Pharmacokinetics of Drugs in Blood III: Metabolism of Procainamide and Storage Effect of Blood Samples

Keyphrases □ Pharmacokinetics—procainamide metabolism, storage effect of blood samples, *N*-acetylprocainamide □ Procainamide metabolism—pharmacokinetics, storage effect of blood samples, *N*-acetylprocainamide

To the Editor:

The distribution kinetics and metabolism of drugs in blood are of importance in pharmacokinetic studies. For instance, if a drug equilibrates slowly between plasma and blood cells, the time elapsed between collection and centrifugation of a blood sample could have a significant effect on the plasma concentration measured, which might differ considerably from the true *in vivo* concentration. This has been recently shown with gentamicin and furosemide (1, 2). A similar problem might also be anticipated if a drug undergoes *in vitro* metabolism in the blood. The above phenomenon has been referred to as the storage effect of blood (1, 2). This communication reports our preliminary studies on the metabolism of procainamide in blood and the storage effect of blood samples for procainamide and its metabolites.

Freshly withdrawn[1], heparinized control blood from five healthy subjects, aged 25–41 years, was used. None of the subjects received any medication for at least 1 month prior to the study. The whole blood (10 ml) in test tubes[2] from each subject was spiked with procainamide[3] stock solution (2 mg/ml of free base) to yield a concentration of 20 μg/ml. After manually mixing for 30 sec, each blood sample was quickly divided (1.0 ml) into 10 vials. The sealed vials were then stored (time zero) in a refrigerator (5°). To prevent any interaction between the drug and the stopper, the screw caps of the test tubes and vials used were all lined with aluminum foil. Similar preparations were carried out with blood samples kept at ambient temperature (25 ± 1.0°). These temperatures were chosen in order to simulate common procedures for handling blood samples. The vials were removed and centrifuged immediately at various times up to 48 hr. All the plasma samples were frozen until analyzed for procainamide and its metabolite, *N*-acetylprocainamide, using a modified high-performance liquid chromatographic (HPLC) method which was developed earlier in this laboratory (3).

Briefly, the assay involved the addition of 0.25 ml acetonitrile to 0.1 ml of plasma sample in a test tube[2]. After vortex-mixing and centrifugation, 20 μl of the supernatant solution was injected directly onto the column. The instrumentation consisted of a solvent delivery pump[4], a syringe-loading sample injector[5], a cation exchange column[6], and a fixed-wavelength detector[7] with 254-nm filter. The mobile phase was made of 75% (v/v) 0.12 *M* ammonium phosphate acidified with phosphoric acid (0.2%) and 25% acetonitrile; the flow rate was 2.5 ml/min. By this method, the detection limit was 0.2 μg/ml for both procainamide and *N*-acetylprocainamide in plasma.

Figure 1 shows the typical plasma concentration profiles of procainamide from the above studies in three subjects. Assuming that procainamide initially was only confined to plasma, based on the individually determined hematocrits, one could estimate its concentrations from the three subjects to be 40, 40, and 35 μg/ml, respectively. However, the results (Fig. 1) show much lower concentrations (15.6–18.7 μg/ml) obtained immediately after spiking and brief mixing, indicating an initial rapid and extensive distribution of the drug to blood cells. Adsorption of the drug onto the glass tube could be ruled out, since there was no initial loss of procainamide from the whole blood in subsequent studies.

The plasma concentrations, in general, decreased with time (Fig. 1). However, fluctuations in the measured concentration were usually found during the initial 12 hr of

Pharmacokinetics of Drugs in Blood III: Metabolism of Procainamide and Storage Effect of Blood Samples

Keyphrases □ Pharmacokinetics—procainamide metabolism, storage effect of blood samples, *N*-acetylprocainamide □ Procainamide metabolism—pharmacokinetics, storage effect of blood samples, *N*-acetylprocainamide

To the Editor:

The distribution kinetics and metabolism of drugs in blood are of importance in pharmacokinetic studies. For instance, if a drug equilibrates slowly between plasma and blood cells, the time elapsed between collection and centrifugation of a blood sample could have a significant effect on the plasma concentration measured, which might differ considerably from the true *in vivo* concentration. This has been recently shown with gentamicin and furosemide (1, 2). A similar problem might also be anticipated if a drug undergoes *in vitro* metabolism in the blood. The above phenomenon has been referred to as the storage effect of blood (1, 2). This communication reports our preliminary studies on the metabolism of procainamide in blood and the storage effect of blood samples for procainamide and its metabolites.

Freshly withdrawn[1], heparinized control blood from five healthy subjects, aged 25–41 years, was used. None of the subjects received any medication for at least 1 month prior to the study. The whole blood (10 ml) in test tubes[2] from each subject was spiked with procainamide[3] stock solution (2 mg/ml of free base) to yield a concentration of 20 μg/ml. After manually mixing for 30 sec, each blood sample was quickly divided (1.0 ml) into 10 vials. The sealed vials were then stored (time zero) in a refrigerator (5°). To prevent any interaction between the drug and the stopper, the screw caps of the test tubes and vials used were all lined with aluminum foil. Similar preparations were carried out with blood samples kept at ambient temperature (25 ± 1.0°). These temperatures were chosen in order to simulate common procedures for handling blood samples. The vials were removed and centrifuged immediately at various times up to 48 hr. All the plasma samples were frozen until analyzed for procainamide and its metabolite, *N*-acetylprocainamide, using a modified high-performance liquid chromatographic (HPLC) method which was developed earlier in this laboratory (3).

Briefly, the assay involved the addition of 0.25 ml acetonitrile to 0.1 ml of plasma sample in a test tube[2]. After vortex-mixing and centrifugation, 20 μl of the supernatant solution was injected directly onto the column. The instrumentation consisted of a solvent delivery pump[4], a syringe-loading sample injector[5], a cation exchange column[6], and a fixed-wavelength detector[7] with 254-nm filter. The mobile phase was made of 75% (v/v) 0.12 *M* ammonium phosphate acidified with phosphoric acid (0.2%) and 25% acetonitrile; the flow rate was 2.5 ml/min. By this method, the detection limit was 0.2 μg/ml for both procainamide and *N*-acetylprocainamide in plasma.

Figure 1 shows the typical plasma concentration profiles of procainamide from the above studies in three subjects. Assuming that procainamide initially was only confined to plasma, based on the individually determined hematocrits, one could estimate its concentrations from the three subjects to be 40, 40, and 35 μg/ml, respectively. However, the results (Fig. 1) show much lower concentrations (15.6–18.7 μg/ml) obtained immediately after spiking and brief mixing, indicating an initial rapid and extensive distribution of the drug to blood cells. Adsorption of the drug onto the glass tube could be ruled out, since there was no initial loss of procainamide from the whole blood in subsequent studies.

The plasma concentrations, in general, decreased with time (Fig. 1). However, fluctuations in the measured concentration were usually found during the initial 12 hr of

study. Similar results were obtained when blood samples were spiked with 6 μg/ml of procainamide. These unusual distribution kinetics were observed in most of our studies either at 25 or 5°. It is felt that the above findings, especially those showing larger fluctuations, could not be an artifact, since the assays were conducted in duplicate and their coefficients of variation were <3.5%. In addition, simultaneous analysis of blood procainamide concentration in separate studies showed essentially a declining pattern, presumably due to metabolism of the drug in blood. At present, the cause or exact mechanism is unclear. Nevertheless, a possible reason might be the formation of Schiff bases between the drug and free fatty aldehydes on cell membranes, as proposed for gentamicin (1).

The formation of *N*-acetylprocainamide occurred in all the *in vitro* studies. This was shown by the appearance of peaks in the chromatograms (Fig. 2), with their retention time identical to that from the authentic samples. Typical time profiles of *N*-acetylprocainamide from subject 2 are depicted in Fig. 3. The *in vitro* formation of this metabolite in the present study appeared to be temperature dependent and to follow approximately a zero-order process, which could last up to 24 hr in some subjects. Based on the apparent linear portion of the curves (Fig. 3), the mean appearance rates of *N*-acetylprocainamide in plasma at 5 and 25° were calculated to be ~0.05 and 0.10 μg/ml/hr, respectively. It should be noted that although *N*-acetylation of procainamide has been found to take place in whole blood (4), the distribution kinetics and its implication were not reported.

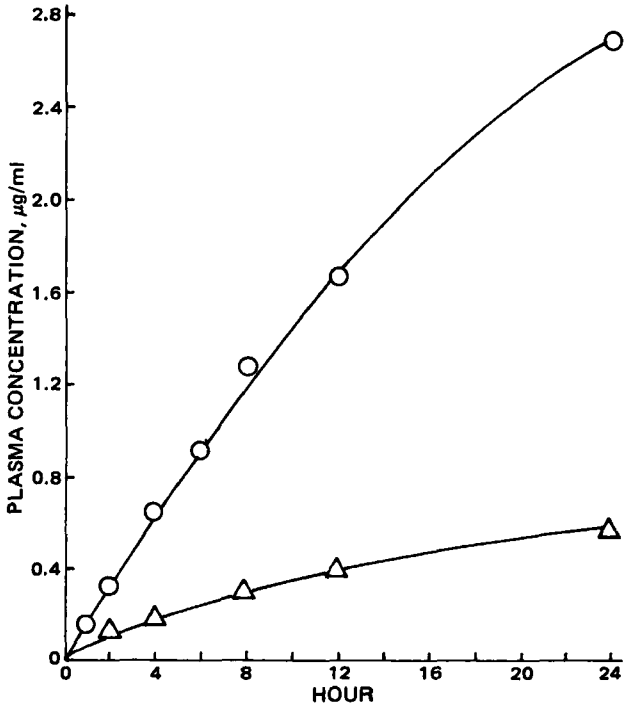

Figure 3—N-*Acetylprocainamide plasma concentration–time profiles from the blood of the second subject spiked with 20 μg/ml of procainamide and kept at 5° (△) and 25° (○).*

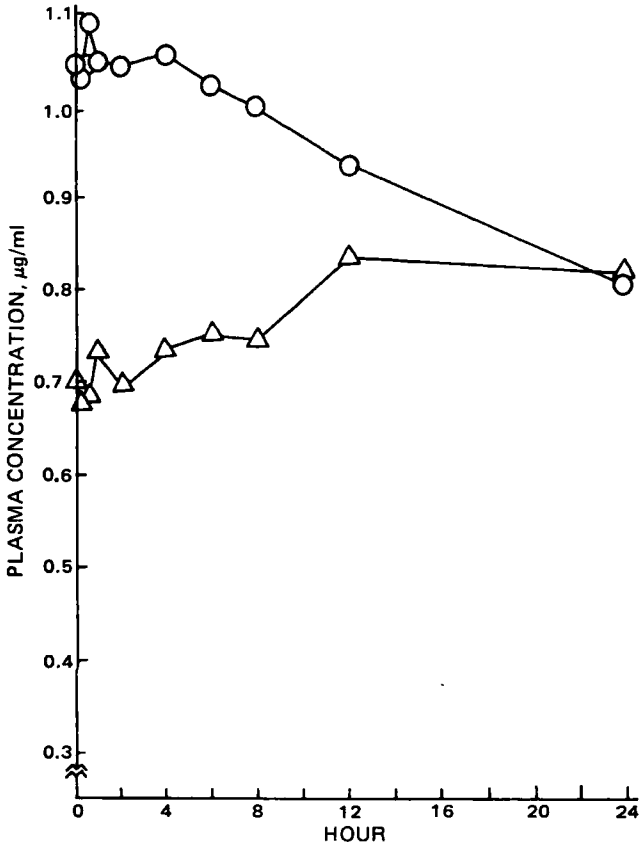

Figure 4—*Procainamide (○) and N-acetylprocainamide (△) plasma concentration–time profiles in a blood sample kept at ambient temperature.*

A second metabolite with shorter retention than *N*-acetylprocainamide (Fig. 2) was found in all chromatograms except those from samples obtained at earlier times. This unidentified metabolite was also found in many cases after the administration of procainamide to rabbits (5) and humans (6). Recent studies (7) have shown that desethyl procainamide and desethyl *N*-acetylprocainamide might be two additional metabolites of procainamide. However, identification of the unknown product was not made due to the lack of authentic samples. According to the relative peak heights, the appearance rate of this unidentified metabolite in plasma also followed a zero-order process in the first 12 hr of study.

To ascertain whether metabolism took place in plasma or blood cells, pooled plasma was spiked with procainamide to yield an initial concentration of 20 μg/ml and kept at ambient temperature for various periods of time. No metabolite formation could be found up to 48 hr, indicating that blood cells are the sole site of metabolism in whole blood. Since the plasma concentrations of procainamide were essentially identical during the study, no degradation of plasma samples could be assumed.

The results of the above *in vitro* studies suggest that the time between collection and centrifugation of a blood sample may have a considerable influence on the measured plasma levels of procainamide and its metabolites. This was supported by another experiment in which ~10 ml of blood was collected shortly before the next scheduled dose from an adult male patient on chronic oral procainamide therapy (Fig. 4). During the 24 hr of storage, the difference between the minimum and maximum plasma concentrations measured for procainamide was ~ 35% and that for *N*-acetylprocainamide was 24%. Similar effects also were observed from two rabbits, whose blood was collected in syringes[8] after intravenous dosing of procainamide.

In light of the results of this study, it appears that a prudent approach is to separate plasma as soon as the blood sample is collected; this might minimize the difference between the true *in vivo* plasma concentration and the measured *in vitro* concentration. More work is required in order to fully assess the potential significance of the present findings in the pharmacokinetic studies.

Nonlinear Regression Approach for Determining Whether Absorption and Elimination Rate Constants are Equal in the One-Compartment Open Model with First-Order Processes

Keyphrases □ Pharmacokinetics—one-compartment open model, nonlinear regression analysis, absorption rate constants, elimination rate constants

To the Editor:

Recently Bialer reported a simple method for determining whether absorption and elimination rate constants are equal in the one-compartment open model with first-order processes (1). The basis for this method is that whenever the product of time of peak drug concentration (t_{max}) is equal to total area under curve (AUC) divided by the base of natural logarithm (e), the absorption rate constant (k_a) must be equal to the elimination rate con-

0022-3549/83/0500-0574$01.00/0

stant (k_e). This method is mathematically sound, but when applied to clinical study data, t_{max} and C_{max} are difficult to determine with sufficient accuracy, and the true t_{max} and C_{max} may be missed with routine sampling protocol. Additionally, the calculation of the AUC requires an accurate estimate of the half-life of the terminal portion of the concentration–time curve to estimate the residual area remaining after the last measured concentration. The terminal half-life estimation requires fitting the terminal portion concentration–time of the curve or, preferentially, the entire profile by some standard fitting procedure to an *a priori* model. Thus, satisfaction of the criterion stated above may not be obvious. It is, therefore, of interest to see if there is an alternate method which can achieve the same result.

In a one-compartment open model with first-order absorption and elimination the plasma–drug concentration (C_b) is defined generally by:

$$C_b = \frac{FDk_a}{V_d(k_a - k_e)}(e^{-k_e t} - e^{-k_a t}) \qquad \text{(Eq. 1)}$$

The relevance of this equation and the relationship between k_a and k_e have been discussed extensively in standard texts (2, 3). Generally speaking, when k_a is larger than k_e, the terminal phase reflects the process of elimination. The other case is the flip-flop model where k_a is smaller than k_e, and the terminal phase reflects the process of absorption. In the special case where k_a is equal to k_e Eq. 1 becomes mathematically irrelevant, since the derivation of Eq. 1 requires that $k_a \neq k_e$. In this case, the general equation describing the plasma–drug concentration has to be derived from the basic model setting $k = k_a = k_e$. By employing a standard technique such as Laplace transform, Eq. 2 can be obtained (1, 2):

$$C_b = \frac{FD}{V_d} kte^{-kt} \qquad \text{(Eq. 2)}$$

There are a number of techniques commonly used to obtain values for the rate constants of absorption and elimination. These include the manual method of residuals (feathering) and computer-based nonlinear regression techniques using least-squares criteria. The Wagner–Nelson method makes no specific compartmental model assumption and can also be used to estimate k_a. However, when $k_a = k_e$, absorption occurs throughout the whole process. Therefore, any technique that involves assuming the terminal phase reflects solely an absorption or elimination process will fail to reveal the true rate constants. This is not the case for nonlinear least-squares regression analysis. Provided that there is some minute difference between k_a and k_e, nonlinear regression may be applied to the data. To test this alternative, data with only rounding error were generated using Eq. 2 with FD/V_d = 10, $k = k_a = k_e = 0.5$ (Table I). Concentrations with 5% random noise are also listed in Table I.

Table I—Simulated Concentration Data Using Eq. 2 with $FD/V_d = 10$ and $k = k_a = k_e = 0.5$

Time	Concentration	Concentration with 5% Noise
0.25	1.10	1.10
0.5	1.95	1.95
1.0	3.03	3.18
2.0	3.68	3.68
3.0	3.35	3.52
4.0	2.71	2.85
5.0	2.05	2.05
6.0	1.49	1.42
8.0	0.73	0.69
10.0	0.34	0.36
12.0	0.15	0.14

With no *a priori* knowledge of the values of k_a and k_e, the two rate constants were estimated by using the method of residuals, the Wagner–Nelson method (4), the decision-making program AUTOAN (5), and the nonlinear regression program NONLIN (6). The results are listed in Table II.

Application of the graphical method of residuals revealed no problems except that the residual line seemed to show some curvature. The values for k_a and k_e obtained by this method were 0.87 and 0.39, respectively. The Wagner–Nelson method also revealed no problems and the values for k_a and k_e obtained by this method were 0.67 and 0.40, respectively. The same data were fitted by the decision-making program AUTOAN. Curve stripping, the first part of the AUTOAN output, indicated that the best number of exponential is 3 and the data are best described by a one-compartment open model with two first-order input steps, k_1 and k_2. The second part of the AUTOAN output using the 1969 version of NONLIN to fit the data according to this model yielded values for k_1, k_2, k_e, and R^2 of 0.707, 2.634, 0.450, and 0.855, respectively. Finally, using rate constants obtained from the method of residuals as initial estimates, and assuming the model described by Eq. 1, the 1974 version of NONLIN successfully converged to the real values. The goodness of fit was exemplified by the R^2 value and the small standard deviation of the parameters estimates (Table II).

The method of residuals, the Wagner–Nelson method, curve stripping, and nonlinear regression are probably the

most routine procedures for determining model rate constants. The first three methods are obviously bad choices when $k_a = k_e$. A nonlinear regression analysis program such as NONLIN, with the simplest model, successfully revealed the real values of k_a and k_e. Bialer's criteria (1) can serve as additional proof of the NONLIN output.

It should be emphasized that although nonlinear regression techniques successfully converged to the real rate constants used to generate the data in the example, this does not imply that Eq. 1 is the only model which can be fitted to the data. The problems associated with obtaining a reliable value for a pharmacokinetic parameter, such as absorption rate constants after oral administration, have been previously identified. For example, a multiple-compartment open model may also be collapsed to a one-compartment open model under certain conditions (7). In reality, the true model is rarely known, and in most cases one can not distinguish one model from another. However, this study demonstrated that if Eq. 1 represents a true model, nonlinear regression analysis separates the rate constants where other methods can not.

Kinetic Interpretation of the Microparameters in Compartmental Modeling When Adjoining Compartments are Sampled

Keyphrases □ Pharmacokinetic analysis—compartmental modeling □ Compartmental modeling—kinetic interpretation of microparameters □ Diffusional transport hypothesis—compartmental modeling

To The Editor:

In linear compartmental modeling, the rate of mass transfer of drug from compartment i to compartment j is $k_{ij}x_i$, and for the reverse transfer $k_{ji}x_j$, where the k's are constant microparameters and the x's stand for the amounts in the compartments (1). It appears tempting to justify compartmental pharmacokinetic analysis by attaching special kinetic significance to the microparameters. However, it is well recognized that this type of modeling is merely an abstract mathematical way of accounting for the combined effect of many complex disposition processes, which are too difficult or impossible to consider individually, in order to explain the concentration profile in a sampled compartment; typically the blood. It is also recognized that in pharmacokinetic practice when dealing with prediction and adjustment of blood levels, in the calculation of dosage regimens and in the evaluation of drug input, there is no need for compartmental modeling. It would be irrational to do so, because the required calculations can (at least for dose-linear systems) be done simply on the basis of the principles of superposition, convolution, or deconvolution. However, there are cases in pharmacokinetics where more than one tissue compartment is sampled for the drug. A compartmental type of kinetic analysis is then definitely justified. The blood–brain barrier (BBB) transfer kinetics of theophylline in dogs has recently been investigated. In the analysis, the classical linear compartmental approach was avoided because it appears completely irrational to assume that the transfer across a membrane is proportional to amounts and not to a concentration differential. A model-independent approach combined with a more rational compartmental transport mechanism was applied instead. In analyzing the equations resulting from this approach an interesting relationship was discovered between the diffusion and binding parameters and the microparameters in a classical compartmental approach. It is of interest to communicate these findings which bring the classical compartmental modeling into a different perspective.

The Diffusion Approach: The diffusion rate of the drug across the BBB is proportional to the difference between the free drug concentrations on the two sides of the barrier:

$$\frac{d}{dt}[V_cC_c(t)] = K_1[F_sC_s(t) - F_cC_c(t)] \quad \text{(Eq. 1)}$$

Subscripts c and s denote cerebrospinal fluid (CSF) and serum, respectively; V, C, and F stand for volume, total drug concentration, and free (unbound) fraction, respectively; while K_1 is a positive diffusion constant. Equation 1 assumes that the drug is not metabolized in the CSF, which is consistent with our current knowledge about the metabolic systems present on the CNS side of the BBB (2). The equation can readily be solved by Laplace transforms to give the following expression relating the total concentration of the drug in the CSF to the total concentration in the serum:

$$C_c(t) = \left(\frac{F_cK_1}{V_c}\frac{F_s}{F_c}\right) C_s(t) * e^{(F_cK_1/V_c)t} \quad \text{(Eq. 2)}$$

where * denotes convolution.

The derivation of Eq. 2 assumes that F_c and F_s do not depend significantly on the drug concentration. The free fractions depend on the unbound protein concentration as well as on the affinity of the protein for the drug. Usually only a small fraction of the available binding sites is occupied at therapeutic drug concentrations; therefore, the

0022-3549/83/0500-0576$01.00/0

most routine procedures for determining model rate constants. The first three methods are obviously bad choices when $k_a = k_e$. A nonlinear regression analysis program such as NONLIN, with the simplest model, successfully revealed the real values of k_a and k_e. Bialer's criteria (1) can serve as additional proof of the NONLIN output.

It should be emphasized that although nonlinear regression techniques successfully converged to the real rate constants used to generate the data in the example, this does not imply that Eq. 1 is the only model which can be fitted to the data. The problems associated with obtaining a reliable value for a pharmacokinetic parameter, such as absorption rate constants after oral administration, have been previously identified. For example, a multiple-compartment open model may also be collapsed to a one-compartment open model under certain conditions (7). In reality, the true model is rarely known, and in most cases one can not distinguish one model from another. However, this study demonstrated that if Eq. 1 represents a true model, nonlinear regression analysis separates the rate constants where other methods can not.

Kinetic Interpretation of the Microparameters in Compartmental Modeling When Adjoining Compartments are Sampled

Keyphrases □ Pharmacokinetic analysis—compartmental modeling □ Compartmental modeling—kinetic interpretation of microparameters □ Diffusional transport hypothesis—compartmental modeling

To The Editor:

In linear compartmental modeling, the rate of mass transfer of drug from compartment i to compartment j is $k_{ij}x_i$, and for the reverse transfer $k_{ji}x_j$, where the k's are constant microparameters and the x's stand for the amounts in the compartments (1). It appears tempting to justify compartmental pharmacokinetic analysis by attaching special kinetic significance to the microparameters. However, it is well recognized that this type of modeling is merely an abstract mathematical way of accounting for the combined effect of many complex disposition processes, which are too difficult or impossible to consider individually, in order to explain the concentration profile in a sampled compartment; typically the blood. It is also recognized that in pharmacokinetic practice when dealing with prediction and adjustment of blood levels, in the calculation of dosage regimens and in the evaluation of drug input, there is no need for compartmental modeling. It would be irrational to do so, because the required calculations can (at least for dose-linear systems) be done simply on the basis of the principles of superposition, convolution, or deconvolution. However, there are cases in pharmacokinetics where more than one tissue compartment is sampled for the drug. A compartmental type of kinetic analysis is then definitely justified. The blood–brain barrier (BBB) transfer kinetics of theophylline in dogs has recently been investigated. In the analysis, the classical linear compartmental approach was avoided because it appears completely irrational to assume that the transfer across a membrane is proportional to amounts and not to a concentration differential. A model-independent approach combined with a more rational compartmental transport mechanism was applied instead. In analyzing the equations resulting from this approach an interesting relationship was discovered between the diffusion and binding parameters and the microparameters in a classical compartmental approach. It is of interest to communicate these findings which bring the classical compartmental modeling into a different perspective.

The Diffusion Approach: The diffusion rate of the drug across the BBB is proportional to the difference between the free drug concentrations on the two sides of the barrier:

$$\frac{d}{dt}[V_cC_c(t)] = K_1[F_sC_s(t) - F_cC_c(t)] \quad \text{(Eq. 1)}$$

Subscripts c and s denote cerebrospinal fluid (CSF) and serum, respectively; V, C, and F stand for volume, total drug concentration, and free (unbound) fraction, respectively; while K_1 is a positive diffusion constant. Equation 1 assumes that the drug is not metabolized in the CSF, which is consistent with our current knowledge about the metabolic systems present on the CNS side of the BBB (2). The equation can readily be solved by Laplace transforms to give the following expression relating the total concentration of the drug in the CSF to the total concentration in the serum:

$$C_c(t) = \left(\frac{F_cK_1}{V_c}\frac{F_s}{F_c}\right) C_s(t) * e^{(F_cK_1/V_c)t} \quad \text{(Eq. 2)}$$

where * denotes convolution.

The derivation of Eq. 2 assumes that F_c and F_s do not depend significantly on the drug concentration. The free fractions depend on the unbound protein concentration as well as on the affinity of the protein for the drug. Usually only a small fraction of the available binding sites is occupied at therapeutic drug concentrations; therefore, the

0022-3549/83/0500-0576$01.00/0

free fraction is relatively constant and independent of the drug concentration (3).

The diffusional transport hypothesis (Eq. 1) was verified kinetically in the following manner according to Eq. 2: A suitable arbitrary function was chosen to approximate the $C_s(t)$ response. (The fitting of a two-exponential expression to the C_s, t data appeared to give an excellent approximation.) The fitting of the arbitrary function to the serum data was done simultaneously with the fitting to the CSF data of a second function resulting from convoluting the first function according to Eq. 2. Good correlations to the CSF and serum data were observed.

The Classical Compartmental Approach: The rate of change of the amount, x_c, of drug in the CSF is

$$\frac{dx_c}{dt} = k_{sc}x_s - k_{cs}x_c \qquad \text{(Eq. 3)}$$

where k_{sc} and k_{cs} are the first-order rate constants for the transfer of drug from serum to CSF and reverse, respectively. Solving Eq. 3 through Laplace transforms gives:

$$x_c(t) = k_{sc}x_s(t)*e^{-k_{cs}t} \qquad \text{(Eq. 4)}$$

so that

$$C_c(t) = k_{sc}\left(\frac{V_s}{V_c}\right)C_s(t)*e^{-k_{cs}t} \qquad \text{(Eq. 5)}$$

By comparing Eqs. 5 and 2 the following relations are obtained:

$$V_c k_{cs} = F_c K_1 \qquad \text{(Eq. 6)}$$

$$V_s k_{sc} = F_s K_1 \qquad \text{(Eq. 7)}$$

One can, therefore, in this case of compartmental analysis with data available from adjoining compartments, relate the microparameters of the abstract mass transfer of classical compartmental modeling to the more meaningful parameters of a rational, diffusional-based transport mechanism (Eq. 1).

The relationships (Eqs. 6 and 7) may be stated simply as follows: The intercompartmental clearances are equal to the intercompartmental diffusion rate constant multiplied by the free fraction of the drug in the respective compartment.

The above analysis is valid for any complexity of the compartmental system as long as one of the two sampled, adjoining compartments is not connected to other compartments.

Predicting the Dose-Dependent Bioavailability of Hydrocortisone and Chlorothiazide in Humans

Keyphrases □ Bioavailability—dose dependency, hydrocortisone, chlorothiazide □ Hydrocortisone—dose-dependent bioavailability, saturable absorption kinetics □ Chlorothiazide—dose-dependent bioavailability, saturable absorption kinetics

To the Editor:

A recent report (1) described the occurrence and mechanisms of dose-dependent saturable absorption kinetics for several commonly used drugs. Equations were also derived, on the basis of the classical Michaelis–Menten approach, to predict such dose-dependent absorption kinetics (1). In the present communication, these equations are applied, in an effort to predict the recently reported, nonproportional dose bioavailability data on hydrocortisone (2) and chlorothiazide (3).

Predicted values for hydrocortisone plasma levels (C_{max}), area under the curve (AUC) and AUC corrected for variance in the first-order rate constant for drug elimination (AUC_{kel}) as well as chlorothiazide urine recovery were calculated using the parameters obtained from the derived equations reported earlier (1). Tables I and II list these calculated parameters and compare the observed values with the predicted values for each dose of hydrocortisone and chlorothiazide, respectively. The excellent correlations between the observed and predicted values attest to the validity of the saturable absorption predictive model for those two drugs. It should be noted that the dose-dependent hydrocortisone tablet data (4) also can be treated in a similar manner with good predictability.

The saturable absorption of chlorothiazide is probably related to the existence of an absorption window (1), inasmuch as the average urinary recovery of chlorothiazide is increased in humans in the presence of food (5) and in dogs following propantheline bromide administration (6).

Table I—Comparison of Observed and Predicted Values for Hydrocortisone

Dose, mg	C_{max}[a], ng/ml		AUC[b], ng·hr/ml		$AUC_{\cdot k_{el}}$[c], ng/ml	
	Obs[d]	Pred[e]	Obs	Pred	Obs	Pred

10	175	188	447	502	248	267
20	263	278	835	838	377	396
40	389	366	1340	1259	553	521
r value	0.990		0.996		0.991	

[a] C_{max} = 533 ng/ml when the Michaelis constant (K_m) is 18.2 mg. [b] AUC_{max} = 2531 ng·hr/ml when K_m = 40.4 mg. [c] $(AUC \cdot k_{el})_{max}$ = 763 ng/ml when K_m = 18.5 mg. [d] Observed values (Obs) from previously published work (2). [e] Predicted values (Pred) calculated using previously derived equations (1).

Table II—Comparison of Observed and Predicted Urine Recovery for Chlorothiazide

Dose, mg	Recovery, mg[a]	
	Obs[b]	Pred[c]
50	28.3	28.0
100	47.0	47.8
250	83.3	82.7
r value	0.999	

[a] $Recovery_{max}$ = 161.6 mg when K_m = 238.2 mg. [b] Observed values (Obs) from previously published work (3). [c] Predicted values (Pred) calculated using previously derived equations (1).

0022-3549/83/0500-0577$01.00/0

free fraction is relatively constant and independent of the drug concentration (3).

The diffusional transport hypothesis (Eq. 1) was verified kinetically in the following manner according to Eq. 2: A suitable arbitrary function was chosen to approximate the $C_s(t)$ response. (The fitting of a two-exponential expression to the C_s, t data appeared to give an excellent approximation.) The fitting of the arbitrary function to the serum data was done simultaneously with the fitting to the CSF data of a second function resulting from convoluting the first function according to Eq. 2. Good correlations to the CSF and serum data were observed.

The Classical Compartmental Approach: The rate of change of the amount, x_c, of drug in the CSF is

$$\frac{dx_c}{dt} = k_{sc}x_s - k_{cs}x_c \qquad \text{(Eq. 3)}$$

where k_{sc} and k_{cs} are the first-order rate constants for the transfer of drug from serum to CSF and reverse, respectively. Solving Eq. 3 through Laplace transforms gives:

$$x_c(t) = k_{sc}x_s(t)*e^{-k_{cs}t} \qquad \text{(Eq. 4)}$$

so that

$$C_c(t) = k_{sc}\left(\frac{V_s}{V_c}\right)C_s(t)*e^{-k_{cs}t} \qquad \text{(Eq. 5)}$$

By comparing Eqs. 5 and 2 the following relations are obtained:

$$V_c k_{cs} = F_c K_1 \qquad \text{(Eq. 6)}$$

$$V_s k_{sc} = F_s K_1 \qquad \text{(Eq. 7)}$$

One can, therefore, in this case of compartmental analysis with data available from adjoining compartments, relate the microparameters of the abstract mass transfer of classical compartmental modeling to the more meaningful parameters of a rational, diffusional-based transport mechanism (Eq. 1).

The relationships (Eqs. 6 and 7) may be stated simply as follows: The intercompartmental clearances are equal to the intercompartmental diffusion rate constant multiplied by the free fraction of the drug in the respective compartment.

The above analysis is valid for any complexity of the compartmental system as long as one of the two sampled, adjoining compartments is not connected to other compartments.

0022-3549/83/0500-0577$01.00/0

Additional evidence for such site-specific absorption of chlorothiazide is presented by way of similar observations for the related drug hydrochlorothiazide in humans (7, 8).

The mechanism for the dose-dependency of hydrocortisone has been suggested to be an increased first-pass metabolism (2). By means of carefully planned studies, saturable binding and formulation factors were ruled out as determinants of the nonproportional dose–concentration relationship for hydrocortisone. Ease of absorption and linear absorption at the higher dosages used in previous studies (9, 10) were cited as the reasons for excluding saturable absorption as a contributing factor.

However, critical analysis of the two cited references (9, 10) on hydrocortisone absorption revealed the following information. First, a limited zone for absorption of hydrocortisone and hydrocortisone acetate existed in the small intestine of humans, inasmuch as the absorption from the proximal zone was nearly twice that from the distal zone. Absorption within the zones was linear. Second, the acetate ester was more efficiently absorbed than hydrocortisone. Third, both rate and extent of absorption was decreased in a malnourished patient in relapse with severe malabsorption. Last, absorption was higher when the gut was perfused under comparable conditions, using 1–5% glucose–Ringer's rather than Ringer's solution. This was probably due to the increased viscosity of the glucose–Ringer's solution and/or its energy-supplying potential as theorized previously (11). It should be mentioned that both the suspension and tablet studies (2, 4) administered the hydrocortisone dose with 180 ml of fluid, probably causing the drug to be washed past the zone of maximal absorption. The parallels between these observations for hydrocortisone and those aforementioned for chlorothiazide and hydrochlorothiazide absorption are all too obvious.

Further proof of a dose-dependent absorption phenomenon being operative for hydrocortisone is obtained by comparing the systemic availability, calculated by dividing mean AUC values after the suspension and tablet doses by those obtained after equivalent intravenous doses (2, 4, 12). The average systemic availability (F/V) of hydrocortisone was 71, 58, 56, 52, and 54% from the 5-, 10-, 20-, 30-, and 50-mg doses. In other words, there was a decrease in F, the fraction absorbed, with increasing dose, which contributed to the decrease in F/V with increasing dose seen in the tablet study (4). If, as suggested (2), there was a dose-dependent increase in the metabolism of an increased free fraction during the first pass, the systemic availability should increase, not decrease, with increasing dose. The latter would occur because of saturation of the hepatic enzymes by the increasing drug fraction. Increased systemic availability with increasing dose has been observed in the literature for propoxyphene (13) and several other drugs (14) known to undergo first-pass metabolism in humans. Additional factors that could possibly contribute to the dose-dependent bioavailability of hydrocortisone in humans include micromeritic and polymorphic effects with attendant stability and dissolution problems, as were observed with other corticosteroids (15).

In conclusion, hydrocortisone and chlorothiazide absorption after increasing, single, oral doses in humans, can be described by site-specific saturable absorption kinetics in the therapeutic dose range. The consequent dose-dependent bioavailability of these two drugs can be effectively predicted by use of the appropriate equations reported earlier (1). Use of these equations in the clinical setting should aid in the development of efficacious dosing protocols for any drug whose oral absorption is limited by the magnitude of the administered dose.

Modified Wagner–Nelson Absorption Equations for Multiple-Dose Regimens

Keyphrases □ Absorption—Wagner–Nelson equations, multiple-dose regimens, one-compartment open model □ Wagner–Nelson equations—modification, multiple-dose regimens, one-compartment model □ Kinetics—absorption, Wagner–Nelson equations

To the Editor:

Equations to calculate the amount of drug absorbed per milliliter of the volume of distribution and the percent absorbed as functions of time for the one-compartment open model (1) are commonly referred to as Wagner–Nelson equations. The nature of such plots when the equations are applied to data obeying the two-compartment open model with first-order absorption was discussed by Wagner (2). In this communication modified equations

0022-3549/83/0500-0578$01.00/0

Additional evidence for such site-specific absorption of chlorothiazide is presented by way of similar observations for the related drug hydrochlorothiazide in humans (7, 8).

The mechanism for the dose-dependency of hydrocortisone has been suggested to be an increased first-pass metabolism (2). By means of carefully planned studies, saturable binding and formulation factors were ruled out as determinants of the nonproportional dose–concentration relationship for hydrocortisone. Ease of absorption and linear absorption at the higher dosages used in previous studies (9, 10) were cited as the reasons for excluding saturable absorption as a contributing factor.

However, critical analysis of the two cited references (9, 10) on hydrocortisone absorption revealed the following information. First, a limited zone for absorption of hydrocortisone and hydrocortisone acetate existed in the small intestine of humans, inasmuch as the absorption from the proximal zone was nearly twice that from the distal zone. Absorption within the zones was linear. Second, the acetate ester was more efficiently absorbed than hydrocortisone. Third, both rate and extent of absorption was decreased in a malnourished patient in relapse with severe malabsorption. Last, absorption was higher when the gut was perfused under comparable conditions, using 1–5% glucose–Ringer's rather than Ringer's solution. This was probably due to the increased viscosity of the glucose–Ringer's solution and/or its energy-supplying potential as theorized previously (11). It should be mentioned that both the suspension and tablet studies (2, 4) administered the hydrocortisone dose with 180 ml of fluid, probably causing the drug to be washed past the zone of maximal absorption. The parallels between these observations for hydrocortisone and those aforementioned for chlorothiazide and hydrochlorothiazide absorption are all too obvious.

Further proof of a dose-dependent absorption phenomenon being operative for hydrocortisone is obtained by comparing the systemic availability, calculated by dividing mean AUC values after the suspension and tablet doses by those obtained after equivalent intravenous doses (2, 4, 12). The average systemic availability (F/V) of hydrocortisone was 71, 58, 56, 52, and 54% from the 5-, 10-, 20-, 30-, and 50-mg doses. In other words, there was a decrease in F, the fraction absorbed, with increasing dose, which contributed to the decrease in F/V with increasing dose seen in the tablet study (4). If, as suggested (2), there was a dose-dependent increase in the metabolism of an increased free fraction during the first pass, the systemic availability should increase, not decrease, with increasing dose. The latter would occur because of saturation of the hepatic enzymes by the increasing drug fraction. Increased systemic availability with increasing dose has been observed in the literature for propoxyphene (13) and several other drugs (14) known to undergo first-pass metabolism in humans. Additional factors that could possibly contribute to the dose-dependent bioavailability of hydrocortisone in humans include micromeritic and polymorphic effects with attendant stability and dissolution problems, as were observed with other corticosteroids (15).

In conclusion, hydrocortisone and chlorothiazide absorption after increasing, single, oral doses in humans, can be described by site-specific saturable absorption kinetics in the therapeutic dose range. The consequent dose-dependent bioavailability of these two drugs can be effectively predicted by use of the appropriate equations reported earlier (1). Use of these equations in the clinical setting should aid in the development of efficacious dosing protocols for any drug whose oral absorption is limited by the magnitude of the administered dose.

Modified Wagner–Nelson Absorption Equations for Multiple-Dose Regimens

Keyphrases □ Absorption—Wagner–Nelson equations, multiple-dose regimens, one-compartment open model □ Wagner–Nelson equations—modification, multiple-dose regimens, one-compartment model □ Kinetics—absorption, Wagner–Nelson equations

To the Editor:

Equations to calculate the amount of drug absorbed per milliliter of the volume of distribution and the percent absorbed as functions of time for the one-compartment open model (1) are commonly referred to as Wagner–Nelson equations. The nature of such plots when the equations are applied to data obeying the two-compartment open model with first-order absorption was discussed by Wagner (2). In this communication modified equations

0022-3549/83/0500-0578$01.00/0

are derived which apply to plasma, serum, or whole blood concentrations of unchanged drug during a dosage interval of any multiple-dose regimen including the steady state. As before (1) the derivation assumes applicability of the one-compartment open-disposition model but no particular kinetics of absorption need be assumed.

Let A_T represent the amount of drug which is absorbed from time zero (beginning of the dosage interval concerned) to some time T in the dosage interval (*i.e.*, $0 \leq T \leq \tau$ where τ is the time at the end of the dosage interval); A_b represent the total amount of drug remaining in the body at time T; A_b^0 be the amount of drug in the body at time zero, resulting from administration of doses previous to the one of interest; A_m be the total amount of drug metabolized between time zero and time T; A_e be the total amount of drug excreted in the urine between time zero and time T; V be the volume of distribution; C_n be the drug concentration in the interval $0 \leq T \leq \tau$; C_n^0 be the drug concentration at time zero as above; and k_e represent the elimination rate constant of the simple one-compartment open model. Then mass balance gives:

$$A_T = A_b - A_b^0 + A_m + A_e \qquad \text{(Eq. 1)}$$

Taking the derivative of Eq. 1 with respect to time gives:

$$\frac{dA}{dt} = \frac{dA_b}{dt} - \frac{dA_b^0}{dt} + \frac{d(A_m + A_e)}{dt} \qquad \text{(Eq. 2)}$$

but,

$$A_b = VC_n \qquad \text{(Eq. 3)}$$

and,

$$A_b^0 = VC_n^0 \qquad \text{(Eq. 4)}$$

and,

$$\frac{d(A_m + A_e)}{dt} = Vk_eC_n \qquad \text{(Eq. 5)}$$

Substituting from Eqs. 3–5 into Eq. 2 gives:

$$\frac{dA}{dt} = V\frac{dC_n}{dt} - V\frac{dC_n^0}{dt} + Vk_eC_n \qquad \text{(Eq. 6)}$$

Integrating Eq. 6 by term between the limits $t = 0$ and $t = T$ gives:

$$A_T = VC_n - VC_n^0 + Vk_e\int_0^T C_n dt \qquad \text{(Eq. 7)}$$

Division of both sides of Eq. 7 by V gives:

$$\frac{A_T}{V} = C_n + k_e\int_0^T C_n dt - C_n^0 \qquad \text{(Eq. 8)}$$

Equation 8 is the same as the single-dose Wagner–Nelson equation (1) except that C_n replaces C and there is the additional term $-C_n^0$ on the right-hand side. This indicates that for multiple-dose data the usual Wagner–Nelson calculation is performed, namely $C_n + k_e \int_0^T C_n dt$, then the value C_n^0 is subtracted from each value calculated. It should be noted that an incorrect set of A_T/V values would be obtained if C_n^0 was subtracted from each C_n value first, followed by the usual Wagner–Nelson calculation.

The total amount of drug absorbed per milliliter of the volume of distribution from the dose of interest A_τ/V is given by:

$$\frac{A_\tau}{V} = k_e\int_0^\tau C_n dt \qquad \text{(Eq. 9)}$$

Equation 9 gives the correct asymptotic value of A_T/V_p when the dose of interest is given at steady state and when absorption of the dose of interest is complete between the time zero and τ. If one or both of these conditions are not met and absorption is not zero order, then it is very difficult to obtain an accurate asymptotic value of the function.

The fraction absorbed (based on the amount of drug absorbed, not the dose) to time T is given by:

$$\text{Fraction absorbed} = \frac{A_T/V}{A_\tau/V} = \frac{A_T}{A\tau} \qquad \text{(Eq. 10)}$$

To appropriately apply Eqs. 8–10 the protocol for most routine multiple-dose pharmacokinetic studies will have to be modified. Modifications should include: (*a*) the dose of interest should be the last of a series of doses and preferably steady state should have been reached; (*b*) there should be intensive sampling of blood during the absorption phase; (*c*) the blood concentrations should be followed down well beyond the end of the dosage interval at τ hr to allow an estimation of k_e which is not biased by continuing absorption; and (*d*) in evaluating the integrals of Eqs. 8 and 9 it is best to use a combination such that the ordinary trapezoidal rule is used when the concentration is increasing or constant and the logarithmic trapezoidal rule when the concentration is decreasing.

Greater accuracy will be attained by determining the kinetics of absorption (if feasible at all) by resolving fraction absorbed values (Eq. 10) rather than A_T/V values (Eq. 8). If absorption is zero order then the slope of the straight line when the fraction absorbed is plotted *versus* time on reactilinear graph paper will be the correct zero-order constant even when the drug obeys two-compartment kinetics as well as one-compartment kinetics. This has been supported by simulations, and details will be published elsewhere. When absorption is first order and the one-compartment open model holds the ratio of the fraction absorbed values given by the method to the actual fraction absorbed, values will be equal to $1/(1 - e^{-k_a\tau})$ where k_a is the first-order absorption rate constant and τ is the uniform dosing interval. In almost all cases this ratio will have a numerical value between 1.001 and 1.100. An exception will be a very long half-life drug which is dosed too frequently.

External Scintigraphy in Evaluating Delivery Techniques of Sodium Cromolyn–[^{99m}Tc] Diethylenetriaminepentacetic Acid Aerosol in the Lungs of the Horse

Keyphrases □ Scintigraphy—noninvasive method of study, aerosol dispersion, horse respiratory tract □ Nebulization—^{99m}Tc-labeled sodium cromolyn, device comparison □ Sodium cromolyn—technectium-99m labeling, nebulization, scintigraphy in the horse

To the Editor:

Aerosol delivery of drugs has been used in the prophylaxis and therapy of acute and chronic conditions of the lower respiratory tract. The aerosol methods for drug delivery allow targeting of the drug in the lungs, thereby eliminating the need for systemic administration. This in turn may reduce the level and frequency of dosing as well as the incidence and severity of adverse drug effects, thereby improving the therapeutic effect–toxicity ratio (1, 2). Administration of the same dose of nebulized drug using different nebulization devices and modes may conceivably give rise to the same blood levels if the drug is systemically absorbed; however, this does not imply uniform distribution of the drug throughout the lung mass.

External scintigraphy may provide a good opportunity for noninvasive study of the distribution of aerosols labeled with gamma ray-emitting nuclides in the lungs. In this investigation, external scintigraphy was used to explore two different modes of administering nebulized sodium cromolyn to the horse. Four male and two female horses ranging in age from 2 to 6 years and in weight from 338 to 540 kg were used in this study. These animals were free from clinical signs of respiratory disease.

Two different devices were used to nebulize a solution of sodium cromolyn[1] (7 ml, 2% w/v) in separate nebulizer studies on the same six animals. The first device was an air compressor assembly[2], connected to a nebulizer chamber[3]. A corrugated delivery tube (105-cm length, 3.2-cm diameter) was connected to the outlet of the nebulizer and to the face mask[4] which completely covered the nostrils and muzzle of the horse. The diameter of 63.1% of the droplets produced from this nebulizer was <6.5 μm[5]. The second device consisted of a noncollapsible nylon tube (100-cm length, 0.5-cm diameter) which bore a sintered glass disk at one end and was connected with a hand-operated nebulizer at the other end. The tube was inserted through the nostril and placed in the pharynx of the horse. The diameter of 99.6% of the droplets produced by this nebulizer was >8.5 μm[5].

The sodium cromolyn solution (7 ml) was mixed with 1 ml of [^{99m}Tc] diethylenetriaminepentacetic acid (I[6], 40 mCi/ml) in the nebulizer to form a homogeneous solution. In both techniques, the delivery of the nebulized sodium cromolyn–[^{99m}Tc]I solution to the lung required multiple inhalations by the animal. Blood samples (5 ml) taken immediately after the aerosol administration was completed showed that the radioactivity levels were <2000 dpm/ml, implying that only a small amount of [^{99m}Tc]I had diffused into the circulation at that point.

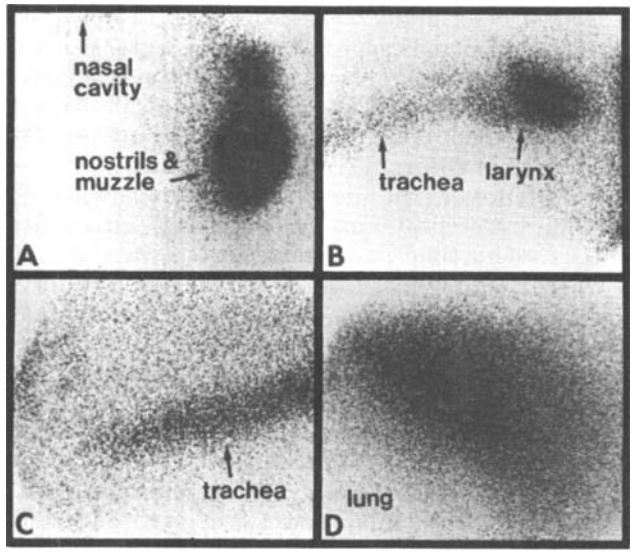

Figure 1—*Scintigraphic images of the distribution of sodium cromolyn–[^{99m}Tc]I aerosol in the respiratory tract of a horse administered through an air compressor–nebulizer–face mask. Radioactivity in the (A) nostrils and muzzle, (B) larynx, and (C) trachea; and (D) homogeneous spread of activity in the lung.*

Each horse was lightly sedated with 100 mg iv of xylazine[7], before administration of the nebulized sodium cromolyn solution. Each horse was then placed parallel to the front of the detector of a gamma camera[8] fitted with a high-resolution parallel-hole collimator. Scintigraphic images in the right lateral plane were obtained of the head, neck, and thorax. A maximum of 100,000 counts were collected for each image. Areas of high activity, such as the nostrils and thorax, required 2–3 min to yield 100,000 counts, while areas of low activity, such as the trachea, yielded only 20,000–60,000 counts in the same period.

Similar distribution patterns were present in all six animals that were administered the nebulized sodium cromolyn solution using the nebulizer connected to the air compressor. A large amount of radioactivity was evident around the nostrils and muzzle, but there was relatively little in the nasal cavity (Fig. 1A). A distinct localized area of radioactivity was detected in the larynx (Fig. 1B). There was very little radioactivity in the trachea, but a homogeneous spread of radioactivity was evident in the lung (Fig. 1C and D).

The distribution pattern of sodium cromolyn solution was different when the hand-operated nebulizer was used. A large amount of radioactivity was present in the posterior pharynx, corresponding to the position of the fritted glass disk (Fig. 2A). Radioactivity extended down the trachea, reaching a peak at the thoracic inlet, suggesting that pooling may have occurred at this level (Fig. 2B). The ^{99m}Tc-labeled sodium cromolyn solution was very poorly

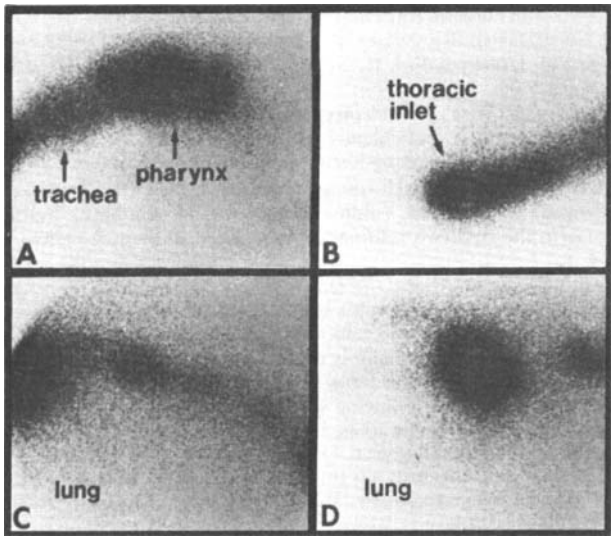

Figure 2—*Scintigraphic images of the distribution of sodium cromolyn-[^{99m}Tc]I aerosol in the respiratory tract of a horse administered through a hand-operated nebulizer. Radioactivity in the (A) posterior pharynx and trachea, (B) thoracic inlet, and (C) and (D) caudodorsal region of the lung.*

distributed in the lungs using this method of administration, detectable radioactivity being largely confined to the caudodorsal region (Fig. 2C and D).

A simple visual comparison of images showed that satisfactory pulmonary distribution of sodium cromolyn aerosol in normal horses occurred following administration by the combination air compressor–nebulizer–face mask. Preliminary analysis of the distribution data of the radioactivity in the respiratory tract indicated that 7.5% of the initial dose remained in the nebulizer, while 30–40% remained in the tubing and face mask. It is estimated that 40–50% of the radioactivity was confined to the nostrils and muzzle, while 10–15% of the radioactivity was distributed in the lungs.

In conclusion, external scintigraphy may provide a convenient noninvasive method for evaluating the different techniques and modes of aerosol administration and visualizing their distribution in the lungs of the horse. Further research is in progress to assess the effect of the droplet size on the resolution of the technique and the distribution of the aerosol in the lungs. In addition, an effort is being made to develop a model in which the count rates taken from the lung area are weighted for tissue attenuation and variable geometry so that more accurate estimates can be obtained.

BOOKS

REVIEWS

Recent Advances in the Biology of Alcoholism. Edited by C. S. LIEBER and B. STIMMEL. (Advances in Alcoholism and Substance Abuse, Vol. 1 No. 2). The Haworth Press, 28 East 22nd Street, New York, N.Y. 10010. 1982. Hardcover.

This book contains several authoritative and timely review articles about the effects of ethanol on the liver and the endocrine system. The coverage is much narrower than indicated by the title: effects of the drug on the brain are not included. The chapters are papers delivered in a 1980 symposium at the Alcohol Research and Treatment Center at the Bronx VA Hospital; several of the papers are by Dr. Lieber and his group at the Center. The authors are recognized experts in their fields, which vary from pure biochemistry to clinical gastroenterology.

J.-P. Von Wartburg provides a lucid review of alcohol metabolism by alcohol and aldehyde dehydrogenases, including recent genetic information about racial differences in responses to alcohol. S. Orrenius writes a concise description of metabolic drug interactions from a biochemist's point of view, and Lieber and Pirola follow with a detailed clinically oriented review of the same topic, with many specific examples. Both reviews of drug interaction emphasize and explain the role of MEOS, the hepatic microsomal ethanol-oxidizing system. Lieber also contributes a general chapter on the effects of ethanol on the liver, largely from his own extensive work. The final chapter by T. J. Cicero covers recent important advances in our understanding of effects of ethanol on the endocrine system, with emphasis on the factors that affect testosterone levels. This is a logical and sensible essay which minimizes controversy and brings scattered data together into a reasonably coherent picture.

Technical details such as typographical errors, poor quality paper, and inadequate reproduction of some figures detract slightly from the otherwise admirable text. More important is the lack of an index, which will greatly reduce the usefulness of this book.

REVIEWS

Recent Advances in the Biology of Alcoholism. Edited by C. S. LIEBER and B. STIMMEL. (Advances in Alcoholism and Substance Abuse, Vol. 1 No. 2). The Haworth Press, 28 East 22nd Street, New York, N.Y. 10010. 1982. Hardcover.

This book contains several authoritative and timely review articles about the effects of ethanol on the liver and the endocrine system. The coverage is much narrower than indicated by the title: effects of the drug on the brain are not included. The chapters are papers delivered in a 1980 symposium at the Alcohol Research and Treatment Center at the Bronx VA Hospital; several of the papers are by Dr. Lieber and his group at the Center. The authors are recognized experts in their fields, which vary from pure biochemistry to clinical gastroenterology.

J.-P. Von Wartburg provides a lucid review of alcohol metabolism by alcohol and aldehyde dehydrogenases, including recent genetic information about racial differences in responses to alcohol. S. Orrenius writes a concise description of metabolic drug interactions from a biochemist's point of view, and Lieber and Pirola follow with a detailed clinically oriented review of the same topic, with many specific examples. Both reviews of drug interaction emphasize and explain the role of MEOS, the hepatic microsomal ethanol-oxidizing system. Lieber also contributes a general chapter on the effects of ethanol on the liver, largely from his own extensive work. The final chapter by T. J. Cicero covers recent important advances in our understanding of effects of ethanol on the endocrine system, with emphasis on the factors that affect testosterone levels. This is a logical and sensible essay which minimizes controversy and brings scattered data together into a reasonably coherent picture.

Technical details such as typographical errors, poor quality paper, and inadequate reproduction of some figures detract slightly from the otherwise admirable text. More important is the lack of an index, which will greatly reduce the usefulness of this book.

Handbook of Dissolution Testing. By WILLIAM A. HANSON. Pharmaceutical Technology Book Division, 320 N. A St., P.O. Box 50, Springfield, OR 97477. 1982. 163 pp. 13 × 22 cm. Price $26.50.

This book describes in detail the two official USP-NF dissolution test methods and the nonofficial flow-through method. The author views dissolution testing solely as a quality control test whether or not the test

results correlate with the drug bioavailability. Hence, throughout the book, major emphasis is given to the procedural details and the regulatory requirements of the test, but little on its importance as predictor of drug bioavailability.

Overall consideration for dissolution testing, presented in Chapter 1, gives a brief historical perspective of the dissolution test development. Only the contributions made by the author and the individuals associated with the USP Drug Standards Laboratories were credited with the early developments in this field. It is unfortunate that the author failed to recognize the contributions made by industry, government, and academia. Instead, the author wrongly criticized them for suggesting test methods because they all had "a private axe to grind."

Chapter 2 deals with the discussion of the classical Noyes-Whitney equation with respect to the dissolution test conditions. The necessity of having laminar, nonturbulent fluid dynamics recommended by the author is unwarranted. Some degree of turbulence is actually desirable for achieving homogeneous mixing of the dissolved drug. A detailed description of the official USP-NF methods including allowable design variables and compendial constraints set for those methods is described in Chapter 3. The following chapter gives a description of the flow-through apparatus and a few other nonofficial methods. Here, as well as in Chapter 8, the author advocates the use of only the official methods. It is doubtful that such a view will be shared by the scientific community, simply because it can stifle future progress in the field. Chapters 5 and 6 deal with the various test variables and provide guidelines for setting-up the official test methods. The last chapter deals with the methods employed for the automated monitoring of dissolution rates. Overall, the book gives practical guidance for the routine analysis of dissolution rates by the current official methods.

Analytical Profiles of Drug Substances, Vol. 11. Edited by KLAUS FLOREY, Academic Press, 111 Fifth Avenue, New York, NY 10003. 1982. 665 pp. 15 × 23 cm. Price $39.00.

In continuation of the yearly volumes of this series, this collection gives (in about 550 pages) analytical profiles of 16 drug substances: aminophylline, ascorbic acid, captopril, cefotaxime, cefoxitin sodium, clofibrate, clotrimazole, dopamine hydrochloride, ergonovine maleate, flufenamic acid, hexestrol, mestranol, noscapine, penicillin G benzathine, phenylbutazone, and sulfadiazine.

A new feature has been introduced in this volume: profile supplements. These profiles are intended to be a regular part of future volumes. The profile supplements, occupying about 110 pages, are for five substances that originally appeared in Volume 1: levarterenol bitartrate, meprobamate, triamcinolone, triamcinolone acetonide, triamcinolone diacetate. The supplements are not a republishing of the original monographs, they are only additions and/or changes. The paragraph numbering of the original profile has been retained, so that the new or altered data can easily be correlated with the original. This volume does not contain the 'Addendum' section which was a feature of several previous volumes.

The profiles in this hard-bound book contain the following nine major sections: description, physical properties, methods of preparation, stability-degradation, methods of analysis, metabolism, biopharmaceutics and pharmacokinetics, toxicity, and references. There are numerous figures of structures and spectra, and tables of properties and chromatographic systems. Since each profile is by a different author, this basic outline may be expanded to other topics or somewhat curtailed, depending upon the information available from the extensive review of the literature and unpublished works. The difference in authorship causes a difference in type size and face style from profile to profile. A cumulative index gives the volume and page number of each substance that is the subject of a particular profile.

This volume, like others in the series, is a valuable reference for those interested in pharmaceutical formulation and pharmaceutical quality assurance and should be available as a reference for those requiring information on drug metabolism, biopharmaceutics, and pharmacokinetics.

Modern Methods of Pharmaceutical Analysis. Edited by ROGER E. SCHIRMER. CRC Press Inc., Boca Raton, FL 33431. 1982. 18 × 25 cm. **Vol. I,** 304 pp. **Vol. II,** 264 pp. Price $81.00 ea. **Vol. III,** 244 pp. Price $72.00.

Modern Methods of Pharmaceutical Analysis is a three-volume set mostly written by R. E. Schirmer. Of the 13 chapters, Dr. Schirmer has written eight. The remaining five have been authored by three scientists from Eli Lilly and Co. Each volume is self-contained with identical Forwards and Introductions. Volume III contains the cumulative index; the indexes in the first two volumes are restricted to their respective contents.

It is not completely clear to this reviewer the rationale for assigning specific chapters to each volume unless it was to restrict each of the "guest" authors to only one volume per author or to keep the number of pages per volume approximately equal. Volume I contains five chapters starting with Separation of Drugs from Excipients. The remaining four chapters describe the following spectroscopic methodologies: UV and Visible Absorption Techniques, IR Methods of Analysis, Fluorometric Analysis, and Optical Rotation. Other methods of separation and purity analysis are not encountered until Volume III. Its five chapters are Gas-Liquid Chromatography, High-Performance Liquid Chromatography, Thermal Analysis, Phase-Solubility Analysis, and The Determination of Isomeric Purity. Situated in the middle is Volume II with Nuclear Magnetic Resonance Spectroscopy, Polarography, and Coulometry.

A better title might have been "Industrial Methods of Pharmaceutical Analysis." The selection of chapters is based on the analytical problems defined by the editor as those commonly encountered in the pharmaceutical industry. These include analysis of the raw materials, synthetic intermediates, the final drug entity, and the formulated product. The analytical methodology must detect types and levels of impurities and degradation products. Lacking is a chapter on mass spectrometry, although there is a brief mention of its use as a detector in chromatography and determination of isomeric purity. Also there is no chapter on immunoassay methodology.

In general each subject is well covered. There is a detailed topic outline for each chapter. The typical format is to begin with a discussion of the principles of the analytical technique followed by a description of the specific instrumentation. Then, depending on the analytical method, there may be an overview of the sample preparation. Each chapter concludes with pharmaceutical applications and a reasonable number of examples. For the most part, the individual chapters should not be considered exhaustive reviews of the pharmaceutical analysis literature. Nevertheless, good bibliographies accompany each chapter. There is good consistency, which probably is due to the majority of the chapters being written by one person.

This is an expensive set of volumes for individual purchase, considering the fact that the basic information of theory, instrumentation, and sample preparation already will be adequately covered in one or more advanced undergraduate or graduate level analytical chemistry textbooks. The cost of the latter is generally lower due to their volume of sales. The on-line searches of the *Chemical Abstracts* data bases permit the analytical chemist to rapidly obtain the most current applications. A few years ago this reviewer probably would have ended with the usual recommendation for library purchase. This is not true in today's economic times. Libraries and individuals should first determine if their collections are adequate and current before making such a major purchase.

There is good consistency, which probably is due to the majority of the chapters being written by one person.

This is an expensive set of volumes for individual purchase, considering the fact that the basic information of theory, instrumentation, and sample preparation already will be adequately covered in one or more advanced undergraduate or graduate level analytical chemistry textbooks. The cost of the latter is generally lower due to their volume of sales. The on-line searches of the *Chemical Abstracts* data bases permit the analytical chemist to rapidly obtain the most current applications. A few years ago this reviewer probably would have ended with the usual recommendation for library purchase. This is not true in today's economic times. Libraries and individuals should first determine if their collections are adequate and current before making such a major purchase.

Dictionary of Organic Compounds, 5th Ed. Edited by J. BUCKINGHAM, J. D. G. CADOGAN, R. A. RAPHAEL, C. W. REES, and an INTERNATIONAL ADVISORY BOARD. Chapman and Hall, 733 Third Avenue, New York, NY 10017. 1982. 7766 pp. 28 × 20.5 cm. Price $1950.00 (Canada $2350.00).

The fifth edition of Heilbron's *Dictionary of Organic Compounds*, now in five volumes with two additional volumes of indexes, includes about 50,000 entries listing more than 150,000 compounds. The intent of the *Dictionary* is to describe structural, chemical, and physical properties of common organic compounds of importance to chemists, biochemists, pharmacologists, and biologists. The present edition includes some types of information not listed previously. Leading literature references are included, and annual supplements (including about 2000 entries each)

are planned. Obviously, the selection of compounds is of paramount importance for a work of this type: the fifth edition has maintained the careful and useful selection that has characterized the previous editions.

Compounds are listed by the most commonly used name, with other names included. The structural formula is included with the entry, which shows the stereochemical configuration where required. The R,S and E,Z systems have replaced the older D,L and *cis-trans* stereochemical conventions. Other information provided in each entry includes the molecular formula and weight, source, physical data for stereoisomeric forms, melting points of both compound and derivatives, spectral data, and use. Hazard and toxicity information is included in this edition, along with a Registry of Toxic Effects of Chemical Substances number. Bibliographic references include both old and new references (up to 1981), and many indicate the type of information included. Physical constants such as pK_a and optical rotations are often listed in the entry; specific references generally indicate synthetic methods, reviews, and some spectroscopic data. Crystallization solvents are also frequently mentioned.

The selection of compounds for inclusion followed these criteria: fundamental organic compounds of simple structure, most compounds of widespread industrial or commercial use, all important natural products, and other compounds of particular chemical or biological interest. More than 12,000 natural products have been entered, and this may well be the most current and extensive compilation of natural products available. Also, more than 10,000 heterocyclics and 1,500 organometallics are recorded. In regard to compounds of pharmaceutical interest, about 450 drug substances are listed under *C* alone, which compares with 118 substances listed under this letter in the *USP XX*.

Page layouts and the typographic plan for each entry have been improved over those of previous editions, and the pages have a distinctly uncluttered appearance. The structural formulae also reflect a new standard. A greater clarity, and consequent ease of use, has been achieved.

Changes over previous editions include a much greater amount of stereochemical data, the inclusion of hazard warnings and toxicity data, greater use of *Chemical Abstracts Service* names, as well as *USAN* and *BAN* names and *CAS Registry* numbers. Also, the annotation of the bibliography is a marked improvement.

Multiple indexes are also included for the first time. Four indexes are provided: a *Name* index, which includes alternative names; a *Molecular Formula* index; a *Heteroatom* index; and a *CAS Registry Number* index. The latter provides a link to computer-based information services which incorporate these numbers.

Heilbron's *Dictionary of Organic Compounds* has been valued by organic chemists for practically 50 years; the fifth edition should be as valuable to biochemists, biologists, and pharmacologists. It is recommended for every library serving these disciplines as a most time-saving and convenient source of information on the more useful organic compounds.

JOURNAL OF PHARMACEUTICAL SCIENCES

A publication of the American Pharmaceutical Association

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C. and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $75; educational institutions $75; individuals *for personal use only* $40; single copies $10. APhA and SAPhA members may subscribe to *J. Pharm. Sci.* for $20.00 per year. All foreign subscriptions add $10 for postage. Subscription rates are subject to change without notice.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., 21 Congress St., Salem, MA 01970. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

Adverse Drug Reactions—A Continuing Problem

During the past year, there have been several major drug recalls and withdrawals from the market. We are referring here to those cases involving toxicity and adverse reactions associated with the active ingredient itself, rather than recalls resulting from product tampering, faulty manufacturing of dosage forms, or other considerations relating to the quality of the drug product.

Two of the more publicized such recalls were for benoxaprofen (Oraflex) and zomepirac (Zomax).

Various interested observers of the national pharmaceutical scene have drawn a variety of conclusions from this rash of recalls. The conclusions have been diverse and, in many cases, filled with conjecture and hypothesis. As such, they have ranged from "look how poorly the new drug approval system is working to allow all these unsuitable drugs to be placed on the market" to the other extreme, namely, "look how well the new drug approval system is working since these adverse reactions were identified and the drugs pulled off the market." But in any event, everyone seems agreed that there are, and will continue to be, instances where significant drug toxicity does not become evident until the product involved goes into general distribution and thereby experiences widespread use in patients.

Given that situation, a problem with a drug will only come to light if a sufficient number of physicians, pharmacists, or other health care practitioners in a position to monitor patient reaction to therapy (*a*) note that a patient has suffered an untoward effect, (*b*) make the critical mental connection between drug and untoward reaction, and (*c*) duly report it to the manufacturer and/or the Food and Drug Administration.

Unfortunately, however, this sequence often does not occur. In fact, the usual pattern is that—*after* the first such clinical experiences are reported in the letters columns of medical journals—there is then a flurry of similar reports from practitioners who had previously failed to make the mental association in patients they had treated earlier. But aside from efforts to make practitioners more alert, to sharpen their association skills, and to urge them to be conscientious in reporting adverse reactions, there seems to be little that can be done to improve the reporting system from the field.

Moving on, then, after adverse reaction reports have been filed with FDA, what happens next?

The apparent general supposition on the part of the public, members of Congress, and many members of the health care professions is that an alarm is immediately triggered, the FDA springs into action, and the drug is immediately whisked off the market. In essence, a reaction is assumed that would be comparable in speed and effectiveness to that expected from our national military defense in the event of a nuclear attack.

Obviously, however, even under the best of circumstances and even under ideal operating conditions, no adverse reaction system will work that well.

So, how well is the present FDA system working?

The answer appears to be: Not very well. In fact, rather poorly, indeed.

A little over a year ago, on March 8, 1982, the watch-dog agency in the federal government—the General Accounting Office, or GAO—released a report on 21 selected prescription drugs and found that it took an average of five months for adverse drug reaction (ADR) reports just to be entered into the computer files of the FDA's Division of Drug Experience.

In summarizing their findings, the GAO said: *"Based on a sample of almost 2,000 adverse reaction reports submitted by manufacturers, (1) 42% of these reports never reached the Drug Experience Division, (2) an additional 14% had been received but either had not been evaluated or were in a backlog waiting to be entered into the system, and (3) reports that had been entered into the system [were entered] an average of five months [after they were received at FDA]."*

This was not the first time the GAO had delved into FDA's ADR reporting system. In fact, it was a follow-up to a 1974 report that had pointed out many qualitatively similar deficiencies. In its current 1982 report, the GAO concluded that the new review *"of FDA's monitoring of prescription drugs showed that many of the problems found in 1974 still exist."*

Now in the spring of 1983, the efficiency and effectiveness of the FDA's system has again come into question.

As part of the "fallout" from the Zomax recall, the U.S. House of Representatives Subcommittee on Intergovernmental Relations held oversight hearings on April 26–27 specifically targeted at reviewing (*a*) the decision to approve the marketing of Zomax, (*b*) the ADR reports that followed its approval, and (*c*) the decision to remove it—at least temporarily—from the market. And from those specific considerations, questions and concerns gradually broadened to the more general subject of the agency's ADR reporting system in overall.

Press reports summarizing the two-day congressional hearing cryptically concluded that even FDA officials admit significant flaws still exist in the system. For example, *The Wall Street Journal* reported:

"The FDA's system for tracking reports of adverse drug reactions is significantly flawed, agency officials suggested in congressional testimony.

"One official told a House subcommittee that he had been surprised to learn from Johnson & Johnson that the company knew of nearly twice as many instances of adverse reactions (1,100) from its prescription pain reliever Zomax than the agency had known about (500 to 600)."

Our purpose here is not to point an accusing finger at FDA or anyone else. The FDA has long recognized its weakness in this area and explains that limitations of personnel and resources are the root cause of such weakness in this as well as several other areas of its responsibility. This prompts many agency observers to wonder whether some readjustment of its priorities and budgetary allocations might not significantly relieve the situation.

But, for purposes of our present consideration, let us accept the FDA's explanation at face value. Doing so suggests to us that the broad issue of postmarketing drug surveillance, that was such a dominant health care concern 3 to 5 years ago—if not *the* dominant concern—is still very much alive. It has not been resolved. It has not gone away. It has simply been pushed aside. And it has been pushed aside not only by FDA but also by other relevant groups—the drug industry, health care practitioners, their professional societies, and pertinent trade and consumerist organizations.

Although practically studied to death by various groups and organizations in the mid- to late-1970s, followed by the usual pattern of reports and recommendations, no clear-cut simple solution to the problem was identified. About the most that interested analysts seemed to be able to agree upon was that efforts should be directed at expanding and upgrading the existing system and fostering a greater awareness among practitioners for their need to participate as an on-going practice.

It is human nature that old, chronic problems spark little interest, and correspondingly little attention is usually devoted to them. In this instance, the potential major health hazards are clearly evident. Hence, they dictate that we cannot allow disinterest or "boredom" to divert us from devoting the needed efforts and resources toward improving this "significantly flawed" system.

Extended Hildebrand Solubility Approach: *p*-Hydroxybenzoic Acid in Mixtures of Dioxane and Water

P. L. WU * and A. MARTIN ˣ

Received April 5, 1982, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication June 2, 1982. *Present address: China Chemical & Pharmaceutical Company, Shu-Lin, Taipei, Taiwan 00238, ROC.

Abstract □ The extended Hildebrand solubility approach was used to reproduce the solubilities of *p*-hydroxybenzoic acid in a dioxane–water system. The solubility parameter of *p*-hydroxybenzoic acid was determined and found to be ~15 $(cal/cm^3)^{1/2}$. Residual plots (scattergrams) were used in conjunction with R^2, F, and standard deviation values to determine whether a quadratic, cubic, quartic, or higher degree polynomial was required in the calculations. The earlier iteration method for back-calculations of solubilities was replaced by the more reliable root-finder method[1]. The solubility profile of *p*-hydroxybenzoic acid in dioxane–water mixtures did not follow a log linear relationship even in the ranges where the solubility parameters of the water–cosolvent mixture might be expected to produce a straight-line function, as observed in other studies.

Keyphrases □ Dioxane—extended Hildebrand solubility approach, *p*-hydroxybenzoic acid, water □ *p*-Hydroxybenzoic acid—extended Hildebrand solubility approach, water □ Hildebrand solubility approach, extended—*p*-hydroxybenzoic acid in mixtures of dioxane and water □ Solubility parameters—*p*-hydroxybenzoic acid in mixtures of dioxane and water

The theory of solutions is one of the most challenging and least understood branches of physical chemistry. The Hildebrand–Scatchard theory of regular solution (1–3) is the pioneer approach in this field. In recent years the solubility parameter concept has been extended to the practical realm of industrial and commercial paints, inks, polymers, plastics, insecticides, and pharmaceuticals. Recently, the Hildebrand–Scatchard equation has been successfully modified and the solubilities of methylxanthines estimated in binary solvents within an error of ≤10% values approximating those of experimentally determined solubilities (4, 5). The original Hildebrand–Scatchard equation has been discussed in a number of papers (4–6) in this series and need not be repeated here.

[1] International Mathematical and Statistical Library.

BACKGROUND

The Hildebrand–Scatchard approach may be used to estimate solubility only for relatively nonpolar drugs in nonpolar solvents according to regular solution theory (1). The solubility parameter, δ, is the square root of cohesive energy density (1), with subscripts 1 and 2 for solvent and solute, respectively. In pharmaceutical solutions, the geometric mean (1) of δ_1^2 and δ_2^2, that is, $\delta_1\delta_2 = (\delta_1^2\delta_2^2)^{1/2}$, is too restrictive and ordinarily provides a poor fit to experimental data in irregular solutions. Instead, $\delta_1\delta_2$ can be replaced by W, which is allowed to take on values as required to yield correct mole fraction solubilities, X_2:

$$-\log X_2 = -\log X_2^i + A(\delta_1^2 + \delta_2^2 - 2W) \qquad \text{(Eq. 1)}$$

where

$$\log X_2^i \cong \frac{\Delta H_m^f}{2.303R}\left(\frac{1}{T_m} - \frac{1}{T}\right) \qquad \text{(Eq. 2)}$$

and

$$A = \frac{V_2\phi_1^2}{2.303RT} \qquad \text{(Eq. 3)}$$

ΔH_m^f is the heat of fusion of the solute and R is the gas constant. T_m is the melting point of the solute, T is the temperature of interest, and both are in °K. The volume fraction of the solvent (ϕ_1) is expressed as:

$$\phi = \frac{V_1(1 - X_2)}{V_1(1 - X_2) + V_2X_2} \qquad \text{(Eq. 4)}$$

V_1 and V_2 are the molar volumes of solvent and supercooled solute, respectively. For drugs in binary solvent mixtures, it has been found (4–6) that the W values may be regressed in a power series on the solvent solubility parameters:

$$W = C_0 + C_1\delta_1 + C_2\delta_1^2 + \ldots\ldots + C_n\delta_1^n \qquad \text{(Eq. 5)}$$

One obtains a reasonable estimate, W_{calc}, by this procedure. W_{calc} is then substituted in Eq. 1 for W to obtain mole fraction solubilities in polar binary solvents which are usually within <10% of the experimental results.

According to well-known thermodynamic principles, the relationship of mole fraction solubility to ideal mole fraction solubility and activity coefficient may be expressed as:

$$-\log X_2 = -\log X_2^i + \log \alpha_2 \qquad \text{(Eq. 6)}$$

[a] V_2 = 94.35 cm³/mole, δ_2 = 15.3 (cal/cm³)$^{1/2}$, $X_2{}^i$ = 0.00747, log $X_2{}^i$ = −2.1267. [b] Eqs. 3 and 4. [c] $K = W/\delta_1\delta_2$, a proportionality factor (13). [d] Eq. 15.

where α_2 is the activity coefficient of the solute in the solution. Equation 1 may be written, in light of Eq. 6, as:

$$\log\left(\frac{X_2{}^i}{X_2}\right) = \log \alpha_2 = A(\delta_1{}^2 + \delta_2{}^2 - 2W) \qquad \text{(Eq. 7)}$$

and

$$(\log \alpha_2)/A = \delta_1{}^2 + \delta_2{}^2 - 2W \qquad \text{(Eq. 8)}$$

Log α_2/A may be regressed directly against δ_1, bypassing W, and obviating the need for δ_2 as described in earlier work (6). The estimated solubility, $X_{2\,calc}$, is identical to that obtained with W_{calc} except for rounding-off errors. The entire procedure, referred to as the Extended Hildebrand Solubility Approach (4), is conducted by a computer program, the regression subroutine of which is found in SPSS (7). The program allows a stepwise addition of independent variables, analysis of variance, and examination of the residuals, $X_2 - X_{2\,calc}$, by means of scatter plots. These plots are useful in indicating when the proper degree of the polynomial has been reached.

EXPERIMENTAL

Materials—*p*-Hydroxybenzoic acid[2] was recrystallized from aqueous ethanol (8) then dried at 105° overnight. The heat of fusion, 7510 cal/mole, of *p*-hydroxybenzoic acid was determined by differential scanning calorimetry[3]. The melting point obtained from this method is 485.9°K which is consistent with the value from a hot-stage method[4]. A pure grade of dioxane[5] was used as received. Since *p*-hydroxybenzoic acid is a weak acid with pK_a equal to 4.54 ($K_a = 2.9 \times 10^{-5}$) at 25° (9), the pH of water affects its solubility. Furthermore, the dissociation constant, K_a, decreases in organic aqueous mixtures (9, 10). To ensure that the *p*-hydroxybenzoic acid was in undissociated form, the pH of the water was adjusted to 2.0 using hydrochloric acid. The pH 2 hydrochloric acid–aqueous solution was used alone or mixed with dioxane as the binary solvent for this study.

Solubility Analysis—The solubility of *p*-hydroxybenzoic acid was determined in binary solvent mixtures of dioxane and water. A suitable amount of dioxane, water, or binary solvent was introduced into screw-capped vials containing an excess amount of solute. After being sealed with several turns of electrical tape, the vials were submerged in water at 25 ± 0.1° and were shaken at 100 cpm for 24 hr in a constant-temperature bath[6]. Preliminary studies showed that this time period was sufficient to ensure saturation at 25°.

After equilibrium had been attained, each vial was removed and analyzed. The solutions were transferred to a syringe and filtered using a filter[7] of pore size <1 μm. After suitable dilution, the solutions were assayed using a spectrophotometer[8] set at the wavelength of maximum absorption of the solute. The solubility of the solute was determined at least six times for each solvent, and the average value was taken. The experimental variation in solubility was <3% in replicate samples and was consistent with a titrimetric assay method used with a number of samples. The densities of the saturated solutions were determined with calibrated pycnometers at 25° and the variation was <0.03% for six determinations.

Stability of Solute—The stability of the solute was tested by subjecting the saturated solutions to TLC[9] using 2-propanol–ammonia–water (8:1:1) (11) as a developing system, then observing the developed TLC plate under a long wavelength UV-lamp[10]. There was no evidence of decomposition within 36 hr.

Ideal Solubility—The ideal solubility of *p*-hydroxybenzoic acid may be calculated from the heat of fusion of the solid and the melting temperature:

$$\log X_2{}^i \cong \frac{\Delta H_m{}^f}{2.303R}\left(\frac{1}{T_m} - \frac{1}{T}\right) \qquad \text{(Eq. 9)}$$

$$\log X_2{}^i = \frac{7510}{(2.303)(1.987)}\left(\frac{1}{485.9} - \frac{1}{298.15}\right)$$

giving:

$$\log X_2{}^i = -2.127 \qquad X_2 = 0.00747$$

Figure 2—*Plot of residuals obtained from quadratic regression equation, Eq. 16, for p-hydroxybenzoic acid in dioxane–water mixtures at 25°. (Log α_2)/A_{calc} is plotted along the vertical axis and residuals along the horizontal axis as described in this report. The residual in Table I is the difference between the observed x_2 and x_{2calc}, whereas the residuals in Figs. 2, 3, and 4 are [(logα_2)/A(obs)] − [(logα_2)/ A(calc)].*

RESULTS AND DISCUSSION

The solubility of *p*-hydroxybenzoic acid in dioxane–water at 25° is found in Table I, and the solubility profile is shown in Fig. 1 where X_2 is plotted against δ_1.

Estimating the Solubility Parameter of *p*-Hydroxybenzoic Acid from its Solubility Profile—It has been shown (12) that the solubility parameter of a solid can be estimated from the point of maximum solubility in a binary solvent, such as ethyl acetate and ethanol. When a solvent mixture is found that yields a peak in the solubility profile for a regular solution, δ_1 is assumed to equal δ_2.

In an irregular solution, these relations do not obtain exactly as in a regular solution, and the geometric mean, $W_{12} = (\delta_1^2\delta_2^2)^{1/2}$, seldom can be assumed to apply. W_{12} and $\delta_1\delta_2$ may be related by introducing a proportionality factor, K (13)[11]:

$$W_{12} = K\delta_1\delta_2 \qquad \text{(Eq. 10)}$$

Equation 8 then becomes:

$$\frac{\log \alpha_2}{A} = \delta_1^2 + \delta_2^2 - 2K\delta_1\delta_2 \qquad \text{(Eq. 11)}$$

The partial derivative of (log α_2)/A is taken with respect to δ_1 and the result is set equal to zero to obtain the value of δ_2 at the peak in the solubility profile:

$$\left(\frac{\partial(\log \alpha_2/A)}{\partial(\delta_1)}\right)_{\delta_2} = 2\delta_1 - 2K\delta_2 = 0 \qquad \text{(Eq. 12)}$$

and

$$\delta_1 = K\delta_2 \qquad \text{(Eq. 13)}$$

Thus, in irregular solutions, δ_1 is not equal to δ_2 at the maximum in the solubility profile, but is equal to $K\delta_2$ (13). As can be seen in Table I and Fig. 1, the maximum solubility of *p*-hydroxybenzoic acid in dioxane–water is at a solvent solubility parameter of 11.33 (*i.e.*, dioxane–water 90:10%, v/v) and K = 1.122. Therefore, the solubility parameter of *p*-hydroxybenzoic acid is 10.10 as obtained from:

$$\delta_2 = \frac{\delta_1}{K} = \frac{11.33}{1.122} = 10.10 \text{ (cal/cm}^3)^{1/2} \qquad \text{(Eq. 14)}$$

Solubility parameters of solid drugs can also be obtained by a group contribution method developed by Fedors (15). The δ value of *p*-hydroxybenzoic acid obtained from Fedors' method[12] is 15.3. A method for obtaining the solubility parameter of a drug molecule using internal pressure values and accurately measured solution densities was also previously suggested (16).

It has been shown that the solubility parameter of the solute obtained from the peak of the solubility profile may vary depending on the mixed solvent used (6). If the cosolvent has the tendency to form a complex with the solute, the maximum solubility may be shifted to the δ_1 value of a mixed solvent which contains a high percentage of this solvating cosolvent. Dioxane is a Lewis base and *p*-hydroxybenzoic acid a Lewis acid; these molecules have a tendency to form a complex, which may account for the shift of maximum solubility to the lower δ_1 value of the dioxane–water mixture. It is not necessary to know δ_2 to calculate the solubility in mixed solvents, for it has been found (4–6) that the estimated solubility can be obtained from a regression of (log α_2)/A against δ_1, obviating the need of δ_2. The back calculation of *p*-hydroxybenzoic acid solubility in dioxane–water is discussed later.

Effect of Solute on the Solubility Parameter of the Solution—The amount of solute in a saturated solution may alter the solubility parameter of the reference solvent (17) when in high concentration, since:

$$\delta_{app} = \Sigma\delta_i\phi_i \qquad \text{(Eq. 15)}$$

where ϕ_i is the volume fraction of component i in the solution. The solubility parameters of the saturated solutions, δ_{app}, are listed in Table I. The two solubility parameters, δ_1 and δ_{app}, are almost identical when the mole fraction solubility is <0.1 (volume fraction of dioxane is <70%). The solubility parameter of the saturated solution is a little higher (less than one unit) than that of the reference solvent when the solvent mixture contains >80% of dioxane. In the extended Hildebrand approach, (log α_2)/A is regressed on the solubility parameter of the solvent in a polynomial equation. A similar approach can be taken by regressing (log α_2)/A against δ_{app}, the solubility parameter of the solution. These two solubility

[11] It should be noted that K as defined by Walker (13) and used here does not have the same meaning as K employed in another previous paper (14). In Ref. 14, K is a constant for a solute over the entire composition of a binary solvent. Here, and in other papers of this series, K varies across the solvent composition. The constant in Ref. 14 should probably be designated by another symbol, such as κ (kappa) to prevent confusion.

[12] [83.94 (Phenylene) + 72.61 (CO_2H) + 78.33 (OH)]$^{1/2}$ = (234.88)$^{1/2}$ = 15.3 (cal/cm^3)$^{1/2}$.

parameter systems yield the same results except for rounding-off error.

Extended Hildebrand Approach Using Polynomial Regression and Scattergrams—The $(\log \alpha_2)/A$ for *p*-hydroxybenzoic acid was regressed against δ_1 values of dioxane–water mixtures at 25°. Three polynomial equations and associated statistical parameters[13] are quadratic:

$$\frac{\log \alpha_2}{A} = 21.02\ (\pm 10.36) - 7.6338\ (\pm 1.3152)\delta_1 + 0.31866\ (\pm 0.03984)\delta_1^2 \quad \text{(Eq. 16)}$$

$n = 13, s = 2.30, r^2 = 0.972, F = 173, F(2, 10, 0.01) = 7.56$

cubic:

$$\frac{\log \alpha_2}{A} = 142.51\ (\pm 34.32) - 31.582\ (\pm 6.683)\delta_1 + 1.82625\ (\pm 0.41788)\delta_1^2 - 0.0303307\ (\pm 0.0083899)\delta_1^3 \quad \text{(Eq. 17)}$$

$n = 13, s = 1.55, r^2 = 0.989, F = 259, F(3, 9, 0.01) = 6.99$

and quartic:

$$\frac{\log \alpha_2}{A} = 564.07\ (\pm 54.45) - 142.18\ (\pm 14.12)\delta_1 + 12.396\ (\pm 1.339)\delta_1^2 - 0.46689\ (\pm 0.05504)\delta_1^3 + 0.0065807\ (\pm 0.0008284)\delta_1^4 \quad \text{(Eq. 18)}$$

$n = 13, s = 0.55, r^2 = 0.999, F = 1550, F(4, 8, 0.01) = 7.01$

The residual plots (scattergrams) (7) of these equations are shown in Figs. 2–4 for quadratic, cubic, and quartic, respectively. In the figures, the horizontal axis represents the residuals standardized by dividing each by its standard deviation, while the vertical axis represents $(\log \alpha_2)/A_{calc}$ against which the residuals are plotted. The residual, or deviation of an estimated value, $(\log \alpha_2)/A_{calc}$, from the observed value, $(\log \alpha_2)/A_{obs}$, indicates which regression equation is the most suitable. As can be seen in Fig. 2, the residuals are not randomly scattered along the vertical axis. Therefore, the quadratic equation is not satisfactory, although R^2 is very high. In Fig. 3 the ordered arrangement of the points of Fig. 2 has mostly disappeared, and in Fig. 4 the residuals are scattered randomly along the vertical axis. None of the points in Fig. 4 is outside of a range of 2 σ. By comparing the statistics of the quadratic, cubic, and quartic equations (Eqs. 16, 17, and 18), it is observed that the quartic equation is the best choice due to its high r^2 and F values, and its small s value. The random scattering of points in the scattergram also shows Eq. 18 to be superior.

[13] The statistical quantities associated with each equation are: r^2 is the squared correlation coefficient (index of determination); s is the standard deviation or average of deviations about the arithmetic mean; F is the Fisher F ratio; n is the number of cases; and $F(k, n-k-1, 0.01)$ is the table value of F with k-independent variables; and k and $(n-k-1)$ degrees of freedom at the 99% confidence level. The ± values in parentheses associated with each regression coefficient, B, is the standard error of B.

In the back calculation, $(\log \alpha_2)/A_{calc}$ obtained from Eq. 18 was multiplied by A and the antilog was taken to obtain the activity coefficient, α_{2calc}. The estimated solubility was obtained from $X_{2\ calc} = X_2^i/\alpha_{2\ calc}$.

The values of A as listed in Table I are calculated (see Eqs. 3 and 4) from experimental solubilities and molar volumes. The back-calculated solubilities may be obtained using Eqs. 3 and 4 and an iteration procedure (18) beginning with a value of 1.0 for ϕ_1 and iterating until X_2 or ϕ_1 no longer changes by more than some desired small value. However, a simple iteration procedure does not always behave in a well-conditioned manner. Assuming that the quartic equation (Eq. 18) is a function of δ_1, *i.e.*, $f(\delta_1)$, and combining it with Eqs. 3 and 4, one obtains:

$$f(X_2) = (\log X_2{}^i - \log X_2)(2.303RT)[V_1(1-X_2) + V_2X_2]^2 - V_2[V_1(1-X_2)]^2 f(\delta_1) = 0 \quad \text{(Eq. 19)}$$

X_2 can now be solved by a trial-and-error root finding method. For example, in pure water, $f_D = 0$, $\delta_1 = 23.45$, $\delta_2 = 15.3$ (cal/cm^3)$^{1/2}$, $V_1 = 18.08$, $V_2 = 94.35$ and $\log X_2{}^i = -2.1267$, and substituting 23.45 for δ_1 in Eq. 18 one obtains $f(\delta_1) = (\log \alpha_2)/A_{calc} = 16.020$. Table II lists the steps during the trial-and-error procedure. This computation can be carried out easily by use of a programmable hand calculator. The root finder subroutine, ZBRENT, found in IMSL (19) can also be used for the computation; the earlier iteration procedure of the extended Hildebrand solubility approach has been replaced in this study by the root finder method (19). The back-calculated solubilities from Eq. 18 are listed in Table I and also plotted in Fig. 1. The results compare well with the observed solubilities, having errors <7%.

Log Solubility and Volume Fraction of the Cosolvent—A log linear relationship between moles/liter or mole fraction solubility and volume fraction of the cosolvent has been proposed (20, 21). The log solubility of *p*-hydroxybenzoic acid in units of moles/liter and mole fraction were plotted against the volume fraction of the cosolvent, dioxane, in Fig. 5 to test whether this relationship holds for *p*-hydroxybenzoic acid solutions. Also marked along the horizontal axis (top of the figure) is the solubility parameter of the mixed solvents. It is evident from Fig. 5 that a log linear relation is not observed in the binary solvent mixture, dioxane and water, as the curves are quite nonlinear. They can, however, be reproduced by use of the following quadratic expressions:

$$\log S_2 = -1.430(\pm 0.050) + 4.874(\pm 0.192)f - 3.374(\pm 0.175)f^2$$
$$r^2 = 0.990, s = 0.056, F = 474, F(2, 10, 0.01) = 7.56 \quad \text{(Eq. 20)}$$

and

$$\log X_2 = -3.178(\pm 0.051) + 5.226(\pm 0.194)f - 3.047(\pm 0.176)f^2$$
$$r^2 = 0.994, s = 0.057, F = 806, F(2, 10, 0.01) = 7.56 \quad \text{(Eq. 21)}$$

where S_2 is the molar and X_2 the mole fraction solubility of *p*-hydroxybenzoic acid in dioxane–water mixtures with various volume fractions f of dioxane at 25°.

In another study (22) it was shown that the log linear rule often holds for drugs in binary solvents of water combined with an organic cosolvent particularly when the cosolvent interacts strongly with the solute and when the solubility parameter of the cosolvent is several units above that

Figure 4—*Plot of residuals obtained from quartic regression equation, Eq. 18, for* p*-hydroxybenzoic acid in dioxane–water mixtures at 25°. The almost complete scatter here indicates that Eq. 18 is superior to Eqs. 16 and 17 (Figs. 2 and 3).*

of the solute. Although dioxane appears to interact with *p*-hydroxybenzoic acid and elevates the solubility of the drug above the ideal solubility line, X_2^i, dioxane does not solvate or complex the solute sufficiently to yield a straight line relationship. Furthermore, the solubility parameter of *p*-hydroxybenzoic acid lies between the solubility parameters of water and dioxane and this militates against a log linear relationship. Instead, these conditions create a peak value on a plot of log solubility *versus* volume fraction of cosolvent or *versus* solubility parameter of mixed solvent.

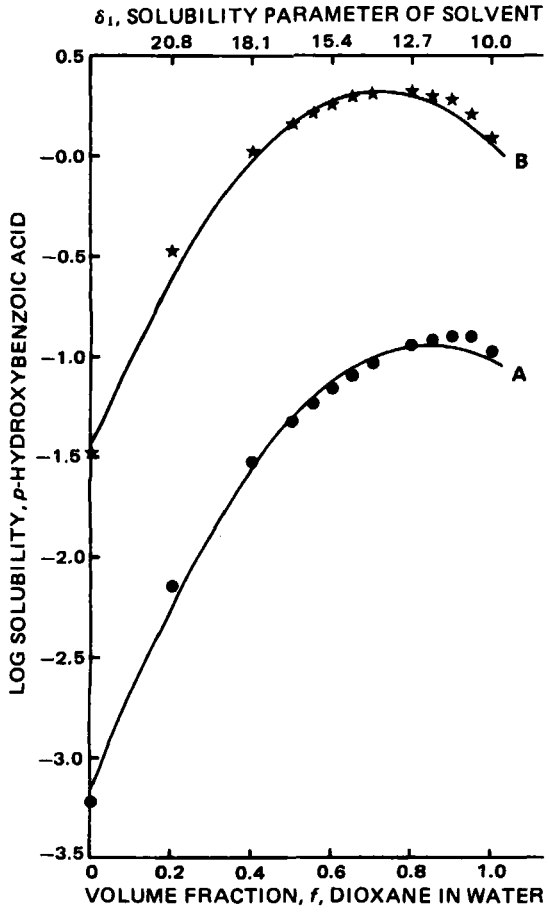

Figure 5—*Log solubility of* p*-hydroxybenzoic acid in dioxane–water mixtures at 25°. Curves A and B are back-calculated from Eqs. 21 and 20, respectively. Key: (★) moles/liter; (●) mole fraction.*

CONCLUSIONS

The solubility parameter of *p*-hydroxybenzoic acid was estimated by determining the peak in the solubility profile, Fig. 1, and by a group-contribution method (15). Interaction of the solute with the cosolvent, dioxane, may have unduly lowered the δ_2 value obtained by the peak solubility technique. The two methods do not yield values that agree closely; the δ_2 value was taken as ~15 $(cal/cm^3)^{1/2}$, a reasonable value for this highly polar compound.

The effect of a saturated solution of the solute on the solubility parameter of the mixed solvent was tested in this system and was found not to influence δ_1 markedly. In predicting solubilities using the extended Hildebrand solubility approach, the slight effect on δ_1 does not change the back-calculated solubility values.

To estimate solubilities of *p*-hydroxybenzoic acid in mixtures of dioxane and water, $(\log \alpha_2)/A$ was regressed in a polynomial on δ_1 of the solvent mixtures according to the extended Hildebrand solubility approach. The residual plots (scattergrams) for the quadratic, cubic, and quartic equations serve together with the standard deviation, r^2 and F values to indicate whether a quadratic equation is satisfactory or whether a cubic, quartic, or higher-order polynomial is required to fit the data. From an analysis of r^2, F, and the scattergram, it was observed that the quartic equation was required to reproduce the solubility data of *p*-hydroxybenzoic acid.

The iteration procedure for the back-calculation of solubilities was studied in detail in this paper, because it was found to be a problem in earlier works, causing an oscillation between two values or a divergence rather than convergence to the proper mole fraction solubility. A root finder method, involving trial-and-error, or better, use of an IMSL subroutine [ZBRENT (19)] proved to be the solution to this problem.

The solubility of *p*-hydroxybenzoic acid in dioxane–water mixtures was observed not to follow a log linear relationship: a regularity earlier observed for some drugs in water combined with nonaqueous cosolvents. The failure of the log linear relationship is expected (22) in this case, however, since the solubility parameter of *p*-hydroxybenzoic acid ($\delta_2 \simeq 15$) lies between that of water ($\delta_1 = 23.4$) and the cosolvent, dioxane ($\delta_1 = 10$).

Molecular Interaction Between Riboflavin and Salicylic Acid Derivatives in Nonpolar Solvents

BYUNG SUL YU ˣ, SANG JONG LEE, SEUNG JIN LEE, and HYUN HO CHUNG

Received November 23, 1981, from the *Department of Physical Pharmacy, College of Pharmacy, Seoul National University, San 56-1, Shinrim-Dong, Kwanak-Ku, Seoul 151, Korea.* Accepted for publication June 2, 1982.

Abstract □ The interaction of riboflavin-2′,3′,4′,5′-tetrabutyrate (I) with salicylic acid (II), aspirin (acetylsalicylic acid, III), and salicylamide (IV) has been spectroscopically investigated to determine the binding mechanism. NMR and absorption spectra were measured in nonpolar solvents. The association constant K of the formation of complex was calculated from the absorption spectra. Compounds I and II form a 1:1 cyclic hydrogen-bonded dimer through the N-3 proton and the C-2 carbonyl oxygen of the isoalloxazine ring, and the carboxylic hydroxyl proton and carbonyl oxygen of II. Compounds I and III form a 1:1 cyclic hydrogen-bonded dimer by the same mode. Compound IV forms a 1:1 cyclic hydrogen-bonded dimer with I through the N-3 proton and the C-2 carbonyl oxygen of the isoalloxazine ring, and the amino proton and the carbonyl oxygen of IV. Salicylates produce marked changes in the absorption spectra of I. These spectral changes are attributed to the formation of the hydrogen-bonded dimer. It appeared that the strongest complex was formed with salicylic acid, a weaker one with aspirin, and an even weaker one with salicylamide.

Keyphrases □ Riboflavin—molecular interactions with salicylic acid derivatives, NMR and absorption spectroscopy in nonpolar solvents, association constant determinations for hydrogen-bonded dimers □ Salicylates—molecular interactions with riboflavin, NMR and absorption spectroscopy in nonpolar solvents, association constant determinations for hydrogen-bonded dimers

Salicylate, one of the oldest synthetic drugs, remains the most widely used analgesic and antipyretic agent. It is known that the hydrogen bonding of salicylates in biological systems is related to their drug action (1). It has been determined experimentally that higher concentrations of salicylates result in marked stimulation of respiration while low concentrations depress this function (2–7). Salicylic acid derivatives act as uncoupling agents on the isolated mitochondrial respiration and lower the respiration rate of dinitrophenol-uncoupled mitochondria; inhibition of state 3 mitochondrial respiration by salicylic acid derivatives is accompanied by an increase in the oxidized state of all electron transport systems (8).

The electron-transfer from nicotinamide adenine dinucleotide (NADH) to flavoprotein, or the charge-transfer complex thus formed, was studied by a number of authors to give an account of the function of the respiratory chain (9–13). It has been determined that reduced NAD-coupling enzyme[1] complex converts spontaneously to the hypothetical intermediate as oxidized NAD-coupling enzyme[2], which is considered indispensable to the formation of adenosine triphosphate (ATP) in the respiratory chain (14). Simultaneously, the electrons in $(NADox)^{-2}$ can be transferred to flavoprotein. It is generally agreed that salicylates, which act as uncoupling agents, cause the breakdown of some high-energy intermediate involved in the phosphorylation process. However, the mechanism of such a breakdown has not previously been determined. The mechanism of action of salicylate could be described as: (*a*) salicylate associates with the adenine moiety of flavin adenine dinucleotide (FAD) or NAD, (*b*) salicylate inhibits the interaction of the flavin moiety with the adenine moiety of FAD or NAD, (*c*) salicylate affects the electronic environment due to an association with flavin, or (*d*) salicylate inhibits the interactions of FAD and the flavin mononucleotide (FMN) with apoprotein. Therefore, it seems worthwhile to examine the molecular interaction between salicylate and riboflavin. In this paper a detailed analysis of the NMR and absorption spectra of the complex will be presented and a structure of the complex will

be proposed. These results may provide a basis for interpreting the mode of action of salicylic acid derivatives.

EXPERIMENTAL

Materials—Riboflavin-2′,3′,4′,5′-tetrabutyrate[3] (I) was obtained commercially. It was recrystallized from chloroform and the purity was confirmed by TLC. Salicylic acid[4] (II), aspirin[5] (III), and salicylamide[5] (IV) were used after recrystallization from chloroform. Deuterochloroform was purified by filtration through an alumina gel column, 5 cm in length. Carbon tetrachloride was treated with methanolic potassium hydroxide solution, washed with water several times, dried over calcium chloride overnight, and fractionally distilled from phosphorus pentoxide through a 120-cm column packed with glass helices. The distillate was refluxed and again fractionally distilled. Benzene was treated with concentrated sulfuric acid several times. After repeated washing with potassium hydroxide solution, it was dried over calcium chloride overnight, fractionally distilled from phosphorus pentoxide through a 120-cm column packed with glass helices, and crystallized twice. It was refluxed and again fractionally distilled.

Methods—^{1}H-NMR spectra were recorded on a 90-MHz spectrometer equipped with a temperature-control unit[6]. For the measurement of NMR spectra, the samples of I and salicylate at various molar ratios were dissolved in deuterochloroform. Sample volumes of 5 ml in 5-mm diameter tubes with polytef caps were used. Tetramethylsilane (0.3%) was added to the deuterochloroform to provide the field lock signal; chemical shifts were measured from the signals. The probe temperature was 35°. Absorption spectra were measured in a UV visible spectrophotometer[7] connected to a linear recorder[8]. Fused quartz cells of 10-mm light path were used, each of which was fitted with a polytef stopper. The slit width was chosen so that the effective band width of the exit beam was sufficiently narrow compared with the width of absorption bands.

To determine the association constant of complex of the absorption spectra as precisely as possible, ternary solutions which contained small amounts of I and II (or III) in nonpolar solvents, such as carbon tetrachloride and benzene, were used. For each set of I and II (or III), several solutions containing equal quantities of I and different amounts of II (or III) were prepared. The actual concentration of I was of the order of 10^{-5} M (3×10^{-5}, 5×10^{-5}, and 8×10^{-5} M), while that of II (or III) ranged from 0 to 10^{-2} M (or 2×10^{-2} M). The concentration of I was small enough to allow the effect of self-association of I molecules to be ignored. The absorbance changes of I were measured at 436 and 446 nm, the association constants were calculated, and the experimental data were treated statistically.

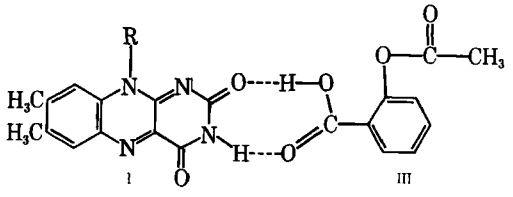
V

RESULTS

NMR Spectra—The ^{1}H-HMR spectra of riboflavin and salicylic acid derivatives in deuterochloroform are relatively simple in the downfield region. In the spectrum of II, the absorption of the carboxyl proton is observed below 10 ppm, the phenol proton is not evident at low concentrations but is weakly observed at high concentrations, and the aromatic protons appear at 6.9–8.1-ppm. The carboxyl proton of III is not evident. In the spectrum of IV, absorption of the amino proton was observed at ~6 ppm and that of the hydroxyl proton below 12 ppm. As the concentration of IV increased, the signal for the hydroxyl proton moved only slightly, but the signal for the amino proton shifted downfield.

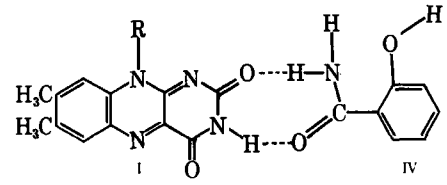


VI

The N-3 proton of I is the most deshielded proton in the molecule and occurs farther downfield than all the other resonances. The C-6 and C-9 protons of I are both downfield from the residual nondeuterated chloroform peak. These two protons are concentration independent. When these protons take part in hydrogen bonding to form cyclic self-association dimers or I–salicylate pairs or triplets, they become less shielded and their resonances shift downfield. The exact positions of the hydroxyl, amino, and imino resonances depend on the degree of association and hydrogen-bond formation; therefore, both vary with temperature and concentration.

To obtain information on the characteristics of complex in deuterochloroform, experiments were performed at constant total concentration. Unlike the results obtained from optical methods, these curves do not show a maximum (or minimum) at the relative concentrations indicative of the stoichiometry of the reaction (15). Figure 1 shows the dependence of the chemical shifts for the N-3 proton of I and the carboxyl proton of II when I was mixed with II. The N-3 proton signal of I shifted downfield as the relative concentration of II increased. The carboxyl proton signal of II also moved downfield as the concentration of I increased. From these observations it can be inferred that the association between I and II is stronger than the self-association of either compound. When I was mixed with III, the dependence of the chemical shifts on the N-3 proton of I was similar to that of II (Fig. 2). In the case of IV, the N-3 proton signal of I changed slightly and the amino proton signal of IV moved downfield slightly as the concentration of I increased and that of IV decreased (Fig. 3). This implies that the association between I and IV is stronger than the self-association of IV and approximately the same as the self-association of I. It may be assumed by the shape of the slope of all three curves that 1:1 complexes are formed in each case (15, 16).

The chemical shifts of the N-3 proton of I were plotted against the



VII

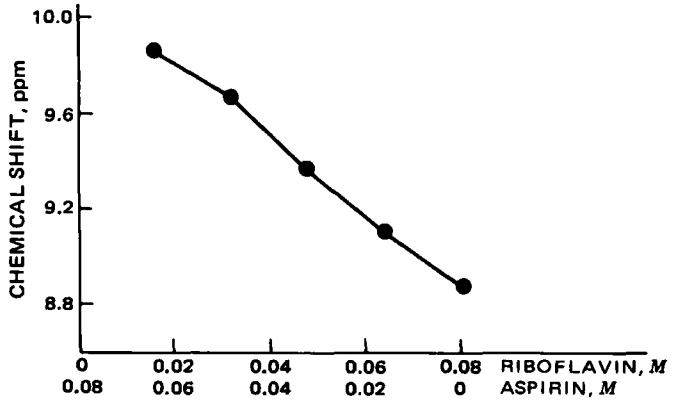


Figure 2—*Stoichiometric pairing of I and III: dependence of the chemical shifts of the riboflavin N-3 proton in a mixing experiment of I and III. Total concentration was constant at 0.08* M.

concentration of the three salicylic acid derivatives at 35°, keeping the concentration of I constant at 0.04 *M* (Fig. 4). The slopes of the N-3 proton curves of I for II and III are much greater than that of the chemical shift due to the self-association of I, while that for IV is slightly greater. These data can be interpreted to indicate that I associates somewhat more strongly with II or III than with IV, which is consistent with the other data obtained. The carboxyl proton signal of II was more upfield as the concentration of II was increased while keeping the concentration of I constant (not shown). From this fact alone, it can be inferred that the association between I and II is stronger than the self-association of II and the mole ratio of complex is the 1:1 type.

Figure 5 shows the chemical shift of the carboxyl and phenol protons of II plotted against the concentration of I, while keeping the concentration of II constant at 0.1 *M*. The curve of the carboxyl proton of II is convex upward, while the curve of the phenol proton is concave upward. As the concentration of I increased, the carboxyl proton signal appeared to broaden whereas the phenol proton signal sharpened. The downfield shift and broadening effect of the carboxyl proton are presumably because this proton takes part in the hydrogen bonding to form a I–II complex. The upfield shift and sharpening effect of the phenol proton indicate the possibility of a stacked configuration or two components of the complex not being in one plane. The N-3 proton signal of I was more upfield as the concentration of I was increased while keeping the concentration of II constant (not shown). From this fact, it can be suggested that the association between I and II is stronger than the self-association of I and the mole ratio of the complex is the 1:1 type. A similar phenomenon was observed with III on addition of I while keeping the concentration of III constant at 0.06 *M* (not shown). In the case of IV, the curve of the amino proton is straight upward (Fig. 6). The phenol proton signal decreased in intensity and then disappeared without a shielding effect as the concentration of I was increased (not shown). This implies that only the amino proton takes part in hydrogen bonding to form a I–IV complex.

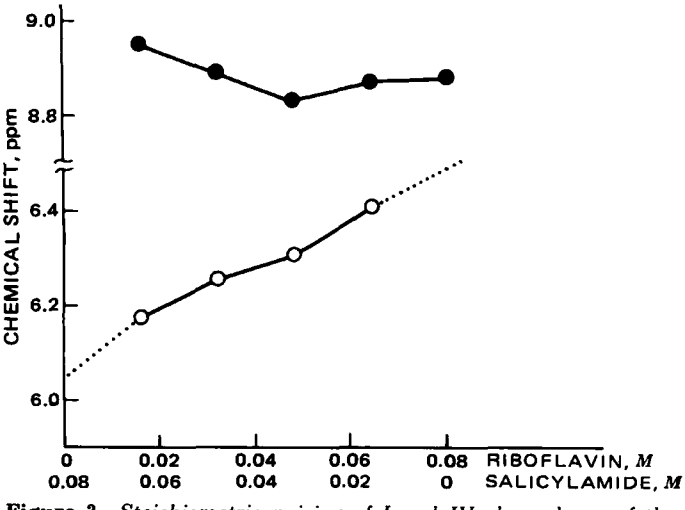

Figure 3—*Stoichiometric pairing of I and IV: dependence of the chemical shifts of the riboflavin N-3 (●) and salicylamide amino (○) protons in a mixing experiment of I and IV. Total concentration was constant at 0.08* M.

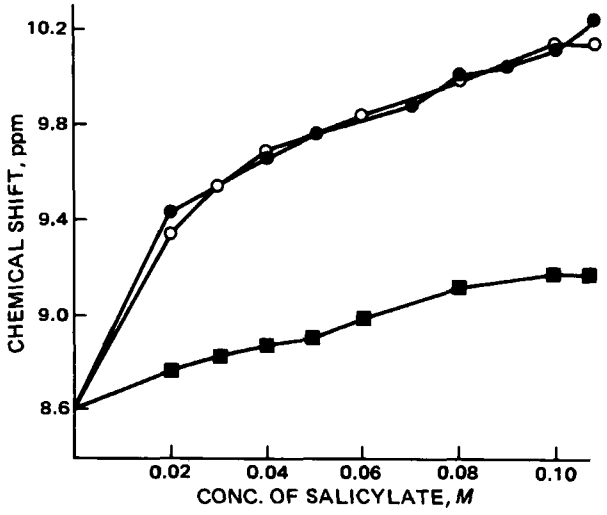

Figure 4—*Effects of the concentrations of salicylates on the chemical shifts of the riboflavin N-3 proton in deuterochloroform, keeping the concentration of I constant at 0.04* M. *Key: (●) salicylic acid, (○) aspirin, and (■) salicylamide.*

Besides the observation of complex formation in the downfield shift of the protons directly involved, a secondary effect also may be noted which is due to a change in the electron density at sites where several bonds are altered in the donor or acceptor atoms during hydrogen-bond formation. Small changes may be produced in the ring currents and the electron densities in the acceptor molecules, resulting in shifts in the resonances of the other protons. It is also possible to produce small changes in the ring resonance positions due to neighboring unsaturated ring systems. The resonances of the C-6 and C-9 protons of I are not shielded. But small upfield shifts were observed in all of the ring protons of II and III. In the case of IV, some of the ring protons moved downfield slightly and others shifted upfield.

Absorption Spectra—As shown in Fig. 7, a marked spectral change was produced on adding II to I in a nonpolar solvent, carbon tetrachloride. It may be assumed that this spectral change is due solely to the formation of a hydrogen bond between I and II. This view is further substantiated by the existence of several isosbestic points in each set of spectra. The shorter wavelength band shifted to the red, the longer band shifted to the blue, and hyperchromism of the longer band was observed. Frequency shifts due to hydrogen bonding were determined from the spectra of the

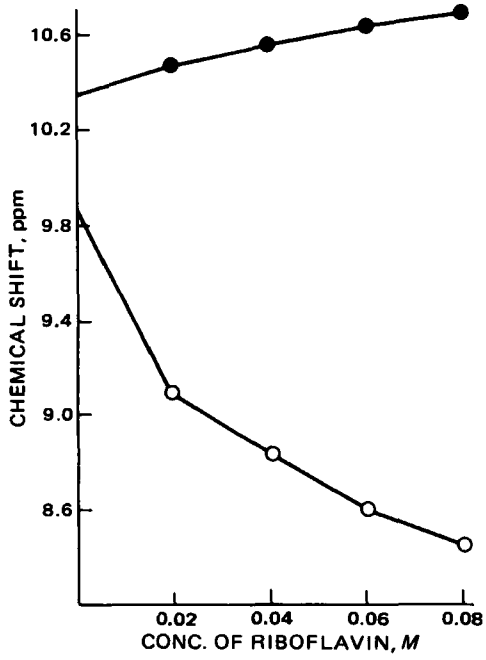

Figure 5—*Effects of the concentration of I on the chemical shifts of the carboxyl (●) and the phenol (○) protons of II in deuterochloroform, keeping the concentration of II constant at 0.1* M.

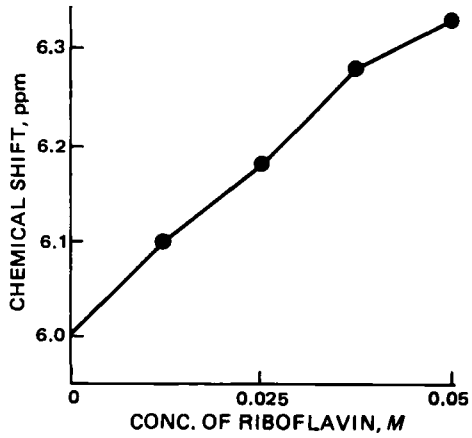

Figure 6—*Effects of the concentration of I on the chemical shifts of the salicylamide amino protons in deuterochloroform, keeping the concentration of IV constant at 0.05* M.

free and hydrogen-bonded species (resulting from the difference between the energy of the hydrogen bond in the excited and ground states). These phenomena were observed with III or IV in carbon tetrachloride. In the other nonpolar solvent, benzene, similar phenomena also were observed.

Determination of the association constant of the complex is possible from spectral data if the complex shows a significantly different spectrum from that of its components. The association constant of the hydrogen-bonding complex was obtained using the following:

$$\frac{1}{\Delta\epsilon_{obs}} = \frac{1}{K(\epsilon_c - \epsilon_a)}\frac{1}{C_b} + \frac{1}{\epsilon_c - \epsilon_a}$$

where $\Delta\epsilon_{obs} = \epsilon_{obs} - \epsilon_a$, ϵ_a and ϵ_c are the molar absorptivities at a given frequency of I in uncomplexed form and in pure complex, respectively, ϵ_{obs} is the observed absorptivity at a given frequency of I in complexed media, C_b is the concentration of salicylates (on some scale defined in the *Experimental* section), and K is the association constant of the complex (17). This can be easily derived with the assumption that the concentration of I is negligibly small compared with that of salicylate; such is actually the case in the present study. From this equation, a plot of $I/\Delta\epsilon_{obs}$ *versus* $1/C_b$ is expected to give a straight line. When both the concentration of I and the cell length are kept constant throughout a set of spectra, the absorptivities (ϵ) in the equation may be replaced by the corresponding absorbances (A). Thus $1/\Delta A_{obs}$ was plotted against $1/C_b$ for various frequencies. These plots gave straight lines, and the extrapolation of the lines for each of the salicylates led to K values which were

Table I—Measured and Calculated Properties of I and Salicylates on Absorption Spectra

Salicylate	Range of Salicylate Concentration, M	Solvent	Association constant (K), M^{-1}
II	1×10^{-3}–1×10^{-2}	Benzene	450
III	1×10^{-3}–1×10^{-2}	Benzene	370
II	1×10^{-3}–1×10^{-2}	Carbon tetrachloride	435
III	2×10^{-4}–1×10^{-3}	Carbon tetrachloride	350

equal to one another within experimental error. One example of such plots is shown in Fig. 8. The K values were calculated from the plots and are summarized in Table I. These association constants were obtained by averaging the values from three different concentrations of I (3×10^{-5}, 5×10^{-5}, and 8×10^{-5} M).

DISCUSSION

High-resolution ^{1}H-NMR techniques provide a direct observation of the hydrogen bonding in solution. As shown in the NMR spectra, the N-3 proton of I, the carboxyl protons of II and III, and the amino protons of IV seem to participate in the bonding. The NMR method utilized here measures the chemical shifts of the donor proton in hydrogen-bond formation. The acceptor atoms do not have protons and therefore do not give rise to resonances. Hence, no direct information can be gained on the identity of these acceptors. Using IR spectra, it was determined which carbonyl group of riboflavin was involved (18). In the 6-μm region of the spectra, the association through the C-2 carbonyl group of the isoalloxazine ring predominates. This is consistent with the suggestion that, in the hydrogen bonding on the isoalloxazine ring, the C-2 carbonyl group is preferred to the one at C-4 (19). This can be illustrated by the fact that the proton affinities of the heteroatoms in the isoalloxazine ring are actually different from one another (14, 19–21). As determined previously (14), the charge density of the C-2 carbonyl oxygen atom in the isoalloxazine ring is greater than that of the C-4 carbonyl oxygen atom; the N-3 proton is extremely labile and a good electron acceptor since the charge density of N-3 nitrogen atom is higher than any of the other heteroatoms. The change of the absorption spectra supports hydrogen-bond formation at the aforementioned binding sites (22).

Thus, the most probable hydrogen bonding is represented in the following manner. Compounds I and II form the 1:1 cyclic hydrogen-bonded dimer (V) through the N-3 proton and the C-2 carbonyl oxygen of the isoalloxazine ring, and the carboxylic hydroxyl proton and carbonyl oxygen of II. Compounds I and III form the 1:1 cyclic hydrogen-bonded dimer (VI) in the same manner. Compound IV forms the 1:1 cyclic hydrogen-bonded dimer (VII) with I through the N-3 proton and the C-2

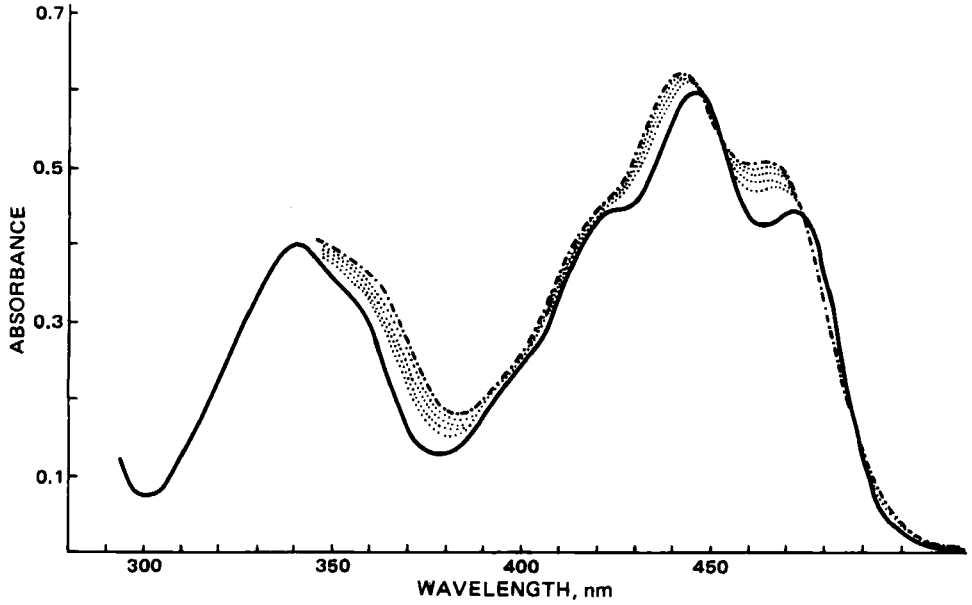

Figure 7—*Effects of II on the absorbance spectrum of I (5×10^{-5} M) in carbon tetrachloride. Salicylic acid was added from 0 to 1×10^{-2} M. carbonyl oxygen of the isoalloxazine ring, and the amino proton and carbonyl oxygen of IV. The frontier orbital density of N-5 is the greatest of all the atoms in the isoalloxazine ring (20). Therefore, N-5 seems to be the entrance of electrons. The formation of various types of hydrogen bonding affects the frontier orbital density of N-5 of the isoalloxazine ring (22). Considering that salicylates interact with riboflavin at the aforementioned sites, the electron affinity of the isoalloxazine ring and the frontier electron density of N-5 increase, which accelerates the electron flow from the substrate to the coenzyme (19–26). The hydrogen bonding involved in flavoproteins may be considered to be significant with respect to their catalytic activity.

In nonpolar solvents (carbon tetrachloride and benzene) marked absorption spectral changes due to hydrogen bonding were produced when salicylates were added to I. Frequency shifts were observed. It is known that the energy of the hydrogen bond in the excited state is differentiated from that in the ground state. The association constants of I with II or III in nonpolar solvents are large, however, with IV it is too small to be calculated from the absorption spectral data. The NMR data produced similar results. On the other hand, in chloroform solution the absorption spectral change due to hydrogen bonding was weak (not shown). This could be attributed to the solute–solvent interaction.

Although II, III, and IV are very similar structurally, their effects on the body may be quite diverse. Sodium salicylate and III effectively depress oxidative phosphorylation while IV is a weak or ineffective uncoupling agent. Compound III is more potent than sodium salicylate as an analgesic and antipyretic, and IV is much less effective than either (27, 28). These facts are consistent with the experimental results obtained in this study. The use of deuterochloroform, carbon tetrachloride, and benzene as solvents in these experiments enabled observation of these interactions free of strong solute–solvent association effects. This environment may mimic in some ways the inside of the enzyme–substrate complex from which water may be excluded. It has been suggested that FAD in the enzyme is surrounded by a hydrophobic environment even in the aqueous phase (29, 30). If one considers that the oxidation–reduction process in these systems occurs in a lipophilic rather than an aqueous environment, it may be worthwhile to research the direct interaction between salicylates and the riboflavin moiety in a nonpolar system. Further quantitative analysis of these data should lead to a more precise fundamental understanding of the riboflavin–salicylate complex formation.

5-Fluorouracil Concentrations in Rat Plasma, Parotid Saliva, and Bile and Protein Binding in Rat Plasma

LEE A. CELIO, G. JOHN DiGREGORIO ˣ, EILEEN RUCH
JOSEPH N. PACE, and ANTHONY J. PIRAINO

Received November 23, 1981, from the *Department of Pharmacology, Hahnemann Medical College, Philadelphia, PA 19102.* Accepted for publication May 7, 1982.

Abstract □ The pharmacokinetics of 5-fluorouracil were studied over a 60-min period in rats that received 12.5, 25.0, and 50.0 mg/kg iv. The plasma concentration–time relationship and the detectability in bile and parotid saliva (a route of elimination heretofore given little or no attention) were examined. Protein binding of 5-fluorouracil at concentrations chosen to approximate those found in plasma was determined by equilibrium dialysis. Bile–plasma and parotid saliva–plasma concentration ratios were calculated. 5-Fluorouracil concentrations were quantitated by high-performance liquid chromatography. Plasma concentrations at all doses studied appeared to rapidly decline. The half-life, however, at the 50.0-mg/kg dose (27 min) was significantly longer ($p < 0.025$) than the corresponding half-life at the 25.0-mg/kg dose (22 min). This may be attributed to an easily saturable hepatic degradation. Although an observed decline in bile–plasma and parotid saliva–plasma concentration ratios at higher doses may represent saturation of these excretary routes, the small amounts of 5-fluorouracil detected in bile and parotid saliva probably contribute negligibly to the elimination of the total drug equivalents administered. Parotid saliva–plasma concentration ratios were not useful in predicting plasma protein binding as determined by equilibrium dialysis. Excretion of intravenously administered 5-fluorouracil in saliva, however, exposes the upper GI tract to this agent and may play a part in causing stomatitis in patients receiving the drug by this route.

Keyphrases □ 5-Fluorouracil—concentrations in rat plasma, bile, and parotid saliva as determined by high-performance liquid chromatography, protein binding, pharmacokinetics □ Chemotherapeutic agents—5-fluorouracil, concentration in rat plasma, bile, and parotid saliva, protein binding, pharmacokinetics *in vivo* □ Pharmacokinetics—of the chemotherapeutic agent 5-fluorouracil in rats, concentrations in plasma, bile, and parotid saliva

5-Fluorouracil, an antineoplastic agent which inhibits the synthesis of DNA (1), is extensively used in the treatment of neoplasms of the breast and GI tract (2), with a trend toward utilizing it in combination with several chemotherapeutic agents in complex schedules for disseminated disease (3–5). Information concerning the concentration–time course in plasma and body excretions may be helpful in establishing dose schedules with a pharmacological rationale. In this work a simple, sensitive, and specific method, high-performance liquid chromatography (HPLC), was used to study the decline of 5-fluorouracil concentration in plasma and its excretion in bile and parotid saliva, a route of excretion heretofore given little or no attention. Bile–plasma and parotid saliva–plasma concentration ratios were calculated and the significance of biliary and parotid saliva excretion as routes of elimination were evaluated. The extent to which 5-fluorouracil is bound to rat plasma proteins, at a concentration chosen to approximate amounts detected in rat plasma, was measured by equilibrium dialysis. The calculated percentage of free drug in plasma was determined from the parotid saliva–plasma concentration ratios and compared with the calculated percentage of free drug determined by equilibrium dialysis.

[a] Data expressed as mean ± *SE*. [b] $n = 5$. [c] $n = 6$.

EXPERIMENTAL

Material—All solvents and reagents were analytical grade. A commercial preparation of 5-fluorouracil[1] (injectable form) and 5-fluorocytosine[1] (powder form) were utilized.

Apparatus—The liquid chromatograph[2] was fitted with a loop injector and fixed-wavelength UV detector (254 nm). A 1-mV recorder[3] was utilized and the detector was attenuated at 0.20 AUFS. A prepacked, 300 × 3.9-mm (i.d.) reverse-phase μ-Bondapak C_{18} analytical column[4] was run at ambient temperature. One liter of 5% glacial acetic acid was added to 27 mg of heptane sulfonic acid for the mobile phase. The mixture was pumped isocratically through the column at a flow rate of 1.5 ml/min.

Animal Experiment—Male Wistar rats, 220–270 g, were anesthetized and prepared for drug administration and parotid saliva collection by the method described by Piraino, DiGregorio, and Ruch (6). In addition, the bile duct was surgically exposed and cannulated with polyethylene tubing[5]. Blood samples (0.5 ml) were collected in heparinized tubes at 0, 5, 10, 15, 30, and 60 min after the administration of 5-fluorouracil through the femoral vein. Parotid saliva and bile were collected over 0–15, 15–30, and 30–60 min postdose.

Equilibrium Dialysis—One-milliliter samples of rat plasma containing 60.0 or 12.5 μg of 5-fluorouracil were placed into bags formed from standard dialysis tubing[6]. The bags were tied and put in 50-ml culture tubes containing 10 ml of 0.067 *M* phosphate buffer and spiked to yield a solution of 100% of the 5-fluorouracil concentration that was placed in the plasma compartment. The tubes were sealed tightly and agitated in a shaker-water bath maintained at 37° for 4–12 hr.

Extractions—Extractions were done using a modified method of Christophides *et al.* (7). Plasma (200 μl), bile (100 μl), parotid saliva (50–100 μl), or dialysis tubing was added to 0.5 ml of saturated sodium sulfate solution and 50 μl of sodium acetate (200 g/liter). 5-Fluorocytosine, the internal standard, was dissolved in distilled water to yield a solution of 1.00 μg/ml, and 100 μl was added to the sample before extraction. The sample was then shaken with 5 ml of a solution of ether and *n*-propyl alcohol (4:1 v/v) for 5 min. After centrifugation the aqueous phase was removed and discarded. The organic phase was evaporated under a steady stream of air in a water bath maintained at 55°. The residue was redissolved in 20–50 μl of distilled water, and a 5–10 μl aliquot was injected into the liquid chromatograph. Quantitation was performed using the method of internal standards.

Calculations—Linear regression analysis of the serum level data from each animal after logarithmic transformation of the serum concentration data was used to calculate half-lives, volumes of distribution, and total body clearances. Statistical significance was determined at $p < 0.05$ using two-sided variance analysis to determine the significance of differences between the groups studied.

RESULTS AND DISCUSSION

The separation and identification of 5-fluorouracil was suitable for monitoring plasma, bile, and parotid saliva concentrations of the drug. The retention time for 5-fluorouracil was 2.0 min; the internal standard, 5-fluorocytosine, had a retention time of 4 min. The separation was reproducible and sensitive for extracted plasma, bile, and parotid saliva. Calibration curves for spiked plasma, bile, and parotid saliva were linear when the injected sample contained 0.05–5.0 μg of 5-fluorouracil, corresponding to concentrations over a range of 0.25–25 μg/ml. Extraction recoveries were 65% for 5-fluorouracil.

Following surgery, parotid saliva and bile flow rates did not differ among experimental groups over the range of doses administered. The mean (±*SE*) plasma, bile, and parotid saliva 5-fluorouracil concentrations in rats receiving 12.5, 25.0, and 50.0 mg/kg iv are presented in Tables I–III. The plasma half-lives (±*SE*) for the 12.5-, 25.0-, and 50.0-mg/kg doses were 22 ± 2, 25 ± 5, and 27 ± 3 min, respectively. The half-life at the 50.0-mg/kg dose was significantly longer ($p < 0.025$) than the corresponding half-life at the 12.5-mg/kg dose. Total body clearances (±*SE*) were 2.4 ± 0.2, 1.6 ± 0.2, and 1.4 ± 0.1 liters/kg/hr in rats receiving 12.5, 25.0, and 50.0 mg/kg iv of 5-fluorouracil, respectively. Volumes of distribution (±*SE*) were 1.23 ± 0.11, 0.89 ± 0.10, and 0.94 ± 0.10 liters/kg. While volumes of distribution did not change significantly over the range of doses studied, the total body clearance of 5-fluorouracil decreased significantly ($p < 0.001$) in animals that received 50.0 mg/kg compared with the group which received 12.5 mg/kg. The mean (±*SE*) bile–plasma and parotid saliva–plasma concentration ratios were calculated and are presented in Tables IV and V. Compared with bile–plasma concentration ratios at 60 min for a dose of 50.0 mg/kg, bile–plasma concentration ratios were approximately two times higher with the administration of 25.0 mg/kg and four times higher with the administration of 12.5 mg/kg (Table IV). The parotid saliva–plasma concentration ratios also tended to decrease at higher doses (Table V). The free plasma 5-fluorouracil concentrations predicted using the parotid saliva–plasma concentration ratios 60 min following the intravenous administration of 5-fluorouracil were 49, 36, and 24% for the 12.5-, 25.0-, and 50.0-mg/kg doses, respectively.

When determined by equilibrium dialysis, however, the extent to which 5-fluorouracil is bound to rat plasma at 18.7 ± 2.0 and 65.7 ± 0.9 μg/ml, was <10%. The percentage of drug calculated to be free from protein binding was >90% for the aforementioned concentrations. The percent protein-bound drug did not vary significantly between 0.40 and 12-hr incubation when the drug was added to both sides of the system. Ninety-eight percent of the measured concentration of 5-fluorouracil added to the dialysis system was accounted for by drug assayed from both sides of the dialysis system after equilibrium. No 5-fluorouracil binding to the dialysis membrane was detected.

5-Fluorouracil, an antimetabolite, is an antineoplastic agent extensively used for a variety of solid neoplasms and has toxicities that include bone marrow suppression and damage to the GI tract (8). Stomatitis and esophagopharyngitis are common side effects. In the past, pharmacokinetic studies using rats have shown saturation of degradative metabolism at high doses, which is presumed to correlate with the clinical observation that increasing doses of 5-fluorouracil results in unproportional increases in toxicity (9, 10). This investigation examined the plasma concentration–time relationship and the detectability and excretion in parotid saliva and bile of intravenously administered 5-fluorouracil in rats. The excretion of 5-fluorouracil in body fluids, in addition to the plasma–concentration time course, may be useful in predicting the mechanisms of clinically encountered toxicities.

In this work 5-fluorouracil plasma concentrations dropped rapidly after intravenous administration. This is consistent with the hypothesis that only a small amount of pharmacologically active drug remains in the tissues, while most of the dose administered is rapidly eliminated from the body (11). As reported previously, the plasma half-life of 5-fluorouracil was found to increase at higher doses (9). While differences in plasma half-life were not striking, the half-life at the 50.0-mg/kg dose appeared significantly ($p < 0.05$) prolonged compared with the corresponding half-life at the 12.5-mg/kg dose.

5-Fluorouracil is metabolized primarily via the liver by an easily saturable pathway (9, 10). Although bile flow rates were unchanged, the proportion of 5-fluorouracil excreted in bile, as reflected by the bile–plasma concentration ratio at a dose of 50.0 mg/kg, was approximately one-fourth and one-half of that at the 12.5- and 25.0-mg/kg doses, respectively. A decline in the bile–plasma concentration ratio at higher doses is consistent with a saturable hepatic excretory process. The relative decrease in biliary excretion probably does not contribute greatly to a longer plasma half-life at higher doses, since 5-fluorouracil is mainly eliminated by urinary excretion (12). In general, low molecular weight compounds are not eliminated primarily *via* bile even in rats with ligated renal pedicles (13). A longer half-life at higher doses remains best explained by saturation of the degradative metabolism. The dependency of half-life on dose can not be attributed to changes in the volumes of distribution since these tended to decrease at higher doses. Total body clearances, however, of 5-fluorouracil decreased at higher doses consistent with a saturable elimination. Ongoing clinical investigations are assessing how alterations in urinary excretion of 5-fluorouracil and its metabolites can account for some of the variation observed in response to therapeutic doses (14).

Although urinary and biliary excretion have been previously studied, heretofore little or no information has been available concerning the detectability and excretion of 5-fluorouracil in saliva. This work demonstrates that this chemotherapeutic agent is excreted in detectable amounts in rat parotid saliva after intravenous administration. The concentration of 5-fluorouracil in parotid saliva is low and probably contributes negligibly to the total drug equivalents eliminated from the body. The calculated percentage of free 5-fluorouracil in plasma predicted by the parotid saliva–plasma concentration ratios consistently yielded values too low to reflect the percentage of free drug in plasma as determined by equilibrium dialysis. Parotid salivary excretions of 5-fluorouracil may be affected by back-diffusion, ion trapping, alterations in blood supply, and damage of the parenchyma of the gland. It is hypothesized that cytological changes in the salivary glands of mice following sublethal doses of 5-fluorouracil may impair the discharge of secretory materials (15). Furthermore, excretion in the saliva exposes the mucosa of the upper GI tract to 5-fluorouracil after intravenous administration. This may correlate with the clinical observation that intravenously administered 5-fluorouracil has been found to cause stomatitis (11). Structural changes similar to those found in the parotid glands of mice have been described in the pancreas (16) of Brunner's glands (17) of rats. 5-Fluorouracil may affect these metabolically active organs by incorpo-

rating into RNA, since it has been reported to inhibit protein synthesis in mammals by this mechanism (16).

In the past rat studies have been used to develop optimal scheduling programs and predict mechanisms of toxicity of 5-fluorouracil (9, 18). Findings of these investigations are presumed to correlate with clinical observations. In this work, concentrations of 5-fluorouracil in the excreted fluids of rats were used to supplement information derived from the plasma concentration time course. This work has demonstrated that unmetabolized 5-fluorouracil is excreted in detectable amounts in rat bile and parotid saliva. Biliary excretion appears to occur *via* a saturable process. Excretion of 5-fluorouracil in parotid saliva exposes the upper GI tract to this agent, even when administered intravenously. These routes of excretion appear to contribute negligibly to the total drug equivalents eliminated from the body.

Liquid Membrane Phenomenon in Reserpine Action

S. B. BHISE, P. R. MARWADI, S. S. MATHUR, and R. C. SRIVASTAVA ˣ

Received March 2, 1982, from the *Birla Institute of Technology and Science, Pilani-333031, Rajasthan, India.* Accepted for publication May 26, 1982.

Abstract □ Reserpine was shown to generate a liquid membrane. Transport of adrenaline, noradrenaline, dopamine, 5-hydroxytryptamine, glutamic acid, and γ-aminobutyric acid in the presence of the reserpine liquid membrane was studied. The data indicate that the phenomenon of liquid membrane formation is likely to play a role in the mechanism of reserpine action.

Keyphrases □ Reserpine—liquid membrane phenomenon, biogenic amines, neurotransmitter amino acids, surface activity □ Liquid membrane phenomenon—reserpine action, biogenic amines, neurotransmitter amino acids, surface activity

Surface activity is exhibited by a wide variety of biologically active agents (1). The fact that surface activity may play a role in the mechanism of action of some drugs is evident from the correlations obtained (2) between surface activity and biological effects. Previous researchers (3) have concluded that in the case of psychotropic drugs, surface activity is the primary factor which determines their potency and not the specific chemical structure.

According to a previous hypothesis (4), surface-active agents, when added to water or aqueous solutions, generate liquid membranes which completely cover the interface at concentrations equal to the critical micelle concentration of the surfactant. It is, therefore, logical to expect that the liquid membranes generated by surface-active drugs may play a role in the mechanism of their action. Studies on haloperidol, a surface-active neuroleptic drug, were recently undertaken (5), and it was shown that the liquid membrane generated by haloperidol contributes significantly to the mechanism of its action.

To establish the role of liquid membrane phenomena in the mechanism of action of surface-active drugs, it is necessary to conduct studies, on structurally dissimilar drugs. Reserpine, a drug structurally different from haloperidol, is discussed in the present report. Existence of a liquid membrane generated by reserpine was demonstrated and data on the transport of biogenic amines and relevant neurotransmitter amino acids, through the liquid membrane generated by reserpine, were obtained.

EXPERIMENTAL

Materials—Reserpine[1], dopamine chlorhydrate[2], adrenaline hydrogen tartrate[2], L-noradrenaline[3], 5-hydroxytryptamine creatinine sulfate[4], L-glutamic acid[5], γ-aminobutyric acid[5], and distilled water (glass-distilled once from potassium permanganate) were used.

Methods—The critical micelle concentration (CMC) of aqueous reserpine was determined from the variation of surface tension with concentration. The surface tensions were measured using a tensiometer[6]. To prepare aqueous solutions of reserpine, the necessary volume of an ethanolic solution of known concentration of the drug was added to the aqueous phase with constant stirring. Since the aqueous solution of reserpine always contained some alcohol, in no case >1%, the blanks used also contained the same amount of alcohol in water. The CMC value of aqueous reserpine was found to be 1.6×10^{-6} *M*.

The all-glass cell described earlier (5, 6) was used for transport studies. A cellulose nitrate millipore filter[7], which acted as a support for the liquid

These routes of excretion appear to contribute negligibly to the total drug equivalents eliminated from the body.

Liquid Membrane Phenomenon in Reserpine Action

S. B. BHISE, P. R. MARWADI, S. S. MATHUR, and R. C. SRIVASTAVA ˣ

Received March 2, 1982, from the *Birla Institute of Technology and Science, Pilani-333031, Rajasthan, India.* Accepted for publication May 26, 1982.

Abstract □ Reserpine was shown to generate a liquid membrane. Transport of adrenaline, noradrenaline, dopamine, 5-hydroxytryptamine, glutamic acid, and γ-aminobutyric acid in the presence of the reserpine liquid membrane was studied. The data indicate that the phenomenon of liquid membrane formation is likely to play a role in the mechanism of reserpine action.

Keyphrases □ Reserpine—liquid membrane phenomenon, biogenic amines, neurotransmitter amino acids, surface activity □ Liquid membrane phenomenon—reserpine action, biogenic amines, neurotransmitter amino acids, surface activity

Surface activity is exhibited by a wide variety of biologically active agents (1). The fact that surface activity may play a role in the mechanism of action of some drugs is evident from the correlations obtained (2) between surface activity and biological effects. Previous researchers (3) have concluded that in the case of psychotropic drugs, surface activity is the primary factor which determines their potency and not the specific chemical structure.

According to a previous hypothesis (4), surface-active agents, when added to water or aqueous solutions, generate liquid membranes which completely cover the interface at concentrations equal to the critical micelle concentration of the surfactant. It is, therefore, logical to expect that the liquid membranes generated by surface-active drugs may play a role in the mechanism of their action. Studies on haloperidol, a surface-active neuroleptic drug, were recently undertaken (5), and it was shown that the liquid membrane generated by haloperidol contributes significantly to the mechanism of its action.

To establish the role of liquid membrane phenomena in the mechanism of action of surface-active drugs, it is necessary to conduct studies, on structurally dissimilar drugs. Reserpine, a drug structurally different from haloperidol, is discussed in the present report. Existence of a liquid membrane generated by reserpine was demonstrated and data on the transport of biogenic amines and relevant neurotransmitter amino acids, through the liquid membrane generated by reserpine, were obtained.

EXPERIMENTAL

Materials—Reserpine[1], dopamine chlorhydrate[2], adrenaline hydrogen tartrate[2], L-noradrenaline[3], 5-hydroxytryptamine creatinine sulfate[4], L-glutamic acid[5], γ-aminobutyric acid[5], and distilled water (glass-distilled once from potassium permanganate) were used.

Methods—The critical micelle concentration (CMC) of aqueous reserpine was determined from the variation of surface tension with concentration. The surface tensions were measured using a tensiometer[6]. To prepare aqueous solutions of reserpine, the necessary volume of an ethanolic solution of known concentration of the drug was added to the aqueous phase with constant stirring. Since the aqueous solution of reserpine always contained some alcohol, in no case >1%, the blanks used also contained the same amount of alcohol in water. The CMC value of aqueous reserpine was found to be 1.6×10^{-6} *M*.

The all-glass cell described earlier (5, 6) was used for transport studies. A cellulose nitrate millipore filter[7], which acted as a support for the liquid

membrane, separated the transport cell into two compartments, C and D (Fig. 1) (5, 6).

Measurements of hydraulic permeability were carried out using the method described earlier (5, 6) at various concentrations of reserpine, ranging from 0 to 6.4×10^{-6} M. The concentration range was selected to get data from both the lower and the higher sides of the reserpine CMC.

For solute permeability of biogenic amines and amino acids, two sets of experiments were performed. In the first set, compartment C of the transport cell (Fig. 1) (5, 6) was filled with the solution of the respective permeable solutes prepared in 6.4×10^{-6} M aqueous solutions of reserpine, and compartment D was filled with distilled water. In the second set of experiments, compartment C was filled with the aqueous solution of the permeable solutes, and compartment D was filled with the aqueous solution of reserpine of 6.4×10^{-6} M concentration. In the control experiments no reserpine was used. The concentration of reserpine of 6.4×10^{-6} M, well above its CMC, was deliberately chosen for solute permeability measurements to ensure formation of a complete layer of liquid membrane on the supporting membrane. The values of the solute permeabilities (ω) were estimated using (7, 8):

$$\left(\frac{J_s}{\Delta\pi}\right)_{J_v=0} = \omega \qquad \text{(Eq. 1)}$$

where $\Delta\pi$ is the osmotic pressure difference, J_s is the solute flux per unit area of the membrane, and J_v is the volume flux. The method of measurement was described earlier (5).

Since reserpine is known to be photosensitive (9), in all the permeability experiments, the part of the transport cell containing reserpine solution was covered with black paper. All measurements including CMC determinations were carried out at 37 ± 0.1°.

Estimation of Biogenic Amines—Transport of adrenaline, noradrenaline, dopamine, and 5-hydroxytryptamine was estimated in the presence of reserpine. Reserpine was observed to interfere with fluorometric estimation of biogenic amines; therefore, the estimations were carried out using a spectrophotometer[8] by measuring absorbance at 282.4 nm (λ_{max}). Calibration curves were constructed by noting the absorbance of the solutions of varying concentrations of biogenic amines; prepared in a solution of a fixed concentration of reserpine, which was equal to its concentration in solute permeability experiments. The calibration curves thus constructed were found to be linear in accordance with Beer's law.

Estimation of Amino Acids—The amounts of glutamic acid and γ-aminobutyric acid were estimated from the amount of their reaction products with ninhydrin[5], measured spectrophotometrically[9] at 570 nm.

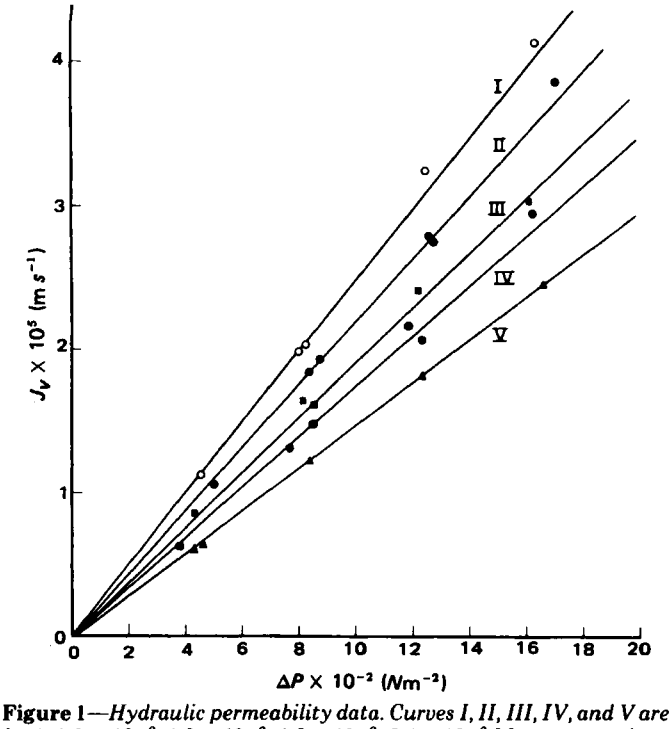

Figure 1—*Hydraulic permeability data. Curves I, II, III, IV, and V are for 0; 0.8×10^{-6}; 1.2×10^{-6}; 1.6×10^{-6}; 6.4×10^{-6} M, concentrations of reserpine, respectively.*

RESULTS AND DISCUSSION

From the hydraulic permeability data at various concentrations of reserpine (Fig. 1), it is observed that the linear relationship:

$$J_v = L\Delta P \qquad \text{(Eq. 2)}$$

where J_v represents volume flux per unit area of the membrane, ΔP the applied pressure difference, and L the hydraulic conductivity coefficient, holds good in all cases. The values of L (Table I) show a progressive decrease with an increase in concentration of reserpine up to its CMC, beyond which the decrease is only nominal. This trend is indicative of progressive coverage of the supporting membrane with the reserpine liquid membrane in accordance with a previous hypothesis (4). The decrease in the values of L beyond the CMC of reserpine possibly is due to an increase in density of the liquid membrane as postulated previously (4).

Analysis of the flow data (Fig. 1, Table I) in relation to a mosaic membrane model (10, 11) further supports the existence of the liquid membrane in series with the supporting membrane. Following the arguments given earlier (5, 6) it can be shown that if the concentration of the surfactant is n times its CMC, with $n \leq 1$, the values of L would be equal to $[(1-n)L^c + nL^s]$ where L^c and L^s represent the values of L at 0 and CMC of the surfactant, respectively.

The values of L, computed at various concentrations of reserpine, lower than its CMC value, match favorably with the values obtained experimentally (Table I).

The values of ω for the biogenic amines and amino acids recorded in Table II indicate that the maximum reduction in the permeability values is observed in the second set of experiments where compartment D was filled with reserpine and compartment C with permeable solute. When reserpine is present in compartment D (Fig. 1) (5, 6) the liquid membrane generated will present the hydrophobic surface to the permeable solute that is present in compartment C. Since reserpine is known to act by reduction in the uptake of biogenic amines (12), it appears that this specific orientation of reserpine with the hydrophobic ends facing the various solutes may be necessary even in biological cells.

Reserpine is known to inhibit intraneuronal storage of catecholamines (12). Although inhibition of the ATP-Mg^{2+}-dependent uptake mechanism in isolated chromaffin granules has been considered to be a factor governing this mechanism (13), effects on other subcellular particles is also believed to occur by a common, nonspecific mechanism (3). The results of the present experiments indicate that the liquid membrane phenomenon is such a nonspecific mechanism. The phenomenon appears to be of special significance because the liquid membrane is formed at micromolar concentrations of the drug.

While some of the wide-ranging actions of reserpine can be explained on the basis of blocking of catecholamine uptake (12), it is difficult to find a common mechanism for other effects such as inhibition of experimentally provoked thrombus formation in rats (14), decreased oxygen utilization in the brain (15) and liver (16), antitumor effects (17), extrapyramidal symptoms (18), and reduction of thyroid secretion (19). pairment of catecholamine release by reserpine has also been reported (20), for which no explanation has been given at a molecular level. The liquid membrane phenomenon seems to offer a common mechanism for all such effects. Alteration in transport of biologically relevant molecules by the reserpine liquid membrane could be a plausible explanation.

Reserpine is also known to reduce the permeability of biological cells to 5-hydroxytryptamine (20), which may contribute to its sedative effect. The present set of experiments also shows reduction in permeability of 5-hydroxytryptamine because of reserpine liquid membrane. Reserpine is known to lower electroshock threshold in rats (21), which is related to depletion of γ-aminobutyric acid in the brain. Since reserpine liquid membrane reduces the permeability of this amino acid (Table II), the above effect can be at least partially assigned to the formation of a liquid membrane by reserpine *in situ*.

Although reduction in the permeabilities of biogenic amines and amino acids (Table II), due to the liquid membrane generated by reserpine, is passive in nature, it is also likely to be accompanied by a subsequent reduction in their active transport. Access of the permeable solutes to the active site located on the biological membrane is likely to be effectively reduced due to the resistance offered by the reserpine liquid membrane.

Studies on the Absorption of Practically Water-Insoluble Drugs Following Injection VII: Plasma Concentration after Different Subcutaneous Doses of a Drug in Aqueous Suspension in Rats

KOICHIRO HIRANO ˣ and HIDEO YAMADA

Received June 30, 1981, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication April 30, 1982.

Abstract □ The response patterns of the time profile of plasma drug level to dose elevation after subcutaneous administration of a practically water-insoluble drug in aqueous suspension were investigated. Equations to predict the plasma drug concentration at any time and the time T_{max} at which it reaches the maximum (C_{max}) at different doses were derived using empirical equations describing the subcutaneous absorption kinetic process as an input function of one- and two-compartment models. Computer simulation for the one-compartment model showed that C_{max} tended to increase curvilinearly with dose elevation accompanied by the retardation of T_{max}. It also showed that this tendency was noticeable in dose elevation at fixed injection volume and became more significant for drugs with a smaller absorption rate and/or a larger elimination rate. This suggested that a more effective means of raising the drug plasma level for such drugs would be improvement of the formulation. The validity of the information obtained from the simulation was confirmed by various subcutaneous administration experiments of N^1-acetylsulfamethoxazole aqueous suspensions in rats. Further, the multiple-point injection method was ascertained to be useful for avoiding the nonlinear increase in plasma drug concentration with dose elevation appearing in the subcutaneous administration of aqueous suspensions.

Keyphrases □ Absorption—studies on practically water-insoluble drugs following injection, plasma concentration after different subcutaneous doses of a drug in aqueous suspensions in rats □ Aqueous suspensions—studies on absorption of practically water-insoluble drugs following injection, plasma concentration after different subcutaneous doses in rats

Aqueous suspensions are extensively used as a parenteral dosage form for practically water-insoluble drugs. Despite their usefulness for early screening and preclinical testing of newly developed drugs in laboratory animals, little is known about the patterns of plasma drug level change with time and dose after subcutaneous, intramuscular, or intraperitoneal administration. This is undoubtedly due to insufficient information on the absorption kinetics for aqueous suspensions when using such administration routes.

Drug administration *via* the subcutaneous route is convenient for early animal experiments because it allows injections of a larger volume than possible with the intramuscular route and does not involve the first-pass effect sometimes observed when the intraperitoneal route is used (1). Previous studies on the subcutaneous absorption kinetics of practically water-insoluble drugs in aqueous suspension using the local clearance method in rats (2) gave a kinetic equation which was not of the first order and which differed from that for oily (3) or surfactant micellar solutions[1]. The rate constant, which was empirically derived from the experimental results, was a complex function of the initial drug concentration and injection volume, *i.e.*, the dose (2).

[1] K. Hirano and H. Yamada, unpublished results.

The purpose of the present study was to examine plasma drug levels after different subcutaneous doses of a practically water-insoluble drug in aqueous suspension. First, pharmacokinetic approaches were made using the previously obtained kinetic equation for absorption as an input function of one- and two-compartment models to generate equations describing the time course of the plasma drug level. Next, computer simulations were undertaken to clarify the response patterns of the plasma drug concentration–time curve for the change in dose or absorption rate constant. Then the validity of the information obtained from the simulation was checked experimentally in rats with aqueous suspensions of N^1-acetylsulfamethoxazole. In addition, the usefulness of multiple-point injections for drugs having an exceedingly slow absorption rate was examined experimentally.

THEORETICAL

Previous investigations have shown that the drug absorption process from aqueous suspensions injected subcutaneously (2) or intramuscularly (4) can be represented, if the injected particles loosely agglomerate and if dissolution (or release) of the drug from the surface of the particle agglomerate is the rate-limiting step for overall drug absorption, by:

$$W = W_0(1 - jt)^3 \qquad (0 \le t \le 1/j) \qquad \text{(Eq. 1)}$$

where W_0 and W are the dose and the amount of the drug remaining at the injection site at any time t, respectively, and j is defined as an apparent absorption rate constant[2]. This constant could be related to the initial drug concentration C_0 and the injection volume V_0 by the following empirical equation:

$$j = fC_0^g V_0^h \qquad \text{(Eq. 2)}$$

where the term f is a constant that depends on the drug, preparation

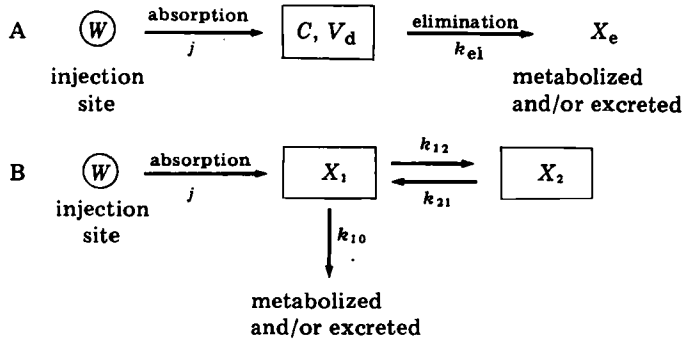

Figure 1—*(A) One- and (B) two-compartment models with nonlinear subcutaneous absorption.*

[2] The term "apparent" is used, since the assumption that Eq. 1 reflects the true absorption of the drug into the systemic circulation was not checked directly by experiments [although its validity was indirectly confirmed by the local clearance method (2, 4)]. The validity will be verified in the latter half of this paper.

0022-3549/83/0600-0602$01.00/0

conditions (particle size, *etc.*), injection site, and physiological state of the subject. The exponents g and h in this equation are constants determined experimentally. For the subcutaneous route in rats, the experimental values for g and h are −0.66 and −0.32, respectively (2).

Applying the above kinetic equations as an input function of a one- or two-compartment model, the following pharmacokinetic approaches can be made to derive equations which give the plasma drug concentration as a function of time.

One-Compartment Model—For the one-compartment model (Fig. 1A), the elimination rate of the drug (dX_e/dt) can be defined as:

$$dX_e/dt = k_{el}CV_d \qquad \text{(Eq. 3)}$$

where X_e is the amount of the drug eliminated from time 0 to t and C represents the plasma concentration of the drug. The parameters k_{el} and V_d are the apparent first-order elimination rate constant and the apparent volume of distribution, respectively. Differentiation of Eq. 1 with respect to time gives the rate of absorption of the drug from the injection site:

$$dW/dt = -3W_0j(1 - jt)^2 \qquad \text{(Eq. 4)}$$

And from mass balance:

$$\frac{dCV_d}{dt} = -\frac{dW}{dt} - \frac{dX_e}{dt} \qquad \text{(Eq. 5)}$$

Combining Eqs. 3–5 results in:

$$\frac{dC}{dt} + k_{el}C = \frac{3W_{0j}}{V_d}(1 - jt)^2 \qquad \text{(Eq. 6)}$$

Solving for C gives two relationships between the plasma drug concentration and time.

For $0 \le t \le t^*$:

$$C = P[Q(1 - e^{-k_{el}t}) + Rt + St^2] \qquad \text{(Eq. 7)}$$

and for $t > t^*$:

$$C = C^*e^{-k_{el}(t-t^*)} \qquad \text{(Eq. 8)}$$

The terms t^*, P, Q, R, S, and C^* are written by setting $\gamma = j/k_{el}$ as follows:

$$\left.\begin{aligned} t^* = 1/j, \quad P = 3W_0/V_d, \quad Q = \gamma(1 + 2\gamma + 2\gamma^2) \\ R = -2j\gamma(1 + \gamma), \quad S = j^2\gamma, \\ C^* = P[Q(1 - e^{-k_{el}t^*}) + Rt^* + St^{*2}] \end{aligned}\right\} \qquad \text{(Eq. 9)}$$

When the plasma concentration reaches maximum (C_{max}) at time T_{max} ($0 < T_{max} < t^*$), then $dC/dt = 0$. Therefore:

$$Qk_{el}e^{-k_{el}T_{max}} + R + 2ST_{max} = 0 \qquad \text{(Eq. 10)}$$

T_{max} is given as one of the real solutions of this transcendental equation. (Numerical analysis may be useful for solving this equation.) C_{max} is obtained by substituting T_{max} for t in Eq. 7.

Two-Compartment Model—Analytical treatment for a multicompartment model with a complex input function not having a simple Laplace transform, is not as simple as a one-compartment model. Also, a previous general treatment for linear mamillary models (5, 6) may not be applicable for such a model.

Recently, a valuable partial transformation approach was reported (7), which avoids Laplace transformation of the input function and the use of convolution integrals, and can be used for treatment of a linear multicompartment model with complex input functions in one or more compartments. According to this approach:

$$X = \Phi(t)[X(0) + \int_0^t \Phi(-t)f(t)dt] \qquad \text{(Eq. 11)}$$

where the ith component of vector X or f is the amount X_i at time t or the input function $f_i(t)$ in the ith compartment, respectively, and $X(0)$ is the vector X at time $t = 0$. The ijth component Φ_{ij} of matrix Φ is given by:

$$\Phi_{ij} = L^{-1}(|S_{ij}|/|S|) \qquad \text{(Eq. 12)}$$

where L^{-1} is the inverse Laplace transform operator, $|S|$ is the determinant of the matrix S, and S_{ij} is the cofactor corresponding to the ijth element. Here, the matrix S is defined as:

$$S = -K + \text{diag}(s + E_1, s + E_2, \ldots, s + E_n) \qquad \text{(Eq. 13)}$$

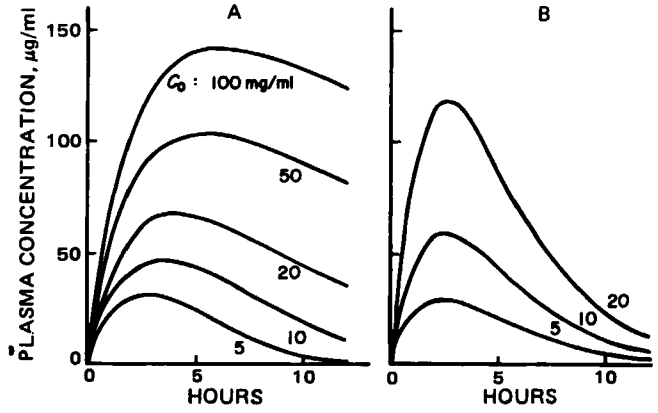

Figure 2—*Computer-predicted plasma levels after different subcutaneous doses of a drug in aqueous suspension (A) and oily solution (B) at fixed injection volume (0.5 ml). Plasma concentrations were calculated from hypothetical parameters:* k_{el}, *0.5 hr*$^{-1}$; V_d, *25 ml*; j*(1) (at* C_0 *= 5 mg/ml and* V_0 *= 0.5 ml), 0.10 hr*$^{-1}$ *(*$t_{1/2}$, *2.06 hr);* k, *0.336 hr*$^{-1}$ *(*$t_{1/2}$, *2.06 hr).*

where the ijth element k_{ij} of the matrix K is the first-order intercompartmental transfer rate constant between the ith and jth compartments, and E_i is the sum of the exit rate constants of the ith compartment. The symbol s represents the Laplace operator and $s + E_i$ is the ith diagonal element of the diagonal matrix, diag$(s + E_1, s + E_2, \ldots, s + E_n)$.

Using Eq. 11 for analytical treatment of the two-compartment model with an input function of Eq. 4 (Fig. 1B) yields the following equations which describe the drug amounts in the central and peripheral compartments (X_1 and X_2, respectively) as a function of time. Thus, for $0 \le t \le t^*$:

$$X_1 = \frac{3(\alpha - k_{21})W_0}{\alpha - \beta}[Q_1(1 - e^{-\alpha t}) + R_1t + S_1t^2] + \frac{3(k_{21} - \beta)W_0}{\alpha - \beta}[Q_2(1 - e^{-\beta t}) + R_2t + S_2t^2] \qquad \text{(Eq. 14)}$$

and:

$$X_2 = \frac{3k_{12}W_0}{\beta - \alpha}[Q_1(1 - e^{-\alpha t}) + R_1t + S_1t^2 - Q_2(1 - e^{-\beta t}) - R_2t - S_2t^2] \qquad \text{(Eq. 15)}$$

For $t > t^*$ (setting t' equal to $t - t^*$):

$$X_1 = \frac{3W_0}{(\alpha - \beta)^2}[\{(\alpha - k_{21})^2 + k_{12}k_{21}\}U_1e^{-\alpha t'} + \{(k_{21} - \beta)^2 + k_{12}k_{21}\}U_2e^{-\beta t'}] \qquad \text{(Eq. 16)}$$

and:

$$X_2 = \frac{3k_{12}W_0}{\beta - \alpha}(U_1e^{-\alpha t'} - U_2e^{-\beta t'}) \qquad \text{(Eq. 17)}$$

where α and β are the real solutions ($\alpha > \beta$) of the equation $y^2 - (k_{10} + k_{12} + k_{21})y + k_{21}k_{10} = 0$. The terms Q_1, Q_2, R_1, R_2, S_1, S_2, U_1, and U_2 are written, using $\gamma_1 = j/\alpha$ and $\gamma_2 = j/\beta$, as follows:

$$\left.\begin{aligned} Q_1 = \gamma_1(1 + 2\gamma_1 + 2\gamma_1^2), \quad Q_2 = \gamma_2(1 + 2\gamma_2 + 2\gamma_2^2) \\ R_1 = -2\gamma_1j(1 + \gamma_1), \quad R_2 = -2\gamma_2j(1 + \gamma_2), \quad S_1 = j^2\gamma_1 \\ S_2 = j^2\gamma_2, \quad U_1 = \frac{2S_1}{\alpha^2} - Q_1e^{-\alpha t^*}, \quad U_2 = \frac{2S_2}{\beta^2} - Q_2e^{-\beta t^*} \end{aligned}\right\} \qquad \text{(Eq. 18)}$$

By introducing the apparent volume (V_c) of the central compartment, the plasma drug concentration (C) is given as:

$$C = X_1/V_c \qquad \text{(Eq. 19)}$$

In addition, T_{max} ($0 < T_{max} \le t^*$) is also given as one of the real solutions of the following transcendental equation:

$$(\alpha - k_{21})(Q_1\alpha e^{-\alpha T_{max}} + R_1 + 2S_1T_{max}) + (k_{21} - \beta)(Q_2\beta e^{-\beta T_{max}} + R_2 + 2S_2T_{max}) = 0 \qquad \text{(Eq. 20)}$$

Thus, plasma concentration C at any time t, T_{max}, and C_{max} can be readily calculated for different doses of a drug when only one absorption rate constant (under certain administration conditions) and other

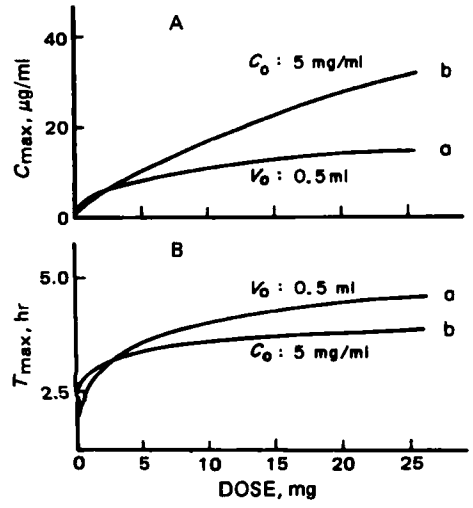

Figure 3—*Relationship between C_{max} (A) or T_{max} (B) and subcutaneous dose of aqueous suspension at fixed injection volume (a) or fixed drug concentration (b). These curves were obtained using hypothetical parameters:* k_{el}, *1.0 hr*$^{-1}$; V_d, *25 ml; j(1) (at* C_0 = *5 mg/ml and* V_0 = *0.5 ml), 0.0238 hr*$^{-1}$.

pharmacokinetic parameters are known; this confers one- or two-compartment characteristics on the body. In the present study, using the one-compartment model as an example, the response pattern of the plasma drug concentration–time curve to a change in dose or absorption rate constant was examined through some simulations and experiments.

EXPERIMENTAL

Calculation of Plasma Concentration—The apparent absorption rate constant j at any drug concentration (C_0) and at any injection volume (V_0), *i.e.*, at any dose, was calculated from one set of known data [$j(1)$ at $C_0(1)$ and $V_0(1)$], assuming the same injection site and an aqueous suspension of the same prescription, using the following equation derived readily from Eq. 2:

$$j = j(1)[C_0/C_0(1)]^g[V_0/V_0(1)]^h \qquad \text{(Eq. 21)}$$

In this study, the experimentally determined values of −0.66 and −0.32 were used for g and h, respectively (2). Drug plasma concentration C at any time t was calculated from Eq. 7 or 8 using values of j obtained from Eq. 21, pharmacokinetic parameters (k_{el} and V_d), and dose W_0. T_{max} was obtained by solving Eq. 10 with the aid of numerical analysis (Newton–Raphson method). For calculation of the sulfamethoxazole plasma concentration after subcutaneous doses of N^1-acetylsulfamethoxazole in aqueous suspension, the experimental value of 0.17 hr^{-1} (C_0 = 5 mg/ml; V_0 = 0.5 ml of N^1-acetylsulfamethoxazole), which was reported in a previous paper (2), was used as $j(1)$. All of the above calculations were carried out with a FACOM 270-20/30 computer.

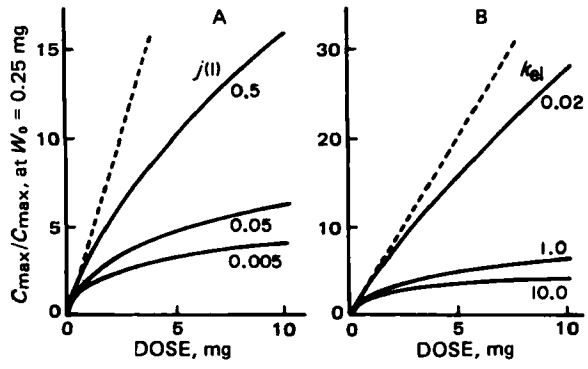

Figure 4—*Curvilinear increase in C_{max} with dose elevation at different j(1) (section A) or k_{el} values (section B) under fixed injection volume (0.5 ml). These curves were calculated from hypothetical parameters:* V_d, *25 ml;* k_{el} *in section A, 1.0 hr*$^{-1}$; *j(1) in section B, 0.05 hr*$^{-1}$. *j(1) shows the* j *value at* C_0 = *5 mg/ml and* V_0 = *0.5 ml.*

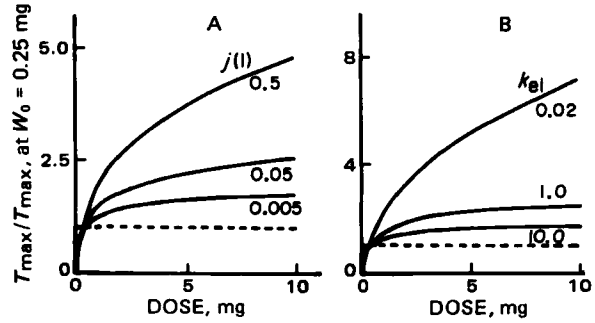

Figure 5—*Retardation of T_{max} with dose elevation at different j(1) (section A) or k_{el} values (section B) under fixed injection volume (0.5 ml). These curves were calculated from the same hypothetical parameters:* V_d, *25 ml;* k_{el} *in section A, 1.0 hr*$^{-1}$; *j(1) in section B, 0.05 hr*$^{-1}$.

Materials and Test Suspensions—N^1-Acetylsulfamethoxazole[3] was selected as a model of a practically water-insoluble drug and aqueous suspensions of the different concentrations (5, 10, 20, 50, and 100 mg/ml), prepared according to the controlled preparation method described in a previous report (4), were used as test suspensions for the subcutaneous administration experiments. N^1-Acetylsulfamethoxazole[3] and a dispersion medium[4] used for these preparations were the same as those reported in the previous paper (2). The mean particle diameter, distribution constant, and sedimentation volume of the test suspensions were 3.7–4.2 μm, 2.4–2.6, and 1.7–1.8 cm^3/g, respectively. These colloidal properties were similar to those reported in the previous paper (2). In addition, sulfamethoxazole solutions (concentration: 1.25, 2.50, and 5.0 mg/ml; medium: saline) were also used for the intravenous administration experiments. These solutions were prepared using the sodium salt[3] of sulfamethoxazole; pH values were adjusted to 8.0 with 1 *N* HCl.

Animal Experiments—Male Wistar albino rats weighing 250–292 g were used in all animal experiments. All test suspensions were administered into the dorsal subcutaneous region of the rats according to the manner described in a previous paper (3). Blood samples were withdrawn periodically through a tail vein. The rats were placed in a conventional cage with free access to water and food, except for a short period during drug administration and blood sampling when they were placed under light anesthesia with ether. One hundred microliters of plasma was collected for the following assay. A group of three to six rats was used in each experiment.

In vitro incubation of N^1-acetylsulfamethoxazole (I) at 37° [concentration of I in medium, 76 μg/ml (below solubility level of I)] with fresh rat plasma or saline shaken with subcutaneous connective tissues and interstitial materials[5], caused >90% of I to be transformed into sulfamethoxazole (II) within a 30-sec period. A similar conversion has been reported (8) for N^1-acetylsulfisoxazole using human plasma. It is inferred from these findings that N^1-deacetylation of I occurs immediately after dissolution in the injection site medium and that II is actually the compound being absorbed. In practice, I could not be detected in blood samples taken at 10 and 20 min and 1, 2, and 5 hr after subcutaneous administration of an aqueous suspension of I (dose: 5 mg/0.5 ml/rat) even in carefully conducted experiments[6].

Although I, when dissolved in the injection site medium, is deacetylated to II, the resultant II disappeared much more rapidly[7] than the dissolution of I. Thus, no significant accumulation of II at the injection site was

[3] Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.

[4] 0.5% (w/v) Methylcellulose (Metolose SM-15) + 0.005% (w/v) polysorbate 80 + 0.9% (w/v) NaCl.

[5] This incubation medium was obtained as follows: The rat was injected at four different points with 0.5 sc ml of saline. Immediately after the injections, the connective tissues containing saline depot were excised, minced, shaken with 2 ml of saline for 30 min, and centrifuged at 3000 rpm for 10 min. The resultant supernatant was used as the medium.

[6] Immediately after blood sampling, 0.2 ml of blood was mixed vigorously with 2 ml of 0.03 *N* HCl kept at 0° and 2 ml of 6% (w/v) $HClO_4$ was added. The mixture was shaken well and centrifuged at 5°. A portion of the clear, deproteinized solution was injected into the high-performance liquid chromatographic (HPLC) system as follows: Shimadzu LC-3A; column, Nucleosil 10C_{18} (4-mm i.d. × 300 mm); mobile phase, pH 6.3 phosphate buffer (50 m*M*)–acetonitrile (3:1, v/v); flow rate, 2 ml/min; detection, UV (290 nm); retention time, 14.1 min for I; detection limit for I (determined using blood samples inactivated with HCl then added with I), 1–2 μg/ml of blood.

[7] For example, the half-life of II in aqueous solution in the injection site was ~8.3 min (dose, 260.4 μg/0.5 ml/rat), while that of I in aqueous suspension was ~70 min (dose, 2.5 mg/0.5 ml/rat).

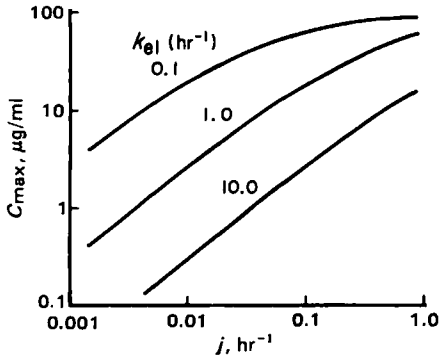

Figure 6—*Relationship between maximum plasma concentration (C_{max}) and absorption rate constant (j) at different k_{el} values under a fixed dose. These curves were obtained using hypothetical parameters: V_d, 25 ml; W_0, 2.5 mg.*

observed under the present administration conditions[8]. Therefore, postabsorptive pharmacokinetic parameters of I were estimated from plasma concentration–time profiles after intravenous administration of II. All test solutions of II were injected into a tail vein, and blood samples were periodically taken from the vein in the other side of the tail.

Analytical Method—Sulfamethoxazole in rat plasma was measured according to the fluorometric method with fluorescamine reported previously (9). To 100 μl of plasma were added 2 ml of pH 4.7 buffer (1 *N* HCl–1 *N* CH_3COONa, 3:7, v/v) and 6 ml of 1,2-dichloroethane. This was shaken well and then centrifuged. Three milliliters was withdrawn from the 1,2-dichloroethane layer, 3 ml of pH 10.6 buffer (0.1 *N* $NaHCO_3$–0.1 *N* Na_2CO_3, 1:9, v/v) was added, and the mixture was shaken and centrifuged. To 2 ml of the buffer layer (after dilution with the same buffer as necessary) were added 5 ml of pH 2.6 buffer (1 *N* HCl–1 *N* CH_3COONa, 1:1, v/v) and 1 ml of fluorescamine[9] reagent (0.2 mg/ml in acetone), and the mixture was shaken vigorously for several seconds. After this had been left standing for ~40 min, its fluorescent intensity was measured with a spectrophotometer[10] at excitation and emission wavelengths of 405 and 490 nm (uncorrected), respectively.

RESULTS AND DISCUSSION

Simulation Study—*Plasma Levels after Different Subcutaneous Doses of a Drug in Aqueous Suspension*—General patterns in the response of plasma concentration to the change in the subcutaneous dose of a drug in aqueous suspension were examined under various administration conditions, using computer simulation with hypothetical data in a one-compartment model. Figure 2A shows computer-simulated time courses of the plasma level after different subcutaneous doses of a drug in aqueous suspension at a fixed injection volume (plasma concentration shown here was calculated from Eq. 7 or 8 using j values generated from Eq. 21). The values of the absorption rate constant $j(1)$ and other pharmacokinetic parameters k_{el} and V_d used for these computations are shown in the legend. For comparison, plasma concentration–time curves for oily solutions are also shown in Fig. 2B as an example of first-order absorption (rate constant, k). Figure 2A shows the typical features of the subcutaneous administration of aqueous suspension, *i.e.*, the curvilinear increase of the maximum plasma concentration and the retardation of T_{max} with dose elevation. It should be noted that these tendencies differ from those of the preparations with first-order absorption characteristics such as oily (3) and surfactant micellar solutions[1] as shown in Fig. 2B. The above two features were more evident in dose elevation with fixed injection volume than with fixed drug concentration, as can be seen from Fig. 3.

Figure 4 compares the degree of deviation from the linear response of the maximum plasma concentration C_{max} to dose elevation among different $j(1)$ values (A) or k_{el} values (B). In this figure, the ratio of C_{max} at any dose to the C_{max} where C_0 = 0.5 mg/ml and V_0 = 0.5 ml was taken as a measure representing such a degree and is plotted against the dose. The downward deviation of this plot from the broken line, which showed

[8] The percentages of the dose disappearing from the injection site at 40, 90, and 180 min after administration of I in aqueous suspension (dose, 2.5 mg/0.5 ml/rat) were ~31, 63, and 75%, respectively, while those for II appearing at the site were ~5, 6, and 4%, respectively (each value was the mean of two experimental determinations).

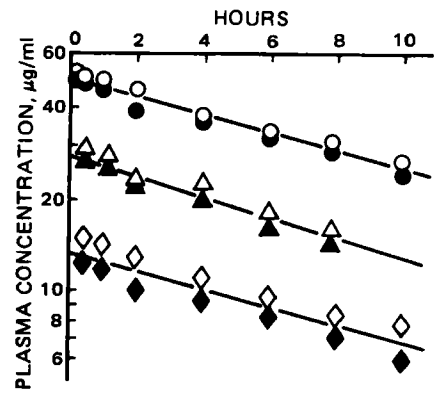

Figure 7—*Plasma concentration–time curves following three intravenous doses of sulfamethoxazole in rats. The data points in the same symbol show the plasma concentrations for each rat. Key (dose per rat): (○, ●) 2.50 mg; (△, ▲) 1.25 mg; (◇, ◆) 0.625 mg.*

a proportional relationship between C_{max} and the dose, demonstrates the phenomenon of deviation from the linear response. The deviation became larger for drugs with smaller absorption rate constants, $j(1)$, and those with larger elimination rate constants, k_{el}. Figure 5 shows the retardation of T_{max} with dose elevation at various $j(1)$ values (A) or k_{el} values (B). Similarly, the ratio of T_{max} at any dose to the T_{max} at C_0 = 0.5 mg/ml and V_0 = 0.5 ml was used as an index for this retardation. This figure indicated that the retardation of T_{max} with dose elevation became more marked the larger the $j(1)$ value and the smaller the k_{el} value.

For the subcutaneous administration of a drug in aqueous suspension, these simulations indicated that the rate of systemic drug availability decreases with increasing dose and that this decrease becomes more significant for drugs having a smaller $j(1)$ and a larger k_{el}.

Relationship Between Peak Plasma Level and Absorption Rate Constant—The parenteral drug absorption rate from an aqueous suspension can be altered by modifying not only preparation conditions such as particle size but also administration conditions such as drug concentration and injection volume (2, 4). The relationship between the absorption rate constant j and the maximum plasma concentration C_{max} at a fixed dose was examined by computer simulation. Figure 6 shows this relationship at various values of the elimination rate constant k_{el} on a log–log scale. This figure demonstrates that the curve representing such a relationship becomes closer to a straight line having a slope of unity with smaller j and larger k_{el}, while it tends to level off with larger j and smaller k_{el}. This also suggests that an attempt to elevate the drug plasma level by particle size reduction is more effective for drugs with a smaller j value [for example, due to a lower water solubility (2)] and a larger k_{el} value.

Comparison of the Results from Simulation Analyses with Experiments—Equation 1 was derived from a model in which injected particles loosely agglomerate and dissolution (or release) of the drug from the surface of the particle agglomerate is the rate-limiting process for overall drug absorption. Equation 2 was derived from the experimental

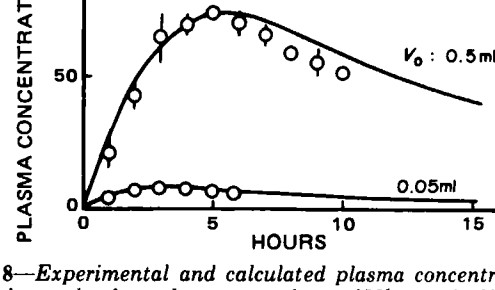

Figure 8—*Experimental and calculated plasma concentrations of sulfamethoxazole after subcutaneous doses of N^1-acetylsulfamethoxazole aqueous suspension at fixed initial drug concentration (10 mg/ml) in rats (mean body weight, 286 g). Each experimental value was given by the mean (open circle) and standard deviation (vertical bar) of three or four rats. Calculated values (solid line) were obtained with the following parameters: k_{el}, 0.072 hr^{-1}; V_d, 49.5 ml; $j(1)$, 0.17 hr^{-1}.*

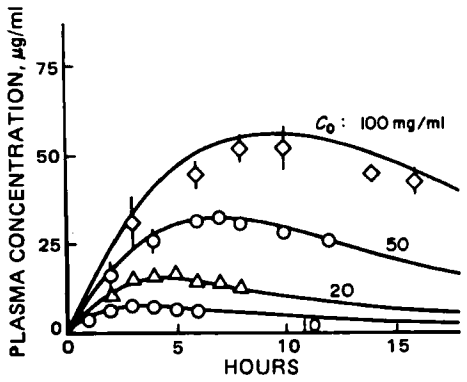

Figure 9—*Experimental and calculated plasma concentrations of sulfamethoxazole after different subcutaneous doses of* N^1*-acetylsulfamethoxazole aqueous suspensions at fixed injection volume (0.048 ml) in rats (mean body weight, 277 g). Each experimental value was given by the mean and standard deviation of four to six rats. Calculated values (solid line) were obtained with the following parameters:* k_{el}, *0.072* hr^{-1}; V_d, *48.0 ml;* $j(1)$, *0.17* hr^{-1}.

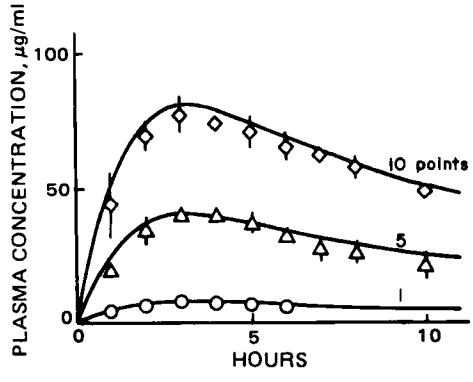

Figure 10—*Experimental and calculated plasma concentrations of sulfamethoxazole after subcutaneous doses of* N^1*-acetylsulfamethoxazole aqueous suspension by the multiple-point injection method in rats (mean body weight, 284 g).* C_0 *and* V_0 *for each injection point were 10 mg/ml and 0.048 ml, respectively. Each experimental value was given by the mean and standard deviation of four to six rats. Calculated values (solid line) were obtained with the following parameters:* k_{el}, *0.072* hr^{-1}; V_d, *49.1 ml;* $j(1)$, *0.17* hr^{-1}.

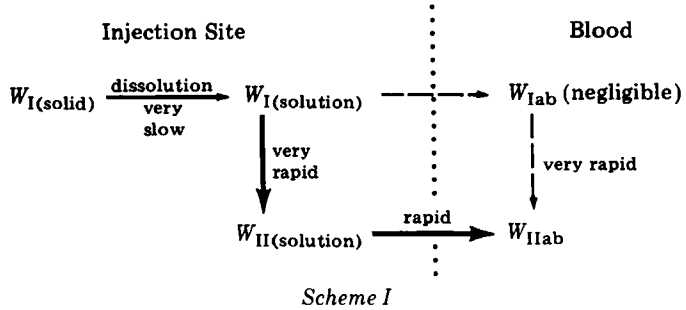
results by the local clearance method in rats (2, 4). Based on the assumption that these equations reflect the true overall absorption of the drug (or active metabolites) into the systemic circulation, the results obtained by computer simulation should be valid. However, until now the validity of this assumption had not been checked directly by experimentation. To check the feasibility of the above simulation results, plasma drug levels after subcutaneous doses using aqueous suspensions of N^1-acetylsulfamethoxazole (I) were followed in rats and compared with the calculated levels.

As mentioned in *Experimental*, I is very rapidly deacetylated to sulfamethoxazole (II) immediately after dissolution in the injection site medium, inferring absorption as II. However, absorption of II formed at the injection site occurred more rapidly than dissolution of I, and, thus, no significant accumulation of II at the injection site was observed under these injection conditions. This indicates that the rate-limiting process in overall absorption of I from aqueous suspension is the dissolution step and that the disappearance rate of I estimated by the local clearance method can be regarded as approximately equivalent to the overall absorption rate of I.

In this case, the absorption behavior for I is summarized in Scheme I:



Scheme I

The amount of I (W_{ab}) absorbed *via* II (W_{IIab}) can be represented as:

$$\left.\begin{aligned} W_{ab} &= W_{IIab} \\ &= W_0 - [W_{I(solid)} + W_{I(solution)} + W_{II(solution)}] \\ &= W_0 - [W_I + W_{II(solution)}] \end{aligned}\right\} \quad \text{(Eq. 22)}$$

where W_0 is the amount injected. Since $W_I = W_{I(solid)} + W_{I(solution)} \gg W_{II(solution)}$, therefore:

$$W_{ab} \simeq W_0 - W_I \quad \text{(Eq. 23)}$$

By differentiation of this equation with respect to time (t), the following equation was obtained:

$$dW_{ab}/dt \simeq -dW_I/dt \quad \text{(Eq. 24)}$$

Accordingly, the disappearance rate of I (dW_I/dt) is approximately equal to the overall absorption rate of I (dW_{ab}/dt).

The equation for the absorption kinetics (Eq. 1) is based on the premise that dissolution (or release) is the rate-limiting step for overall drug absorption. Compound I satisfies this premise and is adequate as a model compound for this study, although it undergoes site metabolism to II.

First, plasma concentrations of sulfamethoxazole (II) after different intravenous doses were measured to examine the postabsorptive pharmacokinetic characteristics of N^1-acetylsulfamethoxazole (I) in rats. The reason for the use of II instead of I is explained in detail in *Experimental* and in the previous paragraphs. Figure 7 shows semilogarithmic plots of plasma concentrations of II as a function of time for each dose in a rat. From the nearly linear relationship of these curves, with a similar slope and linear response of the plasma levels to the intravenous dose, the pharmacokinetic characteristics of II could be explained approximately by a one-compartment model under the described experimental conditions.

From each plot in this figure, the apparent elimination rate constant k_{el} and distribution volume V_d were estimated by the least-squares method. The mean (standard deviation, *SD*) values of k_{el} and V_d' (equal to V_d per body weight) for these six experiments were 0.072 (0.008) hr^{-1} and 0.173 (0.006) ml/g, respectively. These parameters are used below together with the absorption rate constant $j(1)$, described in *Experimental*, to calculate plasma concentrations of II after different subcutaneous doses of aqueous suspensions of I *in rats*.

Single-Point Injection—Plasma concentrations of II after different subcutaneous doses of I in aqueous suspension were determined in rats and compared with calculated plasma concentrations. Figures 8 and 9 show the results of these comparisons for different doses at fixed drug concentration and fixed injection volume, respectively. These comparisons indicated that the observed plasma concentrations for all the doses

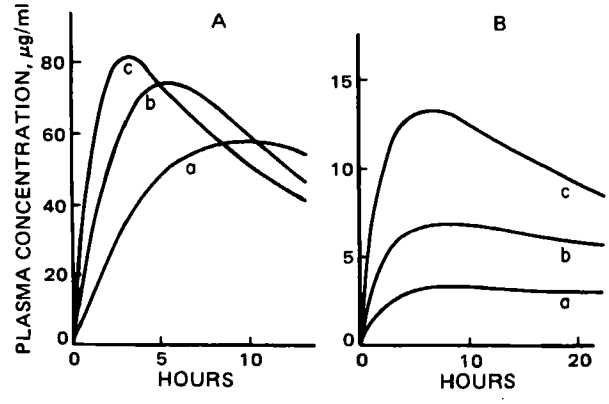


Figure 11—*Comparison of predicted plasma levels after subcutaneous administrations of aqueous suspensions among three injection methods at a fixed dose. The curves in section A were calculated from the parameters of* N^1*-acetylsulfamethoxazole (the same as shown in Fig. 10), and those in section B from hypothetical parameters as follows:* k_{el}, *0.5* hr^{-1}; V_d, *48 ml;* $j(1)$, *0.01* hr^{-1}. *Key:* a, *100 mg/ml–0.05 ml;* b, *10 mg/ml–0.5 ml;* c, *10 mg/ml–0.05 ml (10-point injection).*

examined corresponded with the calculated curves. Also, it should be noted that the curves in Figs. 8 and 9 showed the typical characteristics of subcutaneous administration of aqueous suspensions, *i.e.*, the nonlinear increase in C_{max} and retardation in T_{max} with dose elevation.

These findings appear to support the validity of the aforementioned assumption that Eqs. 1 and 2 reflect the true overall absorption of a drug in aqueous suspension into the systemic circulation.

Multiple-Point Injection—As mentioned above, dose elevation by a single subcutaneous injection of aqueous suspension may result more or less, in a nonlinear increase in plasma drug concentration. In most screening tests or preclinical testing of new drugs in laboratory animals, this phenomenon may be undesirable. It can be overcome by increasing the number of injection points in the neighboring subcutaneous area for dose elevation while keeping the drug concentration and injection volume fixed. In this multiple-point injection method, the drug absorption from each point can be expected to occur independently at nearly equal rates, and, therefore, the plasma drug level would increase in proportion to the number of injection points, *i.e.*, the dose, if the postabsorptive disposition of the drug in the body occurs in a linear manner.

To confirm this expectation, plasma sulfamethoxazole concentrations after 1-, 5-, and 10-point subcutaneous injections of N^1-acetylsulfamethoxazole aqueous suspension (C_0, 10 mg/ml; V_0, 0.048 ml) were followed in rats and compared with calculated plasma concentrations. Figure 10 shows a good agreement between the experimental and calculated values. Therefore, this multiple-point injection method seems to be a simple and convenient way to obtain a high plasma drug level without retardation of T_{max} after subcutaneous administration of a suspension.

Figure 11A compares the predicted plasma concentration–time curves following subcutaneous doses of N^1-acetylsulfamethoxazole aqueous suspension among the three injection methods at a fixed dose: C_0–V_0, (a) 100 mg/ml–0.05 ml; (b) 10 mg/ml–0.5 ml; (c) 10 mg/ml–0.05 ml, 10-point injection. This figure shows that the multiple-point injection is useful for obtaining a higher plasma drug level at a fixed dose. Figure 11B shows similar computer-simulated curves for another drug which has $j(1)$ and k_{el} values one order of magnitude below and above those in Fig. 11A, respectively. The comparison of the two figures suggests that multiple-point injection is especially effective for drugs with a small absorption rate constant and a large elimination rate constant.

The good agreement between the observed and calculated plasma concentrations presented in Figs. 8 and 9 support the validity of the assumption that Eqs. 1 and 2, derived from the experimental results by the local clearance method (2), reflect the true pattern of drug absorption into the systemic circulation. From this finding, it can be predicted that with multiple-point injection, C_{max} should be proportional to the dose without a change in T_{max}, unlike the case of single-point injection; this prediction was verified by the results shown in Fig. 10. In addition, it is indicated that the plasma concentration–time curve should differ considerably even at a fixed dose depending on the administration conditions (Fig. 11). All results of this study confirm the suitability of the analytical treatment chosen for subcutaneous drug absorption from aqueous suspensions.

Information from the simulation study presented here should be useful for predicting the dose-response pattern of plasma concentration–time curves after subcutaneous administrations in aqueous suspensions of other practically water-insoluble drugs with similar pharmacokinetic characteristics. It should also be applicable to intramuscular administrations and to drugs with two- or multicompartmental characteristics in the body.

Studies on the Absorption of Practically Water-Insoluble Drugs following Injection VIII: Comparison of the Subcutaneous Absorption Rates from Aqueous Suspensions in the Mouse, Rat, and Rabbit

KOICHIRO HIRANO ˣ **and HIDEO YAMADA**

Received August 3, 1981, from the *Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication September 14, 1981.

Abstract □ Subcutaneous drug absorption rates from aqueous suspensions were measured in the mouse and the rabbit by a local clearance method and compared with those in the rat. A plot of the cube root of the residual fraction (W/W_0) of the drug at the injection site *versus* time (t) gave a good linear relationship for the former two species. This implied that the kinetic equation for the absorption process in the rat, $(W/W_0)^{1/3} = 1 - jt$, could be applied to them. In addition, the absorption rate constants (j) of the mouse and rabbit were close to that of the rat when the drug concentration (C_0) in the suspension and the injection volume (V_0) were fixed. These results led to the presumption that the correlation between j and C_0 or V_0 in the mouse and rabbit might be similar to that in the rat, and therefore, drug plasma levels for the former two at any dose might be roughly predictable even from one j value of the rat. The validity of this assumption was confirmed by comparison of the observed and predicted plasma concentrations after different subcutaneous doses of aqueous suspensions of N^1-acetylsulfamethoxazole in the mouse and rabbit. These findings strongly supported the idea that for the subcutaneous administration of the drug in aqueous suspension under fixed dose per body weight, the rate of bioavailability should decrease with animal size, and therefore, the plasma drug level in larger species is not likely to be as high as that expected, from the data obtained for smaller species.

Keyphrases □ Absorption—studies of practically water-insoluble drugs following injection, comparison of subcutaneous absorption rates from aqueous suspensions, mouse, rat, rabbit □ Aqueous suspensions—studies on the absorption of practically water-insoluble drugs following injection, comparison of subcutaneous absorption rates, mouse, rat, rabbit

Previous reports (1, 2) showed that the absorption rate process after intramuscular or subcutaneous administration of practically water-insoluble drugs in aqueous suspensions was not linear and had a complicated dose dependency. Therefore, single administration of such drug preparations led to nonlinear response of the plasma–drug concentration, that is, a curvilinear increase of its peak and retardation of the time at which the peak occurred with increasing dose (3).

In earlier testings of pharmacological activities and dispositions of new drugs under development in laboratory animals, the dose elevation experiment is often done, not only when examining the dose response in one animal species, but also when maintaining the same or a similar dose per body weight for scale-up in various animal species. Accordingly, the problem arises that the rate of bioavailability at the same dose per body weight may vary for different species; that is, the rate of bioavailability for larger animals given a comparatively large amount of the drug may be lower compared with that for smaller animals. Since such a phenomenon, in some cases, may result in significant species differences in the drug potency, clarification of this problem is important.

In the present report, three laboratory animals, having different body weights, the mouse, rat, and rabbit, were selected as representatives to examine this problem. First, subcutaneous absorption time courses were compared among the three species using the local clearance method to determine whether a significant species difference existed in the absorption rate. Next, plasma concentrations after subcutaneous doses were followed to confirm the validity of the above comparison using N^1-acetylsulfamethoxazole in aqueous suspension. It is indicated that there is a "pitfall of dose per kilogram" in interpreting the results obtained from subcutaneous administration experiments of aqueous suspensions in various animal species.

EXPERIMENTAL

Materials—Suspensions of *p*-aminoazobenzene, *p*-hydroxyazobenzene, *o*-aminoazotoluene, and N^1-acetylsulfamethoxazole were used as models for practically water-insoluble drugs as reported previously (2). The sodium salt of sulfamethoxazole was used for the intravenous injection preparation as reported previously (3). For the fluorometry of sulfamethoxazole in plasma, fluorescamine[1] was used. All other chemicals were of reagent or analytical grade.

Preparation of Test Suspensions and Solutions—The same vehicle[2] described in the previous paper (3) was used to prepare the test aqueous suspensions. All suspensions were prepared according to the controlled preparation method reported previously (1). Their colloidal properties[3]

			NS	$p < 0.05$	
			NS		

[a] Each j value was obtained from the data shown in Figs. 1 and 2 by the least-squares method and is given with the standard error in parentheses. A t test was performed between j values of two animals each. NS = not significant ($p > 0.1$).

were similar to those reported previously (2). In addition, sulfamethoxazole solutions were prepared by the same method described in the previous paper (3) and used for the intravenous administration experiments.

Animal Experiments—*Animals*—ICR Jcl strain mice (male, 26–34 g), Wistar albino rats (male, 250–305 g), and mongrel rabbits (male, 2.6–4.0 kg) were used. During the experiments, they were kept in cages with free access to water and food.

Absorption Experiment Procedure—All the test suspensions were administered into the subcutaneous region near the center of the shorn dorsum of the animals, and their absorption rates were measured by the local clearance method described previously (4). In the mouse and rat experiments, each animal received a single injection. In the rabbit experiments, three successive injections were given at designated time intervals into different sites sufficiently apart from each other but within the dorsum of each animal; the amount of the drug remaining at each injection site was measured separately. When the experimental period ended, the mice and rats were sacrificed by exsanguination, and the rabbits were killed by intravenous administration of sodium pentobarbital[4]. The drug remaining in the injection site was recovered from the excised tissues including the depot by extraction with ethyl acetate, and its amount was determined. A group of three to six animals was used in each experiment.

Plasma Drug Level—All the aqueous suspensions of N^1-acetylsulfamethoxazole were administered subcutaneously to mice or rabbits in the manner described above. Blood samples from the mice were withdrawn from the heart at set time intervals and from the rabbits, from an ear vein periodically (serial sampling). One-hundred microliters of plasma was collected for the following analysis. *In vitro* incubation of N^1-acetylsulfamethoxazole with fresh plasma at 37° showed that this compound was very quickly transformed into sulfamethoxazole. The following intravenous administration experiments using sulfamethoxazole instead of N^1-acetylsulfamethoxazole were done in mice and rabbits to examine postabsorptive pharmacokinetic characteristics of N^1-acetylsulfamethoxazole subcutaneously administered. Test solutions of sulfamethoxazole were administered *via* a tail vein for mice (0.05 ml) and an ear vein for rabbits (2.5 ml), then blood samples were taken from the heart for the former and from another ear vein for the latter. For each rabbit, the above subcutaneous and intravenous administration experiments were performed alternately every 7–10 days for a 2-month period.

Analytical Method—The remaining amounts of *p*-aminoazobenzene, *p*-hydroxyazobenzene, and *o*-aminoazotoluene from the injection site were analyzed colorimetrically after extraction, as described previously (2). The plasma concentrations of sulfamethoxazole after subcutaneous injections of N^1-acetylsulfamethoxazole and intravenous injections of sulfamethoxazole in mice or rabbits were determined according to a fluorometric method with fluorescamine as described in the previous report (3).

Prediction of Plasma Drug Concentration—Sulfamethoxazole-plasma concentrations after different subcutaneous doses of the controlled suspension of N^1-acetylsulfamethoxazole in mice or rabbits were predicted from their postabsorptive pharmacokinetic parameters (elimination rate constant and volume of distribution) and one basic absorption rate constant $j(1)$ in rats using the equations[5] presented in the previous report (3). The postabsorptive pharmacokinetic parameters were estimated from the plasma concentration–time curves after different intravenous doses of sulfamethoxazole in mice and rabbits. The experimental value of 0.17 hr^{-1} (N^1-acetylsulfamethoxazole concentration in the test suspension, 5 mg/ml; injection volume, 0.5 ml) from a previous report (2) was used as $j(1)$.

Table II—An Example for Comparison of Subcutaneous Absorption Rate Constants (j) at Fixed Dose per Body Weight among Three Animal Species

Animal	Body Weight kg	C_0, mg/ml	V_0, ml	Dose, mg/kg	j/j(rat)[a]
Mouse	0.03	5	0.05	8.3	2.1
Rat	0.3	5	0.5	8.3	1.0
Rabbit	3	50	0.5	8.3	0.29

[a] Estimated from Eq. 2 (using $g = -0.66$ and $h = -0.32$).

RESULTS AND DISCUSSION

Comparison of Subcutaneous Absorption Rates among Three Animals—Previous studies (5, 6) have reported the species difference in the absorption rates of solid drugs implanted subcutaneously. However, few detailed investigations have been done on the species difference in subcutaneous absorptions from aqueous suspensions as well as from other conventional dosage forms. Therefore, the difference in the rate of bioavailability among various animal species has been discussed little until now. The subcutaneous absorption rates of practically water-insoluble drugs in aqueous suspension were compared directly among three popular laboratory animal species, the mouse, rat, and rabbit, using a local clearance method. For this comparison, the dorsal subcutaneous region of each animal was selected as the model injection site.

Figure 1 shows the results for subcutaneous administrations of the controlled aqueous suspension of p-aminoazobenzene. In this comparison, the initial concentration (C_0) of p-aminoazobenzene in the suspension and the injection volume (V_0) were fixed as given in the legend. The cube root of the residual function (W/W_0) at the injection site for each animal species was plotted against time. A previous report (2) indicated that such a plot gave a good linear relationship for rats. This appeared to be also true for mice and rabbits, as indicated in Fig. 1. It was surprising that the slopes of these absorption time curves were close to each other. These tendencies were further examined by similar experiments using other test suspensions of p-hydroxyazobenzene. Figure 2 shows the results. The comparisons under the two conditions of different C_0 and V_0 also showed tendencies similar to those shown in Fig. 1. These results suggested that the kinetic equation for rats should also be applicable for describing the subcutaneous absorption process from aqueous suspensions in other animals such as mice and rabbits; that is:

$$(W/W_0)^{1/3} = 1 - jt \qquad \text{(Eq. 1)}$$

where j was defined as an absorption rate constant (2).

Table I summarizes the absorption rate constants with their standard errors estimated from the data in Figs. 1 and 2 by the least-squares method. This table shows that the difference in j among these three species is not very significant and this tendency may be true for other suspensions with variable drug concentrations and injection volumes. This also implies that the following relationship derived from the rat

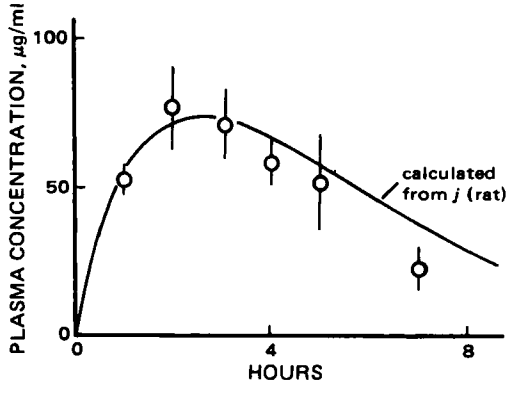

Figure 4—*Observed and predicted plasma concentrations of sulfamethoxazole after subcutaneous administration of* N^1*-acetylsulfamethoxazole aqueous suspension in mice (30.6 ± 1.6 g). Each observed value represents the mean and standard deviation of three mice.* C_0 = *51.6 mg/ml,* V_0 = *0.05 ml. The predicted value (solid line) was obtained using the following parameters:* k_{el}, *0.711 hr*$^{-1}$; V_d, *7.19 ml; j(1) (at* C_0 = *5 mg/ml and* V_0 = *0.5 ml in rats), 0.17 hr*$^{-1}$.

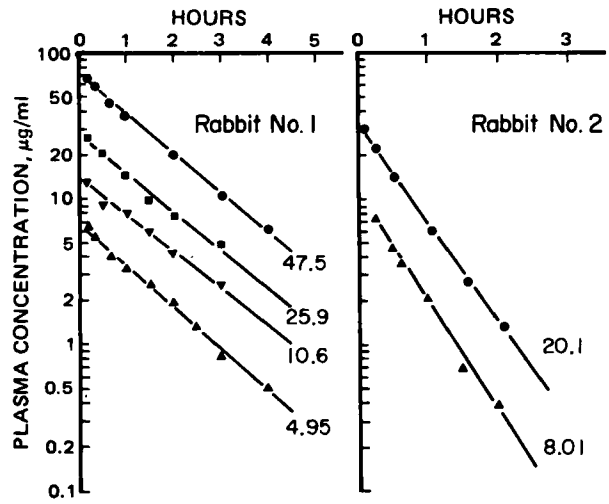

Figure 5—*Plasma concentration after different intravenous doses of sulfamethoxazole in rabbits. The value next to each curve shows the dose of sulfamethoxazole (mg/rabbit). Mean body weights of the rabbits during the experiments: No. 1, 3.96 kg; No. 2, 2.70 kg.*

experiments may also be applied to the subcutaneous absorption in mice and rabbits:

$$j = fC_0^g V_0^h \qquad \text{(Eq. 2)}$$

where g and h are the constants determined empirically [for rats, the experimental values of g and h were -0.66 and -0.32, respectively (2)]. The term f represents a constant that depends on such biological factors as the injection site and its physiological or histological state when the drug and suspension are the same. Such factors would influence the *in vivo* dispersion and dissolution of the injected particles and, hence, the absorption rate. Accordingly, the above results seem to show that the difference in the apparent *in vivo* dissolution rates of the drug among the three species may not be very large.

Comparison of Predicted and Observed Plasma Drug Concentrations in Mouse and Rabbit—It has been shown (3) that Eqs. 1 and 2, which had been derived empirically based on the results obtained from the local clearance method, reflected the true absorption of a drug into the systemic circulation in rats. The check, from the same point of view, was also performed in mice and rabbits, as described below.

The results shown above indicate that the absorption rate did not vary considerably for the mouse, the rat, and the rabbit when the drug concentration and injection volume were fixed, and that Eqs. 1 and 2 might be applicable for animals other than rats. These results also presented a possibility that the absorption rate constant j for the rat can be used, in rough approximation, as a substitute for that used for the mouse and rabbit. To confirm the validity of this presumptive evidence from the absorption experiments by the local clearance method, plasma drug concentration after different doses of the controlled aqueous suspension of N^1-acetylsulfamethoxazole were followed in the mouse and the rabbit, then compared with those predicted from their individual postabsorptive pharmacokinetic parameters and the absorption rate constant of the rat.

Mouse—Prior to subcutaneous administration experiments of N^1-acetylsulfamethoxazole (I) aqueous suspension, intravenous administration experiments of sulfamethoxazole (II) aqueous solution were undertaken to examine the postabsorptive pharmacokinetic characteristics of I. The reason for use of II instead of I was explained in detail in *Experimental*. Figure 3 shows semilogarithmic plots of plasma concentrations of II *versus* time after two intravenous doses (0.103 and 0.502 mg/mouse) of II in mice. Although the experimental values were slightly scattered, the plasma concentration–time curve for each dose could be approximated as a straight line. The plasma level appeared to be in proportion with the dose. These results suggested that the analytical treatment by a one-compartment model should be approximately possible for II in mice under the present experimental conditions. From the data in Fig. 3, the estimates (standard error, SE) of the apparent elimination rate constant (k_{el}) and volume of distribution per body weight (V_d') were calculated by the least-squares method to be 0.711 (0.020) hr^{-1} and 0.235 (0.047) ml/g, respectively. These parameters were used to predict plasma concentrations of II after the subcutaneous administration of I in aqueous suspension.

Table III—Predicted and Observed Percent Absorbed of *o*-Aminoazotoluene at 7.5 hr after Subcutaneous Administration of Its Aqueous Suspension under Fixed Dose per Body Weight in Three Animal Species

Animal	Percent Absorbed[a]		
	Known	Predicted	Observed[b]
Mouse[c]	—	65.7	60.9 ± 12.5
Rat[d]	36.9[e]		
Rabbit[f]	—	9.2	12.2 ± 4.0

[a] At the same C_0 and V_0 as shown in Table II. [b] Mean ± *SD* of three to six animals. [c] Body weight, 29–32 g. [d] Body weight, 290–305 g. [e] Reported previously (2). [f] Body weight, 2.85–3.20 kg.

Figure 4 compares the observed plasma level of II with the predicted level after the subcutaneous dose of I in aqueous suspension in mice (concentration of I in the suspension, 51.6 mg/ml; injection volume, 0.05 ml). The predicted plasma concentrations were calculated from the above estimated k_{el} and V_d (V_d' × mean body weight) in mice and one subcutaneous absorption rate constant in rats, $j(1)$, which had been reported in a previous paper (2), according to the procedure[5] described in the previous report (3). As is evident from Fig. 4, the observed plasma concentrations were in fair agreement with the predicted plasma-concentration curve. These results suggest the applicability of the above rough approximation in which the subcutaneous absorption rate constant of a drug from aqueous suspension in rats can be used as a substitute for that in mice.

Rabbit—Similar examinations were also performed with rabbits. Figure 5 shows time courses of the sulfamethoxazole (II) plasma concentration on a semilogarithmic scale after different intravenous doses of II in two rabbits (Nos. 1 and 2). The plasma concentration of II appeared to be nearly proportional to the dose for each rabbit. Within a short period after injection (0–20 min), some curvatures showing the distribution phase were observed in the plasma drug concentration–time curves and this was similar to results reported previously (7). However, these curvatures were minute under the present experimental conditions, so each time profile was regarded as a straight line. This allowed use of the one-compartment model for treatment of the data in Fig. 5. The apparent elimination rate constant, k_{el} and volume of distribution per body weight, V_d', were estimated for each rabbit. Their estimated values (*SE*) were 0.584 (0.042) hr^{-1} and 0.199 (0.007) ml/g for rabbit 1 and 1.50 (0.09) hr^{-1} and 0.285 (0.057) ml/g for rabbit 2. Since differences in the parameters k_{el} and V_d' were very large between these two rabbits, individual data for these parameters were used below to predict the plasma drug concentration in each rabbit.

Figure 6 compares the observed and predicted plasma concentrations of II after different subcutaneous doses of N^1-acetylsulfamethoxazole (I) in aqueous suspension in each rabbit. In rabbit 1, the plasma concentrations after three doses with a fixed injection volume (1.0 ml) were followed and in rabbit 2, those after two doses with a fixed concentration of I (50 mg/ml) were examined. The predicted plasma concentrations were obtained using one absorption rate constant $j(1)$, which was the same as that used in the mouse experiments, and k_{el} and V_d values for each rabbit are represented by the solid line in Fig. 6. The experimental plasma concentrations, on the whole, appeared to be close to the predicted curves for both rabbits, although slight deviations were occasionally seen. These results suggest that the rough approximation, in which the subcutaneous absorption rate constant in rats is used as a substitute for that in rabbits, is possible.

The above findings in mice and rabbits support the prediction obtained from the local clearance method, that the subcutaneous absorption rate of a drug in aqueous suspension may not vary considerably among the mouse, rat, and rabbit under the same administration conditions and that Eq. 2 may be approximately applicable for the mouse and rabbit as well as the rat.

Problem in Animal Scale-up: The Pitfall of Dose per Kilogram—The action, metabolism, and disposition of new drugs under development are usually examined in various animal species under similar dose per kilogram schedules and species differences are often discussed. This may be adequate in most cases. However, for the case of subcutaneous administration of drugs in aqueous suspension, such discussions should be handled with caution.

The results mentioned above suggest that Eq. 2 originally derived in the rat might be approximately applicable for different animal species (at least for mice and rabbits). This implies that an unexpected phenomenon for early screening tests may occur in animal scale-up: we call

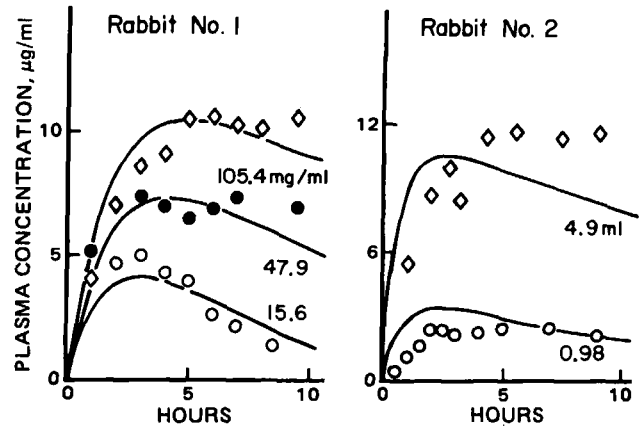

Figure 6—*Observed and predicted plasma concentrations of sulfamethoxazole after subcutaneous administrations of* N^1*-acetylsulfamethoxazole aqueous suspensions in rabbits. The predicted value (solid line) was obtained using the following parameters:* k_{el} *and* V_d, *0.584* hr^{-1} *and 789 ml (Rabbit No. 1,* V_0 *= 1.0 ml), 1.50* hr^{-1} *and 770 ml (Rabbit No. 2,* C_0 *= 50 mg/ml); j(1) (at* C_0 *= 5 mg/ml and* V_0 *= 0.5 ml in rats), 0.17* hr^{-1}.

this the pitfall of dose per kilogram. This pitfall is concretely demonstrated by the following example. Let us consider a case in which the same dose per kilogram of a drug in aqueous suspension is administered subcutaneously to three animal species with different body weights: the mouse, rat, and rabbit. In this case, the amount of drug administered (W_0) must differ among these animal species. Table II shows an example of such an administration schedule. Here, the drug concentration C_0 in the suspension or the injection volume V_0 for each animal is appropriately modified to fix the dose per kilogram. As estimated from Eq. 2, the subcutaneous absorption rate constants in these three animal species under given administration conditions differ from each other. The ratio of the rate constant in the mouse or rabbit to that in the rat, j/j(rat), which can be estimated from Eq. 2 using $g = -0.66$ and $h = -0.32$, are also listed in Table II. Comparisons of these ratios show that the j value in the mouse is about sevenfold as large as that in the rabbit.

The validity of the above predictions was confirmed experimentally using the controlled aqueous suspension of another compound *o*-aminoazotoluene, which has a measured subcutaneous absorption rate constant for rats (2). The absorption rate constants (j) in the mouse and the rabbit after subcutaneous administration of this test suspension under the conditions (C_0 and V_0) shown in Table II can be readily predicted from the j/j(rat) ratios. Then the absorbed fractions (W_{ab}/W_0) of *o*-aminoazotoluene in the mouse and the rabbit at any time (t) are calculated from their individual j values using the equation $W_{ab}/W_0 = 1 - (1 - jt)^3$. The calculation showed that 60–70% of the dose is absorbed at 7.5 hr after administration in the mouse but only ~10% in the rabbit (Table III). Experimental results for the mouse and the rabbit agreed well with the calculated values, as shown in Table III. This ascertains the validity of the predictions in Table II.

The results mentioned above strongly suggest that the absorbed amount of the drug per kilogram for a period after the subcutaneous administration of the drug in aqueous suspension differs considerably among animal species when the same dose per kilogram is given to them: the rate of bioavailability decreases with animal scale-up. This means that the plasma drug level in large animal species may not be as high as expected from the data in small animal species if the elimination rate constant and the apparent volume of distribution per kilogram for the former species are not much smaller than those for the latter. Such a phenomenon may emerge more significantly and seriously for drugs with a slower absorption rate, due to a lower water solubility, for example. This can be understood from the simulation study in our previous report (3).

Accordingly, in the case where species-specific differences in the drug action and disposition are discussed based on the data generated by subcutaneous administration of a drug in aqueous suspension, attention should be paid to the difference in the rate of bioavailability among the species. And it should be noted that the phenomenon called the "pitfall of dose per kilogram" may occur not only for the system presented here but also for drug administration in other heterogeneous dosage forms or for injections into tissues other than the subcutis (e.g., intramuscular administrations). In addition, caution should be exercised against this

pitfall when extrapolating the data from small animal species to humans.

Determination of Salicylamide and Five Metabolites in Biological Fluids by High-Performance Liquid Chromatography

MARILYN E. MORRIS and GERHARD LEVY ˣ

Received April 16, 1982 from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication June 4, 1982.

Abstract □ Two high-performance liquid chromatographic (HPLC) assay procedures were developed for the determination of salicylamide and its metabolites in serum, urine, and saliva. One method involves reverse-phase ion-pair chromatography and UV detection, and is used to determine salicylamide, salicylamide glucuronide, and salicylamide sulfate. The other method, with a different mobile phase and without the *ion-pairing reagent, is used to* determine gentisamide (the hydroxylated metabolite of salicylamide), gentisamide glucuronide, and gentisamide sulfate. The assays are performed by direct injection of the sample after protein precipitation with ethanol containing the internal standard. Increased sensitivity for the determination of low concentrations of salicylamide is obtained by organic extraction of this drug from serum or saliva. Calibration curves for the conjugates of salicylamide and gentisamide were obtained, in the absence of authentic standards, by partial enzymatic hydrolysis, using the decrease of the conjugate peaks and the concomitant increase of free salicylamide or gentisamide concentrations to determine peak area ratio–concentration relationships. Application of the HPLC assay procedures to the determination of salicylamide excretion products in the urine of three normal human subjects resulted in 98.6% (range: 97.1–100.1%) recovery of a 1-g oral dose of the drug. All five metabolites of salicylamide were found in urine, but only salicylamide glucuronide, salicylamide sulfate, and gentisamide glucuronide were found consistently and in appreciable quantities. Salicylamide and all of its metabolites except gentisamide sulfate were found in human and rat serum, and unconjugated salicylamide as well as gentisamide were found in human saliva.

Keyphrases □ High-performance liquid chromatography—assay for salicylamide and metabolites in biological fluids, drug conjugate calibration curves in the absence of authentic standards □ Salicylamide—determination in biological fluids, high-performance liquid chromatography □ Metabolites—salicylamide, determination in biological fluids, high-performance liquid chromatography

Salicylamide has analgesic, antipyretic, and hypnotic activities (1–3) but its clinical effectiveness is limited (4–6) due to extensive presystemic biotransformation after oral administration (7, 8). The drug is, however, a valuable research tool for the exploration of drug conjugation reactions (9, 10), drug absorption (11–14) and metabolism interactions (15, 16), route of administration effects on drug disposition (17, 18), effects of disease on drug disposition (19–21), drug concentration–effect relationships (22), product inhibition (23), fetal development (24), and the clinical assessment of metabolic immaturity and disorders (25–27).

Salicylamide is eliminated almost entirely by biotransformation (Scheme I). Many assay methods are available for the determination of this drug in biological fluids (9, 14, 22, 28–36), but none of these provide for the direct determinations (*i.e.*, without prior hydrolysis) of salicylamide conjugates. Apparently only an indirect colorimetric method (9) and a qualitative TLC method (37) have been used for the determination of gentisamide, the hydroxylated metabolite of salicylamide. To facilitate future pharmacokinetic studies with salicylamide, we have developed high-performance liquid chromatographic (HPLC) procedures for the direct determination of salicylamide, gentisamide, and their glucuronide and sulfate

conjugates in human and rat serum and urine, and human saliva. The assay development for the conjugated metabolites was carried out without authentic standards and exemplifies a general approach that can be used when conjugated drug metabolites are not available in pure form.

EXPERIMENTAL

A high-performance liquid chromatograph[1] equipped with a UV detector[2], automatic injector[3], integrator[4], and an octadecyltrichlorosilane-bonded column[5] was used in this investigation. The column temperature was ambient and the flow rate of the mobile phase varied between 1.6 and 2.0 ml/min in the different assays. The injection volume was 25 μl.

Urine samples were assayed after dilution with distilled water and filtration through a membrane filter[6]. One milliliter of the diluted sample was added to 0.5 ml of a 100-μg/ml aqueous solution of the internal standard, *o*-methoxybenzoic acid[7]. Serum samples were assayed after protein precipitation. One part by volume of serum was added to 2 parts absolute ethanol containing the internal standard (concentration ~40 μg/ml).

An extraction procedure was developed to increase the sensitivity of the assay for unconjugated salicylamide in human serum or saliva. One milliliter of sodium acetate buffer (2 *M*, pH 5.0) plus 1 g of sodium chloride were added to 1 ml of saliva or serum. This mixture was shaken with 6 ml of ether for 10 min and centrifuged. A 4-ml aliquot of the ether phase was removed and the extraction procedure was repeated. The two 4-ml aliquots (one from each extraction) were combined, evaporated to dryness under nitrogen, and redissolved in 0.2 ml of methanol containing the internal standard, *o*-methoxybenzoic acid (concentration ~25 μg/ml).

Salicylamide and its conjugated metabolites were assayed by reverse-phase ion-pair chromatography with UV detection at 254 nm. The mobile phase consisted of 3 m*M* tetrabutylammonium hydroxide[8] in a mixture of 8 parts methanol and 92 parts (v/v) acetic acid 7%.

Low concentrations of unconjugated salicylamide, such as found in human serum or saliva, were assayed after extraction with UV detection at 313 nm. The mobile phase consisted of 1% acetic acid in 25% (v/v) methanol–water solution. Gentisamide and its conjugates were assayed by a separate procedure. The sample preparation and internal standard were the same as described for salicylamide and its conjugates; only one sample preparation was necessary. UV detection was at 313 nm and the mobile phase consisted of 1% acetic acid in 15% (v/v) methanol–water solution. Unconjugated salicylamide is also separated and detected by this procedure.

The intraday reproducibility of the serum salicylamide and gentisamide assay procedures at various concentrations was determined using blank human serum with added salicylamide or gentisamide or pooled rat serum samples obtained after administration of salicylamide.

Gentisamide was synthesized by a previously described procedure (38).

Table I—Reproducibility of Calibration Curves for the Conjugates of Salicylamide and Gentisamide

Metabolite	Number of Samples[a]	Slope Ratio[b]	r^{2c}
Salicylamide	14	0.772	0.982
glucuronide	6	0.772	0.998
Salicylamide	12	0.497	0.984
sulfate	6	0.505	0.992
Gentisamide	13	1.17	0.998
glucuronide	29	1.17	0.992
Gentisamide	5	0.754	0.994
sulfate	3	0.744	0.994
	9	0.750	0.974

[a] Samples assayed in duplicate. [b] Ratio of the slope of the calibration curve for the metabolite to the slope of the calibration curve for the parent compound (salicylamide or gentisamide). Concentration of the metabolites are expressed in terms of the parent compound. [c] Coefficient of determination for the linear regression of the peak area ratio of the metabolite and the concentration of the metabolite (expressed in terms of salicylamide or gentisamide).

It was characterized by NMR, mass spectroscopy, melting point, TLC, HPLC, and elemental analysis[9].

For assay development, the conjugates of salicylamide and gentisamide were quantitated after partial or complete enzymatic hydrolysis of biological samples or sample fractions collected from the HPLC which contain these conjugates. HPLC fractions containing the individual conjugates were lyophilized and reconstituted to various volumes; these solutions were analyzed before and after enzymatic hydrolysis.

Hydrolysis of the glucuronide conjugates was carried out with a β-glucuronidase[10] preparation which, in preliminary studies, produced negligible hydrolysis of the sulfate conjugates. Equal volumes of sample, β-glucuronidase (typically 1250 Fishman U/ml) dissolved in sodium acetate buffer (pH 4.5), and 2.0 or 0.1 *M* sodium acetate buffer pH 4.5

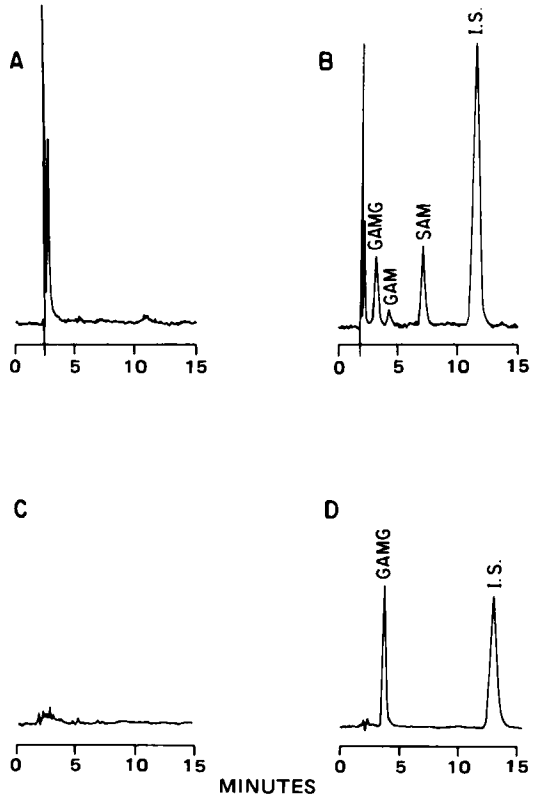

Figure 3—*Chromatograms of human serum and urine samples obtained before and after ingestion of 1 g of salicylamide by a healthy human subject. Key: (A) serum before drug ingestion; (B) serum obtained 1 hr after drug ingestion; (C) control urine diluted 1:25 with water; (D) urine obtained between 1.5 and 2.5 hr after drug ingestion and diluted 1:25 with water. were mixed and incubated at 37° for varying periods of time. Since only partial hydrolysis of the conjugates was desired, the hydrolysis times were kept short (0.5–4 hr). The sulfate conjugates were hydrolyzed with a β-glucuronidase–sulfatase[11] mixture, with and without the addition of the β-glucuronidase inhibitor, saccharo-1,4-lactone[12], at a final concentration of 0.33 mg/ml. Hydrolysis was carried out similarly to that described for the glucuronide conjugates except that a 2.0 or 0.1 *M* sodium acetate buffer (pH 5.2) was used with the β-glucuronidase–sulfatase preparation (which was usually diluted six- to tenfold with buffer). A limpet sulfatase preparation[13] with low β-glucuronidase activity was tried for the quantitation of salicylamide sulfate, but was found to be unsuitable due to assay interference.

The enzymatic hydrolyses of the gentisamide conjugates were carried out with 0.1 *M* buffer solutions, since there was some loss of gentisamide when added to the 2.0 *M* acetate buffer. No such problem was noted with salicylamide, and, therefore, most hydrolysis experiments with salicylamide conjugates were carried out using the 2.0 *M* buffer.

Assay calibration curves were obtained from the results of the hydrolysis of biological samples or HPLC fractions containing the conjugates. The peak area ratio of the conjugate (ratio of the area of the conjugate peak–area of the internal standard peak) was plotted against the concentration of the conjugate, measured and expressed in terms of the parent compound salicylamide or gentisamide. The slope of this plot, calculated by linear regression, and the slope of the plot of the parent compound were determined on the same day. The ratio of the two slopes was calculated. The hydrolysis experiments and slope value determinations for each conjugate were repeated several times within a 6-month period to check the reproducibility of the slope ratios.

The serum, saliva, and urine samples used in the assay development

[a] Salicylamide (1 g) in aqueous solution was ingested and urine collected for 24 hr. Results are expressed as percent of dose. [b] Not detected.

were obtained from healthy human volunteers who ingested salicylamide orally (1 g in aqueous solution), or from rats following intravenous administration of salicylamide or gentisamide (62.5–125 mg/kg) *via* a right jugular cannula.

The results of the HPLC assay were compared with results obtained by colorimetric techniques in terms of urinary recovery of metabolites from healthy volunteers and rats. Three volunteers (one on two occasions) ingested 1 g of salicylamide in aqueous solution and collected urine over a 24-hr period. Urinary recovery of total salicylamide (free and conjugates) determined by HPLC was compared with that determined by the colorimetric method of Levy and Matsuzawa (9). Total gentisamide was determined by HPLC and colorimetrically by the method of Becher *et al.* (37). This method involves the acid hydrolysis of gentisamide and its conjugates to gentisic acid and determination using Folin–Ciocalteu reagent[14]. Two rats were administered gentisamide (100 mg/kg iv) *via* a right jugular cannula and urine was collected for 48 hr. All samples were stored at −20° until analyzed. They were assayed by HPLC and colorimetrically (37).

RESULTS AND DISCUSSION

Salicylamide and its glucuronide and sulfate conjugates in human or rat serum and urine are readily separated and detected by HPLC (Figs. 1 and 2). There are no interferences by endogenous substances. Use of the ion-pairing reagent tetrabutylammonium hydroxide and the low pH of the mobile phase (~2.6) cause a selective increase in the retention time of salicylamide sulfate with only a small effect on the retention time of the glucuronide. Gentisamide and its conjugates are also detected by this assay, but their retention times are inconvenient: gentisamide and its glucuronide are eluted before salicylamide glucuronide, while gentisamide sulfate elutes after salicylamide sulfate.

Table IV—Urinary Excretion Products of Gentisamide in Rats After Administration of Gentisamide [a]

Rat	HPLC				Colorimetric
	Gentisamide Glucuronide[b], mg	Gentisamide Sulfate[b], mg	Free Gentisamide, mg	Total Gentisamide, mg	Total Gentisamide, mg
N	16.5	14.7	1.98	33.2	32.2
O	17.6	16.7	1.51	35.9	33.9

[a] Dose of gentisamide was 100 mg/kg iv; N and O received 40.1 and 43.7 mg, respectively. Urine was collected for 48 hr. [b] Expressed in terms of gentisamide.

A separate HPLC assay procedure was developed for gentisamide and its glucuronide and sulfate conjugates. The internal standard used in this procedure, *o*-methoxybenzoic acid, is the same as that used in the assay of salicylamide and its metabolites. This affords the convenience of only one sample preparation for both assays. The gentisamide assay involves use of a mobile phase without an ion-pairing reagent and UV detection at 313 nm rather than at 254 nm. At this wavelength, gentisamide and its conjugates and salicylamide absorb more strongly, thereby increasing the sensitivity of the assay. On the other hand, the conjugates of salicylamide have little absorptivity at 313 nm and do not appear in the chromatograms. Gentisamide and its glucuronide and sulfate conjugates are well separated and detected in serum and urine (Figs. 3 and 4). Gentisamide sulfate has not been reported previously as a metabolite of salicylamide. In these experiments, it was found regularly in rat urine but only in some human urine samples after salicylamide administration. It is a quantitatively minor metabolite.

Gentisamide sulfate is relatively stable, showing negligible hydrolysis in rat urine at room temperature over 24 hr. Gentisamide glucuronide is less stable; rat urine samples containing this metabolite should not be keep at room temperature for >4 hr. The glucuronide is more stable in human urine and serum.

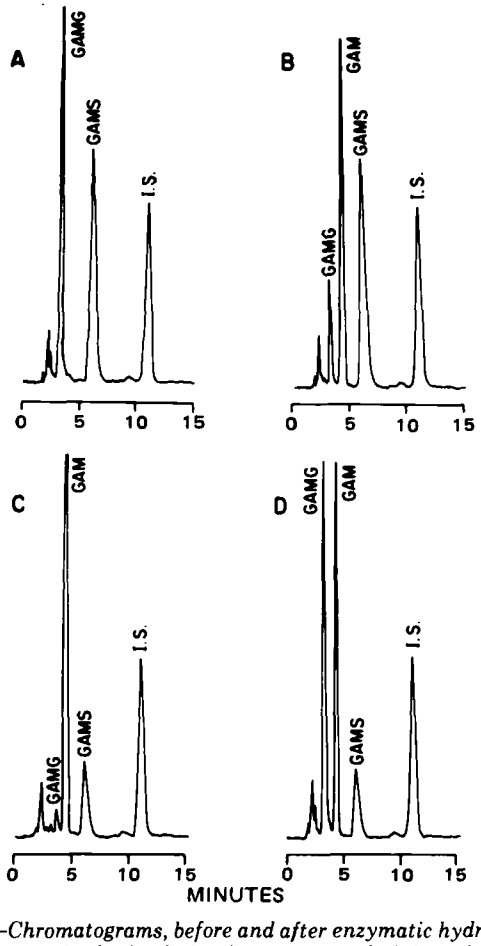

Figure 7—*Chromatograms, before and after enzymatic hydrolysis, of a rat urine sample obtained after intravenous administration of gentisamide (GAM), 100 mg/kg. Key: (A) before hydrolysis; (B) after partial hydrolysis with β-glucuronidase. [There was no hydrolysis of gentisamide sulfate (GAMS) since the peak height ratio of this metabolite to the internal standard is the same as that in A.] (C) after partial hydrolysis with β-glucuronidase–sulfatase mixture; (D) after partial hydrolysis with β-glucuronidase–sulfatase mixture plus saccharo-1,4-lactone, 0.33 mg/ml. [There was no hydrolysis of gentisamide glucuronide (GAMG) in D since the peak height ratio of this metabolite to the internal standard is the same as that in A.] (I.S.) internal standard.*

The relationship between detector response (peak area ratio relative to the internal standard) and concentration of salicylamide and gentisamide is linear over a wide range (at least 4–200 μg/ml for salicylamide and 2–100 μg/ml for gentisamide). The intraday variability of the assay for serum salicylamide in the 10–200 μg/ml concentration range was independent of concentration (n = 5–10 at each of six concentrations), with a coefficient of variation from 1.7 to 3.4%. The coefficient increased to 5.5% at a serum salicylamide concentration of 4 μg/ml. The coefficient of variation for gentisamide in serum (n = 10 per concentration) ranged from 7.0 to 3.3% at concentrations from 2 to 28 μg/ml. The lowest of these concentrations is approximately twice the minimum detectable concentration in these assays.

To increase the sensitivity of the assay for salicylamide, particularly for determinations in serum and saliva, an organic extraction procedure was used and the wavelength for detection was changed from 254 to 313 nm. Use of sodium chloride in the extraction procedure increased extraction efficiency from ~75 to 95%. The coefficient of variation of this more sensitive assay at concentrations of 1–3 μg/ml is <3%. Using the extraction procedure, a chromatogram of saliva obtained from a human subject 45 min after an oral dose of salicylamide indicated the presence of both salicylamide and gentisamide (Fig. 5).

During the assay development for gentisamide conjugates, some loss of gentisamide was observed at high (1–2 M) acetate buffer concentrations. This was not a function of the pH or ionic strength and was not accompanied by formation of gentisic acid. Use of 0.1 M acetate (but not citrate) buffer prevented the loss of gentisamide which may have been due, at least in part, to precipitation.

Calibration (reference) curves for the HPLC assay of salicylamide and gentisamide conjugates were obtained by partial selective hydrolysis of urine samples containing these metabolites (Figs. 6 and 7). The decrease in peak area ratio of a conjugate and the corresponding increase in peak area ratio of the unconjugated compound provided the necessary data for the construction of the calibration curves. The curves were linear over the concentration range examined (~2–60 μg/ml in terms of the parent compound). The slope values of these curves were calculated as a ratio relative to the slope for the unconjugated compound, which was determined on the same day under the same conditions. The slope ratio values for the conjugated metabolites of salicylamide were determined on several occasions over 6 months and were found to be highly reproducible (Table I). Peak area rather than height ratios were used for the calibration curves, since peak height ratios are sensitive to changing column conditions (retention times). This was found to be a problem particularly with salicylamide sulfate, the metabolite with the longest retention time.

The suitability of the HPLC procedures and calibration curves for metabolic studies was tested and confirmed by determining the excretion products of salicylamide in the urine of three human subjects by the HPLC method and by a previously used colorimetric method which requires hydrolysis of the conjugated metabolites. The recovery of salicylamide excretion products was excellent and the results obtained by the two methods were in good agreement (Table II). The HPLC assay revealed the presence of salicylamide and five of its metabolites in human urine, including gentisamide sulfate, a metabolite not previously reported (Table III). The amounts of salicylamide glucuronide, salicylamide sulfate, and total gentisamide recovered are similar to those found in other studies (9, 16, 21).

The results for total gentisamide determined by colorimetry are slightly higher than those obtained by HPLC (Table II). This may be because the colorimetric analysis requires correction for a relatively high (~1 mg/hr) blank value for excretion rate. The colorimetric method detects 2,3,4-trihydroxybenzamide and 2,3-dihydroxybenzoic acid as gentisic acid (the form in which gentisamide is assayed by colorimetry) and may therefore be affected by as yet unidentified minor metabolites of salicylamide and gentisamide.

A limited study of the disposition of gentisamide in rats revealed extensive biotransformation of this compound, including substantial for-

mation of gentisamide sulfate (Table IV). The good agreement between the HPLC and colorimetric assay results for total gentisamide demonstrate the suitability of the HPLC assay for gentisamide and its metabolites.

In conclusion, a combination of two HPLC procedures with the same sample preparation (deproteinization and addition of internal standard) were developed for the direct determination of salicylamide and its metabolites in biological fluids. One of these metabolites, gentisamide sulfate, is reported for the first time. The excretion products of salicylamide in human urine can account for essentially the total amount of administered drug. The HPLC assays for the conjugated metabolites were developed without synthetic or isolated pure standards by a procedure that should be useful also for conjugates of other drugs.

Synthesis, Isolation, and Characterization of Two Stereoisomeric Ring Sulfoxides of Thioridazine

ERIC C. JUENGE *x, CLYDE E. WELLS *, DONALD E. GREEN ‡, IRENE S. FORREST ‡, and JAMES N. SHOOLERY §

Received February 12, 1982, from the **National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101*, the ‡*Veterans Administration Hospital, Palo Alto, CA 94304*, and §*Varian Associates, Palo Alto, CA 94303.* Accepted for publication June 3, 1982.

Abstract □ A selective oxidation of thioridazine to give exclusively its ring sulfoxides and a separation of the resulting products as diastereoisomeric pairs of enantiomers (DL, LD and DD, LL) are reported. These pairs were characterized by TLC, high-performance liquid chromatographic, IR, UV, ^{1}H-NMR, ^{13}C-NMR, GC–MS, and elemental analyses, and by reduction to thioridazine by lithium aluminum hydride. Structural data for the separated diastereoisomeric pairs or their nitric acid salts were obtained from NMR and IR studies. Gram quantities of each of the two diastereoisomeric pairs of enantiomers were isolated in better than 99% purity.

Keyphrases □ Thioridazine—oxidation to ring sulfoxides, separation of the diastereoisomeric pairs of the ring sulfoxides by crystallization of the nitric acid salts, ^{13}C-NMR analysis of thioridazine ring sulfoxides

A single ring sulfoxide of thioridazine has been detected by TLC (1–5), high-performance liquid chromatography (HPLC) (6, 7), and GC (8–10). Also, EKG abnormalities have been attributed "to a single ring sulfoxide" in plasma (8). Recently "two very similar ring sulfoxides" of thioridazine were identified (11) as urinary metabolites and prepared (with other products) by chemical oxidation.

Evidence is presented here that these ring sulfoxides are

0022-3549/83/0600-0617$01.00/0

mation of gentisamide sulfate (Table IV). The good agreement between the HPLC and colorimetric assay results for total gentisamide demonstrate the suitability of the HPLC assay for gentisamide and its metabolites.

In conclusion, a combination of two HPLC procedures with the same sample preparation (deproteinization and addition of internal standard) were developed for the direct determination of salicylamide and its metabolites in biological fluids. One of these metabolites, gentisamide sulfate, is reported for the first time. The excretion products of salicylamide in human urine can account for essentially the total amount of administered drug. The HPLC assays for the conjugated metabolites were developed without synthetic or isolated pure standards by a procedure that should be useful also for conjugates of other drugs.

Synthesis, Isolation, and Characterization of Two Stereoisomeric Ring Sulfoxides of Thioridazine

ERIC C. JUENGE *x, CLYDE E. WELLS *, DONALD E. GREEN ‡, IRENE S. FORREST ‡, and JAMES N. SHOOLERY §

Received February 12, 1982, from the **National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101*, the ‡*Veterans Administration Hospital, Palo Alto, CA 94304*, and §*Varian Associates, Palo Alto, CA 94303.* Accepted for publication June 3, 1982.

Abstract □ A selective oxidation of thioridazine to give exclusively its ring sulfoxides and a separation of the resulting products as diastereoisomeric pairs of enantiomers (DL, LD and DD, LL) are reported. These pairs were characterized by TLC, high-performance liquid chromatographic, IR, UV, ^{1}H-NMR, ^{13}C-NMR, GC–MS, and elemental analyses, and by reduction to thioridazine by lithium aluminum hydride. Structural data for the separated diastereoisomeric pairs or their nitric acid salts were obtained from NMR and IR studies. Gram quantities of each of the two diastereoisomeric pairs of enantiomers were isolated in better than 99% purity.

Keyphrases □ Thioridazine—oxidation to ring sulfoxides, separation of the diastereoisomeric pairs of the ring sulfoxides by crystallization of the nitric acid salts, ^{13}C-NMR analysis of thioridazine ring sulfoxides

A single ring sulfoxide of thioridazine has been detected by TLC (1–5), high-performance liquid chromatography (HPLC) (6, 7), and GC (8–10). Also, EKG abnormalities have been attributed "to a single ring sulfoxide" in plasma (8). Recently "two very similar ring sulfoxides" of thioridazine were identified (11) as urinary metabolites and prepared (with other products) by chemical oxidation.

Evidence is presented here that these ring sulfoxides are

Table I—Chromatographic Detection of Oxidation Products of Thioridazine (I) and Mesoridazine (III) as TLC Spots or HPLC Peaks

Sample[a]	Compound I	IIF[b]	IIS[b]	III	IV[c]	System[d]
A	x	x	x	x		I, II, V[e], VI
B	x	x	x	x	x	I, II, V[f], VI
C				x	x	I, V[g]
D	x	x	x	x	x	I, II, VI
E	x	x	x	x	x	I, V[e]
F	x	x	x	x	x	I, V
G		x	x			I, III[h], IV[h,i], V[e]

[a] Sample A is a synthetic mixture. B–F are oxidation mixtures from hydrogen peroxide treatment and G from nitrous acid treatment. C involves the oxidation of mesoridazine. [b] IIS and IIF were found in about equal amounts in all samples of oxidized I. [c] Further identified by its intense blue fluorescence under long-wavelength UV irradiation. [d] Various solvent systems, I–IV and VI, on silica gel TLC, and an HPLC method, V, were used. [e] Chromatograms are presented in Fig. 1. [f] Approximate compound ratios 2.8:12.5:14.4:37.7:29.9, respectively. [g] Percent of IV (peak area) = 90.1. [h] Failed to separate IIF and IIS. [i] Gave R_f 0.45, close to the literature report of R_f 0.46 (13–15).

actually diastereoisomeric pairs of enantiomers (DL, LD and DD, LL). TLC and HPLC methods used to detect and distinguish these diastereoisomeric pairs and a crystallization method that yields gram amounts of each pair with better than 99% purity are described. These pure materials have been used to develop an HPLC assay of thioridazine and its metabolites in plasma (12).

RESULTS AND DISCUSSION

TLC—Literature methods (1, 2, 13–15) were used. Thioridazine (I), the pairs of enantiomeric ring sulfoxides (IIF and IIS, fast and slow migrators on silica gel, respectively), the side-chain sulfoxide of thioridazine [mesoridazine (III)], and thioridazine disulfoxide (IV) were detected (Table I) in the reaction products from hydrogen peroxide oxidation of thioridazine. Many minor products were also produced. On silica gel, the ring sulfoxides generally tend to elute between thioridazine and mesoridazine. The more polar disulfoxide elutes after mesoridazine, and the less polar sulfone, sulforidazine, elutes just after thioridazine. Both the disulfoxide and sulfone are readily distinguished by their pronounced fluorescence under long-wavelength UV irradiation. Although sulforidazine may occur in relatively high concentrations in thioridazine metabolism (16), it was not found as a product in the chemical oxidations performed in this study. Sulfoxidation occurs before any appreciable *N*-oxidation is observed.

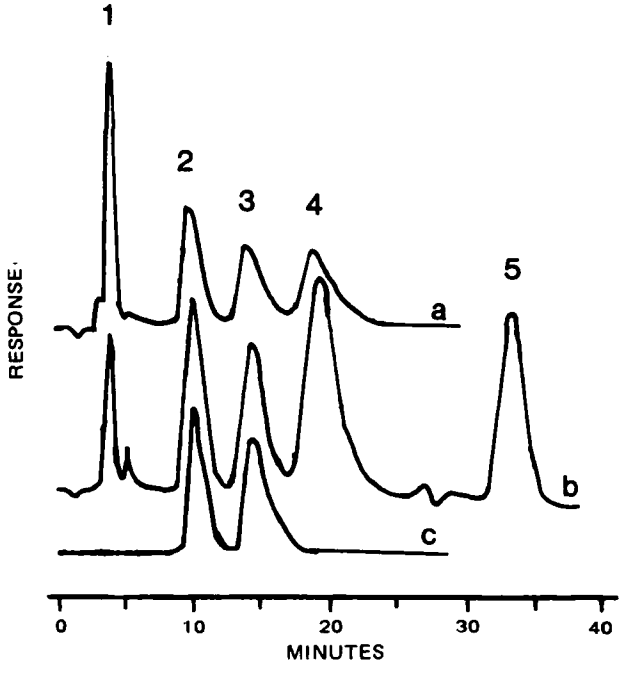

Figure 1—*High-performance liquid chromatograms. Key: a, reference mixture; b, product of reaction of thioridazine and hydrogen peroxide in refluxing alcohol, as previously described (1); and c, product of reaction of thioridazine hydrochloride and nitrous acid. (1) Thioridazine; (2 and 3) thioridazine ring sulfoxides; (4) mesoridazine; and (5) thioridazine disulfoxide. In curve b, the polarity of the mobile phase was increased after peak 4 to achieve elution of the disulfoxide.*

Table II—R_f Values and Color Detection for the Oxidation Products of Thioridazine Formed by Hydrogen Peroxide (in Acetic Acid and Aqueous Solvent) and by Nitrous Acid[a]

Compound	R_f, System I[d]	System VI, Reagents[b] Folin	H_2SO_4	100°	R_f, System II[c] Found	Reported[e]
I	0.71	B–G	—	—	0.75	0.83
IIF	0.62	—	B–V[f]	—	0.55	0.54
IIS	0.54	—	B–V[f]	—	0.50	0.54
III	0.39	P	—	—	0.43	0.45
IV	0.23	—	—	P	0.28	0.29

[a] Nitrous acid oxidation products gave only two spots for the ring sulfoxides (IIF and IIS). [b] Sprays or operations (2) done in sequence to produce the colors shown; B = blue, G = green, P = pink, V = violet. [c] Acetone–12 *N* ammonium hydroxide (100:7) (2). [d] Chloroform–95% ethanol–12 *N* ammonium hydroxide (80:20:1). [e] R_f values from the literature (2), including value for a single ring sulfoxide. [f] Initial B–G spots turned B–V after several hours.

HPLC—A highly sensitive assay method (12), which employs a silica gel column, was used to provide qualitative and semiquantitative data on the distribution of products in some of the oxidation mixtures. Figure 1 (curve a) illustrates a typical chromatogram, obtained from a mixture of ring sulfoxides (IIF and IIS) and reference standards of I and III. Products from the hydrogen peroxide oxidations (*Experimental, Methods* I–III) included both ring sulfoxides, which eluted with the same retention times as shown in Fig. 1 (curve a).

Literature Reports of a Single Ring Sulfoxide—The approach taken in this study was to show that ordinary oxidations of thioridazine, including some published methods (1, 17), gave two enantiomeric pairs (IIF and IIS) of the ring sulfoxides (two TLC spots and not one) and to examine TLC systems, including some reported in the literature (1, 2, 13–15), for their effectiveness in separating IIF and IIS. Next, the isolation of larger amounts of each ring sulfoxide (IIF and IIS) was undertaken to provide samples for identification, particularly by instrumental techniques.

Both ring sulfoxides (IIF and IIS) were found in about equal amounts in all the samples of oxidized thioridazine (Table I; samples and detection systems are described in detail in the *Experimental* section). TLC systems I and II, as well as HPLC system V, separated IIS and IIF, but TLC systems III and IV failed to give a separation. Samples A, B, and D were used to evaluate a reported TLC system (2); solvent system II and spray system VI produced the R_f values and colors presented in Table II. Although this report (2) described a single spot for thioridazine ring sulfoxide, a small but clear separation was obtained in the present work. All materials gave colors that matched those described (2).

Under conditions of more extensive oxidation, more thioridazine disulfoxide (IV) formed at the expense of the ring sulfoxides (II) and mesoridazine (III). After a reaction time of 24 hr, concentrated aqueous hydrogen peroxide gave primarily the disulfoxide (IV) and a small amount of mesoridazine (III), whereas dilute aqueous hydrogen peroxide generated the usual major products, I, IIF, IIS, III, and IV, with some minor products appearing as very faint spots on the TLC plates.

Analysis of Commercial Samples of Thioridazine Ring Sulfoxide—Two samples were assayed by HPLC system V (12). The first contained ~ 98% of IIS and 2% of IIF, and the second ~ 85% of IIS and 15% of IIF. TLC (system I) gave a rough confirmation of these results. The IR spectrum of the first commercial sample matched that of analytically pure IIS.

Study of the Reaction of Zehnder *et al.* (1)—To determine whether ring sulfoxides IIF and IIS were produced under these reaction conditions, the solution of the crude reaction product (sample E) was examined by TLC (Table I) and by HPLC (Fig. 1, curve b). Thioridazine (I), the two ring sulfoxides (IIF and IIS), mesoridazine (III), and the disulfoxide (IV) appeared at essentially the same R_f values and retention times observed for products of the hydrogen peroxide oxidations. The two ring sulfoxides were found in about equal amounts. Retention times in Fig. 1, curve b, matched those of the reference mixture (sample A) in Fig. 1, curve a. The area percentages for substances in curve b are: I, 4.4; IIF, 15.6; IIS, 17.3; III, 34.4; and IV, 23.3.

Effect of pH—Zehnder *et al.* (1) refluxed thioridazine hydrochloride with hydrogen peroxide in ethanol, mildly acidic conditions. Sample E,

Table III—Physical and Analytical Data for Thioridazine Ring Sulfoxides

Compound	Melting Point		Analyses Calc.	Found	Purity, %[a]

II	113.5–128.5°	C	65.25	65.06	—
		H	6.78	6.77	

[a] Based on HPLC analyses of nitric acid salts neutralized with 12 *N* ammonium hydroxide. [b] Mixture of both salts (VF and VS) obtained as the reaction product. [c] The free bases, IIF, IIS, and II, were obtained from the corresponding salts, VF, VS, and V.

obtained in this way, gave an amount of mesoridazine roughly equal to the total amount of the ring sulfoxides. By substitution of the free base of thioridazine in the refluxing medium, sample F was obtained under mildly basic conditions and was found to contain about three times as much mesoridazine as the amount of total ring sulfoxides. Thus, oxidation under mildly basic conditions favors side-chain sulfoxidation. A previous report (16) found that the rates of formation of mesoridazine and sulforidazine (side-chain sulfoxidation) in plasma are greater than that of ring sulfoxidation. One might speculate that oxidation of thioridazine under acidic conditions in the stomach could favor formation of ring sulfoxides and contribute to toxic side reactions (8).

Disadvantages of Hydrogen Peroxide Oxidations—Complex product mixtures are obtained, and intricate, inefficient separations must be used to isolate the pure ring sulfoxides from the hydrogen peroxide oxidations. Thus, a new method for the oxidation of thioridazine exclusively to its ring sulfoxides and a technique for their separation as two pairs of enantiomers should be useful for analytical studies of thioridazine metabolites and perhaps for toxicological studies.

Nitrous Acid Oxidation of Thioridazine Hydrochloride—The nitric acid salts of the ring sulfoxides (VF and VS) are generated exclusively when thioridazine hydrochloride is oxidized with nitrous oxide (sample G, Table I). The freshly prepared reaction mixture was immediately examined by HPLC system V; the product was > 99% thioridazine ring sulfoxides (Fig. 1, curve c), which eluted at the same retention times as the analytically pure sulfoxides (Fig. 1, curve a, peaks 2 and 3). TLC (Table I, system I) also showed essentially only the ring sulfoxides.

Formation of the nitric acid salts can be described by these equations (18) (T = thioridazine).

$$2HNO_2 + T(I) \rightarrow TO(II) + 2NO + H_2O \quad \text{(Eq. 1)}$$

$$4HNO_2 \rightarrow 4NO + O_2 + 2H_2O \quad \text{(Eq. 2)}$$

$$3HNO_2 \rightleftarrows HNO_3 + 2NO + H_2O \quad \text{(Eq. 3)}$$

$$2NO + O_2 \rightarrow 2NO_2 \quad \text{(Eq. 4)}$$

$$2NO_2 + H_2O \rightleftarrows HNO_3 + HNO_2 \quad \text{(Eq. 5)}$$

$$TO(II) + HNO_3 \rightarrow TO \cdot HNO_3(V) \quad \text{(Eq. 6)}$$

Nitrous acid can be an effective oxidizing agent (Eqs. 1 and 2). The nitric acid salt V (Eq. 6) is readily generated from nitrous acid, which is unstable and decomposes to nitric acid (Eq. 3), and also through other reactions (Eqs. 4 and 5). The observed oxidation with nitrous acid is not due to nitric acid. Substitution of sodium nitrate for sodium nitrite in the reaction procedure failed to give any oxidation of thioridazine.

Separation of Ring Sulfoxides as Free Bases—Attempts to isolate the ring sulfoxides (IIF and IIS) by HPLC followed by crystallization yielded only small amounts of material of ~ 95% purity, as determined by HPLC analyses. The UV spectra (λ_{max} = 279 nm, weak peak at 342 nm) of the collected fractions were identical. The free bases crystallized well from hexane or heptane, but such recrystallization failed to purify them. Vacuum sublimation (175°, 1 mm) of the mixed free bases yielded no isomeric enrichment.

Table IV—^{13}C-NMR Data (ppm) for Thioridazine Ring Sulfoxides in Deuterochloroform[a]

[a] TMS added as an internal standard. [b] Four aromatic carbons nearest the ring sulfur. [c] Deuterochloroform lines in spectrum of IIF and IIS demonstrate instrument reproducibility to 0.01 ppm.

Separation of Ring Sulfoxides as Nitric Acid Salts—A mixture of the nitric acid salts of the ring sulfoxides (V) was separated by fractional crystallization (19) from 95% ethanol. After six recrystallizations, all cuts contained essentially one isomer and some were fairly pure, *e.g.*, 99.9% VF and 96.8% VS, as determined by peak ratios from HPLC analyses. After two more recrystallizations from fresh solvent, VS was 99.3% pure (Table III).

These high-purity samples gave TLC R_f values that matched those of the original reaction mixture (Table II). The elemental analyses of the materials were consistent for the nitric acid salts of the ring sulfoxide isomers of thioridazine, and their melting points were sharp (Table III).

Characterization of the Ring Sulfoxides as Free Bases (IIF and IIS)—The free bases were obtained from the purified nitric acid salts and gave material with sharp melting points. Elemental analyses were consistent for the isomeric ring sulfoxides of thioridazine (Table III).

NMR Studies of Thioridazine Ring Sulfoxides as Free Bases—The ^{13}C-NMR spectra of IIF and IIS are tabulated (Table IV). The fact that most of the signals in the spectra of the two compounds agreed to within 0.1 ppm shows that the two types of ring sulfoxides (IIF and IIS) are very similar. Nevertheless, a difference in stereochemistry of the sulfoxide groups of IIS and IIF is suggested by the differences in the signals from the four aromatic carbons nearest the ring sulfur.

NMR Studies of Thioridazine Ring Sulfoxides as Nitric Acid Salts—The ^{13}C-NMR spectra of VF and VS (Table V), taken at 30° in deuterium oxide, are also clearly different for the nonprotonated aromatic carbons located next to the sulfoxide group. The broadening of peaks for aliphatic carbons can be explained if the protonated piperidine coordinates with the sulfoxide group. If the change in the precession frequencies of the aliphatic carbons resulting from the formation of a complex is comparable to the rate of forming and breaking the complex, line broadening will occur.

At 90° (Table V) either the complex is forming and breaking rapidly enough to average the chemical shifts, or it is broken up and the chemical shifts are characteristic of the freely rotating side chain resulting in sharp aliphatic peaks. Merging of aromatic signals at 90° is attributed to conformational mobility of the molecules which leads to some averaging of the aromatic carbon-13 chemical shifts.

Chemical Shifts of *S*- and *N*-Methyl Proton Signals of Thioridazine and Related Compounds—As side-chain sulfoxidation increases, only the *S*-methyl signal is shifted to lower field, but ring sulfoxidation causes a shift of both the *S*- and *N*-methyl proton signals to lower field relative to thioridazine (Table VI).

The *N*-methyl proton singlets from the ring sulfoxide free bases (IIF and IIS) did not show different chemical shifts. The differences in

[a] Twelve aromatic peaks were tabulated in both VF and VS. Many of the peaks from aliphatic carbons appeared as broad areas at the baseline and were not tabulated by the spectrometer. [b] Nonprotonated aromatic carbons located next to the sulfoxide group, 0.96 ppm apart for VF and 1.66 ppm apart for VS. [c] Nine sharp aliphatic peaks were observed and tabulated. Some of the aromatic signals are merged at the higher temperature.

chemical shifts of the *N*-methyl protons in VF and VS may be due to differences in the ring sulfoxide stereochemistry, which influences their coordination with the protonated *N*-methylpiperidinyl moiety. An analogous coordination occurs between the sulfoxide group in dimethyl sulfoxide and the hydroxyl groups in alcohols (20). The lack of dissociation of the protonated amine in the rather nonpolar deuterochloroform is suggested as the cause of *N*-methyl proton splitting in these compounds. Ratios of the salts (VF and VS) in mixtures can be determined by deuterium exchange and by integration of the piperidyl *N*-methyl peaks. Such mixtures are usually soluble enough to permit accurate estimation of the ratios of VF to VS to within 2–5% with a conventional NMR spectrometer.

Reductions with Lithium Aluminum Hydride—In anhydrous ether, lithium aluminum hydride reduced a mixture of the ring sulfoxides (IIF and IIS) to a single product, thioridazine. The reduction product matched reference standard thioridazine in TLC (system I), IR spectra, and GC–MS data. Mesoridazine was also reduced under similar conditions and gave the same TLC, IR, and GLC–MS characteristics for the reaction product, thioridazine.

Mass Spectra of Ring Sulfoxides—Essentially identical spectra were obtained when IIF and IIS were passed through the GC–MS. Programmed-temperature GC of IIF and IIS gave identical retention times; the peaks of these polar compounds were broad and appeared after the thioridazine peak. Upon direct injection, postcolumn with a heated vaporizer, both materials produced spectra showing the molecular ion. The spectra of both IIF and IIS had many peaks in common with thioridazine, including the molecular-ion peak for thioridazine and the base peak for the *N*-methylpiperidyl fragment.

The ring sulfoxides theoretically exist as two diastereoisomeric pairs, and these pairs are separable by physical means such as chromatography or fractional recrystallization. These compounds are of interest because of the known metabolic conversion of thioridazine to such oxidation products. Methods for syntheses of the materials in pure form are described. Elemental analyses and IR data are consistent with the *S*-oxide structure. ^{1}H-NMR clearly rules out the *N*-oxide in favor of the *S*-oxide structure because of the chemical shift of the *N*-methyl group. ^{13}C-NMR gives the unambiguous determination of the site of this oxidation as the ring sulfur atom.

Table VI—Chemical Shifts (ppm) [a] of *S*- and *N*-Methyl Proton Signals of Thioridazine and Related Compounds

Compound (Side-Chain Group)	*S*-Methyl	*N*-Methyl
Shifts Observed After Progressive Side-Chain Sulfoxidation		
I (CH_3S)	2.40	2.20
III (CH_3SO)	2.70	2.20
VI (CH_3SO_2)	3.00	2.20
VII (CH_3SO_2)[b]	3.00	—
Shifts Caused by Ring Sulfoxidation and Splitting Generated by Subsequent Protonation[c]		
IIF (CH_3S)	2.59	2.40
IIS (CH_3S)	2.59	2.40
VF (CH_3S)[d]	2.59	2.38, 2.44[e]
VS (CH_3S)	2.59	2.30, 2.36[e]

[a] In deuterochloroform; compared to thioridazine (I). [b] Methylsulfonylphenothiazine (VII) for comparison as parent structure of sulforidazine (VI). [c] Protons were retained on the more basic piperidine nitrogens. [d] A sensitive Fourier-transform NMR instrument was needed since VF was rather insoluble in deuterochloroform. [e] J_{NH-CH_3} = 5 Hz. Centers of these doublets are chemically shifted by 0.08 ppm. Both doublets collapsed to singlets on treatment with deuterium oxide. Deuterochloroform (100%) must be used to observe sharp peaks.

EXPERIMENTAL

Materials—All chemicals were official or reagent grade. Thioridazine hydrochloride, thioridazine free base, and two samples of ring sulfoxide were obtained commercially[1]. 3-Methylsulfonylphenothiazine (21) and sulforidazine (22) were synthesized.

Instruments—A grating IR spectrophotometer[2], a UV-visible spectrophotometer with recorder[3], a 60-MHz NMR spectrometer[4], and a Fourier-transform 80-MHz NMR spectrometer[4] were used. The 60-MHz instrument was used only for ^{1}H-NMR studies of free bases. The 80-MHz instrument was operated at 79.542 MHz for ^{1}H-NMR and at 20 MHz for ^{13}C-NMR. An electron-impact (70 eV) GLC–MS[5], operated with an 88-cm × 2-mm i.d. glass column[6], was used for the lithium aluminum hydride reduction studies. A GLC–MS[7] equipped with a 61-cm × 2-mm i.d. glass column[8] was used for analysis of the ring sulfoxides; alternatively, these compounds were directly inserted into a postcolumn vaporizer operated at 270°. All UV spectra were obtained with methanol solutions. All melting points were taken on a melting-point stage[9]. All IR frequencies are reported as corrected values. A molecular model set[10] was used for structural analyses. The HPLC system is reported elsewhere (12).

TLC—All chromatograms were performed with fluorescent, precoated silica gel sheets[11], cut to 50 × 75 mm, by ascending development under equilibrated conditions in a tank lined with filter paper[12]. Spots were located by irradiation with short- or long-wavelength UV or by this sequential treatment: spray with Folin reagent[13], spray with 50% H_2SO_4, and heat at 100° for a few minutes (2).

Reactions of Thioridazine and Mesoridazine with Hydrogen Peroxide—*Method I, Oxidation in Acetic Acid*—Thioridazine and mesoridazine bases were oxidized with hydrogen peroxide in glacial acetic acid at 45° as described previously (17). The reaction product was examined by TLC with a solvent system composed of chloroform–95% ethanol–12 *N* ammonium hydroxide (80:20:1). The sample was spotted

beside reference standards of thioridazine (I) and mesoridazine (III) and synthetic samples of the thioridazine ring sulfoxides (IIF and IIS). The chromatograms were inspected by short- and long-wavelength UV irradiation and by a detection system used for locating and identifying the spots by color (1). An HPLC system (12) was also used to identify the reaction products and to obtain approximate product ratios.

Method II—Thioridazine hydrochloride (40.7 mg) was treated in four different reactions with increasing concentrations of aqueous hydrogen peroxide. The drug was dissolved in the following amounts of water, and the following amounts of hydrogen peroxide were added to the solutions over about a 2-min period: 5 ml of water, 0.1 ml of 15% H_2O_2; 15 ml of water, 0.1 ml of 15% H_2O_2; 5 ml of water, 25 μl of 15% H_2O_2; and 15 ml of water, 25 μl of H_2O_2. The studies examined whether more strenuous oxidation conditions would favor formation of the dioxide over that of the ring sulfoxides (IIF and IIS). Products from these reactions were examined by TLC as in Method I.

Method III—Thioridazine hydrochloride and 40% hydrogen peroxide were refluxed 4 hr in ethanol, as described previously (1). The crude reaction product was examined by TLC and HPLC. This oxidation process was also conducted on thioridazine free base to determine whether there was a difference in the distribution of reaction products under mildly basic conditions.

Samples Prepared for Oxidation Studies—Sample A consisted of a mixture of reference standards of I and III with synthetic IIF and IIS, prepared as described below. The rest of the samples were reaction products formed by the following oxidations: B, I with hydrogen peroxide in glacial acetic acid (17); C, III with hydrogen peroxide in glacial acetic acid; D, the hydrochloride of I with hydrogen peroxide in aqueous solution; E, the hydrochloride of I with hydrogen peroxide in refluxing ethanol (1); F, I with hydrogen peroxide in refluxing ethanol; G, I with nitrous acid.

Chromatography Systems Used to Study Oxidation Products—Systems I–IV and VI were used with silica gel TLC: I, chloroform–95% ethanol–12 *N* ammonium hydroxide (80:20:1); II, acetone–12 *N* ammonium hydroxide (100:7) (2); III, ethyl acetate–glacial acetic acid–water (5:2:2) (1); IV, a solution of 1.5 g of ammonium acetate in 10 ml of water mixed with 50 ml of methanol (13–15). System V was an HPLC method (12); identification was made by observation of an increase of peak response without appearance of new peaks after the samples were spiked with appropriate individual components of sample A. System VI: TLC plates were sprayed with Folin reagent, then with 50% sulfuric acid, and were heated at 100° for a few minutes. TLC identifications were made by observing R_f values which were identical to those of the components of sample A.

Specific Oxidation of Thioridazine to Generate Only the Ring Sulfoxides of Thioridazine and Isolation as Nitric Acid Salts (VF and VS)—To a solution of 1.521 g of thioridazine hydrochloride in 100 ml of deionized water was added 10 drops of concentrated hydrochloric acid. To this mixture a sodium nitrite solution (1 g/10 ml) was added dropwise with stirring until the solution turned from blue to yellow-brown or started to turn orange. A small portion of this reaction mixture was analyzed immediately by HPLC; the ring sulfoxides had been formed exclusively. The mixture was extracted with two 30-ml portions of chloroform. The chloroform was removed by evaporation (steam bath) and then heptane (50 ml) was added to the glassy residue, and the solvent was again removed (steam bath) to give a yellow-orange powder. Residual heptane was removed by decantation. A small amount of this decanted heptane was boiled to dryness and contained no dissolved substances. The hard granular solid (VF and VS) after air drying weighed 1.07 g. The reaction was repeated with 3- and 6-g portions of thioridazine hydrochloride to yield 2.18 and 5.02 g, respectively. Melting points are given in Table III.

The nitric acid salts of the thioridazine ring sulfoxides (5.7 g) were fractionally crystallized (19) from 95% ethanol to give 290 mg of 99.9% VF and 360 mg of 99.3% VS. Purity was determined by HPLC (12). Melting points are given in Table III.

Conversion of the Nitric Acid Salts to Free Bases—The salt (VF or VS), 140 mg, was dissolved in 10 ml of warm deionized water. Concentrated ammonium hydroxide (60 μl) was added and an oil separated. The mixture was extracted with two 5-ml portions of chloroform, and the combined extracts were passed through filter paper[9], to remove water. The chloroform was removed (steam bath, nitrogen flush), and then methanol (5 ml) was added and removed in the same manner. The product was recrystallized from hexane or heptane to give a mixture of IIF and IIS (from VF and VS). When VF and VS were treated individually, analytically pure IIF and IIS were obtained. Melting points and analyses are given in Table III. IR (Nujol mull or KBr disk): IIF, 1019 (s) and 1050 (s) cm^{-1}; IIS, 1028 (s) and 1050 (s) cm^{-1}; (cast films): both IIF and IIS, 1028 (s) and 1050 (s) cm^{-1} and superimposable from 4000 to 6000 cm^{-1}. IR sulfoxide bands: II, 1020 and 1045 cm^{-1} (S=O) (1). IR (KBr) commercial sample of ring sulfoxide (IIS–IIF = 85:15): 1028 (s) and 1050 (s) cm^{-1} and superimposable from 4000 to 6000 cm^{-1} with a spectrum of IIS; mass spectrum: *m/z* (relative abundance, percent), IIF, 386 (0.5) (M^+); 370 (M − 16), 98; IIS, 386 (2.0) (M^+); 370 (M − 16), 98.

Reduction of Thioridazine Ring Sulfoxides to Thioridazine with Lithium Aluminum Hydride—The mixed nitric acid salts VF and VS (0.1 g) were converted to the thioridazine sulfoxide free bases IIS and IIF as described directly above. A solution of the free bases in 1.3 ml of anhydrous ether was stirred under a nitrogen atmosphere, and then a slurry of 0.1 g of lithium aluminum hydride in 1.3 ml of anhydrous ether was slowly added. A vigorous reaction occurred, and the solution turned orange and then yellow. After the reaction subsided, the mixture was refluxed for 24 hr. Water was added and the mixture was extracted three times with heptane–toluene (4:1). The solvent was removed to give 35 mg of thioridazine. Mesoridazine was reduced to thioridazine in the same manner. The products were compared with thioridazine by TLC, IR spectrophotometer, and GC–MS (identical retention times with thioridazine): *m/z* 370 (M^+), 98 (base peak, *N*-methyl piperidinyl fragment); instrument correlation index for thioridazine, 0.911.

Simultaneous Assay of Thioridazine and Its Major Metabolites in Plasma at Single Dosage Levels with a Novel Report of Two Ring Sulfoxides of Thioridazine

CLYDE E. WELLS ˣ, ERIC C. JUENGE, and WILLIAM B. FURMAN

Received February 12, 1982, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication June 3, 1982.

Abstract □ A highly sensitive and selective method of analysis of plasma for thioridazine and its major metabolites, including two isomers of the ring sulfoxide, is presented. It is suitable for following the metabolism of thioridazine for 24 hr after a single dose. The method involves extraction of the materials from plasma, high-performance liquid chromatographic separation, and postcolumn oxidation and fluorometric detection. The sensitivity of the method to thioridazine and its metabolites is 2 ng/ml. Recoveries ranged from 87.8 to 100.6% at levels between 20 and 400 ng/ml.

Keyphrases □ Thioridazine—isomeric ring sulfoxides, metabolism, high-performance liquid chromatography with fluorometric detection, determination in plasma □ High-performance liquid chromatography—thioridazine metabolism, formation of two isomeric ring sulfoxides, determination in plasma

In preparation for a clinical study designed to compare the bioavailability of various brands of thioridazine tablets, it was necessary to develop a sensitive, specific method for the determination of thioridazine and its major metabolites in plasma. The metabolites of interest were sulforidazine (thioridazine 2-sulfone), mesoridazine (thioridazine 2-sulfoxide), and the two isomers of thioridazine ring sulfoxide (thioridazine 5-sulfoxide) for which analyses have not been reported in the literature.

The concentrations of thioridazine and its metabolites in biological fluids have been measured by fluorometric (1, 2), TLC (2–5), GLC (2, 6–14), and high-performance liquid chromatographic (HPLC) (15–17) methods. Most of these methods were developed to measure thioridazine and its metabolites in the blood of patients who were placed on a therapeutic regimen of thioridazine. For the study of the metabolism of thioridazine arising from a single dose, a method capable of detecting these compounds in the range of 10–500 ng/ml of plasma was needed. None of the methods reported in the literature provide both the sensitivity and specificity necessary.

Although the fluorometric methods provide the required sensitivity, they are not specific and do not differentiate among the metabolites. The GLC methods are not suitable at levels <50 ng/ml because of the instability of the metabolites on the chromatographic columns. The TLC procedures lack the necessary sensitivity.

The method of Muusze and Huber (15), which employs an HPLC separation of thioridazine and its metabolites followed by postcolumn oxidation and fluorescence, showed the most promise. However, at a sensitivity that would allow the detection of the eluted compounds at levels <50 ng/ml, the baseline signal from the fluorometer became excessively noisy. To eliminate the noisy baseline and allow the detection of lower levels of the metabolites, the detection system was modified to extract the eluted products into a phosphoric acid solution of potassium permanganate for oxidation.

[a] Standard peak height to internal standard peak height. I = thioridazine; II = thioridazine ring sulfoxide (fast eluter); III = thioridazine ring sulfoxide (slow eluter); IV = mesoridazine. [b] ng/ml of plasma. [c] Peak height taken from recorder chart. Recorder set at 20 mV full scale. [d] Peak height reported by integrator. [e] No II, III, or IV detected in blank. [f] Integrator failed to detect peak. [g] Peaks were off-scale on the recorder.

Although that study (15) reported only a single thioridazine ring sulfoxide, another study (18) reported the presence of two isomers. The mobile phase used in the HPLC system was modifed to permit the separation of all the metabolites of interest, including the two ring sulfoxide isomers, and to allow the use of an internal standard.

EXPERIMENTAL

Apparatus—The HPLC system consisted of a pump[1], a syringe injector[1], a recorder[2], an integrator[3], a 3.2- × 250-mm column packed with 10-μm spherical particle silica[4], a 2- × 50-mm precolumn of solid-core silica[5], a peristaltic pump[6], mixing coils and connecting tees[6], and a fluorometer[7] equipped with excitation[8] and emission[9] filters. The transmittance spectra of these filters are shown in Fig. 1. Samples were stored in a freezer[10] at −40°. A vortex mixer[11] and a centrifuge[12] were used in the extraction of the plasma samples. The detection system was assembled as shown in Fig. 2.

Reagents—Potassium permanganate, sodium nitrite, diethylamine, hydrogen peroxide, and phosphoric acid were reagent grade. Ethyl acetate, heptane, 1-chlorobutane, methylene chloride, and 2-propanol were HPLC grade. The water was deionized. Thioridazine hydrochloride[13], mesoridazine besylate[13], thioridazine ring sulfoxide nitric acid salts[14] (18), sulforidazine[14], and triflupromazine hydrochloride[15] were used as standards. Plasma was obtained from the Red Cross blood bank.

The potassium permanganate solution was prepared by dissolving 100 mg of potassium permanganate in 1 liter of 5% aqueous phosphoric acid. The hydrogen peroxide solution was prepared by diluting 1 ml of 30% hydrogen peroxide to 250 ml with water.

HPLC Operating Conditions—The mobile phase was 1-chlorobutane–2-propanol–water–diethylamine (92:7.9:0.08:0.016). The flow rate was 1.5 ml/min at 25°. The potassium permanganate solution flow rate was 2.0 ml/min, and the hydrogen peroxide solution flow rate was 0.4 ml/min. The flow rate through the fluorometer flowcell was 1.8 ml/min. The recorder sensitivity was set at 20 mV full scale (the output of the fluorometer was 100 mV full scale). The fluorometer sensitivity was adjusted so that the internal standard peak height was ~ 80% of full scale on the recorder when 100 μl of sample extract was injected. The integrator was set to measure peak heights. Instrument operating conditions were maintained for 0.5 hr before injection of the first sample or standard solution.

Preparation of the Internal Standard Solution—An aqueous solution of triflupromazine hydrochloride (10 mg/25 ml) was transferred to a separatory funnel. A 1-ml portion of 0.1 *N* hydrochloric acid and a 1-ml portion of sodium nitrite solution (10 g/100 ml) were added, and the funnel was shaken for 2 min. The solution was made alkaline with concentrated ammonium hydroxide, the oxidized triflupromazine was extracted with one 50-ml portion of methylene chloride, and the extract was diluted to 100.0 ml with methylene chloride. A 3.0-ml aliquot of the

[a] For concentrations of other components in these samples, see Tables III–V.

methylene chloride solution was diluted to 250 ml with heptane–ethyl acetate–diethylamine (100:100:1). The internal standard solution gave an HPLC peak with a retention time identical to that of triflupromazine sulfoxide prepared from a previous procedure (19). The latter material was crystallized from ethyl acetate and dried (55°, 3 mm, 3 hr) to give a product, mp 94–96°, which was submitted for carbon and hydrogen elemental analysis.

Anal.—Calc. for $C_{18}H_{19}F_3N_2OS$: C, 58.68; H, 5.20. Found: C, 58.43; H, 5.33.

Preparation of Sample Solutions—A 2.0-ml aliquot of plasma was transferred to a 16- × 100-cm screw-capped test tube containing 2.0 ml of the internal standard solution and 3 ml of heptane–ethyl acetate (1:1). The tube was capped, mixed on a vortex mixer for 2 min, centrifuged for 5 min, and placed in the freezer until the plasma was frozen. The organic layer was decanted into a second tube. The frozen plasma was allowed to thaw and was re-extracted with 3 ml of heptane–ethyl acetate (1:1). The organic layers were combined and evaporated to dryness (steam bath, nitrogen stream). The residue was dissolved in 0.5 ml of the HPLC mobile phase.

[a] For concentrations of other components in these samples, see Tables II, IV, and V. [b] Sample contaminated; not used in calculation of mean, *SD*, and *CV*.

Preparation of Standard Solutions—Portions of the salts of thioridazine, mesoridazine, and the ring sulfoxides equivalent to 20 mg of the corresponding free bases were each dissolved in 95% ethanol and diluted to 100.0 ml. These solutions were diluted with 95% ethanol to give mixed standard solutions containing 0.8, 1.6, 4, 8, 20, 32, and 40 μg of each standard/ml. A 25-μl aliquot of each solution was added to 2 ml of plasma. At this low level, the ethanol neither denaturated the plasma nor influenced the partition coefficients in the extractions. The sample-preparation procedure was used for the extraction of the standard solutions.

Recovery of Thioridazine and Metabolites from Plasma—Four plasma samples containing thioridazine and each of its metabolites at levels of 20 to 400 ng/ml were prepared. Aqueous solutions of the ethanolic standard solutions were added to the plasma to avoid denaturing of the plasma and to avoid changes in the partition coefficients in the extraction steps. Four aliquots of each prepared plasma sample and four aliquots of blank plasma were extracted.

Stability of Thioridazine and Its Metabolites in Plasma—Aliquots of one of the plasma samples used in the recovery experiment were transferred to test tubes and stored in the freezer. At intervals over a 3-week period, the samples were removed from the freezer and extracted. The dried extracts were stored in the freezer until the end of the 3-week period; all extracts were then injected into the HPLC system on the same day. In a second experiment, samples were removed from the freezer and stored at room temperature for 0, 1, 2, 5, and 24 hr before extraction; all five of these extracts were injected on the same day.

HPLC Separation and Analysis—A 100-μl aliquot of the extract of each standard and sample was injected into the liquid chromatograph. The ratios of each peak height to the peak height of the internal standard were calculated from the integrator output and from the recorder chart for those peaks that remained on scale. Linear regression calculations were performed on the standards, and the slope and intercept so obtained were used to calculate the concentration of the sample solutions.

RESULTS AND DISCUSSION

Preliminary tests showed that, at levels < 50 ng of metabolite per ml of plasma, the peak height measurement by the integrator was more reliable than the area measurement. Integration would sometimes stop before the baseline was reached at the end of the peak, causing relatively large errors in the calculations based on peak area.

The peak height ratios of the plasma standards were subjected to a

[a] For concentrations of other components in these samples, see Tables II–IV. [b] Level of mesoridazine in sample 4 not detectable in the presence of 400 ng of the ring sulfoxide/ml of plasma.

linear regression analysis (Table I). Each of the four compounds tested showed a linear response in the 10- to 500-ng/ml range. The peak height ratios calculated from the recorder chart could be used interchangeably with those calculated by the integrator. Occasionally the integrator failed to detect peaks at levels of 10–20 ng/ml. The recorder chart then provided a convenient backup for measurement of the peak height ratio.

Recoveries (Tables II–V) ranged from 87.8 to 100.5%, and coefficients of variation ranged from 0.6 to 7.0%. The largest variations were found for the ring sulfoxides in the 20- to 40-ng/ml range. The recovery of sulforidazine was not studied due to lack of sufficient material.

The results of the stability tests (Tables VI and VII) show that thioridazine and its metabolites are stable in frozen plasma for at least 3 weeks and are stable in plasma at room temperature for at least 24 hr.

Figure 3 shows the integrator curves for blank plasma, plasma with each standard added at the 100-ng/ml level, and a whole blood sample from a patient on thioridazine therapy. Figure 4 shows the recorder tracing of a plasma sample with each standard added at the 10-ng/ml level and that of a plasma blank with the internal standard added. The estimated detection limit for each standard in plasma is 2 ng/ml.

The HPLC system gives good resolution of thioridazine and its major metabolites. When used with the new sample extraction procedure and the new procedures for postcolumn extraction, oxidation, and fluorometric detection reported here, the system provides a highly sensitive and specific method of analysis with minimum interferences.

A modification of the procedure has been used to measure thioridazine and its metabolites in postmortem whole blood samples. Thioridazine,

Antitumor Agents LIX: Effects of Quassinoids on Protein Synthesis of a Number of Murine Tumors and Normal Cells

I. H. HALL *x, Y. F. LIOU *, K. H. LEE *, S. G. CHANEY ‡, and W. WILLINGHAM, JR. ‡

Received February 8, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy and ‡Department of Biochemistry, School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514. Accepted for publication June 2, 1982.

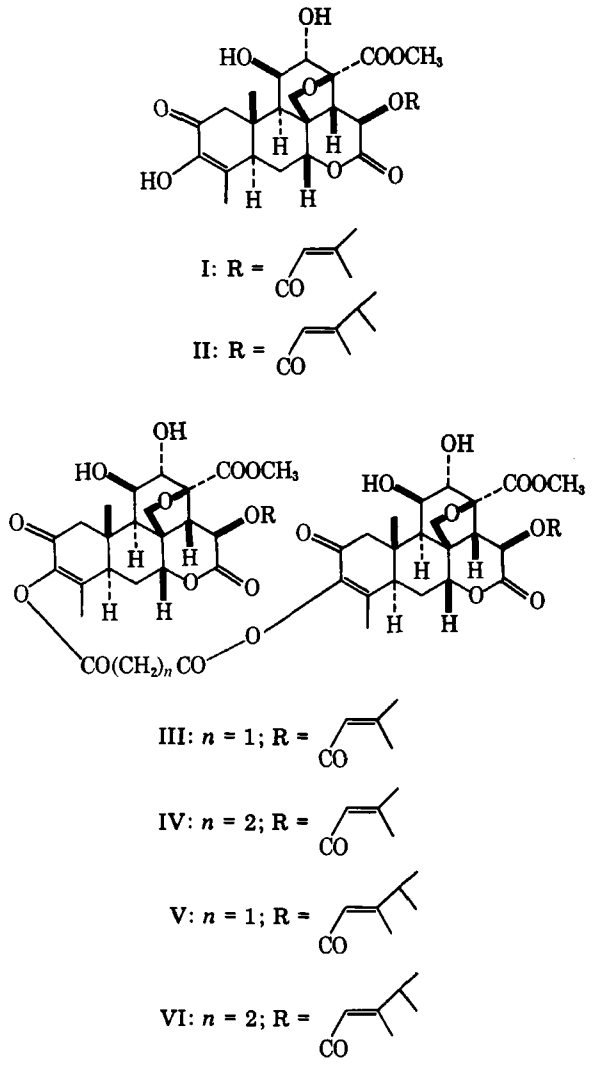
Abstract □ The quassinoids (brusatol, bruceantin, bisbrusatolyl esters, and bisbruceantinyl esters of succinic and malonic acids) were observed not to be universal protein synthesis inhibitors. Rather, they were selective for both the types of cancers, *e.g.*, P-388 lymphocytic leukemia, Ehrlich and hepatoma carcinoma and L-1210 lymphoid leukemia, as well as types of normal tissues (*e.g.*, lymphocytes), in which they demonstrated protein synthesis inhibition. The data suggest that the observed difference in the magnitude of protein synthesis inhibition of two P-388 lymphocytic leukemia cell lines by the quassinoids was at the ribosomal levels, whereas the observed difference in normal livers from various strains of mice involve differences in cell membrane transport of the quassinoids into the various tissues. Detailed studies indicated that the mode of action of the quassinoids as protein synthesis inhibitors was identical in all of the cells where inhibition was observed; *i.e.*, the elongation step of protein synthesis was blocked by the quassinoids. The data derived from assays for polyuridine-directed polyphenylalanine synthesis of isolated ribosomes demonstrated that the ID_{50} values obtained were consistent with the observed inhibition of whole cell protein synthesis inhibition for P-388 cells, as well as for BDF_1 and DBA/2 liver cells. The ID_{50} values obtained from various cells, *e.g.*, P-388 cells and normal liver, were all in the μM range and are consistent with previously published values for the quassinoids in the rabbit reticulocyte and yeast systems.

Keyphrases □ Brusatol—effects on protein synthesis of murine tumors □ Bruceantin—effects on protein synthesis of murine tumors □ Bisbrusatolyl esters—effects on protein synthesis of murine tumors □ Protein synthesis—inhibition by quassinoids, P-388 lymphocytic leukemia cells

Recently a number of quassinoids including brusatol (I), bruceantin (II), bisbrusatolyl malonate (III), bisbrusatolyl succinate (IV), bisbruceantinyl malonate (V), and bisbruceantinyl succinate (VI) were observed to inhibit *in vitro* protein synthesis of P-388 lymphocytic leukemia cells (1). The inhibition of protein synthesis correlated positively with P-388 tumor cell growth inhibition (2), and further work demonstrated that the elongation step of protein synthesis was being inhibited by the quassinoids (1–3). In earlier studies, this laboratory observed that different lines of P-388 lymphocytic cells, P-388-UNC and P-388-NIH, metabolically responded quantitatively differently to the quassinoids; *i.e.*, in the two cell lines different magnitudes of protein synthesis inhibition were observed. Thus, the objectives of the present study were to examine (*a*) the effects of time of incubation to determine how rapidly the agents act on protein synthesis, (*b*) the effects of quassinoids on protein synthesis in two lines of P-388 cells as well as other murine tumor lines, (*c*) the effects of quassinoids on normal tissue protein synthesis to determine if they are ubiquitous mammalian protein synthesis inhibitors, and (*d*) the effects of the quassinoids on *in vivo* protein synthesis using multiple doses and different concentrations (mg/kg) of drugs.

EXPERIMENTAL

Sources of Compounds—The sources of the quassinoids as well as their physical and chemical characteristics have previously been reported



Structures of Quassinoids

(4, 5). All of the agents were homogenized in 0.05% polysorbate-80–water for use in the *in vivo* and *in vitro* studies.

Sources of Tumor and Normal Cells—P-388 lymphocytic leukemia cells were obtained through the National Cancer Institute. The P-388-UNC tumor line was obtained in June 1978 and the P-388-NCI was obtained in December 1980. Both P-388 lymphocytic leukemia lines were maintained in DBA/2 or BDF_1 male mice (~18 g). On day zero, 10^6 P-388 cells were implanted intraperitoneally, and on day 9 the cells were harvested for the *in vitro* studies. Antineoplastic activity was determined for P-388 screen by the NCI protocol (6). The L-1210 lymphoid leukemia line was maintained in DBA/2 male mice (~20 g). On day zero, 10^5 cells were implanted intraperitoneally, and the cells were harvested on day 8 for *in vitro* studies. The hepatoma 129 line was maintained similarly to the P-388 line except the host species was male C_3H mice (~18 g). Cells for the *in vitro* study were removed on day 8. The renal cell carcinoma (RCO_2) was maintained in CDF male mice (~20 g). On day zero, 0.1 ml of ascites fluid was implanted into new donor mice. Three weeks later, cells were harvested for *in vitro* studies.

All of the solid tumors were maintained in male $C_{57}B1/6$ mice (~22 g). On day zero a fragment (~30 mg) was implanted into the mice. For the B-16 melanotic melanoma, brain glioma 261 and the ependymoblastoma, the fragment was implanted into the inguinal region of the hind leg. For the Lewis lung, the tumor was implanted intramuscularly into the hind leg. Cells were harvested on day 14 and homogenized with a loose pestle to obtain individual cells in 0.25 *M* sucrose and 0.001 *M* EDTA (ethylenediaminetetraacetic acid), pH 7.4.

The Ehrlich ascites tumor line was maintained in CF_1 male mice (~20 g) by implanting 2×10^6 cells on day zero. Cells were collected on day 8. The sarcoma 180 ascites tumor line was maintained in Swiss Webster male mice (~20 g). Cells were harvested on day 8. The KB human epidermoid carcinoma of the mouth was maintained as a tissue culture in *minimum essential medium and 10% fetal calf serum containing the* antibiotics, penicillin and streptomycin (7).

Normal tissues were selected from the strain of mice that acted as host for the tumor transplant. Normal kidneys were obtained from CDF_1 male mice; normal brain tissue was obtained from $C_{56}B1/6$ male mice; normal liver was obtained from C_3H male mice, and spleen lymphocytes were obtained from DBA/2 male mice.

***In Vitro* Whole Cell Leucine Incorporation into Protein**—These studies were conducted with 10^6 cells (homogenized and whole cell) from tumor or normal tissues, 1 μCi of L-leucine [4,5-^{3}H, 56.5 Ci/mmole] with minimum essential medium in a total volume of 1 ml, which was incubated 60 min at 37°. The time of incubation was varied in the P-388, L-1210, hepatoma, and Ehrlich ascites studies from 30–120 min. The reaction was stopped with 10% trichloroacetic acid, and the insoluble protein was collected on filters[1] by vacuum suction and the filters counted[2] (8, 9). The results are expressed as dpm/10^6 cells.

Polyuridine-Directed Polyphenylalanine Synthesis—Tumor lysates were prepared by a previous method (10). The following were isolated from tumor lysates by literature techniques: runoff ribosomes (11), pH 5 enzymes (10), and uncharged tRNA (12). The reaction medium (13) contained 50 m*M* *tris*(hydroxymethyl)aminomethane, pH 7.6, 12.5 m*M* magnesium acetate, 80 m*M* KCl, 5 m*M* creatine phosphate, 0.05 mg/ml creatine phosphokinase, 0.36 mg/ml polyuridine [poly(U)]-(A_{280}/A_{260} = 0.34), 0.5 μCi [^{3}H]phenylalanine (536 mCi/mmole), 75 μg uncharged tumor cell tRNA, 70 μg of tumor pH 5.0 enzyme preparation, and 0.9 A_{260} of P-388 tumor cell or liver runoff ribosomes. Test drugs were present in 0–30 μ*M* concentration. Incubation was for 20 min at 30° after which a 35-μl aliquot was spotted on filter papers[3] which were treated for 10 min in boiling 5% trichloroacetic acid and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1), and ether. The filter papers were dried and counted in scintillation fluid[2].

***In Vivo* Studies of Protein Synthesis Inhibition**—In order to determine the effects of quassinoids on normal *in vivo* protein synthesis, CF_1 male mice (~22 g) were injected with brusatol, bruceantin, or bisbrusatolyl malonate at a dose of 0.6 mg/kg ip for 3 days. On the 4th day, 1 hr prior to sacrifice, 10 μCi of [^{3}H]leucine was injected intraperitoneally. The liver, kidney, spleen, and lung were excised, and the protein was extracted by a previous method (14) and counted. Protein content was determined by another method (15). *In vivo* P-388 tumor cell studies were conducted to determine the dose response effect on protein synthesis by implanting 10^6 cells on day zero into BDF_1 mice. On days 7, 8, and 9, brusatol, bruceantin, or bisbrusatolyl malonate was injected intraperitoneally from 0.10 to 0.60 mg/kg/day. On day 10, the cells were harvested and extracted as described above. In other studies, brusatol and bruceantin were injected as a single dose on day 7, as two doses on days 7 and 8, and three doses on days 7, 8, and 9 at 0.3 mg/kg/day. Cells were harvested 6 hr after the last dose. Protein was extracted (14), counted, and protein content (15) determined. Results are expressed as dpm/mg of isolated protein.

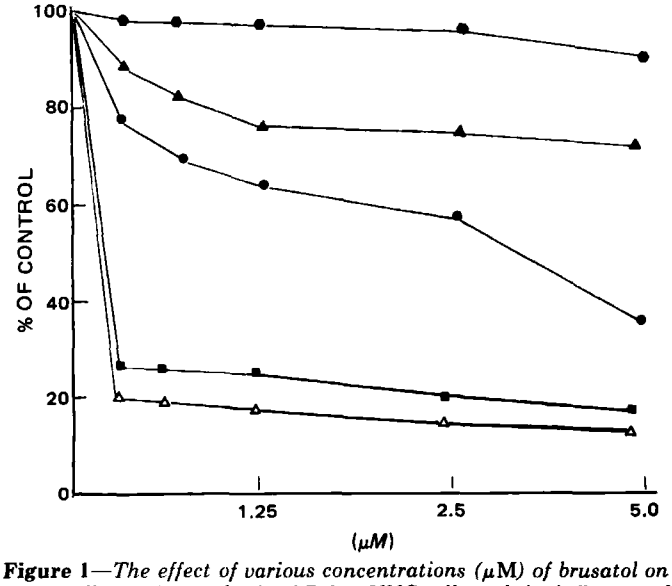

Figure 1—*The effect of various concentrations (μM) of brusatol on whole cell protein synthesis of P-388-UNC cells and the influence of time of incubation. Key: (●) 30 min; (▲) 45 min; (●) 60 min; (■) 90 min; (△) 120 min.*

RESULTS

In initial studies, brusatol (I), bruceantin (II), and bisbrusatolyl malonate (III) were incubated with P-388-UNC lymphocytic leukemia cells between 30–120 min. Brusatol required more than 60 min incubation to obtain maximal inhibition (Fig. 1). Little difference was observed in the extent of inhibition after 90- or 120-min incubations. Similar data were obtained with bruceantin and bisbrusatolyl malonate. Thus, 90-min incubations were used routinely in subsequent experiments. Under these conditions, brusatol was the most effective inhibitor causing an inhibition of 75–80% at concentrations between 1.25 and 5 μ*M* (Fig. 1). The quassinoid esters, III and IV, caused the same magnitude of protein synthesis inhibition but required concentrations of 10–15 μ*M* (Table I). Compound II was not that active as a protein synthesis inhibitor at this concentration range in P-388 cells (Table I). Concentrations above 10 μ*M* were required for II to afford more than 50% inhibition of protein synthesis.

Comparison between two P-388 lymphocytic leukemia lines of tumor (P-388-UNC and P-388-NCI) shows that the quassinoids have a differential effect on tumor growth suppression as well as protein synthesis inhibition (Table I). Compounds I and II at 0.6 mg/kg/day were slightly more active against the growth of the P-388 NCI tumor line compared with the P-388-UNC line (Table II). Compound III was less active against the growth of the P-388-NCI tumor line compared with the P-388-UNC tumor line. Protein synthesis was inhibited (Table II) in a similar manner; *e.g.*, I and II were slightly better inhibitors in the P-388-NCI tumor cell system, whereas III had less effect on protein synthesis in the P-388-NCI tumor line. Approximately the same degree of inhibition of protein

Table II—The Effects of Quassinoids on *In Vivo* P-388 Lymphocytic Leukemia Tumor Growth

		T/C% at 0.6 mg/kg/day	
		P-388 UNC	P-388 NCI
I	Brusatol	149	156
II	Bruceantin	146	162
III	Bisbrusatolyl malonate	212	135
IV	Bisbrusatolyl succinate	217	161
V	Bisbruceantinyl malonate	139	139
VI	Bisbruceantinyl succinate	153	151
	5 Fluorouracil (12.5 mg/kg)	186	209

synthesis was observed for homogenized cell preparations from both P-388 lines (data not shown). Since III is a dimer connected through an ester group, the question arose whether the difference in response in both antineoplastic activity and inhibition of protein synthesis could be the property of the ester linkage. Thus, three other esters were examined: bisbrusatolyl succinate (IV), bisbruceantinyl malonate (V), and bisbruceantinyl succinate (VI). As can be seen in Table II, all three of these esters demonstrated less antineoplastic activity in the P-388-NCI tumor line compared with the P-388-UNC tumor line. The same analogy can be observed with respect to protein synthesis inhibition; i.e., the esters had less activity as protein synthesis inhibitors in the P-388-NCI tumor cell line (Table II).

In vivo protein synthesis studies in BDF_1 mice inoculated with tumor P-388-NCI lymphocytic leukemia cells demonstrated that after a 3-day administration of the quassinoids from 0.10 to 0.60 mg/kg, brusatol had the strongest effect on protein synthesis inhibition causing greater than 80% inhibition at 0.10 mg/kg/day (Fig. 2). Compound II required a dose of 0.30 mg/kg to produce greater than 80% inhibition, whereas bisbrusatolyl malonate only caused 70% inhibition at 0.60 mg/kg for 3 days. Examination of single and multiple dosing of I, II, and III at 0.3 mg/kg shows that 6 hr after the first dose I caused >90% inhibition of *in vivo* protein synthesis (Fig. 3). Bruceantin, on the other hand, only caused 25% inhibition of protein synthesis 6 hr after a single dose, two doses caused 77% inhibition, and three doses were required to cause >90% inhibition of protein synthesis. Three doses of bisbrusatolyl malonate were required to cause greater than 50% inhibition of protein synthesis. Thus, the *in vivo* studies on the effects of quassinoids on P-388-NCI leukemia cell protein synthesis afforded consistent results with *in vitro* studies.

The quassinoids are potent inhibitors of the polyuridine-directed polyphenylalanine synthesis reaction of P-388 ribosomes. The ID_{50} values obtained for I, II, and III were for the P-388-UNC ribosomes 6.4, 11.5, and 1.9, respectively, and for the P-388-NCI ribosomes 0.4, 0.6, and 25 μM, respectively.

Since the specificity of the quassinoids as protein synthesis inhibitors varied so strikingly between the two P-388 cell lines, the effects of these compounds on the inhibition of *in vitro* protein synthesis of a series of unrelated murine tumors were also examined. As can be seen in Table III, compounds I, II, and III were found to be potent protein synthesis inhibitors in both Ehrlich and hepatoma 129 carcinomas at various concentrations. Again, 90-min incubations resulted in the maximum degree of protein synthesis by the quassinoids for inhibition in Ehrlich and hepatoma cells (data not shown). A moderate protein synthesis inhibition was observed by the quassinoids in the L-1210 lymphoid leukemia, B-16 melanotic melanoma, and ependymoblastoma tumor cells. Compounds I and II at the high concentrations (50 μM) produced mild inhibition of protein synthesis in the brain glioma 261 tumor cells. The quassinoids actually stimulated whole cell protein synthesis in the Lewis lung carcinoma, renal cell carcinoma, and human KB tissue culture system.

As can be observed from Table III, normal lungs from C_3H mice and normal kidneys from CDF mice demonstrated the same pattern of protein synthesis as the Lewis lung carcinoma and renal cell carcinoma of that tissue, *i.e.*, an increase in protein synthesis after 90-min incubation with the quassinoids. The quassinoids inhibited both normal spleen lymphocytic and lymphoid leukemia cells in DBA/2 mice. However, the quassinoids did not cause protein synthesis inhibition of normal liver from C_3H mice but did cause inhibition of the hepatoma from this same strain of mice.

As can be noted in Table III, only protein synthesis from noncancerous livers of BDF_1 and DBA/2 mice was inhibited by the quassinoids at 50-μM concentrations. All other whole cell liver studies from different strains of mice, CF_1, CDF, and $C_{56}B1/6$, demonstrated no inhibition of protein synthesis by the quassinoids. Since liver cells from most strains of mice seemed to be relatively resistant to inhibition by the quassinoids, the effect of these compounds on polyuridine-directed polyphenylalanine synthesis *in vitro* for two of these cell types was determined. In BDF_1 liver, compounds I, II, and III afforded ID_{50} values of 0.3, 0.6, and 25 μM, whereas the DBA/2 liver ribosomes, the ID_{50} values were 0.4, 0.7, and >50 μM, respectively. Bruceantin afforded an ID_{50} of >50 μM with CF_1 liver ribosomes.

DISCUSSION

The quassinoids do not appear to be universal protein synthesis inhibitors. Instead, they are selective for the tissue type as well as noncancerous and cancerous tissue cell types. In some cases this selectivity appears to be due to inherent differences at the ribosome level, while in other cases it seems to be a result of differences in tissue cell permeability to the quassinoids. In whole cell studies the quassinoids require an interval of time before they effectively bring about protein synthesis inhibition. This phenomenon may be due to delayed transport of the quassinoid into the cell, to a time lag necessary for binding of the quassinoids to their intracellular target, or to metabolism of the quassinoids to an active species which inhibits protein synthesis.

The quassinoids did appear to exhibit a quantitative difference in blocking protein synthesis of the P-388-NCI and P-388-UNC lymphocytic leukemia lines. The bis-quassinoid esters were not as active in the P-388-NCI tumor line compared with the P-388-UNC leukemia line. In the *in vivo* studies, the inhibition of protein by compounds I, II, and III after 3 days administration was dose related. Brusatol was more active than bruceantin, and bisbrusatolyl malonate was the least active in the

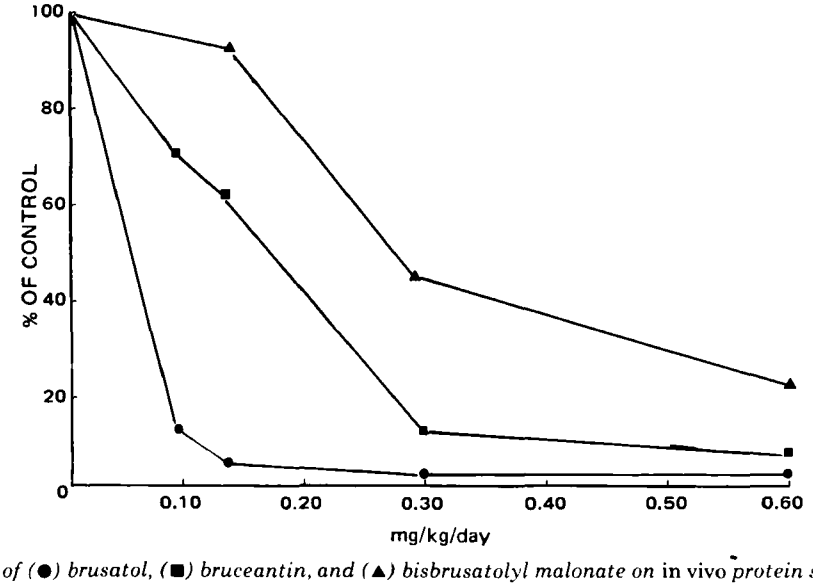

Figure 2—*The effect of dose of (●) brusatol, (■) bruceantin, and (▲) bisbrusatolyl malonate on* in vivo *protein synthesis of P-388-NCI cells.*

[a] μM Concentrations.

P-388-NCI tumor line. The same relationship can also be observed among the quassinoids with respect to the time after administration of the agents to obtain significant protein synthesis inhibition. These quantitative differences were positively correlated with the antineoplastic activity of the quassinoids obtained in the individual P-388 tumor lines. However, in both P-388 tumor lines, the quassinoids acted identically as elongation inhibitors in polyuridine-directed polyphenylalanine synthesis in the fractionated system. Previous studies have shown that inhibition of the polyuridine-directed polyphenylalanine synthesis is a measure of their effectiveness as antineoplastic agents (2). This system does not require initiation or termination factors. Thus, an inhibitor of this reaction can be considered to be an elongation inhibitor of protein synthesis. Detailed studies have previously demonstrated that the peptidyl transferase reaction is blocked by the quassinoids (1–3). The ID_{50} values obtained for each of the quassinoids in the two P-388 cell lines were consistent with the observed whole cell protein synthesis inhibition; *i.e.*, I and II produced ID_{50} values of lower magnitude in the P-388-NCI line, whereas III afforded an ID_{50} value of lower magnitude in the P-388-UNC line. The fact that these quassinoids were equally effective in whole cell suspensions and in homogenates as well as fractionated protein-synthesizing systems derived from P-388 cells rules out differences in transport or metabolism of these drugs by the two different cell lines. In this case the quantitative differences between the sensitivities of these two cell lines appear to reside at the ribosome level.

The quassinoids were potent protein synthesis inhibitors of some murine tumors: Ehrlich ascites and hepatoma carcinoma were significantly inhibited, whereas L-1210 lymphoid leukemia, B-16 melanotic melanoma, and brain ependymoblastoma were moderately inhibited. However, the quassinoids had no effect on other tumors including human KB cells. A reason for this observation is not obvious, but may involve the transport or metabolism of the quassinoids at different rates or manners by the individual tumors or intrinsic differences in ribosome sensitivity to the drugs. In those tumors where whole cell protein synthesis was inhibited (Ehrlich ascites, hepatoma, and L-1210 lymphoid leukemia), similar times were required to observe maximum protein synthesis inhibition (90 min) as were observed for P-388 cells. There did not appear to be a selectivity of protein synthesis inhibition between normal and cancer cells in the same mouse species. Except for hepatoma in C_3H mice, the quassinoids were not specific inhibitors in cancer cells exclusively, but inhibited protein synthesis of some normal tissues such as spleen lymphocytes, which were proliferating regularly, and DBA/2 and BDF_1 liver cells. Interestingly, the ID_{50} values obtained in the polyuridine-directed polyphenylalanine system of ribosomes isolated from different strains of mice again shows that in those livers where good inhibition by the quassinoids of whole cell protein synthesis was observed, the ID_{50} values were of a low magnitude (0.4 and 0.6 μM), whereas when the whole cell inhibition was not significant, the ID_{50} values were high (>50 μM in CF_1 liver). The ID_{50} value for inhibition of polyphenylalanine synthesis in fractionated systems appeared to be in the same concentration range for both DBA/2 and BDF_1 liver cells and P-388 tumor cells. The poor inhibition of protein synthesis in some tumors and normal liver cells, may be due to inability of the quassinoids to enter the cell, particularly in view of the fact that no inhibition was observed in whole cells of CF_1 liver, yet in the ribosomal fractionated system an ID_{50} of ~50 μM was observed. The observation that the quassinoids do not inhibit protein synthesis of all tumors may explain why bruceantin has not been observed in clinical trials to be effective against certain solid tumors. Perhaps it may be necessary to ascertain if the quassinoids are potent *in vitro* protein synthesis inhibitors of human solid tumors obtained by biopsy prior to administering the drug *in vivo*.

High-Performance Liquid Chromatographic Assay of Methadone, Phencyclidine, and Metabolites by Postcolumn Ion-Pair Extraction and On-Line Fluorescent Detection of the Counterion with Applications

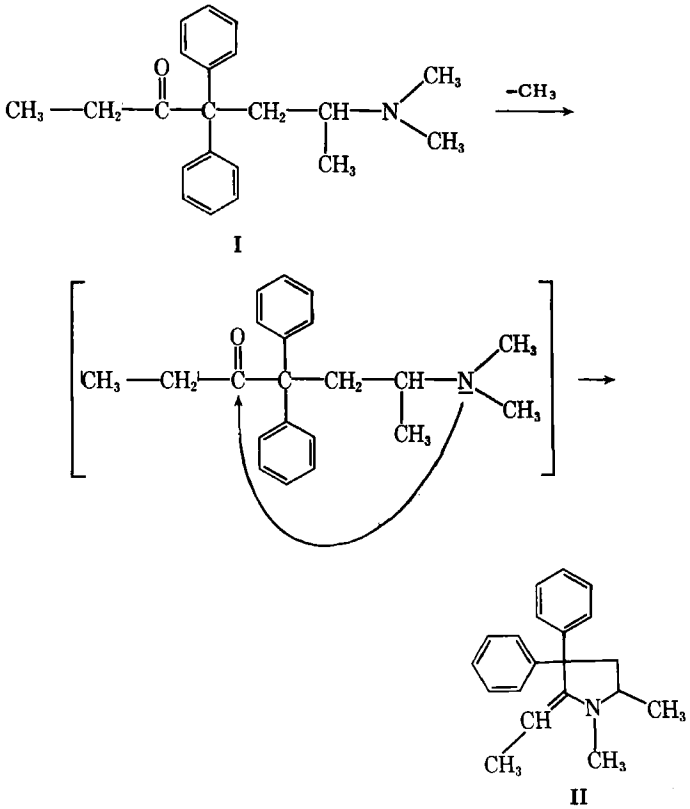
HARTMUT DERENDORF and EDWARD R. GARRETT ˣ

Received February 2, 1982, from *The Beehive, College of Pharmacy, J. H. Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication June 11, 1982.

Abstract □ Methadone, phencyclidine, and their metabolites were extracted from plasma and separated on a high-performance liquid chromatographic (HPLC) column using the fluorescent 9,10-dimethoxyanthracene-2-sulfonic acid as a counterion. The chromatographed mobile phase was subsequently extracted on-line with chloroform. The separated organic phase, containing the fluorescent ion-pairs of the investigated amines, was analyzed in the flow cell of a fluorometer (excitation 380 nm, emission 445 nm). The phase separator volume was as small as possible to avoid dead volume. The method was also applied to the bioassay of cocaine with a sensitivity of 1–6 ng/ml of plasma. Application of these assays gave a red blood cell–plasma water partition coefficient for methadone of 3.39 ± 0.26 (*SD*) in a concentration range up to 20 μg/ml, and demonstrated a time-dependent partition with a diffusion half-life of 1.44 min ± 0.26 min (*SD*). The protein binding of methadone determined by ultracentrifugation was concentration dependent and varied between 75–62% at the highest concentration studied (9 μg/ml). The presence of the major metabolite did not have any influence on the protein binding. The results were confirmed by using the red blood cell-partitioning method to determine the protein binding.

Keyphrases □ Phencyclidine—high-performance liquid chromatographic assay of methadone and metabolites by postcolumn ion-pair extraction, on-line fluorescent detection of counterion with applications □ Methadone—high-performance liquid chromatographic assay of phencyclidine and metabolites by postcolumn ion-pair extraction, on-line fluorescent detection of counterion with applications □ High-performance liquid chromatography—assay of methadone, phencyclidine ion-pair extraction of counterion with applications

Classical high-performance liquid chromatography (HPLC) detection of drugs and their metabolites in biological fluids is by spectrophotometry and fluorescence. These methods were expanded by application of electrochemical detectors (1) and derivatization reactions (2) to get high sensitivities. Unfortunately, these direct detection methods are inadequate for some pharmacokinetic studies of drugs that are given in low doses and show low levels in biological fluids. Sensitive HPLC methods have not yet been developed (3) for methadone (I) and its major metabolite, 2-ethylidene-3,3-diphenyl-1,5-dimethylpyrrolidine (II) (Scheme I), nor for phencyclidine (III) and its hydroxylated metabolites (V, VI). These drugs have insufficient UV-absorbance, no fluorescence, and cannot be readily derivatized. Classical carbonyl reactions are not possible with methadone due to the steric effects of the two phenyl rings. Although cocaine (IV) can be spectrophotometrically detected in HPLC, greater sensitivity than the 15 ng/ml reported (4) would be advantageous in forensic and pharmacokinetic studies.



Scheme I—Major pathway of methadone metabolism.

All of these substances are tertiary amines which are readily protonated. They can be extracted into organic

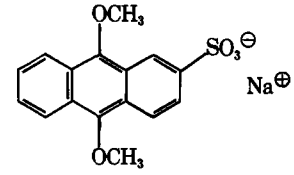
VI

These properties can be utilized after HPLC separation by postcolumn ion-pair extraction and fluorescent detection of the ion-pair. This was described previously (5, 8) where a system was applied to both normal-phase and reverse-phase chromatography. However, a proper phase separator is critical in such systems to provide only one phase for the detector. Commercially available phase separators frequently show significant peak broadening and lessened specificity and sensitivity due to relatively large dead volumes (7). Thus a new phase separator was constructed with a polytef filter and the developed assay systems applied to the determination of the protein binding and red blood cell partitioning of methadone. The plasma protein binding of radiolabeled methadone, reported in the literature, varies widely between 40 and 90% (9–12) with a possible concentration dependence (12).



VII

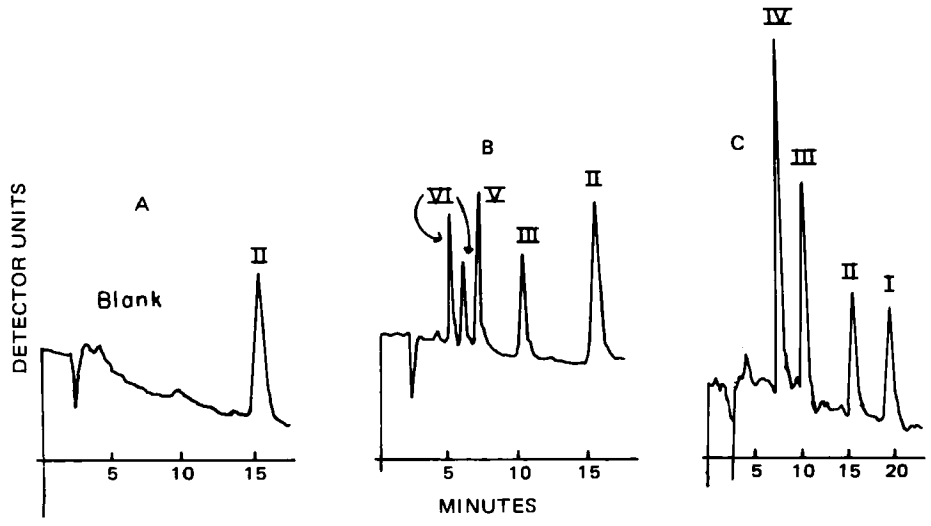


Figure 2—*Chromatograms of 1 ml of plasma alkalinized, extracted with hexane, evaporated to dryness under nitrogen, and reconstituted in 250 μl of 0.025* M *acetate buffer, pH 3.6 with 100 μl injected into the chromatograph. (A) The initial plasma contained 100 ng/ml of internal standard II. (B) The initial plasma contained 50 ng/ml phencyclidine (III), phencyclidine metabolite (V), the* cis- *and* trans-*isomers of phencyclidine metabolite VI, and 100 ng/ml of II as internal standard. (C) The initial plasma contained 60 ng/ml of cocaine (IV), II, methadone (I), and 100 ng/ml of phencyclidine (III) as internal standard.*

EXPERIMENTAL

Materials—The following analytical grade materials were used: sodium acetate[1], acetic acid[1], dibasic and monobasic sodium phosphates[1], sodium chloride[1], and volumetric concentrates of sodium hydroxide[2]. Acetonitrile[3] and chloroform[3] were HPLC-grade; hexane[4] was UV-grade. Methadone[5] (I), 2-ethylidene-3,3-diphenyl-1,5-dimethylpyrrolidine[5] (II), phencyclidine[5] (III), 1-(1-phencyclohexyl)-4-hydroxypiperidine[5] (V) 4-phenyl-4-piperidinocyclohexanol[5] (VI), cocaine[5] (IV), and the sodium salt of 9,10-dimethoxyanthracene-2-sulfonic acid[6] (VII) were used as received. Sodium chloride injection USP[7], sodium heparin injection USP[8], and disposable syringes[9] were used in the preparation of red blood cell suspensions.

Apparatus—For the HPLC assay, the following were used: two pumps[10], an automatic injector[11], a cyano column[12], a fluorescence detector[13], a phase separator constructed from a purchased mixing tee[14] and equipped with a filter made of polytef[15], and a data station[16]. Plasma protein binding was determined with an ultracentrifuge[17]. A laboratory centrifuge[18] was used in the separation of organic extract from plasma and aqueous phases.

HPLC Systems—A postcolumn extraction procedure was used in all HPLC assays (Fig. 1). The mobile phase was a mixture of 0.025 *M* acetate buffer, adjusted to a measured pH of 3.6, and acetonitrile (80:20). It contained 30 mg/liters of 9,10-dimethoxyanthracene-2-sulfonic acid. The flow rate was 2 ml/min with a back pressure of 10 MPa. Immediately after passing the 50°-heated column, the chromatographed mobile phase was mixed with chloroform from another pump at a flow rate of 2 ml/min. The extraction of the ion-pairs into the chloroform was performed in a 0.61-m extraction coil, followed by separation in the constructed phase separator (Fig. 1B).

The phase separator used a mixing tee[14] with upper and lower outlets. It was maintained at a perpendicular angle. Its lower outlet was fitted with a hydrophobic filter made of polytef to increase the efficiency of the phase separation by repelling droplets of the aqueous phase. The back pressures of the two outlets were adjusted so that a constant fraction of the organic phase ran through the lower outlet of the phase separator into the fluorometer with 90% of the extraction mixture going to waste. The excitation wavelength was 380 nm (slit 10 nm), emission 445 nm (slit 5 nm).

Extraction Procedure from Plasma—Freshly prepared dog plasma (1.00 ml) samples were spiked with an appropriate amount of drug and an internal standard. Cocaine, phencyclidine, or its metabolite 1-(1-phenylcyclohexyl)-4-hydroxypiperidine (V) were used as internal standards in the methadone assay. The methadone metabolite (II) was used as an internal standard for the assay of phencyclidine and its metabolites. The plasma was alkalinized with 200 μl of 1 *N* sodium hydroxide and extracted with 6 ml of hexane for 10 min with slow shaking.

The tubes were centrifuged at 2000 rpm for 10 min, and 5 ml of the organic phase was evaporated to dryness under a nitrogen stream. The residue was reconstituted in 250 μl of 0.025 *M* acetate buffer at pH 3.6, and 100 μl was injected into the HPLC system.

Plasma Protein Binding by Ultracentrifugation—Fresh heparinized dog blood was centrifuged for 15 min at 3000 rpm. Plasma aliquots (5 ml) were spiked with different amounts of methadone, and 1 ml was taken for analysis. After ultracentrifugation at 35,000 rpm for 18 hr, 1 ml of the supernatant plasma water was analyzed for methadone.

The influence of the presence of the major metabolite of methadone (II) on the protein binding of methadone was studied in ratios of 1:10, 1:2, 2:1, and 10:1 of II:I.

Red Blood Cell–Buffer Partition Studies of Methadone and its Metabolite (II)—Fresh heparinized dog blood was centrifuged for 15 min at 3000 rpm. The plasma was removed and isoosmotic phosphate buffer pH 7.4, was added to the erythrocytes. Red blood cells were gently suspended and centrifuged for 10 min at 2000 rpm. This washing procedure was repeated three times. Red blood cell suspensions in phosphate buffer were spiked with methadone and its metabolite (II) to yield total drug concentrations in the range of 1–20 μg/ml. The hemocrit was determined routinely using a microcentrifuge with capillary tubes. The spiked suspensions were allowed to equilibrate for 60 min and then centrifuged for 10 min at 2000 rpm. An aliquot of the supernatant solution was analyzed and the red blood cell–buffer partition coefficient was calculated.

Determination of the Protein Binding by Red Blood Cell Partition Method (13)—Fresh heparinized dog blood was spiked with different amounts of methadone, shaken carefully, and centrifuged for 30 min. The plasma concentrations were determined as described previously.

RESULTS AND DISCUSSION

HPLC System with a Postcolumn Extraction—This HPLC system (Fig. 1) can determine amine concentrations indirectly. Substances are chromatographed as ion-pairs on the column with the ion-pairing VII in the mobile phase used for the detection after coextraction into chloroform in stoichiometric ratios with an organic amine. Stoichiometric highly fluorescent dimethoxyanthracene sulfonic acid of the ion-pairs can be detected with high sensitivity in the flow cell of a fluorometer.

A general and highly sensitive method was developed with the system to analyze methadone, phencyclidine and its metabolites, and cocaine. The designed phase separator (Fig. 1B) has a small inner volume and a hydrophobic filter made of polytef to repel water droplets in the separated organic layer. Such droplets would contain the counterion (VII), which would give irregular and interfering background in the fluorescent detection.

Mobile phase was limited to <20% acetonitrile to maintain a reasonable extractability into the chloroform. However, this lengthened the retention times for methadone and its metabolite (II), on the cyano column, the most polar reverse-phase column available. Column heating to 50° lessened the retention times. The described system and conditions were applicable for all the studied compounds with retention times: methadone (I), 17 min; methadone metabolite (II), 14 min; phencyclidine (III), 10 min; phencyclidine metabolite (V), 7 min; phencyclidine metabolite (VI), 5 and 6 min (*cis* and *trans* forms); cocaine (IV), 6 min.

In the chromatogram the background from biological fluids was satisfactory when hexane was used for extraction (Fig. 2A); however, it was unsatisfactory when chloroform was used for extraction. Typical chromatograms of substances at 50–60 ng/ml in plasma are shown in Figs. 2B and 2C. Calibration curves were set up to determine the sensitivity of the method. Statistics for calibration curves of the substances are given in Table I. The limit of sensitivity for all compounds was in the range 1.0–6.0 ng/ml of plasma ($2 \times s_{xy}$).

Determination of the Red Blood Cell–Plasma Water Partition Coefficient—The red blood cell partition coefficient of a drug can be defined as:

$$D = \frac{C_{RBC}}{C_{PW}} = \frac{A_{RBC}}{A_{PW}} \times \frac{V_{PW}}{(V_B - V_{PW})} = \frac{(A_{tot} - A_{PW})V_{PW}}{A_{PW}(V_B - V_{PW})} = \frac{A_{tot} - A_{PW}}{C_{PW}(V_B - V_{PW})} = \frac{A_{tot} - C_{PW}V_{PW}}{C_{PW}(V_B - V_{PW})} \quad \text{(Eq. 1)}$$

where D is the red blood cell partition coefficient, C_{RBC} is the concentration of the drug in the erythrocytes, C_{PW} is the concentration in plasma water, A_{RBC} is the amount of drug in the erythrocytes, A_{PW} is the amount in plasma water, A_{tot} is the total amount of drug added to the red blood cell suspension, V_B is the volume of the red blood cell suspension, and V_{PW} is the volume of plasma water.

Red blood cell–plasma water partition coefficients were determined for 10 different concentrations of methadone (Table II) and averaged D = 3.39 ± 0.26 (*SD*). There was no concentration dependence for partitioning in the studied concentration range up to 20 μg/ml.

The partitioning was time dependent. Diffusion half-life into the red blood cells was determined for three different concentrations and the average was 1.44 ± 0.26 (*SD*) min (Fig. 3).

Protein Binding of Methadone by Ultracentrifugation—The ultrafiltration method for the determination of the protein binding of

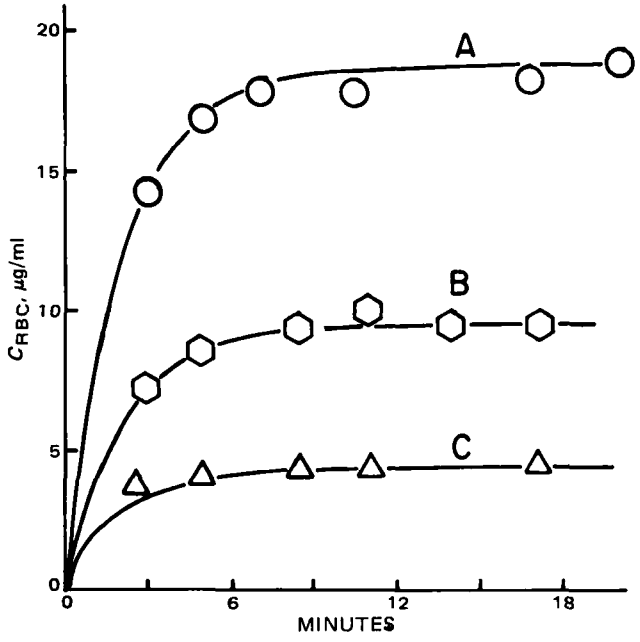

Figure 3—*Time dependence of the red blood cell partitioning in three different concentrations of methadone. The curves through the experimental values, concentrations of drug in red blood cells (C_{RBC}) over time, were fitted for a diffusion half-life of 1.44 min. The concentrations of methadone in plasma water were: (A) 5.7 μg/ml; (B) 2.7 μg/ml; (C) 1.2 μg/ml.*

[a] Drug–metabolite ratio for 2 μg of methadone/ml of plasma. [b] Concentration of methadone in plasma before ultracentrifugation in μg/ml. [c] Concentration of methadone in plasma water after ultracentrifugation in μg/ml. [d] Ratio between the concentrations after and before ultracentrifugation. [e] Volume of ml of spiked solution that was added to 5 ml of plasma. [f] Dilution factor $(5 + V_{dil})/5$. [g] Percentage of methadone bound to plasma proteins.

methadone was not useful because of high binding to the ultrafilters. Therefore, the protein binding was determined by the ultracentrifugation method, where methadone-spiked plasma was separated into plasma proteins and plasma water and the plasma water was assayed. The calculation of the fraction of drug bound to the plasma proteins was based on the following principles.

The equilibrium constant between protein-bound methadone and methadone in the plasma water can be defined as:

$$K = \frac{c_b}{c_f} = \frac{A_b}{A_f} \times \frac{V_{PW}}{A_{Pr}} = \frac{A_b}{A_f} \times \frac{V_{PW}}{c_{Pr} V_{PW}} = \frac{A_b}{A_f c_{Pr}} \qquad \text{(Eq. 2)}$$

where c_b is the concentration of protein-bound methadone, c_f is the concentration of the free methadone in the plasma water, c_{Pr} is the protein concentration of the plasma, A_b is the amount of methadone bound to the protein, A_f is the amount of methadone free in the plasma water, A_{Pr} is the amount of protein in the plasma water, and V_{PW} the volume of the plasma water. If the protein concentration in plasma is constant:

$$K_s = K c_{Pr} \qquad \text{(Eq. 3)}$$

then,

$$K_s = \frac{A_b}{A_f} \qquad \text{(Eq. 4)}$$

Since the plasma is slightly diluted by a volume V_{dil} of the spiking solution, the dilution factor is:

$$m = \frac{V_{PW} + V_{dil}}{V_{PW}} \qquad \text{(Eq. 5)}$$

and the protein concentration after spiking is:

$$c'_{Pr} = \frac{C_{Pr}}{m} \qquad \text{(Eq. 6)}$$

Thus, the equilibrium in the diluted plasma is:

$$K = \frac{c'_b}{c'_f} = \frac{A'_b}{A'_f c'_{Pr}} = \frac{A'_b m}{A'_f C_{Pr}} \qquad \text{(Eq. 7)}$$

Table V—Plasma Protein Binding of Methadone by the Red Blood Cell–Plasma Partition Method[a]

A_{tot}[b]	V_B[c]	H[d]	c_{Pl}[e]	$f_b \times 100$, %[f]
10.0	4.5	0.49	1.90	63.1
20.0	4.5	0.49	4.05	67.2
30.0	4.5	0.49	5.79	64.1

[a] The red blood cell–plasma water partition coefficient used was 3.39. [b] Total amount of methadone added to the blood in mg. [c] Volume of blood in ml. [d] Hematocrit. [e] Concentration of methadone in plasma in μg/ml. [f] Percentage of methadone bound to plasma proteins.

and

$$K_s = m \frac{A'_b}{A'_f} \qquad \text{(Eq. 8)}$$

where the primed values are the amounts in the diluted sample studies.

Methadone concentrations were assayed before (c_{pre} in plasma) and after ultracentrifugation (c_{post} in plasma water). The ratios of these two concentrations are:

$$r = \frac{c_{post}}{c_{pre}} = \frac{A'_f}{A'_f + A'_b} \qquad \text{(Eq. 9)}$$

Thus, from Eqs. 8 and 9:

$$K_s = m \frac{1 - r}{r} \qquad \text{(Eq. 10)}$$

The fraction of methadone bound to the plasma proteins, f_b, is

$$f_b = \frac{A_b}{A_b + A_f} \text{ or } \frac{1}{f_b} = 1 + \frac{A_f}{A_b} \qquad \text{(Eq. 11)}$$

so that on realization of Eqs. 4, 10, and 11, the fraction bound is

$$f_b = \frac{m(1 - r)}{r + m(1 - r)} \qquad \text{(Eq. 12)}$$

and can be calculated from the ratio of the methadone concentrations before and after ultracentrifugation. The results are summarized in Table III. Protein binding of methadone was concentration dependent in agreement with the previous studies by equilibrium dialysis (12) of 100–10,000 ng/ml of plasma. Protein binding varied 75–62% to give the low value at the highest 9 μg/ml of plasma studied.

The determination of the protein binding of methadone was repeated in the presence of different amounts of its major metabolite (II). Ratios, R, between parent drug and metabolite were 10:1, 2:1, 1:2, and 1:10 for a methadone concentration of 2 μg/ml of plasma. The results in Table IV indicate no significant effect of a 10-fold greater concentration of metabolite on the protein binding of methadone.

Protein Binding of Methadone by Red Blood Cell–Plasma Partitioning—Protein binding of a drug can be calculated from the known or assayed concentrations in blood and plasma after equilibration on the premise that only free drug can partition into the erythrocytes. The fraction of the drug bound to the plasma proteins can be calculated (13) from:

$$f_b = 1 - \frac{A_{tot} - c_{Pl} V_b (1 - H)}{D c_{Pl} V_b (1 - H)} \left(\frac{1}{H} - 1 \right) \qquad \text{(Eq. 13)}$$

where A_{tot} is the total amount of drug added to the volume V_b of the blood, D is the red blood cell–plasma water partition coefficient, H the hematocrit, and C_{pl} the concentration of the drug in the plasma. The

results in Table V agree with the results that were obtained by the ultracentrifugation method. Significant amounts of methadone are bound to the plasma proteins in the therapeutic range. The results confirm previous data (12), but disagree markedly from the results of other investigators (9, 10).

Physical Chemistry of Freeze-drying: Measurement of Sublimation Rates for Frozen Aqueous Solutions by a Microbalance Technique

M. J. PIKAL ˣ, S. SHAH, D. SENIOR, and J. E. LANG

Received October 14, 1981, from *Eli Lilly and Company, Indianapolis, IN 46285.* Accepted for publication April 30, 1982.

Abstract □ The sublimation rate of frozen solutions was studied as a function of freezing rate, thickness of dried product (l), temperature, residual air pressure, and solute concentration. Data are presented for pure water, aqueous potassium chloride, aqueous povidone, and aqueous dobutamine hydrochloride–mannitol (System I). The resistance of the dried product to water vapor flow ($\hat{R}_p$) was evaluated from the sublimation rate and the sample temperature. The primary experimental technique was based on freeze-drying a cylindrical microsample isothermally, with the sample suspended from one arm of a vacuum microbalance. Methodology to evaluate resistance data from vial freeze-drying experiments is also described. In separate experiments, samples in the form of a thin (15-μm) film were visually observed through a microscope during freeze-drying. Freeze-drying of most samples appeared to occur by water vapor escaping through open channels created by prior sublimation of ice. Contrary to the usual theoretical model, $\hat{R}_p$ is neither independent of temperature nor directly proportional to l. Rather, $\hat{R}_p$ decreases with increasing temperature and the l dependence is normally of the form $\hat{R}_p = (A_0 + A_1 l)/(1 + A_2 l)$, where A_i ($i = 0, 1, 2$) are constants. In several cases, $\hat{R}_p$ is very large near $l = 0$, decreases sharply at $l \simeq 0.1$ cm, and obeys the above equation where $l > 0.2$ cm, a result suggesting an amorphous surface skin which cracks on desorption of water. The temperature dependence of $\hat{R}_p$ suggests that, as the sample temperature approaches the eutectic (or collapse) temperature, hydrodynamic surface flow of adsorbed water is an important flow mechanism.

Keyphrases □ Sublimation rate—measurement for frozen aqueous solutions, microbalance technique, as a function of process variables □ Freeze-drying—methodology of rate measurements for aqueous solutions, influence of process variables, mechanisms of mass transfer in the dried solid □ Dosage forms—freeze-drying of aqueous solutions, effect of process variables on sublimation rate, mechanisms for mass transfer through the dried solid

As sublimation of ice proceeds during freeze-drying, a dried product layer above the ice is produced which acts as a barrier, or resistance, for transport of water vapor. The dried product resistance is generally regarded as the most important factor in determining the drying rate at fixed sample temperature and therefore has a major impact on the process economics. However, published experimental data are confined to food products or biological tissue samples, and the effects of major process or formulation variables on the dried product resistance have not been studied.

This report describes the direct experimental determination of the resistance of the dried product as a function of freezing rate, thickness of dried product, temperature, residual air pressure, and solute concentration. Data are presented for aqueous potassium chloride, aqueous povidone, and aqueous dobutamine hydrochloride–mannitol in a 1.12:1 weight ratio (System I)[1]. Sublimation rate data for pure water are also presented. To aid in the interpretation of the resistance data, the freeze-drying process was also observed microscopically using thin (~15-μm) samples confined between two glass coverslips. Procedures for determining the dried product resistance from vial freeze-drying studies are also described. Comparison of resistance data determined from vial freeze-drying with corresponding data determined by the microbalance procedure confirms that microbalance data are indeed predictive of the dried product resistance encountered in vial freeze-drying.

BACKGROUND

Freeze-drying, or lyophilization, is a process where a solvent (normally water) is removed from a frozen solution by sublimation. Freeze-drying has several advantages over competing processes for production of pharmaceuticals. First, as freeze-drying is a low temperature process, chemical decomposition is minimized. Second, since the solution may be sterile filtered immediately before introduction into a vial and no powder-handling steps are involved in the subsequent processing of a parenteral product, particulate levels may be reduced to a minimum. Due to the high capital equipment costs and typically long processing times, freeze-drying is frequently regarded as an expensive process. However, due to a lack of fundamental understanding of freeze-drying, a given process is often not optimized for the maximum production rate consistent with product quality. Consequently, freeze-drying, in practice, often is much more expensive than necessary.

However, published experimental data are confined to food products or biological tissue samples, and the effects of major process or formulation variables on the dried product resistance have not been studied.

This report describes the direct experimental determination of the resistance of the dried product as a function of freezing rate, thickness of dried product, temperature, residual air pressure, and solute concentration. Data are presented for aqueous potassium chloride, aqueous povidone, and aqueous dobutamine hydrochloride–mannitol in a 1.12:1 weight ratio (System I)[1]. Sublimation rate data for pure water are also presented. To aid in the interpretation of the resistance data, the freeze-drying process was also observed microscopically using thin (~15-μm) samples confined between two glass coverslips. Procedures for determining the dried product resistance from vial freeze-drying studies are also described. Comparison of resistance data determined from vial freeze-drying with corresponding data determined by the microbalance procedure confirms that microbalance data are indeed predictive of the dried product resistance encountered in vial freeze-drying.

BACKGROUND

Freeze-drying, or lyophilization, is a process where a solvent (normally water) is removed from a frozen solution by sublimation. Freeze-drying has several advantages over competing processes for production of pharmaceuticals. First, as freeze-drying is a low temperature process, chemical decomposition is minimized. Second, since the solution may be sterile filtered immediately before introduction into a vial and no powder-handling steps are involved in the subsequent processing of a parenteral product, particulate levels may be reduced to a minimum. Due to the high capital equipment costs and typically long processing times, freeze-drying is frequently regarded as an expensive process. However, due to a lack of fundamental understanding of freeze-drying, a given process is often not optimized for the maximum production rate consistent with product quality. Consequently, freeze-drying, in practice, often is much more expensive than necessary.

The freeze-drying process may be divided into three stages: freezing, primary drying, and secondary drying. For pharmaceutical products, the solution is normally filled into vials to a depth of ~1 cm, and the vials are placed on refrigerated shelves in the freeze-drying chamber. The specific freezing process influences the size and shape of the ice crystals formed and, therefore, affects the structure of the porous solid product remaining after drying (1–3). Thus, the freezing stage may influence strongly the time required to complete the next two steps of the process as well as influence the properties of the final product. After the solutions are frozen the chamber is evacuated, and the shelf temperature is increased to provide energy for the sublimation of ice during primary drying. A frozen solution dries from the top, thereby producing a dried product layer above the ice which increases in thickness as sublimation proceeds. Secondary drying begins locally when all ice has been removed from that region. Thus, in general, secondary drying proceeds simultaneous with primary drying in different regions of the same sample. Normally, secondary drying continues for some time after all ice has been removed from the sample. During secondary drying, the water removed from the solid phase is either bound as a crystalline hydrate or dissolved in an amorphous solid.

The objective of freeze-drying process development is to minimize the process time within the constraints imposed by product quality specifications. Excessive chemical decomposition must be avoided, residual water content often must be low for acceptable stability (4), and the product appearance must conform to standards. To avoid the foaming or puffing that develops during solution vacuum-drying, freeze-drying must be carried out below the eutectic temperature for a crystalline solute or below the collapse temperature for an amorphous solute (2, 3, 5–8). Selection of the shelf temperature and chamber pressure required to maintain the ice temperature just below the eutectic or collapse temperature in all vials during primary drying is a problem in coupled heat and mass transfer. Heat must be transferred from the shelf to the vial bottom and through the frozen solution to the sublimation interface to compensate for the heat removed by sublimation. The rate of heat transfer increases with increased shelf temperature and chamber pressure (9). Therefore, in principle the ice temperature may be maintained constant by adjustment of shelf temperature and chamber pressure.

Assuming that heat is supplied to maintain constant ice temperature, the sublimation rate, and therefore, the total time required for primary drying, will depend on the total resistance to transport of water vapor from the ice–vapor interface to the condenser. The total resistance has three contributors: resistance of the dried product (a porous solid), resistance of the semistoppered vial, and resistance in transfer from the chamber to the condenser. Mass transfer is discussed in terms of resistance, which is defined as the ratio of the difference in water partial pressure to the water flow rate. Resistance is used rather than permeability (the reciprocal of resistance) since the total resistance is additive for component resistances in series. That the dried product resistance is dominant in most freeze-drying applications (10, 11) is supported by theoretical calculations. Using mass flow equations developed for the flow of rarified gases through tubes and orifices (11, 12) and assuming the dried product equivalent to a bundle of capillary tubes, the resistance may be calculated from the dimensions of the vial, stopper, and freeze-dryer and estimates of the pore size of the dried product. Due to the small dimensions of the pores in a typical dried product, flow in the dried product is Knudsen or free molecular flow (11, 12) and contributes ~90% of the total resistance. Clearly, the dried product resistance is an important parameter which may dominate the economics of the freeze-drying process. It is this property with which we are concerned in this study.

The most common procedure used to estimate the dried product resistance is an indirect method which involves measurement of gas flow rate and corresponding pressure difference across a previously freeze-dried specimen of known area and thickness (11). A theoretical model is used to evaluate pore-size parameters for the porous solid which, in turn, are used to calculate the resistance to water vapor flow during ice sublimation from the sample. However, the validity of the model (in particular the assumption that the resistance is directly proportional to the thickness of the dried layer) may be questioned when the dried product is produced from a frozen solution. Microscopic data (2, 3, 13, 14) suggest that the dried product is not necessarily homogeneous, and the mass transfer rate is not always limited by flow in capillary channels. Given the complexity of freeze-drying from frozen solutions, it would seem prudent to avoid the use of theoretical models and evaluate resistances directly from the sublimation rate data.

Quantitative sublimation rate data are available for several frozen systems (15–18), but [with the exception of one study on guinea pig liver (18)] either the vapor pressure difference across the dried product is not available (16–17) or the sample geometry does not allow resistance data to be evaluated for dried product thicknesses of practical interest. A recording high-vacuum microbalance apparatus designed to determine sublimation rates of frozen solutions at controlled temperatures has been described (19). The sample form is a thin (~1-mm) disk of known area. Since the temperature of subliming ice is known and the partial pressure of water at the dried product–vacuum chamber interface is maintained near zero, the water vapor pressure gradient across the dried product is determined and the dried product resistance may be evaluated. The sample holder design limits studies to relatively low sublimation rates (*i.e.*, temperatures <−30°), and the effect of dried product thicknesses characteristic of those encountered in vial freeze-drying (~1 cm) cannot be studied.

The methodology chosen for this research is based on determination of the sublimation rate of a frozen sample with a recording high-vacuum microbalance and, in this respect, is similar to the methodology used by MacKenzie and Luyet (19). However, the sample cell design is more convenient and permits resistance data to be obtained at higher temperatures (~−10°) for dried product thicknesses up to 1 cm. The sample is contained in a 1.3-mm diameter glass tube which is embedded in an aluminum heat exchanger, allowing isothermal operation at the thermostat temperature for most systems of interest.

EXPERIMENTAL

Materials—The potassium chloride used was recrystallized reagent grade material; the mannitol (USP) and povidone (USP, viscosity average molecular weight of 35,000) were used as received. The dobutamine hydrochloride was commercial material[2] used without further purification. Solutions were prepared by weighing the appropriate quantities of distilled water and solute. System I was aqueous dobutamine hydrochloride–mannitol in a 1.12:1 weight ratio with total solids being 53 mg/ml. Conversion of concentration from weight percent to volume percent was accomplished assuming the solute specific volume in solution is the same as that in the solid[3].

Freeze-Drying Microscope—The high-vacuum cold stage (Fig. 1) used in conjunction with an optical microscope[4] for visual observation of freeze-drying is similar to the designs suggested by Flink and Geil-Hansen (20). A nickel-plated brass vacuum chamber (A) ~10 cm in diameter and 1.5 cm in height was sealed using a rubber "O" ring (B) and a stainless steel lid (C). The sample (D) was a thin (~15-μm) film constrained between two glass coverslips. Thermal contact between the bottom coverslip and the temperature-controlled plate (E) was achieved by glueing the coverslip to the plate with silicone stopcock grease. The plate (E) was nickel-plated brass. The distance from the sample to the

top of the lid was 4–5 mm, allowing the vacuum cold stage to be used with any microscope system having a working distance >5 mm. Temperature control was achieved by passing cold nitrogen gas through channels in the plate. Tubes (F) served as entrance and exit ports for gas flow. The plate was fixed in position ~2 mm from the bottom of the chamber by a plastic spacer (not shown) on the underside of the plate. Temperature of the sample was measured by a thermistor surface probe[5] (G), which was fixed to the top coverslip with silicone stopcock grease. Low pressures (0.02–0.05 torr) were achieved by a tube (H) connected to a vacuum line. Holes (I) cut in the lid and vacuum chamber bottom to allow observation of the sample were covered with glass coverslips sealed to the metal with silicone rubber glue. Rubber supports insulated the cold stage assembly from the microscope stage.

In operation, 5 λ of solution was placed on a 24 × 24-mm coverslip and an 18 × 18-mm coverslip was placed on the droplet, causing the solution to spread evenly over the area of the smaller coverslip. The sample was mounted on the plate (E), the temperature probe (G) was attached, and the lid (C) was placed on the chamber. Nitrogen from a pressurized tank was passed through a 3-Å molecular sieve drying tower and then through copper heat-exchanger coils immersed in liquid nitrogen. Temperature control in the plate was achieved by manual control of the gas flow rate (0–5 liter/min, for ambient to −50°); with periodic adjustment of the nitrogen pressure, temperature control of ±0.5° may be achieved. Accuracy of the temperature measuring system within ±0.5° was established by eutectic and melting point determinations on selected materials spanning the temperature range of interest. The sample was frozen by cooling at a rate of ~1°/min. The samples studied supercooled ~10° below the equilibrium freezing point and froze completely within a few seconds.

Freeze-Drying Microbalance—*Design*—The sample was suspended from one arm of an electronic vacuum microbalance[6] which in turn was connected to a high-vacuum line. For operation at zero pressure, an oil diffusion pump backed by a mechanical pump reduced the air pressure above the sample to ~5×10^{-6} torr. For operation at high residual air pressure, a controlled leak was located ~115 cm downstream from the sample through 2.5-cm diameter tubing. The controlled leak was simply a manually adjusted needle valve. During controlled-leak experiments, only the mechanical pump was operated. Pressure measurements in the range of 0.001–10 torr were made with a capacitance manometer[7] located near the leak site. Residual air pressures <0.001 torr were monitored with a cold cathode ionization gauge[8] ~175 cm downstream from the sample after the vapor stream had passed through a liquid nitrogen cold trap[9].

The sublimation cell, or sample holder, was enclosed by a balance tube–condenser assembly (Fig. 2A) which was connected to the balance using an "0" ring joint (A). The sublimation cell (B) was suspended from the balance beam by a 0.25-mm diameter nichrome wire (C). During operation, the glass balance tube (D) was immersed in a thermostat and the glass side arm tube (E) was immersed in dry ice–acetone to serve as the condenser. A high-vacuum union (F)[10] allowed rapid connection of the balance tube to the rest of the assembly. A copper–constantan thermocouple probe (G) was fitted inside a cylindrical cavity formed by the bottom portion of the sublimation cell. A circular aluminum foil heat shield (H) isolated the thermocouple probe from thermal radiation coming from the sample tube bottom so that the thermocouple probe more accurately sensed the temperature of the sample when the sample and thermostat temperatures differed. High-vacuum wax[11] (I) was used to seal the thermocouple wires (J) to the sample tube (forming a vacuum seal at the point where the wires left the tube) and to support the thermocouple probe in a fixed position at the bottom of the balance tube.

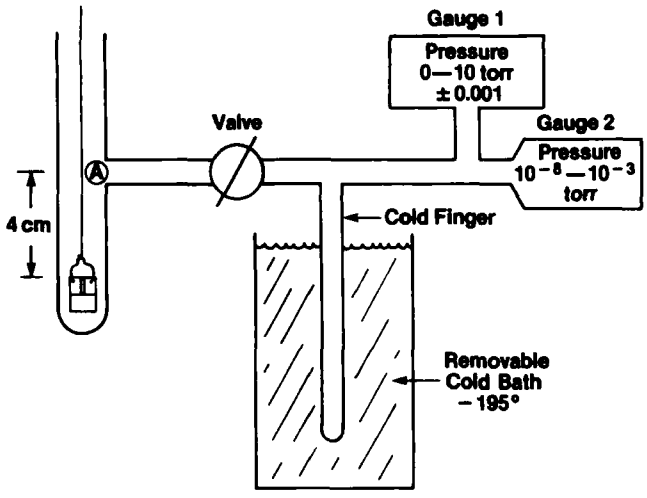

Figure 4—*Balance tube assembly for vapor composition measurements.*

A critical aspect of the sublimation rate measurement is the ability to control and measure the sample temperature. The sublimation cell (Figs. 2B, 3) is essentially a glass capillary tube in good thermal contact with an efficient radiative heat exchanger. This design allows the heat required for sublimation to be transferred from the thermostat to the sample with minimal temperature gradients. The sample (A) was in a glass capillary tube (B) which was fixed into a cylindrical hole in the aluminum heat exchanger by a thin film of high-vacuum wax[11] (C). To maximize radiative heat transfer, the aluminum was given a black anodized finish. The total weight of the sublimation cell was 1.17 g. The top portion of the heat exchanger had four fins (D) at 90° with respect to each other (Fig. 3), while the bottom portion (E) was a cylindrical cavity termed the temperature sensing cavity. The thermocouple probe protruded into this cavity without touching the sublimation cell. To increase the efficiency of heat exchange between the thermocouple probe and the sublimation cell, the effective area of the probe was increased by glueing the thermocouple junction (F) to an aluminum disk (G) with a thin coat of high-vacuum wax (H).

Temperature Measurement—Ideally, the probe measures the cell temperature, which is identical to the sample temperature. In practice, the probe temperature does not exactly measure the cell temperature and, at high sublimation rates, the sample temperature is lower than the cell temperature. A theoretical analysis of heat transfer in the apparatus and a series of calibration experiments (Appendix I) yielded the following relationship between the probe temperature (T_p), the sample temperature (T_s), and ambient temperature (T_a).

$$T_s = T_p - K_p \frac{(1 + 68.1\,P)}{(1 + 87.0\,P)} \dot{m} - K_a(T_a - T_p) \qquad \text{(Eq. 1)}$$

where P is the pressure in the balance tube in torr and $\dot{m}$ is the sublimation rate in mg/min. The parameters K_p and K_a were evaluated by fitting the theoretical model to calibration data, yielding a K_p of 10.2 and K_a of 0.010 at $P = 0$ and K_a of 0.006 for P between 0.05–1 torr, respectively[12]. The probe temperature measured with the system at ambient pressure was identical to the thermostat temperature as measured by the probe thermocouple. Thus, the temperature data for each experiment were corrected for thermocouple inaccuracy by comparing the probe temperature at ambient pressure with the thermostat temperature measured with a glass mercury thermometer (accuracy ±0.1°).

With the above procedures, the magnitude of the uncertainty in T_s was estimated to be 0.5° (due mostly to the uncertainty in K_a) plus 15% of the correction term (Eq. 1) proportional to $\dot{m}$[12]. Thus, the temperature uncertainty was ±0.5° for most of the sublimation experiments but increased to ±1.5° for the experiments with pure water at high temperature and zero pressure.

Background Mass Loss Correction—The rate of mass loss, computed by numerical differentiation from the recorder *versus* time curve[13], contains a background contribution, *i.e.*, mass loss other than sublimation of ice from the sample. The background mass loss arises from loss of adsorbed water from the balance system and the sublimation cell surface; it was determined experimentally by blank runs. No temperature effects were noted between −15 and −25°, and the background effect was assumed to be independent of temperature. The background contribution to the rate of mass loss ($\dot{m}_B$) decreased with time according to the empirical equation:

$$\dot{m}_B = \frac{A}{1 + kt^n} \qquad \text{(Eq. 2)}$$

where t is the time expired after sublimation begins and A, k, and n are constants. With $\dot{m}_B$ in mg/min, the values of A, k, and n, determined by regression analysis of several blank runs, are 0.01252, 0.10836, and 1.0554, respectively. The background correction is significant only for small values of t.

Chamber Pressure and Composition Measurements—Routinely, the pressure in the balance tube and the composition of vapor are not measured. However, such data were determined during representative sublimation experiments. For this series of experiments, a modified balance tube assembly was used (Fig. 4). With the liquid nitrogen cold bath removed, the total pressure at point A was measured using either gauge 1[7] or 2[8], depending on the pressure range studied. The valve was then closed and the cold bath was placed over the cold finger, condensing all water vapor. The residual pressure (due to air) was then measured. This residual pressure was slightly lower than the air pressure in the original vapor since the air remaining in the cold finger was at a lower temperature. The original air pressure was obtained from the measured residual pressure using an empirically determined correction factor (1.10_3 for the apparatus used). The correction factor was determined by measuring the pressure reduction induced by placing the cold bath on the cold finger at high pressure when the vapor was almost entirely air. With the air and total pressures in the sample determined, the water vapor pressure in the sample was obtained by difference[14].

In high-vacuum operation, the mole fraction of water vapor in the sample tube is unity (within experimental error) and the partial pressure of water vapor is <0.01 torr, even for sublimation of pure ice at high temperature. Thus, the partial pressure of water vapor above the sample was negligible compared with the vapor pressure of ice in all experiments carried out at high vacuum. When sublimation was carried out with a controlled air leak into the vacuum system to investigate the effect of air pressure on the sublimation rate, the mole fraction of air in the sample tube (X_2) is found to obey the empirical expression:

$$X_2 = \exp(-0.602\,\dot{m}), \qquad \text{(Eq. 3)}$$

where $\dot{m}$ is the sublimation rate in mg/min. The equation is valid for sublimation from pure ice and frozen solutions over the range in total pressures studied (0.04–0.8 torr). With the frozen solutions studied, $\dot{m}$

[12] Due to a small probe area and significant heat transfer from the ambient through the 30-gauge thermocouple wires (0.023-cm diameter), the thermocouple probe assembly shown here is only partially successful in directly measuring the cell temperature. The design has recently been improved by using smaller thermocouple wire (0.0076-cm diameter) and allowing the wire to equilibrate to the thermostat temperature before entry into the balance tube through the bottom. Also, the probe area is increased by press fitting the thermocouple junction into a finned heat exchanger similar in design to the top portion of the sublimation cell. The area is 1.7 cm², as compared with 0.7 cm² for the probe used to generate the data reported here. With the new finned probe, the value of K_a (Eq. 1) is 0.000 and K_p is 7.1. With the finned probe, the uncertainty in T_s is estimated at ±0.2° with $\dot{m} = 0$.

[13] The balance measures the sum of the gravitational force on the sample and the momentum force resulting from subliming water molecules. As long as the sublimation rate is independent of time, the momentum force is independent of time and the rate of mass loss is correctly computed from the balance readout. However, when the sublimation rate is time dependent, the momentum force is time dependent and contributes to the apparent rate of mass loss (computed from the balance readout). A maximum value for this effect may be estimated by assuming all subliming water molecules leave the sample at right angles to the sample surface. Taking the momentum as the product of the root mean square velocity and the mass of the water molecule, imposing conservation of momentum leads to:

$$\dot{m}_a/\dot{m} = 1 + \frac{1}{g}\left(\frac{3RT}{M_1}\right)^{1/2} \frac{d\ln\dot{m}}{dt}$$

where $\dot{m}_a$ is the apparent (or measured) sublimation rate, $\dot{m}$ is the true sublimation rate, $d\dot{m}/dt$ is the time derivative of the sublimation rate, R is the gas constant, M_1 is the molecular weight of water, T is the absolute temperature, and g is the gravitational constant. Evaluation of the fundamental constants yields:

$$\dot{m}_a/\dot{m} = 1 + 1.0\frac{d\ln\dot{m}}{dt}$$

where time is in min. The correction term $d\ln\dot{m}/dt$ is largest for experiments with pure water at high temperature; but even for this case, the correction is only ~4%.

[14] The cold cathode gauge (gauge 2, Fig. 4) readout was calibrated for air. A calibration curve giving water vapor pressure as a function of gauge reading was obtained by determining the gauge response, while ice in the cold finger slowly sublimed at known temperature and essentially zero air pressure. The water vapor pressure was taken as the equilibrium vapor pressure of ice at the measured temperature corrected for thermal transpiration effects (21).

was small enough that X_2 equaled 1.00 and, even for the studies with pure water, the vapor in the sample tube was mostly air. In experiments with a controlled leak, the total pressure in the balance tube was the same as the total pressure measured at the normal pressure measurement position (located 115 cm downstream from the sample).

Vial Freeze-Drying—*Apparatus*—Vial freeze-drying was carried out in a commercial laboratory freeze-dryer[15] which was modified by inclusion of a temperature-controlled shelf (530 cm^2 area), thermocouple (copper–constantan, 30-gauge) measurement of shelf and product temperature, and pressure measurement[5] in the sample chamber and inside one of the vials.

Pressure inside a vial was measured by connecting a glass tube to the interior of the vial at a location between the vial neck and the top surface of the product. This tube was joined to another tube leading out of the vacuum chamber to the vial pressure sensor. Vial pressure, chamber pressure, and all thermocouple outputs were displayed as a function of time by a 24-channel recorder[16].

Calculation of Sublimation Rate—Calculation of the resistance of the dried product requires the following data: the vapor pressure of ice (evaluated from the product temperature[17]), the pressure in the vial[18], the area of the product (calculated from the vial dimensions), and the sublimation rate. Since the apparatus did not allow the mass of a vial to be monitored continuously, the sublimation rate was evaluated by an alternate procedure.

Phenomenologically the sublimation rate, $\dot{m}$ (in g/hr), is given by:

$$\dot{m} = R_s^{-1}(P_v - P_c) \qquad \text{(Eq. 4)}$$

where R_s is the stopper (or closure) resistance and P_v and P_c are the pressures in the vial and chamber, respectively. Theoretical considerations suggest that the stopper resistance as defined by Eq. 4 should be pressure dependent (12) and may depend slightly on the sublimation rate (22). Empirically for the stoppers used in this research[19], the stopper resistance was found to be essentially independent of sublimation rate and varied with pressure as:

$$R_s = \overline{R}_s/\overline{P} \qquad \text{(Eq. 5)}$$

where $\overline{P}$ is the mean pressure across the stopper [$\overline{P} = (P_v + P_c)/2$)] and, as a first approximation, $\overline{R}_s$ is a constant[20]. Combining Eqs. 4 and 5 yields:

$$\dot{m} = \overline{R}_s^{-1}(P_v^2 - P_c^2)/2 \qquad \text{(Eq. 6)}$$

Since the total mass of water removed during drying (Δm) is known from the solution concentration and fill volume, the value of $\overline{R}_s$ for a given experiment may be evaluated by integration of Eq. 6 over the time period τ_D, where $P_v > P_c$, giving:

$$\overline{R}_s = \frac{1}{2\Delta m}\int_0^{\tau_D}(P_v^2 - P_c^2)dt \qquad \text{(Eq. 7)}$$

where the integration is performed numerically. Since slight variations in stopper placement causes variations in $\overline{R}_s$, a value of $\overline{R}_s$ was determined for each experiment. Once $\overline{R}_s$ was determined using Eq. 7, the sublimation rate at any time during primary drying was evaluated using Eq. 6.

Freezing Procedures—Frozen solutions for microbalance studies were prepared by loading the capillary with 13 λ of solution using a syringe, taking care not to introduce air bubbles. The sublimation cell was suspended from the balance and the balance tube was put into place. The balance tube was then immersed in 2-propanol at −40° (contained in a Dewar flask). When the sample froze, the probe temperature *versus* time plot showed a small change in slope, thereby allowing the freezing temperature to be determined. The studied solutions supercooled 20–25° below the equilibrium freezing point before freezing began. After the probe temperature decreased to <−35°, the 2-propanol bath was removed and the balance tube was immersed in a thermostat at the temperature desired for freeze-drying.

With pure water, 10% v/v potassium chloride, and 22.8% v/v povidone, the temperature history of the sample during freezing was studied by placing two thermocouple junctions (0.0076-cm diameter wire) in the capillary tube. One junction was placed near the tube bottom while the other was placed in the solution at the top of the capillary tube.

NORMALIZED DRIED PRODUCT RESISTANCE

The normalized dried product resistance ($\hat{R}_p$) is defined by:

$$\hat{R}_p = \frac{A_p(P_0 - P_1^D)}{\dot{m}} \qquad \text{(Eq. 8)}$$

where A_p is the geometric cross-sectional area of the product normal to the direction of water vapor flow, P_0 is the equilibrium vapor pressure of ice at the temperature of the subliming ice, P_1^D is the vapor pressure of water above the dried product, and $\dot{m}$ is the sublimation rate. Thus, the normalized dried product resistance is a per-unit-area (or area-normalized) dried product resistance which is a function of the thickness of the dried product layer.

In a vial freeze-drying experiment, P_1^D is the pressure of water vapor in the vial. Since the vapor in the vial during primary drying is essentially all water vapor[18], P_1^D is taken as the measured vial pressure. In a microbalance experiment, P_1^D is essentially zero during high-vacuum operation. During operation with a controlled leak, P_1^D is calculated from the total pressure and the vapor composition given by Eq. 3. Under all conditions studied in this research, P_1^D was small compared to P_0 and was normally negligible. With area in cm^2, pressure in torr, and $\dot{m}$ in g hr^{-1}, the units of $\hat{R}_p$ are cm^2 torr hr g^{-1} and numerically represents the approximate time (in hours) to freeze-dry a solution 1 cm thick at a temperature of −20°.

The thickness of the dried product (l) is evaluated from:

$$l = \frac{m_0 - m_t}{\rho_I A_p \epsilon} \qquad \text{(Eq. 9)}$$

where m_0 is the initial sample mass, m_t is the mass remaining at time t, ρ_I is the density of ice, and ϵ is the porosity or volume fraction of ice. In the microbalance experiment the masses were evaluated directly from the recorder output. In a vial freeze-drying experiment the mass difference, $m_0 - m_t$, was calculated by numerical integration of the sublimation rate over the relevant time interval.

Equation 9 assumes that the ice–vapor boundary remains planar and normal to the axis of the cylindrical container during sublimation. Sublimation of ice from pure ice and frozen aqueous potassium chloride contained in a 1.3-mm diameter capillary tube was examined microscopically by glueing the capillary tube to a glass coverslip and using the aforementioned microscopic observation techniques. The observations demonstrated that this assumption is justified for microbalance experiments. During vial freeze-drying the assumption is valid as a first approximation until near the end of primary drying.

RESULTS AND DISCUSSION

Freezing Rates—Representative data for potassium chloride and povidone are shown in Fig. 5. Onset of freezing is indicated by the sharp increase in temperature, while completion of the freezing process is indicated by a return to the cooling rate characteristic of the sample before

---

[15] Virtis Unitrap.

[16] Esterline Angus Speed Servo II.

[17] Product temperature was routinely measured in the center of the vial at the bottom, in the center about 8 mm up from the bottom, and at the bottom edge. Normally, temperature differences within the vial were small (<1°) and the thermocouple nearest the sublimation surface was used to evaluate the temperature of the subliming ice. If the temperature gradient was significant, the temperature of the ice was calculated using the measured temperature gradient and the estimated distance between the ice interface and the nearest thermocouple.

[18] The partial pressure of water vapor was required but both theoretical calculations and experimental data (23) indicated that the vapor in the vial was essentially 100% water.

[19] In the semistoppered position used during freeze-drying, the 20-mm finish closure has two openings of ~0.4-cm diameter. The 13-mm finish closure, used only for the −15° experiments with System I, has two openings of ~0.2-cm diameter, West Co.

[20] Application of the theories describing flow of rarified gases (12, 22) to the problem of water vapor flow through the closure opening, indicates $\overline{R}_s$ varies with pressure and sublimation rate according to the form:

$$\overline{R}_s^{-1} = a + b\dot{m} + c/[\overline{P}]$$

where a, b and c are constants and the bracket symbols, [ ], indicate the mean for a given experiment. The term in a represents a transport coefficient for viscous flow according to Poiseuille's law, the term in b is a correction of Poiseuille's law for short tubes, and the term in c represents the contribution of free molecular or Knudsen flow. As the pressure decreases and water–stopper collisions become much more frequent than water–water collisions, the term in c dominates and R_s (Eq. 4) becomes independent of pressure.

Regression analysis of $\overline{R}_s$ data for the 20-mm closure determined from Eq. 7 for runs where [P] varied between 0.08 and 0.35 mm and $\dot{m}$ varied between 0.25 and 0.6 g/hr resulted in a = 183, b = −8.0, and c = 3.7. For the pressures and sublimation rates encountered in this research, the term in a dominated, indicating the flow mechanism as mostly viscous. Moreover, during any given experiment designed to measure dried product resistance, variations in $\dot{m}$ and P during primary drying are modest, causing only slight variation in $\overline{R}_s$. Typically, $\overline{R}_s$ deviates from its mean value by no more than ~ ±5% during the portion of primary drying where product resistance data is evaluated, and $\overline{R}_s$ may be regarded as a constant without introducing significant error. For experiments with the 13-mm closure, P was nearly constant so $\overline{R}_s$ also was considered constant.

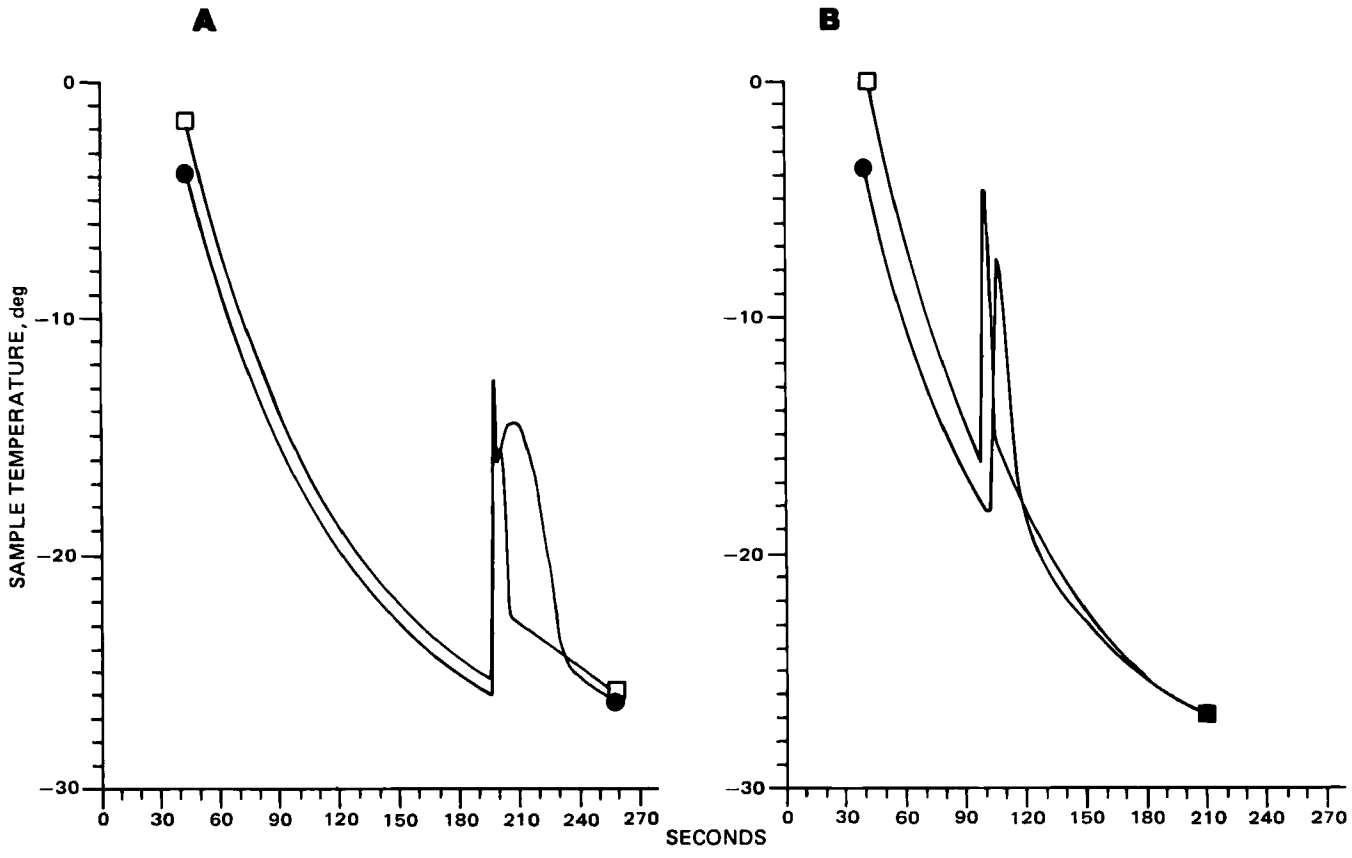

Figure 5—*Freezing curves for microbalance samples of potassium chloride 10% v/v (A) and 22.8% v/v povidone (B). Key: (●) top and (□) bottom of each sample.*

freezing. For both water and potassium chloride, freezing began simultaneously at the top and bottom; for povidone freezing began at the bottom ~4 sec before the top started to freeze. In all cases, freezing was complete at the bottom before the top was completely frozen. The time elapsed between onset and completion of freezing was 13.8 ± 4.2 sec for pure water, 10.2 ± 0.3 sec for povidone, and 31.2 ± 6.0 sec for potassium chloride (mean ± *SD* calculated from replicate experiments).

Cooling curves for the samples frozen in vials qualitatively show the same features exhibited for the microbalance samples (Fig. 5). The samples supercooled, some ice formed throughout the solution quickly, and there was a delay in freezing the remainder of the water, with the top being the last to completely freeze. However, potentially significant quantitative differences exist between the microbalance and vial-freezing behavior. The degree of supercooling for vial-frozen solutions was <50% of that found for the corresponding microbalance solutions, and the time elapsed between onset and completion of freezing was ~30 min for vial-frozen samples. Thus, a vial-frozen sample is subjected to a much slower freezing rate, which may allow ice crystals to anneal or grow in size during freezing.

In both the freeze-drying microscope and microbalance studies, freezing was completed very quickly after the first ice crystals formed; a slow-freezing process which accurately imitates vial freezing was not possible. However, as a first approximation to a vial-freezing process, a sample quick-frozen normally in the microscope or microbalance apparatus was annealed at ~ −8° for 0.5 hr, after which the temperature was reduced to the desired freeze-drying temperature at a rate of ~0.4°/min. This procedure was intended to allow ice crystal growth similar to that which occurs during slow-freezing in a vial.

Microscopic Observation of Freeze-Drying—Photomicrographs (Fig. 6) illustrate the change in structure of a given material on annealing for 0.5 hr at −8°. The darker region at the left of the photograph is the dried sample, while the lighter region on the right still contains ice. Photographs in the left column are quick-frozen samples where the entire sample freezes within seconds, while the right column contains the corresponding annealed samples. Local regions which contain only ice or void are transparent and appear light. The solute is concentrated between the ice crystals and also appears to deposit in a very thin film on the surfaces of the glass coverslips used to contain the sample. The solute concentrated between ice crystals appears dark in both dried and undried regions. The solute deposited on the coverslips is normally semitransparent in the region still containing ice but, at least for crystalline solutes (*i.e.*, potassium chloride), appears dark after the ice has sublimed.

Annealing increased the size of the ice crystals and therefore also increased the size of the voids or pores left after sublimation of the ice. The effect was modest for System I but was marked for both potassium chloride and povidone, where qualitative changes in structure accompanied the growth of ice crystals. The dendrite (1) pattern of ice crystals formed when the aqueous potassium chloride solution froze (Fig. 6A) was lost on annealing (Fig. 6B). The pattern in aqueous povidone (Fig. 6C), which might be classified as irregular dendrite (1, 2), was transformed by annealing to an ice structure largely composed of large globular ice crystals completely surrounded by solute (Fig. 6D). This globular ice structure (Fig. 6C) is qualitatively similar to the ice structure in concentrated (50% solute) aqueous povidone (13).

All nonannealed samples appeared to freeze-dry predominantly by a MacKenzie type I mechanism (13), where water vapor escaped *via* open channels or pores created by prior sublimation of ice until the boundary between dried solute and vacuum chamber (edge of sample) was reached. Both amorphous samples (System I and povidone) showed a glassy region (without ice crystals) at this boundary which developed cracks during drying. This region was presumably a film of solute containing absorbed water which, on partial dehydration, decreased in volume sufficiently to form cracks. Annealed povidone freeze-dried largely by a MacKenzie type II mechanism (13). Here, the water vapor dissolved in and diffused through the solute wall surrounding the ice crystal before leaving the globular cavity. The arrow in the lower center of Fig. 6D indicates the ice–vapor interface in the interior of one partially dried cavity. Thus, the rate of freeze-drying for a type II mechanism potentially is determined by solid-state diffusion of water in the amorphous solute, while the rate for a type I mechanism is determined by flow of water vapor in the porous matrix created by the solute pore structure.

The annealing temperature (−8°) was higher than the eutectic temperature of aqueous potassium chloride (−11°) (24) and the collapse temperature of the povidone used (−17°), but was lower than the collapse temperature of System I[21]. Thus, both potassium chloride and povidone were present in a fluid state during annealing, but the solute in System I was a nonflowable amorphous solid during annealing. The observation that ice crystal growth was rapid in the potassium chloride and povidone

[e] Mean ± *SE*; intended only to provide information on reproducibility between replicate experiments.

systems but slow in System I during annealing suggests that the rate of ice crystal growth is determined, in part, by the fluidity of the solute phase.

Sublimation of Pure Ice—Resistance data calculated from Eq. 8 for pure ice are summarized in Table I. When pure ice is sublimed, $\hat{R}_p$ reflects the resistance in transforming water from the solid state to the vapor state (*i.e.*, the phase change) plus the resistance in transport of water vapor from the ice–vapor interface to the top of the capillary tube. The value of l, as calculated from Eq. 9, is the distance from the ice–vapor interface to the location of this interface at time zero. Since the interface is 0.1 cm below the top of the capillary tube at time zero, the total tube length above the interface (l_T) is given by: $l_T = 0.1 + l$. The $\hat{R}_p$ data were found to increase linearly with increasing l:

$$\hat{R}_p = A_0 + A_1 l \qquad \text{(Eq. 10)}$$

where A_0 and A_1 are constants for a particular temperature. Since the sublimation rates are high and decrease as l increases, the sample temperature increases slightly during an experiment. Thus, both the initial temperature, $t(l = 0)$, and the mean sample temperature during the experiment, $\langle t \rangle$, are reported. The mean normalized product resistance, $\langle \hat{R}_p \rangle$, defined by:

$$\langle \hat{R}_p \rangle = \int_0^1 \hat{R}_p dl \qquad \text{(Eq. 11)}$$

is also tabulated.

The evaporation coefficient (α_v) where $0 < \alpha_v < l$, represents the ratio of the actual sublimation rate to the sublimation rate calculated from simple kinetic theory under conditions of zero resistance offered by the sample container (*i.e.*, the capillary tube). The evaporation coefficient is defined by:

$$\dot{m}(l_T = 0) = \alpha_v A_p \left(\frac{M_1}{2RT}\right)^{1/2} (P_0 - P_1^D) \qquad \text{(Eq. 12)}$$

where $\dot{m}(l_T = 0)$ is the sublimation rate extrapolated to $l_T = 0$, M_1 is the molecular weight of water, R is the gas constant, and T is the absolute temperature (25). All quantities are in CGS units. Combination of Eqs. 8, 10, and 12, evaluation of constants, and conversion to consistent units give:

$$\alpha_v = (1.122)10^{-3}\sqrt{T}/(A_0 - 0.1A_1) \qquad \text{(Eq. 13)}$$

Evaporation coefficients calculated from Eq. 13 and the data in Table I where $P_2^D = 0$ compare favorably with literature data (25–27) (Fig. 7). Since potential errors in sample temperature measurement are much higher for pure ice than for frozen solutions, the agreement shown in Fig. 7 provides strong evidence for the validity of the temperature measurement procedures used in this research.

An increase in residual air pressure (*i.e.*, $P_2^D > 0$) increases both the resistance of the phase change, measured by A_0, and the resistance of the capillary tube, measured by A_1. Both effects presumably originate from collisions between water molecules and air. However, even when P_2^D is approximately equal to the equilibrium vapor pressure of ice (0.350 torr), the sublimation rate remains high, decreasing by a factor of ~2 from the rate at zero pressure.

Dried Product Resistance—*Representation of Data by Empirical Equations*—The variation of normalized product resistance ($\hat{R}_p$) with thickness of dried product (l) is represented by the empirical equation:

$$\hat{R}_p = (A_0 + A_1 l)/(1 + A_2 l), \qquad l' \le l \le 1 \text{ cm} \qquad \text{(Eq. 14)}$$

where $l' = 0$ for most systems studied (*i.e.*, Eq. 14 is valid over the interval $0 \le l \le 1$ cm).

[21] System I does not exhibit a collapse temperature up to −6.5°, where partial melting of the ice crystals (melt-back) occurs.

The parameters A_0, A_1, and A_2 are determined by regression analysis of the raw data. The data are summarized in Table II where the first column provides a curve identification number for each set of experimental conditions, and the corresponding, the A_i ($i = 0, 1, 2$) parameters, mean normalized product resistance ($\langle \hat{R}_p \rangle$), and value of the normalized product resistance at $l = 0$ [$\hat{R}_p(0)$], which are reported in each row. The value of n gives the number of independent replicate experiments. The A_i ($i = 0, 1, 2$) and resistance data tabulated are mean values with the corresponding uncertainty being the standard deviation of the mean. The uncertainty figures are given only to indicate the reproducibility between replicate experiments. Reproducibility of $\hat{R}_p$ data (approximately given by the reproducibility of the corresponding $\langle \hat{R}_p \rangle$ data) was frequently much poorer than one might predict from the scatter in $\hat{R}_p$ *versus* l data from a single experiment, a result perhaps attributable to real differences between samples caused by the inability to precisely control the freezing process. Even for the same chemical system, reproducibility of the raw data (Fig. 8) varies from excellent (curve 16) to poor (curve 15).

In general, Eq. 14 is a valid representation of the raw data even as $l \to 0$, and $\hat{R}_p(0) = A_0$. However, for curves 13, 14, 16, and 17, Eq. 14 is valid only for $l > 0.2$ cm [$\hat{R}_p(0) > A_0$]. In the following discussion all $\hat{R}_p$ *versus* l data were calculated from Eq. 14 where this equation was a valid representation of the raw data. In those cases where Eq. 14 was not valid, mean values of the raw data are used.

Dependence of $\hat{R}_p$ on l—Theoretical models in common use (11, 28) assume the equivalent of $\hat{R}_p \propto l$, which results in the quantity of ice sublimed being directly proportional to the square root of time. Essen-

[a] Parameters for the normalized product resistance equation $\hat{R}_p(l) = (A_0 + A_1 l)/(1 + A_2 l)$. [b] Normalized product resistance equation represents data for only $l > 0.2$ cm. As $l \to 0$, the resistance increases to $\hat{R}_p(0)$. Only one of the duplicate experiments on System I at $P_2^D = 0.190$ showed this phenomenon, resulting in the unusually high uncertainty in $\hat{R}_p(0)$.

tially four classes of $\hat{R}_p$ dependence on l have been observed in this research (Fig. 9), none of which correspond to a simple proportionality to l. With the possible exception of curve 8 (Table II), all data show a nonzero intercept at $l = 0$ and the dependence of $\hat{R}_p$ on l is frequently nonlinear. Type I curves show a linear dependence of $\hat{R}_p$ on l throughout the range $0 \leq l \leq 1$. A type II curve exhibits a sharp decrease in $\hat{R}_p$ at low l, followed by a linear increase in $\hat{R}_p$ with increasing l for $l > 0.2$ cm. Type III and type IV curves are concave toward the l axis, the curvature being slight for type III curves but severe for type IV.

The observation that $\hat{R}_p(0)$ is significantly larger than zero suggests the presence of a surface barrier resulting from a different structure for the dried product near the surface, a conclusion consistent with scanning electron microscopic observations (14). A large resistance accompanying the phase change at the ice–vapor interface would give the same result. However, the $\hat{R}_p(0)$ data for solution systems (Table II) are generally one to two orders of magnitude greater than $\hat{R}_p(0)$ for pure ice (Table I), and it does not appear reasonable that the phase change resistance for ice crystallized from a solution would be that much higher than the corresponding resistance for ice crystallized from pure water. As suggested by the microscopic observations discussed earlier, the surface barrier for type II curves appears to be a relatively high-resistance amorphous skin which, after some water desorption, cracks and decreases in effective resistance.

The nonlinearity of the type III and type IV curves may be related, in part, to a gradual variation in dried product structure as l increases. However, the observation that the curvature is temperature dependent (*i.e.*, compare curves 1–3, 15, and 16) indicate that product heterogeneity is not the only factor.

Effect of Solute Concentration on $\hat{R}_p$—An increase in concentration changed the $\hat{R}_p$ *versus* l curve for potassium chloride from a type III to a type IV curve (Fig. 10). The resistance curves for povidone (Fig. 11) show a transition from type I at low concentration to type II at high concentration, where the resistance at $l = 0$ increased sharply at high

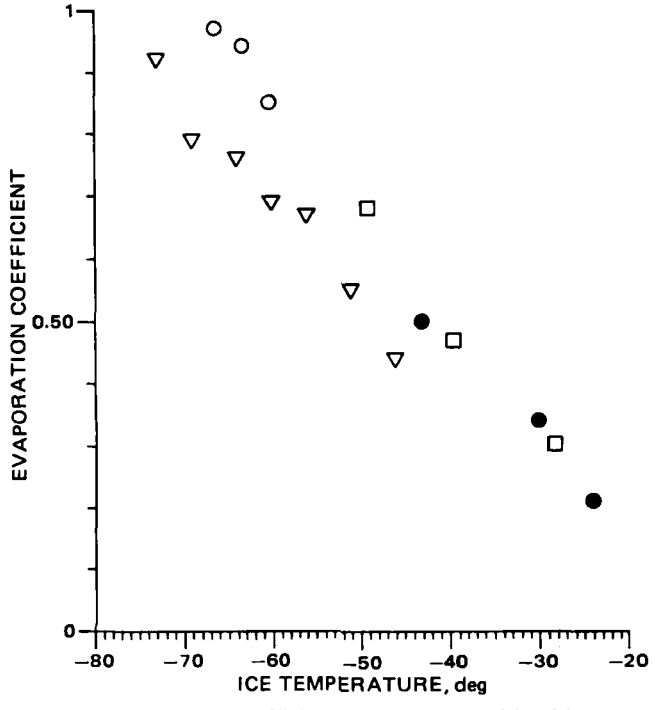

Figure 7—*Evaporation coefficients for ice obtained by this research (●), and (for comparison) taken from Refs. 25 (□), 26 (○), and 27 (▽).*

concentration. Evidently, the postulated amorphous skin phenomenon increases in significance as the concentration increases.

The mean normalized product resistance ($\langle \hat{R}_p \rangle$) increased as the concentration increased (Fig. 12). For potassium chloride, the increase was essentially linear in volume percent solid, while in the case of povidone, $\langle \hat{R}_p \rangle$ increased sharply with increasing concentration only at low concentration. Above ~10% solute (v/v), $\langle \hat{R}_p \rangle$ for povidone is nearly independent of concentration. Therefore, the drying time for a 1-cm deep potassium chloride solution will be twice as long for a 10% as for a 5% solution[22]. As a first approximation, the drying time for a 1-cm deep povidone solution is independent of concentration between 10% and at least 23% solute.

Effect of Annealing—The microscopic studies (Fig. 6) indicate that annealing resulted in larger ice crystals with correspondingly larger voids or pores in the dried solid. For potassium chloride, both quick-frozen and annealed samples appeared to freeze-dry by a type I mechanism, but annealing a povidone system caused a change from a type I to a type II freeze-drying mechanism. Assuming resistance decreases as pore size increases, one would expect that annealing the potassium chloride system would result in a lower product resistance. Since annealing a povidone system changes the freeze-drying mechanism, the net effect of annealing on the product resistance is not obvious.

Comparison of quick-frozen with annealed samples shows a significant decrease in $\hat{R}_p$ at all l values on annealing. This effect is very pronounced for potassium chloride (Fig. 13) and smaller, though still significant, for povidone (Fig. 14). Annealing potassium chloride resulted in a transition from a type III curve (nonlinear) to a curve which is nearly type I (linear). Intuitively, one would expect variations in product structure with l to be reduced by annealing. Thus, the observed effect of annealing on the resistance curve type appears consistent with the postulate that curvature in a resistance curve is related to structural heterogeneity.

[22] The reviewer suggested that the concentration dependence of $\langle \hat{R}_p \rangle$ for potassium chloride may be related to the increase in the ratio of eutectic–pre-eutectic ice as the solute concentration increases. Eutectic ice refers to ice which crystallizes with simultaneous crystallization of solute while pre-eutectic ice denotes ice formed prior to the crystallization of solute. Assuming equilibrium data (24) may be used to calculate the relative amount of eutectic ice formed in a nonequilibrium freezing process, the fraction of ice crystallizing as eutectic ice varies from 0.21 for 2.5% (v/v) to 0.90 for 10% (v/v) potassium chloride. Thus, at 2.5% potassium chloride, $\langle \hat{R}_p \rangle$ should be dominated by the pore structure created by pre-eutectic ice while at 10% potassium chloride the eutectic ice structure should largely determine the resistance behavior. Microscopic observations indicate that eutectic ice is much more finely divided than pre-eutectic ice, and water vapor originating from sublimation of eutectic ice must pass through a network of relatively small pores. Since theory (11) indicates that resistance to vapor flow through pores increases as the pore size decreases, one would expect a higher $\langle \hat{R}_p \rangle$ at higher solute concentration, as observed.

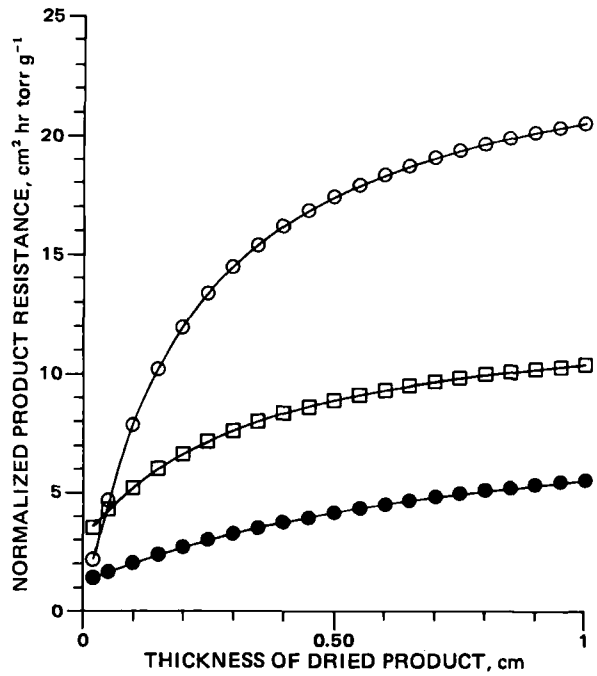

Figure 10—*Effect of solute concentration on $\hat{R}_p$ for potassium chloride at −21°, $P_1^D = 0$. Key: (●) 2.5% v/v; (□) 5.0% v/v; (○) 10.0% v/v.*

Effect of Residual Air Pressure—The data (Table II) indicate a significant increase in $\hat{R}_p$ with increasing air pressure (P_2^D) for 5% povidone at −31° and essentially no pressure effect for System I. The effect of pressure on $\hat{R}_p$ for 5% potassium chloride is small and erratic, probably reflecting sample-to-sample freezing variation more than the effect of pressure. To eliminate the effects of sample variation, the effect of air pressure was studied for a given sample by determining the sublimation rate as a function of pressure at constant l; *i.e.*, during the experiment the pressure was increased stepwise and then decreased stepwise. The mean of the $\hat{R}_p$ values (at corresponding pressures) for the increasing and decreasing parts of the experiment generate a set of $\hat{R}_p$ values at constant l as a function of air pressure. The results (Fig. 15) indicate $\hat{R}_p$ increased with increasing air pressure, the effect being very small for 5% potassium chloride at −21°, but quite significant for 5% povidone at −31°.

One would expect that increasing air pressure would yield an increasing probability of gas phase molecular collisions between water and air. When the frequency of water vapor–air collisions in the dried product becomes comparable in magnitude to the frequency of water vapor collisions with

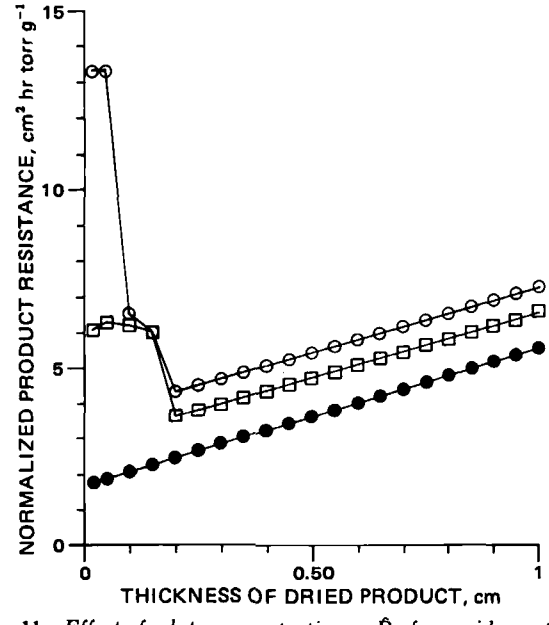

Figure 11—*Effect of solute concentration on $\hat{R}_p$ for povidone at −26°, $P_1^D = 0$. Key: (●) 5.0% v/v; (□) 10.0% v/v; (○) 22.8% v/v.*

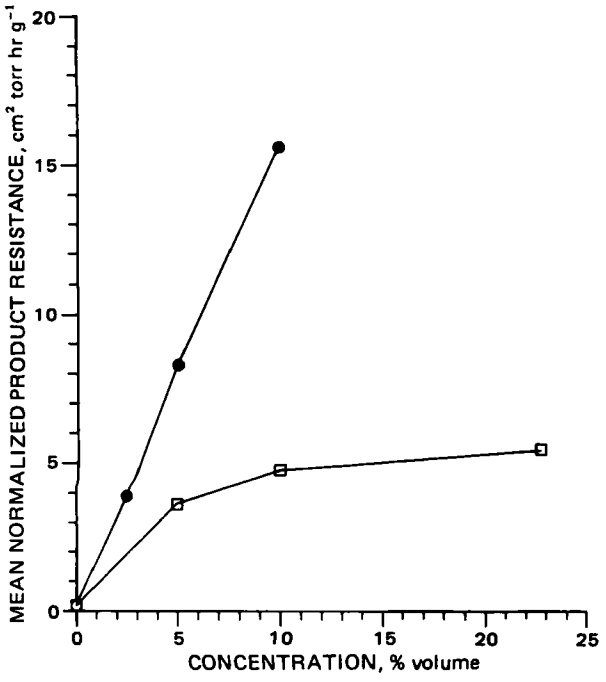

Figure 12—*Mean normalized product resistance ($\langle \hat{R}_p \rangle$) versus solute concentration for (●) potassium chloride at −21°; (□) povidone at −26°.*

the dried product matrix, the resistance due to water–air collisions should become a measurable fraction of the resistance originating from water–matrix collisions. Thus, increasing the air pressure above the sample should increase the product resistance, as observed. As the pore size decreases, the frequency of water–matrix collisions increases and the air pressure at which water–air collisions become comparable to water–matrix collisions will increase. Thus, the product resistance should be less sensitive to air pressure as the pore size decreases. The product resistance of potassium chloride at zero air pressure was much greater than the corresponding resistance for povidone, suggesting that the pore size in freeze-dried potassium chloride is much smaller. Consequently, the slope of the resistance *versus* air pressure curve should be less for potassium chloride than for povidone. The difference in pore size between potassium chloride and povidone is probably a result of the formation

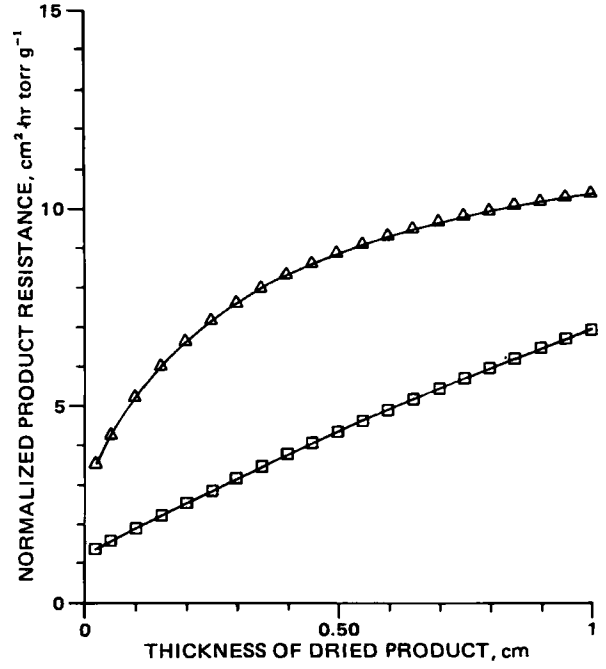

Figure 13—*Effect of annealing on $\hat{R}_p$ for potassium chloride 5% v/v at −21°, P_1^D = 0. Key: (△) not annealed; (□) annealed.*

of eutectic ice in the potassium chloride system. Being amorphous, povidone does not form a eutectic.

The arrows in Fig. 15 indicate the values of the vapor pressure of ice at the corresponding product temperatures (−21.2° for potassium chloride and −31° for povidone). The normalized product resistance increased smoothly as the residual air pressure approached and exceeded the vapor pressure of ice. Thus, the common observation that the sublimation rate decreases sharply as the chamber pressure approaches the vapor pressure of ice (29) is not a result of increasing product resistance. Indeed, sublimation proceeded rapidly even when the residual air pressure was well above the vapor pressure of ice. This apparent anomaly may be resolved by reference to Eq. 8, where the driving force for sublimation is taken as the difference in pressure of water vapor between the ice–vapor

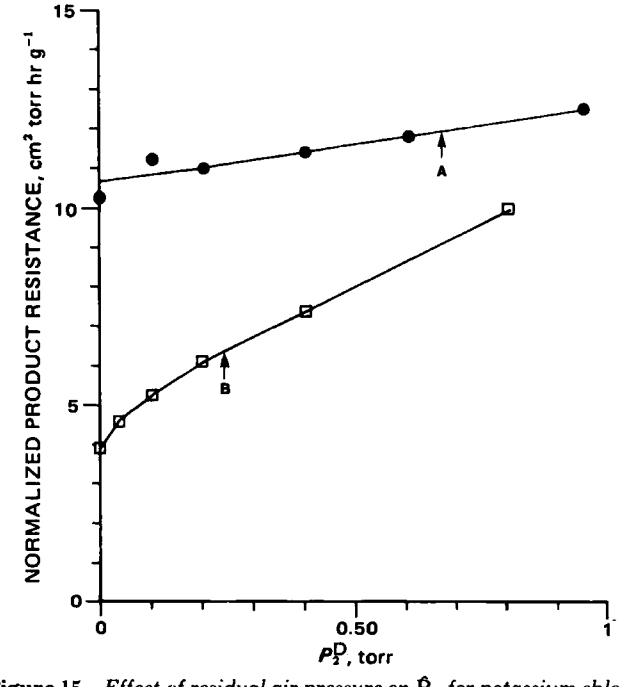

Figure 15—*Effect of residual air pressure on $\hat{R}_p$ for potassium chloride 5% v/v at −21.2°, l = 0.52 cm (●) and 5% v/v povidone at −31.0°, l = 0.70 cm (□). The arrows indicate the vapor pressure of ice (P_0) at −21.2° (A) and −31.0° (B).*

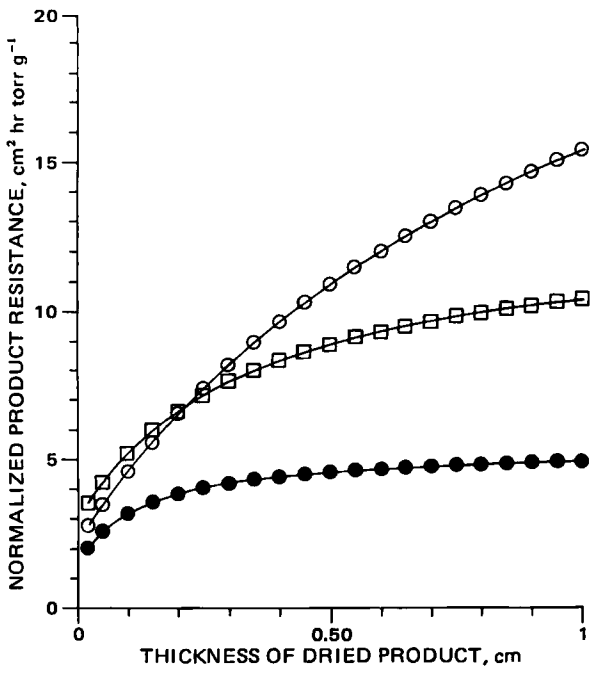

Figure 16—*Effect of temperature on* $\hat{R}_p$ *for potassium chloride 5% v/v,* $P_1^D = 0$. *Key: (●) −13.9°; (□) −20.9°; (○) −29.8°.*

interface (P_0) and the region above the dried product (P_1^D). With the microbalance apparatus, P_1^D is essentially zero even when the chamber pressure is well above the vapor pressure of ice. However, in an apparatus designed for vial freeze-drying, an increase in chamber pressure by means of a controlled air leak increases the value of P_1^D. Indeed, as a first approximation, P_1^D is equal to the chamber pressure. If the shelf temperature is adjusted to maintain constant product temperature, P_0 is constant, and the driving force for sublimation decreases sharply as the chamber pressure approaches P_0, thereby sharply decreasing the sublimation rate.

Effect of Temperature—The effect of temperature (Figs. 16–18) on $\hat{R}_p$ is quite dramatic for potassium chloride and System I, but is barely significant for povidone (between −26 and −31°). An increase in temperature resulted in a transition from a type III (potassium chloride) or a type II (System I) curve to a type IV curve with a significant reduction in $(\hat{R}_p)$ (Fig. 19).

It might be postulated that the observed temperature effect is really a pressure effect. That is, the higher temperature produces a higher mean pressure in the porous medium which, in turn, changes the gas flow mechanism from a free molecular (Knudsen) flow to a viscous flow mechanism. For viscous flow, the dried product resistance is inversely proportional to the mean pressure in the dried product (11, 12), which is one-half the vapor pressure of ice for the data in Figs. 16–18. Thus, if the mean pressure were high enough to result in viscous flow of water vapor, an increase in temperature would decrease the dried product resistance. However, based on the usual theories for flow of rarified gases in channels (11, 12), the mean pressure was far too low for viscous flow of water vapor in the dried product.

For the usual capillary-tube model describing gas flow in a porous system (11, 12, 30), the normalized product resistance is given by:

$$\hat{R}_p = \hat{R}_k[1 - (1 - 35\pi/128)X/(1 + X) + (3\pi/128)X^2/(1 + X)]^{-1} \quad \text{(Eq. 15)}$$

where X is the ratio of the capillary pore diameter (D) to the mean free path (λ): $X = D/\lambda$. The low pressure limit for $\hat{R}_p$ is the Knudsen flow resistance ($\hat{R}_k$) which, in CGS units of dynes sec g^{-1}, is given by:

$$\hat{R}_k = l\frac{\tau^2}{\epsilon}\frac{3}{2}\sqrt{\frac{\pi RT}{2M_1}}\frac{(f)}{(2-f)}\frac{1}{D} \quad \text{(Eq. 16)}$$

where τ is the tortuosity (or ratio of the actual length of a capillary tube to the thickness of the dried product) and f denotes a momentum accommodation coefficient representing the fraction of gas molecule–tube collisions which result in diffuse reflectance upon collision (*i.e.*, for diffuse reflectance the velocity of a molecule after collision is independent of its incident velocity). Normally, f is assumed to be unity.

Since the mean free path is inversely proportional to pressure, X approaches zero at low pressure and $\hat{R}_p \to \hat{R}_k$. At high pressure, $X \gg 1$ and transport of water vapor is by a viscous flow mechanism yielding $\hat{R}_p = \hat{R}_k(128/3\pi)/X$. For a freeze-drying experiment where the mean pressure in the dried product is one-half of the vapor pressure of ice, numerical evaluation yields $X = P_0D$ (μm)/146. Thus, the condition $X \gg 1$ implies $D \gg 100$ μm for the highest pressure studied in this research. However, the pore diameters determined either from the sample surface area[23] (30) or microscopic examination (Fig. 6) are $\ll 100$ μm, indicating $X \ll 1$. Thus, the vapor flow mechanism in freeze-drying closely approximates Knudsen flow, not viscous flow.

The pore diameter for freeze-dried potassium chloride evaluated from the surface area is ~10 μm, while the microscopic data (Fig. 6) indicate that the larger pores or channels have a diameter of ~30 μm. Assuming that f is independent of temperature and vapor pressure, and taking D = 30 μm, the calculated change in $\hat{R}_p$ on increasing the temperature from −30 to −14° is an increase of 5%, obviously not consistent with the data which show a decrease in resistance of ~60%.

If the momentum accommodation coefficient (f) were assumed to decrease as the freeze-drying temperature increases, the data could be reconciled with Eqs. 15 and 16. Accommodation coefficients are extremely sensitive to the nature of the surface and, particularly for very clean solid surfaces, may be much less than unity (12, 21, 31). However, as surface impurities are introduced or the vapor is adsorbed on the surface, accommodation coefficients generally increase, and at a surface coverage of one or more monolayers, diffuse scattering (*i.e.*, $f = 1$) is observed (31). This result is consistent with the observation that the energy accommodation coefficient is unity for liquids and their own vapors (31) and the conclusion that under conditions where the energy accommodation coefficient is unity, the momentum accommodation coefficient is also unity (32). Thus, if the surface coverage would decrease below monolayer coverage as the freeze-drying temperature increased, there would be justification for assuming the temperature dependence of $\hat{R}_p$ is due to a decrease in f.

As the temperature increases at constant water activity, the surface coverage will decrease slightly (33), at least in the submonolayer region. However, in the freeze-drying system, an increase in temperature also increases the thermodynamic activity of water, which increases the surface coverage. The net effect of increasing the temperature will depend on the nature of the adsorption isotherm. Extrapolation of adsorption data for water–alkali halide systems (34–36) to the temperature range of interest in freeze-drying indicates that the mean surface coverage in the dried product at −30° is considerably in excess of monolayer, and the

[23] The specific surface areas for vial freeze-dried samples, determined by BET (Brunauer-Emmett-Teller) treatment of gas adsorption, are: potassium chloride (4 m^2/g), povidone (0.7 m^2/g), and System I (3 m^2/g).

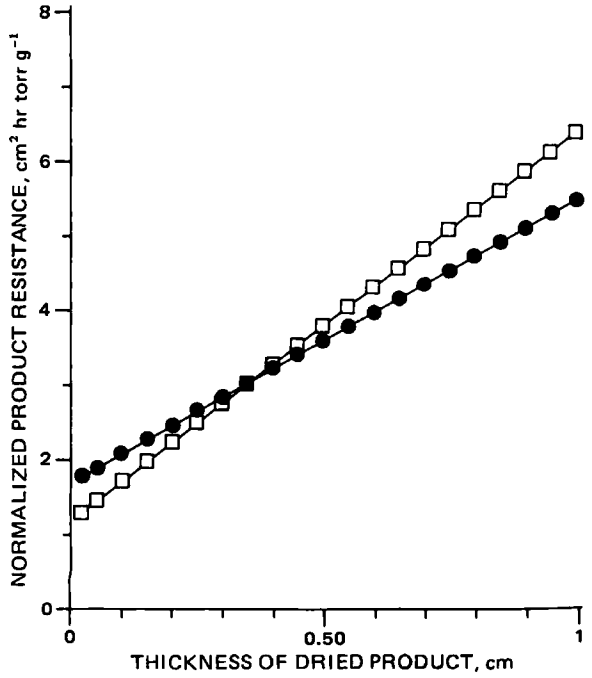

Figure 18—*Effect of temperature on* $\hat{R}_p$ *for 5% v/v povidone,* $P_1^p = 0$. *Key: (●) −26.0; (□) −31.2°.*

surface coverage increases with increasing temperature. Thus, the mean momentum accommodation coefficient should be close to unity at all temperatures; if there is a small change in f with increasing temperature, this change should be an increase toward a limiting value of unity. Thus, the observed decrease in resistance as the freeze-drying temperature increases cannot be attributed to changes in f. Rather it appears that there exists some flow mechanism other than that described by Eq. 16.

Equation 16 describes only the flow of water vapor in the open channels of the porous system. However, experimental and theoretical studies of the flow of condensable gases in porous media indicate that surface flow of the adsorbed gas can be the dominant flow mechanism when the mass of the adsorbed phase in the sample greatly exceeds the mass of the vapor phase (30, 37–39). Since the mass of the adsorbed phase is proportional to the product of the specific surface area (S) and the fraction of surface coverage (θ), surface flow may be important even below monolayer coverage (*i.e.*, $\theta < 1$) provided the specific surface area is large. Alternately, surface flow may be important with samples of moderate surface area provided the pressure is high enough to result in multilayer coverage (*i.e.*, $\theta > 1$). In the submonolayer case, surface flow proceeds by a diffusion mechanism involving activated translational motion from an occupied adsorption site to an unoccupied site. In the multilayer case, particularly when $\theta \gg 1$, surface flow is more properly described as hydrodynamic flow of the adsorbed gas analogous to either flow of a thin liquid film along a surface (large pores) or capillary flow of a liquid (micropores).

We therefore postulate that, at least at high temperature where surface coverage is high, mass transfer in freeze-drying may be dominated by hydrodynamic surface flow of the adsorbed water. As the freeze-drying temperature increases, the surface coverage (θ) and the fluidity of the adsorbed phase increase, both effects increasing the rate of surface flow. Adsorption data (34, 40) for potassium chloride indicate that θ increased very rapidly as the thermodynamic activity of water approached the water activity of the saturated solution, and the adsorbed film reached a thickness of 0.1–1 μm before the solid dissolved. Similarly one would expect that, as the temperature of a freeze-drying system approaches the eutectic temperature (or collapse temperature for an amorphous solute), θ would increase rapidly. Indeed, microscopic observations of a potassium chloride–water system freeze-drying near the eutectic temperature (13) of −11° appear consistent with an adsorbed film of liquid ~1 μm in thickness near −13° which decreased sharply in thickness as the temperature decreased. Since the evidence suggests that θ increases dramatically as the eutectic temperature is approached, one might also expect the ratio of surface flow–gas flow to increase as the temperature increases, resulting in surface flow being dominant near the eutectic (or collapse) temperature where θ is very large. Thus, we propose that the observed decrease in dried product resistance resulting from an increase in temperature is a consequence of the emergence of surface flow as an additional flow mechanism for transport of water.

Comparison of Microbalance and Vial Results—The question of how closely a microsample freeze-drying in a capillary tube represents a macrosample freeze-drying in a vial remains. In principle, since the diameter of the capillary tube is much greater than the pore diameter of the dried product, the normalized resistance should be independent of the sample geometry. However, differences in pore structure caused by differences in thermal history are potentially quite important. Moreover, the effect of a nonzero partial pressure of water vapor above the surface of the dried product (0.1 torr for vial studies *versus* 0.00 torr for microbalance studies) may be significant, at least for an amorphous product where the resistance is determined partially by permeability and cracking of the amorphous skin covering the surface.

Since the thermal history of an annealed microbalance sample more closely resembles the thermal history of a vial-frozen sample, one expects better agreement of the vial data with the annealed microbalance samples than with the quick-frozen microbalance samples. Indeed, for potassium chloride the agreement between vial and annealed microbalance results is nearly quantitative (Table III), whereas the quick-frozen microbalance resistance data are higher by nearly a factor of 2. The data for System I (Table III) demonstrate that the effect of temperature is qualitatively the same for both vial- and quick-frozen microbalance results. In both cases, the resistance increased linearly with l for the −21° data, but when the temperature was increased to ~ −15°, the resistance became independent of l over the range of l values studied and the value of $\langle \hat{R}_p \rangle$ decreased. In the case of povidone, the vial resistance data are in much better agreement with the *quick-frozen* microbalance data. This observation may suggest that annealing is a poor approximation for a slow-freeze when the product changes its freeze-drying mechanism on annealing, as is the case with povidone (Fig. 6). In any case, it may be concluded that agreement between vial and microbalance data is at least qualitative and may be quantitative for some materials if the thermal histories of the samples are similar.

CONCLUSIONS

The effect of the potential process variables on the resistance of the dried product layer have been studied by direct determination of sublimation rate under isothermal conditions using a microbalance technique. The results have at least qualitative validity for vial freeze-drying. Contrary to popular theoretical models, the resistance of the dried product layer is not directly proportional to its thickness (a result attributed to heterogeneity in solute structure) and is not independent of temperature. Current theoretical models assume mass transfer is exclusively *via* the gas phase. This study suggests that, at least at higher

temperatures, hydrodynamic surface flow of adsorbed water is an important flow mechanism which may account for the observed temperature dependence of the dried product resistance.

APPENDIX I: HEAT TRANSFER THEORY AND TEMPERATURE MEASUREMENTS

Although the sublimation cell is designed to maximize heat transfer, numerical estimates suggest that, at least for the high sublimation rates expected for pure water, the temperature difference between thermostat and the subliming ice could be significant. In this section, a theoretical model is developed which, on experimental evaluation of heat transfer parameters, allows the ice temperature to be determined from measurement of probe (or thermostat) temperature, sublimation rate, and residual air pressure in the chamber. The heat transfer coefficients were evaluated with a series of sublimation experiments where the sample temperature was measured by a thermocouple (denoted J) embedded in the sample 1 mm from the bottom of the capillary tube.

Assuming steady state:

$$\dot{m}\Delta\overline{H}_s = \dot{Q}_s = \dot{q}_{bc} + \dot{q}_{pc} + \dot{q}_{aJ} + \dot{q}_{ac} \qquad \text{(Eq. A17)}$$

where $\dot{m}$ is the sublimation rate (g/sec), $\Delta\overline{H}_s$ is the heat of sublimation (cal/g), $\dot{Q}_s$ is the rate of heat removal by sublimation, $\dot{q}_{bc}$ is the heat transfer rate from thermostat (bath) to the sublimation cell by radiation and conduction, $\dot{q}_{pc}$ is the heat transfer rate from the probe to the cell by radiation and conduction, $\dot{q}_{aJ}$ is the heat transfer rate from ambient to the J thermocouple junction in the sample through the 30-gauge (0.23-mm diameter) thermocouple wires, and $\dot{q}_{ac}$ is the heat conducted from the balance at ambient temperature to the cell *via* radiation and conduction through the hang-down wire. Numerical estimates indicate $\dot{q}_{bc} \gg \dot{q}_{pc}$. Since heat transferred to the cell is then transferred to the subliming ice (sample), the rate of heat transfer from cell to sample ($\dot{q}_{cs}$) is:

$$\dot{q}_{cs} = \dot{q}_{bc} + \dot{q}_{pc} + \dot{q}_{ac} \qquad \text{(Eq. A18)}$$

The heat transfer rates, $\dot{q}_{ij}$ (i = a, b, c, p; j = c, s, J) are assumed to be of the form:

$$\dot{q}_{ij} = k_{ij}(T_i - T_j) \qquad \text{(Eq. A19)}$$

where k_{ij} are heat transfer parameters and T_i and T_j are the absolute temperatures of apparatus components i and j, respectively. While Eq. A19 is rigorous for heat transfer *via* conduction, the form of Eq. A19 is only an approximation for heat transferred *via* radiation[24].

The probe thermocouple wire makes thermal contact at three points: with the surroundings at ambient temperature (T_a), with the bath at temperature T_b, and with the cell at temperature T_c. The thermal resistance of the wire between the ambient contact and the bath contact is denoted R_{w1}, the thermal resistance of the bath–wire contact (through the apiezon wax) is denoted R_{wb}, and the thermal resistance of the wire from the bath–wire contact to the probe junction is denoted R_{w2}. With these definitions, analysis of the steady-state heat flow in the probe wire yields:

$$\dot{q}_{pc} = k_{pc}(T_p - T_c) = k_{ap}(T_a - T_p) + k_{bp}(T_b - T_p) \qquad \text{(Eq. A20)}$$

where T_p is the probe temperature and k_{ap} and k_{bp} are composite heat transfer coefficients given by:

$$k_{ap} = \frac{R_{wb}}{R_{wb}(R_{w1} + R_{w2}) + R_{w1}R_{w2}} \qquad \text{(Eq. A21)}$$

[24] For radiative heat transfer between two bodies (22):

$$\dot{q}_{ij} = a_{ij}(T_i^4 - T_j^4)$$

where T_i and T_j are the absolute temperatures of bodies i and j, respectively, and a_{ij} depends on system geometry and emissivities of the bodies. When the temperature difference ($T_i - T_j$) is significantly less than the mean temperature ($\overline{T}_{ij}$):

$$\dot{q}_{ij} = 4\,\overline{T}_{ij}^3 a_{ij}(T_i - T_j) = k_{ij}(T_i - T_j)$$

which is of the same form as Eq. A19. However, the k_{ij} parameter for radiative heat transfer is temperature dependent, whereas the corresponding parameter describing conductivity is essentially independent of temperature. As a first approximation, valid for modest temperature ranges, the temperature dependence of k_{ij} for radiative heat transfer can be ignored. Also, for purposes of numerical estimates, the approximation, $a_{ij} = e\sigma A_{ij}$, will be used, where e is the emissivity (1 for the bodies of interest in this research), A_{ij} is the area common to both bodies, and σ is the Stefan-Boltzmann constant.

Table III—Comparison of Microbalance and Vial Resistance Data

l, cm	Normalized Product Resistance ($\hat{R}_p$), cm² hr torr g⁻¹: Vial[a]	Microbalance, Annealed	Microbalance, Quick-Frozen

[a] The resistance data represent the mean of four replicate experiments for potassium chloride, two replicate experiments for povidone, and two replicate experiments for System I. [b] Uncertainties are estimated standard errors as calculated from reproducibility of replicate experiments. [c] The microbalance samples are amorphous but the vial samples contain some poorly crystallized mannitol (X-ray and microscopic observations).

and

$$k_{bp} = \frac{R_{w1}}{R_{wb}(R_{w1} + R_{w2}) + R_{w1}R_{w2}} \qquad \text{(Eq. A22)}$$

With perfect thermal contact of the probe wire with the bath ($R_{wb} = 0$), $k_{bp} = R_{w2}^{-1}$, and $k_{ap} = 0$.

Combination of Eqs. A17–A20 and use of the approximations[25] $k_{pc}/k_{bc} \ll 1$, $k_{ac}/k_{bc} \ll 1$, $(T_a - T_i)/(T_a - T_s) = 1$ (i = p, J), yields:

$$T_p - T_s = (1 + r_p\alpha k_{cs}^{-1})(1 + r_p)^{-1}\alpha^{-1}\Delta\overline{H}_s\dot{m} + (1 + r_p)^{-1}[k_{ap}/k_{bp} - k_{aJ}\alpha^{-1}(1 + r_p\alpha k_{cs}^{-1}) - k_{ac}/k_{bc}](T_a - T_s) \qquad \text{(Eq. A23)}$$

$$T_b - T_p = r_p(1 + r_p)^{-1}k_{bc}^{-1}\Delta\overline{H}_s\dot{m} - (1 + r_p)^{-1}(k_{ap}/k_{bp} + k_{aJ}r_pk_{bc}^{-1} + r_pk_{ac}/k_{bc})(T_a - T_s) \qquad \text{(Eq. A24)}$$

and

$$T_b - T_s = \alpha^{-1}\Delta\overline{H}_s\dot{m} - (\alpha^{-1}k_{aJ} + k_{ac}/k_{bc})(T_a - T_s) \qquad \text{(Eq. A25)}$$

with α and r_p defined by:

$$\alpha = k_{bc}k_{cs}(k_{bc} + k_{cs})^{-1} \qquad \text{(Eq. A26)}$$

and

$$r_p = k_{pc}/k_{bp} \qquad \text{(Eq. A27)}$$

The temperature of the subliming ice is denoted T_s.

Since both the bath–cell and probe–cell heat transfer coefficients, k_{bc} and k_{pc}, respectively, include contributions from vapor phase heat conduction, both coefficients are pressure dependent. Using the Smoluchowski theory (12) to relate the thermal conductivity of a gas to pressure, the heat transfer coefficients (k_{ic}, i = p,b) are of the form:

$$k_{ic} = k_{ic}^0\left[1 + \frac{(\bar{a}\Lambda_0/k_r)P}{1 + \bar{a}(\Lambda_0/\lambda)d_iP}\right] \qquad \text{(Eq. A28)}$$

where

$$\bar{a} = \frac{a_c}{2 - a_c}\sqrt{\frac{273.2}{T}} \qquad \text{(Eq. A29)}$$

The energy accommodation coefficient (a_c) is a numerical constant near

[25] As a first approximation, the ratio k_{pc}/k_{bc} is equal to the ratio of the probe area–cell area, which is ~0.06.

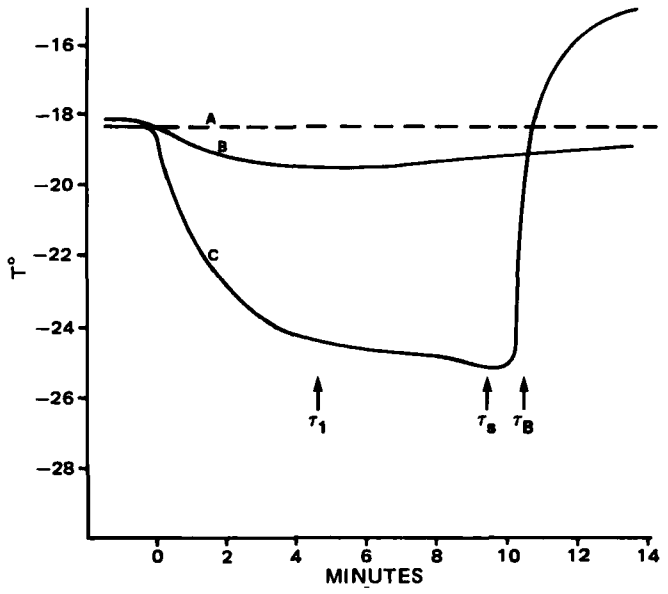

Figure 20—*Temperature* versus *time curve for a calibration experiment at zero pressure using a 10-mg sample of pure water. Key for lines: (A) thermostat; (B) probe; (C) J thermocouple.*

unity (3); k_{ic}^0 represents the radiative heat transfer coefficient; k_r is defined by $k_{ic}^0 = A_i k_r$, where A_i is the area of the probe or cell; Λ_0 is the free-molecule heat conductivity of the gas at 0° (12); λ is the heat conductivity of the gas at ambient pressure (~1 atm); d_i is the separation distance of the hot and cold surfaces, where $d_p = 0.3$ cm and $d_c = 0.6$ cm; P and T are the pressure and absolute temperature, respectively[26].

Preliminary calculations indicate that, as a first approximation, the term $(1 + r_p \alpha k_{cs}^{-1})(1 + r_p)^{-1}$ is essentially independent of pressure. Thus, the pressure dependence in the coefficients of $\dot{m}$ in both Eqs. A23 and A25 is due to the pressure dependence of α, which (from Eqs. A26 and A28) may be written in the form:

$$\alpha^{-1} = (\alpha^0)^{-1} \frac{[1 + (\Lambda_0/\lambda)(d_c + (\lambda/k_r)(1 + k_{cs}/k_{bc}^0)^{-1}P]}{[1 + (\Lambda_0/\lambda)(d_c + \lambda/k_r)P]} \quad \text{(Eq. A30)}$$

where the approximation $\bar{a} = 1$ has been used and the superscript zero on a parameter represents the value of that parameter at zero pressure.

When the sample temperature is not measured directly by a thermocouple embedded in the sample (*i.e.*, as in a normal sublimation experiment), $k_{aJ} = 0$ by definition. A theoretical estimate indicates that k_{ac} is $< 1 \times 10^{-5}$. With this estimate and the experimental value found for k_{bc}, the approximation $k_{ac} = 0$ results in a temperature error of <0.2°. Thus, with $k_{ac} = 0$, combination of Eqs. A23 and A24 gives:

$$T_s = T_p - (1 + r_p^0 \alpha^0 k_{cs}^{-1})(1 + r_p^0)^{-1}\alpha^{-1}\Lambda \bar{H}_s \dot{m} - (1 + r_p)^{-1}(k_{ap}/k_{bp})(T_a - T_p) \quad \text{(Eq. A31)}$$

The parameter k_{cs} in Eq. A31 now refers to the value of the cell–sample heat transfer coefficient in the absence of the J thermocouple wire.

In a temperature calibration experiment the sublimation cell is supported by copper–constantan thermocouple wires (0.23-mm diameter) where the measuring junction (J) is located ~1 mm from the bottom of the capillary tube. This configuration allows the sample temperature to be measured but also prevents the sample mass from being determined. After equilibration of the sample (10.0 mg of pure water) with the thermostat, the chamber was evacuated to the desired pressure and sublimation started. Thermostat, probe, and J thermocouple (T_J) temperatures were monitored as a function of time. When the pressure decreases below ~1 mm and sublimation started (time zero), T_J sharply decreased (Fig. 20) until a steady state was reached at approximately time τ_1. The T_J reading abruptly increased at time τ_B when the ice–vapor interface moved below the bottom of the J thermocouple and thermal contact was broken. When the sublimation rate was high, T_J passed through a minimum at time τ_s, where $\tau_s = 0.9\,\tau_B$. Interpreting τ_s as the time when the ice–vapor interface just covers the measuring junction J, $T_J(\tau_s) = T_s$, where T_s is the temperature of the subliming ice.

In a calibration experiment, the sublimation rate in mg/min at time $\tau_i (i = 1,s)$ is calculated from $\dot{m}_i = (8.8/\tau_B)f_i$, where 8.8 is the difference between the total sample mass of 10.0 mg and the mass remaining at τ_B, the latter calculated assuming the J thermocouple is exactly 1 mm from the bottom of the capillary tube. The factor f_i is the ratio of the sublimation rate at τ_i to the average rate over the time interval $0 \le t \le \tau_B$. This factor, which is near unity, is determined from sublimation experiments where mass is monitored (*i.e.*, no J wire).

A total of 16 calibration experiments were conducted over the bath temperature and chamber pressure ranges $-39° < T_b < -15°$ and $0 < P < 0.6$ mm, respectively, generating the data set (T_b, T_p, T_s, τ_1, τ_s, τ_B, P) for each experiment. These data were used to evaluate the heat transfer parameters appearing in Eqs. A23–A27 *via* regression analysis.

The parameters k_{cs} and k_{aJ} were evaluated by an iterative procedure. First k_{cs} was evaluated from the time dependence of T_J and a preliminary estimate of k_{aJ}, using only data where the sublimation rate was high (Appendix II). Next, k_{bc} and k_{aJ} were evaluated by regression analysis using Eqs. A25 and A30[26]. The resulting value of k_{aJ} was then used to obtain a second approximation of k_{cs}, *etc.* Convergence was obtained after two iterations. Finally, the ratios r_p^0 and k_{ap}/k_{bp} were evaluated from the data by regression analysis using Eqs. A23, A27, and A28. The resulting parameters with their corresponding standard errors are listed in Table IV. Agreement between data and the theoretical model is within the anticipated experimental error. Due to the difficulty in placing the J thermocouple always at the same level in the sample, measurement of the average sublimation rate is subject to sizable random error.

With the evaluated parameters (Table IV), Eq. A31 becomes Eq. 1 (text):

$$T_s = T_p - K_p \frac{(1 + 68.1P)}{(1 + 87.0P)}\dot{m} - K_a(T_a - T_p)$$

where K_p is 10.2 and K_a is 0.010 and 0.006 at $P = 0$ and $P = 0.05$–1.0 torr, respectively. The sublimation rate $\dot{m}$ is in mg/min. In principle, K_a is a smooth function of pressure through r_p. However, the step function representation given above is a simpler yet adequate representation of the data. With the improved probe design described earlier[12], $k_{ap} = 0$ and $r_p \gg 1$ experimentally ($r_p \simeq 14$ in theory). In this case, $K_a = 0$ and $K_p = 7.1$.

Table IV—Values of Heat Transfer Parameters Evaluated from Temperature Calibration Data [a]

Parameter	Value
k_{cs}	$1.55 \times 10^{-3} \pm 0.07 \times 10^{-3}$ cal sec^{-1} °K^{-1}
k_{bc}^0	$2.2 \times 10^{-3} \pm 0.04 \times 10^{-3}$ cal sec^{-1} °K^{-1}
r_p^0	0.61 ± 0.28
k_{ap}/k_{bp}	0.016 ± 0.012

APPENDIX II: THEORY OF CELL–SAMPLE HEAT TRANSFER COEFFICIENT

Heat is transferred from the aluminum cell to the sample through the wall and bottom of the glass capillary tube. Since the area available for heat transfer decreases as the length of the ice column decreases during sublimation, the parameter characterizing this heat transfer (k_{cs}) may not be constant. Moreover, in a calibration experiment, the presence of the thermocouple wire in the capillary tube changes the thermal conductivity of the system and, consequently, k_{cs}. The purpose of this section is to present a semiquantitative theoretical argument which indicates that k_{cs} is indeed a constant during sublimation of all but the last traces of ice, and to provide a theoretical basis for the evaluation of k_{cs} under conditions of a sublimation rate experiment (no thermocouple in the sample) using calibration data obtained where a thermocouple is in the sample. The length of the ice column at time zero is denoted L.

A simple steady-state model for heat transfer in the cell–sample system is illustrated by Fig. 21. Heat conducted from ambient to the sample *via* the J thermocouple ($\dot{q}_{aJ}$), assumed to dissipate at the ice–vapor interface, is not shown. The temperature in the aluminum cell (T_c) is assumed independent of the distance variable, x. The ice at the ice–vapor interface ($x = l$) is at a mean temperature T_s, while the average temperature of the

[26] The parameter k_r is calculated from theory (22) with unit emissivity for a temperature of 253°K. For air, literature data (12) for Λ_0 and λ then yield: $\Lambda_0/\lambda = 68.9$ cm^{-1} torr^{-1}, $\lambda/k_r = 0.662$ cm. The distance parameters d_c and d_p are approximately measured as 0.6 and 0.3 cm, respectively. The calculations are not sensitive to small variations in d_c and d_p. The enthalpy of sublimation $\Delta \bar{H}_s$ is 660 cal/g (41).

sample in any volume element of thickness (dx) is T, where T is a function of x.

In any volume element bounded by planes at $x - dx/2$ and $x + dx/2$, the heat flow out of the volume element through the plane at $x - dx/2$ ($\delta\dot{q}_3$) is the sum of the radial heat flow through the container wall ($\delta\dot{q}_1$) and the vertical heat flow into the volume element at the plane $x + dx/2$ ($\delta\dot{q}_2$). The radial heat flow, $\delta\dot{q}_1$, is proportional to the length of the volume element, dx, and the temperature difference $T_c - T$:

$$\delta\dot{q}_1 = k_w dx(T_c - T) \qquad \text{(Eq. A32)}$$

where k_w is a heat transfer coefficient for heat flow through the apiezon wax and the capillary tube wall, and reflects the heat-flow rate for a tube of unit length with a temperature difference of 1° applied. The vertical heat transfer rate is of the form:

$$\delta\dot{q}_i = k_I \frac{(dT)}{(dx)_{x_i}}, \quad i = 2, 3 \qquad \text{(Eq. A33)}$$

where for $i = 2, x_i = x + dx/2$ and for $i = 3, x_i = x - dx/2$. The parameter k_I is the product of the cross-sectional area and the thermal conductivity of the material present in the capillary tube[27]. During a calibration experiment both ice and the J thermocouple wires contribute to k_I. From Eqs. A33 and A32 and the steady-state requirement $\delta\dot{q}_3 = \delta\dot{q}_1 + \delta\dot{q}_2$, we find:

$$\frac{d^2T}{dx^2} = -\frac{k_w}{k_I}(T_c - T) \qquad \text{(Eq. A34)}$$

With the transformation of variables:

$$y = T_c - T \qquad \text{(Eq. A35)}$$

and

$$z = (x - l)/(L - l) \qquad \text{(Eq. A36)}$$

Eq. A34 becomes:

$$\frac{d^2y}{dz^2} - a^2y = 0, \qquad \text{(Eq. A37)}$$

where:

$$a = (L - l)\sqrt{\frac{k_w}{k_I}} \qquad \text{(Eq. A38)}$$

One boundary condition follows from the requirement that the vertical heat flow at the ice–vapor interface ($z = 0$) is equal to the total heat flow from cell to sample ($\dot{q}_{cs}$):

$$\dot{q}_{cs} = -\frac{k_I}{(L - l)}\left(\frac{dy}{dz}\right), \quad z = 0 \qquad \text{(Eq. A39)}$$

where, denoting $\dot{Q}_s$ as the heat removed by sublimation, $\dot{q}_{cs} = \dot{Q}_s - \dot{q}_{aJ}$. This relationship assumes $\dot{q}_{aJ}$ is dissipated at the $z = 0$ surface. $\dot{Q}_s$ is the product of the sublimation rate and the heat of sublimation per gram: $\dot{Q}_s = \dot{m}\Delta\bar{H}_s$. The second boundary condition is obtained from the requirement that $\dot{q}_{cs}$ is given by the sum of the heat flow through the bottom ($\delta\dot{q}_B$) and the integral of $\delta\dot{q}_1$ over the length of the ice column, $0 \leq z \leq 1$. Since $\delta\dot{q}_B = k_B y(1)$, the boundary condition becomes:

$$\dot{q}_{cs} = k_w(L - l)\int_0^1 y(z)dz + k_B y(l), \qquad \text{(Eq. A40)}$$

[27] The parameter k_I is given by:

$$k_I = \pi r^2 \kappa_I$$

where r is the radius of the capillary tube (0.0648 cm) and κ_I is the thermal conductivity of the material within the capillary tube (ice and, in a calibration experiment, the J thermocouple wires of diameter 0.23 mm):

$$\kappa_I = \frac{1}{A_T}\sum_i A_i\kappa_i$$

where, A_T is the total tube cross-sectional area, while A_i and κ_i are the cross-sectional area and thermal conductivity for the ith material (i = ice, copper, constantan).

Based on handbook data for thermal conductivities, k_I (cal cm sec^{-1} °K^{-1}) is calculated as 6.9×10^{-5} for a normal sublimation experiment (without a thermocouple junction in the sample) and 5.0×10^{-4} for a calibration experiment. The parameters k_w and k_B may be estimated from the relationships:

$$k_w = 2\pi r(l_{wx}/\kappa_{wx} + lg/\kappa_g)^{-1},$$

$$k_B = \pi r^2(l_{wx}/\kappa_{wx} + lg/\kappa_g)^{-1}$$

where l_{wx} and κ_{wx} are the thickness and thermal conductivity of the wax, respectively, and l_g and κ_g are the corresponding parameters for the glass tube. By measurement, $l_{wx} = 10^{-2}$ cm, $l_g = 0.037$ cm. Assuming the apiezon wax has the same thermal conductivity as paraffin, $\kappa_{wx} = 6 \times 10^{-4}$ cal cm^{-1} sec^{-1} °K^{-1}. Since $\kappa_g = 2.6 \times 10^{-3}$ cal cm^{-1} sec^{-1} °K^{-1}, $k_w = 1.3 \times 10^{-2}$ cal cm^{-1} sec^{-1} °K^{-1} and $k_B = 4 \times 10^{-4}$ cal sec^{-1} °K^{-1}.

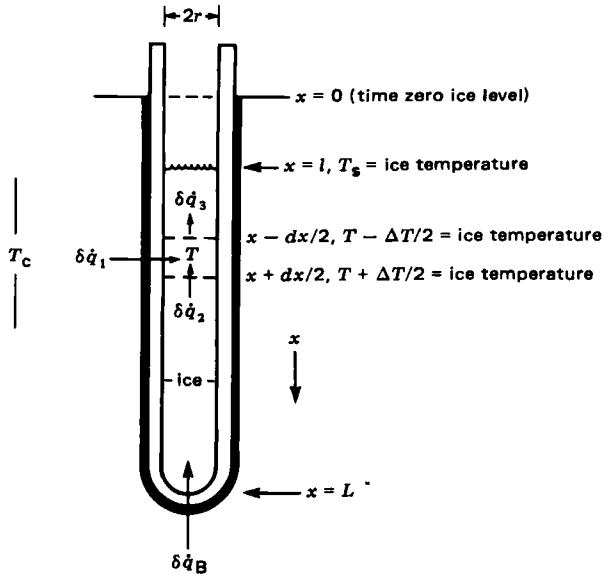

Figure 21—*Schematic of heat flow in the sublimation cell.*

with k_B representing the heat transfer coefficient through the bottom of the capillary tube. Solution of the differential equation (Eq. A37) subject to the boundary conditions (Eqs. A39 and A40) yields:

$$y(z) = b\dot{q}_{cs}\left\{e^{-az} + \frac{e^{-a}(1 - bk_B)\cosh(az)}{\cosh(a)[\tanh(a) + bk_B]}\right\} \qquad \text{(Eq. A41)}$$

where:

$$b^{-1} = \sqrt{k_w k_I} \qquad \text{(Eq. A42)}$$

The constant k_{cs}, defined by $\dot{q}_{cs} = k_{cs}(T_c - T_s)$ where $(T_c - T_s) = y(z = 0)$, is then:

$$k_{cs} = b^{-1}\frac{[\tanh(a) + bk_B]}{[1 + bk_B\tanh(a)]} \qquad \text{(Eq. A43)}$$

The parameter k_I (cal cm sec^{-1} °K^{-1}) is 6.9×10^{-5} with only ice in the capillary tube and is 5.0×10^{-4} in a calibration experiment where thermocouple wires are present[27]. Rough estimates[27] yield, $k_w = 1.3 \times 10^{-2}$ cal cm^{-1} sec^{-1} °K^{-1} and $k_B = 4 \times 10^{-4}$ cal sec^{-1} °K^{-1}. Therefore, in a sublimation rate experiment (no J wire) $\sqrt{k_w/k_I} = 14$ and for $L - l > 0.1$ cm (through ~90% of the sublimation experiment), $a > 1.4$ and Eqs. A41 and A43 simplify to give:

$$y(z) = b\dot{Q}_s e^{-az}, \quad L - l > 0.1 \text{ cm} \qquad \text{(Eq. A44)}$$

and

$$k_{cs} = \sqrt{k_w k_I}, \quad L - l > 0.1 \text{ cm} \qquad \text{(Eq. A45)}$$

As the last traces of ice are sublimed, $l \approx L$ and $k_{cs} = k_B$. Since the estimates indicate $k_B \ll \sqrt{k_w k_I}$, the theory suggests that as $l \to L$, the value of k_{cs} should decrease sharply causing a decrease in ice temperature and a corresponding decrease in the sublimation rate in those cases where the sublimation rate is high. This qualitative prediction is verified in experiments with pure water at high temperature (*i.e.*, −20°) where the sublimation rate is found to sharply decrease when $L - l$ is ~0.1 or less.

Equation A41 may be used to evaluate k_w from the time dependence of T_J determined in a calibration experiment. The resulting value of k_w may then be used with the calculated value of k_I to evaluate k_{cs} using Eq. A43. Denoting T_J as the temperature measured by the thermocouple junction in the sample at location x_J, $T_c - T_J = y(z_J)$, where z_J is given by Eq. A36 with $x = x_J = 0.72$ cm[28]. Equation A41 and the relationship $T_b - T_c = k_{bc}^{-1}\dot{q}_{cs}$ then results in:

$$\left(\frac{T_b - T_J}{\dot{q}_{cs}}\right) = k_{bc}^{-1} + b \cdot G(k_w, l) \qquad \text{(Eq. A46)}$$

where the function $G(k_w, l)$ denotes the terms enclosed in brackets on

[28] At time τ_s, the J thermocouple measures the surface temperature of the ice, the surface located at x_J. From the interpretation given earlier, x_J represents the value of x at the top of the thermocouple measuring junction. Since the junction head is ~0.5 mm in diameter and the bottom of the junction is at $x = 0.77$ cm, $x_J = 0.72$ cm. Since $l = x_J$ at time τ_s and $L = 0.87$ cm, $L - l = 0.15$ cm at τ_s.

the right-hand side of Eq. A41. As indicated, G depends on k_w and the position of the ice–vapor interface, which in turn depends on time. The time when the ice–vapor interface is at the same location as the thermocouple (*i.e.*, $az_J = 0$) is denoted τ_s. The time τ_1 represents a time large enough to establish steady-state heat flow but small enough so that the ice–vapor interface is still several millimeters above the thermocouple. With the above definitions for τ_s and τ_1:

$$\left(\frac{T_b - T_J}{\dot{q}_{cs}}\right)_{\tau_s} - \left(\frac{T_b - T_J}{\dot{q}_{cs}}\right)_{\tau_1} = H(k_w) \qquad \text{(Eq. A47)}$$

where for fixed τ_s and τ_1, H is a function of k_w only, given by:

$$H(k_w) = (k_w k_I)^{-1/2}\left\{\exp(-a_1 z_1) + \frac{\exp(-a_s)(1 - bk_B)}{\cosh(a_s)[\tanh(a_s) + bk_B]} - \frac{\exp(-a_1)(1 - bk_B)\cosh(a_1 z_1)}{\cosh(a_1)[\tanh(a_1) + bk_B]}\right\} \qquad \text{(Eq. A48)}$$

where a_s and a_1 are values of the parameter a (Eq. A38) at times τ_s and τ_1, respectively, and z_1 is the value of z_J (Eq. A36 with $x = x_J$) corresponding to time τ_1. Equation A48 is not sensitive to the precise choice of τ_1. For convenience, τ_1 is always taken as $\tau_1 = 0.4\,\tau_B$, where τ_B is the time for the ice–vapor interface to move below the bottom of the J thermocouple. Sublimation rate experiments (no J wire) indicate that with a sample of 10.0 mg of water ($L = 0.87$ cm), $L - l = 0.53$ cm at τ_1 (= $0.4\tau_B$). Thus, from Eq. A36, $z_1 = 0.72$[28]. The parameter k_B is related to k_w by $k_B = (r/2)k_w$[27] with r representing the radius of the capillary tube (0.0648 cm.). Since k_I may be calculated from theory[27], a_1, a_s, and k_B depend only on k_w and $H(k_w)$ is easily tabulated as a function of k_w.

With $\dot{q}_{cs} = \dot{Q}_s - k_{aJ}(T_a - T_J)$, and $\dot{Q}_s = \Delta\overline{H}_s\dot{m}$, values of $\dot{q}_{cs}$ at times τ_1 and τ_s are evaluated from the sublimation rates ($\dot{m}$) at these times and a value of k_{aJ} is estimated from the calibration data. Sublimation rates are evaluated from τ_B data as outlined in Appendix I. Using only data where the sublimation rate is high, the value of k_{cs} is relatively insensitive to the choice of k_{aJ}.

Thus, with T_b, T_J, and $\dot{q}_{cs}$ determined at τ_s and τ_1, $H(k_w)$ is determined from the data, which then determines an experimental value for k_w. The iterative procedure outlined in Appendix I determines both k_{aJ} and k_w, yielding the result $k_w = 0.035 \pm 0.003$. For a sublimation rate experiment (no J wire), $k_I = 6.9 \times 10^{-5}$ cal cm sec^{-1} °K^{-1} [27], which then gives (Eq. A45) $k_{cs} = 1.55 \times 10^{-3}$ cal sec^{-1} °K^{-1}. The value of k_w obtained is larger than the theoretically estimated value[27]. A strict interpretation of the theory would imply that the wax sealing the capillary tube in the aluminum cell offers essentially zero thermal resistance. However, the difference between the experimental and theoretical k_w values probably reflects, in large part, the theory's neglect of vertical heat transfer in the walls of the glass capillary tube. In any case, use of the experimental k_w should yield a reliable value of k_{cs} for experimental use.

Effects of Surfactants on the GI Absorption of β-Lactam Antibiotics in Rats

ETSUKO MIYAMOTO *, AKIRA TSUJI ‡ ˣ, and TSUKINAKA YAMANA §

Received January 13, 1982, from the **School of Pharmacy, Hokuriku University, Kanagawa-machi, Kanazawa 920-11, Japan*, and the ‡*Faculty of Pharmaceutical Sciences* and §*Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication June 4, 1982.

Abstract □ The effects of various nonionic and ionic surfactants and two bile salts (sodium cholate and sodium taurocholate) on the GI absorption of β-lactam antibiotics were investigated using the *in situ* rat GI perfusion technique. Addition of 10 m*M* polyoxyethylene-23-lauryl ether in the perfusion solution reduced the absorption of propicillin by the stomach and markedly increased the absorption of propicillin and cefazolin by the small intestine. Ester-type nonionic surfactants and bile salts exerted no significant influence on the intestinal absorption of these antibiotics.

Keyphrases □ Surfactants—effects on GI absorption of β-lactam antibiotics in rats □ Propicillin—effects of surfactants on GI absorption □ Cefazolin—effects of surfactants on GI absorption □ Absorption, GI—effects of surfactants, β-lactam antibiotics

Nonionic surfactants have often been employed in pharmaceutical preparations to formulate dispersed and solubilized systems, since they are less toxic to biological systems (1). It is known that drug–surfactant interactions modify the rate of intestinal absorption of drugs (2); some tend to enhance drug absorption and others tend to retard it.

GI absorption of nonabsorbed or poorly absorbed classes of β-lactam antibiotics can be promoted in rats and dogs by nonionic, anionic, and cationic surface-active agents. It was suggested that this promotion of antibiotic absorption was attributable to alteration of the membrane permeability of surfactants (3, 4). In previous studies (5, 6), nonionic and cationic surfactants were found to entrap penicillin molecules under pH conditions found in the stomach, resulting in remarkable stabilization and solubilization of penicillins. On the other hand, anionic surfactant micelles facilitated β-lactam cleavage. These results (3–6) indicated that acid-labile penicillins coated with relatively nontoxic nonionic surfactant micelles may increase the bioavailability after oral administration. The present study was undertaken to determine the effects of anionic, cationic, and nonionic surfactants, as well as bile salts on the GI absorption of β-lactam antibiotics using the *in situ* rat GI perfusion technique.

EXPERIMENTAL

Materials—Propicillin potassium[1] (993 μg/mg) and cefazolin sodium[2] (966 μg/mg) were used as received. Most surfactants employed were supplied by a commercial source[3]. Polyoxyethylene-23-lauryl ether (I), cetyltrimethylammonium bromide (II), and sodium lauryl sulfate (III) were the same as used in a previous study (6). Sodium taurocholate and sodium cholate were obtained commercially[4]. All other chemicals were of reagent grade and used without further purification.

***In Situ* GI Absorption Procedures**—Male albino rats of the Wistar strain, weighing ~200 g, were fasted overnight (20 hr) prior to the experiments, with water freely available. The rats were anesthetized 1 hr prior to surgery with urethan (1.3 g/kg ip). The procedures for rat surgery and absorption experiments using the GI recirculating method were those reported previously (7–9). The small intestine employed was a 30-cm length from the pylorus. The stomach or small intestine was washed with 50 ml of isotonic buffer solution of the desired pH, and then with 10 ml of the same buffer solution containing an appropriate concentration of surfactant. The drug solution was prepared using the buffer–surfactant solution maintained at 37° and perfused in a recirculating fashion with a pump at a rate of 10 ml/min for the stomach and 2 ml/min for the intestine. Unless otherwise stated, the antibiotic concentrations were 1 and 5 mg/ml for the stomach and intestinal experiments, respectively. The perfusion was maintained at the desired pH with a pH-stat[5] during the absorption experiments. The perfusion periods were 3 and 2 hr for the stomach and intestinal experiments, respectively.

At the end of the absorption experiments, the recirculating drug solution and the isotonic buffer solution perfused to wash the GI tract were collected into an appropriate volumetric flask, and the required amount of the same buffer solution was added to achieve the desired volume. To obtain the final sample, the solution was filtered through a 0.45-μm membrane filter[6]. The initial sample was prepared by dilution of un-

perfused drug solution with isotonic buffer solution to the same volume.

The apparent first-order rate constants for the drug disappearance from the perfusate, k_{app}, were calculated as follows:

$$k_{app} = -\frac{1}{t}\ln\frac{C_t}{C_0} \qquad \text{(Eq. 1)}$$

where t represents the perfusion period and C_t and C_0 represent the drug concentrations in the final and initial samples, respectively.

Analytical Procedures—Propicillin and cefazolin in samples from the *in situ* absorption experiments were determined by reverse-phase high-performance liquid chromatography (HPLC) under the following conditions. The liquid chromatograph[7] was equipped with a UV detector[8] set at 254 nm. The stationary phase, made by chemically bonding a octadecylsilanol group to totally porous silica gel, was prepacked into a stainless steel column[9,10]. The mobile phases were 10 and 30% (v/v) acetonitrile–0.01 *M* ammonium acetate for cefazolin and propicillin, respectively. The instrument was operated at ambient temperature and at a flow rate of 1 ml/min. Samples were injected *via* a 100-μl loop injector[11] on flow. Peak heights were used for quantification.

During the *in situ* intestinal absorption experiments, 0.2-ml aliquots of blood were taken periodically from the jugular vein and assayed by the microbiological paper disk method employing *Salutina lutea*[12] as a test organism, after being hemolyzed with an equivalent volume of distilled water. The standard was established by employing pooled fresh blood from control rats.

The lower limit of sensitivity was 10 μg/ml for the HPLC assay and 1 μg/ml for the microbiological assay. The coefficients of variation ($SD \times 100$/mean) of the HPLC and microbiological assays throughout the analytical experiments were 3 and 5%, respectively, from many trials using standard solutions of each antibiotic.

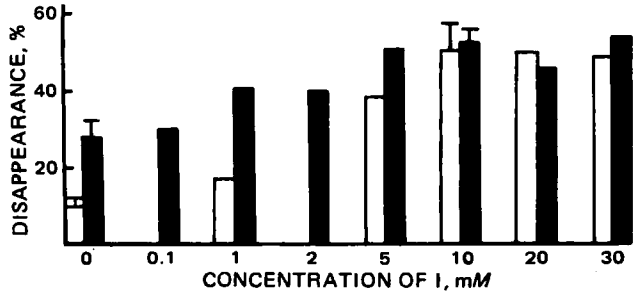

Figure 3—*Percentage disappearance of propicillin (■) and cefazolin (□) from the rat intestinal lumen as a function of the concentration of I. The perfusion solution was recirculated at a rate of 2 ml/min at pH 7.4, maintained constant with a pH-stat.*

RESULTS

Effects of I on Stomach Absorption—The total disappearance of propicillin from the stomach perfusion solution has been reported to follow first-order kinetics (8). In this case, the apparent first-order rate constant undoubtedly includes the rate constants for both acid-catalyzed degradation and absorption, which proceed competitively during the absorption experiments.

As verified previously (7, 8), the apparent first-order rate constant, k_{app}, can be expressed as:

$$k_{app} = CL_a\frac{1}{V} + k_d \qquad \text{(Eq. 2)}$$

where CL_a is the absorption clearance in milliliters/time, k_d is the first-order rate constant for chemical degradation, and V is the volume of re-

[12] IFO 12708, Institute for Fermentation, Osaka, Japan; the strain was derived from ATCC 9341.

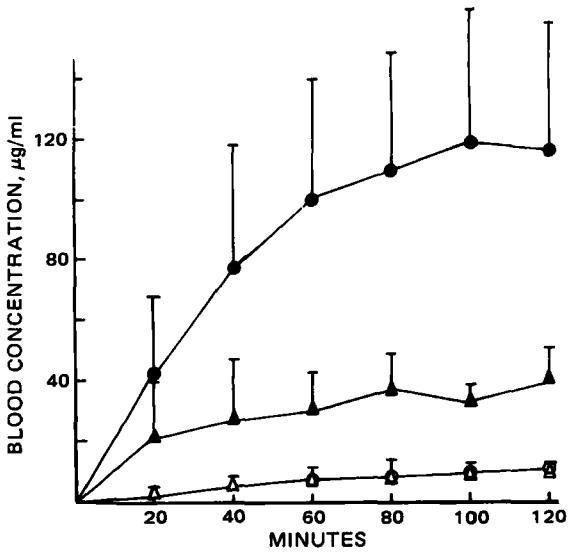

Figure 4—*Mean blood concentrations of propicillin (▲) and cefazolin (●) during* in situ *intestinal perfusion at pH 7.4 in the presence of 10 mM I. Open symbols indicate the blood concentrations in the absence of I. The vertical bars represent* SD *from three or more experiments.*

circulating drug solution. As shown in Fig. 1, plots of k_{app} obtained from absorption experiments with propicillin containing 10 m*M* I in the perfusion solution *versus* $1/V$ yielded a straight line similar to those obtained previously (8) for control experiments in the absence of I. The intercepts of these lines provided k_d values (in min^{-1}), which were evaluated to be 1.06×10^{-3}, 0.40×10^{-3}, and 0.30×10^{-3} at pH 2.00, 3.00, and 4.00, respectively.

It was found that the degradation of propicillin was much slower in the presence of the nonionic surfactant, which is consistent with the previous observations (5, 6). The CL_a of propicillin calculated from the slopes in Fig. 1 is plotted in Fig. 2 as a function of the perfusion solution pH. In this figure, the log CL_a–pH profile for propicillin determined under the same conditions in the absence of I was redrawn from our previous study (8). The absorption of propicillin below pH 3 was inhibited twofold in the presence of 10 m*M* I.

Effect of Surfactants on Intestinal Absorption—*Dependency on Concentration of I*—The effect of I on the intestinal absorption of two β-lactam antibiotics possessing different physicochemical characteristics was investigated. Propicillin was chosen since it has a high lipophilicity (10) and shows some incorporation (5, 6) of its ionized species into micelles of I; cefazolin has a low lipophilicity and exhibits negligible interaction with the surfactant micelles (5, 6).

Since the values of pK_a for the carboxylic acid groups of propicillin and cefazolin are 2.76 (10) and 2.54 (11), respectively, both antibiotics were largely in the form of anion at pH 7.4 in the present absorption experiments. Figure 3 shows the percentage disappearance of both antibiotics after recirculation through the small intestine for 2 hr as a function of the concentration of I. The total percentage disappearance for propicillin and cefazolin were determined previously (9) to be 28.4 ± 4.1 and 9.7 ± 1.8%, respectively. It was also found (9) that the greater disappearance of propicillin could be attributed mostly to intestinal degradation rather than absorption, and that the first-order rate constant ($\times 10^3$ min^{-1}) for the intestinal absorption was 1.29 ± 0.34 for propicillin and 0.85 ± 0.16 for cefazolin.

The relationship between the surfactant concentration and rate of antibiotic absorption represented one important aspect of the action of the surfactants. In the presence of I, the percentage disappearance of both antibiotics first increased markedly with increasing surfactant concentration ≤10 m*M* and then approached a constant value of ~50% >10 m*M*, which is much higher than the critical micellar concentration of 0.092 m*M* under comparative conditions (5, 6). For both antibiotics, no acceleration of the *in vitro* degradation in the presence of I was observed under the present experimental conditions, suggesting that the enhanced disappearance was a result of the absorption.

During the recirculating absorption experiments, the blood concentrations of propicillin and cefazolin were determined in the presence or absence of 10 m*M* I. The results are shown in Fig. 4 and clearly indicate that the presence of I remarkably increased the blood levels of both antibiotics. The accumulation of cefazolin in the gut tissue was only 0.2% after 2 hr. These findings strongly suggest that the amount of antibiotic disappearing from the intestinal perfusate in the presence of I was largely transferred to the serosal site.

Table II—Influence of Perfusion Solution pH on the Percentage Disappearance of Cefazolin from Rat Small Intestine in the Presence of 10 m*M* I Surfactant at 37°

pH	Disappearance, % (±*SD*)	*n*[a]
4.0	63.4(11.5)	3
4.7	50.4(5.8)	3
6.4	52.9(15.3)	3
7.4	50.7(6.6)	5

[a] Number of experiments.

Effect of Various Surfactants and Bile Salts—The promotional effect of surfactants on the intestinal absorption was investigated using concentrations of various surfactants and bile salts. The results are summarized in Table I. Promoted absorption by the surfactants was observed for both the anionic surfactant and the ether-type class of nonionic surfactants. Bile salts revealed no significant promotional effect. For nonionic surfactants used in this study, the ester groups showed a reduced or insignificant effect on cefazolin absorption.

Dependency on Intestinal Solution pH and the Initial Concentration of Drug—Absorption of cefazolin from the rat small intestine was examined in the presence of 10 m*M* I as a function of the perfusion solution pH. The results are shown in Table II. Between pH 4 and 7.4, there was no significant difference in the absorption behavior. Figure 5 gives logarithmic plots of the residual cefazolin concentration in the perfusate containing 10 m*M* I *versus* time for three different initial concentrations (1, 10, and 50 m*M*) at pH 7.4. The observed pseudo first-order rate constants were almost identical and independent of the initial drug concentration.

DISCUSSION

Davis *et al.* (3, 4) described the effects of surfactants on the GI absorption of poorly absorbed β-lactam antibiotics in dogs or rats, and attributed the promoted absorption by surfactants to alteration of the membrane permeability. In the present study, it was found that the absorption of propicillin from the rat stomach was reduced in the presence

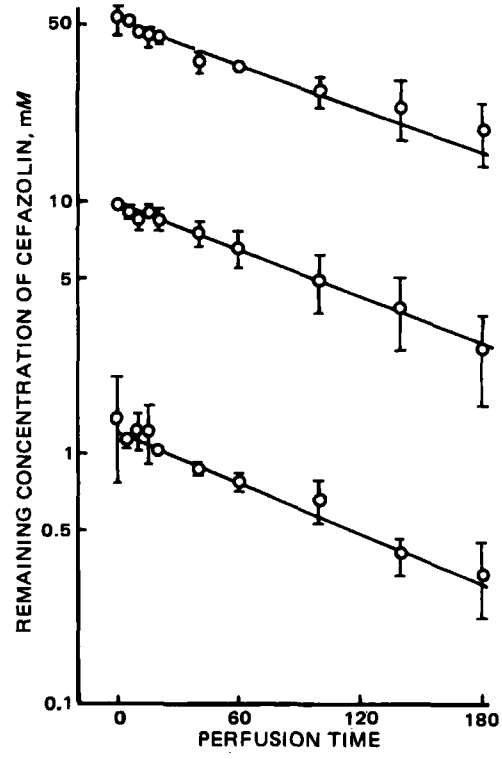

Figure 5—*Plots of the remaining cefazolin concentration in the perfusate* versus *the recirculating time at 37° and pH 7.4, maintained constant with a pH-stat. The perfusion solution was recirculated at a rate of 2 ml/min.*

of 10 m*M* I. Such reduction was interpreted as the result of entrapment of propicillin molecules into micelles of I. A similar phenomenon has been reported in absorption experiments with other drugs (12, 13). While the absorption of antibiotics by the small intestine increased in the presence of surfactants, such promoted absorption depended on the nature of the surfactants rather than the physicochemical properties of the antibiotics. Interestingly, the existence of a significant interaction between antibiotics and surfactants appeared not to influence the absorption by the small intestine. Despite the entrapment of 90% of the anionic propicillin into micelles of II (5, 6), no reduced absorption was observed (Table I). In the presence of 10 m*M* I, absorption of the antibiotic was promoted with 30% of the anionic species incorporated into the micelles. These results suggest that alteration of the membrane permeability by nonionic and cationic surfactants induced the promoted absorption in the small intestine, concurring with the findings made by other laboratories (3, 4).

Walters and Dugard (14) demonstrated that the hydrophilic–lipophilic balance (HLB) of a surfactant represents an important property in determining the promoted absorption. However, our results from the intestinal experiments indicated that significant absorption enhancement was observed only with ether-type surfactants, suggesting that HLB cannot be the sole cause for the observed promotional effect in the intestinal absorption of β-lactam antibiotics. Alteration of the permeability sometimes can be a result of disruption of the membrane structure by surfactants (15–17). In the present study, however, no significant disruption of the membrane was detected by light microscopy. The change in membrane permeability with the surfactant, therefore, may reflect a reversible alteration of the diffusion barrier to lipid soluble, poorly ionized drugs as claimed by Davis *et al.* (3, 4).

Acrylic Microspheres *In Vivo* VI: Antitumor Effect of Microparticles with Immobilized L-Asparaginase Against 6C3HED Lymphoma

PETER EDMAN * and INGVAR SJÖHOLM *x

Received October 13, 1981, from the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication June 7, 1982.

*Present address: Department of Drugs, National Board of Health and Welfare, Division of Pharmacy, 751 25 Uppsala, Sweden.

Abstract □ The antitumor effect of immobilized L-asparaginase was tested against lymphoid leukemia in mice with concomitant scanning of the L-asparagine level in serum. L-Asparaginase was immobilized in microspheres of polyacrylamide or polyacryldextran. These particles were used in C3H mice bearing the L-asparagine-dependent lymphoma (6C3HED). The tumor was maintained as an ascites tumor, 1×10^6 cells were injected intraperitoneally and on day 4 after inoculation, L-asparaginase was injected intramuscularly or intraperitoneally in microparticles. After injection of 5.0 IU ip of L-asparaginase in microparticles, partial remission was induced, generally, however, the cancer relapsed and killed the mice within 2–3 weeks. To obtain complete regression, it was necessary to inject 20 IU of L-asparaginase in microparticles intraperitoneally. The best therapeutic effect was obtained when the particles were administered intramuscularly. After injection of 5 IU the survival time was prolonged, but complete regression was not achieved. The best effect was obtained when the particles were given intramuscularly in two small doses (2.5 IU) at a 3-day interval. Such treatment induced complete regression; 10 out of 12 treated mice were completely cured and lived for several months. It is concluded that the L-asparagine level in serum has to be depressed to <20% of the normal level for at least 6–7 days to obtain complete regression of the tumor.

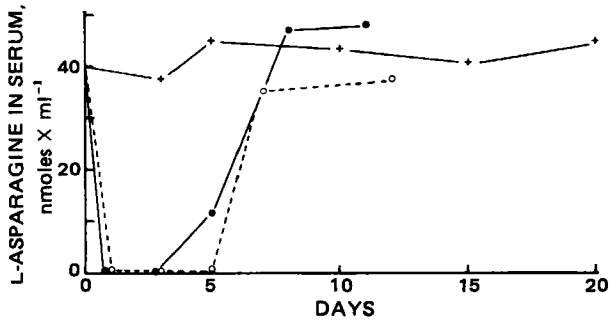

Figure 1—*L-Asparagine concentration in serum of healthy mice after a single intraperitoneal injection of L-asparaginase (5 IU/animal) in free solution (○) or in microparticles (●). Pooled serum from 4 to 6 mice was used for each time interval. The normal L-asparagine concentration (+) was obtained from a control group given physiological saline.*

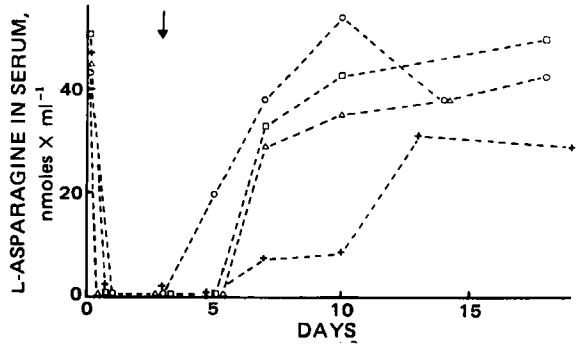

Figure 2—*L-Asparagine concentration in serum after intramuscular injection of L-asparaginase in free form, 5 IU/animal (○), 20 IU/animal (△), 2 × 2.5 IU/animal (□) and 2 × 2.5 IU/tumor-bearing animal (+). In the infected animals, 6C3HED cells (1 × 10⁶) were injected 4 days prior to the first injection on day 0. The arrow shows the time for the second injection of 2.5 IU of L-asparaginase in free form. Pooled serum from five mice was used for each time interval.*

and to some extent of L-glutamine (4). However, the short biological half-life of the enzyme necessitates frequent administration, which often leads to antibody production and hypersensitivity (5). This and other side reactions prevent the prolonged use of L-asparaginase with a subsequent relapse of the tumor and the development of L-asparaginase-resistant tumors.

The stability of enzymes against thermal denaturation and proteolytic degradation is generally improved when they are immobilized or polymerized. L-Asparaginase has been used successfully in immobilized form *in vivo* to prolong the duration of action in monkeys (6), rats (7), rabbits (8), and mice (9–11). When the enzyme is immobilized in porous microparticles of polyacrylamide with a mean diameter of 0.2–0.5 μm, the enzymic characteristics are essentially retained and the effects on the L-asparagine level in plasma is prolonged after intraperitoneal administration in rats (12). When the L-asparaginase microparticles are embedded in a polyacrylic gel the duration of action was prolonged up to ~25 days after implantation in the rat (13).

The present study was undertaken to correlate the L-asparagine-depressing activity of immobilized L-asparaginase in microparticles with the inhibition of tumor growth in mice, as well as to ascertain the optimal route of administration and the minimal dose of the immobilized L-asparaginase, to keep the serum L-asparagine concentration at a low enough level to prevent tumor growth in mice.

EXPERIMENTAL

Materials—L-Asparaginase[1] (E.C. 3.5.1.1), aspartate aminotransferase[2] (E.C. 2.6.1.1) (83 U/mg) isolated from porcine heart, and malic dehydrogenase[2] (E.C. 1.1.1.37) (2000 U/ml) from pigeon breast muscle were used without further purification. Acrylamide[3], *N,N'*-methylenebisacrylamide[3], *N,N,N',N'*-tetramethylethylenediamine[2], α-ketoglutaric acid[2], nicotinamide adenine dinucleotide[2] (NADH, reduced form) L-asparagine monohydrate[4], dextran[5], Nessler's reagent[2] (ammonia color reagent), and other chemicals were of analytical grade. Male mice[6] weighing 20–25 g were used throughout. The cell line used was the Gardner lymphosarcoma 6C3HED. It was grown in ascites form and was propagated every 7th day in C3H mice with 1 × 10⁶ cells suspended in a balanced salt solution ($CaCl_2$ 0.14 g, NaCl 8 g, KCl 0.4 g, $MgSO_4 \times 7 H_2O$ 0.2 g, KH_2PO_4 0.06 g, and water to 1000 g, pH 6.9).

Preparation of Microparticles Containing L-Asparaginase—Microparticles[7] of polyacrylamide (TC = 8-25)[8] or polyacryldextran (DTC = 11-1-75)[8] containing L-asparaginase were prepared according to a reported method (12, 14). L-Asparaginase, corresponding to 10,000 IU, was dissolved with the acrylic monomers (acrylamide, *N,N'*-methylenebisacrylamide or acryldextran) in 5 ml of 0.005 *M* sodium phosphate buffer, pH 7.4. After addition of the catalyst, ammonium peroxydisulphate (100 μl of a solution of 0.5 g/ml), the solution was poured into 200 ml of a mixture consisting of toluene and chloroform (4:1) and 0.5 g of a detergent[9].

The mixture was homogenized to produce a water–oil emulsion. The homogenizer was removed and the emulsion slowly stirred with a magnetic stirrer. The polymerization was started by adding 1 ml of the accelerator *N,N,N',N'*-tetramethylethylenediamine to the emulsion. During the whole procedure, oxygen was excluded from the system by bubbling nitrogen gas through the emulsion.

The microparticles were isolated by centrifugation, washed several times with buffer, and suspended in physiological saline after the last washing. Under the conditions used, the polyacrylamide particles (TC = 8-25) had a mean diameter of 0.1–0.4 μm, and polyacryldextran particles (DTC = 11-1-75) were 0.2–1.2 μm in diameter.

Preparation of Polyacrylamide Gel for Implantation—Microparticles of polyacrylamide (TC = 8–25) containing L-asparaginase (10 or 20 IU) were embedded in 200–300 μl of a polyacrylamide gel (TC = 16-25) prepared in the usual way in a small perspex box (1 × 1 × 0.7 cm). The gel tablet formed was washed with buffer and physiological saline,

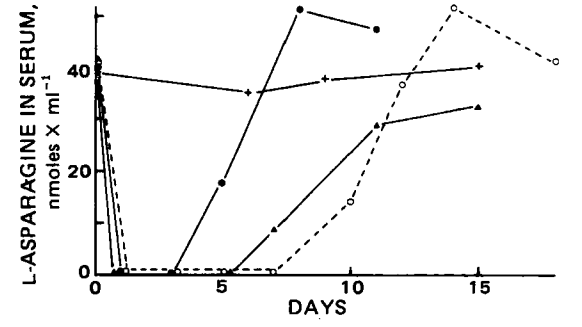

Figure 3—*L-Asparagine concentration in mice bearing the lymphosarcoma 6C3HED, administered intraperitoneally (1 × 10⁶ cells) 4 days prior to the start of the experiment. L-Asparaginase was injected intraperitoneally in free form (5 IU/mouse, ○) or in microparticles (5 IU/mouse, ●, 20 IU/mouse, ▲). A control group was given physiological saline (+). Each point is obtained from the pooled blood from 4 to 6 mice.*

[a] The mice were given 1 × 10^6 6C3HED cells ip, and on the 4th (or 4th and 7th) day after inoculation the mice were treated with different enzyme preparations by different routes. The survival time given is calculated from the day of inoculation. When not otherwise stated, the microparticles used in these experiments had the composition TC = 8–25. [b] The enzyme in free form or in microparticles was administered on the day of inoculation.

as earlier described (13), in order to free it from the remaining catalyst.

Assay of Native and Immobilized L-Asparaginase—L-Asparaginase activity was determined from the amount of ammonia produced by its reaction with the substrate L-asparagine at 37° (15). After the addition of Nessler's reagent, the absorbance was determined at 500 nm. Appropriate enzyme and substrate blanks were included in all assays. A standard curve was prepared with known amounts of ammonium sulphate.

Determination of blood L-asparagine was performed according to a fluorometric method (16). Blood was drawn each time from the tail vein or the orbital plexus from four to six mice. The blood samples were pooled and centrifuged. If not analyzed immediately the serum was frozen and stored at −18° until the analysis.

RESULTS

Serum L-Asparagine after L-Asparaginase Administration in Healthy and Tumor-Bearing Mice—After injection of 5 IU, ip of either immobilized or native L-asparaginase into the mice, serum L-asparagine dropped from a normal level of ~40–45 nmoles/ml to an undetectable level after 1 day and remained so for 4–5 days. Serum L-asparagine became normalized after days 6–7 as seen in Fig. 1.

Figure 2 illustrates the effects on the serum L-asparagine of native *L-asparaginase (2 × 2.5, 5, and 20 IU)* administered intramuscularly to healthy mice. A single injection of 5 IU im of the free enzyme lowered the serum L-asparagine level to zero and maintained it at zero for 3 days.

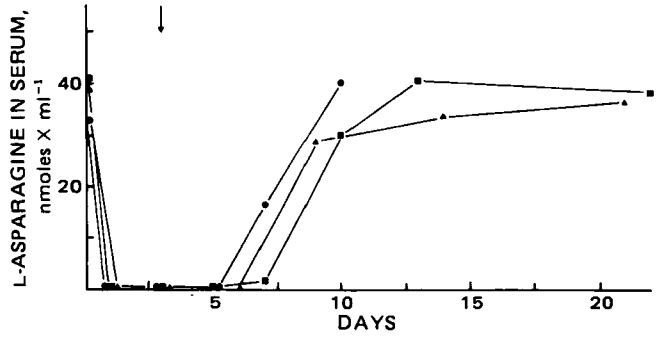

Figure 4—*Blood levels of L-asparagine in mice bearing 6C3HED cells (1 × 10^6 inoculated intraperitoneally 4 days in advance) after intramuscular injection of L-asparaginase in microparticles, 5 IU/animal (●), 20 IU/animal (▲), and 2 × 2.5 IU/animal (■). The arrow indicates the time for the second injection of 2.5 IU of L-asparaginase in microparticles.*

Injection of 2 × 2.5 IU and 20 IU of the free enzyme retained a zero L-asparagine level for up to 5 days. The effect on the serum L-asparagine of free L-asparaginase (2 × 2.5 IU) administered intramuscularly into mice bearing 6C3HED lymphoma is also shown in Fig. 2. The 6C3HED cells (1 × 10^6) were inoculated intraperitoneally 4 days prior to the first injection on day 0. The serum L-asparagine level was depressed to <10 nmoles/ml for 10 days due to the $t_{1/2}$-prolonging effect from the LDH-virus (lactate dehydrogenase-elevating virus) contamination of the cell line.

Figure 3 illustrates the effects on the serum L-asparagine of L-asparaginase (5 or 20 IU) administered intraperitoneally to mice bearing 6C3HED lymphoma. The 6C3HED cells (1 × 10^6) were inoculated intraperitoneally, and at day 4 after inoculation, native or immobilized L-asparaginase was injected intraperitoneally. After injection of the free enzyme, the L-asparagine level dropped from the normal value, was undetectable within 1 day, and remained so for 7 days. The serum L-asparagine level became normal after day 12, which means that the enzymic effect was significantly prolonged in the tumor-bearing mice, when compared with the effect seen in the healthy mice (Fig. 1). The same was seen after injection of 2 × 2.5 IU im as shown in Fig. 2. The prolonged effect is the result of the increased half-life of soluble L-asparaginase, which is caused by the LDH-virus contaminating the 6C3HED and other mouse lymphoma cell lines (4, 17). The increased $t_{1/2}$ of L-asparaginase is a secondary effect of the virus infection, and it is not seen when the 6C3HED cells are inoculated 1 hr after intraperitoneal injection of L-asparaginase (5 IU). In these animals the L-asparagine level followed the same time course as in noninfected mice, as shown in Fig. 1. Thus, the L-asparagine level was maintained at zero for only 5 days.

The therapeutic effect of L-asparaginase in tumor-infected mice is directly related to the duration of the enzymic effect—as will be discussed later—and thus to the $t_{1/2}$ value of the enzyme. In the mice infected with the 6C3HED cells on the same day, administration of L-asparaginase suppressed the growth rate of the lymphoma, but complete regression was not achieved. All the mice died after 14–50 days with grossly enlarged lymph nodes. However, when L-asparaginase was administered on day 4 after infection, 11 out of 12 mice were cured and survived 50 days as a result of the prolonged $t_{1/2}$ value of the enzyme. The results are summarized in Table I.

Immobilized L-asparaginase in microparticles administered intraperitoneally had the same effect on the L-asparagine level in mice bearing the 6C3HED lymphoma as in healthy mice (Figs. 1 and 3). Obviously, the LDH-virus contaminating the 6C3HED cells has no effect on the $t_{1/2}$ of immobilized L-asparaginase. Injection of physiological saline or microparticles without enzyme had no effect on the L-asparagine level.

Figure 4 illustrates the effects of microparticles with L-asparaginase administered intramuscularly in the scapular area of C3H mice bearing the lymphoma 6C3HED. L-Asparaginase (2 × 2.5, 5, and 20 IU) was in-

jected into 8–12 mice in three groups. After injection of 5 IU of immobilized L-asparaginase, normal serum values were obtained on days 8–9, whereas the normal level was reached on days 12–13 when 20 or 2 × 2.5 IU was administered. The results were the same in tumor-bearing and healthy mice. It is obvious that a prolonged effect on the plasma L-asparagine level is obtained by giving L-asparaginase in immobilized form intramuscularly, especially when the effects of 2 × 2.5 IU are compared in infected (Fig. 4) and healthy mice given free enzyme (Fig. 2).

The Growth-Inhibiting Effect of L-Asparaginase on Ascites Tumor—When studied in the ascites form, the tumor cells (1×10^6 cells) were generally given to groups of 12 C3H mice. After 4 days (or after 4 and 7 days), the mice were treated with different doses of L-asparaginase given by different routes or with saline or microparticles not containing any enzyme. Table I summarizes the survival times of differently treated groups. In untreated animals, the tumor grew rapidly and killed the hosts after 10–12 days. Immobilized L-asparaginase (5 IU ip given in microparticles) generally prolonged the survival time to 15–16 days. In a large dose (20 IU) or in polyacryldextran particles (from which enzyme can leak out) immobilized L-asparaginase had a longer effect and was able to cure five and three animals in respective groups.

As mentioned, the effect of native L-asparaginase is prolonged in infected animals and most of the mice (11 out of 12) were cured by 5 IU ip administered as shown in Table I for comparison. As expected and already discussed, the same dose did not cure the animals when the tumor was inoculated concomitantly with the administration of native L-asparaginase. These results are in complete accordance with the effect on the serum L-asparagine level shown in Figs. 1 and 3.

The tumor growth-inhibiting effect of immobilized L-asparaginase is improved when administered intramuscularly. The survival time of the different groups is shown in Table I. Three mice out of eight were cured when 5 IU of immobilized L-asparaginase was given intramuscularly. When 20 IU or 2 × 2.5 IU was administered, 8 and 10 animals, respectively, out of 12 survived for several weeks and were considered to be cured.

Intraperitoneal injection of acryldextran particles (DTC = 11-1-75) with L-asparaginase (5 IU) to C3H mice with 6C3HED cells, prolonged the survival time significantly compared with controls. Figure 5 and Table I summarize the results. After injection of particles with enzyme, normal serum values were obtained on days 9–10.

The Effect on Ascites Tumor by Implantation of L-Asparaginase in Polyacrylamide—L-Asparaginase in microparticles (TC = 8-25) was incorporated into a polyacrylamide gel (TC = 16-25). This gel, containing 10 or 20 IU of L-asparaginase, was then implanted subcutaneously on the backs of the mice.

The effect on the L-asparagine level is shown in Fig. 5. The serum concentration of L-asparagine fell from normal (40 nmoles/ml) to 18 nmoles/ml after 1 day and remained at this level during the rest of the experiment. On days 10–14 after inoculation of the cells (6–10 days after the implantation), all the animals died with one exception. This animal survived for several months and was considered to be cured. Table I summarizes the results. There were no significant differences between implants with 10 or 20 IU of L-asparaginase. These results indicate that it is necessary to depress the L-asparagine concentration at least to <10 nmoles/ml to obtain regression of the lymphoma.

DISCUSSION

It was shown earlier that immobilization of L-asparaginase significantly prolongs the depressive effect on the L-asparagine level in blood (6, 7, 9, 12). Potentially, an immobilized system would be of value to decrease the side effects seen when native L-asparaginase is used in high doses. The purpose of the present work was to correlate the effect on the L-asparagine level and the effect on an L-asparagine-glutamine-dependent lymphoma cell line. In addition, the purpose was to ascertain the optimal route of administration of the immobilized enzyme in microparticles and the minimal dose required to cure infected animals. The 6C3HED ascites tumor growing in C3H mice has been used, but it suffers from the disadvantage shared with other transplantable tumors growing in mice of contamination by the benign LDH-virus (14, 17). Unfortunately, this virus will, by some unknown mechanism, significantly increase the $t_{1/2}$ of native L-asparaginase. The duration of 5 IU L-asparaginase given intraperitoneally (measured by the period during which serum concentration of L-asparagine was undetectable) was increased from 5 to 7 days. However, the virus will have no effect on the duration of L-asparaginase in microparticles, which in essence is determined by the endocytic activity of the reticuloendothelial system (12). In an attempt to simulate the clinical situation, the effect of the enzyme was tested from day 4 after

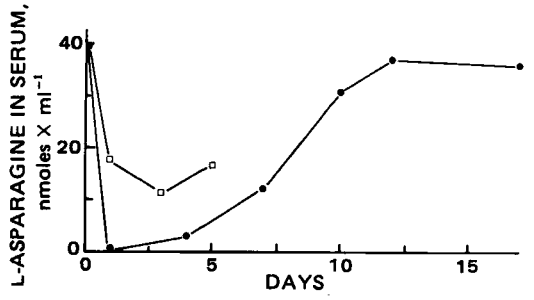

Figure 5—*L-Asparagine concentration in serum after a single intraperitoneal injection of L-asparaginase (5 IU/animal) in microparticles of polyacryldextran (●) or after implantation of 10 IU/animal sc on the backs of the mice (□). The mice were infected by the 6C3HED lymphoma, inoculated 4 days prior to the treatment. Pooled blood from 4 to 6 animals was used for each point.*

inoculation, when the virus already was sufficiently active and the number of tumor cells had significantly increased. This means that evaluation of the effect of the immobilized L-asparaginase unfortunately must be based on the comparison with the effect on the L-asparagine level obtained by giving the native enzyme on the inoculation day (before the cancer has proliferated in the host or in healthy mice).

When administered intraperitoneally, the efficiency of L-asparaginase immobilized in microparticles is equivalent to that of free enzyme, as depicted in Fig. 1. However, intramuscular administration clearly shows that the enzyme in immobilized form had longer L-asparagine-depressing activity than in free form (compare Figs. 2 and 4).

Within some limits the therapeutic effects of L-asparaginase in humans are dose related (3). The primary parameter of this effect, is the L-asparagine serum concentration, which has to be depressed to very low levels in order to prevent the growth of the tumor. We found that this level has to be <10 nmoles/ml in the C3H mice, while the normal value is ~40–45 nmoles/ml. Moreover, it is important that the L-asparagine concentration be kept at this very low level for at least 6–7 days to obtain complete regression of the tumor in the mice (measured as the survival time of 50 days). When the L-asparagine concentration was depressed to 0 values for only 5 days, the cancer growth generally recurred and the mice died within 2–3 weeks.

L-Asparaginase is very stably bound in the porous polyacrylamide microparticles and can therefore not interact directly with the tumor cells. It is obvious that the therapeutic effect of L-asparaginase is mediated *via* its L-asparagine-depressing activity.

In this study, the best L-asparagine-depressing effects were obtained with L-asparaginase in microparticles given intramuscularly. Table I, shows that the groups treated with immobilized enzyme contain more 50-day survivors than those treated with the same doses intraperitoneally. Particles administered intraperitoneally are rapidly cleared by the reticuloendothelial system and stored in the lysosomal vacuomes (18). The enzyme is thus secluded from the systemic circulation and cannot affect the L-asparagine level. The same will happen with microparticles injected intravenously (18), and to date no intravenous studies have been performed. When larger polyacryldextran particles were used intraperitoneally, the systemic effect lasted a little longer than with small polyacrylamide particles, which probably was due to enzyme leaking out from the polyacryldextran particles prior to their phagocytosis. It was shown earlier (14) that proteins immobilized in biodegradable polyacryldextran are not stably bound in such particles.

Microparticles given intramuscularly are eventually taken up by invading macrophages and/or encapsulated by fibroblasts, which will prevent further effects on the systemic L-asparagine level of the immobilized enzyme. In the present case a small dose (2.5 IU im) was administered. Although such a small dose was effective, the duration was limited by the phagocytosis of particles; this was circumvented by giving a second small dose after an interval of 3 days. Such a regimen was shown to be significantly more effective than one single dose of the same amount of L-asparaginase. Ten out of 12 treated mice were completely cured and lived for several months.

In an evaluation of the optimal route of administration, the immunological properties of the immobilized enzyme should be considered. Preliminary results (19) indicate that L-asparaginase in microparticles given intramuscularly is less immunogenic than the native form of the enzyme as manifested by a lower antibody production in mice. In addition, no toxic effects have been detected after injection of moderate doses of microparticles in mice (20).

In summary, all the results indicate that the optimal effect of L-asparaginase is obtained when the enzyme is injected intramuscularly in immobilized form in small doses.

Acrylic Microspheres *In Vivo* VII: Morphological Studies on Mice and Cultured Macrophages

PETER EDMAN *, INGVAR SJÖHOLM *x, and ULF BRUNK

Received October 13, 1981, from the *Departments of Pharmaceutical Biochemistry and Pathology, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication June 7, 1982.

* Present address: Department of Drugs, National Board of Health and Welfare, Division of Pharmacy, S-751 25 Uppsala, Sweden.

Abstract □ Intravenously injected microparticles of polyacrylamide were cleared from the circulatory system in mice predominantly in liver, spleen, and bone marrow in mice by macrophages belonging to the reticuloendothelial system. In these cells, particles were found in dilated secondary lysosomes. The lysosomotropic character of the particles was further demonstrated using cultured peritoneal mouse macrophages. Histological changes of the liver, spleen, and bone marrow detectable by light and electron microscopy could only be seen after administration of massive doses of microparticles corresponding to 160 mg/kg body weight. In such cases, a medium-coarse vacuolization of liver parenchymal cells could be seen 1–2 days after particle administration. After 3–5 days, degeneration and necrotic cellular alteration occurred in the liver, spleen, and bone marrow. One week after particle administration, regeneration started under formation of granulomas which replaced the necrotic areas. The tissues later became normalized (after 2–3 weeks), but small granulomas remained for several weeks. The damage was parallelled by changes in the liver and spleen weights. Electron microscopy of the liver revealed that the initiated vacuolization of the parenchymal cells was due to mitochondrial swelling with rupture of the mitochondrial cristae.

Keyphrases □ Acrylic microspheres—*in vivo*, morphological studies on mice and cultured macrophages, polyacrylamide, liver, spleen, marrow □ Macrophages, cultured—acrylic microspheres, *in vivo*, morphological studies on mice, polyacrylamide, liver, spleen, marrow □ Polyacrylamide—acrylic microspheres, *in vivo*, morphological studies on mice and cultured macrophages, liver, spleen, marrow

Microparticles of highly cross-linked polyacrylamide, or derivatives, have recently been introduced as a slowly degradable carrier system for immobilized enzymes *in vivo* (1). Such particles have a pronounced porous structure allowing substrates to freely penetrate the particles and interact with the immobilized enzymes. They are small enough (mean diameter 0.1–0.4 μm) to be injected intravenously without causing respiratory complications. After intravenous or intraperitoneal injection, the microparticles are taken up by cells of the reticuloendothelial system, essentially in the liver and spleen, where they are probably localized in the lysosomal vacuome, although no direct evidence has yet been presented. Microparticles with immobilized L-asparaginase have been used to depress the level of circulating L-asparagine with resulting growth inhibition of the ascites tumor 6C3HED in mice (2). In addition, particles containing dextranase have successfully been used to treat an artificial storage disease in mice, which is produced by polyacryldextran (3).

In all studies performed to date, no signs of acute toxicity have been detected. Thus, the growth rate and survival time have been unaffected, and no tissue incompatibility has been noticed, besides the normal encapsulation of implants or intramuscularly injected microparticles. Very large doses of microparticles (100–200 mg/kg of body weight), however, have produced a transient hepatosplenomegaly in mice, lasting 4–8 weeks, resulting from the localization of the spheres in the liver and spleen. The purpose of the present work was to study microscopically the possible morphological alterations of several organs following the administration of such provocative doses of

0022-3549/83/0600-0658$01.00/0

In summary, all the results indicate that the optimal effect of L-asparaginase is obtained when the enzyme is injected intramuscularly in immobilized form in small doses.

Very large doses of microparticles (100–200 mg/kg of body weight), however, have produced a transient hepatosplenomegaly in mice, lasting 4–8 weeks, resulting from the localization of the spheres in the liver and spleen. The purpose of the present work was to study microscopically the possible morphological alterations of several organs following the administration of such provocative doses of

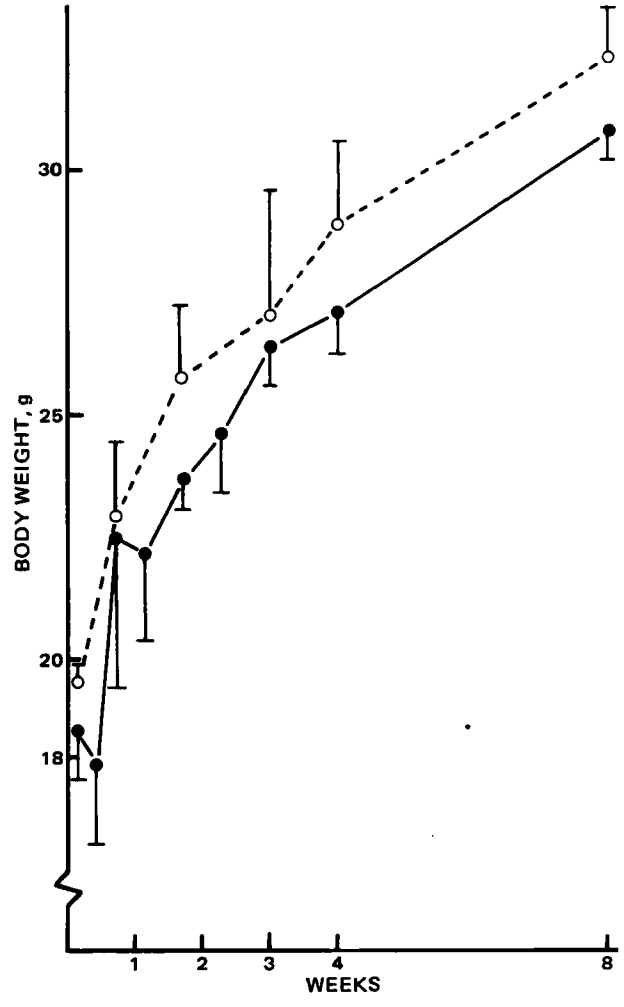

Figure 2—*Body weight of mice given 4 mg of polyacrylamide particles (●) or physiological saline (○) intravenously. Each point represents mean ±SD from five animals.*

Preparation and Administration of Microparticles—Microparticles[5] of polyacrylamide (TC = 8-25)[6] or polyacryldextran (DTC = 11-1-75)[6] were prepared according to a reported method (4, 5). Acrylamide or acryldextran and *N,N'*-methylenebisacrylamide were dissolved in sodium phosphate buffer, pH 7.4. Oxygen was eliminated from this solution with nitrogen gas. The toluene–chloroform mixture (4 + 1) containing a detergent[7] was treated in the same manner. After addition of the catalyst, ammonium peroxydisulfate (dissolved in water), the mixture was homogenized to produce a water-in-oil emulsion. The polymerization of the emulsion was initiated by adding *N,N,N',N'*-tetramethylethylenediamine.

The suspension was stirred for 20 min and the phases were separated by centrifugation. The microparticles located at the bottom of the water phase were washed at least five times, and after the last washing the particles were suspended in physiological saline.

When microparticles with immobilized ferritin or immobilized catalase were prepared, ferritin (52 mg) or catalase (20 mg) was dissolved in 2.5 ml of the acrylic monomer solution. After polymerization, the particles were washed as described above.

The microparticles were resuspended carefully in physiological saline prior to administration. The size of the particles was measured from photographs taken by scanning electron microscopy, which was done as described earlier (4). With the method used, 92.6% of the polyacrylamide particles (TC = 8-25) had a diameter of 0.1–0.4 μm, 2.2% were <0.1 μm, and 5.2% had a diameter of 0.4–0.5 μm. The polyacryldextran particles (DTC = 11-1-75) had essentially a diameter of 0.2–1.2 μm; 72.8% of the particles had a diameter within this range, and 8.9% were <0.2 μm and 5.8% were >2.1 μm.

(d) Liver showing small granulomas (arrow) 16 days after intravenous injection of polyacrylamide microparticle (186×). (e) Liver 8 weeks after intravenous injection of physiological saline (186×).*

Male mice[8] weighing 20–25 g were used throughout. Microparticles of polyacrylamide or polyacryldextran were suspended in physiological saline (0.1 or 0.2 ml) and injected intravenously. The doses corresponded to 1–4 mg of lyophilized microparticles.

[8] NMRI-mice, Anticimex, Stockholm, Sweden.

Preparation of Tissue Samples for Light and Transmission Electron Microscopy—At various time intervals (1–56 days) after exposure to the microparticles, five animals from each group were sacrificed by cervical dislocation, and the liver, spleen, heart, lungs, kidneys, brain, and bone marrow from the spine were collected. At each time interval, three mice from an untreated group were sacrificed and their organs used

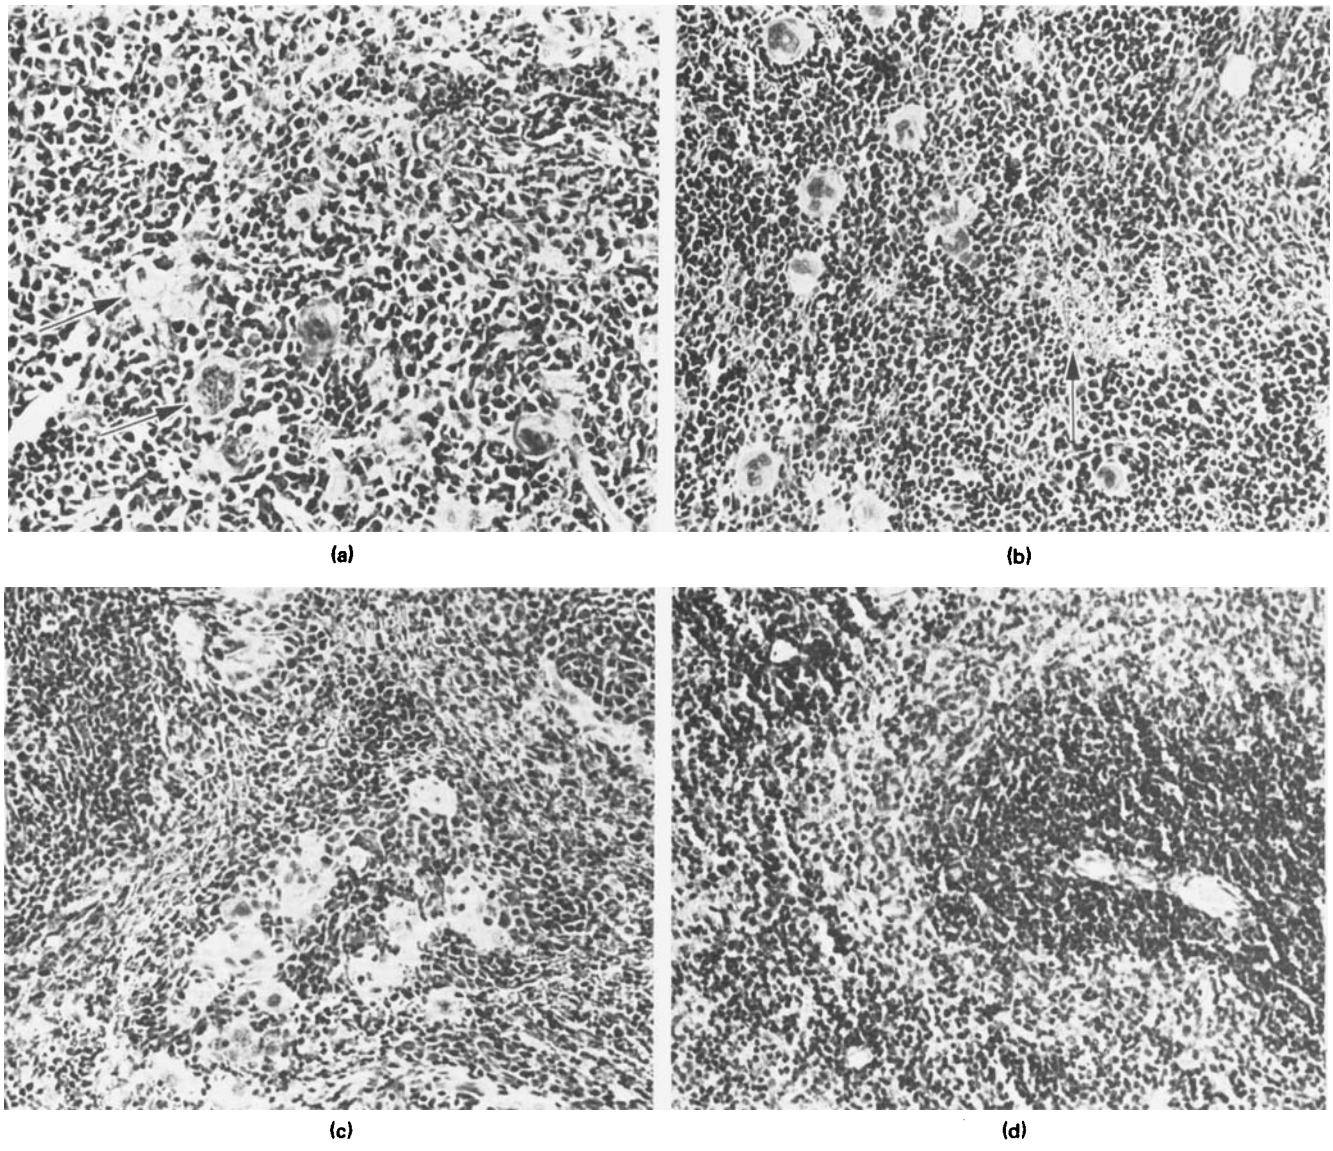

Figure 4—*(a) Spleen 3 days after intravenous injection of polyacrylamide microparticles. The architecture is much altered, with no demarcation between the red and white pulp and heavy infiltration of inflammatory cells. Small abscesses are shown by arrow (186×). (b) Spleen with forming granulomas (arrow) 8 days after intravenous injection of polyacrylamide microparticles (186×). (c) Spleen 21 days after intravenous injection of polyacrylamide microparticles; reconstitution of red and white pulps but remaining granulomas (186×). as the control group. The liver, spleen, heart, lungs, brain, and kidneys were weighed, and thin (2 mm) tissue specimens were cut from the organs immediately, and immersed in chilled 5% formaldehyde in 0.15 *M* phosphate buffer, pH 7.2. The specimens were subsequently embedded in paraffin, cut at 2–3 μm, stained with hematoxylin and eosin, and studied under the light microscope.

For transmission electron microscopy, small samples (<1 mm thick) were removed from the liver immediately after the animals were sacrificed. The specimens were immersed in ice-cold 2% glutaraldehyde in 0.1 *M* sodium cacodylate buffer with 0.1 *M* sucrose (pH 7.2; total osmotic pressure 510 mOsm, effective osmotic pressure 300 mOsm) (6, 7). After glutaraldehyde fixation for 24 hr, the specimens were rinsed in 0.15 *M* sodium cacodylate buffer, pH 7.2, and cut into small pieces which were postfixed in 1% OsO_4 in 0.15 *M* sodium cacodylate buffer for 90 min at room temperature. The specimens were dehydrated in an ethanol series, stained *en masse* with 2% uranyl acetate in 50% ethanol for 12 hr, and embedded in expoxy[9]. Thin sections were cut with diamond knives, stained with lead (8), and examined at 60 kV with an electron microscope[10].

Transmission Electron Microscopy of Negatively Stained Microparticles—A suspension of ferritin-labeled microparticles was placed as a tiny drop on formvar coated 300-mesh copper electron microscopy grids and most of the fluid was immediately removed with a piece of filter paper. A drop of a 0.2% water solution of uranyl acetate was applied for 30 sec and removed with filter paper. After drying, the grids were examined at 80 kV with the electron microscope[10], using a 50-μm objective aperture.

Cultures of Mice Peritoneal Macrophages—Mouse macrophages were collected by washing the unstimulated peritoneum of adult male animals[8] with 3 ml of warm (37°) phosphate-buffered saline. The cells were further suspended in 10 ml of cold (0°) phosphate buffer and mildly spun down at 180×*g* for 10 min. The pellet was resuspended in F-10 medium (9) with 20% newborn calf serum and 15 m*M* *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulfonic acid buffer, supplemented with 10 μg/ml of streptomycin and 100 U/ml of penicillin. The cells were seeded into 50-mm plastic petri dishes at 5×10^5 cells/dish and cultured at 37° in 5% carbon dioxide in air at 85% humidity. The dishes were carefully rinsed with new, complete medium 24 hr after the initial seeding, to eliminate red blood cells, lymphocytes, and macrophages that had not attached to the solid support. During the ensuing cultivation period the medium was changed every 48 hr.

Cultures were exposed to 0.1 mg/ml of microspheres containing ferritin as a marker 24 hr after seeding (immediately after being rinsed). The cells were exposed to these particles for 48 and 72 hr and then fixed in 2% glutaraldehyde in 0.1 *M* sodium cacodylate buffer with 0.1 *M* sucrose (pH

7.2, total osmotic pressure 510 mOsm, effective osmotic pressure 300 mOsm (6, 7) for 60 min at 0°, rapidly rinsed in 0.15 *M* sodium cacodylate buffer and postfixed in 1% OsO_4 in 0.15 *M* sodium cacodylate buffer for 90 min at room temperature. The cells were then dehydrated *in situ* in an ethanol series, counter-stained *en masse* for 12 hr in 2% uranyl acetate in 50% ethanol, and embedded in small capsules in epoxy as described earlier (10). Untreated control cells were harvested at the same time intervals. Thin sections were cut with diamond knives, stained with lead citrate (8), and examined at 60 kV with the electron microscope[10].

RESULTS

Gross Distribution of Microparticles After Intravenous Injection—It was shown in an earlier study (11) that the distribution of large doses of microparticles to the reticuloendothelial system in mice after intravenous injections results in a transient hepatosplenomegaly. To correlate the megaly with the microscopic findings, the weight changes were studied in some detail.

Figures 1a and 1b show the variations in weight of the liver and the spleen, respectively, with time after 4-mg iv injections of microparticles. The liver weight reached its maximum after 5–8 days and was essentially normalized after 4–8 weeks. The effects of the microparticles on the growth of the spleen were relatively greater than on the liver (Fig. 1b). One week after the injection, the weight was ~220% of that of the controls. The megaly was successively retracted, but the organ weight was not normalized within the 8-week study period. In the earlier work (11), the weight of the spleen was normalized after 16–24 weeks. With smaller doses of polyacrylamide (1 mg) or of polyacryldextran (2 mg) enlargement of the liver and spleen was not as great. This weight increase was strictly dose dependent.

The variation in body weight after intravenous injection of 4-mg polyacrylamide microparticles is shown in Fig. 2. As is apparent from the figure, there were no significant differences between the control and test groups. Although the overall weight of the test group was lower at the time of injection, the increase in weight with time was the same. Consequently, the administration of large doses of microparticles to the mice did not affect growth.

Light Microscopy of Mouse Tissue—*Following* the administration of 1 mg of particles, no changes were detected by light microscopy in any of the studied organs. No demonstrable changes were noted in the brain, heart, kidneys, or the lungs, while the liver, spleen, and the bone marrow showed pronounced alterations after injection of 4 mg of particles.

As early as 1 day after particle administration, the parenchymal cells of the liver showed a medium coarse vacuolization, which had a patchy distribution (Fig. 3a). After a few more days, necrotic areas of various sizes had developed corresponding to the areas of initial vacuolization, as well as unicellular necrosis (Fig. 3b). There was a diffuse, sparse infiltration of inflammatory cells (Figs. 3c and d). Later, regeneration started with mitotic activity within the parenchymal liver cell population. After 7–10 days, granulomas composed of macrophages, epithelioid cells, lymphocytes, and polymorphonuclear cells formed and replaced the necrotic cells and areas (Fig. 3d). These granulomas remained for several weeks. The number of Kupffer cells was found to have increased at later time intervals. The normal ultrastructural appearance of the liver 8 weeks after intravenous injection of physiological saline is shown in (Fig. 3e).

In the bone marrow there was an early (after 1 day) and massive infiltration of mature, irregularly distributed polymorphonuclear cells and macrophages with the formation of granulomas. After 7–10 days, the bone marrow had regained an apparently normal appearance.

The spleen showed early and pronounced changes. After 1–3 days, the limits between the white and the red pulps were blurred, the sinusoids were dilated and lined with prominent endothelial cells, and the number of megakaryocytes was increased (Fig. 4a). Later (4–10 days) there was a heavy infiltration of various inflammatory cells under formation of small abscesses and granulomas (Fig. 4b). The tissue became normalized later, but small granulomas, composed of histiocytes, remained for many weeks (Fig. 4c). The normal appearance of the spleen is shown in (Fig. 4d).

Transmission Electron Microscopy of Liver Tissue—The vacuoles of the liver cells, which were so strikingly observed 1 or 2 days after the administration of large amounts of particles, were found to be due to mitochondrial swelling with rupture of the mitochondrial cristae (Fig. 5). There was no obvious alteration of the lysosomal vacuome of the parenchymal cells. The Kupffer cells showed many dilated lysosomes filled with an amorphous material.

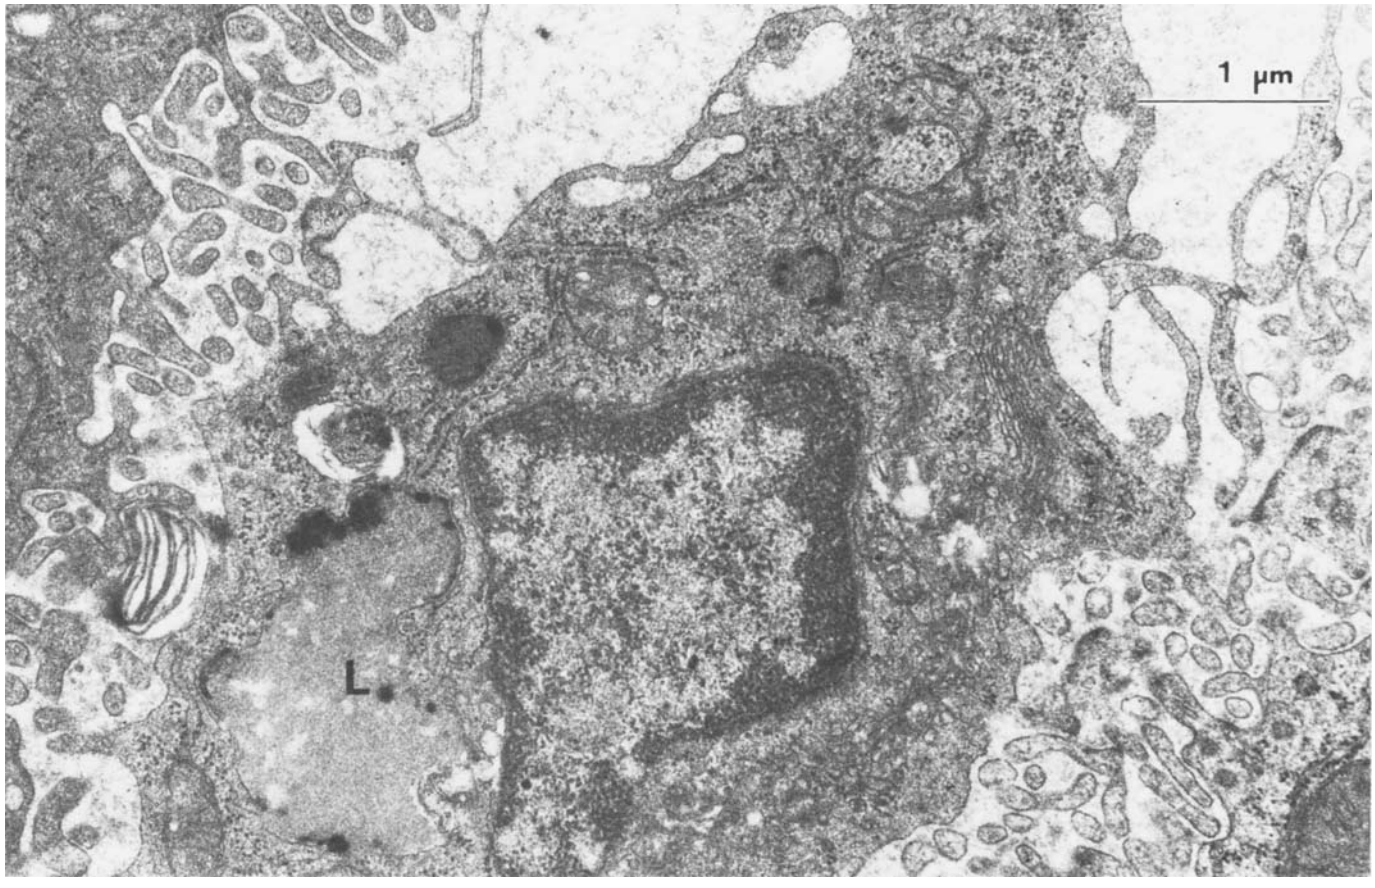

Figure 6—*Kupffer cell 2 months after injection of 4 mg iv polyacrylamide microparticles loaded with catalase. Note large vacuoles (L, secondary lysosomes) filled with an amorphous material.*

At later time intervals, the tissue degeneration prevented detailed studies on cellular alterations until the acute inflammatory response had declined. In the specimens studied ~2 months after the administration of the catalase-loaded particles, these lysosomes were still frequently observed (Fig. 6). It was, however, not possible to discern individual particles either in liver parenchymal or in Kupffer cells. Obviously, the particles have an electron density about equal to that of the embedding resin and do not bind osmium, uranyl, or lead.

Transmission Electron Microscopy of Negatively Stained Microparticles—Transmission electron microscopy of the ferritin-loaded microparticles indirectly confirmed (12) that the polyacrylamide particles were spherical and had a diameter between 0.1 and 0.4 μm. Ferritin gave the particles a dotted appearance.

Transmission Electron Microscopy of Cultured Macrophages—Macrophages exposed to 0.1 mg of microparticles with ferritin per milliliter of medium for 72 hr showed a high increased rate of autophagocytosis and an increased number of secondary lysosomes containing an amorphous material with tiny electron dense particles corresponding to the ferritin of the labeled microspheres. In most lysosomes the electron dense particles were concentrated toward the periphery of the organelles (Figs. 7a and b).

DISCUSSION

As mentioned earlier, no signs of acute toxicity were detected when microparticles of acrylic polymers were used as carriers for enzymes in various experiments on mice and rats (1). When the distribution of such small particles was studied in mice (11) only a transient hepatosplenomegaly was noticed. The present work has, moreover, demonstrated that a large number of spheres must be administered in order to produce any pathological morphological alterations in the liver, spleen, and bone marrow, which constitute the tissues where the microparticles are localized *in vivo* (11). The effects described in the present study are generally obtained after treatment with doses corresponding to 160 mg of dried material per kg of body weight. Such a very large dose is necessary to produce the adverse reactions, which are important to know, since the microparticles are an attractive alternative as enzyme carriers for future human applications.

It is important to stress that when dose levels of 40 mg/kg were used (corresponding to the administration of 1 mg of particles to the mice), only insignificant, hardly detectable morphological reactions could be seen in the liver, spleen, and bone marrow.

The first general reaction in the liver tissue, detected by light microscopy and transmission electron microscopy, on exposure to the high doses of microparticles, was the swelling of the mitochondria of the parenchymal cells, which were eventually ruptured as part of cellular degeneration. Necrosis of the tissues followed, and inflammatory cells migrated into the area, with a megaly as a consequence. The weight changes of the liver and spleen followed very closely the morphological changes seen with the light and electron microscopes and reached maxima at the same time as the maximum of the tissue damage. Thus, the megaly was probably essentially due to the increased number of cells in the liver and spleen, and only to a minor extent a result of cellular edema.

The reason for the initial hepatocellular degeneration is not obvious, and the interpretation of our results is hampered by the fact that the microparticles could not be seen directly with the electron microscope. The spherical form of the ferritin-loaded microparticles was confirmed by negative staining, and ferritin could be used as a marker in the *in vitro* experiments with cultured macrophages to trace the microparticles.

In these studies it was quite evident that the microparticles had been taken up by the cells and introduced into the lysosomal vacuome, as seen both indirectly by the markedly increased number of lysosomes and their swelling, and directly by the localization of large amounts of electron dense material in the lysosomes (Fig. 7b), which was not seen in the control (Fig. 7a). Consequently, it might be suggested that the degenerative cellular alterations, *e.g.*, the swelling and rupture of the mitochondria, giving rise to the vacuolization of the liver parenchymal cells, are due to an altered function of the lysosomal apparatus. It was thus not possible to directly detect the particles in the hepatocytes in the tissue samples. The indirect evidence, however, suggests an uptake both in the Kupffer and the parenchymal cells. Most probably the small size of the particles allows their passage into the space of Dissé through the existing gaps in the sinusoidal endothelium exposing the microparticles to the liver parenchymal cells which could bring about their endocytosis.

The present work is only semiquantitative, in the sense that the toxic

(b)

Figure 7—*(a) Normal mouse peritoneal macrophage cultured* in vitro. *MP denotes the microprecipitate to which the cells have attached. (b) Macrophage 72 hr after exposure to ferritin-labeled polyacrylamide microparticles (0.1 mg/ml of medium). Note the large number of lysosomes (L) containing microparticles with ferritin.*

reactions seen in the mice are proportional to the doses given, and only detectable when the mice are exposed to very high doses exceeding 40 mg/kg of body weight. Quantitative studies are not possible *in vivo*, when the relationship between the number of particles taken up per cell cannot be satisfactorily controlled. For such studies, it is necessary to use suitable *in vitro* systems, *e.g.*, cultured peritoneal macrophages, where the relationship between the number of particles and cells can be carefully controlled. Such studies will be presented separately, showing when exposure of cultured macrophages to microspheres will lead to changed intracellular function and cellular degeneration. Subsequent *in vivo* applications with acrylic microspheres must be based on such studies.

Poly-L-methionine Sulfoxide: A Biologically Inert Analogue of Dimethyl Sulfoxide with Solubilizing Potency

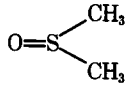
JOSEF PITHA *x, LAJOS SZENTE *, and JUDITH GREENBERG ‡

Received January 18, 1982, from the **National Institutes of Health, National Institute on Aging-GRC, Baltimore, Maryland 21224* and the ‡*National Institute of Dental Research-NIH, Bethesda, Maryland 20205.* Accepted for publication June 8, 1982.

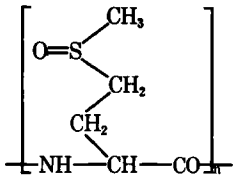
Abstract □ Poly-L-methionine sulfoxide is a water-soluble polymer containing the sulfoxide moiety. The preparation and radiolabeling of this polymer is described and its bioeffects are compared with those of dimethyl sulfoxide. Poly-L-methionine sulfoxide is similar to dimethyl sulfoxide in that it is a potent solubilizer of lipophilic compounds in water. Although the partition coefficient of poly-L-methionine sulfoxide in 1-octanol–water is only 20 times lower than that of dimethyl sulfoxide, it was found not to penetrate into intracellular spaces. In contrast to dimethyl sulfoxide, poly-L-methionine sulfoxide and L-methionine sulfoxide were found to be ineffective in inducing differentiation in murine erythroleukemia cells and inhibiting differentiation of avian neural crest cells, suggesting that compounds effective in these processes must have the ability to penetrate into cells or membrane proteins. Overall lack of bioactivity of poly-L-methionine sulfoxide, combined with low toxicity (2 g/kg, iv, in the mouse with no effect), makes this compound a suitable inert solubilizer and carrier for lipophilic drugs.

Keyphrases □ Dimethyl sulfoxide—poly-L-methionine sulfoxide, biologically inert analogue with solubilizing potency □ Poly-L-methionine sulfoxide—biologically inert analogue of dimethyl sulfoxide with solubilizing potency □ Solubilization potency—poly-L-sulfoxide, biologically inert analogue of dimethyl sulfoxide

A majority of the applications of polymers in pharmacy are based on their mechanical properties and inertness. Also, polymers are able to form complexes with pharmaceuticals; this property has been used relatively rarely, *e.g.*, in decreasing the aggressive properties of iodine by complexation with povidone. Furthermore, polymers possessing complexing power can be used, instead of organic



Dimethyl Sulfoxide



Polymethionine Sulfoxide

solvents, to dissolve nonpolar drugs in aqueous media and to promote sorption of pharmaceuticals. Dimethyl sulfoxide (I), one of the solvents often used for this purpose (1, 2), is relatively nontoxic to cells, yet easily penetrates cellular membranes and, in some cases, triggers very complex biological responses, *e.g.*, induction (3–8) and inhibition (9–12) of cellular differentiation.

It may be advantageous, for both practical applications and for studies of the induction mechanism, to supress some of its bioeffects, *i.e.*, to make a new selective agent by chemical modifications from a pluripotent compound. This may be possible by preparing a macromolecule that contains structural elements of dimethyl sulfoxide. A

nondegradable polymer containing the structural elements of dimethyl sulfoxide was prepared previously by a multi-step synthesis (13). In contrast to that study, this study describes a facile synthesis of a degradable polymer: poly-L-methionine sulfoxide.

EXPERIMENTAL

Preparation of Poly-L-methionine Sulfoxide—A saturated aqueous solution of sodium periodate (321 mg) was added slowly to a stirred solution of 224 mg of poly-L-methionine[1] (average molecular weight 30,000) in 7 ml of acetic acid at room temperature. Stirring was continued for 12 hr. Water (14 ml) was then added to the reaction mixture, the solution was dialyzed against water, clarified by centrifugation (10,000 rpm for 10 min), and freeze-dried. This procedure yielded 120 mg of colorless polymer. To quantitate the extent of oxidation, the polymer was dissolved in deuterium oxide and its NMR spectrum measured on a 60-MHz spectrometer[2]. Resonance of the methyl group of sulfoxide residues occurs at 2.75 ppm and that of sulfone residues occurs at 3.15 ppm; no signal attributable to methylthio groups could be detected. From the integration of the spectrum it was calculated that the sulfoxide methyl group predominates over the sulfone methyl group by a ratio of 5:1.

Tritiation of Poly-L-methionine Sulfoxide—Poly-L-methionine sulfoxide (4 mg) was added to a solution of 3.5 ml of benzene containing [^{3}H]ethyl methanesulfonate (225 μCi, 0.4 mg)[3]. The mixture was stirred for 15 min, frozen, kept at −20° overnight, and then kept at 80° for 1 week; the solvent was then evaporated. The residue was dissolved in water and dialyzed against water. The residue contained 1 μCi of radioactive polymer (3 mg).

All other compounds used were obtained commercially.

Solubilization of Lipophilic Compounds by Poly-L-methionine Sulfoxide—Excess lipophilic compound (5–10 mg) was enclosed in a test tube (polyethylene, volume 1.2 ml) with phosphate-buffered isotonic saline (1 ml) lacking or containing poly-L-methionine sulfoxide (50 mg). The suspension was stirred by rotating the test tube for 1 day in the dark at 20–22°. Thereafter the suspension was centrifuged and the concentration of lipophilic compound in the clear supernatant was determined spectrophotometrically.

Measurement of Distribution of Compounds Between 1-Octanol and Water—Compounds were equilibrated with the above solvents for 6–24 hr at 20–22° and their concentration determined by liquid scintillation counting (dimethyl sulfoxide) or spectrophotometrically (poly-L-methionine sulfoxide, 210-nm wavelength).

Measurement of Distribution of Compounds Between the Cells in Culture and the Medium—The assay contained a 0.2-ml pellet of murine erythroleukemia cells[4] (14) (1×10^8 cells) and the medium[5] in addition to the radioactive compound studied, in a total volume of 1 ml. The equilibrium distribution of the compound studied was established by incubation for 2 hr at 37°. The cells and medium were separated by centrifugation and the concentration of the compound was calculated from the results of liquid scintillation counting.

Induction and Inhibition of Cell Differentiation—Murine erythroleukemia cells were grown in suspension cultures in medium[5] supplemented with 10% calf serum and antibiotics. The cells were exposed to a potential inducer for 5 days, and their differentiation was assayed by calculating the percentage of cells that were stained by benzidine (14).

Cultures of avian neural crest cells were initiated as described previously (12). Cells were subcultured in replicate plates (10,000–15,000 cells/plate) 2 days after explantation (day 2) and grown in a 1:1 mixture of medium[6] and broth[7] supplemented with 2% chick embryo extract and 5% calf serum.

The assay on neural crest cells was run as follows. Cells were grown in the presence or absence of the test compound from day 2 to 7 of culture. On day 7 fresh medium containing the test compound was added. Cells were then labeled for 5 hr with 5 μCi/ml of [^{14}C]tyrosine[8]. Incorporation of radioactivity into the trichloroacetic acid-insoluble fraction of the cells and melanin-specific incorporation was determined as described previously (12). All values given represent means of duplicates that differed by <10%.

RESULTS

The easiest procedure for preparing poly-L-methionine sulfoxide is the one involving the mild oxidation of poly-L-methionine. Various agents oxidize sulfides to sulfoxides (15, 16). *m*-Chloroperbenzoic acid, iodine, and sodium periodate were tested as oxidizing agents. When sodium periodate was used, no detectable methylthio residues remained, and the overoxidation of the sulfoxide group to the sulfone moiety was only ~16% of the total. Radioactive labeling of poly-L-methionine sulfoxide was performed by an exchange of some of the methyl groups in the polymer for [^{3}H]ethyl groups; since only ~0.05% of these groups were exchanged, the effects of such an introduced structural change on the polymer properties may be disregarded. This labeling occurred using only small amounts of radioactive [^{3}H]ethyl methanesulfonate (0.4%); however, good yields of ^{3}H-polymer (75%) were readily obtained in this manner.

Poly-L-methionine was found to be a potent solubilizer of organic compounds. A series of terpenoid-like lipophilic compounds containing up to 40 carbon atoms was evaluated (Table I).

Next, the partition coefficients (1-octanol–water) of dimethyl sulfoxide and poly-L-methionine sulfoxide were measured. The partition coefficient of dimethyl sulfoxide was found to be 0.038 ($\sigma = 0.007$, $N = 10$). This value compares with 0.01 and 0.04 reported previously (17, 18). The partition coefficient of poly-L-methionine sulfoxide was found to be 0.002 ($\sigma = 5 \times 10^{-5}$, $N = 3$).

The partition of a compound between the cultured cells and surrounding medium is a good indicator of the ability of that compound to be adsorbed by and penetrate cells, the latter process being the important one in equilibrium. For calculation of such distribution from the directly measurable concentrations of the compound in the medium and in the cell pellet, it is necessary to estimate the amount of medium that is retained in the cell pellet. Inulin, an electroneutral polysaccharide which does not penetrate into cells and is only slightly adsorbed by cells, was used for this estimate. The results (Table II) show that poly-L-methionine sulfoxide is excluded from cells to the same extent as inulin. On the other

hand, 0.6–1.1 fg of dimethyl sulfoxide were taken up per cell. The partition coefficient (concentration in cells/concentration in medium) of dimethyl sulfoxide, when calculated from these measurements, is 0.52 ($\sigma = 0.1, N = 4$).

The ability of the test compounds to induce differentiation of erythroleukemia cells was assessed by calculating the percentage of hemoglobin-synthesizing cells (*i.e.*, benzidine positive) on the 5th day of exposure to the agent. Dimethyl sulfoxide increased the percentage of benzidine-positive cells up to 40 times over that of the untreated controls (Table III). In contrast, poly-L-methionine sulfoxide was completely inactive. For further comparison L-methionine sulfoxide was also included in the test and found inactive (Table III). Concentrations up to the toxic range were tested (Table III), and additional measurements at longer exposure times were also performed to confirm the above conclusions (results not given).

Dimethyl sulfoxide is known to inhibit differentiation of neural crest cells (melanin synthesis) (12). The effects of dimethyl sulfoxide, poly-L-methionine sulfoxide, and L-methionine sulfoxide on the incorporation of [^{14}C]tyrosine into melanin were compared (Table IV). Dimethyl sulfoxide, as expected, inhibited incorporation, whether it was added to the cells only during the labeling period or was present throughout the culture period. In contrast, poly-L-methionine sulfoxide and L-methionine sulfoxide were inactive at 0.05%.

Toxic effects of poly-L-methionine *in vitro* in culture were relatively insignificant. To measure the toxicity of poly-L-methionine *in vivo* doses of 500, 1000, and 2000 mg/kg were injected intravenously into mice (strain C57B1/6J, 9 weeks old, females) using a peristaltic pump system described previously (19). No toxic effects or weight losses were observed when compared with controls, even with the highest dose.

DISCUSSION

Poly-L-methionine sulfoxide, in contrast to poly-L-methionine, is very water soluble. This solubility, its one-step preparation, and its ease of radiolabeling, make it suitable for biological studies.

Preparation of a macromolecular analogue of a pharmacon often leads to the elimination of some of its effects. Of the various bioeffects of dimethyl sulfoxide, conversion to the macromolecular poly-L-methionine sulfoxide, resulted in the retention of only the solubilization effects. Compounds used in solubilization tests (Table I) are structurally related. β-Ionone, a monocyclic terpene with a short side chain, was efficiently solubilized, whereas retinol, which contains the same monocyclic structure but has a longer side chain, was only moderately solubilized. β-Carotene and lycopene were solubilized to a moderate extent. These data suggest that poly-L-methionine sulfoxide preferentially solubilizes compounds which have a compact structure, *i.e.*, without long hydrocarbon chains. Vitamin D_3, which has such a compact structure, was indeed efficiently solubilized.

Partition coefficients of drugs and other organic compounds between 1-octanol and water have been used extensively in the correlation of their bioeffects. This coefficient is a measure of the ability of the drugs to interact and penetrate the lipid bilayer of cellular membranes, which is thought to be well approximated by 1-octanol. Using this established comparison system it was found that poly-L-methionine sulfoxide distributes less uniformly (0.002) than dimethyl sulfoxide (0.04). The value of the distribution coefficient of poly-L-methionine sulfoxide *per se* is not low enough to lead to the assumption that no penetration into cells or bioeffects may be achieved by this compound (18). Probably, the macromolecular character of poly-L-methionine sulfoxide is another

Table IV—Effect of Compounds on Pigmentation of Neural Crest Cells

Compound	Concentration, %	[^{14}C]Tyrosine Incorporation into Melanin, cpm/cell	
		Day 7	Days 2–7
—	—	0.008	0.004
Dimethyl sulfoxide	1	0	0
Poly-L-methionine sulfoxide	0.5	Not determined	Toxic
	0.05	0.007	0.006
L-Methionine sulfoxide	0.05	Not determined	0.006

contributing factor leading to the observed inertness. Poly-L-methionine sulfoxide was found, as described in the *Results* section, not to penetrate into the cellular spaces and, thus, may only interact with the external surface of cellular membranes.

In the context of the study on the mechanism of changes in cell differentiation induced by dimethyl sulfoxide it is important to note that its nonpenetrating analogue, poly-L-methionine sulfoxide, failed to affect cell differentiation in either of the systems tested. These findings suggest that the mechanism of action of dimethyl sulfoxide requires its entry into cells or into the hydrophobic interior of some protein on the cell surface, a process that can change the structure and function of the protein. The lack of penetration of poly-L-methionine sulfoxide into cells was proven experimentally; entry of a compound into the hydrophobic sections of proteins is possible only for small molecular weight hydrophobic or amphophilic molecules and, thus, poly-L-methionine sulfoxide is automatically excluded (20). A low molecular weight, highly polar analogue of dimethyl sulfoxide, L-methionine sulfoxide, also lacked any inducing ability (Tables III and IV).

In addition to the lack of cell-inducing activity, poly-L-methionine sulfoxide has low acute toxicity, even when given intravenously.

Thus, the most promising application of poly-L-methionine sulfoxide seems to be in the complexing of bioactive lipophilic compounds. This complexing converts the lipophilic compounds into water soluble ones; thus, to an extent poly-L-methionine sulfoxide may functionally imitate carrier serum proteins. Such complexing of drugs has often led to a decrease in their toxicity, as shown, for example, in the case of retinoids (21). Complexing of drugs with poly-L-methionine may possibly have the same consequences.

Nonisothermal Kinetics Using a Microcomputer: A Derivative Approach to the Prediction of the Stability of Penicillin Formulations

J. M. HEMPENSTALL *, W. J. IRWIN *x, A. LI WAN PO*, and A. H. ANDREWS ‡

Received March 2, 1982, from the **Department of Pharmacy, University of Aston in Birmingham, Gosta Green, Birmingham, B4 7ET, UK,* and the ‡ *Beecham Pharmaceuticals, Research Division, Worthing, West Sussex, BN14 8QH, UK.* Accepted for publication June 9, 1982.

Abstract □ A procedure is described for the determination of the shelf-life of pharmaceutical preparations using nonisothermal kinetics. A BASIC computer program, which enables the data analysis to be undertaken rapidly and automatically on a microcomputer, is presented.

Keyphrases □ Kinetics, nonisothermal—derivative approach to the prediction of the stability of penicillin formulations using a microcomputer □ Stability—nonisothermal kinetics using a microcomputer, a derivative approach to the prediction, penicillin formulations □ Penicillin—nonisothermal kinetics using a microcomputer, a derivative approach to the prediction of stability in formulations □ Formulations—penicillin, nonisothermal kinetics using a microcomputer, a derivative approach to the prediction of stability

Nonisothermal methods for the prediction of the shelf-life of pharmaceutical preparations are an attractive alternative to traditional isothermal accelerated storage tests. A nonisothermal study involves a temperature change throughout the reaction and enables a full stability–temperature profile to be determined from one experiment. This procedure offers a considerable reduction in effort for the estimation of shelf-life and has received much attention. Early methods (1, 2) were extended to pharmaceuticals by Rogers (3) who used a defined temperature rise profile to simplify data handling. The validity of this approach, using various heating programs, has been confirmed (4–8), but theoretical and practical limitations have been discussed (9, 10). Greater freedom in experimental design is available if a predetermined temperature–time profile is not demanded. Methodology has therefore been extended to allow the rate of temperature increase to be determined by experimental, rather than theoretical, expedience (11, 12). Nonisothermal–isothermal methods have also been reported (13, 14), and many important applications of nonisothermal kinetics to solid-state degradations have appeared (15, 16). The estimation of the errors involved in these procedures has also received attention (12, 17).

Despite the success of these methods, few applications to formulated products have appeared (18). In this study a general method for the determination of nonisothermal kinetic profiles is described, and a BASIC computer program (NONISO) is presented, which can be implemented on a microcomputer, to undertake the calculations automatically. The procedures are shown to be comparable to methods requiring large computing facilities (12) and prove satisfactory for formulated products.

THEORETICAL

Degradation Rates—The rate of degradation of a drug can be represented by:

$$\frac{-dC_t}{dt} = k_T C_t^n \qquad \text{(Eq. 1)}$$

where C_t is the concentration at time t, k_T is the specific rate constant at temperature T, and n is the order of reaction. For a first order reaction ($n = 1$) this can be written as:

$$C_t = C_0 e^{-k_T t} \qquad \text{(Eq. 2)}$$

In logarithmic form this is:

$$\ln C_t = \ln C_0 - k_T t \qquad \text{(Eq. 3)}$$

and the negative slope of the plot k *versus* $\ln C_t$ yields the rate constant.

When the temperature is continually increased throughout the reaction, the degradation rate progressively increases. The isothermal rate constant is now approximated by:

$$k_T = -\left[\frac{\ln C_t - ln C_{t-\delta t}}{\delta t}\right] \qquad \text{(Eq. 4)}$$

where δt is a small increment of time, over which period the temperature may be considered constant. For an infinitesimal increase in time and temperature, the specific rate constant is given by:

$$k_T = -\frac{d(\ln C_t)}{dt} \qquad \text{(Eq. 5)}$$

The slope of the tangent at a point for the plot of t *versus* $\ln C_t$ for nonisothermal data yields the specific rate constant at the temperature observed.

If other orders of reaction are followed the appropriate equations are:

$$\text{zero order:} \quad k_T = -d(C_t)/dt \qquad \text{(Eq. 6)}$$

$$\text{2nd order (a = b):} \quad k_T = d(1/C_t)/dt \qquad \text{(Eq. 7)}$$

Nonisothermal Kinetics Using a Microcomputer: A Derivative Approach to the Prediction of the Stability of Penicillin Formulations

J. M. HEMPENSTALL *, W. J. IRWIN *x, A. LI WAN PO*, and A. H. ANDREWS ‡

Received March 2, 1982, from the **Department of Pharmacy, University of Aston in Birmingham, Gosta Green, Birmingham, B4 7ET, UK,* and the ‡ *Beecham Pharmaceuticals, Research Division, Worthing, West Sussex, BN14 8QH, UK.* Accepted for publication June 9, 1982.

Abstract □ A procedure is described for the determination of the shelf-life of pharmaceutical preparations using nonisothermal kinetics. A BASIC computer program, which enables the data analysis to be undertaken rapidly and automatically on a microcomputer, is presented.

Keyphrases □ Kinetics, nonisothermal—derivative approach to the prediction of the stability of penicillin formulations using a microcomputer □ Stability—nonisothermal kinetics using a microcomputer, a derivative approach to the prediction, penicillin formulations □ Penicillin—nonisothermal kinetics using a microcomputer, a derivative approach to the prediction of stability in formulations □ Formulations—penicillin, nonisothermal kinetics using a microcomputer, a derivative approach to the prediction of stability

Nonisothermal methods for the prediction of the shelf-life of pharmaceutical preparations are an attractive alternative to traditional isothermal accelerated storage tests. A nonisothermal study involves a temperature change throughout the reaction and enables a full stability–temperature profile to be determined from one experiment. This procedure offers a considerable reduction in effort for the estimation of shelf-life and has received much attention. Early methods (1, 2) were extended to pharmaceuticals by Rogers (3) who used a defined temperature rise profile to simplify data handling. The validity of this approach, using various heating programs, has been confirmed (4–8), but theoretical and practical limitations have been discussed (9, 10). Greater freedom in experimental design is available if a predetermined temperature–time profile is not demanded. Methodology has therefore been extended to allow the rate of temperature increase to be determined by experimental, rather than theoretical, expedience (11, 12). Nonisothermal–isothermal methods have also been reported (13, 14), and many important applications of nonisothermal kinetics to solid-state degradations have appeared (15, 16). The estimation of the errors involved in these procedures has also received attention (12, 17).

Despite the success of these methods, few applications to formulated products have appeared (18). In this study a general method for the determination of nonisothermal kinetic profiles is described, and a BASIC computer program (NONISO) is presented, which can be implemented on a microcomputer, to undertake the calculations automatically. The procedures are shown to be comparable to methods requiring large computing facilities (12) and prove satisfactory for formulated products.

THEORETICAL

Degradation Rates—The rate of degradation of a drug can be represented by:

$$\frac{-dC_t}{dt} = k_T C_t^n \qquad \text{(Eq. 1)}$$

where C_t is the concentration at time t, k_T is the specific rate constant at temperature T, and n is the order of reaction. For a first order reaction ($n = 1$) this can be written as:

$$C_t = C_0 e^{-k_T t} \qquad \text{(Eq. 2)}$$

In logarithmic form this is:

$$\ln C_t = \ln C_0 - k_T t \qquad \text{(Eq. 3)}$$

and the negative slope of the plot k *versus* $\ln C_t$ yields the rate constant.

When the temperature is continually increased throughout the reaction, the degradation rate progressively increases. The isothermal rate constant is now approximated by:

$$k_T = -\left[\frac{\ln C_t - ln C_{t-\delta t}}{\delta t}\right] \qquad \text{(Eq. 4)}$$

where δt is a small increment of time, over which period the temperature may be considered constant. For an infinitesimal increase in time and temperature, the specific rate constant is given by:

$$k_T = -\frac{d(\ln C_t)}{dt} \qquad \text{(Eq. 5)}$$

The slope of the tangent at a point for the plot of t *versus* $\ln C_t$ for nonisothermal data yields the specific rate constant at the temperature observed.

If other orders of reaction are followed the appropriate equations are:

$$\text{zero order:} \quad k_T = -d(C_t)/dt \qquad \text{(Eq. 6)}$$

$$\text{2nd order (a = b):} \quad k_T = d(1/C_t)/dt \qquad \text{(Eq. 7)}$$

0022-3549/83/0600-0668$01.00/0

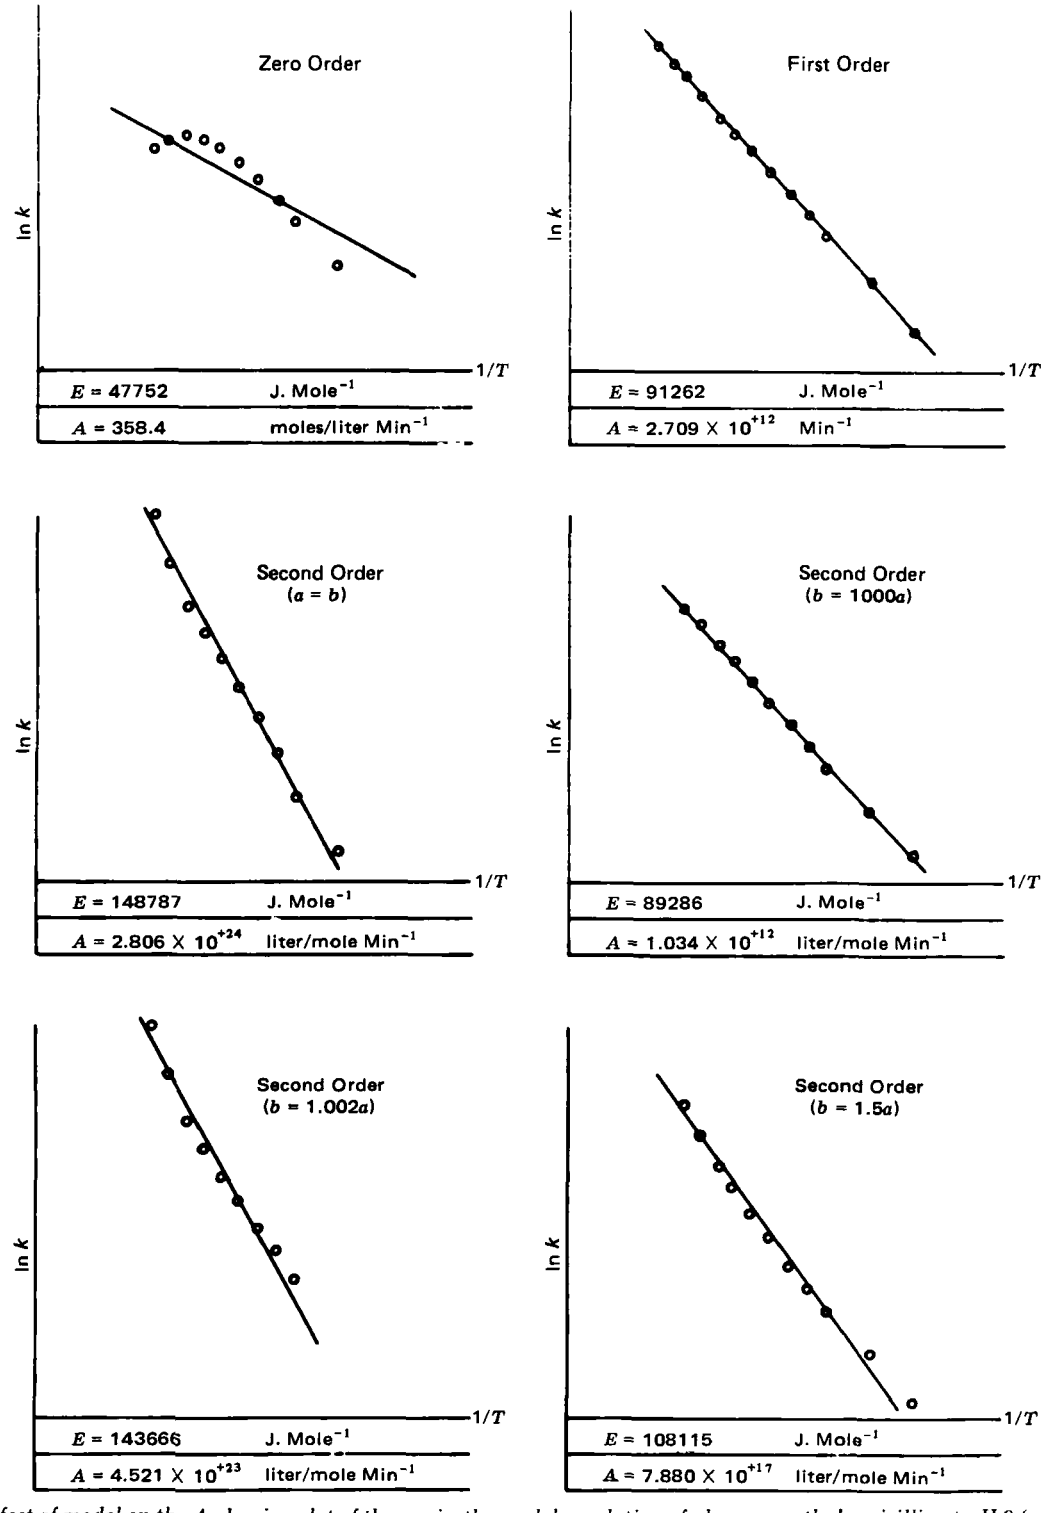

Figure 1—*The effect of model on the Arrhenius plot of the nonisothermal degradation of phenoxymethylpenicillin at pH 9* (a *and* b *refer to the initial concentrations of penicillin and hydroxide in second-order reactions).*

$$\text{2nd order (a} \neq \text{ b):} \quad k_T = \frac{d\left[\left(\frac{1}{B_0 - C_0}\right) \ln \frac{(B_0 - C_0 + C_t)C_0}{C_t B_0}\right]}{dt} \qquad \text{(Eq. 8)}$$

where C_t is the concentration (moles/liter), at time t, of the monitored drug of initial concentration C_0. B_0 is the initial concentration (moles/liter) of the excess reagent in a second-order reaction when the initial concentrations of the two reactants (a,b) are not identical.

The values of k_T are calculated by fitting a polynomial to the transformed data as a function of time. For the first-order case this is:

$$\ln C_t = a_0 + a_1 t + a_2 t^2 \ldots a_n t^n \qquad \text{(Eq. 9)}$$

Differentiation at the experimental points yields the corresponding rate constants:

$$\frac{d(\ln C_t)}{dt} = -k_T = a_1 + 2a_2 t + 3a_3 t^2 \ldots n a_n t^{n-1} \qquad \text{(Eq. 10)}$$

The rate constants at the experimentally measured temperatures are then used to compute the activation energy (E) and pre-exponential factor (A) in the Arrhenius Equation:

$$k_T = Ae^{-E/RT}$$

These data enable the calculation of rate constants at storage temperatures and the prediction of shelf-life ($t_{90\%}$) and half-life ($t_{1/2}$) to be made.

[a] Polynomial coefficients are: 4.60496, -6.75179×10^{-5}, -4.09094×10^{-5}, 6.03266×10^{-7}, -1.93521×10^{-8}, -1.08408×10^{-10}, and 9.47380×10^{-13} (a_0 term first).

EXPERIMENTAL

Nonisothermal Kinetics—*At pH 9*—A borate buffer (500 ml) containing boric acid (5.17 g), sodium hydroxide (1.67 g), and hydrochloric acid (5 *M*, 1.9 ml) was placed in a three-necked round-bottomed flask suspended in a thermostated water-bath (20-liter capacity, 1 kW). A thermometer, graduated to 0.1°, was placed into the buffer solution through one neck, a polytef sampling-tube was fitted through the second neck, and a stirrer rotated at 200 rpm was positioned through the third neck. When the buffer had reached thermal equilibrium, potassium phenoxymethylpenicillin [potassium (2*s*, 5*R*, 6*R*)-3-3-dimethyl-7-oxo-6-(2-phenoxyacetamido)-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate] (250 mg) was rapidly added to the buffer. When solution was complete (2 min), the water-bath heater was set at 100° (providing a temperature increase to 80° in 2 hr). A sample (5 ml) was immediately withdrawn and two 2-ml volumes were accurately measured. To each was added a solution of phenol (2 ml, 0.02% w/v in a phosphate buffer containing 0.9073% KH_2PO_4 adjusted to pH 5) as internal standard. This gave a final solution pH of 7: a more stable value for the penicillin (19). The initial penicillin concentration was determined in duplicate by high-performance liquid chromatographic (HPLC) analysis through interpolation onto a calibration curve prepared similarly over a penicillin concentration range of 0–50 mg/100 ml ($r = 0.999$). At frequent intervals throughout the run, samples (3 ml) were removed and a 2-ml aliquot was assayed. Time and precise temperature were also noted.

Table II—Arrhenius Parameter Estimates for the Nonisothermal Degradation of Phenoxymethylpenicillin at pH 9

Omission of 28.3° Point[b]

Parameter	Value	Range	Units
E	91262	90862–91663	J/mole
A	2.7090 *E* + 12	2.3491 *E* + 12–3.1241 *E* + 12	/Min

[a] Slope −12393.6 ± 915.7 (p = 95%), intercept 32.771 ± 2.722 (p = 95%), r = 0.98367. [b] Slope −10976.6 ± 48.2 (p = 95%), intercept 28.628 ± 0.143 (p = 95%), r = 0.99994.

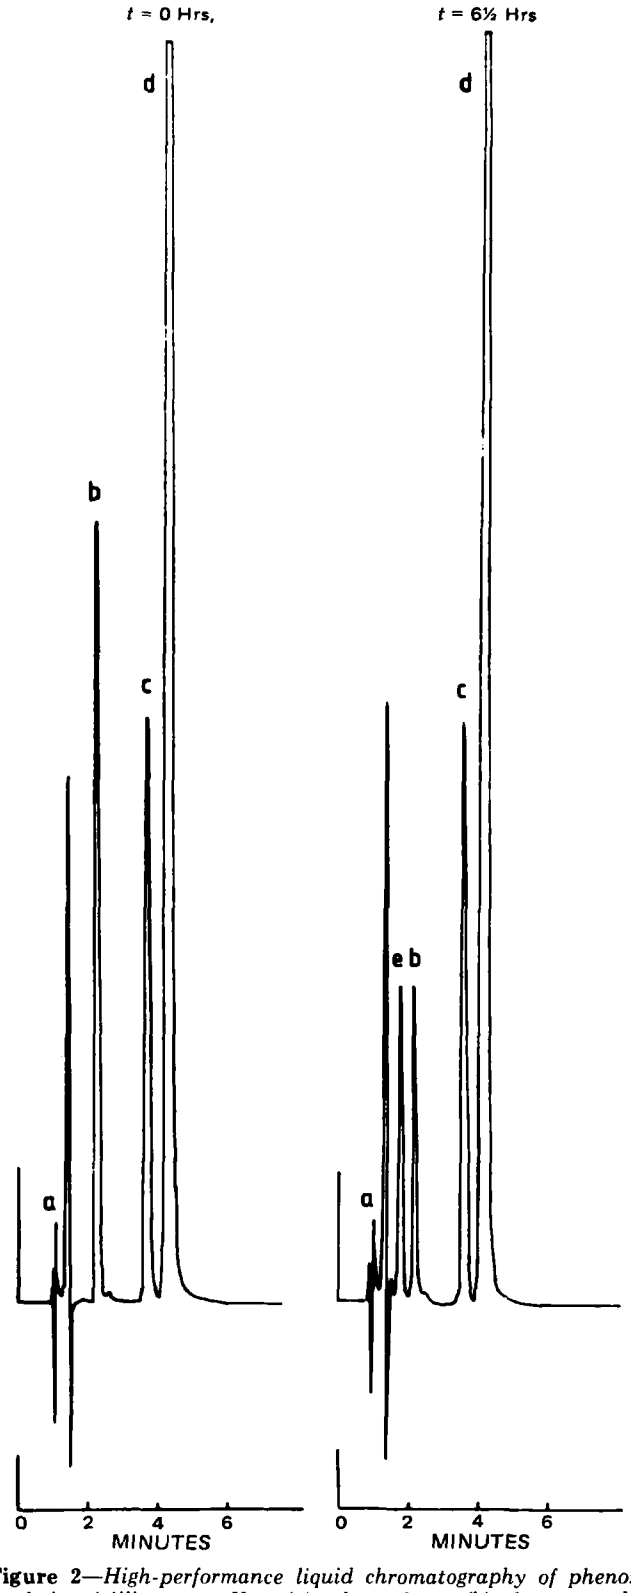

Figure 2—*High-performance liquid chromatography of phenoxymethylpenicillin syrup. Key: (a) solvent front; (b) phenoxymethylpenicillin; (c) phenol (internal standard); (d) methyl paraben; (e) degradation product.*

At pH 6—A citrate buffer (140 ml) containing citric acid (1.76 g) and sodium hydroxide (0.90 g) were placed in a medicine bottle fitted with a thermometer and sampling port. When temperature equilibrium was reached potassium phenoxymethylpenicillin (70 mg) was added, samples were removed, and the temperature program was initiated.

In these experiments the water-bath was programmed to rise from 60 to 95° over a 6-hr period. This was achieved by using a motorized syringe-drive unit to continuously adjust the thermostat. At frequent in-

tervals through the run, samples (3 ml) were removed and a phenol solution (2 ml, 0.02% w/v in water) as internal standard was added to an aliquot (2 ml). HPLC analysis was undertaken through interpolation onto a calibration curve prepared similarly over a penicillin concentration range of 0–50 mg/100 ml (r = 0.999). Time and precise temperatures were noted for each assay point.

Formulated Products—Syrups were reconstituted as directed by the manufacturer. Typically, this involved addition of 70 ml of water to the product (in the case of Syrup 1) and shaking vigorously to facilitate dissolving granules. The reconstituted product of nominal concentration (62.5 mg/5 ml and pH 5.8) was then transferred to a 150-ml clear bottle fitted with a sampling tube and a thermometer.

The stability of the syrups was monitored from 60 to 95° for the pH 6 samples. The HPLC assay was undertaken by adding phenol solution (2 ml, 0.25% w/v in water) to aliquots (1 ml), which were then diluted to 50 ml with water.

Isothermal Kinetics—Isothermal degradation was undertaken as described for the nonisothermal runs except that the selected temperature was held constant throughout the experiment. A series of temperatures within the range of those in the corresponding nonisothermal program was used.

HPLC—The stationary phase[1] was 5 μm in a 10-cm column with a 4.6 mm i.d. The mobile phase was acetonitrile (28% v/v) in phosphate buffer (0.132% $Na_2HPO_4 \cdot 2H_2O$, 0.807% KH_2PO_4; pH 6) pumped[2] at 1 ml min^{-1} under a pressure of ~600 psi. The UV detector[3] was operated at 271 nm with a sensitivity of 0.16 AUFS. Samples (20 μl) were injected onto the column by means of a loop injector[4]. Under these conditions phenoxymethylpenicillin had a retention time of 2.2 min and phenol 3.6 min.

Calculations were undertaken on a computer[5] using a BASIC version (see *Appendix*) of NONISO or by means of a FORTRAN integral nonisothermal kinetics program (12) implemented on a main frame system[6].

RESULTS AND DISCUSSION

Typical results for the nonisothermal degradation of phenoxymethylpenicillin (penicillin V) are shown in Table I. The transformed concentration–time polynomial coefficients for a first-order model and the isothermal rate constants attained by differentiation at the experimental points are also shown. The Arrhenius parameter estimates for these data are presented in Table II. The limits of error about the estimates are rather wide and the poor nature of the fit is further revealed by the correlation coefficient (r = 0.984), the coefficient of variation (CV = 10.52%), and the chi-squared statistic (6.37×10^{-3}; 26 degrees of freedom). Examination of the plotted data reveals that almost all of the variation arises from the first point (28.3°). This is due to the small amount of degradation that occurs over this initial temperature range. The true polynomial gradient is small, and the estimated rate constant is significantly affected by experimental error. The removal of this one point from the data set has a dramatic effect on the quality of the fit (Table II). The activation energy is now estimated to $<\pm 0.5\%$ (p = 95%). The rate constants calculated from these estimates are available for scrutiny and the predicted shelf-lives are shown in Table III. The output from the plotting routine is depicted in Fig. 1, which shows the effect of the chosen model on the Arrhenius plot. This rapid visualization of the data immediately reveals problems in the fit. When the reaction order is unknown, each model can be examined sequentially, and the best-fitting data (low χ^2, CV; high r) can be used for the shelf-life estimates.

To establish the validity of the NONISO approach a series of experiments were undertaken to establish the reproducibility of the method. The results were calculated using NONISO and the FORTRAN program described in an earlier study (12). These data, and those from a traditional isothermal study, are recorded in Table IV. Also included are the results reported previously (12) for riboflavin which have been recalculated using NONISO. Data taken from a graphical presentation in a previous report (8) on the nonisothermal degradation of p-acetamidophenol and procainamide have also been recalculated using NONISO and the integral approach. Parameter estimates from these calculations are also reported in Table IV. The agreement between these various estimates confirms the validity of the NONISO approach reported here.

Table III—Shelf-life Predictions for Phenoxymethylpenicillin at pH 9

Temperature, °	Shelf-life Predictions $t_{1/2}$	First Order Model $t_{90\%}$
5	24.44 days	3.72 days
10	12.18 days	1.85 days
15	149.12 hr	22.67 hr
20	77.87 hr	11.84 hr
25	41.56 hr	6.31 hr
30	22.64 hr	3.44 hr

When all experimental points are used in the computation (typically 25–30) the major source of error occurs in the calculation of rate constants at the temperature range extremes. Inspection of the graphical presentation reveals any deviation, and recalculation with the omission of ill-fitting data dramatically increases the validity of the parameter estimates. For this reason, points that correspond to degradation in excess of 95% for a first-order process or in excess of 80% for the zero- or second-order models are automatically eliminated from the data set. The elimination of points determined in the initial stages of the degradation is left to the operator's discretion. Usually few points require attention so that, providing a reasonably complete data set has been collected, sufficient points remain to establish a valid analysis. In the case of phenoxymethylpenicillin (pH 9) 33 points were collected, 28 were used in the initial calculation (Table I), and the final parameter estimates were derived from 27 observations (Tables II and III). The reduced data set may be recalculated in part, *via* the Arrhenius subroutines, or in total, through the generation of a new polynomial expression. The first option is satisfactory if analytical error is small and has been adopted in all calculations reported here. However, if less precise assay results are available it is more effective to generate a new polynomial equation. The two approaches are compared in Table V. This records the effect of a ±2% random error incorporated into the concentration values and reveals that polynomial regeneration is more effective in providing an acceptable solution with this degree of error. To reduce the effect of analytical error it is advisable to design the nonisothermal temperature program to cover a range not less than 25° and to monitor the degradation over a period of at least one half-life.

Figure 2 is a typical chromatogram from a phenoxymethylpenicillin syrup and shows that excipients and degradation products are detectable but do not interfere with the analysis. The results of the nonisothermal

degradation of formulated products are illustrated in Table VI. A high degree of similarity is observed between shelf-life estimates from NONISO and those obtained using the integral method of Anderson *et al.* (12). The estimates compare well with those predicted from isothermal accelerated tests and with shelf-lives measured at the storage temperature. The advantages of this approach include the availability of a full kinetic profile with no more effort than is required by a single isothermal rate determination. Zero-, first-, and second-order (a = b; a ≠ b) and first-order equilibrium reactions may be handled. A set temperature program is not required and the heating rate can be adjusted readily to suit the stability of the formulation. Only simple apparatus is required, and degradation in the final dispensing container is easily monitored. In addition, the use of an analytical rather than an iterative solution to the kinetic equations requires a relatively short processing time. This allows effective use of a BASIC program, which can be run on inexpensive microcomputers rather than requiring main-frame computing facilities. The use of this approach should enable nonisothermal kinetic procedures to be available on a routine basis.

APPENDIX

NONISO, a BASIC computer program, has been written for implementation on a Z80-based microcomputer with 64K RAM[5] and requires ~22K for the fully labeled version. A listing of the program is available on request, from the authors. Scheme I illustrates the structure of this program. Individual operations have, as far as possible, been incorporated into separate subroutines to allow modification or extension to be easily achieved. Although BASIC does not allow subroutine names, these are used in the discussion for purposes of clarity. DATA (lines 3940–4300) are written into the program before computation. This records the proposed order of reaction, an identifying label for the experiment, the number of data points, and the time units used. This is followed by time, temperature, and residual concentration measurements for each experimental point beginning with time zero.

The segment MAIN (lines 470–1080) sets dimensions, reads in the input data, and transforms the concentration values (compare Eqs. 4–7) so that differentiation of the polynomial yields k_T values. Subsequent calls to the major subroutines follow.

The NORMEQ (lines 1150–1270) routine sets up the normal equations for the solution of the transformed concentration data in terms of a time polynomial. The normal equations take the form:

$$\sum_{i=1}^{N} (\ln C_{t_i}) = a_0 N + a_1 \Sigma t_i + a_2 \Sigma t_i^2 + \ldots + a_n \Sigma t_i^n$$

$$\sum_{i=1}^{N} t_i (\ln C_{t_i}) = a_0 \Sigma t_i + a_1 \Sigma t_i^2 + a_2 \Sigma t_i^3 + \ldots + a_n \Sigma t_i^{n+1} \quad \text{(Eq. 11)}$$

$$\sum_{i=1}^{N} t_i^2 (\ln C_{t_i}) = a_0 \Sigma t_i^2 + a_1 \Sigma t_i^3 + a_2 \Sigma t_i^4 + \ldots a_n \Sigma t_i^{n+2}$$

$$\sum_{i=1}^{N} t_i^n (\ln C_{t_i}) = a_0 \Sigma t_i^n + a_1 \Sigma t_i^{n+1} + a_2 \Sigma t_i^{n+2} + \ldots a_n \Sigma t_i^{2n}$$

where n is the order of the polynomial and N is the number of data points; the program is able to generate polynomials up to the tenth order. The maximum available order, however, is dictated by the word length of the computer used. Values in excess of Σt_i^{2n} are generated and overflow errors may occur. In practice, a sixth-order polynomial was found satisfactory, with higher orders giving no improvement.

The subroutine SIMEQ (lines 1280–1700) solves up to 10 simultaneous equations by the Gauss Elimination Method (20). A typical execution time for 30 points is 90 sec.

POLYOUT (lines 1710–1930) presents the coefficients for the polynomial and the calculated values are compared with the observed transformations. Subroutine FIT (lines 1940–2100) is also called to calculate a determination coefficient, the coefficient of variation, and the chi-squared value.

DIFF (lines 2110–2330) differentiates the polynomial expression and the result is solved for the experimental points to yield the isothermal rate constants throughout the run. The experimental data are modeled well but extrapolation beyond this range rapidly introduces unacceptable error. Transformation for the Arrhenius analysis ($k_T \rightarrow \ln k_T$; $T \rightarrow 1/T$) is thus undertaken, and the parameters (A,E) are estimated by LEASQ (lines 2340–2540), which undertakes a linear least-squares analysis of the data.

The parameter estimates and correlation coefficients are printed by OUTPUT (lines 2550–2780) which also provides 95% error limits for the estimates. The isothermal rate constants predicted by the model are compared with the experimental values, and the degree of correspondence is again assessed by subroutine FIT.

PLOT (lines 3000–3750) is a subroutine that displays the theoretical regression line together with the experimental points, thus allowing a visual assessment of the significance of the fit. Options are available to remove wildly deviating points: in practice, if this is necessary, these are

the initial data points when the concentration is changing slowly and is thus subject to more error. The regression calculations are then repeated on the reduced data set.

When a satisfactory model is obtained, the subroutine PREDICT (2790–2990) calculates the $t_{90\%}$ and $t_{1/2}$ values at typical storage temperatures to assess the shelf-life of the formulation. The model can then be changed by the use of the appropriate code [line 3940; 0—zero-order, 1—first-order, 2—second-order ($a = b$), 3—second-order ($a \neq b$)] and the calculations are repeated.

Topical Vaginal Drug Delivery I: Effect of the Estrous Cycle on Vaginal Membrane Permeability and Diffusivity of Vidarabine in Mice

C. C. HSU, J. Y. PARK, N. F. H. HO, W. I. HIGUCHI ˣ, and J. L. FOX

Received July 13, 1981, from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication June 11, 1982.

Abstract □ Preliminary studies showed that the vaginal membrane permeability coefficients for vidarabine (9-β-D-arabinofuranosyladenine) varied widely within a group of mice of the same species and age. This finding prompted an investigation of the influence of the female mouse sexual cycle on the vidarabine permeability. By means of a vaginal smear technique, the sexual cycle, which was ~5 days in duration, was divided into five phases. The vaginal membrane permeability of vidarabine was determined during each phase. The results revealed that the permeability coefficients for vidarabine during the diestrus phase (3×10^{-6}–4×10^{-5} cm/sec) were 10–100 times higher than those obtained at the early estrus or estrus phases ($1–3 \times 10^{-7}$ cm/sec). Further permeation studies on membranes at early estrus and estrus were performed by separating the cornified layer from the noncornified portion of the membrane. The low permeability coefficient of vidarabine across the cornified layer (4×10^{-7} cm/sec) suggests that this layer may be the major diffusion barrier for vidarabine when the drug is topically applied. Collectively, the data also suggest that during estrus a three-layer diffusion model is appropriate, that during early diestrus a single-layer diffusion model may apply, and that during proestrus and postestrus the situations are intermediate and more complicated.

Keyphrases □ Vidarabine—vaginal membrane permeability in mice, diffusion barriers, effect of the estrous cycle □ Permeability—vaginal membrane to vidarabine, determination of coefficients, effect of the estrous cycle □ Estrous cycle—effect of vaginal membrane permeability to vidarabine in mice

A physical model of simultaneous transport and bioconversion of vidarabine (9-β-D-arabinofuranosyladenine, I) in the hairless mouse skin has been reported, (1, 2). It was concluded that the low efficacy of I in topical therapy involving skin may be due to the extremely low permeability of I through the stratum corneum and the rapid enzymatic decomposition of I to 9-β-D-arabinofuranosylhypoxanthine (II). In more recent reports (3, 4), the model was explored in detail, and a prodrug of I, vidarabine-5′-valerate (III), was investigated for its ability to overcome both the low permeability and enzymatic decomposition problems.

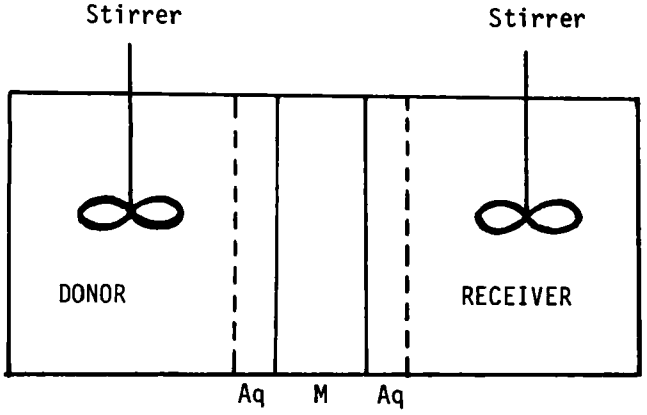

Figure 1—*Diffusion cell for the membrane permeability coefficient determinations. Key: (M) membrane; (Aq) aqueous diffusion layer.*

Since infections of the human genital tract with Herpes simplex virus (HSV types 1 and 2) have become increasingly important (5–7), it is desirable to investigate the deliverability of I, an antiviral drug, in the genital tract using an animal model. In the present report the permeability and diffusivity parameters of I were studied on excised vaginal membranes of the female mouse, with particular emphasis on how the estrous cycle may affect these transport parameters.

THEORETICAL

Aqueous Diffusion Layer Permeability Coefficient—Often the aqueous diffusion layer is unimportant in influencing overall transport in membrane diffusion experiments. However, in instances where the aqueous diffusion layer thickness is relatively large, its influences on both the steady-state transport and the lag time may be appreciable. The aqueous diffusion layer permeability (P_{aq}) of I may be calculated from:

$$P_{aq} = \frac{D_a}{h_{aq}} \qquad \text{(Eq. 1)}$$

where D_a is the aqueous diffusivity of I and h_{aq} is the aqueous diffusion layer thickness. The aqueous diffusion layer thickness has been determined (4) from initial dissolution rate data obtained using benzoic acid disks placed in the same configuration as the membrane in the diffusion cell by means of:

$$\frac{R}{A} = \left(\frac{D}{h_{aq}}\right)(C_s) \qquad \text{(Eq. 2)}$$

where R is the initial dissolution rate of benzoic acid, A is the effective diffusional area, C_s is the aqueous solubility of benzoic acid, and D is the aqueous diffusivity of benzoic acid. The initial dissolution rate of benzoic acid is the initial linear slope obtained by plotting the amount of benzoic acid dissolved in the diffusion cell against time. The aqueous diffusivity of I can be estimated from:

$$D_a = \left(\frac{M}{M_a}\right)^{1/3} D \qquad \text{(Eq. 3)}$$

where M_a is the molecular weight of I and M is the molecular weight of benzoic acid.

Vaginal Membrane Permeability Coefficient—The vaginal membrane permeability coefficient (P) of I can be determined by conducting a permeation experiment in a diffusion cell (Fig. 1). In such an experiment the steady-state flux of I across the membrane is equated to the product of the apparent permeability coefficient and the concentration gradient:

$$\left(\frac{dC_t}{dt}\right)\left(\frac{V}{A}\right) = \frac{1}{\frac{1}{P} + \frac{1}{2P_{aq}}}(C_t^d - C_t) \qquad \text{(Eq. 4)}$$

Where V is the volume of solution in the receiver cell, C_t^d is the donor side concentration of I at time t, and C_t is the concentration of I in the receiver cell at time t. When only initial steady-state flux is used, C_t is much smaller than C_t^d, and $C_t^d - C_t \approx C_0$, where C_0 is the initial donor side concentration of I. Equation 4 may be simplified and solved to give:

$$C_t = \left(\frac{A}{V}\right) C_0 \left(\frac{1}{\frac{1}{P} + \frac{1}{2P_{aq}}}\right)(t - L) \qquad \text{(Eq. 5)}$$

0022-3549/83/0600-0674$01.00/0

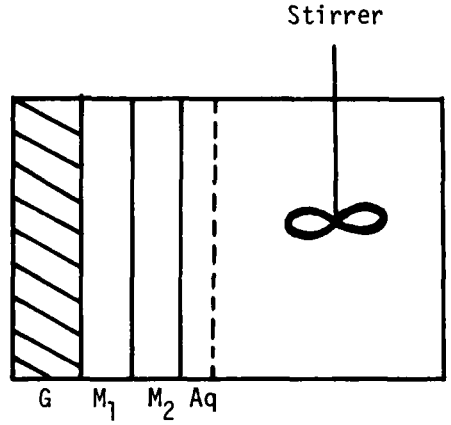

Figure 2—*Diffusion chamber modified for a bilayer membrane desorption experiment. Key: (M_1) membrane sublayer 1; (M_2) membrane sublayer 2; (G) glass block; (Aq) aqueous diffusion layer.*

where L is the lag time and may be obtained from experimental data as the intercept on the time-axis when the steady-state C_t values are plotted against time. The membrane permeability coefficient of I can thus be calculated from the initial linear slope of the concentration–time plot.

Calculation of the Membrane Thickness from the Lag Time—If the vaginal membrane can be viewed as mono- or multi-ply laminate-like skin, it is possible to calculate the theoretical membrane thickness from the permeation lag time. The general relationship between the lag time and the layer thickness for an n-layer laminate (8) is:

$$L = \left[\sum_{i=1}^{n}\left(\frac{h_i}{D_i}\prod_{j=0}^{i-1}k_j\right)\right]^{-1}\left[\sum_{i=1}^{n}\left\{\frac{h_i^2}{2D_i}\sum_{i=i}^{n}\left(\frac{h_i}{D_i}\prod_{j=0}^{i-1}k_j\right)-\frac{h_i^3}{3D_i}\prod_{j=0}^{i-1}k_j\right\}\right.$$

$$\left.+\sum_{i=1}^{n}\left\{\frac{h_i}{D_i}\left(\prod_{j=0}^{i-1}k_j\right)\sum_{\beta=i+1}^{n}\left[\frac{h_\beta}{\prod_{j=0}^{\beta-1}k_j}\sum_{\beta=\beta}^{n}\left(\frac{h_\beta}{D_\beta}\prod_{j=0}^{\beta-1}k_j\right)-\frac{h_\beta^2}{2D_\beta}\right]\right\}\right] \quad \text{(Eq. 6)}$$

where L is the lag time, k_i is the partition coefficient between ith and (i + 1)th layers, D_i is the diffusivity of ith layer, and h_i is the thickness of ith layer.

In the case of a homogeneous membrane, the total number of layers in Eq. 6 is 3 (n = 3), because there exist two identical aqueous diffusion layers, one on each side of the membrane. Also, if it is assumed that the partition coefficient of I between viable tissue and water is unity [which is a good assumption for the solute in this study (4)], then:

$$P_i = \frac{D_i}{h_i} \quad \text{(Eq. 7)}$$

where P_i is the permeability coefficient of the ith layer. Equation 6 can be rewritten as:

$$L = \left(\frac{2}{P_{aq}}+\frac{1}{P}\right)^{-1}\left[\frac{h_{aq}}{P_{aq}}\left(\frac{4}{3P_{aq}}+\frac{1}{P}\right)+\frac{h}{P}\left(\frac{1}{P_{aq}}+\frac{1}{6P}\right)+\frac{h}{P_{aq}^2}\right] \quad \text{(Eq. 8)}$$

where p is the permeability of homogeneous membrane and h is the membrane thickness.

Membrane Diffusivity from a Desorption Experiment—To confirm the diffusivity values obtained from the permeation experiments, an alternative experiment, called the desorption experiment, may be conducted which gives a direct estimate of the membrane diffusivity. In this method, the initial desorption rate of a membrane that has been loaded with a known concentration of drug is measured. The membrane diffusivity is then determined from:

$$\frac{dC_t}{dt}\frac{V}{A} = C_0\sqrt{\frac{D}{\pi t}} \quad \text{(Eq. 9)}$$

and

$$C_t = \left(\sqrt{\frac{4C_0^2A^2D}{V^2\pi}}\right)\sqrt{t} \quad \text{(Eq. 10)}$$

where C_t is the solution concentration at time t, V is the volume of the diffusion cell solution, A is the effective diffusional area, C_0 is the initial drug concentration in the membrane, and D is the diffusivity of the membrane. Equation 9 is solved to give Eq. 10. By plotting the C_t *versus* $\sqrt{t}$, the diffusivity of the membrane can be calculated easily from the initial slope.

If the membrane is effectively multilayered, only the diffusivity of the sublayer facing the diffusion chamber is determined from the initial desorption rate. In the simplest case of a bilayer membrane, the diffusivity of each layer may be measured independently with this method (Fig. 2).

Table I—Microscopic Characteristics of the Vaginal Smear as a Function of the Sexual Cycle

Phase	Duration, days	Microscopic Characteristics of Vaginal Smears
Diestrus	1–3	Exclusively leukocytes
Proestrus	~1	Leukocytes and nucleated epithelial cells
Early estrus	0.5–1	Epithelial cells, may have some cornified cells
Estrus	0.5–1	Exclusively cornified cells
Postestrus	~1	Leukocytes and cornified cells

Table II—Aqueous Diffusion Layer Permeability Coefficients of I

Experiment	$h_{aq} \times 10^2$, cm	$P_{aq} \times 10^3$, cm/sec
1	1.07	1.01
2	1.00	1.08
3	1.02	1.06
Average	1.03	1.05

EXPERIMENTAL

Materials—[^{3}H]-2-I[1] was used after being purified by high-performance liquid chromatography (HPLC), and the purity was further checked by TLC before experiments were started. [^{3}H]-2-II was prepared from [^{3}H]-2-I by treating the latter with adenosine deaminase[2] and TLC purification. Female Swiss Webster mice[3], 10–14 weeks old, were used for the experiments. Liquid scintillation counter cocktail[4], normal saline solution[5], 1% methylene blue in methanol solution, cellulose membrane[6], sulfuric acid[7], and sodium sulfite[7] were also used in the experiments.

Diffusion Cells—Because of the small available area of the mouse vaginal membrane (~0.8 cm × 1.0 cm), specially designed diffusion cells were used in these experiments. The outside dimensions of the glass diffusion cell are shown in Fig. 3. It has two ports, one for the stirrer and the other for sampling access. The stirrer port was 2.2 cm in length and the sampling port was 1.0 cm in length. The diameter of the cell opening was 0.6 cm, which provides an effective diffusional area of 0.28 cm^2 for a cell volume of 1 ml. The stirrer was made of polytetrafluoroethylene[8] and was operated by a constant-speed motor[9].

Vaginal Membrane Preparation—The female mouse was sacrificed by snapping the spinal cord at the neck. The lower abdomen was cut open, and the fat tissue was removed to reveal the Y-shaped reproductive system. A pair of hemostatic forceps were clamped on the uterus ~0.5 cm above the cervix to fix the position while the pubic bone was cut open, and the connection between the system and the surrounding tissue was carefully removed. The vagina, which is located between the cervix and the orifice, was then separated from the uterus. The tube-shaped vagina was carefully checked to free any tissue debris from the surface prior to cutting it open and using it for the experiment.

In cases where only the noncornified part of the membrane was to be used for an experiment, the vagina of the mouse at estrus was obtained by the aforementioned method. After cutting open the membrane, the cornified layer, which is on the mucosal side, was completely removed from the rest of the membrane with a pair of tweezers.

[a] Only the noncornified part of the estrus membrane was used in this experiment. [b] — Not determined.

Vaginal Membrane Thickness Measurement—A micrometer[10] was used to obtain the membrane thickness. The vaginal membrane, after being removed from the body and cut open, was sandwiched between two microscope cover glasses. The total thickness was then measured with the micrometer. The membrane thickness was obtained by subtracting the thicknesses of the cover glasses from the total thickness.

Mouse Estrous Cycle Determination—The female mouse estrous cycle could be determined easily by microscopic examination of the vaginal smears (9). The vaginal smears were obtained by means of an ordinary pipet, the tip of which had been flamed to a smooth, reduced aperture. A few drops of normal saline solution were drawn into the pipet, introduced into the vagina, and then retracted into the pipet. The fluid was transferred to a microscope slide and stained with a drop of methylene blue to add contrast and bring out the nuclei. Examination for cell type was carried out under low- and high-power magnification. Three major types of cells were found in the vaginal smears: leukocytes, epithelial cells, and cornified epithelial cells. The estrous cycle phase was determined by the types of cells present in the vaginal smears (Table I).

Aqueous Permeability Coefficient Determination—Benzoic acid pellets were made by directly compressing 100 mg of the material in a die (1.3-cm i.d.) under a force of 1362 kg (3000 lb) using a laboratory press[11]. The pellet was mounted between one chamber of a diffusion cell and a same-size glass plate. The whole setup was coated with wax and immersed in a 37° water bath. One milliliter of 0.01 *N* HCl, pre-equilibrated at 37°, was introduced into the cell at time zero. The benzoic acid concentration in the solution was determined by UV absorption at 227 nm against a standard curve.

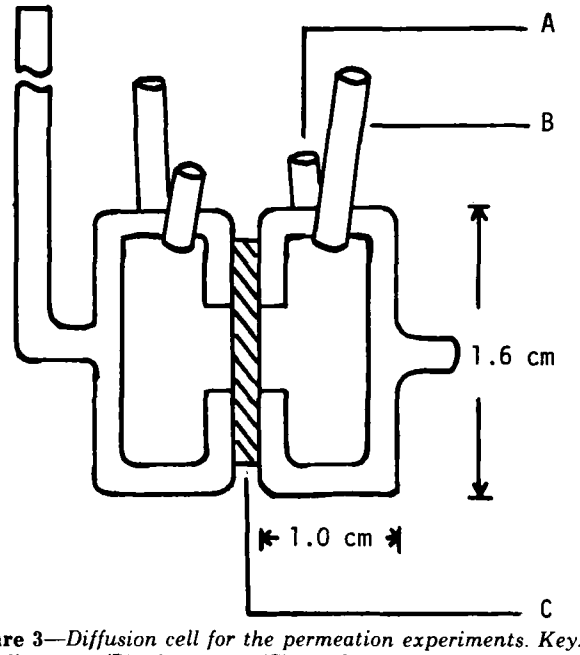

Figure 3—*Diffusion cell for the permeation experiments. Key: (A) sampling port; (B) stirrer port; (C) membrane.*

Vaginal Membrane Permeability Coefficient Determination—As soon as the vaginal membrane was sandwiched between two diffusion cells, 0.9 ml of the normal saline solution, pre-equilibrated at 37°, was introduced into each chamber. The diffusion cell setup was then immersed in a 37° water bath and was allowed to stand for 5 min to reach thermal equilibrium. Normal saline solution (100 μl) was added to the receiver chamber at the end of this 5-min period, and [^{3}H]-2-I or [^{3}H]-2-II in 100 μl of normal saline solution was added to the donor chamber by pipet to start the experiment. Aliquots (100 μl) from the receiver solution were drawn with a micropipet at given time intervals and were transferred immediately into a scintillation vial containing 10 ml of scintillation counter cocktail. An equal volume of normal saline solution was added to the receiver chamber after each draw to replace the removed aliquot. The donor solution concentrations at the first half-minute and at the end of the experiment also were determined in the same way to obtain the initial concentration and to check the mass balance.

Preparation of Cellulose Membrane—The cellulose membrane was cut to a suitable size before it was soaked in running water for 3–4 hr to remove the glycerol. The membrane was then treated with 0.3% sodium sulfite solution, preheated to 80°, for 1 min followed by washing with 60° distilled water for 2 min. The washed membrane was acidified with 0.2% sulfuric acid and then cleaned with distilled water. The purpose of this procedure was to remove sulfides on the membrane.

Cellulose Membrane Permeability Coefficients—Experiments to determine the cellulose membrane permeability coefficients were performed in the same manner as the determination of vaginal membrane permeability coefficients, except that the cellulose membrane was mounted in the diffusion cell.

Stability of the Vaginal Membrane—The vaginal membrane stability under the experimental conditions was studied by performing consecutive permeation experiments on the same membrane. The membrane was washed several times with normal saline solution for 2 hr between the two experiments. The washing solution from both chambers was checked to make certain that the membrane was free of any residue from the previous run. When the cellulose membrane was used to increase the vaginal membrane stability, the excised vaginal membrane was sandwiched between two pieces of cellulose membrane

Table IV—Stability of Cellulose Membrane-Protected Vaginal Membrane with Respect to the Permeability of I[a]

Cycle Phase	Mouse	Permeability Coefficient × 10^6, cm/sec				
		Fresh	t = 2 hr	t = 4 hr	t = 8 hr	t = 24 hr
Diestrus	80113	4.6	5.0	5.2	4.5	7.8
	80139	3.8	3.6	3.2	3.6	3.5

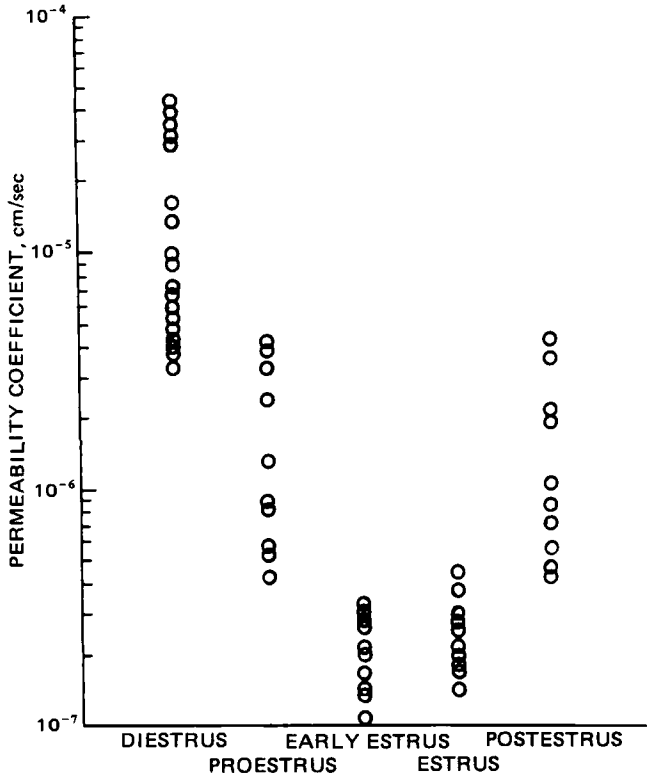

Figure 4—*Vaginal membrane permeability coefficients of I during different estrous cycle phases.*

before being mounted in the diffusion cell. This procedure was carried out very carefully to prevent any air bubbles from being trapped between the vaginal and cellulose membranes.

Desorption Experiment—The prepared vaginal membrane was soaked for 3 hr in 0.5 ml of normal saline with a known amount of compound I in the solution. It was then mounted between a diffusion cell and a glass block. One milliliter of normal saline, pre-equilibrated at 37°, was added to the diffusion chamber at time zero. The concentration in the diffusion cell was determined in the same manner used in the membrane permeability experiment.

RESULTS AND DISCUSSION

Aqueous Diffusion Layer Permeability—Three benzoic acid dissolution experiments were conducted which gave an average aqueous

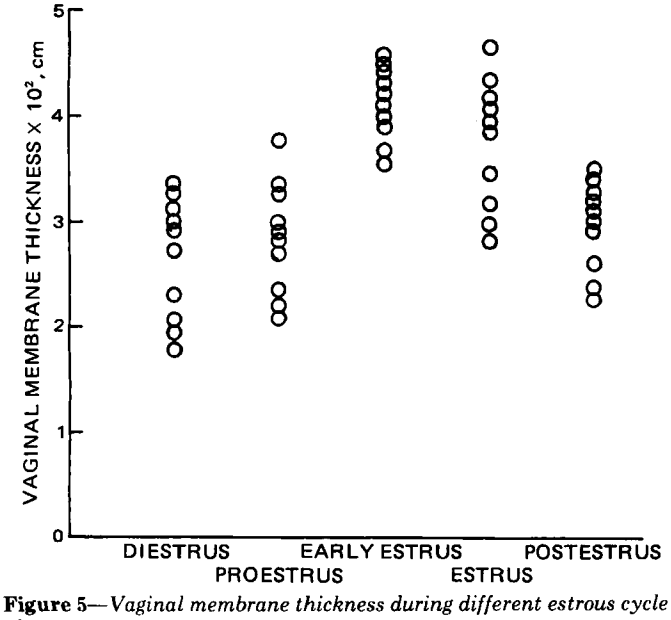

Figure 5—*Vaginal membrane thickness during different estrous cycle phases.*

Table V—Comparison of Vaginal Membrane Permeability Coefficients of I and II[a]

Cycle Phase	Mouse	Permeability Coefficient[b] × 10^6, cm/sec I	II

Table VIII—Permeability Coefficients of I in the Noncornified Part of the Vaginal Membrane at the Estrus Phase

Mouse	Permeability Coefficient × 10^6, cm/sec
79009	0.93
79043	0.98
79067	1.25
80109	1.32
80122	1.32
80127	1.00
Average	1.13 ± 0.07

diffusion layer thickness of 1.03×10^{-2} cm. The aqueous diffusivity of I was estimated from Eq. 3 using a reported value (10) of 1.4×10^{-5} cm^2/sec for the aqueous diffusivity of benzoic acid. The aqueous diffusion layer permeability coefficient was then calculated from Eq. 1 (Table II).

Stability of the Vaginal Membrane—The vaginal membrane stability was checked at two different cycle phases (Table III). The membranes obtained during the diestrus phase could be divided roughly into two groups. Those with lower permeability coefficients ($4–9 \times 10^{-6}$ cm/sec) showed different degrees of drop in the P-values for the first 4–8 hr followed by a slow increase in P afterward. On the other hand, the membranes with high P-valves ($3–5 \times 10^{-5}$ cm/sec) were fairly stable up to 8 hr. The membranes obtained at estrus failed to show good stability.

It was found that membranes protected with the cellulose membrane had increased stability (Table IV). The permeability coefficients were essentially constant up to 8 hr for the protected vaginal membranes. This technique was of great value for those situations in which a direct comparison of P-values was desired using the same vaginal membrane. The

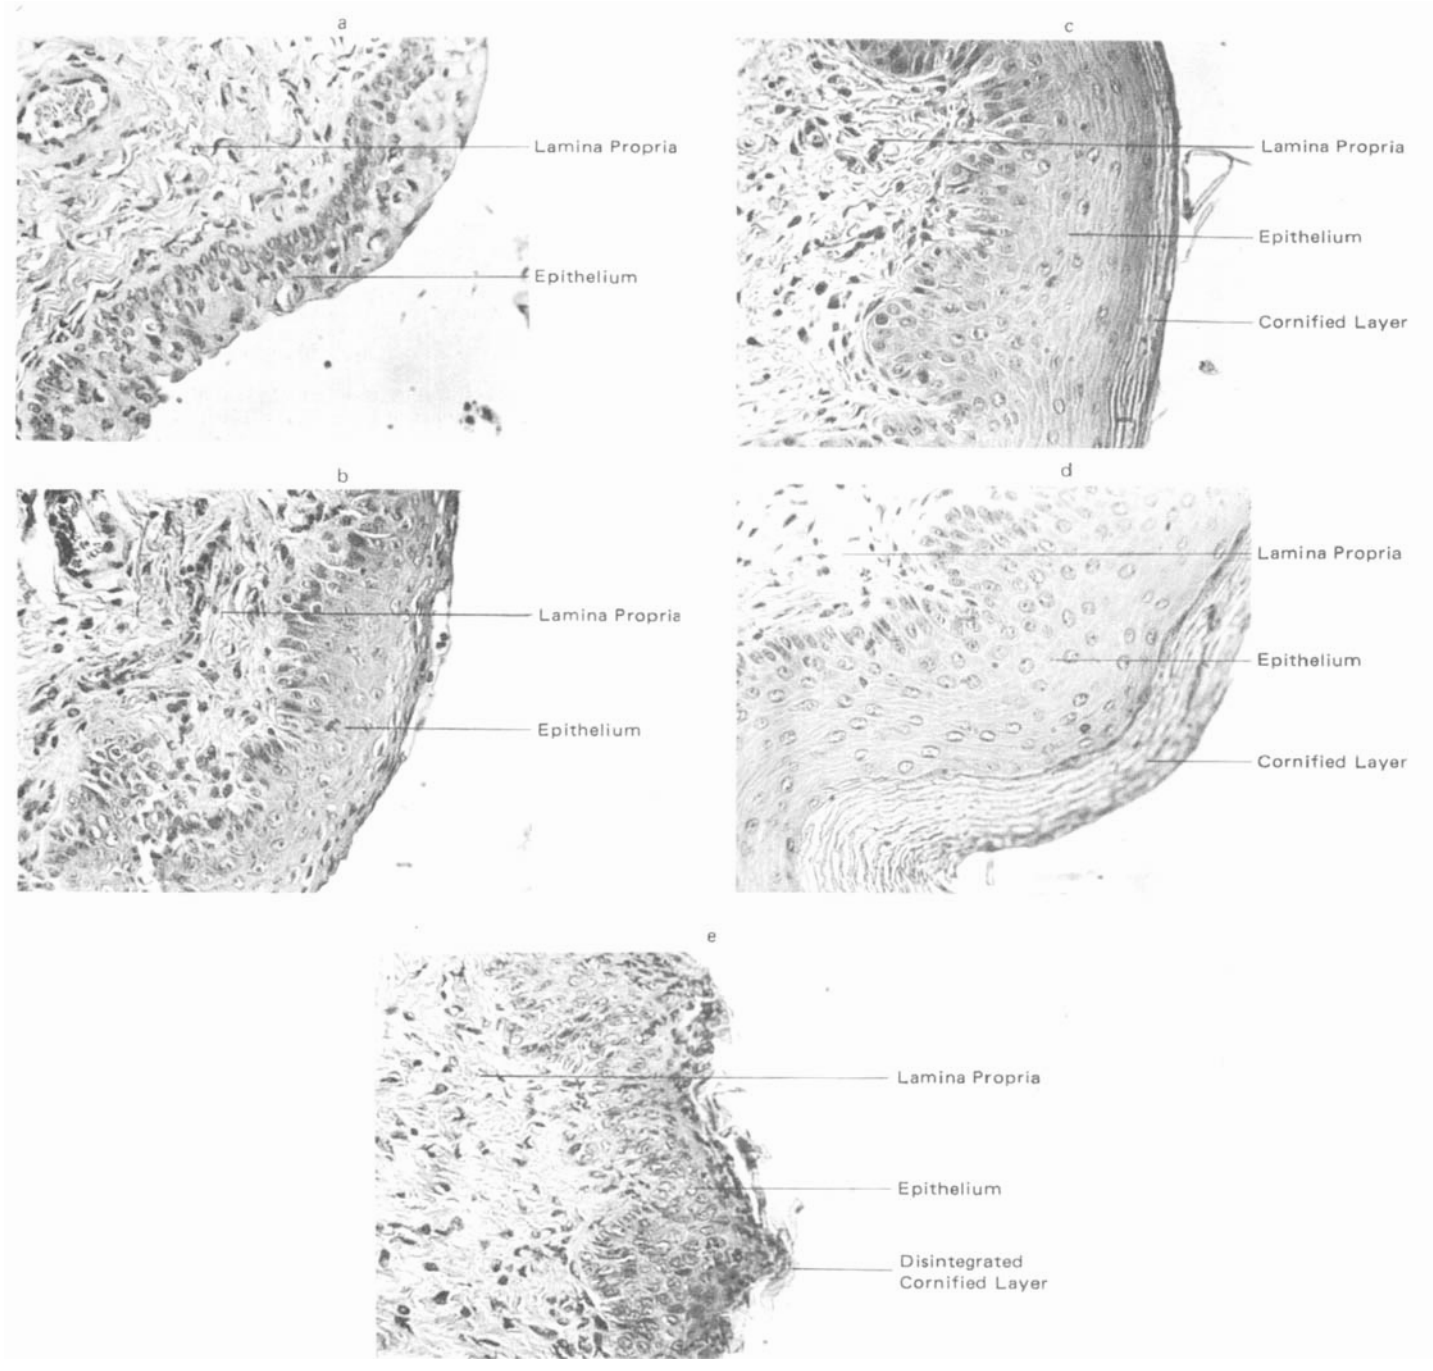

Figure 6—*Cross sections of mice vaginal membrane during different estrus cycle phases. Key: (a) diestrus phase; (b) proestrus phase; (c) early estrus phase; (d) estrus phase; (e) postestrus phase.*

cellulose membrane permeability coefficients of I are also listed in Table IV.

Permeability Coefficients of I and II—Since an adenosine deaminase inhibitor was not used in the experiments, it was necessary to prove that I and its metabolite, II, possessed the same permeability coefficient in the vaginal membrane. The permeability coefficients for both I and II were obtained on the same piece of vaginal membrane using the aforementioned membrane protection technique. As expected, the vaginal membrane permeability coefficients of I and II were essentially identical regardless of the cycle phase (Table V).

Table IX—Permeability Coefficient of Cornified, Noncornified, and Full-Thickness Membrane During the Estrus Phase

Membrane Preparation	Thickness[a] × 10^4, cm	Permeability Coefficient × 10^7, cm/sec
Cornified layer	40	2.98[b]
Noncornified layer	320	11.3 ± 0.07[c]
Full-thickness membrane	410	2.36 ± 0.07

[a] An estimate from direct measurement of the separated cornified layer and from microscopic measurement of the membrane cross section. [b] Calculated from permeability coefficients of the noncornified layer and full-thickness membrane using Eq. 12. [c] Average value from Table VIII.

Effect of the Estrous Cycle on the Vaginal Membrane Thickness and Permeability Coefficient—The permeability coefficient data collected from 58 permeability experiments were grouped according to the different phases of the cycle (Fig. 4). Statistical comparison of these five groups of data was done with the nonparametric Mann-Whitney method[12] and the results are reported in Table VI. It was clear that the differences between the permeability coefficients at the diestrus phase and those at any other phase were highly significant. On the other hand, no significant difference in the permeability coefficients between the early estrus and estrus phases was shown, although these two phases were

Average		35.0 ± 2.0	317 ± 14	302 ± 13	1.10 ± 0.06

[a] Calculated from the permeation lag time using Eq. 8, when $P_{aq} = 1.05 \times 10^{-3}$ cm/sec and $haq = 1.03 \times 10^{-2}$ cm. [b] Calculated (for diestrus only) from the permeability coefficient and measured membrane thickness using Eq. 13. [c] Noncornified part of the membrane only. [d] Early stage of the diestrous phase.

distinguishable with the vaginal smear technique. Since the permeability coefficient was also a function of membrane thickness, the estrous cycle effect on vaginal membrane thickness was estimated; such data are shown in Fig. 5. Although statistical treatment of the data (Table VII) indicated that the membrane thickness at the diestrus phase was different from the thickness at the early estrus or estrus phase, the difference was only about twofold. In contrast, the permeability coefficients of I at estrus or early estrus were at least 10 and up to 100 times lower than those at diestrus. This suggested that the change of the permeability coefficients for I during the estrous cycle probably was due mainly to the physiological changes in the membrane cells rather than simply the increase of membrane thickness. A cross section of the membrane at each phase was examined under a microscope (Fig. 6). It showed that the membrane consisted of either two or three layers, *i.e.*, a loose cornified epithelial layer, a regular epithelial layer, and a combined lamina propria and muscular layer. The cornified epithelial layer, which appeared only at estrus and early estrus, was suspected as the major barrier for the penetration of I into the membrane. The permeability data also showed, however, that the mean permeability coefficient of I for the membrane at proestrus (for which there is not a cornified layer) already was reduced to 1.8×10^{-6} cm/sec. This value was about 10-fold lower than the corresponding value at diestrus. Another point is the relatively wide variation in permeability coefficients of I observed during diestrus. All these suggest that although the cornified epithelial layer could be a primary barrier for the transport of I through the membrane, it was not the sole barrier. A decrease in permeability could be caused also by the changes in the cell properties during proestrus.

Further permeation studies on vaginal membrane at estrus were performed by separating the cornified epithelial layer from the noncornified part of the membrane, the latter consisting of an epithelial layer and the combined lamina propria and muscular layer. Since it was very difficult to obtain intact cornified epithelial layers, only the permeability coefficient of the noncornified part of the membrane was measured (Table VIII). The permeability coefficient of the cornified epithelial layer (P_1) could then be estimated indirectly from:

$$\frac{1}{P_1} = \frac{1}{P_{1+2}} - \frac{1}{P_2} \qquad \text{(Eq. 11)}$$

where the permeability coefficients for the full-thickness membrane at estrus (P_{1+2}) and the permeability coefficients of the noncornified part of the membrane (P_2) were determined experimentally. The results are reported in Table IX. Statistical comparison showed that the permeability coefficients of the noncornified part of the membrane at estrus were significantly lower than those values obtained for the membrane at diestrus. They were, in fact, comparable to the permeability coefficients of the membrane at proestrus. These findings support the previous suggestion that there is a cycle-related low permeability layer in the vaginal membrane in addition to the cornified layer.

Estimation of the Permeability Coefficients of Membrane Sublayers—To investigate the homogeneity of the membranes with respect to diffusivity, theoretical membrane thickness was calculated from permeation lag times using Eq. 8. Two special cases are discussed here. The first is the results obtained using the noncornified part of the membrane obtained at estrus. These results show that the calculated membrane thicknesses are much smaller than those obtained from direct measurement (Table X). The second case involves membranes obtained during the early stage of the diestrus phase. These were the membranes with very large P-values for I. The calculated membrane thicknesses in this case showed no statistically significant differences from measured membrane thickness (Table X). The results from the second case suggest that, although there were two distinct physiological layers in the membrane at this stage in the estrous cycle, the differences between the diffusivities of I in these two layers must be either small or negligible. Therefore, a homogeneous membrane model should be a proper approximation for the membrane at this stage as far as diffusivity is concerned. The diffusivity for I for this homogeneous membrane may be calculated (assuming $k_P = 1$) from:

$$D = P \cdot h \qquad \text{(Eq. 12)}$$

The calculated diffusivity is shown in Table X.

The inconsistency of the calculated and measured membrane thickness in the first case strongly indicates that the noncornified part of the membrane at the estrus phase was not homogeneous. Since it is believed that membrane changes during the estrous cycle involve mainly the epithelial cells (9), the diffusivity of I in the combined lamina propria and muscular layer may be viewed as essentially constant throughout the cycle. Accordingly, the average diffusivity of I in membrane during the early stage of the diestrus phase (Table X) could be used as the diffusivity in the combined lamina propria and muscular layer at estrus. By microscopic estimation, of the thickness of this layer was $\sim 2.5 \times 10^{-2}$ cm; therefore, the estimated permeability coefficient was 4.4×10^{-5} cm/sec. This high permeability coefficient value shows that the combined lamina propria and muscular layer has little influence on the total permeability of I at estrus. As a result, the average permeability coefficient of 1.13×10^{-6} cm/sec obtained from the noncornified part of the membrane at estrus could be treated as the permeability coefficient of the epithelial layer at this phase without causing any serious error.

Direct Measurement of Membrane Diffusivity from Desorption Experiment—The diffusivity data obtained from desorption experiments for both layers of the membrane during the early stage of the diestrus phase of the estrous cycle are given in Table XI. Although the diffusivity of I in the epithelial layer was lower than that of the combined

lamina propria and muscular layer, the differences were small. Thus, the homogeneous membrane model still could be considered a good approximation for the membrane at the early stage of diestrus; this is in agreement with the previous discussion. The average diffusivities (as listed in the last row of Table XI) also were comparable to the diffusivity data calculated from the permeability coefficient (Table X).

In the case of the noncornified part of the membrane obtained at estrus, the results showed a great difference between the diffusivities of I in the two layers (Table XI). The average diffusivity value in the combined lamina propria and muscular layer, 1.61×10^{-6} cm^2/sec, was only slightly higher than the corresponding value, 1.09×10^{-6} cm^2/sec, obtained during diestrus. These results support the concept that the cycle effect is confined to the epithelial layer, as mentioned previously.

Calculation of Epithelial Layer Thickness—By performing the permeability and desorption experiments on the same piece of membrane, the thickness of the epithelial layer for the membrane during estrus could be calculated with better accuracy, using:

$$\frac{1}{P_2} = \frac{h_1}{D_1} + \frac{h_2 - h_1}{D_L} \qquad \text{(Eq. 13)}$$

where P_2 is the permeability coefficient of the noncornified part of the membrane, h_1 is the thickness of the epithelial layer, h_2 is the thickness of the noncornified part of the membrane, D_1 is the diffusivity of I in the epithelial layer, and D_L is the diffusivity of I in combined lamina propria and muscular layer. P_2 could be obtained from the permeability experiment; D_1 and D_L could be obtained from the desorption experiment; h_2 is estimated from direct measurement. The only unknown left is h_1, which then could be calculated easily. The results are listed in Table XII. The average thickness of the epithelial layer, 78.8×10^{-4} cm, is in good agreement with the thickness estimated from the microscopic membrane cross section ($70–90 \times 10^{-4}$ cm).

In Vivo–In Vitro Correlations with a Commercial Dissolution Simulator II: Papaverine, Phenytoin, and Sulfisoxazole

MARTIN K. T. YAU and MARVIN C. MEYER ˣ

Received February 19, 1982, from the *Division of Biopharmaceutics and Pharmacokinetics, Department of Pharmaceutics, College of Pharmacy, University of Tennessee, Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication June 15, 1982.

Abstract □ The dissolution profiles of 11 commercially available papaverine, phenytoin, and sulfisoxazole dosage forms were determined using a dissolution simulator. The products had been the subject of earlier *in vivo* bioavailability studies with human subjects. The use of an absorption simulator, which is designed to provide an estimate of the optimum sampling scheme for the dissolution simulator, did not provide useful data for this purpose. Good *in vivo–in vitro* correlations were found for the papaverine dosage forms, which included nine controlled-release products. Less satisfactory correlations were obtained for the phenytoin capsules and the sulfisoxazole tablet products.

Keyphrases □ *In vivo–in vitro* correlations—papaverine, phenytoin, and sulfisoxazole using a commercial dissolution simulator □ Papaverine—*in vivo–in vitro* correlations using a commercial dissolution simulator □ Phenytoin—*in vivo–in vitro* correlations using a commercial dissolution simulator □ Sulfisoxazole—*in vivo–in vitro* correlations using a commercial dissolution simulator

An earlier paper (1) described attempts to correlate the *in vitro* dissolution and *in vivo* bioavailability of several solid dosage forms, using commercial absorption[1] and dissolution[2] simulators. That study involved the testing of marketed methenamine, nitrofurantoin, and chlorothiazide dosage forms, which had been the subject of human urinary excretion bioavailability studies. Marketed dosage forms of papaverine, phenytoin, and sulfisoxazole, which were previously evaluated in human bioavailability studies (2–4) using plasma concentration measurements, are the subject of the present study.

EXPERIMENTAL

Absorption Simulator Studies—The design and application of the absorption simulator were described previously (1); the experimental conditions were essentially identical to the earlier study. The initial drug concentrations employed in the absorption studies were as follows: papaverine, 100 and 200 μg/ml; phenytoin, 30 μg/ml; and sulfisoxazole, 200 μg/ml. The surface areas of the artificial lipid barriers[3] were as follows: papaverine, 80 cm^2 and 12 cm^2 for the gastric phase; phenytoin, 40 cm^2 for the gastric phase, 80 cm^2 for the intestinal phase; and sulfisoxazole, 40 cm^2 for both the gastric and intestinal phase studies.

Dissolution Simulator Studies—The experimental approach and the design of the dissolution simulator were discussed previously (1). The following sampling rates were utilized: papaverine, 2.5 ml every 4 min for 56 min in the gastric phase and every 6 min for 123 min in the intestinal phase; sulfisoxazole, 2.5 ml every 2.5 min for 32 min in the gastric phase and 188 min in the intestinal phase; phenytoin, 7.5 ml every 0.5 min for 46 min (gastric phase), using distilled water as the dissolution medium.

The 11 papaverine hydrochloride dosage forms, previously identified (2), consisted of one elixir (150 mg/22.5 ml), eight 150-mg sustained-release capsules, one 200-mg sustained-release tablet, and one 30-mg compressed tablet (with a five-tablet dosage). The 11 phenytoin dosage forms were each 100-mg capsules of sodium phenytoin (3), and the 11 sulfisoxazole tablets each contained 500 mg of drug (4).

Analytical Methods—All drug solutions obtained from the absorption and dissolution studies were assayed spectrophotometrically at a wavelength appropriate for the drug and solvent. Papaverine solutions were diluted with 0.06 *N* hydrochloric acid and measured at 252 nm. Sulfisoxazole solutions, diluted when necessary with the buffer solutions employed in the absorption and dissolution studies, were measured at 253 and 267 nm for the pH 6.5 and 1.3 buffer solutions, respectively. In preliminary studies it was determined that constituents of the phenytoin capsules appeared to interfere in the direct spectrophotometric analysis of dissolution samples. Therefore, dissolution samples were acidified with 3 drops of hydrochloric acid, extracted into 20 ml of chloroform–ethanol (20:1, v/v), and back-extracted into 5 ml of 0.1 *N* sodium hydroxide. The aqueous solution was then measured spectrophotometrically at 230 nm. Phenytoin samples obtained with the absorption simulator were diluted with 0.1 *N* sodium hydroxide and measured directly at 230 nm.

Treatment of Dissolution Data—Two approaches were employed in the analysis of the dissolution rate data: simulated absorption data and general correlations. These procedures were described in detail previously (1), using urinary excretion data.

According to the manufacturer of the dissolution simulator (5, 6), the cumulative amount of drug withdrawn from the dissolution vessel (*Mi*) is related to the cumulative amount of drug absorbed *in vivo*. Using the

previously obtained plasma concentration data for each drug, the amount of drug absorbed (A_t) was calculated from:

$$\frac{A_t}{V_d} = C_t + K(\mathrm{AUC})_{0-t}$$

based on the Wagner–Nelson method (7). In this equation, V_d is the apparent volume of distribution; C_t is the plasma concentration at time t; K is the apparent first-order elimination rate constant, assuming a one-compartment model involving first-order absorption and elimination; and $(\mathrm{AUC})_{0-t}$ is the area under the plasma concentration–time curve over the time period 0–t, estimated with the trapezoidal rule. A direct comparison could not be made of the amount of dissolved drug withdrawn from the dissolution fluid (*Mi*) and the amount of drug absorbed *in vivo* (A_t) because the V_d term could not be estimated accurately from the *in vivo* data. To relate the amount dissolved *in vitro* to the *in vivo* plasma drug concentrations, plots were constructed of A_t/V_d *versus Mi*. The slope of the least-squares line forced through the origin was then used to adjust the A_t/V_d data.

A wide variety of correlations were also attempted to relate the *in vitro* and *in vivo* data. Initially, the dissolution rate profiles were examined systematically to determine dissolution rate parameters which exhibited a reasonable rank-order relationship to a given *in vivo* parameter. The correlation was then evaluated further from the statistical analyses of plots of *in vivo versus in vitro* data. The various *in vivo* values considered included the maximum plasma drug concentration, the time of maximum plasma concentration, the total area under the plasma concentration–time curve (AUC) at specific times, the time to achieve a given percent of the total AUC, and the percent of total AUC achieved at a given time. The *in vitro* values tested included the time for a given percentage of drug to be dissolved, the area under the dissolution–time profile at a given time, and the percentage of drug dissolved at a given time.

RESULTS AND DISCUSSION

Analytical Methods—The spectrophotometric methods employed for the analysis of samples obtained with the absorption and dissolution simulator were all relatively simple, and the linearity and reproducibility of the standard curves were excellent. The correlation coefficients describing the various standard curves were all >0.999. The slopes of these curves were reproducible on a daily basis and exhibited relative standard deviations of <3% for three to six determinations.

Absorption Simulator—According to Stricker (5), the diffusion rate constants obtained with the absorption simulator may be employed to determine the optimal sampling rates for the dissolution apparatus. The apparent first-order diffusion rate constants obtained with the absorption simulator are given in Table I, along with the theoretical optimal sampling rates and the sampling rates which were actually employed.

Attempts to study the diffusion of papaverine across the lipid barriers were not successful. The limited solubility of the drug in the receptor fluid (pH 7.5) and the apparent retention of the drug within the membrane resulted in negligible diffusion. Attempts to increase the rate of diffusion with a membrane of smaller surface area (12 cm^2) and a higher papaverine concentration (200 ng/ml) failed to provide adequate diffusion. Thus, the selection of sampling intervals of 4 min (gastric phase) and 6 min (intestinal phase) was based on preliminary trials with the dissolution simulator.

[a] A and B represent duplicate determinations.

The diffusion of the phenytoin across the lipid barriers was quite rapid from both gastric and intestinal media. The theoretical sampling intervals were 1.9 and 0.9 min for dissolution in the simulated gastric and intestinal fluids, respectively, based on the diffusion data. However, phenytoin was poorly soluble in the gastric and intestinal fluids of the dissolution apparatus, and the dissolution fluid was rapidly saturated as the 100-mg dosage form dissolved in 100 ml of the fluid. As a result, the sampling rate was changed to the maximum rate possible with the apparatus: 7.5 ml every 30 sec, for 45 min. In addition, distilled water was employed as the dissolution medium, as currently used in the USP XX dissolution procedure.

In preliminary trials with the dissolution of the sulfisoxazole tablets, it was determined that the theoretical sampling rates suggested by the absorption simulator were satisfactory for the study of these dosage forms. Duplicate determinations were made for sulfisoxazole, and the mean values are given in Table I.

Individual diffusion rate constants differed from the mean by < 3% for both the gastric and intestinal phase studies. Only single determinations were made for phenytoin and papaverine because of the limited value of the absorption simulator for these drugs. As noted in the previous study (1), data obtained with the absorption simulator generally was not applicable to the selection of appropriate conditions for the dissolution tests.

Dissolution Profiles—The dissolution rate profiles of the various formulations of the three drugs are shown in Figs. 1–6. Each data point represents the mean of two dosage forms, except for the papaverine elixir (product 1). Too little of the elixir remained from the earlier studies to permit duplicate dissolution studies. The reference to groups 1 and 2 in each of the dissolution study profiles relates to the fact that each *in vivo* bioavailability study involved two groups of subjects, with a reference (product 1) being common to both groups; e.g., six subjects received each of five papaverine dosage forms and the elixir, and an additional six

subjects received the other five papaverine dosage forms and the elixir (2).

The data for the papaverine formulations (Figs. 1–2) demonstrated rapid dissolution for both the elixir (product 1) and the compressed tablets (product 3). Each of the sustained-release dosage forms dissolved more slowly, including product 5 which was a 200-mg tablet. The amount of drug dissolved for each product decreased when the pH of the dissolution medium was increased to 6.5 after 56 min, suggesting precipitation of the papaverine under these conditions.

The dissolution of the majority of the phenytoin capsules was quite rapid, with all but 3 of the 11 products being at least 85% dissolved within 10 min. Product 2 in group 1 was slowly and incompletely dissolved even after 45 min, and this product also exhibited the poorest *in vivo* bioavailability (3).

The dissolution of each of the sulfisoxazole tablet products (Figs. 5 and 6) proceeded more rapidly after 32 min when the pH of the dissolution fluid was increased to 6.5. The two products which dissolved the slowest, product 5 (group 1) and product 2 (group 2), also failed the USP XVIII dissolution specifications (applicable at the time the *in vivo* studies were conducted).

In general, the reproducibility of the duplicate determinations was reasonably good. Table II summarizes individual dosage form values for the fastest and slowest dissolving formulation of each of the three drugs. By comparison, relative standard deviations for 12 replicate determinations of the dissolution of the phenytoin capsules, using the USP XX method (8), were <5% at each sampling time[4]. At the time of the sulfisoxazole bioavailability study, the various tablets were also subjected to the USP XVIII dissolution test, using six replicates. Samples were obtained only at 30 min. The dissolution values obtained for products 2 and 5 (Table II) were 475–511 mg and 90–125 mg, respectively. There is no official dissolution test for controlled-release papaverine dosage forms; therefore, these products were only studied with the dissolution simulator.

Simulated Absorption Profiles—Using the approach described earlier, attempts were made to relate the amount of drug dissolved *in vitro* and the amount in the body during the *in vivo* studies. This approach was not successful with data from either the phenytoin or the sulfisoxazole studies. Since the dissolution rate determinations for the phenytoin capsules were terminated after only 45 min, comparisons of the *in vitro* and *in vivo* absorption profiles were not meaningful. With the sulfisoxazole tablets, it was determined that the amount dissolved *in vitro*, in general, greatly underestimated the amount of drug absorbed *in vivo* for all products. Thus, no useful relationships could be discerned. However, there was a reasonably good correlation between the *in vitro* and *in vivo* data for the papaverine products, except for products 4 and 5 of group 1. Representative data are shown in Figs. 7 and 8. Since the two *in vivo* study groups differed significantly in the plasma papaverine concentrations obtained with the reference elixir, the data were analyzed separately for the two groups. Plots of A_t/V_d *versus Mi* yielded slopes of 1.77×10^{-5} and 1.15×10^{-5} ml^{-1} for groups 1 and 2, respectively. The slope value can be considered as a correction factor incorporating the V_d term and other *in vivo* variables not present in the *in vitro* system.

General Correlations—This data treatment represents a more classical approach which attempts to relate an *in vitro* parameter, such as percent dissolved at a given time, to an *in vivo* parameter, such as area under the plasma concentration–time curve (AUC), maximum plasma concentration (C_{max}), or time of maximum plasma concentration (t_{max}). Although a wide variety of potential correlations were tested, only those resulting in the best correlation are presented herein.

Papaverine—Good correlations were observed for plots of C_{max} *versus* percent dissolved in 30 min *in vitro*, $r = 0.917$ ($p < 0.01$), and the 0–10 hr AUC, $r = 0.899$ ($p < 0.01$), or C_{max}, $r = 0.869$ ($p < 0.01$), *versus* area under the dissolution–time curve for 3.2 hr. The best correlation (Fig. 9) related the 0–10 hr AUC to the percent dissolved in 30 min, $r = 0.922$ ($p < 0.01$). The group 1 and group 2 data were plotted together by normalizing the group 2 AUC values by the ratio of the AUC values for the reference elixir which was common to both study groups.

Phenytoin—The best correlations resulted when *in vivo* t_{max} values were plotted *versus* the time for 50% dissolution *in vitro* ($t_{50\%}$), $r = 0.909$ ($p < 0.01$), or the percent dissolved in 7 min, $r = 0.827$ ($p < 0.01$). The t_{max} values for the group 2 subjects were normalized by the ratio of the t_{max} values for reference (product 1), which was common to both groups.

As shown in Fig. 10, products 2 and 5 of group 1 did not fit the correlation employed to describe the other nine dosage forms.

Since the completion of these studies, new USP dissolution specifications have been published for phenytoin capsules (9). These dosage forms have been divided into two types, based on dissolution characteristics. "Prompt" capsules must dissolve ≥85% within 30 min, using 900 ml of water and the USP Apparatus I at 50 rpm. "Extended" capsules must dissolve ≤35% in 30 min, 30–70% at 60 min, and ≥80% in 120 min, using the same dissolution system. As shown in Fig. 3, only products 2 and 5 of group 1 failed to dissolve at least 85% in 30 min using the dissolution simulator. However, both products were >35% dissolved at 30 min. Thus, these two products dissolved too slowly to be considered "prompt" and too fast to be considered "extended" using the USP XX criteria. Product 1, which is a formulation that meets the USP XX specifications of "extended," also dissolved ~90% in 30 min using the dissolution simulator. With the exception of product 5 (group 1), the relationship illustrated in Fig. 10 could be employed. This suggests that if the time for 50% dissolution exceeded 5 min, the t_{max} value *in vivo* would exceed 4.5 hr. On the basis of dissolution testing, as well as *in vivo* bioavailability studies, current phenytoin products may be employed in different dosage regimens, depending on whether they are labeled "prompt" or "extended." The "prompt" formulations are recommended for three times a day (TID) administration, while the "extended" capsules may be given once a day after an initial period to reach the optimal titer.

Thus if the data from the dissolution simulator were to be employed to establish such specifications, products 1, 2, and 5 (group 1) and 6 (group 2) each would be considered "extended." However, the t_{max} for product 5, which exhibited the second longest dissolution time, was not appreciably different from that for the majority of the other products. The *in vitro* studies carried out with some of these products using the USP XX method (8) found products 1 and 2 (group 1) and 6 (group 2) to be the slowest dissolving, which is consistent with the present data. However, product 5 (group 1) was one of the more rapidly dissolving products. Thus the USP XX method provided dissolution data which were more consistent with the *in vivo* observations than that obtained with the dissolution simulator employed in the present study.

Sulfisoxazole—As part of the previous *in vivo* studies, all of the tablets

were evaluated using the USP XVIII dissolution method. Products 3 and 5 of group 1 and product 2 of group 2 failed the USP requirement of ≥60% dissolution in 30 min. The extent of dissolution was 12.6, 21.4, and 49% after 30 min for products 2, 5, and 3, respectively. Figure 11 illustrates the best correlation obtained in the present study, $r = 0.87$ ($p < 0.01$), relating time for 50% dissolution to the time to achieve 10% of the total AUC. Attempts to relate more conventional parameters such as total AUC, t_{max}, or C_{max} did not result in meaningful correlations, due in part to the relatively narrow range of *in vivo* bioavailability characteristics. The data of the *in vivo* studies resulted in a conclusion that the 11 dosage forms did not differ significantly in terms of any of the usual bioavailability parameters. Since product 5 (group 1) and product 2 (group 2) were the slowest dissolving tablets with both the USP method and the dissolution simulator, and yet did not differ significantly *in vivo*, there did not appear to be any advantage to the use of the dissolution simulator.

Study Limitations—As with the previous study (1), the expiration dates for several of the products had passed prior to the completion of the dissolution studies. Furthermore, too few dosage units remained to permit a determination of content uniformity. However, 90–100% of the labeled product content was dissolved during the period of the dissolution test for the papaverine elixir and compressed tablets, the majority of the phenytoin capsules, and the sulfisoxazole tablets, indicating no significant degradation had occurred during storage of these products. In addition, the slow dissolution of two of the sulfisoxazole tablets and three of the phenytoin capsules was consistent with other results obtained using USP methodology.

CONCLUSIONS

As was determined in the previous study (1), the use of the absorption simulator did not always provide useful information for establishing the optimum sampling rates for the dissolution simulator. Of the three drugs studied with the dissolution simulator, only the papaverine dosage forms resulted in a reasonable correlation between the *in vivo* bioavailability and the *in vitro* dissolution data. For the phenytoin capsules a reasonable correlation was obtained between the *in vitro* t_{max} and dissolution, except for two slowly dissolving capsules, thus limiting the general applicability of the relationship. Furthermore, other studies of these phenytoin capsules have indicated the present USP XX dissolution method provides better *in vivo–in vitro* correlations. The lack of suitable correlations was probably due, in part, to the limited fluid volume of the dissolution chamber, which was rapidly saturated with phenytoin. Finally, studies involving the sulfisoxazole tablets also failed to provide any significant *in vivo–in vitro* correlations, due in part to the similar *in vivo* characteristics of the 11 products. As with most, if not all *in vitro* dissolution systems, it is not possible to assume *a priori* that data obtained with the dissolution simulator will relate to the *in vivo* performance of a given dosage form.

Abstract □ 3-Fluoro-, 3-chloro-, and 3-bromocyclophosphamide were prepared from the reaction of trifluoromethylhypofluorite, sodium hypochlorite, and bromine with the anticancer drug cyclophosphamide. Treatment of *cis*- and *trans*-4-phenylcyclophosphamide and 5,6-benzocyclophosphamide with sodium hypochlorite afforded *cis*- and *trans*-3-chloro-4-phenylcyclophosphamide and 3-chloro-5,6-benzocyclophosphamide, respectively. ^{31}P-NMR spectroscopy was used to study the reactivity of these compounds: the fluoro derivative was reduced to cyclophosphamide on incubation with mouse liver slices, and the reactivity order for sulfhydryl-induced reduction of the 3-halocyclophosphamides was Br ≅ Cl ≫ F. Compared with the therapeutic efficacy of cyclophosphamide against L-1210 and P-388 cancers in mice, 3-fluoro- and 3-chlorocyclophosphamide were less active, although the fluoro derivative was more efficacious than the 3-chloro compound. The individual *R* and *S* enantiomers of 3-chlorocyclophosphamide, prepared from (*S*)- and (*R*)-cyclophosphamide, respectively, showed no significant difference in therapeutic activity in the P-388 test system.

Keyphrases □ Cyclophosphamide—synthesis of *N*-halogenated derivatives, NMR spectroscopic characterization, therapeutic efficacy in mouse cancers □ Synthesis—of *N*-halogenated derivatives of cyclophosphamide, NMR spectroscopic characterizations, therapeutic efficacy in mouse cancers □ Antineoplastic agents—cyclophosphamide and *N*-halogented derivatives, synthesis and NMR characterization, therapeutic efficacy in mouse cancers

The *N*,*N*-bis(2-chloroethyl)amino functionality has been used frequently in the design of antineoplastic agents (1) and prodrugs (1, 2). Studies of such prodrugs by Zon *et al.* (3–8) have included labile precursors of the well-known anticancer agent cyclophosphamide (I) (9). Since I functions as a prodrug (2, 9), these *in vivo* precursors of cyclophosphamide may be viewed as "pro-prodrugs." For example, 3-(*tert*-butyldimethylsilyl)cyclophosphamide (II) can release I by spontaneous hydrolysis (5), and 3-hydroxycyclophosphamide (III) can afford I by reductive cleavage of the N—O bond (6). While II proved to be inactive against L-1210 leukemia in mice (5), the *in vivo* conversion of III to I was evidenced by comparable antileukemic activities for III and I in the L-1210 system and by the rapid formation of I on incubation of III with liver microsomes (6).

A variety of other biologically reducible linkages (10–14) may be incorporated at the N-3 position of the cyclophosphamide ring system; however, the nitrogen–halogen bond is particularly interesting, since it apparently represents a new moiety for the reversible modification of N—H groups in drugs (11–15). In addition, the N—F modification, exemplified by 3-fluorocyclophosphamide (IV), could allow metabolic studies by ^{19}F-NMR spectroscopy, as with fluorine-labeled amino acids (16). Reports dealing with other types of halogenated cyclophosphamides [*e.g.*, *cis*- and *trans*-5-fluoro- (17, 18), 5-chloro- (17), and 5-bromocyclophosphamide (19)] have been published; however, unlike the *N*-halo series, the drug-design concepts were predicated on the *in vivo* stability of carbon–halogen bonds. 3-Fluoro- (IV) and 3-bromocyclophosphamide (VI) have not, to our knowledge, been previously synthesized; 3-chlorocyclophosphamide (V) has been mentioned only briefly in the literature (20). The present report describes the preparation of IV–VI and several 3-chloro analogues of I (X–XII). Data are also presented regarding the chemical charactristics and anticancer activity of these intended "pro-prodrugs."

[a] The tabulated chemical shifts (δ) refer to internal tetramethylsilane in deuterochloroform solvent, except for III and IV, which were dissolved in deuterium oxide and acetone-d_6, respectively. The values in parentheses are ^{13}C—^{31}P coupling constants in Hz-units. The carbon positions are as shown in the structure for I. [b] J_{CF} = 11.6 Hz. [c] J_{CF} = 9.8 Hz. [d] Other aromatic carbons at δ123.8, 126.5, and 128.8. [e] Other aromatic carbons at δ124.2, 130.6, and 135.9. [f] Other aromatic carbons at δ126.2, 127.8, and 128.7. [g] Other aromatic carbons at δ127.0, 128.0, and 128.8. [h] Other aromatic carbons at δ126.1, 128.3, 129.0, and 146.9. [i] Dilute sample; δ values are approximate and coupling constants were not measured, due to added line broadening.

samples of (+)-(*R*)- and (−)-(*S*)-I·H_2O were used as received[2]. The syntheses of 5,6-benzocyclophosphamide (VII), *cis*-4-phenylcyclophosphamide (VIII), and *trans*-4-phenylcyclophosphamide (IX) were reported elsewhere (22, 23), as were the details of the 40.25-MHz ^{31}P-NMR[3] and 25-MHz ^{13}C-NMR[3] measurements (6). Analogous procedures for data acquisition and processing were employed for obtaining 36.23-MHz[4] and 121.5-MHz[5] ^{31}P-NMR, 22.49-MHz[4] and 75.47-MHz[5] ^{13}C-NMR, 89.55-MHz ^{1}H-NMR[4] and 93.65-MHz ^{19}F-NMR[3] spectra. Chemical shift (δ, ppm) references were as follows: phosphorus-31, 25% (v/v) H_3PO_4 in deuterium oxide (external); carbon-13, tetramethylsilane (internal); fluorine-19, hexafluorobenzene (internal). Electron-impact (70 eV) mass spectra[6] (MS) were recorded with samples introduced *via* a solids' inlet probe, which was heated from ambient temperature to 100°. TLC plates had 0.25-mm coatings of silica gel and were developed by exposure to iodine vapor, which led to either absorptive (brown) or repellent (white) spots.

3-Fluorocyclophosphamide (IV)—A magnetically stirred and dry nitrogen-purged solution of anhydrous I (3.64 g, 13.9 mmoles) in dry methylene chloride (50 ml) was cooled to −78°. Trifluoromethylhypofluorite gas[7] (4.65 mmoles) was slowly introduced over a period of 3 hr into the nitrogen flush line *via* a Y-tube connected with tubing[8] to a cylinder, using a series of valves and a metering gauge that are described elsewhere (24). The nitrogen from the reaction flask was passed into a bubble cylinder containing an alkaline solution of potassium iodide to remove all by-products[9] and unreacted trifluoromethylhypofluorite. After the addition of the hypofluorite, the solution was allowed to gradually warm to room temperature (overnight) using a very slow nitrogen flush. The reaction mixture was filtered, and an aliquot (0.2 ml) of the filtrate was diluted with deuterochloroform (1.8 ml) prior to ^{31}P-NMR analysis. The remaining solution was concentrated on a rotary evaporator, without heating[10], and the resultant oil was chromatographed on a column (2.2 cm × 25 cm) of silica gel using ethyl acetate as the eluent. Compound IV (R_f 0.5, ethyl acetate) was eluted with 85–135 ml of solvent and was obtained as a pale-yellow oil (252 mg, 20% yield); ^{31}P-NMR (deuterium oxide): δ 16.17, J_{PF} = 22 Hz; ^{19}F-NMR (deuterochloroform): δ 83.27, J_{FP} = 22 Hz; ^{13}C-NMR, *cf.* Table I; MS, *m/z* 278, 280, and 282 (M^+, 2 Cl), 229 and 231 (base-peak cluster, $M-CH_2Cl$).

3-Chlorocyclophosphamide (V)—A magnetically stirred solution of I·H_2O (270 mg, 0.97 mmole) in chloroform (15 ml) was cooled with an ice-water bath, and an aqueous solution of sodium hypochlorite[11] [15 ml, 5.25% (w/w) NaOCl, 10.6 mmoles] was added; after 4 hr, the water bath was removed. Aliquots (1 ml) of the chloroform layer were periodically removed, diluted with deuterochloroform (1 ml), and the relative signal intensities for I (δ12.10) and the only detectable product (δ15.95) were measured by ^{31}P-NMR: 50:50, 2 hr; 25:75, 4 hr; 0:100, 18 hr. After 18 hr of stirring, TLC (ethyl acetate) of the chloroform layer confirmed the absence of I (R_f 0.1) and a single spot was evident (R_f 0.5). The 18-hr NMR sample and the remainder of the chloroform layer (13 ml) were combined, washed with water (15 ml) twice, dried with sodium sulfate, and then concentrated *in vacuo* without heating. Based on elemental composition, the resultant oil (280 mg, 87% yield) was identified as V·HCl, which was converted to V (^{13}C-NMR, Table I) by dissolving in chloroform and stirring with solid potassium carbonate.

Anal.—Calc. for $C_7H_{15}Cl_4N_2O_2P$: C, 25.32; H, 4.55; N, 8.44; Cl, 42.71. Found: C, 26.74; H, 4.71; N, 8.55; Cl, 43.12.

Application of the above procedure to (*R*)- and (*S*)-I·H_2O (2-g scale) gave (*S*)- and (*R*)-V, respectively[12], which were identified and checked for purity by TLC.

3-Bromocyclophosphamide (VI)—Bromine (0.135 ml, 2.6 mmoles) was added in one portion to a magnetically stirred, cold (5°) mixture of I·H_2O (0.70 g, 2.5 mmoles) and potassium carbonate (0.34 g, 2.5 mmoles) in methylene chloride (10 ml). After being stirred for 2 hr, the mixture was filtered and the solvent was removed on a rotary evaporator, without heating, and the residue was then placed under a high vacuum. The resultant orange-colored oil was free of TLC-detectable I (R_f 0.1, ethyl acetate), and gave rise to a single spot (R_f 0.4, ethyl acetate) which was identified by ^{13}C-NMR (Table I) as VI (0.88 g, 100% yield).

3-Chloro-5,6-benzocyclophosphamide (X)—Compound VII (31 mg, 0.1 mmole) in chloroform (3 ml) was treated with aqueous sodium hypochlorite (3 ml) as described above for the preparation of V. After stirring at room temperature overnight, the separated chloroform layer was washed with water (6 ml) twice, dried with magnesium sulfate, and then concentrated *in vacuo* to give X as an unstable oil (26 mg, 80% yield): TLC (ethyl acetate): R_f 0.8 for X *versus* R_f 0.4 for VII; see Table I for ^{13}C-NMR data for X *versus* VII. After 24 hr at room temperature, the two sets of protonated aromatic carbon signals for X and VII had relative intensities of ~67% and ~33%, respectively, indicating spontaneous decomposition.

***cis*- and *trans*-3-Chloro-4-phenylcyclophosphamide (XI) and (XII)**—A solution of VIII (28 mg, 0.08 mmole) in chloroform (3 ml) was stirred with aqueous sodium hypochlorite (6 ml) at room temperature for 7 days. Workup, as described above for X, afforded XI as an oil (17.4 mg, 59% yield) that was free of TLC-detectable VIII (R_f 0.5, ethyl acetate) and was seen as a single, faster eluting spot (R_f 0.9, ethyl acetate). A scaled-down version of this reaction using IX (3.5 mg, 0.01 mmole) gave XII (3.5 mg, 94% yield), which showed one spot on TLC (ethyl acetate), R_f 0.8 *versus* R_f 0.3 for IX. Compounds XI and XII were identified by ^{13}C-NMR comparisons with VIII and IX, respectively (Table I).

Incubation Studies—Female Balb/C mice (~25 g) were sacrificed by cervical dislocation. The livers were immediately removed for manual slicing, and the slices were stored temporarily in saline at 5°. Separate saline (10 ml) solutions of III (10 mg, 0.036 mmole) and IV (10 mg, 0.036 mmole), obtained by sonication, were equilibrated at 37° using open 50-ml Erlenmeyer flasks and a shaker incubator, and ~1- and 3-g portions of the liver slices were then added. After 10 min, each of the incubation mixtures was vigorously stirred with chloroform (25 ml) for 20 min; the separated organic layers were then dried with magnesium sulfate, filtered, and concentrated on a rotary evaporator. Both samples derived from III weighed ~10 mg, whereas the 1-g and 3-g incubations with IV afforded ~4 and 2 mg of recovered material, respectively. Each of the extracts was

[2] Otsuka Pharmaceutical Co., Ltd. For (*R*)-I·H_2O (mp 68°), $[\alpha]_D^{25}$ = 2.40 (c = 10, methanol); for (*S*)-I·H_2O (mp 68°), $[\alpha]_D^{25}$ = −2.47 (c = 10, methanol).

[b] (ILS) increased life span; (T/C) test/control. [c] Conducted at Otsuka Pharmaceutical Co. Ltd., Osaka, Japan. [d] Conducted at Johns Hopkins Oncology Center, Baltimore, Md. [e] Conducted at the Division of Cancer Treatment, National Cancer Institute, Bethesda, Md. [f] Taken from Ref. 23. [g] — Unacceptable level of toxicity. [h] Four of six toxicity-day survivors.

analyzed by 40.25-MHz ^{31}P-NMR using deuterochloroform solvent (1.8 ml), a $\pi/2$ pulse, 2-sec pulse-repetition time, and nuclear Overhauser enhancement. The presence of I was established by TLC (ethyl acetate) and addition of authentic I·H_2O (^{31}P-NMR). Integrated signal intensities were measured by the "cut-and-weigh" method.

Partition Coefficients—The ^{31}P-NMR spectrum of 27.9 m*M* I in water [5% (v/v) ^2H_2O] was obtained using a standard set of acquisition parameters [80 pulses ($\pi/2$), no nuclear Overhauser enhancement, and a 10-sec pulse-repetition time] and a standard set of display parameters. Comparison of the resultant signal intensity [(peak height) × (width at half-height) = 283 units] with the signal intensity (153 units) similarly obtained with a saturated solution of V in water gave an initial value of 15.1 m*M* V. A 2-ml aliquot of 27.9 m*M* I was vigorously stirred (25°, 5 min) with 1 ml of 1-octanol, and a 2-ml aliquot of 15.1 m*M* V was extracted with 0.1 ml of 1-octanol in exactly the same manner. The ^{31}P-NMR spectrum for each of the separated aqueous layers was recorded as described above, and the signal intensities (61.2 units for I, 28.5 units for V) were used to compute the concentration of I and V in the water and octanol layers: $[I]_{water}$ = 6.02 m*M*, $[I]_{octanol}$ = 43.71 m*M*, $[V]_{water}$ = 2.81 m*M*, and $[V]_{octanol}$ = 245.6 m*M*. The partition coefficients (P = $[compound]_{octanol}/[compound]_{water}$) for I and V were 7.26 and 87.6, respectively.

Anticancer Screening—On day 0, groups of 4–8 male and/or female mice (~25 g) were inoculated with cancerous cells (either L-1210 or P-388) at a level of either 10^5 or 10^6 cells/mouse. On the specified day (see Tables II and III), the test groups received single intraperitoneal injections of the test compound using a suitable vehicle and various doses; untreated control groups were injected with vehicle only. Each test compound was studied in parallel with I·H_2O, which served as a positive control for the screening protocol. Evaluations using mean survival times for test groups *versus* untreated control groups were scored as either increased life-span or test/control percentages. Pertinent experimental details and results are summarized in Tables II and III.

RESULTS AND DISCUSSION

Syntheses and Structure Determinations—Very little is known (25) about the *N*-fluorination of phosphoramides. The reaction of fluorine with the secondary phosphoramidic moiety, P(O)NHR, results in *N*-fluorination followed by P—N bond cleavage to give *N*-fluoroamines (25), whereas the secondary sulfonamide moiety SO_2NHR, reacts cleanly with trifluoromethylhypofluorite to give the corresponding *N*-fluorosulfonamide (26). Thus, it appeared that IV might be obtained directly from I using this hypofluorite reagent. Consideration of reported reaction mechanisms (26), in addition, suggested that subsequent P—N bond cleavage in IV might be minimized by using a fairly large molar excess of I, relative to the fluorinating reagent. Accordingly, the anhydrous reaction of I with 0.3 equivalents of the fluorinating agent led to ^1H-decoupled ^{31}P-NMR spectra at 40.25 and 121.5 MHz showing a singlet due to residual I (δ10.76) and a 1:1 doublet (J_{PF} = 22 Hz), which was shifted to lower field (δ12.64) and indicated the presence of IV. Following column chromatography, the structure of IV (20% yield) was unambiguously established by MS, ^{19}F-NMR, and ^{13}C-NMR. Comparison of ^{13}C-NMR parameters (Table I) for I, III, and IV showed that the electronegative OH and F substituents caused relatively large downfield shifts ($\Delta\delta$11–13) of the C-4 resonance absorption. This effect, although smaller ($\Delta\delta$1–2),

[a] Conducted at Otsuka Pharmaceutical Co. Ltd., Osaka, Japan. The control groups (n = 23) received 5 ml/kg of the vehicle. [b] Vehicle 4 and ILS as defined on Table II. [c] Injected intraperitoneally; test compounds were given orally on day 2. [d] Doses of 113 mg/kg of (*R*)- or (*S*)-V and 100 mg/kg (*R,S*)-I·H_2O represent equimolar doses. [e] One 30-day survivor.

was evidenced also by the C-5 signal positions, whereas the more remote carbons (C-6, C-α, and C-β) in I, III, and IV were not significantly influenced by the nature of the N-3 substituent. The long-range $^{13}C—^{19}F$ couplings observed for C-4 (J = 11.6 Hz) and C-5 (J = 9.8 Hz) were also indicative of the location of the fluorine substituent in IV[13].

^{31}P-NMR was used to monitor the reaction of I·H_2O with 10 equivalents of sodium hypochlorite in 1:1 (v/v) chloroform–water, and it was found that I (δ12.10) underwent a gradual conversion ($t_{1/2} \cong$ 2 hr) to a single product having a downfield-shifted resonance signal (δ15.95). The ^{13}C-NMR parameters (Table I) measured for the isolated reaction product were in accord with V (87% yield), which gave rise to downfield-shifted absorptions for C-4 ($\Delta\delta$15) and C-5 ($\Delta\delta$3), in comparison with I[14]. Analogous reactions of sodium hypochlorite with 5,6-benzocyclophosphamide (VII) and *cis*- and *trans*-4-phenylcyclophosphamide (VIII and IX) gave 80, 59, and 94% yields, respectively, of the corresponding 3-chloro derivatives, X–XII. The substantial downfield shift of each compound's C-4 signal ($\Delta\delta$6 for X, $\Delta\delta$13 for XI and XII), relative to its precursor, was again characteristic of the assigned structure[15].

The conversion of the 4-phenyl analogues of I to XI and XII were ~5–10-times slower than chlorination of either I or VII. This rate difference was attributed to steric hindrance of the N-3 position by the adjacent 4-phenyl substituent, which is evident in the crystal structure of VIII (23).

Reaction of a methylene chloride solution of I·H_2O with 1.04 equivalents of bromine in the presence of potassium carbonate gave a quantitative yield of VI. As with IV and V, introduction of the 3-bromo substituent resulted in characteristic downfield shifts of the C-4 ($\Delta\delta$17) and C-5 ($\Delta\delta$4) ^{13}C-NMR signals, compared with I (Table I).

Reactivity Studies—Fluoro-derivative IV was indefinitely stable in chloroform solution at −80° and failed to undergo reductive dehalogenation to give I on contact with thiophenol in chloroform (15 hr, 25°). Compound IV was also stable for 4 hr at 25° in a 10:1 (v/v) mixture of 2,6-lutidine (pH 7.2) and *p*-dioxane. On the other hand, ^{31}P-NMR spectra in unbuffered water showed the gradual disappearance of IV (δ16.17) with concomitant formation of decomposition products giving rise to singlets at δ12.78, 12.53, and 1.30. The characteristic doublet for IV was no longer detectable after 16 hr, and the three product signals in the now acidic solution (pH 3) had relative intensities of 33, 50, and 17%, respectively. The absence of resolvable $^{19}F—^{31}P$ couplings in the products indicated the absence of P(O)NF moieties; the addition of potassium dihydrogenphosphate established that the signal at δ1.30 was due to inorganic phosphate, which most likely resulted from proton-catalyzed P—N bond hydrolysis (27, 28). Since the P—N bonds in I are known to be sensitive to acid-catalyzed hydrolysis (27), the aforementioned results were consistent with the decomposition of IV to I and hydrofluoric acid, which then afforded hydrolytic products of the type previously found with I (27). Solutions of IV or IV–bovine serum albumin (20:1) in 0.1*M* NaCl gave results similar to those obtained in unbuffered water.

Surprisingly, ^{31}P-NMR studies of the chloro derivative (V) revealed reactivity patterns opposite to those of IV: V was instantaneously (<3 min) reduced to I by 20-fold molar excesses of either thiophenol (in chloroform) or mercaptoethanol (in water) at 25°, but there was only 8% conversion of V to I in unbuffered water after 7 days at 25°. Analogous results were obtained with the bromo compound (VI) which was somewhat more reactive than V in water, *i.e.*, 8% hydrolysis after 16 hr at room temperature.

The marked susceptibility of V and VI to reductive generation of I *via* reaction with sulfhydryl-containing compounds led to the use of the fluoro derivative (IV) to assess the possibility of an enzyme-mediated reduction process formally analogous to that found for III and mouse liver microsomes (6). Due to the hydrolytic instability of IV, incubations were terminated after 10 min, during which time there was negligible hydrolysis to I. The 37° incubations of IV in saline were performed in parallel with III, which served as a control for establishing the reducing capability of the whole-liver slices. Chloroform extraction of the incubation mixtures containing 3.6 m*M* substrate and 1-g portions of liver slices afforded samples having ^{31}P-NMR spectra which showed 96:4 and 79:21 relative ratios of III–I and IV–I, respectively; however, sample weights and absolute signal intensities for III and IV revealed that, unlike III, ~60% of IV had not been extracted. Thus, the corrected yield of I from IV was ~8%, roughly twice the yield of I from III. Use of 3-g portions of sliced liver failed to significantly increase the yield of I from either III or IV; the recovery of unreacted IV was only ~20%, whereas unreacted III was again quantitatively recovered.

Anticancer Screening—The comparatively stable compounds, *i.e.*, IV, V, and XI, were screened for anticancer activity using established protocols for analogues of I. Unfortunately, however, it was not possible to use a single methodology for the evaluations, as three independent laboratories were involved in these tests. From the data summary given in Table II, it was evident that while IV was the most active analogue in the mouse L-1210 leukemia system, it was less effective than the parent prodrug, I.

The individual enantiomers of V had statistically identical therapeutic efficacy in both the L-1210 (Table II) and P-388 (Table III) screens. The absence of significant therapeutic differences between (*R*)- and (*S*)-V thus paralleled findings reported for the enantiomers of I (29). As found for I and V, the introduction of a 3-chloro substituent (XI) into the 4-phenylcyclophosphamide analogue (VIII) had a negative impact on the anticancer activity.

Partition Coefficients—Conversion of the N—H moiety in I to either N—F or N—Cl moieties must alter solubility characteristics which are related, in part, to the aforementioned anticancer screening results. The magnitude of the solubility change resulting from the *N*-chlorination of I was therefore quantified using ^{31}P-NMR to measure partition coefficients (P) in octanol–water, where $P = [\text{compound}]_{\text{octanol}}/[\text{compound}]_{\text{water}}$. By this method, log P = 0.86 for I[16] and 1.94 for the chloro-derivative V, revealing a 12-fold greater partitioning of V into octanol. The increased lipophilicity resulting from this introduction of chlorine [$\pi_{Cl} \equiv \log P_V - \log P_I = 1.08$] was comparable in magnitude to the influence of introducing a *para* chlorine substituent in phenol [π_{Cl} = 0.93 (31, 32)]. This correlation allowed the calculation of log P for IV, which was not studied by the ^{31}P-NMR method because of possible complications due to solvolysis. The *p*-fluorophenol π_F value of 0.31 (31) thus gave log $P \cong$ 1.22 for IV, indicating only an approximately twofold increase in lipophilicity, relative to I.

CONCLUSIONS

3-Chlorocyclophosphamide (V) was rapidly converted to cyclophosphamide (I) on contact with sulfhydryl-containing compounds and could thus afford the same level of anticancer activity as I, if the unmasking of V were fast, relative to the metabolic oxidative activation (2) of either V or I. On the other hand, the 12-fold increase in the lipophilicity of V, relative to I, might decrease its accessibility to sulfhydryl moieties and thereby account for the lower therapeutic efficacy found for V *versus* I. Sulfhydryl-mediated chemical reduction of the *N*-fluoro analogue IV was a very slow process, by comparison with V; however, IV was calculated to be considerably less lipophilic than V and, moreover, the possibility for *in vivo* enzymatic conversion of IV to I was supported by incubation experiments with mouse liver slices. Consequently, the anticancer activity of IV, although lower than that of I, was tentatively ascribed to its func-

[13] For directly bonded carbon-13 and fluorine-19 in analogous structures, $J \cong$ 175 Hz (17).

[14] The alternative 4-chlorocyclophosphamide structure was ruled out by obtaining the ^{13}C-NMR spectrum with off-resonance hydrogen decoupling, which demonstrated that C-4 was bonded to two protons.

[15] The possibility of benzylic chlorination of VIII to give its 4-chloro derivative was excluded by ^1H-NMR homonuclear decoupling, *i.e.*, simultaneous irradiation of the axial and equatorial C-5 hydrogens (δ2.0–2.3) in product XI led to the observation of the C-4 hydrogen (δ4.7) as a 1:1 doublet with $^3J_{HP}$ = 19 Hz.

[16] Hansch and Leo (30) have cited an unpublished log P value of 0.63 for I in octanol–water.

tioning as an enzyme-activated "pro-prodrug," which reductively released prodrug I for subsequent oxidative conversion of I to a known array of oncostatic metabolites (2). Alternatively, and by analogy to the metabolism of I (2), oxidation of the C-4 position in IV could afford the *N*-fluoro derivative of phosphoramide mustard as the ultimate lethal cytotoxic agent. However, the highly electronegative fluorine substituent would, as in *N*-hydroxyphosphoramide mustard (6), diminish the phosphoramide mustard's alkylating activity by several orders of magnitude, which argues against a mechanism of action for IV wherein the N—F bond remains intact.

For the extensions of the presently reported *N*-fluorination of I, candidate structures having secondary phosphoramide groups include the anticancer drug isophosphamide (8, 9) and various cytotoxic phosphoramidic nitrogen mustards (2). Moreover, there are numerous drugs of various types which contain secondary sulfonamide and, especially, carboxamide groups that offer the possibility for *N*-fluorination by trifluoromethylhypofluorite. It is hoped that the studies reported herein will stimulate an interest in *N*-fluorinated amido groups as a new approach for investigating prodrugs, "pro-prodrugs," and congeners.

Comparative Study of Immunoactivity and Bioactivity of Sodium Insulin

C. R. KOWARSKI *x, B. BADO *, S. SHAH *, D. KOWARSKI§, and A. A. KOWARSKI ‡

Received February 19, 1982, from *Temple University School of Pharmacy, Philadelphia, PA 19140 and the ‡University of Maryland School of Medicine, Baltimore, MD 21201. Accepted for publication May 21, 1982. §Present address: University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Abstract □ The bioactivity of equal doses (by radioimmunoassay) of regular insulin and sodium insulin were measured in six preconditioned female mongrel hound dogs by a previously described bioassay. The hypoglycemic nadir of blood glucose induced by intravenous injection of the drugs was compared with the nadirs induced by a known amount of the international standard insulin. The level of blood glucose was monitored instantaneously and continuously using a nonthrombogenic continuous glucose-monitoring system. The hypoglycemic effect of subcutaneously injected sodium insulin was compared with the effect of subcutaneously injected regular insulin. The two drugs were injected at 1–2-week intervals to seven dogs. While the bioactivity of intravenously administered sodium insulin was equal to the bioactivity of intravenously administered *regular insulin*, the hypoglycemic effect of subcutaneously injected sodium insulin differed from the effect of subcutaneously injected regular insulin. The blood glucose nadir after subcutaneous injection of regular insulin occurred 101 ± 21 min after the injection. The nadir after subcutaneous injection of sodium insulin occurred 163 ± 33 min after the injection.

Keyphrases □ Sodium insulin—comparative study of immunoactivity and bioactivity □ Immunoactivity–comparative study of bioactivity of sodium insulin □ Bioactivity—comparative study of immunoactivity of sodium insulin

Sodium insulin is a new semisynthetic dosage form of insulin. Sodium insulin, like insulin, can be measured by an immunoassay, since both contain the same immunospecific binding site to the antibodies to insulin. However, equal doses of the two types of insulin, as measured by the immunoassay, are not necessarily equal in their biological activity. Also, equal biological activity after intravenous administration does not necessarily mean that the two types of insulin are of equal biological activity when injected subcutaneously.

An improved bioassay for insulin (1) was reported and is based on a previously described nonthrombogenic continuous glucose-monitoring device (2, 3). The bioassay was used to compare the intravenous biological activity of equal doses of sodium insulin and insulin standard (USP reference standard) measured by immunoassay. The hypoglycemic effect of subcutaneously administered sodium insulin was also compared with the effect of an equal dose of regular insulin.

EXPERIMENTAL

Immunoassay of Sodium Insulin—The immunoactivity of sodium insulin was measured six times, using a previously described immunoassay (4). The average of the six immunoassays was used to prepare the solution of sodium insulin used in the bioassay.

Bioassay of Sodium Insulin—*Instrument and Dogs*—Six preconditioned female mongrel hound dogs (16–17 kg) were used. The dogs were fasted overnight and anesthetized in the morning using sodium pentobarbital. Continuous glucose monitoring was initiated using a previously described nonthrombogenic system (2, 3). The instrument consisted of systems for nonthrombogenic blood withdrawal and for blood glucose measurement. The blood withdrawal system included a disposable sterile intravenous needle and tubing, coated with a nonthrombogenic substance connected to a peristaltic pump. The glucose-measuring system used a glucose oxidase sensor generating a continuous record of the level of blood glucose.

Priming Procedure—The bioassay was preceded by a priming procedure consisting of an intravenous administration of insulin followed by glucose.

The blood level of glucose was monitored for at least 30 min in order to establish the baseline level of glucose. Each dog was then given an injection of 0.4 U iv of USP reference standard insulin prepared in accordance with the USP procedure (5). The level of blood glucose fell rapidly reaching the initial priming nadir (N_0) within 30–35 min. After recording N_0, the level of glucose was raised by intravenous administration of 15–20 ml of a 25% solution of glucose. An additional 10 ml of glucose solution was given when necessary, until the blood glucose level stabilized within 10% of the baseline (~45–55 min).

Bioassay Procedure—After ascertaining maintenance of the glucose level at a consistent level for 10 min, the first dose of the USP standard insulin (0.4 U) was administered intravenously in one rapid bolus. The first nadir (N_1) was recorded by the glucose monitor within 35 min after the injection of insulin. As soon as an upturn in the level of blood glucose was established, the level of blood glucose was raised using a 25% intravenous glucose solution administered in 3 to 4 increments as previously described.

After ascertaining the reestablishment of a constant glucose level within 10% of baseline, the procedure was repeated twice: using 0.8 U of USP standard insulin, recording the second nadir (N_2) of blood glucose, and subsequently, using 0.6 U of sodium insulin as measured by immunoassay (4) and measuring the third nadir (N_3).

The bioactivity of the assayed sodium insulin was calculated using a least-squares linear regression of the logarithm of the two standard doses and the three nadirs.

Hypoglycemic Effect of Subcutaneous Sodium Insulin and Regular Insulin—Seven preconditioned female mongrel hound dogs (16–17 kg) were fasted and anesthetized as described previously. A nonthrombogenic catheter was inserted in one of the major veins of the front leg. The catheter was connected to the continuous glucose-monitoring device (2, 3). After a steady glucose level was observed for 10 min, 1 U of sodium insulin dissolved in sterile insulin diluent USP was injected

subcutaneously. The site of injection was always 2.54 cm from the center of the third nipple from the head. The glucose monitor measured the lowering of the blood glucose level. The nadir blood glucose level and the time of its occurrence were noted.

This procedure was repeated in each dog, after a rest period of 1 or 2 weeks, using 1 U of regular insulin instead of 1 U of sodium insulin.

RESULTS AND DISCUSSION

The results of the six repeated bioassays of a solution containing 0.6 U of sodium insulin as measured by immunoassay are shown in Table I. The mean biological activity of sodium insulin was equal to its immunoactivity. The coefficient of variation of the six consecutive immunoassays of sodium insulin was 3%.

The hypoglycemic effects of subcutaneously administered sodium insulin and regular insulin are compared in Table II. There was no significant difference between the nadirs of blood glucose following the two forms of insulin, but the nadir induced by sodium insulin occurred significantly later than the nadir induced by regular insulin.

Chemical manipulation of a biologically active molecule can have a significant effect on its biological as well as its immunological activity. The two effects may differ, leading to a new relationship between the two activities.

We have found that sodium insulin, a new dosage form of insulin, has the same ratio of biological *versus* immunological activity as the USP reference standard insulin.

Even though the biological effect of intravenously injected sodium insulin was equal to the effect of regular insulin, there was a significant difference between the effects of the two dosage forms of insulin when administered subcutaneously. The difference between the activity of subcutaneously administered sodium insulin and regular insulin, therefore, should be attributed only to the difference in the rate at which they are absorbed into the bloodstream.

Supported by Grant HD-16077 of the National Institutes of Health, United States Public Health Service. Sodium insulin and sterile insulin diluent, USP, were a gift from Dr. W. D. Storvick, Manager of Insulin Operation, Eli Lilly and Company. The regular insulin used was Illetin 100 U/ml from Eli Lilly and Company. The sodium insulin was batch 674-91GP-1-2.

Determination of Hydralazine in Human Whole Blood

T. M. LUDDEN *‡x, L. K. LUDDEN ‡, K. E. WADE ‡, and S. R. B. ALLERHEILIGEN *‡

Received January 18, 1982, from the **College of Pharmacy, University of Texas-Austin* and the ‡*Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.* Accepted for publication June 2, 1982.

Abstract □ The time required for the separation of plasma from the cellular components of blood can permit the *in vitro* loss of hydralazine. Thus, a high-performance liquid chromatographic (HPLC) procedure for the measurement of hydralazine in blood has been developed. 4-Methylhydralazine was used as an internal standard. The addition of *p*-anisaldehyde led to the formation of the *p*-anisaldehyde hydrazones of hydralazine and the internal standard. HPLC on a reverse-phase cyano column provided an analytical procedure in which the average relative standard deviation over the concentration range of 1–160 ng/ml was 8.3%. Hydralazine pyruvic acid hydrazone, a known circulating metabolite of hydralazine, yielded only 0.05 mole % hydralazine when submitted to this assay procedure.

Keyphrases □ Hydralazine—whole blood, derivatization, *p*-anisaldehyde hydrazones of hydralazine, analysis, high-performance liquid chromatography □ Whole blood—analysis, hydralazine, high-performance liquid chromatography □ High-performance liquid chromatography—hydralazine, whole blood analysis, *p*-anisaldehyde hydrazone of hydralazine

Selective assays for the measurement of hydralazine in plasma have been recently described (1–3). A major disadvantage of these procedures is the time required for separation of plasma from the cellular components of blood. Hydralazine disappears rapidly from plasma or blood *in vitro* (2, 4–6). Rapid sample processing at reduced temperature has been used to slow the loss prior to derivatization (7–9). The measurement of hydralazine in whole blood would circumvent this problem. In addition, because the clearance of hydralazine is high (7, 8), blood hydralazine concentrations are extremely useful for pharmacokinetic studies. However, attempts to measure hydralazine in whole blood using previously published techniques for plasma (1, 3) resulted in fouling of the chromatographic column after only a few sample injections. This paper describes a high-performance liquid chromatographic (HPLC) assay for the determination of hydralazine in whole blood using a different chromatographic column and a less polar extraction solvent.

EXPERIMENTAL

p	*NS*		<0.001	

subcutaneously. The site of injection was always 2.54 cm from the center of the third nipple from the head. The glucose monitor measured the lowering of the blood glucose level. The nadir blood glucose level and the time of its occurrence were noted.

This procedure was repeated in each dog, after a rest period of 1 or 2 weeks, using 1 U of regular insulin instead of 1 U of sodium insulin.

RESULTS AND DISCUSSION

The results of the six repeated bioassays of a solution containing 0.6 U of sodium insulin as measured by immunoassay are shown in Table I. The mean biological activity of sodium insulin was equal to its immunoactivity. The coefficient of variation of the six consecutive immunoassays of sodium insulin was 3%.

The hypoglycemic effects of subcutaneously administered sodium insulin and regular insulin are compared in Table II. There was no significant difference between the nadirs of blood glucose following the two forms of insulin, but the nadir induced by sodium insulin occurred significantly later than the nadir induced by regular insulin.

Chemical manipulation of a biologically active molecule can have a significant effect on its biological as well as its immunological activity. The two effects may differ, leading to a new relationship between the two activities.

We have found that sodium insulin, a new dosage form of insulin, has the same ratio of biological *versus* immunological activity as the USP reference standard insulin.

Even though the biological effect of intravenously injected sodium insulin was equal to the effect of regular insulin, there was a significant difference between the effects of the two dosage forms of insulin when administered subcutaneously. The difference between the activity of subcutaneously administered sodium insulin and regular insulin, therefore, should be attributed only to the difference in the rate at which they are absorbed into the bloodstream.

Determination of Hydralazine in Human Whole Blood

T. M. LUDDEN *‡x, L. K. LUDDEN ‡, K. E. WADE ‡, and S. R. B. ALLERHEILIGEN *‡

Received January 18, 1982, from the **College of Pharmacy, University of Texas-Austin* and the ‡*Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX 78284.* Accepted for publication June 2, 1982.

Abstract □ The time required for the separation of plasma from the cellular components of blood can permit the *in vitro* loss of hydralazine. Thus, a high-performance liquid chromatographic (HPLC) procedure for the measurement of hydralazine in blood has been developed. 4-Methylhydralazine was used as an internal standard. The addition of *p*-anisaldehyde led to the formation of the *p*-anisaldehyde hydrazones of hydralazine and the internal standard. HPLC on a reverse-phase cyano column provided an analytical procedure in which the average relative standard deviation over the concentration range of 1–160 ng/ml was 8.3%. Hydralazine pyruvic acid hydrazone, a known circulating metabolite of hydralazine, yielded only 0.05 mole % hydralazine when submitted to this assay procedure.

Keyphrases □ Hydralazine—whole blood, derivatization, *p*-anisaldehyde hydrazones of hydralazine, analysis, high-performance liquid chromatography □ Whole blood—analysis, hydralazine, high-performance liquid chromatography □ High-performance liquid chromatography—hydralazine, whole blood analysis, *p*-anisaldehyde hydrazone of hydralazine

Selective assays for the measurement of hydralazine in plasma have been recently described (1–3). A major disadvantage of these procedures is the time required for separation of plasma from the cellular components of blood. Hydralazine disappears rapidly from plasma or blood *in vitro* (2, 4–6). Rapid sample processing at reduced temperature has been used to slow the loss prior to derivatization (7–9). The measurement of hydralazine in whole blood would circumvent this problem. In addition, because the clearance of hydralazine is high (7, 8), blood hydralazine concentrations are extremely useful for pharmacokinetic studies. However, attempts to measure hydralazine in whole blood using previously published techniques for plasma (1, 3) resulted in fouling of the chromatographic column after only a few sample injections. This paper describes a high-performance liquid chromatographic (HPLC) assay for the determination of hydralazine in whole blood using a different chromatographic column and a less polar extraction solvent.

EXPERIMENTAL

Reagents and Chemicals—Hexane, methanol, and acetonitrile were purchased as glass-distilled solvents. The acetonitrile was filtered before

0022-3549/83/0600-0693$01.00/0

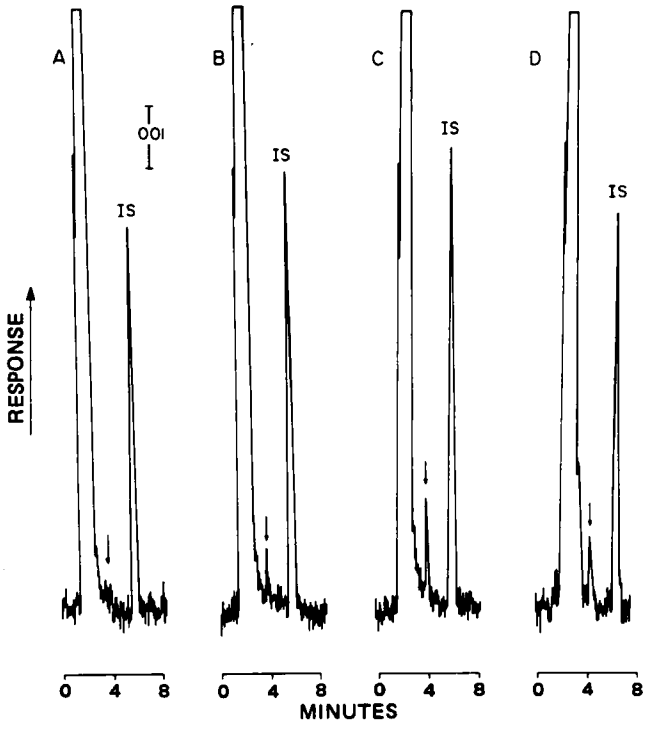

Figure 1—*Chromatograms of derivatized 3-ml blood samples containing 40 ng/ml of internal standard and (A) 0, (B) 1, (C) 2 ng/ml of hydralazine; (D) a sample obtained 150 min after administration of a 1-mg/kg oral dose of hydralazine hydrochloride to a hypertensive patient.*

being used. Hexane, hydralazine hydrochloride[1], 4-methylhydralazine[2], 4-(2-acetylhydrazino)phthalazin-1-one[3], and *p*-anisaldehyde[4] were used as received. Reference samples (3-methyl-*s*-triazolophthalazine, 4-hydrazinophthalazin-1-one) and hydralazine hydrazones of pyruvic acid, α-ketoglutaric acid, acetaldehyde, acetone, and *p*-anisaldehyde were prepared, and their identity and purity verified by gas chromatography–mass spectrometry as previously described (1, 10).

Standard Solutions—No pretreatment of the glassware was used. Hydralazine hydrochloride (61.4 mg) equivalent to 50 mg of the free base, was diluted to 50 ml with normal saline to give a concentration of 1 mg/ml. This stock solution was prepared daily. Standard A was prepared by diluting 0.6 ml of the stock solution to 10 ml with normal saline to yield a concentration of 60 ng/μl. Standard B was prepared by diluting 0.5 ml of Standard A to 10 ml with normal saline resulting in a concentration of 3 ng/μl. The internal standard solution was prepared by dissolving 50 μg of 4-methylhydralazine in 10 ml of 0.01 *N* HCl.

Standard Curve Samples—Three milliliters of whole blood containing EDTA (ethylenediaminetetraacetic acid) as an anticoagulant was placed in a 35-ml centrifuge tube fitted with a polytef-lined screw cap. After addition of 20 μl of *p*-anisaldehyde, appropriate volumes of either standard A or B were added along with 8 μl (40 ng) of the internal standard solution. The tube was capped immediately and mixed for 15 sec on a vortex mixer. Each sample was prepared individually to minimize the intervals between additions. Samples were allowed to stand at room temperature for 10 min. Preliminary studies indicated that 10 min is optimal for the formation of the *p*-anisaldehyde hydrazones of hydralazine and the internal standard. After derivatization, 10 ml of hexane was added and the sample was placed immediately on a reciprocal shaker[5] (180 strokes/min) for 10 min.

Phases were separated by centrifugation at 1000×*g* for 10 min. The organic phase was transferred to a 15-ml conical centrifuge tube and the solvent removed under a nitrogen stream. The remaining aqueous phase was processed as previously described (3) in order to measure the hydralazine pyruvic acid hydrazone concentration.

Chromatography—Each extraction residue was diluted with 100 μl of methanol and the entire volume was injected onto a reverse-phase column (3.9-mm i.d. × 30 cm)[6]. The mobile phase was 70% (v/v) acetonitrile in 0.15 *M* sodium acetate buffer, pH 3.0, pumped[7] at a flow rate of 2 ml/min. Detection[8] was at 365 nm.

Table I—Conversion of Hydralazine Hydrazones to Derivatized Hydralazine During the Analytical Process

Hydrazone	Initial Hydrazone Concentration, μg/ml	Hydralazine *p*-Anisaldehyde Hydrazone Found, mole %[a]
Pyruvic Acid	5	0.05
α-Ketoglutaric Acid	1	0.15
Acetone	1	4.2
Acetaldehyde	1	27.1

[a] Mean of two determinations.

Assay Evaluation—The efficiencies of derivatization and extraction were determined as previously described for plasma (1, 3) using fresh, whole human blood. Selectivity was evaluated by adding known or potential metabolites to whole blood and immediately assaying for hydralazine. Intraassay precision was determined by assaying multiple standard samples containing hydralazine concentrations of 1, 2, 8, 20, 40, 80, and 160 ng/ml.

Patient Samples—Blood, 3 ml, was drawn rapidly and placed in a 35-ml centrifuge tube containing EDTA. The internal standard and 20 μl of *p*-anisaldehyde were added immediately. The time between blood drawing and the addition of derivatizing reagent was <30 sec. After derivatization, samples were immediately extracted and prepared for chromatography as described for standard curve samples.

RESULTS

The retention times for hydralazine *p*-anisaldehyde hydrazone and 4-methylhydralazine *p*-anisaldehyde hydrazone were 3.5 and 6 min, respectively. Typical chromatograms are shown in Fig. 1. Maximum sensitivity for purposes of quantitation was ~1 ng/ml using a 3-ml blood sample. Derivatization efficiency for hydralazine was 103 ± 9% (mean ± *SD*) and extraction recovery was 70.5 ± 1.9%. The 3-methyl-*s*-triazolophthalazine, 4-hydrazinophthalazin-1-one, and 4-(2-acetylhydrazino)phthalazin-1-one yielded no chromatographic peaks when assayed with this procedure.

The acetaldehyde and acetone hydrazones yielded peaks at 4.1 and 2.9 min, respectively, which correspond to the retention times for standards of these materials. These hydrazones, as well as the hydrazones of α-ketoglutaric acid and pyruvic acid, yielded various quantities of derivatized hydralazine (Table I). The pyruvic acid hydrazone, the only one of the four hydrazones known to be present in the circulation (2–4), yields the least amount of apparent hydralazine. The acetaldehyde hydrazone is particularly labile. No significant quantities of this hydrazone or the hydrazones of α-ketoglutaric acid or acetone have been found in humans (2). These four hydrazones have similar stabilities in plasma (Table I).

The results of the intra-assay precision study are shown in Table II. The mean relative standard deviation was 8.3%. Precision is somewhat decreased at the lower concentrations, particularly at 1 ng/ml. This assay has been applied to blood from several patients receiving various drugs, including propranolol, furosemide, hydrochlorthiazide, digoxin, and nitroglycerin, without evidence of interference.

DISCUSSION

The assay described here has two advantages over other recently published techniques for the determination of hydralazine (1–3). First, it can be used to measure hydralazine concentrations in whole blood. This eliminates the time required to separate plasma, during which a significant fraction of hydralazine can continue to react with pyruvic acid to form the corresponding hydrazone. The use of whole blood also decreases the total blood volume required per determination. Second, the sensitivity of the assay has been extended to 1 ng/ml of blood when a 3-ml blood sample is used.

Hydralazine pyruvic acid hydrazone yields only 0.05 mole % hydrala-

Table II—Intraassay Precision of Hydralazine Assay

Hydralazine Added ng/ml	Peak Height Ratio[a]	Hydralazine Found, ng/ml[b]
1	0.120 ± 0.022	1.14
2	0.210 ± 0.027	1.91
8	0.827 ± 0.031	7.22
20	2.24 ± 0.186	19.4
40	4.57 ± 0.245	39.4
80	9.54 ± 0.440	82.2
160	18.6 ± 0.875	160.

[a] Mean ± *SD*, $n = 4$. [b] Based on regression analysis of peak height ratio *versus* added hydralazine concentration weighted by the reciprocal of the peak height ratio.

zine when assayed in this manner. Thus, a plasma concentration of 12.5 μM (2.9 μg/ml) of this hydrazone would be required to yield 1 ng/ml of hydralazine. After multiple 1-mg/kg doses of oral hydralazine, peak hydralazine pyruvic acid hydrazone concentrations averaged only ~2.5 μM, range: 0.9–6.0 μM (9).

Steady-state predose apparent hydralazine concentrations up to 17 μM have been reported for patients with low creatinine clearances who received ≤200 mg of hydralazine hydrochloride daily (11), using a nonselective GLC assay (12) which converts both hydralazine pyruvic acid hydrazone and hydralazine to tetrazolophthalazine (4, 5). However, even this high concentration of acid-labile hydrazones, if composed primarily of hydralazine pyruvic acid hydrazone, would yield less than 2 ng/ml of hydralazine when the current assay is used. Other hydralazine adducts, such as the acetone, α-ketoglutaric acid, and acetaldehyde hydrazones, are less stable, but have not been detected in significant concentrations in plasma (2) or whole blood[9].

Approximately 10% of the α-ketoglutaric acid hydrazone adduct has been reported to be converted to apparent hydralazine in a selective assay procedure (2), while the pyruvic acid and acetone hydrazones did not yield apparent hydralazine. The lowest detectable hydralazine concentration and the stability of the acetaldehyde hydrazone using this procedure were not reported.

The assay procedure described here, as well as other recently published methods applicable to plasma (1–3), are much more selective than older procedures. However, the lability of the various known and potential circulating metabolites of hydralazine makes it difficult to believe that any procedure will be completely selective for unchanged hydralazine. The procedure for measuring hydralazine in whole blood is being evaluated in hypertensive patients with renal failure and in patients with congestive heart failure since these individuals are likely to have the highest concentrations of circulating metabolites.

Quantitation of Meperidine Hydrochloride in Pharmaceutical Dosage Forms by High-Performance Liquid Chromatography

V. DAS GUPTA

Received January 22, 1982, from the *College of Pharmacy, University of Houston, Houston, TX 77030.* Accepted for publication June 2, 1982.

Abstract □ A high-performance liquid chromatographic (HPLC) method for the quantitative determination of meperidine hydrochloride in pharmaceutical dosage forms was developed. The method is reproducible and precise with relative standard deviations (based on six readings) of 1.2% with hydroxyzine and 0.93% with hydroxyprogesterone caproate as the internal standards. A variety of other active and inactive ingredients which were mixed with meperidine hydrochloride did not interfere with the assay procedure. Among the ingredients tested were acetaminophen, atropine sulfate, disodium edetate, metacresol, phenol, promethazine, and sodium metabisulfite. This method appears to be stability-indicating since a hydrolyzed sample of meperidine showed zero potency and a new peak with a different retention time.

Keyphrases □ Meperidine hydrochloride—quantitation in pharmaceutical dosage forms by high-performance liquid chromatography □ Pharmaceutical dosage forms—quantitation of meperidine hydrochloride by high-performance liquid chromatography □ High-performance liquid chromatography—quantitation of meperidine hydrochloride in pharmaceutical dosage forms

Meperidine hydrochloride (ethyl 1-methyl-4-phenylisonipecotate hydrochloride) is widely used as a narcotic analgesic. In addition to single ingredient dosage forms, meperidine is also mixed with acetaminophen, atropine sulfate, and promethazine hydrochloride in commercial dosage forms.

Synthetic Mixture 5	50.0	Acetaminophen 300	99.8	99.2

[a] The percent relative standard deviations based on six readings were 1.2 and 0.93 with hydroxyzine and hydroxyprogesterone caproate as the internal standards, respectively. [b] The excipients were not disclosed on the label. [c] The concentration of promethazine hydrochloride was determined to be 99.1% of the label claim. It was determined by comparing the peak heights of assay and the standard mixtures.

The USP-NF method (1) for the quantitation of meperidine hydrochloride is based on the nonaqueous titration with perchloric acid. Promethazine which is mixed with meperidine in a commercial dosage form[1] is also assayed (2) using the nonaqueous titration with perchloric acid. The method is nonspecific and cannot make a distinction between meperidine and promethazine or other weak bases.

A GLC (3) method for the quantitation of meperidine in plasma has been reported with a relative standard deviation of 9.9%. A suitable high-performance liquid chromatographic (HPLC) method for the analysis of meperidine has not been described.

The purpose of these investigations was to develop an HPLC method for the quantitation of meperidine hydrochloride in pharmaceutical dosage forms which would be useful in the presence of other ingredients.

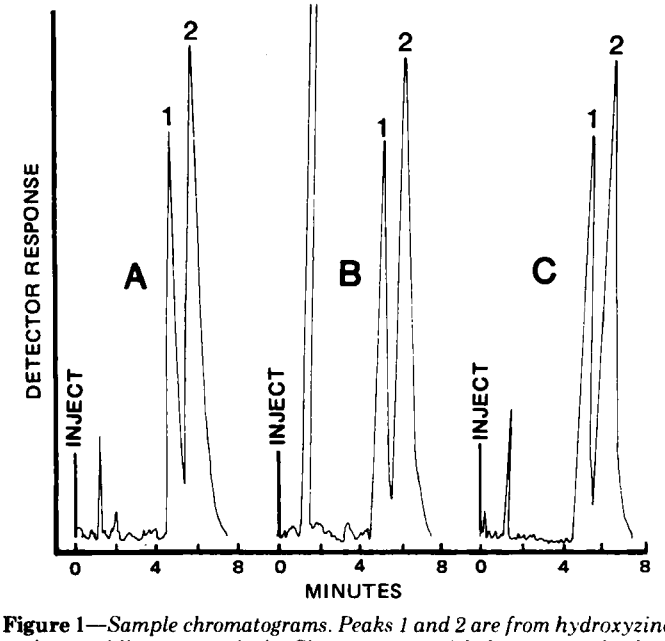

Figure 1—*Sample chromatograms. Peaks 1 and 2 are from hydroxyzine and meperidine, respectively. Chromatogram A is from a standard solution; B from a hydrolyzed sample of meperidine (see* Experimental*) and C from an ampule (number 3 in Table I). For chromatographic conditions, see text.*

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were either USP, NF, or ACS quality and used without further purification. Hydroxyprogesterone caproate[2], hydroxyzine hydrochloride[3], meperidine hydrochloride[4], and promethazine hydrochloride[5] were used as received.

An HPLC[6] equipped with a multiple wavelength detector[7], a recorder[8], and an integrator[9], was used. A μ-Bondapak-C_{18} column[10] (30 cm × 4 mm i.d.) was used at ambient temperature.

Chromatographic Conditions—The mobile phase contained 60% by volume of acetonitrile in 0.02 *M* aqueous solution of ammonium acetate. The flow rate was 2.0 ml/min (3.0 ml/min when hydroxyprogesterone caproate was the internal standard), the sensitivity was 0.04 AUFS at 232 nm, and the chart speed was 30.5 cm/hr.

Preparation of Stock and Standard Solutions—The stock solutions of hydroxyzine hydrochloride, meperidine hydrochloride, and promethazine hydrochloride were prepared by dissolving 100.0 mg of the powder in enough water to make 100.0 ml. The stock solutions were diluted further with water as needed. The standard solution contained 500.0 μg/ml of meperidine hydrochloride and 28 μg/ml of hydroxyzine hydrochloride. A standard mixture containing 250.0 μg/ml each of meperidine hydrochloride and promethazine hydrochloride and 14.0 μg/ml of hydroxyzine hydrochloride was also prepared.

The solutions of acetaminophen (~3 mg/ml), atropine sulfate (20 μg/ml), calcium chloride (10 μg/ml), disodium edetate (30 μg/ml), metacresol (10 μg/ml), phenol (200 μg/ml), and sodium metabisulfite (50 μg/ml) in water were also prepared to determine the possible interference from these ingredients, since they are added to commercial dosage forms.

Preparation of Assay Solutions, Injections (Ampules or Vials)—To an appropriate quantity of the injection containing 50.0 mg of meperidine hydrochloride, 2.8 ml of hydroxyzine hydrochloride stock solution was added and the mixture was diluted to 100.0 ml with water.

Assay solutions were made from syrup (10 mg/ml) by mixing 2.5 ml of the mixture with 1.4 ml of the stock solution of hydroxyzine hydrochloride and diluting to 50.0 ml with water, and from 50-mg tablets by weighing 20 tablets accurately and grinding them to a fine powder. An appropriate quantity of the powder containing 50.0 mg of meperidine hydrochloride was mixed with 50 ml of water and 2.8 ml of the stock solution of hydroxyzine hydrochloride. The mixture was brought to a volume (100.0

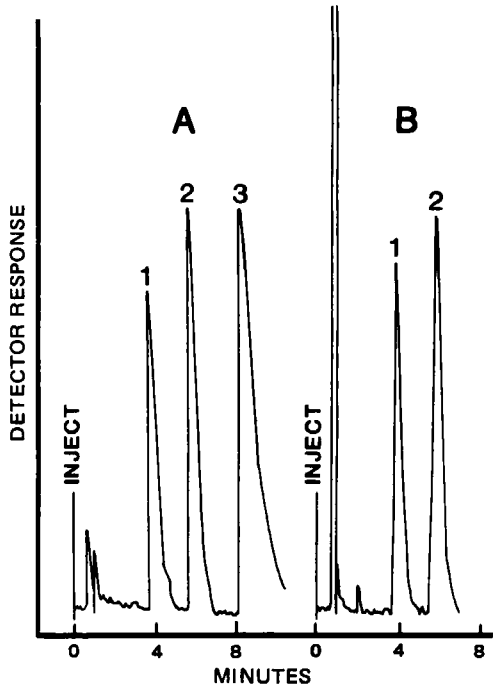

Figure 2—*Sample chromatograms. Peaks 1–3 are from meperidine, hydroxyprogesterone caproate, and promethazine, respectively. Chromatogram A is from a standard mixture containing (in μg per ml): meperidine hydrochloride (310), hydroxyprogesterone caproate (30), and promethazine hydrochloride (50). Chromatogram B is from a syrup with 350 μg/ml of meperidine hydrochloride and 30 μg/ml of hydroxyprogesterone caproate. For chromatographic conditions, see text. Flow rate was 3.0 ml/min.*

ml) with water and then filtered. The first 20 ml of the filtrate was discarded and the remainder collected for the assay.

Modifications with Hydroxyprogesterone Caproate as the Internal Standard—A stock solution of hydroxyprogesterone caproate was prepared by dissolving 100.0 mg of the powder in enough ethanol to make 100.0 ml. The standard solutions were prepared by mixing 3.0 ml of the stock solution with 60 ml of acetonitrile, an appropriate quantity of the meperidine hydrochloride stock solution concentrated (2.0 mg/ml), and enough water to make 100.0 ml. A similar procedure was used to prepare the assay solutions. In the case of tablets, only 30 ml of water was used instead of 50 ml in the extraction procedure. The assay solutions were filtered if necessary.

Assay Procedure—A 20 μl aliquot of the sample was injected into the chromatograph using the described conditions. For purpose of comparison, an identical volume of the standard solution–mixture was injected after the assay material was eluted.

Because preliminary investigations indicated that the ratio of peak heights (meperidine–hydroxyzine or meperidine–hydroxyprogesterone caproate) were directly related to the concentrations (5–13-μg range tested), the results were calculated using a standard curve or the following equation:

$$\frac{(R_{ph})_a}{(R_{ph})_s} \times 100 = \text{percent of the label claim}$$

where $(R_{ph})_a$ is the ratio of the peak heights of the assay solution and $(R_{ph})_s$ is that of the standard solution. The results are presented in Table I and Figs. 1 and 2.

In other experiments a 6.25-ml solution of meperidine hydrochloride (2 mg/ml) was mixed with 1 ml of ~1 *N* NaOH in a 25-ml volumetric flask. The flask (with lid on) was stored in an electric oven at 50° (±1°) for 48 hr. After cooling the mixture, 1 ml of ~1 *N* HCl and 0.7 ml of the stock solution of hydroxyzine hydrochloride were added. The mixture was brought to volume with water and assayed using the procedure described above. The results are presented in Fig. 1B.

RESULTS AND DISCUSSION

The results indicate (Table I, Figs. 1 and 2) that this HPLC method can be used for the quantitative determination of meperidine hydrochloride in pharmaceutical dosage forms. The results on different days were highly reproducible and precise. The relative standard deviations based on six readings were 1.2% with meperidine hydrochloride and 0.93% with hydroxyprogesterone caproate, as the internal standard, respectively. The ratio of the peak heights was directly related to the concentrations of meperidine hydrochloride (5–13-μg range tested).

A variety of other active and inactive ingredients, which are usually mixed with meperidine in commercial dosage forms, did not interfere with the assay procedure. The concentrations (in μg) tested (with 10 μg of meperidine hydrochloride) were: acetaminophen, 60; atropine sulfate, 0.4; calcium chloride, 0.2; disodium edetate, 0.6; metacresol, 0.2; phenol, 4; promethazine hydrochloride, 10; and sodium metabisulfite, 1. In addition to these ingredients, the excipients in syrup such as flavors and preservative(s) eluted immediately after the solvent peak (Fig. 2B) and did not interfere with the assay procedure. The exact nature of the excipients added was not disclosed on the label.

Since meperidine did not separate completely from hydroxyzine (Fig. 1), another internal standard (hydroxyprogesterone caproate) was developed later in these investigations. The results obtained with this internal standard were similar (Table I) to those with hydroxyzine as the internal standard. Hydroxyprogesterone caproate separated completely from meperidine and promethazine (Fig. 2) and is recommended as the internal standard. The relative standard deviations based on six readings were 0.93 *versus* 1.2% with hydroxyzine hydrochloride (an alternative internal standard). To keep hydroxyprogesterone caproate in solution, it was necessary to add 60% (v/v) of acetonitrile (same concentration as in the mobile phase) to the standard/assay solutions. The flow rate was increased to 3.0 ml/min to hasten the assay procedure.

It was possible to determine the concentration of promethazine hydrochloride (Table I, footnote *c* and Fig. 2A) present in the synthetic mixture similar to a commercial dosage form[1]. The promethazine eluted ~4.5 min later (peak 3 in Fig. 2A) than meperidine (peak 1 in Fig. 2A).

The developed method appears to be stability-indicating, since a sample of meperidine which was hydrolyzed to the free acid (see *Experimental*) showed almost zero potency (Fig. 1B), and the product(s) of decomposition eluted immediately after the solvent. The *N*-oxide, another possible degradation product, was not chromatographed.

Involvement of Active Sodium Transport in the Rectal Absorption of Gentamicin Sulfate in the Presence and Absence of Absorption-Promoting Adjuvants

JOSEPH A. FIX ˣ, PATRICIA A. PORTER, and PAULA S. LEPPERT

Received January 13, 1982, from the *INTERx Research Corporation, Subsidiary of Merck & Co., Inc., Lawrence, KS 66045.* Accepted for publication June 4, 1982.

Abstract □ The involvement of active sodium transport in the rectal absorption of gentamicin sulfate was examined in rats, employing aqueous microenemas of known total ionic strength (μ) in the presence or absence of absorption-promoting adjuvants. Rectal gentamicin bioavailability, which is negligible (1 ± 1.2%) at an ionic strength of 0.15 without adjuvants, is significantly ($p < 0.01$) increased by including adjuvants in the formulation (sodium salicylate, 12 ± 4.0%; sodium-5-bromosalicylate, 59 ± 15.1%; disodium ethylene(dinitrilo)tetraacetate, 24 ± 9.3%). Pretreating the rectal mucosa cells with ouabain, a specific inhibitor of active sodium transport, significantly ($p < 0.01$) reduced gentamicin absorption in response to all three adjuvants. In contrast to previous findings with sodium chloride, high ionic strength choline chloride (μ = 1.056) did not promote gentamicin absorption. The data indicate that active sodium transport is an integral component of rectal absorption of water-soluble compounds and may be involved in the mechanism of action of absorption-promoting adjuvants.

Keyphrases □ Gentamicin sulfate—rectal absorption, effect of choline chloride and ouabain □ Choline chloride—effect on rectal absorption of gentamicin sulfate adjuvant enhancement □ Ouabain—effect on the rectal absorption of gentamicin sulfate □ Rectal absorption—gentamicin sulfate, effect of choline chloride and ouabain.

Normal rectal mucosa is capable of transporting sodium chloride and water from the luminal to the serosal side of the epithelial barrier (1). The bidirectional movement of sodium ions is regulated by both passive and active components, and has been shown to be directly correlated with the rectal transluminal potential difference (2). Previous work in this laboratory has shown that increasing the ionic strength in a microenema containing gentamicin, a water-soluble antibiotic, significantly enhanced the rectal absorption of the drug (3). The enhancing effect due to high ionic strength appeared to be additive to the enhanced rectal absorption effected by sodium salicylate, a proven absorption adjuvant (4, 5).

Two factors in a previous study on ionic strength (3) suggested that there was a possible specific involvement of sodium transport in rectal gentamicin delivery, including delivery which was adjuvant (sodium salicylate) assisted. In the absence of sodium salicylate, gentamicin absorption (at ionic strength of μ = 1.054) was twofold greater when sodium chloride, rather than potassium chloride, was the major contributor to total ionic strength. The addition of sodium salicylate to both sodium chloride and potassium chloride microenemas significantly increased rectal gentamicin absorption, but the same twofold difference in efficacy between sodium chloride and potassium chloride was still observed.

In the current study, the possible involvement of active sodium transport was further investigated by employing two agents, ouabain and choline chloride, which alter electrogenic sodium transport. Ouabain is a metabolic inhibitor which specifically blocks the membrane sodium–potassium pump. Choline chloride is used as a sodium chloride substitute since equivalent ionic strength can be established; but choline itself is not transported by the sodium–potassium pump. The use of these agents has provided data suggesting a direct involvement of active sodium transport in the rectal absorption of gentamicin. The results obtained here may also be of general applicability to other water-soluble compounds whose rectal absorption is enhanced by salicylate-type adjuvants (5–7).

EXPERIMENTAL

Adult male Sprague-Dawley rats (200–250 g) were fasted, with free access to water, for 18–24 hr prior to the experiment. Animals were anesthetized with intramuscular injections of urethane (0.5 ml of 43% ethylcarbamate[1] in distilled water per 100 g of body weight).

Aqueous microenemas (250 μl, pH 5) containing 2.5 mg of gentamicin sulfate[1] were administered with a 1-ml syringe at an intrarectal depth of 2.5 cm. Ionic species (sodium chloride, potassium chloride, or choline chloride) and/or absorption adjuvant were included in the microenemas as indicated in the text and legends. In one set of experiments, sodium-free microenemas were prepared by dissolving gentamicin sulfate and salicylic acid in 50-m*M* tromethamine hydrochloric acid (Tris-HCl) buffer. In experiments employing ouabain, animals received a 250-μl microenema of 25 m*M* ouabain either 15 or 30 min prior to administration of the gentamicin formulation. The gentamicin formulation also contained 25-m*M* ouabain in these experiments. Total ionic strength and percent bioavailability were calculated as described previously (3).

RESULTS

Rectal absorption of gentamicin is negligible (1 ± 1.2%, $n = 3$) when the drug is administered in an aqueous microenema at μ = 0.15 and without an adjuvant. Gentamicin absorption was significantly increased by the addition of 20 mg/kg of sodium salicylate (12 ± 4.0%, $n = 6$, $p < 0.01$), disodium ethylene(dinitrilo)tetraacetate (24 ± 9.3%, $n = 3$, $p < 0.01$), or sodium-5-bromosalicylate (59 ± 15.1%, $n = 3$, $p < 0.01$).

Increasing the microenema ionic strength by the addition of sodium chloride or potassium chloride was previously shown to significantly increase rectal gentamicin absorption (3). Data for choline chloride are shown in Fig. 1. Gentamicin bioavailability in the presence of 1.0 *M* choline chloride (μ = 1.054) was 6 ± 1.0% ($n = 3$) with no significant differences at other choline chloride concentrations (μ = 0.304–0.754). Compared with previous data on increasing ionic strength, the relative order of effectiveness in promoting gentamicin absorption was sodium chloride > potassium chloride > choline chloride (Fig. 1A). The incorporation of sodium salicylate into the choline chloride microenema resulted in gentamicin bioavailability greater than that seen with choline chloride alone (Fig. 1B). When the ionic contributions of sodium salicylate were included in calculations of total ionic strength and the results presented as bioavailability *versus* total ionic strength (3) (Fig. 1B), the profiles with salicylate demonstrated higher bioavailabilities and were approximately parallel to the ionic profiles with the salts alone.

Ouabain pretreatment significantly ($p < 0.01$) decreased gentamicin bioavailability in response to sodium salicylate, sodium-5-bromosalicylate, and disodium ethylene(dinitrilo)tetraacetate (Fig. 2). The effect was more pronounced following the 30-min pretreatment. Even though 30-min ouabain pretreatment significantly reduced bioavailabilities, the

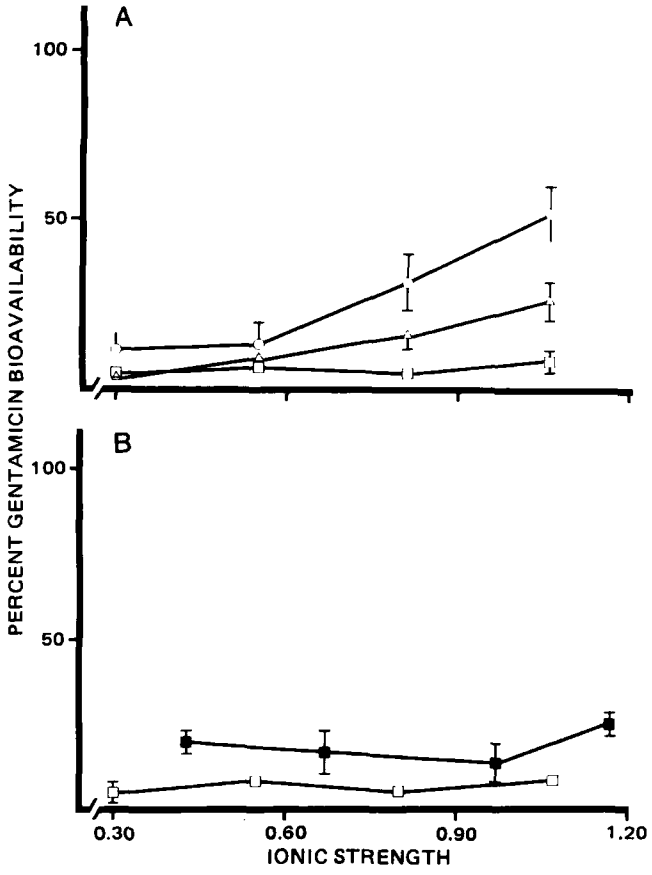

Figure 1—*Gentamicin bioavailability in the presence of various ionic strengths (μ) of sodium chloride (○), potassium chloride (△), and choline chloride (□), choline chloride–sodium salicylate (■). Panel A shows ionic strength profiles for each of the three salts in the absence of sodium salicylate. Panel B shows results of ionic strength profiles with choline chloride in the presence and absence of sodium salicylate. Error bars represent the standard deviation for* n = *3–6 experiments. Where error bars are not shown, the standard deviation is within the dimensions of the symbol.*

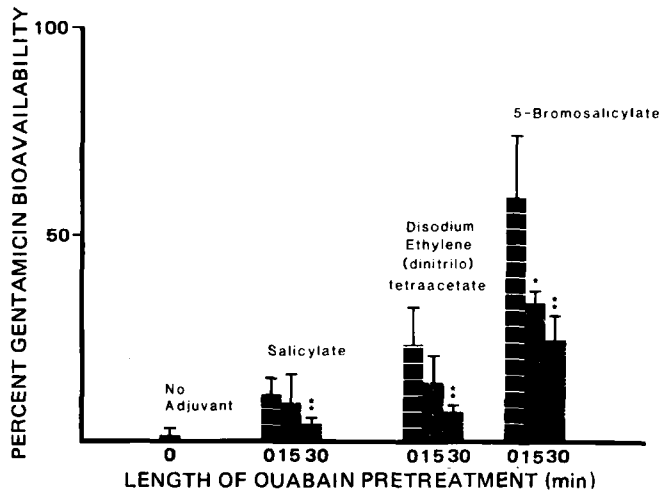

Figure 2—*Effect of ouabain pretreatment on gentamicin bioavailability in response to sodium salicylate, disodium ethylene(dinitrilo)tetraacetate, and sodium-5-bromosalicylate. Gentamicin bioavailability achieved with 20 mg of adjuvant/kg of body weight is represented as 0-min ouabain pretreatment. Histogram bars designated 15 and 30 represent gentamicin bioavailability observed in response to adjuvant activity following a 15 or 30-min exposure of the rectal tissue to 25 m*M *ouabain. Error bars represent the standard deviation for* n = *3–6 experiments. Key: (*)* $p < 0.025$, *(**)* $p < 0.01$.

levels of drug absorption were still greater ($p < 0.05$) than those observed with control microenemas (no adjuvant).

The effect of ouabain pretreatment on salicylate-assisted, high ionic strength rectal gentamicin absorption was examined using microenemas containing 0.5 *M* NaCl. Without ouabain pretreatment, gentamicin bioavailability in the presence of sodium chloride and 20 mg of sodium salicylate/kg body weight ($\mu = 0.574$) was 47 ± 7.1% ($n = 3$). Following a 30-min ouabain pretreatment, bioavailability was reduced to 22 ± 4.4% ($n = 3$, $p < 0.001$).

Sodium-free microenemas, prepared using salicylic acid and nonsodium buffering salts, resulted in gentamicin bioavailability of 9 ± 0.3% ($n = 3$), which was significantly ($p < 0.001$) greater than adjuvant-free control microenemas (1 ± 1.2%, $n = 3$).

DISCUSSION

Previous work in this laboratory suggested the possible involvement of monovalent cation specificity in the rectal delivery of gentamicin, a water-soluble antibiotic (3). Ionic strength profiles demonstrated that sodium chloride afforded higher levels of gentamicin absorption than potassium chloride. The absorption-promoting activity of sodium salicylate appeared to be additive to the enhancing effects of ionic strength.

The possible involvement of active sodium transport was further investigated in this study. Choline chloride, a nontransported ionic equivalent of sodium chloride, and ouabain, a specific inhibitor of the membrane sodium-potassium pump, were tested for effects on rectal gentamicin absorption.

Increasing the microenema ionic strength by the addition of sodium chloride, potassium chloride, or choline chloride demonstrated a preferential response in bioavailability to sodium ions. The inability of high ionic strength choline chloride ($\mu = 1.054$) to promote gentamicin absorption indicated that ionic strength alone was not a major modulator of rectal absorption.

Involvement of the membrane sodium-potassium transport system was further verified in experiments employing ouabain pretreatment of the rectal mucosal cells. The ability of ouabain to significantly reduce gentamicin bioavailability in response to all three adjuvants [salicylate, disodium ethylene(dinitrilo)tetraacetate, 5-bromosalicylate], at normal and elevated sodium chloride ionic strengths, indicates an important influence of active sodium transport in rectal absorption. After 30-min ouabain pretreatment, the level of gentamicin absorption was still significantly greater than the bioavailability observed in experiments with untreated animals given microenemas without adjuvant. One possible explanation for this is that at least a fraction of the adjuvant-enhanced absorption is independent of active sodium transport, assuming that a total inhibition of sodium transport would occur in response to 25 m*M* ouabain pretreatment (not verified by measurements of sodium transport). An alternative explanation is that the ouabain concentration or time of membrane exposure to ouabain may have been insufficient to totally suppress membrane sodium transport. In either case, the definite involvement of active sodium transport in rectal gentamicin absorption has been demonstrated.

The ability of salicylic acid to promote rectal gentamicin absorption when administered as a sodium-free microenema suggests that sodium may not be absolutely required for this delivery system. However, sufficient sodium may normally be present in the fluids of the rectal compartment to permit salicylate-enhanced gentamicin absorption.

The mechanism(s) by which active sodium transport affects rectal absorption of water-soluble compounds is unknown, although the direction and magnitude of fluid movement is significantly affected by the sodium gradient. Regardless of the exact mechanism(s) involved, it is clear that active sodium transport is intimately related to rectal absorption systems. The applicability of these findings to the further development of traditional dosage forms (*e.g.*, suppositories) remains to be demonstrated. However, the regulation of sodium transport may provide a means to predictably alter the permeability of the rectal mucosal cell barrier and to more carefully control adjuvant-enhanced absorption of water-soluble compounds.

Synthesis and Anticonvulsant Screening of 3,3-Diphenyl-2-pyrrolidone Derivatives

GEORGE A. BRINE ˣ **and KARL G. BOLDT**

Received March 3, 1982, from the *Chemistry and Life Sciences Group, Research Triangle Institute, Research Triangle Park, NC 27709.* Accepted for publication June 7, 1982.

Abstract □ Six derivatives of 3,3-diphenyl-2-pyrrolidone were synthesized and screened for anticonvulsant activity. The synthetic route involved a mono-*N*-demethylation of an intermediate *N*,*N*-dimethylaminonitrile with methyl chloroformate followed by cleavage of the carbamate group. Of the six derivatives, (±)-2-imino-1,5-dimethyl-3,3-diphenylpyrrolidine hydrochloride was effective in protecting mice against maximal electroshock (MES) -induced seizures at a 30-mg/kg dose level.

Keyphrases □ Anticonvulsant screening—synthesis of 3,3-diphenyl-2-pyrrolidone derivatives, maximal electroshock-induced seizures, mice □ 3,3-Diphenyl-2-pyrrolidone—synthesis and anticonvulsant screening, derivatives, maximal electroshock-induced seizures, mice

The reported (1) anticonvulsant activity of 2-pyrrolidone (I), the lactam of γ-aminobutyric acid, stimulated interest in 2-pyrrolidone derivatives as potential anticonvulsants. As it incorporated several features of the anticonvulsant diphenylhydantoin (II), the 3,3-diphenyl-2-pyrrolidone (III) system seemed a promising one for the study. When tested in rats, 3,3-diphenyl-2-pyrrolidone (III) itself was less effective than (±)-3-ethyl-3-phenyl-2-pyrrolidone against both pentylenetetrazol[1] and electrically-induced convulsions (2). Somewhat earlier, it was observed (3) that the structurally related α,α-diphenylsuccinimide (IVa) and its *N*-methyl derivative (IVb) ranked first and eighth in a series of 39 succinimides in protecting mice against electrically induced convulsions.

The work on 3,3-disubstituted-2-pyrrolidones (2) and α-phenylsuccinimides (3) showed that the presence of an asymmetric center at the 3-position often enhanced anticonvulsant activity. The present study was undertaken to determine if the introduction of an asymmetric center at the 4- or 5-position of the 3,3-diphenyl-2-pyrrolidone (III) system would have a similar beneficial effect. Accordingly, (±)-1,4-dimethyl-3,3-diphenyl-2-pyrrolidone (Va) and (±)-1,5-dimethyl-3,3-diphenyl-2-pyrrolidone (VIa) were synthesized and evaluated for anticonvulsant activity. The corresponding amidines, Vb and VIb, were also prepared to compare them with the neutral lactams. Moreover, the amidine functionality was expected to provide a handle for further structural modification as exemplified by the acyl derivatives, VIc and VId. The test compounds were prepared using modifications of previously reported (4–6) procedures.

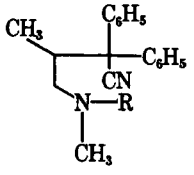
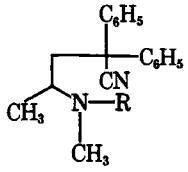
VIc: R = $NCOCH_3$
VId: R = NCO_2CH_3



VIIa: R = CH_3
VIIb: R = CO_2CH_3



VIIIa: R = CH_3
VIIIb: R = CO_2CH_3

RESULTS AND DISCUSSION

Because of the interest in amidines Vb and VIb, the synthetic route (4–6) involving them as intermediates was preferred to other procedures (7, 8) for preparing (±)-1,4-dimethyl-3,3-diphenyl-2-pyrrolidone (Va) and (±)-1,5-dimethyl-3,3-diphenyl-2-pyrrolidone (VIa). The mono-*N*-demethylation of the *N*,*N*-dimethylaminonitriles VIIa and VIIIa was readily effected using excess methyl chloroformate. The subsequent conversion of carbamate VIIIb to VIb hydrochloride was carried out in refluxing hydrochloric acid. In contrast, carbamate VIIb failed to either dissolve or react in hydrochloric acid. Moreover, the compound was recovered essentially unchanged after 17 days of reflux in ethanol–hydrochloric acid (2:1). Ultimately, the transformation of VIIb to Vb was

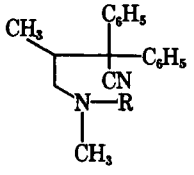
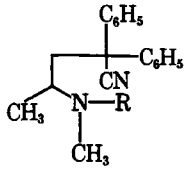
VIc: R = $NCOCH_3$
VId: R = NCO_2CH_3



VIIa: R = CH_3
VIIb: R = CO_2CH_3



VIIIa: R = CH_3
VIIIb: R = CO_2CH_3

RESULTS AND DISCUSSION

Because of the interest in amidines Vb and VIb, the synthetic route (4–6) involving them as intermediates was preferred to other procedures (7, 8) for preparing (±)-1,4-dimethyl-3,3-diphenyl-2-pyrrolidone (Va) and (±)-1,5-dimethyl-3,3-diphenyl-2-pyrrolidone (VIa). The mono-*N*-demethylation of the *N*,*N*-dimethylaminonitriles VIIa and VIIIa was readily effected using excess methyl chloroformate. The subsequent conversion of carbamate VIIIb to VIb hydrochloride was carried out in refluxing hydrochloric acid. In contrast, carbamate VIIb failed to either dissolve or react in hydrochloric acid. Moreover, the compound was recovered essentially unchanged after 17 days of reflux in ethanol–hydrochloric acid (2:1). Ultimately, the transformation of VIIb to Vb was

[1] Metrazol.

0022-3549/83/0600-0700$01.00/0

achieved using hydrogen bromide in glacial acetic acid. In addition, the nitrous acid reaction (4) was found to require a large excess of reagent added in portions in order to effect complete conversion of starting material to product. Throughout the synthesis, the geometric isomers were easily distinguished from each other by the ^{1}H-NMR chemical shifts of the various methyl groups.

The lactams Va and VIa were inactive in all tests at all dose levels. In contrast, amidine VIb was effective in protecting mice against maximal electroshock (MES)-induced seizures at a 30-mg/kg dose level, although it afforded no protection at lower dose levels (3, 10, and 20 mg/kg). Amidine Vb was inactive in all tests at 30 mg/kg. Both Vb and VIb were too toxic to be administered at dose levels >30 mg/kg. Of the acyl compounds derived from VIb, the carbomethoxyimino derivative VId was inactive at all dose levels. The acetimido derivative VIc, on the other hand, appeared to exacerbate the effects of MES and subcutaneous pentylenetetrazol treatment, thereby causing death. Furthermore, at dose levels of 300 and 600 mg/kg, compound VIc caused death through CNS depression.

Since the presence of an *N*-methyl group was shown to decrease the effectiveness of α-phenylsuccinimides against electrically induced convulsions (3), it was reasonable that *N*-demethylation of VIb might yield a compound with improved activity in the MES screen. However, compounds VIb and VIa were both unaffected by refluxing with 47% hydriodic acid. Treatment of compound VIc with excess methyl chloroformate also failed to effect an *N*-demethylation. Moreover, two attempts to further functionalize lactam VIa by nitration of an aromatic ring were unsuccessful.

In summary, the combination of *N*-methylation and the generation of an asymmetric center by introduction of a methyl group at the 4- or 5-position of the 3,3-diphenyl-2-pyrrolidone (III) system had no apparent beneficial effect on anticonvulsant activity. Although the amidine VIb was active in the MES screen at a low dose level, this activity was offset by the neurotoxicity of the compound at higher dose levels. Finally, the preparation of simple acyl derivatives failed to improve the activity, and the chemical inertness of the system made further structural modifications difficult.

EXPERIMENTAL[2]

(±)-4-Dimethylamino-2,2-diphenyl-3-methylbutyronitrile (VIIa) and (±)-4-Dimethylamino-2,2-diphenylvaleronitrile (VIIIa)—The isomeric nitriles were prepared by condensation of diphenylacetonitrile and 2-chloro-1-dimethylaminopropane in the presence of potassium *tert*-butoxide (7). The less soluble valeronitrile (VIIIa) was obtained in isomerically pure form by hexane trituration followed by recrystallization from absolute ethanol. Vacuum distillation of the hexane-soluble fraction afforded a 7:3 mixture of VIIa–VIIIa; bp 131–137° (0.15–0.20 mm). The total yield of nitriles was 58%.

(±) -4- (*N* - Carbomethoxy -*N*- methylamino)-2,2-diphenyl-3-butyronitrile (VIIb)—The 7:3 nitrile mixture (36 g, 0.13 mole), sodium bicarbonate (126 g, 1.5 moles), and methyl chloroformate (208 g, 2.2 moles) were refluxed for 26 hr in chloroform (1.4 liters). The reaction mixture was filtered and the filtrate washed with 3 *N* hydrochloric acid, 5% sodium bicarbonate, and water. Evaporation of the organic layer afforded a 7:3 mixture of VIIb–VIIIb (^{1}H-NMR analysis). Ether trituration removed the more soluble valeronitrile carbonate, VIIIb. Recrystallization of the residual solid from ethyl acetate–petroleum ether gave 19 g (45%) of VIIb as a white solid; mp 145–147°; IR 1697 cm^{-1} (C=O); ^{1}H-NMR δ 1.04 (d, 3, CHCH_3), 2.88 (s, 3, NCH_3), 3.70 ppm (s, 3, OCH_3). There was no detectable amount of the isomeric carbamate by ^{1}H-NMR.

(±) -4- (*N* - Carbomethoxy -*N*- methylamino)-2,2-diphenylvaleronitrile (VIIIb)—A mixture of VIIIa (5.0 g, 0.018 mole), sodium bicarbonate (10.0 g, 0.12 mole), and methyl chloroformate (36 g, 0.38 mole) in chloroform (260 ml) was refluxed for 48 hr with half of the methyl chloroformate being added after 24 hr. Workup as described above afforded 5.8 g (100%) of VIIIb as viscous oil; IR 1695 cm^{-1} (C=O); ^{1}H-NMR δ 1.16 (d, 3, CHCH_3), 2.28 (s, 3, NCH_3), 3.53 ppm (s, 3, OCH_3).

(±)-2-Imino-1,4-dimethyl-3,3-diphenylpyrrolidine (Vb) Hydrochloride—Hydrogen bromide gas was bubbled through a solution of VIIb (7.0 g, 0.022 mole) in glacial acetic acid (250 ml) for 30 min. The resultant mixture was stirred at room temperature for 4 days. Then it was diluted with water, basified with concentrated ammonium hydroxide, and extracted with methylene chloride. The residue obtained from evaporation of the organic extracts was partitioned between ether and 6 *N* hydrochloric acid. The resultant aqueous layer was extracted with chloroform and the extracts evaporated to obtain 5.8 g of crude product as a white foam. Crystallization from methanol–ethyl acetate gave 1.8 g (28%) of Vb hydrochloride as a white solid; mp 241–245° (hot stage) after *in vacuo* drying at 100° overnight [lit (4): mp 239°]; IR 3420, 1690 (C=N) cm^{-1}; ^{1}H-NMR δ 0.87 (d, 3, CHCH_3), 3.67 ppm (s, 3, NCH_3).

Anal.—Calc. for $C_{18}H_{21}ClN_2 \cdot \frac{1}{2} H_2O$: C, 69.75; H, 7.16; N, 9.04. Found: C, 69.69; H, 7.15; N, 8.98.

A subsequent preparation yielded material that had mp 239.5–242° (hot stage) and analyzed for $C_{18}H_{21}ClN_2 \cdot \frac{3}{4} H_2O$. Attempts to prepare Vb hydrochloride by refluxing VIIb in concentrated hydrochloric acid or in ethanol saturated with hydrogen chloride gas were unsuccessful.

(±)-1,4-Dimethyl-3,3-diphenyl-2-pyrrolidone (Va)—Compound Vb (1.5 g, 0.005 mole) was converted to Va using excess nitrous acid (4). Recrystallization of the crude product from 95% ethanol afforded 0.86 g (65%) of Va as clear crystals; mp 122–122.5° [lit. (8): mp 122–123°]; IR 1689 cm^{-1} (C=O); ^{1}H-NMR δ 0.80 (d, 3, CHCH_3), 2.98 ppm (s, 3, NCH_3).

(±)-2-Imino-1,5-dimethyl-3,3-diphenylpyrrolidine (VIb) Hydrochloride—A solution of VIIIb (5.8 g, 0.018 mole) in concentrated hydrochloric acid (150 ml) was refluxed for 43.5 hr under nitrogen. The mixture was cooled, diluted with water (300 ml), and extracted with chloroform. Evaporation of the organic extracts afforded the crude product as a white foam. Crystallization from 2-propanol–ether gave 4.6 g (85%) of VIb hydrochloride as a white solid; mp 281–283° [lit. (5): mp 279–281°]; IR 3420, 1690 (C=N) cm^{-1}; ^{1}H-NMR δ 1.30 (d, 3, CHCH_3), 3.45 ppm (s, 3, NCH_3).

(±)-1,5-Dimethyl-3,3-diphenyl-2-pyrrolidone (VIa)—Compound VIb (4.2 g, 0.015 mole) was converted to VIa using excess nitrous acid (4). Recrystallization from ethanol afforded 2.7 g (73%) of VIa as a white solid; mp 121–123° [lit. (8): mp 121–122°]; IR 1682 cm^{-1} (C=O); ^{1}H-NMR δ 1.25 (d, 3, CHCH_3), 2.88 ppm (s, 3, NCH_3).

(±)-2-Acetimido-1,5-dimethyl-3,3-diphenylpyrrolidine (VIc)—A solution of VIb hydrochloride (3.0 g, 0.01 mole) in pyridine (30 ml) and acetic anhydride (3 ml) was stirred at room temperature overnight. The solvents were removed *in vacuo* and the residue dissolved in chloroform. After washing with water, 10% sodium hydroxide, and saturated sodium chloride, the chloroform layer was evaporated to give an off-white solid. Recrystallization from cyclohexane–ethyl acetate provided 2.3 g (75%) of VIc as a white solid; mp 127–128° [lit. (4): mp 126.5–127.5°]; IR 1630, 1600 (sh) cm^{-1}; ^{1}H-NMR δ 1.27 (d, 3H, CHCH_3), 1.67 (s, 3H, COCH_3), 2.88 ppm (s, 3H, NCH_3).

Anal.—Calc. for $C_{20}H_{22}N_2O$: C, 78.40; H, 7.24; N, 9.14. Found: C, 78.37; H, 7.29; N, 9.08.

(±)-2-Carbomethoxyimino-1,5-dimethyl-3,3-diphenylpyrrolidine (VId)—A mixture of VIb (5.7 g, 0.022 mole), sodium bicarbonate (20 g, 0.24 mole), and methyl chloroformate (12 g, 0.13 mole) in chloroform was refluxed for 24 hr. The reaction mixture was filtered and the filtrate washed with 10% hydrochloric acid and saturated sodium chloride. Evaporation of the organic layer afforded a white solid which was recrystallized from ethyl acetate–petroleum ether to give 5.0 g (71%) of VId as a white solid; mp 166–167°; IR 1690, 1630 cm^{-1}; ^{1}H-NMR δ 1.22 (d, 3, CHCH_3); 2.88 (s, 3, NCH_3), 3.10 (s, 3, OCH_3).

Anal.—Calc. for $C_{20}H_{22}H_2O_2$: C, 74.51; H, 6.88; N, 8.69. Found: C, 74.46; H, 6.89; N, 8.67.

Screening Procedures—The test compounds underwent an anticonvulsant screening[3]. The compounds were screened at 30, 100, 300, and 600-mg/kg dose levels in adult male CF 1 mice (intraperitoneal injection). Compounds Vb hydrochloride and VIb hydrochloride were administered in 0.9% saline solution, other test compounds as suspensions in 30% aqueous polyethylene glycol 400. Each compound was screened in an MES test, a subcutaneous pentylenetetrazol seizure threshold test, and a rotorod test for neurotoxicity. Screening procedures, protocols, and data interpretation have been published (9).

Synthesis of Deuterium-Labeled Prochlorperazine

EDWARD M. HAWES, TREVOR S. GURNSEY, H. UMESHA SHETTY, and KAMAL K. MIDHA ˣ

Received February 18, 1982, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N OWO.* Accepted for publication June 8, 1982.

Abstract □ The propylpiperazine side chain of prochlorperazine was labeled with two, four, or six deuterium atoms by lithium aluminum deuteride reduction of the appropriate amide. The isotopic purity of the products after correcting for chlorine isotopes was >95.7%.

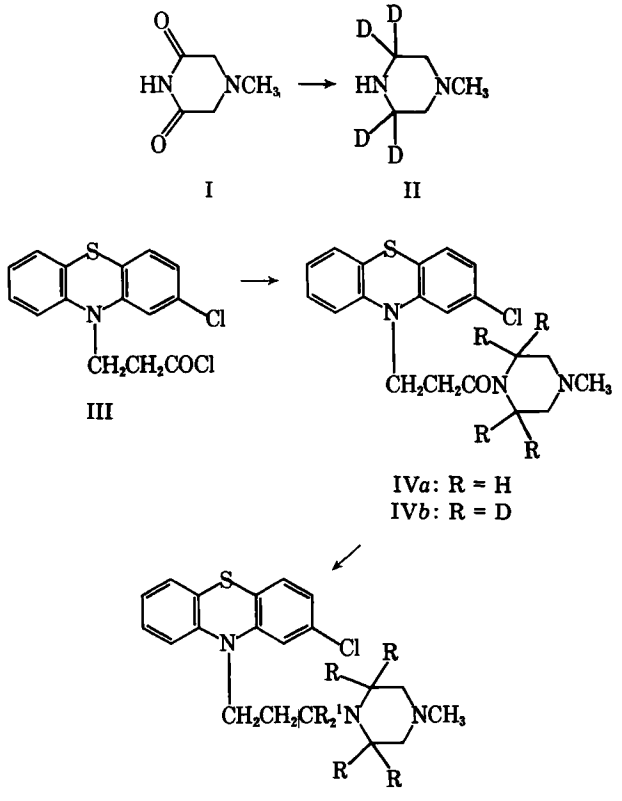
Keyphrases □ Prochlorperazine—deuterium-labeled synthesis □ Deuterium label—prochlorperazine synthesis

Prochlorperazine (V*a*), a piperazine-type phenothiazine, is primarily used as an antiemetic or antipsychotic. There are no literature reports that describe the usual plasma levels of this drug in patients under treatment, and, in fact, no suitable analytical methods have been described. The development of suitable analytical methods for the determination of the plasma concentrations of all piperazine-type phenothiazines has been slow, due to their instability in all stages of sample handling, as well as the extremely low plasma levels observed in the few studies involving humans.

BACKGROUND

The analytical procedures which have met the stringent sensitivity requirements of subnanogram determinations of these piperazine-type phenothiazines are either radioimmunoassay (RIA) or GLC–MS procedures (1, 2). In the case of prochlorperazine, an RIA method, which is capable of quantitating 0.125 ng/ml using 200-μl plasma aliquots, has been developed recently[1]. Following single 5-mg oral doses of prochlorperazine mesylate in healthy volunteers, the peak plasma concentrations were determined by RIA to be between 1–2 ng/ml. To verify the specificity of this sensitive biological procedure, a specific and sensitive chemical method such as GLC–MS is required. A stable isotope analogue of prochlorperazine was needed as a true internal standard for obtaining the required sensitivity by the chemical procedure. In addition, the availability of two other deuterium-labeled prochlorperazine standards will allow reliable pharmacokinetic studies to be carried out with fewer volunteers and animals, by administering these analogues by one or two routes and analyzing the plasma concentrations by GLC–MS using selected ion monitoring. Such studies will allow definitive pharmacokinetics of prochlorperazine to be obtained with far fewer administrations in volunteers.

The propylpiperazine side chain was chosen as the most suitable labeling site, since normally only the *N*-methyl group is lost during metabolism. It also offers adequate variation in the number of labeled atoms. Recently, the synthesis of labeled trifluoperazine, the 2-trifluoromethyl analogue of prochlorperazine, with two, four, or six deuterium atoms in the propylpiperazine side chain was successfully achieved (3). Similarly, this paper describes the synthesis of prochlorperazine with two, four, or six deuterium atoms.



Scheme I

RESULTS AND DISCUSSION

The synthesis (Scheme I) of the key tetradeuterated intermediate, 1-methyl(3,3,5,5-$^2H_4$)piperazine (II), from the lithium aluminum deuteride reduction of 1-methyl-3,5-piperazinedione (I) was previously described (3). Subsequent treatment of the unlabeled or labeled *N*-methylpiperazine in dry benzene with 3-[10-(2-chlorophenothiazinyl)]-

propionyl chloride (III) gave the desired amides (IVa and b). In the case of the labeled *N*-methylpiperazine, the free base could not be obtained in a dry condition, necessitating the use of the hydrochloride in this reaction accompanied by the addition of sodium carbonate. This choice of route, involving an amide intermediate, allowed for the possibility of introducing two additional deuterium atoms. Reduction of the amides with lithium aluminum hydride or deuteride gave the desired prochlorperazine (V) with two, four, or six deuterium atoms in ~55% yield. The isotopic purity of the labeled, purified products was determined by MS spectrometry using a single-ion monitoring technique. The ratio for the molecular ions (^{35}Cl) $^2H_0/^2H_n$ was determined to be 0.43, 0.78, and 0.30% for the di-(n = 2), tetra-(n = 4), and hexa-(n = 6)deuterated prochlorperazine, respectively. The isotopic purities (after correcting for chlorine isotopes) for $^2H_2$, $^2H_4$, and $^2H_6$ were 98.11, 95.77, and 96.16%, respectively. The $^2H_1$ contaminant in the $^2H_2$ isomer was 1.89%, $^2H_2$ and $^2H_3$ contaminants collectively represented 4.23% in $^2H_4$, and $^2H_5$ contaminant in the $^2H_6$ isomer was 3.84%. It is evident that this purity is sufficient for use in GLC–MS and pharmacokinetic studies. These results will be reported elsewhere.

EXPERIMENTAL[2]

2-Chloro-10*H*-phenothiazine-10-propionyl Chloride (III)—A solution of phosphorus pentachloride (1.66 g, 8 mmoles) in 10 ml of dry benzene was added with stirring over 1.5 hr to a stirred suspension of 2-chloro-10-(2-carboxyethyl)-10*H*-phenothiazine (2.14 g, 7 mmoles) (4) in 25 ml of dry benzene at 5°. The reaction was allowed to proceed for 1 hr at room temperature during which time the pink mixture became colorless. Removal of the solvent *in vacuo* at 30° gave an oily residue which, on treatment with petroleum ether (40–60°), gave the acid chloride (III) in a 90% yield, mp 115–116° [lit. (4) mp 114–116°]. The product was unstable at room temperature and was immediately used in the next stage of the synthesis.

2 - Chloro - 10 - [[3-[4-methyl-1-(2,2,6,6-$^2H_4$)piperazinyl]-3-oxopropyl]]-10*H*-phenothiazine (IV*b*)—A mixture of 1-methyl(3,3,5,5-$^2H_4$)piperazine dihydrochloride (II) (3) (0.78 g, 4.4 mmoles) sodium carbonate (1.0 g), and dry benzene (20 ml) was refluxed until the evolution of carbon dioxide ceased. The mixture was then cooled to 0° and a solution of the acid chloride (III) (1.3 g, 4 mmoles) in 10 ml of dry benzene was added with stirring. When the addition was complete, the cooling bath was removed, and the mixture was allowed to warm to room temperature with continued stirring. After 3 hr, water (10 ml) was added, and vigorous stirring continued for 15 min. The organic layer was separated and washed successively with 10% aqueous sodium hydroxide (3 × 5 ml) and water (10 ml). The benzene layer was dried ($MgSO_4$) and evaporated to leave a yellow oil, which was purified by elution from a neutral alumina oxide column using benzene to give IV*b* as a colorless viscous oil in an 80% yield. TLC: R_f 0.44 (benzene–methanol, 95:5); IR (film) 1640 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 2.34 (m, 7H, piperazine-3,5-methylene and NCH_3), 2.85 (t, 2H, CH_2CO, J = 7 Hz), 4.23 (t, 2H, phenothiazine-CH_2, J = 7 Hz), and 6.8–7.4 (m, 7H, aromatic); MS: m/z 391(M^+, 100%), 248(31), 246(83), 234(33), 232(78), 214(27), and 159(77).

[2] *Melting points* were determined with a Gallenkamp melting point apparatus and are uncorrected. All TLCs were performed using Eastman Chromatogram sheets, type 13254 (silica gel with fluorescent indicator); spots were observed under shortwave UV light. IR spectra were taken on a Perkin-Elmer 297 spectrophotometer. NMR spectra were determined on a Varian T-60 instrument with tetramethylsilane as internal reference. Low resolution electron impact mass spectra were recorded on a VG Micromass MM16F instrument at 70 eV. Lithium aluminum deuteride (>99% deuterium) was obtained from Merck Sharp and Dohme, Dorval, Quebec and all other chemicals from Aldrich Chemical Co., Montreal, Quebec.

2-Chloro-10-[3-(4-methyl-1-piperazinyl)(3,3-$^2H_2$)propyl]-10*H*-phenothiazine Dihydrochloride (V*b*)—A solution of 2-chloro-10-[3-(4-methyl-1-piperazinyl)-3-oxopropyl]-10*H*-phenothiazine (IV*a*) (0.39 g, 1 mmole), a previously reported (5) compound prepared in a manner similar to IV*b*, in 5 ml of dry ether was added dropwise over 1 hr to a stirred suspension of lithium aluminum deuteride (0.042 g, 1 mmole) in 5 ml of dry ether at 0°. The mixture was stirred for an additional 15 min, and after treatment with water (0.5 ml) and 20% aqueous sodium hydroxide (1 ml) the ether layer was decanted off. The inorganic material was mixed with sodium chloride (0.25 g), placed in the thimble of a Soxhlet apparatus, and extracted for 3 hr with ether. The combined ether fractions were extracted with 10% HCl (4 × 5 ml). The combined aqueous extracts were then washed with ether (3 × 5 ml) and the pH adjusted to 8.0 with saturated sodium carbonate solution. The product was then extracted with ether (4 × 10 ml), and the combined ether extracts dried ($MgSO_4$) and filtered. Dry hydrogen chloride in ether was added to the filtrate and the separated solid crystallized from ethanol to afford ($^2H_2$)-prochlorperazine (V*b*) as the dihydrochloride salt (0.25 g, 55%), mp 242–243°. Mixed melting points with the authentic nondeuterated samples (V*a*), prepared by the same route with lithium aluminum hydride or prepared from a commercial sample of prochlorperazine free base, were not depressed. TLC: R_f 0.55 (methanol–water–ammonium acetate, 100:20:3); NMR (free base, $CDCl_3$): δ 1.85 (t, 2H, CH_2CD_2, J = 6.5 Hz), 2.24 (s, 3H, NCH_3), 2.40 (s, 8H, piperazine methylene), 3.84 (t, 2H, phenothiazine-CH_2, J = 6.5 Hz), and 6.72–7.20 (m, 7H, aromatic); MS: m/z 375(M^+, 47%), 274(7), 246(8), 232(16), 143(33), and 115(100).

2-Chloro-10-[[3-[4-methyl-1-(2,2,6,6-$^2H_4$)piperazinyl]-propyl]]-10*H*-phenothiazine Dihydrochloride (V*c*)—($^2H_4$)-Prochlorperazine (V*c*) was prepared (55%) from IV*b* and lithium aluminum hydride using the method described above for V*b*: mp and TLC as for V*b*. NMR (free base, $CDCl_3$): δ 1.94 (m, 2H, propyl central CH_2), 2.30–2.66 (m, 9H, CH_2-piperazine, piperazine-3,5-methylene, and NCH_3), 3.88 (t, 2H, phenothiazine-CH_2, J = 6.5 Hz), and 6.60–7.18 (m, 7H, aromatic); MS: m/z 377(M^+, 69%), 273(14), 246(11), 232(13), 145(40), and 117(100).

2-Chloro-10-[[3-[4-methyl-1-(2,2,6,6-$^2H_4$)piperazinyl](3,3-$^2H_2$)propyl]]-10*H*-phenothiazine Dihydrochloride (V*d*)—($^2H_6$)-Prochlorperazine (V*d*) was prepared (55% yield) from IV*b* and lithium aluminum deuteride using the method described above for V*b*: mp and TLC as for V*b*. NMR (free base, $CDCl_3$): δ 1.85 (t, 2H, CH_2CD_2, J = 6.5 Hz), 2.20 (s, 3H, NCH_3), 2.37 (s, 4H, piperazine-3,5-methylene), 3.85 (t, 2H, phenothiazine-CH_2, J = 6.5 Hz), and 6.62–7.15 (m, 7H, aromatic); MS: m/z 379(M^+, 49%), 276(10), 274(10), 246(8), 232(14), 214(8), 147(48), and 119(100).

Spectrophotometric Promethazine Hydrochloride Determination Using Bromcresol Green

ABDOL-ALI M. EMAMI KHOI

Received May 17, 1978, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmacy, Tehran University, Tehran, Iran.* Accepted for publication October 30, 1978.

Abstract □ A spectrophotometric method was developed for determining promethazine hydrochloride (I) complexed with bromcresol green and then extracted with chloroform. The complex in chloroform showed maximum absorption at 415 nm and obeyed Beer's law over 1.2–8.5 μg/ml. The complex molar absorptivity was 1.93×10^4 *M*. Complex formation and extraction were complete and quantitative over pH 2.7–2.8. The promethazine hydrochloride–bromcresol green molar ratio was 1:1. Excipients, coloring matter, flavoring agents, and other substances likely to be present in promethazine preparations did not interfere in the determination. Direct determination in tablet, syrup, and injection preparations were carried out satisfactorily.

Keyphrases □ Promethazine hydrochloride—spectrophotometric analysis, color complex with bromcresol green, various pharmaceutical formulations □ Bromcresol green—promethazine hydrochloride spectrophotometric analysis, various pharmaceutical formations □ Spectrophotometry—analysis, promethazine hydrochloride, various pharmaceutical formulations □ Antihistaminic agents—promethazine hydrochloride, spectrophotometric analysis, various pharmaceutical formulations

Various methods have been described for promethazine hydrochloride (I) determination. The official nonaqueous USP titration method (1) is not applicable to microgram I determinations. Volumetric (2), ion-exchange (3), chromatographic (4), polarographic (5), gravimetric (6), complexometric (7), and luminescence (8) methods all lack simplicity and sensitivity.

Spectrophotometric methods also have been used for the analysis of the base. Eriochrome black T (9), perchloric acid–nitromethane (10), sodium 1,2-naphthoquinone-4-sulfonate in 50% H_2SO_4 (11), and ferric chloride (12) were employed to create a colored product that could be determined spectrophotometrically. Some of these methods are not simple; others are not sensitive.

This report describes a direct, simple, and sensitive spectrophotometric determination for I. This method is applicable to powder, syrup, injection, and tablet forms. The procedure depends on complex formation between I and bromcresol green (II) which is extractable by chloroform at pH 2.7–2.8. This method can be carried out successfully in the presence of caffeine and many other substances.

Bromcresol green has been used for determining small amounts of long-chain tertiary alkylamines and quaternary ammonium salts (13). It was recently used for the direct determination of thebaine in *Papaver bracteatum* Lindl Arya II papulation capsules (14) and to determine diphenhydramine hydrochloride (15).

Table I—Effect of Other Compounds on the Determination of Promethazine Hydrochloride

Substance	Amount Ratio[a]	Recovery %[b]
Ascorbic acid	50	100.0
Sodium saccharin	250	100.9
Cinnamon oil	10	100.0
Orange oil	60	100.5
Clove oil	70	100.0
Amaranth	120	100.2

[a] The ratio of the amount of substances to promethazine hydrochloride in the determination. [b] Promethazine hydrochloride concentration = 3.2×10^{-4} *M*.

EXPERIMENTAL[1]

Apparatus and Reagents.—All glassware was washed with 0.1 *N* HCl followed by distilled water. All reagents were analytical grade.

Bromcresol Green (10^{-4} M)—Accurately weighed bromcresol green powder was dissolved in 2 ml of 0.1 *N* NaOH, and the volume was brought to 1 liter with citric acid-sodium hydrogen phosphate buffer, pH 2.7–2.8. The resulting solution was adjusted to pH 2.7–2.8.

Promethazine Hydrochloride (10^{-4} M) *Standard*—Accurately weighed, dry, pure promethazine hydrochloride powder USP (32.09 mg) was dissolved in water and diluted to 1 liter.

Buffer Solution—A citric acid–sodium hydrogen phosphate buffer (pH 2.2–2.8) was used (16).

Determination—A solution containing 12–80 μg of I was pipetted into a 100-ml separatory funnel followed by 20 ml of 10^{-4} *M* II, and the two solutions were mixed. The yellow complex that formed was extracted with 5-, 3-, and 2-ml portions of chloroform by vigorous shaking. The extracts were collected in a 10-ml volumetric flask. The volume was adjusted with chloroform, and the absorbance was measured within 0.5 hr against chloroform at 415 nm. The amount of I was calculated by comparison with a standard curve.

RESULTS AND DISCUSSION

The yellow I–II complex in chloroform showed maximum absorption at 415 nm. Complex formation and extraction were complete and quantitative over the pH 2.7–2.8 range citric acid-sodium hydrogen phosphate buffer solution. The complex composition was studied by the molar ratio method (17). The ratio of I to II was 1:1, but the required ratio for complete complexation and quantitative extraction was 1:3.

Eight standard series of six samples, 1.0–9.0 μg I/ml, were analyzed. The optimum concentration range for the measurements at 415 nm and 1.00-cm optical path length was 1.2–8.5 μg of promethazine hydrochloride/ml. The complex solution molar absorptivity in chloroform at 415 nm was 1.93×10^4. The relative standard deviation of the calculated absorptivities in the optimum concentration range was ±1%.

To determine the effect of compounds commonly present with I in pharmaceutical preparations, known volumes of standard solutions containing caffeine (23 mg), sodium gentisate (20 mg), ammonium chloride (20 mg), menthol (90 mg), sodium citrate (20 mg), acetaminophen (200 mg), and alcohol (1 ml) were studied at different concentrations. There was no interference in the determinations. Ascorbic acid, sodium saccharin, cinnamon oil, orange oil, clove oil, and amaranth (Table I) also did not interfere and produced slight deviation in the determination only at high concentrations.

Under acid conditions, most substances with a tertiary amine group or quaternary ammonium salts form yellow complexes with II that are extractable with chloroform. Pharmaceutical I preparation from different manufacturers were free of such substances, so a confirmatory test was not needed.

To test the method validity, I was added to pharmaceutical preparations[2] and determined by the proposed procedure. The recovery (99–100.25%) (Table II) proved the selectivity and specificity of the method for direct I determination in pharmaceutical preparations.

[1] A Beckman DB-GT spectrophotometer with 1.00-cm glass cells, a Bausch & Lomb Spectronic 21, and a Beckman H_3 pH meter were used.

NMR Studies and GC Analysis of the Antibacterial Agent Taurolidine

B. I. KNIGHT *, G. G. SKELLERN *, G. A. SMAIL *, M. K. BROWNE ‡, and R. W. PFIRRMANN§ ˣ

Received December 9, 1981, from the **Department of Pharmacy, University of Strathclyde, Glasgow G1 1XW, U.K.*; ‡*Monklands District General Hospital, Airdrie ML6 0JS, U.K.*; and §*Geistlich-Pharma, 6110 Wolhusen, Switzerland.* Accepted for publication June 10, 1982.

Abstract □ The NMR spectrum of taurolidine in deuterium oxide was compared with spectra obtained from model experiments with amines and formaldehyde. Head-space analysis combined with capillary GC showed that there was <0.004% free formaldehyde present in 2% solutions of taurolidine. This value is comparable to the concentration of formaldehyde found when the taurolidine solutions were injected directly onto GC columns.

Keyphrases □ Taurolidine—NMR spectral analysis, head-space analysis–GC methods for the determination of formaldehyde □ NMR spectroscopy—analysis of taurolidine □ GC analysis—direct or combined with head-space analysis, quantitation of formaldehyde concentration in taurolidine □ Head-space analysis—with capillary GC, quantitation of formaldehyde concentration in taurolidine

Taurolidine [4,4′-methylenebis(tetrahydro-1,2,4-thiadiazine 1,1-dioxide), I] is a broad spectrum bactericide and antiendotoxin (1–3) which is being used widely in clinical trials to counteract bacterial infections following GI surgery and to treat peritonitis (4–6). It is administered intraperitoneally *via* a catheter inserted when the abdomen is closed, as a 2% aqueous solution[1] containing 5% povidone[2] (added to increase the solubility of taurolidine).

As a result of NMR studies (7) of aqueous solutions of taurolidine, equilibria are considered to exist between taurolidine, 4-hydroxymethyltetrahydro-2*H*-1,2,4-thiadiazine 1,1-dioxide (II), tetrahydro-2*H*-1,2,4-thiadiazine 1,1-dioxide (III)[3], and formaldehyde.

The existence of such equilibria was studied with the aid of solutions of morpholine–formaldehyde and III–formaldehyde as models. Also, because of the concern regarding toxicity, the determination of the formaldehyde concentration in solutions of taurolidine (which have been used in large volumes for the treatment of septicemia) is of considerable interest. Thus, this paper also describes the quantitative determination of formaldehyde using combined head-space analysis–capillary GC and direct GC.

EXPERIMENTAL

NMR—The NMR spectra of taurolidine were determined in deuterium oxide and deuterodimethylsulfoxide. Taurolidine (20 mg/ml) together with 1-vinyl-2-pyrrolidinone polymer (50 mg/ml) in deuterium oxide, and morpholine and III in deuterium oxide (before and after gaseous formaldehyde had been passed through the solution), were also determined[4]. The reference standard was sodium 3-trimethylsilylpropionate-2,2,3,3-$^2H_4$.

GC Analysis of Formaldehyde—*Head-Space Analysis*—Aqueous solutions (10 ml) of formaldehyde (0.005–0.01%) containing sodium chloride (5 g) were added to 100-ml injection vials which were tightly stoppered. The vials were incubated at 20, 40, or 60° for 1 hr to allow the

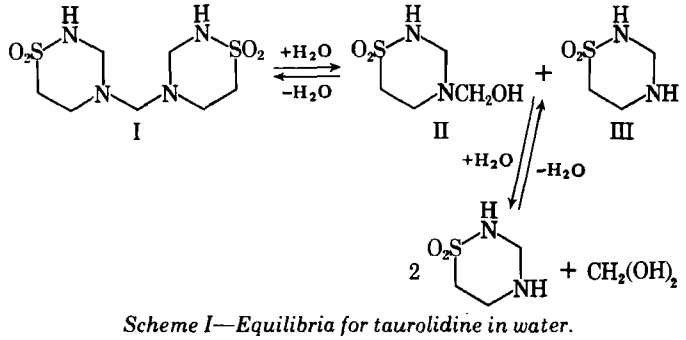
system to equilibrate. A 200-μl sample of the gaseous phase was removed from the vial with a microliter syringe and injected into a gas chromatograph[5] fitted with a 15 m × 0.47-mm capillary column[6] (column A). The temperatures of the injection port, column, and detector were 175, 65, and 150°, respectively. The carrier gas was helium at a pressure of 0.2 bar. Aqueous solutions of taurolidine and taurolidine with 5% 1-vinyl-2-pyrrolidinone polymer were analyzed in a similar manner.

Direct Analysis—Formaldehyde concentrations were also determined by injecting aliquots (1 μl) of taurolidine solution into the gas chromatograph fitted with a glass column (2.1 m × 4 mm) packed with 5% polyoxyethylene glycol stearate[7] on 80–100 mesh chromosorb W-AW (column B). The temperatures of the injection port, column, and detector were 125, 95, and 200°, respectively. The carrier gas was helium at a flow rate of 40 ml/min.

Aqueous solutions of formaldehyde (0.0025–0.01%) were prepared as calibration standards. Formaldehyde (0.0025–0.01%) was added to the taurolidine and taurolidine plus 1-vinyl-2-pyrrolidinone polymer solutions. Formaldehyde concentrations were also determined by injecting aliquots (0.5 μl) of taurolidine solution onto the capillary column (column A) used for head-space analysis.

RESULTS AND DISCUSSION

The singlet at δ3.59 in the NMR spectrum of taurolidine in deuterodimethylsulfoxide (Table I) was assigned to the protons of the methylene group joining the two molecules of II (Scheme I). However in deuterium oxide the signal (δ3.65) due to these protons is reduced to <10% of the intensity observed in deuterodimethylsulfoxide. In deuterium oxide the signals at δ4.47 and δ4.82 have been assigned to the hydroxymethyl group of II and formaldehyde, respectively. That the signal at δ4.47 arises from the hydroxymethyl group has been shown in model experiments with morpholine and formaldehyde, which behave in a manner analogous to solutions of III and formaldehyde (Table II). Thus, the NMR spectrum of a solution of morpholine in deuterium oxide is modified by treatment with formaldehyde gas, the additional peaks observed at δ4.44, δ3.25, and δ4.88 being ascribed to a hydroxymethyl group on the morpholine nitrogen, the methylene bridge of the *N,N'*-methylenediamine, and formaldehyde, respectively. The addition of sodium carbonate eliminated the signal ascribed to the hydroxymethyl group (δ4.44); these derivatives are known to undergo hydrolysis at alkaline pH (8). Solutions of III and



Scheme I—Equilibria for taurolidine in water.

formaldehyde, in turn, mimic the behavior of taurolidine in deuterium oxide: III plus formaldehyde gives an NMR spectrum identical to that of taurolidine in deuterium oxide (Table II).

The equilibria existing between amines and aldehydes in aqueous solutions are not simple (8, 9). There is also evidence[8] to suggest that the equilibria shown in Scheme I only partially represent those that exist in solutions of taurolidine. With saturated solutions of taurolidine in deuterium oxide, the intensity of the signal due to the bridging methylene group (δ3.65) increased and the peak height ratio of the signals ascribed to formaldehyde and the hydroxymethyl group of II decreased in comparison with the ratio of these peaks in the spectrum of the 1% taurolidine solution. Moreover the NMR spectrum of taurolidine (2%) in deuterium oxide containing 5% 1-vinyl-2-pyrrolidinone polymer was comparable to the spectrum of a saturated solution of taurolidine, with respect to the signal intensities due to the bridging methylene protons and formaldehyde, suggesting this substance may influence the equilibria.

Semiquantification of the amount of free formaldehyde present in aqueous solutions of taurolidine has been attempted using NMR spectroscopy (7). Measurement of the area of the signal due to the bridging methylene protons presents problems, since there is not a complete conversion of taurolidine to its hydrolysis products. Theoretically, this means comparing the taurolidine spectrum in deuterodimethylsulfoxide (where no such equilibria exist) with that in deuterium oxide with the assumption that the methylene bridge proton signals are comparable in both solvents. Although NMR spectroscopy would be the method of choice since it is a noninvasive technique and does not disturb the proposed equilibria, integration of this minor peak is unsatisfactory, espe-

Table III—Percentage of Free Formaldehyde Present in Aqueous Solutions of Taurolidine and Taurolidine Plus 1-Vinyl-2-pyrrolidinone Polymer [a]

Method	Taurolidine 1%	Taurolidine 2%	Taurolidine (2%) plus 1-vinyl-2-pyrrolidinone polymer (5%)
Head-space with capillary column A	0.0036 ± 0.0004	0.0037 ± 0.0004	Not measurable due to the presence of isopropyl alcohol
Direct analysis			
Column A	0.0022 ± 0.0006	0.0038 ± 0.0003	Not measurable due to the presence of isopropyl alcohol
Column B	0.0013 ± 0.0001	0.0027 ± 0.0001	0.0032 ± 0.0006

[a] Mean ± *SD*.

cially in the presence of 1-vinyl-2-pyrrolidinone polymer, where signals in this molecule interfere with the signal assigned to the bridging methylene protons.

GC combined with head-space analysis can also be regarded as a noninvasive technique, the amount of gaseous formaldehyde in the head-space being proportional to the concentration of formaldehyde present in the aqueous phase. The assay was carried out at different temperatures to determine whether the equilibria changed. At all temperatures the formaldehyde calibration curves were linear. The equations for the plots at 20, 40, and 60° were $y = 0.032 + 40.93x$, $y = 120x$, and $y = 0.036 + 266.2x$, respectively. The correlation coefficients (r) were 0.99, 1, and 0.99 respectively. The precision of the method was ±3% for a 0.01% formaldehyde solution at 40°. At the three assay temperatures, there was <0.004% free formaldehyde present in the taurolidine solutions (Table III).

Rectilinear relationships between detector response and formaldehyde concentrations for the direct GC method were also observed when known amounts of formaldehyde were added to water or taurolidine solutions, or taurolidine solutions containing 1-vinyl-2-pyrrolidinone polymer ($y = 0.165 + 1407x$, $r = 0.99$). That the slope and intercept were the same in all cases, would indicate that the equilibria did not change, especially in the presence of the polymer. Unfortunately, 1-vinyl-2-pyrrolidinone polymer contains a small amount (60–100 ppm) of isopropyl alcohol (1-vinyl-2-pyrrolidinone is polymerized in this solvent). Since isopropyl alcohol has the same retention time as formaldehyde (1.25 min) on column B, it was necessary to subtract the height of the peak observed when an aliquot of a 5% 1-vinyl-2-pyrrolidinone polymer solution was injected on this column from the height of the peak from the formaldehyde–isopropyl alcohol in the taurolidine–1-vinyl-2-pyrrolidinone polymer solution. Comparable amounts of free formaldehyde were found when solutions of taurolidine were injected directly onto either column A or B, indicating that the direct method could be regarded as a noninvasive technique and was suitable for the determination of formaldehyde.

That the equilibria may be sensitive to the concentrations of the molecular species present but not to the presence of 1-vinyl-2-pyrrolidinone polymer is shown by direct GC analysis (Table III) but head-space analysis GC does not support this contention. The concentration of free formaldehyde is not clinically important since no formaldehyde toxicity has been observed with solutions of taurolidine containing 1-vinyl-2-pyrrolidinone polymer either in humans or experimental animals. Moreover, the formaldehyde concentration is considerably lower than the amount of formaldehyde produced in the body after administration of certain antibiotic prodrugs (10).

Compound III has also been shown to possess antibacterial and antiendotoxin activity similar to taurolidine, although higher concentrations are required[8]. This activity also is not related to the presence of free formaldehyde, since solutions of III have been shown to be stable by NMR and GC, liberating no measurable amounts of formaldehyde.

Solid Dispersions of Testosterone with Reduced Presystemic Inactivation

ALMAS BABAR and C. I. JAROWSKI ×

Received April 1, 1982, from *St. John's University, College of Pharmacy & Allied Professions, Jamaica, NY, 11439.* Accepted for publication June 10, 1982.

Abstract □ Dissolution rates of solid dispersions of testosterone in various lipids or polyethylene glycol 6000 with and without surfactants were determined. In a limited study, selected dispersions were evaluated for oral absorption efficiency in a 32-year-old male. Significant reductions in urinary testosterone metabolites to testosterone ratios were observed with a 1:4 weight ratio of testosterone–polyethylene glycol 6000 and a 1:4:0.25 weight ratio of testosterone–cholesteryl stearate–sorbitan monolaurate.

Keyphrases □ Testosterone—solid dispersions with reduced presystemic inactivation, dissolution, absorption efficiency □ Dissolution—solid dispersions of testosterone with reduced presystemic inactivation, absorption efficiency □ Presystemic inactivation—reduced, solid dispersions of testosterone, absorption efficiency □ Absorption—efficiency, solid dispersions of testosterone with reduced presystemic inactivation

Solid dispersions and eutectic mixtures of drugs with inert carriers such as urea and succinic acid have been used to enhance the rate of dissolution and oral absorption of therapeutic agents poorly soluble in water (1). Previous work (2, 3) has dealt with the *in vitro* dissolution characteristics of such systems. In *in vivo* studies griseofulvin dispersions in polyethylene glycol 6000 were found (4) to be completely and rapidly absorbed after oral administration to humans, and a morphine–tristearin dispersion in a weight ratio of 1:1 exhibited reduced presystemic inactivation in rats (5).

When testosterone therapy is indicated, parenteral administration is preferred, since oral administration is inefficient due to presystemic inactivation (6). Hepatic enzymes were predominantly responsible for the chemical modification of testosterone. It has been reported that twice as much testosterone (I) was required to match the androgenic effect of methyl testosterone when administered sublingually (7). It was recently demonstrated (8) that clinical efficacy upon oral administration required 400-mg doses of I.

The purpose of this investigation was to study the oral absorption efficiency of I from various solid dispersions. The dissolution rates of the dispersions were evaluated *in vitro*, and selected dispersions were chosen for evaluation *in vivo*. The urinary recovery of I and its principal metabolites was used as a measure of oral absorption efficiency in a 32-year-old male.

EXPERIMENTAL

Materials—The following were obtained from commercial sources: I (NF grade)[1], polyoxyethylene (20) sorbitan monooleate (II)[2], sorbitan monolaurate (III)[2], sodium cholate (IV)[3], sodium deoxycholate (V)[3], β-sitosterol (VI)[3], cholesteryl stearate (VII)[3], lactose (VIII)[3], cholesterol (IX)[4], polyethylene glycol 6000 (X)[5], chloroform[6], hydrochloric acid[6], β-glucuronidase (beef liver)[7], androsterone (XI)[8], etiocholanolone (XII)[8], and tripalmitin (XIII)[8].

Equipment—The following equipment was used: spectrophotometer[9], thermal analyzer with differential scanning colorimeter[10], USP dissolution apparatus with basket assembly[11], and a GC equipped with an electronic integrator[12].

Preparation of Solid Dispersions—Micronized I and various surfactants were weighed in ratios of 1:0.05. The mixtures were dissolved in 50 ml of chloroform. The solvent was evaporated in a stream of air while the solution was stirred with a magnetic stirrer. The residue was dried in a vacuum oven at 40°, ground in a mortar, and then passed through an 80-mesh screen. After blending to ensure homogeneity, aliquots were assayed. Only samples assaying 100 ± 5% of I were used in the dissolution and absorption studies. Dispersions containing I–lipid in weight ratios of 1:4, 1:6, and 1:8 as well as I–lipid–surfactants in weight ratios of 1:4:0.05 were prepared in a similar fashion. Polyethylene glycol 6000 dispersions also used chloroform. The I–lipid–lactose dispersions in weight ratios of 1:4:4 were prepared by evaporating the chloroform in the presence of lactose.

Dissolution Studies—The dissolution rates of I and its dispersions were conducted in simulated gastric fluid, without pepsin, by the procedure described in the USP (9). Simulated gastric fluid (900 ml) was placed in a 1-liter beaker and maintained at 37 ±0.5° in a constant-temperature bath. A sintered-glass immersion filter (medium porosity) was placed in a medium for aliquot withdrawals. The basket was lowered to 1 cm above the bottom of the beaker and rotated at 300 rpm. Accurately weighed samples equivalent to 20 mg of I were spread over the surface of the medium. Any aggregates that formed at this stage were submerged by a microspatula within 10 sec after sample addition. Five-milliliter aliquots were removed at intervals of 15, 30, 45, 60, 90, and 120 min using a 5-ml pipet. A constant volume of dissolution medium was maintained by additions of preheated medium. The filtered aliquots were passed through a micropore filter (0.45-μm) and read directly for their absorbance at 248 nm. A cumulative correction was made for the previously removed samples to determine the total quantity of I that had dissolved (10). Sink conditions were maintained, since the solubility of I was determined to be 44 mg/900 ml.

Assay Procedure for Testosterone—Plots of absorbance *versus* wavelength for solutions of I in water, simulated gastric fluid, and methanol were developed. The maximum absorbance values observed were 248 nm for water and simulated gastric fluid and 244 for methanolic solutions of I. Beer's law was followed for 1–20-μg/ml concentrations. The stability of I in simulated gastric fluid was determined. After 24 hr at 37° no potency change was noted.

Assay of Urinary Testosterone and its Metabolites—Selected test samples were evaluated in a healthy, adult male, 32 years of age. Each sample was tested on at least three occasions. The subject was administered an equivalent of 50 mg of I in a hard gelatin capsule after an overnight fast, with 240 ml of water. Food was avoided for at least 2 hr. Urine samples were collected for 24 hr, pooled, and frozen until assayed. One week or more was allowed to elapse between oral dosings. Free I and XI and XII were determined by a modification of published procedures (11, 12). Essentially, the derivatization step was eliminated since adequate quantities of I, XI, and XII were present. In addition, the GC procedure was altered to afford more efficient separation of the components. Details of the assay procedure will be presented in a separate publication.

RESULTS AND DISCUSSION

Dissolution Rate Studies—Only 54.6% of I had dissolved after 2 hr

	4	46.4	10.6	4.4:1
	Average	38.9	7.1	7:1

[a] Weight ratio 1:4.

(Table I). A slight increase was observed when synthetic surfactants were added(I-II, I-III); however, the two bile salts were ineffective (I-IV, I-V). The lipid dispersions of I with 1:4–1:8 weight ratios released the hormone more slowly (I-IX, I-VI, I-VII, and I-XIII). The addition of the various surfactants increased the release rate. The most rapid dissolution rate for the lipid–surfactant dispersions was exhibited by I-VII-III (79.3%). Solvent dispersion of I on lactose with the various lipids resulted in an improvement in the dissolution rates: whereas I-IX released 30.6% of I after 2hr, I-IX-VIII released 49%. The sample exhibiting the fastest rate of dissolution was I-X (99.3%).

The rapid dissolution of I-X is likely due to the release of microcrystalline I as the water-soluble X dissolves. The lipid dispersions without surfactants were dissolution-rate retarding. However, inclusion of surfactants would again ensure the release of microcrystalline particles. The lipids in such preparations would be readily dispersed because of the presence of the surfactants. The beneficial effect of lactose with the solvent-deposited lipid dispersions is most likely the result of greater surface exposure to the aqueous dissolution medium.

Oral Absorption Studies—On the basis of the dissolution data in Table I three dispersions were selected for the oral absorption studies. The urinary excretion data are presented in Table II. The recovery of I ranged from 0.7 to 1.6% following a 50-mg dose of micronized particles. The lipid dispersion plus surfactant produced levels of I ranging from 1.6 to 4.7%. The best recovery of I, as anticipated from the *in vitro* data, was shown by I-X (range: 2.2–10.6%). Metabolite recovery followed a similar progressive increase. The ratios of metabolites-I showed significant decreases with the more efficiently absorbed samples. Thus, the ratio was 21:1 for I alone, whereas for I-X the ratio was reduced to 7:1.

The results of the very limited oral absorption studies correlate very well with the dissolution data. The data suggest that rapid oral absorption of I is a desirable goal, since metabolite formation was reduced. Although a clear advantage was shown by using X as the excipient, a combination of VII and III may be indicated when acid-labile drugs are used. The latter would be expected to release the drugs more slowly in acidic media as compared with the former.

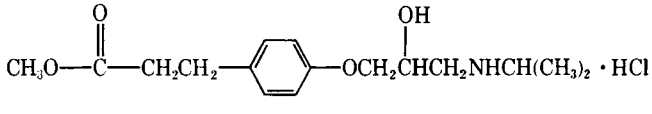
Esmolol: A Pharmacokinetic Profile of a New Cardioselective β-Blocking Agent

Keyphrases □ β-Adrenergic blocking agents—esmolol hydrochloride, pharmacokinetic profile, metabolism □ Pharmacokinetic profile—cardioselective β-adrenergic blocking agent, methyl 3-[4-(2-hydroxy-3-(isopropylamino)propoxy]phenylpropionate hydrochloride □ Esmolol—cardioselective β-adrenergic blocking agent, pharmacokinetic profile

To the Editor:

β-Adrenergic receptor blocking drugs exert their effects by competitively inhibiting the binding of catecholamines to β-adrenergic receptors. To attain therapeutic levels rapidly, intravenous bolus or infusions of β-blockers are usually instituted. However, since these agents have cardiac depressant properties, they are initially used at low doses, and slowly increased until the desired effects are obtained. Because currently available β-adrenergic blocking agents are long acting, the emergence of side effects, especially acute cardiac failure, poses a significant problem in their use because their action cannot be readily terminated. Therefore, there is a need for a β-adrenergic blocking drug with a short onset of action which can be rapidly terminated if side effects develop.

Esmolol (ASL-8052, Scheme I) is a new cardioselective intravenous β-receptor blocking agent with a very short duration of action in humans (unpublished data) and dogs (1). It is extensively metabolized in blood and liver by hydrolysis of the methyl ester functionality to form its major metabolites, ASL-8123 and methanol.



Esmolol (ASL-8052)

Methyl 3-[4-(2-Hydroxy-3-(isopropylamino)propoxy]phenylpropionate hydrochloride

Scheme I

To study the pharmacokinetics of esmolol, eight healthy male subjects (21–27 years old) weighing 62.4–76.2 kg received constant intravenous infusions of 50, 150, and 400 μg/kg/min for 2 hr on three different days. Each subject received an intravenous dose of isoproterenol, which had previously been determined to produce a 50% increase in heart rate. The suppression of the isoproterenol-induced increase in heart rate and blood pressure was determined on several occasions during and up to 60 min after the cessation of the esmolol infusion. At each dose level, blood samples were collected for determinations of esmolol and ASL-8123 by gas chromatography–mass spectrometry and high performance liquid chromatography, respectively (2). Esmolol and ASL-8123 concentrations, as a function of time during and after the infusion, were fitted to equations describing a two-compartment open model (3, 4) and modified one-compartment open model, respectively, by nonlinear least-squares regression analysis.

Esmolol infusion significantly blocked the isoproterenol effects with its action being most evident at the 400-μg/kg/min dose. The duration of action of esmolol was, however, very short with no significant effect evident 30 min after cessation of the infusion at all three doses. There was a significant correlation between the reduction of the isoproterenol-induced increase in heart rate and blood pressure and the logarithm of esmolol blood concentrations. Blood levels of 0.3 and 1 μg/ml esmolol were associated with 50 and 80%, respectively, reduction in heart rate and 30 and 50%, respectively, reduction in blood pressure.

The steady-state concentrations of esmolol increased proportionally with the dose ($r = 0.866$, $p < 0.001$, $n = 24$). The mean concentrations (±*SD*) were 0.164 ± 0.068, 0.569 ± 0.204, and 1.59 ± 0.605 μg/ml, respectively, after 2-hr infusions of 50, 150, and 400 μg/kg/min. The respective values for the total clearance were 363 ± 184, 298 ± 112, and 285 ± 104 ml/min/kg, which were not correlated with dose ($r = 0.210$, $p > 0.3$, $n = 24$). These findings suggest that the elimination of esmolol is linear within the 50–400 μg/kg/min dosing range given for 2 hr.

Table I summarizes several of the key pharmacokinetic parameters for esmolol and ASL-8123 after the 400

Table I—Summary of Some Pharmacokinetic Parameters of Esmolol and its Metabolite after Administration of 400 μg/kg/min infusion of the Drug for 2 hr in Normal Subjects

Pharmacokinetic Parameters	Esmolol	ASL-8123
Steady-state concentration, μg/ml	1.59 ± 0.605[a]	—
Peak concentration, μg/ml	—	77.9 ± 3.93
Peak time, min	—	146 ± 11.1
Terminal half-life, min	9.19 ± 3.51	223 ± 14.0
Half-life of formation of metabolite(s), min	—	2.82 ± 0.592
Total clearance, ml/min/kg	285 ± 104	1.28 ± 0.19
Volume of distribution, liters/kg	3.43 ± 1.42	0.411 ± 0.057
Calculated fraction of metabolite formed[b]	—	0.829

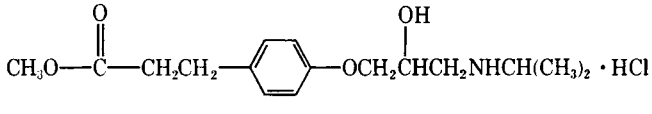
Esmolol: A Pharmacokinetic Profile of a New Cardioselective β-Blocking Agent

Keyphrases □ β-Adrenergic blocking agents—esmolol hydrochloride, pharmacokinetic profile, metabolism □ Pharmacokinetic profile—cardioselective β-adrenergic blocking agent, methyl 3-[4-(2-hydroxy-3-(isopropylamino)propoxy]phenylpropionate hydrochloride □ Esmolol—cardioselective β-adrenergic blocking agent, pharmacokinetic profile

To the Editor:

β-Adrenergic receptor blocking drugs exert their effects by competitively inhibiting the binding of catecholamines to β-adrenergic receptors. To attain therapeutic levels rapidly, intravenous bolus or infusions of β-blockers are usually instituted. However, since these agents have cardiac depressant properties, they are initially used at low doses, and slowly increased until the desired effects are obtained. Because currently available β-adrenergic blocking agents are long acting, the emergence of side effects, especially acute cardiac failure, poses a significant problem in their use because their action cannot be readily terminated. Therefore, there is a need for a β-adrenergic blocking drug with a short onset of action which can be rapidly terminated if side effects develop.

Esmolol (ASL-8052, Scheme I) is a new cardioselective intravenous β-receptor blocking agent with a very short duration of action in humans (unpublished data) and dogs (1). It is extensively metabolized in blood and liver by hydrolysis of the methyl ester functionality to form its major metabolites, ASL-8123 and methanol.



Esmolol (ASL-8052)

Methyl 3-[4-(2-Hydroxy-3-(isopropylamino)propoxy]phenylpropionate hydrochloride

Scheme I

To study the pharmacokinetics of esmolol, eight healthy male subjects (21–27 years old) weighing 62.4–76.2 kg received constant intravenous infusions of 50, 150, and 400 μg/kg/min for 2 hr on three different days. Each subject received an intravenous dose of isoproterenol, which had previously been determined to produce a 50% increase in heart rate. The suppression of the isoproterenol-induced increase in heart rate and blood pressure was determined on several occasions during and up to 60 min after the cessation of the esmolol infusion. At each dose level, blood samples were collected for determinations of esmolol and ASL-8123 by gas chromatography–mass spectrometry and high performance liquid chromatography, respectively (2). Esmolol and ASL-8123 concentrations, as a function of time during and after the infusion, were fitted to equations describing a two-compartment open model (3, 4) and modified one-compartment open model, respectively, by nonlinear least-squares regression analysis.

Esmolol infusion significantly blocked the isoproterenol effects with its action being most evident at the 400-μg/kg/min dose. The duration of action of esmolol was, however, very short with no significant effect evident 30 min after cessation of the infusion at all three doses. There was a significant correlation between the reduction of the isoproterenol-induced increase in heart rate and blood pressure and the logarithm of esmolol blood concentrations. Blood levels of 0.3 and 1 μg/ml esmolol were associated with 50 and 80%, respectively, reduction in heart rate and 30 and 50%, respectively, reduction in blood pressure.

The steady-state concentrations of esmolol increased proportionally with the dose ($r = 0.866$, $p < 0.001$, $n = 24$). The mean concentrations (±*SD*) were 0.164 ± 0.068, 0.569 ± 0.204, and 1.59 ± 0.605 μg/ml, respectively, after 2-hr infusions of 50, 150, and 400 μg/kg/min. The respective values for the total clearance were 363 ± 184, 298 ± 112, and 285 ± 104 ml/min/kg, which were not correlated with dose ($r = 0.210$, $p > 0.3$, $n = 24$). These findings suggest that the elimination of esmolol is linear within the 50–400 μg/kg/min dosing range given for 2 hr.

Table I summarizes several of the key pharmacokinetic parameters for esmolol and ASL-8123 after the 400

Table I—Summary of Some Pharmacokinetic Parameters of Esmolol and its Metabolite after Administration of 400 μg/kg/min infusion of the Drug for 2 hr in Normal Subjects

Pharmacokinetic Parameters	Esmolol	ASL-8123
Steady-state concentration, μg/ml	1.59 ± 0.605[a]	—
Peak concentration, μg/ml	—	77.9 ± 3.93
Peak time, min	—	146 ± 11.1
Terminal half-life, min	9.19 ± 3.51	223 ± 14.0
Half-life of formation of metabolite(s), min	—	2.82 ± 0.592
Total clearance, ml/min/kg	285 ± 104	1.28 ± 0.19
Volume of distribution, liters/kg	3.43 ± 1.42	0.411 ± 0.057
Calculated fraction of metabolite formed[b]	—	0.829

[a] Mean ± *SD*; $N = 8$. [b] Ratio of formation and elimination rate constants (k_f/k_{10}).

μg/kg/min infusion. The half-life of the formation of ASL-8123 averaged 2.82 min, and the calculated fraction of the overall metabolite generated was 82.9%. The elimination half-lives of esmolol and ASL-8123 averaged 9.19 and 223 min, respectively, suggesting accumulation and relatively slow elimination of the metabolite in humans. The peak concentration of ASL-8123 averaged 77.9 μg/ml and occurred 26 min after the cessation of the esmolol infusion. This peak concentration was ~50 times larger than the steady-state concentration of esmolol at which maximum β-blockade was observed.

The total clearance of esmolol was 4 times greater than the total cardiac output (70 ml/min/kg) and 14 times greater than hepatic blood flow (5), suggesting that the high clearance was primarily due to metabolism by esterases in the blood. The rapid metabolism of ASL-8052 results in a very short duration of action. The fact that there was no noticeable β-blockade 30 min after cessation of the infusion (which is the time of peak concentration of the metabolite) also suggests that ASL-8123 does not possess β-blocking activity at the concentrations generated in these subjects.

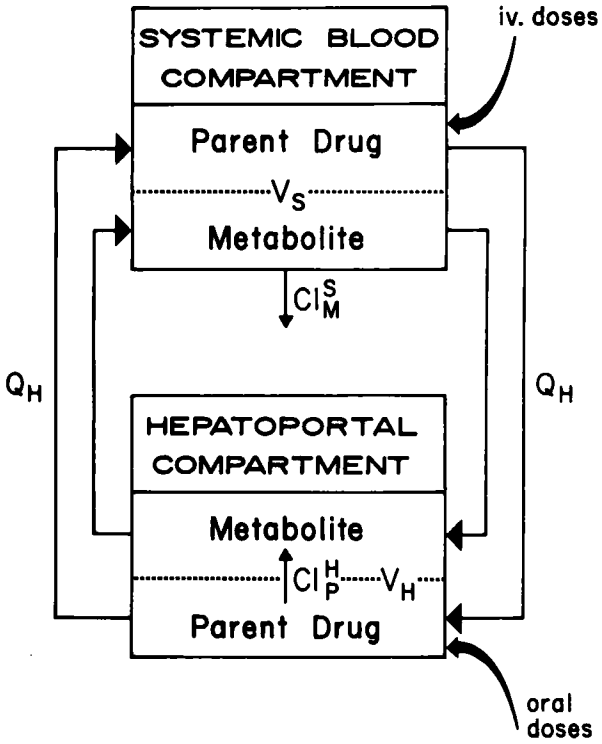
First-Pass, Formation-Rate-Limiting Metabolism

Keyphrases □ First-pass metabolism—impact on pharmacokinetic parameters, use of simulation techniques, formation-rate-limited metabolism □ Formation-rate-limited metabolism—pharmacokinetic parameters, use of simulation techniques □ Pharmacokinetic parameters—use of simulation techniques for first-pass and formation-rate-limited metabolism studies

To the Editor:

It has become increasingly apparent that there is a general misunderstanding of the driving forces that control first-pass and formation-rate-limited metabolism. In fact, a single metabolite can be the result of both first-pass and formation-rate-limited metabolism. To clarify this issue, simulation techniques were used to delineate the causative factors that determine both first-pass and formation-rate-limited metabolism.



Scheme I—First pass metabolism model used to simulate both parent drug and metabolite plasma concentrations under various conditions. Q_H is the hepatic blood flow, CL_M^S is the systemic clearance of the metabolite, CL_P^H is the hepatoportal clearance of parent drug to metabolite, V_P^S, V_P^H, V_M^S, and V_M^H are the systemic and hepatoportal volumes of parent and metabolite, respectively. The volume of distribution for the metabolite ($V_M^S + V_M^H$) is assumed to be equivalent to the systemic volume of distribution (V_P^S) of the parent drug and V_M^H is set equal to 1; e.g., the metabolite is not retained in the liver after formation (60 mg administered). Oral doses (60 mg) are absorbed into the hepatoportal compartment with the rate constant k_a, and intravenous doses (60 mg) are administered instantly into the systemic blood compartment.

The differential equations (see *Appendix*) needed to describe the first-pass metabolism model shown in Scheme I were used for the simulation of plasma concentration–time data for both parent drug and a single metabolite following oral and intravenous doses. The differential equations required to describe the model were used in conjunction with the nonlinear regression program NONLIN (1), to simulate parent drug and metabolite concentration–time data for drugs with varied pharmacokinetic characteristics. A 60-mg dose was used for each simulation. Several biopharmaceutic and pharmacokinetic parameters such as the time (t_{max}) of the maximum observed concentration (C_{max}) following oral doses, the areas under the plasma concentration–time curve (AUC) for parent drug and metabolite following oral (AUC_P^O and AUC_M^O) and intravenous (AUC_P^{IV} and AUC_M^{IV}) doses, the terminal elimination half-lives for parent drugs ($t_{1/2P}$) and metabolite ($t_{1/2M}$), the ratio of oral to intravenous area of parent (F_P) and metabolite (F_M), and the ratio of metabolite–parent drug following oral (R_O) and intravenous (R_{IV}) doses were calculated from the simulated plasma concentration–time data. The constants used for

[a] Parameters defined in text.

the simulations as well as the calculated pharmacokinetic and biopharmaceutic parameters are presented in Table I.

Substantial first-pass metabolism occurs in all cases, because the metabolic organ clearance (CL_P^H) exceeds hepatic blood flow (Q_H). t_{maxP} is earlier than t_{maxM} when the metabolite is not formation-rate limited, (Table I, Cases IIIA and IVA); *i.e.*, the half-life of the metabolite exceeds the half-life of the parent drug. Therefore, it is apparent that t_{maxM} occurs earlier than t_{maxP} only when the metabolite is the result of first-pass metabolism and the elimination of the metabolite is limited by the parent half-life. In addition, it is apparent that the volume of distribution of the parent drug is the controlling factor in determining whether a first-pass metabolite will ultimately be formation-rate limited. Although the clearance of parent drug does not change as the volume of distribution for the parent drug increases, the half-life of the parent drug ($t_{1/2P}$) will ultimately limit the *apparent* rate of elimination of the metabolite ($t_{1/2M}$) as the metabolite formation rather than its elimination becomes rate determining (Table I, Case IIIA–C and Case IVA–C).

The effective hepatic volume of distribution for the parent drug is important to the extent of first-pass metabolism (2). Although the half-life does not change (Table I, Case IA–C *versus* Case IIA–C and Case IIIA–C *versus* Case IVA–C), the extent of first-pass metabolism increases as the hepatic organ clearance (CL_P^H) increases as a function of increasing effective hepatic volume (2), such that the data reflect a decrease in the bioavailability parameter (F_P). The relative bioavailability of the metabolite (F_M) does not change, since all of the administered drug is ultimately converted to metabolite in the simplistic model used for these simulations. If an alternative route of elimination exists for the parent drug, then relative metabolite bioavailability would change as well. The ratios of the metabolite AUC to the parent AUC following oral (R_O) and intravenous (R_{IV}) doses increase as the effective hepatic volume increases (Table I, Case I *versus* Case II). However, due to first-pass metabolism, the increase in R_O is much higher than the increase in R_{IV}.

Additional observations became apparent as a result of the simulation procedures. The concentration–time data simulated from Case IVB are presented in Fig. 1 to illustrate various phenomena that were observed. First, under the conditions of this simulation, metabolite concentrations following oral doses decrease with an apparent half-life shorter than that of the parent drug for an interval of 48 hr before becoming formation-rate limited. If the analytical sensitivity is limiting or its sampling is restricted to 24 hr or less, it would appear that the metabolite was being eliminated more quickly than the parent drug.

In conclusion, it has been demonstrated that first-pass and formation-rate metabolism are not mutually exclusive. In fact, even first-pass metabolites with reasonably long elimination half-lives can be formation-rate limited if the volume of distribution of the parent drug is sufficiently large. This results because the driving force for first-pass metabolism is a high extraction ratio for the parent compound, *i.e.*, high organ clearance, whereas the driving force for formation-rate limited metabolism is a shorter half-life for the metabolite than that of the parent compound. This can occur easily if the volume of distribution of the parent compound is extremely large. Finally, the impact of first-

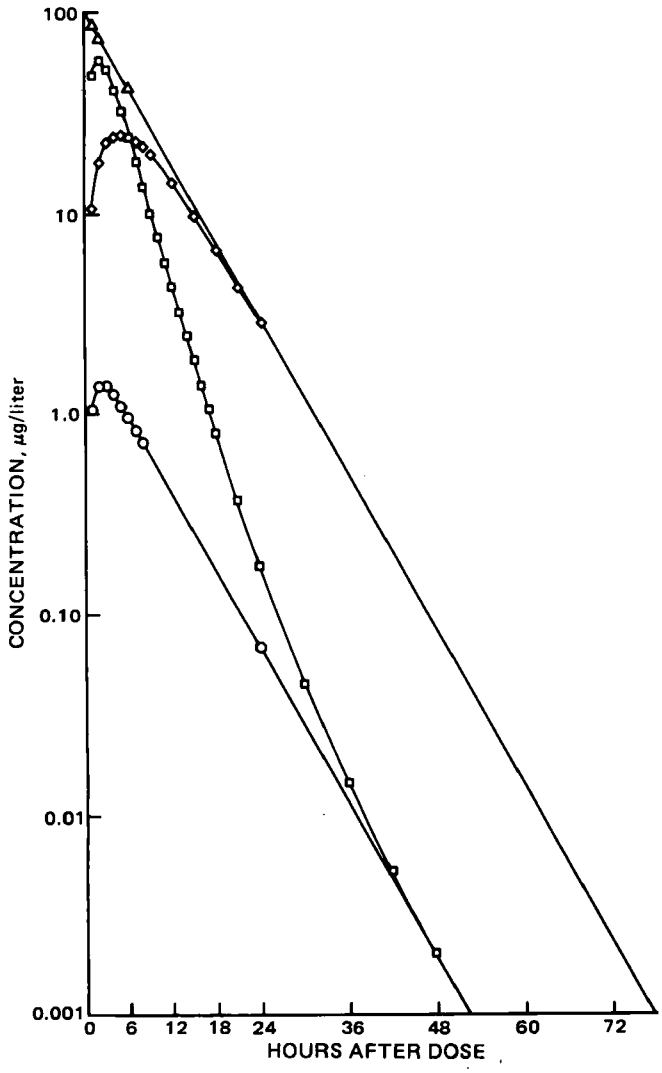

Figure 1—*Blood concentrations of drug and metabolite following oral (○ and □) and intravenous (△ and ◇) doses, respectively, simulated according to Case IVB.*

pass metabolism on various pharmacokinetic parameters has been delineated using simulation techniques.

APPENDIX

The following differential equations were used to simulate the plasma concentration–time data presented in this report.

$$\frac{dC_P^S}{dt} = Q_H \cdot (C_P^H - C_P^S)/V_P^S \qquad \text{(Eq. A-1)}$$

$$\frac{dC_M^S}{dt} = [Q_H \cdot C_M^H - (Q_H + CL_M^S) \cdot C_M^S]/V_M^S \qquad \text{(Eq. A-2)}$$

$$\frac{dC_P^H}{dt} = [k_a De^{-k_{at}} + Q_H \cdot C_P^S - (Q_H + CL_P^H) \cdot C_P^H]/V_P^H \qquad \text{(Eq. A-3)}$$

$$\frac{dC_M^H}{dt} = [Q_H \cdot C_M^S + CL_P^H C_P^H - Q_H C_M^H]/V_M^H \qquad \text{(Eq. A-4)}$$

Where D is the oral dose and the remaining terms have been identified in the text and legend to Scheme I. The $k_a De^{-k_{at}}$ term is the source of drug input for the oral dose. This source is not used for the IV dose, whereas the initial condition for C_P^S is set equal to D/V_P^S for the IV dose.

Factors Affecting the Accuracy of Estimated Mean Absorption Times and Mean Dissolution Times

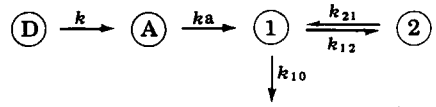
Keyphrases □ Statistical moment analysis—estimation of absorption and dissolution rates, effects of the sampling schedule, importance of the estimate of the terminal elimination rate constant (β)

To the Editor:

Recent discussions in the literature concerning the application of the concept of statistical moments to pharmacokinetic analysis has stimulated interest in the method and its potential utility in the evaluation of pharmacokinetic and bioavailability data. The most appealing aspect of statistical moment analysis is the potential for model-independent estimates of *in vivo* dissolution and absorption rates. A thorough discussion of this method and its potential applications was presented by Riegelman and Collier (1) and Yamaoka *et al* (2).

Using simulation techniques, the present study evaluates the ability of statistical moment analysis to provide accurate estimates of absorption and dissolution rates and the effects of sampling schedule, random error, and the estimate of the terminal elimination rate constant (β) on the accuracy of these estimates.

Simulations of drug concentration–time data corresponding to administration of an intravenous bolus, oral solution, and tablet dosage forms were generated by the CSSL-IV simulation program (3) based on the pharmacokinetic models presented in Scheme I. Unless otherwise specified, the parameter values presented in Table



Scheme I—Two-compartment pharmacokinetic model with sequential first-order dissolution and absorption, where k = *first-order dissolution rate constant and* k_a = *first-order absorption rate constant. To simulate intravenous data, the dose was entered into compartment 1; for oral solution data, the dose was entered into the absorption compartment (A); and for solid oral dosage form data, the dose was entered into the dissolution compartment (D).*

Factors Affecting the Accuracy of Estimated Mean Absorption Times and Mean Dissolution Times

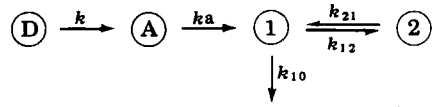
Keyphrases □ Statistical moment analysis—estimation of absorption and dissolution rates, effects of the sampling schedule, importance of the estimate of the terminal elimination rate constant (β)

To the Editor:

Recent discussions in the literature concerning the application of the concept of statistical moments to pharmacokinetic analysis has stimulated interest in the method and its potential utility in the evaluation of pharmacokinetic and bioavailability data. The most appealing aspect of statistical moment analysis is the potential for model-independent estimates of *in vivo* dissolution and absorption rates. A thorough discussion of this method and its potential applications was presented by Riegelman and Collier (1) and Yamaoka *et al* (2).

Using simulation techniques, the present study evaluates the ability of statistical moment analysis to provide accurate estimates of absorption and dissolution rates and the effects of sampling schedule, random error, and the estimate of the terminal elimination rate constant (β) on the accuracy of these estimates.

Simulations of drug concentration–time data corresponding to administration of an intravenous bolus, oral solution, and tablet dosage forms were generated by the CSSL-IV simulation program (3) based on the pharmacokinetic models presented in Scheme I. Unless otherwise specified, the parameter values presented in Table



Scheme I—Two-compartment pharmacokinetic model with sequential first-order dissolution and absorption, where k = *first-order dissolution rate constant and* k_a = *first-order absorption rate constant. To simulate intravenous data, the dose was entered into compartment 1; for oral solution data, the dose was entered into the absorption compartment (A); and for solid oral dosage form data, the dose was entered into the dissolution compartment (D).*

Liquid	100	1.0	—	3.0	0.20	0.60	0.50
Tablet	100	1.0	0.78	3.0	0.20	0.60	0.50

Table II—Sampling Schedules Used for Calculation of Parameters

Schedule	Sampling Times, hr
A	Every 0.05 hr for 36 hr
B	0, 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 10, 12, 18, 24, 36
C	0, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, 12, 24
D	0, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, 12, 24, 48, 72, 96

I were used for all simulations. Four sampling schedules were evaluated (Table II) with schedule A providing parameter estimates corresponding to the theoretical values.

Areas under the concentration–time curves (AUC_0^{24}) and areas under the moment curve ($AUMC_0^{24}$) to 24 hr were calculated using the linear trapezoidal method. Extrapolations to infinity and calculations of mean residence time (MRT), mean absorption time (MAT), and mean dissolution time (MDT) were performed as described previously (1).

For those simulations in which random error was added to the concentration data, data corresponding to sampling schedule C were simulated and normally distributed random error with a coefficient of variation of ±10% was added to each concentration value. This was done for 18 data sets per group. Extrapolations of AUC_0^{24} and $AUMC_0^{24}$ to infinity were performed using the theoretical value of β (*i.e.*, 0.1 hr^{-1}) and the β value generated by linear regression of the transformed data from 8 to 24 hr. Two MDT values were then calculated, one using AUC_0^∞ and $AUMC_0^\infty$ extrapolated with the theoretical β (Footnote *b*, Table III) and one using AUC_0^∞ and $AUMC_0^\infty$ extrapolated with the β value corresponding to the transformed data (Footnote *c*, Table III).

The effect of sampling schedule on the accuracy of the calculated estimates of MAT and MDT is presented in Table IV. As expected, the values of MAT and MDT calculated from sampling schedule A correspond to the theoretical values; *i.e.*, the reciprocal values of MAT and MDT are equivalent to the values of k_a and k used to generate the theoretical data. Comparing the results from sampling schedules B and C with those from schedule A gives an indication of the accuracy of the estimates of MAT and MDT when these reduced sampling schedules are utilized.

In general, sampling schedule B provided reasonably good estimates of the theoretical values of MAT and MDT (Table IV). In many cases, however, the parameters calculated with schedule C (typical for many protocols) were relatively poor estimates of the theoretical values. The accuracy of MAT and MDT tended to decrease as the rate constants k_a and k increased and as the two-compartment characteristics of the concentration–time curve became more pronounced (as k_{21} varied from 0.6 to 0.1 hr^{-1}). Increased sampling during the absorptive phase (schedule B) improved the accuracy of MAT and MDT (compared with schedule C), and the improvement was most pronounced when a k_{21} value of 0.1 hr^{-1} was utilized and when k and k_a were large. It is obvious from these data that the sampling schedule is critical for obtaining accurate and meaningful estimates of mean absorption times and mean dissolution times.

The importance of an accurate estimate of β when calculating various statistical moment parameters has been discussed previously (1, 2) and is demonstrated in our results. Using sampling schedule C and a k_{21} value of 0.2 hr^{-1}, 27% of AUC_0^∞ and 69% of $AUMC_0^\infty$ are due to extrapolation from the last data point to infinity using β. A ±10% error in β yields MDT estimates of −0.15 and 2.60 hr, respectively, compared with 1.07 hr when the correct β value is used. Utilizing sampling schedule D, only 1% of AUC_0^∞ and 6% of $AUMC_0^\infty$ are due to extrapolation, and the same ±10% error in β results in MDT estimates of 0.91 and 1.14 hr, respectively, compared with 1.01 hr when the

0.5	0.33	0.44	0.81	1.28	1.15	0.88	0.33	0.37	0.54	1.28	1.19	1.14

correct value is used. Errors in the estimate of β are inherent due to biological and analytical variability, but their impact can be reduced drastically by expanding the sampling schedule to longer times. Since this is not always possible because of analytical and practical limitations, the use of statistical moments may not be appropriate if there is insufficient sampling to provide accurate and consistent estimates of β.

Routine analytical error in drug concentration data can affect estimates of MAT and MDT in two ways: first, by its effects on the calculation of $AUMC_0^t$ and AUC_0^t, which should be rather insignificant, and second, by its effects on the estimate of β, which in turn may affect the calculation of $AUMC_0^\infty$ and AUC_0^∞ significantly. The first case is illustrated in Table III by the values of MDT^b generated using the theoretical value of β (i.e. 0.1 hr^{-1}) for all extrapolations. The average ($n = 18$) estimated MDT values were good estimates of the theoretical values with coefficients of variation ranging from 23 to 32%. The effect of variations in β caused by random error and the subsequent impact on MDT^c is also shown in Table III. The average MDT^c values were again good estimates of the theoretical values but the coefficients of variation were quite large, ranging from 47 to 81%. With this sampling schedule ~8% of AUC_0^∞ and 31% of $AUMC_0^\infty$ were due to extrapolation, and this would not be uncommon for a typical bioavailability study. The large variability in these MDT values could affect the ability to statistically detect small differences in MDT values under such conditions.

Overall, the results of these studies suggest that the statistical moment approach to the analysis of bioavailability data may offer an attractive alternative to C_{max} and t_{max} or to the model-dependent methods for assessing the rate of drug absorption. However, accurate results and meaningful conclusions using this method are very much dependent on the experimental design of the studies from which the data are generated. To obtain optimal information, frequent sampling during the absorption phase is necessary. In addition, sufficient sampling during the terminal elimination phase is needed to minimize the impact of extrapolation error and to provide an accurate estimate of β. MAT and MDT values calculated from data generated *via* a less than rigorous experimental design may yield poor estimates of the actual values and can result in misleading conclusions. Therefore, an understanding of the influence of the various factors affecting the accuracy of the calculated MAT and MDT values, along with a well-defined pharmacokinetic profile of the drug, are essential to achieve an experimental design which will allow for the determination of meaningful estimates of mean absorption and dissolution times.

Plasma Inorganic Sulfate Concentrations in Pregnant Women

Keyphrases □ Sulfate concentration—effect of pregnancy in humans □ Plasma sulfate concentrations—effect of pregnancy in humans

To the Editor:

The physiological process of sulfation has important biosynthetic and detoxification functions. It is necessary in the developing fetus for the formation of glycosaminoglycans, a structural component of cartilage and other tissues, and cerebroside sulfate, a constituent of the brain (1, 2). The sulfated glycosaminoglycans may also be involved in cell differentiation (2).

The biotransformation of certain phenolic drugs to sulfate conjugates is limited by the availability of inorganic sulfate (3, 4); the formation of such drug conjugates can cause depletion of endogenous inorganic (free) sulfate in animals and humans (4–6). Decreased sulfate availability in pregnant rats, due to administration of salicylamide, which produces sulfate depletion concomitant with salicylamide sulfate formation (3, 5), has been associated with decreased availability and decreased tissue incorporation of sulfate in the fetuses and may be the cause of teratogenic effects (7, 8). Depletion of endogenous sulfate can decrease the rate of sulfation of phenolic drugs, such as acetaminophen, and thereby decrease their clearance (4), while hypersulfatemia, such as occurs in renal dysfunction, can facilitate drug sulfate conjugate formation and thereby increase drug clearance (9). The maternal level of endogenous inorganic sulfate may, therefore, affect fetal development and fetal exposure to certain drugs and other xenobiotics.

The plasma or serum concentrations of most electrolytes tend to decrease slightly during pregnancy (10). We have found only one report concerning the effect of pregnancy on serum sulfate concentrations: Tallgren observed concentrations of 0.592 ± 0.275 mmole/liter (mean ± *SD*) in 118 Scandinavian women during their third trimester and 0.263 ± 0.091 mmole/liter in 42 age-matched nonpregnant controls (11). On the other hand, Lin and Levy recently determined serum sulfate concentrations in 20-day pregnant rats and nonpregnant controls and found no apparent difference between the two groups[1]. The effect of pregnancy on endogenous sulfate concentrations in women was, therefore, reexamined.

Seven Caucasian women in their third trimester of pregnancy and nine Caucasian nonpregnant women of similar age were the subjects in this study. They were medication-free for at least 1 week before the study and were in apparent good health. None of the controls were taking an oral contraceptive. Nine-milliliter blood samples were drawn from an antecubital vein into 10-ml capacity plastic disposable syringes containing 1 ml of trisodium citrate solution each. The citrated blood was centrifuged in plastic tubes at 12,000×*g* for 15 min at 25°, and the plasma was frozen pending assay. Inorganic sulfate concentration was determined by a modification (12) of the turbidimetric method of Berglund and Sörbo (13), using

Table I—Effect of Pregnancy on Sulfate Concentrations in Plasma of Caucasian Women [a]

	Pregnant (n = 7)	Nonpregnant (n = 9)	Significance
Plasma sulfate, mM	0.410 ± 0.035	0.333 ± 0.038	$p < 0.005$
Age, yr	24.4 ± 4.2	27.2 ± 5.5	NS
Gestation age, wk	35.8 ± 3.8		
Total protein, g/dl	6.08 ± 0.29	6.43 ± 0.35	NS
Albumin, g/dl	3.28 ± 0.19	4.14 ± 0.20	$p < 0.001$

[a] Results expressed as mean ± SD.

pooled citrated plasma from nonpregnant women with known concentrations of added sodium sulfate for preparation of a standard curve. All samples were assayed on the same day, and the results were corrected for sample dilution with citrate anticoagulant solution. Total plasma protein concentrations (14) and albumin fraction[2] were also determined. Results were examined by one-way ANOVA, and possible associations between sulfate concentration and other variables were determined by correlation analysis[3].

The results of this study are summarized in Table I. Plasma sulfate concentrations were significantly higher in the pregnant women, but the quantitative difference between the pregnant and nonpregnant women was relatively small. Plasma albumin concentrations were significantly decreased in late pregnancy, consistent with previous observations (15). The difference in sulfate concentration between pregnant and nonpregnant subjects remained when smokers were eliminated (0.427 ± 0.039 mmole/liter in four pregnant women and 0.328 ± 0.036 in eight nonpregnant women, $p < 0.005$). Eight Black women (including two smokers) in their third trimester of pregnancy were also studied; their plasma sulfate concentration (0.360 ± 0.072 mmole/liter) is not significantly different from those of the Caucasian pregnant and nonpregnant women, respectively. There is a significant negative correlation between the plasma sulfate concentration of the 15 pregnant women (Black and Caucasian combined) and their plasma albumin concentration ($r = -0.548$, $p < 0.05$). No other significant correlations were found.

The results of this investigation are in qualitative agreement with those of Tallgren (11) with respect to Caucasian women, but the quantitative difference between pregnant and nonpregnant women is considerably smaller in our study. Our results for nonpregnant females are similar to those described (11), but the inorganic sulfate concentrations in pregnant women are appreciably lower in our study. The intake of proteins rich in sulfur-containing amino acids is an important determinant of endogenous inorganic sulfate levels (11, 16), but it appears unlikely that the difference between the two groups of pregnant women is due to diet, since the two nonpregnant control groups had similar sulfate concentrations. Tallgren's analytical procedure (11) requires incubation of the serum sample for 4 hr at 37° and pH <1, which may favor hydrolysis of endogenous steroid sulfates, while the procedure used by us requires no such incubation. However, the plasma concentrations of these conjugates in pregnancy (17, 18) are much too low to account for the observed differences.

No other significant correlations were found.

The results of this investigation are in qualitative agreement with those of Tallgren (11) with respect to Caucasian women, but the quantitative difference between pregnant and nonpregnant women is considerably smaller in our study. Our results for nonpregnant females are similar to those described (11), but the inorganic sulfate concentrations in pregnant women are appreciably lower in our study. The intake of proteins rich in sulfur-containing amino acids is an important determinant of endogenous inorganic sulfate levels (11, 16), but it appears unlikely that the difference between the two groups of pregnant women is due to diet, since the two nonpregnant control groups had similar sulfate concentrations. Tallgren's analytical procedure (11) requires incubation of the serum sample for 4 hr at 37° and pH <1, which may favor hydrolysis of endogenous steroid sulfates, while the procedure used by us requires no such incubation. However, the plasma concentrations of these conjugates in pregnancy (17, 18) are much too low to account for the observed differences.

Changes in Plasma Protein Binding of Drugs after Blood Collection from Pregnant Women

Keyphrases □ Protein binding—plasma, changes after blood collection from pregnant women □ Unesterified fatty acids—plasma, changes after blood collection from pregnant women

To the Editor:

Drug-protein binding in plasma obtained from 20-day pregnant rats can decrease rapidly *in vitro* after blood collection (1) due to lipolysis and the consequent increase in the concentrations of unesterified fatty acids[1]. These

0022-3549/83/0600-0716$01.00/0

changes are much less pronounced in plasma of nonpregnant rats (1). Since there are pronounced differences in the drug-protein binding characteristics of rat and human plasma and serum (2, 3), this investigation was designed to determine if the rapid and pronounced decrease in drug-protein binding and increase in fatty acid concentrations observed in plasma of pregnant rats occur also in plasma of pregnant women.

Blood samples were obtained from 15 healthy women, 18 to 29 years old, who were in the third trimester of pregnancy and who were not taking any medications. The blood was drawn from an antecubital vein into a heparinized plastic syringe, and plasma was separated immediately by 1-min centrifugation. A 0.1-ml aliquot of the plasma was immediately extracted into hexane for determination of fatty acid concentrations by gas chromatography (4). Fifty microliters of an aqueous solution of either sodium phenytoin or sodium salicylate was added to another 5- to 6-ml aliquot of plasma to yield final concentrations of ~20 and 200 μg/ml (in terms of the acid), respectively. Two milliliters of this plasma was immediately ultrafiltered (35 min) through a cellophane membrane (Visking, molecular weight cut-off 12,000–14,000), another 2 ml was maintained at 37° for 6 hr and then ultrafiltered after removal of 0.1 ml for determination of fatty acid concentrations, and 0.4 ml was placed in a dialysis cell for equilibrium dialysis (6 hr) against an equal volume of 0.13 *M* sodium–potassium phosphate buffer, pH 7.4, at 37°. A 0.1-ml portion of the plasma phase was collected after dialysis for fatty acid assays. Phenytoin and salicylic acid concentrations in ultrafiltrate, dialysate, and plasma phases were determined by high-performance liquid chromatography, as previously described (5), except that *o*-methoxybenzoic acid was used as the internal standard for the salicylate assay. The equilibrium dialysis procedures were repeated ~1 week later, but at 25°. In view of the concentration dependence of salicylate protein binding, sodium salicylate in a concentration approximately equal to that found previously in the ultrafiltrates was added to the buffer solution. No such precaution was required with respect to phenytoin because of the relative concentration independence of its plasma-free fraction value in the therapeutic concentration range. The plasma for the repeat dialysis procedure had been stored frozen at −20°.

The results of the protein binding determinations are summarized in Table I. Neither incubation of the plasma at 37° nor the 6-hr incubation at 25° associated with equilibrium dialysis had any significant effect on the plasma protein binding of phenytoin. These same procedures caused a pronounced decrease of phenytoin protein binding in plasma of pregnant rats (1). Technical difficulties related to the need for immediate ultrafiltration in the clinic prevented measurements at 37°, except for equilibrium dialysis. The phenytoin free-fraction value at 37° (0.175 ± 0.016) is considerably higher than the corresponding value in nonpregnant individuals (≃0.1) and is in good agreement with previous determinations of phenytoin free fraction in pregnant women (6, 7).

Table I—Changes in Plasma Protein Binding of Phenytoin and Salicylate after Blood Collection from Pregnant Women in the Third Trimester of Pregnancy

Procedure	Free Fraction in Plasma × 100, mean ± *SD*	
	Phenytoin[a]	Salicylate[b]
Immediate ultrafiltration at 25°	9.29 ± 2.32	28.2 ± 6.9
Ultrafiltration at 25° after 6 hr at 37°	9.89 ± 2.41	34.9 ± 7.8[c]
Dialysis for 6 hr at 25°	10.9 ± 1.5	28.7 ± 3.7
Dialysis for 6 h at 37°	17.5 ± 1.6	

[a] Concentration, 22.8 ± 1.8 μg/ml; $n = 8$. [b] Concentration, 203 ± 15 μg/ml; $n = 7$. [c] Significantly different from value after immediate ultrafiltration ($p < 0.05$). The ratio of free-fraction values, 6 hr/immediate, is 1.27 ± 0.26.

Table II—Changes in Concentrations of Unesterified Fatty Acids in Plasma after Blood Collection from Pregnant Women in the Third Trimester of Pregnancy

Fatty Acid	Fatty Acid Concentration, μM[a]			Concentration Ratio, 6 hr/immediate
	Immediately after Plasma Separation	6 hr at 37° after Plasma Separation	After 6-hr Dialysis at 37°	
Linoleic	46.4 ± 30.2	63.2 ± 30.5	60.0 ± 25.2	1.67 ± 0.60
Oleic	123 ± 109	143 ± 102	136 ± 102	1.32 ± 0.23
Palmitic	118 ± 63	157 ± 65	146 ± 64	1.46 ± 0.34
Stearic	61.3 ± 25.6	67.3 ± 21.6	58.6 ± 19.0	1.17 ± 0.26
Total	348 ± 218	430 ± 213	401 ± 205	1.36 ± 0.27

[a] Mean ± *SD*, $n = 15$.

The process of equilibrium dialysis at 25° had no apparent effect on the plasma protein binding of salicylate, but incubation of the plasma for 6 hr at 37° decreased protein binding slightly (Table I). Results of equilibrium dialysis at 37° are not listed in the table, because the buffer phase was not spiked with salicylate to prevent a decrease in drug concentration in the plasma phase. However, the free-fraction values (0.242 ±0.035) are in good agreement with those of an earlier study under similar experimental conditions (8).

The results of fatty acid concentration determinations are summarized in Table II. Some lipolysis occurred in plasma during 6 hr of incubation at 37°, but the fatty acid concentrations increased only by 17–67% on average during incubation and somewhat less during equilibrium dialysis. Under similar conditions, total fatty acid concentrations in plasma from pregnant rats increase by ~500% when heparin is used as the *in vitro* anticoagulant and by 200% when EDTA is used as the anticoagulant[1]. Heparin added *in vitro* to plasma from nonpregnant humans has no apparent effect on the protein binding of phenytoin and salicylic acid (3).

In summary, it has been found that the drug-protein binding characteristics of plasma from healthy women in the third trimester of pregnancy are relatively stable, at least with respect to the drugs tested. These observations are consistent with the relatively small increase of fatty acid concentrations due to *in vitro* lipolysis in plasma during incubation or dialysis at 37° for 6 hr after blood collection. While all plasma samples should be processed to minimize *in vitro* lipolysis, this precaution applies much more to pregnant rats (and perhaps other species) than to pregnant women.

Drug Kinetics in Low-Flux (Small) Anatomic Compartments

Keyphrases □ Pharmacokinetics—low-flux peripheral compartment □ Cochlear perilymph—aminoglycoside kinetics

To the Editor:

Small anatomic compartments may be the site of action or toxicity of drugs. Because the kinetics in the anatomic compartment may differ significantly from those in the sampled compartment, pharmacokinetic modeling of such drugs requires the development of explicit expressions for the time course of drug concentrations in the anatomic compartment. Classical compartmental analysis is based on large (kinetic) compartments, which exchange enough drug that measurable alterations in the concentration of drug in the sampled compartment result. A small (anatomic) compartment may not give rise to a detectable alteration in drug concentration in the sampled compartment, because its drug flux is small. In such a case, the anatomic compartment can not be represented by a peripheral kinetic compartment. This communication describes the derivation of an equation for the time course of drug concentrations in such small compartments based on a modified compartmental analysis.

Consider an n-compartment linear mammillary system with first-order rate constants and elimination from the central compartment (denoted by subscript 1) only. Let there be an $(n + 1)$th compartment that exchanges drug with the central compartment but for which the flux of drug into and out of the compartment is so minute that it does not measurably alter levels of the drug in the central compartment. This compartment will be called the low-flux peripheral compartment and will be labeled LF.

The differential equations governing this model are:

$$\frac{dC_1}{dt} = \sum_{j=2}^{n}\left(k_{j1}\frac{V_j}{V_1}C_j - k_{1j}C_1\right) - k_{10}C_1 \quad \text{(Eq. 1)}$$

$$\frac{dC_j}{dt} = k_{1j}\frac{V_1}{V_j}C_1 - k_{j1}C_j,\ n \geq j > 1 \quad \text{(Eq. 2)}$$

$$\frac{dC_{LF}}{dt} = k_{1LF}\frac{V_1}{V_{LF}}C_1 - k_{LF1}C_{LF} \quad \text{(Eq. 3)}$$

where

C_j = concentration of drug in the jth compartment;
V_j = pharmacokinetic volume of distribution of drug in the jth compartment;
k_{ab} = first-order transfer rate constant from the ith to the jth compartment;
k_{10} = first-order elimination rate constant from the central compartment;
C_{LF} = concentration of drug in the low-flux compartment;
k_{1LF}, k_{LF1} = first-order transfer rate constants into and out of the low-flux compartment.

If the drug enters the central compartment as a result of bolus injection, the drug concentration in that compartment, as a function of time, will be a sum of exponentials (1):

$$C_1(t) = \sum_{i=1}^{n} a_i e^{-\lambda_i t} \quad \text{(Eq. 4)}$$

where a_i = coefficient of ith exponential term and λ_i = exponent of the ith exponential term. The general equation for the drug concentration in the jth peripheral compartment is found by the use of Laplace transforms (2):

$$C_j(t) = \frac{V_1}{V_j}\sum_{i=1}^{n}\frac{k_{1j}}{(k_{j1} - \lambda_i)}a_i(e^{-\lambda_i t} - e^{-k_{j1}t}) \quad \text{(Eq. 5)}$$

The equation for the drug concentration in the low flux compartment is:

$$C_{LF}(t) = \frac{V_1}{V_{LF}}\sum_{i=1}^{n}\frac{k_{1LF}}{(k_{LF1} - \lambda_i)}a_i(e^{-\lambda_i t} - e^{-k_{LF1}t}) \quad \text{(Eq. 6)}$$

By similar means, expressions can be found for the drug concentration in the low-flux compartment following entry of the drug into the central compartment by first-order absorption or continuous infusion.

As an example of the application of this model, Eq. 6 is used to describe the kinetics of amikacin, an aminoglycoside antibiotic, in cochlear perilymph, presumably a low-flux compartment. The data are taken from a study performed in guinea pigs, as reported by Brummett *et al.* (3). The concentrations of amikacin were determined in serum and in cochlear perilymph over time following a single subcutaneous injection of the drug (as detailed in Ref. 3). The subcutaneous absorption of amikacin was very rapid, resulting in a monoexponential serum drug concentration *versus* time curve. Therefore, Eq. 4, and consequently Eq. 6, can be used in this case even though the injection was not intravenous.

The equation for the serum drug concentration *versus* time curve is:

$$C_{serum}(t) = 489e^{-0.6992t\,(\text{in hr})} \text{ in micrograms per milliliter}$$

The experimental data and corresponding predicted values are presented in Table I. The perilymph drug concentration *versus* time curve is fitted to a biexponential

Drug Kinetics in Low-Flux (Small) Anatomic Compartments

Keyphrases □ Pharmacokinetics—low-flux peripheral compartment □ Cochlear perilymph—aminoglycoside kinetics

To the Editor:

Small anatomic compartments may be the site of action or toxicity of drugs. Because the kinetics in the anatomic compartment may differ significantly from those in the sampled compartment, pharmacokinetic modeling of such drugs requires the development of explicit expressions for the time course of drug concentrations in the anatomic compartment. Classical compartmental analysis is based on large (kinetic) compartments, which exchange enough drug that measurable alterations in the concentration of drug in the sampled compartment result. A small (anatomic) compartment may not give rise to a detectable alteration in drug concentration in the sampled compartment, because its drug flux is small. In such a case, the anatomic compartment can not be represented by a peripheral kinetic compartment. This communication describes the derivation of an equation for the time course of drug concentrations in such small compartments based on a modified compartmental analysis.

Consider an n-compartment linear mammillary system with first-order rate constants and elimination from the central compartment (denoted by subscript 1) only. Let there be an $(n + 1)$th compartment that exchanges drug with the central compartment but for which the flux of drug into and out of the compartment is so minute that it does not measurably alter levels of the drug in the central compartment. This compartment will be called the low-flux peripheral compartment and will be labeled LF.

The differential equations governing this model are:

$$\frac{dC_1}{dt} = \sum_{j=2}^{n}\left(k_{j1}\frac{V_j}{V_1}C_j - k_{1j}C_1\right) - k_{10}C_1 \quad \text{(Eq. 1)}$$

$$\frac{dC_j}{dt} = k_{1j}\frac{V_1}{V_j}C_1 - k_{j1}C_j,\ n \geq j > 1 \quad \text{(Eq. 2)}$$

$$\frac{dC_{LF}}{dt} = k_{1LF}\frac{V_1}{V_{LF}}C_1 - k_{LF1}C_{LF} \quad \text{(Eq. 3)}$$

where

C_j = concentration of drug in the jth compartment;
V_j = pharmacokinetic volume of distribution of drug in the jth compartment;
k_{ab} = first-order transfer rate constant from the ith to the jth compartment;
k_{10} = first-order elimination rate constant from the central compartment;
C_{LF} = concentration of drug in the low-flux compartment;
k_{1LF}, k_{LF1} = first-order transfer rate constants into and out of the low-flux compartment.

If the drug enters the central compartment as a result of bolus injection, the drug concentration in that compartment, as a function of time, will be a sum of exponentials (1):

$$C_1(t) = \sum_{i=1}^{n} a_i e^{-\lambda_i t} \quad \text{(Eq. 4)}$$

where a_i = coefficient of ith exponential term and λ_i = exponent of the ith exponential term. The general equation for the drug concentration in the jth peripheral compartment is found by the use of Laplace transforms (2):

$$C_j(t) = \frac{V_1}{V_j}\sum_{i=1}^{n}\frac{k_{1j}}{(k_{j1} - \lambda_i)}a_i(e^{-\lambda_i t} - e^{-k_{j1}t}) \quad \text{(Eq. 5)}$$

The equation for the drug concentration in the low flux compartment is:

$$C_{LF}(t) = \frac{V_1}{V_{LF}}\sum_{i=1}^{n}\frac{k_{1LF}}{(k_{LF1} - \lambda_i)}a_i(e^{-\lambda_i t} - e^{-k_{LF1}t}) \quad \text{(Eq. 6)}$$

By similar means, expressions can be found for the drug concentration in the low-flux compartment following entry of the drug into the central compartment by first-order absorption or continuous infusion.

As an example of the application of this model, Eq. 6 is used to describe the kinetics of amikacin, an aminoglycoside antibiotic, in cochlear perilymph, presumably a low-flux compartment. The data are taken from a study performed in guinea pigs, as reported by Brummett *et al.* (3). The concentrations of amikacin were determined in serum and in cochlear perilymph over time following a single subcutaneous injection of the drug (as detailed in Ref. 3). The subcutaneous absorption of amikacin was very rapid, resulting in a monoexponential serum drug concentration *versus* time curve. Therefore, Eq. 4, and consequently Eq. 6, can be used in this case even though the injection was not intravenous.

The equation for the serum drug concentration *versus* time curve is:

$$C_{serum}(t) = 489e^{-0.6992t\,(\text{in hr})} \text{ in micrograms per milliliter}$$

The experimental data and corresponding predicted values are presented in Table I. The perilymph drug concentration *versus* time curve is fitted to a biexponential

0022-3549/83/0600-0718$01.00/0

Table I—Concentration of Amikacin in Serum Following a Bolus Subcutaneous Injection

Time, hr	Amikacin Concentration, μg/ml Experimental	Predicted Value
0.5	315	345
1.0	270	244
2.0	132	121
4.0	25	29
6.0	8	7

Table II—Concentration of Amikacin in Cochlear Perilymph Following a Bolus Subcutaneous Injection

Time, hr	Amikacin Concentration, μg/ml Experimental	Predicted Value
0.5	2.0	2.2
1.0	6	5.7
2.0	9	9.1
4.0	10	9.2
6.0	7	7.0
12.0	2.5	2.1

equation, which is the form prescribed by Eq. 6 and is also as many exponential terms as can confidently be generated for six data points:

$$C_{\text{perilymph}}(t) = 29e^{-0.2169t(\text{in hr})} - 32e^{-0.6019t(\text{in hr})}$$

in micrograms per milliliter

The experimental data and corresponding predicted values are listed in Table II. For both the serum and perilymph, the equations fit the data well.

If the model is appropriate, the values of k_{10} estimated from each of these two equations should be equal. The estimate of k_{10} from the serum drug concentration *versus* time equation is the exponent of the single exponential term, 0.6992 hr^{-1}. The estimate of k_{10} from the perilymph drug concentration *versus* time equation is the exponent for the exponential term with a negative coefficient, 0.6019 hr^{-1}. These estimates show a 16% difference. Such a small difference is within the limits of accuracy expected in such an experimental setting. The close agreement provides evidence of the validity of the model. This model might be found useful in describing other small anatomic compartments of pharmacological interest.

BOOKS

REVIEWS

Encyclopedia of Emulsion Technology, Vol. 1: Basic Theory. Edited by PAUL BECHER. Marcel Dekker, Inc., New York, NY 10016. 1983. 744 pp. 17 × 25 cm. Price $95.00 (20% higher outside the U.S. and Canada).

This book is the first in a series of volumes devoted to various aspects of emulsion science and technology. It contains one of the most comprehensive and authoritative reviews of the basic principles underlying emulsification and emulsion properties now available. Each chapter has been prepared by individuals actively involved in the area about which they have written. The editor, himself widely recognized for his work with emulsions, has done an excellent job in bringing this work together in a well-edited volume.

The book contains nine chapters, all developed at a fairly fundamental level. In Chapter 1, the authors provide an excellent review of basic interfacial chemistry and physics using the oil–water interface as the main focus. The next two chapters address the fundamentals of emulsion formation and stabilization. The former is an extremely unique and in-depth treatment of droplet formation and coalescence and the underlying fluid dynamics involved, while the latter represents the most complete and up-to-date fundamental discussion of emulsion stability that this reviewer has seen.

The remaining chapters provide excellent in-depth coverage of such topics as: microemulsions, phase equilibria and phase inversion temperatures, particle size evaluation, rheology, optical properties, and dielectric properties. The chapter on rheology, written by P. Sherman, presents material which should be read by anyone seriously concerned with the complex problems of evaluating emulsion product stability. The material on the viscoelastic properties of emulsions is particularly relevant for this purpose. The very long chapter on the fundamental dielectric properties of emulsions (over 200 pages) is a unique resource of information which offers interesting possibilities for evaluating emulsion behavior in a new way. The proportion of the book devoted to this chapter, however, is much too large, relative to the importance of the other subjects presented. As in this latter chapter, all of the material in this volume is treated at a fairly fundamental level with the assumption that the reader has a reasonably good basic background in the physical chemistry of surfaces and disperse systems. Consequently, this book should be thought of as primarily suitable for a graduate-level course dealing with emulsions or for the pharmaceutical scientist seriously prepared to approach this subject at a very fundamental level.

BOOKS

REVIEWS

Encyclopedia of Emulsion Technology, Vol. 1: Basic Theory. Edited by PAUL BECHER. Marcel Dekker, Inc., New York, NY 10016. 1983. 744 pp. 17 × 25 cm. Price $95.00 (20% higher outside the U.S. and Canada).

This book is the first in a series of volumes devoted to various aspects of emulsion science and technology. It contains one of the most comprehensive and authoritative reviews of the basic principles underlying emulsification and emulsion properties now available. Each chapter has been prepared by individuals actively involved in the area about which they have written. The editor, himself widely recognized for his work with emulsions, has done an excellent job in bringing this work together in a well-edited volume.

The book contains nine chapters, all developed at a fairly fundamental level. In Chapter 1, the authors provide an excellent review of basic interfacial chemistry and physics using the oil–water interface as the main focus. The next two chapters address the fundamentals of emulsion formation and stabilization. The former is an extremely unique and in-depth treatment of droplet formation and coalescence and the underlying fluid dynamics involved, while the latter represents the most complete and up-to-date fundamental discussion of emulsion stability that this reviewer has seen.

The remaining chapters provide excellent in-depth coverage of such topics as: microemulsions, phase equilibria and phase inversion temperatures, particle size evaluation, rheology, optical properties, and dielectric properties. The chapter on rheology, written by P. Sherman, presents material which should be read by anyone seriously concerned with the complex problems of evaluating emulsion product stability. The material on the viscoelastic properties of emulsions is particularly relevant for this purpose. The very long chapter on the fundamental dielectric properties of emulsions (over 200 pages) is a unique resource of information which offers interesting possibilities for evaluating emulsion behavior in a new way. The proportion of the book devoted to this chapter, however, is much too large, relative to the importance of the other subjects presented. As in this latter chapter, all of the material in this volume is treated at a fairly fundamental level with the assumption that the reader has a reasonably good basic background in the physical chemistry of surfaces and disperse systems. Consequently, this book should be thought of as primarily suitable for a graduate-level course dealing with emulsions or for the pharmaceutical scientist seriously prepared to approach this subject at a very fundamental level.

Polyether Antibiotics, Vol. 1: Naturally Occurring Acid Ionophores. Edited by JOHN W. WESTLEY. Dekker, New York, N.Y. 1982. 565 pp. 15 × 23 cm. Price $65.00 (20% higher outside the U.S. and Canada).

This is the first volume of a two-volume work on the naturally occurring ionophore antibiotics. These antibiotics bind monovalent or divalent cations. The best known and commercially produced ones are the anticoccidia agents lasalocid and monensin.

The book starts with a classification scheme for the 76 polyether antibiotics known by 1982. There are 10 chapters. Chapter 1 is on notation and classification. Structural formulas are used in large number as they should be in such a book. Chapter 2 is on taxonomy of the organisms that produce the antibiotics. One half of the antibiotics are produced by different strains of two species of *Streptomyces.* Chapter 3 discusses biosynthesis, production, and assay. Chapter 4 is on the complexes formed by the antibiotics and cations, and transport of the cations by the complexes. Chapter 5 "provides a broad overview of the many, diverse effects of the carboxylic acid ionophores on biological systems." There is a chapter on veterinary applications, one on the effect of lasalocid and monensin in chickens, one on the pharmacology of lasalocid (cardiovascular action), one on cardiovascular and renal effects of an ionophore, and the final chapter on bromolasalocid as an antihypertensive ionophore. Those with an interest in monensin will find the coverage as complete as published literature permits.

This book has some interesting statistics. Ten of the authors were from Hoffmann-LaRoche, Inc.; the other eight were from medical schools, USDA, *etc.* Of the 465 pages, 200 were text and figures, 135 were tables, 95 were bibliography, 30 were an author index, and 6 were a subject index. The subject index is skimpy for a book of this size and importance. References are collected at the end of each chapter. A very unusual feature is giving of the complete title of each publication cited.

The publisher is to be commended for departing from the current norm of bookmaking by printing the title in large blue letters on a white spine thus enabling the title to be read from a distance greater than 2 feet. This book illustrates one advantage of having a domestic company with close ties to Europe with its concept of scholarly works.

All who work with polyether antibiotics should have a copy of this book.

Trends in Inflammation Research 2. (Agents and Actions Supplements, Vol. 10). Edited by H. BEKEMEIER AND R. HIRSCHELMANN. Birkhäuser Boston, Inc., Cambridge, MA 02139. 1982. 315 pp. 16.5 × 23.5 cm. Price $37.95.

All of the papers in this book were presented at the 4th Summer Colloquium on Pharmacology, Biochemistry, and Immunology of Inflammation held at the Martin Luther University in Germany during July 1981. The title of the book, together with the description of the contents on the outside back cover, suggests that this collection of papers should be a valuable source of information on recent anti-inflammatory research carried out in West Germany.

On closer reading, however, the book proved disappointing. The authors are drawn mainly from just a few research centers so that the book covers only limited aspects of inflammation research. Of the 52 contributors to the volume, no less than 20 come from the Martin Luther University; 40 of the 52 contributors are from just four German universities. Furthermore, of the 23 chapters in the book, 10 are co-authored by H. Bekemeier and 7 are co-authored by R. Hirschelmann.

Other aspects of the book can be criticized. The sentence structure is often very awkward, evidently arising from an inadequate translation from the original German. This makes it difficult for the English-speaking reader to understand the material. It appears as though every paper submitted for publication was accepted without modification. A number of chapters are not written in a proper scientific journal format nor do they appear to have been critically reviewed prior to publication. The book serves as a vehicle for reporting many negative laboratory results that would not be publishable elsewhere. As a result, the quality of the papers in this book is below that found in an average journal.

I cannot recommend this book. It is not of general utility to scientists in the field of anti-inflammatory drug research. The book is difficult to read and too diffuse in subject matter. A few of the papers may be worthy of publication in a scientific journal, but only after appropriate impartial review and editorial revision.

Hormone Drugs. Workshop Organizers, JOHN L. GUERIGUIAN, EDWIN D. BRANSOME, JR., and AUDREY S. OUTSCHOORN. U.S. Pharmacopeial Convention, Inc., 12601 Twinbrook Parkway, Rockville, MD 20852. 1982. 584 pp. 15 × 23 cm. Price $49.00 (plus postage).

This book contains the proceedings of the FDA–USP Workshop on Drug and Reference Standards for Insulins, Somatropins, and Thyroid-axis Hormones, which was held in Bethesda, Maryland, in May 1982.

The volume contains over 50 papers presented at the meeting by experts in the field from Europe, New Zealand, and the United States. The subjects covered are timely from the clinical, scientific, and commercial standpoints, since they concern problems relating to standardization of these substances. Representative examples of papers presented at the Workshop are: "Production of Human Monocomponent Insulin," "Radioimmunological Determinations of Contaminants in Insulins," "Desired Characteristics of Insulins to be used in Insulin Pumps," "Structure and Function of Growth Hormones," "The Human Growth Hormone Gene Family," "Non-Isotopic Methods for Determination of Oral Thyroxine Absorption," and "Hypothalamic Peptide Hormones for Clinical Use."

For each of the three groups of hormone drugs, the proceedings include a summary presentation of current viewpoints regarding standardization with an eventual aim of precise dosage efficacy and safety. Also included is a general overview which describes potential developments in newer forms and formulations for better patient treatment.

This series of well-written papers clearly provides comprehensive information on drug and reference standards for insulins, somatropins, and thyroid-axis hormones and problems relating to the standardization of these substances. It is a valuable resource for scientists with interests in these aforementioned areas.

The subjects covered are timely from the clinical, scientific, and commercial standpoints, since they concern problems relating to standardization of these substances. Representative examples of papers presented at the Workshop are: "Production of Human Monocomponent Insulin," "Radioimmunological Determinations of Contaminants in Insulins," "Desired Characteristics of Insulins to be used in Insulin Pumps," "Structure and Function of Growth Hormones," "The Human Growth Hormone Gene Family," "Non-Isotopic Methods for Determination of Oral Thyroxine Absorption," and "Hypothalamic Peptide Hormones for Clinical Use."

For each of the three groups of hormone drugs, the proceedings include a summary presentation of current viewpoints regarding standardization with an eventual aim of precise dosage efficacy and safety. Also included is a general overview which describes potential developments in newer forms and formulations for better patient treatment.

This series of well-written papers clearly provides comprehensive information on drug and reference standards for insulins, somatropins, and thyroid-axis hormones and problems relating to the standardization of these substances. It is a valuable resource for scientists with interests in these aforementioned areas.

JOURNAL OF PHARMACEUTICAL SCIENCES

A publication of the American Pharmaceutical Association

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C. and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $75; educational institutions $75; individuals *for personal use only* $40; single copies $10. APhA and SAPhA members may subscribe to *J. Pharm. Sci.* for $20.00 per year. All foreign subscriptions add $10 for postage. Subscription rates are subject to change without notice.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., 21 Congress St., Salem, MA 01970. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

Food and Pharmacy—A Close Relationship

Ever since late 1959, when Senator Estes Kefauver launched his epochal hearings on drugs, their prices, and competition within the pharmaceutical industry, we have witnessed an ongoing Congressional fascination with the subject of drug regulation and legislation. This has been most manifest in the form of a variety of highly publicized Congressional committee hearings, chaired at various times by Senators Kefauver, Nelson, or Kennedy, and Congressmen Cellers, Harris, Rogers, or Fountain, among others.

The hearings themselves have covered the full spectrum of drug-related matters from the so-called "drug lag" to bioequivalency, from their relative prices to the adequacy of their existing test standards.

But little—in fact, *very little* congressional attention has been given to food matters, including safety and quality, during this same time period.

As a consequence, we noted with interest that the U.S. Senate Committee on Labor and Human Resources was launching a series of hearings "on the nation's food safety laws and regulations," beginning June 8, 1983.

Interestingly, with a bipartisan touch, the announcement was issued jointly by the Committee Chairman, Orrin Hatch (R-Utah), and the Ranking Minority Member, Edward M. Kennedy (D-Massachusetts). Specifically, they stated their intended thrust as follows: "The hearings will focus on two central issues: (*1*) how recent scientific and technological developments have affected food safety regulation, and (*2*) whether existing law should be revised in order to accommodate advances in science and technology."

They went on to state, "We hope to accumulate a hearing record that addresses advances in food science and toxicological testing, as well as advances in our ability to identify toxicological substances and to estimate or extrapolate the risk to humans posed by such substances."

The balance of the announcement contained strongly expressed intentions to solicit testimony from appropriately qualified scientific experts in the field, to seek the views of former Commissioners of the Food and Drug Administration as to their experiences in enforcing the existing food safety laws, and to explore the question of introducing risk–benefit judgments—based on scientific data and information—in arriving at food safety decisions.

On the surface, food-related issues might appear to be remote to pharmacy, the pharmaceutical sciences, and pharmaceutical scientists. Upon reflection, however, we quickly see that there are many factors that result in a close linkage between foods and drugs.

Historically, the preponderance of drugs and nostrums had a food origin. And certainly, the entire subject of modern-day vitamins and essential minerals is continually a gray area; are they foods or are they drugs? However we may regard them today—*i.e.*, as foods or as drugs or as both, depending on their form and potency—their initial origin was from foods and foodstuffs. And for most people, food constitutes their principal or sole source of vitamins and minerals except when deficiencies arise.

Out of Congressional recognition of the close association between the two subject areas, the first federal law was entitled the "Pure Food and Drugs Act" of 1906; subsequent legislation, including the current "Federal Food, Drug, and Cosmetic Act," as well as virtually all state laws, continue this joint legislative approach.

Similarly, the federal agency charged with administering these laws is known as the "Food and Drug Administration," and it is headed by an official with the title of "Commissioner of Foods and Drugs."

In addition to vitamins and minerals, there are numerous substances that may be regarded as either foods or drugs, depending upon intent, use, or labeling. Classic examples would include sodium chloride and sucrose; but there are many others such as FD&C coloring agents, artificial sweeteners, suspending agents, thickeners, preservatives, solvents, starch, and so on.

The celebrated controversy over the use and safety of saccharin was raised in terms of its food aspects rather than its drug aspects—although both areas were affected in actual practice. This was because the legislation under which it would have been banned is the so-called Delaney Amendment, and this amendment specifically pertains to the potential carcinogenecity of foods and food ingredients.

And there are also pharmacy-related clinical implications involving substances that are clearly foods, *per se*. For example, certain food–drug interactions may be every bit as important and critical to the patient as drug–drug interactions.

Finally, in recent years, APhA has addressed, from a scientific standpoint, the policy implications of several health care related issues directly involving foods. One of these occurred in 1979–1980, when the APhA Policy Committee on Scientific Affairs recommended a policy position on the subject of food labeling as to qualitative and quantitative information about ingredients. A second occurred in 1980–1981, when the Scientific Affairs Committee focussed more specifically on dietary salt and recommended a policy position on the establishment of federal regulations on the inclusion of salt in processed foods. Both of these recommended policy statements were subsequently adopted as formal APhA positions by the APhA House of Delegates.

Consequently, it is evident that there is far more than a casual tie between foods and pharmacy or between foods and the pharmaceutical sciences. As such, we will want to follow with appropriate interest the upcoming Congressional hearings on food safety, its regulations, and its legislation. We earnestly hope they will prove to be productive in meeting their announced objectives.

RESEARCH ARTICLES

Dose-Dependent Elimination of Propranolol and its Major Metabolites in Humans

BERNIE M. SILBER *x, NICHOLAS H. G. HOLFORD, and SIDNEY RIEGELMAN †

Received January 15, 1982, from the *Departments of Pharmaceutical Chemistry and Pharmacy, School of Pharmacy and Division of Clinical Pharmacology, Department of Medicine, School of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication July 1, 1982. *Present address: Department of Pharmaceutics, BG-20, School of Pharmacy, University of Washington, Seattle, WA 98195. †Deceased.

Abstract □ The disposition of propranolol and the formation of its major metabolites, propranolol glucuronide (I), 4-hydroxypropranolol glucuronide (II), and α-naphthoxylactic acid (III), were examined at steady state in four healthy volunteers given oral doses of 40–320 mg/day. The blood to plasma ratio of propranolol was 0.85 ± 0.11 (*SD*). In all subjects, the average steady-state concentration ($\bar{C}_{ss}$) of propranolol in plasma increased disproportionately with dose. There was a 1.8- to 2.6-fold difference in the $\bar{C}_{ss}$ between subjects, a 56 ± 20% reduction in the intrinsic clearance, and a 175% increase in the half-life of propranolol over the range of doses administered. The renal clearance was 75.4 ± 17.5 ml/min for I, 130.6 ± 28.3 ml/min for II, and 56.8 ± 13.3 ml/min for III. The formation of I was saturable in three subjects; the V_{max} and K_m were 103 ± 43 mg/day and 124 ± 46 ng/ml, respectively. In the remaining subject the nonrenal clearance of I was 496 ml/min. The formation of II and III was saturable in all subjects. The V_{max} and K_m were 71 ± 25 mg/day and 46 ± 22 ng/ml, respectively, for II and 92 ± 35 mg/day and 35 ± 24 ng/ml, respectively, for III. In each subject, the formation clearance associated with the unidentified metabolic pathway(s) (accounting for ~45% of the dose) was best described by a saturable process. The V_{max} and K_m estimated for this pathway were 212 ± 34 mg/day and 40 ± 12 ng/ml, respectively. These results suggest that the elimination of propranolol is saturable in the human at doses from 40 to 320 mg/day and can be explained only partly by saturability in the metabolic pathways resulting in the formation of I, II, and III.

Keyphrases □ Propranolol—formation of metabolites, dose-dependent elimination in humans, metabolic pathways □ Metabolites—of propranolol in humans, dose-dependent elimination, metabolic pathways □ Metabolism—of propranolol in the human, elimination, metabolic pathways

Propranolol is used extensively in the treatment of angina pectoris, hypertension, cardiac arrhythmia, and other disease states in which β-adrenergic blockade is desirable. The β-blocking activity of propranolol approaches a maximal therapeutic effect at a plasma concentration of ~80–100 ng/ml (1).

The absorption of propranolol following its oral administration is complete in the human (2); gut-wall metabolism has not been found in the dog (3). The drug has a high extraction ratio and is metabolized virtually completely in the liver (4, 5): <1% of the intact drug is found in the urine (6).

The disposition of propranolol can be affected by age (7, 8); cigarette smoking (6, 7); concomitant drug administration (9); and renal (10), hepatic (11), or thyroid disease (12–14). Pharmacokinetic studies in healthy adults and in patients with various disease states have demonstrated as much as 10- to 20-fold variation in the plasma concentrations of propranolol between individuals after oral, but not intravenous, doses of the drug (15–21). However, Walle *et al.* (22) reported only a threefold intersubject variability in peak concentrations of propranolol with doses of 40–320 mg/day and suggested that their findings resulted from careful study design, control of factors such as concomitant drug intake, and use of specific analytical procedures.

The metabolism of propranolol is complex. More than 18 metabolites have been identified (22–24), with at least four of these having pharmacological activity (25–27). Walle *et al.* (28–30) reported that at steady state, ~60% of an oral dose can be accounted for by metabolites detectable in both plasma and urine. The major metabolites are propranolol glucuronide (I), 4-hydroxypropranolol glucuronide (II), and α-naphthoxylactic acid (III). To our knowledge, no one has investigated whether the formation of these metabolites occurs by first-order or saturable processes.

Kornhauser *et al.* (31) reported an average intrinsic clearance (CL_{int}) of 2.71 liters/min for propranolol (based

0022-3549/83/0700-0725$01.00/0

Table I—Blood to Plasma Ratio (B/P) of Propranolol

Subject	Concentration of Propranolol in Blood, ng/ml 4.9	9.8	24.6	49.1	73.7	98.2	280.4	Mean ± SD

D	25	82	3.85	3.65	4.51	3.42	2.69	−30
							Mean ± SD	−56 ± 20

[a] The intrinsic clearance (CL_{int}) was calculated according to Eq. 4 as described in *Theoretical*. The dosage of propranolol given was 40, 80, 160, 240, and 320 mg/day during weeks 1, 2, 3, 4, and 5, respectively. [b] Percentage difference between weeks 1 and 5.

on whole blood concentrations) at a dose of 240 mg/day. Because urinary recovery of I, II, and III accounts for about one-half of the oral dose at steady state, the CL_{int} accounted for by these metabolites is ~1.36 liters/min. The renal clearance (CL_r) is 57 ml/min for I (30), 60 ml/min for II (29), and 37 ml/min for III (28). Therefore, the CL_{int} for each of these metabolites is much greater than their CL_r. Because the apparent volume of distribution of these metabolites is unknown, the rate constant of formation (k_f) and elimination (k_{el}) for each cannot be determined from administration of propranolol alone. However, if $k_f \gg k_{el}$ for each metabolite, the formation clearances can be determined from steady-state experiments only.

The results of several investigations suggest that an increase in the rate of propranolol dosing results in a disproportionate increase in the observed concentrations of the drug (4, 5, 22, 32). However, these results have been obtained from single-dose studies, steady-state studies spanning a narrow range of doses in a given individual, or steady-state studies employing analytical techniques having questionable specificity. No studies have examined the relationship between the average steady-state concentrations ($\bar{C}_{ss}$) of propranolol over a wide range of doses in the same individual, the variability between individuals under these conditions, or the mechanisms responsible for the nonlinear relationship between the dosing rate and $\bar{C}_{ss}$. This study was designed to examine these points in healthy adult volunteers. Urinary excretion rates of I, II, and III were measured simultaneously to identify the metabolic pathways responsible for differences between individuals.

THEORETICAL

After a sufficient number of oral doses of a drug have been given to reach steady state, the average steady-state concentration of a drug ($\bar{C}_{ss}$) can be related to the dose (D_0) by:

$$\frac{D_0}{\tau} = \frac{CL}{F} \cdot \bar{C}_{ss} \qquad \text{(Eq. 1)}$$

where CL is the systemic clearance of the drug, F is the fraction of the dose reaching the systemic circulation (bioavailability), and τ is the dosing interval. The $\bar{C}_{ss}$ can be defined by:

$$\bar{C}_{ss} = \frac{\int_{t_1}^{t_2} C(t)dt}{\tau} = \frac{AUC_0}{\tau} \qquad \text{(Eq. 2)}$$

where $C(t)$ is an expression describing concentration as a function of time (t) and AUC_0 is the area under the blood or plasma concentration time curve during one dosing interval. Therefore, $\bar{C}_{ss}$ can be estimated from the AUC_0 at steady state and τ; this does not require explicit knowledge of F even though F may change with a change in the dose.

Based on the venous equilibration model described by Rowland *et al.* (33), the intrinsic clearance (CL_{int}), which estimates the activity of the drug metabolizing enzymes in the liver, may be defined. Wilkinson and Shand (34) have shown that the apparent oral clearance (CL_o) of a drug is equivalent to CL_{int} and is defined by:

$$CL_{int} = \frac{D_0}{AUC_0} = \frac{CL}{F} \qquad \text{(Eq. 3)}$$

This relationship assumes that the drug is totally absorbed from the GI tract, that all blood containing the drug passes through the liver before reaching the systemic circulation, and that the liver accounts for all loss processes. Therefore, a change in F results from a change in the hepatic extraction of propranolol by the liver.

A basic presumption in the derivation of CL_{int} (33) is that the drug is undergoing metabolism by a first-order process. If, however, metabolism involves capacity-limited kinetics in the concentration range involved, then the CL_{int} calculated by Eq. 3 will be an average of the values over the concentration range. Substituting CL_{int} for CL/F in Eq. 1 yields:

$$\frac{D_0}{\tau} = CL_{int} \cdot \bar{C}_{ss} \qquad \text{(Eq. 4)}$$

The relationship between the dose rate and C_{ss} may be defined by a series of potential models for propranolol elimination processes symbolized by CL_{int} in Eq. 4:

$$\frac{D_0}{\tau} = f_x \cdot \sum_{i=1}^{n} dAe_{M_i}/dt \qquad \text{(Model 1)}$$

Model 1 assumes that the measured pathways (forming I, II, and III) account for all of the dose. Based on urinary recovery, these major metabolites of propranolol account for <100% of the parent drug. The term $\Sigma_{i=1}^{n} dAe_{M_i}/dt$ is the sum of metabolite formation only accounted for by urinary excretion of I, II, and III. It is possible that these metabolites are also eliminated by extrarenal routes (*e.g.*, biliary). In this model, the term f_x is a unitless number >1.0 which attempts to correct for these extrarenal losses.

$$\frac{D_0}{\tau} = CL_x \cdot \bar{C}_{ss} + \sum_{i=1}^{n} dAe_{M_i}/dt \qquad \text{(Model 2)}$$

In Model 2, the term Cl_x identifies the sum of all first-order metabolic pathways of propranolol to unknown or unidentified metabolites.

Table III—Time[a] to Peak Concentration (t_{peak}) and the Terminal Half-Life ($t_{1/2}$) at Increasing Dosing Levels of Propranolol

Table IV—Akaike Information Criterion (AIC) Calculated for Each Model Describing the Elimination Rate of Propranolol[a]

Subject	Model 1	Model 2	Model 3	Model 4	Model 5
A	187.5	177.7	174.6[b]	181.9	275.9
B	174.2[b]	177.4	176.4	177.4	230.3
C	197.9	191.6	189.6[b]	200.2	200.2
D	214.0	213.9	211.8[b]	215.6	228.2

[a] See *Data Analysis* for a description of the AIC calculation procedure. [b] Model with minimum AIC.

$$\frac{D_0}{\tau} = \frac{V_{max_x} \cdot \bar{C}_{ss}}{K_{m_x} + \bar{C}_{ss}} + \sum_{i=1}^{n} dAe_{M_i}/dt \qquad \text{(Model 3)}$$

In Model 3, the first term represents a saturable clearance pathway for unidentified metabolites with parameters V_{max_x} and K_{m_x}; added to these unidentified metabolites is the sum of the elimination accounted for by known metabolites.

$$\frac{D_0}{\tau} = CL_x \cdot \bar{C}_{ss} + f_x \cdot \sum_{i=1}^{n} dAe_{M_i}/dt \qquad \text{(Model 4)}$$

Model 4 is a combination of Models 1 and 2.

$$\frac{D_0}{\tau} = CL_x \cdot \bar{C}_{ss} + \frac{V_{max_x} \cdot \bar{C}_{ss}}{K_{m_x} + \bar{C}_{ss}} + \sum_{i=1}^{n} dAe_{M_i}/dt \qquad \text{(Model 5)}$$

Model 5 is a combination of Models 2 and 3.

The known (or measured) excretion rate for each metabolite in these models may be calculated from:

$$dAe_{M_i}/dt = \frac{V_{max,M_i} \cdot \bar{C}_{ss}}{K_{m,M_i} + \bar{C}_{ss}} \qquad \text{(Eq. 5)}$$

where V_{max,M_i} and K_{m,M_i} are parameters for each known metabolite formation pathway for propranolol. At steady state, dAe_{M_i}/dt is equal to the formation rate for that particular metabolite.

When the apparent $K_m \gg \bar{C}_{ss}$, the relationship between dAe_{M_i}/dt and $\bar{C}_{ss}$ is linear. The slope of this line is equal to the metabolic clearance for this pathway.

EXPERIMENTAL

Subjects—The subjects were four healthy adult volunteers. Informed consent was obtained, and the protocol approved by the University of California, San Francisco, Committee on Human Research. A medical history, physical examination, electrocardiogram (ECG), complete blood count with differential, urinalysis, and selected blood chemistries were completed for all subjects. There was no evidence of renal or hepatic disease in the medical history, and values of blood urea nitrogen, serum creatinine, urinalysis and urine culture, serum glutamic oxaloacetic transaminase, lactic dehydrogenase, alkaline phosphatase, bilirubin, prothrombin time, and total serum proteins were normal. All were nonsmokers and abstained from alcohol, marijuana, and other medications until completion of the study. On each of the four days per week that propranolol was taken, the subjects had their pulse and blood pressure measured, underwent a 1-min ECG, and were interviewed to determine side effects.

Propranolol Administration—All subjects were given 40, 80, 160, 240, and 320 mg/day of propranolol in divided doses over a 5-week period. Each subject took one-fourth of the daily dose every 6 hr for a total of 13 doses at each dosing rate. No dietary restrictions were imposed, but food was withheld for at least 9 hr before and 3 hr after the 13th dose.

Blood Sampling—Blood samples were obtained at the end of the 8th, 9th, and 12th dosing intervals (trough concentrations) and at 0, 15, 30, 45, 60, and 90 min and 2, 3, 4, 5, 6, 8, 10, and 12 hr following the 13th dose. Venous blood samples were obtained using an indwelling catheter[1]; patency was maintained by flushing with 1 ml of heparinized saline (10 U/ml) after obtaining each blood sample (35). It was shown that these small doses of heparin do not affect the plasma protein binding or disposition of propranolol (36). After discarding 0.5 ml of blood, a 7-ml blood sample was transferred immediately to a 16 × 150-mm polytef-lined[2] screw-cap test tube to which had been added 100 U of aqueous sodium heparin. After gentle mixing, blood samples were centrifuged at 2000 rpm (500×*g*) for 10 min. Plasma was transferred with a disposable pasteur pipet to glass screw-cap vials and stored at −20° until assay.

Urine Sampling—Urine samples were collected during the 5th, 9th, and 12th dosing intervals and at frequent times for up to 12 hr after the 13th dose each week. Urine volumes were recorded and 10 mg of (−)-ascorbic acid was added to prevent oxidation of phenolic metabolites (27); aliquots were stored at −20° until assayed.

Assay Procedures—Propranolol and 4-hydroxypropranolol concentrations were measured in plasma before and after enzymatic hydrolysis of the glucuronide conjugate[3] and in urine after enzymatic hydrolysis (37). The limits of sensitivity are 0.4 and 1.0 ng/ml, respectively. α-Naphthoxylactic acid concentration in plasma and urine were measured directly after protein precipitation by a method previously described (38).

Blood to Plasma Ratio of Propranolol—The equilibrium time for propranolol between human erythrocytes and plasma was reported to be ~5 min (39). The blood to plasma ratio (B/P) was determined over the range of measured concentrations by adding propranolol to test tubes containing 2 ml of fresh blood obtained from each individual and 100 U of heparin (to prevent clotting). After allowing each sample to stand for 2 hr (with gentle agitation every 15 min), the test tubes were centrifuged, and the plasma was measured. These measurements were compared with 2 ml of plasma containing the same amount of drug, to account for possible *in vitro* degradation of propranolol by plasma.

Data Analysis—The CL_{int} of propranolol at each C_{ss} was calculated according to Eq. 4. The AUC of propranolol, I, II, and III during the 13th dosing interval were calculated by the trapezoidal rule. The half-life of propranolol was calculated as 0.693/terminal elimination rate constant (determined by least-squares regression utilizing at least four plasma concentration time points in the log-linear region). The renal clearance (CL_r) of each metabolite was calculated as the slope of the line determined by least-squares regression of the rate of urinary excretion *versus* C_{ss} for each metabolite in plasma. The C_{ss} of propranolol and its metabolites at each dosing rate was calculated from the data obtained during the 13th dosing interval using Eq. 2.

The elimination rate models described in *Theoretical* were specified using MKMODEL (40). The predicted value for C_{ss} was calculated for each rate model using the ROOT function in MLAB (41). This function determines the value of C_{ss} that satisfies the rate model equation. The

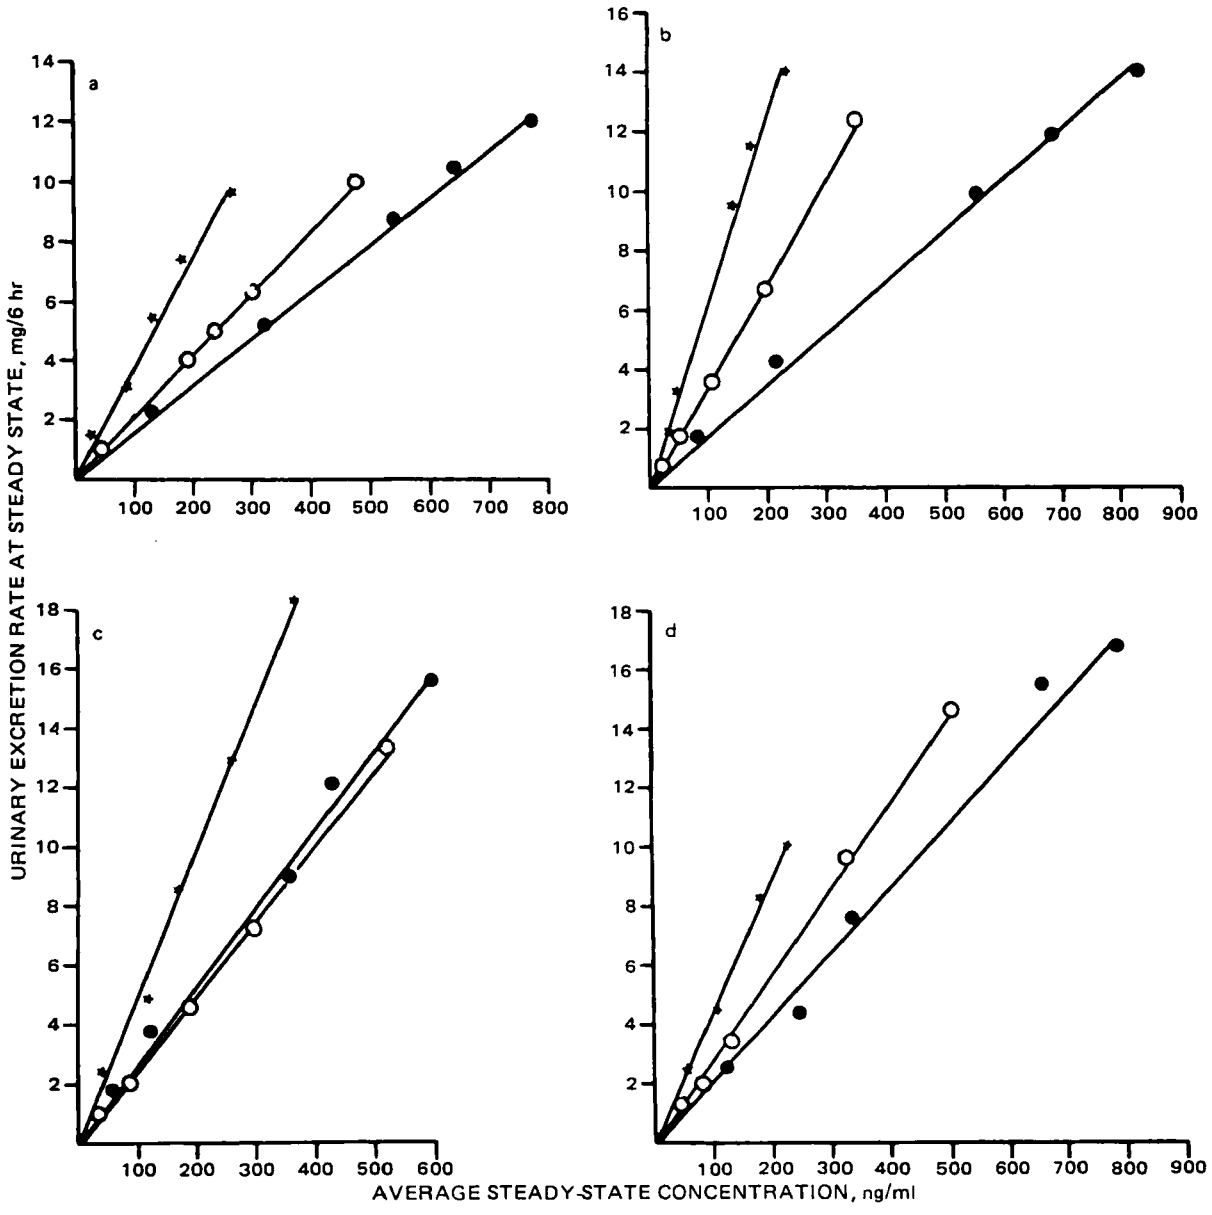

Figure 1—*Urinary excretion rate of each measured metabolite for each subject (a–d) as a function of the average steady-state concentration of the corresponding metabolite in plasma. Key: (○) propranolol glucuronide; (★) 4-hydroxypropranolol glucuronide; (●) α-naphthoxylactic acid.*

parameters of the models were estimated by simultaneous unweighted nonlinear least-squares regression (41) of the dose rate *versus* the measured C_{ss} and metabolite excretion rates.

Discrimination between the models was made with the Akaike information criterion (AIC) (42–44):

$$\text{AIC} = N \ln \text{RSQ} + 2p \qquad \text{(Eq. 6)}$$

where N is the number of observations, p is the number of parameters, and RSQ is the residual sums of squares of the observed points. The model yielding the lowest AIC value was considered to be the best representation of the experimental data for each subject.

Mean values are reported with standard deviations; differences between means were evaluated by one-way analysis of variance and the Newman-Keuls multiple-range test (45). Data anlaysis and graphical examination of the results were performed with the PROPHET (46) computer system[4].

RESULTS

Side Effects—No major adverse effects resulted from the administration of propranolol. The only side effect noted was in subject A while receiving 320 mg/day. Five hours after the 13th dose, he developed weakness and dizziness. After resting supine for 1 hr, he was able to resume his usual activities.

Validation of Steady-State Conditions—In each subject, steady-state trough concentrations were attained by the ninth dose (or less) and, once achieved, were associated with only slight interday variation.

Quantitation of 4-Hydroxypropranolol in Plasma—Because 4-hydroxypropranolol concentrations in plasma were <20 ng/ml and were ~25- to 30-fold greater after enzymatic hydrolysis, 4-hydroxypropranolol glucuronide concentrations were considered to be equivalent to the total 4-hydroxypropranolol concentration posthydrolysis.

Blood to Plasma Ratio of Propranolol—The blood to plasma ratio (B/P) of propranolol measured over the observed concentration range is shown in Table I. The B/P was independent of concentration, and only slight interindividual variability in the B/P was observed. In our subjects, the B/P was 0.85 ± 0.11.

Relationship Between the Intrinsic Clearance and the Dosing Rate of Propranolol—The CL_{int} of propranolol was determined at each of five dosing rates using Eq. 4. There was a 56 ± 20% reduction in CL_{int} on average over the eightfold range in doses (Table II).

Disposition of Propranolol During the 13th Dosing Interval—The time to peak concentration of propranolol during the 13th dosing interval ranged from 2.5 ± 1.0 to 2.8 ± 1.0 hr at doses from 40 to 320 mg/day. As

[4] A specialized resource developed by the Chemical Biological Information Handling Program of the National Institutes of Health.

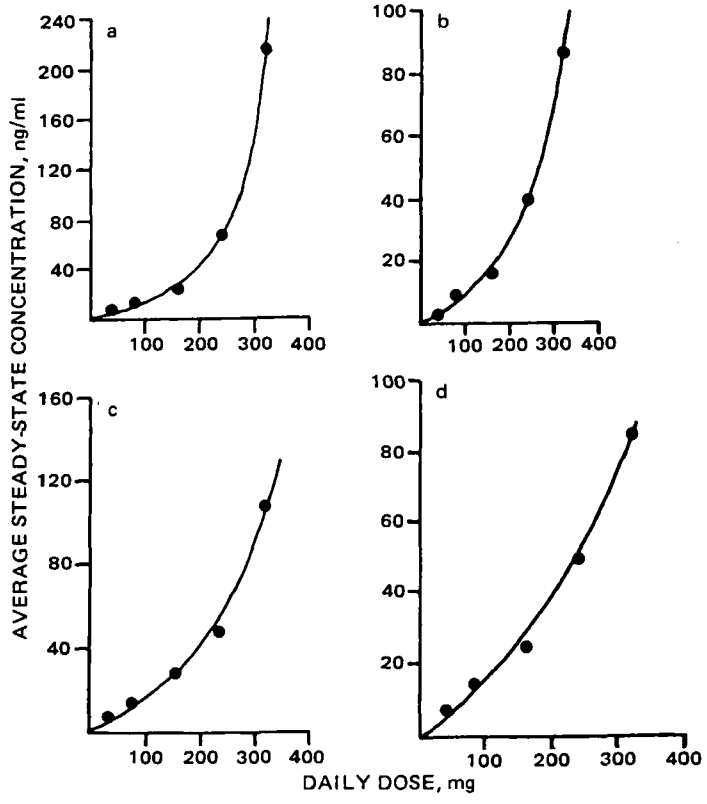

Figure 2—*Average steady-state concentration of propranolol in plasma during the 13th dosing interval at dosing rates from 40 to 320 mg/day. The line is the concentration predicted by the best elimination-rate model for each subject (a–d).*

shown in Table III, the terminal half-life of propranolol increased significantly, from 2.0 ± 0.4 to 5.5 ± 1.9 ($p < 0.05$), as the dose was increased from 40 to 320 mg/day.

Renal Clearance of Propranolol Metabolites—Less than 2% of propranolol was recovered in urine as free propranolol or 4-hydroxypropranol (unconjugated); no α-naphthoxylactic acid glucuronide was detected in the urine. There was a linear relationship between the urinary excretion rate of propranolol glucuronide (I), 4-hydroxypropranolol glucuronide (II), and α-naphthoxylactic acid (III) *versus* $\bar{C}_{ss}$ of each metabolite in plasma over the entire range of observed concentrations. The CL_r was 75.4 ± 17.5 ml/min for I, 130.6 ± 28.3 ml/min for II, and 56.8 ± 13.3 ml/min for III (Fig. 1).

Fraction of Propranolol Excreted in Urine as Propranolol Metabolites—The percentage of propranolol (on a molar basis) excreted in urine increased from 9.6 ± 2.5 to 16.2 ± 2.0 (significant at $p < 0.05$) for I, decreased from 17.7 ± 2.7 to 14.7 ± 3.3 for II, and decreased from 25.1

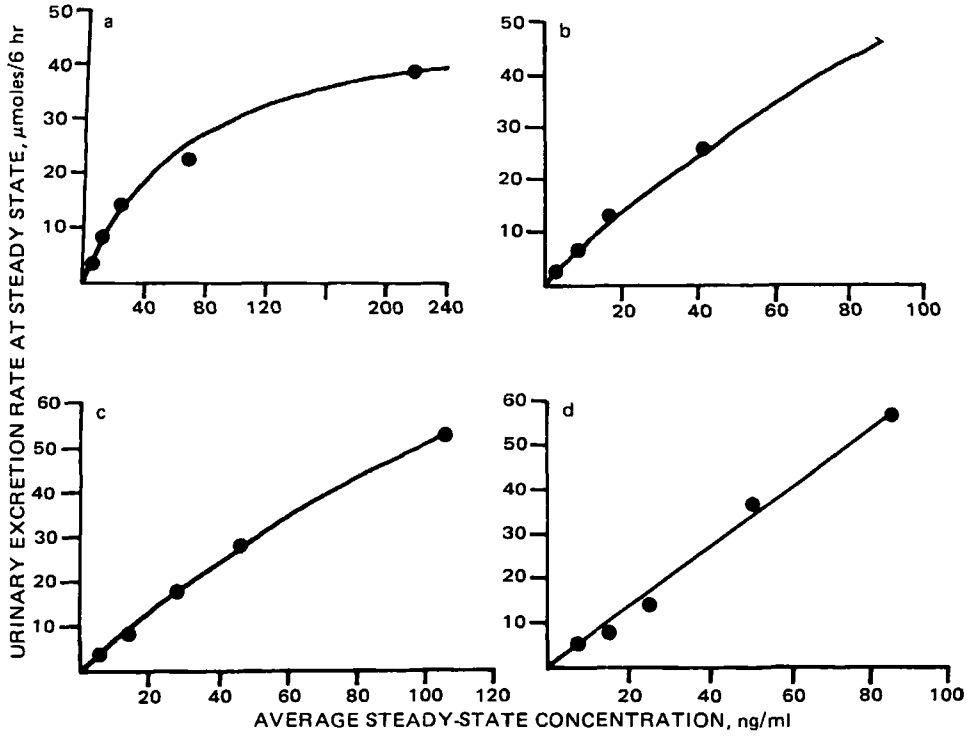

Figure 3—*Urinary excretion rate of propranolol glucuronide during the 13th dosing interval as a function of the average steady-state concentration of propranolol in plasma for each subject (a–d).*

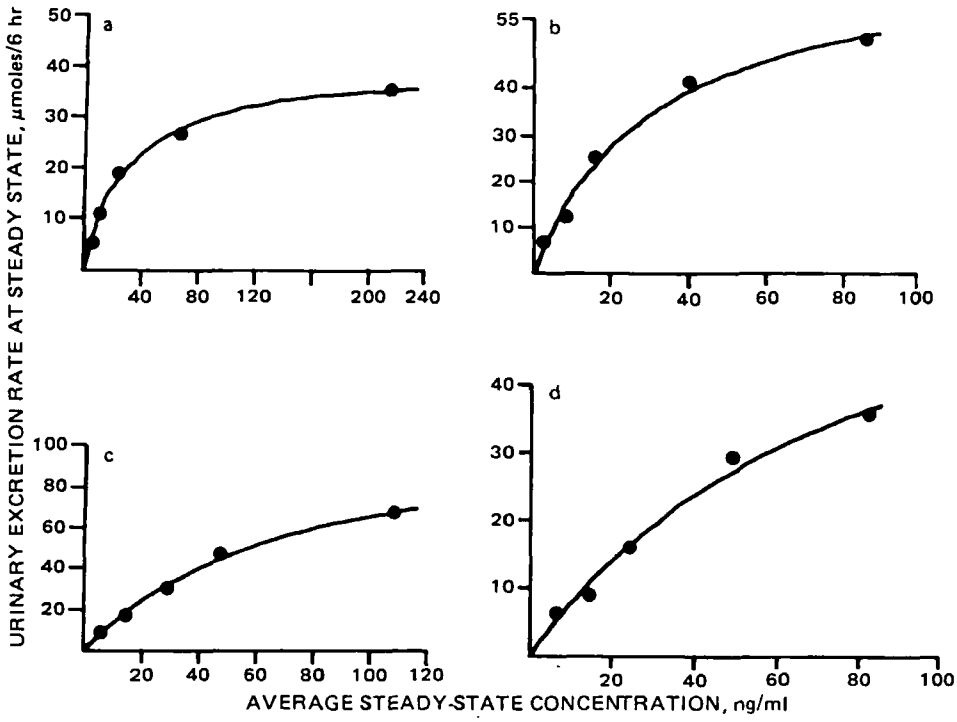

Figure 4—*Urinary excretion rate of 4-hydroxypropranolol glucuronide during the 13th dosing interval as a function of the average steady-state concentration of propranolol in plasma for each subject (a–d).*

± 3.7 to 18.6 ± 3.3 (significant at $p < 0.05$) for III as the dosing rate of propranolol was increased from 40 to 320 mg/day.

Relationship Between the $\bar{C}_{ss}$ of Propranolol and the Daily Dose—There was a disproportionate increase in the $\bar{C}_{ss}$ of propranolol as the daily dose was increased in each subject. There was a 1.8–2.6-fold difference in the $\bar{C}_{ss}$ of propranolol between subjects as the dose was increased from 40 to 320 mg/day (Fig. 2). The clearance associated with the unidentified metabolic pathway(s) was best described by a saturable (Models 1 and 3) rather than a first-order (Model 2) process (Table IV). In three subjects, the parameters of this saturable process were clearly different from those of the measured metabolites (Model 3), but in the remaining subject (B) they were indistinguishable (Model 1). These models were superior to either combination model (Models 4 and 5). The f_x-values estimated from Model 1 were 2.4, 2.0, 1.7, and 1.9 in subjects A, B, C, and D, respectively.

Formation Clearance Estimates for Known and Unknown Metabolic Pathway(s)—The formation of I was best described by a saturable process in three of four subjects (A, B, C) (Fig. 3). Using the estimates from Model 3 for all subjects, the V_{max} for propranolol glucuronide was 114 ± 51 mg/day and the K_m was 140 ± 55 ng/ml. In subject D, the apparent K_m for I was much greater than the C_{ss} of propranolol. The corresponding first-order metabolic clearance estimated from the slope of *dAe/dt versus* C_{ss} of propranolol was 496 ml/min. The formation of II and III was saturable in all four subjects over the dosing range studied (Figs. 4 and 5). The V_{max} for II was 72 ± 25 mg/day, and the K_m was 46 ± 21 ng/ml; the V_{max} for III was 92 ± 35 mg/day, and the K_m was 35 ± 234 ng/ml. The V_{max} for the unidentified metabolic pathway(s) was 212 ± 34 mg/day, and the K_m was 40 ± 12 ng/ml. These results are summarized in Table V.

DISCUSSION

The results from the present investigation demonstrate that the elimination of propranolol is nonlinear with doses of 40–320 mg/day and can be explained by capacity limitation in the major metabolic pathways that result in the formation of propranolol glucuronide (I), 4-hydroxypropranolol glucuronide (II), α-naphthoxylactic acid (III), and unidentified metabolite(s).

The 4-hydroxy metabolite of propranolol (4-hydroxypropranolol, IV) has similar β-blocking activity to the parent drug (25). Free (unconjugated) concentrations of IV reported by other workers following oral doses of propranolol have varied greatly. The ratio of IV to propranolol reported by others has ranged from 0.03 to 1.07, but was generally ~0.2 (29, 47, 48). By employing an analytical technique having a sensitivity limit for IV of ~1.0 ng/ml (37), it was found that concentrations of this metabolite were <20 ng/ml even at propranolol doses of 320 mg/day; the ratio of IV to propranolol was ~0.08. The lower ratio of IV-propranolol observed in this study relative to those by other workers may be due to differences between patients and healthy volunteers. Virtually all (>97%) of IV in the plasma was present as the glucuronide conjugate (II). Therefore, concentrations of II were estimated as the total IV concentration following enzymatic hydrolysis. Unlike propranolol, which is known to undergo conjugation at the secondary hydroxyl group on the side chain yielding an ether linkage, the specific location of the glucuronide on IV in the human is unknown; the conjugate may involve an ether or phenolic linkage, or may be a mixture of both. Fenseleau and Johnson have previously stressed that enzymatic hydrolytic techniques cannot discriminate between potential glucuronide conjugates when multiple sites of glucuronidation are possible (49).

The blood to plasma ratio (B/P) of propranolol was determined for each subject, and, in contrast to previous results (39), it was found that the B/P was unchanged over the 20–50-fold range of observed concentrations (Table I).

In the present study, the intrinsic clearance (CL_{int}) of propranolol varied from 1.8- to 2.6-fold between subjects at doses of 40 and 320 mg/day, respectively (Table II). On average, there was a 56% reduction in the CL_{int} over the eightfold range in daily doses of the drug. Makichan *et al.* (32) reported a 44% decrease in CL_{int} after doses from 10 to 80 mg, and Schneck *et al.* (4) reported a 53% decrease in CL_{int} after 160- and 320-mg doses. These results, however, were obtained from single-dose rather than steady-state experiments. Because CL_{int} is concentration dependent, estimates of its value are best obtained at steady state.

The time to peak concentration was similar, whereas the half-life of propranolol increased approximately threefold as the dose was increased from 40 to 320 mg/day (Table III). If it is assumed that the apparent volume of distribution of propranolol remains unchanged throughout the study, then the observed increase in the half-life must be due to a change in the systemic clearance.

The renal clearance (CL_r) of I, II, and III was linear over the range of observed metabolite concentrations (Fig. 1). The CL_r of II in the present study was about twice that previously reported [130 *versus* 60 ml/min (29)]; the CL_r of I and III were closer to those in previous reports [75 *versus* 57 ml/min (30), and 57 *versus* 37 ml/min (28), respectively]. Stone and Walle recently reported that the plasma concentrations of I, II, and III were ~20-fold greater in uremic patients when compared with patients having normal renal function (50). However, because the pharmacological and toxicological activities of these compounds are unknown, the clinical significance of these findings is uncertain.

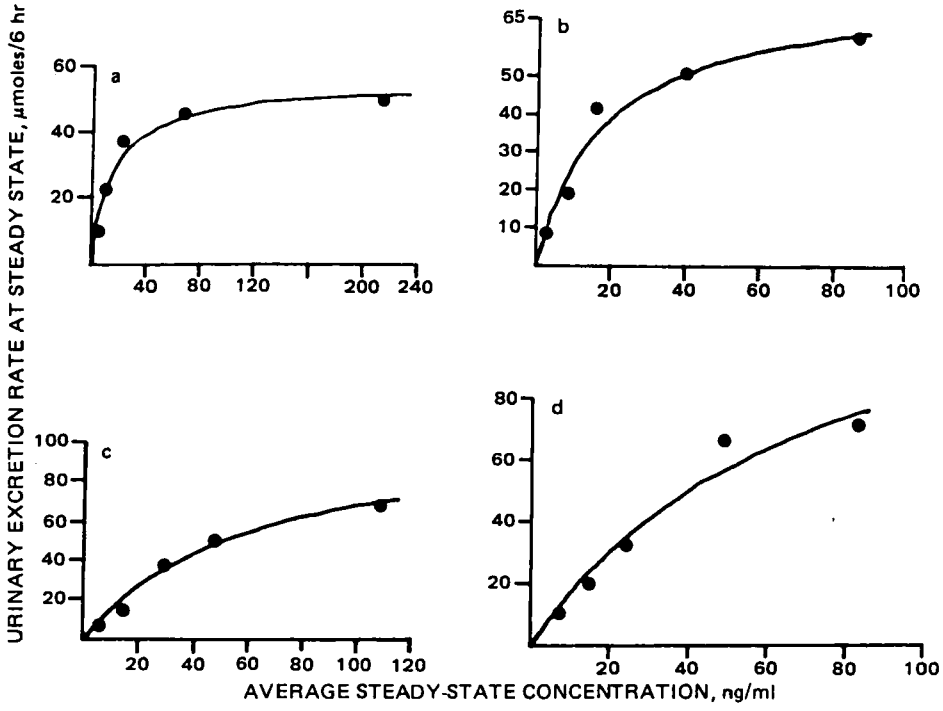

Figure 5—*Urinary excretion rate of α-naphthoxylactic acid during the 13th dosing interval as a function of the average steady-state concentration of propranolol in plasma for each subject (a–d).*

The formation of I from propranolol appeared to be saturable in three of four subjects (Fig. 3). In subject D, the metabolic clearance of I (496 ml/min) was ~6.4 times greater than its renal clearance (77.3 ml/min). Saturable glucuronidation has been reported previously for salicylamide and salicylic acid (51–53).

The V_{max} and K_m for II rather than for IV were estimated (Table V); there was essentially no free IV excreted in the urine. Therefore, saturability in the formation of II could be due either to saturation in the formation of IV from propranolol or in the formation of II from IV. If formation of IV from propranolol was a first-order process and formation of II from IV was saturable, one would expect to see disproportionate increases in IV concentrations (because it would accumulate) as the dose of propranolol was increased. That this was not observed suggests that saturability in the formation of II results from saturation in the formation of IV from propranolol.

In contrast to previous findings (28, 47), it was observed that the formation of III from propranolol was saturable (Fig. 5). However, this contention is predicated on several assumptions, because propranolol is not converted directly to this metabolite. Side-chain oxidation of propranolol first results in the formation of *N*-desisopropylpropranolol (V). Further oxidation of V yields a reactive aldehyde intermediate that can undergo either reduction to propranolol glycol or oxidation to III. In addition, III can be further oxidized to α-naphthoxyacetic acid (VI). Measurable concentrations of V, propranolol glycol (mainly as the glucuronide), and VI were detected in the urine of our subjects. As in previous studies (47), these metabolites accounted for <2% of the dose. Lo observed a similar urinary excretion profile for propranolol metabolism in the dog, but found significant concentrations of propranolol glycol (as the glucuronide) in the bile (3). Because only trace amounts of V, propranolol glycol (glucuronide), and VI are excreted in the urine at steady state (whereas up to 25% of propranolol can be accounted for as III), saturability in the formation of III is probably a reflection of the primary metabolic step in the *N*-dealkylation of propranolol to V. However, the value of V_{max} estimated for III is probably an underestimate of the total V_{max} for this metabolic pathway, since it is likely that other unidentified metabolism *via* this pathway is occurring and not being detected in the urine.

Elimination Models 1 and 3 adequately described the urinary excretion of the three measured metabolites in all individuals (Table IV). There was, however, a consistent underestimation of C_{ss} at the 40- and 80-mg dose rates in each individual (Fig. 2). This error was small (5% of C_{ss}) and does not detract from the overall ability of these models to describe C_{ss}

Table V—Estimated Michaelis–Menten Parameters for Propranolol Metabolism [a]

Subject	Propranolol Metabolite			
	Propranolol Glucuronide	4-Hydroxy-propranolol Glucuronide	α-Naphthoxylactic Acid	Unidentified Metabolic/ Pathway(s)
	V_{max}, mg/day			
A	55	41	56	230
B	142	72	77	205
C	146	101	99	167
D	4,577	72	137	244
Mean	114[b]	72	92	212
(*SD*)	(51)	(25)	(35)	(34)
	K_m, ng/ml			
A	76	29	14	45
B	175	31	18	28
C	168	51	43	33
D	6,297	74	63	55
Mean	140[b]	46	35	40
(*SD*)	(55)	(21)	(23)	(12)

[a] All values of V_{max} and K_m were estimated from Model 3. [b] Excludes values from subject D. Since the apparent K_m for propranolol glucuronide for subject D was much greater than C_{ss}, a metabolic clearance for this pathway of 496 ml/min was estimated from the slope of dAe/dt *versus* C_{ss}.

and metabolite excretion over a wide range of doses. However, it does suggest the existence of some time-related change in one or more clearance pathways. There was no evidence of a first-order elimination process for propranolol distinguishable from the saturable pathways.

To obtain a relationship between the C_{ss} of propranolol and the dosing rate (D_0/τ) using Eq. 4, the fraction of the dose not explained by measurement of I, II, and III had to be accounted for. The metabolic pathway(s) responsible for the formation of these unidentified metabolites was best described by a saturable rather than a first-order process. This may reflect either elimination of I, II, and III by routes other than in urine or in the formation of metabolites not measured (*e.g.*, propranolol glycol glucuronide in bile). The improved fit of Model 3 compared with Model 1 in three of four subjects supports the latter explanation.

The finding of saturable propranolol elimination in each individual studied suggests that clinicians should not presume linear pharmacokinetics when dosing patients with propranolol. It should be anticipated, therefore, that dosage increases may result in disproportionate increases in the plasma concentration of the drug. Although a 2.6-fold variation in the C_{ss} of propranolol between individuals was observed (Fig. 2), there was up to a fourfold difference in K_m for the various metabolic pathways (Table V). This latter finding may be of particular importance if one or more metabolites arising from the various metabolic pathways contribute to the clinical effects of propranolol.

Microbial Transformations of Pergolide to Pergolide Sulfoxide and Pergolide Sulfone

ROBERT V. SMITH *x, PATRICK J. DAVIS ‡, and KATHLEEN M. KERR ‡

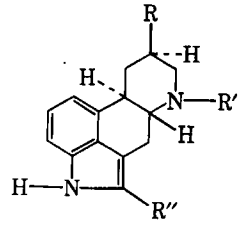
Received February 22, 1982, from the *Drug Dynamics Institute and ‡Division of Medicinal and Natural Products Chemistry, College of Pharmacy, University of Texas at Austin, Austin, TX 78712. Accepted for publication June 22, 1982.

Abstract □ Fifty-eight microorganisms were investigated for their ability to effect the biotransformation of the ergoline alkaloid pergolide. A majority of these organisms formed pergolide sulfoxide, and a *Helminthosporium* species was investigated in greater detail since it yielded significant amounts of pergolide sulfoxide. A preparative-scale transformation afforded material which was identified as the sulfoxide based on melting point, spectral, and chromatographic comparison with authentic material as well as its conversion to pergolide by reduction with triphenylphosphine. An analytical high-performance liquid chromatographic determination of the enzymatic *versus* spontaneous air-oxidation of pergolide in growing cultures and controls showed negligible air-oxidation and an ~40% enzymatic conversion of pergolide to the sulfoxide. Several organisms, including *Aspergillus alliaceus* formed a second metabolite, pergolide sulfone, which was identified on the basis of cochromatographic data.

Keyphrases □ Pergolide—sulfoxide and sulfone metabolites, biotransformation in 58 microorganisms, identification by preparative-scale TLC and high-performance liquid chromatography □ TLC, preparative-scale—of pergolide and its sulfoxide and sulfone metabolites, following microbial transformation □ High-performance liquid chromatography—of pergolide and its sulfoxide and sulfone metabolites, following microbial transformation

The dopaminergic properties of ergoline alkaloids are responsible for their use in the treatment of prolactin-dependent disorders such as galactorrhea and amenorrhea, hyperprolactinemic anovulation, prolactin-dependent breast cancers, and other dopaminergic disorders such as acromegaly and Parkinson's disease (1–8). Ergoline derivatives such as bromocriptine and lergotrile are potential inhibitors of prolactin secretion (9, 10), and bromocriptine also may be useful therapeutically in combination with levodopa for the management of "on–off" reactions in parkinsonism (11). At dose levels needed to treat this disease, however, heptatotoxicity has been observed with lergotrile (11), which has led to the disruption of clinical trials.

As a result of studies undertaken to define the structural requirements necessary for prolactin inhibition and to develop more selective dopaminergic agents for the treatment of hyperprolactinemic states and Parkinson's disease (12–14), a semisynthetic ergoline, pergolide (I), was investigated and found to be one of the most potent dopamine agonists *in vitro* and *in vivo* (15–17). Clinical investigations of I in the treatment of galactorrhea and amenorrhea (18) indicated that I was a more potent prolactin inhibitor than previously studied ergolines, and that it had a longer duration of action with more tolerable side effects. Pergolide also has shown marked advantages compared with bromocriptine and lergotrile, either alone or in combination with levodopa, in the treatment of Parkinson's disease (19).



I: R = CH_2SCH_3, R′ = $CH_2CH_2CH_3$, R″ = H

II: R = $CH_2S(O)CH_3$, R′ = $CH_2CH_2CH_3$, R″ = H

III: R = $CH_2S(O_2)CH_3$, R′ = $CH_2CH_2CH_3$, R″ = H

IV: R = $CH_2C{\equiv}N$, R′ = CH_3, R″ = Cl

Two metabolites of I, pergolide sulfoxide (II) and pergolide sulfone (III), have been reported in mammalian systems[1]. Using the rationale of "microbial models of mammalian metabolism" (20, 21), a study was undertaken to identify microorganisms which form the two metabolites found in mammalian species. The present report describes the investigation of 58 microorganisms for their ability to effect the biotransformation of I, the preparative-scale conversion and identification of the metabolite pergolide sulfoxide (II) from *Helminthosporium* species NRRL 4671 cultures, the identification of pergolide sulfone (III) in *Aspergillus alliaceus* UI 315 cultures, and the high-performance liquid chromatographic (HPLC) determination of the enzymatic *versus* spontaneous air-oxidation of I to II from growing cultures and controls.

EXPERIMENTAL

Materials—Pergolide mesylate[2], pergolide sulfoxide[2], and lergotrile mesylate[2] (internal standard) were used without further purification. Water for use in the HPLC was deionized and double-distilled in glass; acetonitrile[3] was HPLC grade. The mobile phase was prepared by the filtration of individual components[4], mixing, and deaerating prior to use. All other solvents and reagents were analytical reagent quality or better. All extraction tubes, vials, and stage-2 Erlenmeyer flasks used in the analytical studies were silylated using 2% trimethylchlorosilane[5] in toluene and were rinsed prior to use.

Analytical Methods—Analytical TLC was performed with silica gel plates[6] or aluminum oxide plates[7] in the following TLC systems: (*a*) silica gel developed in chloroform–methanol–acetone–28% ammonium hydroxide (63:7:27:2), (*b*) silica gel developed in chloroform–methanol–glacial acetic acid (13:6:1), (*c*) aluminum oxide developed in acetone, and (*d*) aluminum oxide developed in toluene–morpholine (18:2). Under these conditions, the following R_f values were observed: I (*a*) 0.81, (*b*) 0.91, (*c*) 0.95, and (*d*) 0.63; II (*a*) 0.54, (*b*) 0.44, (*c*) 0.52, and (*d*) 0.20; and III (*a*)

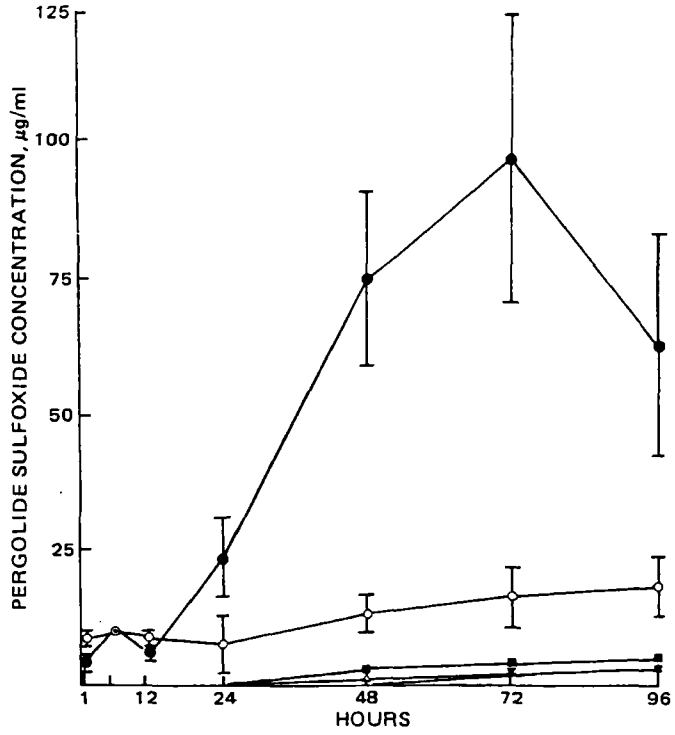

Figure 1—*Enzymatic* versus *spontaneous air-oxidation of pergolide measured by HPLC in live* Helminthosporium *species NRRL 4671 cultures (●) and in controls consisting of autoclaved* Helminthosporium *species culture (○) and phosphate buffers at pH 4 (■), pH 7 (△), and pH 11 (▼). Determinations were made in triplicate; bars represent the* SD *of each mean value.*

0.70, (*b*) 0.71, (*c*) 0.92, and (*d*) 0.39. Plates were visualized under UV light (254 nm) and sprayed with either Van Urks–Salkowski (modified) reagent for indoles (22), or Gibb's (23) and Pauly's (20) reagents in anticipation of hydroxylated metabolites (24). Screening experiments were monitored with TLC system *a*, and co-chromatography of the metabolites II and III with the standard materials was performed using all four TLC systems.

All analytical HPLC analyses were conducted as described previously (25) using an octadecyl reverse-phase 10-μm 3.9 × 300-mm column[8]. The mobile phase consisted of acetonitrile–0.01 *M* ammonium carbonate buffer pH 8.4 (3.75:2); the flow rate was 2 ml/min. Under these conditions, retention times were as follows: I, 6.74 min, II, 3.22 min, III, 2.31 min, and lergotrile (internal standard), 2.42 min. Preparative HPLC was run using an octadecyl reverse-phase, 10-μm, 8 × 500-mm column[9]. The mobile phase was the same as above but used at 3 ml/min. Under these conditions, retention times were as follows: II, 11.98 min and III, 9.49 min.

Mass spectra[10] (MS) gave the following results: I, *m/z* (% relative abundance), 314 (100), 299 (20), 285 (65), 267 (30); II (synthetic material and metabolite), *m/z* (% relative abundance), 330 (25), 315 (15), 313 (100), 301 (10), 267 (35); and III (synthetic material only), *m/z* (% relative abundance), 346 (100), 330 (3), 317 (89), 267 (22). ^{1}H-NMR spectra were recorded on a 100-MHz[11], or a 200-MHz spectrometer[12] using tetramethylsilane as the internal standard: I, δ(ppm) (deuterochloroform), 2.16 [3, s, $-SCH_3$], 6.80–7.22 [4, aromatic protons], 7.95 [1, broad s, NH]; II (synthetic material and metabolite), δ(ppm) (deuterochloroform), 2.64 and 2.63 [3, 2s, $-SOCH_3$], 6.80–7.22 [4, aromatic protons], 8.16 [1, broad s, NH]; and III (synthetic), δ(ppm) (deuterochloroform), 3.00 [3, s, $-SO_2CH_3$], 6.8–7.2 [4, aromatic protons], 7.91 [1, broad s, NH]. Melting points for I (212.7–216.8°) and II (174.0–177.0°) were determined with a Fisher digital melting point analyzer[13] at a rate of 2°/min and are uncorrected.

General Fermentation Conditions—All microorganisms were maintained on refrigerated (4°) slants of either Sabouraud-maltose agar[14], mycophyl agar[15], or ATCC medium 5 sporulation agar[14] and were transferred every 6 months to maintain viability. Incubations were performed in a two-stage fermentation procedure with soybean–dextrose medium (26). Appropriate substrates (I or II) were added to 24-hr stage-2 flasks. Portions (2 ml) were removed at 1, 2, 3, 6, and 10 days and extracted as described previously (26).

Preparative-Scale Production of Pergolide Sulfoxide (II) with *Helminthosporium* Species NRRL 4671—Six milliliters of stage-1 growth was used to inoculate each of six 250-ml stage-2 Erlenmeyer flasks containing 50 ml of soybean–dextrose medium (300 ml total), which were incubated at 27°, 250 rpm, for 24 hr. A total of 75 mg of pergolide mesylate was dissolved in 6 ml of sterile water and aseptically distributed among the flasks (0.25 mg/ml). After 5 days, the cultures were combined and homogenized, adjusted to pH 8.5 with an equal volume of 0.1 *M* sodium carbonate–sodium bicarbonate buffer (pH 8.5), and exhaustively extracted with ethyl acetate in a separatory funnel. The ethyl acetate extracts were combined, concentrated *in vacuo*, and partitioned against 0.05 *N* HCl. The acidic, aqueous extract was adjusted to pH 9 with 1 *N* NaOH and partitioned against ethyl acetate. The final ethyl acetate extracts were combined, concentrated *in vacuo* (520 mg), and chromatographed using preparative-scale TLC plates[16]. After development in TLC system *a* (*Analytical Methods*), the band representing II was scraped from the plate and eluted in a glass column with ethanol to remove the metabolite (46.2 mg). Compound II was recrystallized from ethanol (16.7 mg).

Triphenylphosphine Reduction of Pergolide Sulfoxide (II)—Following the procedure of Castrillon and Szmant (27), 1 mg of II was dissolved in 5.0 ml of carbon tetrachloride in a 1-ml conically tipped and capped vial[17]. Two equivalents of triphenylphosphine (1.66 mg) were added to the vial and the mixture was heated (90°) for 3 hr in a metal heating mantle[18]. After being concentrated under a nitrogen stream, the reaction mixture was analyzed by TLC and HPLC.

Peracid Oxidation of Pergolide (I) to Pergolide Sulfoxide (II)—Following the procedure of Curci and Modena (28), 5 mg of I was dissolved in 10 ml of 0.01 *N* HCl–ethanol (50:50); 2.7 mg of *m*-chloroperbenzoic acid (1 equivalent) was added and the reaction was allowed to proceed at room temperature. After a perioid of 4 hr, the ethanol was removed under a nitrogen stream, the mixture was adjusted to pH 9 with 1 *N* NaOH, and then extracted with ethyl acetate. The ethyl acetate extract was concentrated *in vacuo* to yield an oil which was analyzed by TLC and HPLC.

Peracid Oxidation of Pergolide (I) to Pergolide Sulfone (III)—Compound I (50 mg) and *m*-chloroperbenzoic acid (27 mg) were dissolved in 25 ml of 0.01 *N* HCl–methanol (50:50). After 24 hr, additional peracid (29.7 mg, 1 equivalent plus 10%) was added to the flask, and the reaction was allowed to proceed at 27° for 4 days. The products were extracted as described above and concentrated under a nitrogen stream. The resulting syrup was dissolved in 2 ml of mobile phase, and III was isolated by preparative HPLC, concentrated *in vacuo*, and purified by preparative-scale TLC (8.1 mg, oil) as described above for II.

Determination of the Enzymatic *versus* Spontaneous Air-Oxidation of Pergolide (I) by *Helminthosporium* species NRRL 4671—A 2-ml portion of a stage-1 culture of *Helminthosporium* species NRRL 4671 was used to inoculate each of seven stage-2 cultures which were generated in silylated 125-ml culture flasks[19] containing 22 ml of medium. After incubating at 27° for 24 hr using a gyrorotary shaker[20] at 250 rpm, three of the cultures were autoclaved. Compound I (6.25 mg) in 1 ml of sterile water–ethanol (95:5) was added to each of the autoclaved and three of the live cultures. No substrate was added to the seventh flask to serve as a control for HPLC analyses. Triplicate control incubations were also conducted for I in 25 ml of autoclaved 0.1 *M* potassium phosphate buffer at pH 3, pH 7, and pH 11. A stock solution of the internal standard, lergotrile (IV) (1 mg/ml of methanol), was prepared; a 100-μl portion was placed in all extraction tubes, and the solvent was removed under a nitrogen stream. Two-milliliter portions of incubation samples were removed at 1, 6, 12, 24, 48, 72, and 96 hr; these were extracted and analyzed by HPLC as described previously (25). Results were expressed as amount of II produced (Fig. 1).

[a] Key: (ATCC) American Type Culture Collection, Rockville, Md.; (NRRL) Northern Regional Research Laboratories, Peoria, Ill.; (QM) Quartermaster Collection, Mycological Services, Amherst, Mass.; (UI) College of Pharmacy, University of Iowa, Iowa City, Iowa; (Abushanab) received from Dr. E. Abushanab, University of Rhode Island, Kingston, R.I.; (Ziffer) received from Dr. H. Ziffer, National Institute of Arthritis, Metabolism and Digestive Diseases, Bethesda, Md. [b] These microorganisms formed both pergolide sulfoxide (II) and pergolide sulfone (III).

Determination of the Enzymatic *versus* Spontaneous Air-Oxidation of Pergolide Sulfoxide (II) to Pergolide Sulfone (III) by *Aspergillus alliaceus* UI 315—A 2-ml portion of the stage-1 culture of *Aspergillus alliaceus* UI 315 was used to inoculate each of three stage-2 culture flasks containing 25 ml of medium. After incubating at 27° for 24 hr using a gyrorotary shaker at 250 rpm, one of the cultures was autoclaved. Compound II (6.25 mg) in 1 ml of sterile water–ethanol (95:5) was added to the autoclaved and live cultures and to sterile media used as a control. A fourth culture (without added substrate) served as a control in the TLC analyses. Two-milliliter portions of incubation samples were removed at 1, 2, 3, 6, and 10 days, extracted, and analyzed by TLC system *a*.

RESULTS AND DISCUSSION

The metabolism of many xenobiotics by microorganisms parallels their metabolism in mammalian systems. The observation that xenobiotics are modified chemically in a highly selective way by microorganisms (29) has formed the basis for studies of microbial models of mammalian metabolism (20, 21). A desire to produce sufficient quantities of metabolites of the ergoline pergolide (I) for biological evaluation prompted us to examine 58 microorganisms for their ability to effect the biotransformation of I (Table I). These microorganisms were chosen based on their reported ability to catalyze oxidations of sulfur or affect indole hydroxylations (30–34). A majority of the microorganisms investigated formed pergolide sulfoxide (II), a known mammalian metabolite; several (*A. alliaceus* UI 315, *Aspergillus niger* ATCC 16888, *Calonectria decora* ATCC 14767, and all *Cunninghamella echinulata* strains) formed another known metabolite, pergolide sulfone (III), in addition to II. Additional studies were performed with *Helminthosporium* species NNRL 4671, since it yielded significant amounts of II from I. *A. alliaceus* UI 315 was employed to study the formation of III.

A preparative-scale incubation of I with the *Helminthosporium* species allowed the identification of the major metabolite, II, based on the MS and ^{1}H-NMR spectral data. The melting point of the metabolite was identical to authentic sulfoxide and did not change during mixed melting point determinations. The products of the triphenylphosphine reduction of II and the peracid oxidation of I were cochromatographed with I and II, respectively, in TLC system *a* and by HPLC. Cochromatography of the metabolite with authentic sulfoxide in four TLC systems provided additional evidence of its identity. Characterization of III was based on cochromatography of this metabolite obtained from *A. alliaceus* microbial extracts with synthetic III in all four TLC systems and by its HPLC retention time.

Verification that III was formed enzymatically was accomplished through an analytical experiment in which II was incubated with *A. alliaceus* cultures. The formation of III and I in active cultures, as determined by TLC, indicated that III formed from I *via* the sulfoxide. The fact that sulfide oxidation was reversible and that III did not form in control incubations supports enzyme-mediated reactions.

The problem of the air-oxidation of I to II necessitated a study of the enzymatic *versus* spontaneous air-oxidation of I. HPLC was chosen as the method of analysis based on its demonstrated utility in the rapid analysis of microbial extracts (35). This experiment (Fig. 1) illustrated the large difference between the enzymatic (40%) oxidation of I by *Helminthosporium* species and the maximum spontaneous air-oxidation (6%) of the drug. The substrate, I, was converted maximally after 48 hr, and there were no significant differences (*F* test) in product formation during subsequent time periods.

The utility of the microbial production of pergolide metabolites for biological evaluation was varied. The apparently low yield in the transformation of I to III by *A. alliaceus* makes the chemical preparation of this compound a more viable procedure. There are many examples of the stereoselective formation of sulfoxides by microorganisms (36). However, only minor (if any) stereoselectivity in the formation of one pergolide sulfoxide diastereomer by *Helminthosporium* species was suggested from ^{1}H-NMR data (diastereomeric thiomethyl signals). Other organisms producing the sulfoxide might be examined for a higher degree of stereoselectivity.

In summary, an investigation of 58 microorganisms for their ability to effect the biotransformation of the semisynthetic ergoline alkaloid, pergolide, indicated that a majority produced the known mammalian metabolite pergolide sulfoxide (II), and that several microorganisms formed a second mammalian metabolite, pergolide sulfone (III), in addition to II. These results further support the concept of microbial models of mammalian metabolism.

Stereospecific Radioimmunoassays for *l*-Ephedrine and *d*-Ephedrine in Human Plasma

K. K. MIDHA ˣ, J. W. HUBBARD, J. K. COOPER, and C. MACKONKA

Received December 28, 1981, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N 0W0.* Accepted for publication June 10, 1982.

Abstract □ Haptens were prepared by the reaction of *d*-ephedrine or *l*-ephedrine with methyl acrylate and subsequent alkaline hydrolysis of the methyl ester groups. The haptens were coupled to bovine serum albumin by a mixed anhydride method, and the resulting drug–protein conjugates were used to immunize rabbits. Antiserum raised to these conjugates were highly stereospecific. Neither antiserum cross-reacted with the optical antipode of its substrate nor with racemic pseudoephedrine. Separate radioimmunoassays (RIAs), developed for *d*-ephedrine and *l*-ephedrine, were used to measure the concentrations of the enantiomers of ephedrine in the blood of two volunteers dosed with racemic ephedrine. The RIAs were validated by comparing the sum of the concentrations of the enantiomers, determined by RIA, with total ephedrine concentrations determined by a nonstereoselective GLC–ECD method.

Keyphrases □ Ephedrine—stereospecific radioimmunoassay using (*d*) and (*l*) antisera □ Radioimmunoassay—for *d*- and *l*-ephedrine, stereospecific □ Antisera—for *d*- and *l*-ephedrine, cross-reactivity, use in stereospecific radioimmunoassays

2-Methylamino-1-phenylpropanol has two chiral centers which give rise to four optical isomers. Racemic ephedrine is a mixture of the erythro pair of diastereomers (*l*), (1*R*,2*S*) and (*d*), (1*S*,2*R*), while the threo pair of diastereomers, (*l*), (1*S*,2*S*) and (*d*), (1*R*,2*R*) is called pseudoephedrine (1, 2). The four optical isomers differ from each other in their pharmacological activities (3–7) and rates of metabolism (8–13).

Preparations containing *l*- or *dl*-ephedrine are used for a wide variety of therapeutic applications, such as the treatment of nasal congestion in colds and allergic rhinitis, the treatment of orthostatic hypotension, as mydriatics, and as prophylactics against asthma attacks, urinary incontinence, and motion sickness (14). Of the published analytical methods for ephedrine (15–21), only GLC–ECD (22, 23) and GLC–MS (24) are applicable to the measurement of therapeutic concentrations in plasma; none of the methods distinguish between the enantiomers of ephedrine. Recently however, Findlay *et al.* (25) developed a stereospecific radioimmunoassay (RIA) for *d*-pseudoephedrine. This paper describes the development of separate RIAs for *l*-ephedrine and *d*-ephedrine and their validation by comparison with a GLC–ECD method.

Table I—Cross-Reactions of Ephedrine Antisera

Compound	Cross-Reaction, % *d*-Ephedrine Antiserum	*l*-Ephedrine Antiserum
l-Ephedrine	<2	100
d-Ephedrine	100	<2
dl-Pseudoephedrine	<1	<1
dl-Norephedrine	0	<1
dl-*p*-Hydroxyephedrine	0	0

EXPERIMENTAL

Preparation of Drug–Protein Conjugates—*N*-(2-carboxyethyl) derivatives of both *d*- and *l*-ephedrine[1] were prepared by the treatment of *d*- and *l*-ephedrine with methyl acrylate[2], followed by the subsequent mild alkaline hydrolysis of the resulting methyl esters as described previously (26, 27). The purity of the haptens was established by GLC–FID[3] examination of the appropriate methyl esters prepared by reaction of the carboxylic acids with diazomethane[4]. Each chromatogram contained a single peak which had the same retention time (3.2 min) as the methyl esters obtained directly by the reaction of the ephedrine enantiomers with methyl acrylate. Thus, it was concluded that the haptens were free from reaction side products or other extraneous materials which might couple to carrier-antigen and subsequently compromise the specificity of the antisera. The chemical structures of the haptens (Fig. 1) were confirmed by direct probe mass spectrometry[5].

The haptens were coupled to bovine serum albumin by a modified mixed anhydride method (26). The solutions were dialyzed[6] against bicarbonate buffer (0.042 *M*, pH 8.0, 6 × 500 ml) and then against acetate buffer (0.012 *M*, pH 4.0, 6 × 500 ml). Both buffer systems contained 0.2% sodium azide[2]. After lyophilization[7], the *d*- and *l*-ephedrine–protein conjugates were obtained as white crystalline solids. The numbers of hapten residues per mole of bovine serum albumin, calculated by the isotope dilution technique, were 17 for *d*-ephedrine–protein conjugate and 21 for *l*-ephedrine–protein conjugate.

Immunization—The hapten–protein conjugates (1 mg) were dissolved in 0.25 ml of normal saline and emulsified with 0.25 ml of Freund's complete adjuvant[8]. The emulsion was administered by intradermal injection (0.5 ml) to eight, 4-month-old, female New Zealand White rabbits. At 2-week intervals thereafter, the injections (0.5 ml) were repeated with a similar emulsion prepared with Freund's incomplete adjuvant. Serum samples were obtained from the marginal ear vein at weekly intervals after the third injection. Titers of the antisera were checked by evaluating the binding characteristics of tritiated *dl*-ephedrine[9]. The procedure was essentially as described in *Radioimmunoassay Procedures*, except that various dilutions of the antisera in distilled water were evaluated. Selectivities of the antisera were checked periodically by measuring the ability of *d*- or *l*-ephedrine to displace the radiotracer from its binding sites on the antibodies. The antisera were harvested by cardiac puncture when their selectivities were optimal, lyophilized[7], and stored at −70° until required.

Radioimmunoassay Procedures—A 50–200-μl aliquot of plasma, spiked or from volunteers dosed with *dl*-ephedrine, was transferred to the bottom of a 2 × 75-mm tube[10]. [^{3}H]*dl*-Ephedrine (~2000 cpm) in 300 μl of phosphate buffer (0.2 *M*, pH 6.5) was added, and the solutions were mixed[11]. Antiserum (200 μl of a 10% dilution in distilled water) was added, and the solutions were mixed[11] again and incubated at 4° for 30 min. A suspension (1.0 ml) of dextran-coated charcoal[12], previously chilled to 4°, was added and, after mixing[11], each tube was incubated at 4° for an additional 10 min. The resulting suspension was then centrifuged[13] (1720 × *g*) at 4° for 10 min. The supernatant solution was decanted into a scintillation vial containing 18.0 ml of scintillation cocktail[14] and counted[15].

Table II—Concentrations of Ephedrine as Determined by GLC and as Calculated from the Sum of Enantiomer Concentrations Determined by RIA

Hours	Analysis by RIA		Total Concentration, ng/ml	
	l-Ephedrine, ng/ml	*d*-Ephedrine, ng/ml	RIA	GLC
0.5	77	80	157	164
1	103	125	228	256
1.5	100	119	219	223
2	95	106	201	210
3	82	93	175	190
5	61	68	129	117
7.5	43	42	85	82
24	3.7	3.4	7.1	7.4

Tracer Solutions—Appropriate aliquots of the methanolic solution of tritiated *dl*-ephedrine were diluted daily with phosphate buffer (0.2 *M*, pH 6.5) so that 300 μl of the diluted tracer solution gave ~8000 cpm.

Calibration Curves—*l*-Ephedrine hydrochloride (5 mg) was dissolved in 400 ml of distilled water. Serial dilutions in plasma were made to provide working standards of 2.5, 5.0, 7.5, 10, and 15 ng/ml. Similarly, serial dilutions of *d*-ephedrine in plasma were made to provide working standards of 2.5, 5.0, 10, 15, and 20 ng/ml. Calibration curves for *l*-ephedrine, both with and without the presence of *d*-ephedrine, were obtained by using the spiked plasma samples in the aforementioned RIA procedure (antiserum for *l*-ephedrine). The calibration curves for *l*-ephedrine in the presence of *d*-ephedrine were constructed by pairing a specified concentration of *l*-ephedrine with *d*-ephedrine. The paired *l*-ephedrine–*d*-ephedrine concentrations were 2.5:20.0, 5.0:15.0, 7.5:10.0, 10.0:5.0, and 15.0:2.5 ng/ml of plasma.

Calibration curves for *d*-ephedrine, both with and without the presence of *l*-ephedrine, were obtained in a similar manner except that the antiserum for *d*-ephedrine was used in the RIA. All calibration curves were constructed by plotting percent bound/percent bound at zero concentration (B/B_0) *versus* concentration (in ng/ml) of substrate in the sample.

Specificities—Cross-reactivities of the optical isomers and metabolites of ephedrine were determined according to the criteria of Abraham (28).

Human Studies—Single doses of *dl*-ephedrine hydrochloride (50 mg) were administered to each of two healthy male volunteers. Blood samples were collected in evacuated heparinized collection tubes[16], without allowing the blood to contact the rubber stopper. Samples collected over a 24-hr period were centrifuged, and separated plasma was stored at −15° until analyzed.

Validation Studies—The aforementioned plasma samples were each analyzed by the RIA for *d*-ephedrine, the RIA for *l*-ephedrine, and a published GLC–ECD method (23) for *dl*-ephedrine. Plasma concentration *versus* time plots were constructed for *dl*-ephedrine from the GLC–ECD data and compared with similar plots obtained by adding together the concentrations of the individual enantiomers determined by the RIA procedures.

RESULTS AND DISCUSSION

The cross-reactivities of the antisera for *d*- and *l*-ephedrine are shown in Table I. Both antisera were highly stereospecific. Neither antiserum cross-reacted with the optical antipode of its substrate, nor with racemic pseudoephedrine. Neither antiserum recognized the ring-modified metabolite *dl*-*p*-hydroxyephedrine nor the side chain-modified metabolite *dl*-norephedrine. The latter is particularly significant because many antisera cross-react with compounds that differ in structure from the substrate only at the point of haptenic modification. For example, similar *N*-substituted haptens were used in the development of antisera for chlorpromazine, imipramine, amitriptyline, and *trans*-doxepin. Each antiserum cross-reacted (100%) with the *N*-desmethyl metabolite of its appropriate substrate (29, 30). In the present case, however, the antisera for the enantiomers of ephedrine appear to be specific for both ring system and side chain.

Standard curves for *l*-ephedrine (Fig. 2) and *d*-ephedrine (Fig. 3) were constructed after analysis of spiked plasma which contained the substrate alone or the substrate plus varying quantities of its enantiomer. The concentrations of the contaminating enantiomer were varied from 16.7 to 800% of the substrate concentration. This allowed for the possibility that plasma concentration ratios of the enantiomers differed from unity after dosing with the racemic drug.

The standard curve obtained using the *l*-ephedrine antisera in the presence of only *l*-ephedrine fit the equation $y = -3.18x + 98.31$, with a correlation coefficient of 0.9956 (Fig. 2). When the standard curve for *l*-ephedrine was analyzed in the presence of *d*-ephedrine the resultant standard curve fit the equation $y = -3.42x + 99.57$, with a correlation coefficient of 0.9974. These two curves are virtually superimposable, indicating that the *l*-ephedrine antisera was not sensitive to the presence of *d*-ephedrine (Fig. 2).

When the *d*-ephedrine antiserum was used to construct a standard curve in the presence of only *d*-ephedrine a straight line was obtained which fit the equation $y = -2.30x + 98.58$ and had a correlation coefficient of 0.9952. The standard curve of *d*-ephedrine analyzed in the presence of *l*-ephedrine was also a straight line with the equation $y = -2.35x + 102.22$ and a correlation coefficient of 0.9983 (Fig. 3).

These experiments demonstrated that the presence of the optical antipode has little effect on the standard curves and that the RIA procedures can be used to measure the concentration of *d*-ephedrine or *l*-ephedrine in the plasma of a patient dosed with *dl*-ephedrine.

Figure 4 shows the plasma concentration–time curves obtained for *d*- and *l*-ephedrine after a single 50-mg oral dose of racemic ephedrine hydrochloride was administered to a healthy male volunteer. *d*-Ephedrine reached significantly higher plasma concentrations and was eliminated more slowly than *l*-ephedrine. Similar results (Table II) were obtained when the study was repeated in a second volunteer. Both enantiomers reached higher concentrations in the plasma of the second individual, although the peak concentration of the more active *l*-ephedrine was again significantly lower than that of *d*-ephedrine.

The intraassay variances (31) of the RIA procedures, *i.e.*, the overall coefficients of variation for five replicates each at five concentrations were: *l*-ephedrine antiserum with *l*-ephedrine alone, 1.63 (2.67); *l*-ephedrine antiserum with *l*-ephedrine in the presence of *d*-ephedrine, 2.45 (3.30); *d*-ephedrine antiserum with *d*-ephedrine alone 2.90 (4.20); and *d*-ephedrine antiserum with *d*-ephedrine in the presence of *l*-ephedrine 3.76 (5.73). The value in parentheses is the highest coefficient of variation for each case. Interassay variances were of the same order. In each assay, the detection limit was <0.5 ng of the appropriate ephedrine enantiomer in a 200-μl sample.

To validate the RIA procedures, aliquots of the plasma samples from the two volunteers were examined also by a nonstereoselective, though sensitive, GLC–ECD method (23). This procedure was used to measure the total plasma concentration of ephedrine which was compared with the sum of the concentrations of the individual enantiomers determined by RIA (Table II). The results yielded a straight line when total plasma ephedrine as determined by GLC–ECD was plotted against the sum of *d*-ephedrine and *l*-ephedrine as determined by RIA. The slope of this line was 1.1, with a correlation coefficient of 0.99. These results show the plasma concentration–time curves generated by RIA and by GLC–ECD to be comparable. This indicates that the RIA procedures are not subject to interference from the metabolites of ephedrine or from endogenous plasma constituents.

A Highly Sensitive Pyrogen Test for Antibiotics I: Detection of Trace Amounts of Endotoxin in Injectable Sodium Ampicillin Preparations

S. TAKAHASHI *, S. YANO *, Y. NAGAOKA *, K. KAWAMURA ‡x, and S. MINAMI ‡

Received August 24, 1981, from the **Department of Antibiotics, National Institute of Health, Kamiosaki 2-chome, Shinagawa-ku, Tokyo 141, Japan* and the ‡*Department of Quality Control, Takeda Chemical Industries, Ltd., Doshomachi, Osaka 541, Japan.* Accepted for publication June 17, 1982.

Abstract □ The rabbit pyrogen test (specified in the pharmacopeia) and the Limulus amebocyte lysate (LAL) test are influenced by high concentrations of certain antibiotics. Therefore, it has not been possible to detect trace amounts of endotoxin which may contaminate these antibiotics. To detect trace amounts of endotoxin in injectable sodium ampicillin, an ultrafiltration technique was utilized which removed the antibiotic and left a solution which contained predominantly the endotoxin. After ultrafiltration, a trace amount of pyrogen (which otherwise could not be detected) was found using both the rabbit pyrogen and the LAL tests. The endotoxin was also determined quantitatively using a chromogenic endotoxin reagent which is made by combining the Limulus amebocyte lysate and a synthetic substrate with a suitable chromophore.

Keyphrases □ Ampicillin—detection of trace amounts of endotoxin using ultrafiltration with pyrogen tests, chromogenic assay □ Ultrafiltration—of ampicillin solutions, use with pyrogen tests to detect trace amounts of endotoxin in antibiotics □ Chromogenic assay—of ampicillin solution, detection of trace amounts of endotoxin in antibiotics

It is important to develop highly sensitive methods for detecting trace amounts of pyrogen to ensure that pharmaceutical preparations are completely pyrogen free. Several cases of fever have been reported after the injection of β-lactam antibiotics such as methicillin and cloxacillin (1–6). However, in only one case (methicillin) was the presence of a pyrogen detected (6). Fever is caused in most cases by lipopolysaccharide from the outer layer of the cell walls of Gram-negative bacteria. Pyrogens, a type of endotoxin, are often complex, high molecular weight substances containing lipid A (7).

Endotoxins are usually detected by the pyrogen test using rabbits, or by the Limulus amebocyte lysate (LAL) test. The former method is specified in the pharmaceutical compendia of both the U.S. (8) and Japan (9). The latter method is specified in the United States Pharmacopeia XX (10). In the pyrogen test, the rise in the body temperature of rabbits caused by the endotoxin is sometimes inhibited by the pharmacological activity of the coexistent drugs. The sensitivity of the LAL test also is affected by the presence of certain drugs (11). In such cases, it would be desirable to separate the endotoxin from the drug and concentrate the endotoxin.

Minami *et al.* used an ultrafiltration method to separate endotoxins from antipyretics (12). Sullivan *et al.* showed that β-lactam antibiotics such as sodium penicillin G do not combine with endotoxin using ultrafiltration (13).

It was reported that gel formation in the LAL test was induced by the amidase activity of a clotting enzyme in the lysate, which is activated by a bacterial endotoxin (14). Harada *et al.* applied this principle to the colorimetric determination of endotoxins using a synthetic substrate which activates the amidase activity of the enzyme and releases a chromophore (15).

pyrogen contaminants in injectable sodium ampicillin preparations using ultrafiltration followed by rabbit pyrogen and LAL tests. The quantitative determination of endotoxin by a chromogenic assay method using a reagent made from the Limulus amebocyte lysate and a synthetic substrate is also reported in this paper.

EXPERIMENTAL

Materials—*Samples and Reagents*—An injectable sodium ampicillin preparation in vials of 1 g(potency), suspected to be contaminated with pyrogen, was used as the test sample. A sodium ampicillin preparation for injection manufactured prior to the test sample was used as the control. Commercially available endotoxin from *Escherichia coli* (0111-B4)[1] was dissolved in physiological saline solution immediately before use and diluted to the required concentration, to provide a standard endotoxin. The Limulus amebocyte lysate[2] and chromogenic endotoxin assay[3] reagents were obtained commercially. The chromogenic endotoxin assay reagent is made from Limulus amebocyte lysate and the *p*-nitroaniline derivative of a synthetic oligopeptide as the substrate. Tromethamine hydrochloride[1] (0.1 *M*, pH 8.0) was used as a buffer. The blue dextran solution (2 μg/ml of dye-combined dextran, average molecular weight 2,000,000)[4] was used after it was confirmed to be pyrogen free.

Ultrafiltration Apparatus—The ultrafiltration apparatus[5] (stirring type) was used after washing with pyrogen-free distilled water and drying at 60° for 1 hr. The ultrafiltration membrane[6] had a fraction molecular weight of 10,000 and a diameter of 76 mm. It was used after soaking overnight in 0.1 *N* NaOH solution; the surface of the membrane was washed with distilled water for injection prior to use.

Untreated solution (I)	++	+	+	±	−
Ultrafiltrated solution (II)	++	++	++ ~ +	±	−

[a] After the mixture was incubated at 37° for 1 hr and then allowed to stand for 5 min. [b] The original concentration of the solution was 5 ng/ml. The key is as listed in the text.

Rabbits—Japanese white, male rabbits weighing 2.0–2.7 kg were bred and maintained in a room kept at 25 ± 2° with a relative humidity of 50 ± 10%. They were fed daily (~100 g of solid food[7]) with an automatic rabbit feeding apparatus. Water was supplied *ad libitum* using an automatic water-supplying system. Only those rabbits that maintained their weight for at least 1 week were used in the experiments. They were conditioned for 1–3 days prior to the pyrogen test by conducting sham tests (*i.e.*, without injection).

Methods—*Ultrafiltration*—All glass apparatus were depyrogenized by heating at 250° for 2 hr. After the ultrafiltration membrane was attached to the apparatus, the apparatus was washed three times with pyrogen-free distilled water and once with 0.01 *N* NaOH solution. The surface of the membrane was coated with 100 ml of dye-combined dextran (average molecular weight 2,000,000) solution to prevent adsorption of the pyrogen. The inside of the apparatus was rinsed with 30 ml of physiological saline solution using manual stirring; the washings were confirmed to be pyrogen free by the LAL and rabbit pyrogen tests (dose: 10 ml/kg).

The samples of sodium ampicillin were dissolved in physiological saline, placed in the ultrafiltration apparatus, and filtered under pressure using nitrogen gas (3.5 kg/cm^2) until the volume of the residual solution was reduced to one-tenth the original volume. If the concentration of sodium ampicillin in the residual solution exceeded 10 mg (potency)/ml, the dilution and filtration were repeated until the concentration of sodium ampicillin became ≤10 mg(potency)/ml. The membrane filter was changed between treatments.

Determination of Endotoxin—For the rabbit pyrogen test, rabbit rectal temperatures were measured using a thermoelectric couple-type thermometer[8]. Temperatures were measured three times at 45-min intervals prior to administration; the third measurement was regarded as the control. Immediately thereafter, the sample solutions (10 ml/kg) were

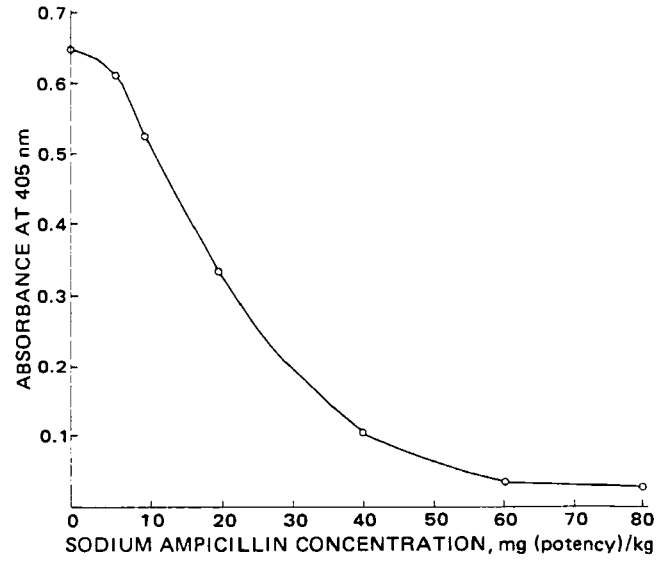

Figure 2—*Influence of the concentration of sodium ampicillin on the determination of endotoxin by the chromogenic assay method. The sample solution was* E. coli *endotoxin at 0.4 ng/ml; the incubation time was 50 min.*

Table III—Influence of the Ampicillin Concentration on the LAL Test

Concentration of Endotoxin[a], ng/ml	Concentration of Ampicillin[b], mg(potency)/ml							
	100	60	40	20	10	5	1	0
10	−	−	+	++	++	++	++	++
1	−	−	±	+~±	+	+	+	+

[a] *E. coli* 0111-B4. [b] Key is as given in the text.

administered intravenously through the auricular vein. Rectal temperatures were taken at 1, 1.5, 2, and 3 hr postadministration. The difference between the highest temperature recorded after injection and the control temperature was regarded as the rise in temperature.

For the LAL test, the limulus amebocyte lysate reagent was dissolved in 0.1 ml of pyrogen-free distilled water in an ampule. The sample solutions (0.1 ml) were added to the reagent and the ampules were allowed to stand in an incubator at 37° for 1 hr. After incubation, the ampules were allowed to stand an additional 5 min at room temperature, then were slanted at 45°. Each ampule was judged using the following four grades: (++) a solid gel was formed and it did not move when the ampule was slanted; (+) although a gel was formed, it moved when the ampule was slanted; (±) a coarse granular gel was formed and the viscosity was increased; and (−) the media remained in the liquid state without any change.

For the chromogenic assay method, the contents of each vial of the chromogenic assay reagent were dissolved in 0.1 ml of 0.1 *M* tromethamine buffer (pH 8.0) while being cooled in an ice-water bath. Aliquots (0.1 ml) of the test solution were added to the vials, and the mixtures were incubated for 40 or 50 min in a water bath at 37°. After incubation, the reaction mixture was cooled rapidly in an ice-water bath and then was quenched by adding 1.0 ml of a 12.5% acetic acid solution. The absorbance was measured at 405 nm using a spectrophotometer.

RESULTS

Rabbit Pyrogen Test—Temperature rises in rabbits for samples of sodium ampicillin were measured according to the method in the Japanese Minimum Requirements for Antibiotics [25 mg(potency)/kg] and Code of Federal Regulation (20 mg/kg). No differences in the temperature rise were noted between the test and control samples in the dose range of 20–25 mg(potency)/kg.

After being concentrated by ultrafiltration, the ampicillin solution test samples were administered to rabbits, and the temperature rise was monitored. When the test samples of 0.2–5 g(potency)/kg were administered without ultrafiltration, no significant temperature differences were observed between the test and control samples (Fig. 1). However, when the test samples corresponding to 0.2–25 g(potency)/kg of the original samples were administered after ultrafiltration, temperature rises were clearly observed and were found to be dose dependent. The difference in the temperature rise was highly significant between the test and control samples at 5 g(potency)/kg.

Recovery of Endotoxin After Ultrafiltration—An endotoxin solution was prepared by diluting 200 ng of standard endotoxin (*E. coli* 0111-B4) with 40 ml of physiological saline solution (solution I). This solution was diluted by 400 ml and concentrated again to 40 ml by ultrafiltration (solution II). Solutions I and II were diluted stepwise and tested by the LAL test. As shown in Table II, almost complete recovery of endotoxin was obtained. These results were consistent with the results of Minami *et al.* (12) and Sullivan (13).

Effect of Sodium Ampicillin on the LAL Test—The effect of various amounts of the control sample of sodium ampicillin on the LAL test was studied. As shown in Table III, the gel reaction by 10 ng/ml of endotoxin was inhibited by >40 mg(potency)/ml of sodium ampicillin, and 1 ng/ml of endotoxin was inhibited by >20 mg(potency)/ml of sodium ampicillin. These results indicate that the gel reaction by the LAL test is inhibited by certain concentrations of sodium ampicillin, in agreement with Newsome's data (11).

LAL Test of Samples After Ultrafiltration—Four groups of 60 vials each of injectable sodium ampicillin preparations (1 g of test sample/vial) were treated by ultrafiltration to separate and concentrate the suspected pyrogen contaminant, and then were tested by the LAL test. The results are shown in Table IV. Although the data for the test samples showed some variation, they clearly exhibited a stronger gel reaction than that shown by the control sample. The control sample also showed a slightly positive reaction, possibly due to the sensitivity of this method. Trace amounts of pyrogen were detected in the distilled water used as the blank.

Table IV—LAL Test of Ampicillin After Ultrafiltration

Sample	Test Run	Equivalent[a]/Residual[b] Amount of Ampicillin, mg(potency)/ml: 250[a]/5[b] (×2)	125[a]/2.5[b] (×4)	62.5[a]/1.25[b] (×8)	Endotoxin Reference[c]
Test sample	1	++	++	+	
	2	++	+	±	±
	3	++	+	±	±
	4	++	++	+	+
Blank	1	+	±	−	+
	2	±	−	−	±
	3	+	−	−	±
	4	−	−	−	+
Control		+	±	−	+
Blank		±	−	−	+

[a] The equivalent amount of ampicillin is the initial concentration before ultrafiltration. [b] The residual amount of ampicillin is determined after ultrafiltration. The number in parentheses is the dilution. The key is as in the text. [c] *E. coli* 0111-B4, 1 ng/ml.

Chromogenic Assay Method—This assay is possibly more sensitive and leads to better quantitation than the LAL test. It was used to detect endotoxin in the injectable sodium ampicillin preparations with and without prior ultrafiltration. The effect of sodium ampicillin on this assay method was examined. To 0.4 ng/ml of the standard endotoxin was added 6, 10, 20, 40, 60, and 80 mg(potency)/ml of control sodium ampicillin, and the mixtures were incubated at 37° for 50 min. As shown in Fig. 2, when the concentration of sodium ampicillin was increased, the absorbance decreased depending on the drug dose. It has been reported that the minimal detectable amount of endotoxin varies and depends on the incubation time (15). Therefore, calibration curves were obtained for 0.1–0.6 ng of endotoxin in the presence of the control sodium ampicillin [20 mg(potency)/ml] for incubation periods of 40 and 50 min (Fig. 3). The curves indicated that the absorbance at 405 nm varied depending on the incubation time. The absorbance observed was ~0.3 for 0.6 ng/ml of en-

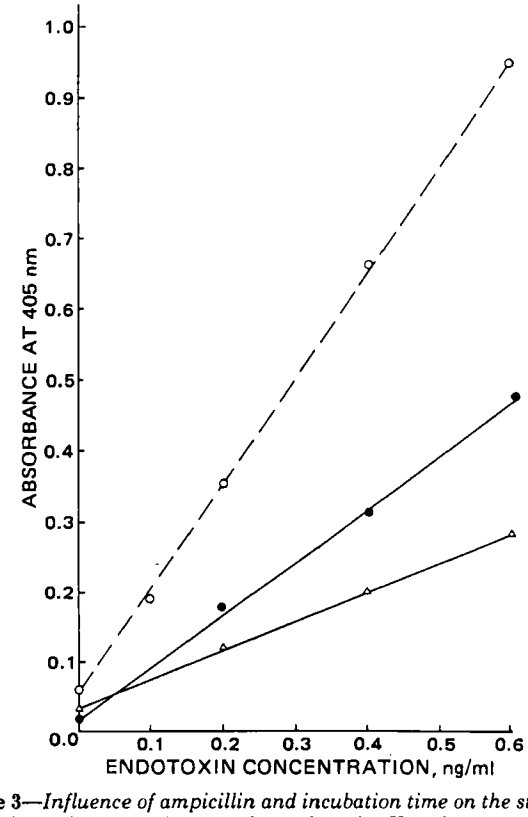

Figure 3—*Influence of ampicillin and incubation time on the standard curve of the chromogenic assay for endotoxin. Key: (○) 50-min incubation without ampicillin; (●) 50-min incubation with 20 mg of ampicillin/ml; (△) 40-min incubation with 20 mg of ampicillin/ml.*

dotoxin after a 40-min incubation and ~0.5 after 50 min. However, for the reaction mixture without ampicillin, the observed absorbance was ~0.95 for 0.6 ng/ml of endotoxin after 50 min.

From the calibration curve obtained in the presence of sodium ampicillin, the amount of endotoxin in the concentrated sample which was used in the rabbit pyrogen LAL tests was determined. It was revealed that 1 g (potency) of sodium ampicillin was contaminated with 6.4 ng of endotoxin (*E. coli* 0111-B4 endotoxin). Furthermore, the endotoxin in each vial was determined quantitatively without ultrafiltration by this chromogenic assay method using 40 vials (1 g/vial) of test samples. The results showed that the sodium ampicillin test samples were contaminated with an average of 4.73 ng of endotoxin (expressed as *E. coli* 0111-B4 endotoxin activity) per vial (gram) with a standard deviation (*SD*) of 1.75 ng/vial.

DISCUSSION

In the injectable sodium ampicillin test sample suspected of contamination, a trace amount of pyrogen (endotoxin) was detected by three methods. For each method, experiments were performed using a pyrogen-free sodium ampicillin preparation and as a control endotoxin derived from *E. coli*. The data indicate the following:

1. The presence of sodium ampicillin interferes with the detection of endotoxin, but sodium ampicillin could be separated from the endotoxin by ultrafiltration. Using ultrafiltration. it is possible not only to eliminate the coexistent drugs but also to concentrate the endotoxin. This makes it possible to detect the endotoxin in minute amounts.
2. The results obtained by the rabbit pyrogen test, LAL test, and chromogenic assay method indicated that the test samples of sodium ampicillin were contaminated with small amounts of endotoxin.
3. The endotoxin could be determined quantitatively in the presence of <20 mg/ml of sodium ampicillin. This study showed that the LAL test and the rabbit pyrogen test gave consistent results, suggesting that the *in vitro* method may become a useful method for the detection of pyrogens in drug preparations.

Evaluation of the Teratogenicity of Morphine Sulfate Administered *Via* a Miniature Implantable Pump

ARTHUR A. CIOCIOLA and RONALD F. GAUTIERI ˣ

Received May 14, 1982, from the *Temple University, School of Pharmacy, Department of Pharmacology, Philadelphia, PA 19140.* Accepted for publication June 29, 1982.

Abstract □ A technique has been developed for the implantation of miniature infusion pumps in pregnant mice with minimal teratogenic and toxic side effects. In 7- to 10-day pregnant CF-1 mice receiving constant low doses of morphine sulfate *via* the infusion pump, the results, including fetal weight reduction and various skeletal and soft tissue abnormalities, were similar to those reported in previous investigations using single injections.

Keyphrases □ Delivery systems—implantable infusion pump, teratology studies □ Morphine sulfate—use of implantable infusion pumps for teratology studies, comparison with conventional techniques □ Infusion pump—delivery of test drug in teratology studies, comparison to conventional techniques

Teratology studies have often shown that drugs can affect the developing fetus, thereby dispelling the myth of a fully protective placental barrier. Many of these drugs have been administered to the pregnant animal in a single dose on a specific day of gestation allowing investigators to observe their teratogenic effects at different times of fetal development (1–3). However, with the introduction of a new type of drug dosing, the miniature infusion pump[1], a distinctly different approach can be used to study the possible teratogenic influence of drugs. This instrument is a constant-flow delivery system which allows the long-term steady-state effects of a drug on the developing fetus to be ascertained. Because there has been no reported use of this constant-flow delivery system for teratology studies, the feasibility of using the miniature infusion pump in such a study was investigated.

To determine if the use of the miniature infusion pump was a reasonable alternative to other types of drug dosing, a pilot study was undertaken comparing the fetal effects of saline administered *via* the pump and by hypodermic injection. The pump implantation procedure and the presence of the pump during pregnancy was observed to have a minimal effect on the fetus, thereby providing the

rationale for a full investigation of the long-term steady-state effects of a drug on the developing fetus. Because this laboratory has conducted several studies with morphine sulfate and elucidated its teratogenic effects, this drug was selected for the test system. The reproductive effects of low constant doses of morphine sulfate administered *via* the miniature infusion pump throughout specific critical days of gestation are reported herein.

EXPERIMENTAL

Animals—CF-1 albino mice[2], weighing at least 25 g, were used in all of the procedures. All females were placed in aggregate cages, each containing 10 animals. They were allowed to acclimatize for 2 weeks. Following this period, those females weighing at least 25 g were allowed to mate. The male mice were housed in individual cages measuring 12.5 × 15 × 10 cm, each with a wire mesh front and floor[3]. Food[4] and tap water were offered *ad libitum;* artificial light was supplied with a 12-hr light/dark cycle.

Drugs and Solutions—Normal saline[5] was used as the vehicle for the morphine sulfate[6] solutions (40, 4.0, and 0.4 mg/ml); fresh solutions were prepared weekly. In addition, normal saline was administered to all vehicle controls including subcutaneous injection and infusion pump groups. All injections were given subcutaneously with a 1-ml glass syringe equipped with a 0.5-cm 26-gauge needle. All pumps were filled with filtered solutions[7] using a specially designed blunt-tipped 26-gauge steel needle[8]. The injection volume was 0.3 ml; the pump release was 0.17 ml of solution.

The bone-staining solution and decalcifying Bouin's solution were prepared according to previously published reports (2).

Breeding, Group Selection, and Treatment—The breeding procedure has been described previously (4). Gravid females were randomly assigned to the 21 experimental groups. The controls consisted of one untreated group and four groups given single subcutaneous saline injections on day 7, 8, 9, or 10 of gestation. There were 16 treatment groups; infusion pumps containing either saline or a 4.0% (40 mg/ml), 0.4% (4.0 mg/ml), or 0.04% (0.4 mg/ml) solution of morphine sulfate were implanted in each mouse on day 7, 8, 9 or 10 of gestation.

Surgical Procedure—On the day of treatment, the body hair of the animals in the dorsal-scapular area was sheared with scissors, and the mice were anesthetized with ether[9]. A small skin incision (1–1.5 cm) was made perpendicular to the backbone in the dorsal-scapular area. The infusion pump was inserted into a subcutaneous pouch made by separating the skin from the underlying muscle and secured by the closure of the incision with three or more interrupted sutures. The anesthesia duration was ~3 min, and an antiseptic solution[10] was used as a postoperative wound dressing. All animals, regardless of the treatment, were allowed to recover undisturbed.

Examination of Fetuses—On day 18 (1 day prior to full term), each mouse was weighed; the terminal maternal weight was adjusted for pump weight if necessary. Each mouse was then sacrificed by cervical dislocation, at which time the number and position of the fetuses and resorption sites (metrial glands) were recorded. The fetuses were blotted dry and checked for viability by reflex movement on stimulation with a blunt probe. Further examination consisted of the observation of each fetus under a dissecting microscope[11] for gross defects and sex; the weight of each fetus was recorded to the nearest hundredth of a gram on a torsion balance[12]. One-half of the fetuses were then randomly selected for preparation in a bone-staining solution for skeletal examination by the method of Staples and Schnell (5). The remaining fetuses were prepared in Bouin's solution for soft tissue examination by the method of Wilson (6). The statistical significance of the observations was determined using Student's t test and the uncorrected chi-square test for a binomial population.

RESULTS AND DISCUSSION

Effects of Pumps Implantation—*Maternal Effects*—Two deaths occurred during the pump implantation procedures; both were attributed to an overdose of the ether anesthesia and not to surgical trauma. There were no maternal deaths due to drug toxicity or postsurgical complications observed in any treatment group.

Most animals became fully conscious within minutes following the pump implantation procedure, although spontaneous activity was suppressed for several hours. This was judged to be the result of the proce-

[a] Based on six litters per group. Key: significantly different ($p < 0.05$) from the pump saline control on a litter basis (L), a fetal basis (F), or both (B).

dure and not a drug effect, because similar observations were noted for the saline groups and, also, several hours are needed for the pump to reach full capacity. Observation of the spontaneous activity of the animals on subsequent days showed little difference between the treatment (pump-implanted) groups and the untreated controls. On sacrifice of the animals, the pumps were excised and the pouch area examined. In no case was there any evidence of gross infection or any type of inflammation present in or around the pouch area.

The only maternal variable measured during this experiment was the maternal weight gain. There were no significant differences between the untreated controls and any treatment group. However, when the pump-saline-10[13] group was compared with the injection-saline-10 group (Table I), there was a significant decrease in maternal weight gain observed, obviously a direct consequence of the pump implantation procedure.

Fetal Effects—A crucial point in this study was to determine the feasibility of the pump implantation procedure for use in a teratology study. The fetal effects resulting from the pump implantation procedure were determined by the statistical comparison of saline administered *via* the infusion pump *versus* subcutaneous injection. Only one group (pump-saline-7) showed any significant differences: an increase in mean fetal weight and a reduction in the number of fetuses in the left uterine horn. Because the number of fetal resorptions was not significantly different, these effects are possibly due to an increased uterine blood supply and not the pump implantation procedure (which is performed after uterine implantation of the ova). Therefore, there does not appear to be any major difference in the fetal effects of saline administered *via* subcutaneous injection or the pump implantation procedure.

Effects of Morphine Sulfate—The doses used in this study were only a fraction of the morphine sulfate doses administered in previous studies (7–9). The exact dose administered is a function of the animal body weight as the drug concentration and release rate is the same in all cases.

Maternal Effects—Observation of the animals implanted with a pump containing morphine sulfate showed the discernable effects of the drug to be quite minimal. The maternal weight gain significantly decreased in only one group (pump-0.04% morphine sulfate-7), which is in general agreement with previous reports (7–9).

Fetal Effects—A significant reduction in mean fetal weight was noted which agreed with previous data (7–9). Significant fetal resorptions, which were noted in one of the previous studies (7), did not occur in the present investigation.

Three groups (pump-4.0% morphine sulfate-8, pump-0.04% morphine sulfate-7, and pump-0.04% morphine sulfate-10) showed significant increases in the total number of soft tissue and/or skeletal defects when compared with the pump saline controls. A trend in the mean values of the total number of soft tissue/skeletal abnormalities and fetal weights is evident. With the exception of the soft tissue anomalies of the pump-morphine sulfate-8 groups, the lowest doses of morphine sulfate (0.04%) have nearly twice the number of abnormalities and much lower mean fetal weights compared with the corresponding gestation day for the highest doses (4.0%). This trend is supported statistically, as significance was noted for dose comparisons involving the mean fetal weight and total number of soft tissue and/or skeletal abnormalities (Table I), with the greatest difference appearing between the highest (4.0%) and lowest doses (0.04%) of morphine sulfate.

In view of the type of dosing and since it is well known that constant morphine administration induces tolerance to many of its physiological effects, a logical explanation for these trends might be the induction of microsomal liver enzymes. However, the induction of microsomal liver enzymes does not explain the increase in fetal defects at the lowest dose of morphine as compared with the high dose; the enzymatic *N*-demethylation of morphine is reduced with chronic administration (10–12). This reduction of the *N*-demethylation of morphine can be partially reversed by nalorphine (10). Because of the similar substrate stereospecificity between the liver enzymes and the opiate receptors, Axelrod (10) suggested that the depression of enzymatic activity may be related to a similar depression of receptor activity, seen physiologically as the development of tolerance. To further elucidate the similarity of the stereospecificity between the enzyme, *N*-demethylase, and the opiate receptor, Mannering and Takemori (11) used the steric isomers of 3-hydroxy-*N*-methylmorphinan (dextrorphan and levorphan) in chronic doses and measured the *N*-demethylase enzyme activity in response to a test dose of morphine. Dextrorphan is known to lack most morphine-like properties, while levorphan produces many morphine-like effects. Mannering and Takemori (11) reported that the rate of enzymatic *N*-demethylation of morphine was inhibited with chronic administration of levorphan, while dextrorphan was observed to be relatively noneffective.

If the teratogenic effects of morphine are expressed through the opiate receptor activity, the inhibition of the receptor by chronic administration of morphine may result in a lower incidence of fetal anomalies at higher doses (4.0%). There is a possibility that constant administration at the lowest dose of morphine (0.04%) may not be sufficient to inhibit the receptor but is large enough to cause fetal abnormalities. With morphine *N*-demethylation inhibited at higher doses, the production of the end product (formaldehyde) is also inhibited; with constant administration of low doses of morphine, tissue levels of formaldehyde, a secondary teratogenic agent, may build up. However, the development of tolerance and the induction of fetal defects by morphine are probably not due to a single cause, but to multiple and presently unknown factors.

The fetal abnormalities produced in significant numbers as a result of morphine sulfate administration *via* the infusion pump have been listed in Table II. Specifically, those malformations include exencephaly, hydronephrosis, intestinal hemorrhage, split supraoccipital bone, (malformed, crankshaft, fused, poly, and split) sternebrae, and malformed (butterfly and split) xiphoid bone. In addition, various soft tissue anomalies were also observed in this study, although their incidence was not significant. These defects included: cleft palate, cryptorchidism, ectopic ovary or testis, hydrocephaly, microphthalmia, missing lens, skin bumps, abnormal tail, and polydactyly. There were also numerous skeletal defects observed in significant numbers, including: brachygnathia; delayed ossification of the ribs, skull, sternebrae, and xiphoid; split ribs; malformed basiphenoid, xiphoid, and centrum; and missing sternebrae and supraoccipital bone.

It is known that the specific fetal malformation is related to the fetal organs most susceptible to injury at the time of drug challenge (7–9). Therefore, one would expect that litters from dams with the morphine-containing pump implanted on day 7 of gestation should show all the defects observed in the litters from dams implanted on subsequent days because of the continually present drug levels. However, the data does not show such a trend. Possibly, the teratogenic insult is greatest on the first day of drug administration (and on the organs developing at that time) and lessens thereafter.

In conclusion, this study has proven that the infusion pump is a feasible dosage form in teratology studies. The methodology necessary for future studies of this type has been developed. In administering morphine sulfate *via* the implantable pump, this study has shown fetal abnormalities similar to those observed in previous (injection) studies.

[13] Each group was designated by method of delivery—solution administered-gestation day of dosing.

Pharmacokinetics and Bioavailability of Intravenous and Topical Nitroglycerin in the Rhesus Monkey: Estimate of Percutaneous First-Pass Metabolism

RONALD C. WESTER *x, PATRICK K. NOONAN ‡, STEPHEN SMEACH, and LARRY KOSOBUD

Received April 1, 1982, from *Searle Research and Development, G. D. Searle & Co., Skokie, IL 60076.* Accepted for publication June 28, 1982. Present address: *Department of Dermatology and ‡School of Pharmacy, University of California, San Francisco, CA 94143.

Abstract □ [^{14}C]Nitroglycerin was administered intravenously and topically to three rhesus monkeys and the pharmacokinetics were determined. The rhesus monkey is an animal model for which percutaneous absorption is similar to that in the human. After intravenous administration the decline in plasma nitroglycerin concentration was biexponential with an initial half-life of 0.8 min (2–5 min postadministration) and a terminal half-life of 18 min (5–60 min postadministration). After topical application in an ointment, plasma concentrations of unchanged nitroglycerin were first detectable at 0.25 hr postapplication. Peak plasma nitroglycerin concentrations occurred between 4–6 hr, and nitroglycerin was still detectable at 24 hr postapplication. Plasma levels fit a biexponential curve with an α-phase half-life of 3.0 hr, a β-phase half-life of 4.3 hr, and a lag time of 0.5 hr. The absolute bioavailability of topical nitroglycerin was 56.6 ± 5.8%. The differences in bioavailability estimates between unchanged nitroglycerin and total carbon-14 is considered to be the amount of nitroglycerin which is metabolized as it is absorbed through the skin (percutaneous first-pass effect). This value for topical nitroglycerin was quite small, only 16–21% depending on the method of comparison.

Keyphrases □ Nitroglycerin—percutaneous absorption pharmacokinetics in the rhesus monkey, comparison of intravenous and topical administration bioavailability □ Pharmacokinetics—nitroglycerin in the rhesus monkey, comparison of intravenous and topical administration bioavailability □ Bioavailability—topical nitroglycerin in the rhesus monkey, comparison with intravenous administration, pharmacokinetics □ Percutaneous absorption—topical nitroglycerin, determination of first-pass effect

Nitroglycerin is a drug shown to be effective in angina pectoris (1–4) which may be effective in other cardiac diseases (5). The usual dosage form is a sublingual tablet, which has the disadvantage of a short duration of action. Nitroglycerin is also administered orally; however, first-pass metabolism during absorption is estimated to be large (6, 7). A third route of administration is transdermal delivery. Transdermal administration results in a longer duration of action than sublingual administration and may bypass the first-pass metabolism seen with oral administration. The result is a dosage form that delivers nitroglycerin over an extended time period. Recent publications attest to the clinical effectiveness of topically applied nitroglycerin (4, 5). Thus, it is important to determine the pharmacokinetic parameters of nitroglycerin after topical administration. This information can help in understanding the effectiveness of the drug and perhaps can be used to improve nitroglycerin therapy.

The animal model chosen for the study of the transdermal delivery of nitroglycerin was the rhesus monkey. Percutaneous absorption of several compounds in the rhesus monkey have been shown to be similar to that in the human (8–11).

EXPERIMENTAL

Female rhesus monkeys weighing ~4–6 kg were used. The monkeys were lightly anesthetized with 50–100 mg ketamine[1] for placement in the metabolism chairs. The monkeys were restrained in the metabolism chairs for 24 hr after drug administration (length of topical application) and then returned to metabolism cages for continued blood and urine collection. The monkeys had free access to food and water in the metabolism cages; they were hand fed and watered while confined to the metabolism chairs. In the topical application studies, the wrists of the monkey were taped to the sides of the chair to prevent the monkey from removing the applied dose. Each animal had an indwelling catheter in the saphenous vein for blood collection; a saline drip was connected to the cathether while blood samples were not being collected.

[^{14}C]Nitroglycerin was prepared from uniformly labeled glycerol and had a specific activity of 128 μCi/mg. The synthetic material was purified by chromatography on silica gel (toluene) followed by further purification using high-performance liquid chromatography (HPLC) on a μ-Bondapack C-18 column (water–methanol, 60:40) at a flow rate of 2 ml/min. The chemical and radiochemical purity, as determined by HPLC and TLC, was 99%.

The intravenous dosage form was 1.92 mg of labeled nitroglycerin with a specific activity of 250 μCi in 0.5 ml of ethanol. Administration was by bolus injection in the saphenous vein of the noncatheterized leg. The topical dosage form was 2% nitroglycerin ointment[2] containing 19.0 mg of labeled nitroglycerin (specific activity 210 μCi) spread over a 50-cm^2 area of skin. [^{14}C]Nitroglycerin was added to the ointment using the procedure of Lindsay *et al.* (12). Topical administration was to the inner upper arm. The area was lightly clipper shaved, which does not affect percutaneous absorption in the rhesus monkey (8). [The application site also has been determined not to affect the percutaneous absorption of nitroglycerin in the rhesus monkey (13).] The topical application was occluded with aluminum foil and adhesive tape. The ointment was left in place for 24 hr, and then the site was washed with soap and water. There was a 1-week period between drug administrations.

At each sampling time, ~3 ml of blood was drawn and placed in a

heparinized tube. The tube was centrifuged immediately (5 min from start-up to finish); the plasma was removed, placed in a vial containing 50 μl of 1.0 *M* silver nitrate for protein precipitation, and mixed. The samples were then frozen in a mixture of isopropyl alcohol and solid carbon dioxide. The majority of each plasma sample (1.0 ml) was utilized for nitroglycerin assay; a small aliquot (0.1 ml) was utilized for carbon-14 assay.

Blood sampling times following intravenous administration were 0, 1, 2, 3, 5, 15, 30, and 45 min and 1, 2, 3, 6, 24, 48, and 72 hr. Blood was withdrawn following topical administration at 0, 15, 30, and 45 min and 1, 2, 3, 4, 6, 8, 12, 24, 48, and 72 hr. Urine samples for carbon-14 analysis were collected at 0–24, 24–48, and 48–72 hr.

A GC method modified from Yap *et al.* (14) was used to analyze the nitroglycerin content in the monkey plasma. Nitroglycerin and the internal standard, isosorbide dinitrate, were extracted from plasma with hexane. The extract was then evaporated, reconstituted with ethyl acetate, and analyzed by GC[3] using an electron-capture detector. A glass column (1.2 m × 2 mm) was packed with 3% OV-1 liquid phase on Chromosorb W-HP, 100–200 mesh[4]. The injection port, column, and detector temperatures were 200°, 110°, and 200°, respectively. The carrier gas was 5% methane–argon and had a flow rate of 25 ml/min. The retention times for nitroglycerin and isosorbide dinitrate were 1.8 and 6.0 min, respectively.

Bioavailability of nitroglycerin was determined by the ratios of the areas under the concentration–time curves (AUC $0 \rightarrow \infty$) for intravenous and topical plasma nitroglycerin and plasma carbon-14. The trapezoidal area was measured to the last data point, and the remaining area was determined using the terminal slope of the concentration–time curve. The ratio of the topical AUC to the intravenous AUC is the absolute bioavailability of nitroglycerin following topical administration. Bio-

[a] Mean ± *SEM* for three monkeys.

availability of nitroglycerin was also determined from the urinary excretion of carbon-14 following topical and intravenous administration. Blood levels were fit to the appropriate pharmacokinetic model using NONLIN (15).

The absolute bioavailability of nitroglycerin and carbon-14 was estimated by:

$$\text{percentage} = \frac{\text{AUC topical/topical dose}}{\text{AUC intravenous/intravenous dose}} \times 100 \quad \text{(Eq. 1)}$$

where the AUC is expressed as ng hr ml^{-1}. Bioavailability was estimated from urinary excretion using:

$$\text{percentage} = \frac{\text{total [}^{14}\text{C] excretion topical administration}}{\text{total [}^{14}\text{C] excretion intravenous administration}} \times 100 \quad \text{(Eq. 2)}$$

RESULTS

Table I and Fig. 1 show the plasma concentrations of unchanged nitroglycerin following intravenous administration. The decline in plasma nitroglycerin concentration was biexponential with an initial half-life of 0.8 min (2- to 5-min interval) and a terminal half-life of 18 min (5- to 60-min interval). The first data point (0.02 min) was not used in the NONLIN analysis.

Table I and Fig. 2 show the plasma concentrations of unchanged nitroglycerin following topical administration of the ointment. Nitroglycerin was first detected at 0.25 hr postapplication. Peak plasma nitroglycerin concentration occurred between 4 and 6 hr and nitroglycerin was still detectable at 24 hr postapplication. The NONLIN analysis best fit a biexponential curve with an α-phase half-life of 3.0 hr, a β-phase half-life of 4.3 hr, and a lag time of 0.5 hr.

Table II gives the plasma concentrations of carbon-14 following intravenous and topical administration of [^{14}C]nitroglycerin. After intravenous administration, plasma concentrations of carbon-14 fluctuated for the first 3 hr, probably due to metabolite formation. Levels then declined and by 72 hr had decreased 10-fold. After topical administration, plasma carbon-14 concentrations did not peak until 12 hr postadministration. Urinary excretion of carbon-14 was also determined (Table III). Within 72 hr 53.7 ± 3.9 (*SEM*) % of the intravenous dose and 38.8 ± 3.7% of the topical dose were excreted. Most of the radioactivity was excreted in the first 24 hr. Radioactivity not accounted for in urinary excretion probably was excreted by some other route (*e.g.*, feces).

Based on the data given in Tables I–III, the topical bioavailability of nitroglycerin was estimated by three methods; these are summarized in Table IV. The absolute bioavailability of topical nitroglycerin, determined from the ratio of the nitroglycerin AUC values following intravenous and topical administrations, was 56.6 ± 2.5% for the three monkeys. Bioavailability determined from the ratio of the plasma carbon-14 AUC values was 77.2 ± 6.7%, and the estimate from the urinary excretion of carbon-14 was 72.7 ± 5.8%.

The difference in bioavailability estimates between unchanged nitroglycerin and total carbon-14 is the amount of nitroglycerin which is metabolized as it is absorbed through the skin (percutaneous first-pass effect). By comparison of the plasma nitroglycerin AUC with the plasma carbon-14 AUC, the estimate of first-pass percutaneous metabolism is 20.6%; by comparison to urine carbon-14 excretion, the estimate is 16%. Therefore, we can conclude that the percutaneous first-pass effect is quite small, only 16–21% depending on the method of comparison.

DISCUSSION

Yap and Fung (16) studied the pharmacokinetics of nitroglycerin in rats after intracardiac, oral, and topical administrations. Nitroglycerin had a half-life of ~4 min after intracardiac administration and showed "flip-flop" kinetics after oral administration. The oral bioavailability was

Table IV—Bioavailability of Topical Nitroglycerin[a]

Pharmacokinetic Parameter	Monkey			Mean Bioavailability[b]
	1	2	3	
Dose, mg

[a] Determined from the plasma nitroglycerin AUC, plasma carbon-14 AUC, and urinary excretion of carbon-14. [b] Mean ± *SEM*.

1.6%, supporting the concept of extensive first-pass metabolism (17). No detectable levels of nitroglycerin after topical administration were found (16). However, it was suggested later (18) that this may have been due to site-dependent absorption. Site-dependent absorption also occurs in the rhesus monkey and the human (19); however, this does not occur with the topical administration of nitroglycerin in the rhesus monkey (13).

In the human, information on the topical administration of nitroglycerin is limited. In one subject, nitroglycerin was not detected until 20 min after topical application (20). When the study was stopped (60 min) nitroglycerin was still detected. This suggested a sustained delivery of nitroglycerin since administration of a sublingual tablet afforded measurable plasma nitroglycerin levels at 3 min and no detectable amounts at 16 min. Maier-Lenz *et al.* (21) similarly reported that the half-life of nitroglycerin with sublingual administration was 8 min, but with topical administration a lag time of 14 min existed and measurable levels of nitroglycerin were present through a 3-hr period. Clinically, the effectiveness of topical nitroglycerin in patients with angina has been demonstrated for up to 8 hr after administration (22).

The data in this study agree with the literature reports on sublingual and topical nitroglycerin administration. Intravenously administered nitroglycerin disappeared from the blood very rapidly with a terminal half-life of 18 min. With topical administration there was a lag time of 0.5 hr with detectable levels of nitroglycerin occurring through a 24-hr period with peak levels at 4–6 hr postapplication. Topical nitroglycerin ointment can be considered a sustained-release dosage form, especially when compared with a sublingual tablet.

The pharmacokinetics of topical nitroglycerin administration are of interest since the short half-life seen with intravenous administration was not present. Instead, the plasma concentration–time curve was a broad curve with an α-phase half-life of 3 hr and a β-phase half-life of 4.3 hr. It seems reasonable that these phases of the curve are part of the complex absorption process and that any true elimination phase for nitroglycerin is lost among the absorption kinetics. It should be stated also that the AUC values following topical administration may be overestimated due to the inability to accurately calculate β. The degree of error for the total is dependent on the degree of error in β and the fraction of the total AUC composed of the fraction from 24 hr. However, this degree of error probably is small since the extrapolated area fraction involves only ~5% of the total AUC.

The absolute bioavailability of nitroglycerin following topical administration was 56.6%. There are no literature values for comparison. The mean bioavailability in male volunteers of isosorbide dinitrate from an ointment was ~30% of the bioavailability from the sublingual tablet (23). Plasma levels of isosorbide dinitrate were present up to 120 min following sublingual administration and up to 32 hr following topical administration. These estimates of 30–60% are certainly greater than the very low bioavailability estimates for oral preparations.

Nitroglycerin bioavailability measurements using the plasma AUC (total carbon-14) method were similar to those obtained by total urinary excretion of the radioactive label. Estimates from carbon-14 analysis were only 16–21% above the absolute bioavailability, a difference probably due to percutaneous first-pass effect. Use of plasma carbon-14 AUC and total urinary carbon-14 excretion to estimate percutaneous absorption has

been reported previously (24). The methods seem appropriate for estimates of transdermal absorption if a specific analytical procedure is not available and percutaneous first-pass metabolism is not extensive.

N-Acetyl-D-Mannosamine Analogues as Potential Inhibitors of Sialic Acid Biosynthesis

ANTHONY F. HADFIELD ˣ, SHARON L. MELLA, and ALAN C. SARTORELLI

Received March 29, 1982, from the *Department of Pharmacology and Developmental Therapeutics Program, Comprehensive Cancer Center, Yale University School of Medicine, New Haven, CT 06510.* Accepted for publication June 22, 1982.

Abstract □ The 1,3,6-tri-*O*-acetyl and 1,3,6-tri-*O*-acetyl-4-*O*-mesyl analogues of *N*-acetyl-D-mannosamine and the corresponding *N*-trifluoroacetyl derivative have been synthesized, and their effects on the proliferation of Friend erythroleukemia cells in culture have been evaluated. The acetamido series showed a dependency on the 4-substituent for optimum cytotoxicity while the trifluoroacetamido series did not. Thus, the 1,3,4,6-tetra-*O*-acetyl and 1,3,6-tri-*O*-acetyl-4-*O*-mesyl analogues of *N*-acetyl-D-mannosamine were 10-fold and 42-fold more active, respectively, than 2-acetamido-1,3,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranose as inhibitors of cellular replication. The corresponding trifluoroacetamido analogues were essentially equiactive and had a potency equivalent to that of the 4-*O*-mesyl derivative in the acetamido series.

Keyphrases □ *N*-Acetyl-D-mannosamine—synthesis of acetamido and trifluoroacetamido analogues, effects on the proliferation of Friend leukemia cells □ Analogues—of *N*-acetyl-D-mannosamine, acetamido and trifluoroacetamido series, synthesis, effects on the proliferation of Friend leukemia cells □ Antileukemic agents—potential, acetamido and trifluoroacetamido analogues of *N*-acetyl-D-mannosamine, tested against Friend leukemia cells

2 - Acetamido - 1,3,4,6 - tetra - *O* - acetyl - 2 - deoxy - β-D-mannopyranose (I), the peracetylated analogue of *N*-acetyl-D-mannosamine, a metabolic precursor in the biosynthetic pathway for sialic acid (1) (Fig. 1), and the corresponding trifluoroacetamido analogue (V) were recently reported to be inhibitors of the growth of Friend erythroleukemia cells in culture (2). Both analogues were equipotent inhibitors of the incorporation of [^{3}H]*N*-acetyl-D-mannosamine into the glycoprotein-bound sialic acid of Friend erythroleukemia cells (2); however, different enzymatic sites appeared to be involved. Compound I caused an accumulation of radioactivity from [^{3}H]*N*-acetyl-D-mannosamine in *N*-acetylneuraminic acid and a decrease in cytidine monophosphate-*N*-acetylneuraminic acid in the ethanol-soluble metabolites of cells, while V caused an accumulation of [^{3}H]cytidine monophosphate-*N*-acetylneuraminic acid. In addition, both I and V produced an increase in the amount of neuraminidase-hydrolyzable sialic acid-like material on the surface of treated cells, presumably as a result of their metabolic utilization and incorporation into cellular macromolecules (3).

Since intracellular deacetylation must precede metabolism of these analogues along the sialic acid biosynthetic pathway, we presumed that I would ultimately give the noncytotoxic metabolite, *N*-acetyl-D-mannosamine; it was therefore surprising to find that I was relatively active as an inhibitor of cellular replication. Consideration of the hydroxyl groups which are required for the conversion of *N*-acetyl-D-mannosamine to *N*-acetylneuraminic acid-9-phosphate (1) (Fig. 1), reveals that such metabolic conversion only necessitates the removal of acetyl groups from the 1, 3, and 6 positions of I, thereby suggesting that the 4-*O*-acetyl group remains intact and is responsible for the

biological and biochemical effects of this agent in erythroleukemia cells. In an effort to gain evidence to support these conclusions, the preparation and evaluation of the cytotoxicity in Friend erythroleukemia cells of 2-acetamido-1,3,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranose (II), 1,3,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-α-D-mannopyranose (VI), and their corresponding 4-*O*-mesylates (III and VII) was undertaken.

BACKGROUND

The carbohydrates present on mammalian cell surfaces exist as components of glycolipid, glycoprotein, and glycosaminoglycan macromolecules, which collectively participate in functional properties such as adhesion, cellular interactions, and immunological phenomena (4). In recent years, studies directed at the surface properties of neoplastic cells have highlighted many structural and functional differences between tumor cells and their normal counterparts (5). Although no universal property characteristic of malignancy has resulted from such studies, they have stimulated drug design targeted at the neoplastic cell membrane (6). Of the various cell-surface components, sialic acid (7) is of special interest, since it appears to be involved in fundamental properties of neoplastic cells such as the capacity to metastasize (8–10).

Elevated levels of sialyltransferase activity (11, 12) and cell surface-bound sialic acid (13, 14) have been reported in some transformed cell lines in culture. Although such changes have not been observed uniformly, elevated levels of sialic acid and sialyltransferase activity have been reported in the serum of animals (15–17) and humans (16, 18–20) bearing malignant neoplasms, and a variety of human lung carcinomas also have been shown to contain higher levels of protein-bound sialic acid than corresponding normal tissue (21). Since drugs that are capable of altering the synthesis, and thereby the content, of cell surface sialic acid-containing macromolecules may have utility as therapeutic agents, analogues of *N*-acetyl-D-mannosamine (a biosynthetic precursor of sialic acid) have been prepared.

EXPERIMENTAL[1]

Methods—All evaporations were performed under reduced pressure, and melting points[2] were uncorrected. Column chromatography[3] and TLC[4] were performed on silica gel, the latter being developed by heating after the application of an ethanol–5% sulfuric acid spray. ^{1}H-NMR spectra[5] were run in deuterochloroform. Petroleum ether refers to a fraction having a bp of 35–60°.

2-Acetamido-1,3,6-tri-O-acetyl-2-deoxy-α-D-mannopyranose (II)—Aliquots of acetyl chloride were added to a solution of *N*-acetyl-β-D-mannosamine·H_2O (1 g, 4.5 mmoles) in pyridine (15 ml) at room temperature. The reaction was monitored by TLC (chloroform–methanol, 9:1, v/v) until optimal conversion to an anomeric mixture of tri-*O*-acetyl derivatives was obtained. Toluene was added and the mixture was evaporated under reduced pressure. The residue was chromatographed on silica gel (chloroform–methanol, 97.5:2.5) to give a mixture of tri-*O*-acetyl derivatives (0.51 g, 33%) which showed as three major spots on TLC. This material was crystallized from acetone–petroleum ether to give II (0.19 g, 12%), mp 216–217° (dec), $[\alpha]_D^{23}$ − 63° (*c* 1, methanol); ^{1}H-NMR[6]: δ 5.84 (d, 1, $J_{1,2}$ 1.5 Hz, H-1), 5.76 (d, 1, $J_{2,NH}$ 9.1 Hz, NH), 4.90 (dd, 1, $J_{2,3}$ 4.0, $J_{3,4}$ 9.5 Hz, H-3), 4.73 (m, 1, H-2), 4.52 (dd, 1, $J_{5,6}$ 4.1, $J_{6,6'}$ −12.2 Hz, H-6), 4.30 (dd, 1, $J_{5,6'}$ 1.6 Hz, H-6'), 3.76–3.63 (m, 2, H-4, H-5), 2.80 (d, 1, $J_{4,OH}$ 3.7 Hz, OH), 2.14 (3, $NHCOCH_3$), 2.10, 2.08, 2.07 (9H, $OCOCH_3$).

Anal.—Calc. for $C_{14}H_{21}NO_9$: C, 48.41; H, 6.05; N, 4.03. Found: C, 48.29; H, 6.22; N, 4.25.

2-Acetamido-1,3,6-tri-O-acetyl-2-deoxy-4-O-mesyl-α-D-mannopyranose (III)—Methanesulfonyl chloride (0.05 g, 0.44 mmole) was added to a solution of II (0.1 g, 0.29 mmole) in pyridine (5 ml) cooled to −10°. The mixture was allowed to stand at room temperature overnight, after which time TLC (chloroform–methanol, 9:1, v/v) indicated a new product. Toluene was added and the mixture was then evaporated under reduced pressure. The residue was chromatographed on silica gel to afford the 4-mesylate III, (chloroform–methanol, 49:1) as a syrup (0.1 g, 82%), $[\alpha]_D^{23}$ − 18.9° (c 1, chloroform); ^{1}H-NMR[6]: δ 5.86 (d, 1, $J_{1,2}$ 1.8 Hz, H-1), 5.81 (d, 1, $J_{2,NH}$ 8.8 Hz, NH), 5.14 (dd, 1, $J_{2,3}$ 4.1, $J_{3,4}$ 9.9 Hz, H-3), 4.82–4.75 (m, 2, H-2, H-4), 4.45 (dd, 1, $J_{5,6}$ 4.4, $J_{6,6'}$ −12.4 Hz, H-6), 4.25 (dd, 1, $J_{5,6'}$ 2.2 Hz, H-6'), 3.86 (m, 1, $J_{4,5}$ 9.5 Hz, H-5), 3.07 (OSO_2CH_3), 2.11, 2.10, 2.05 (12, $NHCOCH_3$, $OCOCH_3$).

Anal.—Calc. for $C_{15}H_{23}NO_{11}S$: C, 42.35; H, 5.41; N, 3.29; S, 7.53. Found: C, 42.10; H, 5.68; N, 3.02; S, 7.74.

2-Deoxy-2-trifluoroacetamido-D-mannopyranose (IV)—A solution of methanol (5 ml) and ethyl trifluoroacetate (1 ml) was added to a mixture of D-mannosamine hydrochloride[7] (0.5 g, 2.3 mmoles) and sodium carbonate (0.25 g). The reaction was shown by TLC (ethyl acetate–methanol, 4:1, v/v) to be essentially complete after 2–3 hr. The mixture was evaporated with silica gel and applied to a dry-packed column of silica gel. Elution with chloroform–methanol (9:1, v/v) afforded IV (0.44 g, 69%) as an immobile syrup, $[\alpha]_D^{23}$ + 19° (c 1, methanol).

Anal.—Calc. for $C_8H_{12}F_3NO_6$: C, 34.91; H, 4.36; N, 5.09; F, 18.54. Found: C, 35.13; H, 4.67; N, 4.89; F, 18.16.

1,3,6-Tri-O-acetyl-2-deoxy-2-trifluoroacetamido-α-D-mannopyranose (VI)—Acetyl chloride was added to a solution of IV (2.83 g, 7.1 mmoles) in pyridine (180 ml) at room temperature. The reaction was conducted and processed as described for the preparation of II. Chromatography of the mixture of products on silica gel (chloroform), afforded the anomeric mixture of tri-*O*-acetyl derivatives (0.88 g, 21.2%) from which VI (0.22 g, 5.3%) was obtained on crystallization from ether, mp

Assay of Cytotoxic Activity in Cell Culture—Friend erythroleukemia cells were grown at 37° in a suspension culture of Dulbecco's modified Eagle's medium containing 15% fetal calf serum and 0.02 m*M* glutamine. Exponentially growing Friend cells were seeded in 25-cm² plastic culture flasks at 1 × 10^5 cells/ml in 5 ml of medium. The test substance at various concentrations in phosphate-buffered saline was added at time zero, and the cells were incubated for 48 hr. The total number of cells in each of duplicate flasks was determined for the three separate experiments with a particle counter[8].

RESULTS AND DISCUSSION

In an effort to determine whether the biological properties of 2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-mannopyranose (I) were related to the presence of a more stable 4-*O*-acetyl group relative to the other acetyl groups and, in addition, to ascertain whether this substituent is also involved in the cytotoxic action of the trifluoroacetamido analogue (V), 2-acetamido-1,3,6-tri-*O*-acetyl-2-deoxy-α-D-mannopyranose (II), 1,3,6-tri-*O*-acetyl-2-deoxy-2-trifluoroacetamido-α-D-mannopyranose (VI), and their corresponding 4-*O*-mesylates (III) and (VII) were prepared and evaluated for their cytotoxicity in culture. It was speculated that removal of the 4-*O*-acetyl group from I to give II would result in a significant reduction in the cytotoxic properties in culture, while substitution of the 4-*O*-mesyl group, which is structurally similar and might be expected to be relatively more resistant to enzymatic hydrolysis, would result in greater activity than I.

The synthesis of trifluoroacetamido derivatives has been reported utilizing a variety of reagents, including ethyl trifluoroacetate (22, 23), trifluoroacetyl triflate (24), and trichlorotrifluoroacetone (25). *S*-Ethyl trifluorothioacetate (26) and trifluoroacetic anhydride (27–30) have been used previously in the synthesis of amino sugar nucleosides, in which the trifluoroacetyl moiety served as an *N*-blocking group. Accordingly, treatment of D-mannosamine hydrochloride with ethyl trifluoroacetate in methanol in the presence of sodium carbonate afforded 2-deoxy-2-trifluoroacetamido-D-mannopyranose (IV) as an immobile syrup in 69% yield. Compounds II and VII were prepared by a selective reaction involving treatment of *N*-acetyl-β-D-mannosamine and IV in pyridine with acetyl chloride until an optimum conversion to a triacetylated mixture was apparent. These products were purified by silica gel column chromatography, to afford anomeric mixtures of triacetylated derivatives from which the appropriate α-anomers II and VII were crystallized in 12% and 5.3% yields, respectively.

The structures of the analogues were confirmed by ^{1}H-NMR spectroscopy. The $J_{1,2}$ coupling constants for II and VI were 1.5 and 1.8 Hz, respectively, indicating the α-configuration (31). The signals due to H-4 coincided with H-5 (δ 3.76–3.63) in II and appeared at 3.74 in VI, essentially resonating at a higher field when compared with the other ring protons (as would be expected). Doublets at δ 2.80 in II and δ 2.86 in VI were assigned to the OH groups at H-4, since addition of deuterium oxide caused the signals to collapse while the triplet of doublets due to H-4 in VI reverted to a triplet. Further treatment of II and VII with methanesulfonyl chloride in pyridine afforded mesylates (III) and (VII) as syrupy products. The ^{1}H-NMR spectra of III and VII both showed shifts of their H-4 resonance signals to lower field in comparison with II and VI, respectively, while three proton singlets at δ 3.07 in II and δ 3.08 in VII were assigned to the mesyl groups.

Compounds I–III and V–VII were tested for their ability to inhibit the growth of Friend erythroleukemia cells in culture. The tetraacetate (I) had an ID_{50}[9] of ~9 × 10^{-5} *M*, while that of II and III were ~8.5 × 10^{-4} *M* and 2 × 10^{-5} *M*, respectively (Fig. 2). In contrast, the trifluoroacetamido analogues V, VI, and VII all gave similar ID_{50} values of 2–3 × 10^{-5} *M* (Fig. 3)[10]. The triacetate (II) is, therefore, 10-fold less active than I, while the 4-*O*-mesylate (III) is at least fourfold more active. These findings support the conclusion that the 4-*O*-acetyl and 4-*O*-mesyl groups play an important role in the cytotoxic properties of these compounds. The finding of similar activity for analogues in the trifluoroacetamido series (V–VII) implies that the biological properties of these compounds are due predominantly to the trifluoroacetamido moiety and are independent of substituents at the 4-position.

High-Performance Liquid Chromatographic Determination of Pralidoxime Chloride and Its Major Decomposition Products in Injectable Solutions

DAVID G. PRUE ˣ, RAYMOND N. JOHNSON, and BOEN T. KHO

Received April 23, 1982, from *Ayerst Laboratories, Inc., Rouses Point, NY 12979.* Accepted for publication June 22, 1982.

Abstract □ A high-performance liquid chromatographic (HPLC) method for the simultaneous determination of pralidoxime chloride (I) and its major decomposition products in an injectable formulation is described. I and its decomposition products were detected and quantitated by their UV absorbances at 270 nm, after being separated from related compounds and formulation excipients on a reverse-phase C-18 column using a mobile phase consisting of 52% acetonitrile and 48% of an aqueous solution containing 0.005 *M* phosphoric acid and 0.001 *M* tetraethylammonium chloride. The major decomposition products of I in the injectable formulation were identified by their retention times and stop-flow spectroscopy as 2-carboxy-*N*-methylpyridinium chloride, *N*-methyl-2-pyridone, 2-carbamoyl-*N*-methylpyridinium chloride, 2-hydroxymethyl-*N*-methylpyridinium chloride, and 2-cyano-*N*-methylpyridinium chloride. A substance of unknown identity also was detected in degraded solutions of I. Stop-flow spectroscopy, employing the spectral discrimination technique, showed that the method is specific for I. Recovery of I from a spiked placebo formulation averaged 99.9%. The accuracy of the method was also demonstrated for the decomposition products over a range of concentrations representing 1–50% decomposition. Replicate determinations of I in degraded solutions gave coefficients of variation of 1.0 and 1.5%, while the precision of determining the decomposition products range from 1.3 to 6.5%. Regression lines with correlation coefficients >0.9999 were obtained for I and its decomposition products, and solutions of these compounds were shown to be stable in the mobile phase for several days. Results for I by the HPLC and USP procedures are compared.

Keyphrases □ Pralidoxime chloride—decomposition products in aqueous solutions, concurrent high-performance liquid chromatographic determination □ High-performance liquid chromatography—concurrent determination of pralidoxime chloride and its decomposition products in aqueous solutions, comparison to USP procedure □ Degradation products—of pralidoxime chloride, concurrent high-performance liquid chromatographic determination

Pralidoxime chloride, 2-[(hydroxyimino)methyl]-1-methylpyridinium chloride (I), is a reactivator of organophosphate-inhibited cholinesterase. It has therapeutic value as an antidote to poisoning by organophosphate agricultural chemicals, chemical warfare agents, and drugs acting as cholinesterase inhibitors. Compound I is typically formulated as an aqueous injectable solution which is administered intramuscularly immediately after the onset of anticholinesterase poisoning.

Unfortunately, aqueous solutions of the various salts of pralidoxime have been shown to be unstable. The instability of pralidoxime in both acidic and basic media was first described in a series of reports (1–4) which proposed the existence of several decomposition products of pralidoxime iodide: the iodide salts of the 2-carboxy-, 2-formyl-, 2-carbamoyl-, and 2-cyano-*N*-methylpyridinium ions and *N*-methyl-2-pyridone. In addition, two major decomposition products were detected in solutions of pralidoxime

The instability of pralidoxime in both acidic and basic media was first described in a series of reports (1–4) which proposed the existence of several decomposition products of pralidoxime iodide: the iodide salts of the 2-carboxy-, 2-formyl-, 2-carbamoyl-, and 2-cyano-*N*-methylpyridinium ions and *N*-methyl-2-pyridone. In addition, two major decomposition products were detected in solutions of pralidoxime

methanesulfonate (5), which were identified as the methanesulfonate salts of the 2-carbamoyl- and 2-cyano-*N*-methylpyridinium ions. The kinetics of the hydrolysis of the cyano-pyridinium ions were studied (6), and it was shown that 99.1% of the material from the alkaline hydrolysis of the 2-cyano-*N*-methylpyridinium ion could be accounted for as 2-carbamoyl-*N*-methylpyridinium ion and *N*-methyl-2-pyridone. A fluorescent product was isolated from the alkaline hydrolysis of I (7). On the basis of physical and physicochemical properties, it was concluded that this product was 2-cyano-1-methyl-4-pyridone.

Although a complete decomposition profile of I has not been described in the literature, it was anticipated that the decomposition of I would lead to the same decomposition products as reported for the corresponding iodide and methanesulfonate salts. The procedure in the USP XX (8) for determining I does not adequately separate and isolate these decomposition products before analysis. I is quantitated in the presence of its decomposition products at the UV wavelength of 336 nm, which is sensitive for I but has only minimal sensitivity for the decomposition products. A number of high-performance liquid chromatographic (HPLC) procedures (9–11) for determining pyridinium aldoximes have been reported; however, not one is suitable for studying the stability of I.

In this present study, a specific HPLC method has been developed which separates and simultaneously quantitates I and its major decomposition products. In addition, this chromatographic system separates I from its primary synthetic precursor, pyridine-2-aldoxime, and a number of other structurally related compounds. This method was used to study the stability of an injectable formulation of I and two previously unreported decomposition products were detected.

EXPERIMENTAL

Reagents—Phosphoric acid[1] was reagent grade; tetraethylammonium chloride[2] was used without further purification; acetonitrile[3] was UV grade, distilled in glass. The following reference compounds were used: pralidoxime chloride[4] (I), 2-carboxy-*N*-methylpyridinium chloride[5] (II), *N*-methyl-2-pyridone[5] (III), 2-cyano-1-methyl-4-pyridone[6] (IV), pyridine-2-aldoxime[5] (V), *syn*-pralidoxime chloride[7] (VI), 2-formyl-*N*-methylpyridinium chloride[8] (VII), 2-carbamoyl-*N*-methylpyridinium

chloride[9] (VIII), 2-aminomethyl-*N*-methylpyridinium chloride[9] (IX), 2-hydroxymethyl-*N*-methylpyridinium chloride[9] (X), 2-cyano-*N*-methylpyridinium chloride[10] (XI), and *N*-methylpyridinium chloride[9] (XII).

Chromatographic System—The high-performance liquid chromatograph consisted of a mobile-phase pump[11] operated at 0.8 ml/min (1600 psi), a sample injector[12] set for a 15-μl injection volume, a variable-wavelength UV detector[13] at 270 nm (0.08 AUFS), a precolumn[14] positioned between the pump and the injector, and an analytical reverse-phase C-18 column[15]. Areas under the chromatographic peaks were measured by electronic integration[16]. The mobile phase consisted of 52% acetonitrile and 48% of an aqueous solution of 0.005 *M* phosphoric acid and 0.001 *M* tetraethylammonium chloride. Chromatographic data were acquired at ambient temperature.

Analytical Procedure—*Preparation of Sample and Standard Solutions*—A volume equivalent to 330 mg of I was transferred to a 250-ml volumetric flask and diluted to volume with water. A 1.0-ml aliquot of this solution was pipetted into a 50-ml volumetric flask and diluted to volume with the mobile phase.

Stock solutions were prepared by accurately weighing ~25, 50, and 75

mg of I, transferring these amounts to separate 50-ml volumetric flasks, and dissolving them in water. A 1.0-ml aliquot of each stock solution was diluted separately to 50 ml with mobile phase. A standard solution containing II, III, VIII, and XI was prepared by accurately weighing ~33 mg of each compound, transferring these amounts to a single 50-ml volumetric flask, and dissolving and diluting them to volume with water. A 10.0-ml aliquot of this solution was diluted to 50 ml with water. A 1.0-ml aliquot of this diluted solution was pipetted into a 50-ml volumetric flask, which contained 1.0 ml of the stock solution containing 50 mg of I. The mixture was diluted to volume with the mobile phase.

System Suitability Test—The detector wavelength was set to 270 nm, 15 μl of the middle (50 mg) standard preparation was injected, and the flow rate of the mobile phase and sensitivity of the detector were adjusted so that the I peak eluted in ~7.5 min (~0.8 ml/min) and was at least 50% of full scale (~0.08 AUFS). After the chromatographic conditions stabilized, 15 μl of the middle (50 mg) standard preparation and 15 μl of the

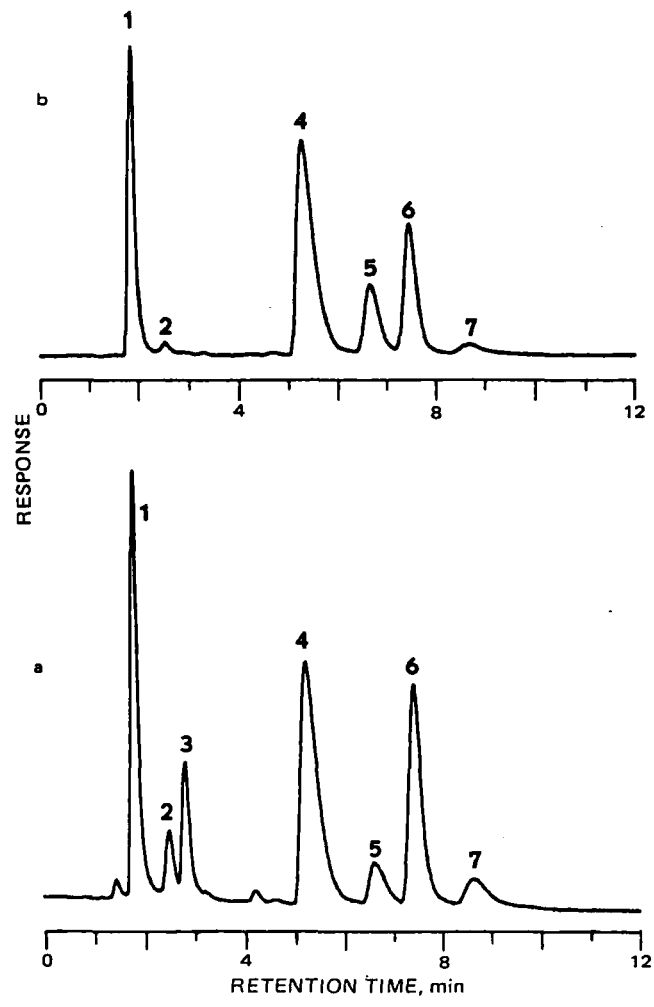

Figure 5—*Chromatograms of the injectable formulation stored at 80° for 4 weeks, using a detector wavelength of 200 nm (a) or 270 nm (b). Key: (1) II, (2) III, (3) benzyl alcohol, (4) VIII, (5) X and the unknown compound, (6) I, and (7) XI.*

standard preparation containing II, III, VIII, and XI were injected. The areas of the I peak in each chromatogram were obtained and compared; the chromatographic system was considered suitable for use if the areas were within 2%.

Injection Procedure—A 15-μl aliquot of each standard preparation was injected and the areas of the peaks for I, II, III, VIII, and XI were obtained. The same volume of each sample preparation was injected and the corresponding peak areas were determined.

Calculations—A least-squares linear regression line of the peak area *versus* weight of I (W_p) was obtained. The weight (W) corresponding to the peak area of I in the sample preparation was obtained from the regression line. The concentration of I in the sample was calculated from:

$$[\text{mg/ml}] = (W)(5)(P)(1/V) \qquad \text{(Eq. 1)}$$

where W is the weight of I corresponding to the area of I in the sample preparation chromatogram, P is the strength of the I reference standard (decimal), V is the volume (ml) of sample solution assayed, and 5 is the dilution factor (250/50). The concentration of each decomposition product detected in the sample was calculated from:

$$[\text{mg/ml}] = (A_2/A_1)(W_d)(P)(1/V) \qquad \text{(Eq. 2)}$$

where A_1 and A_2 are the areas of the appropriate decomposition product peaks (II, III, VIII, or XI) in the standard and sample preparations, respectively; W_d is the weight (mg) of the decomposition product; and P is the strength of the decomposition product standard (decimal). If a peak(s) was observed eluting between that of VIII and I (~6.7 min), a response equal to the latter was assumed and the concentration was calculated accordingly.

Table I—Wavelength Absorbance Ratios for Reference I and Injectable Formulation Stored for 2 Weeks at 80° [a]

RESULTS AND DISCUSSION

Specificity and Identification of Decomposition Products—Previous reports (1–7) have indicated that the degradation of I can proceed *via* hydrolysis or dehydration to form a number of decomposition products. Among those decomposition products previously reported are II, III, IV, VII, VIII, and XI. Since pyridinium compounds readily form decomposition products, some of which may not have been described in these original studies, additional compounds including V (the primary synthetic precursor of I), VI (the *syn*-isomer of I), IX, X, and XII were also studied.

To accurately monitor the stability of I in the injectable formulation, it is mandatory that the chromatographic system be capable of separating I from all its possible decomposition products. Because of the quaternary structure of the pyridinium aldoximes, ion-pair HPLC was expected to provide the required separation. However, various mobile phase combinations employing classical ion-pairing reagents of opposite charge, *e.g.*, *N*-heptanesulfonic acid and sodium dodecanesulfonate, produced only partial separations and tailing of some peaks. Mobile phases employing tetraethylammonium chloride, a modifier with the same charge as the pyridine aldoximes, produced superior separations and more symmetrical peaks. Control of retention and peak shape by a modifier of the same charge as the sample is not considered to be the classical ion-pairing phenomenon, but is better explained by the broader-scoped concept of ion interaction (13).

The separation of I from II–XII using the aforementioned HPLC system is shown in Fig. 1. Compound XII is not shown in the chromatogram due to its excessively long retention time of 27.4 min. Experience with this chromatographic system has shown that different batches of Spherisorb-ODS have slightly different separation characteristics. These differences are attributed to variations in the amounts of free silanols present on the bonded silica. These differences can be minimized by modifying the composition of the mobile phase. The retention time of I can be shortened or lengthened by increasing or decreasing, respectively, the concentrations of tetraethylammonium chloride. Modifiers such as tetraethylammonium chloride minimize the interactions of the sample with residual silanols on the surface because the modifier can cover, or mask, these silanol groups. This coverage of accessible silanols is the basis of the competing base concept (14).

Table II—Wavelength Absorbance Ratios for Reference I and the Injectable Formulation Stored for 4 Weeks at 80° [a]

Other[c]	15.5	5.4	22.3	3.0

[a] n = 10, five determinations on each of 2 days. [b] — None detected. [c] Composite of X and an unknown compound; assumes a response equal to I.

Figure 2 depicts the loss of I and the formation of its decomposition products in the injectable formulation which was stored at 80°. After 2, 4, and 8 weeks at 80°, the amounts of I remaining were 65, 20, and 3% of the initial concentration, respectively. Use of another mobile phase, which shortened the retention time of XII to 8 min, indicated that XII was not formed in measurable quantities in any of the degraded samples of the formulation.

The peaks corresponding to the decomposition products in Fig. 2 were tentatively identified by comparison of their respective retention times with those of reference compounds I–XII. Confirmation of the identity of each peak was made by comparison of its stop-flow UV absorption spectra with the stop-flow spectra of the reference compound of corresponding retention time. Stop-flow UV spectra of peaks 1–6 in Fig. 2c (injectable formulation stored for 4 weeks at 80°) are given in Fig. 3.

Other investigators (11) have recently studied the degradation of I under both acidic and basic conditions using ion-pair HPLC. Unfortunately, in the chromatographic system they employed, VII and VIII have the same retention time. Nevertheless, based on retention time data, it was reported that the only hydrolytic byproduct of I in acid solution (0.1 *N* HCl) was VII. Under basic conditions (0.1 *N* NaOH) it was reported that II, III, and VIII were formed. Although acid hydrolysis was the expected mode of decomposition in the injectable formulation (which is buffered at pH 2.5), it is evident from Fig. 2 that primarily products usually associated with base hydrolysis are formed. It is readily seen that the major decomposition products of I in the injectable formulation are II and VIII; III and XI are also formed, but in relatively small amounts. Compound VII, which is separated from VIII in Fig. 1, is not observed in any of the chromatograms in Fig. 2.

In addition to peaks corresponding to decomposition products previously reported, another peak (peak 4) with a retention time of 6.7 min was observed in the chromatograms in Fig. 2. The retention time of this peak corresponds exactly to X, since compound IX has a retention time of 6.5 min. As shown in Fig. 3d, the frontside of peak 4 has a stop-flow UV spectra consistent with the reference spectra of X, but the backside of

Table VI—Comparison of HPLC and USP Results For I in the Injectable Formulation

Storage Conditions	Concentration of I, mg/ml HPLC	USP
Initial	324	328
2 Days, 80°	309	316
6 Days, 80°	285	294
9 Days, 80°	272	281
13 Days, 80°	249	255
21 Days, 80°	156	160
28 Days, 80°	62.6	66.6

the peak has a spectra which does not match any of the reference compounds. These differing spectra suggest that peak 4 is a composite of X and another substance. This was later confirmed when peak 4 was resolved into two components using a different mobile phase. The first component was identified as X. The identity of the second component is unknown, but is of major interest because it has been detected in solutions of I when no other decomposition peaks are observed (Fig. 4). This substance seems to be formed soon after the dissolution of I in aqueous media, then gradually increases to an equilibrium concentration of ~3% (area percent relative to I). Similar observations have been made by other investigators[17] using a method based on ion-pairing HPLC. As of this writing, the presence of X and the unknown compound in degraded solutions of I has not been reported in the literature.

The formulation that was decomposed at 80° for 4 weeks (Fig. 2c) was chromatographed at the nonspecific wavelength of 200 nm to observe any other peaks that might appear and are not detected at 270 nm. Figure 5 demonstrates that no other decomposition peaks of significant intensity were detected at 200 nm, and that the analytical wavelength of 270 nm provides adequate sensitivity for I and the corresponding decomposition products. However, a formulation excipient, benzyl alcohol, was detected at 200 nm (Fig. 5a).

Stop-flow spectroscopy, employing the spectral discrimination technique (15), was performed on the peaks corresponding to I in the injectable formulations that were decomposed at 80° for 2 (Fig. 2b) and 4 weeks (Fig. 2c). These storage conditions produced 35 and 80% decomposition of I, respectively. Absorbance readings at nine discrete wavelengths across the UV spectrum were obtained on the front, middle, and back of each I peak. Similarly, absorbances at each wavelength were obtained on a reference peak of I from a separation injection. If the ratio (Q) of absorbance values at each wavelength between the reference and sample peaks remains constant ($D = Q_{max}/Q_{min} \leq 1.5$), evidence is strong that the sample peak has the same identity as the reference peak. Likewise, if the ratio of absorbances taken from different portions of a single peak are constant, then the peak is considered homogeneous and is, therefore, the response of a single molecular species. For all cases, the test for peak identity and peak homogeneity was positive, *i.e.*, the values of the spectral discriminator (D) were between 1 and 1.5 (Tables I and II). These data strongly suggest that the chromatographic system separates I from all UV-absorbing components in the degraded formulation.

Accuracy—Known amounts of I corresponding to 80, 100, and 120% of the label claim (330 mg/ml) were added to a placebo of the injectable formulation and assayed. The recoveries of I from the spiked formulations were 100.2, 99.9, and 99.6%, respectively.

The accuracy of determining various concentrations of the decomposition products (those actually detected in the decomposed formulation) was determined by adding known amounts of II, III, VIII, and XI to the formulation at levels corresponding to 1, 2, 5, 10, 20, and 50% decomposition. Therefore, the spiked formulation representing 1% decomposition contained ~3.3 mg/ml of each decomposition product, the spiked formulation representing 10% decomposition contained ~33 mg/ml of each decomposition product, *etc.* Recoveries of II, III, VIII, and XI were calculated from a single chromatogram that represented each spike level. The results are given in Table III. The accuracy of determining the concentration of X was not evaluated because its peak, being a composite of two substances in the degraded formulation, precludes such a determination.

Precision—Replicate assays were performed on the injectable formulation which was stored for 7 and 26 days at 80° to promote decomposition. Assays were performed 10 times over a period of 2 days using freshly prepared standards on each day of analysis. Between determinations the solutions were stored at 4°. The results are given in Table IV and indicate that the method has acceptable precision for determining all compounds of interest.

Linearity—The UV absorbance of I at 270 nm increased linearly (r = 0.9999874, y-intercept = −338) with concentration in the range corresponding to 125–375 mg/ml in the injectable formulation. Although the analytical method does not require that a calibration curve be prepared for each decomposition product, the responses of II, III, VIII, and XI at 270 nm are linear over the range 3.3 (limit of detection) to 165 mg/ml in the injectable formulation. The correlation coefficients for curves in this range were: II, r = 0.9999504, y-intercept = 452; III, r = 0.9999574, y-intercept = 243; VIII, r = 0.9999806, y-intercept = −73; and XI, r = 0.9999516, y-intercept = 62. An evaluation of the y-intercepts of each curve indicated that they were not statistically different from zero at $p < 0.05$.

Stability of I and Decomposition Products in Mobile Phase—The stability of I and its decomposition products during the time required to perform the analytical procedure is an important consideration. During the determination, I and its decomposition products should not be subjected to conditions of acid or base hydrolysis other than that which has actually occurred in the formulation. The high pH requirements of the UV procedure in USP XX for determining I in the presence of its decomposition products promotes base hydrolysis and requires that the analytical measurements be performed as rapidly as possible. The UV method does not easily lend itself to unattended operation because of this requirement.

The stability of I and its decomposition products during the time required to perform the HPLC procedure was assessed by preparing solutions of I, II, III, VIII, and XI in accordance with the analytical procedure, and assaying them at various intervals after storage at ambient laboratory conditions. The results (Table V) indicate that solutions of these compounds are stable in the mobile phase not only for the time required to perform the procedure, but for extended times up to several days. Consequently, with the use of an autoinjector, unattended chromatographic separation and measurement may be performed.

Comparison of HPLC and USP Procedures on Degraded Formulations—A comparison of the concentrations of I in degraded formulations found by the HPLC and USP procedures is given in Table VI. Although good agreement is observed, there is a consistent bias of ~2–3% between the two procedures. The higher values obtained by the USP procedure may be the result of interference, since the USP procedure requires that the measurement of I be made in the presence of its decomposition products. To its advantage, the HPLC procedure separates the decomposition product prior to the determination of I.

Dissolution Kinetics of a Three-Component Solid I: Ethylparaben, Phenacetin, and Salicylamide

MICHAEL SIMPSON and EUGENE L. PARROTT ˣ

Received March 12, 1982, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication June 29, 1982.

Abstract □ The dissolution rates of each component in compressed spheres consisting of three components were measured under sink conditions. A film diffusion model is discussed and presented diagrammatically to illustrate the 13 possible dissolution behaviors of a three-component solid. Experimental dissolution rates compare favorably to dissolution rates calculated according to the model at mass fractions representative of the 13 dissolution behaviors

Keyphrases □ Ethylparaben—dissolution kinetics of a three-component solid, phenacetin, salicylamide □ Phenacetin—dissolution kinetics of a three-component solid, ethylparaben, salicylamide □ Salicylamide—dissolution kinetics of a three-component solid, ethylparaben, phenacetin

A limited number of reports on dissolution rates have been concerned with multicomponent solids. Recently, a general model for the dissolution rates of a nondisintegrating sphere composed of any number of components was presented (1). The purpose of this study was to develop a dissolution model for a three-component solid (ethylparaben, phenacetin, and salicylamide). The model suggests 13 possible dissolution behaviors, which are dependent on composition. A further purpose was to compare the experimental dissolution rates of each of the components with the dissolution rates predicted by the model.

EXPERIMENTAL

Preparation of Spheres—Twenty grams of each composition were prepared by blending the appropriate amounts of 60/80-mesh size fraction of ethylparaben[1], phenacetin[2], and salicylamide[3] for 15 min in a V-blender[4]. By means of a hydraulic press[5] fitted with a spherical punch and die set, each composition was compressed at a force of 2268 kg into spheres having a diameter of 1.273 ± 0.005 cm. The compositions (represented by solid circles) were selected according to the scheme shown in Fig. 1. Each corner of the triangle represents a compressed sphere composed of a single component. The three straight lines joining the corners of the triangle represent two-component compositions. Thus, the lines AB, BC, and AC represent two-component mixtures of A and B, B and C, and A and C, respectively. Each side of the triangle was divided into 10 equal segments. For example, a point on line AC midway between A and C represents a composition of 50% A and 50% C with no component B. The area within the triangle represents all mass fraction compositions of A, B, and C in a three-component system. The intercept of any three lines parallel to one of the lines AB, BC, and AC represents the composition of a particular three-component mixture. With high percentages of phenacetin the spheres were not readily formed, and heat was used to facilitate formation. With compositions containing ethylparaben the die was at 110°, and the force of compression was exerted for 3 min. In the absence of ethylparaben a temperature of 134° was used. Comparison of the dissolution rates of compacts made at room temperature to those made with heat showed that the difference did not exceed 2.7%, which was considered to be within experimental error.

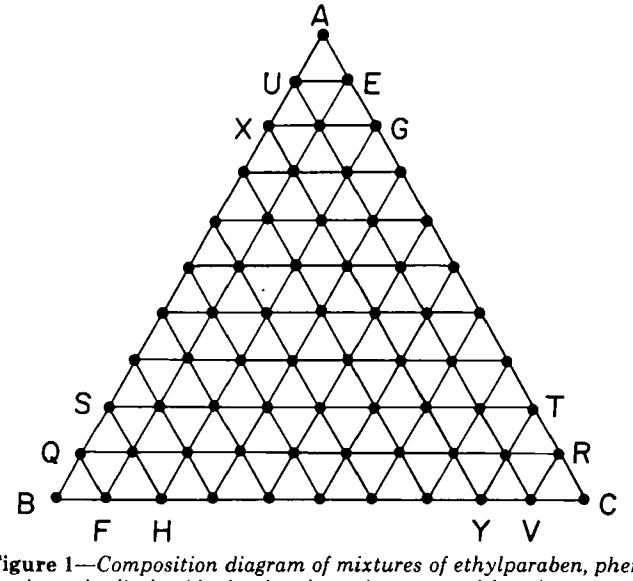

Figure 1—*Composition diagram of mixtures of ethylparaben, phenacetin, and salicylamide showing the various compositions (represented by solid circles) selected for investigation.*

Dissolution Rate—The dissolution rate was determined in distilled water at 25 ± 0.1°, as described previously (2, 3), under conditions where the concentration of the solutes did not exceed 5% of solubility. The dissolution apparatus and method were described previously (3, 4).

Solubility—Solubility measurements were made at 25°, as reported earlier (5). The solubilities of ethylparaben, phenacetin, and salicylamide are 0.939 ± 0.010, 0.842 ± 0.016, and 2.511 ± 0.018 mg/ml, respectively.

Analytical Procedure—The UV spectrum for each component was determined in a solution of that component containing 1.0 ml of 1.0 *N* sodium hydroxide in 25.0 ml of solution. The wavelengths of 296, 244, and 329 nm were selected. The standard curve of each component at each wavelength exhibited a Beer's law relationship. From these plots the nine

Table I—Molar Absorptivities of Ethylparaben, Phenacetin, and Salicylamide

Wavelength, nm	Molar Absorptivity		
	Ethylparaben	Phenacetin	Salicylamide
244	1,227	11,328	6,733
296	23,268	492	1,419
329	510	0	5,632

molar absorptivities were calculated (Table I). For a three-compartment system since absorbancies are additive:

$$A_1 = a_{11}C_A + a_{12}C_B + a_{13}C_C \quad \text{(Eq. 1)}$$

$$A_2 = a_{21}C_A + a_{22}C_B + a_{23}C_C \quad \text{(Eq. 2)}$$

$$A_3 = a_{31}C_A + a_{32}C_B + a_{33}C_C \quad \text{(Eq. 3)}$$

in which a_{ij} is the molar absorptivity of the species i at wavelength j, and A_j is the absorbance of the mixture at wavelength j. When the values of A_j and a_{ij} are substituted into Eqs. 1–3, and the equations are solved simultaneously, the concentrations C_A, C_B, and C_C are determined. Thus, the concentration of each component was obtained by UV absorbance at three selected wavelengths. The method was tested with seven solutions containing known concentrations of the three components. The percent determined by the analytical procedure ranged from 98.9 to 102.8% of the known concentration. The concentration was converted to amount dissolved in order to express a dissolution rate.

THEORY

With the dissolution of three-component solids if one assumes a Noyes–Whitney film theory, there are 13 dissolution behaviors possible. In Case IV dissolution behavior as shown in Fig. 2, the three components coexist at the solid–liquid interface, because as dissolution proceeds their boundaries recede at the same rate. This dissolution behavior occurs at a unique composition (critical composition) of the components at which:

$$\frac{N_A}{N_B} = \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 4)}$$

$$\frac{N_A}{N_C} = \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 5)}$$

and

$$\frac{N_B}{N_C} = \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 6)}$$

where N_A, N_B, and N_C are the mass fractions of components designated in general as A, B, and C; C_A, C_B, and C_C are their solubilities; and D_A, D_B, and D_C are their diffusion coefficients, respectively.

In Case V component C dissolves faster than components A and B, and

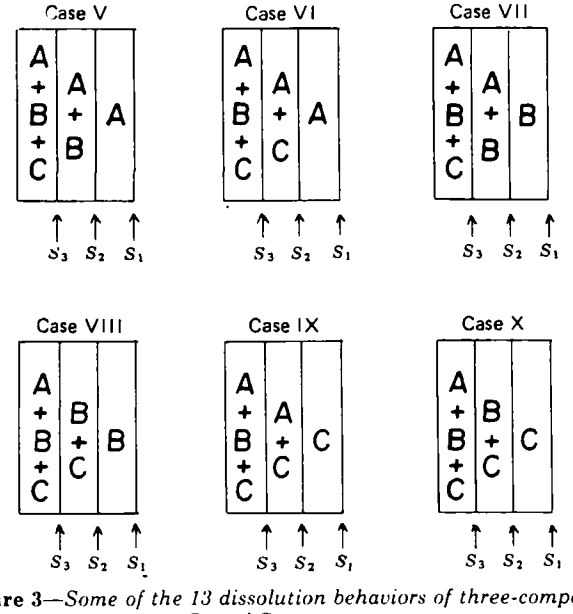

Figure 3—*Some of the 13 dissolution behaviors of three-component solids of components A, B, and C.*

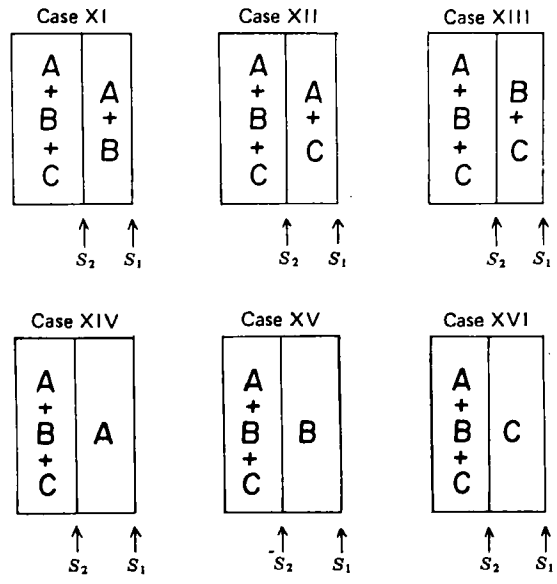

Figure 4—*Other possible dissolution behaviors of three-component solids of components A, B, and C.*

the dissolving boundary of component C recedes into the solid, as shown in Fig. 3. Component B dissolves faster from the solid surface than component A, so that the dissolving boundary of component B recedes within the solid leaving a surface layer of component A. Case V dissolution behavior occurs under the condition that:

$$\frac{N_A}{N_B} > \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 7)}$$

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 8)}$$

and

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 9)}$$

Cases VI, VII, VIII, IX, and X in Fig. 3 describe dissolution behaviors similar to Case V; however, the order of dissolving and the receding of the boundaries are different with different mass fractions of components A, B, and C.

In Case XI component C dissolves faster than the other two components and as dissolution proceeds the boundary of component C recedes within the solid leaving a layer of components A and B, which coexists

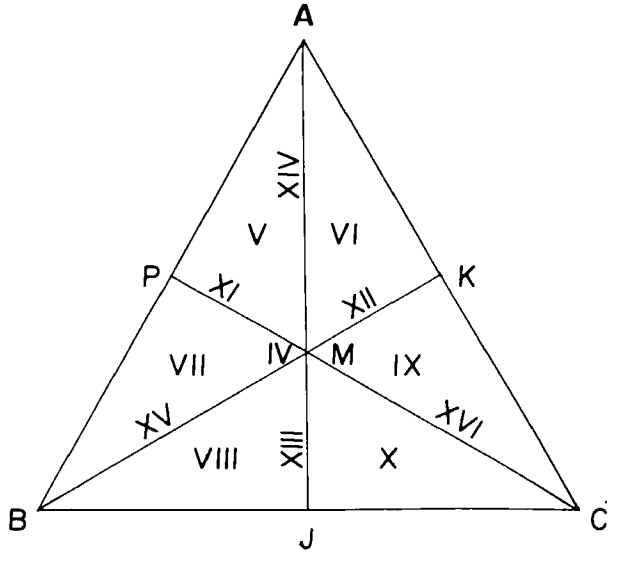

Figure 5—*Composition diagram for a three-component mixture of components having equal solubilities and diffusion coefficients showing the regions corresponding to the 13 dissolution behaviors. Roman numerals refer to the use of dissolution behavior described in the text.*

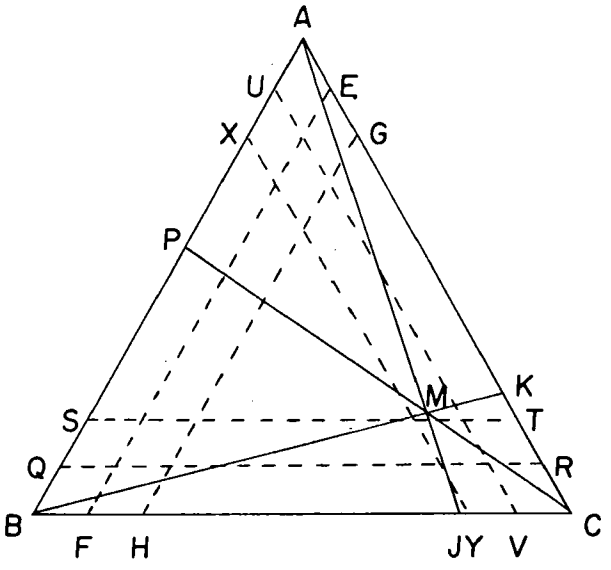

Figure 6—*Composition diagram for mixtures of ethylparaben, phenacetin, and salicylamide showing the regions corresponding to the 13 dissolution behaviors and their relationship to the compositions selected for investigation according to Fig. 1.*

at the surface, as shown in Fig. 4. Case XI dissolution behavior occurs under the conditions that:

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 10)}$$

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 11)}$$

and

$$\frac{N_A}{N_B} = \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 12)}$$

Cases XII and XIII in Fig. 4 describe dissolution behaviors similar to Case XI; however, the order of dissolving and the receding of the boundaries are different with different mass fractions of components A, B, and C.

In Case XIV both components B and C dissolve faster than component A and at the same rate, so that the boundaries of components B and C recede at the same rate and both coexist at the same boundary leaving a surface layer of component A. Case XIV dissolution behavior occurs under the conditions that:

$$\frac{N_A}{N_B} > \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 13)}$$

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 14)}$$

and

$$\frac{N_B}{N_C} = \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 15)}$$

Cases XV and XVI in Fig. 4 describe dissolution behaviors similar to Case XIV; however, the order of dissolving and the receding of the boundaries are different with different mass fractions of components A, B, and C.

Using any two combinations of Eqs. 4, 5, or 6 and Eq. 16,

$$N_A + N_B + N_C = 1 \quad \text{(Eq. 16)}$$

the critical composition of components A, B, and C may be calculated. Similarly, for two-component mixtures of components A and B, components A and C, and components B and C, the critical composition may be calculated by use of the appropriate relationships. Dissolution behaviors of two-component solids have been previously described (6) and are presented as Cases I, II, and III in Fig. 2. Using these critical compositions a composition diagram can be drawn for a three-component system. Figure 5 shows the compositions corresponding to the 13 dissolution behaviors cited for three hypothetical components, which have equal solubilities and diffusion coefficients. Case IV dissolution behavior

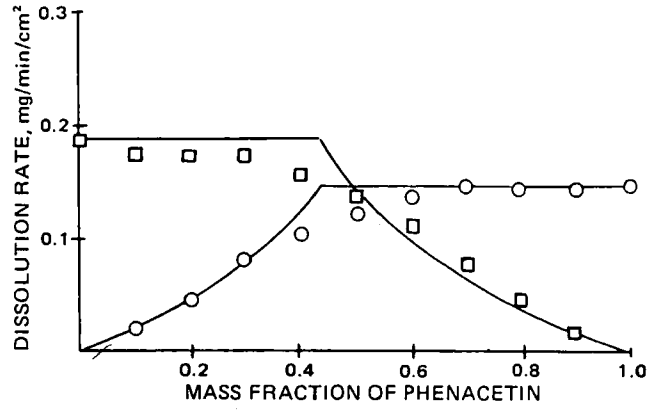

Figure 7—*Comparison of experimental dissolution rates of the components of ethylparaben and phenacetin mixtures corresponding to line AB of Fig. 1 and the smooth curves representing the theoretical rates. Key: (□) ethylparaben; (○) phenacetin.*

at the critical composition of the three-component mixture is represented by point M. Points P, J, and K represent the critical compositions of two-component mixtures of components A and B, components B and C, and components A and C, respectively. The line AMJ represents a three-component mixture, which contains components B and C (both in a mass fraction the same as the critical mass fraction for a two-component mixture of components B and C) with component A. From A to J the mass fraction of component A decreases while the mass fractions of components B and C increase.

The region APMK represents the condition in which components B and C have their boundaries within the solid coexisting, or following one another, depending on which portion is being considered. If the compositions of the three-component mixtures are on the line AM, there is a Case XIV dissolution behavior in which both components B and C coexist and have dissolving and receding boundaries within the solid, and component A is at the surface of the solid. Compositions within the region APM represent Case V dissolution behavior in which the dissolving boundary is deeper for component C than for component B, which in turn is deeper than that of component A, the surface component. Compositions within the region AMK represent Case VI dissolution behavior in which the dissolving boundary is deeper for component B than for component C, which in turn is deeper than that of component A, the surface component. Similarly, Case XI is represented by line PM; Case XII is represented by line MK; Case XIII is represented by line MJ; Case XIV is represented by line AM; Case XV is represented by line BM; and Case XVI is represented by line CM. Case VII is represented by the region BMP; Case VIII is represented by the region BMJ; Case X is represented by the region CMJ; and Case IX is represented by the region CMK.

The derivation of equations to describe dissolution of a three-component solid is illustrated for Case V dissolution behavior. Let S_1, S_2, and S_3 be the coordinate values representing the component A–solution boundary, component A–components A and B boundary, and compo-

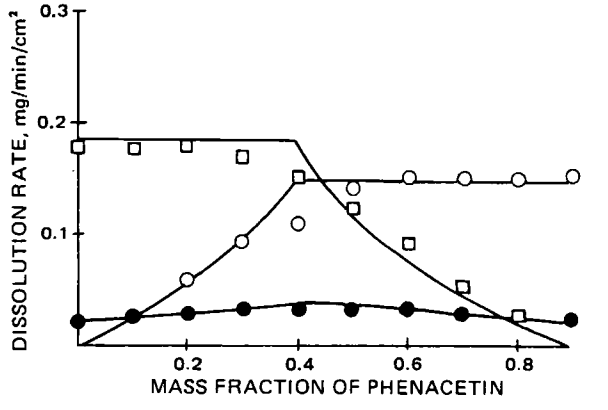

Figure 8—*Comparison of experimental dissolution rates of the components of ethylparaben, phenacetin, and salicylamide mixtures with a constant mass fraction of 0.1 salicylamide corresponding to line EF of Fig. 1 and the curves representing the theoretical rates. nents A, B, and C–components A and B boundary, respectively. These are defined so that at a time $t = 0, S_3 = S_2 = S_1 = 0$. At $t > 0, S_2 - S_1$ is the thickness of the layer of component A, and $S_3 - S_2$ is the thickness of the layer of components A and B. Since component A is always on the surface, the dissolution rate (R_A) of component A is:

$$R_A = \frac{D_A C_A}{h} \qquad \text{(Eq. 17)}$$

where h is the effective diffusion layer thickness.

Component B must diffuse through the layer of component A of thickness $S_2 - S_1$, porosity ϵ_1, and tortuosity τ_1, and the liquid diffusion layer. The dissolution rate (R_B) of component B is:

$$R_B = \frac{D_B C_B}{h + (\tau_1/\epsilon_1)(S_2 - S_1)} \qquad \text{(Eq. 18)}$$

Component C must diffuse not only through the liquid diffusion layer but also through the interstitial space between the undissolved components A and B of thickness, $S_3 - S_2$, porosity, ϵ_2, and tortuosity, τ_2, and through the layer of component A of thickness $S_2 - S_1$, porosity ϵ_1, and tortuosity τ_1. The dissolution rate (R_C) of component C is:

$$R_C = \frac{D_C C_C}{h + (\tau_1/\epsilon_1)(S_2 - S_1) + (\tau_2/\epsilon_2)(S_3 - S_2)} \qquad \text{(Eq. 19)}$$

The dissolution rates may also be expressed:

$$R_A = A_A \frac{dS_1}{dt} \qquad \text{(Eq. 20)}$$

$$R_B = A_B \frac{dS_2}{dt} \qquad \text{(Eq. 21)}$$

$$R_C = A_C \frac{dS_3}{dt} \qquad \text{(Eq. 22)}$$

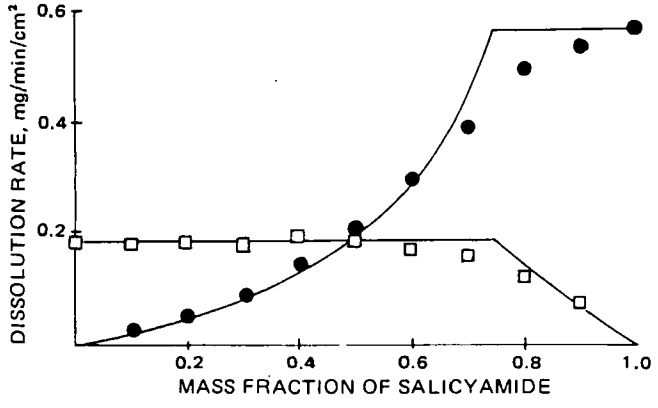

Figure 10—*Comparison of experimental dissolution rates of the components of ethylparaben and salicylamide mixtures corresponding to line AC of Fig. 1 and the smooth curves representing the theoretical dissolution rates. Key: (□) ethylparaben; (●) salicylamide.*

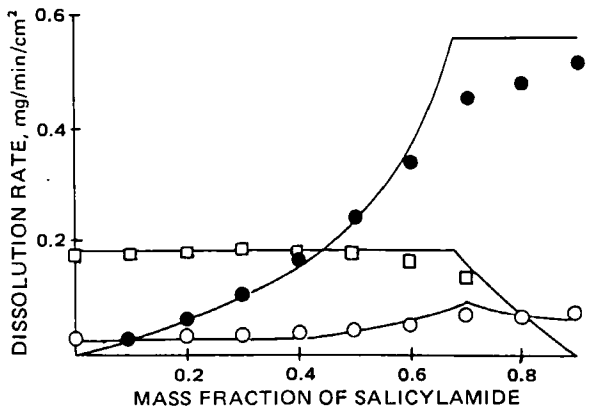

Figure 11—*Comparison of experimental dissolution rates of the components of ethylparaben, phenacetin, and salicylamide mixtures with a constant mass fraction of 0.1 phenacetin corresponding to line UV of Fig. 1 and the curves representing the theoretical rates. Key: (□) ethylparaben; (○) phenacetin; (●) salicylamide.*

where A_A, A_B, and A_C are the amounts per unit volume of component A, B, and C in the mixture. These equations state that the dissolution rate of a component is the product of the rate of movement of its boundary and the concentration in that layer. The amount of components B and C remaining in solution in the pores have not been considered. As the dissolution rate of component A is represented by Eqs. 17 and 20, it follows that:

$$A_A \frac{dS_1}{dt} = \frac{D_A C_A}{h} \qquad \text{(Eq. 23)}$$

$$\frac{dS_1}{dt} = \frac{D_A C_A}{A_A h} \qquad \text{(Eq. 24)}$$

When $S_1 = 0$ at $t = 0$, the solution to Eq. 24 is:

$$S_1 = \frac{D_A C_A t}{A_A h} \qquad \text{(Eq. 25)}$$

Substituting Eq. 25 into Eq. 18 and combining it with Eq. 22 yields:

$$\frac{dS_2}{dt} = \frac{D_B C_B}{A_B[h + (\tau_1/\epsilon_1)(S_2 - D_A C_A t/h)]} \qquad \text{(Eq. 26)}$$

$$= \frac{K_2}{h + (\tau_1/\epsilon_1)(S_2 - K_1 t)} \qquad \text{(Eq. 27)}$$

where $K_1 = D_A C_A / A_A h$ and $K_2 = D_B C_B / A_B$.

Using Laplace transforms (7) if $S_2 = 0$ at $t = 0$, the solution to Eq. 27 is:

$$t = 1/K_1[S_2 - (\epsilon_1/\tau_1)(K_2/K_1 - h)(1 - \exp -(K_1\tau_1/K_2\epsilon_1)S_2)] \qquad \text{(Eq. 28)}$$

If $S_2 \gg \epsilon_1 K_2/\tau_1 K_1 = \epsilon_1 D_B C_B A_A h/\tau_1 D_A C_A A_B$, Eq. 28 is approximately:

$$t = 1/K_1[S_2 - (\epsilon_1/\tau_1)(K_2/K_1 - h)] \qquad \text{(Eq. 29)}$$

which may be rearranged to:

$$S_2 = K_1 t + (\epsilon_1/\tau_1)(K_2/K_1 - h) \qquad \text{(Eq. 30)}$$

Differentiation of Eq. 30 yields:

$$\frac{dS_2}{dt} = K_1 = \frac{D_A C_A}{A_A h} \qquad \text{(Eq. 31)}$$

Substitution of Eq. 31 into Eq. 21 yields:

$$R_B = \frac{A_B D_A C_A}{A_A h} \qquad \text{(Eq. 32)}$$

$$R_B = \frac{N_B}{N_A} R_A \qquad \text{(Eq. 33)}$$

where N_A and N_B are the mass fractions of component A and B, respectively.

To derive the equation for the dissolution rate of component C, Eqs. 25 and 30 are substituted into Eq. 19 to yield:

$$R_C = \frac{D_C C_C}{h + (\tau_1/\epsilon_1)(K_1 t + Y - K_1 t) + (\tau_2/\epsilon_2)[S_3 - (K_1 t + Y)]} \qquad \text{(Eq. 34)}$$

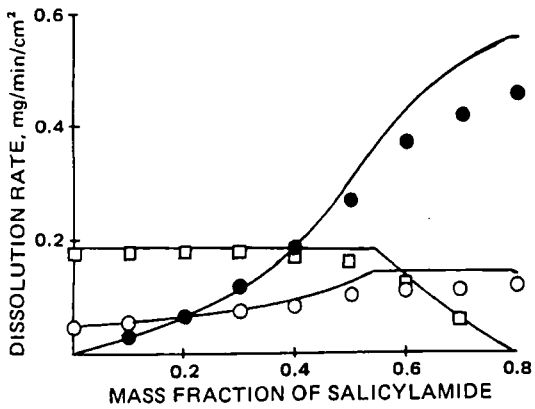

Figure 12—*Comparison of experimental dissolution rates of the components of ethylparaben, phenacetin, and salicylamide mixtures with a constant mass fraction of 0.2 phenacetin corresponding to line XY of Fig. 1 and the curves representing the theoretical rates. Key: (□) ethylparaben; (○) phenacetin; (●) salicylamide.*

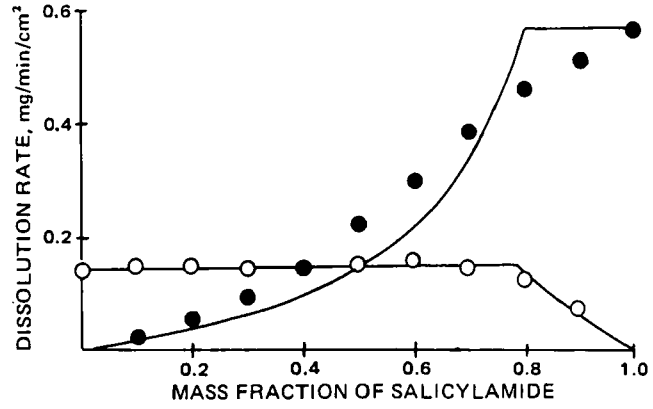

Figure 13—*Comparison of experimental dissolution rates of the components of phenacetin and salicylamide mixtures corresponding to line BC of Fig. 1 and the curves representing the theoretical rates. Key: (○) phenacetin; (●) salicylamide.*

where $Y = (\epsilon_1/\tau_1)(K_2/K_1 - h)$. Combining of Eqs. 22 and 34:

$$\frac{dS_3}{dt} = \frac{K_3}{h + (\tau_1/\epsilon_1)(Y) + (\tau_2/\epsilon_2)[S_3 - (K_1t + Y)]} \quad \text{(Eq. 35)}$$

and $K_3 = D_C C_C / A_C$.

Using Laplace transforms, the solution to Eq. 35 is:

$$t = 1/K_1[S_3 + (\epsilon_2/\tau_2)(K_3K_4 - K_3/K_1) \times (1 - \exp -(\tau_2K_1/\epsilon_2K_3)S_3)] \quad \text{(Eq. 36)}$$

where $K_4 = 1/K_3[h + Y([\tau_1/\epsilon_1] - [\tau_2/\epsilon_2])]$ and $Y = (\epsilon_1/\tau_1)(K_2/K_1 - h)$. If $S_3 \gg \epsilon_2K_3/\iota_2K_1 = \epsilon_2D_CC_CA_Ah/\tau_2D_AC_AA_C$, Eq. 36 simplifies to:

$$t = 1/K_1[S_3 + (\epsilon_2/\tau_2)(K_3K_4 - K_3/K_1)] \quad \text{(Eq. 37)}$$

Differentiating Eq. 37:

$$\frac{dS_3}{dt} = K_1 \quad \text{(Eq. 38)}$$

where $K_1 = D_AC_A/A_Ah$. Substituting Eq. 37 into Eq. 22:

$$R_C = \frac{A_CD_AC_A}{A_Ah} \quad \text{(Eq. 39)}$$

$$R_C = \frac{N_C}{N_A}R_A \quad \text{(Eq. 40)}$$

Equations 17, 33, and 40 may be used to calculate the theoretical dissolution rates of each of the components in a three-component mixture with the dissolution behaviors represented by Cases VI, VII, VIII, IX, and X.

By differential equations similar to those employed in the discussion of Case V dissolution behavior, the theoretical dissolution rate equations for Case XI dissolution behavior are:

$$R_A = \frac{D_AC_A}{h} \quad \text{(Eq. 41)}$$

$$R_B = \frac{D_BC_B}{h} \quad \text{(Eq. 42)}$$

$$R_C = \frac{N_C}{N_A}R_A = \frac{N_C}{N_B}R_B \quad \text{(Eq. 43)}$$

The dissolution rate equations for Case XII and XIII dissolution behavior are similar to those of Case XI.

The dissolution rate equations for Case XIV dissolution behavior are:

$$R_A = \frac{D_AC_A}{h} \quad \text{(Eq. 44)}$$

$$R_B = \frac{N_B}{N_A}R_A \quad \text{(Eq. 45)}$$

$$R_C = \frac{N_C}{N_A}R_A \quad \text{(Eq. 46)}$$

The dissolution rate equations for Case XV and XVI dissolution behavior are similar to those of Case XIV.

The dissolution rate equations for Case IV dissolution behavior are

$$R_A = \frac{D_AC_A}{h} \quad \text{(Eq. 47)}$$

$$R_B = \frac{D_CC_B}{h} \quad \text{(Eq. 48)}$$

$$R_C = \frac{D_CC_C}{h} \quad \text{(Eq. 49)}$$

as the three components coexist at the solid–liquid interface.

RESULTS AND DISCUSSION

Dissolution rates were measured at 25° under sink conditions at the various compositions shown as solid circles in Fig. 1 on lines AB, EF, GH, AC, UV, XY, BC, QR, and ST. For the system investigated A represents ethylparaben, B represents phenacetin, and C represents salicylamide. Lines AB, EF, and GH correspond to varying compositions of ethylparaben and phenacetin with a constant mass fraction of salicylamide of 0, 0.1, and 0.2, respectively. A similar interpretation is given to the other axes of the ternary diagram.

Dissolution rates were measured under identical experimental conditions used previously (3) to determine the effective diffusion layer thickness to be 3×10^{-3} cm. The solubility was experimentally measured. When the dissolution of a nondisintegrating pure solid occurring in a nonreactive medium at sink conditions is diffusion controlled, the dissolution rate may be expressed as (5):

$$R = \frac{DC_s}{h} \quad \text{(Eq. 50)}$$

The only unknown term in Eq. 50 is the diffusion coefficient. Rearranging Eq. 50 and substituting the experimental values for ethylparaben gives:

$$D = \frac{0.0031 \times 3 \times 10^{-3}}{0.939} = 1.00 \times 10^{-5} \text{ cm}^2/\text{sec} \quad \text{(Eq. 51)}$$

In a similar manner the diffusion coefficients of phenacetin and salicylamide were found to be 0.86×10^{-5} and 1.124×10^{-5} cm²/sec, respectively.

To determine the critical composition at which each of the components coexist at the solid–liquid interface with their dissolving boundaries receding at the same rate, the values of the diffusion coefficient and the solubility of the components were substituted into any two combinations of Eqs. 4, 5, or 6 with Eq. 16. By simultaneous solution the critical mass fractions are 0.209 ethylparaben, 0.163 phenacetin, and 0.628 salicylamide.

Similarly, by using the values of solubility and diffusion coefficient and appropriate equations (6), the critical mass fractions for two-component mixtures were calculated. The critical mass fractions are 0.562 ethylparaben and 0.438 phenacetin, 0.25 ethylparaben and 0.75 salicylamide, and 0.794 phenacetin and 0.206 salicylamide.

With these critical compositions for two- and three-component mixtures, Fig. 6 was constructed to show the regions that represent 13 dissolution behaviors and the lines of Fig. 1 from which the various com-

positions were chosen for investigation. By consideration of Fig. 6 and by then employing appropriate equations, the theoretical dissolution rates were calculated from dissolution behavior in the various regions of the diagram.

For Case IV dissolution behavior at the critical composition of the three components, the boundaries recede at the same rate, and the dissolution rates according to Eqs. 47–49 are:

$$R_A = \frac{1.00 \times 10^{-5} \times 0.939}{3 \times 10^{-3}} = 0.0031 \text{ mg/sec/cm}^2 \ (0.188 \text{ mg/min/cm}^2) \quad \text{(Eq. 52)}$$

$$R_B = \frac{0.86 \times 10^{-5} \times 0.842}{3 \times 10^{-3}} = 0.0024 \text{ mg/sec/cm}^2 \ (0.145 \text{ mg/min/cm}^2) \quad \text{(Eq. 53)}$$

$$R_C = \frac{1.124 \times 10^{-5} \times 2.511}{3 \times 10^{-3}} = 0.0094 \text{ mg/sec/cm}^2 \ (0.565 \text{ mg/min/cm}^2) \quad \text{(Eq. 54)}$$

To illustrate other calculations, consider the line QR passing through the regions BMP, BJM, CMJ, and CKM of Fig. 6. In the BMP region the dissolution behavior described as Case VII exists. A composition of 0.75 phenacetin, 0.10 ethylparaben, and 0.15 salicylamide on line QR lies in this regions in which:

$$\frac{N_B}{N_A} > \frac{D_B C_B}{D_A C_A} \quad \text{(Eq. 55)}$$

and

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 56)}$$

Thus, phenacetin exists in a layer at the solid surface while the boundaries of ethylparaben and salicylamide have receded into the solid. At this composition:

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 57)}$$

so that the dissolving and receding boundary of salicylamide recedes further than that of ethylparaben.

The dissolution rate of phenacetin according to Eq. 50 is:

$$R_B = \frac{0.86 \times 10^{-5} \times 0.842}{3 \times 10^{-3}} = 0.0024 \text{ mg/sec/cm}^2 \ (0.145 \text{ mg/min/cm}^2) \quad \text{(Eq. 58)}$$

The dissolution rates of ethylparaben and salicylamide are:

$$R_A = \frac{0.1}{0.75} \times 0.145 = 0.019 \text{ mg/min/cm}^2 \quad \text{(Eq. 59)}$$

and

$$R_C = \frac{0.15}{0.75} \times 0.145 = 0.029 \text{ mg/min/cm}^2 \quad \text{(Eq. 60)}$$

according to Eqs. 33 and 40.

For a solid composition of three components with mass fractions of 0.1 ethylparaben, 0.6 phenacetin, and 0.3 salicylamide on lines QR and BM separating regions BMP and BJM of Fig. 6:

$$\frac{N_B}{N_A} > \frac{D_B C_B}{D_A C_A} \quad \text{(Eq. 61)}$$

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 62)}$$

and

$$\frac{N_A}{N_C} = \frac{D_C C_A}{D_C C_C} \quad \text{(Eq. 63)}$$

This composition is described as Case XV dissolution behavior in which both ethylparaben and salicylamide have their dissolving and receding boundaries at the same rate within the solid leaving phenacetin at the solid surface.

The dissolution rate of phenacetin according to Eq. 50 is 0.145 mg/min/cm^2. The dissolution rates of ethylparaben and salicylamide are:

$$R_A = \frac{0.1}{0.6} \times 0.145 = 0.023 \text{ mg/min/cm}^2 \quad \text{(Eq. 64)}$$

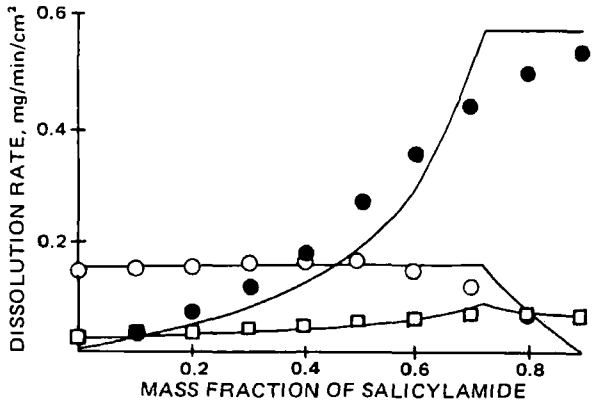

Figure 14—*Comparison of experimental dissolution rates of the components of ethylparaben, phenacetin, and salicylamide mixtures with a constant mass fraction of 0.1 ethylparaben corresponding to line QR of Fig. 1 and the curves representing the theoretical rates. Key: (□) ethylparaben; (○) phenacetin; (●) salicylamide.*

and

$$R_C = \frac{0.3}{0.6} \times 0.145 = 0.073 \text{ mg/min/cm}^2 \quad \text{(Eq. 65)}$$

according to Eqs. 45 and 46.

A solid composition of 0.1 ethylparaben, 0.4 phenacetin, and 0.5 salicylamide is described by Case VIII dissolution behavior in region BJM in which:

$$\frac{N_B}{N_A} > \frac{D_B C_B}{D_A C_A} \quad \text{(Eq. 66)}$$

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 67)}$$

and

$$\frac{N_C}{N_A} > \frac{D_C C_C}{D_A C_A} \quad \text{(Eq. 68)}$$

The dissolution rate of phenacetin according to Eq. 50 is 0.145 mg/min/cm^2. The dissolution rates of salicylamide and ethylparaben are:

$$R_C = \frac{0.5}{0.4} \times 0.145 = 0.181 \text{ mg/min/cm}^2 \quad \text{(Eq. 69)}$$

and

$$R_A = \frac{0.1}{0.4} \times 0.145 = 0.036 \text{ mg/min/cm}^2 \quad \text{(Eq. 70)}$$

A solid composition of three components with mass fractions of 0.1 ethylparaben, 0.184 phenacetin, and 0.716 salicylamide on line QR is described by Case XIII dissolution behavior on line JM (which separates regions BJM and CMJ) on which:

$$\frac{N_A}{N_B} < \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 71)}$$

$$\frac{N_A}{N_C} < \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 72)}$$

and

$$\frac{N_B}{N_C} = \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 73)}$$

The dissolution rates of phenacetin and salicylamide according to Eqs. 41 and 42 are 0.145 and 0.565 mg/min/cm^2. The dissolution rate of ethylparaben according to Eq. 43 is:

$$R_A = \frac{0.1}{0.184} \times 0.145 = 0.079 \text{ mg/min/cm}^2 \quad \text{(Eq. 74)}$$

A solid with a mass fraction of 0.1 ethylparaben, 0.13 phenacetin, and

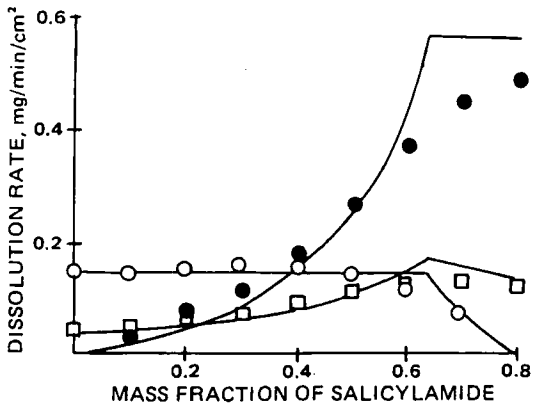

Figure 15—*Comparison of experimental dissolution rates of the components of ethylparaben, phenacetin, and salicylamide mixtures with a constant mass fraction of 0.2 ethylparaben corresponding to line ST of Fig. 1 and the curves representing the theoretical rates. Key: (□) ethylparaben; (○) phenacetin; (●) salicylamide.*

0.77 salicylamide on line QR has a Case X dissolution behavior in the region CMJ in which:

$$\frac{N_C}{N_A} > \frac{D_C C_C}{D_A C_A} \quad \text{(Eq. 75)}$$

$$\frac{N_C}{N_B} > \frac{D_C C_C}{D_B C_B} \quad \text{(Eq. 76)}$$

and

$$\frac{N_B}{N_A} > \frac{D_B C_B}{D_A C_A} \quad \text{(Eq. 77)}$$

In Case X dissolution behavior the dissolving and receding boundary of ethylparaben is deepest within the solid, the boundary of salicylamide is at the surface, and the boundary of phenacetin is between the two boundaries. The dissolution rate of salicylamide according to Eq. 50 is 0.565 mg/min/cm². The dissolution rate of phenacetin is:

$$R_B = \frac{0.13}{0.77} \times 0.565 = 0.095 \text{ mg/min/cm}^2 \quad \text{(Eq. 78)}$$

The dissolution rate of ethylparaben is:

$$R_A = \frac{0.1}{0.77} \times 0.565 = 0.073 \text{ mg/min/cm}^2 \quad \text{(Eq. 79)}$$

A solid composition with mass fractions of 0.1 ethylparaben, 0.075 phenacetin, and 0.825 salicylamide on line QR is described by Case XVI dissolution behavior on line CM (which separates regions CMJ and CKM) on which:

$$\frac{N_C}{N_A} > \frac{D_C C_C}{D_A C_A} \quad \text{(Eq. 80)}$$

$$\frac{N_C}{N_B} > \frac{D_C C_C}{D_B C_B} \quad \text{(Eq. 81)}$$

and

$$\frac{N_A}{N_B} = \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 82)}$$

At this composition salicylamide forms the surface layer, and the dissolving and receding boundaries of ethylparaben and phenacetin recede at the same rate within the solid. The dissolution rate of salicylamide according to Eq. 50 is 0.565 mg/min/cm². The dissolution rate of ethylparaben is:

$$R_A = \frac{0.1}{0.825} \times 0.565 = 0.068 \text{ mg/min/cm}^2 \quad \text{(Eq. 83)}$$

The dissolution rate of phenacetin is:

$$R_B = \frac{0.075}{0.825} \times 0.565 = 0.051 \text{ mg/min/cm}^2 \quad \text{(Eq. 84)}$$

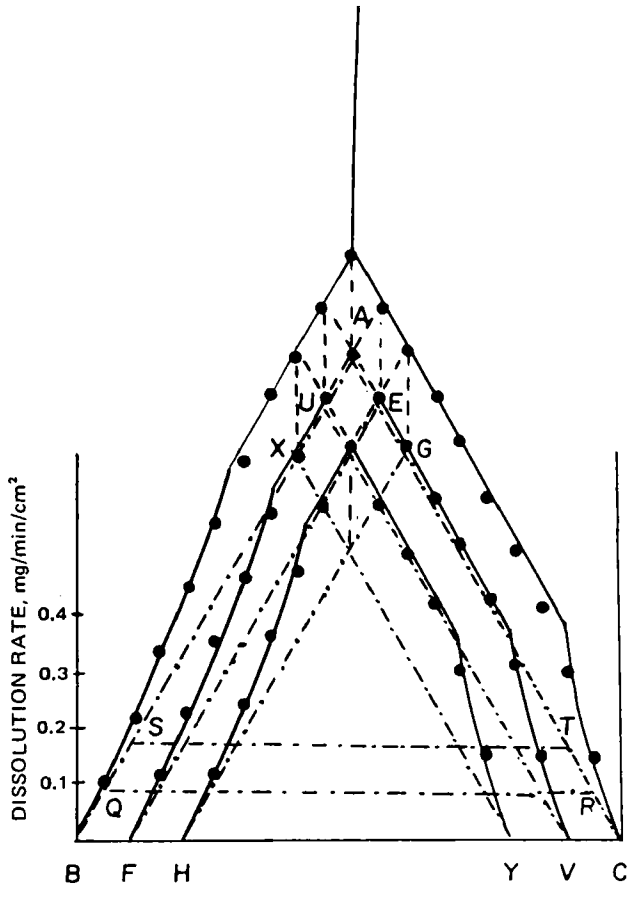

Figure 16—*Comparison of experimental dissolution rates of ethylparaben in solids of various compositions of ethylparaben, phenacetin, and salicylamide with theoretical dissolution rates represented by the solid lines in a three-dimensional perspective. Key: (A) ethylparaben; (B) phenacetin; (C) salicylamide.*

A solid composition with mass fractions of 0.1 ethylparaben, 0.05 phenacetin, and 0.85 salicylamide is described by Case IX dissolution behavior in region CKM in which the dissolving and receding boundary of phenacetin is deepest within the solid, the boundary of salicylamide is the surface layer, and the boundary of ethylparaben is between the two boundaries. The dissolution rate of salicylamide according to Eq. 50 is 0.565 mg/min/cm². The dissolution rate of ethylparaben is:

$$R_A = \frac{0.10}{0.85} \times 0.565 = 0.066 \text{ mg/min/cm}^2 \quad \text{(Eq. 85)}$$

The dissolution rate of phenacetin is:

$$R_B = \frac{0.05}{0.85} \times 0.565 = 0.033 \text{ mg/min/cm}^2 \quad \text{(Eq. 86)}$$

For two-component mixtures the dissolution rates were calculated according to the equations presented previously (6) for Cases I, II, and III. For example, a mixture of ethylparaben and phenacetin has a critical composition of 0.562 ethylparaben and 0.438 phenacetin at which:

$$\frac{N_A}{N_B} = \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 87)}$$

At the critical composition as represented by point P on line AB in Fig. 6, the dissolution rates of ethylparaben and phenacetin according to Eq. 50 are 0.188 and 0.145 mg/min/cm², respectively. A two-component solid composed of mass fractions of 0.3 ethylparaben and 0.7 phenacetin is represented by line BP on which:

$$\frac{N_A}{N_B} < \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 88)}$$

Phenacetin exists as the surface layer with the dissolving and receding boundary of ethylparaben within the solid. The dissolution rate of

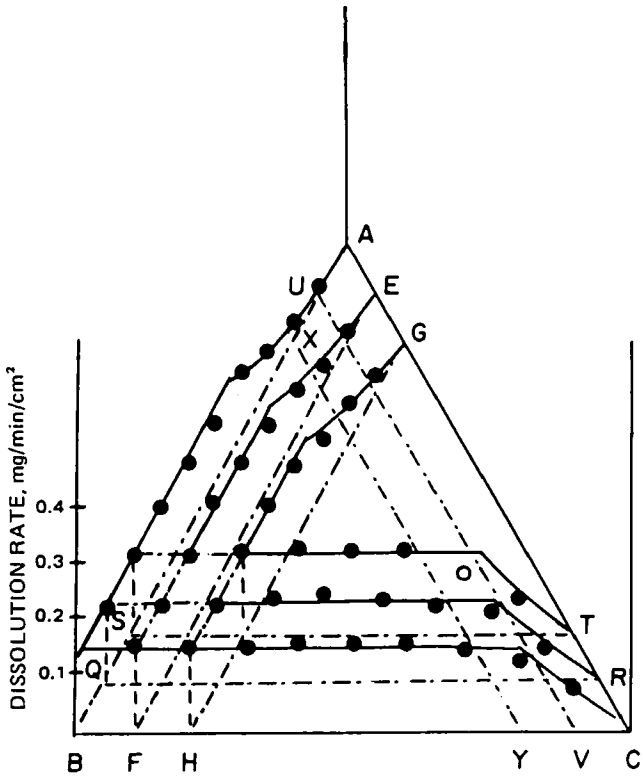

Figure 17—*Comparison of experimental dissolution rates of phenacetin in solids of various compositions of ethylparaben, phenacetin, and salicylamide with theoretical dissolution rates represented by solid lines in a three dimensional perspective. Key: (A) ethylparaben; (B) phenacetin; (C) salicylamide.*

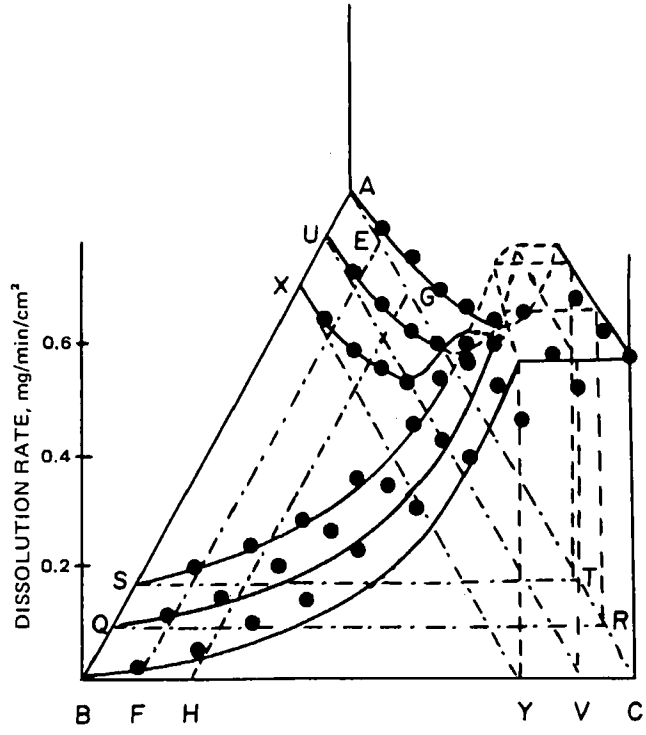

Figure 18—*Comparison of experimental dissolution rates of salicylamide in solids of various compositions of ethylparaben, phenacetin, and salicylamide with theoretical dissolution rates represented by the solid lines in a three dimensional perspective. Key: (A) ethylparaben; (B) phenacetin; (C) salicylamide.*

phenacetin according to Eq. 50 is 0.145 mg/min/cm^2. The dissolution rate of ethylparaben is:

$$R_A = \frac{0.3}{0.7} \times 0.145 = 0.062 \text{ mg/min/cm}^2 \quad \text{(Eq. 89)}$$

In a similar manner the predicted dissolution rates of each component were calculated and compared in Figs. 7–15 to the experimental dissolution rates at corresponding compositions. In Figs. 7, 10, and 13 the experimental dissolution rates of two-component mixtures of ethylparaben and phenacetin, ethylparaben and salicylamide, and phenacetin and salicyamide correspond in Fig. 6 to lines AB, AC, and BC, respectively. The experimental dissolution rates approximate the predicted dissolution rates for the ethylparaben and phenacetin mixture and for the ethylparaben and salicylamide mixture. As it has been observed previously (4, 6), the greatest difference between the predicted and experimental values occurs about the critical composition. This may result because the model ignores the amount of components in solution in the pores of the layers. In Fig. 13 for the phenacetin and salicylamide mixture, the experimental dissolution rates of salicylamide are faster than the predicted dissolution rates at mass fractions of 0.1–0.7 salicylamide. These faster dissolution rates may be attributed to the greater solubility of salicylamide, which dissolves faster leaving a surface layer of phenacetin. The mechanically weak surface of phenacetin, which possesses poor bonding characteristics, erodes slightly, and the increase in the effective surface area because of flaking results in a greater quantity dissolving per unit time.

In Figs. 8, 9, 11, 12, 14, and 15 the theoretical and experimental dissolution rates are compared for compositions in which the mass fraction of one component is constant and the mass fractions of the other components are varied. Figures 8 and 9 show the comparison of the predicted and experimental dissolution rates of ethylparaben, phenacetin, and salicylamide with a constant mass fraction of salicylamide of 0.1 and 0.2 corresponding to lines EF and GH, respectively, and varying mass fractions of ethylparaben and phenacetin. The predicted and experimental dissolution rates vary only about the critical composition. In Fig. 9 the experimental dissolution rates are faster than the predicted dissolution rates at mass fractions >0.5 phenacetin for solids with a constant mass fraction of 0.2 salicylamide. Again this may be attributed to the weak mechanical strength and consequential flaking due to the weak bonding of phenacetin.

The dissolution rates of ethylparaben, phenacetin, and salicylamide are shown in Figs. 11 and 12 with a constant mass fraction of phenacetin of 0.1 and 0.2 corresponding to lines UV and XY of Fig. 6. The dissolution rates of ethylparaben, phenacetin, and salicylamide are shown in Figs. 14 and 15 with a constant mass fraction of ethylparaben corresponding to lines QR and ST in Fig. 6.

A diagram of three-dimensional perspective is shown in Fig. 16 for the experimental and predicted dissolution rates of ethylparaben from three-component mixtures. Similarly, the experimental and predicted dissolution rates of phenacetin and salicylamide from three-component mixtures are presented in Figs. 17 and 18, respectively.

The experimental dissolution rates of the components of various compositions of ethylparaben, phenacetin, and salicylamide from compressed spheres essentially substantiates the suggested model for the dissolution kinetics of a three-component, nondisintegrating solid.

Dissolution Kinetics of a Three-Component Solid II: Benzoic Acid, Salicylic Acid, and Salicylamide

E. L. PARROTT ˣ, M. SIMPSON, and D. R. FLANAGAN

Received March 22, 1982, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication May 24, 1982.

Abstract □ The dissolution rates of each component in compressed spheres consisting of three components were measured under sink conditions. The observed dissolution rates of benzoic acid, salicylic acid, and salicylamide compare favorably to the predicted dissolution rates according to a previously presented kinetic model.

Keyphrases □ Benzoic acid—dissolution kinetics of a three-component solid, salicylic acid, salicylamide □ Salicylic acid—dissolution kinetics of a three-component solid, benzoic acid, salicylamide □ Salicylamide—dissolution kinetics of a three-component solid, benzoic acid, salicylic acid

A dissolution model has been presented to describe the 13 dissolution behaviors of three-component, nondisintegrating solids (1). In continuing the study of dissolution phenomena the dissolution rates of benzoic acid, salicylic acid, and salicylamide from compressed spheres were determined and compared to calculated dissolution rates in order to examine the suitability of the suggested dissolution model.

EXPERIMENTAL

Preparation of Spheres—Twenty grams of each composition was prepared by blending the appropriate amounts of 60/80-mesh size fraction of benzoic acid[1], salicylic acid[2], and salicylamide[3] for 15 min in a V-blender[4]. By means of a hydraulic press[5] fitted with a spherical punch and die set, each composition was compressed at a force of 2268 kg into spheres having a diameter of 1.273 ± 0.005 cm. The compositions were selected according to a scheme previously described (1).

Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

Dissolution Rate—The dissolution rate was determined in distilled water at 25 ± 0.1° at 300 rpm, as described previously (2, 3), under conditions where the concentration of the solutes did not exceed 5% of solubility.

Solubility—Solubility measurements were made at 25 ± 0.1° as reported earlier (4). The solubilities of benzoic acid, salicylic acid, and salicylamide are 3.428 ± 0.064, 2.239 ± 0.027, and 2.511 ± 0.018 mg/ml, respectively.

Analytical Procedure—The absorbance of each sample was measured at 269.5, 298, and 329 nm. The standard curve of each component at each wavelength exhibited a Beer's law relationship. From these plots the nine molar absorptivities were calculated (Table I). As previously described (1) the concentration of each component in solution was obtained by the solution of simultaneous equations. The method was tested with seven solutions containing known concentrations of the three components. The percent determined by the analytical procedure ranged from 98.9 to 101.8% of the known concentration. The concentration was converted to amount dissolved in order to express a dissolution rate.

RESULTS AND DISCUSSION

A detailed discussion of a model for dissolution of a three-component solid has been presented (1). The 13 dissolution behaviors at various compositions are identified by the Roman numerals in Fig. 1. For the system investigated, A represents salicylic acid, B represents benzoic acid, and C represents salicylamide.

Dissolution rates (R) were measured at 25° under sink conditions at various compositions. The solubilities (C_s) were experimentally measured. When the dissolution of a nondisintegrating pure solid occurring in a nonreactive medium at sink conditions is diffusion controlled, the dissolution rate may be expressed (2):

$$R = \frac{DC_s}{h} \qquad \text{(Eq. 1)}$$

Table I—Molar Absorptivities of Benzoic Acid, Salicylic Acid, and Salicylamide

Wavelength, nm	Molar Absorptivity		
	Benzoic Acid	Salicylic Acid	Salicylamide
269.5	578	680	195
298	0	3,522	1,477
329	0	256	5,632

0022-3549/83/0700-0765$01.00/0

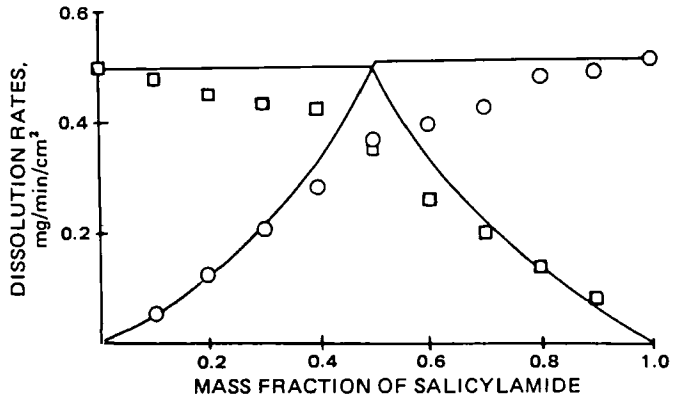

Figure 3—*Comparison of experimental dissolution rates of the components of salicylic acid and salicylamide mixtures corresponding to line AC of Fig. 1 and the smooth curves representing the theoretical rates. Key: (□) salicylic acid; and (○) salicylamide.*

where h is the effective diffusion layer thickness. The diffusion coefficient of salicylamide was reported (1) to be 1.12×10^{-5} cm²/sec. The only unknown term in the equation is h, which may be calculated by rearrangement and substitution of experimental values for salicylamide:

$$h = \frac{1.12 \times 10^{-5} \times 2.51}{0.505/60} = 0.0033 \text{ cm} \quad \text{(Eq. 2)}$$

Using this value of h, the diffusion coefficients of benzoic acid and salicylic acid were calculated to be 1.19×10^{-5} and 1.21×10^{-5} cm²/sec, respectively.

The critical composition (Case IV at point M of Fig. 1) at which the three components coexist at the solid–liquid interface may be expressed:

$$\frac{N_A}{N_B} = \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 3)}$$

$$\frac{N_A}{N_C} = \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 4)}$$

and

$$\frac{N_B}{N_C} = \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 5)}$$

where N is the mass fraction of a component, and C is the solubility of that component. Since:

$$N_A + N_B + N_C = 1 \quad \text{(Eq. 6)}$$

substitution of the values of diffusion coefficient and solubility of the components into any two combinations of Eqs. 3, 4, or 5 with Eq. 6 and solution of the simultaneous equations permit the calculation of the mass fraction of each component. The critical mass fractions are 0.425 benzoic acid, 0.293 salicylamide, and 0.282 salicylic acid.

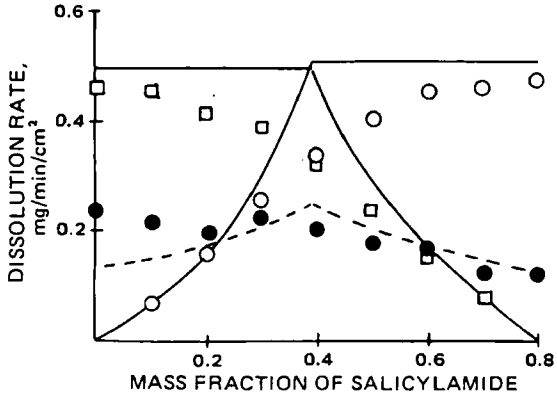

Figure 4—*Comparison of experimental dissolution rates of the components of benzoic acid, salicylic acid, and salicylamide mixtures with a constant mass fraction of 0.2 benzoic acid corresponding to line XY of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

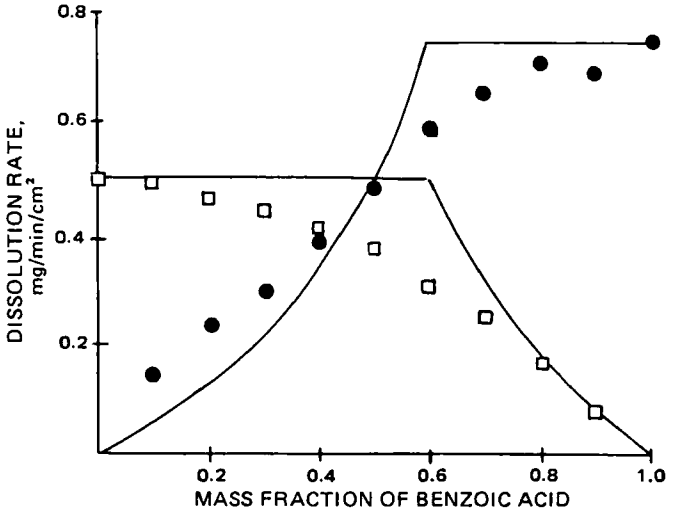

Figure 5—*Comparison of experimental dissolution rates of the components of salicylic acid and benzoic acid mixtures corresponding to line AB of Fig. 1 and the smooth curve representing the theoretical rates. Key: (□) salicylic acid; and (●) benzoic acid.*

Similarly, by use of the values of solubility and diffusion coefficient and appropriate equations (5), the critical mass fractions for two-component mixtures were calculated. The critical mass fractions are 0.40 salicylic acid and 0.60 benzoic acid, 0.59 benzoic acid and 0.41 salicylamide, and 0.49 salicylic acid and 0.51 salicylamide.

Using these critical compositions for two- and three-component mixtures, Fig. 1 was constructed to show the regions that represent the 13 dissolution behaviors. By considering Fig. 1 and by then using appropriate equations, the theoretical dissolution rates were calculated for dissolution behavior in the various regions of the diagram.

For Case IV dissolution behavior at the critical composition of the three components and boundaries recede at the same rate, and the dissolution rates may be calculated by Eq. 1. The dissolution rates of benzoic acid, salicylic acid, and salicylamide are 0.742, 0.493, and 0.505 mg/min/cm², respectively.

A constant mass fraction of 0, 0.1, and 0.2 benzoic acid and varying mass fractions of salicylic acid and salicylamide are represented by lines AC, UV, and XY, respectively, in Fig. 1. In considering line UV at point U there is a two-component solid for which salicylic acid is the surface layer, and the dissolution behavior is expressed by Case II behavior in which:

$$\frac{N_A}{N_B} > \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 7)}$$

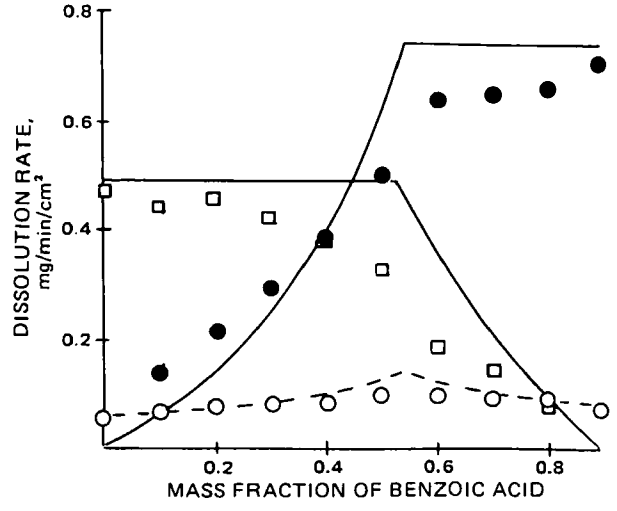

Figure 6—*Comparison of experimental dissolution rates of the components of benzoic acid, salicylic acid, and salicylamide mixtures with a constant mass fraction of 0.1 salicylamide corresponding to line EF of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

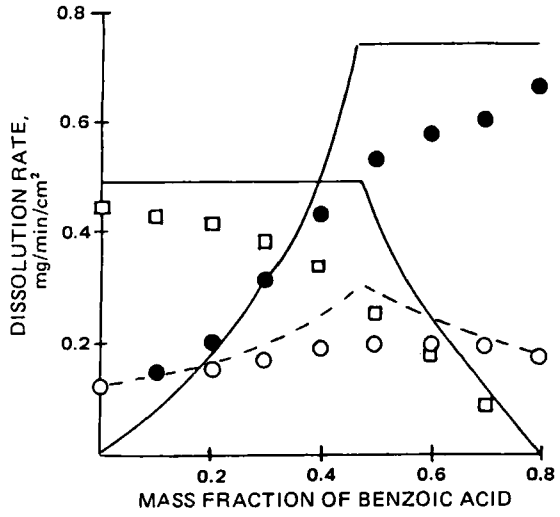

Figure 7—*Comparison of experimental dissolution rates of the components of benzoic acid, salicylic acid, and salicylamide mixtures with a constant mass fraction of 0.2 salicylamide corresponding to line GH of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

and the dissolution rate of salicylic acid according to Eq. 1 is 0.493 mg/min/cm², and the dissolution rate of benzoic acid is:

$$R_B = \frac{N_B}{N_A} R_A \qquad \text{(Eq. 8)}$$

$$R_B = \frac{0.1}{0.9} \times 0.493 \qquad \text{(Eq. 9)}$$

$$= 0.055 \text{ mg/min/cm}^2$$

Since the mass fraction of salicylamide is progressively increased along line UV, the dissolution behaviors are expressed by Case V in region APM, Case XIV on line AM, Case VI in region AMK, Case XII on line MK, Case IX in region KMC, Case XVI on line MC, and Case X in region MCJ. At point V there is a two-component solid for which:

$$\frac{N_C}{N_B} > \frac{D_C C_C}{D_B C_B} \qquad \text{(Eq. 10)}$$

and the dissolution rate of salicylamide according to Eq. 1 is 0.511 mg/min/cm², and the dissolution rate of benzoic acid is:

$$R_B = \frac{N_B}{N_C} R_C \qquad \text{(Eq. 11)}$$

$$R_B = \frac{0.1}{0.9} \times 0.511 \qquad \text{(Eq. 12)}$$

$$= 0.057 \text{ mg/min/cm}^2$$

In Case V dissolution behavior, salicylamide dissolves faster than benzoic acid and salicylic acid, and the boundary of salicylamide recedes into the solid. Benzoic acid dissolves faster from the solid surface than salicylic acid, so that the dissolving boundary of benzoic acid recedes within the solid leaving a surface layer of salicylic acid. This dissolution behavior occurs under the conditions that:

$$\frac{N_A}{N_B} > \frac{D_A C_A}{D_B C_B} \qquad \text{(Eq. 13)}$$

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \qquad \text{(Eq. 14)}$$

and

$$\frac{N_B}{N_C} > \frac{D_B C_B}{D_C C_C} \qquad \text{(Eq. 15)}$$

Since salicylic acid is always on the surface at compositions represented by Eqs. 13–15, its dissolution rate (R_A) is calculated by Eq. 1 is 0.493 mg/min/cm². The benzoic acid must diffuse through the layer of salicylic acid and the liquid diffusion layer, and its dissolution rate (R_B) is:

$$R_B = \frac{N_B}{N_A} R_A \qquad \text{(Eq. 16)}$$

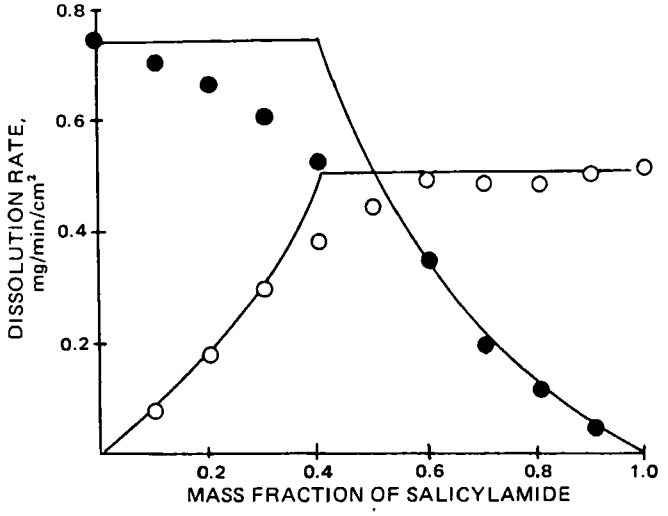

Figure 8—*Comparison of experimental dissolution rates of the components of benzoic acid and salicylamide mixtures corresponding to line BC of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; and (○) salicylamide.*

For example, at mass fractions of 0.1 benzoic acid, 0.88 salicylic acid, and 0.02 salicylamide, the dissolution rate of benzoic acid (R_B) is:

$$R_B = \frac{0.1}{0.88} \times 0.493$$

$$= 0.056 \text{ mg/min/cm}^2 \qquad \text{(Eq. 17)}$$

The salicylamide must diffuse through the layer of benzoic acid and salicylic acid, the layer of salicylic acid, and the liquid diffusion layer, and its dissolution rate (R_C) is:

$$R_C = \frac{N_C}{N_A} R_A \qquad \text{(Eq. 18)}$$

At mass fractions of 0.1 benzoic acid, 0.88 salicylic acid, and 0.02 salicylamide, the dissolution rate of salicylamide (R_C) is:

$$R_C = \frac{0.22}{0.88} \times 0.493$$

$$= 0.011 \text{ mg/min/cm}^2 \qquad \text{(Eq. 19)}$$

Case VI, IX, and X in Fig. 1 describe dissolution behaviors similar to Case V; however, the order of dissolving and the receding of the boundaries are different with different mass fractions of salicylic acid and salicylamide along line UV. The dissolution rates may be calculated by the same reasoning used for Case V dissolution behavior.

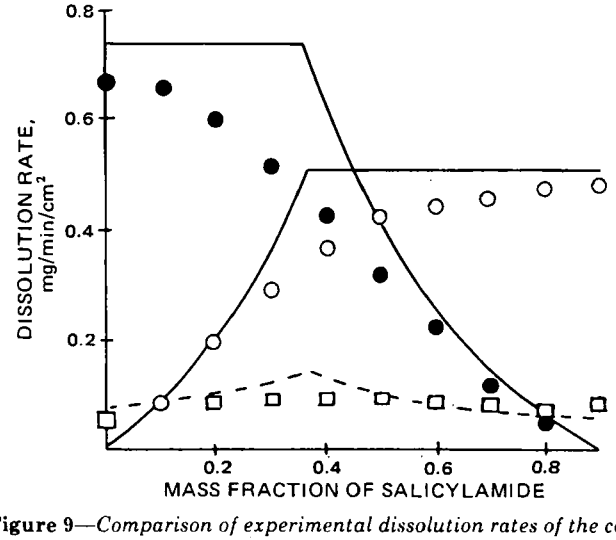

Figure 9—*Comparison of experimental dissolution rates of the components of benzoic acid, salicylic acid, and salicylamide mixtures with a constant mass fraction of 0.1 salicylic acid corresponding to line QR of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

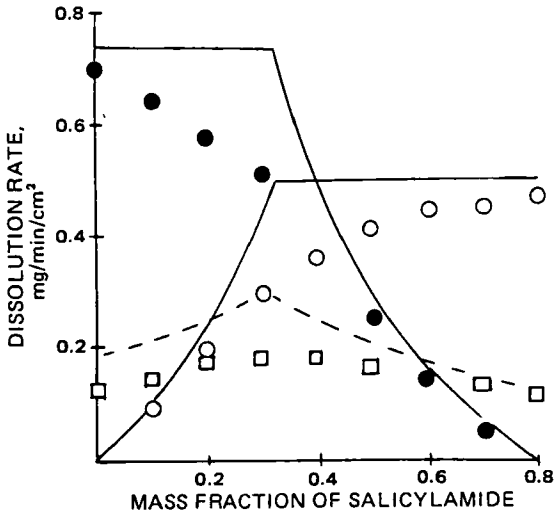

Figure 10—*Comparison of experimental dissolution rates of the components of benzoic acid, salicylic acid, and salicylamide mixtures with a constant mass fraction of 0.2 salicylic acid corresponding to line ST of Fig. 1 and the smooth curves representing the theoretical rates. Key: (●) benzoic acid; (□) salicylic acid; and (○) salicylamide.*

In Case XIV dissolution behavior on line AM, both benzoic acid and salicylamide dissolve faster than salicylic acid so that the boundaries of benzoic acid and salicylamide recede at the same rate and coexist at the same boundary leaving a surface layer of salicylic acid. Case XIV dissolution behavior occurs under the condition that:

$$\frac{N_A}{N_B} > \frac{D_A C_A}{D_B C_B} \quad \text{(Eq. 20)}$$

$$\frac{N_A}{N_C} > \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 21)}$$

and

$$\frac{N_B}{N_C} = \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 22)}$$

The dissolution rate equations for Case XIV dissolution behavior are:

$$R_A = \frac{D_A C_A}{h} \quad \text{(Eq. 23)}$$

$$R_C = \frac{N_B}{N_A} R_A \quad \text{(Eq. 24)}$$

and

$$R_C = \frac{N_C}{N_A} R_A \quad \text{(Eq. 25)}$$

At mass fractions of 0.831 salicylic acid, 0.1 benzoic acid, and 0.069 salicylamide, the dissolution rate of salicylic acid as calculated by Eq. 23 is 0.493 mg/min/cm². The dissolution rate of benzoic acid according to Eq. 24 is:

$$R = \frac{0.1}{0.831} \times 0.493 = 0.056 \text{ mg/min/cm}^2 \quad \text{(Eq. 26)}$$

and the dissolution rate of salicylamide according to Eq. 25 is:

$$R = \frac{0.069}{0.831} \times 0.493 = 0.041 \text{ mg/min/cm}^2 \quad \text{(Eq. 27)}$$

Case XVI dissolution behavior is similar to Case XIV except that the order of dissolving and the receding of the boundaries are different with their respective mass fractions of salicylic acid and salicylamide. The dissolution rates may be calculated by the same reasoning used for Case XIV dissolution behavior.

In Case XII dissolution behavior benzoic acid dissolves leaving a surface layer of salicylic acid and salicylamide under the conditions that:

$$\frac{N_B}{N_A} < \frac{D_B C_B}{D_A C_A} \quad \text{(Eq. 28)}$$

$$\frac{N_B}{N_C} < \frac{D_B C_B}{D_C C_C} \quad \text{(Eq. 29)}$$

and

$$\frac{N_A}{N_C} = \frac{D_A C_A}{D_C C_C} \quad \text{(Eq. 30)}$$

The dissolution rates as calculated by use of Eq. 1 are 0.493 and 0.511 mg/min/cm² for salicylic acid and salicylamide, respectively. The dissolution rate of benzoic acid is:

$$R_B 2 = \frac{N_B}{N_A} R_A \quad \text{(Eq. 31)}$$

$$R_B = \frac{0.1}{0.46} \times 0.493 = 0.107 \text{ mg/min/cm}^2 \quad \text{(Eq. 32)}$$

Thus, along line UV from point U to point V the nine dissolution behaviors and the calculation of the dissolution rates of the components at each composition have been considered as shown in Fig. 2. Similarly, the dissolution rates of benzoic acid, salicylic acid, and salicylamide are shown at various compositions with a constant mass fraction of 0 and 0.2 benzoic acid along lines AC and XY in Figs. 3 and 4, respectively.

The dissolution rates of benzoic acid and salicylic acid at various compositions along line AB are shown in Fig. 5. The dissolution rates of benzoic acid, salicylic acid, and salicylamide are shown at various compositions with a constant mass fraction of 0.1 and 0.2 salicylamide along lines EF and GH in Figs. 6 and 7, respectively.

The dissolution rates of benzoic acid and salicylamide at various compositions along line BC are shown in Fig. 8. The dissolution rates of benzoic acid, salicylic acid, and salicylamide are shown at various compositions with a constant mass fraction of 0.1 and 0.2 salicylic acid along lines QR and ST in Figs. 9 and 10, respectively.

The agreement of the theoretical dissolution rates with the experimental data is satisfactory. The greatest variance occurs in the vicinity of the critical composition at which the experimental dissolution rates are slower. The model neglects the amount of the components that remained as solutions in the pores of the layers. This may contribute to the variance. Variance may also be caused by lack of uniformity of the blend and the limits of the analytical method at small mass fractions of a component.

CONCLUSION

The dissolution rates of each component of benzoic acid, salicylic acid, and salicylamide compacts were measured and compared to theoretical dissolution rates based on a previously described model. On initially presenting the model a similar comparison was made for ethylparaben, phenacetin, and salicylamide compacts (1). The agreement between the experimental and calculated dissolution rates for both systems support the suitability of the model.

Stabilization of Aluminum Hydroxide Gel by Specifically Adsorbed Carbonate

CARLOS J. SERNA ‡, JILL C. LYONS *, JOE L. WHITE ‡, and STANLEY L. HEM *x

Received April 26, 1982, from the *Department of Industrial and Physical Pharmacy and the ‡Department of Agronomy, Purdue University, West Lafayette, IN 47907. Accepted for publication July 1, 1982.

Abstract □ Ion-free aluminum hydroxide gel, prepared by the hydrolysis of aluminum tri-*sec*-butoxide, was observed by IR, X-ray analysis, and pH-stat titration to undergo rapid structural changes leading to the formation of pseudoboehmite and bayerite. The rate of development of order was directly related to the water–aluminum molar ratio. The Al—O bands at 625 and 470 cm^{-1} were the most sensitive indicators of the development of order in the gel structure. Direct evidence for the stabilizing effect of specifically adsorbed carbonate was obtained when carbon dioxide was introduced during the hydrolysis of aluminum tri-*sec*-butoxide. The resulting aluminum hydroxycarbonate gel possessed excellent antacid properties, retained its amorphous nature upon aging, and contained no cations other than aluminum. Hydrolysis of aluminum tri-*sec*-butoxide in the presence of stoichiometric amounts of sodium bicarbonate resulted in the immediate formation of crystalline sodium aluminum hydroxycarbonate (dawsonite).

Keyphrases □ Hydrolysis of aluminum tri-*sec*-butoxide—use of carbon dioxide-saturated water, formation of amorphous aluminum hydroxycarbonate gel, excellent properties, free of sodium and potassium □ Aluminum hydroxide gel—stabilization by specifically adsorbed carbonate □ Ion-free aluminum hydroxide gel—ordered structure, as an antacid

Aluminum hydroxide gel is an effective antacid largely due to its high rate of acid neutralization and its ability to react with acid at a pH of 3.5–4.0 (1). The chemical name implies a compound consisting of three hydroxyl groups per aluminum atom. This formula describes the crystalline forms of aluminum hydroxide known as gibbsite, bayerite, or norstrandite. These polymorphs have a very low rate of acid neutralization and are, therefore, not useful as antacids. However, a number of reports have suggested that the aluminum hydroxide gel used as an antacid contains specifically adsorbed anions and that these anions act to stabilize the gel structure (2–7) and facilitate the acid neutralization reaction (8).

The anions that are incorporated in the gel structure are usually supplied by the reactants used in the precipitation, such as carbonate from sodium carbonate or sodium bicarbonate or sulfate from aluminum sulfate (3). Aluminum hydroxide gel may also be prepared by the controlled hydrolysis of aluminum tri-*sec*-butoxide, I (9–14). This method permits precipitation under ion-free conditions as well as in the presence of selected ions. This system was used to study the structure and acid reactivity of ion-free aluminum hydroxide gel as well as the stabilizing effect of specifically adsorbed carbonate on the gel structure.

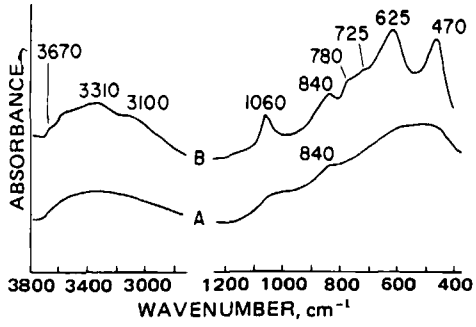

Figure 1—*IR spectra of ion-free aluminum hydroxide gel precipitated with water–aluminum ratio of 3. Key: (A) initial; (B) after 1 week at 25°.*

EXPERIMENTAL

Ion-free aluminum hydroxide gel was prepared by dissolving 6.15 g of I in 40 ml of anhydrous isopropyl alcohol and adding the required quantity of water with agitation. For example, 1.35 ml of water was used to hydrolyze I at a water–aluminum molar ratio of 3.

Aluminum hydroxycarbonate gel was prepared by hydrolyzing I with 3 moles of water/mole of I. The water was saturated with carbon dioxide prior to its addition to I. In addition, carbon dioxide was vigorously bubbled into the I solution during the hydrolysis reaction.

Compound I was hydrolyzed in the presence of 1 mole of sodium bicarbonate/mole of I. Because of the limited solubility of sodium bicarbonate, a water–aluminum molar ratio of 41 was needed to dissolve the sodium bicarbonate.

The hydrolysis products were analyzed for equivalent aluminum oxide content (15). Acid reactivity was determined by pH-stat titration of a sample containing 38 meq aluminum oxide at pH 3, 25° (16).

For X-ray analysis, the samples were dried at room temperature and ground to a fine powder. The diffraction patterns were recorded from 4 to 60° 2θ using CuK_α radiation. The same powder samples were diluted in potassium bromide (2 mg/300 mg) and examined by IR spectroscopy.

RESULTS AND DISCUSSION

Ion-Free Aluminum Hydroxide Gel—Ion-free aluminum hydroxide gel, precipitated with 3 moles of water/mole of I, undergoes very rapid structural changes which were observed by IR and X-ray analysis. The development, within a week, of absorption bands at 3670, 3310, and 3100 cm^{-1} (Fig. 1), indicates that the initial random structure changed rapidly and that the hydroxyl groups became part of a more uniform environment as the gel aged (17).

The most striking changes are observed in the IR region between 1200 and 400 cm^{-1}. The two strong absorption bands at 625 and 470 cm^{-1} are in a similar position as the Al—O vibrations observed in boehmite (18). The environment around the Al—O bonds became ordered more rapidly during aging than the environment of the hydroxyl groups. Thus, this IR region is more useful for detecting the earliest stages of crystallization. The vibrations in the hydroxyl region have been useful for monitoring long-term aging (17–19).

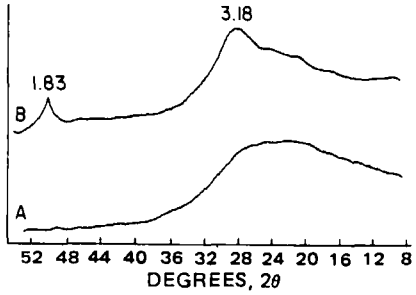

Figure 2—*X-ray diffractograms of ion-free aluminum hydroxide gel precipitated with water–aluminum ratio of 3. Key: (A) initial; (B) after 1 week at 25°.*

0022-3549/83/0700-0769$01.00/0

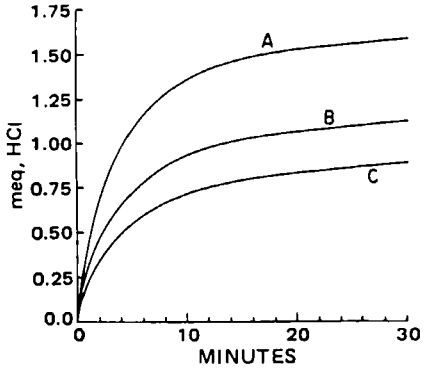

Figure 3—*pH Stat titrigraphs at pH 3, 25° of ion-free aluminum hydroxide gel aged at 25°. Key: (A) initial; (B) after 2 days; (C) after 4 days.*

The similarity in the IR spectrum of the hydroxyl vibrations at 3310, 3100 (stretching), and 1060 cm^{-1} (bending) to the spectrum of boehmite suggests that the developing crystalline phase was a disordered boehmite (pseudoboehmite) (13). This conclusion is supported by the X-ray diffractogram (Fig. 2). Initially an amorphous material was formed. At 1 week, the presence of pseudoboehmite was indicated by reflection peaks at 3.18, 1.83, and 1.44 Å (20).

The rate of reaction with acid decreased rapidly as the gel aged. As seen in Fig. 3, the development of an ordered structure in the gel was accompanied by an increase in the fraction of slowly reacting material present in the gel. Theoretically, the 38-meq aluminum oxide sample will neutralize 2.235 meq-HCl. Thus, the ion-free aluminum hydroxide gel would not be effective as an antacid, since only a small fraction of the ion-free aluminum hydroxide will react during the estimated gastric residence time for antacids of 15 min (21).

The rate of development of order was directly related to the amount of water used to hydrolyze I (13). The IR spectra of the aluminum hydroxide gels prepared using 3, 6, 12, and 24 moles of water/mole of I and aged for 24 hr at 25° are shown in Fig. 4. At lower water-aluminum ratios, amorphous aluminum hydroxide was observed, as indicated by the broad absorption bands.

As noted previously, the Al—O vibration gives the earliest indication of the development of order. At a water-aluminum ratio of 6, a featureless absorption band for the hydroxyl groups was observed between 3700 and 2600 cm^{-1}, while the presence of more ordered Al—O bonds was observed at 620 and 480 cm^{-1}. This absorption, together with the band at 1055 cm^{-1}, indicates that pseudoboehmite, $AlOOH{\cdot}H_2O$, is forming.

IR spectroscopy (Fig. 4) is a more sensitive technique to follow the development of order than X-ray diffraction, because the X-ray diffractograms of the aluminum hydroxide gels prepared with water-aluminum ratios of 3 and 6 were amorphous. However, in the presence of a large excess of water, a mixture of pseudoboehmite and bayerite was produced. Characteristic bands of pseudoboehmite were observed at 3300,

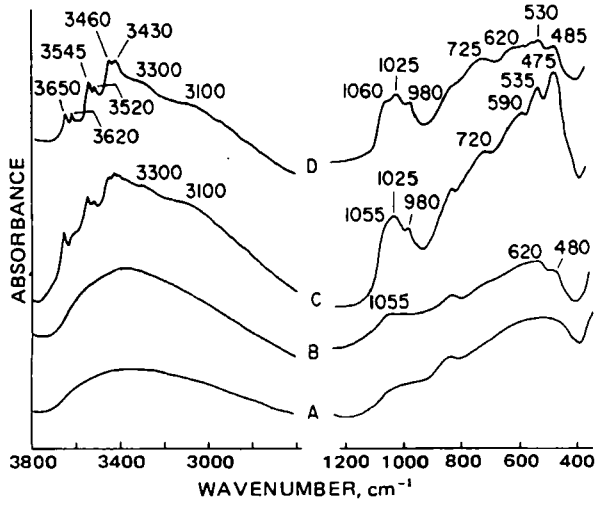

Figure 4—*IR spectra after 1 day at 25° of ion-free aluminum hydroxide gel hydrolyzed with various water-aluminum ratios. Key: (A) 3; (B) 6; (C) 12; (D) 24.*

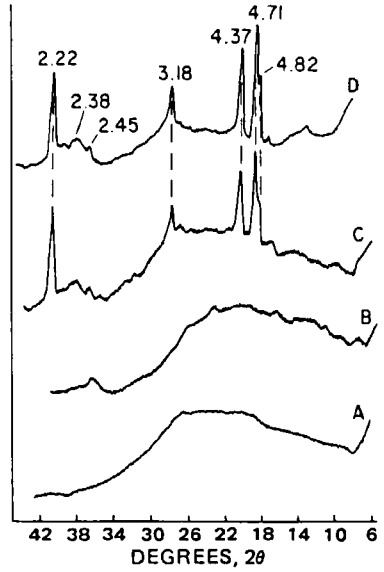

Figure 5—*X-ray diffractograms after 1 day at 25° of ion-free aluminum hydroxide gel hydrolyzed with various water-aluminum ratios. Key: (A) 3; (B) 6; (C) 12; (D) 24.*

3100, and 1055 cm^{-1} for the hydroxyl stretching and bending vibrations. Bayerite, $Al(OH)_3$, was observed at a water-aluminum ratio of 12 and predominated at higher water content. The more defined environment of the hydroxyl groups in the bayerite structure was indicated by the sharpness of the absorption bands at 3650, 3545, and 3430 cm^{-1}. The low IR region was not useful in detecting the mixture of pseudoboehmite and bayerite, since the Al—O vibrations are similar in both compounds.

The X-ray diffractograms (Fig. 5) support the conclusions drawn from IR analysis. At a water-aluminum ratio of 12, bayerite was indicated by the peaks at 4.71, 4.37, 3.18, and 2.22 Å. The transformation of pseudoboehmite to bayerite at higher water content was indicated by the loss of the broad background reflection between 30 and 22° 2θ that corresponds to the broad reflection peak at 3.18 Å for pseudoboehmite.

Small amounts of gibbsite were present in the aluminum hydroxide gel precipitated at a water-aluminum ratio of 24 as indicated by the IR bands at 3620 and 3520 cm^{-1} and by the diffraction peak at 4.82 Å (Figs. 4 and 5).

Stabilization of Aluminum Hydroxide Gel—The stabilizing effect of anions present at the time of precipitation has been hypothesized based on indirect evidence such as the relationship between anion content and the rate of loss of acid reactivity (2, 6), the effect of washing (5), and the dependence of the rate of crystallization on the nature of the anion (2, 3). The hydrolysis of I provides an excellent system to demonstrate directly the stabilizing action of anions. The interaction of carbonate anion with aluminum hydroxide was achieved by saturating the water used for hydrolysis with carbon dioxide and by bubbling carbon dioxide into the reaction medium during hydrolysis. X-ray diffraction patterns of the product were amorphous both initially and after aging for 1 month at 25°. This result agrees with Torkar's earlier observation that the reaction product of aluminum ethoxide and water saturated with carbon dioxide remained amorphous for 20 days at 22° (22).

The IR spectrum of the precipitate formed in the presence of carbon dioxide-saturated water (Fig. 6) indicates an amorphous aluminum hydroxycarbonate gel. The broad hydroxyl stretching band at 3460 cm^{-1}

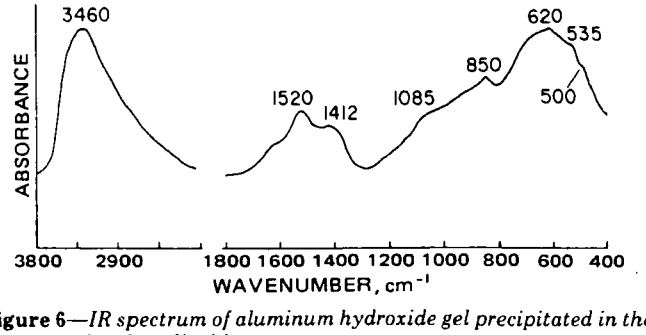

Figure 6—*IR spectrum of aluminum hydroxide gel precipitated in the presence of carbon dioxide.*

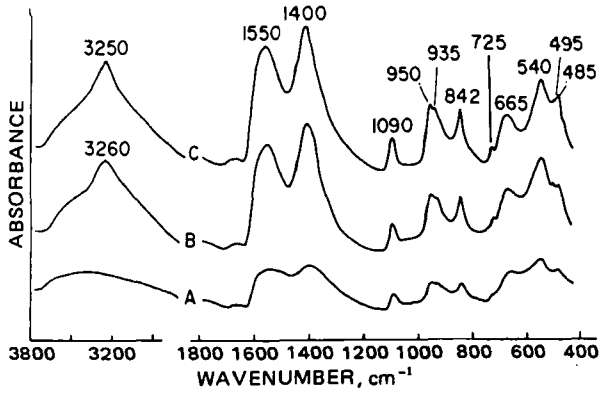

Figure 7—*IR spectra of the precipitate obtained by the hydrolysis of I in the presence of sodium bicarbonate aged at 25°. Key: (A) initial; (B) 30 min; (C) 1 day.*

indicates that the hydroxyl groups are disordered, while the ν_3 carbonate bands at 1520 and 1412 cm^{-1} indicate that carbonate is directly coordinated to aluminum in the gel structure (4, 6, 23–25). The absorption band at 1085 cm^{-1} (ν_1) also supports the direct coordination of carbonate to aluminum since this absorption is only active in the Raman when the carbonate anion has full symmetry.

The amorphous aluminum hydroxycarbonate gel reacted completely with acid and exhibited a T_{50} of 3 min by pH-stat titration. The rate of acid neutralization was virtually unchanged during the 1-month evaluation period.

Compound I was also hydrolyzed in the presence of carbonate ion using 1 mole of sodium bicarbonate per mole of I. The sodium bicarbonate was dissolved in the water for hydrolysis. This reaction resulted in the immediate formation of sodium aluminum hydroxycarbonate which is known mineralogically as dawsonite (13) and is contained in the USP as dihydroxyaluminum sodium carbonate (26). As can be seen in Fig. 7, the initial IR spectrum showed the split carbonate band, ν_3, at 1550 and 1400 cm^{-1}, which is characteristic of the distortion of carbonate in dawsonite (13). Rapid structural development occurred during the first 30 min as evidenced by the appearance of a hydroxyl stretching band at 3260 cm^{-1} and the general sharpening of the bands observed in the initial spectrum. Little indication of further structural development is observed in the 24-hr spectrum.

The IR spectrum of the 1-day sample was identical to the spectrum of dawsonite (27), except that the bands are broader suggesting a more poorly ordered structure of a smaller particle size than the mineralogical sample.

The rapid structural development of dawsonite was also observed in the X-ray diffractograms (Fig. 8), which exhibit the major peaks of

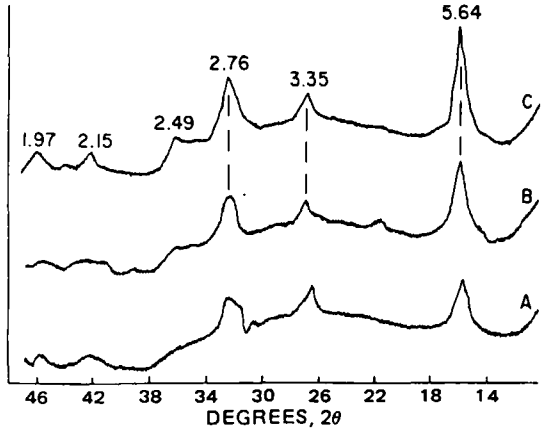

Figure 8—*X-ray diffractograms of the precipitate obtained by the hydrolysis of I in the presence of sodium bicarbonate aged at 25°. Key: (A) initial; (B) 30 min; (C) 1 day.*

dawsonite immediately after precipitation and show some refinement in the structure upon aging.

The synthetic dawsonite exhibited a rapid rate of acid neutralization as evidenced by its T_{50} of 3 min. The rate of neutralization was virtually unchanged during the 1-month observation period. The presence of a stoichiometric amount of sodium bicarbonate at the time of precipitation produced a highly reactive, crystalline hydroxycarbonate which contains 158 mg of sodium per gram of sodium aluminum hydroxycarbonate.

Summary—Aluminum hydroxide gel produced under ion-free conditions rapidly developed an ordered structure which reacts too slowly with acid to be effective as an antacid. The use of carbon dioxide-saturated hydrolysis water as the source of carbonate ion produced an amorphous aluminum hydroxycarbonate gel which exhibited excellent antacid properties and was totally free of foreign cations such as sodium or potassium. The use of a stoichiometric amount of sodium bicarbonate as the source of carbonate resulted in the formation of crystalline sodium aluminum hydroxycarbonate which possesses excellent antacid properties but which has a high sodium content.

Membrane-Coated Tablets: A System for the Controlled Release of Drugs

GÖRAN KÄLLSTRAND and BO EKMAN ˣ

Received May 18, 1981, from the *Pharmaceutical Research and Development, AB Ferrosan, S-201 80 Malmö, Sweden.* Accepted for publication June 28, 1982

Abstract □ Membrane-coated tablets were developed to provide a dosage form which exhibits zero-order kinetics. The delivery system consisted of a soluble tablet core surrounded by a porous membrane which controls the diffusion rate. In the system studied, the diffusion rate of potassium chloride was found to be more constant than with other controlled-release products and independent of pH changes within the physiological range. The release profile of a drug can be varied by changing the composition of the membrane. Substantial amounts of the active substance can be loaded into membrane-coated tablets. The membrane protects the gastric mucosa from direct contact with the undissolved active substance. This delivery system has a potential for use with all water-soluble agents where a controlled release is desirable.

Keyphrases □ Controlled release of drugs—membrane-coated tablets, zero-order delivery, potassium chloride, potential use for all water-soluble drugs □ Delivery systems—membrane-coated tablets, controlled release, potassium chloride

The concept of the slow release of drugs has attracted much interest, and numerous delivery systems are commercially available. The purpose of these preparations is to release the drug continuously during its passage through the GI tract, thereby giving a constant plasma concentration over a long period of time and possibly reducing side effects. Slow-release delivery would be suitable for drugs with a rapid clearance from plasma or drugs that cause adverse effects locally or systemically. An ideal slow-release preparation depends only on the dissolution rate of the active substance. Factors such as mechanical influence, enzymes, viscosity, surface tension, pH, and salt concentration should not affect the release of the active substance. However, the absorption phase must be completed within 8–10 hr for most drugs to achieve good biological availability (1). Drug dissolution from tablets prepared by a technique called membrane coating, using potassium chloride as a model drug, is described.

Uncoated and enteric-coated potassium chloride tablets cause side effects in the GI tract with a high degree of frequency (2). The only difference between the standard tablets and the enteric-coated ones has been the localization of the ulceration in the gut. Several cases of duodenal ulceration resulting in stenosis of the intestine have been caused by enteric-coated potassium chloride tablets (3, 4).

If potassium chloride is delivered at a constant rate for a longer period of time while in the GI tract, the side effects can be minimized. Newer controlled-release potassium chloride tablets have a slow dissolution rate, which gives

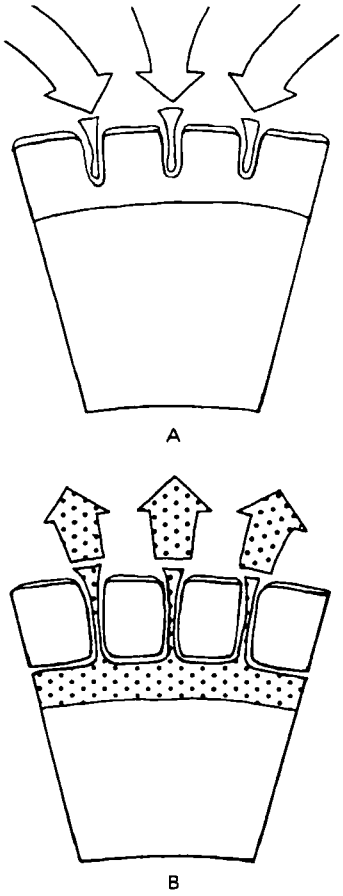

Figure 1—*Segment of membrane-coated tablet (A) liquid penetrating into the membrane, dissolving the sucrose particles and (B) drug solution diffusing through the membrane.*

a considerably lower concentration of the drug in the GI tract and, consequently, a lower frequency of adverse reactions (5, 6). The principle of delivering drugs by solution diffusion through a rate-controlling microporous membrane has been shown earlier to be dependable (7). This report describes a practical way to utilize this technique.

Membrane coating involves coating a tablet with a porous, water-permeable membrane, which is insoluble in the GI tract. The gastric juices penetrate the tablet through the pores and dissolve the drug (Fig. 1).

The following quality controls must be met when choosing a water-insoluble polymer. It must have low toxicity and be unaffected by the GI fluids and by the motility of the intestinal system. It should have good solubility in a nontoxic solvent, appropriate for tablet coating, and give films of good mechanical stability. After testing several different polymers (cellulose derivatives, nylon, and various acrylic polymers) we decided to investigate a polyvinyl chloride plastic. This polymer combines the favorable properties of good mechanical resistance and satisfactory adhesion to the potassium chloride surface of the tablet core.

EXPERIMENTAL

Preparation of Tablet Core—Potassium chloride was granulated with a 50% solution of polyvinyl pyrrolidone in ethanol–acetone (1:1). A 32-g volume of the solution was mixed with 1000 g of KCl. The wet granulation was screened through a 0.5–0.7-mm aperture and dried in a forced-air oven at 40° for 2 hr. Circular, biconvex tablets with a 12-mm diameter were compressed to a hardness of 8 kp[1]. The disintegration time in water at 37° was 8 min[2]. The tablet weight was 1016 mg, of which 1000 mg was potassium chloride.

Preparation of Membrane-Coated Tablets—The polymeric film coatings were applied to the tablets in batch sizes of 5000 in a conven-

Table I—Reproducibility of the Membrane-Coating Process [a]

Batch	Potassium Chloride Released During 1st hr, %	Time for 90% release of Potassium Chloride, hr
A	16.9	5.9 ± 0.6 0.4
B	15.9	5.8 ± 0.8 0.6
C	16.7	5.8 ± 0.6 0.5
D	17.0	6.1 ± 0.8 0.5

[a] Six tablets were analyzed out of each of the four batches, using the rotating-basket method. The values for 90% release also show the two most extreme values obtained in the analysis.

tional 50-cm diameter coating pan without baffles. Coating consisted of 13% w/v polymer[3] in acetone. Because of their high viscosity, it was not possible to use more concentrated solutions. Different amounts of micronized sucrose (particle size <10 μm) was suspended in the polymer solutions. Coating was achieved by spraying the various suspensions on the moving bed of tablets with an airless sprayer[4], using a 0.1-mm nozzle. Spray rate was 30 ml/min. Coating was continued until the weight of the coat on each tablet was 50 mg.

Drug Diffusion Studies—Potassium chloride diffusion from tablets was followed by using the modified beaker method (8, 9), the ascending-column method (10, 11), and the rotating-basket method (USP/NF). Diffusion studies according to the beaker method were performed using 1000 ml of dissolution medium at 37° and a paddle stirrer rotating at 60 rpm. Studies with the rotating-basket method were carried out in a 1000-ml cylindrical vessel at 37° with the tablet held in a 40-mesh stainless steel basket. Rotating speed was 100 rpm. The ascending-column method utilized a flow-through cell 25-mm high with a 14-mm diameter. The tablet was placed on a net at the bottom of the cell (Fig. 2). Fresh dissolution medium (37°) was pumped through the cell at a rate of 40 ml/min, and the concentration of potassium chloride was measured at the outlet every 3rd min. Results obtained by the three methods for determining drug diffusion from membrane-coated tablets showed excellent agreement.

Deionized water was used as the dissolution medium, except in the pH influence studies. In these experiments, artificial gastric juice without pepsin was used according to USP XIII, pH 1.2. Artificial intestinal juice was prepared according to USP XIII, without pancreatin, and potassium

dihydrogen phosphate substituted with sodium dihydrogen phosphate, pH 7.5. Potassium chloride concentrations were determined by conductometry in most experiments. In the pH influence studies, however, atomic absorption spectrometry was used for potassium. Slow-release potassium chloride preparations[5] used in the comparison studies were purchased commercially.

Measurement of Membrane Strength—The mechanical resistance of the membrane coat was measured on empty coating shells after the complete release of potassium chloride. Empty coating shells were obtained by placing membrane-coated potassium chloride tablets in a large volume of distilled water for 24 hr. When the drug was diffused from the tablets and the solid core was replaced with liquid the shells floated and became layered beneath the liquid surface. The visible appearance of the tablets did not change. A tool was developed for checking the mechanical resistance of the membrane-coated shell (Fig. 3). The empty coating shell was compressed in a cylinder by a piston which was regulated by compressed air. The resistance of the coating shell against the movement of the piston was registered by a manometer. Compressed air (8 kg/cm^2) reached the throttle valve and penetrated the cylinder. The piston moved upward and pressed the coating shell against the lid of the cylinder. When the coating shell was compressed or burst, the channels were free and the air escaped. This procedure was recorded by a manometer which showed the pressure of the air in kp/cm^2 at the moment the coating shell burst. The maximal air pressure at the compression represents a measure of the mechanical resistance of the membrane.

RESULTS AND DISCUSSION

Characteristics of the Membrane Coating—The coating consists of a water-insoluble polymer and a dispersed water-soluble pore-creating substance. When a membrane-coated tablet is swallowed, the gastric juice dissolves the pore forming substance (Fig. 1). The structure of the membrane can be seen in Fig. 4, as observed by scanning electron microscopy before and after removal of the water-soluble material.

The amount of residual monomer (vinyl chloride) was determined by GC. The accuracy of the method is ~1 ppm, and our results show that the content of monomer is <1 ppm. The pore-forming substance consists of micronized sucrose, which proved to be ideally suited with regard to toxicity and solubility.

Drug Diffusion Studies—The diffusion of dissolved substances from the tablet through the pores can be calculated by using Fick's first law of diffusion.

$$q = D\,(C_s - C_u)\,\frac{A}{h} \qquad \text{(Eq. 1)}$$

where q is the rate of diffusion, D the diffusion constant, A the surface area, and h the thickness of the diffusion layer.

As long as the membrane coating contains a saturated solution together with solid drug substance the concentration inside the coating shell, C_s, is much higher than the concentration outside the coating shell, C_u. For potassium chloride C_s is ~25%, while C_u in our *in vitro* studies has reached maximally 0.1%. Thus, the diffusion has taken place during sink conditions (which means C_u is negligible compared with C_s) and Eq. 1 is reduced to:

$$q = D\,\frac{C_s}{h}\,A \qquad \text{(Eq. 2)}$$

This implies that the diffusion should proceed at a constant rate (zero-order reaction). At the point where no solid substance is left within the membrane coating, the rate of diffusion declines with decreasing concentration (first-order reaction).

The release pattern of active substance from a membrane-coated tablet is shown in Fig. 5. When the release of potassium chloride begins, the sucrose particles in the membrane are dissolved. The rate increases sharply to a maximum in a few minutes.

Theoretically, 70–80% of the potassium chloride should be released

[5] Kalium-Duretter, 0.75 g, Hässle Sweden (formulation A); Slow-K, 0.6 g, Ciba (formulation B).

Table III—Diffusion of Potassium Chloride During 6 hr from Three Different Formulation Principles

Hours	Percent Released from Tablets[a]		
	Membrane-Coated Tablets	Formulation A	Formulation B
1st	16.7	39.6	32.4
2nd	19.8	17.2	25.5
3rd	17.4	11.3	16.0
4th	15.6	8.7	11.2
5th	13.7	6.7	7.8
6th	10.7	4.9	5.3
Total	93.9	88.4	98.2

[a] The figures given are mean values of six single tablet analyses. Released potassium chloride is expressed as percentage of the total content of the different products. The amounts of potassium chloride were: membrane-coated tablets, 1 g; formulation A, 0.75 g; and formulation B, 0.6 g.

at a constant rate. In practical situations, however, the rate decreases slowly and linearly until ~80% of the content is released. At this point there is no solid potassium chloride left in the shell and the rate accordingly decreases rapidly.

The effect of the dissolution medium pH on the potassium chloride diffusion was studied. Figure 5 shows the release pattern in deionized water, artificial intestinal juice (pH 7.5), and artificial gastric juice (pH 1.2). The three media, which represent the physiological pH range, did not influence the diffusion significantly. As can be seen from Fig. 5, the amount of potassium chloride dissolved in 6 hr varies between 80 and 90%.

The reproducibility of the coating process is high. Table I shows release characteristics of four consecutive batches of membrane-coated potassium chloride tablets. The ratio of soluble components to insoluble polymer in the coating material influences the release rate. The importance of this ratio is evident from the data in Table II. A high ratio of soluble/insoluble components gives a high-porosity coating. This ratio is used to produce tablets with a desired release pattern.

Studies on the Membrane Strength—The main factor influencing shell hardness was found to be the thickness of the membrane. Minor changes from the composition of the membrane given in the *Experimental* section do not significantly alter the mechanical strength of the membrane. The compression resistance of membrane-coated tablets measured according to the method described in the *Experimental* section is ~7 kp. To investigate if this is sufficient for the *in vivo* conditions, a study was performed on the empty shells after passage through the GI tract. One membrane-coated tablet/day was given to ten volunteers during 2 days. The stools were collected and the empty shells were examined for ruptures. No ruptures of the membrane were found. (Tablets of different membrane-coat thickness were prepared for this study and checked for membrane strength, which ranged between 5.2 and 7.2 kp.) This proves that the mechanical stability is sufficient to withstand passage through the human GI tract.

Comparison with Other Controlled-Release Principles Used for Potassium Chloride—The membrane-coated potassium chloride tablet was compared with two commercially available slow-release formulations of potassium chloride. These formulations utilize the so-called embedment principle, which means that potassium chloride is embedded in a carrier substance that either forms an insoluble matrix (formulation A) from which the potassium chloride diffuses (12), or a wax matrix (formulation B) which releases the potassium chloride by a combination of diffusion and erosion. Determinations of potassium chloride have been performed according to the method described in the *Experimental* section (rotating basket, 37°).

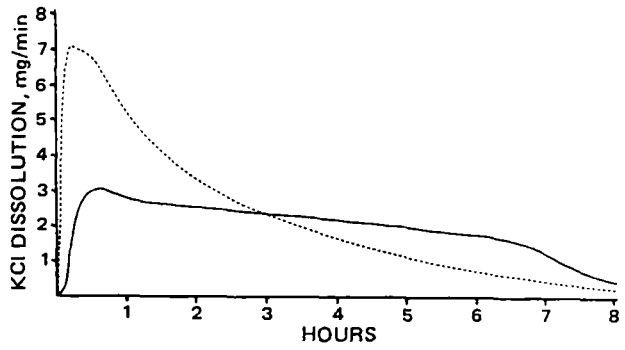

Figure 6—In vitro *release rate of potassium chloride from membrane-coated tablets [1 g (—)] and formulation B [0.6 g (- - - -)]. Data for formulation B have been recalculated in relation to 1 g of KCl.*

As can be seen from Table III, the two commercially available preparations initially released large amounts of active substances. The rate of release then gradually decreased. Membrane-coated tablets, however, gave a slower and more uniform release during the 6-hr period. Figure 6 shows a comparison between membrane-coated tablets and formulation B. An ideal formulation would show a constant diffusion rate, thereby releasing constant amounts of active substance each hour until no more substance remained in the tablet. In the study the membrane-coated tablets have a release pattern that is closer to the ideal situation.

Kinetics of Decomposition and Formulation of Hydrocortisone Butyrate in Semiaqueous and Gel Systems

Y. W. YIP, A. LI WAN PO ˣ, and W. J. IRWIN

Received February 3, 1982, from the *Department of Pharmacy, University of Aston, Gosta Green, Birmingham, UK.* Accepted for publication June 29, 1982.

Abstract □ The stability of hydrocortisone butyrate in semiaqueous and formulated gel systems has been investigated. It was shown that hydrocortisone butyrate underwent reversible isomerization to the C-21 ester of butyric acid. This ester then hydrolyzed to hydrocortisone, which in turn degraded to a complex mixture of compounds. This step is metal catalyzed and can be inhibited by the addition of EDTA [disodium(ethylenedinitrilo)tetraacetate]. The kinetics of decomposition is modeled using nonlinear regression analysis, and the rate constants for the various decomposition pathways are quantified.

Keyphrases □ Hydrocortisone butyrate—decomposition in semiaqueous and gel systems, kinetics □ Kinetics—decomposition of hydrocortisone butyrate in semiaqueous and gel systems □ Decomposition—hydrocortisone butyrate in semiaqueous and gel systems, kinetics □ Dosage forms, topical—hydrocortisone butyrate, decomposition in semiaqueous and gel systems, kinetics

Hydrocortisone butyrate (I) is available in various formulations for topical application. Studies *in vivo* have shown that the ester is many times more active than the parent alcohol, hydrocortisone (1). The presence of the ester function appears to improve delivery of corticosteroids to the site of action as well as increase steroidal activity by imparting resistance to the cutaneous metabolic enzymes involved in the disposition of the steroids from the site of action (2, 3).

Steroid-17-esters, however, readily rearrange to the thermodynamically more stable but topically less active (1) 21-esters under nonideal conditions (4). It was shown that in some extemporaneously diluted ointments, the half-life of betamethasone valerate may be <1 hr at room temperature (5). Previous studies (6, 7) showed that hydrocortisone butyrate (I) underwent acyl migration to the 21-ester (II) followed by hydrolysis of this ester to hydrocortisone (III). This paper reports the formulation and stability of the steroid in semiaqueous and gel systems.

EXPERIMENTAL

Steroid Analysis—High-performance liquid chromatography (HPLC) analyses were performed on an apparatus constructed from a constant-flow solvent pump[1], an injector[2] fitted with a 20-μl loop, and a variable-wavelength monitor[3] equipped with an 8-μl flow-cell. Aqueous acetonitrile[4] mixtures were used as the mobile phase, and hydrocortisone acetate (0.08 mg/ml) was the internal standard for reverse-phase chromatography on a 10-cm, 5-μm ODS column[5]. Normal-phase chromatography was performed as previously described (7) using caffeine (0.1 mg/ml) as the internal standard.

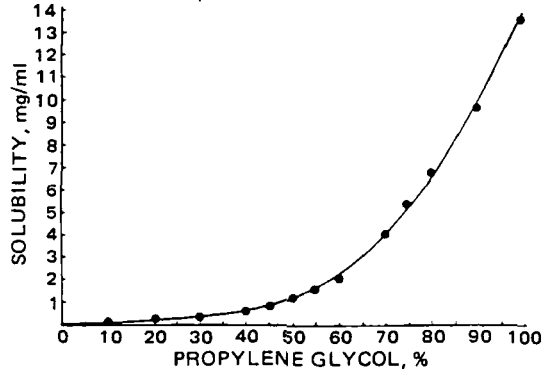

Figure 1—*Solubility profile of hydrocortisone butyrate (I) in aqueous propylene glycol mixtures at 25°.*

HPLC-grade solvents[4], propylene glycol BP[6], hydrocortisone[7], and the buffer salts[8] were purchased from various manufacturers. The hydrocortisone butyrate[9] and the gelling agents[10] were gifts and were used as supplied.

Preparation of Gels—To prepare a carboxypolymethylene polymer gel, 0.8 g of the polymer was dissolved in 30 g of propylene glycol and ~45 g of water. The product was neutralized with 2.5 ml of 2.5 *N* NaOH, and 0.1 g of the steroid was incorporated into the resultant gel using the remaining 20 g of propylene glycol. The gel was adjusted to 100 g with water to produce a 0.1% w/w hydrocortisone butyrate gel for subsequent studies. Entrapped air was removed by vacuum suction in a desiccator.

The other gel systems were prepared as recommended by the manufacturers. Initial experiments with these systems showed that, following topical application, unacceptable films were formed on the skin. All subsequent formulations, therefore, were carried out with the carboxypolymethylene polymers.

Preparation of Aqueous Propylene Glycol–Steroid Solutions—Both nonbuffered and buffered aqueous propylene glycol solutions were used in the kinetic experiments. Aqueous propylene glycol solutions (50% v/v) were adjusted to the required pH by addition of sodium hydroxide. These are referred to as nonbuffered solutions although such solutions should possess some buffer capacity. The buffered aqueous propylene glycol solutions were prepared by mixing equal volumes of propylene glycol and McIlvaine's citrate buffer adjusted to a constant ionic strength of 0.5 *M* with potassium chloride (8). As expected, addition of propylene glycol to an aqueous buffer produced large changes in the pH. Typically, a buffer with an initial pH of 6.91 was altered to pH 7.60 on dilution with an equal volume of propylene glycol. The pH quoted in the stability studies are all final values in the aqueous propylene glycol systems.

Solubility of Hydrocortisone Butyrate—The solubility of hydrocortisone butyrate (I) in aqueous propylene glycol or propylene glycol was determined by adding excess steroid to 10 ml of the appropriate propylene glycol solution preheated to 80°. The suspension was then placed in an ultrasonic bath for 15 min and transferred to a shaking water bath, maintained at 25°. The solution was filtered after overnight storage at this temperature, and an aliquot of the filtrate was assayed by HPLC. Initial estimates were obtained using normal-phase chromatography (6) and confirmed by reverse-phase chromatography. No decomposition was observed during the storage under the conditions described.

Storage and Assay of Gel—The hydrocortisone butyrate gels were stored at 60° in a water bath. Samples of ~1.2 g were withdrawn at appropriate intervals, and 5 ml of 0.5% w/v hydrochloric acid was added to quench the reaction. The tubes were shaken until homogeneous, and 10 ml of chloroform was added. The chloroform extracts were assayed by HPLC (6). Recovery studies showed a mean value of 99.17 ± 0.52% on six replicate determinations.

Storage and Assay of Aqueous Propylene Glycol–Steroid Solutions—The solutions (1 mg/ml) were stored in water baths maintained

at 60°, and 1-ml aliquots were withdrawn at appropriate intervals for assay by reverse-phase HPLC. The reaction was halted by the addition of 4 ml of 0.024 *M* hydrochloric acid in 50% aqueous acetonitrile. Such diluted samples could be stored at 4° for at least a week without measurable decomposition. The samples were diluted with an additional 5 ml of the acetonitrile–hydrochloric acid mixture which contained 0.16 mg/ml of hydrocortisone acetate as an internal standard. When hydrocortisone was studied alone, an internal standard concentration of 0.32 mg/ml was used to obtain more precise data. EDTA [disodium(ethylenedinitrilo)tetraacetate] (0.05% w/v) was added when indicated.

RESULTS AND DISCUSSION

Products commercially available indicate that a 0.1% w/w hydrocortisone butyrate concentration would be a useful starting point when formulating a topical preparation of the steroid. To enhance percutaneous absorption of the steroid from the gel system, it was necessary to optimize the thermodynamic activity of the steroid in the formulation. Since a solution system was considered desirable, the continuous phase vehicle ideally should be chosen in such a way that the concentration of steroid is as close as possible to the saturation concentration. To do this quantitatively, a solubility profile of hydrocortisone butyrate in aqueous propylene glycol, the chosen continuous phase, was constructed (Fig. 1). On the basis of the data obtained, a 48% w/w propylene glycol in water solution was chosen for formulating the 0.1% w/w hydrocortisone butyrate gel.

Analysis of the steroids by HPLC and by reference to authentic specimens showed that, like betamethasone valerate, hydrocortisone butyrate (I) isomerizes to the corresponding C-21 ester of butyric acid (II), which then hydrolyzes to hydrocortisone (III) as shown in Scheme I.

To obtain adequate HPLC resolution of the steroids, three aqueous acetonitrile mixtures were necessary. Quantitation of I and II was carried out using a 50% v/v acetonitrile–water mixture. Under these conditions, hydrocortisone showed significant overlap with other minor decomposition products (Fig. 2*a*). Decreasing the acetonitrile concentration prolonged the retention times of all the steroids. The quantitative assay of hydrocortisone was possible with a mobile phase consisting of 35% v/v acetonitrile–water (Fig. 2*b*). Although I and II were resolved from the other steroids using this weaker solvent, the quantitation was not satisfactory because of peak broadening. In the initial stages of decomposition, a 40% v/v acetonitrile–water mixture was adequate in resolving hydrocortisone for quantitative assay (Fig. 2*c*). Considerable time could be saved using this system instead of the 35% v/v aqueous acetonitrile mixture. Whenever possible, therefore, the 40% mixture was chosen for assaying hydrocortisone in the presence of the other steroids.

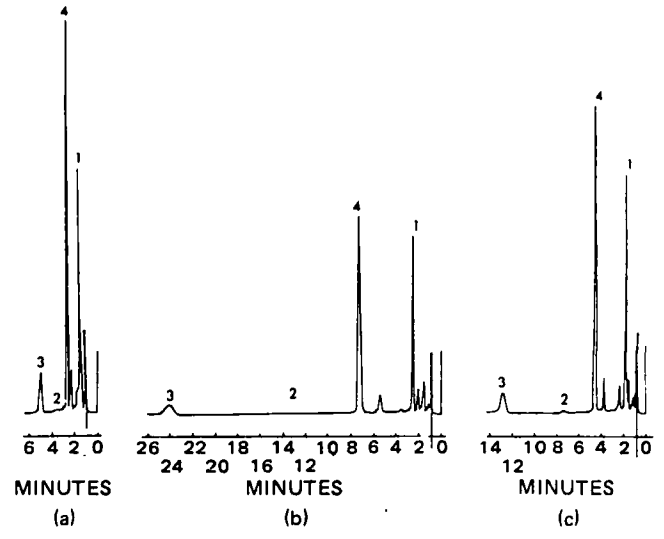

Figure 2—*HPLC separation of I from its decomposition products using an aqueous acetonitrile mobile phase at concentrations of 50% (a), 35% (b), and 40% v/v (c). Key: (1) hydrocortisone; (2) I, (3) II; (4) internal standard.*

Where the assay solutions were diluted prior to injection, care was taken to ensure that the final solvent composition was identical to that used for the standard solution. This was necessary because, as previously reported (9), peak height ratios can show considerable variation, depending on the solvent used.

Kinetic analysis of the gel data (Fig. 3) showed that disappearance of I followed first-order kinetics. Unlike betamethasone valerate (5, 6), however, the overall decomposition did not follow a sequential first-order pattern. Monitoring the decomposition at various pH values showed that the isomerization of I to the C-21 ester (II) was base catalyzed, and pH dependent (Table I). Such base catalysis has been shown in semisolid systems (7, 9, 10). The changes in pH do not appear to be the only factor of importance, since dilution of a betamethasone valerate ointment with a different ointment base significantly altered the decomposition rate even though the pH was near that of the stable undiluted product (7).

To dissociate any effects produced by the gelling agent from other effects, the kinetics of decomposition of I was followed in the absence of the vinyl polymer. The data obtained showed that the decomposition was again pH dependent (Table II); but, unlike the gel system, even the disappearance rate of I in this nonbuffered system did not follow first-order kinetics. The profile for the three steroids in a 50% v/v aqueous propylene glycol system adjusted to pH 7.9 with sodium hydroxide is illustrated in Fig. 4. At this stage it was postulated that base was consumed during at least one of the reactions involved in the overall degradation of I since there was a pH change of ~2 units. To test this, the decomposition was

followed in buffered aqueous propylene glycol systems. Under such conditions one would expect linearization of the data if the reaction sequence was indeed a sequential, irreversible, first-order pathway (Table III, model 1). In fact, the data obtained gave a reasonable fit when subjected to nonlinear regression analysis (11). For most stability prediction studies, such a fit would be adequate, and the confidence limits of the data support this (Table IV). For precise modeling, however, the computerized plot of the experimental data against the predicted data using model 1 shows that discrepancies are present (Fig. 5).

The integrated form of the rate equations were used in the computation. These (Eqs. A1–A4) and equations relevant to the other kinetic models used in this study are listed in *Appendix I*. The kinetic parameters are listed in Tables IV–VIII.

Both previous (12) and the present data show that other products besides II and the free alcohol are produced during the decomposition at 60°. HPLC of a decomposed sample (Fig. 2) clearly demonstrates the complexity of the pathways. Hansen and Bundgaard (12) have reported that at least seven products are formed during the decomposition of hydrocortisone. If the decomposition of hydrocortisone to other products were all first-order parallel processes, the sequential first-order model would hold because the rate constant for the decomposition (K_3) would then equal the sum of the individual rate constants.

The possibility that experimental error accounted for the results was discounted by repeating the experiment: similar deviations were noted in both sets of data. There was good agreement between the estimates for the rate constants (Table IV). Two alternative models to account for the discrepancies are possible. The first is that the isomerization of I to II is reversible, and that the reverse rate constant is not negligible (Table III, model 2). An analogous situation has been previously reported in studies on tricyclic antidepressants (13, 14). In a recent study, Anderson and Taphouse showed that acyl migration from the C-21 to the C-17 position was also possible with methylprednisolone hemisuccinate (15). The second alternative is that I hydrolyzes to hydrocortisone directly and not solely *via* the formation of II (Table III, model 3). To test these possibilities, the hydrolysis of II was followed in samples initially free of I (Table VI, $|B|_0 = 100\%$). Formation of I would show any reversibility. This was the case, and the kinetic parameters for this system under identical conditions are shown in Table V. The improved fit to the model can be seen in Fig. 6. Since K_1 is ~14 times greater than K_4, these rate

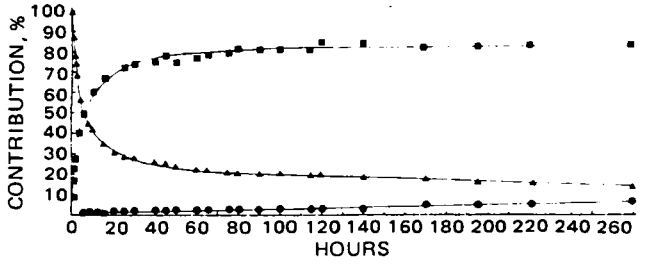

Figure 4—*Profile of I (▲), II (■), and hydrocortisone (●) during the decomposition at 60° of the steroid-17-ester in an aqueous propylene glycol solution (initial pH 7.9).*

Table III—Kinetic Models for the Decomposition of Hydrocortisone Butyrate

Model	Decomposition Scheme
1	$I \xrightarrow{K_1} II \xrightarrow{K_2} III \xrightarrow{K_3} IV$
2	$I \underset{K_4}{\overset{K_1}{\rightleftharpoons}} II \xrightarrow{K_2} III \xrightarrow{K_3} IV$
3	$I \underset{K_4}{\overset{K_1}{\rightleftharpoons}} II \xrightarrow{K_2} III \xrightarrow{K_3} IV$, $II \xrightarrow{K_5} III$

constants are expected to be imprecise when derived from experiments where the initial concentration of I is zero. This is reflected in the wide confidence limits (Table VI).

It is interesting to note that the reverse rate constant for betamethasone valerate isomerization to the C-21 ester was negligible (6), while the ratio of the forward and reverse rate constants for methylprednisolone hemisuccinate was 3–5 (15). The diacidic nature of succinic acid and the C-16 methyl group in betamethasone may explain the observed differences. The free acid function of prednisolone is able to interact freely with the C-17 hydroxyl group without ester function cleavage. In betamethasone, the C-17 hydroxyl group is sterically hindered to a greater extent than in the other two steroids. Its interaction with the C-21 ester function, therefore, is associated with a higher energy barrier and hence a lower reverse rate constant. The experiment does not exclude reversibility in the hydrolysis of I. Therefore, the decomposition of hydrocortisone was studied in the presence of an equimolar amount of sodium butyrate and in the absence of the esters. A control was carried out without the sodium butyrate: no hydrocortisone ester was detected throughout the run, and the rate constants in the control and test systems (0.0096 and 0.0102 hr^{-1}, respectively) were equal within experimental error. Having confirmed that the isomerization, but not the hydrolysis, of I was reversible, the fit to models 2 and 3 were compared to exclude

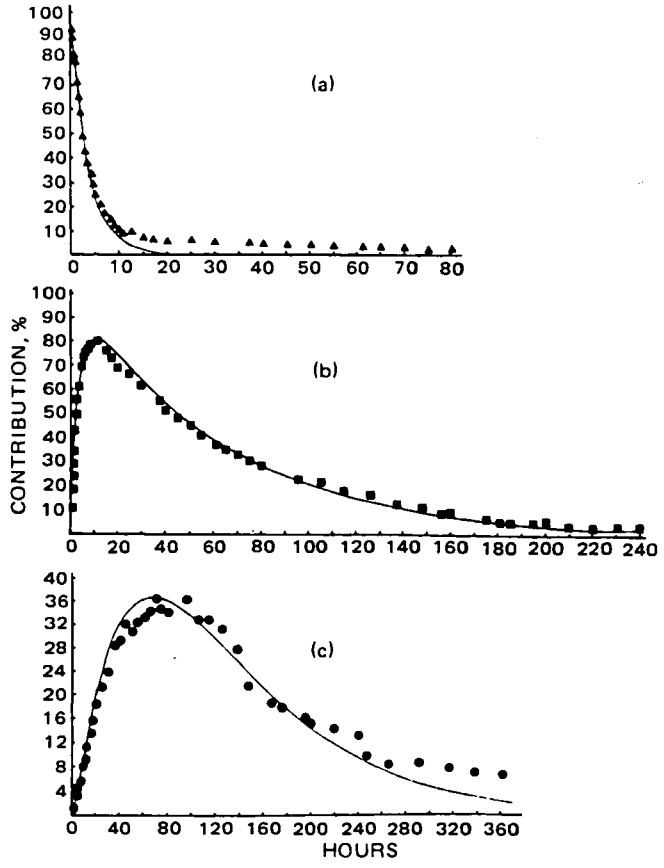

Figure 5—*Profiles for I (a), II (b), and hydrocortisone (c) during the decomposition at 60° of the steroid-17-ester in a buffered aqueous propylene glycol solution (50% v/v, pH 7.6). The lines represent the theoretical predictions according to model 1.*

the possibility that I is converted directly to hydrocortisone. The statistical data and the plots (Figs. 6 and 7) show that direct conversion was likely. Because of the small magnitude of the rate constant for the direct conversion of the I to hydrocortisone (K_5) relative to the other routes, the estimate for its value is imprecise, as is evident in the wide span of 95% confidence limits (Table VII).

Preliminary work on the effect of buffers on the decomposition indicated that the decomposition rates of I to II and of the latter to III were not significantly affected by doubling the buffer concentration. However, the rate of hydrocortisone disappearance was increased (Tables VII and VIII). Recent work has shown that the decomposition of III was metal catalyzed and that EDTA significantly decreased the rate of decomposition (12). Indeed, buffer effects were rationalized on the basis of trace metal contaminants both for hydrocortisone (12) and prednisolone (16). In the present system, the isomerization and hydrolysis steps were unaffected; these steps were not expected to be metal catalyzed. Using different batches of the same grade[11] of buffer salts, the same rate constants for the decomposition of III were obtained (Table IX). However, this does not exclude metal catalysis.

The effect of EDTA on the decomposition therefore was investigated. In addition to explaining in part the mechanism of decomposition, the data was expected to aid in selecting suitable methods for stabilizing the hydrocortisone formulations. Additionally, it had been suggested that some of the decomposition products were potentially immunogenic (17). When compared with control systems (free from the chelating agent),

[a] As defined in Table III with initial conditions: $|A|_0 = 100\%$ and $|B|_0 = |C|_0 = 0$. [b] Reactions in buffered (pH 7.6) aqueous propylene glycol (50% v/v) at 60°. [c] Function designation in parentheses.

a stabilizing effect on hydrocortisone was observed when EDTA was added. As expected, the isomerization and hydrolysis rate constants were not significantly altered (Table X). Comparison of the chromatograms (Fig. 8) for the decomposed solutions shows that the profiles for hydrocortisone and the minor decomposition products were markedly different when the system with added EDTA was compared with a control. At 105 hr, the residual steroid concentrations in the control system were 1.2% for I, 21% for II, and 32.6% for III; the respective concentrations for the system with added EDTA were 1.8, 24, and 52%. No attempt was made to identify the minor decomposition products, but published work suggests that oxidation of the side chain of hydrocortisone (leading to the formation of steroid glyoxals, 17-oxo-steroids, and glycolic acids) was likely (12).

The rate constants for the loss of hydrocortisone were lower for solutions initially containing only hydrocortisone compared with solutions

initially composed of only I (Tables IV and IX). The rate constant in the latter system had to be obtained by curve-fitting, and, as expected, the value of the rate constant for the loss of hydrocortisone was less accurate than that for the simpler system with hydrocortisone alone. This discrepancy in the rate constants for hydrocortisone disappearance also accounts for the deviation between the predicted and actual hydrocortisone profiles at longer time intervals (Figs. 5–7).

CONCLUSIONS

It has been shown that, in the systems studied, hydrocortisone butyrate (I) underwent reversible isomerization to hydrocortisone butyrate (II). Compound II was then hydrolyzed to hydrocortisone (III) which in turn degraded to a complex mixture of oxidation products. Although the decomposition pathways are complex, they can satisfactorily be modeled by a series of first-order equations. Nonlinear regression analysis of the data indicated that both models 2 and 3 (Table III) satisfactorily described the decomposition, and that model 3 appeared to be a marginally better fit. Direct hydrolysis of I to III and the reverse rate constant for its isomerization to II were so small relative to the hydrolysis rate of II

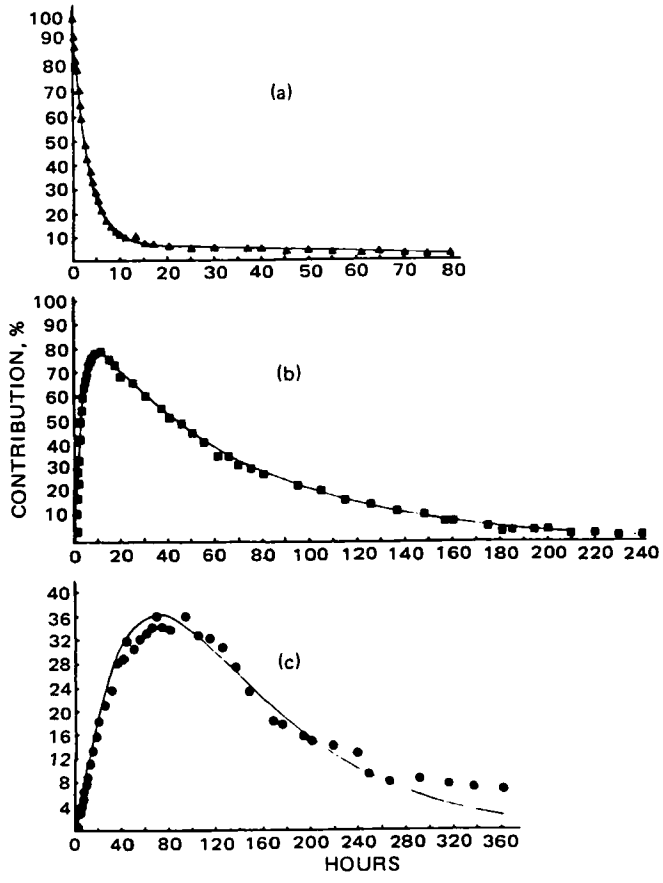

Figure 7—*Profiles for I (a), II (b), and hydrocortisone (c) during the decomposition at 60° of the steroid-17-ester in a buffered aqueous propylene glycol solution (50% v/v, pH 7.6). The lines represent the theoretical predictions according to model 3.*

and the forward rate constant of isomerization that, for most shelf-life predictions, estimates using model 1 (Table III) should be adequate. While the decomposition of III is slow when compared with that of the esters, the suggestion (16) that some of the products may be immunogenic indicates that these slow rates may need to be taken into consideration for the expiration dating of hydrocortisone esters. This requires confirmation; but if such is the case, the more complex models described in this paper should be adequate for this purpose.

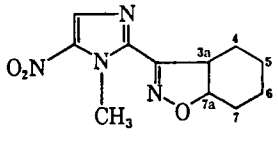
Abstract □ Twelve *in vitro* oxygenated metabolites of 3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436) were produced by incubation of this antiprotozoal agent with the postmitochondriai supernatant (S9) fraction isolated from the livers of rats treated with phenobarbital. Metabolite structure elucidation was achieved using NMR and mass spectrometry. Seven monohydroxy and two dihydroxy metabolites were fully characterized; two other metabolites were partially characterized as dihydroxy derivatives of the drug. The major *in vitro* metabolite is the 5 axial hydroxy compound, and a minor metabolite is the corresponding ketone. In all cases metabolite formation involved biotransformation on the hexahydrobenzisoxazole ring.

Keyphrases □ 3a,4,5,6,7,7a - Hexahydro -3- (1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole—synthesis of *in vitro* oxygenated metabolites, characterization by NMR and mass spectrometry, biotransformations on the hexahydrobenzisoxazole ring □ Metabolites—of 3a,4,5,6,7,7a - hexahydro -3- (1-methyl-5-nitro-1*H*-imidazol -2- yl)-1,2-benzisoxazole, characterization by NMR and mass spectrometry □ Antiprotozoal agents—3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole and its metabolites, characterization by NMR and mass spectrometry

Seven canine urinary metabolites of the antiprotozoal agent 3a,4,5,6,7,7a-hexahydro-3-(1-methyl-5-nitro-1*H*-imidazol-2-yl)-1,2-benzisoxazole (MK-0436, I) have been identified; all of the compounds (II–VIII) are formed by hydroxylation of the hexahydrobenzisoxazole ring (1, 2). Several dihydroxy analogues of I have been synthesized



I

and at least one, the 6,7-*cis*-dihydroxy compound, exhibits higher antibacterial activity against *Salmonella schottmuelleri* in mice and greater trypanocidal activity *in vivo* against *Trypanosoma cruzi* (Brazil strain) than I (1). Incubation of I with the microsomal cytosol fraction (S9) from the livers of mice produced antibacterial activity not seen with the drug alone, suggesting the *in vitro* formation of antibacterial metabolites (1). The present study was undertaken to identify the metabolites of I generated *in vitro* by the rat liver postmitochondrial supernatant fraction (S9).

EXPERIMENTAL

***In Vitro* Incubations**—The postmitochondrial supernatant fraction was isolated from livers of rats that had been treated with phenobarbital. The 9–12-week-old rats were injected with phenobarbital for four consecutive days at a dose of 80 mg kg/day ip. Twenty-four hours after the last injection the rats were killed and the postmitochondrial S9 supernatant was isolated using the method of Ames (3).

The incubation mixture used was the same as that described by Ames for the S9 mixture (3) and used previously (1). It contained 0.1 *M* sodium phosphate (pH 7.4), 8 m*M* magnesium chloride, 33 m*M* potassium chloride, 5 m*M* glucose-6-phosphate, 4 m*M* nicotinamide adenine dinucleotide phosphate, homogenate equal to 0.78 g wet weight liver, and 4 mg of I (labeled with carbon-14 in the 3a and 7a positions) in 200 μl of dimethylsulfoxide with a total volume of 10.4 ml. The incubation was carried out in a 250-ml Erlenmeyer flask with shaking at room temperature. At the end of the 80-min incubation (determined to be optimum for metabolite production from preliminary experiments) an equal volume of cold methylene chloride was added.

Metabolite Isolation—The metabolites of I were isolated by dilution of the incubation mixture with 10 ml of water followed by three successive extractions with 20-ml portions of methylene chloride. This procedure resulted in the extraction of 80% of the radioactivity present in the incubation mixture. The organic phases were combined and the methylene chloride removed under a stream of nitrogen (water bath, 40°) to yield a tan residue. The latter was dissolved in methanol and subjected to TLC[1] (solvent system A; see below) to yield seven metabolite fractions. Further purification of these fractions, if necessary, was achieved by use of TLC with three other solvent systems (systems B–D; see below). Appropriate zones (visualized by radioscanning[2] or short-wavelength UV[3]) were scraped from the plate and the silica gel washed three times with ethyl acetate–methanol, 4:1. The eluates were combined and, following removal of solvent under a nitrogen stream at 40°, the residue was partitioned between ethyl acetate (2 ml) and water (0.1 ml) to minimize the amount of silica gel present in the isolated metabolite fraction.

TLC and Radioactivity Assay—Isolation of metabolite fractions *via* TLC involved the use of four solvent[4] systems: toluene–ethyl acetate, 3:1 (system A); methylene chloride (system B); methylene chloride–methanol, 9:1 (system C); and trimethylpentane–2-propanol, 4:1 (system D). Metabolite fractions were assayed for radioactivity by use of liquid scintillation counting[5] techniques.

Derivatization—Methoxime formation was carried out by dissolving an aliquot of the metabolite fraction in a pyridine solution of methoxyamine hydrochloride[6] (5 mg/ml) and allowing the reaction to proceed for 2 hr at room temperature. The trimethylsilyl derivative was prepared by dissolving an aliquot of the metabolite fraction in a 1:1 (v/v) mixture of *bis*(trimethylsilyl)trifluoroacetamide[7]–pyridine and allowing the reaction to proceed for 1 hr at room temperature.

NMR and Mass Spectrometry—NMR spectra[8] were obtained from metabolite fractions dissolved in deuterochloroform. Mass spectra[9] of metabolite fractions were obtained by use of the direct probe technique under the following operating conditions: 3.5 kV accelerating potential, 60 μA trap current, 70 eV ionizing energy, and 250° source temperature. Capillary column GLC–mass spectrometry[10] was carried out using a 15 m × 0.25-mm i.d. SE-30 column operated at 220° (helium carrier gas, 1

RESULTS AND DISCUSSION

The nitroimidazole I and its known hydroxyl group-containing metabolites exhibit strong short-wavelength UV absorption (254 nm) which facilitates their detection on a TLC plate. Further, as the drug used in these studies was ^{14}C-labeled, radioscanning of a developed TLC plate also allowed the detection of metabolites. The electron impact mass spectra of these compounds normally possess intense fragment ions at *m/z* 153 and 195 (1), and these, plus the presence of molecular ions at *m/z* 266 or 282 (16 and 32 AMU greater than the molecular ion of I, respectively), facilitate recognition of the unknown compounds as mono- or dihydroxylated analogues of I. When the metabolites are trimethylsilylated, their molecular ions increase by 72 AMU for each hydroxyl group present to yield signals at *m/z* 338 and 426 (molecular ions, low intensity) and *m/z* 323 and 411 (the corresponding M-15 ions).

Analytical TLC (solvent system A) with UV and/or radioscanning and capillary column GLC–mass spectrometry (as trimethylsilyl derivatives) of a methylene chloride extract of the incubation mixture (~80% of the radioactivity was extractable) demonstrated that it was multicomponent in nature, containing at least seven compounds related to I (Fig. 1, Table I). None of the parent drug was present. Preparative scale TLC (solvent system A) was employed to isolate the seven metabolite fractions in quantities suitable for structure elucidation. These were examined by mass and NMR spectrometry. In all cases the mass spectrometric data showed the metabolites to be mono- or dioxygenated derivatives of I, with the metabolic transformation occurring on the hexahydrobenzisoxazole ring (Table II).

One of the isolated metabolites was shown to be the 7-equatorial hydroxy compound, previously identified as a canine urinary metabolite of I (2) and is thus referred to as metabolite VI (the previous designation). This is the second most abundant of the *in vitro* metabolites.

The major *in vitro* metabolite, IX, is also a monohydroxy derivative of I (molecular ion, *m/z* 266). On the basis of NMR data [4.60 ddd, 7.5, 4.0, 4.0 (H_{7a}); 4.17 br s, $w_{1/2}$: 11 H_3 (H_{5eq}); 3.82 dt, 10.0, 7.5, 7.5 (H_{3a})] the hydroxyl group is assigned to the 5-position with an axial conformation.

Metabolite X is the third most abundant metabolite arising from the S9 incubation. It also possesses a molecular weight of 266, as determined by mass spectrometry. The location of the hydroxyl group was shown by NMR to be at C_{7a}, since the characteristic H_{7a} signal was absent. Other pertinent NMR data included the signal at 3.47 dd, 10.5, 7.5 (H_{3a}). This metabolite was found to dehydrate on prolonged exposure to silica gel to yield an olefin (molecular weight 248) identified as the $\Delta^{3a,7a}$ compound.

Metabolite XI, the fourth of the monohydroxy metabolites, was shown by NMR [key features include signals at 4.66 m (H_{7a}); 3.22 t, 8.3 (H_{3a}); and 3.59 ddd, 11.5, 8.0, 5.0 (H_{4ax})] to possess an equatorial hydroxyl group at C-4. Although hydroxylation at C-4 of I has been recognized previously for an *in vivo* metabolite [4,5-di-equatorial dihydroxy, II (2)], this is the first instance of monohydroxylation at this position.

The minor metabolite fractions Y and Z were found, on the basis of NMR (presence of several N—CH_3 signals) and mass spectrometry (interscan variation of relative ion intensities), to be multicomponent in nature. Preparative scale TLC (solvent system D; Table I) was employed to isolate two metabolites (one major, one minor) from Y and three metabolites (two major, one minor) from Z. The two major components of Z were shown to be the 5- and 6-equatorial monohydroxy metabolites, both previously found as canine urinary metabolites of I (2) and are thus designated (as before) metabolites IV and VII.

The minor components of Y and Z and the major component of Y all possess molecular ions of *m/z* 282 and are thus dihydroxy metabolites of I. As with all of the other known metabolites of this drug, their mass spectrometric behavior indicated that hydroxylation had occurred on the hexahydrobenzisoxazole ring. The exact positions and stereochemistry of the two hydroxyl groups of the major Y metabolite (VIII) were shown by NMR to be 5-axial and 7a. The NMR spectrum of VIII is characterized by the absence of an H_{7a} signal and the presence of a new *H*COH peak of 4.16δ. An equatorial configuration for the 4.16δ methine is inferred based on the broad singlet character and relatively narrow linewidth ($w_{1/2}$10 Hz). Since the coupling patterns of H_{3a} and H_{7a} axial exclude C-4 and C-6 as possible sites, VIII is assigned as the 5-axial,7a-dihydroxy analogue. The minor components of Y (XII) and Z (XIII) were not further characterized.

A very minor metabolite (XIV) was found by mass spectrometry to possess a molecular weight of 264 (*versus* 250 for I). This shift of 14 mass units suggested that the metabolic transformation involved formation of a ketone. Compound XIV was exposed to methoxime-forming conditions (4); mass spectrometry showed a shift in molecular weight from 264 to 293, demonstrating the ketonic nature of the metabolite. The exact site of the keto group on the hexahydrobenzisoxazole ring was shown by NMR [5.19 dt, 11.5, 3.5, 3.5 (H_{7a}); 4.38 ddd, 11.3, 7.3, 3.5 (H_{3a}); 2.96 dd 16.4, 3.5; 2.77 dd 16.4, 7.5 (4-CH_2); 2.44 m, 2.32 m (6,7-CH_2)] to be the 5-position. This metabolite presumably arises from IX *via* oxidation of the 5-axial hydroxyl group.

When the 6,7-epoxide of I is incubated under the conditions that yield the metabolites discussed above, the major metabolite is the 5-axial hydroxy derivative of the 6,7-epoxide. The mass spectrum of this metabolite contains a molecular ion at *m/z* 280 with *m/z* 195 as base peak, the same base peak as found in the mass spectrum of IX (which also possesses an axial hydroxyl group at C-5). The NMR of the hydroxylated epoxide showed peaks at 5.13 d, 11.0 (H_{7a}); 4.10 ddd, 11.0, 5.0, 3.0 (H_{3a}); 3.88 dd, 11.5, 5.0 (H_{5a}); 3.42 br s ($H_{6,7}$); 2.72 ddd, 14.0, 5.0, 4.0 (H_{4eq}); 1.95 ddd, 11.5, 11.5, 5.5 (H_{4ax}).

A preliminary incubation, in which only 10% of the radioactivity was extractable from the aqueous system by methylene chloride, gave six metabolites isolated by TLC (Table I)[12]. Again, no I was found in the extract (as measured by TLC). Four of these compounds were shown by TLC, mass spectrometry, and/or NMR to be metabolites IV, VI, VII, and IX. The two others are newly recognized *in vitro* metabolites of I. One is the 7-axial hydroxy analogue (metabolite V, previously found as a conjugate in dog urine); the second is the 4-equatorial,5-axial dihydroxy analogue (metabolite XV, not found in dog urine). The mass spectrum of this latter metabolite exhibits a molecular ion at *m/z* 282 and fragment

ions characteristic of hydroxylation at C-4 and C-7 of the hexahydrobenzisoxazole ring. The NMR of this compound is characterized by signals at 4.68 m (H_{7a}); 3.54 dd, 8.0, 3.5 (H_{4ax}); 4.10 br s, $w_{1/2}$10 Hz (H_{5eq}); and 3.40 t, 8.0 (H_{3a}).

The outcome of this preliminary experiment (which yielded metabolites IV–VII, IX,and XV) might have resulted from a lack of sufficient air in the reaction flask during the incubation or possibly from secondary metabolism resulting from a high enzyme to substrate ratio and extended incubation. In any event, it is clear that routes and extent of *in vitro* metabolism of I are heavily dependent on the incubation conditions. Whether a radically different metabolism (*e.g.*, transformations of the nitro group or the heterocyclic rings) occurs or whether further oxidative metabolism of the hexahydrobenzisoxazole ring leads to highly polar, ring-opened derivatives is not known at present.

Earlier work demonstrated that at least four dihydroxy metabolites (two fully characterized) and at least five monohydroxy metabolites of I are found (free and/or conjugated) in dog urine (1, 2). The current study shows that monohydroxylation is by far the major *in vitro* pathway, but that dihydroxylation is not precluded. A total of 14 *in vivo* and *in vitro* metabolites of I resulting from introduction of one or two oxygen atoms into the hexahydrobenzisoxazole ring have now been recognized.

The extensive oxidative metabolism of I is another example of the ability of the hepatic microsomal mixed-function oxidases to metabolize a compound at several sites (5–7). It is of interest that the alicyclic carbons of the saturated benzisoxazole ring are the targets of metabolism, whereas the N—CH_3 group appears resistent to metabolic attack under the conditions used. Likewise, to date no metabolism has been found to occur at the 3a-position. So although extensive, the metabolism is quite selective. Other nitroimidazoles undergo metabolism on their hydrocarbon moieties. Metronidazole and ipronidazole are hydroxylated on the 2-CH_3 group (8) and the 2-isopropyl group (9), respectively, misonidazole undergoes *O*-demethylation (10), and 5-isopropyl-1-methyl-2-nitro-1*H*-imidazole undergoes extensive metabolism at the isopropyl group (11). Although reduction of the nitro group is considered the mechanism by which nitroimidazoles exert their therapeutic activity, modification of other parts of the molecules can enhance or diminish this therapeutic activity, as shown previously (1).

Metabolism of Isosorbide Dinitrate in the Isolated Perfused Rabbit Lung

PHILIP R. MAYER*, WILLIAM C. LUBAWY, PATRICK J. MCNAMARA, and HARRY B. KOSTENBAUDER ˣ

Received February 1, 1982, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536.* Accepted for publication June 25, 1982. *Present address: School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

Abstract □ The uptake and metabolism of isosorbide dinitrate was investigated in the recirculating isolated perfused rabbit lung and in lung homogenate 9000×*g* supernatant. Concentration *versus* time profiles from the isolated lung experiments indicate rapid metabolism of isosorbide dinitrate and corresponding increases in the metabolites 5-isosorbide mononitrate, 2-isosorbide mononitrate, and isosorbide. The data suggest that the mononitrates formed in the lung tissue were converted to isosorbide at an extraordinarily high rate. Surprisingly, the rate of appearance of completely denitrated isosorbide was greater when isosorbide dinitrate was administered to the lung than when the mononitrate metabolites of isosorbide dinitrate were administered. The results suggest rapid metabolism of a substantial portion of the mononitrates formed endogenously from isosorbide dinitrate before partitioning of mononitrates into the perfusion medium could occur. The metabolism of isosorbide dinitrate in lung homogenate 9000×*g* supernatant exhibited a metabolic scheme kinetically different from the intact lung studies, as isosorbide was formed slowly from a mononitrate intermediate and not by a near-simultaneous cleavage of both nitrate ester groups. Intravascular multiple-dose studies did not demonstrate any inhibition between isosorbide dinitrate and the mononitrates.

The lung has been evaluated previously for many functions other than the physiological exchange of gases. The lung is now known to absorb many drugs, filter the air and blood, and serve in fibrinologic, endocrinologic, and metabolic capacities (1, 2). Uptake of a drug into the lung may be by passive diffusion (3) or carrier-mediated transport (4) and may have reversible, competitive, or saturable components (5). The lung can metabolize efficiently many biologically active substances once they are distributed in the lung (2, 3, 6).

Isosorbide dinitrate is a vasodilator used primarily in the treatment of angina pectoris and congestive heart failure (7, 8). Organic nitrates including isosorbide dinitrate are metabolized extensively by the enzyme glutathione organic nitrate reductase (9, 10), and their oral effectiveness has been questioned due to extensive first-pass liver metabolism (11, 12). The objective of this study was to investigate the uptake and metabolism of isosorbide dinitrate in the isolated perfused rabbit lung, and to evaluate in a preliminary manner this organ as a route of administration.

EXPERIMENTAL

Materials—Randomly labeled [^{14}C]isosorbide dinitrate (168 mCi/mmole)[1] was purified by the chromatographic procedure described in *Analytical Methods* and extracted from the silica gel with methanol. A working solution of >96% purity was obtained and checked at 6-month intervals. Radiolabeled metabolites were recovered in the same manner. Nonlabeled isosorbide dinitrate was obtained as a 25% lactose mixture[2], and the pure compound was recovered by extraction with ethyl acetate and evaporation of the solvent. Nonlabeled 5-isosorbide mononitrate[3], 2-isosorbide mononitrate[4], and isosorbide[5] were used without further purification. All other solvents and reagents were reagent grade.

Isolated Perfused Rabbit Lung Experiments—The isolated lung preparation has been modified slightly from procedures described previously (6, 13). The isolated lung was perfused at 225 ml/min by 100 ml of an artificial medium prepared the day of or day before an experiment. The perfusion medium was composed of Krebs–Henseleit bicarbonate buffer (500 ml) with 4.5% bovine serum albumin (22.5 g)[6] and 5 mmoles of glucose (90 mg)[7]. The pH, adjusted to 7.4, was maintained during the experiment by a constant 0.005-ml/min infusion of a 1.0 meq/ml sodium bicarbonate solution containing 10% glucose and by appropriate adjustments in an air–carbon dioxide ventilating mixture supplied to the lungs.

For intravascular bolus administration, the compounds were presented to the lung by addition to the upper reservoir. Generally ~8 μCi of the compound was added in each study, and supplementary unlabeled compounds were added to achieve the required dose. Doses ranged from 10^{-7} to 10^{-5} mole for isosorbide dinitrate and were 10^{-6} mole for the mononitrates. Each experiment was performed in duplicate. One-milliliter perfusion medium samples were withdrawn from the upper reservoir at appropriate intervals during the 1–2 hr experiment. In the multiple-dose studies, a second (10^{-7}-mole) dose of isosorbide dinitrate was given 60 min after the first (10^{-5}-mole) dose, with subsequent metabolism followed for an additional 60 min.

Lung 9000×*g* Homogenate Experiments—The lungs of New Zealand rabbits were separated from all extraneous tissue, weighed, and

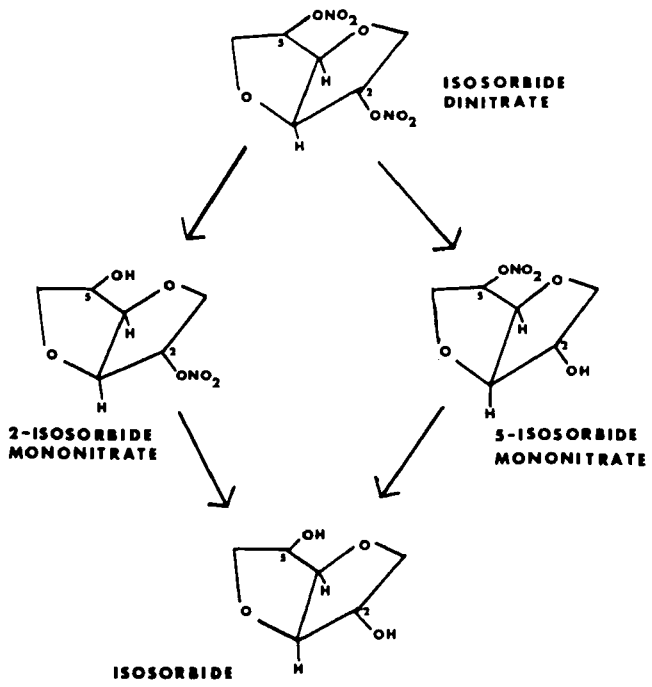

Scheme I—Pathways of isosorbide dinitrate metabolism.

added to a beaker containing two volumes of 0.04 *M* phosphate buffer, pH 7.4. The lungs were homogenized and centrifuged at 9000×*g* for 15 min in a centrifuge kept at 0°. For the incubations, 24 separate culture tubes were arranged containing 10^{-9} mole of isosorbide dinitrate, 5-isosorbide mononitrate, or 2-isosorbide mononitrate to allow a more precise quantitation of each metabolic step. Reduced glutathione[8] and sodium cyanide[9] were added in quantities of 2×10^{-9} moles each, according to the method of Needleman and Krantz (9). The experiment was initiated by the addition of 0.5 ml of the 9000×*g* supernatant. The culture tubes were placed in a shaker incubator kept at 37°, and one culture tube containing each compound was removed at every time interval for analysis. A control experiment was conducted to measure the hydrolysis of isosorbide dinitrate in the presence of glutathione, cyanide, and phosphate buffer. Each experiment was performed in duplicate.

Analytical Methods—The perfusion medium and homogenate samples were extracted with 10 ml of ether, and the organic phase was evaporated to dryness in a water bath not allowed to exceed 40°. Residues were reconstituted in 100 μl of methanol; half of this solution was streaked across 250-μm silica gel TLC plates[10]. Chromatograms were developed 15 cm with dichloromethane–ethyl acetate (4:1). A radiochromatogram scanner[11] was used to locate the radioactive zones on the TLC plates corresponding to isosorbide dinitrate, 5-isosorbide mononitrate, and 2-isosorbide mononitrate, which had R_f values of 0.63, 0.19, and 0.32, respectively. Appropriate bands were scraped into a scintillation vial[12] and dispersed with 15 ml of a scintillation gel prior to counting in a liquid scintillation counter[13]. The gel was composed of 112 g of naphthalene, 14 g of 2,5-diphenyloxazole (PPO), and 0.7 g of 1,4-bis[2-(4-methyl-5-phenyloxazolyl)-benzene] (dimethyl POPOP) dissolved in 1400 ml of a mixture of xylene (1 part), dioxane (3 parts), and ethylene glycol monoethyl ether (3 parts), followed by the addition of 84 g of a thixotropic gelling agent[14]. All samples were corrected for quenching by an external standardization method.

Isosorbide was measured by suspending 0.1 ml of the perfusion medium remaining after the ether extraction in a toluene–ethoxyoctylphenol[15] scintillation cocktail (6). To confirm that only isosorbide was measured, perfusion medium samples from a lung experiment were streaked on TLC plates and developed with a solvent system of 2-propanol–ammonium hydroxide (4:1) (14). The plates were scanned, scraped, and counted in 15 ml of the silicon dioxide cocktail. Unlabeled, authentic isosorbide was visualized by spraying the plates with a reagent composed of sodium metaperiodate, potassium permanganate, and sodium carbonate (15). Isosorbide concentrations found in the 2-propanol–ammonium hydroxide TLC system corresponded within 15% to those seen by direct measurement of the 0.1 ml postextraction perfusion-medium sample.

RESULTS AND DISCUSSION

The perfusion medium concentrations obtained after a 10^{-6}-mole iv dose of isosorbide dinitrate are shown in Fig. 1. The metabolites (5- and 2-isosorbide mononitrate) show increasing perfusion medium levels which peak after 40 min and have a slight decline when there is virtually no isosorbide dinitrate left to be converted. The 2-isosorbide mononitrate levels are only half those attained by the 5-isosorbide mononitrate, probably due to the stereoselective cleavage of the 2-nitrate group (Scheme I). The isosorbide concentration shows the same rapid increase, but no tendency to decline at the end of the experiment.

Similar concentration *versus* time profiles were obtained for the 10^{-5}- and 10^{-7}-mole doses of isosorbide dinitrate. Pharmacokinetic parameters for isosorbide dinitrate disposition obtained from these studies are given in Table I. Areas under the isosorbide dinitrate perfusion medium concentration *versus* time curve (AUC) were obtained by the trapezoidal rule. Clearances were calculated as the dose divided by the respective AUC. Rate constants and half-lives were obtained from the slope of a line determined from a least-squares analysis of the isosorbide dinitrate concentrations. Linear first-order kinetics appeared to be in effect at the

[a] Based on initial rate data.

lower two doses, as demonstrated by the closeness in the clearance values. Lower clearances at high concentrations suggest some saturation of the organic nitrate reductase enzyme at the largest dose.

The role of the lung in the metabolism of isosorbide dinitrate in relationship to the overall disposition of the drug can be elucidated by comparison of the clearance and flow rate of the perfusion medium. The fraction of the dose which passes through the lung vasculature but is not eliminated would be calculated by:

$$F = 1 - \frac{CL}{Q_B}$$

where CL is the perfusion medium clearance (ml/min) and Q_B is the perfusion flow rate (ml/min) (16). For the case of isosorbide dinitrate, nearly 90% of the drug entering the lung would escape first-pass pulmonary metabolism. This relatively slight metabolism suggests that lung metabolism would not be a major factor in the overall elimination of this compound compared with the rapid hepatic denitration demonstrated by isolated, perfused rat liver experiments (17).

Initial rates of formation for the individual metabolites after administration of isosorbide dinitrate were determined from rectilinear plots using a tangent drawn to the respective data points collected in the first 2 min of the experiment. The corresponding apparent first-order rate constants were calculated by dividing these initial rates by the average isosorbide dinitrate concentration in the same time period. Rate constants for the formation of each of the individual metabolites are presented in Table II. In all cases, 5-isosorbide mononitrate was formed more rapidly than isosorbide, which in turn was formed more rapidly than 2-isosorbide mononitrate. The rapid monoexponential decline of the parent drug (Table I) corresponded to the rate of increase in metabolite levels as determined from the sum of the rate constants for the appearance of the three metabolites (Table II). The mean difference of these rate constants was 6.1% ($SD \pm 6.6\%$).

The profiles following administration of 10^{-6}-mole doses of 5- and 2-isosorbide mononitrate are shown in Figs. 2 and 3, respectively. The

Table III—Apparent First-Order Rate Constants for the Formation of Isosorbide from Isosorbide Dinitrate, 5-Isosorbide Mononitrate, and 2-Isosorbide Mononitrate in Isolated Perfused Lung [a]

Compound	Rate Constant, min^{-1}
Isosorbide dinitrate	0.038 ± 0.003 [b]
5-Isosorbide mononitrate	0.0025 ± 0.0005 [c]
2-Isosorbide mononitrate	0.0073 ± 0.0011 [c]

[a] Mean ± *SD*. [b] $n = 4$. [c] $n = 2$.

2-isosorbide mononitrate shows a more rapid disposition (0.0073 min^{-1}) than the 5-isosorbide mononitrate (0.0025 min^{-1}), probably due to the exo positioning of the 2-nitrate group. In both cases, the rate constants were determined from semilogarithmic rate plots of the ascending isosorbide concentrations. The slight decrease in mononitrate levels appeared also to correlate well with the terminal slopes of the mononitrates in the isosorbide dinitrate experiments.

In Table III, rate constants for the formation of isosorbide from the two mononitrates (as determined from the terminal slopes of the semilogarithmic mononitrate plots) are compared with the apparent first-order rate constant calculated from initial rates of appearance of isosorbide after administration of 10^{-6}- and 10^{-7}-mole doses of isosorbide dinitrate to the lung. These results indicate that the isosorbide was formed much more rapidly when isosorbide dinitrate was given as the dose rather than 5- or 2-isosorbide mononitrate. The rate constants for formation of isosorbide when mononitrates were added to the lung account for <25% of that formed when isosorbide dinitrate was added. These data show that the large amount of isosorbide formed in the isosorbide dinitrate experiments could not have been formed by either mononitrate that had partitioned from the lung into the perfusion medium. The rapid formation of isosorbide from these experiments was not typical of a two-step metabolic process. There is no indication from the mononitrate concentration–time profiles in the perfusion medium that these compounds serve as intermediates to the completely denitrated molecule. Therefore, the rapid formation of isosorbide following isosorbide dinitrate administration appears to be the result of a high intrinsic clearance of the mononitrates formed in the metabolizing organ prior to their diffusion into the perfusion medium.

The differences in the rate of elimination of the mononitrates following

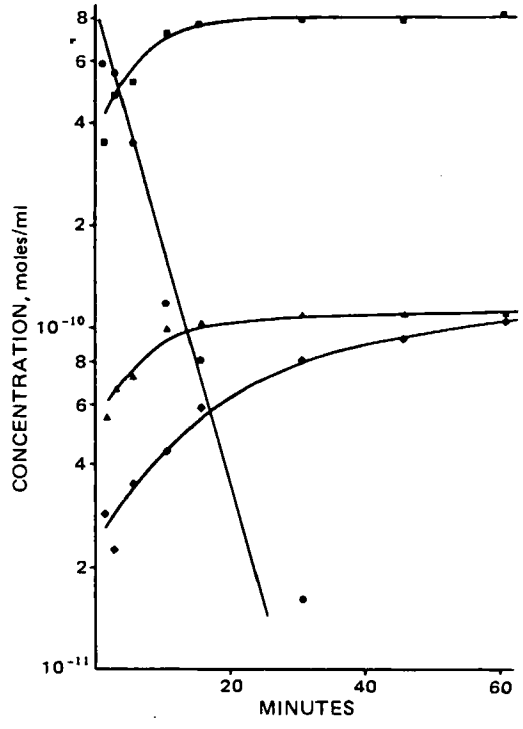

Figure 4—*Semilogarithmic concentration* versus *time profiles showing metabolism of 10^{-9} mole of isosorbide dinitrate in lung homogenate 9000×g supernatant. Key: (●) isosorbide dinitrate; (■) 5-isosorbide mononitrate; (▲) 2-isosorbide mononitrate; (◆) isosorbide. Lines are visual aids only.*

administration of preformed mononitrates to the isolated perfused lung and the rate of production of isosorbide following administration of isosorbide dinitrate may be attributed to the different distribution characteristics of the mononitrates and the dinitrate. As a precursor, isosorbide dinitrate may deliver the 5- and 2-isosorbide mononitrates to sites in the proximity of the metabolizing tissue of the lung, to which the mononitrates themselves have relatively poor access. The second nitrate ester could be quickly denitrated at that point. The mononitrates formed in the lung may also diffuse into the perfusion medium, where their distribution characteristics lead to the slower metabolism seen after an intravascular dose of the mononitrates. Thus, the accessibility to the enzymatic site will directly affect the metabolism of the mononitrates to isosorbide.

There is other evidence that the rate at which a metabolite formed in a metabolizing organ achieves its fate cannot be assumed to be the same as a preformed metabolite presented to that organ. In the studies of Brazzell and Kostenbauder (18), greater metabolism of isoproterenol in the lung was observed when it was formed by the hydrolysis of two diester prodrugs than when it was delivered to the isolated perfused rabbit lung as isoproterenol. The extensive experiments of Pang and Gillette (19) demonstrated the sequential elimination of acetaminophen as it was

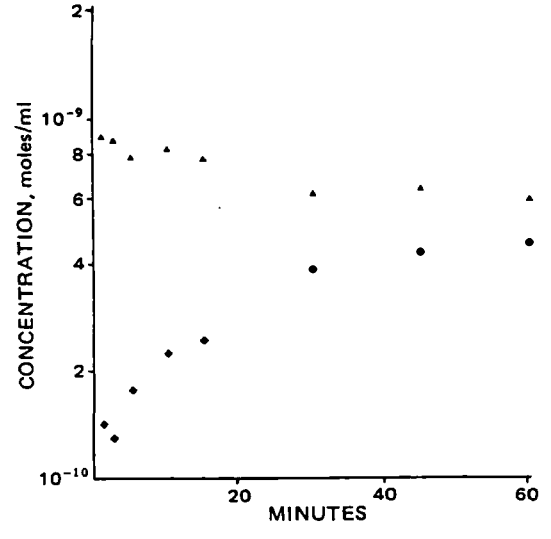

Figure 6—*Semilogarithmic concentration* versus *time profiles showing metabolism of 10^{-9} mole of 2-isosorbide mononitrate in lung homogenate 9000×g supernatant. Key: (▲) 2-isosorbide mononitrate; (◆) isosorbide.*

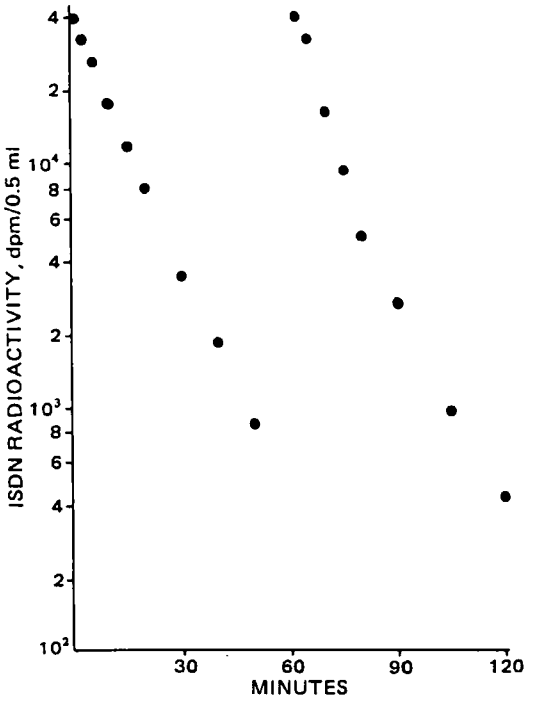

Figure 7—*Semilogarithmic radioactivity* versus *time profile of isosorbide dinitrate following successive doses of 10^{-5} and 10^{-7} mole.*

being formed from phenacetin in a single pass through the isolated perfused liver. Although diffusional barriers were not needed for an explanation of the differences in the metabolism of preformed acetaminophen and acetaminophen formed from phenacetin, these types of barriers to metabolism were hypothesized (20). Rate-limiting diffusional parameters have also been shown to affect metabolism and subsequent elimination in the isolated perfused rat kidney (21). Due to diffusion into renal tubular cells, salicylic acid was cleared more rapidly when it was formed in the kidney from salicyluric acid than when it was presented to the kidney as intact salicylic acid.

The 9000×*g* lung homogenate studies were designed to investigate the rates of metabolism of these organic nitrates independent of any cell wall barriers that might exist. In these experiments, isosorbide dinitrate was rapidly metabolized to the mononitrates in the lung supernatant (Fig. 4). The rate of appearance of isosorbide lagged behind that of both mononitrates and was consistent with sequential first-order dinitrate-to-mononitrate-to-isosorbide metabolism. This concentration *versus* time profile is markedly different from the virtually simultaneous appearance of mononitrate and isosorbide following administration of isosorbide dinitrate to the isolated perfused lung.

Figures 5 and 6 show examples of the slow metabolism of the 5- and 2-isosorbide mononitrates, respectively, in 9000×*g* supernatant. There is only a slight increase in isosorbide levels as these mononitrates are slowly denitrated. Further, the amount of isosorbide formed from the mononitrates in these lung homogenate experiments confirms that the isosorbide formed in the isosorbide dinitrate experiments is a direct product of the metabolism of the mononitrate intermediates alone. Therefore, in the homogenate studies, unlike the intact lung studies, isosorbide formation kinetics are not altered quantitatively by administering isosorbide dinitrate instead of a mononitrate. In a control experiment, isosorbide dinitrate was not hydrolyzed in the presence of reduced glutathione and sodium cyanide, so the metabolism was a direct result of the lung supernatant. The homogenate studies were interesting in the requirement of cyanide for the metabolism of isosorbide dinitrate. In the presence of lung 9000×*g* supernatant and reduced glutathione alone, the drug was not metabolized. The addition of sodium cyanide kept glutathione in its reduced form (9), and isosorbide dinitrate was metabolized quite rapidly.

The multiple-dose experiments were designed to investigate the possibility of product inhibition of the organic nitrate reductase enzyme. A constant infusion of the mononitrates, with coadministration of isosorbide dinitrate, would be inappropriate to demonstrate inhibition, since only small amounts of the mononitrates would reach the enzymatic site. By administering the parent compound, the mononitrates could reach that site by virtue of lung metabolism. Therefore, two separate intra-

vascular doses of isosorbide dinitrate, 10^{-5} and 10^{-7} moles, were given 60 min apart, and the rate of elimination was ascertained for each dose. Plots of isosorbide dinitrate radioactivity for the two doses of the drug in one experiment are shown in Fig. 7. Two parallel lines, representing a half-life of 8 min, indicated that there was no increase in the half-life exhibited with the second dose. There was thus no indication from these studies that the mononitrate metabolites could inhibit denitration of isosorbide dinitrate, whether the mononitrates were preformed or formed *in situ*.

In summary, this paper illustrates how access to selected organs or tissues may alter the expected metabolism of a drug. Release of a drug from a precursor in the proximity of metabolizing tissue may lead to more rapid metabolism than seems likely from studies involving presentation of the preformed drug to that organ or tissue.

Age-Related Pharmacokinetics of *N*-Acetylprocainamide in Rats

AVRAHAM YACOBI ‡×, BURDE L. KAMATH *, HERMAN F. STAMPFLI, ZEE M. LOOK, and CHII-MING LAI

Received April 19, 1982, from the *Department of Pharmaceutical Development, Research and Development Department, American Critical Care, McGaw Park, IL 60085.* Accepted for publication June 18, 1982.

Present Address: *Xavier University, College of Pharmacy, New Orleans, LA 70125. ‡Lederle Laboratories, Pharmacodynamics Dept., Pearl River, N.Y. 10965.

Abstract □ The pharmacokinetics of *N*-acetylprocainamide, administered orally or intravenously, were studied in 3-, 6-, and 12-month-old rats using a two-way crossover study design. At 3, 6, and 12 months of age, the half-life values of *N*-acetylprocainamide were 1.66, 1.82, and 2.29 hr, respectively; the apparent volumes of distribution were 4.75, 3.35, and 1.98 liter/kg, respectively. The elimination rate constant, clearance, and absolute bioavailability of the drug (determined by AUC measurements and the amounts excreted unchanged in the urine) decreased significantly with age. The rate of absorption remained unchanged. The amounts of *N*-acetylprocainamide in the liver and kidneys were significantly higher in the 12-month-old animals. These results clearly demonstrate a significant alteration with age in the bioavailability, distribution, and elimination of *N*-acetylprocainamide in rats. In long-term toxicity studies of this and other drugs that show age-dependent pharmacokinetics, an adjustment in the chronically administered dose is essential.

Keyphrases □ *N*-Acetylprocainamide—oral and intravenous pharmacokinetics in rats, bioavailability, age-related changes □ Pharmacokinetics—*N*-acetylprocainamide in rats after oral and intravenous administrations, age-related changes □ Bioavailability—*N*-acetylprocainamide in rats after oral and intravenous administrations, age-related changes

It has been established that many physiological changes are associated with aging. Lean body mass, plasma albumin, and total body water decrease with age. In humans, the cardiac output decreases 1%/year from ages 19 to 86, and the blood flow to the kidneys is also reduced with age (1). In rats, there are pronounced decreases (>30%) in the cardiac index and in hepatic, renal, and GI tract blood flow at 11–12 months of age (2). These changes can account for significant alterations in the pharmacokinetics and pharmacodynamics of drugs. In toxicity and oncogenicity studies in animals, which are conducted over a long period of time (1 year or more), aging may account for (3, 4): (*a*) diminished absorption of drugs through the GI tract; (*b*) diminished rate of metabolism and renal excretion of drugs; (*c*) accumulation of drugs in blood and receptor sites; (*d*) changes in affinity and sensitivity of the receptor sites to drug molecules; and (*e*) an increased rate of mortality. For these reasons, it was considered prudent to

[a] The dose was 100 mg/kg. [b] Determined by model-independent equations. [c] The values for all parameters were significantly different ($p < 0.05$, Duncan's t test) at 6 months (*versus* 3 months) and 12 months (*versus* 3 and 6 months). The sample size was 7 at 3 and 12 months and 11 at 6 months. [d] Extrapolated time zero plasma concentration.

conduct age-dependent disposition studies in parallel with the long-term oncogenicity testing of *N*-acetylprocainamide in rats.

EXPERIMENTAL

Two-hundred Charles River CD rats[1] were randomly selected from large populations intended for long-term toxicity and oncogenicity testing. Each animal was housed in an individual stainless steel cage with free access to food[2] and water. The animals weighed 260–390 g (mean 320 g) at 3 months, 381–576 g (mean 481 g) at 6 months, and 512–735 g (mean 587 g) at 12 months. At each interval, a group of 12 rats was randomly selected from the population, and the pharmacokinetics of absorption, distribution, and elimination were studied.

A cannula was inserted surgically into a jugular vein of each rat under light ether anesthesia 1 day before drug administration. The preparation of the cannulas and the surgical procedures were described elsewhere (5). Food was withheld for 15 hr prior to drug administration and during the blood sampling period (10 hr). Water was freely accessible to the animals at all times.

The rats were divided into two groups, and the study was conducted according to a balanced two-way crossover design. One group received 100 mg/kg iv of *N*-acetylprocainamide hydrochloride[3] in distilled water through the jugular cannula; the other group received the same amount of drug by oral gavage. After 3 days, the crossover experiment was conducted. A solution containing 100 mg/ml of *N*-acetylprocainamide hydrochloride in distilled water was used for both administration routes. The volume of the administered solution ranged from 0.260 to 0.735 ml. Because of the difficulty in maintaining patent cannulas, the study was completed for 7, 11, and 7 rats at 3, 6, and 12 months, respectively.

Serial blood samples (0.4 ml each) were drawn at 0.5, 1, 1.5, 2, 4, 6, 8, and 10 hr postdose. After collection of each sample, 0.4–0.5 ml of normal saline containing 1% heparin sodium solution (5000 USP U/ml) was infused to flush the cannula and to replace the lost volume. Plasma was separated and frozen immediately. Urine and feces were collected quantitatively at 24 and 48 hr. At each urinary collection time, the animals were induced to empty their bladder by ether inhalation. Feces samples were homogenized[4] in distilled water. Aliquots of urine and feces homogenates were frozen immediately.

After completion of the crossover study, four animals received an additional 100 mg/kg iv of *N*-acetylprocainamide. One-half hour later, the animals were sacrificed by exsanguination *via* the portal vein under ether anesthesia. Plasma, liver, heart, and kidneys were harvested. Immediately after removal, the organs were sliced, blotted in tissue paper to remove excess blood, and weighed. A known volume of saline (3–5 times the weight of the organ) was added to the tissues. The mixture was homogenized[4] in an ice-water bath. An aliquot of each homogenate was frozen immediately.

Concentrations of *N*-acetylprocainamide in plasma, serum, and urine were determined in duplicate by a specific high-performance liquid chromatographic (HPLC) method (6). This procedure was modified for analysis of the drug in tissue homogenates (7) and in feces (8). The pharmacokinetic parameters describing the absorption, distribution, and elimination of *N*-acetylprocainamide were estimated as follows. Biological half-life was calculated from the terminal disposition rate constant (β) which was determined by regression analysis of the logarithm of the plasma concentration *versus* time curve at the postabsorption distribution phase. Area under the plasma concentration *versus* time curve (AUC) was determined by the trapezoidal method. Total clearance (CL_{tot}) was determined by dividing the administered intravenous dose (or amount absorbed) by the AUC. For oral administration, the ratio of AUC_{oral}/AUC_{iv} was used to account for the amount absorbed. The volume of distribution (V_d) was calculated by CL_{tot}/β.

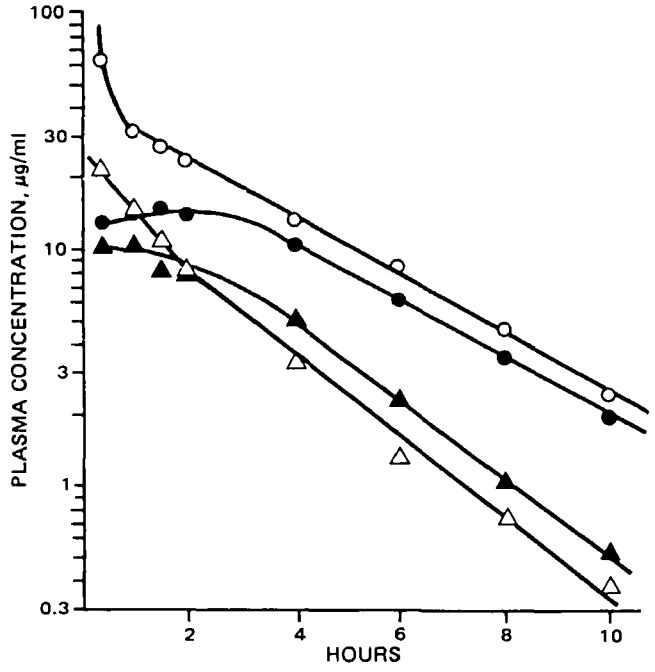

Figure 1—*Time course of* N-*acetylprocainamide in plasma after administration by intravenous injection and by oral gavage. Key: (△) 3-month-old rats, intravenous (n = 7); (▲) 3-month-old rats, oral (n = 7); (○) 12-month-old rats, intravenous (n = 6); (●) 12-month-old rats, oral (n = 6).*

RESULTS

Figure 1 depicts the time course of *N*-acetylprocainamide in plasma after administration by intravenous injection and by oral gavage in 3- and 12-month-old rats. These profiles show: (*a*) higher plasma concentrations of the drug in 12-month-old animals after administration by either route; (*b*) that the ratio of oral–intravenous plasma concentrations decreased with age, suggesting a decline in the bioavailability of *N*-acetylprocainamide; and (*c*) that the rate of decline of the postabsorption distribution plasma concentration was slower in older rats, indicating a longer elimination half-life following administration of the drug by either route.

Table I summarizes the pharmacokinetic parameters for distribution and elimination of *N*-acetylprocainamide in 3-, 6-, and 12-month-old rats following intravenous administration of the drug. The extrapolated time zero plasma concentrations and the AUC values increased significantly with age. Consistent with this, there was a significant decrease (58%) in the volume of distribution, from 4.75 liter/kg at 3 months to 1.98 liter/kg at 12 months of age. There was also a significant elongation of the biological half-life (38%) and a significant decrease in the total clearance (67%) in the 12-month-old animals as compared with the 3-month-old rats. In general, the coefficients of variation in all parameters increased with age: 11–18% in the 3-month-old rats to 22–71% in the 12-month-old animals.

Table II lists the parameters describing the absorption and excretion of unchanged *N*-acetylprocainamide in 3-, 6-, and 12-month-old rats. There was essentially no significant difference in the absorption half-life among the three age-groups. The elimination half-life became significantly longer with age after either intravenous or oral administration of the drug. Also, the ratio of the half-lives (oral–intravenous) increased from 1.05 after 3 months to 1.29 after 12 months, probably impacted by the changes in the absorption of the drug in the older rats. The AUC

X_f, % of Dose	7.99	10.1	0.674	5.65	4.75	1.29	6.83	6.81 [d]	1.19

[a] The dose was 100 mg/kg. [b] The sample size was 7 at 3 and 12 months and 11 at 6 months. [c] Without one unusually high value ($n = 6$). One urine sample after intravenous injection was very low, presumably due to incomplete collection. [d] $n = 6$.

Table III—Effect of Age on Tissue Distribution Following Intravenous Administration of *N*-Acetylprocainamide in Rats [a]

Tissue	Drug Concentration [b] 3 Months Mean	3 Months *SD*	6 Months Mean	6 Months *SD*	12 Months Mean	12 Months *SD*
Plasma	34.7	5.24	37.8	2.31	43.6	5.44
Liver	83.0	3.00	82.0	4.55	197	12.7
Heart	76.0	5.00	108	12.7	101	8.67
Kidney	294	90.0	299	47.9	528	256
Liver–Plasma Ratio	2.44	0.390	2.12	0.211	4.55	0.552
Heart–Plasma Ratio	2.24	0.370	2.80	0.208	2.33	0.0932
Kidney–Plasma Ratio	8.34	1.27	7.72	0.900	12.0	5.50

[a] The dose was 100 mg/kg. The animals were sacrificed 0.5 hr after receiving the drug. [b] The concentration is expressed as μg/g except for plasma, which is reported as μg/ml. The sample size is 4 at all time intervals.

values increased with age after intravenous and oral administrations. The ratio of the oral AUC to intravenous AUC decreased from 1.01 after 3 months to 0.747 after 12 months, showing a 25% decrease in bioavailability. Consistent with this finding, the oral–intravenous ratio of the percentage of unchanged *N*-acetylprocainamide excreted in the urine (X_u) also showed a decrease (from 1.04 to 0.812), a change of 22%. The oral–intravenous ratio of the amount eliminated in the feces (X_f), however, increased from 0.674 to 1.19 (a change of 77%), which might indicate poor GI absorption in the older rats.

Table III summarizes the effect of age on the distribution in heart, liver, and kidneys following intravenous administration of *N*-acetylprocainamide in rats. There was a significant increase in the tissue concentrations with increasing age, which is consistent with a decrease in the percentage of lean body mass in older rats. The tissue–plasma concentration ratios for liver and kidneys increased significantly ($p < 0.05$, Student's t test) after 12 months. The heart–plasma concentration ratios remained unchanged.

DISCUSSION

This study was conducted in conjunction with a long-term oncogenicity study of *N*-acetylprocainamide in rats. The goal was to determine the age-related changes in the pharmacokinetics of absorption, distribution, and elimination of the drug, which will allow a better understanding of the toxicological effects. For example, if there is a decrease in the GI absorption of the drug, the plasma concentration will decrease accordingly and, thus, a lesser exposure of tissues and organs to the drug will be expected. The opposite situation, however, may occur if the elimination is diminished. In this case, the plasma concentrations will be elevated, which may lead to augmentation of the pharmacological and toxicological response.

Consistent with previous findings in rats (7–9), *N*-acetylprocainamide was found to be: (*a*) primarily eliminated unchanged in the urine (Table II) by an active renal process in rats; (*b*) eliminated in the feces by biliary excretion to a small extent with the remainder eliminated in the urine, presumably after biotransformation to more polar compounds; (*c*) rapidly distributed in the body showing a higher affinity for heart, kidney, and liver tissues than plasma proteins; and (*d*) rapidly and completely absorbed from oral solution in young rats. These parameters were determined repeatedly in the same rats over a period of 12 months.

The data observed in this study show that the rate of absorption of *N*-acetylprocainamide from the GI tract is not age dependent. Similar results have been reported for intestinal absorption of sulfamethazole, paracetamol, amino acids, and glucose (10–14). The data from the present study, however, also indicate that the extent of absorption of *N*-acetylprocainamide (as reflected by the decrease in the oral–intravenous ratios of AUC values and the amounts of unchanged drug excreted in the urine) decreased significantly in the older rats. The fact that the GI blood flow diminished significantly would suggest that the rate of drug absorption should be affected proportionally. These conflicting results, however, may be due partially to the effect of changes in gastric pH, permeability of the GI wall, gastric emptying, and GI motility and, in part, to the simplified pharmacokinetic model used to analyze the data. In any case, the lower bioavailability did not result in a decrease in plasma concentrations of *N*-acetylprocainamide. The elimination rate and the clearance of the drug declined to a greater extent, and this presumably caused a pronounced accumulation of the drug in the body.

The age-related changes in the pharmacokinetic parameters obtained in this study are consistent with the age-related changes in other physiological parameters (2), *e.g.*, significant diminution in renal function in older rats (15, 16). Yates and Hiley (2) reported several hemodynamic parameters in young-adult (3–4 months) and middle-aged rats (11–12 months). Table IV summarizes some of these parameters as well as

Table IV—Effect of Age on Tissue Blood Flow and Related Pharmacokinetic Parameters of *N*-Acetylprocainamide

Parameters	Young Adult Rats 3–4 Months n	Young Adult Rats 3–4 Months Mean	Young Adult Rats 3–4 Months *SD*	Middle-Aged Rats 11–12 Months n	Middle-Aged Rats 11–12 Months Mean	Middle-Aged Rats 11–12 Months *SD*	Ratio of Means Middle-Aged/ Young Adult

[a] Physiological parameters taken from Ref. 2. [b] Hepatic artery. [c] Hepatic artery, spleen, pancreas, and GI tracts.

pharmacokinetic parameters, which might have been impacted directly by the physiological changes. There were significant decreases in the cardiac index (41%), hepatic blood flow (31%), renal blood flow (44%), and GI tract blood flow (60%) in older animals. These changes may account for the decreased renal clearance (68%), total clearance (67%), volume of distribution (57%), and bioavailability (25%). The renal clearance values were 3.9 and 2.4 times larger than the respective renal blood flow in young-adult and middle-aged rats indicating a significant active renal secretion of *N*-acetylprocainamide, consistent with previous findings (9). The nonrenal clearance values were 82 and 52 times larger than the respective hepatic blood flow in young-adult and middle-aged rats, indicating a combination of active biliary secretion and biotransformation of the drug in the liver. The decrease in the volume of distribution might have been due also to a change in body composition in the older animals. While the fatty tissue and skin account for a larger percentage of the body weight in older animals, the percentages of lean body mass and body water decrease.

The distribution of *N*-acetylprocainamide in the liver and kidneys was also affected by age. The liver–plasma and kidney–plasma concentration ratios increased with age (86 and 44%, respectively). This elevation of the drug level in the organs seems to be inversely proportional to the decrease in liver and kidney blood flow (31 and 44%, respectively) in the older rats. The drug accumulation in the organs of the older rats probably is caused by: (*a*) higher plasma levels of *N*-acetylprocainamide (initial concentrations of 19 and 46 μg/ml in 3- and 12-month-old animals, respectively); (*b*) the diminution in the blood flow to the organs (the redistribution of *N*-acetylprocainamide from the tissues was affected to a greater extent by this than by the actual distribution of the drug in the organs); and (*c*) changes in the composition of the liver and kidney tissues which favored a larger drug uptake. Interestingly, with the minor change in heart blood flow (12%), the heart–plasma concentration ratio did not change much with age.

In conclusion, the data show an age-dependent reduction in the bioavailability of orally administered *N*-acetylprocainamide solution in rats. The elimination of the drug, however, is impaired to a greater extent with age, which results in significant accumulations in the plasma and tissues after chronic administration. This finding indicates that in long-term toxicity testings of this and other drugs which show age-dependent pharmacokinetics, an adjustment in the chronically administered dose is essential.

Synthesis and Antiallergenic Properties of 3-*n*-Pentadecyl- and 3-*n*-Heptadecylcatechol Esters

MAHMOUD A. EISOHLY ˣ, DANIEL A. BENIGNI, LOLITA TORRES, and E. SUE WATSON

Received February 12, 1982, from the *Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication June 11, 1982.

Abstract □ A synthetic procedure is described for the preparation of 3-*n*-pentadecyl- and 3-*n*-heptadecylcatechols and their acetate and alaninate esters. The Wittig reagent prepared from 2,3-dimethoxybenzyltriphenylphosphonium bromide (III) was coupled with 1-tetradecanal or 1-hexadecanal to give the olefins IV and V, respectively. Catalytic reduction of IV and V followed by demethylation with boron tribromide afforded VIII and IX. The acetates were prepared using acetic anhydride and pyridine, while the alaninates were prepared using *N*-(*tert*-butoxycarbonyl)-L-alanine and dicyclohexylcarbodiimide followed by removal of the *tert*-butoxycarbonyl group with hydrogen chloride gas. The esters were active in guinea pigs in the production of tolerance and desensitization or hyposensitization to poison ivy-type contact dermatitis.

Keyphrases □ Synthesis—3-*n*-pentadecyl- and 3-*n*-heptadecylcatechols, acetate and alaninate esters □ Urushiols—poison ivy and poison oak, synthesis of saturated congeners □ 3-*n*-Pentadecylcatechol—synthesis, acetate and alaninate esters □ 3-*n*-Heptadecylcatechol—synthesis, acetate and alaninate esters

Poison ivy (*Toxicodendron radicans*), poison oak (*T. diversilobum*), and poison sumac (*T. vernix*) are the primary cause of occupational dermatitis in the United States. Other genera of the plant family Anacardiaceae with dermatogenic constituents include *Anacardium* (cashew nuts), *Semicarpus* (india ink tree), *Metopium* (poison wood), and *Mangifera* (mango). The allergenic components in most of these plants are 3-*n*-alk-(en)-yl catechols with C-15 or C-17 side chains and different degrees of unsaturation (0–3 olefinic bonds) (1–5).

Extracts of poison ivy, poison oak, and poison sumac have been used for diagnosis and prophylactic treatment of poison ivy, oak, and sumac dermatitis (6–8). However, the efficacy of these extracts in producing desensitization is questionable (9). Kligman (10) found that, in humans, only hyposensitization was possible by oral or intramuscular injection of either poison ivy oleoresin or pentadecylcatechol. Oleoresin produced hyposensitization after intramuscular injection of 2–2.5 g or after oral administration of 3.5–4.0 g in multiple doses. The hyposensitization was temporary, and the individuals regained their original sensitivity within 6–10 months after cessation of the treatment.

A previous publication (11) reported a new method for

the induction of tolerance to poison ivy and oak urushiol in guinea pigs by intravenous injection of pentadecylcatechol-associated autologous red blood cells 2 weeks prior to attempted contact sensitization. It was also reported (12) that intravenous administration of the esterified urushiol (poison ivy or poison oak urushiol acetate) was effective in producing immune tolerance in naive guinea pigs and desensitization or hyposensitization in already sensitized animals. This paper reports the improved synthesis of the saturated congeners of poison ivy and poison oak urushiol acetates (diacetyl-3-*n*-pentadecylcatechol and diacetyl-3-*n*-heptadecylcatechol), and their efficacy in the production of tolerance and hyposensitization. In addition, the synthesis and activity of a water-soluble ester of heptadecylcatechol (heptadecylcatechol-dialaninate dihydrochloride) is described.

EXPERIMENTAL[1]

Synthesis—*2,3-Dimethoxybenzyl Bromide (II)*—A solution of 25 g (148.8 mmoles) of 2,3-dimethoxybenzyl alcohol (I) in 400 ml of dry ether was stirred at room temperature for 2.5 hr with 8 ml of phosphorus tribromide. The organic layer was washed with water, dried (anhydrous sodium sulfate), and the solvent removed at reduced pressure to give 33.7 g of II (98% yield); IR: ν_{max} (liquid film) 2940, 2830, 1585, and 1480 cm^{-1}; UV: λ_{max} (log ϵ) 219 (4.10) and 286 (3.24) nm; ^{1}H-NMR: δ 7.03–6.72 (3, m), 4.53 (2, s), 3.97 (3, s), and 3.80 (3, s) ppm; mass spectrum: *m/z* (%): 230 (35), 232 (M^+ +2, 34), 151 (88), and 136 (100).

2,3-Dimethoxybenzyltriphenylphosphonium Bromide (III)—A solution of 28 g of II (120 mmoles) in 500 ml of benzene containing 32 g (121 mmoles) of triphenylphosphine was allowed to reflux for 5 hr, whereupon a copious white precipitate formed. The precipitate was removed by filtration, washed with benzene, and dried to give 59 g (99% yield) of III; mp 233–234°; IR: ν_{max} (KBr) 2940, 2830, 2780, 1580, 1480, 1470, and 1430 cm^{-1}; UV: λ_{max} (log ϵ) 225 (4.46), 265 (sh, 3.61), 268 (3.67), 275 (3.66), and 282 (sh, 3.37) nm; ^{1}H-NMR: δ 8.00–7.50 (15, m), 7.00–6.60 (3, m), 5.13 (2, br, d, J = 14 Hz), 3.77 (3, s), and 3.50 (3, s).

2,3-Dimethoxy-$\Delta^{1'}$-pentadecenylbenzene (IV)—A dispersion of 5 g (10 mmoles) of the aforementioned phosphonium salt (III) in 100 ml of tetrahydrofuran (dried over sodium hydride) was stirred under nitrogen while 6 ml (10.2 mmoles) of a 1.7 *M* solution of *n*-butyllithium in hexane was added slowly. After 10 min the solution developed a deep-red color, at which time a solution of 2.65 g (10 mmoles) of 80% tetradecyl aldehyde[2] in 10 ml of tetrahydrofuran was added in a dropwise manner. The mixture slowly turned yellow and was stirred at room temperature for 2 hr. The mixture was refluxed for 16 hr and then cooled to room temperature. TLC (hexane–ethyl acetate, 95:5) on silica gel showed one spot (R_f 0.90) and no starting aldehyde (R_f 0.75). The solvent was removed under reduced pressure, and the residue was added to ethyl acetate (150 ml) and water (50 ml). The organic phase was washed with water (50 ml) and then dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure to give 7.0 g of a pale amorphous solid which was filtered through 15 g of silica gel-60 (hexane–ethyl acetate, 97:3) to yield 3.3 g of a colorless solid. GC (2% OV-17) showed two peaks (*cis* and *trans* isomers of IV in a 2:3 ratio, respectively). GC/MS analysis showed the following ions: *cis m/z* 346 (M^+, 91%), 177 (100%), and 151 (83%); *trans m/z* 346 (M^+, 100%), 177 (90%), and 151 (70%).

2,3-Dimethoxy-pentadecylbenzene (VI)—The *cis* and *trans* isomeric mixture of IV (3.3 g) was dissolved in 40 ml of *tert*-butyl alcohol and 640 mg of 10% palladium-on-carbon was added. The mixture was hydrogenated on a Parr hydrogenator at 1.41 kg/cm^2 for 16 hr. Filtration of the product through diatomaceous earth[3] followed by evaporation of the solvent resulted in 3.3 g of VI as a white solid, mp 35–36°; IR: ν_{max} (liquid film) 2920, 2855, 1597, 1583, 1478, 1272, 1087, 1015, and 747 cm^{-1}; UV: λ_{max} (log ϵ) 207 (3.99), 213 (sh, 3.84), 270 (3.01), and 276 (3.00) nm; ^{1}H-NMR: δ 0.90 (3, t, J = 5 Hz), 1.28 (26, br, s), 2.62 (2, t, J = 6 Hz), 3.80 (6, s), and 6.82–6.46 (3, m) ppm; mass spectrum: *m/z* 348 (M^+, 40%), 151 (100%), and 136 (90%).

3-n-Pentadecylcatechol (VIII)—A solution of 2,3-dimethoxy-pentadecylbenzene (VI) (500 mg, 1.44 mmoles) in 30 ml of methylene chloride was cooled to 0° under nitrogen. A solution of boron tribromide in methylene chloride (1.1 ml of 12% v/v) was added and the mixture was allowed to slowly come to room temperature. After standing for 90 min, 3 ml of water was added followed by sodium bicarbonate (until no more gas evolution was noticeable). The organic layer was dried over anhydrous sodium sulfate, and the solvent was evaporated to yield a light brown residue (408 mg). Crystallization from hexane–isooctane yielded colorless needles of VIII, mp 55–56°; IR: ν_{max} 3400, 2910, 2840, 1615, 1590, 1475, 1285, 1055, 942, 827, and 725 cm^{-1}; UV: λ_{max} (log ϵ) 278 (3.23) and 230 (3.19) nm; ^{1}H-NMR (FT): δ 0.90 (3, t, J = 5 Hz), 1.26 (26, br, s), 2.55 (s, t, J = 6 Hz), 5.10 (2, br, s, exchangeable with D_2O), and 6.72 (3, br, s) ppm; mass spectrum: *m/z* 320 (M^+, 4%) and 123 (base peak).

Diacetyl-3-n-pentadecylcatechol (X)—Acetylation of VIII was carried out by stirring 400 mg with 1 ml each of acetic anhydride and pyridine at room temperature for 4 hr. The mixture was poured onto ice, and then extracted with chloroform (3 × 30 ml). The combined chloroform extract was washed successively with 20 ml of ice water, 20 ml of chilled 10% H_2SO_4, 20 ml of water, saturated sodium bicarbonate solution, and then 30 ml of water. The chloroform layer was dried over anhydrous sodium sulfate, and the solvent was evaporated to give a white solid (502 mg). Recrystallization from chloroform–ethanol afforded rosette crystals of X, mp 51–52°; IR: ν_{max} 2910, 2840, 1770, 1760, and 1470 cm^{-1}; UV: λ_{max} (log ϵ) 278 (sh, 1.65), 258 (2.45), and 210 (4.11) nm; ^{1}H-NMR: δ 7.30–7.00 (3, m), 2.50 (2, t, J = 6 Hz), 2.28 (3, s), 2.22 (3, s), 1.27 (26, br, s), and 0.88 (3, t, J = 6 Hz) ppm; mass spectrum: *m/z* 404 (M^+, 0.3%), 320 (48%), and 123 (100%).

2,3-Dimethoxy-$\Delta^{1'}$-heptadecenylbenzene (V)—Compound V was prepared from 5 g (10 mmoles) of the phosphonium salt (III) and 2.8 g (11.6 mmoles) of *n*-hexadecylaldehyde[4] following the same procedure used for the synthesis of IV. The reaction was filtered, the filtrate evaporated under reduced pressure, and the residue partitioned between chloroform (150 ml) and water (3 × 30 ml). The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure. The residue was dissolved in 15 ml of hexane, filtered, and the filtrate chromatographed on silica gel-60 (50 g, hexane–ethyl acetate, 95:5) to yield 3.6 g of a colorless solid. GC and GC/MS examination showed a mixture of *cis* and *trans* isomers (2:3, respectively); mass

[1] Melting points are uncorrected and were determined on a Thomas-Hoover Unimelt apparatus. The UV absorption spectra were obtained in methanol using a Beckman-Acta Model IV recording spectrophotometer. IR absorption spectra were recorded using a Perkin-Elmer 281B infrared spectrophotometer. ^{1}H-NMR spectra were recorded on a JEOL Model C-60 HL spectrometer. Fourier transform ^{1}H- and ^{13}C-NMR spectra were obtained on a JEOL NJM-FX60 spectrometer. Chemical shifts were reported in δ units with tetramethylsilane as the internal standard and deuterochloroform as the solvent. Mass spectral analyses were performed on a Finnigan 3200 GC/MS/DS. GC analyses were performed on a Beckman GC-65 using a 3% OV-17 or 5% OV-225 column and FID detector with 30 ml/min carrier gas (nitrogen).

[a] ^{13}C-NMR data on the alaninate derivatives are provided in *Experimental*. [b] In the proton-decoupled spectrum, the benzylic methylene carbon appeared at δ 25.7 ppm as a doublet (J = 48.8 Hz) as a result of coupling with phosphorus. The aromatic carbons of the triphenylphosphine residue of III also appeared as doublets at δ 135.1, 134.1, 130.2, and 118.1. We have also observed long-range coupling between phosphorus and carbons 1, 2, 3, 5, and 6. [c] The *trans* isomer of IV was separated by column chromatography; ^{13}C-NMR was recorded on the mixture and on the *trans* isomer. The data obtained on the *cis* isomer was by subtraction. No attempt was made to separate the *trans* isomer of V. [d] The carbonyl carbon atoms of the acetate groups were observed at δ 168.0 and 167.9 ppm while the methyl signals were observed at δ 20.5 and 20.1 ppm. [e] The carbonyl carbon atoms of the acetate groups were observed at δ 168.1 ppm (double intensity) and the methyl signals were observed at δ 20.6 and 20.2 ppm.

spectrum: *cis* m/z 374 (M^+, 56%), 177 (100%), and 151 (78%); *trans* m/z 374 (M^+, 61%), 177 (100%), and 151 (58%). The ^{1}H-NMR spectrum of the mixture showed peaks at δ 0.90 (3, t, J = 6 Hz), 1.30 (26, br, s), 2.48–2.10 (2, br, d), 3.88, 3.85 and 3.83 (6, 3s), and 5.48–7.15 (5, m).

2,3-Dimethoxy-heptadecylbenzene (*VII*)—Catalytic hydrogenation of V (3.6 g) was carried out as outlined for the preparation of VI to give a quantitative yield of VII as a colorless solid, mp 44–46°; IR: ν_{max} 1595, 1580, 1470, 1270, 1083, 1013, 737, and 717 cm^{-1}; UV: λ_{max} (log ε) 231 (3.16), 271 (3.03), and 276 (3.02) nm; ^{1}H-NMR: δ 0.90 (3, t, J = 5 Hz), 1.30 (30, br, s), 2.18 (2, t, J = 6 Hz), 3.85 (3, s), 3.83 (3, s), and 6.62–7.00 (3, m); mass spectrum: m/z 376 (M^+, 50%), 151 (97%), and 136 (100%).

3-n-Heptadecylcatechol (*IX*)—2,3-Dimethoxy-heptadecylbenzene (VII), 3.01 g, was demethylated with boron tribromide, following the procedure described for the preparation of VIII, to give 2.16 g (78% yield) of a colorless solid. Recrystallization from hexane–isooctane gave fine needles of IX, mp 63–64°; IR: ν_{max} 3380, 2920, 2847, 1617, 1592, 1475, 1468, 1282, 1190, and 720 cm^{-1}; UV: λ_{max} (log ε) 230 (3.19) and 275 (3.21) nm; ^{1}H-NMR: δ 0.89 (3, t, J = 6 Hz), 1.26 (30, br, s), 2.63 (2, t, J = 6 Hz), 4.99 (1, s, exchangeable with D_2O), 5.09 (1, s, exchangeable with D_2O), and 6.72 (3, s); mass spectrum: m/z 348 (M^+, 30%) and 123 (base peak).

Diacetyl-3-n-heptadecylcatechol (*XI*)—Compound XI was prepared by acetylation of IX following the same procedure as used for preparation of X. Crystallization from chloroform–ethanol afforded rosettes, mp 56–57°; IR: ν_{max} 2930, 2855, 1785, 1770, and 1480 cm^{-1}; UV: λ_{max} (log ε) 276 (sh, 1.64), 257 (2.47), and 210 (4.08) nm; ^{1}H-NMR: δ 7.30–7.00 (3, m), 2.50 (2, t, J = 6 Hz), 2.28 (3, s), 2.22 (3, s), 1.26 (30, br, s), and 0.88 (3, t, J = 5 Hz); mass spectrum: m/z 432 (M^+, 0.2%), 348 (15%), and 123 (100%).

3-n-Heptadecylcatechol-dialaninate Dihydrochloride (XIII)—A solution of dicyclohexylcarbodiimide (2.11 g, 10.2 mmoles) in 120 ml of acetonitrile was cooled in an ice bath for 10 min and then 1.94 g (10.3 mmoles) of *N*-(*tert*-butoxycarbonyl)-L-alanine was added. This solution was stirred in an ice bath for 30 min during which time a cloudy white precipitate appeared. Two portions of IX were then added (618 mg and 1.22 g) and the mixture was stirred at room temperature for 2 hr after each addition. TLC analysis of the reaction product using 2% methanol in chloroform showed some starting material (R_f 0.3, blue black with ferric chloride) an appreciable amount of the diester (XII) (R_f 0.75, yellow with chlorine tolidine reagent), and some monoester (R_f 0.70, yellow with chlorine tolidine reagent). Therefore, 1.03 g (5 mmoles) of dicyclohexylcarbodiimide in 30 ml of acetonitrile (cooled to 0°) and 950 mg (5 mmoles) of *N*-(*tert*-butoxycarbonyl)-L-alanine was stirred in an ice bath for 20 min and then was added to the above mixture. After stirring overnight, the reaction was filtered, and the solvent was removed by evaporation. The residue was chromatographed on 50 g of silica gel-60 (chloroform) to yield 3.25 g (4.7 mmoles) of XII as an oil (94% yield); $[\alpha]_D^{22°}$ − 19° (c 0.59, $CHCl_3$); UV: λ_{max} (log ε) 257 (2.40) and 220 (3.40) nm; IR: ν_{max} ($CHCl_3$); 3440, 3370, 2915, 2860, 1770, 1705, and 1500 cm^{-1}; ^{1}H-NMR: δ 1.30 (30, br, s), 1.50 (18, s), 2.70 (2, br, t, J = 6 Hz), 4.60–4.50 (2, br, s), 5.50 (1, br, s), 5.63 (1, br, s), and 7.10–7.00 (3, m); ^{13}C-NMR: δ 14.0 (q), 17.9 (q), 18.1 (q), 22.7 (t), 28.5 (q), 29.4 (t), 29.7 (t), 32.0 (t), 49.5 (d), 49.8 (d), 79.9 (s), 120.7 (d), 126.2 (d), 127.3 (d), 136.9 (s), 140.5 (s), 142.7 (s), 155.6 (s), 170.8 (s), and 171.0 (s) ppm.

Conversion of XII to XIII—A solution of XII (2.75 g) in ethyl acetate (50 ml) was chilled at 0° for 25 min, and then was saturated with hydrogen chloride for 3 min. The mixture was stirred for 20 min at 0° and then the solvent was evaporated to yield 1.81 g of XIII, mp 204–205° (dec); $[\alpha]_D^{25}$ + 107° (c 0.52, $CHCl_3$); UV: λ_{max} (log ε) 264 (2.54) and 210 (4.04) nm; IR: ν_{max} (KBr) 3420, 2920, 2840, 1790, and 1600 cm^{-1}; mass spectrum: m/z 419 (3%), 348 (23%), 136 (10%), and 123 (100%). Due to the insolubility of the material, the ^{1}H and ^{13}C-NMR spectra were not obtained.

3-n-Pentadecylcatechol-dialaninate Dihydrochloride (XV)—Reaction of VIII with *N*-(*tert*-butoxycarbonyl)-L-alanine in the manner previously described for the preparation of XIII afforded XIV; UV: λ_{max} (log ε) 280 nm (sh, 2.02), 258 (2.47), and 219 (3.40) nm; IR: ν_{max} ($CHCl_3$) 3440, 3370, 2930, 1770, 1700, and 1500 cm^{-1}; ^{1}H-NMR: δ 7.22–7.17 (3, m), 5.70 (1, br, s), 5.55 (1, br, s), 4.63 (2, br, q, J = 6 Hz), 2.60 (2, t, J = 6 Hz), 1.50 (18, s), 1.28 (26, br, s), and 0.92 (3, t, J = 6 Hz); ^{13}C-NMR: δ 171.1 (s), 170.8 (s), 155.5 (s), 142.6 (s), 140.5 (s), 136.9 (s), 127.3 (d), 126.3 (d), 120.7 (d), 80.0 (s), 49.8 (d), 49.4 (d), 32.0 (t), 30.1 (t), 30.0 (t), 29.7 (t), 29.5 (t), 29.4 (t), 28.5 (q), 22.7 (t), 18.1 (q), 17.9 (q), and 14.0 (q). The *tert*-butyloxycarbonyl protecting groups of XIV were removed with hydrogen chloride in ethyl acetate in the aforementioned manner to yield the dialaninate dihydrochloride XV.

Biological Studies—*Animals*—Female Hartley line-bred guinea pigs weighing 450–500 g were used; guinea pig food and water supplemented with vitamin C were offered *ad libitum*. Groups of 6–12 animals were used, and in all cases a sensitive control group was administered the vehicle only. Sensitization and skin testing were carried out using procedures previously described (11, 12).

Dosing—Doses of 1 or 10 mg of 3-*n*-pentadecylcatechol diacetate (X) per animal were administered intravenously. Emulsions containing the acetates were prepared using polyoxyethylene (20), sorbitan monostearate, and sorbitan monooleate[5] in saline as previously described (12). For tolerance studies, the drug was given to the animals 2 weeks prior to the attempted sensitization. Emulsions of either X or XI were given orally after sensitization of the guinea pigs for desensitization studies. The water-soluble ester (XIII) was given in aqueous solution. The animals were given a cumulative dose equivalent to 52.5 mg of the free catechols (VIII or IX) in the ester form over a period of 3 weeks as follows: (*a*) three doses of 2.5 mg each given on alternate days during the first week; (*b*) three doses of 5 mg each during the second week; and (*c*) three doses of 10 mg each during the third week. The animals were sensitized and skin

[5] Atlas Chemical Industries Inc., Wilmington, Del.

tested prior to dosing, and their sensitivity was measured again the week after the last dose.

RESULTS AND DISCUSSION

Poison ivy dermititis is a major problem among outdoor workers in the U.S. It is estimated that over 1.5 million cases of poison ivy dermatitis are encountered every year with a loss of over 152,000 work days in the United States[6].

In our search for ways to control contact dermatitis caused by the urushiols of poison ivy, oak, and sumac, two successful procedures were developed in this laboratory using guinea pigs as the animal model (11, 12). Of particular interest was the discovery that the esterified urushiol (urushiol acetate) had the ability to block the development of sensitivity in guinea pigs if administered prior to the attempted sensitization (tolerance induction), as well as the ability to desensitize or hyposensitize already sensitive animals (12). This study described the synthesis of the saturated congeners of poison ivy and poison oak urushiols and the ability of their esters to induce tolerance and desensitization or hyposensitization. The synthesis of VIII and IX (the saturated components of poison ivy and oak urushiols, respectively) have been previously described (14–17). These methods involved initially a Grignard reaction of the appropriate alkylmagnesium halide with either 2,3-dimethoxybenzaldehyde or 2,3-dimethoxybenzyl chloride. In addition, the reaction of the Grignard reagent with the phenolic aldehyde was investigated (18).

However, these procedures provided inconsistent results, and the final products were difficult to purify. Use of the Wittig reaction afforded high yields of products which were easy to purify. The Wittig reagent was prepared from 2,3-dimethoxybenzyl halide since the long-chain alkyl halide failed to form the phosphonium salt. The use of boron tribromide in methylene chloride for the demethylation was superior to previously used reagents such as hydrochloric acid, hydroiodic acid, or pyridinium chloride. Demethylation took place in two steps *via* the monomethyl ether, with demethylation of the more sterically hindered group occurring first.

In addition to the acetate esters, the water-soluble dialaninate ester dihydrochlorides (XIII and XV) were prepared. Spectral data are given in *Experimental*. Table I shows the ^{13}C-NMR data on compounds I–XI.

The synthetic compounds were tested for their ability to induce tolerance or desensitization to poison ivy and poison oak urushiols. Guinea pigs were used as the animal model, and immune tolerance was produced by a single- or 10-mg iv dose of X. Over 90% of the animals treated with X were completely tolerant (not reactive to ≤ 3.2-μg test doses of VIII for 6 weeks); none of the control animals were tolerant to VIII. The esters X, XI, and XIII were tested orally (gastric gavage) for their ability to desensitize or hyposensitize guinea pigs which were previously sensitized to poison ivy or oak urushiol. The dosage schedule consisted of consecutive escalating doses for 3 weeks: an amount of the ester equivalent to 2.5 mg of the parent catechol 3 times a week for the first week, doubling each week thereafter. The animals were tested with poison ivy or oak urushiol the week following the last dose and again 4 weeks later. Thity-eight percent of the guinea pigs receiving X were desensitized to 3-μg doses of poison ivy urushiol. There was also significant reduction of the sensitivity (hyposensitization) of the remaining animals as judged by the Driaze method (19) of evaluating skin erythema and edema. Compounds XI and XIII were also found to hyposensitize guinea pigs to poison oak urushiol.

A more detailed comparison of the toxicity and efficacy of free urushiols and their corresponding esters will be published[7].

[6] These figures were obtained from the Public Health Service for 1969, the last year for which there are figures available.

Acrylic Microspheres *In Vivo* VIII: Distribution and Elimination of Polyacryldextran Particles in Mice

PETER EDMAN and INGVAR SJÖHOLM ˣ

Received March 22, 1982, from the *National Board of Health and Welfare, Department of Drugs, Division of Pharmacy, S-751 25 Uppsala, Sweden.* Accepted for publication June 21, 1982.

Abstract □ The disposition of different ^{14}C-labeled, biodegradable polyacryldextran microparticles after intravenous injection has been studied in the mouse. The particles were rapidly cleared from the circulatory system by the reticuloendothelial system. They were predominantly (60–80%) found in the liver and spleen and to some extent in the bone marrow. Large particle aggregates were found in the lungs 6 hr postinjection. After redistribution, the particles were eliminated from the organs with an apparent $t_{1/2}$ of 12–30 weeks, depending on the composition of the particles. Highly cross-linked particles with 2% acrylic groups (DTC = 11-2-75) had a half-life similar to that of polyacrylamide particles (TC = 8-25). The metabolism rate was also correlated with the degradation *in vitro* with isolated rat lysosomes. After intravenous injection of small ^{14}C-labeled polyacrylamide particles (0.2–0.5 μm), significant amounts of radioactivity were detected in the bile and gallbladder.

Keyphrases □ Polyacryldextran—microparticles, *in vitro* degradation, *in vivo* metabolism and elimination in mice □ Microparticles—of polyacryldextran, *in vitro* degradation, *in vivo* metabolism and elimination in mice □ Metabolism—of polyacryldextran microparticles in mice following intravenous injection □ Elimination—of polyacryldextran microparticles in mice by the reticuloendothelial system following intravenous injection

Previous studies have revealed that proteins immobilized in microparticles of polyacrylamide can retain biological properties (1). The particles are small enough (0.2–1 μm in diameter) to be injected intravenously without respiratory problems (2). When such particles were injected parenterally, they were cleared rapidly from the circulatory system by cells of the reticuloendothelial system (RES), predominantly *via* the liver and spleen, where the particles were localized in the lysosomal vacuome (3). The spheres were eliminated from these organs with a half-life of ~20–25 weeks (2).

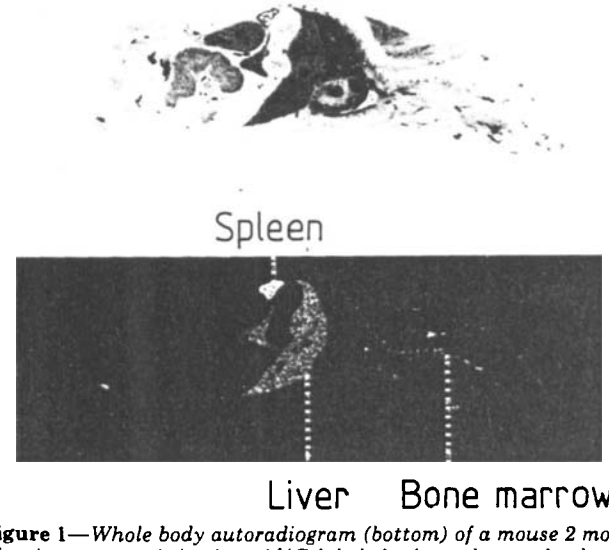

Figure 1—*Whole body autoradiogram (bottom) of a mouse 2 months after intravenous injection of ^{14}C-labeled microspheres of polyacryldextran, DTC = 11-1-75 (48,200 dpm in 2.6 mg). The top is the corresponding stained section, 20 μm.*

Derivatized natural polymers (*e.g.*, acryldextrans) recently have been introduced as a matrix for the preparation of microparticles, particularly for use *in vivo* (4), as substantially fewer synthetic polymer threads are then needed to form the microspheres. The total concentration of acrylic groups is only 0.5–2% in the water phase prior to the polymerization and formation of polyacryldextran. Moreover, the amount of protein immobilized in the microparticles is increased without any significant loss of the biological properties of the immobilized protein, with improved stability against heat denaturation (4). Such particles carrying immobilized dextranase have been used successfully to treat an artificially induced storage disease in mice (5). The present paper will describe quantitatively the distribution of polyacryldextran microparticles in mice and the influence of the polyacryl chains on the degradation of the microparticles *in vivo* and by dextranase *in vitro*.

EXPERIMENTAL

Materials—Acrylamide[1], *N,N'*-methylenebisacrylamide (BIS)[1], *N,N,N',N'*-tetramethylethylenediamine[2], dextran[3], 4-methylumbelliferyl-2-acetamido-2-deoxy-β-D-glucopyranoside[2], 4-methylumbelliferone[2], and other chemicals were of analytical grade. Acrylic acid-glycidyl[4], dextranase[2] (E.C. 3.2.1.11), and [^{14}C]paraformaldehyde[5] were used without further purification. ^{14}C-Labeled *N,N'*-methylenebisacrylamide was prepared as described by Sjöholm and Edman (2).

Synthesis of Acrylic Dextran—Acrylic dextran was prepared using a reported method (4). Dextran (T-40, mol. wt. 40,000) was dissolved in 250 ml of 0.01 *M* phosphate buffer, pH 9.0. Acrylic acid-glycidyl (25 ml) was added, and the emulsion was stirred with a magnetic stirrer for 9–10 days at room temperature. The dextran was precipitated and washed with ethanol. The precipitated dextran was dissolved in phosphate buffer, precipitated again, and washed with ethanol. This procedure was repeated at least five times. The content of acrylic groups in the dextran was determined by halogenation of the double bonds, as described previously (4).

Preparation of Microparticles—^{14}C-Labeled microparticles (DTC = 11-1-75, DTC = 11-2-75, and TC = 8-25)[6] were prepared by the methods of Ekman *et al.* (1) and Edman *et al.* (4). In a typical example, the monomers (acrylamide, ^{14}C-labeled *N,N'*-methylenebisacrylamide, and acryldextran) were dissolved in 5 ml of 0.1 *M* phosphate buffer, pH 7.4. Oxygen was removed from the solution using nitrogen gas. At the same time, 200 ml of a mixture of toluene and chloroform (4:1), containing a detergent[7] (0.5 g), was flushed with nitrogen. After addition of the catalyst, ammonium peroxodisulfate (100 μl of a 0.5-g/ml solution), the

[6] The particles prepared are characterized using the nomenclature suggested by Hjertén (6) and Edman *et al.* (4). The first numeral denotes the concentration of derivatized dextran (D) participating in the particle formation (g/100 ml of solvent). The second numeral denotes the total amount (T) of acrylic monomers (g/100 ml of solvent) and the third, the amount of cross-linking agent (C), *N,N'*-methylenebisacrylamide, expressed as the percentage (w/w) of the total amount of monomers.

[a] Distribution of ^{14}C-labeled polyacryldextran particles in the liver, spleen, lung, and kidneys after injection of 2.6 mg iv of polyacryldextran particles with compositions of DTC = 11-1-75 and DTC = 11-2-75 containing 48,300 and 56,600 dpm, respectively. Each value is the mean obtained from 4–5 animals ± *SE*.

water phase was homogenized in toluene–chloroform to produce a water-in-oil emulsion. The polymerization was started by adding 1 ml of the accelerator, *N,N,N′,N′*-tetramethylethylenediamine, to the emulsion. The suspension was stirred for 20 min, and the phases were separated by centrifugation. The organic phase was removed, and the microparticles located at the bottom of the water phase were washed several times with buffer and physiological saline. Under the conditions used, the polyacrylamide particles (TC = 8-25) had a mean diameter of 0.2–0.5 μm; the polyacryldextran particles (DTC = 11-1-75 and DTC = 11-2-75) had a mean diameter of 0.5–1.5 μm.

Determination of Particle Size—The size of the particles was determined from photographs taken by scanning electron microscopy, using a previously described method (2). With this method, 85.0% of the polyacryldextran particles with DTC values of 11-2-75 used in this study had a diameter of 0.2–1.2 μm, 1.7% were <0.2 μm, and 4.0% were >2.4 μm. Among the particles having DTC = 11-1-75, 72.8% had a diameter of 0.2–1.2 μm, 8.9% were <0.2 μm, 12.5% had a diameter of 1.2–2.1 μm, and 5.8% were >2.1 μm. More than 300 particles were measured from the photographs in each case.

Distribution and Elimination of Polyacryldextran Particles After Intravenous Injection—Male mice[8], weighing 18–20 g at the beginning of the experiments, were used. The radiolabeled particles were dispersed in physiological saline (0.1–0.2 ml) and then injected intravenously. The doses corresponded to 2.6 mg of lyophilized microparticles DTC = 11-1-75 and DTC = 11-2-75, containing 48,200 and 56,600 dpm, respectively. At different time intervals (6 hr, 1, 2, 4, 8, 12, and 20 or 27 weeks) animals were killed by cervical dislocation, and the liver, spleen, lung, and kidneys were removed and prepared for radioactivity measurements. Tissues (the spleen, both lungs, one kidney, or 0.2–0.3 g of the liver) were dissolved in 2 ml of a tissue solubilizer[9]. After digestion at 37° for 12–14 hr (yielding a clear solution), 2-propanol and hydrogen peroxide were added to bleach the samples and minimize color quenching. A scintillation cocktail was added, and the radioactivity was measured after appropriate equilibration. The counting efficiency, generally ~75–80%, was calculated with an external standard.

Determination of Dextranase Activity—The activity of the dextranase was determined photometrically by the method of Janson and Porath (7). The enzyme in free form (0.1 ml) was added to dextran in 0.1 *M* potassium phosphate buffer (1.9 ml). After incubation for 30 min at 37°, 1 ml of the incubation solution was mixed with 1.0 ml of a color reagent (5 g of 3,5-dinitrosalicylic acid, 1 g of phenol, 0.25 g of sodium sulfite, and 100 g of potassium sodium tartrate in 500 ml of 2% NaOH) and heated in a boiling water bath for 15 min. After dilution with 10 ml of water, the absorbance was measured at 540 nm. A standard curve was prepared with maltose: one unit of activity caused the release of 1.0 μmole of maltose/min under the aforementioned conditions.

Autoradiography—Whole-body autoradiography was performed using the method of Ullberg (8). ^{14}C-Labeled particles were injected intravenously in mice. After 2 months, the animals were killed with ether and frozen in a mixture of solid carbon dioxide and hexane (−78°). The mice were embedded in an aqueous carboxymethylcellulose gel, freeze-dried (−15°), and cut into 20- or 60-μm sagittal sections with a microtome. Autoradiograms were made by apposition of the freeze-dried sections to X-ray films, the time of exposure was 6 months.

Isolation of Lysosomes from Rat Liver Homogenate—The livers from untreated male adult Sprague-Dawley rats were removed immediately after sacrifice and immersed in a beaker containing ice-cold 0.25 *M* sucrose, pH 5.5. After weighing, the tissue was cut into pieces and dispersed in 3 volumes of the medium with a homogenizer[10]. The resulting mixture was centrifuged at 750×*g* and 4° for 10 min. The sediment was rehomogenized three times and centrifuged. The resulting supernatants were pooled and centrifuged at 12,000×*g* for 10 min. The supernatant was discarded, and the pellet was dissolved in 0.25 *M* sucrose and centrifuged for 10 min at 6500×*g*. The sediment was redispersed in approximately the same quantity of medium and centrifuged at 6500×*g*

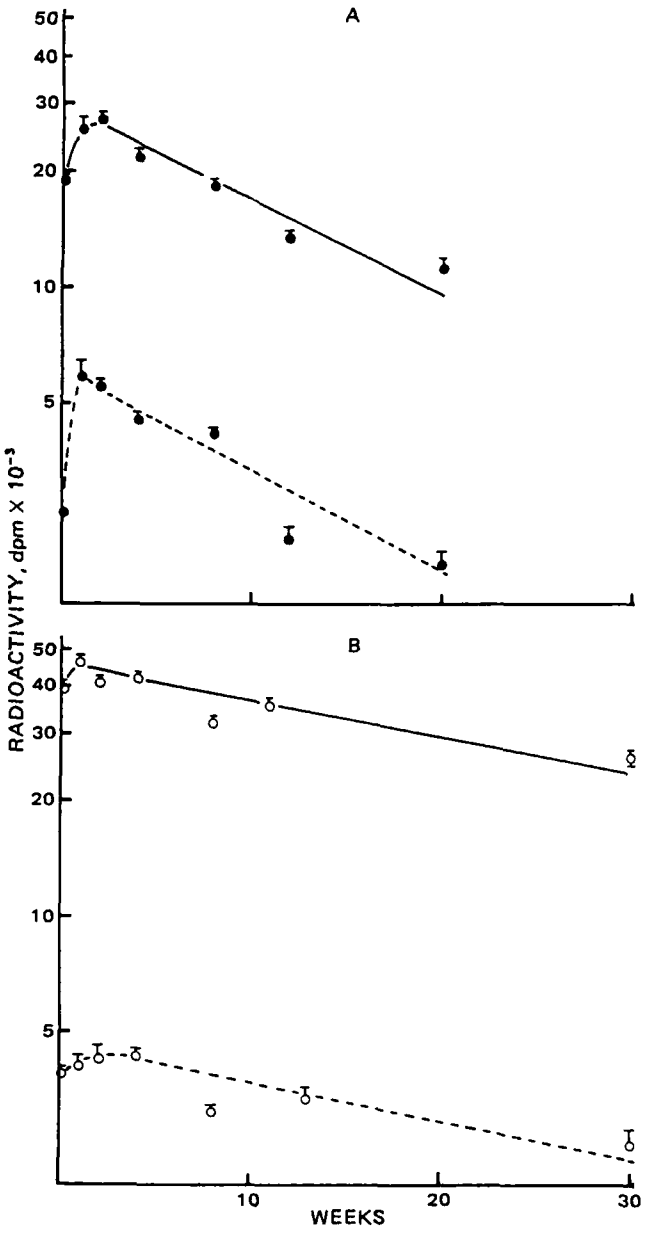

Figure 2—*Radioactivity content of the liver (—) and spleen (- - -) after a single 2.6-mg iv dose of ^{14}C-labeled polyacryldextran particles with composition of DTC = 11-1-75 (●) or DTC = 11-2-75 (○). Each point represents the mean ± SEM for 4–5 animals.*

for 10 min. This procedure was repeated three times. The supernatants from the washings were combined and centrifuged at 12,000×*g* for 15 min. The resulting pellet was redispersed in medium (pH 4.5) to a final volume equal to that of the original tissue. The isolated lysosomal fraction was usually preserved with benzylpenicillin and streptomycin. The described procedure follows that outlined by Beaufay *et al.* (9).

The concentration of lysosomes in the different supernatants and pellets during the preparation was determined by assay of a lysosomal enzyme, β-*N*-acetyl glucosaminidase (10). This enzyme was determined by using 1.5 m*M* 4-methylumbelliferyl-2-acetamido-2-deoxy-β-D-glucopyranoside as substrate in 1 ml of 0.15 *M* acetate–acetic acid buffer, pH 4.2. The sample (0.5 ml) was added, and the mixture was incubated at 37° for 15 min. The reaction was terminated by adding 3 ml of 0.5 *M* Na_2CO_3, pH 10.5, to each tube, and the free 4-methylumbelliferone was estimated by spectrophotometry at 360 nm. Standards containing 4-methylumbelliferone in buffer were included in every assay. The protein contents in the different fractions were estimated according to the method of Lowry *et al.* (11).

Preparation of Liver and Spleen Samples for Microscopic Studies—Tissue samples were cut from the organs immediately after sacrifice and immersed in chilled 5% formaldehyde in 0.15 *M* phosphate buffer, pH 7.2. The specimens were embedded in paraffin in a routine manner, cut at 2–3 μm, stained with hematoxylin and eosin, and examined under a light microscope.

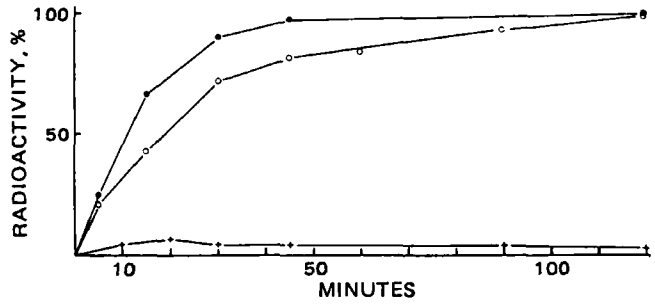

Figure 3—*Degradation of microparticles of polyacryldextran at 23° and pH 6.2 with 0.5 IU of dextranase/ml. Key: (●) DTC = 11-1-75; (○) DTC = 11-2-75; (+) TC = 8-25 (polyacrylamide).*

RESULTS

Distribution and Elimination of ^{14}C-Labeled Polyacryldextran Particles *In Vivo* After Intravenous Injection—On intravenous injection in mice, the microparticles were rapidly cleared from the circulatory system with a $t_{1/2}$ of ~60 min[11]. The distribution of the polyacryldextran particles (DTC = 11-1-75 and DTC = 11-2-75) was followed qualitatively and quantitatively in mice. The autoradiogram (Fig. 1) indicates, as expected, that the particles are phagocytosed by the macrophages belonging to the reticuloendothelial system (RES). The spheres were found in the liver, spleen, and bone marrow. Microparticles with 1% (DTC = 11-1-75) or 2% (DTC = 11-2-75) acrylic groups showed the same distribution pattern, which was also seen with particles containing no derivatized dextran (TC = 8-25) (2).

The quantitative distribution of the particles in the liver, spleen, kidneys, and lung was followed with time (Table I). Initially, some of the largest spheres and/or aggregates were entrapped in the lung capillaries, giving a higher radioactivity in the lungs than earlier noted with polyacrylamide particles (2). This phenomenon is due to the somewhat larger size of the polyacryldextran spheres. However, the aggregates were soon dissociated, and the radioactivity was <1% of the injected dose after 1–2 weeks. The values obtained from the lungs after 2 weeks, therefore, are not included in the table, nor are those from the kidneys which contained only very small amounts of radioactivity after 2 weeks.

The apparent half-life of the different microparticles in the liver and spleen was calculated from the curves in Fig. 2. As is evident, particles made of dextran containing a smaller number of acrylic groups (DTC = 11-1-75) were eliminated more rapidly than those containing more acrylic groups (DTC = 11-2-75). The terminal half-lives, as found by linear regression analysis, were 12.5 and 12 weeks and 33 and 29 weeks, respectively, in the liver and spleen. The figures also indicate that a redistribution took place after the first rapid elimination from the circulatory system, so that the maximal radioactivity was seen after 1–2 weeks in the liver and spleen, independent of the particle composition. About 70–80% of the total injected radioactivity was recovered in these tissues 2 weeks after injection. The uptake of the particles into the liver and spleen resulted in an enlargement of these organs. The weight increase compared with the control regressed after 4–8 weeks.

Ultrastructural Studies—Intravenous injection of a 2.6-mg dose of polyacryldextran particles (DTC = 11-1-75) produced pronounced changes in the liver and spleen. After 1–2 days, the sinusoids were dilated, and vacuolization of the liver parenchymal cells could be seen. The spleen showed an infiltration of inflammatory cells. Weight changes of the liver and spleen paralleled the ultrastructural changes seen microscopically. Formation of small abscesses and granulomas was observed after this period. After 4–8 weeks, the tissues appeared normal except for small granulomas. When a dose of <1 mg was given to the mice, only insignificant morphological changes could be detected in the liver and spleen.

Degradation of Polyacryldextran Particles *In Vitro* with Dextranase—To investigate the stability of the polymer polyacryldextran, ^{14}C-labeled particles of different polymer composition were incubated with dextranase (0.5 IU/ml of particle suspension) for up to 2 hr at 22° and pH 6.2. After centrifugation for 5 min at 4°, the supernatant was withdrawn and the dissolved radioactivity determined (Fig. 3). Micro-

[11] P. Artursson, T. Laakso, and P. Edman, unpublished observation, 1982.

particles of polyacrylamide (TC = 8-25) were not significantly affected. Polyacryldextran particles with composition DTC = 11-1-75 were rapidly hydrolyzed, and all the radioactivity was found in the supernatant after 45 min. Particles with a higher cross-linking degree, DTC = 11-2-75, were more stable, but were dissolved after digestion for 120 min.

Degradation of Different Polyacryldextran Particles *In Vitro* with Isolated Lysosomes from Rat Liver—^{14}C-Labeled particles (dry weight, 0.5 mg) of different gel-composition, (TC = 8-25, DTC = 11-1-75 and 11-2-75) were mixed with 1.0 ml of isolated lysosomes from rat liver homogenate in small plastic tubes. They were incubated at 37° for 1, 3, 6, 24, and 48 hr and then centrifuged for 10 min at 4°. The resulting supernatant was filtered through a filter[12] with 0.45-μm pore size. The radioactivity content in 300 μl of the filtrate was determined in the scintillation counter. Polyacrylamide particles (TC = 8-25) were not significantly affected during 48 hr: only background values were obtained. Polyacryldextran particles with DTC = 11-2-75 composition behaved in the same manner as the polyacrylamide particles. However, polyacryldextran particles with DTC = 11-1-75 were metabolized to some extent, and 0.56 ± 0.003% (mean ± *SD*, n = 4) of the radioactivity in the particles was recovered from the filtrate after incubation for 48 hr.

Excretion of Microparticles in Bile—The biliary excretion of microparticles was studied after a 4-mg iv injection of ^{14}C-labeled polyacrylamide microparticles (containing 400,000 dpm) in mice. The particles had a TC value of 8-25 and a diameter of 0.1–0.4 μm (92.6% of the particles had a diameter within this range, 2.2% were <0.1 μm, and 5.2% had a diameter of 0.4–0.5 μm). The particles were dispersed in physiological saline prior to injection to avoid aggregation. At different time intervals (3, 9, and 27 weeks), animals were killed, and the gallbladder with remaining bile was taken out and digested in 1 ml of 0.5 *M* quaternary ammonium hydroxide. Irrespective of the time elapsed after the injection of particles, the bile contained radioactivity (38, 91, and 34 dpm after 3, 9, and 27 weeks, respectively) after subtraction of background values obtained from untreated mice. The counting times used were long enough to minimize the statistical error to 2–3% for samples and blanks.

DISCUSSION

The most obvious conclusion which can be drawn from the results presented herein is the similarity of the disposition of polyacryldextran and polyacrylamide particles in mice. The half-life of the microparticles in the circulatory system and the general distribution of the microparticles in the mice are similar. They are predominantly taken up by the reticuloendothelial system (*i.e.*, liver, spleen, and bone marrow) as shown by autoradiography and quantitative meaurements in the tissues. Moreover, the morphological changes detected microscopically after intravenous administration of large doses (>50–100 mg dry weight/kg body weight) are similar (3) and parallel the weight changes observed. It is obvious that incorporation of cross-linked dextran in the microparticles does not change the distribution *in vivo*, and it is highly likely that the observations are representative for any uncharged particulates of the same size (*i.e.*, 0.2–1.0 μm in diameter) injected intravenously or intraperitoneally.

Similar effects—morphological changes in the liver—have also been detected with liposomes. A study with mice (12) on the effects of negatively charged liposomes given intravenously revealed that liposomes caused an enlargement of the Kupffer cells with vacuolization observed 7 hr postinjection.

The polyacryldextran particles exhibited a somewhat larger initial uptake in the lungs than seen with polyacrylamide particles. The uptake was reversible, and was detected only in the sample taken 6 hr after the injection. After a week, insignificant amounts of the radioactively labeled microparticles remained. This phenomenon may be due to the larger size of the polyacryldextran particles, with ~15% exceeding 1.2 μm in diameter; the polyacrylamide particles had diameters between 0.2 and 0.5 μm. The reason for the difference in size between the two different particle preparations is that the higher viscosity of the dextran aqueous solution makes it more difficult to prepare small polyacryldextran particles (<0.5 μm). It is important to stress that only small-sized particles should be used *in vivo* to avoid respiratory distress. This point was clearly illustrated in studies with dogs (13, 14), in which polystyrene particles (mean diameter 3 μm) injected intravenously resulted in death for three of four dogs, probably due to lung emboli.

The most significant advantages of the polyacryldextran particles over the polyacrylamide particles is the faster metabolism. Both the experiments *in vitro* with lysosomal enzymes or dextranase and those performed in the mice clearly showed that the degradation and elimination is related to the hydrocarbon content of the microparticles. The lysosomal preparations were able to release >0.5% of the radioactivity within the first 48 hr from particles containing 1% acryl groups. As expected, these particles were also degraded much faster with dextranase than those containing 2% acryl groups. The terminal half-lives *in vivo* in the liver and spleen were also significantly shorter for the polyacryldextran particles with 1% acryl groups (~12 weeks) than for the other particles. The results suggest that it is possible to control elimination by changing the composition of the microparticles, which is of great value when the particles are used as enzyme carriers. In such cases, the composition of the carrier should be chosen such that the degradation of the particles agrees with the denaturating rate of the enzyme. It is, however, also obvious that the size of the particles is a decisive factor for the rate of elimination, and it should be remembered that the polyacryldextran particles used in this study were larger than the polyacrylamide particles used previously (2).

An earlier report from this laboratory indicated that microparticles after intravenous injection were identified in two layers of the gut lumen, the microvilli region and the basal membrane, as judged by the whole-body autoradiograms (2). The reason for such a specific localization was unclear, but long-term studies have now shown that small but significant amounts of radioactivity—originating from the polyacrylamide particles—were found in the gallbladder. Thus the radioactivity in or at the microvilli may be radioactive metabolites excreted from the liver.

Abstract □ The steric contact spaces associated with the reaction of the enantiomeric isomers of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (I) with the exocyclic amino group of guanine of dinucleoside dimer structures were examined for a fixed transition-state geometry. This reaction is sterically prohibited for the B form DNA conformation. If, however, the nucleic acid structure is deformed, such that the distance between two adjacent base pairs (one containing guanine and cytosine) is maximized, sterically allowed transition-state geometries can be identified. It was not possible to uniquely identify the preferred transition-state complex with respect to nucleic acid structure or isomer of I. However, two types of general transition-state geometries were observed. In one, I was located "outside" the nucleic acid structure; in the other geometry, I was intercalated between adjacent base pairs in the transition state. The intercalation process might serve as a physical catalyst for the alkylation of NH_2-guanine by I.

Keyphrases □ 7,8-Dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzene[*a*]pyrene—enantiomeric isomers, alkylation of dinucleoside dimers, transition-state geometry □ Dinucleoside dimers—alkylation by enantiomeric isomers of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene, transition-state geometry □ Transition-state geometry—of the alkylation of dinucleoside dimers by enantiomeric isomers of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene, intercalation

The chemical carcinogen benzo[*a*]pyrene (II) is metabolized to a diol-epoxide derivative (I) which is enzymatically formed in two stereoisomeric forms: 7β,8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydrobenzo[*a*]-pyrene [III, designated *anti* or *trans*(eq,eq′)] and 7β,8α-dihydroxy-9β,10β-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene [IV, designated *syn* or *cis*(ax,ax′)] (1–6). Each has a complement, *trans*(ax,ax′) and *cis*(eq,eq′), respectively, and each of these four isomers can exist as a (+) or (−) enantiomer. The eight possible enantiomeric isomers are shown in Fig. 1, described in terms of our previous nomenclature (7).

Evidence to support the concept that activated metabolites of II are important for carcinogenesis has been presented (8–10). These studies have shown that NADPH-dependent mixed-function oxidases in liver microsomes produce reactive intermediates (epoxides) which can bind covalently to nucleic acids and proteins. Further studies have shown that epoxides are cleaved by a second microsomal enzyme, epoxide hydratase, to form dihydrodiols (11). The dihydrodiols are substrates for aryl hydrocarbon hydroxylase, which then generates diol-epoxides. It is the diol-epoxides of selected polycyclic aromatic hydrocarbon carcinogens that are thought to be the ultimate carcinogenic metabolites, binding to macromolecules to initiate tumor formation. Specific diol-epoxides of II such

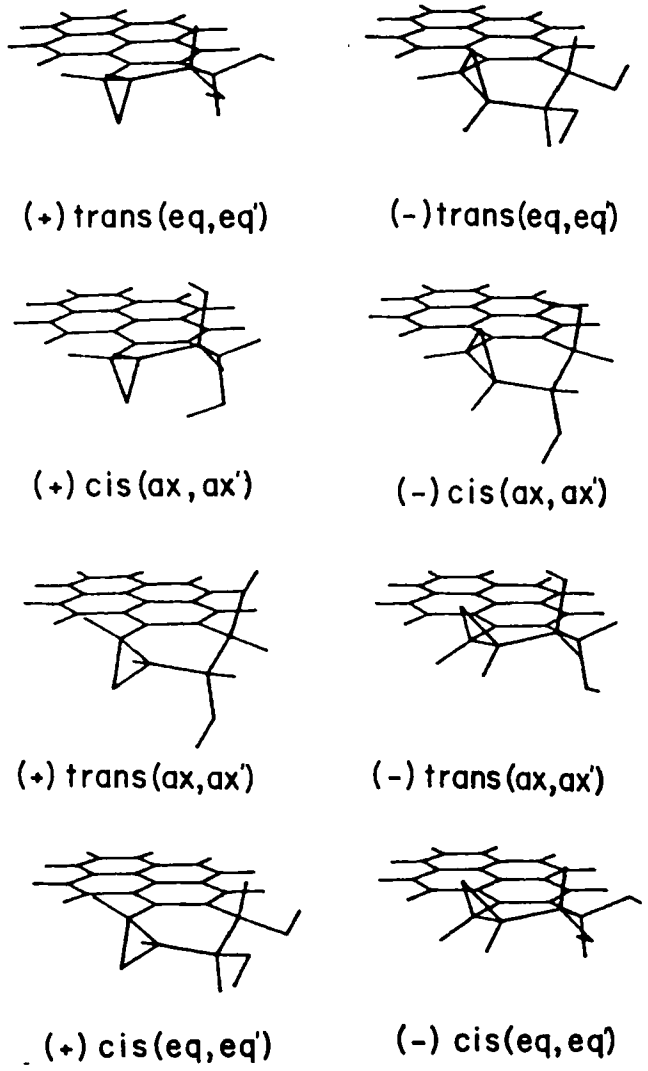

Figure 1—*Computer-drawn representations of the structure-optimized geometries of the eight enantiomeric isomers of I.*

as (+)-7β,8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene have been shown to be potent inducers of neoplasia in mouse skin (12, 13). This pattern of metabolic reaction has been shown to occur in the skin and in cultured keratinocytes (14).

There is also considerable evidence that III residues bind covalently to both RNA (6) and DNA (15) predominantly at the 2-amino group of guanine. Cytosine and adenosine residues in nucleic acids are also alkylation targets to a

smaller extent, both *in vitro* (15–17) and *in vivo* (15, 18). The three bases contain an exocyclic amino group which presumably is the common alkylation site. This is relatively unusual since alkylation usually occurs at the N(7) position of guanine (19).

It has been reported (20) that 60–80% of the total adduct formed by (±)III with DNA involves the (+) enantiomer with the 2-amino group of *d*-guanine residues. A minor adduct is formed from the reaction of the (−) enantiomer with DNA. This minor adduct is present in greater amounts in denatured DNA than in native DNA. Small amounts of III–*d*-adenosine and III–*d*-cytosine adducts are also detected for both single- and double-stranded DNA. No differences in the total extent of (±)III binding to double- and single-stranded calf thymus DNA have been detected. It is thus of interest to identify I–DNA

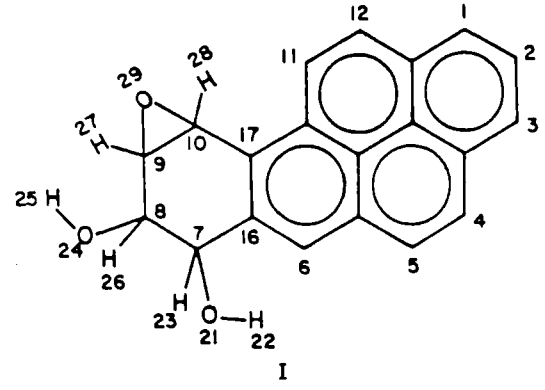
[a] Using the numbering scheme presented in Table I.

stereochemical reaction models that are consistent with these experimental observations. Such theoretical models are essential for working hypotheses to explain the chemical reactivity of these carcinogenic species and, perhaps, their relative tumor induction potencies.

EXPERIMENTAL

The electronic structure of four isomers of I have been investigated and previously reported (7). In this study several approximations were employed for the estimation of the molecular structures of isomers of I. The substructure of the epoxy group was assumed to be the same as that of ethylene oxide. The local conformation of the two hydroxyl groups was fixed at that of ethylene glycol. Moreover, the "L" version (21) of the



I

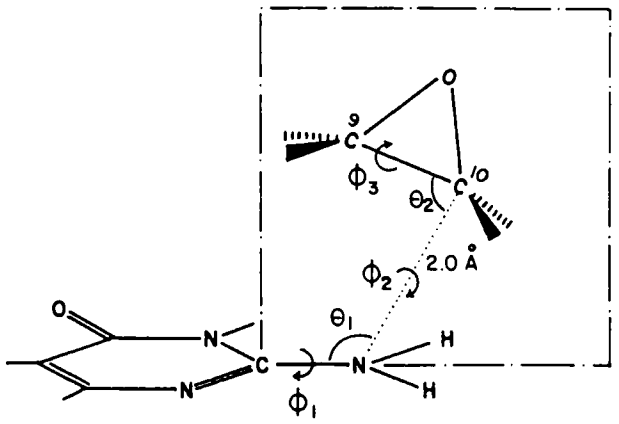


Figure 2—*Transition-state geometry used to perform the steric reaction calculations. In the specific I–NH_3 transition-state geometry (7) used as the starting point in these calculations, $\phi_1 = 100°$, $\theta_1 = 110°$, $\phi_2 = 90°$, $\theta_2 = 80°$, and $\phi_3 = 0$ or $180°$.*

semiempirical CNDO/2 method was employed in which only π-electrons were explicitly taken into account for the conjugated subsystem.

In the present study, the conjugated part of the molecule was fixed at the idealized structure (C—C = 1.40 Å, C—H = 1.10 Å, angles = 120°). All other structural parameters were optimized using the CNDO/2 method. The optimized molecular parameters for each isomer are reported in Table I. Computer-drawn representations of the structure-optimized geometries of the eight enantiomeric isomers are shown in Fig. 1. The charge distributions and total energies for the structure-optimized molecules are reported in Table II. As found in the previous study (7), the *trans*(eq,eq′) isomer (III) is more stable than the *trans*(ax,ax′) isomer, and the *cis*(ax,ax′) isomer (IV) is more stable than the *cis*(eq,eq′) isomer. The angle between the epoxy group and the conjugated hydrocarbon ring system is larger in the more stable *trans* and *cis* isomers than in the corresponding less stable isomers. The longer C(3)—O(9) and O(9)—H(14) bond lengths (Table I) for IV are due to hydrogen bonding between the hydroxyl group and the epoxy oxygen. These results are consistent with those obtained in our previous study (7), although small differences in valence geometry exist.

In the previous study (7), the reactivity of the four isomers of I with the simple nucleophile ammonia was modeled. Isomer IV was found to be the most reactive. These calculations allowed the identification of a unique transition-state geometry for alkylation. The transition state of I with ammonia corresponds to $\phi_1 = 100°$, $\theta_1 = 110°$, $\phi_2 = 90°$, $\theta_2 = 80°$, $\phi_3 = 0$ or $180°$, and $r = 2.0$ Å (Fig. 2).

Table III—Least Number of Bad-Contacts at Three Nucleophilic Sites in Four Base-Pair Sequences Using (+)III

Site	Base-Pair Sequence			
	C—G / G—C / C—G	G—C / G—C / G—C	T—A / G—C / T—A	A—T / G—C / A—T
N(7)	8	9	10	11
O(6)	9	10	8	14
2-NH_2	34	38	31	37

The calculations involving I and ammonia indicated that III and IV are both more stable, and also more reactive with the nucleophile, than the respective isomer complements, *trans*(ax,ax′) and *cis*(eq,eq′). This may explain why III is observed to be the major metabolic isomer relative to *trans*(ax,ax′). Unfortunately, corresponding experimental studies of isomers of I with ammonia are not reported in the literature. The current studies have focused on (±)III and (±)IV, since biochemical observations have clearly indicated their particular importance.

The large size of I would be expected to impose steric constraints regarding its capacity to alkylate DNA. These steric constraints may limit the ways in which a transition-state geometry may be realized between an enantiomeric isomer of I and the exocyclic amino group of guanine in DNA. Therefore, it is necessary to examine intermolecular reaction geometries for the I–DNA complex. To do this it was assumed that the transition-state geometry for I–NH_2-guanine is the same as that found for the complex of I and ammonia (7). The "bad-contacts" between pairs of atoms from I and DNA were sought for the transition-state geometry shown in Fig. 2.

A bad-contact is assigned to an atom pair if the distance is shorter than a critical distance. If a specific conformation has one or more bad-contacts, it is assumed to have a high energy and cannot be realized. The critical distance, r_c, was selected to be the van der Waals distance for all interactions involving atoms of the aromatic rings of I. Smaller values than the corresponding van der Waals distances were chosen for interactions involving epoxide, diol, and saturated ring atoms (including hy-

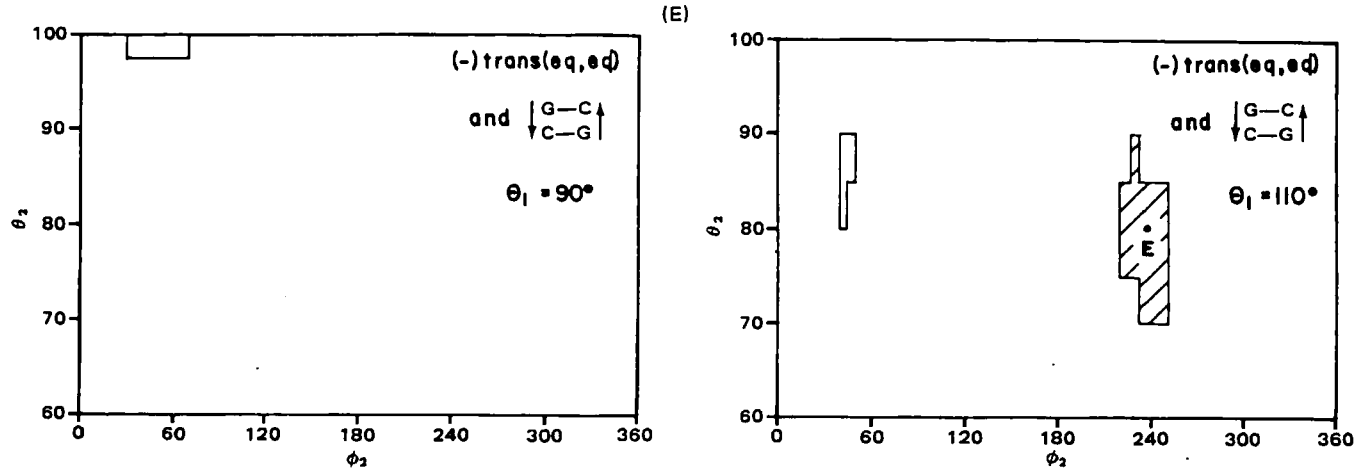

Figure 5—*Steric contact plots of θ_2 versus ϕ_2 for different sequences of unwound dinucleoside dimer, (±)III, (±)IV, and two different values of θ_1. The shaded regions correspond to allowed intercalation transition-state geometries. The open regions identify transition-state geometries in which I is outside the dinucleoside dimer. The letters A through E on the steric contact maps define the (ϕ_2,θ_2) values used to construct the stereo model figures in Fig. 7. The criteria for constructing the steric boundaries are given in* Experimental.

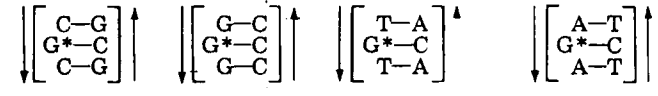
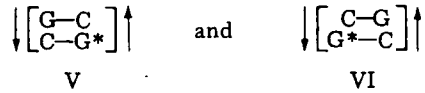
drogens) to qualitatively account for the uncertainty in molecular geometry and flexibility at the transition state. A set of r_c values that give a 5 kcal/mole repulsive energy in the 6–12 potential (22) for each unique atom pair was chosen subjectively in this work.

Four base-pair sequences of trinucleoside dimers in the B conformation (23) were considered:



The reaction of the central guanine (G*) with (±)III and (±)IV was investigated. In each case the isomer was located "above" the central base pair, as shown in Fig. 2. In the first series of calculations, all conformational variables, except ϕ_2, were held fixed. ϕ_2 was allowed to fully rotate in each case. For completeness, transition-state conformational analyses were also performed for the N(7) and O(6) positions on guanine. Transition-state geometries found in earlier studies (24) for these two sites were used as constraints in the analyses.

The transition-state I-NH_2-guanine conformational analyses were next repeated for two deformed dinucleoside dimer sequences:



V VI

The particular deformed conformation selected is that with the largest possible base-pair separation distance, d = 6.76 Å; it has been used previously in nucleic acid–drug intercalation studies (25). The atomic coordinates of this structure (along with (+)III intercalated between base pairs) are in Table IV. The nitrogen atom of the 2-amino group in the lower guanine, G*, is attacked by the C(10) atom of I using the transition-state geometry shown in Fig. 2. Once again the conformational studies are characterized in terms of bad contacts. Since the N—C(10) distance is fixed at 2.0 Å and d = 6.76 Å, the upper base pair has minimal influence on specifying bad contacts. The conformational degrees of freedom, defined in Fig. 2, were varied over the same range of values as used in the calculations for B form DNA.

RESULTS

The least number of bad contacts (N) was determined for each of the N(7), O(6), and 2-amino reactions with (±)III and (±)IV. As an example, these least numbers are reported in Table III for (+)III [(+)*trans*(eq,eq') isomer]. Relative magnitudes in Table III may not be important. The essential observation is that in all cases bad contacts were found to exist. Figure 3 is a more detailed steric description of the 2-amino alkylation by (+)III. Nucleic acid sequence does not appear to alter the steric repulsions occurring in the transition state of the reaction. Figure 4 shows the dependence of N for 2-amino alkylation by (±)III and (±)IV as a function of transition-state conformation for d-(cytosine–guanine)$_2$. The steric effects in the 2-amino alkylation process by the (+) enantiomers are different from those of the (−) enantiomers. Nevertheless, alkylation by each form of I at the 2-amino position in guanine appears to be sterically unlikely from a study of Fig. 4. Alkylation at the N(7) or O(6) of guanine was also found to be sterically prohibited. It can be concluded from these conformational analyses that the B form of DNA cannot react with I because of steric hindrance for the selected transition-state geometries. Thus the experimental evidence (6, 8) which indicates 2-amino alkylation of guanine must be explained in terms of a deformation of the B form DNA structure. Of course, these results are dependent on the calculated transition-state geometry.

The two conformational degrees of freedom most critical to generating a stereochemically acceptable alkylation complex are θ_2 and ϕ_2. Steric maps that define complexing geometries that are possible for the transition state are shown in Fig. 5. The shaded areas correspond to intermolecular geometries in which I is intercalated between base pairs. The other areas correspond to structures in which the I isomer is located outside the dinucleoside dimer. Several typical complex structures are shown in stereo-stick model representation in Fig. 6.

Both (+)III and (+)IV can react with the 2-amino group of guanine for V. Reaction with VI is more restricted for both these isomers. There is little difference in the steric constraints for (+)III and (+)IV alkylation to V. The results suggest that (+)*trans*(eq,eq') and (+)*cis*(ax,ax') alkylation with V should occur subsequent to intercalation.

There is no difference between the electronic structures of (+)III and (−)IV. However, experiments indicate that the (+) enantiomer alkylates guanine more efficiently than (−)III (20). Thus the intercalation and chemical reaction may be controlled by the absolute configurations of these enantiomers. Figures 5A and 5C indicate a large difference in the steric effect due to the enantiomeric properties of III. The (−) enantiomer is not expected to react with the 2-amino group of guanine in the V dimer through intercalation. However, for VI, different possible reaction geometries are predicted for (+) and (−)III (Figs. 5D and 5E). The (+) enantiomer is expected to intercalate and react with the 2-amino group

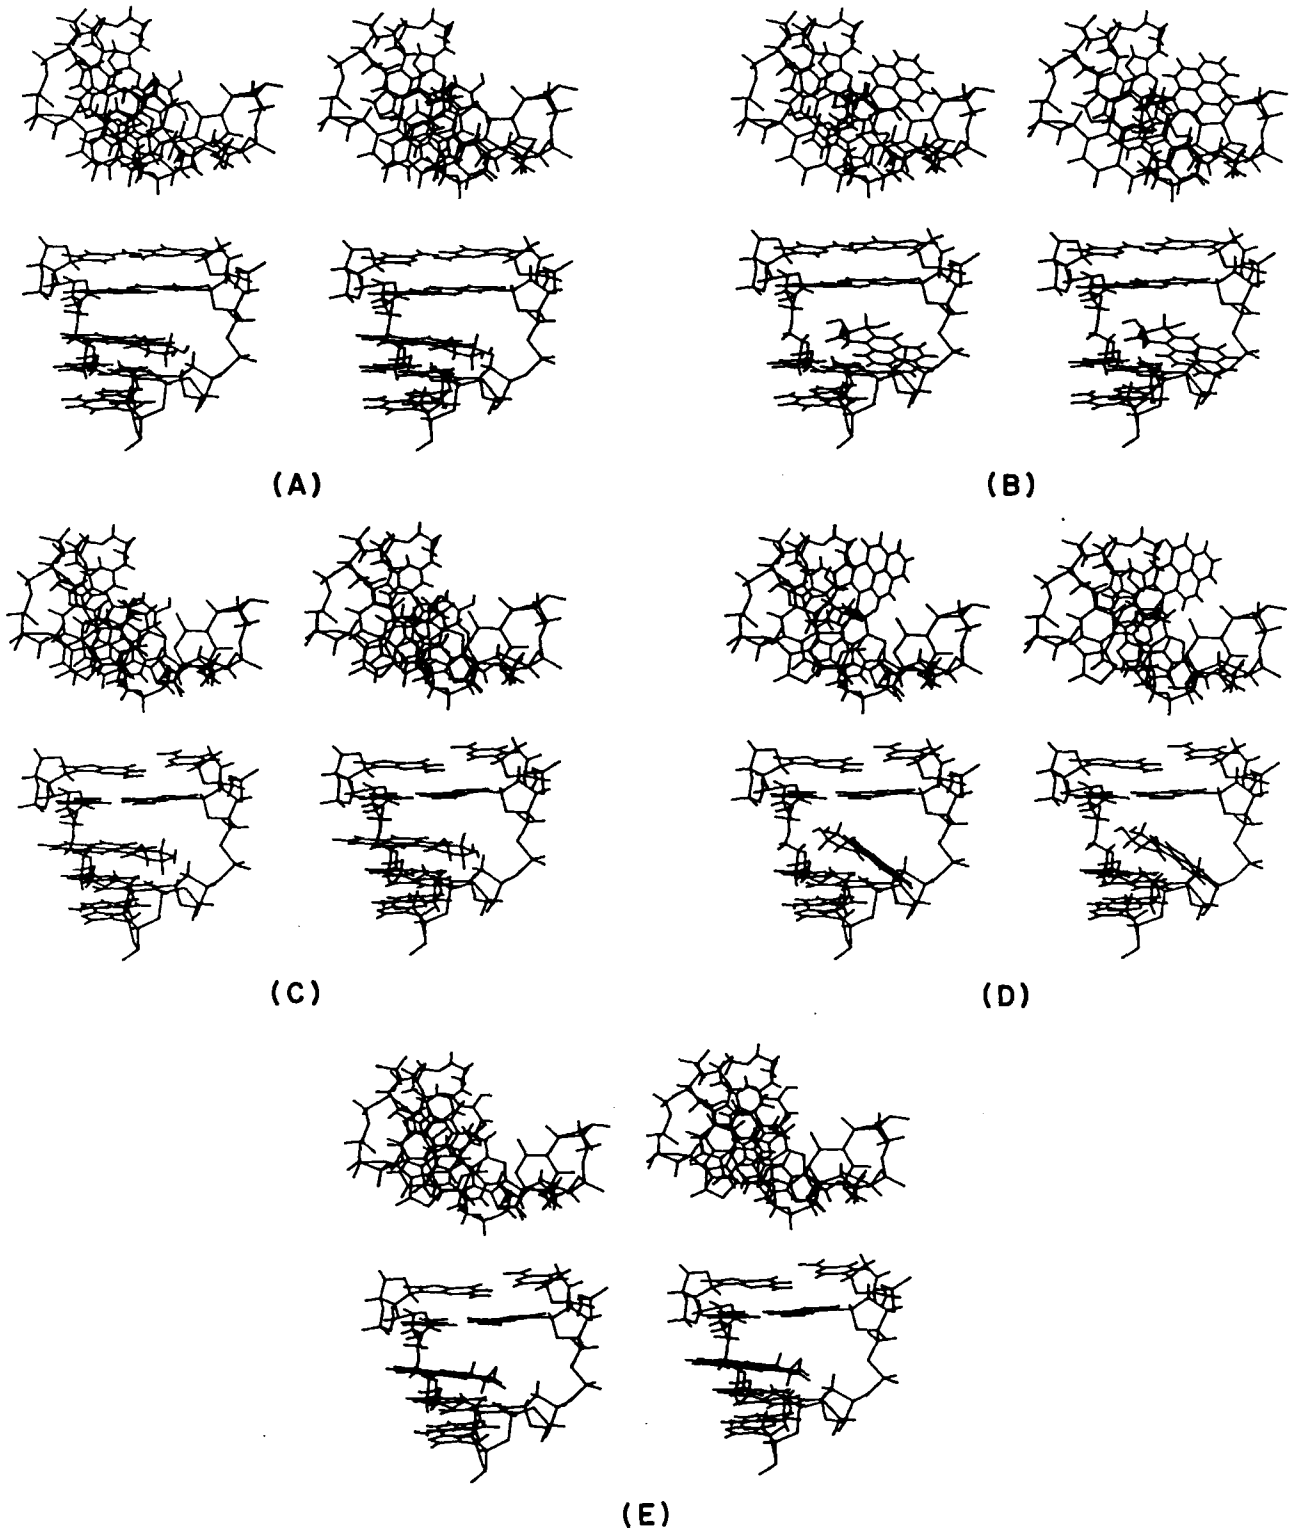


Figure 6—*Stereo-stick models of sterically allowed I–dinucleoside dimer transition-state geometries defined in Fig. 6 (A–E on the steric contact maps). The top views are looking down the helix axis of the nucleic acid structure; the bottom figures are side views.*

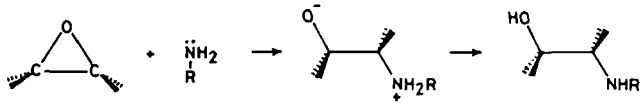
of guanine just above the nitrogen atom ($\theta_1 = 90°$, Fig. 5D). The intercalated (−) enantiomer can reach the reaction site from slightly outside the dimer ($\theta_1 = 110°$, Fig. 5C). Both the (+) and (−) enantiomers of III can react from outside the dimer helix. It is, however, not possible to deduce which reaction geometry is preferred since energetics are not included in the analysis.

The intercalation of isomers of I as a prerequisite for alkylation of the 2-amino of guanine is an interesting hypothesis. The intercalation process could be conceptualized as a physical catalyst which stabilizes the reaction geometry in a manner analogous to enzyme–substrate–inhibitor interactions. However, the intercalation model requires that the I component of the reaction product remains between the base pairs. Experimental studies indicate, however, that the adduct involving I is located outside the DNA structure (26). The conformational analysis of the I open-form model of DNA indicates that the part of the reaction product involving I cannot come outside of the base pairs by rotation about the adduct C(10)—N bond unless the hydrogen bond involving the exocyclic amino group of guanine and the cytosine oxygen is broken.

Thus the change in the hydrogen bonding energy for such a reaction process (Scheme I) was examined, and the relative energies of the three



Scheme I

states of the G–C base pair (Fig. 7) were compared. The CNDO/2 method was used (27). The methyl group attached at the nitrogen atom was placed above the base-pair plane to fit the reaction product model with I held between base pairs. The results of these calculations suggest that if the hydrogen bond between the 2-amino group of guanine and the O of cytosine is broken during the alkylation process, allowing I to rotate out from between the base pairs, the resultant base-pairing structure could be of lower, or at least comparable, energy to that of the intercalation structure (Fig. 8).

DISCUSSION

Two major hypotheses were made in this study: (*a*) the transition-state geometries of isomers of I with the exocyclic amino group of guanine are identical to that calculated for isomers of I interacting with ammonia (7), and (*b*) the sterically allowed transition-state geometries of isomers of I with dinucleoside dimers can be identified using the aforementioned stereochemical model (*Experimental*).

The most clear-cut finding from the investigation is that neither (±)III or (±)IV can alkylate the 2-amino group of guanine for B form DNA. This reaction is stereochemically prohibited based on the postulated transition-state geometries. The deformation in the conformation of double-stranded DNA that is associated with this alkylation process has not been uniquely identified. However, if a dinucleoside dimer is unwound, so that the distance between base pairs is maximized (d = 6.76 Å), two possible geometric reaction models result. In one, alkylation occurs when I is located outside the nucleic acid structure; in the other, I is intercalated between base paris for the alkylation transition state. Intercalation of I could serve as a physical catalyst, or provide at least substrate stabilization, for NH_2-guanine alkylation. The alkalyation transition-state geometry is sensitive to nucleic acid sequence for both the isomeric and enantiomeric forms of I.

The choice of the deformed structure of the double-stranded DNA model is somewhat arbitrary. However, the structure selection should correspond to that in which one strand exerts the least steric influence on the interaction between I and the other strand. This is an important consideration since the total extent of (±) binding to I to single- and double-stranded DNA is the same (20). Conversely, this observation also requires that the stereochemical constraints for NH_2-guanine alkylation in double-stranded structures are no more severe than in the single-stranded DNA. This study has focused on double-stranded DNA because its local conformational properties are better understood, and because the double-stranded structure introduces more steric repulsive sites than a single strand.

The calculations reported here are based in part on "soft" steric contact distances (those atoms of the diols, epoxide, and saturated ring of I). As such, this model cannot be used to identify the preferred transition-state geometry. The following paper explores in detail the physical interaction of I with nucleic acid structures to better quantify allowed intermolecular geometries, with special emphasis on possible intercalation mechanisms.

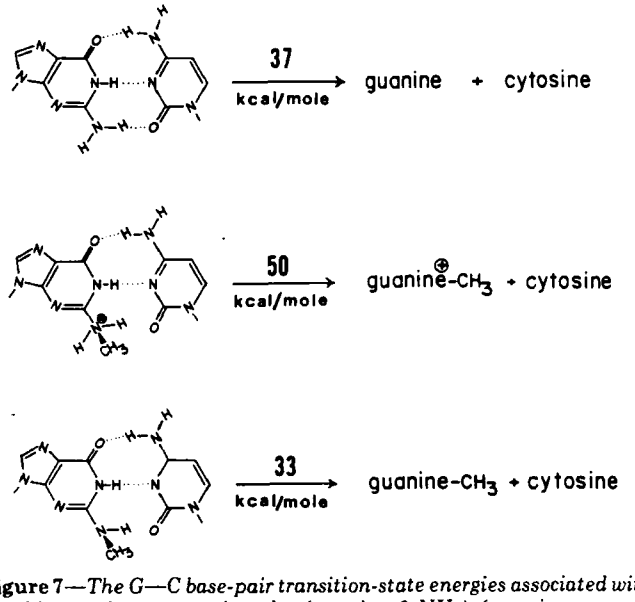


Figure 7—*The G—C base-pair transition-state energies associated with breaking and restructuring the (guanine 2-NH_2)-(cytosine oxygen) base-pair hydrogen bond.*

Abstract □ The minimum-energy intercalation-complex geometries of the (±)enantiomers of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene (I) with two dinucleoside dimers were determined. The purpose of these calculations was to see if I could intercalate into DNA in such a way that the observed alkylation of the 2-amino group of guanine could occur subsequent to intercalation. For both dinucleoside dimer sequences, it was found that the (+)-(9α,10α) isomer could form a stable intercalation complex in which the orientation and distance of the epoxide of I to the 2-amino group of guanine was close to the calculated critical transition-state geometry for the alkylation reaction. The (−)enantiomers can intercalate, but not in a manner close to the transition-state geometry necessary for the alkylation of the 2-amino group of guanine.

Keyphrases □ 7,8-Dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene—enantiomeric isomers, alkylation of dinucleoside dimers, intercalation-complex geometry and energetics □ Dinucleoside dimers—alkylation by enantiomeric isomers of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene, intercalation-complex geometry and energetics □ Intercalation—of 7,8-dihydroxy-9,10-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene into dinucleoside dimers, energetics, complex geometry

The previous paper (1) reported that a sterically acceptable transition-state geometry for the alkylation of the amino group of guanine by 7β,8α-dihydroxy-9α,10α-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene (II) and 7β,8α-dihydroxy-9β,10β-epoxy-7,8,9,10-tetrahydrobenzo[a]pyrene (III) could involve intercalation. Also, a noncovalent complex formation between benzo[a]pyrene and calf thymus DNA has been observed recently (2). This interaction is postulated to involve intercalation of the aromatic hydrocarbon between adjacent base pairs. An equivalent type of intermolecular geometry could also be expected for single-stranded DNA in which the isomeric forms of I are associated with a nucleic acid base or a pair of adjacent bases. This is an important consideration since the total extent of the alkylation of the 2-amino group of guanine by (±)II is observed to be the same for both single- and double-stranded DNA (3). In addition, (+)III forms the major adduct (60–80% of total adducts) with the amino group of guanine (3).

These findings have prompted the exploration of the possibility that the intercalation process might occur as a prior step to alkylation of the 2-amino group of guanine by I in double-stranded DNA. The energetics of the intercalation of (±)II and (±)III (Fig. 1) with dinucleoside dimer sequences was investigated using molecular mechanics energy calculations (4). The results of these calculations are reported herein.

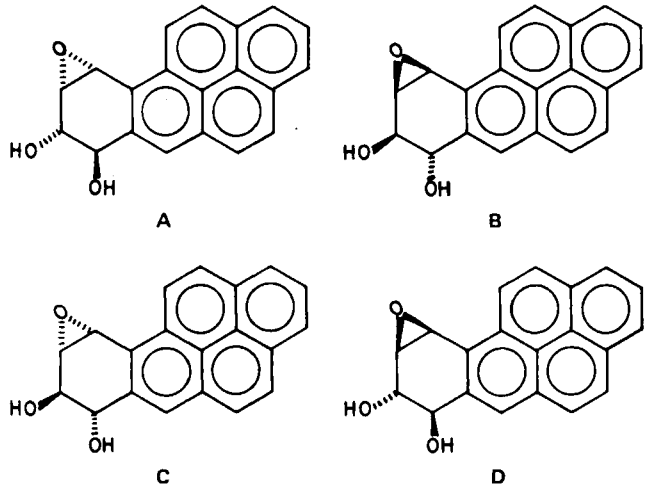

Figure 1—*The enantiomeric isomers of I. Key: (A) (+)II; (B) (−)II; (C) (+)III; (D) (−)III.*

EXPERIMENTAL

The overall procedure for these calculations is identical to that employed previously for the intercalation investigation of doxorubicin (5); a summary of the procedure follows. The DNA structure was represented by a dinucleoside dimer containing guanine. The same geometries used in the doxorubicin study were assigned to the dinucleoside dimers. There are seven unique ways of interacting I with guanine bases in dinucleoside dimers (Fig. 2). One sequence, has two possible 2-amino alkylation sites. Thus eight intermolecular complexes should be studied. However, if

[a] The transition-state geometric variables. The geometry for I–NH_3 is r = 2.0 Å, θ_1 = 110°, θ_2 = 80°, ϕ_1 = 100°, ϕ_3 = 0 or 180°, with ϕ_2 variable. [b] As defined by the intercalation complex geometries in Fig. 5. The designation i–j indicates a reaction-state geometry between two of the designated complexes.

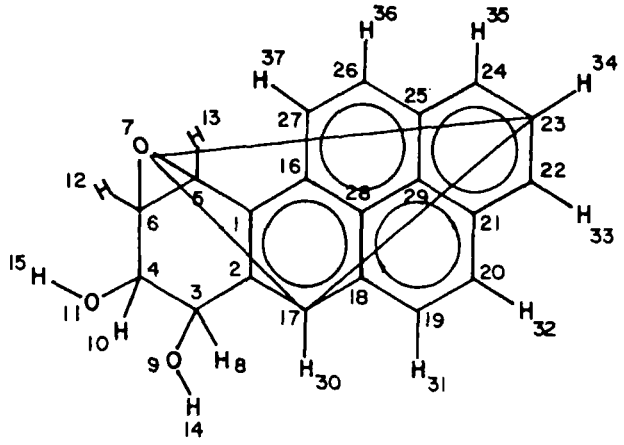

Figure 3—*Structure of I (indicating the internal atomic numbering used) with the descriptive intercalation triangle superimposed.*

detailed sequence specificity is set aside, there are only two cases to consider for the position of an isomer of I. One case involves an isomer of I interacting with guanine from the 3′-side of the base-pair plane, the other case an interaction from the 5′-side of the base-pair plane. Only these two possibilities were considered in this study. Two dinucleoside sequences were employed in the intercalation analyses:

↓(C—G)↑ (5′ side) IV ↓(T—A)↑ (3′ side) V

A specialized version of the MASS (Molecular Assembly Software System) option in the CHEMLAB software package (6, 7) was used to carry out the molecular mechanics calculations. The molecular and electronic structures of (±)II and (±)III used in the study are based on previous calculations (1, 8). The valence geometries of these molecules were held rigid in the intercalation calculations. The structure of I with a superimposition of the descriptive intercalation triangle, involving atoms O(7), C(17), and C(23) as vertices, is shown in Fig. 3. The descriptive intercalation triangle makes it possible to visualize easily the orientation of an isomer of I relative to a dinucleoside dimer. The atomic coordinates of II and V have been given previously (1).

The complexing energy was minimized as a function of the six intermolecular degrees of freedom defined in Fig. 4. Each enantiomer of II and III was placed such that the epoxide ring was above or below the guanine base. Six selected starting positions were chosen in each energy minimization (Fig. 5). It is seen from Fig. 5 that both major and minor groove intercalation were considered.

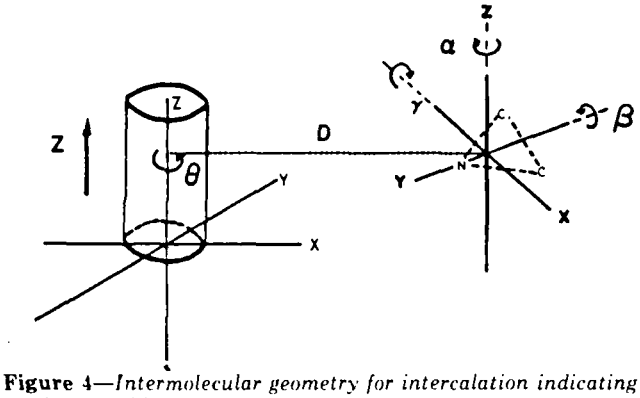

Figure 4—*Intermolecular geometry for intercalation indicating the six degrees of freedom (from Ref. 7).*

RESULTS

The minimum energy complexes for both dinucleoside dimer sequences are reported in Table I. The preferred intercalation structures are vir-

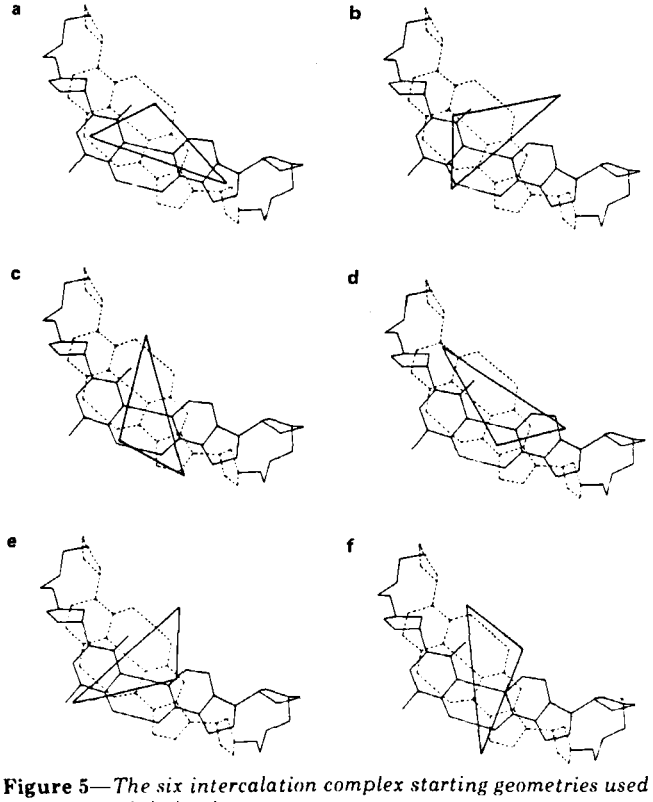

Figure 5—*The six intercalation complex starting geometries used in the energy minimizations.*

tually independent of the approach of I from either the major or minor groove. The position of each enantiomeric isomer is reported in terms of the geometric variables of the transition state (1, 8). Many of the complex energies are close to one another (~1 kcal/mole). Consequently, it is not possible to identify the most stable intermolecular complex as a function of isomer and/or base sequence. The uncertainty in these computed energies is probably larger than several of the corresponding differences, thus negating such a structural assignment. However, the important observation is that intercalation geometries predisposed for NH_2-alkylation are among the most stable intermolecular structures.

The minimum-energy transition-state geometry has been computed for isomers of I with ammonia as $r = 2.0$ Å, $\theta_1 = 110°$, $\theta_2 = 80°$, $\phi_1 = 100°$, and $\phi_3 = 0$ or 180°, with ϕ_2 variable (8). This model system (Fig. 6) should be a reasonable approximation for I alkylating the 2-amino group of guanine and has been used to evaluate the reactive potential of the various intermolecular complexes.

The complexing energies show a moderate sensitivity to both choice of isomer and base-pair sequence. One consistent observation is that (+)III forms the least stable intercalation complex with the two dinucleoside dimers. The (+)III intercalation complex also possesses the minimum C(10)—NH_2 interaction distance of all complex structures. The second smallest interaction distance occurs in the (+)II–dinucleoside dimer complexes. However, (+)III undergoes a steric repulsion involving its 7-hydroxyl group with an upper base if it approaches closer than 3.1 Å to the amino group of guanine.

DISCUSSION

Intercalation complexes having isomers of I oriented toward the amino group of guanine close to the model transition-state geometry should be particularly reactive. From Table I it is seen that the (+) isomers of both II and III have their epoxide groups oriented toward the 2-amino group of guanine, similar to the model transition-state geometry for both dinucleoside dimers. Moreover, these two intercalated stereoisomers also have the minimum distances between the atoms involved in the alkylation process: C(10) of I (defined as atom number 5 in Fig. 3) and the nitrogen of the amino group of guanine. The distances are 3.7 and 3.1 Å for (+)II and (+)III, respectively. Thus, the (+) enantiomers should be more reactive toward DNA if intercalation is a prereactive step in the alkylation process. This conclusion is consistent with experimental observation (3).

The intercalation complex involving (+)II should be expected from these calculations to be the most reactive state if intercalation is part of the reaction process. Table II summarizes the relationship between the mode of intercalation and location of (+)II relative to the base alkylation sites for IV. Clearly, mode d–e is critical to the explanation of the experimental observations (3). It should be noted also that the second most stable intercalation complex corresponds to the epoxide of II being close to the amino group of cytosine. The exocyclic amino group of cytosine is postulated to be the alkylation site for the minor cytosine–II adducts that are observed (9–12). These intercalation calculations may provide both a geometric and energetic base for this assumed reaction site. Stereo-stick models of the (+)II–IV complex are shown in Fig. 7. The transition-state orientation of the epoxide group relative to the 2-amino group of guanine is easily seen.

Table II—Intercalation Modes of (+)II with IV

Mode[a]	Intercalation Energy, kcal/mole	Position of Epoxide to Base
a–b	−84.00	cytosine-NH_2
c	−82.96	cytosine ring

Hypolipidemic Activity of Substituted 2-Pyrrolidinones in Rodents

GEORGE H. COCOLAS, JAMES M. CHAPMAN, Jr., P. JOSÉE VOORSTAD, and IRIS H. HALL[x]

Received March 11, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, The University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication June 25, 1982.

Abstract □ A series of substituted 2-pyrrolidinones was evaluated for hypolipidemic activity at 20 and 30 mg/kg/day in CF_1 male mice. 4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone was the most potent compound at 30 mg/kg/day, reducing serum triglyceride levels 52% after 14 days of dosing and serum cholesterol levels 48% after 16 days of dosing. 4-Phenyl-5-carbethoxy-2-pyrrolidinone and 4-phenyl-3,5,5-tricarbethoxy-2-pyrrolidinone also demonstrated significant activity. Those compounds which contained a phenyl substituent were more potent than either the unsubstituted, the alkyl, or the dicarbethoxy 2-pyrrolidinone analogues.

Keyphrases □ 2-Pyrrolidinones—synthesis of substituted analogues, hypolipidemic activity in mice □ Antihyperlipidemic agents—substituted 2-pyrrolidinone analogues, synthesis, hypolipidemic activity in mice □ Succinimide—2-pyrrolidinone congeners, synthesis of substituted analogues, hypolipidemic activity in mice

Studies on the antihyperlipidemic activity of *N*-substituted phthalimides (1) and related imide analogues (2) revealed a wide variety of imides which caused a reduction in serum cholesterol and triglyceride levels in rodents. Succinimide was observed to be active at a dose of 20 mg/kg/day ip, affording a 27% reduction in serum cholesterol levels after 16 days and a 32% reduction of serum triglyceride levels after 14 days in mice (2). As an extension of these studies, the hypolipidemic activity of a series of 2-pyrrolidinone derivatives as congeners of succinimide was examined; those results are reported herein.

EXPERIMENTAL

Chemistry—Of the 18 compounds studied (Table I), 2-pyrrolidinone[1] (I) and L-pyroglutamic acid[2] (IV) were purchased commercially. 5-Carboxy-2-pyrrolidinone (III), 4-phenyl-5-carboxy-2-pyrrolidinone (used to prepare XIV), 5,5-dicarbethoxy-2-pyrrolidinone (V), and 5,5-dicarboxy-2-pyrrolidinone (VI) were prepared by the method of Cocolas and Hartung (3). 5-Carbethoxy-2-pyrrolidinone (II) was prepared by esterification of D,L-5-carboxy-2-pyrrolidinone (III) with ethanol–hydrochloric acid. The four alkyl-5,5-dicarbethoxy-2-pyrrolidinones (VII–XIII) were prepared by a Michael addition of an α,β-unsaturated ester to diethyl acetamidomalonate and subsequent cyclization as reported by Kim and Cocolas (4).

4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone (XIV)—The method of Kim and Cocolas (4) was used. To 400 mg (0.019 g-atom) of sodium dissolved in 200 ml of absolute ethanol of alcohol was added 21.7 g (0.1 mole) of diethyl acetamidomalonate and 22 g (0.125 mole) of ethyl cinnamate. The mixture was refluxed overnight (10–12 hr), cooled to room temperature, and then neutralized with glacial acetic acid. The solvent was removed under reduced pressure to give solid material which was recrystallized from toluene to give 16 g of product, mp[3] 96–97°.

Anal.—Calc.[3] for $C_{16}H_{12}NO_5$: C, 62.95; H, 6.23; N, 4.59. Found[3]: C, 62.82; H, 6.19; N, 4.74.

4-Phenyl-5-carbethoxy-2-pyrrolidinone (XV)—4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone (XIV), 26.9 g (0.088 mole), was dissolved in 125 ml of absolute ethanol, and 250 ml of 20% ethanolic potassium hydroxide solution was added slowly. The resulting solution was refluxed for 9 hr and allowed to cool, and the white solid precipitate was collected and dissolved in 150 ml of hot water. The solution was made strongly acidic with 6 *N* HCl and the resulting precipitate filtered to give 10.8 g of 4-phenyl-5,5-dicarboxy-2-pyrrolidinone. Decarboxylation at 160–165° under vacuum and recrystallization from ethanol gave 3.04 g of 4-phenyl-5-carboxy-2-pyrrolidinone, mp 180°. Esterification with ethanolic hydrochloric acid yielded 4-phenyl-5-carbethoxy-2-pyrrolidinone, mp 140–141°.

Anal.—Calc. for $C_{13}H_{15}NO_3$: C, 66.94; H, 6.48; N, 6.00. Found: C, 66.79; H, 6.67; N, 6.03.

4-Phenyl-3,5,5-tricarbethoxy-2-pyrrolidinone (XVI)—The method of Kim and Cocolas (4) was used. A solution containing 1.15 g (0.05 g-atom) of sodium metal, 10.85 g (0.05 mole) diethyl acetamidomalonate, and 12.5 g (0.05 mole) diethyl benzalmalonate in 100 ml absolute ethanol was maintained at room temperature for 3 days. The reaction mixture was then neutralized with glacial acetic acid and cooled to precipitate 20 g of XVI. The product was recrystallized from 95% ethanol, mp[3] 107–109°.

Anal.—Calc.[3] for $C_{19}H_{23}NO_7$: C, 60.47; H, 6.14; N, 3.71. Found[3]: C, 60.81; H, 6.22; N, 3.54.

4-Isopropyl-3,5-dicarbethoxy-2-pyrrolidinone (XVII)—Compound XVII was prepared according to the procedure of Kim and Cocolas (5).

3-Methyl-5,5-dicarbethoxy-2-pyrrolidinone (XVIII)—Compound XVIII was prepared according to the method of Cocolas *et al.* (6).

Biological Testing—Compounds were tested at 20 and 30 mg/kg/day ip in CF_1 male mice (~25 g). On days 9 and 16, blood was collected *via* a tail vein, and the serum was separated by centrifugation. Serum cholesterol was determined by a modification of the Leibermann–Burchard reaction (8). A separate group of mice were bled on day 14 and their serum triglyceride levels were determined using a commercial kit[4].

RESULTS AND DISCUSSION

The 2-pyrrolidinone derivatives were potent hypolipidemic agents in mice after dosing for 14–16 days at 20 and 30 mg/kg/day (Table II). The unsubstituted compounds demonstrated very poor activity. 4-Phenyl-5,5-dicarbethoxy-2-pyrrolidinone (XIV) gave the best anticholesteremic activity resulting in a 42% reduction of serum cholesterol levels at 20 mg/kg/day and a 48% reduction at 30 mg/kg/day. At the latter dose, serum triglycerides were reduced 52%. The other two derivatives containing a phenyl substituent, XV and XVI, also reduced cholesterol serum levels significantly but to a lesser degree. 4-Phenyl-5-carbethoxy-2-pyrrolidinone XV was more effective than 4-phenyl-3,5,5-tricarbethoxy-2-pyrrolidinone XVI, causing cholesterol reductions of 37 and 24%, respectively, at 20 mg/kg/day and 35 and 42%, respectively, at 30 mg/kg/day. Compound XV reduced serum triglyceride content 44%.

4-Alkyl substitution on the 5,5-dicarbethoxy-2-pyrrolidinone nucleus improved the reduction of serum triglycerides and cholesterol in mice.

[a] $n = 6$. [b] $p \leq 0.001$. [c] $p \leq 0.010$.

Reduction of serum cholesterol ranged from 21 to 38% at 20 mg/kg/day and 32 to 48% at 30 mg/kg/day compared with the control. 4-Isobutyl-5,5-dicarbethoxy-2-pyrrolidinone (XII) caused the greatest reduction of these 4-alkyl derivatives, 38% at 20 mg/kg/day and 42% at 30 mg/kg/day. The serum triglyceride levels were reduced 33% by XII at 30 mg/kg/day, 46% by X at 30 mg/kg/day, and 43% by XI at 20 mg/kg/day.

4-Isopropyl-3,5-dicarbethoxy-2-pyrrolidinone (XVII) reduced serum cholesterol levels by 32% on day 16 at 20 mg/kg/day, being slightly more active than the 4-isopropyl-5,5-dicarbethoxy analogue (X) which suppressed serum cholesterol levels by 25% at this dose level. However, X was more active than XVII at 30 mg/kg/day in lowering serum cholesterol.

3-Methyl-3,5-dicarbethoxy-2-pyrrolidinone (XVIII) was less effective in reducing both triglyceride and serum cholesterol levels than the 4-methyl analogue (VII).

The 4-*n*-propyl-5,5-dicarbethoxy-2-pyrrolidinone (IX) gave the best antitriglyceridemic activity of all the compounds when tested at 20 mg/kg/day, reducing serum levels by 37%. L-Pyroglutamic acid (IV) was one of the less effective compounds tested and had the same level of hypolipidemic activity as the racemic compound, III.

These studies demonstrate that the 2-pyrrolidinones possess antihyperlipidemic effects in mice. The compounds appear to be more potent than clofibrate which is inactive in the 20–30 mg/kg/day dose range. The hypolipidemic activity of these pyrrolidinones is, in general, equal to succinimide and similar imide-containing structures.

Potential Antitumor Agents IX: Synthesis and Antitumor Activity of Two Analogues of Ketocaine

ALDO ANDREANI *x, GIANCARLO SCAPINI *, IRAKLIS GALATULAS ‡, and ROSARIA BOSSA ‡

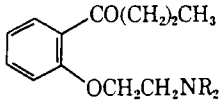
Received November 3, 1981, from the **Istituto di Chimica Farmaceutica e Tossicologica, University of Bologna* and the ‡*Istituto di Farmacologia, University of Milan, Italy.* Accepted for publication June 14, 1982.

Abstract □ The reaction between *o*-hydroxybutyrophenone and tris(2-chloroethyl)amine gave two analogues (II, V) of the well-known local anesthetic ketocaine (I). Compounds II and V showed interesting antitumor activity in mice implanted with Ehrlich ascites tumor cells (% T/C = 149 at 5 mg/kg and 171 at 50 mg/kg, respectively). Further studies on the pharmacological behavior of these new compounds are in progress.

Keyphrases □ Antitumor agents—synthesis and antitumor activity of two analogues of ketocaine, potential □ Ketocaine—potential antitumor agents, synthesis and antitumor activity of two analogues

The antimitotic properties associated with the bis(2-chloroethyl)amino group is well known, and a number of compounds bearing this group are of therapeutic interest. The choice of a suitable supporting moiety for this pharmacophoric group is very important (1). The local anesthetic ketocaine (I) (2) at high concentrations reduces the oxygen consumption by cerebral tissue, while at lower concentrations is able to stimulate intensely this consumption, not only by cerebral tissue, but also by tissues with prevailing anaerobic metabolism (HeLa cells, KB cells) (3–6). In particular, ketocaine inhibits the mitosis of lymphocytes in culture stimulated by phytohemoagglutinine, a process which has been correlated with the stimulating effect of this local anesthetic on oxygen consumption by tissues with prevailing anaerobic metabolism (7).

These observations prompted us to attach the bis(2-chloroethyl)amino group to the phenolic group in *o*-hydroxybutyrophenone, in order to potentiate and/or specialize the antimitotic action of the parent drug, ketocaine. Such a compound also is in agreement with the N—O—O triangulation hypothesis recently proposed for some antineoplastic agents (8).



I R = —$CH(CH_3)_2$
II R = —CH_2CH_2Cl

RESULTS AND DISCUSSION

Replacement of the two isopropyl groups of ketocaine (I) with two 2-chloroethyl groups was effected by treating *o*-hydroxybutyrophenone(III) with one equivalent of tris(2-chloroethyl)amine (IV) in ethanolic sodium ethoxide. This not only furnished the expected *N*-[2-(2-butanoyl)phenoxyethyl]-*N*,*N*-di(2-chloroethyl)amine (II) but also *N*,*N*-di[2-(2-butanoyl)phenoxyethyl]-*N*-(2-chloroethyl)amine (V) (Scheme I). The IR and ^{1}H-NMR spectra of compounds II and V are in agreement with the assigned structures (see *Experimental*).

For antitumor testing, female Swiss mice (average weight 21 ±1 g) were implanted on day 0 with 10^6 Ehrlich ascites tumor cells from donor mice. After 24 hr the animals were treated with compound II dissolved in water (1, 5, or 20 mg/kg, i.p.) or compound V dissolved in dimethyl sulfoxide (10, 50, or 200 mg/kg, i.p.). The amount of dimethyl sulfoxide used was shown previously, in analogous experiments, not to affect tumor growth. Deaths were recorded for the 60-day period. The activities were measured as the ratio of the mean survival time of the test animals to that of the control animals expressed as a percentage (% T/C). Significant activity is achieved with an increased life span of 25% (T/C ≥ 125).

Both compounds prolonged the life span of mice bearing Ehrlich ascites carcinoma beyond that of untreated animals: increase for compound II was 48.7% at a 5 mg/kg, i.p. dose and for compound V was 71.2% at 50 mg/kg, 24 hr after tumor implantation (Table I).

The activity of compounds II and V is related to toxicity. While compound II may act as a cross-linking agent (similar to melphalan, chlorambucil, and cyclophosphamide), the antitumor activity of compound V may be due only to its alkylating properties; its lower toxicity is in agreement with the data reported for other monofunctional agents (1).

EXPERIMENTAL[1]

Synthesis of Compounds II and V—*o*-Hydroxybutyrophenone (III: 16.4 g, 0.1 mole) and tris(2-chloroethyl)amine hydrochloride (IV: 24.1 g, 0.1 mole) were added to a solution of sodium ethoxide (0.2 mole) in absolute ethanol (150 ml). The mixture was refluxed for 3 hr, and the solvent was evaporated under reduced pressure. The residue was treated with water and a few drops of 34% ammonium hydroxide until alkaline, then extracted with chloroform, dried with anhydrous sodium sulfate, and evaporated under reduced pressure. Column chromatography of the residue gave 6 g of starting material (III), then 12 g of II, and finally 3 g of V. Compounds II and V, oily at room temperature, were then converted into the corresponding hydrochlorides: II HCl: mp 113–115° (absolute ethanol).

Anal.—Calc. for $C_{16}H_{23}Cl_2NO_2$·HCl: C, 52.11; H, 6.56; N, 3.80. Found: C, 52.19; H, 6.44; N, 3.72. IR (cm^{-1}): 2400–2300, 1690, 1600, 1580, 975, 760. ^{1}H-NMR (δ): 0.96 (t, 3, CH_3); 1.68 (m, 2, CH_2—CH_3); 2.84 (t, 2, $COCH_2$); 3.86 (m, 6, 3 $CH_2N^{(+)}\lesssim$), 4.10 (m, 4, 2 CH_2Cl); 4.61 (t, 2, O—CH_2); 6.9–7.7 (m, 4 aromatic).

V·HCl: mp 83–85° (toluene). *Anal.*—Calc. for $C_{26}H_{34}ClNO_4$·HCl: C, 62.90; H, 7.11; N, 2.82. Found: C, 63.18; H, 7.32; N, 2.81. GLC Determination of (−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine in Human Plasma and Urine

H. B. HUCKER ˣ and J. E. HUTT

Received July 30, 1981, from the *Merck Institute for Therapeutic Research, West Point, PA 19486.* Accepted for publication June 18, 1982.

Abstract □ (−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine (MK-160) was extracted from human plasma and urine with petroleum ether and quantitated by GLC using a nitrogen-sensitive detector. A homologue of the drug served as the internal standard. The method is specific for the drug in the presence of potential metabolites and is capable of measuring concentrations in plasma as low as 6 ng/ml.

Keyphrases □ GLC determination—(−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohept-5-ylidene)piperidine (MK-160) in plasma and urine

(−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine (I)[1] shows stereospecific antipsychotic, antidopaminergic, and anticholinergic activities in the mouse, rat, and squirrel monkey (1, 2). Clinical trials in human subjects necessitated an analytical method capable of measuring low nanogram concentrations of I in plasma without interference from potential metabolites of the drug. This report describes a GLC method using a nitrogen–phosphorus detector which meets these requirements with acceptable precision and accuracy.

EXPERIMENTAL

Chemicals and Reagents—Heptane, petroleum ether (35–60°), and methanol were reagent grade; isoamyl alcohol was spectroscopic quality. Stock solutions of I HCl and II were prepared in methanol and serially diluted with methanol to the desired concentrations. All concentrations are expressed as the free base of I.

Apparatus—GLC analysis was performed with a gas chromatograph[2] equipped with a nitrogen–phosphorus detector and a 91-cm × 2-mm column packed with 3% OV-17 on Gas Chrom Q (80–100 mesh)[3]. The

[1] Melting points are uncorrected. Bakerflex plates (Silica-gel IB2-F) were used for TLC. For column chromatography, Kieselgel 60 (Merck) was used, activated at 120° for 2 hr: the eluent was a mixture of petroleum ether (bp 60–80°)–acetone 80:20. The IR spectra were recorded in Nujol with a Perkin-Elmer 298 spectrometer. ^{1}H-NMR spectra were recorded in $CDCl_3$ (10% w/v) with a 90-MHz spectrometer (Varian EM 390) using TMS as an internal standard.

GLC Determination of (−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine in Human Plasma and Urine

H. B. HUCKER ˣ and J. E. HUTT

Received July 30, 1981, from the *Merck Institute for Therapeutic Research, West Point, PA 19486.* Accepted for publication June 18, 1982.

Abstract □ (−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine (MK-160) was extracted from human plasma and urine with petroleum ether and quantitated by GLC using a nitrogen-sensitive detector. A homologue of the drug served as the internal standard. The method is specific for the drug in the presence of potential metabolites and is capable of measuring concentrations in plasma as low as 6 ng/ml.

Keyphrases □ GLC determination—(−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohept-5-ylidene)piperidine (MK-160) in plasma and urine

(−)-1-Cyclopropylmethyl-4-(3-trifluoromethylthio-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)piperidine (I)[1] shows stereospecific antipsychotic, antidopaminergic, and anticholinergic activities in the mouse, rat, and squirrel monkey (1, 2). Clinical trials in human subjects necessitated an analytical method capable of measuring low nanogram concentrations of I in plasma without interference from potential metabolites of the drug. This report describes a GLC method using a nitrogen–phosphorus detector which meets these requirements with acceptable precision and accuracy.

EXPERIMENTAL

Chemicals and Reagents—Heptane, petroleum ether (35–60°), and methanol were reagent grade; isoamyl alcohol was spectroscopic quality. Stock solutions of I HCl and II were prepared in methanol and serially diluted with methanol to the desired concentrations. All concentrations are expressed as the free base of I.

Apparatus—GLC analysis was performed with a gas chromatograph[2] equipped with a nitrogen–phosphorus detector and a 91-cm × 2-mm column packed with 3% OV-17 on Gas Chrom Q (80–100 mesh)[3]. The

[1] This compound is designated as MK-160 by Merck & Co., Inc.

instrument was operated isothermally with column oven, detector, and injection port temperatures of 250, 275, and 300°, respectively. The carrier gas (helium), hydrogen, and air flow rates were 30, 3, and 50 ml/min, respectively. With daily use, the usable lifespan of the rubidium bead detector was ~2 months.

Procedure—To 1 ml of plasma or urine in a 13-ml glass-stoppered centrifuge tube were added 100 ng of II in 50 μl of methanol and, for plasma analysis only, 1 ml of 0.1 *N* HCl. Eight milliliters of petroleum ether–isoamyl alcohol (100:1) was added, and the tube was shaken for 10 min and centrifuged (600×*g*). Approximately 6.5 ml of the organic layer was transferred to a 13-ml centrifuge tube. The bulk of the solvent was evaporated in a stream of nitrogen in a water bath at 45°, leaving a small volume of isoamyl alcohol. The contents were dissolved in 50 μl of heptane, and 3 μl was injected into the GLC column. A standard curve was prepared by analysis of control human plasma or urine samples containing 6.25, 12.5, 25, 50, and 100 ng of I/ml and 100 ng of II/ml in a total volume of 50 μl of methanol. The ratios of the peak areas of I–II were plotted *versus* nanograms of I added.

6	31
8	29
24	8
32	4[a]

[a] Estimated value since 6.25 ng/ml was the lowest standard concentration analyzed.

RESULTS AND DISCUSSION

As shown in Fig. 1, I and II were adequately separated by the method, with retention times of 2.4 and 3.2 min, respectively. Control plasma or urine samples assayed concurrently gave no significant interfering peaks. Several potential metabolites of I (its sulfoxide, sulfone, and descyclopropylmethyl analogues) had retention times of 5.7, 4.9, and 1.3 min, respectively, and thus would not interfere in the determination of I.

The precision and accuracy of the method were demonstrated by analysis of replicate plasma samples containing known concentrations of I. The results are shown in Table I. The reproducibility of the method was indicated by the relative standard deviations of 18.3, 13.9, 9.6, 6.6, and 2.9%, respectively, for 6.25, 12.5, 25, 50, and 100 ng of I/ml. The accuracy of the procedure was demonstrated by the relative errors of −4, 2, 0, +0.6, and −0.9%, respectively, for 6.25, 12.5, 25, 50, and 100 ng of I/ml. The precision and accuracy of urine analyses were similar to that observed for plasma. The relative standard deviations were 15.9, 2, and 2.9%, respectively, for 6.25, 12.5, and 25 ng of I/ml of urine. The relative errors were +0.8, −4, and 3.2%, respectively, for the same concentrations. The overall recoveries for plasma and urine were ~92 and 78%, respectively.

Although I is a basic compound, its recovery from plasma was considerably higher at slightly acidic, rather than alkaline, pH values. A similar phenomenon has been reported for cinnarizine, a basic substituted piperazine with antihistaminic properties (3).

Plasma levels of I in a human subject are listed in Table II. Peak levels of drug were present at 2 hr postdose; only very low concentrations were observed after 24 or 32 hr. The urine contained no detectable amounts of I at any time after drug administration, nor was any detected in the urine of volunteers given multiple oral doses of I[4]. These results suggest that I is extensively metabolized in humans; studies with [^{3}H]I in animals indicated that I was well absorbed after oral administration. Approximately 10–30% of the dose was excreted in the urine but little or no unchanged I was present in the urine or feces[5].

This report describes a method which has adequate sensitivity to determine I in human plasma after therapeutic dosing. The use of a structurally similar internal standard obviated any need to correct the results for extraction volumes or for incomplete recovery of I from plasma or urine. Lack of interference in the assay by several potential metabolites of the drug was demonstrated.

Oral Bioavailability and Intravenous Pharmacokinetics of Amrinone in Humans

GEORGE B. PARK *, RONALD P. KERSHNER *, JON ANGELLOTTI *, ROGER L. WILLIAMS ‡, LESLIE Z. BENET ‡, and JEROME EDELSON *x

Received April 19, 1982, from the **Department of Drug Metabolism, Sterling-Winthrop Research Institute, Rensselaer, NY 12144* and the ‡*Drug Studies Unit, University of California, San Francisco, CA 94143.* Accepted for publication June 24, 1982.

Abstract □ Fourteen healthy males received two 75-mg doses of amrinone as a single capsule and as an intravenous solution in a single-dose crossover study. The mean (±*SD*) bioavailability, based on the area under the plasma concentration *versus* time curves, was 0.93 ± 0.12. The plasma data for these subjects during the intravenous phase was described by an open two-compartment body model with a mean (±*SD*) apparent first-order terminal elimination rate constant, β, of 0.19 ± 0.06 hr^{-1}, which corresponds to a half-life of 3.6 hr.

Keyphrases □ Amrinone—plasma levels in humans after oral and intravenous doses, pharmacokinetics, bioavailability □ Pharmacokinetics—amrinone after an intravenous dose, described by an open two-compartment body model □ Bioavailability—amrinone after oral and intravenous doses, plasma levels, pharmacokinetics

Amrinone[1], 5-amino[3,4′-bipyridin]-6(1*H*)-one, is a novel cardiotonic agent (1–4) which has demonstrated inotropic activity after both oral and parenteral administration to patients suffering from congestive heart failure (5–8). Previous investigations into the relationship between intravenous and peroral amrinone doses have suggested that it required twice as much amrinone by the oral route to achieve the same inotropic response as with an intravenous bolus (9). This report describes the results of our investigations into the bioavailability of amrinone, and includes a nonlinear least-squares estimate of the pharmacokinetic parameters of amrinone following intravenous administration.

EXPERIMENTAL

Study in Human Volunteers—In this single-dose crossover study, 14 healthy male volunteers each received two 75-mg doses of amrinone, as a single oral capsule and as an intravenous solution, with a 1-week washout interval between medications. The sequence of drug administration for each subject was determined by random assignment. Appropriate institutional review and approval were obtained. No subject had a history suggestive of renal, hepatic, or cardiac dysfunction. The mean (±*SEM*) age of these volunteers was 28.9 ± 1.2 years; the mean weight was 77.4 ± 3.4 kg and the mean height was 180 ± 1.7 cm. Blood samples were collected (potassium oxalate) before medication and at 0.17, 0.33, 0.50, 0.75, 1.0, 1.25, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, 10.0, 12.0, 15.0, and 24.0 hr postdose. The blood was centrifuged; plasma was separated and frozen until it was assayed.

Assay Procedure—The analysis of plasma amrinone followed a published procedure (10) with the following minor changes: a 40° water bath was used to evaporate the residual ethyl acetate and ~2.3% (by volume) of tetrahydrofuran was added to the mobile phase. Plasma standards, which were prepared in normal human plasma, were extracted and analyzed with each set of plasma samples from the subjects in the study. The concentration of amrinone in plasma was determined by comparison with the regression line of the peak height ratios of the standards. The minimum quantifiable level of amrinone was estimated as the concentration whose lower 80% confidence limit just encompassed zero[2] and was ~0.02 μg/ml.

systems were used. Each contained an automatic injector, a pump, a precolumn[3], a column[4], and an UV detector scanning the effluent from the column at 340 nm.

Pharmacokinetic Calculations—The data obtained from the analysis of the human plasma samples during the intravenous phase of the study was described by an open two-compartment body model by means of an unweighted nonlinear regression (NLIN) procedure (11). An attempt was made to describe the plasma concentration data obtained during the oral phase of the study by either an open one- or two-compartment body model with first-order absorption.

In addition to the regression-dependent parameters, the plasma concentration data also was analyzed with respect to the following model-independent parameters: the maximum observed plasma concentration (C_{max}), the time at which the maximum concentration was observed (t_{max}), and the area under the plasma concentration *versus* time curve (AUC_0^{24}). The latter was calculated by trapezoidal rule, including all of the data for the study period. For those subjects who had detectable concentrations of amrinone in the last sample examined, the AUC was extrapolated to infinite time.

RESULTS AND DISCUSSION

The concentrations of amrinone in the plasma samples from each of the volunteers were determined. After intravenous medication, the plasma concentrations declined biexponentially with time, suggesting that a two-compartment body model would be appropriate. Pharmacokinetic parameters for each subject were estimated after computer-fitting the plasma data by an iterative nonlinear least-squares regression technique (11); results are shown in Table I.

The mean apparent first-order terminal elimination half-life for amrinone was ~3.6 hr. The mean apparent volume of distribution at steady state was 94 liters or, dividing by the mean body weight, 1.2 liters/kg. This value suggests that amrinone may be bound to, or partition favorably into tissues. The mean value for α, 8.94 hr^{-1}, corresponds to a half-life of <5 min. The model-independent clearance (dose/AUC_0^∞) is in reasonable agreement with the clearance calculated from the open two-compartment body model (Table I). Although there is a threefold difference between the highest (subject 5) and lowest (subject 6) clearances, the observed concentration data during the intravenous phase was described adequately by the model for both of these subjects; a comparison of the observed and predicted concentrations is shown in Fig. 1. The agreement between the observed values and those predicted by the open two-compartment body model is apparent. The AUC during the intravenous phase of the study was estimated by the trapezoidal method (Table I). The mean ($\pm SD$) value was 4.23 ± 1.74 μg hr/ml.

The plasma concentration data obtained during the oral phase of the study was not described adequately by either the open one- or two-compartment body model with first-order absorption; several weighting schemes were tried. The AUC was determined by the trapezoidal method and, if necessary, extrapolated to infinite time by use of the plasma concentration in the last observed sample and the apparent first-order terminal elimination rate (Table II).

The mean ($\pm SD$) absolute bioavailability, or oral–parenteral ratio (defined as the ratio of the AUC_0^∞ for the capsule to the regression-independent AUC_0^∞ for the intravenous solution) is 0.93 ± 0.12. Analysis of variance shows that the AUC_0^∞ values for medication by either the intravenous or oral route are not significantly different ($p = 0.24$).

Although no rigorous pharmacokinetic analysis was performed, estimates of the terminal elimination half-life of amrinone from the bloodstream of healthy volunteers have been reported (12). The mean values were 2.6 hr after intravenous medication and 3.7 hr after oral treatment. These previously reported values are less than those obtained in the present study, probably due to the shorter time period during which

[3] Phenyl-Corasil; Waters Associates, Milford, Mass.
[4] μ-Bondapak phenyl; Waters Associates, Milford, Mass.

meaningful observations were made. Converting the mean terminal elimination rate constants generated in this study to half-lives results in values of 3.6 and 4.3 hr for the intravenous and oral treatments, respectively. In contrast, chronic congestive heart failure patients who received oral amrinone had a mean terminal elimination half-life of 8.3 hr (7). Since these patients all had symptoms that were sufficient to place them in class III or IV of the New York Heart Association classification, it is not surprising that their low cardiac output should result in a relatively long half-life for amrinone. Therefore, from the pharmacokinetic considerations discussed above, it would seem that an oral dosage regimen involving medication every 8 hr should be adequate for the treatment of patients with congestive heart failure.

Influence of Food on Aspirin Absorption from Tablets and Buffered Solutions

WILLIAM D. MASON[x] and NATHANIEL WINER

Received May 3, 1982, from the *Pharmacokinetics Laboratory, University of Missouri-Kansas City, Schools of Pharmacy and Medicine, Kansas City MO 64108.* Accepted for publication July 14, 1982.

Abstract □ After a standard meal, 12 normal volunteers received three aspirin dosage forms in a single-dose, complete crossover study. The three dosage forms were an unbuffered tablet, an effervescent solution with 16 meq of buffer, and an effervescent solution with 34 meq of buffer. Plasma and urine aspirin, salicylic acid, and salicyluric acid were measured for 10 hr. Significant differences in the absorption kinetics of aspirin were observed, with aspirin from the two solutions being absorbed faster than from the tablet. Urine pH and renal clearance for all three acid compounds were influenced by the buffer during the first 2 hr only. Area under the curve (AUC) and urine accumulation comparisons suggest that 15–20% more aspirin reaches the general circulation after the tablet, but that the total salicylate absorbed is not different. Comparison with an earlier study indicates the solution with 34 meq of buffer is virtually unaffected by the presence of the meal while the solution with 16 meq buffer and the tablet are more slowly absorbed in the nonfasted state.

Keyphrases □ Aspirin absorption—influence of food, comparison of tablets and buffered solutions □ Absorption—aspirin, influence of food

Aspirin is the drug of choice when a mild analgesic–antipyretic is required, and it is also a primary agent used in the chronic management of rheumatoid arthritis and osteoarthritis. After oral administration, rapid absorption is desirable to provide the rapid onset of effects and to reduce contact time with the gastric mucosa. The potential influence of food on the absorption kinetics of aspirin from two different buffered effervescent solutions and an unbuffered tablet dosage form is the subject of this report.

BACKGROUND

A recent report (1) from this laboratory describes the kinetics of aspirin absorption after oral administration of a tablet and two buffered solutions in fasting subjects. It was noted that while the solution with 16 meq of buffer was absorbed more rapidly than the one with 34 meq of buffer, both provided more rapid and less variable absorption than the tablet dosage form. Because the formulation with 34 meq of buffer is frequently used to treat the combined symptoms of headache and upset stomach associated with overindulgence in food and drink, the absorption kinetics of the same three formulations in nonfasted subjects were evaluated.

A recent review (2) describes the effects of food on drug bioavailability in general. Aspirin absorption from two conventional tablet dosage forms is clearly delayed and slowed when administered after a meal (3). Studies of salicylic acid kinetics suggest dispersed dosage forms such as granules (4) and effervescent solutions (5) are less subject to delayed absorption when food is present in the stomach.

Clearly the composition, quantity, and time of aspirin dosing relative to a meal can be significant factors (2, 3) in evaluating the effects of food on drug absorption kinetics. The meal chosen for the present study was previously evaluated (6) to characterize the associated physiological responses of the stomach including emptying rate, pH, and total acid production. Because the titratable acid reaches a maximal plateau between 1 and 2 hr after eating, a dose time 1 hr postcibus should provide a maximal test of the buffered solutions. The study described herein is identical to the one reported previously (1) in all aspects except the subjects in the present study ate a standard meal 1 hr prior to dosing. Two subjects were used in both studies.

EXPERIMENTAL

Dosage Forms—Three commercially available dosage forms were used to provide approximately equal doses of aspirin: two unbuffered tablets[1], each containing 325 mg of aspirin (T); one effervescent tablet[2] containing 640 mg of aspirin, 1.825 g of sodium bicarbonate, and 1.079 g of citric acid (16 meq of buffer) (S-16); and two effervescent tablets[3], each containing 324 mg of aspirin, 1.904 g of sodium bicarbonate, and 1.0 g of citric acid (34 meq of buffer) (S-34).

Terminal log-linear half-life, min	39.0 ± 13.8 b	30.6 ± 14.4 c	23.4 ± 5.4 c

[a] A common letter following the standard deviation indicates no significant difference ($p < 0.05$) (*i.e.*, for AUC to 120 min T and S-16 do not differ and S-16 and S-34 do not differ; however, T and S-34 do differ). [b] MRT is the mean residence time and MAT is the mean absorption time per refs. 7 and 8. MAT computation assumes MRT_{IV} to be 15.6 min for all subjects.

Subjects—Twelve healthy male volunteers, 21–27 years old and weighing 56.9–88.6 kg, were evaluated by a comprehensive physical examination, blood chemistry profile (including blood count and differential), and complete urinalysis. None of the subjects had a history of GI disease or surgery. All were free of any active disease process and none had any medication for 14 days prior to the study.

Methods—A Latin-square design for three treatment in 12 subjects over three consecutive weekends was employed. A 10-hr fast (overnight) was followed by a standard meal (6) consisting of 90 g (uncooked weight) of tenderloin steak, 0.1 g of salt, 25 g of white bread, 8 g of butter, 60 g of vanilla ice cream, 35 g of chocolate syrup, and 240 ml of water. The total caloric value was 458 with approximately 40% fat, 40% carbohydrate, and 20% protein. If blended, the meal provided 540 mosmoles at pH 6.0.

One hour after completing the meal, which was eaten evenly over 30 min, predose blood and urine samples were collected and the aspirin doses administered. A total volume of 240 ml of water, as described previously (1), was given with each dose. After dosing, 100 ml of water was administered at 1, 2, and 3 hr, and each subject ate a uniform meal after the 4-hr blood sample. Subjects remained standing or sitting throughout the day, and exercise was limited to walking about the room. Blood and urine collection and the method of analysis were identical to those used in the preceding study (1).

RESULTS

The mean plasma concentrations and computed parameters for aspirin and salicylic acid are presented in Tables I and II, respectively. The rank order and profile projected in the tables was the same in all 12 subjects except the tablets frequently showed two or three maxima. Urine pH, flow rate, and drug recovery were almost identical to that reported without the meal (1) and, therefore, are not presented in detail herein. From the accumulation as aspirin, salicylic acid, and salicyluric acid in the urine over 10 hr the recovery (projected to infinity) ranged between 65 and 71% for the 36 doses, with no differences among the three dosage forms. Also, the renal clearance of aspirin, salicylic acid, and salicyluric acid agreed with the previously reported fasting study (1), with the salicylurate clearance between 33 and 38 liter/hr for all treatments.

Statistical moments as described by Yamaoka *et al.* (7) and Riegelman and Collier (8) were used and computed as in the previous report (1), with one change. Comparison of the terminal log linear half-lives for aspirin (*i.e.*, 39 ± 13.8, 30.6 ± 14.4, and 23.4 ± 5.4 min) in Table I are longer than previously reported: 14.9 min by Rowland and Riegelman (9) and 15.6 min by Mason and Winer (1), for the elimination half life of aspirin, thus indicating a flip-flop model. Therefore the terminal half-life cannot be used to estimate the elimination rate for aspirin or be used to compute the mean absorption time (MAT). The MAT values in Table I were computed by assuming that each subject has an aspirin elimination half-life of 15.6 min (*i.e.*, MRT_{IV} = 22.5 min), which was the mean estimate in the previous study (1). Computed in this manner the MAT values are estimates of the actual MAT values and represent the differences among the three dosage forms if the total aspirin clearance is constant over the 3 weeks.

DISCUSSION

Although the urine recovery shows the total salicylate absorbed to be about the same for all three dosage forms, there are significant differences in the rate and extent of bioavailability. After the meal, the plasma aspirin curves produced by the two effervescent solutions are almost identical, while the tablets produced later and lower maximum concentrations. The maximal aspirin concentrations for two effervescent solutions are nearly twice that for the tablet dosage form with higher aspirin concentrations by the 5-min sampling time. In addition, the maxima occurs in approximately one-third the time for the effervescent solutions compared with the tablets. These differences and the greater area under the curve (AUC) for the first 2 hr indicate the delaying effect of food on the rate of aspirin absorption from tablets but not on aspirin absorption from effervescent solutions. The areas under the aspirin and salicylic acid curves (when extrapolated to infinity) are ~15% greater for the tablets than for either of the solutions. Consistent with the earlier report (1), greater salicylic acid areas for the tablet dosage form can be attributed to the higher renal clearance with the buffered solutions. The larger aspirin area for the tablet suggests more drug has undergone gastric absorption, thus escaping intestinal metabolism. This hypothesis is supported by the fact that only a small proportion (1–2%) of aspirin clearance is renal, and thus even the observed twofold changes cannot significantly alter the plasma time curve.

Aspirin absorption kinetics can be complex with tablet dissolution, gastric absorption, and gastric emptying all being rate-determining processes. The statistical moment approach makes no assumption concerning the absorption kinetics and treats aspirin kinetics as a purely stochastic process. The MRT values for the tablet are almost twice those for the two solutions and reflect the longer residence time for aspirin in the body after the tablets. If the total aspirin clearance is constant for the three treatments then the greater MRT for the tablets is due to its remaining in the GI tract longer. The MAT values show that a longer time interval (about 40 min) is required for 63.2% of the aspirin to be absorbed after administration of the tablets than after administration of the solutions. These results primarily reflect the rate at which aspirin leaves the stomach and enters the intestine and/or the continued dissolution of the tablets. As noted above, the acid gastric contents and longer residence in the stomach result in some absorption occurring through the gastric mucosa and less intestinal metabolism.

In the fasting subjects S-16 was absorbed more rapidly than S-34 and

Table II—Mean Plasma/Urine Salicylic Acid Data and Computed Parameters

Renal Clearance[b] 0–2 hr, liter/hr	0.11 ± 0.14 b	0.19 ± 0.12 b	0.39 ± 0.25 c
Terminal log-linear half-life, hr.	3.55 ± 1.06 b	2.76 ± 0.63 c	2.76 ± 0.62 c

[a] A common letter following the standard deviation indicates no significant difference ($p < 0.05$) (*i.e.*, at the 4-hr salicylate concentration all three means are significantly different as none share a common letter). [b] Although the renal clearance for S-16 and T do not differ significantly at $p < 0.05$ one can reject the null hypothesis if the willingness to accept a Type I error is increased to about 10% (*i.e.*, $p < 0.1$).

had a greater AUC (1). The presence of a meal has eliminated these differences. The more highly buffered solution (S-34) has the same profile and almost identical estimated kinetic parameters (MAT_{meal} = 18.8 min; $MAT_{fasting}$ = 19.81 min) for absorption with and without a meal, while the S-16 solution is absorbed more slowly with a meal present (MAT_{meal} = 21.9 min, $MAT_{fasting}$ = 15 min).

The report by one group (3) that very little aspirin is bioavailable (*i.e.*, 5–8% nonfasting and 16–18% fasting) is not consistent with the 68% estimated by Rowland and Riegelman (9). The difference probably results from the application of a compartment model (3) to estimate elimination and absorption rate constants when delayed and/or continued absorption rendered such modeling inappropriate (flip-flop model). As discussed previously (1) the bioavailability of aspirin is influenced by the ratio of gastric emptying rate to gastric absorption rate, with the absolute bioavailability in the ~50–60% range.

In summary, the absorption of aspirin from tablets after a meal is significantly slower than from buffered effervescent solutions. Both 16 and 34 meq of soluble buffer produce relatively rapid absorption with similar peak aspirin plasma concentration. Comparisons with an earlier work show the 34 meq of buffer to provide plasma aspirin and salicylate profiles which are the same for fasted and nonfasted subjects. These data suggest that for occasional therapy intended to produce high plasma aspirin concentrations rapidly in both fasted and nonfasted individuals, buffered effervescent solutions are significantly better than nonbuffered aspirin tablets.

Rapid and Simplified Assay for Thyroid in Pharmaceutical Preparations by Potentiometric Titration

STEVEN L. RICHHEIMER ˣ **and MERL S. SCHACHET**

Received April 12, 1982, from the *Quality Control Division, Pharmaceutical Basics, Inc., Denver, CO 80223.* Accepted for publication July 1, 1982.

Abstract □ A procedure for the determination of thyroid (thyroid hormone) in pharmaceutical preparations by titration with 1 m*M* silver nitrate using an ion-selective electrode was developed and evaluated. Samples were combusted according to the USP procedure and analyzed with a minimum of work-up for iodine content. The results obtained by this method were compared with those obtained by the official methods. The recovery of iodide from spiked placebo samples was investigated. The method is applicable to content uniformity analyses as well as to bulk material and to the analysis of organically bound iodide in other pharmaceutical preparations such as sodium levothyroxine tablets. The method is fast, simple, accurate, applicable to automation, and is suitable for routine quality control use.

Keyphrases □ Thyroid—determination in pharmaceutical preparations, potentiometric titration of iodide □ Thyroid and sodium levothyroxine analyses—assay by potentiometric titration, content uniformity analyses

The USP XX method (1) for the assay of thyroid (thyroid hormone) in tablets and bulk material involves combustion of the samples at 675–700° with potassium carbonate followed by oxidation under acidic conditions to iodate by heating with excess bromine. The addition of potassium iodide converts the iodate to iodine, which is then titrated with sodium thiosulfate (2). The method for content uniformity analyses involves oxygen flask combustion followed by conversion of the iodine to triiodide ion and spectrophotometric determination. These methods are lengthy and filled with difficulties.

This report describes a simplified method for the assay of organically bound iodide, which uses an iodide-selective electrode (3–6). The method is applicable to the analysis of not only thyroid in tablets and bulk material but also to other pharmaceutical preparations in which organically bound iodine is determined.

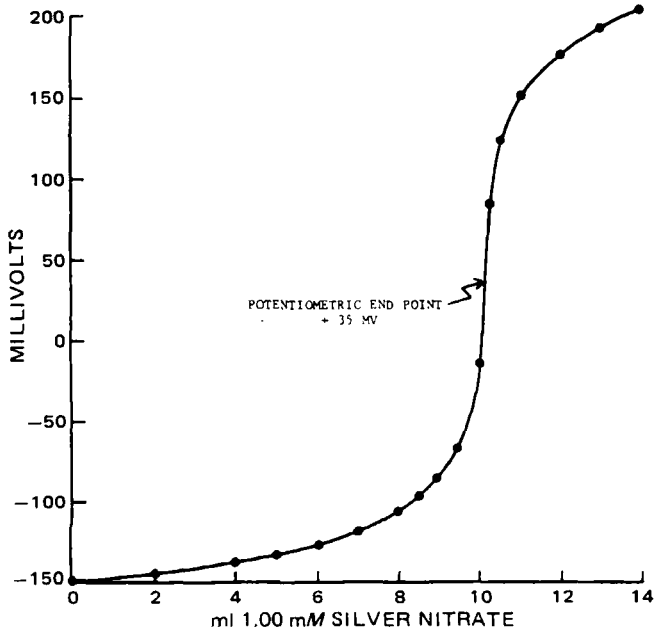

Figure 1—*Titration curve of a titrated thyroid sample containing ~0.01 meq of iodide with 1.00 m*M *silver nitrate using an iodide-sensing electrode, pH 2.5. Arrow indicates potentiometric end point + 35 mV.*

EXPERIMENTAL

Reagents and Materials—Sodium iodide reference standard (0.100 *M*)[1] was used as received or diluted as required with water; 1.00 m*M* silver nitrate solution was prepared by dilution of 0.100 *M* silver nitrate solution[2] and standardized by potentiometric titration against 1.00 m*M* iodide standard. This solution is quite stable if protected from light. Anhydrous potassium carbonate[3] was technical grade; dilute phosphoric acid was made by 1:1 dilution of reagent grade (85%) phosphoric acid[4]; deionized water[5] was used throughout; crucibles were porcelain[6] and all other tablet excipients were pharmaceutical grade and obtained commercially. The thyroid tablets were manufactured by Pharmaceutical Basics, Inc.

Apparatus and Equipment—A muffle furnace[7] was used for sample combustion. The specific ion electrodes used were an iodide-sensing electrode[8] and a silver-sulfide-sensing electrode[9]; the reference electrode was a double-junction type[10]. The potentiometric titrations were performed either automatically or manually to a predetermined millivolt end point using an end-point titrator fitted with a 20-ml dispensing buret unit and an antidiffusion buret tip[11].

Sample Preparation—*Uncoated Tablets and Bulk Material*—Twenty tablets were ground to a fine powder and a portion equivalent to ~635 mg of thyroid (proportionately less should be used if the iodine content is >0.2%) was weighed into a large crucible; this portion was mixed with ~8 g of anhydrous potassium carbonate, compressed, and then overlayed with 16 g of carbonate. The mixture was ignited at 675–700° in a preheated muffle furnace for 25 min. The cooled char was transferred to a 600-ml beaker, using water to facilitate the transfer, and then acidified to pH 2.5 ± 1 with dilute phosphoric acid while stirring vigorously with a magnetic stirrer. Water was added to bring the volume to 400 ml, and the mixture was titrated immediately with 1 m*M* silver nitrate to the potentiometric end point using an iodide-sensing electrode and a suitable reference electrode. (Each milliliter of 1 m*M* silver nitrate is equivalent to 0.1269 mg of iodine.)

Coated Tablets—The coated sample was prepared in the same way as the uncoated tablets except that the char was treated with hot water, filtered and then acifidied with dilute phosphoric acid, and the volume brought to 400 ml with water. (If calcium sulfate is used in the formulation, the acidified solution is boiled for at least 30 min.) The solution was cooled to room temperature and titrated with 1 m*M* silver nitrate to the potentiometric end point.

Content Uniformity Analyses—The procedure for uncoated or coated tablets was followed, except that 10 tablets were individually analyzed.

Sodium Levothyroxine Tablets—Twenty tablets were finely powered and an amount equivalent to 1–2 mg of sodium levothyroxine was weighed into a crucible. The procedure for uncoated tablets was followed

RSD, %	4.6	3.6	3.4

except that each milliliter of 1 m*M* silver nitrate was equivalent to 0.1997 mg of sodium levothyroxine.

RESULTS AND DISCUSSION

Figure 1 shows the titration curve obtained with a typical thyroid sample containing ~0.01 meq of iodide is titrated with 1 m*M* silver nitrate using an iodide-sensing electrode and a suitable reference electrode. The end point occurs at about +35 milivolts mV in this sample but may vary according to the electrode pair used. A similar curve is obtained using a silver-sensing electrode. The iodide electrode can also be used to quantitatively measure inorganic iodide in thyroid preparations. Changing the pH of the solution from 1.5 to 3.5 has very little effect on the overall titration curve and the end point (± 5 mV). For content uniformity determinations of low-strength thyroid preparations (16–65 mg), the curve is shifted somewhat to a lower millivolt end point. Therefore, it is advisable to determine the end point of such samples in advance by titrating a representative sample and plotting the titration curve. Since the break in the curve near the end point is sharp, and since there is a change of almost 200 mV within ±0.5 ml of the end point, it is practical to titrate thyroid samples automatically using either an end-point titrator or recording titrator. It is also possible to perform the titrations manually using a pH–mV meter and buret to the predetermined end point.

Comparison of the USP XX Method—A 130-mg (2 gr) uncoated thyroid tablet was assayed by potentiometric titration and by the USP XX method. The results are shown in Table I and indicate that this method gives results equivalent to the USP method. Filtration of the charcoal produced in the combustion process is not necessary for ordinary compressed tablets if the sample is titrated immediately. However, stirring the sample in the presence of charcoal at pH 2.5 slowly oxidizes the iodide. In addition to this tablet, numerous lots of thyroid tablets (both coated and uncoated) and capsules and bulk material were assayed by both the USP and potentiometric titration methods. The two methods agreed closely, although the proposed method gave somewhat more consistent results, which were also closer to the theoretical input.

Recovery of Iodide from Spiked Placebos—Placebo mixtures containing excipients found in typical coated and uncoated thyroid tablets were prepared and spiked with iodide over the range of 0.0085–0.0115 meq (equivalent to 0.17–0.23% iodine). The recovery of iodide from the spiked samples was quantitative, and the relative standard deviations (*RSD*) of the recoveries varied from 0.58 to 1.24%. Linearity was excellent (r = 1.00), and placebo blanks showed that there was no interference from the tablet excipients (millivolt reading past the end point). The results are summarized in Table II.

Table II—Recovery of Iodide Added to Placebo Preparations

Average recovery, %	98.9	100.9	100.7
Number of determinations	10	10	10
Range, %	96.0–104.0	98.8–103.7	98.4–101.9
RSD, %	3.33	1.60	1.60

Effect of Calcium Sulfate—When calcium sulfate is used in the formulation of coated tablets, sulfide is produced in the combustion process. Since sulfide interferes with both the iodide and silver-sensing electrodes, methods were investigated to remove this interfering ion. The addition of heavy metals, such as Ni(II), was not successful in removing the interference, while addition of hydrogen peroxide oxidized the sulfide but also slowly oxidized the iodide. Boiling of the filtered, acidified solution was found to be an acceptable method for removing the interfering sulfide. However, in samples with less sulfide, such as content uniformity samples, the boiling step can be eliminated by acidifying the char before filtration. Apparently the charcoal produced in the combustion process oxidizes the sulfide to a noninterfering form (possibly persulfide), since the addition of ascorbic acid again generates sulfide.

Content Uniformity Assays—The described method has been successfully applied to routine quality control work for content uniformity determinations of tablets ranging in potency from 16 to 324 mg of thyroid. For low-potency tablets the volume of titrant is small and the electrode response is slower; such samples may require manual titration. Table III summarizes the results obtained when placebo samples spiked with 0.00025, 0.001, and 0.003 meq of iodide (corresponding to 16-, 65-, and 195-mg tablets) are assayed by the present method. The results indicate that recovery of the added iodide is quantitative and that reproducibility is good.

Analysis of Sodium Levothyroxine Tablets—The above procedure provides a fast and accurate method for the analysis of sodium levothyroxine (I) in tablets. Sample preparation is the same as for uncoated thyroid tablets, except that an amount of powered tablets equivalent to 1–2 mg of I is used. Mean recoveries of I added to placebo mixtures were 99.8% (11 determinations; *RSD* 1.8%) for a 0.1-mg preparation and 99.2% (six determinations; *RSD* 0.7%) for a 0.3 mg tablet. Linearity of the method in both cases was excellent (r = 0.99).

Cobaltous Chloride-Induced Hypothermia in Mice III: Effect of Pretreatment with 5-Hydroxytryptaminergic Agents

DAVID H. BURKE ˣ, JACK C. BROOKS, and SUZANNE B. TREML

Received June 10, 1982, from the *Divisions of Pharmacology and Physiology, Marquette University School of Dentistry, Milwaukee, WI 53233.* Accepted for publication July 1, 1982.

Abstract □ The influence of various 5-hydroxytryptaminergic agonist and antagonist drugs on body-temperature response to cobaltous chloride in mice was noted. Pretreatment with *p*-chloroamphetamine, *p*-chlorophenylalanine, and *p*-iodoamphetamine antagonized the body-temperature response to cobalt. *p*-Chloroamphetamine and *p*-chlorophenylalanine reduced, while *p*-iodoamphetamine elevated, brain serotonin levels. The uptake inhibitor agents, fluoxetine and nisoxetine, failed to modify the ability of *p*-chloroamphetamine to antagonize cobalt hypothermia. Cyproheptadine, methergoline, and xylamidine pretreatment enhanced rather than antagonized body-temperature depression by cobalt. Tryptophan hydroxylase inhibitors antagonized cobalt hypothermia, but receptor-blocking agents were without influence, indicating that antagonism was mediated through mechanisms other than the depletion of serotonin. Elevation rather than depletion of brain serotonin by *p*-iodoamphetamine and failure of uptake inhibitors to modify *p*-chloroamphetamine antagonism of cobalt hypothermia lend further support for a nonserotonergic role of these amines in their ability to antagonize body-temperature depression by cobaltous chloride in mice.

Keyphrases □ Cobaltous chloride—induced hypothermia in mice, pretreatment with 5-hydroxytryptaminergic agents □ Hypothermia—induction in mice with cobaltous chloride, effects of pretreatment with 5-hydroxytryptamingeric agents

Cobaltous chloride has been reported to produce a dose-dependent depression of body temperature in several species, apparently through a centrally mediated decrease in heat production (1). Subsequent studies in this laboratory revealed that chlorpromazine was capable of antagonizing cobalt-induced hypothermia in mice, and it was concluded that central α-receptor blockade and/or peripheral antihistaminic activity, but not anticholinergic activity, may have contributed to this partial antagonism (2). Most recently, *p*-chloroamphetamine hydrochloride has been shown to attenuate markedly the body temperature response to cobalt in this same species (approximately 60% antagonism) (3). Although this compound has not been extensively studied in mice, it appeared possible that its well-known antiserotonin qualities may contribute to antagonism of the body temperature depression. The present report describes the influence of various 5-hydroxytryptaminergic agonists and antagonists on the body-temperature response to cobaltous chloride in mice.

EXPERIMENTAL

Male Swiss albino mice (20–30 g) were used in this investigation. The animals were housed in groups of 6–20 with *ab libitum* access to food[1] and water for at least 3 days prior to use. The mice were kept in a draft-free room under constant-temperature conditions (23 ± 1°) and maintained on a 12-hr light/dark cycle. All drugs were freshly prepared with distilled water in concentrations (calculated as the salt) such that a volume of 0.01 ml/g was delivered. Methergoline was solubilized with distilled water acidified to pH 3.8 with ascorbic acid. All injections were delivered by the intraperitoneal route.

A thermistor thermometer[2] was used for obtaining rectal temperature. Temperatures were recorded with a thermistor probe inserted 2.5 cm and held in position until constant readings were attained.

At the beginning of each experiment the mice were placed in individual circular wire-mesh cages, and weights were obtained with a triple-beam balance[3], after which initial temperatures were recorded and the treatment was administered. Temperatures were recorded again at various intervals. Control animals received distilled water (0.01 ml/g). To study the influence of various serotonergic agonist and antagonist agents on cobalt-induced hypothermia, pretreatment injections (water, *p*-chloroamphetamine HCl[4], *p*-iodoamphetamine HCl[5], *p*-chlorophenylalanine methyl ester HCl[4], fluoxetine HCl[5], nisoxetine HCl[5], cyproheptadine HCl[6], methergoline[7], and xylamidine tosylate[8]) were given at specified intervals prior to recording the initial temperatures.

Serotonin levels were recorded with a spectrophotofluorometer[9] according to the method of Curzon and Green (4), modified by Hyyppä *et al.* (5), with a standard curve relating relative fluorescence to serotonin concentration.

To compare mean temperature changes (*i.e.*, the difference between temperature immediately prior to and at the appropriate interval following treatment), statistical significance was determined by use of Student's *t* test. Temperature differences were considered significant at the probability level of 5% or less.

RESULTS

Cobaltous chloride (25 mg/kg ip) was administered at the appropriate interval following pretreatment with *p*-chloroamphetamine, *p*-iodoamphetamine, and *p*-chlorophenylalanine in groups of at least eight animals; body temperatures were monitored for a 4-hr period. The results of this experiment are shown in Fig. 1. Pretreatment with a single daily dose of 100 mg/kg of *p*-chlorophenylalanine for 3 consecutive days prior to the intraperatoneal administration of cobaltous chloride resulted in a reduction in the intensity and duration of the body temperature response. This antagonism was similar, but of less magnitude, to that seem in the case of *p*-chloroamphetamine (10 kg/kg ip 1 hr prior to cobalt). *p*-Iodoamphetamine pretreatment (10 mg/kg ip 1 hr before cobalt) also antagonized cobalt hypothermia and was less potent than *p*-chloroamphetamine.

Whole-brain serotonin levels were determined 2 hr following administration of *p*-chloroamphetamine and *p*-iodoamphetamine and 24 hr following the last of three single daily doses of 100 mg/kg of *p*-chlorophenylalanine in mice. *p*-Chloroamphetamine and *p*-chlorophenylalanine both significantly reduced whole-brain serotonin levels, while *p*-iodoamphetamine increased serotonin levels at the 2-hr interval (Table I).

The influence of fluoxetine and nisoxetine on the ability of *p*-chloroamphetamine to antagonize cobalt body temperature depression is presented in Table II. These uptake inhibitor agents both failed to modify the *p*-chloroamphetamine antagonism in doses known to reduce *p*-chloroamphetamine-induced serotonin depletion.

The body-temperature response to cobaltous chloride (25 mg/kg ip) was monitored at various intervals following the administration of 1 mg/kg each of cyproheptadine, methergoline, and xylamidine. In every

Table I—Effect of Intraperitoneal *p*-Chloroamphetamine, *p*-Chlorophenylalanine, and *p*-Iodoamphetamine on Serotonin Concentration in Mice Brains

Drug	Serotonin, μg/g ± *SE*[a]		
	Controls	Treated[b]	Change, %
p-Chloroamphetamine	0.6585 ± 0.012	0.4413 ± 0.015	−32.98
p-Chlorophenylalanine	0.6612 ± 0.025	0.5904 ± 0.020	−10.71
p-Iodoamphetamine	0.6549 ± 0.022	0.7208 ± 0.021	+10.06

[a] Brains were removed from groups of at least eight mice 2 hr following the injection of 10 mg/kg of *p*-chloroamphetamine and *p*-iodoamphetamine and 24 hr following the third of three consecutive daily injections of 100 mg/kg of *p*-chlorophenylalanine. Control animals received 0.01 ml/g body weight of water instead of drug treatment. [b] Compared with appropriate water-treated control, $p < 0.05$.

case, 5-hydroxytryptaminergic receptor-blocking agent pretreatment enhanced rather than antagonized body temperature depression (Table III). The ascorbic acid vehicle for solubilizing methergoline did not alter body temperature, nor did it influence the body temperature response to cobaltous chloride.

DISCUSSION

The nature of body temperature response to cobaltous chloride in mice at present is poorly understood. However, the recent observation that cobalt hypothermia could be antagonized in part by pretreatment with *p*-chloroamphetamine suggests a possible serotonergic involvement (3). For example, cobalt may have acted indirectly in the CNS to release serotonin from neuronal storage sites into the vicinity of postsynaptic serotonergic receptors involved in the regulation of body temperature. One problem, however, with the use of *p*-chloroamphetamine as a pharmacological tool in the short term is its lack of specificity. For example, in addition to depletion of serotonin, this halogenated arylalkylamine has been shown to alter dopamine and norepinephrine synthesis in the rat (6). Thus, it is conceivable that other (nonserotonergic) mechanisms might also contribute to the development of hypothermia following the administration of cobaltous chloride.

The influence of *p*-chloroamphetamine on serotonergic nerve function has been extensively studied in the rat. Pletscher *et al.* (7) first reported that this compound causes a marked reduction in brain concentrations of 5-HT and 5-hydroxyindoleacetic acid in this species. Several mechanisms have been proposed to explain the action of this agent at the cellular level. Of these mechanisms, the inhibition of the rate-limiting enzyme tryptophan hydroxylase might possibly account for the rapid depletion of serotonin by *p*-chloroamphetamine in the short term. *p*-Iodoamphetamine also has been reported to decrease serotonin synthesis through the inhibition of tryptophan hydroxylase (8). One of the most commonly employed tryptophan hydroxylase inhibitors is *p*-chlorophenylalanine (9). The present investigation has shown that all three tryptophan hydroxylase inhibitors were capable of reducing the intensity and duration of cobalt hypothermia. These findings suggest that antagonism was accomplished through serotonin depletion, perhaps through inhibition of the rate-limiting enzyme in the synthesis of serotonin. However, similar antagonism of cobalt-induced hypothermia with central or peripheral serotonin receptor-blocking agents could not be demonstrated. The latter observations do not support the suggestion that *p*-chloroamphetamine antagonism of cobalt hypothermia was mediated through an antiserotonin influence.

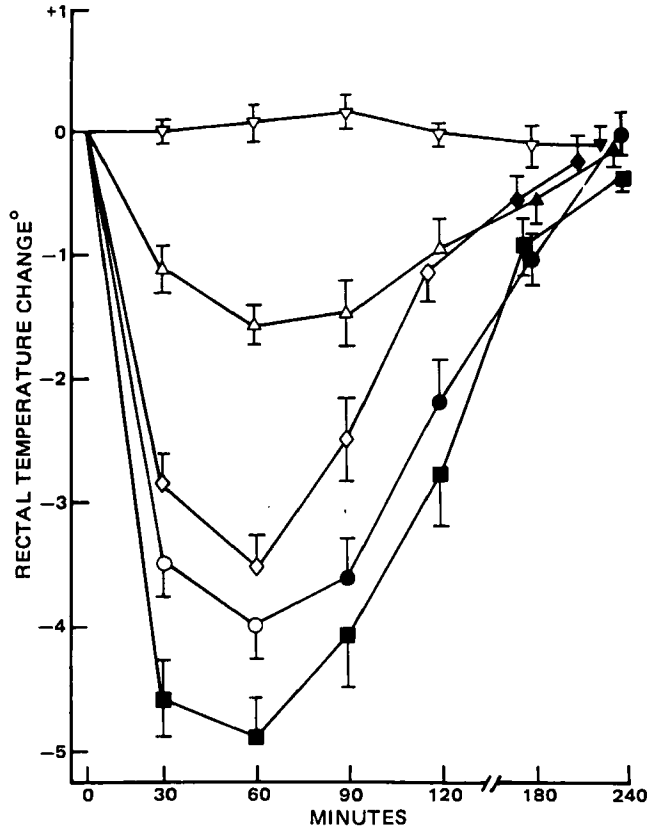

Figure 1—*Time course of the effect of 0.01 ml/g ip of distilled water (-▼-); 25 mg/kg ip of cobaltous chloride (-■-); 10 mg/kg ip of* p-*chloroamphetamine hydrochloride 1 hr prior to 25 mg/kg ip of cobaltous chloride (-▲-); three consecutive daily doses of 100 mg/kg ip of* p-*chlorophenylalanine methyl ester hydrochloride 24 hr prior to 25 mg/kg ip of cobaltous chloride (-●-); 10 mg/kg ip of* p-*iodoamphetamine 1 hr prior to 25 mg/kg ip of cobaltous chloride (-◆-) on the rectal temperature in mice. Water and cobaltous chloride were administered at time zero. Open symbols denote significant difference ($p < 0.05$) from cobalt treatment at the corresponding time interval. Each point represents the average of at least eight determinations. Vertical bars represent standard errors.*

Little information exists in the literature with respect to halogenated amphetamine effects on serotonergic neuronal function in mice, particularly in the case of *p*-iodoamphetamine. A previous study showed that *p*-chloroamphetamine causes depletion of serotonin from the brains of mice (3). In the present study we were unable to demonstrate a similar depletion with *p*-iodoamphetamine. In contrast, serotonin levels were significantly increased at the 2-hr interval following the intraperitoneal injection of *p*-iodoamphetamine. These observations suggest that mechanisms other than depletion of serotonin are involved in antagonism of cobalt-induced hypothermia by the halogenated arlalkylamines, *p*-

Table II—Interaction of Fluoxetine and Nisoxetine with *p*-Chloroamphetamine on the Body Temperature Response to Cobaltous Chloride in Mice

Pretreatment[a]	Treatment[b]

chloroamphetamine and *p*-iodoamphetamine. In addition, the finding that uptake inhibitors (fluoxetine and nisoxetine) failed to modify halogenated amphetamine reversal of cobalt hypothermia further supports an extraserotonergic role of these amines in their ability to antagonize body temperature depression by cobaltous chloride.

The results presented in this report do not support the suggestion that cobaltous chloride hypothermia is mediated through the release of serotonin from intraneuronal storage sites. For example, the serotonin receptor-blocking agents, cyproheptadine, methergoline, and xylamidine, were incapable of attenuating the body temperature response. While it seems inviting to postulate an influence of cobalt on the neuronal storage of dopamine and/or norepinephrine, previous studies utilizing 6-hydroxydopamine failed to reveal catecholaminergic involvement (2). It is likely that cobalt produces hypothermia through a mechanism or mechanisms which are at present undefined.

Effect of Cimetidine on the Pharmacokinetics of Quinidine and Lidocaine in the Rat

RICHARD J. FRUNCILLO ˣ, G. JOHN DiGREGORIO, and ADAM SOLL

Received March 23, 1982, from the *Department of Pharmacology, Hahnemann Medical College and Hospital, Philadelphia, PA 19102.* Accepted for publication July 9, 1982.

Abstract □ Because of previously reported drug interactions involving cimetidine and liver-metabolized drugs, the intravenous pharmacokinetics of quinidine (25 mg/kg) and lidocaine (15 mg/kg) were investigated in anesthetized rats pretreated with a single intraperitoneal dose of cimetidine (60 mg/kg) and compared with saline pretreated controls. Significant reductions of 35 and 23% in the respective total clearances of quinidine and lidocaine were observed in the presence of cimetidine. The quinidine volume of distribution was significantly decreased in the cimetidine-treated rats, while the lidocaine volume of distribution was not altered significantly. There was no significant change in the elimination half-life for either drug in the presence of cimetidine. These results suggest cautious use of quinidine or lidocaine when cimetidine is prescribed concurrently.

Keyphrases □ Cimetidine—inhibition of lidocaine and quinidine clearances in the rat, kinetics □ Lidocaine—inhibition of clearance in the rat by cimetidine, kinetics □ Quinidine—inhibition of clearance in the rat by cimetidine, kinetics □ Kinetics—of the inhibition of lidocaine and quinidine clearances in the rat by cimetidine

Cimetidine, a histamine H_2-receptor antagonist, is prescribed widely for the therapy of peptic ulcers. Human pharmacokinetic studies have demonstrated that cimetidine in therapeutic doses impairs the elimination of drugs metabolized by cytochrome P-450-dependent pathways, such as antipyrine (1), theophylline (1), diazepam (2),

Table III—Effect of Pretreatment with 5-Hydroxytryptaminergic Receptor Blocking Agents on the Body Temperature Response to Cobaltous Chloride in Mice

Pretreatment[a]	Treatment[b]			
	Water		Cobaltous Chloride	
	Initial Temperature °[c]	Temperature Change °[d] (Mean ± SE)	Initial Temperature °[c]	Temperature Change °[d] (Mean ± SE)
Water	36.83	+0.13 ± 0.09	36.96	−4.73 ± 0.33[e]
Methergoline[f]	36.83	+0.25 ± 0.14	37.02	−6.12 ± 0.47[g]
Cyproheptadine	37.28	+0.03 ± 0.23	37.22	−5.97 ± 0.48[g]
Xylamadine	36.85	+0.22 ± 0.13	36.74	−5.56 ± 0.34[g]

[a] Water (0.01 ml/g), methergoline (1 mg/kg), cyproheptadine hydrochloride (1 mg/kg), and xylamidine tosylate (1 mg/kg) were administered intraperitoneally to groups of 10 animals. [b] Intraperitoneal water (0.01 ml/g) and cobaltous chloride (25 mg/kg) treatments were given 4 hr following pretreatment injection. [c] Initial temperatures were recorded immediately prior to water or cobalt treatment. [d] Temperature changes represent the difference between body temperature recorded initially and that obtained 30 min after treatment. [e] Compared with water–water (Pretreatment–Treatment), $p < 0.05$. [f] Methergoline was solubilized in distilled water acidified to pH 3.8 with ascorbic acid. [g] Compared with water–cobalt (Pretreatment–Treatment), $p < 0.05$.

chloroamphetamine and *p*-iodoamphetamine. In addition, the finding that uptake inhibitors (fluoxetine and nisoxetine) failed to modify halogenated amphetamine reversal of cobalt hypothermia further supports an extraserotonergic role of these amines in their ability to antagonize body temperature depression by cobaltous chloride.

The results presented in this report do not support the suggestion that cobaltous chloride hypothermia is mediated through the release of serotonin from intraneuronal storage sites. For example, the serotonin receptor-blocking agents, cyproheptadine, methergoline, and xylamidine, were incapable of attenuating the body temperature response. While it seems inviting to postulate an influence of cobalt on the neuronal storage of dopamine and/or norepinephrine, previous studies utilizing 6-hydroxydopamine failed to reveal catecholaminergic involvement (2). It is likely that cobalt produces hypothermia through a mechanism or mechanisms which are at present undefined.

chlordiazepoxide (3), propranolol (4), warfarin (5), and phenytoin (6). The clearances of drugs such as lorazepam and oxazepam, which are eliminated by glucuronidation, are unaffected by cimetidine (7). Studies using *in vitro* rat liver homogenates have revealed that cimetidine inhibits aminopyrine *N*-demethylation and benzo[*a*]pyrene hydroxylation in a concentration-dependent manner (8). Similar results were found in homogenates obtained from human liver biopsies (9). Quinidine and lidocaine are two popular antiarrhythmic agents dependent on cytochrome P- 450 liver metabolism for inactivation (10). This present study investigates the effect of cimetidine on the pharmacokinetics of these drugs in the rat.

EXPERIMENTAL

Male Sprague–Dawley rats[1], weighing 220–250 g on the day of the study, were used. They were housed in groups of four in plastic cages over corn cob bedding in a well-ventilated room (24° ± 0.5°) with alternate 12-hr periods of light and dark. Food[2] and water were provided *ad libitum*.

After being acclimated to their cages for at least 5 days, the rats were anesthetized with 1.7 g/kg of urethane, an anesthetic that does not inhibit drug metabolism (11) and which has been reported to maintain hepatic blood flow at a level equal to that of an awake animal (12). The right and left jugular veins were surgically exposed by superficial skin incisions above both clavicles, and either 60 mg/kg of cimetidine or 1 ml/kg of saline was injected intraperitoneally. Thirty minutes after the injections, both groups of rats received either 15 mg/kg (free base) of lidocaine or 25 mg/kg (free base) of quinidine intravenously through the right jugular vein. Blood samples (0.4 ml) were taken at 10, 20, 30, 40, and 50 min postinjection (lidocaine) or at 0.5, 1, 2, 3, and 4 hr postinjection (quinidine). Samples were obtained by needle puncture of the left jugular vein using heparinized tuberculin syringes. Plasma lidocaine and quinidine concentrations were measured by commercially available enzyme immunoassay kits[3], as described previously (13).

The plasma disappearance of both drugs was treated as a one-compartment model and considered to follow the exponential function $C(t) = Ae^{-\lambda t}$ where $C(t)$ is the plasma concentration at time t, A is the time zero intercept, and λ is the elimination rate constant. The elimination half-life was calculated by $t_{1/2} = 0.693/\lambda$, the volume of distribution by V_D = dose/A, and the clearance by $CL = V_D\lambda$. The parameters were calculated for each animal by least-squares analysis of a semilogarithmic plot of drug concentrations *versus* time. Statistical calculations were performed using the two-tailed Student's t test.

RESULTS AND DISCUSSION

Figures 1 and 2 illustrate the respective average plasma disappearance curves for quinidine and lidocaine in cimetidine- and saline-pretreated rats; Table I shows the derived pharmacokinetic parameters. The administration of cimetidine caused a 35% reduction in quinidine clearance compared with saline-treated rats (significant at the $p < 0.05$ level). Likewise, cimetidine produced a significant (23%) reduction in lidocaine clearance ($p < 0.05$). There was a significant decrease in the quinidine volume of distribution in the cimetidine-treated rats ($p < 0.05$); however, the lidocaine volume of distribution was not significantly altered. There was no significant change in elimination half-life for either drug.

These results demonstrate that cimetidine, in a single dose, will prolong the clearance of either quinidine or lidocaine in the rat. They are similar to the findings of Desmond *et al.* (14), in which a single dose of cimetidine significantly prolonged the half-life of aminopyrine in the rat. All of the human pharmacokinetic studies reported to date were done after multiple doses of cimetidine; however, Patwardhan *et al.* (15) reported a decreased clearance of chlordiazepoxide as early as 24 hr after treatment with cimetidine, with recovery to baseline clearance 48 hr after discontinuing the cimetidine. Thus, it appears that a certain level of cimetidine is needed in the organism to manifest the inhibitory affect on drug metabolism. The exact mechanism by which cimetidine exerts its effect at the enzyme level is not entirely certain. Both competitive and noncompetitive inhibition of *in vitro* drug-metabolizing enzymes has been shown for various substrates (16).

There has been speculation that H_2-receptor blockade may play a role in the observed depression of drug clearances. However, a recent report demonstrated that the new H_2-receptor antagonist ranitidine did not inhibit drug metabolism (16). This fact supports the concept that the imidazole structure of cimetidine is responsible for its inhibitory effects, since similar structures are known to depress drug metabolism (17); ranitidine has a furan ring structure.

Table I—Effect of Cimetidine on the Pharmacokinetics of Quinidine and Lidocaine

Parameter	Quinidine[b] Treated: Saline Pretreatment (5)	Quinidine[b] Treated: Cimetidine Pretreatment (4)

CL ml/min/kg	46.5 ± 3.8	36.0 ± 2.1[c]

[a] Animals were pretreated with cimetidine 60 mg/kg ip or saline and received the test drug 30 min later. Results are means ± *SEM* with the number of animals in parentheses. [b] Dosage levels were 25 and 15 mg/kg iv, respectively, for quinidine and lidocaine. [c] $p < 0.05$ *versus* saline-treated animals, two-tailed Student's t test.

Quinidine and lidocaine are drugs that have intermediate-to-high hepatic extraction ratios and metabolites formed by the hepatic mixed-function oxidase system (10). Therefore, their clearances should be dependent both on liver blood flow and drug-metabolizing enzyme activity (18). The most likely explanation for the decreased clearances observed in this study is inhibited drug metabolism; however, decreased liver blood flow may play a role since a single dose of cimetidine has been shown to reduce hepatic blood flow 25% in humans (4). Since quinidine and lidocaine are drugs with narrow therapeutic ranges, decreases in their clearances could potentially lead to drug accumulation with resultant toxicity. Evaluated blood levels of quinidine have been associated with cinchonism, arrhythmias, and syncope, while increased lidocaine levels have been linked to confusion, seizures, and respiratory arrest (10). Therefore, frequent measurement of quinidine and lidocaine serum levels are recommended when cimetidine is prescribed concurrently, pending human pharmacokinetic studies on these interactions.

Acetaminophen–Aluminum Hydroxide Interaction in Rabbits

MING-MEEI CHEN *, CHARLES LEE ‡, YORISHIGE IMAMURA *, and JOHN H. PERRIN *x

Received March 25,1982, from the **Department of Pharmaceutics, College of Pharmacy, University of Florida, Gainesville, FL 32610*, and the ‡*Pharmaceutics Department, College of Pharmacy, University of Houston, Houston, TX 77030.* Accepted for publication July 8, 1982.

Abstract □ Acetaminophen–aluminum hydroxide interaction was investigated in a crossover study using six rabbits. Blood samples were collected at various time intervals for up to 6 hr following the oral administration of acetaminophen alone or in combination with aluminum hydroxide. Aluminum hydroxide at a 40-mg/kg dose did not appear to affect the rate and extent of acetaminophen absorption. The influence of aluminum hydroxide on gastric emptying could be compromised by gastric absorption of acetaminophen, resulting in a negligible effect on the overall bioavailability of acetaminophen.

Keyphrases □ Acetaminophen and aluminum hydroxide interaction—crossover study in rabbits, pharmacokinetics □ Aluminum hydroxide—effect on rate and extent of acetaminophen absorption in rabbits □ Pharmacokinetics—rate and extent of acetaminophen absorption in rabbits with and without aluminum hydroxide administration

Retarded drug absorption in the presence of aluminum hydroxide has been demonstrated in animals and humans (1). This pharmacokinetic interaction probably results from a slowed gastric emptying (1). *In vitro*, aluminum ion inhibits the contractile response of human and rat gastric strips to acetylcholine (2). This effect is possibly due to the antagonization by aluminum of calcium influx into smooth muscle cells during depolarization, leading to a delay in muscle contractions (3).

Acetaminophen (weak acid, pK_a 9.5) is a common, nonprescription, analgesic drug. It is not clear whether acetaminophen is completely free of damaging effects on the gastric mucosa, although minimal or no gastric structural damage has been found to be induced by acetaminophen in marked contrast to aspirin (4). Since acetaminophen is believed to cause less damaging effects, it has replaced aspirin as the analgesic of choice in many situations. However, acetaminophen is frequently used in combination with aspirin in nonprescription drugs (5), necessitating the use of antacids to avoid the gastric damage induced by aspirin, or perhaps acetaminophen.

[a] Mean data of six rabbits. Statistical difference of the mean was tested by Student's paired t test, $p > 0.8$ for α, $p > 0.75$ for β, and $p > 0.55$ for AUC.

The delayed absorption of salicylic acid from tablets buffered with aluminum hydroxide has been documented previously (6). A recent review of drug interactions with acetaminophen and aspirin was presented by Hayes (7). This study is undertaken to verify the drug interaction between acetaminophen and aluminum hydroxide using the rabbit model.

EXPERIMENTAL

Materials—Acetaminophen[1] and aluminum hydroxide[2] were reagent grade and were used without further purification. Appropriate strengths of acetaminophen alone or in combination with aluminum hydroxide were prepared in warm deionized water (37°) prior to oral administration to rabbits.

Animal Studies—The validity of the rabbit model for drug absorption has been discussed in a previous publication (8). Six male New Zealand rabbits weighing 2.8–4.6 kg were studied in a crossover design, with a 2-week washout period allowed between studies. Rabbits were fasted for 38–42 hr prior to the experiment, but water was allowed *ad libitum*. Food and water were withheld during the experiment. Acetaminophen (100 mg/kg) alone or in combination with aluminum hydroxide (40 mg/kg) was dissolved in 70 ml of warm deionized water and was administered orally to the rabbit by intubation. The intubation line was flushed with 30 ml of warm water to ensure complete delivery of the drugs to the stomach. Blood samples (0.5 ml each) were collected from the ear vein in heparinized tubes[3] at 0 (just before experiment), 0.25, 0.5, 0.75, 1.0, 1.5, 2, 3, 4, 5, and 6 hr. After centrifugation of the blood samples, plasma aliquots were obtained for analysis of acetaminophen content.

Drug Assay—Plasma acetaminophen was assayed by a high-performance liquid chromatographic method (9). Vanillin[4] was used as an internal standard. The assay method provided a minimum detectable concentration of 0.5 μg/ml in plasma. However, since 0.2-ml aliquots of plasma were the maximal volume available for analysis, the minimum detectable quantity was 0.1 μg.

RESULTS AND DISCUSSION

Acetaminophen, alone or in combination with aluminum hydroxide, was rapidly absorbed in rabbits, with the peak plasma concentration occurring within 15 min of drug administration. Mean plasma data obtained from the two crossover studies are presented in Table I. Following the administration of acetaminophen alone and in combination with aluminum hydroxide, similar plasma levels of acetaminophen were observed at corresponding time intervals for all the rabbits. Since plasma concentrations of acetaminophen appeared to decay biexponentially, data were fitted to a biexponential function using the NONLIN program (10). The distribution parameter (α) and the elimination parameter (β) thus obtained from the curve fitting are presented in Table II. The mean parameter values are not significantly different from each other ($p > 0.8$ for α; $p > 0.75$ for β). The lack of difference in mean values of α and β was expected, since aluminum hydroxide presumably affected drug absorption but not the distribution and/or elimination.

Values for area under the plasma concentration–time curve (AUC) were estimated according to the trapezoidal rule and the extrapolation method. Values for mean AUC were similar, 45.39 μg hr/ml for acetaminophen alone and 43.26 μg hr/ml for acetaminophen in combination, indicating no significant difference in the extent of acetaminophen absorption between the two treatments ($p > 0.55$). Since blood sampling was not carried out during the first 15 min after drug administration, it was not clear whether aluminum hydroxide affected the rate of acetaminophen absorption. However, a drug interaction of this magnitude would be of minimal clinical significance if it indeed occurred. By the same token, since areas covering 0–15 min constituted <10% of the total estimated areas, the effect of aluminum hydroxide, if indeed seen in the first 15 min, would not affect the overall bioavailability of acetaminophen. Therefore, it is to be concluded, based on these data, that aluminum hydroxide affected neither the rate nor the extent of acetaminophen absorption.

Aluminum salts have been known to delay the absorption of various drugs in animals and in humans. *In vitro* experiments have demonstrated that aluminum ion antagonizes the contractile response of human and rat gastric strips to acetylcholine. Although *in vitro* experiments demonstrating the antagonizing effect of aluminum ion have not been conducted in rabbits, a similar conclusion to that found for the human and rat would be drawn. At the 40-mg/kg dose used in this study, aluminum hydroxide did not appear to affect the rate and extent of acetaminophen absorption. This dose, on a weight basis, was approximately three times the therapeutic dose of the antacid used in humans. Acetaminophen is an acidic compound, a fact that favors its absorption from the stomach according to the pH partition theory. Although the gastric emptying might be delayed in the presence of aluminum hydroxide, the effect could be compromised by the gastric absorption of acetaminophen. The acetaminophen dose used in this study, 100 mg/kg, was approximately three times the recommended maximal daily dose for humans; whereas, the 40-mg/kg dose of aluminum hydroxide was similar to that used in a drug–antacid interaction study in humans (11).

Hurwitz (1) proposed that only drug products in which absorption is not rate limited by dissolution are subject to a significant gastric emptying effect. Acetaminophen is in this category. To eliminate the dissolution factor, a solution of acetaminophen instead of solid dosage forms was used in this study. Therefore, any interaction found in this study was the exclusive effect of gastric emptying and gastric absorption of the interactants. Since acetaminophen is available as solid dosage forms for human use, direct extrapolation of rabbit data to the human situation is not deemed appropriate. However, it is felt that any acetaminophen–aluminum hydroxide interaction, if indeed one occurs in humans, will be of minimal clinical significance based on results of this study in rabbits. The proof awaits further investigation in humans.

High-Yield Synthesis of Warfarin and Its Phenolic Metabolites: New Compounds

ERNIE BUSH and WILLIAM F. TRAGER ˣ

Received April 15, 1982, from the *Department of Medicinal Chemistry, University of Washington, Seattle, WA 98195.* Accepted for publication June 29, 1982.

Abstract □ A novel synthesis of warfarin and phenolic warfarin metabolites is presented which results in higher yields than previous methods.

Keyphrases □ Warfarin—phenolic metabolites, new high-yield synthetic method □ Synthesis—warfarin and its phenolic metabolites, new high-yield method

The oral anticoagulant warfarin [4-hydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (I) has found extensive clinical use in the treatment of such pathological conditions as thrombophlebitis, pulmonary emboli, and myocardial infarction (1). It is also used widely as a rodenticide to help control rat populations (2) and more recently has been used as a probe to investigate the multiplicity and catalytic activity of microsomal and purified cytochrome P-450 preparations (3–7). Because of its clinical and pharmacological importance, considerable effort has been expended to develop analytical methods to quantitate both warfarin and its metabolites from biological matrices (8–11). However, one of the impediments to progress in this area has been the lack of a high-yield synthetic procedure for these materials. Since mechanistic work in this laboratory on cytochrome P-450 required the synthesis and optical resolution of specifically deuterated warfarin analogues as substrates and multideuterated metabolites as GC–MS assay internal standards, the need for a reproducible, high-yield synthesis for these compounds was evident.

Although successful synthetic routes to these materials are documented in the literature, the reported yields are poor to moderate at best (12). Warfarin has been synthesized by the Michael addition of 4-hydroxycoumarin to benzalacetone under a number of acid- or base-catalyzed conditions (13). Traditionally, the reaction has most often been run in water containing a catalytic amount of triethylamine (~5 mole %). Hermodson *et al.* (12), using essentially the same conditions, extended this synthesis to the phenolic metabolites of warfarin by condensing benzalacetone with the appropriately substituted 4-hydroxycoumarin. Fasco *et al.* (14) followed a similar route, but to obtain a homogeneous system substituted dioxane as the solvent and piperidine as the catalyst. A further refinement was reported by Cook *et al.* (15) who, in their synthesis of 3′-bromowarfarin, heated a solution of *m*-bromobenzalacetone and 4-hydroxycoumarin in pyridine at reflux. However, rarely was the overall yield of warfarin or hydroxywarfarin >65%. In the case of 7-hydroxywarfarin, it was invariably much lower.

II:	Warfarin Ethyl Ether	C_2H_5	H	H
III:	Cyclocoumarol	CH_3	H	H
IV:	6-Hydroxywarfarin	H	OH	H
V:	7-Hydroxywarfarin	H	H	OH
VI:	6-Hydroxycyclocoumarol	CH_3	OH	H
VII:	7-Hydroxycyclocoumarol	CH_3	H	OH

RESULTS AND DISCUSSION

Numerous attempts in this laboratory to improve previous yields by alternate reaction pathways failed. A new approach was conceived when it was found that warfarin was quantitatively converted to its ethyl ether (II) by refluxing in absolute ethanol. This observation suggested that in absolute ethanol, the acidity of 4-hydroxycoumarin might be sufficient to catalyze its condensation with benzalacetone to generate warfarin. Once formed, the reaction would be driven to completion by the subsequent and essentially irreversible formation of the ethyl ether under these conditions. Initial experiments investigating this possibility proved successful. Complete removal of the ethanol, however, proved to be difficult; therefore, methanol was substituted as the solvent, with equal success. This extended the necessary reaction time, presumably because of the lower reaction temperature; however, the lower temperature also allowed the relatively unstable starting material (4,7-dihydroxycoumarin) to be converted to the warfarin methyl ether (VII) in high yield.

The reaction involved stirring an appropriate coumarin analogue with benzalacetone in refluxing methanol. After 4–24 hr, as determined by TLC, the corresponding methyl ether was obtained in high yield. The ether can be quantitatively converted back to the warfarin analogue by acid hydrolysis. Typically, overall yields are >70%, and often yields as high as 95% are obtained. This dramatic increase in reaction yields should significantly aid in the development of warfarin as a tool to probe metabolic pathways.

EXPERIMENTAL[1]

Warfarin [4-Hydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (I)—4-Hydroxycoumarin (1.0 g, 0.0069 mole) was stirred

[1] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. NMR spectra were recorded on a Varian EM-360A spectrometer using tetramethylsilane as internal standard. 4-Hydroxycoumarin was purchased from the Aldrich Chemical Co., and benzalacetone was purchased from MCB Reagents. 4,6- and 4,7-Dihydroxycoumarin were gifts from Dr. Lawrence Low, University of Washington. TLC was performed on EM Reagents analytical silica gel chromatography plates with flourescent indicator (no. 5539). All other solvents and reagents were of reagent purity.

RESULTS AND DISCUSSION

Numerous attempts in this laboratory to improve previous yields by alternate reaction pathways failed. A new approach was conceived when it was found that warfarin was quantitatively converted to its ethyl ether (II) by refluxing in absolute ethanol. This observation suggested that in absolute ethanol, the acidity of 4-hydroxycoumarin might be sufficient to catalyze its condensation with benzalacetone to generate warfarin. Once formed, the reaction would be driven to completion by the subsequent and essentially irreversible formation of the ethyl ether under these conditions. Initial experiments investigating this possibility proved successful. Complete removal of the ethanol, however, proved to be difficult; therefore, methanol was substituted as the solvent, with equal success. This extended the necessary reaction time, presumably because of the lower reaction temperature; however, the lower temperature also allowed the relatively unstable starting material (4,7-dihydroxycoumarin) to be converted to the warfarin methyl ether (VII) in high yield.

The reaction involved stirring an appropriate coumarin analogue with benzalacetone in refluxing methanol. After 4–24 hr, as determined by TLC, the corresponding methyl ether was obtained in high yield. The ether can be quantitatively converted back to the warfarin analogue by acid hydrolysis. Typically, overall yields are >70%, and often yields as high as 95% are obtained. This dramatic increase in reaction yields should significantly aid in the development of warfarin as a tool to probe metabolic pathways.

EXPERIMENTAL[1]

Warfarin [4-Hydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (I)—4-Hydroxycoumarin (1.0 g, 0.0069 mole) was stirred

[1] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. NMR spectra were recorded on a Varian EM-360A spectrometer using tetramethylsilane as internal standard. 4-Hydroxycoumarin was purchased from the Aldrich Chemical Co., and benzalacetone was purchased from MCB Reagents. 4,6- and 4,7-Dihydroxycoumarin were gifts from Dr. Lawrence Low, University of Washington. TLC was performed on EM Reagents analytical silica gel chromatography plates with flourescent indicator (no. 5539). All other solvents and reagents were of reagent purity.

0022-3549/83/0700-0830$01.00/0

at reflux for 20 hr with benzalacetone (1.0 g, 0.0069 mole) in 50 ml of methanol. At this time, TLC (cyclohexane–ether, 1:1) indicated that all of the starting material had been converted to cyclocoumarol (III). The solvent was removed under reduced pressure and the residue was dissolved in 50 ml of acetone. An equal volume of 5 *N* HCl was added, and the solution was agitated in a 37° water bath for 4 hr or until TLC indicated complete hydrolysis to warfarin. Saturated aqueous NaCl (10 ml) was added and the mixture was extracted three times with 50 ml of ether. The combined ether extracts were back-extracted three times with 20 ml of 10% NaOH; the aqueous layer was filtered and reacidified to pH 2 with 5 *N* HCl. The resulting precipitate was collected by filtration, triturated with ether, and dried. Recrystallization from acetone–water (13) gave 1.98 g (93% yield) of I, mp 159–161° [lit. (12) 161°]. The NMR (dimethyl sulfoxide-d_6) was identical to that of authentic warfarin.

6-Hydroxywarfarin [4,6-Dihydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (VI)—6-Hydroxywarfarin was synthesized following the aforementioned procedure using 4,6-dihydroxycoumarin (0.5 g, 0.0028 mole) and benzalacetone (0.5 g, 0.0034 mole) in 30 ml of methanol. The product was recovered as described above and recrystallized from acetone–chloroform (12) to give 0.83 g (91% yield) of VI, mp 217–220° [lit. (12) 219–220°].

7-Hydroxywarfarin [4,7-Dihydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (VII)—7-Hydroxywarfarin was synthesized following the aforementioned procedure using 4,7-dihydroxycoumarin (0.2 g, 0.0011 mole) and benzalacetone (0.2 g, 0.0014 mole) in 20 ml of methanol. The product was recovered as described above and recrystallized from acetone–chloroform (12) to give 0.27 g (77% yield) of VII, mp 206–209° [lit. (12) 208–210°].

Synthesis of 4-Substituted *N*-[(Dimethylamino)methyl]benzamides: New Compounds

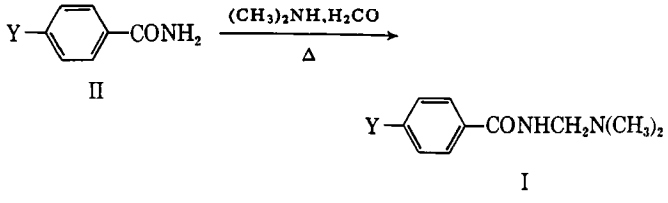
NILO ZANATTA and ROBERTO RITTNER *x

Received November 23, 1981 from the Instituto de Química, Universidade de São Paulo, C.P. 20.780, São Paulo, Brazil. Accepted for publication June 16, 1982. *Present address: Instituto de Química—UNICAMP, Caixa Postal 6154, 13.100—Campinas—São Paulo, Brazil.

Abstract □ Nine 4-substituted-*N*-[(dimethylamino)methyl]benzamides were obtained in high yield from the corresponding 4-substituted benzoic acids *via* the corresponding benzamides.

Keyphrases □ *N*-[(Dimethylamino)methyl]benzamides—4-substituted synthesis *via* Mannich–Einhorn reaction □ Amidomethylation reaction—synthesis of 4-substituted *N*-[(dimethylamino)methyl]benzamides

To investigate the possible relationship between electronic structure and local anesthetic properties, simple model compounds were required. The 4-substituted *N*-[(dimethylamino)methyl]benzamides[1] (I) were chosen as models since they are closely related to the procainamides, which are widely used as local anesthetics (1). These compounds have the advantage of being readily available from the 4-substituted benzamides (II) in a single step, using the Mannich–Einhorn reaction (2, 3). The 4-substituted benzamides (II) are either commercially available (4), or are readily prepared by conventional methods (5–9).



Y = H,F,Cl,Br,I,OCH$_3$,CH$_3$,N(CH$_3$)$_2$.

Scheme I

This study reports the application of the Mannich–Einhorn reaction (Scheme I) to the synthesis of I, and discusses the preparation of the starting materials (II), which were not commercially available.

EXPERIMENTAL[2]

4-Substituted *N*-[(dimethylamino)methyl]benzamide (I) was prepared by refluxing a mixture of a 4-substituted benzamide (II) (0.071 mole), 40% aqueous dimethylamine (17.4 ml; 0.142 mole), 35% aqueous formaldehyde (12.2 ml; 0.142 mole), and water (15 ml) with stirring for 4 hr.

[1] The key to the labeling of the 4-substituted amides (I) is in Table I.

[2] Melting points were determined in a Kofler apparatus and are uncorrected. IR spectra were determined in a Perkin-Elmer 457A spectrophotometer. NMR spectra were obtained with a Varian T-60 spectrometer using tetramethylsilane as the internal standard. Elemental analyses were performed at the Microanalysis Laboratories of the Instituto de Química—USP, São Paulo.

The resulting precipitate was collected by filtration, triturated with ether, and dried. Recrystallization from acetone–water (13) gave 1.98 g (93% yield) of I, mp 159–161° [lit. (12) 161°]. The NMR (dimethyl sulfoxide-d_6) was identical to that of authentic warfarin.

6-Hydroxywarfarin [4,6-Dihydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (VI)—6-Hydroxywarfarin was synthesized following the aforementioned procedure using 4,6-dihydroxycoumarin (0.5 g, 0.0028 mole) and benzalacetone (0.5 g, 0.0034 mole) in 30 ml of methanol. The product was recovered as described above and recrystallized from acetone–chloroform (12) to give 0.83 g (91% yield) of VI, mp 217–220° [lit. (12) 219–220°].

7-Hydroxywarfarin [4,7-Dihydroxy-3-(1-phenyl-3-oxobutyl)-2*H*-1-benzopyran-2-one] (VII)—7-Hydroxywarfarin was synthesized following the aforementioned procedure using 4,7-dihydroxycoumarin (0.2 g, 0.0011 mole) and benzalacetone (0.2 g, 0.0014 mole) in 20 ml of methanol. The product was recovered as described above and recrystallized from acetone–chloroform (12) to give 0.27 g (77% yield) of VII, mp 206–209° [lit. (12) 208–210°].

Synthesis of 4-Substituted *N*-[(Dimethylamino)methyl]benzamides: New Compounds

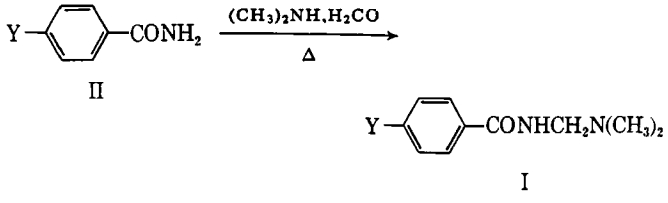
NILO ZANATTA and ROBERTO RITTNER *x

Received November 23, 1981 from the Instituto de Química, Universidade de São Paulo, C.P. 20.780, São Paulo, Brazil. Accepted for publication June 16, 1982. *Present address: Instituto de Química—UNICAMP, Caixa Postal 6154, 13.100—Campinas—São Paulo, Brazil.

Abstract □ Nine 4-substituted-*N*-[(dimethylamino)methyl]benzamides were obtained in high yield from the corresponding 4-substituted benzoic acids *via* the corresponding benzamides.

Keyphrases □ *N*-[(Dimethylamino)methyl]benzamides—4-substituted synthesis *via* Mannich–Einhorn reaction □ Amidomethylation reaction—synthesis of 4-substituted *N*-[(dimethylamino)methyl]benzamides

To investigate the possible relationship between electronic structure and local anesthetic properties, simple model compounds were required. The 4-substituted *N*-[(dimethylamino)methyl]benzamides[1] (I) were chosen as models since they are closely related to the procainamides, which are widely used as local anesthetics (1). These compounds have the advantage of being readily available from the 4-substituted benzamides (II) in a single step, using the Mannich–Einhorn reaction (2, 3). The 4-substituted benzamides (II) are either commercially available (4), or are readily prepared by conventional methods (5–9).



Y = H,F,Cl,Br,I,OCH$_3$,CH$_3$,N(CH$_3$)$_2$.

Scheme I

This study reports the application of the Mannich–Einhorn reaction (Scheme I) to the synthesis of I, and discusses the preparation of the starting materials (II), which were not commercially available.

EXPERIMENTAL[2]

4-Substituted *N*-[(dimethylamino)methyl]benzamide (I) was prepared by refluxing a mixture of a 4-substituted benzamide (II) (0.071 mole), 40% aqueous dimethylamine (17.4 ml; 0.142 mole), 35% aqueous formaldehyde (12.2 ml; 0.142 mole), and water (15 ml) with stirring for 4 hr.

[1] The key to the labeling of the 4-substituted amides (I) is in Table I.

[2] Melting points were determined in a Kofler apparatus and are uncorrected. IR spectra were determined in a Perkin-Elmer 457A spectrophotometer. NMR spectra were obtained with a Varian T-60 spectrometer using tetramethylsilane as the internal standard. Elemental analyses were performed at the Microanalysis Laboratories of the Instituto de Química—USP, São Paulo.

The cooled solution was poured into a saturated aqueous sodium carbonate solution (50 ml), extracted with diethyl ether (3 × 30 ml), and dried over magnesium sulfate. The solvent was evaporated *in vacuo*, and the residue was recrystallized from benzene–petroleum ether to give a 40–90% yield of product.

DISCUSSION

The syntheses of the starting materials (II) for the Mannich–Einhorn reaction, were carried out as described previously (5–9). Oxidation of 4-anisaldehyde, 4-tolualdehyde, and 4-*N*-dimethylaminobenzaldehyde with an aqueous solution of silver nitrate–sodium hydroxide (10) gave the corresponding benzoic acids in yields of 40, 53, and 81%, respectively. The alternative procedure using silver oxide–ammonium hydroxide (5) failed and led to an explosive mixture. The 4-fluoro-, 4-bromo-, and 4-iodobenzoic acids were prepared as described previously (6–8) in yields of 86, 52, and 50%, respectively, following the diazotization of 4-aminobenzoic acid. Benzoic, 4-chlorobenzoic, and 4-nitrobenzoic acids were commercial products. All 4-substituted benzoic acids were converted to the corresponding benzoyl chlorides using thionyl chloride and catalytic amounts of dimethylformamide (11). The crude products were poured onto an excess of concentrated ammonium hydroxide (9) which led to the formation of the corresponding benzamides in yields of 70–80%. These 4-substituted benzamides, when treated with 35% aqueous formaldehyde and 40% aqueous dimethylamine gave the corresponding Mannich bases (I) (12), which were characterized by physical and spectral data (Tables I and II, respectively).

Estimating the Accumulation of Drugs

Keyphrases □ Drug accumulation—estimation during chronic dosing, theoretical *versus* empirical calculations □ Accumulation ratios—impact of lag time, effect of dosing

To the Editor:

Several methods are available to estimate the accumulation (R) of drugs during chronic dosing. The following equations are the ones most commonly used:

$$R_1 = \frac{AUC^1_{0-\infty}}{AUC^1_{0-\tau}} = \frac{AUC^{ss}_{0-\tau}}{AUC^1_{0-\tau}} \quad \text{(Eq. 1)}$$

$$R_2 = \frac{C_{min(ss)}}{C_{min(1)}} \quad \text{(Eq. 2)}$$

$$R_3 = 1/1 - e^{-\beta\tau} \quad \text{(Eq. 3)}$$

where $AUC^1_{0-\tau}$ and $AUC^1_{0-\infty}$ are the areas under the plasma concentration–time curves during a dosing interval and from time 0 to ∞ following a single dose, and $AUC^{ss}_{0-\tau}$ is the area under the plasma concentration–time curves during a dosing interval at steady state. $C_{min(1)}$ and $C_{min(ss)}$ are the plasma concentrations immediately prior to the administration of the second dose and any dose at steady state, respectively; and β and τ are the elimination rate constant and dosing interval, respectively.

Equations 1 and 2 can be determined empirically, whereas equation 3 is a theoretical calculation. If the pharmacological effect of the drug is a function of the plasma concentration, the R_1 values reflect the relevant accumulation, in that R_1 is a simple ratio of the observed concentrations during a dosing interval after a dose at steady state divided by the observed concentrations during the dosing interval after the first dose. R_2 values would be expected to closely approximate the relevant accumulation ratio (R_1) when k_a is larger compared with β but diverge as k_a approaches β, since the time of the maximum plasma concentration (C_{max}) moves closer to the time of drug administration during multiple dosing (1), and this will result in differences in C_{min} during multiple dosing. In general, the equation that uses β as the sole determinant of R (R_3) would be expected to deviate the most from R_1 and, in fact, only truly represents the accumulation during intravenous bolus administration.

Accumulation ratios (R) were estimated with a dosing interval equal to the half-life under known conditions using each of these equations with and without a lag time (t_{lag}) prior to the onset of absorption. The results of these calculations are presented in Table I. R_1 is always larger than R_2 and R_3. As the absorption half-life increases and k_a/β decreases these differences become more pronounced. In addition, when a lag time is incorporated the deviations among the three methods become more obvious. The reason for this deviation due to a lag time is displayed graphically in Fig. 1. Following the first dose, the lag time reduces the area during a dosing interval, whereas at steady state the lag time does not affect the area during a dosing interval.

Table I—Accumulation Ratios (R) Estimated by Various Commonly Used Methods with a Dosing Interval of 24 hr [a]

Parameter	k_a/β 24		12		4		2		1.1	
t_{lag}, hr	0	2	0	2	0	2	0	2	0	2
R_1	2.1	2.2	2.2	2.4	2.8	3.1	4.0	4.5	6.1	6.9
R_2	2.0	2.0	2.0	2.0	2.1	2.2	2.7	2.8	3.7	4.0
R_3	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0	2.0

[a] $t_{1/2}\,k_a$ = 1, 2, 6, 12, and 21.8 hr; $t_{1/2}\,\beta$ = 24 hr; τ = 24 hr.

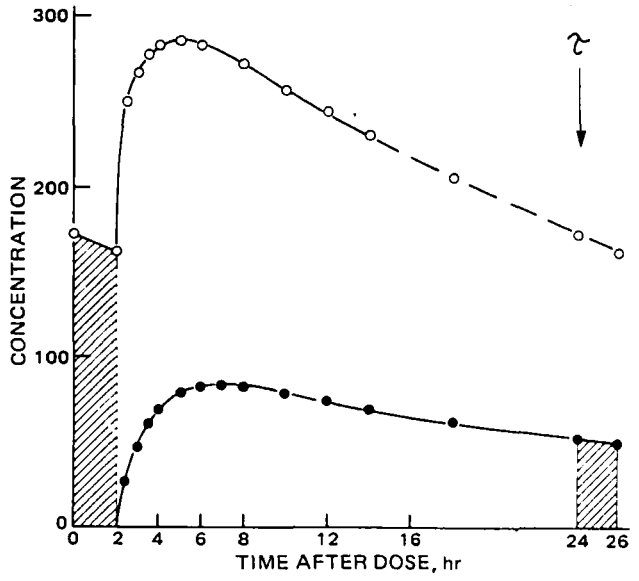

Figure 1—*Concentration–time profiles during a 24-hr dosing interval following first (—) and steady-state (- - -) doses when an absorption lag time occurs. The area that affects the prediction of accumulation is shaded. No area is lost at steady state, whereas the AUC from 24 to 26 hr is lost after a single dose.*

R values simulated when the same k_a/β ratios are employed but the dosing interval (τ) is altered are presented in Table II. It is apparent that the dosing interval significantly influences the deviations from R_1. Shorter dosing intervals cause greater deviations from the relevant accumulation ratio (R_1).

A composite view shows that several factors including lag time, dosing interval, and the ratio of k_a/β can influence the predictive capacity of Eqs. 2 and 3 compared with the true accumulation ratio estimated by Eq. 1. Although the need to use Eqs. 2 and 3 with caution and under specific conditions has been recognized (2), the impact of lag time and the actual deviations observed under appropriate use has been generally overlooked (3, 4). When one doses every

Table II—Accumulation Ratios (R) Estimated by Various Commonly Used Methods with a Dosing Interval of 12 or 48 hr [a]

Parameter	k_a/β 24		12		4		2		1.1	
τ, hr	12	48	12	48	12	48	12	48	12	48
R_1	3.8	1.4	4.3	1.4	7.1	1.5	11.6	1.8	19.8	2.4
R_2	3.4	1.3	3.5	1.3	4.6	1.3	6.8	1.4	10.8	1.7
R_3	3.4	1.3	3.4	1.3	3.4	1.3	3.4	1.3	3.4	1.3

[a] $t_{1/2}\,k_a$ = 1, 3, 6, 12, and 21.8 hr; $t_{1/2}\beta$ = 24 hr.

0022-3549/83/0700-0833$01.00/0

half-life, as is generally accepted as optimum therapy from a pharmacokinetic point of view, deviations occur even when k_a/β is large. When the dosing interval is decreased the deviations become greater. When k_a/β approached unity, as would be expected from certain controlled-release dosage forms, the deviations become enormous. In addition, it must be realized that although R_2 more closely reflects R_1 values than does R_3, it is not a predictive method, in that one must achieve steady state to determine $C_{min(ss)}$, whereas R_1 and R_3 can be used predictively following a single dose. These variables must be kept in mind when one is attempting to anticipate or predict drug accumulation and consequent pharmacological effects from single-dose data.

Fraction Unbound in Interstitial Fluid

Keyphrases □ Pharmacokinetics—fraction unbound in interstitial fluid, relationship between binding in interstitial and vascular space

To the Editor:

The influence of protein binding of drugs on their pharmacological effect and pharmacokinetic disposition has been widely studied (1–3). However, most of the experimental observations have involved the interaction of drugs with plasma or serum proteins and not extravascular proteins. The lack of useful, experimental observations in this area is a result of the difficulty in obtaining representative tissue samples and the inadequate methods for performing tissue-binding studies (4). A mathematical approach has been derived (5) for estimating the fraction unbound in the "tissue" space utilizing a calculated volume of distribution term and anticipating physiological spaces. However, this approach is limited and only provides a complex average fraction unbound located outside the vascular space. Therefore, alternative theoretical approaches, as well as experimental methods need to be developed.

Nowhere is the role of plasma and tissue binding of greater interest than in the area of antibiotic therapy (6, 7). In general, β-lactam antibiotics are restricted in their distribution to the vascular space and the interstitial fluids; they do not penetrate intracellularly. Attempts to study the tissue (interstitial) binding of these antibiotics have centered on the collection of fluid from tissue cages (8), but the physiological character of the collected fluid has been questioned (9). The purpose of the present communication is to derive a theoretical relationship that relates the binding of a drug in the extravascular–extracellular or interstitial space to the binding in the vascular space. The original model on which this work is based was put forth by Øie *et al.* (10) and was recently used to describe the distribution of ceftriaxone (11). This theoretical relationship is used to explain the lack of distributional changes occurring with ceftriaxone despite the dramatic changes in the fraction unbound in the plasma (11).

The interaction of drugs with plasma proteins is usually described by the following Langmuir binding isotherm:

$$C_{BP} = \sum_{i=1}^{m} \frac{n_i P^* C_U}{Kd_i + C_U} \qquad \text{(Eq. 1)}$$

where C_{BP} is the plasma concentration of bound drug, m is the number of classes in binding sites, n_i is the number of binding sites for the ith class of binding sites, P is the concentration of the binding protein located in the vascular space, C_U is the concentration of unbound drug, and Kd_i is the equilibrium dissociation constant for the ith class of binding sites.

The presence of plasma proteins (*i.e.*, albumin) in the interstitial fluids has been well documented (12). If one assumes that the drug–protein interaction in the interstitial space is identical to the interaction in the vascular space (equivalent capacity and affinity constants), then a similar Langmuir relationship can be written for the interstitial binding:

$$C_{BE} = \sum_{i=1}^{m} \frac{n_i E^* C_U}{Kd_i + C_U} \qquad \text{(Eq. 2)}$$

where C_{BE} is the interstitial concentration of the bound drug and E is the concentration of binding protein in the interstitial space.

Equation 1 can be rewritten to factor out the protein and unbound concentration to yield:

$$C_{BP} = P^* C_U^* \sum_{i=1}^{m} \frac{n_i}{Kd_i + C_U} \qquad \text{(Eq. 3)}$$

For ease of manipulation, let a new parameter, S, replace the summation term:

$$C_{BP} = P^* C_U^* S \qquad \text{(Eq. 4)}$$

Given the assumptions concerning equivalent binding proteins in the vascular and interstitial spaces, and the additional assumptions of: (*a*) equal unbound drug concentration in both physiological spaces; (*b*) Kd_i does not change at lower protein concentrations; (*c*) other mechanisms of tissue distribution such as active transport, selective membrane permeability, and ion trapping are not present, then the S term for both C_{BP} and C_{BE} are equal, and a similar rearrangement and substitution can be written for C_{BE}:

$$C_{BE} = E^* C_U^* S \qquad \text{(Eq. 5)}$$

By definition, the fraction unbound in the plasma or vascular space (f_P) may be written as:

$$f_P = \frac{C_U}{C_U + C_{BP}} = \frac{1}{1 + P^* S} \qquad \text{(Eq. 6)}$$

A similar fraction unbound in the interstitial space (f_E) may be written as:

0022-3549/83/0700-0834$01.00/0

half-life, as is generally accepted as optimum therapy from a pharmacokinetic point of view, deviations occur even when k_a/β is large. When the dosing interval is decreased the deviations become greater. When k_a/β approached unity, as would be expected from certain controlled-release dosage forms, the deviations become enormous. In addition, it must be realized that although R_2 more closely reflects R_1 values than does R_3, it is not a predictive method, in that one must achieve steady state to determine $C_{min(ss)}$, whereas R_1 and R_3 can be used predictively following a single dose. These variables must be kept in mind when one is attempting to anticipate or predict drug accumulation and consequent pharmacological effects from single-dose data.

Fraction Unbound in Interstitial Fluid

Keyphrases □ Pharmacokinetics—fraction unbound in interstitial fluid, relationship between binding in interstitial and vascular space

To the Editor:

The influence of protein binding of drugs on their pharmacological effect and pharmacokinetic disposition has been widely studied (1–3). However, most of the experimental observations have involved the interaction of drugs with plasma or serum proteins and not extravascular proteins. The lack of useful, experimental observations in this area is a result of the difficulty in obtaining representative tissue samples and the inadequate methods for performing tissue-binding studies (4). A mathematical approach has been derived (5) for estimating the fraction unbound in the "tissue" space utilizing a calculated volume of distribution term and anticipating physiological spaces. However, this approach is limited and only provides a complex average fraction unbound located outside the vascular space. Therefore, alternative theoretical approaches, as well as experimental methods need to be developed.

Nowhere is the role of plasma and tissue binding of greater interest than in the area of antibiotic therapy (6, 7). In general, β-lactam antibiotics are restricted in their distribution to the vascular space and the interstitial fluids; they do not penetrate intracellularly. Attempts to study the tissue (interstitial) binding of these antibiotics have centered on the collection of fluid from tissue cages (8), but the physiological character of the collected fluid has been questioned (9). The purpose of the present communication is to derive a theoretical relationship that relates the binding of a drug in the extravascular–extracellular or interstitial space to the binding in the vascular space. The original model on which this work is based was put forth by Øie *et al.* (10) and was recently used to describe the distribution of ceftriaxone (11). This theoretical relationship is used to explain the lack of distributional changes occurring with ceftriaxone despite the dramatic changes in the fraction unbound in the plasma (11).

The interaction of drugs with plasma proteins is usually described by the following Langmuir binding isotherm:

$$C_{BP} = \sum_{i=1}^{m} \frac{n_i P^* C_U}{Kd_i + C_U} \qquad \text{(Eq. 1)}$$

where C_{BP} is the plasma concentration of bound drug, m is the number of classes in binding sites, n_i is the number of binding sites for the ith class of binding sites, P is the concentration of the binding protein located in the vascular space, C_U is the concentration of unbound drug, and Kd_i is the equilibrium dissociation constant for the ith class of binding sites.

The presence of plasma proteins (*i.e.*, albumin) in the interstitial fluids has been well documented (12). If one assumes that the drug–protein interaction in the interstitial space is identical to the interaction in the vascular space (equivalent capacity and affinity constants), then a similar Langmuir relationship can be written for the interstitial binding:

$$C_{BE} = \sum_{i=1}^{m} \frac{n_i E^* C_U}{Kd_i + C_U} \qquad \text{(Eq. 2)}$$

where C_{BE} is the interstitial concentration of the bound drug and E is the concentration of binding protein in the interstitial space.

Equation 1 can be rewritten to factor out the protein and unbound concentration to yield:

$$C_{BP} = P^* C_U^* \sum_{i=1}^{m} \frac{n_i}{Kd_i + C_U} \qquad \text{(Eq. 3)}$$

For ease of manipulation, let a new parameter, S, replace the summation term:

$$C_{BP} = P^* C_U^* S \qquad \text{(Eq. 4)}$$

Given the assumptions concerning equivalent binding proteins in the vascular and interstitial spaces, and the additional assumptions of: (*a*) equal unbound drug concentration in both physiological spaces; (*b*) Kd_i does not change at lower protein concentrations; (*c*) other mechanisms of tissue distribution such as active transport, selective membrane permeability, and ion trapping are not present, then the S term for both C_{BP} and C_{BE} are equal, and a similar rearrangement and substitution can be written for C_{BE}:

$$C_{BE} = E^* C_U^* S \qquad \text{(Eq. 5)}$$

By definition, the fraction unbound in the plasma or vascular space (f_P) may be written as:

$$f_P = \frac{C_U}{C_U + C_{BP}} = \frac{1}{1 + P^* S} \qquad \text{(Eq. 6)}$$

A similar fraction unbound in the interstitial space (f_E) may be written as:

0022-3549/83/0700-0834$01.00/0

$$f_E = \frac{1}{1 + E^*S} \quad \text{(Eq. 7)}$$

One can rearrange Eq. 6 to obtain the S parameter in terms of f_P and P via:

$$S = \frac{1 - f_P}{P^* f_P} \quad \text{(Eq. 8)}$$

Substituting Eq. 8 into Eq. 7, one can now write an expression for f_E in terms of f_P, P, and E:

$$f_E = \frac{1}{1 + \frac{E}{P}\left(\frac{1 - f_P}{f_P}\right)} \quad \text{(Eq. 9)}$$

Figure 1 illustrates the theoretical relationship between f_P and f_E, when the ratio of protein concentration (E/P) is normal (0.32), less than normal (0.10), or greater than normal (0.64) (12). Two distinct trends are apparent from the data. As might be expected, decreasing or increasing the relative concentration of interstitial protein results in a larger or smaller fraction unbound in the interstitial space (f_E) relative to the vascular space (f_P). A second trend is the observation that as f_P values <0.1 the relationship between f_E and f_P becomes linear, irrespective of the value of E/P. This fixed ratio of f_E to f_P can be explained readily if one evaluates Eq. 9 as f_P approaches zero.

In this case:

$$f_E = \frac{P}{E} {}^* f_P \quad \text{(Eq. 10)}$$

Therefore, for drugs that are highly bound, the ratio of their fraction unbound in the interstitial and vascular spaces (f_E/f_P) is inversely related to the ratio of the concentration of binding protein located in those physiological spaces (E/P). Furthermore, any increases in f_P will result in proportional changes in f_E, such that the ratio of the two drugs (f_E/f_P) will remain relatively constant at f_P values <0.1.

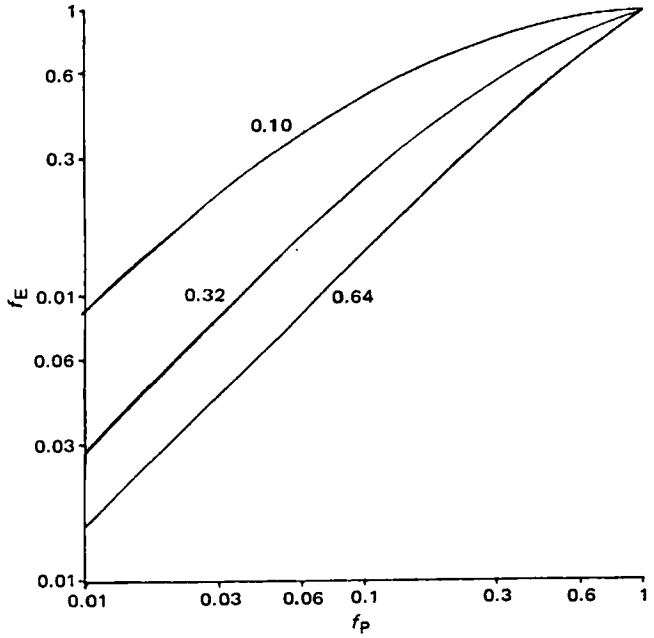

Figure 1—*Interrelationship of f_E and f_P as defined by Eq. 9; inset numbers refer to* E/P *values.*

One of the important implications for this theoretical observation lies in the distribution of drug mass. The pharmacokinetic parameter which best reflects shifts in drug distribution is the apparent volume of distribution at steady state calculated with reference to total drug levels (V_{ss}^T). As mentioned above, we have previously put forth a conceptual model or approach based on the work of Gillette (13) which relates V_{ss}^T to drug binding and physiological spaces (5). The following equation represents a modification of the original work:

$$V_{ss}^T = V_P + \frac{f_P}{f_E} V_E \quad \text{(Eq. 11)}$$

where V_P and V_E are the physiological volumes of the plasma and interstitial spaces, respectively.

Table I illustrates the influence of the ratio of the fractions unbound (f_E/f_P) on V_{ss}^T as f_P increases. In agreement with the observed ceftriaxone data (where f_P increased from 0.03 to 0.1), the change in V_{ss}^T is very small. Therefore, for this particular system under the stated conditions, one should expect no substantial shift in drug mass out of the vascular compartment as a result of an increase in f_P.

The stable nature of V_{ss}^T is contrasted by the large changes that occur in the parameter V_{ss}^U (Table I). The V_{ss}^U parameter can be derived experimentally from the analysis of the unbound concentration *versus* time profile (11) and has been theoretically described by the following equation:

$$V_{ss}^U = \frac{V_P}{f_P} + \frac{V_E}{f_E} \quad \text{(Eq. 12)}$$

As f_P and f_E increase, V_{ss}^U decreases strikingly. These dramatic changes in V_{ss}^U **do not** reflect any changes in the distributional space. They merely reflect the substantial shift in the ratio of unbound concentration in the plasma to the amount of drug in the body (*i.e.*, dose). The utility of V_{ss}^U is described elsewhere (11).

In conclusion, we have presented a conceptually useful equation which describes the fraction unbound in the interstitial space and provides a theoretical explanation for the observed behavior of the apparent volume of distribution for ceftriaxone. The equation was developed for

Table I—Influence of Increasing f_P Values and Various Ratios of E/P on V_{ss}^T and V_{ss}^U as Calculated by Eqs. 9, 11, and 12 [a]

antibiotics, but may have wider application. However, this application must be preceded by an appreciation (and if possible the testing) of the underlying assumptions of this relationship. The major assumption remains that the only binding that occurs outside the vascular space is to plasma proteins located there, and that the binding constants remain the same.

Creatinine XII: Comparison of Assays of Low Serum Creatinine Levels Using High-Performance Liquid Chromatography and Two Picrate Methods

Keyphrases □ Creatinine—assay in serum using HPLC, automated picrate method, modified picrate method, comparison of methods □ High-performance liquid chromatography—creatinine assay in serum, comparison with two picrate methods

To the Editor:

Endogenous creatinine has been commonly employed to estimate the glomerular filtration rate for the study of renal function or for modifying dosages in patients with renal impairment (1–5). Clinically, the automated picrate method[1], based on a complex color reaction between creatinine and picrate in the alkaline medium, is probably most widely used to assay creatinine in plasma or serum (6–10). This method, however, is known to be nonspecific due to potential interferences by endogenous and/or exogenous substances, and often results in an overestimate of "true" creatinine levels (7–9). It appears that to date most of assay comparisons between this method and the more specific high-performance liquid chromatographic (HPLC) method were carried out in samples containing higher levels (such as >0.8 mg%) of creatinine (10, 11). Since lower levels are often found in patients, it would seem important to evaluate potential discrepancies using low-level samples. The modified picrate method of Yatzidis (12, 13) was also chosen for the present evaluation, since it has been reported to be highly specific.

A total of 30 random serum samples from patients determined by the automated picrate method in a clinical laboratory[2] and found to contain less than 0.8 mg% of creatinine, were employed in the study. The HLPC method (14) used in the present study is a slight modification of the method developed earlier in our laboratory (3). Briefly, the method involved the deproteinization of 0.1 ml of serum with 0.25 ml of acetonitrile. After vortexing and centrifugation, 50 μl of the supernatant was injected directly into the cation-exchange column[3]. The recovery in the above sample preparation is essentially 100% (3). The mobile phase with a flow rate of 3 ml/min contained 0.035 *M* monobasic ammonium phosphate adjusted to pH 4.8 with 0.01 *N* NaOH. The creatinine was monitored at 254 nm using a fixed wavelength detector[4] with a sensitivity setting of 0.005 AUFS. The retention time for creatinine was about 4.5 min. The present assay has a detection limit of 0.05 mg% (based on a signal/noise ratio of 3.0), and has a coefficient of variation for both interassay and intraassay between 1.2 and 3.0%. No interferences were found in the present and earlier (14) studies with samples obtained from patients or volunteers. It should be noted that the variable wavelength UV detector (without a noise damper) used in our earlier studies (3, 10) was much less sensitive; it had a larger base-line noise even at a previously used sensitivity setting of 0.05 AUFS. Duplicate analyses were performed using both the HPLC method and the Yatzidis method.

The results of the serum creatinine measured by the above three methods are summarized in Table I. The automated method overestimated serum creatinine by an average of 15.2% with a −16.7 to 66.7% range when compared with the HPLC method. Although the mean overestimation found in the present study is similar to the previous study (14.5%, $n = 30$) using samples with generally much higher serum levels (10), it is of interest to note (Table I) that for two samples the overestimations were >50%, and for eight samples the results were essentially identical. The above results suggest that the amount and nature of interfering substances may vary considerably with individuals.

The overestimations of serum creatinine by the modified picrate method were much higher with an average of 55.2% (ranging from −58.3 to 168%). In the previous report (10), a similar modified method (15) was found to overestimate

[a] Only one significant figure was provided for concentrations <1.0 mg% by the printout of the instrument.

by an average of 32% in serum samples with a wider range of creatinine levels (0.62–18.5 mg% based on the HPLC method). However, for samples (n = 3) with serum levels in the range of 0.6–0.7 mg% (10) the mean overestimation was 88.2%. Thus, both of the modified picrate methods (12, 13, 15) resulted in consistently much higher creatinine values. The reason for the apparent discrepancy between their claimed specificity (12, 15) and the present as well as the previous (10, 16) findings remains to be investigated.

The results of the present study indicate that one should be cautious in using the automated and modified picrate methods for creatinine determinations. Since the HPLC method is generally considered to be more specific (3), its use should be preferred when accurate determinations are required.

It has been recently reported that creatinine might be extensively secreted and reabsorbed by renal tubules in both humans (17, 18) and animals (18, 19), and there might also be a significant nonrenal elimination in normal humans (19, 20) and normal rabbits (19). The full implications of these findings in the use of creatinine remain to be explored.

Crystalline Anhydrous–Hydrate Phase Changes of Caffeine and Theophylline in Solvent–Water Mixtures

Keyphrases □ Phase changes—in crystals, anhydrous to hydrate, caffeine, theophylline, solubility studies □ Caffeine—crystalline phase changes, anhydrous to hydrate, solubility studies □ Theophylline—crystalline phase changes, anhydrous to hydrates solubility studies

To the Editor:

The extended Hildebrand solubility approach (1–3) was recently developed and evaluated for calculation of solubilities in solvent–water systems that are not adequately described by the regular solution theory (4). The approach is based on regression analysis of solubility data to calculate solute–activity coefficients as a function of the solubility parameter of the solvent mixture.

A problem exists with several of the solutes used in the evaluation of the extended Hildebrand approach: crystalline anhydrous–hydrate phase transformation as the water content of the solvent mixture is changed. In the dry solvent it is clear that only a nonhydrated (anhydrous or solvated) form can be present at equilibrium (5); but in aqueous solvent mixtures the equilibrium form may be anhydrous solvated or hydrated crystals. This was recently demonstrated for cholesterol in water–glyceryl-1-monooctanoate solutions (6). The transition between anhydrous and monohydrate forms occurred at 5% water (37°) and was temperature dependent. In this system the max-

[a] Only one significant figure was provided for concentrations <1.0 mg% by the printout of the instrument.

by an average of 32% in serum samples with a wider range of creatinine levels (0.62–18.5 mg% based on the HPLC method). However, for samples (n = 3) with serum levels in the range of 0.6–0.7 mg% (10) the mean overestimation was 88.2%. Thus, both of the modified picrate methods (12, 13, 15) resulted in consistently much higher creatinine values. The reason for the apparent discrepancy between their claimed specificity (12, 15) and the present as well as the previous (10, 16) findings remains to be investigated.

The results of the present study indicate that one should be cautious in using the automated and modified picrate methods for creatinine determinations. Since the HPLC method is generally considered to be more specific (3), its use should be preferred when accurate determinations are required.

It has been recently reported that creatinine might be extensively secreted and reabsorbed by renal tubules in both humans (17, 18) and animals (18, 19), and there might also be a significant nonrenal elimination in normal humans (19, 20) and normal rabbits (19). The full implications of these findings in the use of creatinine remain to be explored.

Crystalline Anhydrous–Hydrate Phase Changes of Caffeine and Theophylline in Solvent–Water Mixtures

Keyphrases □ Phase changes—in crystals, anhydrous to hydrate, caffeine, theophylline, solubility studies □ Caffeine—crystalline phase changes, anhydrous to hydrate, solubility studies □ Theophylline—crystalline phase changes, anhydrous to hydrates solubility studies

To the Editor:

The extended Hildebrand solubility approach (1–3) was recently developed and evaluated for calculation of solubilities in solvent–water systems that are not adequately described by the regular solution theory (4). The approach is based on regression analysis of solubility data to calculate solute–activity coefficients as a function of the solubility parameter of the solvent mixture.

A problem exists with several of the solutes used in the evaluation of the extended Hildebrand approach: crystalline anhydrous–hydrate phase transformation as the water content of the solvent mixture is changed. In the dry solvent it is clear that only a nonhydrated (anhydrous or solvated) form can be present at equilibrium (5); but in aqueous solvent mixtures the equilibrium form may be anhydrous solvated or hydrated crystals. This was recently demonstrated for cholesterol in water–glyceryl-1-monooctanoate solutions (6). The transition between anhydrous and monohydrate forms occurred at 5% water (37°) and was temperature dependent. In this system the max-

imum cholesterol solubility coincided with the anhydrous–hydrate crystalline phase change.

The water content at which a given compound has the potential to convert to its hydrate is not predictable. A metastable form may remain supersaturated for long periods, particularly if the degree of supersaturation is not large. In addition, little is known about the effects of such crystal changes on solubility profiles in mixed solvents. Based on these and other considerations discussed below, compounds subject to such phase changes are not appropriate for modeling by the extended Hildebrand approach. Caffeine, theophylline, and theobromine all form hydrates, although they have been used as model compounds for evaluation of the extended Hildebrand approach (1–3). The purpose of this communication is to point out that knowledge of the crystal phase present at equilibrium is essential for the study of solubility. Furthermore it is especially important to identify the solid phase at equilibrium in mixed solvents.

To illustrate these points we examined the solid phases present when caffeine or theophylline were equilibrated at 25° in 0–50% water–dioxane solutions for 3–5 days[1]. These conditions were similar to those employed previously (1, 2). To avoid compositional bias, separate samples were equilibrated which contained either the anhydrous or monohydrate forms. At equilibrium the solid phases were filtered, dried under ambient conditions, and analyzed by differential scanning calorimetry (DSC)[2]. The hydrates were prepared by aqueous recrystallization and found to be monohydrates using Karl Fischer titrimetry[3]. At ambient conditions the hydrates were stable for at least 24 hr with respect to dehydration (7), and the anhydrous forms did not react with atmospheric moisture to form the hydrates. For some samples, solubilities were measured spectrophotometrically after 0.2-μm membrane filtration[4]. When heated in the DSC at 10°/min, the presence of water crystallization was verified by the broad dehydration endotherm centered at about 80° (caffeine) and 90° (theophylline). In these experiments the heat of dehydration was not measured and, thus, samples with the hydrate peak could also contain some anhydrous material. The solubilities were consistent with the previously reported data (1–3) except as described below.

For theophylline systems above ~5% water, the hydrate was always present at equilibrium. Below this concentration the anhydrous form was isolated. These findings were independent of the solid form initially added to the solvent, indicating that equilibrium was achieved with the more stable form. With a few exceptions, samples of caffeine equilibrated with 10–50% water, however, remained in the crystal form initially added. This apparent resistance to nucleation and crystallization of caffeine monohydrate led to significant differences in solubility. For example, at 50% water the solubilities were 71 mg/ml (hydrate) and 86 mg/ml (anhydrous). As the solvent water content decreased the solubilities became more similar [49 mg/ml (hydrate) *versus* 51 mg/ml (anhydrous)]. This behavior may explain the irregularity of the reported solubility profile in water–dioxane (3). With 0–5% water, samples initially prepared with hydrate were found to be anhydrous at equilibrium. There was no correlation between maximum solubility [at ~30–50% water (3)] and the crystal form change (at 5–10% water) in these systems. This is probably related to the extensive self-association of caffeine in water (8).

The regular solution theory (4) was developed to describe the solubility of molecular crystals, *i.e.*, single component substances. For solubility calculations the heat (or entropy) of fusion and the melting point of the solute are required. In the previous work these constants were obtained for the anhydrous forms by DSC (1–3). Since the equilibrium crystal form was most often the hydrate, these values should not have been used for calculation of solubility. The different calorimetric heats of solution (25°) in water for anhydrous caffeine (3.4 kcal/mole) and the hydrate (5.0 kcal/mole) show that the forms have quite different crystal energies (8). Further work will be required to develop the appropriate equations and physical constants for solubility modeling of hydrated (or solvated) crystalline compounds.

Pharmacokinetic Absorption Plots from Oral Data Alone or Oral/Intravenous Data and An Exact Loo–Riegelman Equation

Keyphrases □ Deconvolution—amount absorbed as a function of time for all common disposition models; amount of drug in peripheral compartments of mammillary model from measurement in central compartment □ Wagner-Nelson equation—drug absorption □ Loo–Riegelman equation—drug absorption

To the Editor:

The purposes of this Communication are: (*a*) to give exact absorption equations when drug disposition is described by one, two, or three exponential terms; (*b*) when disposition is described by two exponential terms to show that one of the new absorption equations is an exact Loo–Riegelman equation and simpler and easier to use than the latter; and (*c*) to describe and illustrate use of the equations in a preliminary manner only.

The models to be considered are shown as models I, II, and III below.

0022-3549/83/0700-0838$01.00/0

The bolus intravenous (disposition) equations corresponding to models I–III are given as Eqs. 1–3, respectively.

Model I: $$C = C_1 e^{-\lambda_z t} \quad \text{(Eq. 1)}$$

Model II: $$C = C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} \quad (\lambda_1 < \lambda_2) \quad \text{(Eq. 2)}$$

Model III: $$C = C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} + C_3 e^{-\lambda_3 t} \quad (\lambda_1 < \lambda_2 < \lambda_3) \quad \text{(Eq. 3)}$$

In Eqs. 1–3, C is the plasma (serum or whole blood) concentration of unchanged drug at time t, λ_z is the slope of the least-squares line when $y = \ln C$ and $x = t$, and C_i and λ_i are coefficients and exponents obtained by nonlinear least-squares fitting of C,t data. If the drug is administered by infusion and appropriate polyexponential functions fitted to the pre- and/or postinfusion C,t data, then the coefficients can be converted to those corresponding to a bolus intravenous injection as described by Wagner (1). There are 3 two-compartment disposition models (2) and model II is one of these. There are 21 three-compartment disposition models (3a, 4) and model III is one of these. The parameters k_{12}, k_{21}, and k_{el} of model I are estimated from the C_1, C_2, λ_1, and λ_2 of eq. 2 and the dose administered (3b). The parameters k_{12}, k_{21}, k_{13}, k_{31}, and k_{el} of model III are estimated from C_1, C_2, C_3, λ_1, λ_2, and λ_3 of Eq. 3 and the dose (5). In using the absorption equations given below it is extremely important to derive the microscopic rate constants for models I to III, which have central compartment input and elimination, and not for one of the other possible models whose disposition is also described by eqs. 2 and 3. Erroneous absorption data would be obtained if one used microscopic rate constants, derived for one of the other two- or three-compartment disposition models, with the absorption equations given below. However, Vaughan and Dennis (6) and Wagner (3c) have shown that the Loo–Riegelman equations (7) is model independent, and for similar reasons, the new absorption equations are also model independent, providing input is into the central compartment. (But elimination need not be from the central compartment.) It is also assumed that the central compartment is the one sampled. Thus, if oral data were generated from one of the two- or three-compartment disposition models other than model II or III, and one derived the parameters of model I or III and used these in the absorption equations below, one would obtain the correct input data as has been shown formerly by Wagner (3c) for the Loo–Riegelman equation.

The equations giving the amount absorbed per unit volume are:

Model I: $$\frac{A_T}{V} = C_T + \lambda_z \int_0^T C dt \quad \text{(Eq. 4)}$$

Model II: $$\frac{A_T}{V_p} = C_T + k_{el} \int_0^T C dt + k_{12} e^{-k_{21} T} \int_0^T C e^{k_{21} t} dt \quad \text{(Eq. 5)}$$

Model III: $$\frac{A_T}{V_p} = C_T + k_{el} \int_0^T C dt + k_{12} e^{-k_{21} T} \int_0^T C e^{+k_{21} t} dt + k_{13} e^{-k_{31} T} \int_0^T C e^{k_{31} t} dt \quad \text{(Eq. 6)}$$

In Eqs. 4–6, A_T is the amount of drug absorbed between time zero (time of administration) and the blood sampling time, T ($0 \le T \le t$), after a single dose of drug, t is clock time, V is the volume of the compartment of model I, V_p is the volume of the central compartment of models II and III, C_T (or C) is the plasma (serum or whole blood) concentrations of unchanged drug at time T, and the λ_Z and subscripted k parameters are first-order rate constants. Equation 4 is the Wagner–Nelson equation (8), and Eqs. 5 and 6 are new as written. Equation 5 is derived in the Appendix and Eq. 6 may be derived in a similar manner. The Loo–Riegelman equation provides approximate A_T/V_p data for model II, since it assumes a linear segment between any two C,t points where the differences are ΔC and Δt. Equations 7 and 8 are the long form of the Loo–Riegelman equation in the symbolism of this article.

$$\frac{A_T}{V_p} = C_T + k_{el} \int_0^T C dt + \left(\frac{A_2}{V_p}\right)_{T_n} \quad \text{(Eq. 7)}$$

$$\left(\frac{A_2}{V_p}\right)_{T_n} = \left(\frac{A_T}{V_p}\right)_{T_{n-1}} e^{-k_{21}\Delta t} + \frac{k_{12}}{k_{21}} C_{T_{n-1}} [1 - e^{-k_{21}\Delta t}] + \frac{k_{12}}{k_{21}} \Delta C - \frac{k_{12}}{k_{21}} \cdot \frac{\Delta C}{\Delta t} [1 - e^{-k_{21}\Delta t}] \quad \text{(Eq. 8)}$$

Equation 5 is an exact Loo–Riegelman equation. The third term on the right-hand side of Eq. 5 is an exact equation for $(A_2/V_p)_T$ and replaces the entire right-hand side of Eq. 8. In Eqs. 7 and 8 $(A_2)_{T_n}$ is the amount of drug in the peripheral compartment of model II at time T_n, and $(A_2)_{T_{n-1}}$ is the amount at the previous sampling time T_{n-1}. Similarly Eq. 6 is an exact equation for model III, and the last two terms of the right-hand side give the amounts of drug in the peripheral compartments 2 and 3 of model III divided by the volume V_p, *i.e.*, $(A_2/V_p)_T$ and $(A_3/V_p)_T$.

When estimating A_T/V or A_T/V_p with Eqs. 4 to 6, the areas (*i.e.*, integrals) may be determined by segmenting each area into trapezoids using the regular trapezoidal rule when concentrations are increasing or remaining constant and the logarithmic trapezoidal rule when the concentrations are decreasing (9).

The apparent fraction of drug absorbed to time T, F_a, is given as:

$$F_a = \frac{A_T/V_p}{A_\infty/V_p} = \frac{A_T}{A_\infty} \qquad \text{(Eq. 9)}$$

where A_∞/V_p is the asymptotic value of A_T/V_p and is given as:

$$\frac{A_\infty}{V_p} = k_{el}\int_0^\infty C dt \qquad \text{(Eq. 10)}$$

When using Eq. 4 it is usually preferable to obtain A_∞/V_p by averaging the values of the right side of Eq. 4 for those points used to estimate the apparent elimination rate constant, λ_z (3d). When using Eqs. 5, 6, 9, and 10 the subscripted k parameters would be obtained from intravenous data, and the remainder of the variables in the equations would be obtained from extravascular data.

The differential forms of Eqs. 4–6 are shown as:

Model I:
$$\left(\frac{dA}{dt}\right)_T = V\left(\frac{dC}{dt}\right)_T + V\lambda_z C_T \qquad \text{(Eq. 11)}$$

Model II:
$$\left(\frac{dA}{dt}\right)_T = (k_{12}+k_{el})V_p C_T + V_p\left(\frac{dC}{dt}\right)_T - k_{12}k_{21}e^{-k_{21}T}V_p\int_0^T Ce^{k_{21}t}dt \qquad \text{(Eq. 12)}$$

Model III:
$$\left(\frac{dA}{dt}\right)_T = (k_{12}+k_{13}+k_{el})V_p C_T + V_p\left(\frac{dC}{dt}\right)_T - k_{12}k_{21}e^{-k_{21}T}V_p\int_0^T Ce^{k_{21}t}dt - k_{13}k_{31}e^{+k_{el}T}\int_0^T Ce^{k_{31}t}dt \qquad \text{(Eq. 13)}$$

In Eqs. 11–13, $(dA/dt)_T$ is the rate of absorption at the specific time T, $(dC/dt)_T$ is the rate of change of drug concentration with respect to time at T, and other symbols have been defined formerly. Equation 11 has been derived formerly (8, 3e). Equations 12 and 13 in different form were derived by a deconvolution technique (10, 11) (see *Appendix*). Use of Eqs. 11–13 requires an estimate of the derivative $(dC/dt)_T$ at each sampling time T; such estimates may be obtained by fitting C,t data with a cubic spline function as described by Pedersen (10, 11) or a spline and Akima method as described by Wagner (3f). Equations 5–8, 12, and 13 require prior intravenous data for application. Equations 4 and 11 may be applied to extravascular data without intravenous data, and such application is appropriate when bolus intravenous data are fitted well to Eq. 1 as is sometimes the case (12–15). A special application of Eqs. 4 and 9 when input obeys zero-order kinetics will be the subject of a subsequent article.

Oral and intravenous data were simulated using Model II with first-order input and parameter values of $k_{12} = 1.5\ hr^{-1}$, $k_{21} = 0.5\ hr^{-1}$, $k_{el} = 0.5\ hr^{-1}$, $k_a = 4\ hr^{-1}$, $V_p = 10$ liters, $FD_{po} = 1000$ mg. These parameters with Model II gave $\lambda_1 = 0.15669\ hr^{-1}$ and $\lambda_2 = 2.3933\ hr^{-1}$. Equation 14 corresponds to Eq. 2 for this simulation. The simulated

$$C_{iv} = 17.2675e^{-0.10436t} + 82.7325e^{-2.3956t} \qquad \text{(Eq. 14)}$$

oral data were given by:

$$C_T = 17.7301e^{-0.10436T} + 206.2640e^{-2.3956T} - 223.9941e^{-4T} \qquad \text{(Eq. 15)}$$

For this example the actual F_a values, shown in the last column of Table I, are given as:

$$F_a = 1 - e^{-k_a T} = [1 - e^{-4T}] \qquad \text{(Eq. 16)}$$

Table I lists the sampling times, T, the C_T values obtained with Eq. 15, and the stepwise calculation of the component parts of Eq. 5 in columns 3–8. Note that a number in column 8 is the product of the numbers in the same row of columns 6 and 7 and that a number in column 9 is the sum of the numbers in the same row of columns 2, 4, and 8. Numbers in columns 3 and 6 were obtained by applying a combination of the regular and logarithmic trapezoidal rules (see text) to the numbers in columns 2 and 5, respectively, and the time values in column 1.

Table I—Simulation Example

		Components of Eq. 5							Calculated[b]	Actual

[a] A combination of the regular and logarithmic trapezoidal rules (see text) was used to estimate these integrals using data in the adjacent columns and the time values. [b] Estimation of AUC $0-\infty$ by the usual method (ref. 3g) directly from the T,C_T data gave AUC $0-\infty = 200.33$ μg hr/ml, hence $A_\infty/V_p = k_{el}(\text{AUC } 0-\infty) = (0.5)(200.33) = 100.2$ μg/ml, and this value was used to calculate the F_a values using Eq. 9.

Table II compares the F_a values estimated by the new Eq. 5 and Eq. 9 with those calculated by the long form of the Loo–Riegelman equation (Eqs. 7 and 8) and Eq. 9. For this example with error-free data the accuracy of the two methods are essentially identical as the percent errors in Table II indicate. In using Eqs. 5 and 6 one must be careful to carry enough decimal places since at the higher time values one is multiplying a very large number ($\int_0^T Ce^{k_{21}t}dt$) by a very small number ($k_{12}e^{-k_{21}T}$). Care must be taken also to estimate the asymptote A_∞/V_p correctly with Eq. 10 and not average terminal A_T/V_p values as done in application of the Wagner–Nelson method.

If absorption is first order then one can obtain an estimate of the absorption rate constant, k_a, by applying the method described by Wagner and Ayres (16). With reference to Table II one performs linear least-squares regression using the $x = \Delta F_a$ (second column of Table II) and $y = F_a$ (column 3); *i.e.*, the x,y pairs for this example are: 0.219, 0.328; 0.147, 0.547; 0.099, 0.694; 0.067, 0.793; and 0.043, 0.860. For this example the equally spaced $\Delta t = 0.1$ hr. The equation of such a line is:

$$(F_a)_i = (F_a)_\infty - \left[\frac{1}{1 - e^{-k_a \Delta t}}\right] \cdot \Delta F_a \qquad \text{(Eq. 17)}$$

ordinate: $(F_a)_i$; intercept: $(F_a)_\infty$; slope: $\left[\frac{1}{1 - e^{-k_a \Delta t}}\right]$; abscissa: ΔF_a

For the above data set the intercept was 0.994 (instead of the theoretical 1.00) and the slope was −3.0368.

$$k_a = \frac{-\ln\left[1 - \frac{1}{\text{slope}}\right]}{\Delta t} = \frac{-\ln\left[1 - \frac{1}{3.0368}\right]}{0.1} = 3.99 \text{ hr}^{-1} \qquad \text{(Eq. 18)}$$

where the known value was 4.0 hr^{-1}.

More extensive applications of the equations in this article will be published subsequently.

APPENDIX

Derivation of Eq. 5—Let D = the dose, and, at some time T let A_r = the amount of drug remaining at the absorption site, A_T = the amount absorbed, A_1 = amount in the central compartment of model II, A_2 = the amount in the peripheral compartment, and A_e = the amount of drug which has been eliminated by metabolism and excretion. Then mass balances give:

$$D = A_r + A_1 + A_2 + A_e \qquad \text{(Eq. 19)}$$

$$A_T = D - A_r \qquad \text{(Eq. 20)}$$

$$A_T = A_1 + A_2 + A_e \qquad \text{(Eq. 21)}$$

Now:

$$A_1 = V_p C_1 \qquad \text{(Eq. 22)}$$

The clearance equation for model II is:

$$\frac{dAe}{dt} = V_p k_{el} C_1 \qquad \text{(Eq. 23)}$$

which, upon integration between the limits $t = 0$ and $t = T$ yields:

Table II—Comparison of Results with Eqs. 5 and 9 *versus* Eqs. 7–9

1		0.976	0.977	−0.61	−0.51
1.5		1.03	0.999	Mean −0.62	−0.64
2		1.00	1.00		
3		1.00	1.01		
4		1.00	1.00		
6		1.01	1.00		
12		1.08	1.00		
18		0.92	1.00		

$$A_e = V_p k_{el} \int_0^T C_1 dt \qquad \text{(Eq. 24)}$$

The differential equation for the peripheral compartment of model II is:

$$\frac{dA_2}{dt} = k_{12} V_p C_1 - k_{21} A_2 \qquad \text{(Eq. 25)}$$

Rearrangement of Eq. 25 and multiplication of both sides by $e^{k_{21}t}$ gives:

$$e^{k_{21}t}\left[\frac{dA_2}{dt} + k_{21}A_2\right] = k_{12}V_p C_1 e^{k_{21}t} \qquad \text{(Eq. 26)}$$

But Eq. 26 may be written as:

$$\frac{d(A_2 e^{k_{21}t})}{dt} = k_{12} V_p C_1 e^{k_{21}t} \qquad \text{(Eq. 27)}$$

Integrating Eq. 27 between the limits $t = 0$ and $t = T$ yields:

$$A_2 e^{k_{21}T} = k_{12} V_p \int_0^T C_1 e^{k_{21}t} dt \qquad \text{(Eq. 28)}$$

hence

$$A_2 = k_{12} e^{-k_{21}T} V_p \int_0^T C_1 e^{k_{21}t} dt \qquad \text{(Eq. 29)}$$

Substituting for A_1, A_2, and A_e from Eqs. 22, 29, and 24, respectively, into Eq. 21, followed by dividing by V_p gives:

$$\frac{A_T}{V_p} = C_1 + k_{el} \int_0^T C_1 dt + k_{12} e^{-k_{21}T} \int_0^T C_1 e^{k_{21}t} dt \qquad \text{(Eq. 30)}$$

Equation 30 is the same as Equation 5, since C_1 of Eq. 30 is equivalent to C_T or C of Eq. 5 and $e^{-k_{21}T}$ and $e^{k_{21}t}$ of Eq. 30 are equivalent to $e^{-k_{21}T}$ and $e^{k_{21}t}$, respectively, of Eq. 5.

Derivation of Eq. 12—To convert Eq. 67 of Veng-Pedersen (10) to Eq. 12, one must use the equalities shown below:

$$-\frac{a_1\lambda_1 + a_2\lambda_2}{(a_1 + a_2)^2} = \frac{V_p}{D_{iv}}(k_{12} + k_{el}) \qquad \text{(Eq. 31)}$$

$$\frac{a_1a_2(\lambda_1 - \lambda_2)^2}{(a_1 + a_2)^3} = \frac{V_p}{D_{iv}}(k_{12}k_{21}) \qquad \text{(Eq. 32)}$$

$$\frac{a_1\lambda_2 + a_2\lambda_1}{a_1 + a_2} = \frac{V_p}{D_{iv}}k_{21} \qquad \text{(Eq. 33)}$$

$$-\frac{\lambda_1\lambda_2}{a_1\lambda_2 + a_2\lambda_1} = \frac{V_p}{D_{iv}}k_{el} \qquad \text{(Eq. 34)}$$

Derivation of Eq. 13—Using similar equalities based on model III (5, 10) Veng-Pedersen's Eq. 74 may be converted to Eq. 13.

BOOKS

REVIEWS

Good Manufacturing Practices for Pharmaceuticals—A Plan for Total Quality Control. 2nd Ed. By SIDNEY H. WILLIG, MURRAY M. TUCKERMAN, and WILLIAM S. HITCHINGS IV. Marcel Dekker, New York, NY 10016. 1982. 259 pp. 15 × 23 cm. Price $49.75 (20% higher outside the U.S. and Canada)

In the preface to the second edition of this book, the authors state the following:

> "This volume is a revised and expanded second edition. Substantial changes have been made in organization in order to have the text follow 21 CFR 210 and 211 (43 FR 54076, September 29, 1978). Many examples of violations which led to recall have been added to the text in order to illustrate problems encountered by the industry and to suggest ways in which they could have been avoided. In addition, several new chapters, which are not direct comments on the regulations but which are, nevertheless, pertinent to compliance, have been added. These chapters deal with repackaging and relabeling; FDA inspection; recalls; safeguarding controlled substances; and how the manufacturer is designated on the label, as well as an appendix giving the standards for potable water. These additions, made in response to users of the first edition, should make this second edition even more useful."

This statement fulfills the promises of this excellent book. The authors present each of the parts of the Current Good Manufacturing Practices (CGMP) with clear explanations and discussions. They present, in detail, not only their own interpretation of the regulations, but relevant interpretations by others. The authors also include both their own and FDA views of the underlying CGMP regulations, specifically and overall, in a philosophical vein, a most refreshing approach. In addition, practical examples and court cases are presented where relevant.

Particularly useful are the authors' clear discussion and clarification of the intent of the regulations. These discussions frequently include additional information which can be very useful for professionals in the pharmaceutical industry. Some examples should give an idea of the kinds of material included in this volume:

- Details of screening, hiring, and administrating quality control personnel.
- Details of building specifications and segregation of pharmaceutical manufacturing facilities.
- A comprehensive list of raw material specifications.
- Details of paperwork including records, procedures, flow of records, assignment of control numbers, and storage.
- Receipt of raw materials and certificates of analysis.
- Analytical production and quality control procedures and controls.
- Description of labels.
- In-process controls.
- Laboratory controls: containers (glass and otherwise) and stability (physical, chemical, and container).
- Requirements and recommendations for records and reports. Design of records and reports—what kinds and how long to keep them.
- Numbering system for quality control records and systems.
- Problems with returned or salvaged product.
- FDA inspections and legal aspects.
- Recalls.

The CGMP regulations often are broad in their definitions. This book clarifies the regulations with many practical examples. The authors expand on the regulations, demonstrating their relation and applicability to the function and implementation of the Quality Control department. The authors further expand the discussion by freely offering their own opinions. Although one may not agree with their views all of the time, they are always stimulating and provocative. For example, the philosophy behind the following statement (page 22) could be fuel for a very interesting discussion:

> "The quality control supervisor must have a questioning nature. Some say a supervisor must be naturally distrustful. This applies to all matters in his or her area, including calculations and conclusions reached by peers and superiors from an organization viewpoint. It certainly applies to findings submitted by vendors and vendees of the operation and by its subcontractors. If the supervisor is other than such, the reputation will be that of a buck passer."

This unique and information-packed book should be an indispensable part of the libraries of all industrial pharmaceutical quality control, manufacturing, pharmacy, and legal departments.
