivated, is capable of increasing considerably the decay of the radicals. It could have been expected that the electron-donating substituents, such as $-SCH_2CH_3$, would tend to stabilize the cation radicals in solution (22); however, in this case this was not so.

The constant decay can be related also to the $E_{1/2}$ (23, 24). The R_2 and R_{10} substituents affect the halfwave potentials as given in Table III. It is observed that a higher $E_{1/2}$ corresponds to a higher constant decay of the compound or at higher halfwave potential, less stability of the radical.

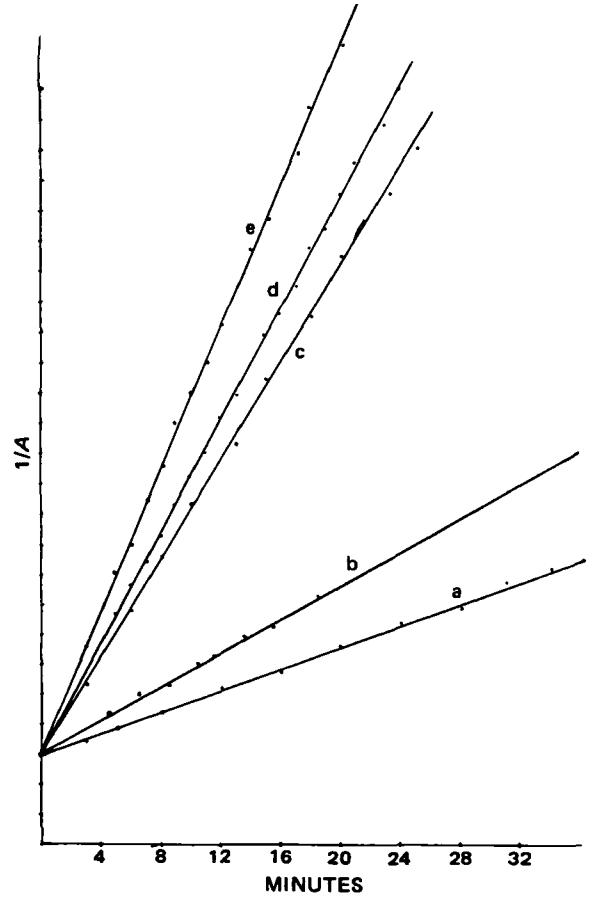

Figure 4—1/A versus *time for (a) perazine; (b) promazine; (c) thiethylperazine; (d) prochlorperazine; (e) trifluoperazine, in 2 N sulfuric acid.*

Relative Stability and Pharmacological Activity of the Radicals—It has been suggested that the phenothiazine derivative radical cation may be of some importance in the biological activity of phenothiazine (25), and in some cases it has been related to the stability of these radicals.

Since the pharmacological activity of the compounds studied, such as neuroleptics, depends on the R_2 substituents as: $-CF_3 > -Cl > -SCH_2CH_3 > -H$, and as it has been determined that the stability of their radicals varies inversely with the activity as neuroleptics, then the activity of these compounds cannot be related to the stability of the corresponding radical. However, the activity of these compounds could be related to the ability to form (CTC) charge transfer complexes whenever there are adequate receptors, with the cation radical as an intermediate in the biological action as has been suggested (26).

CONCLUSIONS

It can be concluded that the R_{10} substituents seem not to affect the transitions corresponding to the radical cation, but the R_2 substituents considerably affect such transitions in two ways: first, on the λ characteristics of the reference spectrum by bathochromic shifts (—Cl, and $-SCH_2CH_3$) and second, increasing (the $-CF_3$) or decreasing (—Cl and $-SCH_2CH_3$) the intensity of the corresponding bands.

From the final decay spectra of the radicals it can be seen that there exists a correlation between the band characteristics of the sulfoxide and the neutral form of each radical cation with the milieu, depending on the prevalence of one of the forms on the acidity of the solution employed. Thus, the neutral derivative dominates over the sulfoxide in water; however, this last compound seems to dominate the former in acidic solutions.

From the K-values obtained, it can be concluded that for each compound studied the radicals are only stable in high acidic solutions, and their stability decreases as the acidity of the environment decreases. Here it can be seen that the R_2 and R_{10} substituents' effect on the stability of radicals with longer chains are capable of producing a more stable radical. On the contrary, none of the R_2 substituents studied different than $R_2 \neq H$ are capable of generating a more stable radical. All substituents affect considerably the stability of the corresponding radicals. The more unstable the product with a strong electron-withdrawing effect ($-CF_3$), the more the other compounds (—Cl and $-SCH_2CH_3$) will also decrease the stability of their radicals but less than $-CF_3$.

This seems to indicate that the stability of the radicals can not be related to the activity of these compounds as neuroleptics, for the more

active (trifluoperazine) seems to be the less stable, and as soon as the radical is free and independent in solution, it suffers disproportionation and disappears as that radical.

Simultaneous Stability-Indicating Determination of Phenylephrine Hydrochloride, Phenylpropanolamine Hydrochloride, and Guaifenesin in Dosage Forms by Reversed-Phase Paired-Ion High-Performance Liquid Chromatography

GARY W. SCHIEFFER ˣ and DAVID EMLYN HUGHES

Received December 4, 1981, from *Norwich-Eaton Pharmaceuticals, Norwich, NY 13815.* Accepted for publication March 5, 1982.

Abstract □ A method for the quantitative determination of phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and guaifenesin in commercial formulations was developed. A reversed-phase paired-ion high-performance liquid chromatographic technique resolves the active from degradation products, colorings, and flavor and was found applicable to seven commercial dosage forms.

Keyphrases □ Phenylephrine hydrochloride—simultaneous determination with phenylpropanolamine hydrochloride and guaifenesin, reversed-phase paired-ion high-performance liquid chromatography □ Phenylpropanolamine hydrochloride—simultaneous determination with phenylephrine hydrochloride and guaifenesin, reversed-phase paired-ion high-performance liquid chromatography □ Guaifenesin—simultaneous determination with phenylephrine hydrochloride and phenylpropanolamine hydrochloride, reversed-phase paired-ion high-performance liquid chromatography □ High-performance liquid chromatography—reversed-phase paired-ion, simultaneous determination of phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and guaifenesin

The simultaneous determination of the active components in a specific dosage form offers advantages to separate analyses. Simultaneous GLC determinations are typically successful in assaying for phenylpropanolamine hydrochloride and other amines (1–8). At least one GLC assay for guaifenesin (glyceryl guaiacolate) is available in which guaifenesin is extracted and derivatized (9). Simple and reliable procedures for the simultaneous GLC determination of the underivatized phenylephrine hydrochloride and other amines are absent from the chemical literature. Studies are available in which 71 drugs were determined using nitrogen-selective and flame-ionization (FID) detectors (2); 50 amines of pharmaceutical interest (5) and 23 physiologically active amines (8) were determined. None of these methods were responsive to phenylephrine hydrochloride.

To overcome problems arising from the presence of phenylephrine hydrochloride in pharmaceutical formulations, high-performance liquid chromatographic (HPLC) procedures have been developed for simultaneous assay. The desired chromatographic separation involves phenylephrine hydrochloride (I), phenylpropanolamine hydrochloride (II), and guaifenesin (III). The only HPLC method reported in the literature separating I, II, and III with high resolution used a bonded phase cation exchange column (10). A reversed-phase HPLC method employing ion-pairing was preferred, since bonded-phase ion-exchange columns tend to have short lifetimes and poor reproducibility from column to column (11).

Numerous reversed-phase ion-pairing methods have been reported for various combinations of I, II, and III and other drugs. A previous report (12) used a nitrile column

Simultaneous Stability-Indicating Determination of Phenylephrine Hydrochloride, Phenylpropanolamine Hydrochloride, and Guaifenesin in Dosage Forms by Reversed-Phase Paired-Ion High-Performance Liquid Chromatography

GARY W. SCHIEFFER ˣ and DAVID EMLYN HUGHES

Received December 4, 1981, from *Norwich-Eaton Pharmaceuticals, Norwich, NY 13815.* Accepted for publication March 5, 1982.

Abstract □ A method for the quantitative determination of phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and guaifenesin in commercial formulations was developed. A reversed-phase paired-ion high-performance liquid chromatographic technique resolves the active from degradation products, colorings, and flavor and was found applicable to seven commercial dosage forms.

Keyphrases □ Phenylephrine hydrochloride—simultaneous determination with phenylpropanolamine hydrochloride and guaifenesin, reversed-phase paired-ion high-performance liquid chromatography □ Phenylpropanolamine hydrochloride—simultaneous determination with phenylephrine hydrochloride and guaifenesin, reversed-phase paired-ion high-performance liquid chromatography □ Guaifenesin—simultaneous determination with phenylephrine hydrochloride and phenylpropanolamine hydrochloride, reversed-phase paired-ion high-performance liquid chromatography □ High-performance liquid chromatography—reversed-phase paired-ion, simultaneous determination of phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and guaifenesin

The simultaneous determination of the active components in a specific dosage form offers advantages to separate analyses. Simultaneous GLC determinations are typically successful in assaying for phenylpropanolamine hydrochloride and other amines (1–8). At least one GLC assay for guaifenesin (glyceryl guaiacolate) is available in which guaifenesin is extracted and derivatized (9). Simple and reliable procedures for the simultaneous GLC determination of the underivatized phenylephrine hydrochloride and other amines are absent from the chemical literature. Studies are available in which 71 drugs were determined using nitrogen-selective and flame-ionization (FID) detectors (2); 50 amines of pharmaceutical interest (5) and 23 physiologically active amines (8) were determined. None of these methods were responsive to phenylephrine hydrochloride.

To overcome problems arising from the presence of phenylephrine hydrochloride in pharmaceutical formulations, high-performance liquid chromatographic (HPLC) procedures have been developed for simultaneous assay. The desired chromatographic separation involves phenylephrine hydrochloride (I), phenylpropanolamine hydrochloride (II), and guaifenesin (III). The only HPLC method reported in the literature separating I, II, and III with high resolution used a bonded phase cation exchange column (10). A reversed-phase HPLC method employing ion-pairing was preferred, since bonded-phase ion-exchange columns tend to have short lifetimes and poor reproducibility from column to column (11).

Numerous reversed-phase ion-pairing methods have been reported for various combinations of I, II, and III and other drugs. A previous report (12) used a nitrile column

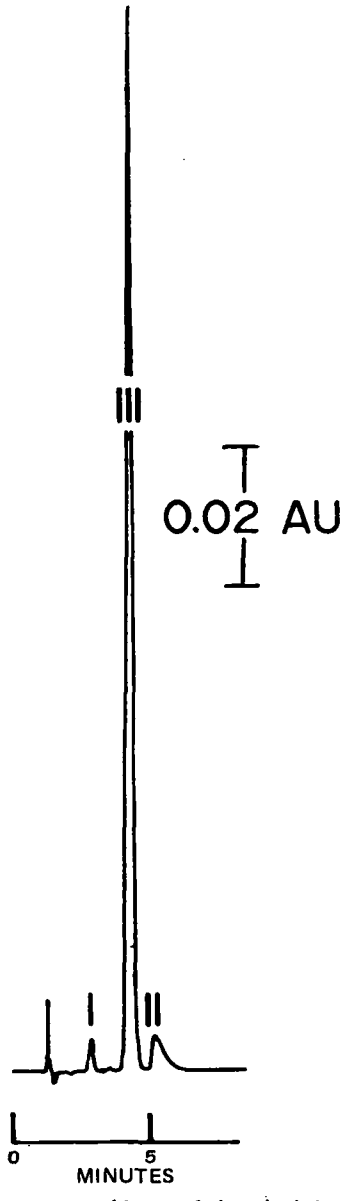

Figure 1—*Chromatogram of 0.8 μg of phenylephrine hydrochloride (I), 8 μg of phenylpropanolamine hydrochloride (II), and 36 μg of guaifenesin (III) with a C_{18} column packed in the lab. See text for chromatographic conditions.*

and an aqueous acetonitrile, acetic acid, heptanesulfonic acid salt ion-pair eluent to barely resolve I and II. Although the hydrophobic C_{18}-bonded phase has not been extensively used for this separation, the more polar phenyl bonded phase has been employed with a methanol, water, acetic acid, heptanesulfonic acid salt ion pair to yield a separation of I, II, and III with k' values of 1.2, 1.9, and 1.4, respectively (13); and to separate II and III at retention times of 15–18 min (14).

Another report (15) separated phenylephrine hydrochloride from other active compounds using a C_{18} column and an aqueous methanol and acetic acid eluent containing heptanesulfonic acid. Determinations involving guaifenesin on C_{18} columns have been characterized by the absence of an ion-pairing agent (16, 17). Phenylephrine hydrochloride and phenylpropanolamine hydrochloride were assayed (18) using a silica gel column with a methylene chloride, methanol, and aqueous ammonia eluent. The purpose of the present work was to improve the separation

Table I—Linearity Area Ratios

of I, II, and III with a reversed-phase column and ion pairing to yield a method with simplified sample handling (leaching followed by direct injection) and sufficient specificity for stability-indicating analysis.

The specificity requirement dictates knowledge of the known and expected degradation products of I, II, and III. However, II and III have been reported to be stable in dosage form (15, 19) and require extreme conditions for degradation: III can be hydrolyzed to guaiacol with hot

concentrated hydrochloric acid (16) and II can be oxidized to benzaldehyde with periodate (20). Analyte I, however, has been reported to readily undergo decomposition in aqueous buffer solutions at 85° to 1,2,3,4-tetrahydro-4,6 (and 4,8)-dihydroxy-2-methylisoquinoline and other minor products with *m*-hydroxybenzaldehyde as an intermediate (21).

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were ACS, USP, or NF quality and were used without further purification. Phenylephrine hydrochloride, phenylpropanolamine hydrochloride, and guaifenesin were used as received[1].

Apparatus—A high-performance liquid chromatograph[2] equipped with a reciprocating pump[3], an absorbance detector at 254 nm[4] (analytical wavelength), and an injector[5] with a 20-μl loop was used. The detector was monitored with a strip-chart recorder and integrator[6]. A variable-wavelength detector[7] set at 270 nm and a fixed-wavelength detector[4] at 280 nm were used for absorbance ratio studies.

Columns—The octadecylsilane columns used were packed[8] in the lab (25 cm × 4-mm i.d.) and commercially packed[8] (30 cm × 4-mm i.d.). The more polar octyl columns examined were a commercially packed column[9] (25 cm × 4.6-mm i.d.) and two columns packed in the lab (25 cm × 4.6-mm i.d. and 30 cm × 4.0-mm i.d.) of the same material[9]. Particle size was 10 μm in all cases.

Chromatographic Conditions—For the C_8 columns, the mobile phase consisted of 300 ml of methanol, 675 ml of water, and 25 ml of pentanesulfonic acid sodium salt in glacial acetic acid[10] to yield an eluent that was 5 m*M* in ion-pairing salt and 1.7% in acetic acid. For the C_{18} columns, the basic mobile phase was 350 ml of methanol, 625 ml of water, and 25 ml of pentanesulfonic acid sodium salt in glacial acetic acid[10]. The methanol concentration had to be adjusted to between 25 and 40% for the different C_{18} columns. Readjusting the eluent for different C_8 columns was not necesary. The flow rate was 2.0 ml/min in all cases.

Standard Solution Preparation—The final method (C_8 column) used a standard solution containing 0.04 mg/ml of I, 0.4 mg/ml of II, 1.8 mg/ml of III, and 0.4 mg/ml of 2,5-dihydroxybenzoic acid internal standard with water as solvent.

Sample Preparation—For the capsule and tablet samples, 1 g of the ground sample was leached with ~250 ml of water containing a controlled amount of 2,5-dihydroxybenzoic acid internal standard (~0.4 mg/ml). The sample was injected directly after a 10-min sonication and 5-min centrifugation at 2500 rpm. For the liquid samples, 4.0–25.0 ml (depending on label claim) was diluted to ~250 ml with water containing the internal standard. The sample was then injected directly.

Thermally Degraded Samples—One-gram samples of a well-mixed capsule material containing I, II, and III as active ingredients were

weighed into several 500-ml Erlenmeyer flasks. One flask was placed in the oven at 95° for 9 days. Twenty milliliters of 0.5 *M* HCl and 20 ml of 0.5 *M* NaOH were added to two other separate flasks, and both were stored at room temperature for 9 days. In addition, one container was stored in direct sunlight for 13 days, and one container containing sample and 20 ml of 0.5 *M* NaOH was stored at 90° for 3 days. At the end of the required time period, the acidic and basic solutions were neutralized, internal standard added, and all the samples assayed. The analyte and internal standard peaks were also examined for homogeneity by absorbance ratios at 254 and 270 nm, except for the sample stored in 0.5 *M* NaOH at 90°, which was examined at 254 and 280 nm. Analyte I was degraded by the literature method (21) by dissolving 100 mg of standard I in 50 ml of a pH 6.8, 0.04 *M* ammonium acetate buffer and storing the solution in a 95° oven for 13 days.

Calculations—Results for I, II, and III, were calculated from their integrated peak areas and the peak area of the internal standard using the appropriate dilution factors.

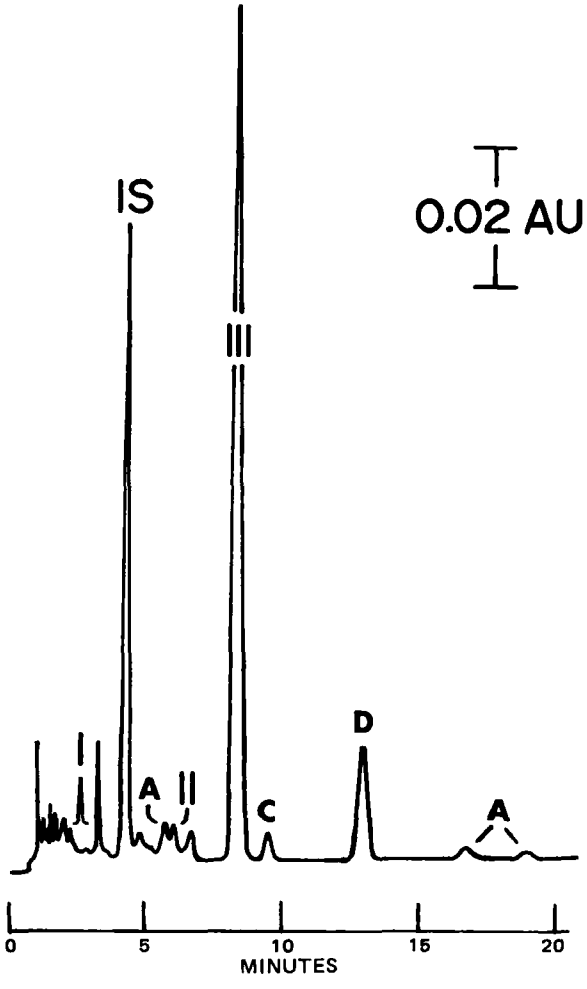

Figure 4—*Chromatogram of forced degraded (0.5 M NaOH at 90°) capsule sample: phenylpropanolamine hydrochloride (II); guaifenesin (III); 2,5-dihydroxybenzoic acid internal standard (IS): phenylephrine hydrochloride degradants (A); guaiacol (B); benzaldehyde (C). The peak for phenylephrine hydrochloride (I), which is totaly degraded, is drawn above the chromatogram.*

RESULTS AND DISCUSSION

Initial attempts to develop a reversed-phase simultaneous determination employed a C_{18} column with a methanol, water, and pentanesulfonic acid eluent yielded an assay that resolved I, II, and III from each other (Fig. 1). The chromatographic system lacked the retention and efficiency to meet the specificity requirement for guaiacol to be resolved from III. Additionally, relative retention appeared to change from column to column, often with packing from the same manufacturer. For example, II eluted after III with column packed in the lab and before III with a commercially packed column.

Exploratory experiments with a more polar octyl column were initiated and good results were obtained. The three analytes were well separated with k' values of 0.9, 2.4, and 3.7 for I, II, and III, respectively (Fig. 2). Identical chromatograms were obtained for a commercially packed column and several columns packed in the lab.

The linearity data for I, II, and III, determined by plotting peak area ratios *versus* standard weight ratios, are presented in Table I. Linearity was observed over the range studied: 0.5–1.5 μg for I; 4.8–14.4 μg for II; and 21–64 μg for III.

Assays of 11 synthetic capsule samples made by spiking placebo with solutions containing known amounts of standard I, II, and III at levels of 50–125% of theoretical yielded average recoveries and relative standard deviations of 100.9 ± 2.1%, 100.3 ± 1.3%, and 100.7 ± 0.8%, respectively.

A chromatogram of a solution containing 2.0 ml of the degraded standard solution of I (after 13 days at 95°), 20 mg of 2,5-dihydroxybenzoic acid, 2 mg of I, 20 mg of II, 89 mg of III, <5 mg of guaiacol (not completely soluble in water), 0.2 mg of *m*-hydroxybenzaldehyde, and <2 mg of benzaldehyde (not completely soluble in water) in 50 ml of water is shown in Fig. 3. All of the actual and postulated degradants were resolved. When the degraded standard solution of I was examined after only one day in the oven, a peak with the same retention time as *m*-hydroxybenzaldehyde was observed. This compound was postulated as an intermediate in a previous report (21), but was not observed.

Assay values for the thermally degraded capsule samples are listed in Table II. Except for the sample stored in 0.5 *M* NaOH at 90°, no extra peaks were noted and no significant degradation was observed. Examination of absorbance ratios indicated homogeneous peaks within experimental error.

A chromatogram (Fig. 4) of the sample solution stored in sodium hydroxide at 90° yielded several additional peaks and low assay values for I, II, and III, as shown in Table II. The difference in retention observed between Figs. 3 and 4 is caused by use of extensively used and freshly packed columns, respectively. Absorbance ratios (254/280 nm) and retention times of pure standards indicated peaks C and D, Fig. 4 were guaiacol and benzaldehyde, respectively. The internal standard and III peaks were also indicated to be homogeneous (II yielded no signal at 280 nm).

α-Aminopropiophenone, a precursor and possible trace impurity in II (23, 24), was found to elute immediately following the II peak. Although not quite baseline resolved, it could be detected down to at least 0.1% of the II concentration. It was not observed in any of the samples.

The assay results for several commercial dosage forms representing liquid, tablet, and capsule preparations are presented in Tables III and IV. None of the excipients in the formulations coeluted with the active ingredients or the internal standard.

The actives I, II, and III in the capsule sample were also determined spectrophotometrically. Analyte I was assayed colorimetrically by the

characteristic reaction of phenols with 4-aminoantipyrine described previously (25). The order of addition of reagents was altered to achieve acceptable precision. With these samples, it was necessary to add the bicarbonate buffer first. Analyte II in an aqueous solution of the sample was quantitatively oxidized to benzaldehyde with alkaline periodate by the procedure described previously (20). The benzaldehyde was then extracted from the solution with chloroform and determined spectrophotometrically. Guaifenesin was extracted from the samples with chloroform and determined by its UV absorbance. As the data in Table III indicate, the spectrophotometric assays are in good agreement with the HPLC assay presented here.

Kinetics and Mechanism of Degradation of Cefotaxime Sodium in Aqueous Solution

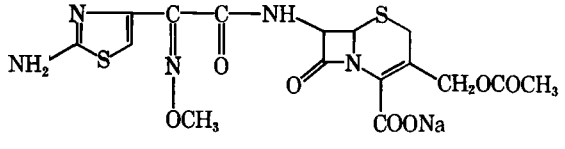
S. M. BERGE ˣ, N. L. HENDERSON, and M. J. FRANK

Received January 13, 1982, from the *Pharmaceutical Development Department, Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876.* Accepted for publication March 15, 1982.

Abstract □ The degradation kinetics and mechanism of a potent new cephalosporin, cefotaxime sodium, in aqueous solution were investigated at pH 0–10 at 25° and an ionic strength of 0.5. The degradation rates were determined by high-pressure liquid chromatography and were observed to follow pseudo first-order kinetics with respect to cefotaxime sodium concentration. The data suggested that the rate of degradation was influenced significantly by solvolytic, hydrogen ion, and hydroxide ion catalysis. No primary salt effects were observed in the acid or neutral regions; however, a positive salt effect was observed at pH 8.94. Buffer catalysis due to the buffer species employed was not seen during the kinetic studies. The pH–rate profile at 25° indicated that the maximum stability of cefotaxime sodium occurred in the pH 4.5–6.5 region. In aqueous solution, cefotaxime was shown to degrade by two parallel reactions: de-esterification at the C-3 position and β-lactam cleavage. Good agreement between the theoretical pH–rate profile and the experimental data support the proposed degradation process.

Keyphrases □ Kinetics—mechanism of degradation of cefotaxime sodium in aqueous solution □ Degradation—kinetics and mechanism, cefotaxime sodium in aqueous solution □ Cefotaxime sodium—kinetics and mechanism of degradation in aqueous solution □ Cephalosporins—cefotaxime sodium, kinetics and mechanism of degradation in aqueous solution

Cefotaxime sodium (I) is a potent new third generation cephalosporin possessing a broad spectrum of activity. Chemically, it is characterized by a 2-amino-4-thiazolyl ring which, in comparison to other cephalosporins, increases antibacterial activity against Gram-negative strains, and by an α-methoximino group which enhances



I

stability to β-lactamases (1–4). Compound I is active against Gram-positive and Gram-negative organisms, especially multiresistant strains, including many aminoglycoside-resistant strains. *In vitro*, its activity against Gram-negative organisms has been shown to be 10–200 times greater than that of the recently developed second generation cephalosporins (5).

The present report describes the stability kinetics of I in aqueous solution. The investigation was initiated to elucidate the mechanism by which I decomposes and to determine those kinetic parameters that will be of value in predicting the stability of the reconstituted antibiotic under a wide range of conditions.

EXPERIMENTAL

Materials—Cefotaxime sodium (I)[1] and desacetylcefotaxime (II)[2] were used without further purification. Desacetylcefotaxime lactone (III) was prepared using a modification of the method for cephalothin de-

Scheme I—Reaction pathways for the degradation of I in aqueous solution.

scribed previously (6). Buffers and all other chemicals were reagent grade.

Buffers—The buffers used in the kinetic studies were hydrochloric acid–potassium chloride (pH −0.10, 0.48, 1.15, and 2.23), citrate buffer (pH 2.83), acetate buffer (pH 3.93, 4.58, 5.07, and 5.52), phosphate buffer (pH 5.85, 6.51, 6.90, 7.57, and 7.93), borate buffer (pH 8.41, 8.93, and 9.06), and carbonate buffer (pH 9.89). The buffers were 0.1 *M* with respect to hydrochloric acid, citrate, acetate, phosphate, borate, and carbonate ions (except when a buffer effect was investigated), and they were adjusted to an ionic strength of 0.5 with potassium chloride, except when primary salt effects were studied. They were prepared by dissolving specific molar ratios of the buffer pair together with potassium chloride in water or by dissolving the acidic member of the buffer pair together with potassium chloride and adjusting the pH with 1.0 *N* NaOH. The pH of each solution was measured using a pH meter[3] equipped with a combination electrode[3].

Kinetic Procedure—Approximately 100 mg of I was accurately weighed and dissolved in 100 ml of the appropriate buffer to produce a solution having a concentration of 2.09×10^{-3} *M*. All buffers were preheated to the temperature of the study. The flasks were maintained at a constant temperature (±0.2°) in a thermostatically controlled water bath. Aliquots were withdrawn at desired time intervals, diluted, and immediately analyzed.

Analytical Procedure—Residual I was determined using a high-pressure liquid chromatographic (HPLC) method. The liquid chromatograph[4] was equipped with a variable wavelength UV detector[5] set at 235 nm; the separation was carried out using a 300 × 3.9-mm octadecylsilane column[6] with a methanol–phosphate buffer (pH 7.5) (12:88) mobile phase. The column pressure was 1700–1800 psi at a flow rate of 1.2–1.3 ml/min. Peak areas, which were calculated by a programmable integrator[7], were used to quantitate the amount of I remaining. Standard curves of the peak area of I *versus* concentration exhibited linear response in the working concentration range of 10–100 μg/ml. The sample peak areas were converted to concentrations by comparison with a standard curve which was obtained daily.

RESULTS AND DISCUSSION

Degradation Reactions, Reaction Order, and Observed Rate Constants—Compound I, a 3-acetoxymethylcephalosporin, has three possible sites at which degradation can occur: the amide side chain, the β-lactam ring, and the acetoxy ester group. Under conditions of pharmaceutical interest, the β-lactam ring opening and acetoxy hydrolysis predominate. The degradation reactions for I have been proposed and are shown in Scheme I. Such a scheme has been shown to be valid for other 3-acetoxymethylcephalosporins (6–10) and is supported by the experimental results observed in this study. Compound I undergoes two parallel reactions simultaneously: β-lactam ring opening (k_1) and deesterification at the C-3 position (k_2). At pH values <4, II can undergo an internal ring closure (k_4) to form III. Both II and III are susceptible to β-lactam hydrolysis (k_3,k_5). Figure 1 shows typical chromatograms

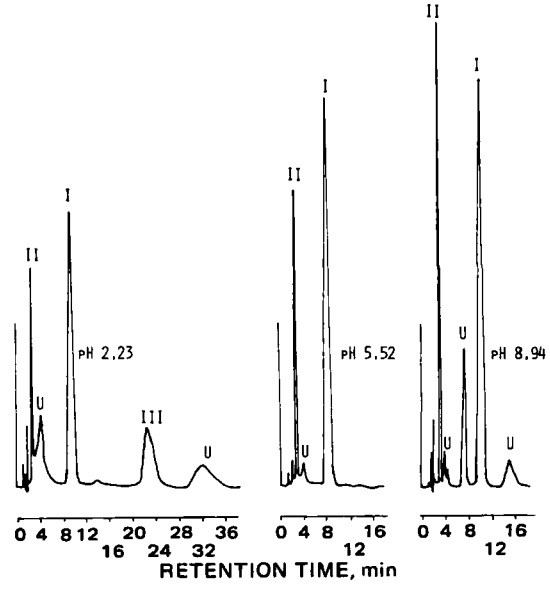

Figure 1—*High-pressure liquid chromatographs of 40–70% degraded I at 25°, μ = 0.5, and several pH values. Key: (I) cefotaxime; (II) desacetylcefotaxime; (III) desacetylcefotaxime lactone; (U) unknown peak.*

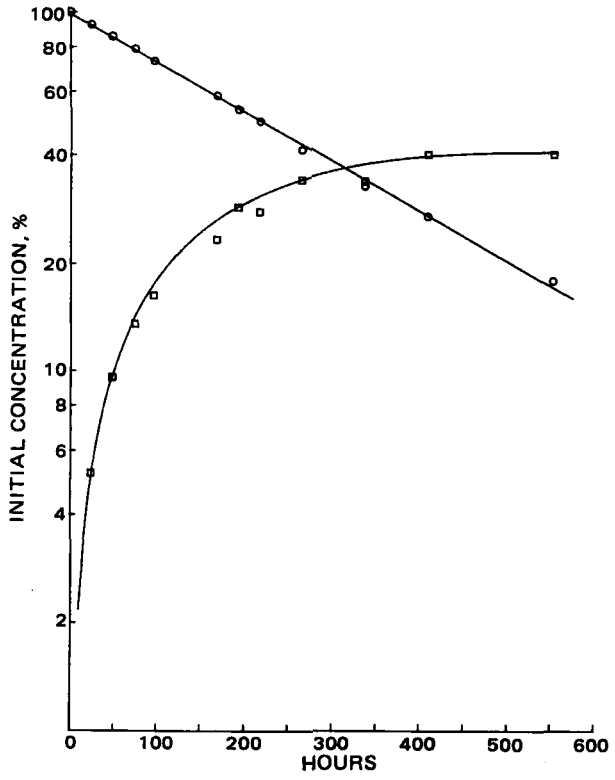

Figure 2—*Time courses for I (○) and II (□) during the degradation of I at pH 5.52, 25°, and μ = 0.5.*

of acidic (pH 2.23), neutral (pH 5.52), and basic (pH 8.94) reaction mixtures of I, which illustrate the formation of the degradation products described in Scheme I. The de-esterification reaction (k_2) occurs more rapidly, being ~1.8 times faster than the β-lactam ring opening (k_1) at pH 5.52. Figure 2 illustrates the kinetics of the disappearance of I and the formation of II at pH 5.52. The observed rate constants, k_{obs}, determined in this study are actually the sum of k_1 and k_2.

The degradation of I followed pseudo first-order kinetics at constant pH, temperature, and ionic strength over the pH range studied. This first-order dependence on the concentration of I is illustrated in Fig. 3, which shows that at pH 5.52, the log concentration *versus* time plots are

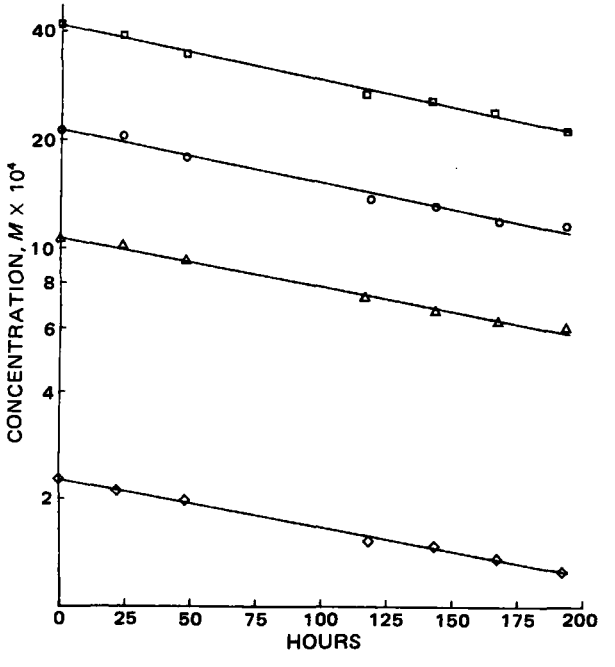

Figure 3—*Plots illustrating first-order dependence on the concentration of I at pH 5.52, 25°, and μ = 0.5. Key: (□) 2.0 mg/ml; (○) 1.0 mg/ml; (△) 0.5 mg/ml; (◇) 0.1 mg/ml.*

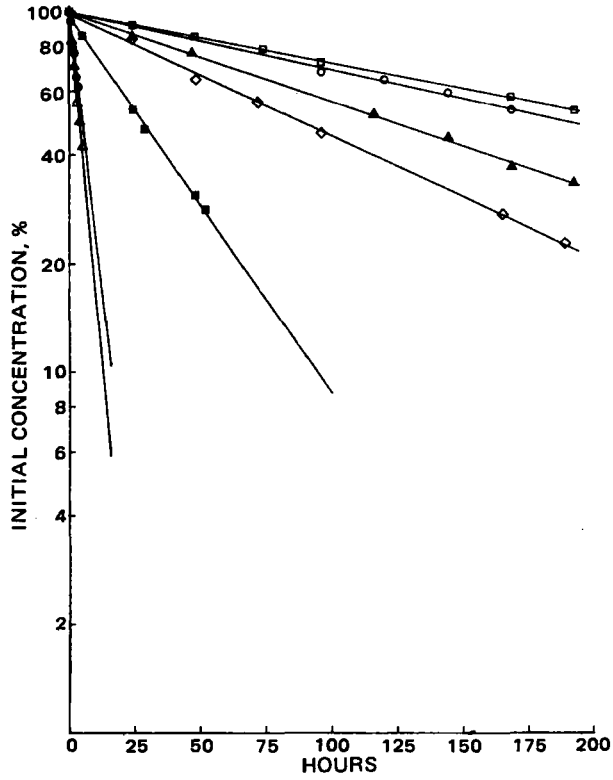

Figure 4—*Observed pseudo first-order plots for the degradation of I at various pH values, 25°, and μ = 0.5. Key: (□) pH 5.52; (○) pH 3.93; (▲) pH 7.93; (◇) pH 2.23; (■) pH 8.94; (●) pH 0.48; (△) pH 9.89.*

linear and parallel over a 20-fold concentration range (2.09×10^{-4}–4.19×10^{-3} *M*). Similar results were observed at pH 2.23 and 8.94. Further evidence of first-order kinetics is that semilogarithmic plots of the percent residual I *versus* time are linear over the pH range studied as shown in Fig. 4. The observed rate constants and the buffer systems employed are listed in Table I.

Catalytic Effect of Buffer Systems—The catalytic effect of the buffer systems used in the kinetic studies was determined at constant pH, temperature, ionic strength (μ = 0.5), and drug concentration, with only the buffer concentration varying (0.05–0.2 *M*). This experiment was done at several pH values within the effective range for each buffer employed. No appreciable effect on the degradation of I was observed for any of the buffer species used in the study.

Primary Salt Effect—The primary salt effect on the hydrolysis of

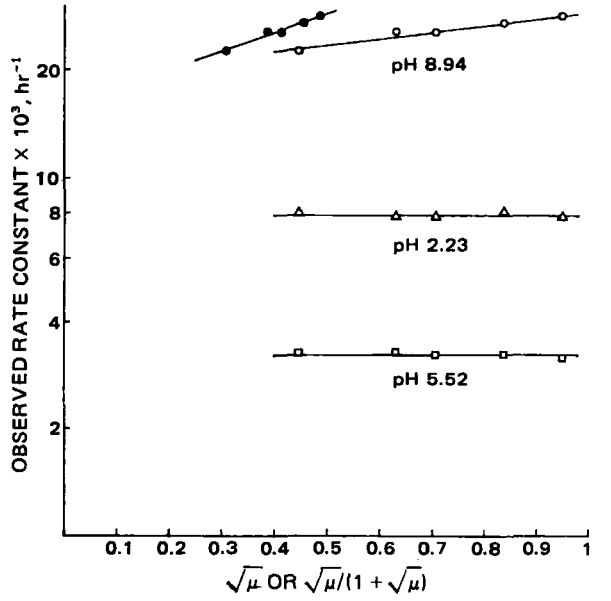

Figure 5—*Plots of log* k_{obs} versus $\sqrt{\mu}$ (○, △, and □) or $\sqrt{\mu}/(1+\sqrt{\mu})$ (●) *for the degradation of I at several pH values and 25°.*

Table II—Effect of Ionic Strength on Pseudo First-Order Rate Constants for the Degradation of I at pH 2.23, 5.52, and 8.94

Ionic Strength	k_{obs}, $hr^{-1} \times 10^3$		
	pH 2.23	pH 5.52	pH 8.94
0.2	7.99	3.28	22.6
0.4	7.82	3.30	25.6
0.5	7.82	3.24	25.5
0.7	8.07	3.25	27.1
0.9	7.79	3.17	28.3

I was studied at constant pH, temperature, and drug concentration, but the ionic strength was varied by potassium chloride addition. Studies were conducted at pH 2.23, 5.52, and 8.94 for ionic strength values ranging from 0.2 to 0.9. The data at these pH values and differing ionic strengths are given in Table II.

Within limits of the Debye-Huckel expressions, plots of k_{obs} *versus* $\sqrt{\mu}$ or $\sqrt{\mu}/(1+\sqrt{\mu})$ should yield slopes theoretically equal to $2AZ_AZ_B$, where A is a constant for the solvent at a given temperature ($A = 0.509$ at 25°, water) and Z_A and Z_B are the charges on reaction species A and B, respectively (11). Plots of k_{obs} *versus* $\sqrt{\mu}/(1+\sqrt{\mu})$ are perhaps preferred in that it has been pointed out that the use of $\sqrt{\mu}/(1+\sqrt{\mu})$ instead of $\sqrt{\mu}$ at higher ionic strengths more frequently produces values of $2AZ_AZ_B$ that are in agreement with the predicted values (12).

Figure 5 is a plot of the log k_{obs} *versus* $\sqrt{\mu}$ and $\sqrt{\mu}/(1+\sqrt{\mu})$ from the data in Table II. No kinetic salt effects were observed at pH 2.23 or 5.52, indicating that at least one of the reacting molecules is uncharged, while at pH 8.94 plots of $\sqrt{\mu}$ and $\sqrt{\mu}/(1+\sqrt{\mu})$ give positive slopes of +0.19 and +0.52, respectively. This result can be used as evidence that two negatively charged ions are reacting.

pH–Rate Profile—The pH dependence of the overall first-order rate constant for the degradation of I at 25° and an ionic strength of 0.5 is shown in Fig. 6. The pH–rate profile exhibits a U-shape which is typical of cephalosporins without an α-amino group in the C-7 side chain (7–9). This type of curve is characteristic of reactions that are susceptible to specific acid–base catalysis and that obey the general rate law:

$$k_{obs} = k_H a_{H^+} + k_w + k_{OH}[OH^-] \qquad \text{(Eq. 1)}$$

where k_H and k_{OH} are the second-order rate constants for the hydrogen ion-catalyzed degradation and hydroxide ion-catalyzed degradation, respectively; k_w is the first-order rate constant of spontaneous or water catalyzed degradation; a_{H^+} is the activity of hydrogen ion as measured by the glass electrode; and $[OH^-]$ is the hydroxide ion concentration.

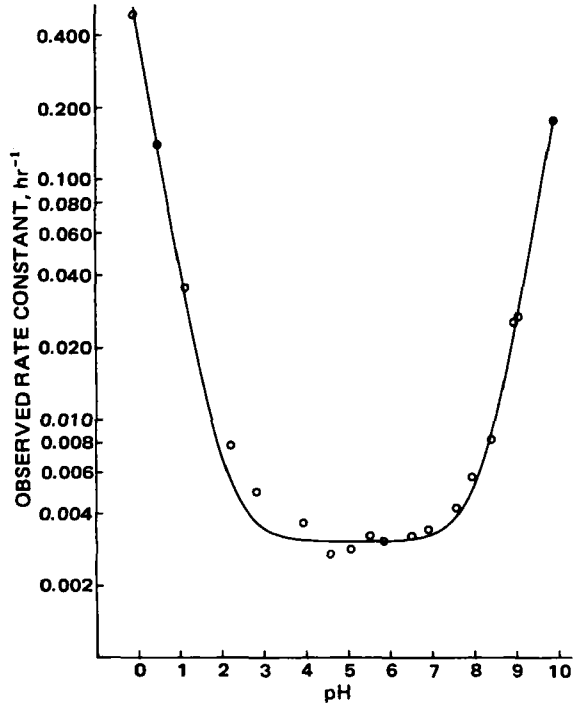

Figure 6—*Log k_{obs}–pH profile for the degradation of I in aqueous solution at 25° and $\mu = 0.5$. The points are experimental values, and the solid line is the theoretical curve calculated from Eq. 1.*

Table III—Effect of Temperature on the Degradation of I in Buffer Solutions at $\mu = 0.5$

pH	Temperature	k_{obs}, $hr^{-1} \times 10^3$	E_a, kcal/mole	log A, hr^{-1}	$k_{25°}$, $hr^{-1} \times 10^3$ (theoretical)	$k_{25°}$, $hr^{-1} \times 10^3$ (observed)
2.23	35	24.0	21.1	13.4	7.46	7.82
	45	71.2				
	55	196.7				
5.52	35	13.2	24.7	15.6	3.30	3.24
	45	44.7				
	55	154.2				
8.94	35	87.2	9.4[a]	15.2	24.50	25.50
	45	279.8				
	55	851.4				

[a] The calculated energy of activation E_a, was 22.9 kcal/mole, but this value includes the heat of ionization of water, which at 25° equals 13.5 kcal/mole (13).

Estimates of k_H, k_w, and k_{OH} were obtained from a simultaneous solution of k_{obs} (Eq. 1) at pH 0.48, 5.85, and 9.89. The hydroxide ion concentration was calculated according to:

$$[OH^-] = K_{w(exp)}/a_{H^+}\gamma\pm \qquad \text{(Eq. 2)}$$

where $K_{w(exp)} = 1.008 \times 10^{-14}$ and $\gamma\pm$ is the mean ionic activity coefficient product of water which is equal to 0.73, both at 25° and $\mu = 0.5$ (13). The resulting rate constants were $k_H = 0.4137\ M^{-1}\ hr^{-1}$, $k_w = 3.064 \times 10^{-3}\ hr^{-1}$ and $k_{OH} = 1616.5\ M^{-1}\ hr^{-1}$. The theoretical profile generated using these constants adequately describes the behavior of I and can be interpreted kinetically as follows:

Acid catalysis is important <pH 4 and base catalysis occurs >pH 8. The linear portions of the curve >pH 1.2 and 8.9 have slopes of −0.92 and +0.92, respectively, indicating that specific acid and specific base catalysis is occurring in these pH regions. The horizontal portion between pH 4 and 7 is pH independent, suggesting that the predominating reaction is the attack of water on the ionized species of I. The positive deviation in the pH 2–4 range can be postulated as being due to an intramolecular general acid catalysis of the carboxyl group on the deacetylation reaction. Such an explanation is logical in view of the facts that the pKa of I at 25° is 3.4[8] and that the drug concentration is significant in relation to the

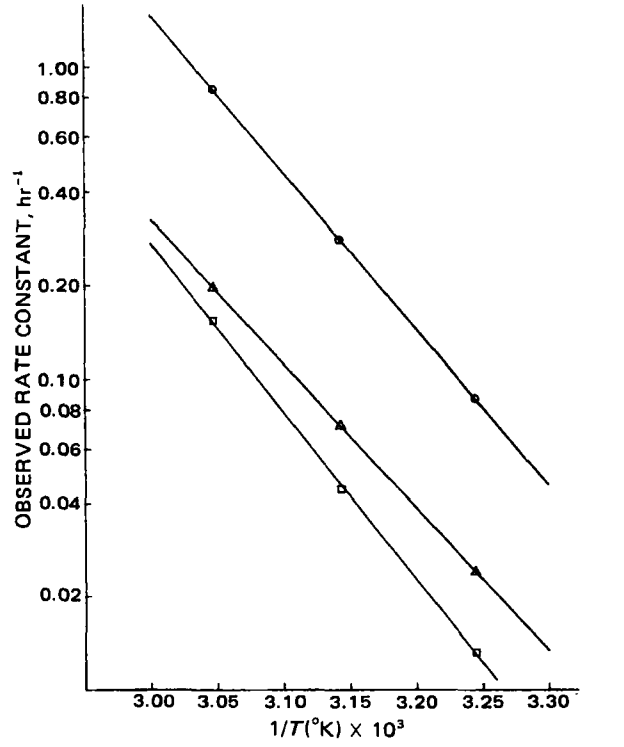

Figure 7—*Arrhenius plots for the degradation of I at several pH values and $\mu = 0.5$. Key: (△) pH 2.23; (□) pH 5.52; (○) pH 8.94.*

[8] Personal communication.

hydrogen ion concentration in this pH region. Ionic strength effects support this interpretation.

The theoretical pH minimum for the degradation of I obtained by taking the derivative of Eq. 1 and equating it to zero was pH 5.13.

Temperature Dependency—The dependence of degradation of I on temperature was determined by measuring the rate of decomposition at 35, 45, and 55° at pH 2.23, 5.52, and 8.94 and ionic strength is 0.5. The values of k_{obs}, E_a, and log A are given in Table III, and the corresponding Arrhenius plots are shown in Fig. 7. The theoretical $k_{25°}$ calculated using the energy of E_a, activation was in good agreement with the experimentally determined $k_{25°}$ at each of the three pH values, indicating that the data can be used to predict the stability of I over a wide range of pH and temperature conditions.

Synthesis and Biological Activity of an Amino Analogue of a Tripeptide Inhibitor of Angiotensin-Converting Enzyme

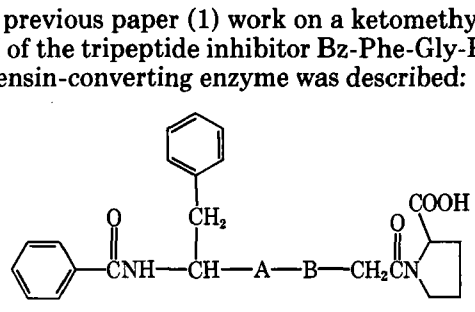
RONALD G. ALMQUIST ˣ, PAMELA H. CHRISTIE, WAN-RU CHAO, and HOWARD L. JOHNSON

Received September 8, 1980, from the *Bio-Organic Chemistry Laboratory, SRI International, Menlo Park, CA 94025.* Accepted for publication February 25, 1982.

Abstract □ An amino analogue of *N*-benzoyl-phenylalanyl-glycyl-proline, a tripeptide inhibitor of angiotensin-converting enzyme, was synthesized. The analogue (III) has the phenylalanyl-glycine amide linkage of *N*-benzoyl-phenylalanyl-glycyl-proline reduced to a methylene amine. Compound III was tested as an inhibitor of porcine plasma angiotensin-converting enzyme and has an I_{50} of 620 μM compared with an I_{50} of 9.6 μM for its parent tripeptide. These results are explained in terms of a proposed model of the converting-enzyme active site.

Keyphrases □ Angiotensin-converting enzyme—synthesis and biological activity of an amino analogue of *N*-benzoyl-phenylalanyl-glycyl-proline, a tripeptide inhibitor □ *N*-Benzoyl-phenylalanyl-glycyl-proline—tripeptide inhibitor of angiotensin-converting enzyme, synthesis and biological activity of an amino analogue

In a previous paper (1) work on a ketomethylene analogue I of the tripeptide inhibitor Bz-Phe-Gly-Pro (II) of angiotensin-converting enzyme was described:



I: A = CO, B = CH_2
II: A = CO, B = NH
III: A = CH_2, B = NH

The replacement of the peptide amide linkage in II with a ketomethylene group was designed to stabilize this portion of the peptide molecule to peptidase cleavage. This substitution yielded a peptide analogue (I) with >100 times the inhibition activity against angiotensin-converting enzyme of the parent peptide.

A second approach to stabilizing this same peptide amide linkage in II to peptidase cleavage would be to reduce it to the corresponding methyleneamino compound (III). This compound has been synthesized and its inhibition activity against angiotensin-converting enzyme will be discussed.

BACKGROUND

A method for the synthesis of III was desired which would maintain the same stereochemistry around the optical centers as that found in the tripeptide (II). Initially, numerous attempts were made to selectively reduce the amide, but not the ester, group of *N*-benzyloxycarbonyl-phenylalanyl-glycine ethyl ester with borane, as reported previously (2), with *N*-benzyloxycarbonyl-glycyl-leucine methyl ester as the starting material. In contrast to those results the ester group of *N*-benzyloxycarbonyl-phenylalanyl-glycine ethyl ester was reduced more rapidly than the amide group by borane.

Because selective reduction of the desired amide functionality did not seem possible in this case, the dipeptide acid *N*-benzyloxycarbonyl-phenylalanyl-glycine (IV) was used as a starting material for the synthesis of III (Scheme I). The 9-fluorenyl-methoxycarbonyl amino blocking group (3) was used because of its stability to acidic conditions such as the Jones oxidation (4).

The low yield obtained for the transformation of VI to VIII was

0022-3549/83/0100-0063$01.00/0

hydrogen ion concentration in this pH region. Ionic strength effects support this interpretation.

The theoretical pH minimum for the degradation of I obtained by taking the derivative of Eq. 1 and equating it to zero was pH 5.13.

Temperature Dependency—The dependence of degradation of I on temperature was determined by measuring the rate of decomposition at 35, 45, and 55° at pH 2.23, 5.52, and 8.94 and ionic strength is 0.5. The values of k_{obs}, E_a, and log A are given in Table III, and the corresponding Arrhenius plots are shown in Fig. 7. The theoretical $k_{25°}$ calculated using the energy of E_a, activation was in good agreement with the experimentally determined $k_{25°}$ at each of the three pH values, indicating that the data can be used to predict the stability of I over a wide range of pH and temperature conditions.

Synthesis and Biological Activity of an Amino Analogue of a Tripeptide Inhibitor of Angiotensin-Converting Enzyme

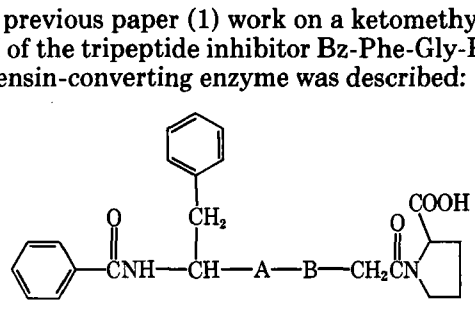
RONALD G. ALMQUIST ˣ, PAMELA H. CHRISTIE, WAN-RU CHAO, and HOWARD L. JOHNSON

Received September 8, 1980, from the *Bio-Organic Chemistry Laboratory, SRI International, Menlo Park, CA 94025.* Accepted for publication February 25, 1982.

Abstract □ An amino analogue of *N*-benzoyl-phenylalanyl-glycyl-proline, a tripeptide inhibitor of angiotensin-converting enzyme, was synthesized. The analogue (III) has the phenylalanyl-glycine amide linkage of *N*-benzoyl-phenylalanyl-glycyl-proline reduced to a methylene amine. Compound III was tested as an inhibitor of porcine plasma angiotensin-converting enzyme and has an I_{50} of 620 μM compared with an I_{50} of 9.6 μM for its parent tripeptide. These results are explained in terms of a proposed model of the converting-enzyme active site.

Keyphrases □ Angiotensin-converting enzyme—synthesis and biological activity of an amino analogue of *N*-benzoyl-phenylalanyl-glycyl-proline, a tripeptide inhibitor □ *N*-Benzoyl-phenylalanyl-glycyl-proline—tripeptide inhibitor of angiotensin-converting enzyme, synthesis and biological activity of an amino analogue

In a previous paper (1) work on a ketomethylene analogue I of the tripeptide inhibitor Bz-Phe-Gly-Pro (II) of angiotensin-converting enzyme was described:



I: A = CO, B = CH_2
II: A = CO, B = NH
III: A = CH_2, B = NH

The replacement of the peptide amide linkage in II with a ketomethylene group was designed to stabilize this portion of the peptide molecule to peptidase cleavage. This substitution yielded a peptide analogue (I) with >100 times the inhibition activity against angiotensin-converting enzyme of the parent peptide.

A second approach to stabilizing this same peptide amide linkage in II to peptidase cleavage would be to reduce it to the corresponding methyleneamino compound (III). This compound has been synthesized and its inhibition activity against angiotensin-converting enzyme will be discussed.

BACKGROUND

A method for the synthesis of III was desired which would maintain the same stereochemistry around the optical centers as that found in the tripeptide (II). Initially, numerous attempts were made to selectively reduce the amide, but not the ester, group of *N*-benzyloxycarbonyl-phenylalanyl-glycine ethyl ester with borane, as reported previously (2), with *N*-benzyloxycarbonyl-glycyl-leucine methyl ester as the starting material. In contrast to those results the ester group of *N*-benzyloxycarbonyl-phenylalanyl-glycine ethyl ester was reduced more rapidly than the amide group by borane.

Because selective reduction of the desired amide functionality did not seem possible in this case, the dipeptide acid *N*-benzyloxycarbonyl-phenylalanyl-glycine (IV) was used as a starting material for the synthesis of III (Scheme I). The 9-fluorenyl-methoxycarbonyl amino blocking group (3) was used because of its stability to acidic conditions such as the Jones oxidation (4).

The low yield obtained for the transformation of VI to VIII was

probably due to partial removal of the 9-fluorenylmethoxycarbonyl group during the hydrogenolysis step (5).

RESULTS AND DISCUSSION

The results of testing some of the compounds for inhibition of angiotensin-converting enzyme are shown in Table I. The amino analog (III) has 1/66th the inhibition activity of its parent tripeptide (II) but is about four times more active than the *N*-acetyl derivative (XII). Kinetic studies on III (Figs. 1 and 2) show it to be a competitive inhibitor of converting enzyme with either hippuryl-histidyl-leucine or angiotensin I as substrates.

The low activity of III is interesting in light of its structural similarities to the potent inhibitors (Table II) reported previously (6). Table II shows structure–activity data for some of these compounds that exhibit inhibition of the angiotensin-converting enzyme. One noteworthy conclusion from this table is that a phenethyl group in the R_1 position (*i.e.*, compound XV) yielded a more potent inhibitor than that obtained with other alkyl R_1 substituents. In previous studies on peptides (7) and tripeptide inhibitors (1), optimum activity was also obtained when the inhibitor contained an aromatic group (*i.e.*, compound II) that was the same distance from the carboxylic acid group of proline as was the phenyl group in XV. It was also found that an aromatic acyl group at the amino terminus yielded a more active inhibitor than tripeptides with either a nonaromatic or no acyl group in this position (1). Therefore, there appear to be binding points within the converting enzyme active site for groups located at the amino terminal portion of III.

Examination of the hypothetical active site of the angiotensin-converting enzyme (Fig. 3) proposed previously (8) might explain the low activity of III. One important binding functionality that all the known potent inhibitors and substrates of the angiotensin-converting enzyme have in common is a functionality that is positioned properly to interact with the enzyme-bound zinc ion. Such functionalities vary from a carbonyl (as in II) or a carboxylic acid (as in XIII–XV) to a thiol (as in captopril). The amino group in III must not be positioned properly to fulfill the role of a zinc-binding functionality. The low enzyme-inhibition activity of III exemplifies the major importance of the zinc interaction for good enzyme inhibition.

EXPERIMENTAL[1]

***N*-(2*S*-2-Benzyloxycarbonylamino-3-phenylpropyl)aminoethanol (V)**—To an ice-cold solution of *N*-benzyloxycarbonyl-L-phenylalanyl-glycine (5) (IV, 700 mg, 1.96 mmoles) in 8 ml of dry (lithium aluminum hydride-distilled) tetrahydrofuran was added 8.50 ml (8.50 mmoles) of 1 *M* borane under a nitrogen atmosphere. The solution was refluxed for 1 hr, then cooled in ice and treated dropwise with 0.5 *N* ethanolic HCl to pH 4. The mixture was stirred at room temperature for 2 hr, then cooled in ice, and filtered to give 408 mg (56% yield) of the hydrochloride as a white solid, mp 183–184°.

[1] Melting points were determined on a Thomas-Hoover Uni-melt and are uncorrected. Optical rotations were measured using a Perkin-Elmer 141 automatic polarimeter. Mass spectra were taken on an LKB 9000 GC–MS spectrometer. The ^{1}H-NMR spectra were taken on a Varian EM390 spectrometer. TLC was carried out on Uniplates from Analtech coated with 250 μm of silica gel GF. Evaporations were performed at 40° under house vacuum on a Buchi Rotavapor unless otherwise stated. Elemental analyses were conducted by Mr. Eric Meier, Stanford University, Stanford, California. Preparative high-pressure liquid chromatography (HPLC) was performed using the Waters Prep LC/System 500 and silica gel cartridges. The existence of solvents of crystallization was confirmed by ^{1}H-NMR whenever possible. Many of the compounds in this series had a strong tendency to trap solvents within their solid structure. Heating these compounds at 60–100° under 0.1-mm Hg vacuum for 24 hr would not completely remove the last traces of solvent. Continued heating under vacuum beyond this point began to decompose the compounds. All of these compounds were homogeneous by TLC and had spectra (mass spectra and/or ^{1}H-NMR) characteristics of the desired compounds. Elemental analyses have, therefore, been reported with solvents of crystallization.

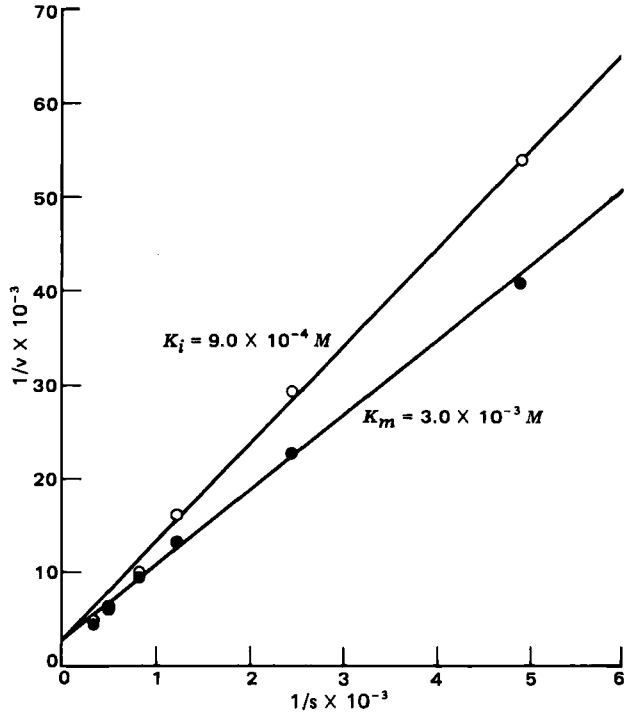

Figure 1—*Double-reciprocal plots of the effect of compound III as an inhibitor of porcine plasma angiotensin-converting emzyme with hippuryl-histidyl-leucine as substrate. Key: (●) no inhibitor; (○) with compound III at a concentration of 0.33 m*M. *Lines were drawn by the method of least squares.*

The hydrochloride was mixed with water (20 ml) and chloroform (20 ml). The aqueous layer was adjusted to pH 11 with 1 *N* NaOH while stirring vigorously. The chloroform layer was separated and the aqueous phase was extracted twice with chloroform (2 × 20 ml). The combined chloroform extracts were dried with calcium sulfate and evaporated to dryness to give 298 mg (46%) of the free base as a white solid, mp 93–95°; IR (mineral oil): 3300 and 3250 (amide NH), 1695 (CO), 1550 (amide CNH).

Anal.—Calc. for $C_{19}H_{24}N_2O_3$: C, 69.49; H, 7.37; N, 8.53. Found: C, 69.16; H, 7.26; N, 8.70.

***N*-(2*S* - 2-Benzyloxycarbonylamino-3-phenylpropyl) - *N* - (9-fluorenylmethyloxy-carbonyl)aminoethanol (VI)**—To an ice-cold solution of V (1.68 g, 5.12 mmoles) in 49 ml of 4Å sieve-dried acetone was added sodium bicarbonate (2.24 g, 26.7 mmoles) followed dropwise by a solution of 9-fluorenylmethyl chloroformate (1.98 g, 7.63 mmoles) in 5 ml of dry acetone. The mixture was stirred at 0° for 5 hr, then at room temperature for 1.5 hr, and finally stored at 4° for 64 hr.

The solid was removed by filtration. The filtrate was treated with methanol (20 ml) and evaporated to dryness. The residue was redissolved in methanol (20 ml) and again evaporated to dryness. This oil was dissolved in 20 ml of 50% ether in chloroform and added dropwise with rapid stirring to 400 ml of petroleum ether (bp 30–60°). The mixture was cooled at 4° for 20 hr. The solvent was decanted and the residual oil was dissolved in chloroform (50 ml), washed twice with water (2 × 50 ml), dried with calcium sulfate, and evaporated to dryness to give 2.54 g of a foam. This was chromatographed on silica gel preparative plates with 2% methanol in chloroform. The UV absorbing band at R_f 0.40 was extracted with 20% methanol in chloroform to give 2.07 g (73% yield) of VI as a foam; ^{1}H-NMR ($CDCl_3$): δ 4.90 (2 H, s, benzyloxy CH_2), 7.13 (18 H, m, aromatic).

Anal.—Calc. for $C_{34}H_{34}N_2O_5 \cdot 0.40\ CHCl_3$: C, 69.05; H, 5.79; N, 4.68. Found: C, 69.13; H, 6.04; N, 4.41. Subsequent larger runs were purified by HPLC with 20% ethyl acetate in chloroform.

***N*-(2*S*-2-Benzamido-3-phenylpropyl)-*N*-(9-fluorenylmethyloxy-carbonyl)aminoethanol (VIII)**—A solution of VI (3.09 g, 5.62 mmoles) in 300 ml of glacial acetic acid was hydrogenated at atmospheric pressure with 2.90 g of 10% palladium-on-carbon for 2 hr. The mixture was filtered through diatomaceous earth. The filtrate was evaporated to dryness to give the crude amine (VII) as an oil (2.65 g).

Sodium bicarbonate (1.13 g, 13.5 mmoles) was added to an ice-cold solution of the amine in 360 ml of 4Å sieve-dried dichloromethane fol-

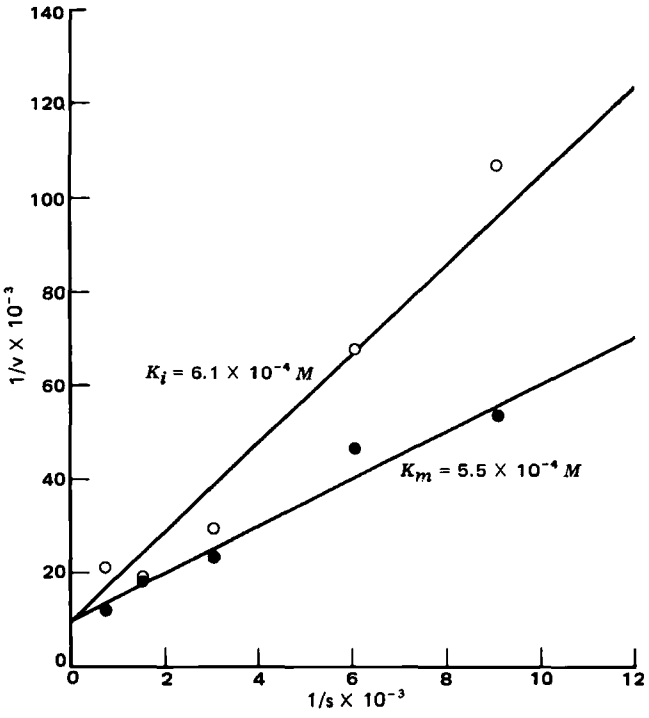

Figure 2—*Double-reciprocal plots of the effect of III as an inhibitor of porcine plasma angiotensin-converting enzyme with angiotensin I as substrate. Key: (●) no inhibitor; (○) with compound III at a concentration of 0.66 mM. Lines were drawn by the method of least squares.*

lowed dropwise by benzoyl chloride (0.785 ml, 6.74 mmoles). The mixture was stirred at room temperature for 18 hr. Another 0.523 ml of benzoyl chloride was added and stirring was continued for an additional 3 hr.

The solid was removed by filtration. The filtrate was treated with methanol (50 ml) and evaporated to dryness. The residue was redissolved in methanol (50 ml) and again evaporated to dryness. This oil was dissolved in 10 ml of chloroform and added dropwise with rapid stirring to 500 ml of petroleum ether (bp 30–60°). The mixture was cooled at 4° for 64 hr. The solvent was decanted and the residual oil was dissolved in chloroform (50 ml), washed with 0.2 *N* HCl (2 × 50 ml), saturated sodium bicarbonate solution (50 ml), and water (50 ml). The chloroform extract was dried with calcium sulfate and evaporated to dryness to give 2.06 g of a foam. This was purified by preparative HPLC using 1:1 chloroform–ethyl acetate, which afforded 1.05 g of VIII (36% yield from VI) as a white solid foam; R_f 0.5 (1:1 chloroform–ethyl acetate): mass spectrum 593 (M^+ + trimethylsilyl + H).

Anal.—Calc. for $C_{33}H_{32}N_2O_4 \cdot 0.10\ CHCl_3$: C, 74.65; H, 6.08; N, 5.26. Found: C, 74.50; H, 6.44; N, 5.16.

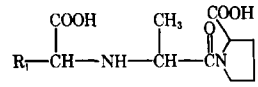
***N*-(2*S*-2-Benzamido-3-phenylpropyl)-*N*-(9-fluorenylmethyloxycarbonyl)aminoacetic Acid (IX)**—To an ice-cold solution of compound VIII (1.01 g, 1.94 mmoles) in 38 ml of acetone was added dropwise a solution of chromium trioxide (457 mg, 4.57 mmoles) in 9.7 ml of 35% H_2SO_4. The reaction was stirred at room temperature for 1 hr and then added to 200 ml of water and extracted with chloroform (3 × 100 ml). The chloroform extracts were washed with water (100 ml), dried with sodium sulfate, and evaporated to dryness to give compound IX as a foam (1.07 g), which was used directly in the next step.

An analytical sample was obtained in an earlier, small-scale run by crystallization from chloroform–ether following chromatography on a preparative silica gel plate with 10% methanol in chloroform. The tan solid softened at 139–142° and melted at 167–171°; R_f 0.4 (10% methanol chloroform): mass spectrum 606 (M^+ + trimethylsilyl).

Anal.—Calc. for $C_{33}H_{30}N_2O_5 \cdot 0.25\ CHCl_3$: C, 70.22; H, 5.40; N, 4.96. Found: C, 70.06; H, 5.37; N, 4.98.

***N*-[*N*-(2*S*-2-Benzamido-3-phenylpropyl)-*N*-(9-fluorenylmethyloxycarbonyl)aminoacetyl]-L-proline Benzyl Ester (X)**—To a stirred ice-cold solution of compound IX (1.07 g, 2.01 mmoles), L-proline benzyl ester hydrochloride (0.485 g, 2.01 mmoles), 1-hydroxybenzotriazole (0.300 g, 2.01 mmoles), and triethylamine (0.280 ml, 2.01 mmoles, distilled from phthalic anhydride) in 34 ml of 4Å sieve-dried dichloromethane was added a solution of dicyclohexylcarbodiimide (0.415 g, 2.01 mmoles) in 10 ml of dry dichloromethane. The mixture was stirred at 5° for 0.5 hr, then at room temperature for 45 hr.

Table II—Inhibition of Porcine Plasma Angiotensin Converting Enzyme



R_1	Compound	I_{50} (μM)[a]
H	XIII	2.4 (36)
CH_3	XIV	0.09 (1.3)
$-(CH_2)_2C_6H_5$	XV	0.0038 (0.057)
	Captopril	0.02 (0.30)

[a] Concentration required for 50% enzyme inhibition (1, 6). The numbers in parentheses are relative to a captopril I_{50} of 0.30 μM as reported in Table I.

The reaction mixture was cooled and filtered. The filtrate was washed with ice-cold 2 *N* HCl (25 ml), 0.3 *N* NaOH (25 ml), and water (25 ml), then dried with calcium sulfate and evaporated to dryness. The light yellow solid foam was purified by preparative HPLC with chloroform as solvent. The yield of white solid foam X was 1.06 g (73%); ^{1}H-NMR ($CDCl_3$): 7.00–7.85 (23 H, m, aromatic), 1.85 (4 H, m, proline CH_2, s); R_f 0.30 (chloroform).

Anal.—Calc. for $C_{45}H_{43}N_3O_6 \cdot 0.20\ CHCl_3$: C, 72.48; H, 5.84; N, 5.63. Found: C, 72.81; H, 5.82; N, 5.60.

***N*-[*N*-(2*S*-2-Benzamido-3-phenylpropyl)-*N*-(9-fluorenylmethyloxycarbonyl)aminoacetyl]-L-proline (XI)**—A solution of X (1.01 g, 1.40 mmoles) in 100 ml of glacial acetic acid was hydrogenated at atmospheric pressure with 1 g of 10% palladium on carbon for 2 hr. The reaction was filtered through diatomaceous earth and evaporated to dryness to give 0.900 g of crude compound XI as a gum. A white solid (mp 151–152°) analytical sample of compound XI was obtained by chromatography on a silica gel preparative plate with 7% methanol in chloroform followed by crystallization from chloroform–ether; ^{1}H-NMR ($CDCl_3$): 7.00–7.85 (18 H, m, aromatic), 1.95 (4 H, m, proline CH_2, s); R_f 0.2 (7% methanol in chloroform).

Anal.—Calc. for $C_{38}H_{37}N_3O_6 \cdot 0.60\ CHCl_3$: C, 65.92; H, 5.39; N, 5.97. Found: C, 65.52; H, 5.41; N, 5.90.

***N*-[*N*-(2*S*-2-Benzamido-3-phenylpropyl)aminoacetyl]-L-proline (III)**—Crude compound XI (836 mg, 1.32 mmoles) was stirred in 40 ml of liquid ammonia under nitrogen atmosphere for 3 hr. The ammonia was evaporated and the residue was stirred vigorously for 10 min in a mixture of 20 ml of water and 20 ml of ethyl acetate. The water layer was separated and evaporated to dryness to give a white solid. This was triturated with methanol (10 ml) to give 280 mg (52% yield) of III, mp 200–201°; mass spectrum 553 (M^+ + 2 trimethylsilyl); $[\alpha]_D^{31}$ −92.4° (*c* = 0.953, 1 *N* NH_4OH).

Anal.—Calc. for $C_{23}H_{27}N_3O_4 \cdot 0.25\ CH_3OH$: C, 66.82; H, 6.76; N, 10.06. Found: C, 66.94; H, 6.64; N, 10.00.

***N*-[*N*-Acetyl-*N*-(2*S*-2-benzamido-3-phenylpropyl)aminoacetyl]-L-proline (XII)**—The amino acid (III) (100 mg, 0.244 mmoles) was stirred in 10 ml of water and 10 ml of acetic anhydride for 2-⅓ hr at room temperature. The reaction was evaporated to dryness at 35°. Another 10 ml of water was added to the residue and the mixture was again evaporated to dryness. The residue was dissolved in chloroform (20 ml) and washed with cold 2 *N* HCl (20 ml) and water (20 ml), dried with calcium sulfate, and evaporated to dryness. The gummy residue was crystallized from chloroform–ether to give 58 mg (53% yield) of compound XII as a white solid, mp 156–158°; ^{1}H-NMR ($CDCl_3$–methanol-d_4 2:1): δ 2.01 (3 H, d, acetamide CH_3); mass spectrum 523 (M^+ + trimethylsilyl).

Anal.—Calc. for $C_{25}H_{29}N_3O_5 \cdot 0.25\ H_2O$: C, 65.85; H, 6.52; N, 9.21. Found: C, 65.88; H, 6.39; N, 9.20.

Fluorometric Assay of Angiotensin-Converting Enzyme—Materials used were porcine plasma-converting enzyme[2], hippuryl-histidyl-leucine[3], histidyl-leucine[3], *o*-phthaldehyde[3], and angiotensin I[4]. All chemicals used were reagent grade.

The enzyme assay (9) activity was conducted with fluorometric determination of histidyl-leucine, a product of the enzyme reaction. The substrate used was hippuryl-histidyl-leucine or angiotensin I. The concentration ranges were 2.6×10^{-4}–2.04×10^{-3} *M* and 1.1×10^{-4}–1.4×10^{-3} *M* for hippuryl-histidyl-leucine and angiotensin I, respectively. The

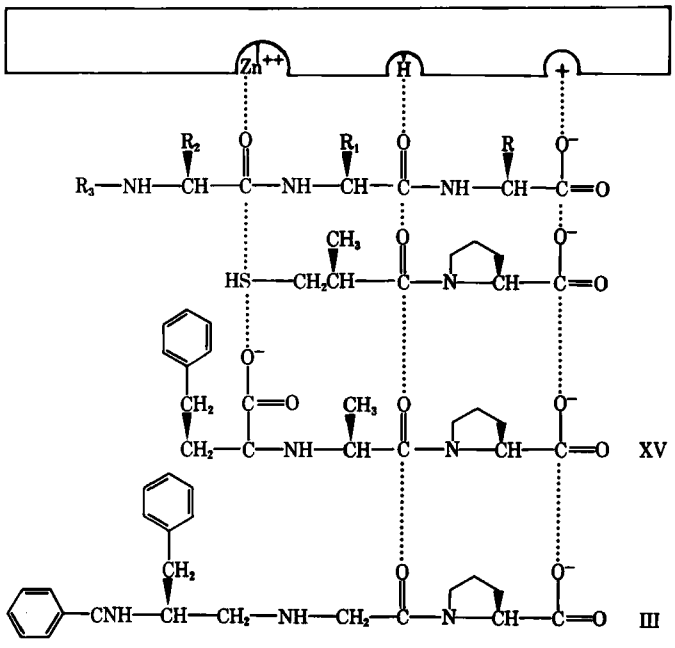

Figure 3—*Schematic representation of the binding of inhibitors and substrates at the hypothetical active site of angiotensin-converting enzyme as proposed previously (8).*

assay was carried out by mixing 10 μl of phosphate buffer (0.1 *M*, pH 7.6, containing 0.3 *M* NaCl) containing the testing inhibitor with substrate dissolved in 10 μl of phosphate buffer. Then 1 mg of porcine plasma-converting enzyme in 50 μl of buffer was added. The mixture was incubated at 37° for 90 min with constant shaking, and the reaction was stopped by adding 50 μl of 10% trichloroacetic acid. The samples were then diluted with 0.7 ml of water followed by 0.4 ml of 2 *N* NaOH. To the alkalized mixture, 0.1 ml of 1% (w/v) *o*-phthaldehyde in methanol was added. After exactly 4 min, 0.2 ml of 6 *N* HCl was added. The contents of all tubes were thoroughly mixed after each addition. The samples were then centrifuged at 10,000×*g* for 10 min, and the fluorescence of the supernatant was measured[5] with excitation at 365 nm and emission at 495 nm. The fluorescent product of histidyl-leucine with *o*-phthaldehyde is not stable in alkaline solution, but is stabilized upon acidification. The fluorescence of the acidified solution is stable up to 1 hr, so all readings should be made within that period (10).

A standard curve of histidyl-leucine was prepared for each assay by mixing various amounts of histidyl-leucine with 1 mg of enzyme in 70 μl of phosphate buffer. The tubes containing the standards were treated identically to those containing the samples. A reagent blank containing all reagents but no substrate was also run for each assay.

Test for the Effect of Inhibitors—For testing the effect of inhibitors on angiotensin-converting enzyme, two assays were run in parallel. One contained the substrate (2 m*M*), enzyme (1 mg), and various concentrations (1 n*M* to 10 m*M*) of an inhibitor; the other contained only the substrate and enzyme. The assay conditions were the same as described above. The product formed with an inhibitor relative to that without an inhibitor was calculated to give the percent of inhibition. By plotting the percent inhibition *versus* various concentrations of an inhibitor, the I_{50} was obtained.

For determination of the kinetics and the K_i of an inhibitor, the enzyme assay was carried out as described above using various concentrations of substrate with and without inhibitor. When hippuryl-histidyl-leucine was used as substrate, the concentrations were 2×10^{-4}–3×10^{-3} *M*. When angiotensin I was used as substrate, the concentrations were 1.1×10^{-4}–1.3×10^{-3} *M*. By using the Michaelis–Menten equation (11) and double-reciprocal plot (12), the K_m and K_i can be calculated.

Synthesis of Sulfanilamido-Naphthoquinones as Potential Antituberculous Agents

S. A. A. OSMAN ˣ, A. A. ABDALLA, and M. O. ALAIB

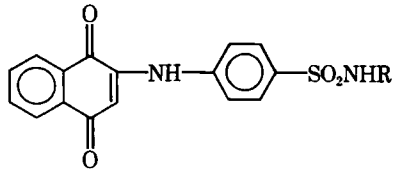
Received May 12, 1981, from the *Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Khartoum. Khartoum, Sudan.* Accepted for publication March 3, 1982.

Abstract □ *p*-Aminobenzoic acid, the acid hydrazides of benzoic acid, salicylic acid and isonicotinic acid, and 4,4′-diaminodiphenyl sulfone were condensed with *p*-aminobenzenesulfonyl chloride to give the corresponding N^1-substituted sulfanilamides. These molecules were then treated with 1,4-naphthoquinone to yield 2-substituted-1,4-naphthoquinones. The partition coefficient for the substituted quinones showed, in some cases, high diffusion rates to the organic phase, benzene, from physiological Tyrode's solution. These compounds are effective in low concentration in dioxane against the human sensitive strain of *Mycobacterium tuberculosis* H_{37} Rv. Sulfanilamides obtained from *p*-aminosalicylic acid and thiosemicarbazide failed to react with 1,4-naphthoquinone. These sulfanilamides also showed high activity against the same *Mycobacterium*.

Keyphrases □ Antituberculous agents—potential, synthesis of sulfanilamido-naphthoquinones □ Sulfanilamides—synthesis of sulfanilamido-naphthoquinones as potential antituberculous agents

It has been postulated that the penetration through the Tubercle bacilli cell wall is a limiting factor in the effectiveness of the tuberculostatic agents. Consequently, trials were made to improve the cell penetration of these drugs. Surface active agents (1, 2), used to promote cell penetration, were found to be effective through modification of the surface lipids of the bacilli (3, 4).

The isolation of phthiocol (2-hydroxy-3-methyl-1,4-naphthoquinone) from the human bacilli (5, 6), indicated that the compound could be a natural metabolite of the organism; thus showing the tolerance of the latter to the *p*-quinonoid structure. Earlier reports have also indicated the use of *p*-quinonoid moieties as carriers for certain tuberculostatic agents (7, 8). These facts, beside the high lipid solubility of naphthoquinone suggested using 1,4-naphthoquinone as a carrier of certain sulfonamides, with the objective that the *p*-quinonoid moiety will facilitate the diffusion of the compounds through the cell wall giving them a better opportunity to exert their effects on the organism. The present work is concerned with the synthesis of 2-(substituted sulfanilamido)-1,4-naphthoquinones:



The routes by which these compounds were synthesized are shown in Scheme I.

RESULTS AND DISCUSSION

Chemistry—The key intermediates, sulfanilamide compounds, were prepared by adding *p*-acetamidobenzenesulfonyl chloride to *p*-aminobenzoic acid, *p*-aminosalicylic acid, isonicotinic acid hydrazide, benzoic acid hydrazide, salicylic acid hydrazide, and 4,4′-diaminodiphenyl sulfone according to a previously used technique (9). The products were then deacetylated. The sulfanilamide compounds obtained were allowed to react with 1,4-naphthoquinone. The 2-substituted-1,4-naphthoquinones were obtained, where the sequence of the reaction could follow the same route proposed for the reaction of the arylamine and 1,4-naphthoquinone (10, 11). The sulfanilamides obtained from *p*-aminosalicylic acid and thiosemicarbazide (II, VII) did not react with the quinone, while (VI) the ethyl ester of (II) underwent the reaction successfully. The sulfanilamide obtained from *p*-aminobenzoic acid was esterified after combining it with the 1,4-naphthoquinone (XVI, XVII). The unsubstituted 4,4′-diaminodiphenyl sulfone reacted with one molecule of 1,4-naphthoquinone (XV) and the same compound, condensed as sulfanilamide derivative, reacted with two molecules of the quinone (XIV).

Table I—Partition Coefficient $\left(\frac{A_2}{A_1 - A_2}\right)$ between Benzene and Tyrode's Solution [a]

XVII	1.0 R	1.5 R	2.0 S

[a] Resistant. [b] Sensitive.

The purity and the identity of the compounds were determined by TLC on silica gel using different solvent systems, melting points (uncorrected), IR spectra using a spectrophotometer[1] as nujol mull on sodium chloride plates and elemental microanalysis.

A number of the compounds prepared (IX–XVII) showed high diffusion rates to the organic solvent, benzene, from physiological Tyrode's solution. The values of the partition coefficient between the solvents were calculated using the ratio $A_2/A_1 - A_2$, where A_1 and A_2 are the absorbances in benzene before and after extraction with the Tyrode's solution at wavelength 450 nm (Table I).

Biology—Most of the prepared compounds proved to be effective in low concentrations against the human strain of *Mycobacterium tuberculosis* H_{37} Rv[2].

A concentration of 0.1 μg/ml wet weight of 3-week-old cultures of the *Mycobacterium* was found suitable. Lowenstein–Jensen medium without

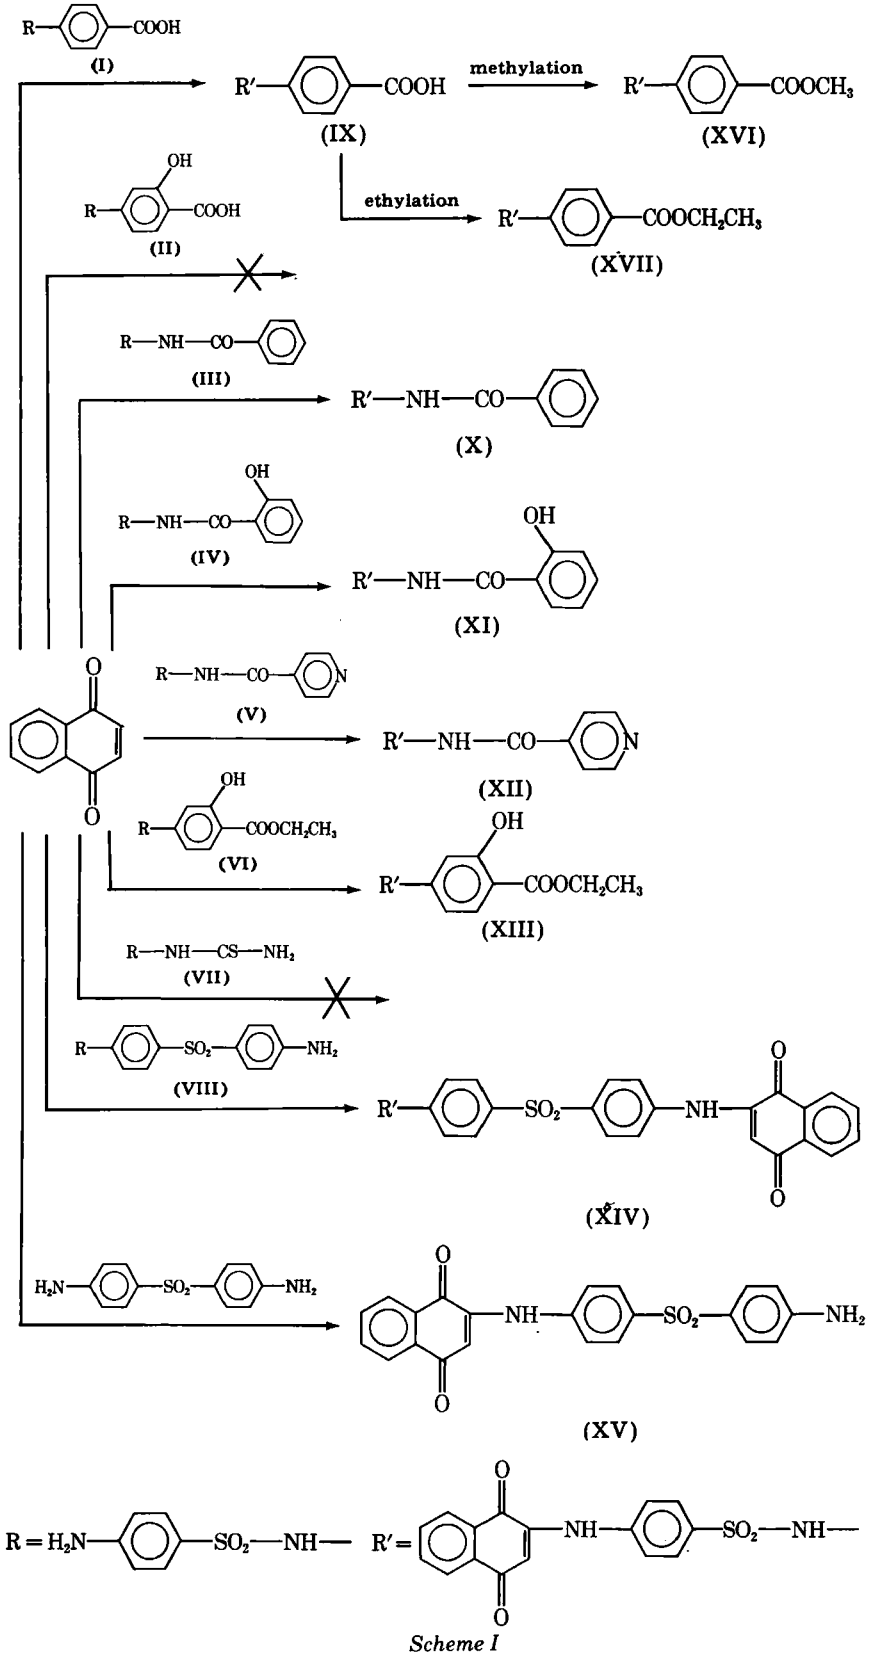

Scheme I

potato was used. No growth or growth of <20 colonies indicated that the strain was sensitive to the compounds in the given concentrations, provided that the compound-free control yielded >100 colonies.

All compounds tested were found effective against the human sensitive strain of the *Mycobacterium* in concentrations of 1–2 μg/ml. However, compounds IX–XII gave the same effect in lesser concentrations (Table II).

On comparing data from Tables I and II, structural variations of the compounds appear to show uncorrelated effects on the activities and the rates of diffusion of the compounds into the organic phase. Some of the highly active compounds were also highly diffusible, *e.g.*, compounds XI and XII. Such a relationship does not hold with the other compounds. A detailed comparative study of the effect of the structural variations involving quinonoid and unquinonoid compounds on both activities and

rates of diffusion and their relationship to each other is presently being conducted.

EXPERIMENTAL

All compounds mentioned in Tables III and IV were prepared by the following general procedures. All the figures of analysis and the IR spectra of the compounds were in agreement with the structures.

***p*-Acetamidobenzenesulfanilamido Derivatives**—*p*-Acetamidobenzenesulfonyl chloride (10 mmoles) was added gradually to a solution of the appropriate derivative (20 mmoles) in 2 *N* NaOH solution (30 ml) with constant stirring. The stirring continued for 10–15 min. The alkaline solution was extracted with ether, then acidified with hydrochloric acid, when the *p*-acetamidobenzenesulfonamido compound separated. The compound was then filtered and crystalized from 95% ethyl alcohol. The IR spectra of the pure compounds showed absorption bands at 1740 cm^{-1} (C=O in $COCH_3$), 1600—1590 cm^{-1} (C=C aromatic), 1680 cm^{-1}, 1570 cm^{-1} (CONH amides I & II), 1370–1335 cm^{-1}, 1180 cm^{-1} (SO_2NH) beside others for different compounds.

Benzenesulfanilamido Derivatives—The hydrolysis (deacetylation) of the *p*-acetamidobenzene derivatives was carried out either by heating with alkali on a steam bath or by gently refluxing for 30 min with twice its weight of diluted hydrochloric acid. The IR spectra of the hydrolyzed compounds showed the disappearance of the C=O band of the $COCH_3$ group at 1740 cm^{-1} and the appearance of a typical primary N—H pair of bands at 3300 and 3130 $cm.^{-1}$ (Table III).

***N*¹-(*p*-Carboethoxy-*m*-hydroxyphenyl) Sulfanilamide (VI)**—A solution of II (10 mmoles) was esterified by warming with excess 95% ethyl alcohol in the presence of concentrated sulfuric acid. The ethyl ester, mp 230–231° was obtained in a 60% yield. The IR spectrum marked the disappearance of the bands at 1690 cm^{-1} (C=O in COOH) and 3000 cm^{-1}

(OH carboxylic) and the appearance of the band at 1665 cm^{-1} (C=O in $COOC_2H_5$).

Anal.—Calc. for $C_{15}H_{16}N_2O_5S$: C, 53.56; H, 4.79; N, 8.33; S, 9.53. Found: C, 53.06; H, 4.71; N, 8.30; S, 9.66.

Sulfanilamido-1,4-naphthoquinone Derivatives—A solution of 1,4-naphthoquinone (20 mmoles in 40 ml of 95% ethyl alcohol) was gradually added over a period of 30 min to a solution of the appropriate sulfanilamido derivative (10 mmoles in 10–30 ml of glacial acetic acid). Sodium acetate (20 mg) was added with constant stirring at 60°. Stirring was continued for 30 min, then refluxed for 1 hr, and left overnight at room temperature. A black precipitate was separated and filtered. Water was added to the filtrate when a brownish material separated. It was then filtered, washed with hot water, dried at 80°, and crystallized from 95% ethyl alcohol as light crystals. The IR spectra of the compounds showed the appearance of two bands at 1650 and 1630 cm^{-1} for the C=O of the naphthoquinone. The pair of bands of the primary NH_2 at 3300 and 3130 cm^{-1} disappeared, while the N—H stretching absorption was shown at 3245 cm^{-1} (Table IV).

4-Amino-4′-[2-(1,4-naphthoquinonyl)]aminodiphenylsulfone (XV)—This was obtained by the same procedure for the preparation of the sulfanilamido-1,4-naphthoquinone derivatives, from 1,4-naphthoquinone (20 mmoles in 40 ml of 95% ethyl alcohol) and 4,4′-diaminodiphenyl sulfone (10 mmoles in 35 ml of glacial acetic acid). The product was crystallized from 95% ethyl alcohol. Yield: 91%, mp 306–307°.

Anal.—Calc. for $C_{22}H_{16}N_2O_4S$: C, 65.34; H, 3.96; N, 6.93; S, 7.92. Found: C, 65.25; H, 4.14; N, 6.72; S, 7.71.

2-{N^4-[N^1-(*p*-Carbomethoxy)phenyl]sulfanilamido}-1,4-naphthoquinone (XVI)—A solution of IX (10 mmoles) was esterified by warming with excess methyl alcohol in the presence of concentrated sulfuric acid. The methyl ester recrystallized from glacial acetic acid was obtained in 37% yield, mp 253°. In the IR spectrum the bands at 1700 cm^{-1} (C=O in COOH) and 3245 cm^{-1} (OH carboxyl) disappeared and a band at 1750 cm^{-1} (C=O in $COOCH_3$) appeared.

Anal.—Calc. for $C_{24}H_{18}N_2O_6S$: C, 62.34; H, 3.89; N, 6.06; S, 6.90. Found: C, 61.93; H, 3.67; N, 5.64; S, 6.68.

2-[N^4-[N^1-(*p*-Carboethoxy)phenyl]sulfanilamido}-1,4-naphthoquinone (XVII)—Obtained as XVI from IX by esterification with 95% ethyl alcohol. Yield: 35%, mp 261–262°. In the IR spectrum the bands at 1700 cm^{-1} (C=O in the carboxyl group) and 3245 cm^{-1} (OH carboxyl) disappeared, and a band at 1665 cm^{-1} (C=O in $COOC_2H_5$) appeared. appeared.

High-Performance Liquid Chromatographic Determination of Alizapride, a New Antiemetic Compound, and Its Application to a Dose-Dependent Pharmacokinetic Study

G. HOUIN *, F. BREE *, N. LERUMEUR ‡, and J. P. TILLEMENT *x

Received November 20, 1980, from the **Department of Pharmacology, Faculty of Medicine of Paris XII, 8 Rue du Général Sarrail—94000 Creteil*, and the ‡*Department of Medical Statistics, Hopital du Bocage—21000 Dijon, France.* Accepted for publication March 4, 1982.

Abstract □ An assay was developed to measure alizapride (a new antiemetic compound) in biological specimens. The method involved reversed-phase high-performance liquid chromatography and fluorescence detection. The detection limit was 5 ng/ml in plasma or urine samples. The value of the assay was demonstrated with a dose-dependent pharmacokinetic study. It showed a two-phase decrease in plasma concentrations, after intravenous injection, with half-lives of 7.5-min and 2.5-hr, respectively. From plasma and urine results, pharmacokinetic parameters remained constant in the dose range of 50–200 mg.

Keyphrases □ High-performance liquid chromatography—determination and dose-dependent pharmacokinetic application of alizapride, new antiemetic compound □ Alizapride—new antiemetic compound, high-performance liquid chromatographic determination and dose-dependent pharmacokinetic application □ Antiemetic compound—high-performance liquid chromatographic determination and dose-dependent pharmacokinetic application of alizapride □ Pharmacokinetic application—dose-dependent, alizapride, new antiemetic compound, high-performance liquid chromatographic determination

Alizapride[1], *N*-[(1-allyl-2-pyrrolidinyl)methyl]-6-methoxy-1*H*-benzotriazole-5-carboxamide (I), is a new compound with antiemetic properties (1, 2). For bioavailability studies a sensitive and specific assay for plasma and urine concentrations was needed. According to the physicochemical properties of the compound, a high-performance liquid chromatographic (HPLC) assay with a fluorescence detector was selected. This study describes the procedure used for the analysis of biological samples and the preliminary results on pharmacokinetic parameters calculated in a dose-dependency study.

EXPERIMENTAL

Materials—Alizapride was obtained from commercial suppliers and showed no impurities in two different TLC systems. Methanol, chloroform, and tris(hydroxymethyl)aminomethane buffer (pH 8.1) were commercially available analytical grades and used without further purification.

(OH carboxylic) and the appearance of the band at 1665 cm^{-1} (C=O in $COOC_2H_5$).

Anal.—Calc. for $C_{15}H_{16}N_2O_5S$: C, 53.56; H, 4.79; N, 8.33; S, 9.53. Found: C, 53.06; H, 4.71; N, 8.30; S, 9.66.

Sulfanilamido-1,4-naphthoquinone Derivatives—A solution of 1,4-naphthoquinone (20 mmoles in 40 ml of 95% ethyl alcohol) was gradually added over a period of 30 min to a solution of the appropriate sulfanilamido derivative (10 mmoles in 10–30 ml of glacial acetic acid). Sodium acetate (20 mg) was added with constant stirring at 60°. Stirring was continued for 30 min, then refluxed for 1 hr, and left overnight at room temperature. A black precipitate was separated and filtered. Water was added to the filtrate when a brownish material separated. It was then filtered, washed with hot water, dried at 80°, and crystallized from 95% ethyl alcohol as light crystals. The IR spectra of the compounds showed the appearance of two bands at 1650 and 1630 cm^{-1} for the C=O of the naphthoquinone. The pair of bands of the primary NH_2 at 3300 and 3130 cm^{-1} disappeared, while the N—H stretching absorption was shown at 3245 cm^{-1} (Table IV).

4-Amino-4′-[2-(1,4-naphthoquinonyl)]aminodiphenylsulfone (XV)—This was obtained by the same procedure for the preparation of the sulfanilamido-1,4-naphthoquinone derivatives, from 1,4-naphthoquinone (20 mmoles in 40 ml of 95% ethyl alcohol) and 4,4′-diaminodiphenyl sulfone (10 mmoles in 35 ml of glacial acetic acid). The product was crystallized from 95% ethyl alcohol. Yield: 91%, mp 306–307°.

Anal.—Calc. for $C_{22}H_{16}N_2O_4S$: C, 65.34; H, 3.96; N, 6.93; S, 7.92. Found: C, 65.25; H, 4.14; N, 6.72; S, 7.71.

2-{N^4-[N^1-(*p*-Carbomethoxy)phenyl]sulfanilamido}-1,4-naphthoquinone (XVI)—A solution of IX (10 mmoles) was esterified by warming with excess methyl alcohol in the presence of concentrated sulfuric acid. The methyl ester recrystallized from glacial acetic acid was obtained in 37% yield, mp 253°. In the IR spectrum the bands at 1700 cm^{-1} (C=O in COOH) and 3245 cm^{-1} (OH carboxyl) disappeared and a band at 1750 cm^{-1} (C=O in $COOCH_3$) appeared.

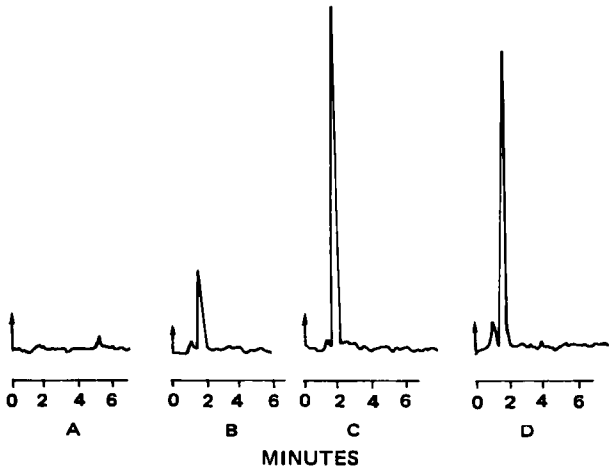

Figure 1—*High-performance liquid chromatograms of alizapride. Graph A corresponds to plasma free of alizapride, graphs B and C to plasma spiked with 50 and 250 ng of alizapride respectively, and graph D to plasma samples obtained during pharmacokinetic study.*

Apparatus—A liquid chromatograph[2] equipped with a fluorescence detector[3] and a continuous flow cell of 8-μl capacity was used. According to the fluorescence spectrum of alizapride, excitation and emission wavelengths were 323 and 380 nm, respectively. A 250-mm steel column was used, packed with a monomolecular layer of octadecyltrichlorosilane chemically bonded to Porasil beads with an average particle size of 10 μm[4]. The chromatographic solvent, methanol–pH 8.1 buffer (80:20, v/v), was delivered at a 2-ml/min flow rate.

Table I—Alizapride Recovery from Spiked Plasma Samples[a]

Recovered, ng	Added, ng						
	25	50	100	250	500	1000	2000
$\bar{m}$	25.5	49.5	99.8	248.6	501.2	1001.3	2003.0
SD	1.6	3.0	6.2	7.0	8.5	14.7	64.0
CV%	6.1	6.0	6.2	2.8	1.7	1.5	3.2

[a] Total of five assays.

Sample Preparation Procedure—For statistical analysis, human plasma was spiked with known amounts of alizapride to reach 5–2000 ng/ml and equilibrated by shaking for 30 min. In human experiments, blood samples were immediately centrifuged, and the plasma was stored at −20° until analysis.

Extraction Procedure—To a 1-ml plasma sample, 1 ml of pH 8.1 buffer and 5 ml of chloroform were added. The mixture was shaken at room temperature for 1 min on a vortex-type mixer and centrifuged at 3000 rpm for 10 min. A 4.8-ml volume of the organic phase was evaporated to dryness under a smooth nitrogen stream. The residue was reconstituted with 35 μl of the chromatographic solvent; 25 μl of the mixture was injected onto the HPLC column.

Quantitation—Calibration curves were calculated using peak height and amounts of drug added to plasma, using the least-squares method.

Human Experiments—Six subjects gave informed consent to participate in the study. They were free from cardiac, renal, hepatic, and respiratory diseases and allergies according to clinical and biological examinations. None of the subjects received any drugs for at least 15 days prior to the study. Each subject received four doses (50, 100, 150, and 200 mg) at one-week intervals, three of them intravenously and the others orally, in tablet form.

A 7-ml heparinized blood sample was withdrawn at 0, 3, 6, 10, 15, 20, 30, 45, 60, 90, and 120 min and 3, 4, 6, 8, 10, 12, and 24 hr after administration. Urine samples were collected every 2 hr during the first 12 hr, once during the next 12 hr, and every 24 hr during the next 4 days.

Calculation—Statistical and pharmacokinetic calculations were performed with a table microcomputer[5] using programs developed previously (3).

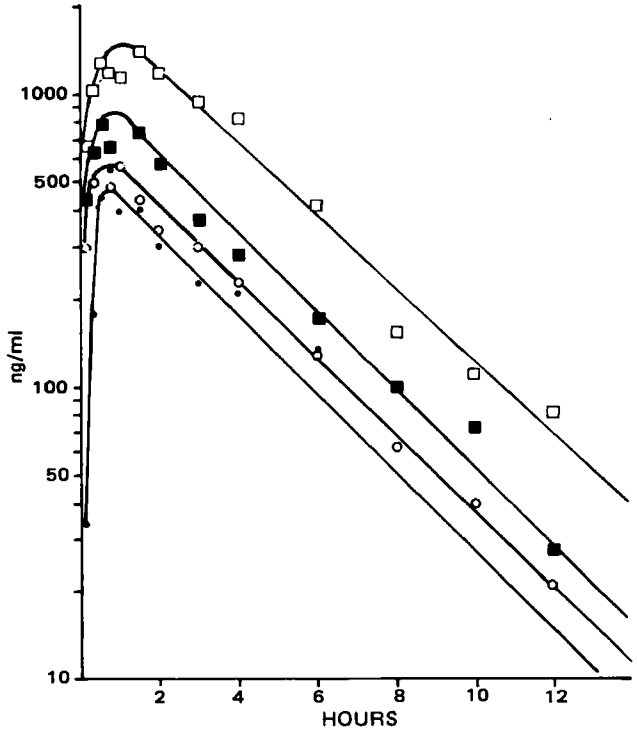

Figure 3—*Mean alizapride plasma concentration curves obtained in three subjects for each orally administered dose. Key: (●) 50 mg; (○) 100 mg; (■) 150 mg; (□) 200 mg.*

RESULTS AND DISCUSSIONS

Figure 1 shows examples of chromatographic tracings. No peak corresponding to endogenous compounds interferes with the drug. A standard curve obtained with eight points had a mean slope of 0.0528 (1.12% *SD*), a mean correlation coefficient of 0.9998, and a mean *y*-intercept of 0.0146 (0.1% *SD*). These data indicate that the peak height at the origin is not significantly different from zero, which correlates with the absence of endogenous interfering peaks, and a linearity between 5 and 2000 ng of alizapride/ml of plasma.

Recovery of the drug from spiked plasma samples (n = 5) was determined (Table I) at several concentrations. Mean results appear to be very close to the theoretical concentrations, which show reasonable recovery and accuracy. The standard deviation decreased to a minimum of 1.5% obtained when the analyzed concentration was ~1 μg/ml. Under these conditions, assay sensitivity of alizapride in plasma was 5 ng/ml.

Blood Sample Analysis—*Intravenous Administration*—Mean alizapride concentrations obtained from the three subjects receiving intravenous doses are shown in Fig. 2. Individual concentrations have been systematically interpreted according to three different pharmacokinetic models, *i.e.*, one-, two-, or three-compartment open models. At each step, a statistical Fischer test using the least-squares criterion was performed to evaluate the benefit of increasing the number of compartments. After intravenous administration a two-compartment open model was chosen. Mean pharmacokinetic parameters are presented in Table II. It shows a very rapid distribution phase corresponding to a 0.125 ± 0.07-hr half-life (range: 0.057–0.210 hr) and an elimination phase with a 2.51 ± 1.49-hr mean half-life (range: 1.25–6.79 hr). Volumes of distribution are large: 3.9–44.5 liters (mean: 30.4 ± 4.2 liters) for the central compartment and 37.0–115.1 liters (mean: 57.5 ± 11.2 liters) for the peripheral compartment.

Oral Administration—Mean alizapride concentrations obtained from the three subjects receiving oral doses are shown in Fig. 3. With this route of administration, the better fit was obtained with the one-compartment open model with first-order absorption. However, the two curves observed after the 200-mg administration in two subjects were better described with a two-compartment open model with first-order absorption. Results are presented in Table III, and it can be seen that the apparent elimination half-life is in the same range as that obtained after intravenous administration. The area under the plasma concentration curves are lower, with the systemic availability calculated in this preliminary study being 72.5%.

Urine Sample Analysis—*Intravenous Administration*—Sigma-minus plots of the urinary excretion of unchanged alizapride is shown in Fig. 4. Corresponding pharmacokinetic parameters are presented in Table II, and it can be seen that they are remarkably constant. Two parameters are of particular interest. The first is the urinary elimination half-life of alizapride (2.60 ± 0.57 hr) compared with the terminal half-life of plasma concentration decay $t_{1/2}$ = 2.51 ± 1.49 hr. The paired t test failed to show differences in these values. The overall urinary elimination of unchanged drug, 73.0 ± 9.9% of the administered dose, shows that urinary excretion is the mean phenomenon responsible for plasma alizapride decay. About 30% of the administered dose was not recovered

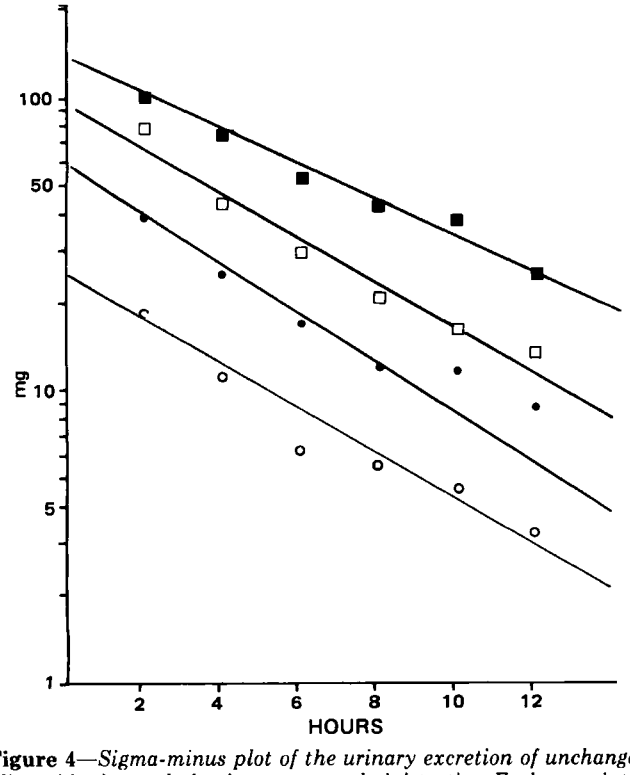

Figure 4—*Sigma-minus plot of the urinary excretion of unchanged alizapride observed after intravenous administration. Each curve is the mean of three subjects (○) 50 mg; (●) 100 mg; (□) 150 mg; (■) 200 mg.*

during this study. Since urine was collected for 5 days and the elimination half-life is ~2.5 hr, a good approximation of the amount excreted in the urine at infinity exists. So the difference must be accounted for in the metabolism. The metabolic pathway of alizapride is unknown in humans. No extra peaks appeared on the chromatographic plots of the urine fractions collected. Furthermore, an attempt was made to see if one or more of the metabolites was eluted from the column simultaneously with the parent drug. For this reason, urine extracts have been chromatographed using different solvent systems, *i.e.*, methanol–pH 8.1 buffer from 20:80 (v/v) to 80:20 (v/v). No extra peak separated from the main peak. Either the metabolites are not extracted in chloroform or the solvent is unable to elute them from the HPLC column.

Oral Administration—Sigma-minus plots of the urinary excretion of unchanged alizapride are shown in Fig. 5, and corresponding pharmacokinetic parameters are presented in Table III. The urinary elimination half-life was 2.45 ± 1.38 hr, which is comparable to that observed after intravenous administration.

The unchanged urinary alizapride recovery amounted to 65.5 ± 22.7% of the administered dose. Compared with intravenous administration, a greater individual variation is observed after oral administration. This leads to a mean apparent systemic availability of 89.7%. This value is higher than the value found with corresponding AUC. However, the two values are not statistically different. This is probably due to the small number of subjects studied and the variations observed in urinary excretion after oral administration.

Dose-Dependency Analysis—From plasma results, dose-dependency has been checked by three methods. An example of the superposition method is shown in Fig. 6. Plasma concentrations divided by the administered dose as a function of time show reasonable superposition for the four doses tested. According to Dost's law (4), if pharmacokinetic parameters are independent of the dose, the area under the plasma concentration curve must be linearly related to the injected dose. The mean correlation coefficient was 0.9999, 0.9997, and 0.9928 for each subject. Despite the good correlation observed, there is little confidence in the results of this analysis because of the small amount of data used for the least-squares regression analysis. Accordingly, an ANOVA (5) was carried out for AUC, normalized to a 100-mg dose with the total amount of data available, obtained after either intravenous or oral administration. It failed to show a significant difference among the subjects ($^5_{16}F = 2.54$) and between administered doses ($^3_{16}B\ F = 0.74$), but, a significant difference at the 0.01 level was found between intravenous and oral administration. This must be related to the absolute availability of the oral form, which was calculated to be 72.5%.

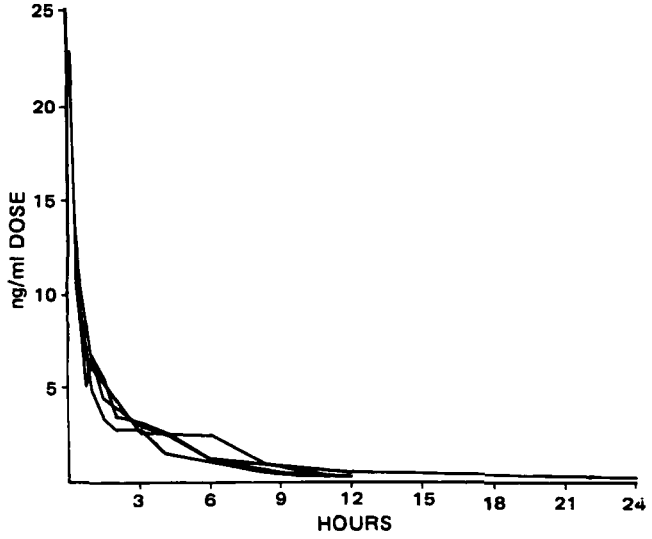

Figure 6—*Superposition of the plasma concentration curve divided by the injected dose in function of time, in subject C.*

Similarly, the same ANOVA analysis failed to show any difference between administered doses ($^3_{16}F = 0.61$) when considering urinary unchanged alizapride percentages. Nevertheless, it showed significant differences among individuals ($p < 0.05$) and between intravenous and oral administrations ($p < 0.01$).

From these three methods, it can be concluded that, in the range of administered doses, pharmacokinetic parameters of alizapride are not sensitive to dose variations.

Accordingly, variance analysis of the values of unchanged eliminated drug found for the different doses is unable to show any difference in drug elimination. The relationship between drug elimination and administered dose shows highly significant mean correlation coefficients in each subject.

The fluorescent HPLC method for biological sample analysis of alizapride has been shown to be sensitive enough to allow human pharmacokinetic studies of the drug. Preliminary results show a very rapid distribution phase with a mean half-life of 7.5 min followed by an elimination phase with a mean half-life of 2.5 hr. Urinary excretion represents the major phenomenon responsible for this elimination. In the range of tested doses, pharmacokinetic parameters of alizapride are linear.

Received June 17, 1981, from the *Central Research Division, Takeda Chemical Industries, Ltd., 2-17-85 Juso, Yodogawa, Osaka 532, Japan.* Accepted for publication March 1, 1982

Abstract □ Organic acids such as citric acid enhance the vaginal absorption of luteinizing hormone-releasing hormone, the potent analogue (leuprolide), and insulin. The mechanism of this absorption enhancement was investigated with leuprolide and hydrophilic markers such as phenol red and Evan's blue. The absorption of the analogue was increased by lowering the pH of the solution and increased more by adding citric, succinic, tartaric, and malonic acids. The absolute bioavailability after vaginal administration of the 5% citric acid solution was 16.7% at pH 3.5 and 38.4% at pH 1.8. The enhancing potency of the absorption correlated well with the chelating ability of the organic acids. The vaginal absorption of phenol red was also enhanced with citric acid and edetic acid, but the enhancing effect of edetic acid was eliminated by adding equimolar calcium ion. These results suggest that the acidifying and chelating abilities of the acids may result in a potent enhancement of the vaginal absorption of leuprolide. A leakage experiment using Evan's blue on the vaginal membrane indicated that the blood–vaginal epithelium barrier was loosened with the administration of citric acid; this change was overcome rapidly.

Keyphrases □ Leuprolide—vaginal absorption, potent luteinizing hormone-releasing hormone analogue in rats, mechanism of absorption enhancement with organic acids □ Absorption, vaginal—potent luteinizing hormone-releasing hormone analogue in rats, mechanism of absorption enhancement with organic acids □ Hormones—potent luteinizing hormone-releasing hormone analogue (leuprolide) in rats, vaginal absorption, enhancement with organic acids

In a previous study (1), an investigation on the administration routes of leuprolide (I), a potent luteinizing hormone-releasing hormone (II) analogue, was carried out in rats to establish a self-administration method for antitumor therapy in humans:

(Pyro)Glu-His-Trp-Ser-Tyr-D-Leu-Leu-Arg-Pro-NH-CH_2CH_3
I

(Pyro)Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2
II

Good absorption of the analogue was observed with vaginal suppositories containing organic acids such as citric acid and succinic acid, and the vaginal application was proposed as a rational dosage method of the analogue for long-term therapy.

A series of investigations on the vaginal absorption of alcohols and alkanoic acids have been reported (2–6), but a few studies on the hydrophilic compounds and their absorption enhancement have been reported (7).

Most of the organic acids, which enhanced the vaginal absorption in the previous study, have a chelating ability. On the other hand, compounds possessing strong chelating ability, such as edetic acid (8–10) and tetracyclines (11), have been known to enhance the intestinal absorption of hydrophilic compounds, and the enhancement was supposedly due to the direct interaction with calcium or magnesium ions in the intestinal membrane.

In the present study, the mechanism of the vaginal absorption enhancement by the organic acids was investigated with leuprolide and hydrophilic marker compounds (phenol red and Evan's blue). The vaginal absorption-enhancing effect of citric acid was also confirmed on other hydrophilic, high-molecular compounds, II and insulin.

EXPERIMENTAL

Animals and Materials—Sexually mature female Sprague-Dawley rats[1] aged 120–150 days and weighing 250–330 g were used. Animals exhibiting two or more consecutive 4-day estrous cycles on daily morning examination of vaginal smears were used at diestrus.

Leuprolide [2]and II[2] were used after dehydration (1). Chemicals of reagent quality were used without further purification.

Vaginal Absorption of Leuprolide—The vaginal absorption of leuprolide was evaluated by determining the ovulation-inducing activity (1). The analogue was dissolved in 0.1 *M* glycine buffer (pH 2.02 and 3.47), 0.2 *M* phthalate buffer (pH 4.76), 0.2 *M* phosphate buffer (pH 6.70), 0.01 *N* HCl (pH 2.08), and 0.9% NaCl solution (pH 5.13) and administered vaginally with cotton balls at doses of 0.2–2 μg/kg/0.2 ml. Tonicity of the solution was measured by an osmometer[3] and adjusted to be isotonic with sodium chloride. Bovine serum albumin[4] and aprotinin[5] were added to each solution of leuprolide to prevent the loss by adsorption or proteolysis (1). After administration of the solution, the vaginal orifice was closed with a surgical adhesive.

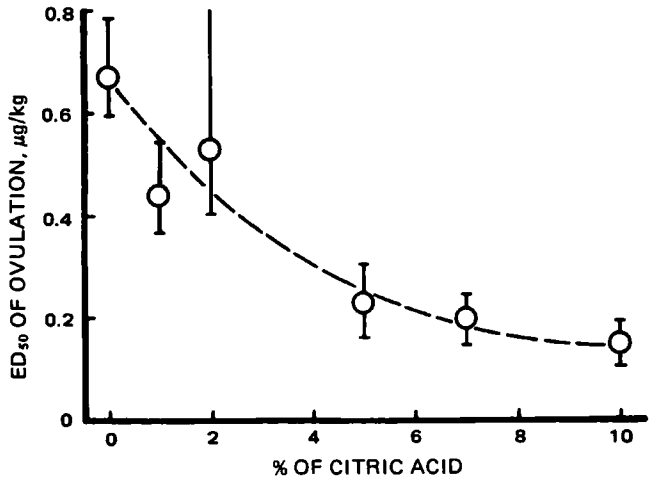

Figure 2—*Ovulation-inducing activity of leuprolide after vaginal administration in the aqueous solutions containing different concentrations of citric acid to diestrous rats. Each solution was adjusted to pH 3.5 with 10* N *NaOH or 2* N *HCl and to be isotonic with sodium chloride. Bars represent the 95% fiducial limits.*

Citric, succinic, tartaric, malonic, malic, acetic, lactic, and ascorbic acids were used at a concentration of 0.238 *M* to enhance the vaginal absorption of the analogue. The analogue dose was 400 ng/kg/0.2 ml. Each solution was adjusted to pH 3.5 with 10 *N* NaOH or 2 *N* HCl to be isotonic with sodium chloride.

The concentration effect of citric acid on the absorption enhancement was determined at 1, 2, 5 (0.238 *M*), 7, and 10% of the acid at pH 3.5. The enhancing effect of 5% dipotassium edetate solution (pH 3.5) and 5% citric acid solution (pH 1.8) were also examined.

Vaginal Absorption of Phenol Red—Phenol red was administered vaginally at a dose of 2 mg/kg/0.2 ml in the buffer (pH 2.0, 3.5, 5.0, and 6.7), 5 and10% citric acid (pH 3.5), 5% citric acid (pH 6.6), 0.12 *M* edetic acid (pH 6.7), and 0.12 *M* edetic acid and calcium chloride (pH 6.7) solutions under pentobarbital (50 mg/kg) and phenobarbital (100 mg/kg) anesthesia. Urine was collected at 3-hr intervals by a polyethylene tube[6] cannula and the collection was completed by washing the bladder with 1 ml of 0.9% NaCl solution through the catheter. Phenol red in the urine was determined by a modified method (12). Statistical evaluation of the data was performed using Student *t* test.

Effect of Citric Acid on the Leakage of Evan's Blue—To examine the time-course of the local reaction with citric acid, leakage of Evan's blue from the blood capillary on the vaginal membrane was evaluated. Evan's blue (10 mg/kg/ml) was intravenously injected immediately, or 0.5, 1.5, and 3.5 hr after vaginal administration of 5 or 10% citric acid solution, and the rats were sacrificed by decapitation 30 min later to examine the vaginal membrane. For the recovery examination, the vaginal membrane was treated with 10% citric acid solution for 1 hr, then washed with 10 ml of 0.9% NaCl solution. Evan's blue was injected immediately, 0.5, and 1.5 hr after washing.

Vaginal Absorption of II and Insulin—The ovulation-inducing activity of II after vaginal administration of a suppository consisting of an oleaginous base[7] with or without 10% citric acid was estimated in rats as described previously (1).

For evaluation of vaginal absorption of insulin, plasma glucose levels were determined using *o*-toluidine–boric acid (13). Insulin at doses of 0.5–20 U/kg iv was administered in 0.9% NaCl solution and vaginally by means of a cotton ball (~12 mg) soaked with 0.05 *M* KCl–HCl buffer solution (pH 1.70) or 10% citric acid solution (pH 1.72) to rats under anesthesia. Blood was taken from the tail vein 0.5, 1, 2, 3, 4, and 6 hr after the administration. The decrease of plasma glucose level (percent × hour) was expressed by integrating the decrease to the initial level from 0 to 6 hr.

RESULTS

Vaginal Absorption of Leuprolide—The ovulation-inducing activity of leuprolide after vaginal administration in the various pH solutions is shown in Fig. 1. The activity was increased by acidification to a level ~4 times greater at pH 2.02 than at pH 6.70.

Table I—Ovulation-Inducing Activity of Leuprolide after Vaginal Administration in Aqueous Solution Containing Organic Acids to Diestrous Rats

Organic Acid	Ovulation[a]	Chelating Ability[b]
None	0/10	—
Citric	9/10	1.21
Succinic	10/10	0.80
Tartaric	2/10	0.37
Malonic	7/10	0.25
Malic	3/10	0.13
Acetic	5/10	—
Lactic	1/10	0.06
Ascorbic	0/10	—

[a] Number of rats induced ovulation per number of rats examined. Each solution containing 0.238 *M* of the organic acid was adjusted to pH 3.5 with 10 *N* NaOH or 2 *N* HCl to be isotonic with sodium chloride. Leuprolide was administered at a dose of 400 ng/kg/0.2 ml. [b] Gram ions of calcium ion sequestered by 1 *M* of organic acids at pH 10 and 30° (Ref. 7). The value of edetic acid was 1.75.

The activity of the analogue after vaginal administration in a pH 3.5 aqueous solution containing 0.238 *M* organic acids is shown in Table I. Polybasic carboxylic acids such as citric, succinic, malic, and malonic acids markedly enhanced the absorption. The enhancing effect was also recognized with acetic acid but not with lactic and ascorbic acids.

The concentration effect of citric acid on the ovulation-inducing activity of the analogue is shown in Fig. 2. The activity was potentiated with increasing concentration and approached a maximum level at >7% of the acid.

In addition, marked enhancing effects were obtained with 5% citric acid solution (pH 3.5 and 1.8) or 5% dipotassium edetate solution (pH 3.5) (Table II). Acidification of the solution from pH 3.5 to 2.0 doubled the activity of the analogue, and a further addition of 5% citric acid increased the activity by 3 times at both pH 3.5 and 1.8. Edetic acid showed a slightly stronger enhancing effect.

Vaginal Absorption of Phenol Red—Vaginal absorption of phenol red was evaluated by the urinary excretion (Fig. 3). After intramuscular injection, phenol red was rapidly excreted into the urine at 90.1 ± 3.0% (mean ±*SE*) of dose in 3 hr, and 96.3 ± 3.2% in 6 hr. After vaginal administration, excretion was sustained during 6 hr. Urinary excretion after vaginal administration in pH 2.0–6.7 buffer solutions was 28.9–38.4% of the dose in 6 hr and tended to decrease slightly with reduced pH.

Vaginal absorption of phenol red was also increased by the addition of 5 or 10% citric acid in pH 3.5 solution but was not affected by the addition of 5% citric acid in pH 6.6 solution. Although edetic acid significantly enhanced the absorption ($p < 0.01$), further addition of equimolar calcium chloride cancelled the enhancement effect.

Effect of Citric Acid on the Leakage of Evan's Blue—The time-course of the local reaction of citric acid on the vaginal membrane and its recovery from the reaction were evaluated by a leakage experiment of Evan's blue. Five percent citric acid solution induced faint staining after only 30 min, whereas 10% citric acid solution induced deep staining after 30 min and 1 hr, which gradually faded 2 and 4 hr after administration. Change of the vaginal membrane induced by 1-hr treatment with 10% citric acid solution was rapidly recovered by washing the lumen with 0.9% NaCl solution; there was a faint staining at 1 hr but none 2 hr after washing.

Vaginal Absorption of II and Insulin—Ten percent citric acid enhanced the ovulation-inducing activity of II by 30 times after the vaginal administration (Table III).

The decreased plasma levels of glucose (percent × hour) after intravenous and vaginal administration of insulin are shown in Fig. 4. A 1.1-U/kg intravenous dose of insulin caused a 125% × hr plasma glucose level decrease in 6 hr. The comparably effective doses for the vaginal administration were 30.0 U/kg in the buffer solution (pH 1.70) and 6.0 U/kg in 10% citric acid solution (pH 1.72). Absolute bioavailability, estimated by the effective doses of the latter, was 18%.

DISCUSSION

Our previous study (1) revealed that good absorption of leuprolide occurred after vaginal administration, and this absorption was enhanced by the addition of some carboxylic acids. In the present study, to establish the mechanism of absorption enhancement, the effects of pH and organic acids on the vaginal absorption of the analogue as well as a few hydrophilic compounds were determined.

The vaginal absorption of leuprolide was enhanced by a pH reduction in the solution, whereas that of phenol red tended to decrease with

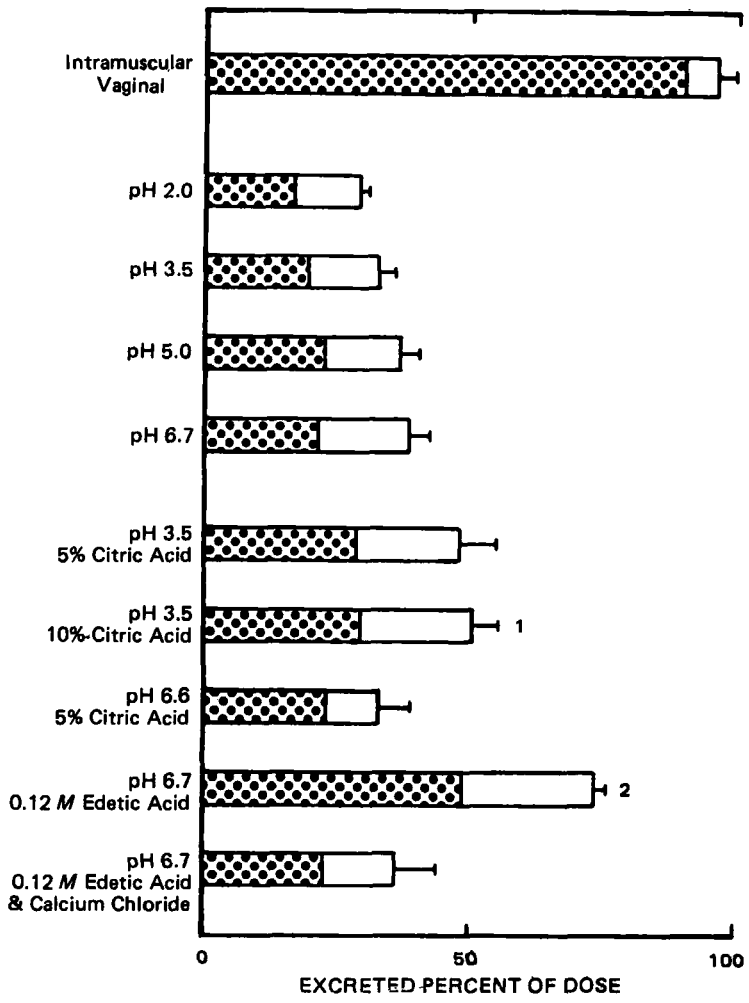

Figure 3—*Effects of pH, citric acid, and edetic acid on vaginal absorption of phenol red in diestrous rats. Each solution was adjusted to be isotonic with sodium chloride. acidification. Leakage of Evan's blue on the vaginal epithelium was not induced by a moderate pH change, but it was slightly induced by a strong acid or alkali solution[8]. It can be assumed that the effect of pH on the vaginal absorption of leuprolide is due mainly to structural changes of the epithelial membrane but is also due to the self-association and conformational change of the peptide or to the change of electric charge on the epithelial surface. It is known that the pH of the vaginal tract of normal women is 3.5–3.9 (14) and that of the vaginal fluid is 4.0–4.7 (15). Therefore, an acid preparation of pH 3–4 should not disturb the normal condition of the vaginal tract. Surface of the vaginal membrane of rats exhibited a pH close to that of the applied bulk solution[8] [this is also true in rabbits (5)].

The polybasic carboxylic acids enhanced the vaginal absorption of leuprolide from aqueous solution (adjusted to pH 3.5) as well as from an oleaginous suppository, whereas lactic and ascorbic acids did not elicit the effect. The enhancing effect with 5% citric acid solution was of the same degree at both pH 1.8 and 3.5 (Table II). Bioavailability of the analogue after vaginal administration of the 5% citric acid solution (pH 1.8) was 38.5 and 58.8% of that after intravenous and subcutaneous injection, respectively.

The chelating ability of the organic acids given by gram ions of calcium ion sequestered is summarized in Table I (16). Edetic acid with the strongest ability (1.75) is followed successively by citric, succinic, tartaric, malonic, and malic acids. Lactic acid has the weakest ability. It is likely that the enhancing effect of the carboxylic acids on vaginal absorption of leuprolide, which has a good correlation with the chelating ability of the acids, is due to chelating ability as well as to the acidification of the solution. Acetic acid, which has negligible chelating ability, also enhanced vaginal absorption. This may be due to the fact that acetic acid is known to corrode mucous membranes and to have a strong interaction with peptides. The 0.12 *M* edetic acid solution enhanced the absorption of phenol red by 2 times ($p < 0.01$); the enhancement was cancelled by the addition of equimolar calcium ion. This result also supports the assumption that the chelating ability of carboxylic acids causes the enhancement of vaginal absorption. The vaginal absorption of phenol red

[a] Number of rats induced ovulation per number of rats examined. [b] 95% fiducial limits.

was also enhanced with citric acid at pH 3.5 but only slightly enhanced at pH 6.6. This was also observed with leuprolide (1).

The vaginal absorption of leuprolide was enhanced by an increase in citric acid concentration but reached a maximum level at >7% of the acid. The vaginal absorption of phenol red was also enhanced with 5% citric acid but increased less with 10% citric acid. The hypertonic solution with sodium chloride showed a tendency to decrease the absorption[8]. The leakage of Evan's blue on the vaginal epithelium was obviously enhanced by an increase in acid concentration. These results indicate that the enhancement of permeability of the membrane for the hydrophilic compounds is caused by an increase in the acid concentration, but the apparent absorption most likely is suppressed by exudation of body fluid from the vaginal membrane due to hypertonicity of the acid solutions.

A time-course study on the change of vaginal epithelial membrane with citric acid revealed that faint staining by Evan's blue injected intravenously was observed in the early stage after treatment with 5% citric acid solution and deep staining 30 min and 1 hr after treatment with 10% citric acid solution; even in the latter, the stain gradually faded. The change in vaginal membrane treated with 10% citric acid solution recovered rapidly following washing with physiological saline solution, and the stain was barely visible 1 hr later. It is suggested that the 5% acid concentration in aqueous solution or jelly, sufficient to exert an enhancement on vaginal absorption of the analogue, will produce only a slight change and, hence, a rapid recovery of the vaginal epithelium.

The vaginal absorption of II and insulin, which are hydrophilic and high molecular compounds, was also enhanced markedly by adding citric acid.

It appears that the acidification and chelating abilities of organic acids result in their potent absorption-enhancing activity on the vaginal absorption of leuprolide. Changes in the vaginal epithelial membrane induced with citric acid are slight and recovery of the epithelium is relatively rapid.

Hydration and Percutaneous Absorption IV: Influence of Hydration on *n*-Alkanol Permeation Through Rat Skin; Comparison with Hairless and Swiss Mice

CHARANJIT RAI BEHL *x, ABDEL AZIZ EL-SAYED ‡, and GORDON L. FLYNN §

Received November 6, 1981 from the *Roche Laboratories, *Pharmaceutical Research, Hoffmann-LaRoche, Inc., Nutley, NJ 07110*, the ‡*Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66044*, and the §*University of Michigan, College of Pharmacy, Ann Arbor, MI 48109.* Accepted for publication, March 15, 1982.

Abstract □ The effect of protracted aqueous contact of rat skin on its permeability to methanol, *n*-butanol, and *n*-hexanol was investigated. With the aid of small diffusion cells, sets of intermittent permeation experiments, each ~7 hr in duration, were performed on excised rat skin sections over periods lasting several days, and permeability coefficients were calculated as a function of the duration of the hydration. The permeability coefficient of methanol increased gradually to an asymptote 2.5 times higher than the initial value over the first 80 hr of immersion and then remained essentially invariant through an additional 70 hr. In contrast, the butanol permeability coefficient increased by only a small fraction (~25%) through the first 5 hr of hydration, and it remained at the higher value through to the end of the experiment at 80 hr. For more hydrophobic hexanol, the permeability coefficient increased by ~40% over the first 10 hr and then declined, returning to near the initial value by the second day. It was relatively constant past this point—up to 150 hr. When these data were compared with similarly obtained data from earlier studies involving two strains of mice, the Swiss mouse and a hairless mouse mutant, parallelism was noted in the behavior of the rat and Swiss mouse skins, which set them both apart from the behavior of the skin of the hairless mouse. The comparison suggests that, irrespective of animal species, the development of a thick coat of hair occurs with commensurate functional changes in the chemical barrier properties of the epidermis.

Keyphrases □ Permeability—hydration and percutaneous absorption, influence on *n*-alkanol through rat skin, Swiss and hairless mice comparison □ Hydration—percutaneous absorption, influence on *n*-alkanol permeation through rat skin, Swiss and hairless mice comparison □ Absorption—hydration, influence on *n*-alkanol through rat skin, Swiss and hairless mice comparison

The relative influences of moisture absorption and retention on different animal skins serves as one point of comparison of the skins and, therefore, is a factor to be considered when animals are to be used instead of human subjects in percutaneous absorption research. In recent studies the permeabilities of the skins of two strains of laboratory mice affected by protracted immersion in an isotonic saline medium were explored (1–3). Permeability, and its alteration by these extreme hydrating conditions, was shown to be dependent on the strain of mouse chosen and, within a strain, on the chemical structure of the permeant. This had mechanistic implications with regard to the functioning of the Swiss mouse and the hairless mouse ($SKh\text{-}hr^{-1}$) skins as chemical barriers. The strikingly different behaviors noted between these two strains were presumed primarily to be related to the disparity in abundance and prominance of hair and, possibly, to a change in the relative importance of the transepidermal and transfollicullar routes. It could be assumed further that the absorption behaviors of animal skins may be related more to the similarity of their coats than to the species involved, but this has yet to be proven.

Therefore, the present study was undertaken to assess the effect of hydration on the permeability of rat skin using several of the same reference permeants and under identical conditions as in the mouse experiments. The diffusional behaviors of the hairy skins of the Swiss mouse and Sprague-Dawley rat proved to be somewhat similar and set apart from that of the hairless mouse. This has implications for the choice of animals used for certain dermatological research.

EXPERIMENTAL

Chemicals—[^{3}H]methanol[1], [^{14}C]butanol[2], and [^{14}C]hexanol[2] were used as received. The radiochemicals were diluted with 0.9% sodium chloride irrigation medium[3] (saline) for the permeation experiments. The final chemical concentrations in the diffusional medium were $\leq 10^{-4}$ *M*.

Animals—Sprague-Dawley adult male rats (~300 g) were used. They had free access to food and water. All skins used in the permeation experiments were denuded of hair by the nondestructive and nonirritating procedure of close cropping with a pair of surgical scissors (2). Rats have a relatively large skin area, considering that the opening between diffusion cell compartments is on the order of 0.6 cm^2. Therefore, it was possible to take nine or more separate sections of skin from the dorsal surface of the animal, as indicated in the sketch in Table I. Differences in skin site were minimized by this technique, and only a few rats were needed to complete the study.

Permeation Procedure—Two-compartment glass diffusion cells (1) were employed to determine skin permeability. Ten skin sections were excised from the dorsal surface of one rat, sacrificed by administering sodium pentobarbital. The external medium of the diffusion cell was saline. The half-cell contents were stirred at 150 rpm. All experiments were carried out at 37°. Permeation was followed by monitoring the receiver chamber concentration for ~2 hr. The half-cell facing the stratum corneum was always the donor compartment, and the half-cell facing the dermis was always the receiver compartment. Therefore, net diffusion occurred from the stratum corneum to the dermis side. Complete hydration profiles were obtained on each piece of skin by running eight sequential experiments covering up to 150 hr of conditioning, with thorough rinsing done between the runs (1).

Radioisotopic Assay—The concentration of the radiolabeled permeant was determined by placing discrete samples in a scintillation solution[4] and assaying on a liquid scintillation counter[5]. Using the technique of dual labels, methanol–butanol and methanol–hexanol were paired. Methanol thus served as a common solute in both sets of the experiments providing a means of assuring membrane integrity.

Data Analysis—The data were plotted as receiver chamber concentration (in terms of counts per minute) as a function of time. The permeability coefficient was calculated from (3):

$$P = \frac{V}{A}\frac{(dc/dt)}{\Delta C} \qquad \text{(Eq. 1)}$$

where P is the permeability coefficient in centimeters per hour, A is the diffusional area (~0.6 cm^2), ΔC is the concentration difference across

the membrane, which was taken to be equal to the donor concentration (cpm), V is the half-cell volume (1.4 ml), and dc/dt is the quasi steady-state slope (cpm/cm^3/hr).

RESULTS

Figure 1 contains a representative set of eight subplots obtained in sequential permeation experiments carried out on one piece of skin over 150 hr of hydration using [^{3}H]methanol and [^{14}C]hexanol as dual permeants. A linear relationship between the receiver concentration *versus* time is indicative of good approximation of steady-state transport conditions. Also, the lag times do not seem to change with hydration time. This is consistent with the permeation behavior reported for hairless (1, 3) and Swiss (2) mice. Slopes of these linear plots were used to compute permeability coefficients.

Table I contains the individual and average permeability coefficients of methanol as a function of hydration time. Both sets of methanol data, one run with butanol as the copermeant and the second run with hexanol as the copermeant, are presented. Tables II and III contain similar data for butanol and hexanol, respectively.

From data reported in Tables I–III, the percent change in permeability at any time relative to the permeability at time zero was computed (2). (The first diffusional run began immediately after placing a skin section in the diffusion cell.) These changes are reported in Figs. 2–4 for each of the permeants in terms of the percent change as a function of hours of hydration.

DISCUSSION

Effect of Hydration on Alkanol Permeation—The permeability coefficient of methanol through rat skin approaches an asymptote 2.5 times the initial value (150% hydration influence) as a function of time, with the limiting value essentially obtained at the 80-hr point (Fig. 2).

[a] 
Dorsal surface of the rat.

With hairless mouse skin, the methanol permeability coefficient was unaffected by such conditioning (1). The behavior of rat skin to methanol, however, is qualitatively similar to that previously seen for the Swiss mouse (2). In the latter strain of mouse, the methanol permeability coefficient was increased by 80% (1.8 times) by hydration, with the effect leveling out by ~20 hr.

In the rat, the butanol permeability coefficient appeared to be increased marginally by hydration (20–25%) with the effect noted as early as 5 hr (Fig. 3). The permeability coefficient then appeared invariant up to 78 hr. This contrasts with the hairless mouse where a doubling of the parameter took place over the first 10 hr of experimentation (1) and with the Swiss mouse where a slightly greater than twofold increase was noted by 15 hr (2). In the Swiss mouse skin, the permeability coefficient appears to gradually and linearly decrease past 15 hr, so that the increase at the end of the second full day measured only 85%.

In the rat, hexanol permeation appears to have a unique hydration dependency (Fig. 4). Over the first 10 hr of saline immersion, the permeability coefficient appears to increase. There is, on the average, a 44% enlargement at the 10-hr point. The trend then reverses, with a systematic return to the initial, baseline value by 78 hr. In the hairless mouse hexanol behaves as butanol; there is a twofold increment which is largely complete by 10 hr. No data were obtained for hexanol passing through Swiss mouse skin.

The up and down type of pattern, apparent for butanol in the Swiss mouse and for hexanol in the rat, surfaces in the hairless mouse skin at an alkanol alkyl chain length of 8 (*n*-octanol). The absolute values of the alkanol permeability coefficients through rat skin increase from methanol to hexanol. Taking the permeability coefficients after 10 hr of conditioning as representative, the average values are 3.2×10^{-3} cm/hr for methanol, 6.4×10^{-3} cm/hr for butanol, and 13.5×10^{-3} cm/hr for hexanol. The ratio of the hexanol and methanol values of ~4 indicates a marginal dependency of permeation on hydrophobicity through the series. By way of comparison, the factor at 10 hr of hydration in the hairless mouse is >20, pointing to a more acute lipid–water partitioning reliance of the permeation process in this tissue (1).

[a] See Table I.

Significance of the Findings—It is difficult to interpret these collective observations, but the following factors affect the permeation process. The development of a coat of hair generally is accompanied by thickening of the skin, especially its dermal elements in which the follicles are anchored. This magnifies the diffusional importance of the living and functionally aqueous strata beneath the stratum corneum when these are a part of the membrane mounted in the diffusion cell. Thus, it is to be expected that the thicker skins of the furry animals will have earlier onset of rate control by the viable epidermal and the dermal strata with increasing hydrophobicity (as the alkyl chain is extended) and that the limiting rate of diffusion as aqueous tissue control is approached will also be lower; each appears to be the case.

This in part explains the more compressed range of permeability coefficient values for the alkanols in the full thickness Swiss mouse and rat skins. This influence of the thickened subcorneal elements creates a false impression of permeability of the skin in that in the living animal the peripheral blood flow collects permeant at the immediate undersurface of the epidermis, eliminating much of the diffusional resistance experienced in the nonblood perfused skins of *in vitro* measurement.

Strata thickness variations cannot explain the different hydration sensitivities of methanol permeation through the skin of the hairless mouse and the furry integuments as the permeability coefficients are small, signifying rate control by strata elsewhere in the skins. For the hairless mouse, stripping (4) and other experiments (5–7) establish the stratum corneum as the principal source of diffusional resistance for methanol. Also, both the alkanol alkyl chain length profile and the hydration effect data for the hairless mouse tissue indicate that this solute finds some pathway through the skin which is around rather than through the lipid domains of the horny layer. Thus, it is possible to conclude that the hairy epidermises function differently as barriers to methanol. The

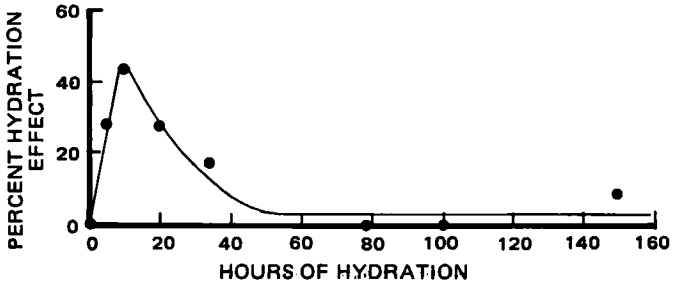

Figure 4—*Plot of percent hdyration effects* versus *hydration time for hexanol.*

difference centers around the increased prominence and number of hair follicles. Probably diffusion across the transfollicular shunt is greatly enhanced, to the point where it becomes the principal pathway. The horny layer of the epidermis is also affected by the formation of a thick coat of hair. Since the hairy mat restricts insensible perspiration, the stratum corneum associated with furry skin need not be as impermeable to water, and it is typically thinner and less well formed than when the surface is hairless. Thus, structural and compositional changes in the horny layer also provide a basis for explaining the differing hydration sensitivities. It is likely that both factors are important.

This study provides further evidence of intra- and interspecies complexities of animal skins as mass transport regulators. To a degree it demonstrates that skins covered with thick coats of hair do not behave diffusionally as hairless skins, whether of mouse or humans. Previous work (1–8) indicates a high degree of parallelism in the chemical barrier properties of hairless mouse and human skins. This study adds support for the use of hairless animals for research on percutaneous absorption, primary irritancy, topical drug delivery, *etc.*, when it is not possible or practicable to use human subjects.

NOTES

In Vitro Adsorption of Phenobarbital onto Activated Charcoal

KARAMAT A. JAVAID ˣ **and BUTHAINA H. EL-MABROUK**

Received June 15, 1981, from the *Department of Pharmaceutics, Faculty of Pharmacy, Al-Fateh University, Tripoli, Libya (SPLAJ).* Accepted for publication January 29, 1982.

Abstract □ *In vitro* experiments were performed to determine the extent and duration of adsorption and desorption of phenobarbital onto and from activated charcoal in solutions of various pHs. The results of studies supported the evidence of the effectiveness of charcoal as an adsorbent. Adsorption was dependent upon the quantity of charcoal used. With amounts of charcoal ≥0.5 g, adsorption was complete within 60 min. Desorption was rapid, quantity dependent, and pH independent. The results of adsorption isotherms indicated no change in binding capacity of the drug from solutions of different pH.

Keyphrases □ Phenobarbital—*in vitro* adsorption onto activated charcoal, desorption, binding □ Adsorption, *in vitro*—phenobarbital onto activated charcoal, desorption, binding

The importance of activated charcoal cannot be overemphasized as an emergency treatment in drug poisoning. Activated charcoal given orally as a slurry can effectively adsorb and hold many drugs such as alkaloids, glycosides, and barbiturates (1). Acute barbiturate poisoning is common and it accounts for ~1500 deaths annually in the United States (2). Barbiturates are the second most frequent cause of poisoning in children (3).

Phenobarbital is one of the major barbiturates used in many products as a sedative–hypnotic and antiepileptic agent. It has a therapeutic range of 0.03–0.6 g daily in divided doses, and its potential for poisoning is great, having a fatal range of 1–10 g (4). Data collected on the use of phenobarbital in adsorption studies with activated charcoal can be useful.

A slurry of activated charcoal given 30 min after hypnotic doses of phenobarbital or glutethimide resulted in a plasma drug concentration at least 50% lower in treated than in untreated dogs, even when charcoal was allowed to pass through the entire GI tract (5). Adsorbed material is retained tenaciously throughout passage in the gut. There is a concern that part of the poison in the intestine may later be released because of less favorable pH conditions. It was found that the reduction in the amount of available poison is markedly high as compared to insignificant elution of the poison in the intestine (6). Administration of large amounts of activated charcoal is considered to be a routinely useful procedure. In view of the delayed emetic action of ipecac syrup, there is an increasing speculation that activated charcoal may be of more importance as an emergency treatment for accidental poisoning. Recent studies (7–9) have shown the importance of adsorption of different drugs onto activated charcoal.

The purpose of this study was to investigate and understand the extent of adsorption of phenobarbital sodium

0022-3549/83/0100-0082$01.00/0

difference centers around the increased prominence and number of hair follicles. 0022-3549/83/0100-0082$01.00/0

Table I—Percent of Phenobarbital Desorbed at the End of 2 hr from Various Concentrations of Activated Charcoal [a] by Solutions of Various pH

pH	Charcoal Concentration, g			
	0.1	0.5	0.7	1.0
1.2	54.0	4.61	0.88	0.59
4.0	52.3	4.55	1.64	1.69
8.0	51.5	3.87	1.82	0.91

[a] For prior adsorption, different charcoal amounts were equilibrated for 2 hr with standard solution of phenobarbital sodium at pH 1.2.

onto activated charcoal as related to the effect of time, duration of equilibrium, extent of desorption, and the pH of the medium.

EXPERIMENTAL

Materials—Phenobarbital sodium BP[1] solutions, 1 mg/ml, were prepared with the following vehicles: simulated gastric fluid, USP, without pepsin, pH 1.2; McIlvaine's citrate–phosphate buffer, pH 4.0; phosphate buffer USP, pH 6.0; alkaline borate buffer USP, pH 8.0 and 9.6.

Analysis—Concentrations of phenobarbital calculated as phenobarbital sodium were determined by diluting the samples with alkaline borate buffer pH 9.6 and reading them on a spectrophotometer[2] at 240 nm.

Adsorption—Various amounts of activated charcoal[3] (0.1–1.0 g) were shaken for different time intervals, each with 50 ml of the standard phenobarbital sodium solution with pH values of 1.2, 4.0, 6.0, and 8.0. The suspensions were shaken at 44 rpm in a water bath at 37.5°. Samples were periodically removed, filtered through a double filter, and assayed. For adsorption isotherms, suspensions of 50 mg of charcoal were shaken with 50 ml of 0.02, 0.03, 0.05, 0.075, 0.09, and 0.1% solutions of the drug for 24 hr. Suspensions were filtered and the filtrate assayed.

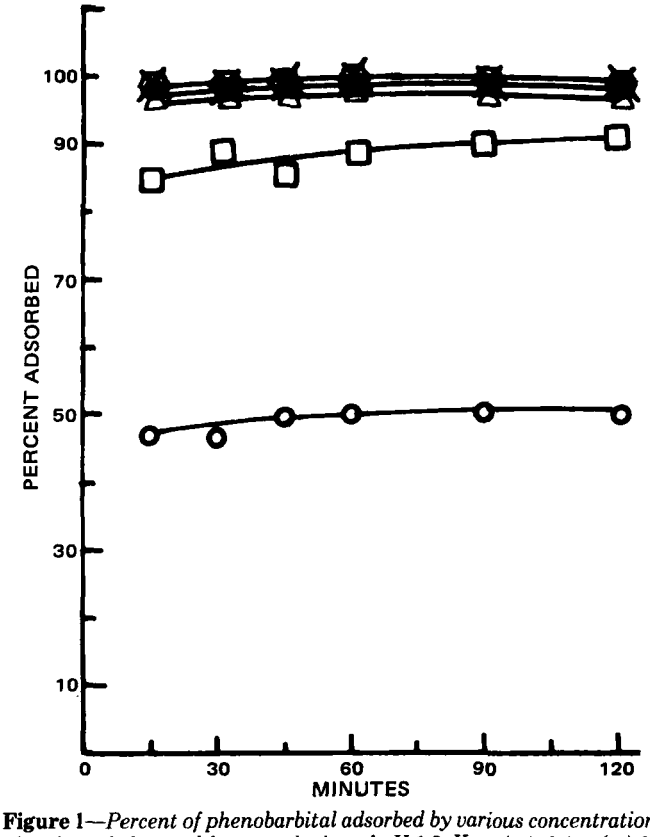

Figure 1—*Percent of phenobarbital adsorbed by various concentrations of activated charcoal from a solution of pH 1.2. Key: (○), 0.1 g; (□) 0.3 g; (△) 0.5 g; (●) 0.7 g; (×) 0.9 g; (○) 1.0 g.*

Table II—Value of Constants of Langmuir Adsorption Isotherms at 37.5° in Solutions of Various pH

pH	Slope (n)	Adsorption Capacity $\left(\frac{1}{n}\right)$, mg	Intercept (b)	Correlation Coefficient (r)
1.2	3.42	292	0.62	1.00
4.0	3.76	265	0.65	1.00
6.0	3.86	259	0.86	1.00
8.0	3.83	261	1.17	1.00

Desorption—Various amounts of charcoal powder were equilibrated for 2 hr with the standard solution of phenobarbital sodium at pH 1.2. Two hours was selected for equilibrium during adsorption studies. This time period was found to be sufficient for adsorption to be complete. The samples were centrifuged at 2500 rpm; supernatants were aspirated and assayed. Fifty milliliters of fresh buffers without phenobarbital sodium at pH 1.2, 4.0, and 8.0 was added as an eluting medium to transfer the sediments to the flasks. The suspensions were shaken for 15, 30, 60, and 120 min. The samples were periodically removed, filtered, and assayed.

Particle Size—Average particle diameter for the activated charcoal powder used was 5.1 μm. It was determined by an air permeability device[4].

RESULTS AND DISCUSSION

Activated charcoal is a potent adsorbent that rapidly inactivates many poisons if administered before much absorption of poison has taken place. The rapid and marked effectiveness of activated charcoal *in vivo* emphasizes the potential usefulness of this antidote in the management of acute poisoning due to a rapidly absorbed chemical agent. Adsorption

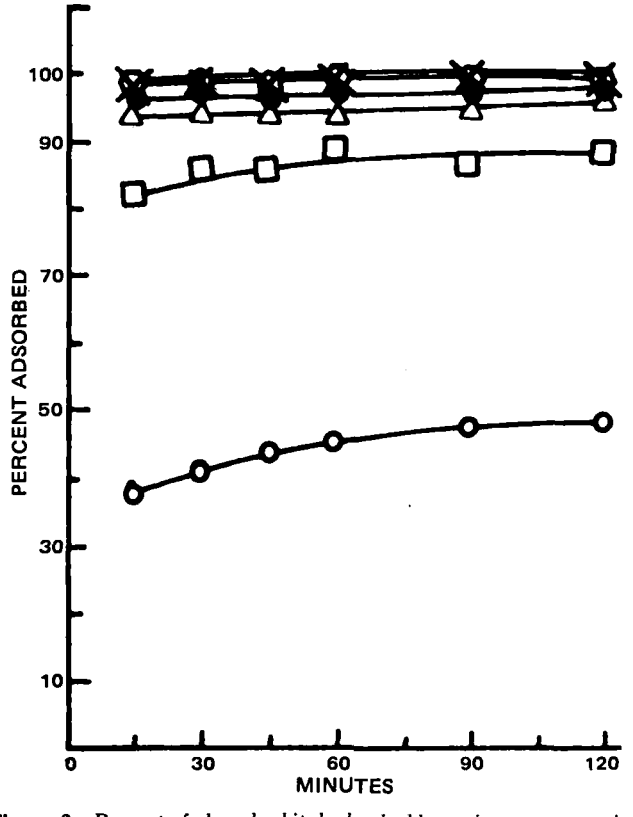

Figure 2—*Percent of phenobarbital adsorbed by various concentrations of activated charcoal from a solution of pH 4.0. Key: (○) 0.1 g; (□) 0.3 g; (△) 0.5 g; (●) 0.7 g; (×) 0.9 g; (○) 1.0 g.*

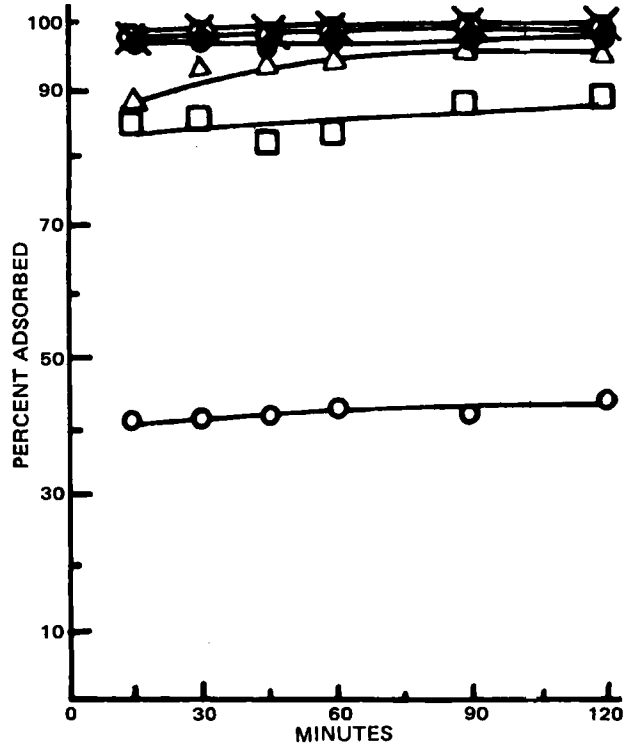

Figure 3—*Percent of phenobarbital adsorbed by various concentrations of activated charcoal from a solution of pH 6.0. Key: (○) 0.1 g; (□) 0.3 g; (△) 0.5 g; (●) 0.7 g; (×) 0.9 g; (◇) 1.0 g.*

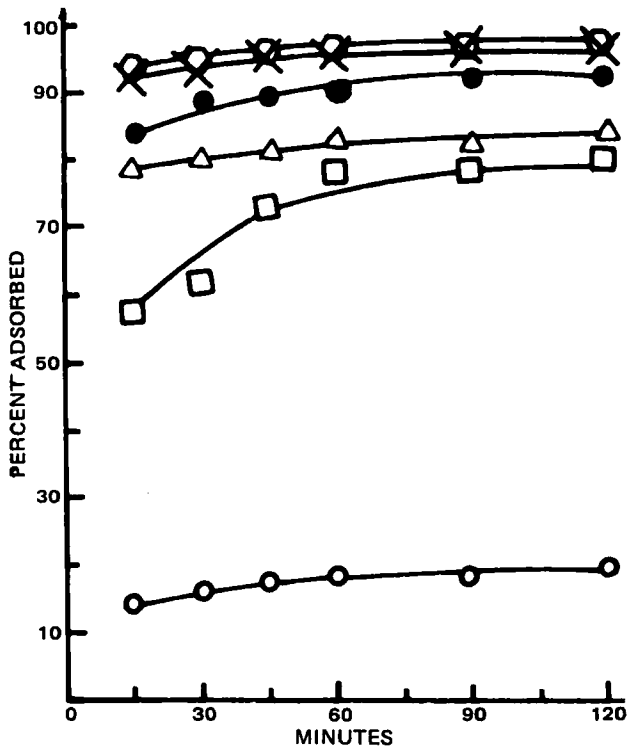

Figure 4—*Percent of phenobarbital adsorbed by various concentrations of activated charcoal from a solution of pH 8.0. Key: (○) 0.1 g; (□) 0.3 g; (△) 0.5 g; (●) 0.7 g; (×) 0.9 g; (◇) 1.0 g.*

experiments were performed to see the amounts of phenobarbital adsorbed onto activated charcoal as a function of time and hydrogen ion concentration.

Figures 1–3 show that an increase in the amount of activated charcoal resulted in higher amounts of phenobarbital adsorbed from solutions of pH 1.2, 4.0, and 6.0. A sudden rise was noted when the amount of charcoal was increased from 0.1 to 0.3 g. In solutions of pH 1.2, 4.0, and 6.0, 0.5 g of charcoal resulted in a moderate increase in the amount of drug adsorbed. As seen in Figs. 1–3, the amount of drug adsorbed by 0.5–1.0 g of charcoal is approximately the same.

As observed from Fig. 4, the amount of phenobarbital adsorbed by 0.1 g of charcoal from a solution of pH 8.0 is significantly lower than from solutions of pH 1.2, 4.0, and 6.0. Even though 0.3 g of charcoal recorded a significantly higher increase in the amount of drug adsorbed from a solution of pH 8.0, the increase was not as high as from solutions of pH 1.2, 4.0, and 6.0. For other amounts of charcoal as 0.5, 0.7, 0.9, and 1.0 g in solutions of pH 8.0, the increase was gradual and about equally distributed as far as the increment in the amount of charcoal is concerned. At pH 8.0, most of the drug exists as ionized molecules. Since adsorption onto charcoal is greater for nonionized compounds, low adsorption values obtained from a solution of pH 8.0 may be due to this reason.

It is evident that most of the phenobarbital was adsorbed onto charcoal within 60 min and adsorption was practically complete with all amounts of charcoal (except 0.1 and 0.3 g) over the pH range tested. Hpwever, the percent of phenobarbital adsorbed was dependent upon the quantity of charcoal used. The adsorption by 0.1 and 0.3 g of charcoal was not complete even at the end of 120 min, but at the 0.5-g level the adsorption was almost complete at the end of 60 min. Further increments of 0.2 g above 0.5 g did not appreciably increase the extent of adsorption in adsorbing the phenobarbital from 50 ml of standard phenobarbital sodium solution.

Desorption studies were performed in solutions of various pHs containing different amounts of charcoal to determine how much of the phenobarbital once adsorbed would be desorbed as a result of a change in the pH of the eluting medium. Table I illustrates the effect of variation of the eluting media pH on the extent of desorption at the end of 2 hr from various concentrations of charcoal. It is evident that 0.1 g of charcoal was not sufficient to hold all of the drug, and ~50% of the drug was eluted. But with 0.5 g and higher amounts of charcoal, the extent of desorption was <5%. These findings substantiate previous results (10, 11) which suggested that the charcoal–poison complex remains stable throughout the GI tract. In general, desorption from lower amounts of charcoal was essentially complete within 15 min, decreased with increasing amounts of charcoal, and was independent of pH. Therefore, it can be summarized that 0.5–0.7 g of charcoal seems to be the optimum quantity at which minimum desorption takes place. Further increments in the amount of charcoal did not significantly contribute to holding the drug particles.

Langmuir adsorption isotherms for the adsorption of phenobarbital calculated as phenobarbital sodium onto charcoal were determined from solutions of various pH. The Langmuir isotherm may simply be defined as:

$$c/(x/m) = nc + b \qquad \text{(Eq. 1)}$$

where c is the concentration of phenobarbital sodium in milligrams per milliliter at equilibrium, x is the amount of drug adsorbed in milligrams per m milligrams of charcoal. The isotherm constants n and b were determined by linear regression analysis at each pH value. Parameters presented in Table II substantiate the theory that no change in binding is indicated at different pH levels (with the numbers under the adsorption capacity column being practically the same), and that these results can possibly be construed to indicate the stability of the charcoal–drug complex throughout the physiological pH range.

Determination of Ciramadol in Plasma by Gas–Liquid Chromatography

SAMUEL F. SISENWINE ˣ, HAZEL B. KIMMEL, CESARIO O. TIO, ANN L. LIU, and HANS W. RUELIUS

Received December 14, 1981, from the *Drug Metabolism Subdivision, Wyeth Laboratories, Inc., Philadelphia, PA 19101.* Accepted for publication February 25, 1982.

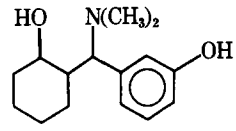
Abstract □ An analytical method for determining ciramadol concentrations in plasma was developed and evaluated for its specificity, precision, linearity, and sensitivity. GLC–electron capture detection of a dipentafluorobenzoyl derivative of the drug was used for quantitation. An isomer of the drug served as an internal standard. Resulting mean ratios of the peak height of derivatized drug to that of derivatized internal standard varied with a coefficient of variation that ranged from 3.8 to 11.1%. The mean ratio was linearly related to ciramadol content (8.75–175 ng) with a correlation coefficient >0.999. The minimum quantifiable concentration was 4 ng/ml with a 2-ml specimen. An application of this method is presented.

Keyphrases □ Ciramadol—analgesics, GLC determination in plasma □ GLC—determination of ciramadol in plasma, analgesics □ Analgesics—GLC determination of ciramadol in plasma

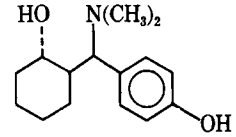
Ciramadol [(−)*cis*-2-(α-dimethyl (I) amino-*m*-hydroxybenzyl)cyclohexanol hydrochloride] is a potent analgesic when administered to animals, and indications of its effectiveness in relieving mild to moderate pain in malignant disease and moderate to severe postoperative pain in humans have been reported (1–3). During previous metabolic disposition studies (4), it was recognized that a very sensitive assay for the drug in biological fluids would be required during preclinical studies and especially when clinical bioavailability studies were performed. Maximum concentrations in the plasma of rats given single 1-mg/kg intragastric doses of the drug were highest (105 ng/ml) at the earliest sampling time (15 min), and when studies were conducted in rhesus monkeys, maximum concentrations in plasma never exceeded 4 ng/ml after a similar dose. In the current report, an assay for ciramadol, which meets the desired requirements, is presented. It is based on the electron-capturing capability of a dipentafluorobenzoylated derivative following a GLC separation.

EXPERIMENTAL

Standards and Reagents—Ciramadol (I) and the internal standard [*trans*-2-(α-dimethylamino-*p*-hydroxybenzyl)cyclohexanol hydrochloride hemiethanolate, II] were synthesized in these laboratories[1]. Deionized water was prepared by passing distilled water through an ion-exchange system[2]. Pentafluorobenzoyl chloride and all other reagents and solvents were purchased from commercial sources.



I



II

Pentafluorobenzoyl chloride was purified by distillation prior to use. The fraction boiling at 158–159° was collected and stored in a sealed container at 5°.

Calibration standards were prepared from a stock solution containing 1 mg of drug/ml of deionized water. Subsequently, solutions containing 0.01, 0.02, 0.05, 0.1, and 0.2 μg of drug/100 μl, or, respectively, 8.75, 17.5, 43.75, 87.5, and 175 ng of free base/100 μl were prepared. All concentrations of ciramadol in biological fluids are expressed as free base.

The concentration of the internal standard solution prepared in water was 100 ng/100 μl.

Preparation of Pentafluorobenzoyl Derivatives—One gram of ciramadol (as free base) was dissolved in 80 ml of benzene and 30 ml of pyridine. To the solution, 2.5 g of pentafluorobenzoyl chloride was added dropwise with stirring at 25° for 2 hr. The reaction mixture was washed with 100 ml each of water, 10% Na_2CO_3, water, 0.5 *N* H_2SO_4, 10% Na_2CO_3, and water. The organic layer was separated, dried over anhydrous sodium sulfate, treated with 2 g of charcoal[3], filtered, and evaporated. A pale yellow syrup was obtained. After treating again with charcoal the syrup was analyzed.

Anal.—Calc. for $C_{29}H_{21}NO_4F_{10}$: C, 54.64; H, 3.32; N, 2.20. Found: C, 54.64; H, 3.44; N, 2.27.

Compound II (200 mg) was dissolved in 16 ml of benzene and 6 ml of pyridine. To the solution, 0.5 g of pentafluorobenzoyl chloride was added dropwise with stirring at 25° for 2 hr. The reaction mixture then was washed sequentially (20-ml portions) and treated with charcoal as described above. After the solvent was removed under reduced pressure, a syrup was obtained. A pale yellow crystalline product precipitated after the syrup was dissolved in warm ethanol and cooled at 4°. The precipitate was collected, recrystallized from ethanol, and dried in air. Yield: 75 mg.

Anal.—Calc. for $C_{29}H_{21}NO_4F_{10}$: C, 54.64; H, 3.32; N, 2.20. Found: C, 54.43; H, 3.49; N, 2.65.

Mass Spectrometry—Mass spectrometric analysis of the two derivatives was performed on a mass spectrometer[4] (electron beam, 70 eV; source temperature, 200°) equipped with a data system[5]. Samples were examined by direct introduction in the electron-impact mode.

Analysis of Ciramadol in Plasma—*Extraction and Derivatization*—Standards (0.01, 0.02, 0.05, 0.1, and 0.2 μg of ciramadol) were added to a series of 16 × 125-mm culture tubes (polytef lined[6] screw cap) containing 1 ml of control (drug free) dog plasma. To each sample was added

[a] Internal standard (100 ng) was added to a 1-ml sample of control dog plasma. [b] Values were obtained by linear regression analysis of known concentrations of ciramadol (as free base) *versus* mean ratios of peak heights.

100 ng of the internal standard in 0.10 ml of water, 1 ml of 5 *N* NH_4OH, and 5 ml of ether. Each sample was mixed thoroughly and centrifuged, and 4 ml of the ether extract was transferred to another tube. The aqueous phase was extracted once more with 5 ml of ether, and the ether phase was combined with the original extract. One ml of 5 *N* acetic acid was added to the combined ether extracts, and the contents were mixed thoroughly and centrifuged. The ether phase was aspirated, and the aqueous extract was washed with 5 ml of ethyl acetate. After aspirating the ethyl acetate wash, any remaining ethyl acetate was removed by heating the aqueous extract in a water bath at 60° for 5 min under flowing nitrogen. Sodium chloride (800 mg), 1 ml of 5 *N* NH_4OH, and 1 ml of toluene were added to each sample. The contents were mixed and centrifuged, and then 0.7 ml of the toluene extract was transferred to a 12 × 75-mm test tube and reacted with 0.10 ml of pyridine and 0.05 ml of pentafluorobenzoyl chloride at 25° for 30 min with shaking after 15 min. The reaction tube containing the mixture was washed with 1 ml of 10% Na_2CO_3, 1 ml of 0.2 *N* H_2SO_4, 1 ml of 10% Na_2CO_3, and 1 ml of water, successively, and refrigerated until analysis by GLC.

GLC Conditions—GLC analyses were performed with a gas–liquid chromatograph[7] equipped with a 1.8 m × 2-mm glass column containing 2% OV-101 Chromosorb W-HP (80/100 mesh)[8]. The column was maintained at 230°, the injection port at 260°, and the electron detector (nickel 63) at 340°. The carrier gas was ultra-high pure nitrogen. The column was pretreated by injecting 4 μl of a toluene–lecithin solution (1 mg/ml).

Calculations—The ratio of the peak heights for derivatized ciramadol to derivatized internal standard at each concentration of the drug in plasma was determined. The line of best fit relating the ratio of peak heights to ciramadol concentration was calculated by a linear regression analysis.

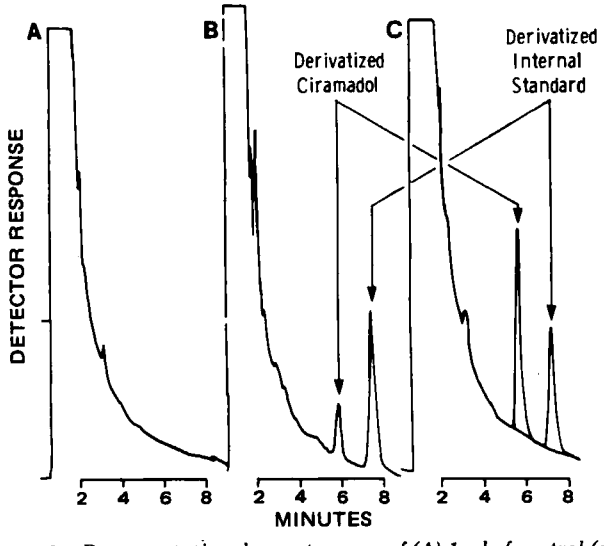

Figure 1—*Representative chromatograms of (A) 1 ml of control (drug free) plasma; (B) plasma sample (1 ml) from a dog given ciramadol; (C) 100 ng of ciramadol and 100 ng of internal standard added to 1 ml of control dog plasma.*

RESULTS

Mass Spectrometry—A mass ion at *m/z* 637 in the mass spectrum of derivatized ciramadol demonstrated that a dipentafluorobenzoyl derivative, which is consistent with the elemental analysis, occurred. The most predominant fragment was observed at *m/z* 344 and represented

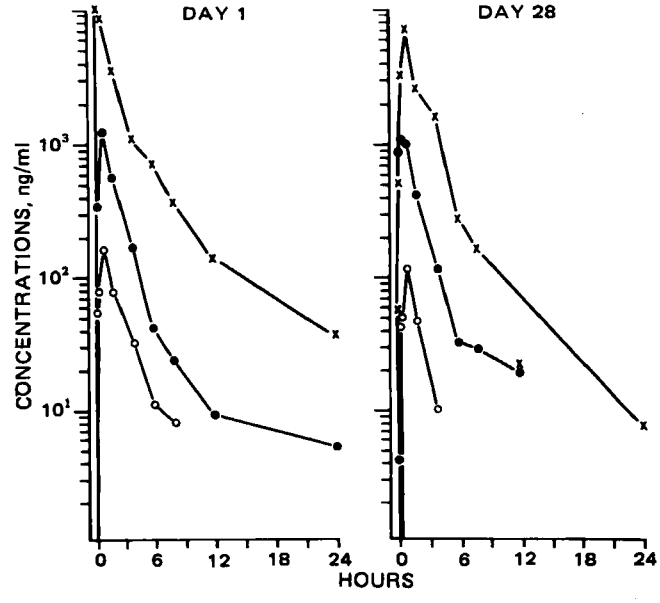

Figure 2—*Mean concentrations of ciramadol in plasma of dogs on day 1 and day 28 following the administration of daily 2- (○), 12- (●), and 72-mg/kg (×) oral doses of ciramadol.*

[7] Varian 3700, Varian Instrument Group, Palo Alto, Calif.

[8] Supelco, Inc., Bellefonte, Pa.

the facile cleavage of the derivative to the fragment $(CH_3)_2\dot{N}{=}CH{-}C_6H_4{-}OCOC_6F_5$. A fragment observed at m/z 195 indicated the loss of a pentafluorobenzoyl moiety. The mass spectrum of the derivatized internal standard was similar.

GLC—The retention time of the derivatized drug and internal standard was 5.8 and 7.6 min, respectively. A representative chromatogram is shown in Fig. 1. No interfering peaks were observed in control (drug free) plasma.

The mean ratio of the peak height for derivatized ciramadol to derivatized internal standard and its coefficient of variation at each concentration of drug added to control plasma (three experiments) is shown in Table I. The coefficient of variation for each mean ratio ranged from 3.8 to 11.1%. Standard curves relating ciramadol concentration to peak height ratio were linear with correlation coefficients ranging from 0.9995 to 1.0000. With a 2-ml plasma sample, the minimum quantifiable concentration was 4 ng/ml (as free base).

DISCUSSION

The results of the present study demonstrate that the specificity, linearity, precision, and sensitivity of the GLC assay for ciramadol is satisfactory for measuring the drug in plasma in concentrations >4 ng/ml. This method has been applied to samples obtained in studies on ciramadol disposition in rhesus monkeys, dogs, and humans. Urine specimens have also been analyzed by this procedure. An example of the application of the assay, which demonstrates its utility in a multiple dose study in dogs, is presented in Fig. 2. The assay permitted the observation that multiple dosing did not affect the metabolic disposition of ciramadol in dogs. No peaks interfered with the detection of drug or internal standard in samples obtained from other investigated species.

Other methods of analysis have been attempted but were not pursued for various reasons. These included GLC and HPLC analysis of underivatized ciramadol as well as other nonfluorinated derivatives of ciramadol. None proved to be as sensitive as the described procedure.

GLC–Mass Fragmentographic Determination of Mannitol and Sorbitol in Plasma

TERUYOSHI MARUNAKA ˣ, EIJI MATSUSHIMA, YUKIHIKO UMENO, and YOSHINORI MINAMI

Received September 18, 1981, from the *Research Laboratory, Taiho Pharmaceutical Co., Ltd., Kawauchi-cho, Tokushima, 771-01, Japan.* Accepted for publication February 25, 1982.

Abstract □ A GLC–mass fragmentographic method was developed for the simultaneous determination of mannitol and sorbitol as their *n*-butyldiboronate derivatives in plasma. The plasma sample was deproteinized, and the subsequent supernatant was concentrated to dryness; the resulting residue was then dissolved in pyridine containing *n*-butylboronic acid to allow derivation. An aliquot of this solution was injected into the gas chromatograph–mass spectrometer and analyzed by a selected-ion monitoring method using galactitol as the internal standard. Detection was limited to 20 ng/0.1 ml of plasma for both mannitol and sorbitol. A rapid, precise, and sensitive assay for the determination of mannitol and sorbitol in plasma was established.

Keyphrases □ Mannitol—GLC–mass fragmentographic analysis in plasma □ Sorbitol—GLC–mass fragmentographic analysis in plasma □ GLC–mass fragmentography—analysis, mannitol and sorbitol in plasma □ Hexiol—mannitol and sorbitol in plasma, GLC–mass fragmentographic analysis

Mannitol and sorbitol (glucitol) have been used as artificial sweeteners in pharmaceutical preparations.

Many methods employing GLC with a flame ionization detector have been reported for the determination of common hexitols. Authentic samples of mannitol and sorbitol have been analyzed by this GLC method in studying the acetyl (1–7), trifluoroacetyl (8, 9), trimethylsilyl (10), phenyldiboronate (11), and *n*-butyldiboronate derivatives (12). However, the mannitol and sorbitol contents were determined (13) in pharmaceuticals as their *n*-butyldiboronate derivatives. Mannitol, sorbitol, and other polyols were assayed (14) in human plasma or cerebrospinal fluid as their acetyl derivatives. Furthermore, mannitol was measured (15) in body fluids as an *n*-butyldiboronate derivative.

However, these GLC methods indicate several problems in determining mannitol and sorbitol in plasma samples, such as poor sensitivity or the influence of glucose pooled in plasma. Thus, a GLC–mass fragmentographic determination of mannitol and sorbitol in plasma was examined, and a rapid, precise, and sensitive analytical method for their assay was established. The present method was also found applicable to other human biological fluids.

EXPERIMENTAL

Materials—Mannitol[1], sorbitol[1], galactitol[1] (dulcitol), zinc sulfate[1], barium hydroxide[1], and other chemicals used were obtained commercially. *n*-Butylboronic acid[2] and pyridine[3] were derivating agents for *n*-butyldiboronate formation.

GLC–Mass Fragmentographic Conditions—A mass spectrometer[4] with an electron-impact ion source connected to a gas chromatograph[5] was used.

The coiled glass column (1 m × 2-mm i.d.) of the gas chromatograph was packed with 3% OV-17 on Chromosorb W-AW, 80–100 mesh[6] and conditioned at 280° for 24 hr. The temperatures of the injector, column,

the facile cleavage of the derivative to the fragment $(CH_3)_2\dot{N}{=}CH{-}C_6H_4{-}OCOC_6F_5$. A fragment observed at m/z 195 indicated the loss of a pentafluorobenzoyl moiety. The mass spectrum of the derivatized internal standard was similar.

GLC—The retention time of the derivatized drug and internal standard was 5.8 and 7.6 min, respectively. A representative chromatogram is shown in Fig. 1. No interfering peaks were observed in control (drug free) plasma.

The mean ratio of the peak height for derivatized ciramadol to derivatized internal standard and its coefficient of variation at each concentration of drug added to control plasma (three experiments) is shown in Table I. The coefficient of variation for each mean ratio ranged from 3.8 to 11.1%. Standard curves relating ciramadol concentration to peak height ratio were linear with correlation coefficients ranging from 0.9995 to 1.0000. With a 2-ml plasma sample, the minimum quantifiable concentration was 4 ng/ml (as free base).

DISCUSSION

The results of the present study demonstrate that the specificity, linearity, precision, and sensitivity of the GLC assay for ciramadol is satisfactory for measuring the drug in plasma in concentrations >4 ng/ml. This method has been applied to samples obtained in studies on ciramadol disposition in rhesus monkeys, dogs, and humans. Urine specimens have also been analyzed by this procedure. An example of the application of the assay, which demonstrates its utility in a multiple dose study in dogs, is presented in Fig. 2. The assay permitted the observation that multiple dosing did not affect the metabolic disposition of ciramadol in dogs. No peaks interfered with the detection of drug or internal standard in samples obtained from other investigated species.

Other methods of analysis have been attempted but were not pursued for various reasons. These included GLC and HPLC analysis of underivatized ciramadol as well as other nonfluorinated derivatives of ciramadol. None proved to be as sensitive as the described procedure.

GLC–Mass Fragmentographic Determination of Mannitol and Sorbitol in Plasma

TERUYOSHI MARUNAKA ˣ, EIJI MATSUSHIMA, YUKIHIKO UMENO, and YOSHINORI MINAMI

Received September 18, 1981, from the *Research Laboratory, Taiho Pharmaceutical Co., Ltd., Kawauchi-cho, Tokushima, 771-01, Japan.* Accepted for publication February 25, 1982.

Abstract □ A GLC–mass fragmentographic method was developed for the simultaneous determination of mannitol and sorbitol as their *n*-butyldiboronate derivatives in plasma. The plasma sample was deproteinized, and the subsequent supernatant was concentrated to dryness; the resulting residue was then dissolved in pyridine containing *n*-butylboronic acid to allow derivation. An aliquot of this solution was injected into the gas chromatograph–mass spectrometer and analyzed by a selected-ion monitoring method using galactitol as the internal standard. Detection was limited to 20 ng/0.1 ml of plasma for both mannitol and sorbitol. A rapid, precise, and sensitive assay for the determination of mannitol and sorbitol in plasma was established.

Keyphrases □ Mannitol—GLC–mass fragmentographic analysis in plasma □ Sorbitol—GLC–mass fragmentographic analysis in plasma □ GLC–mass fragmentography—analysis, mannitol and sorbitol in plasma □ Hexiol—mannitol and sorbitol in plasma, GLC–mass fragmentographic analysis

Mannitol and sorbitol (glucitol) have been used as artificial sweeteners in pharmaceutical preparations.

Many methods employing GLC with a flame ionization detector have been reported for the determination of common hexitols. Authentic samples of mannitol and sorbitol have been analyzed by this GLC method in studying the acetyl (1–7), trifluoroacetyl (8, 9), trimethylsilyl (10), phenyldiboronate (11), and *n*-butyldiboronate derivatives (12). However, the mannitol and sorbitol contents were determined (13) in pharmaceuticals as their *n*-butyldiboronate derivatives. Mannitol, sorbitol, and other polyols were assayed (14) in human plasma or cerebrospinal fluid as their acetyl derivatives. Furthermore, mannitol was measured (15) in body fluids as an *n*-butyldiboronate derivative.

However, these GLC methods indicate several problems in determining mannitol and sorbitol in plasma samples, such as poor sensitivity or the influence of glucose pooled in plasma. Thus, a GLC–mass fragmentographic determination of mannitol and sorbitol in plasma was examined, and a rapid, precise, and sensitive analytical method for their assay was established. The present method was also found applicable to other human biological fluids.

EXPERIMENTAL

Materials—Mannitol[1], sorbitol[1], galactitol[1] (dulcitol), zinc sulfate[1], barium hydroxide[1], and other chemicals used were obtained commercially. *n*-Butylboronic acid[2] and pyridine[3] were derivating agents for *n*-butyldiboronate formation.

GLC–Mass Fragmentographic Conditions—A mass spectrometer[4] with an electron-impact ion source connected to a gas chromatograph[5] was used.

The coiled glass column (1 m × 2-mm i.d.) of the gas chromatograph was packed with 3% OV-17 on Chromosorb W-AW, 80–100 mesh[6] and conditioned at 280° for 24 hr. The temperatures of the injector, column,

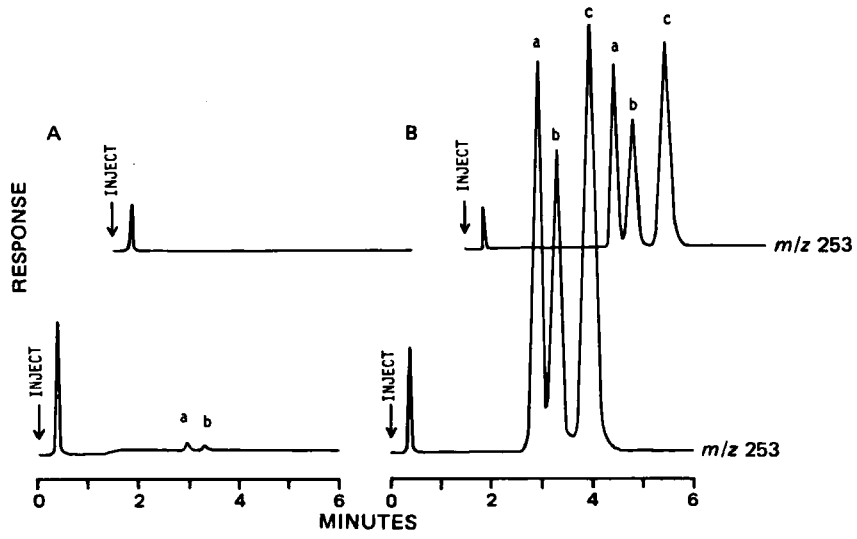

Figure 1—*GLC–mass fragmentograms of human control plasma (A) and human plasma prepared following addition of authentic samples at 500 ng/0.1 ml for each compound (B). Results are for the n-butyldiboronate derivatives and are recorded under two different attenuators. Key: (a) mannitol; (b) sorbitol; and (c) galactitol (internal standard).*

and ion source were 280, 270, and 250°, respectively. Helium was used as the carrier gas at a flow rate of 30 ml/min.

For mass fragmentography the mass spectrometer was set at the following conditions: ionization energy, 70 eV; ionization current, 300 μA; accelerating voltage, 3.0 kV; and ion multiplier voltage, 1.2–1.4 kV. The peak of *m/z* 253 for each *n*-butyldiboronate derivative of mannitol, sorbitol, and the internal standard galactitol was selected for mass fragmentographic analysis. The chromatograms were recorded under four different attenuators (1, 2, 5, and 10×10^2).

The mass spectra of the *n*-butyldiboronate derivatives of mannitol, sorbitol, and galactitol were measured under the same GLC–MS conditions.

Analytical Procedure—Blood samples were collected in heparinized containers and centrifuged to separate the plasma. The plasma then was frozen until analysis.

The plasma (0.1 ml) was diluted with 1.0 ml of 0.13 *M* $ZnSO_4$ and 0.1 ml of aqueous solution containing 100 ng of galactitol (internal standard) and mixed well. To this suspension 1.0 ml of 0.125 *M* $Ba(OH)_2$ was then added, mixed again, and centrifuged at 2000×*g* for 15 min to remove the precipitates. The supernatant was concentrated to dryness under nitrogen gas at 50° or in a freezing desiccator. The residue was dried thoroughly over phosphorus pentoxide under reduced pressure and subjected to *n*-butyldiboronate derivation at room temperature for a few minutes by the addition of ~10–15 mg of *n*-butylboronic acid and 100 μl of pyridine. Analyses by GLC–mass fragmentography were carried out on 1–3-μl samples of the resultant solution.

Calibration Curves—Calibration curves were prepared by adding known amounts of mannitol and sorbitol to plasma and then assaying the mixture by the same extraction procedure.

The calibration curves for the determination of mannitol and sorbitol by GLC–mass fragmentography were obtained by plotting the ratio of the peak heights of the respective *n*-butyldiboronate derivatives to that of the *n*-butyldiboronate derivatives of the internal standard, galactitol, against the concentration of each compound. These calibration curves were linear.

RESULTS AND DISCUSSION

To obtain suitable derivatives of mannitol and sorbitol for GLC separation with a flame ionization detector, various derivation procedures were examined on the basis of previous reports (1–15). The silylation procedure enabled rapid progress, but this method did not provide a good chromatographic separation. Although the acetylation procedures gave a suitable chromatographic separation, it was somewhat time consuming. The *n*-butyldiboronate derivation procedure, however, was completed almost immediately, gave excellent chromatographic separation, and was capable of providing quantitative results as reported previously (12, 13, 15). Consequently, the derivation procedure of *n*-butyldiboronate was used in the present experiments.

Since the *n*-butyldiboronate derivatives of mannitol and sorbitol are poorly separated from those of glucose and fructose on a gas-liquid chromatograph, two methods for removing glucose and fructose from plasma were examined (12, 15). One method involved a complicated procedure by transforming the glucose and fructose to their phosphate derivatives (14); however, the excess phosphoric acid hindered the formation of the *n*-butyldiboronate derivative of mannitol and sorbitol. Another method using hydrogenation of glucose and fructose with sodium borohydride (15) or sodium amalgam converted glucose to sorbitol, while fructose produced equal amounts of mannitol and sorbitol. As these methods were not suitable to remove the glucose and fructose, these two sugars were not removed from the plasma samples.

Plasma samples containing glucose and fructose were deproteinized with zinc sulfate followed by the addition of barium hydroxide to remove the surplus zinc sulfate. The supernatant obtained by centrifugation without removing glucose and fructose was dried and subjected to the *n*-butyldiboronate derivation with *n*-butylboronic acid and pyridine. An aliquot of the resultant solution was then injected into the gas chromatograph–mass spectrometer.

Galactitol, a hexitol, was chosen as the internal standard for the simultaneous determination of mannitol and sorbitol by a selected-ion detection technique. This internal standard can also form an *n*-butyl-

B	1.096 (6.02)	1.030 (5.65)
C	0.741 (4.07)	0.814 (4.47)
D	0.872 (4.79)	0.902 (4.95)
E	0.793 (4.35)	0.961 (5.27)
F	0.720 (3.95)	0.788 (4.33)
G	1.055 (5.79)	1.019 (5.59)
H	1.098 (6.02)	1.159 (6.36)
I	0.546 (3.00)	0.729 (4.00)
J	0.614 (3.37)	0.596 (3.27)
Mean ± *SD*	0.892 ± 0.248 (4.90 ± 1.61)	0.923 ± 0.186 (5.06 ± 1.01)

diboronate derivative in the same way as mannitol and sorbitol (12), and the mass spectrum of this derivative is similar to that of the mannitol or sorbitol derivative. The mass fragment ion detected for GLC–mass fragmentography was the *m/z* 253 ion $[C_4H_5O_4B_2(C_4H_9)_2]^+$, since no influence of glucose, fructose, or other plasma constituents could be observed. This *m/z* 253 ion is a characteristic fragment ion formed from the molecular ion, *m/z* 380 $[C_6H_8O_6B_3(C_4H_9)_3]^+$, of each compound by loss of $C_2H_3O_2BC_4H_9$ and is not observed in the mass spectra of glucose and fructose. The GLC–mass fragmentography monitoring molecular ions or base peaks, *m/z* 127 $[C_2H_3O_2BC_4H_9]^+$, showed poor sensitivity and was mainly affected by glucose in certain samples.

To overcome the difficulties in the determination of samples containing high concentrations of mannitol and sorbitol, the ion multiplier voltage of the mass spectrometer was run at ranges from 1.2 to 1.4 kV, or the reactive solution was diluted. On the other hand, the method of simultaneous detection by a combination of GLC–mass fragmentography and GLC–mass spectrometry for total ion monitoring could not be adopted, since the latter method provided poor sensitivity, as was also the case for the GLC method with a flame ionization detector.

Known amounts of mannitol and sorbitol were added to human plasma, and the samples were analyzed. The chromatogram by GLC–mass fragmentography of the *n*-butyldiboronate derivatives of mannitol, sorbitol, and the internal standard, galactitol, prepared from human plasma following addition of authentic samples at 500 ng/0.1 ml for each compound and the chromatogram of the extract of human plasma control are shown in Fig. 1. The retention times of mannitol, sorbitol, and galactitol as their *n*-butyldiboronate derivatives were 3.0, 3.3, and 4.0 min, respectively, and the time required for the assay was ~5.0 min. As summarized in Table I, the recoveries from plasma were 93.1 ± 1.3% for mannitol and 93.2 ± 1.4% for sorbitol.

The detection limit for both mannitol and sorbitol using this GLC–mass fragmentographic method was 20 ng/0.1 ml for plasma. The reproducibility of this method was ±1.7–2.3%.

In addition, the following experiment was conducted. The *n*-butyldiboronate derivatives of mannitol, sorbitol, and galactitol prepared from human plasma were examined at room temperature and 5° under nitrogen gas for stability. As shown in Table II, it was found that no significant difference between the concentrations of the hexitol derivatives in the control and test samples could be observed over a period of several days.

The present method was also applied to other human biological fluids (*e.g.*, urine, cerebrospinal fluid, ascites fluid, bile, or lymph). The results obtained for the GLC–mass fragmentographic separations, recoveries, and sensitivities were in good agreement with those obtained with plasma. This method may also find application in the biological fluids of animals.

Table III shows the results obtained by the present GLC–mass fragmentography for the concentrations of mannitol and sorbitol present in the plasma of 10 healthy males. The quantitative results are the scope of this study.

The present method utilizing GLC–mass fragmentography for the simultaneous determination of mannitol and sorbitol in plasma is rapid and precise and has higher sensitivity than the GLC method with a flame ionization detector (1–15). Furthermore, small amounts of samples (0.1 ml) can be assayed.

Thus, this method should be useful or helpful for clinical profiling of various patients (*e.g.*, uremic, diabetic, or neurological) and for clinicopharmacological studies on therapy with mannitol, sorbitol, or mannitol plus fructose, which is an osmotherapeutic agent for treating increased intracranial pressure (16, 17) and urinary disorders (18).

A Simple Radiometric *In Vitro* Assay for Acetylcholinesterase Inhibitors

TOMAS R. GUILARTE, H. DONALD BURNS *x, ROBERT F. DANNALS, and HENRY N. WAGNER, JR.

Received August 10, 1981, from the *Division of Radiation Health Sciences, Department of Environmental Health Sciences, The Johns Hopkins Medical Institutions, Baltimore, MD 21205.* Accepted for publication February 24, 1982. * Present address: Johns Hopkins University, Baltimore, MD 21211.

Abstract □ A radiometric method for screening acetylcholinesterase inhibitors has been described. The method is based on the production of [^{14}C]carbon dioxide from the hydrolysis of acetylcholine. The inhibitory concentration at 50% (IC_{50}) values for several known acetylcholinesterase inhibitors were in agreement with literature values. The new radiometric method is simple, inexpensive, and has the potential for automation.

Keyphrases □ Acetylcholinesterase inhibitors—a simple radiometric *in vitro* assay □ Radiometric method—*in vitro* assay for acetylcholinesterase inhibitors

Acetylcholinesterase activity and the effect of its inhibitors is measured by the rate of hydrolysis of acetylcholine, its natural substrate (1). The rate of acetylcholine hydrolysis can be measured in a variety of ways; the separation and quantitation of [^{14}C]acetic acid from [^{14}C]-acetylcholine is currently the most commonly used method (2–5). However, this method although sensitive and specific, requires some manual manipulation (*e.g.*, extraction of [^{14}C]acetic acid) in measuring acetylcholinesterase activity or in screening compounds exhibiting an inhibitory effect.

In the present report, an alternative radiometric method that is simple, fast, and has the potential for automation is presented.

EXPERIMENTAL

Materials and Methods—Electric eel (1200 U/ml solid) acetylcholinesterase[1] (acetylcholine acetylhydrolase, EC 3.1.1.7), acetylcholine chloride, neostigmine bromide, physostigmine bromide, and decamethonium bromide were obtained from a commercial source[2]. Phenyltrimethylammonium iodide was synthesized by methylation of *N,N*-dimethylaniline with iodomethane and characterized by melting point, elemental analysis, and IR and PMR spectroscopy. *d*-Tubocurarine chloride[3] and edrophonium chloride[4] were obtained from commercial pharmaceutical sources. [^{14}C]Sodium bicarbonate[5] with a specific activity of 56 mCi/mmole was diluted with deionized water to a specific concentration of 1 μCi/0.1 ml. All other reagents were of reagent chemical grade and commercially available. Twenty-milliliter assay vials[6], aluminum seals[7], and rubber liners[8] were obtained from commercial sources. The electric eel acetylcholinesterase was diluted in 5 m*M* $NaHCO_3$ buffer (pH 8.4) to yield a 0.1 U/μl concentration. This enzyme preparation was stable for several days if stored at −20°. Acetylcholine chloride and the various inhibitors were diluted with 5 m*M* bicarbonate buffer (pH 8.4) prior to assay.

Effect of Acetylcholine Concentration on Acetylcholinesterase Activity—The effect of acetylcholine on acetylcholinesterase activity was studied by varying the acetylcholine concentration, as all other variables were fixed. Acetylcholine standard solutions (4 and 15 m*M*) were made with 5 m*M* sodium bicarbonate buffer (pH 8.4). To 20-ml assay vials, 0.25, 0.5, 1, 0, 2.0, and 3.0 ml of the 4 m*M* acetylcholine standard solution and 1.0, 2.0, 3.0, 4.0, and 5.0 ml of the 15 m*M* acetylcholine standard solution were added. The volume was brought to 5 ml with 5 m*M* sodium bicarbonate (pH 8.4). The final pH of vial contents was 8.0. This gave a 1–75 μmole of acetylcholine/vial range. All vials were capped with aluminum seals, which were fitted with rubber liners, and chilled in ice after which 1 μCi (0.1 ml) of [^{14}C]sodium bicarbonate and 10 μliters of acetylcholinesterase (1 U) were injected. Incubation was carried out at 37° for 30 min. After incubation vials were chilled in ice water prior to measuring [^{14}C]carbon dioxide production. Figure 1 represents the effect of increasing concentration of acetylcholine on acetylcholinesterase activity.

An acetylcholinesterase activity *versus* time curve was obtained to check for linearity. To four 20-ml assay vials, 2 ml of a 30 m*M* acetylcholine solution was added and volume made up to 5 ml with 5 m*M* sodium bicarbonate buffer (pH 8.4). One unit of actylcholinesterase and 1 μCi of [^{14}C]sodium bicarbonate were used. Test vials were incubated at 37° for 15-min intervals after which they were chilled in ice and the [^{14}C]carbon dioxide was measured (Fig. 2).

***In Vitro* Inhibition of Acetylcholinesterase**—To screen each of the known acetylcholinesterase inhibitors, the following experiment was performed.

Control Vials—To 2 ml of a 30 m*M* acetylcholine chloride solution, 3 ml of a 5 m*M* bicarbonate buffer (pH 8.4) was added to make a volume of 5 ml.

Test Vials—To test for the inhibitory effect of the various compounds, a series of vials containing the same amount of acetylcholine as the controls with varying concentrations of inhibitor were prepared and the volume made up to 5 ml with 5 m*M* bicarbonate buffer (pH 8.4). All vials

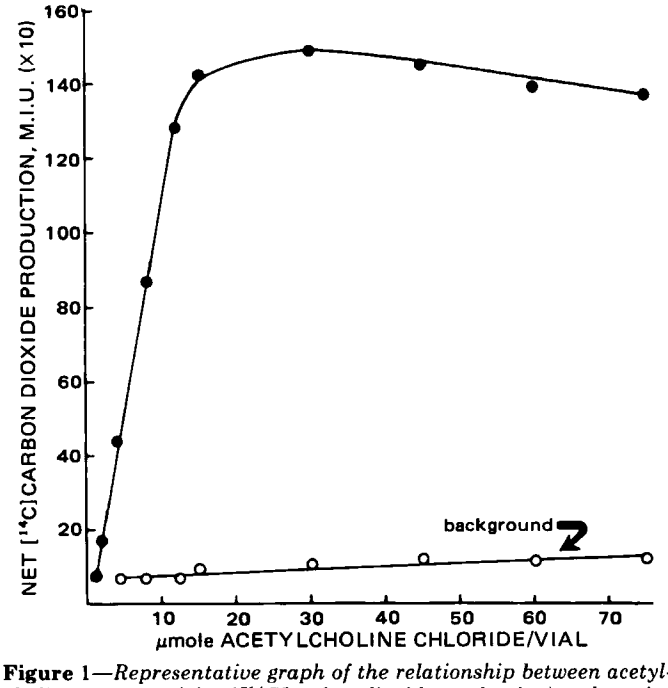

Figure 1—*Representative graph of the relationship between acetylcholinesterase activity ([^{14}C]carbon dioxide production) and varying concentrations of acetylcholine. One microcurie of [^{14}C]sodium bicarbonate and 1 U of electric eel acetylcholinesterase were used. Incubation was done at 37° for 30 min.*

Table I—Inhibitory Potency of Known Acetylcholinesterase Inhibitors as Ranked by the Radiometric Method

Compound	IC_{50} Value	
	Radiometric, *M*	Literature, *M*
Phenyltrimethylammonium Iodide	2.7×10^{-3}	4.4×10^{-4} (9)
d-Tubocurarine Chloride	1.1×10^{-4}	9.0×10^{-4} (10)
Decamethonium Bromide	3.6×10^{-5}	2.5×10^{-5} (11)
Neostigmine Bromide	6.6×10^{-6}	3.0×10^{-6} (12)
Edrophonium Chloride	1.9×10^{-6}	1.3×10^{-5} (13)
Physostigmine Chloride	2.5×10^{-6}	10^{-6}–10^{-8} (9)

were capped with aluminum seals, which were fitted with rubber liners, and chilled in ice. One microcurie of ^{14}C-labeled sodium bicarbonate followed by 1 U (10 μl) of electric eel acetylcholinesterase were injected into each vial. Appropriate blanks (*i.e.*, background) to account for nonenzymatic hydrolysis of acetylcholine were prepared. The background vials contained all ingredients as test and control vials with the exception that no enzyme was added, thus, measuring nonenzymatically hydrolyzed acetylcholine. All vials were incubated at 37° for 30 min. The concentration of inhibitor which reduced the control value by 50% was defined as inhibitory concentration 50% (IC_{50}). This value was determined from the net [^{14}C]carbon dioxide production *versus* inhibitor concentration curve (Fig. 3).

Measurement of [^{14}C]Carbon Dioxide Produced—The amount of [^{14}C]carbon dioxide generated was quantified using a bacteriological detection system[9] which contained an ionization chamber. [^{14}C]Carbon dioxide activity was expressed as metabolic index units (miu.), where 100 miu. equals 0.031 μCi of [^{14}C]carbon dioxide. This instrument is widely used in clinical laboratories as well as in industry. Technical details have been described elsewhere (6, 7).

RESULTS AND DISCUSSION

A new and simple radiometric method was developed to screen potential acetylcholinesterase inhibitors. This technique is based on the hydrolysis of acetylcholine by acetylcholinesterase to acetic acid and choline. The acetic acid formed from the enzymatic hydrolysis of acetylcholine reacts with [^{14}C]sodium bicarbonate to generate [^{14}C]carbon dioxide, which is measured using the ionization chamber system. The

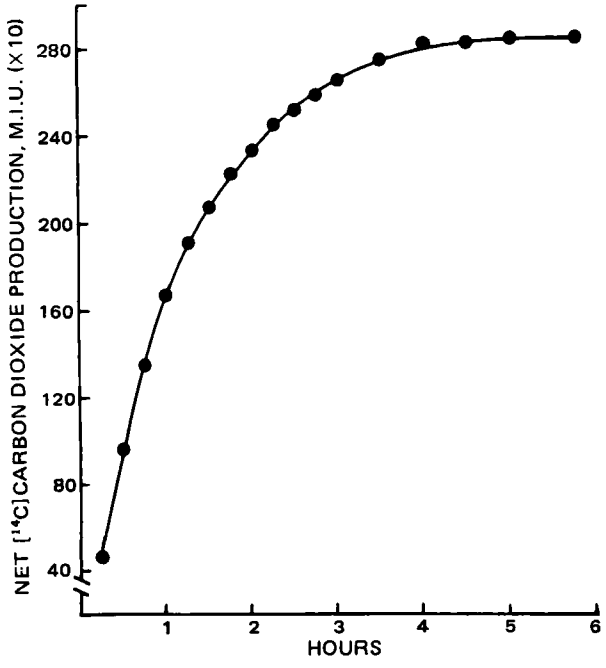

Figure 2—*Representative graph of electric eel acetylcholinesterase activity (1 U) versus time. One microcurie of [^{14}C]sodium bicarbonate and a 30 mM acetylcholine solution was used as substrate. Test vials were incubated for 15-min intervals at 37° after which [^{14}C]carbon dioxide production was quantified.*

[9] Bactec R301, Johnston Laboratories, Cockeysville, Md.

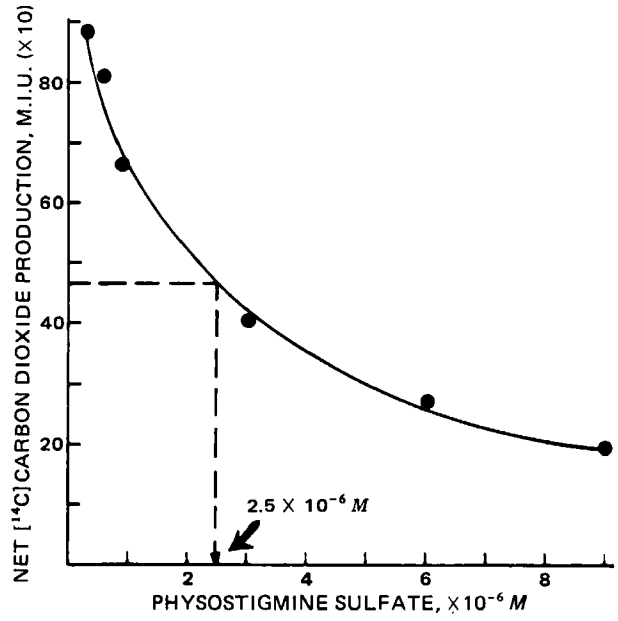

Figure 3—*Effect of increasing concentration of physostigmine sulfate on the activity of 1 U of electric eel acetylcholinesterase. IC_{50} represents the concentration of inhibitor which reduces the production of [^{14}C]-carbon dioxide by 50% of control vial containing no inhibitor. Incubation time was 30 min at 37°. (Control = 928; IC_{50} = 928/2 = 464.)*

[^{14}C]carbon dioxide evolved is proportional to the amount of acetylcholine hydrolyzed (Fig. 1).

The effect of increasing concentrations of acetylcholine on acetylcholinesterase activity was studied. Figure 1 indicates that for 30-min incubation at 37° there was a linear response of acetylcholinesterase activity from 1 to 15 μmoles of acetylcholine/vial followed by saturation at 3×10^{-3} *M* acetylcholine concentration and an actual decrease in activity as the substrate concentration increases. The decrease on acetylcholinesterase activity is a result of substrate inhibition (8). An acetylcholinesterase activity *versus* time curve was obtained to determine the incubation time of test vials (Fig. 2).

Preliminary studies with known acetylcholinesterase inhibitors have shown that the new radiometric method can be used to rank such compounds according to their inhibitory potency on acetylcholinesterase (Table I). Even though comparison of absolute IC_{50} values cannot be made between the described method and those obtained by other methods due to different experimental conditions, the results presented are in general agreement with those reported in the literature (Table I).

The new radiometric method is simple, fast, and inexpensive and has the potential for automation. Many samples can be prepared and analyzed in a few hours. It can be applied as a rapid test in the screening of such compounds as pesticides and chemicals of medical interest.

The method is not only applicable for assaying acetylcholinesterase activity and the effect of its inhibitors, but it can be extended to other enzyme systems in which a proton is generated as a result of the enzymatic action.

Microbial Metabolism Studies on the Major Microbial and Mammalian Metabolite of Primaquine

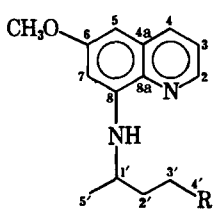
CHARLES D. HUFFORD *x, ALICE M. CLARK *, IRIS N. QUINONES *, JOHN K. BAKER ‡, and J. D. McCHESNEY *

Received December 12, 1981, from the **Department of Pharmacognosy* and the ‡*Department of Medicinal Chemistry, School of Pharmacy, the University of Mississippi, University MS 38677.* Accepted for publication February 26, 1982.

Abstract □ The microbial metabolism of 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (II), a known microbial and mammalian metabolite of the antimalarial drug primaquine (I), was investigated using selected organisms. *Streptomyces rimosus* produced a single metabolite that was identified as an amide derivative of II (V) by spectroscopic methods. The amide (V) was synthesized by ammonia treatment of the methyl ester (IV). The lactam derivative (VI) was also prepared by treatment of II with *N*-ethoxycarbonyl-2-ethoxy-1,3-dihydroquinoline.

Keyphrases □ Primaquine—microbial studies on the major microbial and mammalian metabolite, high-performance liquid chromatography □ High-performance liquid chromatography—microbial metabolism studies on the major microbial and mammalian metabolite of primaquine

The utilization of microorganisms as models for studying mammalian metabolism is a concept that has been advocated as an aid for future metabolic studies (1). Recent studies with phencyclidine (2) and imipramine (3) have shown that microorganisms do produce the same metabolites as mammalian systems. Primaquine (I), an antimalarial drug, has also been subjected to a microbial metabolic study since little or no information has been reported regarding its mammalian metabolism (4). The two major microbial metabolites identified were the carboxylic acid derivative (II) and the *N*-acetyl derivative of the primary amine (III). In parallel studies, the mammalian metabolism of I using rats has been studied, and II has been identified as the major mammalian metabolite as well (5). The tissue distribution of I has been studied, and even though substantial evidence indicated that I was rapidly metabolized by the rat, no mammalian metabolites were identified (6). Having microbial metabolites as reference standards for conducting mammalian metabolic studies can be useful. The purpose of this investigation was to study further the biotransformations of the major mammalian metabolite (II) of primaquine using microbial systems.



I: R = $-CH_2NH_2$
II: R = $-CO_2H$
III: R = $-CH_2NHCOCH_3$
IV: R = $-CO_2CH_3$
V: R = $-CONH_2$

RESULTS AND DISCUSSION

A total of 60 microorganisms typical of those used previously (3, 7) were used in the screening of 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (II) for microbial metabolites. Of these, *Streptomyces rimosus*[1] was chosen for preparative scale fermentations, since TLC indicated complete conversion in 3 days to one major metabolite. Other microorganisms showing this same metabolite as determined by TLC were *Streptomyces flocculus*[2], *Polyporus sanguineus*[3], and *Fusarium oxysporum* f. sp. *cepae*[4] although large amounts of II were also present even after 7–10 days.

Incubation of 300 mg of II with submerged cultures of *S. rimosus* for 4 days and extraction of the entire culture with ethyl acetate resulted in 700 mg of ethyl acetate solubles. Chromatography of a 400-mg sample of this residue using preparative layer silica gel and alumina plates resulted in the isolation of 18 mg of the pure metabolite by TLC and HPLC (overall yield, 12%).

The ^{1}H-NMR spectrum of the metabolite showed the aromatic protons to have nearly the same δ positions and J values as reported for II (4). The spectrum also confirmed that the methoxyl group and the secondary methyl were present. This suggested that the biotransformation had occurred in the side chain. The mass spectrum was consistent for $C_{15}H_{19}O_2N_3$ (M^+ 273, 10%) and showed significant fragments at m/z 215 (51%) and 201 (100%), further confirming that the aromatic nucleus had not been transformed (4). The IR spectrum indicated absorption at 3400, 3510, and 1760 cm^{-1}. The ^{13}C-NMR spectral data (Table I) was nearly identical to that of the methyl ester of II (IV). The collective spectroscopic data suggested the microbial metabolite was an amide derivative represented by V. This was confirmed by treating IV with methanol saturated with ammonia in a sealed tube at 140°. The product of this reaction was identical in all respects to the metabolite (V). No evidence of the lactam derivative (VI) was noted in this reaction, although VI was noted as a product of heating IV in the gas chromatograph (5). Attempts to prepare

Table I—^{13}C-NMR Data for IV, V, and VI [a]

Carbon No.	IV	V	VI [b]
2	144.4d	144.4d	147.7d
3	121.9d	121.9d	121.8d
4	134.8d	134.9d	134.0d
4a	130.1s	130.0s	130.3s
5	92.3d	92.3d	105.6d
6	159.7s	159.6s	157.4s
7	97.1d	97.2d	123.0d
8	145.2s	145.2s	140.8s[1]
8a	135.6s	135.5s	136.4s[1]
1′	47.7d	47.7d	57.1d
2′	31.0t[1]	32.4t	31.3t[2]
3′	32.0t[1]	32.4t	28.0t[2]
4′	174.0s	175.3s	175.8s
5′	20.6q	20.7q	20.6q
OCH_3	55.3q	55.2q	55.7q
CO_2CH_3	51.5q	—	—

[a] Data were obtained in deuterochloroform. The data and assignments for IV have been reported (4) and are listed here for comparison with V and VI. Signals bearing the same numerical superscript may be reversed. [b] The assignments listed for VI are based on comparison with IV and V and SFORD.

V from II by using such reagents as thionyl chloride and ethyl chloroformate followed by ammonia treatment were unsuccessful. The major product appeared to be VI (TLC). The lactam (VI) could be efficiently prepared by treatment of II with *N*-ethoxycarbonyl-2-ethoxy-1,3-dihydroquinoline (VII).

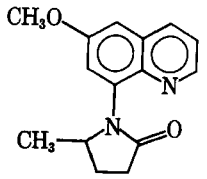
Similar biotransformations of carboxylic acids to primary amides have been reported for biotin and desthiobiotin (8, 9), but they do not appear to be common microbial reactions. The conversion of mycophenolic acid to amide derivatives of glycine and alanine have also been reported (10). Whether these biotransformations play a role in the mammalian metabolism of II remains to be established, but conjugation of glycine with similar compounds is common (11).

EXPERIMENTAL[5]

Fermentation Procedures—Initial screening studies to identify microorganisms capable of metabolizing 8-(3-carboxy-1-methylpropylamino)-6-methoxyquinoline (II) were accomplished using the usual two-stage fermentation procedure (2–4, 7). Cultures were grown in 25 ml of dextrose–yeast extract–peptone medium (4) held in 125-ml Erlenmeyer flasks equipped with stainless steel tops. The substrate (II) was added to 24-hr-old second-stage cultures (0.2 mg of substrate/milliliter of culture medium) as a 5% solution in dimethylformamide. Cultures were incubated on a rotary shaker[6] at 250 rpm and room temperature.

Culture controls consisted of fermentation blanks, in which organisms were grown under identical conditions but without the substrate. Substrate controls consisted of sterilized 24-hr-old second-stage cultures containing the substrate and incubated at 250 rpm and room temperature.

The cultures were sampled at periodic intervals by homogenizing 5 ml of the culture, adjusting to pH 7–8, and extracting with 5 ml of ethyl acetate. The ethyl acetate layer was evaporated to dryness, the residue redissolved in 100 μl of ethyl acetate, and 20 μl of the solution was spotted on silica gel G TLC plates. The plates were developed in either acetone (solvent A), ether–acetone (1:1, solvent B), or 10% methanol in chloroform (solvent C). In solvent A the R_f values were 0.6 (II) and 0.56 (V); in solvent B, R_f = 0.58 (II), and 0.49 (V); and in solvent C, R_f = 0.45 (II) and 0.39 (V). Visualization was accomplished with UV light and by spraying with diazotized *p*-nitroaniline followed by spraying with concentrated hydrochloric acid. All spots were dull yellow after spraying. HPLC analyses were carried out using a C_{18}-reversed-phase column[7] and a mobile phase consisting of 6.6 g of K_2HPO_4, 8.4 g or KH_2PO_4, 4.0 g of *N,N*-dimethyl-*n*-octylamine, 2.4 liters of water, and 1.6 liters of methanol at a flow rate of 1.0 ml/min. An HPLC pump[8] and a microsyringe-loaded loop injector[9] were used with a dual wavelength UV detector[10] (254 and 280 nm). Extracts were dissolved in 1.0 ml of methanol and 40 μl was injected for analysis. In this system, the metabolite (V) has a relative retention time (relative to II) of 0.73 and an A_{254}/A_{280} value equal to 4.73.



VI

Microbiological Preparation of 8-(3-Carboxamido-1-methylpropylamino)-6-methoxyquinoline (V)—*Streptomyces rimosus*[1] was grown in 1.5 liters of medium held in fifteen 500-ml Erlenmeyer flasks. A total of 300 mg of II was distributed evenly among the cultures. The cultures were incubated at room temperature and 250 rpm for 4 days after substrate addition. The cultures were pooled and extracted with ethyl acetate (2 × 700 ml, 1 × 1000 ml). The combined ethyl acetate layers were dried (sodium sulfate) and evaporated *in vacuo* to leave an oily residue (702 mg). Preparative layer chromatography of 400 mg of the residue was carried out using precoated silica gel G plates[11] (2.0 mm thick, 20 × 20 cm) developed in ether–acetone (1:1). The major band, corresponding to metabolite V, was located by UV light, scraped off, and the silica gel was extracted with ethyl acetate. Evaporation of the solvent afforded 66 mg of a crystalline residue. Crystallization from ether yielded a crystalline material, which was shown by ^{1}H-NMR to be unrelated to the primaquine nucleus. It appeared to be a simple organic constituent that was not further characterized. This substance could be separated from the metabolite on TLC alumina plates[11] using benzene–ethyl acetate–ammonium hydroxide (50:45:5). It could be visualized under UV light but it did not react with the spray reagent.

The mother liquor residue was subjected to another preparative layer chromatography over alumina plates (1.0 mm thick, 20 × 20 cm) using benzene–ethyl acetate–ammonium hydroxide (50:45:5). The metabolite band was extracted with ethyl acetate and after evaporation yielded 18 mg of the metabolite V pure by TLC and HPLC as an oily residue; IR ($CHCl_3$) ν_{max} 3510, 3490, 3400, 1670, 1612, 1595, 1575, and 1520 cm^{-1}, ^{1}H-NMR ($CDCl_3$) δ 8.53 (1H, dd, *J* = 1.5, 4.5 Hz, C-2 H), 7.93 (1H, dd, *J* = 1.5, 9.0 Hz, C-4 H), 7.30 (1H, dd, *J* = 4.5, 9.0 Hz, C-3 H), 6.34 (2H, s, C-5 H, and H-7), 6.0 (1H, br, NH), 5.6 (2H, br, NH_2), 3.87 (3H, s, OCH_3), 3.7 (1H, m, H-1′), 2.4 (2H, m, H-3′), 2.1 (2H, m, H-2′), and 1.30 (3H, d, *J* = 6.0 Hz, CH_3); CD (0.005% methanol) $[\theta]_{350-210}$ = 0; mass spectrum: M^+ at *m/z* 273 (10%), 257 (1%), 215 (51%), and 201 (100%). The metabolite sample was identical to that prepared from IV (TLC, cobalt-TLC, HPLC, IR, ^{1}H- and ^{13}C-NMR).

Synthesis of 8-(3-Carboxamido-1-methylpropylamino)-6-methoxyquinoline (V) from IV—8-(3-Carbomethoxy-1-methylpropylamino)-6-methoxyquinoline (IV, 80 mg) (4) was dissolved in a few drops of methanol and placed in a glass tube (2-mm thick, 3-mm i.d. × 30 cm) and treated with 0.5 ml of methanol saturated with anhydrous ammonia gas. Additional ammonia was bubbled into the tube while cooling in an ice bath. The tube was then sealed and heated in an oven at 140° for 4 days. The reaction mixture was evaporated *in vacuo* to leave a brown oily residue (98 mg). TLC analysis of the mixture showed the presence of two major components corresponding to starting material (IV) and the amide product (V). There was no evidence (TLC) of the presence of the lactam derivative (VI) [solvent B, R_f = 0.69 (IV), 0.22 (VI)[12], 0.49 (V)]. The reaction mixture was purified by preparative layer chromatography on alumina plates[11] (20 × 20 cm, 1.0-mm thick) using benzene–ethyl acetate–ammonium hydroxide (50:45:5) as the developing solvent. The band corresponding to the product (R_f = 0.30) was located under UV light, scraped off, and extracted with 25% methanol–ether. Filtration and evaporation of the solvent afforded 17 mg of an oily residue that was pure by TLC, HPLC, and ^{1}H-NMR. For ^{13}C-NMR data see Table I; mass spectrum: M^+ at *m/z* 273 (14%), 257 (2%), 215 (48%), 201 (100%).

Synthesis of VI From II—A 50-mg sample of II (4) was dissolved in 1 ml of methylene chloride containing 0.03 ml (1.1 eq.) of triethylamine to which was added 75 mg of VII (1.5 eq.). The clear solution was allowed to stand at room temperature for 3 days, after which time the solution was extracted with 1 ml of 1 *N* sodium hydroxide to remove traces of II. The methylene chloride layer was filtered through cotton, evaporated,

[5] IR spectra were run in chloroform using a Perkin-Elmer 281b spectrophotometer. The ^{1}H-NMR spectra (90 MHz) were recorded in deuterochloroform on a Varian EM 390 spectrometer using tetramethylsilane as an internal standard. The ^{13}C-NMR spectra (15.03 MHz) were recorded on a JEOL-FX60 FT spectrometer using tetramethylsilane as internal standard.

Synthesis and Anticonvulsant Activity of Some 2-Methyl-3-phenylcarbamoyl-2,3-diazabicyclo-[2.2.1]heptanes

MILTON J. KORNET ˣ and JOHN YEOU-RUOH CHU

Received January 25, 1982, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication March 12, 1982.

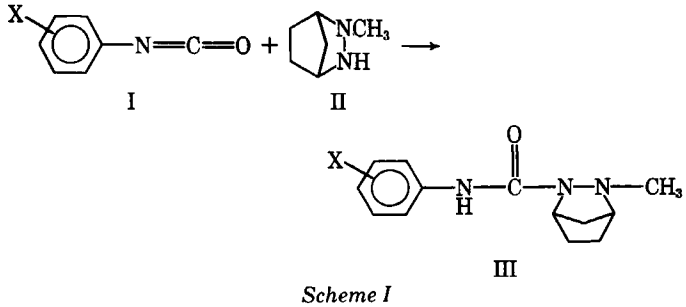
Abstract □ A series of 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]heptanes were obtained by treating aryl isocyanates with 2-methyl-2,3-diazabicyclo[2.2.1]heptane. The compounds showed only minimal anticonvulsant activity.

Keyphrases □ 2-Methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]-heptanes—synthesis and anticonvulsant activity □ Anticonvulsants—synthesis of some 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]-heptanes

A previous report (1) describes the synthesis and anticonvulsant activity of a series of 1-methyl-2-phenylcarbamoylpiperidazines. Four members of this series showed significant activity. The present report describes the synthesis and anticonvulsant activity of a series of 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]heptanes (III). The series of III, with their cage structure, would be expected to provide different steric and basic properties in comparison with the monocyclic compounds (1).

BACKGROUND

The synthesis of 2-methyl-2,3-diazabicyclo[2.2.1]heptane (II) was accomplished in two steps from 2,3-dicarboethoxy-2,3-diazabicyclo[2.2.1]heptane (IV) (2). Partial saponification of IV gave 2-carboethoxy-2,3-diazabicyclo[2.2.1]heptane (V), which underwent reduction with lithium aluminum hydride to afford the base, II (Scheme I). Compound II reacted with aryl isocyanates (I) to produce III in good yields (Scheme II; Table I).



Scheme I

Compounds III*a–j* were tested in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in male mice[1] by reported procedures (3). None of the compounds showed activity in either test at 100 mg/kg.

In the maximal electroshock seizure test, compounds III*a*, *d*, *g*, *i*, and *j* exhibited activity at 300 mg/kg at 30 min. Compounds III*a* and *i* showed no toxicity at this dose level, whereas III*d*, *g*, and *j* displayed some toxicity. Two compounds were active in the subcutaneous pentylenetetrazol seizure test at 300 mg/kg. Compound III*j* was active at 30 min; compound III*b* showed activity at 4 hr with no toxicity. Apparently, the introduction

and the residue (142 mg) was purified using flash chromatography (12) (silica gel, ether, then ether–acetone, 1:1). A total of 24 mg of VI was obtained, mp 109–110° (*iso*-propyl ether); IR (KBr) ν_{max} 1690, 1615, 1590, and 1490 cm^{-1}; ^1H-NMR ($CDCl_3$) δ 8.75 (1H, dd, J = 1.5, 4.5 Hz, C-2 H), 8.06 (1H, dd, J = 1.5, 8.5 Hz, C-4 H), 7.35 (1H, dd, J = 4.2, 8.5 Hz, C-3 H), 7.29 (1H, d, J = 2.7 Hz, C-7 H), 7.07 (1H, d, J = 2.7 Hz, C-5 H), 4.72 (1H, ddq, J = 6.0, 6.0, 6.0 Hz, C-1′ H), 3.90 (3H, s OCH_3), 2.6, and 1.8 (3H and 1H, m, C-3′ H, C-2′ H), 1.03 (3H, d, J = 6.0 Hz, CH_3); mass spectrum M^+ at m/z 256 (18%), 228 (18%), 213 (21%), 200 (81%), 187 (52%), 186 (51%), 159 (100%); ^{13}C-NMR data (Table I); TLC, solvent B, R_f 0.22[12].

Synthesis and Anticonvulsant Activity of Some 2-Methyl-3-phenylcarbamoyl-2,3-diazabicyclo-[2.2.1]heptanes

MILTON J. KORNET ˣ and JOHN YEOU-RUOH CHU

Received January 25, 1982, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication March 12, 1982.

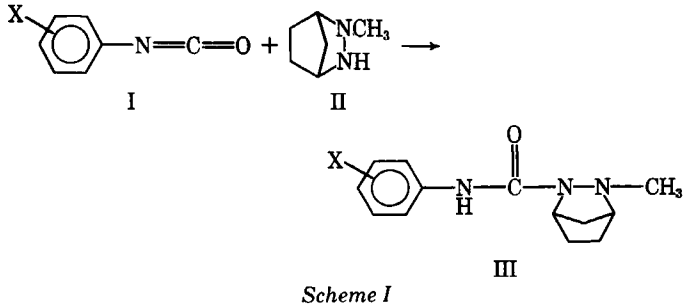
Abstract □ A series of 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]heptanes were obtained by treating aryl isocyanates with 2-methyl-2,3-diazabicyclo[2.2.1]heptane. The compounds showed only minimal anticonvulsant activity.

Keyphrases □ 2-Methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]-heptanes—synthesis and anticonvulsant activity □ Anticonvulsants—synthesis of some 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]-heptanes

A previous report (1) describes the synthesis and anticonvulsant activity of a series of 1-methyl-2-phenylcarbamoylpiperidazines. Four members of this series showed significant activity. The present report describes the synthesis and anticonvulsant activity of a series of 2-methyl-3-phenylcarbamoyl-2,3-diazabicyclo[2.2.1]heptanes (III). The series of III, with their cage structure, would be expected to provide different steric and basic properties in comparison with the monocyclic compounds (1).

BACKGROUND

The synthesis of 2-methyl-2,3-diazabicyclo[2.2.1]heptane (II) was accomplished in two steps from 2,3-dicarboethoxy-2,3-diazabicyclo[2.2.1]heptane (IV) (2). Partial saponification of IV gave 2-carboethoxy-2,3-diazabicyclo[2.2.1]heptane (V), which underwent reduction with lithium aluminum hydride to afford the base, II (Scheme I). Compound II reacted with aryl isocyanates (I) to produce III in good yields (Scheme II; Table I).



Scheme I

Compounds III*a–j* were tested in the maximal electroshock seizure and subcutaneous pentylenetetrazol seizure threshold tests for anticonvulsant activity and in the rotorod test for neurotoxicity in male mice[1] by reported procedures (3). None of the compounds showed activity in either test at 100 mg/kg.

In the maximal electroshock seizure test, compounds III*a*, *d*, *g*, *i*, and *j* exhibited activity at 300 mg/kg at 30 min. Compounds III*a* and *i* showed no toxicity at this dose level, whereas III*d*, *g*, and *j* displayed some toxicity. Two compounds were active in the subcutaneous pentylenetetrazol seizure test at 300 mg/kg. Compound III*j* was active at 30 min; compound III*b* showed activity at 4 hr with no toxicity. Apparently, the introduction

of a methylene bridge into the 1,2-diazacyclohexane ring (1) leads to compounds with reduced anticonvulsant activity.

EXPERIMENTAL[2]

2-Carboethoxy-2,3-diazabicyclo[2.2.1]heptane (V)—This compound was prepared by saponification of 2,3-dicarboethoxy-2,3-diazabicyclo[2.2.1]heptane (IV) (2) according to the methods (4, 5) used in the preparation of 1-ethoxycarbonylpiperidazine. It was obtained as a colorless oil in 50% yield, bp 116–120° (1.3 mm). The NMR showed contamination by the starting material, and a satisfactory carbon analysis could not be obtained. Since the purity of this compound was ~95%, it was used directly in the next step.

2-Methyl-2,3-diazabicyclo[2.2.1]heptane (II)—This compound (6) was obtained from the lithium aluminum hydride reduction of V according to the same procedure (1) used for the preparation of 1-methylpiperidazine. It distilled as a colorless oil in 78% yield, bp 151–153°. This base was used directly in the preparation of III.

[2] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. The IR spectra were taken on a Perkin-Elmer 700 spectrophotometer as either liquid films or as potassium bromide pellets. NMR spectra were recorded on a Varian EM-360 or T-60 spectrometer using tetramethylsilane as the internal reference. Mass spectra were obtained on a RMU-7 double focusing spectrometer by Hitachi/Perkin-Elmer. Elemental analyses were performed by Micro-Analysis, Inc., Wilmington, Del., and Dr. Kurt Eder, Geneva, Switzerland. All compounds exhibited PMR and mass spectra consistent with the structures shown.

2-Methyl-3-phenylcarbamoyl-2,3-diazabicyclo-[2.2.1]heptanes (III)—Compound IIIj was prepared from 2.0 g (0.0178 mole) of 2-methyl-2,3-diazabicyclo[2.2.1]heptane (II) and 2.38 g (0.0162 mole) of 2,6-dimethylphenyl isocyanate (I) in 35 ml of dry benzene according to the procedure previously described (3). Workup gave 2.7 g (64%) of white solid, mp 130–132°. Recrystallization from cyclohexane afforded analytically pure material, mp 131.5–132.5°.

A New Method for Assaying Propantheline and Its Degradation Product, Xanthene-9-carboxylic Acid Using High-Performance Liquid Chromatography

B. G. CHARLES ˣ **and P. J. RAVENSCROFT**

Received November 3, 1981, from the *Department of Clinical Pharmacology, Princess Alexandra Hospital, Woolloongabba, Q. 4102 Australia.* Accepted for publication March 10, 1982.

Abstract □ A rapid, specific, and precise high-performance liquid chromatographic method is described for the simultaneous analysis of propantheline bromide and its hydrolysis product, xanthene-9-carboxylic acid. Reversed-phase chromatography was conducted using a mobile phase of 40:60, acetonitrile–0.05 *M* phosphate buffer (pH 2.5) delivered at 2 ml/min. Detection was at 254 nm. Methantheline bromide (internal standard), propantheline bromide, and xanthene-9-carboxylic acid gave retention times of 4.1, 5.4, and 8.3 min, respectively. Within-day, between-day, and total precision (*CV*) for assay of 15 mg/10 ml propantheline bromide are 1.2, 1.1, and 1.6%, respectively ($n = 20$). Similar precision was obtained for xanthene-9-carboxylic acid. The limit of detection was 2 ng. The assay is useful for routine quality assurance of propantheline in dosage forms and for stability and kinetic studies.

Keyphrases □ Propantheline—new method of high-performance liquid chromatographic assay, degradation product, xanthene-9-carboxylic acid □ Xanthene-9-carboxylic acid—degradation product, new method of high-performance liquid chromatographic assay of propantheline □ High-performance liquid chromatography—new method for assaying propantheline and its degradation product, xanthene-9-carboxylic acid

Propantheline bromide [(2-hydroxyethyl)diisopropylmethylammonium bromide xanthene-9-carboxylate] is a parasympatholytic agent which has been used to treat conditions such as urinary incontinence and GI ulceration. The development of efficient methods to measure propantheline in dosage formulations has received little attention in recent times. Some of the compendial methods to assay the drug are time consuming, often requiring several extractions followed by nonaqueous titration (1, 2). The measurement of propantheline by direct UV assay is not specific for the drug with the risk of interference from formulation excipients, drug impurities, or decomposition products of propantheline. Several organic dye–salt partition techniques have been used to assay propantheline in biological fluids (3, 4) and in pharmaceuticals (5). Various modifications of these procedures are used in the pharmaceutical industry for the quality assurance of propantheline. Most of these methods are lengthy and complex, requiring multiple extractions with one or more organic solvents before the dye–propantheline complex is measured by visible or fluorescence spectroscopy.

Propantheline has also been measured in plasma and urine by gas chromatography–mass spectroscopy (6); however, this requires highly expensive and specialized instrumentation and is unsuitable for routine assay of the drug in dosage forms.

A method for assaying propantheline by reversed-phase, high-performance liquid chromatography (HPLC) is reported here. The assay requires minimal sample preparation and has the ability to codetermine xanthene-9-carboxylic acid, a major degradation product of propantheline.

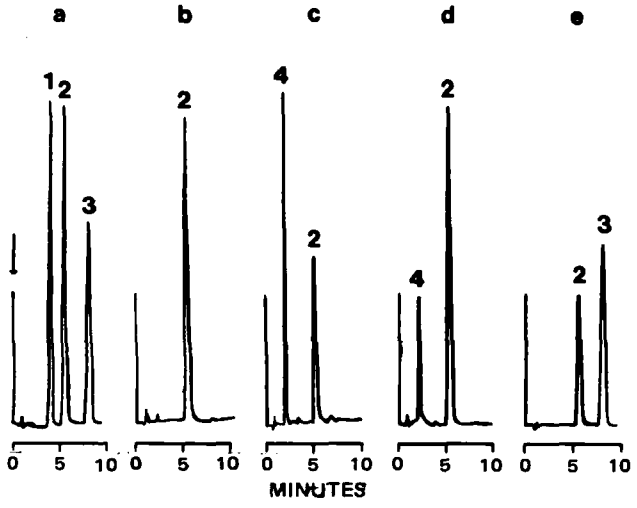

Figure 1—*Representative chromatograms for the HPLC assay of: (a) methantheline bromide, propantheline bromide, and xanthene-9-carboxylic acid reference compounds; (b) propantheline bromide tablet, 15 mg (brand A); (c) propantheline bromide tablet, 15 mg (brand B); (d) propantheline bromide ampule, 30 mg (brand A); (e) propantheline bromide hydrolysis reaction, (pH 10.1, 0.05* M *carbonate buffer, room temperature, 25 min). Key: (1) methantheline bromide; (2) propantheline bromide; (3) xanthene-9-carboxylic acid; (4) unidentified peak (see text). The injection event is represented by the arrow.*

EXPERIMENTAL

Apparatus—High-performance liquid chromatography was performed on a modular system consisting of pump[1], injector[2], bonded-phase microparticulate column[3], fixed wavelength detector[4], and chart recorder[5].

Reagents—Methantheline bromide[6], propantheline bromide[6], and xanthene-9-carboxylic acid[7] were used as received. Potassium dihydrogen orthophosphate, orthophosphoric acid, sodium carbonate, and sodium bicarbonate were analytical grade. Acetonitrile and methanol, HPLC grade[8], and reagent grade water[9] were used throughout the study.

Liquid Chromatography—Phosphate buffer (0.05 *M*) was prepared by dissolving potassium dihydrogen orthophosphate (6.805 g) in 900 ml of water, adjusting to pH 2.5 with orthophosphoric acid, and making up to 1 liter with water. The mobile phase was prepared by slowly adding 400 ml of acetonitrile to 600 ml of rapidly stirred phosphate buffer. Solutions were routinely filtered[10] and vacuum deoxygenated before chromatography. The mobile phase was delivered at 2 ml/min at a pressure of 1500 psi. Injections were made with a special high-performance liquid chromatographic (HPLC) syringe[11], and the column eluent

[a] 15 mg/10 ml.

was monitored at 254 nm with the detector set at 0.05 or 0.1 aufs. Chromatograms were obtained with the recorder set for a 10-mV input and a chart speed of 2.5 mm/min. All chromatography was conducted at ambient temperature (~22°).

Analytical Procedure—*Calibration Standards*—Methanolic stock solutions (100 mg in 10 ml) of propantheline bromide, methantheline bromide, and xanthene-9-carboxylic acid were prepared daily. Working standards were prepared by pipetting 3, 2, 1, and 0.5 ml of the propantheline and xanthene-9-carboxylic acid stock solutions into four 10-ml volumetric flasks. One milliliter of methantheline bromide stock solution was added to each flask and the solutions were adjusted to volume with methanol. Thus, the working standards contained 30, 20, 10, and 5 mg of both propantheline bromide and xanthene-9-carboxylic acid in 10 ml, with 10 mg of methantheline bromide as the internal standard. These standards were analyzed by HPLC. Calibration graphs were constructed daily by plotting the ratios of the peak heights of both propantheline and xanthene-9-carboxylic acid to methantheline *versus* the weights of propantheline and xanthene-9-carboxylic acid in the standards. The calibration data were analyzed by standard, linear least-squares regression methods.

Quality Assurance—For determination of the propantheline bromide content of tablets, the following procedure was followed: A 15-mg tablet of propantheline bromide was pulverized and a 10-ml solution of methanol containing 10 mg of the internal standard was added. The solution was stirred for at least 15 min and filtered or centrifuged to obtain a particle-free solution. One microliter of the solution was injected onto the liquid chromatograph. Alternatively, intact tablets may be dissolved in 0.1 *M* hydrochloric acid or an aqueous buffer of <pH 5.0 containing the internal standard. For the assay of freeze-dried ampules of propantheline bromide (30 mg), 1 ml of methanol (containing 20 mg of internal standard) was injected into the vial. The solution was dissolved by shaking, and 0.5 ml was withdrawn and diluted to 10 ml with methanol. One microliter was injected.

Assay Precision—Methanolic stock solutions of both propantheline bromide and xanthene-9-carboxylic acid (75 mg in 5 ml) and the internal standard (50 mg in 5 ml) were prepared. Four replicate dilutions of the stocks were made in methanol so that each contained 15 mg of both propantheline bromide and xanthene-9-carboxylic acid and 10 mg of the internal standard in 10 ml. The four replicates were analyzed by HPLC, as described previously. The entire procedure was repeated daily, for 5 days, using fresh mobile phase each day. The data were treated statistically using one-way ANOVA.

Propantheline Hydrolysis—One hundred microliters of a methanolic stock solution of propantheline bromide (15 mg/10 ml) was dried under a stream of air and reconstituted in 1.0 ml of carbonate buffer (0.05 *M*, pH 10.1). A sample (1.0 μl) was withdrawn after 25 min and injected into the liquid chromatograph.

RESULTS AND DISCUSSION

Figure 1 shows chromatograms obtained following the HPLC analysis of propantheline bromide, methantheline bromide, and xanthene-9-carboxylic acid reference compounds, commercially available propantheline bromide tablets and ampules, and a propantheline hydrolysis reaction. Retention times of 4.1, 5.4, and 8.3 min were obtained for methantheline, propantheline, and xanthene-9-carboxylic acid, respectively, as seen in Fig. 1(a). For each compound, sharp, symmetrical peaks were obtained with baseline resolution and minimal tailing. Methantheline bromide served as an ideal internal standard, since it has similar spectral and chromatographic properties to propantheline. Interestingly, methantheline bromide and propantheline bromide belong to the quaternary nitrogen class of compounds, the members of which often require the presence of heptane- or pentanesulfonic acid counterions in the mobile phase for reversed-phase HPLC analysis. With the present method, paired-ion chromatography is unnecessary for the assay of propantheline bromide. The minimum detectable amount of propantheline bromide and xanthene-9-carboxylic acid was ~100 ng, although this could be decreased to ~2 ng using a 50-μl injection with the detector set to 0.01 aufs.

The chromatograms in Fig. 1(b, c) were obtained during the analysis of two commercially available brands of propantheline bromide tablets (15 mg). The peak height obtained with brand A (Fig. 1b) was similar to that obtained when a standard solution of propantheline bromide (15 mg/10 ml) was assayed. However, the results in Fig. 1(c) indicate that only half the nominal amount of the drug was present in the brand B tablets. Repeated assays of tablets from different batches of this preparation confirmed that the propantheline content was consistently <15 mg. Furthermore, an extra peak with a retention time of 2 min appeared in these chromatograms, indicating the presence of a breakdown product or impurity. As seen in Fig. 1(d), a peak with similar retention time appeared when propantheline bromide ampules (brand A) were assayed, although the height in this case was considerably less than found in the brand B tablets. While the identity of the unknown peak is yet to be established, it is interesting to note that all products tested were from new stock.

A previous study (7) has shown that propantheline is hydrolyzed to xanthene-9-carboxylic acid in aqueous solutions of pH >5.0. In this regard, the present assay may be useful when the stability of propantheline is under investigation, particularly since both the substrate and hydrolysis product can be measured in a single chromatographic run. To support this, the results in Fig. 1(e) show the decrease in propantheline concentration and appearance of xanthene-9-carboxylic acid following exposure of propantheline bromide (15 mg/10 ml) to pH 10.1 carbonate buffer for 25 min at room temperature.

The analysis of standard solutions of propantheline bromide and xanthene-9-carboxylic acid gave calibration graphs which were linear from 5 mg/10 ml to at least 30 mg/10 ml. The average of five replicate sets of standards (one replicate per day) gave calibration graphs of $y = 0.066x + 0.026$ ($r > 0.999$) for propantheline and $y = 0.122x + 0.052$ ($r > 0.999$) for xanthene-9-carboxylic acid, where y is the peak height ratio and x is the analyte concentration. Methanolic stock solutions of methantheline bromide, propantheline bromide, and xanthene-9-carboxylic acid were stable for at least 3 weeks when stored at room temperature.

The precision of the assay was assessed by analyzing solutions of propantheline bromide and xanthene-9-carboxylic acid, four times daily, on each of 5 days using new stock solutions and mobile phase each day. We chose a solution of 15 mg in 10 ml, since this is the nominal concentration obtained when a 15-mg propantheline bromide tablet is assayed by the recommended procedure. Estimates of the day-to-day, within-day, and total precision of the assay were calculated from ANOVAs of the data as described previously (8). These results appear in Table I. Coefficients of variation for the assay were determined from the mean peak height ratio for all assays of propantheline (1.021) and xanthene-9-carboxylic acid (1.903) and the appropriate standard deviation. It is preferable to use an internal standard in the assay, since the injection volume (1 μl) is less than the maximum volumes accommodated by commercially available sample loops. If samples >1 μl are to be injected, it is recommended that the samples be diluted appropriately, otherwise nonlinearity in the calibration graphs may result. Moreover, if the internal standard is not used, it is advisable that at least two duplicate injections be made per sample.

In conclusion, the present assay provides a rapid, specific, and precise method for the simultaneous determination of propantheline bromide and xanthene-9-carboxylic acid by HPLC.

This novel assay would be useful for the routine, quality assurance of propantheline and for assessing the stability and reaction kinetics of the drug.

Assessment of 75/75 Rule: FDA Viewpoint

Keyphrases □ Bioavailability—studies involving subjects with intersubject coefficient of variation, assessment of 75/75 Rule, FDA viewpoint □ Bioequivalence—bioavailability studies involving subjects with intersubject coefficient of variation, assessment of 75/75 Rule, FDA viewpoint.

To the Editor:

Recently, the new 75/75 specification proposed by the FDA for Bioequivalency Studies came under criticism (1) as being scientifically invalid and unpredictable in bioavailability studies involving subjects with intersubject coefficient of variation (*CV*) of 60% and intrasubject *CV* of 20–30%. Similar criticism also has been launched at the FDA for application of the 75/75 Rule in establishing an *in vitro–in vivo* correlation. Although the FDA does not disagree with the calculated results on hypothetical problems in the published article and the application of the Pittman–Morgan test when appropriate, the authors of the proposed FDA rule do disagree with the underlying assumptions of the author, *i.e.*, that such large variations are the norm in bioequivalency studies.

It has been observed by the FDA that for the large majority of drugs for which bioavailability bioequivalence data are submitted as part of a New Drug Application, the coefficient of variation is generally <40%, assuming that a properly validated analytical assay is employed. To substantiate the latter claims, a review of FDA reports over a 5-year period by a primary FDA contractor (2) is summarized in Table I. The FDA review reveals that the coefficients of variation among 106 total drug products involving 12 drug entities were generally well within the 40% range. Only in the case of diphenhydramine (Table I) was

Assessment of 75/75 Rule: FDA Viewpoint

Keyphrases □ Bioavailability—studies involving subjects with intersubject coefficient of variation, assessment of 75/75 Rule, FDA viewpoint □ Bioequivalence—bioavailability studies involving subjects with intersubject coefficient of variation, assessment of 75/75 Rule, FDA viewpoint.

To the Editor:

Recently, the new 75/75 specification proposed by the FDA for Bioequivalency Studies came under criticism (1) as being scientifically invalid and unpredictable in bioavailability studies involving subjects with intersubject coefficient of variation (*CV*) of 60% and intrasubject *CV* of 20–30%. Similar criticism also has been launched at the FDA for application of the 75/75 Rule in establishing an *in vitro–in vivo* correlation. Although the FDA does not disagree with the calculated results on hypothetical problems in the published article and the application of the Pittman–Morgan test when appropriate, the authors of the proposed FDA rule do disagree with the underlying assumptions of the author, *i.e.*, that such large variations are the norm in bioequivalency studies.

It has been observed by the FDA that for the large majority of drugs for which bioavailability bioequivalence data are submitted as part of a New Drug Application, the coefficient of variation is generally <40%, assuming that a properly validated analytical assay is employed. To substantiate the latter claims, a review of FDA reports over a 5-year period by a primary FDA contractor (2) is summarized in Table I. The FDA review reveals that the coefficients of variation among 106 total drug products involving 12 drug entities were generally well within the 40% range. Only in the case of diphenhydramine (Table I) was

a significant problem encountered in utilizing the 75/75 Rule. Of 106 drug products tested in 18 bioavailability studies, 94 products had <40% *CV*.

The author of the original article pointed out that given a true correlation coefficient, $\rho = 0.90$, the probability of success utilizing the 75/75 Rule was 90% in bioavailability trials involving 24 subjects where the intersubject *CV* is 40% for both the test and reference drug, and the intrasubject *CV* is 30%. The probability of success of applying the 75/75 Rule will significantly increase when the inter- and intrasubject variations are reduced to <40 and 30%, respectively (Table II) (2). The proportion of 1000 studies involving as few as 12 subjects meeting the 75/75 Rule utilizing drugs with an intersubject *CV* of <40% and an intrasubject *CV* of <20% is >88%, and 98% with inter- and intrasubject *CV*s of 30 and 15%, respectively.

The application of the 75/75 Rule is only valid for drugs having a well-defined reference standard that has reproducible pharmacokinetic properties in terms of absorption and clearance. Drugs having a large coefficient of variation associated with extensive first-pass metabolism are often required to undergo multiple-dose steady-state study comparisons or other more appropriate study design as a basis of drug approval. To achieve these results, the FDA often utilizes an oral solution as a basis of comparison where the reference drug has poor bioavailability. Also, the 75/75 Rule is only applied in conjunction with a proper analysis of variance and the FDA relies on additional data analyses.

FDA 75/75 Rule: A Response

Keyphrases □ Bioavailability—studies involving subjects with intersubject coefficient of variation, FDA 75/75 Rule □ Bioequivalance—studies involving subjects with intersubject coefficient of variation, FDA 75/75 Rule

To the Editor:

Dr. Cabana's communication (1) refers to an article (2) that is critical on statistical grounds of the FDA Division of Biopharmaceutic's proposed 75/75 Rule for bioequivalency studies. We emphasize that the point deserving discussion here is not the rigor of the 75/75 Rule, but rather, the fatal flaws inherent in its form. The same flaws would exist even if the rule were less rigorous (50/50) or more rigorous (90/90), because it would retain the same undesirable form: the dispersion of certain ratios. We applaud the vast majority of the pharmacokinetic–bioavailability–bioequivalency regulations and guidelines as contributing to the improvement of health care; we also are glad to see that the FDA accepts the Pitman–Morgan *F*-test as the proper test for equality of test-product and reference-product variation in crossover bioavailability–bioequivalency studies. This *F*-test is described in the statistical literature as "uniformly most powerful" (3); therefore, no other test of variation in a study can have as much statistical power for detection of true differences in standard deviations. The word uniform indicates that this superiority holds for differences of all magnitudes.

In essence we agree with the communication (1) which states that the intersubject coefficient of variation (*CV*) of 40% used previously (2) is not the norm. The choice of 40% per se is not critical; however, the question is whether the results would be much different at a 35% *CV*. Such large coefficients of variation reflect the skewness of the distributions. It also should be noted that the intrasubject *CV* is 20 or 30%, common values for the error term in the analysis of variance (ANOVA).

The performance in a certain region of a proposed statistical test, such as the 75/75 Rule, generally is not very interesting to the statistician designers and the users of such a rule. The main interest in the performance of the proposed test centers on how the more variable drug products are treated by the test—whether they are treated fairly in this respect. The number of such drug products is not negligible, accounting for ≥10% (depending on a cutoff *CV* of 35 or 40%) of drugs studied, according to Dr. Cabana's Table I (1). (If other parameters for a test product have unacceptable values, they should not obscure the point under consideration.) "Are they treated fairly?" is the question addressed earlier (2) for the case of equal averages, and the answer is that they are not. For example, according to the 75/75 Rule, a test product for chlorothiazide with a variation of *AUC* values that is 50% greater than the variation of the reference product *AUC* values usually has a greater chance of being declared bioequivalent than does a test product for phenytoin with the same variation as its reference product.

The main flaw of the 75/75 Rule lies in the fact that the degree of dispersion of the ratio depends on the dispersion or both products, test and reference, without distinction. Thus, a test product which fails the 75/75 Rule in a study may do so because the reference product standard deviation is relatively large—the reference product should fail the dispersion test in that study. For example, for the 12 drugs in Dr. Cabana's Table I (1), suppose that in each study a test product always had the smallest coefficient of variation shown for that drug and the reference product had the largest coefficient of variation—both products with the same average. The unadjusted *F*-values would be, for the *AUC* columns of Table I (1): 7.9, 1.9, 4.7, 2.8, 2.4, 3.1, 3.3, 2.1, 3.4, 1.6, 3.7, 2.4, 1.8, 2.6, 5.2, 2.6. 1.8, and 5.6. Superior uniformity would be indicated for such test products but probably many would fail the 75/75 Rule falsely, because the greater variability is that of the reference products.

The statement that the 75/75 Rule "is only applied in conjunction with a proper analysis of variance" (1) implies a remedy, probably subjective, but the fatal flaws remain; the rule should be withdrawn. Furthermore, since the performance of the 75/75 Rule is affected by differences in the two mean *AUC*s (for test and reference materials),

0022-3549/83/0100-0099$01.00/0

a significant problem encountered in utilizing the 75/75 Rule. Of 106 drug products tested in 18 bioavailability studies, 94 products had <40% *CV*.

The author of the original article pointed out that given a true correlation coefficient, $\rho = 0.90$, the probability of success utilizing the 75/75 Rule was 90% in bioavailability trials involving 24 subjects where the intersubject *CV* is 40% for both the test and reference drug, and the intrasubject *CV* is 30%. The probability of success of applying the 75/75 Rule will significantly increase when the inter- and intrasubject variations are reduced to <40 and 30%, respectively (Table II) (2). The proportion of 1000 studies involving as few as 12 subjects meeting the 75/75 Rule utilizing drugs with an intersubject *CV* of <40% and an intrasubject *CV* of <20% is >88%, and 98% with inter- and intrasubject *CV*s of 30 and 15%, respectively.

The application of the 75/75 Rule is only valid for drugs having a well-defined reference standard that has reproducible pharmacokinetic properties in terms of absorption and clearance. Drugs having a large coefficient of variation associated with extensive first-pass metabolism are often required to undergo multiple-dose steady-state study comparisons or other more appropriate study design as a basis of drug approval. To achieve these results, the FDA often utilizes an oral solution as a basis of comparison where the reference drug has poor bioavailability. Also, the 75/75 Rule is only applied in conjunction with a proper analysis of variance and the FDA relies on additional data analyses.

FDA 75/75 Rule: A Response

Keyphrases □ Bioavailability—studies involving subjects with intersubject coefficient of variation, FDA 75/75 Rule □ Bioequivalance—studies involving subjects with intersubject coefficient of variation, FDA 75/75 Rule

To the Editor:

Dr. Cabana's communication (1) refers to an article (2) that is critical on statistical grounds of the FDA Division of Biopharmaceutic's proposed 75/75 Rule for bioequivalency studies. We emphasize that the point deserving discussion here is not the rigor of the 75/75 Rule, but rather, the fatal flaws inherent in its form. The same flaws would exist even if the rule were less rigorous (50/50) or more rigorous (90/90), because it would retain the same undesirable form: the dispersion of certain ratios. We applaud the vast majority of the pharmacokinetic–bioavailability–bioequivalency regulations and guidelines as contributing to the improvement of health care; we also are glad to see that the FDA accepts the Pitman–Morgan *F*-test as the proper test for equality of test-product and reference-product variation in crossover bioavailability–bioequivalency studies. This *F*-test is described in the statistical literature as "uniformly most powerful" (3); therefore, no other test of variation in a study can have as much statistical power for detection of true differences in standard deviations. The word uniform indicates that this superiority holds for differences of all magnitudes.

In essence we agree with the communication (1) which states that the intersubject coefficient of variation (*CV*) of 40% used previously (2) is not the norm. The choice of 40% per se is not critical; however, the question is whether the results would be much different at a 35% *CV*. Such large coefficients of variation reflect the skewness of the distributions. It also should be noted that the intrasubject *CV* is 20 or 30%, common values for the error term in the analysis of variance (ANOVA).

The performance in a certain region of a proposed statistical test, such as the 75/75 Rule, generally is not very interesting to the statistician designers and the users of such a rule. The main interest in the performance of the proposed test centers on how the more variable drug products are treated by the test—whether they are treated fairly in this respect. The number of such drug products is not negligible, accounting for ≥10% (depending on a cutoff *CV* of 35 or 40%) of drugs studied, according to Dr. Cabana's Table I (1). (If other parameters for a test product have unacceptable values, they should not obscure the point under consideration.) "Are they treated fairly?" is the question addressed earlier (2) for the case of equal averages, and the answer is that they are not. For example, according to the 75/75 Rule, a test product for chlorothiazide with a variation of *AUC* values that is 50% greater than the variation of the reference product *AUC* values usually has a greater chance of being declared bioequivalent than does a test product for phenytoin with the same variation as its reference product.

The main flaw of the 75/75 Rule lies in the fact that the degree of dispersion of the ratio depends on the dispersion or both products, test and reference, without distinction. Thus, a test product which fails the 75/75 Rule in a study may do so because the reference product standard deviation is relatively large—the reference product should fail the dispersion test in that study. For example, for the 12 drugs in Dr. Cabana's Table I (1), suppose that in each study a test product always had the smallest coefficient of variation shown for that drug and the reference product had the largest coefficient of variation—both products with the same average. The unadjusted *F*-values would be, for the *AUC* columns of Table I (1): 7.9, 1.9, 4.7, 2.8, 2.4, 3.1, 3.3, 2.1, 3.4, 1.6, 3.7, 2.4, 1.8, 2.6, 5.2, 2.6. 1.8, and 5.6. Superior uniformity would be indicated for such test products but probably many would fail the 75/75 Rule falsely, because the greater variability is that of the reference products.

The statement that the 75/75 Rule "is only applied in conjunction with a proper analysis of variance" (1) implies a remedy, probably subjective, but the fatal flaws remain; the rule should be withdrawn. Furthermore, since the performance of the 75/75 Rule is affected by differences in the two mean *AUC*s (for test and reference materials),

0022-3549/83/0100-0099$01.00/0

as well as differences in the two standard deviations, and since the means themselves are tested for equality in the ANOVA, the 75/75 Rule also might be said to place the test product in double jeopardy.

The stress placed previously (1) on a "well-defined reference standard which has reproducible pharmacokinetic properties in terms of absorption and clearance" or "an oral solution" makes us ask just where the criterion of acceptable reproducibility of a reference standard is set down?

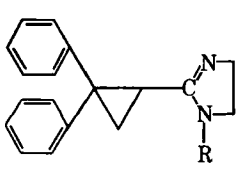
Radioimmunoassay for the New Antiarrhythmic Agent Cibenzoline in Human Plasma

Keyphrases □ Cibenzoline—new antiarrhythmic agent, radioimmunoassay in human plasma □ Antiarrhythmic agent—cibenzoline, radioimmunoassay in human plasma □ Radioimmunoassay—cibenzoline, a new antiarrhythmic agent, human plasma

To the Editor:

Cibenzoline [*dl*-4,5-dihydro-2-(2,2-diphenylcyclopropyl)-1H-imidazole] (I), a new oral antiarrhythmic agent with a novel chemical structure, is presently undergoing clinical evaluation. The present report describes the development and characteristics of a radioimmunoassay for cibenzoline which permits its quantitation directly in human plasma.

To obtain antibodies to cibenzoline, an immunogen was first prepared by covalently coupling the N_1-acetic acid derivative of cibenzoline[1] (II), as a hapten, to bovine serum albumin using a mixed anhydride procedure (1). Rabbits were immunized with the resulting conjugate, and the antiserum with the highest titer of antibodies of cibenzoline was used.



I: R = —H
II: R = CH_2CO_2H

The radioligand used for the assay was [^{3}H]cibenzoline with a specific activity of 10.8 Ci/m*M*[2]. Prior to use, radiochemical purity was established by TLC on silica gel using ethyl acetate–methanol–ammonia (80:15:5) as the solvent system.

The radioimmunoassay was carried out in 12 × 75-mm disposable glass tubes using 0.1 *M* phosphate buffered saline (pH 7.4) containing 0.1% gelatin and 0.1% sodium azide as the assay buffer. Plasma samples (0.02–0.1 ml) containing standard or unknown concentrations of cibenzoline were mixed with 0.2 ml of [^{3}H]cibenzoline in buffer (10,000 cpm) followed by 0.2 ml of diluted antiserum (1:600), and the mixture was incubated at 4° for 30 min. Then, 1 ml of a stirred suspension of a polymer-bound second antibody (goat anti-rabbit IgG)[3] was added and the tube contents were vortexed briefly and allowed to stand at 4° for 1 hr. Following centrifugation at 2000 rpm for 10 min, each supernatant was aspirated off, the pellet suspended in 0.4 ml of 1 *M* acetic acid, and mixed with 3 ml of scintillation fluid[4]. The tube was capped and radioassayed directly in a liquid scintillation counter[5] modified as described previously (2). A calibration curve was generated using a four-parameter logistic curve-fitting program for a desktop calculator[6] (3).

The logit-log calibration curve for cibenzoline was linear from 4 to 200 ng/ml using a 0.1-ml sample of plasma. Such sensitivity is adequate for the quantitation of cibenzoline following administration of therapeutic doses of the drug. The intra- and interassay coefficients of variation (n = 6) did not exceed 6.5 and 10%, respectively, over a range of 38–219 ng/ml of cibenzoline in a selection of random clinical samples. Although the antiserum was found to cross-react almost 100% with the 4,5-dehydro derivative of cibenzoline, a known metabolite of the drug in the dog[7], the specificity of the radioimmunoassay for the analysis of human plasma samples was evaluated by comparison with a specific electron-capture GLC method which was developed and utilized at another research institution[8]. For 57 clinical samples analyzed by both procedures (radioimmunoassay = y), the correlation coefficient, regression line slope, and y-intercept were 0.98, 0.93, and 16, respectively, over a range of 12–287 ng/ml. Although the slope and intercept were significantly different than 1 and 0, only 4 of the 57 highly correlated (r = 0.98) observed data points lay outside the 95% confidence limits of the fitted regression line, which indicates that the radioimmunoassay is in reasonable agreement with a specific chromatographic procedure for the quantitation of cibenzoline. It has been shown by high-performance liquid chromatography (4) that only trace amounts of the 4,5-dehydro metabolite of cibenzoline are present in human plasma, and the metabolite is separated from the parent drug in the electron-capture GLC assay.

In subjects who had received 65 mg of the drug three times a day for 6 days, the peak plasma concentrations at steady-state were ~300 ng/ml of cibenzoline.

A simple radioimmunoassay procedure with adequate sensitivity and specificity was developed for the quanti-

[1] The hapten was prepared from cibenzoline by alkylation with ethyl chloroacetate in ethanol followed by base hydrolysis and crystallized from isopropanol–ether as a partial hydrate, mp 202–204°. The MS and NMR spectra were compatible with the proposed structure.

as well as differences in the two standard deviations, and since the means themselves are tested for equality in the ANOVA, the 75/75 Rule also might be said to place the test product in double jeopardy.

The stress placed previously (1) on a "well-defined reference standard which has reproducible pharmacokinetic properties in terms of absorption and clearance" or "an oral solution" makes us ask just where the criterion of acceptable reproducibility of a reference standard is set down?

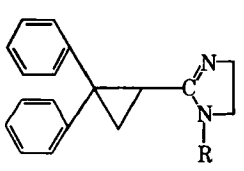
Radioimmunoassay for the New Antiarrhythmic Agent Cibenzoline in Human Plasma

Keyphrases □ Cibenzoline—new antiarrhythmic agent, radioimmunoassay in human plasma □ Antiarrhythmic agent—cibenzoline, radioimmunoassay in human plasma □ Radioimmunoassay—cibenzoline, a new antiarrhythmic agent, human plasma

To the Editor:

Cibenzoline [*dl*-4,5-dihydro-2-(2,2-diphenylcyclopropyl)-1H-imidazole] (I), a new oral antiarrhythmic agent with a novel chemical structure, is presently undergoing clinical evaluation. The present report describes the development and characteristics of a radioimmunoassay for cibenzoline which permits its quantitation directly in human plasma.

To obtain antibodies to cibenzoline, an immunogen was first prepared by covalently coupling the N_1-acetic acid derivative of cibenzoline[1] (II), as a hapten, to bovine serum albumin using a mixed anhydride procedure (1). Rabbits were immunized with the resulting conjugate, and the antiserum with the highest titer of antibodies of cibenzoline was used.



I: R = —H
II: R = CH_2CO_2H

The radioligand used for the assay was [^{3}H]cibenzoline with a specific activity of 10.8 Ci/m*M*[2]. Prior to use, radiochemical purity was established by TLC on silica gel using ethyl acetate–methanol–ammonia (80:15:5) as the solvent system.

The radioimmunoassay was carried out in 12 × 75-mm disposable glass tubes using 0.1 *M* phosphate buffered saline (pH 7.4) containing 0.1% gelatin and 0.1% sodium azide as the assay buffer. Plasma samples (0.02–0.1 ml) containing standard or unknown concentrations of cibenzoline were mixed with 0.2 ml of [^{3}H]cibenzoline in buffer (10,000 cpm) followed by 0.2 ml of diluted antiserum (1:600), and the mixture was incubated at 4° for 30 min. Then, 1 ml of a stirred suspension of a polymer-bound second antibody (goat anti-rabbit IgG)[3] was added and the tube contents were vortexed briefly and allowed to stand at 4° for 1 hr. Following centrifugation at 2000 rpm for 10 min, each supernatant was aspirated off, the pellet suspended in 0.4 ml of 1 *M* acetic acid, and mixed with 3 ml of scintillation fluid[4]. The tube was capped and radioassayed directly in a liquid scintillation counter[5] modified as described previously (2). A calibration curve was generated using a four-parameter logistic curve-fitting program for a desktop calculator[6] (3).

The logit-log calibration curve for cibenzoline was linear from 4 to 200 ng/ml using a 0.1-ml sample of plasma. Such sensitivity is adequate for the quantitation of cibenzoline following administration of therapeutic doses of the drug. The intra- and interassay coefficients of variation (n = 6) did not exceed 6.5 and 10%, respectively, over a range of 38–219 ng/ml of cibenzoline in a selection of random clinical samples. Although the antiserum was found to cross-react almost 100% with the 4,5-dehydro derivative of cibenzoline, a known metabolite of the drug in the dog[7], the specificity of the radioimmunoassay for the analysis of human plasma samples was evaluated by comparison with a specific electron-capture GLC method which was developed and utilized at another research institution[8]. For 57 clinical samples analyzed by both procedures (radioimmunoassay = y), the correlation coefficient, regression line slope, and y-intercept were 0.98, 0.93, and 16, respectively, over a range of 12–287 ng/ml. Although the slope and intercept were significantly different than 1 and 0, only 4 of the 57 highly correlated (r = 0.98) observed data points lay outside the 95% confidence limits of the fitted regression line, which indicates that the radioimmunoassay is in reasonable agreement with a specific chromatographic procedure for the quantitation of cibenzoline. It has been shown by high-performance liquid chromatography (4) that only trace amounts of the 4,5-dehydro metabolite of cibenzoline are present in human plasma, and the metabolite is separated from the parent drug in the electron-capture GLC assay.

BOOKS

Pharmaceutics and Pharmacy Practice. Edited by GILBERT S. BANKER and ROBERT K. CHALMERS. Lippincott, East Washington Square, Philadelphia, PA 19105. 1981, 421 pp. 18 × 25 cm. Price $27.50.

Pharmaceutics and Pharmacy Practice, for the most part, is well written, with each chapter containing much good information, with 23 authors contributing some interesting chapters.

The preface states that the book represents a new approach by interrelating pharmaceutical and clinical pharmacy knowledge about drugs and their delivery systems; however, it contains a standard chapter on physical–chemical principles and another on basic biopharmaceutics. Since the later chapters on drug-delivery systems (oral, topical, parenteral, *etc.*) relate appropriate physical–chemical and biopharmaceutics to their specific subjects, there would be no loss if the physical–chemical chapter were deleted. The chapter on biopharmaceutics could be shortened, except for the portion relative to proper interpretation of blood level curves and evaluation of bioequivalence, which could have been expanded.

The chapter, "Drug Development and Quality Evaluation," would benefit from an expansion of the discussion of selection of multisource drug products and a condensation of federal drug regulatory matters. Similarly, the chapter, "Patient Factors that Influence Dosage Form Selection," should have been edited to remove dosage, patient acceptance (also covered in "Oral Drug-Delivery Systems") and biopharmaceutic matters, while the chapter, on patient education could have been expanded in order to more closely approach the interrelation of knowledge. The style of the chapter on literature resources appears to be better suited to a work book and is repetitious.

The last six chapters are gems. Each one contains relevant anatomy and physiology, routes of drug delivery, drug-delivery systems (dosage forms), and therapeutic considerations. They also contain appropriate physical–chemical considerations and biopharmaceutical aspects. In this manner are covered the drug-delivery systems for oral, parenteral, topical (skin), topical (eye, ear, nose), inhalation, and rectal, vaginal, and urethral administration. A few considerations of extemporaneous preparation of delivery systems are to be found in all of these chapters.

While the book is described as being intended for adult professionals, the preface refers to the book's predecessor as being *Prescription Pharmacy*, which would indicate that one concern would be the dispensing function (the pharmacy practice of the title). Noticeably lacking is any information about processing the prescription, maintenance of prescription files or records, legal aspects of dispensing controlled substances, hospital pharmacy, or the use of computers in pharmacy. While the chapter on parenteral drug-delivery systems contains good material on TPN and electrolyte therapy, no mention is made of aseptic methods appropriate for making intravenous admixtures, *etc.* Thus, the book appears to be written from the aspect of pharmaceutical technology rather than pharmacy practice.

Although the editors were only partly successful in their attempt to interrelate pharmaceutical and clinical pharmacy to pharmacy practice, this book contains much excellent information presented in a highly readable manner.

Analytical Profiles of Drug Substances, Vol. 10. Edited by KLAUS FLOREY, *et al.* Academic, 111 Fifth Ave., New York, NY 10003. 1981. 735 pp. 14 × 23 cm.

Analytical Profiles of Drug Substances, Vol. 10 continues the successful series of complete monographs for important drug substances. This series is compiled under the auspices of the Pharmaceutical Analysis and Control Section of the Academy of Pharmaceutical Sciences. Volume 10 contains monographs on aminosalicylic acid, azathioprine, benzyl benzoate, clindamycin hydrochloride, codeine phosphate, colchicine, cyanocobalamin, emetine hydrochloride, glibenclamide, heroin, hydrochlorothiazide, ketoprofen, methylphenidate hydrochloride, nabilone, natamycin, oxytocin, penicillamine, probenecid, salbutamol, succinylcholine chloride, and trioxsalen. There also are *errata* for cefamandole nafate, fluphenazine decanoate, gentamicin sulfate, and nadolol.

The typical monograph contains the following information: First, there is an initial description including nomenclature, formula, and other physical descriptions followed by a physical properties section which usually covers crystal properties, melting point characteristics, solubility, and spectral properties including reproductions of IR, UV, NMR, and mass spectra. Usually there is a discussion on the drug's synthesis or biosynthesis followed by the drug's metabolism. The monographs usually conclude with a literature review of different methods for analyzing the drug.

There is no question that this series fills a need. The surprising fact is, that after nine previous volumes, the editors still have not developed a standard format for the monographs. Here are some examples of inconsistencies. The Chemical Abstracts Service (CAS) Registry Number is given in 11 of the 21 monographs. When present, it may be in Section 1.1 1, 1.23, 1.2.3, 2.1, 1.2.1, 1.12, or 1.14. Wiswesser Line Notation is present in five of the monographs, and the elemental composition will be found in only eight monographs. Six of the monographs open with one or more introductory paragraphs containing information on the drug's history and use. When this is present, the nomenclature material found in Section 1 now goes into Section 2.

Section 5.5, when present, can be UV spectrometry, proton magnetic resonance spectrometry, radioassay, phosphorimetry, colorimetry, and other unrelated topics. Putting it another way: suppose an analytical chemist wishes to examine the applicability of high-pressure liquid chromatography for a drug analysis whose monograph has been published in this series. Where does he or she look? Answer: Somewhere near the end of the monograph, but be careful, because the material on chromatography may be divided between methodology, analysis of dosage forms, and analysis from biological fluids.

Make no mistake, *Analytical Profiles of Drug Substances* belongs in the personal libraries of drug analysts. Teachers in the field should purchase it as well as school, university, and company libraries. In addition, the publishers and editors should be encouraged to investigate a student rate for graduate students in pharmaceutical analysis. At the same time, some active editing would correct glaring inconsistencies and deficiencies and make the *Analytical Profiles* series reflect the care and consistency expected of the profession and the Academy.

Handbook of Chemical Property Estimation Methods, Edited by W. J. LYMAN, W. REEHL, and D. ROSENBLATT, McGraw-Hill, 1221 Avenue of the Americas, New York, NY 10020. 1982. 960 pp., 71 illustrations. 19 × 24 cm. Price $42.50.

This handbook of chemical property estimation methods is an outgrowth of a combined U.S. Army–Arthur D. Little project to assess properties of organic chemicals that are of environmental concern. Much basic physical and chemical data needed to perform a proper assessment of the risk of these chemicals to humans and the environment is evidently lacking in existing literature. Therefore, an estimation of the most important properties for selected chemicals would aid in this assessment and, thus, is the basis for this scientific contribution.

A review of existing literature reveals that approximately 50 physicochemical properties of organic compounds are of interest, but estimation methods are only available for about half of these properties. A total of 26 properties and their estimation methods are included in the handbook. Two or more estimation methods were selected for each property. These estimation methods were chosen for their range of applicability, ease of use, minimum input data requirements, and accuracy. Among the physicochemical properties covered that would be of pharmaceutical interest are octanol–water partition coefficient, solubility in water, solubility in various solvents, acid dissociation constant, rate of hydrolysis, rate of biodegradation, vapor pressure, densities of vapors, liquids and solids, surface tension, dipole moment, and index of refraction. The handbook is divided into chapters with each property covered in a given chapter. The Editors have maintained some degree of uniformity in style and content in each chapter. For each property, there is introductory material describing the property, background data on available estimation methods, a description of the recommended estimation method(s) with specific instructions for calculation, examples of each method, a listing of symbols and definitions associated with the method, and pertinent literature references.

Aside from deficiencies and errors in the handbook, the basic limitation is that only single-component organic chemicals are covered. There are plans to cover organic mixtures in future editions. A definite plus for the handbook is that the chapters were rigorously reviewed by individual scientists connected with the U.S. Army, the Environmental Protection Agency, Arthur D. Little, various universities, and other organizations.

The Handbook should be beneficial to those who need to estimate selected physicochemical properties where such data are either unavailable or nonexistent. The user should be able to obtain the estimation quickly using only a hand calculator and the handbook instructions. The price is not too prohibitive to prelude addition to an individual's library. It is not meant to be used as a course textbook, but could be easily utilized as a reference text, especially for courses in pharmaceutics and medicinal chemistry. I do not especially recommend the handbook for acquisition by a School of Pharmacy Library or Reading Room facility, but feel that it should be available for use on campus in a Science Library.

Pharmaceutical Dosage Forms: Tablets Vol. 3. Edited by HERBERT A. LIEBERMAN and LEON LACHMAN. Dekker, 270 Madison Avenue, New York, NY 10016. 1982. 472 pp. 18 × 25.5 cm. Price $59.75 (20% higher outside U.S. and Canada).

This volume, the concluding volume of this treatise, empathizes the final stages in the evolution of a finished tablet product. As with the earlier volumes, each chapter is a logical self-contained entity, not critically dependent on familiarity with preceding chapters. In spite of this, the editors have continued to skillfully prevent any repetition by the various authors of the redevelopment of information for processes completed prior to those covered in their chapter describing the next stage of tablet production.

The first four chapters of this volume are specific to the unit processes involved. They are Principles of Improved Tablet Production System Design, Pan Coating of Tablets and Granules, Particles Coating Methods, and Sustained Drug Release from Tablets and Particles through Coating. Each is clearly, logically, and completely developed.

The next two chapters, entitled Stability/Kinetics and Quality Assurance, review the testing of the final product and the documentation of the adherence to GMP throughout every processing step.

As with the previous volumes, the indexing is good. With computer type-setting it is unfortunate that an additional cumulative index for the three volumes was not compiled.

Each chapter in this set is written by qualified experts and clearly represents the state-of-the-art for the immediate future. It is hoped that to create a complete treatise the editors will soon move on to additional volumes to cover other pharmaceutical dosage forms.

CRC Handbook of Chromatography Drugs. Vols. I and II. Edited by RAM N. GUPTA with series Editors-in-chief, GUNTER ZWEIG and JOSEPH SHERMA, CRC Press Inc., Boca Raton, FL 33431. 1981. Vol. I: 340 pp., Vol. II: 404 pp. 17.5 × 25.5 cm. Price Vol. I: $59.95, Vol. II: $59.95.

Earlier editions of this handbook attempted to cover a wider range of compounds in two volumes, but the growth of the literature demanded a new approach resulting in a series of separate books more selective in scope. These two volumes are intended as a reference source of the different chromatographic techniques available for the analysis of drugs, except steroids which are to be treated separately. Coverage embraces specimens from pharmaceutical dosages to biological matrixes. There is a brief, useful introductory section on collection, storage and processing of samples. The comments on interferences from commercial blood sampling containers are marred, however, by incorrect figure legends and a missing reference (No. 78).

The major part of the volumes presents useful tables listing separately the main features of gas, high-pressure liquid, and thin-layer chromatographic methods available for each drug listed. Key chromatographic conditions are cited, together with type of method, *e.g.*, *D* = dosage form, sample size, and sensitivity on a scale of 1–3. (The latter would be more useful if a concentration were estimated.)

This book would be a useful desk reference for those who do not have ready access to a library. However, its utility is compromised by the incomplete (or selective) compilation of methods with no explanation of the criteria for choice of the particular methods tabulated. Thus, methods for such drugs as allopurinol, digoxin, oxyphenbutazone, quinine, and promethazine—among others in this reviewer's files—are not cited.

It would also be useful in such handbooks if the date of literature coverage (apparently to the end of 1979) were quoted, as some methods cited have already become outdated by later advances, *e.g.*, GLC of isosorbide, HPLC of chlorpromazine, naproxen, and propanolol, an inevitable consequence of the advances with useful technique. One is left with the impression that this handbook would be more useful for those analysts involved with biological samples rather than raw materials or formulations.

Handbook of Chemical Property Estimation Methods, Edited by W. J. LYMAN, W. REEHL, and D. ROSENBLATT, McGraw-Hill, 1221 Avenue of the Americas, New York, NY 10020. 1982. 960 pp., 71 illustrations. 19 × 24 cm. Price $42.50.

This handbook of chemical property estimation methods is an outgrowth of a combined U.S. Army–Arthur D. Little project to assess properties of organic chemicals that are of environmental concern. Much basic physical and chemical data needed to perform a proper assessment of the risk of these chemicals to humans and the environment is evidently lacking in existing literature. Therefore, an estimation of the most important properties for selected chemicals would aid in this assessment and, thus, is the basis for this scientific contribution.

A review of existing literature reveals that approximately 50 physicochemical properties of organic compounds are of interest, but estimation methods are only available for about half of these properties. A total of 26 properties and their estimation methods are included in the handbook. Two or more estimation methods were selected for each property. These estimation methods were chosen for their range of applicability, ease of use, minimum input data requirements, and accuracy. Among the physicochemical properties covered that would be of pharmaceutical interest are octanol–water partition coefficient, solubility in water, solubility in various solvents, acid dissociation constant, rate of hydrolysis, rate of biodegradation, vapor pressure, densities of vapors, liquids and solids, surface tension, dipole moment, and index of refraction. The handbook is divided into chapters with each property covered in a given chapter. The Editors have maintained some degree of uniformity in style and content in each chapter. For each property, there is introductory material describing the property, background data on available estimation methods, a description of the recommended estimation method(s) with specific instructions for calculation, examples of each method, a listing of symbols and definitions associated with the method, and pertinent literature references.

Aside from deficiencies and errors in the handbook, the basic limitation is that only single-component organic chemicals are covered. There are plans to cover organic mixtures in future editions. A definite plus for the handbook is that the chapters were rigorously reviewed by individual scientists connected with the U.S. Army, the Environmental Protection Agency, Arthur D. Little, various universities, and other organizations.

The Handbook should be beneficial to those who need to estimate selected physicochemical properties where such data are either unavailable or nonexistent. The user should be able to obtain the estimation quickly using only a hand calculator and the handbook instructions. The price is not too prohibitive to prelude addition to an individual's library. It is not meant to be used as a course textbook, but could be easily utilized as a reference text, especially for courses in pharmaceutics and medicinal chemistry. Maintaining Excellence in Pharmacy Education

In "The Merchant of Venice," William Shakespeare wrote that "The quality of mercy is not strained . . . ." That may be true for mercy, but it is not true for education. Pharmacy education, in particular, is being subjected to stresses and strains that are expected to intensify and grow worse in the years immediately ahead.

The best facilities, the best students, and the best curricula will rarely produce high-quality graduates in the absence of a teaching faculty that is of comparable talent. And it is in that area of faculty quality that a growing number of individuals and groups are beginning to express serious concern.

Current faculties are generally competent and adequate. The great majority of faculty members received their advanced training when new graduate students regularly constituted "the cream of the crop" from the previous year's graduating class. Following advanced study and after taking advanced degrees, a major portion of these select graduate students chose teaching as a career. As a consequence, each new generation of students received its training from the very best of the previous generation's crop.

In recent years, however, this pattern has been changing, and it is this change that is arousing concern.

APhA Academy of Pharmaceutical Sciences President Kenneth R. Heimlich addressed the matter in his November 1982 interim report.

". . . graduate education in the pharmaceutical sciences received considerable discussion (by the APS Executive Committee). Concern was raised over both the ability to attract talented students to graduate studies in the pharmaceutical sciences and to obtain funding for those students who do apply."

Dr. Heimlich went on to describe specific actions taken by the APS and several of its sections in an effort to focus attention on the problem of declining graduate student quality.

Pharmacy students themselves have noted this trend of declining interest in graduate study; the Student APhA has gone so far as to pass a resolution regarding the problem, and to sponsor several programs in an effort to identify remedies for it.

Years ago, when the undergraduate program in pharmacy was being shifted to a minimum five-year curriculum, many educators expressed concern that it would ultimately have an adverse effect on pharmacy graduate degree programs. Acknowledging the benefits of a five-year program for professional practice, many of these same educators suggested a "two-track" undergraduate program in which the student could opt either for a five-year professional degree or a four-year degree as preparation for graduate school studies and an advanced academic degree—generally as preparation for a career in research and/or teaching.

But even that "two-track" approach was not without its problems. In particular, many young people do not know clearly what their career objectives are when they finish four or five years of college. To expect them to make such specific choices at the beginning of their college work would be an unrealistic expectation.

Consequently, no simple or readily apparent answer appears currently available to resolve this dilemma.

In the meantime, a very large proportion of the applicants to graduate studies in the pharmaceutical sciences are graduates of four-year nonpharmacy programs or from four-year foreign pharmacy schools. And the admission standards for the five-year graduate of American pharmacy schools are much lower than in the past. The cummulative result of these factors is that the overall talent reflected in the present and recent graduate student bodies is not of the traditional select caliber that was the norm until about 10 years ago.

Gradually, the composite excellence of those granted M.S. and, in particular, Ph.D. degrees has been declining. In turn, the same erosion of high quality is beginning to occur within pharmacy faculty and research ranks as these recent graduates have emerged to take their place in the classroom and research laboratory.

Unfortunately, we have no ready solution to offer. At this time, we can only join Dr. Heimlich and his colleagues in the APS in noting the existence of the problem and in urging that prompt attention be devoted to it by appropriate groups. In particular, this would appear to be a key issue for review and study by the APhA Task Force on Pharmacy Education. As discussed above, it is an issue that will have an ultimate impact on the very heart of the quality of pharmacy education.

Nonlinear Pharmacokinetics of the New Positive Inotropic Agent Sulmazole in the Dog

EDWARD R. GARRETT ˣ **and WILLY ROTH** *

Received December 14, 1981, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication April 15, 1982. *Present address: Department of Biochemistry, Dr. Karl Thomae GmbH, 795 Biberach, Federal Republic of Germany.

Abstract □ Sulmazole (I) 2-[2-methoxy-4-(methylsulfinyl)phenyl]-1*H*-imidazo[4,5-*b*]pyridine, a new positive inotropic agent, is based on a pyridoimidazole nucleus. Sulmazole pharmacokinetics were monitored in plasma and urine by a specific, sensitive reverse-phase fully automated HPLC system with fluorimetric detection. The hydroxylated metabolite, III, was also monitored in the urine, and unusual pharmacokinetics were observed. Sulmazole disappeared and metabolite II appeared in plasma by zero-order rates for most of their time courses in the 2–15-mg/kg range with a 75% conversion to II. Pure Michaelis–Menten pharmacokinetics were not applicable, and the v_{max} value increased with increasing dose. Pharmacokinetics of sulmazole and II at 0.7-mg/kg iv doses were characterized by a first-order two-compartment body model. Metabolite III at 0.7- and 2-mg/kg iv doses showed no dose-dependent pharmacokinetics. The unchanged drug and its major metabolite, II, were negligibly excreted renally (0.5–2%). Their renal clearance showed urine flow rate dependencies. The plasma protein bindings were: sulmazole, 40.8 ± 1.0%; II, 54 ± 2%; III, 43 ± 1%, and they were concentration independent.

Keyphrases □ Pharmacokinetics—nonlinear, sulmazole, in the dog □ Models, pharmacokinetic—nonlinear, sulmazole, in the dog □ Sulmazole—nonlinear pharmacokinetics in the dog

Sulmazole[1] (I) has shown positive inotropic activity in an isolated dog heart preparation and in intact dogs (1–4). The onset and magnitude of cardiovascular response of this new nonglycosidic cardiotonic drug was studied in humans (5–10). The drug's action started immediately after intravenous administration, indicating that action was due to the parent compound (5) on the presumption that the time course of pharmacological action was related to the time course of the active drug in the central circulation.

Pharmacokinetic studies of radiolabeled I have been conducted in the rat (11, 12), baboon (13), rabbit and dog (14), and rhesus monkey (15), but only total radioactivity was measured. These studies did not reveal the pharmacokinetic behavior of the extensively metabolized I (16).

The present paper reports on the pharmacokinetics of I as a function of dose using specific and sensitive high-performance liquid chromatographic (HPLC) assays (17, 18). The stability, protein binding, and red blood cell partitioning of I, administered intravenously in dogs, and its metabolites, excreted in the urine, were also studied. Various methods of challenging the possible Michaelis–Menten pharmacokinetics of sulmazole were developed and applied to the data.

EXPERIMENTAL

Materials—Sulmazole, 2-[2-methoxy-4-(methylsulfinyl)phenyl]-1*H*-imidazo[4,5-*b*]pyridine, I, was obtained in ampules of 1000 mg/10 ml[1]. Synthesized (19) ^{14}C-I had >99% chromatographic purity by TLC with subsequent liquid scintillation counting of extracted material and by radioscanning. This purity was substantiated by HPLC analysis. Reference compounds II and III were also obtained[2]. The solvents and reagents used were anhydrous dibasic sodium phosphate[3], 85% phosphoric acid[4], acetonitrile HPLC grade[4], 30% hydrogen peroxide[4], and phenobarbital sodium USP XIV granular[5]. A toluene base scintillation fluid[6] was used for the radioactive counting with a liquid scintillation counter[7]. Standard catheters were used for catheterization of the jugular[8] and the foreleg[9] veins. Blood was withdrawn into heparinized containers[10].

Pharmacokinetic Studies in Dogs—Three healthy male mongrel dogs (23–27 kg) were used for the pharmacokinetic investigations. Their blood analysis showed no pathogenic abnormality or presence of microfilaria. The dogs were fasted at least 17–20 hr before each study and were given water *ad libitum*. The animals were supported by a dog sling in a frame[11] placed on a laboratory table. The dogs were given 120 ml of water, 30–45 min prior to the experiments, followed by intravenous saline infusion (35 drops/min) until drug administration when the intravenous drip was reduced to 20 drops/min. One day before the experiment, the animals were catheterized with a 30.5-cm standard catheter in the jugular vein after local anesthesia with mepivacaine hydrochloride[12]. A second catheter was also implanted in a foreleg vein (vena brachialis). On the following day, the drugs were injected directly into the jugular catheter (1–4 sec) followed by flushing of the catheter with 20 ml of physiological saline. Then, the catheter was connected by a three-way stopcock[13] to the saline infusion bottle[14]. Blood samples (4 ml) were taken into a heparinized vacutainer[10] after filling the dead volume of the catheter with blood by aspirating with an extra syringe. These samples were discarded. During the first hour, blood was taken from the foreleg vein with subsequent sampling from the jugular. In several studies, samples were taken simultaneously from both sites in the first hour. The heparinized blood was centrifuged immediately for 5–8 min at 3000 rpm, and plasma was removed with sterile glass pipets. The red blood cells were suspended in 2 ml of physiological saline and stored in an ice bath for reinfusion at the end of the study. Plasma was injected directly and immediately into an HPLC system after appropriate dilution and recentrifugation. Urine was collected from the dogs through a urinary catheter[15] at 15–30-min intervals up to 10–24 hr. Withdrawal time, volumes, and urinary pH were recorded, and aliquots of each sample were frozen until analyzed.

One 24-kg dog, previously studied at several intravenous doses, was administered orally 16 mg/kg/day of phenobarbital in gelatin capsules[8] for 13 days. Subsequently, the pharmacokinetics of an intravenous bolus of 2 mg/kg of I were studied in this dog.

HPLC Assays—A fully automated HPLC system (18) permitted the direct injection of body fluids. The drugs and metabolites were trapped on either of two alternately working enrichment precolumns and dry-filled with reverse-phase material[16], while nonlipophilic material was separated by flushing the precolumns for 3 min with deionized water with a 2-ml/min flow rate. Backflush elution with the mobile phase was used to desorb the drugs from the precolumns to the analytical column in order to chromatographically separate and quantify. The equipment consisted of an autosampler[17], two HPLC pumps[18], a fluorescence detector[19], a chromatographic data station[20], and a self-made precolumn switching system activated by pressurized air (18). The mobile phase for I and II was acetonitrile–0.05 *M* dibasic sodium phosphate buffer (1:2.3, mobile phase A) apparent pH 6.8, with respective retention times of 2.40 and 3.01 min. The mobile phase for III (mobile phase B) had a retention time of 5.74 min and was mobile phase A diluted 1:1.13 with deionized water when urine was assayed after administration of I. When III was administered intravenously, there were no interferences at its 2.03-min retention time, and mobile phase A was used. A self-packed steel column[21] with reverse-phase material[22] was used with a working pressure of 8.5 megapascals at 49° (flow rate: 2 ml/min for mobile phase A; 2.5 ml/min for mobile phase B). The wavelengths (excitation/emission) in urine and plasma were 330 and 370 nm for compounds I and II and 345 and 515 nm for III. These wavelength selections permitted no mutual interferences of III with I and II. The slit width was adjusted to 10 nm (excitation) and 5 and 10 nm (emission) for I, II, and III, respectively. Calibration curves were established in the biological fluid as concentration *versus* peak area (19).

Stability Studies—Solutions of ~100 and 1000 ng/ml of I, II, and III were prepared in 1.0 *N* NaOH[23] and 1.0 *N* HCl[23], and the concentrations were monitored by specific HPLC assay after 0, 4, and 20 hr at 20 and 47°. Similar studies were conducted in fresh dog plasma and urine at 20 and 37.5°.

Protein Binding—Protein binding was studied by ultrafiltration (20) and ultracentrifugation in freshly prepared dog plasma obtained by centrifugation of heparinized dog blood (5000 U of heparin[24]/50 ml of blood) for 20 min at 2000 rpm. [^{14}C]-I and metabolites II and III were used.

Ultrafiltration—Ultrafiltration membrane cones[25] were immersed for 5 hr in refrigerated deionized water, and excess liquid was removed by centrifugation for 5 min at 1000 rpm. Since I showed markedly unspecific binding to the filter cones in the range of 17.6–33% at concentrations of 3.5×10^{-3}–3.5×10^{-5} *M*, all cones were presaturated with appropriate concentrations prior to the experiment, which reduced the unspecific binding to 0–4.3% (20). The fraction bound was calculated from the HPLC and liquid scintillation counting assay of the total concentration prior to the ultrafiltration of 2.5–3 ml of plasma and in the plasma water filtrate after 30% filtration.

Ultracentrifugation—Drug concentrations between 10^{-6} and 10^{-8} *M* in dog plasma were centrifuged[26] for 20 hr at 45,000 rpm at 20°. Initial and supernatant concentrations were determined by liquid scintillation counting for I and by HPLC for I, II, and III.

Red Blood Cell Partitioning—The time dependency of red blood cell partitioning of I (1.02 μg/ml) was investigated in prepared heparinized dog blood with a previously determined hematocrit. The blood (5 ml) was maintained at 37.5°, and 200-μl aliquots were removed at 2-min time intervals and digested for 5 hr with 2 ml of a mixture of 2-propanol[4]–commercial solvent[27] (1:1.5). Decoloration was effected with 0.2 ml of hydrogen peroxide for 30 min, then 10 ml of scintillation fluid[6] was added. After an adaptation period of 6 hr at 10°, liquid scintillation counting was performed. The centrifuged plasma was assayed similarly, and the red blood cell–plasma water partition coefficients were determined similarly. Freshly prepared red blood cells, obtained by centrifugation of heparinized dog blood at 1500 rpm, were washed four times with plasma water with subsequent centrifugation and were then resuspended in plasma water. They were also resuspended in iso-osmolar physiological buffer (5.52 g of Na_2HPO_4, 0.86 g of KH_2PO_4, and 32 g of NaCl/liter). The hematocrit was determined and the suspension was spiked with eight different concentrations of I in the range of 9.8×10^{-6}–9.6×10^{-8} *M*. After 20 min of incubation at 37.5° under gentle mixing, aliquots were taken, the hematocrit determined, and the partition coefficient calculated (21).

RESULTS AND DISCUSSION

HPLC Assays—The described automated system permits direct injection of urine and plasma (diluted at least 1:1.5 with deionized water) from an automatic injection system for assays of I, II, and III. The sample adsorbed on the reverse-phase material of the precolumn was washed

for 3 min with deionized water to remove water soluble substances in the plasma and urine. Subsequently, the mobile phase backflushed the adsorbed material into the analytical column for HPLC assay, and the printer-plotter was activated to record the chromatogram 3 min after injection on the precolumn. The automated system of switching valves permitted injection and flushing of water soluble substances on one precolumn, while the second precolumn was backflushed for assay. The total time for a single assay was 12–15 min and 64–80 assays can be performed automatically in an 8-hr period.

In the assays of I (2.40 min) and II (3.01 min) in urine with mobile phase A, a peak due to an unknown metabolite was observed at 2.20 min that did not interfere with these fluorimetric assays at 330-nm excitation and 370-nm emission. In the assay of III (5.74 min) in dog urine with mobile phase B, peaks due to unknown metabolites were observed at 2.21, 3.63, 6.85, and 9.05 min with the fluorimetric assay at 345-nm excitation and 515-nm emission. These peaks did not appear in blank urine when III was administered intravenously, and mobile phase A could be used for a retention time of 2.03 min at 345-nm excitation and 515-nm emission.

The regression statistics (22) of calibration curves (n = 13–27) of concentrations *versus* peak area in the range of 20–1000 ng/ml for I and II and 40–1000 ng/ml for III gave analytical sensitivities (2 times the standard error of the estimate of concentration on peak area) of 15–18 ng/ml for plasma and 12–26 ng/ml for urine. All curves showed intercepts not significantly different from zero, correlation coefficients >0.990, standard errors of regression coefficient of 0.4–0.9% of the coefficient, and standard errors of the intercept within ±4.1 ng/ml.

Protein Binding—Plasma protein binding percentages (percent of 100 times the concentration in plasma–water/concentration in plasma) for different concentrations of drug and metabolites showed no apparent dose dependencies of protein binding. The percent protein bindings of I in the plasma concentration range of 50–15,000 ng/ml were consistent by both ultrafiltration (41.5 ± 1.2%, n = 6) and ultracentrifugation (40.5 ± 1.5%, n = 11) techniques, and the overall average was 40.8 ± 1.0% (*SEM*). The percent protein binding of II and III were 54 ± 2% (n = 3) and 43 ± 1% (n = 3), respectively, as determined by the ultracentrifugation technique in the 140–1500-ng/ml plasma range.

Red Blood Cell–Plasma Water Partitioning—The red blood cell–plasma water partition coefficient is the ratio of concentrations in the red blood cell to that in the plasma water. It can be calculated from the drug concentrations in plasma before and after equilibration with red blood cells with a known hematocrit, $H = V_{RBC}/V_{blood}$, and when the fraction, f, of the drug bound to plasma proteins is known, by means of an equation developed previously (21, Eq. 9). The time-dependent studies showed that red blood cell–plasma equilibration was achieved within 10 min (n = 7), since there was no significant difference in radioactivity counts of the supernatant, 2246 ± 36 cpm/ml (*SD*) of plasma water after that time. The partition coefficients, D, calculated from studies in whole blood and for red blood cells suspended in plasma–water showed no significant dose dependencies. The calculated partition coefficients averaged 3.10 ± 0.05 (*SEM*) in whole blood in the range of 67–6000 ng/ml (n = 6) and 2.72 ± 0.30 in red blood cell suspensions in plasma water in the range of 28–2820 ng/ml (n = 7). There was no significant difference when physiological buffer was used for the red blood cell suspensions. At 157 ng/ml, D was 3.20 ± 0.09 and 3.10 ± 0.13 from plasma–water and buffer, respectively.

Studies at 200 ng of I/ml also were conducted with the use of the HPLC assay for nonradiolabeled compound, where D = 2.59 for 6.9×10^{-7} M in blood and 5.52×10^{-7} M in plasma and D = 2.07 for 200 ng/ml in the red blood cell suspension and 140 ng/ml in the plasma water.

Stability of Compounds—The concentrations from the HPLC assays of I after appropriate dilution when subjected to 1.0 N NaOH and 1.0 N HCl for 20 hr were no different than when assayed at time zero. The maximum decrease in concentrations of I, II, and III at 100 and 1000 ng/ml of fresh dog plasma after 24 hr at 37.5° was 4 and 0.5% for I; 0.0 and 0.1% for II; and 0.1 and 0.0% for III. The values were the same when the samples were incubated in fresh dog urine. Thus, there was no significant degradation within 1 day for I, II, and III in strong acid, strong alkali, or in plasma or urine.

Nonlinear Plasma Pharmacokinetics of Sulmazole: Data Analysis on the Presumption of Michaelis–Menten Kinetics—The semilogarithmic plots of plasma levels of I *versus* time (Fig. 1) are given for several studies at different doses in dogs. Data was obtained from blood taken from the foreleg vein during the first hour and from the jugular after that. The concentrations of sulmazole in jugular blood were up to 3.0 times higher than that of foreleg blood in the first 15 min during the 2 mg/kg iv study in dog 1. Subsequently, the values coincided. The S-shapes of such curves are indicative of primarily saturable elimination processes

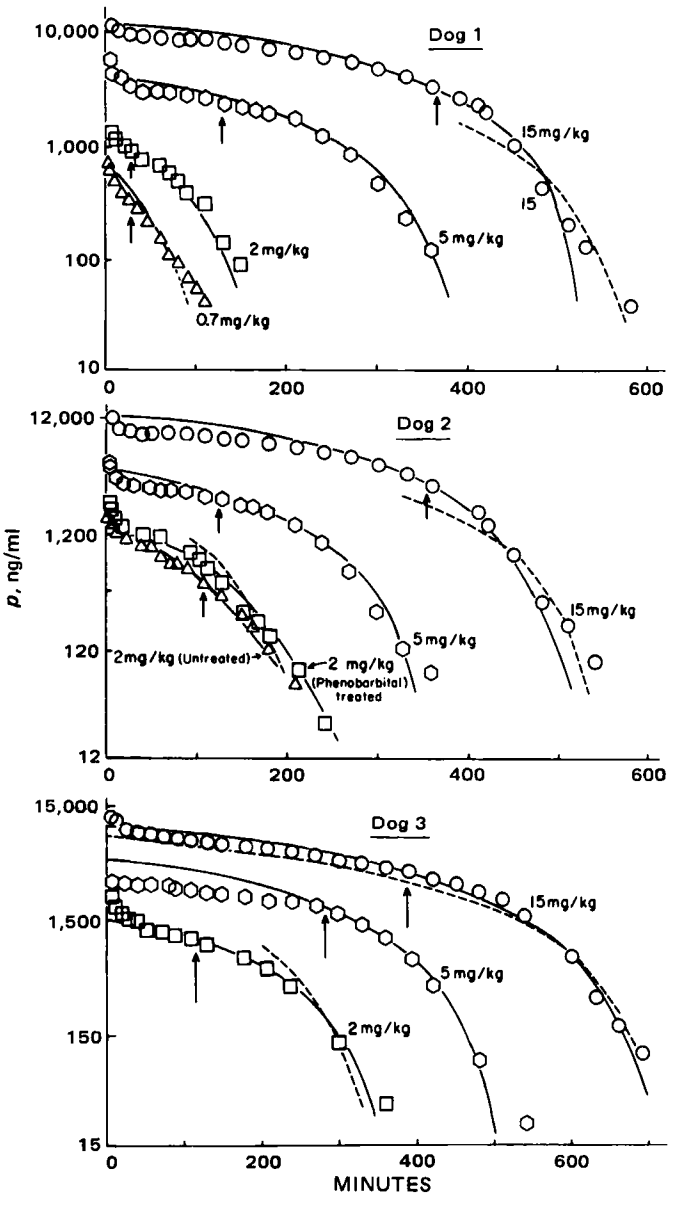

Figure 1—*Semilogarithmic plots of plasma levels of sulmazole on intravenous bolus administration of the labeled dose to dogs. The solid curves through the experimental values were calculated by Eq. 6 from the parameters given in Table I for each dog study. The squared symbols for dog 2 are for a study at 2 mg/kg after the dog had been treated daily with 16 mg/kg of oral phenobarbital over 13 days. The dashed lines for each dog study were plotted by Eq. 6 using the parameters for the 5-mg/kg dose study for each dog (Table I). The arrows designate the plasma level (p_1) values taken at time t_1 for the calculation of t_2 for any plasma level p_2. The initial estimation of Michaelis–Menten parameters by application of Eq. 5 were made from paired values subsequent to that time, t_1.*

in the disposition phase (23). The initial sharp decrease can be assigned to distribution and the subsequent increasing slopes with time to disposition. If there were only one saturable process and no significant parallel first-order elimination, the rate of plasma concentration (p) decrease subsequent to equilibration of the drug in the body would be characterized by:

$$-dp/dt = \frac{v_{max}\, p}{K_m + p} \qquad \text{(Eq. 1)}$$

where v_{max} is the maximum possible rate of decrease of plasma concentration (ng/ml/min) at maximal plasma levels, and v_{max}/K_m is the apparent first-order rate constant for terminal first-order elimination of drug when plasma levels approach zero:

$$\lim_{p \to \infty} -dp/dt = v_{max} \qquad \text{(Eq. 2)}$$

[a] The ± values for the averages are the *SEM* for the values averaged. [b] $1/v_{max}$ and K_m/v_{max} values were determined from the slopes and intercepts, respectively, of the statistical regression of $(t_2 - t_1)/\ln(p_1/p_2)$ against $(p_1 - p_2)/\ln(p_1 - p_2)$ in accordance with Eq. 5 for all pairs of I plasma levels, p_1 and p_2, at their respective times, t_1 and t_2, in the postdistributive phases. The correlation coefficients ranged between 0.9559 and 0.9888. The values of v_{max} and v_{max}/K_m and their error estimates were calculated from the respective reciprocals of the slope ± s slope, and of the intercept ±s intercept. [c] Intercept, K_m/v_{max}, divided by slope, $1/v_{max}$. [d] Best estimate of slope of plasma level of I against time on the presumption of zero-order kinetics in the disposition phase. [e] $V_I = D_0/C_0$ where D_0 is dose of I in milligrams and C_0 is the extrapolated intercept of the estimated zero-order loss, k_0^I/V_I (ng/ml/min). [f] $V_I = D_0/C_0$ where C_0 was obtained from the extrapolated intercept of a line through the plateau values in the 40–100-min interval (Fig. 3) after intravenous administration. [g] $k_0^I = V_I \times k_0^I/V_I$. [h] $(k_0^I)' = V_I \times k_0^I/V_I$. [i] Total area (ng/ml/min) under plasma level–time curve of I per mg/kg of I dose. [j] The apparent zero-order rates of formation of II, k_0^{II}/V_I, and its subsequent clearance per unit volume, Cl^{II}/V_{II}, were determined from the respective slopes and intercepts of plots (Fig. 7) in accordance with Eq. 16. [k] Parameters for first-order elimination of II after cessation of formation from I in accordance with $C_0^{II} = e^{-\beta_{II}t}$ where C_0^{II} is the extrapolated value to zero time. [l] Nanograms of II formed/min from I calculated from $V_{II}(k_0^{II}/V_{II})$ where V_{II} was taken as the 48,558-ml apparent overall volume of distribution determined from the study after administration of 0.7 mg/kg iv of II. [m] Fraction of rate of loss of I transformed to II, *i.e.*, $k_0^{II}(corr)/k_0^I = (k_0^{II}/k_0^I)$ mol. wt. I/mol. wt. II = 0.9473 (k_0^{II}/k_0^I). The overall average is given with the values for 2-mg/kg doses in dogs 1 and 2 omitted. [n] AUC_∞^{II} is by trapezoidal rule of area under plasma level of II *versus* time on intravenous administration of I plus $[II]_n/\beta_{II}$ where $[II]_n$ is the terminal plasma level at t_n used to estimate $AUC_{t_n}^{II}$ up to that time. This value is divided by the dose of I (mg/kg).

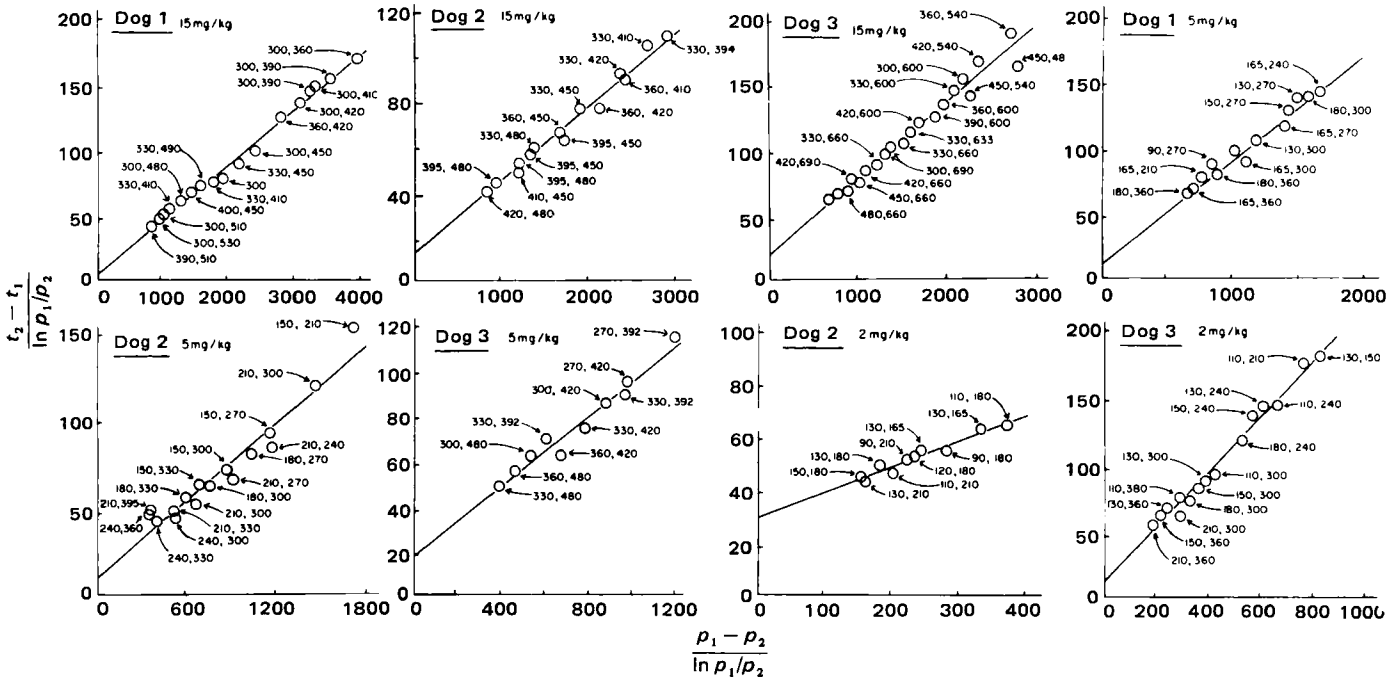

Figure 2—*Plots of paired sulmazole plasma level–time data after the time given by the arrow in Fig. 1 in accordance with Eq. 5 to estimate* $1/v_{max}$ *from the slope and* K_m/v_{max} *from the intercept. Each data point is labeled with the times after administration of the data pair used (*p_1 *at* t_1 *and* p_2 *at* t_2*).*

and

$$\lim_{p \to 0} -dp/dt = (v_{max}/K_m)p \qquad \text{(Eq. 3)}$$

If the elimination process can be attributed to saturable metabolism, K_m can be interpreted as the affinity constant for the available enzymes where the metabolic rate is proportional to the amount of drug–enzyme complex. When all enzymes are complexed in the steady state, the maximal zero-order rate, v_{max}, would be achieved. The data for all doses appeared to approach a final first-order loss of drug from the plasma (Fig. 1) with visually estimated apparent half-lives of 30.0 ± 5.9 (*SD*) ± 2.9 min (*SEM*) for dog 1 (n = 4), 27.2 ± 7.0 (*SD*) ± 4.0 min (*SEM*) for dog 2 (n = 3), and 30.8 ± 1.0 (*SD*) ± 0.6 min (*SEM*) for dog 3 (n = 3).

These estimates of the terminal half-lives are approximate and likely overestimate $0.693/(v_{max}/K_m)$, since they may be based on an estimated linearity of a slightly curving semilogarithmic plot of the terminal plasma concentrations against time (Fig. 1).

The saturable disposition phase after complete equilibration of the drug among the tissues of the body can be characterized by the integrated form (24) of Eq. 1:

$$(p_1 - p_2) - K_m \ln \frac{p_2}{p_1} = v_{max}(t_2 - t_1) \qquad \text{(Eq. 4)}$$

where p_1 and p_2 are plasma concentrations in the postdistribution phase taken at times t_1 and t_2, respectively. This transcendental equation has no explicit solution for plasma concentration with time. Equation 4 can be rearranged to:

$$\frac{t_2 - t_1}{\ln (p_1/p_2)} = \frac{p_1 - p_2}{\ln (p_1/p_2)} \frac{1}{v_{max}} + \frac{K_m}{v_{max}} \qquad \text{(Eq. 5)}$$

where $1/v_{max}$ and K_m/v_{max} are the respective slopes and intercepts that can be estimated from linear plots of $(t_2 - t_1)/\ln(p_1/p_2)$ against $(p_1 - p_2)/\ln(p_1/p_2)$ for any pair of plasma levels, p_1 and p_2, at their respective times, t_1 and t_2, in the postdistributive phase. Examples of such plots are given in Fig. 2 and the resulting calculated values of K_m and v_{max} are listed in Table I. Such plots must be restricted to plasma levels subsequent to the achievement of pseudo steady-state equilibration among the tissues of the body, *i.e.*, the establishment of a one-compartment body model. Also, they are only valid for estimation of parameters (Table I) when there is only one saturable elimination process and no significant amount of drug is eliminated by any parallel first-order process. Thus, p_1-values were not taken at earlier times. The p_1-values, taken after body equilibration of drug was assumed (arrows in Figs. 1 and 3), were then paired with later p_2-values, not too close in time, to produce the plots of Fig. 2 in accordance with Eq. 5. The v_{max}- and K_m-values were then substituted into a rearranged Eq. 4:

$$t_2 = \frac{p_1 - p_2}{v_{max}} - \frac{K_m}{v_{max}} \ln \frac{p_2}{p_1} + t_1 \qquad \text{(Eq. 6)}$$

An experimental value for p_1 at a known time t_1 (designated by the arrows in Figs. 1 and 3) in the presumed pseudosteady-state phase was assumed to be valid, and t_2-values were calculated for various p_2-values. The solid curves in Fig. 1 and the dashed curves in Fig. 3 were calculated in this manner.

Although the parameters v_{max} and K_m (Table I) for Eqs. 4 and 6 obtained in this manner permit good fit to the experimental plasma level–time data (Figs. 1 and 3) subsequent to the time when pseudo steady-state equilibrations among body tissues are probably established, the calculated plasma level values significantly overestimate the experimental values in the early time periods subsequent to the usual relatively rapid (α-phase) tissue distribution.

Table II—Parameters for Apparent Linear Pharmacokinetics of Sulmazole and Metabolites II and III in the 24.2-kg Dog 1

Parameter	Compound I	II	III	
Dose, mg/kg	0.7	0.7	1.0	2.0

[a] Parameter description of time course of plasma concentrations, $p = ae^{-\alpha t} + be^{-\beta t}$. [b] $Cl_{tot} = AUC_\infty$/dose (ng) where the total area under the plasma level–time curve is $AUC_\infty = A/\alpha + b/\beta$. [c] Slope of plot of cumulative drug *excreted at time* t, ΣU_t, against the area under the plasma level–time curve until that time, where $AUC_t = (a/\alpha)(1 - e^{\alpha t}) + (b/\beta)(1 - e^{-\beta t})$. [d] $Cl_{met} = Cl_{tot} - Cl_{ren}$. [e] Apparent volume of distribution of central compartment referenced to plasma concentration, $V_c = p_0$/dose (ng) = $(a + b)$/dose (ng). [f] Apparent overall pseudo steady-state volume of distribution referenced to plasma concentration, $V_d = Cl_{tot}/\beta$. [g] Apparent overall volume of distribution on the assumption of the one-compartment body model, V_{extrap} = b/dose (ng).

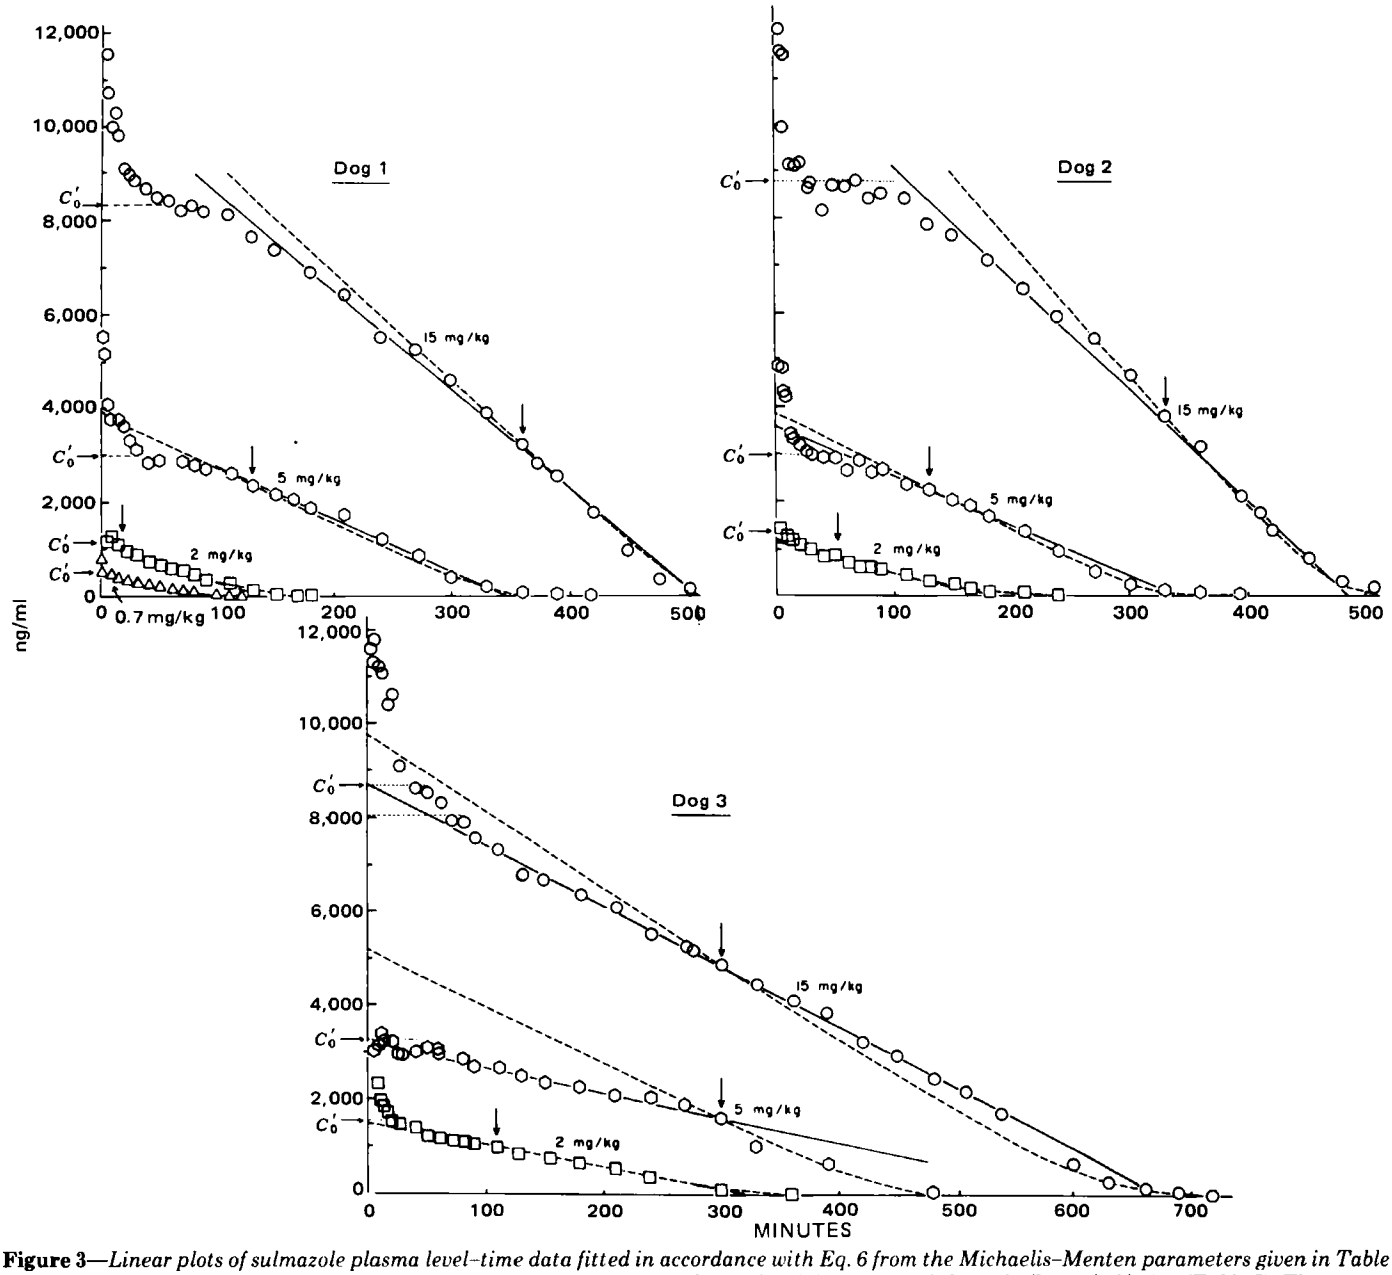

Figure 3—*Linear plots of sulmazole plasma level–time data fitted in accordance with Eq. 6 from the Michaelis–Menten parameters given in Table I (- - -) and fitted on the presumption of constant zero-order rates of plasma level decay (—) of slopes* k_0/V *(ng/ml/min) (Table I). The arrows designate the plasma level* (p_1) *values taken at time* t_1 *for the calculation of* t_2 *for any plasma level* p_2 *by Eq. 6.*

This can be seen at the 15-mg/kg dose but less so at the 2-mg/kg dose. One possible explanation of the constantly recurring plateau or increase in plasma levels for all three dogs at 40–100 min after drug administration may be the presence of enterohepatic recirculation, the delayed continuous reabsorption of biliary excreted sulmazole from the GI tract.

The v_{max}-values of Table I have reasonable precision that average ±7% and show a decided dose effect: 23.9 ± 3.9, 13.3 ± 0.3, and 8.7 ± 1.9 ng/ml/min (*SEM*) at the 15-, 5-, and 2-mg/kg iv doses of sulmazole, respectively. The estimated K_m-values with their much higher variability averaging ±32% do not permit any conclusion as to dose dependencies. The overall average of 232 ± 36 ng/ml (*SEM*) is relatively small and does not disturb the linearities of the concentration–time plots of sulmazole for the greatest portion of the time course.

The fact that one set of v_{max}/K_m-values fails to characterize the plasma level–time values of sulmazole for all doses is apparent when the set of values for the 5-mg/kg dose was used to attempt to fit the data at all doses (dashed lines in Fig. 1).

The v_{max}/K_m-values and the derived $(t_{1/2})_{v_{max}}/K_m$-values (Table I) provide estimates of the apparent first-order rate constant effective at low drug concentrations in plasma in accordance with the postulation of one saturable elimination process directing the elimination that conforms to Michaelis–Menten kinetics.

Although there appears to be a systematic decrease in the averages of the v_{max}/K_m-values and an accompanying systematic increase in the averages of the apparent half-lives with decreasing dose (0.7 ± 1.5, 10.0 ± 1.5,and 15.0 ± 3.4 min (*SEM*) at 15, 5, and 2 mg/kg of sulmazole, respectively), the standard errors do not permit an absolute decision. The data for dog 3 were contrary to those of the averages.

The plasma level–time curve for sulmazole at the lowest dose studied, 0.70 mg/kg, is plotted semiliogarithmically in Fig. 4. At this dose the pharmacokinetics appear to be linear; the drug appears to be eliminated by first-order processes from a two-compartment body model. The pharmacokinetic parameters are listed in Table II. The terminal half-life of 29.5 min confirms the indicated increase of the terminal half-life with decreasing dose.

Data Analyses on the Presumption of Zero-Order Pharmacokinetics—Constant slopes k_0^I/V_I (ng/ml/min) can be obtained from the slopes of the plotted data in Fig. 3 and can reasonably characterize the plasma level–time data of sulmazole. These are given in Table I and are close to the estimated v_{max}-values. Considering that they give less weight to the terminal data, they show similar dose dependencies.

The dose dependencies of k_0/V_I and v_{max} permit the conclusion that the simple model of a Michaelis–Menten single saturable elimination process with a constant v_{max} cannot describe the sulmazole plasma

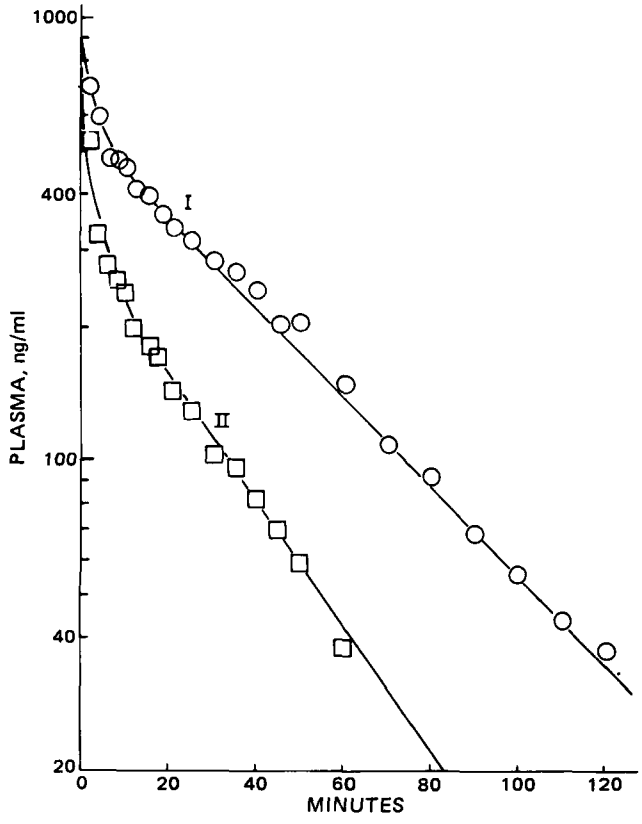

Figure 4—*Semilogarithmic plots of plasma levels of sulmazole (I) and II after intravenous administration of 0.7 mg/kg of each to dog 1. The curves through the data were constructed from the parameters given in Table II in accordance with* $p = ae^{-\alpha t} + be^{-\beta t}$.

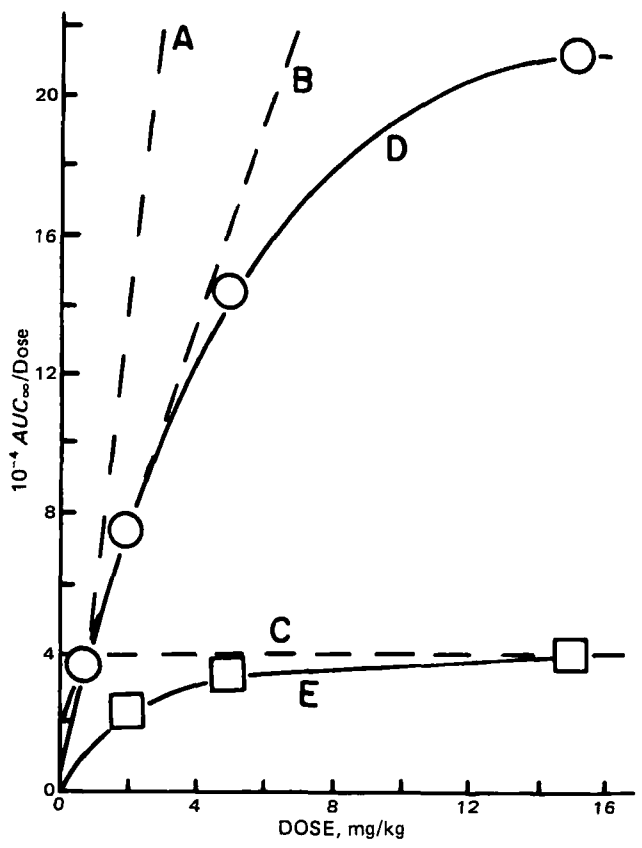

Figure 5—*Plots of ratios of total area under the curve (ng/min/ml^{-1}) to dose (mg/kg) against dose for sulmazole (○), curve D, and metabolite II (□), curve E. The anticipated forms of curves expected are given as dashed lines for (A) zero-order kinetics with constant elimination rates at all doses, (B) saturable pharmacokinetics with constant Michaelis–Menten parameters at all doses, and (C) first-order elimination rates.*

level–time data at all doses, even though it may give a reasonable fit at a given dose. The linearities of the plasma level–time data (Fig. 3) over such long time periods deny the existence of significant parallel first-order processes of elimination. Such processes could increase elimination rates at higher doses and plasma concentrations.

The apparent zero-order rate constants, k_0^I/V_I (ng/ml/min) in the 2–15-mg/kg dose range can be well characterized by the linear plot of their average values *versus* dose of sulmazole (mg/kg), $r = 0.9996$, to give:

$$k_0^I/V_I(\pm 0.26) = 0.985(\pm 0.027) \times \text{Dose} + 4.17 \pm 0.25 \quad \text{(Eq. 7)}$$

The apparent overall volumes of distribution referenced to plasma concentration of sulmazole apparently were dose independent and were obtained from the intercept, C_0, obtained from the extrapolation of the *straight line* of best fit through the plasma level–time data and averaged V_I = dose (ng)/C_0 (ng/liter) = 36.5 ± 1.7 liters. The value of V_I by this method was 30 liters for the 0.7-mg/kg dose (Table II, Fig. 4). These volumes could also be estimated from the intercept, C_0', obtained from extrapolation of the plateau in the 40–100-min interval (Fig. 3) after intravenous administration and a V_I' = dose (ng)/C_0' (ng/liter) = 41.0 ± 1.1 liters. The latter equation may be the more valid estimate if enterohepatic circulation did exist. Its existence would cause an overestimation of C_0 in the equilibrated fluids of the body and an underestimation of the apparent volume of distribution by the former method. The lower standard error of the mean of the latter (V_I') with respect to the former (V_I) at several doses confirms this. The values are listed in Table I. The averages of the $(k_0^I)' = V_I'(k_0/V_I)$ of sulmazole eliminated from the body are correlated well with the dose in milligrams per kilogram in the 2–15-mg/kg range, $r = 0.9982$, by:

$$k_0^I \pm 0.161 = (0.426 \pm 0.167) \times \text{Dose} + 1.71 \pm 0.15 \quad \text{(Eq. 8)}$$

Areas Under Plasma Sulmazole Level–Time Curves and Possible Relations to Doses—The total area under the plasma level–time curve for saturable (Michaelis–Menten) disposition pharmacokinetics for the one-compartment body model (23) of volume V with an intravenous bolus is:

$$AUC_\infty^{sat} = \frac{D}{v_{max}V}\left(\frac{D}{2V} + K_m\right) = \frac{D}{k_0}\left(\frac{D}{2V} + K_m\right) \quad \text{(Eq. 9)}$$

Thus:

$$AUC_\infty^{sat} = \frac{D^2}{2v_{max}V^2} + \frac{K_mD}{v_{max}V} = \frac{D^2}{2k_0V} + \frac{K_mD}{k_0} \quad \text{(Eq. 10)}$$

The ratio of the total area under the plasma level–time curve for zero-order elimination (k_0) to dose (D) for the one-compartment body model with an intravenous bolus is:

$$\frac{AUC_\infty^0}{D} = \frac{D}{2v_{max}V^2} = \frac{D}{2k_0V} \quad \text{(Eq. 11)}$$

where $v_{max} = k_0/V$.

In Eqs. 10 and 11 plots of the ratio of total area–dose should be linear functions of dose with a positive slope. In the saturable case (Eq. 10), the intercept should be positive; in the zero-order case (Eq. 11), the intercept should be zero.

The ratio of the total AUC for first-order elimination to the doses is a constant:

$$AUC_\infty^I/D = 1/\beta V = 1/Cl_{tot} \quad \text{(Eq. 12)}$$

where the total clearance (Cl_{tot}) is a product of the terminal rate constant (β) and the apparent overall volume of distribution (V).

Such ratios of AUC–dose in milligrams per kilogram are given in Table I for sulmazole, AUC_∞^I/D. The ratio for the 0.7-mg/kg dose was 36,000. A plot of the ratio *versus* dose is given in Fig. 5 for sulmazole. The ratio increases with dose to indicate nonlinear pharmacokinetics, but it does not increase linearly. Sulmazole does not conform to the patterns anticipated for true saturable or zero-order pharmacokinetics in the one-compartment body model. This is a consequence of the apparent increases of v_{max} or k_0^I/V (Fig. 3, Table I) with the initial dose, where k_0^I/V, the zero-order rate of elimination, persists throughout the major time course of the drug in the plasma.

Pharmacokinetics of the Formation of II from Sulmazole—The time courses of formation of II in the plasma on intravenous administration of sulmazole at 2, 5, and 15 mg/kg are plotted in Fig. 6 for the

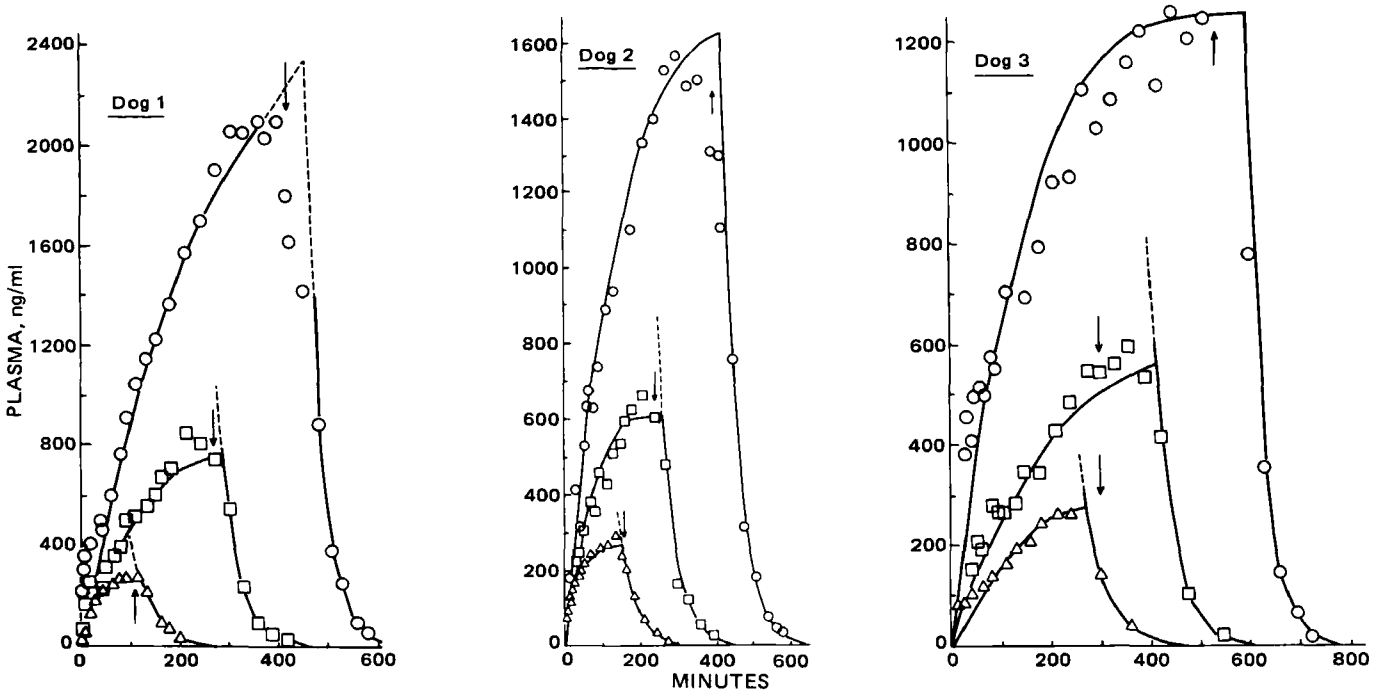

Figure 6—*Linear plots of plasma levels of metabolite II as formed with time after intravenous administration of 2 (△), 5 (□), and 15 (○) mg/kg of sulmazole to dogs 1–3. The arrows designate the approximate times of cessation of zero-order depletion of sulmazole in the plasma. The curves drawn through the points prior to the maxima were calculated from [II] = $(k_0^{II}/V_{II})t - (Cl^{II}/V_{II})AUC_{II}$. The curves drawn through the points subsequent to the maxima were calculated from $C_0^{II}e^{-\beta_{II}t}$ where the pertinent parameters are given in Table I.*

studies in dogs 1, 2, and 3. The shapes of the curves imply a zero-order formation of II up to the times marked by the arrows, where sulmazole was depleted from the plasma and a subsequent first-order elimination. This hypothesis was challenged.

If first-order formation and elimination existed, the amount of II formed could be expressed as:

$$II = Cl^{I\to II}AUC^{I} - Cl^{II}AUC^{II} \qquad \text{(Eq. 13)}$$

where AUC^{I} and AUC^{II} are the respective areas under plasma level–time curves for I and II, and $Cl^{I\to II}$ and Cl^{II} are the clearances of I–II and of II, respectively. Since the amount of II = V_{II} [II], where V_{II} is the apparent overall volume of distribution of II, and [II] is the plasma level, Eq. 13 can be rearranged to:

$$[II]/AUC^{I} = Cl^{I\to II}/V_{II} - (Cl^{II}/V_{II})AUC^{II}/AUC^{I} \qquad \text{(Eq. 14)}$$

However, plots of the ratio of the plasma level [II] at a time t to the area under the plasma sulmazole–time curve up to that time t (AUC^{I}) against the ratio of the areas of plasma metabolite–time to plasma sulmazole–time (AUC^{II}/AUC^{I}) were decidedly nonlinear, contraindicating the validity of the postulation of first-order formation of II from sulmazole with a constant clearance $Cl^{I\to II}$ with subsequent first-order elimination or constant clearance of II, Cl^{II}.

A zero-order formation of the amount of II from sulmazole with subsequent first-order elimination can be expressed as:

$$II = k_0^{II}t - Cl^{II}AUC^{II} \qquad \text{(Eq. 15)}$$

This expression can be rearranged to:

$$[II]/AUC^{II} = (k_0^{II}/V_{II})(t/AUC^{II}) - Cl^{II}/V_{II} \qquad \text{(Eq. 16)}$$

and plots of the ratio of plasma levels of the metabolite [II] at a given time (t) to that of the area under the plasma metabolite concentration (AUC^{II}) to that time against the ratio of the time (t) to the AUC^{II} should be linear with a slope k_0^{II}/V_{II} (ng/ml/min) and a negative intercept of Cl^{II}/V_{II} (min^{-1}), the apparent overall rate constant of elimination of the metabolite from its equilibrated tissues. These plots (Fig. 7) were linear to confirming the postulation of zero-order formation of the metabolite, II, with its subsequent first-order elimination. The obtained zero-order rates of formation of II from sulmazole, k_0^{II}/V_{II} (ng/ml/min), and the apparent clearance per unit volume of II, Cl^{II}/V_{II} (min^{-1}), are given in Table I.

The plasma values of II with time were calculated with these parameters and plotted as the curves through the data before the maximal values in Fig. 6. The values of maximum time corresponded to the cessation times of the zero-order rate of depletion of sulmazole in the plasma (Figs. 3 and 4).

Subsequent to the maximal values, metabolite plasma levels of II decreased by an apparent first-order process which could be characterized by:

$$[II] = C_0^{II}e^{-\beta II t} \qquad \text{(Eq. 17)}$$

where the values for C_0^{II}, the apparent plasma level extrapolated to zero time, and β_{II}, the apparent overall first-order elimination rate constant of II, are listed in Table I. These latter values appear to be dose-independent for plasma concentrations <2000 ng/ml of II, and the half-lives average 26.5 ± 1.2 min, consistent with the terminal half-life of 21.2 min when 0.7 mg/kg of II was administered (Fig. 4, Table II), a dose when the pharmacokinetics of II appear to conform to a two-compartment body model with first-order processes. The plasma values of II on sulmazole administration, subsequent to the maximal values, were calculated from the obtained C_0^{II} and β_{II}-values of Table I and were plotted through the experimental data in Fig. 6.

The rate of appearance of II (ng/min), k_0^{II}, was calculated from the product of the k_0^{II}/V_{II}-values (Table I) and the apparent overall volume of distribution, V_{II} = 48,558 ml, obtained from the administration of 0.7 mg/kg iv of II (Table II). Although the k_0^{II}-values of II appearance decreased consistently (5.07 ± 0.31–2.89 ± 0.73 ng/min) with the decrease of sulmazole dose from 15 to 5 mg/kg, the values at 2 mg/kg of sulmazole were high for dogs 1 and 2 (>1). A possible reason is that the volume of distribution for II (V_{II}) obtained from the single 0.7-mg/kg iv bolus study of II and used to convert k_0^{II}/V_{II}, the zero-order rate of II appearance per unit of volume, to k_0^{II} was not valid in these particular studies. If these values were not included, the ratio of k_0^{II} (corrected to sulmazole equivalents) to k_0^{I}, the apparent zero-order rates of II appearance and sulmazole disappearance, respectively, averaged 0.75 ± 0.04 (Table I) and were reasonably consistent among doses and dogs. The two anomalous values at 2 mg/kg for dogs 1 and 2 showed ratios of 1.77 and 1.87, respectively. It is concluded that 75% of the sulmazole is transformed to its major metabolite, II, by the zero-order process, 73 ± 3% at 15 mg/kg and 81 ± 6% at 5 mg/kg of sulmazole.

If, as shown in Table I, a relatively constant fraction of II was formed from I and if II were eliminated only by first-order processes or dose-independent clearances, the ratio of the area under the plasma level–time curve for II to the dose would not change with dose in accordance with Eq. 12. The fact that there is an increase of the ratio AUC_{∞}^{II}/dose with dose (Table I, Fig. 5), although not as significantly great as the comparable

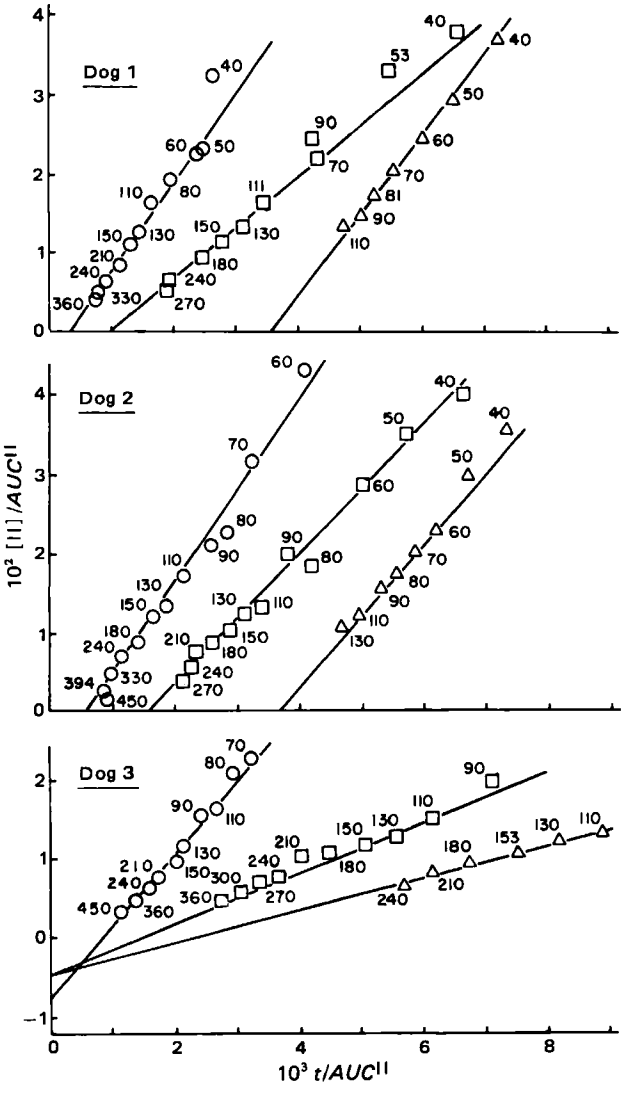

Figure 7—*Plots in accordance with Eq. 16 for the estimation of the zero-order appearance of metabolite II (slope = k_0^{II}/V_{II}, ng/ml/min^{-1}) and its first-order disappearance (intercept = $-Cl^{II}/V_{II}$, min^{-1}) for intravenous doses of 2 (△), 5 (□), and 15 (○) mg/kg of sulmazole.*

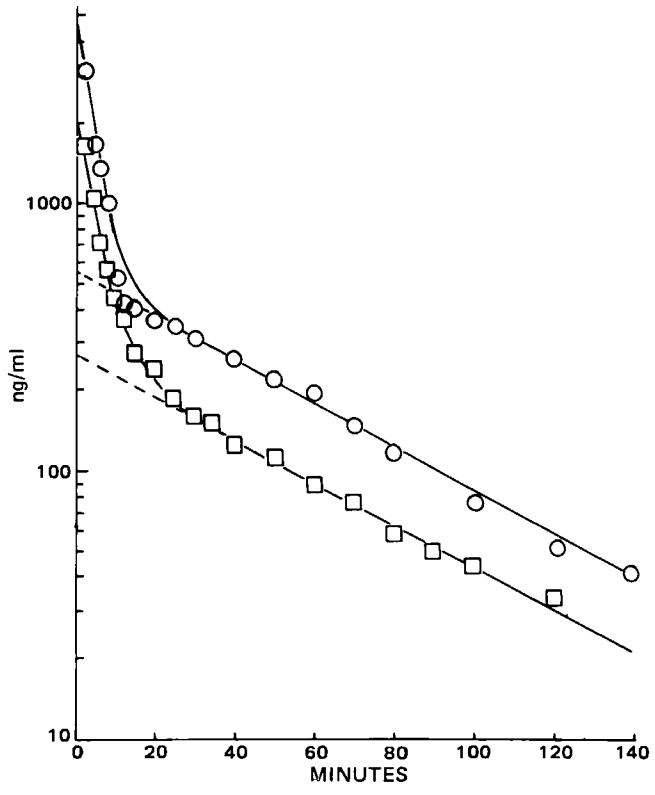

Figure 8—*Semilogarithmic plots of plasma levels of metabolite III against time when III was administered intravenously at 1 (□) and 2 (○) mg/kg. The curves through the data are drawn in accordance to* $p = ae^{-\alpha t} + be^{-\beta t}$ *where the pharmacokinetic parameters are given in Table II.*

ratio for sulmazole, indicates some degree of nonlinear pharmacokinetics for II at the higher sulmazole doses.

Pharmacokinetics of III—There was negligible renal excretion of unchanged I, II, and III. A possible route of metabolism of sulmazole, in addition to its oxidation to II, is its hydroxylation to III, since III is observed in the urine, although plasma III levels, even at 15 mg/kg of sulmazole, were below the analytical sensitivities.

The pharmacokinetics of III were studied at 1.0 and 2.0 mg/kg after intravenous administration of III and conformed to a two-compartment body model with apparent first-order transferences (Table II, Fig. 8). There were no apparent dose dependencies. Total clearances (1040 ml/min), terminal half-lives (37.3 min), and volumes of the central compartment (10 liters) and overall volumes (56 liters) were not significantly different for the two doses.

The lack of significant plasma levels and the fact that a week-long phenobarbital regimen did not increase sulmazole elimination rates significantly over the prephenobarbital regimen study at a dose of 2 mg/kg of sulmazole (Fig. 1) indicates that the hydroxylated compound is not a major product in sulmazole elimination. Phenobarbital is a well-known inducer of phenyl ring hydroxylation.

Renal Elimination of I and Metabolite II—Unchanged I was excreted renally at an average of 2.3 ± 0.4% of the administered dose (Table III) with no apparent statistically significant dose effects. Similarly, an average of 0.27 ± 0.05% of the administered sulmazole dose was excreted renally as metabolite II. Typical plots of cumulative amounts excreted with time are given in Fig. 9.

When there were narrow ranges of urine flow rates (Table III) reasonably constant renal clearances could be obtained from the regressions:

$$\Delta U/\Delta t = Cl_{ren} p_{t_{mid}} \quad \text{(Eq. 18)}$$

where $\Delta U/\Delta t$ is the amount (ΔU) of material excreted in a time interval (Δt), where $p_{t_{mid}}$ is the plasma level at the mid time of that interval, and:

$$\Sigma U = Cl_{ren} AUC \quad \text{(Eq. 19)}$$

where ΣU is the cumulative amount of material excreted at a time when AUC is the area under the plasma level–time curve up to that time.

In those cases where the urine flow rates varied over wider ranges, it was not possible to obtain reasonable correlations for Eqs. 18 and 19. The apparent renal clearance (Cl_{ren}^{app}) showed significant functional dependence on urine flow rate ($\Delta V/\Delta t$):

$$Cl_{ren}^{app} = (\Delta U/\Delta t)/p_{t_{mid}} = a \pm s_a + (b \pm s_b)(\Delta V/\Delta t) \quad \text{(Eq. 20)}$$

Examples of this dependence are shown in Fig. 10. Fittings of cumulative amounts of materials excreted into the urine with time are shown in Fig. 9 for the premises of constant renal clearance and renal clearances varying with urine flow rates using the parameters of Eq. 20 listed in Table III.

The apparent renal clearances of sulmazole varied between 1.6 and 7.4, except for the 13.8 ml/min of the 0.7-mg/kg dose with an overall average of 3.9 ± 0.8 ml/min. The apparent renal clearance of metabolite II varied between 1.0 and 3.4 ml/min, except for the 6.4 ml/min from the 0.7-mg/kg dose of sulmazole, with an overall average of 1.8 ± 0.3 ml/min. Even when corrected for protein binding, the respective renal clearance referenced to free drug in plasma of I and II did not exceed 6.6 and 3.91 ml/min. This is strong evidence for a high excess of tubular reabsorption which is supported by the dependence of apparent renal clearance on urine flow rate (Eq. 20).

The renal clearance of 0.7 mg/kg of intravenously administered II was 3.0 ml/min from the plot in accordance with Eq. 18 (Fig. 11). The renal clearance of 1.0 and 2.0 mg/kg of intravenously administered III was independent of dose (0.25 ml/min) (Fig. 11). The plots of cumulative urinary excretion against time of III are given in Fig. 12 and conformed to the values calculated in accordance with Eq. 19.

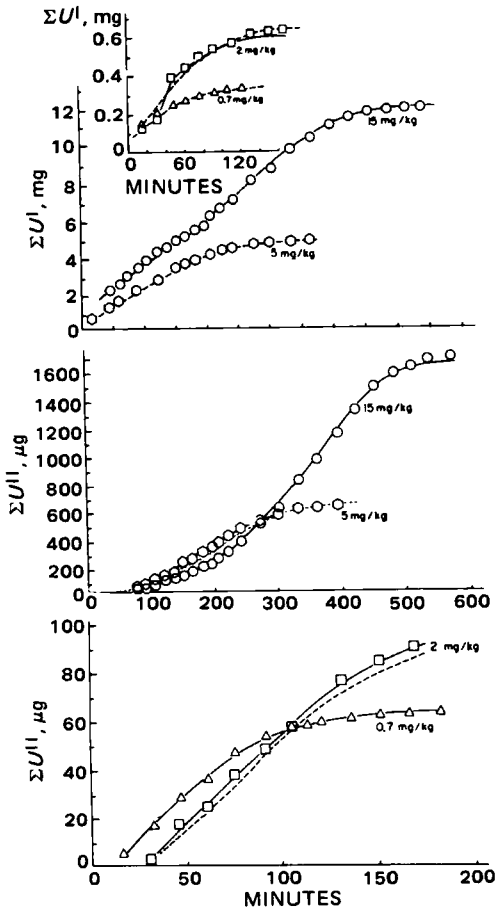

Figure 9—*Plots of cumulative amounts of unchanged sulmazole and metabolite II excreted in urine for the labeled amounts of sulmazole administered intravenously to dog 1. The dashed lines are plotted for an assumed sulmazole constant renal clearance, Cl^{I}_{ren}, of 7.4, 7.77, and 13.8 ml/min for the 5-, 2-, and 0.7-mg/kg doses, respectively, in accordance with $\Sigma U^{I} = Cl^{I}_{ren} AUC^{I}$. Dashed lines are plotted for an assumed metabolite II constant renal clearance, Cl^{II}_{ren}, of 3.35 and 2.77 ml/min for the sulmazole doses of 5 and 2 mg/kg, respectively, in accordance with $\Sigma U^{II} = Cl^{II}_{ren} AUC^{II}$. The solid lines are calculated for a urine flow-dependent renal clearance, $Cl_{ren} = a + b(\Delta V/\Delta t)$ where the a and b constants are given in Table III.*

Possible Rationales for the Unusual Nonlinear Pharmacokinetics of Sulmazole—The higher maximal zero-order rates of sulmazole elimination and transformation over large sulmazole concentration ranges at higher initial doses of sulmazole cannot be described by simple Michaelis–Menten kinetics. It is possible to speculate why. The hypothesis of product-inhibited processes (as by hydroxylated metabolite) (25) cannot explain this phenomenon, since this factor would lower maximal zero-order rates with the higher dose. In addition, it has been shown that *p*-hydroxylation of the phenyl ring is not the major metabolic route.

It was recently argued (25) that the Michaelis–Menten model for nonlinear processes has definite limitations, in that its basic premise is the establishment of a quasi-equilibrium process; *i.e.*, the validity of Eq. 1 is based on the premise of ready establishment of an equilibrium between the drug and the metabolizing enzyme where the subsequent rate-determining step depends on the concentrations of enzyme-bound substrate. A general unsteady-state model was proposed which denies the steady-state postulate underlying Michaelis–Menten kinetics. These concepts were applied to the simulation of plasma level–time curves on the premise of competition of metabolic products with substrate for plasma-, enzymes-, and tissue-binding sites to demonstrate that product-inhibited transformations would not necessarily conform to Michaelis–Menten kinetics.

The unsteady state concept may be useful to model this system, where the apparent zero-order elimination rate of sulmazole disappearance and metabolite II appearance seems to be dose- and initial plasma concentration-dependent. Speculation on the basis of an unsteady state possibly could lead to explanations of the unusual nonlinear pharmacokinetics

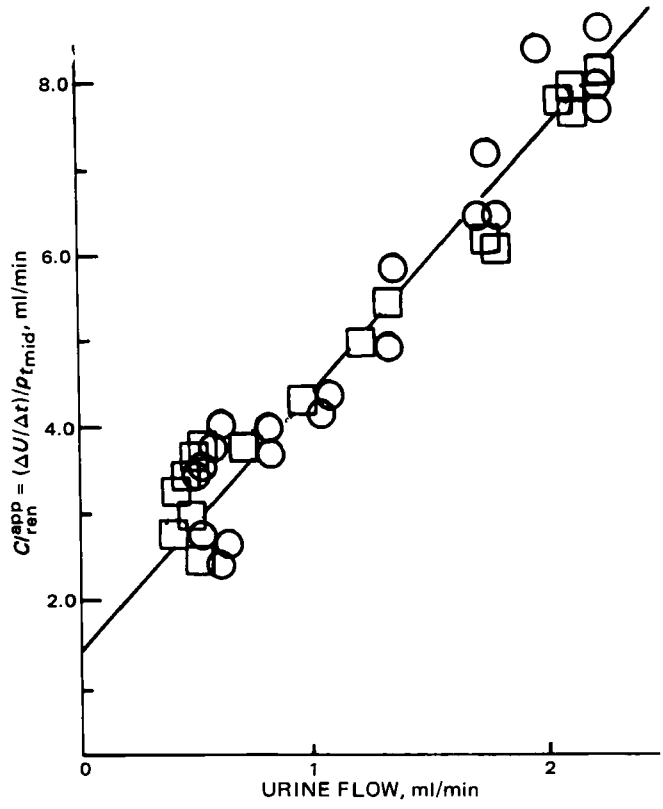

Figure 10—*Example of the dependence of the apparent renal clearance, Cl^{app}_{ren}, of sulmazole (○) and II (□) for a urine collection interval on the urine flow rate, $\Delta V/\Delta t$, in that interval for dog 1 (15-mg/kg dose study).*

of sulmazole where the major route of sulmazole substrate metabolism to II can be postulated as:

$$S + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (SR) \xrightarrow{k_3} (MR) \xrightarrow{k_4} M + R \qquad \text{(Eq. 21)}$$

and it can be conjectured that substrate (S) has noninstantaneous but high affinity to large numbers (R) of receptor sites.

If the rate of transformation of receptor-bound substrate (SR) to receptor-bound metabolite (RM) and the subsequent regeneration of free receptor sites by dissociation of metabolite (M) were not instantaneous processes, there could be a preliminary interval when few free receptor sites would be available to bind to the substrate. This would explain the existence of initial plateaus in the plasma level–time curves of Fig. 3 subsequent to an initial drop in plasma levels and provide an alternative explanation to enterohepatic circulation as their cause.

Also, if the transformation of receptor-bound substrate (SR) to receptor-bound metabolite (RM) and its subsequent dissociation were rate-determining and time-dependent processes, the release of receptor-bound metabolite and the removal of substrate by available receptor sites would be greater for initially higher doses (or concentrations) of

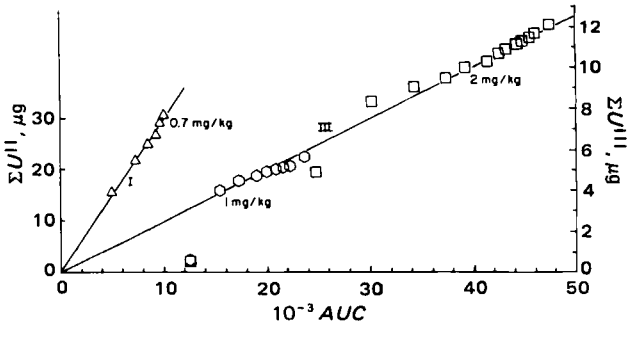

Figure 11—*Renal clearance plots in accordance with Eq. 19 for intravenous administration to dog 1 of 0.7 mg/kg of II (△, left ordinate, Cl^{II}_{ren} = 3.0 ml/min) and 1.0 (□) and 2.0 (○) mg/kg of III (right ordinate, Cl^{III}_{ren} = 0.25 ml/min).*

[c] Regression coefficient and its standard error of estimate for plots of rate of excretion in an interval against the plasma level at the midtime of that interval. [d] Specified plots were nonlinear due to Cl_{ren} dependence on urine flow. [e] Constants for the linear regression and their standard errors (22) of apparent renal clearances [$Cl_{ren} = (\Delta U/\Delta t)/p_{t_{mid}}$ (ml/min)], the ratio of amount of compound excreted in a time interval, Δt, divided by the plasma level of compound at the midtime of that interval, on the urine flow rate [$\Delta V/\Delta t$, ml urine/the collection interval (ml/min)] in accordance with $Cl_{ren} = (b \pm s_b)(\Delta V/\Delta t) + a \pm s_a$. [f] Insufficient variation in urine flow ($\Delta V/\Delta t$) to warrant attempted regression of Cl_{ren} or no significant regression. [g] Correlation coefficient for dependence of apparent renal clearance on urine flow rate.

sulmazole when the plasma levels reach those initially obtained from lower doses than when the lower doses were administered. Thus, a dose-dependent rate of loss of sulmazole would be observed, since there would be slower overall rates of metabolism at lower doses where the available sites would be occupied by metabolites for greater fractions of the time course and not available for the depletion of plasma levels.

This model has been confirmed by simulation on the analogue computer. The conformity of the simulations with the observed data will be presented in detail in the future.

Summary—The experimental data indicate that the higher dose and initial concentration give the greater constant rate of sulmazole loss from plasma. The proposed nonsteady-state model would account for these unusual nonlinear pharmacokinetics if it is speculated that all receptor sites can be potentially occupied by substrate, but not instantaneously, that there is a time- and plasma concentration-dependent rate of occupation of receptor sites and a time-dependent release of metabolite to provide unreacted receptor sites.

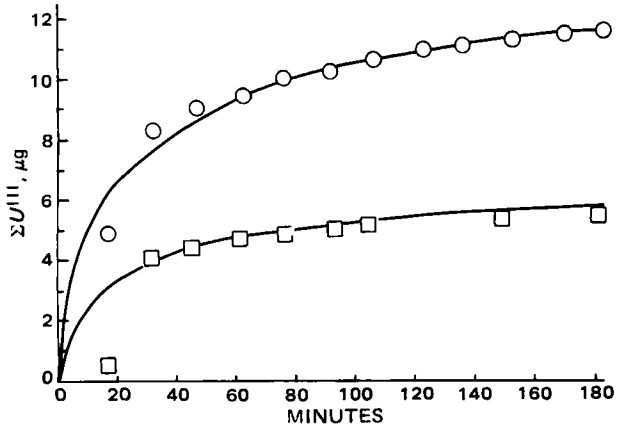

Figure 12—*Cumulative plots of III excreted with time at 1.0 (□) and 2.0 (○) mg/kg iv of III administered to dog 1. The curves drawn through the data were plotted in accordance with* $\Sigma U^{III} = Cl^{III}_{ren}AUC$ *where* $Cl^{III}_{ren} = 0.25$ *ml/min.*

An alternative explanation can be based on the hypothesis that high concentrations of sulmazole, metabolite II, and/or another metabolite can cause an irreversible, allotropic modification of the receptor so that binding of substrate, transformation to metabolite, and/or release of metabolite are enhanced.

Effect of Insulin and Dinoprostone on D-Glucose and 2-Deoxy-D-Glucose Uptake by Normal and Diabetic Rat Hepatocytes

A. B. BIKHAZI *x, H. M. NUBANI, and E. L. COE ‡

Received July 17, 1981, from the **Department of Physiology and the* ‡*Department of Biochemistry, Faculty of Medicine, American University of Beirut, Beirut, Lebanon.* Accepted for publication November 25, 1981.

Abstract □ Suspensions of deaggregated hepatocytes were prepared by a collagenase perfusion technique from livers of both normal rats and rats rendered diabetic by streptozocin treatment. Uptake of D-glucose and 2-deoxy-D-glucose was estimated by adding ^{14}C- or ^{3}H-labeled hexose to a stirring suspension of cells in Krebs–Henseleit buffer at 37°, separating the cells by rapid centrifugation, and measuring radioactivity in the packed cell pellet. Uptake, calculated after correction for entrapped extracellular fluid, includes any hexose bound to, transported into, or otherwise immobilized in the cells. High concentrations of glucose (5–20 m*M*) establish an intracellular–extracellular distribution ratio near 1.0 within 1 min, indicating a facilitated diffusion transport system. In contrast, a low level of glucose (71 n*M*) almost immediately (<15 sec) establishes ratios of between 3 and 4, which suggests a significant amount of glucose binding to cell membrane. Such binding would not be detected at the high glucose levels because of its small magnitude. Hepatocytes from diabetic rats exhibit a decrease in this apparent binding to ~60% of normal; preincubation with 0.1 IU/ml insulin increases this toward normal values, although it does not affect the binding by normal hepatocytes themselves. Preincubation with 0.1 μ*M* dinoprostone depresses glucose binding in cells from both normal and diabetic rats. A low concentration (1.2 n*M*) of 2-deoxy-D-glucose establishes even higher intracellular–extracellular distribution ratios of between 4 and 6, but the apparent binding of this sugar is identical in normal and diabetic rat hepatocytes and is not affected by preincubation with either insulin or dinoprostone alone. However, combined treatment with both agents causes a significant increase in 2-deoxyglucose binding. The results suggest that insulin promotes formation of hexose-binding sites and conversion of these to specific glucose-binding sites while dinoprostone may act by blocking the latter conversion.

Keyphrases □ Insulin—effect on D-glucose and 2-deoxy-D-glucose uptake, normal and diabetic rat hepatocytes, dinoprostone □ Dinoprostone—effect on D-glucose and 2-deoxy-D-glucose uptake, normal and diabetic rat hepatocytes, insulin □ Hepatocytes—rat, normal and diabetic, effect of insulin, dinoprostone on D-glucose, 2-deoxy-D-glucose uptake

The roles of insulin and prostaglandins on glucose retention by adipocytes, muscle cells, and hepatocytes have been the subject of contention in the literature. Although some have denied the existence of any stimulatory action of insulin on sugar retention by normal hepatocytes (1, 2), others have demonstrated an increase in liver glycogen deposition in response to this hormone (3, 4). Treatment of diabetic animals with insulin is reported to augment glucose uptake by liver (5, 6), and insulin may also enhance sugar uptake by adipocytes (7) and muscle cells (8, 9). Dinoprostone stimulates glucose uptake and oxidation by adipocytes (10) and intravenous infusion of dinoprostone in humans increases blood glucose levels (11). The present study demonstrates that insulin specifically enhances binding of low levels of glucose to hepatocytes and that dinoprostone inhibits this binding

EXPERIMENTAL

Preparation of Rat Hepatocytes—Liver parenchymal cells were isolated and prepared by the procedure of Bikhazi *et al.* (12), which modified procedures previously described by Berry and Friend (13) and Ingebretsen and Wagle (14).

Tests for Cell Viability—Trypan blue exclusion test for cellular viability was routinely performed before and after the experiments and preparations showing 90% viable cells or more were used.

The metabolic state of the hepatocytes during the incubation period was examined by following the respiration rate of cell suspensions in several separate experiments. Oxygen tension was recorded continuously with the aid of a biological oxygen monitor[1]. Rates were determined from the slopes of the oxygen tension curves and were calculated in terms of μl of oxygen/mg of cell protein. Protein was determined by the biuret reaction, using bovine serum albumin as a standard on centrifuged cell pellets dissolved in 1 *N* NaOH to minimize possible interference from medium components.

Preparation of Diabetic Rats—Rats were rendered diabetic by streptozocin treatment following the procedure of Chandramouli and Carter (15) as modified by Bikhazi *et al.* (12).

Isotopically Labeled Hexose—In all experiments with labeled glucose, 10 μCi of [1-^{14}C]D-glucose (58 mCi/mmole) was added to 226 ml of buffer to give a final concentration of 71 n*M*. In experiments with labeled 2-deoxyglucose, 5 μCi of [1-^{3}H]-2-deoxy-D-glucose (18.8 Ci/mmole) was added to the same volume to give a final concentration of 1.2 n*M*.

Determination of Hepatocyte Count and Mean Diameter—Hepatocyte count (1.2×10^8 cells per liver) and mean diameter (20 μm) were estimated by the procedure of Bikhazi *et al.* (12) using an automated counting machine[2].

Uptake of D-Glucose and 2-Deoxy-D-glucose by Hepatocytes—In general, 15×10^6 cells obtained from one rat liver were added to 225 ml of stirred Krebs–Henseleit solution in a water-jacketed beaker at 37° (the data in Tables I and II represent results from six different animals). After 45 min a small volume of isotopically labeled hexose was added, and 1.5 ml aliquots of suspension were periodically withdrawn, transferred to

+I+P	0.0257 ± 0.0008	6.12	5.12	172	h

[a] Significant differences ($N = 6$). $p < 0.01$ (a,d), (b,d), (c,d), (e,h), (f,h), (g,h). No other combinations show significant differences. Extracellular concentration of 2-deoxyglucose: 1.18 n*M*. Expected intracellular concentration based on Table III: 1.00 n*M*. Other calculations and conditions are as described in Table I.

a 1.5-ml plastic centrifuge tube, and centrifuged at 10,000×*g* for 30 sec in a microcentrifuge[3]. The supernatant solution was removed, the sedimented cell pellet was rinsed 2–3 times with phosphate buffer, and the tip of the plastic tube containing the pellet was cut with a knife and placed in a scintillation vial. The pellet was solubilized with 1 ml of 1% papain solution, 5 ml of scintillation fluid was added, and radioactivity measured using a three-channel liquid scintillation spectrometer[4]. The amount of hexose retained in the pellet was estimated from the radioactivity measured in standard samples of the hexose.

The effects of insulin and dinoprostone and a combination of these two substances were evaluated with a series of four incubations carried out in parallel. A concentrated cell suspension was divided into 4 aliquots, each containing ~15 × 10^6 cells. The first aliquot was added to 225 ml of buffer solution; the second was added to the same volume of buffer solution containing 0.10 IU of insulin/ml; the third to the buffer solution containing 0.10 μM dinoprostone; and the fourth to the buffer solution containing both insulin and dinoprostone. After 45 min of preincubation, labeled hexose was added and the procedure described above was followed.

Uptake of high concentrations (5, 10, and 20 m*M*) of glucose was measured after addition of normal hepatocytes to 225 ml of buffer containing the indicated concentrations of glucose plus a tracer dose of [1-^{14}C]D-glucose.

Measurement of Extracellular Space in the Packed Pellet—The general procedure for uptake of hexoses was applied, as described above, except that labeled hexose was replaced by 5 μCi of [^{3}H]inulin. The radioactivity retained in a packed cell pellet of known volume was used to calculate the volume of medium contained within the pellet, assuming that inulin is excluded from the intracellular space. The inulin space (extracellular space) in the packed cell pellet ranged from 35 to 40%, and averaged 38%, a value consistent with the extracellular space around closely packed spheres. All estimates of uptake were corrected for inclusion of 38% of extracellular fluid in the packed cell pellet.

Statistical Treatment—Data were statistically treated and the tests of significance were checked by the standard error of the mean (*SEM*) using the Student's *t* test distribution table.

RESULTS

Viability of Hepatocytes During the Course of the Experiments—The trypan blue exclusion test indicates that almost all cells retain their ability to exclude the dye over the 45-min period of incubation. Moreover, the mean cell diameter remains constant during the incubation in either insulin or dinoprostone. A QO_2 of ~1.0 μl/mg dry weight/hr is estimated which is lower than that reported for liver slices, but is within the range of normal mammalian cells (16). The protein content of hepatocytes is ~16% of the wet weight, near the value reported for whole liver (16). The usual hexose uptake experiments were conducted after the steady-state rate of respiration had been established.

Uptake of High Concentrations of Glucose by Hepatocytes of Normal Rats—The data in Fig. 1 and Table III indicate a carrier-mediated facilitated mode of transport for glucose as expected with most mammalian cells. The intracellular concentration of glucose reaches an equilibrium value near the extracellular concentration within 1.0 min. The initial velocity of transport is too great to be estimated by the procedure used; hence, calculation of a K_M for glucose transport is impossible, although it is known to be in the millimolar range for other cell types (3).

Uptake of a Low Concentration of Glucose—Table I summarizes the uptake of glucose by hepatocytes from both normal and diabetic rats in the presence and absence of insulin and dinoprostone. Several features were evident:

1. The uptake exceeded that expected of a facilitated diffusion transport. Instead of a ratio of near 1.0 (0.885 in Table III), ratios between 2.5 and 3.5 were obtained for the intracellular–extracellular distribution.
2. Uptake was greatly reduced in hepatocytes from diabetic animals under all conditions. In terms of percent binding, untreated cells from

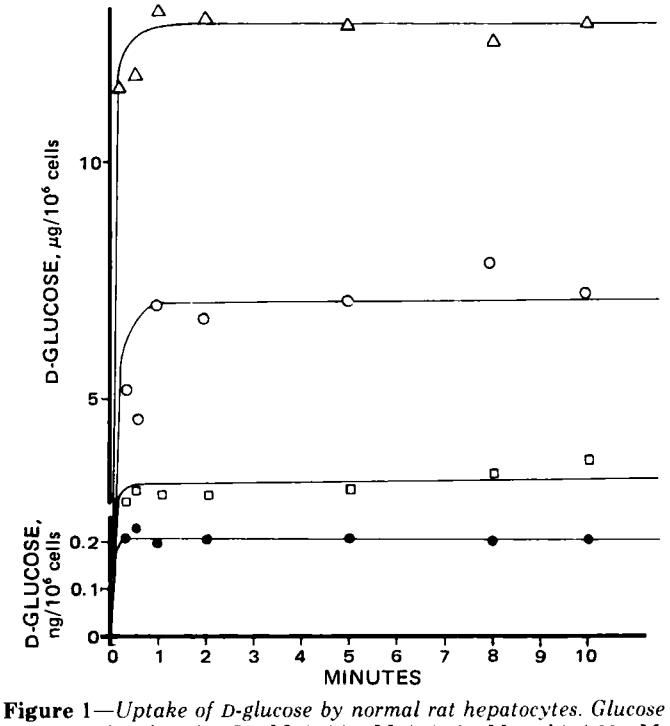

Figure 1—*Uptake of D-glucose by normal rat hepatocytes. Glucose concentrations key: (●) 71 n*M*, (□) 5 m*M*, (○) 10 m*M*, and (△) 20 m*M*. Note that the scale used for the low concentration differs from the scale for the three high concentrations.*

Table III—Uptake of High Concentrations of Glucose by Normal Hepatocytes [a]

Extracellular Concentration, m*M*	Uptake, nmoles / 10^6 cells	Intracellular Concentration, m*M*	Concentration Ratio, Intracell / Extracell
5.0	18	4.3	0.87
10.0	39	9.3	0.93
19.9	72	17.1	0.86
		Mean	0.885

[a] Uptake was estimated from the levels shown in Fig. 1. Intracellular concentration was based on cell volume estimated from a mean cell diameter of 20 μm, which gave a volume of 4.2 μl/10^6 cells. All values for uptake have been corrected for an estimated 38% inclusion of extracellular fluid in the packed cell pellet (see text).

diabetic rats were found to bind only 58% as much glucose as their normal counterparts.

3. Insulin significantly increased (but not to the normal value) the uptake by the cells from diabetic animals, but had no effect on hepatocytes from normal rats.

4. Dinoprostone tended to depress glucose uptake in both normal hepatocytes and in insulin-treated cells from diabetic rats.

Uptake of a Low Concentration of 2-Deoxyglucose—As in the case of glucose, the uptake of 2-deoxyglucose considerably exceeded the uptake expected from facilitated diffusion and gave even higher intracellular–extracellular distribution ratios (Table II). However, there are several striking differences between the glucose and 2-deoxyglucose uptake patterns.

1. There was no difference in the uptake of 2-deoxyglucose with or without insulin when cells from normal and diabetic animals were compared.

2. Dinoprostone had no depressing effect on 2-deoxyglucose uptake.

3. The only significant effect of any treatment was the marked increase in uptake and apparent binding when either cell type was exposed to a combination of insulin and dinoprostone.

DISCUSSION

A previous report (2) showed that insulin had no effect on the uptake of sugars by enzymatically dispersed normal hepatocytes. The effect of insulin in the present study was rendered evident by two factors: first, the use of hepatocytes from diabetic rats, which had a depressed glucose uptake responsive to insulin, in contrast to hepatocytes from normal rats which may already have been maximally stimulated; and second, the use of an extremely low level of glucose, much less than the physiological concentrations (~5 m*M*) usually employed in such experiments.

The excess uptake detected by the use of a very low glucose concentration probably reflects some change in the glucose binding sites in the cell. The possibility that this excess uptake is attributable to an active transport system cannot be ruled out absolutely, although it appears unlikely because of the speed of equilibration which appears within 15 sec (Fig. 1). Assuming that the excess does indeed represent glucose binding, the question remains as to what relationship this binding has to the transport mechanism and whether it indicates some change in a transport carrier protein.

The most striking difference between the excess uptake of a low level of glucose and an even lower level of 2-deoxyglucose was the lack of effect of diabetes and insulin on the 2-deoxyglucose uptake. This may indicate that different sites and/or some differential change in relative affinities of the same sites are involved in the binding of the two sugars. In either case, it appeared that the insulin effect is specific for glucose.

In conclusion insulin increases the uptake of glucose by hepatocytes from diabetic rats and not by those from normal rats, possibly because the normal cells are already maximally stimulated as is evident at low concentrations (<100 n*M*) of glucose. The insulin effect is specific for glucose since the hormone does not enhance binding of 2-deoxy-D-glucose. The results suggest that insulin promotes formation of hexose binding sites and conversion of these to specific glucose binding sites, while dinoprostone may act by blocking the latter conversion.

Method for Predicting Fill Weight Variation When Packing Powders Using Vacuum/Purge Fillers

R. C. LIJANA [x] **and J. D. TAULBEE**

Received December 18, 1981, from the *Procter & Gamble Co., Miami Valley Laboratories, Cincinnati, OH 45247.* Accepted for publication March 15, 1982.

Abstract □ The present report demonstrates that for at least four pharmaceutical powders, the variation in fill weight associated with a vacuum/purge filling port is correlated with the length–diameter ratio of that port. This relationship has been mathematically modeled, and a design curve based on production data is presented, which depicts this relationship over a wide range of length–diameter ratios. For powders with properties similar to those presented, the design curve may be used to determine the dimensions of the port which will yield acceptable process weight control. Fill weight variances also can be predicted given a fixed port diameter. For other powders, the model can be used to create design curves with a few data points.

Keyphrases □ Vacuum/purge fillers—method for predicting fill weight variation when packing powders □ Pharmaceutical powders—method for predicting fill weight variation when packing powders using vacuum/purge fillers □ Models, mathematical—method for predicting fill weight variation when packing powders using vacuum/purge fillers

Industry employs a variety of methods to fill containers with measured amounts of solids (1–6). The pharmaceutical industry most frequently uses vacuum/purge filling: the powder to be filled is drawn under vacuum from a hopper into a cylindrical port of preset dimensions. The powder is held against a piston under vacuum until a container is available for loading, then light air pressure replaces the vacuum and discharges the powder.

The weight of the powder slug is determined by the bulk density of the powder and the geometry of the filling port. The diameter of the port (d) is determined by the choice of a filling wheel and can be varied only by changing wheels. The depth of the port, or the length (l), can be adjusted at any time but is generally set before a filling run begins. The choices of filling wheels and port length settings to achieve the proper powder weight delivery are normally determined by trial and error, requiring a large number of determinations. Since variability around the desired weight is an important consideration in pharmaceutical solid dose preparation, selecting the combination of settings yielding the minimum variation is desirable.

Design curves, *i.e.*, mathematical models fitted to empirical data and correlating equipment variables with desired results, frequently have been used in the chemical process industries to reduce dependence on trial and error adjustments. Unfortunately, the literature is lacking convenient mathematical relationships by which the operation and precision of filling equipment for the pharmaceutical industry can be predicted and optimized. Piston compaction/ejection equipment was studied (7), and the compaction forces needed to achieve the required fill weight, given powder bed height, and piston height were tested. Earlier, a mathematical model was developed (8) for filling gelatin capsules. Similar fillers were studied (9) but there was only an interest in the packing properties of various powders as a source of fill-weight variation. Thus, none of these contributions are directly applicable to the stated problem.

The object of the present work, therefore, was to develop a design curve relating the variance of powder fill weights to equipment variables for a specific set of vacuum/purge fillers and a specific set of pharmaceutically useful powders. It was hoped that the technique and the design curve used might also be shown to be more generally useful.

THEORETICAL

The variance in powder fill weights can be transformed into a dimensionless parameter and normalized by a new variable, CV, the coefficient of variation, defined as:

$$CV = \frac{S}{\overline{W}} \times 100\% \qquad \text{(Eq. 1)}$$

where S is the standard deviation of fill-weight data, and $\overline{W}$ is the average fill weight.

The independent variable for the model can incorporate both equipment and component effects as follows. Assuming the walls of an individual cylindrical port to be smooth, then the variation in the weight of a powder plug is proportional to the exposed lateral surface area and to the pressure drop across the cylinder. Assuming further that the pressure drop is constant across the length of the powder plug (distance) and time, then the pressure drop is solely a function of component properties and the integrity of the piston/filler which is used to set port length: $\Delta p = f$ (crystallinity, particle size, particle shape, piston integrity).

The component properties can be related to the bulk density of a material. Piston integrity can decrease during the course of routine filling due to blinding, but measured port pressure changes alert the operator to the need for piston replacement. Thus, $\Delta p = f$ may be reduced to:

$$\Delta p \propto \rho \qquad \text{(Eq. 2)}$$

where ρ is the material bulk density.

Viewed from another perspective, the bulk density of a material determines the length of a contained powder plug and, therefore, the length of exposed cylinder for a specified fill weight and port diameter. This diameter, in turn, is an equipment parameter which determines the exposed lateral surface areas. Therefore, the independent dimensionless variable for the design curve may be:

$$\frac{l}{d} \qquad \text{(Eq. 3)}$$

where l is the length of the powder plug and d is the diameter of the port.

Consideration of certain boundary conditions, which will be more fully discussed, suggests that the model should have both vertical and horizontal asymptotes. Such a model can be constructed as follows:

$$y = A + B_1/(x - v) + B_2/(x - v)^2 + \ldots + B_n/(x - v)^n \qquad \text{(Eq. 4)}$$

where y is CV, x is the l/d ratio, A is the horizontal asymptote, and v is the vertical asymptote.

The vertical asymptote should be fixed at zero, otherwise the model has the unrealistic characteristic that once the l/d ratio is less than v, the CV begins to decrease with decreasing l/d ratio.

The model of choice to attempt to fit the design curve, then, is:

$$y = A + B_1/x + B_2/x^2 + \ldots + B_n/x^n \qquad \text{(Eq. 5)}$$

where terms are added until the parameter for the last term is not statistically different from zero.

The interpretation of Eq. 5 is that A is the smallest value of CV, which can be attained by varying the l/d ratio. Implied also is that CV will increase as the l/d ratio becomes small. This is reasonable, because with

0022-3549/83/0200-0119$01.00/0

Table I—Filler Dimensions and Calculated Packed Densities for Zinc Acetate Powder Filling

	Plug Diameter	Plug Length	Density g/cm³	*l/d*

constant	0.95 cm	2.5 cm	0.664	2.7
	0.95 cm	3.8 cm	0.656	4.0
	0.95 cm	5.0 cm	0.659	5.3
l	0.48 cm	2.5 cm	0.666	5.3
constant	0.79 cm	2.5 cm	0.640	3.2
	0.79 cm	2.5 cm	0.638	3.2
	0.95 cm	2.5 cm	0.664[a]	2.7
	0.95 cm	2.5 cm	0.664	2.7
	0.95 cm	2.5 cm	0.643	2.7
	1.3 cm	2.5 cm	0.678	2.0
	1.3 cm	2.5 cm	0.660	2.0

[a] This measurement was repeated from the first section of Table I.

l/d ratio decreasing, the cylinder is becoming shorter and wider, and large surface area effects would contribute to a more variable fill. Conversely, if the cylinder becomes very long in relation to its diameter, pressure drop effects would add to variability and *CV* would be expected to rise. Therefore, the minimum *CV* would be expected to occur at an *l/d* ratio between the extremes.

The model (Eq. 5) does not provide for increasing *CV* with very high *l/d* values, because this phenomenon did not occur in this work. If necessary, the model (Eq. 5) can easily be modified by adding a term Ce^x, where *C* would be a small positive number. The parameter Ce^x would not contribute noticeable amounts to the expression until *x* (the *l/d* ratio) became quite large.

EXPERIMENTAL

Materials—Two vacuum/purge powder fillers were used. When small quantities of containers were packed, a semi-automatic portable powder filler[1] was used at a rate of ~5–10 containers/min. Larger quantities of containers were filled at a rate of 15–65 containers/min using an automatic powder filler[2].

Use of these two units provided port diameters ranging from 0.48 to 1.3 cm and lengths ranging from 0.19 to 9.5 cm.

Four powders currently used in marketed or investigational pharmaceutical finished-dose forms were available for study. The four materials are listed with their bulk densities. All are fine powders (<15-μm average particle size), low and constant in moisture content, and nonfree-flowing.

Material	g/cm³
1. Erythromycin base[3]	0.520
2. Zinc acetate[4]	0.655
3. Tetracycline hydrochlorides[5] and sodium bisulfite[6]	0.745
4. Similar to 3, but with different proportions	0.732

Methods—Since the first purpose of this work was to develop design curves for two fillers in use, actual production conditions and data were used. Values of *l/d* commonly used were selected and fill weights were measured. For each unique combination of product, filler, filling port diameter, and filling port *l/d* ratio, 10–60 weight measurements were taken. In all, four materials, seven port diameters, and 39 *l/d* ratios from 0.20 to 10.0 were tested. Eighty-eight coefficients of variation were calculated.

In addition to measuring fill weights, packed densities were calculated for a number of the combinations. These densities were used to test the implicit assumption of constant density in the model.

RESULTS AND DISCUSSION

Figure 1 shows the design curve relating *CV* to the *l/d* ratio for all collected data. The equation for this curve is:

$$CV = 0.35 + \frac{1.3}{l/d} \qquad \text{(Eq. 6)}$$

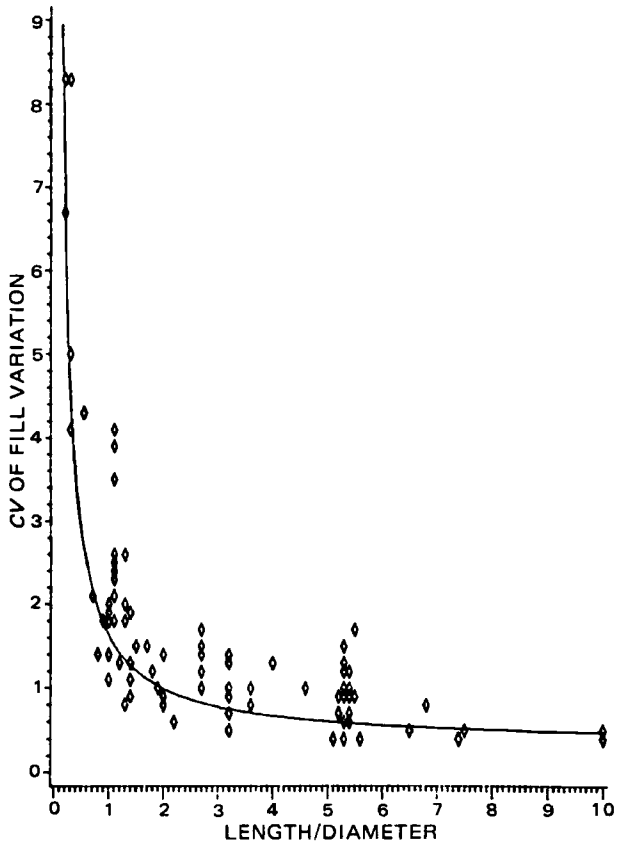

Figure 1—*Powder filling precision* versus *port size (powder plug and port dimensions) for vacuum/purge filling of four pharmaceutical powders.*

Table I shows the packed densities for samples taken during filling of zinc acetate powder.

The model was fit for each separate component using a weighted least-squares procedure with weights $1/y^2$.

Weighting was thought desirable for two reasons: the estimated *CV*s for low *l/d* ratios were expected to have higher variability, and the estimate of *A*, the minimum achievable *CV*, is an important result of curve fitting and weighting the lower *CV* values gives a better picture of the true minimum.

This proved to be reasonable, since the sum of squared deviations of the data about the model was less when the weighting procedure was used.

In all cases, the actual version of the model (Eq. 5) derived was:

$$y = A + B_1/x \qquad \text{(Eq. 7)}$$

because terms in higher powers of $1/x$ did not have coefficients that were statistically significantly different from zero, as seen in Table II. (All tests of statistical significance were done at a two-sided, 5% level.)

To examine whether another form of model might provide a better fit to the data, another fit was examined:

$$y = a \exp(b/x) \qquad \text{(Eq. 8)}$$

where *a* and *b* are the parameters of interest.

This model, like the other model (Eq. 7), has a horizontal asymptote, *a*, and a vertical asymptote, $x = 0$. The model (Eq. 8) was fitted to the zinc acetate powder data. The sum of weighted squared deviations about the model was 8.29, >1.5 times that obtained with the model (Eq. 7) for the same data (Table II). The chosen model (Eq. 7) gives a better fit than the (Eq. 8) model.

The curve in Fig. 1 is the result of combining the data for all materials. To test the validity of combining the data, statistics of the two largest blocks of data were examined. A comparison of the estimates of *A* and B_1 (Table II) of the zinc acetate data with those of erythromycin showed no statistically significant differences between them (*p*-values of 0.50 and 0.95 for *A* and B_1, respectively). There is no statistical evidence to indicate a difference in design curves for the types of powders or equipment used. Thus, it is concluded that one general physical phenomenon underlies these data and dictates the shape of the curve.

All four [c]	0.408	0.94	0.0001	0.37	2.63	0.55
All four [d]	0.347	1.29	0.0001	0.73	195.84	10.86

[a] Model from Eq. 5. [b] Filled with Model LM-14, Perry Industries, Inc., Hicksville, N.Y. [c] Filled with Model E-1200, Perry Industries, Inc., Hicksville, N.Y. [d] Combinations of powders filled with Model LM-14 or Model E-1200, Perry Industries, Inc., Hicksville, N.Y.

The shape of the curve describes several things about the characteristics of vacuum/purge fillers. It indicates that, in most cases, a powder plug l/d ratio ≥ 1.5 will yield acceptably small fill-weight variances. It indicates, further, that as the l/d ratio decreases to <1.5, powder-filling precision rapidly becomes worse and is extremely sensitive to l/d ratio changes. This is logical since the exposed surface area becomes a much greater percentage of the total surface areas as the l/d ratio decreases. It also indicates that when the l/d ratio rises >1.5, precision approaches a nonzero limiting value. This asymptote predicts that efforts to increase weight control through port (or component) changes in this region will go unrewarded.

It could be speculated that the validity of the entire approach rests on the assumption of a constant packed powder density. A variable packed density could lead to random variation in fill weight which would confound any model. To examine this, data in Table I were used. These density data are shown in two sections: one with a constant d value and one when l is constant. When d is constant and l increases, density does not significantly change. When l is constant and d increases, density does not change either. Thus, the implicit assumption of constant density used in the model development is valid.

This provides a basis for selecting the length for a filling port of preset diameter from a design curve, thereby eliminating the necessity for large-scale experimental testing of different port sizes. Given the bulk density of a powder or a mixture of powders and the required fill weight, one may use the design curve to determine the port length yielding acceptable process weight control for any preset port diameter (l/d ratio of ~ 1.5 is a good general choice). In addition, the curve allows prediction of fill-weight variances given a fixed port length. The model has been established with a large data base, it fits the data well, and it satisfies engineering constraints.

For powders similar to those used in this work, the design curve can be used as is. For powders with significantly different characteristics, a few data points will allow the curve to be established. In any such operation, various l/d ratios producing the desired fill weight should be established, then the model (Eq. 5) fitted to the data with nonsignificant terms deleted. If very high l/d ratios are used, Ce^x should be added to the model, where C is to be estimated. A plot of the data with the fitted curve will then allow a reasonable choice of the l/d ratio.

Antacid Effects on the Gastrointestinal Absorption of Riboflavin

STUART FELDMAN[x] and WYATT HEDRICK

Received November 14, 1977, from the *Department of Pharmaceutics, University of Houston, Houston, TX 77030.* Accepted for publication March 17, 1982.

Abstract □ The effect of aluminum hydroxide, magnesium hydroxide, and a combination of aluminum–magnesium hydroxide suspensions on the oral absorption of riboflavin was examined in five subjects. Coadministration of aluminum hydroxide or magnesium hydroxide suspension with riboflavin (30 mg) resulted in an increase in time of peak urinary excretion rate of riboflavin when compared with control studies. There was no increase in the peak excretion rate or total urinary excretion of riboflavin when the antacid-treated subjects were compared to the control studies. *In vitro* experiments indicated that significant binding of riboflavin to the aluminum hydroxide and magnesium hydroxide suspensions occurred. The results of the present investigation are consistent with the reported effect of aluminum ion on GI motility and the known influence of gastric emptying on the absorption of riboflavin from the GI tract.

[a] The riboflavin dose was 30 mg.

complexes (1), alterations in gastric pH (2), and changes in the rate of gastric emptying (2, 3).

It was shown (2) that aluminum hydroxide gel delayed the GI absorption of pentobarbital sodium in the rat by retarding gastric emptying. A similar effect of aluminum hydroxide gel has been shown (4) to alter the rate of disappearance of [^{51}Cr]sodium chromate from the stomach of leukemic children. In the five patients studied, administration of aluminum hydroxide gel slowed the mean maximal emptying rate from 5.1 to 1.8%/min. Effects of other antacids or combinations of antacids on gastric emptying have not been well documented.

The present investigation examines the influence of commercially available preparations of aluminum hydroxide, magnesium hydroxide, and an aluminum–magnesium hydroxide combination on the GI absorption of riboflavin in humans. The suitability of riboflavin to study the effect of antacids on gastric emptying stems from the fact that riboflavin is absorbed by a specialized transport system (5) in the proximal portion of the small intestine, and alterations in gastric emptying can produce significant changes in the rate and extent of riboflavin absorption from the GI tract (6, 7).

EXPERIMENTAL

Subjects—Five healthy male subjects (age 22–30 years; weight, 66–81 kg) volunteered for the study and gave written, informed consent. No vitamin preparations were taken for at least 1 month prior to and during the course of the study. The study was conducted over a period of 4 consecutive weeks in a randomized, crossover manner with each subject receiving riboflavin[1] control, riboflavin with aluminum–magnesium hydroxide oral suspension[2], riboflavin with aluminum hydroxide gel[3], or riboflavin with magnesium hydroxide oral suspension[4].

Riboflavin Absorption Study—After an overnight fast, each subject ingested 50 ml of water 1 and 0.5 hr prior to the administration of the drug. At the time of riboflavin administration, the bladder was voided and 30 mg of riboflavin was suspended in water and ingested in a total volume of 100 ml. This dose of riboflavin was utilized in other studies of riboflavin absorption in humans (5) and reflected alterations in gastric emptying patterns. Total urine samples were collected in plastic bags[5] at 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, 12, and 16 hr after administration of riboflavin and at convenient intervals up to 36 hr after taking the drug. Food was not ingested for 4 hr following administration of the riboflavin dose. Fifty milliliters of water was ingested after each urine sample for as long as necessary to maintain adequate urinary output. Glacial acetic acid (3 ml/100 ml of urine) was added for stability purposes. The urine samples were stored in a refrigerator or freezer until assayed. Blank urinary excretion rates of riboflavin were obtained from 2- to 4-hr urine samples collected on the day prior to the experiment.

Antacid–Riboflavin Absorption Study—One hour before administration of riboflavin, 50 ml of water was ingested. One-half hour before administration of the drug, 20 ml of either aluminum hydroxide gel or aluminum–magnesium hydroxide suspension, or 10 ml of magnesium hydroxide suspension was ingested with either 30 or 40 ml of water. At the time of riboflavin ingestion, 20 ml of aluminum hydroxide or aluminum–magnesium hydroxide or 10 ml of magnesium hydroxide followed by 30 mg of riboflavin suspended in a total volume of 100 ml of water was ingested. The collection procedure was identical to that followed for the riboflavin control samples. The antacid dose was chosen to represent minimum dosages according to label directions. A lower dose of magnesium hydroxide was necessary to minimize the possibility of a laxative effect from magnesium hydroxide. At least 1 week separated each of the riboflavin absorption studies.

Assay—After suitable dilution, the urine samples were assayed using a modified USP assay for riboflavin (5), and fluorescence was measured on a filter fluorimeter[6].

Binding Studies—Various volumes of each antacid suspension were added to two different concentrations (1.6 and 4.9 μg/ml) of riboflavin in glass bottles. These concentrations reflected the low solubility of riboflavin in aqueous solution and represented only an approximation of *in vivo* levels. The resulting suspensions were shaken in a water bath[7] at 37° for at least 30 min. Equilibrium was established by repetitive sampling. The suspensions were centrifuged[8] in warm (40°) centrifuge tubes for 2 min at 3000 rpm, and the supernatant solution was assayed for riboflavin content by the described assay method.

RESULTS AND DISCUSSION

One measure of gastric emptying rate is the time to peak urinary excretion rate of an oral dose of riboflavin. Peak excretion rate data for the five subjects studied are presented in Table I. The data, when analyzed by ANOVA and the Dunnett test (8), reveal that coadministration of aluminum hydroxide gel or magnesium hydroxide suspension with the riboflavin suspension results in a significant ($p < 0.05$) increase in the time to peak excretion rate.

The data for the peak urinary excretion rate of riboflavin in the control- and antacid-treated subjects are presented in Table II. The coadministration of the antacid mixtures with the riboflavin suspension results in a slight increase in the mean peak urinary excretion rates of riboflavin, but these data were not significantly different from control values.

The percent urinary recovery of riboflavin for the control and in the presence of each antacid studied for each subject is presented in Table III. Control riboflavin urinary recovery ranged from 12.1 to 38.0% of the 30-mg dose with a mean value of 21.4 ± 9.3%. Examination of the data in Table III reveals no change in the percent of riboflavin dose excreted in urine following concomitant administration of the antacids.

Typical plots of the urinary excretion rate of riboflavin *versus* time in one subject for each experiment are presented in Fig. 1. Administration of aluminum hydroxide gel results in a significant delay in the excretion peak time rate of riboflavin when compared with control values. This is consistent with the reported activity of Al^{3+} as a smooth muscle relaxant (9). The smooth muscle relaxing effect of aluminum hydroxide would reduce the gastric emptying rate and, therefore, result in a delay in the time until riboflavin reached its absorption site in the small intestine.

Table III—Percent Dose of Riboflavin [a] Excreted in Urine in Control and Antacid-Treated Subjects [b]

Subject	Control	Aluminum–Magnesium Hydroxide	Aluminum Hydroxide	Magnesium Hydroxide
A	38.0	43.7	29.1	31.1
B	12.1	23.2	15.6	24.9
C	24.0	12.5	20.1	28.7
D	13.6	23.4	16.1	23.8
E	19.4	21.8	24.1	19.9
Mean	21.4	24.9	21.0	25.7
SD	9.3	10.2	5.1	3.9

[a] The riboflavin dose was 30 mg. [b] Cumulative amount of riboflavin excreted per dose × 100.

Under these conditions, coadministration of aluminum hydroxide gel should result in a significant increase in the peak urinary excretion rate of riboflavin, since decreased gastric emptying would lead to a decrease in the rate in which the vitamin reaches the absorption site in the small intestine and, thereby, result in an increase in peak absorption rate (5–7). If this were the case, an increase in riboflavin bioavailability in the presence of aluminum hydroxide gel would be expected. Table III indicates that this is not the case. The mean percent riboflavin urinary recovery in control studies was 21.4%, while the percent recovery in aluminum hydroxide treated subjects was 21.0%. A possible explanation for this occurrence is presented in Table IV, which lists the percent riboflavin bound as a function of antacid and riboflavin concentration in the *in vitro* studies. As can be seen from this table, in the *in vitro* experiment, riboflavin binding to the aluminum hydroxide suspension (50%) at an initial riboflavin concentration of 1.6 μg/ml was 30.9% and was 26.9% at a riboflavin concentration of 4.9 μg/ml. If binding occurs *in vivo*, it could potentially reduce the total amount of riboflavin available for absorption and result in no apparent net change in the amount of riboflavin excreted in urine in the presence of aluminum hydroxide suspension when compared with control experiments.

Administration of magnesium hydroxide suspension to the five subjects also resulted in a significant alteration in the time to peak excretion rate,

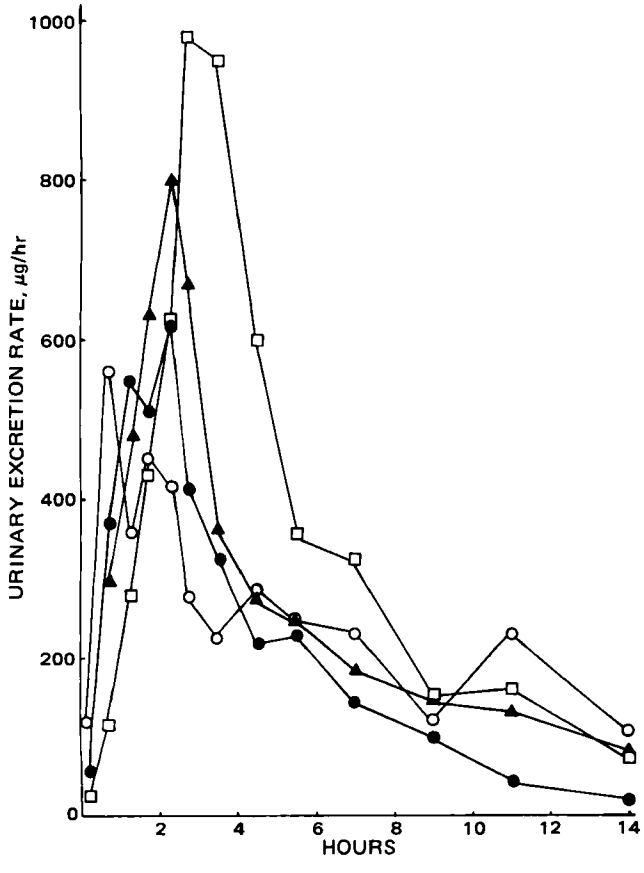

Figure 1—*Urinary excretion rate of riboflavin as a function of time in subject E for control (●), aluminum–magnesium hydroxide (○), magnesium hydroxide (▲), and aluminum hydroxide (□) treatments.*

Table IV—Percent Riboflavin Bound as a Function of Riboflavin and Antacid Concentration

Antacid [a]	Initial Concentration of Riboflavin, μg/ml 1.6	4.9
Aluminum–magnesium hydroxide (50)	10.9 ± 1.4 [b]	11.8 ± 1.0
Aluminum–magnesium hydroxide (17)	2.7 ± 0.7	2.4 ± 0.5
Aluminum hydroxide (50)	30.9 ± 0.8	26.9 ± 1.6
Aluminum hydroxide (17)	4.1 ± 0.4	5.7 ± 0.4
Magnesium hydroxide (50)	83.0 ± 0.8	80.8 ± 0.4
Magnesium hydroxide (17)	53.3 ± 1.7	68.3 ± 0.9

[a] Numbers in parentheses are the percent of v/v liquid antacid used. The total volume was 30 ml. [b] Percent riboflavin bound; mean ± *SD* of five determinations.

with no change in peak excretion rate and the amount of riboflavin excreted in the urine. However, an increase in peak rate and extent of riboflavin excretion was noted in four of the five subjects studied. It was shown in rats (3) that magnesium hydroxide suspension can decrease gastric emptying through an effect on gastric fluid volume. Of additional interest is the percent riboflavin bound to magnesium hydroxide suspension in the *in vitro* studies presented in Table IV. In a 50% magnesium hydroxide suspension, ~83% of a 1.6-μg/ml riboflavin solution was bound, while 81% of a 4.9-μg/ml solution was bound. This high percentage of binding could reduce substantially the dose of riboflavin available at the GI absorption site. Further experiments would be necessary to support this possibility.

There was no apparent effect of coadministration of the magnesium–aluminum hydroxide combination suspension on riboflavin absorption from the GI tract. This was surprising in view of the effects of both aluminum hydroxide and magnesium hydroxide on the pattern of riboflavin absorption in humans. One possible explanation is the Al^{3+} dose contained in each dosage form. The total dose of aluminum hydroxide gel administered contained 2.56 g of aluminum hydroxide (10), while the aluminum–magnesium hydroxide combination contained 1.8 g of aluminum hydroxide (10). However, the magnesium hydroxide dose was identical (1.6 g) in both the combination antacid and magnesium hydroxide suspension (10). Since no dose–effect relationship of the antacid dose to riboflavin absorption has been studied, other possibilities cannot be ruled out. However, it was shown (3) that of a series of aluminum-containing antacids studied, only aluminum hydroxide gel produced significant concentrations of aluminum ion capable of altering gastric emptying after reaction with acid. This reportedly is due to the relatively low pH (4.5) of the aluminum hydroxide antacid compared with the pH (7.2) of the aluminum–magnesium hydroxide combination. The relatively low degree of binding (~11%) of riboflavin to the combination antacid product (Table IV) should be noted.

The results of the present investigation reveal an alteration in the absorption profile of a drug that is reported to be absorbed by a specialized process in the upper portion of the small intestine when the drug is administered with aluminum hydroxide gel or magnesium hydroxide suspension. While additional work needs to be done in relation to the effect of dose and dosing regimen, it is apparent that antacids can influence the absorption pattern of a specialized transport drug, the effect being dependent upon type of antacid or product administered and the degree of drug binding.

Validation of High-Performance Liquid Chromatographic Methods for Analysis of Sustained-Release Preparations Containing Nitroglycerin, Isosorbide Dinitrate, or Pentaerythritol Tetranitrate

LOREN GELBER[x] and ANDREW N. PAPAS

Received December 14, 1981, from the *Winchester Engineering and Analytical Center, Food and Drug Administration, Winchester MA 01890.* Accepted for publication March 16, 1982.

Abstract □ The assay of sustained-release tablets or capsules containing nitroglycerin, isosorbide dinitrate, or pentaerythritol tetranitrate by high-performance liquid chromatography is described. Acetonitrile was found to be the sample preparation solvent with the most general applicability to these products. Anisole was used as an internal standard for nitroglycerin and pentaerythritol tetranitrate, while 4-chloroacetanilide was used for isosorbide dinitrate. The method, which uses a C_{18} bonded-phase column, a methanol–water mobile phase, and 214-nm detection, was shown to be accurate, linear, and reproducible.

Keyphrases □ High-performance liquid chromatography—analysis of sustained-release preparations containing nitroglycerin, isosorbide dinitrate, or pentaerythritol tetranitrate □ Sustained-release preparations—high-performance liquid chromatographic analysis of preparations containing nitroglycerin, isosorbide dinitrate, or pentaerythritol tetranitrate □ Nitroglycerin—high-performance liquid chromatographic analysis of sustained-release preparation □ Isosorbide dinitrate—high-performance liquid chromatographic analysis of sustained-release preparation □ Pentaerythritol tetranitrate—high-performance liquid chromatographic analysis of sustained-release preparation

Recently, the analysis of nitroglycerin ointment was reported by this laboratory (1). Nitroglycerin and the related drugs, isosorbide dinitrate and pentaerythritol tetranitrate, are also formulated as sustained-release capsules and tablets. Pharmaceutical glaze and/or various cellulosic polymers are used to delay release of the active ingredient. Sustained-release nitroglycerin tablet analysis by column partition chromatography (2), sustained-release isosorbide dinitrate by GLC (3), and sustained-release pentaerythritol tetranitrate analysis by color development with phenoldisulfonic acid (4) have been reported. However, high-performance liquid chromatography (HPLC) has advantages over all of these, since it is less time consuming than column chromatography, more specific than phenoldisulfonic acid, and does not subject the samples to heat, which may cause thermal decomposition (5).

The chromatography used for nitroglycerin ointment was based on a previously described method (6) and was adapted to the sustained-release preparations by varying the methanol content of the mobile phase to achieve the desired separation. A study was made of the ability of various solvents to extract the drug from the sustained-release matrix, since this is the most critical step in the analysis.

EXPERIMENTAL

Materials—The water[1] and acetonitrile[2] used were HPLC grade; methanol[3] was distilled in glass; dimethyl sulfoxide, dicalcium phosphate, calcium sulfate, stearic acid, and ferric oxide[4] were ACS reagent grade; and magnesium stearate[4] was laboratory grade. Intestinal fluid was simulated intestinal fluid T.S. (7) without enzymes. Ethyl cellulose, carnauba wax[4], povidone[5], talc[6], colloidal silica[7], pharmaceutical glaze[8], nonpareil seeds[9], starch[10], lactose, polyethylene glycol, guar gum[11], carboxypolymethylene, hydrogenated vegetable oil[12], hydroxymethylpropylcellulose[13], zein[14], microcrystalline cellulose[15], sodium starch glycolate[16], dried malt syrup[17], FD&C blue No. 1, FD&C yellow No. 5, and D&C yellow No. 10[18] were used as received without further purification.

Standard nitroglycerin was as described previously (1), standard isosorbide dinitrate triturate[19] assayed at 25.06% by the compendial method (8), and standard pentaerythritol tetranitrate triturate[20] assayed at 18.52% by the compendial method (9).

Instrumentation—Instrumentation was as reported previously (1). For Table I, HPLC column 1 was μBondapak C_{18}[21] and column 2 was Ultrasphere ODS[22]. In addition, for analysis of authentic mixtures an electronic integrator[23] was used.

Chromatographic Conditions—Typical chromatographic parameters [calculated as reported previously (1)] are summarized in Table I.

Procedure—Twenty tablets or the pellet contents of 20 capsules from the sample to be analyzed were accurately weighed and ground until just reduced to a fine powder. An appropriate weight of composite was transferred to a glass-stoppered Erlenmeyer flask or centrifuge tube and 10.0 or 20.0 ml of the solvent being tested, containing internal standard (except as noted) was added. Flasks or tubes were stoppered, sealed with paraffin film and vigorously shaken with a wrist-action mechanical shaker for 1 hr. The following concentrations were used: nitroglycerin, 0.1 mg/ml in intestinal fluid, 1 mg/ml in dimethyl sulfoxide, and 0.5 mg/ml in acetonitrile; isosorbide dinitrate, 0.25 mg/ml in water, 0.5 mg/ml in dimethyl sulfoxide, and 0.5 mg/ml in acetonitrile; pentaerythritol tetranitrate, 1 mg/ml in dimethyl sulfoxide, and 0.5 mg/ml in acetonitrile. For nitroglycerin and pentaerythritol tetranitrate, anisole, as reported previously (1), was used as an internal standard, except for the intestinal fluid trials, where no internal standard was used. For isosorbide dinitrate, 4-chloroacetanilide was used as an internal standard in all solvents. Internal standards were selected for suitable retention parameters; it was not considered desirable to use compounds of similar chemistry as internal standards due to the difficulties in handling polynitro compounds. The solutions were filtered[24] except for dimethyl sulfoxide solutions, which were centrifuged. The clarified solutions were injected onto the liquid chromatograph. All detection was at 214 nm.

[a] A is the percent of the declared assay. [b] R is the percent recovery from spiked sample. [c] n.d. is not determined.

Spiked samples were prepared from one-half the appropriate composite weight and one-half the appropriate standard weight and treated as described. Authentic samples were prepared by combining individual weighings of the appropriate excipients and standards and analyzing them according to the method.

RESULTS AND DISCUSSION

The results of solvent comparison (reported as the average of two determinations) are presented in Tables II–IV. Solvents were selected to span a range of polarities consistent with the solubility properties of the analytes and compatability with reverse-phase HPLC. Preliminary trials with methanol and water–methanol gave poor recoveries for isosorbide dinitrate. Since a single sample solvent for all products was considered desirable, no further consideration was given to methanol. The data indicate that acetonitrile is the solvent with the most general applicability to these products. Aqueous solvents gave good extraction of the active ingredient in only about one-half of the cases in which they were tried. In addition, an interfering excipient peak was observed when 2.5-mg nitroglycerin capsules from manufacturer No. 2 were prepared with intestinal fluid. Since pentaerythritol tetranitrate is practically insoluble in water (8) aqueous extraction was not attempted for this drug. Due to their solubility in dimethyl sulfoxide, cellulose derivative excipients caused interference (a broad peak between dimethyl sulfoxide and nitroglycerin in samples from manufacturer No. 3) when dimethyl sulfoxide was the solvent. Acetonitrile has further advantages over dimethyl sulfoxide, since it can be filtered through nylon or perfluoroelastomer membranes and does not give a large solvent peak, allowing a more polar mobile phase to be used. The most serious disadvantage of dimethyl sulfoxide is that the solvent peak obscures the presence of any incompletely nitrated impurities, which are reported to elute before the fully nitrated product (6). These impurities can be detected if acetonitrile is the extracting solvent.

Since acetonitrile was the best solvent, the methods in which it was used were subjected to further validation. Authentic mixtures containing the excipients and drug expected in these products at the levels most likely to be used in commercial formulations were analyzed. In the case of manufacturers No. 1 and No. 2, where two potency levels were under consideration, authentic samples were prepared corresponding to the lower potency. Since the formulations of the two potencies are similar, the lower potency is more likely to reveal any possible interferences. For nitroglycerin the excipients used were nonpareil seeds, talc, colloidal silica, povidone, pharmaceutical glaze, magnesium stearate, dicalcium phosphate, ferric oxide, ethyl cellulose, hydroxymethylpropylcellulose, and D&C yellow No. 10. The excipients used for isosorbide dinitrate were starch, lactose, talc, pharmaceutical glaze, ethylcellulose carboxypolymethylene, magnesium stearate, stearic acid, colloidal silica, hydroxymethylpropylcellulose, hydrogenated vegetable oil, povidone, FD&C blue No. 1, and FD&C yellow No. 5. For pentaerythritol tetranitrate the excipients studied were carnauba wax, hydrogenated vegetable oil, zein,

Table V—Authentic Recoveries, Acetonitrile Sample Preparation Solvent

Formulation Type[a]	Recovery of Label Claim, %	
Nitroglycerin		
1	97.5	100.8
2	101.1	100.5
3	100.3	100.4
4	98.3	101.8
5	101.3	99.7
	average	100.1
	CV[b] 1.25%	
Isosorbide Dinitrate		
3	100.6	101.6
5	97.8	98.3
6	102.0	100.6
7	100.0	99.2
	average	100.0
	CV 1.50%	
Pentaerythritol Tetranitrate		
6	99.0	99.2
7	99.9	100.1
8	98.2	99.8
	average	99.4
	CV 0.72%	

[a] Formulation types correspond by number to manufacturer numbers in previous tables. [b] Coefficient of variation.

magnesium stearate, talc, dried malt syrup, microcrystalling cellulose, sodium starch glycolate, calcium sulfate, stearic acid, starch, colloidal silica, lactose, polyethylene glycol, guar gum, FD&C blue No. 1 and FD&C yellow No. 5. Placebo mixtures without active ingredient or internal standard gave no peaks past the solvent front. Excipient peaks would not interfere with the detection of incompletely nitrated impurities.

The results of assays of authentic mixtures containing active ingredient are given in Table V. The average recoveries of 99.4–100.1% with 0.72–1.50% *CV* indicate that the accuracy and reproducibility of the method are acceptable for the analysis of this type of product. The results of the spiked authentic samples demonstrate that 60-min shaking time is adequate to extract the drug. Since this is compatible with requirements of chromatograph start-up and equilibration, shorter times were not investigated.

Linearity was tested using authentic mixtures. For nitroglycerin linearity was demonstrated from 0.2 to 0.8 mg/ml, representing 40–160% of label declaration. A correlation coefficient of 0.9990 was obtained (10) from the analysis of 0.2-, 0.4-, 0.5-, 0.6-, and 0.8-mg/ml samples. For isosorbide dinitrate linearity was demonstrated from 0.27 to 0.8 mg/ml, representing 54–160% of label declaration. A correlation coefficient of 0.9998 was obtained (10) by measuring 0.27, 0.45, 0.55, 0.63, and 0.80 mg/ml. For pentaerythritol tetranitrate linearity was demonstrated from 0.5 to 1.5 mg/ml, representing 50–150% of label declaration. A correlation coefficient of 0.9999 was obtained (10) by measuring 0.5, 0.78, 1.0, 1.24, and 1.5 mg/ml.

It appears that reverse-phase HPLC, after sample preparation with acetonitrile, is a useful method for the analysis of nitroglycerin, isosorbide dinitrate, and pentaerythritol tetranitrate sustained-release tablets and capsules. Since nitroglycerin hydrolysis products were recently demonstrated to elute substantially prior to nitroglycerin in this system (11), the method is anticipated to be stability indicating for nitroglycerin.

Titrimetric Determination of Ascorbic Acid with 2,6-Dichlorophenol Indophenol in Commercial Liquid Diets

DAVID EMLYN HUGHES

Received November 9, 1981, from the *Analytical Chemistry Division, Norwich Eaton Pharmaceuticals, Inc., Norwich, NY 13815.* Accepted for publication March 18, 1982.

Abstract □ The titrimetric determination of ascorbic acid in the presence of a variety of potentially physically and chemically interfering species in commercial liquid diets is presented. The titrant and indicator was a solution of 2,6-dichlorophenol indophenol. Iron(II), copper(II), cysteine, glutathione, sulfite, and tin(II) do not interfere.

Keyphrases □ Ascorbic acid—titrimetric determination with 2,6-dichlorophenol indophenol in commercial liquid diets □ 2,6-Dichlorophenol indophenol—titrimetric determination of ascorbic acid in commercial liquid diets □ Titrimetric determination—ascorbic acid determination with 2,6-dichlorophenol indophenol in commercial liquid diets

Ascorbic acid frequently appears in multicomponent media, except in simple synthetic preparations such as ascorbic acid injection (1). In commercial liquid diets, for example, it is accompanied by proteins, amino acids, saccharides, lipids, and minerals (2). Methods involving oxidation of ascorbic acid are complicated by oxidizable metal ions, notably iron(II) and tin(II) (3).

magnesium stearate, talc, dried malt syrup, microcrystalling cellulose, sodium starch glycolate, calcium sulfate, stearic acid, starch, colloidal silica, lactose, polyethylene glycol, guar gum, FD&C blue No. 1 and FD&C yellow No. 5. Placebo mixtures without active ingredient or internal standard gave no peaks past the solvent front. Excipient peaks would not interfere with the detection of incompletely nitrated impurities.

The results of assays of authentic mixtures containing active ingredient are given in Table V. The average recoveries of 99.4–100.1% with 0.72–1.50% *CV* indicate that the accuracy and reproducibility of the method are acceptable for the analysis of this type of product. The results of the spiked authentic samples demonstrate that 60-min shaking time is adequate to extract the drug. Since this is compatible with requirements of chromatograph start-up and equilibration, shorter times were not investigated.

Linearity was tested using authentic mixtures. For nitroglycerin linearity was demonstrated from 0.2 to 0.8 mg/ml, representing 40–160% of label declaration. A correlation coefficient of 0.9990 was obtained (10) from the analysis of 0.2-, 0.4-, 0.5-, 0.6-, and 0.8-mg/ml samples. For isosorbide dinitrate linearity was demonstrated from 0.27 to 0.8 mg/ml, representing 54–160% of label declaration. A correlation coefficient of 0.9998 was obtained (10) by measuring 0.27, 0.45, 0.55, 0.63, and 0.80 mg/ml. For pentaerythritol tetranitrate linearity was demonstrated from 0.5 to 1.5 mg/ml, representing 50–150% of label declaration. A correlation coefficient of 0.9999 was obtained (10) by measuring 0.5, 0.78, 1.0, 1.24, and 1.5 mg/ml.

It appears that reverse-phase HPLC, after sample preparation with acetonitrile, is a useful method for the analysis of nitroglycerin, isosorbide dinitrate, and pentaerythritol tetranitrate sustained-release tablets and capsules. Since nitroglycerin hydrolysis products were recently demonstrated to elute substantially prior to nitroglycerin in this system (11), the method is anticipated to be stability indicating for nitroglycerin.

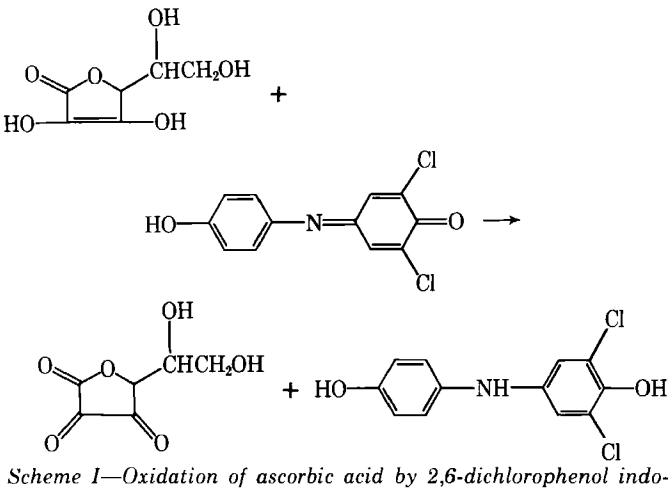

Scheme I—Oxidation of ascorbic acid by 2,6-dichlorophenol indophenol

ascorbic acid to the two keto groups of dehydroascorbic acid by 2,6-dichlorophenol indophenol (Scheme I) lacks specificity in all but the most chemically inert systems. Other traditional methods are available. Microbiological assays are specific, but they are lengthy and suffer from poor precision. A popular colorimetric procedure (4) and a modification using *p*-nitroaniline are sensitive to impurities and unresponsive at low ascorbic acid concentrations. An existing microfluorometric assay (5) does not distinguish between ascorbic acid and dehydroascorbic acid; this may be a serious shortcoming in stability studies, since dehydroascorbic acid is the principal degradation product of ascorbic acid. Methods for selective ascorbic acid determination appear to require extensive sample clean-up (6) or a sophisticated chromatographic system with selective detection such as high-performance liquid chromatography (HPLC) (7, 8), ion-exchange chromatography (9), electrochemical detection (10), amperometric detection (11), or differential-pulse polarography (12).

Although the HPLC methods mentioned are sensitive, frequently they are unable to resolve ascorbic acid from the water-soluble B vitamins. The more sophisticated detectors may not be available in many laboratories. The speed and accuracy of a titrimetric method is especially attractive where ascorbic acid analysis is done on a large number of samples or on a routine basis. The purpose of this report is to present a modification of the standard 2,6-dichlorophenol indophenol titration such that it may be run in the presence of a large number of potential physical and chemical interferences present in commercial liquid diets.

BACKGROUND

Almost 50 years ago, the desirability of increasing the specificity of the 2,6-dichlorophenol indophenol titration to exclude the ferrous ion and glutathione was well understood (13–15). The titrimetric method was then sufficiently well developed to spawn its use in an impressive list of media including fruit and vegetable juice, milk, body tissues, cerebral fluid, plant extracts, and animal organs (16, 17). The animal and vegetable media offer few interferences, but biological systems often contain enough oxidizable metal ions, notably ferrous ions, to interfere. Since the 1940s, the 2,6-dichlorophenol indophenol titration has been unearthed and the ferrous ion interference eliminated by carrying out the titration in acid. Hence, the ferrous ion interference was eliminated by titrating in acetic acid (18). The interference also was removed by titrating in hydrochloric acid solution (19), and hydrochloric acid–acetate mixtures (20). Aqueous acetic acid solutions also were used to eliminate ferrous ion interference

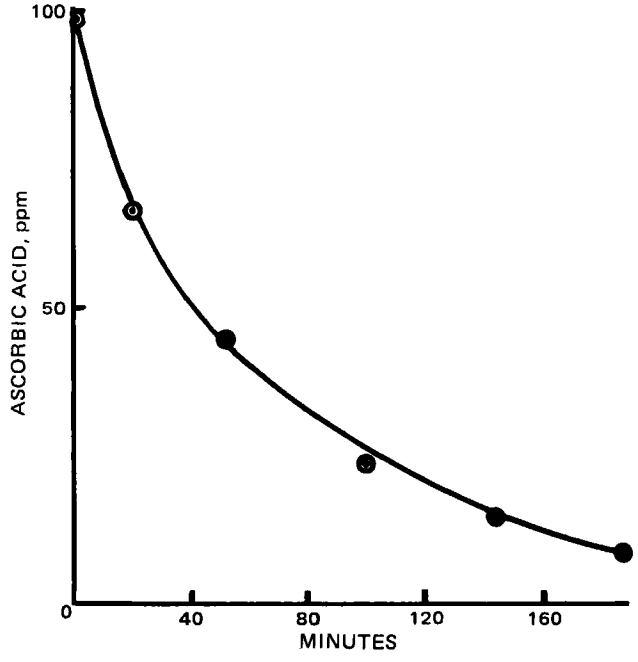

Figure 1—*Degradation of ascorbic acid in an unmasked sample (pH 5.0).*

(21, 22). In a two-step titration of ferrous ion and ascorbic acid, the ferrous ion was masked by an aqueous succinic or adipic acid solution (23). Despite these successful attempts to mask the ferrous ion during the ascorbic acid determination, extension of the method to include other redox interferences is absent from the chemical literature.

An example of a redox interference is the presence of a reducible species in the sample such as cupric or ferric ions. The metal ions are reduced, and the ascorbic acid is oxidized yielding erroneously low ascorbic acid values. The reaction, $e^- + Cu^{2+} \rightarrow Cu^+$, occurs stoichiometrically with the ascorbic acid oxidation, and the cupric ion has been used to determine ascorbic acid (24). The ferric ion interference may be masked in some samples with the tartrate ion.

Oxidizable metal ions and organic species, notably the mercaptans, cysteine and glutathione, interfere and yield high ascorbic acid assay values. The 2,6-dichlorophenol indophenol reacts with both the ascorbic acid and the oxidizable mercaptan. These interferences may be avoided by low pH solutions, and weak organic acids may be preferred since ascorbic acid is destroyed in very acidic solutions.

Sulfur dioxide interference has been eliminated by addition of acetone, hydrogen peroxide, or formaldehyde. Strongly colored solutions have been decolorized with tablets[1] (25) to allow a visual endpoint.

The standard 2,6-dichlorophenol indophenol titration is seen to be usable when other species in solution are not easily oxidized or reduced. Prevention of one oxidation reaction, $Fe^{2+} \rightarrow Fe^{3+} + e^-$, may be accomplished by dissolving the sample in a solution of a weak acid. The standard titration is not selective enough for analysis of biological fluids (since they often contain oxidizable species such as cysteine and glutathione), soft drinks that contain the sulfite ion, and vitamin formulations containing the stannous ion. None of the previous reports (18–23) attempted to modify the 2,6-dichlorophenol indophenol titration to select ascorbic acid in the presence of any oxidizable species except ferrous ion. The present report investigates sample handling conditions which would mask cysteine, glutathione, sulfite, and tin(II) and, hence, extend the utility of 2,6-dichlorophenol indophenol titration to systems where selectivity is important.

EXPERIMENTAL

Reagents—All chemicals were analytical reagent grade unless otherwise noted.

Procedure—A sample containing ~10 mg of ascorbic acid was weighed and transferred to a 125-ml Erlenmeyer flask having a ground-glass stopper. In addition to ascorbic acid, the samples contained glucose oligosaccharides, L-glutamine, L-aspartic acid, glycine, L-phenylalanine,

4	237	240
5	160	
6	166	

[a] Label value for all products was 160 ppm of ascorbic acid. [b] Ref. 30.

L-proline, L-leucine, L-lysine hydrochloride, L-alanine, L-arginine hydrochloride, magnesium gluconate dihydrate, sodium citrate dihydrate, L-methionine, L-valine, L-threonine, L-isoleucine, L-serine, calcium glycerophosphate, L-histidine hydrochloride monohydrate, sodium glycerophosphate, potassium citrate monohydrate, safflower oil, L-tryptophan, potassium chloride, potassium sorbate, L-tyrosine, polyoxyethylene sorbitan monooleate, ferrous gluconate dihydrate, choline bitartrate, zinc acetate dihydrate, α-tocopherol acetate, niacinamide, manganese glycerophosphate, D-calcium pantothenate, cupric citrate, ascorbyl palmitate, pyridoxine hydrochloride, riboflavin phosphate sodium salt, vitamin A acetate, thiamine hydrochloride, folic acid, *d*-biotin, potassium iodide, phytonadione, ergocalciferol, and cyanocobalamin. About 20–40 ml of 1.5 *N* acetic acid was added. The sample was titrated immediately with the titrant consisting of 0.2 g of 2,6-dichlorophenol indophenol and 0.2 g of sodium bicarbonate and distilled water sufficient to make 1000 ml of solution. The endpoint was a distinct pink color which lasted for 30 sec and was more intensely colored than a phenolphthalein endpoint. Similarly, a semimicro titration was performed. For a 5-ml buret, the titrant was prepared from 1.2 g of 2,6-dichlorophenol indophenol and 1.2 g of sodium bicarbonate to make 1 liter of solution. The titrant was standardized by titration against a standard solution of 100 mg of USP ascorbic acid[2] in 100 ml of 1.5 *N* aqueous acetic acid. Two milliliters of this standard solution was pipeted and titrated for the titrant standardization in both the macro and semimicro titrations.

Wet additions of cysteine, glutathione, sodium sulfite, and tin(II) chloride were made to a final concentration in the sample solutions of 66.6–333 μg/ml. The samples were then assayed for ascorbic acid using the semimicro titration procedure.

RESULTS AND DISCUSSION

Some confusion exists in the literature over the nomenclature for the determination of ascorbic acid by oxidation to dehydroascorbic acid. Some investigators choose ascorbic acid, L-ascorbic acid, vitamin C, or total vitamin C as the species determined. Since the 2,6-dichlorophenol indophenol oxidation does not distinguish between D and L forms, and since vitamin C is defined (26) as L-ascorbic acid, the generic term ascorbic acid may be less misleading. Total vitamin C is defined as the arithmetic sum of the L-ascorbic acid plus dehydroascorbic acid content of the sample. Dehydroascorbic acid has the same molar biological (antiscorbutic) activity as ascorbic acid (26), and, hence, assays of biological origin usually attempt to determine total vitamin C. Any assay specific for ascorbic acid does not necessarily measure the biological activity, since some or all of the ascorbic acid in the sample may have been oxidized to dehydroascorbic acid. Conforming to official USP nomenclature, the species determined by the described procedure is ascorbic acid (D and L forms). Dehydroascorbic acid (and, therefore, the total vitamin C or biological activity) is neither determined nor does its presence interfere. If an assay for total vitamin C is desired, prior reduction of dehydroascorbic acid with hydrogen sulfide may be possible (27, 28).

In many solid samples, the formation of dehydroascorbic acid follows dissolution in water. In standard solutions, the aerial ascorbic acid to dehydroascorbic acid conversion is slow, requiring 24 hr for 0.3% dehydroascorbic acid to be formed (29). Inert atmospheres of carbon dioxide, nitrogen, and hydrogen have been employed to slow degradation further. Although it would appear that no special sample handling is required, even minute amounts of ferric and cupric ions present in samples, strongly catalyze the ascorbic acid oxidation (2). In Fig. 1, considerable oxidation of ascorbic acid is seen to occur in the samples used in this study, even in an acidic medium. Even when the ferric ion has been eliminated by complexation or masking as a direct interference, the ion is still capable of catalysis of the ascorbic acid to dehydroascorbic acid conversion. When the dissolution medium is 1.5 *N* acetic acid, no degradation is observed for at least the first 5 min.

[a] Average = 99.2%. *SD* = 1.95. *RSD* = 1.96%.

Initial attempts to increase the specificity of the 2,6-dichlorophenol indophenol oxidation of ascorbic acid using 0.1 *M* hydrochloric, nitric, and sulfuric acid media for dissolution were unsuccessful. The samples containing the ferrous ion yielded an assay equal to ascorbic acid plus the ferrous ion content. Five percent aqueous trichloroacetic acid was then used to dissolve some of the samples. The assay values were time-dependent, *i.e.*, the longer the titration time, the lower the ascorbic acid content. *m*-Phosphoric acid (0.1 *M*), sulfuric acid, and oxalic acid were tested, since they have been reported to increase the specificity of the reaction (28). None yielded satisfactory recoveries when sulfite was present. After trials with several mixed solvent and weak organic acid combinations, aqueous acetic acid was found to be the most applicable sample medium. The most dilute solution, which consistently masked ferrous ions, stannous ions, sulfite, cysteine, and glutathione was 1.5 *N* CH_3CO_2H. This dissolution medium was also found to mask cupric ions and other excipients listed in *Experimental*. Several commercial liquid diets were assayed titrimetrically and the results appear in Table I. Since commercial liquid diets frequently contain a large excess of ascorbic acid, some formulations were also assayed by the colorimetric determination of the 2,4-dinitrophenylhydrazine derivative of dehydroascorbic acid (30). The two methods are in good agreement.

The selectivity of the titrimetric procedure presented here compares favorably with other oxidative titrations. Titration with *N*-bromosuccinimide, for example, is complicated by cysteine, glutathione, and sulfite (31). The selectivity of the basic chloramine T procedure (32) is limited to samples without sulfite and sulfhydryl compounds, thiosulfates, sulfides, or tin(II). The modified 2,6-dichlorophenol indophenol determination is seen to be highly selective when compared with other titrimetric procedures.

The utility of the 2,6-dichlorophenol indophenol titration of ascorbic acid has been extended to systems of a biological composition in the presence of iron(II), copper(II), cysteine, glutathione, sulfite, tin(II), and other redox interferences. The data for 18 dry recovery samples are presented in Table II. The ascorbic acid was introduced to the placebo at six levels ranging from 0.5–2.34 mg. The average recovery was 99.2% with a relative standard deviation of 1.96%. For the precision of the procedure, 11 samples ranging from 4.34–6.48 g were assayed. All samples

[a] Mean = 665 μg. *SD* = 5.0 μg. *RSD* = 0.75%.

were obtained from the same lot and the theoretical ascorbic acid content was 97.5 μg/g. The samples displayed good homogeneity and assayed at an average of 101 μg of ascorbic acid/g of sample or 104% of label value. The data appear in Table III. In Table IV data are presented for the recovery of ascorbic acid in the presence of known redox interferences. In each case a wet spike of the interference was made to a standard containing 666 μg of ascorbic acid. The resulting solution was then 333 μg/ml in ascorbic acid and from 66.6–333 μg/ml (20–100% of the ascorbic acid concentration) interference. The titration was also performed without the acetic acid masking solution, and in each case, the recoveries were markedly <100%. Dissolution of samples in 1.5 *M* acetic acid masks commonly encountered interferences and allows the use of a titrimetric procedure where more sophisticated methods were previously required.

The simplicity of the method cannot be overstated. The titrant is the only reagent required for the titration (since the titrant is also the indicator) and is stable for at least 1 month. The sample preparation consists of shaking with 1.5 *M* acetic acid for several seconds. Other titrimetric procedures not only are more time consuming for the determination itself, but require special procedures or unstable reagent. Reduction of the 1,2-enediol group by *N*-bromosuccinimide, for example, requires titration with an unstable reagent. Titration of ascorbic acid with chloramine T in some cases requires a carefully prepared sodium tetrathionate solution which is thermally and photochemically degradable. Although a recent report (32) describes the determination of ascorbic acid with chloramine T in the presence of sulfhydryl compounds or sulfite, it does not outline a procedure for safely distilling the acrylonitrile. Some analysts may be unwilling to distill as highly toxic, flammable, and explosive (33) a liquid as acrylonitrile. The oxidation of the 1,2-enediol group by 2,6-dichlorophenol indophenol appears to be the fastest and safest titrimetric determination of ascorbic acid presently available.

External Scintigraphy in Monitoring the Behavior of Pharmaceutical Formulations *In Vivo* I: Technique for Acquiring High-Resolution Images of Tablets

MICHAEL C. THEODORAKIS *§x, DAVID R. SIMPSON *, DOMINIC M. LEUNG *, and MICHAEL DEVOUS, Sr. *‡

Received February 18, 1981, from the *University of Illinois at Urbana-Champaign, *Section of Nuclear Medicine and Radiopharmacology and ‡Department of Bioengineering, Colleges of Veterinary Medicine and Engineering, Urbana, IL 61801.* Accepted for publication March 16, 1982. §Present address: College of Pharmacy, Department of Pharmaceutics, University of Florida, Gainesville, FL 32610.

Abstract □ A new method for monitoring tablet disintegration *in vivo* was developed. In this method, the tablets were labeled with a short-lived radionuclide, technetium 99m, and monitored by a gamma camera. Several innovations were introduced with this method. First, computer reconstruction algorithms were used to enhance the scintigraphic images of the disintegrating tablet *in vivo*. Second, the use of a four-pinhole collimator to acquire multiple views of the tablet resulted in high count rates and reduced acquisition times of the scintigraphic images. Third, the magnification of the scintigraphic images achieved by pinhole collimation led to significant improvement in resolution. Fourth, the radioinuclide was incorporated into the granulation so that the whole mass of the tablet was uniformly labeled with high levels of activity. This technique allowed the continuous monitoring of the disintegration process of tablets *in vivo* in experimental animals. Multiple pinhole collimation and the labeling process permitted the acquisition of quality scintigraphic images of the labeled tablet every 30 sec. The resolution of the method was tested *in vitro* and *in vivo*.

Keyphrases □ Disintegration—external scintigraphy in monitoring the behavior of pharmaceutical formulations *in vivo*, technique for acquiring high-resolution images of tablets □ Tablet formulation—external scintigraphy in monitoring the behavior *in vivo*, technique for acquiring high-resolution images of tablets □ Scintigraphy—external, monitoring the behavior of pharmaceutical formulations *in vivo*, technique for acquiring high-resolution images of tablets □ Radionuclides—^{99m}Tc-labeled tablets, external scintigraphy in monitoring the behavior of pharmaceutical formulations *in vivo*, technique for acquiring high-resolution images of tablets

Several techniques have been developed that permit the direct observation *in vivo* of pharmaceutical formulations such as tablets and capsules. The advantages and shortcomings of these techniques have been reviewed in a number of reports (1–3). Although at the present time the pharmaceutical scientists evaluate the formulation work by *in vitro* disintegration and dissolution studies coupled with *in vivo* blood studies, there are instances where the formulations of locally acting chemotherapeutic agents, antibiotics, antacids, and endogenous substances such as iron, potassium, and calcium salts do not provide distinguishable blood levels. Therefore, in such cases it is necessary to observe the *in vivo* disintegration time of the formulation in order to confirm the *in vitro* findings (2, 4). Furthermore, questions regarding the site of disintegration in the GI tract, the completeness of disintegration, the effectiveness of different enteric coatings, the rate of transition of the formulation through the different segments of the GI tract with respect to the age of the individual, the gastric and intestinal malfunctions, and diseases can be only answered by direct observation of the formulation within the GI tract. However, examination of the scientific literature during the last 50 years has revealed that only limited information is available on disintegration of formulations *in vivo*. This can be attributed to the fact that the previous techniques were difficult to perform and were invasive to both animal and human subjects. The development of the gamma scintillation camera coupled with the availability of short-lived gamma-ray emitting nuclides and devices for fast acquisition, processing, and storage of digital data has provided an opportunity to develop a useful method for performing such *in vivo* studies on tablets or capsules (3, 5–8). Furthermore, the development of mathematical methods of image reconstruction and enhancement of objects emitting gamma radiation has made it possible to enhance the resolution of the images of small objects acquired by the gamma scintillation camera (5, 6, 9).

The present report addresses further the application of external scintigraphy and image reconstruction in the acquisition of high-resolution scintigraphic images of labeled tablets *in vitro* and *in vivo*.

EXPERIMENTAL

Image Acquisition and Processing—A standard gamma camera[1] with a sodium iodide–thallium iodide crystal (diameter 25.4 cm; thickness 1.25 cm) optically connected to 19 photomultiplier tubes was used to acquire the scintigraphic images of the labeled tablet phantoms and tablets *in vitro* and *in vivo*. The images were digitized and stored on magnetic tape[2] of the video image processor[3] prior to transmission to another computer[4] where the four pinhole images were back-projected

into one image which was enhanced by using filtered back-projection (Figs. 1B and 2). The final image was either displayed on the CRT screen of the video image processor, which also has photographic capability, or printed on a printer[5] using a 32-level gray scale display. The different interfaced devices and the flow of data are shown as a block diagram in Fig. 1A. A four-pinhole collimator was used to acquire four images of the labeled object. The distance between tablet and camera was optimized to provide the maximum magnification while all four images remained within the field of view of the camera. Serial images of the tablet were recorded at 30-sec intervals on the video image processor. The duration of data acquisition for each image was 30 sec.

Pinhole Collimator—A pinhole collimator was used to magnify and create four images of the tablet phantoms. The detachable pinhole assembly of a standard single-pinhole collimator was replaced by a lead cap of uniform thickness (0.3 cm) bearing four pinholes 0.119 cm in diameter, equally spaced on the periphery of a circle 3.8 cm in diameter (Figs. 1B and 3).

Pinhole Collimator Optimization—The diameter of the pinholes was optimized by imaging a ^{99m}Tc-labeled tablet (0.4 mCi). Images were taken with the tablet placed flat under the collimator and with the tablet placed on its edge. The counting time needed to accumulate 50,000 counts was plotted *versus* the pinhole diameter (Fig. 4).

Labeling of Tablets and Tablet Phantoms—Sodium [^{99m}Tc]pertechnetate (I) in saline (10 mCi/ml) received from a molybdenum-99–technetium-99m generator[6] was sprayed on the tablet granulation. The granulation was mixed, dried, and compressed[7] in tablets of specified hardness. Each tablet was labeled with 50,000–500,000 cpm as determined by the gamma camera detector. The diameter of the tablet was 1.04 cm and the thickness was 0.40 cm.

Five tablet phantoms were made of leather (Fig. 5A). Each phantom has a diameter of 0.8 cm and a thickness of 0.3 cm. Defects representing 0–9.9% of the weight of the phantom were artificially created (Table I). The phantoms were labeled by exposure to an aqueous solution of I. Each phantom was labeled with 100,000–200,000 cpm as determined by the gamma camera detector.

Back-Projection—The four images of the labeled phantom were back-projected into a single image by the following process. The distance between phantom and collimator was determined either by direct measurement or by the displacement of the images on the gamma camera crystal. This constant was used to determine the location of the four images on the crystal of the gamma camera. Then a two-dimensional array consisting of 64 × 64 picture elements (pixels[8]) was established around the center of each image. The four arrays were added together to form the back-projection image (Figs. 2A and B). The flow chart of the computer program used in back-projection is shown in Fig. 6A.

Image Enhancement—Pixels in the back-projected image were transformed into the Fourier domain first by rows then by columns, filtered (as will be described) and retransformed to the spatial domain. Image enhancement was completed when every pixel of the back-projected image was filtered. An example is given in Fig. 2. The flow chart of the computer algorithms used is shown in Fig. 6B.

Filter Optimization—To enhance the edges of the tablet and therefore increase the resolution, a modified ramp frequency filter[9] was used to filter the back-projected image of the tablet. This modified ramp frequency filter was derived by multiplying a basic ramp frequency filter with different frequency filters[9]. Several filters were constructed (Fig. 7). The best modified ramp frequency filter[9] was selected by evaluating the image–noise ratio (Table II). The image–noise ratio was established

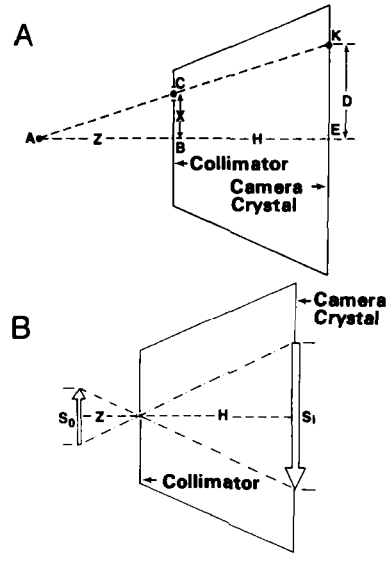

Figure 3—*(A) The location of the image (K) of tablet A, at distance D from the center of the gamma camera's sodium iodide–thallium iodide crystal was determined by the use of similar triangles ABC and AEK; (B) demonstration of image magnification and inversion by pinhole imaging.*

by dividing the number of counts in the pixels of the back-projected image of phantom tablet 1 (Fig. 5A) by the number of counts in an equal number of pixels in the background. The same frequency ramp filter was also evaluated in terms of image–defect ratio, which was established by dividing the average of the number of counts in the pixels corresponding to three intact portions, a, b, c, of the phantom tablet by the number of counts in the pixels corresponding to the defective area, d, of the tablet phantom 5 (Figs. 5A and B). All four areas, a, b, c, d, had an equal number of pixels.

Sensitivity to Defect Size—The labeled tablet phantoms, 2–5, were placed at different distances from the collimator, and their images were acquired and enhanced. The image–defect ratio was calculated for each defective phantom at different distances (Fig. 8). The image–defect ratio was used as a measure of evaluating the resolution of the technique with regard to the defect size of the tablet phantom and its distance from the collimator.

***In Vitro* Imaging Studies**—The *in vitro* imaging studies involved two parts. In the first part, ^{99m}Tc-labeled intact or defective tablet phantoms (Fig. 5A) were placed 6 cm in front of the collimator of the

gamma camera and their images were acquired and reconstructed (Fig. 5B) according to the process described previously. The second part involved ^{99m}Tc-labeled tablets which were left to disintegrate in a shallow dish covered with distilled water. The water was lightly agitated occasionally. Scintigraphic images as well as photographs of the disintegrating tablet were taken every 30 sec (Fig. 9). The acquired images were reconstructed and enhanced.

***In Vivo* Imaging Studies**—The labeled tablet was administered orally to a dog weighing 13 kg. The animal was tranquilized[10] for imaging, placed in a supine position on a table, and the abdomen then was positioned under the collimated detector of the gamma camera. Data were accumulated for up to 75 min. During that period, scintigraphic images of the abdominal area were taken, back-projected, and enhanced (Fig. 10).

RESULTS

The acquisition and processing of the scintigraphic images are illustrated in Fig. 1A. The signal from the gamma camera console to the video image processor consisted of an x,y grid location of each detected emission within the specified energy range. Each of the images was digitized into a matrix of 64 × 64 pixels and stored on magnetic tape. The digitized images were transmitted to a general purpose computer[4] (16 bit, 512K) where the back projection and filtering of the scintigraphic image was conducted. The enhanced image was then displayed on the video image processor. The flow charts of the algorithms used for back-projecting and filtering the scintigraphic images are illustrated in Fig. 6.

The optimum diameter of the pinhole was determined experimentally by plotting the time needed to acquire 50,000 cpm from a ^{99m}Tc-labeled tablet *versus* the pinhole diameter size (Fig. 4). The optimum diameter was chosen to be 0.119 cm. The four pinholes were arranged equidistantly on the periphery of a cycle with a 3.8-cm diameter. The diameter was determined by using Eq. A1 (see *Appendix*) which was derived by geometric consideration of Fig. 3A. Distance (H) was constant at 16.7 cm. When a ^{99m}Tc-labeled tablet or tablet phantom placed at distance (Z) ranging from 3.3 to 7.5 cm, the image (K) was formed 11.5 and 6.1 cm from the center (E) of the crystal. The magnification was determined by Eq. A2, which was also derived by geometric consideration of Fig. 3. For instance, a tablet phantom with a 0.8-cm diameter placed 3.3 cm away from the collimator was magnified five times.

The back-projected image, $b(x,y)$, was in a sense the sum of the four images, $P_i(a,b)$, of the labeled tablet, $f(x,y)$, which were created by the four-pinhole collimator (Figs. 2A, B, and C). This back-projected image contained the true image in a single plane, and it was marked by interference due to natural background radioactivity, loss of small amounts of radioactivity because of the disintegration and dissolution process, and electronic noise (Fig. 2D). Each row and column of the 4096 pixel matrix (64 × 64) of each back-projected image was transformed from the spatial domain to the frequency domain by means of a Fourier transformation (Eq. A4). This is shown in Fig. 2E. The resulting frequencies from each column and row of pixels were filtered by the use of a modified ramp frequency filter[9], $f(k_x,k_y)$, which had been optimized experimentally (Eq. A5). The use of a frequency filter in the Fourier domain improved the image created by the process of back-projection by minimizing the very high-frequency components which were associated with the background interference and yet enchanced the frequency component of the back-projected image corresponding to the edges of the tablet. Each point of the filtered Fourier frequency spectrum (Fig. 2F) was transformed back to the spatial domain by means of an inverse Fourier transformation (Eq. A6), and the enhanced image of the tablet was obtained (Fig. 2G).

The modified ramp frequency filter[9], $f(k_x,k_y)$ (Eq. A5), was constructed by multiplying the relative magnitude of the ramp filter with the relative magnitude of another filter[9] at the same distance from the

[10] Rompun (Xylazine), 1.1 mg/kg, Bagvet, Division of Cutter Laboratories, Shawnee, Kan.

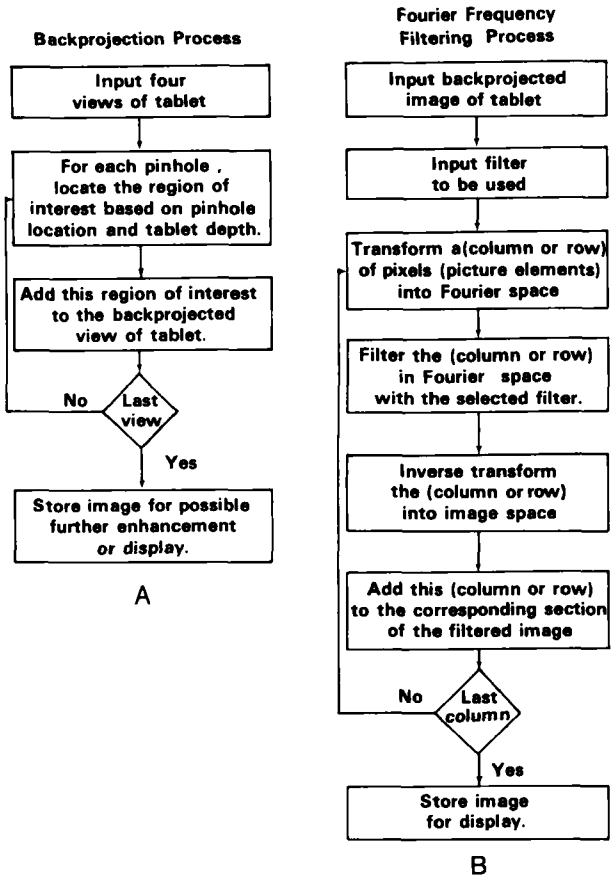

Figure 6—*Flow charts of the computer programs for back-projection (A) and for the filtering process (B).*

origin in the Fourier domain (Fig. 7). Several modified ramp frequency filters were used to enhance the images of the ^{99m}Tc-labeled tablets and tablet phantoms (Fig. 7). The image–noise ratio increased from filter 2 to 5 and then decreased gradually; on the other hand, the image–defect ratio declined rapidly from filter 2 to 5 and then leveled off (Table II). Frequency filter 3 (Fig. 7) was chosen for image enhancement and reconstruction as a reasonable compromise between image–noise and image–defect ratios.

The resolution of the method was tested *in vitro* by imaging a series of ^{99m}Tc-labeled tablet phantoms bearing artificial defects on the periphery (Fig. 5A). The labeled tablet phantoms were imaged at different distances from the collimator and the image–defect ratio was calculated (Fig. 8). When the image–defect ratio was ≥5, the defect was visible in the reconstructed image. The 0.62-mm^2 defect could not be resolved because it was smaller than the area of the pinhole (1.11 mm^2). Defect sizes as small as 1.42 mm^2 were discernible at a distance of 4.0 cm from the collimator. As the distance from the collimator increased and the magnification decreased, the resolution decreased rapidly (Fig. 8). For larger defects (5 mm^2), the resolution was independent of the magnification for distances ranging from 3.3 to 7.5 cm. The filtered back-projected images of each phantom are illustrated in Fig. 5B.

The resolution of the method was further tested *in vitro* with a series of experiments in which a rapidly disintegrating tablet labeled with

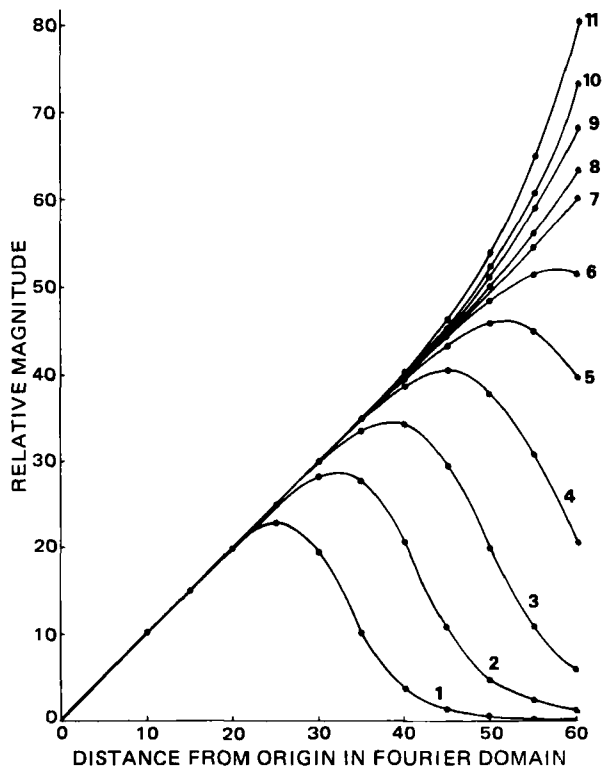

Figure 7—*Modified ramp frequency filters tested.*

technetium-99m was monitored with a gamma camera. The acquired scintigraphic images were processed and compared with photographs of the disintegrating tablet taken simultaneously with the images (Fig. 9). The disintegration started at 120 sec after the labeled tablet came in contact with the water and terminated 300 sec later (Fig. 9A). The scintigraphic images showed that the onset of the disintegration process was 180 sec after contact with the water (Fig. 9C).

The resolution of the technique was tested *in vivo* in the dog (Fig. 10). From the scintigraphs of the unprocessed image (Fig. 10A) and the corresponding back-projected and enhanced images (Fig. 10B), the onset of disintegration was evident 30 min postingestion, while at 75 min postingestion the tablet had undergone extensive disintegration.

DISCUSSION

The size of the pinhole was chosen to be 0.119 cm which was a compromise between the desired counting time (<60 sec) for a tablet labeled with 0.4 mCi of technetium-99m and the desired resolution which cannot be smaller than the diameter of the pinhole itself (10). The counting time was inversely proportional to the square of the radius of the pinhole and proportional to the square of the distance between labeled tablet and the collimator.

The spacing of the pinholes on the collimator was also critical. If the pinholes were very close together, then the four images formed on the camera crystal overlapped as the labeled tablet moved away from the camera. However, if the pinholes were spaced far apart, then the images were formed outside of the crystal as the labeled tablet moved closer to the collimator. Therefore, with an established pinhole size of 0.119 cm in diameter as optimum and with the equidistant spatial arrangement of the four pinholes on a circle 3.8 cm in diameter, the imaging of a tablet was feasible in distances ranging from 3.3 to 7.5 cm away from the collimator. The advantage of using a four-pinhole collimator was that four images were collected simultaneously. This increased the efficiency of detection by increasing the total counts collected in a certain time or by decreasing the time needed to acquire an image with a certain number of counts. In turn, short times of image acquisition minimized the effect of the slight perturbations of the tablet due to GI motility. Also, the interference of background was reduced by increasing the count rate. Finally, the pinhole magnified the image thereby improving the resolution (Fig. 3B).

The back-projection process (Figs. 2A–D) made the use of the four-pinhole collimator beneficial, while the process of Fourier enhancement (Figs. 2E–G) improved the resolution by eliminating the high-frequency

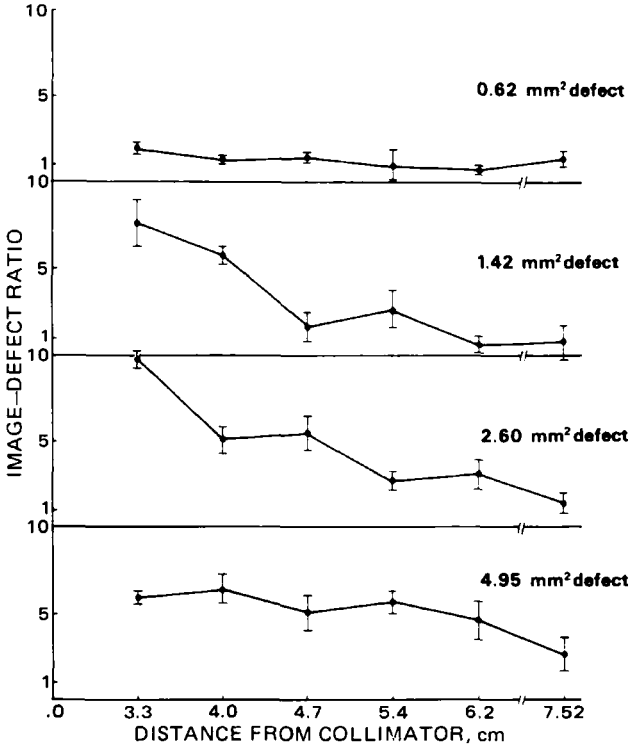

Figure 8—*The image-defect ratio as a function of distance and defect size. Image-defect ratio, larger than five yields observable defects.*

components (interference) of the back-projected image (Fig. 2). The reconstructed image (Fig. 2G) had more sharply defined edges than the back-projected image (Fig. 2D).

The resolution of the technique depended on the size of the pinhole diameter (10) and the type of frequency filter used to filter the Fourier spectrum of the back-projected image of the tablet (Figs. 2E and F). Every pixel of the back-projected image was transformed from the spatial domain to the frequency domain by Eq. A4, and then the modified ramp frequency filter was applied to eliminate the background interference and sharpen the edges of the tablet (Eq. A5). The image-noise and image-defect ratios (Table II) are a good measure for testing the resolution of the technique and selecting the optimum modified ramp frequency filter from other alternatives (Fig. 7). Defects of 5 mm^2 were readily recognizable at distances ranging from 3.3 to 7.5 cm. The *in vitro* experiments using ^{99m}Tc-labeled tablets with a 1.04-cm diameter showed that the resolution was improved by the enhancement process and the onset of disintegration became evident 60 sec after the process had started (Fig. 9). In the *in vivo* experiments, the onset of disintegration became evident ~30 min postingestion. This was because the resolution was compromised due to the interference of the abdominal and stomach tissue; therefore, the observable defect was probably >5 mm^2. The disintegration *in vivo* was slower than *in vitro*, thus, confirming observations of previous investigators (11).

The incorporation of the radioisotope, technetium-99m, into the tablet granulation in the form of spray of a saline solution of I ensured the uniform distribution of the label throughout the entire mass of the tablet. This method of labeling gave better results than a previously reported method where the labeling was achieved by exposing the tablet itself to vapors of iodine-131 (3). In that method, the surface of the tablet was uniformly coated with iodine-131; however, the penetration of the label into the core was inadequate. The mass of I that was incorporated into the tablet was negligible (~10^{-11} g of I/tablet), and, therefore, the physical or chemical integrity or characteristics of the formulation remained unaffected. The radioactivity of the labeled tablets ranged from 50,000 to 500,000 cpm/tablet. Finally, in instances where the formulation is sensitive to moisture, the technetium-99m can be added in the form of a dry powder derived by lyophilization of a solution of I in saline or [^{99m}Tc]-methylene disphosphonate in saline.

The technique of external scintigraphy has been applied before for the purpose of monitoring the disintegration *in vivo* of tablets and capsules (3, 7, 8). However, in both instances the technique did not involve enhancement of the scintigraphic images, and thus, the detection of small defects that would signify the onset of the disintegration process could

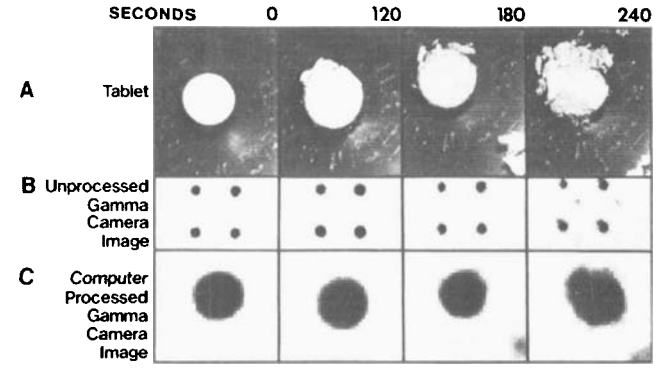

Figure 9—*Photographs (A) and* in vitro *scintigraphic images of a ^{99m}Tc-labeled tablet before (B) and after enhancement (C).*

not be evidenced due to the lower resolution of the technique. On the other hand, the present technique, which combines external scintigraphy with image enhancement, increased the resolution of the system so that small defects on the formulation can be detected, and it reduced the interference of the background activity, which may be attributed either to natural radioactivity, dissolution of the label to the dispersal of the fine labeled granules, or to a combination of these factors. This reduction of the background interference facilitates the monitoring of disintegration of small fragments of the formulation and, thus, enables the observer to determine the end of the disintegration process. Furthermore, reduction of the background interference will be useful when the determination of the transition times of the disintegrating formulation through the GI tract will be attempted, especially at the stages where considerable portions of the formulation have disintegrated.

A similar technique which also involved labeling of the formulation with gamma ray emitters such as iron-59, technetium-99m or chromium 51 and made use of two simple sodium iodide–thallium iodide crystal detectors has been applied in evaluating the disintegration and dissolution of tablets and capsules *in vivo* (4, 12). However, this technique did not allow direct observation of the formulation; thus, the onset and end of the disintegration *in vivo* could not be determined with any reasonable accuracy.

In the past, most of the techniques that were developed for determining the disintegration time of tablets *in vivo* were based on the use of roentgenography or fluoroscopy with or without the inclusion of radiopaque materials in the formulation (1, 2, 11, 13). Those techniques exposed the animal or human subject to high radiation doses of X-rays; they did not allow magnification or enhancement of the tablet's image; they could not be used for continuous monitoring of the formulation in the GI tract; and finally, rendering a nonradiopaque formulation radiopaque required inclusion of large amounts of radiopaque substances relative to the mass of the formulation, thus, effectively altering the composition of the formulation. In contrast, the proposed technique is free of the aforementioned shortcomings. The main feature of this method is the high resolution. The high resolution was achieved by using a four-pinhole collimator, which magnified the four scintigraphic images of the labeled tablet phantom or tablet, and by image enhancement of the back-projected image using Fourier transformation and filtering.

APPENDIX

Initial testing of image reconstruction and enhancement algorithms were performed with scintigraphic images of tablet phantoms. The method of image acquisition and enhancement applied in this study involved three separate steps. First, the determination of the location of the four pinhole projections of the tablet phantom on the crystal of the gamma camera; second, the back-projection of the four projected images to form a single back-projected image; and third, the enhancement of the back-projected image using filtering techniques based on Fourier transformations.

The determination of the location of the phantom's images on the crystal of the gamma camera involved simple Euclidean geometry (Fig. 3A). The displacement D of the tablet's image K from the center of the camera crystal is given by:

$$D/(Z + H) \approx X/Z \qquad \text{(Eq. A1)}$$

where Z is the distance from center of the collimator to tablet A, H is the distance from center of the collimator to the center of camera crystal (16.7

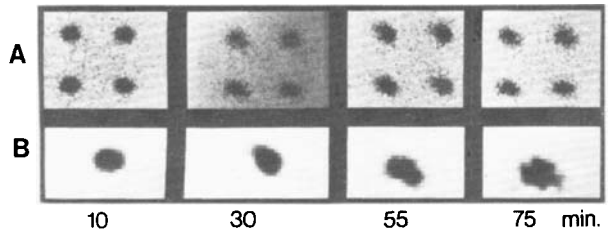

Figure 10—*Scintigraphs of a disintegrating tablet* in vivo *before (A) and after processing (B).*

cm), and X is the distance from the center of the collimator to the pinhole (1.9 cm).

The image magnification (Fig. 3B) is given by the size relationship between tablet phantom, S_o, and its image S_i, described by:

$$S_o/S_i = Z/H \qquad \text{(Eq. A2)}$$

The four images (projections), $P_i(a,b)$, of the tablet phantom were then combined to form the back-projected image, $b(x,y)$. Mathematically, the process is described by:

$$b(x,y) = \sum_{i=1}^{m} P_i(a,b) \qquad \text{(Eq. A3)}$$

where $b(x,y)$ was a point in the back-projected image, $P_i(a,b)$ was the point on the ith image corresponding to $b(x,y)$, and m was the number of images obtained. The back-projection process is described diagrammatically in Figs. 2A and B. Four images (P_1–P_4) of the labeled tablet phantom $f(x,y)$ were taken (Fig. 2A). The four images were then combined (back-projected) to form the back-projected image, $b(x,y)$ (Fig. 2B). The back-projected image actually contained the true image of the labeled tablet which was masked by background interference (noise artifacts) during the process of back-projection (Fig. 2D).

The back-projected image of the tablet phantom was improved by frequency domain filtering using Fourier transformations. It was based on the fact that both edges and noise artifacts in the image were represented by very high frequencies when the image was transformed into the frequency domain. Thus, by transforming the image from its spatial domain into its frequency domain, filtering can be performed to enhance the edges and, at the same time, try to reduce the background interference by filtering out the very high-frequency components.

The process of frequency filtering of the back-projected image involved three steps. In the first step, each row and column of pixels in the image was transformed into the Fourier domain, $F(k_x k_y)$, by performing two-dimensional Fourier transformation as given by:

$$F(k_x,k_y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} b(x,y)\exp(-2_\pi i(k_x x + k_y y)dxdy) \qquad \text{(Eq. A4)}$$

where $b(x,y)$ is the back-projection image pixel values, k_x and k_y are variables representing distances from the origin in the Fourier domain, and $i = \sqrt{-1}$ (14, 15).

In the second step, each Fourier coefficient $F(k_x k_y)$ was multiplied by a modified ramp frequency filter[9] $f(k_x,k_y)$, and thereby converted to the Fourier coefficients $F_I(k_x,k_y)$ of the final image:

$$F_I(k_x,k_y) = F(k_x,k_y) \times f(k_x,k_y) \qquad \text{(Eq. A5)}$$

In the third step, the Fourier coefficients of the final image, $F_I(k_x,k_y)$, were transformed back to the spatial domain by application of the inverse Fourier transformation:

$$b'(x,y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F_I(k_x,k_y)\exp(2_\pi i(k_x x + k_y y)dxdy) \qquad \text{(Eq. A6)}$$

where $b'(x,y)$ was the pixel value in the final image.

The process of Fourier transformation and filtering is shown in Figs. 2B, E, and F. In Fig. 2C the four images taken from the four-pinhole collimator are shown. The four images are then back-projected to form the back-projected image (Fig. 2D). Discrete Fourier transformation is performed on the image (Fig. 2E). The origin of the frequency domain is in the middle of the image. The components around the four corners represented random noise. The frequency domain was then filtered, and the filtered spectrum is shown in Fig. 2F. The very high-frequency components, which represent noise, are filtered out, and the high frequencies are enhanced. The filtered frequency domain is then transformed back to the spatial domain and the enhanced, back-projected image is shown in Fig. 2G.

Systemic Absorption of Δ^9-Tetrahydrocannabinol after Ophthalmic Administration to the Rabbit

CHIA-WHEI N. CHIANG *x, GENE BARNETT *, and DOLORES BRINE ‡

Received December 2, 1981, from the **Division of Research, National Institute on Drug Abuse, Rockville, MD 20857* and ‡*Research Triangle Institute, Research Triangle Park, NC 27709.* Accepted for publication March 18, 1982.

Abstract □ Δ^9-Tetrahydrocannabinol was given by ophthalmic administration to the rabbit. Plasma concentrations were measured for two strengths of ophthalmic solution and compared with intravenous data to establish bioavailability. Absorption was variable, while maximum plasma levels were sustained for several hours.

Keyphrases □ Absorption—systemic, Δ^9-tetrahydrocannabinol after ophthalmic administration, rabbits □ Bioavailability—systemic absorption of Δ^9-tetrahydrocannabinol after ophthalmic administration, rabbits □ Pharmacokinetics—intravenous administration, half-lives systemic absorption of Δ^9-tetrahydrocannabinol after ophthalmic administration, rabbits □ Δ^9-Tetrahydrocannabinol—systemic absorption after ophthalmic administration, rabbits

Marijuana has been shown to reduce intraocular pressure in humans when smoked in the form of a cigarette (1). Δ^9-Tetrahydrocannabinol (I), the primary psychoactive ingredient of marijuana, has also been shown to reduce intraocular pressure in clinical studies when given either by the intravenous (2) or oral (3) route of administration. Although efficacy for topical application in clinical studies has not been established (4), dosage form development should be undertaken as this route of administration is expected to minimize the undesired psychotropic side effects.

Studies with the rabbit indicate that I in light mineral oil is an efficient dosage form to allow penetration of I into the eye (5). Related studies have also demonstrated that I applied topically to one eye lowers intraocular pressure in both eyes (6). Since the rabbit has become one of the animal models used to evaluate the therapeutic potential of I for treatment of glaucoma, studies have been carried out to determine the systemic absorption of I after topical ophthalmic application.

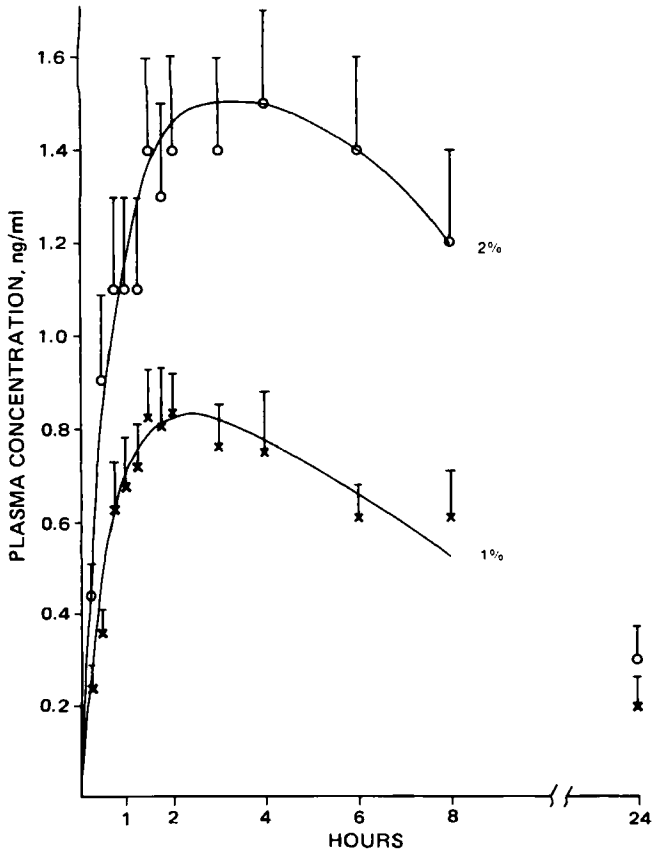

Figure 1—*Plasma concentration of I after ophthalmic administration to rabbits.*

EXPERIMENTAL

Adult albino rabbits weighing 3.4–4.8 kg were given [1′,2′-$^3H_2$]-I, which was used for intravenous and ophthalmic dosage forms. The intravenous solution, containing 170 μCi/mg of [^{3}H]-I, was prepared by dissolving [^{3}H]-I in ethanol, which was then added to a solution of 25% rabbit serum albumin. The solution was sterilized by filtering through a 0.22-μm membrane filter[1] before administration. An intravenous dose of a 0.2-ml solution contained 15 μg of I and 2 μl of ethanol.

Ophthalmic solutions were prepared in light mineral oil NF[2] viscosity of 9.5 centistokes at 21.5° (50–60 Saybolt Universal Seconds) to a strength of 1% I, 138 μCi/mg, and 2% I, 165 μCi/mg. The animals were dosed by ophthalmic topical application with 25 μl of I solution, which was applied to both eyes simultaneously to ensure measurable plasma levels of I. Each animal was dosed with 1 and 2% solutions on *separate occasions*, and four of the animals were also given a dose of 15 μg iv of I through an ear vein. A washout period of 1 month was allowed between all studies.

Blood samples were collected from an ear notch at 15, 30, 45, 60, 75, 90, 105, 120, 180, 240, 360, 480, and 1440 min after ophthalmic dosing and at 1.5, 5, 10, 20, 30, 45, 60, 90, 120, 240, 360, and 480 min after intravenous dosing. Blood samples of 2 ml were drawn, centrifuged, separated, and the plasma was immediately frozen until the assay was carried out. The ophthalmic administration, carried out with a syringe[3], yielded such small losses (≤7% of the dose) that no corrections were made.

Quantitative analysis of plasma for the concentration of I was carried out by TLC according to a previously described method (7, 8). Plasma samples were extracted twice with petroleum ether containing 1.5% isoamyl alcohol. The extracts were then concentrated and chromatographed on silica gel plates[4]. Developing solvents were acetone–*tert*-butyl alcohol–chloroform (3:5:92). Zones of I were scraped and counted. The TLC method was shown to correlate well with electron-capture GLC and with GLC–MS methods of analysis.

RESULTS

Plasma concentrations of I after ophthalmic administration of 1 and 2% solutions are reported as average values for eight animals in Fig. 1. The concentration increases to maximum values over the first 1–2 hr and then declines very slowly up to 24 hr. Variability in the data is indicated by the standard errors which are also given in the figure. Data for individual animals are presented in Table I for the maximum plasma concentration, C_{max}, which is actually a limited range of values, the time of these peak values t_{peak}, the time interval over which the C_{max} range extends, and the area under the plasma curve from t = 0 to 24 hr,

Table II—Pharmacokinetic Parameters of I Following Intravenous Administration[a] to Rabbits[b]

Animal No.	k_{12} hr^{-1}	k_{21} hr^{-1}	k_{10} hr^{-1}	V_1^{-1}, liter^{-1}	$t_{1/2\alpha}$ min	$t_{1/2\beta}$ hr	AUC, ng/ml hr
1	6.12(48)	1.50(25)	2.76(57)	0.27(65)	4	1.7	1.25
4	0.85(15)	0.47(31)	1.46(13)	0.15(10)	17	2.6	1.65
5	0.97(20)	0.82(21)	1.61(9)	0.13(9)	14	1.5	1.30
6	3.55(18)	1.08(10)	1.65(13)	0.31(14)	7	2.3	3.27

[a] Administration of a 15-μg dose. [b] The percent coefficient of variation of each parameter is given in parentheses. The half-life values are calculated from α and β which are calculated from: $1/2[(k_{12} + k_{21} + k_{10}) \pm (k_{12} + k_{21} + k_{10})^2 - 4\,k_{21}k_{10})^{1/2}]$.

$AUC_{0-24\ hr}$. Inspection of the individual data shows that the plasma concentration increases relatively rapidly to a maximum value, which then varies very little for the next several hours as a plasma plateau exists over an extended period of time. Animal 1 in the 1% study had a C_{max} which varied in a range from 1.0 to 1.3 ng/ml during the time t_{peak} from 60 to 240 min postdose. Similarly, the 2% solution for the same animal gave a C_{max} range of 1.8–2.3 ng/ml for the plasma plateau, which existed during the 240–480-min period, and showed higher plasma levels as compared with the 1% data during the plateau. The dose-normalized AUC values for animal 1 were approximately the same for both doses. Table I shows that the plasma maxima were higher for the 2% dose but were usually not double the lower values. The time plateau, which always extended over several hours, usually showed no difference between doses for most animals. The AUC ratio for the 2:1% solutions was >1 for the four of the animals and ~1 for the other animals.

For the intravenous studies, the average plasma data for four animals is shown in Fig. 2. The curve is biphasic for each animal in agreement with work reported earlier (9). The pharmacokinetic parameters were obtained by nonlinear regression analysis to solve the standard two-compartment open model (10) in terms of:

$$dC_1/dt = -(k_{10} + k_{12})C_1 + k_{21}C_2 \quad \text{(Eq. 1)}$$

$$dC_2/dt = k_{12}C_1 - k_{21}C_2 \quad \text{(Eq. 2)}$$

with the initial condition:

$$V_1^{-1} = C_{1(t=0)}/\text{Dose} \quad \text{(Eq. 3)}$$

Table II presents the micro rate constants k_{12}, k_{21}, k_{10}, the reciprocal volume V_1^{-1}, and the respective coefficients of variation (CV) for the four parameters. For animal 1 the CV values are so large as to render the computer fit questionable, but for the remaining three animals the CVs indicate a good computer estimate of the pharmacokinetic parameters. For the three animals the value for k_{12} has a range of 1.0–3.6 hr^{-1}, while the value for k_{21} is in closer agreement (0.5–1.1 hr^{-1}). The elimination rate constant k_{10} was well estimated with a small range, 1.5–1.7 hr^{-1}. The computer estimate of V_1^{-1} ranges from 0.1 to 0.3 liters^{-1}. The calculated half-lives are 4–17 min for $t_{1/2\alpha}$ and 1.5–2.6 hr for $t_{1/2\beta}$.

The bioavailability for the two ophthalmic solutions relative to the intravenous dose calculated by AUC ratios reported for the four animals

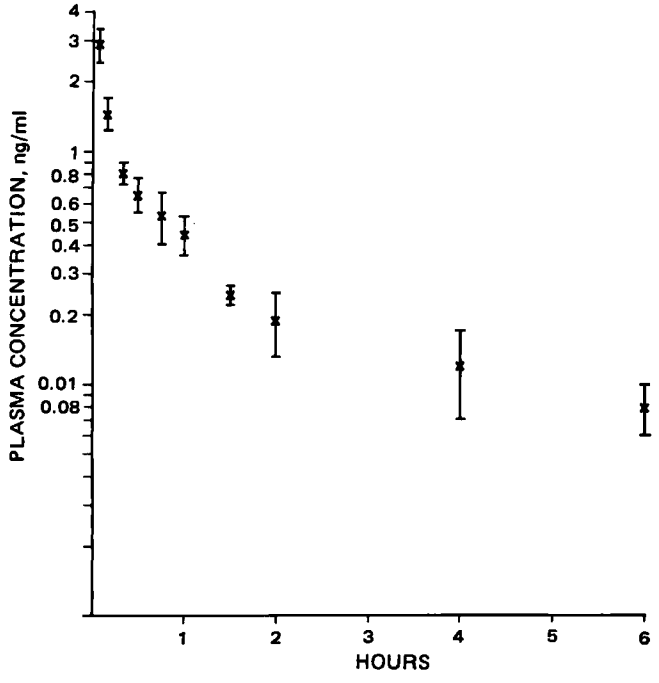

Figure 2—*Plasma concentration of I after intravenous administration of a 15-μg dose to rabbits.*

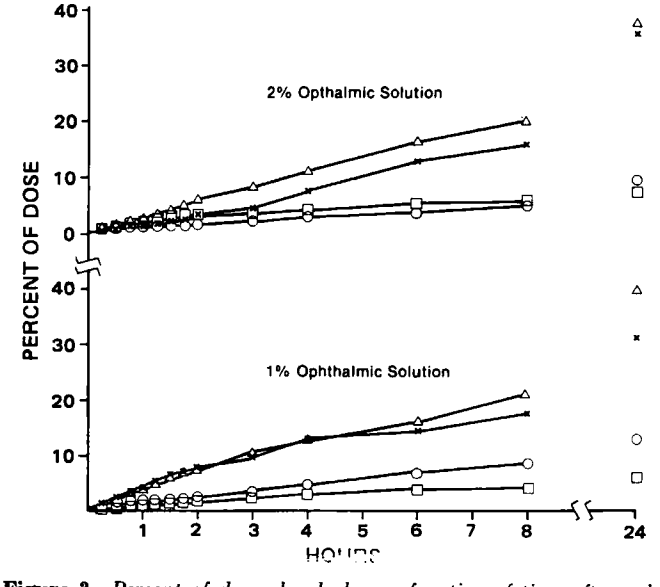

Figure 3—*Percent of dose absorbed as a function of time after ophthalmic administration to rabbits. Key: (X) rabbit 1; (○) rabbit 4; (△) rabbit 5; (□) rabbit 6.*

in Table I is approximately constant. An estimate of the fraction of dose absorbed as a function of time after opthalmic administration can be obtained from (10):

$$A_t/\text{Dose} = [C_t + k_1 AUC_{(0-t)} + (X_t)V_1^{-1}] \times V_1/\text{Dose} \quad \text{(Eq. 4)}$$

This equation was applied to the experimental data from t = 0–8 hr only, and the 24-hr points were determined separately from the dose-normalized AUC ratios. The fraction of dose absorbed as a function of time is presented in Fig. 3 for the 1 and 2% ophthalmic doses for the four animals using the parameters reported in Table II. From Fig. 3 it can be seen that absorption continues until at least 8 hr after administration for all animals at both doses. Furthermore, the fraction absorbed as a function of time does not appear to change for the two doses. The curves for animals 4 and 6 indicate a slower rate of absorption and appear to be flattening out at 8 hr, suggesting that absorption is essentially complete. The curves for animals 1 and 5 suggest that both the rate and extent of absorption is considerably greater.

The present study indicates that systemic absorption of I in the rabbit is slow and highly variable after ophthalmic administration. Prior work with rabbits demonstrates the possibility that both local and systemic mechanisms are involved in ocular pressure lowering (5, 6, 11). It would be desirable to have more detailed effect–time data together with plasma–time data in order to investigate possible I plasma–effect relationships. Clinical studies with glaucoma patients using both oral I and smoking marijuana cigarettes also show effective lowering of intraocular pressure. The pharmacodynamics is consistent with the clinical pharmacokinetics for both routes of administration, since the effect has a much slower onset and considerably longer duration for the oral study than occurs in the smoking study. The studies reported here do not differentiate local and systemic mechanisms. For ophthalmic administration, which should minimize systemic side effects, further work is needed to develop an effective dosage form (4).

Use of Metzler's NONLIN Program for Fitting Discontinuous Absorption Profiles

JAMES J. ZIMMERMAN

Received July 13, 1981, from the *Department of Pharmaceutics, School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication March 17, 1982. Present address: Clinical Research Department, Stuart Pharmaceuticals, Wilmington, DE 19897.

Abstract □ An alternative to the use of integral hybrid flow/compartmental model (HFCM) equations in fitting cases I and II discontinuous absorption profiles is presented. It is proposed that HFCM-integral equations be replaced by a system of differential equations in which sequential sets of equations describe the absorption profile from time zero to infinity. The required sets of differential equations for these two cases are presented as they apply to a two-compartment drug, potentially undergoing multiple absorption steps. It was shown that the use of the NONLIN program in the differential equation mode provides good fits for some unusually shaped absorption profiles of buformin, sulfisoxazole, and griseofulvin. The values of the parameter estimates and the sum of squared deviations, ΣSD, obtained with NONLIN were almost identical to those obtained with the FITSI2 program utilizing HFCM equations. While HFCM-integral equations required less computer time, they introduced the potential for negative absorption times. This problem is avoided by use of the differential equations method.

Keyphrases □ Absorption—fitting discontinuous profiles, use of NONLIN program □ NONLIN program—use for fitting discontinuous absorption profiles

Recently, discontinuous absorption processes in relation to linear pharmacokinetic models were reported (1). Integral equations for hybrid flow/compartmental models (HFCM) were derived for application to single- and multicompartment drugs exhibiting two special cases of discontinuous absorption.

In case I, absorption is assumed to begin at time t_1 and end at time t_2. The mathematical treatment of this case allows for a negative, zero, or positive value of t_1. Zero and positive values of t_1 have been used universally up to the present time in fitting data to equations for the extravascular administration of drugs exhibiting continuous absorption profiles (2). A positive t_1-value indicates the presence of an absorption lag time, while $t_1 = 0$ indicates the absence of a lag time. Negative values of t_1, however, have not been used previously and are difficult to rationalize. It was suggested that negative t_1 values obtained from computer fits using HFCM equations signify a rapid initial absorption phase (1). The absorption rate constant for this phase, however, is not estimable from these equations. Values of t_2 are always positive. When t_2 approximates the time to peak concentration, the absorption profile exhibits a discontinuity or sharp break, at which point the subsequent shape of the profile is governed only by the dispo-

0022-3549/83/0200-0138$01.00/0

in Table I is approximately constant. An estimate of the fraction of dose absorbed as a function of time after opthalmic administration can be obtained from (10):

$$A_t/\text{Dose} = [C_t + k_1 AUC_{(0-t)} + (X_t)V_1^{-1}] \times V_1/\text{Dose} \quad \text{(Eq. 4)}$$

This equation was applied to the experimental data from t = 0–8 hr only, and the 24-hr points were determined separately from the dose-normalized AUC ratios. The fraction of dose absorbed as a function of time is presented in Fig. 3 for the 1 and 2% ophthalmic doses for the four animals using the parameters reported in Table II. From Fig. 3 it can be seen that absorption continues until at least 8 hr after administration for all animals at both doses. Furthermore, the fraction absorbed as a function of time does not appear to change for the two doses. The curves for animals 4 and 6 indicate a slower rate of absorption and appear to be flattening out at 8 hr, suggesting that absorption is essentially complete. The curves for animals 1 and 5 suggest that both the rate and extent of absorption is considerably greater.

The present study indicates that systemic absorption of I in the rabbit is slow and highly variable after ophthalmic administration. Prior work with rabbits demonstrates the possibility that both local and systemic mechanisms are involved in ocular pressure lowering (5, 6, 11). It would be desirable to have more detailed effect–time data together with plasma–time data in order to investigate possible I plasma–effect relationships. Clinical studies with glaucoma patients using both oral I and smoking marijuana cigarettes also show effective lowering of intraocular pressure. The pharmacodynamics is consistent with the clinical pharmacokinetics for both routes of administration, since the effect has a much slower onset and considerably longer duration for the oral study than occurs in the smoking study. The studies reported here do not differentiate local and systemic mechanisms. For ophthalmic administration, which should minimize systemic side effects, further work is needed to develop an effective dosage form (4).

Abstract □ An alternative to the use of integral hybrid flow/compartmental model (HFCM) equations in fitting cases I and II discontinuous absorption profiles is presented. It is proposed that HFCM-integral equations be replaced by a system of differential equations in which sequential sets of equations describe the absorption profile from time zero to infinity. The required sets of differential equations for these two cases are presented as they apply to a two-compartment drug, potentially undergoing multiple absorption steps. It was shown that the use of the NONLIN program in the differential equation mode provides good fits for some unusually shaped absorption profiles of buformin, sulfisoxazole, and griseofulvin. The values of the parameter estimates and the sum of squared deviations, ΣSD, obtained with NONLIN were almost identical to those obtained with the FITSI2 program utilizing HFCM equations. While HFCM-integral equations required less computer time, they introduced the potential for negative absorption times. This problem is avoided by use of the differential equations method.

Keyphrases □ Absorption—fitting discontinuous profiles, use of NONLIN program □ NONLIN program—use for fitting discontinuous absorption profiles

Recently, discontinuous absorption processes in relation to linear pharmacokinetic models were reported (1). Integral equations for hybrid flow/compartmental models (HFCM) were derived for application to single- and multicompartment drugs exhibiting two special cases of discontinuous absorption.

In case I, absorption is assumed to begin at time t_1 and end at time t_2. The mathematical treatment of this case allows for a negative, zero, or positive value of t_1. Zero and positive values of t_1 have been used universally up to the present time in fitting data to equations for the extravascular administration of drugs exhibiting continuous absorption profiles (2). A positive t_1-value indicates the presence of an absorption lag time, while $t_1 = 0$ indicates the absence of a lag time. Negative values of t_1, however, have not been used previously and are difficult to rationalize. It was suggested that negative t_1 values obtained from computer fits using HFCM equations signify a rapid initial absorption phase (1). The absorption rate constant for this phase, however, is not estimable from these equations. Values of t_2 are always positive. When t_2 approximates the time to peak concentration, the absorption profile exhibits a discontinuity or sharp break, at which point the subsequent shape of the profile is governed only by the dispo-

[a] The parameter t_1 corresponds to the t_1-value permitted in the integral equations described previously (1).

sition of the drug. When t_2 is very large compared with absorption half-life, then the general equations reduce to those for the more typical case for continuous absorption (2).

In case II, t_1 may also assume a negative, zero, or positive value, but absorption does not end at t_2; it merely proceeds at a new rate. Consequently, two absorption rate constants are generated from the computer fit for the two sequential absorption phases. The absorption profile again shows a discontinuity at t_2, at which point there is a change in slope in the ascending region of the profile.

From a mechanistic point of view, case I discontinuities may represent situations where the absorption efficiency of the intestine reduces to zero at some location in the GI tract or where the release of drug from the dosage form abruptly ceases. Case II discontinuities may result from the existence of intestinal segments with different absorption efficiencies, or alternatively, from a change in the release characteristics of the formulation or from a pH-induced change in the concentration of absorbable drug species at the membrane site (1).

The usefulness of the HFCM equations was demonstrated (1) by obtaining nearly perfect fits for some unusual absorption profiles of griseofulvin (3), buformin (4), and sulfisoxazole (5). For each of these drugs, less exact fits were obtained when equations for continuous absorption were used in the fitting process.

The present report describes an alternative approach for the computer fitting of discontinuous absorption profiles. An alternative approach is needed that does not produce potentially negative absorption times as a result of the mathematical analysis. It is proposed that HFCM integral equations be replaced by a system of differential equations in which sequential sets of equations describe the absorption profile from time zero to infinity. It was shown that Metzler's NONLIN program (6), utilized in the differential equation mode, may be used to implement the proposed approach[1].

THEORETICAL

The use of Metzler's NONLIN program for implementing the proposed method for fitting discontinuous absorption profiles requires that a DFUNC subroutine be written employing differential equations[2]. Prior to writing the subroutine, however, it is necessary to choose an appropriate kinetic model, write differential equations for each species in the model, and correctly order the equations within the subroutine. The choice of kinetic model requires decisions with respect to both the compartmental and absorption characteristics of the drug. The compartmental characteristics may usually be obtained from previous studies or from a graphical treatment of the experimental data. Discontinuous absorption characteristics may be inferred from a graphical representation of the experimental data or from poor computer fits obtained using continuous absorption models. A correct ordering of the equations within

[1] The NONLIN program is available for use on (*a*) IBM (C. M. Metzler, The Upjohn Co., Kalamazoo, MI 40991) and (*b*) CDC (M. Rowland, Department of Pharmacy, University of Manchester, Manchester, M139PL, England) computers with the CDC version having the added advantage of providing residual plots and statistics for the residuals.

[2] While differential equations require more computer time than integral equations, the writing of DFUNC subroutines for discontinuous absorption processes is greatly simplified, particularly for complex models, when differential equations are used.

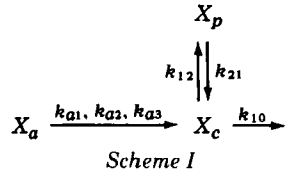
[a] Data from Ref. 4. [b] Run on a PDP 11/10 computer. [c] Run on a CDC Cyber 174/2550 computer. [d] The parameter t_1' was a constant in NONLIN, and 0.50 hr is the time of the first blood sample after drug administration; $t_0 = 0$. [e] The parameter F is the systemic availability. [f] The parameter D_0 is the dose. [g] Fortran execution time without line printer plots and statistics for residuals.

the subroutine requires that the user follow instructions given in the NONLIN manual regarding the use of differential equations and that selected Fortran IF statements be employed to provide a logical kinetic flow while stressing the discontinuities. The development of a functional DFUNC subroutine is illustrated using Scheme I for a drug exhibiting known two-compartment characteristics and potential multiple absorption steps. The approach could be applied equally well to a drug characterized by either a fewer or a greater number of compartments.



Scheme I

where X_a is the amount of drug at the absorption site; X_c is the amount of drug in the central compartment; X_p is the amount of drug in the peripheral compartment; k_{a1}, k_{a2}, and k_{a3} are the first-order absorption constants for the first, second, and third absorption steps, respectively; k_{12} and k_{21} are the first-order rate constants for the transfer of drug between compartments; and k_{10} is the first-order elimination constant.

Table I presents a summary of the systems of differential equations (Eqs. 1–9) associated with Scheme I for case I, case II, and combined cases I and II discontinuous absorption processes. For each of the cases, the differential equations are subgrouped further according to values of $t_1 < 0$, $= 0$, and > 0 and according to the time interval involved. The time-interval grouping introduces discontinuity into the model. Each time interval for a given initial value of t_1 corresponds to a different set of differential equations. For example, in case I ($t_1 < 0$), Eqs. 1–3 define absorption, distribution, and elimination (ADE) during the initial rapid absorption phase for the time interval, t_0–t_1', and Eqs. 3–5 describe the same events for the slower absorption phase from t_1' to t_2. Equations 3 and 6 describe the disposition of the drug after cessation of all absorption during the time interval, t_2–t_∞. The intervals, t_0–t_1' and t_1'–t_2, replace the single interval, t_1–t_2, reported previously (1). Since $t_0 = 0$, all absorption times are positive, and an absorption rate constant for the initial rapid absorption phase replaces a negative time constant. When data are scarce for the early absorption period, t_1' usually will be a constant taking on the time for the first blood sample after drug administration. For case I ($t_1 = 0$), the required set of differential equations includes Eqs. 1–3 for a single ADE cycle from t_1 to t_2 and Eqs. 3 and 6 for disposition for t_2 to t_∞. The required set of equations for case I ($t_1 > 0$) include those for case I ($t_1 = 0$) and Eq. 7, which accounts for the lag time from t_0 to t_1. For case II ($t_1 < 0$), Eqs. 1–3 and 3–5 represent the ADE processes for the first two absorption phases during the time intervals, t_0–t_1' and t_1'–t_2, respectively. These two intervals again replace the single interval, t_1–t_2. Equations 3, 8, and 9 represent the ADE processes for the third absorption phase from t_3 to t_∞. For case II ($t_1 = 0$) and case II ($t_1 > 0$), the required sets of differential equations involve an appropriate combination selected from Eqs. 1–5 and 7. Similarly, for the combination of cases I and II ($t_1 < 0$, $t_1 = 0$, $t_1 > 0$), the required sets of differential equations are chosen from Eqs. 1–9.

[a] Data from Ref. 5. [b] Run on a PDP 11/10 computer. [c] Run on a CDC Cyber 174/2550 computer. [d] The parameter t_1' was a constant in NONLIN, and 0.50 hr is the time of the first blood sample after drug administration; $t_0 = 0$. [e] The parameter F is the systemic availability. [f] The parameter D_0 is the dose. [g] Fortran execution time without line printer plots and statistics for residuals.

Equations 1–6 are written in a form consistent with the actual input quantities. Thus, Eqs. 2, 3, 5, and 6 are written in terms of concentrations. The latter conversions are made by dividing the rate expressions for X_c and X_p in Scheme I by V_c, the apparent volume of distribution for the central compartment. The concentration of drug in the peripheral compartment is also referred to the central compartment, since V_p, the apparent volume of distribution for the peripheral compartment, can only be estimated when experimental data for that compartment are available.

The ordering of differential equations within the DFUNC subroutine is accomplished by using the required NONLIN format (7) and selected IF statements for discontinuity[3].

EXPERIMENTAL

The version (*b*) of Metzler's NONLIN program[1] and a version of the FITSI2 program[4] for fitting discontinuous absorption data were obtained and made operational on a computer[5] by the university computer staff.

The data sets used in the computer fits were those used previously (1): griseofulvin (3), rat 11; buformin (4), patient 1; and sulfisoxazole (5) subject 3. Plots of the NONLIN computer fits were obtained with a plotter[6] and are reproduced as tracings in Figs. 1–3.

The initial estimates of the parameters used with both FITSI2 and

[3] The DFUNC subroutines used in fitting the data in Figs. 1–3 are available from the author upon request.

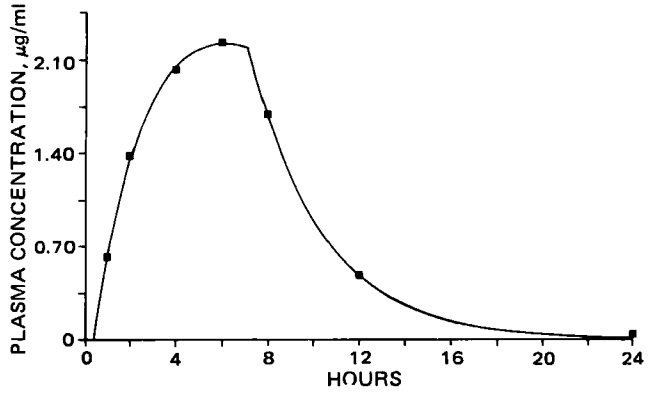

Figure 3—*Plasma concentration–time plot for the discontinuous fit of griseofulvin data obtained with NONLIN. Key: theoretical (—); data points (■).*

NONLIN were published values (1). The final estimates of the parameters were obtained by repeatedly entering the computed parameter values as initial estimates until the values stabilized.

In computer fits with NONLIN, the program default values for the parameters, DELINT, SSSTOP, and DELDER, were utilized. The DIG(I) parameter was set at 0.01, 0.001, and 0.001 to obtain the best fits for buformin, sulfisoxazole, and griseofulvin, respectively. All the data points shown in Figs. 1–3 were weighted equally.

RESULTS AND DISCUSSION

The results of the computer analyses of the three data sets are summarized in Tables II–IV and Figs. 1–3. In Tables II and III, parameter estimates obtained from NONLIN and FITSI2 are compared with those described previously (1). In both of these tables, values of α and β listed under NONLIN were calculated from quadratic relationships (8) using the NONLIN estimates of k_{12}, k_{21}, and k_{10}. In Table IV parameter estimates obtained from NONLIN are compared with those described previously (1). Less than perfect agreement between the two methods is expected since different algorithms are used in the two computer solutions and because Scheme I is not exactly the same model used previously (1).

Buformin (Case I: $t_1 < 0$)—The plasma data for buformin (4) in Fig. 1 was obtained in a diabetic patient after the oral administration of 100 mg of [^{14}C]buformin hydrochloride in a wax matrix. Based on first-order *in vitro* release characteristics of the dosage unit and two-compartment disposition characteristics *in vivo* (9), the data were fitted with NONLIN using a DFUNC subroutine for Scheme I, case I: $t_1 < 0$. The NONLIN estimates of k_{12} and k_{10} needed for calculating α and β were 0.116659 and 0.106853 hr^{-1}, respectively.

The model used in fitting the buformin data predicts two distinct absorption phases with absorption abruptly ending during the second and longer absorption time period. Accordingly, use of HFCM equations yields a negative value of t_1 and a positive value of t_2 as shown in columns 2 and 3 of Table II. An absorption rate constant, k_{a2}, is given for the second absorption phase but not for the short initial absorption phase. Use of the proposed differential equations method, however, provides absorption rate constants for both absorption phases and values for t_1' and t_2 as observed in column 4 of Table II. The estimated values of k_{12}, k_{21}, α, β, t_2, and V_c/F obtained with NONLIN (column 4) show closer agreement with values obtained with FITSI2 (column 3) run on a computer b^1 than with the published values (1) (column 2). However, the agreement in these parameters is not perfect for the described reasons. The extreme value of V_c/F in column 2 is apparently in error, since both NONLIN and FITSI2 gave much lower and almost identical estimates for this parameter.

Table IV—Parameter Values For The Fitting of Griseofulvin Data [a]

Parameters	Values HFCM[b] (Ref. 1)	Values NONLIN[c]
k_{a1}, hr^{-1}	0.09066	0.08944
k, hr^{-1} [d]	0.3090	0.3096
V_c/F, liters[e]	3.9393	3.9224
t_1, hr	0.3612	0.3308
t_2, hr	7.168	7.192
D_0, mg[f]	50.0	50.0
ΣD^2	—	0.001979
CP, sec[g]	—	2.43

[a] Data from Ref. 3. [b] Run on a PDP 11/10 computer. [c] Run on a CDC Cyber 174/2550 computer. [d] The parameter k is the elimination constant. [e] The parameter F is the systemic availability. [f] The parameter D_0 is the dose. [g] Fortran execution time without line printer plots and statistics for residuals.

Based upon the sum of squared deviations, ΣD^2, NONLIN and FITSI2 yielded almost identical fits to the data. It was observed, however, that NONLIN required more computer time for obtaining the parameter estimates than did FITSI2. The increased execution time with NONLIN is expected, since curve-fitting procedures using differential equations are inherently more time consuming than those using integral equations. The good fit provided by NONLIN is illustrated in Fig. 1.

Sulfisoxazole (Case II: $t_1 < 0$)—The plasma data for sulfisoxazole (5) in Fig. 2 was obtained from a healthy male subject after the oral administration of a 2.0-g tablet of sulfisoxazole. Because of the reported two-compartment behavior after intravenous administration (5), the data were fit with NONLIN using a DFUNC subroutine for Scheme I, case II: $t_1 < 0$. The NONLIN estimates of k_{12} and k_{10} required in calculating α and β were 0.0589257 and 0.122213 hr^{-1}, respectively.

The model used in fitting the sulfisoxazole data predicts three distinct absorption phases with absorption continuing sequentially throughout the three phases. The discontinuities in this case are incurred only by abrupt changes in the absorption rate, not by termination of absorption during the usual absorption period. Consequently, the use of HFCM equations yields a negative value for t_1 and a positive value for t_2, as listed in columns 2 and 3 of Table III. Columns 2 and 3 list estimates only of k_{a2} and k_{a3} for the second and third absorption phases. By contrast, the differential equations method (column 4) provides estimates of the absorption rate constants for all three absorption phases, together with values for t_1' and t_2.

The parameters in Table III estimated with NONLIN (column 4) show closer agreement with those obtained with FITSI2 (column 3) than those described previously (1) (column 2). For this data set, NONLIN yielded almost identical parameter estimates, but again, required more execution time for the discussed reasons. Based on the ΣD^2, almost identical fits were obtained with NONLIN and FITSI2. The exactness of the fit obtained with NONLIN is illustrated in Fig. 2.

The potential mechanisms for the irregular absorption profile for sulfisoxazole were discussed (5) (Fig. 2). Apparently, a small fraction of the 2.0-g dose dissolves rapidly to saturate the existing gastric fluid. A large fraction of the dose, however, remains as undissolved solid during its time in the stomach because of the small volume of fluid available for dissolution and the low membrane surface area available for absorption. Therefore, a rapid but limited absorption of this weak organic acid is possible from the stomach. Unabsorbed sulfisoxazole emptied into the small intestine undergoes a more rapid and complete absorption because of a more favorable pH for dissolution and an increased membrane surface area for absorption. Absorption phases 1 and 2 reflect gastric absorption, while absorption phase 3 reflects intestinal absorption.

Griseofulvin (Case I: $t_1 > 0$)—The plasma data for griseofulvin (3) in Fig. 3 was obtained in a rat after the oral intubation of 50 mg/kg of griseofulvin in a corn oil suspension. This data was fit with NONLIN using a modified DFUNC subroutine for Scheme I, case I: $t_1 > 0$, in which k_{12} and k_{21} equal zero.

The model used in fitting the data predicts a lag time before absorption begins and a single absorption phase that abruptly ends before absorption ceases. Accordingly, the use of HFCM equations yields positive values for both t_1 and t_2 and a value for the single absorption rate constant, k_{a1}, as observed in column 2 of Table IV. The proposed method in this case provides estimates of the same parameters, and there is good agreement between the estimates given in columns 2 and 3. The close-fitting plot obtained using NONLIN is given in Fig. 3.

ACKNOWLEGMENTS

The author acknowledges the assistance of the following members of the Temple University computer staff: Roslyn Gorin for procuring NONLIN; Liliane Clever for implementing NONLIN; Drusilla Gifford for implementing the Calcomp plots; and Bridget Peezick for implementing FITSI2.

The suggestion of Dr. C. M. Metzler for increasing the efficiency of the DFUNC subroutines used in this study is appreciated.

Kinetics and Thermodynamics of Interfacial Transfer

ROBERT FLEMING *, RICHARD H. GUY * § ×, and JONATHAN HADGRAFT ‡

Received January 13, 1981, from the **Department of Pharmaceutical Chemistry, The School of Pharmacy, University of London, London, WC1N 1AX, UK.* and the ‡*Department of Pharmacy, University of Nottingham, University Park, Nottingham, NG7 2RD, UK.* Accepted for publication March 25, 1982. §Present address: School of Pharmacy, University of California, San Francisco, CA 94143.

Abstract □ The kinetic barrier against the transport of methyl and ethyl nicotinates across the water–isopropyl myristate interface has been studied as a function of temperature using a rotating diffusion cell. The temperature dependence of the interfacial transfer kinetics has enabled calculation of the thermodynamic parameters for the process. It is evident from the results that, for the transferring solutes considered, the activation energy barrier is enthalpic, because there is a large positive entropy for transfer into the interfacial region.

Keyphrases □ Interfacial transfer—kinetics and thermodynamics, water–isopropyl myristate interface, methyl and ethyl nicotinates □ Kinetics—interfacial transfer thermodynamics, water–isopropyl myristate interface, methyl and ethyl nicotinates □ Thermodynamics—interfacial transfer kinetics, water–isopropyl myristate interface, methyl and ethyl nicotinates

An important physical process, common to all systems in which a solute transports from a high concentration aqueous phase across an organic membrane barrier into a low concentration aqueous phase, is the interfacial transfer of the substrate at the aqueous–organic and organic–aqueous interfaces. Few investigations into the kinetics and thermodynamics of interfacial transfer have been made, and the contribution of the phenomenon to overall membrane permeation has generally been assumed insignificant. However, recent studies have shown that transfer across the interfacial barrier can require a significant free energy input (1–3), and it is possible to identify circumstances for which the rate of interfacial transfer becomes the rate-determining step in membrane transport. For example, in the simplest case, consider the transport of drug molecules from an aqueous reservoir across an organic membrane into a perfect sink. Assuming that there is no stagnant diffusion layer in the aqueous reservoir phase, then the drug molecules must overcome two barriers so as to reach the sink on the far side of the membrane. These barriers are present due to interfacial transfer at the aqueous phase–membrane interface and due to diffusion through the organic membrane. The interfacial transfer is characterized by a heterogeneous rate constant k_{-1} (m/sec), which is related to the aqueous–organic partition coefficient of the drug (K) by the rate constant k_1 for interfacial transfer in the opposite direction (organic → aqueous), $K = k_1/k_{-1}$. Diffusion through the membrane is dependent upon the thickness of the membrane (l) and the diffusion coefficient of the drug in the membrane (D_{org}). Both processes also depend upon the cross-sectional area of the membrane. The relative contributions of the two components of the barrier may be compared by their reciprocal permeabilities [or resistivities (4)] and for interfacial transfer kinetics to have a significant effect on the overall rate of transport therefore requires:

$$1/Kk_{-1} \geq l/D_{org} \qquad \text{(Eq. 1)}$$

For certain small organic drug molecules, Kk_{-1} has been shown (1–3) to be $\sim 10^{-6}$ m/sec, and, taking a typical D_{org} of 10^{-10} m^2/sec, the inequality (Eq. 1) is satisfied by $l \leq 100$ μm. This degree of thickness is relevant not only to many biological membranes but also to emulsion systems and sustained-release formulations. Therefore, in neglecting slow interfacial transfer, it is possible that a major contribution to the transport rate-determining process in these systems is being ignored.

In this study, the kinetic barrier against interfacial transfer was investigated as a function of temperature. The

The model used in fitting the data predicts a lag time before absorption begins and a single absorption phase that abruptly ends before absorption ceases. Accordingly, the use of HFCM equations yields positive values for both t_1 and t_2 and a value for the single absorption rate constant, k_{a1}, as observed in column 2 of Table IV. The proposed method in this case provides estimates of the same parameters, and there is good agreement between the estimates given in columns 2 and 3. The close-fitting plot obtained using NONLIN is given in Fig. 3.

ACKNOWLEGMENTS

The author acknowledges the assistance of the following members of the Temple University computer staff: Roslyn Gorin for procuring NONLIN; Liliane Clever for implementing NONLIN; Drusilla Gifford for implementing the Calcomp plots; and Bridget Peezick for implementing FITSI2.

The suggestion of Dr. C. M. Metzler for increasing the efficiency of the DFUNC subroutines used in this study is appreciated.

Kinetics and Thermodynamics of Interfacial Transfer

ROBERT FLEMING *, RICHARD H. GUY * § ×, and JONATHAN HADGRAFT ‡

Received January 13, 1981, from the **Department of Pharmaceutical Chemistry, The School of Pharmacy, University of London, London, WC1N 1AX, UK.* and the ‡*Department of Pharmacy, University of Nottingham, University Park, Nottingham, NG7 2RD, UK.* Accepted for publication March 25, 1982. §Present address: School of Pharmacy, University of California, San Francisco, CA 94143.

Abstract □ The kinetic barrier against the transport of methyl and ethyl nicotinates across the water–isopropyl myristate interface has been studied as a function of temperature using a rotating diffusion cell. The temperature dependence of the interfacial transfer kinetics has enabled calculation of the thermodynamic parameters for the process. It is evident from the results that, for the transferring solutes considered, the activation energy barrier is enthalpic, because there is a large positive entropy for transfer into the interfacial region.

Keyphrases □ Interfacial transfer—kinetics and thermodynamics, water–isopropyl myristate interface, methyl and ethyl nicotinates □ Kinetics—interfacial transfer thermodynamics, water–isopropyl myristate interface, methyl and ethyl nicotinates □ Thermodynamics—interfacial transfer kinetics, water–isopropyl myristate interface, methyl and ethyl nicotinates

An important physical process, common to all systems in which a solute transports from a high concentration aqueous phase across an organic membrane barrier into a low concentration aqueous phase, is the interfacial transfer of the substrate at the aqueous–organic and organic–aqueous interfaces. Few investigations into the kinetics and thermodynamics of interfacial transfer have been made, and the contribution of the phenomenon to overall membrane permeation has generally been assumed insignificant. However, recent studies have shown that transfer across the interfacial barrier can require a significant free energy input (1–3), and it is possible to identify circumstances for which the rate of interfacial transfer becomes the rate-determining step in membrane transport. For example, in the simplest case, consider the transport of drug molecules from an aqueous reservoir across an organic membrane into a perfect sink. Assuming that there is no stagnant diffusion layer in the aqueous reservoir phase, then the drug molecules must overcome two barriers so as to reach the sink on the far side of the membrane. These barriers are present due to interfacial transfer at the aqueous phase–membrane interface and due to diffusion through the organic membrane. The interfacial transfer is characterized by a heterogeneous rate constant k_{-1} (m/sec), which is related to the aqueous–organic partition coefficient of the drug (K) by the rate constant k_1 for interfacial transfer in the opposite direction (organic → aqueous), $K = k_1/k_{-1}$. Diffusion through the membrane is dependent upon the thickness of the membrane (l) and the diffusion coefficient of the drug in the membrane (D_{org}). Both processes also depend upon the cross-sectional area of the membrane. The relative contributions of the two components of the barrier may be compared by their reciprocal permeabilities [or resistivities (4)] and for interfacial transfer kinetics to have a significant effect on the overall rate of transport therefore requires:

$$1/Kk_{-1} \geq l/D_{org} \qquad \text{(Eq. 1)}$$

For certain small organic drug molecules, Kk_{-1} has been shown (1–3) to be $\sim 10^{-6}$ m/sec, and, taking a typical D_{org} of 10^{-10} m^2/sec, the inequality (Eq. 1) is satisfied by $l \leq 100$ μm. This degree of thickness is relevant not only to many biological membranes but also to emulsion systems and sustained-release formulations. Therefore, in neglecting slow interfacial transfer, it is possible that a major contribution to the transport rate-determining process in these systems is being ignored.

In this study, the kinetic barrier against interfacial transfer was investigated as a function of temperature. The

transport of the methyl and ethyl esters of nicotinic acid across the water–isopropyl myristate (I) interface has been followed using a rotating diffusion cell (1). This cell uses the hydrodynamics of the rotating disk system (5) to impose a known pattern of convective diffusion on either side of a filter[1]. The rotation of the cell produces a stagnant diffusion layer of known thickness on both sides of the filter. In the experiments reported here, two interfaces were established with the aqueous phase above and below the filter which was saturated with the organic phase. The choice of I as the organic liquid reflected the suggestion by several workers that it is a good model compound for skin lipids (6). The rate constants for interfacial transfer were determined at three temperatures and converted to free energies of activation. An Arrhenius relationship has enabled the enthalpic contribution to the energy barrier to be found and the entropic component was obtained by difference. The data indicate that the free energy barrier to transfer is essentially enthalpic, there being a large positive entropy for transfer into the interfacial region. The results show the same pattern as that recently found for salicylic acid crossing the same aqueous–organic interface (3). Finally, the thermodynamic parameters for interfacial transfer are compared with those corresponding to solute transfer between the bulk IPM and bulk aqueous phases (the values being determined from the temperature dependence of the partition coefficient), and the marked differences are discussed.

[1] Millipore Corp., Bedford, Mass.

EXPERIMENTAL

Comprehensive descriptions of the rotating diffusion cell and its method of operation have been given previously (1, 2, 7). The transport of methyl and ethyl nicotinates at 25, 30, and 37° was followed from an aqueous inner compartment across a filter[1] saturated with I into a larger aqueous outer compartment. The flux of ester into the receptor phase was determined as a function of rotation speed by periodically sampling the outer compartment and analyzing the nicotinate concentration using UV spectrophotometry.

Partition coefficients were found by continuously shaking an aqueous solution of nicotinate with an equal volume of I for a period of ~48 hr and then analyzing for the substrate spectrophotometrically.

Diffusion coefficients for the two nicotinates in water and in I were determined at 25° using the Goüy interferometric technique. The results for methyl nicotinate were found to be in good agreement with the published values (1). Diffusion coefficients at the higher temperatures were obtained using the Stokes–Einstein relation and a ratio technique previously described (1–3, 7).

All chemicals were supplied commercially at least 99% pure and were used without further purification. Solutions were prepared with distilled water from an all-glass apparatus.

THEORETICAL

For the experiments described in this paper, the flux (J/mole/sec) of diffusing species from the inner compartment of the rotating diffusion cell to the outer is given by

$$J = kA(C_I - C_O) \qquad \text{(Eq. 2)}$$

Table I—Experimental Results from Figs. 1 and 2 and the Associated Solute Diffusion Coefficients [a]

°K	$10^9 D_{aq}$/ $m^2 s^{-1}$	$10^9 D_{org}$/ $m^2 s^{-1}$	10^{-6}Gradient[b]/ $s^{1/2} m^{-1}$	10^{-6}Intercept/ $m^{-1} s$
		Methyl Nicotinate		
298	0.88	0.41	0.137	0.341

		Ethyl Nicotinate		
298	0.76	0.37	0.151	0.161
303	0.89	0.42	0.134	0.129
310	1.06	0.46	0.116	0.074

[a] Diffusion coefficient values at 298°K were measured experimentally using a high precision Goüy diffusiometer (Ref. 9). The Stokes–Einstein relationship and a ratio technique were used to determine the values at the two higher temperatures. [b] These values were calculated using the corresponding aqueous diffusion coefficients and kinematic viscosities (Ref. 10). The gradients have then been forced through the experimental points in Figs. 1 and 2 to obtain the intercepts given in the final columns of this table.

where A is the area of the filter and C_I and C_O are the bulk concentrations in the inner and outer compartments, respectively. Detailed treatment of this expression has been presented previously (1) and the variation of the concentrations with time was shown to be:

$$[(C_{O,t} - C_{O,0})(1 + V_O/V_I)]/(C_{I,0} - C_{O,0}) = 1 - \exp[-kA(V_I^{-1} + V_O^{-1})t] \quad \text{(Eq. 3)}$$

where V_I and V_O refer to the respective volumes of the inner and outer compartments and the second subscripts on C refer to time. Furthermore, analysis of the flux equations for the double interface systems of this study indicates that the rate constant k be interpreted as follows (1):

$$k^{-1} = 2Z_D/D_{aq} + Kl/a'D_{org} + 2/a'k_{-1} \quad \text{(Eq. 4)}$$

In this equation, $2Z_D/D_{aq}$ describes the diffusion through the aqueous stagnant diffusion layers established on either side of the filter by the rotating disk hydrodynamics. The thickness of these layers (Z_D) is given by the equation (8):

$$Z_D = 0.643\, \upsilon^{1/6} D_{aq}^{1/3} W^{-1/2} \quad \text{(Eq. 5)}$$

where υ is the kinematic viscosity of water, D_{aq} the aqueous diffusion coefficient of the solute, and $W(s^{-1})$ the rotation speed of the filter. The second term in Eq. 4 describes the diffusion of the solute through the organic liquid filled filter of length l; K is the aqueous–organic partition coefficient of the substrate, and D_{org} its diffusion coefficient in the organic phase. The factor a' is the area of the pores of the filter divided by A. The final term $2/a'k_{-1}$ describes the interfacial transfer of the solute, the factor of two arising because there are two interfaces. For transfer of a substrate M, the forward and backward interfacial transfer rate constants (k_1 and k_{-1}) have the following significance:

$$M_{org} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M_{aq}: \qquad K = k_1/k_{-1} \quad \text{(Eq. 6)}$$

The largest of the three terms in Eq. 4 wil be the most important in determining the rate of the overall transfer process.

RESULTS AND DISCUSSION

The samples periodically removed from the outer compartment of the rotating diffusion cell enable values of k^{-1} to be calculated using Eq. 3. Figures 1 and 2 show that the linear relationship, predicted by Eqs. 4 and 5, between k^{-1} and $W^{-1/2}$ is experimentally verified for both methyl and ethyl nicotinates at each of the three temperatures considered. In these figures, the theoretical gradients calculated using Eq. 5 are forced through the experimental points to obtain the intercepts on the k^{-1} axis. Experimental data lie very close to the theoretical slopes, indicating that the correct hydrodynamics are indeed set up by the rotation of the diffusion cell. The aqueous diffusion coefficients and theoretical gradients together with the derived intercepts at $W^{-1/2} = 0$ are given in Table I for both nicotinic acid esters.

The intercepts in Table I and Figs. 1 and 2 correspond to the flux at infinite rotation speed when the Z_D term in Eq. 4 is zero. The remaining two terms describing diffusion through the filter and interfacial transfer may be separated using known values of K, D_{org}, l, and a': the partition coefficients for both esters at the three temperatures were determined and are presented in Table II; values for D_{org} were also found and are given in Table I; and the parameters[2] l and a' are 150 μm and 0.75, respectively, for the 0.22-μm pore size filters used. Independent verifications of the values of l and a' have been reported (11, 12). Hence, the intercepts provide direct measurements of k_{-1} for both esters at three temperatures. These rate constants, and the corresponding k_1 values calculated from Eq. 6, are given in Table II, and the interfacial transfer contributions to the intercepts are shown in Figs. 1 and 2. Furthermore, in Table II, the kinetic terms have been converted to free energy barriers using Eq. 7 (1)

Table II—Interfacial Transfer Parameters

°K	K	$10^6 k_1$/ m/sec	$10^6 k_{-1}$/ m/sec	$\Delta G°_{1,\#}$/kJ mole^{-1}	$\Delta G°_{-1,\#}$/kJ mole^{-1}
			Methyl Nicotinate		
298	0.45	9.9	22	39.7	37.8
303	0.42	16	38	39.4	37.2
310	0.39	34	86	38.4	36.0
			Ethyl Nicotinate		
298	0.14	4.4	31	42.0	37.1
303	0.13	5.2	40	42.2	37.1
310	0.11	11	102	41.3	35.5

$$\Delta G°_{\pm 1,\#} = -RT \ln(k_{\pm 1}/Z) \quad \text{(Eq. 7)}$$

which includes a frequency factor (Z) of 10^2 m/sec (13).

Because the interfacial transfer rate constants have been determined as a function of temperature, the enthalpy of transfer into the interfacial region may be estimated using an Arrhenius relation:

$$\ln k_{\pm 1} = \text{constant} - \Delta H°_{\pm 1,\#}/RT \quad \text{(Eq. 8)}$$

Plots of the natural logarithm of the $k_{\pm 1}$ values in Table II against $1/T$ were constructed and the enthalpy changes obtained from the gradients are given in the first columns of Tables III and IV for methyl and ethyl nicotinates, respectively. The magnitude of the entropy changes for interfacial transfer may then be calculated by difference using:

$$\Delta S°_{\pm 1,\#} = (\Delta H°_{\pm 1,\#} - \Delta G°_{\pm 1,\#})/T \quad \text{(Eq. 9)}$$

The results obtained for the two nicotinates at 298°K are again given in the left-hand columns of Tables III and IV.

The thermodynamic parameters for solute transfer between the bulk phases, *i.e.*, the energy difference between molecules in the bulk I and in the bulk aqueous phase, have been calculated from the partition coefficients in Table II. The results at 298°K are summarized in the second columns of Tables III and IV for methyl and ethyl nicotinates, respectively.

Consideration of the thermodynamic data in Tables II–IV provides the following observations:

1. The free energy of activation for interfacial transfer in either direction (organic ⇌ aqueous) is always in the region of 39 kJ/mole. The free energy differences between the molecules in the bulk phases, however, are comparatively small at 298°K.
2. For interfacial transfer in both directions, there is a reasonably large positive enthalpy of activation. The temperature dependence of the nicotinates water–I partition coefficients, though, indicates that transfer from the bulk I phase to the bulk aqueous phase is an exothermic process $\Delta H \simeq$ 10–15 kJ/mole. The transfer between the bulk phases in the opposite direction has a correspondingly positive ΔH.
3. For both solutes, in either direction, there is a large significant positive entropy for transfer into the interfacial region. This implies that the free energy barrier to interfacial transfer discussed above is essentially enthalpic rather than entropic. For solute transfer from the bulk I to the bulk aqueous phase, on the other hand, ΔS is negative. Furthermore, in this situation, the negative entropy changes are responsible for the positive free energy changes calculated from the partition coefficients.

The constancy of the interfacial transfer free energy of activation has been reported previously (1, 3), and the results of this study are in good agreement with the data in the literature. The values also compare favorably with a result for $\Delta G°_{\#}$ determined using a Stokes cell (14). In

$\Delta S/J$ mole$^{-1}K^{-1}$	121	−37

Water → I

	Water (interface) $\xrightarrow{k_{-1}}$ I (interface)	Water (bulk) $\xrightarrow{1/K}$ I (bulk)[b]
$\Delta G/kJ$ mole^{-1}	37.8	−2.0
$\Delta H/kJ$ mole^{-1}	85.1	9.1
$\Delta S/J$ mole$^{-1}K^{-1}$	159	37

[a] ΔG in this column is calculated using $\Delta G = -RT \ln K$, ΔH is found from the slope of an Arrhenius plot of ln K *versus* $1/T$, and ΔS is determined by difference. [b] In this case, $\Delta G = +RT \ln K$, ΔH is found by plotting ln K^{-1} against $1/T$, and ΔS is again determined by difference.

Table IV—Ethyl Nicotinate: Thermodynamic Values at 298°K

I → Water

	I (interface) $\xrightarrow{k_1}$ Water (interface)	I (bulk $\xrightarrow{K}$ Water (bulk)[a]
$\Delta G/kJ$ mole^{-1}	42.0	4.9
$\Delta H/kJ$ mole^{-1}	67.2	−15.6
$\Delta S/J$ mole$^{-1}K^{-1}$	85	−69

Water → I

	Water (interface) $\xrightarrow{k_{-1}}$ I (interface)	Water (bulk) $\xrightarrow{1/K}$ I (bulk)[b]
$\Delta G/kJ$ mole^{-1}	37.1	−4.9
$\Delta H/kJ$ mole^{-1}	84.1	15.6
$\Delta S/J$ mole$^{-1}K^{-1}$	158	69

[a] ΔG in this column is calculated using $\Delta G = -RT \ln K$, ΔH is found from the slope of an Arrhenius plot of ln K *versus* $1/T$, and ΔS is determined by difference. [b] In this case, $\Delta G = +RT \ln K$, ΔH is found by plotting ln K^{-1} against $1/T$, and ΔS is again determined by difference.

this case, the system contained only one interface (set up on the surface of the sinter of the cell) between I and water, and the transferring substrate was *p*-methyl benzyl chloride. It seems unlikely that the technique of this earlier determination and the rotating diffusion cell suffer from the same experimental errors or artifacts. The good agreement between the two sets of results is believed (1), therefore, to provide confirmation of both the existence of the interfacial transfer process and of the reliability of the rotating diffusion cell.

Investigations of the temperature dependence of the interfacial transfer process have produced somewhat disparate results. For example, the interfacial barrier for *p*-methyl benzyl chloride crossing the water–I interface (14) was found to be almost totally enthalpic, with little or no entropic contribution. However, an earlier investigation of methyl nicotinate traversing the same interface (1), indicated that the interfacial transfer rate constants passed through a minimum as the temperature was raised from 11 to 37°. The data obtained at 21 and 37° support the trend in values found in this work. The discrepancy arises because of the enhanced rate of transfer measured at 11°, for which there appears to be no straightforward explanation. Most recently, the transfer of salicylic acid across the water–I interface has been considered (3), and substantially the same pattern of results was obtained as reported for the nicotinates in this paper; *i.e.*, the entropy of transfer across the interfacial region acts so as to reduce the overall free energy barrier, to which there exists a large positive enthalpic contribution.

The large positive entropy of activation found for interfacial transfer in either direction warrants further consideration. For both nicotinates [and salicylic acid (3)], transfer from the bulk I to the bulk aqueous phase involves a negative entropy change. This seems reasonable, since it is undoubtedly true that the solvation of the solute molecules will be more efficient in water than in I. The transfer from bulk I to bulk water will, therefore, produce an increase in the order of the system. However, this is not true in the region of the interface where nicotinate transfer causes a large increase in disorder. It is possible that this observation reflects the absence of any solvation sheath around the solutes as they traverse the interfacial regions. Alternatively it seems reasonable to suggest that a I–water interface possesses a well-ordered structure in which the ester groups of the I moieties will be oriented toward and solvated by the adjacent water molecules. The transport of a solute molecule through this rather ordered structure must destroy the I–water interactions, thereby contributing toward a positive entropy charge.

Further conclusions from the kinetic and thermodynamic parameters reported here cannot be drawn until more experiments are performed in which the nature of the solutes and solvents used are systematically varied. Like most two-phase and solvation phenomena, a variety of behavior may be expected. However, it has been demonstrated that the role of interfacial transfer in the permeation of organic barriers by the solutes described in this and other work should be considered significant to the overall transport process taking place in these systems.

Kinetic Study and Analytical Application of the Hexadecyltrimethylammonium Bromide-Catalyzed Reaction of 1-Fluoro-2,4-dinitrobenzene with Amines

MICHELLE P. WONG and KENNETH A. CONNORS ˣ

Received March 9, 1982, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication April 1, 1982.

Abstract □ Arylation of amines by reaction with 1-fluoro-2,4-dinitrobenzene is catalyzed by micelles of cetrimonium bromide. This catalysis has been exploited to reduce the analysis time in the spectrophotometric determination of amines as their dinitrophenyl derivatives. The kinetics of the catalysis were studied for the five amines: alanine, phenylalanine, aniline, 4-methylaniline, and 4-methoxyaniline. The dependence of rate constant on surfactant concentration can be quantitatively accounted for by Berezin's model, in which uptake of the amine and the 1-fluoro-2,4-dinitrobenzene by the micelle is described as a partitioning phenomenon for both species. An alternative model is developed in which one reactant partitions into the micellar phase and the other binds to the micelle with 1:1 stoichiometry; the two models are formally equivalent. Intrinsic catalytic rate constants and binding constants were evaluated. About one-third to one-half of the maximum observed micellar acceleration is attributed to a true micellar catalysis, the remainder being ascribed to an increase in local reactant concentrations in the micelle.

Keyphrases □ 1-Fluoro-2,4-dinitrobenzene—hexadecyltrimethylammonium bromide-catalyzed reaction with amines, kinetics, analytical application □ Hexadecyltrimethylammonium bromide-catalyzed reaction—1-fluoro-2,4-dinitrobenzene with amines, kinetics, analytical application □ Kinetics—hexadecyltrimethylammonium bromide-catalyzed reaction of 1-fluoro-2,4-dinitrobenzene with amines, analytical application

1-Fluoro-2,4-dinitrobenzene undergoes nucleophilic aromatic substitution by amines to give dinitrophenylamines, which are useful derivatives for the spectrophotometric analysis of amines (1–5). Typical reaction times are 10–20 min at 65°. The catalysis of this reaction by the surfactant cetrimonium bromide was previously described (6). It was later suggested (7, 8) that this catalysis could be applied to the analytical system to reduce the reaction times. A preliminary communication showed that this was practical, and described analytical conditions making use of the micellar catalysis (9). The present paper extends the investigation of this analytical application and reports kinetic studies, and their interpretation, of the cetrimonium bromide-catalyzed reaction of 1-fluoro-2,4-dinitrobenzene with five amines.

EXPERIMENTAL

Materials—Cetrimonium bromide[1] was purified by a previous procedure (10). 1-Fluoro-2,4-dinitrobenzene was distilled under reduced pressure. Aniline[2] was distilled; bp 181°. 4-Methylaniline[3] (*p*-toluidine) was distilled under reduced pressure; bp 61.5°/2 mm Hg, mp 44.5–45° [lit. mp 44.8° (11)]. 4-Methoxyaniline[3] (*p*-anisidine) was distilled under reduced pressure; bp 98°/2 mm Hg, mp 56.5–57° [lit. mp 57° (12)]. Other chemicals were used directly.

Product Identification—Alanine and 1-fluoro-2,4-dinitrobenzene were reacted in pH 9.2 borate buffer in the presence of cetrimonium bromide. The solution was acidified to below pH 3 with concentrated HCl and was extracted with diethyl ether. The ether layer was dried, redissolved in ether, and then spotted on silica gel TLC plates[4]. This was developed with a mixed solvent of ether–glacial acetic acid–water (100:3:3). The product (2,4-dinitrophenylalanine) isolated in this way was recrystallized from 50% ethanol, and its IR spectrum was determined in solid potassium bromide for comparison with the spectrum of an authentic sample of 2,4-dinitrophenylalanine[5]. UV spectra were also measured.

The hydrolysis of 1-fluoro-2,4-dinitrobenzene was studied in pH 9.2 borate buffer containing cetrimonium bromide, but no amine. After hydrolysis the solution was acidified, extracted with ethyl acetate, the extract was evaporated to dryness, and the residue was dissolved in methanol for spotting on TLC plates. The development solvent was chloroform–methanol–glacial acetic acid (40:10:0.5). The spot was scraped off, dissolved in methanol, and centrifuged. The supernatant was dried, and the residue was compressed with potassium bromide for IR spectroscopy[6]. An authentic sample of 2,4-dinitrophenol was carried through the same procedure.

Kinetic Studies—For reactions in which the reagent (1-fluoro-2,4-dinitrobenzene) concentration was higher than the amine concentration, typical initial conditions were: 5×10^{-4} *M* amine and 0.035 *M* cetrimonium bromide in 0.065 *M* pH 9.2 borate buffer; the reaction was initiated by adding 1.0 ml of 1.3% v/v 1-fluoro-2,4-dinitrobenzene (dissolved in acetone) to 19 ml of thermostated aqueous solution. Samples of 1.0 ml were removed at recorded times and were added to 9.0 ml of a 1:100 dilution of concentrated HCl in dioxane (4). The absorbance was measured[7] at the wavelength of maximum absorption (usually 350 nm) in a 1.0-cm cell against a reagent blank carried through the same procedure.

For reactions in which the amine concentration exceeded the 1-fluoro-2,4-dinitrobenzene concentration, the reaction was monitored directly in the thermostated spectrophotometer cell compartment.

Proposed Analytical Method—To a 25-ml volumetric flask 0.25 g of cetrimonium bromide and enough of the amine sample should be added so that its final concentration will be 10^{-4} *M*; the solution brought to 19 ml with 0.065 *M* pH 9.2 borate buffer; the flask brought to the desired reaction temperature (25–45°); and the reaction initiated by adding 1.0 ml of 1.3% v/v 1-fluoro-2,4-dinitrobenzene in acetone. After ~5 half-lives at the experimental temperature, a 1.0-ml portion should be added to 9.0 ml of a 1:100 dilution of concentrated hydrochloric acid in dioxane, and the absorbance immediately measured at the absorption maximum against a reagent blank carried through the same procedure. A standard curve should be prepared by subjecting known concentrations of the same amine to the procedure.

RESULTS

Analytical Method—Analytical conditions require that the concentration of reagent (1-fluoro-2,4-dinitrobenzene) should be greater than that of the amine. Under these conditions, light absorption by the 2,4-dinitrophenolate produced through concurrent hydrolysis of the reagent interferes with direct observation of the dinitrophenylated amine. It is, therefore, necessary to withdraw samples and to acidify them, which stops the reaction and concomitantly alters the spectrum of the phenol so that it does not interfere with the detection of the amine derivative (4).

Figure 1 shows the extent of the catalysis by cetrimonium bromide in the reaction of alanine with 1-fluoro-2,4-dinitrobenzene. The apparent first-order plots were linear for two or more half-lives in both the presence and absence of surfactant. Table I lists half-lives for numerous amines subjected to this procedure, and the rate enhancement produced by the surfactant is given in the final column. Rate enhancements for aliphatic amino acids and peptides are in the range of 10–20, whereas aromatic amino acids show much greater enhancements. The neutral aniline has

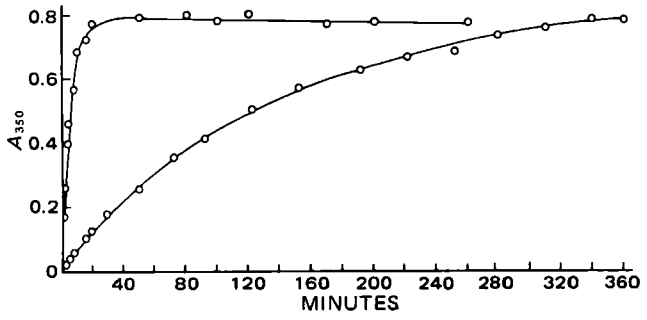

Figure 1—*Change of absorbance at 350 nm with time for the arylation of alanine at 23°: 5 × 10⁻⁴ M alanine, 3.5 × 10⁻³ M 1-fluoro-2,4-dinitrobenzene, pH 9.2. Upper curve, 0.035 M cetrimonium bromide; lower curve, no surfactant.*

the lowest relative rate in the table. These data suggest that the catalysis by the cationic micelle is assisted by anionic and hydrophobic sites on the amine. When both features are present, as in 11-aminoundecanoic acid, a very large rate enhancement can occur. The half-lives in Table I can guide the analyst in selecting appropriate reaction times.

The effect of temperature on the reaction rate was studied in the presence and absence of 0.0175 *M* surfactant to learn the extent of the analytical advantage to be gained by working at a higher temperature. The reaction was studied at 15, 25, 35, and 45°; the Arrhenius plots were linear. In the absence of surfactant, the activation enthalpy $\Delta H^{\ddagger}$ was 16.1 (*SD* 0.5) Kcal/mole and the activation entropy $\Delta S^{\ddagger}$ was −11.2 (*SD* 0.5) EU (entropy units). In the presence of surfactant, $\Delta H^{\ddagger}$ was 13.7 (*SD* 0.4) Kcal/mole and $\Delta S^{\ddagger}$ was −14.6 (*SD* 1.3) EU. No mechanistic interpretation is given to these results, because they include several effects (the micellar rate effect and the uptake of the two reactants by the micelle). However, the analytical reaction time can be reduced by a factor of ~3 by raising the temperature from 25 to 45°. The slopes of the concentration-absorbance curves were identical for reactions run at 25 and 45°.

The product identification studies showed, by means of TLC, IR spectroscopy, and UV spectroscopy, that the products of the reaction of 1-fluoro-2,4-dinitrobenzene with alanine in the presence of cetrimonium bromide were 2,4-dinitrophenylalanine and 2,4-dinitrophenol.

Reaction Order—In the analytical studies the reagent was in excess by necessity, but for studying the reaction kinetics it is more convenient to have the amine in excess. This permits the reaction to be monitored directly in the spectrophotometer. However, 1-fluoro-2,4-dinitrobenzene undergoes two reactions in this system, yielding the two products, a 2,4-dinitrophenylamine and 2,4-dinitrophenol. The following kinetic treatment takes this into account. Scheme I is the kinetic scheme, where *R* represents 1-fluoro-2,4-dinitrobenzene, *D* is the dinitrophenylamine derivative, *P* is dinitrophenol, k_D is an apparent first-order rate constant for the production of *D*, and k_P is an apparent first-order rate constant for the production of *P*.

$$R \xrightarrow{k_D} D$$

$$R \xrightarrow{k_P} P$$

Scheme I

Then $-d[R]/dt = (k_D + k_P)[R] = k[R]$, where $k = k_D + k_P$; the loss of *R* is a first-order process, and $[R] = [R]_0 \exp(-kt)$. The rate of formation of *D* is $d[D]/dt = k_D[R] = k_D[R]_0 \exp(-kt)$. Integrating this with the initial condition $[D] = 0$ at $t = 0$ gives:

$$[D] = \frac{k_D[R]_0}{k}(1 - e^{-kt}) \qquad \text{(Eq. 1)}$$

In the same way, Eq. 2 is obtained:

$$[P] = \frac{k_P[R]_0}{k}(1 - e^{-kt}) \qquad \text{(Eq. 2)}$$

The absorbance of the solution (in a 1-cm cell) at any time is given by:

$$A = \epsilon_R[R] + \epsilon_D[D] + \epsilon_P[P] \qquad \text{(Eq. 3)}$$

Combining Eqs. 1–3 gives:

$$A = \frac{[R]_0}{k}(\epsilon_D k_D + \epsilon_P k_P) + \frac{[R]_0}{k}(\epsilon_R k - \epsilon_D k_D - \epsilon_P k_P)e^{-kt} \qquad \text{(Eq. 4)}$$

Table I—Micellar Catalysis of Amine–1-Fluoro-2,4-dinitrobenzene Reactions by Cetrimonium Bromide [a]

Amine	Half-life/min: No Surfactant	Half-life/min: 0.035 *M* Surfactant	Rate Enhancement
Glycine	36.0	2.0	18.0
Alanine	87.4	4.7	18.6

Tryptophan	9.0	<0.1	>90
Glycylglycine	63.5	5.4	11.8
Glycylglycylglycine	94.0	7.5	12.5
Glutamic acid	72.0	<0.3	>240
p-Aminobenzoic acid	137.5	3.0	45.8
11-Aminoundecanoic acid	133.0	<0.1	>1330
Aniline	60.0	7.5	8.0

[a] At pH 9.2 and 23°; 0.0035 *M* 1-fluoro-2,4-dinitrobenzene.

If the absorbance is measured at a wavelength where $\epsilon_D = \epsilon_P = \epsilon$, Eq. 4 simplifies to:

$$\epsilon[R]_0 - A = (\epsilon - \epsilon_R)[R]_0 e^{-kt} \qquad \text{(Eq. 5)}$$

But $\epsilon[R]_0 = A_\infty$, the absorbance when reaction is complete. Therefore, a conventional plot of $\log(A_\infty - A)$ against *t* should be linear, the slope yielding $k = k_D + k_P$. Since k_P can be measured in a separate experiment in the absence of amine, the desired rate constant (k_D) is accessible. Absorbance measurements were made at 350 nm, where $\epsilon_D = \epsilon_P$, and the first-order plots were linear for over three half-lives.

At pH 9.2 with alanine serving as the amine substrate, the kinetic dependence on the amine and the reagent was established. In the presence of 0.035 *M* cetrimonium bromide, the rate was directly dependent on the concentrations of amine and 1-fluoro-2,4-dinitrobenzene, confirming the first-order dependence upon each of these reactants in the presence of the surfactant.

Kinetic Dependence on Surfactant Concentration—The kinetics of the reaction of five amines (alanine, phenylalanine, aniline, 4-methylaniline, and 4-methoxyaniline) were studied in the presence of varying concentrations of surfactant at 25° and pH 9.2; the amine concentrations were 0.001–0.1 *M*, and the 1-fluoro-2,4-dinitrobenzene concentration was 6.32×10^{-5} *M*. Figure 2 is a plot of the first-order rate constant (k_D) against the total surfactant concentration (C_T) for phenylalanine. The general pattern in Fig. 2 was seen with all amines, namely an increase in rate at low surfactant concentrations with a saturation-type effect setting in at high concentrations. However, instead of an invariant plateau level, a maximum is observed in the plot (13).

At very low surfactant concentrations, the rate constant depends linearly on surfactant concentration, as shown in Fig. 3 for three concentrations of alanine. The discontinuity in the plot marks the effective critical micelle concentration (*CMC*); below this concentration the surfactant exists solely as the monomer.

DISCUSSION

The Partitioning–Partitioning Model—The kinetic dependence of micellar catalysis on surfactant concentration is often described by means of a kinetic scheme analogous to the Michaelis–Menten model of enzyme kinetics (14). This description is appropriate for a first-order reaction (*i.e.*, one in which a single substrate is taken up by the micelle), for which it predicts a saturation curve with an invariant plateau value at high surfactant concentrations. Evidently, the Michaelis–Menten model cannot provide a quantitative treatment of a reaction like the nucleophilic substitution described here, for the concentration dependence of the rate reveals a maximum. It is necessary to take into account the uptake of two reactants by the micelle in this second-order reaction, and this leads to a quantitative description of the experimental curve. This was accomplished previously (15–18) by workers who investigated (among other systems) the acceleration of the aminolysis of 1-fluoro-2,4-dinitrobenzene with *N*-benzoyl-L-histidine methyl ester in the presence of cetrimonium bromide. To account for the dependence of rate on surfactant concentration they proposed a model in which both the 1-fluoro-2,4-dinitrobenzene (designated *R*) and the amine (*S*) are distributed between the micellar (*M*) and aqueous (*W*) phases in conformity with the simple distribution law. This model is referred to here as the partitioning–partitioning model, since it postulates a partitioning mechanism for the uptake of both solutes.

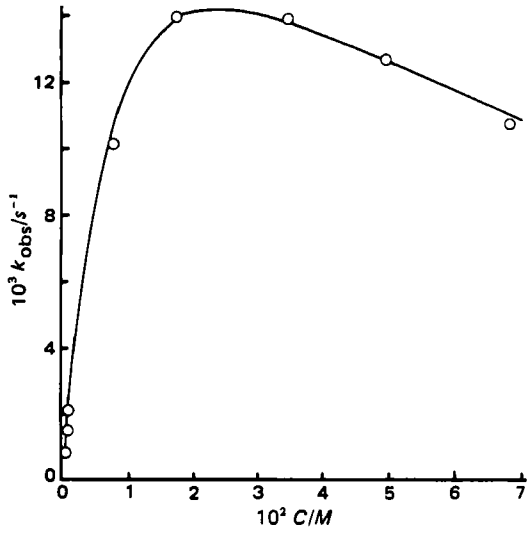

Figure 2—*Plot of first-order rate constant for the phenylalanine–1-fluoro-2,4-dinitrobenzene system at 25° and pH 9.2 as a function of surfactant concentration. The phenylalanine concentration is 1.04 × 10^{-3} M. The smooth line was drawn with Eq. 33.*

If V_T, V_M, and V_W represent the total volume of the system, the volume of the micellar phase, and the volume of the aqueous phase, respectively, then $V_T = V_M + V_W$, and:

$$\frac{V_W}{V_T} = 1 - \frac{V_M}{V_T} \qquad \text{(Eq. 6)}$$

A mass balance on R yields:

$$[R]_T V_T = [R]_M V_M + [R]_W V_W \qquad \text{(Eq. 7)}$$

and similarly for S. Substituting into Eq. 2 from Eq. 1:

$$[R]_T = [R]_M \frac{V_M}{V_T} + [R]_W \left(1 - \frac{V_M}{V_T}\right) \qquad \text{(Eq. 8)}$$

The molar concentration of surfactant present as micelles, C, is defined:

$$C = C_T - (CMC) \qquad \text{(Eq. 9)}$$

Letting V be the molar volume of surfactant, it follows that the product CV is the liters of surfactant present as micelles per liter of solution, or the volume fraction of the micellar phase, hence:

$$CV = V_M/V_T \qquad \text{(Eq. 10)}$$

which, combined with Eq. 8, gives:

$$[R]_T = [R]_M CV + [R]_W(1 - CV) \qquad \text{(Eq. 11)}$$

The distribution equilibria, according to this model, are:

$$R_W \rightleftharpoons R_M$$

$$S_W \rightleftharpoons S_M$$

Scheme II

The partition coefficient for R is defined:

$$P_R = \frac{[R]_M}{[R]_W} \qquad \text{(Eq. 12)}$$

and similarly for S. Eqs. 11 and 12 are combined to yield:

$$\frac{[R]_T}{[R]_W} = 1 + (P_R - 1)CV \qquad \text{(Eq. 13)}$$

The quantity K_R is defined:

$$K_R = (P_R - 1)V \qquad \text{(Eq. 14)}$$

Then Eq. 15 is written for R, and Eq. 16 is the analogous equation for S:

$$\frac{[R]_T}{[R]_W} = 1 + K_R C \qquad \text{(Eq. 15)}$$

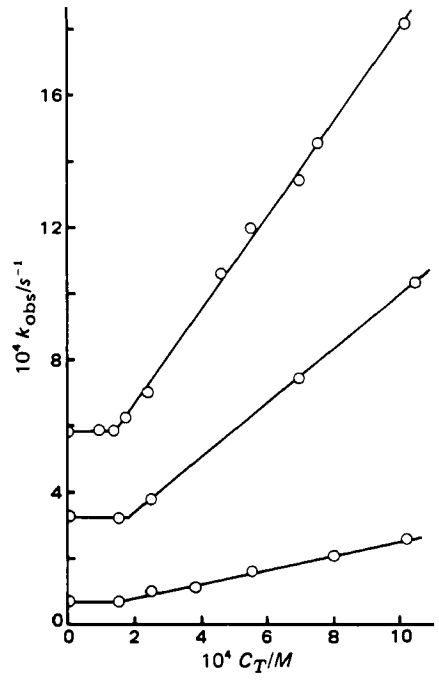

Figure 3—*Plot of first-order rate constant for the alanine–1-fluoro-2,4-dinitrobenzene system as a function of total surfactant concentration. Alanine concentrations, top to bottom: 0.025* M, *0.0125* M, *0.00267* M.

$$\frac{[S]_T}{[S]_W} = 1 + K_S C \qquad \text{(Eq. 16)}$$

In these equations K_R and K_S have the units of M^{-1}; *i.e.*, they have the character of 1:1 binding constants.

The bimolecular reaction between R and S can occur in both phases, with corresponding rate equations:

$$v_M = k_M[R]_M[S]_M \qquad \text{(Eq. 17)}$$

$$v_W = k_W[R]_W[S]_W \qquad \text{(Eq. 18)}$$

The observed velocity (v) is equal to the sum of the products of the velocities in the individual phases and the volume fractions of the phases:

$$v = v_M CV + v_W(1 - CV) \qquad \text{(Eq. 19)}$$

An experimentally observed second-order rate constant can be defined:

$$v = k_{exp}[R]_T[S]_T \qquad \text{(Eq. 20)}$$

Equations 19 and 20 are combined with 15 and 16 and the partition coefficient definitions:

$$k_{exp} = \frac{k_M P_R P_S CV + k_W(1 - CV)}{(1 + K_R C)(1 + K_S C)} \qquad \text{(Eq. 21)}$$

Equation 21 can be simplified for the present purpose. When partitioning into the micelle is favored, as with anionic and hydrophobic species, P is much larger than unity, and the binding constants from Eq. 14 can be written as $K_R = P_R V$ and $K_S = P_S V$. Moreover, when $CV \ll 1$, Eq. 21 becomes:

$$k_{exp} = \frac{k'_M K_R K_S C + k_W}{(1 + K_R C)(1 + K_S C)} \qquad \text{(Eq. 22)}$$

where $k'_M = k_M/V$.

This model can account for the appearance of a maximum in the dependence of k_{exp} on C. As Berezin points out (17), to account for this maximum it is necessary to describe the uptake of both solutes, making the model, and the corresponding equation, qualitatively different from the Michaelis–Menten model.

A Binding–Partitioning Model—It is now shown that a result formally equivalent to the Berezin partitioning–partitioning model can be obtained with a different physical picture of the process. It is postulated that one of the reactants, the one in large excess (S in this case) partitions

between the micellar and aqueous phases, whereas the other reactant binds to the micelle with 1:1 stoichiometry. These equilibria are:

$$S_W \rightleftarrows S_M$$

$$R + MS \rightleftarrows MSR$$

Scheme III

In this formulation, $[S]_M$ is the concentration of S in the micellar phase, and $[MS]$ is the solution concentration of S-containing micelles. There are no micelles without S, but there can be micelles without R. This is physically reasonable when $[S]_T >$ [micelles] $> [R]_T$. By arguments given above, Eq. 16 applies to S, whereas Eq. 23 defines the binding constant for R.

$$K'_M = \frac{[MSR]}{[R]_W[MS]} \qquad \text{(Eq. 23)}$$

The rate equation for loss of R is given by:

$$-\frac{d[R]}{dt} = k_W[R]_W[S]_W + k_M[MSR][S]_M \qquad \text{(Eq. 24)}$$

The mass balance on surfactant is:

$$C_T = [CMC] + n[MS] + n[MSR] \qquad \text{(Eq. 25)}$$

where n is the micelle aggregation number. Combining Eqs. 9, 23, and 25:

$$[MS] = \frac{C}{n + nK'_M[R]_W} \qquad \text{(Eq. 26)}$$

The mass balance on R is:

$$[R]_T = [R]_W + [MSR] \qquad \text{(Eq. 27)}$$

since $[MSR]$ is the concentration of micelles each containing an R. This leads to:

$$[R]_W = \frac{[R]_T}{1 + K'_M[MS]} \qquad \text{(Eq. 28)}$$

Combining the partition coefficient $P_S = [S]_M/[S]_W$ with Eqs. 23, 24, and 28 gives the rate equation:

$$-\frac{d[R]_T}{dt} = \left[\frac{k_M K'_M P_S[MS] + k_W}{1 + K'_M[MS]}\right][S]_W[R]_T \qquad \text{(Eq. 29)}$$

This is first-order in $[R]_T$, with the apparent first-order rate constant k_{obs}:

$$k_{obs} = \left[\frac{k_M K'_M P_S[MS] + k_W}{1 + K'_M[MS]}\right][S]_W \qquad \text{(Eq. 30)}$$

Eq. 26 is combined with Eq. 30 to give:

$$k_{obs} = \left[\frac{\dfrac{k_M K'_M P_S C}{n + nK'_M[R]_W} + k_W}{1 + \dfrac{K'_M C}{n + nK'_M[R]_W}}\right][S]_W \qquad \text{(Eq. 31)}$$

Equation 31 is simplified by using the reasonable assumption $K'_M[R]_W \ll 1$, substituting $K_S = P_S V$, and replacing $[S]_W$ from Eq. 16 to give:

$$k_{exp} = \frac{k'_M K_M K_S C + k_W}{(1 + K_M C)(1 + K_S C)} \qquad \text{(Eq. 32)}$$

where $k'_M = k_M/V$, $K_M = K'_M/n$, and $k_{exp} = k_{obs}/[S]_T$. Equation 32 for the binding-partitioning model is identical in form with Eq. 22 for the partitioning-partitioning model. In these equations the quantity K_S has the same significance, but K_R in Eq. 22 is interpreted as K'_M/n in Eq. 32 as a consequence of the different assumptions concerning the uptake of R into the micelle.

Estimation of the Model Parameters—Equations 22 and 32 can be written in the equivalent form:

$$k_{obs} = \left[\frac{k'_M K_M K_S C + k_W}{(1 + K_M C)(1 + K_S C)}\right][S]_T \qquad \text{(Eq. 33)}$$

The parameters can be estimated in several ways from the dependence of k_{obs} on C.

A plot of k_{obs} against C_T, at very low C_T, will give $k_W[S]_T$ as the value of k_{obs} below the CMC. Above the CMC, the slope of the straight line is equal to $k'_M K_M K_S[S]_T$, from which the product $k'_M K_M K_S$ is found. The intersection of the straight line segments marks the CMC. Figure 3 shows plots of this type.

A plot of k_{obs} against C over the full range of C, as shown in Figure 2,

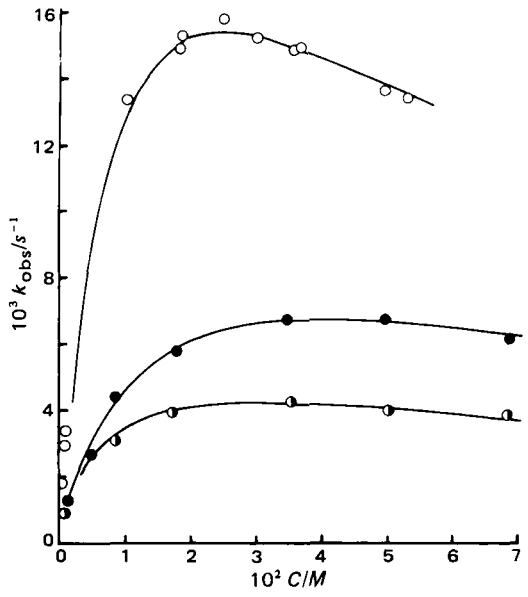

Figure 4—*Dependence of* k_{obs} *on surfactant concentration for aniline (○), 4-methylaniline (●), and 4-methoxyaniline (◑). The smooth curves were drawn with Eq. 33 and the parameters in Table II. The amine concentrations were: aniline, 0.0988* M; *4-methylaniline, 0.00807* M; *4-methoxyaniline, 0.0243* M.

exhibits a maximum if Eq. 33 describes the system. The concentration C_{max} corresponding to this maximum is found by setting the derivative dk_{obs}/dC equal to zero:

$$C_{max} = (K_M K_S)^{-1/2} \qquad \text{(Eq. 34)}$$

This result yields the product $K_M K_S$, and k'_M is obtained from this and the estimate of $k'_M K_M K_S$.

Inserting Eq. 34 into Eq. 32, and neglecting k_W, leads to Eq. 35, where k_{exp}^{max} is the value of k_{exp} when $C = C_{max}$:

$$\left[\frac{k_{max}^{exp}}{k'_M}\right]^{-1/2} = K_M^{-1/2} + K_S^{-1/2} \qquad \text{(Eq. 35)}$$

With these relationships, the four parameters k_W, k'_M, K_M, and K_S can be evaluated. Because Eq. 33 is symmetrical in K_M and K_S, it is not possible to assign these quantities unambiguously.

Another approach is a modification of a method described previously (18). Eq. 32 can be rearranged to:

$$k_{exp} - k_W = \left[\frac{K_M C}{1 + K_M C}\right]\left[\frac{k'_M K_S}{1 + K_S C} - k_W\right] \qquad \text{(Eq. 36)}$$

From this, Eq. 37 is obtained:

$$\frac{C}{k_{exp} - k_W} = \frac{1}{A} + \frac{(K_M + K_S)}{A}C + \frac{K_M K_S}{A}C^2 \qquad \text{(Eq. 37)}$$

where $A = k'_M K_M K_S - k_W K_M(1 + K_S C)$. A plot of $C/(k_{exp} - k_W)$ against C is a curve, whose intercept at $C = 0$ is $1/(k'_M K_M K_S - k_W K_M)$. If the k_W term is negligible, this gives an estimate of $k'_M K_M K_S$.

Equation 32 is then rearranged to:

$$\frac{k'_M K_M K_S C + k_W - k_{exp}}{k_{exp} C} = K_M K_S C + (K_M + K_S) \qquad \text{(Eq. 38)}$$

A plot of the left side against C yields $K_M K_S$ and $(K_M + K_S)$ from the slope and intercept.

By either of these methods K_M and K_S are found by solving the quadratic formula. In some instances the solution is indeterminate—that is, the estimates $K_M K_S$ and $(K_M + K_S)$ are mutually inconsistent, because of experimental error. The individual constants are then evaluated by a curve-fitting method, in which Eq. 33 is fitted to the experimental points. This is a straightforward process, because the quantities $k'_M K_M K_S$ and $K_M K_S$ serve as constraints. Figures 2 and 4 show some of these curves.

Interpretation of the Micellar Catalysis—Table II gives the values of K_M, K_S, k_W, k'_M, and k_M for the cetrimonium bromide-catalyzed reaction of 1-fluoro-2,4-dinitrobenzene with five amines. The second-order rate constant k_M was obtained from the relationship $k_M = k'_M/V$, where V is the molar volume of surfactant; in this calculation V was taken as 0.35 liter/mole, as estimated by Berezin and coworkers (15, 18), who have

Table II—Parameters for the Cetrimonium Bromide-Catalyzed Reaction of 1-Fluoro-2,4-dinitrobenzene with Some Amines at 25° [a,b]

Amine	K_S, M^{-1}	K_M, M^{-1}	k'_M, s^{-1}	k_M, $M^{-1}s^{-1}$	k_W, $M^{-1}s^{-1}$	k_M/k_{exp}^{max}

	(1.0)	(3.3)	(0.0063)			

[a] Symbols refer to Eq. 33. [b] Standard deviations in parentheses.

also discussed the uncertainty involved in estimating V (17). The assignment of K_M and K_S to the binding constant estimates is based on two chemical factors: (*a*) it is expected that phenylalanine will be taken up by the micelle more extensively than will alanine; (*b*) the K_S values for the three anilines vary roughly as their partition coefficients in the octanol–water system (19). K_M represents binding of 1-fluoro-2,4-dinitrobenzene to the micelle; the variation in this quantity is greater than expected, indicating that the nature of the amine taken up by the micelle influences binding of the second reactant.

The uncertainties assigned to the K_S, K_M, and k'_M values in Table II are based upon the uncertainties in the products $k'_M K_M K_S$ and $K_M K_S$, which are the quantities directly evaluated from the data. Division of the uncertainty in $K_M K_S$ between K_M and K_S was based on the assumption that the uncertainty was weighted by the value of the constant, according to the relationship $s_{K_M}/s_{K_S} = K_M/K_S$, where s represents standard deviation.

Table II includes the k_W values, and it is seen that the ratio of k_M/k_W is substantially greater than unity for all of the amines. The last column of the table gives the ratio of k_M to k_{exp}^{max}, the maximum value of the observed second-order rate constant. This ratio is a measure of the fraction of true *micellar catalysis* contributing to the total micellar acceleration effect, as suggested:

$$\frac{k_M}{k_{exp}^{max}} = \frac{k_M/k_W}{k_{exp}^{max}/k_W}$$

That is, approximately one-third to one-half of the maximum observed acceleration is a consequence of catalysis by the micelle, the remainder being a concentration effect, through which the micelle increases the local concentrations of the reactants.

A previous study (18) carried out a similar analysis for the cetrimonium bromide-catalyzed reaction of 1-fluoro-2,4-dinitrobenzene with *N*-benzoyl-L-histidine methyl ester. These authors found that k_M/k_W was in the range of 1–2, and they concluded that most of the micellar acceleration was a result of the concentration of the reactants in the micellar phase. They also measured the binding constants by an independent solubility method, finding the value of 27 M^{-1} at 18° for 1-fluoro-2,4-dinitrobenzene. This value will be smaller at 25° because the heat of binding is negative. This result is not in good agreement with the K_M assignment in Table II, and this assignment is therefore in some doubt[8].

[8] One factor that may influence the binding constants is the composition of the solvent, which in the present studies contained 5% acetone. Another possible factor may be the buffer species.

Interaction of Cyclazocine and the Sympathetic Nervous System

GARY D. RUSSI * and F. GENE MARTIN ˣ

Received November 30, 1981, from the *Department of Pharmacology and Toxicology, School of Pharmacy, University of Kansas, Lawrence, KS 66045.* Accepted for publication March 29, 1982. * Present address: Drake University, Department of Pharmacology, College of Pharmacy, Des Moines, IA 50311.

Abstract □ Cyclazocine, a benzomorphan derivative narcotic agonist–antagonist, reduced the uptake of tritiated norepinephrine and reduced the recovery of [^{3}H]3,4-dihydroxymandelic acid, but did not significantly alter the recovery of [^{3}H]normetanephrine in the rat heart *in vivo*. Cyclazocine also reduced endogenous levels of norepinephrine in the rat heart. Comparatively, desipramine reduced the uptake of [^{3}H]norepinephrine, the recovery of [^{3}H]3,4-dihydroxymandelic acid, and the recovery of [^{3}H]normetanephrine in the rat heart *in vivo*. Further, cyclazocine added to the perfusion medium or administered systemically reduced the uptake of radiolabeled norepinephrine by the isolated rat heart. The cyclazocine-induced decrease in the accumulation of [^{3}H]norepinephrine in the rat heart *in vivo* and *in vitro* presumably is due to an alteration of sympathetic function through the inhibition of neuronal uptake. It is further suggested that cyclazocine has other actions on the sympathetic nervous system, such as promoting neurotransmitter release.

Keyphrases □ Cyclazocine—interaction with the sympathetic nervous system □ Sympathetic nervous system—interaction with cyclazocine

Cyclazocine was first synthesized in the search for nonaddicting analgesics. Although cyclazocine is an effective analgesic in animals (1) and humans (2, 3), it has been shown to be a potent narcotic antagonist (4, 5). Consequently, it has been employed in the treatment of narcotic addiction (6–9). In these patients, a cyclazocine-induced euphorigenic and antidepressant action was noticed (7). Subsequently, the clinical evaluation of cyclazocine in depressed patients was reported (10, 11). It was concluded that cyclazocine exhibited a clinical antidepressant action with a range of activity very similar to imipramine.

Support for clinical data (10) was found by demonstrating that the cyclazocine-induced electroencephalogram changes were similar to those induced by imipramine in depressed patients. Likewise, electroencephalogram changes induced by cyclazocine and imipramine have been reported to be similar in the rabbit (12, 13).

Tricyclic antidepressants (imipramine and related compounds) have been shown to potentiate certain cardiovascular responses to norepinephrine in cats (14) and humans (15), presumably by preventing the uptake of norepinephrine by sympathetic neuronal structures (16, 17). Likewise, cyclazocine potentiates certain actions of norepinephrine *in vivo* and *in vitro* (18).

Since these studies suggest that cyclazocine may possess pharmacological actions similar to tricyclic antidepressants, the possibility that cyclazocine may alter sympathetic nervous system function was investigated.

EXPERIMENTAL

Cannulation of Vessels—The animals (male Sprague-Dawley rats, 200–350 g) were anesthetized with ether, and the right femoral vein was cannulated to facilitate intravenous drug injections. Each injection was washed into the vein with a 0.2-ml solution of normal saline.

Perfusion of the Rat Heart—All rats were given 1000 U ip of heparin 5 min prior to decapitation to reduce intravascular clotting. The hearts were removed and perfused by the Langendorff technique (19). After a 10-min perfusion of amine-free modified Krebs-bicarbonate solution at 60 mm Hg, the hearts were perfused until a constant volume was reached (~10 min), with modified Krebs-bicarbonate solution containing 3.3 nCi of [^{3}H]norepinephrine, diluted with nonradioactive norepinephrine to a final concentration of 10 ng/ml. Following the amine perfusion, the extraneuronal norepinephrine was removed by a 2-min wash with amine-free medium. This washing technique has been reported to remove 95% of the extracellular norepinephrine (20). The heart was removed from the perfusion apparatus, blotted, weighed, and assayed for [^{3}H]norepinephrine.

Each liter of bathing medium, continuously bubbled with a mixture of 5% carbon dioxide in oxygen, contained (m*M*): NaCl (118); $NaHCO_3$ (25); KCl (4.75); $MgSO_4$ (1.19); KH_2PO_4 (1.19); $CaCl_2 \cdot 2H_2O$ (2.5); glucose, 2 g; disodium edetate, 0.010 g.

Norepinephrine and Metabolite Assay—The isolation procedure for radioactive and endogenous norepinephrine and its metabolites was carried out by the use of ion-exchange resins and alumina (21).

Norepinephrine was made to fluoresce by the trihydroxyindole technique (22). The fluorescence was read on a spectrofluorometer[1]. Efficiency of the assay was determined by the use of a standard carried completely through the assay. Reagent fluorescence was determined after carrying each reagent used for elution through the assay. Mean recovery rates were: norepinephrine, 90%; normetanephrine, 72%; dihydroxymandelic acid, 85%.

For estimation of the tritiated catecholamine and the tritiated metabolites, 1 ml of the appropriate eluate containing the tritiated norepinephrine or metabolite was added to 10 ml of a commercial counting cocktail[2] and counted in a liquid scintillation counter[3]. Efficiency and quench were determined by using a tritium external standard.

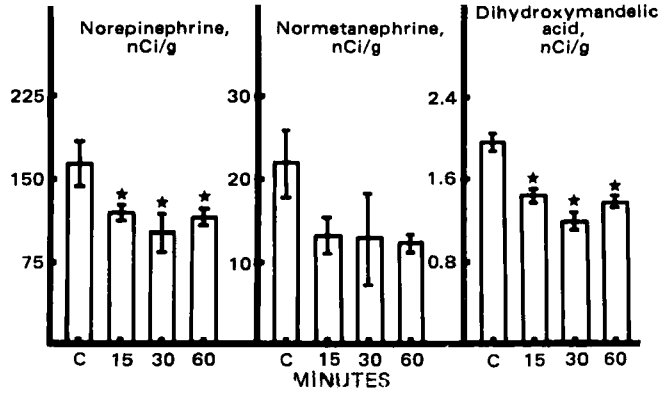

Figure 1—*The effect of cyclazocine on the uptake and metabolism of tritiated norepinephrine in rat hearts* in vivo. *Rats were given cyclazocaine (5 mg/kg iv) 15, 30, and 60 min prior to an infection of 10 μCi iv % tritiated norepinephrine. Control animals received an intravenous injection of saline. The hearts were removed 30 min later and assayed for the radiolabeled compounds, norepinephrine, normetanephrine, and 3,4-dihyroxymandelic acid. All values represent the means (horizontal bar) ± SEM (vertical bar) from four rats. Key: (*), postcyclazocine values significantly different from control values (C) at* $p < 0.05$.

Table I—Effect of Cyclazocine on Endogenous Heart Norepinephrine in the Rat [a]

Time, hr	Heart Norepinephrine, μg/g			
	Cyclazocine, mg/kg			
	5	10	20	40
Control	0.87 ± 0.07	0.91 ± 0.03	0.93 ± 0.03	0.95 ± 0.05
1	0.79 ± 0.09	0.79 ± 0.02[b]	0.70 ± 0.08[b]	0.80 ± 0.07
2	0.87 ± 0.04	0.70 ± 0.02[b]	0.65 ± 0.05[b]	0.69 ± 0.03[b]
4	0.88 ± 0.08	0.57 ± 0.01[b]	0.83 ± 0.04	0.79 ± 0.11

[a] $n = 4$; all values represent the mean ± *SEM*. [b] $p < 0.05$.

Drugs and Solutions—Cyclazocine[4] was dissolved in acidic aqueous solution prior to use. In the perfused heart studies, cyclazocine was dissolved using 10% polysorbate 80[5] as a cosolvent in water and added directly to the bathing medium. The medium containing no cyclazocine received an equivalent amount of polysorbate 80.

[7-^{3}H]DL-Norepinephrine (5.0 or 15.8 Ci/m*M*)[6] solutions were made by diluting a proportion of the commercial stock solution with 0.1 *N* HCl containing 0.85% NaCl and norepinephrine bitartrate[7] to the desired specific activity.

Desipramine hydrochloride[8] was dissolved in double distilled water containing 0.85% NaCl.

Statistical Analysis—The data presented as means ± *SE* were analyzed with a randomized complete block analysis of variance with Duncan's new multiple range test (23). Values of $p < 0.05$ were considered significant.

RESULTS

Influence of Cyclazocine on the Uptake and Metabolism of [^{3}H]norepinephrine *In Vivo*—Cyclazocine significantly altered the uptake and metabolism of tritiated norepinephrine in the rat heart. After an intravenous injection of cyclazocine (15, 30, and 60 min) (5 mg/kg) the uptake of [^{3}H]norepinephrine (10 μCi) was significantly reduced (Fig. 1). Cyclazocine did not significantly alter the catechol-*O*-methyltransferase metabolite, normetanephrine, although there appeared to be some reduction. The monoamine oxidase metabolite, 3,4-dihyroxymandelic acid, was significantly reduced by cyclazocine at all three time periods measured.

An evaluation was made of the effect of three doses of cyclazocine, 2.5, 5.0, or 10 mg/kg iv on the uptake of the tritiated amine at the 30-min interval. The uptake of [^{3}H]norepinephrine was significantly reduced at doses of 2.5, 5.0, and 10 mg/kg (Fig. 2).

Effect of Desipramine on the Uptake and Metabolism of [^{3}H]-Norepinephrine *In Vivo*—Intravenous desipramine (5 mg/kg) significantly reduced the uptake of [^{3}H]norepinephrine and altered the formation of radiolabeled dihydroxymandelic acid at all time periods tested (Fig. 3). Unlike cyclazocine, desipramine significantly altered tritiated normetanephrine at all time periods measured.

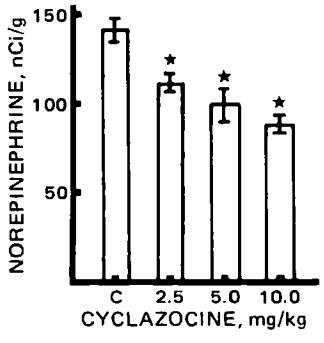

Figure 2—*The effect of various doses of cyclazocine on the uptake of tritiated norepinephrine in the rat heart* in vivo. *Rats were given cyclazocine 2.5, 5.0, or 10.0 mg/kg 30 min prior to an injection of 10 μCi iv of tritiated norepinephrine. Control animals received an intravenous injection of saline. The hearts were removed 30 min later and assayed for tritiated norepinephrine. All values represent the mean (horizontal bar) ± SEM (vertical bar) from four rats. Key: (*), postcyclazocine values significantly different from control values (C) at* $p < 0.05$.

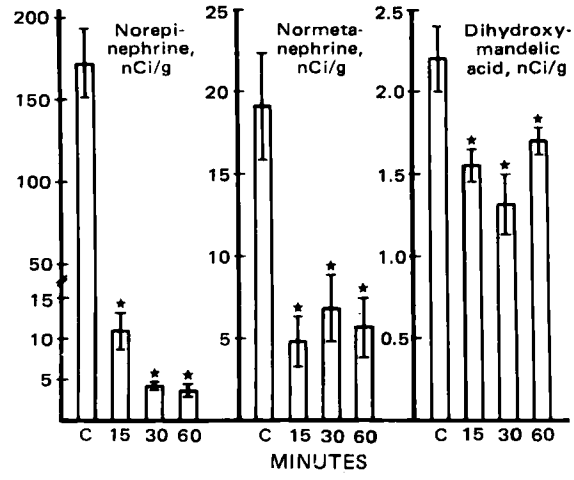

Figure 3—*The effect of desipramine on the uptake and metabolism of tritiated norepinephrine in rat hearts* in vivo. *Rats were given desipramine (5 mg/kg iv) 15, 30, and 60 min prior to an injection of 10 μCi of [^{3}H]norepinephrine. Control animals received an intravenous injection of saline. The hearts were removed 30 min later and assayed for the radiolabeled compounds, norepinephrine, normetanephrine, and 3,4-dihydroxymandelic acid. All values represent the mean (horizontal bar) ± SEM (vertical bar) from four rats. Key: (*), postdesipramine values significantly different from control values (C) at* $p < 0.05$.

Influence of Cyclazocine on the Uptake of Tritiated Norepinephrine *In Vitro*—The intraperitoneal injection of cyclazocine, 2.5, 5, or 10 mg/kg, 1 hr before the removal of the rat heart and subsequent perfusion with radiolabeled norepinephrine significantly reduced the uptake of the tritiated norepinephrine (Fig. 4). Cyclazocine added directly to the bathing medium in concentrations of 10^{-5} and 10^{-4} *M*, likewise, significantly reduced the uptake of [^{3}H]norepinephrine by the isolated perfused rat heart (Fig. 5).

Effect of Cyclazocine on Heart Endogenous Norepinephrine—Table I shows the influence of cyclazocine, *5, 10, 20, or 40 mg/kg ip on rat* heart norepinephrine 1, 2, or 4 hr after cyclazocine. Cyclazocine significantly reduced rat heart norepinephrine levels at doses of 10, 20, and 40 mg/kg, but did not alter the levels at 5 mg/kg.

DISCUSSION

These results support the hypothesis that cyclazocine produces alterations in sympathetic nervous system function by virtue of changes in uptake processes at adrenergic nerve endings.

A reduced recovery of [^{3}H]norepinephrine in rat heart *in vivo* produced by cyclazocine could be related to an altered uptake of norepinephrine

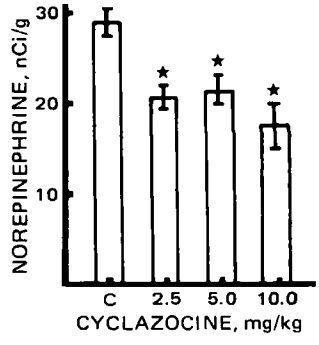

Figure 4—*The effect of systemic cyclazocine on the uptake of tritiated norepinephrine by the isolated perfused rat heart. Rats were given cyclazocine 2.5, 5.0, or 10.0 mg/kg ip 1 hr prior to removal of the heart. Control rats received an intraperitoneal injection of saline. The hearts were perfused with tritiated norepinephrine (10 ng/ml, 3.3 nCi/ml). All values represent the mean (horizontal bar) ± SEM (vertical bar) from four rats. Key: (*), postcyclazocine values significantly different from control values (C) at* $p < 0.05$.

into sympathetic nerves. Such an inference is supported by a significant cyclazocine-induced decrease in the formation of [^{3}H]dihydroxymandelic acid. Since monoamine oxidase appears to be principally located in the adrenergic neuron and has been shown to catalyze the oxidative deamination of intraneuronal norepinephrine, a decrease in neural uptake would be expected to result in a decrease in the deaminated metabolite of norepinephrine, dihydroxymandelic acid. In comparing the effect of desipramine, a compound that has been reported to decrease neuronal uptake in the rat heart (24), cyclazocine was less active in suppressing the accumulation of tritiated norepinephrine by the rat heart and did not produce a significant decrease in the formation of [^{3}H]normetanephrine (Figs. 1 and 3).

The observed changes in the recovery of radiolabeled normetanephrine from the heart induced by cyclazocine and desipramine were of interest in light of the reported increases in normetanephrine accumulation produced by agents that inhibit neuronal uptake in brain tissue (25, 26). These results are consistent with those presented previously (27, 28). It was shown that agents that inhibit adrenergic neuronal uptake (cocaine or imipramine) reduce the recovery of tritiated normetanephrine from heart tissue when [^{3}H]norepinephrine is administered intravenously. One explanation for the difference in the recovery of normetanephrine in brain and heart tissue produced by an agent that impedes neural uptake might be that the diffusion rate of the *O*-methylated metabolite out of the tissues varies markedly (29).

Since the *in vivo* results suggested a cyclazocine-induced inhibition of neuronal uptake, the effect of cyclazocine on the uptake of [^{3}H]norepinephrine was examined in isolated rat heart perfused with a concentration of norepinephrine (10 ng/ml) that when recovered would be indicative of neuronal uptake (19, 26). Cyclazocine added directly to the medium or given to the animal significantly decreased the uptake of tritiated norepinephrine into the isolated perfused heart, presumably at the level of the sympathetic nerve terminals.

Cyclazocine caused a depletion of endogenous cardiac norepinephrine at 10, 20, and 40 mg/kg. Cyclazocine has been shown to decrease levels of norepinephrine in brain tissue (30). It could be suggested that the depletion of endogenous cardiac norepinephrine was due to an inhibition of uptake; however, such a conclusion is not warranted, since tricyclic antidepressants with potent neuronal uptake inhibitory actions do not deplete catecholamine stores (31, 32). One possible mechanism is that cyclazocine releases norepinephrine, thereby, reducing stores of the catechol in the rat heart.

An earlier study (33) can be cited in support of such an alternate hypothesis. It was theorized that pentazocine, a chemically related compound to cyclazocine, produces a calcium-dependent action on vasculature and that the ability of pentazocine to decrease norepinephrine concentrations is related to an enhanced calcium influx into the nerve terminal, causing a release and subsequent depletion of the neurotransmitter.

Although the results presented in this paper suggest that cyclazocine interacts with the sympathetic nervous system by impeding neuronal uptake, they do not negate the possibility that cyclazocine alters sympathetic neural activity by other actions, *e.g.*, by enhancing release of neurotransmitter.

Furthermore, the results add support to the hypothesis that cyclazocine can induce central nervous system effects by not only interacting with opiate receptors but by altering adrenergic nerve function (34, 35).

Dependence of Renal Clearance on Urine Flow: A Mathematical Model and its Application

D. DAN-SHYA TANG-LIU, THOMAS N. TOZER ˣ, and SIDNEY RIEGELMAN†

Received August 21, 1981, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication March 29, 1982. † Deceased.

Abstract □ A mathematical model is developed to explain the dependence of renal clearance on urine flow rate. The model is tested using human data from the literature on compounds that are neither secreted nor reabsorbed by active or pH-sensitive mechanisms. The physiologically derived model explains and predicts the relationship between renal clearance and urine flow for a broad spectrum of compounds (*i.e.*, butabarbital, chloramphenicol, creatinine, ethanol, theophylline, and urea) for which appropriate data are available.

Keyphrases □ Excretion, renal—dependence of renal clearance on urine flow, mathematical model, application, reabsorption (□) Urine flow—dependence of renal clearance, mathematical model, application, reabsorption □ Reabsorption—dependence of renal clearance on urine flow, mathematical model, application

Passive reabsorption is a major process controlling the renal excretion of many organic substances (1, 2). The magnitude of passive reabsorption depends on the nature of the substance, *i.e.*, its lipophilicity and its extent of ionization. It also depends on the urine flow rate and the pH of the luminal fluid in the renal tubule. For a compound readily undergoing reabsorption, its rate of urinary excretion can be elevated by increasing the urine flow (2–4). This dependence on urine flow leads to problems in clinically or pharmacokinetically assessing urine data, because of a large variability in renal clearance or excretion rate–plasma concentration. However, the dependence can be used beneficially. For example, forced diuresis hastens the elimination of drugs and shortens the time required to detoxify patients overdosed on certain drugs (5–7). Experiments have demonstrated this flow dependence of renal excretion (8–11).

In this work a model based upon physiological considerations was derived. Literature data on the renal clearance–urine flow relationship for representative compounds were fitted to the model. Factors determining the urine flow dependence are discussed and exemplified by computer simulation.

BACKGROUND

The functional unit of the kidney, the nephron, is composed of the glomerulus, the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct, each of varying dimensions [Table I, (12)]. The glomerulus receives the arterial blood and a portion of the plasma water is filtered. About two thirds of the glomerular filtrate is reabsorbed isoosmotically in the proximal tubule (13). The wall of the ascending loop of Henle is thought to be relatively impermeable to water. Further reabsorption of water occurs in the distal tubule and collecting ducts. The volume of plasma water filtered per unit of time at the glomerulus, the glomerular filtration rate, is ~120 ml/min in an average 20-year-old male. Because of the extensive reabsorption of water, the urine flow rate averages ~1–2 ml/min. The renal plasma flow, ~650 ml/min, and the glomerular filtration rate are reasonably constant, but because of the variable reabsorption of water in the distal tubule and collecting duct, the urine flow rate is quite variable.

Table I—Dimensions of Renal Tubule in Humans

Segment of Renal Tubule	Length, mm[a]	Outside Diameter, μm[a]	Outer Surface Area,[b] M^2
Proximal	12–24	50–65	6.6
Loop of Henle, thin	0–14	14–22	1.0
thick	6–18	—	
Distal	2–9	20–50	1.2
Collecting duct	22	up to 200	20.7

[a] Obtained from R. F. Pitts (12). [b] π(average outer diameter)(average length) × 2(number of nephrons per kidney) (Ref. 25).

The renal excretion rate of a drug is the net result of filtration, secretion, and reabsorption:

$$\text{rate of excretion} = \text{rate of filtration} + \text{rate of secretion} - \text{rate of reabsorption} \quad \text{(Eq. 1)}$$

Because only drug in plasma water (the unbound drug) is filtered at the glomerulus:

$$\text{rate of filtration} = F\alpha C_p \quad \text{(Eq. 2)}$$

For definition of symbols, see the Appendix.

Substituting Eq. 2 into Eq. 1 and dividing by plasma drug concentration, the renal clearance, a proportionality constant relating the rate of excretion to the plasma drug concentration, is obtained:

$$CL_r = \alpha F + \frac{\text{rate of secretion} - \text{rate of reabsorption}}{C_p} \quad \text{(Eq. 3)}$$

A renal clearance of less than αF, therefore, indicates that reabsorption occurs. If a drug is secreted, reabsorption must then be greater than secretion.

The renal clearance of a nonpolar compound that is nonionized at physiological conditions shows flow dependence. The extent of the dependence is determined by its lipophilicity and the membrane permeability. For drugs that are not secreted, the renal clearance is expressed by:

$$CL_r = \alpha F - \frac{\text{rate of reabsorption}}{C_p} \quad \text{(Eq. 4)}$$

The following model applies to a drug that is neither secreted nor ionized at physiological pH.

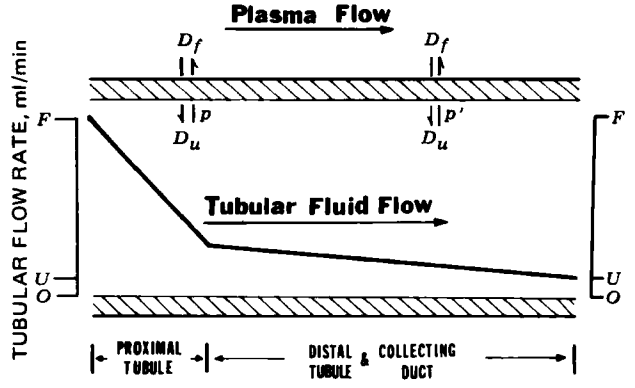

Figure 1—*Schematic diagram of drug and water reabsorption in an average functional nephron. The exchange of drug in luminal fluid (D_u) and free drug in plasma (D_f) is characterized by the permeability constant, P or P′, of each region of the nephron. The decline of the luminal fluid flow rate is assumed to be linear within the proximal and post proximal parts of the tubule. The glomerular filtration rate (F), the urine flow (U), and the origin (O) are also shown on the y-axes.*

0022-3549/83/0200-0154$01.00/0

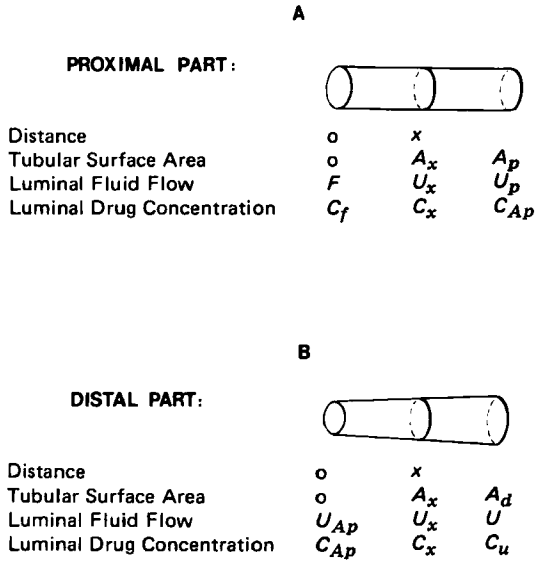

Figure 2—*Scheme for symbols used in model derivation. Proximal part of the renal tubule (A); and distal part of the renal tubule (B).*

THEORETICAL

To develop a model for the urine flow rate dependence of renal clearance for a nonsecreted, poorly ionized drug, the following assumptions are made:

1. Each nephron behaves, on average, as a single functional unit as depicted in Fig. 1.
2. There is a constant reabsorption flux of water within the proximal and distal regions of the tubule. The net rate of the change of luminal fluid volume per unit of surface area of membrane is P_w in the proximal and P'_w in the rest of the nephron. Urine flow alterations reflect a physiological change in P'_w.
3. The rate of reabsorption of a compound at any point in the tubule is proportional to the difference between the concentrations in luminal fluids and in plasma and depends on the permeability of the drug in the tubular membrane. The permeability of the membrane per unit of surface area for a given compound is assumed to be constant within each of the regions of the tubule.

Reabsorption in the Proximal Tubule—At point x, the rate of change of luminal fluid flow is:

$$\frac{dU_x}{dA_x} = -P_w \qquad \text{(Eq. 5)}$$

and the proximal luminal fluid flow, U_x, in the model (Fig. 2A), is described by:

$$U_x = F - P_w A_x \qquad \text{(Eq. 6)}$$

Thus, the luminal fluid flow rate declines from F to $F - P_w A_p$, or U_{Ap}. The rate of reabsorption of drug depends on the permeability constant, P, and the concentration gradient of the exchangeable drug (unbound) across the membrane at point x. Therefore:

$$\text{rate of reabsorption} = P(C_x - \alpha C_p)dA_x \qquad \text{(Eq. 7)}$$

The rate of loss of the drug from the tubule is:

$$-d(U_x C_x) = -U_x dC_x - C_x dU_x \qquad \text{(Eq. 8)}$$

Because these two rates must be the same, it follows that:

$$U_x \frac{dC_x}{dA_x} + C_x \frac{dU_x}{dA_x} = -P(C_x - \alpha C_p) \qquad \text{(Eq. 9)}$$

By substituting Eqs. 5 and 6 into Eq. 9:

$$(F - P_w A_x)\frac{dC_x}{dA_x} + C_x(P - P_w) = \alpha C_p P \qquad \text{(Eq. 10)}$$

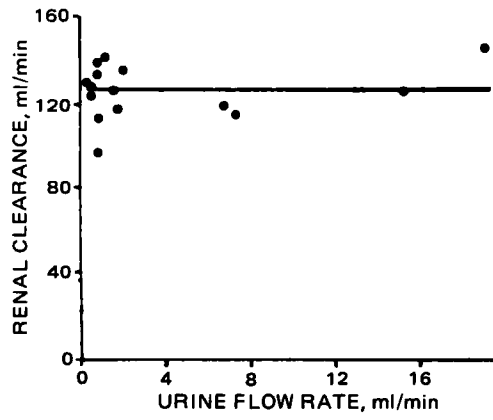

Figure 3—*Relationship between renal clearance of creatinine and urine flow rate. Data from Ref. 14. The solid line is the computer fit using the model.*

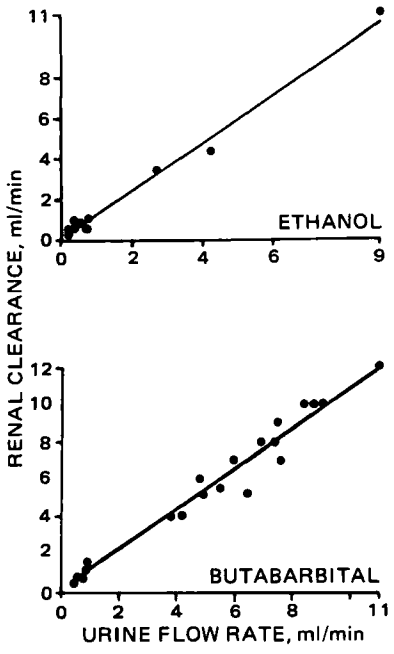

Figure 4—*Urine flow-dependence of renal clearance for ethanol and butabarbital. Data from Refs. 14 and 7, respectively. Solid lines are the computer fits of the model.*

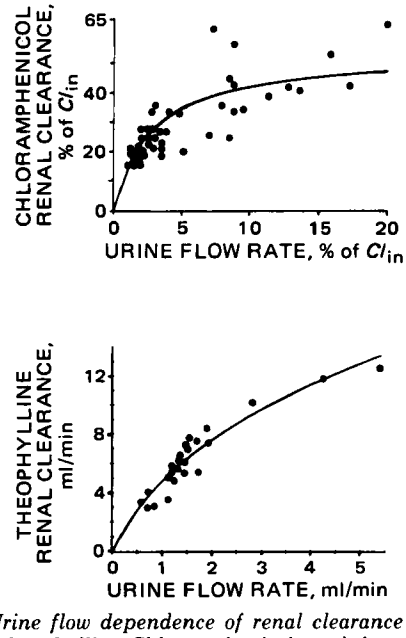

Figure 5—*Urine flow dependence of renal clearance for chloramphenicol and theophylline. Chloramphenicol renal clearance and urine flow were normalized by inulin clearance (CL_{in}). Data for chloramphenicol are from Ref. 15. The theophylline data are unpublished (17). Solid lines are the computer fits of the model.*

Table II—Parameter Values of Model[a]

Parameter	Urea[b] A	Urea[b] B	Urea[b] C	Creatinine	Ethanol	Butabarbital	Chloramphenicol	Theophylline
ϵ, ml/min	6.7	8.0	9.1	0	665	120	13.9	27.5
δ	0.013	0.016	0.018	0	5	1.01	0.028	0.25
α	1	1	1	1	1	0.72[c]	0.47[d]	0.47[e]
F, ml/min	125	85	145	125	140	120	133	118

[a] ϵ, δ, and F values from fit of Eq. 28 to data (7, 14–18). [b] From three subjects. [c] Ref. 19. [d] Ref. 20. [e] Ref. 17.

On rearrangement:

$$\frac{dC_x}{dA_x} + \left(\frac{P - P_w}{F - P_w A_x}\right) C_x = \frac{\alpha C_p P}{F - P_w A_x} \qquad \text{(Eq. 11)}$$

Integration of this first-order linear differential equation gives:

$$C_x = \frac{\alpha C_p \delta}{\delta - 1} + \beta (F - P_w A_x)^{-W} \qquad \text{(Eq. 12)}$$

where $W = 1 - \delta$, δ is P/P_w, and β is the constant of integration. Because only the unbound drug is filtered at the glomerulus, the drug concentration in the initial filtrate, where A_x is zero, is αC_p. Accordingly, the integration constant is:

$$\beta = -\alpha C_p \left(\frac{1}{\delta - 1}\right) F^W \qquad \text{(Eq. 13)}$$

and the luminal drug concentration at any point x within the proximal tubule is:

$$C_x = \frac{\alpha C_p}{\delta - 1}\left[\delta - \left(\frac{F}{F - P_w A_x}\right)^W\right] \qquad \text{(Eq. 14)}$$

At the end of the proximal tubule, the luminal concentration becomes:

$$C_{Ap} = \frac{\alpha C_p}{\delta - 1}\left[\delta - \left(\frac{F}{F - P_w A_p}\right)^W\right] \qquad \text{(Eq. 15)}$$

Because ~70% of the glomerular filtrate is reabsorbed in the proximal tubule (13), $P_w A_p$ can be approximated by $0.7F$. Therefore:

$$C_{Ap} = \frac{\alpha C_p}{\delta - 1}(\delta - 0.3^{-W}) \qquad \text{(Eq. 16)}$$

Reabsorption in the Distal Tubule and the Collecting Duct—The luminal flow through an annulus at point x in the distal part of the nephron (Fig. 2B) is:

$$U_x = 0.3F - P'_w A_x \qquad \text{(Eq. 17)}$$

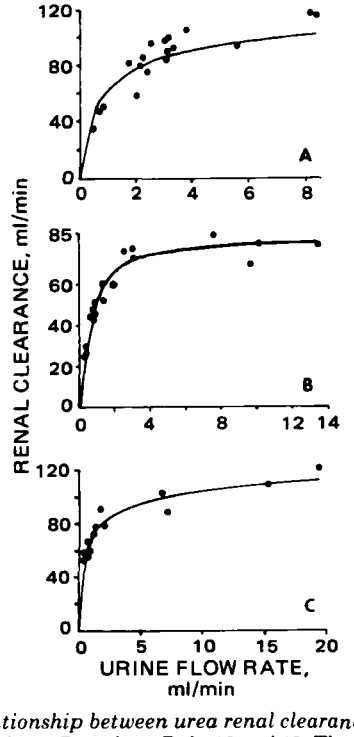

Figure 6—*Relationship between urea renal clearance and urine flow rate in three subjects. Data from Refs. 16 and 18. The solid lines are the computer fits of the model.*

The rate of reabsorption of luminal fluid at any annulus is obtained from the derivative of Eq. 17, *i.e.*:

$$\frac{dU_x}{dA_x} = -P'_w \qquad \text{(Eq. 18)}$$

The rate of reabsorption of the drug within the annulus at point x is:

$$\text{rate of reabsorption} = P'(C_x - \alpha C_p) dA_x \qquad \text{(Eq. 19)}$$

By equating Eqs. 8 and 19, with substitution of Eqs. 17 and 18, and rearranging, we obtain:

$$\frac{dC_x}{dA_x} + \left(\frac{P' - P'_w}{0.3F - P'_w A_x}\right) C_x = \frac{\alpha C_p P'}{0.3F - P'_w A_x} \qquad \text{(Eq. 20)}$$

On integrating:

$$C_x = \frac{\alpha C_p P'}{P' - P'_w} + \gamma (0.3F - P'_w A_x)^{-Z} \qquad \text{(Eq. 21)}$$

where $Z = 1 - P'/P'_w$, and γ is the constant of integration. The drug concentration at the entry of distal tubule ($A_x = 0$) is that at the end of the proximal tubule (Eq. 16). Therefore, solving for the integration constant using Eqs. 16 and 21 (when $A_x = 0$), the luminal drug concentration at any point x within the distal part of the nephron is:

$$C_x = \alpha C_p \left[\frac{P'}{P' - P_w'} + \left(\frac{\delta}{\delta - 1} - \frac{0.3^{-W}}{\delta - 1} - \frac{P'}{P' - P'_w}\right)(0.3F)^Z (0.3F - P'_w A_x)^{-Z}\right] \qquad \text{(Eq. 22)}$$

At the end of the collecting duct ($A_x = A_d$) the luminal concentration is the observed urine concentration (C_u), therefore:

$$C_u = \alpha C_p \left[\frac{P'}{P' - P'_w} + \left(\frac{\delta}{\delta - 1} - \frac{0.3^{-W}}{\delta - 1} - \frac{P'}{P' - P'_w}\right)\left(\frac{0.3F}{U}\right)^Z\right] \qquad \text{(Eq. 23)}$$

The ratio of urine and plasma concentrations becomes:

$$\frac{C_u}{C_p} = \alpha \left[\frac{P'}{P' - P'_w} + \left(\frac{\delta}{\delta - 1} - \frac{0.3^{-W}}{\delta - 1} - \frac{P'}{P' - P'_w}\right)\left(\frac{0.3E}{U}\right)^Z\right] \qquad \text{(Eq. 24)}$$

The value of P'_w is related to the luminal flow rates at two boundaries, $0.3F$ and U, *i.e.*, at the end of the distal region, P'_w is $(0.3F - U)/Ad$ (from Eq. 17). To minimize the number of parameters and to simplify the final form of the model, let:

$$\epsilon = P'Ad \qquad \text{(Eq. 25)}$$

and therefore:

$$\frac{P'}{P'_w} = \frac{\epsilon}{0.3F - U} \qquad \text{(Eq. 26)}$$

Renal clearance relates the urinary excretion rate to the plasma drug concentration. Experimentally, the excretion rate is calculated from urine flow and drug concentration in urine:

$$Cl_r = U\frac{C_u}{C_p} \qquad \text{(Eq. 27)}$$

and from Eqs. 24 and 26, the dependence of renal clearance on urine flow, α, δ, ϵ, and F is obtained:

$$Cl_r = \alpha U \left[\frac{\epsilon}{\epsilon - 0.3F + U} + \left(\frac{0.3^{-W} - \delta}{W} - \frac{\epsilon}{\epsilon - 0.3F + U}\right)\left(\frac{0.3F}{U}\right)^Z\right] \qquad \text{(Eq. 28)}$$

where $W = 1 - \delta$, and $Z = 1 - \epsilon/0.3F - U$.

Renal clearance and urine flow data for compounds demonstrating various degrees of urine flow dependence, namely, alcohol (14), chlor-

amphenicol (15), creatinine (16), butabarbital (7), theophylline (17), and urea (16, 18) were used to test the validity of the model. When tables of data were not available (*i.e.*, chloramphenicol and butabarbital), renal clearance and urine flow values were estimated from figures in the respective references using a ruler with a millimeter scale. Intraindividual values were used except for chloramphenicol, for which renal clearance and urine flow were normalized to inulin clearance (CL_{in}), *i.e.*, CL_r/CL_{in} and U/CL_{in}. Data analysis and graphical examination of the urine flow dependencies were performed by nonlinear regression of Eq. 28 using the PROPHET computer system. The best-fits of the parameters were determined by the minimized residual sum of squares.

RESULTS AND DISCUSSION

The passive diffusion of a drug across the tubular membrane proceeds toward an equilibrium state in which the diffusible species attains the same concentration in both luminal and plasma fluids. The reabsorption of water along the renal tubule produces disequilibrium with an increased concentration of drug in the luminal fluid. The greater the reabsorption of water, the more the drug is concentrated and, perhaps, the longer it stays in the tubule. Drugs can be classified into three categories: one in which no drug is reabsorbed, one in which drug is reabsorbed to equilibrium, and one in which drug is reabsorbed but equilibrium is not achieved.

If a drug is not reabsorbed at all (*e.g.*, creatinine, inulin, gentamicin, and kanamycin), the δ and ϵ values approach zero and the urinary excretion rate is the filtration rate. Under these conditions, the renal clearance is αF (Eq. 4) and is independent of urine flow. This relationship is demonstrated by creatinine (Fig. 3). If a drug is reabsorbed to equilibrium, its ability to diffuse must be equal to or greater than that of water. This category is exemplified by alcohol and butabarbital (Fig. 4), compounds with high δ and ϵ values (Table II). Because of the rapid exchange of the drugs, their plasma unbound and urine concentrations are identical at all urine flow conditions. As the values of δ and ϵ approach infinity (Eq. 28), the renal clearance becomes:

$$CL_r = \alpha U \qquad \text{(Eq. 29)}$$

Within the range of plasma concentrations in which there is a constant fraction unbound, a linear relationship between CL_r and U is observed (Fig. 4).

For many drugs with medium δ and ϵ values, equilibrium is not achieved, because the diffusional rate of the drug (*e.g.*, theophylline, chloramphenicol, and urea) is less than that of water. Various degrees of water reabsorption in the distal portion of the tubule result in various urine flow rates and different disequilibrium states. For theophylline and similar drugs, a convex-ascending relationship can be observed for flow-dependent renal clearance (Fig. 5). Among compounds in this group, urea has received the most attention. Urea clearance increases markedly with urine flow, up to ~3 ml/min, and thereafter increases only slightly if at all (Fig. 6). The model visually fits the urea data well and predicts an asymptotic value of αF; *i.e.*, at higher urine flow rates virtually all the filtered urea is excreted into the urine. This is a classic example of urine flow dependence of renal clearance.

Changes in renal clearance with urine flow predicted by the model for compounds of varied permeability are shown in Fig. 7. The larger the permeability as reflected by δ and ϵ, the greater the dependence on urine flow, and the smaller the value of renal clearance.

It is the unbound drug in plasma that is filtered at the glomerulus. Consequently, the greater the value of α, the larger the filtered load (Eq. 2) for a given plasma concentration. For two compounds of the same permeability, the one with the higher value of α is expected to have the higher renal clearance. This conclusion applies to drugs in all three categories.

There are three more factors to be considered to complete a general model for flow-dependent renal clearance of all drugs. They are: secretion, active reabsorption, and the change of pH in the tubular fluid along the nephron. The present model does not incorporate these factors. The compounds discussed here were chosen because they are neither secreted nor extensively ionized at physiological pH.

Secretion is an active process. If a drug is highly secreted into the lumen, its plasma concentration along the tubule may decline dramatically even if highly bound to plasma proteins. This leads to a perfusion limitation in the excretion of the drug and difficulty in estimating the concentration gradient along the tubule. Furthermore, only a portion of the renal blood flow reaches the distal part of the nephron. These considerations make prediction of urine flow dependence difficult.

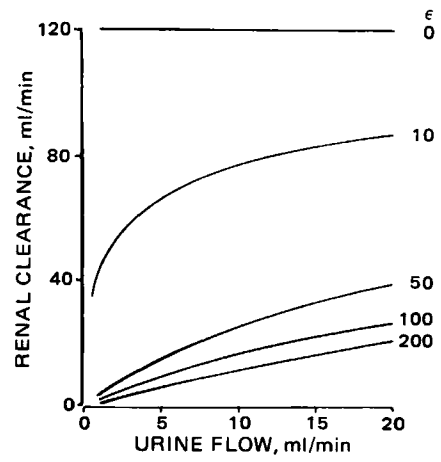

Figure 7—*Simulation of the effect of permeability on the urine flow-dependence of drug renal clearance. Values of parameters used in simulation were: drug unbound fraction in plasma, 1.0; glomerular filtration rate, 120 ml/min; $\epsilon/\delta = 100$.*

Active reabsorption usually occurs for endogenous compounds, *e.g.*, vitamins, electrolytes, glucose, and amino acids. However, the reabsorption process for drugs, mostly exogenous compounds, is mainly passive diffusion. Therefore, the model was restricted to the passive processes.

The luminal fluid starts with a pH of 7.4 at the glomerulus and ends its journey at a pH of 4.5–8.0 (1). Usually, the urine pH is 6.25 ± 0.36 (mean ±*SD*). There is evidence that the greater change of pH occurs in the distal part of the nephron, *i.e.*, mostly in the collecting ducts (21–23). For acidic and basic compounds with pKa values sensitive to physiologic pH changes, their fractions nonionized vary with their location in the tubule. Of the compounds tested, only butabarbital (pK_a = 7.9) and theophylline (pK_a = 8.8) are slightly ionizable at physiologic pHs. The urine pH was not reported with the data of butabarbital. It was assumed that samples were collected under these conditions and the pH sensitivity of butabarital renal clearance is not expected. In one theophylline study, subjects took ammonium chloride orally to maintain acidic urine. The urine pH was successfully maintained below 5.5 under normal urine flow conditions. However, the urine pH increased when urine flow rate was increased (due to the diuretic effect of theophylline). Presumably, at high urine flow rates, the controlling mechanism (located mainly in the collecting ducts) has less effect on the pH of the fluid. Therefore, the pH of the tubular fluid not only varies with the distance the luminal fluid travels in the tubule, but also is a function of urine flow rate.

The model explains and predicts the dependence of renal clearance on permeability and urine flow. The model was tested using literature data for compounds that are apparently not secreted, actively reabsorbed, or pH sensitive, but represent a wide spectrum of lipophilicity. From the fits of the model, it can be concluded that the urine flow dependence of renal clearance can be adequately described and predicted by our physiologically derived model.

APPENDIX

A_d = Surface area of the distal tubule and collecting ducts, centimeter squared
A_p = Surface area of the proximal tubule, centimeter squared
A_x = Surface area of membrane from the integration starting point to point x, centimeter squared
C_{Ap} = Concentration of the drug in luminal fluid at the end of the proximal tubule, micrograms per milliliter
C_f = Free drug concentration in plasma, micrograms per milliliter
CL_r = Renal clearance of the drug, milliliter per minute
C_p = Total drug concentration in plasma, micrograms per milliliter
C_u = Drug concentration in urine, micrograms per milliliter
C_x = Luminal drug concentration in annulus at point x, micrograms per milliliter
F = Glomerular filtration rate, milliliter per minute
P = Permeability constant of the drug in the proximal tubule, centimeters per minute

P' = Permeability constant of the drug in the distal tubule and collecting ducts, centimeter per minute
P_w = Reabsorption flux of water in the proximal tubule, centimeter per minute
P'_w = Reabsorption flux of water in the distal tubule and collecting duct, centimeter per minute
pK_a = The dissociation constant of the drug
U = Urine flow rate, millimeter per minute
U_{Ap} = Luminal fluid flow rate at the end of the proximal tubule, milliliter per minute
U_x = Luminal fluid flow rate in annulus at point x, millimeter per minute
α = Unbound fraction of drug in plasma
δ = Ratio of P/P_w
ϵ = Product of $P'A_d$, ml/min

Absorption Kinetics and Steady-State Plasma Concentrations of Theophylline Following Therapeutic Doses of Two Sustained-Release Preparations

O. ANDERSEN, M. K. NIELSEN, P. B. ERIKSEN, M. FENGER, and P. J. KNUDSEN ˣ

Received October 5, 1981, from the *Department of Clinical Chemistry, Centralsygehuset i Naestved, DK 4700 Naestved, Denmark.* Accepted for publication March 19, 1982.

Abstract □ Ten healthy volunteers received two sustained-release preparations as a single and multiple dose regimen in an open crossover study. Plasma theophylline concentrations were measured by an enzyme immunoassay. The limited fluctuation of the theophylline levels at steady state, with twice daily administration, clearly demonstrated the marked sustained release properties of both preparations. Results indicate similar properties for the two preparations. Significant correlations between the single dose period and steady state were found for C_{max} and AUC (r = 0.76 and 0.87, respectively) with one formulation, whereas this was not the case for the other (r = 0.27 and 0.49). The daily dose necessary to keep the plasma concentration within the therapeutic range of 55–110 μmole/liter varied from 7.9 to 22.9 mg/kg. Only mild side effects were recorded, but they were not correlated to the plasma theophylline concentration.

Keyphrases □ Absorption—kinetics and steady-state plasma concentrations of theophylline following therapeutic doses of two sustained-release preparations □ Kinetics—absorption and steady-state plasma concentrations of theophylline following therapeutic doses of two sustained-release preparations □ Theophylline—absorption kinetics and steady-state plasma concentrations following therapeutic doses of two sustained-release preparations

Theophylline produces relaxation of bronchial smooth muscles and is widely used in the treatment of reversible obstructive lung disease. The bronchodilator effect of theophylline increases with serum concentrations over a range of 28–110 μmoles/liter (5–20 μg/ml), but at levels of >110 μmoles/liter there is an increased risk of serious toxicity (1). Maximal bronchodilation with minimal toxicity occurs at levels between 55–110 μmoles/liter (10–20 μg/ml), and this is therefore normally considered the therapeutic range (2). It is very difficult to maintain serum

Received October 5, 1981, from the *Department of Clinical Chemistry, Centralsygehuset i Naestved, DK 4700 Naestved, Denmark.* Accepted for publication March 19, 1982.

Abstract □ Ten healthy volunteers received two sustained-release preparations as a single and multiple dose regimen in an open crossover study. Plasma theophylline concentrations were measured by an enzyme immunoassay. The limited fluctuation of the theophylline levels at steady state, with twice daily administration, clearly demonstrated the marked sustained release properties of both preparations. Results indicate similar properties for the two preparations. Significant correlations between the single dose period and steady state were found for C_{max} and AUC (r = 0.76 and 0.87, respectively) with one formulation, whereas this was not the case for the other (r = 0.27 and 0.49). The daily dose necessary to keep the plasma concentration within the therapeutic range of 55–110 μmole/liter varied from 7.9 to 22.9 mg/kg. Only mild side effects were recorded, but they were not correlated to the plasma theophylline concentration.

Keyphrases □ Absorption—kinetics and steady-state plasma concentrations of theophylline following therapeutic doses of two sustained-release preparations □ Kinetics—absorption and steady-state plasma concentrations of theophylline following therapeutic doses of two sustained-release preparations □ Theophylline—absorption kinetics and steady-state plasma concentrations following therapeutic doses of two sustained-release preparations

Theophylline produces relaxation of bronchial smooth muscles and is widely used in the treatment of reversible obstructive lung disease. The bronchodilator effect of theophylline increases with serum concentrations over a range of 28–110 μmoles/liter (5–20 μg/ml), but at levels of >110 μmoles/liter there is an increased risk of serious toxicity (1). Maximal bronchodilation with minimal toxicity occurs at levels between 55–110 μmoles/liter (10–20 μg/ml), and this is therefore normally considered the therapeutic range (2). It is very difficult to maintain serum

theophylline concentrations within this narrow therapeutic range during treatment with conventional tablets, due to the large interindividual variation in theophylline clearance, fast absorption, and relatively short half-life. A growing interest in sustained-release preparations has appeared during recent years and a number of different preparations are now on the market in several countries. This report deals with a comparison of two sustained-release preparations, containing theophylline–ethylenediamine and theophylline, respectively, after single dose administration, as well as repeated dosage to give levels within the therapeutic range. The theophylline dosage form was studied previously (3), and it was shown that a mean C_{max} value of 41 μmoles/liter (7.5 μg/ml) was obtained with 8 mg/kg every 12 hr. Levels of theophylline–ethylenediamine within the therapeutic range have only been investigated in single dose studies (4, 5) and the preparation has not been compared with other sustained-release preparations.

EXPERIMENTAL

Preparations—Tablet A[1] was a theophylline–ethylenediamine formulation with 350 mg of theophylline–ethylenediamine (equivalent to 255 mg of anhydrous theophylline) given as whole or half tablets. Tablet B[2] was a theophylline formulation with 200 or 300 mg of anhydrous theophylline, given as whole tablets only.

Subjects—Ten healthy volunteers (5 females and 5 males), age 26–54 years, mean 38, were included in the study. Their heights ranged from 160 to 192 cm, mean 175, and they weighed from 50 to 89 kg, mean 67. Five were smokers and five nonsmokers. All were found healthy by physical examination and laboratory testing for functions of liver, heart, kidney, and bone marrow.

Study Design and Dosage—The study was an open crossover study in which half of the subjects were randomly allocated to start on one preparation and the other half on the other preparation. The subjects received only one dose (510 mg of theophylline for tablet A and 500 mg for tablet B) for the first 24 hr. From the second day on the dose was gradually increased, starting with ~400 mg of theophylline daily and increasing in steps of 25% every 3 days (6). The final dose for each individual subject was determined by the occurrence of one of the following criteria: (*a*) The next increase in dose gave rise to side effects; (*b*) the plasma theophylline concentration 6 hr after the morning dose was within the therapeutic range (55–110 μmoles/liter); or (*c*) the dose had reached 13 mg/kg or 900 mg/day. The dosage used in the first period was used in the second period. Each preparation was given for 13 days with an 8-day wash-out period in between. The subjects were instructed not to take methylxanthine-containing beverages or food 12 hr before and on the day of blood sampling. They were also instructed to make notes on side effects during the study.

Blood Sampling—On day 1 of each period 10-ml blood samples were drawn before, and 2, 4, 6, 8, 10, 12, and 24 hr after drug administration. On the last day of each period the same sequence of blood sampling was followed after the morning dose, the maximum dose having been administered for at least 3 days. Blood samples were drawn from a cubital

[a] Normalized by division by dose in milligrams of theophylline.

vein using an evacuated heparinized container[3] and using stasis times of <1 min. Within 1 hr the plasma was separated from blood cells by centrifugation and transferred to a clean vial. The theophylline concentrations were determined immediately or after storage at −20° for <24 hr. No significant decrease was found in plasma samples stored at −20° for 6 months.

Drug Estimation—Plasma theophylline was measured by an enzyme immunoassay[4] (7) adapted for use with a biochromatic analyzer[5]. Comparative analyses of patient samples analyzed by the enzyme immunoassay and HPLC methods have confirmed the lack of interference from metabolites or structurally related molecules in the enzyme immunoassay (8). The accuracy of this enzyme immunoassay is the same as the HPLC methods usually used in clinical pharmacological studies of theophylline (9). In the present study the within-day coefficient of variation was 1.4% and the between-day coefficient of variation was 3.9%.

Data Treatment—The elimination rate constant (β) was calculated from the slope of the concentration line, from 12 to 24 hr after administration, in a semilogarithmic plot as $\beta = -2.303$ slope. The area under the plasma concentration curve after the first dose ($AUC_{0\to\infty}$) was calculated by the trapezoidal rule in the time period of 0–24 hr ($AUC_{0\to24}$) and by the formula C_{24}/β in the period 24 hr to infinity ($AUC_{24\to\infty}$). In the steady-state period, the area under the curve in a dosage interval ($AUC_{0\to12}$) was calculated by the trapezoidal rule. The different parameters (concentrations dose corrected) obtained with the two preparations were compared by a paired-sample *t* test (10). The regression line illustrating the correlation of the parameters from the single dose period with those from the steady-state period with the same preparation was calculated by the least-square method [Pearson's product moment correlation (11)].

RESULTS

Plasma concentration–time curves obtained during the study are shown in Fig. 1. The plasma concentration curves show a rather large variation between the individual subjects, but do not indicate that one preparation gives more consistent plasma levels than the other.

The single (first) dose periods are compared in Fig. 2A. The curves show that the maximum plasma concentration after tablet A appeared earlier than after tablet B. This was confirmed by a statistically significant difference found by a paired *t* test (Table I). The curves also show a higher maximum plasma concentration and a larger area under the curve (AUC) after tablet A, but the statistical analysis showed no difference.

Mean plasma theophylline concentrations after repeated administration to steady state appear in Fig. 2B. The mean dose (±*SD*) on repeated administration was 10.0 (±1.5) mg/kg for tablet A, and 10.1 (±1.2) mg/kg for tablet B, giving mean peak plasma concentrations at 4 hr after administration for tablet A (67 μmoles/liter) and at 6 hr after tablet B (58 μmoles/liter). The corresponding minimum values (mean of 0 and 12 hr) were 45 μmoles/liter and 42 μmoles/liter, respectively. There was a tendency toward an earlier maximum with tablet A, but the difference was not significant (Table I). Also, values for C_{max}, C_{min} (mean of C_0 and C_{12}), and $AUC_{0\to12}$ tended to be higher for tablet A but with no significant difference. The fluctuations in the dosage interval expressed as the C_{max}–C_{min} ratio, are similar for the two preparations being a mean of 1.5 and 1.4 for tablets A and B, respectively (Table I).

The dosage, *giving* a concentration within the therapeutic range of 55–110 μmoles/liter throughout the entire period, can be calculated from the minimum concentration measured during steady state in each subject. For tablet A this dose was a mean (range) 12.8 (7.9–18.3) mg/kg/day, and for tablet B 14.1 (9.3–22.9) mg/kg/day.

A correlation analysis on the different parameters shows, that C_{max} and AUC (both normalized by division by dose) are significantly correlated in the single dose and steady-state periods ($r = 0.76$ and 0.87, respectively) during administration of tablet A, but not with tablet B ($r = 0.27$ and 0.49) (Fig. 3). Time of maximum, T_{max}, did not show correlation between single dose and repeated administration for either of the preparations.

The reports on side effects are shown in Fig. 1; it appears that the frequency of side effects was similar from the two preparations. The symptoms reported include palpitations, tremor, vomiting, nausea, headache, and insomnia, subjectively estimated as ranging from mild to severe.

DISCUSSION

The present investigation clearly demonstrates the marked sustained-release properties of the two preparations. This is in accordance with earlier investigations in which the two preparations were compared to conventional tablets (3–5, 9). The limited fluctuation seen during the steady-state dosage interval of 12 hr shows that this frequency of dosing would be reasonable during maintenance therapy with any one of these two sustained-release preparations. As expected, the dose necessary to keep the plasma theophylline concentration within the therapeutic range varied considerably between individuals (7.9–22.9 mg/kg/day).

The preparations did not differ significantly as to maximum plasma concentration, minimum plasma concentration, fluctuation in plasma concentration during the dosage interval, and area under the plasma concentration curve. This indicated that the amount of theophylline absorbed from the two preparations was the same, and that the absorption took place at almost the same rate. The significantly earlier average time of individual peak occurrence seen with tablet A in the single dose period may indicate that absorption is slightly faster with this preparation, but it does not significantly influence the steady-state plasma concentration curve. Tablet B contained theophylline only, whereas tablet A, in addition to theophylline, contained ethylenediamine to increase the solubility of theophylline. This difference does not seem to influence absorption considerably.

There is a difference, however, between the two preparations on one point. The plasma levels for tablet A after the first dose (expressed as dose normalized C_{max} or AUC) correlated significantly with those found at steady state, whereas no such correlation was found with tablet B. This indicates less intraindividual variation with tablet A possibly because of more stable release of drug from this preparation. Moreover it means that in subjects receiving tablet A it is possible to perform measurements on the first dose (C_{max} or AUC), and from these obtain a guideline for choosing the dose for further treatment. This does not, however, render a later monitoring of the drug level unnecessary. The present results do not indicate that it would be of any help to measure plasma levels after the first dose with tablet B.

In connection with the calculation of the AUC values after single dose administration, an elimination rate constant, β, has been calculated. As this value is only based on two concentrations, C_{12} and C_{24}, and one cannot be sure that absorption is complete at 12 hr after administration, β is encumbered with some uncertainty. However, the values obtained (0.06–0.18) give half-lives in the range of 3.9–11.6 hr, which are in agreement with the half-lives normally found for theophylline (1). Moreover it supports the view that the steady state can be reached with 3 days of constant dosage. A difference in half-lives between smokers and nonsmokers as demonstrated by others (12–14), could not be found, but the reason for this may be that none of the volunteers were heavy smokers. A comparison of $AUC_{0\to\infty}$ after single dose and $AUC_{0\to12}$ after dosing to steady state shows that the AUC values are not significantly different. This means that the pharmacokinetics of theophylline have not changed during treatment.

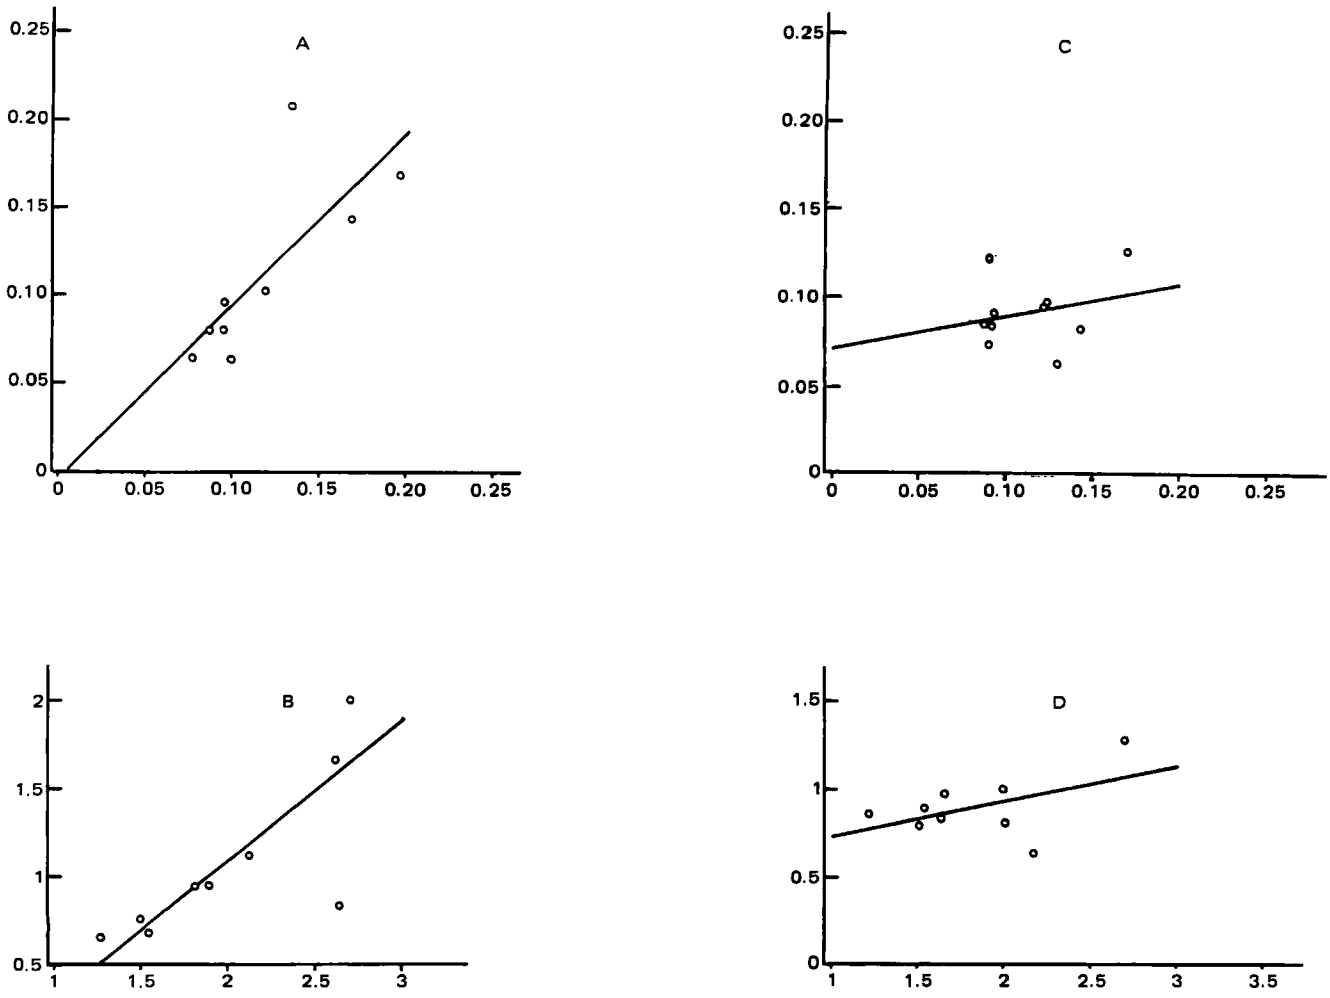

Figure 3—*Correlations between single dose (abscissa) and steady state (ordinate). Key: (A) Tablet A,* C_{max}, $y = 0.972x - 0.005$, $r = 0.76$; *(B) Tablet A,* AUC, $y = 0.799x - 0.511$, $r = 0.87$; *(C) Tablet B,* C_{max}, $y = 0.189x + 0.070$, $r = 0.27$; *(D) Tablet B,* AUC, $y = 0.199x + 0.529$, $r = 0.49$. C_{max} *values are μmoles/liter/mg of theophylline.* AUC *values are μmole hr/liter/mg of theophylline.*

The design of this investigation does not allow conclusions considering side-effects. Appearance of side-effects was not related to plasma theophylline concentrations in the range investigated. Some subjects experienced more side-effects from one preparation than from the other, whereas the opposite was experienced by others. Similarly for some, the first period seemed to be worse than the second and *vice versa.* Some subjects did not experience any adverse side-effects at all. Thus, it seems that each individual patient must be allowed to try whichever preparation is most suitable.

Dissolution of a Soluble Drug Substance from Vinyl Polymer Matrices

C. BROSSARD *‡, D. LEFORT DES YLOUSES §, D. DUCHÊNE *, F. PUISIEUX *, and J. T. CARSTENSEN *x

Received July 30, 1980, from the *Faculté de Pharmacie, Laboratoire Galénique, Université de Paris-Sud, 92290 Châtenay-Malabry, France, the ‡School of Pharmacy, University of Wisconsin, Madison, WI 53706, and the §Faculté de Medecine et de Pharmacie, 87032, Limoges, France. Accepted for publication March 19, 1982.

Abstract □ It was shown that vinyl polymers form good bases for *in vitro* sustained-release matrices, and that the character of the release curves is basically in line with their pH–solubility profiles. For a flow cell, the release curves may be approximated by the equation: $\ln (m/m_0) = -K(t - t_i)$, where m is the amount not dissolved, m_0 is the initial drug content, K is a dissolution constant, t is time, and t_i is a lag time. Furthermore, it was shown that K is a function of tablet hardness (H) and polymer content (Q, percent). This functionality is well represented by the equation: $\ln K = \alpha H + \gamma \ln Q + \epsilon$, where α, γ, and ϵ are polymer-dependent parameters. Matrix erosion is represented by an exponential decay: $(p/p_0) = \exp(-Dt + a)$, where p is the amount not eroded, p_0 is the initial weight, D is an erosion constant, and a is a soluble polymer-dependent parameter. In the case of these soluble polymers, K is not solely a function of D.

Keyphrases □ Dissolution—soluble drug substances from vinyl polymer matrices □ Polymers—vinyl polymer matrices, dissolution of a soluble drug substance □ Matrices—vinyl polymer, dissolution of a soluble drug substance

The fundamental dissolution relationship from sustained-release preparations have been studied extensively. Matrix formulations are based on a published model (1), and the ensuing square root law has been well established (2). In these formulas, the matrix is completely insoluble.

BACKGROUND

Several reports (3–13) have appeared describing dissolution from rapidly disintegrating dosage forms. The dissolution frequently appears to follow an exponential decay law. It would be expected that the dissolution should adhere to a cube root law; that it does not is due to the effect of disintegration of the tablet in the dissolution apparatus. This effect (3) gives rise to a dissolution equation of the form:

$$\ln (p/p_0) = -Dt \qquad \text{(Eq. 1)}$$

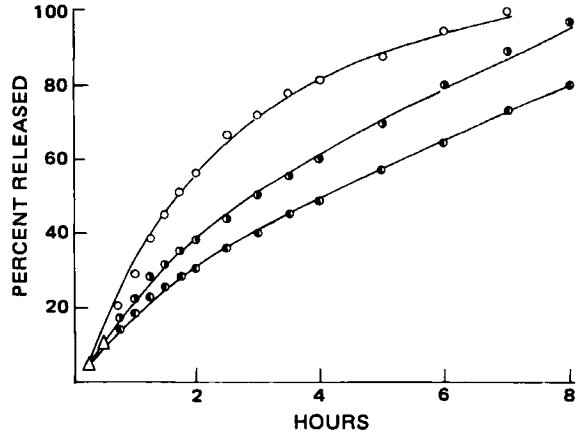

Figure 1—*Example of release curves by half-change method in flow cell under sink conditions of polyvinyl phthalate acetate, 60% directly compressed. Key: (○) 5-kg hardness; (◑) 10-kg hardness; (◐) 15-kg hardness; (△) points that are graphically indistinguishable between the three hardnesses.*

where p is the amount not disintegrated at time t (p_0 at time zero) and D is a disintegration constant. For a tablet where disintegration is rapid, Eq. 1 in conjunction with a cube root equation leads to a dissolution curve of the type:

$$\ln (m/m_0) = -K(t - t_i) \qquad \text{(Eq. 2)}$$

where m is the amount not dissolved, m_0 is the amount of drug present in the tablet, K is a dissolution constant, and t_i is a lag time. The parameter is frequently a function of D by the relation:

$$\ln K = a' + n \ln D \qquad \text{(Eq. 3)}$$

where a' and n are constants.

Contrary to previous studies, many sustained-release preparations can be formulated where the matrix is not completely insoluble, *i.e.*, the tablets disintegrate or erode to some extent during the dissolution process. The word erosion is preferred over the word disintegration, although at times a sharp distinction between the two is not possible.

One of the purposes of the present report is to examine matrices that are not completely insoluble, and to (*a*) elucidate the general dissolution profile, (*b*) estimate the effect of formulation and processing parameters on the dissolution profile, and (*c*) estimate the disintegration or erosion profile in the dissolution apparatus to assess its effect on the dissolution profile.

The conditions of study are such that a half-change method is used. Long-acting tablets were prepared with polymers of different types such that they: (*a*) are acid soluble, but alkali insoluble (giving an initial phase where dissolution is correlated to disintegration and where the final phase should be by diffusion), (*b*) are alkali soluble but acid insoluble (giving the reverse effect), (*c*) are soluble over the entire pH range, and (*d*) are insoluble over the entire pH range.

Since flow methods (11) are commonly used in Europe, one of the purposes of the work reported in this study was to investigate erosion and dissolution behavior in such an apparatus. Erosion profiles in flow cells are not well understood. Some reports on disintegration time (6) have appeared, but elucidation of erosion time curves have not been attempted previously.

The present investigation also reports on formulas that possess *in vitro* release characteristics making them good candidates for sustained-release preparations. The empirical equations serve as a means of obtaining optimum operating conditions for producing the sustained-release tablets and for obtaining the most desirable tablet formula for a given set of specifications for the amount released at two time points.

The drug selected was especially chosen because its solubility is not particularly pH dependent. This allows study of the dissolution behavior to be aimed at the effect of the matrix. The rationale for sustained-release preparations of the compound and its biopharmaceutical characteristics have been described (13).

The use of polyvinyl polymers for sustained-release matrices has been reported in general (14–17). Polyvinyl alcohol has been used extensively for pharmaceutical purposes: in coating (18–23) and as a binder in granulation (24). Povidone has also been used extensively for coating (18, 21, 24–27), as a binder in granulation (28–31), and for sustained-release matrices (32). Polyvinyl acetate has been used in coating (18, 33–37), in matrices (17, 38–40), and in sustained-release capsule beads (41, 42). Povidone–vinyl acetate has been used in coating (43, 44) in granulations (45), and in cast films (46–48). Polyvinyl acetate phthalate has been used for coating (49–53), and polyvinyl acetal diethylaminoacetate has been used in coating (54, 55), studied in cast films (56, 57), and used in matrices (14).

EXPERIMENTAL

Dyphylline was selected for study in the sustained-release preparations because of its high solubility (~25% w/v in water at 25°) and the ease of assay (spectrophotometric). Tablets were made by both direct compression and wet granulation.

Direct Compression—The formulas used for direct compression are shown in Table I. The polymer and dyphylline were sieved, and the fraction finer than 315 μm was used. The powders were mixed in a turbulent action mixer[1] for 10 min and were compressed at three pressures, giving hardnesses of 5, 10, and 15 kg.

The experimental conditions (punch pressures) giving these conditions had been established, and hardness was within 5%. All experiments were carried out immediately after manufacture of the tablets. Tablets were compressed on a single-punch tablet machine[2], at a tablet weight of 500 mg using a flat, nonbeveled punch, 12-mm diameter. The machine was instrumented with strain gauges to record upper and lower punch forces.

Wet Granulation—The chemical properties and the granulation solvents are listed in Table II. The general formula for the wet granulation

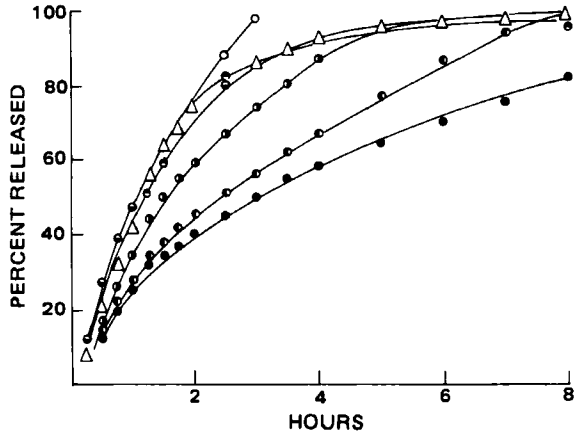

Figure 4—*Release curves at a particular pressure for each of the directly compressed polymer formulas tested, shown for general comparison. Key: (○) polyvinyl alcohol–acetate, 60% at 5 kg; (◒) povidone–vinyl acetate, 15% at 10 kg; (◒) povidone, 30% at 15 kg; (◑) polyvinyl acetal diethylamino acetate, 60% at 15 kg; (◐) polyvinyl acetate phthalate, 30% at 10 kg; (●) polyvinyl acetate, 60% at 5 kg, (△) graphically indistinguishable points.*

is in the last column of Table I. The sieved dyphylline was mixed with the dibasic calcium phosphate for 5 min in a planetary mixer[3]. A 50% w/w solution of the polymer in the solvent was added to the mixture in the planetary mixer, and kneading was carried out for 5 min. The remaining solvent was added and kneading was performed for an additional 5 min. The wet mass was passed through an oscillating granulator[4] equipped with a 2-mm screen. The granulation was dried at 60° in a fluid bed dryer[5] to a moisture content of 2% (loss on drying in an IR moisture balance[6]). Drying time was ~30 min for alcohol wet granulations and ~1 hr for water wet product. The dried granulation was passed through an oscillating granulator with a 1-mm screen, lubricated for 5 min in the turbulent action mixer, and compressed.

Testing—Dissolution was carried out at 37° in a continuous flow apparatus with a flow cell[7], under sink conditions, using the half-change method. One tablet was placed in the cell, and simulated gastric fluid without enzymes was added; after 1 hr this was changed to a 50% mix of simulated gastric fluid and simulated intestinal fluid, both without enzymes. After 2 hr the acid concentration was reduced to 25%. The pH values recorded were: 0–1 hr, 1.2; 1–2 hr, 2.0; 2–3 hr, 6.4; 3–4 hr, 7.0; 4–5 hr, 7.2; 5–6 hr, 7.3; 6–7 hr, 7.4; and 7–8 hr, 7.5. The test was carried out under sink conditions, *i.e.*, fluid was not returned to the cell once it had passed. The assays were carried out spectrophotometrically at 274 nm. The results were converted to amount of drug, m (in milligrams or percent), not released at time t. The testing intervals were typically as shown in Figs. 1 and 2. The hardness of the tablets was tested using a moving-stationary anvil fracture strength tester[8].

The disintegration mode was studied by a described method (4, 9) and yielded the weight of tablet, p (on a dry basis), not disintegrated at time

[a] g is wet granulated.

t. Testing intervals were typically 1, 2, 3, 4, 6, and 8 hr, except for periods during dissolution in particular cases where disintegration was rapid. In these cases the intervals were shortened.

RESULTS AND DISCUSSION

The dissolution curves obtained are all of the shape shown in Figs. 1–4, which is a type profile frequently encountered in dissolution work. The general, mutual position of the curves is in good agreement with the physical characteristics of the polymers, the most soluble giving rise to the most rapid release and the least soluble giving rise to the slowest. This is illustrated in Fig. 4, where all formulas are shown at one hardness (per polymer). It is seen from Fig. 2 that wet granulation causes a marked increase in dissolution rate.

It is to be expected that hardness (H) and polymer content (Q) would affect the rate of release. Figures 1–3 demonstrate this in a qualitative way. In a more quantitative fashion, the dissolution constant (K, hr^{-1}) would have to be a function of both Q and H.

To establish a function that could describe this dependence, the effect of hardness will first be examined, and then the effect of both hardness and polymer concentration will be scrutinized.

It is conventional to fit dissolution data to one of several types of functions (11), an exponential decay (Eq. 2) being one such relationship. In this case the plotting should follow:

$$\ln (m/m_0) = -Kt + a \qquad \text{(Eq. 4)}$$

where m_0 is the initial drug content. Figure 5 shows this type of plotting to be well adhered to, and the least-squares fit parameters for all the preparations are shown in Table III. From the correlation coefficients, the empirical choice of Eq. 4 is well justified.

Table V—Amount Disintegrated as a Function of Time for Three Polymers

Polymer	Percent	Hardness	Fraction Not Disintegrated at Time t, hr

VI	+1.86	−0.054	−0.434	−0.048

It was mentioned earlier that K decreases with increasing hardness, H, and inspection of Table III leads to the plausibility of a relation of the type:

$$\ln K = \alpha H + \beta \qquad \text{(Eq. 5)}$$

The least-squares values for K for all the preparations in Table III have been treated according to Eq. 5, and for each polymer (i), the least-squares fit parameters β_i and α_i are listed in Table IV. A dimensionless plot, as described previously (10, 12), is shown in Fig. 6; the ordinate values are the individual values of $y = \ln K_i - \beta_i$, and the abscissa values are $x = \alpha_i H_i$, and since according to Eq. 5:

$$(\ln K_i) - \beta_i = \alpha_i H \qquad \text{(Eq. 6)}$$

a line with unity slope and zero intercept should follow. Figure 6 indicates that this is the case, showing that Eq. 5 is a reasonable choice of function representing the dependence of K on H, and all values for all the preparations are included.

Table IV shows that the wet granulated preparations are less sensitive to hardness (tableting pressure) than the directly compressed tablets.

The parameter K is not only a function of H but also of the drug content, Q (percent), of the polymer. There are four of the cases where K decreases with increasing polymer concentration, and two cases (povidone and povidone–vinyl acetate) where K increases with increasing polymer concentration. These latter two cases are in accord with previously reported findings where povidone (58–61) and providone–vinyl acetate (45) have been found to increase dissolution rates. However, as seen in Table V, erosion rates also increase with increasing concentration of these two polymers, so that dissolution (diffusion) rate increase or erosion rate increase (or both) could account for the increase in K with an increase in the polymer concentration. Table V shows that K probably approaches a limiting value (K') as Q increases. This requires four parameter fits (*i.e.*, $K = F(H,Q,K')$, where F denotes function of. Since K' would have to be obtained by iteration, the resulting statistics would be of questionable robustness. Instead, it has been assumed here that K for a given hardness

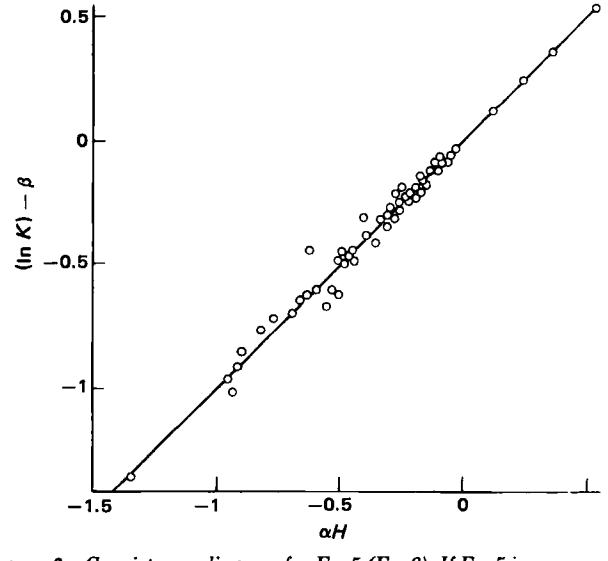

Figure 6—*Consistency diagram for Eq. 5 (Eq. 6). If Eq. 5 is a reasonable fit, then* y = x, *where* x = αh *and* y = ln K − β. *The least-squares fit of the line is* y = 1.002x − 0.0004, i.e., *the slope is close to unity, the intercept is close to zero, and the equation is close to* y = x.

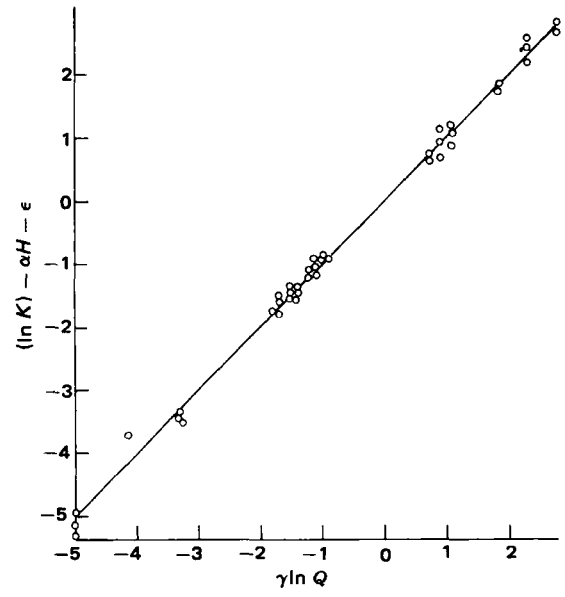

Figure 7—*Data treated according to Eq. 7. The abscissa is* x = γln Q *and the ordinate is* y = (ln K) − αH − ϵ. *The least-squares fit is* y = $(1 \times 10^{-5})x + 5 \times 10^{-4}$, *so that the slope is close to unity and the intercept close to zero as required for Eq. 7 to be a reasonable function* (r = 0.997).

changes in log–log fashion with Q, *i.e.*, retaining the format of Eq. 5 for the H-dependence:

$$\ln K = \alpha H + \epsilon + \gamma \ln Q \qquad \text{(Eq. 7)}$$

The data have been treated by multiple regression, and the least-squares fit values are shown in Table VI. The data are shown in dimensionless presentation in Fig. 7. The ordinate is $y = \ln K - \alpha_i H - \epsilon_i$, where the subscript i is the individual parameter values for the ith polymer. The abscissa is $\gamma_i \ln Q$, so the line, $y = x$, should have unity slope and zero intercept, which is the case. Equation 7, therefore, is a reasonable overall empirical function for the data. The values of α in Tables IV and VI should be close to one another, and as shown in the last column of Table VI, they are.

The value of the phenomonological approach is as follows. For development of sustained-release products, it is usually the intent to obtain a certain *in vitro* release curve. This is often of the military specification type with a range of percent release after (for example) 1 hr, and a range of percent released after 4 hr. At this starting point there is already a benefit from knowing the release equation. If the specifications were, *e.g.*, 25–30% after 1 hr and 40–60% after 4 hr, then the type release found here

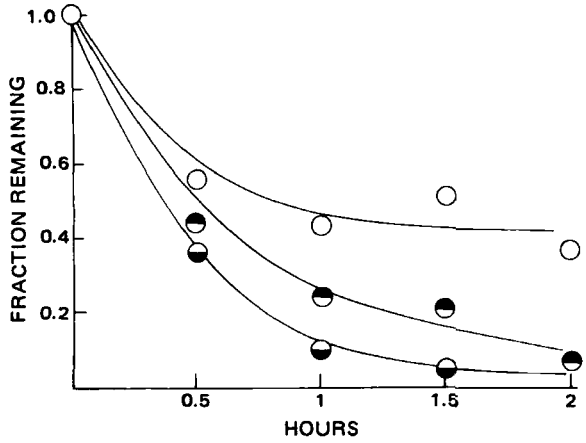

Figure 8—*Disintegration data for polymers with non pH-dependent solubilities. The ordinate is fraction not disintegrated (eroded) at time* t. *Key: (○) providone–vinyl acetate, 15%, 15-kg hardness; (◒) povidone, 60%, 15-kg hardness; (◓) polyvinyl alcohol–acetate, 30%, 5-kg hardness.*

Polymer, %	Parameters for Eq. 15			
	P_∞ (Fraction)	a	D	Correlation Coefficient, r
15g[a]	0.16	−0.318	1.076	−0.98
15	0.18	−0.244	−0.973	−0.99
30	0.26	−0.30	−1.36	−1.0
60	0.33	−0.40	−1.50	−1.0

[a] g is wet granulated.

Table VIII—Values of (p/p_0) for Polyvinyl Acetate Phthalate Formulations

Time, hr	Formula (Polymer, %; Hardness, kg)				
	15%, 15 kg	30%, 15 kg	60%, 15 kg	60%, 10 kg	60%, 5 kg
0	1	1	1	1	1
1	0.7	0.81	0.97	0.98	0.96
2	0.7	0.79	0.97	0.98	0.97
4	0.62	0.66	0.93	0.81	0.77
6	0.34	0.55	0.78	0.63	0.63
8	0.27	0.39	0.54	0.47	0.39
D	0.208	0.130	0.138	0.135	0.170
a	0.289	0.126	0.512	0.340	0.470
$t_i = a/D$	1.39	1.97	3.72	2.49	2.75
r	−0.97	−0.98	−0.97	−0.99	0.97

(Eq. 2) would not be adequate[9]. It should be pointed out that most sustained-release patterns are of this type. That it would not be adequate is seen from the following. The K-value calculated from the 4- and 1-hr restrictions must be in the range:

$$\text{1 hr: } -\ln 0.75 < K < -\ln 0.70 \text{ or } 0.29 < K < 0.35 \qquad \text{(Eq. 8)}$$

$$\text{4 hr: } -0.25 \ln 0.6 < K < -0.25 \ln 0.4 \text{ or } 0.13 < K < 0.23 \qquad \text{(Eq. 9)}$$

Since the two intervals do not overlap, it is not possible to meet the specification range requirements. Without knowing the dissolution pattern, it would be possible to spend considerable time attempting to obtain a formulation which could not possibly meet the given requirements.

If, instead, the required release ranges were 25–35% after 1 hr and 55–75% after 4 hr, then similar calculations would give:

$$\text{1 hr: } 0.29 < K < 0.43 \qquad \text{(Eq. 10)}$$

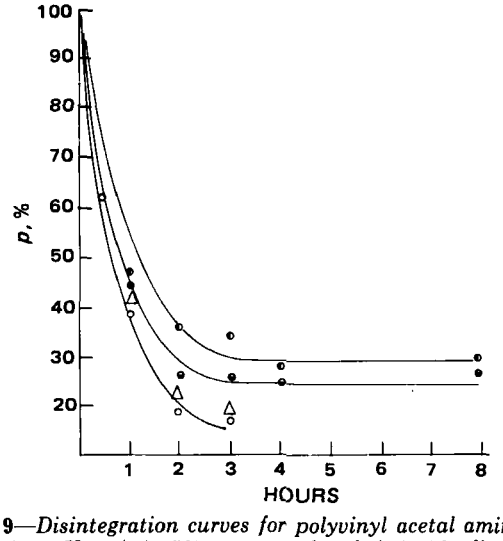

Figure 9—*Disintegration curves for polyvinyl acetal aminoacetate preparations. Key: (○) 15% wet granulated; (△) 15% directly compressed; (◒) 30% directly compressed; (◐) 60% directly compressed. The parameter* p *is the amount not disintegrated in percent.*

[9] It should be noted that an immediate release component in the formulation might solve this. An extension of the argument is that if a specification is set in addition at, *e.g.*, 8 hr, a similar impossible situation might arise.

Table IX—Disintegration Data Treated According to Eq. 17

Polymer	Percent (Q)	Hardness (H)	Correlation Coefficient, r	a	D	ln D	ln K^c
V	15	15	−0.92	−0.408	0.365	−1.01	0.162
	30	15	−1.0[b]	0.243	1.832	0.605	−0.274
	60	15	0.98	0.644	2.455	0.898	0.412
	15g[a]	15	−0.95	−0.208	0.987	−0.013	−0.020
IV	15	15	−0.84	−0.489	0.270	−1.309	−0.301
	30	15	−1.0[b]	−0.155	0.860	−0.151	−0.357
	60	15	−0.99	0.079	1.837	0.608	0.270
	15g[a]	15	−0.93	−0.320	0.307	−1.181	−0.128
VI	15	10	−0.99	−0.267	0.910	−0.094	0.140
	30	5	−0.97	−0.069	1.138	0.129	0.058
	60	5	−0.99	−0.105	0.586	−0.534	−0.163
	15g[a]	15	−0.99	−0.343	0.661	−0.414	−0.051

[a] g is wet granulated. [b] Only two points were available and were not included in Fig. 12. [c] From Table III.

$$4 \text{ hr: } 0.20 < K < 0.35 \qquad \text{(Eq. 11)}$$

i.e., K must be in the interval: $0.29 < K < 0.35$.

If polymer II is used, and a 8–11-kg hardness is required, then (Table VI, line 2):

$$\ln K = -0.065\,H - 0.41 \ln Q + 1.04 \qquad \text{(Eq. 12)}$$

Inserting lower limits for K and H gives:

$$\ln 0.29 + (0.065 \times 8) - 1.04 = -0.41 \ln Q \text{ or } Q = 73 \qquad \text{(Eq. 13)}$$

and inserting upper limits for K and H:

$$\ln 0.35 + (0.065 \times 11) - 1.04 = -0.41 \ln Q \text{ or } Q = 29 \qquad \text{(Eq. 14)}$$

Therefore, in this case, Q must be between 30 and 73, and narrowing the specification limits or the hardness limits would produce a narrower range of Q, but the example gives a starting point for the final phase of product development for a product of this type. Other factors may affect release (*e.g.*, moisture content and machine speed) and such factors can (at increased experimentation) be included in a multivariable phenomonological equation. Preliminary factorial experimentation on two levels may sort out the variables of importance prior to model experimentation. If many variables are included, then it is best, as suggested previously (62) to assume that all the relations can be described by two-power polynomials and approach the problem by fractional factorials. In this case there is no experimental testing of the actual functionality: it is assumed to be a two-power polynomial.

Erosion Curves—Disintegration is presumably erosion due to dissolution of the polymer. If this is so, then the erosion is a function of polymer solubility. It should follow a cube root law if the solubility is absolutely pH independent; as pointed out previously (63), cube root relations often resemble exponential decays. Because of the differences in solubility profiles as a function of pH, the cases will be discussed individually in the following, but typical examples of disintegration patterns for polymers with pH-insensitive solubility are shown in Fig. 8, and the erosion figures are given in Table V.

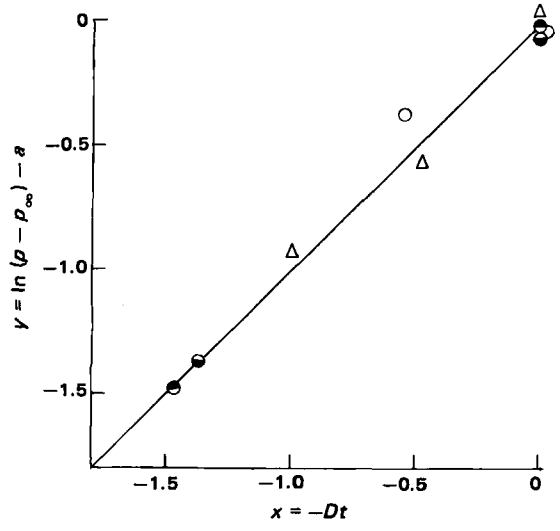

Figure 10—*Consistency diagram in dimensionless units for Eq. 8, using data in Table VII. The parameter* p *is here in fraction. For Eq. 8 to be a reasonable function, the data should be linear and the line should go through the origin (*y = x *as shown). Key: (Δ) 15% wet granulated; (○) 15% directly compressed; (◒) 30% directly compressed; (◓) 60% directly compressed.*

Table X—Disintegration Data (p/p_0) for Polyvinyl Acetate Preparations

Time, hr	Fraction disintegrated at the time indicated (Polymer, %; Hardness, kg)			
	15%, 15 kg	30%, 15 kg	60%, 15 kg	15%, 15 kg, g[a]
0	1	1	1	1
0.5				0.8
1	0.77	0.81	0.94	0.75
1.5				0.74
2	0.69	0.77	0.96	0.72
4	0.74	0.81	0.95	
6	0.76	0.79	0.93	
8	0.69	0.78	0.91	

[a] g is wet granulated.

Polyvinyl Acetal Diethylaminoacetate (I)—Polyvinyl acetal diethylaminoacetate is acid soluble and alkali insoluble; therefore, it should be subject to erosion (dissolution) only in the first 2 hr, as seen in Table VII. The value of p in Eq. 2 should approach an asymptotic value different from zero (unless erosion were complete within 2 hr, which is not the case). The erosion equation should reflect this as:

$$\ln (p - p_\infty) = -Dt + a \qquad \text{(Eq. 15)}$$

where p_∞ is the amount of matrix not disintegrated at infinite time, p is the matrix, and the data in Table VI, referring to polyvinyl acetal diethylamino acetate have been subjected to this adjustment. The data are shown in Fig. 9. Reasonable asymptote values can be estimated from the figure, and the data have been subjected to dimensionless plotting in Table VII. The dimensionless plot is shown in Fig. 10 and establishes that Eq. 8 is a reasonable function for treating the erosion data.

The erosion constant is of the same order of magnitude in the first 2

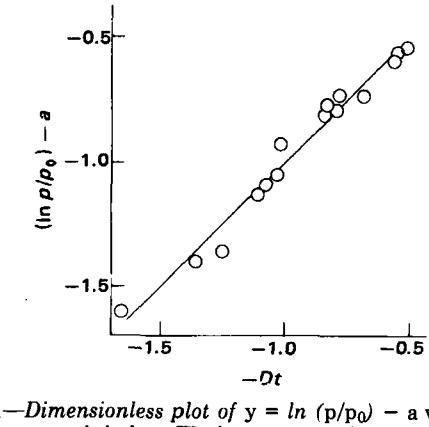

Figure 11—*Dimensionless plot of* y = *ln* (p/p0) − a versus −Dt *for polyvinyl acetate phthalate. The least-squares fit is* y = *0.998*x − *0.002, i.e., a straight line with close to unity slope and close to zero intercept, showing applicability of Eq. 1 to this system (*r = *0.99).*

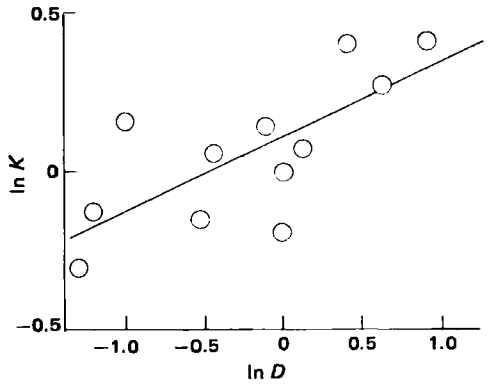

Figure 12—*ln* K *as a function of ln* D *(Table IX). The least-squares fit line is ln* K = *0.229 ln* D + *0.105 (r = 0.79).*

hr as the dissolution constant in the remainder of the dissolution period, so that the overall dissolution curve will be well represented by Eq. 4. It may be concluded that the rate-controlling process is twofold: erosion in the first 2 hr and diffusion in the remainder of the dissolution period (during this latter period the matrix weight remains constant and the dissolution is log-linear).

Polyvinyl Acetate Phthalate—In this case the polymer is acid insoluble and alkali soluble. Dissolution of the polymer should not occur until after the second hour. It is seen in Table VIII that in the case of the two lower polymer concentrations (15 and 30%) there is a certain amount of erosion immediately. Apparently this is an effect of the excipients and does not occur at the high concentration. After this immediate erosion the weight remains constant for 2 hr (during which time the pH is low and the polymer does not dissolve), and after 2 hr the increase in pH causes the solubility of the polymer to increase and erosion to begin. It is seen in Table VIII that the erosion after the 2-hr point appears to follow Eq. 1, and the least-squares fit values are listed. Since the disintegration actually does not occur substantially until a certain time, t_i (presumably between 2 and 4 hr), the correct form of Eq. 1 would be:

$$\ln (p/p_0) = -D(t - t_i) \qquad \text{(Eq. 16)}$$

so that a is equal to Dt_i. Values of t_i calculated in this fashion are shown in Table VIII and are in the correct range for the higher concentration.

The data in Table VIII are shown in dimensionless presentation in Fig. 11, and the adherence of this plot to linearity with unity slope and zero intercept shows that the disintegration is well represented by Eq. 16.

Povidone, Povidone–Vinyl Acetate, and Polyvinyl Alcohol–Acetate—These three polymers have solubilities that are not pH dependent. The disintegration of the formulas follow Eq. 1 fairly well, and the least-squares fit parameters are shown in Table IX. The effect of flow cells on disintegration has been reported for povidone (6).

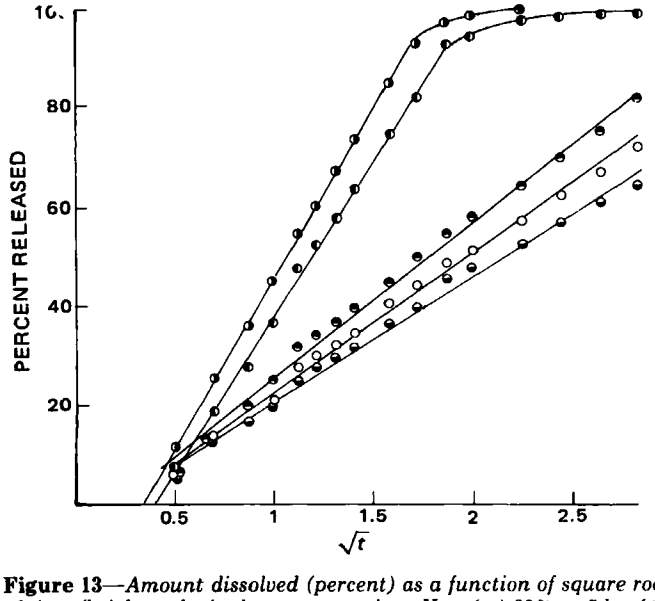

Figure 13—*Amount dissolved (percent) as a function of square root of time (hr) for polyvinyl acetate matrices. Key: (●) 60% at 5 kg; (○) 60% at 10 kg; (◒) 60% at 5 kg; (◐) 30% at 15 kg; (◑) 15% at 15 kg.*

In addition, the disintegration behavior in rotating baskets (2–5, 64–66) has been shown to lead to exponential decay dissolution profiles (Eq. 2) with lag time when disintegration is the rate-limiting factor. Therefore, correlations between K and D frequently occur in rotating dissolution apparatuses (4, 9–11) when rapidly disintegrating formulas are tested. Such a correlation is not necessarily to be expected in the case of the polymers reported here; however, the data in Table IX imply a correlation of the type:

$$\ln D = q \ln K + j \qquad \text{(Eq. 17)}$$

where q and j are constants. The data in Table IX are shown by a dimensionless representation in Fig. 12 using Eq. 17. There is fair linearity, the slope is close to unity, and the intercept is close to zero, so that Eq. 17 is not an unacceptable function, but the scatter about the line is such that other effects might be expected. Presumably, the amount, m, not released at time t, would be a complex function of both K and D, where K and D are not entirely independent of one another.

Polyvinyl Acetate—In this case there should be insolubility throughout the pH range. As shown earlier, only the 60% preparation is free from some initial disintegration (erosion). In the case of the two lower concentrations, the amount of weight lost is in excess of drug released, *e.g.*, for the 30% polymer concentration 30 mg (6% of the tablet weight) of drug is dissolved after 1 hr as opposed to the fact that the weight loss is 23%. In the case of polyvinyl acetate, the matrix should be insoluble, and the release pattern should come close to being a square root of time dependence (1). Figure 13 and Table X shows this to be the case, although the deviations from the line are first negative, then positive, then negative (+ − +) so that [Durbin–Watson statistics (67)] the fit is not exact. The initial lag time and the end effect is to be expected (2). It is apparent that the release is also well represented by a semilogarithmic relationship (Eq. 2). These latter frequently simulate square root in time functions (68).

Evaluation of Mosquito Repellent Formulations

WILLIAM G. REIFENRATH ˣ **and LOUIS C. RUTLEDGE**

Received December 21, 1981, from the *Division of Cutaneous Hazards, Letterman Army Institute of Research, The Presidio of San Francisco, CA 94129.* Accepted for publication April 7, 1982.

Abstract □ *N,N*-Diethyl-*m*-toluamide was formulated with several acrylate polymers in ethanol solution and various silicone polymers in 2-propanol suspension; the ratio of polymer to *N,N*-diethyl-*m*-toluamide (I) was varied. Formulations that had drying times of <10 min were evaluated for film hardness and elasticity. Contact angles made by water on films cast from the formulations were measured when such films were uniform. For the acrylate formulations, containing polymers that are solid at room temperature, the presence of I increased drying times; decreased film hardness and elasticity resulted from decreasing the ratio of polymers to I. Lower contact angle with water resulted from decreasing the ratio of acrylate polymer to I. However, this effect was less pronounced with the lower molecular weight acrylate polymer formulations. Films cast from the silicone formulations had low contact angles with water. In addition, formulations of repellents, ethohexadiol and *N,N*-diethyl-*p*-toluamide, each in combination with a silicone polymer, were evaluated. Films with short drying times, high contact angle, and measurable hardness could be cast from the *N,N*-diethyl-*p*-toluamide–silicone formulations due to the film-forming ability of the repellent itself. The physical properties of the ethohexadiol–silicone formulations were similar to the I–silicone formulations. Selected formulations received preliminary evaluation for duration of effectiveness against *Aedes aegypti* mosquitoes *in vitro* and in animal test systems. Except for one formulation of I with a lower molecular weight acrylate polymer, these formulations did not enhance the duration of effectiveness of I on hairless dogs. The *in vitro* ED_{50} of the test repellent for *A. aegypti* was significantly enhanced in 5 of 15 formulations tested. The 4-hr ED_{50} of the test repellent on white mice was significantly enhanced in 6 of 15 formulations tested.

Keyphrases □ Repellents, mosquito—film hardness and elasticity evaluation for *N,N*-diethyl-*m*-toluamide–acrylate polymer formulations □ *N,N*-Diethyl-*m*-toluamide—formulation with acrylate polymer, evaluation for film hardness and elasticity in mosquito repellents □ Polymers—*N,N*-diethyl-*m*-toluamide formulations, evaluation for film hardness and elasticity in mosquito repellents

The duration of protection afforded by a mosquito repellent is limited by the ways it can be lost from the skin surface, such as abrasion and removal by water immersion (1) and excessive evaporation and penetration into the skin (2, 3). Many efforts have been made to improve the persistance of mosquito repellents by incorporating the active ingredient (usually *N,N*-diethyl-*m*-toluamide, I) with a variety of materials such as polysaccharide esters or silicone and acrylic polymers (4), clay (5), zinc oxide (6), vanillin (7), and others. However, there remains to be found a repellent formulation which has acceptable cosmetic and toxicologic properties and has significantly

[a] Contact angle measurements were replicated three times, except where the number of replicates are indicated in parentheses following value, mean ± *SD*. [b] Film surface was too irregular for determination of contact angle with water.

better duration of protection than unformulated I. In an effort to understand better the results obtained by adding I to various polymers, I was formulated in varying ratios to several commercially available silicone and acrylate polymers, some of which have been used extensively by the cosmetic industry.

EXPERIMENTAL

Materials—The materials used for the preparation of mosquito repellent formulations were acrylate polymers[1] I–IV, silicone polymers[2] V–VIII, and the mosquito repellents *N,N*-diethyl-*m*-toluamide[3], *N,N*-diethyl-*p*-toluamide[4], and ethohexadiol[5]. The composition of the formulations is listed in Tables I and II. Acrylate polymers III and IV required heating to effect solution in ethanol.

Determination of Drying Times—Films were cast on glass microscope slides by using a mechanical drive[6] and an applicator[7] with 0.19-mm wet film thickness and allowed to dry at ambient conditions (40% relative humidity and 23°). Using a cotton ball, the slide was checked for a dry tack-free surface every 2 min up to 15 min, every 10 min up to 1 hr, and then every hour up to 8 hr. Drying times were done in duplicate.

Film Hardness, Film Thickness, and Modulus of Elasticity—These were determined by published procedures (8). Films were cast as for drying time determinations; however, the substrate was a polished aluminum plate. Films were tested 4 hr after they were cast. The modulus of elasticity (E) was calculated by:

$$E = \frac{KR^3}{T^3}$$

where R is the Sward hardness (number of rocks) and K is a constant for thickness (T) determined by extrapolation from data in the literature (9).

Contact Angle—Films were cast on a glass microscope slide cut in half lengthwise, by the same procedure as for drying time determinations. Fifteen minutes after the film was cast, the slide was inserted in the contact angle viewer[8]. A drop of distilled water was placed on the film, and the angles, formed by the base of the drop on its left and right sides, were read. The volume of the drop was then increased by small increments until the left and right side angles were the same and remained constant. This final angle is reported as the contact angle. The determination was replicated three times.

Protection Time—The protection time of the formulations was determined on hairless dogs using a published procedure (10). After all the application sites on the dog's skin had failed, the skin was scrubbed with soap[9] and water to remove residual polymer. Dogs were usually rested 3–4 days between tests.

Median Effective Dosage—The median effective doses (ED_{50}) of 19 formulations for the yellow fever mosquito, *Aedes aegypti*, were determined by a previous method (11). This method utilizes an *in vitro* mosquito blood-feeding system having test surfaces of goldbeater's skin (the prepared outside membrane of the large intestine of cattle used for separating the leaves of metal in goldbeating).

Four-Hour Median Effective Dose—Four-hour ED_{50} values of 19 formulations for *A. aegypti* were determined on 7–10-day-old white mice. Four mice were wetted with serial dilutions of the test formulation, and a fifth (the control) was wetted with a corresponding solvent (ethanol or 2-propanol). The mice were held at 27° for 4 hr, after which they were transferred to a 30 × 30 × 30-cm mosquito cage containing 100 nulliparous, 5–15-day-old female *A. aegypti*. The number of mosquitoes feeding on each mouse was recorded at 2 min intervals for a period of 30 min. The totals of the 10 feeding counts obtained for each of the mice were combined with the corresponding totals from subsequent replicates of the test, and the totals for each dose were then converted to percentages of

[1] Acrylate polymer I is Carboset 515, II is Carboset 514, III is Carboset 526, and IV is Carboset 525. Polymers were obtained from B. F. Goodrich Chemical Co., Cleveland, Ohio.

the total for the control. The 4-hr ED_{50} was computed from the percentages and the logarithm doses by probit analysis.

RESULTS AND DISCUSSION

The composition and contact angle measurements of the acrylate formulations are given in Table I and of the silicone formulations in Table II. Film thickness, Sward hardness, and modulus of elasticity of the acrylate and silicone formulations with drying times <10 min are given in Table III. The protection times determined on the hairless dog of the acrylate formulations are given in Table IV and of the silicone formulations in Table V. The ED_{50}s and 4-hr ED_{50}s are given in Tables VI and VII and VIII and IX, respectively.

The acrylate polymers are derived from acrylic acid esters, methacrylic acid esters, and α,β-unsaturated carboxylic acids. The mean molecular weight of polymer I is 7000, II is 30,000, III is 200,000, and IV is 260,000. Polymer I is a viscous liquid at room temperature, while polymer II was obtained as a 30% solution of polymer in ammonia water with a final pH of 7.5; percentages of polymer II in Table I are based on the weight of polymer in solution.

For the I–acrylate formulations containing the higher molecular weight polymers, III and IV, increasing the ratio of polymer to a constant amount of I resulted in higher contact angles (Table I). The same trend was observed with Compound I–polymer I and II formulations, although it was less pronounced. The low contact angles for polymer II formulations were probably the result of the presence of water in polymer II and salt formation between the ammonia present and carboxylic acid functional groups.

[a] Dose obtained when 0.4 ml of formulation is spread over a 49-cm² skin area. [b] Number of replicates. [c] Significance was tested at the 95% confidence level using Dunnett's test for comparing *K* means with a control. [d] *N,N*-Diethyl-*m*-toluamide, dissolved in alcohol, was applied to the skin using the same volume as was used for application of the formulation to give the same dose of *N,N*-diethyl-*m*-toluamide.

The silicone polymers, V and VI, are linear polydimethylsiloxanes. Polymer V has ~200 dimethylsiloxane units and a molecular weight of ~15,000. Polymer VI has a molecular weight of ~25,000, which corresponds to 336 dimethylsiloxane units. Polymer VII is composed of a linear polydimethylsiloxane (~100 dimethylsiloxane units) and a highly crosslinked trimethylsiloxysilicate resin. Polymer VIII is related to polymer VII and is made by a slightly different manufacturing procedure[10].

Contact angles of water with the silicone formulations were generally low relative to those of the acrylate formulations and bore little apparent relationship to the ratio of repellent to polymer. The exception was formulation 13. In this case the *N,N*-diethyl-*p*-toluamide (which is a solid at room temperature, in contrast to the *meta* isomer) itself forms a film (visible films of *N,N*-diethyl-*p*-toluamide sometimes can be observed after the repellent is applied in alcoholic solution to human skin).

For each silicone polymer tested, formulations containing higher ratios of polymer to I than those in Table II were prepared along with suspensions of silicone polymers alone in 2-propanol. Films cast from these suspensions did not dry, and the surface of the films were too irregular for measurement of the contact angle with water.

With the exception of formulations 13, 18, and 19 (Table III), all of the mosquito repellent polymer formulations had drying times >8 hr (formulations containing silicone polymers or acrylate polymer I were not expected to dry, because the polymers are liquid at room temperature), and films cast from these formulations were not tested for hardness because of a probable change in component ratios due to evaporation of the repellent during the drying period required. The plasticizing effect of I on the acrylate polymers III and IV was shown by comparing formulation

61 with 17 for polymer III and comparing formulation 62 with 41 for polymer IV. The contact angle with water was higher, drying time was shorter, and films cast from the formulations were harder when I was absent. A similar observation can be made for polymer II (compare formulation 64 with 33); however, in this case, the presence of ammonia and water in the polymer obscures the effect of I on the contact angle. Since polymer I is a liquid, the effects of Compound I on drying time and film hardness are irrelevant. The plasticizing effect of I is not limited to the acrylate polymers. This effect occurs with a variety of polymers, which causes user acceptability problems (*e.g.*, softening or marring of plastics and painted surfaces).

The effect of the increasing modulus of elasticity (Table III) with higher ratios of polymer III to constant levels of I is illustrated in the following observations. Formulations 17–19 were applied to hairless dogs along with a I–ethanol control which gave the same dose of I per unit area (0.32 mg/cm^2). Four hours after application, the sites were observed. As expected, the I–ethanol treated sites were not noted to be any different than the surrounding nonapplication areas of skin. A film was visible on five of the eight sites to which formulation 17 was applied; however, there was no evidence of cracking or peeling. With formulation 18, a film had peeled from two of the application sites. With formulation 19, six sites were peeling, and on another site the film had cracked.

The results of the longer drying times associated with lower ratios of polymer III to compound I were the production of sticky, cosmetically unacceptable films when formulation 25 was tested on human subjects (4).

If the contact angle to water by films cast from the formulations is an indication of the wash resistance of the formulation, then the acrylate

formulations such as those made from polymers III or IV would be expected to provide greater wash resistance than the I–silicone formulations. In tests on human subjects, acrylate formulations such as 25, but not silicone formulations, enhanced I wash resistance (4). However, the contact angles would not necessarily reflect a difference in wash resistance due to a difference in film adhesion to the skin or a difference between a solid flexible film and a liquid film with similar contact angles.

In a preliminary test on hairless dogs, only one of the I formulations (28) appeared to provide greater duration of protection against *A. aegypti* mosquitoes than unformulated I. Results obtained by the ED_{50} and 4-hr test methods were more promising. The ED_{50} of the test repellent was significantly enhanced in two of the seven repellent–acrylate polymer formulations and in three of the eight repellent–silicone polymer formulations (Tables VI and VII). The 4-hr ED_{50}, which measures the combined effects of repellency and persistence on the skin of the test animal, was enhanced significantly in three of the seven repellent–acrylate polymer formulations and in three of the eight repellent–silicone polymer formulations (Tables VIII and IX). Both ED_{50} and 4-hr ED_{50} were enhanced in only one formulation (16, Tables VII and IX). This demonstrates that repellency and persistence on the skin are fundamentally different properties of the repellent formulation. As has been pointed out (12), these two properties of topical repellents have usually been confounded in the past.

In future studies with mosquito repellent formulations, the release kinetics of the repellent (either to evaporation or penetration) will be examined using an *in vitro* skin evaporation–penetration apparatus. Additional knowledge will permit more than an empirical approach to the design of longer lasting mosquito repellent formulations.

Vaginal Absorption of a Potent Luteinizing Hormone–Releasing Hormone Analogue (Leuprolide) in Rats III: Effect of Estrous Cycle on Vaginal Absorption of Hydrophilic Model Compounds

HIROAKI OKADA ˣ, TAKATSUKA YASHIKI, and HIROYUKI MIMA

Received February 2, 1982, from the *Central Research Division, Takeda Chemical Industries, Ltd., 2-17-85 Juso, Yodogawa, Osaka 532, Japan.* Accepted for publication April 1, 1982.

Abstract □ The effect of estrous cycle stages on vaginal absorption was determined by the use of insulin, phenolsulfonphthalein, and salicylic acid as hydrophilic model compounds. Absorption of these compounds was markedly affected by the stage, possibly due to the change of transport rate through the pore-like pathways. The absorption of phenolsulfonphthalein during proestrus and estrus is roughly one-tenth of that during metestrus and diestrus. An increase of the nonionized form of salicylic acid, produced by a lowered pH, resulted in an enhancement of absorption during proestrus and diestrus; higher contribution of the transport through the cell membrane possibly reduced an effect of the estrous cycle. However, consecutive daily administration of leuprolide halted the cycle at diestrus and reduced the cycle effect on the vaginal absorption of phenolsulfonphthalein; when the treatment was started at any of the four stages of the cycle, vaginal absorption was enhanced ~20%, with less variance than that observed in normal diestrous rats.

Keyphrases □ Absorption, vaginal—luteinizing hormone–releasing hormone, leuprolide, effect of estrous cycle on vaginal absorption of hydrophilic model compounds □ Leuprolide—effect of estrous cycle on vaginal absorption of hydrophilic model compounds □ Luteinizing hormone–releasing hormone analogue—effect of estrous cycle on vaginal absorption of hydrophilic model compounds □ Releasing hormone analogue—luteinizing hormone, effect of estrous cycle on vaginal absorption of hydrophilic model compounds

In previous studies (1, 2), vaginal application was proposed as a rational dosage method for long-term self-administration of hydrophilic drugs, because leuprolide (I), a potent luteinizing hormone–releasing hormone (II) analogue, and several hydrophilic compounds (phenolsulfonphthalein, insulin, and II) are well absorbed through the vaginal membrane of diestrous rats.

In those studies, vaginal absorbability was estimated at the diestrus only, since the ovulation-inducing activity of leuprolide could be examined during other stages.

The estrous cycle of the rat is completed in 4–5 days, and during this cycle changes in the vaginal mucosal membrane, the ovaries, and the uterus occur (3). Similar, but not as remarkable, changes of the vaginal mucosa occur in women during the menstrual cycle (4).

In the present study, the effect of estrous cycle stages on vaginal absorption was determined with phenolsulfonphthalein, insulin, and salicylic acid in rats. Furthermore, as continuous administration of leuprolide halts the estrous cycle of rats at diestrus (5), the vaginal absorption of phenolsulfonphthalein following consecutive subcutaneous injection of the analogue over a 10-day period was also estimated.

formulations such as those made from polymers III or IV would be expected to provide greater wash resistance than the I–silicone formulations. In tests on human subjects, acrylate formulations such as 25, but not silicone formulations, enhanced I wash resistance (4). However, the contact angles would not necessarily reflect a difference in wash resistance due to a difference in film adhesion to the skin or a difference between a solid flexible film and a liquid film with similar contact angles.

In a preliminary test on hairless dogs, only one of the I formulations (28) appeared to provide greater duration of protection against *A. aegypti* mosquitoes than unformulated I. Results obtained by the ED_{50} and 4-hr test methods were more promising. The ED_{50} of the test repellent was significantly enhanced in two of the seven repellent–acrylate polymer formulations and in three of the eight repellent–silicone polymer formulations (Tables VI and VII). The 4-hr ED_{50}, which measures the combined effects of repellency and persistence on the skin of the test animal, was enhanced significantly in three of the seven repellent–acrylate polymer formulations and in three of the eight repellent–silicone polymer formulations (Tables VIII and IX). Both ED_{50} and 4-hr ED_{50} were enhanced in only one formulation (16, Tables VII and IX). This demonstrates that repellency and persistence on the skin are fundamentally different properties of the repellent formulation. As has been pointed out (12), these two properties of topical repellents have usually been confounded in the past.

In future studies with mosquito repellent formulations, the release kinetics of the repellent (either to evaporation or penetration) will be examined using an *in vitro* skin evaporation–penetration apparatus. Additional knowledge will permit more than an empirical approach to the design of longer lasting mosquito repellent formulations.

Abstract □ The effect of estrous cycle stages on vaginal absorption was determined by the use of insulin, phenolsulfonphthalein, and salicylic acid as hydrophilic model compounds. Absorption of these compounds was markedly affected by the stage, possibly due to the change of transport rate through the pore-like pathways. The absorption of phenolsulfonphthalein during proestrus and estrus is roughly one-tenth of that during metestrus and diestrus. An increase of the nonionized form of salicylic acid, produced by a lowered pH, resulted in an enhancement of absorption during proestrus and diestrus; higher contribution of the transport through the cell membrane possibly reduced an effect of the estrous cycle. However, consecutive daily administration of leuprolide halted the cycle at diestrus and reduced the cycle effect on the vaginal absorption of phenolsulfonphthalein; when the treatment was started at any of the four stages of the cycle, vaginal absorption was enhanced ~20%, with less variance than that observed in normal diestrous rats.

EXPERIMENTAL

Animals and Materials—Mature female Sprague-Dawley rats[1] (age, 120–150 days; weighing 250–330 g) exhibiting two or more consecutive 4-day estrous cycles were used.

Leuprolide and insulin were of the same quality used previously (1, 2), and the other chemicals were of reagent grade.

Effect of Estrous Cycle on Vaginal Absorption of Insulin and Phenolsulfonphthalein—Twenty units of porcine insulin (26.29 U/mg) in an oleaginous base[2] containing 10% citric acid was administered vaginally to proestrous, estrous, metestrous, and diestrous rats under pentobarbital (50 mg/kg) and phenobarbital (100 mg/kg) anesthesia. Blood was collected from the tail vein 0.5, 1, 2, 3, 4, and 6 hr after the administration, and 30 μl of the plasma was used for the assay of glucose levels (2).

Phenolsulfonphthalein was administered vaginally at a dose of 2 mg/kg/0.2 ml in pH 6.68, 0.03 *M* phosphate buffer solution (isotonic) to rats exhibiting the four different stages of the estrous cycle. Phenolsulfonphthalein in the urine collected for 6 hr by cannula was determined (2).

Vaginal Absorption of Salicylic Acid at Various pHs in Diestrous and Proestrous Rats—Salicylic acid dissolved at 1% in 0.2 *M* phthalate–hydrochloric acid buffer (pH 3.49), 0.2 *M* phthalate–sodium hydroxide buffer (pH 4.08 and 4.80), 0.1 *M* glycine–hydrochloric acid buffer (pH 3.53 and 4.53), and 0.03 *M* phosphate buffer (pH 5.73), and at 0.4% in 0.2 *M* potassium chloride–hydrochloric acid buffer (pH 2.29), was

$pH_{observed}$ (buffer)	Diestrus	Proestrus
2.29 (KCl–HCl)	7.1(1.5)[b]	10.4(2.5)
3.49 (phthalate)	18.2(2.1)	28.9(10.0)
3.53 (glycine)	44.0(1.8)	80.7(0.7)
4.08 (phthalate)	32.0(2.8)	58.3(2.9)
4.53 (glycine)	55.8(5.2)	82.1(11.4)
4.80 (phthalate)	35.2(2.1)	71.4(1.1)
5.73 (phosphate)	32.1(3.5)	71.3(12.2)

[a] Salicylic acid was administered at a dose of 2 mg/kg/0.2 ml, except at pH 2.29 (0.8 mg/kg/0.2 ml). [b] Each value represents the mean ± *SE* of three rats.

administered vaginally at a dose of 0.2 ml/kg with cotton balls to diestrous and proestrous rats under anesthesia. Each solution was adjusted to be isotonic with sodium chloride. Rats were decapitated 1 hr after administration, and the salicylic acid remaining in the vaginal tract was determined by a modified method (6). The vaginal tract was homogenized[3] in 5 ml of 0.9% NaCl solution and extracted with 8 ml of ethylene dichloride after acidification by the addition of 1 ml of 6 *N* HCl. Six milliliters of the organic layer was re-extracted with 4 ml of iron reagent [0.05% $Fe(NO_3)_3$–0.0035 *N* HNO_3 solution]. Absorbance of the aqueous layer was determined spectrophotometrically at 530 nm.

Vaginal Absorption of Phenolsulfonphthalein after Consecutive Subcutaneous Injection of Leuprolide—Leuprolide (100 μg/kg) was administered subcutaneously once a day for 10 consecutive days to rats exhibiting four different stages of estrous cycle on the initial day, and the vaginal smear was examined during administration. Phenolsulfonphthalein was administered vaginally at a dose of 2 mg/kg/0.2 ml in 5% citric acid solution (pH 3.5) with cotton balls to the pretreated animals, and the urinary excretion was determined (2).

RESULTS

Effect of Estrous Cycle on Vaginal Absorption of Insulin and Phenolsulfonphthalein—The plasma levels of glucose after vaginal administration of insulin to rats at different stages of the estrous cycle are shown as a percentage against the initial level (100%) in Fig. 1. A slight decrease of glucose level was observed only at an early period during proestrus; whereas, a distinct decrease was obtained during estrus and a more remarkable decrease during metestrus and diestrus. The integrated values (mean ± *SE*) of decreased plasma glucose level from 0 to 6 hr were −14.2 ± 38.2% hr for proestrus, 142.1 ± 94.2% hr for estrus, 364.2 ± 12.7% hr for metestrus, and 378.8 ± 9.3% hr for diestrus.

Vaginal absorption of phenolsulfonphthalein during the estrous cycle is shown by the urinary excretion in Fig. 2. The percentage excreted

[a] (I) proestrus; (III) estrus; (IV) metestrus; (V) diestrus. The analogue was administered once a day at a dose of 100 μg/kg, and the stage of estrous cycle was determined by an examination of vaginal smears each morning. [b] (—) not determined.

(mean ± *SE*) of dose in 6 hr after vaginal administration of phenolsulfonphthalein was 31.4 ± 5.3% during diestrus, 37.5 ± 1.6% during metestrus, 5.5 ± 1.1% during estrus, and 2.4 ± 0.3% during proestrus.

The estrous cycle stage affects vaginal absorption of both insulin and phenolsulfonphthalein.

Vaginal Absorption of Salicylic Acid at Various pHs in Diestrous and Proestrous Rats—The remaining percentage of salicylic acid 1 hr after vaginal administration at various pHs to diestrous and proestrous rats (Table I) are plotted together with the calculated fraction of the ionized form (pK_a of the acid, 3.00) against the pH of the solution in Fig. 3. The disappearance of the acid from the vaginal tract during diestrus was relatively rapid even at pHs where most of the acid was ionized (pH 4.08, 4.80, and 5.73), and the disappearance rate increased at lower pH (pH 3.49 and 2.29). During proestrus the disappearance rate was reduced in nonionized form, but at lower pHs it approached the rate observed during diestrus. The disappearance rate of the ionized form was 66%/hr for diestrus and 29%/hr for proestrus. The absorption from the glycine buffer solutions (pH 3.53 and 4.53) was reduced during both stages.

Vaginal Absorption of Phenolsulfonphthalein after Consecutive Subcutaneous Injection of Leuprolide—After one normal estrous cycle, all rats treated with leuprolide settled in the diestrous stage (Table II). No matter at which stage of the estrous cycle the pretreatment began, the urinary excretion of phenolsulfonphthalein was enhanced ~20% with less variance compared to excretion in the untreated diestrous rats, especially during the 3 hr immediately following vaginal administration (Fig. 4).

DISCUSSION

Vaginal absorption of insulin and phenolsulfonphthalein in rats was dependent on the stage of estrous cycle: absorption was poor during proestrus, slightly improved during estrus, and good during metestrus and diestrus. These results can be explained by changes in vaginal epithelium (3) as follows. The epithelium during metestrus and diestrus is thin and highly porous, so many leukocytes can migrate through it. During proestrus, the superficial layers consist of tightly bound fresh cells and the epithelium is at its thickest. During estrus, the superficial layers become squamous, cornified, and are exfoliated into the vaginal lumen.

To estimate the absorption pathway of hydrophilic and hydrophobic compounds, vaginal absorption for the nonionized and ionized form of salicylic acid was also investigated during proestrus and diestrus. The disappearance of the nonionized acid from the vagina was increased markedly, and similar rates occurred during both stages. The disappearance of the ionized form was different: 66% of the dose in 1 hr during diestrus and 29% during proestrus. In a previous study (1), it was postulated that transport through pore-like pathways, such as intercellular channels, rather than permeation by partition to the cell membrane should cause good absorption of hydrophilic compounds. Thus, the postulation may be supported by the fact that the vaginal absorption of hydrophilic compounds highly depend on the estrous cycle stages which dominate the change of porosity of the membrane. The results also reveal the possibility of vaginal application of hydrophilic compounds during diestrus and metestrus. The high disappearance rate at lowered pHs during both stages possibly are caused by the increased permeation of the nonionized form through the cell membrane, and, in the case of salicylic acid, by the enhancing effect on the mucosal absorption of the drug (7). Since such an enhancing effect was not observed with phenolsulfonphthalein, the vaginal absorption would be more dependent on transport through pore-like pathways. Thus, the apparent porosity during diestrus is presumed to be more than 10 times that during proestrus and estrus (Fig. 2).

In addition, the correlation curve of the remaining percent of salicylic acid with pH during diestrus and proestrus shifted in the direction of higher pH than the theoretical ionized fraction *versus* pH curve (Fig. 3). This phenomenon may be ascribed to the pH difference between bulk solution and the unstirred layer on the membrane or the absorption-enhancing effect of the acid itself. The absorption from glycine buffer was significantly reduced during both proestrus and diestrus. Glycine also reduced the ovulation-inducing activity of leuprolide applied vaginally in an oleaginous base (1). The effects may be due to the stabilizing activity of glycine on the epithelial membrane.

The vaginal epithelium of a mature woman is known to change during the menstrual cycle, and changes of surface ultrastructure have been reported (4). In the follicular phase, the surface of the epithelium consists of a cluster of proliferated, nonkeratinized squamous cells. In the luteal phase, desquamation takes place on the superficial epithelial layer, proceeded by loosening of the intercellular grooves. After ovulation, intercellular porosity is confirmed by the observation of pore-like intercellular crevices and open intercellular connections (dissociated desmosomes). Thus, a similar effect of the reproductive cycle on the vaginal absorption may be expected as observed in rats. The vaginal epithelium is also subject to change with aging (neonate, prepuberty, adult, and senescence), pregnancy, and hormonal disorder. These specific structural changes of vaginal epithelium would influence vaginal absorption, and must be taken into account as a significant factor in the vaginal application of drugs, especially of hydrophilic compounds.

Previously, the continuous administration of leuprolide was found to affect the estrous cycle of rats (5). In the present study, it was confirmed by daily cytological examination of vaginal smears that the cycle was halted at the subsequent diestrus by consecutive treatment with the analogue. During the treatment, the vaginal mucosa was thin and similar to that of normal diestrus except that the smear contained more mucilage.

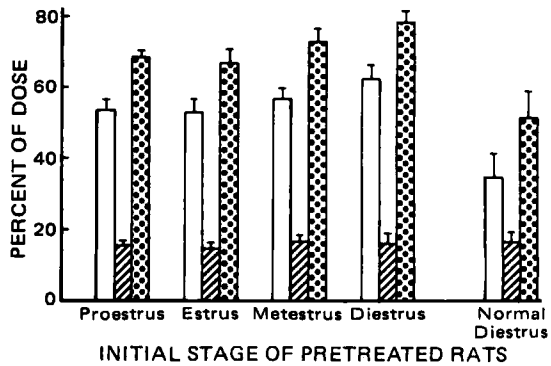

Figure 4—*Urinary excretion of phenolsulfonphthalein after vaginal administration to rats pretreated subcutaneously with leuprolide for 10 days. Phenolsulfonphthalein was administered vaginally at a dose of 2 mg/kg/0.2 ml in 5% citric acid solution (pH 3.5) to rats pretreated with 100 μg/kg/day of the analogue. Each bar represents the mean ± SE of four or five (normal) rats. Key: (□) 0–3 hr; (▨) 3–6 hr; (▩) total.*

Furthermore, the vaginal absorption of phenolsulfonphthalein after the consecutive administration resulted in an enhanced absorption with less variance, regardless of the initial stage of the estrous cycle (Fig. 4). The better absorption supports the halt of the cycle at diestrus and possibly reveals the thinner epithelial membrane.

In long-term therapy with vaginal application of leuprolide, the reproductive cycle effects would be leveled off by continuous administration, either parenterally or vaginally, although some fluctuation in absorption may be unavoidable at the initial period of administration. The authors' previous proposal of the vaginal application of leuprolide as a rational method for long-term anticancer therapy was supported by the findings of the present study.

Methaqualone–Diphenhydramine Interaction Study in Humans

K. W. HINDMARSH *x, S. M. WALLACE *, C. B. SCHNEIDER *, and E. D. KORCHINSKI ‡

Received November 3, 1981, from the **College of Pharmacy and* ‡*College of Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.* Accepted for publication April 12, 1982.

Abstract □ Twelve healthy subjects received three single oral doses (250 mg) of methaqualone alone or in combination with diphenhydramine (25 mg). Blood samples were collected for a 48-hr period after each dose and analyzed for methaqualone and its major metabolite, 2-methyl-3-(2′-hydroxymethylphenyl)-4(3H)-quinazolinone. Peak blood concentrations ranging from 1.0 to 2.7 μg/ml occurred ~1–2 hr after the oral dose. The area under the blood level–time curve, peak plasma level, and elimination half-life for methaqualone were not significantly different (three-way ANOVA, $p > 0.05$) when methaqualone was administered alone, in combination with a diphenhydramine elixir or as a commercial product (capsule) containing both methaqualone and diphenhydramine. Statistically significant intersubject differences in the area under the curve were eliminated if the area was corrected for subject differences in elimination. Blood levels of the metabolite reached an average peak of 314 ng/ml (±107) between 4 and 8 hr after the dose and remained elevated for the 48-hr sampling period. The areas under the blood level time curve of the metabolite were not significantly different for the three treatments. Diphenhydramine administered at the dosage level used in therapeutic combination products did not alter the blood levels of methaqualone or its metabolite. In addition, no significant differences in methaqualone availability from the two commercial formulations tested could be detected.

Keyphrases □ Methaqualone—interaction study with diphenhydramine in humans, elimination, metabolism □ Diphenhydramine—interaction study with methaqualone in humans, elimination, metabolism □ Elimination—methaqualone–diphenhydramine interaction study in humans, metabolism □ Metabolism—methaqualone–diphenhydramine interaction study in humans, elimination

Although the therapeutic use of the methaqualone–diphenhydramine combination has declined, abuse continues to flourish (1–3). The reasons for the enhanced CNS effects claimed by drug abusers is not clearly understood.

Metabolism of methaqualone by the 10,000-g supernatant fraction of rat liver homogenates is inhibited *in vitro* by diphenhydramine (4). Concurrent oral administration of methaqualone and diphenhydramine to rats increases the blood and brain levels of methaqualone (3), whereas concurrent intravenous administration has no significant effect (5).

In humans, diphenhydramine has been credited with increasing the sedative-hypnotic effect of methaqualone (6), although the mechanism has not been elucidated. A previous study (7) compared methaqualone plasma concentrations achieved after administration of two commercially available diphenhydramine–methaqualone combination products and three methaqualone products. Differences in plasma levels were noted and attributed to formulation factors. An earlier study (8), comparing plasma levels after single dose administration of commercial products containing methaqualone, methaqualone hydrochloride, and methaqualone plus diphenhydramine, is difficult to interpret since no subject appears to have received more than one formulation. In a subsequent study (9) reduction of buccal absorption was reported when methaqualone powder was administered with diphenhydramine powder, but there was no difference in plasma levels after oral administration of the combination.

The objective of the present study was to compare, in healthy subjects, the concentrations of methaqualone and its major metabolite in blood (2-methyl-3-(2′-hydroxymethylphenyl)-4(3H)-quinazolinone), after administration of methaqualone alone and in combination with diphenhydramine. The possibility of a formulation effect was anticipated by including in the study design administration of diphenhydramine–methaqualone as a commercial combination product and as a mixture of a methaqualone capsule and diphenhydramine elixir.

Methaqualone–Diphenhydramine Interaction Study in Humans

K. W. HINDMARSH *x, S. M. WALLACE *, C. B. SCHNEIDER *, and E. D. KORCHINSKI ‡

Received November 3, 1981, from the **College of Pharmacy and* ‡*College of Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.* Accepted for publication April 12, 1982.

Abstract □ Twelve healthy subjects received three single oral doses (250 mg) of methaqualone alone or in combination with diphenhydramine (25 mg). Blood samples were collected for a 48-hr period after each dose and analyzed for methaqualone and its major metabolite, 2-methyl-3-(2′-hydroxymethylphenyl)-4(3H)-quinazolinone. Peak blood concentrations ranging from 1.0 to 2.7 μg/ml occurred ~1–2 hr after the oral dose. The area under the blood level–time curve, peak plasma level, and elimination half-life for methaqualone were not significantly different (three-way ANOVA, $p > 0.05$) when methaqualone was administered alone, in combination with a diphenhydramine elixir or as a commercial product (capsule) containing both methaqualone and diphenhydramine. Statistically significant intersubject differences in the area under the curve were eliminated if the area was corrected for subject differences in elimination. Blood levels of the metabolite reached an average peak of 314 ng/ml (±107) between 4 and 8 hr after the dose and remained elevated for the 48-hr sampling period. The areas under the blood level time curve of the metabolite were not significantly different for the three treatments. Diphenhydramine administered at the dosage level used in therapeutic combination products did not alter the blood levels of methaqualone or its metabolite. In addition, no significant differences in methaqualone availability from the two commercial formulations tested could be detected.

Keyphrases □ Methaqualone—interaction study with diphenhydramine in humans, elimination, metabolism □ Diphenhydramine—interaction study with methaqualone in humans, elimination, metabolism □ Elimination—methaqualone–diphenhydramine interaction study in humans, metabolism □ Metabolism—methaqualone–diphenhydramine interaction study in humans, elimination

Although the therapeutic use of the methaqualone–diphenhydramine combination has declined, abuse continues to flourish (1–3). The reasons for the enhanced CNS effects claimed by drug abusers is not clearly understood.

Metabolism of methaqualone by the 10,000-g supernatant fraction of rat liver homogenates is inhibited *in vitro* by diphenhydramine (4). Concurrent oral administration of methaqualone and diphenhydramine to rats increases the blood and brain levels of methaqualone (3), whereas concurrent intravenous administration has no significant effect (5).

In humans, diphenhydramine has been credited with increasing the sedative-hypnotic effect of methaqualone (6), although the mechanism has not been elucidated. A previous study (7) compared methaqualone plasma concentrations achieved after administration of two commercially available diphenhydramine–methaqualone combination products and three methaqualone products. Differences in plasma levels were noted and attributed to formulation factors. An earlier study (8), comparing plasma levels after single dose administration of commercial products containing methaqualone, methaqualone hydrochloride, and methaqualone plus diphenhydramine, is difficult to interpret since no subject appears to have received more than one formulation. In a subsequent study (9) reduction of buccal absorption was reported when methaqualone powder was administered with diphenhydramine powder, but there was no difference in plasma levels after oral administration of the combination.

The objective of the present study was to compare, in healthy subjects, the concentrations of methaqualone and its major metabolite in blood (2-methyl-3-(2′-hydroxymethylphenyl)-4(3H)-quinazolinone), after administration of methaqualone alone and in combination with diphenhydramine. The possibility of a formulation effect was anticipated by including in the study design administration of diphenhydramine–methaqualone as a commercial combination product and as a mixture of a methaqualone capsule and diphenhydramine elixir.

EXPERIMENTAL

Materials—Methaqualone hydrochloride[1], 1-chlorobutane[2], ammonium carbonate[3], imipramine hydrochloride[4], bis-(trimethylsilyl)-trifluroacetamide with trimethylchlorosilane (1%)[5], dichloromethane[6], ethyl acetate[6], and glacial acetic acid[7] were obtained commercially and appropriate aqueous or methanolic solutions were prepared as required. The solvent used for extracting biological fluids was prepared by mixing dichloromethane with ether (11:14 v/v) (10). An acetate buffer (pH 5.2) was prepared by mixing 21 ml of 0.1 *M* acetic acid with 79 ml of 0.1 *M* sodium acetate.

***In Vitro* Blood–Plasma Distribution Studies**—Methaqualone hydrochloride (1 μg/ml of solution in methanol) was added to Erlenmyer flasks in sufficient quantity to produce a final methaqualone hydrochloride concentration of 1–20 μg/ml (0.87–17.5 μg/ml of methaqualone). The methanol was evaporated and 20 ml of blood[8] added. The flasks were covered[9] and incubated[10] for 2 hr (37°). Two hours had been established previously as sufficient time to ensure equilibration. A portion of the blood from each flask was centrifuged[11] to separate plasma. Aliquots (1 ml) of blood and plasma were extracted and methaqualone concentrations were determined by GLC. Hematocrits were determined[12] and red blood cell concentrations were calculated (11).

Study Design—Twelve volunteers (4 female, 8 male) weighing between 50.2 and 83.9 kg each and ranging in age from 21 to 38 years participated in the study. All subjects received a medical examination and a series of standard laboratory tests prior to entering the study. All subjects gave their written informed consent according to an approved[13] *protocol.*

Each subject received a single dose each of methaqualone hydrochloride in a 250-mg capsule[14], methaqualone hydrochloride capsule[14] plus 25 mg of diphenhydramine hydrochloride [elixir][15] and a methaqualone (250 mg)–diphenhydramine hydrochloride (25 mg) capsule[16]. The order of treatments was randomized according to a Latin-square design with a minimum period of 2 weeks between each treatment (*i.e.*, each drug administration). Drugs were administered with water after a 12-hr fast. Food was not consumed until at least 4 hr after the drugs had been administered. One subject received a fourth treatment of methaqualone hydrochloride and 50 mg of diphenhydramine hydrochloride[17].

Blood samples (7 ml) were collected[18] at 0, 0.5, 1, 2, 4, 8, 24, 32, and 48 hr after each drug administration, and were refrigerated until extracted and analyzed for methaqualone concentration by GLC. For 9 of the 12 subjects, blood samples were also analyzed for 2-methyl-3-(2'-hydroxymethylphenyl)-4(3H)-quinazolinone by GLC. All samples were extracted within 48 hr of collection.

A portion of the blood collected for five of the subjects, after one of the drug doses, was centrifuged[11] to separate plasma. Both plasma and blood samples were analyzed for methaqualone by GLC.

GLC–mass spectrometry was performed on a GLC-mass spectrometer linked to a data system[19].

Extraction of Biological Fluids—For samples from *in vitro* studies, aliquots (1 ml) of blood and plasma were added to centrifuge tubes containing the internal standard, imipramine (4 μg). The samples were diluted with distilled water (1 ml), basified (10 *M* NaOH) and extracted[20] twice with 1-chlorobutane (5 ml) for 1.0 min. The pooled organic layers were evaporated[21] (at 85°) to dryness under a flow of air. The residue was quantitatively transferred to glass vials (1 ml)[22] using small portions of methanol. The methanol was evaporated[23]. The residue was dissolved in methanol (20 μl) and 1–2 μl injected onto the GLC.

Table I—*In Vitro* Distribution of Methaqualone Between Plasma and Erythrocytes

Methaqualone Concentration, μg/ml			
Blood[a], C_B	Plasma, C_P	Erythrocytes[b], C_{RBC}	Blood–Plasma Ratio
1.0	1.25	0.60	0.80
2.0	2.37	1.41	0.84
3.0	3.30	2.52	0.91
4.0	4.71	2.87	0.85
5.0	4.47	5.72	1.12
10.0	6.20	15.1	1.61
15.0	8.20	24.2	1.83
20.0	9.03	34.8	2.21

[a] Concentration added to blood. [b] Calculated from $C_B = C_P(1 - H) + C_{RBC}(H)$, where the hematocrit (H) is 38.5% for concentrations of 1–4 μg/ml and 42.5% for concentrations of 5–20 μg/ml.

Table II—*In Vivo* Distribution of Methaqualone in Blood[a]

Time after Administration, hr	Methaqualone Concentration, μg/ml		Blood–Plasma Ratio
	Blood	Plasma	
0	0	0	
0.5	0.44 ± 0.46	0.47 ± 0.31	0.95 ± 0.03[b]
1	1.10 ± 0.64	1.21 ± 0.69	0.90 ± 0.14
2	1.18 ± 0.14	1.32 ± 0.22	0.90 ± 0.09
4	0.66 ± 0.12	0.80 ± 0.10	0.82 ± 0.09
8	0.42 ± 0.09	0.50 ± 0.07	0.82 ± 0.05
24	0.24 ± 0.02	0.25 ± 0.02	0.97 ± 0.05
32	0.21 ± 0.02	0.23 ± 0.02	0.92 ± 0.06
48	0.17 ± 0.01	0.19 ± 0.02	0.93 ± 0.09

[a] Values are the mean ± *SD* for 5 subjects (1, 6, 8, 10, and 12) with hematocrits of 0.45, 0.48, 0.52, 0.42, and 0.47, respectively. [b] Two of five blood and plasma concentrations had a value of zero at 0.5 hr.

For analysis of samples from the *in vivo* study, 1-ml aliquots of blood or plasma were diluted with 1 ml of distilled water containing 3 μg/ml of imipramine hydrochloride. Ammonium carbonate (1 g) was added, and the samples were extracted twice with 4 ml of ether–dichloromethane (14:11) for 10 min[23]. The tubes were centrifuged at 2000 rpm[11] for 10 min. The pooled organic layers were evaporated[21] at 85° under a gentle flow of nitrogen. The residue was dissolved in 500 μl of methanol. For analysis of methaqualone concentrations, 2–5-μl aliquots were injected onto the GLC. For analysis of the methaqualone metabolite in blood the remaining methanol was evaporated under a flow of nitrogen. Silyl ether derivatives were prepared by adding ethyl acetate (300 μl dried over molecular sieves) and bis-(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane (50 μl) to the residue in each tube. The tubes were capped and incubated[21] at 85° for 1 hr. The solvent was evaporated under a flow of nitrogen. The residue was dissolved in ethyl acetate (500 μl), and 2–5-μl aliquots were injected onto the GLC.

GLC Analysis—For analysis of samples from *in vitro* studies, a GLC[24] equipped with a flame-ionization detector was used. The chromatographic column was 1.2-m × 3.2-mm o.d. coiled, stainless-steel tubing packed with 3% methyl silicone coated on a high-performance diatomite support (80–100 mesh)[25]. The column was conditioned by maintaining the oven at 290° with low carrier gas flow for 18 hr. Operating temperatures were: injection port, 270°; column, 220°; detector, 265°.

The nitrogen flow was 30 ml/min. Hydrogen and compressed air flow rates were adjusted to give maximum response. Methaqualone concentrations were determined from a standard curve plotted as the peak height ratio (methaqualone–internal standard) against methaqualone concentration.

For analysis of methaqualone and its metabolite in blood obtained during the *in vivo* study, a GLC[26] equipped with a nitrogen–phosphorus detector was used. The chromatographic column was 1.2-m × 2.0-mm i.d. coiled-glass tubing packed with 2% methyl silicone on a high-performance diatomite support (100–120 mesh)[25]. Operating temperatures were: injection and detector ports, 300°; column, 240° (for methaqualone) or 220° (for the methaqualone metabolite). The helium flow rate was 30 ml/min, and the hydrogen and compressed air flow rates were adjusted to 3 ml/min and 50 ml/min, respectively. Concentrations of methaqualone and its metabolite were calculated from standard curves plotted as peak area (methaqualone) or peak height (metabolite) ratio (compound–internal standard) against concentration. All standard curves for analysis of samples were prepared as extracted standard curves by adding known amounts of methaqualone (or metabolite) to blood and extracting the standards as previously described.

Data Analysis—Slope and intercept of standard curves were calculated by least-squares linear regression[27]. The disposition rate constant (β) for methaqualone was determined by log-linear regression[27] of the last 3–4 data points of the blood level–time curve. The biological half-life ($t_{1/2\beta}$) was calculated as $0.693/\beta$. The area under the blood level time curve for methaqualone (AUC_0^{48}) and its metabolite ($AUC_{0\,met}^{48}$) was estimated using the trapezoidal rule. To obtain the total area under the curve for methaqualone (AUC_0^∞), the area from the last sampling point to infinity (plasma level at 48 hr/β) was added to AUC_0^{48}. All parameters, except the time of peak plasma levels (t_{max}) and $t_{1/2\beta}$, were corrected for subject differences in the milligram per kilogram dose (*i.e.*, by dividing by the ratio of the dose of methaqualone base to the subject's weight) (12). The AUC_0^∞ was corrected for changes in elimination by multiplying by β ($AUC_0^\infty\,\beta$). All parameters (AUC_0^{48}, AUC_0^∞, $AUC_0^\infty\beta$, $AUC_{0\,met}^{48}$, t_{max}, C_{max}, and $t_{1/2\beta}$) were then analyzed statistically by three-way ANOVA[28] for treatment, period (*i.e.*, order of treatment), and subject effects; effects were considered significant if $p \leq 0.05$.

RESULTS AND DISCUSSION

GLC analysis of blood extracts revealed a well-defined peak (I, Fig. 1B) adequately separated from the internal standard, imipramine, (Peak II, Fig. 1B) and endogenous material (Fig. 1A). Peak I was identified, by GLC–mass spectrometry, as methaqualone. A molecular ion at m/z 250 and the base peak at m/z 235 due to the loss of the methyl group at the 2-position of the molecular ion were noted. A column temperature of 240° gave a relative retention time (with respect to imipramine) of 0.86 min for methaqualone. The standard curve for the GLC analysis of methaqualone was linear (r^2, coefficient of determination = 0.996) over a concentration range of 0.15–2.40 μg/ml.

Chromatography of silylated blood samples revealed one major peak (Peak II, Fig. 2B) not found in control blood extracts (Fig. 2A). Peak II (Fig. 2B) had a relative retention time of 1.39 min with respect to the internal standard, imipramine (Peak I, 2B). GLC–MS confirmed that Peak II was the trimethylsilyl derivative of the monohydroxy methaqualone metabolite, 2-methyl-3-(2′-hydroxymethylphenyl)-4(3H)-quinazolinone. Similar fragment ions to those previously reported for this metabolite (13, 14) were detected. The standard curve for GLC analysis of the metabolite was linear (r^2, coefficient of determination = 0.99) over a concentration range of 0.06–0.96 μg/ml. Mean recoveries of methaqualone and the metabolite from blood were 89.4 ± 6.6 (*SD*) and 87.2 ± 11.2%, respectively.

While forensic studies of methaqualone overdosage tend to report blood levels of the drug (15–17), pharmacokinetic studies measure the concentration of the drug in plasma or serum (18–20). Erythrocyte concentrations at <50% of the corresponding plasma concentration have been reported (9, 21). Another study (22) claimed >90% of the methaqualone in plasma phase with little, if any, bound to the cellular elements of blood. In the present report, however, concentrations of methaqualone in blood and plasma did not differ greatly except for blood concentrations of 5 μg/ml or greater (Table I).

After administration of a single 250-mg dose of methaqualone to healthy subjects, the blood–plasma ratio of methaqualone concentrations ranged from 0.82 to 0.97 over the 48-hr period studied (Table II). *In vitro* distribution studies yielded similar results for the concentration range of 1–4 μg/ml of blood. At higher blood concentrations, *in vitro*, erythrocyte concentrations of methaqualone were significantly greater than plasma concentrations (Table I). A larger fraction free in plasma would not account for the changing blood–plasma ratios, since a relatively constant fraction (95%) of methaqualone is bound *in vitro* to human plasma proteins over the concentration range of 5–20 μg/ml plasma (unpublished observations).

One may speculate that larger blood–plasma ratios result from a cooperative binding to erythrocytes at higher methaqualone concentrations. The reasons for the apparent accumulation in erythrocytes were not investigated. Blood and plasma concentrations appear to be approximately equivalent at the lower methaqualone concentrations encountered in pharmacokinetic studies. However, in overdose cases, blood and plasma

levels may not be equivalent and the difference should perhaps be considered when evaluating a patient. For the purposes of the present investigation, blood was chosen as the biological fluid for analysis, because cleaner extracts with less GLC baseline interference were obtained.

To determine whether methaqualone blood levels differed when methaqualone was administered orally with diphenhydramine, blood was sampled over a 48-hr period in 12 healthy subjects. Data from subject 6 are presented as representative of methaqualone blood levels achieved with oral administration of a single dose of methaqualone with and without diphenhydramine (Fig. 3). The time of blood collection (48 hr) was too short to obtain a pharmacokinetically accurate value for the elimination half-life, but the estimates for $t_{1/2}$ were within the range previously reported for methaqualone (19.6–41.5 hr) (18). Peak blood levels ranged from 1.0–2.7 μg/ml at 1–2 hr after oral administration (Table IV). The t_{max} and $t_{1/2\beta}$ values were not significantly different for the three treatments (methaqualone HCl capsule, methaqualone HCl capsule plus diphenhydramine elixir, methaqualone–diphenhydramine capsule). All other parameters were corrected for the mg/kg dose of methaqualone administered. No treatment or formulation effect was evident for AUC_0^{48}, AUC_0^{∞}, $AUC_0^{\infty}\beta$, or C_{max} (p for treatments >0.05) (Table III). The power of the statistical test was such that a difference of 20% would have been detected (23). Significant intersubject differences (p <0.05) were noted for AUC_0^{48}, AUC_0^{∞}, C_{max}, and $t_{1/2\beta}$. No significant intersubject differences in $AUC_0^{\infty}\beta$ were apparent, thus suggesting the major factor contributing to intersubject differences in the AUC value for methaqualone was the elimination of the drug.

Maximum blood levels of the methaqualone metabolite, 2-methyl-3(2′-hydroxymethylphenyl)-4(3H)-quinazolinone), occurred between 4 and 8 hr after methaqualone administration and remained elevated over the 48-hr sampling time (Fig. 4). The average maximum metabolite level was 314 ng/ml ± 107 (SD). The $AUC_{0\,met}^{48}$ values after administration of methaqualone with and without diphenhydramine were not significantly different.

No major differences in blood levels could be detected between the methaqualone HCl capsule and methaqualone–diphenhydramine HCl capsule formulation. Diphenhydramine administered at the dosage level

48	0.16 ± 0.07	0.16 ± 0.07	0.18 ± 0.06

[a] Values (μg/ml) are the mean ± *SD* for 12 subjects. [b] Means were calculated using the approximate time of blood collection; exact collection times were recorded and used for *AUC* and $t_{1/2}$ determinations.

used in therapeutic combination products (25 mg) did not affect blood levels of methaqualone or its major metabolite.

An important consideration, in comparing the present study conducted in healthy humans to previous studies conducted in the rat (3), may be the relative doses of diphenhydramine and methaqualone hydrochloride administered. Although the ratio of methaqualone–diphenhydramine doses were similar (8:1 for rats and 10:1 for humans), the doses administered per kilogram of body weight were higher in animal studies (40 mg/kg for methaqualone HCl; 5 mg/kg for diphenhydramine HCl) than in human studies (3.7 mg/kg for methaqualone HCl and 0.4 mg/kg for diphenhydramine HCl). For the one subject who received a fourth dose of methaqualone in combination with a larger dose of diphenhydramine (50 mg), the $t_{1/2}$ for methaqualone increased and the urinary metabolite excretion decreased with increasing diphenhydramine dosage. While the AUC_0^∞ had increased, after correction for the increase in $t_{1/2}$, the $AUC_0^\infty\beta$ had decreased with the larger diphenhydramine dosage. Thus, larger doses of diphenhydramine, as might be favored by drug abusers, may elicit a pharmacokinetic interaction. The possibility of a dose-dependent interaction was not specifically investigated and would require further study.

This study was concerned only with investigating a pharmacokinetic interaction, and therefore does not preclude the possibility of a pharmacological interaction between methaqualone and diphenhydramine.

Photolytic Decomposition of Hydrochlorothiazide

SWASONO R. TAMAT and DOUGLAS E. MOORE ˣ

Received January 25, 1982, from the *Department of Pharmacy, The University of Sydney, Sydney 2006, Australia.* Accepted for publication April 9, 1982.

Abstract □ Hydrochlorothiazide decomposes upon irradiation with near-UV light ($\lambda > 310$ nm) both in methanol and aqueous solutions. In the photolysis the chlorine substituent is removed to be replaced by either —H or —OR from the solvent ROH. Hydrolysis of the thiadiazine ring is superimposed upon the dechlorination. The presence of oxygen inhibits the decomposition. The mechanism of the photolysis is suggested to involve cation radical formation which facilitates the hydrolysis step. 5-Chloro-2,4-disulphonamido-aniline, the normal hydrolysis product from hydrochlorothiazide, is also susceptible to photolytic dechlorination by a similar mechanism.

Keyphrases □ Hydrochlorothiazide—photolytic decomposition, irradiation, dechlorination, hydrolysis □ Decomposition, photolytic—hydrochlorothiazide, irradiation, dechlorination, hydrolysis □ Hydrolysis—photolytic decomposition of hydrochlorothiazide, dechlorination, irradiation

used in therapeutic combination products (25 mg) did not affect blood levels of methaqualone or its major metabolite.

An important consideration, in comparing the present study conducted in healthy humans to previous studies conducted in the rat (3), may be the relative doses of diphenhydramine and methaqualone hydrochloride administered. Although the ratio of methaqualone–diphenhydramine doses were similar (8:1 for rats and 10:1 for humans), the doses administered per kilogram of body weight were higher in animal studies (40 mg/kg for methaqualone HCl; 5 mg/kg for diphenhydramine HCl) than in human studies (3.7 mg/kg for methaqualone HCl and 0.4 mg/kg for diphenhydramine HCl). For the one subject who received a fourth dose of methaqualone in combination with a larger dose of diphenhydramine (50 mg), the $t_{1/2}$ for methaqualone increased and the urinary metabolite excretion decreased with increasing diphenhydramine dosage. While the AUC_0^∞ had increased, after correction for the increase in $t_{1/2}$, the $AUC_0^\infty\beta$ had decreased with the larger diphenhydramine dosage. Thus, larger doses of diphenhydramine, as might be favored by drug abusers, may elicit a pharmacokinetic interaction. The possibility of a dose-dependent interaction was not specifically investigated and would require further study.

This study was concerned only with investigating a pharmacokinetic interaction, and therefore does not preclude the possibility of a pharmacological interaction between methaqualone and diphenhydramine.

Photolytic Decomposition of Hydrochlorothiazide

SWASONO R. TAMAT and DOUGLAS E. MOORE ˣ

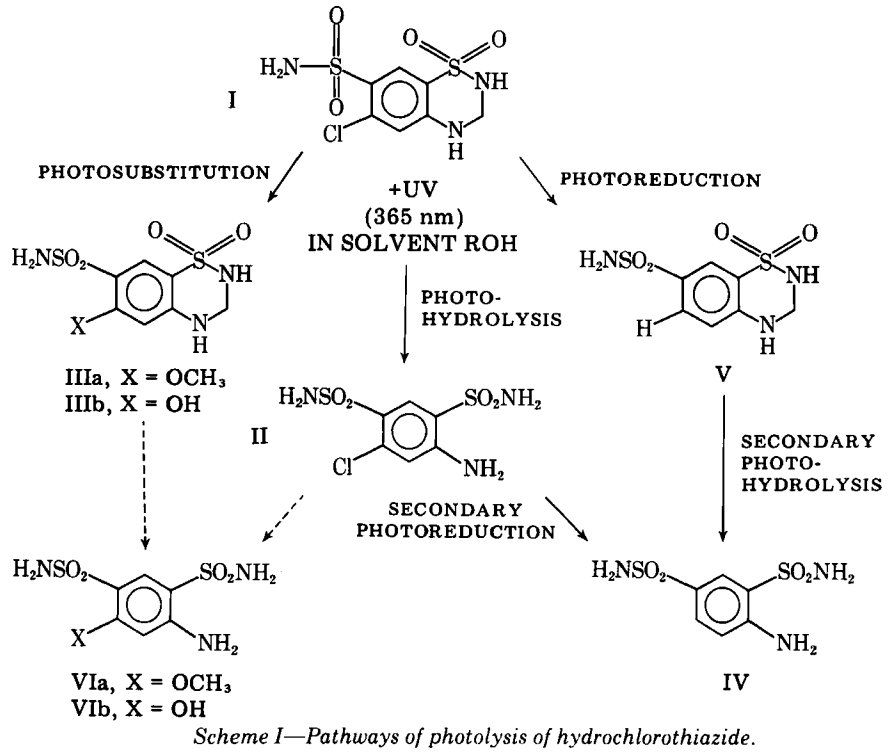
Received January 25, 1982, from the *Department of Pharmacy, The University of Sydney, Sydney 2006, Australia.* Accepted for publication April 9, 1982.

Abstract □ Hydrochlorothiazide decomposes upon irradiation with near-UV light ($\lambda > 310$ nm) both in methanol and aqueous solutions. In the photolysis the chlorine substituent is removed to be replaced by either —H or —OR from the solvent ROH. Hydrolysis of the thiadiazine ring is superimposed upon the dechlorination. The presence of oxygen inhibits the decomposition. The mechanism of the photolysis is suggested to involve cation radical formation which facilitates the hydrolysis step. 5-Chloro-2,4-disulphonamido-aniline, the normal hydrolysis product from hydrochlorothiazide, is also susceptible to photolytic dechlorination by a similar mechanism.

Keyphrases □ Hydrochlorothiazide—photolytic decomposition, irradiation, dechlorination, hydrolysis □ Decomposition, photolytic—hydrochlorothiazide, irradiation, dechlorination, hydrolysis □ Hydrolysis—photolytic decomposition of hydrochlorothiazide, dechlorination, irradiation

Hydrochlorothiazide [6-chloro-3,4-dihydro-1,2,4-benzothiadiazine-7-sulphonamido-1,1-dioxide] (I) is a widely used diuretic effective in small doses. Within a few years of its introduction there were reports of its implication in skin photosensitization (1). From oxygen uptake measurements and free radical polymerization (2), I and some

0022-3549/83/0200-0180$01.00/0



Scheme I—Pathways of photolysis of hydrochlorothiazide.

thiazide derivatives were found to be capable of acting as photosensitizers by both free radical and excited singlet molecular oxygen mechanisms. Subsequently, it was reported (3) that the chlorine substituent in I is photolabile.

In a study to determine the mutagenic activity of a number of drugs, I proved to be weakly mutagenic (4). Mutagenicity appeared to depend on the presence of an aromatic chlorine substituent and required activation by light. This study suggests that the drugs undergo photodehalogenation, yielding a reactive form, which can damage DNA. The nature of the photolysis products of I has now been examined and found to involve ring opening (hydrolysis) as well as dechlorination.

The chlorine substituent in 5-chloro-2,4-disulphonamidoaniline II, the normal hydrolysis product of I, has also been found to be photolabile.

EXPERIMENTAL

Materials—Hydrochlorothiazide (I)[1] and 5-chloro-2,4-disulphonamidoaniline (II)[2] were indicated to be >99% pure by high-performance liquid chromatography (HPLC).

2,4-Disulphonamidoaniline (IV) and 2,4-disulphonamido-5-methoxyaniline (VIa) were prepared by the action of chlorosulphonic acid on aniline and *m*-anisidine, respectively, followed by hydrolysis with ammonium hydroxide, by analogy to a previous method (5). Colorless crystals, mp 233–235° for IV and 252–253° for VIa, were obtained after recrystallization from water.

Cyclization of VIa with paraformaldehyde to 6-methoxy-3,4-dihydro-1,2,4-benzothiadiazine-7-sulphonamido-1,1-dioxide (referred to as methoxyhydrothiazide) (IIIa) was based on the method for I (6). Colorless crystals, mp 273–275°, were obtained after recrystallization from water. All compounds synthesized gave the expected NMR and mass spectra.

Trimethylanilinium hydroxide, a methylating agent for GC, was obtained as 2 *M* solution in methanol[3]. Acrylamide[4] was twice recrystallized from redistilled chloroform. All other chemicals and solvents were of analytical grade[5]. Doubly distilled water was used in aqueous systems.

Methods—A solution of I was irradiated at a concentration of 5×10^{-4} *M* in either methanol or water containing 5% methanol (to assist in dissolution). A medium pressure mercury lamp and a glass reaction vessel were used as previously described (3), so that the solution was exposed to UV light of >310-nm wavelength. The solution was presaturated with nitrogen or oxygen as required by bubbling for 90 min, and the gas flow was maintained to stir the solution during the irradiation. The product mixture was sampled at various times and analyzed by:

1. HPLC[6] with a fixed-wavelength UV detector at 254 nm and a reverse-phase 10-μm column (0.4 × 25 cm)[7] (mobile phase: 10% methanol in water);
2. GC[8] with hydrogen flame-ionization detector, nitrogen carrier gas, and phenyl methyl silicone stationary phase[9]. Following a previous method (7) the irradiated solution of I was concentrated 10-fold, and to 100 μl was added 2.5 μl of 2 *M* trimethylanilinium hydroxide. Methylation of I occurred in the heated injection port at 290°. The column and detector temperatures were 260° and 310°, respectively;
3. GC–chemical-ionization mass spectrometry[10] using the column as above and methane carrier gas.

Photopolymerization of acrylamide (0.125 *M*) initiated by I, II, IIIa, or chlorpromazine (8×10^{-5} *M*) was performed using the apparatus and procedures described previously (2).

RESULTS AND DISCUSSION

Photolysis of Hydrochlorothiazide in Methanol Solution—The photolysis of I dissolved in methanol saturated with nitrogen leads to dechlorination and hydrolysis of the thiadiazine ring in approximately equal proportions as shown in Scheme I. The quantum yield for Cl^- production was 0.18 ± 0.05, as previously reported (3). Under the conditions of irradiation used, the dechlorination was complete in ~6 hr, as determined by potentiometric titration. Other product formation is shown in Fig. 1 as a function of time from HPLC analysis of aliquots withdrawn at various times. For the major products the relative peak areas have been corrected by subsequent calibration with authentic samples of the compound. Confirmation of the identity of the major

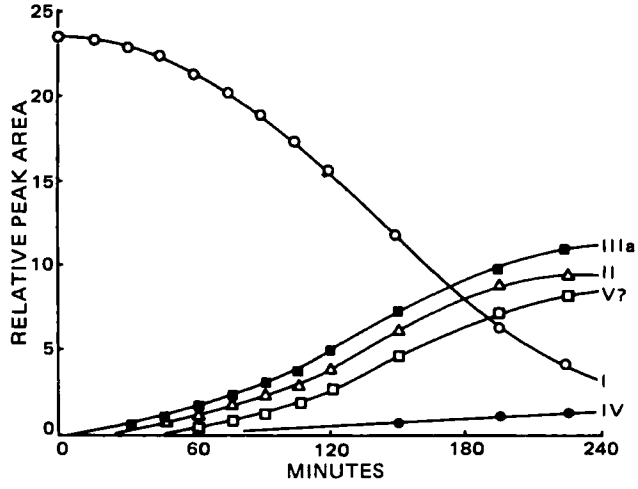

Figure 1—*Photodegradation of hydrochlorothiazide (0.5 mM) in oxygen-free methanol solution at 30° from HPLC analysis of aliquots withdrawn at various times.*

products was achieved by comparison of the chromatographic behavior of authentic samples of the hydrolysis product, 5-chloro-2,4-disulphonamidoaniline (II) and the reduced and substituted derivatives of I and II, namely, methoxyhydrothiazide (IIIa) and 2,4-disulphonamidoaniline (IV). On the basis of reported photoreactions of chloroaromatic compounds in methanol (8), coupled with the hydrolysis of I, other expected products were hydrothiazide (V) and 5-methoxy-2,4-disulphonamidoaniline (VIa). The latter compound was synthesized but its HPLC retention did not correspond to any of the photolysis products. Compound V, however, proved difficult to synthesize.

GC–MS analysis of trimethylanilinium hydroxide-treated samples of the photolysis mixture was complicated by the existence of such a large number of active protons in I and the photolysis products. Nevertheless, molecular ions corresponding to permethylated derivatives of II, IIIa, IV, and V were detected. For each one the GC peak height correlated approximately with the amounts detected by HPLC.

Figure 1 shows that dechlorination and hydrolysis occur simultaneously upon irradiation, where the concentrations of both II and IIIa build up to a maximum level after ~4 hr. Thereafter, II diminished as dechlorination proceeded as a secondary reaction. There was no hydrolysis detected in an unirradiated methanol solution of I after 6 hr at 30°, although complete hydrolysis can be achieved in ~1 hr by refluxing in 1 *M* NaOH, as reported previously (9).

Direct photolysis of II was also examined under the same conditions with the observation of dechlorination occurrence, leading predominantly to IV (~85%). A minor product was found, but its HPLC retention did not correspond to that of VIa. This correlated with the fact that VIa was not observed as a product from photolysis of I. In the GC–MS analysis of irradiated II a minor peak with *m/z* 319 was observed. This value

Chlorpromazine	5.70	0.40

[a] Error in rate data ±5%.

corresponded to tetramethyl-V, suggesting that ring closure to form the thiadiazine ring had occurred to a small extent under irradiation. This assignment was confirmed by TLC separation, followed by solid-probe MS of the separated compounds without derivatization. That ring closure is a possibility comes from the observation that the hydrolysis of I is reversible (9).

When the methanol solution of I was saturated with oxygen before irradiation, both dechlorination and hydrolysis reactions were markedly inhibited. Loss of I and formation of II and IIIa occur at ~one-tenth the rate seen in the absence of oxygen. This is in agreement with the chloride yields already reported (3). Similarly, when II was irradiated in an oxygen-saturated solution, the dechlorination was inhibited, and only product IV was detected.

Photolysis of Hydrochlorothiazide in an Aqueous System—The solubility of I in pure water is relatively low, and the addition of 5% methanol was necessary to achieve the concentration of 0.5 m*M* used for the irradiation. Under these conditions and in the absence of oxygen, photodecomposition of I occurred at ~50% the rate in oxygen-free methanol, as shown in Fig. 2. It should be noted that the chloride ion appeared at the same rate in both solvents (3). The product distribution is seen to be different, with the hydrolyzed and dechlorinated IV as the dominant product. A relatively minor amount of the intermediate II was found, suggesting that dechlorination of I was occurring first followed by rapid hydrolysis. The other significant product was suspected of being VIb on the basis of its chromatographic retention, but samples collected were insufficient for direct MS confirmation. Molecular ions corresponding to permethylated compounds II, IV, and VIb were found by GC–MS analysis.

When the system was saturated with oxygen before irradiation, IV was the only product detected following a much slower reaction.

When the direct photolysis of II was examined in the aqueous system in the absence of oxygen, IV and the compound suspected of being VIb were found in the approximate ratio of 3:1.

Mechanism of the Photodegradation—The dechlorination step in the photolysis of both I and II leads to either reduction (Aryl-H) or substitution (Aryl-OR) involving the solvent ROH, as observed for other chloroaromatic compounds (8, 10). Additionally, photohydrolysis of the thiadiazine ring of I occurs, as has been observed for some other drugs susceptible to alkaline hydrolysis such as pentobarbitone (11) and indapamide (12).

It was proposed (8, 13) that photoreduction and photosubstitution of simple chloroaromatic compounds in methanol involves the formation of a pair of radical ions from the triplet state. The precursor of the reduction product (Aryl-H) is suggested to be a radical anion (Aryl-Cl^{-}), while a radical cation (Aryl-Cl^{+}) is postulated as the precursor of the substitution product (Aryl-OR). Alternatively, flash photolysis experiments with chlorpromazine in 2-propanol (10) led to the suggestion that a direct homolysis of the C–Cl bond occurs from the triplet state. We have observed (3) that chlorpromazine is moderately active as a triplet state photosensitizer in methanol solution, while in aqueous solution the predominance of photoionization as the primary photochemical event with phenothiazines (14) results in a significantly lower rate for this type of reaction.

Photoionization is reported for other heteroaromatic compounds not containing chlorine substituents *e.g.*, 4-hydroxybenzothiazole (15). The cation radical of chlorpromazine was postulated as the main initiating species of the photopolymerization of acrylamide following studies in cationic and anionic surfactants (16).

In view of the information available on the photochemistry of chlorpromazine, it was used as a standard against which the reactivity of other drugs might be compared. Hydrochlorothiazide was found to react in the same manner as chlorpromazine in triplet state photosensitization (3). The rates of photopolymerization of acrylamide in aqueous buffer and methanol solutions, sensitized by I, II, IIIa, and chlorpromazine were

measured, as shown in Table I. Since these four compounds have similar UV absorption characteristics, the rates of polymerization should provide an approximate indication of relative radical yields and reactivity. In aqueous solution the values of the rates suggest that cation radical production does not depend upon loss of chloride, as evidenced by the comparatively high rate sensitized by IIIa. However, in methanol solution the three compounds that lose chlorine show about the same rate of polymerization, a higher value than that for IIIa.

On the basis of the above results, the primary photochemical processes occurring on irradiation of hydrochlorothiazide appear similar to those found for chlorpromazine, with photoionization predominating in aqueous solution and triplet state formation mainly in methanol. However, it is possible that the polymerization technique is not an adequate indicator of radical ion formation in methanol where ion recombination or reaction with solvent may occur more readily than in water. A phenomenon that is indicative of excited state electron transfer is the quenching of fluorescence by an electron donor (17). We have observed that the fluorescence of I (50 μM in methanol) is quenched to 50% by 6 mM triethylamine. In contrast, the fluorescence of chlorpromazine is unaffected (18).

The fact that hydrolysis of I is stimulated by irradiation implies the formation of a cation radical in the thiadiazine ring, thereby rendering it more susceptible to attack by nucleophiles. This is most evident in the aqueous system where the expected intermediate IIIb was not detected. The dechlorination is presumably effected by the solvated electron formed in the photoionization.

In methanol the formation of cation radicals is indicated by the presence of significant amounts of the hydrolyzed compound II. However it is not clear if the cation radicals result from photoionization or radical-ion-pair formation from the triplet state. Flash photolysis experiments are needed to clarify the primary photochemical events. However, as pointed out elsewhere (10, 16), it is believed that the formation of free radicals following absorption of UV radiation is the significant factor in the initiation of a photobiological effect.

Received September 28, 1981, from the **College of Pharmacy and Pharmacal Sciences, Department of Biomedicinal Chemistry, Howard University, Washington, DC 20059*, and the ‡*Southern School of Pharmacy, Department of Biomedical Sciences, Mercer University, Atlanta, GA 30312.* Accepted for publication March 3, 1982.

Abstract □ A series of *N*-substituted hydrazines were condensed with various spiro[4.5] and [5.5]anhydrides and the resultant *N*-substituted azaspiranediones were evaluated for antimicrobial activity. None displayed any significant activity in a variety of organisms tested.

Keyphrases □ Antimicrobial agents—potential, evaluation of various *N*-substituted azaspiranedione derivatives □ Azaspiranedione—evaluation of various derivatives as potential antimicrobial agents

Previous works (1, 2) have shown a wide variety of biological effects for the azaspiro nucleus. It was of interest to extend this work to various 2-substituted-2-azaspiro-[4.5]decane-1,3-diones (I) and 3-substituted-3-azaspiro-[5.5]undecane-2,4-diones (II) and to evaluate these hydrazinoimides as potential antimicrobial agents.

It has been demonstrated (3–6) that in the fused 4-azacholestane ring various 4-alkyl-substituted derivatives

0022-3549/83/0200-0183$01.00/0

measured, as shown in Table I. Since these four compounds have similar UV absorption characteristics, the rates of polymerization should provide an approximate indication of relative radical yields and reactivity. In aqueous solution the values of the rates suggest that cation radical production does not depend upon loss of chloride, as evidenced by the comparatively high rate sensitized by IIIa. However, in methanol solution the three compounds that lose chlorine show about the same rate of polymerization, a higher value than that for IIIa.

On the basis of the above results, the primary photochemical processes occurring on irradiation of hydrochlorothiazide appear similar to those found for chlorpromazine, with photoionization predominating in aqueous solution and triplet state formation mainly in methanol. However, it is possible that the polymerization technique is not an adequate indicator of radical ion formation in methanol where ion recombination or reaction with solvent may occur more readily than in water. A phenomenon that is indicative of excited state electron transfer is the quenching of fluorescence by an electron donor (17). We have observed that the fluorescence of I (50 μM in methanol) is quenched to 50% by 6 mM triethylamine. In contrast, the fluorescence of chlorpromazine is unaffected (18).

The fact that hydrolysis of I is stimulated by irradiation implies the formation of a cation radical in the thiadiazine ring, thereby rendering it more susceptible to attack by nucleophiles. This is most evident in the aqueous system where the expected intermediate IIIb was not detected. The dechlorination is presumably effected by the solvated electron formed in the photoionization.

In methanol the formation of cation radicals is indicated by the presence of significant amounts of the hydrolyzed compound II. However it is not clear if the cation radicals result from photoionization or radical-ion-pair formation from the triplet state. Flash photolysis experiments are needed to clarify the primary photochemical events. However, as pointed out elsewhere (10, 16), it is believed that the formation of free radicals following absorption of UV radiation is the significant factor in the initiation of a photobiological effect.

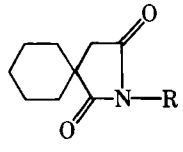
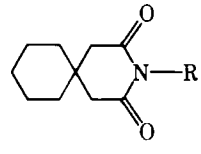
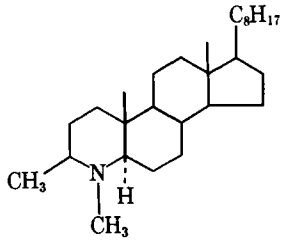
(III, IV) possessed antimicrobial activity. Thus, it was of interest to determine whether this activity could be extended to the spiro nucleus as well.



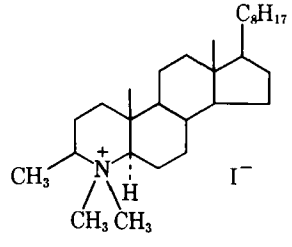
(I)



(II)

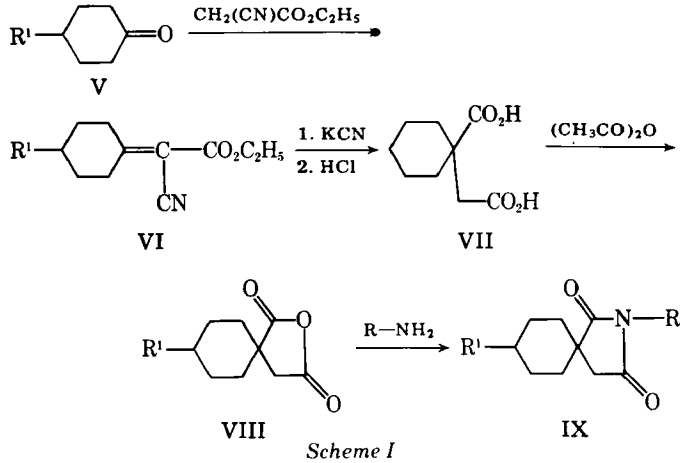


(III)



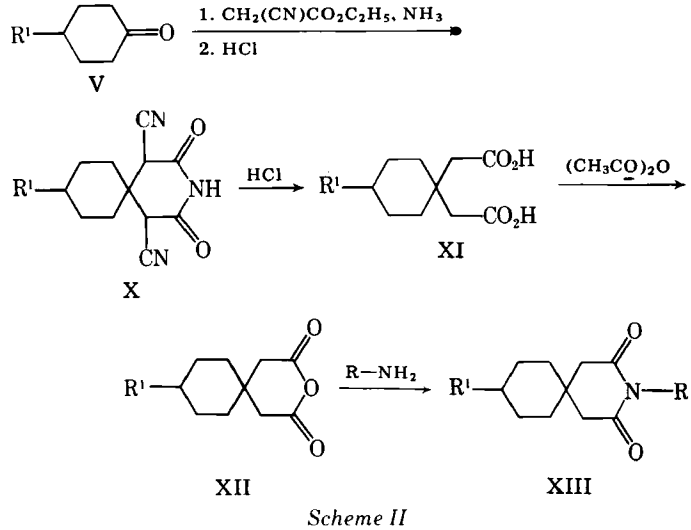
(IV)

The reaction sequence for the 2-azaspiro[4.5]decane series is shown in Scheme I:



Scheme I

The ketone (V) is subjected to a Cope procedure (7) using ammonium acetate and acetic acid as catalysts. The resultant alkylidene cyanoacetic ester (VI) was obtained in purified form on distillation. (This ester should be used within several days as decomposition is noted even under the most careful conditions.) Addition of potassium cyanide followed by acid hydrolysis produced the 1-carboxy-1-acetic acid derivative (VII), which was quantitatively converted to the anhydride (VIII), with excess acetic anhydride. Condensation of the anhydride with substituted hydrazines in the presence of a high-boiling solvent and molecular sieves followed by distillation produced the desired 2-substituted-2-azaspiro[4.5]decane (IX). The reaction sequence for the 3-azaspiro[5.5]undecane series is shown in Scheme II:



Scheme II

In this sequence, the ketone was subjected to 2.0 moles of ethyl cyanoacetate in the presence of anhydrous ammonia to yield the ammonium salt of the Guareschi imide (8) which was converted to the imide (X), on acidification

with hydrochloric acid. Sulfuric acid hydrolysis converted the imide into the 1,1-bisacetic acid compound (XI). Acetic anhydride, followed by hydrazine condensation as in the previous scheme, produced the anhydride (XII) and the 3-azaspiro[5.5]undecane-2,4-dione derivative (XIII), respectively. The imides were tested against a variety of microorganisms for antibacterial activity.

EXPERIMENTAL

Instruments—Melting points were obtained using a capillary melting point apparatus[1] and are uncorrected. Observed boiling points were also uncorrected. IR spectra were obtained on a spectrophotometer[2] as a Nujol mull or neat. NMR spectra were determined on a 60-MHz spectrometer[3] with tetramethylsilane as the internal reference. Elemental analyses were also performed[4].

Reagents—All ketones, ethyl cyanoacetate, and hydrazine[5], *N*-aminopiperidine, and *N*-aminomorpholine[6] were distilled before use.

Ethyl α-Cyclohexylidene-α-cyanoacetate (VI, R¹=H)—The general procedure (7) was followed using 1.0 mole of cyclohexanone and 1.0 mole of ethyl cyanoacetate with 7.7 g of ammonium acetate and 12 g of acetic acid in a 500-ml flask. Yield: 125 g (65%), bp 104–107° (0.25 mm). [lit. 150–151° (9 mm) (7), 151° (12 mm) (9), 163° (15 mm) (10), 151° (10 mm) (11–13)] IR (neat) 4.45μ (Sharp, C≡N).

Ethyl α-(4-Methylcyclohexylidene)-α-cyanoacetate (VI, R¹=CH₃)—Using the above procedure and the same molar quantities, 145 g (70%) was obtained, bp 98–104° (0.7 mm) [lit. 165–168° (14 mm), 175° (20 mm), 167° (14 mm)].

Cyclohexane-1-carboxy-1-acetic Acid (VII, R¹=H)—Using a previous procedure (9) employing 0.18 mole of ester and 0.36 mole of potassium cyanide, after solvent removal and 16 hr of refluxing in 250 ml of concentrated hydrochloric acid, 14 g (42%) of the acid was obtained, mp 132–133° (ligroin–ethyl acetate). The yield was improved to 50% by chilling the acid filtrate overnight and collecting the additional crude acid [lit. 134° (9, 14), 132° (10, 15)]. IR(Nujol) 5.75μ (Sharp, C=O).

4-Methylcyclohexane-1-carboxy-1-acetic Acid (VII, R¹=CH₃)—The same method (9) was employed on the same molar quantities of ester and cyanide as with compound VII above. Yield: 19 g (53%) mp 173–174° (ligroin–ethyl acetate).

Anal.—Calc. for $C_{10}H_{16}O_4$: C, 59.97, H, 8.00. Found: C, 59.73, H, 7.90.

Cyclohexane-1-carboxy-1-acetic Acid Anhydride (VIII, R¹=H)—Using a previous procedure (9), from 0.05 mole of acid 8.1 g (90%) of anhydride was obtained, bp 112° (1.75 mm), which slowly solidified on standing, mp 57° [lit. 56° (9), 57° (14)]. IR(Nujol) 5.50μ (Sharp, C=O).

4-Methylcyclohexane-1-carboxy-1-acetic Acid Anhydride (VIII, R¹=CH₃)—As previously indicated, the title compound was quantitatively prepared, bp 124–126° (3 mm), solidifying on standing, mp 60–61°.

Anal.—Calc. for $C_{10}H_{14}O_3$: C 65.90; H, 7.76. Found: C, 65.90; H, 7.64.

The Guareschi Imide-9-methyl-1,5-dicyano-3-azaspiro[5.5]-undecane-2,4-dione (X, R¹=CH₃)—A general procedure (16) was modified using 1.0 mole of ketone and 2.0 moles of ethyl cyanoacetate in a 1.5-liter thick-wall flask. After cooling to −5°, 400 ml of absolute ethanol saturated with anhydrous ammonia and cooled to −5° was added, the flask stoppered, taped securely, and stored at 0° for 1 week. The crude ammonium salt of the Guareschi imide (8, 17) was filtered, washed with alcohol and then ether, and air dried. The product was dissolved in 1 liter of boiling water, filtered, and the hot solution acidified with excess concentrated hydrochloric acid. The product, on cooling, was filtered, washed with water, and dried at 100° to give 115 g (47%), mp 217–218° (methanol) [lit. 217–218° (16)].

4-Methylcyclohexane-1,1-diacetic Acid (XI, R¹=CH₃)—Using a previous procedure (16), 0.5 mole of imide, 240 ml of concentrated sulfuric acid, which after standing overnight at room temperature, was diluted with 225 ml of water and refluxed for 24 hr, resulting in a product, 140 g (65%), mp 157–158° [lit. 158° (16)].

4-Methylcyclohexane-1,1-diacetic Acid Anhydride (XII, R¹=CH₃)—The previous procedure produced the desired product, bp 152–154° (1.25 mm), which solidified on standing, mp 53° [lit. bp 212° (20 mm), mp 53° (16)].

General Procedure for the Preparation of Azaspiranediones—The anhydride, 0.05 mole, and the substituted hydrazine were added to 10 ml of xylene (distilled from sodium) in a 50-ml flask containing molecular sieves[7]. The mixture was stirred magnetically and refluxed for 2–8 hr. The product precipitated on cooling overnight, and after separation, the residual oil was seeded and chilled. The entire residue was combined and either chromatographed or distilled. The distillate was then either chromatographed or recrystallized (Tables I and II). As previously reported (2), azaspiro[5.5]undecane-2,4-diones formed unstable hydrochloride salts. This was also observed with the undecanes synthesized in this study as well as the azaspiro[4.5]decane-1,3-diones.

RESULTS AND DISCUSSION

In addition to the potential antimicrobial activity of various *N*-substituted azasteroids (3–6), adamantane spiro compounds (18, 19) have been evaluated for antiviral activity and spirofluorene (20) and spiroperimidines (21) have been tested for antineoplastic activity. Compounds XIV–XVI and XXI–XXIII were thus submitted for antimicrobial screening. The analyses were performed by the use of the Kirby–Bauer technique (22) with the following organisms: *Escherichia coli*, *Staphylococcus aureus*, *Sarcina lutea*, *Bacillus subtilis*, and *Pseudomonas aeruginosa* (23). The compounds showed no activity at concentrations up to 100 μm/ml.

Dissolution Apparatus for Gels

HO-LUN WENG and EUGENE L. PARROTT ˣ

Received January 11, 1982, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication March 11, 1982.

Abstract □ A modification of the USP Dissolution Apparatus 2 is presented for use in the measurement of the release of a medicinal compound from a pharmaceutical gel.

Keyphrases □ Dissolution—apparatus for gels, modification of the USP Dissolution Apparatus 2 □ Pharmaceutical gels—dissolution apparatus, modification of the USP Dissolution Apparatus 2

The *in vitro* test methods for measuring the dissolution of a medicinal compound from a tablet or a capsule are defined in the United States Pharmacopeia (USP) (1). Mathur *et al.* (2) appear to be the first to have reported *in vitro* dissolution testing of suspensions. It seems that dissolution testing of any dosage form that may restrict the delivery of molecules of the medicinal compound to the GI epithelium is advisable.

This report presents a modification of the USP Dissolution Apparatus 2, that can be used to measure dissolution profiles from pharmaceutical gels.

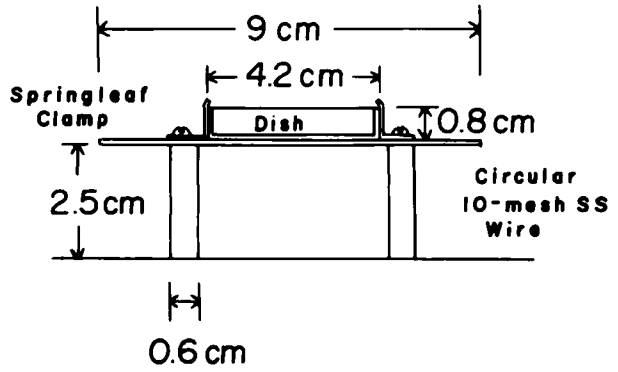

Figure 1—*Modification of the USP Dissolution Apparatus 2 for gels.*

EXPERIMENTAL

Dissolution Apparatus—A circular, 10-mesh stainless-steel cloth with a 9.0-cm diameter was fitted with four 2.5-cm plastic legs (diameter 0.6 cm) so that, as it rested on the bottom of the reaction vessel, the wire cloth was at the point of curvature of the base of the vessel. Four springleaf clamps were affixed to the upper surface of the wire cloth to hold the glass dish in the center of the platform (Fig. 1). The dish was cut from a 50-ml beaker and had 3.9-cm i.d. and an outer height of 0.8 cm.

A 5-g sample of the gel was weighed in the dish on an analytical balance, and using forceps the dish was gently lowered through the dissolution medium in the assembled apparatus and was inserted into the clamps. The time required by an experienced operator was ~30 sec. With thin gels, the level spontaneously adjusted to the horizontal plane; with very viscous gels, the surface may be leveled by use of a spatula prior to weighing. In the gels investigated, the 5-g samples completely filled the dish to the rim. If a particular gel had a high density, it would be advisable to use a greater weight, which would fill the dish. The dissolution medium was 900 ml of distilled water or 0.1 *N* HCl at 37 ± 0.5°. The paddle of the modified USP Dissolution Apparatus 2 was centrally positioned 2.5 cm above the rim of the dish. The apparatus was then started. Samples were withdrawn by a pipet through a glass filter. Ephedrine sulfate was assayed using a previously described method (3).

Dosage Forms—Tablets containing 25 mg of ephedrine sulfate was prepared by direct compression in a single-punch tablet machine. A portion of the batch was compressed to a hardness of 4 kg; the remainder was compressed to an 8-kg hardness. The formulation was:

Ephedrine sulfate[1]	25 mg
Microcrystalline cellulose[2]	190 mg
Lactose[3]	382 mg
Magnesium stearate[4]	3 mg

Dissolution Apparatus for Gels

HO-LUN WENG and EUGENE L. PARROTT ˣ

Received January 11, 1982, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication March 11, 1982.

Abstract □ A modification of the USP Dissolution Apparatus 2 is presented for use in the measurement of the release of a medicinal compound from a pharmaceutical gel.

Keyphrases □ Dissolution—apparatus for gels, modification of the USP Dissolution Apparatus 2 □ Pharmaceutical gels—dissolution apparatus, modification of the USP Dissolution Apparatus 2

The *in vitro* test methods for measuring the dissolution of a medicinal compound from a tablet or a capsule are defined in the United States Pharmacopeia (USP) (1). Mathur *et al.* (2) appear to be the first to have reported *in vitro* dissolution testing of suspensions. It seems that dissolution testing of any dosage form that may restrict the delivery of molecules of the medicinal compound to the GI epithelium is advisable.

This report presents a modification of the USP Dissolution Apparatus 2, that can be used to measure dissolution profiles from pharmaceutical gels.

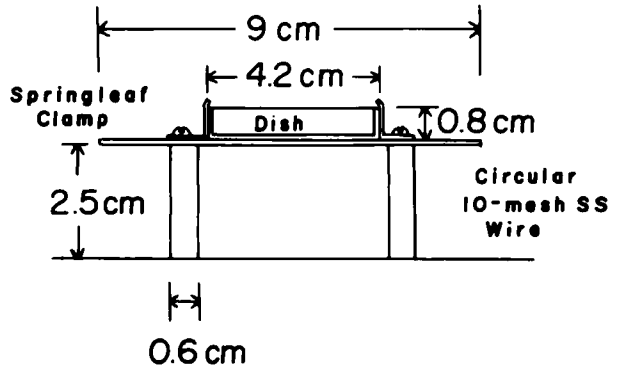

Figure 1—*Modification of the USP Dissolution Apparatus 2 for gels.*

EXPERIMENTAL

Dissolution Apparatus—A circular, 10-mesh stainless-steel cloth with a 9.0-cm diameter was fitted with four 2.5-cm plastic legs (diameter 0.6 cm) so that, as it rested on the bottom of the reaction vessel, the wire cloth was at the point of curvature of the base of the vessel. Four springleaf clamps were affixed to the upper surface of the wire cloth to hold the glass dish in the center of the platform (Fig. 1). The dish was cut from a 50-ml beaker and had 3.9-cm i.d. and an outer height of 0.8 cm.

A 5-g sample of the gel was weighed in the dish on an analytical balance, and using forceps the dish was gently lowered through the dissolution medium in the assembled apparatus and was inserted into the clamps. The time required by an experienced operator was ~30 sec. With thin gels, the level spontaneously adjusted to the horizontal plane; with very viscous gels, the surface may be leveled by use of a spatula prior to weighing. In the gels investigated, the 5-g samples completely filled the dish to the rim. If a particular gel had a high density, it would be advisable to use a greater weight, which would fill the dish. The dissolution medium was 900 ml of distilled water or 0.1 *N* HCl at 37 ± 0.5°. The paddle of the modified USP Dissolution Apparatus 2 was centrally positioned 2.5 cm above the rim of the dish. The apparatus was then started. Samples were withdrawn by a pipet through a glass filter. Ephedrine sulfate was assayed using a previously described method (3).

Dosage Forms—Tablets containing 25 mg of ephedrine sulfate was prepared by direct compression in a single-punch tablet machine. A portion of the batch was compressed to a hardness of 4 kg; the remainder was compressed to an 8-kg hardness. The formulation was:

Ephedrine sulfate[1]	25 mg
Microcrystalline cellulose[2]	190 mg
Lactose[3]	382 mg
Magnesium stearate[4]	3 mg

[1] USP.
[2] Avicel PH 101.
[3] USP, spray dried.
[4] NF.

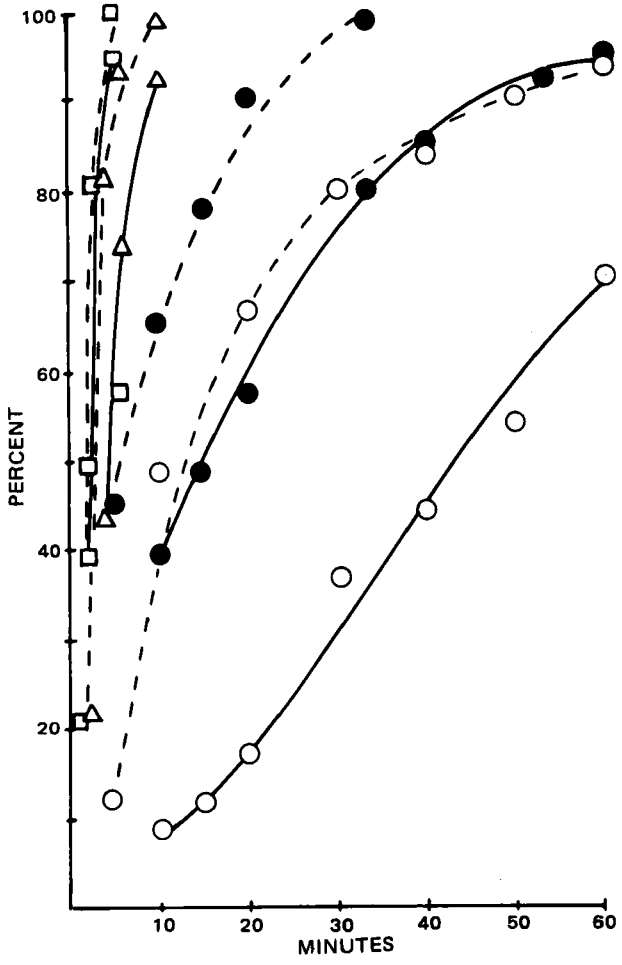

Figure 2—*Comparison of percent of ephedrine sulfate released from tablets having a hardness of 8 kg as determined by the USP Dissolution Apparatus 2 and a modification for gels at various speeds. Key: (- - -) USP; (—) modified for gel apparatus; (○) 12 rpm; (●) 30 rpm; (△) 60 rpm; (□) 100 rpm.*

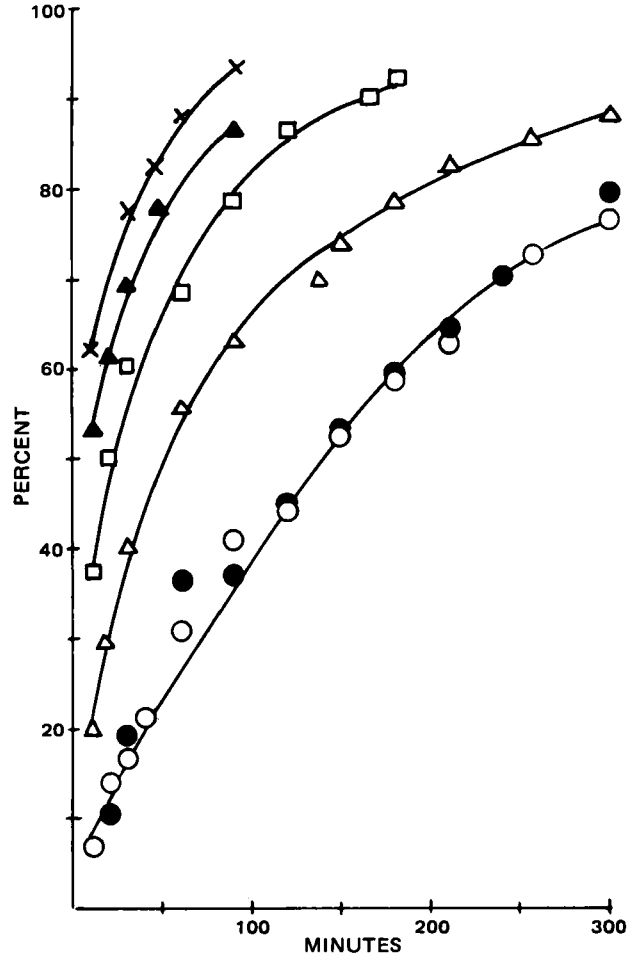

Figure 3—*Release profile of ephedrine sulfate from a methylcellulose gel at various speeds. Key: (○) 12 rpm; (●) 30 rpm; (△) 60 rpm; (□) 70 rpm; (▲) 80 rpm; (×) 90 rpm.*

The formulation of the gel used as a model was:

Ephedrine sulfate	20 mg
Methylcellulose[5]	200 mg
Distilled water	4780 mg

RESULTS AND DISCUSSION

Gels are semisolid systems consisting of either suspensions made up of small inorganic particles or large organic molecules interpenetrated by a liquid (4). Gels with wide viscosities may be used as vehicles for a dissolved or a suspended medicinal compound. The wide range of viscosities of pharmaceutical gels limits the use of the USP dissolution apparatus. For example, with USP Dissolution Apparatus 1, a gel of low viscosity may drip from the basket assembly, and a gel of high viscosity will tend to clog the wire mesh.

It is desirable to have an apparatus for all dosage forms that is not markedly different than the officially accepted dissolution apparatus. To compare the agitation and the dissolution profiles obtained by the USP Dissolution Apparatus 2 and the modification, dissolution from tablets of ephedrine sulfate was studied at 12, 30, 60, and 100 rpm in 900 ml of distilled water. The dissolution profiles are given in Fig. 2 for tablets with a hardness of 8 kg. From Fig. 2, and a similar plot for tablets with a hardness of 4 kg, the times required for 50% ($t_{1/2}$) and 66.7% ($t_{2/3}$) of the ephedrine sulfate to dissolve from the tablets were determined and are listed in Table I.

At 60 and 100 rpm (speeds frequently utilized in official tests) there is no apparent difference in the dissolution profiles as obtained by the USP Dissolution Apparatus 2 and the modification suggested for de-

[5] USP, type 400 cps.

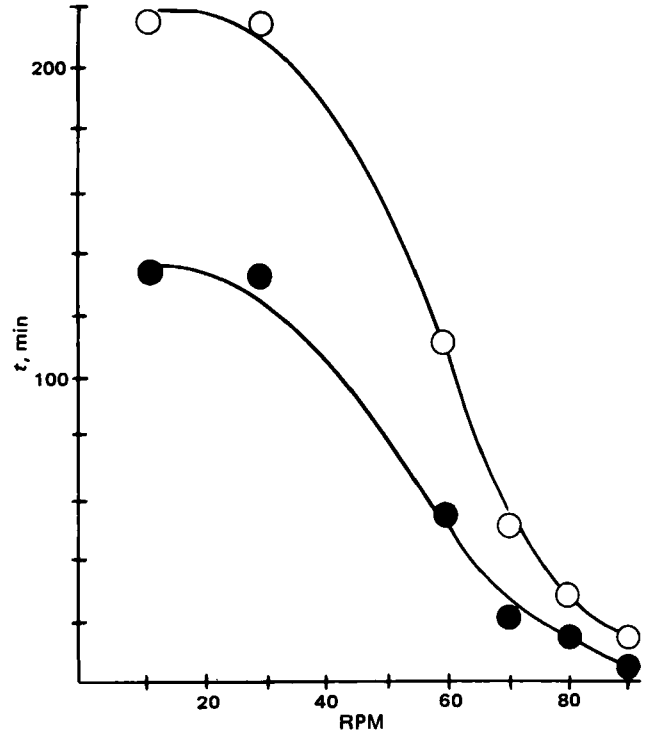

Figure 4—*Influence of speed on dissolution. Key: (○) $t_{2/3}$; (●) $t_{1/2}$.*

termining the release profile from gels. Thus, at these speeds the factors contributing to dissolution are similar, and a comparison of release from a solid dosage form (tablet) and the release from a gel would be valid.

The release of ephedrine sulfate from the model gel was studied at 12, 30, 60, 70, 80, and 90 rpm as shown in Fig. 3. At the higher speeds, the agitation moves portions of the gel in a random manner so that filaments

Table I—Comparison of Dissolution as Measured by the USP Dissolution Apparatus 2 and by the Apparatus Modified for a Gel Using Compressed Tablets Containing 25 mg of Ephedrine Sulfate

Speed, rpm	$t_{1/2}$, min[a]		$t_{2/3}$, min[a]	
	USP Apparatus 2	Gel Apparatus	USP Apparatus 2	Gel Apparatus
		Hardness (4 kg)		
12	9	35	15	47
30	5	5	7	11
60	~1	2	~1	3
100	~1	1	~1	2
		Hardness (8 kg)		
12	10	43.5	19	59
30	6.5	15	11	22
60	~2	~4	~2	5
100	2	~3	~3	4

[a] Rounded to the nearest 0.5 min.

and masses of the gel may move away from the gel in the dish and at times become entwined around the shaft of the paddle. At lowest speeds, the release from the gel to the bulk of the dissolution medium is slow and requires an inconveniently long testing period (>4 hr). Intermediate speeds did not grossly disturb the gel in the dish and did not unduly prolong the release of the ephedrine sulfate; thus, 30 and 60 rpm appear to be practical speeds. The influence of speed on dissolution is shown in Fig. 4.

The release of the ephedrine sulfate from the model gel was determined in distilled water and in 0.1 *N* HCl at 30 and 60 rpm and is plotted in Fig. 5. At 30 rpm the values of $t_{1/2}$ are 135 and 80 min in water and 0.1 *N* HCl, respectively. At 60 rpm the values of $t_{1/2}$ are ~45 min in water and 0.1 *N* HCl.

^{1}H- and ^{13}C-NMR Spectra of Fenobam

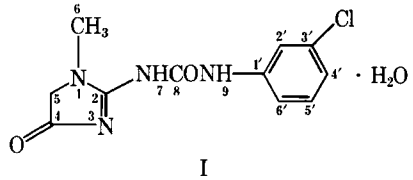
G. PELLIZER *x and F. RUBESSA ‡

Received October 7, 1981, from the **Istituto di Chimica and the* ‡*Istituto di Chimica Farmaceutica, Università di Trieste, Italy.* Accepted for publication March 12, 1982.

Abstract □ ^{1}H- and ^{13}C-NMR data and spectral assignments are reported for fenobam using noise modulated gated, single frequency off resonance, and single frequency selective proton decoupling techniques.

Keyphrases □ Fenobam—^{1}H- and ^{13}C-NMR spectroscopic analysis □ ^{1}H- and ^{13}C-NMR spectroscopy—analysis of fenobam

Fenobam (I), *N*-(3-chlorophenyl)-*N'*-(4,5-dihydro-1-methyl-4-oxo-1*H*-imidazol-2-yl)urea monohydrate, has been shown to possess selective anxiolytic properties in animals and in clinical trials, with a mode of action different from that of the benzodiazepines (1, 2).



I

NMR parameters, especially ^{13}C-chemical shifts, are being widely used to establish structure–activity relationships. As a part of a study on psychoactive molecules, the ^{1}H- and natural abundance ^{13}C-NMR spectra of I are reported. Their assignments are accomplished by gated, single frequency off resonance, and single frequency selective proton decoupling, and by comparison with other structurally related compounds.

EXPERIMENTAL

The NMR spectra were recorded at room temperature from 0.3 *M* solutions of I in $^2H_6$-dimethyl sulfoxide in 5 mm (^{1}H-NMR) and 10-mm (^{13}C-NMR) tubes[1]. Tetramethylsilane was used as the internal standard for ^{1}H-NMR spectra, while the ^{13}C-multiplet of the deuterated solvent served as the internal reference. Chemical shifts were converted to tetramethylsilane scale using:

$$\delta = \delta\ (^2H_6\text{-dimethyl sulfoxide}) + 39.6\ \text{ppm}$$

^{1}H-NMR spectra were measured at 80 MHz using 90° pulse, sweep widths of 800 and 400 Hz, and single-scan and Fourier transform. ^{13}C-NMR spectra were obtained at 20.1 MHz using 2-μsec pulses (a 90° tip angle required a pulse width of 6.5 μsec), acquisition time 0.9102 sec (corresponding to a sweep width of 4500 Hz), accumulation of free induction decays, and Fourier transform. No delay was given between the end of acquisition and the next pulse. Line broadening (0.5 Hz) was introduced in the spectrum by exponential multiplication of free induction decays. The decoupler was used in broad band, broad band gated, single frequency off resonance, and single frequency selective decoupling modes. Carbon–proton coupling constants were measured from undecoupled spectra and gated proton decoupled spectra.

Monohydrated I was dissolved in $^2H_6$-dimethyl sulfoxide without further purification. A dehydrated sample was prepared by heating at 85° and 1 torr. In the final IR spectrum the water peak disappeared. This sample was dissolved in anhydrous $^2H_6$-dimethyl sulfoxide.

RESULTS AND DISCUSSION

Anhydrous and monohydrated fenobam show identical ^{1}H-NMR spectra. A detailed interpretation of the spectrum was made in order to use single frequency proton decoupling for carbon assignments. The results are presented in Table I.

[a] Parts per million from tetramethylsilane. [b] Values may be interchanged.

The values for the aromatic protons were obtained through iterative simulation[2]. Assignments of H-2′ and H-5′ are straightforward from spectral pattern. The peaks of the multiplet at 7.53 ppm are appreciably broader than those at 6.99 ppm, indicating that the former are due to H-6′ (*ortho* to nitrogen). Assuming additivity in the substituent effect on the aromatic protons chemical shifts and using the values reported previously (3) for the chlorine atom, it turns out from the above assignment that the ureido group has relevant deshielding effects only on the two protons, H-2′ and H-6′, which are in *ortho* positions.

The broad band proton decoupled ^{13}C spectrum consists of 11 well-separated peaks (Table II).

In the gated proton decoupled spectrum, the resonances centered at 30.3 and 51.1 ppm appear as a quartet and a broadened triplet and are attributed to C-6 and C-5, respectively. The resonances centered at 117.1, 118.1 and 121.5 ppm appear as doublets of multiplets reflecting couplings with two *meta* protons and are ascribed to C-6′, C-2′, and C-4′, respectively. In particular, C-4′ originates a doublet of quartets (the two J_{meta} are ~6 and 8 Hz), while the doublet of 1:3:3:1 quartets associated with C-2′ and the doublet of unresolved multiplets assigned to C-6′ indicate a relevant coupling with proton 9. For C-6′, there is also a significant coupling with H-5′. Centered at 130.3 ppm there is a doublet due to C-5′. These assignments are further confirmed by single frequency proton decoupling experiments. The resonances centered at 133.2, 142.3, 157.3, 160.8, and 171.6 ppm belong to quaternary carbons and appear, respectively, as a doublet of unresolved multiplets, another broad doublet, an unresolved multiplet, a slightly broadened singlet, and a triplet.

Selective irradiation of H-2′ causes the complete collapse of the multiplet centered at 118.1 ppm which, therefore, is unambiguously assigned to C-2′. As expected, all the aromatic carbon resonances are strongly affected, *i.e.*, all long-range couplings collapse while the direct C—H bond couplings are strongly reduced in magnitude. The residual splitting decreases in the order C-4′ > C-5′ > C-6′, *i.e.*, as the resonance frequency of the attached proton approaches the decoupling frequency (Table I). This observation and single frequency off resonance experiments support the assignment here reported for C-4′, C-5′, and C-6′. Decoupling of H-2′ has much weaker effects on the resonances at 157.3, 160.8, and 171.6 ppm.

However, irradiation of methylene protons transforms the triplet at 171.6 ppm into a sharp singlet and the unresolved multiplet at 157.3 ppm into a broad singlet, indicating that these resonances are due to imidazolinone ring carbons C-4 and C-2, respectively, the former being coupled only with H-5 protons and the latter with both H-5 and methyl protons. Irradiation of the methyl protons confirms these assignments. Further-

Table II—^{13}C-NMR Data

Assignment	δ^a	Multiplicity
C-2	157.3 (169.5[b], 156.7[c])	Unresolved multiplet
C-4	171.6 (188.8[b], 172.0[c])	Triplet, $^2J_{CH}$ = 5 Hz
C-5	51.1 (56.4[b], 54.1[c])	Triplet, $^1J_{CH}$ = 147 Hz
C-6	30.3 (30.2[b], 31.2[c])	Quartet, $^1J_{CH}$ = 140 Hz
C-8	160.8	Singlet
C-1′	142.3	Broad doublet, $^3J_{CH} \simeq 9$ Hz
C-2′	118.1	Doublet of 1:3:3:1 quartets $^1J_{CH}$ = 168 Hz; $^3J_{CH\text{-}4'} \simeq {}^3J_{CH\text{-}6'} \simeq {}^3J_{CH\text{-}9} \simeq 5$ Hz
C-3′	133.2	Doublet of unresolved multiplets, $^3J_{CH} \simeq 11$ Hz
C-4′	121.5	Doublet of quartets, $^1J_{CH}$ = 168.5 Hz, $^3J_{CH} \simeq 6$ and 8 Hz
C-5′	130.3	Doublet, $^1J_{CH}$ = 163 Hz
C-6′	117.1	Doublet of unresolved multiplets, $^1J_{CH}$ = 165 Hz

[a] Chemical shifts in parts per million relative to tetramethylsilane. [b] Values of 2-amino-1,5-dihydro-1-methyl-4*H*-imidazol-4- one. [c] Values for its corresponding monohydrochloride.

more, these decouplings, apart from the collapse of C-5 and methyl carbon resonances, have weak effects on the aromatic carbon resonances, and the splittings due to small C—H couplings are still observable.

The assignment of 142.2 and 133.2 ppm resonances was made by comparison with similar compounds. Assuming that the substituent effects on the shifts of the aromatic carbons are additive and using the data reported previously (4) for the chlorine atom, the values calculated for the ureido group are very close to those determined for other aromatic ureas (5) and acetanilide (4).

The chemical shifts of C-2, C-4, C-5, and C-6 are close to those of 2-amino-1,5-dihydro-1-methyl-4*H*-imidazol-4-one hydrochloride in $^2H_6$-dimethyl sulfoxide (Table II) (6). The ureido ^{13}C-chemical shift (160.8 ppm) is nearer to urea (160.5 ppm) (7) than diphenylurea (152.7 ppm) or di-*p*-anisylurea (153.0 ppm) (5).

Dissolution Profiles for Finely Divided Drug Suspensions

JOHN W. MAUGER ˣ, STEPHEN A. HOWARD, and KIRIT AMIN

Received September 3, 1981, from the *School of Pharmacy, West Virginia University, Morgantown, WV 26506.* Accepted for publication March 16, 1982.

Abstract □ A suspension of micronized prednisolone acetate was separated into four fractions by the technique of centrifugal elutriation. Data showed that each fraction had a narrow particle size. The dissolution experiments were carried out under sink conditions (<10% of saturation concentration) in a dissolution apparatus with a rotating filter assembly and a continuous circulation of filtered fluid samples through a recording spectrophotometer. The dissolution profile was highly reproducible and substantially different for each fraction. As expected, fractions with the smallest and largest particles showed the fastest and slowest dissolution, respectively. Almost the entire dissolution profiles for four small particle size fractions can be satisfactorily described by the Higuchi–Hiestand model with the dissolution rate constant, K, in the range of 1.5–2.0 × 10^{-9}cm^2/sec. This is ~3.5 times greater than the value for K calculated on the basis of reported reasonable values for diffusion coefficient, density, and solubility.

Keyphrases □ Dissolution—profiles for drug suspensions, prednisolone acetate, centrifugal elutriation □ Drug suspensions—dissolution profiles, prednisolone acetate, centrifugal elutriation □ Prednisolone acetate—dissolution profiles for drug suspensions, centrifugal elutriation

Dissolution models for multisized drug particles have been proposed and studied experimentally. However, few studies deal specifically with finely divided drug particles (micrometer range). There were notable exceptions (1, 2) published more than a decade ago which showed approximate agreement between diffusional model theory and experimental data for micronized methylprednisolone particles. A more recent study (3) of the dissolution kinetics of micronized steroid particles was unable to confirm the application of the diffusion-based law for the decay of particle size used in those earlier studies (1, 2). To date, the relationship between diffusional-based dissolution theory for finely divided drug particles, and its experimental justification remains fragile.

One of the reasons for the inability to relate the theory with experimental data may be the difficulties encountered in obtaining very small particles with known narrow particle size distributions. The aforementioned studies used multisized drug particle populations in which the dissolution kinetics for the largest and smallest particles may have differed. This possibility has been discussed (4) and an interpolation formula provided which mixes the diffusion kinetics for large and small particles. Therefore, the possibility of mixed models makes critical testing of a specific model difficult. With recent advances in centrifugal elutriation separation and particle size measurement techniques (5) in conjunction with the spin filter dissolution apparatus, it has become possible to test the dissolution models with more rigorously controlled experiments.

Dissolution Profiles for Finely Divided Drug Suspensions

JOHN W. MAUGER ˣ, STEPHEN A. HOWARD, and KIRIT AMIN

Received September 3, 1981, from the *School of Pharmacy, West Virginia University, Morgantown, WV 26506.* Accepted for publication March 16, 1982.

Abstract □ A suspension of micronized prednisolone acetate was separated into four fractions by the technique of centrifugal elutriation. Data showed that each fraction had a narrow particle size. The dissolution experiments were carried out under sink conditions (<10% of saturation concentration) in a dissolution apparatus with a rotating filter assembly and a continuous circulation of filtered fluid samples through a recording spectrophotometer. The dissolution profile was highly reproducible and substantially different for each fraction. As expected, fractions with the smallest and largest particles showed the fastest and slowest dissolution, respectively. Almost the entire dissolution profiles for four small particle size fractions can be satisfactorily described by the Higuchi–Hiestand model with the dissolution rate constant, K, in the range of 1.5–2.0 × 10^{-9}cm^2/sec. This is ~3.5 times greater than the value for K calculated on the basis of reported reasonable values for diffusion coefficient, density, and solubility.

Keyphrases □ Dissolution—profiles for drug suspensions, prednisolone acetate, centrifugal elutriation □ Drug suspensions—dissolution profiles, prednisolone acetate, centrifugal elutriation □ Prednisolone acetate—dissolution profiles for drug suspensions, centrifugal elutriation

Dissolution models for multisized drug particles have been proposed and studied experimentally. However, few studies deal specifically with finely divided drug particles (micrometer range). There were notable exceptions (1, 2) published more than a decade ago which showed approximate agreement between diffusional model theory and experimental data for micronized methylprednisolone particles. A more recent study (3) of the dissolution kinetics of micronized steroid particles was unable to confirm the application of the diffusion-based law for the decay of particle size used in those earlier studies (1, 2). To date, the relationship between diffusional-based dissolution theory for finely divided drug particles, and its experimental justification remains fragile.

One of the reasons for the inability to relate the theory with experimental data may be the difficulties encountered in obtaining very small particles with known narrow particle size distributions. The aforementioned studies used multisized drug particle populations in which the dissolution kinetics for the largest and smallest particles may have differed. This possibility has been discussed (4) and an interpolation formula provided which mixes the diffusion kinetics for large and small particles. Therefore, the possibility of mixed models makes critical testing of a specific model difficult. With recent advances in centrifugal elutriation separation and particle size measurement techniques (5) in conjunction with the spin filter dissolution apparatus, it has become possible to test the dissolution models with more rigorously controlled experiments.

EXPERIMENTAL

Particle Separation—A previous study (5) demonstrated that centrifugal elutriation[1,2] is capable of separating fractions of small particles with very narrow particle size distributions. In this study a 0.6% suspension of micronized prednisolone acetate in 0.9% sodium chloride solution presaturated with drug was separated into four fractions by the technique of centrifugal elutriation. Four fractions were obtained. Pump speeds of 30 and 52 ml/min and centrifuge speeds of 2000, 1000, and 500 rpm were utilized.

Particle Sizing—An electronic particle sizing device[3] with either a 50- or 200-μm aperture tube was used for particle size analysis. An electrolyte solution[4] presaturated with micronized prednisolone acetate was used as a vehicle. This multichannel instrument provides detailed information about particle size distribution. The particles were classified and counted into one of 14 channels. The first two channels were not used. Almost all of the particles in each fraction were distributed over not more than three to four consecutive channels indicating a narrow particle size distribution.

Dissolution—All dissolution experiments were carried out in an apparatus reported previously (6) which is well-suited for monitoring the dissolution of suspended particles. The rotating filter assembly used in this device provides a variable intensity of mild liquid agitation, and it also functions as an *in situ* nonclogging filter to allow continuous filtration of the dissolution fluid without removing the dissolving particles during the dissolution process.

Procedure—A prednisolone acetate suspension was prepared and elutriated as described, and then a measured sample of each fraction was dissolved in water for 24 hr and assayed. The concentrations thus obtained were utilized in adjusting the suspension concentration of each fraction so that a 5-ml sample would allow for perfect sink conditions to exist in the dissolution test.

Immediately prior to dissolution testing the sample was sized electronically as described, and within 5 min of sizing dissolution testing was initiated. The dissolution experiments were initiated by injecting 5 ml of the desired fraction of prednisolone acetate suspension in a liter of distilled water. The temperature was maintained at 37° and the stirring speed of the filter assembly was set at 600 rpm. Filtered fluid samples were continuously circulated through a spectrophotometer[5] and back into the dissolution flask at the rate of 100 ml/min. The absorbance at 247 nm was continuously recorded as a function of time. The final concentration of prednisolone acetate in the dissolution medium was kept below 10% of saturation.

RESULTS

Four size fractions of prednisolone acetate were obtained, sized, and dissolution tested. The results were then compared to the multisize form of the Higuchi–Hiestand model (1). Weight fraction remaining undissolved, $W(F)$, as a function of time, t, was calculated from the dissolution data in the following manner. The time scale was first corrected for the lag time by subtracting lag time (~15 sec), and the absorbances were corrected by subtracting absorbance due to dilution of the saturated solution (5 ml of saturated solution used in the dissolution experiment).

After corrections, the absorbance at each time, $A(T)$, was divided by the maximum absorbance, A_{max}, to obtain weight fraction dissolved at time, T, $W(DT)$. Thus, $W(DT) = A(T)/A_{max}$ and $[1 - W(DT)] = W(F)$, weight fraction undissolved at time T.

According to the Higuchi–Hiestand model for micronized range size, spherical particles dissolving under sink conditions by a diffusion controlled process the diameter, A, of a single particle at time T is given by

$$A(T) = (A_0^2 - KT)^{1/2} \qquad \text{(Eq. 1)}$$

where $A(T)$ is the diameter in centimeters at time T (sec); A_0 is the diameter at time zero; K is $(8DC)/\rho$, (cm²/sec); D is the diffusion coefficient for solute (5×10^{-6} cm²/sec); C is the solubility of solute (1.5×10^{-5} g/cm³); and ρ is the density of solute (1.3 g/cm³).

The weight fraction, $W(F)$, of a particle remaining undissolved at time T is:

$$W(F) = A(T)^3/A_0^3 = [(A_0^2 - KT)/A_0^2]^{3/2} \qquad \text{(Eq. 2)}$$

The weight fraction, $W(F)$, of multisized particles remaining undissolved at time T is:

$$W(F) = [(A_{0I}^2 - KT)/A_{0I}^2]^{3/2}(F_I) \qquad \text{(Eq. 3)}$$

where I is the channel number corresponding to the particle size range on the electronic particle size measurement instrument; A_{0I} is the initial diameter of particles in the Ith channel; and F_I is the fraction of the total volume (weight) of particles in the Ith channel.

The dissolution rate constant, K, in the above equation was varied to obtain the best fit for the dissolution profile. The calculated value for K would be $8DC/\rho = 4.6 \times 10^{-10}$ cm²/sec. Particle size distributions based on volume fraction in each channel obtained from the electronic counter were used to generate theoretical curves for $W(F)$ as a function of time.

Particle size distributions of the two small particle size fractions (fractions 1 and 2) are presented in Table I. These data represent an average of results of three experiments. Fraction 1 with the smallest particles has a mean particle diameter of 4.9 μm. Fraction 2 consists of slightly larger particles with a mean particle diameter of 7.1 μm. The narrowness of each fraction is noteworthy. For fraction 1, over 80% of the population, based on volume, is located in only 6 channels (channels 8–13), and 73% is located in only 4 channels (channels 9–12). For fraction 2, over 90% of the population, based on volume, is located in only 5 channels (channels 10–14), and 79% is located in only 3 channels (channels 11–13).

Dissolution profiles for fractions 1 and 2 are given in Fig. 1, and $W(F)$ as a function of time is plotted in this figure. Each point on these graphs represents an average of at least three experiments.

As expected, fraction 1 with smaller particles dissolves considerably faster than the one with larger particles. As can be seen from Fig. 1, almost the entire dissolution profile for each of the two fractions can be satisfactorily described by the Higuchi–Hiestand model with the dissolution rate constant, K, being 1.50×10^{-9} cm²/sec and 1.85×10^{-9} cm²/sec for fractions 1 and 2, respectively. This is ~3.5 times larger than the calculated values for K of 4.6×10^{-10} cm²/sec.

The particle size data for fractions 3 and 4 are shown in Table II. The mean for fraction 3 is 10.6 μm and the mean for fraction 4 is 13.5 μm. The narrowness for each fraction is again demonstrated with 86% of the population for fraction 1 found in 4 channels (channels 6–9), and 82% of the population for fraction 2 also found in 4 channels (channels 7–10).

Dissolution profiles for fractions 3 and 4 are presented in Fig. 2. Fraction 3, as anticipated, dissolved more rapidly than fraction 4. The dissolution profile for each fraction could be adequately described theoretically with K values of 2.0×10^{-9} and 1.7×10^{-9} cm²/sec for fractions 3 and 4, respectively. However, as with fractions 1 and 2 the K values from the experimental data are about four times larger than the theoretical value of 4.6×10^{-10} cm²/sec. It has been concluded from the previous data that the Higuchi–Hiestand model describes a relationship between particle size and dissolution rate but that the K values obtained were approximately four times the theoretical value.

DISCUSSION

It is noteworthy that the K values obtained from the dissolution profiles of four distinct narrow particle size distributions of prednisolone acetate are very similar. This finding suggests that particles ranging in average size from ~5–14 μm in diameter dissolve with one mechanism predominating. This is in keeping with the simulated data reported (7) in which it was demonstrated that a narrow distribution of drug particles, where the smallest and largest particles in the population were 2 and 20 μm in diameter, obeyed a single diffusional model. The suggestion that one mechanism predominates is further substantiated with the recognition that theory and the experimental data agree over the entire dissolution profile and not just during the initial portions of the profile.

Important to a test of this model is recognition that the shape of each experimental dissolution profile is very similar to the shape of the profile generated by the model. This observation suggests that the model is physically realistic.

While the experimental data and theory agree quite well, certain limitations must be recognized. A major finding of this study is that the theory cannot be used to predict actual dissolution profiles, since the calculated K value is ~3.5–4 times greater than the theoretical one. Part of the discrepancy may be related to the physical–chemical data used to calculate the theoretical value for K. In particular, the diffusion coefficient value is only approximate. Further, the particle size data are artificially put into discrete distribution form by the electronic counting device. The resulting histogram of particle sizes may not exactly represent the underlying distribution. However, the K value calculated in connection with Eq. 3 is dependent on the fraction of the total weight of particles in any particular channel.

As previously mentioned (2), the theory assumes that the particles are spheres, and a shape factor may account to some extent for the difference between the calculated and theoretical value for K. However, it is not expected that inclusion of a shape factor would correct for the magnitude of differences found in this study.

One other reason for the discrepancy may be related to a fundamental property of the diffusion-based model. The differential equation for the steady-state form of the model as previously used (1) is:

$$\frac{dm}{dt} = \frac{-D\Delta CA}{a} \qquad \text{(Eq. 4)}$$

where m is the weight of a solid particle, a is the particle radius at time t, and A is the area ($4\pi a^2$). Thus, one can see the similarity between this expression and the commonly used form of Fick's first law, with the particle radius, a, replacing h as the apparent diffusion layer thickness. If the value for the diffusion layer thickness was changed, albeit arbi-

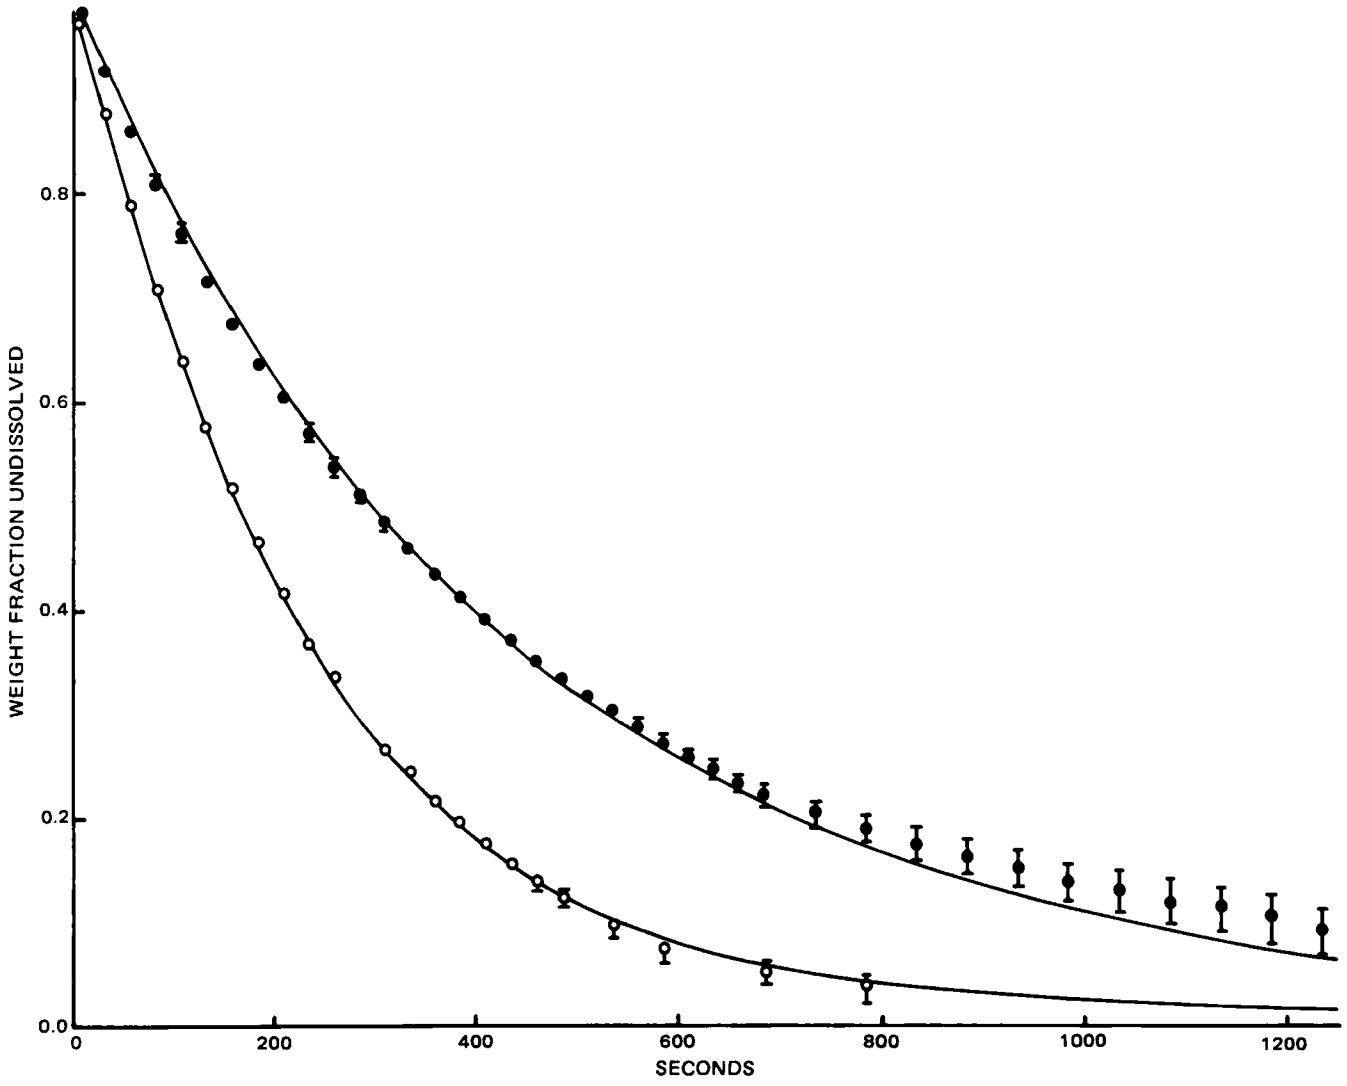

Figure 2—*Dissolution profiles for third and fourth prednisolone acetate fractions. Key: (○) experimental values for fraction 3, solid line calculated from theory with* $K = 2.0 \times 10^{-9}$ *cm²/sec; (●) experimental values for fraction 4, solid line calculated from theory with* $K = 1.7 \times 10^{-9}$ *cm²/sec.*

trarily, then the value for K calculated from the experimental data set could easily be rationalized. Unfortunately, an arbitrarily chosen proportionality constant does not provide any mechanistic insight.

The fact that the calculated value for K is greater than the theoretical one poses a question as to whether or not the diffusion layer thickness for small particles is a function of stirring. While this relationship is not predicted from convective diffusion theory for particles in the size range in this study (7), experimental verification of the actual hydrodynamic effects remains untested.

In summary, excellent correlation exists between a diffusion-based dissolution model and the experimental dissolution profiles for four narrow distributions of prednisolone acetate particles. It is noteworthy that the correlation exists over the entire dissolution profile. Similar rate constants, K, were used to fit the dissolution profile for each prednisolone acetate fraction, indicating a similar dissolution mechanism for each particle size distribution. The rate constants used to fit the experimental data are ~3–4 times greater than the theoretical rate constant calculated using independently determined or calculated values for the solute diffusion coefficient, solubility, and density.

High-Performance Liquid Chromatographic Assay for Partially Nitrated Glycerins in Nitroglycerin

DAVID M. BAASKE ˣ, NANCY N. KARNATZ, and JAMES E. CARTER *

Received December 18, 1981, from the *Analytical Development Group, Product Development Section, Pharmaceutical Development Department, Research and Development Division, American Critical Care, Division of American Hospital Supply Corporation, McGaw Park, IL 60085.* Accepted for publication March 17, 1982. * Present address: Drug Characterization, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.

Abstract □ A high-performance liquid chromatographic method for determining the concentration of mononitroglycerins and dinitroglycerins in the commonly used pharmaceutical raw material nitroglycerin (10% w/w) on lactose USP is presented. A coefficient of variation of <5% for the partially nitrated glycerins was achieved over the range examined (0–4.0 μg/mg). Thirteen lots of raw material were examined and found to contain a total of <0.13% w/w partially nitrated glycerins. A variable wavelength detector (λ = 218 nm) and a microphenyl column were employed. The mobile phase was acetonitrile–water (36:64) pumped at 2 ml/min. The internal standard was isosorbide dinitrate. Total analysis time was 12 min.

Keyphrases □ High-performance liquid chromatography—assay for partially nitrated glycerins in nitroglycerin □ Nitroglycerin—high-performance liquid chromatographic assay for partially nitrated glycerins □ Glycerin—partially nitrated, high-performance liquid chromatographic assay for nitroglycerin

Nitroglycerin has been used orally and topically for many years for the treatment of angina pectoris. Recently, research has led to several new indications for nitroglycerin, all of which take advantage of the benefits of intravenous administration (1–3). The increase in the use of intravenous administration of nitroglycerin has prompted the FDA to seek additional data on the stability and purity of the raw materials used in the manufacture of drugs. To supply this data, a rapid and accurate assay for the partially nitrated glycerins (1,2-dinitroglycerin, 1,3-dinitroglycerin, 1-mononitroglycerin, and 2-mononitroglycerin) in nitroglycerin is needed.

BACKGROUND

Nitroglycerin is the triester of nitric acid and glycerol and is synthesized from glycerol and nitric acid using sulfuric acid as a catalyst. The addition of the nitro groups presumably proceeds in a stepwise manner. Metabolism and the nonexplosive chemical degradation occur by an opposite process—a stepwise loss of nitro groups. Partial completion of any of these processes would result in the contamination of nitroglycerin with partially nitrated glycerins (Scheme I).

Another potential source of partially nitrated glycerins in nitroglycerin is contamination. Most of the nitroglycerin made is intended for use as explosives. Pharmaceutical nitroglycerin is a small proportion of the production. Several explosive mixtures contain significant quantities of partially nitrated glycerins by design, and since they are made by the same manufacturer as the nitroglycerin intended for pharmaceutical use, the potential for cross contamination exists.

There are two widely used colorimetric methods for quantitating nitroglycerin which can be made stability indicating (4, 5). One is the basis for compendial monographs (4). However, the colorimetric methods and a published kinetic assay (6) do not allow the direct quantitation of partially nitrated glycerins.

Gas chromatographic (GC) and high-performance liquid chromatographic (HPLC) methods offer the potential to quantitate the partially nitrated glycerins in nitroglycerin. However, all GC methods require a tedious extraction into an organic phase (7–13), and only two have been employed for dosage-form types of solutions (7, 13), while the rest were designed for blood level assays. The HPLC methods are faster since they do not employ an extraction step (14–17). Of all the chromatographic methods only four demonstrate the potential quantitation of partially nitrated glycerins (12–15) and none specifically do so.

A sensitive HPLC method is described here that specifically allows the rapid direct quantitation of partially nitrated glycerins in nitroglycerin raw materials.

EXPERIMENTAL

Materials—Nitroglycerin[1] (10% w/w on lactose, USP) and isosorbide dinitrate[2] (25% w/w on lactose) were used as received. 1,2-Dinitroglycerin (10% w/w on lactose), 1,3-dinitroglycerin (10% w/w on lactose), 1-mononitroglycerin, and 2-mononitroglycerin were synthesized using literature methods (18). All standards were calibrated by the USP phenoldisulfonic acid assay for nitroglycerin (19). Glass-distilled acetonitrile and methanol were used for all procedures[3]. Purified water was further purified[4] prior to use.

Instrumentation—The liquid chromatographic system consisted of a solvent pumping system[5], an automatic fixed-loop sample injector[6], a variable wavelength detector[7], and a 10-mv recorder[8]. A 30 cm × 3.9-mm column packed with alkylphenyl-bonded silica gel[9] (10 μm), a detector wavelength of 218 nm (AUFS = 0.05), and a chart speed of 20 cm/hr were employed. Sample injections of 100 μl were used.

Mobile Phase—Approximately 1 liter of mobile phase was prepared fresh daily by thoroughly mixing 360 ml of acetonitrile and 640 ml of water. The mobile phase was always filtered through a 0.5-μm filter[4] prior to use. The mobile phase was pumped at a constant rate of 2 ml/min which yielded a pressure of <2000 psi.

Standard Curve—Stock standard solutions were prepared by transferring an accurately weighed sample of partially nitrated glycerin equivalent to 25 mg of active ingredient to a 50-ml volumetric flask. They were then dissolved in 5 ml of alcohol (USP) and brought to volume with water.

Working standard concentrations of ~20, 10, 5, and 2.5 μg/ml in both a mononitroglycerin and a dinitroglycerin were prepared from the stock standards by diluting in water 2-mononitroglycerin (or 1-mononitroglycerin) stock standard solution and 1,2-dinitroglycerin (or 1,3-dinitroglycerin) stock standard solution.

An accurately weighed sample of isosorbide dinitrate (25% w/w on lactose) of 500 mg was placed into a 250-ml volumetric flask, dissolved in 25 ml of alcohol and swirled for 5 min. It was brought to volume with water and mixed well. Ten milliliters of this solution was diluted to 100 ml to yield a final concentration of 50 μg/ml.

An accurately weighed sample of nitroglycerin (10% w/w on lactose), equivalent to 50 mg of active ingredient, was placed in a 100-ml volumetric flask, dissolved in 10 ml of alcohol, and brought to volume with water.

To 1.0 ml of each standard or sample was added 500 μl of isosorbide dinitrate (50 μg/ml) internal standard. Each solution was vortexed[10] for 5 sec and chromatographed. Peak heights for the partially nitrated glycerins and isosorbide dinitrate were measured manually. The peak areas were measured by a laboratory data system[11]. The peak area ratios

were then plotted *versus* concentration to yield a calibration curve. Identical results were obtained using peak height ratios.

RESULTS AND DISCUSSION

The direct quantitation of the partially nitrated glycerins in nitroglycerin (10% w/w on lactose) is reported for the first time. It is based on a modification of an HPLC procedure for nitroglycerin which has been used successfully for over 3 years on almost 10,000 samples (14). Alcohol has been used to speed the dissolution of the various nitrates but is not required.

This procedure does not resolve the dinitroglycerins from one another, nor does it resolve the mononitroglycerins from one another. For the purpose of quantitating partially nitrated glycerins in nitroglycerin raw material the resolution of the isomers is unnecessary. It was demonstrated that not only do the pairs of isomers coelute, but they yield superimposable calibration lines. Thus, it is simpler and more practical to quantitate the isomers employing only one mononitroglycerin and one dinitroglycerin standard. Chromatograms illustrating the obtainable separations are shown in Fig. 1.

The described procedure, using 1 ml of sample or standard and 0.5 ml of internal standard, allows an accurate assay of partially nitrated glycerins over the concentration range commonly encountered in nitroglycerin raw materials (0.0–4.0 μg/mg). It is possible to detect the partially nitrated glycerins down to a level of 0.02 μg/mg by using the maximum detector sensitivity of AUFS 0.002. Even greater sensitivities are theoretically achievable using greater sample sizes or an extraction, but were not required for this study.

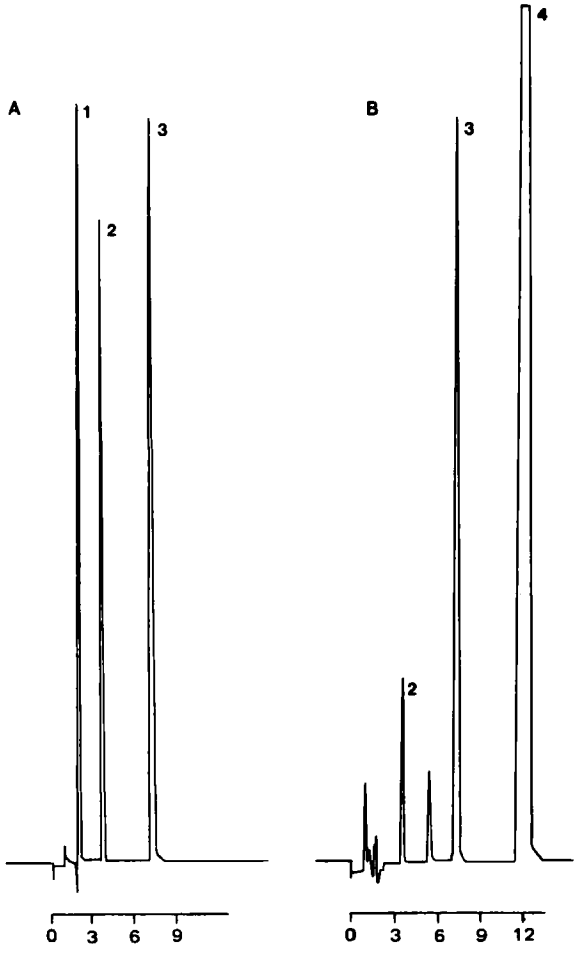

Figure 1—*A—Typical chromatogram of a partially nitrated glycerin standard. Combined partially nitrated glycerin concentration equal to ~0.6% w/w in raw material. Key: (1) mononitroglycerins peak of 14.15 μg/ml; (2) dinitroglycerins peak of 16.40 μg/ml; (3) isosorbide dinitrate. B—Typical chromatogram of a nitroglycerin on lactose raw material sample. No mononitroglycerins detected. Key: (2) dinitroglycerins peak of ~0.1% w/w in raw material; (3) isosorbide dinitrate; (4) trinitroglycerin.*

L	0	0.09
M	0	0.09

[a] Thirteen lots of nitroglycerin (10% w/w on lactose), raw material in percent. [b] 0 = < 0.001%.

Accuracy and Precision—Four replicate, partially nitrated glycerin standards (20, 10, 5, and 2.5 μg/ml) were chromatographed. A correlation coefficient of >0.99 was consistently obtained for both partially nitrated glycerins, as was a coefficient of variation of <3% for the dinitroglycerins and 5% for the mononitroglycerins. Finally, accuracy for the mono- and dinitroglycerins of >95 and 98%, respectively, were found.

Applicability—The method has been applied to nitroglycerin in alcohol, nitroglycerin in propylene glycol (USP), and nitroglycerin (10% w/w on lactose). The practicality of the method was demonstrated by the analysis of 13 lots of nitroglycerin triturate (Table I). In all instances the level of mononitroglycerins was zero. Under the conditions of the experiment this was equivalent to <0.05 μg/ml in the assay solution or 0.001% w/w in the raw material. The dinitroglycerins were present at levels of <0.15% (w/w) in all samples, even after storage at room temperature for 4 years.

Simultaneous Determination of Acetaminophen, Guaifenesin, Pseudoephedrine, Pholcodine, and Paraben Preservatives in Cough Mixture by High-Performance Liquid Chromatography

LAURA CARNEVALE

Received August 3, 1981, from the *Quality Control Department, Fisons Pty. Ltd., Sydney, Australia.* Accepted for publication March 25, 1982.

Abstract □ The separation and simultaneous determination, by high-performance liquid chromatography, of acetaminophen (I), guaifenesin (II), pseudoephedrine hydrochloride (III), and pholcodine (IV), together with a series of parabens (methyl to butyl, V–VIII) in a cough mixture, has been demonstrated using a chemically bonded octadecylsilane stationary phase with a mobile phase of methanol–water–acetic acid (45:55:2) containing the ion-pairing agent octanesulfonic acid. Retention volumes for the active ingredients were 3.8 ml, 5.4 ml, 9.4 ml, and 15.6 ml for compounds I–IV, respectively. Corrected retention volumes for the parabens [5.4 ml for methyl (V), 9.6 ml for ethyl (VI), 18.5 ml for propyl (VII), and 37.9 ml for butyl (VIII)] showed an exponential relationship with chain length of the esterifying alcohols. Excipients did not interfere with the estimation of any of the compounds, hence pretreatment of the sample was unnecessary. Average recoveries of the active ingredients and of the parabens from laboratory prepared samples were essentially 100% of theoretical with standard deviations of 1.7, 0.3, 1.5, 0.3, 0.3, 3.3, 0.7, and 2.7% for I–VIII, respectively.

Keyphrases □ Acetaminophen—simultaneous determination of guaifenesin, pseudoephedrine, pholcodine, and paraben preservatives in cough mixture by high-performance liquid chromatography □ Pseudoephedrine—simultaneous determination of acetaminophen, guaifenesin, pholcodine, and paraben in preservatives in cough mixture by high-performance liquid chromatography □ Paraben—simultaneous determination of acetaminophen, guaifenesin, pseudoephedrine, and pholcodine in preservatives in cough mixture by high-performance liquid chromatography □ High-performance liquid chromatography—simultaneous determination of acetaminophen, guaifenesin, pseudoephedrine, pholcodine, and paraben preservatives in cough mixture

High-performance liquid chromatography (HPLC) has become a powerful tool for the analysis of pharmaceutical products. Mixtures used for the treatment of coughs and colds may be complexes containing several active ingredients including a decongestant, an antihistamine, frequently an analgesic, preservatives, dyes, and flavors. The active materials cover a range of structures with widely varying polarities and include both acidic and basic compounds.

A number of conventional methods have been applied to the present series. Pholcodine has been estimated by UV spectrophotometry following separation by TLC and colorimetry (1, 2). Pseudoephedrine and acetaminophen have been determined spectrophotometrically (3, 4) and by GLC (5, 6). Guaifenesin has been determined in pharmaceutical preparations by GLC (7, 8). The parabens may be assayed by GLC (9) or by UV spectroscopy following sample clean-up by column chromatography (10).

Spectrophotometric, GLC, or methods requiring TLC separation when applied to samples such as cough mixtures can be lengthy and/or subject to interferences by the matrix of the sample, and they are generally not suitable for simultaneous assay. The simultaneous assay of the drugs and preservatives described in this report cannot be achieved by any of the techniques mentioned here.

The application of HPLC procedures to various combinations of drugs and parabens has been reported (11–19), and some attention has been given to the effect of carbon chain length of the alkylsulfonic acid ion-pairing agents on retention times of several drugs (20, 21). The effect of chain length on resolution of mixtures of materials with varying polarity was tested, and a procedure was developed by which eight components, four active materials and four preservatives, may be determined with one injection.

EXPERIMENTAL

Materials—All active ingredients and paraben preservatives were of BP quality except guaifenesin which conformed to BPC standard. All were used without further purification.

Mobile Phase—The mobile phase, methanol[1]–water–glacial acetic acid (45:55:2) containing 0.005 *M* octanesulfonic acid[2], was filtered through a 0.45-μm filter[3]. The flow rate was 2.5 ml/min.

Instrumentation—The liquid chromatograph consisted of a constant flow pump[4], a low-pressure injector[5], a dual channel absorbance detector[6] set at 254 and 280 nm, and a 30-cm × 4-mm i.d. octadecylsilane column[7]. Outputs from the 280-[8] and 254-nm[9] channels were quantitated. Separate monitoring at 254 nm was required for pseudoephedrine which is not detected on the 280-nm channel.

Standard Solutions—The stock solution of analytes in methanol contained 25.00, 5.00, 5.00, 0.75, 0.61, 0.20, 0.33, and 0.20 mg/ml of I–VIII, respectively. Aliquots (2, 3, 4, 5, 6, and 7 ml) of this solution were diluted to 100 ml with water and filtered through a 0.45-μm filter[10]. A calibration

Table I—Percent Recovery of Compounds I–IV from Prepared Mixtures

Amount added as Percent of Theoretical	Acetaminophen (I)	Guaifenesin (II)	Pseudoephedrine Hydrochloride (III)	Pholcodine (IV)
80	103.8	98.5	96.4	100.0
100	99.7	98.5	98.7	99.3
120	100.9	99.1	99.9	99.9
Mean	101.5	98.7	98.3	99.7
SD	2.1	0.3	1.8	0.4

curve for each compound was prepared from triplicate, 20-μl injections of these solutions.

Quantitation of the Actives and Preservatives in Synthetic and Commercial Cough Mixtures—For the determination of recoveries, small laboratory batches of a cough mixture were prepared containing 80, 100, and 120% of the theoretical amount of each of the active ingredients and the four parabens: 500.0, 100.0, 30.0, 15.0, 13.4, 4.0, 6.6, and 4.0 mg of I–VIII/20 ml, respectively.

A control sample containing all ingredients except the actives and parabens was also prepared. Sample analysis was carried out by diluting 5–100 ml with water and filtering through a 0.45-μm filter.

Duplicate, 20-μl injections were made of each filtered sample solution and the results were calculated by reference to a standard containing the theoretical sample concentration. The response of the standard was determined by making four replicate injections, two before and two after the samples were run.

Commercial mixtures were assayed by diluting 5–100 ml with water, filtering with a 0.45-μm filter, and injecting 20 μl. The results were calculated by reference to a single standard containing the theoretical sample level of actives and preservatives.

RESULTS

A typical chromatogram from a cough syrup prepared with the four actives and the four preservatives is shown in Fig. 1. Detector response was linear for all eight compounds between 40 and 140% of the theoretical sample level. Deviations of points from linearity for compounds I–VIII were ≤3.9%.

Preparation of the control sample (*i.e.*, without I–VIII) permitted checking on the possibility of the presence of interfering peaks. The results of the recoveries, shown in Tables I and II, indicate satisfactory

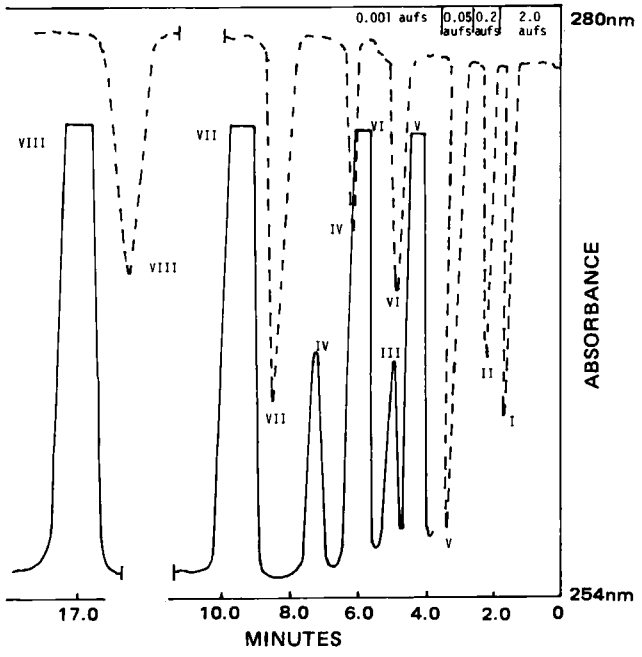

Figure 1—*High-performance liquid chromatogram of a cough preparation. Peaks I–VIII are acetaminophen, guaifenesin, pseudoephedrine hydrochloride, pholcodine, methyl–butyl paraben, respectively.*

Table II—Percent Recovery of Compounds V–VIII from Prepared Mixtures

Amount added as Percent of Theoretical	Methyl Paraben (V)	Ethyl Paraben (VI)	Propyl Paraben (VII)	Butyl Paraben (VIII)
80	99.3	103.1	99.4	105.0
100	99.3	98.0	100.2	100.0
120	99.9	104.2	98.5	104.2
Mean	99.5	101.8	99.4	103.1
SD	0.3	3.3	0.9	2.7

method precision and accuracy, the highest standard deviation for the recovery of any one compound being 3.3% and the average recoveries for all eight compounds lying within the range of 98.3–103.1%.

A result emerging coincidentally from this work was the determination of the structure–retention volume relationship for the parabens. A plot of corrected retention volume *versus* chain length of the esterifying alcohol shows the exponential type relationship which reduces to a semilog linear plot (Fig. 2).

The overall accuracy was evaluated by making a single injection of each of nine commercial preparations of known composition and calculating the results by comparison with nine replicate injections of a single standard solution (Table III).

DISCUSSION

The simultaneous analysis of this group of compounds presented several problems. The difference in polarity between I and VIII rendered separation of I–VI difficult, if VII and VIII were to be eluted within a reasonable time. The large differences in detector response and concentration between acetaminophen and the other components restricted the amount of sample that could be injected without overloading the detector on both channels. Even at the concentration described, maximum absorbance of acetaminophen on the 280-nm channel approaches 2.0. However, this concentration was necessary in order to obtain quantifiable peaks for pseudoephedrine and pholcodine. Difficulties were encountered because there were three classes of compounds [acidic (I), basic (III, IV) and nonpolar (II, V–VIII)] undergoing analysis simultaneously. Ideally, two types of chromatography would be required to achieve the desired separation: reverse-phase with ion-pairing reagents for acidic and basic compounds and ordinary reverse-phase for nonpolar compounds. An alkylsulfonic acid was added to the mobile phase to obtain retention and separation of the two basic compounds (III and IV) present in the mixture. The acetaminophen elutes close to the solvent front but does not suffer from interference by coeluting impurities from the sample matrix.

Mean Recovery[b]	100.6	98.1	100.0	100.6	99.2	99.9
SD[c]	1.5	1.6	1.5	2.3	1.8	2.1

[a] Recoveries expressed as percent of theoretical. [b] Calculated from nine replicates. [c] Standard deviations of a single determination calculated from nine replicates.

Initially hexanesulfonic acid[11] was chosen with a water–methanol ratio of 70:30, but this resulted not only in a long retention time for VIII, as its retention is not dependent on the ion-pairing agent, but also gave a poor separation of III and V. By using octanesulfonic acid as the ion-pairing agent and changing the water–methanol–acetic acid ratio of the mobile phase to 55:45:2, a satisfactory separation was achieved. Addition of acetic acid reduced tailing of III and peak broadening of IV.

The analytical results demonstrate the ability of ion-pair reverse-phase HPLC to simultaneously assay four actives and four paraben preservatives. A particular advantage of the method is the minimum time required for sample preparation and analysis of the complete separation requiring only 18 min. The method has been successfully used on a routine basis for over 6 months. Special column clean-up procedures have not been required during this time and no significant loss of column performance has been observed.

Synthesis and Pharmacological Activity of Benzo[*b*]thiophene-3-carboxylic Acid Derivatives

A. SHAFIEE * ×, M. A. HEDAYATI *, M. M. SALIMI ‡, and S. M. FAGHIHI ‡

Received December 7, 1981, from the **Department of Chemistry, College of Pharmacy* and the ‡*Department of Animal Physiology and Pharmacology, School of Veterinary Medicine, Tehran University, Tehran, Iran.* Accepted for publication March 31, 1982.

Abstract □ Several dialkylaminoethyl benzo[*b*]thiophene-3-carboxylates, *N*-(2-dialkylaminoethyl)benzo[*b*]thiophene-3-carboxamides, 2-dialkylaminoethyl benzo[*b*]thiophene-3-carbamates, and substituted ureas with benzo[*b*]thiophene moiety, were prepared and tested for local anesthetic, anticholinergic, and antihistaminic activities. Several of the compounds showed significant activity

Keyphrases □ Benzo[*b*]thiophene-3-carboxylic acid derivatives—synthesis and pharmacological activity, local anesthetic, anticholinergic, and antihistaminic activity □ Anesthetics, local—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives □ Anticholinergics—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives □ Antihistamines—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives

Many of the clinically active local anesthetics are dialkylaminoalkyl esters and dialkylaminoalkylamides of carboxylic acids (1). Some dialkylaminoalkylesters of 2- or 3-benzo[*b*]thiophenecarboxylic acid have been reported to have hypotensive, antiviral, and antifungal activities (2), as have some benzo[*b*]thiophene-2-carboxamides (3). Synthesis and Pharmacological Activity of Benzo[*b*]thiophene-3-carboxylic Acid Derivatives

A. SHAFIEE * ×, M. A. HEDAYATI *, M. M. SALIMI ‡, and S. M. FAGHIHI ‡

Received December 7, 1981, from the **Department of Chemistry, College of Pharmacy* and the ‡*Department of Animal Physiology and Pharmacology, School of Veterinary Medicine, Tehran University, Tehran, Iran.* Accepted for publication March 31, 1982.

Abstract □ Several dialkylaminoethyl benzo[*b*]thiophene-3-carboxylates, *N*-(2-dialkylaminoethyl)benzo[*b*]thiophene-3-carboxamides, 2-dialkylaminoethyl benzo[*b*]thiophene-3-carbamates, and substituted ureas with benzo[*b*]thiophene moiety, were prepared and tested for local anesthetic, anticholinergic, and antihistaminic activities. Several of the compounds showed significant activity

Keyphrases □ Benzo[*b*]thiophene-3-carboxylic acid derivatives—synthesis and pharmacological activity, local anesthetic, anticholinergic, and antihistaminic activity □ Anesthetics, local—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives □ Anticholinergics—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives □ Antihistamines—synthesis and pharmacological activity of benzo[*b*]thiophene-3-carboxylic acid derivatives

Many of the clinically active local anesthetics are dialkylaminoalkyl esters and dialkylaminoalkylamides of carboxylic acids (1). Some dialkylaminoalkylesters of 2- or 3-benzo[*b*]thiophenecarboxylic acid have been reported to have hypotensive, antiviral, and antifungal activities (2), as have some benzo[*b*]thiophene-2-carboxamides (3). has been demonstrated that some dialkylaminoalkylesters and dialkylaminoalkylamides of benzo[*b*]thiophene-2-carboxylic acid have local anesthetic activity (4). Recently, antibacterial and antifungal activities of alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid have been reported (5).

In a continuing effort to find a potent pharmacologically active compound with low toxicity (6), a series of dialkylaminoethyl benzo[*b*]thiophene-3-carboxylates, *N*-(2-dialkylaminoethyl)benzo[*b*]thiophene-3-carboxamide, 2-dialkylaminoethyl benzo[*b*]thiophene-3-carbamates, and substituted ureas with the benzo[*b*]thiophene moiety were prepared and the efficacy was determined.

DISCUSSION

Chemistry—Dialkylaminoethyl benzo[*b*]thiophene-3-carboxylates were synthesized using readily available benzo[*b*]thiophene-3-carboxylic acid (I) (5). Reaction of I with thionyl chloride and the subsequent reaction of the acyl halide with dialkylaminoethanol gave the desired compound III (Scheme I).

Benzo[*b*]thiophene-3-carboxamide derivatives (IV or V) were obtained through the reaction of benzo[*b*]thiophene-3-carbonyl chloride (II) with 2-dialkylaminoethylamine or *N*-methylpiperazine (Scheme I).

2-Dialkylaminoethyl benzo[*b*]thiophene-3-carbamates (VII) were prepared through the reaction of benzo[*b*]thiophene-3-carboxazide (VI) (5) with 2-dialkylaminoethanol (Scheme II).

Substituted ureas with the benzo[*b*]thiophene moiety (VIII or IX) were obtained through the reaction of VI with a dialkylaminoalkylamine or *N*-methylpiperazine (Scheme II).

The physical data for the prepared compounds are summarized in Tables I–IV.

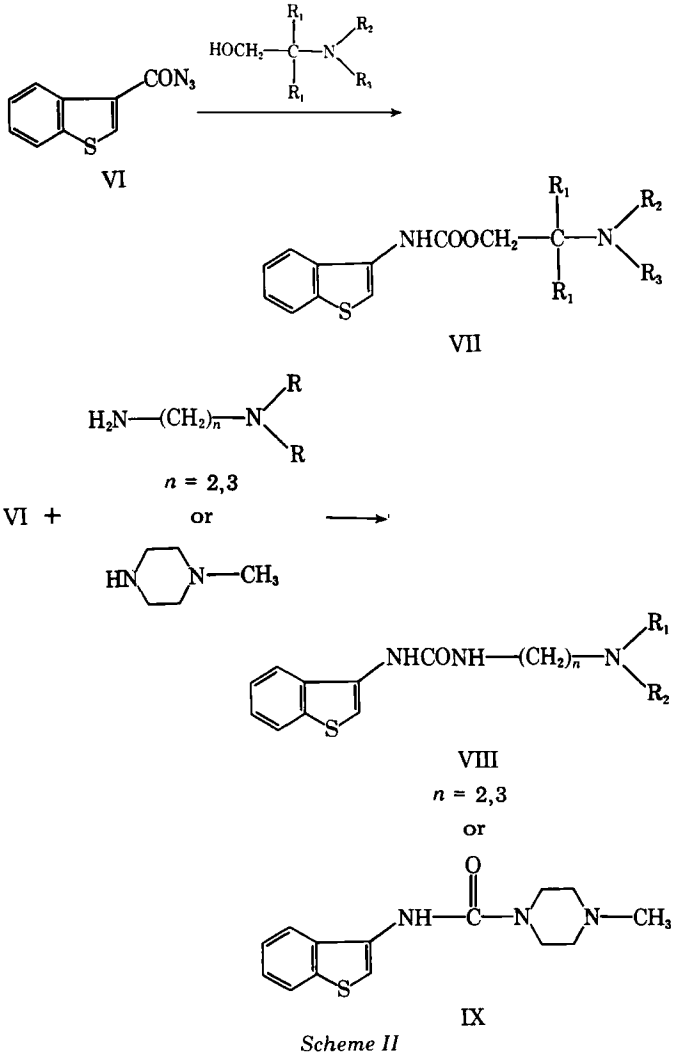
[a] All compounds were crystallized as hydrochlorides and the recrystallization solvent was ethanol–ethyl acetate. [b] IR, NMR, and mass spectra of all compounds were consistent with the structural assignments.

Pharmacological Assay—The compounds listed in Tables I–IV were screened for surface anesthetic, anticholinergic, and antihistaminic activities. For surface anesthetic activity, a rabbit conjunctival sac was kept filled with the aqueous solution of the hydrochloric salt of the compounds for 60 sec. The cornea was tested once every minute, and the duration of anesthesia was followed for 18 min. Lidocaine hydrochloride was used for comparison. The results are presented in Table V.

Compounds III*e*, III*f*, IV*b*, and VIII*d* were the most potent. The LD_{50} values of compounds III*e*, III*f*, and IV*b* in mice, estimated by the moving average method (7), were 424.7 (395.9–455.6), 274.2 (255.2–294.8), and 179.5 (158.3–204.2) mg/kg, respectively, when injected intraperitoneally.



Scheme II

Apart from transient irritation, no conjunctival intolerance or corneal opalescene was observed 24 and 48 hr and 1 week after drug application.

Anticholinergic and antihistaminic activities were tested on isolated guinea pig ileum. The results are presented in Table V.

Compounds III*a*, III*f*, IV*b*, VII*c*, and VIII*d* were the most potent as anticholinergics; and compounds III*a*, V, VII*c*, and VIII*d* were the most potent as antihistamines.

EXPERIMENTAL[1]

Benzo[*b*]thiophene-3-carbonyl Chloride (II)—A mixture of the acid, I (17.8 g, 0.1 mole), and thionyl chloride (35 ml) was refluxed for 4 hr. Excess thionyl chloride was removed under reduced pressure, and the residue was fractionated to give 17.7 g (90%) of the desired compound, bp 149–150°; 4 mm Hg [lit. (11) bp 296–298°, 758 mm Hg].

Anal.—Calc. for C_9H_5ClOS: C, 54.96; H, 2.54. Found: C, 55.07; H, 2.39.

2-Dimethylaminoethyl Benzo[*b*]thiophene-3-carboxylate (III*a*)—A solution of 2-dimethylaminoethanol (0.89 g, 0.01 mole) and II (1.965 g, 0.01 mole) in 20 ml of dry benzene was refluxed for 4 hr. The solvent was evaporated, and the residue was crystallized from ethanol–ethyl acetate to give III*a* (2.43 g, 88%), mp 131–132°; IR (potassium bromide): 1710 and 1195 (ester) cm^{-1}; NMR (deuterochloroform, as free base): 8.67 (m, 1H, H_4), 8.43 (s, 1H, H_2), 7.90 (m, 1H, aromatic), 7.50 (m, 2H, aromatic), 4.47 (t, 2H, OCH_2), 2.73 (t, 2H, CH_2N), and 2.33 (s, 6H, NCH_3) ppm; *m/z* 249.

Compounds III*b–f* were prepared similarly (Table I).

***N*-(2-Dimethylaminoethyl)benzo[*b*]thiophene-3-carboxamide (IV*a*)**—A solution of II (1.965 g, 0.01 mole) and 2-dimethylaminoethylamine (0.88 g, 0.01 mole) in 30 ml of dry benzene was refluxed for 2 hr. The solvent was evaporated and the residue was crystallized from ethanol–ethyl acetate to give IV*a* (1.74 g, 70%), mp 134–135°; IR (potassium bromide): 3260 (NH) and 1640 (amide) cm^{-1}; NMR (deuterochloroform, as free base): 8.45 (m, 1H, H_4), 7.95 (s, 1H, H_2), 7.86 (m, 1H, aromatic), 7.45 (m, 2H, aromatic), 6.96 (bs, 1H, NH), 3.56 (q, 2H, $CONCH_2$), 2.46 (q, 2H, CH_2N), and 1.26 (s, 6H, NCH_3) ppm; *m/z* 248.

Compounds IV*b*, IV*c*, and V were prepared similarly (Table II).

2-Dimethylaminoethyl Benzo[*b*]thiophene-3-carbamate (VII*a*)—A solution of benzo[*b*]thiophene-3-carboxazide (VI, 2.03 g, 0.01 mole) (5) in 20 ml of dry benzene was refluxed for 2 hr, 2-dimethylaminoethanol (0.89 g, 0.01 mole) was added, and reflux was continued for an additional 2 hr. The solvent was evaporated and the residue was crystallized as a hydrochloride from ethanol–ethyl acetate to give VII*a* (2.34 g, 78%), mp 174–175°; IR (potassium bromide): 3180 (NH), 1710 (carbonyl) cm^{-1}; NMR (deuterochloroform, as free base): 8.06–7.40 (m, 6H, aromatic and NH), 4.42 (t, 2H, OCH_2), 2.70 (t, 2H, CH_2N), and 2.36 (s, 6H, NCH_3) ppm; *m/z* 264.

Compounds VII*b–e* were prepared similarly (Table III).

***N*$_1$-(Dimethylaminoethyl)-*N*$_3$-(benzo[*b*]thiophene-3-yl)urea (VIII*a*)**—A solution of VI (2.03 g, 0.01 mole) in 20 ml of dry benzene was refluxed for 2 hr, 2-dimethylaminoethylamine (0.88 g, 0.01 mole) was

[1] Melting points were taken on a Kofler hot-stage microscope and are uncorrected. IR spectra were recorded using a Perkin-Elmer model 267 spectrograph. NMR spectra were determined using a Varian T-60 spectrometer and chemical shifts (δ) are in parts per million relative to internal tetramethylsilane. Mass spectra were recorded on a Varian MAT-311 instrument.

Binding of Several Phenothiazine Neuroleptics to a Common Binding Site of α_1-Acid Glycoprotein, Orosomucoid

SAFAA EL-GAMAL *§, UWE WOLLERT *†, and WALTER E. MÜLLER ‡ ×

Received December 14, 1981, from the **Pharmakologie und Toxikologie für Naturwissenschaftler, Fachgereich Pharmazie, Universität Mainz* and the ‡*Pharmakologisches Institut der Universität Mainz, Obere Zahlbacher Strasse 67, D-6500 Mainz, West Germany.* Accepted for publication April 1, 1982. §Present address: Department of Pharmaceutics, Faculty of Pharmacy, Alexandria University, Alexandria, Egypt. †Deceased.

Abstract □ The interaction of several phenothiazine neuroleptics with α_1-acid glycoprotein was investigated using circular dichroism and equilibrium dialysis techniques. For chlorpromazine only, one high-affinity binding site of the protein was found. The binding of the drug to this single site generated typical polyphasic extrinsic Cotton effects. Since several other phenothiazine neuroleptics gave qualitatively comparable extrinsic Cotton effects in the presence of α_1-acid glycoprotein and potently inhibited the binding of chlorpromazine to the single site, it was concluded that all phenothiazine derivatives investigated bound preferentially to only one common binding site of the α_1-acid glycoprotein molecule.

Keyphrases □ Phenothiazines—neuroleptics, binding to a common binding site of α_1-acid glycoprotein, orosomucoid □ Neuroleptic agents—binding of phenothiazines to a common binding site of α_1-acid glycoprotein, orosomucoid □ α_1-Acid glycoproteins—binding of several phenothiazine neuroleptics to a common binding site, orosomucoid □ Orosomucoid—binding of several phenothiazine neuroleptics to a common binding site of α_1-acid glycoprotein

While for most neutral or anionic drugs the predominating role of the albumin fraction as the major binding component in human blood is established, increasing evidence has been presented during recent years that this is not the case for several basic drugs where other proteins also contribute considerably to the plasma binding. Out of these, orosomucoid (α_1-acid glycoprotein) received the most attention because of its possible significance for the pharmacokinetic pattern of basic drugs (1). Thus, large variations in the blood levels of α_1-acid glycoprotein observed in patients suffering from various disease states could have been responsible for similarly large variations of the free plasma levels of some basic drugs measured in the same patients (1–3). Since the average plasma levels of α_1-acid glycoprotein are rather low, usually between 10 and 40 μmole/liter (2, 3), a fairly strong drug binding to this protein has to be assumed if variations of its plasma levels were to contribute considerably to the free fraction of a drug. Some recent work shows that several basic drugs are bound very strongly to α_1-acid glycoprotein (4–8). An example of this is the phenothiazine derivative, perazine, which is bound with very high affinity to mainly one site of the α_1-acid glycoprotein molecule (5–7).

The present study reports similar findings for chlorpromazine. Evidence is presented that a variety of phenothiazine neuroleptics, including perazine and chlorpromazine, are preferentially, if not exclusively, bound to only one common binding site of the α_1-acid glycoprotein molecule.

EXPERIMENTAL

Materials—α_1-Acid glycoprotein[1] (orosomucoid) had an electrophoretic purity >99%. [^{14}C]Chlorpromazine[2] had a specific activity of 80 mCi/mmole and a radiochemical purity >99%. All chlorpromazine derivatives were gifts from the manufacturers[3]. All other chemicals were obtained from commercial suppliers. All solutions were prepared with deionized water.

Circular Dichroism Measurements—Circular dichroism measurements were carried out with a spectropolarimeter[4] calibrated with *d*-camphorsulfonic acid. All spectra were recorded in cylindrical cells with 10-mm path length using a full-scale deflection of 0.02° θ and a spectral band width of 2 nm. All measurements were made in 0.07 *M* phosphate buffer (pH 7.4). Results are expressed as molar ellipticity ($[\theta]$) calculated with reference to the α_1-acid glycoprotein concentration (25 μM).

Equilibrium Dialysis—Binding of [^{14}C]chlorpromazine to α_1-acid glycoprotein was determined by equilibrium dialysis using a protein concentration of 12.5 μM and varying concentrations of the drug. All solutions were prepared in 0.07 *M* phosphate buffer (pH 7.4); 0.9 ml of the protein solution was dialyzed for 16 hr in the dark against 0.9 ml of buffer containing [^{14}C]chlorpromazine. One-milliliter dialysis cells and

Binding of Several Phenothiazine Neuroleptics to a Common Binding Site of α_1-Acid Glycoprotein, Orosomucoid

SAFAA EL-GAMAL *§, UWE WOLLERT *†, and WALTER E. MÜLLER ‡ ×

Received December 14, 1981, from the **Pharmakologie und Toxikologie für Naturwissenschaftler, Fachgereich Pharmazie, Universität Mainz* and the ‡*Pharmakologisches Institut der Universität Mainz, Obere Zahlbacher Strasse 67, D-6500 Mainz, West Germany.* Accepted for publication April 1, 1982. §Present address: Department of Pharmaceutics, Faculty of Pharmacy, Alexandria University, Alexandria, Egypt. †Deceased.

Abstract □ The interaction of several phenothiazine neuroleptics with α_1-acid glycoprotein was investigated using circular dichroism and equilibrium dialysis techniques. For chlorpromazine only, one high-affinity binding site of the protein was found. The binding of the drug to this single site generated typical polyphasic extrinsic Cotton effects. Since several other phenothiazine neuroleptics gave qualitatively comparable extrinsic Cotton effects in the presence of α_1-acid glycoprotein and potently inhibited the binding of chlorpromazine to the single site, it was concluded that all phenothiazine derivatives investigated bound preferentially to only one common binding site of the α_1-acid glycoprotein molecule.

Keyphrases □ Phenothiazines—neuroleptics, binding to a common binding site of α_1-acid glycoprotein, orosomucoid □ Neuroleptic agents—binding of phenothiazines to a common binding site of α_1-acid glycoprotein, orosomucoid □ α_1-Acid glycoproteins—binding of several phenothiazine neuroleptics to a common binding site, orosomucoid □ Orosomucoid—binding of several phenothiazine neuroleptics to a common binding site of α_1-acid glycoprotein

While for most neutral or anionic drugs the predominating role of the albumin fraction as the major binding component in human blood is established, increasing evidence has been presented during recent years that this is not the case for several basic drugs where other proteins also contribute considerably to the plasma binding. Out of these, orosomucoid (α_1-acid glycoprotein) received the most attention because of its possible significance for the pharmacokinetic pattern of basic drugs (1). Thus, large variations in the blood levels of α_1-acid glycoprotein observed in patients suffering from various disease states could have been responsible for similarly large variations of the free plasma levels of some basic drugs measured in the same patients (1–3). Since the average plasma levels of α_1-acid glycoprotein are rather low, usually between 10 and 40 μmole/liter (2, 3), a fairly strong drug binding to this protein has to be assumed if variations of its plasma levels were to contribute considerably to the free fraction of a drug. Some recent work shows that several basic drugs are bound very strongly to α_1-acid glycoprotein (4–8). An example of this is the phenothiazine derivative, perazine, which is bound with very high affinity to mainly one site of the α_1-acid glycoprotein molecule (5–7).

The present study reports similar findings for chlorpromazine. Evidence is presented that a variety of phenothiazine neuroleptics, including perazine and chlorpromazine, are preferentially, if not exclusively, bound to only one common binding site of the α_1-acid glycoprotein molecule.

EXPERIMENTAL

Materials—α_1-Acid glycoprotein[1] (orosomucoid) had an electrophoretic purity >99%. [^{14}C]Chlorpromazine[2] had a specific activity of 80 mCi/mmole and a radiochemical purity >99%. All chlorpromazine derivatives were gifts from the manufacturers[3]. All other chemicals were obtained from commercial suppliers. All solutions were prepared with deionized water.

Circular Dichroism Measurements—Circular dichroism measurements were carried out with a spectropolarimeter[4] calibrated with *d*-camphorsulfonic acid. All spectra were recorded in cylindrical cells with 10-mm path length using a full-scale deflection of 0.02° θ and a spectral band width of 2 nm. All measurements were made in 0.07 *M* phosphate buffer (pH 7.4). Results are expressed as molar ellipticity ($[\theta]$) calculated with reference to the α_1-acid glycoprotein concentration (25 μM).

Equilibrium Dialysis—Binding of [^{14}C]chlorpromazine to α_1-acid glycoprotein was determined by equilibrium dialysis using a protein concentration of 12.5 μM and varying concentrations of the drug. All solutions were prepared in 0.07 *M* phosphate buffer (pH 7.4); 0.9 ml of the protein solution was dialyzed for 16 hr in the dark against 0.9 ml of buffer containing [^{14}C]chlorpromazine. cellophane dialysis membranes[5] were used. The radioactivity at both sides of the membrane was determined by liquid scintillation spectrometry[6].

RESULTS AND DISCUSSION

Plotting the binding data obtained by the equilibrium dialysis experiments for the interaction of [^{14}C]chlorpromazine with α_1-acid glycoprotein according to Scatchard (9) revealed a straight line with an abscissa intercept of 0.9, indicating that [^{14}C]chlorpromazine binds within the concentration range investigated (up to a molar drug–protein ratio of 5) to only one site of the α_1-acid glycoprotein moleculer (Fig. 1B). As indicated by the association constant, k, $\sim 3 \times 10^6\ M^{-1}$, the affinity of this single site for chlorpromazine is very high and within the range of the strongest drug interactions with human serum albumin (10–12).

The binding of chlorpromazine to α_1-acid glycoprotein profoundly

changes the native intrinsic circular dichroism spectrum of the protein between 250 and 350 nm (4, 13). In the difference spectrum, when the intrinsic Cotton effects of the protein alone have been subtracted, typical polyphasic extrinsic Cotton effects can be seen (Fig. 2). For chlorpromazine, a large positive band around 255 nm and two weaker negative bands around 27 nm can be seen (Fig. 2). The change in intensity of all three bands depends on the drug–protein concentration ratio in a similar fashion which can be demonstrated using the data for the strong positive band at 255 nm (Fig. 1A). The results show that maximum induction of the Cotton effects occurs when the drug–protein ratio reaches 1, indicating that the induction of Cotton effects is associated with the binding of chlorpromazine to only one site.

Several other phenothiazine neuroleptics also generate extrinsic Cotton effects in the presence of α_1-acid glycoprotein which are qualitatively similar to those of chlorpromazine (Fig. 2). The two most pronounced exceptions are the presence of an additional positive band >300 nm in the case of acepromazine and trifluoperazine and the positive sign of the band of acepromazine around 270 nm, instead of the negative sign observed for all other derivatives (Fig. 2). For trifluopromazine no extrinsic Cotton effects up to a molar excess of five were observed. The extrinsic Cotton effects of all phenothiazine derivatives depend on the drug concentration in a manner similar to that of chlorpromazine as shown for the positive band around 260 nm (Table I). Thus, the induced Cotton effects of the five chlorpromazine derivatives may also be associated with one preferential binding site. Moreover, the qualitatively comparable spectra suggest that the steric parameters of these interactions are similar for the drugs investigated, which might indicate that all phenothiazine derivatives investigated share the same high-affinity binding site with chlorpromazine. In agreement with these assumptions are the findings that all derivatives investigated inhibit the binding of [^{14}C]chlorpromazine to the single binding site; however, there are different potencies (Table I). Thus, considering these observations and the findings of only one high-affinity binding site of perazine (5–7), the assumption of one common high-affinity binding site of α_1-acid glycoprotein for most phenothiazine neuroleptics is justified.

In contrast to the rather unspecific binding of phenothiazine neuroleptics to serum albumin where good correlations between hydrophobic character and binding have been reported (14, 15) there is neither a clear correlation between lipophilicity (indicated by the partition coefficients in Table I) and the potencies of the derivatives as inhibitors of [^{14}C]-chlorpromazine binding nor between lipophilicity and the intensities of the induced Cotton effects (Table I). Structural parameters other than the lipophilicity are more important. As far as it is possible with the limited data available at the present state, it seems that for the intensity of the extrinsic Cotton effects and for the binding itself (indicated by the increase of the free fraction of [^{14}C]chlorpromazine) the substituent —R_1 on the phenothiazine nucleus is much more important than the aliphatic side chain (—R_2). This is best seen when comparing the data for promazine with either the data of acepromazine or trifluopromazine or comparing promazine with perazine. However, to draw final conclusions about the structural parameters leading to high-affinity binding and strong induced Cotton effects in the case of the interaction of phenothiazine derivatives with α_1-acid glycoprotein, more data using more derivatives are needed.

In conclusion, the data reported indicate that for the phenothiazine neuroleptics investigated in this study, binding to α_1-acid glycoprotein is mediated mainly by only one common high-affinity binding site of the protein.

Complexation of Procainamide with Hydroxide-Containing Compounds

V. DAS GUPTA

Received September 18, 1981, from the *University of Houston, College of Pharmacy, Houston, TX 77030.* Accepted for publication April 2, 1982.

Abstract □ The complexation of procainamide with hydroxide-containing compounds, ethanol, fructose, glucose, glycerin, lactose, maltose, propylene glycol, sorbitol, and sucrose, have been studied. Procainamide formed a complex with glucose, lactose, and maltose, all of which contain a hemiacetal group, whereas fructose and sucrose do not. The percent of complex formed was dependent on the pH of the solution, with an optimum range of ~4–5.2. As with glucose, the percent of complex formed was directly related to the concentration of lactose in the solution. In dry mixtures, procainamide did not form a complex with glucose or lactose. The complex formed with lactose or maltose could be completely reversed by adding hydrochloric acid. A similar observation with glucose was reported earlier. In the optimum pH range, equilibrium was established in ~24 hr, and the process of complexation followed the equation for reversible reactions.

Keyphrases □ Complexation—procainamide with hydroxide-containing compounds □ Procainamide—complexation with hydroxide-containing compounds □ Hydroxide-containing compounds—complexation with procainamide

An earlier report (1) reviewed the literature concerning stability and complexation problems of procainamide in the presence of glucose. The report also presented the results of a study on the complexation of procainamide with glucose. (These two compounds are often mixed in hospitals for intravenous infusion for the treatment of cardiovascular diseases.)

Since procainamide oral dosage forms also are used widely, the formation of complex with some of the excipients seemed possible. The present report investigated the formation of procainamide complexes with hydroxide-containing compounds, ethanol, fructose, glucose, glycerin, lactose, maltose, propylene glycol, sorbitol, and sucrose.

EXPERIMENTAL

Materials—All chemicals and reagents were USP, NF, or ACS grade and were used as received. Procainamide hydrochloride[1] (I) was used without further purification.

A high-performance liquid chromatograph[2], equipped with a multiple wavelength detector[3], a recorder[4] and digital integrator[5], was used.

A semipolar column[6] (30 cm long × 4-mm i.d.) consisting of a monomolecular layer of cyanopropylsilane permanently bonded to silica gel was used.

Chromatographic Conditions—The mobile phase was 40% (v/v) acetonitrile in water containing 0.02 *M* ammonium acetate (pH ~7)[7], and the flow rate was 2.0 ml/min. The detector was set at 280 nm (the wavelength of maximum absorption), the sensitivity was 0.04, the temperature was ambient, and the chart speed was 30.5 cm/hr.

Methods—The stock solutions of procainamide hydrochloride (1.0 mg/ml) and the internal standard, methapyrilene hydrochloride (5.0 mg/ml) in water, were prepared fresh daily. A standard solution was prepared by transferring a 1.5-ml quantity of the stock solution of I and a 4.0-ml quantity of the stock solution of methapyrilene hydrochloride (II) to a 100-ml volumetric flask and then diluting with water to volume.

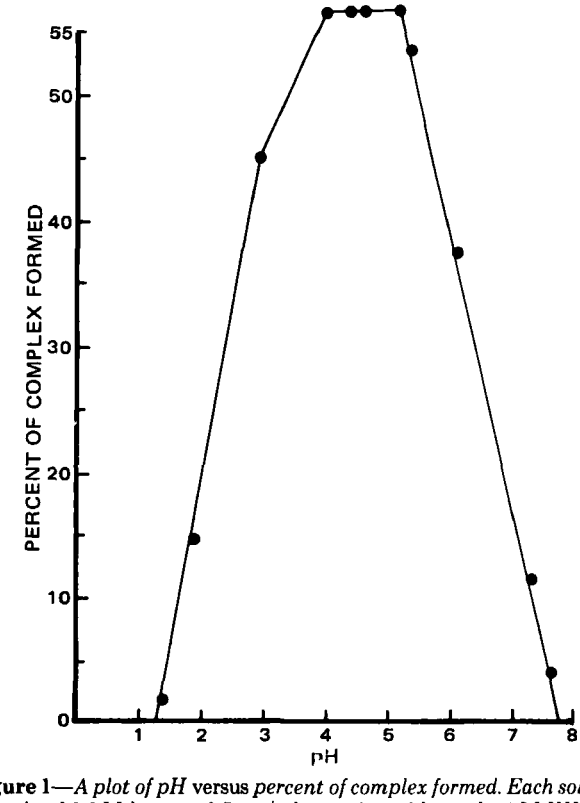

Figure 1—*A plot of pH* versus *percent of complex formed. Each solution contained 0.2* M *lactose, 0.5 mg/ml procainamide, and 0.2* M KH_2PO_4. *Solution of pH 1.4 was buffered with ~1* N *HCl. A similar plot was obtained with glucose.*

144	42.3	41.8	84.4	76.8	67.4	60.2	—	—

[a] See Table I. [b] Without sodium edetate.

All solutions prepared for the investigations of procainamide complexes are reported in Table I. All were prepared using a simple solution method. The solutions were assayed, transferred to amber-colored bottles[8], and stored at room temperature (24 ± 1°). They were assayed after appropriate intervals, and pH values were also determined.

All solutions were diluted with water to contain 15.0 μg/ml of I (based on the label claim) and 200.0 μg/ml of II (internal standard).

A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the standard solution was injected after the assay solution eluted.

[8] Brockway Glass Co., Brockway, Pa.

Calculations—The results were calculated using:

$$\frac{(Ph)_a}{(Ph)_s} \times 100 = \text{Percent of the label claim} \qquad \text{(Eq. 1)}$$

where $(Ph)_a$ is the ratio of the peak heights of procainamide and methapyrilene of the assay solution and $(Ph)_s$ is that of the standard solution of identical concentrations.

Other Experiments—A 1.5-ml quantity of 1-day-old solution in 0.2 *M* lactose (solution 12 in Table I) or in 0.1 *M* maltose (solution 42 in Table I) was mixed with 1.5 ml of ~5 *N* HCl. The mixture was allowed to stand for ~15 min, then 4.0 of the stock solution of the internal standard was added, the mixture brought to volume (100.0 ml) with water, and assayed.

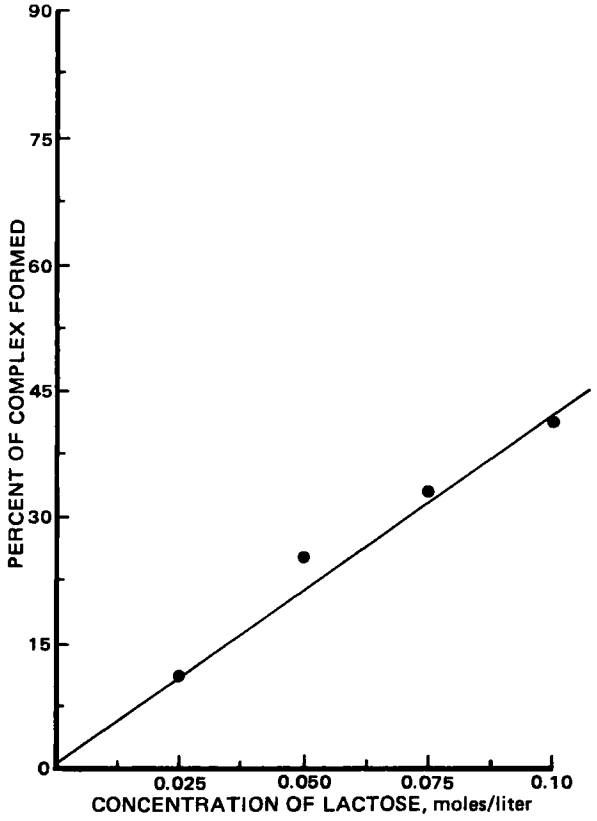

Figure 2—*A plot of lactose concentration (moles/liter)* versus *percent of complex formed.*

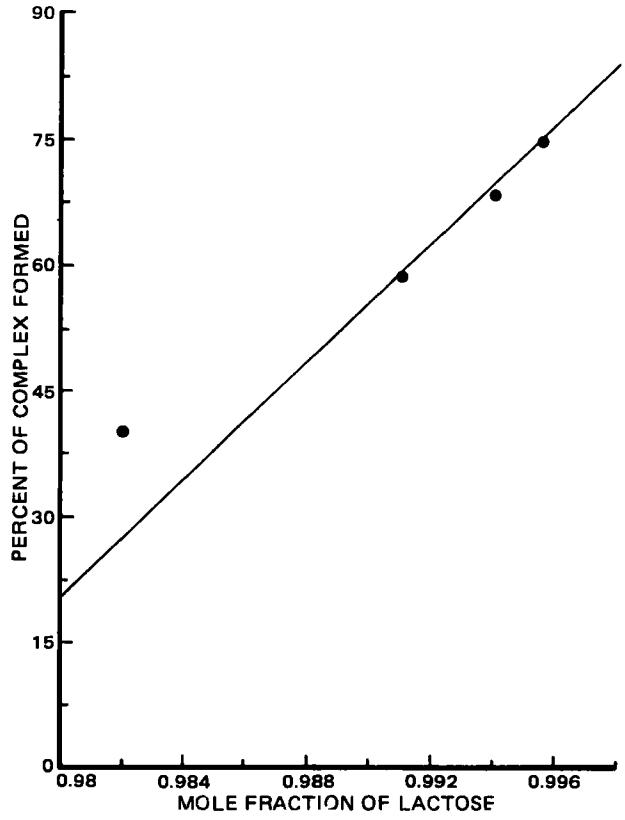

Figure 3—*A plot of lactose concentration (mole fraction)* versus *percent of complex formed.*

A 25.0-mg quantity of procainamide was mixed thoroughly with either 1.8 g of glucose or 3.6 g of lactose; the dry mixtures were allowed to stand overnight and assayed.

The solutions containing 0.2 *M* glucose/lactose, 0.2 *M* KH_2PO_4, and 0.5 mg/ml of procainamide were prepared and assayed at appropriate intervals up to 144 hr.

RESULTS AND DISCUSSION

The results indicate (Table I) that procainamide forms complexes with glucose, lactose (solutions 1–15, Table I), and maltose (solution 42 in Table I). The other hydroxide-containing compounds, ethanol, fructose, glycerin, propylene glycol, sorbitol, and sucrose, did not form complexes with procainamide (Table I). Therefore, it appears that a hemiacetal group is necessary for the formation of a complex. This group is present only in glucose, lactose, and maltose and not in other hydroxide-containing compounds.

The percent of procainamide complexed with lactose (as with glucose) was dependent on the initial pH value of the solution (solutions 25–40, Table I). For both glucose and lactose, the optimum pH range for the formation of complex appears to be ~4–5.2 (Fig. 1). The percent of complex formed with lactose and maltose were similar (solutions 21 and 42, Table I).

In a biologically useful pH range (7.3–7.5), the formation of complex was low (solutions 33 and 40, Table I). For example, only 11.2% of procainamide was complexed with lactose at pH 7.3, whereas almost 57% complexed between pH 4 and 5.2. Similar results were obtained with glucose.

Initially, when solution 2 in Table I was compared with solution 4, the percent of complex formed with lactose appeared much higher than with glucose. Nevertheless, in buffered solutions of identical pH (solutions 9 and 11, Table I), the difference was negligible.

The formation of complex was not affected by the addition of sodium edetate (solutions 11 and 12, Table I) or potassium chloride (solutions 29 and 30 and 35 and 36, Table I). As in glucose, the percent of complex formed was directly related to the concentration of lactose in the solution. At lower concentrations, molar concentrations of lactose were related and higher concentration mole fractions were related (Figs. 2 and 3). The formation of the complex could be completely reversed by adding hydrochloric acid (a similar observation was reported earlier with glucose). For example, solution 12 in Table I had only 42.4% of free procainamide after 24 hr of storage. On treatment with hydrochloric acid (*Other Experiments*), the concentration of free procainamide was 100.3%.

When solutions 17–20 (Table I) were reassayed after 6 days, there was only slight change in the concentration of free procainamide in solution 17 (Table II). In others, no significant change was noted (Table II). In solutions 9 and 12, the equilibrium was established in ~24 hr (Table II). The process of complexation followed the equation of reversible reactions as explained previously (1) for glucose.

In dry mixtures (*Other Experiments*), procainamide did not form a complex with glucose or lactose (Table II). Apparently, water is necessary for the formation of the complex.

Correlation between Dissolution and Disintegration in Dissolution Apparatuses

Keyphrases □ Dissolution—disintegration, mathematical model linking dissolution and disintegration □ Disintegration—dissolution, mathematical model linking dissolution and distintegration

To the Editor:

El-Yazigi (1) in a recent article has proposed a model that links dissolution and disintegration in a dissolution apparatus. In deriving a convenient mathematical presentation mode, he assumes that the rate of appearance of dissolved material (A_s) is proportional to the mass of undissolved particles (A_p):

$$\frac{dA_s}{dt} = k_s A_p \qquad \text{(Eq. 1)}$$

where t is time and k_s is a dissolution rate constant (obviously in units of reciprocal time). He correctly cautions that this is not necessarily correct. The reason for using the mass dependence ($k_s A_p$ in Eq. 1) rather than a surface dependence:

$$\frac{dA_s}{dt} = k' \cdot \Gamma \cdot (A_p)^{2/3} \qquad \text{(Eq. 2)}$$

in which Γ is a shape factor (2), is presumably a mathematical convenience. It is an interesting approach, and it is the intent of this communication to compare the conclusion of El-Yazigi with those of previous investigators (3, 4). In the latter case the conditions of Eq. 2 and sink conditions were employed (*i.e.*, a cube root law was assumed) for the dissolution of drug from particles. The equations arrived at were for a basket apparatus, but a similar approach with similar conclusions can be arrived at for the simpler paddle apparatus.

The equations in the previous report (1) predict a biphasic exponential decay of undissolved mass, where the exponential term in the later phase depends on k_s. Several previously published treatments (3–6) have dealt with this problem. Carstensen *et al.* (3, 4) predicted (and demonstrated experimentally) that the undissolved mass should decay in a biphasic manner in the (often encountered) particular cases where disintegration (k_d in reciprocal time units) is rate determining. The latter phase is an exponential decay, but with the exponent dependent on k_d, *i.e.*, being a function of disintegration. This, however, is not universally applicable and only holds if the disintegration is rate limiting. A similar model has been developed (5) using (and demonstrating) a cube root dissolution model for the powder in a tablet, and for an established dissolution curve the disintegration curve was back calculated (6). This latter approach was found to be of a power exponential type [$\exp(-tb/a)$, where a and b are Weibull constants]. Other reports supporting surface dependent models have appeared in the literature (7).

In any event, the approach (1) is interesting and contains some supporting data which allow for some comparisons. Eq. 11 of Ref. 1 states:

$$DT_{calc} = 6 \cdot 0.693/k_d \qquad \text{(Eq. 3)}$$

where DT_{calc} is the calculated disintegration time obtained from the exponent of the initial phase of the dissolution plot. It is, as shown, based on the assumption that 1.56% of the tablet weight remaining (6 half-lives) constitutes complete disintegration. This is as good a conservative termination point as any, but it should be pointed out that there is nothing magical about it, and that, for instance, five half-lives would have been a good estimate as well. From a physical point of view, it might be rational to assume that the point where the tablet has been reduced to the size of a granule (8) (either the one used in producing the tablet or the one produced by disintegration) might be the cutoff point.

If, on the other hand, the number of half-lives, n, is assumed unknown than Eq. 3 takes the form:

$$DT = n\ 0.693/k_d \qquad \text{(Eq. 4)}$$

where DT stands for disintegration time. In logarithmic form this becomes:

$$\ln(DT) = \ln n + \ln 0.693 - \ln k_d \qquad \text{(Eq. 5)}$$

If this is equated to the experimentally determined disintegration time (DT), then $\ln(DT)$ should be linear in $\ln k_d$ with a slope of -1. The data from Table II of Ref. 1 are repeated in this form in Table I, and $\ln(DT)$ is shown as a functon of $\ln k_d$ in Fig. 1. It is seen that there is fair

Table I—Data from Table II of Reference 1

$\ln DT_{exp}$	$\ln k_d$
2.64	−1.136
2.34	−0.774
1.91	−0.785
2.43	−1.008
2.29	−0.884
3.20	−1.595
Slope[a]	−1.314
Intercept[a]	1.114
Correlation Coefficient[a]	−0.994

[a] Regression of $\ln DT$ on $\ln k$.

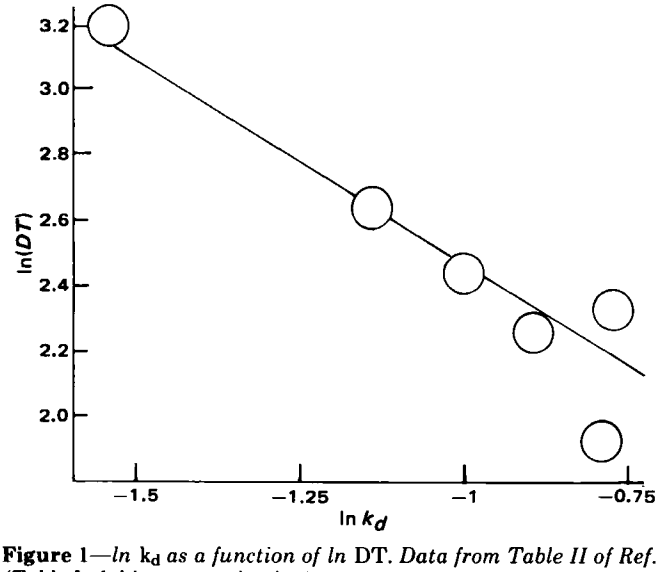

Figure 1—*ln* k_d *as a function of ln* DT. *Data from Table II of Ref. 1 (Table I of this communication).*

0022-3549/83/0200-0208$01.00/0

linearity (the correlation coefficient being 0.994 as shown in Table I). The least-squares fit is:

$$\ln(DT) = -1.32 \ln k_d + 1.114 \qquad \text{(Eq. 6)}$$

Although the slope is (significantly) different from −1, it is of the same order of magnitude so that this fact in no way disproves the utility of the previous method[1]. From the intercept it can be concluded that $\ln(0.693n) = 1.114$, *i.e.*, $n = 3.0/0.693 = 4.4$ half lives.

It is seen that further analysis of the data (1) do not disprove the hypothesis put forth. Whether the model of El-Yazigi is more applicable than previously proposed models (3, 4) is a point for future experimentors to verify.

BOOKS

Annual Review of Pharmacology and Toxicology. Vol. 22. Edited by ROBERT GEORGE, RONALD OKUN, and ARTHUR K. CHO. Annual Reviews Inc., 4139 El Camino Way, Palo Alto, CA 94306. 1982. 739 pp. 16 × 23 cm. Price $22.00 ($25.00 outside USA).

Traditionally, the first chapter of each volume of this annual review has been devoted to a historical/philosophical/autobiographical topic. This year it is an autobiographical statement by Thomas H. Maren. Traditionally also, the last chapter has been reserved for Chauncey Leake's "Review of Reviews." Since Leake's death, that feature has been continued in a very creditable fashion by E. Leong Way, although with a somewhat narrower perspective. The remainder of the book consists of 23 reviews of the literature, which have been sorted into 13 sections with 1–4 chapters each.

The sections of this year's review are titled: Mechanisms of Action of Drugs and Chemicals; Perinatal Pharmacology; Antimicrobial, Antiviral, and Antiparasite Chemotherapy; Cardiovascular Pharmacology; Renal Pharmacology; Neuropharmacology and Neurochemistry; Behavioral and Psychopharmacology; Anesthetics, Analgesics, and Anti-Inflammatory Agents; Endocrine Pharmacology; Comparative Pharmacology; Environmental and Industrial Pharmacology and Toxicology; Clinical Pharmacology and Drug Interaction; and Techniques.

One would presume that the chapters within each section would be clumped together but, in actuality, they are randomly distributed among the chapters of other sections. Therefore, the practice of dividing the table of contents into sections seems to be an unnecessary gesture since the readers of this volume will be quite capable of grasping the general content of each chapter from the titles themselves.

Individuals in the pharmaceutical sciences will find the review by H. H. Szeto on "Pharmacokinetics in the Ovine Maternal–Fetal Unit" to be of interest and the review on "Food and Drug Interactions" by C. Jelleff Carr to be useful but rudimental. Especially effective literature reviews are M. J. Antonaccio's "Angiotensin Converting Enzyme (ACE) Inhibitors," J. Torretti's "Sympathetic Control of Renin Release," and H. E. Brezenoff and R. Giuliano's "Cardiovascular Control by Cholinergic Mechanisms in the Central Nervous System." Perhaps the most provocative review is "Neurochemical Basis of Acupuncture Analgesia" by J. S. Han and L. Terenius, while the most debatable offering is "Sociopharmacology" by M. T. McGuire, M. J. Raleigh, and G. L. Brammer.

This reviewer has a standing order for this series and considers it essential as a continuing education tool and as a quick reference source. The number of primary references per review ranges from 67 to 318 for this volume. Considering the current prices for technical books, this series is a bargain by any standard that might be applied.

Topics in Pharmaceutical Sciences Edited by D. D. BREIMER and P. SPEISER. Elsivier/North Holland Biomedical Press, Amsterdam, The Netherlands 1981. 535 pp. 16 × 24 cm. Price $69.74 U.S., 150 Dfl.

The book, which contains over thirty chapters, is the proceedings of the 41st International Congress of FIP, held in Vienna, Austria, Sept. 1981. There chapters are divided into seven symposia which cover some of the major areas of thrust in the pharmaceutical sciences. The symposium titles are:

Advances in Pharmacokinetics;
Pharmaceutical Aspects of Anti-Cancer Drug Treatment;
Biopharmaceutics: Advances in Drug Delivery
Drug Stability *in vitro* and *in vivo;*
Analysis and Drug Metabolites in the 80s;
Pharmaceutical Technology;
Gene Manipulation, Cell Cultures, and Pharmaceutical Sciences.

An author index is provided but, unfortunately, there is no subject index. The price is rather high for a symposium proceeding produced from camera-ready copy.

Since *Topics in Pharmaceutical Sciences* covers a very broad spectrum of subjects, it cannot be recommended for anyone seeking an in-depth discussion on any particular subject. (It averages less than 80 pages per symposium.) It can, however, be recommended for those who want an overview of the current thinking in the subjects covered.

Therefore, the practice of dividing the table of contents into sections seems to be an unnecessary gesture since the readers of this volume will be quite capable of grasping the general content of each chapter from the titles themselves.

Individuals in the pharmaceutical sciences will find the review by H. H. Szeto on "Pharmacokinetics in the Ovine Maternal–Fetal Unit" to be of interest and the review on "Food and Drug Interactions" by C. Jelleff Carr to be useful but rudimental. Especially effective literature reviews are M. J. Antonaccio's "Angiotensin Converting Enzyme (ACE) Inhibitors," J. Torretti's "Sympathetic Control of Renin Release," and H. E. Brezenoff and R. Giuliano's "Cardiovascular Control by Cholinergic Mechanisms in the Central Nervous System." Perhaps the most provocative review is "Neurochemical Basis of Acupuncture Analgesia" by J. S. Han and L. Terenius, while the most debatable offering is "Sociopharmacology" by M. T. McGuire, M. J. Raleigh, and G. L. Brammer.

This reviewer has a standing order for this series and considers it essential as a continuing education tool and as a quick reference source. The number of primary references per review ranges from 67 to 318 for this volume. Considering the current prices for technical books, this series is a bargain by any standard that might be applied.

Topics in Pharmaceutical Sciences Edited by D. D. BREIMER and P. SPEISER. Elsivier/North Holland Biomedical Press, Amsterdam, The Netherlands 1981. 535 pp. 16 × 24 cm. Price $69.74 U.S., 150 Dfl.

The book, which contains over thirty chapters, is the proceedings of the 41st International Congress of FIP, held in Vienna, Austria, Sept. 1981. There chapters are divided into seven symposia which cover some of the major areas of thrust in the pharmaceutical sciences. The symposium titles are:

Advances in Pharmacokinetics;
Pharmaceutical Aspects of Anti-Cancer Drug Treatment;
Biopharmaceutics: Advances in Drug Delivery
Drug Stability *in vitro* and *in vivo;*
Analysis and Drug Metabolites in the 80s;
Pharmaceutical Technology;
Gene Manipulation, Cell Cultures, and Pharmaceutical Sciences.

An author index is provided but, unfortunately, there is no subject index. The price is rather high for a symposium proceeding produced from camera-ready copy.

Since *Topics in Pharmaceutical Sciences* covers a very broad spectrum of subjects, it cannot be recommended for anyone seeking an in-depth discussion on any particular subject. (It averages less than 80 pages per symposium.) It can, however, be recommended for those who want an overview of the current thinking in the subjects covered.

Molecular Basis of Drug Action. Edited by THOMAS P. SINGER and RAUL N. ONDARZA. Elsevier/North-Holland, New York, NY 10017. 1981. 408 pp. 16 × 24 cm. Price $55.00.

This book contains the proceedings of the International Symposium on the Molecular Basis of Drug Action held in Queretaro, Mexico in October 1980. The editors have dedicated the book to the memory of Dr. Eugene C. Jorgensen. The warmth of the picture of Gene in the front of the book and the clear sparkling quality of his chapter brings us poignant reminders of the humanistic and scientific qualities of this man.

The book is divided into five sections; each section having three to six chapters. The section topics are: Drugs Against Microbial Invaders, Suicide Inhibitors, New Directions in Molecular Pharmacology, Ionic Channels and Pumps, and Mechanisms of Drug Resistance.

The book is unusual for a symposium volume for several reasons. The chapters have been carefully guided and edited so that there is more than the usual background information found in symposia volumes. Most chapters are mini reviews. The tables, schemes, figures, and art work are well-designed and attractive. Most importantly, they enrich the information content of the chapter. The choice of sections and articles covers quite thoroughly most of the current work in this dynamic approach. The distinguished contributors bring together in one volume a valuable collection of articles on the molecular basis of drug action.

The book is of such significant quality that individual drug scientists may want to purchase it for their libraries. It is certainly a fitting memorial to Gene Jorgensen, one of the pioneers in this field.

The Alkaloids. Chemistry and Physiology, Vol. 19. Founding Editor, R. H. F. MANSKE, Edited by R. G. A. RODRIGO. Academic Press, Inc., New York, NY 10003 1981. 227 pp. 15 × 23 cm. Price $39.00.

Volume 19 of *The Alkaloids* marks the continuation of this classic series, which reviews advances in alkaloid chemistry. Included in this volume are groups of alkaloids which have not been reviewed for over 10 years. These new groups are *Sceletium*, *Solanum* steroids, and phenanthroindolizidine and phenanthroquinolizidine alkaloids.

Peter W. Jeffs has written an excellent comprehensive review of the *Sceletium* (Fam. *Aizoaceae*) alkaloids. The number of alkaloids from this genus has increased to more than 25. They fall into four structural classes based on four different ring systems: the mesembrine, joubertiamine, pyridine-dihydropyridone, and tortuosamine. Detailed descriptions are given of chemical and spectral methods of structure elucidation, synthetic methods, chemical transformations, and biosynthetic studies.

A chapter by Helmut Ripperger and Klaus Schreiber reviews the *Solanum* steroid alkaloids. This well-organized chapter presents work since 1966 in tables which supplement similar surveys in Volume 10. There are tables of the occurrence of *Solanum* glycoalkaloids and alkamines, composition of the glycoalkaloids, and physical constants of all the glycosides, alkamines, and their derivatives (over 500) described since 1967. The physical constants are arranged by tables according to the five different C_{27}-carbon skeletons comprising the *Solanum* steriodal alkamines. The structure elucidation of new alkamines, syntheses, and chemical degradations are described in detail. Interest has been renewed in these alkaloids as a source of starting material for making hormonal steroid drugs.

In another chapter Ralph C. Bick and Wannee Sinchai review all 16 phenanthroindolizidine and two phenanthroquinolizidine alkaloids that are known. The phenanthroindolizidines are often called *Tylophora* alkaloids, since they frequently occur in this genus (Fam. *Asclepiadaceae*). Spectral methods are described in separate sections with specific examples of how the techniques are used for structure characterization. The chapter also features a section on the various synthetic schemes which have been developed for these alkaloids. The large interest in syntheses stems from reported biological activities of these compounds, including antitumor activity.

This volume of *The Alkaloids* maintains the high quality of the series and should be added to the collections of alkaloid chemists.

The Alkaloids. Chemistry and Physiology, Volume 20. Founding Editor, R. H. F. MANSKE, Edited by R. G. A. RODRIGO. Academic Press, Inc., New York, NY 10003. 1981. 341 pp. 15 × 23 cm. Price $59.50.

This 20th volume of the excellent series on advances in alkaloid chemistry is devoted to bisindole and eburnamine–vincamine alkaloids. The exacting thoroughness with which these groups of alkaloids are covered is characteristic of the reviews in this series.

Geoffrey A. Cordell and J. Edwin Saxton have combined discussions of various bisindole alkaloids into a single review, whereas in previous volumes the dimeric alkaloids have been a part of more specific reviews on alkaloids of a particular genus or structural type. The unifying factor of the bisindoles lies in their containing two tryptophan-derived nuclei. The sections of the review are organized based on progressing biosynthetic pathways from simple tryptamine units to two monoterpenoid indoles. Special sections on ^{13}C-NMR data or various synthetic schemes of particular groups of alkaloids are also included. References for plant sources and physical data of all structurally identified bisindoles are summarized by table.

The other group of alkaloids covered in this volume is the eburnamine–vincamine type which is reviewed by Werner Döpke. Much of the recent work on these pentacyclic indole alkaloids is in the area of establishing absolute configurations. New stereoselective syntheses have been achieved, especially for vincamine, which has recently been found to have medicinal uses. Extensive discussions on specific alkaloids are restricted mainly to the new alkaloids of this type which have been isolated since the last review in Volume 11.

Volume 20 continues the well-organized style of this outstanding series. It should be of particular interest to indole alkaloid chemists and others who wish to have exceptional reviews of these important classes of alkaloids.

Restoring the Oracle of Science

When the APhA member pays his or her annual membership dues, that member is helping to support or "buy"—among other benefits, services, and programs—a certain amount of representation in the halls of Congress and the offices of the federal executive agencies. Such representation includes offering advice, technical counsel, and scientific persuasion to those in government.

We recently read an article in the Sunday magazine section of *The Washington Post*, the thesis of which is that no one in Washington really has "power" in the usual sense of the word. What they do have is "access," and "access" translates into "influence," which is the true common denominator in politics as practiced in Washington, D.C. Consequently, the success of organizations in the nation's capital is largely dependent upon how well those organizations are able to establish access to the right people and, in turn, exert influence over those people *via* that access.

In the case of APhA—as with other national health care and scientific membership societies—representation at the national political level is only one of several equally important purposes or objectives of the organization. And, within that sphere, representation and influence regarding scientific matters and technical issues constitutes an even more limited scope of activity and basis for APhA's existence.

In contrast, the geographic "next-door neighbor" to APhA on Constitution Avenue is the National Academy of Sciences–National Research Council (NAS–NRC). This venerable institution was chartered by Congress and President Abraham Lincoln in 1863 with the express purpose of serving as a, if not "the," private-sector science advisory body for the federal government. But many things have changed over the past 120 years.

The federal government itself has grown immensely and in that growth has added all sorts of technical, scientific, and research groups to its regulatory agencies, to the cabinet executive departments, and in the support services provided to Congress as the legislative wing of the United States government. For example, in the health area, these groups range from the Food and Drug Administration's National Center for Drugs and Biologics, to the National Institutes of Health, to the Congressional Office of Technology Assessment. Moreover, a host of independent or quasi-independent bodies have also sprung up including the National Science Foundation, The Brookings Institute, the Carnegie Institution, the Rand Corporation, and so on. Finally, since approximately the end of the World War II era, most U.S. Presidents have recognized the value of appointing a special Science Advisor to the President or having a Presidential Office of Science Policy.

So no longer is there any shortage of science advice and willing and eager science advisors on the Washington political scene. Indeed, they often agressively compete among and between themselves for attention, visibility, and the opportunity to be heard even if their advice may not be accepted or followed.

All of this has spelled trouble—with a capital "T"—for the prestigious NAS–NRC. Its prominence and reputation went unchallenged for many years, and, as in the case with many venerable and stodgy institutions of a by-gone era, it was ill-prepared to meet the onslaught of competition from younger, more vigorous, and more aggressive purveyors of scientific counsel and technical advice. Unsurprisingly, the result is that NAS–NRC has gone into at least a partial eclipse as its once undisputed position suddenly declined.

Thirteen years ago, an effort to reverse this situation was started when Philip Handler was named NAS–NRC President. Although he happened to be a distinguished biochemist, that facet of his background was incidental to his new assignment. Basically, what was needed was a skilled administrator—which Handler generally proved to be—and his past reputation as a research biochemist was simply a bonus that helped him to open doors, gain attention, and win the respect of his scientific peers.

But years of benign neglect and an activist and often hostile climate of operation limited what any one leader could accomplish. Due to economic considerations, the NAS–NRC day-to-day operation was forced to undertake fee-for-service activities numbering in the hundreds but almost all of extremely narrow scope. The hundreds of committees, panels, and boards were all diligently studying and dissecting the trees while ignoring the forest.

Science and Government Report, a Washington-based publication that describes itself as "The Independent Bulletin of Science Policy," devoted much of one of its 1982 issues to a close look at the NAS–NRC in an article titled "Academy of Sciences Stakes Out a New Role." Editor Daniel S. Greenberg reviewed and analyzed what he characterized as the "institutional shaking, headrolling, and reorganizing that's going on at the venerable NAS."

It is Greenberg's thesis that Handler's successor, former Presidential Science Advisor Frank Press, is trying to reshape the Academy and to restore it to its former position "as the high temple of science." Greenberg sees the new NAS president as having a markedly different agenda than that followed during the Handler era.

"In Press's vision of the Academy of the future, the institution would focus its scholarly resources on big issues and eventually get out of the role of job shop for any government agency that wants to hire its prestige . . . . Press would like to see the Academy revert to its early role as a staging area for science's political interests in Washington. Lots of wheeling and dealing aimed at starting or stopping something on the federal scene used to go on at the Academy."

But the key to being able to pull off such a change is money. It was the "job shop" projects that paid the bills for the Academy to operate over the past generation or longer. Without the infusion of a lot of financial donations from some philanthropic source, there will not be the wherewithal to do what Press is described as trying to accomplish.

And in a budget-tight economy, with an Administration looking for every place to cut further on expenditures, the prospect of Uncle Sam becoming Santa Claus is extremely remote.

Moreover, to date the Reagan Administration has shown little desire, need, or interest in tapping any outside source for the purpose of major shaping of science policy.

Collectively, all of this projects a relatively dismal prognosis for the NAS. Academy President Press will need to muster not only his considerable personal administrative talents, but also the strong and unified support of the entire scientific community, if the NAS is to regain its former exalted position as the pinnacle of science policy.

Renal Clearance of Inorganic Sulfate in Rats: Effect of Acetaminophen-Induced Depletion of Endogenous Sulfate

JIUNN HUEI LIN and GERHARD LEVY ˣ

Received February 4, 1982, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication May 14, 1982.

Abstract □ Certain drugs that are eliminated partly by conjugation with sulfate cause appreciable depletion of endogenous inorganic sulfate in animals and humans. The limited availability of endogenous inorganic sulfate contributes to, or is responsible for, dose-dependent elimination kinetics and can cause pronounced time-dependent changes in the disposition of drugs that are metabolized to sulfate conjugates. A comprehensive characterization of the pharmacokinetics of such drugs requires, therefore, an interdigitation with the kinetics of endogenous inorganic sulfate. The latter is cleared from the body primarily by renal excretion. The purpose of this investigation was to determine the relationship between the renal clearance and the serum concentration of inorganic sulfate, particularly in the subnormal concentration range during acetaminophen-induced sulfate depletion. Administration of acetaminophen, 150 mg/kg iv, to adult male rats reduced their serum inorganic sulfate concentration from $\simeq$1 m*M* to <0.1 m*M* without affecting the renal clearance of creatinine. The renal clearance ratio, sulfate–creatinine, decreased from between 0.2 and 0.3 at $\simeq$1 m*M* serum sulfate to $\simeq$ 0.05 at <0.1 m*M* serum sulfate concentration. When serum sulfate concentration was increased to $\simeq$1.5 m*M* by iv infusion of sodium sulfate, the sulfate–creatinine renal clearance ratio increased abruptly to $\simeq$1 without affecting creatinine renal clearance. Acetaminophen had no effect on the high renal clearance of inorganic sulfate during hypersulfatemia. The pronounced serum concentration dependence of sulfate renal clearance facilitates inorganic sulfate homeostasis. A survey of the literature indicates that the relatively low endogenous serum sulfate concentration ($\simeq$0.3–0.4 m*M*) in humans (compared with dogs, rabbits, and rats) is due primarily to low formation rate rather than high renal clearance of inorganic sulfate.

Keyphrases □ Inorganic sulfate—renal clearance in rats, effect of acetaminophen-induced depletion of endogenous sulfate □ Renal clearance—inorganic sulfate in rats, effect of acetaminophen-induced depletion of endogenous sulfate □ Acetaminophen—renal clearance of inorganic sulfate in rats, effect of induced depletion of endogenous sulfate

Conjugation with sulfate is an important biotransformation pathway for certain phenolic drugs and for many endogenous compounds including certain steroids and biogenic amines (1). Administration of therapeutic or pharmacologic doses of acetaminophen or salicylamide results in depletion of endogenous sulfate, as reflected by decreased serum concentrations and urinary excretion of inorganic sulfate in humans and animals (2–6). This depletion of inorganic sulfate, and the consequent decrease in the availability of activated sulfate (3′-phosphoadenosine-5′-phosphosulfate) as a cosubstrate for sulfate conjugation, can cause or contribute to pronounced dose dependency in the pharmacokinetics of drugs that are eliminated by conjugation with sulfate and can also cause the pharmacokinetics of such drugs to exhibit marked time-dependency (7, 8). A comprehensive characterization of the pharmacokinetics of these drugs requires, therefore, mathematical models that include a description of the kinetics of endogenous sulfate formation and elimination.

Endogenous sulfate is derived primarily from oxidation of sulfur-containing amino acids and, partly, from inorganic sulfate contained in the diet (9–11). Thus, previous researchers (9) were able to demonstrate a strong correlation between the urinary excretion of sulfate and the dietary intake of methionine and cystine in human subjects. The urinary excretion of sulfate by children with kwashiorkor is only about one-third of normal due to their protein-deficient diet and the resultant reduced intake of sulfur-containing amino acids (10). Inorganic sulfate is eliminated from the body predominantly by urinary excretion as such (12). In nonmedicated humans on a normal diet and with normal renal function, only ~7–20% of total sulfate is excreted in bound form, *i.e.*, as endogenous sulfate conjugates (3,13). The ratio of bound to free sulfate excretion by normal rats is similar to (14) or even lower than in humans (3). Reduced or absent renal function is associated with pronounced retention of inorganic sulfate; there is a strong, positive correlation between the serum concentrations of creatinine and inorganic sulfate in hu-

mans (15) and rats (8) with renal dysfunction. Thus, renal clearance is the major determinant of inorganic sulfate elimination kinetics.

Studies on healthy humans and animals (dogs, rabbits, and rats) have shown that the renal clearance of inorganic sulfate is ~10–35% of glomerular filtration rate (GFR) under normal physiological conditions and increases to a rate approximately equal to GFR when serum sulfate concentrations are increased substantially by administration of sodium sulfate (15–20). This renal clearance–serum concentration profile is consistent with glomerular filtration of inorganic sulfate and partial renal tubular reabsorption by a capacity-limited process (19, 20). However, more recent studies have revealed also the presence of a tubular secretory process for sulfate ion in mammals, but it is quite clear that net reabsorption is predominant (21,22). To date, *in vivo* investigations of sulfate renal clearance have been performed under conditions in which serum sulfate concentrations were in the physiological range or elevated by administration of inorganic sulfate. For considerations of the role of endogenous sulfate levels in the elimination of drugs that are subject to sulfate conjugation, the renal clearance of inorganic sulfate at subnormal serum sulfate concentrations

Table I—Urinary Excretion Rate of Inorganic Sulfate, Acetaminophen Sulfate, and Total Conjugated Sulfate Before and After Injection of Acetaminophen [a]

is more relevant. This investigation has been designed particularly to determine the concentration dependence of inorganic sulfate renal clearance during sulfate depletion, *i.e.*, in the subnormal serum sulfate concentration range.

EXPERIMENTAL

Adult, male Sprague-Dawley rats (330–380 g) had a cannula implanted in the right jugular vein (23) and another in the urinary bladder, under light ether anesthesia 1 day before the experiment. The animals were kept unrestricted in individual plastic metabolism cages. Food and water were withdrawn in the morning and withheld for the duration of the experiment, which was started in the morning.

The general experimental design is illustrated in Fig. 1. Urine was collected at 2-hr intervals, usually for 12 hr. Each time, the bladder was

12	0.59 ± 0.22	2.96 ± 1.22	0.64 ± 0.13	3.40 ± 1.28

[a] Results are expressed as mean ± *SD*, $n=11$ (for acetaminophen) or $n=6$ (for sodium sulfate). [b] 150 mg/kg iv at 4 hr. [c] 9.6 mg/hr was infused for 8 hr starting at the 4th hour of the experiment.

washed with three 1-ml portions of normal saline solution and these were combined with the collected urine. Blood samples were obtained at frequent intervals, as shown in Fig. 1. After a 4-hr control period for collection of two 2-hr urine samples and two blood samples (one for creatinine and the other for inorganic sulfate determination), the animals received an injection of acetaminophen, 150 mg/kg iv, through the cannula. The drug was administered as a 2.5% solution in 40% propylene glycol–normal saline. Blood samples (0.35 or 0.60 ml) were collected in plastic syringes, and serum was separated by centrifugation. To ensure that mainstream blood was obtained, the saline solution (without heparin) in the cannula and a small volume of blood were aspirated into another syringe before sample collection and then reinjected. One milliliter of normal saline solution was also injected after each blood withdrawal, to replace blood volume, fill the cannula, and stimulate urine flow.

Another group of rats had an additional cannula implanted in the left carotid artery for sodium sulfate infusion. These animals received 9.6 mg/hr/rat, as an isotonic solution containing 0.8% sodium sulfate and 0.45% sodium chloride in water. The solution was infused at a rate of 1.2 ml/hr from the 4th to the 12th hour of the experiment. The urine and blood collection schedule for this experiment is shown in Fig. 3. Some rats received both acetaminophen and sodium sulfate, the former as an injection at 4 hr and the latter as an infusion from the 8th to the 12th hour.

The concentration of inorganic sulfate in serum or urine was determined by the turbidimetric method of Berglund and Sörbo (24) as modified by Krijgsheld *et al.* (25). The method was scaled down for serum assays to a serum volume of 0.15 ml. The concentration of bound sulfate in urine was determined as the difference in sulfate concentrations before and after acid hydrolysis (diluted urine–10 *N* hydrochloric acid, 10:1, v/v, heated for 2 hr at 100°).

Creatinine concentrations in serum and urine were determined with a commercial kit[1], which is based on a modification of a previous assay procedure (26).

Acetaminophen sulfate in urine was assayed by high-performance liquid chromatography (HPLC) based on a previous method (27,28).

Renal clearances of inorganic sulfate and creatinine in the control periods were determined as excretion rate divided by serum concentration, and were normalized for body weight. During periods of changing serum sulfate concentrations, (after acetaminophen injection and during sodium sulfate infusion), the renal clearance of inorganic sulfate was calculated as the amount excreted in the urine divided by the area under the serum concentration–time curve during the urine collection interval. Some of the results are reported as clearance ratio, *i.e.*, the renal clearance of sulfate divided by the renal clearance of creatinine.

RESULTS

Control renal clearance determinations were made on 32 animals. The serum sulfate concentration was 0.89 ± 0.08 m*M*, urinary excretion of inorganic sulfate averaged 0.55 ± 0.26 μmole/min/kg, and renal clearance of inorganic sulfate was 0.64 ± 0.24 ml/min/kg. Serum creatinine concentrations were 0.72 ± 0.24 mg/dl, and creatinine clearance was 3.0 ± 1.2 ml/min/kg. The renal clearance ratio of inorganic sulfate was 0.24 ± 0.14. All of these results are mean values ±*SD*.

Injection of acetaminophen, 150 mg/kg, produced a rapid, pronounced, and persistent decline of serum concentrations and urinary excretion of inorganic sulfate (Fig. 1). A separate study showed that under these conditions, acetaminophen concentrations in plasma average ~150 μg/ml initially and decline with an apparent half-life of ~1 hr (7).

The urinary excretion of sulfate before acetaminophen administration consisted mostly of inorganic (free) sulfate; <10% of total sulfate was of the bound form (*i.e.*, sulfate conjugated with endogenous substances). The pronounced reduction of inorganic sulfate excretion after acetaminophen administration was accompanied by a very large increase in the excretion rate of bound (conjugated) sulfate, mostly in the form of acetaminophen sulfate (Table I).

Acetaminophen had no apparent effect on the serum concentration and urinary excretion rate of creatinine and, therefore, on the renal clearance of endogenous creatinine (Fig. 1 and Table II). This lack of effect became apparent in preliminary experiments and justified a reduction of serum creatinine determinations (which required an extra 0.25-ml of blood per sample) to four during 12 hr, to minimize blood volume depletion. Sulfate renal clearance ratios were, therefore, determined on the basis of an average creatinine clearance for each animal, calculated by dividing the 12-hr creatinine excretion rate by the average of the four successive serum creatinine concentrations.

Control experiments were performed to determine the possible effects of normal saline solution and propylene glycol on the renal clearances of creatinine and inorganic sulfate in otherwise unmedicated rats. Seven rats were studied during a 4-hr control period and during 4 hr of normal saline infusion at a rate of 1.2 ml/hr. The ratios, control–treatment, of individual creatinine and sulfate clearance values were 1.00 ± 0.18 (*SD*) and 0.93 ± 0.15, respectively. The effect of propylene glycol was determined in an experiment identical to that described in Fig. 1 except for the omission of acetaminophen. The injection solution consisted of 40% propylene glycol in normal saline, 6 ml/kg. Again, there was no effect on the renal clearance of creatinine or sulfate; the control–treatment ratios were 0.92 ± 0.15 for creatinine and 1.02 ± 0.18 for sulfate renal clearance.

Infusion of sodium sulfate caused a significant increase of serum concentrations and urinary excretion rates of inorganic sulfate, without any apparent effect on the serum concentrations and renal clearance of creatinine (Fig. 2 and Table II).

Depletion of endogenous inorganic sulfate by acetaminophen and supplementation by sodium sulfate administration permitted determination of the relationship between serum concentration and renal clearance of sulfate over a wide concentration range (Fig. 3). To rule out a possible direct effect of acetaminophen on sulfate clearance (*i.e.*, an

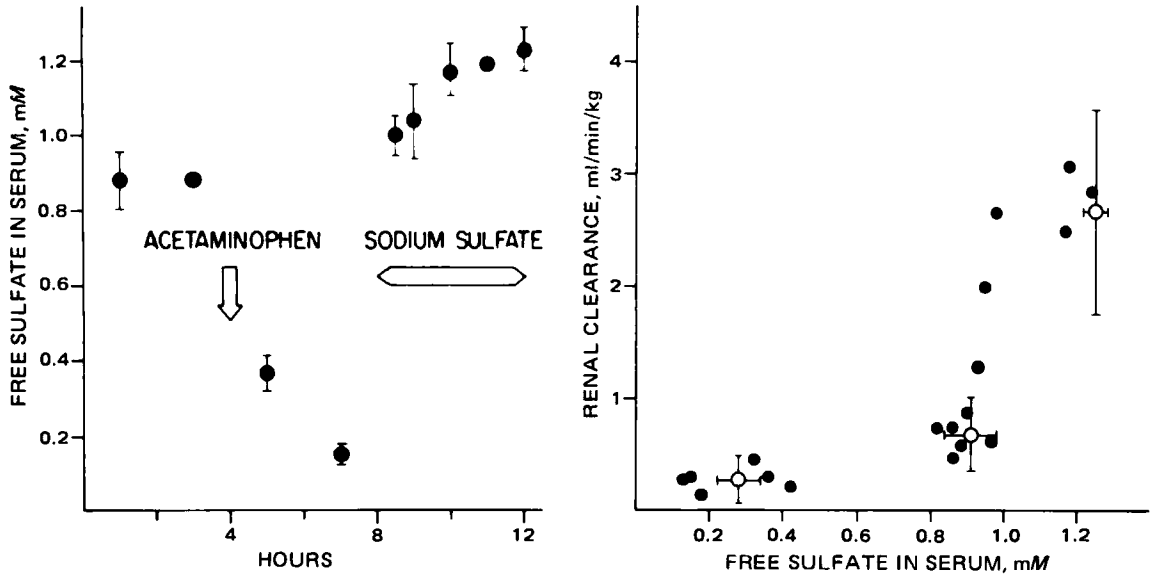

Figure 4—*Effect of acetaminophen on the renal clearance of inorganic sulfate at subnormal and supernormal serum sulfate concentrations in rats. Left panel: Inorganic sulfate concentrations (mean ±SD) in serum of 3 rats during a 4-hr control period and after intravenous injection of acetaminophen at 4 hr followed by a 4-hr infusion of sodium sulfate, 9.6 mg/hr, from 8 to 12 hr. Right panel: Renal clearance of inorganic sulfate as a function of sulfate concentration in serum, derived from the experiment shown in the left panel (●). Also shown (○) are results obtained, at selected concentration ranges, from animals who received either only acetaminophen or only sodium sulfate, or neither (mean ±SD).*

effect unrelated to the acetaminophen-induced diminished serum sulfate concentrations), sulfate depletion following acetaminophen administration was reversed by infusion of sodium sulfate. The renal clearance of inorganic sulfate at elevated serum sulfate concentrations was unaffected by acetaminophen (Fig. 4).

A summary of all renal clearance data obtained over a wide range (<0.1–1.5 m*M*) of serum sulfate concentrations is presented in Fig. 5. Excluded from that figure are data from two rats with some evidence of renal dysfunction. To facilitate the presentation of the combined results of experiments on 15 rats, the data were normalized with respect to creatinine clearance by being expressed as clearance ratios. The clearance ratio of inorganic sulfate is very low (<0.1 on the average) at serum sulfate concentrations <0.1 m*M* and increases to ≃1 when serum sulfate concentration is ~1.5 m*M*. There is a very steep increase of the clearance ratio when serum sulfate concentration slightly exceeds 1 m*M*, *i.e.*, the usual physiological level of inorganic sulfate in rats. In the serum concentration range from <0.1 to 1 m*M* (*i.e.*, during hyposulfatemia in rats), the renal clearance of sulfate also increases with increasing serum concentration, albeit not as steeply as between serum concentrations from 1 to 1.5 m*M*. The serum concentration dependence of sulfate renal clearance in the subnormal concentration range was established by the following objective criteria, applied to the group of animals that received acetaminophen: (*a*) comparison of renal clearance values at serum sulfate concentrations <0.25 m*M* to those at >0.5 m*M* indicated the latter to be significantly higher ($p < 0.001$ by paired t test), and (*b*) analysis of data for each animal separately showed a strong positive correlation between renal clearance and serum concentration of sulfate for every rat in the study ($r > 0.85$, $p < 0.05$).

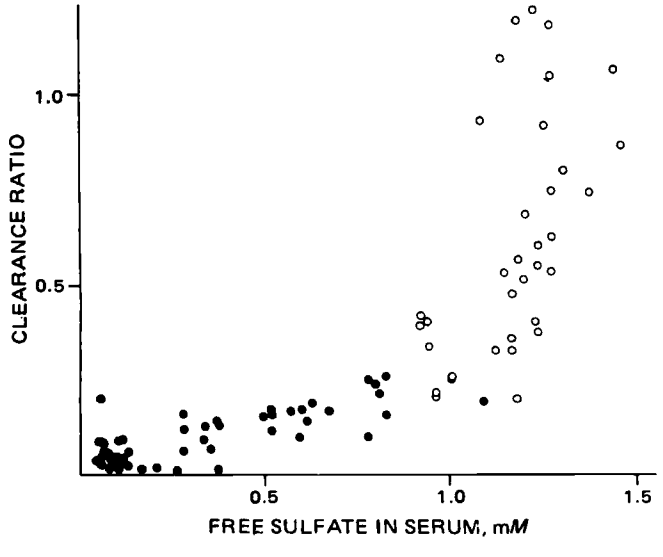

Figure 5—*Renal clearance ratio of inorganic sulfate (sulfate clearance–creatinine clearance) as a function of sulfate concentration in serum of nine rats before and after acetaminophen injection (●) and six rats before and during sodium sulfate infusion (○).*

DISCUSSION

Baseline data obtained during the control periods in this investigation are in excellent agreement with literature values. This includes serum inorganic sulfate concentration (11, 19, 29), urinary excretion rate of inorganic sulfate (3, 11), serum creatinine concentration (30), and renal clearance of creatinine (31) in rats. Previous researchers (14) observed a circadian rhythm with respect to serum concentration and urinary excretion rate of inorganic sulfate in rats; serum sulfate concentration decreased rapidly from ≃0.9 to ≃0.6 m*M* in the evening while sulfate excretion increased. Apparently, this phenomenon does not occur consistently, since the same investigators reported essentially constant serum sulfate concentrations in rats during a 24-hr period in another study (11). Experiments in this investigation were always started in the morning and lasted 12 hr; serum concentrations and urinary excretion of inorganic sulfate remained essentially constant during this time in unmedicated rats.

It appears that the renal tubular reabsorption of sulfate is coupled to active transport of sodium through a sodium–sulfate cotransport system (32, 33). Under certain conditions, administration of sodium chloride causes a transient decrease of serum sulfate concentrations in rats (5, 25). The use of sodium chloride in this investigation to adjust the tonicity of the sodium sulfate infusion solution and, as normal saline solution, to replace blood volume and stimulate urine flow, had no apparent effect on the serum concentration and urinary excretion of endogenous inorganic sulfate. Propylene glycol, used as a solvent for acetaminophen, also had no effect on endogenous sulfate serum concentration and urinary excretion under the experimental conditions.

Under normal physiological conditions, the renal clearance of sulfate is considerably below GFR even though sulfate in plasma is completely ultrafiltrable (34). Thus, inorganic sulfate undergoes considerable renal tubular reabsorption. This process is saturable, causing sulfate renal clearance to increase with increasing serum sulfate concentration. This concentration dependence is strikingly apparent in the rat when serum sulfate concentrations are increased by infusion of sodium sulfate (Figs. 3 and 5). More problematical has been the search for the existence of a

Table III—Interspecies Comparison of Free Sulfate Kinetics

renal tubular secretory process for sulfate. Studies in several species, including humans and dogs, have failed to demonstrate that renal clearance of sulfate can exceed GFR (18, 20, 35). While sulfate renal clearance ratios in the present investigation have occasionally exceeded unity at high serum sulfate concentrations (Fig. 5), these values have all been close to unity. Clearance ratio determinations are based on four measurements (sulfate and creatinine in serum and urine) and are therefore subject to some error. The results of our renal clearance experiments at elevated serum sulfate concentrations provide no definitive evidence of renal secretion of sulfate and are consistent with the experiences of other investigators who have not been able to demonstrate conclusively, by conventional clearance determinations in mammals, that inorganic sulfate is subject to renal tubular secretion (22). However, a renal secretory process for sulfate has been found by tubular microperfusion techniques but appears to be rudimentary (21, 22). In any event, the focus of this investigation has been on the concentration dependence of sulfate in the subnormal serum concentration range where the secretory process is overshadowed by the reabsorption process.

The use of a drug to deplete endogeneous sulfate has permitted, apparently for the first time, the determination of sulfate renal clearance at subnormal serum sulfate concentrations. This information is important for the comprehensive characterization of the pharmacokinetics of drugs that are subject to sulfate conjugation and whose biotransformation is associated with a depletion of endogenous sulfate. It was found that the renal clearance of sulfate decreases continuously with decreasing serum sulfate concentrations. When endogenous sulfate is severely depleted, there occurs almost complete reabsorption of sulfate from the glomerular filtrate. Thus, the serum concentration dependence of renal sulfate clearance in rats facilitates sulfate homeostasis by retaining sulfate when this ion is depleted and by excreting it rapidly when serum concentrations are elevated above normal. These conclusions apply also to humans, as is evident from the results of an ongoing investigation[2].

There are very large species differences in serum sulfate concentrations; the goat and rooster have concentrations $\simeq$2.5 m*M*, the rat and mouse $\simeq$1 m*M*, and the monkey and humans are at the lower extreme with concentrations $\simeq$0.3 m*M* (14). The two most likely reasons for these species differences are variations in the formation rate (or dietary intake) of sulfate and in the renal sulfate clearance. Volume of distribution differences are much less likely; sulfate ion is not protein bound and distributes almost exclusively in extracellular space (36, 37). A survey of the literature shows that, based on body weight, the renal clearance of sulfate in humans under physiological conditions is similar to that of rats, rabbits, and dogs (Table III). The low serum sulfate concentration in humans under these conditions suggests that their sulfate formation rate is relatively low, perhaps due to lower dietary intake of precursors. This conclusion is supported by the fact that the urinary excretion rate of free sulfate (which is a good approximation of the formation rate since tracer doses of sulfate-S^{35} are excreted largely as such), is much less in humans than in the other three species (Table III).

Effects of Breed, Season, Temperature, and Solvents on the Permeability of Frozen and Reconstituted Cattle Skin to Levamisole

IAN H. PITMAN ˣ, SUSAN J. ROSTAS, and LEANNE M. DOWNES

Received October 13, 1981, from the *Victorian College of Pharmacy Ltd., Parkville, 3052, Australia.* Accepted for publication April 8, 1982.

Abstract □ *In vitro* measurements have been made of the permeability of frozen and reconstituted cattle skins to levamisole. Breeds used were Red Poll cross, Hereford/Shorthorn cross, Hereford/Santa Gatrudis cross (or Brahman), Friesian (or Friesian/Jersey cross), and Hereford cattle killed in early fall, early summer, or winter. Inter- and intrabreed differences in skin permeability were small, but skin permeability in summer and fall was appreciably greater than in winter. Increases in skin temperature also increased skin permeability. The solvent properties of the skin toward neutral molecules appeared to be similar to those of water, suggesting that skin is a relatively polar barrier.

Keyphrases □ Levamisole—effects of breed, season, temperature, and solvents on permeability, frozen and reconstituted cattle skin □ Permeability—frozen and reconstituted cattle skin, effects of breed, season, temperature, and solvents, levamisole □ Skin, cattle—frozen and reconstituted, effects of breed, season, temperature, and solvents on permeability to levamisole

It has been shown recently (1) that the outer 1 mm of frozen and reconstituted skin from a Hereford calf (*i.e.*, stratum corneum, viable epidermis, papillary layer of the dermis, and associated appendages) acts as a homogenous barrier to the diffusion of molecules of levamisole (I). This observation highlights a significant difference between the barrier properties of cattle skin and those of similarly treated human skin in which the stratum corneum is the rate-determining barrier to diffusing molecules (2, 3). Consequently, it is probable that different mechanisms are involved in the transport of molecules across cattle and human skin, and different steps must be taken when formulating topical products for cattle than those taken when formulating topical products for humans.

Steps that can be taken to control topical absorption of drugs by humans have been reviewed previously (4, 5).

The effects of breed, season, skin temperature, and solvents on the *in vitro* permeability of frozen and reconstituted[1] cattle skin to I are reported here.

It is anticipated that the results of this study will be directly applicable to the development of liquid dosage forms that are intended to promote systemic drug delivery [*i.e.*, pour-ons (6)] to cattle.

EXPERIMENTAL

The methods used to harvest and store cattle skins were identical to those described earlier (1). Details of the cattle used and of the times when skins were harvested are in Table I.

Materials—Compound I (mp 61°), I hydrochloride (mp 228°), polyoxypropylene-15-stearyl ether, sorbitan sesquioleate, the nonaromatic hydrocarbon fraction, and 2-ethoxyethanol were used as received[2] as was formulation C (Table II). All other chemicals were analytical reagents unless otherwise stated. Formulations are listed in Table II.

Measurement of Skin Permeability—The procedures, including analytical methods, described previously (1, 7) were employed to determine the permeability of the skins to I. Skin penetration was followed for 300 min, and lag times varied from 4 min (for penetration from toluene) to 120 min (for penetration from aqueous and alcoholic solutions). In two studies, measurements were made of the penetration of tritiated water (^3H_2O) through cattle skin. Approximately 0.5 μCi of tritiated water was added to either the aqueous pH 8.9 solution or the pH 6.0 solution of I, and 1.0 ml of the mixture was applied to the epidermal surface of the skin. Samples (0.2 ml) of the donor solutions were taken at 0 and 300 min, and samples (1.0 ml) of the receptor solutions were taken at 300 min. The samples were adjusted to 1 ml with water and to each was added 10 ml of scintillation liquid (0.4% 2,5-diphenyloxazole in toluene–tyloxopol[3], 2:1 v/v). After thorough mixing, the samples were counted on a liquid scintillation spectrometer[4].

The temperature of the water bath in which all experiments, except those carried out to study variation of permeability with temperature, was 37.0 ± 0.1°. Thermistor measurements indicated that the temperature of the outer surface of the skin in these experiments was 30.6 ± 0.5°.

Statistical Analysis—Unless otherwise stated, a multiple comparison statistical technique previously described (8) and modified[5] was used to analyze the experimental results.

RESULTS AND DISCUSSION

As a consequence of the finding (1) that the outer 1 mm of cattle skin behaves as an homogenous barrier to the diffusion of molecules of I, it follows that:

1. The product of the permeability constant (k_p, cm min^{-1}) and the thickness of the skin specimen (r, cm, *i.e.*, $k_p r$ cm^2 min^{-1}) is a constant for diffusion through skin specimens with thicknesses in the range of 0.3–1.0 mm;
2. The diffusion coefficient (D, cm^2 min^{-1}) of I in skin specimens with thicknesses in the range of 0.3–1.0 mm can be calculated from the lag time for diffusion (L, min) by:

$$D = r^2/6L \qquad \text{(Eq. 1)}$$

3. The partition coefficient (PC) for I from the formulation into skin specimens with thicknesses up to 1.0 mm can be calculated from:

$$PC = k_p r/D \qquad \text{(Eq. 2)}$$

The derivations of Eqs. 1 and 2 are discussed in a previous report (1).

Values of $k_p r$, D, and PC for penetration of I through the skins of a number of cattle from a single formulation and from several formulations are in Tables III and IV, respectively. The skin specimens used in all experiments had thicknesses in the range of 0.3–1.0 mm.

Intra- and Interbreed Variation in Skin Permeability—Table III contains mean values of $k_p r$, D, and PC for penetration of I through skins of four Hereford calves from formulation A. The calves were about the same age, and the skin was harvested in early fall.

Statistical analysis of the data indicates that there was no significant difference at the 1% level between the permeability of the four skins and suggests that intrabreed differences are likely to be small for animals with similar histories treated during the same season.

Two pieces of evidence suggest that interbreed differences (involving mainly European breeds) in skin permeability are also likely to be small for animals of similar ages that are treated during the same seasons.

Thus, the permeability of the skin of a Friesian calf to I from formu-

[1] Results to be published shortly from this laboratory establish that there are no significant differences at the 5% level in the permeability of fresh, frozen, and reconstituted cattle skin.

Table I—Details of Cattle and Time of Skin Harvesting

Calf Number	Approximate Age, months	Breed	Time of Harvesting
115	6	Red Poll Cross	Late August (winter)
110	9–11	Hereford/Shorthorn cross	Late August (winter)
109	6–8	Hereford/Santa cross Gatrudis or Brahman	
F1	4–6	Friesian (or Friesian/Jersey cross)	Early December (early Summer)
16	10–12	Hereford	Mid March (early fall)
21	8	Hereford	Mid March (early fall)
29	8–10	Hereford	Mid March (early fall)
34	8–9	Hereford	Mid March (early fall)

lation A in early summer was similar (there was no significant difference at the 1% level) to that of skins of the four Hereford calves in early fall (Table III). Similarly, the results in Table IV show that interbreed differences for the permeability of the winter skins of a Red Poll (No. 115), a Hereford/Shorthorn cross (No. 110), and a Hereford/Santa Gatrudis cross or Brahman (No. 109) to I from formulation A and of those of calves Nos. 110 and 109 to formulations B and C, aqueous pH 8.9 and 6.0 solutions, were not significant at the 1% level.

Seasonal Variation—Comparison of the results in Table III for the permeability to I from formulation A of the skin of the four Hereford calves killed in early fall (Nos. 16, 21, 29, and 34) with similar data in Table IV for skins of calves killed in winter (Nos. 115, 110, and 109) indicate that the skin is significantly more permeable to I in the fall than in the winter (a two-tailed t test on the means for each group of results indicated that $p < 10^{-7}$).

This result is consistent with an observation that greater blood levels of I were achieved in cattle following application of a pour-on in summer than were achieved in winter[6].

Furthermore, while the values of both the diffusion coefficient and partition coefficient for I were greater in fall skin than in winter skin ($p < 10^{-2}$ and $p < 10^{-4}$, respectively), inspection of the data reveals that the increase in the value of the partition coefficient is much larger. The greater partition coefficient in fall indicates that for I fall skin is a better solvent than winter skin.

The solvent properties of the skin will be discussed further after considering the effect that different formulations and different temperatures have on skin permeability.

Formulation Variation—A noticeable feature of the data in Table IV is that I penetrated the skins of calves 110 and 109 ~30 times faster ($p < 10^{-2}$) from the aqueous pH 8.9 solution (where I existed to the extent of 90% as a neutral molecule[7]) than from the aqueous pH 6.0 solution (where I existed to the extent of 99% as a cation).

To test whether the pH value of aqueous buffers affected the intrinsic permeability of the skin, experiments were conducted using aqueous solutions of I buffered at pH 8.9 and 6.0 and containing tritiated water. Measurements were made of the rate at which both tritiated water and I penetrated the skin from each formulation. The results in Table V indicate that the percent of the applied amount of tritiated water penetrating the skin in 300 min was essentially the same at pH 8.9 and 6.0. This result is consistent with the conclusion that the variation of pH values from 8.9 to 6.0 does not significantly alter the intrinsic permeability of the cattle skin. In the same experiments, the percent of the applied dose of I that penetrated the skin in 300 min was ~ 10 times higher than the pH 8.9 buffer than from the pH 6.0 buffer.

The data in Table IV indicate that whereas the value of the diffusion coefficient for I in cattle skin is essentially the same from aqueous pH 8.9 and 6.0 solutions (differences are not significant at the 1% levels), the value of the partition coefficient of I from pH 8.9 solution into the skin is >10 times that from the pH 6.0 solution ($p < 10^{-2}$).

This result suggests that the skin has similar solvent properties to water for neutral molecules for I but is an inferior solvent for I cations.

Comparison of the data in Table IV for penetration of neutral molecules of I through the skins of calves Nos. 110 and 109 from formulations A (largely 2-ethoxyethanol), B (largely 2-ethoxyethanol), and C (largely 2-propanol) and water indicates that for I the skin permeability is greatest from water. Also, while the values of the diffusion coefficient for I from each of the above formulations are similar, the value of the partition coefficient for I into the skin is significantly greater from water than from the organic solvents ($p < 10^{-2}$).

Table IV also includes data for the penetration of neutral molecules of I through the skin of calf No. 109 from 80% dimethyl sulfoxide (in water) and from toluene. These results differ from those from the other formulations studied, in that the values of the diffusion coefficients of I in the skin were significantly larger ($p < 10^{-2}$) when 80% dimethyl sulfoxide and toluene were used as solvents. These results arose because the lag times for diffusion from these solvents were much less than those from aqueous pH 8.9 solution, aqueous pH 6.0 solution, or from formulations A, B, and C.

In the case of penetration from 80% dimethyl sulfoxide, the value of $k_p r$ was six times less than that from aqueous pH 8.9 solution, although the value of the diffusion coefficient in the former system was 8.6 times larger. The determining factor in this case was the fact that the value of the partition coefficient of I between the aqueous pH 8.9 solution and skin was ~60 times that between 80% dimethyl sulfoxide and skin.

The value of $k_p r$ for penetration from toluene was comparable to that from aqueous pH 8.9 solutions at the 1% level. In this case, although the partition coefficient of I from toluene into skin was 0.06 that from aqueous pH 8.9 solution, the value of the diffusion coefficient in the former case was 18.7 times that in the latter.

These results are difficult to explain at the present time, but it is probable that they arise because dimethyl sulfoxide and toluene dissolve away or displace certain components of the skin and thereby change its permeability characteristics. It is known (9) that the application of ether removes a significant proportion of the lipid and stratum corneum from cattle skin.

An important conclusion that can be drawn from these observations is that dimethyl sulfoxide may not be a universal promoter of penetration of neutral molecules through cattle skin to the same extent as it is for human skin penetration (10, 11). It has previously been shown (7) that dimethyl sulfoxide impedes rather than promotes the absorption of I through sheep skin.

Table II—Formulations

Designation	% w/v I	Formulation
Aqueous pH 8.9 solution	0.85	I HCl 1% Borate Buffer to 100% Final pH 8.9
Aqueous pH 6.0 solution	0.85	I HCl 1% Phosphate Buffer to 100% Final pH 6.0
80% Dimethyl sulfoxide	1	I 1% Water 20% Dimethyl Sulfoxide to 100%
Toluene	0.85	I to 0.85% Toluene to 100%
Formulation A[a]	10	I 10% Poloxypropylene-15-stearyl ether 12% Nonaromatic Hydrocarbons 15% 2-Ethoxyethanol to 100%
Formulation B	10	I 10% Sorbitan Sesquioleate 10% Nonaromatic Hydrocarbons 20% 2-Ethoxyethanol to 100%
Formulation C[a]	10	I 10% Spindle Oil 10% Isopropanol to 100%

109	C	0.6(0.1)	20(15)	0.05(0.03)
110	Aqueous pH 8.9 solution	11.3(3.6)	15(3)	0.79(0.24)
109	Aqueous pH 8.9 solution	10.2(3.1)	10(4)	1.10(0.47)
110	Aqueous pH 6.0 solution	0.4(0.1)	11(7)	0.04(0.05)
109	Aqueous pH 6.0 solution	0.3(0.1)	12(13)	0.06(0.06)
109	80% Dimethyl Sulfoxide [b]	1.6	86	0.02
109	Toluene	13.1(1.1)	188(14)	0.07

[a] As described in Table I. [b] Only one experiment was performed.

Table V—Relative Rates of Penetration of I and Tritiated Water through the Skin of Calf No. 115 at 37°

Formulation	Applied Dose of I Penetrating in 300 min, % (1)	Applied Dose of Tritiated Water Penetrating in 300 min, % (2)	(1)/(2)
Aqueous pH 8.9 solution + tritiated water	1.6	2.6	0.6
Aqueous pH 8.9 solution + tritiated water	1.7	1.3	1.3
Aqueous pH 6.0 solution + tritiated water	0.1	2.1	0.05
Aqueous pH 6.0 solution + tritiated water	0.2	2.0	0.08

Temperature Variation—Table VI contains values of $k_p r$, diffusion coefficient (D), and partition coefficient (PC) for penetration of I from formulation A through the skin of calf No. F1 at different temperatures.

As expected for a diffusional process, the rate of penetration, as reflected in the value of $k_p r$, increased with an increase in temperature. (Differences between values of $k_p r$ at the two lower temperatures and at the two higher temperatures were not significant at the 5% level, but $k_p r$ values at the higher temperatures were greater than those at lower temperatures.)

This result is important when taken in conjunction with the observation that the permeability of animal skin in early fall (and presumably summer) is greater than that in winter. Hence, the higher ambient temperatures that are likely to exist in fall as compared with winter are likely to contribute to very much greater permeability in fall (and summer) as compared with winter.

The complexity of the effect of temperature on skin permeability is highlighted by the fact that at both the 1 and 5% level there was no significant difference in values of D and PC as the skin temperature was raised from 24.1 to 32.7°.

Diffusion Model and Solvent Properties of Cattle Skin—It was postulated (1) that the major mechanism by which I, and presumably other neutral molecules, is transported across cattle skin involves diffusion into and down the hair follicles and into their associated sweat and sebaceous ducts to a capillary bed, at which point they enter the blood. It was also suggested (1) that the emulsified sebum [which is expelled from the common sweat and sebaceous ducts into the infundibulae of the hair follicles and which seeps up through the outer layers of the stratum corneum and down the hair follicle (12)] has a profound influence on skin permeability.

A potentially useful model for cattle skin penetration involves the following steps:

1. Drug molecules rapidly partition from applied topical formulations into the emulsified sebum which is associated with the skin. The partition coefficient for this step is the PC value calculated from *in vitro* diffusion experiments.
2. Drug molecules diffuse through the emulsified sebum and eventually pass down the hair follicles and reach the capillary beds where they pass into the blood. The parameter (D) that is calculated from *in vitro* experiments would be the diffusion coefficient for this process.

Results to date indicate that the value of D is not significantly affected by solvents such as water, 2-ethoxyethanol, and 2-propanol, but is affected by toluene and 80% dimethyl sulfoxide. It was suggested earlier that those latter solvents might modify the diffusion barrier (the emulsion) by dissolving or displacing a component.

A rationalization of the solvent properties of emulsified sebum, and consequently of values of PC, can be achieved by considering those features that determine what is a good or a poor solvent for I.

Table VII contains values of the partition coefficients for neutral molecules of I from aqueous pH 8.9 solution into liquid paraffin, toluene, and dimethyl sulfoxide. These results indicate that I is less soluble in water than in each of the other solvents, but that a complex relationship exists between the solubility of I and the polarity (dielectric constant ϵ) or solubility parameter (δ) of the solvent. For the purposes of these comparisons, liquid paraffin has been assigned the same values of ϵ and δ that are possessed by n-hexane (1.89 at 20° and 7.3 hr (13), respectively).

Hence, although the solubility of I in liquid paraffin, toluene, and dimethyl sulfoxide increases as both the dielectric constant increases [1.89 at 20° (13), 2.38 at 25° (13), and 45 (14)] and the solubility parameter increases [7.3 H, 8.9 H, 12.0 H (13)], it is least soluble in water, the solvent with the highest dielectric constant [78.54 at 25° (13)] and solubility parameter [23.4 H (13)]. It appears that specific dipole–dipole or other solvent–solute interactions are of at least equal importance to polarity in determining the solubility of I in a given solvent.

The PC values in Table IV that relate to partitioning of I between various solvents and the barrier (*i.e.*, the emulsion) suggest that the latter has similar solvent properties to water toward I, but that it is poorer than the alcohol-based solvents in formulations A, B, and C as well as toluene or 80% dimethyl sulfoxide. The results also show that while the barrier has similar solvent properties to water toward neutral molecules of I, it is a poorer solvent than water toward cations.

Table VI—Effect of Temperature on the Permeability of Cattle Skin [a] to I from Formulation A

Bath Temperature	Skin Temperature	No. Experiments	$10^6 k_p r$, $cm^2\ min^{-1}$	$10^6 D$, $cm^2\ min^{-1}$	Partition Coefficient
25.0°	24.1°(0.2)	6	8.2(1.7)	16(5)	0.59(0.29)
30.0°	27.3°(0.5)	5	13.2(3.1)	16(4)	0.90(0.39)
37.0°	30.6°(0.5)	11	24.0(3.7)	23(6)	1.09(0.35)
40.0°	32.7°(0.5)	2	22.6(1.1)	21(6)	1.19(0.40)

[a] The skin was from the dorsal region of calf F1. [b] The temperature of the skin was measured periodically using a thermistor.

Table VII—Partition Coefficients[a,b] for I at 37°

Solvent 2	Solvent 1	Partition Coefficient (*PC*), (±*SD*)
Liquid paraffin	aqueous pH 8.9 solution	2.3(0.6)
Toluene	aqueous pH 8.9 solution	5.2(2.1)
Dimethyl sulfoxide	aqueous pH 8.9 solution	14.4[c]

[a] *PC* = [I] solvent 2/[I] solvent 1. [b] Data are from Ref. 7. [c] Calculated by dividing *PC* from aqueous pH 8.9 solution into liquid paraffin (2.3) by *PC* from dimethyl sulfoxide into liquid paraffin (0.16).

The results in Tables III and IV reveal that the solvent properties of the skin toward I increase in the fall as compared with winter.

The complex nature of the solubility of I does not allow simplistic statements to be made. However, it is very likely that changes in the composition of the emulsified sebum, perhaps even phase changes, led to the observed changes in permeability.

There appears to be very little difference between the skin permeabilities of European breeds of cattle at any particular time, and intrabreed differences are small.

Because the permeability of cattle skin appears to be 10 times greater in early fall as compared with winter and to increase with increasing temperature, it can be predicted that the skin permeability of cattle in the field in mid-summer will be substantially higher than that in mid-winter. Cattle skin is a relatively polar solvent with properties similar to water towards neutral organic molecules. Consequently, water or poorer solvents than water for particular drugs should be selected for topical formulations in preference to better solvents than water in order to maximize the rate of drug penetration.

Studies aimed at characterizing the solvent properties of domestic animal skins are currently underway.

Determination of Antimicrobial Preservatives in Pharmaceutical Formulations Using Reverse-Phase Liquid Chromatography

THOMAS P. RADUS * and GRETCHEN GYR ˣ

Received November 20, 1981, from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication April 15, 1982. *Present address: Westinghouse Electric Corporation, Bettis Atomic Power Laboratory, West Mifflin, PA 15122.

Abstract □ A specific stability-indicating reverse-phase high-performance liquid chromatographic analytical method has been developed to quantitate the antimicrobial preservatives methylparaben, propylparaben, butylparaben, sorbic acid, and benzoic acid in a series of typical pharmaceutical formulations. The mobile phase of this system is a water–acetonitrile mixture, modified by various acids and buffers. The proportions of water and acetonitrile as well as the type and amounts of modifiers are varied in order to achieve optimum chromatography. This method has been used successfully to quantitate preservatives in solutions, suspensions, creams, lotions, and ointments, and can be readily adapted to routine automated assays, either for routine product evaluation or stability programs.

Keyphrases □ Preservatives, antimicrobial—determination in pharmaceutical formulations using reverse-phase liquid chromatography □ Reverse-phase liquid chromatography—determination of antimicrobial preservatives in pharmaceutical formulations

Antimicrobial preservatives are materials added to formulations to protect the product from microbial contamination. A given preservative material can be used in a wide variety of products and also may be used in combinations with other preservatives. Separate testing methods for each product–preservative combination would not make efficient use of laboratory resources if the tests are to be performed frequently; thus a method which is generally applicable is desirable. However, the analytical methods should be specific to ensure that decomposition products and impurities are not inadvertently measured. Regulatory agencies have also shown interest in specific test methods for preservatives (1, 2). The challenge for the methods developer is to come up with a method that satisfies both criteria of assay efficiency and specificity.

It is currently of interest within the pharmaceutical industry to assure that specific, stability-indicating, and validated testing methods are available for antimicrobial preservatives. This study reports the development of a reverse-phase high-performance liquid chromatographic (HPLC) assay system that, with minor modifications in

Table I—Data for the Preservative Assays for Pharmaceutical Products Containing Only the Parabens as Preservatives

Product Type	Preservatives	Internal Standard	Mobile Phase	Average Recovery, %	*RSD*, %	Concentration Range Validated
Ointment (5)[a]	Methylbaraben	Calusterone	1	100.3	1.4	0.1–0.3 mg/g
	Butylparaben			100.0	1.4	0.9–2.7 mg/g
Cream A (2)	Methylparaben	Calusterone	1	100.5	1.2	0.5–2.0 mg/g
	Butylparaben			100.1	1.2	2.0–6.0 mg/g
Cream B (1)	Methylparaben	Calusterone	1	98.0	1.2	0.5–2.0 mg/g
	Butylparaben			99.8	1.8	2.0–6.0 mg/g
Cream C (2)	Methylparaben	Calusterone	1	100.9	1.3	2.0–6.0 mg/g
	Butylparaben			101.7	1.5	1.5–4.5 mg/g
Lotion (2)	Methylparaben	Calusterone	1	98.7	0.8	1.0–3.0 mg/g
	Butylparaben			99.7	1.0	1.5–4.5 mg/g
Sterile Suspension D (1)	Methylparaben	Butylparaben	1	98.3	1.0	0.8–3.2 mg/ml
	Propylparaben			102.7	1.5	0.09–0.36 mg/ml
Fluid E (1)	Methylparaben	Butylparaben	1	99.8	1.0	0.5–2.0 mg/ml
Sterile Suspension F (1)	Methylparaben	Butylparaben	1A	99.6	1.8	0.4–1.6 mg/ml
	Propylparaben			99.3	1.3	0.04–0.18 mg/ml
Fluid G (1)	Methylparaben	Ethylparaben	1B	100.2	1.4	0.35–1.5 mg/ml
	Propylparaben			98.1	1.3	0.10–0.5 mg/ml

[a] Number of products in parentheses.

the mobile phase, is capable of quantitating the preservatives methylparaben, propylparaben, butylparaben, sorbic acid, and benzoic acid in a wide range of pharmaceutical formulations.

BACKGROUND

Validation criteria have been developed for the potency assays for pharmaceutically active ingredients (3). This system was used as the starting point for the criteria that would be applied to the preservative assays. However, it was realized that in several important aspects, quantitating preservatives is significantly different from quantitating the active pharmaceutical ingredient, and that consideration of these aspects will influence the criteria used to judge the validity of the test method. If appropriate criteria are established before development work begins, it should be possible for both the developer and the ultimate user of the testing methods to utilize their resources as effectively as possible. These aspects will now be considered in more detail.

Preservatives are neither pharmacologically active, nor are they inert formulation excipients. They are, however, considered essential ingredients because they are active in maintaining product integrity (1).

Efficiency in a Routine Environment—A completely new testing method may be required for a new product, or even for an old drug in a new formulation, to satisfy requirements for potency or impurity quantitation methods. A given preservative material may, however, be used in a wide range of products and types of formulations. To have a different testing method for each different occurrence of the preservative would not be very efficient for laboratory operations but would allow the flexibility of developing a highly precise, accurate assay method. However, the highest laboratory efficiency would be gained if only one automated assay system were needed for all products containing the given preservative, but accuracy and precision would suffer, considering the wide variety of samples to be processed. An automated system is not available for preservatives, and the most reasonable compromise would involve a minimum number of testing methods with assay variabilities between the two extremes, and with only minimal detrimental effects on efficiency. The method reported here is an example of such a system.

Table II—Data for the Preservative Assays for Pharmaceutical Products Containing Sorbic Acid and the Parabens as Preservatives ●

Product Type	Preservatives	Average Recovery, %	*RSD*, %	Concentration Range Validated, mg/ml
Suspension H (2)[b]	Sorbic Acid	100.1	0.5	0.5–2.0
	Methylparaben	100.7	1.0	1.0–4.0
Solution J (2)	Sorbic Acid	98.8	0.8	0.5–2.0
	Methylparaben	99.3	0.7	0.3–1.5
	Propylparaben	99.8	1.1	0.1–0.4
Cream K (1)	Sorbic Acid	99.4	0.5	1.0–4.0

[a] The mobile phase used was mobile phase 2; the internal standard was ethylparaben. [b] Number of products in parentheses.

Preservative Concentrations—Preservatives are generally formulated at concentrations of 1 mg/ml, which can be as much as two orders of magnitude less than the active ingredient. This can put preservatives in the sample at the approximate levels of impurities or degradation products. This can cause problems of interferences from these extra materials leading to poor reproducibility and/or assay bias.

Variation with Time–Degradation Products—The concentration of preservatives may decrease over the shelf-life of a product at a rate faster than that of the drug itself. The analytical testing method must be validated well below the usual preservative concentration to quantitate these amounts, and must be specific for degradation products. (Although in most cases it is not known what contribution, if any, to the preservative capacity of the system could be made by these compounds.) To quantitate these lower levels demands analytical methods that are accurate, linear, and which have acceptable slope and intercept values (ideally one and zero, respectively, within experimental error for plots of amounts added *versus* amounts recovered).

Assay Variability—For a drug in a product, the lowest acceptable concentration is frequently specified by a compendial limit. For preservatives, the lowest acceptable concentration is stated implicitly as the minimum amount which will allow the formulation to pass preservative efficacy tests. Because of the nature of these microbiological tests, this concentration cannot be accurately specified. The analytical method which measures that concentration need not be any more accurate than required by the normal variability of the microbial tests. Since the coefficient of variation of liquid chromatographic analytical methods of the type used here is less than the variability of the microbial tests, liquid chromatographic methods are more than suitable for this purpose.

The approach used in the development of these analytical methods was to start with a water–acetonitrile binary system and add other modifiers as necessary to achieve satisfactory chromatography. However, any mobile phase not otherwise modified was made to contain 2% acetic acid to be in agreement with the mobile phase previously suggested for quantitating parabens[1]. In all cases reported here, satisfactory chromatography could be achieved by adjusting the water–acetonitrile ratio and/or the buffer–pH combinations.

EXPERIMENTAL

The equipment used in these studies included standard HPLC pumping systems[2], injector[3], columns[4], and UV detectors[5]. Sample injections were made by an autosampler system[6], which also actuated the injector valve (4). Solvent[7] flow rates were typically 2 ml/min, and in-

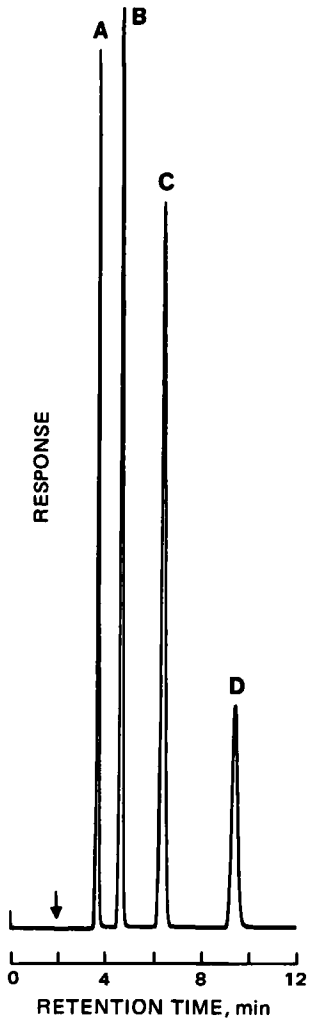

Figure 1—*Chromatogram of a mixture of methylparaben (A), ethylparaben (B), propylparben (C), and butylparaben (D) using mobile phase 1. The solvent front is indicated by the arrow. The mixture was prepared by dissolving 7 mg of methylparaben, 13 mg of ethylparaben, 15 mg of propylparaben, and 7 mg of butylparaben in 100 ml of mobile phase.*

jection volumes were 10 μl. Quantitation was performed by measuring peak heights. The mobile phase compositions referenced later in the text by number are: 1, water–acetonitrile–glacial acetic acid (58:40:2); 1A, water–acetonitrile (70:30) 0.2 *M* ammonium acetate, pH 7.2; 1B, water–acetonitrile (65:35) 0.01 *M* ammonium dihydrogen phosphate, pH 2.2 with concentrated phosphoric acid; and 2, water–acetonitrile (70:30) 0.01 *M* potassium acetate, pH 5.4 with glacial acetic acid.

Recovery Studies—For each product type a sample was prepared containing all ingredients (including active ingredients) in their proper proportion except for the preservatives. Reference standard preservative material was then added to portions of the sample in amounts ranging from 50 to 150% of the normal preservative concentration. These spiked samples were quantitated against the reference standard to determine recovery and linearity for the analytical method. Replicate assay results on several production lots were pooled to determine the relative standard deviation (*RSD*). All analytical methods reported here showed acceptable linearity and have a slope of 1.00 within experimental error for plots of amounts recovered *versus* amount added. Tables I–III list the product type, number of individual products within each type, preservatives, internal standard used, mobile phase, average recovery as a percentage of the amount added, *RSD* calculated for the method, and range of concentrations validated. All recoveries and *RSD*s satisfied the validation criteria.

Sample Preparation for Products Containing Only Parabens (Table I)—*Ointments*—The four ointment products[8] studied make use

[8] Cortaid, Neo-Cortef, Mycitracin, Neo-Oxylone.

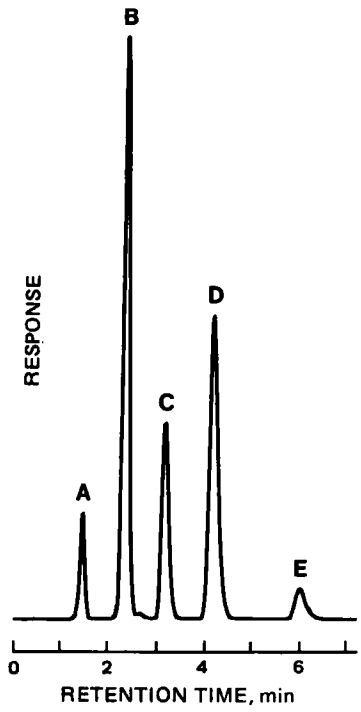

Figure 2—*Chromatogram of a production lot of fluid product J using mobile phase 2. The peaks are: (A) Solvent front and excipients, (B) sorbic acid, (C) methylparaben, (D) ethylparaben, and (E) propylparaben.*

of a typical hydrocarbon ointment base. This base would not dissolve in any solvents that were compatible with the mobile phase. Quantitative recovery was achieved by extraction into dimethylformamide. A 10.0-ml volume of this solvent was added to 1.0 g of ointment and 20.0 ml of the internal standard in a water–acetonitrile solution. The mixture was shaken in a hot water shaker bath at 50° and then centrifuged. The undissolved base congealed at the top and an aliquot of the clear lower layer was assayed.

Creams—The three cream product types[9] (five products) were all variations of typical oil-in-water emulsions. A measure of 0.5 g of each cream was added to 100.0 ml of tetrahydrofuran and 5.0 ml of the internal standard in a water–acetonitrile solution. The samples were shaken for 15 min and then chromatographed.

Lotions—The two lotions[10] were very similar to the cream formulations. The sample preparation was the same as for the cream products.

Sterile Product—Sterile suspension D[11] (1.0 ml) was diluted with 30 ml of water containing the internal standard, mixed, centrifuged to remove the undissolved drug, and chromatographed.

Nonsterile Fluid—The fluid formulation E[12] was an oral antibiotic suspension. One milliliter of this fluid was added to 30.0 ml of an acidified (acetic acid) acetonitrile–water solution of the internal standard to increase solubility and prevent the formation of an emulsion. The sample was then mixed, centrifuged, and chromatographed.

Sample Preparation for Products Containing Sorbic Acid and Parabens (Table II)—One milliliter of fluid samples H and J[13] was added to 30.0 ml of a solution of the internal standard in mobile phase, mixed, and chromatographed. Cream product K[14] (1.0 g) was dissolved in 100 ml of tetrahydrofuran. Five milliliters of this solution was added to 5.0 ml of internal standard in mobile phase, mixed, and chromatographed.

RESULTS AND DISCUSSION

Products Containing Parabens Only—Methyl, propyl, and butyl paraben can occur in these products either singly or in pairs. Ethyl par-

Table III—Data for the Preservative Assays for Pharmaceutical Products Containing Benzoic Acid as the Preservative

Product	Internal Standard	Mobile Phase	Average Recovery, %	*RSD*, %	Concentration Range Validated, mg/ml
Fluid L	Ethylparaben	1B	100.1	0.5	0.5–2.0
Fluid M	Ethylparaben	1B	100.3	0.7	0.5–2.0

aben was not used as a preservative in the formulations studied and, thus, could serve as an internal standard. Figure 1 shows a chromatogram obtained by injecting a solution of these four materials dissolved in mobile phase 1. Excellent resolution was obtained between all four materials. The primary degradation product of all of these compounds was *p*-hydroxybenzoic acid, which eluted with the solvent front under these conditions. The total chromatographic time was ~10 min.

As previously suggested[1], the majority of the products containing only parabens as the preservative could be chromatographed using this mobile phase. The sample preparations were described earlier. The products successfully chromatographed by this method are creams, ointments, lotions, and sterile solutions and suspensions. The products are grouped in Table I by product type, where a product type is a group of products of essentially identical composition except for the active ingredient.

Products Requiring Different Mobile Phases—Two products containing only parabens as preservatives could not be chromatographed successfully by this system: a sterile penicillin suspension (F) and an oral tetracycline suspension (G). In both cases the active ingredient interfered with the preservatives. For the penicillin product it was found that the acidic mobile phase produced decomposition products which could not be adequately separated from the preservatives. By reducing the acetonitrile concentration and buffering mobile phase IA at an apparent pH of 7.2, decomposition could be avoided and all components were resolved. The sample preparation was identical to that for sterile suspension D.

For the oral tetracycline product (fluid G) it was found that the drug eluted as a broad, tailing peak with mobile phase 1. Lowering the pH narrowed the peak and moved it toward the solvent front. At pH 2.3 the tetracycline tail no longer interfered in the quantitation of the methyl paraben. Below pH 2.2, however, no improvement in peak shape was seen. Mobile phase IB was developed with the adjustment to an apparent pH of 2.2 with concentrated phosphoric acid. The sample was prepared by adding 1.0 ml of the fluid to 1.0 ml of a 0.2 *M* $NH_4H_2PO_4$ solution adjusted to pH 1.6. This solution was then diluted with 20.0 ml of an acetonitrile–water solution containing the internal standard. The sample was then mixed and chromatographed.

Recovery data for both products are included in Table I.

Products Containing Sorbic Acid With or Without Parabens—Several products were evaluated which use sorbic acid, either alone or in combination with methylparaben or methyl- and propylparaben. When these samples were chromatographed using mobile phase 1, the sorbic acid and methylparaben coeluted. Since it is well known that the retention times of weak acids are dependent on the pH of the system, it was decided to adjust the pH in an attempt to achieve optimum resolution. An acetic acid–acetate buffer at pH 5.4 was found to give the best chromatography and to separate all formulation excipients as well as *p*-hydroxybenzoic acid. The mobile phase used was mobile phase 2. The apparent pH was adjusted to 5.4 with acetic acid. This system allowed the use of ethylparaben as the internal standard. Products included suspensions (H), solutions (J), and a cream (K).

The results are listed in Table II. All recoveries and *RSD*s satisfy the validation criteria. Figure 2 shows a chromatogram of the solution product (J) and indicates the separation achieved between the three preservatives (sorbic acid, methylparaben, and propylparaben) and the internal standard (ethylparaben). The total chromatographic time was 8 min.

Benzoic Acid—Benzoic acid is used in two fluid products[15] (L and M). Mobile phase 1 was not able to resolve all excipients from the benzoic acid peak. Adopting the same approach as for sorbic acid, it was found that changing the pH could improve peak resolution. Optimum separation was achieved at pH values of ~2.5. Since this value was close to the pH used for mobile phase 1B, that system was tried. Mobile phase 1B did resolve the components sufficiently, and this offered the opportunity to consolidate several products on one analytical system, which would improve laboratory efficiency. The samples were prepared by diluting 1.0 ml of the fluids in 20.0 ml of an acetonitrile–water internal standard solution and chromatographing. The results are shown in Table III.

This paper has reported on a reverse-phase HPLC method which has been used successfully to quantitate antimicrobial preservatives in typical pharmaceutical formulations. The mobile phase used was basically an acetonitrile–water mixture, with various modifiers added as necessary to optimize the chromatography. This method was used successfully on five preservative materials: methylparaben, propylparaben, butylparaben, sorbic acid, and benzoic acid. This system can be easily adapted for automated sample analysis.

Immobilization of Urokinase on Agarose Matrices

HYUN PYO KIM, SI MYUNG BYUN, YOUNG IL YEOM, and SUNG WAN KIM *x

Received October 9, 1981, from the *Department of Biological Science & Engineering, Korea Advanced Institute of Science & Technology, Seoul, Korea*, and the **Department of Pharmaceutics, University of Utah, Salt Lake City, UT, 84112.* Accepted for publication April 20, 1982.

Abstract □ Immobilization of urokinase, a plasminogen activator, was carried out to determine the effect of spacer length used on the immobilized enzyme activity. The enzyme was covalently coupled to agarose gel, both directly to the matrix and also *via* interposing different lengths of spacer groups. The specific activity of immobilized urokinase increased as the spacer length (n') increased to a certain length and tended to decrease thereafter. The maximal activity was shown when the value of n' was 7 for the agarose-NH-$(CH_2)_n$-CO-NH-$(CH_2)_2$-CO-NH-urokinase series. The coupling yield of the enzyme activity was from 33 to 68% depending on various forms of immobilized urokinase. The immobilized urokinase was characterized with regard to pH, temperature, storage, and thermal stabilities.

Keyphrases □ Urokinase—immobilization on agarose matrices, effect on spacer length, enzyme activity □ Agarose—immobilization of urokinase on matrices, effect of spacer length, enzyme activity □ Immobilization—urokinase on agarose matrices, effect of spacer length, enzyme activity

Urokinase, a plasminogen activator, has been used for the treatment of thrombosis and/or vascular obstruction. For the purpose of thrombolytic therapy the immobilization of urokinase was attempted (*a*) to increase the *in vivo* half life, (*b*) to obtain local fibrinolytic activity for thromboembolic disorders, and (*c*) to develop antithrombogenic materials (1–6). Previous results suggested the potential clinical application of the immobilized urokinase (2–6).

Urokinase has been immobilized (1, 2) onto agarose matrices using the cyanogen bromide activation technique. Polyamide has been used as a matrix for the immobilization of urokinase (3, 5, 6) and other studies have utilized polyamide, polyester, polyvinyl chloride, polyurethane, and polydimethyl siloxane for this purpose (4, 6). The results demonstrated that the immobilized urokinase activated plasminogen. In a previous study streptokinase, a metabolic product of β-hemolytic *Streptococci* was immobilized for this purpose (7).

Steric considerations in the immobilization of bioactive agents appear to be important. It has been reported that urokinase immobilized onto a polyethyleneimine copolymer *via* a nitrophthalic acid spacer group showed better fibrinolytic activity than urokinase immobilized directly onto polyamide (4). Recently, researchers (8) immobilized heparin on polymers using different spacer group lengths. When immobilized, heparin activity increases rapidly, beginning with 8 carbon diaminoalkane spacer groups. In this work, the immobilization of urokinase onto an agarose surface was carried out by varying the spacer length between the enzyme and substrate.

EXPERIMENTAL

Materials—Crude urokinase was prepared from fresh human urine and human Cohn fraction III[1]. Crude urokinase, adsorbed onto silica gel, was extracted with 30% ethanol followed by dialysis and freeze-drying. Human plasminogen was purified from human Cohn fraction III according to a previous method (9) by using a lysyl-agarose affinity column. Human plasmin was prepared by eluting plasminogen into the column containing immobilized urokinase. One hundred milliliters of plasminogen solution, consisting of 0.5 CTA[2] units/ml of 0.1 *M* tromethamine hydrochloride buffer (pH 7.5), was passed through the column at a flow rate of 0.3 ml/min. The eluted plasmin was used for the standard curve calibration of the urokinase assay. Bovine serum albumin, α-casein, α-aminobutyric acid, ε-aminocaproic acid, and ω-aminocaprylic acid[3] were used as received. Glycine, *N*-hydroxysuccinimide, β-alanine[4], 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide metho-*p*-toluenesulfonate (I), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride[5] (II) were used as received. Agarose beads (III)[6] were used as the substrate for urokinase immobilization. (All other reagents were commercially available reagent grades.)

Urokinase Immobilization—*Direct Coupling of Urokinase on the Matrix*—Compound III was activated with cyanogen bromide according to a previously described procedure (11). A 10-ml slurry of washed III, consisting of equal volumes of the gel and water, was added to 10 ml of 2 *M* sodium carbonate and gently mixed. One gram of cyanogen bromide in 0.5 ml of acetonitrile was then added, and the slurry was stirred for 2 min. The cyanogen bromide-activated beads were then collected by filtration on a glass filter and washed successively with 100 ml each of cold 0.1 *M* sodium bicarbonate and 0.1 *M* sodium borate buffer.

To 10 ml of an activated slurry of III was added 50 mg of urokinase (1500 CTA units) in 20 ml 0.1 *M* sodium borate buffer (pH 7.5) containing 0.05 *M* HCl and 50 m*M* $CaCl_2$, which was then gently swirled overnight at 4°. The beads were collected on a coarse glass filter and washed with 300 ml each of cold water, 0.5 *M* NaCl, 2 *M* urea, and 0.1 *M* sodium borate buffer.

Coupling of Diaminoalkanes to Cyanogen Bromide-Activated III—Ten milliliters of activated III, prepared as previously described, was suspended in 10 ml of cold 0.1 *M* sodium bicarbonate, pH 9.0, and mixed with 10 ml of the various 1 *M* α,ω-diaminoalkane solutions which had been previously adjusted to pH 9.0 with 6 *N* HCl. The coupling was carried out overnight at 4° by stirring with a synchronized stirrer. After the reaction was completed, III was again sequentially washed with cold water, 0.1 *M* $NaHCO_3$, 0.05 *M* NaOH, water, 0.1 *M* CH_3COOH, and water.

Coupling of Urokinase to ω-Aminoalkyl-III with I and II—Ten milliliters of each of the above aminoalkyl-III beads was suspended in 10 ml of 0.1 *M* borate buffer solution, pH 7.5, containing 40 mg of I or II and 50 mg of urokinase (1500 CTA units). The reaction was continued overnight at 4°. Compound III was filtered and thoroughly washed with cold water, 0.5 *M* NaCl, and 2 *M* urea. The final immobilized urokinase was stored in 0.9% NaCl solution at 4° until use.

Coupling of Aminoalkyl Carboxylic Acids to Cyanogen Bromide-Activated III—Aminoalkyl carboxylic acid-coupled III was prepared according to the procedure for diaminoalkane coupling described above. Ten milliliters of the various 1 *M* aminoalkyl carboxylic acids was added to 10 ml of cyanogen bromide-activated III. The other procedures were similar to those described for diaminoalkane coupling.

Coupling of Urokinase to Carboxylic Alkyl-III with N-hydroxysuccinimide—The ω-carboxylic alkyl-III beads were activated with *N*-hydroxysuccinimide according to previous procedures (12, 13).

Ten milliliters of each washed carboxylic alkyl-III, which was prepared as previously described, was washed with anhydrous dioxane extensively to obtain anhydrous conditions. Compound III was suspended in dioxane to make a total volume of 30 ml. The *N*-hydroxysuccinimide, 346 mg, was

Table I—Comparative Results of Various Immobilized Urokinases on III

	Spacer length, n'	Activity, CTA units/ml, wet gel	Specific Activity, CTA units/mg, bound urokinase
Direct-coupled urokinase (III-urokinase)	0	56	14.4
III—NH—$(CH_2)_n$—C(=O)—NH-urokinase			
$n = 2$	3	49	33.6
$n = 3$	4	52	37.0
$n = 5$	6	112	45.0
$n = 7$	8	89	31.6
III—NH—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—C(=O)—NH-urokinase			
$n = 2$	6	78	56.2
$n = 3$	7	102	64.0
$n = 5$	9	93	42.4
$n = 7$	11	84	41.4

added to the gel suspension to obtain 0.1 *M* concentration, an equal molar quantity of dicyclohexylcarbodiimide was then added and the suspension was stirred gently for 70 min at room temperature. Activated III was washed with dioxane, followed by washing with methanol and dioxane. After drying the gels briefly in air, slightly moist cakes of the activated gels were subjected to coupling. Each gel was added rapidly to 10 ml of 0.1 *M* sodium borate buffer, pH 7.5, which contained 50 mg of urokinase. After stirring for 8 hr at 4°, 750 mg of glycine was added to react any remaining *N*-hydroxysuccinimide-activated spacer groups. After 2 hr, the gels were sequentially washed with cold deionized water, 2 *M* urea, and 0.5 *M* NaCl.

Coupling of β-Alanine to Carboxylic Alkyl-III—β-Alanine-coupling reaction was conducted for 8 hr as described in the previously mentioned experiment. β-Alanine (890 mg) was mixed with 10 ml of each *N*-hydroxysuccinimide-activated alkyl-III.

Coupling of Urokinase to β-Alanine-Linked III—Ten milliliters of each β-alanine-linked III was activated with *N*-hydroxysuccinimide as previously described. Urokinase (10 mg) was coupled to 2 ml of each β-alanine-linked III.

Determination of Urokinase Bound to III—To determine the amount of the immobilized urokinase on III[6] the amino acid content was determined by an auto amino acid analyzer after the immobilized urokinase, on the various gel matrices, was hydrolyzed with 6 *N* HCl (13). Soluble urokinase was also subjected to amino acid determination for reference purposes.

One milliliter of packed gel volume of the various immobilized urokinase gels was filtered on a glass filter and washed thoroughly with distilled water, followed by amino acid hydrolysis with 2 ml of 6 *N* HCl in a sealed tube at 110° for 24 hr. After hydrolysis, the hydrogen chloride was neutralized with 0.1 *M* sodium citrate, and the amino acid solutions were concentrated by rotoevaporatization. The amounts of amino acids were determined with a fully automated amino acid analyzer[7]. With a comparison to soluble urokinase, the amount of urokinase bound to the various gels was calculated based on quantities of alanine, lysine, and arginine.

Procedures for Enzyme Activity Assays—The activities of urokinase, plasminogen, and plasmin were determined by the caseinolytic assay method (10). Thirty CTA units of urokinase was used in the experiment. The activity of the immobilized urokinase was also determined by the same methods, constantly stirring the immobilized enzyme with the incubation mixture using a water-immersed magnetic stirrer. Protein concentrations were determined according to a previous method (14) using bovine serum albumin as a standard. The medium in which the immobilized enzyme was stored was assayed and showed no urokinase activity due to possible leakage.

RESULTS

Immobilization of Urokinase—To minimize steric hinderance for improved plasminogen accessibility to the coupled urokinase, various immobilized systems were prepared interposing different spacer group

[7] Beckman Model 118-BL, Mountain View, CA 94043.

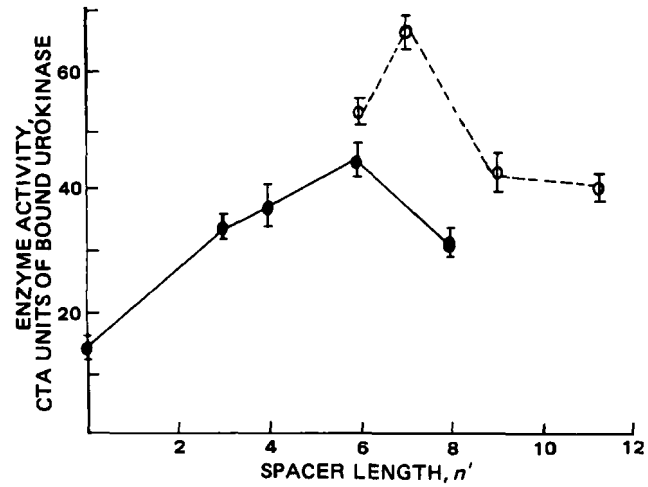

Figure 1—*Effect of spacer length on the activity of the immobilized urokinase. The length of spacer is represented by n' corresponding to: [—$(CH_2)_n$—C(=O)—] for III—NH—$(CH_2)_n$—C(=O) NH-urokinase series and [—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—C(=O)—] for III—NH—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—C(=O)—NH—urokinase series, respectively; (●—●) III—NH—$(CH_2)_n$—C(=O)—NH—urokinase series; (○ . . . ○) III—NH—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—NH-urokinase series.*

lengths between III and the immobilized urokinase, as described. The results are summarized in Table I.

In the III—NH—$(CH_2)_n$—C(=O)—NH-urokinase series, the activity of immobilized urokinase increased as the length of spacer increased up to $n = 5$ ($n' = 6$). However, the highest activity was observed when $n = 3$ ($n' = 7$) in the III—NH—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—C(=O)—NH-urokinase series. Above $n = 3$ ($n' = 7$) the activity decreased.

In immobilized urokinase activity experiments where it was immobilized onto diaminoalkane-derivatized III through carboxylic groups on the enzyme, it was found that the immobilized urokinase retained no activity. The loss in activity was found to be due to urokinase cross-linking by the carbodiimides during the immobilization step, resulting in the complete loss of enzyme activity.

The directly coupled urokinase ($n' = 0$) showed higher immobilization yields than those for III—NH—$(CH_2)_n$—C(=O)—NH-urokinase, when $n' = 3$ or 4. However, the enzymatic activity was much lower for the directly coupled urokinase relative to spacer arm mediated immobilized urokinase.

Figure 1 illustrates the effects of increasing spacer length (n') between the matrix and enzyme on the activities of the immobilized urokinase. The activity per milligram of bound enzyme was calculated from the data obtained by amino acid analysis of the immobilized urokinase. The enzymatic activity increased as spacer lengths extended to a certain length and tended to decrease thereafter. The maximum enzymatic activity was observed when $n' = 7$ for the III—NH—$(CH_2)_n$—C(=O)—NH—$(CH_2)_2$—C(=O)—NH-urokinase series.

Properties of the Immobilized Urokinase—Properties of the immobilized urokinase in terms of activity *versus* pH and temperature and the thermal stability were measured for III-urokinase and III—$(CH_2)_5$—C(=O)—NH-urokinase ($n' = 6$). Figure 2 illustrates the pH effects on the activity of urokinase in solution and the immobilized urokinase. The optimum pH of the soluble urokinase and III-urokinase was between 7.5 and 8.0, while III—$(CH_2)_5$—C(=O)—NH-urokinase was most active over a pH range from 7.5 to 9.0.

The effect of temperature on the activity of the immobilized urokinase was compared with that of the solution. The result indicated that the optimal temperature was 40° for both enzymes (Fig. 3).

Figure 4 shows the retention of the activity of immobilized urokinase in 0.9% NaCl solution at 4°. Both urokinase solution and III—NH—$(CH_2)_5$—C(=O)—NH-urokinase are stable in these storage conditions for 10 days without loss of activity, while III-urokinase (direct coupled urokinase) lost almost 40% of its original activity within 10 days. The urokinase immobilized with aminoalkane carboxylic acid spacer groups maintained well over 90% activity even after 60 days.

After heat treatment at 70° for 30 min, the urokinase solution lost activity completely, while III—NH—$(CH_2)_5$—C(=O)—NH-urokinase retained 45% of its activity by the same treatment.

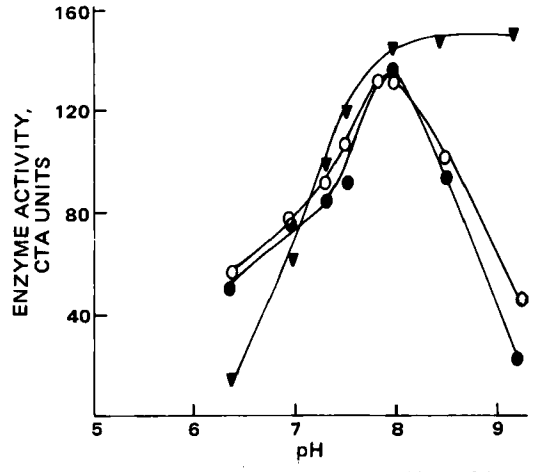

Figure 2—*Effects of pH on the activity of soluble and immobilized urokinase at 40°. Key: (○—○) soluble urokinase; (●—●) direct coupled urokinase (III-urokinase); (▼—▼) III—NH—$(CH_2)_5$—C(=O)—NH-urokinase.*

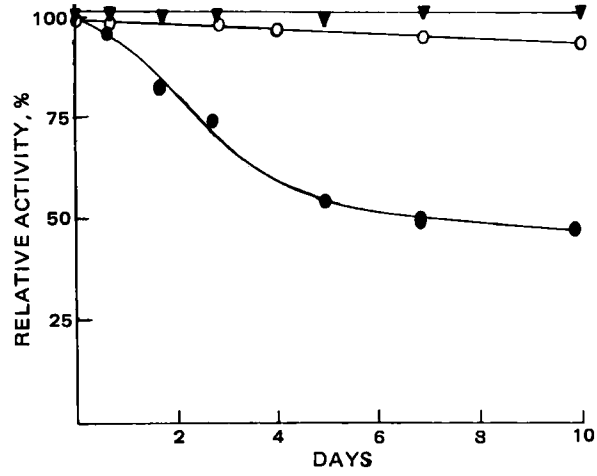

Figure 4—*Storage stability of soluble and immobilized urokinase. Key: (○—○) soluble urokinase; (●—●) direct coupled urokinase (III-urokinase); (▼—▼) III—NH—$(CH_2)_5$—C(=O)—NH-urokinase.*

DISCUSSION

Urokinase has been immobilized onto various matrices, and the results suggest a potential clinical use for thrombolytic therapy (2–6). Among them, polyamide, polyesters, and polyurethane-immobilized urokinase are useful clinically (3–6). Nevertheless, it can be said that an immobilized urokinase may experience steric hindrance from the polymer matrix. This has been postulated previously (4), where the polyamide–spacer–urokinase showed better fibrinolytic activity than the directly coupled polyamide–urokinase.

We first immobilized urokinase onto aminoalkyl-III which was prepared by a previously described method (13, 15). Unfortunately, unlike pronase (13), aminoalkyl-III-urokinase and III—NH—$(CH_2)_n$—NH—C(=O)-urokinase retained <5% of the initial urokinase enzymatic activity. It appears that urokinase was inactivated due to cross-linking by the carbodiimide I or II, which was used as a condensing agent in the immobilization step. We tested the inactivation of urokinase by treating free urokinase in solution with I or II in the presence or absence of aminoalkyl-III. In either case it was shown that urokinase retained no activity, whereas pronase activity remained when treated in a similar way.

Interposing spacer lengths (n') from 0 to 11, we have observed that the enzymatic activity of the immobilized urokinase increased as the spacer length (n') increased to a certain length, and tended to decrease thereafter (Table I, Fig. 1).

For a series of III—NH—$(CH_2)_n$—NH—C(=O)-urokinase, the highest activity was observed when $n' = 6$ (6.4 Å), while $n' = 7$ (9 Å) for a series of III—NH—$(CH_2)_n$—NH—C(=O)—$(CH_2)_2$—C(=O)—NH-urokinase resulted in maximum activity. Alternatively, direct attachment

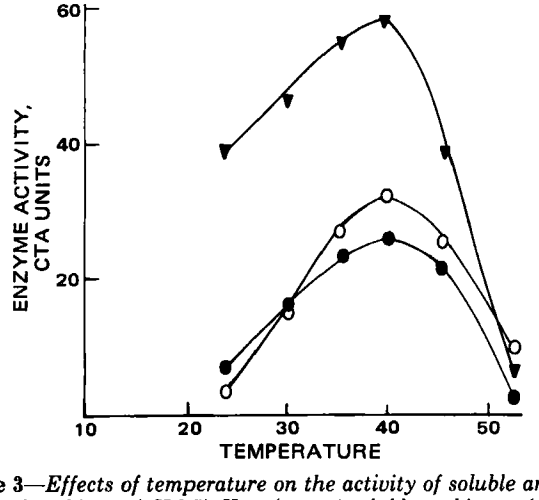

Figure 3—*Effects of temperature on the activity of soluble and immobilized urokinase (pH 8.5). Key: (○—○) soluble urokinase; (●—●) direct coupled urokinase (III-urokinase); (▼—▼) III—NH—$(CH_2)_5$—C(=O)—NH-urokinase.*

of urokinase to the matrix resulted in lower activity for plasminogen as shown in Table I. Differences of maximum enzymatic activity for the above two series of spacer arms are not clear and may be due to the different microenvironment of the hydrophilic polymers. An additional group from β-alanine provides a more hydrophilic environment which may introduce better accessibility of plasminogen to the immobilized urokinase.

As previously suggested (16), the dramatic effects associated with increasing the spacer length may in part be explained by relief of steric restrictions imposed by the matrix and in part by the increased flexibility and mobility of the urokinase as it protrudes further into the solvent phase. Plasminogen could then approach more readily the immobilized urokinase. This flexibility and folding of the spacer could also account for an apparent decrease in urokinase activity observed when the spacer lengths (n') >6 or 7 were interposed between the matrix and urokinase bond. This decreasing trend may be caused by the increased hydrophobicity of the spacer arms and/or rapid folding within immobilized urokinase by cohesive interactions.

The critical role of the matrix in the determination of accessibility of the coupled molecules to interacting macromolecule has been especially emphasized for affinity chromatography (15–17). A previous study (15) reported that a spacer length from 4 to 8 of interposed methylene groups (5–10 Å) elicited a substantial increase in enzyme binding affinities for kinases and pyrimidine nucleotide-dependent dehydrogenases with insoluble derivatives of adenosine triphosphate and nicotinamide adenine dinucleotide.

In conclusion, steric considerations appeared to be important in urokinase immobilization and maximum enzymatic activity was observed when the length of the spacer group was in the region of 6.4–9.0 Å.

The optimum pH with regard to the activity of soluble urokinase and III-urokinase was between 7.5 and 8.5. However, III—NH-$(CH_2)_5$—C(=O)—NH-urokinase showed maximum activity over a pH range from 7.5 to 9.0 (Fig. 2). The unchanged maximum activity for immobilized urokinase over the alkaline pH range may be due to unreacted carboxylic groups from aminoalkyl carboxylic spacers, which could neutralize the alkaline pH at the solvent–immobilized urokinase interface.

After heat treatment at 70° for 30 min, III—NH—$(CH_2)_5$—C(=O)—NH-urokinase retained activity. Activities of the soluble urokinase and III—NH—$(CH_2)_5$—C(=O)—NH-urokinase proved to be stable during storage in 0.9% NaCl at 4°, whereas III-urokinase was unstable under the same conditions (Fig. 4).

Since urokinase immobilized on matrices such as polyamide, polyester, and polyurethane had a proven antithrombotic action *in vivo*, steric problems in urokinase immobilization should be considered to improve immobilized urokinase activity with *in vivo* systems.

Prevention of Insulin Self-Association and Surface Adsorption

SHUJI SATO, CHARLES D. EBERT, and SUNG WAN KIM ˣ

Received November 30, 1982, from the *Department of Pharmaceutics, University of Utah, Salt Lake City, UT 84112.* Accepted for publication April 14, 1982.

Abstract □ The self-association of insulin monomers into oligomers and macromolecular aggregates leads to complications in the administration of insulin, both in conventional administration and in the development of long-term insulin delivery systems. These problems are aggravated by the tendency of insulin to adsorb onto the surface of solution containers and infusion devices. Furthermore, with insulin infusion devices, shear rates can be generated which can accelerate the self-association and surface adsorption processes. The effects of urea on shear-induced insulin self-association and surface adsorption were investigated. It was found that the addition of a certain concentration range of urea to insulin solutions greatly reduces both insulin self-association and surface adsorption. Circular dichroic studies established that these concentrations of urea also preserve insulin conformation under high shear rates, where conformations are altered without urea. Higher urea concentrations lead to insulin denaturation and accelerated self-association.

Keyphrases □ Insulin—prevention of self-association and surface adsorption, circular dichroism □ Adsorption, surface—insulin, prevention of self-association □ Self-association—insulin, prevention of surface adsorption

The self-association of insulin molecules into dimers, tetramers, hexamers, and macromolecular aggregates has been studied by numerous groups, and in general, is a multiparameter process dependent upon insulin concentration, pH, solvent composition, ionic strength, and solvent dielectric properties (1–3). This self-association process leads to complications in the administration of insulin for the control of diabetes, both in the conventional administration and in the development of long-term insulin delivery systems. These problems are further complicated by the tendency for insulin to adsorb onto the surfaces of insulin solution containers and infusion devices, perhaps by mechanisms similar to those inducing aggregation.

Investigations have attempted to overcome the self-association and surface adsorption phenomena by the addition of various agents to the insulin preparations. These additives include various organic solvents (1), autologous serum (2), and amino acids (3). This report focuses on the effects of additives on insulin conformation, self-association, and adsorption onto various polymeric surfaces. In addition to the effects on insulin aggregation caused by the additives, the effects of shear stresses on macromolecular aggregation were studied. Depending on the infusion device, substantial shear rates can be developed during insulin infusions which can influence insulin self-association and macromolecular aggregation and limit the effective duration of such devices. These effects must also be considered in the development of insulin delivery systems.

This report studies the effects of additives on the insulin conformation–self-association process under constant shear, solvent pH, and ionic strength. The adsorption of insulin onto various polymers was also studied under the above conditions as a prerequisite to the development of a diffusion controlled, self-regulating insulin delivery system presently under development.

EXPERIMENTAL

Reagents—Bovine zinc–insulin[1] was used without further treatment. This insulin preparation had an activity of 25.5 IU/mg. Gentamicin sulfate[1] was used at a concentration of 25 μg/ml in all insulin aggregation and polymer adsorption studies to prevent bacterial growth. A pH 8.0 phosphate-buffered saline, containing 0.0945 *M* Na_2HPO_4, 0.0055 *M* KH_2PO_4, and 0.015 *M* NaCl, was used as the buffer solution in all studies. Hydroxyethyl methacrylate[2] was polymerized with azobisisobutyronitrile[3]. Poly(dimethylsiloxane)[4] was cured with 0.5% (w/w) stannous octoate. Cellulose sheets were obtained from a hemodialyzer[5] and soxhlet extracted for 24 hr, with double-distilled water. A segmental poly(urethane ether) copolymer[6], was dissolved in dimethylformamide and cast

into sheets. The above polymers were used in insulin adsorption studies.

Circular Dichroic (CD) Studies—All CD spectra were obtained with a CD spectrophotometer[7] at 25°. Mean residue ellipticities, $[\theta]_\lambda = \theta_\lambda Mo/C \cdot l$ (where θ_λ is the observed ellipticity at wavelength λ, Mo is the mean residue molecular weight for insulin (112 g/residue), C is the insulin concentration in grams per milliliter, and l is the pathlength in centimeters) were calculated for the various wavelengths and insulin concentrations.

Effects of Shear on Insulin Self-Association and Adsorption—To

evaluate the effects of shear on insulin macromolecular aggregation, 100-ml portions of various concentrations of insulin were stirred at 1550 rpm with a mechanical stirrer. This stirring velocity was selected because it represents an extreme case for shears that could be developed with infusion devices, and because these conditions will be utilized in current insulin–polymer diffusion experiments for the development of the self-regulating insulin delivery system previously described. Periodic samples were withdrawn and visibly evaluated for macroaggregation. Approximately 1-cm^2 disks of poly(hydroxyethyl methacrylate), cellulose, poly(dimethylsiloxane), and poly(urethane ether) were placed in the above insulin solutions and withdrawn after 7 days. These polymer samples were vacuum dried, gold coated, and a scanning electron microscopy[8] of the resultant polymer surfaces was conducted.

Table I—The Effect of Additives on Insulin Aggregation Time[a]

Additive	Concentration of Additive	Time for Aggregation
No Additive	—	2–3 days
Lysine	0.01 *M*	3–4 days
Lysine	0.002 *M*	3–4 days
+ I[b]	0.005 *M*	
I[b]	0.005 *M*	2–3 days
Urea	0.5 mg/ml	3–4 days
Urea	1.0 mg/ml	7 days
Urea	2.0 mg/ml	7 days
Urea	3.0 mg/ml	7 days
Urea	5.0 mg/ml	3–4 days

[a] Insulin concentration set at 0.1 mg/ml in all cases. [b] EDTA (I).

Effects of Additives on Insulin Self-Association and Adsorption Under High Shear—The effects of various concentrations of lysine[1], urea[1], and disodium edetate (I)[1] on insulin circular dichroism, macromolecular aggregation, and adsorption on polymer surfaces were evaluated under high shear conditions as described.

RESULTS AND DISCUSSION

The CD spectra of insulin at various concentrations is presented in Fig. 1, where mean residue ellipticity, $[\theta]_\lambda$ in deg cm^2/*d*mol × 10^{-3}, is plotted *versus* wavelength. At an insulin concentration of 5 mg/ml, negative maxima were observed at 245, 262, and 283 nm, the trough at 262 nm having been assigned to phenylalanine at B24 and/or B25 residues, while the trough at 283 nm was assigned to tyrosine at B26 (4).

Two negative maxima at ~245 and 270 nm were observed between 1.0 and 0.4 mg/ml. The trough at ~270 nm was assigned to tyrosine and phenylalanine aromatic residues in the B23–28 region of the antiparallel β-structure formed between insulin monomers in insulin aggregated states. Attenuation of this band has been associated with disaggregation of insulin (5), while strengthening of the band is associated with conditions that enhance insulin aggregation (6). The optical activity of the aromatic residues contributing to this band is, therefore, dependent upon the state of insulin self-association. As insulin concentration decreased, the strength of this band progressively decreased indicating reduced insulin self-association. At 0.2 mg/ml the 270-nm trough was greatly diminished and a negative maxima at ~225 nm was the dominant band. This trough was the predominant feature of the insulin CD spectra for 0.2, 0.1, and 0.01 mg/ml insulin concentration. The appearance of this trough at ~225 nm was assigned to the antiparallel β-structure of insulin dimers (7). This band was the predominant feature of the insulin dimer. Furthermore, this peak was not attenuated upon dilution from 0.2 to 0.01 mg/ml, suggesting that insulin dimers are the prominent species in that concentration range. At an insulin concentration of 0.02 mg/ml, mean residue ellipticity at 225 nm decreased and the trough was broadened, demonstrating negative ellipticity at ~210 nm. Negative ellipticity at ~210 nm has long been associated with an α-helical structure. The attenuation of negative ellipticity at 225 nm combined with the appearance of negative ellipticity at 210 nm suggests that insulin dimers are less prevalent at this concentration.

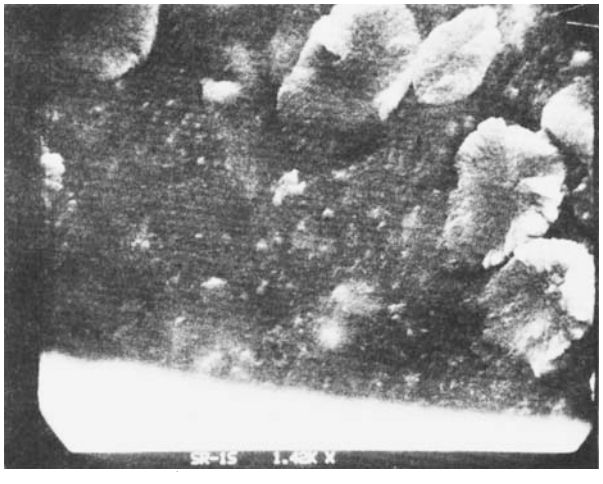

Figure 4—*Insulin adsorbed onto silicone rubber under high shear, 1600 ×.*

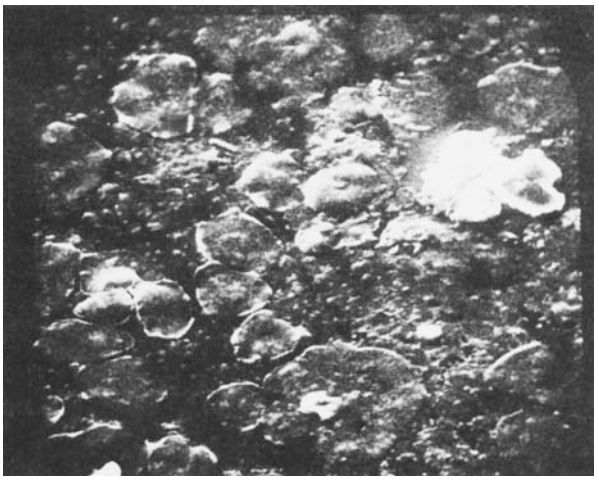

Figure 5—*Insulin adsorbed onto the segmental poly(urethane ether) copolymer under high shear, 600 ×.*

Results from the data reported here and studies by others (4, 7) suggest that the ~225- and 270-nm bands provide an indication of insulin self-association. When mean residue ellipticity is plotted *versus* insulin concentration, Figure 2, it is evident that the ~225-nm band is the more sensitive indicator of insulin self-association, insulin self-association into dimers, tetramers, hexamers, *etc.*, in turn having previously been correlated by others with insulin concentration (4, 8).

Using insulin CD as the indicator of insulin self-association, the effects of various additives on insulin self-association under high shear rate conditions were evaluated. These results are presented in Fig. 3, where the lighter tracing represents the CD spectra at time 0 and the darker tracing represents the CD spectra for the same insulin solution at the indicated time. The insulin concentration was set at 0.1 mg/ml for all spectra presented. At a urea concentration of 2.0 mg/ml, no changes in the 225-nm peak were observed even after 7 days under high shear rate conditions. Changes in the CD spectra were observed for higher and lower concentrations of urea at ~4 days providing spectra similar to aggregated insulin without additives. Interestingly, the small trough at 270-nm disappears under high shear rates indicating a loss in optical activity for the B23–28 aromatic residues.

Table I summarizes the effects of additives on shear-induced insulin macromolecular aggregation, all data obtained at an insulin concentration of 0.1 mg/ml where insulin dimers were the prevalent species. Macromolecular aggregation was observed without additives within 2–3 days. The same aggregation time was observed for 0.005 *M* EDTA (I). The addition of 0.01 *M* lysine or a combination of 0.01 *M* lysine and 0.005 *M* I prolonged macromolecular aggregation of insulin by ~2 days. The addition of 0.5 mg/ml of urea produced aggregation times similar to the lysine–I combination; however, aggregation times were >7 days

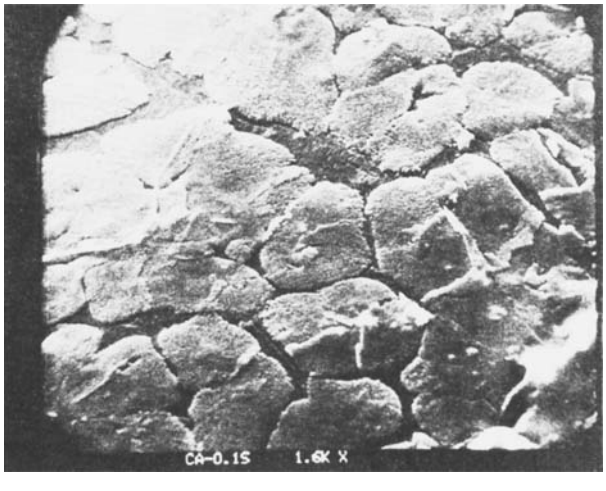

Figure 6—*Insulin adsorbed onto cellulose under high shear, 1600 ×.*

Figure 7—*Insulin adsorbed onto the segmental poly(urethane ether) copolymer under high shear with 2.0 mg/ml urea, 2100 ×.*

for urea concentrations ranging from 1.0 to 3.0 mg/ml. At higher urea concentration, aggregation times were ~4 days.

Scanning microscopy revealed that insulin adsorption onto various polymer surfaces was substantially greater under high shear as compared with static conditions. The morphology of the adsorbed insulin was found also to be dependent on shear conditions. Scanning electron micrographs of insulin adsorbed under high shear onto poly(dimethylsiloxane), poly(urethane ether), and cellulose are presented in Figs. 4–6, respectively. Under high shear, insulin adsorbs onto all of the polymers evaluated as disk-like structures. Without high shear rates, such disk-like insulin adsorbates were not observed over the time frame evaluated. Under high shear, the morphology of the adsorbed insulin appears independent of the polymer nature, disk-like adsorbates were observed on all types of polymer surfaces. However, under static conditions the morphology may be dependent upon the polymer substrate.

Concentrations of urea that prolonged insulin macromolecular aggregation times were found also to inhibit insulin adsorption onto polymer surfaces. Disk-like insulin adsorbates were not observed on the various polymer surfaces with the addition of 2.0 mg/ml urea under high shear, as shown for poly(urethane ether) in Fig. 7 as a representative case.

The self-association of insulin molecules in solution and the adsorption of insulin onto container surfaces pose complications in the administration of insulin. These problems are of particular importance with long-term insulin infusion devices where insulin crystals on the various surfaces of such devices have been observed by several investigators (9, 10). With such systems, insulin can be subjected to shear rates that can greatly effect and potentiate this process.

The addition of urea in a limited concentration range (*i.e.*, 1–3 mg/ml of urea) inhibits both insulin self-association and surface adsorption. It has been suggested that the initial step in insulin self-association is the hydrophobic association of the B23–28 regions on insulin monomers to form insulin dimers which further associate into larger oligomers. Urea, a water structure-breaking solute, was found to greatly inhibit insulin self-association and surface adsorption presumably by decreasing interactions between dimers to prevent further self-association. Higher urea concentrations were found to denature insulin, leading to rapid macromolecular aggregation times. The concentration range of urea that inhibits these processes poses little to no toxicity risks and can stabilize insulin preparations for extended periods, both for conventional administration preparations and for the development of long-term insulin delivery systems.

Conformational Study of Two Polymorphs of Spiperone: Possible Consequences on the Interpretation of Pharmacological Activity

M. AZIBI *, M. DRAGUET-BRUGHMANS *, R. BOUCHE *x, B. TINANT ‡, G. GERMAIN ‡, J. P. DECLERCQ ‡, and M. VAN MEERSSCHE ‡

Received December 18, 1981, from the **Laboratoire d'Analyse des Médicaments, Institut de Pharmacie UCL 7340, 1200, Bruxelles, Belgium*, and the ‡*Laboratoire de Chimie physique et de Cristallographie, Université de Louvain, Place Louis Pasteur, 1348, Louvain-la-Neuve, Belgium.* Accepted for publication April 15, 1982.

Abstract □ A second polymorph of spiperone, 8-[3-(*p*-fluorobenzoyl)-propyl]-1-phenyl-1,3,8-triazaspiro[4,5]decan-4-one, has been isolated and characterized by thermal analysis and IR spectrometry. Its structure was solved by X-ray diffraction analysis. The results are compared with those previously obtained on spiperone, the main difference being in the conformation of the side chain and in the nature of the hydrogen bonding.

Keyphrases □ Spiperone—polymorphs, conformational study, possible consequences on interpretation of pharmacological activity □ Pharmacological activity—conformational study of two polymorphs of spiperone, possible consequences of interpretation □ Polymorphs—spiperone, conformational study, possible consequences on interpretation of pharmacological activity

Complete data about the crystal structure and solid-state molecular conformation of different polymorphs of the same drug are rarely available. The main reason lies in the difficulty in obtaining single crystals of good quality from the different polymorphs. Studies of drug polymorphism are generally restricted to determination of IR

Figure 7—*Insulin adsorbed onto the segmental poly(urethane ether) copolymer under high shear with 2.0 mg/ml urea, 2100 ×.*

for urea concentrations ranging from 1.0 to 3.0 mg/ml. At higher urea concentration, aggregation times were ~4 days.

Scanning microscopy revealed that insulin adsorption onto various polymer surfaces was substantially greater under high shear as compared with static conditions. The morphology of the adsorbed insulin was found also to be dependent on shear conditions. Scanning electron micrographs of insulin adsorbed under high shear onto poly(dimethylsiloxane), poly(urethane ether), and cellulose are presented in Figs. 4–6, respectively. Under high shear, insulin adsorbs onto all of the polymers evaluated as disk-like structures. Without high shear rates, such disk-like insulin adsorbates were not observed over the time frame evaluated. Under high shear, the morphology of the adsorbed insulin appears independent of the polymer nature, disk-like adsorbates were observed on all types of polymer surfaces. However, under static conditions the morphology may be dependent upon the polymer substrate.

Concentrations of urea that prolonged insulin macromolecular aggregation times were found also to inhibit insulin adsorption onto polymer surfaces. Disk-like insulin adsorbates were not observed on the various polymer surfaces with the addition of 2.0 mg/ml urea under high shear, as shown for poly(urethane ether) in Fig. 7 as a representative case.

The self-association of insulin molecules in solution and the adsorption of insulin onto container surfaces pose complications in the administration of insulin. These problems are of particular importance with long-term insulin infusion devices where insulin crystals on the various surfaces of such devices have been observed by several investigators (9, 10). With such systems, insulin can be subjected to shear rates that can greatly effect and potentiate this process.

The addition of urea in a limited concentration range (*i.e.*, 1–3 mg/ml of urea) inhibits both insulin self-association and surface adsorption. It has been suggested that the initial step in insulin self-association is the hydrophobic association of the B23–28 regions on insulin monomers to form insulin dimers which further associate into larger oligomers. Urea, a water structure-breaking solute, was found to greatly inhibit insulin self-association and surface adsorption presumably by decreasing interactions between dimers to prevent further self-association. Higher urea concentrations were found to denature insulin, leading to rapid macromolecular aggregation times. The concentration range of urea that inhibits these processes poses little to no toxicity risks and can stabilize insulin preparations for extended periods, both for conventional administration preparations and for the development of long-term insulin delivery systems.

spectra and thermal properties, determination of dissolution characteristics, and recording of X-ray powder diffraction spectra (1–3).

Many crystal and molecular structures of neuroleptics belonging to the family of butyrophenones have been published, without reference to possible polymorphism (4–13). Among those was the crystal structure of spiperone[1] (Fig. 1), one of the most potent neuroleptic drugs (5). The structure of spiperone is mainly characterized by its unique conformation of the side chain and is often used as reference in studies of the structure–activity relationship for testing the conformational resemblance of neuroleptics to dopamine (14, 15).

This paper characterizes the crystal structure of a second polymorph of spiperone, compares this polymorph with the known structure, and discusses the possible consequences on the interpretation of the pharmacological activity.

EXPERIMENTAL

IR Spectrometry[2]—IR spectra were recorded in potassium bromide pellets (0.5%, w/w).

X-Ray Diffraction[3]—The intensities of 2551 reflections were measured on a four-circle diffractometer by the ω-scan technique up to $2\theta = 44°$. Incident radiation was graphite-monochromatized Mo$K\alpha$: $\lambda = 0.7107$ Å. Only 921 reflections with $I > 2.5\sigma(I)$ were considered as observed and retained for the resolution and refinement of the structure. The structure was solved by direct methods using the MULTAN 80 computer system[4]. The refinement was carried out by the SHELX 76[5] program with anisotropic thermal parameters. The positions of the hydrogen atoms were calculated by SHELX. The final conventional R index was 0.079. For crystal data see Table I.

Thermal Analysis[6]—Thermal behavior was studied on a differential scanning calorimeter at a heating rate of 5°/min. Temperatures of fusion were measured at the onset point of each peak.

Preparation of Crystals[7]—Good quality crystals were obtained by slow evaporation at 60° of n-heptane (form I) and by slow evaporation at 60° of 2-propanol (form II).

RESULTS AND DISCUSSION

Two polymorphs of the title compound were isolated and characterized by differential scanning calorimetry. Form I[8] melted at 209.8° (heat of fusion: 52.3 kJ/mole), whereas form II melted at 207.0° (heat of fusion 51.8 kJ/mole). These two forms showed an equivalent stability at room

[6] Perkin-Elmer DSC-model 2.

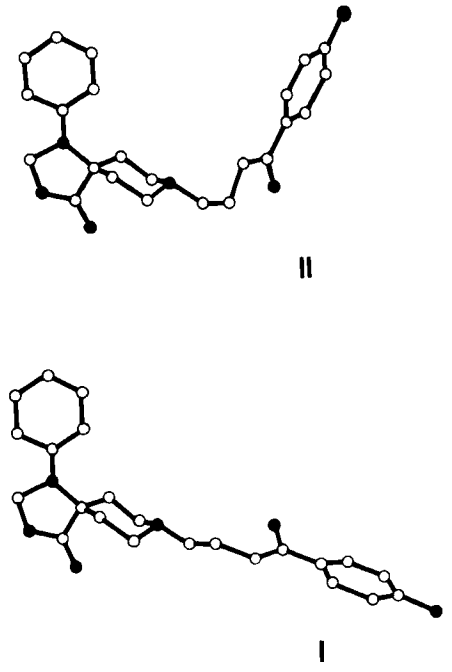

Figure 5—*Molecular conformation of spiperone I and II.*

Unit cell parameters of form II corresponded to those published earlier (5), while the crystal lattice of form I was different (Table I). Complete crystal structure of form I was thus determined and compared with that of form II (Tables II–V, Fig. 4).

The main difference between the molecular conformation of the polymorphs was found to be in the conformation of the side chain. Form I was shown to have the same side-chain conformation as aceperone[11], azaperone[12] I, benperidol[13] I, moperone[14] I, III (R1838)[15,19]-I, pipamperone[16], IV (R1616 hydrochloride)[17,19], haloperidol hydrobromide[18],

moperone hydrobromide (4, 6, 7, 9, 11, 12, 14, 15) (Fig. 5). The side-chain conformation of form II was found to be different from the compounds described above.

This modification of the conformation between the two polymorphs of spiperone is not surprising since PCILO (16) calculations have showed the possible existence of five isoenergetic minima for the propyl chain of butyrophenones (5, 14–17). The piperidine ring of form I is in the usual chair form encountered in most butyrophenones.

The angle between the mean plane of the piperidine and phenyl rings, and the corresponding torsion angles, are nearly identical in the two polymorphs (Table V). This fact may be explained by the coplanarity of the phenyl and five-membered rings that are attached by a $C(sp_2)$-$N(sp_3)$ single bond with lengths of 1.404 Å (I) and 1.394 Å (II), respectively (18). As a result the rotation of the phenyl ring is not allowed. The PCILO potential energy curve of the phenyl ring-containing moiety of spiperone leads to an identical interpretation (15, 17). Experimental values of torsion angles of spiperone I fall in the same minimum of the PCILO curve as those of spiperone II, thus confirming the existence of a potential barrier.

The two polymorphs differ entirely from one another in the nature and the force of hydrogen bonding. Indeed, in form II, each molecule is bonded to another by two hydrogen bonds, [N(3) to O(1)], and the crystal is made up of dimers which are held together by packing forces only (5). On the other hand, in form I only one type of hydrogen bond, [N(3) to N(8)] contributes to the building of a polymeric lattice (Table VI). Differences between intermolecular bonding of the two forms are visible in IR spectra. In form I, the stretching of the NH—N polymeric bond appears in the 3000–3100 cm^{-1} region as a broad peak, whereas the narrow bands observed at 3190 and 3110 cm^{-1} in form II indicate that the NH vibrator included has a more localized bond, such as a dimeric structure. Nevertheless, the shift of the C=O(1) vibration frequency (1705 cm^{-1}) is not visible because the N(3)H to O(1)C hydrogen bond taken individually is not very strong; intensity of the corresponding absorption band is only increased.

The two polymorphs of spiperone exhibit different crystal structures. Their molecular conformation and intermolecular bonds in solid state differ entirely.

The study of molecular conformation of the two polymorphs confirms the flexibility of the side chain of butyrophenone derivatives claimed previously by PCILO calculations (15, 17). Moreover, existence of two conformations of the side chain for the same compound proves definitively that this conformation is not influenced by the nature of the phenyl ring-containing moiety and by the substituents on that ring.

Several authors have attempted to explain the high level of activity of spiperone by relatively high local concentrations in brain regions, caused by dimerization *in vivo*, considering that spiperone preferentially forms dimers (14). The structure of form I proves that a stable nondimerized form of spiperone can exist with a high probability of occurrence.

Analysis of Theophylline by Automated Multidimensional High-Performance Liquid Chromatography Involving Direct Plasma Injection

SHAW F. CHANG ˣ, TERESA M. WELSCHER, and ROBERT E. OBER

Received November 23, 1981, from the *Drug Metabolism Department, Riker Laboratories, Inc., Subsidiary of 3M, St. Paul, MN 55144.* Accepted for publication April 20, 1982.

Abstract □ A procedure of direct injection of whole plasma for the analysis of theophylline by an automated multidimensional high-performance liquid chromatographic (HPLC) technique is described. The procedure requires as little as 30 μl of plasma sample and has a linear range of 0.25–30 μg/ml. Unknown plasma samples, after the addition of internal standard, are directly injected into the HPLC system. The chromatographic procedure is fully automated, thus the attention and time required from the analyst is reduced to a minimum. About 70 samples can be analyzed per day with ~3 hr of analyst time.

Keyphrases □ Theophylline—analysis by automated multidimensional high-performance liquid chromatography involving direct plasma injection □ High-performance liquid chromatography—automated multidimensional analysis of theophylline involving direct plasma injection □ Direct plasma injection—analysis of theophylline by automated multidimensional high-performance liquid chromatography

Multidimensional high-performance liquid chromatography (HPLC) has been in use for quite some time. However, the majority of the applications do not involve the direct injection of plasma samples (1–5).

The purpose of the present investigation was to test the concept of analyzing drugs in plasma by the multidimensional column chromatography technique and to determine if the technique could be completely automated. The test compound in this case was theophylline. After the investigation was completed, an abstract outlining the feasibility of the concept for theophylline was published (6). In the present report, the successful application of a fully automated multidimensional HPLC technique for the routine analysis of theopnylline is described.

BACKGROUND

Monitoring plasma levels of drugs in clinical management of patients or studying pharmacokinetic parameters for a marketed or developmental drug both require the quantitative determination of the drug in biological fluids, most often in plasma. Generally used procedures require the separation of the drug from the plasma proteins by a solvent extraction or protein precipitation technique prior to quantitation. With the recently available gel permeation columns designed to separate water soluble polymers, it is possible to employ a gel permeation column in place of the normal extraction procedure for the purpose of separating the drug from the plasma proteins. Thus, a coupled-column or multidimensional column chromatography technique can be used. In this technique, the drug is first separated from the plasma proteins on a gel permeation column based on molecular size difference, then the drug is selectively transferred *via* a switching valve onto a reverse-phase column where, on the basis of partition characteristics, it is further separated from any endogenous material with a similar range of molecular weight. The first step eliminates the plasma proteins, and the second step separates and quantitates small molecular weight substances.

EXPERIMENTAL

Reagents and Apparatus—The tetrahydrofuran was distilled in glass[1], and the methanol was suitable for liquid chromatographic use[2]. All chemicals were analytical reagent grade. All HPLC analyses were performed using a liquid chromatograph equipped with two solvent delivery systems[3], an automatic liquid sampler[4], and a detector[5] with a 280-nm filter. Peak heights were measured by an integrator[6]. The two columns used were a gel permeation column[7] and a 25-cm × 4.6-mm i.d. reverse-phase column[8]. A 4-port switching valve with air actuator[9] was placed in line, and the valve switching was controlled by the integrator through an external relay. The integrator was programmed to turn the valve at a certain time during each sample run. Figure 1 shows the arrangement of apparatus.

Standard Solutions—Standard solutions of theophylline and β-hydroxyethyl theophylline[10] were prepared by diluting 400-μg/ml stock solutions of each compound. Concentrations used were 0.3, 0.6, 1.8, 4.2, 9.0, 18.0, and 36.0 μg of theophylline/ml for the theophylline standard and 8.0 μg of β-hydroxyethyl theophylline/ml for the internal standard. All solutions were made in 0.05 *M* sodium phosphate buffer, pH 7.0, and were kept refrigerated.

Mobile Phase—Mobile phase A consisted of 0.05 *M* sodium phosphate buffer, pH 7.0. The phosphate buffer was prepared from 0.1 *M* dibasic sodium phosphate and 0.1 *M* monobasic sodium phosphate. Mobile phase B was prepared by mixing 70 ml of methanol, 10 ml of tetrahydrofuran, 92 ml of 0.1 *M* sodium acetate buffer pH 5.0, and 828 ml of distilled water. The final composition was methanol–tetrahydrofuran–0.01 *M* sodium acetate buffer pH 5.0 (7:1:92, v/v/v). This mobile phase was reported previously for the analysis of theophylline by HPLC (7). The mobile

phases were filtered through a membrane filter[11] (pore size 0.45 μm) and deoxygenated prior to use.

Sample Preparation and Injection—Plasma, internal standard, and phosphate buffer (0.05 *M*, pH 7.0) were mixed in the ratio 30:25:25 (v/v/v). The minimum volume of plasma used was 30 μl. Eight theophylline standards were prepared by mixing blank plasma, internal standard, and the theophylline standard in the same ratio as above. The standard concentrations were 0, 0.25, 0.5, 1.5, 3.5, 7.5, 15, and 30 μg/ml plasma. To prevent overloading the gel permeation column, no more than 53 μl of the mixture (equal to 20 μl plasma) was injected into the liquid chromatograph. If duplicate injections are desired, the volumes for mixing should be doubled.

At 0 min, the valve was positioned so that mobile phase A flowed through the gel permeation column to the waste. Simultaneously, mobile phase B flowed through the reverse-phase column to the UV detector. The sample was injected onto the gel permeation column which separated the plasma proteins from the lower molecular weight materials, including theophylline. At the beginning of the theophylline peak the valve was switched so that effluent from the gel permeation column was directed onto the reverse-phase column. Mobile phase B then flowed directly to waste. The theophylline was concentrated at the head of the reverse-phase column by the aqueous mobile phase A. At 2 min after the switching, the valve was turned back to the original position. Mobile phase B was then flowing through the reverse-phase column where further separation of theophylline and the other lower molecular weight materials occurred. Actual switching times can vary by ±0.4 min, depending upon the retention time of theophylline on different gel permeation columns.

Method of Calculation—The construction of a standard curve, and subsequent calibration of unknown samples with the standard curve, was fully automated and was performed by a computing integrator. The integrator collected the peak height ratios (theophylline–internal standard) from the standards during a run, and the slope (A) and intercept (B) for the least-squares line between the peak height ratios (*x*-axis) and the theophylline concentrations (*y*-axis) were determined. The slope and intercept were automatically entered into the integrator's memory. For the unknown samples, the integrator determined the peak height ratio for each sample, retrieved the slope and intercept from the memory, and calculated the theophylline concentration in the following manner: theophylline concentration = peak height ratio × A + B. The final result of each unknown is reported in micrograms per milliliter.

RESULTS AND DISCUSSION

Determination of Valve-Switching Time—The purpose of the multidimensional technique was to separate the plasma proteins from the drug. This was accomplished through the switching valve. Thus, the time and duration that the valve is switched become a critical part of the overall procedure. An early switch will result in the transfer of plasma proteins onto the reverse-phase column and the rapid deterioration of that column. A late switch will result in the loss of the drug to waste. The duration of the time the valve was in the switching configuration controlled the quantitative transfer of the drug onto the reverse-phase column. For each drug studied and each gel permeation column used, the time and duration of the valve switching were predetermined. Figure 2 shows a set of typical chromatographic profiles of the gel permeation column alone. The majority of the UV-absorptive materials were eluted before 6 min. The theophylline started eluting at 6.3 min and peaked at 6.5 min; thus 6 min after the injection was chosen as the switching time of the valve. The peaks at 6.7 and 6.9 min from the blank plasma were also transferred onto the reverse-phase column, but were separated from theophylline and the internal standard and constitute no interference with the assay. Based on experimental results for theophylline, it was found that if the valve remained in the switching configuration for at least 2 min, a quantitative transfer of theophylline onto the reverse-phase column resulted.

Separation—The separation of theophylline and internal standard from endogenous materials in the plasma by the multidimensional technique is shown in Fig. 3. Baseline separation was achieved between theophylline and the internal standard. The retention times were 14.3 and 15.1 min, respectively, under the experimental conditions. There were

Table I—Intraday Precision and Accuracy

Sample Concentration[a], μg/ml	Mean ± *SD*, μg/ml	*RSD*, %	Relative Error, %
0.38	0.35 ± 0.01	2.9	−9.2
2.5	2.48 ± 0.05	2.0	1.0
11.3	11.35 ± 0.26	2.3	0.4
22.5	22.75 ± 0.70	3.1	1.1

[a] Four samples were used at each concentration.

two major peaks from the plasma which were also transferred onto the reverse-phase column during the switch; their retention times were 12 and 12.8 min, respectively, and constituted no interference with theophylline and the internal standard. The results clearly indicated that for theophylline, adaptation of an existing HPLC separation (7) to the multidimensional technique presented no chromatographic problems.

The application of the multidimensional technique did not prolong the elution time in comparison with the reported retention times of theophylline and the internal standard with the use of the same mobile phase and the same reverse-phase column alone; 15 and 17.5 min were reported for theophylline and the internal standard, respectively (7). The reason that this elution process with a rather long elution time was chosen for the multidimensional technique was that the procedure provided better specificity than most of the other HPLC methods for theophylline. The caffeine metabolite, 1,7-dimethylxanthine, was also separated from theophylline. The other major peaks seen in the chromatogram were due to the change of pressure and mobile phase on the reverse-phase column at the valve-switching step of the procedure. For repeated injections, the next injection was made before the last sample was completely eluted from the system. Under the experimental conditions, a sample was injected every 11 min. About 70 samples can be analyzed per day with ~3 hr of analyst time. This procedure is ideal for maximum utilization of the liquid chromatographic equipment for overnight runs with minimum requirement of an analyst's time for sample preparation.

Calibration Curve and Linearity—Daily calibration curves were prepared by spiking blank human plasma with theophylline standards resulting in final concentrations of 0, 0.25, 1.5, 3.5, 7.5, 15, and 30 μg/ml. The theophylline concentrations and the peak height ratios for theophylline and internal standard were fitted by the computing integrator to a straight line by the least-squares method. The mathematical representation of the line was y (theophylline concentration) = 0.2186x (response ratio) + 0.0182. The correlation coefficient was 0.9999. A linear relationship was demonstrated between response and theophylline concentration over a range of 0.25–30 μg/ml. The relationship was not tested beyond 30 μg/ml. At the 0.25 μg/ml concentration level, the response was 3–5 times the noise level of the system.

Precision and Accuracy—Intraday precision and accuracy were established by spiking blank human plasma in quadruplicate with theophylline at four concentration levels: 0.38, 2.5, 11.3, and 22.5 μg/ml. These spiked samples were analyzed by the procedure outlined in *Experimental*. The results are shown in Table I. The intraday precision, expressed as the relative standard deviation, was 2.9, 2.0, 2.3, and 3.1% for 0.38, 2.5, 11.3, and 22.5 μg/ml levels, respectively. The accuracy, expressed as relative error, was −9.2, 1.0, 0.4, and 1.1% for the four concentrations. The intraday precision and accuracy were excellent and certainly adequate for the monitoring of theophylline levels in clinical therapeutic settings and for more research-oriented pharmacokinetic studies. The interday precision was established by analyzing seven theophylline standards, 0.25, 0.5, 1.5, 3.5, 7.5, 15.0, and 30.0 μg/ml plasma, five separate times over an 8-month period. During this time, different

Table II—Interday Precision

Sample Concentration[a], μg/ml	Mean ± *SD*, μg/ml	*RSD*, %
0.25	0.31 ± 0.04	12.9
0.5	0.58 ± 0.11	19.0
1.5	1.52 ± 0.04	2.6
3.5	3.52 ± 0.08	2.3
7.5	7.44 ± 0.18	2.4
15.0	14.68 ± 0.24	1.6
30.0	30.16 ± 0.17	0.6

[a] Five samples were used at each concentration.

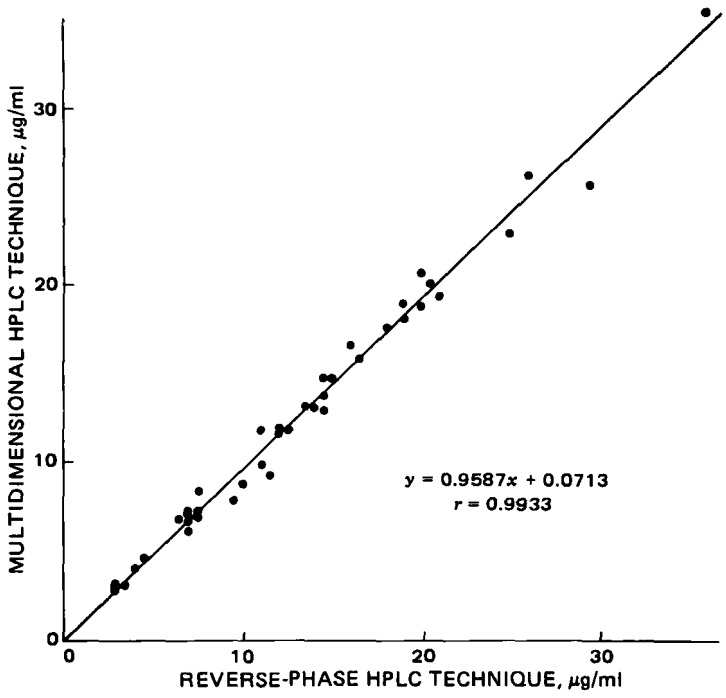

Figure 4—*Comparison of the multidimensional HPLC technique with an established reverse-phase HPLC method.*

theophylline standard solutions, gel permeation columns, and reverse-phase columns were used. The results are tabulated in Table II. Excellent day-to-day reproducibility over the concentration range of 1.5–30.0 μg/ml of plasma was demonstrated with the relative standard deviation ≤2.6% in each case. At lower concentrations, 0.25 and 0.5 μg/ml of plasma, larger relative standard deviations were obtained.

Comparison with Other Methods—Plasma samples were obtained from a local hospital. These samples were initially analyzed by the hospital using an HPLC method (8), and were reanalyzed using the multidimensional technique. Both results are presented in Fig. 4 and exhibit excellent correlation (slope = 0.96, r = 0.99) between methods for these 42 samples over a concentration range of 2.9–36 μg/ml.

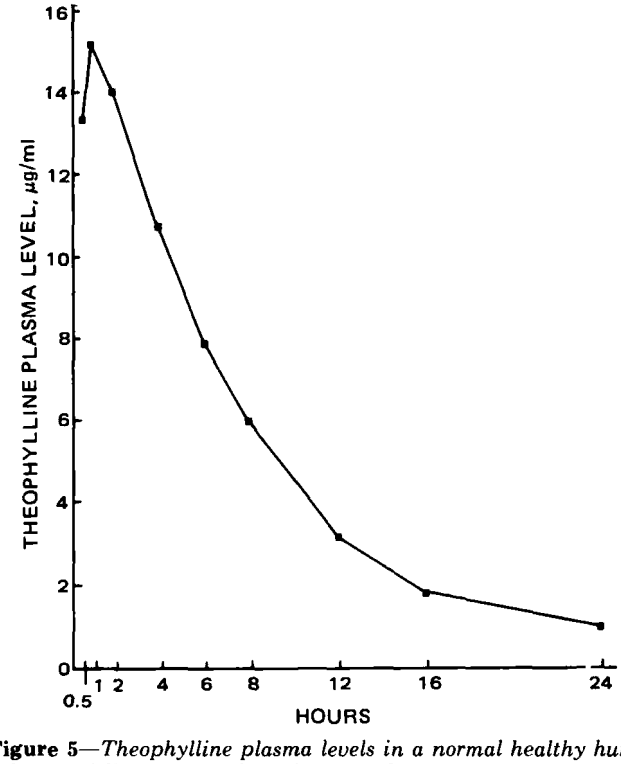

Figure 5—*Theophylline plasma levels in a normal healthy human volunteer following a single oral 500-mg dose.*

Interferences—Dietary xanthines, theophylline and caffeine metabolites, and several drugs that could be administered with theophylline in a therapeutic situation, were tested for interference. The compounds that were tested and found not to interfere with the assay procedure are: acetaminophen, ampicillin, caffeine, ceforamide, cephalothin sodium, cephloridine, corticosterone, dilantin, 1,3-dimethyluric acid, 1,7-dimethylxanthine, ephedrine, hypoxanthine, isoproterenol, 1-methyluric acid, 3-methyluric acid, 1-methylxanthine, 3-methylxanthine, 7-methylxanthine, phenobarbital, theobromine, uric acid, and xanthine.

Applicability—This method has been used in the evaluation of new theophylline formulations in dogs and in bioavailability studies of theophylline formulations in healthy human volunteers. Figure 5 is a typical theophylline plasma level–time profile following the oral administration of a 500-mg theophylline dose to a human volunteer.

It has been demonstrated that theophylline can be efficiently analyzed by the automatic multidimensional HPLC technique, thus, totally eliminating the extraction step. With the use of a computing integrator (as described in this report) to automate the data reduction step, the total analysis of plasma theophylline has been reduced to manually mixing the unknown plasma sample with the internal standard solution in a small glass tube of the autosampler; the rest of the procedure is performed automatically by instruments.

Esterase Activities in Adult Rabbit Eyes

VINCENT H. L. LEE

Received January 11, 1982, from the *School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication April 14, 1982.

Abstract □ The rational design of prodrugs to improve the therapeutic efficacy of existing drugs would be expedited if the nature of the *in vivo* enzymatic conditions that regenerate the drugs from their prodrugs is known. Using albino and pigmented rabbits as models, this research seeks to delineate the esterase activities in their corneas, irises, ciliary bodies, and aqueous humor, which are intimately involved in the disposition of drugs from topical dosing. This was achieved by monitoring the hydrolysis kinetics of α-naphthyl acetate, both in the presence and absence of esterase inhibitors, upon incubation with aqueous humor and homogenates of cornea, iris, and ciliary body. It was found that in both breeds of rabbits, esterase activity was the highest in the iris–ciliary body followed by the cornea and then the aqueous humor, and that multiple esterases probably existed in the aqueous humor and the ocular tissues studied. However, the esterase activity in the cornea and iris–ciliary body of the pigmented rabbit was greater when compared with the albino rabbit. Based on these results, drugs and prodrugs containing ester linkages can undergo varying extents of esterase-mediated hydrolysis while permeating the cornea and upon entering the aqueous humor, iris, and ciliary body. Moreover, in view of the differences in esterase activity that exist between the albino and pigmented rabbits, it would be necessary to employ both breeds of rabbits in evaluating the rate and extent to which ocular ester prodrugs would be converted to their parent compounds.

Keyphrases □ Esterase activities—adult rabbit eyes, disposition, hydrolysis kinetics □ Eyes, adult rabbits—esterase activities, disposition, hydrolysis kinetics □ Disposition—esterase activities in adult rabbit eyes, hydrolysis kinetics □ Kinetics, hydrolysis—esterase activities in adult rabbit eyes, disposition

Until recently, there have been few reports on drug metabolism in the eye (1). Invariably, they are concerned with polycyclic aromatic compounds entering the uveal circulation and reaching the photoreceptor cells through the choriocapillaries. Because of its dual capability to terminate the pharmacological activities of inherently active drugs and to transform inactive drugs to their active moieties, drug metabolism in the eye is an important aspect of drug action. In view of the necessarily close association between esterase activities in the various segments of the eye and the extent of metabolic alterations of drugs containing ester linkages, knowledge of esterase activities in the eye would allow a first estimation of the clinical efficacy of such drugs as pilocarpine, atropine, and dipivefrin.

During the past 5 years, the prodrug approach (2) of preparing bioreversible derivatives of existing drugs has been successfully extended to the topical ophthalmic drug epinephrine (3). In principle, several other topical ophthalmic drugs that are currently available should also benefit from this approach, since they, like epinephrine, contain functional groups amenable to ester prodrug derivatization.

For these ester prodrugs to be useful clinically, esterase activity must be available in the ocular tissues to regenerate the parent compounds. Several investigators (4–10) have evidence to support the presence of esterases predominantly in innervated ocular tissues. They include the cornea, iris–ciliary body, retina, and optic nerve. However, the level of esterase activities in each tissue and the biochemical properties of these esterases remain to be determined. It is reasonable to expect that when such information is available, the rational design of ester prodrugs would follow.

The first step in the eventual characterization of esterases present in the various ocular tissues of both albino and pigmented rabbits is the determination of esterase activities in their corneas, irises, ciliary bodies, and aqueous humor, and this is the subject of this report. The rationale for studying esterases in both albino and pigmented rabbit

Esterase Activities in Adult Rabbit Eyes

VINCENT H. L. LEE

Received January 11, 1982, from the *School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication April 14, 1982.

Abstract □ The rational design of prodrugs to improve the therapeutic efficacy of existing drugs would be expedited if the nature of the *in vivo* enzymatic conditions that regenerate the drugs from their prodrugs is known. Using albino and pigmented rabbits as models, this research seeks to delineate the esterase activities in their corneas, irises, ciliary bodies, and aqueous humor, which are intimately involved in the disposition of drugs from topical dosing. This was achieved by monitoring the hydrolysis kinetics of α-naphthyl acetate, both in the presence and absence of esterase inhibitors, upon incubation with aqueous humor and homogenates of cornea, iris, and ciliary body. It was found that in both breeds of rabbits, esterase activity was the highest in the iris–ciliary body followed by the cornea and then the aqueous humor, and that multiple esterases probably existed in the aqueous humor and the ocular tissues studied. However, the esterase activity in the cornea and iris–ciliary body of the pigmented rabbit was greater when compared with the albino rabbit. Based on these results, drugs and prodrugs containing ester linkages can undergo varying extents of esterase-mediated hydrolysis while permeating the cornea and upon entering the aqueous humor, iris, and ciliary body. Moreover, in view of the differences in esterase activity that exist between the albino and pigmented rabbits, it would be necessary to employ both breeds of rabbits in evaluating the rate and extent to which ocular ester prodrugs would be converted to their parent compounds.

Keyphrases □ Esterase activities—adult rabbit eyes, disposition, hydrolysis kinetics □ Eyes, adult rabbits—esterase activities, disposition, hydrolysis kinetics □ Disposition—esterase activities in adult rabbit eyes, hydrolysis kinetics □ Kinetics, hydrolysis—esterase activities in adult rabbit eyes, disposition

Until recently, there have been few reports on drug metabolism in the eye (1). Invariably, they are concerned with polycyclic aromatic compounds entering the uveal circulation and reaching the photoreceptor cells through the choriocapillaries. Because of its dual capability to terminate the pharmacological activities of inherently active drugs and to transform inactive drugs to their active moieties, drug metabolism in the eye is an important aspect of drug action. In view of the necessarily close association between esterase activities in the various segments of the eye and the extent of metabolic alterations of drugs containing ester linkages, knowledge of esterase activities in the eye would allow a first estimation of the clinical efficacy of such drugs as pilocarpine, atropine, and dipivefrin.

During the past 5 years, the prodrug approach (2) of preparing bioreversible derivatives of existing drugs has been successfully extended to the topical ophthalmic drug epinephrine (3). In principle, several other topical ophthalmic drugs that are currently available should also benefit from this approach, since they, like epinephrine, contain functional groups amenable to ester prodrug derivatization.

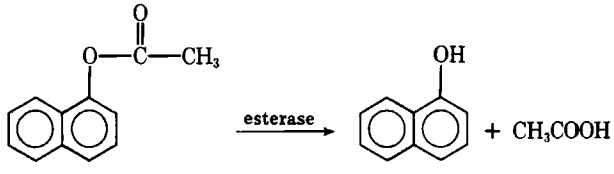
For these ester prodrugs to be useful clinically, esterase activity must be available in the ocular tissues to regenerate the parent compounds. Several investigators (4–10) have evidence to support the presence of esterases predominantly in innervated ocular tissues. They include the cornea, iris–ciliary body, retina, and optic nerve. However, the level of esterase activities in each tissue and the biochemical properties of these esterases remain to be determined. It is reasonable to expect that when such information is available, the rational design of ester prodrugs would follow.

The first step in the eventual characterization of esterases present in the various ocular tissues of both albino and pigmented rabbits is the determination of esterase activities in their corneas, irises, ciliary bodies, and aqueous humor, and this is the subject of this report. The rationale for studying esterases in both albino and pigmented rabbit

0022-3549/83/0300-0239$01.00/0

eyes comes from an earlier observation (11) that the extent and rate of hydrolysis of pilocarpine to pilocarpic acid are one to two orders of magnitude greater in the eyes of pigmented rabbits than in the eyes of albino rabbits. The cause underlying this apparent disparity is unclear, although it could be related to differences in the concentration, activities, or perhaps type of esterases.

α-Naphthyl acetate was chosen as the model substrate, since it has been shown to be a substrate for most esterases (12), and because at this stage of the study screening for esterase activity was of primary concern. The advantage offered by this substrate is that at an excitation wavelength of 317 nm and emission wavelength of 470 nm, it is practically nonfluorescent when compared with its hydrolytic product α-naphthol. Consequently, the progress of esterase-mediated hydrolysis, and therefore esterase activity, can be monitored by noting the increase in fluorescence with time. Scheme I presents the stoichiometry of the reaction.



α-naphthyl acetate α-naphthol

Scheme I—Hydrolysis of α-naphthyl acetate.

Recognizing that multiple esterases are likely to be present in each ocular tissue and in the fluid and that each esterase may possess its own ester substrate specificity, the esterase activities reported here, at best, represent mean values. During preliminary investigation two other esterase substrates, ethyl *p*-aminobenzoate and dipivefrin, were also considered, but for a variety of reasons were found to be unsuitable to screen for esterase activity.

EXPERIMENTAL

Male albino rabbits[1], weighing ~2.4 kg, were used throughout the study. All chemicals were either reagent or analytical grade and were used as received.

Preparation of Substrate Solutions—*α-Naphthyl Acetate*—A 2×10^{-3} *M* solution of α-naphthyl acetate[2] was prepared by first dissolving 0.0372 g of the compound in 10 ml of 95% ethyl alcohol followed by dilution to 100 ml with an isotonic tromethamine buffer at pH 7.4. From this stock solution 1.5×10^{-5} *M* and 5.85×10^{-5} *M* solutions were prepared for the enzymatic hydrolysis studies. These concentrations covered the range of drug concentrations typically achieved in ocular tissues.

The 10 ml of alcohol was found to be necessary to maintain the α-naphthyl acetate in solution. Two other solutions, one in 15% and the other in 20% alcohol, were also prepared to study the effect of alcohol on esterase activity. The cornea was the only tissue whose esterase activity showed statistically significant ($p < 0.05$) reduction as the ethyl alcohol concentration was varied 10–20%. Nonetheless, there was a tendency toward reduced esterase activity in the presence of ethyl alcohol. Provided a given concentration of ethyl alcohol inhibited esterase activity in the aqueous humor, cornea, iris, and ciliary body to roughly the same extent, a comparison of the relative esterase activities in them should still be valid. The remaining experiments, unless otherwise indicated, were conducted using α-naphthyl acetate solutions in 10% ethyl alcohol.

L-Leucyl-β-Naphthylamide Solutions—A solution of L-leucyl-β-naphthylamide[2], a peptidase substrate, was selected to screen for the presence of peptidases and to correct for their contribution to the esterase activity observed using α-naphthyl acetate. The peptidases, cathepsins, have been found in the eye (13) and shown to possess esterase activity (14).

A 4.67×10^{-4} *M* solution of L-leucyl-β-naphthylamide was prepared by first dissolving 0.0114 g of the compound in 10 ml of 95% ethyl alcohol followed by dilution to 100 ml with a 0.0612 *M* tromethamine buffer at pH 8.2.

Fluorescence Intensities of α-Naphthol, α-Naphthyl Acetate, β-Naphthylamine and L-Leucyl-β-Naphthylamide—The wavelengths of maximum excitation and emission were determined for each compound using a spectrophotometer[3] and a spectrofluorometer[4], respectively. They were found to be as follows:

Compound	λ_{ex}, nm	λ_{em}, nm
α-naphthol	317	470
β-naphthylamine	277.5	412

The corresponding esters were found to be nonfluorescent at the wavelengths chosen. The fluorescence intensity varied linearly with α-naphthol[5] concentration in the range of 10^{-7}–10^{-5} *M*, and with β-naphthylamine[5] concentration in the range of 6×10^{-8}–5×10^{-5} *M*. Potential interference of the fluorescence intensity of α-naphthol by α-naphthyl acetate was determined by spiking 1×10^{-6} *M* solutions of α-naphthyl acetate with α-naphthol (concentrations: $0.1–1 \times 10^{-6}$ *M*). This procedure was repeated with a 1.5×10^{-5} *M* L-leucyl-β-naphthylamide solution to which was added 1.5×10^{-4} *M* β-naphthylamine. At these concentrations, neither α-naphthyl acetate nor L-leucyl-β-naphthylamide quenched the fluorescence due to α-naphthol and β-naphthylamine, respectively. Thus, the increase in fluorescence intensity in subsequent enzymatic hydrolysis experiments could only be due to the hydrolytic products.

Preparation of Ocular Tissues for Enzymatic Hydrolysis Studies—Albino and pigmented rabbits, approximately 10 of each, were kept in restraining boxes in a normal upright posture. They were sacrificed by a rapid injection of a 30% sodium phenobarbital solution into a marginal ear vein. After withdrawing 10 to 15 ml of blood through intracardiac puncture, the corneal surfaces were rinsed with saline and blotted dry. About 150 μl of aqueous humor was aspirated using a 27-gauge × 1.27 cm needle attached to a 1-ml tuberculin syringe, and the cornea, iris, and ciliary body[6] were removed in sequence using a surgical scalpel.

Immediately following their removal, the tissues were transferred to homogenization vessels and the aqueous humor and blood to culture tubes. All were placed in an ice bath. The tissues were homogenized in ~10 ml of ice-cold isotonic potassium chloride solution for ~80 sec using a motor-driven tissue grinder[7]. The homogenate was centrifuged at 755×*g* in a refrigerated (4°) centrifuge[8], and the supernatant was saved for enzymatic hydrolysis studies. The blood was allowed to coagulate, and the fibrin clot and blood cells were removed by centrifugation under the same conditions as for ocular tissue homogenates. The protein content of each supernatant was then determined using a protein–dye binding assay[9] (15) with rabbit serum albumin as the standard.

During aspiration it was possible that the aqueous humor was contaminated with esterases from the cornea and the iris–ciliary body. However, the probability of this occurring was low. This was suggested by the different response to modulators of esterase activity by aqueous humor samples as compared with cornea and iris–ciliary body samples (Fig. 1). The complicating factors, of course, were that the esterases might not partition into the aqueous humor in exact proportion to their concentrations in the tissues, and that homogenization of the tissues might release other enzymes or proteins which altered the esterases.

Enzymatic Hydrolysis of Various Substrates in the Absence of Their Inhibitors—Prior to initiating enzymatic hydrolysis studies, the presence of esterases in selected ocular tissues/fluids was ascertained by electrophoresis on 7.5% polyacrylamide gels[9] and staining proteins (16), esterases (12), and peptidases (17).

α-Naphthyl Acetate—To 3 ml of a 1.5×10^{-5} *M* or 5.85×10^{-5} *M* α-naphthyl acetate solution in a fluorescence cuvet was added 100 μl of ocular tissue supernatant, aqueous humor, or serum. After mixing, the

fluorescence intensity was monitored at ambient temperature every 25 sec for the first 200 sec, then every 100 sec for the next 400 sec. By applying suitable conversions, the initial hydrolysis rate in unit[10] per milligram of protein was calculated from the initial slope of a plot of fluorescence intensity *versus* time. Because no attempt was made to free membrane-bound esterases, the esterase activity thus determined should only be interpreted as that due to soluble esterases. The implicit assumption was that the fraction of soluble proteins that was esterases paralleled the total protein. As demonstrated by the lack of increase in fluorescence intensity with time in the control solution, which contained 3 ml of α-naphthyl acetate and 100 μl of 1.17% KCl, no chemical hydrolysis of α-naphthyl acetate occurred during enzymatic hydrolysis. Between three and four determinations were made for each ocular tissue or fluid of a rabbit.

The purpose of determining esterase activity in serum was to estimate the contribution of esterases in the blood, which perfuses the iris and ciliary body, to the total activity found in the iris and ciliary body. As shown in Fig. 2, this amounted to ~15% in the albino rabbit and ~25% in the pigmented rabbit.

L-Leucyl-β-Naphthylamide—One hundred microliters of tissue supernatant, aqueous humor, or serum was incubated with 2.6 ml of an activator solution[11] at 45° for 5 min. After cooling the mixture to room temperature, 300 μl of 95% ethyl alcohol was added. Hydrolysis was initiated by adding 100 μl of the amide solution to this mixture. The fluorescence intensity was monitored at ambient temperature every 100 sec for 600 sec. By applying suitable conversions, the initial hydrolysis rate in unit[10] per milligram of soluble proteins was calculated from the initial slope of a plot of fluorescence intensity *versus* time. No chemical hydrolysis of the amide occurred during enzymatic hydrolysis, as demonstrated by the lack of increase in fluorescence intensity with time in the control solution, which contained 3 ml of L-leucyl-β-naphthylamide and 100 μl of 1.17% KCl. Between three and four determinations were made for each ocular tissue/fluid of a rabbit.

The preceding procedure was also repeated with a 1.5×10^{-5} *M* α-naphthyl acetate solution to study the effect of heat on esterase activity. As shown in Fig. 1, except for the aqueous humor of the albino rabbit, the ocular esterase activity at 45° was significantly lower than that at 25°, suggesting that ocular esterases, like dermal esterases (19), were temperature sensitive.

Enzymatic Hydrolysis of α-Naphthyl Acetate in the Presence of Inhibitors—To ensure that the observed esterase activity was due to true esterases, the hydrolysis of α-naphthyl acetate was conducted in the presence of various inhibitors. They were acetazolamide[5], a carbonic anhydrase inhibitor; physostigmine sulfate[2], neostigmine bromide[2], and isofluorophate[12], all cholinesterase inhibitors; and *p*-chloromercuribenzoate[2] and edetic acid[2], modulators of carboxylesterase and aryl esterase activity. With the exception of acetazolamide, which was employed at a concentration of 2×10^{-5} *M*, the concentration of each inhibitor solution was 1×10^{-3} *M*. None of these concentrations altered the fluorescence intensity due to α-naphthol.

One hundred microliters of tissue supernatant was incubated with 2.9 ml of an inhibitor solution for 15 min prior to initiation of hydrolysis by adding 100 μl of a 4.5×10^{-5} *M* α-naphthyl acetate solution, thus generating 1.5×10^{-5} *M* α-naphthyl acetate solution. The fluorescence intensity was monitored as a function of time in the same manner as those experiments that did not involve inhibitors. This substrate concentration, 1.5×10^{-5} *M*, was well below the concentration where substrate inhibition occurred. This was demonstrated by the fact that the initial hydrolytic rate continued to increase as the α-naphthyl acetate concentration was increased to 5.85×10^{-5} *M*.

RESULTS AND DISCUSSION

The presence of esterases or esterase activity in the cornea has been implied by the hydrolysis of pilocarpine to pilocarpic acid (11) and by the conversion of the prodrugs dipivefrin (3, 8, 9) and pivenfrine (10, 20) to their corresponding parent compounds. This study demonstrated this to be the case. As shown in Fig. 3, when α-naphthyl acetate, the model substrate, was incubated with aqueous humor and the supernatant derived from the cornea, iris, and ciliary body, the fluorescence intensity increased with time, indicating that esterase activity was present in ocular tissues and fluids aside from the cornea. This esterase activity can be derived from true esterases like acetylcholinesterase, peptidases like cathepsins (14) and carbonic anhydrase (21), all of which are known or said to be present in the eye (6, 13, 22). With L-leucyl-β-naphthylamide as the substrate, peptidase activity could only be detected in the iris–ciliary body of the albino rabbit, one of the few ocular tissues enriched

[10] Unit is defined as μmoles of substrate hydrolyzed per minute.

[11] The activator solution was 0.0768 *M* in tromethamine, 1.28×10^{-4} *M* in $CoCl_2 \cdot 6H_2O$, 0.128 *M* in $MgSO_4 \cdot 7H_2O$ and 2.01×10^{-4} *M* in $MnCl_2$. It was adjusted to pH 8.2 with 3 *N* HCl. This solution was reported by Wolff and Resnick (18) to be optimal for peptidase activity.

in cathepsins (13). This peptidase activity was calculated to be 3.95 ± 0.24 × 10^{-5} U/mg of protein[10], which was ~1/400 of the esterase activity in the same tissue determined under similar incubation conditions. This result, which was in agreement with previous findings (23), suggests that peptidases contributed insignificantly to total esterase activity. For unknown reasons the iris–ciliary body of the pigmented rabbit did not hydrolyze L-leucyl-β-naphthylamide and on this basis was judged to be devoid of peptidase activity.

Besides peptidases, carbonic anhydrase is another enzyme that possesses esterase activity (21), and this was verified in our laboratory[13] by incubating rabbit erythrocyte carbonic anhydrase with α-naphthyl acetate. Based on the reduction in esterase activity when acetazolamide, a specific carbonic anhydrase inhibitor that has little or no effect on true esterases (24), was included in the incubation medium, the iris–ciliary body of the pigmented rabbit was the only ocular tissue of both breeds of rabbits in which a percentage of total esterase activity could be ascribed to carbonic anhydrase. This was estimated to be 24% of total esterase activity.

Thus, true esterases were principally responsible for the esterase activity observed in the cornea, iris–ciliary body, and aqueous humor of albino and pigmented rabbits. Their behavior towards modulators of esterase activity suggested that they were a heterogeneous group of enzymes, in accord with the heterogeneity known of other esterases such as hepatic esterases (25). For the time being, two of the possible members in this group could be acetylcholinesterase and pseudocholinesterase. Their presence was suggested by the reduction in esterase activity, seen in the cornea and iris–ciliary body only (Fig. 1), in the presence of physostigmine sulfate, neostigmine bromide, and isofluorophate. Because *p*-chloromercuribenzoate, an agent that acts on free sulfhydryl groups in a noncompetitive fashion, also altered esterase activity in the iris–ciliary body, and also because free sulfhydryl groups have been shown to be nonessential for acetylcholinesterase activity, other esterases like arylesterase could also be present in the iris–ciliary body. As suggested by the results shown in Fig. 1, at least some of the esterases present in the aqueous humor were different from those in the cornea, iris, and ciliary body.

Taking the albino and pigmented rabbits as a group, the net effect of these esterases in the aqueous humor, cornea, iris, and ciliary body was to generate a rank order of esterase activity such that the activity was the highest in the iris–ciliary body followed by the cornea and then the aqueous humor. Specifically, the esterase activity in the cornea and aqueous humor was, respectively, 50 and 2–5% of that seen in the iris–ciliary body. The higher level of esterase activity in the iris and ciliary body may be due to the fact that these tissues are more cellular than both the cornea and the aqueous humor and, therefore, are more abundant in esterases. It may also be due to the presence of intrinsically more active esterases in the iris and ciliary body. Further work is needed to distinguish between these two possibilities as well as to identify additional ones. Nonetheless, the presence of esterase activity in the iris and ciliary body ensures that drugs containing ester linkages reaching this tissue from the systemic circulation will be hydrolyzed to some extent prior to distribution to the remaining ocular tissues.

Even though the cornea is not as enzymatically active as the iris and ciliary body, it is still in a strategic position to determine the amount of intact drug ultimately reaching the internal eye from topical dosing. The reason is that the major pathway of drug entry into the eye following topical dosing is permeation through the cornea. Partly because of this requirement, the cornea may fortuitously appear to be the primary site of hydrolysis when in fact the iris and ciliary body are enzymatically more

Table I—Michaelis–Menten Parameter Estimates for Esterases in the Cornea and Iris–Ciliary Body of Albino and Pigmented Rabbits

active. This would be observed for drugs like dipivefrin (9) which are extensively hydrolyzed during permeation through the cornea.

The preceding discussion was presented in general terms, without emphasizing the possible variation of ocular esterase activity, as suggested previously (11), with rabbit strain. Based on the more extensive hydrolysis of pilocarpine to pilocarpic acid in the eye of the pigmented rabbit as compared with the albino rabbit, it was speculated (11) that the pigmented rabbit possessed greater esterase activity in the ocular tissues. This study confirmed this speculation for the cornea, iris, and ciliary body, but not for the aqueous humor. Thus, the faster rate of pilocarpine hydrolysis reported for the pigmented rabbit's cornea was more likely the result of greater esterase activity in the cornea rather than a fast permeation rate and the resultant greater accessibility of the drug to the esterases in the cornea. At an α-naphthyl acetate concentration of 1.5 × 10^{-5} M, the esterase activity in the pigmented rabbit's cornea and iris–ciliary body was ~2.0 and 1.6 times that in these tissues of the albino rabbit, respectively. However, such differences ceased to exist at a slightly higher substrate concentration of 5.85 × 10^{-5} M, suggesting that the apparent differential rate of pilocarpine hydrolysis in the two breeds of rabbits could be a substrate concentration or dose-dependent phenomenon.

Crude estimates on the Michaelis–Menten parameters associated with the ocular esterases of the rabbits, presented in Table I, suggest that the esterases in the cornea and iris–ciliary body of the pigmented rabbit show a higher affinity for the substrate than those found in the albino rabbit, but suffer from a lower maximum initial velocity. Conceivably, at a certain substrate concentration, these two factors offset one another, thereby giving identical initial rates of hydrolysis, and the esterase activity in the two breeds of rabbits would then appear to be equal. However, so long as the substrate concentration in a given ocular tissue is much less than the Michaelis–Menten constant (K_m), not at all an unlikely situation, the pigmented rabbit will appear to have a higher esterase activity than the albino rabbit.

In light of the different values obtained for the Michaelis–Menten parameters for the esterases in the cornea and iris–ciliary body of the two breeds of rabbits, it is possible that several of these esterases are unique to either the albino or the pigmented rabbit. This is further supported by the manner in which the esterase activity in the ocular tissues of the albino and pigmented rabbits responded to modulators of esterase activities, as shown in Fig. 1. Thus, in the albino rabbit, a reduction in esterase activity of the cornea and iris–ciliary body was observed with physostigmine sulfate and isofluorophate only; with the other esterase inhibitors, either an increase or no change in activity was observed. In addition, esterases which require polyvalent ions for their activity appeared to be present in the albino but absent in the pigmented rabbit.

In summary, several esterases, probably heterogeneous with respect to their substrate specificities, are present in the cornea, iris, ciliary body, and aqueous humor of albino and pigmented rabbits. In both types of rabbits, the iris and ciliary body possess twice the esterase activity detected in the less cellular cornea and 20–50 times the esterase activity detected in the acellular aqueous humor. At the concentration of α-naphthyl acetate used, the cornea and iris–ciliary body of the pigmented rabbit exhibit an esterase activity approximately double that in the same tissues of the albino rabbit. Extrapolating this observation to humans, it is probable that the greater drug requirement in brown-eye as compared to blue-eye subjects, a well-known phenomenon, can be attributed to both greater propensity of the drug for esterase-mediated hydrolysis and binding of the drug to the pigments in the iris and ciliary body.

Studies are now underway to fractionate these esterases and to characterize them with respect to substrate specificity and stereospecificity, susceptibility to substrate and product inhibition, the nature of their catalytic sites, and the pH for optimal enzymatic action. The effect of chain length on the rate of ester hydrolysis catalyzed by each esterase will also be investigated, and this information will be combined with that on the effect of chain length on tissue permeation to allow the judicial selection of a prodrug that gives the desired rate of release and even site localization. It is hoped that in so doing the bioavailability and therapeutic efficacy of drugs for such disease states as glaucoma will be improved.

Monolayer Studies of Insulin–Lipid Interactions

DAVID L. SCHWINKE, M. G. GANESAN, and N. D. WEINER ˣ

Received December 28, 1981, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication April 30, 1982.

Abstract □ The interactions between insulin and various lipids were studied by monolayer penetration experiments at constant surface area. The increase in surface pressure, $\Delta\Pi$, of a lipid film depended upon the particular lipid used and the concentration of insulin in the subphase. For all lipids studied, $\Delta\Pi$ was dependent on the initial surface pressure of the lipid film. Evidence of the interaction between insulin and the lipids was found in the ability of insulin to penetrate lipid films with initial pressures >16 dynes/cm, the maximum surface pressure obtained by insulin alone. For phospholipids, both the nonpolar and polar regions influenced the degree of interaction with insulin. Saturated chain lecithins exhibited less penetration than phospholipids with unsaturated hydrocarbon chains. The net charge of the lipid was not found to be an important determinant of penetration; however, the structure of the polar group can have a dramatic effect. Insulin penetration of mixed lipid films cannot be predicted by the penetration characteristics of the pure components. The possible role of these interactions in determining the geography of the insulin molecule within the liposome and its resultant effects on the stability is discussed.

Keyphrases □ Insulin—monolayer studies of interactions with lipids □ Monolayer studies—insulin–lipid interactions □ Lipids—monolayer studies of interactions with insulin

Monolayer interactions between proteins and lipids are of much interest in the study of cell membrane structure (1, 2), hormonal action (3, 4), and enzyme activity (5). Early studies (6) established the technique of injecting a protein into the subphase beneath a lipid film at constant surface area. Since then modifications of this procedure have been used in an effort to gain a more detailed understanding of the nature of these interactions.

Recent attempts to develop an oral dosage form of insulin have utilized liposomal entrapment in order to protect the hormone from proteolytic degradation in the GI tract. In theory, to achieve the necessary degree of protection, the entrapped insulin should not penetrate or decrease the stability of the lipid bilayer. The geography of the insulin molecule within the liposome should be dependent upon the degree and type of its interactions with the lipid components. This report investigates the interactions of insulin with cholesterol, stearylamine, and various phospholipids through the use of monolayer penetration studies.

BACKGROUND

The increase in surface pressure of a lipid film with the addition of protein has been termed penetration, although the exact nature of this phenomenon remains unclear. For example, as more protein is added to the subphase, the increase in surface pressure may be attributed to an increase in the number of protein molecules at the surface, enhanced interaction between the surface components, or protein–protein interactions just below the surface, which may alter molecular orientation at the surface. Although the various mechanisms cannot always be differentiated, the results of such penetration studies are still of value in determining the criteria that affect lipid–protein interactions.

The great variation in the behavior of lipid–protein films reported in the literature can be ascribed to the wide range of physical properties of the proteins used. The unique characteristics of each protein or polypeptide prevent accurate predictions of the nature and magnitude of its interactions with lipids. Also, relative protein penetration does not show consistent results based on the type of lipid involved. Therefore, it is necessary to individually assess the effect of insulin on films of pure lipids or lipid mixtures in order to better understand their interactions.

Monolayer Studies of Insulin–Lipid Interactions

DAVID L. SCHWINKE, M. G. GANESAN, and N. D. WEINER ˣ

Received December 28, 1981, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication April 30, 1982.

Abstract □ The interactions between insulin and various lipids were studied by monolayer penetration experiments at constant surface area. The increase in surface pressure, $\Delta\Pi$, of a lipid film depended upon the particular lipid used and the concentration of insulin in the subphase. For all lipids studied, $\Delta\Pi$ was dependent on the initial surface pressure of the lipid film. Evidence of the interaction between insulin and the lipids was found in the ability of insulin to penetrate lipid films with initial pressures >16 dynes/cm, the maximum surface pressure obtained by insulin alone. For phospholipids, both the nonpolar and polar regions influenced the degree of interaction with insulin. Saturated chain lecithins exhibited less penetration than phospholipids with unsaturated hydrocarbon chains. The net charge of the lipid was not found to be an important determinant of penetration; however, the structure of the polar group can have a dramatic effect. Insulin penetration of mixed lipid films cannot be predicted by the penetration characteristics of the pure components. The possible role of these interactions in determining the geography of the insulin molecule within the liposome and its resultant effects on the stability is discussed.

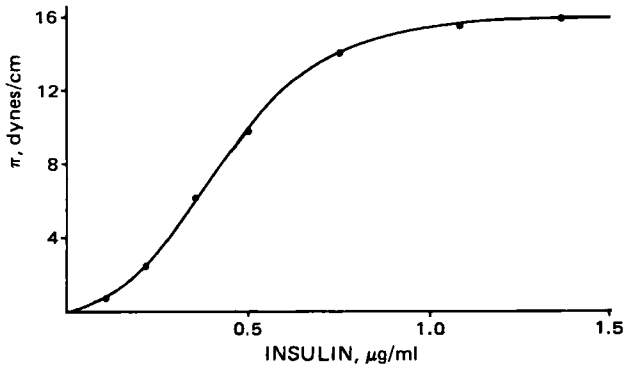

Figure 1—*The surface pressure–concentration profile of insulin upon injection into 0.05* M N-*2-hydroxyethylpiperazine-*N′*-2-ethanesulfonic acid in 0.9% NaCl buffer, pH 7. The surface pressure was measured 30 min after each insulin addition. A limiting or collapse pressure for insulin of 16 dynes/cm was observed.*

EXPERIMENTAL

Phosphatidylcholine[1] (I) was purified on an activated alumina column. Cholesterol[2] was purified by recrystallizing three times from ethanol solution. All other lipids were used as supplied[2] and stored at 0°. TLC of all lipids revealed a single spot.

The subphase buffer was prepared from triple-distilled water, the second distillation was from alkaline permanganate. An all-glass distillation apparatus was used to prevent contamination. Sodium chloride, reagent grade, was heated to 600° to remove organic impurities. All other chemicals were reagent grade.

Research grade crystalline porcine insulin[3] with an activity of 28.5 units/mg and containing 0.6% zinc was used. The only impurity noted by polyacrylamide gel electrophoresis and high-performance liquid chromatographic (HPLC) analysis was 1–2% monodesamido insulin. Stock solutions of 4.0 mg/ml were prepared in 0.01 *N* HCl and stored at 4°. Further dilutions were prepared in 0.05 *M* *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid in 0.9% NaCl buffer, pH 7. The glass vials used for these dilutions were rinsed twice with the insulin solution to avoid loss of insulin due to adsorption.

The monolayer penetration studies were a modification of previous studies (6). The experiments were performed at 25 ± 1° on a surface tensiometer[4] having a sensitivity of 0.04 dynes/cm, using a sandblasted platinum Wilhelmy plate. The subphase consisted of 90 ml of 0.05 *M* *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid in 0.9% NaCl buffer, pH 7, contained in a circular polytetrafluoroethylene dish having an area of 46 cm^2. A polytetrafluoroethylene-coated magnetic stirrer was used for mixing of the subphase. The entire apparatus was enclosed to reduce airborne contamination.

All lipids were spread from solutions of hexane–ethanol (9:1) in a micrometer syringe[5] in amounts sufficient to produce the desired initial surface pressure. Each mixed lipid film was spread from a single solution in which the appropriate lipids were dissolved. The addition of the spreading solvent alone to a clean buffer surface produced no measurable change in surface tension. The dissolved lipids were stored below 0° under a dry nitrogen atmosphere for no longer than 5 days.

A stationary needle with a removable glass syringe was used to deliver concentrated insulin solutions beneath the surface into the subphase. Insulin was added in 1–2-ml increments, and an equal volume of the subphase was discarded prior to the additions. The needle and syringe were rinsed three times after each addition of insulin by withdrawing and reinjecting 1–2 ml of the subphase. A magnetic stirrer (10 rpm) mixed the subphase for 15 min, and the mixture was allowed to settle for 15 min for the monolayer to equilibrate before recording the surface tension. Surface pressure changes due to insulin addition were found to be virtually complete within 30 min.

Surface pressure (Π) was calculated as the difference in surface tension in the absence of the film (γ_0 = 72.3 dynes/cm) and that of the film-covered surface (γ). The change in surface pressure ($\Delta\Pi$) was calculated as the difference in pressure of the lipid film upon injection of insulin into the subphase (Π) and that of the film in the absence of insulin, *i.e.*, at its initial surface pressure (Π_0).

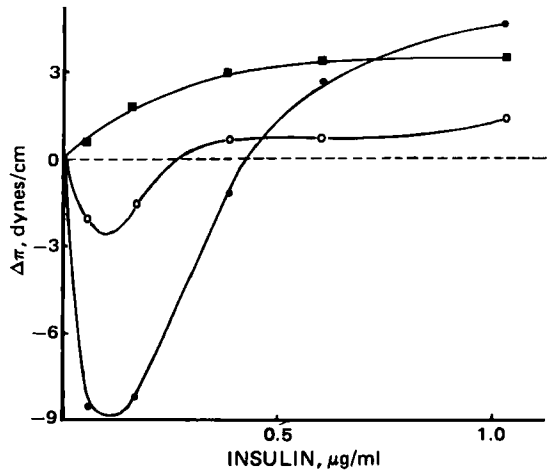

Figure 2—*The time-dependent changes in surface pressure of phosphatidic acid (II) monolayers upon the injection of insulin into the subphase. Each curve represents a film with an apparent initial surface pressure of ~13 dynes/cm. The delay times that followed the spreading of the films before the start of the experiments are as follows: (●) no delay; (○) 60 min; (■) 120 min. In control studies the surface pressure of films of II required 120 min to attain a stable value, which then remained constant for at least 3 hr.*

RESULTS

The insulin protein, although soluble in aqueous solutions, is a surface-active molecule denaturing at the air–water interface to give rise to surface pressures as high as 20 dynes/cm (7). Under the conditions of these experiments, the surface pressure–concentration (Π–*C*) curve of insulin approached a limiting or collapse pressure of 16 dynes/cm at pH 7, as seen in Fig. 1. This is in agreement with the collapse pressure obtained from the Π–*A* isotherms in a previous study (7) for insulin at pH 7.4.

The stability of the lipid films for the duration of the experiments (~3 hr) was confirmed by measuring the surface pressure as a function of time. With most of the lipids studied, a constant surface pressure was obtained within 15 min after spreading. However, with phosphatidic acid (II), phosphatidylserine (III), dipalmitoylphosphatidylcholine (VI), and distearoylphosphatidylcholine (VII) a slow decrease in surface pressure was observed for 1–2 hr, followed by constant values for at least 3 hr thereafter. Recognizing this time effect is important in obtaining accurate

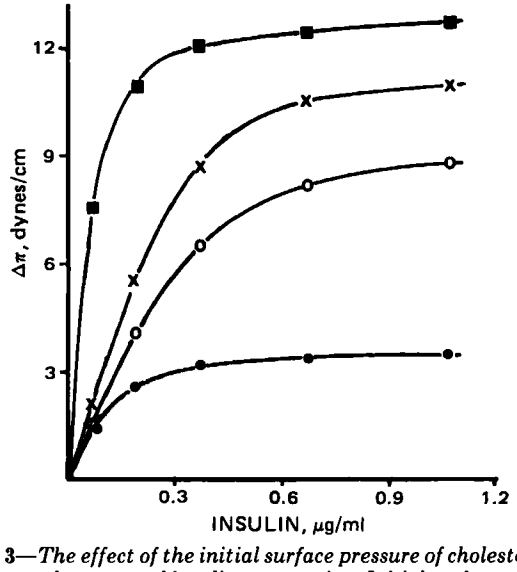

Figure 3—*The effect of the initial surface pressure of cholesterol monolayers on the extent of insulin penetration. Initial surface pressures (dynes/cm) are: (■) 4.8; (×) 11.1; (○) 15.8; (●) 19.5. This set of curves is qualitatively similar to those of all lipids studied in these experiments.*

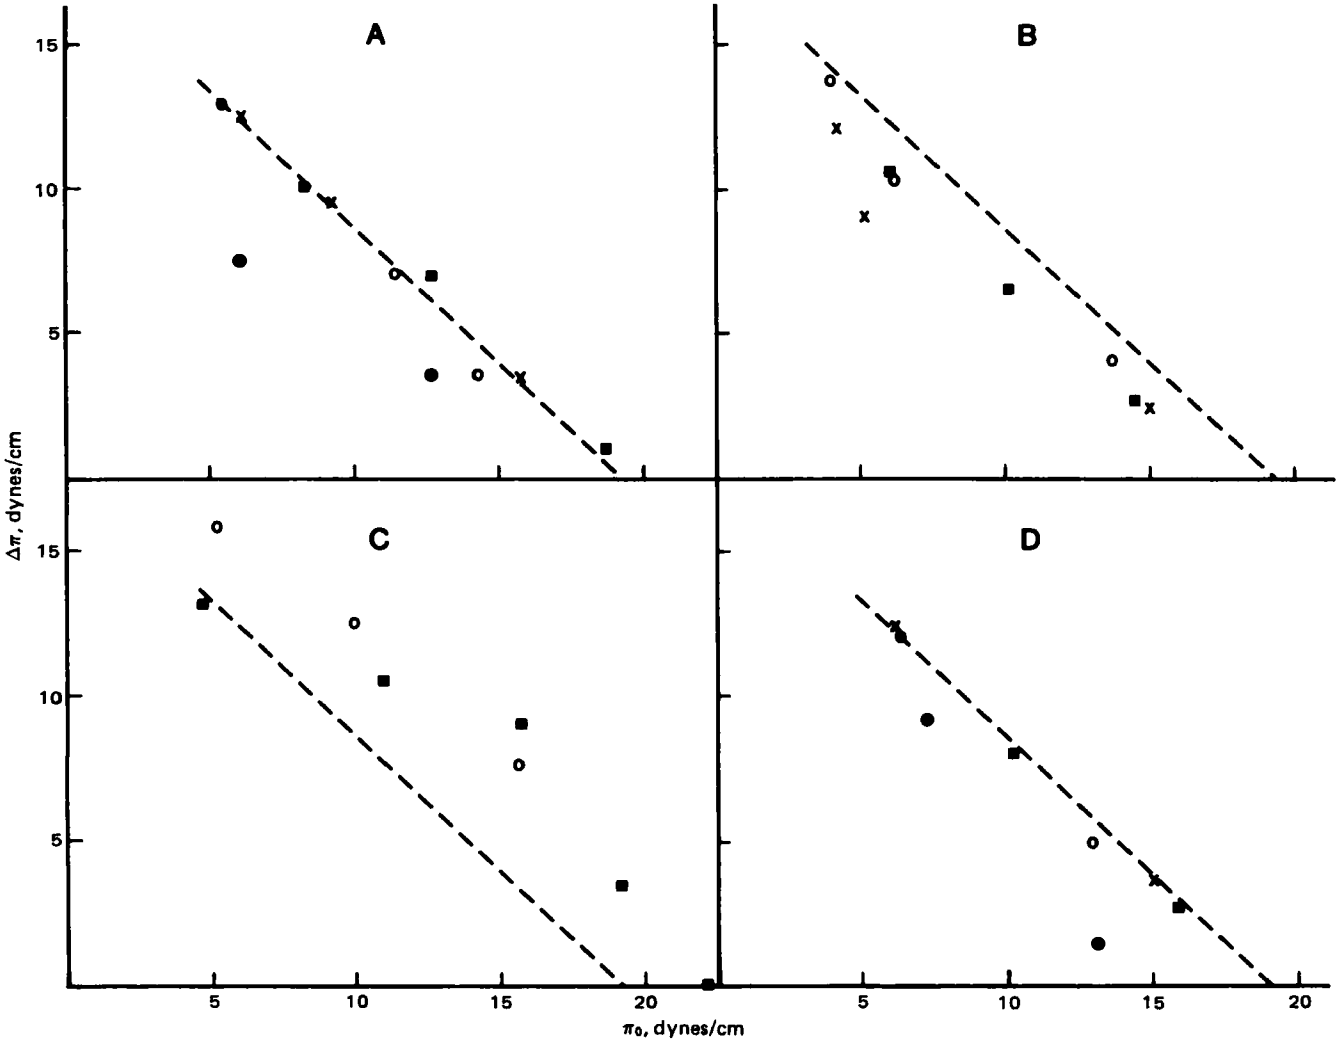

Figure 4—*Penetration of insulin (1.0 μg/ml) into monolayers of various lipids. Key: (A) unsaturated phospholipids: (■) phosphatidylcholine (I); (●) phosphatidic acid (II); (○) phosphatidylserine (III); (×) phosphatidylinositol (IV); (B) saturated lecithins: (■) dimyristoyl-(V); (×) dipalmitoyl-(VI); (○) distearoylphosphatidylcholine (VII); (C) other lipids: (■) cholesterol; (○) stearylamine; (D) mixed lipid films: (■) phosphatidylcholine–cholesterol (2:1) (VIII), (×) phosphatidylcholine–cholesterol–phosphatidic acid (4:2:1) (IX); (○) phosphatidylcholine–cholesterol–stearylamine (4:2:1) (×); (●) dipalmitoylphosphatidylcholine–cholesterol (2:1) (XI).*

results. The most dramatic pressure drop was observed with II. Figure 2 depicts three $\Delta\Pi$–C curves for films of II, each of which had an apparent initial surface pressure of ~13 dynes/cm. As can be seen, if the lipid film is not given sufficient time to equilibrate prior to addition of insulin to the subphase, both the magnitude and the shape of the curve is affected. For example, at 0- and 60-min delays, an initial condensation effect was observed (decrease in surface pressure), whereas with a 120-min delay, only an expansion effect (increase in surface pressure) was seen.

Placing additional pure spreading solvent on a film of II after its pressure had stabilized resulted in virtually no pressure change after 10 min, indicating that solvent retention in the lipid film was not a problem. Another study (8) also reported no evidence of solvent retention with a hexane–ethanol (9:1) solvent in lecithin and phosphatidylethanolamine films when $\Pi_0 > 2$ dynes/cm.

Two of the saturated lecithins, VI and VII, also showed a slow decrease in surface pressure during the first hour after spreading. With respect to the equilibrium-spreading pressure, Πe, which is defined as the pressure at which the monolayer is in equilibrium with the bulk lipid phase (9), films of both of these lipids may be considered thermodynamically unstable. For lecithins, it has been determined that spreading from the bulk phase does not occur below the gel–liquid crystal transition temperature (T_c), hence, $\Pi_e = 0$ at temperatures below T_c (10). The values of T_c for VI and VII are 41 and 60°, respectively (11); therefore, their solvent-spread films at 25° are not at true thermodynamic equilibrium. The spread films, however, do maintain a constant surface pressure and thus can be considered metastable (8–10), since the attainment of equilibrium (collapsing of the monolayer to the gel state) is a slow process and does not occur within the time frame of the experiments.

For all lipids studied the degree of penetration or association of insulin into the monolayer, as measured by the magnitude of $\Delta\Pi$ (6), was very dependent on the initial surface pressure, Π_0, as is generally expected with insulin (12) and other proteins (6, 13–18). A greater degree of penetration was observed at lower Π_0 values as indicated both by the magnitude of $\Delta\Pi$ and the initial slope of the $\Delta\Pi$–C curves. Figure 3 shows a set of typical $\Delta\Pi$–C curves.

Plots of $\Delta\Pi$ *versus* Π_0 for the single component and mixed lipid films are shown in Fig. 4A–D. The data were obtained from $\Delta\Pi$–C curves for the various lipids at an insulin concentration of 1.0 μg/ml. For all lipids, the changes in $\Delta\Pi$ were virtually complete at this concentration of insulin. It was found that the lipids fell into three distinct groups based on the magnitude of $\Delta\Pi$. The first group (Fig. 4A, D), consisting of the unsaturated lipids I, III, and phosphatidylinositol (IV), and the mixed lipid films phosphatidylcholine–cholesterol (2:1) (VIII), phosphatidylcholine–cholesterol–phosphatidic acid (4:2:1) (IX), and phosphatidylcholine–cholesterol–stearylamine (4:2:1) (X), showed an intermediate degree of penetration by insulin. Their behaviors, as indicated by the dashed line, is included as a reference in these four plots. Cholesterol and stearylamine (Fig. 4C) form a second group of lipids characterized by enhanced penetration by insulin. The third group of lipids, those showing reduced or inhibited penetration, consists of the saturated lecithins dimyristoylphosphatidylcholine (V), VI, and VII (Fig. 4B), the unsaturated phospholipid II (Fig. 4A), and the mixed film of dipalmitoylphosphatidylcholine–cholesterol (2:1) (XI) (Fig. 4D). In all cases, $\Delta\Pi$ de-

creases with increasing values of Π_0 until at a critical Π_0 value, no pressure change is observed. This value of Π_0, where $\Delta\Pi = 0$ is termed the limiting Π (18). For the lipids in the second group a limiting Π of 19.2 dynes/cm was in close agreement with the value obtained previously (12) of 19 dynes/cm for phosphatidylcholine, stearyl alcohol, and stearic acid monolayers. For cholesterol, however, our limiting Π value of ~22 dynes/cm is lower than that of a previously derived value of 27 dynes/cm (12). Repeated trials with cholesterol films at pressures between 22 and 24 dynes/cm failed to show any response to insulin under our conditions.

Insulin, which is soluble in the subphase, is able to penetrate monolayers with an initial surface pressure greater than the collapse pressure of insulin alone (16 dynes/cm). This indicates that insulin is interacting in some manner with the lipids, and that the observed behavior is not merely competition for the surface by two different surface-active molecules.

The combined data for the three saturated lecithins (Fig. 4B) indicate a limiting Π value of 17.7 dynes/cm. The absence of double bonds in the acyl chains in these lecithins results in closer packing of their molecules at the air–water interface (15, 19) as compared with unsaturated lecithin (I). As a result, insulin penetration is reduced. The temperature at which the experiments were performed (25°) is above the gel–liquid crystal transition temperature of V (T_c = 23°) (11), but is below that of VI and VII as previously mentioned. The influence of this parameter alone was not found to be of great importance in determining the degree of insulin penetration in this monolayer system.

Of the three lipids (II, III, and IV) with a net negative charge, only II showed decreased penetration (Fig. 4A). Since all three lipids, like I, are unsaturated, it is likely that the structure of the polar group, not the charge, is a more important determinant of penetration. The positively charged stearylamine films enhanced penetration by insulin, which has a net negative charge of pH 7; this effect may be due to electrostatic interactions. However, direct comparisons between stearylamine and lecithin films are inappropriate due to gross structural differences.

The mixed lipid films showed some interesting behavior and, as expected, were unique with respect to their individual components. Although cholesterol is strongly interactive with both I and VI as shown by monolayer studies (19, 20), the addition of cholesterol to films of I did not change the degree of insulin penetration, whereas incorporation of cholesterol into films of VI significantly reduced the penetration of insulin into the mixed monolayer. In both negatively (IX) and positively (X) charged mixed films, the individual behavior of the charged lipid was not apparent and the films demonstrated penetration similar to that of films of VIII or I.

DISCUSSION

Previously published results on the penetration or association of various proteins with lipid monolayers have yielded few consistent patterns of behavior based on the type of lipid involved. Since proteins encompass a wide range of physical properties including net charge, structure, and hydrophobicity, it is reasonable to expect that their interactions with lipids will be dependent on the structure and orientation of the lipid. The present results, which indicate decreased penetration by insulin into films of saturated lecithins as compared with I were also observed for α-lactalbumin (14) and delipidated high-density lipoprotein (21). However, a previous study (22) reported that I and fully hydrogenated I showed identical penetration by rabbit IgG. With β-casein (17, 21) and a fraction of delipidated lipoprotein (17), more penetration was observed into saturated lecithins than into I. Cholesterol films have consistantly allowed greater penetration than films of I (12, 13, 22), which is also apparent from the results of the present study.

It is widely recognized that properties of the subphase can affect the interactions of proteins with lipid films. Variations in pH (6, 14, 16, 18), temperature (13), ionic strength (18, 23), and the method of introducing the lipid and protein at the surface (13) all determine, in part, the changes in the interfacial region.

The mechanism of protein penetration and interaction with lipid films remains a topic of current research. The structure of proteins in lipid films and bilayers is also receiving more attention as new and more powerful analytic methods become available. Early work (24, 25) suggested that various proteins, including insulin, formed two distinct layers under a lipid film. The first layer was said to consist of fully denatured protein interacting by an ionic mechanism with the choline residue of lecithins, with penetration into the film by hydrophobic side chains of the protein producing a change in surface pressure. Beneath this was adsorbed a second layer of native protein. A monolayer study of insulin (12) stressed that hydrophobic interactions control penetration. However, results here indicate that this is not the only factor.

Several mechanisms of monolayer and membrane interactions have been proposed (1, 13, 22, 26) with proteins dependent upon the nature of both the lipid and protein. In these studies the role of many factors, including protein hydrophobicity and flexibility, lipid compressibility, electrostatic interactions, and water structuring about the lipid polar groups, are discussed. Other reports (16–18, 21, 27) also conclude that lipid–protein interactions cannot be explained on the basis of hydrophobic or electrostatic mechanisms alone. The importance of lipid compressibility (6) has also been discussed in reports of film penetration experiments with β-casein and apoprotein (17). However, the contention that decreased compressibility due to the incorporation of cholesterol in a lecithin film (2, 15) should lead to decreased penetration was not apparent in several of the mixed films which were studied. Measurements of the surface concentration of proteins indicate that $\Delta\Pi$ is not necessarily a measure of the amount of penetrating protein (22), and protein continues to adsorb beneath a film after a maximum in $\Delta\Pi$ has been attained (18, 27).

Monolayer penetration experiments are a valuable tool for exploring the interactions between lipids and proteins and can, with limitations, provide insight into the interactions occurring in liposomal systems (2, 8, 16, 17). We can conclude from our data that insulin is capable of some degree of penetration into lipid films, which can be controlled by the choice of lipid. Such penetration into the bilayer of a liposome may render the hormone susceptible to attack by proteases present in the external medium and also change the bilayer integrity. Saturated lecithins alone or in combination with cholesterol, which exhibit inhibited penetration, would be good candidates for liposomal delivery systems of insulin. These lipids would be better able to confine insulin within the aqueous compartments of the liposome than lipids that allow greater penetration.

Adsorption of insulin on the external and internal faces of the bilayer is also variable and can greatly affect the degree of entrapment. The incubation of liposomes in solutions of free insulin can result in the irreversible binding of the protein on the vesicle surface (28). Many reports of oral administration (29, 30) include externally bound insulin when calculating entrapped insulin and the administered dose. Upon oral administration, such insulin would be expected to undergo rapid destruction.

A better understanding of the underlying insulin–lipid interactions may aid in the design of an effective and reliable oral insulin dosage form.

Bilirubin-Displacing Effect of Ampicillin, Indomethacin, Chlorpromazine, Gentamicin, and Parabens *In Vitro* and in Newborn Infants

ROLF BRODERSEN *x **and FINN EBBESEN** ‡

Received November 23, 1981, from the *Department of Biochemistry, University of Aarhus, DK-8000 Aarhus C, and the ‡Department of Neonatology, Rigshospitalet, DK-2100 Copenhagen φ, Denmark. Accepted for publication April 30, 1982.

Abstract □ Displacement of bilirubin bound to human serum albumin by ampicillin, indomethacin, chlorpromazine, gentamicin, methylparaben, and propylparaben was investigated quantitatively. Two methods were used *in vitro*: measurement of bilirubin displacement by studying the rate of bilirubin oxidation with hydrogen peroxide and peroxidase and determination of the albumin reserve for binding of bilirubin by observation of the dialysis rate of an added trace amount of a deputy ligand monoacetyldapsone (*p*-acetamido-*p'*-aminodiphenyl sulfone). The latter method was also used for the determination of the albumin reserve in sera from treated newborn infants. The following doses were given: ampicillin, 100 mg/kg iv; indomethacin, 0.2 mg/kg iv; chlorpromazine hydrochloride, 0.7 mg/kg im; gentamicin sulfate, 2.5 mg/kg im. The parabens were present in injectable preparations of chlorpromazine and gentamicin and were therefore given in the following doses: methylparaben, 0.35 mg/kg, and propylparaben, 0.05 mg/kg. All drugs were given in a single dose. A few additional additives and metabolites were studied *in vitro*. Ampicillin, given to 19 infants, produced a small, significant decrease in plasma albumin reserve, to 82% of the pretreatment level and, thus, had a slight bilirubin-displacing effect, quantitatively consistent with a weak displacing effect measured *in vitro*. None of the other substances showed any measurable displacement *in vivo*, likewise in agreement with the results from *in vitro* studies.

A few drugs, notably sulfonamides, are capable of occupying the bilirubin-binding capacity of albumin in plasma, thereby increasing the risk of kernicterus in icteric human neonates (1, 2) as well as in experimental animals (3). Studies of such binding interactions *in vitro* have indicated displacing effects of ampicillin (4), indomethacin (4), some antimicrobial additives (parabens and sodium benzoate) (4–6) and chlorpromazine (7). Gentamicin in itself does not interfere with binding of bilirubin to albumin but is marketed with displacing additives (8). Measurement of the rate of dialysis of an added trace amount of monoacetyldapsone (I) into an otherwise identical plasma sample without this additive has recently been introduced as a technique for quantitative studies of occupation of albumin by drugs (9). Compound I serves as a deputy ligand for bilirubin, since one molecule of I competes selectively with binding of one molecule of bilirubin to human albumin (10). Determinations in undiluted sera at 37° are possible with this technique. Drug effects can thus be studied quantitatively *in vivo* as well as *in vitro*.

Previous work (11, 12) has shown that the concentration of free bilirubin in plasma may return quickly to the pretreatment level after administration of a bilirubin-displacing drug. Since there are no suitable methods for measuring the free bilirubin concentration in undiluted samples of infant serum (often hemolytic) at body temperature, it was decided to base the present *in vivo* studies on a combination of three measurements: determinations of albumin, bilirubin (bound), and albumin reserve in serum samples obtained before giving a single dose of the drug and at one point of time thereafter. The theoretical basis for this principle will be discussed, and the drugs mentioned will be tested accordingly.

albumin reserve determinations. Bilirubin[2] was purified according to a previous study (13). The drugs for *in vitro* studies were obtained commercially. The following solutions were used for injections: ampicillin[3], 1.0 g of the sodium salt was dissolved in 5 ml of sterile water. Indomethacin[4]; 20 mg dissolved in 2 ml of sterile water. Chlorpromazine[5] was obtained as an injectable solution containing 2.0 mg of chlorpromazine hydrochloride and 1.0 mg/ml of methylparaben. Gentamicin[6] injectable solution contained 10 mg of gentamicin sulfate, 1.3 mg of methylparaben, 0.2 mg of propylparaben, and 3.2 mg of sodium pyrosulfite/ml.

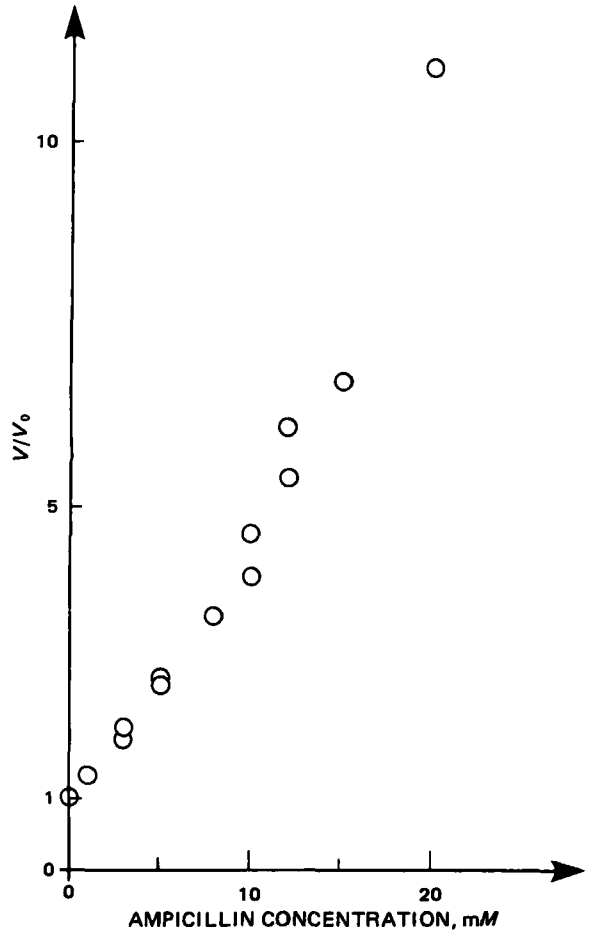

Figure 1—*Rate of oxidation of bilirubin with hydrogen peroxide and horseradish peroxidase in a solution containing 30 μM of human serum albumin and 15 μM of bilirubin as a function of varying concentrations of ampicillin (abscissa). The ordinates are oxidation rates relative to the rate without ampicillin. Sodium phosphate buffer, 66 mM, pH 7.4, 37°.*

Bilirubin-displacing effects of the drugs were studied *in vitro* by the following two techniques. The increase of free bilirubin dianion concentration in pure solutions of albumin and bilirubin with the addition of varying concentrations of the drugs was measured by the rate of bilirubin oxidation with hydrogen peroxide and horseradish peroxidase, as previously described (14) at pH 7.4, 37°. None of the drugs studied inhibited the peroxidase process in the absence of albumin. The amount of available albumin after addition of the drug was measured by the rate of dialysis of I, added in low concentration, into an identical volume of the same solution without added I (9). This method was used in its micromodification (10) with ^{14}C-labeled I and with 20-μl compartment volumes of the dialysis chambers. One volume of 0.53 *M* sodium phosphate buffer was added to 15 volumes of the sample to obtain a pH close to 7.4. The temperature was 37°, dialysis time was 10 min. The latter technique was used for studies with pure solutions of albumin as well as with infant serum, in both cases with drugs added in varying concentrations.

The following patients were used for investigations *in vivo*. Nineteen newborn infants suspected of having sepsis were given ampicillin, 100 mg iv/kg of body weight. Six newborn, preterm infants with patent ductus arteriosus received indomethacin, 0.2 mg/kg iv. Six newborns with narcotic withdrawal syndrome were given chlorpromazine hydrochloride, 0.7 mg/kg im. Fourteen newborn infants suspected of having sepsis were

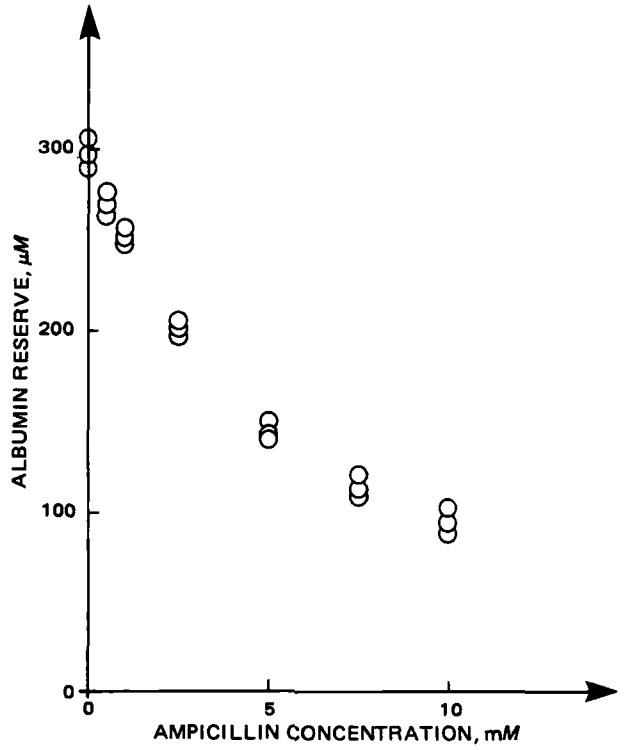

Figure 2—*Reserve albumin concentration for binding of I (ordinates), determined by measuring the rate of dialysis of an added trace amount of [^{14}C]I through a membrane into another compartment containing the same sample without added I. The sample was a solution of human serum albumin, 300 μM, varying concentrations of ampicillin (abscissa). Buffer and temperature as in Fig. 1.*

[b] Drug concentration doubling rate of dialysis of I (test system contains human serum albumin, 300 μM, and I, 3 μM). [c] Drug concentration if dose were distributed in infant's plasma volume.

given gentamicin sulfate, 2.5 mg/kg im. Pretreatment data of the patients are summarized in Table I.

Capillary blood samples were obtained by heel prick. One sample was taken immediately before the administration of a single dose of the drug. A second sample was obtained 15 min after giving the intravenously injected drugs and 30 min after those given intramuscularly.

Total unconjugated bilirubin was determined in serum by a modification (15) of a previous method (16). This method was chosen under the assumption that it is more specific than the diazo method. Fifty microliters of serum and 1250 μl of acetone were mixed and centrifuged, thereafter the absorbance of the supernatant was measured at absorption maximum 454 nm[7]. Purified bilirubin (13), dissolved in 0.1*M* potassium cyanide in formamide (17) and added to human serum, was used for the standardization. The coefficient of variation of the analysis was 2% by duplicate determinations.

Albumin was determined in serum by an electrophoretic method (18). The coefficient of variation of the analysis was 3% by duplicate determinations.

The concentration of reserve albumin for binding of I was determined in serum samples from the patients as mentioned above. By triplicate determinations, the coefficient of variation of the analysis was 5–6%, the intraday coefficient of variation being 4–5%.

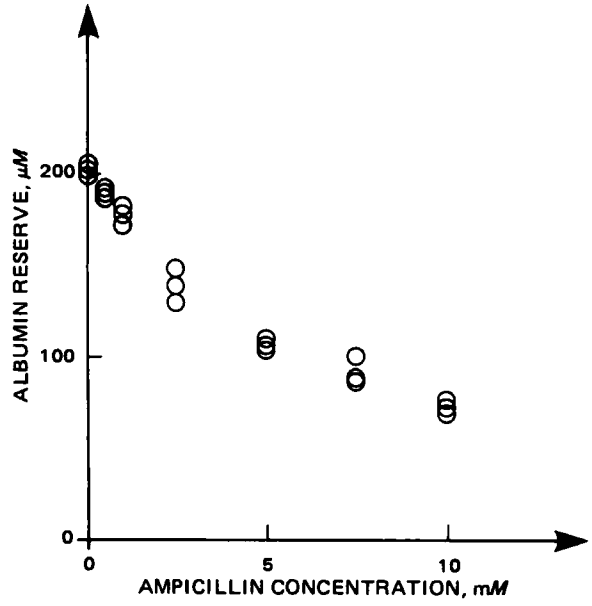

Figure 3—*Reserve albumin concentration for binding of I, determined as in Fig. 2 but in pooled infant (umbilical cord) sera with varying concentrations of added ampicillin, pH 7.4, 37°. Albumin concentration in the infant serum was 500 μM, nonesterified fatty acids, 460 μM. Note that the albumin reserve for binding of I, and thereby for binding of bilirubin, is only 40% of the total albumin concentration and in agreement with previous findings (19).*

[7] Zeiss PM2D spectrophotometer.

Statistical analyses were performed using the *t* test for paired observations. Ninety-five percent confidence limits for the true change in the plasma concentrations of unconjugated bilirubin, reserve albumin, and albumin, have been calculated from the formula: Confidence limits = $\bar{x} \pm t_{0.975} \times SD/\sqrt{n}$, where $t_{0.975}$ is the 97.5 percentile of the *t* distribution with $n - 1$ degrees of freedom.

Informed consent was obtained from the mothers of all infants included in the study.

RESULTS

***In Vitro* Studies**—All drugs and additives except gentamicin, showed some degree of bilirubin displacement (Table II, Figs. 1–3). Drug concentrations giving a twofold increase of oxidation rate in the peroxidase method, and a twofold increase of dialysis rate in the I method, are reported. In both techniques this ideally should be the concentration of drug needed to establish a binding equilibrium in which half of the vacant albumin capacity for binding of bilirubin is occupied by bound drug, increasing the free bilirubin concentration twofold. Major discrepancies are seen between the two methods and will be discussed later.

***In vivo* Studies**—Table III shows the observed changes in plasma concentrations of unconjugated bilirubin, reserve albumin for binding of I, and albumin, caused by a single injection of the four preparations studied.

Ampicillin, injected intravenously in a dose of 100 mg/kg, resulted in a significant decrease of average reserve albumin for binding of I by 18% in samples taken 15 min after the injection. The plasma albumin concentration remained unchanged, indicating that the decrease of reserve albumin was not caused by dilution of the infants' blood. It is noteworthy that the concentration of unconjugated bilirubin in the plasma was not influenced by injection of ampicillin. Individual values of reserve albumin concentrations for binding of I, obtained from plasma samples before and 15 min after giving ampicillin to 19 infants, are plotted in Fig. 4. The albumin reserve after treatment ranged from 62 to 100% of pretreatment levels. Unconjugated bilirubin and albumin concentrations remained unchanged.

The other preparations examined, indomethacin, chlorpromazine with methylparaben, and gentamicin with methylparaben and propylparaben, did not cause any change of the measured parameters.

DISCUSSION

Choice of Analytical Methods—Methods for the study of bilirubin-displacing effects of drugs *in vitro* and *in vivo* should measure either the free bilirubin dianion concentration or the reserve albumin for binding of bilirubin. Results should be obtained in quantitative terms, measurements should be performed in undiluted serum or plasma and at a pH and temperature the same as that of the patient. Techniques should be avoided in which the parameter to be measured is shifted by the addition of large amounts of binding dyes, by removal of bilirubin to agarose, or by attempted titration of albumin binding capacity with bilirubin, as previously discussed (20). The peroxidase method, whereby changes of free bilirubin dianion concentration are estimated by variations of the rate of oxidation with hydrogen peroxide and peroxidase (14), can be used for *in vitro* studies in pure solutions of albumin in low concentrations. False indications of displacement are, however, obtained

with certain drugs, forming free radicals on oxidation, especially with some derivatives of phenol and phenothiazine (5, 7), as exemplified by the parabens and chlorpromazine. Also, due to the presence of hemoglobin, which has a peroxidase effect, the peroxidase method cannot be used in infant sera.

An alternative approach is determination of the concentration of albumin available for binding of bilirubin. In the presence of a displacing drug, the albumin reserve is generally decreased in the same proportion as the free bilirubin concentration is increased. A trace amount of a deputy ligand for bilirubin, I, is added to the sample, and the binding of this ligand is assessed by observing its rate of dialysis into a compartment containing the same sample without added I. The difficulties connected with determination of free bilirubin are obviated. On the other hand, individual drugs may displace I and bilirubin to different degrees due to differences of allosteric effects, a difficulty avoided in the peroxidase method where displacement of bilirubin itself is studied.

Results Obtained *In Vitro*—Table II shows considerable differences between results obtained for displacement of bilirubin with either of the two methods. These are explained by the above-mentioned free-radical effects, by possible differences of allosteric effects upon binding of bilirubin and I, and by the differences of albumin concentrations.

At equilibrium, half of the available albumin molecules will be occupied by a drug at a specific site when the concentration of free drug is equal to the inverse binding constant. The total drug concentration needed to obtain this comprises the concentrations of free drug, of drug bound to the specific site, and of drug bound to other sites on the albumin molecule. A higher albumin concentration was used in the I method than in the peroxidase test, and it was expected that half-saturation of the bilirubin site required a higher concentration of the drug in the former technique. The discrepancy could be avoided if equal concentrations of albumin were employed. This is not practical for routine purposes, since increased concentrations in the peroxidase method cause increased rates of unspecific oxidation reactions (7), while decreased concentrations in the I technique resulted in poor precision due to weak binding of I. Previous experience with sodium benzoate and other substances has shown, however, that identical results may be obtained if equal concentrations of albumin are used in both methods (9).

Ampicillin gave fairly consistent results in the two methods (Table II); the somewhat higher concentration of ampicillin needed to occupy half of the albumin in the I method is explained by the higher concentration of albumin. The dose of ampicillin injected during the *in vivo* studies would, if it were evenly distributed in the plasma volume of the infant, give a slightly higher concentration, as seen in the last column of Table II, and would thus occupy slightly more than half of the total amount of circulating albumin. Due to distribution of the drug into tissues, smaller degrees of occupation of albumin would be expected at 15 min after the injection. Distribution volumes for ampicillin, calculated from literature data (21), range from 8 to 12 times the plasma volume. It is thus theoretically conceivable that ampicillin, in a dose of 100 mg/kg iv, would occupy a fraction of the plasma albumin somewhere between 5 and 50%.

Indomethacin is bound firmly to albumin, and it seems likely that the higher concentration needed to occupy half of the albumin in the I method, when compared with the peroxidase results, can be explained by the higher albumin concentration in the former technique. The I method gave a more reliable basis for an estimate of the displacing effect *in vivo* and showed that larger amounts of indomethacin than given would be needed to occupy an appreciable fraction of the albumin. It was concluded that the dose of indomethacin was too small to cause any considerable bilirubin displacement.

Chlorpromazine gave a false indication of displacement in the peroxidase method, as previously reported (7), and again the I method must be relied upon. The dose given was too small to produce a significant displacement.

Gentamicin, in agreement with previous reports (8), did not occupy bilirubin-binding loci on the albumin molecule in any of the two tests and, therefore, was not expected to cause displacement.

The parabens, and their metabolite, *p*-hydroxybenzoic acid, again gave falsely high displacements in the peroxidase method. The doses given were apparently too low to cause displacement.

Benzyl alcohol and sodium benzoate are sometimes used as antimicrobial additives in injection medicines, and sodium benzoate is present in many foods, naturally or added. These substances and their metabolite, sodium hippurate, must be added in fairly high concentrations in the I technique in order to occupy half of the albumin. Excessive doses would probably be needed to produce a significant displacement. This is in agreement with results published previously (22).

Sulfisoxazole has been tested for comparison. Therapeutic plasma concentrations of this drug are in the range of ~800 μM, considerably in excess of the concentrations needed to occupy half of the albumin in both techniques. Sulfisoxazole should thus be capable of producing displacement *in vivo*, in agreement with clinical experience (1, 2).

Procedure for Testing *In Vivo*—Due to shortcomings in the *in vitro* methods, as discussed above, and due to possible displacing effects of drug metabolites, it may be necessary sometimes to test a drug *in vivo*. Some information can be obtained from experiments in Gunn rats, observing displacement by a fall of total bilirubin concentration in plasma after drug administration (3, 23) or by damage to Purkinje cells after drug-induced displacement of bilirubin into the central nervous system (24). However, species differences of drug metabolism and of binding to albumin prevent final conclusions from animal experiments. The ultimate test must be conducted in human patients.

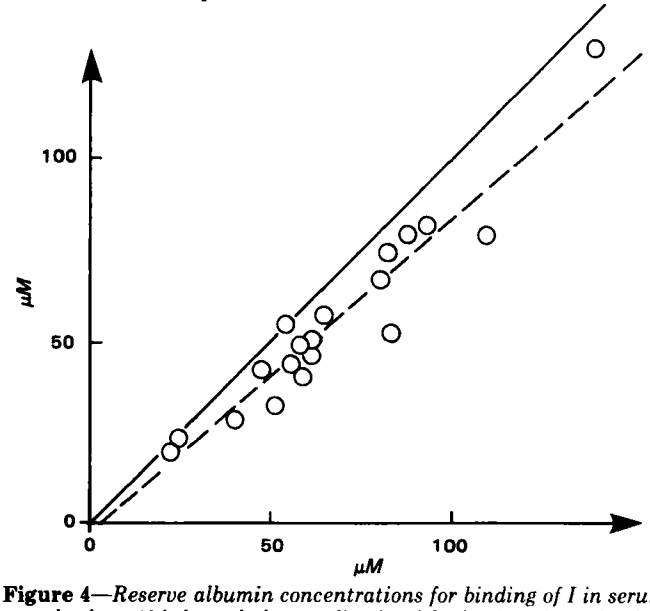

Figure 4—*Reserve albumin concentrations for binding of I in serum samples from 19 infants, before medication (abscissa), and 15 min after giving ampicillin (ordinate) by intravenous injection, dose 100 mg/kg. pH 7.4, 37°. A full line, x = y, is shown. The regression line, stippled, is y = 0.87x − 3 μM. The average decrease of reserve albumin concentration was 18% of the pretreatment level with 95% confidence limits, 12 and 24%. The average decrease was significant, p < 0.001, by paired t test.*

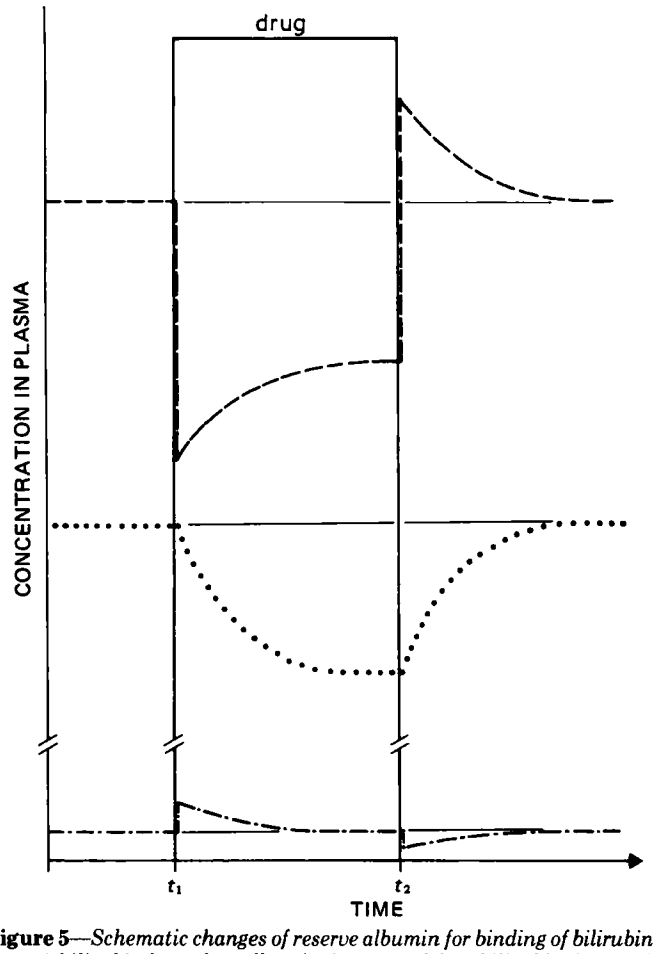

Figure 5—*Schematic changes of reserve albumin for binding of bilirubin (- - -) bilirubin bound to albumin (····), and free bilirubin (- · - · -) resulting from administration of a drug. A constant plasma concentration of the drug is hypothetically established during the interval of time from* t_1 *to* t_2.

The pharmacokinetic consequences of giving a displacing drug should be considered before a final choice of technique for *in vivo* studies is made. Wennberg and Rasmussen (25) have pointed out that "kernicterus may develop from bilirubin displaced during transient high serum concentrations of a competing drug." A theory has been worked out by Levy and Yacobi (11). As a consequence, the following train of events may be envisioned (Fig. 5). A steady state is thought to be present before the drug is given, with constant plasma concentrations of bound bilirubin, free bilirubin, and reserve albumin with a vacant capacity for binding of bilirubin. A constant concentration of the drug is established at the time t_1. The concentration of reserve albumin decreases immediately, since the binding capacity is partially occupied by the drug. This causes an immediate increase of free bilirubin concentration followed more slowly by transfer of bilirubin from plasma into tissues or to red blood cells, whereby the bound bilirubin concentration in plasma decreases. The reserve albumin increases with the decrease of bilirubin until a new steady state is established with the pretreatment level of free bilirubin and with decreased bound bilirubin and reserve albumin.

Such changes of free and bound bilirubin have been experimentally verified (12) after giving sulfisoxazole to rats, in which it was found that the free bilirubin concentration, after a sharp, transient increase, returned to its pretreatment value in spite of continued infusion of the displacing drug. If the drug is now removed instantly (time t_2), the concentration of reserve albumin will increase to above pretreatment level, resulting in a fall of free bilirubin which again will cause back-diffusion of bilirubin from tissues to plasma, leading to re-establishment of the original steady state.

These changes have not been experimentally verified and will be less acute when the drug level recedes gradually. It will, however, be theoretically possible to have normal or increased levels of reserve albumin when the drug concentration is declining. In this case, the bound bilirubin concentration will be below pretreatment value.

In conclusion, if a single blood sample is obtained after giving the drug, as in the present study, it will be possible to observe an unchanged level, either of bound bilirubin or of reserve albumin, even if the drug has caused displacement of bilirubin. However, unchanged concentrations of both bilirubin and reserve albumin cannot occur at the same time if a displacing drug was given. The concentration of bound bilirubin[8] as well as that of reserve albumin should be measured accordingly. In addition to this, determination of albumin should be done, since hemodilution by injection of the drug theoretically may cause low values of bound bilirubin and reserve albumin, imitating displacement of bilirubin. The sample should be obtained while the drug level is high. If all three concentrations (bound bilirubin, albumin, and reserve albumin), under these circumstances are unchanged by the medication, it may be concluded that bilirubin displacement was not observed.

Results Obtained *In Vivo*—After giving ampicillin, a small, statistically significant decrease of reserve albumin was observed (Table III, Fig. 4), indicating that a fraction of the available albumin binding capacity for bilirubin was occupied by this drug. The average occupancy observed, 18%, and the range of individual values is in good agreement with those expected from the *in vitro* tests.

Indomethacin, chlorpromazine, gentamicin, and the parabens did not cause any change of reserve albumin, total unconjugated bilirubin, or albumin concentrations and did not show displacing effects in the doses given (Table III). This again is consistent with expectations from *in vitro* results.

The practical significance of the bilirubin-displacing effect of ampicillin may be evaluated as follows. Effective plasma concentrations of ampicillin are usually considered to be in the range of 120–180 μM (40–60 μg/ml). These concentrations would cause a 3–5% increase of free bilirubin concentration, as measured by the peroxidase method (Fig. 1), using a low albumin concentration of 30 μM. The real displacement of bilirubin in plasma would be less. The I technique, applied to infant sera with varying added concentrations of ampicillin, shows that the reserve albumin concentrations would be decreased by 1.5–2.5% (Fig. 3), and the free bilirubin concentration would be increased by a similar percentage. This latter estimate seems to indicate a very small or insignificant increase of the risk of bilirubin encephalopathy, if weighted against the benefit obtained from the antibacterial effect of the drug. Somewhat higher degrees of displacement were seen in the present study; in one patient as much as 38% of available albumin for binding of I was occupied, presumably indicating an increase of free bilirubin concentration by a percentage of the same order of magnitude. In cases of threatening kernicterus, when such an increase of free bilirubin concentration may be unwanted, ampicillin could be given by slow injection, or by continuous infusion, thus avoiding significant occupation of albumin by the drug (26).

In previous rat experiments (12) the plasma concentration of unconjugated bilirubin dropped acutely to a lower level in <5 min after intravenous administration of a displacing drug. No change of bilirubin concentration was observed in the patients, in a sample taken 15 min after giving ampicillin. It might appear as if this finding could be taken as evidence against a bilirubin-displacing effect of ampicillin in human infants. Considerations of the rate of the expected decline of plasma bilirubin concentration show, however, that a measurable change could not be anticipated within 15 min, even after administration of a drug occupying half of the available albumin. The rats received a continuous infusion of bilirubin, regulated after a larger initial dose to a continuous rate of 100-fold that of normal bilirubin turnover in the rat, resulting in a high, constant concentration of unconjugated bilirubin in the plasma. The rate of infusion of bilirubin was 0.55 μmole/kg/min, the plasma bilirubin pool of the rats in the stationary state was ~7 μmoles/kg, and the turnover time of plasma bilirubin was thus ~13 min. However, in the infants, bilirubin turnover was of the order of 0.005 μmole/kg/min, and the total plasma bilirubin pool in the average patient was ~5 μmoles/kg (total unconjugated plasma bilirubin concentration, 94 μM, and plasma volume, 55 ml/kg), which gives a turnover time of ~1000 min for plasma bilirubin of the infants.

If a drug that occupies half of the available albumin is given to the infant one can expect that the free bilirubin concentration is doubled and that the rate of bilirubin removal from the plasma is doubled. This will result in a decline of the bound (and total) bilirubin concentration to a final value of ~50% of the pretreatment level. This decline would proceed slowly, with a rate constant of 0.001/min. In 15 min, the total bilirubin concentration would thus decline from 100 to 99.2 μM, an immeasurable

[8] The concentration of bound bilirubin for practical purposes is measured as that of total, unconjugated bilirubin, since the concentration of the free pigment is very low compared with the bound.

change. In addition, observation of such a slow change is precluded by the fact that the bound bilirubin concentration in these infants increases by an average of 2 μM/hr when no treatment is given. Observation of total plasma bilirubin concentrations alone, in consequence, cannot be used for estimating bilirubin-displacing effects of drugs, given to human infants. Measurement of the albumin reserve should be the main tool for this purpose. As shown above, plasma bilirubin and albumin concentrations should be measured in parallel. Unchanged values of all three parameters, observed at a point in time when the drug concentration in plasma is high, constitute evidence against a bilirubin-displacing effect.

These results underline the necessity of using quantitative methods for evaluation of bilirubin-displacing effects. Drugs cannot be rated as displacing or nondisplacing; dosage and plasma concentrations should be related to the displacing effect, expressed in quantitative terms. This method using monoacetyldapsone (I) seems feasible for such studies *in vitro* and *in vivo*.

Elementary Osmotic Pump for Indomethacin

F. THEEUWES *[x], D. SWANSON *, P. WONG *, P. BONSEN *, V. PLACE *, K. HEIMLICH [‡], and K. C. KWAN [‡]

Received January 22, 1982, from the **ALZA Corporation, Palo Alto, CA 94304* and [‡]*Merck Sharp & Dohme, Inc., West Point, PA.* Accepted for publication April 14, 1982.

Abstract □ Based on the principles of an elementary osmotic pump, systems were designed to deliver indomethacin in solution at a constant rate, Z, to contain a total amount of drug, M_t, and to deliver 80% of their content at time t_{80}. To allow selection of the optimal delivery rate into the body, three different prototypes were prepared with respective values for Z, M_t, and t_{80} of: 7 mg/hr, 85 mg, 11 hr; 9 mg/hr, 85 mg, 8 hr; and 12 mg/hr, 85 mg, 6 hr. These systems were found to deliver 70% of each system's contents at zero-order rates. Delivery rates were independent of pH, method of measurement, and stirring rate. In keeping with these results, the systems in the GI tract of dogs delivered at the same rate as *in vitro*, which qualifies the *in vitro* test as a bioanalogous method predictive of the *in vivo* performance of the dosage forms. Preliminary results in normal volunteers yielded similar urinary recoveries, while plasma profiles were different from each other and distinct from those following conventional capsules.

Keyphrases □ Indomethacin—design and preliminary evaluation of an oral osmotic delivery system, zero-order drug delivery □ Osmotic pump—oral, design and preliminary evaluation, indomethacin □ Drug delivery—design and preliminary evaluation of an oral osmotic delivery system containing indomethacin □ Anti-inflammatory agents—indomethacin, design and preliminary evaluation of an oral osmotic delivery system

The concept of continuous drug delivery that maintains the lowest delivery rate and that will elicit a therapeutic effect has much appeal. Intuitively, such a situation should represent the most efficacious use of the drug, while presenting a minimal risk of adverse reactions. Within certain prescribed constraints, theoretical analyses (1, 2) appear to favor dosing patterns that approach a constant *infusion*. However, direct experimental support for this hypothesis is limited (3). In part, this shortcoming may result from a lack of a practical way to deliver a suitable drug chronically and at a constant rate.

The recent development of an oral dosage form, based

Elementary Osmotic Pump for Indomethacin

F. THEEUWES *[x], D. SWANSON *, P. WONG *, P. BONSEN *, V. PLACE *, K. HEIMLICH [‡], and K. C. KWAN [‡]

Received January 22, 1982, from the **ALZA Corporation, Palo Alto, CA 94304* and [‡]*Merck Sharp & Dohme, Inc., West Point, PA.* Accepted for publication April 14, 1982.

Abstract □ Based on the principles of an elementary osmotic pump, systems were designed to deliver indomethacin in solution at a constant rate, Z, to contain a total amount of drug, M_t, and to deliver 80% of their content at time t_{80}. To allow selection of the optimal delivery rate into the body, three different prototypes were prepared with respective values for Z, M_t, and t_{80} of: 7 mg/hr, 85 mg, 11 hr; 9 mg/hr, 85 mg, 8 hr; and 12 mg/hr, 85 mg, 6 hr. These systems were found to deliver 70% of each system's contents at zero-order rates. Delivery rates were independent of pH, method of measurement, and stirring rate. In keeping with these results, the systems in the GI tract of dogs delivered at the same rate as *in vitro*, which qualifies the *in vitro* test as a bioanalogous method predictive of the *in vivo* performance of the dosage forms. Preliminary results in normal volunteers yielded similar urinary recoveries, while plasma profiles were different from each other and distinct from those following conventional capsules.

Keyphrases □ Indomethacin—design and preliminary evaluation of an oral osmotic delivery system, zero-order drug delivery □ Osmotic pump—oral, design and preliminary evaluation, indomethacin □ Drug delivery—design and preliminary evaluation of an oral osmotic delivery system containing indomethacin □ Anti-inflammatory agents—indomethacin, design and preliminary evaluation of an oral osmotic delivery system

The concept of continuous drug delivery that maintains the lowest delivery rate and that will elicit a therapeutic effect has much appeal. Intuitively, such a situation should represent the most efficacious use of the drug, while presenting a minimal risk of adverse reactions. Within certain prescribed constraints, theoretical analyses (1, 2) appear to favor dosing patterns that approach a constant *infusion*. However, direct experimental support for this hypothesis is limited (3). In part, this shortcoming may result from a lack of a practical way to deliver a suitable drug chronically and at a constant rate.

The recent development of an oral dosage form, based

0022-3549/83/0300-0253$01.00/0

Table I—Properties of Drug Core-Determining Shape of Release Rate Profile

Property	Symbol	Value
Mutual solubility of indomethacin sodium trihydrate	S_d	201.2 mg/ml
Total osmotic pressure	π_t	140 atm
Tablet core surface area	A	1.6 cm^2
Membrane density	ρ_m	1.3 g/ml

on the principles of an elementary osmotic pump, permits a close approximation to zero-order drug delivery (4). The present report describes the design and preliminary evaluation of an oral osmotic delivery system containing indomethacin, a potent anti-inflammatory agent used chronically 2–4 times daily in various forms of arthritis. Indomethacin (I) has a relatively short biological half-life (~4 hr) but is well absorbed throughout the GI tract (5–7).

THEORETICAL

Delivery of any agent in solution from the elementary osmotic pump can be achieved at a rate proportional to the solubility of the agent inside the system (S_d) and the osmotic pressure of the formulation inside the system (π_t). Given a tablet size with surface area, A, and given the membrane permeability and thickness, the desired rate can be obtained by incorporating into the core formulation substances that affect either S_d or π_t. Such a formulation can be called the composite core.

Delivery of potent agents may require the incorporation of formulating agents to permit fabrication of a system of acceptable size. (These agents are also added during the formulation of conventional tablets.) If these agents are water soluble, system performance can be predicted from the knowledge of certain parameters and the theoretical considerations presented here. The zero-order release rate of drug, $(dm_d/dt)_z$, from such a system, assuming a negligible osmotic pressure of the environmental fluid, is then given by:

$$Z \equiv \left(\frac{dm_d}{dt}\right)_z = k\frac{A}{h}\pi_t S_d \qquad \text{(Eq. 1)}$$

where k is the osmotic permeability coefficient of the membrane, A is the membrane area, h is the membrane thickness, and π_t and S_d are as defined above. The zero-order rate will persist from time $t = 0$ to $t = t_z$, at which time the solids—drug and osmotic agent—have gone into solution. The nonzero-order rate will decline parabolically as a function of time (4).

Table II—Average Zero-Order Release Rate and Membrane Weight for Three Lots of EOP-Indomethacin

System Designation[a]	Average Zero-order Rate, mg/hr	Rate-controlling Membrane Weight, mg[b]
7/85	7.2	16.9
9/85	9.6	11.9
12/85	12	8.4

[a] Nominal release rate (milligrams per hour)/total drug content (milligrams). [b] Estimated from total solids applied and coating efficiency factor (see *Experimental*).

Equation 1 provides a convenient way of calculating the membrane permeability (k) for a set of systems with the same release rate. Alternatively, for systems with different membrane thicknesses and release rates, the slope of the line of the release rate *versus* the inverse of the membrane thickness provides a means of calculating the membrane permeability. Consequently, the release rate can be expressed as a function of membrane weight (W), since this weight is related to membrane thickness:

$$W = \rho_m A h \qquad \text{(Eq. 2)}$$

where ρ_m is the membrane density, and A and h are as specified above. By substituting Eq. 2 into Eq. 1, one obtains:

$$Z_d = k\frac{A^2}{W}\rho_m \pi_t S_d \qquad \text{(Eq. 3)}$$

The membrane permeability, therefore, can be obtained from the slope of the line Z_d *versus* $1/W$.

Equation 3 indicates the parameters to which the average zero-order release rate will be sensitive. These parameters are: membrane permeability (k), tablet core surface area (A), membrane weight (W) and density (ρ_m), total osmotic pressure (π_t), and drug solubility (S_d). When a composite composition is chosen, π_t and S_d become fixed for the zero-order release period. The fixed composition also determines the total surface area (A) of the tablet core. When the membrane is chosen and applied reproducibly, values for k and π_m are fixed. Therefore, when testing is conducted at a constant temperature, the average zero-order release rate should be a function of the weight of the membrane applied.

To designate the zero-order release rate and total drug content of a system, the following convention was developed. Each system is described by a release rate (x) and total content (y) of indomethacin and designated as EOP-indomethacin x/y. Therefore, a system designed to deliver sodium indomethacin at 7 mg/hr (expressed as equivalents of indomethacin-free acid) from a system that contains 85 mg total (expressed as free

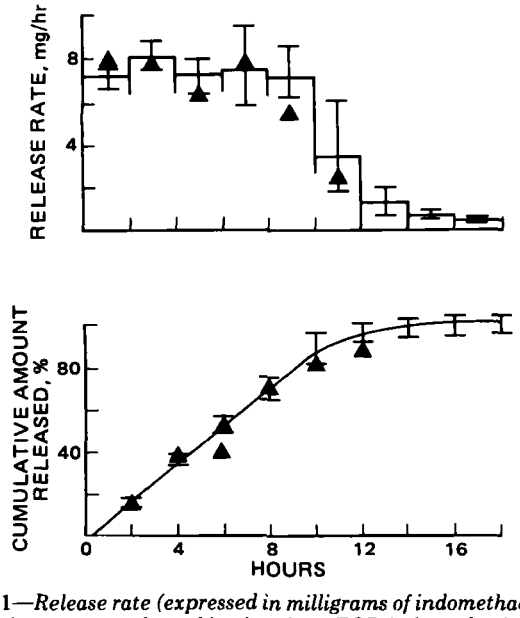

Figure 1—*Release rate (expressed in milligrams of indomethacin) and cumulative amount released* in vitro *from EOP-indomethacin 7/85,* N = 10. *Key: (▲) USP intestinal fluid (I) range (0–4 hr: gastric USP; 4–18: intestinal USP).*

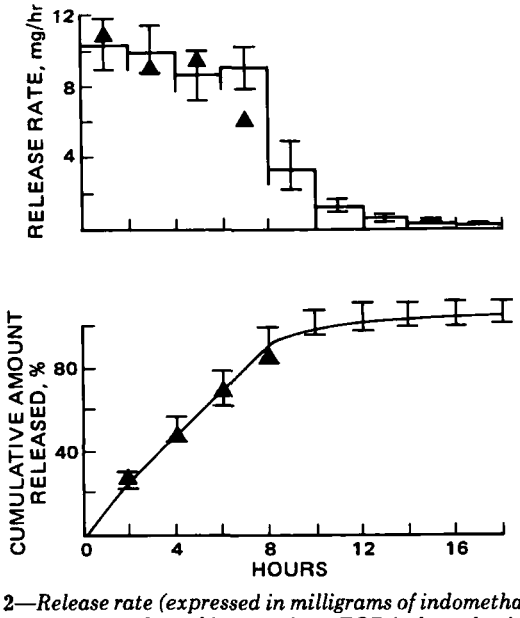

Figure 2—*Release rate (expressed in milligrams of indomethacin) and cumulative amount released* in vitro *from EOP-indomethacin 9/85,* N = 10. *Key: (▲) USP intestinal fluid (I) range (0–4 hr: gastric USP; 4–18: intestinal USP).*

acid) is designated EOP-indomethacin 7/85. This convention is used throughout the present report for three systems with different release rates but the same indomethacin content (85 mg) designated as EOP-indomethacin 7/85, 9/85, and 12/85.

EXPERIMENTAL

Materials—The tablet, membrane, and laboratory reagents for these studies were USF, NF, or ACS grades and were used without further purification. Sodium indomethacin trihydrate (II) was a gift[1].

Potassium bicarbonate was selected as the osmotic driving agent because of its high osmotic pressure and buffer capacity. In addition, when the dosage form operates in an acid environment, such as the stomach, carbon dioxide bubbles are produced that disperse the indomethacin acid formed. This process produces a finely dispersed drug formulation that readily redissolves and remains available for absorption. Details of the formulation are discussed elsewhere (8).

Determination of Solubilities and Osmotic Pressures—The solubility at 37° was determined for sodium indomethacin trihydrate in the presence of potassium bicarbonate. Excess amounts of each material were added to water in glass vials; the vials were capped tightly and equilibrated at 37° in a water bath for 24 hr. Aliquots of the resulting solutions were withdrawn from the vials using a preheated syringe and 0.2-μm filter. The sodium indomethacin content was determined by UV analysis after appropriate dilution.

Osmotic pressures of these same solutions were determined[2] at 37°.

Fabrication of System—Tablet cores were compressed on a rotary press[3] using 7.9-mm diameter, standard concave (IPT) tooling.

The membranes were applied by an air suspension coater[4], and membrane densities were obtained from volume and weight measurements.

Coated systems were dried in a forced-air oven at 50° until the residual solvent levels were <500 ppm. Systems were then equilibrated at ambient conditions to obtain the equilibrium trihydrate form of sodium indomethacin.

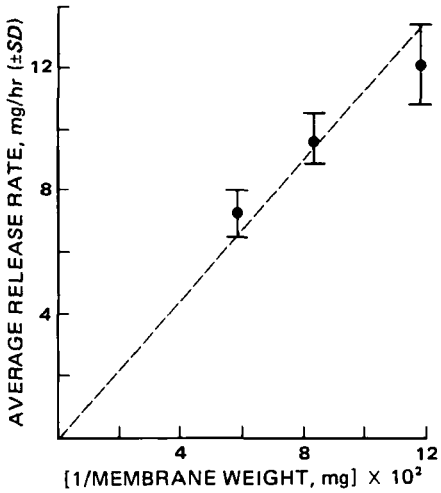

Figure 7—*Relation between weight of the membrane coating and average release rate from the EOP-indomethacin.*

Exit ports were drilled in each system by a high-speed mechanical drill or by an automated laser.

Release Rates—Differential release rates were determined by placing a finished system in a loose mesh bag and attaching the bag to a glass or plastic rod. The rod was attached to a horizontal arm connected to a vertically reciprocating shaker. The arms containing several systems were then positioned over a water bath (37°) that contained several test tubes. Each tube contained a known amount of release rate receptor media—simulated gastric or intestinal fluid without enzymes with 0.2% polysorbate 20. When the shaker started, the systems were immersed in the release rate media and stirred vertically at an amplitude of 3 cm and frequency of 0.25–0.5 cycle/sec. After 2 hr, the systems were removed from the first receptor container and moved to a second receptor; the stirring then was resumed. This procedure continued until the systems had been tested for 12 hr. Each receptor solution then was analyzed for sodium indomethacin content. The release rate in milligrams per hour for each system for each interval was determined by dividing the amount released in each receptor by 2 hr. The cumulative amount released was determined by taking the sum of the amount released by each system in each interval.

Cumulative amounts released were measured in the USP Dissolution Apparatus 1 (basket) or 2 (paddle); 900 ml of simulated intestinal fluid without enzyme with 0.2% polysorbate 20, pre-equilibrated to 37°, was used. For Apparatus 2, each system was placed in a loose mesh bag weighted with a few small glass beads. Samples were withdrawn from the receptor container at appropriate intervals for analysis, and the amount released was calculated after solution volume corrections were made.

Average zero-order differential release rates for each system were determined by averaging the rates into and including the periods up to the point where 70% of the drug was released.

After the average rate for each system was calculated, an average batch rate was determined using the average rates for all individual systems. The standard deviation obtained from this calculation was the between-system variation. Averaging the rates for all systems in all zero-order intervals provided the same batch average as before but also provided the overall standard deviation. Subtracting the variation between systems from the overall variation provided the variation within systems. This standard analysis of variance is routinely incorporated into all differential release rate determinations.

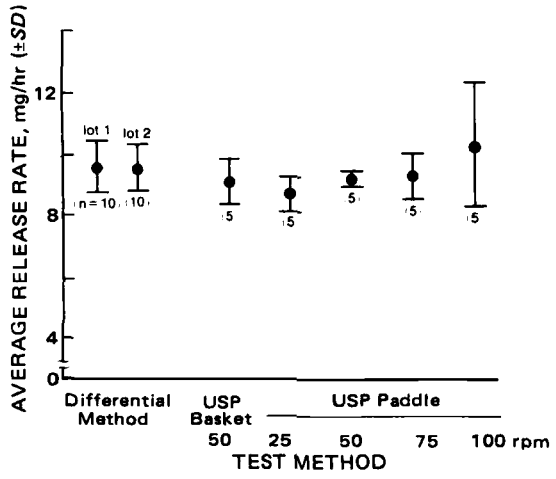

Figure 8—*Average release rate from EOP-indomethacin as a function of the test method (SD between-system variation).*

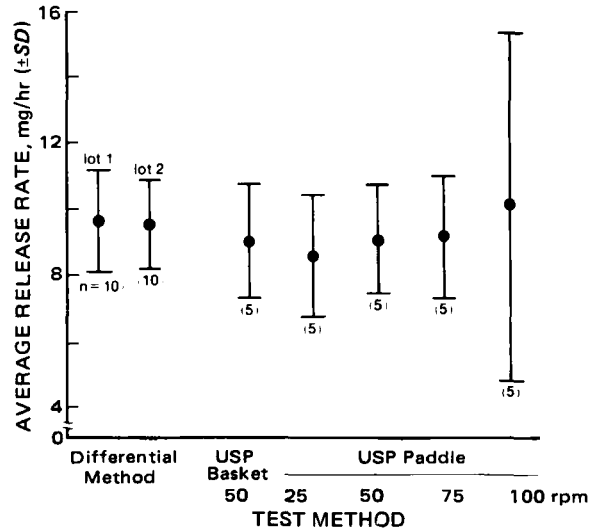

Figure 9—*Average release rate from EOP-indomethacin as a function of test method (SD within-system variation).*

Calculations were made as follows:

$$\text{standard deviation between systems} = \sqrt{\frac{\sum_{j=1}^{S}(\bar{Z}_j - \bar{Z})^2}{(S-1)}} \quad \text{(Eq. 4)}$$

$$\text{standard deviation within systems} = \sqrt{\frac{\sum_{j=1}^{S}\sum_{i=1}^{I}(Z_{ij} - \bar{Z}_j)^2}{(N-S)}} \quad \text{(Eq. 5)}$$

$$\text{standard deviation overall} = \sqrt{\frac{\sum_{j=1}^{S}\sum_{i=1}^{I}(Z_{ij} - \bar{Z})^2}{(N-1)}} \quad \text{(Eq. 6)}$$

where S is the number of systems tested, I is the number of zero-order intervals, $\bar{Z}$ is the average batch rate, $\bar{Z}_j$ is the average rate for system j, and $N = SI$.

Cumulative Amounts Released *In Vivo* and *In Vitro*—The release rate performance of these systems *in vitro* was compared with their performance *in vivo* using a dog model. Forty systems were individually weighed and marked with a number in indelible ink. The height (thickness) and diameter of each were measured. These were divided into two groups of 20.

Four mongrel dogs were used after a 3-week quarantine. They were fasted the night before and the day of the study but were allowed water *ad libitum*.

One system was administered orally to each dog 10, 8, 6, 4, and 2 hr before sacrifice, and the time of administration was recorded. Each dog was monitored each hour throughout the study, and all fecal and regurgitated material was examined for the presence of a system. If one was found, the time of recovery was recorded, and the system was washed and stored for analysis. Two hours after the last administration, each dog received an appropriate dose of euthanasia solution[5]. The entire GI tract was removed and opened. Each system was recovered and its recovery location in the tract and time of recovery recorded. All fecal and intestinal material adhering to the systems was carefully rinsed away. Each system was analyzed for its residual drug content.

Concurrent with administration to the dogs, systems were placed in

[5] T-61 euthanasia solution.

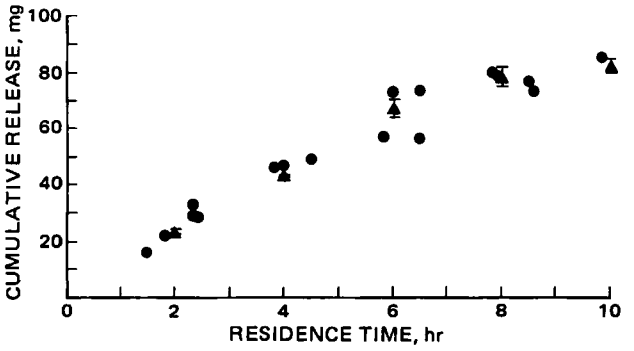

Figure 10—*Cumulative amount of indomethacin released by EOP-indomethacin 9/85 (expressed as milligrams of indomethacin)* in vitro *and in the GI tract of dogs. Key: (●) in vivo (dog); (▲) mean in vitro.*

release rate receptor medium. Each system remained in one container of medium for the study. All systems were attached to the vertically reciprocating shaker mechanism. At the end of the study, all systems were removed from the receptor media and each analyzed for residual drug content.

Separately, 10 systems were weighed and analyzed for total drug content; their average fractional drug content (Q) was then determined. The parameter Q was then multiplied by the weight of the 20 systems studied *in vivo* and the 20 systems studied *in vitro* to determine the initial drug content of each system. By subtracting the analyzed residual amount from the calculated initial content, the amount of drug released for various time intervals could be determined *in vivo* (dog) and *in vitro*. The data were plotted on the same graph (amount released as a function of residence time) for comparison.

Preliminary Assessment of Extent of Drug Absorption in Humans—Two four-way crossover studies were designed to determine the total urinary excretion and temporal pattern of plasma indomethacin concentrations in healthy volunteers. Six fasting subjects received single doses of EOP-indomethacin[6] 7/85, 9/85, 12/85 and indomethacin capsules[7] (3 × 25 mg) in randomized crossover fashion at weekly intervals. In a multiple-dose study, a total of eight doses of the four different formulations were administered at twelve 1-hr intervals to three other subjects. There was a 2-week period between the first dose of each treatment.

During the single-dose study, blood samples were collected at one-half hr preadministration and 1, 2, 4, 6, 12, and 24 hr postadministration; timed urine samples were collected incrementally. During the multiple-dose study, urine samples were collected over 120 hr at 10 equal intervals. The plasma and urine samples were analyzed by HPLC (9).

RESULTS AND DISCUSSION

Release rate data are expressed as milligrams per hour of indomethacin acid, the pharmacologically active drug moiety. Release rate performance, however, as it relates to the physicochemical constants discussed in *Theoretical*, depends on properties of the drug salt, sodium indomethacin trihydrate, contained in the core (Table I). Molecular weights of indomethacin and its trihydrate salt are 357.8 and 433.8, respectively. The solubility of indomethacin is then obtained from the solubility of its salt, S_d, by dividing the solubility (Table I) by the ratio of the molecular weights (1.212). The content of indomethacin per system was selected at 85 mg, which is equivalent to 103 mg of salt.

Table II lists the three dosage forms by their nominal release rate–total drug content and shows their actual zero-order release rates and membrane weights.

pH Independent Release Rate *In Vitro*—Release rates of three different types of systems (Figs. 1–3) were measured by the differential method from which the cumulative amounts released were calculated and expressed as percent of total drug content. The data, with bars expressing the range of data, were obtained from measurements in gastric fluid for the first 4 hr and in intestinal fluid for the remainder of the test. In a separate experiment, release rates of systems from the same batch were studied in intestinal fluid. Average release rates obtained in this fashion are represented by the triangle. The release rates in either gastric or intestinal fluid were the same.

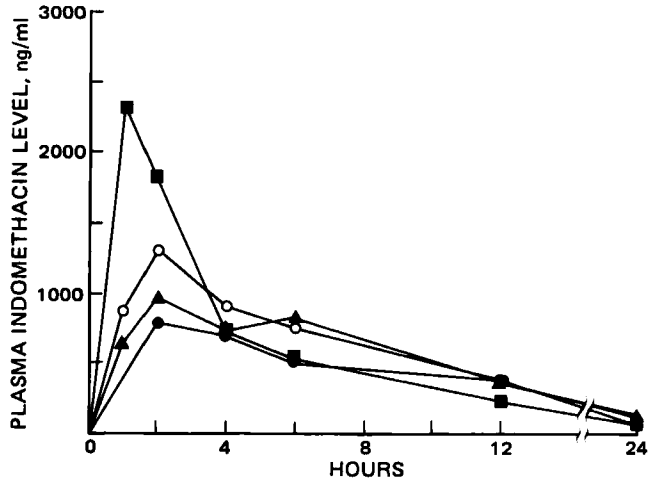

Figure 11—*Average (n = 6) indomethacin plasma profiles after single doses of indomethacin capsules (3 × 25 mg) and the EOP-indomethacin 7/85, 9/85, and 12/85. Key: (■) Indomethacin capsules (3 × 25 mg), (●) EOP-indomethacin 7/85, (▲) EOP-indomethacin 9/85, (○) EOP-indomethacin 12/85.*

Predictable Release Rates—The relationship between the release rate and membrane permeability for this type of system has been treated elsewhere (4). The purpose of this section, then, is not intended to prove the validity of Eqs. 1 and 3 but to use them as a tool to correlate the data of three sets of experiments on the release rate from systems 7/85, 9/85, and 12/85 (Figs. 4–6). These three systems were coated with the same membrane formulation of which only the thickness and, therefore, weight differed. The average zero order rates (Z_d) of these systems can be plotted *versus* $1/W$, the inverse of the average membrane weight (Fig. 7). From the slope of the best straight line through the origin, the membrane permeability constant (k) is estimated to be 1.4×10^{-6} cm^3/hr atm according to Eq. 3.

This estimate is used to calculate the total release rate profile in Figs. 4–6. The theoretical and actual release rates agree to within 10%.

Release Rate Independent of Stirring Rate—The effect of stirring rates on the average zero-order rate was studied on a second lot of the 9/85 system using the three different methods listed. Results are shown in Figs. 8 and 9. Average zero-order release rates, calculated as previously described, are the same for lots 1 and 2 of the 9/85 system. Standard deviations between and within those systems, calculated according to Eqs. 4 and 5, are comparable (Figs. 8 and 9). A two-tailed Student's t-test of these data indicated no significant differences ($p > 0.1$) between the two lots of systems in rates determined by the differential method. As seen from Figs. 8 and 9, the average rates obtained by the differential method and USP Apparatus 1 (50 rpm) (basket) and 2 (25–75 rpm) (paddle) demonstrate no differences in averages or in deviations from average values. Release rates were measured in artificial intestinal fluid containing 0.2% polysorbate 20.

Comparison of the average release rate for lot 2, determined by the differential method, to the average rates obtained from the USP Apparatus 1 (50 rpm) and 2 (25–100 rpm), showed that no significant differences exist as determined by a Student's t-test ($p > 0.1$). When the overall variance for lot 2 is compared to those for the USP methods, only method 2 at 100 rpm is significantly different ($p < 0.05$), as determined by a variance ratio (f) test. That deviation was due to rupture of the membrane by the vigorous stirring, making the results at this stirring rate invalid. In all other cases, overall agreement exists between the various *in vitro* methods reported here.

Release Rate *In Vivo versus* Release Rate *In Vitro*—The release rate *in vivo* cannot readily be measured with the differential method used *in vitro*. Cumulative amounts released *in vivo* were obtained instead and compared (Fig. 10) with cumulative amounts released *in vitro* and also measured directly. The ranges of experimental *in vitro* data are indicated with error bars, while amounts released from individual systems in the GI tract of four dogs are listed as separate data points. The systems studied were of the 9/85 type and were obtained from the batch for which data are given in Fig. 2. The average release rate for each separate system, *in vitro* or *in vivo*, which released an amount Δm_i in a residence time Δt_i is found as:

$$Z_i = \Delta m_i / \Delta t_i \qquad \text{(Eq. 7)}$$

Table III—Mean Urinary Recovery and Renal Clearance (±*SD*) of Indomethacin Following Single Doses in Six Subjects

Treatment	Renal Clearance, ml/min	Percent Recovered in Urine
Capsules	32.4 ± 14.3	17.3 ± 12.5
EOP-7/85	33.9 ± 11.9	22.3 ± 7.7
EOP-9/85	35.1 ± 11.4	23.8 ± 5.9
EOP-12/85	42.1 ± 14.2	28.1 ± 7.1

The average zero-order rate for systems that delivered for a time period ≤6 hr was found to be:

In vitro:

$$\bar{Z}_1 = \frac{\sum_i^{12} Z_i}{12} = 10.8 \pm 9.4\% \qquad \text{(Eq. 8)}$$

In vivo:

$$\bar{Z}_2 = \frac{\sum_i^{12} Z_i}{12} = 10.6 \pm 16\% \qquad \text{(Eq. 9)}$$

The *in vitro* and *in vivo* rates are equal and are not significantly different from the rate obtained by the differential method.

Plasma Concentrations and Extent of Drug Absorption from Two Limited Studies in Humans—Plasma profiles from the single-dose study illustrated the controlled-release properties of the EOP-indomethacin dosage forms. Compared with the indomethacin capsules, they produced more constant and prolonged plasma levels (Fig. 11); renal clearance and total urinary recoveries of indomethacin and conjugates are shown in Table III. Relative to capsules of indomethacin, which are known to be completely absorbed (5, 7), the bioavailability of the 7/85, 9/85, and 12/85 systems were estimated to be 0.80, 0.84, and 0.88, respectively (10, 11).

Total 120-hr urinary recovery of indomethacin (free and conjugated) for the multiple-dose study was 130.2 ± 26.7, 139.4 ± 8.9, and 147.7 ± 23.1 mg, respectively, following EOP-indomethacin 7/85, 9/85, and 12/85, and was 128.8 ± 39.1 mg following indomethacin capsules. Similar urinary recovery of indomethacin suggests comparable bioavailability.

Summary—Preliminary studies in humans showed that the extent of absorption from EOP-indomethacin systems 7/85, 9/85, and 12/85 is similar to that after 75 mg of indomethacin in capsules. Plasma concentration profiles are consistent with the planned differences in drug delivery rate and the anticipated effects of enterohepatic circulation (5–7).

Prediction of Stability in Pharmaceutical Preparations XX: Stability Evaluation and Bioanalysis of Cocaine and Benzoylecgonine by High-Performance Liquid Chromatography

EDWARD R. GARRETT ˣ and KAZIMIERZ SEYDA

Received December 7, 1981 from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication April 22, 1982.

Abstract □ Specific, sensitive, reverse-phase high-performance liquid chromatographic (HPLC) assays of cocaine (I) and its hydrolysis products, benzoylecgonine (II) and benzoic acid (III), have been devised with analytical sensitivities as low as 15 ng/ml of plasma for I using spectrophotometric detection at 232 nm. Cocaine can be separated from its hydrolysis products by extraction at pH 7.5 with haloalkanes. Benzoylecgonine and benzoic acid can be extracted at pH 3.0 with 1-butanol. The evaporated residues were reconstituted in acetonitrile–water for HPLC assay. The assay was used to determine the stabilities of I and II in aqueous solutions, to establish log k–pH profiles at various temperatures, and to evaluate Arrhenius' parameters. Hydrolyses were by specific acid–base catalysis. Cocaine showed hydrogen and hydroxyl ion attack on protonated I with 40 and 90% proceeding through the benzoylecgonine route, respectively, as well as hydroxyl ion attack on neutral cocaine, with only 6% proceeding through the benzoylecgonine route. Cocaine is relatively unstable in the neutral pH range with a half-life of 5 hr in buffer at pH 7.25 and 40°. Similar half-lives were observed in fresh dog plasma at 300 and 30 μg/ml, although one study at 0.5 μg/ml indicated a doubling of the rate.

Keyphrases □ Cocaine—stability evaluation and bioanalysis, hydrolysis products, high-performance liquid chromatography □ High-performance liquid chromatography—cocaine, benzoylecgonine, and benzoic acid in buffers in biological fluids □ Stability—prediction and bioanalysis of cocaine and benzoylecgonine in plasma and buffers, high-performance liquid chromatography □ Benzoylecgonine—hydrolysis product of cocaine, stability evaluation and bioanalysis by high-performance liquid chromatography □ Protein binding—cocaine and its hydrolysis products, benzoylecgonine and benzoic acid, stability evaluation and bioanalysis, high-performance liquid chromatography

Cocaine (I) is metabolized *in vivo*, principally to its solvolytic products (1, 2), with an apparent terminal half-life in humans ranging between 40 and 91 min (3). Although available data on the stability of I in plasma *in vitro* is sparse (3), a rough estimate of the half-life in human plasma of 150 min at 25° can be made.

0022-3549/83/0300-0258$01.00/0

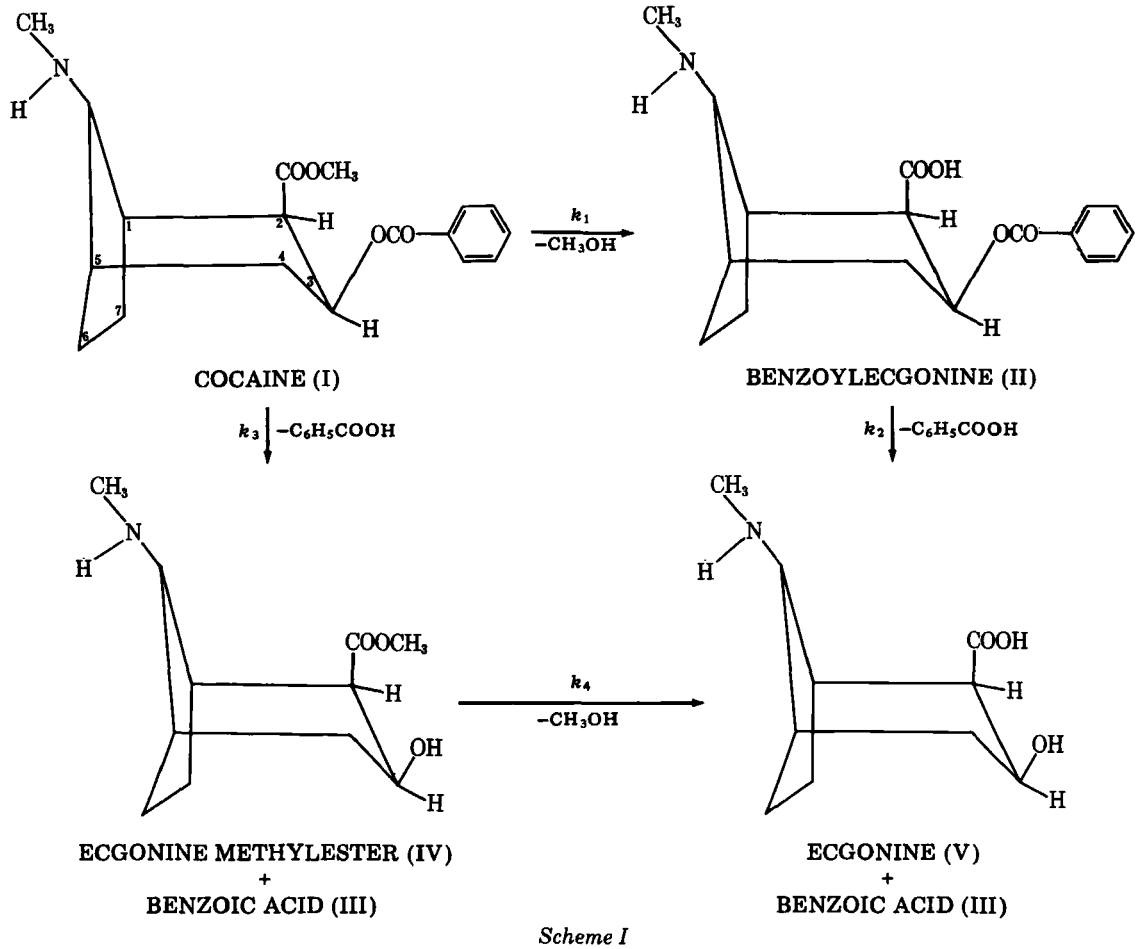

Scheme I

The aqueous solvolysis of 10 mg of I/ml was studied by assaying unchanged drug with time between pH 1 and 8.8 (5). Cocaine was extracted with ether from 5% sodium bicarbonate solutions and spectrophotometrically assayed after reextraction into 0.01 *N* HCl. The maximum stability was stated to be at pH 1.95 and benzoylecgonine (II) was claimed to be the solvolytic product (5).

The present study develops and applies specific and sensitive HPLC assays of I and its solvolytic products (Scheme I) to kinetic studies of stability and mechanisms of solvolyses of both I and II in aqueous and biological fluids, and establishes complete log k–pH profiles at several temperatures in preparation of systematic pharmacokinetic investigations of the drug and its metabolites. The validity of the use of basic physicochemical relations in predicting the stability of drugs under all conditions and optimizing valid assays has been demonstrated (6–9).

An HPLC assay has been claimed to detect I and II at 200 and 235 nm for ~100 ng/ml from 5 ml of urine after selective pH extraction. A valid linear calibration curve was claimed to exist over a range of 0.5–10 μg/ml of urine, although no quantitative assays were given (10). A more

Table I—Typical Statistics of HPLC Calibration Curves of I, II, and III in Aqueous Solutions and Plasma [a]

IV′(232)[e]	I	0.05–0.40	0.0073	0.282	0.008	−0.0026	0.0069	5	0.9989

[a] Statistics are in accordance with $C(\mu g/ml) \pm s_{C\cdot PHR} = (m \pm s_m)\ PHR + b \pm s_b$ from aqueous solutions (HPLC procedure I) and plasma (HPLC procedures II–IV). All values are for concentrations in the final assayed solutions except for IV′ which is for concentrations in the original plasma. The constants m and b are the slope and intercept, respectively, of the regression of concentration (C, μg/ml) on peak height ratio to internal standard (PHR) where $s_{C\cdot PHR}$, s_m, and s_b are standard errors of estimate (μg/ml) (14) of concentration on peak height ratio, of the slope (m), and of the intercept (b), respectively. [b] Degrading buffered solutions of I were diluted to one-sixth the original concentration before assaying in mobile phase solution. [c] Plasma (0.5 ml) denatured with 0.5 ml acetonitrile and the supernatant assayed. [d] Evaporated chloroform extracts of 1.0 ml of plasma were reconstituted in 0.5 ml of aqueous acetonitrile and assayed for I at twice the original plasma concentration. Evaporated 1-butanol extracts of the plasma were reconstituted similarly, and II and III were assayed at twice the original plasma concentration. [e] As in footnote *d* except the compounds were 6.7 times the original 2.0-ml plasma concentration. Plasma components at these low II and III concentrations and at 232-nm detection interfered with their assays.

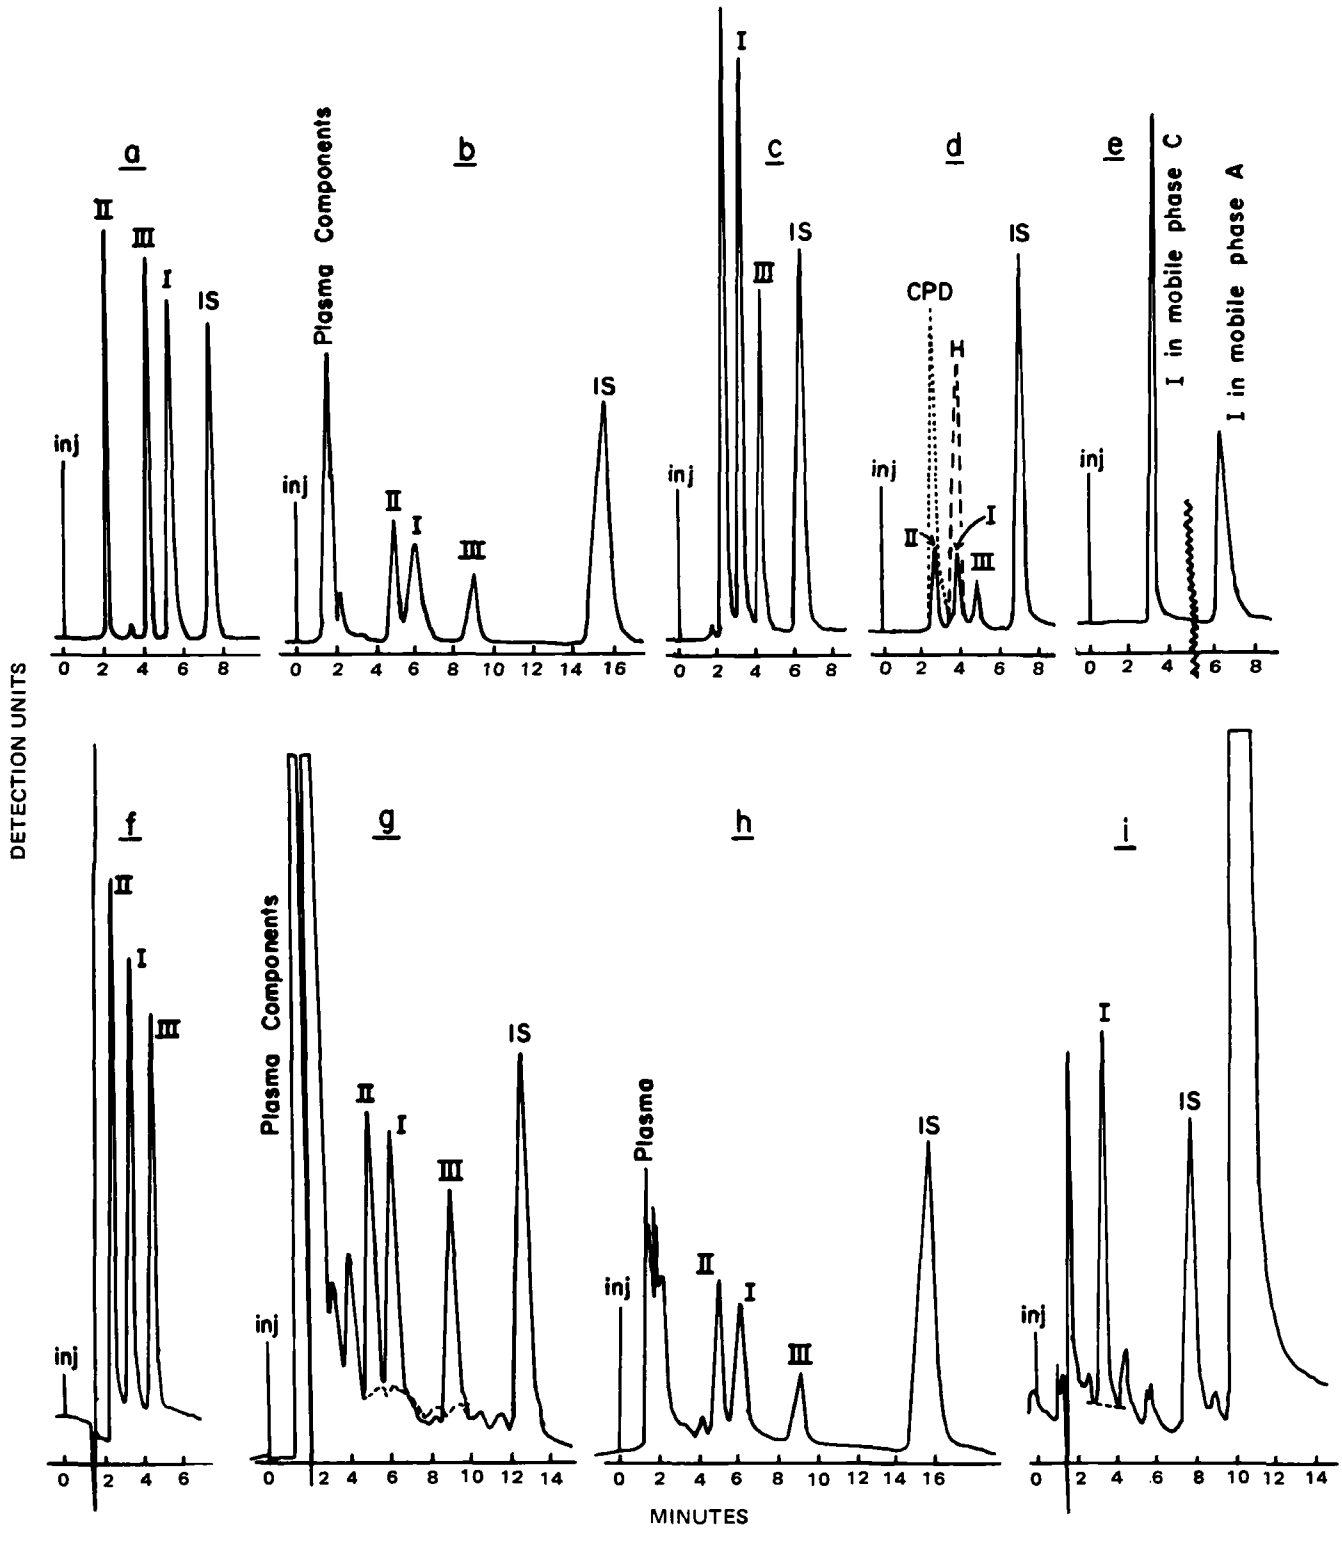

Figure 1—*Examples of reverse-phase HPLC chromatograms at 254-nm detection with 25 μl injected: (a) Aqueous solution containing 2.98 × 10^{-4} M (90.4 μg/ml) I, 1.415 × 10^{-4} M (42.92 μg/ml) II, 3.034 × 10^{-4} M (37 μg/ml) III, and 3.517 × 10^{-4} M (48 μg/ml)* m-*toluic acid (IS) in mobile phase A. (b) Heparinized plasma solution denatured (1:1) with acetonitrile in mobile phase B. The mixture contained 1.98 × 10^{-4} M (60 μg/ml) I, 1.864 × 10^{-4} M (56.5 μg/ml) II, 2.044 × 10^{-4} M (25 μg/ml) III, and 1.057 × 10^{-3} M (144 μg/ml)* o-*toluic acid (IS). (c) Aqueous solution containing 1.65 × 10^{-4} M (50 μg/ml) I, 1.553 × 10^{-4} M (45 μg/ml) II, 1.703 × 10^{-4} M (20.8 μg/ml) III, and 2.968 × 10^{-4} M (40.4 μg/ml)* o-*toluic acid (IS) into mobile phase C. (d) Aqueous solution containing 2.475 × 10^{-5} M (7.5 μg/ml) I, 2.33 × 10^{-5} M (7.07 μg/ml) II, 2.555 × 10^{-5} M (3.12 μg/ml) III, and 2.968 × 10^{-5} M (4.04 μg/ml)* o-*toluic acid (IS) in mobile phase C. The dashed line is the chromatogram for the same composition with heparin (H). continued on next page

recent paper claims an HPLC detection limit for I, II, and norcocaine of 1.0 μg/ml of biological fluid from 0.5 ml of sample at 235 nm after extraction at pH 9.0 and reconstitution of the evaporated organic extract in 250 μl of water (11).

In a recent guide to I and metabolite analysis in biological material (12), it was stated that "surprisingly very few papers utilizing this technique for the determination of cocaine and its metabolites have appeared . . ."

One of the HPLC methods presented has an analytical sensitivity in plasma of 15 ng/ml for I.

EXPERIMENTAL

Materials—The following analytical grade materials were used: cocaine hydrochloride[1], benzoylecgonine·4H_2O[1], benzoic acid[2], *m*-toluic acid[3], *o*-toluic acid[3], glacial acetic acid[2], sodium acetate[2], boric acid[4], sodium borate[4], sodium chloride[2], monobasic sodium phosphate[4], dibasic sodium phosphate[2], 1 *M* hydrochloric acid[5], 1 *M* sodium hydroxide[5], 0.4 *M* tetrabutylammonium hydroxide in water[6], acetonitrile[6], chloroform[2], and 1-butanol[4].

Apparatus—A high-performance liquid chromatograph[7] equipped with fixed[8] and variable[9] wavelength UV detectors was used with a reverse-phase μBondapak C_{18} column.

HPLC Procedures—*Procedure I: Kinetics in Aqueous Solution*—The mobile phase (A) acetonitrile–0.085 *M* acetate buffer (25:75) (pH 3.6) with UV detection at 254 nm was used to assay degrading aqueous solutions of I and II with 4.22×10^{-4} *M* *m*-toluic acid as the internal standard. All reaction samples were diluted with acetonitrile and acetate buffer (pH 3.6) which contained the internal standard to give the same composition as the mobile phase, and 25 μl was injected into the chromatograph.

Procedure II: Acetonitrile Denaturation for Higher Concentrations of I in Plasma—Plasma (0.5 ml) was denatured with 0.5 ml of acetonitrile containing 2.113×10^{-4} *M* *o*-toluic acid as internal standard, with vortexing after subsequent centrifugation at 3000 rpm for 10 min. A 25-μl aliquot of the supernatant was injected into the chromatograph with a mobile phase (B) of acetonitrile–0.0002 *M* tetrabutylammonium hydroxide in 0.085 *M* acetate buffer (15:85) (pH 3.63) and UV detection at 254 or 232 nm.

Procedure III: Extraction Procedure for Higher Concentrations of I in Plasma—Plasma (1.0 ml) was extracted twice with 1.00 ml of chloroform. The combined organic extract was evaporated to dryness under nitrogen, reconstituted in 0.5 ml of acetate buffer (pH 3.6)–acetonitrile (1:1) which contained 1.187×10^{-3} *M* *o*-toluic acid as internal standard. Then, 25 μl was injected into the chromatograph to assay I with a mobile phase (C) at 254 nm detection of acetonitrile–0.0002 *M* tetrabutylammonium hydroxide in 0.085 *M* acetate buffer (25:75) (pH 3.63). The extracted plasma was adjusted to pH 3 and again extracted with 10 ml of 1-butanol. The organic extract was evaporated to dryness under nitrogen, reconstituted as above, and 25 μl was injected into the chromatograph to assay II and benzoic acid (III) with mobile phase B at 254 nm detection.

Procedure IV: Extraction Procedure for Lower Concentrations of I in Plasma—Plasma (2.0 ml) was extracted with 3.0 ml of chloroform. The extract (2.0 ml) was evaporated to dryness under nitrogen and reconstituted with 0.2 ml of acetonitrile–acetate buffer (1:3) (pH 3.6) mixture which contained 1.665×10^{-5} *M* *p*-chloroaniline as internal standard. A 25-μl injection was used with mobile phase C for analysis of I at 232 nm detection. Once extracted, the plasma was adjusted to pH 3 and extracted twice with 5 ml of 1-butanol. The combined extracts were taken to dryness, reconstituted as above, and 25 μl was assayed with mobile phase B for II and III. At the low drug concentrations, extracted plasma components interfered with the assay of II. All procedures used flow rates of 2.0 ml/min which gave back pressures of 1800–2100 psi.

Kinetics of Hydrolytic Degradation of I and II—*Acid Hydrolyses*—Aliquots of aqueous solutions of a drug were mixed with appropriate amounts of standardized concentrate to give 0.1, 0.04, and 0.02 *M* HCl solutions that were 1.32×10^{-3} *M* in I or 8.518×10^{-4} *M* in II (Table I). Aliquots (1.5 ml) were put in tightly closed 10-ml vials that were placed in 90, 80, or 70° thermostated oil baths. The vials were withdrawn periodically, ice-cooled, and 0.5 ml of the reaction mixtures was mixed with 2.5 ml of quenching solution containing 4.22×10^{-4} *M* *m*-toluic acid as internal standard. The rates were sufficiently slow such that the time of thermal equilibration did not affect the studies significantly. The quenching solution was an appropriate mixture of acetate buffer–acetonitrile to yield the same ultimate composition of the used mobile phase A in HPLC procedure I.

Alkaline Hydrolyses—Aliquots of aqueous stock solutions of a drug were mixed with thermally preequilibrated appropriate sodium hydroxide solutions (Table I) prepared from a standardized concentrate to obtain 2.472×10^{-3} *M* of I or 8.518×10^{-4} *M* of II. Aliquots (0.5 ml) of the thermostated samples were pipeted periodically into 2.5 ml of a quenching solution that contained acetate buffer, acetonitrile, and hydrochloric acid for neutralization of excess sodium hydroxide and internal standard and was 4.22×10^{-4} *M* in *m*-toluic acid. The HPLC procedure I was used for the assay.

Solvolysis Studies at Intermediate pH-Values—Acetate (pH 3.98–5.67), phosphate (pH 6.22–7.25), and borate (pH 7.72–11.85) buffers were prepared with ionic strengths of 0.1 adjusted with sodium chloride. The buffer solutions were preequilibrated in a constant-temperature bath before addition of appropriate amounts of stock solutions of I or II to obtain concentrations of 1.32×10^{-3} *M* and 8.51×10^{-4} *M* for I and II, respectively. Aliquots (0.5 ml) were removed periodically into 2.5 ml of quenching solution which contained 4.22×10^{-4} *M* *m*-toluic acid as internal standard to obtain the same composition as the HPLC mobile phase A. HPLC Procedure I was used for the assay.

Buffer Catalysis—Kinetic studies were conducted at several concentrations of buffers at a pH equal to the pK_a of appropriate buffer and constant ionic strength 0.1 (Table I). Additional studies at different pH values and concentrations of acetate buffer were effected. No significant buffer catalysis was observed in any of the buffers.

Potentiometric Determination of $pK_{a'}$ Values of I and II—Compound I or II (0.00017 mole) was dissolved in 5 ml of 0.1 *M* HCl, diluted with 20 ml of deionized water, and titrated potentiometrically with 0.1 *M* NaOH. The blank solutions, without I or II, were titrated similarly. The $pK_{a'}$ values were estimated from the plots of the difference between the number of milliliters of titer necessary to bring both blank solutions and solutions containing a drug to the same pH value (13). The $pK_{a'}$ values of I were estimated at several temperatures by half neutralizing solutions of I maintained at those temperatures and measuring the pH values as a function of time and extrapolating pH values back to time zero. This method was complicated by the 10–20 sec necessary to obtain electrode equilibration and the relatively fast degradation of I at these pH values and higher temperatures.

Kinetics of Degradation of Higher Concentrations of I in Plasma—An aliquot (0.4 ml) of an aqueous solution of 3.3×10^{-3} *M* I hydrochloride was evaporated under nitrogen to dryness, and the residue was mixed with 15 ml of heparinized fresh dog plasma, thermally equil-

containing 9.075×10^{-6} M (2.75 μg/ml) I, 8.54×10^{-6} M (2.6 μg/ml) II, and 9.368×10^{-6} M (1.14 μg/ml) III into mobile phase C. (g) Plasma obtained with citrate phosphate dextrose USP as anticoagulant and denatured 1:1 with acetonitrile. The mixture containing 9.075×10^{-6} M (2.75 μg/ml) I, 8.54×10^{-6} M (2.6 μg/ml) II, 9.368×10^{-6} M (1.14 μg/ml) III, and 4.14×10^{-5} M (5.28 μg/ml) p-chloroaniline (IS) was injected into mobile phase B after denaturation (1:1) with acetonitrile. (h) Plasma (1.0 ml) with 1.087×10^{-4} M II, 1.155×10^{-4} M I, and 1.192 M III was extracted with 2 ml of chloroform, adjusted to pH 3, and extracted with 10 ml butanol. The combined extracts were evaporated, reconstituted in 1.0 ml of mobile phase containing 5.94×10^{-4} M o-toluic acid (IS) and 25 μl was injected with mobile phase B. (i) Plasma (2.0 ml) at 0.50 μg/ml of I was extracted with 3.0 ml chloroform. An aliquot (2.0 ml) of extract was evaporated, the residue reconstituted in 0.2 ml of mobile phase, and 25 μl of 7.58×10^{-6} M solution (2.3 μg/ml) injected into mobile phase C (Procedure IV). The dashed line is for a sample treated similarly without I. The internal standard (IS) was 2.22×10^{-5} M p-chloroaniline in the injected sample.

Table II—Apparent Partition Coefficients for I (C_{org}/C_{buffer}) with Various Organic Phases

pH	Diethyl Ether	Hexane	Benzene	Methylene Chloride	Chloroform
10.7	161	46	—	220	>200
9.0	159	32	212	>200	237
8.2	22	7.5	135	—	185
5.9	0.023	0.07	1.6	4.0	5.5
3.9	—	—	0.04	0.22	0.30

ibrated at the body temperature of the dog (38.9°) to give an 8.8×10^{-3} *M* (299 μg/ml) or 8.8×10^{-4} *M* (29.9 μg/ml) solution. The residues were assayed with time by Procedures II and III, respectively.

Kinetics of Degradation of Lower Concentrations of I in Plasma—Since heparin interfered with the use of Procedure IV for the assay of low concentrations of cocaine, a citrate, phosphate, and dextrose solution USP[10] was used as the anticoagulant for assays of I in plasma at an initial concentration of 1.471×10^{-6} *M* (0.5 μg/ml) and 38.9° by this procedure. The spiked plasma was prepared in the same manner as described earlier.

Kinetics of Degradation of II in Plasma—An aliquot (0.35 ml) of an acetonitrile solution of 3.105×10^{-2} *M* II·4H_2O was evaporated under nitrogen to dryness, and the residue was mixed with 15 ml of heparinized fresh dog plasma to give a 7.245×10^{-4} *M* solution. Aliquots (0.5 ml) at 38.9° were periodically mixed with 0.5 ml of acetonitrile supernatant to be assayed by Procedure II.

Partition Studies as Function of pH—Partition studies between appropriate volume ratios of water-saturated organic solvent and buffer solutions of various pH values were effected by shaking mixtures containing I·HCl or II. Higher relative volumes of organic phase were used at the lower pH values of the buffer and lower volumes of organic solvent at higher pH values in the cocaine studies. Higher relative volumes of organic phase were used in the studies of II in each experiment. Aliquots of the separated organic phases were evaporated under nitrogen to dryness and assayed by HPLC Procedure I after reconstitution in the mobile phase. The aqueous phases were adjusted to the composition of the mobile phase and assayed similarly.

Red Blood Cell–Plasma and Buffer Partitioning—Aliquots of a stock solution of I hydrochloride (0.02 mg/ml) were evaporated to dryness and reconstituted with whole blood with an hematocrit of 41.5 or with a red blood cell suspension in plasma–water or buffer with an hematocrit of 32.5 and maintained at 38.9°. After 1 and 2 hr, the vials were centrifuged at 3000 rpm, and 0.5 ml of plasma or buffer layer was extracted with 1.0 ml of chloroform. An aliquot of the chloroform (0.75 ml) was evaporated and reconstituted in 1 ml of acetonitrile–0.085 *M* acetate buffer (25:75) (pH 3.6), and 25 μl was injected into mobile phase C for HPLC detection at 232 nm.

[a] Rate constants for overall hydrolysis of I, for hydrolysis to II (k_1, sec^{-1}), and to IV (k_3, sec^{-1}) and for the hydrolysis of II (k_2, sec^{-1}) to ecgonine in hydrochloric acid and sodium hydroxide solutions (Scheme I). [b] Final compositions. Sufficient alkali was added to neutralize the added I hydrochloride. [c] The pH values for [NaOH] and [HCl] solutions were calculated from $pH = pK_w + \log f_{NaOH}[NaOH]$ and $pH = -\log f_{HCl}[HCl]$, respectively, from the pK_w values and activity coefficients, f_{NaOH} and f_{HCl}, available in the literature (15) for the designated temperatures, $pK_w = 2715(1/T) + 4.87$.

filtered, and the filtrates were assayed by the described HPLC procedures. Cones pre-equilibrated by filtering 2.5 ml of 6.0 ml of phosphate buffer (pH 7.5) containing 1 and 2 μg/ml, respectively, of I were also used. The same amount of plasma with the same concentrations of I were filtered through the respective cones, and the filtrate was assayed.

RESULTS AND DISCUSSION

HPLC Assays—The specific HPLC assays developed for cocaine (I) and its solvolysis products, benzoylecgonine (II) and benzoic acid (III), were applied to kinetic studies of the solvolysis of I and II and to partition studies of these compounds. Statistics of typical calibration curve regressions are given in Table I; HPLC chromatograms are given in Fig. 1. The analytical sensitivities ($2 \times s_{C\text{-}PHR}$) of 0.5–1.6 μg/ml (Procedure I, Table I; Fig. 1a) with UV detection at 254 nm with mobile phase A, of 1.0–3.0 μg/ml (Procedure II, Table I; Fig. 1b) were modified to 70–120 ng/ml by the use of a variable wavelength detector of 232 nm with a modified mobile phase B (Fig. 1g) or C (Fig. 1f; Procedure II, Table I) containing 0.0002 M tetrabutylammonium hydroxide in the 0.085 M acetate buffer.

Tetrabutylammonium hydroxide in mobile phase C increased the peak height sensitivity of the assay of I by decreasing its retention time (Fig. 1e). A concentration of 0.0002 M tetrabutylammonium hydroxide decreased the retention time of I from 6.6 to 3.2 min and 0.0004 M to 2.4 min. The tetrabutylammonium cation blocks adsorption sites on the column from I and effectively lowers the retention volume of I. The peak heights and retention times of the acidic II (2.3 min) and III (4 min) at pH 3.63 of the mobile phases, close to the pH of maximum stability of I and II, were not significantly affected by the tetrabutylammonium hydroxide.

Mobile phase B (Figs. 1b, 1g, and 1h) was advantageous in the assay of plasma solutions, in that plasma component peaks did not interfere with those of I and II in this system as they did in mobile phases A and C (Fig. 1i). The plasma component peaks did not interfere with the cocaine assay using mobile phase C in the extraction HPLC procedures III and IV (Fig. 1i), although some interferences were observed in C but not B at low concentrations of II. The sequential extraction procedures of III and methylecgonine (IV) permitted the selective assay of II in mobile phase B where there was no interference.

The retention times of heparin and I were similar in mobile phases B and C (Fig. 1d shows mobile phase C). Thus, the noninterfering citrate phosphate dextrose solution USP was used as the anticoagulant in plasma studies for the assay of low concentrations of I in mobile phase C (Fig. 1d). In this mobile phase, the anticoagulant, citrate phosphate dextrose solution USP, interfered with the peak of II (Fig. 1d) but did not interfere when mobile phase B was used (Fig. 1h).

The use of the developed extraction procedures with reconstitution into small volumes of the dried extracts gives analytical sensitivities from plasma of 15 ng/ml (Procedure IV and IV′, Table I) for I.

The apparent partition coefficients for I into several organic solvents are given in Table II for several pH values. All of the solvents listed showed potential complete extractions of I above pH 8.0. Chloroform appeared best suited for extraction at plasma pH values.

Compound II, at a pH of 6.32 where it exists as the zwitterion, had the following partition coefficients in the designated solvents: 0.4, ethyl acetate–acetonitrile (1:1); 0.79, isobutyl alcohol; and 0.87, *sec*-butyl alcohol. The partition coefficients for 1-butanol at pH 7.67, 6.32, and 3.89 were 1.02 ± 0.02 and were 0.30 ± 0.1 for *n*-butyl alcohol–chloroform (1:3). The partition coefficients for chloroform and methylene dichloride extraction of II were 0.12 ± 0.01 at pH 4, 6, 8, 9, and 11. Thus, 1-butanol was the most effective solvent for extraction of II.

These partition studies served as the basis for designing the sequential extraction of I and its metabolites. A primary extraction of I with limited amounts of chloroform at >pH 7 would remove negligible amounts of II, which could be reasonably extracted subsequently with 1-butanol. At pH 3, III would be readily extracted as well.

Kinetics of Solvolysis of I and II—At constant pH, I degrades by an apparent first-order process. Representative semilogarithmic plots of concentrations, C, against time are given for hydrochloric acid solutions (Figs. 2 and 3), sodium hydroxide solutions (Figs. 4 and 5), and buffers (Figs. 6 and 7), where the apparent first-order rate constants, k, were obtained from the slopes in accordance with:

$$\log C = -\frac{k}{2.303}t + \log C_0 \qquad \text{(Eq. 1)}$$

where C and C_0 are the concentrations at time t and time zero, respectively. These k-values are listed in Tables III and IV.

The pH values of the degrading buffer solutions were determined experimentally at the temperature of the study. The pH values for hydrochloric acid solutions were calculated from:

$$pH = -\log \gamma[HCl] \qquad \text{(Eq. 2)}$$

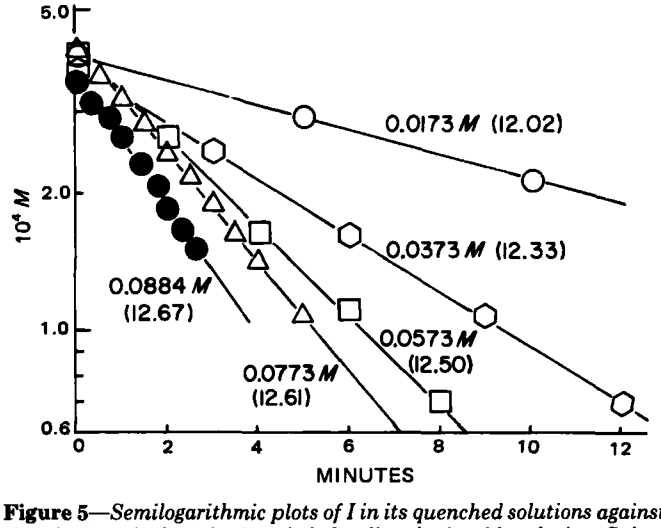

Figure 5—*Semilogarithmic plots of I in its quenched solutions against time for its solvolysis in the labeled sodium hydroxide solution. Calculated pH values at 30.0° are given in parentheses.*

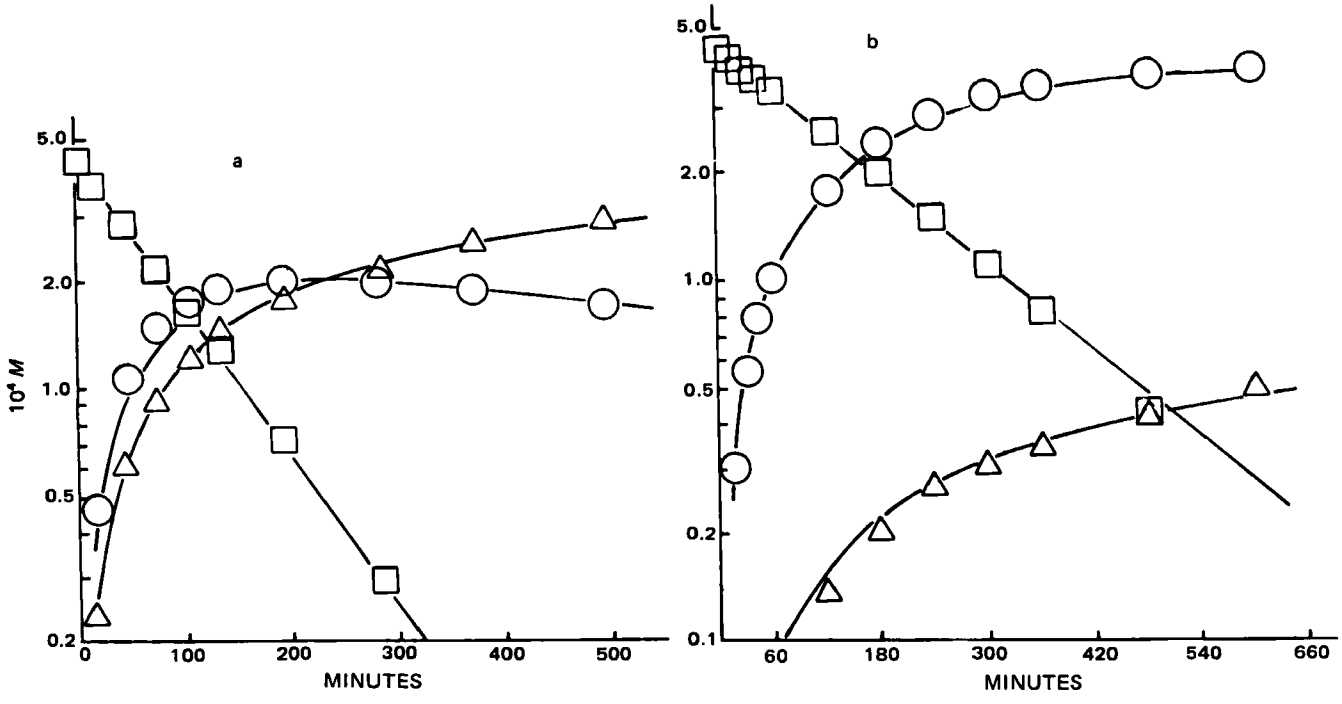

Figure 6—*Example of semilogarithmic plots of I, II, and III against time on I solvolysis in buffered solutions. The curves through the data were calculated from the equations given in the text based on the kinetic constants given in the tables. The specific conditions of the kinetic studies were for initial concentration of 2.65 × 10^{-3} M I at 30.0° at a) pH 10.33 and b) pH 9.09. The initial theoretical concentrations of the assayed quenched solutions were 4.41 × 10^{-4} M in I. Key: (□) I; (○) II; (△) III.*

where γ is the mean activity coefficient for the hydrochloric acid solutions. For sodium hydroxide solutions:

$$\text{pH} = pK_w - \text{pOH} = pK_w + \log \gamma[\text{NaOH}] \qquad \text{(Eq. 3)}$$

where γ is the mean activity coefficient for the sodium hydroxide solution (15) and values of pK_w are $-\log K_w$ where K_w is the hydrolysis constant for water.

In a similar manner, some direct measurements of the first-order rate constants, k_2, for II solvolysis to ecgonine (V) and III, (Scheme I) were determined. Examples of the semilogarithmic plots of concentrations, C, against time are given in Fig. 8, and the determined rate constants k_2 at the specified conditions are given in Table V.

Determination of Rate Constants in the Sequential Hydrolysis of I—The overall rate constant, k, for the hydrolysis of I is the sum of the separate constants, k_1 and k_3, for the routes to II and III plus IV, respectively (Scheme I):

$$k = k_1 + k_3 \qquad \text{(Eq. 4)}$$

If I were hydrolyzed solely to II, *i.e.*, $k_3 = 0$, the concentration of generated II would be (16):

$$[\text{II}]' = [\text{I}]_0 \frac{k}{k_2 - k}(e^{-kt} - e^{-k_2 t}) \qquad \text{(Eq. 5)}$$

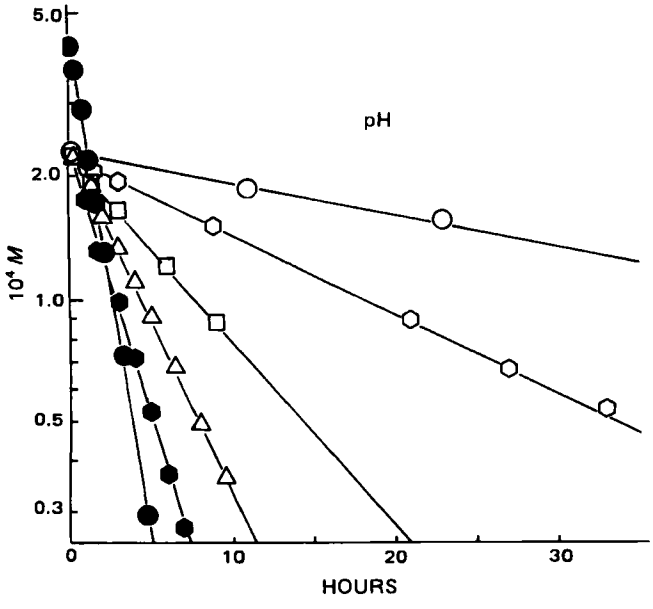

Figure 7—*Semilogarithmic plots of I in its quenched solutions against time for its solvolysis in the buffer at 30.0°. Key: (●) pH 10.33; (●) pH 8.94; (△) pH 8.55; (□) pH 8.15; (○) pH 7.72; (○) pH 7.25.*

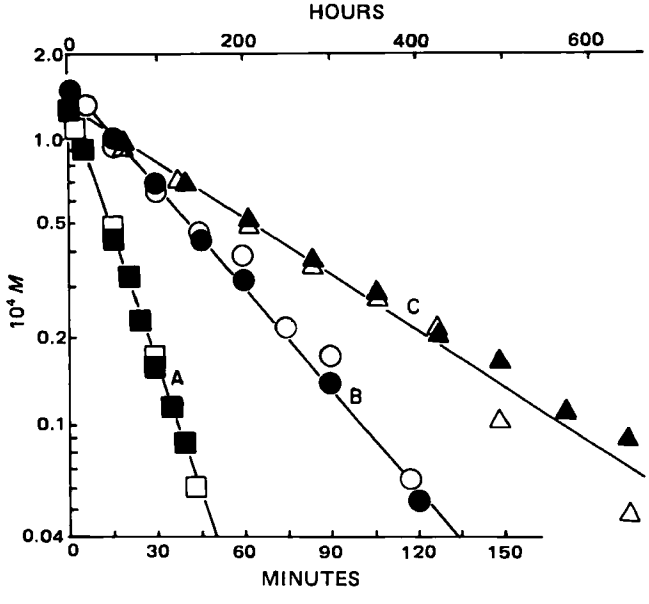

Figure 8—*Semilogarithmic plots of II concentrations (c_0 = 1.42 × 10^{-4} M) in quenched solutions against time. The solid symbols are for plots of II against time. The open symbols are for the difference plots of III, $[III]_\infty - [III]$ against time: A) 0.060 M NaOH, pH 12.32 at 30.0° against time scale in minutes; B) borate buffer, pH 8.92 at 80.0° against time scale in minutes; C) 0.04 M HCl solution, pH 1.41 at 80.0° against time scale in hours. The initial concentration of II in the reaction mixture was 8.52 × 10^{-4} M.*

Table IV—First-Order Rate Constants (k, sec^{-1}) [a]

[a] Rate constants for overall hydrolysis of I, for hydrolysis to II (k_1, sec^{-1}) and IV (k_3, sec^{-1}) and for the hydrolysis of III (k_2, sec^{-1}) to ecgonine in buffer solutions at 0.1 ionic strength (Scheme I). [b] The composition of the borate buffer in the reaction mixture was 0.1 *M* NaH_2BO_3 + 0.1 *M* H_3BO_3. [c] The borate buffer in footnote *b* was diluted 1:1 with 0.1 *M* NaCl. [d] The borate buffer in footnote *b* was diluted 1:3 with 0.1 *M* NaCl. [e] The composition of the phosphate buffer in the reaction mixture was 0.017 *M* NaH_2PO_4 + 0.017 *M* Na_2HPO_4 + 0.033 *M* NaCl. [f] The phosphate buffer of footnote *e* was diluted 1:1 with 0.1 *M* NaCl. [g] The phosphate buffer of footnote *e* was diluted 1:3 with 0.1 *M* NaCl. [h] The composition of the acetate buffer in the reaction mixture was 0.011 *M* CH_3COOH + 0.089 *M* CH_3COONa + 0.011 *M* NaCl. [i] The acetate buffer of footnote *h* was diluted 4:1 with 0.1 *M* NaCl. [j] The composition of the acetate buffer in the reaction mixture was 0.05 *M* CH_3COOH + 0.05 *M* CH_3COONa + 0.05 *M* NaCl. [k] The acetate buffer of footnote *j* was diluted 1:1 with 0.1 *M* NaCl. [l] The acetate buffer of footnote *j* was diluted 1:3 with 0.1 *M* NaCl. [m] The composition of the acetate buffer in the reaction mixture was 0.083 *M* CH_3COOH + 0.017 *M* CH_3COONa + 0.083 *M* NaCl. [n] The acetate buffer of footnote *m* was diluted 4:1 with 0.1 *M* NaCl. [o] The acetate buffer of footnote *m* was diluted 1:1 with 0.1 *M* NaCl. [p] The acetate buffer of footnote *m* was diluted 1:4 with 0.1 *M* NaCl.

where $[I]_0$ is the initial concentration of I and [II]′ is the predicted concentration of II on the presumption that the sole route of hydrolysis is:

$$I \xrightarrow{k} II + CH_3OH \xrightarrow{k_2} III + IV$$

However, if IV and III were also products of the hydrolysis of I, the actual concentration of II, would be (9, 17):

$$[II] = [I]_0 \frac{k_1}{k_2 - k}(e^{-kt} - e^{-k_2t}) \qquad \text{(Eq. 6)}$$

where

$$k_1/k = [II]/[II]' \qquad \text{(Eq. 7)}$$

Thus, the ratios of the observed experimental concentrations of II, [II], to the concentrations generated by Eq. 5 for a given time [II]′, will be constant, and the k_1 and k_3 values can be estimated from Eqs. 7 and 4, respectively.

The apparent first-order rate constant, k_2, for the hydrolysis of II could be obtained from the terminal slope of the semilogarithmic plots of its generation from I with time (Figs. 2, 4, and 6) or from the direct kinetic studies of II (Fig. 7, Table V).

An alternate method to deduce k_1 and k_2 values is to best fit Eq. 6 to the time-course data of experimentally determined concentrations of II with appropriate adjustments of k_1 and k_2 as was done in Figs. 2, 4, and 6 where the curves drawn through the data were drawn in accordance with Eqs. 1 and 6 for I and II, respectively. The appropriate constants are listed in Tables III–V. The calculated time curve for [III] was calculated from:

$$[III] = [I]_0 - [II] \qquad \text{(Eq. 8)}$$

The data show that, contrary to prior implications (5), the route to II is not the only route of hydrolysis of I at pH >1.0.

The fraction through the route for II on hydrogen ion attack on protonated I <pH 2.0 is 0.4 (Fig. 2 and Table III). The fraction through this route for hydroxide ion attack on neutral I >pH 11.5 is only 0.06 (Fig. 4, Table III), whereas the hydroxide attack on protonated I between pH 4 and 10 gives a fraction of 0.90 (Fig. 6, Table IV). There are intermediate fractions between the stated pH ranges.

Log k–pH Profiles for I—The log k–pH profiles (6) for the overall hydrolysis of I (Fig. 9), the log k_1–pH profiles for the hydrolysis of I through II (Fig. 10), and the log k_3–pH profiles for the hydrolysis of I through IV and III (Fig. 11) are fitted in accordance with:

$$k_i = (k'_{OH})_i\, a_{OH}\, [I] + (k_{OH})_i\, a_{OH}[IH^+] + (k_H)_i\, a_{H^+}\, [IH^+] \qquad \text{(Eq. 9)}$$

where k_i is k, k_1, or k_3; a_{H^+} and a_{OH^-} are the respective activities of the hydrogen and hydroxyl ions; [I] and $[IH^+]$ are the respective concentrations of neutral and protonated I; $(k'_{OH})_i$ is the specific bimolecular rate constant for hydroxide ion attack on neutral I; $(k_{OH})_i$ is the specific bimolecular rate constant for hydroxide ion attack on protonated I; and $(k_H)_i$ is the specific bimolecular rate constant for hydrogen ion attack on protonated I.

The acid branches of the log k_i–pH profiles can be fitted to:

$$\log k_i = \log (k_H)_i - pH \qquad \text{(Eq. 10)}$$

to obtain estimates of $(k_{H^+})_i$.

The alkaline branches are characterized by:

$$k_i = (k'_{OH})_i\, f_I\, a_{OH} + (k_{OH})_i\, f_{(IH^+)}\, a_{OH} \qquad \text{(Eq. 11)}$$

where f_I is the fraction of I concentration that is the neutral species, and $f_{(IH^+)}$ is the fraction that is the protonated species. These fractions can be calculated from the known pH, pK'_a, and pK_w values from:

$$f_I = \frac{K'_a}{K'_a + a_{H^+}} \qquad \text{(Eq. 12)}$$

$$f_{(IH^+)} = \frac{a_{H^+}}{K'_a + a_{H^+}} \qquad \text{(Eq. 13)}$$

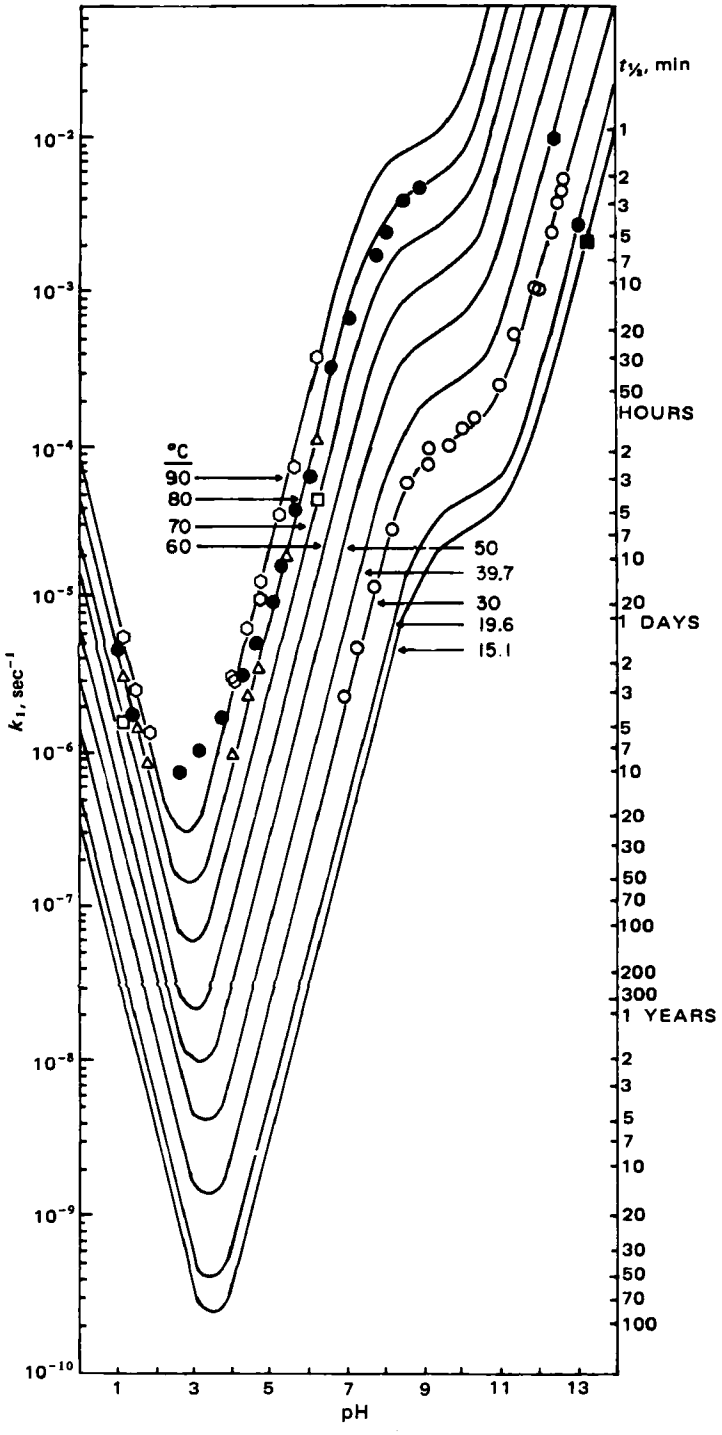

Figure 9—*Fitted and predicted log* k–*pH profiles for the overall hydrolyses of I at the designated temperatures. The fits and predictions are in accordance with:* $k = k_{H}a_{H^+} + k_{OH}\,[K_w/(K'_a + a_{H^+})] + k'_{OH}\,[K'_aK_w/(K'_a + a_{H^+})]$ *and* $\ln k_j = \ln P - 10^3\,(\Delta H_a/R)(1/T)$ *where the pertinent parameters are listed in Table VI,* ΔH_a *is in kcal/mole,* $a_{H^+} = 10^{-pH}$ *and* T *is in degrees Kelvin. The solid symbols are previously reported data (Ref. 5) for rate constants obtained at 80° plotted against the stated pH values for the various buffer solutions.*

where $a_{H^+} = 10^{-pH}$, $K_w = 10^{-pK_w}$ and $K'_a = 10^{-pK'_a}$. Since $K_w = a_{H^+}a_{OH^-}$, Eq. 11 can be modified to:

$$k_i = (k'_{OH})_i \frac{K'_a K_w}{(K'_a + a_{H^+})a_{H^+}} + (k_{OH})_i \frac{K_w}{(K'_a + a_{H^+})} \qquad \text{(Eq. 14)}$$

which was used to fit the alkaline branches of the log k_i–pH profiles of Figs. 9–11 with the parameters listed in Table VI.

The potentiometrically determined pK'_a of I was 8.81 at 25°. The apparent pK'_a values obtained by extrapolation of the pH-values of half-neutralization back to time zero were 8.81 at 25°, 8.70 at 30°, 8.30 at 60°, 8.19 at 70°, 8.04 at 80°, and 7.95 at 90°. These pK'_a values can be characterized by $1429(1/T) + 4.02$, where T is degress Kelvin but are suspect, since degradation of I at these pH-values and temperatures were fast. When the kinetic pK'_a values of best fit at 30 and 80° were used to esti-

[a] The pH-values for [NaOH] and [HCl] solutions were calculated from $pH = pK_w + \log f_{NaOH}[NaOH]$ and $pH = -\log f_{HCl}[HCl]$, respectively, from the pK_w values and activity coefficients, f_{NaOH} and f_{HCl}, available in the literature (15) for the designated temperatures.

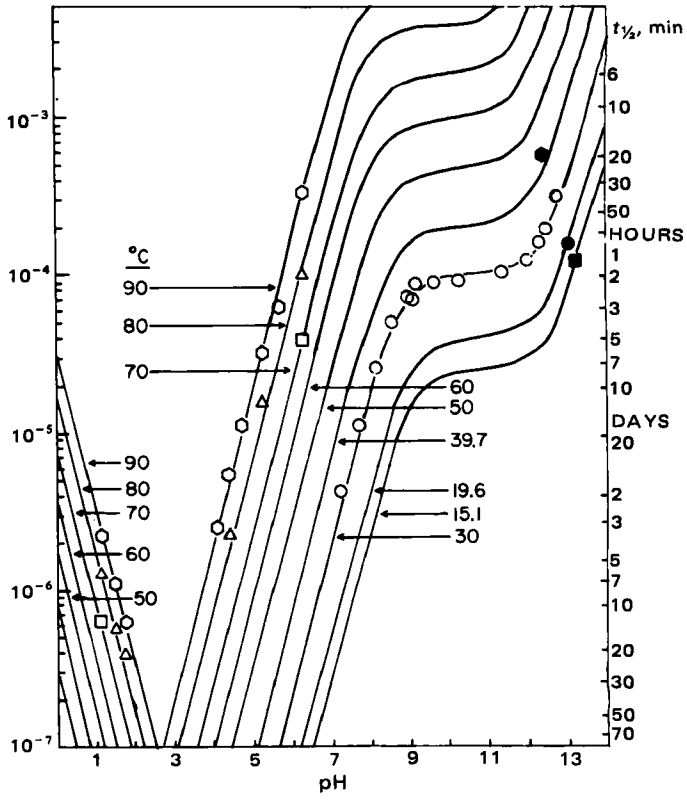

Figure 10—*Fitted and predicted log* k_1–*pH profiles for the hydrolysis of I to II at the designated temperatures. The fits and predictions are in accordance with:* $k_1 = (k_H)_1a_{H^+} + (k_{OH})_1\,[K_w/(K'_a + a_{H^+})] + (k'_{OH})_1\,K'_aK_w/[(K'_a + a_{H^+})a_{H^+}]$ *and* $\ln k_j = \ln P - 10^3(\Delta H_a/R)(1/T)$ *where the pertinent parameters are listed in Table VI,* ΔH_a *is in kcal/mole,* $a_{H^+} = 10^{-pH}$ *and* T *is in degrees Kelvin.*

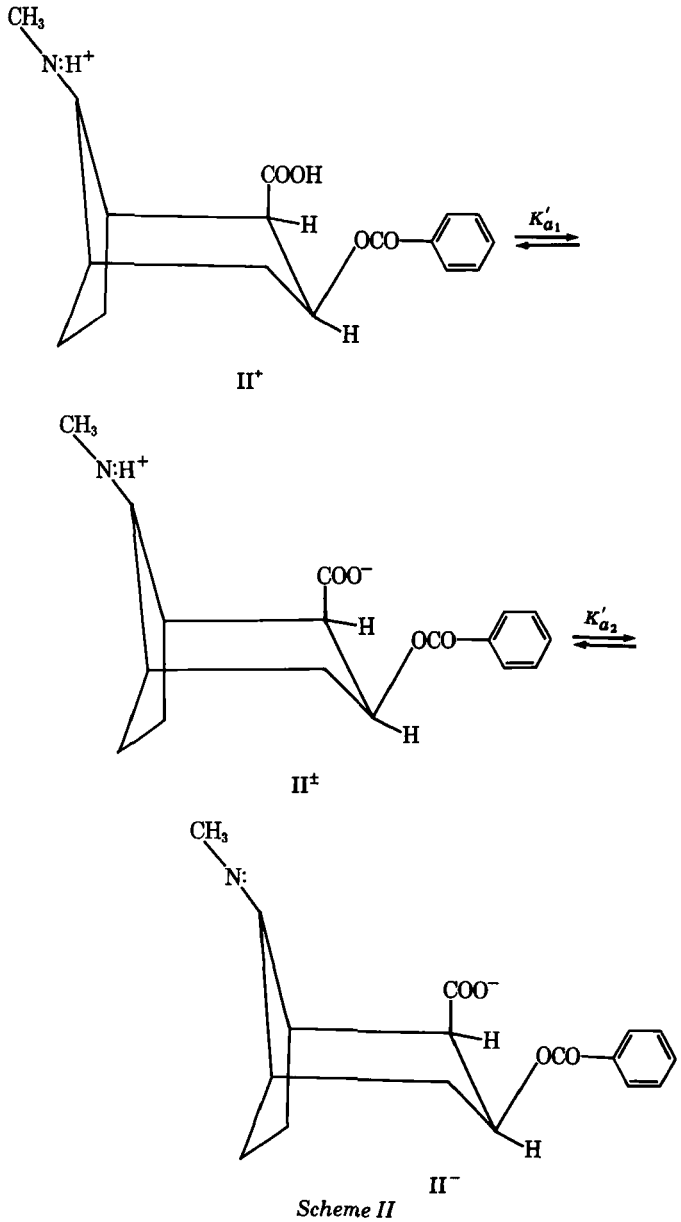

Scheme II

mate temperature dependency, the expression was $1938(1/T) + 2.22$. These values were used in the predicted log k–pH profiles of Figs. 9–11 and are listed in Table VI. The kinetic pK'_a of 7.7 at 80° was estimated from previously reported data (5) on the assumption that the given pH values were measured at the temperature of the reaction. Unfortunately, it was not stated (5) whether or not this was true, so that the possibility of erroneously chosen pH values at 80° cannot be excluded.

The apparent first-order rate constants given previously (5) for studies conducted at 80° and at concentrations tenfold higher than those studied here agreed with the predicted values (Fig. 9) in the 5–6.5 and 0–2 pH ranges. The values were significantly higher than the predicted values in the 2.5–4.5 range. It was probably due to the observed (5) enhancing buffer effects on rate by the citric acid–potassium citrate buffer solution used in the pH 2.2–4.8 range. No general acid–base effects were observed with the buffers used in these present studies.

Log k_2–pH Profiles for II—The log k_2–pH profiles for the solvolysis of II are given in Fig. 12 and were fitted with the estimated parameters given in Table V. The two pK'_a values for II (Scheme II) at room temperature were determined potentiometrically and were 11.75 and 2.1. In this case the acid branch (Eq. 10) of the log k–pH profile would be for the attack of hydrogen ion on the protonated II, whereas below the pK'_{a2} of 11.75, the alkaline branch would be for the hydroxide ion attack on the zwitterion. Above this value, the attack of hydroxide ion would be on the negatively charged compound, and:

$$k_2 = (k'_{OH})_2 f_{II^+} a_{OH} + (k_{OH})_2 f_{II^\pm} a_{OH} \qquad \text{(Eq. 15)}$$

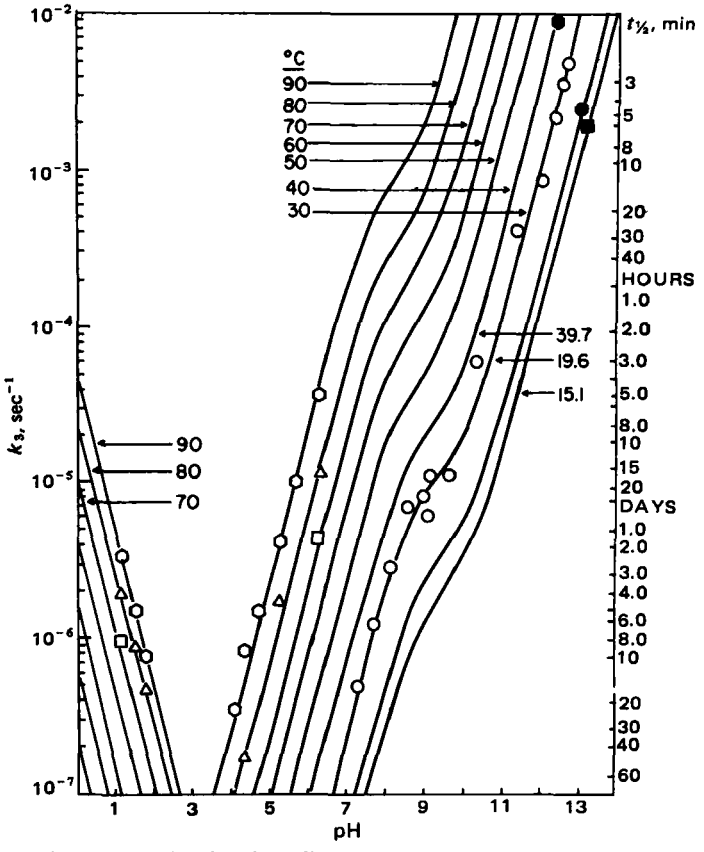

Figure 11—*Fitted and predicted log* k_3*–pH profiles for the hydrolysos of I to IV at the designated temperatures. The fits and predictions are in accordance with:* $k_3 = (k_H)_3 a_{H^+} + (k_{OH})_3 [K_w/(K'_a + a_{H^+})] + (k'_{OH})_3 K'_a K_w/[(K'_a + a_{H^+})a_{H^+}]$ *and ln* $k_j = ln\ P - 10^3(\Delta H_a/R)(1/T)$ *where the pertinent parameters are listed in Table VI,* ΔH_a *is in kcal/mole,* $a_{H^+} = 10^{-pH}$ *and T is in degrees Kelvin.*

where the respective fractions of anionic II (f_{II^-}) and zwitterionic II ($f_{II^\pm}$) >pH 3 are:

$$f_{II^+} = \frac{(K'_{a2})_{II}}{(K'_{a2})_{II} + a_{H^+}} \qquad \text{(Eq. 16)}$$

and:

$$f_{II^\pm} = \frac{a_{H^+}}{(K'_{a2})_{II} + a_{H^+}} \qquad \text{(Eq. 17)}$$

where the pertinent charged structures are given in Scheme II.

Thus, the alkaline branch above pH 6 can be fitted to:

$$k_2 = \frac{(k'_{OH})_2 (K'_{a2})_{II} K_w}{[(K'_{a2})_{II} + a_{H^+}]a_{H^+}} + \frac{(k_{OH})_2 K_w}{(K'_{a2})_{II} + a_{H^+}} \qquad \text{(Eq. 18)}$$

and the acid branch $<pK'_{a1}$ of 2.1 can be fitted to:

$$k_2 = (k_{H^+})_2 f_{II^+} a_{H^+} \qquad \text{(Eq. 19)}$$

where the fraction of protonated II (Scheme II) is:

$$f_{II^+} = \frac{a_{H^+}}{(K'_{a1})_{II} + a_{H^+}} \qquad \text{(Eq. 20)}$$

The fact that there is a pH-independent segment of the log k_2–pH profile at pH 4–5 at the studied temperatures of 80 and 90°, indicates an additional functional dependency for the first-order rate constant, k_2. This additional factor can be rationalized by an hydroxyl ion attack on positively charged II or its kinetic equivalent of water attack on the zwitterion ($II^\pm$):

$$(k_0)_2 f_{II^\pm} = (k''_{OH})_2 a_{OH} f_{II^+} = (k_0)_2 \frac{K'_{a1}}{a_{H^+} + K'_{a1}}$$

$$= (k''_{OH})_2 a_{OH} \frac{a_{H^+}}{a_{H^+} + K'_{a1}} = \frac{(k''_{OH})_2 K_w}{a_{H^+} + K'_{a1}} \qquad \text{(Eq. 21)}$$

where $(k''_{OH})_2 K_w = (k_0)_2 K'_{a1}$.

Thus, an additional dip ~pH 2–4 in the log k_2–pH profile of II can be

[a] Log k_i–pH profiles are from Figs. 9–11; the apparent first-order rate constants (k, k_1, and k_3) for the routes of Scheme I are in sec^{-1}, where the given bimolecular rate constants are in liter/mole/sec, ΔH_a is in kcal/mole, and $\Delta S^\ddagger$ is in entropy units (eu) where $\Delta S^\ddagger = R[\ln P - (\ln k_B T/k)]$, the Boltzmann constant $k_B = 1.387 \times 10^{-16}$ erg/deg and the Planck constants $h = 6.623 \times 10^{-27}$ erg sec, and T is 313°K. [b] Values at 30 and 80° were obtained from the best log k–pH fit at these temperatures. Values at other temperatures were calculated from $pK'_a = 1938(1/T) + 2.22$.

predicted (dashed line in Fig. 12). This could be calculated exactly if the K'_{a1} values of Eq. 20 were known at all temperatures. The total dependency would be:

$$k_2 = (k_H)_2 a_{H^+} \frac{a_{H^+}}{a_{H^+} + K'_{a1}} + (k_0)_2 \frac{K'_{a1}}{a_{H^+} + K'_{a1}} + (k_{OH})_2 \frac{K_w}{K'_{a2} + a_{H^+}} + (k'_{OH})_2 \frac{K'_{a2} K_w}{[K'_{a2} + a_{H^+}] a_{H^+}} = (k_H)_2 a_{H^+} f_{II^+} + [(k_0)_2 + (k_{OH})] f_{II^\pm} + (k'_{OH})_2 f_{II^-} \quad \text{(Eq. 22)}$$

Temperature Dependency and Strategy for Stability Prediction—Studies of this nature delineate stabilities or reaction rates at all temperatures and pH-values with a minimum of experimental effort. An appropriate strategy is to determine first the functional kinetic dependencies from the dependence of the apparent first-order rate constant, k, on pH at a given temperature. If this were accomplished, pH regions could be ascertained where the only significant reaction was due to the attack of one ion on only one ionic species of substrate, *e.g.*, hydroxyl ion attack on protonated I with a bimolecular rate constant of k_{OH}. Similarly, the k_H bimolecular rate constant (Eq. 22) for hydrogen ion catalysis could be determined in the highly acidic pH region.

The specific bimolecular rate constant for hydroxyl ion catalysis, k_{OH}, of a unique ionic substrate species can be determined readily, since:

$$\log k_{OH} = \log k + pK_w - \text{pH} \quad \text{(Eq. 23)}$$

and k_{OH} can be estimated from any k–pH pair in the region where a linear positive slope of unity exists in the log k–pH profile. Similarly, the bimolecular rate constant for hydrogen ion catalysis, k_H, of a unique ionic substrate species can be determined from:

$$\log k_H = \log k + \text{pH} \quad \text{(Eq. 24)}$$

and k_H can be estimated from any k–pH pair where a linear negative slope of unity exists in the log k–pH profile.

Such bimolecular rate constants, k_j, which may be either k_{OH}, k'_{OH}, or k_H, can be related to temperature by the Arrhenius rule:

$$\ln k_j = \ln P - \left(\frac{10^3 \Delta H_a}{R}\right)\frac{1}{T} \quad \text{(Eq. 25)}$$

where ΔH_a is the heat of activation (kcal/mole) and T is the absolute temperature (degrees Kelvin). The k_j-values at several temperatures could be estimated from a single k–pH pair obtained at a given temperature in the pH region, where only one catalytic process was extant. Arrhenius plots of such bimolecular rate constants for the solvolysis of I and II in accordance with Eq. 25 are given in Fig. 13, and the determined Arrhenius parameters, ΔH_a and ln P, are listed in Tables VI and VII. For the experimental convenience of limiting the times of kinetic studies without being excessively fast, Arrhenius parameters were obtained at high temperatures (70–90°) for hydrogen ion (k_H) and hydroxyl ion (k_{OH}) attack on protonated I ($I{\cdot}H^+$) and at low temperatures (15–40°) for hydroxyl ion attack (k'_{OH}) on neutral I (Figs. 9–11). Similar choices of appropriate temperatures and pH ranges were made in the studies of II (Fig. 12) for appropriate calculations of bimolecular rate constants (k_j) and subsequent estimations of their Arrhenius parameters (Fig. 13, Table VII).

If pK'_a values were known at several temperatures, as from independent potentiometric titrations, the apparent first-order rate constants, k_i, could be calculated readily in the intermediate pH regions where several rate processes exist concomitantly, from expressions such as Eq. 14 for the solvolysis of I and Eqs. 18 and 22 for the solvolysis of II. The respective bimolecular rate constants, k_j, at the respective temperatures as listed in Tables VI and VII could be calculated from Eq. 25 using the determined Arrhenius parameters.

If apparent first-order rate constants were obtained in the pH region of transition from one rate process to another (*e.g.*, at pH 7–11 where solvolytic dependencies of I change from hydroxyl ion attack on the protonated species to that on a neutral species as in Figs. 9–11), the pK'_a for the dissociation of the substrate as an acid can be obtained by fitting the more complex dependency of the apparent first-order rate constant, k, on pH on K'_a. In the case of I, Eq. 14 was fitted with a best-estimated pK'_a in this transition region at 30°, where k_{OH} and k'_{OH} had been determined from linear segments of the log k–pH profiles from application of Eq. 23.

In the case of II, Eq. 18 could be fitted with a best-estimated K'_{a2} in the transition pH region where reaction dependency changes from hydroxyl ion attack on the zwitterion to hydroxyl ion attack on the anion of II if the $(k_{OH})_2$ and $(k'_{OH})_2$ values were known. Unfortunately, the high pK'_{a2} (11.75 at room temperature) of the zwitterion of II (Scheme III) does not

Table VII—Parameters for the log k_2^a–pH Profiles for the Hydrolyses of II

[a] The parameter $\ln k_i = \ln P - (10^3\,\Delta H_a/R)(1/T)$ where R = 1.987 cal/deg and ΔH_a is in kcal/mole.

permit the immediate determination of $(k'_{OH})_2$ from a linear segment of the pH profile (Fig. 12) above a pH equal to pK'_{a2}. The experimentally determined apparent first-order rate constants (k_2) for the solvolysis of II in strong alkali were still in the region of the pK'_{a2} value. Estimates of both pK'_{a2} and $(k'_{OH})_2$ that were consistent with the first-order rate constants, k_2 in this transition region, were made in accordance with Eq. 18 and are given in Table VII. These pK'_{a2} values can be characterized by $4556(1/T) - 3.33$. The pK'_{a2} values calculated accordingly were used in the predicted log k_2–pH profiles of Fig. 12 and are listed in Table VII.

There is a caveat for those who wish to use these strategies in prediction of stabilities. Prediction at temperatures other than those studied should not be made based on Arrhenius parameters (Eq. 25, Table VIII, Fig. 14) for studies conducted in the same buffer solutions at several temperatures. Comparison of apparent heats of activation for the bimolecular rate constants (Table VI) and the apparent first-order rate constants (Table VIII) shows wide discrepancies in many instances. For example, the estimated $(\Delta H_a)_{k_j}$ (kcal/mole) for the apparent first-order rate constants of solvolysis of I in pH 6.25 phosphate buffer were 26.2, k; 26.5, k_1; and 27.3, k_3; whereas the $(\Delta H_a)_{k_j}$ values for the bimolecular rate constants representative of hydroxyl ion attack on protonated I were 12.3, k_{OH}; 11.8, $(k_{OH})_1$; and 11.8, $(k_{OH})_3$. These latter values are typical of hydroxyl ion-catalyzed solvolysis of esters.

The reason for these discrepancies are simple. Since:

$$k = k_{OH}a_{OH} = k_{OH}K_w/a_{H^+} \qquad \text{(Eq. 26)}$$

or in general:

$$k_i = k_j a_{OH} = k_j K_w/a_{H^+}$$

then:

$$\ln k = \ln k_{OH} - \text{pOH} = \ln k_{OH} + \text{pH} - pK_w \qquad \text{(Eq. 27)}$$

Each apparent logarithm of the rate constant and that of the K_w can be expressed by a relation such as Eq. 25, and therefore:

$$\ln P_{k_i} - (\Delta H_a)_{k_i}/RT = \ln P_{k_j} - (\Delta H_a)_{k_j}/RT + \text{pH} - (\ln P_{K_w} + \Delta E_{K_w}/RT) = \ln P_{k_j} - \ln P_{K_w} + \text{pH} - [(\Delta H_a)_{k_j} - (\Delta E)_{K_w}]/RT \qquad \text{(Eq. 28)}$$

Table IX—Red Blood Cell Partitioning of I

	$[I]_0$, μg/ml	Equilibration time, min	D
Whole blood	10	60	0.754
	10	120	0.752
Red blood cell–phosphate buffer (pH 7.4)	10	60	0.789
	10	120	0.612
Red blood cell–plasma water	4	35	0.758
	3	35	0.902
	2	35	0.753

Table X—Red Blood Cell Partitioning of II [a]

		D	
$[II]_0$	Blood	Red Blood Cell–Phosphate Buffer (pH 7.4)	Red Blood Cell–Plasma Water
10	0.91	0.88	—
5	1.18	1.34	1.34
1	0.88	0.66	0.95, 0.84
0.5	0.85	0.98	—
2.5	0.88, 0.67, 0.74	—	—

[a] After 25-min equilibration.

Thus:

$$\ln P_{k_i} = \ln P_{k_j} - \ln P_{K_w} + \text{pH} \qquad \text{(Eq. 29)}$$

and entropies of activation calculated from $\ln P_{k_i}$ are pH dependent and are not valid estimates. Also:

$$(\Delta H_a)_{k_i} = (\Delta H_a)_{k_j} - \Delta E_{K_w} \qquad \text{(Eq. 30)}$$

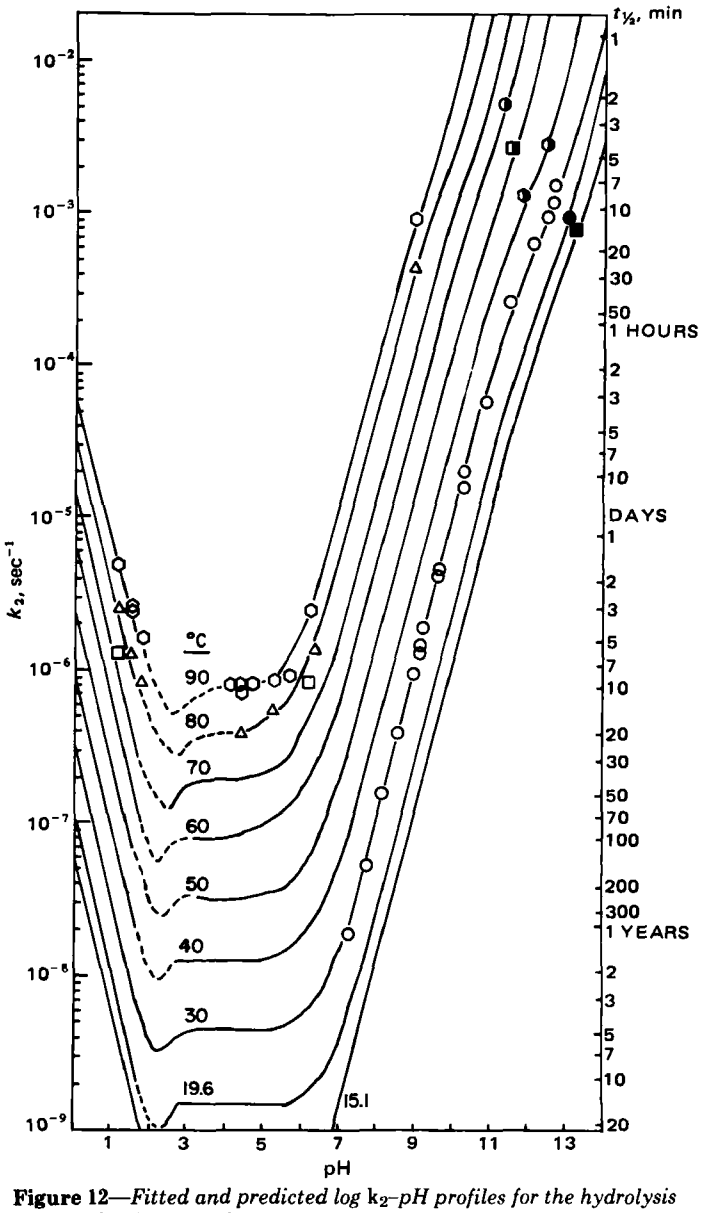

Figure 12—*Fitted and predicted log* k_2*–pH profiles for the hydrolysis of II at the designated temperatures. The fits and predictions are in accordance with:* $k_2 = (k_H)_2 a_{H^+}\,[a_{H^+}/(a_{H^+} + K'_{a_2})] + (k_0)_2\,[(K'_a)_1/(a_{H^+} + K'_{a_1})] + (k_{OH})_2\,[K_w/(K'_{a2} + a_{H^+})] + (k'_{OH})_2\,[K'_{a2}K_w/(K'_{a2} + a_{H^+}a_{H^+})]$ *and* $\ln k_j = \ln P - 10^3(\Delta H_a/R)(1/T)$ *where the pertinent parameters are listed in Table VII,* ΔH_a *is in kcal/mole,* $a_{H^+} = 10^{-pH}$ *and T is in degrees Kelvin. Since the* $p(K'_a)_1 = 2.1$ *was only estimated at room temperature, the given dashed segments of the profiles at other temperatures are only estimates of the dependencies.*

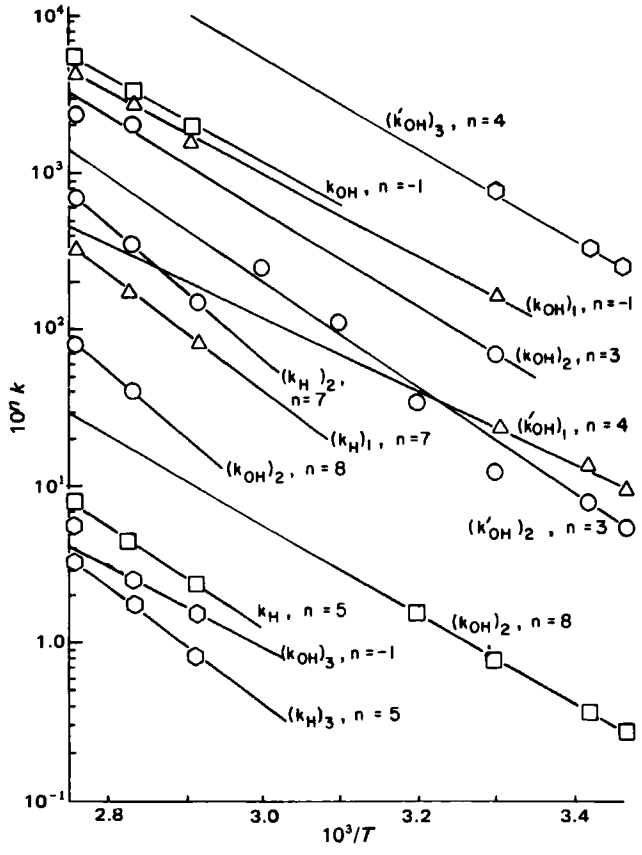

Figure 13—*Arrhenius plots (ln* k_j, *liters mole*$^{-1}$ *sec*$^{-1}$, versus *1/T where T is in degrees Kelvin) for the bimolecular rate constants for hydrogen ion-catalyzed solvolyses of I: overall,* k_H; *to II* $(k_H)_1$; *to IV* $(k_H)_3$; *and for the acid-catalyzed solvolysis of II,* $(k_H)_2$. *Also, for the hydroxyl ion-catalyzed solvolysis of protonated and neutral I, respectively: overall,* k_{OH} *and* k'_{OH}; *to II,* $(k_{OH})_1$ *and* $(k'_{OH})_1$; *to IV,* $(k_{OH})_3$ *and* $(k'_{OH})_3$; *and for the respective hydroxyl ion-catalyzed solvolysis of zwitterionic and anionic II,* $(k_{OH})_2$ *and* $(k'_{OH})_2$. *The* $(k_0)_2$ *is for the attack of water on the zwitterion of II.*

and heats of activation calculated from the apparent first-order rate constants obtained from the same buffer solutions studied at different temperatures always exceed the heats of activation calculated from the bimolecular rate constants and are not valid estimates.

The assertions (5) that the maximum stability of I was pH 1.95 and that II was the solvolytic product needs to be modified in light of these present studies; compound IV is also produced (Tables III and IV, Fig. 11). The maximum stabilities of I are at the minima of the log-pH profiles of Fig. 9 and vary between pH 3.2 and 3.8 from 15 to 90°. The maximum stabilities of II (Fig. 12) are ~pH 1.8.

The apparent heats of activation of the apparent first-order rate constants for solvolysis of I were given previously (5) as 22.9 kcal/mole at pH 6.8, 25.6 kcal/mole at pH 5.0, and 23.4 kcal/mole at pH 2.2. The values were not inconsistent with that of 26.2 kcal/mole determined at pH 6.25 in this investigation.

Applications of Plasma Assays to Stabilities of I in Fresh Plasma—The stability of I was monitored by HPLC assay in fresh dog plasma. A study of 8.8×10^{-3} *M* (299 μg/ml) I at 38.9° (Fig. 15) by HPLC Procedure II showed an apparent half-life of 5.44 hr ($k = 3.54 \times 10^{-5}$ sec^{-1}), close to the half-life of I in phosphate buffer at that temperature (Table IV, Fig. 9). The data for II in Fig. 15 could be well-fitted by the procedures outlined relative to Eqs. 4–8 and were consistent with 90% of I being hydrolyzed through the route for hydrolysis of II, the same product of aqueous solvolysis at this pH. An approximate estimate of hydrolysis of II could be estimated with a half-life of >100 hr ($k_2 = 1.9 \times 10^{-6}$ sec^{-1}).

An additional study at an initial concentration of 8.8×10^{-4} *M* I in dog plasma (30 μg/ml) using HPLC procedure III showed a similar apparent half-life (Fig. 15) for I of $t_{1/2}$ = 6.0 hr and demonstrated no significant change for this tenfold dilution of substrate. However, the fraction hydrolyzing through the route for II was only 0.5 under these conditions.

Additional studies on plasma stability of I were conducted at 1000, 500, and 250 ng/ml in the same fresh dog plasma by HPLC procedure IV (Fig. 15) and showed half-lives of 1.98, 2.08, and 1.9 hr, respectively. This signified a more than doubling of the plasmolysis rate at the lower concentrations of I to indicate a possible saturation of hydrolyzing enzymes at the higher concentrations of I. The possible increase in hydrolysis rates (dashed lines, Fig. 15) at high initial cocaine concentrations was confirmed.

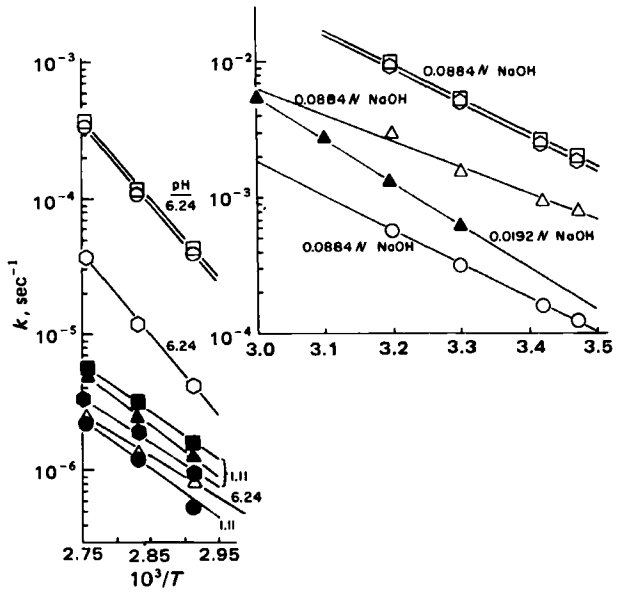

Figure 14—*Arrhenius plots (ln* k_i *sec*$^{-1}$ versus *1/T where T is in degrees Kelvin) for (□)* k, *(○)* k_1, *(△)* k_2, *and* k_3 *(○) rate constants at the labeled specified conditions.*

Red Blood Cell–Plasma and –Buffer and –Plasma Water Partitioning and Protein Binding of I and II—The assayed plasma or plasma water concentrations of I, $[I]_p$, were substituted into the following

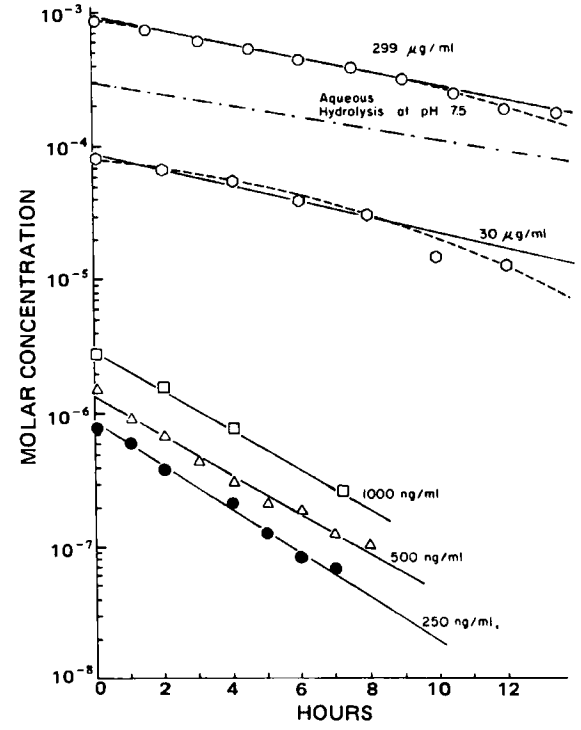

Figure 15—*Semilogarithmic plots of I in fresh dog plasma against time at 38.9° with the designated initial concentrations of I* (I_0). *The solid lines were drawn on the premise of first-order disappearance of I, although accelerating rates with time (dashed lines) are possible at the higher concentrations. The time course of hydrolysis of I in aqueous pH 7.5 buffers is also given (---) for comparison. Key: (●) 250 ng/ml; (△) 500 ng/ml; (□) 1000 ng/ml; (○) 30 μg/ml; (○) 299 μg/ml.*

equation to determine the concentration of I in red blood cells ($[I]_{RBC}$):

$$[I]_{RBC} = \frac{I - [I]_p V(1 - H)}{VH} \quad \text{(Eq. 31)}$$

where I is the amount of cocaine added to a volume (V) of blood or synthetic blood with an H fraction of this volume as red blood cells. The I-values used were calculated from $I = I_0 e^{-kt}$ where I_0 is the amount of I added at t minutes before assay, and k is the apparent first-order rate constant of degradation of I in the system. The apparent red blood cell–plasma partition coefficient was $D = [I]_{RBC}/[I]_p$; values are given in Table IX. The fact that there is no significant difference among systems with and without plasma proteins is indicative of no significant protein binding of I.

Similar studies were conducted with II (Table X). Although the data are more variable than in the case for I, the reasonable consistency of red blood cell–plasma and red blood cell–buffer or plasma water coefficients (D) in parallel studies at a given concentration of II ($[II]_0$) is indicative of negligible plasma protein binding of II.

Since I has relatively high solvolysis rates in plasma and buffers, plasma protein binding studies by equilibrium dialysis or ultracentrifugation are not applicable, since they take relatively long periods of time. An attempt to use ultrafiltration through filter cones (17) was not satisfactory, since I was variable and highly bound to the filter cones. When 4 ml of plasma and 4 ml of plasma–water were filtered to the same extent through individual fresh cones, the percent of the filtered 1-μg/ml solution recovered was 32 ± 1% for plasma–water and 23 ± 1% for plasma to indicate a possible plasma protein binding of 8% for I. The filter cones were pre-equilibrated with buffer containing the same concentrations of I in plasma that were to be filtered through those same cones. The percent concentration recovered in the filtrate in the same cone from buffer filtration and subsequent plasma filtration, respectively, was 46.3 and 54.6 at 2 μg/ml and 48.8 and 54.6 at 1 μg/ml.

However, when the same two filtrations in the same cone were effected using only buffer, the percent concentration of I recovered in the same cone was 43.8 and 56.2 at 1 μg/ml and 38.8 and 61.3 at 0.5 μg/ml. This mimicked the situation when the second filtration was of I-spiked plasma to show that the loss of I in the filtrate was due to its binding to the cones on successive filtrations and that it could not be assigned to plasma protein binding.

Spectral Analysis of the Configuration and Solution Conformation of Dihydrodigoxigenin Epimers

HOWARD N. BOCKBRADER * and RICHARD H. REUNING ˣ

Received November 21, 1980, from the *College of Pharmacy, The Ohio State University, Columbus, OH 43210.* Accepted for publication May 12, 1982.

*Present address: Pharmaceutical Research Division, Warner-Lambert/Parke-Davis, Ann Arbor, MI 48106.

Abstract □ The C_{20} configuration and solution conformation of each epimer of dihydrodigoxigenin has been studied by circular dichroism (CD) and NMR spectroscopy. Results from the CD spectra indicate that the two epimers have opposite orientations of the β-carbon in the lactone ring. This finding, together with X-ray crystallographic data from a separate study on the minor epimer, establishes the C_{20} configuration of the minor epimer as *S* and of the major epimer as *R*. NMR evidence indicates that the average lactone rotamer for the minor epimer has the C_{22} position located on the C_{12} side of the steroid nucleus, whereas the average lactone rotamer for the major epimer has the C_{21} position located on the C_{12} side of the steroid nucleus. Molecular models indicate that these are the least-hindered positions for the respective rotamers. Physical data characterizing the two epimers are provided.

0022-3549/83/0300-0271$01.00/0

I R = H
II R = digitoxose$_3$

ylene chloride extract of urine present as II. Of the 50 subjects in this study, 48 had detectable urinary levels of II. Urine samples of 100 patients taking oral digoxin for the control of heart disease were investigated more recently (8, 9). The average percent of cardanolides present in the 0–24-hr urine was 12% (range 2–52%) based on the total methylene chloride extractable cardiac glycoside content. Out of the 100 patients, 53 excreted >10% while seven excreted >35% as the cardanolide metabolites.

Reduction of the 20,22-unsaturated lactone ring of digoxin introduces a center of asymmetry at C_{20} and generates three aspects of stereochemistry that must be investigated in order to determine the conformation of any epimers of I or II. First, the resulting saturated γ-lactone has the β-carbon out of plane, thus creating the possibility of the enantiomeric pair illustrated in Fig. 1 (10, 11). Second, the chiral center at C_{20} can have either an *R* or *S* configuration. Finally, the overall asymmetry of the steroid nucleus and the likely steric hindrance to free rotation of the lactone ring about the C_{17}—C_{20} bond results in the possibility of preferred rotamers for the lactone.

Research on the C_{20} configuration and the lactone conformation of the reduced metabolites of digoxin has been inhibited by the lack of methodology for effective separation of any epimers that may be formed either biologically or chemically. Most of the metabolic studies (1–9, 12, 13) have utilized either TLC or GC techniques which have yielded only a single peak for either reference or biologically produced I or II. In an investigation of the crystallographic conformation, C_{20} configuration, and biological activity of various cardanolides (14–17), a TLC procedure was recently reported capable of separating certain 20*R* and 20*S* cardanolide epimers (18). However, this method has not yet been applied to the epimers of I or II.

Since II is an important metabolite of digoxin, it is critical that the stereochemical properties of this metabolite be determined. Essential to this determination is the

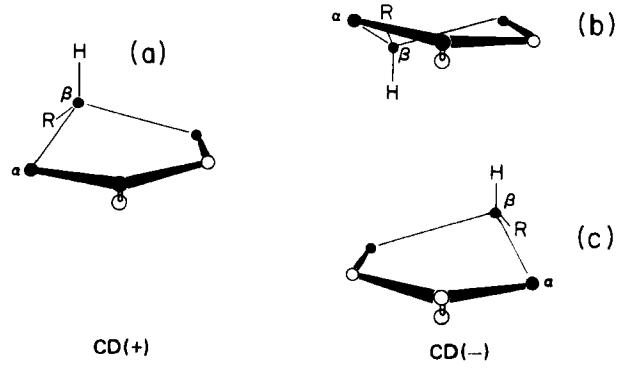

Figure 1—*Perspective representation of the two stable conformations of the γ-lactone. A positive CD spectrum is associated with conformation (a) and a negative CD spectrum with (b). Representation (c) is rotated 180° about the β carbon compared with (b) and* R *represents the steroid nucleus shown in I.*

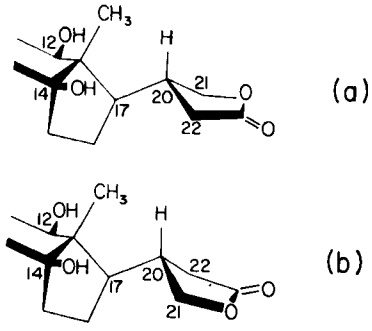

Figure 2—*Perspective representation of the relationships of the γ-lactone to the steroid nucleus wherein the 17—20 bond is pseudoequatorial, and the lactone rotamer has the oxygens oriented away from the methyl substituent at C_{13}. Structure (a) has the* R *configuration at C_{20}, and structure (b) has the* S *configuration.*

identification of suitable synthetic references with known stereochemistry so that subsequent comparisons to biologically produced metabolites may be made. Previous researchers (19) hydrogenated digoxigenin and fractionally crystallized the product yielding two epimers. However, that stereochemical assignment was based only on melting point and optical rotation values. The purpose of the present investigation was to define the C_{20} configuration and solution conformation of the epimers of synthetic I, the aglycone of II. It was not possible to carry out a definitive study on II because of interference from the sugar moieties in the interpretation of the various spectra.

RESULTS AND DISCUSSION

Catalytic hydrogenation of either digoxin or digoxigenin yielded two components that were separable as the 3,5-dinitrobenzoyl esters on high-performance liquid chromatography (HPLC). The component with the longer retention time on a normal phase system was present in larger amount and is designated the major fraction. Isolation of the derivatized major and minor fractions of I was accomplished by collecting the HPLC eluate. The corresponding underivatized fractions were then obtained by base hydrolysis. It was also possible to isolate the major underivatized fraction of I by fractional crystallization, but not the minor underivatized fraction. These major and minor fractions were each then subjected to spectral analysis for information concerning the conformation of the lactone ring, the configuration at C_{20}, and the preferred average rotamer of the lactone in relation to the steroid backbone.

Lactone Conformation and C_{20} Configuration—Associated with the optically active lactone is the $n \rightarrow \pi^*$-absorption band in the region of 214–219 nm. Circular dichroism studies have shown that a lactone ring will have a CD curve whose sign and magnitude are determined by the interactions within the lactone ring structure (10). Previous evidence (10, 11, 20, 21) has shown that the sign of the lactone CD curve for γ-lactones is associated with the location of the β-carbon relative to the planar lactone ring. The orientation of the plane is such that the α- and γ-carbons and the lactone moiety form the plane, the carbonyl function faces forward, and the ring oxygen is located to the right (Fig. 1a and b). The CD curve is positive when the conformation of the γ-lactone has the β-carbon above the plane and negative when the β-carbon is below the plane.

Results of the CD study of I revealed that the underivatized major component had a positive CD curve ($[\theta]_{218} = 136$) and the underivatized minor component had a negative CD curve ($[\theta]_{216} = -206$). These results indicate that the β-carbon of the lactone (C_{20} of I) is oriented as in Fig. 1a for the major component of I and as in Fig. 1b for the minor component. The energetically preferred position for the steroid substituent on the β-carbon would appear to be pseudoequatorial as shown in Fig. 1. In support of this viewpoint, the 22-methylene analogue of dihydrodigitoxigenin has been shown by X-ray crystallographic data (16) to have the steroid part of the molecule in a pseudoequatorial position at C_{20}. If this is the case for dihydrodigoxigenin, then the configuration at C_{20} (β-carbon of the lactone) is 20*R* for the major component and 20*S* for the minor component of I. This interpretation of the spectral data with respect to lactone conformation and C_{20} configuration has been confirmed by direct

X-ray crystallographic determination of the structure of the minor epimer (22).

Preferred Rotamer For Lactone—When either the 20*R* or 20*S* epimer of I is illustrated with Dreiding models and the molecule is rotated about the C_{17}—C_{20} bond, the conformation having the least steric hindrance with the C_{18}-methyl is that rotamer in which the lactone is oriented away from the C_{18}-methyl. This is illustrated for the 20*R* epimer of I in Fig. 2a. To orient the lactone away from the C_{18}-methyl in the 20*S* epimer it is necessary to rotate the lactone conformation shown in Fig. 1b by ~180° to that shown in Fig. 1c. The result for the dihydrodigoxigenin 20*S* epimer is shown in Fig. 2b.

A strategy was developed for testing the hypothesis that the two epimers of I have the lactones oriented as shown in Fig. 2. Advantage was taken of the fact that the tertiary 14-hydroxyl group does not form esters (23). Thus, esterification with 3,5-dinitrobenzoyl chloride at the 3 and 12 positions of I yields a derivative that should have the added aromatic moiety at the 12 position sufficiently close to the C_{21} protons in the *R* epimer (Fig. 2a) to influence the NMR spectrum of these protons. For the *S* epimer (Fig. 2b) the NMR of the C_{22} protons should be influenced by their proximity to the C_{12} aromatic moiety.

The NMR spectra of the underivatized major and minor components of I lacked similarity in the regions of the C_{21} protons (3.9–4.5 ppm) and the C_{22} protons (2.1–2.7 ppm, Fig. 3, spectra b and d). Differences in the chemical shifts occurring in these two regions were compared in the underivatized and derivatized forms of each component. A comparison of the NMR spectrum of the underivatized major component of I with that of the derivatized major component (Fig. 3, spectra b and a) reveals that the 3,5-dinitrobenzoate ester at the C_{12} position induces significant chemical shift changes in the C_{21} protons (underivatized major component of I apparent triplets at 4.00 and 4.40 ppm, derivatized major component at 3.76 and 4.53 ppm). However, the results are different with respect to the C_{22} protons. Overlap of the apparent triplets in the region of 2.2–2.5 ppm makes this segment of the NMR spectrum difficult to interpret, but only minor differences exist in this region when the underivatized major component of I is compared with the derivatized major component (suspected location of apparent triplets for C_{22} protons, underivatized major component at 2.34 and 2.48 ppm, derivatized major component at 2.35 and 2.57 ppm).

In comparing the NMR spectrum of the underivatized minor component of I with that of the derivatized minor component, the reverse effect was observed for the C_{21} and C_{22} protons (Fig. 3, spectra d and c). Minimal differences occurred in the chemical shift locations of the C_{21} protons when the underivatized minor component (4.05 and 4.35 ppm) was compared with the derivatized minor component (4.02 and 4.40 ppm). Again, the NMR spectra are difficult to interpret in the C_{22} region; however, significant differences do exist in this region between the underivatized minor component of I and the derivatized minor component (Fig. 3). The suspected location of the C_{22} protons for the underivatized minor component is 2.29–2.53 ppm and for the derivatized minor component 2.02–2.64 ppm.

The results of the NMR studies indicate that the major and minor components of I are opposite rotamers at the C_{17}—C_{20} bond. The influence of derivatization on the chemical shift of the C_{21} protons of the major component of I but not the C_{22} protons confirms the predictions from the Dreiding model of the preferred average rotamer for the *R* epimer, as illustrated in Fig. 2a. The opposite effect of derivatization on the chemical shift of the C_{21} and C_{22} protons of the minor component is consistent with the predicted average rotamer for the *S* epimer, as shown in Fig. 2b.

Determination of the Influence of the Isolation Procedure on the Spectral Observations—The major and minor components of I were separated by derivatization with 3,5-dinitrobenzoyl chloride, HPLC of the derivatives yielding separate peaks for the two components and then base hydrolysis of the separated components. As a control to determine the influence of the isolation procedure on the structure of I, the major component was also prepared by fractional crystallization. Attempts to purify the minor component by fractional crystallization were not successful. Comparison of the NMR spectrum of the recrystallized major component with the NMR of the same component isolated by derivatization, HPLC, and base hydrolysis revealed that the spectra were essentially the same. Thus, the derivatization and base hydrolysis procedures required for the isolation of the two components of I did not alter the starting material, dihydrodigoxigenin (I).

Conclusion—The agreement for the minor epimer of I between the CD results and the results of a separate X-ray crystallography study (22) establishes the C_{20} configuration as *S* and the lactone conformation as shown in Fig. 2b. NMR evidence suggests that the average lactone rotamer in solution is approximately as shown in Fig. 2b for the minor epimer. The CD results for the major epimer indicate the opposite conformation of the β-carbon in the lactone compared with the minor epimer. This result, together with the X-ray crystallography data for the minor epimer, establishes the *R* configuration at C_{20} for the major epimer. NMR evidence suggests that the average lactone rotamer for the major epimer is approximately as shown in Fig. 2a.

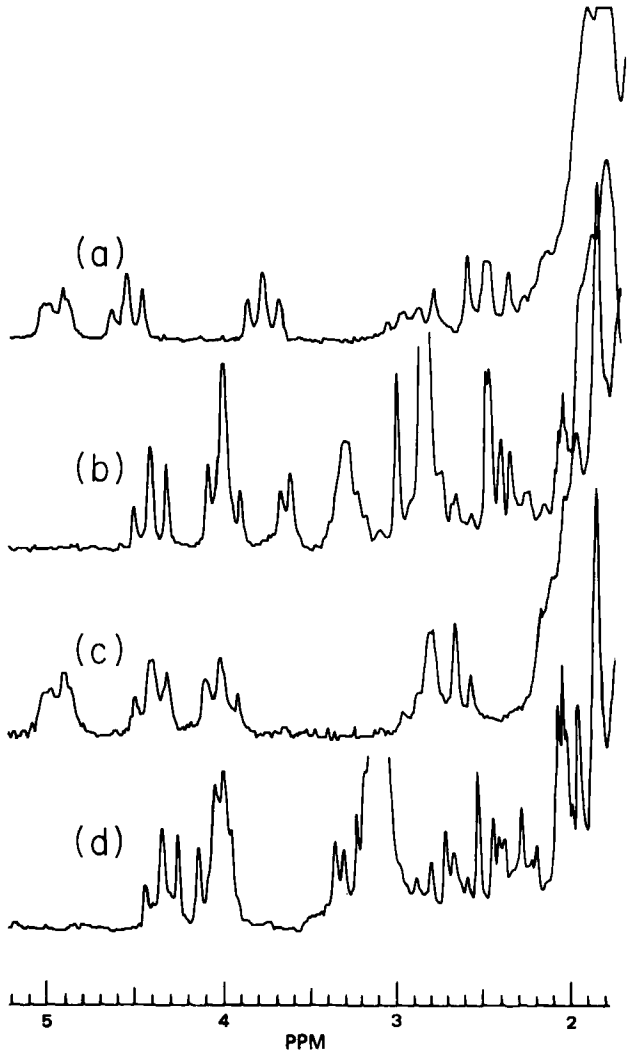

Figure 3—*Partial proton NMR spectrum of (a) derivatized major component of I (in deuterated chloroform), (b) underivatized major component of I (in deuterated acetone), (c) derivatized minor component of I (in deuterated chloroform), and (d) underivatized minor component of I (in deuterated acetone). The derivatizing agent was 3,5-dinitrobenzoyl chloride.*

EXPERIMENTAL

Hydrogenation of Digoxigenin to Dihydrodigoxigenin (I)—Digoxigenin[1] (500 mg) was added to a hydrogenation bottle containing 60 ml of ethanol and 85 mg of platinum oxide catalyst. The digoxigenin was hydrogenated for 12 hr at 30 psi. The platinum oxide was removed by filtering the ethanol solution through a fritted glass filter, and the ethanol was evaporated under a stream of nitrogen at 50°.

Fractional Crystallization of I—Five hundred mg of I was recrystallized from ethyl acetate. The resulting crystals were recrystallized four additional times from ethyl acetate to yield 23 mg. *Less than 4% contamination of the major component of I with the minor component was* detected based on high-performance liquid chromatography (HPLC): mp 189–213°; NMR (CD_3COCD_3) integration (35.4 protons, theoretical 36 protons) δ 4.40 (t J = 8 Hz, 1, C_{21}—H), 4.00 (s, 1, C_3—H), 4.00 (t, one

[1] Boehringer Mannheim Biochemicals, Indianapolis, Ind.

peak under the 4.00 s, J = 8 Hz, 1, C_{21}—H), 2.26–2.65 (m, with major peaks at 2.26, 2.34, 2.39, 2.46, 2.65, 2, C_{22}—H), 0.90, and 0.93 (each s, 6, C_{18}—H, and C_{19}—H).

Derivatization and Liquid Chromatography of (I) to Isolate the Major and Minor Components—One g of I was derivatized with 3,5-dinitrobenzoyl chloride by taking 10-mg aliquots of I and dissolving in 13 ml of pyridine which had been distilled and stored over sodium hydroxide pellets. Next, 1.077 g of 3,5-dinitrobenzoyl chloride[2] (recrystallized from petroleum ether) was added and the solution was heated for 30 min in a water bath (50°). After the major portion of pyridine was removed under vacuum (60°), 10 ml of 5% $NaHCO_3$ solution containing 20 mg of 4-dimethylaminopyridine[2] was added to hydrolyze the excess derivatizing agent and 10 ml of chloroform was added to solubilize and extract the derivatized I. Following the removal of the aqueous phase, the organic phase was washed with 10 ml of 5% $NaHCO_3$ followed by four 30-ml washings with a 0.05 N HCl solution containing 5% NaCl. The chloroform solution from each aliquot was concentrated to a total of 10 ml by evaporating the chloroform under a nitrogen stream at 50°. This solution was washed eight times with the acid wash to remove any residual pyridine, and the final volume of 2 ml was achieved by evaporation under nitrogen (50°). Aliquots of this solution were chromatographed by HPLC using a mobile phase of hexane–methylene chloride–acetonitrile (3:1:1) and a silica gel stationary phase[3]. Appropriate fractions were collected to isolate the derivatized major and minor components of I. Purity with respect to the opposite component was determined by HPLC. Derivatized major component of I, <1% cross-contamination from derivatized minor component; NMR[4] ($CDCl_3$) δ 9.12–9.28 (m, with major peaks at 9.12, 9.14, 9.21, 9.23, 9.25, 9.28, 6, aromatic H), 5.49 (s, 1, C_3—H), 4.88 (m, 1, C_{12}—H), 4.52 (t, J = 8 Hz, 1, C_{21}—H), 3.75 (t, J = 8 Hz, 1, C_{21}—H), 2.25–2.76 (m, with major peaks at 2.34, 2.44, 2.56, 2, C_{22}—H), 1.22 (s, 3, C_{19}—H), 1.09 (s, 3, C_{18}—H). Derivatized minor component of I, <1% cross-contamination from derivatized major component; NMR ($CDCl_3$) δ 9.12–9.24 (m, with major peaks at 9.12, 9.14, 9.24, 6, aromatic-H), 5.48 (s, 1, C_3—H), 4.90 (m, 1, C_{12}—H), 4.40 (t, J = 8 Hz, 1, C_{21}—H), 4.02 (t, J = 8 Hz, 1, C_{21}—H), 2.64 (t, J = 8 Hz, 1, C_{22}—H), 2.02 (t, J = 8 Hz, 1, C_{22}—H), 1.23 (s, 3, C_{19}—H), 1.10 (s, 3, C_{18}—H).

Base Hydrolysis of the Derivatized Major and Minor Components of I—A mixture of chloroform (1.5 ml), methanol (13.5 ml), and 5% $KHCO_3$ (1.5 ml) containing either 100 mg of the derivatized major component of I or 131 mg of the derivatized minor component was refluxed for 90 min. After increasing the volume of the aqueous phase with 3 ml of distilled water, the aqueous phase was extracted three times with methylene chloride (40 ml). To ensure against opening of the lactone ring from the base hydrolysis procedure (24), the aqueous phase was acidified to ~pH 2 with 0.2 N HCl. Twelve hours later the solution was adjusted to pH 10 with 5% $KHCO_3$ and extracted three times with methylene chloride (40 ml). After combining like fractions and evaporating the methylene chloride, each component was crystallized from ethyl acetate. Purity was determined by HPLC. Major component of I (37.3 mg, 37.3% yield) <1% contamination from minor component; mp 235–237°; NMR (CD_3COCD_3) integration (35.1 protons, theoretical 36 protons), δ 4.41 (t, J = 8 Hz, 1, C_{21}—H), 4.00 (s, 1, C_3—H), 4.00 (t, one peak under the 4.00 s, J = 8 Hz, 1, C_{21}—H), 2.24–2.54 (m, with major peaks at 2.24, 2.34, 2.40, 2.46, 2.48, 2.54, 2, C_{22}—H), 0.90 and 0.93 (each s, 6, C_{18}—H and C_{19}—H); $[\alpha]_D^{21}$ + 20.2° (C 0.436); CD $[\theta]_{218}$ 136[5].

Anal.—Calc. for $C_{23}H_{36}O_5$: C, 70.38; H, 9.24. Found: C, 70.02; H, 9.46.

Minor component of I (41.6 mg, 31.8% yield), <1% contamination from major component; mp 209.5–211.5°; NMR (CD_3COCD_3) integration (35.9 protons, theoretical 36 protons), δ 4.35 (t, J = 8 Hz, 1, C_{21}—H), 4.01 (s, 1, C_3—H), 4.05 (t, J = 8 Hz, 1, C_{21}—H), 2.20–2.62 (m, with major peaks at 2.20, 2.29, 2.38, 2.45, 2.53, 2.62, 2, C_{22}—H), 0.92 (s, 6, C_{18}—H and C_{19}—H); $[\alpha]_D^{21}$ + 17.9° (C 0.29); CD $[\theta]_{216}$–206.

Anal.—Calc. for $C_{23}H_{36}O_5$: C, 70.38; H, 9.24. Found: C. 70.10; H, 9.38.

Sensitive High-Performance Liquid Chromatographic Method for the Determination of Etodolac in Serum

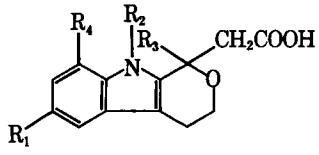
L. COSYNS, M. SPAIN *, and M. KRAML ˣ

Received February 5, 1982, from *Ayerst Research Laboratories, Montreal, Quebec, H3C 3J1 Canada.* Accepted for publication April 30, 1982. *Present address: Chromatography Sciences Co., Montreal, Quebec, Canada.

Abstract □ A sensitive high-performance liquid chromatographic method for the determination of etodolac in serum was developed. The limit of detection was 0.2 μg/ml. The specificity of the method was demonstrated by the lack of response obtained with a variety of control sera, sera spiked with etodolac congeners, and sera obtained from rats treated with a variety of other drugs.

Keyphrases □ Etodolac—sensitive high-performance liquid chromatographic method for determination in serum □ High-performance liquid chromatography—sensitive method for the determination of etodolac in serum □ Serum specificity—sensitive high-performance liquid chromatographic method for the determination of etodolac □ Analgesics—etodolac, sensitive high-performance liquid chromatographic method for determination in serum □ Anti-inflammatory agents—etodolac, sensitive high-performance liquid chromatographic method for determination in serum

Experiments in laboratory animals have demonstrated that etodolac [1,8-diethyl-1,3,4,9-tetrahydropyrano[3,4-*b*]indole-1-acetic acid[1], (I)] is a potent nonsteroidal, anti-inflammatory and analgesic agent (1, 2). To carry out pharmacokinetic studies in both animals and humans, a



I

sensitive and reliable analytical method was needed. Etodolac can be quantitated by a fluorometric method that has been developed for its 1-propyl congener, prodolic acid (3); however, because of endogenous fluorescent substances, the limit of detection is only 2–3 μg/ml. Therefore, a specific and sensitive (0.2 μg/ml) high-performance liquid chromatographic (HPLC) method has been developed.

EXPERIMENTAL

Reagents—Isopentyl alcohol[2], hexane[3], methanol[3], and acetonitrile[4] were used as supplied. All other chemicals, monobasic potassium phosphate, hydrochloric acid, phosphoric acid, and glycine, were analytical reagent grade. Etodolac and its 1-propyl, 1-phenyl, 1,9-dimethyl, and 6-hydroxy congeners were synthesized as described previously (4, 5) as was [^{14}C]etodolac (6). Drugs used for specificity studies were purchased from commercial sources.

Instrumentation—The liquid chromatographic system employed consisted of an automatic variable-volume injector[5], a high-pressure pump[6], a variable wavelength spectrophotometer[7], and a recorder[8].

Column Preparation—Two 250 × 4.6-mm stainless steel HPLC columns were employed in the experiments: Chromosorb LC-7[9] (ODS, 10 μm; column A) and Spherisorb[10] (ODS, 5 μm; column B). Using 2-propanol slurries, the columns were packed at 6000 psi with a compressed air pump[11]. The columns were mounted with a glass water-jacket to provide temperature control. At a flow rate of 1.8 ml/min and a temperature of 50°, typical back pressures of 750 and 1680 psi were obtained for columns A and B, respectively.

Extraction and Mobile Phases—For both columns, the mobile phase was a mixture of 0.1 *M* potassium phosphate (pH 6.0) and acetonitrile. To provide similar retention times, the concentration of acetonitrile was varied from 30% (column B) to 38% (column A). The extraction phase was prepared by mixing isopentyl alcohol and hexane in a ratio of 1:19 (v/v).

Standards—A stock standard of 1.0 mg/ml of etodolac was prepared by dissolving 10.0 mg in 1.0 ml of methanol and completing to 10.0 ml with distilled water. Dilute, nonextracted test-tube standards were prepared at the desired concentration by appropriate dilution in 0.1 *M* glycine buffer (pH 11.0). In recovery studies and in actual analytical runs, working standards were prepared by diluting the stock standard in pooled rat, dog, or human control serum.

Procedure—Solutions of 4.0 ml of 1.0 *N* HCl and 5.0 ml of isopentyl alcohol–hexane were added to 1.0 ml of serum (or plasma) in a 15-ml screw-capped glass[12] tube. The tube was capped and agitated mechanically for 15 min. The two phases were separated by low-speed centrifugation (5 min, 1000 rpm), and 4.0 ml of the upper phase was transferred to a clean tube, and 1.0 ml of 0.1 *M* glycine buffer[13] was added. The tube was agitated for an additional 15 min, and a 0.8-ml aliquot of the aqueous phase was transferred to a clean tube. Prior to injection onto the HPLC column, 20 μl of 2.5 *M* phosphoric acid was added to partially neutralize the glycine buffer. With each analytical run, column performance was monitored by injecting test-tube standards. Control serum blanks and control serum, spiked with the appropriate concentration of etodolac (in triplicate), were carried through the method.

Chromatographic conditions were as follows: injected sample volume, 50–150 μl; temperature, 50°; flow rate, 1.8 ml/min; mobile phase, acetonitrile–phosphate buffer (30 or 38% for columnns B or A, respectively); UV detector settings, 226 nm and 0.05 AUFS (running at high sensitivity). Quantitation was based on peak height of the unknowns relative to that of the spiked control serum standards.

Recovery—Human serum spiked with 1.0–10.0 and 5.0–50.0 μg/ml of etodolac was carried through the procedure, in triplicate, to provide data on the linearity and reproducibility. Recovery was based on the response of test-tube standards injected concurrently. Recovery from a variety of aqueous media, *i.e.*, rat, dog, or human serum, and distilled water was also carried out on replicate samples at concentrations of 1.0, 10.0, and 50.0 μg/ml.

Sensitivity and Specificity—The specificity of the procedure was evaluated using three criteria: (*a*) interference due to similar chromatographic characteristics (retention times) and spectral properties (UV absorption at 226 nm) of endogenous constituents of serum, (*b*) the potential for interference from etodolac metabolites (or congeners), and (*c*) interference from other drugs that may be administered concurrently.

Typical serum blanks were measured by processing replicate (10–23) samples of rat, dog, and human control sera through the method.

Interference from etodolac congeners was estimated by injecting the pure compounds and evaluating their retention times relative to that of etodolac.

Table I—Recovery of Etodolac [a] from Water and Rat, Dog, and Human Sera

Medium	n	Mean ± SE
Water	18	93.1 ± 1.0
Sera		
Rat	17	86.2 ± 1.7
Dog	18	88.0 ± 1.2
Human	18	91.5 ± 2.1

[a] Six replicates of 1.0, 10.0, and 50.0 μg/ml.

In random serum samples from rats and dogs given etodolac orally at a 50-mg/kg dose, etodolac concentrations were estimated by the fluorometric procedure (3) and in a second aliquot by the HPLC procedure (using a 5 μm Lichrosorb RP-2 column).

In selected studies in rats and dogs (7), [^{14}C]etodolac was administered orally in doses of 10 and 50 mg/kg, and total carbon 14 and unchanged etodolac were estimated at 0.25, 0.5, 1, and 3 hr postdosing.

Interference from a concurrently administered drug, or its metabolite(s), was estimated by treating rats with a high dose of the drug, obtaining a blood sample 2 hr postdosing, and processing the serum through the etodolac method. Interference was estimated from the response, at the retention time of etodolac, compared to that of serum from saline-treated control rats. Drugs tested and dose administered, in milligrams per kilogram, were: ethacrynic acid (300), salicylic acid (400), acetominophen (400), niacin (300), propoxyphene (60), phenobarbital (100), hydrochlorothiazide (100), tolbutamide (200), glyburide (200), indomethacin (25), phenylbutazone (200), phenytoin (100), dicumarol (250), and diazepam (350).

Stability—The stability of etodolac in serum was determined by analyzing serum samples spiked at 60.0 μg/ml after 1-, 3-, and 7-day storage at 20° or in the refrigerator at 4°.

RESULTS AND DISCUSSION

Chromatography—Typical liquid chromatograms of an etodolac standard, a control serum extract, and an extract of control serum spiked with etodolac are presented in Fig. 1. Using column B (250 × 4.6-mm) and a mobile phase of 30% acetonitrile–phosphate buffer, etodolac had a retention time of 5.0 min (flow rate, 1.8 ml/min). No interfering peaks were seen in the scan obtained with control serum. With column A a similar retention time is obtained if the concentration of acetonitrile is increased to 38%.

The linearity in the peak height response of the detector was demonstrated for low (1–10 μg/ml) and high (5–50 μg/ml) concentrations of etodolac. The regression line for the low test-tube standards was: $y = 21.4x - 1.23$ ($R = 0.9999$). For the high concentration standards the regression line was: $y = 4.79x - 3.93$ ($R = 0.9996$).

Recovery Studies—The linearity of recovery of etodolac from pooled human serum was also tested at two concentration ranges. For triplicate samples, covering the range of 1.0–10.0 μg/ml, the recovery was independent of etodolac concentration. The regression line for the recovery was: $y = 10.28x - 0.39$ ($R = 0.9984$). At high concentrations (5–50 μg/ml), linearity was maintained [regression line: $y = 2.57x - 3.55$ ($R = 0.9970$)]. In separate experiments small differences were noted when recoveries from rat, dog, and human sera and distilled water were evaluated at concentrations of 1.0, 10.0, and 50.0 μg/ml (Table I). The highest recovery (93.1%) was obtained with water, and with the sera recoveries varied from 86.2 (rat) to 91.5% (humans). Over a period of 6 months to 1 year, recovery of etodolac from pooled human serum varied from a low of 70 to a high of 94% [mean ± SE, 81.0 ± 1.6%]. The variations in day-to-day recovery from the same pooled serum were of the same order of magnitude as the differences found for various sera.

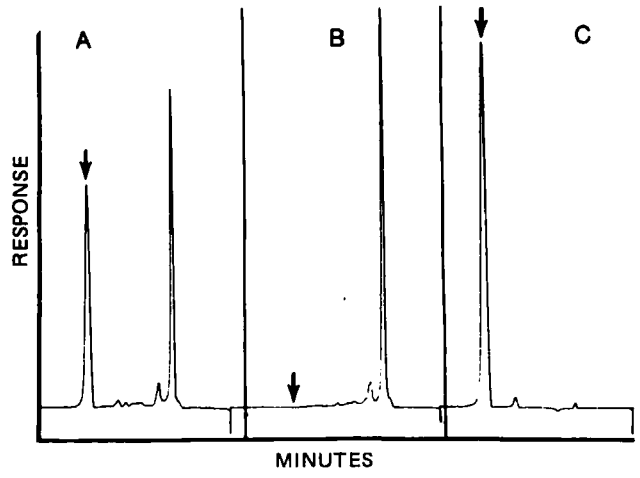

Figure 1—*HPLC chromatograms of: (A) extract of control serum spiked with etodolac (5 μg/ml); (B) extract of human control serum; and (C) etodolac standard (5 μg/ml), retention time (↓) 5.0 min, column 5 μm Spherisorb ODS.*

In the course of these experiments, it became apparent that variations in recovery were to a large extent due to instability of the etodolac test-tube standards (see *Stability*). To ensure that the small day-to-day and species-to-species variations in recovery do not result in an error in the estimation of etodolac, in actual analytical runs, standardization is based on appropriate serum standards spiked and run concurrently.

Sensitivity and Specificity—Control sera from rats ($n = 10$), dogs ($n = 23$), and humans ($n = 17$) were processed through the method and injected on the liquid chromatograph, operating at its highest sensitivity (0.05 AUFS). With the exception of one spurious sample (the apparent etodolac concentration was 0.7 μg/ml) none of the extracts revealed any UV absorption in the region of emergence of etodolac. The limit of detection of the method, consistent with baseline noise, was conservatively taken as 0.2 μg/ml. In contrast to the fluorometric procedure (3) with respect to endogenous substances, the HPLC method is specific.

When randomly selected serum samples were analyzed by both the fluorometric (3) and HPLC procedures, a good correlation was found. The mean etodolac concentrations in dog serum were estimated as 20.8 (fluorometric) and 18.3 μg/ml (HPLC). For rats the corresponding values were 78.7 and 80.2 μg/ml. The differences of 2.2 ± 1.2 and −1.5 ± 1.1 μg/ml were within the limit of reproducibility of the fluorometric method. When higher concentrations of etodolac are being measured, the more rapid fluorometric procedure can be employed, as long as the values are corrected for the 2–3 μg/ml of apparent etodolac found in control sera.

When sera from rats and dogs treated with [^{14}C]etodolac were analyzed for unchanged drug and total carbon 14 (Table II), 85–95% of the carbon 14 was accounted for by unchanged etodolac. In serum extracts used for chemical analysis, the percentage would be even higher. This explains why the inherently more specific HPLC method and the fluorometric method provide similar values. Finally, the ready separation of etodolac from its congeners, especially the phenolic analogue (Table III), suggests that the method is specific with regard to potential metabolites.

The potential for interference from selected drugs or their metabolites with the HPLC method was tested as follows. Rats were given high doses of each drug, bled 2 hr postdosing, and the serum was processed through the etodolac procedure. The HPLC chromatograms were examined for the presence of interfering peaks. Serum from control rats served as reference. The sample extracts were injected on both columns A and B. When ethacrynic acid, niacin, propoxyphene, phenobarbital, hydro-

Table IV—Stability of Etodolac in Serum [a]

Temperature	Recovery (%) on day 1	3	7
20°	100.5 ± 0.5	97.6 ± 0.4	100.2 ± 0.5
4°	98.6 ± 0.5	97.4 ± 0.5	100.4 ± 0.6

[a] Pooled serum spiked with 60 μg/ml of etodolac.

chlorothiazide, glyburide, or diazepam were administered, no peaks were seen in the HPLC scans. Phenylbutazone and dicumarol produced strong interfering peaks with either column. With indomethacin, acetominophen, and salicylate, peaks separate from etodolac were noted, but due to tailing, these peaks partially overlapped the etodolac peak when injected on column A. A better separation was achieved on column B. Because concomitant administration of salicylate or acetominophen is likely to occur clinically, pooled rat serum spiked with etodolac was supplemented with 50–500 μg/ml of salicylate or 20–250 μg/ml of acetominophen, carried through the HPLC procedure, and analyzed on column B. No interference could be demonstrated, nor was there any adverse effect on the recovery of etodolac. In the presence of coadministered drugs, column B is preferred.

Stability—When etodolac was added to pooled serum and kept for up to 7 days at room temperature (20°) or in the refrigerator (4°), no significant loss of etodolac was detected at either temperature (Table IV).

Because of day-to-day variations in recovery, the stability of the test-tube standards and the extracted spiked control serum standards was also investigated. The peak height response of the test-tube standards (n = 12) declined from 100.0 ± 1.3 to 91.5 ± 1.2% in 1 hr. In contrast, the extracts from spiked control serum remained unchanged: 100.0 ± 1.3 *versus* 100.7 ± 2.2%. For this reason, the test-tube standard is used only to adjust mobile phase concentrations when the method is being set up. Quantitation is based on the stable extracts from spiked control sera, and no recovery factor is needed.

Application of the method—Initial studies in humans have indicated that activity is achieved with 100-mg etodolac doses given twice daily. At these doses the peak concentrations of etodolac varied between 4.0 and 14.3 μg/ml, and the daily minima between 0.3 and 3.5 μg/ml. Thus, the HPLC procedure possesses the specificity and sensitivity required to monitor etodolac concentrations in humans.

Analysis of Chlorobutanol in Ophthalmic Ointments and Aqueous Solutions by Reverse-Phase High-Performance Liquid Chromatography

DANNY L. DUNN ˣ, WILLIAM J. JONES, and EDWIN D. DORSEY

Received March 3, 1982, from the *Analytical Chemistry Department, Alcon Laboratories, Inc., Fort Worth, TX 76134.* Accepted for publication May 6, 1982.

Abstract □ A reverse-phase high-performance liquid chromatographic assay for chlorobutanol was developed and found suitable for the routine analysis of ophthalmic ointments and aqueous solutions. The method utilized a column packed with 10-μm octadecylsilane with a mobile phase of methanol–water (50:50). Peak detection was by UV absorption at 210 nm. In this chromatographic system, chlorobutanol had a capacity factor (K') of 4.1. Standard curves obtained in the presence of ointment vehicle containing an aminoglycoside were linear, intercepted at zero, and averaged 99.4% recovery. Degradation studies indicated that the method was stability indicating. The analytical results for a complete experimental ophthalmic ointment and an aqueous ophthalmic diluent are presented. This high-performance liquid chromatographic method of analysis represents an alternative to GC procedures for determining chlorobutanol.

Keyphrases □ Chlorobutanol—analysis in opthalmic ointments and aqueous solutions by reverse-phase high-performance liquid chromatography □ High-performance liquid chromatography—reverse-phase, analysis of chlorobutanol in ophthalmic ointments and aqueous solutions □ Ophthalmic ointments—aqueous solutions, chlorobutanol, analysis by reverse-phase high-performance liquid chromatography □ GC—alternative method for analysis of chlorobutanol in opthalmic ointments and aqueous solutions, reverse-phase high-performance liquid chromatography

Chlorobutanol (1,1,1-trichloro-2-methyl-2-propanol) is a commonly used preservative in ophthalmic medications. It is readily degraded by base as shown in Scheme I to form acetone, carbon monoxide, and chloride ion (1). Chlorobutanol is also highly volatile, and loss by evaporation from ophthalmic solutions was reported through porous plastic bottles and closures (2).

BACKGROUND

A variety of analytical methods were developed for the analysis of chlorobutanol. Originally, analysis consisted of decomposing chlorobutanol by heating with base and then analyzing for chloride ion. This was done titrametrically (3, 4) iodometrically (5), gravimetrically (6), and amperometrically (7). Degradation using a known amount of base and determination of excess base by acid titration and degradation followed by an iodometric determination of acetone (8) also were used. These

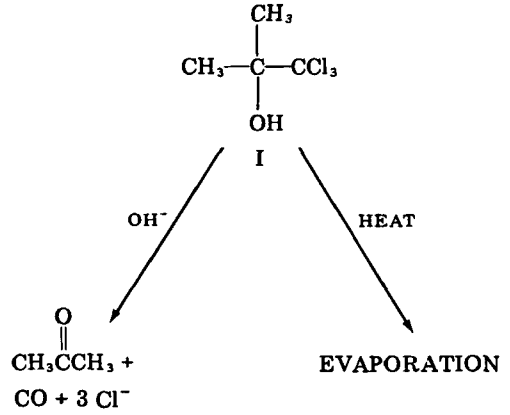

Scheme I—Potential routes for the loss of chlorobutanol (I) from ophthalmic formulations.

methods are not specific, because they are unable to differentiate from excipient chloride sources such as electrolytes or other organic compounds which also contain chlorine. In addition, tedious sample preparation such as steam distillation is often required.

Two colorimetric procedures were developed. The Fujiwara alkali–pyridine colorimetric reaction for chloroform has been used successfully to analyze for chlorobutanol (9, 10). By using 3-substituted pyridines, increased sensitivity to chlorobutanol was reported (11). Reaction of hydroxylamine and chlorobutanol in basic solution forms a product which produces a colored complex with ferric ion (12). Both colorimetric reactions lack specificity, and colors are produced with a variety of organic moieties.

Instrumental methods of analysis include polarography, which is sensitive but requires separation of chlorobutanol from excipients by steam distillation (13), and NMR spectrometry (14), which is difficult to justify for a routine analysis. IR spectrophotometry has also been used for samples eluted through a diatomaceous earth column to remove excipients (15, 16). Because of the high volatility of chlorobutanol, the most successful method of analysis has been gas chromatography (GC). Flame ionization detection is satisfactory with a large number of different stationary phases (2, 15, 16). In one reported GC method, electron capture detection was used (17).

The official USP analytical method for chlorobutanol is a GC procedure utilizing flame ionization detection, a 5% polyethylene glycol 20M stationary phase, and a benzaldehyde internal standard (18). However, attempts to analyze chlorobutanol in an experimental ointment formulation containing an aminoglycoside using a similar GC procedure yielded results which slowly increased according to the length of time samples were allowed to stand at room temperature before analysis. Evidence indicated that the benzaldehyde was slowly reacting with the vehicle, and the resulting variance in internal standard concentration was causing variance in the results.

A high-performance liquid chromatographic (HPLC) method of analysis for chlorobutanol is discussed, which uses an octadecylsilane column with UV peak detection at 210 nm. This reversed-phase system was found to be satisfactory for the routine analysis of chlorobutanol in ophthalmic ointments and aqueous solutions. Data is included to demonstrate that the procedure gives a linear response and reproducible recoveries from an ointment vehicle. The actual analyses of a complete bulk experimental ointment formulation and an aqueous ophthalmic diluent are presented. The results for the aqueous diluent are compared with the results obtained from a GC method using a cyclohexanol internal standard instead of benzaldehyde.

Table I—GC Analysis of a Chlorobutanol Vehicle Standard Using a Benzaldehyde Internal Standard

0.469	14.45	0.467	99.6

[a] A standard containing 0.375 mg of chlorobutanol/ml was extracted and used to calculate these concentrations.

EXPERIMENTAL

Reagents and Solvents—Chlorobutanol hemihydrate[1], USP grade, was used without further purification. Its absolute purity on an anhydrous basis was established by titration of total chloride (3), and all subsequent calculations were corrected using this factor. Methanol[2] and hexane[2] were reagent grade.

Gas Chromatography—The gas chromatograph[3] was equipped with a flame ionization detector and a 91.4-cm × 6.4-mm glass column packed with 5% polyethylene glycol 20M[4] coated on 100–120 mesh diatomaceous earth[5]. The temperatures of the injector, column, and detector were 140, 80, and 250°, respectively. The gas flow rates of helium, hydrogen, and compressed air were 20, 20, and 350 ml/min, respectively.

Preparation of GC Ointment Samples—A sample of ointment equivalent to ~25 mg of chlorobutanol was weighed into a 60-ml separatory funnel. After dissolving in hexane (35 ml), the cloudy solution was extracted with three 7-ml portions of methanol. Each time the lower (methanol) layer was drained into a 50-ml volumetric flask. A 1.0-ml al-

Table III—HPLC Analysis of Complete Ophthalmic Samples

Sample (Age)	Chlorobutanol Analysis, Percent Label[a]
Experimental bulk ointment sample (14 days)	111.8, 112.1, 112.4, 111.2, 111.2
Experimental bulk ointment sample (15 days)	109.0, 111.7, 112.6, 112.5, 112.7
Aqueous diluent (5 months)	107.8, 107.8, 107.8, 108.3, 107.8, 107.5, 107.9, 107.9, 107.9

[a] The chlorobutanol concentrations were labeled 5.0 mg/g; however, since a 15% excess was added, the theoretical content is 115% of label.

iquot of a 7-mg/ml methanolic benzaldehyde solution was added, and the mixture was diluted to volume with methanol. A 1.0-μl injection of this solution was made directly into the gas chromatograph.

High-Performance Liquid Chromatography—A liquid chromatograph, equipped with a high-pressure pump[6], a variable-wavelength UV detector[7], an autoinjector[8], and a strip-chart recorder[9] was used with a 25-cm × 4.0-mm i.d. column packed with 10-μm octadecylsilane[10]. A 10-cm × 2.0-mm i.d. precolumn packed with 47-μm octadecylsilane[11] was used to protect the analytical column from the absorption of ointment vehicle.

Mobile Phase—Methanol (500 ml) and water (500 ml) were mixed and filtered through a 0.47-μm filter[12] before use.

Analysis Conditions—The mobile phase was pumped through the column at a flow rate of 1.8 ml/min. UV detection was at 210 nm, and the injection size was 100 μl. A sample was injected every 6 min. The plate count for the column, determined at a chart speed of 5.08 cm/min with a 0.37-mg/ml chlorobutanol solution, was 3000 plates/m[13]. After completion of the analysis, methanol was pumped through the column prior to storage.

Preparation of Standard Curves—The following were prepared using a methanolic 2.35 mg/ml of chlorobutanol stock solution:

Chlorobutanol Standard Curve—Five aliquots, giving final concentrations in the range of 0.28–0.48 mg of chlorobutanol/ml, were added to different 125-ml separatory funnels. Hexane (50 ml) was added and the methanolic layer adjusted to 15 ml with methanol–water (75:25). After shaking, the lower (methanolic) layer was drained into a 50-ml volumetric flask. The mixture was extracted twice more with 15 ml of methanol–water (75:25), and the lower layers were collected each time. The extracts in the volumetric flask were diluted to volume with methanol–water (75:25), and the resulting solution was injected directly into the HPLC.

Chlorobutanol Vehicle Standard Curve—The same series of aliquots used for the standard curve was added to different 125-ml separatory funnels which contained 4.0 g of ointment vehicle. The samples were dissolved in hexane and extracted with a methanol–water (75:25) solution as described above.

Preparation of Ophthalmic Ointment Samples—A sample of ointment equivalent to ~20 mg of chlorobutanol was weighed into a 125-ml separatory funnel. After dissolving in hexane (50 ml) the sample was extracted as described above. A standard was prepared by extracting 8.0 ml of a methanolic 2.5 mg of chlorobutanol/ml stock solution in a similar manner.

Preparation of Ophthalmic Aqueous Solutions—The sample was diluted with methanol to a final concentration of 0.5 mg of chlorobutanol/ml. A chlorobutanol standard of similar concentration was prepared in methanol.

RESULTS AND DISCUSSION

The chlorobutanol analysis of an experimental ointment formulation containing an aminoglycoside by gas chromatography was found to change if the samples were allowed to stand before being analyzed. In an attempt to isolate the problem, a vehicle standard containing 0.57 mg of chlorobutanol/ml was prepared and injected into a gas chromatograph every 10 min. The results presented in Table I show an apparent increase in chlorobutanol concentration with time at room temperature. This is probably due to a slow removal of the benzaldehyde internal standard caused either by oxidation to benzoic acid or reaction with the aminoglycoside present. A methanol chlorobutanol standard similarly injected showed no increase in concentration with time.

Since long automated runs were clearly impossible using this GC procedure, a reverse-phase HPLC system was developed. Using the HPLC conditions described under *Experimental*, chlorobutanol eluted at ~6 min, which corresponds to a capacity factor (K') of 4.1. Typical chromatograms are given in Fig. 1.

Table IV—HPLC Analysis of Forcibly Degraded Chlorobutanol Vehicle Standards Containing 4.0 g of Ointment Vehicle

Method of Degradation[a]	Theoretical Chlorobutanol Concentration, mg/ml	Chlorobutanol Peak Height, cm	Chlorobutanol Concentration Found, mg/ml	Recovery, %[b]
Heat alone	0.3773	2.20	0.0722	19.1
Heat + Acid	0.3773	5.00	0.1641	43.5
Heat + Base	0.3773	4.60	0.1509	40.0
Heat + Peroxide	0.3773	2.85	0.0935	24.8

[a] All samples were heated at 110° overnight. [b] No interfering HPLC peaks were observed.

Five chlorobutanol standards prepared in methanol over the concentration range of 0.28–0.48 mg/ml were extracted with hexane, as if they were ointment samples, and analyzed. A least-squares regression analysis of these results yielded a coefficient of determination (R^2) of 0.9983, a y-intercept of −0.24 cm, a slope of 29.54 cm/mg/ml, and a standard error of 0.093. Five vehicle standards containing ~4.0 g of ointment vehicle were also prepared over approximately the same concentration range and analyzed (Table II). A coefficient of determination (R^2) of 0.9990, a y-intercept of 0.19 cm, a slope of 30.28 cm/mg/ml, and a standard error of 0.070 were calculated. These statistics indicate that the HPLC analysis gives a linear response, and a single point standard may be used. The recoveries from 10 vehicle standards containing ointment vehicle averaged 99.4 ± 0.2%[14].

Two complete ophthalmic formulations were analyzed for chlorobutanol content (Table III). One was an experimental ophthalmic ointment which contained an aminoglycoside, mineral oil, and petrolatum as excipients. The other formulation was an aqueous ophthalmic diluent[15] which contained boric acid and polysorbate 80.

The ointment was analyzed on 2 consecutive days to check assay reproducibility. Fourteen days after manufacture, the chlorobutanol analysis of five samples taken from the bulk ointment averaged 111.7 ± 0.5%[14]. On the next day, five new samples were analyzed. The results were 111.7 ± 1.6%[14]. Fifteen percent excess chlorobutanol had been added, so the theoretical content was 115% of label. These data indicate that the HPLC assay has good day-to-day reproducibility with a standard deviation for each set of samples in the range acceptable for the analysis of a preservative.

Nine samples of the aqueous ophthalmic diluent were diluted with methanol and analyzed for chlorobutanol. Theoretical content was 115% of label. The results averaged 107.9 ± 0.2%[14]. These samples were also later analyzed using a GC method similar to the one described under *Experimental*, but utilizing a cyclohexanol internal standard instead of benzaldehyde and a 3% polyethylene glycol 20M stationary phase. By this procedure, the chlorobutanol content averaged 107.4% label, which is in good agreement with the HPLC results.

Four vehicle standard samples of chlorobutanol containing ~4.0 g of ointment vehicle were forcibly degraded to ensure that chlorobutanol or excipient degradation products did not interfere with the HPLC assay. To the first sample several drops of concentrated hydrochloric acid was added, to the second several drops of concentrated ammonium hydroxide was added, to the third several drops of 30% hydrogen peroxide was added, and to the fourth nothing was added. The vials were tightly capped and heated at 110° overnight. These samples correspond to the potential degradation pathways catalyzed by acid, base, oxidation, and heat.

Degradation was observed (Table IV), but no interfering HPLC peaks were present. The HPLC method thus appears to be stability indicating.

Analysis of chlorobutanol by HPLC using UV detection at 210 nm is a reasonable alternative to the GC methods of analysis. Several years ago, the HPLC analysis of 'non-UV absorbers,' such as chlorobutanol, was thought to be difficult if not impossible (20); however, modern UV detectors can readily operate at the lower wavelengths (*i.e.*, 200–220 nm), and the quantitation of 'non-UV absorbers' has now become routine.

Abstract □ The promoting effect of glyceryl esters of acetoacetic acid on the rectal absorption of insulin and inulin was studied. A decrease in the serum glucose level was observed in rabbits following the administration of an insulin suppository containing glyceryl-1,3-diacetoacetate (adjuvant II) or 1,2-isopropylideneglycerine-3-acetoacetate (adjuvant IV). The promoting effects of adjuvants II and IV on the rectal absorption of insulin and inulin were suppressed by the addition of calcium and magnesium to the suppository. This indicates that adjuvant interaction with the calcium and magnesium ion located in the rectal membrane is involved in the enhanced absorption of insulin and inulin. Adjuvant release from the suppository formulation in addition to adjuvant lipid solubility were found to be other important factors for enhanced absorption of insulin and inulin.

Keyphrases □ Insulin—adjuvant effects of glyceryl esters of acetoacetic acid on rectal absorption, rabbits, inulin □ Inulin—adjuvant effects of glyceryl esters of acetoacetic acid on rectal absorption, rabbits, insulin □ Glyceryl esters—acetoacetic acid, adjuvant effects on rectal absorption of insulin and inulin, rabbits

In a previous paper (1), the effect of enamine derivatives of DL-phenylglycine on the rectal absorption of insulin was reported. It was suggested that rectal absorption of insulin was enhanced due to an interaction between the enamine derivatives and the calcium ions in the membrane. This interaction caused a temporary change in the integrity of the membrane allowing the insulin to pass more easily through the barrier. The active forms of the phenylglycine enamines are considered to be predominantly anionic. The interaction of these adjuvants with calcium and magnesium may be through the carboxylate moiety and/or the enamine moiety.

It has been reported (2) that intravenous administration of acetoacetic acid enhanced the distribution of chloropropamide and sulfadimetoxide to the red blood cells, indicating some change in erythrocyte membrane permeability. In the present paper, the glyceryl esters of acetoacetic acid were examined as adjuvants for promoting the rectal absorption of insulin and inulin. The ability of these nonionic compounds to be released from the suppository formulations, to permeate the rectal membrane, and to interact with divalent metal ions was examined.

EXPERIMENTAL

Materials—Glyceryl esters of acetoacetic acid were routinely synthesized by adding acetoacetic acid to glycerol or 1,2-isopropylideneglycerol in the presence of potassium acetoacetate (a catalyst) at

6	II or IV	Added only with adjuvant II	—	X	X	X	—
7	II or IV	Added only with adjuvant II	—	X	X	—	X

[a] X indicates compounds present.

100–110° while stirring. The insolubles, if necessary, were removed from the mixture by filtration. The crude products obtained were purified by liquid chromatographic methods (Table I). Commercially available crystalline beef insulin (zinc content 0.5% w/w on dry basis, 24.5 IU/mg) was used throughout the experiments[1]. Other reagents used were of analytical grade.

Preparation of Suppositories—Suppositories were prepared by combining the adjuvant, silicon dioxide[2], and either insulin or inulin with a triglyceride suppository base[3] (melted on a hot plate at 40°) according to the formulas in Table II. Silicon dioxide was added to the suppositories prepared with adjuvants II and III to disperse each adjuvant in the suppository base. The molten liquid was poured into disposable plastic molds[4]. The suppositories were allowed to stand for 2 hr at room temperature and were then stored in a refrigerator until used. Each suppository was slightly conical in shape with a rounded apex, measured 25 mm in length and 7 mm in maximum diameter, and weighed ~1 g.

***In Vivo* Studies**—Male white rabbits (2.5–3.0 kg) were fasted (with water available) for 16 hr prior to experimentation. One-milliliter control blood samples were collected from a marginal vein before the rectal administration of the suppository. After rectal administration of the suppository, the anus was closed with a plastic clip to prevent leakage of the rectal contents during the experiments. Blood samples were collected at specific time intervals for 3 hr. Each sample was frozen until assays of glucose and insulin were made.

***In Vitro* Studies**—Male Sprague-Dawley rats (250–300 g) were fasted (with water available) for 24 hr prior to the experiments. After decapitation and excision of the gut, the rectum and anus were washed with a Krebs-Ringer's solution containing 0.3% glucose (pH 7.4). The rectal segment was ligated at the anus, a 0.1-g liquified suppository was placed

Table III—Control Experiments in Rabbits without Insulin [a]

Triglyceride as Suppository Base	Serum Glucose Level mg/100 ml, 0	0.5	1.0	1.5	2.0	2.5, hr
+ I	108.6 (12.6)	127.4 (6.9)	113.5 (14.8)	120.3 (12.6)	117.2 (18.3)	114.8 (13.9)

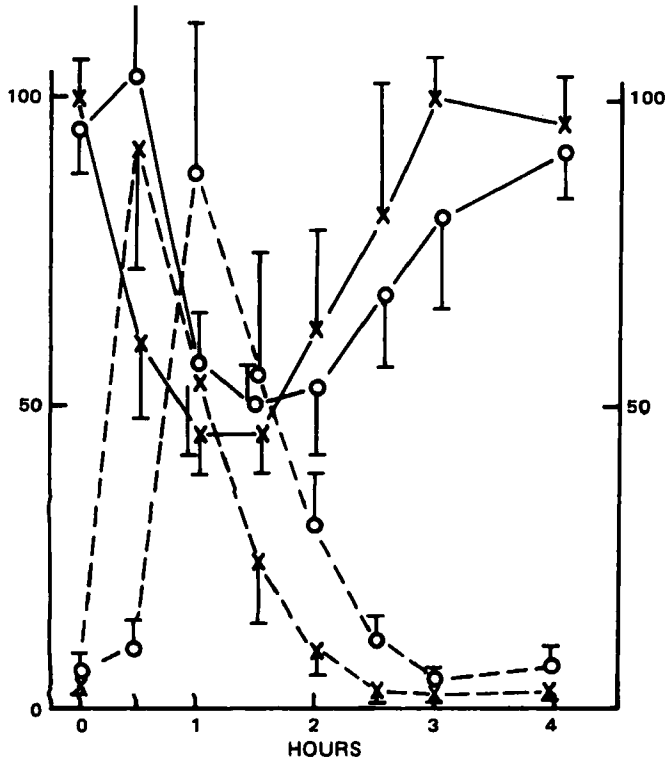

Figure 1—*Changes in serum glucose levels (—) (mg/100 ml) and serum insulin levels (---) (μIU/ml) in rabbits after administration of insulin suppositories containing 3 IU of insulin and 50 mg of adjuvant II (○) or adjuvant IV (×). The suppositories administered were prepared following formulas 1 and 2 (Table II). Each value in the figure indicates the mean and standard deviation of six rabbits.*

inside, and the other end of the segment was closed by ligation. The sac was placed into a test tube containing 40 ml of Krebs-Ringer's solution. The solution was held at 37° and aerated with an oxygen–carbon dioxide mixture (95:5). The concentration of glycerine esters in solution was determined by the assay described below.

Interaction of Glyceryl Esters with Calcium—The interaction of glyceryl esters with calcium was studied following a turbidimetric titration method previously described (3) with modifications (1).

Release of Adjuvants from Suppositories—The release of adjuvants from suppositories was studied using a previous method (4). A special apparatus[5] and a membrane filter (pore size 3.0 μm)[6] were used in the study of drug release from suppositories.

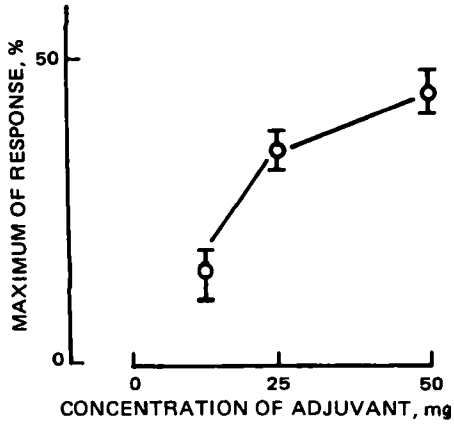

Figure 2—*Concentration effect of adjuvant II in suppositories containing 3 IU/body of insulin. The maximum response expressed in terms of the maximum change in glucose level as a percent of the initial level. Each value indicates the mean and standard deviation of six rabbits.*

Each value indicates the mean and standard deviation of six rabbits.*

Assays—The serum glucose level was determined with the *o*-toluidine boric acid method (5) with a modification using a glucose test kit[7]. Serum insulin levels of rats were determined by a radioimmunoassay method described previously (5) using an insulin assay kit containing an agarose-bound antibody[8]. Inulin was determined as previously described (6) with the following slight modifications. A 0.5-ml sample was mixed with 1 ml of 0.1% resorcinol in 95% ethanol and 2.5 ml of 30% hydrochloric acid in a glass-stoppered test tube. The test tube was kept in a water bath at a temperature of 80 ± 0.5° for 25 min. After cooling with running water for 3 min, the color of the solution was spectrophotometrically determined at 490 nm. The concentration of glyceryl esters of acetoacetic acid in solution was determined according to a previous method (1) as a function of acetoacetate.

RESULTS AND DISCUSSION

As control experiments, 1.0-g suppositories containing glyceryl-1-monoacetoacetate (adjuvant I), glycerine-1,3-diacetoacetate (adjuvant II), glyceryl-1,2,3-triacetoacetate (adjuvant III), or 1,2-isopropylidene glyceryl-3-acetoacetate (adjuvant IV) at doses of 100 mg were administered to rabbits (Tables I and III). None of these control suppositories had any effect on the rabbits' serum glucose levels.

After rectal administration of suppositories (formulas 1 and 2 in Table II) containing 3 IU of insulin and only 50 mg of adjuvant, the serum glucose and serum insulin profiles were measured (Fig. 1). The administration of the suppositories containing adjuvants II and IV caused a dramatic decrease in glucose levels with minimums at 60–120 min and 60–90 min, respectively (Table I). Concomitantly, the serum insulin concentrations increased rapidly and reached maximum levels at 60 min for the suppositories containing adjuvant II and 30 min for adjuvant IV.

[7] Wako Pure Chemical Ind. Co., Japan.
[8] Pharmacia Co., Ltd., Japan.

Adjuvants I and III failed to reduce the serum glucose and did not increase the serum insulin level in these experiments. Adjuvants I and III also failed to enhance the rectal absorption of inulin. When 1.0-g suppositories (formula 5 in Table II) containing 25 mg of inulin/g and 50 mg of the adjuvant were rectally administered to rabbits, only adjuvants II and IV promoted inulin absorption (Table IV).

To study the effect of adjuvant concentration on the serum glucose

level, 1.0-g suppositories were prepared with concentrations ranging between 12.5 and 50 mg of adjuvant II or IV and containing 3 IU of insulin (Figs. 2 and 3). The insulin response was expressed as the maximum change in glucose relative to the initial level. With increasing adjuvant concentration in the suppositories, the maximum change in the serum glucose level increased accordingly. Rectal administration of 3 IU of insulin in the presence of 50 mg of adjuvant II or IV caused a 50% reduction in rabbit serum glucose concentration.

To study the dose–reponse profiles of insulin, 1.0-g suppositories containing 1.5–6.0 IU of insulin and 100 mg of adjuvant II were administered to rabbits (Fig. 4). The maximum response increased asymptotically with an increase in the insulin dose. Normal glucose level recovery took longer with higher concentrations of insulin. Similar results were obtained with adjuvant IV (Fig. 5).

In a previous paper (1), it was suggested that the absorption-promoting efficacy of enamine derivative was linearly related to their interacting ability with calcium ions located in the rectal membrane. In the present experiment, the addition of calcium gluconate or magnesium chloride

Table VI—Interacting Ability of Glycerol Derivatives with Calcium at pH 10.0 [a]

Adjuvant	Calcium gram per mole of compound
I	0.26
II	0.34
III	0.36
IV	0.28

[a] Gram of calcium ion interacting with 1 mole of glycerol derivative; results represent the mean of 3 determinations.

to suppositories markedly suppressed the promotive efficacy of adjuvants II and IV on the rectal absorption of insulin and inulin (Fig. 6 and Table V). The depressive effects of calcium and magnesium on the action of adjuvants were dramatically observed at doses shown in formulas 3, 4, 6, and 7 (Table II). Half doses of calcium and magnesium caused only small changes in the serum glucose compared with doses without the ions. These results appear to indicate that the promotive efficacy of glyceryl esters as well as enamine derivatives may be partly dependent on the interaction of the adjuvant with calcium and magnesium ions located in the rectal membrane. This interaction may cause transient gaps to form in the membrane allowing the insulin or inulin to permeate the rectal membrane more readily.

Even though the calcium binding ability of the four glyceryl esters was found to be similar to that of the enamine derivatives (Table VI), adjuvants I and III did not promote the rectal absorption of either insulin or inulin. Therefore, the promotive efficacy of adjuvants II and IV can not totally be explained by their ability to interact with calcium. To further explore possible absorption-enhancing mechanisms of these adjuvants, release of adjuvants from triglyceride base to water (maintained at 37° and continually stirred with a magnetic stirring bar) was studied (Fig. 7). The rates of release of the adjuvants were found to be in the order of I ($k_1 = 0.207$ min^{-1}), II ($k_1 = 0.115$ min^{-1}), IV ($k_1 = 0.029$ min^{-1}), and III (unmeasurable) as calculated by the following equation:

$$\frac{d(A_t/V)}{d_t} = k_1\left(\frac{A_0 - A_t}{V}\right) \qquad \text{(Eq. 1)}$$

where A_0 is the total amount of glycerol derivative in the system, A_t is the released amount of glycerol derivative at time t, V is the volume of the solution, and k_1 is the release rate constant.

Adjuvant III was inadequately released from the base owing to its poor water solubility. Thus, the deficiency in the promotive activity of adjuvant III may be explained by its inadequate partitioning property.

To investigate the deficiency in the promotive activity of adjuvant I, permeation of adjuvants and inulin through the excised sac of the rat rectum was studied (Fig. 8). Permeation rates were calculated using Eq. 2:

$$\frac{d(A_t/V)}{d_t} = k_2\left(\frac{A_0 - A_t}{V}\right) \qquad \text{(Eq. 2)}$$

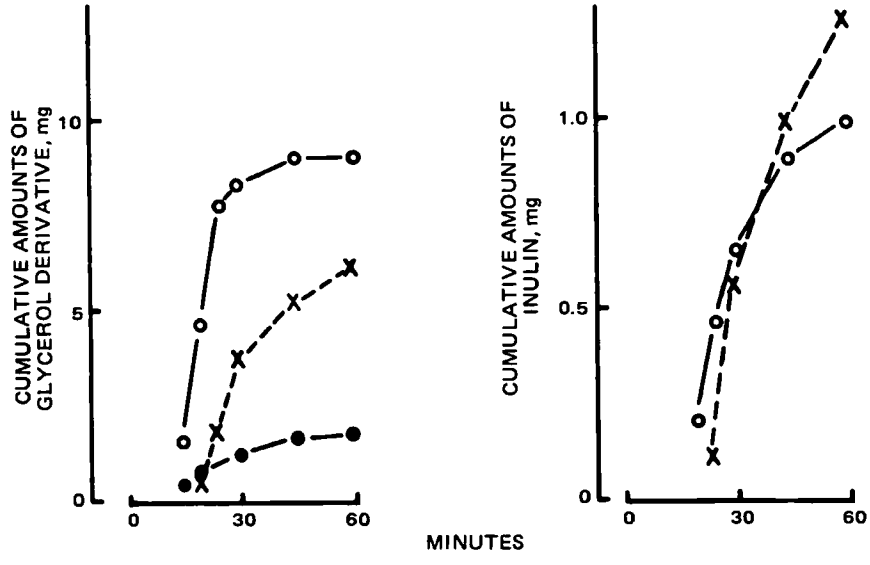

Figure 8—*Permeation of adjuvants I (●), II (○), and IV (×) with inulin through the excised sac of the rat rectum. Liquified suppositories (0.1 g) containing 10% of one of the glycerol derivatives and 30 mg of inulin/g of suppository were used.*

where all symbols are the same as before and k_2 is the permeation rate constant. Adjuvant I ($k_2 = 0.42 \times 10^2$ min^{-1}) did not readily cross the rectal membrane, possibly due to its strong lipophobicity. Adjuvants II ($k_2 = 7.29 \times 10^2$ min^{-1}) and IV ($k_2 = 1.91 \times 10^2$ min^{-1}) which are more lipophilic, easily permeated the rectal membrane and promoted the absorption of inulin.

Thus, adjuvant enhancement of rectal absorption of insulin and inulin appears to depend on at least three factors: adjuvants must be effectively released from the suppository, be able to permeate the membrane, and be able to interact with the calcium and magnesium ions in the membrane.

Analysis and Prediction of Partition Coefficients of *meta*- and *para*-Disubstituted Benzenes in Terms of Substituent Effects

TOSHIO FUJITA

Received November 13, 1981, from the *Department of Agricultural Chemistry, Kyoto University, Kyoto, Japan 606.* Accepted for publication May 5, 1982.

Abstract □ The hydrophobic substituent parameter for a system of *meta*- and *para*-disubstituted benzenes, XC_6H_4Y, defined as $\pi_{X/PhY} = \log P_{XC_6H_4Y} - \log P_{C_6H_5Y}$, where P is the octanol–water partition coefficient and X and Y are variable and fixed substituents, respectively, varies from one system to another, according to the variation in substituent effects on the hydrogen bonding association of substituents with solvents. Using parameters from monosubstituted benzenes, $\pi_{X/PhH}$ as the reference, the π_X values were analyzed by such relations as $\pi_{X/PhY} = a\pi_{X/PhH} + \rho_Y\sigma_X + \rho_X\sigma_Y$, where ρ_Y and ρ_X are susceptibilities of the relative hydrogen bonding association of substituents Y and X with two partitioning solvents to the electronic effect of X and Y, respectively. For substituents incapable of hydrogen bonding such as alkyl and halogen, the ρ value is 0. The parameter a is a constant $\simeq 1$. The relationship was applied in calculating log P values of disubstituted benzenes.

Keyphrases □ Partition coefficient—octanol–water, analysis and prediction, *meta*- and *para*-disubstituted benzenes in terms of substituent effects □ Disubstituted benzenes—*meta*- and *para*-, analysis and prediction of partition coefficient, substituent effects □ Structure–activity relationships—analysis and prediction of partition coefficient of *meta*- and *para*-disubstituted benzenes in terms of substituent effects

In recent years, log P values (P is the 1-octanol–water partition coefficient) have been widely used as a parameter of the hydrophobic property of organic compounds in structure–activity studies (1). Log P values of complex molecules often can be calculated from those of suitable reference molecules and π values, where π is defined as $\pi_X = \log P_X - \log P_H$ (P_X is the coefficient value of a derivative on which the substituent X is carried and P_H is the coefficient value of a reference).

As pointed out earlier, however, the π value varies from one solute system to another (2). It was suggested that the variation in π values of aromatic substituents in various disubstituted benzene systems should be rationalized in terms of electronic interactions between substituents when no significant steric interaction is involved (2). For *meta*- and *para*-X substituents in disubstituted benzene systems of the type XC_6H_4Y, it was proposed that the variation in π relative to the value obtained for the monosubstituted benzene system, XC_6H_4H, depends on electronic interaction between each of the X-substituents and the fixed function Y, and is formulated, in general, as:

$$\Delta\pi = \pi_{X/PhY} - \pi_{X/PhH} = \rho_Y\sigma_X + \rho_X\sigma_Y \quad \text{(Eq. 1)}$$

where ρ_Y and ρ_X are the susceptibility constants of substituents Y and X to the solubility-modifying effects of substituents X and Y, respectively.

Since interest in the use of log P values in quantitative structure–activity studies is growing rapidly, it is important to clarify the composition of π values from various solute systems. The present report examines how far relations such as Eq. 1 can be applied in predicting π values for calculation of log P values.

EXPERIMENTAL

Solute Systems—Seventeen sets of π values (a total of 360 values) were used for the study. They were calculated from log P values of 17 disubstituted benzene solute systems and the corresponding reference monosubstituted benzenes. The majority of the log P values were taken from earlier reports (2, 3).

Several were determined[1] according to the reported procedure (2). Other values, *e.g.*, those for substituted benzamides (4), formanilides (5), acetanilides (6), and pyridines (7), are from the literature.

General Procedure—It was assumed that the solubility-modifying effect of substituent X on Y, as well as that of Y on X, was due primarily to the variation in hydrogen bonding association of substituents with solvents, according to the variation in the electronic environment of substituents X and Y. In actual examination of the applicability of Eq. 1, analysis was performed according to equations where $\pi_{X/PhY}$ and $\pi_{X/PhH}$ were used as dependent and independent variables, respectively. Although it should be close to 1, the slope of the $\pi_{X/PhH}$ term is not necessarily equal to 1. To avoid giving the unsubstituted solute excessive weight, an intercept term, c, has been included which should be close to 0. Equation 2 is employed when the fixed substituent Y is capable of hydrogen bonding:

$$\pi_{X/PhY} = a\pi_{X/PhH} + \rho_Y\sigma_X + \rho_X\sigma_Y(meta) + \rho_X\sigma_Y(para) + c \quad \text{(Eq. 2)}$$

[a] $\pi_{X/PhY} = a\pi_{X/PhH} + \rho_Y\sigma_X^0 + \rho_X\sigma_Y^0(m) + \rho_X\sigma_Y^0(p) + c$; unless noted, all of the terms except for the intercept values are justified above the 99.5% level; figures in parentheses are the 95% confidence intervals. [b] Standard deviation. [c] Correlation coefficient. [d] Number of points used for correlations. [e] Justified at the 95% level. [f] Justified at the 93% level. [g] Justified at the 50% level.

For cases when Y is incapable of association:

$$\pi_{X/PhY} = a\pi_{X/PhH} + \rho_X\sigma_Y(meta) + \rho_X\sigma_Y(para) + c \quad \text{(Eq. 3)}$$

Since the effect of Y on X is accounted for either by $\sigma_Y(meta)$ or $\sigma_Y(para)$, depending on the position of X-substituents, the term $\rho_X\sigma_Y$ in Eq. 1 should be separated as in Eqs. 2 and 3. Each of the $\rho_X\sigma_Y$ terms is only applicable to each of the corresponding *meta*- and *para*-substituents. For nonhydrogen-bonding variable substituents X, the value of ρ_X should be taken as 0. For π values derived from a set of XC_6H_4Y compounds where a fixed substituent Y is capable of hydrogen-bonding while the variable X substituents are not, Eq. 2 can be simplified as:

$$\pi_{X/PhY} = a\pi_{X/PhH} + \rho_Y\sigma_X + c \quad \text{(Eq. 4)}$$

According to recent studies on the hydrogen-bonding effect on oil–water partitioning of substituted benzene derivatives, substituents such as hydrogen, halogen, alkyl, phenyl, trifluoromethyl (CF_3), and pentafluorothio (SF_5) are discriminated as nonhydrogen bonders (8).

Values of σ^0 were used throughout this study. Preliminary examinations showed that σ^0 works better than σ^- for π values from phenols and anilines. Even π values from benzoic acids and benzamides were better correlated by σ^0 than σ. Values for $\pi_{X/PhH}$ (1) and σ^0 (9) used for correlations were taken from the literature.

The values for a, ρ_Y, σ_Y (*meta*), σ_Y (*para*), and c were determined by regression analysis. If the correlation is complete, σ_Y (*meta*) and σ_Y (*para*) values determined as regression coefficients of ρ_X terms should be equal to the respective σ values of the fixed substituent Y.
