Preliminary Analysis—To carry out analyses using Eqs. 2 and 3, ρ_X values for hydrogen bonding variable substituents were needed. In the first six cases in Table I, data for only nonhydrogen bonding X substituents were fit to an equation of the form of Eq. 4 to get an approximate value for ρ_Y for such Y substituents as carboxyl, carboxylmethyl (CH_2COOH), carboxylmethoxy (OCH_2COOH), hydroxy, carbamoyl ($CONH_2$), and amino. The assumption for the first approximation was that $\rho_X = 0$. In the next three cases in Table I, σ_Y^0 values of functional groups such as *m*- and *p*-hydroxymethyl(CH_2OH), *p*-formylamido(NHCHO), and *p*-acetamido ($NHCOCH_3$) were essentially 0 (1, 9); hence, there was no electronic effect, for example, of hydroxymethyl on hydrogen bonding X substituents to affect π. Therefore, these three examples, including hydrogen bonding and nonhydrogen bonding substituents can be fit to the same type of equation as the first six. This provided the approximate ρ_Y values altogether for nine hydrogen bonding Y substituents.

For the benzonitriles, nitrobenzenes, acetophenones, and anisoles, few derivatives with nonhydrogen bonding X substituents have reported π values; therefore, in these examples, equations of the type derived for the

[a] $\pi_{X/PhY} = a\pi_{X/PhH} + \rho_Y\sigma_X^0 + \rho_X\sigma_Y^0(m) + \rho_X\sigma_Y^0(p) + c$; see footnotes *a–d* in Table I. [b] Those already indicated in Table I are not listed. [c] Justified at the 95% level. [d] Justified at the 94% level. [e] Justified at the 97.5% level. [f] Justified above the 99.5% level. [g] Justified at the 99% level.

first nine data sets of Table I were not appropriate, so hydrogen bonding X substituents had to be included in these cases. The electronic effect of substituents from Y to X should be taken into account. The ρ_X value for each of the hydrogen bonding X substituents should be identical to the ρ_Y value for a solute system where the corresponding hydrogen bonding substituent was invariant. Values of ρ_Y, calculated for the nine

		OH	0.94(±0.11)

hydrogen bonding Y substituents, could be substituted for either of the ρ_X terms of Eq. 2 for these hydrogen bonding X substituents. The values of ρ_X for nonhydrogen bonding substituents was taken as 0. Performing the regression analysis yielded Eqs. 14–17 (Table I) with four new approximate ρ_Y values for hydrogen bonding Y substituents, nitro, cyano, acetyl, and methoxy. Values of σ_Y^0 were determined as regression coefficients of ρ_X terms. In the case of the benzonitriles, ρ_Y was essentially 0. The results of these primary correlations are shown as Eqs. 5–17 (Table I). The level of significance of all of the correlations in Table I was >99.5%, as determined by the *F* test.

Final Regression Analysis—The 13 primary ρ_Y values can now be substituted into Eq. 2 for the ρ_X values for hydrogen bonding X substituents. The regression analysis was performed by including nonhydrogen bonding as well as hydrogen bonding substituents. For π values from benzyl alcohol, formanilides, and acetanilides, it was unnecessary to refit, since σ_Y^0 is 0 in these examples, no matter what the ρ_X values were. The ρ_Y values for hydrogen bonding Y substituents determined for 10 series of π values were slightly different from the corresponding primary values; thus, this process was repeated by substituting newly derived ρ_Y values into Eq. 2 for ρ_X values until constant ρ_Y values were obtained. In the course of the calculations, ρ_X terms were found to be insignificant in the correlation equations for phenylacetic acids and phenoxyacetic acids; hence, it was possible to include hydrogen bonding X substituents for which the ρ_X values were not known in the final correlations.

Values of π_X from substituted toluenes and chlorobenzenes, where the fixed function is nonhydrogen bonding, were analyzed by means of Eq. 3 using self-consistent ρ_X values. Finally, π values from substituted phenyl *N*-methylcarbamates and pyridines were applied to Eq. 2. Since σ values of the substituent *N*-methylcarbamoyloxy ($OCONHCH_3$) were not available and, since there is some uncertainty for σ values of aza(—*N*=) function, π_X values of $OCONHCH_3$ and —*N*= as X substituents were not included in correlations, except for a few cases where the σ_X term was insignificant. In deriving Eq. 31 for those of phenyl-*N*-methylcarbamates, the ρ_X values of alkoxyl groups were approximated by that of the methoxyl group and those of acyl and carbomethoxyl groups by that of the acetyl group.

RESULTS

The results for 14 sets of π values are shown in Table II as Eqs. 18–31. All the correlations and the terms other than the intercepts are justified >99.5% by *F* and *t* tests, unless noted. Those for π values of benzyl alcohols, formanilides, and acetanilides are the same as the primary correlations, Eqs. 11–13 in Table I. Values of *a* and ρ_Y observed in Eqs. 18–23 of the correlations including hydrogen bonding substituents are practically identical with those in Eqs. 5–10 for only nonhydrogen bonding X substituents; this seems to support the assumptions made to formulate Eq. 1. The effect of X on Y and Y on X are mutually independent, and the effects are additive in determining the variation of π values.

As expected, the value of *a*, the slope of the $\pi_{X/PhH}$ term, and the *c* value (the intercept) are close to 1 and 0, respectively, in most of the equations in Tables I and II. For substituted pyridines, however, the value for *a* is considerably lower than 1 (0.80 ± 0.06) in Eq. 30. The ρ_X terms for toluenes (Eq. 28) and the σ_X^0 term for pyridines (Eq. 30) are insignificant. For substituted toluenes (Eq. 28), chlorobenzenes (Eq. 29), and pyridines (Eq. 30), the *c* value is significant, >99.5%. It was expected that the correlations without an intercept may reveal different features such as different and/or significant slope values of respective terms for these three sets from those of Eqs. 28–30; in fact, the deletion of the intercept seems to yield more reasonable results as shown in Eqs. 28*a*–30*a*, although the quality of correlations in terms of standard deviation becomes slightly poorer. In Eq. 28*a* for toluene π values, the slope of the ρ_X (*para*) term is now significant, coinciding with the authentic σ^0 (p-CH_3) value. In Eq. 30*a* for pyridine π values, the value of *a* comes close to 1, the σ_X^0 term becomes significant, and the σ_Y^0 values estimated for the β- and γ-aza (—*N*=) groups get closer to the values derived from hydrolytic rates of isonicotinic and nicotinic acid esters (10) and IR frequency studies of substituted pyridines (11). The following discussion will be made on the basis of final correlations: Eqs. 11–13 in Table I and Eqs. 18–27, 28*a*–30*a*, and 31 in Table II.

DISCUSSION

Intrinsic Hydrophobicity of Substituents—Although the values of *a* are close to 1, most of the values from 17 sets of π values are slightly <1; the average is 0.94 ± 0.03, which is attributable to the fact that the assumption leading to Eq. 1 is not entirely valid. After separating the effects due to hydrogen bond formation, the intrinsic hydrophobicity of substituents in disubstituted benzenes is lower than that in monosubstituted benzenes. When a substituent is introduced in the monosubstituted benzene ring, the extent of the iceberg formation could be slightly lower than that formed by the introduction into the unsubstituted benzene.

Susceptibility in Hydrogen Bonding Association of Fixed Substituents to Electronic Effect of Variable Substituents, ρ_Y Values—The ρ_Y values are summarized in Table III. The sign of the ρ_Y values can be explained by considering the relative hydrogen bonding effect of substituents with solvents. For hydrogen-accepting Y substituents, such as acetyl in acetophenones where the carbonyl oxygen works as a hydrogen acceptor, a type of solvation such as >C=O . . . HOR (I) is only possible where R=H or n-C_8H_{17} in each of the water and octanol phases. Water, being more acidic than 1-octanol, would effectively compete in this type of solvation; thus, the strongly electron-withdrawing substituents would not be favorable to the hydration at the basic group and raise the partition coefficient.

For amphiprotic substituents such as hydroxyl in substituted phenols, there are two types of hydrogen bonding, XC_6H_4OH . . . R—O—H (II) and XC_6H_4H—O . . . HOR (III). Octanol, being more basic and less acidic than water, would favor the association of type II, whereas water would more effectively undergo the type III association. The more electron-withdrawing the substituent X, the more the amount of type II solvation with octanol (and the less the ratio of type III hydration). This effect results in a higher partition coefficient; therefore, regardless of whether the Y group is hydrogen-accepting, -donating, or amphiprotic, the electron withdrawal of X substituents is expected to make the $\pi_{X/PhY}$ value higher than the $\pi_{X/PhH}$ value. The positive ρ values for most of the Y groups in Table III can be understood on this basis.

For amphiprotic functions, the ρ_Y value for the relative solvation effect seems to roughly depend on the distance between the ring and associable hydrogen. The higher ρ values are found for phenols, anilines, and anilides, while the lowest value is for phenylacetic acids. Almost identical ρ values are observed for carboxyl, carbamoyl, and hydroxymethyl functions where the location of the hydrogen is similar.

The ρ values for hydrogen-acceptor functions are lower than what might be anticipated from the location of the association sites; in particular, the value for the benzonitriles is insignificant. The low ρ value for the relative solvation effect at basic functions seems to reflect a difference in hydrogen-donating ability smaller than that in hydrogen-accepting ability between water and octanol; the type II solvation would be more susceptible to the substituent effect than types I and III. At the present time, no relevant rationalization can be found for the negative ρ value found for the nitro group.

Electronic Effect of Fixed Substituents on Hydrogen Bonding Association of Variable Substituents, σ_Y^0 Values—The regression coefficients of the ρ_X terms are compared with available authentic σ_Y^0 values in Table IV (12). The calculated σ_Y^0 values coincide with respective authentic values within the 95% confidence intervals. Although the sequence of magnitude of calculated σ_m^0 and σ_p^0 values for some pairs of *meta*- and *para*-substituents is reversed from that of the authentic values, the general agreement between calculated and authentic σ_Y^0 values seems good. The correlation between these values for 30 *meta*- and *para*-substituents is expressed by:

$$\sigma^0 \text{ (calculated)} = 1.058(\pm 0.091)\sigma^0 \text{ (authentic)} - 0.019(\pm 0.036) \quad \text{(Eq. 32)}$$

where *n* is 30, *r* is 0.971, and *s* is 0.081. The electronic effect of fixed substituents Y actually is represented by σ_Y^0 values and exhibited only toward hydrogen bondable variable substituents X. This is believed to

support the fundamental assumption leading to the present procedure.

Prediction of Log *P* Values of Disubstituted Benzenes—The present work indicates that the variations in π values of *meta*- and *para*-aromatic substituents from one system to another are due primarily to variations in the extent of hydrogen bonding solvation of substituents. Practically no outliers from correlations are found using the present procedure. The substituent effects governing this variation, in general, are bidirectional. The π value of a certain substituent is modified not only by its own effect on a fixed function but also by a backward effect from the fixed function. These modifications depend on susceptibilities of substituents to relative hydrogen bond formation with solvents, and the susceptibility varies from one substituent to another. Thus, $\pi_{X/PhH}$ values could be used as fixed substituent constants in predicting log *P* values of aromatic compounds as a first approximation only when aromatic substituents are rather insensitive to and/or not influential on the relative hydrogen-bonding effect.

Had more ρ_X values been determined for hydrogen-bondable X substituents, a large number of log *P* values of disubstituted aromatic compounds could have been predicted more precisely according to the present procedure using relations such as:

$$\pi_{X/PhY} = 0.94\pi_{X/PhH} + \rho_Y\sigma_X^0 + \rho_X\sigma_Y^0 \text{ (}meta\text{ or }para\text{)} \quad \text{(Eq. 33)}$$

Furthermore, had the present procedure been combined with the recently developed method to analyze the *ortho* effect (13), it would have been possible to calculate even the log *P* values of *ortho*-disubstituted benzenes.

The full account of this study, including theoretical considerations on the bidirectional Hammett relationship governing the $\Delta\pi$ values as well as the data and parameters used for correlations, will be published elsewhere (14).

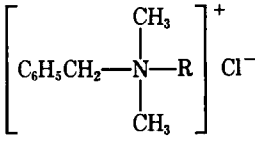
Abstract □ A new specific and sensitive method of analysis for samples of benzalkonium chlorides is presented. Chemical-ionization mass spectroscopy has been used to identify and determine the proportions of various alkyl chain lengths in commercial mixtures of benzalkonium chlorides. This method allows the direct and simultaneous determination of individual benzalkonium chlorides.

Keyphrases □ Benzalkonium chloride—determination by chemical-ionization mass spectroscopy, alkyl chain lengths □ Chemical-ionization mass spectroscopy—determination of benzalkonium chloride, alkyl chain lengths

Benzalkonium chlorides (I) USP are a mixture of benzalkonium chlorides, where R = *n*-alkyl and *n* can vary from C_{10} to C_{18}. The relative amounts of these different species greatly affects both the antimicrobial spectrum and



I

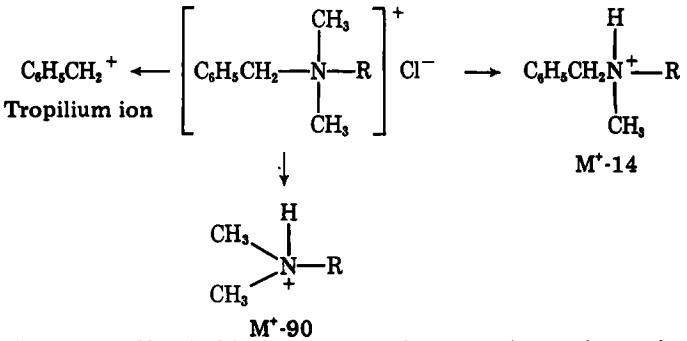
activity of the mixture (1–3). The current methods of identification of benzalkonium chloride solutions according to the USP (4), rely upon titrimetric analysis of total alkyl benzyldimethylammonium chloride based upon potassium iodate equivalents. Additionally, the ratio of the various *n*-alkyl components of benzalkonium chlorides can be determined by microhydrogenation followed by solvent extraction and GLC. The ratio of alkyl components is then calculated and must meet specific USP requirements. These requirements state that the C_{12} homologue must comprise at least 40% of the total benzalkonium chloride content and that the C_{14} homologue must be at least 20%. Furthermore, these two homologues must comprise together 70% of the total content. Other methods have been used for the determination of benzalkonium chlorides: ion-pairing techniques (5–8), direct titration involving tetraphenylboron (9) and iodate (10), reverse-phase HPLC (11), and pyrolytic GLC (12).

The present method directly determines the chemical composition and alkyl chain length ratios of benzalkonium chloride species in commercial samples.

EXPERIMENTAL

Apparatus—Measurements were conducted upon a spectrometer[1] fitted with an electron-impact–chemical-ionization (EI–CI) source and a DS-55 data system.

Reagents and Solvents—Individual benzalkonium chloride standards were prepared with R = C_1–C_{20}, by a previous method (13) and characterized by spectroscopic and elemental analysis. Purity was in all cases



Scheme 1—Chemical-ionization mass fragmentation pathways for benzalkonium chloride (1).

>99.6%. The commercial benzalkonium chloride mixtures were obtained from three different manufacturers. Samples for analysis were prepared as millimolar solutions in methanol[2].

Assay—Standard solutions were prepared as 2 μl methanol solutions containing R = C_9 internal standard (0.01 *M*) together with pure synthetic benzalkonium chloride (0.001–0.01 *M*) with R = C_{10}, C_{12}, C_{14}, C_{16}, and C_{18}. Samples were applied as methanol solutions by the direct-inlet technique at 200° on a glass probe tip and evaporated into the chemical-ionization plasma of ammonia gas. Evaporation profiles were deter-

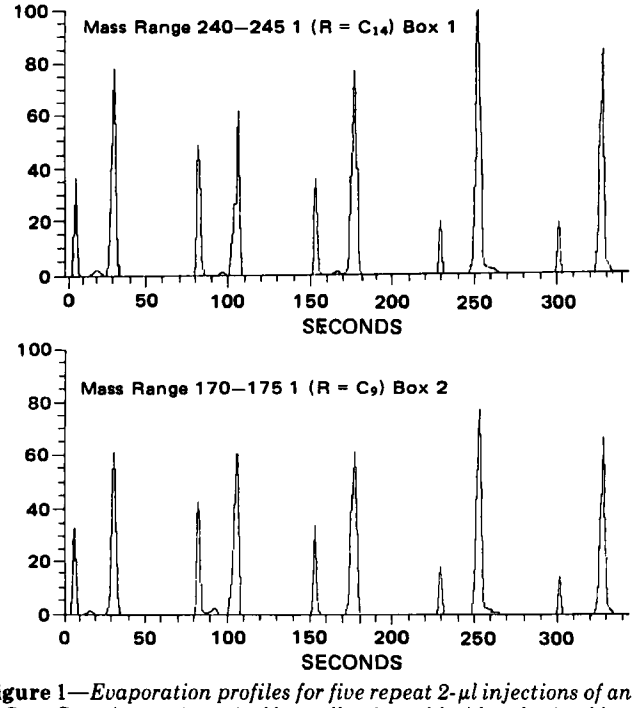


Figure 1—*Evaporation profiles for five repeat 2-μl injections of an R = C_9 + C_{14} mixture (50:50) of benzalkonium chlorides obtained by simultaneous monitoring of the M^+ −90 ions. (The first peak in each evaporation profile is observed as a result of evaporation off the probe before the heater switches in. The second peak is the main evaporation profile. Total ions were collected at one time by continuous scanning.)*

Sample B	0.0	0.0	100.0	60.0	10.6	0.0	0.0
Sample C	0.0	7.6	100.0	23.2	6.6	0.0	0.0

mined and total ions for diagnostic peaks collected by continuous scanning. Average ion currents for particular diagnostic peaks were determined as ratios to that of the R = C_9 internal standard. Calibration curves were constructed for ions of particular interest. Such calibration curves were used in the quantitative analysis of commercial benzalkonium chloride mixtures.

RESULTS AND DISCUSSION

The chemical-ionization mass spectra of pure benzalkonium chlorides have been measured, and predictable, characteristic fragmentation patterns affording diagnostic ions of use in structural identification were determined (Scheme I). Diagnostic ions were observed at $M^+ -14$ (loss of CH_3 plus addition of H) and $M^+ -90$ (loss of $C_6H_5CH_2$ plus addition of H). A low-intensity peak was also observed for the benzalkonium cation. A common peak was found at *m/z* 91 due to the tropilium ion. Table I shows the fragmentation data for a series of pure benzalkonium chloride standards where R = C_{10}, C_{12}, C_{14}, C_{16}, and C_{18}. From these data it was possible to determine the molecular weight of the individual

Table IV—Total Ion-Current Ratios for $M^+ -90$ Ions and Calculated Molar Ratios of Component Benzalkonium Chlorides in Commercial Mixtures and R = C_9 Internal Standard

Commercial Mixture	R	Total Ion-Current Ratio, C_n/C_9	Molar Ratio in Mixture, %
Sample A	C_{12}	0.021 ± 0.0024	2
	C_{14}	0.035 ± 0.0028	2
	C_{16}	0.350 ± 0.0038	26
	C_{18}	1.080 ± 0.0093	70
Sample B	C_{12}	1.812 ± 0.018	71
	C_{14}	0.529 ± 0.020	24
	C_{16}	0.121 ± 0.014	4
Sample C	C_{10}	0.438 ± 0.0157	5
	C_{12}	1.119 ± 0.0488	68
	C_{14}	0.334 ± 0.0640	23
	C_{16}	0.054 ± 0.0223	5

benzalkonium chloride, since a significant M^+ peak (2–10% relative intensity) in addition to medium intensity ions at $M^+ -14$ and $M^+ -90$ was observed. The $M^+ -90$ peak was the most intense in all the spectra examined and was chosen for quantitative investigations. Replicate 2-μl analytical samples containing varying proportions of the R = C_9 standard and the appropriate benzalkonium chloride were introduced into the mass spectrometer, and the total-ion currents for their $M^+ -90$ ions, together with their peak heights, were simultaneously determined to give relative evaporation profiles. Evaporation profiles for all the compounds were

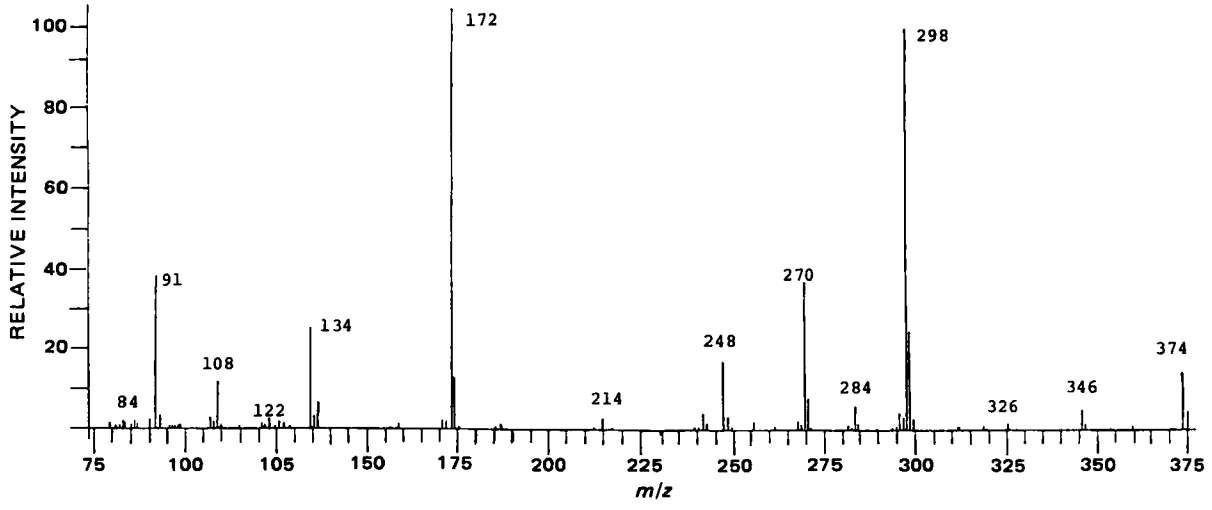

Figure 2—*Chemical-ionization mass spectrum of commercial sample A benzalkonium chloride containing C_9 internal reference from* m/z *75–400.*

similar to one another, as illustrated in Fig. 1 for R = C_{14} and R = C_9 internal standard. Results were expressed as total ion-current ratios for R = C_n/C_9. Table II gives total ion-current ratios together with coefficients of variation for repeat integrations of varying molar proportions of R = C_9 and benzalkonium chloride standards C_{10}–C_{18}. Interestingly, the integral ratios R = C_n/R = C_9 varied with alkyl chain length (Table II); consequently, it was necessary to construct calibration curves for each individual benzalkonium chloride species examined. These were constructed by assay of various dilutions of test compound, spiked with internal standard. Graphs of total ion-current ratio *versus* concentration were linear in nature for all benzalkonium chlorides examined.

Samples of commercial benzalkonium chloride mixtures were prepared as methanol solutions (1 mg/ml). Spectra were obtained for these mixtures (illustrated in Fig. 2 for sample A), and the relative intensities of their component benzalkonium chloride species were determined (Table III). As can be seen, sample A contains R = C_{12}, C_{14}, C_{16}, and C_{18}, with R = C_{18} predominating, whereas samples B and C are predominant in R = C_{12} species but are qualitatively different. Having determined the species content of the mixtures, quantitative measurements were carried out by the simultaneous monitoring of each M^+ −90 ion relative to the M^+ −90 ion of the internal standard. Concentrations of benzalkonium chloride species were obtained by relating total ion-current ratios (Table II) to those from the calibration data. From these data it can be observed that two of the three commercial samples comply with the USP limits, while the remaining sample varies quite markedly in alkyl chain compositions (See Table IV).

Solubility in Binary Solvent Systems III: Predictive Expressions Based on Molecular Surface Areas

WILLIAM E. ACREE, JR. and J. HOWARD RYTTING ˣ

Received February 8, 1982, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication May 13, 1982.

Abstract □ The nearly ideal binary solvent model, which has led to successful predictive equations for the partial molar Gibbs free energy of the solute in binary solvent mixtures, was extended to include molecular surface areas as weighting factors. Two additional expressions were derived and compared to previously developed equations (based on molar volumes as weighting factors) for their ability to predict anthracene and naphthalene solubilities in mixed solvents from measurements in the pure solvents. The most successful equation in terms of goodness of fit involved a surface fraction average of the excess Gibbs free energy relative to Raoult's law and predicted experimental solubilities in 25 systems with an average deviation of 1.7% and a maximum deviation of 7.5%. Two expressions approximating weighting factors with molar volumes provided accurate predictions in many of the systems studied but failed in their ability to predict anthracene solubilities in solvent mixtures containing benzene.

Keyphrases □ Binary solvents—solubility, predictive expressions based on molecular surface areas □ Solubility—binary solvent systems, predictive expressions based on molecular surface areas □ Molecular surface area—solubility in binary solvent systems □ Anthracene—prediction of solubility in binary solvent systems based on molecular surface areas □ Naphthalene—prediction of solubility in binary solvent systems based on molecular surface areas

The use of binary solvents for influencing solubility and multiphase partitioning has many potential applications in the pharmaceutical industry. However, maximum realization of these applications depends on the development of equations that enable *a priori* prediction of solution behavior in mixed solvents from a minimum number of additional observations. Ideally, the ability to predict a drug molecule's solubility and partition coefficients based solely on a consideration of molecular structure is desired, but for more practical applications, a less fundamental approach must often suffice.

The nearly ideal binary solvent (NIBS) approach developed previously (1–6) provides a relatively simple method for estimating the excess partial molar properties of a solute, $\overline{Z}_3^{ex}$, at infinite dilution in a binary solvent (components 1 and 2):

$$\overline{Z}_3^{ex} = f_1^0(\overline{Z}_3^{ex})_1 + f_2^0(\overline{Z}_3^{ex})_2 - \Gamma_3(X_1^0\Gamma_1 + X_2\Gamma_2)^{-1}\,\overline{Z}_{12}^{ex} \quad \text{(Eq. 1)}$$

$$f_1^0 = 1 - f_2^0 = X_1^0\Gamma_1/(X_1^0\Gamma_1 + X_2^0\Gamma_2) \quad \text{(Eq. 2)}$$

in terms of a weighted mole fraction average of the properties of the solute in the two pure solvents [$(\overline{Z}_3^{ex})_1$ and $(\overline{Z}_3^{ex})_2$] and a contribution due to the unmixing of the solvent pair by the presence of the solute. This equation leads to accurate predictions of solubilities (3, 5–8), gas–liquid partition coefficients (4, 9), and enthalpies of solution (1, 2) in systems of nonspecific interactions when the weighting factors (Γ_i) are approximated with molar volumes.

A simpler approximation of equating all three weighting factors provides considerably poorer predictions for systems in which the molar volumes of the components differ appreciably. The superiority of expressions based on molar volumes suggests that the relative sizes of the molecules are an important consideration. The use of surface areas as weighting factors may be revealing, since surface area often represents a different measure of molecular size.

Keyphrases □ Binary solvents—solubility, predictive expressions based on molecular surface areas □ Solubility—binary solvent systems, predictive expressions based on molecular surface areas □ Molecular surface area—solubility in binary solvent systems □ Anthracene—prediction of solubility in binary solvent systems based on molecular surface areas □ Naphthalene—prediction of solubility in binary solvent systems based on molecular surface areas

The use of binary solvents for influencing solubility and multiphase partitioning has many potential applications in the pharmaceutical industry. However, maximum realization of these applications depends on the development of equations that enable *a priori* prediction of solution behavior in mixed solvents from a minimum number of additional observations. Ideally, the ability to predict a drug molecule's solubility and partition coefficients based solely on a consideration of molecular structure is desired, but for more practical applications, a less fundamental approach must often suffice.

The nearly ideal binary solvent (NIBS) approach developed previously (1–6) provides a relatively simple method for estimating the excess partial molar properties of a solute, $\overline{Z}_3^{ex}$, at infinite dilution in a binary solvent (components 1 and 2):

$$\overline{Z}_3^{ex} = f_1^0(\overline{Z}_3^{ex})_1 + f_2^0(\overline{Z}_3^{ex})_2 - \Gamma_3(X_1^0\Gamma_1 + X_2\Gamma_2)^{-1}\,\overline{Z}_{12}^{ex} \quad \text{(Eq. 1)}$$

$$f_1^0 = 1 - f_2^0 = X_1^0\Gamma_1/(X_1^0\Gamma_1 + X_2^0\Gamma_2) \quad \text{(Eq. 2)}$$

in terms of a weighted mole fraction average of the properties of the solute in the two pure solvents [$(\overline{Z}_3^{ex})_1$ and $(\overline{Z}_3^{ex})_2$] and a contribution due to the unmixing of the solvent pair by the presence of the solute. This equation leads to accurate predictions of solubilities (3, 5–8), gas–liquid partition coefficients (4, 9), and enthalpies of solution (1, 2) in systems of nonspecific interactions when the weighting factors (Γ_i) are approximated with molar volumes.

A simpler approximation of equating all three weighting factors provides considerably poorer predictions for systems in which the molar volumes of the components differ appreciably. The superiority of expressions based on molar volumes suggests that the relative sizes of the molecules are an important consideration. The use of surface areas as weighting factors may be revealing, since surface area often represents a different measure of molecular size.

0022-3549/83/0300-0292$01.00/0

Experimental solubilities of naphthalene (10–12) and *p*-dibromobenzene (13) are available in the literature for several binary solvent mixtures and can be used to compare the various approximations for weighting factors. However, these systems encompass a narrow two-fold range of mole fraction solubilities. The applicability of Eq. 1 is not very sensitive to errors in the relative magnitude of the weighting factors whenever the solubility of the solute is identical (or nearly identical) in both the pure solvents, but these errors become much more significant as the range of solubilities increases. For this reason, anthracene solubilities were determined in several mixtures containing benzene, which cover up to a sixfold range.

During the course of this investigation, it was noted that the NIBS model predicted a slight maximum solubility in binary solutions of cyclohexane and *n*-heptane. Such synergistic effects in simple systems are usually explained by solubility parameter theory in terms of the solubility parameter of the solute being bracketed by the solubility parameters of the two pure solvents (14, 15). However, the solubility parameter of anthracene ($\delta = 9.9$) is far greater than either the solubility parameters of cyclohexane ($\delta = 8.2$) or *n*-heptane ($\delta = 7.4$). Solubility determinations of anthracene in this binary solvent mixture will provide an additional test of the basic NIBS model.

EXPERIMENTAL

Anthracene[1] was used as received. Cyclohexane[2], *n*-heptane[3], isooctane[3], *n*-octane[4], cyclooctane[4], *n*-hexane[4], and benzene[5] were stored over molecular sieves[6]. Binary solvent mixtures were prepared by weight so that compositions could be calculated to a mole fraction of 0.0001.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant-temperature bath at 25.0° for several days. The attainment of equilibrium was verified by repetitive measurements after several additional days and in some cases by approaching equilibrium from supersaturation by pre-equilibrating the solution at a higher temperature. Aliquots of saturated anthracene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with methanol. Concentrations were determined spectrophotometrically[7] at 356 nm. Experimental solubilities of anthracene in several binary solvent mixtures are given in Table I, with the measurements being reproducible to within ±1%.

RESULTS AND DISCUSSION

The following three equations have been derived previously for solubility in binary solvent systems containing only nonspecific interactions:

$$RT \ln(a_3^{solid}/X_3^{sat}) = (1 - X_3^{sat})^2[X_1^0(\overline{G}_3^{ex})_1 + X_2^0(\overline{G}_3^{ex})_2 - \overline{G}_{12}^{ex}] \quad \text{(Eq. 3)}$$

$$RT \ln(a_3^{solid}/X_3^{sat}) = (1 - \phi_3^{sat})^2 [\phi_1^0(\overline{G}_3^{ex})_1 + \phi_2^0(\overline{G}_3^{ex})_2 - V_3(X_1^0V_1 + X_2^0V_2)^{-1}\,\overline{G}_{12}^{ex}] \quad \text{(Eq. 4)}$$

and:

$$RT\left[\ln(a_3^{solid}/\phi_3^{sat}) - (1 - \phi_3^{sat})\left(1 - \frac{V_3}{(X_1^0V_1 + X_2^0V_2)}\right)\right] = (1 - \phi_3^{sat})^2[\phi_1^0(\overline{G}_3^{fh})_1 + \phi_2^0(\overline{G}_3^{fh})_2 - V_3(X_1^0V_1 + X_2^0V_2)^{-1}\,\overline{G}_{12}^{fh}] \quad \text{(Eq. 5)}$$

in which V_i is the molar volume of a pure liquid, X_i is mole fraction, ϕ_i is volume fraction, $\overline{G}_{12}^{ex}$ is the molar excess Gibbs free energy of the binary solvent relative to Raoult's law, and:

$$\overline{G}_{12}^{fh} = \overline{G}_{12}^{ex} + RT[\ln(X_1^0V_1 + X_2^0V_2) - X_1^0 \ln V_1 - X_2^0 \ln V_2] \quad \text{(Eq. 6)}$$

Numerical values of $\overline{G}_{12}^{ex}$ can be found in the chemical literature for many common binary systems. For example, the thermodynamic excess properties of several hundred binary systems have been listed (16). The superscript (0) indicates that the solvent composition is calculated as if the solute were not present. The activity of the solid solute (a_3^{solid}), relative to the supercooled liquid, can be calculated by:

$$\ln a_3^{solid} = -\frac{\Delta H_3^{fus}(T_m - T)}{R\,T_m\,T} + \frac{\Delta C_p(T_m - T)}{RT} - \frac{\Delta C_p}{R}\ln(T_m/T) \quad \text{(Eq. 7)}$$

[a] RMS deviations (%) = $(100/N^{1/2})\{\sum_{j=1}^{N}[\ln(X_{calc}^{sat}/X_{exp}^{sat})]^2\}^{1/2}$; the algebraic sign indicates that all deviations were of the same sign.

from the molar heat of fusion (ΔH_3^{fus}) at the normal melting point (T_m) and the differences between the molar heat capacities of the liquid and solid.

Introduction of molecular surface areas (A_i) into Eq. 1 results in the development of two more predictive expressions:

$$RT\ln(a_3^{solid}/X_3^{sat}) = (1-\theta_3^{sat})^2[\theta_1^0(\overline{G}_3^{ex})_1 + \theta_2^0(\overline{G}_3^{ex})_2 - A_3(X_1^0A_1 + X_2^0A_2)^{-1}\,\overline{G}_{12}^{ex}] \quad \text{(Eq. 8)}$$

and:

$$RT\left[\ln(a_3^{solid}/\phi_3^{sat}) - (1-\phi_3^{sat})\left(1-\frac{V_3}{(X_1^0V_1 + X_2^0V_2)}\right)\right] = (1-\theta_3^{sat})^2[\theta_1^0(\overline{G}_3^{fh})_1 + \theta_2^0(\overline{G}_3^{fh})_2 - A_3(X_1^0A_1 + X_2^0A_2)^{-1}\overline{G}_{12}^{fh}] \quad \text{(Eq. 9)}$$

depending on whether a regular solution model (Eq. 8) or a Flory–Huggins model (Eq. 9) is used to describe solution ideality. The use of these five predictive equations for solubility predictions in binary solvents is as follows: the quantities $(\overline{G}_3^{ex})_i$ or $(\overline{G}_3^{fh})_i$ are calculated from the experimental solubility of the solute in the pure solvents, then these properties are used in the appropriate equation to calculate the solubility as X_3^{sat} or ϕ_3^{sat} in the solvent mixture using a reiterative process. The quantity $(1 - f_3^{sat})$ is taken as unity in the first approximation, and convergence is rapid unless the solubility is large. A numerical example is presented in the *Appendix* illustrating the prediction of naphthalene solubility in a binary mixture containing *n*-hexane and carbon tetrachloride using Eq. 4.

The predictive abilities of these equations are compared in Table II for 25 systems for which solubility data and the excess free energy of the binary solvent are available at or near the same temperature. Surface areas of the individual molecules were taken from tabulated values presented in previous reports (17–20), with the exception that the surface area of carbon tetrachloride was provided[8]. In all cases, the surface areas exclude solvent molecules which may be located within the atomic radii. Table III lists numerical values of the surface areas and molar volumes used in these predictions.

Based on surface areas as weighting factors for the excess free energy relative to Raoult's law, Eq. 8 is seen to be the most generally applicable with an overall average (RMS) deviation[9] of 1.7% and a maximum error for a single data point of 7.5%. This maximum deviation occurs in a system (benzene–*n*-heptane) in which conflicting values of $\overline{G}_{12}^{ex}$ have been reported. As shown in Table II, deviations between predicted and observed solubilities depend to a large extent on which literature source is used for the solvent properties. This leads to two sets of predicted anthracene solubilities that differ from each other by as much as 6%. Discrepancies in the reported values of $\overline{G}_{12}^{ex}$ were not noted for the remaining 15 binary solvent systems. The primary advantage of Eq. 8 over expressions based on molar volumes, Eqs. 4 and 5, is its applicability to anthracene solubilities in solvent mixtures containing benzene. If these systems are excluded from the calculations, Eqs. 4 and 5 are slightly better than equations based on surface areas. All five equations correctly predict a maximum mole fraction solubility for anthracene in cyclohexane–*n*-heptane mixtures.

Solubility in simple binary solvents, C_3^{sat}, was described (21) as:

$$C_3^{sat} = K_1C_1 + K_2C_2 \quad \text{(Eq. 10)}$$

and:

$$K_i = (C_3^{sat})_i/C_i^* \qquad i = 1, 2$$

where C is molar concentration, and C_i^* is the concentration in a pure solvent. For solutes of limited solubility, it was demonstrated (4) that Eq. 3 is equivalent to:

$$X_3^{sat} = X_1^0(X_3^{sat})_1 + X_2^0(X_3^{sat})_2 \quad \text{(Eq. 11)}$$

While Eq. 11 gives reasonable predictions for several of the anthracene systems studied, these predictions are off by as much as 50% for *p*-benzoquinone in the *n*-heptane–carbon tetrachloride system (8) and off by a factor of two for benzil in the isooctane–carbon tetrachloride system (7)[10]. Inspection of Eq. 4 reveals that the mathematical form is incapable of completely describing systems having either a maximum or minimum mole fraction solubility. Anthracene exhibits a maximum solubility in binary mixtures of cyclohexane and *n*-heptane, and a slight minimum solubility has been observed for iodine in binary mixtures containing cyclohexane and octamethylcyclotetrasiloxane (6). It has been suggested

[8] The authors thank Robert S. Pearlman, University of Texas, for providing the surface area of carbon tetrachloride.

[9] RMS Deviations (%)

$$= (100/N^{1/2})\left\{\sum_{j=1}^{N}[\ln(X_{calc}/X_{exp})]^2\right\}^{1/2},$$

and these values are then averaged for all of the systems listed in Table II.

[10] For solutes having greater solubility $C_i = X_i/(X_1V_1 + X_2V_2 + X_3Y_3)$ and Eq. 10 can be shown to be equivalent to:

$$\frac{X_3^{sat}}{1-X_3^{sat}} = X_1^0\left(\frac{X_3^{sat}}{1-X_3^{sat}}\right)_{X_2^0=1} + X_2^0\left(\frac{X_3^{sat}}{1-X_3^{sat}}\right)_{X_2^0=1}$$

This consideration does not significantly alter the large deviations for the solubilities of *p*-benzoquinone and benzil. This extended form cannot predict either a maximum or minimum solubility.

Table III—Properties Used in Calculations

Component	$\overline{V}$, ml/mole	$\overline{A}$, Å²/mole	
Benzene	89.41	109.5	
Carbon tetrachloride	97.08	118.7	
Cyclohexane	108.76	120.8	
Hexadecane	294.12	323.2	
n-Heptane	147.48	160.3	
n-Hexane	131.51	142.1	
Cyclooctane	134.88	148.8	
Octane	163.46	178.4	
Isooctane	166.09	163.1	
Toluene	106.84	126.5	
Ethylbenzene	123.06	144.9	
Naphthalene	123.00	155.8	(a_3^{solid} = 0.312)
p-Dibromobenzene	118.00	156.6	(a_3^{solid} = 0.248)
Anthracene	150.00	202.2	(a_3^{solid} = 0.01049)

(22) that the incorporation of mixed solvates into Eq. 11 is a way to explain maximum solubilities:

$$1{\cdot}3 + 2 \rightleftharpoons 1{\cdot}2{\cdot}3$$

$$K' = \frac{C_{1\cdot2\cdot3}}{C_{1\cdot3}C_2}$$

$$C_3^{sat} = K_1C_1 + K_2C_2 + K'K_1C_1C_2 \qquad \text{(Eq. 12)}$$

Postulation of mixed solvates is not needed in the nearly ideal binary solvent model, as its predictive equations correctly predict the existence of the maximum anthracene solubility as well as the minimum iodine solubility.

The Scatchard–Hildebrand (23) equation:

$$RT \ln(a_3^{solid}/X_3^{sat}) = V_3(1 - \phi_3^{sat})^2 (\delta_{12} - \delta_3)^2 \qquad \text{(Eq. 13)}$$

$$\delta_{12} = \frac{\phi_1\delta_1 + \phi_2\delta_2}{\phi_1 + \phi_2} \qquad \text{(Eq. 14)}$$

describes solubility in simple binary solvent mixtures in terms of the solubility parameters (δ_i) of the individual pure components. For liquids, the solubility parameters are available in the literature or can be determined experimentally from the temperature dependence of vapor pressures. The solubility parameters of crystalline compounds are obtained indirectly from solubility measurements, and several calculated methods (24–26) have been suggested recently for determining the best value of δ_3. Examination of Eqs. 13 and 14 reveals that the solute should exhibit a maximum mole fraction solubility only when its solubility parameter is between the solubility parameters of the two pure solvents. Since the solubility parameter of anthracene (δ = 9.9) is greater than either the solubility parameter of cyclohexane (δ = 8.2) or *n*-heptane (δ = 7.4), a maximum anthracene solubility would not be predicted by Eq. 13. Similar failures of Eq. 6 have been observed for benzoic acid in cyclohexane–*n*-heptane and cyclohexane–*n*-hexane mixtures (5) and for anthracene in benzene–iodobenzene, benzene–iodoethane, cyclohexane–iodoethane, and cyclohexene–iodoethane mixtures (27). It was noted (5) that Eqs. 3–5 predicted the existence of maximum benzoic acid solubilities for both the monomeric and dimeric treatment of monofunctional carboxylic acids. Because of the unavailability of binary $\overline{G}_{12}^{ex}$ values, it was not possible to apply the NIBS model to the anthracene solubilities listed above. The fact that the nearly ideal binary solvent model correctly predicts maximum solubilities in three of these binary solvent mixtures suggests its greater application.

CONCLUSIONS

An important consequence of this research involves earlier contentions that the failure of Eq. 1 may be taken as an indication of specific solute–solvent or solvent–solvent interactions. While this concept is relatively straightforward in principle, its practical applications are complicated by the various weighting factor approximations. For example, does the failure of Eqs. 4 and 5 to predict anthracene solubilities in binary solvent mixtures containing benzene indicate specific solute–solvent (π–π) interactions, or does the success of Eq. 8 indicate that surface areas provide better approximations of weighting factors in systems containing both a planar solute and solvent molecule.

Unfortunately, this research does not indicate clearly whether weighting factors are better approximated with molar volumes or surface areas. From the standpoint of calculational simplicity and the ready availability of molar volumes, Eq. 4 is preferred, and some support for this form can be found in its adaptability to the Scatchard–Hildebrand solubility parameter theory. Similar support for Eq. 8 (and Eq. 9) can be found in correlations of partition coefficients with surface areas and in several semi-empirical expressions developed for predicting liquid–vapor equilibria. However, Eq. 5 is also applicable to polymer solutions, and this form often is preferred, because it is more directly related to gas–liquid chromatographic partition coefficients and to molarity-based equilibrium constants.

APPENDIX

The following example illustrates the prediction of naphthalene solubility in a binary solvent mixture containing *n*-hexane and carbon tetrachloride. For calculational purposes, the initial mole fraction composition of the solvent mixture is taken to be $X_1^0 = X_{hexane}^0 = 0.5000$. This corresponds to a volume fraction of *n*-hexane of $\phi_1^0 = 0.5753$. The naphthalene solubilities in the pure solvents, $(X_3^{sat})_1 = 0.1168$ and $(X_3^{sat})_2 = 0.2591$ are taken from a previous report (10), and the excess free energy of mixing of the solvent mixture at $X_1^0 = 0.5000$, $\overline{G}_{12}^{ex} = 35.5$ cal/mole, is taken from other reported data (46).

The NIBS prediction begins by calculating the excess partial molar Gibbs free energy of the solute $(\overline{G}_3^{ex})_i$ in the two pure solvents:
For *n*-hexane:

$$(\overline{G}_3^{ex})_1 = (1 - 0.1101)^{-2}\,(1.987)(298.15)\ln(0.312/0.1168)$$
$$= 735.02 \text{ cal/mole}$$

and for carbon tetrachloride:

$$(\overline{G}_3^{ex})_2 = (1 - 0.3070)^{-2}$$
$$(1.987)(298.15)\ln(0.312/0.2591)$$
$$= 229.2 \text{ cal/mole}$$

The properties in the two pure solvents are then combined with $\overline{G}_{12}^{ex}$ to give:

$$(1.987)(298.15)\ln(0.312/X_3^{sat}) = (1 - \phi_3^{sat})^2\,[(0.5753)(735.02)$$
$$+ (0.4247)(229.2) - (123.00)(114.30)^{-1}(35.5)]$$

In the first approximation $(1 - \phi_3^{sat}) \approx 1$, and solving for the mole fraction solubility gives:

$$X_3^{sat} = 0.1383$$

The first approximation is then used to calculate $(1 - \phi_3^{sat})$, and this quantity is then used to obtain a second approximation:

$$(1.987)(298.15)\ln(0.312/X_3^{sat}) = (1 - 0.1483)^2[(0.5753)(735.02)$$
$$+ (0.4247)(229.2) - (123.00)(114.30)^{-1}(35.5)]$$

The second approximation of X_3^{sat} (= 0.1729) is used to calculate a new value of $(1 - \phi_3^{sat})$, and the calculations are repeated until a constant mole fraction solubility is obtained. As mentioned previously, this convergence is quite rapid unless the solubility is large.

Transport of Prostaglandins Through Normal and Diabetic Rat Hepatocytes

ANWAR B. BIKHAZI ˣ, GHASSAN M. BAASIRI, NABIL Z. BOULOS, and RAJA N. KHURI

Received May 15, 1980, from the *Department of Physiology, Faculty of Medicine, American University of Beirut, Beirut, Republic of Lebanon.* Accepted for publication April 14, 1982.

Abstract □ Transport of alprostadil (prostaglandin E_1) and dinoprost (prostaglandin $F_{2\alpha}$) was studied in enzymatically dispersed normal and streptozocin-treated rat hepatocytes prepared by collagenase perfusion. Cell suspensions incubated at 37° were sampled at time intervals for a period of 5 min and the supernatant analyzed for prostaglandins after centrifugation. The data analysis employed a theory and a model for solute transfer at the cell membrane–water interphase. Biophysical parameters such as the effective partition and the apparent permeability constants were used to define the transport mechanism. The apparent permeability coefficient of alprostadil and dinoprost transfer through normal hepatocytes was calculated to be 5×10^{-3} and 3×10^{-3} cm/sec with a mean partition coefficient of 1345 and 764 for both solutes, respectively. The permeability coefficient of alprostadil and dinoprost transfer through diabetic hepatocytes were 3×10^{-3} and 2×10^{-3} cm/sec with partition coefficient of 572 and 206, respectively. The results showed differences in prostaglandin transport between normal and diabetic hepatocytes, resulting from morphological and lipid alteration in the cytoplasmic membrane.

Keyphrases □ Prostaglandins—transport through normal and diabetic rat hepatocytes, alprostadil and dinoprost □ Alprostadil—transport through normal and diabetic rat hepatocytes □ Dinoprost—transport through normal and diabetic rat hepatocytes □ Hepatocytes, rat—normal and diabetic, transport of alprostadil and dinoprost □ Permeability—transport of alprostadil and dinoprost through normal and diabetic rat hepatocytes □ Partition coefficient—transport of alprostadil and dinoprost through normal and diabetic rat hepatocytes

Multicomponent and multicompartment diffusional models have been used to study transport of solutes across biological membranes. For example, erythrocyte permeability (1), lymphocyte permeability (2), Ehrlich ascites tumor cell permeability (3), and Burkitt lymphoma cell permeability (4) have been reported. The majority of the studies dealt with solute transfer through blood cell components and tissue culture cell suspensions. However, few mechanistic studies were attempted on cell suspensions obtained by enzymatic dispersion, *e.g.*, embryonic heart cells (5), adipocytes (6), and hepatocytes (7, 8).

Alprostadil (prostaglandin E_1) and dinoprost were chosen as solute models to mechanistically explain the transfer of acidic lipids through normal and diabetic rat hepatocytes. Furthermore, autoradiographic studies in mice have shown high concentrations of alprostadil and dinoprost in the liver 15 min after intravenous injection (9).

The present report describes the uptake mechanism of alprostadil and dinoprost through enzymatically dispersed normal and diabetic adult rat hepatocytes. The techniques, methodology, and the theoretical model employed are well suited to characterize interfacial barriers to interface transport in biological systems.

Transport of Prostaglandins Through Normal and Diabetic Rat Hepatocytes

ANWAR B. BIKHAZI ˣ, GHASSAN M. BAASIRI, NABIL Z. BOULOS, and RAJA N. KHURI

Received May 15, 1980, from the *Department of Physiology, Faculty of Medicine, American University of Beirut, Beirut, Republic of Lebanon.* Accepted for publication April 14, 1982.

Abstract □ Transport of alprostadil (prostaglandin E_1) and dinoprost (prostaglandin $F_{2\alpha}$) was studied in enzymatically dispersed normal and streptozocin-treated rat hepatocytes prepared by collagenase perfusion. Cell suspensions incubated at 37° were sampled at time intervals for a period of 5 min and the supernatant analyzed for prostaglandins after centrifugation. The data analysis employed a theory and a model for solute transfer at the cell membrane–water interphase. Biophysical parameters such as the effective partition and the apparent permeability constants were used to define the transport mechanism. The apparent permeability coefficient of alprostadil and dinoprost transfer through normal hepatocytes was calculated to be 5×10^{-3} and 3×10^{-3} cm/sec with a mean partition coefficient of 1345 and 764 for both solutes, respectively. The permeability coefficient of alprostadil and dinoprost transfer through diabetic hepatocytes were 3×10^{-3} and 2×10^{-3} cm/sec with partition coefficient of 572 and 206, respectively. The results showed differences in prostaglandin transport between normal and diabetic hepatocytes, resulting from morphological and lipid alteration in the cytoplasmic membrane.

Keyphrases □ Prostaglandins—transport through normal and diabetic rat hepatocytes, alprostadil and dinoprost □ Alprostadil—transport through normal and diabetic rat hepatocytes □ Dinoprost—transport through normal and diabetic rat hepatocytes □ Hepatocytes, rat—normal and diabetic, transport of alprostadil and dinoprost □ Permeability—transport of alprostadil and dinoprost through normal and diabetic rat hepatocytes □ Partition coefficient—transport of alprostadil and dinoprost through normal and diabetic rat hepatocytes

Multicomponent and multicompartment diffusional models have been used to study transport of solutes across biological membranes. For example, erythrocyte permeability (1), lymphocyte permeability (2), Ehrlich ascites tumor cell permeability (3), and Burkitt lymphoma cell permeability (4) have been reported. The majority of the studies dealt with solute transfer through blood cell components and tissue culture cell suspensions. However, few mechanistic studies were attempted on cell suspensions obtained by enzymatic dispersion, *e.g.*, embryonic heart cells (5), adipocytes (6), and hepatocytes (7, 8).

Alprostadil (prostaglandin E_1) and dinoprost were chosen as solute models to mechanistically explain the transfer of acidic lipids through normal and diabetic rat hepatocytes. Furthermore, autoradiographic studies in mice have shown high concentrations of alprostadil and dinoprost in the liver 15 min after intravenous injection (9).

The present report describes the uptake mechanism of alprostadil and dinoprost through enzymatically dispersed normal and diabetic adult rat hepatocytes. The techniques, methodology, and the theoretical model employed are well suited to characterize interfacial barriers to interface transport in biological systems.

EXPERIMENTAL

Preparation of Rat Hepatocyte Suspensions—Suspensions of isolated liver parenchymal cells were prepared by a modification of a previously described procedure (10). Male Sprague-Dawley rats weighing

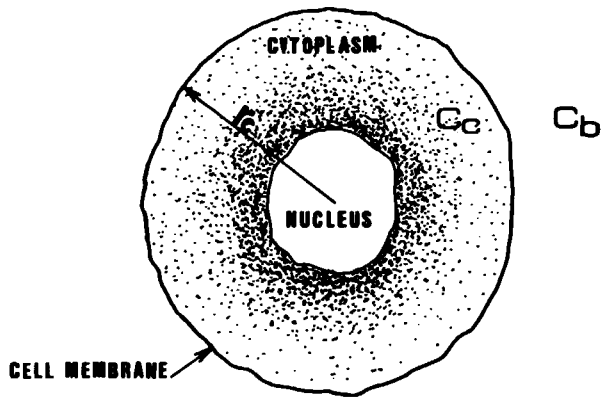

Figure 1—*Physical model describing uptake across hepatocyte–water interface.*

200–250 g and fed *ad libitum* were anesthetized by injection of 80 mg/kg ip of the sodium salt of 5-*sec*-butyl-5-ethyl-2-thiobarbituric acid[1]. The liver was initially perfused through the portal vein at a flow rate of 30–40 ml/min with 200-ml heparinized Ca^{2+}-free Krebs–Henseleit (I) solution to clear it of its blood supply. Perfusion was continued with 250 ml of I containing 0.4 mg/ml of collagenase[2] at a flow rate of 100 ml/min using a peristaltic pump[3]. All perfusion media were aereated with 95% oxygen–5% carbon dioxide throughout the experiment. After 30 min of perfusion, the fibrous tunic was scraped and the hepatocytes dispersed by gentle motion. The cells were filtered through a course 250-μm nylon-mesh filter, washed and suspended into 30 ml of Ca^{2+}- and Mg^{2+}-free phosphate buffered saline (II) (pH 7.4). Hepatocyte viability was then estimated by the trypan blue exclusion test.

Preparation of Diabetic Rats—Male rats were injected with 65 mg/kg iv streptozocin[4] in saline acidified to pH 4.5 with 0.05 *M* solution of sodium citrate. They were fed *ad libitum* and checked daily for diabetes by urine sugar analysis paper[5] and a blood glucose test (11). Animals whose blood glucose levels were >250 mg/100 ml after day 7 were used in the experiments; their livers were perfused by the same procedure mentioned above to obtain cells from diabetic rats.

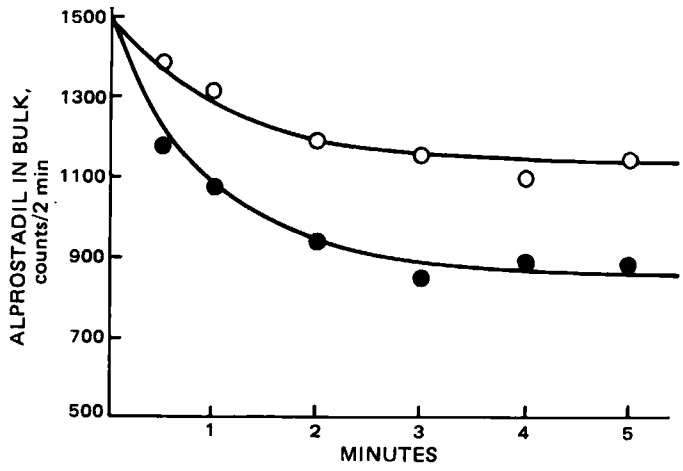

Figure 3—*Comparison of experimental data with theory for uptake of alprostadil by normal hepatocytes. Key: (○) 13,169,475 cells; (●) 27,362,137 cells;* P = 5 × 10^{-3} *cm/sec;* K = 1345.

Determination of Mean Hepatocyte Count and Diameter—An automated counter[6] was used to determine the mean hepatocyte count and diameter. The instrument was precalibrated with a suspension of polystyrene divinyl benzene latex (16.6-μm diameter).

The hepatocyte suspension (0.5 ml) was placed in a 200-ml solution of II, and cell counts were read at thresholds 2, 5, 10, 15, 20, 30, 35, 40, 60, 80, and 100, respectively.

Uptake of Alprostadil and Dinoprost by Hepatocytes from Normal and Diabetic Rats—One microcurie (~0.635 n*M*) of [5,6(*n*)-^{3}H]-alprostadil or 1 μCi (~3.81 n*M*) or [1-^{14}C]dinoprost[7] was added to 225 ml of a solution of II at 37° in a water-jacketed beaker. A 1-ml sample from time zero was withdrawn from the beaker into a liquid scintillation vial for radioactive assay in a liquid scintillation counter. Following this, a measured volume of hepatocyte suspension was added into the beaker to obtain ~1.3 × 10^{7} or 2.6 × 10^{7} cells/225 ml of a solution of II. The hepatocytes were kept in suspension throughout the experiment by stirring with a 120-rpm synchronous motor. At 0.5-, 1-, 2-, 3-, 4-, and 5-min intervals, 3-ml aliquots of the suspension were withdrawn and the cells immediately sedimented by centrifugation at 800×*g* for 15 sec. One-milliliter samples of the supernatant solutions were assayed for their radioactive content.

THEORETICAL

The selected experimental method involves the dispersion of hepatocytes in an isotonic aqueous phase. The following discussion describes a physical model with relevant interrelationships between experimental

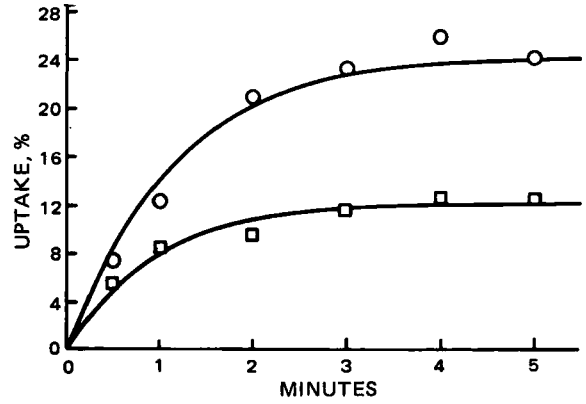

Figure 4—*Normalized plot, by percent uptake, of experimental data with theory of alprostadil by normal and diabetic hepatocytes. Key: (○) 13,169,475 normal cells;* P = 5 × 10^{-3} *cm/sec;* K = 1345; *(□) 13,450,000 diabetic cells;* P = 3 × 10^{-3} *cm/sec;* K = 572.

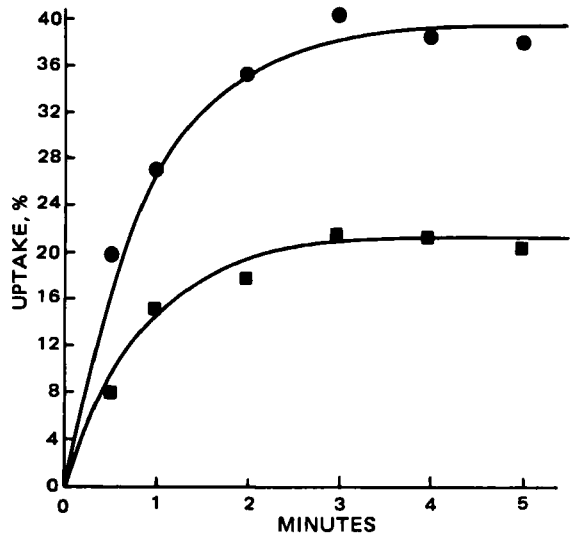

Figure 5—*Normalized plot, by percent uptake, of experimental data with theory of alprostadil by normal and diabetic hepatocytes. Key: (●) 27,362,137 normal cells;* P = 5 × 10^{-3} *cm/sec;* K = *1345; (■) 27,000,000 diabetic cells;* P = 3 × 10^{-3} *cm/sec;* K = *572.*

and theory which incorporates parameters physically describing the system.

The model shown in Fig. 1 is similar to the one proposed previously (12) for rapid equilibration in the heterogeneous cytosol with no binding of solute molecules to components outside the cell. The model describes a hepatocyte of radius r_c suspended in buffer II with C_c as the intracellular solute concentration and C_b as the aqueous bulk solute concentration. The resistance to solute transport may be described as a barrier to transfer across the cytoplasmic membrane. It is best characterized by a transport coefficient (permeability coefficient, P) which can be a function of solute and membrane characteristics.

A quasi-steady-state rate of uptake of solute by a cell was described (13) by:

$$\frac{dC_c}{dt} = \frac{4\pi r_c^2 P}{V_c}\left(C_b - \frac{C_c}{K}\right) \qquad \text{(Eq. 1)}$$

where P is the apparent permeability coefficient for the interfacial resistance, K is the effective cell-water partition coefficient, and V_c is the hepatocyte volume.

From mass balance:

$$T_{Ab} + T_{Ac} = \text{Constant} \qquad \text{(Eq. 2)}$$

can be written where T_{Ab} and T_{Ac} are the total amounts of solute in the bulk phase and in the cells at any time t. Therefore:

$$V_b C_b + 4/3\pi r_c^3 N C_c = \text{Constant} \qquad \text{(Eq. 3)}$$

where V_b is the bulk volume, and N is the number of hepatocytes in the suspension.

Differentiating C_b and C_c in Eq. 3 with respect to time and rearranging:

$$\frac{dC_b}{dt} = -\frac{4/3\pi r_c^3 N}{V_b}\frac{dC_c}{dt} \qquad \text{(Eq. 4)}$$

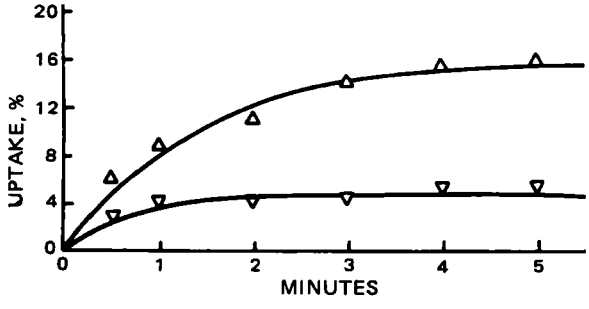

Figure 6—*Normalized plot, by percent uptake, of experimental data with theory of dinoprost by normal and diabetic hepatocytes. Key: (△) 11,948,182 normal cells;* P = 3 × 10^{-3} *cm/sec;* K = *860; (▽) 13,033,125 diabetic cells;* P = 2 × 10^{-3} *cm/sec;* K = *206.*

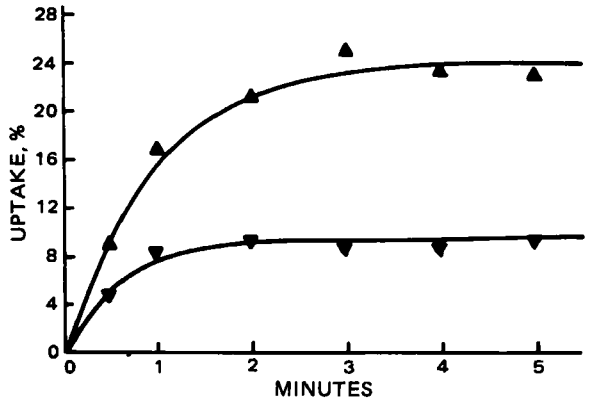

Figure 7—*Normalized plot, by percent uptake, of experimental data with theory of dinoprost by normal and diabetic hepatocytes. Key: (▲) 26,320,500 normal cells;* P = 3 × 10^{-3} *cm/sec;* K = *667; (▼), 27,169,687 diabetic cells;* P = 2 × 10^{-3} *cm/sec;* K = *206.*

Equations 1 and 4 are combined to give:

$$\frac{dC_b}{dt} = -\frac{4\pi r_c^2 NP}{V_b}\left(C_b - \frac{C_c}{K}\right) \qquad \text{(Eq. 5)}$$

Equations 1, 3, and 5 are used to solve for C_b as a function of time when V_b, K (which can be calculated from the steady-state data points and Eq. 3), r_c, P, and C_b^0 (concentration of solute in bulk phase at $t = 0$) are known. These equations can be solved analytically to yield a solution of the form:

$$C_b = Ae^{-\alpha t} + B \qquad \text{(Eq. 6)}$$

where A, α, and B are constants and are expressed as:

$$A = \frac{C_b^0 K V_c N}{(KV_c N + V_b)} \qquad \text{(Eq. 7)}$$

$$\alpha = \frac{3NP(KV_c N + V_b)}{r_c V_b K} \qquad \text{(Eq. 8)}$$

and:

$$B = \frac{C_b^0 V_b}{(KV_c N + V_b)} \qquad \text{(Eq. 9)}$$

However, to manipulate this solution is tedious and prone to errors considering the expressions for A, α, and B, especially in situations of nonuniformity in size distribution of the cells (14). A more practical approach is to resort to numerical methods using the Hamming's predictor–corrector method. The computer program calls on a subroutine which employs the fourth-order Runge–Kutta method to yield the starting values for Hamming's algorithm (15). Comparing the numerical solution with that obtained analytically for some of the data yielded a very close fit, thus, supporting the results.

RESULTS

Determination of Mean Hepatocyte Count and Diameter—The number of isolated cells per liver was ~1.2 × 10^8 hepatocytes. Hepatocyte preparations showing ≥90% viable cells were used in the experiments.

The mean hepatocyte count corresponds to threshold 17 for the calibration material polystyrene divinyl benzene latex (16.6-μm diameter). Figure 2 represents a plot of the number of normal oversize cells *versus* threshold of the suspension with mean count at threshold 30. Identical size distribution curves were observed for hepatocytes from diabetic animals. A procedure similar to the one reported previously (16) was used to calculate the mean diameter, which was estimated to be 20 μm.

Uptake Studies—Uptake studies of alprostadil and dinoprost by 6 × 10^4 and 12 × 10^4 cells/ml from normal and diabetic rats were attempted to verify that the calculated physical constants remain the same, irrespective of cell number in the uptake medium. The theoretical calculations are presented as smooth curves in Figs. 3–7 with the apparent permeability coefficient (P) experimentally determined as the value which gives the best fit to the data points.

Uptake of Alprostadil and Dinoprost by Hepatocytes from Normal Rats—Figure 3 compares the experimental data with theory for uptake of alprostadil by normal hepatocytes. A similar graph was obtained for dinoprost uptake. Steady state was observed in 5 min, and the effective cell-water partition coefficient was 1345 and 764 for alprostadil

and dinoprost, respectively. The apparent P-value for both solutes was in the range of 5×10^{-3} and 3×10^{-3} cm/sec, respectively.

Uptake of Alprostadil and Dinoprost by Hepatocytes from Diabetic Rats—Plots similar to Fig. 3 were observed with diabetic cells. The effective cell–water partition coefficient was 572 for alprostadil and 206 for dinoprost. The apparent P-value was estimated to be 3×10^{-3} and 2×10^{-3} cm/sec, respectively.

Normalized Plots of the Data—Figures 4–7 are normalized plots for alprostadil and dinoprost uptake by hepatocytes from normal and diabetic rats at almost identical cell counts. At steady state the percent uptake of alprostadil and dinoprost by normal cells was almost double that of cells from diabetic rats, because of differences in the K-values of both solutes between the two types of cells.

DISCUSSION

Diffusion- and Permeability-Controlled Transfer Through Cell Suspension Models—Solute transfer through cell suspensions is generally controlled by two physically defined situations, namely the diffusion of the solute from bulk phase to the proximity of the cell membrane, and then the permeation of the solute through the membrane. In the present study, movement of solute from the bulk phase to the hepatocyte membrane interface will be contributing minimally, if any, to the rate of solute transport. Therefore, solute transfer through the cell membrane becomes rate limiting. Membrane permeation is then physically assessed by the isolation of the apparent permeability coefficient. Since this coefficient is in the range of 10^{-3} cm/sec, then the effective diffusivities (D) of both solutes in an ~100-Å thick (d_c) hepatocyte membrane may be estimated to be in the range of 10^{-9} cm^2/sec. Therefore, the lag time for solute transport may be expressed by:

$$\tau = \frac{d_c^2}{D} \qquad \text{(Eq. 10)}$$

where τ has a value of $\sim 10^{-3}$ sec, a short lag time when compared with 5 min, the time needed to reach steady state.

Assessment of the Data—It was reported (11) that in streptozocin-treated rats, cell membranes have shown significant changes in sialic acid and cholesterol content which support the findings on concanavalin A-induced agglutination[8] that cells from diabetic rats flocculate at a slower rate than those from controls. This suggests that diabetic cells, when compared with normal cells, are either less rich in glycoprotein receptors (sialic acid-rich receptors) or the receptors are arranged differently in the cell membrane. The data on the K-values presented here show that normal cells are more lipoidal than diabetic ones. For example, the ratio of the K-values of both prostaglandins in normal cells (1345 for alprostadil and 763 for dinoprost) is 1.76, which agrees fairly well with previous data (17) on the partition coefficient ratio of alprostadil and dinoprost between n-octane and water (ratio 1.72). Furthermore, the ratio of the K-values of the same solutes in diabetic cells is 2.78, which agrees with the ratio of their partition coefficients (ratio 2.11) between 1-octanol and water as well.

The initial rate of transport of alprostadil and the apparent permeability coefficients are larger in normal as compared with diabetic hepatocytes (Figs. 4 and 5). This is also observed in Figs. 6 and 7 for dinoprost. However, alprostadil is transported faster and to a greater extent in both normal and diabetic cells than dinoprost (Figs. 4 and 6, Figs. 5 and 7, respectively). Therefore, it can be concluded that solute partitioning plays a prominant role in the transport mechanism, since the apparent permeability coefficient is a function of the effective partition coefficient.

High-Performance Liquid Chromatography of Preparations of Ribonucleic Acid Inactivator(s) from Cupric Ion and Hydroquinone Before and After Treatment with Histidine

G. R. DUBES *x, A. N. MASOUD ‡¶, and M. I. AL-MOSLIH §

Received March 22, 1982, from the *Departments of Medical Microbiology and ‡Anesthesiology, University of Nebraska College of Medicine, Omaha, NE 68105, and the §Department of Microbiology, University of Baghdad College of Medicine, Baghdad, Iraq. Accepted for publication May 17, 1982. ¶Present address: Division of Toxicology, Department of Environmental Health Sciences, School of Hygiene and Public Health, Johns Hopkins University, Baltimore, MD 21205.

Abstract □ Preparations of viral RNA inactivator(s) produced during the cupric ion-catalyzed oxidation of hydroquinone were analyzed by high-performance liquid chromatography (HPLC) using UV and electrochemical (EC) detectors. In addition to hydroquinone and the main oxidation product (*p*-benzoquinone), which is known not to be the inactivator(s), the analysis showed three unidentified components (I–III). Partial UV absorption spectra of I–III were determined by HPLC with the UV detector set at various wavelengths. Components II and III, but not I, were highly unstable in the presence of L-histidine, which is an excellent chelator of cupric ion and can promptly stop ongoing viral RNA inactivation by the inactivator(s). The product *p*-benzoquinone was also highly unstable in the presence of L-histidine; the reaction between these two compounds (with or without copper) resulted in a cascade of products. The possibility that the inactivator(s) is II or III, or both, is discussed.

Keyphrases □ Hydroquinone—high-performance liquid chromatography of preparations of ribonucleic acid inactivator(s) from cupric ion after treatment with histidine □ Histidine—high-performance liquid chromatography of preparations of ribonucleic acid inactivator(s) from cupric ion and hydroquinone □ High-performance liquid chromatography—preparations of ribonucleic acid inactivator(s) from cupric ion and hydroquinone before and after treatment with histidine

Cupric ion and many lots of commercial reagent-grade phenol interact to produce a potent inactivator(s) of the naked RNA from poliovirions; even after redistillation, the purified phenol shows a strong capacity to interact with cupric ion to produce the RNA inactivator(s) (1, 2). This RNA inactivator(s) can be a serious problem when phenol is used for the isolation of RNAs.

However, phenol purified by steam distillation shows no activity, the activity being recoverable from the aqueous residue remaining after the steam distillation (1). The activity of this residue has been shown to be due, at least in part, to hydroquinone and catechol, which occur as impurities in the commercial reagent grade phenol (2, 3). In addition to hydroquinone and catechol, two other phenols have been shown to be active: pyrogallol and orcinol (2). Hydroquinone is the most active of the four phenols (2).

When cupric ion and hydroquinone are mixed together in buffer (pH 7.3) under air, the copper-catalyzed oxidation of the hydroquinone to *p*-benzoquinone starts promptly and proceeds rapidly, and inactivator activity rises in parallel with the rise in *p*-benzoquinone concentration (4). However, as shown by direct tests, *p*-benzoquinone is not the inactivator(s), nor is cuprous ion (4).

In the present report, preparations of inactivator(s) from cupric ion and hydroquinone were examined by HPLC using UV and EC detectors with the aim of detecting additional chemical species which could be candidates for the role of inactivator(s); three such species were found. Because of the effect of L-histidine, an excellent chelator of cupric ion (5), in promptly stopping ongoing inactivation of RNA by the inactivator(s) (1), the effect of L-histidine on the stability of these three species was determined.

EXPERIMENTAL

Chemicals—The following chemicals were used: *p*-benzoquinone, practical grade[1]; cupric chloride, reagent grade[2]; hydroquinone, purified[2]; 85% orthophosphoric acid, reagent grade[3]; potassium dihydrogen phosphate, reagent grade[3]; L-histidine monohydrochloride monohydrate[4]; tetramethylammonium hydroxide pentahydrate[5].

Distilled water was deionized, demineralized, and then double-distilled in glass before use.

The commercial hydroquinone was recrystallized twice from water before use. Solutions of the recrystallized hydroquinone in water were stored frozen under nitrogen.

Preparation of Viral RNA Inactivator(s)—Inactivator preparations were made by incubating cupric chloride at 1.11 m*M* and hydroquinone at 2.22 m*M* in buffer under air at 23° for 5 min (6). The buffer used was 137 m*M* NaCl, 2.69 m*M* KCl, 8.15 m*M* Na_2HPO_4, and 1.46 m*M* KH_2PO_4, pH 7.3. To obtain the UV absorption spectra, the incubation was for 20 instead of 5 min so that higher concentrations of the unknown products I–III would be obtained.

Treatment of Inactivator Preparation with L-Histidine—Solutions of buffer containing L-histidine hydrochloride at 167 m*M* and with the pH adjusted with sodium hydroxide back to 7.3 were prepared. One volume of the buffer with L-histidine, at 23°, was mixed with three volumes of fresh inactivator preparation. Samples were taken immediately and after various periods of incubation at 23°. Controls were done in the same way, except that plain buffer was used instead of buffer with L-histidine.

Treatment of *p*-Benzoquinone with L-Histidine—One volume of the above mentioned buffer with L-histidine, at 23°, was mixed with three volumes of a reference solution of 0.300 m*M* *p*-benzoquinone in buffer with cupric chloride at 1.11 m*M* or without cupric chloride. This reference solution had been preincubated under air at 23° for 5 min, in simulation of the incubation used in preparing the viral RNA inactivator(s). Samples were taken immediately and 15 min after adding the L-histidine. In the controls, plain buffer replaced the buffer with L-histidine.

HPLC—An isocratic HPLC system similar to that previously described was used (7). The fixed-volume injector[6] contained a 20-μl loop. A 250 × 4-mm reverse-phase column packed with Lichrosorb[7] RP-18, 10 μm, with a slurry packing technique was used. A guard column RP-18 MPLC[8] was incorporated into the system. An aqueous mobile phase containing 100 m*M* KH_2PO_4 and 12.5 m*M* tetramethylammonium hydroxide, pH adjusted to 3.9 using 14.7 *M* H_3PO_4, was prepared using the triple-distilled deionized demineralized water. This mobile phase was

filtered through a 0.2-μm porosity membrane filter[9], deaerated under vacuum, and kept at 40° during chromatography. The UV detector was set at 260 nm and 0.05 absorbance units full scale in most experiments. In some experiments, as described, the UV detector was set at wavelengths shorter or longer than 260 nm. The EC detector was set at 0.7 V and 100 nA full scale.

RESULTS

Components of Preparations of RNA Inactivator(s)—HPLC of RNA inactivator preparations made using the 5-min incubation of cupric chloride with hydroquinone showed six peaks (Fig. 1A): the solvent front peak, where cupric ion elutes; hydroquinone; *p*-benzoquinone; and three unidentified products (I–III). At the UV wavelength of 260 nm used for this chromatogram, product III appears as a trailing shoulder on the peak due to product II; but when 230-nm UV was used, II and III were seen as two peaks (Fig. 2). The peak due to component I was also more obvious when 230-nm UV was used (Fig. 2). The peak between component I and hydroquinone (Fig. 2) was due to one of the components, possibly unknown component XI (see below), appearing only after incubation of the cupric chloride and hydroquinone together for more than 5 min. Chromatograms of such inactivator preparations were found to be highly reproducible when the same conditions for production of inactivator(s), for separation, and for detection were used.

Partial UV Absorption Spectra of Components I–III—Partial UV absorption spectra of components I–III were determined from chromatograms of replicate inactivator preparations with the UV detector set at various UV wavelengths from 200 to 320 nm and are shown in Fig. 3.

Components Appearing upon Further Incubation of RNA Inactivator Preparations—In this study, attention was concentrated on components I–III, because of their presence after incubation of cupric ion with hydroquinone for only 5 min, and since previous experiments had shown that the production of RNA inactivator(s) from cupric ion and hydroquinone proceeds rapidly and without lag (4).

When the reaction between cupric chloride and hydroquinone was prolonged beyond 5 min, as in the controls where one-third volume of plain buffer was added at 5 min and the incubation continued at 23°, additional unknown products appeared. This result was shown by tests of samples that were taken after additional incubation periods of 5, 15, 30, 60, 180, and 420 min and analyzed by HPLC using both detectors with the UV detector set at 260 nm. These chromatograms showed seven additional unknown products (VIII–XIV) with retention times of <1 hr. Referred to by the earliest time of their appearance in min after starting the additional incubation, by the detector(s) *sensitive to them and by* their retention times in minutes and seconds, these seven products were: VIII, 5UV and EC5:45; IX, 5UV and EC17:15; X, 15UV4:45; XI, 15UV8:05; XII, 60EC4:15; XIII, 180UV14:15; XIV, 420UV41:35.

Effects of Histidine—The addition of L-histidine to inactivator preparations resulted in the rapid loss of components II and III but not of component I (Figs. 1 and 4). The synthesis of additional component I was, however, greatly diminished by L-histidine. The addition of L-histidine had other effects, which may be grouped in two sets.

The first set consists of effects that are connected or probably connected with the capacity of L-histidine to chelate cupric ion. One such effect was the very rapid formation of chelate complex(es) of cupric ion and L- histidine (8) (Fig. 1B); the offscale UV-absorbing peak at the solvent front (*S*) was due mainly to such complex(es), as shown by control chromatograms of L-histidine and cupric chloride chromatographed individually and after being mixed together. Another effect was the virtually immediate cessation of the oxidation of hydroquinone. A third effect was the blocking of the production of VIII, IX, XI, XIII, and XIV. Production of X was not blocked. Whether production of XII was blocked was not ascertained, due to interference from new compounds appearing after adding L-histidine (Fig. 1 and below).

The second set of effects of L-histidine consists of those which were

[9] Millipore.

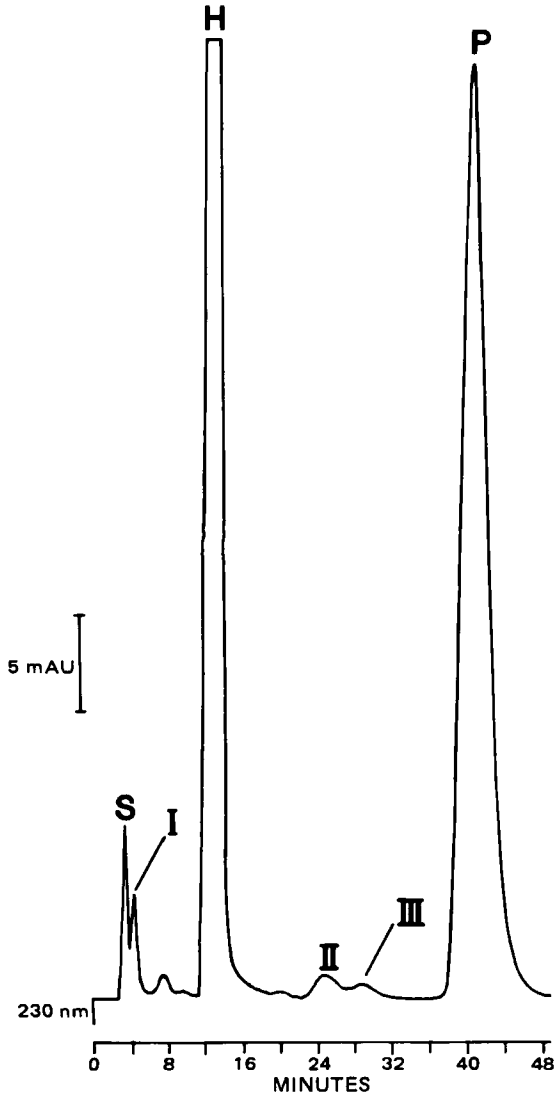

Figure 2—*Chromatogram of RNA inactivator prepared using 20-min incubation. Symbols as in Fig. 1.*

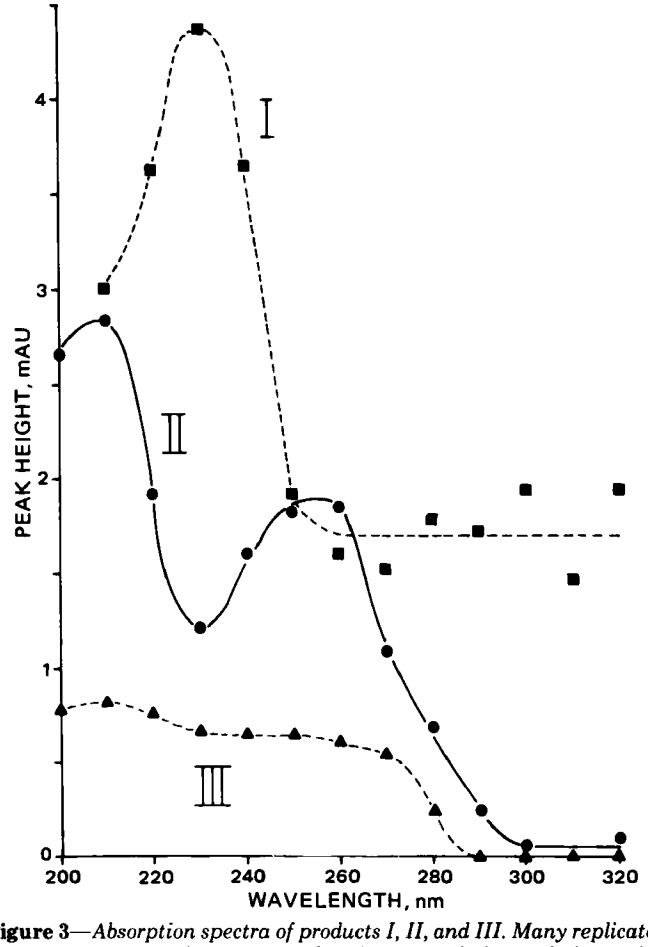

Figure 3—*Absorption spectra of products I, II, and III. Many replicate inactivator preparations were made using a 20-min instead of a 5-min incubation, the addition of plain buffer, and immediate sampling for analysis by HPLC using the UV detector, which was set at 200, 200, 220, 230, 240, 250, 260, 270, 280, 290, 300, 310, and 320 nm, respectively, for the replicate preparations. For each chromatogram, peak heights in milliabsorbance units (mAU) for unknown components I–III were estimated. The point for component I at 200 nm was missed due to interference from the offscale solvent front.*

found to be independent of the capacity of L-histidine to chelate cupric ion. These effects were (*d*) the rapid loss of *p*-benzoquinone (Figs. 1 and 4), (*e*) the increase in hydroquinone (Figs. 1 and 4), and (*f*) the appearance of a cascade of new compounds including IV–VII (Figs. 1 and 5).

Evidence of the cascade of new compounds was seen soon after the addition of L-histidine. Within 15 min after this addition, four new components, IV–VII, appeared. Components IV and V were detected by the EC detector and VI and VII by the UV detector (Fig. 1B). The kinetics of production of IV–VII and the kinetics of the later decrease or disappearance of IV, VI, and VII are shown in Fig. 5. These four components did not appear in the controls not containing L-histidine. At times > 15 min after adding L-histidine, additional new compounds appeared which did not appear in the corresponding controls that had received only plain buffer. At least four of these additional compounds are shown in Fig. 1C, where the inactivator preparation had been incubated for 3 hr after adding the L-histidine. Such chromatograms are highly reproducible. To avoid cluttering the figure, these additional unknown compounds have not been numbered.

That the above effects (*d*), (*e*), and (*f*) are independent of copper was shown by tests of the effect of L-histidine on *p*-benzoquinone with and without cupric ion. Buffer with L-histidine, or plain buffer for the controls, was added to solutions of commercial *p*-benzoquinone in buffer with and without cupric chloride; and the mixtures were analyzed either immediately or after 15 min at 23°. The chromatograms showed that L-histidine, with or without copper, caused a rapid decrease in the concentration of *p*-benzoquinone. In two experiments, after 15 min only 14 and 9.3% of the starting *p*-benzoquinone remained when cupric chloride was not added; when cupric chloride was added the corresponding figures were 17 and 21%. In the controls where plain buffer was added, there was no significant change in the concentration of *p*-benzoquinone in 15 min with or without cupric chloride. In the commercial *p*-benzoquinone used there was a very small amount of hydroquinone, detectable by the EC detector. In 15 min after adding L-histidine, the amount of hydroquinone increased five- to eightfold with or without cupric chloride. In the controls where plain buffer was added, there was no significant change in the concentration of hydroquinone in 15 min without cupric chloride; but with cupric chloride there was, as expected, a marked reduction in the concentration of hydroquinone after 15 min, due to cupric ion-catalyzed oxidation. The chromatograms of samples taken 15 min after the addition of L-histidine to the *p*-benzoquinone with and without cupric chloride showed peaks virtually identical to unknown components IV–VII both in retention time and in detector response ratios of the UV and EC detectors.

These experiments show that L-histidine reacts with *p*-benzoquinone, that direct or indirect products of the reaction are hydroquinone and unknown components IV–VII, and that copper is not necessary for this reaction or for the production of these five products. These effects of the reaction between L-histidine and *p*-benzoquinone can account for the above-described effects (*d*), (*e*), and (*f*).

DISCUSSION

The most significant aspects of this work are that components other than hydroquinone and *p*-benzoquinone were sufficiently stable to be detected by HPLC in preparations of RNA inactivator(s) and that two of these components, II and III, were unstable in the presence of L-histidine. This instability casts II and III as candidates for the role of inac-

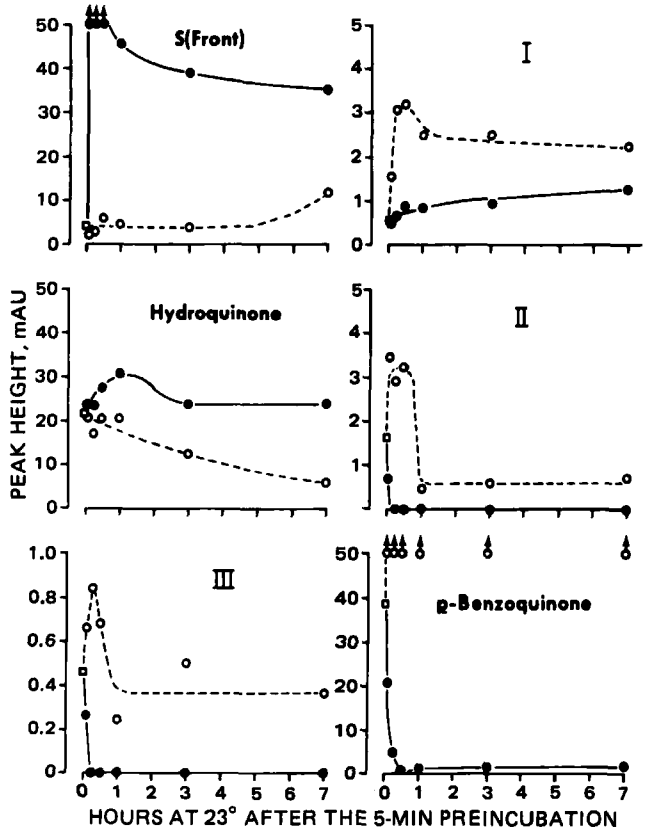

Figure 4—*Effect of L-histidine on six UV-absorbing peaks from inactivator preparation. The inactivator preparation was made and the control and experimental additions were made as in Fig. 1. A sample of the control was immediately injected for analysis by HPLC, using the same chromatographic conditions as in Fig. 1. Incubation of control and experimental continued at 23°, under air, and samples taken at the various times shown were analyzed by HPLC. Key: mAU, milliabsorbance unit; S, peak at solvent front; I–III, three unknown components shown in Fig. 1A. Figure 5—*Kinetics of appearance and disappearance of unknown components IV–VII after addition of L-histidine. Inactivator preparations were made and L-histidine then added, as in experimentals of Fig. 1B and C. Samples were analyzed by HPLC 5, 15, 30, 60, 180, and 420 min later. Components IV and V were analyzed by EC detector, VI and VII by UV detector, as in Fig. 1. mAU, milliabsorbance unit.*

tivator(s). What connection, if any, components II and III may have with the free radical species at the one-electron oxidation step, namely, *p*-benzosemiquinone and its anion as well as the complex of this anion with cupric ion (9), is presently unknown.

Another important aspect of the work is that it shows the multiplicity of the effects of L-histidine on RNA inactivator preparations. It appears that most or all of these effects can be attributed to just two properties of L-histidine: its capacities to chelate cupric ion and to react with *p*-benzoquinone.

For more than a century, various amines have been known to react with *p*-benzoquinone (10). The reaction leads successively to several products. For example, reaction with an aromatic amine may yield 2-arylaminohydroquinone, 2,5-diarylaminohydroquinone, and from these products the corresponding quinones through oxidation by remaining *p*-benzoquinone; moreover, this oxidation would in turn also yield hydroquinone. If the reacting amine were L-histidine, the substituent on the hydroquinone and on the quinone would be relatively polar, and the substituted compounds would be expected to show shorter retention times in the HPLC system used here than the corresponding unsubstituted compounds. Also, it would be expected that the substituted quinones would be detectable by the UV detector at 260 nm but probably not detectable by the EC detector as used here, whereas the substituted hydroquinones would probably be more readily detected by the EC detector. Thus, such a series of reactions could explain several of the observations regarding the reaction between *p*-benzoquinone and L-histidine, namely: (*a*) the rapid production of four unknown components (IV–VII), (*b*) that two of these were detected by EC, whereas the other two were detected by UV, (*c*) the retention times of IV–VII relative to the retention times of hydroquinone and *p*-benzoquinone, and (*d*) the increase in hydroquinone.

Abstract □ Structural juxtaposition of the 3,4,5-trimethoxyphenyl group in the same molecule with a piperazine or homopiperazine ring has been realized in a series of mescaline analogues (I–IV) as part of an investigation into the pharmacological properties of the seven-membered perhydro-1,4-diazepines (homopiperazines). The analogous six-membered piperazines were synthesized and tested as reference substances to determine whether the seven-membered ring conveyed special properties. A variety of pharmacological tests of action on the CNS showed that replacement of the amino group in mescaline by the heterocycles significantly alters the biological activity. In particular, both the piperazine and the homopiperazine derivatives displayed sedative activity to about the same extent.

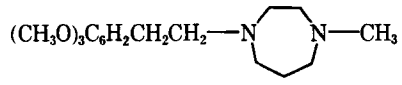
Keyphrases □ Mescaline analogues—synthesis and action on the CNS, containing piperazine or homopiperazine rings □ CNS agents—synthesis and action of mescaline analogues containing piperazine or homopiperazine rings □ Piperazine rings—mescaline analogues, synthesis and action on the CNS □ Homopiperazine rings—mescaline analogues, synthesis and action on the CNS

The 3,4,5-trimethoxyphenyl moiety attached to an amino nitrogen through a two- or three-carbon bridge is well known as a pharmacophoric group in drugs that possess sedative, hypotensive, antiarrhythmic, and vasodilating properties (1). Furthermore, there are numerous commercial drugs containing the piperazine ring, and a few with the perhydro-1,4-diazepine (homopiperazine) ring. At least two drugs contain both the homopiperazine ring and the trimethoxyphenyl group: 1-methyl-4-(3,4,5-trimethoxybenzoyloxy)methylhomopiperazine, an antihypertensive agent, and 1,4-bis[3-(3,4,5-trimethoxybenzoyloxy)propyl]homopiperazine (dilazep), a coronary vasodilator.

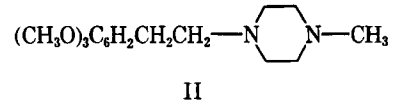
Mescaline, 2-(3,4,5-trimethoxyphenyl)ethylamine [3,4,5-$(CH_3O)_3C_6H_2CH_2CH_2NH_2$], a simple trimethoxyphenyl derivative, has been known as an hallucinogen and an agent on the CNS. The present study explored the biological effects on the CNS of a molecule that closely juxtaposes the trimethoxyphenyl group with the homopiperazine ring. This arrangement was obtained by replacing the amino group in mescaline with the homopiperazine ring. The piperazine analogue also was examined for comparison. These lines of inquiry were suggested by earlier investigations on the conformational (2, 3) and pharmacological (4) properties of homopiperazines.

DISCUSSION

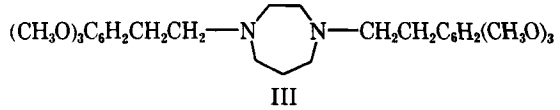
The synthetic objective was attachment of the heterocycles, piperazine or homopiperazine, through a bismethylene fragment to the trimethoxyphenyl group. One approach attached the heterocycle to the bismethylene carbon through one nitrogen, and the second nitrogen carried a methyl group (compounds I and II, respectively). In another approach, both nitrogens of the heterocycles were supplied with the trimethoxyphenyl substrate (compounds III and IV, respectively). The synthesis of these four molecules began with 3,4,5-trimethoxyphenylacetic acid [3,4,5-$(CH_3O)_3C_6H_2CH_2CO_2H$].



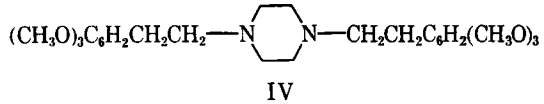
I



II



III



IV

Reduction of the corresponding methyl ester and treatment with thionyl chloride produced the chloride, 3,4,5-$(CH_3O)_3C_6H_2CH_2CH_2Cl$, which was allowed to react with the cyclic amines to give the four desired compounds, 1-methyl-4-[2-(3,4,5-trimethoxyphenyl)ethyl]perhydro-1,4-diazepine (I); 1-methyl-4-[2-(3,4,5-trimethoxyphenyl)ethyl]piperazine (II); 1,4-bis[2-(3,4,5-trimethoxyphenyl)ethyl]perhydro-1,4-diazepine (III); and 1,4-bis[2-(3,4,5-trimethoxyphenyl)ethyl]piperazine (IV). Alternatively, the ester, 3,4,5-$(CH_3O)_3C_6H_2CH_2CO_2CH_3$, was converted through the acid chloride to the amide containing the heterocycle, and the amide was reduced to the desired product. The structures of all products were confirmed by spectral and elemental analysis.

The four compounds were used in nine separate tests of pharmacological activity. In several tests, the dose level as a ratio of the LD_{50} was varied. No differences were found between the control group, which received doses of 0.9% NaCl, and the groups that received doses of compounds I–IV, for the following properties: body temperature, behavioral despair, central action of 3-(3,4-dihydroxyphenyl)-L-alanine (levodopa), apomorphine-induced stereotypy, or convulsant action of pentylenetetrazol. None of the compounds eliminated the aggressiveness of isolated mice. Quantitative data for apomorphine behavior are given in Table I. Other negative results are omitted. Thus, these compounds do not exhibit activity typical of tranquilizers.

Positive, dose-related results for three other tests are listed in Table I. All four tested compounds prolonged sleeping time and inhibited locomotor activity in mice. Reduction in amphetamine-induced locomotor stimulation was observed in mice for all four compounds, but the results are significant at the 95% level only for I and II, which contain a single

trimethoxyphenyl residue. Thus, the results of these tests indicate that I–IV exhibit sedative activity.

The presence of the piperazine or homopiperazine ring in place of the simple amino group in mescaline significantly alters the effect of the compound on the CNS. Within this group of compounds, there was little difference in sedative activity between the six- and seven-membered rings. Previously tested (5) homopiperazine-containing compounds, which were esters or amides of *p*-chlorobenzoic acids, did not exhibit a depressive effect on the CNS. Consequently, the sedative activity of I–IV is caused at least in part by the presence of the 3,4,5-trimethoxyphenylethyl moiety. Since neither mescaline nor *N,N*-dimethylmescaline (6) exhibits this behavior, it was concluded that the sedative activity requires both the trimethoxyphenyl group and the cyclic, tertiary amine.

EXPERIMENTAL

Chemistry—Melting points (uncorrected) were determined in open glass capillaries[1]. IR spectra were obtained on a scanning spectrophotometer[2], either as a neat thin film or as potassium bromide disks. NMR spectra were recorded[3] with respect to tetramethylsilane. Mass spectra[4] were obtained by direct injection. Microanalysis[5] for carbon, hydrogen, and nitrogen were within 0.4% of calculated values. Piperazine, 1-methylpiperazine, homopiperazine, and 3,4,5-trimethoxyphenylacetic acid were commercially available[6]. 1-Methylhomopiperazine was prepared according to the literature (7).

2-(3,4,5-Trimethoxyphenyl)ethanol—Trimethoxyphenylacetic acid[6] was converted to its ester, which was reduced according to a previous method (8), with a change in the ratio of lithium aluminum hydride to 1.5 moles/mole of the methyl-3,4,5-trimethoxyphenylacetate: 76% yield, bp 160–164°/0.8 mm Hg.

Anal.—Calc. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60. Found: C, 62.02; H, 7.55.

1-Chloro-2-(3,4,5-trimethoxyphenyl)ethane — 1-Chloro-2-(3,4,5-trimethoxyphenyl)ethane was prepared by treatment of the alcohol with thionyl chloride in pyridine (8): 74% yield, bp 158–160°/0.8 mm Hg.

Anal.—Calc. for $C_{11}H_{15}ClO_3$: C, 57.27; H, 6.55. Found: C, 57.01; H, 6.48.

3,4,5-Trimethoxyphenylacetyl Chloride — 3,4,5-Trimethoxyphenylacetic acid[6] (17.8 g, 0.15 mole) was added to a benzene solution (100 ml) of thionyl chloride (22.6 g, 0.1 mole). The reaction mixture was heated to reflux until evolution of sulfur dioxide ceased. Benzene and excess thionyl chloride were removed by rotary evaporation, and the residue was distilled to give 16.2 g (72.3%) of the product: bp 154–156°/1 mm Hg, mp 96–98° (from petroleum ether).

Anal.—Calc. for $C_{11}H_{13}ClO_4$: C, 53.99; H, 5.35. Found: C, 53.55; H, 5.25.

1-Methyl-4-(3,4,5-trimethoxyphenylacetyl)perhydro-1,4-diazepine—The acid chloride (4 g, 0.016 mole) was added dropwise with boiling to a benzene solution (50 ml) of 1-methylhomopiperazine (1.82 g, 0.016 mole) and sodium carbonate (2.1 g, 0.02 mole). Stirring and heating were continued for 3 hr, and the hot reaction mixture was filtered from the inorganic salts. The solvent was removed by rotary evaporation, and the residue was recrystallized from diethyl ether–benzene: 2.6 g, 50% yield, mp 111–114°; NMR (chloroform-*d*) δ 1.85 (m, 2H, CCH_2C), 2.29 (s, 3H, NCH_3), 2.50 (m, 4H, $RNCH_2$), 3.58 (m, 6H, $CONCH_2$), 3.82 (s, 9H, OCH_3), and 6.5 (s, 2H, aromatic); IR (KBr) 3050, 1670, and 1620 cm^{-1}.

Anal.—Calc. for $C_{17}H_{26}N_2O_4$: C, 63.33; H, 8.13; N, 8.69. Found: C, 63.20; H, 8.21; N, 8.90.

1-Methyl-4-[2-(3,4,5-trimethoxyphenyl)ethyl]perhydro-1,4-diazepine (I)—In a dropwise fashion, 1-chloro-2-(3,4,5-trimethoxyphenyl)ethane (10 g, 0.04 mole) in 75 ml of a 1:1 solution of toluene–dimethylformamide was added to a refluxing solution of toluene (75 ml) and dimethylformamide (75 ml) containing 1-methylhomopiperazine (4.5 g, 0.04 mole) and anhydrous potassium carbonate (11.04 g, 0.08 mole). Stirring and heating were continued for 14 hr. The inorganic salts were filtered, and the solvents were removed by rotary evaporation. The residue was distilled to give 6.5 g (52.7%) of the product: bp 175–190°/0.2 mm Hg, n_D^{20} 1.5365; NMR (chloroform-*d*): δ 1.85 (m, 2H, CCH_2C), 2.42 (s, 3H, NCH_3), 2.77 (m, 12H, CH_2), 3.88 (s, 9H, OCH_3), 6.47 (s, 2H, aromatic); IR (film) 3050, 1620, and 1520 cm^{-1}.

The dihydrochloride was prepared by acidification of I in absolute diethyl ether with an ether solution of anhydrous hydrogen chloride: mp 240–241°.

Anal.—Calc. for $C_{17}H_{30}Cl_2N_2O_3$: C, 53.54; H, 7.93; N, 7.35. Found: C, 53.23; H, 7.67; N, 7.20.

Reduction of 1-methyl-4-(3,4,5-trimethoxyphenylacetyl)perhydro-1,4-diazepine with lithium aluminum hydride in tetrahydrofuran afforded I (45%) that was identical chemically and spectroscopically to the material obtained above.

1-Methyl-4-[2-(3,4,5-trimethoxyphenyl)ethyl]piperazine (II)—Treatment of 1-chloro-2-(3,4,5-trimethoxyphenyl)ethane with piperazine[6] in a manner analogous to the preparation of I produced II: 6.3 g, 53.5% yield, bp 174–184°/0.2 mm Hg, n_D^{20} 1.5335; NMR (chloroform-*d*): δ 2.38 (m, 15H, CH_3/CH_2), 3.79 (s, 9H, OCH_3), and 6.38 (s, 2H, aromatic); IR (film) 3050, 1620, 1510, and 1150 cm^{-1}. The dihydrochloride was prepared as described for I, mp 257–258° dec.

Anal.—Calc. for $C_{16}H_{28}Cl_2N_2O_3$: C, 52.32; H, 7.68; N, 7.63. Found: C, 52.01; H, 7.61; N, 7.45.

1,4-Bis[2-(3,4,5-trimethoxyphenyl)ethyl]perhydro-1,4-diazepine (III)—To a refluxing solution of toluene (75 ml) and dimethylformamide (75 ml) containing homopiperazine[6] (1.5 g, 0.015 mole) and anhydrous potassium carbonate (8.26 g, 0.06 mole) was added 1-chloro-2-(3,4,5-trimethoxyphenyl)ethane (7.0 g, 0.03 mole) in 50 ml of 1:1 toluene–dimethylformamide, in a dropwise fashion. Stirring and heating were continued for 14 hr. The inorganic salts were filtered, and the solvents were removed by rotary evaporation. The thick, oily residue (7 g, 95% yield) appeared by spectroscopy to be pure but failed to crystallize. It was purified as the hydrochloride, which was prepared as described for I: 6 g, 75% yield, mp 198–200° (absolute methanol–diethyl ether); NMR (chloroform-*d*): δ 1.80 (m, 2H, CCH_2C), 2.68 (m, 16H, CH_2), 3.71 (s, 18H, OCH_3), and 6.32 (s, 4H, aromatic); IR (film of crude product) 3050, 1600, 1510, and 1130 cm^{-1}.

Anal.—Calc. for $C_{27}H_{42}Cl_2O_6N_2$: C, 57.75; H, 7.54; N, 4.99. Found: C, 57.55; H, 7.34; N, 4.57.

1,4-Bis[2-(3,4,5-trimethoxyphenyl)ethyl]piperazine (IV)—Compound IV was prepared in the same manner as described for III, but with piperazine[6]. After evaporation of the solvents, the residue crystallized from 1:1 diethyl ether–petroleum ether: 2.3 g, 32% yield, mp 120–122°; NMR (chloroform-*d*): δ 2.65 (s, 16H, CH_2), 3.87 (s, 18H, OCH_3), and 6.41 (s, 4H, aromatic). IR (KBr) 3040, 1620, 1500, and 1160 cm^{-1}. The dihydrochloride was prepared as described for I: mp 259–260° dec.

Anal.—Calc. for $C_{26}H_{40}O_6N_2Cl_2$: C, 57.03; H, 7.36; N, 5.12. Found: C, 56.85; H, 7.23; N, 5.01.

Pharmacology—The experiments were performed on male Swiss white mice (18–26 g) and male Wistar rats (150–180 g). The investigated compounds were administered intraperitoneially in aqueous solutions.

The LD_{50} values were determined by a previous method (9).

The effect of I–IV on locomotor activity in normal and amphetamine-treated mice was recorded throughout 30-min sessions in photoresistant cages. The investigated compounds (administered intraperitoneally) and amphetamine (5 mg/kg sec) were administered 60 and 30 min, respectively, before testing.

The effect on the apomorphine-induced stereotypy was investigated in rats. Apomorphine (1.25 mg/kg sec) was injected 60 min after the tested compounds.

For the effect on sleeping time in mice, hexobarbital (70 mg/kg ip) was injected 60 min after the test compounds.

Anticonvulsant activity was investigated by the minimal and maximal pentylenetetrazol shock (pentylenetetrazol, 80 and 50 mg/kg sc, respectively). The number of animals protected against clonic convulsions in minimal shock or tonic extensions of limbs in maximal shock was registered.

The effect on behavioral despair in mice was examined by a previous method (10). The compounds were injected 60 min before examination.

The effect on the central action of 3-(3,4-dihydroxyphenyl)-L-alanine (levodopa) was tested on mice by modifications of a previous method (11). The alanine (100 mg/kg) was injected 4 hr after pargyline (40 mg/kg po) and 1 hr after the investigated compounds.

The effect on the aggressiveness of isolated (3 weeks) mice was examined by a previous method (12). Behavior was tested at 1-hr intervals for 4 hr.

Rectal body temperature in mice was measured with a thermometer for 3 hr after administration of the test compounds.

Phenytoin I: *In Vitro–In Vivo* Correlation for 100-mg Phenytoin Sodium Capsules

VINOD P. SHAH ˣ, VADLAMANI K. PRASAD, TREVA ALSTON, BERNARD E. CABANA, RICHARD P. GURAL *, and MARVIN C. MEYER ‡

Received March 9, 1981, from the *Division of Biopharmaceutics, Food and Drug Administration, Washington, DC 20204*, and the **School of Pharmacy, University of Tennessee, Memphis, TN 37916.* Accepted for publication April 6, 1982. ‡Present Address: Clinical Drug Metabolism, Schering Corp., Bloomsfield, NJ 07003.

Abstract □ *Dissolution profiles for 11 brands of phenytoin sodium capsules were carried out by the basket and paddle methods (USP) and the spin-filter method. The results from the dissolution studies have been correlated with observed differences in in vivo parameters (C_{max} and t_{max}). The dissolution by the basket method at 50 rpm in water gave a correlation >0.9. The results suggest the existence of two types of phenytoin sodium products on the market.*

Keyphrases □ Phenytoin—*in vitro–in vivo* correlation for sodium phenytoin capsules, dissolution □ Dissolution—*in vitro–in vivo* correlation for sodium phenytoin capsules □ *In vitro–in vivo* correlation—sodium phenytoin capsules, dissolution

Increasing evidence has been presented in the scientific literature which show correlations between the *in vivo* performance of formulations and their *in vitro* dissolution behavior (1–3). To obtain an *in vitro–in vivo* correlation for any product, two criteria are essential: (*a*) the differences in *in vivo* parameters such as *AUC*, t_{max}, C_{max}, or C_p at a time among different lots tested and (*b*) differences in the *in vitro* dissolution rates of the same products. In cases where differences are observed in *in vivo* behavior, the *in vitro* parameter can be altered to optimize the correlation with *in vivo* data. This is achieved by varying such parameters as dissolution methodology, dissolution medium, rate of agitation, *etc.* In many instances, it has been possible to obtain correlations with *in vivo* data where a discriminating and reproducible *in vitro* test is employed (1–3). *In vitro–in vivo* correlations can generally be achieved with any reproducible method provided the proper selection of medium and the degree of agitation are made so as to permit discrimination among drug products. The key elements are reproducibility of the method, proper choice of medium, and degree of agitation.

Phenytoin is a commonly used anticonvulsant drug and has been classified as a drug with high risk potential with

respect to bioavailability problems (4). Because of its physicochemical properties, narrow therapeutic range, and dose-dependent kinetics, phenytoin has been identified as a critical drug with a potential bioavailability–bioequivalence problem (5–9). Phenytoin sodium capsules are manufactured by several companies whose formulations have exhibited bioavailability–bioequivalence problems (4, 6, 9). It has been documented that phenytoin products of different manufacturers have pronounced influence on the rate and extent of absorption of the new drug resulting in bioinequivalence (6, 9).

A number of studies, using marketed phenytoin dosage forms were conducted to establish a correlation between the *in vivo* bioavailability and *in vitro* dissolution parameters.

EXPERIMENTAL

All dissolution studies were carried out by USP methods I and II as described in USP XX with an agitation speed of 50 rpm for both methods in distilled water (10) and by the spin-filter method with an agitation speed of 300 rpm in distilled water (11). All samples were analyzed using a spectrophotometer[1].

The studies involving human subjects were carried out after obtaining appropriate clearances and approval[2]. The study design, the analytical method, and the results are published elsewhere (12).

RESULTS AND DISCUSSIONS

The bioequivalence study was conducted in healthy volunteers using 11 lots of marketed 100-mg phenytoin sodium capsules manufactured by eight different companies[3] in two groups (six products each) using the innovator's product[4] as a reference product (12). All products were evaluated with respect to *AUC*, C_{max}, t_{max}, and plasma levels at different time intervals. The results of the previous study (12) show a significant

difference in rate (C_{max} and t_{max}) and in the extent of bioavailability (*AUC*) in one group, and only a difference in C_{max} in the other group. The bioavailability of the products is defined both with respect to rate and extent. Because of a narrow therapeutic range and dose-dependent metabolism of phenytoin, even small changes in the rate of absorption may result in major changes in serum drug concentration, thus resulting in serious clinical consequences in some patients. Therefore, a clear distinction must be made between slow-absorbing and fast-absorbing phenytoin products.

The *in vitro* dissolution studies for these products were carried out under various conditions in order to obtain the correlation with *in vivo* data. The *in vivo* data obtained are invariant and are dependent on the

behavior of the dosage forms administered. The *in vitro* procedures can be altered such that correlations can be made between *in vitro* dissolution results and *in vivo* pharmacokinetic parameters. Such correlations can be statistically significant with respect to one or more of these *in vivo* parameters. Occasionally, there may be a product that exhibits an anomalous behavior with respect to an *in vitro* or *in vivo* parameter.

The *in vitro* dissolution studies were carried out by using the USP dissolution methods *I and II* (basket and paddle) with an agitation of 50 rpm and by the spin-filter method with an agitation of 300 rpm in water. A marked difference in dissolution profiles of these products was observed, both in terms of rate of extent of dissolution in 1 hr (Fig. 1, Table I). The amount of drug dissolved in 30 min (basket method, 50 rpm) varied between 18 and 100% and between 56 and 100% in 60 min. Based on the dissolution characteristics, the products could be classified in two major groups: products that dissolved slowly and achieved only 50–60% dissolution in 1 hr (*e.g.*, product F, Fig. 1) and products that dissolved rapidly and achieved >80% dissolution in 30 min (*e.g.*, product C, Fig. 1). This observed difference in the dissolution profiles of the phenytoin sodium products manifested itself in the *in vivo* performance of the product, resulting in a significantly different rate, but not the extent of bioavailability.

The correlation between C_{max} and percent drug dissolved in 30 and 60 min, and between t_{max} and percent drug dissolved in 30 and 60 min is shown in Figs. 2 and 3, respectively. Among the methods correlated, the basket method resulted in the best correlation ($r = 0.94$) followed by the spin-filter method ($r = 0.836$) and then the paddle method ($r = 0.694$).

These studies suggest that there are two types of phenytoin sodium products on the market. Because of the wide divergence in the dissolution rate of marketed phenytoin products and because of the very slow dissolution characteristics of the most commonly prescribed reference product, it is difficult to set a single dissolution standard covering all products. Therefore, a more definitive study comparing the slow-dissolving phenytoin sodium reference product and the fast-dissolving phenytoin sodium product with a phenytoin sodium solution as a reference standard was carried out. This study will be described in a subsequent report.

Phenytoin II: *In Vitro–In Vivo* Bioequivalence Standard for 100-mg Phenytoin Sodium Capsules

VINOD P. SHAH ˣ, VADLAMANI K. PRASAD, CORINNE FREEMAN, JEROME P. SKELLY, and BERNARD E. CABANA

Received March 9, 1981, from the *Division of Biopharmaceutics, Bureau of Drugs, Food and Drug Administration, Washington, DC 20204.* Accepted for publication April 6, 1982.

Abstract □ A bioequivalence study was undertaken using an oral solution, a fast-dissolving capsule and a slow-dissolving phenytoin sodium capsule. The *AUC*, t_{max} and C_{max} correlated with *in vitro* dissolution data. The results of the present studies substantiate the presence of two types of phenytoin sodium products on the market. On the basis of these studies, *in vitro* specifications for fast- and slow-dissolving phenytoin sodium capsules as well as the *in vivo* bioequivalence requirements for these two types of products are recommended.

Keyphrases □ Phenytoin—*in vitro–in vivo* bioequivalence standard for phenytoin sodium capsules, dissolution □ Dissolution—*in vitro–in vivo* bioequivalence standard for phenytoin sodium capsules □ Bioequivalence—*in vitro–in vivo* standard for phenytoin sodium, capsules, dissolution

A good correlation between *in vitro* dissolution and *in vivo* parameters for phenytoin sodium (sodium salt of 5,5-diphenylhydantoin) capsules has been established (1). Previous work indicated that there are two types of phenytoin sodium products on the market, *i.e.*, fast and slow dissolving (1). It was shown that some of the marketed products including the innovator's phenytoin sodium capsules[1] dissolved slowly. Furthermore, the slow-dissolving innovator's product achieved significantly lower peak concentration at a later time (t_{max}) compared with other faster-dissolving products used in the study. Since there are differences between products, bioavailability studies using a solution as a reference standard were initiated. Two studies (single and multiple dose) were carried out using a slow-dissolving product, a fast-dissolving product, and a phenytoin sodium solution. The multiple-dose study was reported previously (2).

EXPERIMENTAL

***In-Vitro* Dissolution Studies**—The dissolution studies were carried out with distilled water using USP method I (rotating basket method) as described in USP XX with an agitation speed of 50 rpm (3).

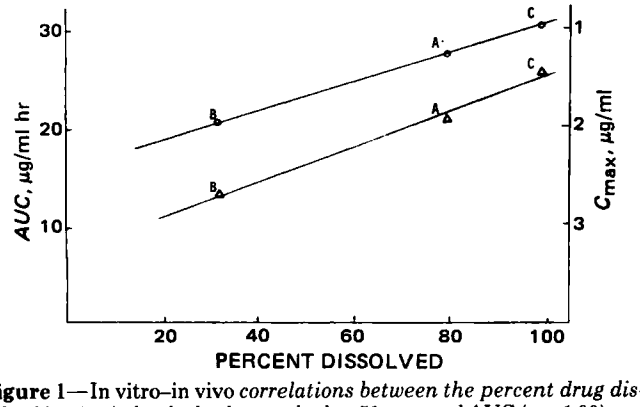

Figure 1—In vitro–in vivo *correlations between the percent drug dissolved in 30 min by the basket method at 50 rpm and* AUC (r = *1.00) and* C_{max} (r = *0.98) for products A, B, and C. Key:* (○) AUC; (△) C_{max}.

[1] Parke-Davis.

Using a randomized Latin-square design, the single-dose study was carried out in 15 healthy volunteers employing the following phenytoin sodium products: a fast-dissolving 100-mg phenytoin sodium capsule (product A); a slow-dissolving 100-mg phenytoin sodium capsule (product B); and a 100-mg phenytoin sodium solution (product C)[2,3]. Blood and saliva samples were collected over a period of 32 hr and analyzed by the published GC method with minor modifications (4).

The multiple-dose study was carried out in 24 epileptic patients using a fast-dissolving 100-mg phenytoin sodium capsule (product D), a slow-dissolving 100-mg phenytoin sodium capsule (product E), and a 100-mg phenytoin sodium solution (product F)[4,5] on a regimen of three doses per day for a 2-week period (2). Blood samples were collected and analyzed by a previous high-performance liquid chromatographic method (5).

RESULTS AND DISCUSSION

The evaluation of the data from the earlier single-dose study suggested that the reference phenytoin sodium product commonly used was slow dissolving and gave lower peak plasma concentrations (4). The C_{max} for this product was 0.93 μg/ml compared to C_{max} values of 1.06–1.44 μg/ml for other products (4).

Table I summarizes the various pharmacokinetic parameters obtained in this single-dose study. Statistical analysis of the data indicates a significant difference in *AUC*, C_{max}, and t_{max} for the three products tested. The use of a phenytoin sodium solution resulted in a higher C_{max}, higher *AUC*, and shorter t_{max} than the fast-dissolving capsule which, in turn, was higher and faster than the slow-dissolving capsule. The relative bioavailability of the slow-dissolving product was 73% compared with the solution and 80% compared with fast-dissolving product. As expected, these data correlate very well (r = 1.00 for *AUC*, and r = 0.98 for C_{max}) with the dissolution data (Fig. 1, Table I). The correlation between values of C_{max}, t_{max}, and the percent dissolved in 30 min by the basket method is shown in Fig. 1.

The results from the multiple-dose study summarized in Table II support the results of the single-dose study. The analysis of the steady-state blood level data from the multiple-dose study showed a significant difference in C_{max} and *AUC* values achieved with fast- and slow-dissolving products. The fast-dissolving phenytoin sodium product (D) and the phenytoin sodium solution resulted in significantly higher steady-state plasma levels when compared with the slow-dissolving phenytoin sodium product (E). The fast-dissolving product (D) was equivalent to the solution in C_{max} and *AUC*. Comparison of the C_{min} values revealed little, if any, difference in the three products tested. However, in 40% of the patients, therapeutically significant differences in plasma levels (> ±25%) were observed. In some instances plasma level differences of >5 μg/ml were observed (2, 6). These data substantiate the premise that the rate of dissolution is an important contributing factor in determining the rate of absorption and bioavailability of the product. The details of this study will be published elsewhere.

used in these bioavailability studies were carried out by the basket method in water at 50 rpm (1). The fast-dissolving product showed a dissolution of ~80% in 30 min. The slow-dissolving product showed a dissolution of ~35% in 30 min, 60% in 60 min and 85% in 120 min.

***In Vitro–In Vivo* Correlations**—A number of researchers have attempted to study the correlation between *in vitro* dissolution and *in vivo* performance of phenytoin sodium products. A good correlation has been reported (7) for a variety of phenytoin products (including free acid, sodium salt, and calcium salt in tablet or capsule dosage forms) and the percent drug dissolved in 30 min when the dissolution is carried out by the USP basket method at 150 rpm in pH 9 borate buffer. Correlations of 0.920 and 0.950 were observed between percent dissolved in 30 min and C_{max} and *AUC* values, respectively (7). In this report, correlations of 0.98, 0.97, and 1.00 were observed between percent drug dissolved in 30 min and C_{max}, t_{max}, and *AUC* values, respectively (Table I, Fig. 1).

Poor correlation between *in vivo* and *in vitro* data, in spite of observed significant differences in *AUC*, C_{max}, and t_{max} has also been reported (8). Dissolution studies were carried out by the basket method in pH 9 borate buffer at 120 rpm (9). The lack of correlation found by these researchers can be attributed to the dissolution conditions employed. However, the phenytoin products were found to be acceptable, but were not considered to be interchangeable. The *in vivo* studies described here substantiate these findings. However, because of the differences in the dissolution methodologies employed, it is possible to correlate the *in vitro* results with *in vivo*, thus substantiating previous work (7).

The studies described here and in a previous report (1) have demonstrated a wide variance in the dissolution performance of marketed phenytoin sodium products which has been correlated with significant differences in *in vivo* performance. Because of the critical nature of this drug and documented bioinequivalence of phenytoin, an approved New Drug Application is required before marketing a phenytoin or phenytoin sodium drug product. Based on dissolution data, bioavailability data from single-dose and multiple-dose studies, and *in vitro–in vivo* correlation, it appears that there are two distinct types of phenytoin sodium products on the market, a slow-dissolving phenytoin sodium capsule (or extended phenytoin sodium capsule) and a fast-dissolving phenytoin sodium capsule (or prompt phenytoin sodium capsule). Phenytoin often is administered on a long-term basis. Due to its dose-dependent metabolism and narrow therapeutic range, even small changes in bioavailability profile can cause major changes in serum phenytoin concentration and can have serious clinical implications. Because of the differences in rate of drug delivery and absorption, it is possible that a patient accustomed to the slow-dissolving product and changed over to the fast-dissolving product may achieve higher, possibly toxic, blood levels. If the patient is accustomed to the fast-dissolving product, he or she may not achieve therapeutic levels when changed over to the slow-dissolving product. These products are not interchangeable and are therefore, not therapeutically equivalent.

Based on the information available, two separate *in vitro* and *in vivo* bioequivalence requirements for the two types of phenytoin sodium products, fast- and slow-dissolving, can be established. The *in vitro* dissolution specifications have already been accepted by the USP.

For fast-dissolving or prompt phenytoin sodium products, the bioequivalence requirements are:

Table II—Steady-State Pharmacokinetic Parameters During Administration of 100-mg Phenytoin Sodium Three Times a Day

Product	C_{min}, μg/ml	C_{max}, μg/ml	*AUC*, μg/ml hr
D	12.2	14.0	100
E	10.8	11.8	86
F	12.4	14.3	103
ANOVA	No difference	D ≠ E E ≠ F D = F	D ≠ E E ≠ F D = F

1. The test product shall be deemed to meet the *in vitro* bioequivalence requirement if it dissolves ≥80% in 30 min, and 95% in 60 min when the dissolution is carried out in water using the rotating basket method at 50 rpm.
2. The test product shall be deemed to meet the *in vivo* requirement when a satisfactory single-dose bioavailability study in humans is carried out comparing the test product with phenytoin sodium solution and the reference product.

For slow-dissolving or extended phenytoin sodium products, the *in vivo* bioequivalence testing will involve satisfactory human single-dose and multiple-dose study data. The single-dose bioavailability study should compare the test product with the reference product and a phenytoin sodium solution. The multiple-dose study should compare equivalent doses of the test and reference product administered once a day in patients. The USP labeling requirement for rapidly dissolving phenytoin sodium products contains the statement "not for once a day dosing" (10). The extended-release (slow-dissolving) phenytoin sodium products can be given once a day, and the prompt-release (fast-dissolving phenytoin sodium products are for two or three times a day dosing and not for once a day.

A good correlation has been observed with *in vitro* dissolution and *in vivo* bioavailability data. Based on *in vitro* and *in vivo* data, specifications for fast- and slow-dissolving phenytoin sodium capsules have been established. These products are not interchangeable because they are not therapeutically equivalent.

Hornick and Merril J. Snyder of the Division of Infectious Disease, School of Medicine, University of Maryland, Baltimore, Maryland for their assistance in the clinical studies.

Biliary Excretion of [^{14}C]Temazepam and its Metabolites in the Rat

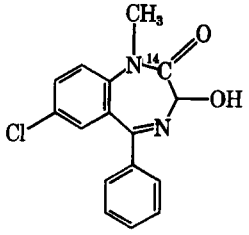
FRANCIS L. S. TSE ˣ, FRANCES BALLARD, and JAMES M. JAFFE

Received January 20, 1982, from the *Drug Metabolism Section, Sandoz, Inc., East Hanover, NJ 07936.* Accepted for publication April 13, 1982.

Abstract □ The excretion of temazepam and its *N*-desmethyl metabolite, oxazepam, and their respective *O*-conjugates was examined following a single intravenous dose of [^{14}C]temazepam to two groups of bile fistula rats, with and without bile replenishment to the animals *via* duodenal cannulae. During an 8-hr collection period, the two groups produced virtually identical bile volumes, and there were no significant differences between them in the amount of total radioactivity, free temazepam, or the identified metabolites in the bile, as determined by TLC and liquid scintillation counting. Elimination of the radioactive dose was rapid during 0–8 hr, with a half-life of ~1 hr. Approximately 85–90% of the administered radioactivity was recovered in the bile: <1% as free temazepam, 3% as oxazepam, and ~10% as their *O*-conjugates.

Keyphrases □ Temazepam—^{14}C-labeled, biliary excretion metabolites in the rat □ Excretion, biliary—[^{14}C]temazepam and its metabolites in the rat □ Metabolism—biliary excretion of [^{14}C]temazepam in the rat

Temazepam (7-chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one) is a benzodiazepine hypnotic agent recently introduced in the United States. The pharmacokinetic profile of temazepam in humans as well as in mice, rats, and dogs have been described (1). Orally administered temazepam is well absorbed in all species studied. However, there is considerable interspecies variation with respect to drug excretion and metabolite patterns in blood and urine. In humans, temazepam is completely metabolized prior to excretion, with 80% of the dose eliminated in the urine and 12% in the feces. The major metabolite is its *O*-conjugate with glucuronic acid, while *N*-desmethyl temazepam (oxazepam) and its *O*-conjugate have also been identified. In animal models, particularly the rat, biliary excretion appears to play a more important role, with as much as 78% of the dose recovered in the rat feces. Therefore, the effect of possible enterohepatic circulation must be considered in the interpretation of pharmacokinetic data obtained from these animal species.



[^{14}C]temazepam

Previous studies using radiolabeled drug in the rat (1) have shown that free temazepam and oxazepam constitute ~40% of the radioactivity in blood, while neither these compounds nor their *O*-conjugates appears in more than trace quantities in the urine. Similar information on the excretion of temazepam in bile is not available. Since the rate and extent of GI reabsorption depend in part on the nature of the compound excreted in the bile, the present study was undertaken to examine the extent of biliary excretion of temazepam and its known metabolites in rats with bile fistula, following a single intravenous dose of the parent compound. Furthermore, the possible effects of bile depletion due to bile duct cannulation on bile flow and biliary excretion of the drugs were also investigated.

EXPERIMENTAL

Animal Preparation—Six male Wistar strain rats[1], average weight ~250 g, were equally divided into two groups, A and B. The bile duct of each rat was cannulated proximal to the liver under light ether anesthesia. In addition, a silicone tube[2], 0.019-cm i.d., was inserted into the duodenum of each rat in group A opposite the sphincter of Oddi and secured by ligation with a surgical silk suture. The tubings were passed subcutaneously and the distal end exteriorized through a stab incision at the back prior to closure of the abdomen with sutures.

The rats were housed individually in special metabolism cages with covers that allowed passage of the cannulae (2). The cover also served as a restraint for the rat, while allowing some freedom of movement inside the cage.

The duodenal cannulae of the rats in group A were subsequently connected *via* 0.013-cm i.d. silicone pump tubes[3] to a peristaltic pump[4]. Previously collected control rat bile was pumped into these rats at a rate of 0.9 ml/hr, approximately the rate of bile secretion of rats of this size.

Dosing and Sample Collection—The radioactive temazepam[5] (labeled at the 2-position of the benzodiazepin structure with carbon-14, specific activity 52.25 μCi/mg) was diluted with nonradioactive drug to a final specific activity of 26.13 μCi/mg. The [^{14}C]temazepam dose, 2 mg/kg, was prepared as a 2.5 mg/ml solution in a phosphate buffer (pH 7.3) containing 40% polyethylene glycol 400 and 10% ethanol. After recovering from anesthesia, each rat received 0.2 ml of the solution as a single, rapid injection *via* the tail vein. Food and a 5% solution of glucose in Ringer's solution were provided *ad libitum*.

The bile of each rat was collected quantitatively at hourly intervals for 8 hr postdosing. All bile samples were stored frozen until analyzed.

Analysis of Radioactivity—Radioactivity was measured in a liquid scintillation counter[6]; the quench correction and efficiency of the counter were determined using ^{14}C-labeled hexadecane[7] of known specific activity as an internal standard. The bile and dose preparations were assayed directly by counting aliquots in a scintillation cocktail consisting of 2,5-bis-2-(5-*tert*-butylbenzoxazolyl) thiophene[8] in toluene (8.3 g/liter).

Thin-Layer Chromatography—Free temazepam and oxazepam were determined by TLC on silica gel[9]. A 1–2 μl bile sample was applied to the chromatographic sheet, which was subsequently developed in ethyl acetate–methanol–ammonium hydroxide (15:4:1). Standard solutions obtained by adding temazepam and oxazepam to control bile were developed concurrently, and the R_f values of these two compounds were determined by visualization under UV light (254 nm)[10].

The sample strip was cut into eight 1.5-cm sections and placed indi-

7–8	0.90 ± 0.10	0.73 ± 0.15	0.31 ± 0.076	0.57 ± 0.29
0–8	6.9 ± 0.34	6.5 ± 1.5	85.9 ± 7.7	89.5 ± 6.2

[a] No significant differences between groups, $p > 0.05$. [b] No significant differences between groups, $p > 0.05$, except the 1–2 hr period, $p < 0.05$. [c] Standard deviation, $n = 3$.

Table II—Mean Biliary Excretion (0–3 hr) of Temazepam and Some Metabolites in Rats with (group A) and without (group B) Bile Replenishment

Compound	Percent of Dose[a]	
	Group A	Group B
Temazepam	0.5 ± 0.3	0.5 ± 0.2
Temazepam Conjugate	4 ± 7	3 ± 4
Oxazepam	3 ± 0	3 ± 1
Oxazepam Conjugate	5 ± 4	7 ± 4
Total Identified Compounds	13 ± 10	12 ± 9

[a] No significant differences between groups, $p > 0.05$.

vidually in scintillation vials. The ^{14}C-labeled drug or metabolite was eluted by the addition of 5 ml of methanol. The scintillation cocktail (15 ml) was then added and the radioactivity determined by direct counting in a liquid scintillation counter. Thus, the radioactivity from the zones corresponding to temazepam and oxazepam, as well as total radioactivity in the bile sample, were obtained.

Similarly, total (free plus conjugated) temazepam and oxazepam were determined by the above procedure after enzymatic hydrolysis of the glucuronate or sulfate conjugates. Aliquots (100 μl) of bile were hydrolyzed by diluting with 100 μl of pH 5.2 acetate buffer, adding an excess (20 μl) of a mixture of enzymes including β-glucuronidase and sulfatase[11], and incubating at 37° for 2 hr.

Statistical Analysis—The effects of bile depletion on bile flow and biliary excretion of temazepam and its metabolites were examined by comparing the data obtained from the two groups of rats, using the two-tailed t test.

RESULTS

The mean bile flow and biliary excretion of administered radioactivity, together with statistical analysis, are given in Table I. There were no significant differences in the volume of bile produced by the two groups of rats during each hourly interval. The secretion rate appeared constant during 0–8 hr; total bile volumes produced in this period were 6.9 and 6.5 ml for rats with and without bile replenishment, respectively.

In the rats with bile replenishment *via* duodenal cannulae (group A), 52% of the radioactive dose was recovered in the bile in 1 hr, and the excretion rate gradually decreased to 0.3%/hr during 7–8 hr. Total biliary excretion in 8 hr was 86% of the dose. Similar results were obtained from the rats without bile replenishment (group B); comparison by t tests showed no signficant differences in the biliary excretion of the two groups during all but one (1–2 hr) collection interval. Total 8-hr biliary excretion in group B was 90% of the administered radioactivity.

Linear regression analysis of the logarithmic values of the excretion rates in Table I *versus* the midpoint of the time periods yielded overall elimination rate constants of 0.73 hr^{-1} ($r = -0.99$) for group A and 0.63 hr^{-1} ($r = -1.00$) for group B (3). These corresponded to half-lives of 1.0 and 1.1 hr, respectively, for the rats with and without bile replenishment.

Since nearly 80% of the dose in both groups was excreted in the bile during the first 3 hr postdosing, only these bile samples were analyzed for temazepam, oxazepam, and their conjugates. TLC analysis enabled separation of temazepam and oxazepam from other metabolites on the sheet; R_f values were 0.61 for temazepam and 0.50 for oxazepam. Thus, the relative amounts of temazepam, oxazepam, and their conjugates in each bile sample were calculated and, combined with the data in Table I, yielded the biliary excretion of each compound as a percent of the dose. The mean 0–3-hr cumulative excretion, together with statistical analysis, are shown in Table II.

Biliary excretion of free temazepam constituted <1% of the dose, while an additional 3–4% was found as temazepam conjugate. The *N*-desmethyl metabolite, oxazepam, and its conjugate in the bile accounted for 3 and 5–7% of the dose, respectively. Thus, only 12–13% of the dose was recovered in the bile as these four identified compounds. Again, there were no significant differences in the excretion of each compound by the two groups of rats.

DISCUSSION

Previous experiments in the rat have shown that the depletion of bile caused by bile duct cannulation could result in a 10- to 20-fold increase in bile salt synthesis and a decrease in the amount of bile excreted; these changes occurred within 1–2 weeks (4). The potential effects of such changes in the biliary excretion and recycling of drugs are well recognized, and sophisticated instruments have been designed for enterohepatic circulation studies in order to eliminate these artifacts (5). In the present study, however, comparison of data obtained from bile fistula rats without bile replenishment *versus* those from the rats with duodenal cannulae showed no significant differences between the two groups in the rate of bile secretion, probably due to the relatively short collection period. Thus, the results would suggest that the loss of bile has little effect on experiments of short duration (<1 day). Also, the excretion of total radioactivity, free temazepam, and the identified metabolites in the bile are unaffected by bile depletion.

Results of this study confirmed the biliary route as the major excretion pathway of temazepam in the rat. Furthermore, although temazepam, oxazepam, and their *O*-conjugates accounted for nearly 50% of the radioactivity in blood (1), they were present in much smaller proportions in the bile of rats. Less than 1% of the [^{14}C]temazepam dose was recovered unchanged, the rest extensively metabolized prior to rapid biliary excretion. Nevertheless, the clinically inactive metabolites (6) may be reverted, *e.g.*, through deconjugations, to the parent compound in the GI tract (7) and subsequently reabsorbed, thus contributing to the overall effectiveness of the temazepam dose. The demonstrated importance of the biliary excretion route warrants further studies to determine the significance of enterohepatic circulation for this drug.

Improved Microscopic Techniques for Droplet Size Determination of Emulsions

HANS SCHOTT ˣ and ALAN E. ROYCE

Received October 21, 1981, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication April 5, 1982.

Abstract □ A novel, disposable cell for microscopic determination of the droplet size of emulsions is described. It is made from a piece of adhesive tape in which a hole has been punched which is placed between a glass slide and a cover glass. This cell is easier to fill with emulsions thickened to reduce Brownian motion and creaming than commercial counting chambers, and it prevents field flow. Droplet size averages and distributions obtained with this cell and another counting chamber agreed, provided that the emulsion viscosity was ~20 cp or higher. The sample size required to provide arithmetic mean diameters with a specified accuracy at a preselected confidence probability was calculated.

Keyphrases □ Droplet size determination—improved microscopic techniques for emulsions □ Emulsions—improved microscopic techniques for droplet size determination

While microscopic droplet size measurements are more laborious than other methods for determining the various averages and the distribution of the droplet sizes of emulsions, the results are subject to less uncertainty (1). Experimental problems encountered in microscopic size determinations by direct visual measurements and by measurements from photomicrographs include Brownian motion, creaming, and field flow.

Field flow is the motion of the entire volume of emulsion in the field of view in a given direction. It is caused by pressure exerted on the cover glass, especially from an immersion objective, by convection currents due to heating by the light source, or by evaporation of the continuous phase from the edge of the cover glass.

The present report describes a novel, disposable cell for microscopic measurements and compares droplet size averages and distributions obtained with the cell and a counting chamber. The effect of emulsion viscosity, through its influence on the velocities of Brownian motion and creaming, on droplet size averages and distribution, is examined with both cells.

The number of droplets that must be counted to obtain estimates for the mean diameter with a specified accuracy at a given confidence probability is calculated.

EXPERIMENTAL

Materials—The oil phase was hexadecane[1], and the water was double distilled. The surfactant, octoxynol 9 NF[2], a nonionic polyoxyethylated octylphenol, has an average of 9–10 ethylene oxide units/molecule. Polyvinyl alcohol[3] was 99% hydrolyzed. Gelatin[4] was granular, USP grade.

Emulsification—Preliminary emulsification was made by adding 33.31 g of hexadecane to a solution of 0.067 g of octoxynol 9 in 66.62 g of water in a tall-form 200-ml beaker and agitating for 20 min with a stirrer equipped with two counter-rotating propellers[5] at an input of 30 V. Subsequently, the emulsion was given three passes through a stainless steel hand-operated homogenizer, applying maximum tension to the spring. The emulsion was diluted with an aqueous octoxynol 9 solution to a final composition of 25% (w/w) hexadecane and 0.1% (w/w) octoxynol 9, based on the weight of the water. All measurements were made on a single emulsion batch which had been aged for 7 months to minimize changes in droplet size during the 8-hr period required to make those measurements.

Microscope—The binocular microscope had a 100× achromatic oil immersion objective and 10× wide-field eyepieces. The eyepiece micrometer had a 5-mm scale comprising 50 divisions with each division measuring 0.976 μm.

Dilution Media—The emulsion was diluted ~600-fold for droplet size measurements. The five media employed were 0.1% octoxynol 9, glycerin, 0.1% octoxynol 9 thickened with 1–2% polyvinyl alcohol, and 5% gelatin (2), respectively. The aqueous gelatin, warmed to 40°, was a liquid of medium viscosity. Emulsion drops were blended with a 600-fold excess of this solution under gentle agitation to avoid breaking up oil droplets and changing the particle size distribution. The mixture was transferred into the cells while warm. Once it reached room temperature, it set to a soft gel.

Cells for Droplet Size Determination—Three kinds of hemacytometers and a Helber-type counting chamber[6] (H-cell) were commercial products. The chambers were filled by touching the edge of the cover glass with a capillary containing the emulsion, whereupon the liquid was drawn into the cell by capillary action without the aid of gravity.

A novel cell (T-cell) was made as follows. A circular hole with a 4.76-mm ($3/16''$) diameter was made with a one-hole paper punch in a piece of pressure-sensitive adhesive tape[7]. The tape was laid on a standard plain 7.62 × 2.54-cm (3″ × 1″) microscope slide and flattened by running the edge of another slide, held in a slanted position, across it.

The thickness of the tape was 57 ± 3, 60 ± 1, or 62 ± 4 μm when measured with a thickness gauge in cross-section with a microscope, or flat by the vertical travel of the objective when the focus was moved from the upper surface of the tape to the upper surface of the glass slide supporting the tape. Aside from its thickness, the choice of adhesive tape is probably not important. The cover glasses had a diameter of 18 mm and a thickness of 0.18 ± 0.02 mm. To fill the T-cell, a cover glass was placed flat on the slide to cover most of the hole in the tape. A small drop of diluted emulsion, extruded from the tip of a glass capillary, was positioned to touch the edge of the cover glass directly above the uncovered portion of the hole. Capillarity combined with gravity caused the emulsion to fill the hole rapidly. The cover glass was then moved sideways so that it covered the hole completely, closing the cell. Excess emulsion was squeezed out of the cell by applying gentle pressure to the cover glass.

Emulsion aliquots diluted with gelatin were also examined between a glass slide and a cover glass (S and C). The application procedure was to hold together two microscope slides, immerse them vertically into the mixture of 5% gelatin solution and emulsion held at 40°, withdrawing and separating the slides, and placing cover glasses on the gelatin film on the outer surfaces of the two slides. The purpose of holding two slides together was to minimize contamination of their bottom surfaces with the gelatin mixture. The thickness of the gelled emulsion layers between the cover glass and microscope slide ranged from 40 to 70 μm.

RESULTS AND DISCUSSION

Droplet size distributions were determined in 1-μm increments with five combinations of cells and dilution media. The five combinations and their droplet size averages are listed in Table I. Droplet size distributions, represented by frequency polygons, are shown in Fig. 1. The equations

used to compute the mean volume diameter D_v and the mean volume–surface diameter D_{vs} are (3–5):

$$D_v = \left(\frac{\Sigma N_i D_i^3}{\Sigma N_i}\right)^{1/3} \quad \text{(Eq. 1)}$$

$$D_{vs} = \frac{\Sigma N_i D_i^3}{\Sigma N_i D_i^2} \quad \text{(Eq. 2)}$$

where D_i is the diameter equal to the midpoint of the ith size range and N_i the number of droplets in that range. The droplets contribute to the arithmetic mean diameter only in proportion to the first power of their diameters. Therefore, the mean volume and mean volume–surface diameters are larger than the arithmetic mean diameter and, unlike it, only slightly affected by submicroscopic droplets.

Creaming and Brownian motion affect microscopic droplet size measurements adversely by overemphasizing the largest droplets. Since the velocity of creaming is proportional to the square of the droplet diameter, larger droplets rise considerably faster toward the cover glass and the focal plane than smaller droplets. Brownian motion affects especially the smallest droplets. It prevents creaming for droplets having a diameter smaller than the critical diameter given previously [(6), Eq. 25]. For hexadecane–water emulsions at 20°, this diameter is 2.24 μm for a 1-sec and 0.90 μm for a 100-sec time interval. In the present emulsion, 46 and 28% of the droplets had diameters equal to or smaller than these two critical values, respectively.

Another adverse effect of Brownian motion is that it makes the smaller droplets move randomly in and out of focus, causing them to be undercounted. The mean displacement along a given axis such as the vertical direction in water is 0.62 μm for droplets with diameters equal to the critical diameter, 2.24 μm, for an observation time of 1 sec; it is 9.8 μm for droplets having the critical diameter of 0.90 μm for an observation time of 100 sec [(6), Eq. 22].

For comparison, the visual depth of focus of an objective with numerical aperture 1.40 at a 1000× magnification is <0.5 μm, increasing with decreasing magnification and numerical aperture. The photographic depth of focus is less than one-quarter of that encountered in visual observation (7). The distance travelled in random Brownian motion in 1 sec by almost one-half of the droplets, thus, is comparable to or larger than the depth of focus, making it difficult to measure the smallest and fastest moving droplets.

Cells and Dilution Media—Glycerin, the diluting and thickening medium of choice (1, 8), could not be used because its refractive index was too close to that of hexadecane. A 69% glycerin content is required to increase the viscosity of water to 20 cp, which constitutes about the lowest useful level. The refractive index of that medium differs from that of hexadecane by only 0.015 unit, rendering the hexadecane droplets indistinct. The dilute aqueous polymer media were viscous enough to reduce or eliminate Brownian motion and creaming while changing the refractive index of water only slightly.

System I gave considerably larger mean diameter values than the other four systems (Table I) and a distinctly different droplet size distribution (Fig. 1). The remaining four frequency polygons are practically identical.

Comparison of the five arithmetic mean diameters by the variance ratio or F-test (9, 10) showed that the null hypothesis did not apply; the calculated F-value was larger than the critical value for the 1% level. However, the F-value obtained by comparing the arithmetic mean diameters of systems II–V was smaller than the critical F-value for the 25% level. System I produced a significantly larger arithmetic mean diameter while the differences between the other four values were not statistically significant. This discrepancy is ascribed to the combination of Brownian motion and creaming in the nonthickened medium.

The velocities of Brownian motion and of creaming are inversely proportional to the one-half and first powers of the viscosity of the contin-

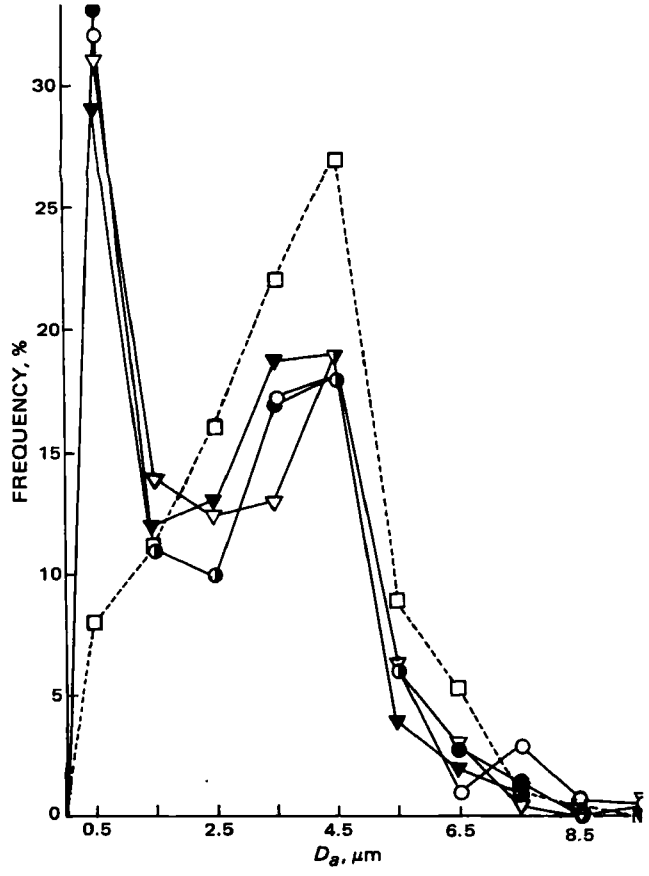

Figure 1—*Frequency polygons for the particle size distributions obtained with five systems. Key: (□) system I; (○) system II; (▼) system III; (●) system IV; (▽) system V.*

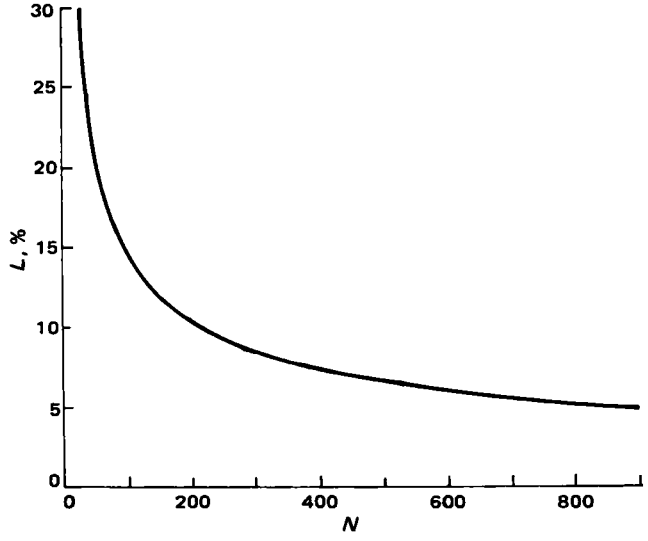

Figure 2—*Number of droplets,* N, *to be counted for the experimental arithmetic mean diameter to lie within* ±L, *the 95% confidence interval, of the true arithmetic mean diameter,* d_a. *The parameter* L *is expressed as percent of the 2.642-μm value of* d_a.

uous phase, respectively (6). The agreement of systems II and III thickened with polyvinyl alcohol to ~20 cp with IV and V, thickened with gelatin to a gel, supports the conclusion that a 20-cp viscosity reduces Brownian motion and creaming sufficiently for microscopic droplet size determinations of fine emulsions. A viscosity of 10 cp was insufficient.

The S and C cell could not be used with a polyvinyl alcohol-thickened emulsion because of field flow. While the S and C cell was used successfully with a gelatin-gelled emulsion, the variation in the thickness of the emulsion layer and the occasionally observed distorted droplets were disadvantages not met with the T-cell. Hemacytometers could not be used. The depth of their cells, ~0.1 mm, plus the thickness of their cover glasses, 0.4–0.6 mm, exceeded the working distance of the immersion objective and made focusing impossible. Furthermore, the ruling is at the bottom of the cells while the hexadecane droplets rose slowly, except in the gelatin medium.

The H-cell was only 0.02-mm deep and its cover glass 0.2-mm thick, so that it could be used with the immersion objective. Disadvantages of the H-cell were the long times required for filling it with viscous emulsions thickened with polyvinyl alcohol or gelatin and for cleaning. The T-cell could be filled faster, because the opening between the cover glass and tape hole could readily be increased for viscous emulsions while the clearance of the H-cell was narrow and constant. Being easy and inexpensive to make and disposable were added advantages of the T-cell. Moreover, it eliminated field flow even in nonthickened emulsions because it prevented evaporation of water, and the pressure exerted by the immersion objective on the cover glass was borne by the tape and the glass slide.

Sample Size—Since most emulsions have broad droplet size distributions, many investigators count several thousand droplets per sample to obtain reliable average droplet sizes (11–13). The number of droplets that must be counted to obtain estimates of the mean diameter with a predetermined accuracy is discussed.

The true arithmetic mean diameter, d_a, is the diameter that would be obtained if all droplets of the entire emulsion batch were measured. The confidence probability that the experimental arithmetic mean diameter of the sample, D_a, lies within a specified percentage limit or interval, L, of d_a, *i.e.*, the probability that D_a is correct within $\pm L$, is calculated for a sample size of $N = 200$ droplets.

Since the differences between the average droplet sizes measured with systems II–V were not statistically significant, the four sets of data, comprising a total of 767 droplets, were pooled. The overall D_a, 2.642 μm, is assumed to equal d_a. The standard deviation for the measurement of a single diameter, computed from the values of 767 droplets, 1.956 μm, is assumed to be equal to the standard deviation of the entire emulsion batch.

The pertinent expression is then (14):

$$2.642 - 1.956Z/\sqrt{N} \leq D_a \leq 2.642 + 1.956Z/\sqrt{N} \qquad \text{(Eq. 3)}$$

and the specified limit is (14):

$$L = 1.956Z/\sqrt{N} \qquad \text{(Eq. 4)}$$

The value of Z corresponding to any given confidence probability is found in a table of cumulative normal frequency distribution.

The use of such a table is predicated on an emulsion with a normal droplet size distribution. A plot of cumulative percent frequency for the pooled droplet size data of systems II–V *versus* diameter on normal probability graph paper was approximately linear, as were plots for the distributions of the four individual systems.

If the specified limit L is 10% of d_a or 0.264 μm, $Z = 1.91$ for $N = 200$. This Z-value corresponds to a 94% confidence probability that the experimental D_a lies within ±10% of d_a. The confidence probability that D_a lies within ±15% of d_a is 99.6%.

In the opposite approach, the confidence probability is set at 95%. The number of droplets that must be counted so that the experimental arithmetic mean diameter lies inside the 95% confidence interval of the true arithmetic mean diameter is calculated by Eq. 4 as a function of the size of that interval. The value of Z is 1.96. In Fig. 2, the number of droplets to be counted is plotted against the two-tailed 95% confidence limit expressed as percent of the 2.642-μm value of the true arithmetic mean diameter. This plot begins to level off in the vicinity of $L \cong 10\%$ $N \cong 200$ droplets. It shows that the increased accuracy gained by counting >400 droplets is marginal.

Effect of Different Water-Soluble Additives on Water Sorption into Silicone Rubber

V. CARELLI and G. DI COLO ˣ

Received March 24, 1981, from the *Pharmaceutical Technology Laboratory, Institute of Pharmaceutical Chemistry, University of Pisa, 56100 Pisa, Italy.* Accepted for publication April 30, 1982.

Abstract □ The ability of ethylene glycol; glycerin; polyethylene glycols 200, 400, and 6000; polysorbate 80; and lactose dispersed in silicone rubber, to promote water sorption into the polymer was investigated in water and in isotonic (pH 7.4) phosphate buffer. Polyethylene glycols 200 and 400, lactose, and, especially, glycerin were effective water carriers. Marked differences in the kinetics of rubber swelling were observed, depending on the carrier. The swelling patterns relative to ethylene glycol, glycerin, and polyethylene glycol 200 showed a maximum due to significant leaching of these additives from the polymer. Steady swelling degrees were afforded by polyethylene glycols 400 and 6000 and by polysorbate 80. The interdependent processes of polymer imbibition and carrier release were speeded up without altering their kinetic patterns by increasing the initial surface–volume ratio of the devices. A proportionality resulted between maximal swelling and initial carrier concentration, although the swelling patterns were substantially unaffected by this variable.

Keyphrases □ Silicone rubber—effect of different water-soluble additives on water sorption □ Sorption—water, effect of different water-soluble additives on water sorption into silicone rubber □ Water-soluble additives—effect on water sorption into silicone rubber □ Swelling behavior—effect of different water-soluble additives on water sorption into silicone rubber

The advantages offered by the use of silicone rubber matrices as long-acting drug delivery systems are manifest in the literature (1–9). A number of water-soluble substances recently have been shown to promote water sorption into silicone rubber pellets containing morphine sulfate, thereby enhancing both *in vitro* and *in vivo* release of this drug (2, 3). In view of their potential use for control of drug release, other hydrophilic materials should be investigated with regard to their suitability to be dispersed in silicone rubber and to act as water carriers.

The present work is concerned with a study of the swelling behavior of silicone rubber devices containing different water-soluble additives: ethylene glycol; glycerin; polyethylene glycols 200, 400, and 6000; polysorbate 80; and lactose.

EXPERIMENTAL

Materials—Polydimethylsiloxane elastomer and silica filler[1]; stannous octoate[2]; ethylene glycol[3]; glycerin[3]; polyethylene glycols 200, 400, and 6000[4]; polysorbate 80[5]; monobasic sodium phosphate[3]; and dibasic sodium phosphate[3] were used as received. Lactose[3] was passed through a 140-mesh screen prior to use.

Preparation of Devices—The additive (ethylene glycol, glycerin, lactose, polyethylene glycol 200 or 400, or polysorbate 80) or a solution of the additive in chloroform (polyethylene glycol 6000) was dispersed in polydimethylsiloxane elastomer in the desired proportion by levigating for ~3 min. Five-gram amounts of the mixture generally were used. Stannous octoate catalyst (1 drop, ~20 mg; or 2 drops with polyethylene glycol 200) was levigated into 1 g of the above dispersion for ~0.5 min (after evaporation of chloroform in the case of polyethylene glycol 6000). The mixture then was added rapidly to a plastic mold, pressed with a plastic plate into a sheet of uniform thickness (0.2 or 0.05 cm), and allowed to cure overnight at room temperature. A cylinder (0.5-cm diameter, 0.2-cm thick) or a disk (1-cm diameter, 0.05-cm thick) was cut from the polymerized sheet and immediately used for the swelling experiments. The cylinders or the disks had dry weights which were between 46.2 and 54.4 mg or 49.1 and 53.5 mg, respectively, depending on the additive and its concentration.

Swelling Determinations—The sample being studied was flushed with distilled water and then rapidly placed between filter paper to remove clinging water. Its dry weight then was determined. Next, it was immersed in 20 ml of phosphate buffer (0.13 *N*, pH 7.4), or distilled water which was maintained at 37°. At measured intervals, the swollen sample was removed from the solvent, cleared of water with filter paper, weighed in a weighing bottle, and quickly immersed in 20 ml of fresh solvent prewarmed to 37° (time zero of the next interval). Each experiment was run in triplicate, and the data were averaged. The range of the measured values was not >±5% of the mean. Shaking had practically no effect on the swelling kinetics.

RESULTS AND DISCUSSION

The swelling kinetics of silicone rubber cylinders containing 12% (w/w) carrier, determined in isotonic phosphate buffer (pH 7.4) or in pure water, is presented in Figs. 1 and 2, respectively, where the ratio of the weights of swollen–dry sample, γ, defined as swelling degree, was plotted against time. The plots in Fig. 1 relative to ethylene glycol, glycerin, and polyethylene glycol 200 went through a maximum, thus, pointing to a change in the sign of the swelling pressure. Such a pattern was indicative of significant leaching of these substances from the silicone polymer. Much slower leaching, if any, of polyethylene glycols 400 and 6000 and polysorbate 80 was suggested by the respective swelling degrees which apparently attained steady equilibrium values. At any given swelling degree, a considerably higher swelling rate in pure water than in buffer was always observed. This was in accord with a higher osmotic pressure differential in the case of the pure water.

The swelling kinetics of silicone rubber disks (1-cm diameter and 0.05-cm thick), having the same volume and carrier concentration as the cylinders in Fig. 1, was followed to study the effect of varying the surface–volume ratio of the polymeric device. Disks filled with polyethylene glycol 6000 did not swell, and their weight decreased slightly upon hy-

Concentrations substantially exceeding the values indicated for each additive by the arrows gave nonreproducible data.*

dration. The cause of this behavior could reside in an inadequate dispersion of this additive. Due to a comparatively high surface–volume ratio, the fraction of carrier undergoing a rapid dissolution from the disk surface predominated in this case over the carrier fraction in the disk core. The opposite occurred with the cylinders, which gave reproducible swelling data. The profile of the γ *versus* time plots, as well as the maximal swelling degrees of disks (not reported), remained unchanged with respect to the corresponding properties of cylinders, although the process was speeded up considerably in all cases with the disks. Since swelling was carrier driven, a similar effect of the surface–volume ratio on the release process of the leachable carriers could be inferred. The relevance of these findings to the release of water-soluble drugs embedded in silicone rubber is apparent.

Cylinders were used to study the effect of carrier concentration. Devices formulated with varying concentrations of the same additive all gave swelling plots similar in shape (not reported), although the magnitude of swelling was concentration dependent. Figure 3 shows the plots of the maximal swelling degree (γ_{max}) attained in buffer by the cylinders *versus* initial carrier concentration. Concentrations substantially exceeding the values indicated for each carrier in Fig. 3 did not yield reproducible results. A straight line with zero intercept was obtained with all of the additives studied. Such an apparent proportionality is intriguing, since the extent of swelling depended on numerous factors which in turn could be complex functions of initial carrier concentration. These are the osmotic activity of carrier (free or bound to the polymer through hydrogen or covalent bonding), the rate of carrier release from polymer, the polymer contractility, and the polymer plasticizing effect of the carrier. The slopes of the plots in Fig. 3, which can be referred to as the specific swelling power of the single carriers, appeared to be different for carriers of a similar physical and chemical nature, such as ethylene glycol and glycerin, or similar for additives of a different physical and chemical nature, such as polyethylene glycol 200 and lactose.

The variation range of all reported data was $\leq \pm 5\%$. This reproducibility is indicative of an inherent ease in additive dispersal in polydimethylsiloxane, because of the simplicity of the mixing technique. With the liquid additives, especially with polyethylene glycol 200, higher than usual catalyst concentrations were needed to crosslink the polymer. Such an interference of these additives with the action of the initiator needs further investigation because of possibility that these compounds may be part of the crosslinking reaction. Shaking of the device–solvent systems did not affect the swelling data, suggesting the absence of boundary layer effects on the swelling kinetics.

In conclusion, polyethylene glycols 200 and 400, lactose, and especially glycerin were effective water carriers. Their actual role in drug release from silicone rubber will be assessed in future studies.

Potential Anticonvulsants VI: Condensation of Isatins with Cyclohexanone and other Cyclic Ketones

HOSSEIN PAJOUHESH, RANDY PARSON, and FRANK D. POPP ˣ

Received March 1, 1982, from the *Department of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110.* Accepted for publication April 15, 1982.

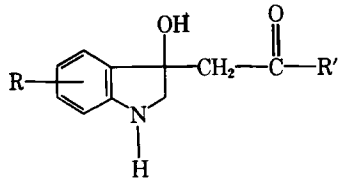
Abstract □ Cyclohexanone, substituted cyclohexanones, and other cycloalkanones have been condensed with isatin and substituted isatins to give a series of new 3-hydroxy-3-substituted oxindoles. A number of these 3-hydroxyoxindoles possess anticonvulsant activity.

Keyphrases □ Anticonvulsants—potential, condensation of isatins with cyclohexanone and other cyclic ketones □ Isatins—condensation with cyclohexanone and other cyclic ketones, potential anticonvulsants □ Cyclohexanones—condensation of isatins, potential anticonvulsants

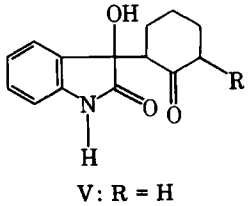
It has been reported (1, 2) that I exhibited anticonvulsant activity in the maximal electroshock seizure test[1] with an ED_{50} of 102 mg/kg and a protective index of ~4 and that II had an ED_{50} of 40 mg/kg and a protective index of 12 in that same test. The 3-hydroxyoxindole derivative, II, was also active at 300 mg/kg in the pentylenetetrazol seizure threshold test[1]. Compound III had an ED_{50} of 56 with a protective index of 3 in the maximal electroshock seizure test, while IV had an ED_{50} of ~115 and a protective index of ~4 in both tests (2).

Compound V was derived from isatin and cyclohexanone and was active in the maximal electroshock seizure (MES) screen (2). Dehydration to VI resulted in an increase in activity. This latter observation is in contrast to the observation that the dehydration products of I and II were inactive. A number of products from isatin and cyclic ketones (3) were prepared, and it was found that VII had an ED_{50} of 171 and a protective index of 8 in the MES screen and that VIII was active in both screens.

The present investigation reports on the condensation of various alicyclic ketones with isatins to give additional analogs of V–VIII.



I: R = H, R′ = C_6H_5
II: R = H, R′ = CH_3
III: R = 4-Cl-7-CH_3, R′ = CH_3
IV: R = 7-CH_3, R′ = CH_3



V: R = H
VII: R = CH_3

EXPERIMENTAL[2]

Condensation of Isatin with Ketones—The compounds in Tables I–IV were prepared, as previously described (1–3, 5, 6), by heating on a steam bath a solution of the isatin and the appropriate ketone in absolute ethanol containing a few drops of diethylamine.

Dehydration of 3-Hydroxyoxindoles—The compounds in Table V were prepared, as previously described (1, 2, 5), by heating the 3-hydroxyoxindoles on a steam bath in acetic acid containing a small amount of hydrochloric acid.

DISCUSSION

Cyclohexanone was condensed in the presence of diethylamine with a variety of substituted isatins to give compounds of type V. These products are included in Table I. With the exception of the product derived from 4-chloro-7-methoxyisatin, none of these derivatives were as active as V in the MES screen. In contrast, a considerable number of these analogs were active in the pentylenetetrazol seizure threshold test (Met) screen. Worthy of particular note were those products formed from 7-methyl-, 4-chloro-7-methoxy-, and 6-chloro-7-methylisatin. 5-Chloro-, 5-methyl-, and 5-nitroisatin also led to compounds active in the Met test.

In view of the activity of VIII (3), a number of cycloalkanones of various ring sizes were condensed with isatins to give the compounds shown in Table II. With the exception of a high degree of Met test activity in the product from 5-bromoisatin and cyclopentadecanone, none of the compounds, including several from cyclopentanone and substituted isatins, were as active as VIII.

Although the products from isatin and 4-substituted cyclohexanones were inactive (3), compound VII had good MES activity. In view of this, a number of 2-substituted cyclohexanones and 3-methylcyclohexanone were condensed with isatins to give the products shown in Table III. In the case of VII the introduction of substituents in the isatin portion of the molecule or replacement of the methyl by phenyl or cyclohexyl led to a loss of activity. A single exception is the activity of the 5-nitro analogue of VII, which is active in the Met test. Replacement of 2-methylcyclohexanone by 3-methylcyclohexanone gave an active product both with isatin and with 1-methylisatin.

Although it has been reported that dehydration of I (1) and II (2) to IX causes a loss of activity, dehydration of V to VI leads to an increase of activity in the MES test. Unfortunately, dehydration of a number of analogues of V and VII resulted in a decrease or loss of activity. These dehydration products are shown in Table V.

Table IV includes a number of additional examples of compounds of type I. None of these compounds exhibited any significant anticonvulsant activity.

This series of investigations has reported (1–3, 5, 6) on the synthesis of a number of 3-substituted oxindoles with anticonvulsant activity.

[1] Anticonvulsant screenings were carried out through the Antiepileptic Drug Development Program of the NINCDS, National Institutes of Health. The standard screening protocol of that group was followed.

[2] All compounds exhibited IR spectra consistent with the structures shown and with those previously reported (1–3). Melting points are uncorrected, and analyses were carried out by Spang Microanalytical Laboratory.

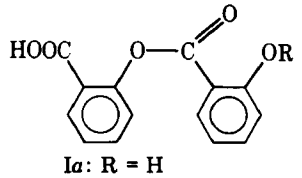
Thermal Decomposition of Aspirin: Formation of Linear Oligomeric Salicylate Esters

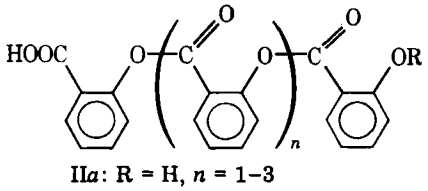
Keyphrases □ Decomposition, thermal—aspirin, formation of linear oligomeric salicylate esters □ Aspirin—thermal decomposition, formation of linear oligomeric salicylate esters □ Salicylate esters—thermal decomposition of aspirin, formation of linear oligomeric salicylate esters

To the Editor:

Although there are numerous reports on aspirin stability or degradation described in terms of decreasing amounts of aspirin or increasing amounts of salicylic acid, few recognize the existence of decomposition products other than salicylic acid. Pyrolysis of aspirin with simultaneous distillation of products at 300–350° (15 mm) produces cyclic polymers of salicylic acid, referred to as salicylides; the *cis*-disalicylide and the trisalicylide have been isolated[1] (1–4). Salicylsalicylic acid (I*a*) (5) and acetylsalicylsalicylic acid (I*b*) (6, 7) have also been recognized as decomposition products of aspirin. Aspirin anhydride (8), salicylsalicylic acid (I*a*) (9), and acetylsalicylsalicylic acid (I*b*) (10) have been detected as impurities in aspirin tablets. Presented here is the discovery that thermal decomposition of aspirin, in the solid state or in organic solution, produces not only



I*a*: R = H
I*b*: R = —$COCH_3$



II*a*: R = H, n = 1–3
II*b*: R = —$COCH_3$, n = 1–4

I*a* and *b*, but higher linear oligomeric salicylate esters (II*a*) and their acetate derivatives (II*b*).

When a mixture of aspirin and magnesium carbonate[2] (2:1) was heated in the solid state at 85° for 2 hr, a complex mixture was obtained[3]. The reverse-phase C-18 high-performance liquid chromatogram of this mixture showed components corresponding in retention time to salicylic acid, I*a*, I*b*, and several components with longer retention times (Fig. 1). Chromatographic separation and crystallization provided several pure compounds, three of which were shown to be salicylic acid, I*a*, and I*b* by comparison with authentic compounds. Compounds with longer retention times had UV spectra characteristic of salicylates.

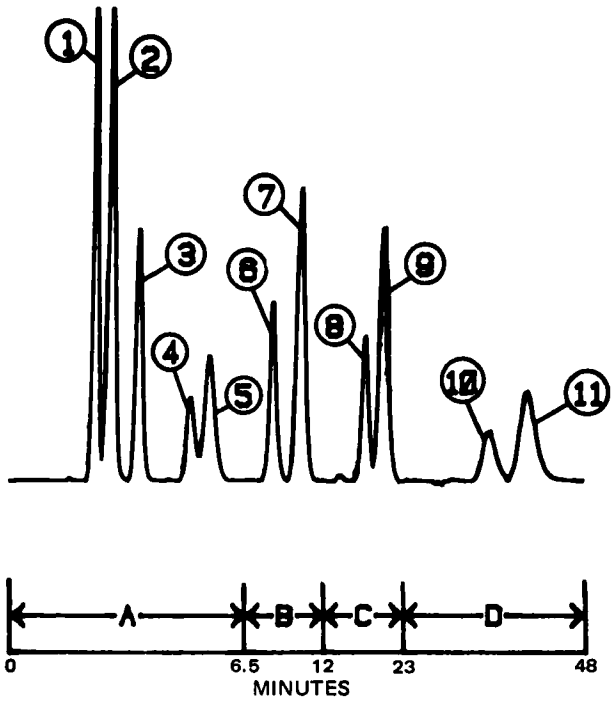


Figure 1—*Reversed-phase C-18 high-performance liquid chromatogram of decomposed aspirin. Mobile phase: water–acetic acid–methanol (420:10:570); flow rate: 2.0 ml/min; detection: UV absorbance at 254 nm. Recorder settings (att = attenuator (2↑), cs = chart speed, cm/min): (A) att 9, cs 0.5; (B) att 6, cs 0.2; (C) att 4, cs 0.1; (D) att 3, cs 0.1. Key (each compound is followed by its retention time in minutes): (1) aspirin, 2.19; (2) salicylic acid, 2.62; (3) Ib, 3.40; (4) Ia, 4.88; (5) IIb (n = 1), 5.40; (6) IIa (n = 1), 8.26; (7) IIb (n = 2), 10.18; (8) IIa (n = 2), 17.23; (9) IIb (n = 3), 19.63; (10) IIa (n = 3), 33.93; (11) IIb (n = 4), 39.13.*

Acetyl compounds (I*b* and II*b*) could be readily differentiated from free phenolic compounds (I*a* and II*a*) by a significant difference in their absorbance maxima (near 278 nm for acetyl compounds and 309 nm for free phenols) in acidic or neutral aqueous alcohol and very rapid cleavage of the acetate esters in 0.01 *N* aqueous ethanolic sodium hydroxide, a reaction completed in 2 min at room temperature, to form the corresponding free phenolic compounds, whose absorbance maxima were near 340 nm in basic solution.

Hydrolysis of the salicylate esters in 0.01 *N* aqueous ethanolic sodium hydroxide occurred over several hours, much slower than acetate ester hydrolysis, and eventually each oligomer (I*a*, I*b*, II*a*, II*b*) was completely converted to salicylic acid (λ_{max} 297 nm). This afforded a means to measure the equivalent weight of each compound in terms of the number of salicyl moieties in the molecule. This technique was suitable for the lower oligomers; however, the higher the oligomer, the closer its equivalent weight approaches those of its neighboring homologues, making it more difficult to differentiate among them.

Like aspirin, I*a* also undergoes thermal decomposition[4]. Being free of acetyl compounds, decomposed I*a* was a

[1] Tetra- and hexasalicylides were also isolated when salicylic acid was treated with phosphorus oxychloride or when salicyloyl chloride was heated (1, 2).

[2] Although aspirin itself decomposes when heated, the rate is greatly accelerated by weak bases such as magnesium carbonate.

[3] A similar mixture was obtained when aspirin was heated in benzene or toluene with or without magnesium carbonate in suspension.

[4] The rate of decomposition of I*a* is slower than that of aspirin. This is attributed to the lower reactivity of the salicylate ester relative to the acetate ester. As with aspirin decomposition, I*a* decomposition is catalyzed by magnesium carbonate.

0022-3549/83/0300-0322$01.00/0

much less complex mixture than decomposed aspirin, and its components were more easily separated. The linear trimer (II*a*, $n = 1$) was isolated from decomposed I*a* as a white crystalline solid, mp 150–152°; UV: λ_{max} (ethanol) 228 (ϵ 27,200), 281 (4350), and 310 (4900) nm; IR (chloroform): ν_{max} 1746 (strong, unassociated ester C=O stretching) and 1696 (strong, intramolecular hydrogen-bonded ester C=O stretching[5] and intermolecular hydrogen-bonded acid C=O stretching) cm^{-1}; NMR (deuterochloroform): δ 10.07 (s, 2H, COOH and OH, exchanged with deuterium), 8.43–7.87 (m, 3H, aromatic protons *ortho* to C=O), and 7.87–6.57 (m, 9H, remaining aromatic protons) ppm.

Anal.—Calc. for $C_{21}H_{14}O_7$: C, 66.67; H, 3.73. Found: C, 66.88; H, 3.92.

Compound II*a* ($n = 1$) was acetylated to provide a compound identical to II*b* ($n = 1$) isolated from decomposed aspirin. Compound II*b* ($n = 1$) was obtained as a white crystalline solid, mp 161.5–163°; UV: λ_{max} (ethanol) 227 (ϵ 29,900) and 277 (4500) nm; IR (chloroform): ν_{max} 1750 (strong, C=O stretching of three ester groups) and 1703 (weak, intermolecular hydrogen-bonded acid C=O stretching) cm^{-1}; NMR (deuterochloroform): δ 8.43–7.80 (m, 4H, COOH proton, which exchanged with deuterium, and three aromatic protons *ortho* to C=O), 7.80–6.90 (m, 9H, remaining aromatic protons), and 2.23 (s, 3H, $—CH_3$) ppm.

Anal.—Calc. for $C_{23}H_{16}O_8$: C, 65.72; H, 3.84. Found: C, 65.53; H, 4.03. Compound II*b* ($n = 1$) was also found in several samples of buffered aspirin tablets; it was isolated from one of them and identified.

The tetramer (II*a*, $n = 2$) was isolated from decomposed I*a* as white crystals, mp 177–183° (dec); IR (chloroform): ν_{max} 1744 (strong, stretching of two unassociated ester carbonyl groups) and 1693 (strong, intramolecular hydrogen-bonded ester carbonyl stretching[5] and intermolecular hydrogen-bonded acid carbonyl stretching) cm^{-1}.

Anal.—Calc. for $C_{28}H_{18}O_9$: C, 67.47; H, 3.64. Found: C, 67.63; H, 3.77.

In the aromatic region the NMR spectrum (deuterochloroform) had two multiplets that were not fully resolved until the solution was shaken with deuterium oxide, which indicated that the exchangeable phenolic and carboxylic acid protons were obscured by aromatic proton absorption.

The methyl esters of I*a*, I*b*, trimer (II*a*, $n = 1$), tetramer (II*a*, $n = 2$), and acetyl-trimer (II*b*, $n = 1$) were synthesized by treatment of the acids with methyl iodide; solid–liquid phase transfer catalysis (11) was used to avoid acetate or salicylate ester hydrolysis during methylation. IR spectra for each of the five methyl esters in carbon tetrachloride supported their structures; the following assignments were made for carbonyl stretching frequencies: ν_{max} 1735–1731 (methyl esters), 1758–1754 (unassociated carbonyl of ester groups between aromatic rings), 1700–1695 (intramolecular hydrogen-bonded ester[5]), 1780–1779 (acetate ester) cm^{-1}. The NMR spectrum (deuterochloroform) of each compound had a singlet near δ 3.7 (methyl ester protons) and two multiplets, one downfield from δ 7.8 (aromatic protons *ortho* to C=O) and the other upfield from δ 7.8 (remaining aromatic protons). In addition to these peaks, the spectra of the three phenolic compounds showed a sharp singlet near δ 10.25 (hydroxide proton, which was exchangeable with deuterium), and the spectra of the two acetyl derivatives showed a singlet at δ 2.25 ($CH_3CO_2—$). The integrals of each compound's spectrum gave the proper ratio of protons for the assigned structures.

Additional proof that these compounds were oligomers was provided by their relative retention on a reverse-phase C-18 high-performance liquid chromatogram. Plots of logarithms of capacity factors (k') for a homologous series have been shown to be linear in a number of cases (12). A plot of log k' *versus* number of salicyl moieties for each of the components in decomposed I*a* was found to be linear[6]. Two linear plots were obtained for decomposed aspirin: one for the free phenols[6], components corresponding in retention time to components in decomposed I*a*, and one for the acetyl compounds[7], the remaining components in the chromatogram. The linear oligomers, produced from aspirin at low temperatures as reported here, are undoubtedly precursors to the previously reported cyclic salicylate oligomers (1–4) produced at much higher temperatures.

Sample analyses showed that the levels of linear salicylate oligomers were generally higher in buffered than in plain aspirin tablets. Subsequent experiments revealed that the thermal decomposition reaction was catalyzed by weakly basic substances, such as magnesium hydroxide or magnesium carbonate, compounds often used in buffered aspirin formulations.

[5] A strong intramolecular hydrogen bond exists between the ester carbonyl on the terminal aromatic ring and the phenolic group *ortho* to it.

[6] Log k' *versus* salicyl moieties was plotted for four compounds corresponding to dimer (I*a*) through pentamer (II*a*, $n = 3$); the correlation coefficient was 0.9994.

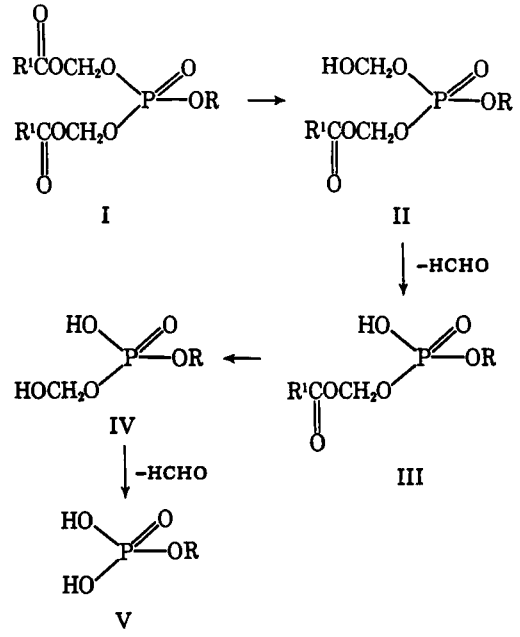
[7] Log k' *versus* salicyl moieties was plotted for five compounds corresponding to dimer (I*b*) through hexamer (II*b*, $n = 4$); the correlation coefficient was 0.9998. Each acetyl compound eluted from the C-18 column prior to its corresponding free phenol.

Biologically Reversible Phosphate-Protective Groups

Keyphrases □ Phosphate-protective groups—biologically reversible, acyloxymethyl groups □ Acyloxymethyl groups—biologically reversible phosphate-protective groups □ Chemotherapeutic agents—biologically reversible phosphate-protective groups, acyloxymethyl groups, as a means of traversing biological membranes

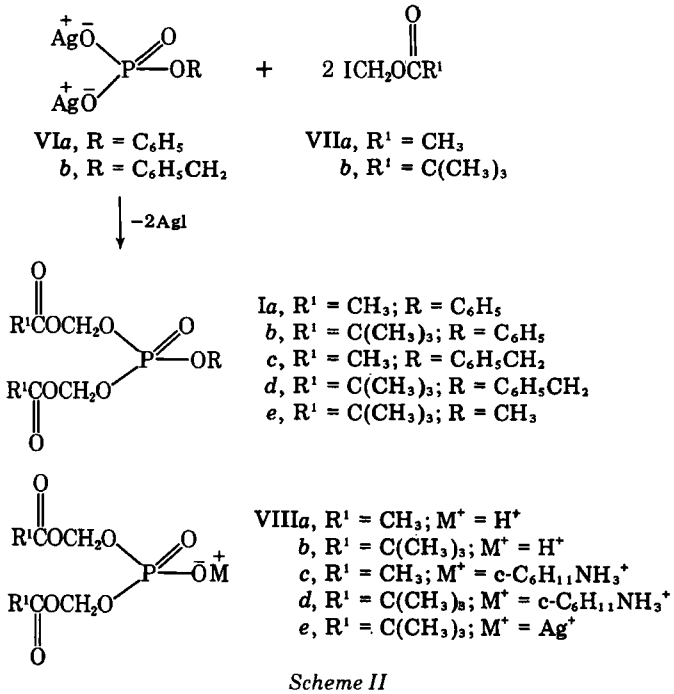
To the Editor:

The inability of nucleotides and other ionic organophosphate esters to traverse biological membranes (1, 2) constitutes a major impediment to the use of such compounds as chemotherapeutic agents. In an attempt to overcome this limitation, we have investigated the potential of acyloxymethyl groups as biologically reversible phosphate-protective groups. Conceivably, neutral acyloxymethyl phosphotriesters[1] could penetrate cell membranes by passive diffusion and revert, intracellularly, to the parent ionic phosphate after cleavage of the acyloxy group by carboxylate esterase and elimination of formaldehyde (Scheme I). To explore synthetic routes to bis(acyloxymethyl) phosphotriesters and to investigate the chemical properties of this class of compounds, we chose phenyl phosphate as a model organophosphate monoester.



Scheme I

Reaction of disilver phenyl phosphate[2] (VI*a*) with a 2.5 mole excess of iodomethyl acetate (VII*a*) (3) in anhydrous benzene at room temperature for 5 hr gave bis(acetoxymethyl) phenyl phosphate[3,4] (I*a*) in 53% yield. Bis(pivaloyloxymethyl) phenyl phosphate[3] (I*b*) was prepared similarly from (VI*a*) and iodomethyl pivaloate (VII*b*) (3) in 54% yield (Scheme II).



Scheme II

Compound I*a* was stable in neutral aprotic solvents (*e.g.*, benzene, diethyl ether, ethyl acetate); however, in protonic solvents (*e.g.*, ethanol, water, 0.05 *M* potassium phosphate buffer, pH 7.4) it was converted[5] slowly ($t_{1/2}$ > 4 hr) to mono(acetoxymethyl) phenyl phosphate (III, R = C_6H_5, R^1 = CH_3). This product is presumably formed by solvolysis of I*a* to the hydroxymethyl intermediate[6] (II, R = C_6H_5, R^1 = CH_3), followed by spontaneous loss of formaldehyde. When incubated at 37° in 0.05 *M* potassium phosphate buffer (pH 7.4) with hog liver carboxylate esterase[7] (E.C. No. 3.1.1.1) (1.6 mg of protein/ml) or mouse plasma (50% by volume), I*a* (2 m*M*) was rapidly degraded[8] ($t_{1/2}$ < 15 min), first to the mono(acetoxymethyl) analogue

[1] To the best of the authors' knowledge, such compounds have not previously been reported.

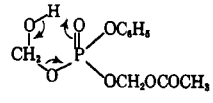
[2] Obtained from the corresponding disodium salt by reaction with silver nitrate in water.

[3] Obtained as a viscous oil.

[4] All compounds gave satisfactory elemental analyses and exhibited spectral characteristics (NMR, MS, IR) consistent with the assigned structures.

[5] The solutions were analyzed by high-performance liquid chromatography (HPLC) (Waters model ALC 204). The disappearance of I was monitored by reverse-phase chromatography on a column of μBondapak-C_{18} (30 cm × 4-mm i.d., 10 μm; Waters Assoc., Milford, Mass.) using solutions of 0.01 *M* potassium phosphate buffer (pH 7.0)–methanol (various proportions, typically 25–50% alcohol) as mobile phase. The formation of III and V was monitored by ion-pair chromatography on μBondapak-C_{18} using the same buffer system as described for I except that tetrabutylammonium hydroxide was added to a concentration of 2×10^{-3} *M*, or by anion-exchange chromatography on a column of Partisil SAX (25 cm × 4.6-mm i.d., 10 μm; Whatman) using a linear gradient of 0.01–0.1 *M* potassium phosphate buffer (pH 6.5) as eluent. The flow rates ranged from 1.0 to 2.0 ml/min. The column effluents were monitored at 254 nm with a Schoeffel model 450 UV detector, and the concentrations of I, III, and V were determined by comparison of the peak areas with those of reference standards.

[6] A labile intermediate was detected in some solutions by HPLC but was not characterized. The hydroxymethyl compound II (R = C_6H_5, R^1 = CH_3) is expected to facilely dissociate, probably by a six-membered cyclic transition state, to give mono(acetoxymethyl) phenyl phosphate and formaldehyde:



[7] Obtained from Sigma Chemical Co., St. Louis, Mo.

[8] At appropriate intervals, aliquots (100 μl) of the incubation mixtures were diluted with 3 volumes of methanol than agitated for 1 min on a Vortex shaker. The precipitated protein was separated by centrifugation at 10,000×*g* for 5 min, and the supernatants were analyzed by HPLC as described in footnote 5.

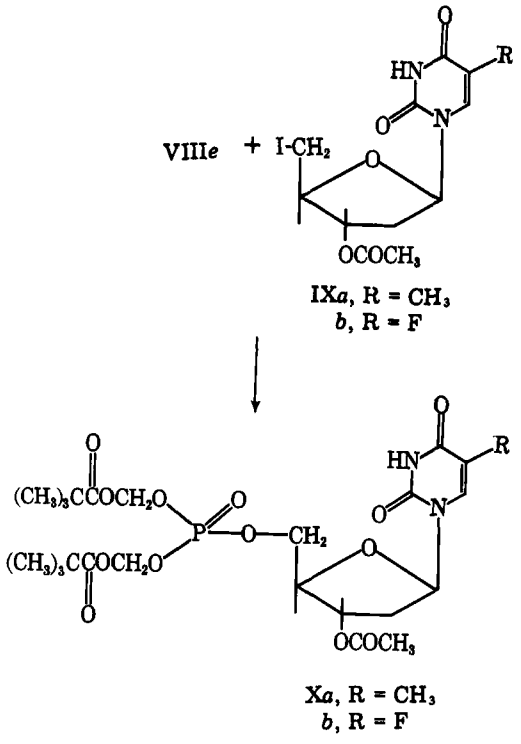
0022-3549/83/0300-0324$01.00/0

(III, R = C_6H_5, R^1 = CH_3) and then to phenyl phosphate (V, R = C_6H_5).

The bis(pivaloyloxymethyl) phosphotriester[3] (I*b*), by comparison, was much more resistant to both chemical and enzymatic hydrolysis. Thus, it was stable in protonic solvents and had a half-life ≃5 hr when incubated with mouse plasma under conditions identical to that described for I*a*. Clearly, the nature of the acyl substituent has a marked influence on the susceptibility of bis(acyloxymethyl) phosphotriesters to hydrolysis.

The benzyl phosphotriesters, I*c*[3] and I*d*[3], were prepared similarly from disilver benzyl phosphate[2] (VI*b*). Catalytic hydrogenolysis of these compounds over 5% palladium-on-charcoal Pd-C in cyclohexane gave the corresponding monobasic acids, VIII*a* and *b* which were isolated as their cyclohexylammonium salts, VIII*c* and *d*. Silver bis(pivaloyloxymethyl) phosphate (VIII*e*) was prepared from VIII*d* by successive ion-exchange[9]. Reaction of VIII*e* with benzyl bromide or methyl iodide in benzene for 5 hr at room temperature gave bis(pivaloyloxymethyl) benzyl phosphate[3] (I*d*) and bis(pivaloyloxymethyl) methyl phosphate[3] (I*e*), respectively, in nearly quantitative yield. These reactions illustrate the utility of VIII*e* in the synthesis of bis(acyloxymethyl) phosphotriesters.

Reactions of VIII*e* with 5′-deoxy-5′-iodo-3′-*O*-acetylthymidine (IX*a*) (4) in toluene under reflux for 5 hr gave bis(pivaloyloxymethyl)-3′-*O*-acetylthymidine-5′-phosphate (X*a*), 39% yield (Scheme III). Similarly, the reaction



Scheme III

of VIII*e* with 2′,5-dideoxy-5′-iodo-3′-*O*-acetyl-5-fluorouridine[10] (IX*b*) gave X*b* (15% yield). Compound X*b* prevented the growth of Chinese hamster ovary cells in culture (5) at a concentration of 5.0×10^{-6} *M* (5-fluoro-2′-deoxyuridine control, 1.0×10^{-6} *M*).

Further chemical and biological studies of these compounds are in progress.

[9] Prepared on Dowex 50 Na^+ and Dowex 50 Ag^+.

[10] Prepared from 3′-*O*-acetyl-2′-deoxy-5-fluorouridine in 65% yield, according to the general procedure described previously (4).

Estimation of the Extent of Drug–Excipient Interactions Involving Croscarmellose Sodium

Keyphrases □ Croscarmellose sodium—estimation of the extent of drug–excipient interactions □ Drug–excipient interactions—estimation of the extent involving croscarmellose sodium □ Excipients—estimation of the extent of drug–excipient interactions involving croscarmellose sodium

To the Editor:

In a recent communication (1), a pH-dependent interaction of oxymorphone derivatives with croscarmellose sodium, Type A, NF XV[1] was identified. Any drug–excipient interaction is potentially serious if it has a deleterious influence on the bioavailability of the drug from the dosage form. However, as in this case, the excipient may be responsible for certain dosage form properties which promote or at least ensure reproducible drug delivery.

There is a need to be able to assess the risk which may be involved before advocating or indicting an excipient. The objectives here are to provide a means for determining when an interaction with the disintegrant croscarmellose sodium might be expected and a means for estimating the extent of the interaction when it occurs.

Certain aspects of the interaction were presented in the previous communication (1); although, the general utility of these results is limited. Details were not given con-

cerning analytical procedure, the method of altering pH, and the units of drug and disintegrant concentration. Without this information, it is not possible to estimate the extent of an interaction that might be expected under a different set of conditions.

An effort is underway in this laboratory to characterize the interaction of ionized weak bases with croscarmellose sodium. In light of the preceding discussion, we present a portion of our results that they may provide a qualitative and quantitative guide to these interactions. Figure 1 represents the results of a study of the interaction of chlorpheniramine maleate[2] with croscarmellose sodium at varying pHs. The experimental variables are defined in Table I, along with the values used to generate the results in Fig. 1. In an effort to keep the ionic strength low, the pH was adjusted in each case by the dropwise addition of 0.1 *N* HCl or 0.1 *N* NaOH, whichever was appropriate. After a 24-hr equilibration period, during which the drug–ex-

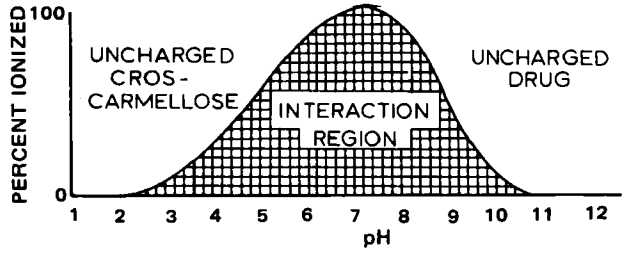

Figure 2—*Croscarmellose interaction profile for a hypothetical weakly basic drug with pKa = 9.0. (See text for details.)*

cipient suspension was maintained at 25°, the suspension was allowed to settle, and an aliquot of the supernatant was withdrawn with a syringe. The aliquot was freed of particles by rapid filtration through a borosilicate microfiber glass depth filter pad[3], and free drug concentrations were determined by UV spectrophotometric analysis of the filtrate at the pH-dependent wavelength of a maximum absorbance (261.5–264.5 nm). Free drug concentrations are presented in terms of molar concentration, because it is anticipated that these results can be extended to weak bases other than chlorpheniramine. The amount of drug adsorbed was determined by mass balance with quantitative corrections made for the slight adsorption to the filter, which occurred at high concentrations of drug.

It appears that the interaction is of electrostatic origin, involving ionized croscarmellose (negatively charged, pH >2) and cations. Thus, any weakly basic drug in an environment whose pH is >2 and near or below the pK_a of the weak base should be expected to interact with the ionized polymer. This generalization is presented graphically in Fig. 2 for a hypothetical weakly basic drug with a pK_a of 9.0. The ionization of the drug has been calculated from the pK_a assuming ideal behavior. The ionization of the drug outlines the interaction region at higher pHs. The ionization of croscarmellose has been estimated from the maximum binding data (r[max]) in Fig. 1. At pH 7, r[max] = 24×10^{-4} moles of drug/g of excipient, and the assumption is made that this value represents the maximum number of binding sites available. The fraction of croscarmellose ionized at any pH may be estimated by comparing the number of sites at that pH to the value at pH 7. At pH 4, for example, r[max] = 6×10^{-4} moles of drug/g of excipient, and the amount of croscarmellose ionized is estimated to be 25%. The outline of the interaction region at lower pHs has been generated by similar calculations.

An independent attempt to determine the pK_a of croscarmellose by titration produced spurious results, possibly due to the competitive equilibria for binding sites involving sodium and hydrogen ions. The influence of sodium ions on binding is addressed in subsequent discussion.

A diagram may be constructed for a drug with any pK_a by reconstructing the drug ionization curve. The area of the interaction region increases the higher the pK_a of the weak base. If the drug is a weak acid or nonelectrolyte, no interaction is anticipated.

Assuming that the interaction is nonspecific, reversible, and can be characterized as an equilibrium relationship, Fig. 1 can be utilized to estimate the fraction of drug bound

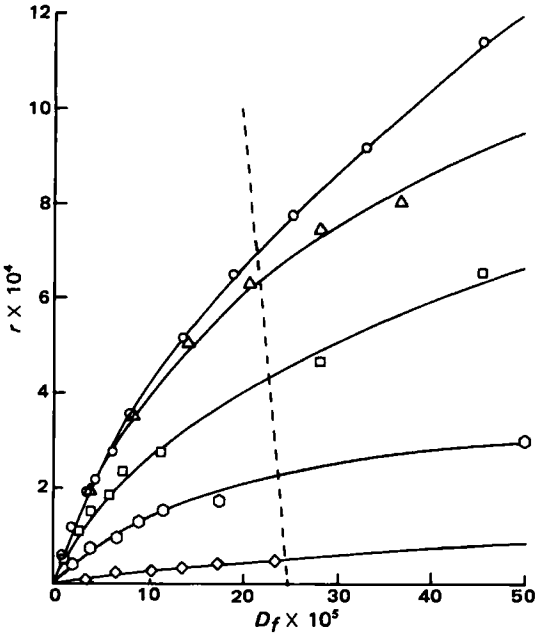

Figure 3—*Low concentration interaction isotherms of chlorpheniramine with croscarmellose sodium in aqueous dispersion at various hydrogen ion activities at 25°. Dashed line defines an interaction profile for the following conditions:* $D_T = 2.5 \times 10^{-5}$ *moles,* $A_T = 0.005$ *g,* V = *0.100 liter. (See Table I for definition of symbols and units.) Key: (○) pH 7; (△) pH 6; (□) pH 5; (○) pH 4; (◇) pH 3.*

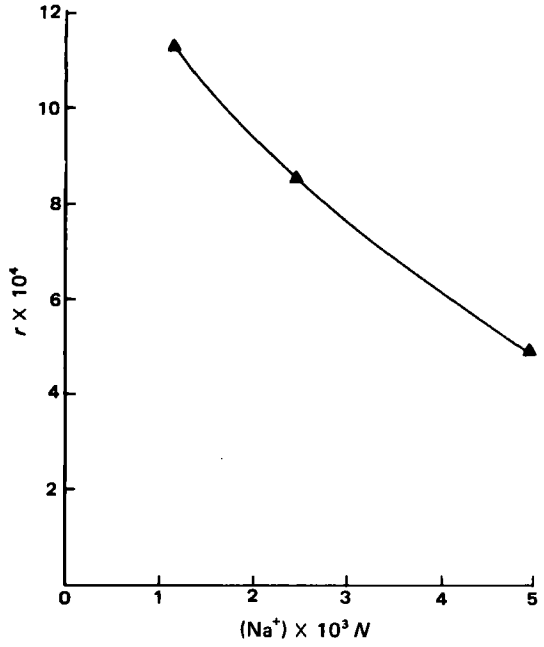

Figure 4—*Effect of added sodium ion concentration on the interaction of chlorpheniramine with croscarmellose sodium at pH 7.0 and 25°;* $D_T = 2.06 \times 10^{-4}$ *moles,* $A_T = 0.100$ *g,* V = *0.200 liter. (See Table I for definition of variables.)*

for any combination of A_T, D_T, and V, as long as the pH is ≤7 and the drug has a $pK_a \geq 9.0$. For purposes of illustration, and because there is particular concern for low dose drugs, Fig. 3 presents an expanded segment of the data from Fig. 1. For this analysis, the following mass balance will be used:

$$D_T = (D_f)V + rA_T \quad \text{(Eq. 1)}$$

where the variables are defined in Table I. By rearrangement:

$$r = \frac{D_T}{A_T} - (D_f)\frac{V}{A_T} \quad \text{(Eq. 2)}$$

It can be seen that r is a linear function of (D_f) when D_T, A_T, and V are fixed. The intercepts of this function:

$$(D_f) = \frac{D_T}{V} \quad \text{(Eq. 3)}$$

when $r = 0$ and:

$$r = \frac{D_T}{A_T} \quad \text{(Eq. 4)}$$

when $D_f = 0$ and/or the slope $(-V/A_T)$ permit construction of a specific binding profile for any set of conditions.

As an example, consider a tablet containing 10 mg of a weakly basic drug, with a pKa >9, a molecular weight of 400, containing 5 mg of croscarmellose sodium as a disintegrant, and placed in 100 ml of liquid.

Thus, $D_T = 2.5 \times 10^{-5}$ moles, $A_T = 0.005$ g, and $V = 0.100$ liter. The dashed line constructed in Fig. 3 from Eq. 2 can be used to determine a pH profile for this particular situation. The free drug concentration at any pH can be determined from the intersection of this line and the appropriate binding isotherm. At pH 7.0, for example, $D_f = 21.5 \times 10^{-5}$ M, and therefore, ~14% of the drug is bound.

The success of this approach depends upon the nonspecificity of the interaction and the validity of the binding data in Figs. 1 and 3. While we are still investigating the former, a comment about the binding results can be made at this time: Interactions in distilled water are generally higher than that predicted by this method. In retrospect, the method of elevating pH in this study, by adding sodium hydroxide, was a poor approach because of the specific competition of binding sites for sodium. Figure 4 presents the results of a simple study where total drug and excipient concentrations were held constant, and sodium ion concentration was increased by adding progressively larger quantities of sodium hydroxide and then adjusting the pH with standardized hydrochloric acid. It can be seen that increases in added sodium ion concentration significantly reduce the amount of drug bound. Thus, the data in Figs. 1 and 2 probably underestimate the extent of binding which would occur at higher pHs in the absence of added sodium ion or other competitive cations. On the other hand, the mean level of sodium ion in gastric fluid is 4.9×10^{-2} N (2), a concentration which must substantially reduce the extent of drug interaction.

Several important questions remain which we will address as further progress is made, and our studies will include *in vivo* work if there is evidence of a potential influence on bioavailability.

Introduction to Alkaloids—A Biogenetic Approach. By GEOFFREY A. CORDELL. Wiley-Interscience, New York, N.Y. 1981. 1055 pp. 17 × 24 cm. Price $50.00.

As the title implies, this introductory text uses the concept of biogenesis to organize a vast and heterogeneous group of natural products, the alkaloids. Comprehensive coverage of alkaloids with specific chemical nuclei have been presented in the past in the form of edited texts and an edited series of volumes. These treatises are predominantly chemically oriented.

Dr. Cordell's effort to cover many aspects of the various biogenetic classes of alkaloids was as a single author and not as an editor. He should be highly commended for his enthusiasm and dedication in the writing of this excellent work. It surely was a monumental, but necessary, task in an era where the alkaloid field is expanding at such a rapid rate.

The book consists of almost 1000 pages divided into 12 chapters. As would be expected, the first chapter involves background material with concise presentations of history, occurrence, classification, properties, detection, isolation, purification, structure elucidation, and pharmacology of the alkaloids. The second chapter focuses on alkaloid biosynthesis and biogenesis and establishes the organizational tenor for the remainder of the text. The next nine chapters deal with alkaloids derived from ornithine, lysine, nicotinic acid, polyacetate, anthranilic acid, phenylalanine and tyrosine, tryptophan, histidine, and isoprenoid metabolism. The last chapter presents several very interesting miscellaneous alkaloids. The Appendix lists formulas for many of the useful alkaloid detecting reagents. In addition to the usual subject index, the organism index provides additional utility to this book.

The individual chapters are sectioned with each section comprising a single important alkaloid or group of related compounds derived from a common biosynthetic precursor. Within each section there are discussions involving chemistry, biosynthesis, and pharmacology. In certain cases useful synthetic and spectral data are presented. Most sections conclude with a listing of selected key literature references.

Although some scientists may be disappointed in the limited coverage of certain groups of alkaloids, Dr. Cordell has done a good job in keeping relative importance in perspective. For instance, Chapters 8 (Alkaloids Derived from Phenylalanine and Tyrosine) and 9 (Alkaloids Derived from Tryptophan) constitute over half of the book. However, these compounds probably deserve this degree of attention because of the great deal of published research on their medicinal value. This perspective and unity of presentation is one important advantage of a single author covering a broad scientific topic.

In conclusion, this book is a useful reference for scientists interested in various aspects of alkaloid research. The illustrations are excellent. Grammatical, spelling, and chemical structure errors are minimal. The utility of this interesting text, however, may be limited by its price.

Textbook of Organic Medicinal and Pharmaceutical Chemistry, 8th Ed. Edited by ROBERT F. DOERGE. Lippincott/Harper, East Washington Square, Philadelphia, PA 19105. 1982. 876 pp. 21 × 26 cm. Price $47.50.

Because of its consistently high quality, the latest edition of this classical textbook, intended for use in undergraduate courses in Medicinal and Pharmaceutical Chemistry, was a pleasure to review. Despite the loss due to death or retirement of several of the prominent contributors to previous editions, those remaining, together with their new collaborators, have written excellent chapters. The combined effort is impressive. The first chapter is a broad overview of medicinal chemistry. This is followed by an effective summary of the basic material of the discipline, such as how structure relates to the drug–receptor interaction, and an excellent exposition of the medicinal chemistry of drug metabolism.

The anti-infectives, a specific group of therapeutical agents, is dealt with in the fourth chapter. Here, and in the remaining chapters, all treating specific groups of agents, one sees a consistent pattern of a thorough overview of the group under consideration and compact discussions of the chemical and biological properties of each of the members of the group.

Chapters dealing with sulfonamides, antimalarials, antibiotics, and antineoplastic agents are all very thorough and well written. Local anesthetics and antihistamines are also treated in well-written chapters. Excellent reviews of analgesics and steroids are also found in this text.

CNS depressants and stimulants and material from the Seventh Edition are substantially updated. Adrenergic agents and cholinergic agents are given highly competent treatment in subsequent chapters.

The chapter on diuretics is impressively updated and another chapter takes us easily through cardiovascular agents, a potentially difficult group.

Carbohydrates, proteins, and vitamins are skillfully treated. A concluding chapter effectively brings together a diverse group of agents, one example of which is diagnostic agents.

Two valuable appendixes describe properties of pharmaceutical aids and list pKa values for a number of drugs. Finally, the index is detailed and should prove to be useful.

All of the chapters of this text show signs of painstaking preparation. Revising and updating over the Seventh Edition is extensive. Literature citations are also extensive and current. Coordination between chapters is very good, and there is little redundancy. There is a high degree of consistency among the chapters in the nature of the material presented and the format for its presentation. A useful feature for pharmacy students is that pertinent chemical properties of the individual agents are given.

In summary, this is a most impressive textbook, judged for completeness, cohesiveness, and balance. The authors have used care and good judgment in making it an appropriate textbook for undergraduate pharmacy students.

Physicochemical Principles of Pharmacy. By A. T. FLORENCE and D. ATTWOOD, Chapman and Hall, New York, N.Y. 10017. 1982. 509 pp. 15 × 23 cm. Price $29.95.

The purpose of this book is to provide the physicochemical background to the design and use of pharmaceutical products. Processing technology is not discussed. Special problems of the various routes of administration and of duration of activity are presented if the mechanism is physical and not biological.

An effort is made to demonstrate that often the same forces operate in inanimate and animate systems. The authors assume that undergraduates using this book will have had a standard physical chemistry course. Since it is aimed at undergraduates, the reference lists have been kept to a minimum.

The book is divided into 11 chapters, which are entitled: Gases; Properties of the Solid State; Liquids; Solutions; Solubilty of Drugs in Liquids; Surface Chemistry; Colloidal and Coarse Lyophobic Dispersions; Polymeric Systems; Principles of Drug Absorption and Routes of Administration; Drug Interactions and Incompatibilities: a physicochemical viewpoint; and Chemical Stability of Drugs.

There is an abundance of easily comprehended figures to supplement the text. Although examples are given, perhaps the inclusion of a greater number of sample calculations would have been helpful to the student. The chapters on principles of drug absorption and drug interactions and incompatibilities are especially valuable additions to a book dealing with physicochemical principles. This is a fine text which fulfills its purpose.

SYMPOSIUM ARTICLES

Further Studies on the Catalysis of Hydrolysis and Aminolysis of Benzylpenicillin by Metal Chelates

HISAO TOMIDA * and MICHAEL A. SCHWARTZ ˣ

Received January 15, 1982, from the *College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication, June 14, 1982. *Present address: Faculty of Pharmaceutical Sciences, Fukuyama University, Fukuyama City, Japan.

Abstract □ It was suggested previously that the very rapid catalysis of benzylpenicillin hydrolysis and aminolysis by zinc ion and tris(hydroxymethyl)aminomethane (tromethamine) was mediated by a ternary complex in which the metal ion not only held the substrate and tromethamine in close proximity but also lowered the pK_a of a bound tromethamine hydroxyl group making it a very powerful nucleophile. In this study the scope of this reaction was explored further by examining the effects of changes in substrate side chain, metal ion, and amino alcohols. All of the penicillins studied showed about the same rate of reaction. Of the other metal ions examined Cu^{2+} and Ni^{2+} showed no activity, Mn^{2+} very slight activity, and Cd^{2+} and Co^{2+} somewhat greater activity. The latter was the most effective of this group but was 40 times slower than zinc. The results with a number of amino alcohols provided additional evidence for the ternary complex mechanism. Studies with the methyl ester of benzylpenicillin indicated that the metal ion is bound to the antibiotic at the carboxylate site and that a different mechanism is involved in the slower catalysis observed with the ester. Some comparison is made with a zinc-dependent β-lactamase.

Keyphrases □ Benzylpenicillin—mechanism of hydrolysis and aminolysis, catalysis by divalent cations and amino alcohols, ternary complex formation □ Metal-ion catalysis—hydrolysis and aminolysis of benzyl penicillin, mechanism, ternary complex formation

It was previously shown that zinc ion in the presence of tromethamine buffer in the 7–10 pH range is a very facile catalyst for the hydrolysis and aminolysis of benzylpenicillin (1). Evidence was offered to show that the mechanism of this catalysis most probably involved a ternary complex in which zinc ion acts as a template to bring the reactants, tromethamine and penicillin, together. In this complex the bound hydroxyl group of tromethamine can become a very powerful nucleophile, by virtue of a lowering of its pK_a as a result of coordination of zinc ion, and attack the β-lactam carbonyl of penicillin. The resulting tromethamine ester then hydrolyzes to penicilloic acid or reacts with another molecule of tromethamine to form an amide.

The present study was undertaken to explore the scope of this reaction, *i.e.*, the activity of other metal ions and other ligands, as well as the effects of structural changes in the substrate side chain.

EXPERIMENTAL

Materials—Benzylpenicillin[1], phenethicillin[1], and methicillin[1] were used as received. Methylpenicillin was prepared by acetylating 6-aminopenicillanic acid as reported previously (2). The methyl ester of benzylpenicillin was prepared as follows.

Potassium benzylpenicillin and methyl iodide were stirred in dimethylsulfoxide for 4 hr at room temperature. The mixture was diluted with water, extracted with ether, and then the extract was dried and the solvent removed *in vacuo*. A small volume of ethyl acetate was added to the resulting oil and the solution chromatographed on silica gel 60[2] with ethyl acetate as the developing solvent. The fractions containing ester were combined and solvent removed *in vacuo*. The resulting oil crystallized on trituration with *n*-hexane and was recrystallized twice from carbon tetrachloride. Its structure was confirmed by IR and NMR spectroscopy.

Tromethamine was a very pure grade[3]; ethanolamine, diethanolamine, and triethanolamine were all reagent grade[4]; 2-amino-2-methyl-1,3-propanediol was recrystallized from ethanol; 2-methoxyethanolamine and 2-diethylaminoethanol were redistilled prior to use.

Zinc chloride solution was prepared from reagent grade zinc metal as previously described (1). The other metal ions were in the form of chloride salts and were reagent grade.

Imidazole was recrystallized twice from benzene and washed with ether.

Kinetics—All rate measurements were carried out at 35° with the ionic strength brought to 0.5 by the addition of potassium chloride. The amines normally acted as their own buffers. In some cases where buffer capacity was too low, the pH was maintained constant on a radiometer pH-stat.

Rate of loss of penicillin from solution was followed either by following the decrease in absorbance at 235 nm (3) or by sampling the reactant solution and assaying for residual penicillin by the method of Bundgaard and Ilver (4). Initial concentration of penicillin was 5×10^{-4} *M* in the

Penicillin	Side Chain, R	k_T [b]	k_{OH} [c]
Benzylpenicillin		0.032 [d]	12.5
Phenethicillin		0.039	12.6
Methicillin		0.0263	6.5
Methyl penicillin		0.0294	10.6

[a] Rate constants in M^{-1} min^{-1}. [b] Reactions carried out at 35°, I = 0.5 with tromethamine alone. [c] Reactions carried out at 31.5°, I = 0.2 (2). [d] From Ref. (1)

direct spectrophotometric method and 2.75×10^{-4} *M* in the sampling method. When the methyl ester was used, the reaction mixture included 4.5% acetonitrile to keep the ester in solution.

Ionization Constants—The apparent pK_a of each of the amines was determined at 35° and ionic strength 0.5 by potentiometric titration.

RESULTS AND DISCUSSION

Effect of Penicillin Side-Chain Structure —The rates of the reaction of several penicillins with tromethamine were measured in both the absence and presence of zinc ion. Table I presents the second-order rate constants for the aminolysis of the penicillins by tromethamine in the absence of zinc ion and compares these with the alkaline hydrolysis rate constants. It can be seen that the order of reactivity is the same in both cases, reflecting the relatively small effect of the side chain on the susceptibility of the β-lactam ring to nucleophilic attack.

In Fig. 1 is shown the dependence on tromethamine concentration of the rate of loss of penicillins in the presence of zinc ion at pH 8.0. In these studies 3×10^{-6} *M* zinc ion was used, and the first-order rate constants were corrected for rate with tromethamine alone and normalized with respect to zinc ion.

It can be seen that differences in the side-chain structure exert only a very small effect on the rate of β-lactam cleavage. The rates with all the penicillins are very rapid relative to the rate in the absence of zinc ion, but there is only a less than twofold difference in rate. This result would be expected if binding of the drug to zinc ion were at the carboxyl group of the thiazolidine ring as has been proposed (5, 6). To further test this hypothesis, rates of reaction under similar conditions were carried out with the methyl ester of benzylpenicillin.

Effect of Esterification of Carboxyl Group—In the absence of zinc ion the methyl ester of benzylpenicillin reacts more rapidly with tromethamine than the free penicillin, as shown in Fig. 2. It should be noted that the reaction in both cases is at the β-lactam carbonyl. The ester is more susceptible to attack at this point than the free penicillin, because

[a] Reactions run at pH 8.0, 35°, containing 4.5% acetonitrile with initial concentration of penicillin 2.75×10^{-4} *M*.

the negative charge on the latter tends to repel nucleophiles such as hydroxyl ion (7) and tromethamine. The presence of 3×10^{-6} *M* zinc ion causes, as shown in Table II, only a very small effect on the methyl ester of penicillin relative to the free penicillin. Again, if penicillin is coordinated to zinc ion at the carboxylate ion one would expect the result obtained.

At much higher concentrations of zinc ion there is observed a significant effect on the loss of methyl ester of penicillin in the presence of tromethamine, as shown in Fig. 3. Here the rate constant is a linear function of zinc ion concentration up to 10^{-3} *M*. The dependence of the rates of this reaction on tromethamine concentration is shown in Fig. 4, where it is compared with that of free benzylpenicillin.

Both curves show a maximum near 0.02 *M* tromethamine, but there are significant differences in slope of the curve as well as the magnitude of the rates. At the maximum, the rate constant for the ester is about 1400 times slower than that of the free penicillin. At tromethamine concentrations above 0.02 *M* the rate constant for the free penicillin decreases much more rapidly than that of the ester. These results, coupled with the great difference in rate, indicated that the reaction with the ester involves a different mechanism than the reaction with penicillin. In the latter it was proposed that catalysis is mediated by a ternary complex, in which both tromethamine and penicillin are bound to a zinc ion with nucleophilic attack by a tromethamine hydroxyl on the β-lactam carbonyl taking place within the complex. At high tromethamine concentrations a second tromethamine would compete with penicillin for the binding site of the zinc ion and reduce the reaction rate by reducing the relative amount of ternary complex that could be formed. Blocking of the penicillin carboxyl in the ester prevents the formation of this ternary complex, and, even if the ester binds to zinc it must be with a much lower affinity than the free acid, and the predominant species in solution would be chelates of tromethamine with zinc ion (ZnT and ZnT_2). With the ester one possible mechanism suggested by the tromethamine dependence is a direct intermolecular nucleophilic attack by these chelates on the β-lactam carbonyl. When tromethamine is coordinated to zinc ion through the amine and one of the hydroxyl groups, the pK_a of the coordinated hydroxyl group can be lowered substantially (*i.e.*, 3 or 4 units), but the alkoxide ion thus formed will retain the nucleophilicity of a group with the higher pK_a (8). Thus, these groups in the chelates can become relatively powerful nucleophiles at a pH close to neutrality. Also, it would be expected that the pK_a of the hydroxyl group in ZnT and ZnT_2 would

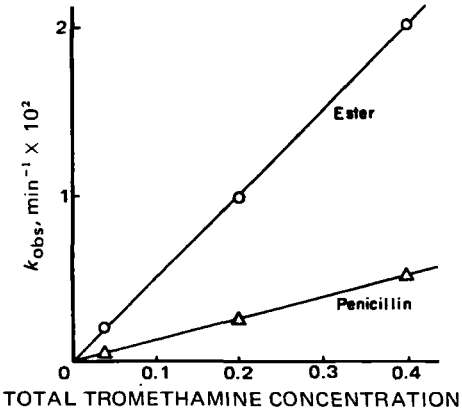

Figure 2—*Dependence of observed rate constant (k_{obs}) on tromethamine concentration, pH 8.0, EDTA 1×10^{-5} M, 4.5% acetonitrile. Key: (△) benzylpenicillin, (○) methyl ester.*

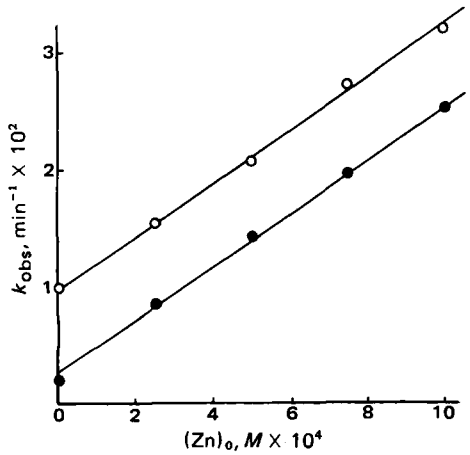

Figure 3—*Dependence of observed rate constant for loss of methyl ester of benzylpenicillin on zinc ion. Key: (○) tromethamine base 0.1* M, *(●) tromethamine base 0.02* M.

not be very different, and hence the rate constants for their reaction with the penicillin ester would be expected to be similar. That they are is evidenced by the tromethamine dependence shown in Fig. 4, where the decrease in rate at high tromethamine is relatively small. We may express the overall rate constant as follows:

$$k_T/[Zn]_0 = k_1[ZnT^{1+}] + k_2[ZnT_2^{1+}]$$

where k_T is the observed rate constant corrected for the rate with tromethamine alone, and $[Zn]_0$ is the stoichiometric total zinc ion concentration. Using values previously estimated for the affinity constants of the zinc–tromethamine chelates (1), and assuming the pK_a value for the two chelates are equal (pK_a = 8.7), values for the rate constants were calculated as $k_1 = 220\ M^{-1}\ min^{-1}$ and $k_2 = 120\ M^{-1}\ min^{-1}$. These values are in the range one would expect for nucleophiles with pK_a values ~12–13 (9), which is probably in the pK_a range of uncomplexed tromethamine.

It should be noted that this type of reaction probably also could occur with the free penicillin, but with a rate so low that it would be insignificant relative to that of the ternary complex pathway.

Effects of Other Metal Ions—It was of interest to examine the effects of other metal ions in this system. Rates of loss of benzylpenicillin in solution in the presence of Co^{2+}, Cd^{2+}, Mn^{2+}, Cu^{2+}, and Ni^{2+} were measured at pH 8, at constant tromethamine concentration. The results are shown in Fig. 5 where these are compared with Zn^{2+}. Both Cu^{2+} and Ni^{2+} showed no activity at concentrations up to 10^{-4} M. The other metal ions all show a linear dependence on metal ion concentration and much lower rates than zinc ion.

In Fig. 6 is shown the dependence of the rate of penicillin loss on tromethamine concentration in the presence of three metal ions. Here again, the rate constants were corrected for the rate with tromethamine alone and normalized with respect to metal ion concentration. While the curve for Co^{2+} ion shows a maximum similar to that of zinc ion, Cd^{2+} ion shows only a plateau, and the curve for Mn^{2+} reveals only a steady increase in

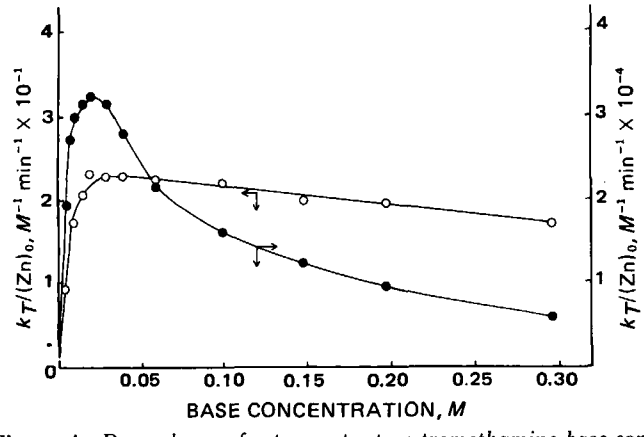

Figure 4—*Dependence of rate constant on tromethamine base concentration at pH 8.0. Key: (○) methyl ester, (●) penicillin.*

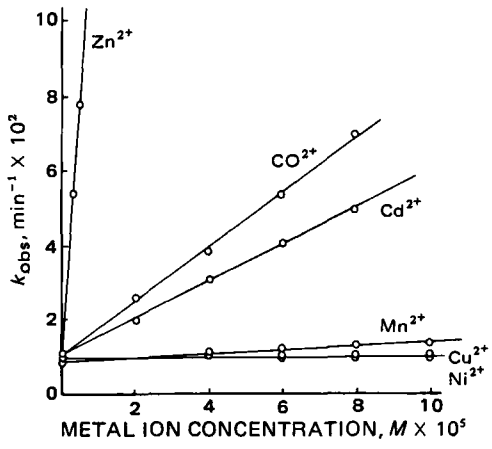

Figure 5—*Effect of concentration of metal ions on observed rate constant for penicillin loss at pH 8.0, 0.2* M *tromethamine buffer.*

rate with increasing tromethamine. Based on the mechanism proposed for zinc ion with benzylpenicillin, the differences in these curves might be thought to result from differences in the formation constants of the metal chelates with tromethamine. This appears to be the case particularly with Co^{2+}, but with Cd^{2+} the plateau suggests a different mechanism, perhaps similar to that proposed for the reaction of zinc–tromethamine chelates with penicillin methyl ester.

The rates of loss of the methyl ester of benzylpenicillin with these metal ions were also measured and are reported in Table III as the rate constant at the maximum in the tromethamine dependence curve divided by the metal ion concentration, except in the case of Mn^{2+} where no maximum was reached. Here the rates are compared at the same tromethamine concentration. In all cases the rate for the penicillin is much greater than that of the ester but these differences decrease markedly in the order shown in Table III.

Such a result may be expected if the reaction with the free penicillin, as proposed at least with zinc and cobalt, is mediated by a ternary complex in which an appropriate conformation of tromethamine and substrate would be necessary for optimum reaction rate. If an optimum fit is obtained with zinc ion, then large differences would be expected with other ions of different size. On the other hand, with the ester, where the reaction may involve bimolecular nucleophilic attack by the metal chelate, smaller differences would be expected based more on the effect of the metal ion on pK_a of the tromethamine hydroxyl, steric factors, *etc.* Thus, while these data are not inconsistent with the proposed mechanism, a good deal more information on the nature of the tromethamine complexes and the effect of pH on reaction rate would be necessary to make more definitive conclusions.

In terms of this system as a potential model for the zinc-dependent β-lactamases, it is interesting to note that other metal ions may replace zinc in the enzyme with some retention of activity (10). It has been reported that replacement with Co^{2+} ion gives an enzyme with 12.6% of the activity of the zinc-containing enzyme. With Mn^{2+} and Cd^{2+} the activity was reduced to 6.7 and 1%, respectively. No enzymic activity was noted

with Cu^{2+} and Ni^{2+}. Thus, there is a considerable degree of similarity between the relative order of activity of metal ions in the enzyme and this model system.

Effect of Ligand Structure—As an initial approach to determining the effect of ligand structure on catalytic activity, the rates of loss of benzylpenicillin were measured in the presence of zinc ion with several amino alcohols and one in which the hydroxyl group was blocked. The results are shown in Figs. 7 and 8 and summarized in Table IV.

These data provide further evidence for the intermediacy of a ternary complex (amine–zinc ion–penicillin) in this type of reaction, as opposed to nucleophilic attack by amine on a metal ion–penicillin complex. If the latter were the predominant pathway, one would not expect to observe a great difference in rate between ethanolamine and methoxyethylamine, since their pK_a values are very close, unless the latter had a much greater affinity for the metal ion. One would expect however, that ethanolamine would show the greater affinity, because of the opportunity for a bidentate complex with the free hydroxyl group.

On the other hand, these data are entirely consistent with the ternary complex mechanism in which the hydroxyl of the ethanolamine, coupled to metal ion, is the attacking species. Methoxyethylamine cannot enter into a ternary complex, in which it can behave as a nucleophile, because of the blocked hydroxyl group.

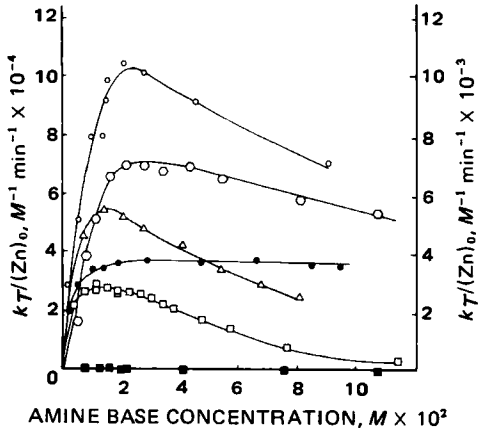

Figure 7—*Dependence of rate constant on amine concentration. Key: Left ordinate: (○) tromethamine, (△) 2-amino-2-methyl-1,3-propanediol (□) ethanolamine, (○) diethanolamine; right ordinate: (●) triethanolamine (■) 2-methoxyethylamine.*

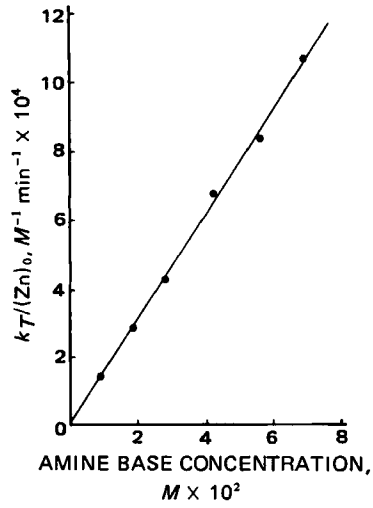

Figure 8—*Dependence of rate constant on concentration of 2-diethyl-aminoethanol.*

The relative values of the rate constants for tromethamine, 2-amino-2-methyl-1,3-propanediol and ethanolamine also lend support to the ternary complex hypothesis. If the other mechanism were predominant, one would expect the rates to increase with increasing pK_a, as they do in the absence of metal ion. The order of reactivity, however, seems to be determined more by the number of hydroxyl groups available for binding to the metal ion (*i.e.*, a statistical effect), which would be expected if the affinity for metal ion in a ternary complex was the most important factor involved.

The same general effect is seen in comparing the rate constants for diethanolamine with ethanolamine. Though the latter has a higher pK_a and reacts more rapidly with penicillin in the absence of zinc ion, its rate in the presence of zinc ion is significantly lower. Again, the rate constants with zinc ion are related more to the number of hydroxyl groups and this factor further supports the ternary complex mechanism.

With triethanolamine two factors are of interest: the relatively low rates with zinc ion and the shape of the concentration-dependence curve. The latter may indicate that triethanolamine forms only a 1:1 complex with zinc as it does with cupric ion (12). The plateau indicates either that the same species is present throughout the concentration range studied or that a higher complex has the same activity. The former seems more likely, in view of the fact that Cu^{2+} forms only a 1:1 complex with triethanolamine. The inability of triethanolamine to form higher complexes is probably due to steric inhibition. The lower rate with penicillin may reflect the same kind of steric inhibition of formation of a ternary complex with substrate.

The concentration dependence of rates with diethylaminoethanol is of interest, because it shows no maximum up to 0.1 *M*. This apparently results from formation of only a 1:1 complex perhaps due to steric inhibition or to a relatively low affinity of the compound for zinc ion. Yet the rates are relatively high, and it may be of interest to further study the concentration and pH dependence of this reaction. This type of compound may also be of more interest as a β-lactam model, since the product, with a tertiary amine, should be only penicilloic acid as with the enzyme rather than a mixture of the acid with an amine as with primary amines.

In summary, additional evidence presented here provides further support for the previously proposed mechanism for the catalysis of hydrolysis and aminolysis of penicillin by zinc ion and tromethamine, involving a ternary complex intermediate. The relative rates of reaction of other metal ions substituted for zinc are in the same general order as in a zinc-dependent β-lactamase. Thus, this system may be a model for the enzyme.

Interaction of Nitroglycerin With Human Blood Components

T. D. SOKOLOSKI ˣ, C. C. WU *, L. S. WU, and A. M. BURKMAN

Received October 6, 1981, from the *College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication December 31, 1981. * Present address: Ayerst Laboratories, Rouses Point, N.Y.

Abstract □ Nitroglycerin is rapidly lost from solution when incubated with red blood cells or whole blood. The assumption that the loss is enzymatic in nature may not be true, since no major metabolite is detected during this incubation. Explanation on the basis of a chemical reaction is also difficult, since the products of the chemical hydrolysis of nitroglycerin are the same as the metabolic products. After an initial rapid loss, nitroglycerin disappearance at 37° follows an apparent first-order process in the concentration range of 10–480 ng/ml when incubated with washed red blood cells suspended in normal saline solution. The half-life for the reaction of the apparent first-order phase varies with the initial concentration and increases as the concentration increases (4 min at 10 ng/ml, 52 min at 480 ng/ml), suggesting a mixed kinetic mechanism. Metabolites of nitroglycerin (1,2- and 1,3-dinitroglycerin) react similarly to nitroglycerin in terms of an apparent initial, fast step, a secondary first-order dependence, and concentration-dependent rate effects; however, the rate of the reaction is much slower ($t_{1/2}$ = 33 min at 10 ng/ml) for the metabolite. These data suggest the possibility of a physical mechanism for the loss of nitroglycerin. Since the loss to red blood cells can be rapid, it seems that the mechanism should be delineated, and that the rate of disappearnce be considered in an analysis of the pharmacodynamics of the drug.

Keyphrases □ Kinetics—nitroglycerin loss to red blood cells □ Nitroglycerin—rate of loss to red blood cells □ 1,2- and 1,3-Dinitroglycerin—rate of loss to red blood cells □ Disposition—reactivity of nitroglycerin and its metabolites with blood

It has been reported that when nitroglycerin is incubated with whole blood (fresh or outdated), resuspended red blood cells, serum, or plasma, the drug is lost from solution by an apparent first-order process. A relatively rapid loss occurred in blood or resuspended cells (1–3) ($t_{1/2}$ = 6 min) and rat serum ($t_{1/2}$ = 20 min) (4) with a slower loss occurring in plasma, $t_{1/2}$ = 53 (1) or 175 min (5). The rate of loss in the presence of erythrocytes approaches the biological half-life of organic nitrate (1.9 min) (1). The interaction of nitroglycerin with blood cells, serum, or plasma has been assumed by other workers to be an enzymatic reaction. However, our earlier work using an assay with resuspended red blood cells that could detect the major nitroglycerin metabolites (1,2-dinitroglycerin and 1,3-dinitroglycerin) showed that there was no metabolite in the medium over the entire time course of the loss of nitroglycerin (3). This observation led to the conclusion that the loss of nitroglycerin may not be enzymatic in nature. In this paper further studies are reported which probe the mechanism of loss of nitroglycerin when the drug is incubated with red blood cells. Since the rate of loss of nitroglycerin is rapid, it would appear that a knowledge of the mechanism of its loss would have significant impact on an analysis of the disposition kinetics of the drug and possibly its physiological activity as well.

EXPERIMENTAL

Nitroglycerin stock solutions were prepared from an alcoholic extract of a 10% aqueous solution of lactose adsorbate[1]. The major metabolites of nitroglycerin, 1,2-dinitroglycerin and 1,3-dinitroglycerin, were prepared from 2,3-dibromopropanol[2] and 1,3-dibromopropane-2-ol[3] using the method of Dunstan *et al.* (6). The purity of the compounds was determined by high-performance liquid chromatography (HPLC) and TLC and the solutions standardized as reported by Yuen *et al.* (7). All other chemicals used were obtained commercially and were reagent grade or better.

An electron capture gas chromatograph[4] was used with a data processor[5]. The GLC assay for nitroglycerin was reported earlier (9% QF-1[6] on 60–80 mesh Supelcoport[7]) (3). The column was silanized glass 2 mm × 0.915 m and the temperatures of the injection port, the column, and the detector were 150, 125, and 200°, respectively. The carrier gas was 5% methane in argon used at a flow rate of 21 ml/min. Under these conditions the retention times were: mixture of 1,2-dinitroglycerin and 1,3-dinitroglycerin, 3 min; nitroglycerin, 6.3 min; and internal standard (1-fluoro-2,4-dinitrobenzene[8]) 7.57 min. The system does not separate the two isomeric metabolites but does optimize their combined detection.

For the assay of 1,2- and 1,3-dinitroglycerin a method was used that was a slight modification of our earlier method (8). The column (silanized glass, 2 mm × 50 cm) consisted of 3% Carbowax 20M-TPA[9] on 60–80 mesh Supelcoport[7]. The injection port, column, and detector were at 150, 135, and 200°, respectively and the flow rate of the carrier gas was 20 ml/min. Using these conditions the two metabolites could be separated from each other and from nitroglycerin. The approximate retention times in minutes were: nitroglycerin, 2.7; *o*-iodobenzyl alcohol[10] (internal standard), 3.4; 1,2-dinitroglycerin, 6.5; and 1,3-dinitroglycerin, 8.2.

The concentration of nitroglycerin or its metabolite in the various

Interaction of Nitroglycerin With Human Blood Components

T. D. SOKOLOSKI ˣ, C. C. WU *, L. S. WU, and A. M. BURKMAN

Received October 6, 1981, from the *College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication December 31, 1981. * Present address: Ayerst Laboratories, Rouses Point, N.Y.

Abstract □ Nitroglycerin is rapidly lost from solution when incubated with red blood cells or whole blood. The assumption that the loss is enzymatic in nature may not be true, since no major metabolite is detected during this incubation. Explanation on the basis of a chemical reaction is also difficult, since the products of the chemical hydrolysis of nitroglycerin are the same as the metabolic products. After an initial rapid loss, nitroglycerin disappearance at 37° follows an apparent first-order process in the concentration range of 10–480 ng/ml when incubated with washed red blood cells suspended in normal saline solution. The half-life for the reaction of the apparent first-order phase varies with the initial concentration and increases as the concentration increases (4 min at 10 ng/ml, 52 min at 480 ng/ml), suggesting a mixed kinetic mechanism. Metabolites of nitroglycerin (1,2- and 1,3-dinitroglycerin) react similarly to nitroglycerin in terms of an apparent initial, fast step, a secondary first-order dependence, and concentration-dependent rate effects; however, the rate of the reaction is much slower ($t_{1/2}$ = 33 min at 10 ng/ml) for the metabolite. These data suggest the possibility of a physical mechanism for the loss of nitroglycerin. Since the loss to red blood cells can be rapid, it seems that the mechanism should be delineated, and that the rate of disappearnce be considered in an analysis of the pharmacodynamics of the drug.

Keyphrases □ Kinetics—nitroglycerin loss to red blood cells □ Nitroglycerin—rate of loss to red blood cells □ 1,2- and 1,3-Dinitroglycerin—rate of loss to red blood cells □ Disposition—reactivity of nitroglycerin and its metabolites with blood

It has been reported that when nitroglycerin is incubated with whole blood (fresh or outdated), resuspended red blood cells, serum, or plasma, the drug is lost from solution by an apparent first-order process. A relatively rapid loss occurred in blood or resuspended cells (1–3) ($t_{1/2}$ = 6 min) and rat serum ($t_{1/2}$ = 20 min) (4) with a slower loss occurring in plasma, $t_{1/2}$ = 53 (1) or 175 min (5). The rate of loss in the presence of erythrocytes approaches the biological half-life of organic nitrate (1.9 min) (1). The interaction of nitroglycerin with blood cells, serum, or plasma has been assumed by other workers to be an enzymatic reaction. However, our earlier work using an assay with resuspended red blood cells that could detect the major nitroglycerin metabolites (1,2-dinitroglycerin and 1,3-dinitroglycerin) showed that there was no metabolite in the medium over the entire time course of the loss of nitroglycerin (3). This observation led to the conclusion that the loss of nitroglycerin may not be enzymatic in nature. In this paper further studies are reported which probe the mechanism of loss of nitroglycerin when the drug is incubated with red blood cells. Since the rate of loss of nitroglycerin is rapid, it would appear that a knowledge of the mechanism of its loss would have significant impact on an analysis of the disposition kinetics of the drug and possibly its physiological activity as well.

EXPERIMENTAL

Nitroglycerin stock solutions were prepared from an alcoholic extract of a 10% aqueous solution of lactose adsorbate[1]. The major metabolites of nitroglycerin, 1,2-dinitroglycerin and 1,3-dinitroglycerin, were prepared from 2,3-dibromopropanol[2] and 1,3-dibromopropane-2-ol[3] using the method of Dunstan *et al.* (6). The purity of the compounds was determined by high-performance liquid chromatography (HPLC) and TLC and the solutions standardized as reported by Yuen *et al.* (7). All other chemicals used were obtained commercially and were reagent grade or better.

An electron capture gas chromatograph[4] was used with a data processor[5]. The GLC assay for nitroglycerin was reported earlier (9% QF-1[6] on 60–80 mesh Supelcoport[7]) (3). The column was silanized glass 2 mm × 0.915 m and the temperatures of the injection port, the column, and the detector were 150, 125, and 200°, respectively. The carrier gas was 5% methane in argon used at a flow rate of 21 ml/min. Under these conditions the retention times were: mixture of 1,2-dinitroglycerin and 1,3-dinitroglycerin, 3 min; nitroglycerin, 6.3 min; and internal standard (1-fluoro-2,4-dinitrobenzene[8]) 7.57 min. The system does not separate the two isomeric metabolites but does optimize their combined detection.

For the assay of 1,2- and 1,3-dinitroglycerin a method was used that was a slight modification of our earlier method (8). The column (silanized glass, 2 mm × 50 cm) consisted of 3% Carbowax 20M-TPA[9] on 60–80 mesh Supelcoport[7]. The injection port, column, and detector were at 150, 135, and 200°, respectively and the flow rate of the carrier gas was 20 ml/min. Using these conditions the two metabolites could be separated from each other and from nitroglycerin. The approximate retention times in minutes were: nitroglycerin, 2.7; *o*-iodobenzyl alcohol[10] (internal standard), 3.4; 1,2-dinitroglycerin, 6.5; and 1,3-dinitroglycerin, 8.2.

The concentration of nitroglycerin or its metabolite in the various

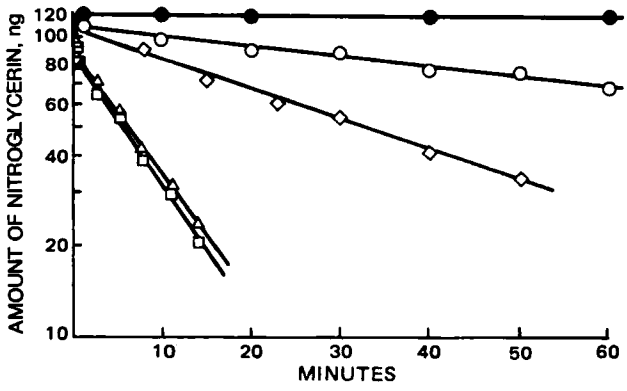

Figure 1—*Relationship between the logarithm of the amount of nitroglycerin (ng) extracted from 2 ml of several preparations initially at 60 ng/ml and the time in minutes. The preparations used at 37° together with their interpolated half-lives (in parentheses) were: (●) normal saline and protein free plasma (∞); (○) plasma (130); (◇) washed red cells diluted 1/3 of normal erythrocyte count (30); (△) red cells at normal erythrocyte count (7); (□) whole blood (6.7).*

samples used (described below) was determined relative to the internal standard (3). Using the QF-1 chromatographic system the precision was ~ ±8% at 1 ng/ml. The lower limit of nitroglycerin detection was ~50 pg/ml. The metabolites had a detector response of ~1/2 that of an equal amount of nitroglycerin, and the precision was ±10% at 3 ng/ml using the Carbowax 20 M-TPA system.

The loss of nitroglycerin or metabolite was followed in a number of different systems: whole blood, washed and resuspended red blood cells, plasma, protein-free plasma, and normal saline solution. The majority of the studies reported used resuspended cells, since the loss of nitroglycerin is the same in these systems as in whole blood (1, 3), and the resuspended cells represent more clearly defined systems that yield trouble-free reference blanks.

The various systems used in the several studies were obtained using approximately 100-ml portions of heparinized whole blood obtained from normal subjects. The blood was transferred to centrifuge tubes, centrifuged at 1200 rpm at 5° for 15 min, and then the plasma was separated from the cells. A portion of this plasma was used for a set of experiments. The remainder of the plasma was rendered protein free by ultrafiltration at 30 psi using a suitable membrane[11]. The cells obtained by centrifugation were washed three times with saline solution and reconstituted after centrifugation to 100 ml with saline solution. The cell count in such preparations was measured[12] and adjusted if necessary to a normal erythrocyte count (~5 × 10^6 cells/μl).

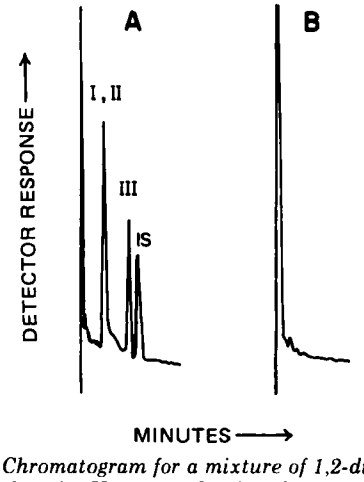

Figure 2—*(A) Chromatogram for a mixture of 1,2-dinitroglycerin, I, and 1,3-dinitroglycerin, II, 1 ng each; nitroglycerin, III (1 ng) and 1-fluoro-2,4-dinitrobenzene, IS, (internal standard) using a 9% QF-1 column. The retention times found in minutes were: I and II = 3; III = 6.3; IS = 7.6. (B) Chromatogram for red cell sample without drug.*

[12] Micro-Computerized Elzone, Model APC-80XY, Particle Data, Inc., Elmhurst, IL 60126. Dilution procedure for red cell count accompanies the instrument manual.

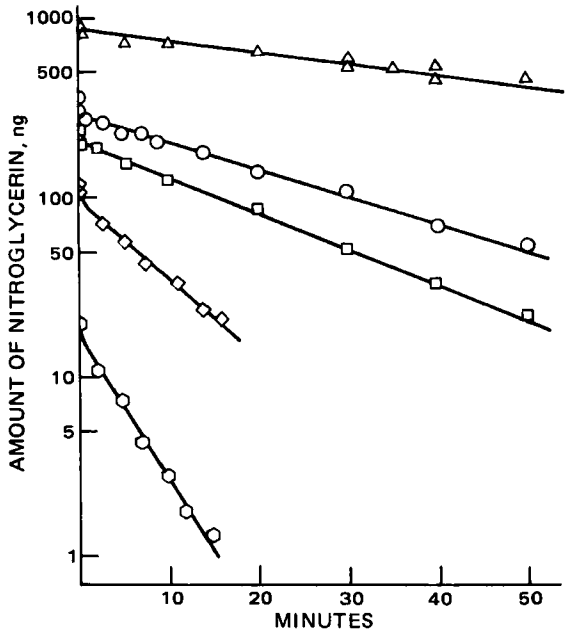

Figure 3—*Relationship between the logarithm of the amount of nitroglycerin (ng) extracted from 2 ml of washed red blood cells in normal saline and the time in minutes. The suspensions at normal erythrocyte count and at 37° were incubated with varying initial concentrations of nitroglycerin. The concentrations used and the interpolated half-lives were: (△) 480 ng/ml, 52 min; (○) 180 ng/ml, 20 min; (□) 120 ng/ml, 16 min; (◇) 60 ng/ml, 7 min; (○) 10 ng/ml, 4 min.*

In general, 2 ml of a particular preparation (whole blood, resuspended cells, plasma, protein-free plasma, or saline) was transferred to each of a series of 12-ml silanized tubes and equilibrated at 37° (~20 min). An aliquot (~50 μl) of a solution of nitroglycerin metabolite in normal saline was added to each tube to give a final concentration in each set of tubes of 10, 20, 60, 120, 180, or 480 ng/ml. The tubes were gently stirred using a rotator submerged in a water bath at 37°. Periodically over a given time interval, a tube was removed, the internal standard was added (if necessary), and the preparation was immediately extracted twice with 3 ml of ethyl acetate[13]. Both extracts were combined and concentrated or diluted for GC analysis. A portion of this solution (5 μl) was injected into the gas chromatograph for determination of the nitroglycerin and/or metabolite concentration.

The extraction efficiencies of nitroglycerin, 1,2-dinitroglycerin, and 1,3-dinitroglycerin in the red cell suspensions were previously reported: 84, 84, and 75%, respectively (3). The extraction efficiency for the metabolites from plasma was 81% (9).

RESULTS AND DISCUSSION

When nitroglycerin is incubated with whole blood or with red blood cells that are washed and suspended at a normal erythrocyte level, the loss of nitroglycerin in either preparation is the same, and after an apparent initial rapid step, it follows an apparent first-order process. Figure 1 shows the loss of nitroglycerin initially at 60 ng/ml in both whole blood and washed red cells. The half lives for the first-order loss are 7 min in whole blood and 6.7 min in red blood cells. These results are similar to those found by Armstrong *et al.* (1): 6.2 and 6.6 min, respectively, for the whole blood and suspended cell preparations at an initial nitroglycerin level of 50 ng/ml at 37°. The rate of reaction is dependent on the number of cells in the system at a constant concentration. If the initial concentration is held at 60 ng/ml and the concentration of cells is reduced threefold, the first-order half-life increases to 30 min (Fig. 1).

In whole blood and resuspended cell systems no metabolite (or hydrolysis product) accumulates in the medium. The dinitro compounds are the principal hydrolysis or metabolic products of nitroglycerin. This observation supports our earlier conclusion (3) that loss of nitroglycerin from whole blood and red cell systems may not be enzymatic, as assumed by others (1, 2). Figure 2A shows a chromatogram of a mixture of 1,2-

The suspensions at 37° were incubated with varying initial concentrations of metabolite. The concentrations of the metabolite (I = 1,2-dinitroglycerin; II = 1,3-dinitroglycerin) used, and the interpolated half-lives were: (○) II, 480 ng/ml, 228 min; (□) II, 180 ng/ml, 141 min.; (△) I, 60 ng/ml, 51 min; (■) II, 60 ng/ml, 40 min; (●) II, 10 ng/ml, 33 min.*

dinitroglycerin (1 ng), 1,3-dinitroglycerin (1 ng), nitroglycerin (1 ng), and internal standard. The base line for a red cell blank containing no drug or metabolite is given in Fig. 2B and clearly shows no interfering materials. If metabolites were present in the blood or red cell systems, as presented in Fig. 1, the assay would have detected them.

The loss of nitroglycerin in human plasma at the same initial concentration as in whole blood or in red cell suspension follows an apparent first-order process (Fig. 1) without a detectable rapid initial phase. The reaction occurs at a much slower rate in comparison with blood studies: half-life 130 min at an initial concentration of 50 ng/ml at 37°. This slower rate in plasma was also observed by Armstrong *et al.* (1) who reported a half-life of 53 min and by Maier *et al.* (5) who reported a half-life of 175 min. The latter group used a slightly diluted sample. The decomposition of nitroglycerin in plasma may be associated with its interaction with protein, since protein-free plasma and normal saline solution containing the same initial concentration of nitroglycerin show no drug loss (Fig. 1). It is not possible to unequivocally state that the loss of nitroglycerin in plasma does not result in dinitroglycerin formation. The levels of 1,2-dinitroglycerin or 1,3-dinitroglycerin that would be expected over a 1-hr period would not be detected with any certainty. The reason for this is that the detector sensitivity for the dinitro compounds is about one-half that of nitroglycerin (8). The interaction of nitroglycerin with sulfhydryl groups (e.g., on protein) *via* a nonenzymatic process would generate denitrated compounds. This is a possibility since the nitroxyl groups of nitroglycerin should be good leaving groups. In support of this possible reactivity, Needleman reported that the interaction of nitroglycerin with sulfhydryl groups leads to the same products in the presence or absence of enzyme (10).

The effect of various initial concentrations of nitroglycerin on drug loss following its incubation with a constant level of red blood cells at 37° is given in Fig. 3. The loss of nitroglycerin initially at 10, 60, 120, 180, and 480 ng/ml follows a terminal first-order process at all concentrations. At concentrations ≤180 ng/ml an initial fast reaction phase is suggested. The first-order half-life increases as the initial concentration increases. The apparent half-lives as determined by graphical interpolation are: 4 min at 10 ng/ml, 7 min at 60 ng/ml, 16 min at 120 ng/ml, 20 min at 180 ng/ml, and 52 min at 480 ng/ml. Therapeutic levels of nitroglycerin are believed to be in the range of 1.2–11.1 ng/ml (11), and thus the interaction of the drug with red blood cells should probably be a factor to be considered in an analysis of nitroglycerin pharmacokinetics or pharmacodynamics.

At each of the several concentrations of nitroglycerin used in the studies summarized in Fig. 3, no metabolite or hydrolysis product of nitroglycerin accumulated in the medium. This led to the question of whether or not any denitrated products formed and, having reacted very rapidly with cells, did not accumulate in the medium. To get an answer to this question, the kinetics of the loss of the dinitro compounds to red blood cells was undertaken. The assay method utilizing a 3% Carbowax 20M-TPA column and an ethyl acetate extraction provided a method for accurate separation and determination of both dinitro isomers. Figure 4A shows the chromatogram for a mixture of nitroglycerin, *o*-iodobenzyl alcohol (internal standard), and the two isomeric dinitroglycerins. The amounts of components injected were: 1 ng nitroglycerin, 2 ng 1,2-dinitroglycerin, and 1.6 ng 1,3-dinitroglycerin. Figure 4B showing the chromatogram for a red cell system with no drug or metabolite added indicates that no interfering materials are extracted. The amount of metabolite extracted from samples incubated at a constant level of red cells in normal saline at 37° at various times is presented in Fig. 5. After a possible initial phase, the loss of metabolite followed an apparent first-order process at each level of 1,3-dinitroglycerin studied and the single level of 1,2-dinitroglycerin used. The half-lives for the 1,3-isomer interpolated from the plots increased as the initial concentration increased: at 10 ng/ml, 33 min; at 60 ng/ml, 40 min; at 180 ng/ml, 141 min; and at 480 ng/ml, 228 min. Although the same trend is found for the dependence of half-life on initial concentration as for nitroglycerin, the reaction at comparable concentrations is much slower for the dinitro compound. This suggests that if nitroglycerin loss results in the formation of metabolites released to the medium, the metabolites should have been detected. Figure 5 also shows that the first-order rate of loss of the 1,2-isomer is about the same as the 1,3-isomer. When both are initially present at 60 ng/ml, the half-life interpolated for 1,2-dinitroglycerin is 51 min and that for 1,3-dinitroglycerin is 40 min. Therefore, even if one isomer were preferred in the denitration of nitroglycerin, it would have been detected in the loss of the drug incubated with red blood cells. It would also seem that whatever the mechanism of loss of nitroglycerin to red blood cell is, the loss of metabolite may follow a similar mechanism since the same general kinetic behavior is found for it.

Although the mechanism of loss of nitroglycerin incubated with erythrocytes is not known, based on the observations presented here and elsewhere (3, 12) it appears that the loss of nitroglycerin to red blood cells need not be enzymatic in nature, although the possibility is not entirely eliminated. This evidence is primarily the absence of metabolite in the medium following the loss of nitroglycerin, and the inactivity toward nitroglycerin of the glutathione transferase isolated from erythrocytes as reported by Marcus *et al.* (12). The erythrocyte enzyme designated as the ρ form is quite different from the most active δ form found in the liver or indeed different from any of the liver forms, α–ϵ (12). The unusual rate dependence (Fig. 3) and the absence of metabolite or hydrolysis product suggest that the loss could be physical in nature. It would appear that a mixed kinetic process or processes occur when intervening steps involve slow and fast kinetic states. The mechanism (or mechanisms) of nitroglycerin loss in blood should be established since its elucidation will not only impinge on valid pharmacodynamic analysis but even impinge on factors such as obtaining meaningful blood level determinations. Studies are currently being undertaken to explore an adsorption/ab-

sorption mechanism. No particular mechanism is concluded, nor has an enzymatic mechanism been conclusively eliminated. If the interaction with red cells is physical in nature, it is possible that interaction with other biotissues can be quite significant and that what has been found with red blood cells is only one of many important interactive phenomena. Indeed, McNiff *et al.* have recently suggested that the target tissue (blood vessels) for nitroglycerin might have a higher concentration of drug than found in plasma (13). Furthermore, Armstrong *et al.* conclude that the intact *nitroglycerin molecule is essential* for initiation of relaxation based on dose-response curves of nitroglycerin effects on phenylephrine-contracted canine dorsal pedal arteries and medial saphenous veins (14). These workers found that relaxation occurred without the release of detectable amounts of metabolites into the incubation medium.

Liquid Crystal Solubilization of Cholesterol: Potential Method for Gallstone Dissolution

JOSEPH B. BOGARDUS

Received January 15, 1982 from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536* Accepted for publication April 2, 1982.

Abstract □ Solubilization rate and phase equilibrium studies were conducted for cholesterol in aqueous sodium oleate solutions. The components interacted to form a lamellar liquid crystalline phase, and this phenomenon was investigated as a potential method for cholesterol gallstone dissolution. Phase equilibria data for cholesterol–sodium oleate–water showed that the mesophase contained approximately equimolar amounts of cholesterol and oleate with large amounts of water. The cholesterol solubilization rate from a static pellet in sodium oleate solutions was much faster than dissolution in sodium cholate solutions and was independent of oleate concentration from 2.5 to 10%. In these experiments, the medium became a cloudy disperson of liquid crystalline phase in the micellar solutions. The rate-limiting step in the solubilization process appears to be dispersion of fragments from the liquid crystalline layer on the cholesterol surface. This hypothesis was consistent with the kinetic effects of viscosity, stirring rate, and oleate concentration. By converting cholesterol to a liquid crystalline phase, the solubilization process avoids the limitations of micellar solubility and interfacial resistance which control cholesterol dissolution in bile salt-containing media.

Keyphrases □ Cholesterol—solubilization in fatty acid salt solutions, dissolution in bile salt solutions, potential method for gallstone dissolution □ Solubilization—cholesterol in fatty acid salt solutions, bile salt solutions, potential method for gallstone dissolution

Cholecystectomy is the primary method for elimination of gallstones, which are composed primarily of cholesterol. In ~5% of cases, because of size or location, some stones in the ductal system cannot be removed using physical extraction techniques and are retained (1). A number of approaches have been tried for *in situ* dissolution of common bile duct stones using solvents such as ether and chloroform and solutions of bile salts or heparin (2). Recent clinical studies have shown that infusion of monooctanoin (glyceryl monooctanoate), an excellent solvent for cholesterol *in vitro* (3), dissolves common duct stones in 50–70% of patients, although treatment for 2–3 weeks is required (4, 5). The solution is infused into the bile duct *via* a T-tube drain in postcholecystectomy patients or through a nasobiliary tube inserted using a duodenoscope.

This paper reports initial investigations toward development of liquid crystal solubilization as a method for cholesterol gallstone dissolution. Ekwall *et al.* (6, 7) reported the formation of liquid crystalline droplets on the surface of cholesterol monohydrate crystals suspended in fatty acid salt solutions. Longer chain-length salts interacted more strongly with cholesterol than did shorter ones. In the present study, the rate of solubilization of cholesterol was much faster than simple dissolution in sodium cholate solutions. The cholesterol was present in the medium primarily in the form of droplets of liquid crystalline phase dispersed in the micellar solution.

EXPERIMENTAL

Phase Equilibria—Mixtures of cholesterol (1.6–11.8%), sodium oleate (1.2–14.8%), and water were weighed into glass ampules. The ampules were flushed with nitrogen, sealed, warmed to 80° in a water bath, cooled to room temperatures (22–24°), and then allowed to stand for 3 weeks with periodic shaking. A sample of the contents of each ampule was ob-

0022-3549/83/0400-0338$01.00/0

sorption mechanism. No particular mechanism is concluded, nor has an enzymatic mechanism been conclusively eliminated. Liquid Crystal Solubilization of Cholesterol: Potential Method for Gallstone Dissolution

JOSEPH B. BOGARDUS

Received January 15, 1982 from the *College of Pharmacy, University of Kentucky, Lexington, KY 40536* Accepted for publication April 2, 1982.

Abstract □ Solubilization rate and phase equilibrium studies were conducted for cholesterol in aqueous sodium oleate solutions. The components interacted to form a lamellar liquid crystalline phase, and this phenomenon was investigated as a potential method for cholesterol gallstone dissolution. Phase equilibria data for cholesterol–sodium oleate–water showed that the mesophase contained approximately equimolar amounts of cholesterol and oleate with large amounts of water. The cholesterol solubilization rate from a static pellet in sodium oleate solutions was much faster than dissolution in sodium cholate solutions and was independent of oleate concentration from 2.5 to 10%. In these experiments, the medium became a cloudy disperson of liquid crystalline phase in the micellar solutions. The rate-limiting step in the solubilization process appears to be dispersion of fragments from the liquid crystalline layer on the cholesterol surface. This hypothesis was consistent with the kinetic effects of viscosity, stirring rate, and oleate concentration. By converting cholesterol to a liquid crystalline phase, the solubilization process avoids the limitations of micellar solubility and interfacial resistance which control cholesterol dissolution in bile salt-containing media.

Keyphrases □ Cholesterol—solubilization in fatty acid salt solutions, dissolution in bile salt solutions, potential method for gallstone dissolution □ Solubilization—cholesterol in fatty acid salt solutions, bile salt solutions, potential method for gallstone dissolution

Cholecystectomy is the primary method for elimination of gallstones, which are composed primarily of cholesterol. In ~5% of cases, because of size or location, some stones in the ductal system cannot be removed using physical extraction techniques and are retained (1). A number of approaches have been tried for *in situ* dissolution of common bile duct stones using solvents such as ether and chloroform and solutions of bile salts or heparin (2). Recent clinical studies have shown that infusion of monooctanoin (glyceryl monooctanoate), an excellent solvent for cholesterol *in vitro* (3), dissolves common duct stones in 50–70% of patients, although treatment for 2–3 weeks is required (4, 5). The solution is infused into the bile duct *via* a T-tube drain in postcholecystectomy patients or through a nasobiliary tube inserted using a duodenoscope.

This paper reports initial investigations toward development of liquid crystal solubilization as a method for cholesterol gallstone dissolution. Ekwall *et al.* (6, 7) reported the formation of liquid crystalline droplets on the surface of cholesterol monohydrate crystals suspended in fatty acid salt solutions. Longer chain-length salts interacted more strongly with cholesterol than did shorter ones. In the present study, the rate of solubilization of cholesterol was much faster than simple dissolution in sodium cholate solutions. The cholesterol was present in the medium primarily in the form of droplets of liquid crystalline phase dispersed in the micellar solution.

EXPERIMENTAL

Phase Equilibria—Mixtures of cholesterol (1.6–11.8%), sodium oleate (1.2–14.8%), and water were weighed into glass ampules. The ampules were flushed with nitrogen, sealed, warmed to 80° in a water bath, cooled to room temperatures (22–24°), and then allowed to stand for 3 weeks with periodic shaking. A sample of the contents of each ampule was ob-

0022-3549/83/0400-0338$01.00/0

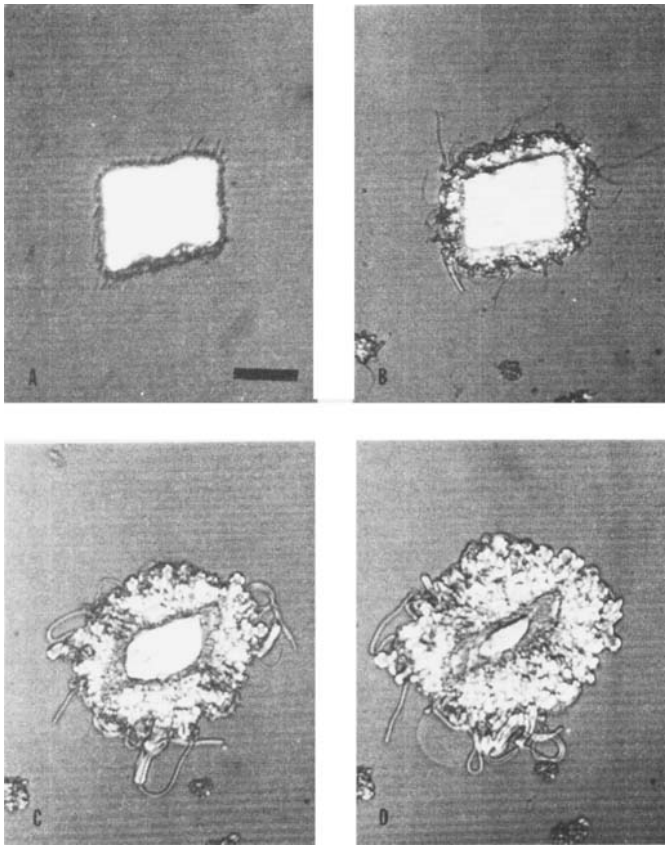

Figure 1—*Liquid crystal solubilization of cholesterol monohydrate in a 5% sodium oleate solution. Key: (A) 5–10 sec after mixing (bar = 100 μm), (B) after 1 min, (C) after 5 min, and (D) after 10 min.*

served on a polarizing microscope[1], and the remaining material was centrifuged[2] at 22–25° for 18 hr at 25,000×*g*. The phases were carefully separated using a syringe, checked microscopically for homogeneity, and analyzed by high-performance liquid chromatography (HPLC).

Solubilization Rate—Pellets of cholesterol monohydrate were compressed in a 1.27-cm diameter die with a laboratory press[3]. The pellet-die was placed in the bottom of a vessel containing 300 ml of medium thermostated at 37°. A flat-faced paddle and constant-speed stirrer[4] agitated the medium at the desired rate. Samples were periodically removed, extracted with ether, and assayed by HPLC.

HPLC—An HPLC method was developed for direct separation of cholesterol–oleic acid mixtures using a C_{18} column[5]. The compounds were detected at 205 nm[6] due to the weakly absorbing UV chromophores present. Quantitation was by peak height measurement. To obtain adequate retention of oleic acid, mobile phases previously reported for cholesterol, 100% acetonitrile (8) or 50:50 isopropyl alcohol–acetonitrile (9), were modified. Optimum separation was obtained with 3:97 methanol–acetonitrile at 1.5 ml/min. Oleic acid eluted as a doublet at 3.0 and 3.6 min followed by cholesterol at 9 min.

Samples of cholesterol–sodium oleate mixtures from equilibrium or solubilization rate experiments containing 5–50 mg of the components were weighed accurately in a screw-cap tube and 2 ml of 0.5 *M* citric acid was added. The resulting oily emulsion was then extracted with 10 ml of ether. The ether phase was appropriately diluted with acetonitrile, and this solution was analyzed by HPLC. Preliminary studies indicated that both components were quantitatively extracted by this procedure. Standards containing both compounds were prepared in ether, diluted with acetonitrile, and injected periodically for peak height standardization.

Microscopy—Samples of the phases in the equilibrium study and from the pellet surface during solubilization were examined by polarizing light microscopy. Based on the classifications of Rosevear (10), the liquid crystalline phase appears to be of the lamellar (or neat soap) type.

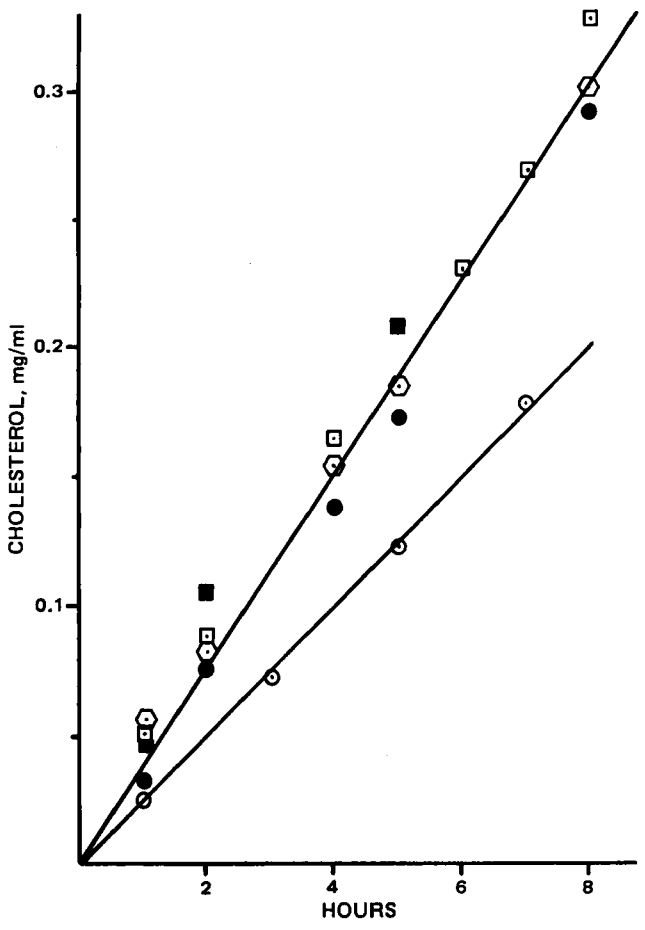

Figure 2—*Cholesterol solubilization in sodium oleate solutions at 37°, 150 rpm. The line for 2.5–10% data has slope = 25 × 10^{-4} mg cm^{-2} sec^{-1} and zero intercept. The slope for the 1% oleate data is 16 × 10^{-4} mg cm^{-2} sec^{-1}. Percent oleate key: (⊙) 1.0%, (●) 2.5%, (⊡) 5.0%, (■) 7.5%, and (⊛) 10%.*

Materials—Cholesterol USP[7], oleic acid[8], and lauric acid[7] were obtained commercially. Chromatographic solvents were HPLC grade and the source did not affect the assay.

Cholesterol was recrystallized from 10% aqueous acetone which gave the monohydrate. Problems in removal of ethanol were encountered after recrystallization from 95% ethanol. The vacuum-drying conditions needed to remove residual ethanol lowered the water content to ~1% (Karl Fischer titration) and presumably formed anhydrous cholesterol, which did not readily revert to the monohydrate in the presence of water (11). Using the acetone–water method, the solvent evaporated (air-drying for 0.5–1 hr at ambient temperature and humidity), and the water content was near the theoretical value for the monohydrate (4.4% water).

Sodium oleate and sodium laurate were prepared in ethanol from the respective acids by neutralization with 25% sodium methoxide in methanol[9]. The end point was confirmed with bromothymol blue and the solvents were removed using a rotary evaporator. Purity of the sodium oleate was checked by HPLC comparison with oleic acid.

RESULTS AND DISCUSSION

Phase Equilibria—Figure 1 is a photomicrograph of the liquid crystalline phase forming on the surface of crystalline cholesterol monohydrate. The mesophase forms rapidly upon contact with sodium oleate solutions, and smaller crystals are solubilized on the microscope slide within a few minutes. In a separate experiment, a coarse suspension of 300 mg of cholesterol with 300 mg/10 ml sodium oleate solution was solubilized within 24 hr at room temperature with occasional shaking.

These observations are consistent with previous work on the interaction between fatty acid salt solutions and cholesterol (6). The minimum concentration at which the mesophase was observed decreased as fatty acid chain length increased from C_9 to C_{18}. For sodium oleate, the mesophase formed at concentrations as low as 3×10^{-4} *M*; for sodium nonanoate, it was present only at concentrations >0.14 *M*. This stronger interaction of cholesterol with longer chain-length compounds was not observed in solubility studies in homologous normal alkanols or fatty acid ethyl esters (3). For these solvents, cholesterol solubility was maximum at a chain length of ~6–7 carbon atoms. However, crystalline solvates of cholesterol were observed in some of the solvents which influenced the solubility trends. In addition, the energetic and structural requirements for mesophase formation in water are likely to be quite different than those for solvation and interaction in the nonpolar solvents.

Preliminary phase equilibrium studies were conducted in the dilute solution region for cholesterol–sodium oleate–water, as shown in Table I. Additional data will be necessary before the phase diagram can be constructed. The system viscosity increased at higher component concentrations making equilibration and phase separation more difficult. The phases present at equilibrium and their composition are dependent on the amounts of cholesterol and oleate in the original mixtures. When the cholesterol–oleate ratio was <1, the cholesterol was completely solubilized, and the system consisted of isotropic micellar solution and liquid crystalline phase, which were readily separated by centrifugation. Vesicles were observed in samples with low lipid concentrations and ratios approaching 1:1. The existence of cholesterol–oleate vesicles was reported by Hargreaves and Deamer (12) who investigated the potential use of these systems for drug delivery and as model biomembranes. In Table I, the liquid crystalline phase and vesicles are considered as a single phase, since the two cannot be readily differentiated microscopically. The lipid concentrations in the isotropic solution reflect the solubilization of cholesterol in sodium oleate micelles but are generally lower than the initial amount due to presence of the mesophase or undissolved cholesterol.

As shown in Table I, the relative amounts of cholesterol–oleate in the liquid crystalline phase ranged from 0.68 to 1.71. The lower ratios in the mesophase occurred with low initial concentration of lipids; the higher ratios were observed when the isotropic phase was absent and the mesophase was saturated with cholesterol. The structure of the mesophase is likely to be a bilayer of alternating cholesterol and oleate molecules. Thus, it is not solubilization in the micellar sense in which a number of surfactant molecules are present for each substrate molecule. Small angle X-ray diffraction data would be necessary to determine the structure of the mesophase.

Solubilization Rate—Cholesterol solubilization rate plots from a static compressed disk of cholesterol monohydrate are shown in Fig. 2. After a short time, the medium became a cloudy-milky fluid dispersion of liquid crystalline phase in the isotropic micellar solution. The amount of cholesterol solubilized, and thus the approximate amount of oleate precipitated as mesophase, was much less than the original oleate concentrations in all cases. A single line was drawn through the data at 2.5–10% sodium oleate. The solubilization rate in this range was essentially independent of oleate concentration. The slower rate with 1% oleate may be indicative of a change in the rate-limiting step for the solubilization process. Microscopic observations confirm that the mesophase forms at oleate concentrations <1% (6, 7).

Least-squares analysis of individual runs showed a slight positive intercept which increased with concentration, although the terminal slopes were constant within experimental error. The apparently higher initial rates may be due to the initial dissolution of cholesterol prior to establishment of the liquid crystalline surface layer. Early in the experiment, the mesophase would be expected to dissolve in the bulk medium until its saturation level was reached. Despite the high oleate–cholesterol ratio in the bulk medium, saturation apparently occurred early in the experiments, judging from the turbidity.

Addition of electrolytes is known to increase the cholesterol dissolution rate in simulated bile solutions (13). In these systems, the salt decreases the interfacial resistance to dissolution, a dominant factor in the dissolution rate process. In sodium oleate solutions, sodium chloride decreased the solubilization rate of cholesterol, as shown in Table II. The origin of this effect may be related to the viscosity, the nature of the micellar solution, or that of the mesophase. The viscosity of sodium oleate solutions with added salt was noticeably higher at 5 and 10% oleate, although quantitative data were not obtained. The higher viscosity would be expected to decrease the shear at the pellet surface.

Since the solubilization process is physically different from dissolution, limited data were obtained on the effect of stirring rate (Table III). The ratio of the rates at the two rotational speeds was similar to the square root dependence (1.414) predicted by the Levich equation for a diffusion-controlled process (14). This result was surprising because cholesterol dissolution in bile salt or bile salt–lecithin solutions is relatively insensitive to stirring rate. In this case, interfacial resistance to micellar solubilization of cholesterol is a dominant characteristic (14, 15). The stirring rate dependence in the present experiments probably does not imply that the rate process is diffusion controlled. The presence of the liquid crystalline surface layer and the rate independence of oleate concentration also must be considered in the description of the solubilization process. Experiments using a rotating disk apparatus would be required

to quantitatively evaluate the relative importance of diffusional, interfacial, and surface shear processes in this system.

The solubilization rate of cholesterol monohydrate, prepared by recrystallization from 10% water–acetone, was not sensitive to the compression load used to make the pellet. At loads of 1364, 2045, and 3182 kg (3000, 4500, and 7000 lb, respectively) and oleate concentrations of 2.5, 5.0, and 10%, the rate was essentially unchanged. In preliminary studies, however, problems were encountered with reproducibility at the lower pressures; therefore, 3182 kg was used as a standard compression load for this investigation.

In Table IV, the solubilization rate in 5% sodium oleate is compared with 5% sodium laurate and 5% sodium cholate. The two fatty acid salts show similar solubilization rates. Previous work (6) found that the minimum concentration of sodium laurate which formed a mesophase with cholesterol was 0.007 *M*, approximately 20-fold higher than the minimum for sodium oleate. Thus, it appears that the concentration for mesophase formation and solubilization rate cannot be directly correlated. The solubilization rates are clearly much faster than dissolution in micellar sodium cholate solutions. The sodium cholate rate is somewhat slower than that reported by Feld and Higuchi, 0.73×10^{-4} mg cm^{-2} sec^{-1}, (15) in 5% sodium cholate with 0.1 *M* phosphate buffer, pH 8.0. Buffer effects (13), different assay methods, apparatus, and method of cholesterol monohydrate preparation are potential explanations for the difference in rate. The last factor was recently found to affect strongly the dissolution rate (15). Due to these differences, further comparisons with literature data are not likely to be meaningful.

Solubilization Mechanism—The solubilization mechanism of cholesterol in fatty acid salt solutions is considerably different from dissolution in bile salt solutions. Mesophase formation generally does not occur in dilute bile salt or bile salt–lecithin solutions. Formation of a liquid crystalline phase has been observed only with ursodeoxycholate and then only after several hours of contact with cholesterol (16, 17). In dissolution studies with this bile salt, cholesterol release did not level off at the apparent micellar solubility but continued to higher values with formation of the mesophase. An equilibrium model was suggested whereby cholesterol could be dissolved in the micellar solution or directly incorporated into the mesophase (17). After several days when the micelles were saturated with cholesterol, the primary mass transport process was thought to proceed by liquid crystal solubilization. For sodium oleate, the mesophase forms immediately (Fig. 1), and the system has a lower capacity for micellar solubilization of cholesterol.

A hypothetical model for cholesterol solubilization in fatty acid salt solutions is shown in Fig. 3. Rapid formation of a multilamellar region of liquid crystalline material on the crystal surface was observed microscopically. This surface layer grows by diffusion of cholesterol away from the crystal and diffusion of oleate and water from the bulk solution. Figure 1 shows that buildup of a significant surface layer under static conditions does not strongly inhibit solubilization of additional cholesterol from the crystal. Diffusion within the mesophase layer must be rapid in both the inner (cholesterol-rich) and outer (oleate-rich) regions. Scrapings from the pellet surface during the rate studies confirmed the presence of mesophase, even at 150 rpm. The primary mode of mass transfer of cholesterol to the bulk medium is thought to be by dispersion or shearing of liquid crystalline fragments from the surface, as shown in Fig. 3. These so-called myelin figures can be composed entirely of mesophase (spherulites) or have an aqueous core (vesicles or tubules). After dispersal into the bulk solution, the fragments may either dissolve into the micellar solution (which would occur early in the experiment) or remain in the liquid crystalline state.

The solubilization mechanism in this system can be considered as two major steps: (*a*) diffusional processes involved with formation and growth of the liquid crystalline surface layer and (*b*) physical dispersion or shearing of liquid crystalline fragments into the bulk medium. The present data support the proposal that the second step is rate limiting in the 2.5–10% oleate solutions. Under these conditions, the rate of surface mesophase formation is assumed to be faster than its removal by stirring. Reasons for this proposal are:

1. The observed relationship between stirring and solubilization rates (Table III) is probably due to the effect of higher shear on the surface layer, increasing the dispersal rate of the mesophase into the bulk solution. The alternate explanation of diffusional control does not seem to be consistent with the physical system under study.

2. If the first step of the solubilization mechanism were rate limiting, a kinetic dependence on oleate concentration but independence on stirring rate would be expected. Both these conditions are in disagreement with the data. Under static conditions on the microscope, however, the rate of solubilization was clearly increased with increasing oleate concentrations. Except for viscosity effects, the rate of a hydrodynamically controlled process (step *b*) should not be dependent on oleate concentration. This assumes that the process in the surface layer occurs much faster than the mass transport of fragments away from the surface. The slower solubilization rate with 1% oleate may be indicative of a change from hydrodynamic to surface control. As the oleate concentration is reduced, the rate of step *a* should decrease until this process is similar in rate to step *b*. At this point, a crossover between the two processes would have to occur.

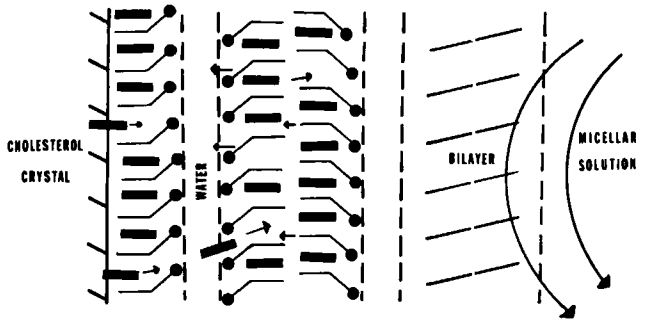

Figure 3—*Schematic diagram for the liquid crystal solubilization of cholesterol in sodium oleate solutions (bars represent cholesterol, angles represent oleate). Small arrows represent diffusion of the species within the mesophase layer. Large arrows indicate dispersion of surface material into the medium.*

3. The effect of salt (Table II) may be primarily due to the higher viscosity of the medium rather than to significant changes in the solution or the mesophase. Increased viscosity would reduce the shear on the rate-controlling surface layer.

4. Finally, the similarity in rates with oleate and laurate, but not cholate (Table IV), is consistent with a hydrodynamically controlled process. Laurate does not interact with cholesterol as strongly as oleate (6). Despite this difference in affinity, the solubilization rates were almost equal. This suggests a common rate-controlling step for both salts, which is independent of mesophase formation on the cholesterol surface.

Unloading and Postcompression Viscoelastic Stress *versus* Strain Behavior of Pharmaceutical Solids

DOUGLAS W. DANIELSON *, WILLIAM T. MOREHEAD, and EDWARD G. RIPPIE ˣ

Received March 1, 1982, from the *Department of Pharmaceutics, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication June 11, 1982. *Present address: Merrell National Laboratories, Cincinnati, OH 45215.

Abstract □ The viscoelastic properties of several compacts composed of drugs and direct compression excipients have been measured during the stress unloading and postcompression phases of the tablet compression process. Measurements of applied strains and the resultant stresses, generated in the tablet structure under compaction, were made using a rotary press. The press was instrumented to measure punch and die wall stresses at normal operating speeds. The three-dimensional viscoelastic theory, used in data analysis, provides for the separate characterization of tablet behavior into its dilation and distortion components. The tablets investigated were found to behave elastically in dilation, but to have both viscous and elastic contributions to their stress/strain relaxation in distortion. This latter behavior could be modeled well as a Kelvin solid. Data derived from an elastic-in-dilation, Kelvin-in-distortion analysis of tablets, compressed at similar machine speeds but at various peak pressures, were found to vary widely depending on tablet composition. Dependence of the viscous and elastic parameters on compression conditions was found to be predictive of conditions under which capping or lamination of the compact would occur.

Keyphrases □ Viscoelastic behavior—of compacts of drugs and direct compression excipients □ Tablet formulation—viscoelastic behavior of compacts during stress unloading and postcompression, parameters predictive of capping and lamination □ Compression—viscoelastic behavior of tablets, conditions predictive of capping and lamination

The physical properties of pharmaceutical tablets are of practical interest not only because they dictate manufacturing methodology and determine resistance to physical damage in handling, but also because they can influence drug bioavailability through the processes of tablet disintegration and dissolution. These properties or physical parameters can be categorized roughly in terms of those which may be observed under either changing or static conditions, or both. Viscoelastic properties of solids can be elucidated fully only if measurements of the dynamic relationships between stress and strain are made.

BACKGROUND

Effects of the time-dependent viscoelastic behavior of compressed tablets have been observed under a variety of transient conditions (1–6) and are distinguishable from the hysteretic effects, due to plastic failure, observed in radial *versus* axial pressure cycles measured under quasistatic or equilibrium conditions (3, 7, 8).

The successful formation of a pharmaceutical tablet by the compression of solid particulate matter depends on interparticulate bonding across particle–particle interfaces. The areas of virtual contact, necessary for bonding, are both formed and destroyed during the compression and decompression phases, and possibly also during ejection from the die. The net area of such interparticulate contacts, during and after compression, is expected to depend on the time-dependent flow of material which occurs in conjunction with instantaneously responding elastic deformations. Coupling of these processes results in the viscoelastic behavior observed during the compression of tablets at normal production speeds and, often, at slower speeds. The viscoelastic parameters of tablets and their components, therefore, are expected to be indicative of the relative sensitivity of tablet formation to the rates of compression and decompression, and the rate and nature of ejection from the die. More fundamentally, these parameters provide for insight into the kinetically controlled formation and destruction of interparticulate bonds and the resultant changes in internal structure which occur during and after these periods.

THEORETICAL

The temporal relationships between stress and strain which are exhibited by many materials can be described and analyzed in terms of viscoelastic theory and its related mathematical models. The elements of such models consist of springs, representing elastic behavior, and dashpots, corresponding to viscous flow characteristics.

The simplest application of this theory is to fully dense materials, either fluids or solids, in which voids do not occur. However, the presence of crystal dislocations, grain boundaries, or other structural irregularities in such solids can have a significant effect on their mechanical properties. Provided the test process does not in itself change these material properties, the viscoelastic constants determined by a given test procedure will be independent of the test and are true material constants. In applications such as powder metallurgy or pharmaceutical tablets, however, the structure under study is not fully dense. In these cases, the nature of the pores, crevices, or other voids is a significant part of the structure and is reflected in the measured viscoelastic parameters. Thus, these parameters are a function of the architecture of the tablet as well as the characteristics of the units of which it is constructed. Further, both the nature of the architecture and the material comprising the units can be expected to depend on the strain *versus* time profile of the compaction process; *i.e.*, the compression stress *versus* strain event as a function of time, together with the material constants of the tablet components (which are themselves likely to be dependent on the compression event), determine the viscoelastic parameters of the tablet proper. In the remainder of this paper when material behavior is discussed, the material referred to is the compact and not individual particles of its component substance(s).

The theory of linear three-dimensional viscoelasticity (9, 10) permits the dynamics of tablet compression to be mathematically separated into two components: isostatic contraction/dilation and distortion at constant volume. The former process occurs because the volume occupied by the tableted material is substantially reduced during compression and then increases slightly due to rebound. Because the tablet is confined radially by the die, the majority of this volume change occurs in the axial direction causing a change in the tablet height–diameter ratio, resulting in a distortion in shape.

Several three-dimensional viscoelastic models have been developed to describe the behavior of various materials in a rotary press and were tested against experimental stress/strain data collected during and after compression. Among those tested, four models were found to provide a good statistical fit to the data: Kelvin-in-dilation/Kelvin-in-distortion, elastic-in-dilation/three parameter solid-in-distortion, elastic-in-dilation/four parameter solid-in-distortion, and elastic-in-dilation/Kelvin-in-distortion. The latter was selected since it was the simplest model that fit the data.

Three sets of equations representing this model were developed (11). The first two sets describe the time dependence of axial stress (σ_{zz}) and radial stress (σ_{xx}) during the period of stress unloading:

$$\sigma_{zz} = A_1 - A_2[(r_1 + r_2)^2 - (r_3 \sin \omega t - x_2)^2]^{1/2} + \frac{A_3 \omega r_3 \cos \omega t (r_3 \sin \omega t - x_2)}{[(r_1 + r_2)^2 - (r_3 \sin \omega t - x_2)^2]^{1/2}} \quad \text{(Eq. 1)}$$

where the macroconstants are defined by:

$$A_1 = (2/3)[(q_0'' - q_0')\epsilon_{xx} + (2q_0' + q_0'')|z_0|/L] \quad \text{(Eq. 2)}$$

$$A_2 = (2/3)(2q_0' + q_0'')/L \quad \text{(Eq. 3)}$$

$$A_3 = (4/3)q_1'/L \quad \text{(Eq. 4)}$$

[a] Calculated from mean macroconstants derived from triplicate compressions. [b] Units are MPa for q_0' and q_0'' and MPa sec for q_1' (±*SE*). [c] Macroconstants used in calculation of viscoelastic constants. [d] Weak friable tablets. [e] Frequent capping and lamination on ejection. [f] Occasional capping and lamination on ejection.

and:

$$\sigma_{xx} = B_1 - B_2[(r_1 + r_2)^2 - (r_3 \sin \omega t - x_2)^2]^{1/2} - \frac{B_3 \omega r_3 \cos \omega t (r_3 \sin \omega t - x_2)}{[(r_1 + r_2)^2 - (r_3 \sin \omega t - x_2)^2]^{1/2}} \quad \text{(Eq. 5)}$$

where the macroconstants are defined by:

$$B_1 = (1/3)[(2q_0'' + q_0')\epsilon_{xx} + 2(q_0'' - q_0')|z_0|/L] \quad \text{(Eq. 6)}$$

$$B_2 = (2/3)(q_0'' - q_0')/L \quad \text{(Eq. 7)}$$

$$B_3 = (2/3)q_1'/L \quad \text{(Eq. 8)}$$

In the above equations: q_0' and q_0'' are the elastic microconstants in distortion and dilation, respectively; q_1' is the viscous microconstant in distortion; ϵ_{xx} is the radial strain; z_0 is the vertical punch displacement at separation from the tablet; ω is the turret angular velocity; x_2 is the horizontal distance between the vertical center line of the upper punch and the center of vertical curvature of the punch head rim; r_1 and r_2 are the radii of the compression roller and punch head rim, respectively; r_3 is the radial distance between the turret and punch axes; and L is the tablet thickness.

Following compression and prior to tablet ejection, the radial stress can be expressed as:

$$\sigma_{xx} = [\sigma_{xx}(0) - C_1] \exp(-C_2 t) + C_1 \quad \text{(Eq. 9)}$$

where:

$$C_1 = \frac{3q_0' q_0'' \epsilon_{xx}(0)}{2q_0' + q_0''} \quad \text{(Eq. 10)}$$

$$C_2 = (2q_0' + q_0'')/2q_1' \quad \text{(Eq. 11)}$$

and the microconstants are as defined above.

EXPERIMENTAL

Materials—Twelve substances, including drugs and popular organic excipients, were chosen to represent a broad spectrum of physical properties. Materials were selected which comprise a substantial volume fraction of tablets in which they appear, and whose tableting characteristics are generally well known. These range from brittle to plastic, from highly to poorly cohesive, and from highly crystalline to mixed partially amorphous monomers and polymers derived from natural sources.

Substances were dried in an oven for 14 hr at 70° and stored over anhydrous calcium sulfate prior to compression. Except for drying, all materials were used as received and were not mixed with a lubricant or other substance prior to compression. Because of a tendency to cake, dextrate[1] was not dried by heating. Other excipients included starch USP[2], sucrose[3], dextrose[4], mannitol[5], and sulfanilamide[6], sulfamerazine[7], salicylic acid[8], salicylamide[5], acetylsalicylic acid[4], acetaminophen[5], and phenacetin[9].

Methods—Details of the experimental setup and methodology have been reported previously (11) and are outlined here. Tablets were compressed on a rotary tablet machine[10] using 9.525-mm flat-faced punches. Punch and die wall stresses were measured using resistance strain gauges during and after compression. Signals displayed on an oscilloscope were photographed for later analysis. Because of the difficulty in mounting displacement transducers, punch displacements were calculated as a function of time from the known mechanical geometry of the machine. All tablets were compressed in the same location in the instrumented die, at the same angular velocity ($\omega = 2.76$ rad/sec) of the die table, and at the same punch settings. The die wall was lubricated prior to each compression by swabbing with a 10% slurry of magnesium stearate in ethanol. Compressions were ~70–80 msec in duration from punch contact to punch separation; experiments were conducted in triplicate at each of three peak punch pressures (125, 208, and 333 MPa). Pressures were adjusted by control of the fill weight of individually weighed charges.

Numerical data obtained by electronic digitization of scope photographs were analyzed in terms of Eqs. 1–11 using statistical regression programs (12, 13). Viscoelastic constants corresponding to elastic behavior in dilation and to Kelvin solid behavior in distortion were calculated from the regression coefficients in Eqs. 1 and 5. These equations describe punch and die stresses during the punch stress unloading phase of compression where the elastic contributions predominate. The viscous constant relating to distortion was obtained from the postcompression data using the exponential regression coefficient of Eq. 9, expressed as Eq. 11, together with previously determined elastic constants. The rationale for this method of viscoelastic microconstant calculation from the regression macroconstants has been discussed previously (11).

RESULTS AND DISCUSSION

Within the categories of drugs and excipients studied here, there was a degree of correlation between overall viscoelastic behavior and chemical composition. With the exception of starch, the carbohydrates (mannitol, dextrose, sucrose, and dextrate) were found to produce hard, well-formed tablets. As shown in Table I, all three viscoelastic parameters were seen to increase with increasing peak pressure, except for dextrose. In this latter case, the distortional constants decreased slightly at a peak pressure of 333 MPa. These compacts showed increased internal structural strength with increased pressure, as reflected by their viscoelastic properties. This is characteristic of readily compressible materials, and these carbohydrates are useful as binders when included in tablet formulations. It should be noted that the higher pressures employed in these studies were somewhat above those normally used in production. They were chosen to reveal the pressure sensitivity of viscoelasticity and to include the range of slugging pressures.

Before discussing starch and the remaining materials, it is necessary to consider the meaning of negative elastic and viscous microconstants in relation to internal tablet structure. Positive or negative elasticity can be related to the behavior of a simple spring. Consider the elastic behavior of a tablet in response to the confinement imposed on it by the die and punches. This condition corresponds to that of a spring under compression. A normal spring, *i.e.*, one having a positive modulus, would exert a decreased force on the die and punches with a decrease in its degree of compression. Conversely, a spring having a negative modulus would exert an increased force with a decrease in compression. Tablets undergoing unloading, following the application of the peak pressure, are springing back toward their final dimensions. This entails both an expansion in volume and a distortion in shape, since the diameter is held constant by the die. If, in the generation of increased voids produced by this process, sufficient interparticulate bonds are broken, internally borne stresses residing in elastically deformed particles will be transferred to the die wall. This behavior corresponds to a negative elastic modulus and reflects a disruption of internal structure. These constants are not solely a reflection of the nature of the materials comprising the tablet, but are strongly influenced by the efficiency of survival of the bonded areas within the tablet during elastic recovery. These bonds, which are formed during compaction, are a consequence of molecular forces acting across interfaces in zones of true interparticulate contact. If sufficient plastic deformation occurs at the bonded areas (or elsewhere in the structure) so that the stresses developed by elastic recovery do not exceed bond strength, the bonds will survive. However, if the disruption is sufficient, the integrity of the tablet will be destroyed.

Further, consider the case of a plastic body subjected to a shear stress sufficient to produce flow. In materials possessing positive coefficients of viscosity, an increase in the flow rate implies an increase in the applied stress. In such a system, the greater the rate of shear imposed, the greater the thrust or drag produced by the flow. Again (as seen with negative elasticity) an increasing breakdown of internal structure with increasing shear rates may be indicated. It must be emphasized that the substances which comprise compacts exhibiting negative viscoelastic parameters do not in themselves have negative elastic or viscous properties. Instead, it is the destruction of bonds within the structure of the tablet during elastic recovery that leads to such behavior. The viscoelastic constants reported here must be considered to reflect the behavior of the compact itself and are not primary constants related to the individual fully dense components only. This conclusion is supported further by the observed dependence of the viscoelastic parameters on pressure. Tablet microstructure can be expected to depend on compaction forces, and changes in structure resulting from changes in the compression process will be manifested by changes in the parameters.

Starch, as shown in Table I, exhibited all negative microconstants at a peak compaction pressure of 333 MPa. This was the only material–pressure combination of those studied which showed this behavior; an intact tablet could not be made at this pressure. A crumbled tablet also resulted at 125 MPa peak pressure, on ejection. Only at the intermediate pressure were intact, although fragile, tablets obtained. Their weak character is reflected by the very low values of the microconstants.

The sulfas are brittle crystalline materials which are noted for tablet-making difficulties due to lamination and capping. Sulfanilamide produced intact tablets at all pressures while sulfamerazine capped and laminated at 125 MPa.

Fracture and splitting of the tablets made from the salicylates was a common occurrence. Despite lubrication of the die and punches, die wall and punch face adhesion could not be avoided totally. Acetaminophen and phenacetin also are known for the difficulties experienced in forming tablets from them. Their general behavior was similar to that of the salicylates, with frequent capping and lamination.

Although the 12 materials studied exhibited diverse viscoelastic behavior, as shown by the wide range in the numerical value of their microconstants, they may be separated into two distinct groups: those having negative distortional elastic moduli and those which do not. While all tablets in the former group did not laminate on ejection, they could be laminated easily with the fingernail. Moreover, all tablets which laminated showed negative q_0' values.

The group of materials exhibiting positive microconstants, over the range of pressures reported, could be divided further into two categories: those showing increased viscoelastic parameters with increased pressure and those with decreasing or relatively constant parameters at high pressures. Of the materials reported, only sulfanilamide fell in the latter category. These materials were compressed at peak pressures above 333 MPa to observe their tendency to laminate. Because of the danger to the instrumented die posed by these pressures (up to ~425 MPa), a standard die was used, and therefore, viscoelastic data are not available. A substantial fraction of the tablets in the second category capped and/or laminated, whereas this was a rare occurrence with the first four materials listed in Table I. The rate at which the compacts relax their stresses following compaction can be seen from Eq. 11 to be dependent not only on the viscous constant but also on the elastic constants. The latter constants serve to drive the plastic flow and also, in conjunction with the lateral strain, determine the residual die wall stress.

When tablets are ejected from the die, they are subjected to a transverse shearing stress at the point where they emerge from the die. This results from externally unsupported radial stresses in the portion of the tablet above the die face. The transverse shearing stress builds to a limit as progressively more of the tablet extends above the die and the tablet is ejected. Structural failure due to this stress, coupled with an

inadequate tablet shear strength, is thought to be the principal cause of capping and lamination, although there is some disagreement on this point (7). In support of this view (4), tablet formulations found to consistently laminate or cap were satisfactorily made with a press utilizing flexible die walls which retreat from the tablet prior to ejection.

In any case, it is apparent that the ejection of the tablet from the die subjects it to significant shear stresses. It is likely, therefore, that some internal strutural changes occur even in tablets that survive ejection and appear intact. For this reason, viscoelastic microconstants, when considered together with die wall stress, indicate the mechanical properties of the tablet within the die cavity and reflect the ability of the tablet to withstand ejection. In many, if not all, cases these parameters will not apply to the ejected tablet even though it has escaped gross fracture.

Because tablets were allowed to remain in the die for an extended period (several minutes in many cases) before being ejected manually by prying up the lower punch, the ejection event was atypical and did not reproduce production conditions. Studies utilizing an instrumented ejection cam to produce normal ejections are in progress to investigate this and other aspects of tablet viscoelasticity.

Inhibition of Oral Lead Absorption in Rats by Phosphate-Containing Products

BRUCE J. AUNGST and HO-LEUNG FUNG ˣ

Received January 15, 1982, from *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication April 30, 1982

Abstract □ Recent studies indicate that elevated blood lead levels in children are largely a result of exposure to this metal *via* the oral route. A logical approach to decrease or prevent lead intoxication would be to reduce its absorption as soon as lead ingestion is known or suspected. Presently, however, there are no readily available products recommended to accomplish this goal. It was found that a phosphate-buffered, saline laxative reduced lead absorption over 50% in rats administered a single oral lead acetate dose, presumably by promoting the formation of less soluble lead salts. A popular phosphate-containing carbonated beverage also decreased lead absorption ~30% after oral lead acetate or lead-based paint doses, possibly by decreasing solubility, dissolution rate and/or GI motility. It is possible that these household products, and those with similar ingredients, may be safely used to reduce lead absorption in humans.

Keyphrases □ Lead absorption—reduction *in vivo* in rats by administration of phosphate-containing products □ Phosphate—lowering of blood lead levels in rats after oral administration of lead acetate or lead-based paint.

Ingested lead is the major source of the body burden of lead for most people (1). Children are exposed to lead from household dust (2), paint (3), and hand-to-mouth activity (4). Because they absorb a greater percentage of ingested lead than do adults (5), children have a higher risk of lead intoxication. Children with pica may be prone to chronic and repeated lead intoxication (6). Therapeutic intervention is not initiated, however, until blood-lead concentrations become elevated or symptoms of lead toxicity appear. It is recognized that subtle effects of lead on behavior and intelligence may occur in children at levels of exposure which do not produce elevated blood-lead concentrations or symptoms of lead intoxication (7). Prevention of lead exposure is therefore extremely important. Reduction of environmental lead and maintenance of sufficient dietary mineral intake partially achieve this objective. Presently there are no methods recommended to prevent or reduce the absorption of ingested lead.

A logical biopharmaceutical approach to reduce the extent of intestinal lead absorption, and thereby lead intoxication, is to decrease its solubility and dissolution rate in the GI tract. For some compounds, the extent of oral absorption is directly related to the absorption rate (8), which in turn may be limited by the rate of dissolution of the solid compound in the gut fluids (9). Dissolution rate is proportional to solubility, among other factors (10). Since the solubility products of lead phosphate and hydroxide are very low (Ksp $Pb_3(PO_4)_2 = 8 \times 10^{-43}$, Ksp of $Pb(OH)_2 = 1.2 \times 10^{-15}$) (11), it is possible that products containing phosphate or hydroxide ions might significantly reduce the extent of lead absorption by promoting the formation of insoluble lead phosphate and hydroxide salts in the GI tract. Since several household products contain

inadequate tablet shear strength, is thought to be the principal cause of capping and lamination, although there is some disagreement on this point (7). In support of this view (4), tablet formulations found to consistently laminate or cap were satisfactorily made with a press utilizing flexible die walls which retreat from the tablet prior to ejection.

In any case, it is apparent that the ejection of the tablet from the die subjects it to significant shear stresses. It is likely, therefore, that some internal strutural changes occur even in tablets that survive ejection and appear intact. For this reason, viscoelastic microconstants, when considered together with die wall stress, indicate the mechanical properties of the tablet within the die cavity and reflect the ability of the tablet to withstand ejection. In many, if not all, cases these parameters will not apply to the ejected tablet even though it has escaped gross fracture.

Because tablets were allowed to remain in the die for an extended period (several minutes in many cases) before being ejected manually by prying up the lower punch, the ejection event was atypical and did not reproduce production conditions. Studies utilizing an instrumented ejection cam to produce normal ejections are in progress to investigate this and other aspects of tablet viscoelasticity.

Inhibition of Oral Lead Absorption in Rats by Phosphate-Containing Products

BRUCE J. AUNGST and HO-LEUNG FUNG ˣ

Received January 15, 1982, from *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication April 30, 1982

Abstract □ Recent studies indicate that elevated blood lead levels in children are largely a result of exposure to this metal *via* the oral route. A logical approach to decrease or prevent lead intoxication would be to reduce its absorption as soon as lead ingestion is known or suspected. Presently, however, there are no readily available products recommended to accomplish this goal. It was found that a phosphate-buffered, saline laxative reduced lead absorption over 50% in rats administered a single oral lead acetate dose, presumably by promoting the formation of less soluble lead salts. A popular phosphate-containing carbonated beverage also decreased lead absorption ~30% after oral lead acetate or lead-based paint doses, possibly by decreasing solubility, dissolution rate and/or GI motility. It is possible that these household products, and those with similar ingredients, may be safely used to reduce lead absorption in humans.

Keyphrases □ Lead absorption—reduction *in vivo* in rats by administration of phosphate-containing products □ Phosphate—lowering of blood lead levels in rats after oral administration of lead acetate or lead-based paint.

Ingested lead is the major source of the body burden of lead for most people (1). Children are exposed to lead from household dust (2), paint (3), and hand-to-mouth activity (4). Because they absorb a greater percentage of ingested lead than do adults (5), children have a higher risk of lead intoxication. Children with pica may be prone to chronic and repeated lead intoxication (6). Therapeutic intervention is not initiated, however, until blood-lead concentrations become elevated or symptoms of lead toxicity appear. It is recognized that subtle effects of lead on behavior and intelligence may occur in children at levels of exposure which do not produce elevated blood-lead concentrations or symptoms of lead intoxication (7). Prevention of lead exposure is therefore extremely important. Reduction of environmental lead and maintenance of sufficient dietary mineral intake partially achieve this objective. Presently there are no methods recommended to prevent or reduce the absorption of ingested lead.

A logical biopharmaceutical approach to reduce the extent of intestinal lead absorption, and thereby lead intoxication, is to decrease its solubility and dissolution rate in the GI tract. For some compounds, the extent of oral absorption is directly related to the absorption rate (8), which in turn may be limited by the rate of dissolution of the solid compound in the gut fluids (9). Dissolution rate is proportional to solubility, among other factors (10). Since the solubility products of lead phosphate and hydroxide are very low (Ksp $Pb_3(PO_4)_2 = 8 \times 10^{-43}$, Ksp of $Pb(OH)_2 = 1.2 \times 10^{-15}$) (11), it is possible that products containing phosphate or hydroxide ions might significantly reduce the extent of lead absorption by promoting the formation of insoluble lead phosphate and hydroxide salts in the GI tract. Since several household products contain

high contents of phosphate or hydroxide, the feasibility of lead absorption inhibition with these products was tested.

EXPERIMENTAL

Precipitation of Lead *In Vitro*—The effects of several household products on lead solubility were examined in preliminary *in vitro* experiments. The test products included a carbonated beverage[1], a phosphoric acid solution with the same phosphate content (0.56 *M*) and pH (2.4) as the carbonated beverage, a phosphate-buffered, saline laxative[2] diluted 10-fold and 250-fold, and an antacid containing magnesium and aluminum hydroxides[3]. The carbonated beverage was stored in an open container prior to use to allow liberation of carbon dioxide. In a glass tube, 0.25 ml of a lead acetate solution (10 mg of Pb/ml, pH 4.5) was mixed with 1 ml of the test product. The pH and the amount of lead remaining in the 1000×*g* supernatant solution were measured. Lead analyses were performed using atomic absorption spectrophotometry[4].

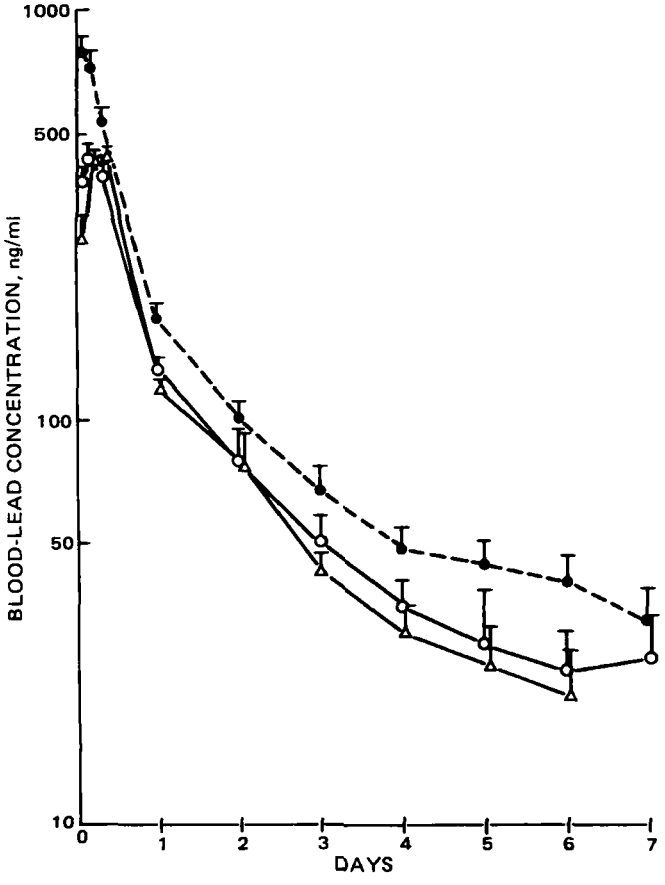

Figure 1—*Effects of a carbonated beverage (○) and a phosphoric acid solution (△) on absorption of lead after oral administration of a lead acetate solution, compared with control (●). Values represent mean* + SE.

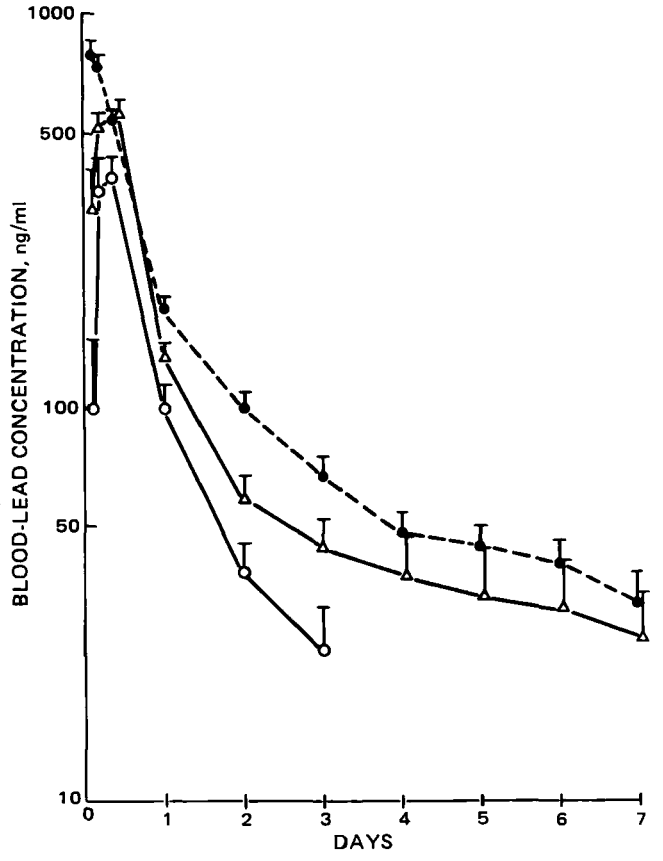

Figure 2—*Blood-lead concentrations in rats administered a 10 mg/kg oral lead dose followed by water (●), or a phosphate-buffered saline laxative diluted 1:10 (○) or 1:250 (△). Values are mean* + SE.

***In Vivo* Studies—**After an overnight fast, male Sprague-Dawley rats[5] (200–300 g) were administered, by gastric intubation, a single lead dose followed immediately by 1 ml of a test product or control treatment. Lead was administered as lead acetate (10 mg of Pb/ml, pH 4.5) or as powdered lead-based paint[6] suspended in 2% methylcellulose. The doses were 10 mg of Pb/kg, when administering lead acetate, and 50 mg of Pb/kg, when administering the lead-based paint. The amounts of lead and test product administered were similar to those used in the *in vitro* experiment. The control groups were administered 1 ml of distilled water following the lead dose. There were 5–9 rats in each group. Blood samples were collected in heparinized glass tubes by tail clipping and milking at 2, 4, and 8 hr, and every day for 7 days postdose, and were frozen immediately. Whole blood lead concentrations were determined using a previously described atomic absorption spectrophotometric method (12). During the course of the experiments the animals were housed in stainless steel cages with wire mesh floors.

Data Analysis—The area under the blood-lead concentration *versus* time curve (AUC) from 0 to 7 days was calculated for each rat. This parameter has been shown to be a good indicator of the extent of lead absorption (13). Systemic lead clearance was assumed to be unaffected by these oral treatments. Differences between any two groups were tested for significance using the Student's *t* test. All data are expressed as mean ± *SE*.

RESULTS AND DISCUSSION

Precipitation of Lead *In Vitro*—The effects of each test product on the solubility of a lead solution typical of a lead dose are shown in Table I. All test products precipitated lead from the solution, with greater precipitation at higher phosphate–lead ratios, as expected. At equal

phosphate content, the carbonated beverage was not as effective as phosphoric acid in precipitating lead. The presence of other ingredients in the carbonated beverage might have altered the solubility product of lead phosphate.

Effects on Oral Lead Absorption—Decreased lead solubility *in vitro* was associated with an apparently decreased rate of *in vivo* absorption. The blood-lead concentration *versus* time profiles for those groups administered lead acetate and control, carbonated beverage, or phosphoric acid treatments are shown in Fig. 1. Similar results were observed following the administration of the phosphate laxative (Fig. 2). Although absorption rates were not calculated, the time to reach the maximum blood-lead concentration (C_{max}) was longer in each of these treatment groups than in the control group. The majority of rats administered phosphate, in either the carbonated beverage, phosphoric acid, or laxative, reached C_{max} at either 4 or 8 hr; whereas in the control group five rats reached C_{max} at 2 hr, four rats at 4 hr, and none at 8 hr. In addition to delaying absorption, each of these treatments resulted in a lower value of C_{max}, as compared with the control (Table II). The AUC, a direct index of the bioavailability of an oral lead dose, was significantly reduced when either the carbonated beverage, phosphoric acid solution, or laxative diluted 10-fold was administered after lead ingestion. The 250-fold diluted laxative also appeared to decrease the AUC, but not significantly.

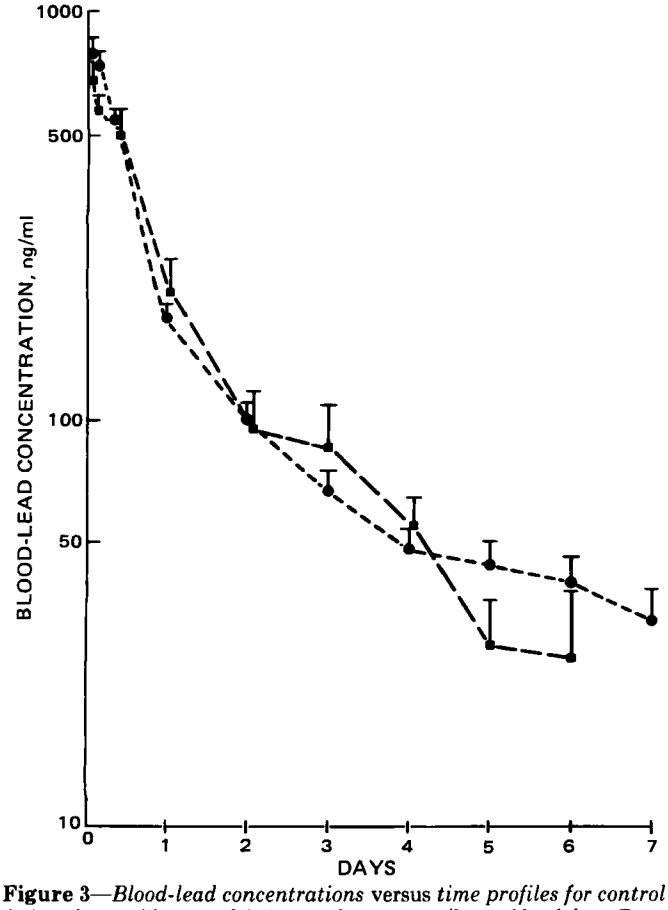

Figure 3—*Blood-lead concentrations* versus *time profiles for control (●) and antacid-treated (■) rats after a 10 mg/kg oral lead dose. Data represent mean* + SE.

Administration of the antacid after the lead dose had no apparent effect on either the blood-lead concentration *versus* time profile (Fig. 3), C_{max}, or AUC (Table II). Although the antacid caused significant precipitation of lead *in vitro*, it was ineffective in inhibiting *in vivo* lead absorption. The reasons for this lack of effect are unclear at present[7].

The effect of the carbonated beverage on lead absorption from a lead-based paint was also examined. As shown in Fig. 4, blood-lead concentrations were reduced by treatment with the carbonated beverage. The carbonated beverage again apparently decreased the rate of lead absorption, as indicated in the delay in the time C_{max} was observed (8 hr). The value of C_{max} was reduced as well (Table II). The AUC was significantly less than that observed in control rats, which were administered water after the paint dose.

The efficacies of the various treatments in reducing lead absorption were not predictable based on the amount of phosphate administered, and other effects of these treatments must be considered. Changes in gastric emptying rate, GI motility, solid particle size, and volume of fluid

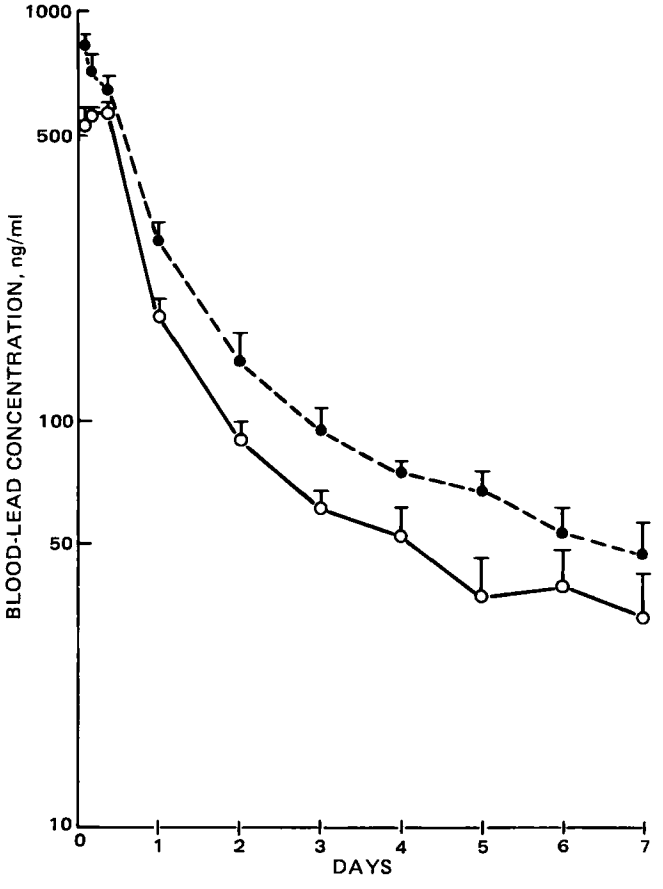

Figure 4—*Blood-level concentrations (mean* + SE*) in rats administered 50 mg of Pb/kg as a lead-based paint. Rats were also administered water (●) or a carbonated beverage (○).*

[7] In a follow-up experiment, stomach acidity was measured in three rats 20 min after dosing with the lead solution and antacid. The stomach pH in these animals was elevated to 4.5, 6.0, and 7.0, respectively, compared with control values of 2.5–3.0 in animals not treated with antacid. It appears possible that the pH effect on lead solubility might have been compensated by other effects of the antacid, *e.g.*, gastric emptying and GI motility, on lead absorption.

in the gut might also have been important. Houston and Levy reported that by inhibiting gastric emptying and GI motility, the same carbonated beverage used in this study altered the absorption rates of riboflavin and salicylamide (14). These effects were due to the phosphoric acid and carbohydrate in the carbonated beverage. In another study (15) the authors showed that propantheline bromide, an inhibitor of gastric emptying and GI motility, decreased the rate and extent of lead absorption by ~50%, suggesting that lead absorption is modified by the degree of agitation of the gut contents, among other factors. The phosphate-buffered, saline laxative functions as such by retaining water in the gut, and indirectly increases GI motility (16). Both of these actions could have counteracted the effect of decreased solubility on lead absorption.

Although abolition of lead absorption was not achieved by these products, the inhibitory effects are comparable to those shown for excess calcium and iron; administration of lead with 250-fold and 1000-fold molar excesses of calcium decreased lead absorption 46 and 43%, respectively, in rats (17, 18). Iron, at amounts 100-fold and 1000-fold greater than lead, decreased lead absorption in rats 20 and 80%, respectively (19).

Since the consequences of lead intoxication are severe (20), especially in children, prevention of undue lead exposure is very important. The household products identified here have been shown to significantly reduce lead absorption in rats when administered acutely. These agents might, therefore, also be useful in decreasing lead exposure after lead ingestion in humans. Their relatively nontoxic nature and easy accessibility make them attractive candidates for such use, particularly for children with a history of pica. Of course, the potential for use of these products is suggested only as an adjunct or supportive measure, and is not intended to replace therapeutic intervention for relief of the symptoms of lead toxicity.

Zn(II)–Theophylline–Ethylenediamine: Structure and pH Stability

MARK J. GARDNER, FRANCIS X. SMITH, and ELI SHEFTER ˣ

Received November 27, 1981, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication February 19, 1982.

Abstract □ A zinc-containing salt of theophylline, Zn(II)-aminophylline, was synthesized and its structure determined by X-ray diffraction techniques. The zinc ion is coordinated to two theophylline anions and a molecule of ethylenediamine in a tetrahedral arrangement. The solubility of the compound in water at 30° (0.047 mg/ml) is 180-fold lower than that of theophylline (8.40 mg/ml). The complex is relatively stable in the alkaline pH range, but it hydrolyzes, releasing theophylline in acidic environments. The rate of theophylline release is pH dependent. These properties are useful in formulating chewable tablets and liquid suspension dosage forms that overcome the characteristic bitter taste of theophylline, yet provide for efficacious treatment of diseases involving the respiratory tract.

Keyphrases □ Zn(II)–Aminophylline—structure determination by X-ray diffraction, release rate of theophylline, potential for use in oral preparation □ X-ray diffraction—Zn(II)–aminophylline, release rate of theophylline, potential for use in oral preparations □ Theophylline release rate—Zn(II)–aminophylline complex, X-ray diffraction, potential for use in oral preparations

Theophylline, a naturally occurring xanthine alkaloid derivative, possesses potent bronchodilating properties. Consequently, for nearly half a century both it and its ethylenediamine salt, aminophylline, have been used extensively in the treatment of diseases involving the respiratory tract (1). In particular, they have been shown to be efficacious in the treatment of asthma (2), exercise-induced bronchospasm (3), Cheyne-Stokes respiration (4), and chronic bronchitis/emphysema (5).

Although the pharmacologic properties of this drug are beneficial for such disorders, some of its physicochemical properties hinder totally effective therapy. First, the

aqueous solubilities of theophylline and aminophylline at 25° are 8.33 and 200.00 mg/ml, respectively (6). Such solubilities lead to considerable dissolution of the compounds in human saliva. This coupled with the fact that xanthine derivatives impart a characteristic bitter taste (7), leads to palatability problems. Of special concern are chewable tablets and liquid preparations. Attempts to mask this characteristic bitter taste in the latter dosage form have not been highly successful (8), and this has resulted in noncompliance problems (8, 9). Failure to take this drug as prescribed could be exacerbated further by the characteristics of the population most likely to be medicated with these oral dosage forms. In particular, Blackwell (9) has reported that noncompliance occurs most often in the extreme age groups: the pediatric and geriatric patient populations.

Second, once ingested as a conventional tablet dosage form, theophylline is rapidly absorbed from the GI tract. This can result in a spiking effect, where theophylline serum concentrations rise very quickly. It is widely accepted that serum concentrations of theophylline should be maintained within the range of 10–20 μg/ml to facilitate effective therapy and avoid side effects (10). Such rapid

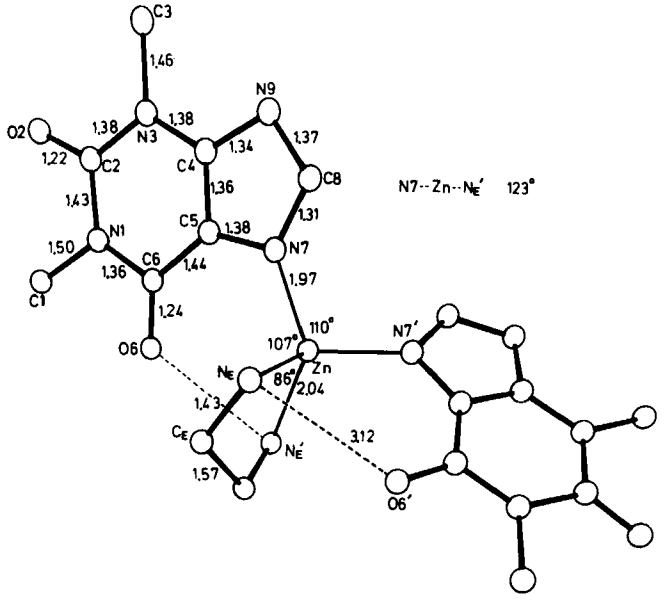

Figure 1—*Molecular structure of Zn(II)–aminophylline as determined by single-crystal X-ray diffractometry. Relevant bond angles and lengths are indicated.*

Table II—Intermolecular Contacts

Atom	Atom	Symmetry Operation Applied to Coordinates of Second Atom	Distance
N(E)	O(2)	1 + x, 1 − y, 0.5 + z	3.00(2)Å
N(E)	O(6)	x, y, z	3.12(2)Å
N(E)	N(7)	−x, y, 0.5 − z	3.23(2)Å
N(E)	N(9)	0.5 + x, y − 0.5, z	3.27(2)Å
C(8)	O(2)	0.5 + x, 1.5 − y, 0.5 + z	3.32(2)Å

absorption of theophylline can lead to serum concentrations that exceed 20 μg/ml, resulting in toxic side effects.

In an effort to overcome some of the problems associated with the use of theophylline, a zinc–aminophylline complex has been prepared. The preparation, molecular structure and physicochemical properties of this salt are discussed.

EXPERIMENTAL

Preparation—Fifty grams of anhydrous theophylline[1] was dissolved in 250 ml of an ethylenediamine solution (4.2% by volume) and subsequently diluted to 2.5 liters. It is important to maintain the pH of the solution between 8.0–9.0 to maximize the yield; it should be adjusted by the addition of ethylenediamine.

After warming the solution to approximately 60°, 250 ml of a 10% aqueous solution of $ZnSO_4 \cdot 7H_2O$[2] was added. The crystals of the zinc–aminophylline complex that formed were filtered and washed with cold water.

The initial precipitate that was formed in the reaction vessel had a colloidal appearance, but slowly transformed into octahedral prisms. The transformation could be accelerated by heat.

Recently, Zitzman *et al.* (11) used a similar procedure to prepare zinc(II) complexes of theophylline with ammonia and methylamine.

Crystal Structure Analysis—The isolated crystals were subjected to X-ray diffraction analysis to determine their molecular structure. They were found to be monoclinic, belonging to space group C 2/c based on systematic absences observed in the diffraction pattern of single-crystal crystals. The measured cell dimensions for these crystals are a = 11.222(4), b = 10.550(3), c = 19.496(10) Å, and β = 122.66(3) Å.

Intensity data were measured by the stationary counter-stationary crystal technique using balanced filters for the CuK radiation used on a diffractometer[3]. In the range of data collection ($20 \leq 110°$) 1154 reflections of the 1303 unique data had peak intensities significantly greater than background. An absorption correction, based on the anisotropy of transmission of the X-rays as a function of the diffractometer angle ϕ, was applied to the data as well as the usual Lorentz-polarization correction.

A trial structure was obtained by direct methods using the program MULTAN (12). The structure was refined by the Fourier and least-squares methods. The positions of the hydrogens could not be accurately assessed from difference electron density maps and were excluded from the refinement. The final R value (usual crystallographic reliability factor) was 0.11 for the observed data. The final positional parameters for the molecule are listed in Table I.

Solubility—The apparent aqueous solubilities of the complex and theophylline were determined at 30°. An excess quantity of material was added to a flask containing deionized water. The flasks were then placed in a water bath (30°) and allowed to equilibrate with agitation. Samples were withdrawn through a 1-μm millipore filter[4] and subsequently assayed for theophylline by a high-performance liquid chromatographic technique (13).

Hydrolysis of Complex—The hydrolysis of the complex was evaluated by placing 300 mg into 200 ml of a buffered solution (0.1 *N* HCl, pH 0.96; 0.1 *N* NaOAc, pH 4.73; 0.1 *N* Na_3PO_4, pH 7.39). These solutions were agitated by means of a magnetic stirrer and their temperature maintained at 25°. Filtered samples were withdrawn at regular intervals and assayed for theophylline spectrophotometrically at 270 nm.

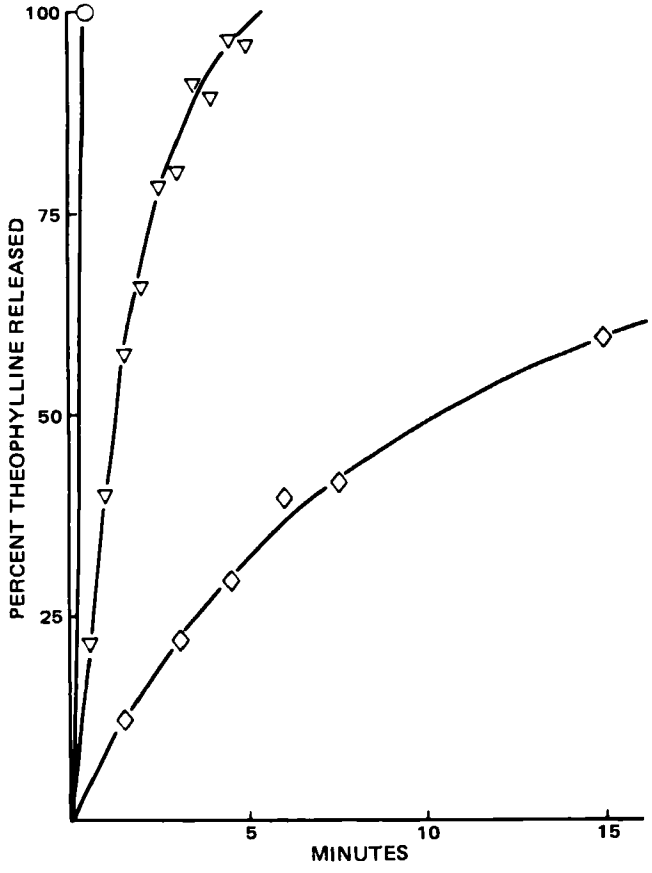

Figure 2—*Apparent hydrolysis of Zn(II)–aminophylline as a function of time at various pH values. Key: (○) 1; (▽) 4.8; (◇) 7.4.*

Though the same batch of material was used throughout these studies, its particle size distribution was not determined.

Two hundred milligrams of pure theophylline was placed in 200 ml of the appropriate buffer for each system. These solutions were sampled in tandem with the complex–buffer systems to serve as appropriate controls. The pH of the solution was monitored periodically throughout the course of these studies.

RESULTS AND DISCUSSION

Molecular Structure—The spatial disposition of theophylline and ethylenediamine around the zinc ion is shown in Fig. 1. The zinc atom is tetrahedrally coordinated. The distortion of the coordination angles from their ideal tetrahedral value of 109.5° is to a large measure due to steric factors and hydrogen-bond interactions.

Zinc is commonly found to be tetrahedrally coordinated in complexes with nitrogen ligands. The Zn—N distances in such complexes range from 1.99 to 2.10 Å (14–16). The more basic the nitrogen ligand the shorter the length; in this case the distances between theophylline and zinc are significantly shorter than those between ethylenediamine and zinc.

In general, the intramolecular bonding parameters found for the theophylline anion are quite similar to those reported for the acidic form of theophylline (17–19). There is one bond which appears to undergo a substantial change upon dissociation of the N(7) proton. The C(9)—N(9) is longer in the anionic form (1.37 Å) than the acidic form (range 1.31–1.33 Å).

The theophylline moiety exhibits a small but significant degree of distortion from planarity. This has previously been observed for theophylline (18, 19), and a wide variety of purine compounds. In most instances the purine ring is bent above the C(4)—C(5) bond. The two rings comprising the purine nucleus are only slightly tilted from planarity (0.7 Å) in this structure.

The ethylenediamine residue is in the *synclinal* conformation. The torsion angle about the ethylene bond is 53°.

Intermolecular Bonding—The ethylenediamine nitrogen atoms, N(E), are in close proximity to a number of atoms (Table II). Although the hydrogen atoms attached to N(E) were not clearly discernible from electron density maps, geometrical considerations of these short contacts suggest that they are hydrogen bond interactions. It appears that both hydrogen atoms on N(E) are involved in bifurcated hydrogen bonds: one hydrogen being shared by N(7) and O(2) and the other by N(9) and O(6). In addition to these intermolecular interactions, the hydrogen on C(8) appears to be involved in a weak hydrogen bond with O(2). This type of interaction has been observed in the other reported theophylline structures (17–19).

Apparent Hydrolysis—The hydrolysis of the Zn(II)–aminophylline complex was found to be strongly affected by changes in pH (Fig. 2). The lower the pH the faster the hydrolysis. Complete hydrolysis is accomplished in <1 min at pH 1. At pH 7.4, the apparent hydrolytic rate was markedly reduced. As noted in Fig. 2, after 15 min only 60% of the total theophylline content in the complex was released. Since this phenomenon is directly influenced by particle size, the hydrolytic rate could be slowed by increasing the particle size of the sample.

A separate solubility experiment was conducted at 30° to determine the apparent aqueous solubility of the complex in relation to that of theophylline. It was determined that the apparent aqueous solubility of the complex was 0.047 mg/ml as compared with 8.40 mg/ml for theophylline. This reflects a 180-fold difference. Apparent solubility studies for the complex alone are impossible to conduct at pH values lower than 8.2, due to hydrolysis.

Figure 2 gives some insight into the usefulness of this new salt in formulating liquids and chewable tablets. At salivary pH, 6.40–8.24 for children (20) and 5.8–7.1 for adults (21), these profiles predict relatively slow release of theophylline from the complex, and consequently a substantial reduction in the bitterness associated with theophylline therapy.

Once the complex is ingested, the pH of the gastric environment is sufficiently low to effect rapid hydrolysis. This has been borne out in some preliminary human and animal bioavailability studies[5]. The theophylline plasma concentration after oral administration of the complex was comparable to those following dosing with anhydrous theophylline. However, with the use of appropriate buffering excipients, formulations have been designed that can control the hydrolysis rate and, therefore, the release rate of theophylline from the complex in the GI tract.

High-Performance Liquid Chromatography of Cisplatin

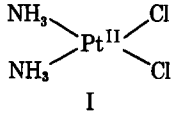
C. M. RILEY, L. A. STERNSON[x], and A. J. REPTA

Received October 13, 1981 from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication March 19, 1982.

Abstract □ The retention behavior of cisplatin on a variety of stationary phases has been investigated using aqueous mobile phases modified by the addition of various electrolytes and methanol. Cisplatin is poorly retained on reverse-phase or silica columns but satisfactorily retained on chemically bonded or solvent-generated anion exchangers. The retention of the neutral complex on positively charged stationary phases is explained in terms of ion–dipole interactions and rationalized by the application of solvophobic theory. The use of solvent-generated anion exchangers for the analysis of cisplatin offers significant advantages over the chemically bonded system in terms of peak shape, column efficiency, and stability. By the use of column switching and off-line atomic absorption, solvent-generated anion exchange high-performance liquid chromatography (HPLC) is applicable to the determination of cisplatin in urine.

Keyphrases □ High-performance liquid chromatography—analysis for cisplatin in urine, solvent-generated anion exchange, column switching technique □ Cisplatin—analysis in urine, high-performance liquid chromatography using column-switching techniques

The demonstrated ability of platinum complexes to inhibit cell division in *Escherichia coli* (1) has led to extensive studies of their antitumor activity (2, 3). Although ~1300 platinum complexes have been investigated as potential anticancer agents (3), the prototype, *cis*-diamminedichloroplatinum(II) (cisplatin, structure I), remains the most widely used in the clinical setting.



I

Cisplatin readily undergoes nucleophilic substitution (4, 5) with loss of chloride ion. These nucleophilic reactions have been implicated in its biological activity (3), biotransformation (3), and chemical degradation (3, 6, 7). Consequently, ligand selectivity is a necessary requirement of any analytical procedure for cisplatin. While X-ray fluorescence (8) and flameless atomic absorption spectrophotometry (9) provide the necessary sensitivities, these methods are nonselective. High-performance liquid chromatography (HPLC) offers the potential for good functional group selectivity (10); however, the poor solubility of cisplatin in nonaqueous media precludes the use of many conventional chromatographic techniques. Additionally, the UV absorptivity of cisplatin is low ($\epsilon = 150$ at 301 nm), and until a sensitive platinum detector is developed, off-line atomic absorption spectroscopy after separation is necessary for the determination of therapeutic drug concentrations in biological fluids. HPLC methods involving precolumn derivatization with diethyldithiocarbamate provide the required sensitivity (11, 12); however, they respond only to total platinum levels. Cisplatin has been retained on and eluted intact from strong anion exchangers (13); however, these systems suffer from poor peak shape and provide only moderate selectivities. Furthermore, the high concentrations of methanol required for adequate solute retention (>60%) are incompatible with injections of urine and efficient use of reaction detectors. This report describes the chromatographic behavior of cisplatin on anion-exchange columns and application to its analysis in biological fluid.

EXPERIMENTAL

Materials—Crystalline cisplatin was obtained from the National Cancer Institute[1] and used as received. All other chemicals were of reagent grade, except for the methanol which was HPLC grade[2]. Glass-distilled water was used throughout.

High-Performance Liquid Chromatography—The liquid chromatograph was comprised of a constant flow-rate pump[3], an injector[4] fitted with a 20-μl loop, and a fixed wavelength[5] (280 nm) UV detector. Six columns containing various stationary phases were used in the course of the study. Columns A[6], B[6], and C[7] contained reverse-phase material,

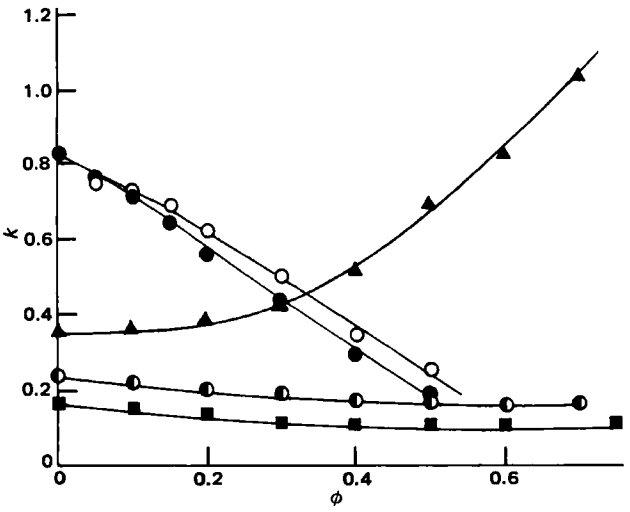

Figure 2—*The relationship between the capacity ratio of cisplatin (k) and the volume fraction (ϕ) of methanol in the mobile phase using various stationary phases at 30°. Key: (▲) column F, (■) column D, (◐) column A, (○) column A plus 0.99 μmoles/m² of 10^{-4} M hexadecyltrimethylammonium bromide, and (●) column A plus 0.99 μmoles/m² of 10^{-5} M hexadecyltrimethylammonium bromide.*

columns D[8] and E[9] contained silica gel, and column F[10] was a strong anion exchanger. Columns A, B, D, and F were obtained from commercial sources; columns C and E were slurry packed using standard procedures (14, 15).

Solute capacity ratios (k) were determined in duplicate by:

$$k = (t_r - t_0)/t_0 \qquad \text{(Eq. 1)}$$

using deuterium oxide as the unretained marker, where t_r and t_0 are the elution times of the solute and deuterium oxide, respectively.

Solvent-generated anion exchangers were prepared by the adsorption of hexadecyltrimethylammonium bromide onto the surfaces of columns A, B, C, and E. Solutions (0.5% w/v) of hexadecyltrimethylammonium bromide were pumped through the columns until a rise in baseline, attributed to equilibration of the system, was observed (16). After each working day (~10 hr) the columns were washed with water and then with successively increasing concentrations of methanol in water (up to 50%), except column F which was regenerated according to the manufacturer's specifications.

Chromatography was performed either at room temperature (~22°) or at 30° in which case the column was thermostated by the use of a water jacket[11] and a recycling water heater[12].

For the analysis of cisplatin in urine, an automated column-switching system was used (Fig. 1). Columns C and E were connected in series *via* a six-port switching valve[13], which was positioned so that the eluent from column E either could be passed to waste or transferred to column C. A three-port switching valve[14] was positioned after the detector so that the eluent from column C either could be passed to waste or transferred to the fraction collector[15]. All chromatographic events were controlled externally by the use of a microprocessor[16]. A mobile phase of 10^{-2} M citrate buffer (pH 7.0) containing 10^{-4} M hexadecyltrimethylammonium bromide was delivered from a common reservoir by two pumps[3] at a rate of 1.0 ml/min through both columns.

The urine samples were injected automatically[17] onto column E and eluted to waste for 1.6 min, after which time the valve was switched and the fractions containing cisplatin were loaded onto column C. After loading column C, the valve was returned to its original configuration and the remaining endogenous material eluting from column E was vented to waste at a high flow rate (3.0 ml/min). At the same time, cisplatin was separated on column C from the endogenous material with which it coeluted from column E. After passing through the detector, the eluent fraction containing cisplatin was collected and subsequently analyzed for platinum content by atomic absorption. The cisplatin concentration was determined by comparison with calibration curves prepared by treating standard solutions of cisplatin (2–200 μg/ml) in 0.9% NaCl (normal saline) in an identical manner.

Platinum Determination—Platinum determinations were made on an atomic absorption spectrophotometer[18] fitted with a carbon rod atomizer. A constant lamp current of 10 mA was used and the platinum line monitored at 265.95 nm. A three-stage heating program was used: 95° for 45 sec (dry), 1400° for 15 sec (ash), and 2300° for 0.5 sec (atomize) with a ramp rate of 600°/sec. Depending on concentration 2–20-μl samples were injected directly onto the carbon rod.

Clinical Urinalysis—Urine samples (10 ml) were taken from three patients treated with cisplatin (50 mg/m²) for ovarian cancer. Urine specimens were divided (providing duplicate samples), frozen rapidly, and stored over solid CO_2 prior to analysis. The samples were thawed, sonicated for 2 min, passed through 3-μm filters[19], and analyzed immediately. The cisplatin concentration was determined by the aforementioned HPLC procedure, and the total platinum concentration was determined directly by atomic absorption after appropriate dilution with normal saline.

Table I—Relationship Between τ Values of Electrolytes Added to the Mobile Phase and the Capacity Ratios of Cisplatin [a]

Electrolyte	τ [b]	k [c]
Citrate buffer (pH 7)	3.12	3.97
Sodium sulfate	2.73	3.22
Sodium nitrate	1.32	0.86
Sodium bromide	1.06	0.74

[a] Mobile phase: 10^{-4} M hexadecyltrimethylammonium bromide, 0.1 M electrolyte. Stationary phase: 1.31 μmoles/m² hexadecyltrimethylammonium bromide supported by column B. Temperature: 30°. [b] Constants describing the effect of electrolyte on the surface tension of water (Eq. 3, Ref. 21). [c] $k = (t_r - t_0)/t_0$ (Eq. 1).

RESULTS AND DISCUSSION

The Chromatography of Cisplatin—Due to its very low solubility in organic solvents, the chromatography of cisplatin is limited to systems employing aqueous mobile phases modified by polar solvents such as methanol. The retention of cisplatin on various stationary phases was investigated using aqueous methanol mobile phases (Fig. 2). Cisplatin was poorly retained (k = 0.25, Eq. 1) on both silica (column D) and hydrophobic (column A) reverse-phase columns, and its retention decreased slightly with an increase in methanol concentration. In contrast, cisplatin was significantly retained on stationary phases possessing cationic functionalities in the form of either chemically bonded (column F) or physically adsorbed (column A modified by a monolayer of hexadecyltrimethylammonium bromide) quaternary ammonium groups. By the observation of breakthrough times (16) it was found that a monolayer of 0.99 μmole/m² hexadecyltrimethylammonium bromide was adsorbed onto the hydrophobic stationary phase (column A). With a purely aqueous mobile phase, the stability of the modified stationary phase was maintained by a low concentration (10^{-4} or 10^{-5} M) of surfactant in the mobile phase. The addition of methanol to the mobile phase resulted in displacement of some of the surfactant from the stationary phase. With 10^{-5} M hexadecyltrimethylammonium bromide in the mobile phase, partial displacement of the adsorbed surfactant was observed when the methanol volume fraction ϕ exceeded 0.10, and successive increases in methanol concentration produced further displacement. With 10^{-4} M surfactant in the mobile phase no displacement of adsorbed surfactant was observed at $\phi \leq 0.15$. These observations indicate that the surface of the modified reverse-phase column consisted of a mixture of adsorbed surfactant and methanol, the proportions of which were determined by the composition of the mobile phase.

Although cisplatin was retained on both chemically bonded and solvent-generated anion exchangers, Fig. 2 indicates that the retention mechanism and the influence of methanol was different in the two systems. Initially, with a purely aqueous mobile phase, cisplatin was retained better on the solvent-generated anion exchanger than on the chemically bonded anion exchanger. Increasing the methanol concentration de-

creased retention on the former while increasing retention on the latter. Below $\phi = 0.10$, cisplatin retention on the modified reverse-phase column was independent of surfactant concentration in the mobile phase, which indicates that the contribution to retention of solute–surfactant interactions in the mobile phase was negligible. At higher concentrations of methanol, cisplatin retention was dependent on the concentration of hexadecyltrimethylammonium bromide in the mobile phase due to displacement of the adsorbed surfactant. However, this desorption does not explain the initial decrease in retention with increasing methanol concentration on the modified reverse-phase column.

The retention of cisplatin on either of the cationic stationary phases is explained most readily in terms of ion–dipole interactions between the neutral platinum complex and the positively charged stationary phase. The differences between the two systems may be explained in terms of the different environments in which these interactions occur and the influence of methanol on those environments. The cationic groups on column A are situated in an apolar, hydrophobic environment, whereas the quaternary ammonium groups on the chemically bonded column (F) are in a polar environment in close proximity to a silica backbone. In both systems methanol is adsorbed at the stationary phase–mobile phase interface (17, 18), which decreases the polarity of the cationic groups of column F while increasing the polarity of the corresponding groups on column A.

The effects of methanol may be further rationalized by the application of solvophobic theory. According to solvophobic theory, retention in HPLC systems employing aqueous mobile phases may be described by:

$$\ln k = a + b + \frac{\gamma \Delta A}{RT} \qquad \text{(Eq. 2)}$$

which is a summation of all the possible solute–solvent–stationary phase interactions contributing to retention (19, 20). The first term, a, is related to the properties of the mobile and stationary phases and is independent of the nature of the solute. In the present system, b may be taken as a measure of the ion–dipole interactions which contribute to retention. The third term is a measure of the hydrophobic interactions where γ is the mobile phase surface tension and ΔA is the decrease in hydrophobic surface area on binding of the solute to the stationary phase. Since the chemically bonded anion exchanger has little hydrophobic character, the contribution of the third term is probably negligible in this system, and the increased retention observed with increasing methanol concentration arises from an increase in the contribution of b.

In the solvent-generated system, increasing the methanol concentration may influence both b and the hydrophobic term ($\gamma \Delta A/RT$). The increase in polarity of the environment in which the interactions occur, due to the presence of methanol, can be expected to result in a decrease in the contribution of b and decreased retention. Also, the addition of methanol lowers the mobile phase surface tension (19), further reducing retention. As indicated previously, a third effect is introduced at higher methanol concentrations at which hexyldecyltrimethylammonium bromide is displaced from the column, reducing the contributions of both a and b.

Solvophobic theory may be applied also to the explanation of the effects of electrolyte on the retention of cisplatin on solvent-generated anion exchangers (Table I). In this study column B was used as support for the adsorbed surfactant. This column produced a higher uptake of surfactant (1.31 μmoles/m²) which resulted in a correspondingly increased retention of cisplatin. The addition of the monovalent electrolytes

sodium bromide and sodium nitrate (both 0.1 M) to the mobile phase decreased the retention of cisplatin. Conversely, the addition of the polyvalent electrolytes, sodium citrate and sodium sulfate, produced a significant enhancement of retention. These effects may be explained in terms of the effect of the added salts on the mobile phase surface tension as described by the relationship:

$$\gamma = \gamma_0 + \tau m \qquad \text{(Eq. 3)}$$

where m is the molality of the electrolyte, γ_0 is the surface tension of the pure solvent and τ is a constant for the particular electrolyte. Combining Eqs. 2 and 3 gives a prediction of the linear relationship between ln k and τ at a fixed salt concentration:

$$\ln k = a + b + \frac{(\gamma_0 + \tau m)\, A}{RT} \qquad \text{(Eq. 4)}$$

The relationship between ln k and τ (21) at an electrolyte concentration of 0.1 M for the cisplatin solvent-generated anion exchange system was found to be:

$$\ln k = 0.85\,\tau - 1.23 \quad r = 0.998,\ n = 4 \qquad \text{(Eq. 5)}$$

Increasing the ionic concentration of the mobile phase may also reduce the thermodynamic activity of the cationic stationary phase binding sites due to ion–ion interactions which in turn leads to a decreased contribution of a and b (Eq. 4) and decreased retention of cisplatin. The excellent linearity of Eq. 5 indicates that this latter contribution is constant for the different salts examined at a concentration of 0.1 M and is more than compensated for by the increase in mobile phase surface tension produced by the polyvalent electrolytes having large values of τ.

Urinalysis—The use of columns A and B was associated with short column lives and considerable batch-to-batch variation. Consequently, column C was used as the support for the cationic surfactant in the analysis of cisplatin in urine. This material produced a higher coverage of adsorbed surfactant (1.96 μmoles/m^2) and a correspondingly greater retention of cisplatin. As a result, it was possible to use a lower concentration of citrate (10^{-2} M) in the mobile phase and still maintain adequate retention of cisplatin (k = 4.68).

Despite optimal retention of cisplatin on column C coated with hexadecyltrimethylammonium bromide, the drug still coeluted with several endogenous urine components (Fig. 3). Additionally, a number of highly retained peaks were observed, resulting in long analysis times. These interfering compounds were not satisfactorily removed by the use of a silica precolumn (column E). However, it was observed that cisplatin was significantly retained (k = 2.83) on this precolumn and that on silica it coeluted with different urine components (Fig. 4). Since it has been shown that cisplatin was virtually unretained on silica (Fig. 2) it was concluded that the silica had been modified by the presence of hexadecyltrimethylammonium bromide and that it was behaving as a solvent-generated anion exchanger with a different selectivity from that produced by adsorbing the surfactant onto a reverse-phase column. This hypothesis was confirmed by uptake studies which revealed significant amounts of surfactant (0.63 μmole/m^2) adsorbed onto the silica surface.

By the application of column-switching techniques (Fig. 1) the different selectivities of the two solvent-generated anion exchangers bonded to silica and hydrophobic supports were utilized and complete resolution of cisplatin from urine was achieved (Fig. 5). The system was fully automated, under microprocessor control, and designed so that only the cisplatin-containing fraction which eluted from column E was transferred to column C. After column transfer, cisplatin was separated from the components with which it coeluted from the first column. The remaining urine components were eluted from the first column at a higher flow rate (3.0 ml/min) and vented to waste.

Due to the poor sensitivity provided by UV spectroscopy, off-line flameless atomic absorption was preferred for the analysis of urine containing cisplatin at <100 μg/ml. After chromatography, the fraction containing cisplatin was collected and determined by atomic absorption spectrophotometry. The platinum absorbance of the collected fraction A_{Pt} was linear with respect to the amount of cisplatin injected (calibration curve prepared as described in *Experimental*), as defined by:

$$A_{Pt} = 0.65\ [\text{cisplatin}] + 0.001 \quad r = 0.999,\ n = 6 \qquad \text{(Eq. 7)}$$

and offered a detection limit of 2 μg/ml. Although the use of off-line atomic absorption introduces an extra step in the analysis, it provides a specific platinum-detection system which potentiates the selectivity of the HPLC.

It was found that urine samples containing cisplatin could not be satisfactorily stored in a freezer (−11°) since >30% was lost from one sample over a period of 48 hr. No degradation of cisplatin was observed in urine stored over solid CO_2 (~ −60°) for 48 hr. The recovery of drug (50 μg/ml) from urine samples stored in this manner was 101% with a relative *SD* of 3.6% (n = 9).

The developed methodology was applied to the analysis of the urine taken from three patients treated with cisplatin for ovarian cancer (Fig. 6). The amount of unchanged cisplatin excreted was determined by HPLC, and total platinum concentration was determined directly by atomic absorption spectroscopy. There was wide variation in the concentration of cisplatin found; the amounts and percentages of the total dose excreted unchanged were similar. The ratios of cisplatin–total platinum excreted varied between 75 and 95%, indicating that the previous results (3) reporting low levels of cisplatin in urine may be due to degradation during storage, either in the bladder or after sample collection, rather than extensive biotransformation. Furthermore, the presence of high concentrations of unchanged cisplatin in urine may be related to its clinical utility in the treatment of bladder cancers (3, 22).

Kinetics and Equilibrium of the Reversible Alprazolam Ring-Opening Reaction

M. J. CHO ˣ, T. A. SCAHILL, and J. B. HESTER, Jr.

Received April 9, 1981, from the *Pharmaceutical Research and Development Division, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication June 25, 1981.

Abstract □ Alprazolam underwent a facile 1,4-benzodiazepine ring-opening reaction in an acidic aqueous solution to form a benzophenone compound. The reaction was demonstrated by means of UV, IR, and ^{1}H- and ^{13}C-NMR spectroscopy. Its reverse cyclization reaction to alprazolam occurred when an acidic solution was neutralized. Both the ring-opening and the cyclization rate constants were obtained from the overall rate constant measured at 25° over a pH range of 0.5–8.0; the latter was measured by monitoring the UV spectral change of the reaction. Although the equilibrium was favored for the benzophenone compound in acidic solutions, it was possible to directly measure the cyclization rate at three acidic pH values by providing a sink condition for the product, alprazolam, using a biphasic reaction system. The bell-shaped cyclization rate pH profile was interpreted in terms of a change in the rate-determining step. The pH profile of the ring-opening rate showed an inflection point indicating a different reactivity of mono- and dicationic alprazolam. The apparent equilibrium between alprazolam and the benzophenone compound at a given pH was estimated from the rate constants for the ring-opening and cyclization reactions. The results agree with the apparent pK_a measured by a conventional UV spectrophotometry and a titration technique. The pK_a of monocationic alprazolam, the reactive species for the covalent hydration, was determined from the pH dependence of the initial absorbance when an alprazolam solution is acidified.

Keyphrases □ Alprazolam—kinetics and equilibrium of reversible ring-opening reaction □ Kinetics—alprazolam, reversible ring-opening reaction □ Equilibrium—alprazolam, reversible ring-opening reaction

The relationship between structure and chemical reactivity is an important research subject in physical organic chemistry. In heterolytic reactions involving nucleophilic reagents, an activated electrophile is often chosen as a model substrate and its reaction with a variety of nucleophiles studied. The nucleophilicity is determined from the observed reaction rates, preferably in the form of linear free-energy relationships. Such studies are well documented for substrates containing carbonyl groups (1–7) and to a lesser extent for substrates containing imino (C=N—) bonds (8). A systematic structural change in a series of analogous substrates toward a given nucleophile such as water has not been incorporated as commonly in mechanistic studies, presumably because of a limited choice of substrates. This practice is usually the case, especially when looking for a series of substrates containing an activated imino bond (9).

BACKGROUND

Analogues of 1,4-benzodiazepine provide an excellent opportunity to investigate the structural influence on the lability of a C=N— bond toward a given nucleophile, since many 1,4-benzodiazepines undergo nucleophilic covalent hydration across the C(5)—N(4) double bond, which is followed by ring opening to the corresponding benzophenone compounds (10–21).

A detailed kinetic study on the reversible ring-opening reaction of alprazolam (8-chloro-1-methyl-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepine)[1] was undertaken. In addition to the azomethine bond in the seven-membered ring, alprazolam contains other weakly basic centers on the 1,2,4-triazole. The opened-ring compound carries a primary amino function; thus, the observed rate constant (which is the sum of the ring opening and the cyclization rate constants) was a composite function of several microscopic rate constants. The present study attempted to determine these constants separately. Comparison of these constants with the corresponding rate constant of other benzodiazepines may eventually clarify the structure–activity relationships associated with an imino bond.

The facile reversibility of the ring-opening reaction required solution of the multiple equilibria involved. An attempt was made to solve these equilibria in terms of pH change through experimentally determined ionization constants and the apparent equilibrium between the two compounds engaged in the reversible reaction.

EXPERIMENTAL

Materials and Equipment—A buffer system of low ionic strength (0.01 *M*) (22) was used throughout the kinetic study to avoid any possible buffer catalysis. At pH <2, the ionic strength was inevitably >0.01 *M*; however, only hydrochloric acid was present in the system. For the pH ranges of 2.0–3.8, 4.0–6.0, 6.0–7.0, and 7.0–8.5, chloroacetate, succinate, phosphate, and tromethamine buffers were used, respectively. The buffer components were analytical grade.

A UV spectrophotometer[2] with a cell compartment between thermoplates was used throughout the kinetic study. A constant temperature of 25 ± 0.1° was maintained by a circulating water bath[3]. When UV scanning was necessary, a different spectrophotometer[4] equipped with an automatic repetitive scanning device was used. Titration for pK_a determination as well as pH measurement was done using an automatic titrator[5]. When continuous flow of a reaction system through a spectrophotometer was required, a two-piston pump with a low dead volume[6] was used for circulation.

NMR Studies—All spectra were reported on a 200-MHz NMR spectrometer[7] with a magnetic field strength of 4.7 tesla. The instrument was operated in the FT mode and the lock was provided by the deuterium signal from the solvent.

^{1}H-NMR spectra were run at 200 MHz at ambient probe temperature (20.5°). Typical instrument settings were: sweep width, 2600 Hz; acquisition time, 1.5 sec; data points, 8K (with zero filling); and pulse width, 5 μsec. Typically, <100 transients were needed for a good signal-to-noise ratio.

^{13}C-NMR spectra were run at 50.3 MHz at ambient probe temperature (21.5°). Typical instrument settings were: sweep width, 10,000 Hz; acquisition time, 0.720 sec; data points, 16K (with zero filling); and pulse width, 5 μsec (30° tip angle). Typically, 20,000 transients were needed for a good signal-to-noise ratio.

Samples for ^{1}H- and ^{13}C-NMR spectra were prepared by dissolving 250 mg of alprazolam (~0.8 mmole) or compound *C* (Scheme I; ~0.75 mmole) in 2.0 ml of deuterated chloroform[8]. To this was added 158 μl of trifluoroacetic acid[9] (~2 meq) and 50 μl of deuterated water[8].

Reversible Reaction Kinetics—The overall reaction was initiated either by acidifying a neutral solution of alprazolam to a desired pH or by neutralizing an acidic solution which previously had been equilibrated at a pH close to 1.0. In the former case, ~160 μl of a stock solution of alprazolam in methanol (~10 mg/25 ml) was injected directly into a 1.0-cm

(B) A typical tracing of absorbance at 260 nm as a function of time: a to b, reversible overall (largely ring-opening) reaction; b to c, cyclization reaction only (alprazolam is continuously extracted to chloroform layer); c to d, alprazolam partitioning process at given hydrodynamics.*

cell containing 3.0 ml of a given buffer. A Hamilton microsyringe (250 μl) was used for introducing the alprazolam stock solution. After rapid mixing, the absorbance increase at 260 nm was continuously monitored. The concentration of alprazolam and methanol in the final reaction system was 6.2×10^{-5} *M* and 5.0% (v/v), respectively.

At pH >3.5, the absorbance change was so small that the overall reaction rate constant was obtained by neutralizing an acidic solution. A typically acidic stock solution of alprazolam was prepared by dissolving ~10 mg of alprazolam in 25 ml of 0.2 *N* HCl containing 20% (v/v) methanol. The solution was left at room temperature for at least 10 min but not more than 30 min prior to use. This stock solution (160 μl) was introduced into a cell containing 3.0 ml buffer at the desired pH. The reaction was then initiated by rapidly injecting 160 μl of 0.2 *N* NaOH. After mixing, the absorbance increase at 240 nm was continuously recorded. The concentration of alprazolam in the final reaction mixture was the same as in the first case; however, the methanol concentration was only ~1.0% (v/v). The final ionic strength was no longer 0.01 *M*; it was calculated to be ~0.02 *M*. A separate series of experiments established that a methanol concentration of ≤5% (v/v) did not influence the observed rate constant within experimental error.

In both of the described procedures, the pH determined at the end of the reaction was considered to be the pH maintained during the reaction. The observed rate constant (k_{obs}) was calculated in a conventional manner, *i.e.*, from the slope of the plot of $\log(A_\infty - A_t)$ *versus* time, where A_t is absorbance at a given time t and A_∞ is that at equilibrium. In general, excellent first-order kinetics were observed over three half-lives. Under extremely acidic pH, however, a small but significant deviation from linearity was observed after the reaction was more than 75% completed.

Kinetics of Irreversible Cyclization Reaction—At pH 2.41, 2.75, and 3.35 the rate of cyclization of the opened-ring compound to alprazolam was measured by providing a sink condition for the product. Approximately 0.7 ml of an alprazolam stock solution in methanol (~1.38 mg/ml) was added to 50 ml of a given buffer solution which had been placed in a jacketed beaker at 25°. The absorbance change at 260 nm was followed immediately by circulating the reaction mixture through a 1.0-cm flow-through cell at a flow of ~18 ml/min. After the equilibrium was established and k_{obs} was obtained, 50 ml of chloroform previously saturated with the buffer solution and kept at 25° was gently added. The binary mixture was vigorously stirred with a magnetic stirrer while the aqueous upper layer was being continuously circulated through the spectrophotometer.

Every 5–10 min, 20 ml of the chloroform layer was replaced with fresh chloroform to make sure that a perfect sink condition for alprazolam was maintained. The decrease in UV absorption 260 nm from the aqueous layer was recorded continuously down to zero. To be sure that under the hydrodynamic conditions adoped the observed rate did not merely represent the transport rate across the interface, the following test was made at the end of a kinetic run. The pH of the aqueous layer remaining on top of chloroform was readjusted to 8.0–8.5 by adding a concentrated solution of tromethamine. To this, ~0.7 ml of the alprazolam stock solution in methanol was introduced and the disappearance was monitored. Throughout this operation, the hydrodynamics remained the same as previously. The experimental setup and a typical absorbance tracing are shown in Fig. 1.

Determination of pK_a—The pK_a of the primary amino function present in the opened-ring compound was determined from a rapidly obtained titration curve. An accurately known amount of alprazolam between 50 and 100 mg was dissolved in 2.50 ml of methanol. To this, 15

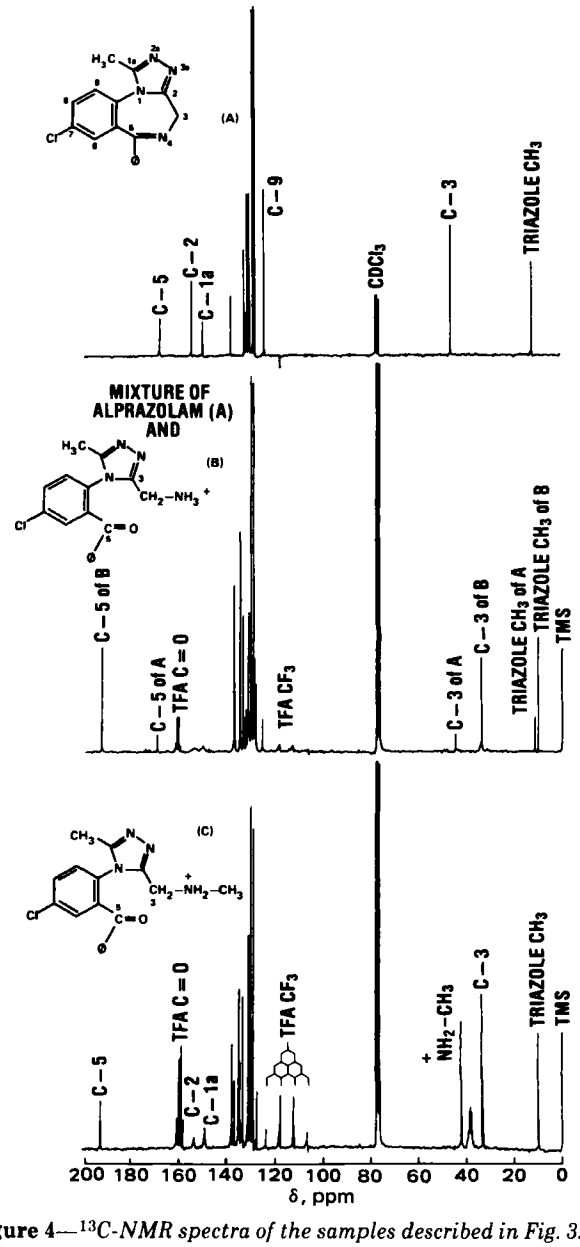

Figure 4—^{13}C-*NMR spectra of the samples described in Fig. 3.*

ml of water and 3.0 ml of 0.1 *N* HCl were added. The solution was left for at least 30 min, and the pH was accurately measured (2.0–2.5). Immediately after adding 3.0 ml of 0.1 *N* NaOH, the solution was rapidly titrated with 0.1 *N* HCl. The starting pH was ~8.5. The titration was repeated three times, and it took <4 min on the average to complete the titration. The pH observed at half of the titration end point was taken as the pKa of the primary amino group of the benzophenone compound. Since less than 2.0 ml of the titrant was consumed at the titration end point, the concentration of alprazolam and methanol near the pKa was on the order of 0.01 *M* and 10% (v/v), respectively. Although the system contained as much as 10% methanol, precipitation was observed at ~5–10 min after completion of titration (pH ~2.75), but not during the titration.

An attempt was made to measure the pKa of protonated alprazolam (the reactive species) from the pH-dependence of the initial absorbance at a given wavelength immediately after acidification of a series of alprazolam solutions at a given concentration. The experimental procedure was essentially the same as the procedure in which k_{obs} was measured. Into a 1.0-cm UV cell containing 3.0 ml of a given buffer, 100 μl of an alprazolam stock solution in methanol (0.719 mg/ml) was rapidly introduced through a 250-μl Hamilton syringe. Absorbance at 310 nm was monitored immediately and the initial absorbance value was estimated from extrapolation to the time of mixing. At a certain pH, the ring-opening reaction occurred quite rapidly (*i.e.*, $t_{1/2} \simeq 2$ min at pH 1.5). In such a case, the absorbance at the moment of mixing was estimated from the first-order kinetic plot by extrapolation to $t = 0$.

The conventional UV spectrophotometric pK_a determination (23) was carried out by scanning a series of alprazolam solutions at a given concentration (6.13×10^{-5} *M*) after the solutions were left at room temperatures for at least 30 min. The methanol concentration in these solutions was 5.0% (v/v). Each UV scan was made against the corresponding buffer as a reference.

RESULTS AND DISCUSSION

System Characterization—At an early stage of drug development, it was found that alprazolam undergoes the reversible reaction shown in Scheme I; the opened-ring compound *B* was favored in an acidic solution and alprazolam was favored in a neutral or alkaline solution. The identity of the reaction was established by means of IR, UV, and ^{1}H- and ^{13}C-NMR spectroscopy.

The solid product obtained immediately after neutralizing an acidic solution of alprazolam contained two compounds: alprazolam and a compound with an IR spectrum closely resembling that of compound *C* (benzophenone C=O absorption band at 1665 cm^{-1}). Attempts to isolate this second component in free form were not successful. Exhaustive crystallization only produced alprazolam. A similar difficulty in obtaining the opened-ring compound was reported previously for a related 1,4-benzodiazepine system (10).

On the other hand, when an alprazolam solution was acidified, the UV spectrum changed continuously and rapidly with two isosbestic points at 246 and 274 nm (Fig. 2). At pH ~1.0, the equilibrium UV spectrum (λ_{max} 262 nm and λ_{min} 239 nm) was found to be virtually identical to that of compound *C* or *D* (λ_{max} 263 nm and λ_{min} 238 nm; ϵ_{263} 1.01×10^4 and ϵ_{238} 5.80×10^3). Compounds *C* and *D* do not cyclize to form a 1,4-benzodiazapine ring. Similarly, when an acidic solution of alprazolam was neutralized with a concentrated sodium hydroxide solution, the UV spectrum slowly changed back to that of the neutral alprazolam species (λ_{max} 222 nm and λ_s 245 nm; ϵ_{222} 4.27×10^4 and ϵ_{245} 1.86×10^4).

In the ^{1}H-NMR spectrum, the nonequivalent protons at C-3 of alprazolam appeared at 5.4 and 4.10 ppm (Fig. 3A). These doublets merged into a singlet at 4.10 ppm when trifluoroacetic acid and deuterated water were added (Fig. 3B). In addition, the singlet at 2.60 ppm, which corresponds to the methyl group on the triazole moiety, underwent an upfield shift to 2.00 ppm. The resulting ^{1}H-NMR spectrum of the compound produced from alprazolam in the presence of trifluoroacetic acid and deuterated water closely resembled the ^{1}H-NMR spectrum of a model compound *C* obtained under identical conditions (s at 4.35 ppm for 2H and s at 2.32 ppm for 3H) (Fig. 3C).

Changes in the ^{13}C-NMR of alprazolam (Fig. 4A) that occurred upon addition of trifluoroacetic acid and deuterated water provided more direct evidence for the reaction shown in Scheme I. A downfield shift took place for C-5, from 168 to 192 ppm, supporting the presence of a benzophenone carbonyl carbon (Fig. 4B). The upfield shift of C-3 from 46 to 34 ppm was also in accordance with the ring-opening reaction. As expected, the signal corresponding to the methyl group on the triazole moiety changed very little with an upfield shift of ~1.5 ppm.

Finally, the overall ^{13}C-NMR spectrum of the reaction product was nearly identical to that of compound *C* (Fig. 4C), with the benzophenone carbonyl at 193 ppm, C-3 at 34 ppm, and the triazole methyl at 10 ppm. This is consistent only if the reaction product has the same benzophenone-type structure as compound *C*.

The reaction that alprazolam undergoes in an aqueous acidic solution can be further characterized based on the aforementioned spectroscopic data. IR and NMR (particularly ^{13}C-NMR) data positively identify the reaction as that in Scheme I. The product *B* is favored under acidic conditions and *A* under neutral or alkaline conditions. The reaction is similar to the ring-opening reaction of other 1,4-benzodiazepines (10–21).

The presence of isosbestic points in the UV spectral change supports the conclusion that there were no significant side reactions, during the attainment of equilibrium. Under a strongly acidic condition (pH < 0.5), however, the isosbestic points were found to drift. The nature of this slow side reaction has not been established.

The UV spectrum of alprazolam cation ($\lambda_{max} \simeq 274$ nm; Fig. 2), which rapidly changes as the ring-opening reaction takes place, is different from that of neutral alprazolam (λ_{max} 222 nm and λ_s 245 nm).

Cyclization Kinetics—The UV spectrum of alprazolam changed very little when a neutral solution was acidified to pH 5 or above, indicating that alprazolam is the predominant species at a neutral or an alkaline pH. The spectral change that occurred when an acidic solution was neutralized to pH >6 reflected the cyclization reaction exclusively. On the other hand, the rate of UV spectral change on acidification of an alprazolam solution to a pH <5 reflected the rate of both the ring-opening and the cyclization reactions. To separately determine the cyclization rate for this pH range, a sink condition for the product (alprazolam) was provided by continuously replacing chloroform in the system. A critical assumption made here was that only alprazolam partitions into the chloroform layer in a quantitative manner. This assumption appears to have been warranted by the pK_a of the primary amino function of the ring-opened compound in the range of 7.0 (see below); the benzophenone compound should exist exclusively as a cation over the pH range of the determination. Alprazolam is extremely insoluble in water (~0.1 mg/ml at 37°) but freely soluble in chloroform, and the pK_a of monocation is 2.4.

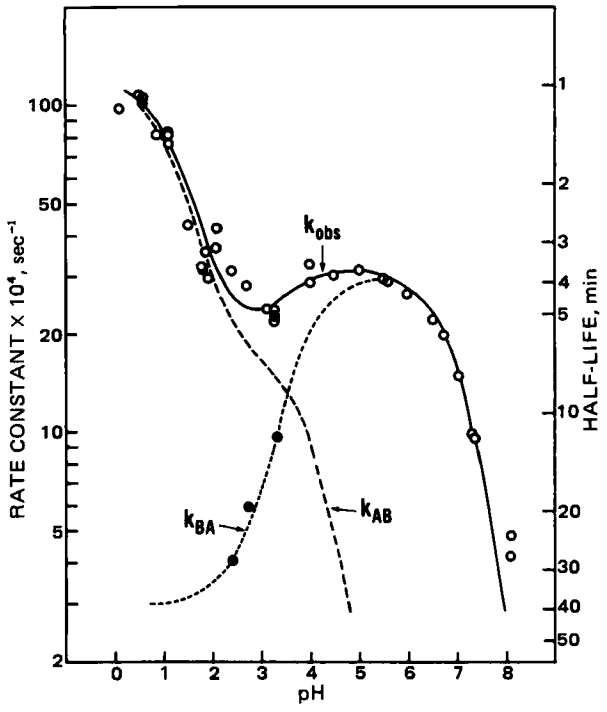

Figure 5—*pH Dependence of the overall alprazolam ring-opening and cyclization reaction rate constant (k_{obs}), ring-opening reaction rate constant (k_{AB}; dashed line), and cyclization rate constant (k_{BA}; dotted line up to pH 5.5 and descending solid line thereafter); all at 25°. The rates were also expressed in terms of half-life (right-hand side coordinate). Closed circles represent k_{BA} determined from an irreversible* B → A *reaction condition.*

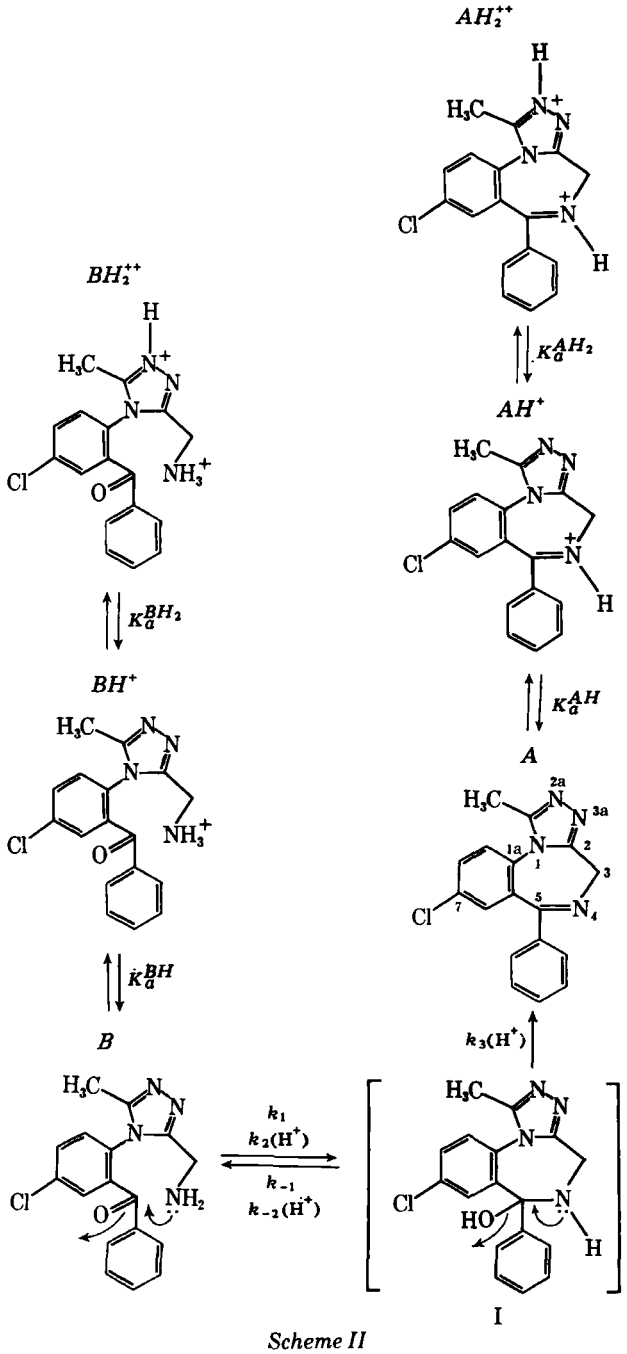
The three data points (Fig. 5) obtained from the described biphasic system together with the data points at pH values >5.5 resulted in a bell-shape pH-profile of the cyclization rate constant (Fig. 5). The cyclization reaction is analogous to a Schiff-base formation reaction, the kinetics of which have been thoroughly studied (24). The bell-shape pH-profile arises from a change in the rate-determining step with the pH change. Under acidic conditions, formation of the carbinolamine intermediate (*I* in Scheme II) is rate-controlling, since the concentration of kinetically reactive —NH_2 is extremely low and the dehydration of *I* is facilitated by protonation of the —OH group to form an excellent leaving group, H_2O. However, as the pH increases, approaching the pK_a of the primary amino group, the nucleophilic attack of the —NH_2 group on the benzophenone carbonyl group becomes faster than the dehydration of the carbinolamine intermediate *I*.

Closely following the kinetic treatment developed by Jenck (24), the following expression for the overall cyclization rate constant as a function of $[H^+]$ was derived:

$$k_{BA} = \frac{k_3[H^+](k_1 + k_2[H^+])}{k_{-1} + k_{-2}[H^+] + k_3[H^+] + k_3[H^+]} \times \frac{K_a^{BH}}{K_a^{BH} + [H^+]} \quad \text{(Eq. 1)}$$

Definitions of K_a^{BH} and several microscopic rate constants in Eq. 1 are shown in Scheme II. In this treatment, the dicationic species BH_2^{2+} does not need to be differentiated from the monocationic species BH^+ and that each of the rate constants can represent a kinetically equivalent reaction pathway; *e.g.*, the specific acid-catalyzed —NH_2 attack ($k_2[H^+]$ process) is equivalent to H_2O catalyzed *I* formation from BH^+.

Crude approximates of the rate constants were first obtained as described previously (24). These, together with the experimentally deter-



Scheme II

mined K_a^{BH} value, served as the first approximates in the final curve fitting by means of the SIMPLEX least-square computer program. Values for the individual microscopic rate constants and K_a^{BH} obtained using three data points at pH <3.4 and at 11 points at pH >5 are listed in Table I. The reliability of these values can be exemplified as follows: the experimentally determined pK_a^{BH} in the presence of 10% (v/v) methanol was 6.78 ± 0.02 (n = 3), whereas that from the numerical analysis of the pH profile was 7.02 with a range of 6.77–7.29 at a 95% confidence level. The bell-shaped curve, the dotted line up to pH 5.5 and the descending solid line thereafter (Fig. 5), was generated with the constants listed in Table I and Eq. 1. The positive deviation from a slope of +1 that one may expect on the log k_{BA}–pH profile when pH decreases from 3.5 was attributed to the steady increase in concentration of the protonated benzophenone carbonyl group, which should be extremely reactive toward the nucleophilic attack of —NH_2. This reaction pathway was implicitly included in the mathematical expression for k_{BA} (24).

Sites of Protonation on Alprazolam—Alprazolam contains four potentially basic nitrogens. It was challenging to determine the basicity ranking in an aqueous solution. In nonaqueous systems, three important pieces of evidence support that N-2*a* on the triazole ring is most basic:

Table I—Rate and Equilibrium Constants Associated with the *A* ⇌ *B* Reaction at 25°

Constants	Lower Limit[a]	Upper Limit[a]
$k_1 = 7.32\ sec^{-1}$	—	—
$k_2 = 4.26 \times 10^3\ sec^{-1}\ M^{-1}$	—	—
$k_{-1}/k_3 = 2.27 \times 10^{-4}\ M$	—	—
$k_2/k_3 = 0.343$	—	—
$K_a^{BH} = 9.51 \times 10^{-8}\ M (pK_a^{BH} = 7.02)$	5.13×10^{-8}	1.71×10^{-7}
$K_a^{BH} = 1.66 \times 10^{-7}\ M (pK_a^{BH} = 6.78)$[b]	—	—
$k_4 \cdot K \cdot K_a^{AH2}/K_a^{IH2} = 1.15 \times 10^{-2}\ sec^{-1}$	1.02×10^{-2}	1.30×10^{-2}
$k_4 \cdot K \cdot K_a^{AH2} = 9.02 \times 10^{-5}\ sec^{-1}\ M^{-1}$	2.67×10^{-5}	2.94×10^{-4}
$K_a^{IH2} = 7.84 \times 10^{-3}\ M (pK_a^{IH2} = 2.11)$	—	—
$K_a^{AH2} = 5.62 \times 10^{-2}\ M (pK_a^{AH2} = 1.25)$	3.16×10^{-2}	1.08×10^{-1}
$K_a^{AH} \cdot K_a^{AH2} = 3.95 \times 10^{-6}\ M^2$[c]	4.89×10^{-8}	4.27×10^{-5}
$K_a^{AH} = 7.03 \times 10^{-5}\ M (pK_a^{AH} = 4.15)$	—	—
$K_a^{AH} = 3.98 \times 10^{-3}\ M (pK_a^{AH} = 2.40)$[b]	—	—
$K_a^{BH2} = 3.16 \times 10^{-2}\ M (pK_a^{BH2} = 1.50)$[d]	—	—

[a] At a 95% confidence level. [b] Experimental data. [c] Not reliable (see the wide range of variation). [d] Estimated from the pKa of compound *C*.

(*a*), X-ray crystallographic study on the hydrogen bromide salt which was prepared from a nonaqueous system, indicated that a proton resides on N-2*a* (25); (*b*), ^{15}N-NMR spectrum of alprazolam in deuterated chloroform showed that N-2*a* undergoes a more profound upfield shift than any other nitrogen when trifluoroacetic acid is successively added to the system (26); and (*c*) in many chemical manipulations, N-2*a* proved to be the most nucleophilic and very likely the most basic; *e.g.*, simple alkylation preferably takes place at N-2*a* (27).

When the basicity of N-2*a* is compared with that of N-3*a*, the facts listed are in accordance with what is expected from the consideration of electronic effects; N-3*a* is linked with C(2)—CH_2(3)—N(4), whereas N-2a is linked with C(1*a*)—CH_3. The aniline N-1 should exert an identical electronic effect on both nitrogens. Thus, the electron-withdrawing effect of the aromatic azomethine bond, C(5)=N(4), should make the protonation at N-3*a* more difficult than at N-2*a*. On the other hand, N-1 is believed to be less basic than N-4 for reasons similar to that of medazepam (28). The latter is very similar to alprazolam structurally; instead of a triazole ring, a methyl group is attached to N-1. These two considerations leave either N-4 or N-2*a* to be the most basic center on the alprazolam molecule in aqueous solutions.

When alprazolam was methylated in methylene chloride at N-2*a* to form a quaternary ammonium compound, the UV spectrum hardly changed (27). Similarly, the UV spectrum of compound *C*, a compound containing a triazole ring but not a 1,4-diazepine ring, underwent a very small bathochromic shift of 4–5 nm when the pH of the sample solution was systematically changed from 4.0 to 0.3. Thus, it was apparent that protonation or methylation at N-2*a* is associated with little UV spectral change. This is perhaps because the lone-pair electrons on N-2*a* are not engaged in the aromaticity of 1,2,4-triazole. Although the opened-ring compound *C* underwent a very small bathochromic shift when dissolved in acidic solutions, it was possible to estimate the pK_a from the pH dependence of the absorbance at 280 nm. The pK_a of N-2*a* was found to be 1.5 or less.

The UV spectrum obtained immediately after acidifying an alprazolam solution to a pH below 0.5 shows an absorption maximum at 280 nm (Fig. 2). Appearance of this peak, which disappears again as the ring-opening reaction proceeds, amounts to a bathochromic shift of as much as 35 nm of the shoulder peak of alprazolam at 245 nm. The absorbance of this transient UV spectrum at a given wavelength was extrapolated to the time of acidification, and its dependence on the pH to which the alprazolam solution was acidified yielded an apparent pK_a of 2.40 (Fig. 6). This pK_a should correspond to that of N-4, and the large bathochromic shift observed reflects the resonance interaction of the positive charge with adjacent benzene rings.

The conclusion that N-4 should be more basic than N-2*a* in aqueous solutions is in contrast to many experimental evidences that N-2*a* is most basic in various nonaqueous environments. One possible explanation is based on the difference in steric hindrance that each nitrogen is subject to. In aqueous solutions, the proton donor is the relatively small hydronium ion. In nonaqueous systems in which N-2*a* was found to be more basic than N-4, the proton or alkyl group donors were all bulky: hydrogen bromide, trifluoroacetic acid, or trimethyloxonium fluoroborate (25–27). X-ray crystallographic data (25) indicate that N-1 and N-4 are subject to a higher degree of steric hindrance than the other two triazole nitrogens, making them less accessible to bulky proton donors. In this context

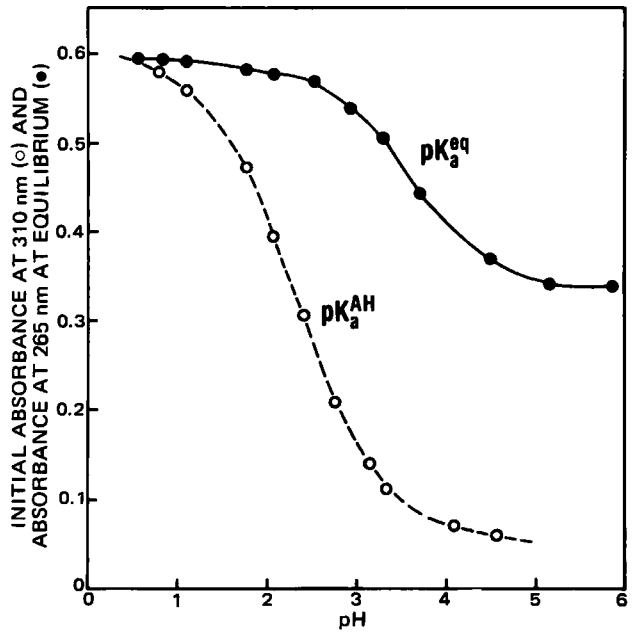


Figure 6—*Spectrophotometric determination of pK_a of monocationic alprazolam (pK_a^{AH}) and apparent equilibrium pK_a.*

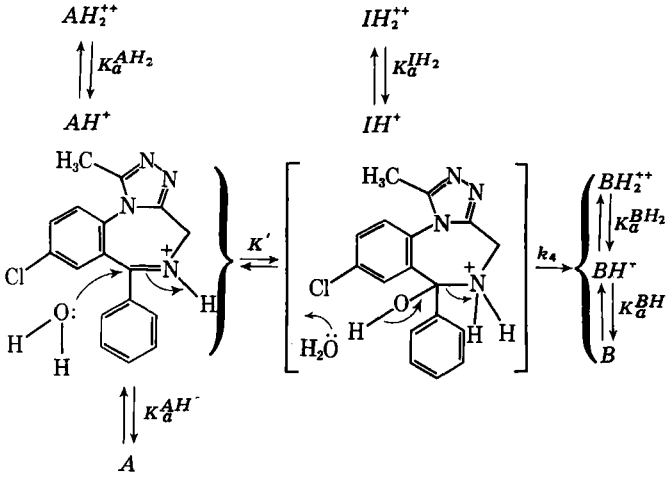
it should be noted that the ^{15}N-NMR upfield shift associated with protonation of nitrogens in alprazolam with trifluoacetic acid was ordered N-2*a* > N-3*a* > N-4 > N-1 (26). It is not uncommon that the usual basicity order for a series of compounds can be completely inverted when bulky proton donors are used in the protonation (29).

Kinetics of Alprazolam Ring-Opening Reaction—The pH profiles of the ring-opening rate constant (k_{AB}) was obtained by subtracting k_{BA} from the spectrophotometrically determined overall rate constant (k_{obs}). That is, the value of k_{AB} was calculated at each pH where k_{obs} was measured in such a way that the sum of k_{BA} and k_{AB} best accommodated a total of 35 experimental data points of k_{obs}. In this manipulation, the pH dependence of k_{BA} was dictated by Eq. 2.

In deriving a mathematical expression for k_{AB} in terms of hydronium ion concentration, it was first assumed that the carbinolamine intermediate (IH^+) formation is much faster than the subsequent abstraction of a proton to form the benzophenone compound (BH^+; Scheme III) over the entire pH range studied. This is in accordance with the principle of microscopic reversibility applied to the cyclization reaction discussed earlier; however, it will create some error especially at a pH >4. The concentration of IH^+ can then be simply represented by an equilibrium constant, $K' = (I_T)/(A_T)$, and $d(B_T)/dt = k_4(I_T)$ by definition of k_4. Note that the only base which abstracts a proton from IH^+ is H_2O and, therefore, this step should be pH independent. In other words, the observed pH dependence of k_{AB} arises from the pH dependence of the apparent equilibrium constant K' in the kinetic scheme, and the equillibrium concentration of the intermediate at a given pH is ultimately governed by the reactivity of different ionic species of alprazolam present at that particular pH. This analysis simplifies the kinetic scheme tremendously, and the following expression for k_{AB} was derived, in which $K = (IH^+)/(AH^+)$, a pH independent equilibrium constant. Other constants included in the expression are all self-explanatory from Scheme III:



Scheme III

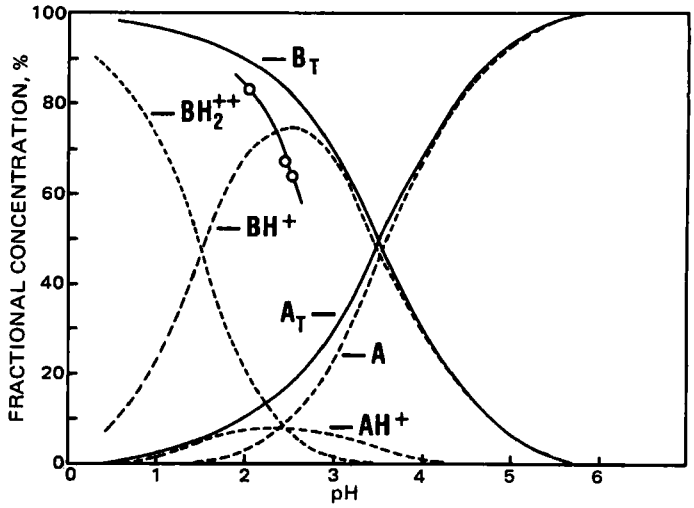


Figure 7—*Fractional concentration of various ionic species involved in the A ⇌ B reaction as a function of pH. Open circles represent the total concentration of the opened-ring compound determined by a rapid back-titration technique.*

$$k_{AB} = \frac{k_4K(K_a^{A2H}/K_a^{I2H})[H^+]^2 + k_4KK_a^{A2H}[H^+]}{[H^+]^2 + K_a^{A2H}[H^+] + K_a^{AH}K_a^{A2H}} \quad \text{(Eq. 2)}$$

Various constants present in the equation for k_{AB} were obtained from the SIMPLEX least-squares program and are listed in Table I. The dashed line on Fig. 5 was generated from these values and Eq. 2.

The presence of an inflection point on the pH profile of k_{AB} implies that the AH_2^{2+} is somewhat more reactive than AH^+. Protonation on the triazole moiety would exert an electron-withdrawing inductive effect to make the C(5)=N(4) bond more susceptible to a nucleophilic attack at C-5. However, the position of the inflection point which will determine the kinetically measurable pKa of alprazolam is subject to a significant error in the present study in that the pH-profile of k_{AB} was obtained second hand. It was not surprising that the kinetically obtained pK_a^{AH} (4.15) is very different from that obtained experimentally (2.40). The pK_a of dicationic alprazolam ($pK_a^{A2H} \simeq 1.25$) is in a fair agreement with the pK_a of compound *C* (~1.5 or below).

Over the pH range where the ring-opening reaction takes place to significant extent, the rate-determining step is largely the breakdown of intermediate IH^+, and it was not possible to isolate the reactivity of the N(4)=C(5) bond toward the H_2O attack. This is believed to be the case for other 1,4-benzodiazepines; however, the pH-dependence of K' itself should result in some interesting structure–reactivity relationships among them.

Multiple Equilibria—In the context of the present discussion, the term "equilibrium" is defined as a state of the $A \rightleftharpoons B$ system after 5–10 reaction half-lives. This restricted definition is particularly important for strongly acidic aqueous solutions in which alprazolam and/or compound *B* undergoes another slow reaction which is yet to be identified.

Equilibrium UV spectra of alprazolam at different pH values tend to produce an isosbestic point at 254 nm for pH 0.5–6.0. This finding implies that there are only two predominant species in terms of UV absorption and the apparent equilibrium concentration of these two species is identical at pH 3.50 (*i.e.*, equilibrium $pK_a = 3.50$, Fig. 6). From the values of k_{AB} and k_{BA}, the pH dependence of the apparent equilibrium of $A \rightleftharpoons B$ can also be estimated (Fig. 7). These kinetically determined equilibrium constants also showed that at pH 3.50 the total concentration of *A* is equal to that of *B*.

Fractional concentrations of different ionic species of alprazolam and the opened-ring compound are then determined by the pK_a of the species involved. Since pK_a^{BH} (6.80, determined from the rapidly obtained titration curve) is much greater than 3.5, one can safely rule out the neutral species of the opened-ring compound as an important species at any pH. Similarly, dicationic alprazolam is also not included in the present analysis. The pK_a of dicationic opened-ring compound (pK_a^{BH2}) was

assumed to be 1.5, the pK_a of compound *C*. On the other hand, the pK_a of protonated alprazolam was determined from the initial absorbance at 310 nm after a methanolic solution was diluted to a given pH (Fig. 6); the pK_a^{AH} was 2.40. Note that at 310 nm the opened-ring compound or its analogue *C* absorbed very little UV energy (Fig. 2) and the pH dependence shown on Fig. 6 should reflect the protonation at N-4. From the values of equilibrium pK_a, pK_a^{AH}, and pK_a^{BH2}, the fractional concentration of important ionic species involved in the $A \rightleftharpoons B$ equilibrium was calculated (Fig. 7).

The concentration of the opened-ring compound was also estimated experimentally. An alprazolam solution in methanol was first acidified with HCl and left to attain equilibrium. The mixture was then neutralized with an equivalent amount of hydroxide ion and immediately back-titrated. The titration end point should represent the amount of the opened-ring compound which was generated from the acid treatment. A critical assumption was that during the neutralization and the titration no significant $A \rightleftharpoons B$ reaction occurred. Since the titration end point occurs at a pH betweeen 4 and 6, alprazolam was never protonated in the titration. Three determinations of the total opened-ring compound by this rapid titration technique are shown on Fig. 7 (open circles). Since the titration system contained as much as 10% (v/v) methanol, the total concentration of the opened-ring compound recovered at a given pH was expected to be much lower than in the absence of methanol. In this particular instance, not only should the activity of water have been lower but the pK_a^{AH} was also expected to decrease significantly to result in a displacement of pH profile for the fractional concentration of opened-ring compound toward lower pH.

Factorial Designs in Pharmaceutical Stability Studies

SANFORD BOLTON

Received October 26, 1981, from the *College of Pharmacy and Allied Health Sciences, St. John's University, Jamaica, NY 11439.* Accepted for publication May 27, 1982.

ABSTRACT □ An approach to analyzing and interpreting kinetic data from stability studies using factorial designs is presented. This may be useful for screening purposes or as an aid in identifying significant effects in complex systems. A typical 2^n factorial experiment is discussed, and methods of variance estimation and statistical testing are presented. An example of simulated data is used to demonstrate how typical results may be analyzed, as well as the potential and limitations of this design in interpretation and construction of kinetic models.

Keyphrases □ Factorial designs—in pharmaceutical stability studies, kinetic models, statistical analysis □ Stability studies, pharmaceutical—factorial designs, kinetic models, statistical analysis

Factorial designs are extremely useful in a wide variety of experimental situations, and applications of these designs to pharmaceutical problems have appeared in the recent literature (1–3). Factorial designs applied to stability studies of pharmaceuticals can be used for screening purposes or to help interpret complex systems. This paper deals with an approach to the design and statistical analysis of such experiments.

BACKGROUND

A factorial experiment considers the effects of various *factors* (*e.g.*, temperature, pH, drug concentration, buffer concentration) at several *levels* (*e.g.*, 2 pHs, one high pH and one low pH) where results of all combinations of the factor levels are observed. Modifications of the complete factorial design may be used in situations where it is not convenient or possible to do all of the combinations or trials (4). For this presentation, only experiments with all factors at two levels, a 2^n factorial design (where n is the number of factors, the effects of which are to be investigated), will be considered. The *main effect* is the difference in response (*e.g.*, rate constant) caused by the change in level of a factor (pH,

0022-3549/83/0400-0362$01.00/0

assumed to be 1.5, the pK_a of compound *C*. On the other hand, the pK_a of protonated alprazolam was determined from the initial absorbance at 310 nm after a methanolic solution was diluted to a given pH (Fig. 6); the pK_a^{AH} was 2.40. Note that at 310 nm the opened-ring compound or its analogue *C* absorbed very little UV energy (Fig. 2) and the pH dependence shown on Fig. 6 should reflect the protonation at N-4. From the values of equilibrium pK_a, pK_a^{AH}, and pK_a^{BH2}, the fractional concentration of important ionic species involved in the $A \rightleftharpoons B$ equilibrium was calculated (Fig. 7).

The concentration of the opened-ring compound was also estimated experimentally. An alprazolam solution in methanol was first acidified with HCl and left to attain equilibrium. The mixture was then neutralized with an equivalent amount of hydroxide ion and immediately back-titrated. The titration end point should represent the amount of the opened-ring compound which was generated from the acid treatment. A critical assumption was that during the neutralization and the titration no significant $A \rightleftharpoons B$ reaction occurred. Since the titration end point occurs at a pH betweeen 4 and 6, alprazolam was never protonated in the titration. Three determinations of the total opened-ring compound by this rapid titration technique are shown on Fig. 7 (open circles). Since the titration system contained as much as 10% (v/v) methanol, the total concentration of the opened-ring compound recovered at a given pH was expected to be much lower than in the absence of methanol. In this particular instance, not only should the activity of water have been lower but the pK_a^{AH} was also expected to decrease significantly to result in a displacement of pH profile for the fractional concentration of opened-ring compound toward lower pH.

Factorial designs applied to stability studies of pharmaceuticals can be used for screening purposes or to help interpret complex systems. This paper deals with an approach to the design and statistical analysis of such experiments.

BACKGROUND

A factorial experiment considers the effects of various *factors* (*e.g.*, temperature, pH, drug concentration, buffer concentration) at several *levels* (*e.g.*, 2 pHs, one high pH and one low pH) where results of all combinations of the factor levels are observed. Modifications of the complete factorial design may be used in situations where it is not convenient or possible to do all of the combinations or trials (4). For this presentation, only experiments with all factors at two levels, a 2^n factorial design (where n is the number of factors, the effects of which are to be investigated), will be considered. The *main effect* is the difference in response (*e.g.*, rate constant) caused by the change in level of a factor (pH,

0022-3549/83/0400-0362$01.00/0

for example) averaged over all levels of the other factors. This has meaning in a practical sense if the effect of pH is not dependent on the levels of the other factors. If the effect of pH is dependent on the level of another factor (buffer, for example) an interaction between pH and buffer is said to exist. In this case a description of the effect of the factor, pH, would not be complete without consideration of the buffer level. This concept may be extended to higher order interactions. Thus, if an AB interaction exists and is dependent on the level of, say, factor C, the level of C should be specified when describing the AB interaction. This latter situation describes a 3-factor ABC, interaction.

A 2^3 factorial experiment with factors A, B, and C each at two levels consists of the following eight trials using the usual notation: (1), a, b, ab, c, ac, bc, abc. In this case (1) refers to all factors at their low level, a refers to the experiment with factor A at the high level and B and C at low levels, *etc.* The main effect of A is computed as $\frac{1}{4}$ [{a + ab + ac + abc} − {(1) + b + c + bc}]; the interaction AB is $\frac{1}{4}$ [{(1) + ab + c + abc} − {a + b + ac + bc}]; *etc.* Thus, the results of all experiments are used to calculate each main effect and interaction.

A relatively simple method of calculating the effects, is described by Davies (4).

THEORETICAL

The usual approach to kinetic studies is to examine, one at a time, the factors that are thought to affect the reaction rate. In many cases this approach is sufficient, since either some fundamental relationship is to be examined, or the effect of the various factors may be fairly well understood. One disadvantage of this experimental method is that, when present, interactions of factors may not be observed. Usually, little or no extra effort is required to uncover all possible effects by use of the factorial design. Factorial experiments are particularly advantageous in situations in which (*a*) the effects of several factors (and their interactions) are to be determined simultaneously in the absence of prior information, (*b*) a relatively small preliminary screening experiment is desired to obtain an estimate of the magnitude of effects of various variables, (*c*) the effects of factors are determined in a complex experimental situation (*e.g.*, many simultaneously varied factors), and (*d*) the experimental error (*e.g.*, assay) is relatively large. Statistical techniques may then be applied to test the significance of the main effects and interactions.

In typical kinetic studies, effects are usually additive. Thus, the following might describe a kinetic model:

$$k_{obs} = k_b[B] + k_c[C] + \ldots$$

in which [B] and [C] might represent hydroxide ion and buffer concentration, respectively. One objective is to estimate the rate constants, k_b, k_c, *etc.*

Since the usual statistical analysis is based on additivity of effects, it is important to consider carefully any analyses based on a model that also shows multiplicative relationships. For example, if ionic strength were a factor, the model could be of the following form:

$$k_{obs} = f(A)\{k_b[B] + k_c[C] + \ldots\}$$

in which $f(A)$ is a function of ionic strength.

If interaction of the multiplicative factor A (*e.g.*, ionic strength) with the additive factors B and C is present[1], the usual statistical analysis will be difficult, if not impossible, to interpret. In these cases, it is recommended that two separate analyses be performed, one at each level of A. Then, the effects of B and C can be estimated under the experimental conditions, *i.e.*, A constant at either the low or high level.

If interactions with A are absent, then the usual ANOVA of the rate constants (suitably weighted as described below) would, in general, provide a valid statistical test for the significance of the BC interaction only. The effects of the additive factors will be confounded with the multiplicative effects, and the effects of the additive factors should be evaluated separately at each level of A.

The factorial analysis of ln k (if CV is small and the k values are suitably weighted) will result in approximately valid statistical tests for A, AB, AC, and ABC under the null hypothesis that AB = AC = 0 (A is assumed not to interact with the additive factors B and C). In the absence of these interactions, the antilog of the A effect approximates the multiplicative effect of A (if CV is small).

Otherwise, the usual assumptions for ANOVA are considered to hold, as discussed later in this paper.

Because of the above implications, some knowledge of the functional relationships of the factors is helpful to come to meaningful conclusions. This knowledge may come from inspection of the data or from prior experience.

Statistical Considerations—In addition to the additivity concept discussed above, other assumptions inherent in the usual analysis of factorial experiments are that the errors are normally and independently distributed, and the variance (σ^2) is the same for each observation (homoscedasticity). In general, this latter assumption does not hold for experimentally determined rate constants, and the treatment of the data needs special consideration.

The variation or error in these studies arises from several factors, among which are assay error, other manipulative errors, and, possibly, the fact that the theoretical functional relationships such as linearity are not exactly satisfied. Measurement of the variance may be checked at several points during the study. Thus, it is useful during the assay development to check the assay variation at several concentrations of intact drug. Often the standard deviation is found to be proportional to the concentration of drug, *i.e.*, CV is constant; ($CV = S/C$, where S is the standard deviation and C is the concentration.) If the CV is constant and not too large, the logarithms of the assayed concentrations will have approximately equal variance at different concentration levels of drug (see *Appendix*). In this case the slope of the ordinary least-squares fit of the line, ln C *versus* time (first-order plot), is an unbiased estimate of the rate constant, k. The remainder of the discussion will be based on the assumption that the CV is constant and the reactions follow first-order kinetics. Certain modifications of the following analysis may be necessary if the kinetics are other than first order (see *Appendix*).

The variance of concern is the variation of ln C, σ^2 (which is approximately constant). Two estimates of σ^2 are available: (*a*) an estimate of the variance of ln C from replicates of assays of intact drug and (*b*) the variance estimate obtained from the least-squares line fit. If the error is due only to assay-related variation, these two estimates should show good agreement. In general, there will be sources other than assay variation contributing to the experimental error, and the line fitting should give a more realistic estimate of the variance. Another check on the error estimate could be obtained from replicate runs. (A run consists of determining the concentration as a function of time at specified levels of the factors.) Each set of replicates will contribute $n - 1$ degrees of freedom (df) to the error estimate in which n is the number of replicates. The details of this calculation for replicate runs (*i.e.*, repeat assessments of k with factor levels the same) are described in the *Appendix*.

Other studies[2] have shown excellent agreement of the variance estimate using replicates and line fitting. The line fitting approach has distinct advantages compared with replicates, since less runs are needed and more degrees of freedom for error are available.

An independent estimate of the variance as described is particularly important in this type of study. Higher order interaction terms (third order or higher) are often assumed to be nonexistent and are used to obtain estimates of the error. This approach has the disadvantage of yielding few degrees of freedom for error and possibly making false assumptions about the existence of such interactions. Most importantly, the computation of an independent variance estimate enables us to calculate the significance of the effects and all interactions in a relatively uncomplicated manner without prior consideration of the magnitude of interaction terms. As previously mentioned, the usual analysis of factorial designs assumes the variance of the observations to be equal. Under conditions usually present in kinetic studies this will very rarely be the case. The variance of a slope (the rate constant in this case) is $\sigma^2/\Sigma(t - \bar{t})^2$, in which t is the time at which the sample is assayed. Since $\Sigma(t - \bar{t})^2$ will, in general, be different for the different runs, the situation is one of variance inequality. The variance of ln k is $\sim\sigma^2/k^2\Sigma(t - \bar{t})^2$, if σ^2/k^2 is small (see *Appendix*). Interestingly, if, for each run, the same number of equally spaced time intervals are used that go to the same point of decomposition (say, 1 half-life), $k^2\Sigma(t - \bar{t})^2$ will be constant, and the variance of the ln k values will be approximately equal. This situation could be closely realized in practice if the approximate *magnitude of the* rates were known in advance. Then the usual factorial analysis of the ln k values could be used with the variance estimated as σ^2/K, with $K = k^2\Sigma(t - \bar{t})^2$. In the more realistic case, the variances are expected to differ, and, thus, one must approach the analysis differently. Initially, the main effects and interactions may be computed in the usual way (4). This is

[1] A is defined as not interacting if the response at high A is a constant multiple of the response at low a for all combinations of the additive factors, *i.e.*, ab/b = ac/c = abc/bc = a/(1).

[2] To be reported in a subsequent publication; S. Bolton, personal data.

Average = 4.49			Total 133.56	4.58

an appropriate unweighted average of the 2^n trials. The variance of these effects is estimated as described below, and the usual t test is applied by forming the ratio:

$$t = \frac{|\text{effect}|}{\sqrt{\text{Variance (effect)}}}$$

If t exceeds the tabulated α% value with appropriate degrees of freedom, the effect is significant. Nonsignificance does not necessarily mean that the effect is not present, but rather that it cannot be dissociated from error. This is important because most factors probably will affect the rate to some extent. If the effect is so small that it cannot be dissociated from error, it would probably not be of interest from a practical standpoint. The variance estimates of an effect may be calculated as follows: a main effect or interaction is the change in the rate constant due to changes in the levels of a factor or combination of factors appropriately averaged over all runs:

$$\hat{\sigma}^2 \text{ effect} = \frac{\hat{\sigma}^2\Sigma 1/\Sigma(t-\bar{t})^2}{2^{2n-2}} \qquad \text{(Eq. 1)}$$

in which $\hat{\sigma}^2$ is the estimated variance and $1/\Sigma(t-\bar{t})^2$ is summed over all 2^n trials or runs.

For ln rate constants:

$$\hat{\sigma}^2 \text{ effect} = \frac{\hat{\sigma}^2\Sigma 1/[k^2\Sigma(t-\bar{t})^2]}{2^{2n-2}} \qquad \text{(Eq. 2)}$$

In an experiment where many factors are being investigated, it may be convenient to look at segments of the data in which some factors are kept constant, while others are allowed to vary. The same statistical analysis as above may be used, but the summation in Eqs. 1 and 2 will include only those experiments that are appropriate to that segment of the experiment.

Example of Analysis—To illustrate the analysis described above, a hypothetical experiment was simulated with three factors, each at two levels, conforming to the following model:

$$k_{obs} = 10^{k_A\sqrt{A}}(k_B[B] + k_c[C])$$

The levels of A, B, and C are as follows:

Factor	Low Level	High Level
A	0	0.09
B	10^{-3}	2×10^{-3}
C	0.1	0.2

k_a, k_b, and k_c were assumed to be equal to 1, 1000, and 10, respectively.

A constant 0.2 CV, using random normal deviates, was imposed upon concentration readings at arbitrary time intervals, and the rate constants were calculated. (Duplicate runs were made for each of the eight combinations comprising the factorial, a total of 16 runs.) It should be mentioned that this error is relatively large for kinetic work; if anything, one should expect better results with real data. Pertinent results are shown in Table I.

The average rate constants and average ln rate constants were calculated as a weighted average of the respective duplicates with the weights being equal to $\Sigma(t-\bar{t})^2$ and $k^2\Sigma(t-\bar{t})^2$, respectively. The last two columns in Table I represent the weighting factors for computing the variances of the effects for rate constants and ln rate constants respectively, as shown in Eqs. 1 and 2; here $\Sigma[\Sigma(t-\bar{t})^2]$ is the sum from the two replicates.

The variance calculated from the line fitting (16 plots of ln C *versus* time) was 0.039 with 44 *df*. The variance calculated from the duplicate runs (using rate constants) was 0.060 with 8 *df*. This latter calculation

Table II—Effects Based on Data of Simulation Study (Untransformed Values)

Source	Average Effect
A	3.12
B	1.95
AB	1.03
C	1.09
AC	0.20
BC	−0.30
ABC	0.01

is described in the *Appendix*. The theoretical value should be ~0.04 ($CV^2 = 0.2^2$) and the results are within expectation, especially in view of the approximations involved. In this case the more dependable value of 0.039 determined from the least-squares line fitting for the variance will be used.

If the usual analysis on the untransformed rate constants is performed, one may expect to obtain estimates only for the BC interaction because of the multiplicative effects of A in the model. Table II shows the average effects based on the rate constants. The variance of an effect, calculated according to Eq. 1 is:

$$\frac{1}{16}\left[\frac{1}{\Sigma[\Sigma(t-\bar{t})^2]}\right]\hat{\sigma}^2$$

where $\hat{\sigma}^2 = 0.039$ and the summation includes all runs. The square root of the variance yields the standard deviation which, in this case, is 0.57 $[\sqrt{(0.039)(133.56)/16}]$. The BC interaction (−0.30) is not significant at the 5% level (Fig. 1). Keeping the multiplicative factor (A) constant, the results can be examined separately at both levels of A. With A at the low level, Eq. 1 is used where the summation includes readings (1), b, c, and bc. The *SD* of an effect is now 0.206. The results show that the main effects, B and C (0.92 and 0.89, respectively) are significant and the BC interaction (−0.32) is not. Similarly, an analysis with A at the high level yields 0.535 *SD*. As before, both main effects, B and C, are significant (2.98 and 1.29) while, again, the interaction (−0.29) is not (Table III).

Analysis of the log rate constants gives information on the effect of A and its interactions. The calculated effects are listed in Table IV. The standard deviation of an effect is 0.106 (Eq. 2), $\sqrt{0.039(4.58)/16}$.

The main effect of A is significant, and in the absence of interaction the antilog estimates its effect. The antilog of 0.70 is 2.01, which is very close to the known effect, 2. The analysis of these results also shows that all interactions with A are not significant. The results for B, C, and BC are difficult to interpret, since the additive and multiplicative properties are now confused with these effects.

Once the significant effects have been identified, it is of interest to estimate the rate constants associated with the different factors, which may be hydrogen ion concentration, buffer concentration, ionic strength, *etc.*, in a real example. Also, it would be most useful to construct a kinetic model that can be used to predict stability under various conditions (different levels of the factors). The fitting of such a model, however, would be rather precarious in the case of a design with factors at only two levels. In this situation, responses must be assumed to be linear functions

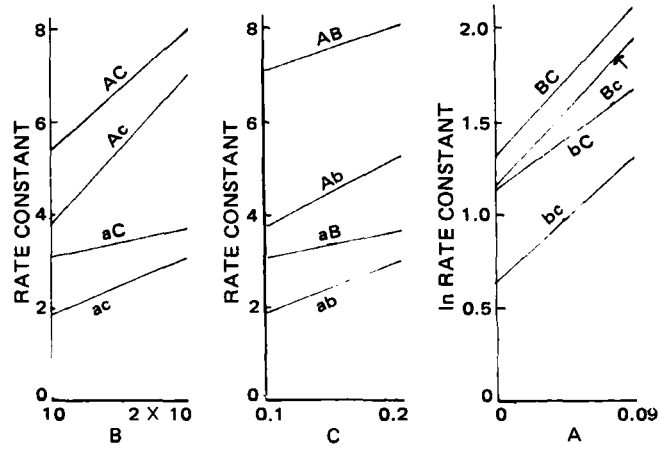

Figure 1—*Plot showing lack of interaction of factors. Capital letters are factors at high levels; lower case letters are factors at low levels. For example, aC is factor A at low level (0) with factor C at high level (0.2).*

Table III—Effects at Low and High Level of A

A = 0		A = 0.09	
Source	Average Effect	Source	Average Effect
B	0.92	B	2.98
C	0.89	C	1.29
BC	−0.32	BC	−0.29

of the factor levels. If a curved response exists, a 2^n design will not be sufficient to fit a proper model.

The rate constant associated with a factor is the slope of the observed rate constant *versus* factor level plot (Fig. 2). For example, in the case of factor B, at the low level of A (the multiplicative factor), the main effect is 0.92. The term k_B can be determined as follows: The average result at the high level of B (2×10^{-3}) is 3.39 ({3.10 + 3.67}/2), and the average result at the low level of B is 2.47 ({1.87 + 3.07}/2). The rate constant, k_B, is $(3.39 - 2.47)/(2 \times 10^{-3} - 1 \times 10^{-3}) = 920$. If interactions or multiplicative effects are not present, the rate constants can be simply calculated. If interactions exist, kinetic models may not be simply and clearly described in a single equation, and it may be preferable to describe the system at each level of the interacting factors. If a multiplicative factor is present, one may wish to include this as part of the final model. In this example the observed rate constant can be expressed as:

$$k_{obs} = 10^{k_A\sqrt{A}}(k_B[B] + k_C[C]) \qquad \text{(Eq. 3)}$$

Since interactions are nonsignificant in this example, it is convenient to express the kinetics in terms of Eq. 3.

To determine k_A, proceed as described, but use the main effect of A, expressed as $\log_{10}$:

$$k_a = \frac{0.70/2.303}{\sqrt{0.09} - \sqrt{0}} = 1.01 \qquad \text{(Eq. 4)}$$

One way to estimate k_B to satisfy Eq. 3 is to initially estimate the main effect of B, taking into account the multiplicative effect of A. From Table II, it is seen that the main effect of B is 1.95, which is the average of the main effects at low A and high A ({0.92 + 2.98}/2), as shown in Table III. Since the result of increasing the level of A is to multiply the effect of B by 2.01 (antilog of 0.70), the effect of B can be estimated: 2.01 (B $\text{effect}_{\text{low A}}$) + B $\text{effect}_{\text{low A}} \simeq 3.90$ (Note: 2.01 (B $\text{effect}_{\text{low A}}$) = B $\text{effect}_{\text{high A}}$):

$$\text{B effect}_{\text{low A}} \cong \frac{3.90}{3.01} \cong 1.30 \qquad \text{(Eq. 5)}$$

$$k_B \cong \frac{1.30}{2 \times 10^{-3} - 1 \times 10^{-3}} \cong 1300 \qquad \text{(Eq. 6)}$$

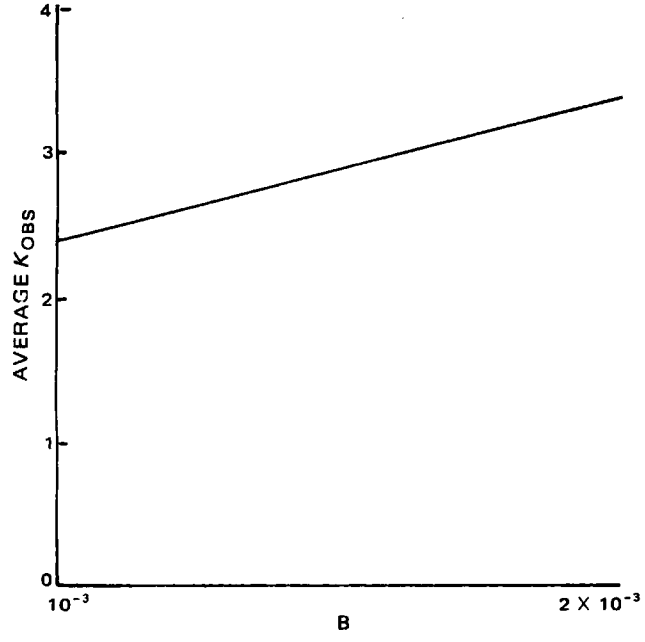

Figure 2—*Plot showing calculation of effect of factor B at low level of factor A, averaged over both levels of factor C. Slope = k_B = 920.*

Table IV—Factorial Analysis of ln Rate Constants

Source	Average Effect
A	0.70
B	0.43
AB	0.07
C	0.32
AC	−0.09
BC	−0.14
ABC	0.03

Similarly, $k_c = 7.24$, and the model (Eq. 3) can be estimated:

$$k_{obs} = 10^{\sqrt{A}}(1300[B] + 7.24[C]) \qquad \text{(Eq. 7)}$$

For example, this equation can be used to predict the rate constant with the combination, abc (A = 0.09, B = 2×10^{-3}, C = 0.2):

$$k_{obs} = 10^{\sqrt{0.09}}(1300[2 \times 10^{-3}] + 7.2[0.2]) = 8.10 \qquad \text{(Eq. 8)}$$

Without multiplicative effects, a model may also be constructed based on multiple regression techniques. In the case of a factorial design, it is convenient to use transformed (coded) values of the factor levels, where the low level equals −1 and the high level equals +1. The transformation is:

$$\frac{\text{Factor Level} - \dfrac{\text{Low Level} + \text{High Level}}{2}}{\dfrac{\text{High Level} - \text{Low Level}}{2}}$$

For Factor B, the transformation is:

$$\frac{\text{Factor Level} - 1.5 \times 10^{-3}}{0.5 \times 10^{-3}}$$

For transformed values (+1 or −1), in general, the coefficients for factors in the model are the main effects divided by 2. With the multiplicative factor A equal to 2.01, the coefficients are equal to the main effects divided by (1 + 2.01) = 3.01. For example, the coefficient for factor B is: 1.95/3.01 = 0.65. When coded values are used, an intercept value is usually calculated as the average of the rate constants, 4.49 (Table I). With the multiplicative factor A in the model, one can calculate the intercept as the average of the rate constants at the low level of A as follows:

$$\frac{2.93 + 6.05}{3.01} = \frac{\text{Average at low A + average at high A}}{3.01} = 2.98 \qquad \textit{(Eq. 11)}$$

The final equation is:

$$k_{obs} = 10^{1.0\sqrt{A}}(2.98 + 0.65[B'] + 0.36[C']) \qquad \text{(Eq. 12)}$$

where B′ and C′ are the transformed values[3], *i.e.*, the levels are transformed to equal ±1.

APPENDIX

(*a*) Approximation to the Variance of ln *y*—Using a Taylor series expansion, it can be shown that variance (ln *y*) = $CV^2(1 + \frac{1}{2}CV^2 + \ldots)$. If the *CV* is small, variance (ln *y*) = $CV^2 = \sigma^2/y^2$. Obviously, the smaller the *CV*, the better the approximation.

This result may be used to calculate the approximate variance of ln rate constant, ln *k*. The estimated variance of a rate constant is $\hat{\sigma}^2/\Sigma(t - \bar{t})^2$. Thus, the approximate variance of ln *k* is $\hat{\sigma}^2_k/k^2 = \hat{\sigma}^2/k^2\Sigma(t - \bar{t})^2$.

(*b*) The Use of Weighting in Line Fitting and Variance Estimation—The ordinary least-squares line fitting procedure assumes equal variance at each point, C. If the *CV* is constant, the variance (σ^2) is not constant, but depends on the value of C. However, in view of the above discussion, if the *CV* is constant, ln C has approximately equal variance (CV^2) and the fitting of the line, ln C *versus* time, can be computed as usual. The residual variance estimates CV^2.

[3] Note that this equation is not exactly equivalent to the equation previously constructed due to differences in calculating the multiplicative effect. If the error and interactions are small, different ways of calculating the effect of A will be very close. Here, where the error is relatively large, the results are equivocal. For example, the effect of A can be determined as the antilog of the effect of A when analyzing ln rate constants (2.01); as the ratio of the average results at high A compared with the average at low A (2.01); or as the average, in this example, of the four ratios of the rate at high level with the rate at low level of A under constant conditions of the other factors, B and C, *i.e.*, the average of a/(1), ab/b, ac/c, and abc/bc (2.06).

If the variance is constant at each point C, a fit of ln C *versus* time would require weighting each point proportional to the reciprocal of the variance, approximately C^2 in the case of constant CV. With constant variance, a zero-order plot would require no weighting.

From similar considerations, an estimate of σ^2 (equal to CV^2 in the case of constant CV and a first-order reaction) can be obtained from replicate determinations of the rate constant using the formula:

$$\Sigma w(k - \bar{k}_w)^2/(n - 1)$$

Where $\bar{k}_w$ is the weighted mean, n is the number of replications and w is $\Sigma(t - \bar{t})^2$. (Term w is equal to $k^2\Sigma(t - \bar{t})^2$ in the case of ln k). A shortcut formula for $\Sigma w(k - \bar{k})^2$ is $\Sigma wk^2 - \Sigma w(\bar{k}w)^2$.

An example of some calculations for the combination ab follows. The duplicate determinations of the rate constants were 5.86 and 8.22, and $\Sigma(t - \bar{t})^2$ was 0.0125 for each determination:

(1) The weighted average, $\bar{k}_w$, = [(0.0125)5.86 + (0.0125)8.22]/(0.025 + 0.025) = 7.04 (since the weights are equal, the weighted average equals the ordinary arithmetic average).

(2) σ^2 (One degree of freedom) from the duplicates = $[\Sigma wk^2 - \Sigma w(\bar{k}_w)^2]/(n - 1)$ = [(0.0125)(5.86)^2 + (0.0125)(8.22)^2 − 0.025 (7.04)^2]/1 = 0.0348

(3) The weighted average of ln k = ln k_w = [(5.86)^2(0.0125) ln 5.86 + (8.22)^2(0.0125)ln 8.22]/[(5.86)^2(0.0125) + (8.22)^2(0.0125)] = 1.99

The approximations inherent in the method should be kept in mind, namely the transformation to logs and the fact that observed values are used rather than true values in the weighting. However, if the CV is not large, the reliability of any conclusions from this analysis should not be in doubt.

Kinetics and Mechanism of Hydroxy Compound Cinnamoylation in Acetonitrile Catalyzed by *N*-Methylimidazole and 4-Dimethylaminopyridine

CHUKWUENWENIWE J. EBOKA and KENNETH A. CONNORS ˣ

Received March 25, 1982 from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication June 14, 1982.

Abstract □ The kinetics of reaction of the acylating agents *trans*-cinnamic anhydride and *trans*-cinnamoyl chloride with the hydroxy compounds *n*-propyl alcohol and water in the presence of *N*-methylimidazole and 4-dimethylaminopyridine were studied spectrophotometrically in acetonitrile solution at 25°. The acid chloride reacted *via* the intermediate formation of the *N*-acyl catalyst, which underwent general base-catalyzed reaction with the hydroxy compound. The anhydride did not form the *N*-acyl intermediate, but instead underwent direct general base catalysis. In the presence of water, all systems formed the *N*-acyl intermediate. The mechanistic route followed by the system was determined by the nucleophilicity of the catalyst, the ability of the leaving group, and the polarity of the solvent.

Keyphrases □ Cinnamoylation—hydroxy compounds in acetonitrile, catalyzed by *N*-methylimidazole and 4-dimethylaminopyridine, kinetics □ Kinetics—cinnamoylation of hydroxy compounds in acetonitrile □ 4-Dimethylaminopyridine catalysis—cinnamoylation of hydroxy compounds, kinetics □ *N*-Methylimidazole catalysis—cinnamoylation of hydroxy compounds, kinetics

Acylation is an important synthetic and analytical reaction. Pyridine is the classical acylation catalyst, but during the past decade more powerful catalysts have been introduced, most notably 4-dimethylaminopyridine, which has been used in synthesis (1–4) and analysis (5–8). More recently this laboratory introduced *N*-methylimidazole as an analytical acylation catalyst (9–13).

Acylation reactions are usually carried out in nonaqueous solvents. Although the mechanisms of acyl transfer in aqueous systems have been well studied (14–16), the nature of these reactions in nonhydroxylic solvents is not yet understood. Among the features that have been suggested as important in determining the kinetics and mechanisms of these reactions are the balance between nucleophilic and general base catalysis, the complex nature of rate equations (17–19), the possibility of kinetically significant ion-pair formation (3, 20, 21), competing reactions (22), and formation of molecular complexes (23). Some of these factors were addressed in a recent study on the kinetics of acetylation of alcohols by acetic anhydride and acetyl chloride, catalyzed by *N*-methylimidazole and 4-dimethylaminopyridine, in acetonitrile solution (24).

Since the cinnamoyl group, $C_6H_5CH{=}CHCO$, is a powerful UV chromophore, it is an interesting analytical acyl group (25, 26). An earlier study (27) reported the kinetics of hydrolysis of *trans*-cinnamic anhydride and of its reactions with some alcohols, catalyzed by pyridine, 4-dimethylaminopyridine, and *N*-methylimidazole, but the study was not designed to explore the detailed nature of the mechanism. In the present paper the reactions of *trans*-cinnamic anhydride and *trans*-cinnamoyl chloride with *n*-propyl alcohol and water, in acetonitrile solution, are described. The catalysts were *N*-methylimidazole and 4-dimethylaminopyridine; the reactions were studied by UV spectrophotometry.

EXPERIMENTAL

Materials—*trans*-Cinnamoyl chloride[1] was distilled under reduced pressure to give colorless crystals, mp 34–35° [lit. mp 35–36° (28)]. The molar absorptivity at 298 nm, in acetonitrile, was 2.42 × 10^4 liter/mole cm. *trans*-Cinnamic anhydride was synthesized as previously described (27), mp 136–137° [lit. mp 136° (29)]. Its molar absorptivity at 294 nm was 4.26 × 10^4 liter/mole cm. *N*-Methylimidazole[1] was distilled under

If the variance is constant at each point C, a fit of ln C *versus* time would require weighting each point proportional to the reciprocal of the variance, approximately C^2 in the case of constant CV. With constant variance, a zero-order plot would require no weighting.

From similar considerations, an estimate of σ^2 (equal to CV^2 in the case of constant CV and a first-order reaction) can be obtained from replicate determinations of the rate constant using the formula:

$$\Sigma w(k - \bar{k}_w)^2/(n - 1)$$

Where $\bar{k}_w$ is the weighted mean, n is the number of replications and w is $\Sigma(t - \bar{t})^2$. (Term w is equal to $k^2\Sigma(t - \bar{t})^2$ in the case of ln k). A shortcut formula for $\Sigma w(k - \bar{k})^2$ is $\Sigma wk^2 - \Sigma w(\bar{k}w)^2$.

An example of some calculations for the combination ab follows. The duplicate determinations of the rate constants were 5.86 and 8.22, and $\Sigma(t - \bar{t})^2$ was 0.0125 for each determination:

(1) The weighted average, $\bar{k}_w$, = [(0.0125)5.86 + (0.0125)8.22]/(0.025 + 0.025) = 7.04 (since the weights are equal, the weighted average equals the ordinary arithmetic average).

(2) σ^2 (One degree of freedom) from the duplicates = $[\Sigma wk^2 - \Sigma w(\bar{k}_w)^2]/(n - 1)$ = [(0.0125)(5.86)^2 + (0.0125)(8.22)^2 − 0.025 (7.04)^2]/1 = 0.0348

(3) The weighted average of ln k = ln k_w = [(5.86)^2(0.0125) ln 5.86 + (8.22)^2(0.0125)ln 8.22]/[(5.86)^2(0.0125) + (8.22)^2(0.0125)] = 1.99

The approximations inherent in the method should be kept in mind, namely the transformation to logs and the fact that observed values are used rather than true values in the weighting. However, if the CV is not large, the reliability of any conclusions from this analysis should not be in doubt.

Kinetics and Mechanism of Hydroxy Compound Cinnamoylation in Acetonitrile Catalyzed by *N*-Methylimidazole and 4-Dimethylaminopyridine

CHUKWUENWENIWE J. EBOKA and KENNETH A. CONNORS ˣ

Received March 25, 1982 from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication June 14, 1982.

Abstract □ The kinetics of reaction of the acylating agents *trans*-cinnamic anhydride and *trans*-cinnamoyl chloride with the hydroxy compounds *n*-propyl alcohol and water in the presence of *N*-methylimidazole and 4-dimethylaminopyridine were studied spectrophotometrically in acetonitrile solution at 25°. The acid chloride reacted *via* the intermediate formation of the *N*-acyl catalyst, which underwent general base-catalyzed reaction with the hydroxy compound. The anhydride did not form the *N*-acyl intermediate, but instead underwent direct general base catalysis. In the presence of water, all systems formed the *N*-acyl intermediate. The mechanistic route followed by the system was determined by the nucleophilicity of the catalyst, the ability of the leaving group, and the polarity of the solvent.

Keyphrases □ Cinnamoylation—hydroxy compounds in acetonitrile, catalyzed by *N*-methylimidazole and 4-dimethylaminopyridine, kinetics □ Kinetics—cinnamoylation of hydroxy compounds in acetonitrile □ 4-Dimethylaminopyridine catalysis—cinnamoylation of hydroxy compounds, kinetics □ *N*-Methylimidazole catalysis—cinnamoylation of hydroxy compounds, kinetics

Acylation is an important synthetic and analytical reaction. Pyridine is the classical acylation catalyst, but during the past decade more powerful catalysts have been introduced, most notably 4-dimethylaminopyridine, which has been used in synthesis (1–4) and analysis (5–8). More recently this laboratory introduced *N*-methylimidazole as an analytical acylation catalyst (9–13).

Acylation reactions are usually carried out in nonaqueous solvents. Although the mechanisms of acyl transfer in aqueous systems have been well studied (14–16), the nature of these reactions in nonhydroxylic solvents is not yet understood. Among the features that have been suggested as important in determining the kinetics and mechanisms of these reactions are the balance between nucleophilic and general base catalysis, the complex nature of rate equations (17–19), the possibility of kinetically significant ion-pair formation (3, 20, 21), competing reactions (22), and formation of molecular complexes (23). Some of these factors were addressed in a recent study on the kinetics of acetylation of alcohols by acetic anhydride and acetyl chloride, catalyzed by *N*-methylimidazole and 4-dimethylaminopyridine, in acetonitrile solution (24).

Since the cinnamoyl group, $C_6H_5CH{=}CHCO$, is a powerful UV chromophore, it is an interesting analytical acyl group (25, 26). An earlier study (27) reported the kinetics of hydrolysis of *trans*-cinnamic anhydride and of its reactions with some alcohols, catalyzed by pyridine, 4-dimethylaminopyridine, and *N*-methylimidazole, but the study was not designed to explore the detailed nature of the mechanism. In the present paper the reactions of *trans*-cinnamic anhydride and *trans*-cinnamoyl chloride with *n*-propyl alcohol and water, in acetonitrile solution, are described. The catalysts were *N*-methylimidazole and 4-dimethylaminopyridine; the reactions were studied by UV spectrophotometry.

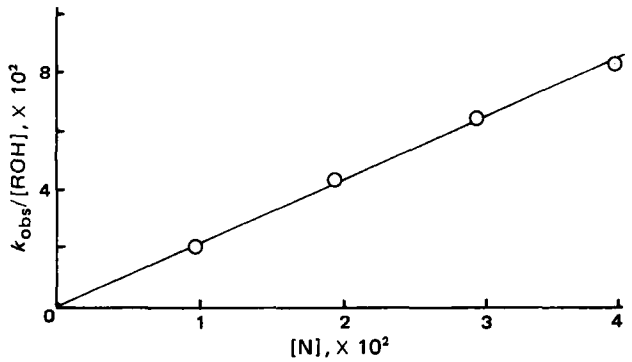

Figure 1—*Plot of Eq. 1 for the cinnamoyl chloride–dimethylaminopyridine–n-propyl alcohol system. Initial cinnamoyl chloride concentration was 2.71 × 10^{-5} M and the alcohol concentrations ranged from 0.08 to 0.61* M.

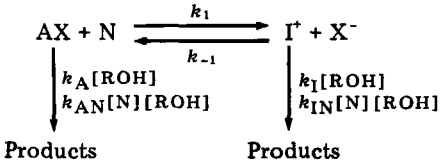
reduced pressure, bp 55° at 14–16 mm Hg. 4-Dimethylaminopyridine[1] was recrystallized from *n*-hexane, mp 113.5° [lit. 112–113° (3)]. Acetonitrile[2] was spectrophotometric grade.

Procedures—A typical kinetic run was carried out as follows. Solutions of the acylating agent, the catalyst, and the hydroxy compound were prepared in acetonitrile. Appropriate portions of the catalyst and hydroxy compound were mixed to give a volume of 4.8 ml; this solution was equilibrated at 25°. Reaction was initiated by adding 0.2 ml of the acylating agent solution. The progress of the reaction was followed by recording the absorbance, at a wavelength suitable for the particular system, as a function of time[3]. The absorbance at the completion of the reaction was measured after the lapse of at least 10 half-lives. In all cases the catalyst and hydroxy compound were in large excess to establish pseudo first-order conditions with respect to the acylating agent.

For the measurement of the rate of intermediate formation in the cinnamic anhydride–dimethylaminopyridine system in aqueous acetonitrile, 3.5 ml of a mixture of catalyst, water, and acetonitrile was equilibrated in a 1-cm spectrophotometer cell in the thermostated cell compartment. Fifty microliters of a solution of cinnamic anhydride in acetonitrile was added to the cell and the mixture was stirred. The absorbance was monitored at 350 nm; recording of the absorbance began <10 sec after adding the acylating agent. All data reported are at 25.0 ± 0.1°.

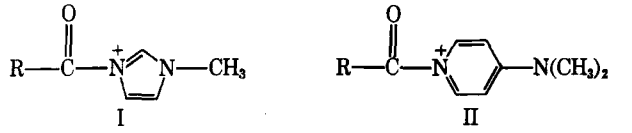
RESULTS AND DISCUSSION

Kinetic Scheme—The reactions of acetic anhydride and acetyl chloride in acetonitrile, in the presence of *N*-methylimidazole or 4-dimethylaminopyridine, were previously described (24). This same kinetic scheme (Scheme I) was used in the present study to analyze the kinetic data.



Scheme I

In Scheme I, AX represents the acylating agent (cinnamic anhydride or cinnamoyl chloride), N is the catalyst (*N*-methylimidazole or 4-dimethylaminopyridine), ROH is the hydroxy compound (*n*-propyl alcohol or water), X^- is the leaving group (cinnamate or chloride ion), and I^+ is the *N*-cinnamoylated catalyst, *i.e.*, I or II, where R is $C_6H_5CH{=}CH$.



Scheme I includes several possible kinds of kinetic behavior, dependent on the relative values of the rate constants (especially the ratio k_1/k_{-1},

[2] Burdick and Jackson.

[3] Cary Model 14 spectrophotometer equipped with a thermostated cell compartment.

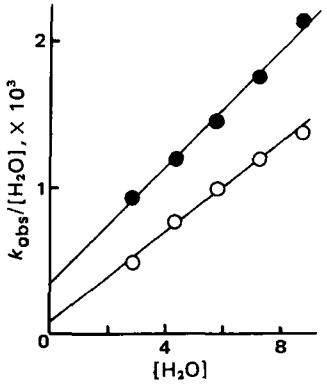


Figure 2—*Plot of Eq. 2 for the hydrolysis of cinnamoyl chloride in acetonitrile with 4-dimethylaminopyridine as catalyst. Initial cinnamoyl chloride concentration: 8.05 × 10^{-5}* M. *Catalyst concentrations: (○) 7.81 × 10^{-3}* M, *(●) 13.02 × 10^{-3}* M.

which largely determines the level of intermediate I^+ in the system). The rate constants for product formation can be described as: (k_A) the uncatalyzed reaction, (k_{AN}) general base catalysis, (k_I) nucleophilic reaction, and (k_{IN}) general base catalysis of the nucleophilic reaction.

The general experimental approach was to examine the reaction mixture spectrophotometrically for evidence of the presence of I^+. The kinetics were followed by observing the decrease in concentration of either AX or I^+ on reaction with ROH. Rate constants were evaluated from semi-logarithmic pseudo first-order plots. Derivations for those systems that can be described by the same rate equations developed for the acetylation kinetics (24) are not presented in this paper.

Cinnamoyl Chloride–Dimethylaminopyridine–*n*-Propyl Alcohol—A mixture of cinnamoyl chloride and dimethylaminopyridine exhibited UV absorption at longer wavelengths than either of the solution components. The new spectrum is ascribed to *N*-cinnamoyl dimethyl aminopyridinium chloride. In the presence of excess catalyst, the intermediate was formed very rapidly; in the presence of excess cinnamoyl chloride, up to several minutes was required. Quantitative conversion to the intermediate was demonstrated by using various amounts of catalyst and cinnamoyl chloride. The intermediate shows λ_{max} 350 nm, log ϵ_{max} 4.6. This system belongs to the special case $k_1 >>> k_{-1}$ in Scheme I; so, as shown previously (24), the kinetics may be described by:

$$\frac{k_{obs}}{[ROH]} = k_I + k_{IN}[N] \qquad \text{(Eq. 1)}$$

In Eq. 1, k_{obs} is the observed first-order rate constant and [N] is the free catalyst concentration. Since the intermediate is quantitatively formed, $[N] = [N]_0 - [AX]_0$, where the subscripted quantities are initial concentrations.

Pseudo first-order behavior was observed for >3 half-lives, with reactions monitored at 350 nm. The k_{obs} values were linearly dependent on the *n*-propyl alcohol concentration at constant $[N]_0$. Figure 1 shows the plot according to Eq. 1. The estimates $k_I = 0.14 \times 10^{-3}\ M^{-1}\ sec^{-1}$ (*SD*

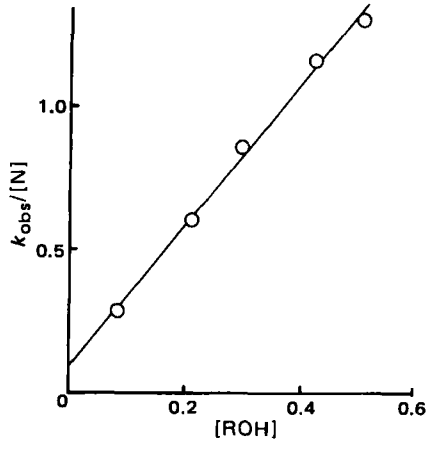

Figure 3—*Plot of Eq. 3 for the cinnamic anhydride–dimethylaminopyridine–n-propyl alcohol system. Catalyst concentration: 0.0125* M, *initial anhydride concentration: 3.50 × 10^{-4}* M.

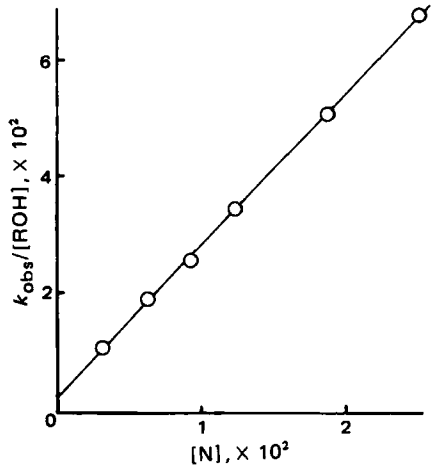

Figure 4—*Plot of Eq. 4 for the cinnamic anhydride–dimethylaminopyridine–n-propyl alcohol system. Alcohol concentration: 0.426* M.

2.6×10^{-3}) and $k_{IN} = 2.18\ M^{-2}\ sec^{-1}$ (*SD* 0.10) were obtained from this plot, thus k_I is not significantly different from zero.

Cinnamoyl Chloride–*N*-Methylimidazole–*n*-Propyl Alcohol—This system also gave quantitative intermediate formation, with λ_{max} 340 nm. The data were analyzed using Eq. 1, yielding $k_I = 5.3 \times 10^{-3}\ M^{-1}\ sec^{-1}$ (*SD* 1.6×10^{-3}) and $k_{IN} = 0.229\ M^{-2}\ sec^{-1}$ (*SD* 0.007).

Cinnamoyl Chloride–Dimethylaminopyridine–Water—Since the intermediate was formed quantitatively in this system, the loss of intermediate on reaction with water was followed at 350 nm. The water concentration ranged from 2.8 to 8.8 *M*. First-order kinetics were observed for the higher water concentrations, but significant deviations were seen at low water concentrations. The pseudo first-order rate constants were linearly dependent on the catalyst concentration, but did not vary linearly with the water concentration. The dependence suggested a rate equation both first- and second-order in water:

$$k_{obs} = (k_I + k_{IN}[N])[H_2O] + (k_I^W + k_{IN}^W[N])[H_2O]^2 \quad \text{(Eq. 2)}$$

If Eq. 2 describes the system, a plot of $k_{obs}/[H_2O]$ *versus* $[H_2O]$ should be linear and, from the dependence of the intercept and slope on [N], the individual constants can be estimated (Fig. 2). The rate constants found were $k_I = -2.8 \times 10^{-3}\ M^{-1}\ sec^{-1}$ (*SD* 3.2×10^{-3}), $k_{IN} = 0.045\ M^{-2}\ sec^{-1}$ (*SD* 0.012), $k_I^W = 7.2 \times 10^{-5}\ M^{-2}\ sec^{-1}$ (*SD* 8.1×10^{-5}), and $k_{IN}^W = 0.010\ M^{-3}\ sec^{-1}$ (*SD* 0.001). Thus k_I and k_I^W are not significantly different from zero. Scheme I requires modification for this system to include catalysis of the "IN" route by a molecule of water.

The cinnamoyl chloride–*N*-methylimidazole–water system was also examined. At low water concentrations the kinetic behavior was similar to that described for dimethylaminopyridine, but at high water concentrations serious deviations from first-order kinetics were seen. This may be a consequence of the formation of cinnamic anhydride *in situ*, as postulated for the analogous acetyl system (24).

Cinnamic Anhydride–Dimethylaminopyridine–*n*-Propyl Alcohol—The mixture of cinnamic anhydride and dimethylaminopyridine in acetonitrile exhibited an absorption spectrum that nearly could be accounted for as the sum of the spectra of the two solutes. But at high concentrations (~0.2 *M* for each solute), some absorption at longer wavelength was seen, presumably a consequence of the formation of a small amount of the intermediate. In this system, therefore, $k_1 \ll k_{-1}$. Reaction may take place *via* AX, I^+, or both. This kinetic system was described previously and (24) leads to:

$$\frac{k_{obs}}{[N]} = k_I + \left(\frac{k_A}{[N]} + k_{AN}\right)[ROH] \quad \text{(Eq. 3)}$$

and

$$\frac{k_{obs}}{[ROH]} = k_A + \left(\frac{k_1}{[ROH]} + k_{AN}\right)[N] \quad \text{(Eq. 4)}$$

If [N] is held constant and [ROH] is varied, Eq. 3 is plotted; if [ROH] is constant and [N] varies, Eq. 4 is used. From the slopes and intercepts the rate constants can be evaluated.

The reaction was followed at 320 nm, and good first-order kinetics were followed for >3 half-lives. Figures 3 and 4 show the plots according to Eqs. 3 and 4, respectively. The values found were: $k_1 = 0.096\ M^{-1}\ sec^{-1}$ (*SD* 0.039); $k_A = 0.33 \times 10^{-2}\ M^{-1}\ sec^{-1}$ (*SD* 0.16×10^{-2}); and $k_{AN} = 2.18\ M^{-2}\ sec^{-1}$ (*SD* 0.09). Evidently this reaction occurs mainly by the general base (k_{AN}) route; k_A is essentially zero, as verified in the corresponding *N*-methylimidazole system.

Table I—Mechanisms of Cinnamoylation Reactions in Acetonitrile [a]

Catalyst	Leaving Group: Chloride	Leaving Group: Cinnamate
N-Methylimidazole	*Via* I^+	*Via* AX
4-Dimethylaminopyridine	*Via* I^+	Mainly *via* AX

[a] Symbols as defined in Scheme I.

Cinnamic Anhydride–*N*-Methylimidazole–*n*-Propyl Alcohol—This system displayed the same kinetic behavior as the preceding system and Eqs. 3 and 4 were applied. The kinetics were first-order for >3 half-lives. The rate constants were $k_1 = 0.029 \times 10^{-2}\ M^{-1}\ sec^{-1}$ (*SD* 0.037×10^{-2}), $k_A = 0.69 \times 10^{-4}\ M^{-1}\ sec^{-1}$ (*SD* 0.96×10^{-4}), and $k_{AN} = 2.16 \times 10^{-2}\ M^{-2}\ sec^{-1}$ (*SD* 0.12×10^{-2}). Clearly k_1 and k_A are not significantly different from zero.

Cinnamic Anhydride–*N*-Methylimidazole–Water—On the addition of cinnamic anhydride to a solution of *N*-methylimidazole in aqueous methanol, light absorption was observed at wavelengths longer than the spectra of the added solutes, implying that the increased polarity of the medium (relative to dry acetonitrile) promotes formation of the intermediate. This behavior was seen also in the corresponding acetic anhydride system (24), which was described by:

$$k_{obs} = \left[\frac{k_I' + R'k_A'}{1 + R'}\right][H_2O] \quad \text{(Eq. 5)}$$

where $k_I' = k_1 + k_{IN}[N]$, $k_A' = k_A + k_{AN}[N]$, and $R'\ [X^-]/K[N] + k_I'[H_2O]/k_1[N]$ with $K = k_1/k_{-1}$. As the water concentration increases, both K and k_1 will increase and R' will decrease. At high water concentrations R' approaches zero and k_{obs} approaches $k_I'[H_2O]$: the reaction proceeds solely *via* the intermediate. At extremely low water concentration, R' becomes very large and k_{obs} approaches $k_A'[H_2O]$; the reaction then occurs solely *via* the anhydride. At intermediate water concentrations where R' is finite, both routes may be involved. According to Eq. 5, moreover, if R' is finite and varies during the course of a reaction, deviations from first-order kinetics may be observed.

The reaction was monitored at 340 nm. At low water concentrations (0.56–2.56 *M*) significant deviations from first-order kinetics were seen. The k_{obs} values estimated from the first half-life were linearly dependent on [N] and $[H_2O]$. At high water concentrations (11.1–27.8 *M*), the reactions were strictly first-order and k_{obs} was directly dependent on [N]. The dependence on water concentration in this region, however, was not linear, suggesting the possible involvement of a second molecule of water.

Cinnamic Anhydride–Dimethylaminopyridine–Water—This system showed spectral and kinetic behavior very similar to that observed with the *N*-methylimidazole system. During the very early stage after mixing the components, the absorbance at 350 nm (attributed to the intermediate) increased on a time scale accessible to measurement. At time zero, the concentrations $[I^+]$ and $[X^-]$ are very small, so the back-reaction (k_{-1} step) and reaction with water (k_I' step) are negligible. Hence the initial rate, measured as the absorbance change per sec, is equal to $\epsilon_I k_1[N]_0[AX]_0$, where ϵ_I is the molar absorptivity of I^+. Over the first 20 sec of reaction the absorbance was a linear function of time. Experiments were carried out at several water concentrations, with these results: $[H_2O]$ 5.65 *M*, k_1 46.5 M^{-1} sec−1; $[H_2O]$ 10.9 *M*, k_1 57.5 $M^{-1}\ sec^{-1}$; $[H_2O]$ 16.4 *M*, k_1 69.7 $M^{-1}\ sec^{-1}$; $[H_2O]$ 21.9 *M*, k_1 82.0 $M^{-1}\ sec^{-1}$; and $[H_2O]$ 27.3 *M*, k_1 106.4 $M^{-1}\ sec^{-1}$.

Catalytic Mechanisms—Table I summarizes the qualitative observations of this study. The acid chloride reacts by forming the intermediate

Table II—Comparison of Rate Constants for Some Acylation Reactions in Acetonitrile at 25°

Catalyst [a]	Alcohol	Acyl Group [b]	Acid Chloride [c] k_{IN}	Anhydride [c] k_{AN}
NMIM	*n*-Propyl Alcohol	Acetyl	0.50	0.0403
NMIM	*n*-Propyl Alcohol	Cinnamoyl	0.23	0.0216
DMAP	*n*-Propyl Alcohol	Cinnamoyl	2.18	2.18
NMIM	Isopropyl Alcohol	Acetyl	0.053	0.0041
DMAP	Isopropyl Alcohol	Acetyl	1.3	0.5

[a] NMIM = *N*-methylimidazole, DMAP = 4-dimethylaminopyridine. [b] Acetyl data from Ref. 24. [c] Units are $M^{-2}\ sec^{-1}$.

acylammonium ion (I^+ in Scheme I), whereas the anhydride does not form the intermediate unless the catalyst is very powerful. When the solvent polarity is increased by adding water, intermediate formation is favored even in the anhydride systems. These conclusions are identical with those reached in the study of acylations with acetyl chloride and acetic anhydride (24). This insensitivity of mechanistic pathway to the nature of the acyl group suggests that the mechanism is determined primarily by three factors: the catalyst nucleophilicity, the leaving group ability, and the solvent polarity. Increases in any of these factors will promote the formation of intermediate and the possibility of product formation through the k_I and k_{IN} routes. That the acid anhydrides react mainly by the general base catalyzed (k_{AN}) route, even in the presence of strong nucleophilic catalysts, has been an unexpected finding of these studies.

Table II lists rate constants for the cinnamoylation reactions reported here and includes, for comparison, some data (24) on acetylation reactions. Several patterns can be seen. In comparable systems, the general base catalysis quantities k_{AN} and k_{IN} are larger for 4-dimethylaminopyridine than for *N*-methylimidazole, reflecting the greater base strength of the former catalyst. The acetyl substrates are two-fold more reactive than the corresponding cinnamoyl compounds. For a given acyl group and alcohol, the chloride–anhydride (k_{IN}/k_{AN}) ratio is >10 for *N*-methylimidazole and close to unity for 4-dimethylaminopyridine. Since k_{IN} describes the reaction of the intermediate, this indicates that *N*-methylimidazole is a better leaving group than is a carboxylate, whereas 4-dimethylaminopyridine is about as good a leaving group as a carboxylate. These relationships are not expected on the basis of the leaving group basicities, but they may reflect a relatively greater resonance stabilization of the *N*-acyl-4-dimethylaminopyridinium intermediate.

Solvent Effects on the Cinnamoylation of *n*-Propyl Alcohol Catalyzed by *N*-Methylimidazole and 4-Dimethylaminopyridine

KENNETH A. CONNORS ˣ **and CHUKWUENWENIWE J. EBOKA**

Received April 5, 1982 from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication June 24, 1982.

Abstract □ The kinetics of reaction of *trans*-cinnamic anhydride or *trans*-cinnamoyl chloride with *n*-propyl alcohol, catalyzed by *N*-methylimidazole or 4-dimethylaminopyridine, were studied spectrophotometrically at 25° in methyl ethyl ketone, ethylene dichloride, methylene chloride, and toluene. The acid chloride reacted in all solvents *via* the intermediate formation of the *N*-acyl catalyst, which underwent reaction with the alcohol catalyzed by another molecule of the base. The anhydride did not form the intermediate in any of the solvents, but underwent direct general base catalysis. The rate of the anhydride reactions was not sensitive to solvent polarity, whereas the rate of the chloride reactions tended to increase as the solvent polarity decreased. A kinetic analysis is given of the effect of ion-pair formation on the kinetics of acyl transfer in systems where the charged *N*-acyl catalyst intermediate is formed.

Keyphrases □ Cinnamoylation—of *n*-propyl alcohol, catalysis by *N*-methylimidazole and 4-dimethylaminopyridine, solvent effects □ 4-Dimethylaminopyridine—catalyses, cinnamoylation of *n*-propyl alcohol □ *N*-methylimidazole—catalyses, cinnamoylation of *n*-propyl alcohol

Although the kinetics and mechanisms of acyl transfer reactions in water have been carefully studied (in large part because such reactions serve as models for enzyme-catalyzed reactions), acyl transfers in nonaqueous media are less well understood despite their great importance in synthesis and analysis. The relatively recent introduction of powerful acylation catalysts like 4-dimethylaminopyridine (1) and *N*-methylimidazole (2) has stimulated in-

0022-3549/83/0400-0369$01.00/0

acylammonium ion (I^+ in Scheme I), whereas the anhydride does not form the intermediate unless the catalyst is very powerful. When the solvent polarity is increased by adding water, intermediate formation is favored even in the anhydride systems. These conclusions are identical with those reached in the study of acylations with acetyl chloride and acetic anhydride (24). This insensitivity of mechanistic pathway to the nature of the acyl group suggests that the mechanism is determined primarily by three factors: the catalyst nucleophilicity, the leaving group ability, and the solvent polarity. Increases in any of these factors will promote the formation of intermediate and the possibility of product formation through the k_I and k_{IN} routes. That the acid anhydrides react mainly by the general base catalyzed (k_{AN}) route, even in the presence of strong nucleophilic catalysts, has been an unexpected finding of these studies.

Table II lists rate constants for the cinnamoylation reactions reported here and includes, for comparison, some data (24) on acetylation reactions. Several patterns can be seen. In comparable systems, the general base catalysis quantities k_{AN} and k_{IN} are larger for 4-dimethylaminopyridine than for *N*-methylimidazole, reflecting the greater base strength of the former catalyst. The acetyl substrates are two-fold more reactive than the corresponding cinnamoyl compounds. For a given acyl group and alcohol, the chloride–anhydride (k_{IN}/k_{AN}) ratio is >10 for *N*-methylimidazole and close to unity for 4-dimethylaminopyridine. Since k_{IN} describes the reaction of the intermediate, this indicates that *N*-methylimidazole is a better leaving group than is a carboxylate, whereas 4-dimethylaminopyridine is about as good a leaving group as a carboxylate. These relationships are not expected on the basis of the leaving group basicities, but they may reflect a relatively greater resonance stabilization of the *N*-acyl-4-dimethylaminopyridinium intermediate.

vestigations of acylation reactions in nonaqueous solvents by several laboratories. There are features of these reactions, however, that remain obscure: one of these is the effect of the solvent on the mechanism and rate of the reaction. This is the subject of the present paper.

There are two general routes available in an acyl transfer reaction when a nucleophile (base) is present. One of these is a direct reaction of the acylating agent with the acyl acceptor, either general base-catalyzed or uncatalyzed; the other is transfer of the acyl group from the acylating agent to the nucleophile to give an ionic intermediate, which then reacts with the acyl acceptor (in catalyzed or uncatalyzed reactions). Since the latter nucleophilic route presumably involves extensive charge separation in the transition state, it would be expected that high solvent polarity should favor this route. Thus, solvent polarity must be considered in any treatment of solvent kinetic effects. Unfortunately there is no single measure of solvent polarity applicable in all circumstances, so quantitative description is difficult. Many measures of polarity have been devised (3). Besides this general effect of the solvent on the mechanistic route, several specific rate effects have been implicated in acylation reactions. In solvents of low dielectric constant, ionic dissociation is less extensive than in polar solvents and ionic aggregates (particularly ion-pairs) may be present, which may have kinetic consequences. Several workers have suggested that ion-pair formation between the cationic acylated nucleophile and the anionic leaving group may be responsible for some unusual kinetic behavior in these systems (4, 5). Molecular complex formation has been proposed as a factor of importance in nonpolar solvents (6). An interesting observation is that acylation may proceed faster in nonpolar aprotic solvents than in polar protic solvents; this has been attributed to the favored collapse of the charged intermediate to uncharged products (7). The rate equations observed for acylations in solvents of low polarity sometimes are very complex (8).

Earlier work in this laboratory made use of the acid chlorides and anhydrides of acetic and cinnamic acids as acylating agents, 4-dimethylaminopyridine and *N*-methylimidazole as catalysts, and acetonitrile or aqueous acetonitrile as solvents (9, 10). The cinnamoyl group is particularly useful because of its convenient spectral properties, which permit the sensitive observation of the intermediate, if present (10). In the present study the solvent effect on the mechanism and the rate of acylation of *n*-propyl alcohol by *trans*-cinnamoyl chloride or *trans*-cinnamic anhydride, catalyzed by 4-dimethylaminopyridine or *N*-methylimidazole, has been studied in several solvents that are less polar than acetonitrile.

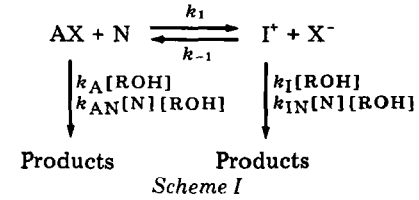
EXPERIMENTAL

Materials—The *trans*-cinnamic anhydride, *trans*-cinnamoyl chloride, 4-dimethylaminopyridine, and *N*-methylimidazole used were as previously described (10, 11). The solvents were of spectrophotometric grade[1] and were used as obtained.

Procedures—Reactions were followed spectrophotometrically[2] as described previously (10). All kinetics reported here are at 25.0°.

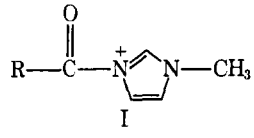
RESULTS AND DISCUSSION

Kinetic Scheme—Earlier work (9, 10) in acetonitrile and acetonitrile–water mixtures showed that Scheme I describes most of the kinetic observations.

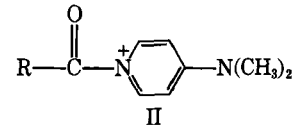


Scheme I

In this kinetic scheme, AX represents the acylating agent (cinnamic anhydride or cinnamoyl chloride), N is the catalyst (4-dimethylaminopyridine or *N*-methylimidazole), X^- is the leaving group (cinnamate or chloride ion), ROH is *n*-propyl alcohol, and I^+ is the *N*-cinnamoylated catalyst I or II, where R is $C_6H_5CH{=}CH$.



I



II

Although Scheme I does not include possible ion-pair formation (this phenomenon is treated in the later discussion), it was found to account for most of the observed behavior. Reaction of AX with ROH (the "A" route) may occur *via* uncatalyzed (k_A) or general base-catalyzed (k_{AN}) reactions; nucleophilic reaction of AX with N to form the intermediate I^+ may lead to reaction of I^+ with ROH (the "I" route) *via* uncatalyzed (k_I) and general base-catalyzed (k_{IN}) reactions[3].

The system was examined spectrophotometrically for evidence of the intermediate and the kinetics were measured by following the loss of AX or I^+ as appropriate. The initial concentrations of alcohol and catalyst were much larger than the acylating agent concentration and pseudo first-order rate constants were obtained from plots of log $(A_t - A_\infty)$ against time, where *A* represents absorbance. For most systems these plots were linear for >3 half-lives; exceptions are noted. Rate constants k_A, k_{AN}, k_I, and k_{IN} were determined as described in detail elsewhere (9).

Kinetics in Nonpolar Solvents—The results of these studies consist, in general terms, of two components: (*a*) demonstration of the presence or absence of the intermediate I^+ and (*b*) evaluation of the pertinent rate constants in Scheme I, *i.e.*, k_A and k_{AN} if the intermediate is absent or k_I and k_{IN} if I^+ is present. It is conceivable that these assignments of rate constants are in error because an intermediate, though present, may not be on the reaction path. On the other hand, the intermediate may be present at undetectably low concentrations even though all of the reaction occurs by this route. However, the interpretation given here is the simplest one and is consistent with the observations.

The acid chloride was studied with both catalysts; the anhydride was studied only with 4-dimethylaminopyridine. The anhydride–*N*-methylimidazole system was not studied because earlier work (9, 10) made it clear that no intermediate would be detected in this system. The solvents used were methyl ethyl ketone, ethylene dichloride, methylene chloride, and toluene.

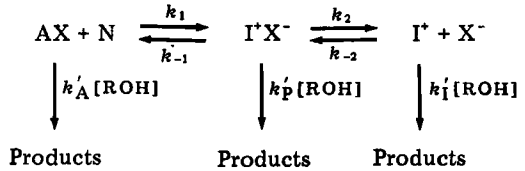
In all solvents, the acid chloride showed evidence of intermediate formation, with both catalysts, with intense absorption in the 340–350 nm region (10). The acid chloride–*N*-methylimidazole system gave strict

[1] Burdick and Jackson.
[2] Cary 14 spectrophotometer.
[3] The k_I route in Scheme I is widely described as nucleophilic catalysis, but it should be observed that if $k_I < k_A$, diversion through this route will actually inhibit the reaction. The k_{IN} reaction can be described as general base-catalyzed nucleophilic reaction.

first-order kinetics in all solvents; however, in toluene the intermediate salt precipitated and it was necessary to increase the concentration of *n*-propyl alcohol (to at least 0.04 *M*) to solubilize the intermediate. The acid chloride–dimethylaminopyridine system gave first-order kinetics in ethylene dichloride and toluene (in toluene at least 0.2 *M* propyl alcohol was added to solubilize the intermediate). In methyl ethyl ketone this system showed first-order behavior for ~3 half-lives and then showed a slight upward curvature. In methylene this system gave more complicated kinetics: the reaction became faster with time and finally, after up to 1 half-life, became satisfactorily first order. The values of k_I and k_{IN} were obtained, for all the acid chloride systems, from the dependence of the observed first-order rate constants on the catalyst and alcohol concentrations by methods described earlier (9, 10). The first-order rate constants were linearly dependent on catalyst and alcohol concentrations[4]. Table I lists the k_I and k_{IN} values found for the acid chloride systems. Most of the k_I values are not significantly different from zero. A qualitative summary of the eight acid chloride systems shows: (*a*) first-order kinetics were observed in six systems, with minor deviations in two; (*b*) in one system the rate seemed to be independent of alcohol concentration (this system is therefore omitted from Table I); and (*c*) in two systems anomalous dependence on catalyst concentration was seen[4]. In general the kinetics appear to be fairly uncomplicated.

In all of the anhydride systems, there was no spectral evidence of intermediate formation, strict first-order kinetics were observed, and the first-order rate constant was linearly dependent on the initial concentrations of catalyst and alcohol[5]. The treatment of the kinetic data (9, 10) yields estimates of k_1, k_A, and k_{AN} (Table II). There appears to be neither high sensitivity nor direct dependence of k_1 on the solvent polarity [in acetonitrile (10) k_1 is 0.096 M^{-1} sec^{-1}], which is surprising if this assignment of k_1 is correct.

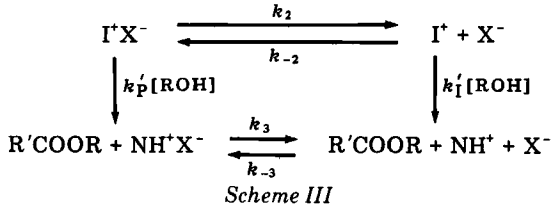
Kinetic Effects of Ion-Pairs—It was pointed out that in solvents of low dielectric constant, ion-pair formation is possible, and since in general ion-pairs and dissociated ions may have different properties, kinetic consequences of ion-pairing may be anticipated. To analyze this quantitatively, Scheme I was modified by incorporating the ion-pair I^+X^- as shown:



Scheme II

In Scheme II it is expected that the primed quantities have the form $k_A' = k_A + k_{AN}[N]$, *etc.*

In systems such as acid chlorides in the presence of strongly nucleophilic catalysts, intermediate formation is essentially quantitative and Scheme II can be drawn as:



Scheme III

An expression was sought for the rate of loss of reactant. The basic rate equation is:

$$-\frac{d([I^+X^-] + [I^+])}{dt} = k_I'[ROH][I^+] + k_P'[ROH][I^+X^-] \quad \text{(Eq. 1)}$$

The ion-pair equilibrium is assumed to be much faster than the reactions with ROH, so the ion-pair dissociation constant expression (K_d^{IX}) is always satisfied. This may be expressed as:

$$K_d^{IX} = \frac{[I^+][X^-]}{[I^+X^-]} \quad \text{(Eq. 2)}$$

Setting $[X^-]/K_d^{IX} = P$ gives $[I^+X^-] = P[I^+]$, so $-d[I^+X^-]/dt = -P(d[I^+]/dt)$, and Eq. 2 may be expressed as:

$$-\frac{d([I^+X^-] + [I^+])}{dt} = -(1 + P)\frac{d[I^+]}{dt} \quad \text{(Eq. 3)}$$

Equating Eqs. 1 and 3 gives:

$$-\frac{d[I^+]}{dt} = \left(\frac{k_I' + Pk_P'}{1 + P}\right)[I^+][ROH] \quad \text{(Eq. 4)}$$

and similarly:

$$-\frac{d[I^+X^-]}{dt} = \left(\frac{k_I' + Pk_P'}{1 + P}\right)[I^+X^-][ROH] \quad \text{(Eq. 5)}$$

It follows from the above relationships:

$$-\frac{d([I^+X^-] + [I^+])}{dt} = \left(\frac{k_I' + Pk_P'}{1 + P}\right)[ROH]([I^+X^-] + [I^+]) \quad \text{(Eq. 6)}$$

Equation 6 has a first-order form, with apparent first-order rate constant k_{obs} given by:

$$k_{obs} = \left(\frac{k_I' + Pk_P'}{1 + P}\right)[ROH] \quad \text{(Eq. 7)}$$

P is inversely proportional to K_d^{IX}; in solvents of high dielectric constant, P will approach zero, whereas in low dielectric constant solvents, P will become very large. Under pseudo first-order conditions of large catalyst and alcohol concentrations, the quantity k_{obs} will be equal to $k_I'[ROH]$ in polar dissociating solvents, but k_{obs} will approach $k_P'[ROH]$ in nonpolar nondissociating solvents. In solvents whose *polarity permits* the significant coexistence of both the ion-pair and the dissociated ions, k_{obs} is given by Eq. 7.

There is a possible kinetic consequence of Eq. 7 that can be observed if P makes a finite contribution to k_{obs}. During the time course of a reaction, if P is a function of time, k_{obs} may vary detectably and deviations from first-order kinetics may be seen. (This is a possible cause of the deviations that were observed in some of the cinnamoyl chloride systems.) This variaton can be analyzed as follows. The ion Cl^- is a much weaker base than is N in these systems, where N represents 4-dimethylaminopyridine or *N*-methylimidazole. Therefore, the protons produced in the acylation of the alcohol will be accepted predominantly by the catalyst. As a consequence there are two ion-pair equilibria in the solution, as shown in Scheme III. The dissociation constant K_d^{NHX} is defined by:

$$K_d^{NHX} = \frac{[NH^+][X^-]}{[NH^+X^-]} \quad \text{(Eq. 8)}$$

It is instructive to write this in the logarithmic form:

$$pX = pK_d^{NHX} + \log\frac{[NH^+]}{[NH^+X^-]} \quad \text{(Eq. 9)}$$

which is analogous to the Henderson–Hasselbalch equation for aqueous buffer action. That is, the concentration $[X^-]$ is established by a buffer consisting of the protonated catalyst. Since P in Eq. 7 *is equal to* $[X^-]/K_d^{IX}$, evidently the buffer capacity with respect to $[X^-]$ is important in determining the constancy of k_{obs}. This buffer capacity should be maximal when $pX = pK_d^{NHX}$, and it should increase with time since the total buffer concentration ($[NH^+] + [NH^+X^-]$) increases with time. (This may explain why, in the cinnamoyl chloride–dimethylaminopyridine–methylene chloride system, the first-order plot became linear after an initial nonlinear portion.) Whether P increases or decreases with time

Table II—Rate Constants for the 4-Dimethylaminopyridine-Catalyzed Reaction of Cinnamic Anhydride with *n*-Propyl Alcohol at 25°

Solvent	k_1/M^{-1} sec^{-1}	$k_A, \times 10^4 M^{-1}/$ sec^{-1}	k_{AN}/M^{-2} sec^{-1}
Methyl ethyl ketone	0.063(0.019)[a]	19.0(13.3)[a]	1.50(0.11)[a]
Ethylene dichloride	0.274(0.049)	19.0(2.0)	2.93(0.13)
Methylene chloride	0.179(0.063)	10(40)	2.45(0.27)
Toluene	0.198(0.028)	4(10)	3.62(0.10)

[a] Standard deviations in parentheses.

[4] For the dimethylaminopyridine system in toluene the rate constants were linearly dependent on catalyst but independent of alcohol concentration. In methyl ethyl ketone the chloride–dimethylaminopyridine system, and in toluene the chloride–*N*-methylimidazole system, gave different intercepts at different catalyst concentrations when k_{obs} was plotted against alcohol concentration. This may have been caused by reaction with a second trace constituent, possibly water (12).

[5] At high alcohol concentrations the linear dependence is lost for the ethylene dichloride system.

Table III—Third-Order Rate Constants for the Cinnamoylation of *n*-Propyl Alcohol at 25°

Solvent	ϵ[a]	k_{AN} (anhydride, DMAP)[b]	k_{IN} (chloride, DMAP)[b]	k_{IN} (chloride, NMIM)[b]
Acetonitrile[c]	35.9	2.18	2.18	0.23
Methyl ethyl ketone	18.5	1.50	3.06	0.19
Ethylene dichloride	10.4	2.93	65.1	0.70
Methylene chloride	8.9	2.45	47.0	0.39
Toluene	2.4	3.62	—	6.70

[a] Dielectric constant. [b] (Acylating agent, catalyst); units of rate constants are as given in Tables I and II. [c] Data from Ref. 10.

depends on the ratio K_d^{NHX}/K_d^{IX}, because as reaction occurs the species I^+X^-/I^+ are replaced by NH^+X^-/NH^+:

$$P = \frac{[X^-]}{K_d^{IX}} = \frac{[I^+X^-]}{[I^+]} = \frac{K_d^{NHX}[NH^+X^-]}{K_d^{IX}[NH^+]} \qquad \text{(Eq. 10)}$$

Values of ion-pair dissociation constants are extremely sensitive to the solvent dielectric constant, with typical values (13) of 10^{-16}–10^{-12} at dielectric constants of 2–3 and as high as 10^{-5} at dielectric constants near 6. In solvents more polar than acetonitrile, ion-pair formation is probably kinetically negligible. In a given solvent the ratio of ion-pair dissociation constants for two ion-pairs is controlled largely by the effective ionic sizes.

Solvent Effect on Rates and Mechanism—Table III collects k_{AN} and k_{IN} values for the cinnamoylation of *n*-propyl alcohol in five solvents. The k_{AN} values, describing the general base catalysis, are not very sensitive to the nature of the solvent; this is consistent with earlier data on alcohol acetylation by acetic anhydride catalyzed by *N*-methylimidazole (14)[6]. The k_{IN} values for the acid chloride systems reveal considerable variation with solvent polarity, the less polar solvents tending to give higher rates. In solvents that are very nonpolar k_{IN} may be influenced by ion-pair formation, as discussed in connection with Scheme III; therefore, the k_{IN} in Table III may be a composite reflecting both the ion-pair and the dissociated ion routes.

[6] The titrimetrically determined third-order rate constants in these acetic anhydride systems (14) can be interpreted as k_{AN} in Scheme I.

Since the acid chloride and the anhydride react by different mechanisms, it is dangerous to compare them. Several workers have noted that an anhydride appears to be more reactive than the acid chloride in nonpolar solvents, yet (according to Table III) $k_{IN} > k_{AN}$ for a common catalyst. An explanation of these apparently contradictory observations (9) is that formation of the intermediate from the acid chloride consumes an equimolar amount of catalyst, whereas in the anhydride system this depletion of catalyst concentration does not occur, causing $k_{AN}[N]$ in the anhydride system to be greater than $k_{IN}[N]$ is in the acid chloride system.

Abstract □ Soft-alkylated derivatives of 6-mercaptopurine, its riboside, and 2-amino-6-mercaptopurine riboside have been prepared and evaluated to improve the delivery of the thiopurines through the skin. The soft-alkylated derivatives were prepared by the alkylation of the thiopurines with acylheteroalkyl halides under neutral or basic conditions. The penetration of the derivatives through hairless mouse skin was measured using diffusion cells. All of the derivatives underwent extensive degradation during their diffusion through skin so that the parent thiopurine, even in the case of the ribosides, was the major product observed in the receptor phase. The pivaloyloxymethyl derivatives showed the greatest potential for enhancing the penetration of the thiopurines through the skin. Among the 6-mercaptopurine derivatives, VII and XI were the most effective; they delivered 5 and 13 times, respectively, more 6-mercaptopurine than 6-mercaptopurine itself.

Keyphrases □ Prodrugs of 6-thiopurines—soft-alkylated derivatives of 6-mercaptopurine, enhanced delivery through the skin, pivaloyloxymethyl derivatives □ Hairless mouse skin—penetration of prodrugs of 6-thiopurines, pivaloyloxymethyl derivatives. □ Pivaloyloxymethyl derivatives—prodrugs of 6-thiopurines, penetration through hairless mouse skin

Many high-melting drugs are insoluble in water and organic solvents; consequently, they have poor biphasic solubilities and are also poorly absorbed through biological membranes. The thiopurines represent one class of such drugs that exhibit these properties. One approach to increasing the solubilities of the thiopurines, while at the

Methyl ethyl ketone	18.5	1.50	3.06	0.19
Ethylene dichloride	10.4	2.93	65.1	0.70
Methylene chloride	8.9	2.45	47.0	0.39
Toluene	2.4	3.62	—	6.70

[a] Dielectric constant. [b] (Acylating agent, catalyst); units of rate constants are as given in Tables I and II. [c] Data from Ref. 10.

depends on the ratio K_d^{NHX}/K_d^{IX}, because as reaction occurs the species I^+X^-/I^+ are replaced by NH^+X^-/NH^+:

$$P = \frac{[X^-]}{K_d^{IX}} = \frac{[I^+X^-]}{[I^+]} = \frac{K_d^{NHX}[NH^+X^-]}{K_d^{IX}[NH^+]} \qquad \text{(Eq. 10)}$$

Values of ion-pair dissociation constants are extremely sensitive to the solvent dielectric constant, with typical values (13) of 10^{-16}–10^{-12} at dielectric constants of 2–3 and as high as 10^{-5} at dielectric constants near 6. In solvents more polar than acetonitrile, ion-pair formation is probably kinetically negligible. In a given solvent the ratio of ion-pair dissociation constants for two ion-pairs is controlled largely by the effective ionic sizes.

Solvent Effect on Rates and Mechanism—Table III collects k_{AN} and k_{IN} values for the cinnamoylation of *n*-propyl alcohol in five solvents. The k_{AN} values, describing the general base catalysis, are not very sensitive to the nature of the solvent; this is consistent with earlier data on alcohol acetylation by acetic anhydride catalyzed by *N*-methylimidazole (14)[6]. The k_{IN} values for the acid chloride systems reveal considerable variation with solvent polarity, the less polar solvents tending to give higher rates. In solvents that are very nonpolar k_{IN} may be influenced by ion-pair formation, as discussed in connection with Scheme III; therefore, the k_{IN} in Table III may be a composite reflecting both the ion-pair and the dissociated ion routes.

[6] The titrimetrically determined third-order rate constants in these acetic anhydride systems (14) can be interpreted as k_{AN} in Scheme I.

Since the acid chloride and the anhydride react by different mechanisms, it is dangerous to compare them. Several workers have noted that an anhydride appears to be more reactive than the acid chloride in nonpolar solvents, yet (according to Table III) $k_{IN} > k_{AN}$ for a common catalyst. An explanation of these apparently contradictory observations (9) is that formation of the intermediate from the acid chloride consumes an equimolar amount of catalyst, whereas in the anhydride system this depletion of catalyst concentration does not occur, causing $k_{AN}[N]$ in the anhydride system to be greater than $k_{IN}[N]$ is in the acid chloride system.

same time ensuring delivery of only the thiopurine, is to prepare prodrugs of the thiopurines.

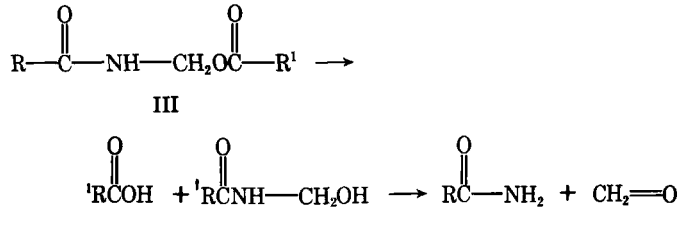
BACKGROUND

Since cancer and psoriasis are both characterized by proliferation of cells in an uncontrolled manner, it is not surprising that a recurrent theme in psoriasis therapy has been the use of the latest cancer chemotherapeutic drugs. In fact, psoriasis has been effectively treated by the systemic administration of cancer chemotherapeutic agents such as methotrexate (1), azaribine (2), 6-mercaptopurine (3), hydroxyurea (4), and mycophenolic acid (5). Unfortunately, these same agents have generally been found to be ineffective when applied topically. However, the real possibility exists that the systemic toxicity of such agents can be either circumvented entirely or at least minimized, and efforts have been continued to find anticancer agents that are effective topically.

Until recently, the reason for the topical ineffectiveness of many anticancer agents had not been investigated. Now, it has been found that the effect of topical antiproliferative drugs on epidermal DNA synthesis in hairless mice correlates well with the clinical effectiveness of the same topical agents in humans (6), but that there is little correlation between the clinical effectiveness of a topical agent and its ability to decrease epidermal DNA synthesis in essential fatty acid-(EFA) deficient mice. Apparently, the compromised epidermal barrier in the EFA-deficient mice allows some agents to penetrate the skin that are not capable of penetrating the skin of psoriatic patients or hairless mice. For instance, methotrexate, which had failed repeatedly in clinical tests as a topical antipsoriasis agent (7) and which was ineffective in decreasing DNA synthesis in the hairless mouse, was effective in decreasing DNA synthesis by 30% in EFA-deficient mice. Similarly, 15% 6-mercaptopurine and 10% thioguanine sodium were inactive clinically in humans and in the hairless mouse but were active in the EFA-deficient mouse. Thus, the reason that a number of the topically administered anticancer agents tried have been found to be ineffective may be simply that they are not absorbed: they do not penetrate the skin in their present form.

It is easy to see why 6-mercaptopurine and thioguanine are not well absorbed topically. Both purines are high-melting solids (Table I) with very low water or lipid solubility. On the other hand, well-absorbed topical drugs exhibit good water and lipid solubilities which allow their facile penetration through the biphasic epidermal barrier. One way to improve the biphasic solubilities of 6-mercaptopurine (I) and thioguanine (II) is to use the prodrug approach. An attractive prodrug strategy in this case is alkylation rather than the more routinely employed strategy of acylation, since chemical precedent suggests that the sulfur or imidazole acylates that would result are too unstable to be practical.

Inspection of the melting points and solubilities of the products obtained from the alkylation of the pyrimidine uracil shows that a correlation exists between a decrease in melting point and an increase in aqueous solubility (8). However, *N*-alkylation is normally not an easily reversible process *in vivo*, so that the biological activity profile of the parent compound is usually drastically changed by such a modification. On the other hand, in the case of uracil (8), and other amides and imide-like molecules (9), the formation of *N*-hydroxymethyl derivatives results not only in a decrease in the melting point and an increase in the water solubility of the prodrug compared with its parent, but also results in an easily reversible derivative. These *N*-hydroxymethyl derivatives are "soft-alkylated" prodrugs[1] of amides, imides, and amines: they are reversed by chemical hydrolysis rather than initially requiring a metabolically activating oxidation step. However, the range of physical properties of hydroxymethyl derivatives is limited by the relatively small number of aldehydes that will form the hydroxyalkyl adducts and by the fact that a hydroxyl group is introduced into the molecule in each case. Thus, with hydroxymethyl derivatives there is a limit to the concomitant increase in lipid solubility that is both possible and essential for efficient penetration of the epidermal membrane by the prodrug. This difficulty has been overcome by several investigators (10–14) who have acylated the hydroxymethyl derivative to give acyloxymethyl derivatives of the general formula III. Cleavage of the acyl group by esterases gives the hydroxymethyl derivative that, in turn, liberates the parent amide or imide. The acyloxymethyl derivatives, then, are also soft-alkylated derivatives which differ from the hydroxymethyl derivatives in that they must first undergo enzymatic hydrolysis before undergoing chemical hydrolysis.



III

[1] These soft-alkylated derivatives are not soft drugs, although other soft-alkylated compounds are soft drugs. For example see N. Bodor, J. Kaminski, and S. Selk, *J. Med. Chem.*, **23**, 469 (1980).

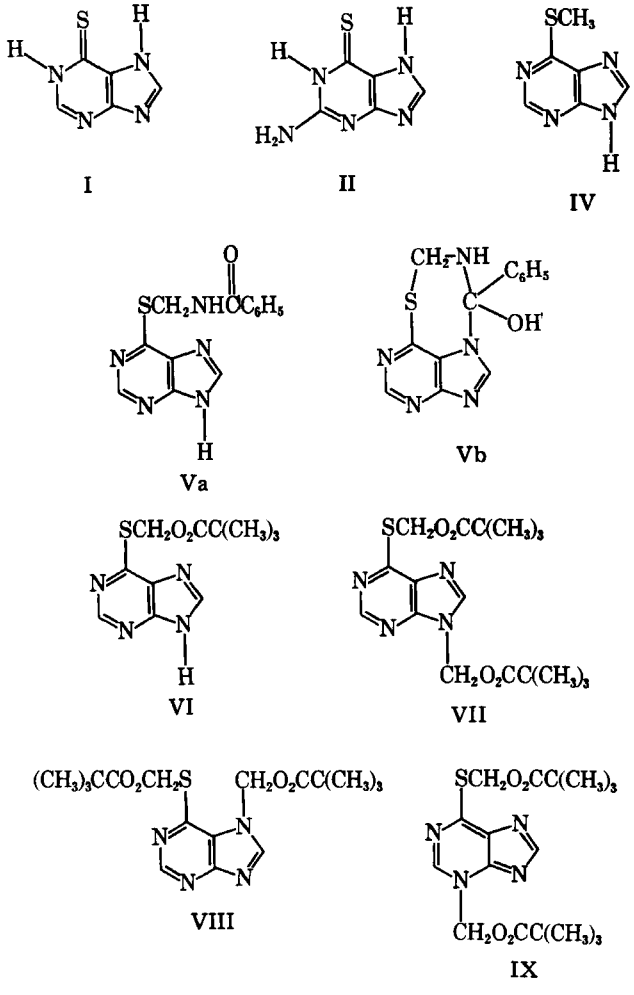
[a] Chemical shifts in δ in $CDCl_3$. [b] Run in DMSO-d_6 + $CDCl_3$ (1:5). [c] Run in DMSO-d_6.

The advantage of this type of modification can be illustrated by the case of theophylline (12) in which prodrugs with increased water or lipid solubility or with partition coefficients of ~1 were obtained by varying the acyl group R^1 in III above. Selected derivatives in this series were also found to penetrate the epidermal barrier better than theophylline and to revert to theophylline *in vivo*. In addition, these same derivatives were found to decrease the synthesis of DNA in hairless mice after their topical administration. Thus, it is possible to reduce the melting point and increase not only the biphasic solubility but also the ability of amide and imide drugs to penetrate the epidermal barrier by acyloxyalkylation.



It is clear from the data listed in Table I that alkylation on nitrogen in 6-mercaptopurine does not drastically decrease the melting point of the 6-mercaptopurine derivative. This is probably because I and its 7- and 9-alkylated derivatives exist primarily in the thioamide form (15). On the other hand, S-alkylation drastically reduces the melting point of the 6-mercaptopurine derivative, either by itself or more dramatically in combination with N-alkylation; there are similar trends in the melting points of the alkylated 2-amino-6-mercaptopurine (II) series. Therefore, as a first step in determining whether the lack of clinical activity exhibited by I and II was due to their inability to penetrate the epidermis, a number of S-acylheteroalkylated derivatives of I and XVI were synthesized and their physical properties examined. The preliminary results of that work are reported here.

RESULTS AND DISCUSSION

There have not been any previous reports on the synthesis of S-acylheteroalkyl derivatives of heterocyclic thione amides such as I or II. However, the alkylations were relatively straightforward. Representatives of two types of acylheteroalkyl derivatives were prepared for I. The first type was the S-acylaminomethyl derivative V. Compound V was prepared from the reaction of chloromethylbenzamide with I in dimethylsulfoxide. Under these conditions, alkylations of I with other alkylating agents have been shown to take place exclusively on sulfur (18). In addition, the elemental analysis, and the NMR and mass spectra were consistent only with a monoalkylated derivative. Among the possible monoalkylated derivatives, the UV spectrum (Table I) was consistent only with the S-alkylated derivative (compare Va with IV).

The only unusual feature of this reaction was the formation of two monoalkylated products, which have been designated as Va and Vb. Compound Va differs significantly from Vb in its TLC, melting point, solubility, and UV and mass spectra. The NMR spectra (Table II) of the two compounds are identical except for the difference in the position of the (C2)H absorptions, which is comparable to the difference exhibited by the (C2)H absorptions in the imidazole alkylated tautomers VII and VIII. The UV spectral difference between Va and Vb is also similar to the difference between 6-methylthio-7- and 6-methylthio-9-methylpurine and between VII and VIII. In each case the S^6,7-disubstituted product exhibits a UV maximum at a longer wavelength than that of the S^6,9-disubstituted product. However, although the spectral data suggest that Va and Vb are simply 9-H and 7-H tautomers, the separation and isolation of the two tautomers should be impossible because the energy difference between the 7-H (Vb) and 9-H (Va) tautomers is only about 3.5 kcal (19). On the other hand, the 7-H tautomer can form a cyclic adduct, which is shown as Vb[2]. There is chemical precedent for the formation of similar cyclols from amide–amide adducts in small peptides (20). In this case the adduct stabilizes the less stable 7-H tautomer of V as Vb.

Only one representative of the S-acylaminoalkyl-type derivative was studied in diffusion cell experiments. Although the melting points of both derivatives (Va and Vb) were lower than that of I, only the lower melting derivative Va was studied. Derivative Va did not enhance the diffusion of I through the skin (Table III). Apparently the amide N—H group of this type of derivative introduces too much polarity into the derivative to provide much assistance to the diffusion of 6-mercaptopurine.

The second type of acylheteroalkyl derivative of I and II is the pivaloyloxymethyl derivative. The pivaloyloxymethyl group has been used previously as a protecting and reaction-steering group in some alkylation reactions of adenine examined by Rasmussen and Leonard (21). However, this is the first report of the pivaloyloxymethyl group being used as a protecting group for sulfur. In this study it was possible to condense I with chloromethyl pivalate in dimethylsulfoxide to give the monoalkylated derivative VI, albeit in very low yield especially compared with the good yields of V that were obtained above. The structure of VI followed from its UV and NMR spectra which were consistent with monoalkylation on sulfur[3]. Derivative VI was not tested in the diffusion cells because other, lower-melting representatives of this class of acylheteroalkylated I were more attractive candidates.

It was also possible to prepare dialkylated derivatives of I. Compound I was condensed with excess chloromethyl pivalate in the presence of base in dichloromethane to give a mixture of dialkylated products based on the NMR spectrum of the crude reaction product. Although chemical precedent (18) suggests that the S-alkylated product is formed as an intermediate, such as intermediate (VI) is much more soluble in dichloromethane than I and is more available than I itself for further reactions with chloromethyl pivalate. Thus, VI was not obtained as a product under these reaction conditions even when only one equivalent of chloromethyl pivalate was used; instead, unreacted I and the same mixture of the dialkylated products were obtained. Methyl iodide did not react with I in dichloromethane in the presence of triethylamine. On the other hand, chloromethylbenzamide did react to give two high-melting dialkylated products of undetermined structure. Their diffusion through skin was not studied because of their melting points.

[2] Based on mass spectral considerations, K. B. Sloan and Alice Ng, unpublished results.

[3] The UV absorption maxima for the 1-, 3-, 7-, or 9-monomethyl derivatives are all at much longer wavelengths (see Table I).

The structures of the dipivaloyloxymethylated products were determined by a combination of NMR and UV spectroscopy. The dialkylated products VII and VIII were assigned the S^6,9- and S^6,7-structures because their NMR spectra contained both SCH_2O and NCH_2O absorptions (Table II), and because their UV spectra were very similar to those of the corresponding S^6,9- and S^6,7-dimethyl derivatives of I (Table I);[4] the UV spectra are characteristic of the respective dialkyl substitution patterns in I.

The dialkylated product IX was assigned the S^6,3-dialkylated structure because its NMR spectrum contained the SCH_2O and NCH_2O groups and its UV spectrum contained a UV maximum at 326 nm. The only other possible sulfur, nitrogen-dialkylated I candidate which exhibits similar UV spectral properties to IX is the S^6,1-dialkylated structure. However, such structures are very unstable as the free base, while IX has been observed to be stable at room temperature for 2 years. The formation of IX is not surprising in view of the fact that the alkylation of I with methyl tosylate under neutral conditions gives S^6,3-dimethylmercaptopurine (22). Furthermore, since the reactions between triethylamine and chloromethyl pivalate and between triethylamine and VI were found to be incomplete reactions, there was ample opportunity for VI, rather than its ion, to react with chloromethyl pivalate.

The fourth product (X) that was isolated from the reaction mixture was also a dialkylated product, but its NMR spectrum lacked the SCH_2O absorption. Therefore, it was not an *S,N*-dialkylated product but rather a *N,N*-dialkylated product. The various possible *N,N*-dialkylated products arise by alkylation of a *S,N*-dialkylated product followed by *S*-dealkylation. In the case of the 3,7- or 3,9-dialkylated products, *S*-dealkylation only takes place by thio-hydrolysis and would not occur spontaneously under the above reaction conditions. On the other hand, 1,7- or 1,9-dialkylated products have been shown to form spontaneously from S^6,1,9- and S^6,1,7-trialkylated intermediates during the alkylation of 1-methyl-6-mercaptopurine (18) with methyl iodide or benzyl chloride, respectively. Thus, X is probably a 1,7- or 1,9-dialkylated product based on its NMR and UV spectra. To check the possibility that X was formed from further alkylation of the major product VII, VII was allowed to react for 2 days with chloromethyl pivalate either in excess or with triethylamine in excess; no reaction at all occurred. Since the only reactions leading to 1,7- or 1,9-dialkylated products start with 1-alkyl-6-mercaptopurine, it appears likely that in addition to initial *S*-alkylation of I some small amount of 1-alkylation also takes place under these reaction conditions and ultimately leads to the formation of X.

Compounds XI and XII were also prepared under basic conditions but in acetone using potassium carbonate as the base. The riboside hydroxyl groups in these cases were converted to their acetate esters to protect them from possible side reactions with chloromethyl pivalate. The structures of XI and XII follow from their UV and NMR spectra. The UV spectrum of XI is very similar to that of VII, which is characteristic of the S^6,9-substitution pattern of dialkylated 6-mercaptopurine. Both XI and XII exhibited an absorption at δ 5.90 in their NMR spectra, which is characteristic of the SCH_2O group.

The results from the diffusion studies with the *S*-acylheteroalkyl derivatives are shown in Table III. It is obvious that all of the *S*-alkylated prodrugs of I (except for Va) enhance the delivery of I to the receptor phase, and that in any comparison among prodrugs the lower melting prodrug is the one that produces the higher level of 6-mercaptopurine in the receptor phase (compare for instance VII and IX). Compounds VII, XI, and XII appear to be the most attractive candidates for screening in the hairless mouse model (6).

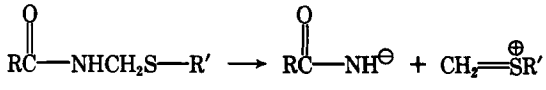
[4] The 1,9-, 1,7-, 3,7-, 3,9-, S^6,1-, and S^6,3-dimethyl derivatives all exhibit UV absorption maxima at much longer wavelengths and between the S^6,7- and S^6,9-derivatives the derivative exhibiting the shorter wavelength UV maximum is the S^6,9-dimethyl derivative.

The results from the diffusion studies also illustrate the advantage that soft alkylation enjoys over the more traditional approach, *i.e.*, esterification, to prodrug modification of the physical chemical properties of drugs. The triacetyl riboside of I (XIII), although marginally more effective than the riboside itself (XIV), is <7% as effective as the soft-alkylated prodrug based on the triacetylated riboside (XI). Thus, to significantly improve the delivery of I through the skin, it is imperative that the thione amide group be alkylated in a transient manner.

The prodrugs deliver very little if any of the intact prodrug to the receptor phase. This does not appear to be due to degradation of the prodrug in the receptor phase after diffusion of the intact prodrug, because even the earliest samples taken of the receptor phase (3 hr) show the same ratio of prodrug to 6-mercaptopurine, and the prodrugs are stable at pH 7.4 for that length of time (Table IV). The fact that primarily 6-mercaptopurine (I) and 2-amino-6-mercaptopurine (II) are found in the receptor phase after the absorption of the alkylated forms of I, its riboside, and the riboside of II, is a consequence of using fresh skin with metabolic systems that were still active and of the sensitivity of the nucleosides to nucleoside phosphorylase (23).

In the case of XII, it was impossible to determine quantitatively the amount of 2-amino-6-mercaptopurine or XII in the receptor phase. The major product appeared to be 2-amino-6-mercaptopurine (II), but there were a number of other unidentified products also formed which interfered with its analysis. Based only on the very small amount of XII remaining in the donor phase, it seems that XII is a very efficient prodrug form for the delivery of II or XVI.

It is interesting that the *S*-benzamidomethyl derivative Va hydrolyzed completely during its diffusion through the skin. Although the stability of *S*-benzamidomethyl cysteine (24) has not been reported, *S*-acetamidomethyl cysteine is reportedly completely stable at pH 13 and 1 (25). Apparently, amidomethyl derivatives of thioamides such as I are much more labile than those of aliphatic thiol groups. The mechanism for the hydrolysis of *S*-acetamidomethyl or *S*-benzamidomethyl groups is not known, but it may be similar to the mechanism proposed for the hydrolysis of amidomethylamines (26) which involves a unimolecular N—C cleavage as the rate-determining step. The relatively short $t_{1/2}$ in buffer which increases[5] with increasing methanol concentration (decreasing dielectric constant) suggests that such an interpretation has merit.



Based on the solubility data in Table IV, the prodrugs that were completely soluble in isopropyl myristate at the concentration at which they were applied were the prodrugs that gave the greatest absorption. Thus, since flux is directly proportional to concentration of the drug in the applied phase (27), it is possible, and even probable, that the reason that I and Va were not absorbed more completely was primarily that they were not soluble enough in the vehicle and, hence, not available for absorption while VII, XI, and XII were available. The prodrug approach in this case then may be considered (*a*) as a quasi-formulation approach to enhancing delivery which overcomes the poor solubility of the drug in a commonly used component of formulations or (*b*) as actually increasing the diffusivity of the prodrug in the skin. There is not enough information available to decide between these two explanations. However, this should not detract from the practical result that more I is delivered by using these *S*-acyloxymethyl prodrugs than by using I, XIII, or XIV.

There does not appear to be any linear correlation between the lipo-

[5] K. B. Sloan and Alice Ng, unpublished results.

Table IV—Physicochemical Characteristics of Thiopurines and Selected Prodrugs

Compound	Solubility, m*M*			log k' Methanol–Water 50:50	$t_{1/2}$ (hr) for Loss of Intact Prodrug at pH 7.4
	pH 7.4 Buffer	Isopropyl Myristate	Chloroform		
I	0.2	−0[a]	0.004	−0.336	
II				−1.074	
Va	0.003	0.42		0.820	0.53
VII		>10.0		1.659	
IX		0.74		1.142	
XI	0.02	>10.0	>2.0	1.260	31.2
XII	0.02	>10.0	>2.0	0.877	30.3
XIII	7.8	0.16	>2.0	0.735	25.6
XIV		0.01		−0.513	196

philic index log k' (28) generated from HPLC data and the absorption of the prodrugs.

Finally, from a practical point of view, since both VII and XI primarily deliver I, which is subsequently converted to the corresponding riboside phosphate by hypoxanthine–guanine phosphoribosyltransferase (29) *in vivo*, and the riboside XIV cannot be converted to its phosphate directly, the greater cost of the starting material (XIV compared with I) for XI balances the greater efficiency of delivery of I by XI. Thus, depending on the relative activity of VII and XI in inhibiting DNA synthesis in the hairless mouse model, VII may be the more practical prodrug form of I in spite of the fact that it actually enhances the delivery of I less than XI.

EXPERIMENTAL[6]

Synthesis of 6-Benzamidomethylmercaptopurine (Va)(Vb)—To a dimethylsulfoxide solution (4 ml) containing 0.80 g (0.0047 mole) of 6-mercaptopurine hydrate was added 0.90 g (0.0053 mole) of freshly prepared chloromethylbenzamide. The solution was stirred at room temperature overnight to give a suspension which was dissolved in 10 ml of chloroform, and then stirred with 1 ml of triethylamine for 30 min. The solution was diluted to 100 ml with dichloromethane and was then extracted with 50 ml of water. The water layer was quickly separated, because a precipitate formed in the dichloromethane layer immediately after the water wash. The dichloromethane suspension was filtered. The residue was dried to give 0.60 g (mp 205–211°, 45% yield) of Vb as white crystals. A 0.21-g sample of Vb was crystallized from methanol to give an analytical sample of Vb that was identical with the crude product by TLC, NMR, and IR spectroscopy: 0.19 g, mp 273.5–274.5°, IR (KBr) 1640 and 1660 cm^{-1} (s) (C=O); TLC (silica gel, ether–methanol, 10:3) R_f 0.52 (6-mercaptopurine R_f 0.47); ^1H NMR (DMSO-d_6) δ 9.77 (t, 1, J = 6 Hz, N—*H*), 8.0–7.73 (m, 2, aromatic *H*), 7.7–7.33 (s, 3, aromatic *H*), 5.47 (s, 1, imidazole N—*H*).

Anal.—Calc. for $C_{13}H_{11}N_5OS$: C, 54.74; H, 3.88; N, 24.56. Found: C, 55.03; H, 3.88; N, 23.99.

The dichloromethane filtrate from the above isolation of Vb was concentrated to give a yellow wax which was crystallized from methanol and dichloromethane to give 0.38 g (mp 206–208°, 29% yield) of Va as yellow crystals. A 65-mg sample of Va was recrystallized from 20 ml of chloroform to give 50 mg (*foamed at* 150°; resolidified at 175°; mp 222–223°) of Va as white crystals which was identical with the crude Va by TLC, NMR, and IR spectroscopy: IR (KBr) 1660, 1650, and 1640 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$-DMSO-d_6, 5:1) δ 8.0–7.73 (m, 2, aromatic *H*) and 7.7–7.33 (s, 3, aromatic *H*).

Anal.—Calc. for $C_{13}H_{11}N_5OS$·0.4 $CHCl_3$: C, 48.31, H, 3.45, N, 21.02 Found: C, 47.97; H, 3.05; N, 20.98.

When the chloroform solvate was heated to 200° for 2 min then cooled, the light-yellow solid (mp 215–218°) that was obtained exhibited only one spot upon TLC analysis and the same UV spectrum as the solvate.

Anal.—Calc. for $C_{13}H_{11}N_5OS$: C, 54.74; H, 3.89; N, 24.56. Found: C, 54.34; H, 3.66; N, 24.33.

6-Pivaloyloxymethylmercaptopurine (VI))—A dimethylsulfoxide solution (3 ml) containing 0.85 g (0.0057 mole) of chloromethyl pivalate was allowed to react with 0.63 g (0.00375 mole) of 6-mercaptopurine hydrate at room temperature overnight. The reaction mixture was processed as above. However, not all of the precipitate in the reaction mixture was soluble in the dichloromethane, and when that suspension was filtered 0.35 g (mp >270°, 56% recovery) of 6-mercaptopurine was obtained as a yellow solid. After the filtration, the dichloromethane solution was washed with water, but a precipitate did not form in the dichloromethane solution as above. The residue from the dichloromethane solution was chromatographed on silica AR CC-7 using ether as the eluent. An oil was obtained which was crystallized from hexane–dichloromethane to give a total of 25 mg (mp 179–182°, 2.5% yield, 5.7% conversion) of VI as white fibrous crystals: IR (KBr) 1740 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.2 [s, 9, (CH_3)$_3$C]; TLC (silica gel, ether) R_f 0.12. The 25 mg which had been used for the NMR sample was recrystallized from dichloromethane–hexane to give 11 mg (mp 189–190°) of an analytical sample of VI, which was identical with the crude product by IR spectroscopy and TLC.

Anal.—Calc. for $C_{11}H_{14}N_4O_2S$: C, 49.61; H, 5.30; N, 21.04. Found: C, 49.53; H, 5.34; N, 20.99.

Reaction of Chloromethyl Pivalate with 6-Mercaptopurine Hydrate: The Preparation of VII, VIII, IX, and X—To 2.0 g (0.0118 mole) of 6-mercaptopurine hydrate suspended in 10 ml of dichloromethane and 6 ml of triethylamine was added 5.28 g (0.035 mole) of chloromethyl pivalate. The reaction was stirred at room temperature overnight to give a suspension which was diluted to 100 ml with dichloromethane to give a clear-yellow solution. The solution was washed with water (50 ml), 10% concentrated HCl (50 ml), and water (50 ml) and then was dried over sodium sulfate and concentrated. The residue was triturated with 50 ml of ether and allowed to stand overnight. The suspension was filtered to give 0.40 g of IX as a yellow solid. This material was recrystallized from dichloromethane–ether (2:8 ml) to give 0.35 g (mp 193.5–195.0°, 8% yield) of IX as yellow crystals: IR (KBr) 1735 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.2 [s, 18, (CH_3)$_3$C]; TLC (silica gel, ether) R_f 0.0.

Anal.—Calc. for $C_{17}H_{24}N_4O_4S$: C, 53.66; H, 6.36; N, 14.73. Found: C, 53.68; H, 6.30; N, 14.80.

The ether filtrate described above was chromatographed on silica AR CC-7 using ether as the eluent to give three fractions. The first fraction was crystallized from petroleum ether (bp 37–42°)-heptane (20:15 ml) to give 2.05 g (mp 87–89°, 45% yield) of VII as white crystals: IR (KBr) 1735 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.18 [s, 18, (CH_3)$_3$C]; TLC (silica gel, ether) R_f 0.52.

Anal.—Calc. for $C_{17}H_{24}N_4O_4S$: C, 53.66; H, 6.36; N, 14.73. Found: C, 53.88; H, 6.51; N, 14.80.

The second fraction was crystallized from ether to give 17 mg (mp 135–137°, 0.3% yield) of VIII as yellow crystals: IR (KBr) 1735 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.18 [s, 18, (CH_3)$_3$C]; TLC (silica gel, ether) R_f 0.25.

Anal.—Calc. for $C_{17}H_{24}N_4O_4S$: C, 53.66, H, 6.36, N, 14.73. Found: C, 53.48; H, 6.41; N, 14.67.

The third fraction was also crystallized from ether to give 43 mg (mp 183–188°, 1% yield) of an unknown compound X: IR (KBr) 1720 and 1745 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.18 [s, 18, (CH_3)$_3$C]; TLC (silica gel, ether) R_f 0.21.

Anal.—Calc. for $C_{17}H_{24}N_4O_4S$: C, 53.66; H, 6.36; N, 14.73. Found: C, 53.60; H, 6.36; N, 14.69.

[6] TLC were run on Brinkman Polygram Sil G/UV 254; ether or ether–methanol mixtures. Melting points (uncorrected) were taken with a Thomas-Hoover Capillary apparatus. NMR spectra were recorded on a Varian T-60. IR spectra were obtained on a Beckman Accu Lab 4 infrared spectrophotometer. Microanalyses were obtained by Midwest Microlab, Ltd., Indianapolis, Ind. or by Atlantic Microlab, Atlanta Ga. The benzamide, chloromethyl pivalate, formaldehyde, acetyl chloride, and thionyl chloride were obtained from Aldrich. The 6-mercaptopurine, 6-mercaptopurine-9-riboside, 6-mercapto-2-aminopurine, 6-mercapto-2-aminopurine riboside, and 6-methylmercaptopurine were obtained from Sigma. The bulk solvents were obtained from Mallinckrodt. The hairless mice (SKH-hr-1) were obtained from the Temple University Skin and Cancer Hospital and the diffusion cells were obtained from Kercso Engineering Consultants., Palo Alto, Calif. The HPLC system was a Water Associates instrument using a Chrompack C_{18} column.

Preparation of 9-β-D-Ribofuranosyl-6-pivaloyloxymethylthio-9H-purine 2′,3′,5′-triacetate (XI)—Chloromethyl pivalate (112 mg) in acetone (10 ml) was allowed to react with sodium iodide (135 mg) in the dark for 40 min. The solution was decanted into a solution of 9-β-D-ribofuranosyl-6-thio-9H-purine 2′,3′,5′-triacetate (16) (254 mg, 0.00062 mole) in 30 ml of acetone. Potassium carbonate (1.0 g) was added to the resulting solution and the mixture was stirred in the dark. When the reaction was complete by TLC[7], the reaction mixture was filtered and the filtrate was evaporated. The residue was dissolved in ethyl acetate, and the solution was washed with water (three times), dried over sodium sulfate, and the solvent removed to yield a residue (350 mg, contaminated with traces of pivaloyloxymethyl halides) which was dissolved in ethyl acetate and filtered through silica gel (12.5 g). Compound XI was obtained as a pale white waxy solid (296 mg 91%) and showed one spot on TLC: IR (neat) 1755, cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$)δ 1.10 [9, s, $(CH_3)_3C$], 2.03 (3, s, CH_3CO_2), 2.06 (3, s, CH_3CO_2), 2.15 (3, s, CH_3CO_2), 4.43 (3, $CH_2OAc + 4'H$), 5.70 (1, m, 3′H), 6.0 (1, 6, 2′H), 6.25 (1, d, 1′H); TLC (silica gel, ethyl acetate–chloroform, 1:1) R_f 0.32; exact mass calculated for $C_{22}H_{28}N_4O_9S$ (m/z) 524.1575 (M^+): Found, 524.1561 (m/z).

Preparation of 9-β-D-Ribofuranosyl-2-amino-6-pivaloxymethylthio-9H-purine 2′,3′,5′-triacetate (XII)—To a solution of chloromethyl pivalate (106 mg) in acetone (15 ml) was added sodium iodide (130 mg). The suspension was stirred for 35 min while protected from light. The supernatant was decanted from the precipitated sodium chloride and added to a solution of thioguanosine triacetate (16) (250 mg, 0.00059 mole) in acetone (25 ml). Potassium carbonate (1.0 g) was added to the reaction mixture, stirring was continued for 69 hr, and then the suspended solid was filtered and washed with acetone. The filtrate was evaporated to dryness. The residue was dissolved in ether, and the resulting solution washed with water (three times), dried over sodium sulfate, and then the solvent was evaporated. The residue was purified by chromatography on silica gel (12.5 g, chloroform–ethyl acetate 1:1), to give the pivaloyloxymethyl derivative XII (82 mg, 57.4%) as a foam which showed one spot on TLC: IR (film) 3380 and 3490 cm^{-1} (s) (NH) 1738 cm^{-1} (s) (C=O); ^1H NMR ($CDCl_3$) δ 1.15 [9, s, $(CH_3)_3C$] 2.05 (3, s, CH_3CO_2), 2.08 (3, s, CH_3CO_2), 2.13 (3, s, CH_3CO_2), 4.41 (3, s, $CH_2OAc + 4'H$), 5.20 (2, s, NH_2), 5.80 (1, broad, 3′H), 5.96 (1, t, 2′H), 6.0 (1, d, 1′H); exact mass calculated for $C_{22}H_{29}N_5O_9S$, 539.1683 (m/z): Found, 539.1680 (m/z); TLC (silica gel[3], ethyl acetate–chloroform, 1:1) R_f 0.32.

Diffusion Cell Studies—Full thickness dorsal skin of 12- to 14-week-old female hairless mice was used. The mice were sacrificed by snapping the spinal cord. The excised skin was gently scrapped to remove fat and visceral debris and then gently secured over the diffusion cell with a rubber gasket. The diffusion cells themselves have been previously described (17). The receptor side of the cell (43 ml) was filled with pH 7.4 isotonic phosphate buffer containing 100-ppm gentamicin, which was stirred magnetically. The compounds were applied as 0.01 *M* solutions or suspensions in 500 μl of isopropyl myristate to the donor side of skin. The cells were kept at 32° and 1-ml samples were removed at 3, 9, 24, and 48 hr; 1 ml of buffer was added to the receptor after each sample was withdrawn. Samples were frozen immediately after they were taken and stored at 0° until analyzed. Controlled studies showed that using this procedure, no change in the sample composition took place during the cold storage time. After 48 hr the donor side was washed with 25 ml of methanol, and the methanol and buffer samples were analyzed for the prodrug and its parent drug by high-performance liquid chromatography (HPLC). The HPLC analysis was performed at 25° using mixtures of methanol and distilled water as the mobile phase and a flow rate of 1–2 ml/min. The results for each compound studied are for four diffusion cells.

Solubility Studies—The lipophilic indices ($\log k' = \log [(t_r - t_0)/t_0]$, where t_r is the retention time and t_0 is the elution time of solvent) for the prodrugs were determined by HPLC using mixtures of methanol and distilled water on Chrompack C_{18} column at 25°. There was no effect of pH 3–10 of the mobile phase on the retention time of the prodrugs Va, VII, IX, XI, and XII; of pH < 7.5 on the retention time of XIII; and of pH < 4 on the retention time of I and XIV. A plot of log *k′ versus* percent methanol was linear in each case over four methanol–water concentrations. The values for log *k′* are given in Table IV along with some miscellaneous solubility data. These solubilities were obtained by suspending an excess of the drug or prodrug in the appropriate solvent and sonicating the suspension for 20 min. The suspension was then quickly equilibrated at 37° and centrifuged. The supernatant was then filtered, diluted with more of the solvent, and analyzed by HPLC using the above conditions.

Stability Studies—The rates of degradation of the thiopurines and their prodrugs were determined by adding 50 μl of a 0.025 m*M* methanol solution of the compound to 10 ml of a pH 7.4 phosphate buffer solution at 37°. The solutions were shaken vigorously and then stirred magnetically during sampling. Samples were stored at 0° until analyzed. Analysis was accomplished by HPLC using the above conditions.

Sustained Release of Theophylline from Hydroxypropylcellulose Tablets

MASAHIRO NAKANO *x, NAOKO OHMORI *, AKO OGATA ‡, KAZUKO SUGIMOTO *, YUKIKO TOBINO *, REIKO IWAOKU *, and KAZUHIKO JUNI *

Received November 27, 1981, from the **Department of Pharmaceutical Services, Kumamoto University Hospital, 1-1-1 Honjo, Kumamoto 860, Japan* and the ‡*Faculty of Pharmaceutical Sciences, Hokkaido University, Kita-ku, Sapporo 060, Japan.* Accepted for publication September 24, 1982.

Abstract □ Compressed tablets were prepared from theophylline and hydroxypropylcellulose. Effects of the viscosity grades of the polymer, the mixing ratios of two polymers with different viscosity grades, and the polymer contents in the tablets on release patterns of theophylline were examined *in vitro*. Release rate was decreased with increasing viscosity designation and polymer contents in the tablets. In salivary level profiles of theophylline following oral administration of sustained-release tablets to five human volunteers, a low but sustained level was noted indicating sustained release of the drug from the tablets *in vivo*.

Keyphrases □ Theophylline—hydroxypropylcellulose tablets □ Hydroxypropylcellulose—viscosity grades, mixing ratio, contents □ Compressed tablets—sustained release *in vitro*, oral administration □ Salivary levels—reverse-phase high-performance liquid chromatography

Since most of the commercially available water-soluble cellulose derivatives (1) are considered to be stable against microbial attack and safe when ingested orally, it appeared to be worthwhile to evaluate them as suitable materials for sustained-release preparations.

Although several studies have reported the sustained release of drugs from compressed hydrophilic matrices prepared from cellulose derivatives (2–8), few have examined the relationship between release rates *in vitro* and drug concentration profiles in body fluids (7).

Following the examination of representative viscosity grade polymers of methylcellulose, sodium carboxymethylcellulose, hydroxypropylmethylcellulose, and hydroxypropylcellulose, hydroxypropylcellulose was selected for further studies, since it exhibited release patterns suitable for a sustained-release preparation.

In the present study, modification of the release rate of theophylline from compressed hydroxypropylcellulose tablets was examined by changing viscosity grades of the polymer, mixing ratios of two polymers with different viscosity grades, and changing polymer contents in the tablets. Theophylline was used as a representative drug, since sustained-release formulations are desirable because of the short elimination half-life in humans, especially in children (9). To evaluate body fluid level profiles of theophylline in volunteers, saliva levels were measured, since correlation of serum and saliva theophylline concentrations after administration of a sustained-release preparation has been reported (10).

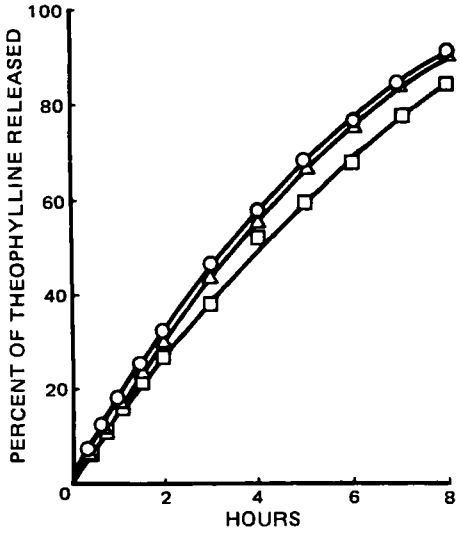

Figure 1—*Release profiles of theophylline from tablets prepared from 1:1 mixture of theophylline (250 mg) and hydroxyproylcellulose (1:1 mixture of low- and medium-viscosity grades) by compressing the drug–polymer mixture for 5 sec (○), 30 sec (△), or 120 sec (□). Average of three determinations.*

EXPERIMENTAL

Materials—Three viscosity grades of hydroxypropylcellulose[1] were used. Theophylline (anhydrous) and 7-(2-hydroxyethyl)theophylline were used as supplied [2]; and all other chemicals were of reagent grade.

Preparation of Tablets—Flat-faced tablets (500 mg, 13-mm diameter, and ~3-mm thickness) were prepared by compressing mixtures of theophylline and hydroxypropylcellulose directly under 180 kg/cm^2 for 30 sec using a potassium bromide tablet die and a hydraulic press[3].

To examine the effect of compression pressure on drug release, pressures of 60, 180, or 540 kg/cm^2 were applied to the drug–polymer mixture for 30 sec. To examine the effect of compression periods on drug release, a compression pressure of 180 kg/cm^2 was applied to the drug–polymer mixture for 5, 30, or 120 sec.

Release Studies—A tablet was suspended by means of a polyethylene net in a 200-ml release medium in a wide-mouthed bottle. Since the release rate of theophylline from hydroxypropylcellulose tablets is not very dependent on the pH values of the medium, a 0.2% NaCl solution, ad-

Sustained Release of Theophylline from Hydroxypropylcellulose Tablets

MASAHIRO NAKANO *x, NAOKO OHMORI *, AKO OGATA ‡, KAZUKO SUGIMOTO *, YUKIKO TOBINO *, REIKO IWAOKU *, and KAZUHIKO JUNI *

Received November 27, 1981, from the **Department of Pharmaceutical Services, Kumamoto University Hospital, 1-1-1 Honjo, Kumamoto 860, Japan* and the ‡*Faculty of Pharmaceutical Sciences, Hokkaido University, Kita-ku, Sapporo 060, Japan.* Accepted for publication September 24, 1982.

Abstract □ Compressed tablets were prepared from theophylline and hydroxypropylcellulose. Effects of the viscosity grades of the polymer, the mixing ratios of two polymers with different viscosity grades, and the polymer contents in the tablets on release patterns of theophylline were examined *in vitro*. Release rate was decreased with increasing viscosity designation and polymer contents in the tablets. In salivary level profiles of theophylline following oral administration of sustained-release tablets to five human volunteers, a low but sustained level was noted indicating sustained release of the drug from the tablets *in vivo*.

Keyphrases □ Theophylline—hydroxypropylcellulose tablets □ Hydroxypropylcellulose—viscosity grades, mixing ratio, contents □ Compressed tablets—sustained release *in vitro*, oral administration □ Salivary levels—reverse-phase high-performance liquid chromatography

Since most of the commercially available water-soluble cellulose derivatives (1) are considered to be stable against microbial attack and safe when ingested orally, it appeared to be worthwhile to evaluate them as suitable materials for sustained-release preparations.

Although several studies have reported the sustained release of drugs from compressed hydrophilic matrices prepared from cellulose derivatives (2–8), few have examined the relationship between release rates *in vitro* and drug concentration profiles in body fluids (7).

Following the examination of representative viscosity grade polymers of methylcellulose, sodium carboxymethylcellulose, hydroxypropylmethylcellulose, and hydroxypropylcellulose, hydroxypropylcellulose was selected for further studies, since it exhibited release patterns suitable for a sustained-release preparation.

In the present study, modification of the release rate of theophylline from compressed hydroxypropylcellulose tablets was examined by changing viscosity grades of the polymer, mixing ratios of two polymers with different viscosity grades, and changing polymer contents in the tablets. Theophylline was used as a representative drug, since sustained-release formulations are desirable because of the short elimination half-life in humans, especially in children (9). To evaluate body fluid level profiles of theophylline in volunteers, saliva levels were measured, since correlation of serum and saliva theophylline concentrations after administration of a sustained-release preparation has been reported (10).

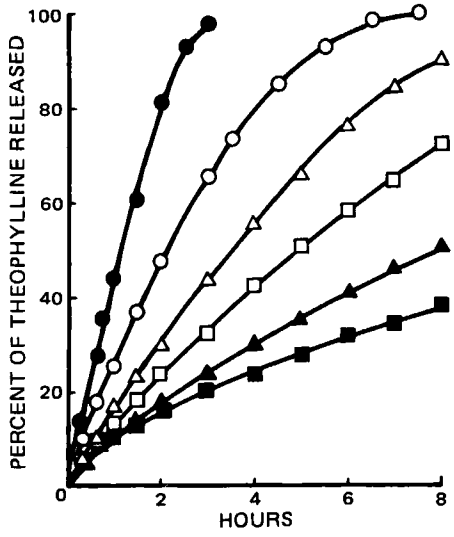

Figure 2—*Release profiles of theophylline from tablets prepared from 1:1 mixture of theophylline (250 mg) and hydroxypropylcellulose of various compositions. Average of three determinations. Key: Viscosity grades of the polymer: (●) low; (▲) medium; (■) high-viscosity grade polymer, and (○) (3:1) (△), 1:1, and (□) 1:2 mixtures of low- and medium-viscosity grade polymers.*

justed to pH 1.2 was used as a release medium. The medium was kept at 37° and stirred with a magnetic stirrer. At predetermined intervals, 1-ml portions of the medium were pipetted for the spectrophotometric determination of the theophylline concentration at 272 nm after dilution with 0.2 *M* acetate buffer, pH 5.0.

Measurement of Salivary Levels in Human Volunteers—Five healthy volunteers, two males and three females (23–31 years of age), participated in the study. To eliminate ingestion of theophylline from other sources and possible formation of theophylline *in vivo* following intake of caffeine (11), the subjects were told to abstain from any drinks containing caffeine. Blank saliva samples were collected a few minutes before administering the preparation. After overnight fasting, a single 250-mg dose of theophylline powder (as a fast-dissolving preparation) or a hydroxypropylcellulose tablet (as a sustained-release preparation) containing the same amount of the drug was administered, with 100-ml water, wrapped in a wafer sheet to eliminate possible contact of the drug with mucosa of the mouth. Saliva samples were collected at appropriate intervals up to 24 hr. A small amount (~10 mg) of citric acid, a salivary flow stimulant, was put on the tongue and held in the mouth for 1–2 min, then a 2-ml sample of the saliva was collected in a test tube and kept frozen until analysis. No food was taken for 4 hr postdose. A crossover design was used and a minimum interval of 1 week was allowed between trials.

Analysis of Theophylline Levels in Saliva—Reverse-phase high-performance liquid chromatography for theophylline in saliva (12) was employed using 7-(2-hydroxyethyl)theophylline as an internal standard. A liquid chromatograph[4] equipped with UV detector set at 270 nm and a reverse-phase-type column (Zorbax ODS, 4.6 ϕ × 0.25 m) was used.

RESULTS AND DISCUSSION

Effect of Compression Pressure and Compression Period on Drug Release—Figure 1 shows the release patterns of theophylline from tablets prepared by compressing the drug–polymer mixture for various periods. Only a slight decrease in release rate was observed with 6- and 24-fold increases in compression period.

In the examination of the effect of compression pressure on release rate, three pressure levels covering a ninefold change in pressure were applied to the mixture. Release patterns (not shown) of theophylline from tablets thus prepared were practically superimposable. Thus, compression pressure and compression period are not important factors in modifying the release pattern of the drug.

Effect of Viscosity Grades of the Polymer—Figure 2 shows the release patterns of theophylline from tablets with 250 mg of theophylline and 250 mg of one of three viscosity grades of hydroxypropylcellulose.

[4] Model LC-3A, Shimadzu Manufacturing Co., Kyoto.

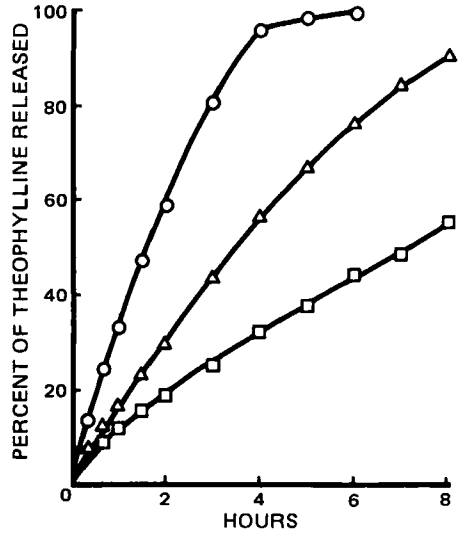

Figure 3—*Release profiles of theophylline from tablets prepared from (○) 1:1/3, (△) 1:1 and (□) 1:3 mixtures of theophylline (250 mg) and hydroxypropylcellulose (1:1 mixture of low- and medium-viscosity grade polymers). Average of three determinations.*

The drug release rate was fast from the tablets made of the low-viscosity grade polymer, while the release rate was slow from tablets made of the polymers of medium- and high-viscosity grades. Therefore, tablets made from mixtures of low-viscosity grade polymer and medium-viscosity grade polymer in the mixing ratios, as shown in Fig. 2, were examined to obtain an appropriate release rate. With an increase in the contents of the medium-viscosity grade polymer, the release rate was decreased. Therefore, the drug release rate can be modified by changing the mixing ratio of two polymers with different viscosity grades depending on the required sustained period.

To examine a release mechanism of theophylline from compressed hydrophilic tablets, the amount of the drug released was plotted (not shown) against square root of time according to the Higuchi equation (13). The lines obtained were upward curves, indicating a different release mechanism from that expected from the Higuchi equation for release of drug from solid matrices. The tablet expanded as water penetrated forming a layer of gel on the surface of the tablet, but it gradually eroded afterward. Thus the following processes are likely to operate: penetration of water through matrices to form a gel in the outer layer, dissolution of a drug in the gel, permeation of the drug through the gel, release of the drug from the gel to a release medium, and slow dissolution of the gelled polymer in the outermost layer in the release medium.

Effect of Polymer Contents—Figure 3 shows the release patterns of theophylline from three tablets containing the same amount of the drug

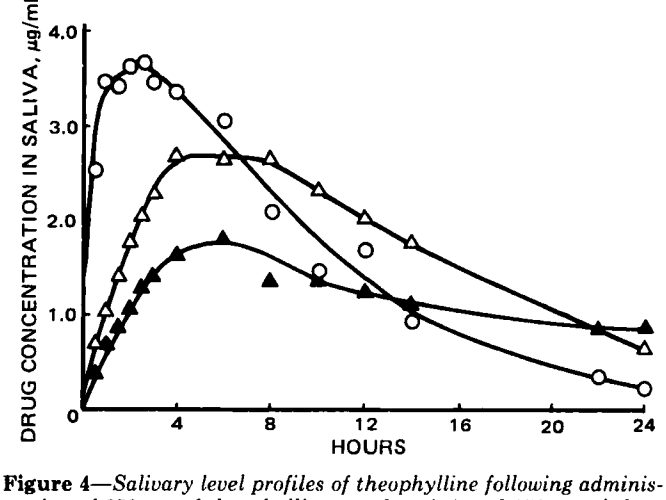

Figure 4—*Salivary level profiles of theophylline following administration of 250 mg of theophylline powders (○) and 250 mg of theophylline–250 mg of hydroxypropylcellulose [1:1 mixture of low- and medium-grade polymers (△) or medium-viscosity grade polymer alone (▲)] tablets to volunteers. Average of five subjects.*

but different amounts of the polymer. The polymer mixture used in the test was a 1:1 mixture of the low-viscosity grade polymer and the medium-viscosity grade polymer. As expected, the drug was released from tablets more slowly with an increase in polymer contents; therefore, the release rate of the drug can be modified by changing the polymer contents in the tablets.

Salivary Levels Following Oral Administration—In Fig. 4, the average salivary levels of theophylline following oral administration of two kinds of sustained-release tablets were compared with those of fast-dissolving powders. After the administration of the tablets, salivary levels were lower at earlier hours but higher afterward compared with salivary levels following administration of powders. The lowest salivary levels observed after administration of the tablet prepared from the medium-viscosity grade polymer reflect a slow release rate, as shown in Fig. 2, demonstrating that different drug level profiles in body fluids are obtainable by modifying the release patterns of drug. Although it is shown that the rate of bioavailability is decreased with a decrease in release rate *in vitro*, the effect of release rate on the extent of bioavailability has to be examined by extending sampling periods to 36–48 hr.

The present study demonstrated that the release of theophylline from compressed tablets prepared from hydroxypropylcellulose can be modified by changing viscosity grades of the polymer, mixing ratios of two polymers with different viscosity grades, and changing polymer contents in the tablets. Sustained-release *in vitro* is reflected in drug level curves after oral administration of sustained-release tablets.

Characterization of Spray Patterns of Inhalation Aerosols Using Thin-Layer Chromatography

ERIC J. BENJAMIN, JOSEPH J. KROETEN, and EFRAIM SHEK ˣ

Received November 27, 1981 from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication May 5, 1982.

Abstract □ The spray pattern of an inhalation aerosol was characterized using photography and by observing the impaction pattern on a TLC plate. The aerosol plume was conical in shape, and its cross section increased with increasing distance from the actuator. Three puffs of the aerosol, at a distance of 3 cm between actuator and the TLC plate, produced a spot that had approximately the same diameter as the cross section of the aerosol plume at that distance from the actuator. The TLC technique with these parameters was selected to develop an assay characterizing the spray pattern of an inhalation aerosol because of its specificity, simplicity, and speed.

Keyphrases □ Aerosols, inhalation—spray pattern characterizations using photography and TLC □ TLC—characterization of spray patterns for inhalation aerosols □ Spray patterns—of inhalation aerosols, characterized by TLC and photography

Pressurized inhalation aerosols are generally used for drug administration into the lower respiratory tract. Only a minor part of the dose administered reaches the lung directly (1–3). Recently, using an *in vivo* radioactive technique, it was estimated directly that an average 8.8% of the administered dose was deposited in the lungs with 80% deposited in the mouth (4). The remainder of the drug (9.8%) was either exhaled or deposited in the aerosol actuator. Various test methods for the control of aerosol products have been developed (5–7). These include tests for net contents, medication delivered per dose, particle size distribution, valve delivery, vapor pressure, leakage rate, moisture contents, and spray pattern.

One of the important objectives in developing an aerosol product is to obtain the spray pattern best suited for the intended application. Various factors can affect the spray pattern. These factors are the design of the valve and the actuator, the pressure in the container, and its content composition (8, 9). The spray pattern is affected by the size and shape of the actuator orifice as well as by the valve (10). Therefore, characterization of spray patterns is important for evaluating the valve and actuator performances. In addition to its pattern, other tests generally used to characterize the spray are particle size distribution of the drug substance delivered and spray angle (11).

Several methods have been devised to record and compare the spray pattern of aerosol products. One method is based on the impingement of the spray on a piece of paper, glass, silica gel, or paper that has been treated with a dye–talc mixture (12, 13). Photographic (14) and laser holographic[1] methods also have been used. Miszuk *et al.* (15) recently described a technique that utilizes two orthogonal video images. These methods are best suited for solution aerosols in which the active ingredient is dissolved

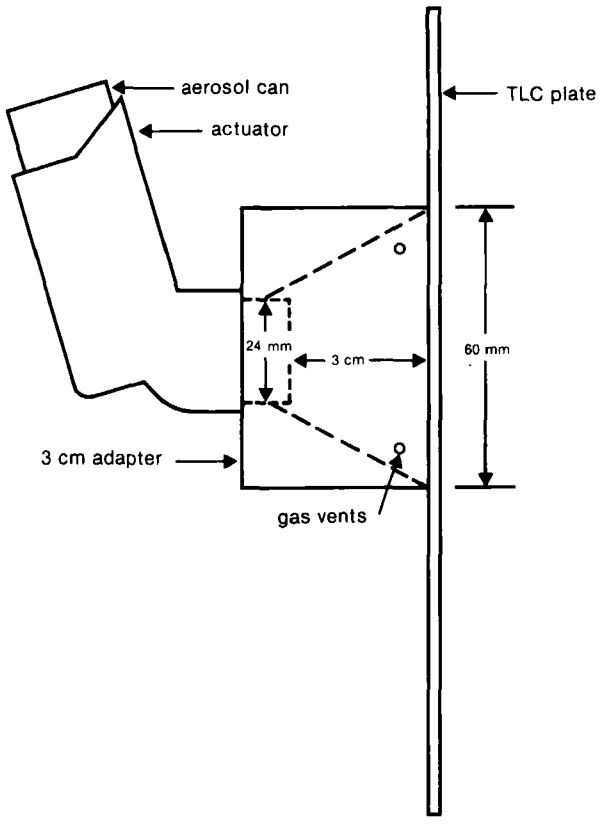

Figure 1—*Equipment and setup used to test the plume of corticosteroid aerosol by TLC method.*

in the solvent/propellant. In the case of heterogeneous aerosols (*e.g.*, suspensions), a major portion of the resulting spray consists only of the propellants. In such cases the aforementioned methods, being nonselective, do not provide sufficient information about distribution of the solid drug particles in various regions of the spray. The purpose of this study was to develop a specific method to characterize the spray pattern with respect to drug distribution in a plume pattern of an heterogeneous inhalation aerosol system.

EXPERIMENTAL

Materials—The aerosol formulations consisted of a suspension of micronized corticosteroid in a chlorofluorocarbon propellant system containing a surfactant. Dosage was controlled by a metered aerosol valve[2], with a 50-μl metering chamber and stainless steel stem. The valve gave a metered puff of formulation upon each actuation. The actuation of the valve was effected by a plastic actuator[2], also serving as a mouthpiece.

Four actuators were selected for this study. Three of them were modified as follows: the orifice diameter of actuator 2 was reduced to 0.483 mm; the orifice diameter of actuator 3 was enlarged to 0.864 mm; and the orifice exit angle with respect to the axis of the delivery tube for actuator 4 was changed and the orifice diameter was reduced to 0.406 mm. Actuator 1 was used as manufactured, with an orifice size of 0.533 mm.

Photography—Photographs of the spray were taken using a camera[3] with a 127-mm lens which was loaded with black and white film[4]. The aperture was set at f/16 and the shutter speed set at 0.5 sec. A flood light[5] was used to illuminate the aerosol plume from below. The actuator and shutter release were coordinated manually.

TLC Method—A plastic adapter was attached to the actuator. These were used to actuate an aerosol can to deliver a spray on a 20 × 20-cm silica gel TLC plate[6] from a fixed distance. The resulting spot was observed and outlined under UV light. Both the long and the short diameters of the spot were measured. The equipment and setup used is diagrammed in Fig. 1.

Corticosteroid Contents—In addition to measuring the diameters of the spots, corticosteroid contents in the spot were also determined. This was accomplished by scraping the silica gel corresponding to the spot from the plate and transferring it quantitatively into a test tube. This was followed by extraction of the corticosteroid with ethanol and quantitation by blue tetrazolium colorimetry (16).

Particle Size Distribution—The actuator was connected to the air sampler[7] by a stainless steel tubular throat. The nozzle of the aerosol can was inserted into the actuator, and a fixed number of puffs were sprayed into the eight-stage air sampler. The airflow through the air sampler was set at 28.5 liters/min. The acutator, throat, and the various stages were rinsed with ethanol. The corticoid deposited on the various stages was quantitated by reverse-phase high-performance liquid chromatography (HPLC) using an octadecylsilane column[8]. The mobile phase was water–acetonitrile (65:35) containing 1% acetic acid.

Table I—Cross Sections of Aerosol Plumes at Various Distances from the Actuator [a]

[a] Measurements were taken from photographs.

RESULTS AND DISCUSSION

Photography—The photograph of an aerosol plume generated using actuator 1 (unaltered) shows that the plume is conical, symmetrical, and ~31–33 cm in length (Fig. 2). Photographs of six sprays using two actuators (1A and B) were taken. The widths of the aerosol plumes at various distances from the actuator were measured from these photographs. The data are given in Table I, and a plot of the plume width *versus* distance from actuator is shown in Fig. 3.

An ideal aerosol plume is considered to be a symmetrical cone of optimum apical angle to provide considerable clearance from the mouthpiece of the actuator (15). In addition, there should be only a few large particle dropouts from the spray cone (14). Actuator 1 yielded a plume consistent with the above criteria. However, the plumes produced by actuators 2, 3, and 4 (modified) had one or more deviations from such an ideal plume (Fig. 2). The actuator with the small orifice (actuator 2) yielded a misty and irregular-shaped spray with considerable amounts of streaks (dropouts). The apical angle appeared to be large and resulted in inadequate clearance from the actuator nozzle. The plume yielded by actuator 4 had about the same characteristics as 2. In addition, there was a displacement of the plume from the center and more dropouts. The effect of actuator 3 on the plume shape was not very obvious; however, the plume had a slightly larger apical angle and more dropouts than the regular actuator. This demonstrates that photography is capable of differentiating some defects in the actuators.

TLC Method—The spots effected by spraying the aerosol onto a TLC plate using the regular actuator (actuator 1) were circular in shape (Fig. 4). They consisted of an inner dark area surrounded by an outer diffused zone. The size of the spot varied with the number of puffs sprayed and the distance between the TLC plate and the actuator. The average diameter of the spot as a function of the number of puffs sprayed and the distance from the actuator is given in Table II, and graphical representations are shown in Fig. 3. For any fixed distance between the TLC plate and the actuator, the diameter of the spot increased with increasing number of puffs.

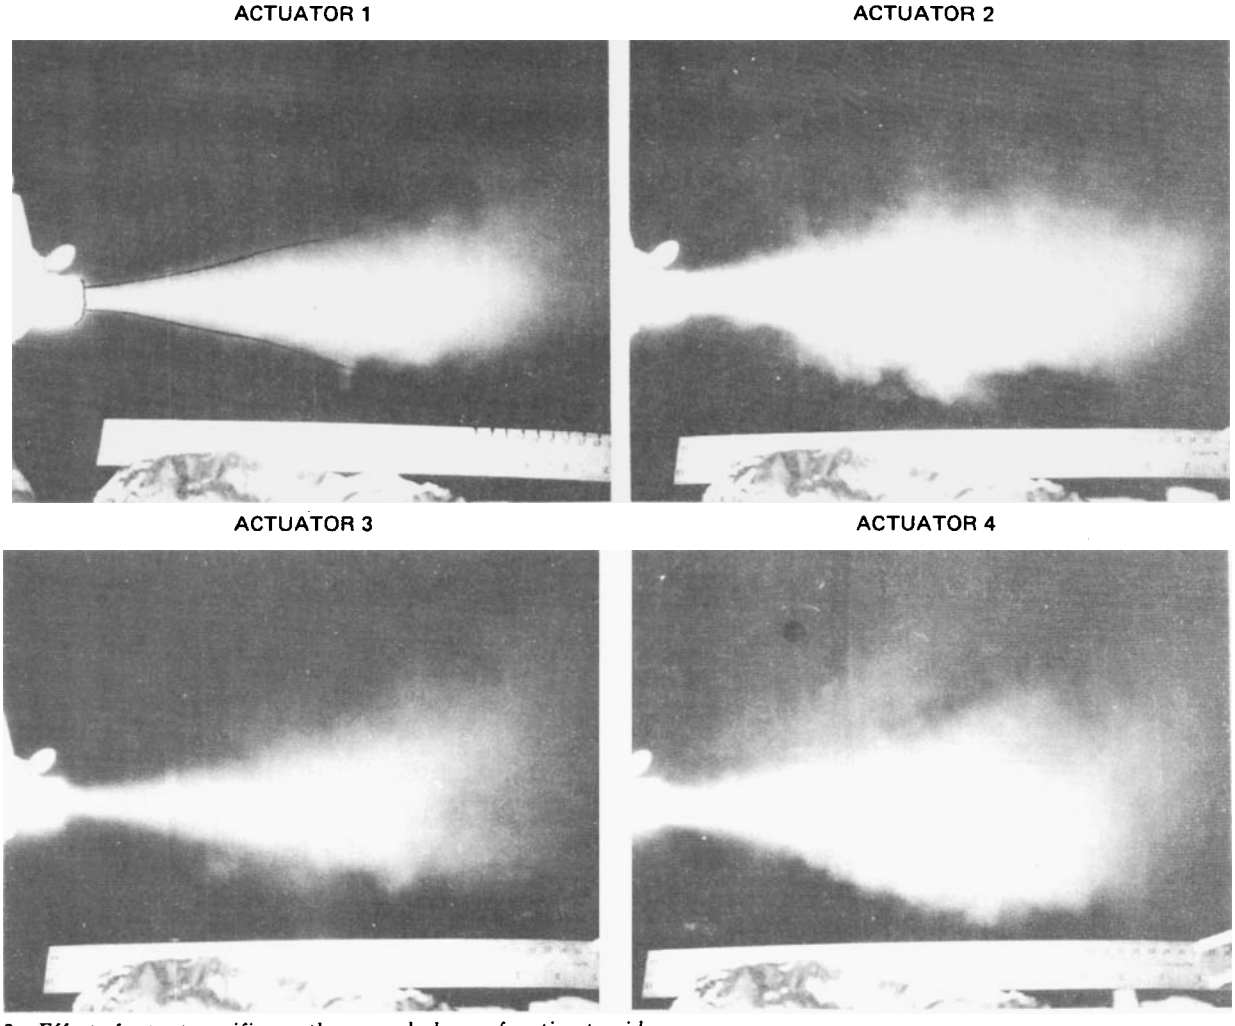

Figure 2—*Effect of actuator orifice on the aerosol plume of corticosteroid.*

Examination of the effect of varying this target distance, however, yielded some interesting facts. When three or fewer puffs were used, the diameter of the spot decreased with increasing distance from the actuator. On the other hand, the use of five or more puffs resulted in larger spot size with increase in distance from the actuator. Assuming that the aerosol plume has a conical shape (as shown by photography, Fig. 2), one would expect an increase in the size of the spot with increasing distance of the TLC plate from the actuator, irrespective of the number of puffs sprayed. This discrepancy could be due to the fact that photography does not distinguish between drug substance particles and propellant droplets in the plume. Thus, photography gives no indication of the drug substance density gradient in the aerosol plume (*i.e.*, between the center and outer part). On the other hand, the TLC method directly examines drug substance particles in the cross section of the plume, as the spot on the TLC plate (being the only UV absorbing species) is mainly produced by the drug. It is possible that the effective plume (containing the drug substance) is really a narrow jet burst rather than an expanding conical spray. Thus, the drug substance might be denser, to some extent, in the center of the plume cross section than at its outer zone. As more puffs are sprayed onto the TLC plate the concentration of the drug in the outer zone now increases and contributes to the observable diameter of the spot. This is consistent with the increase in the diameter of the TLC spot with increasing number of puffs sprayed.

The shapes of the spots (outlines) produced from the aerosol unit using four different experimental actuators are shown in Fig. 4. Using the regular actuator (actuator 1) a circular spot was produced. The modified actuators produced distinctly distorted spots. Actuator 3 with the largest orifice produced a slightly oval or kidney-shaped spot. Actuators 2 and 4 gave crescent-shaped spots indicating deflection of the spray from the actuator nozzle due to its displacement from the center. This information indicates that the TLC method is equal or better than photography in detecting defects in the size and shape of the actuator orifice. Moreover,

Table II—Diameters of the TLC Spots Produced by Spraying Various Puffs of the Inhalation Aerosol at Various Distances from the Actuator

Distance from the Actuator, cm	Mean Diameter[a] ± *SD*, mm

the TLC method being specific for the drug substance itself provides direct information about the spray pattern of the latter rather than the propellant or solvent.

Correlation of Drug Contents and Dimensions of the TLC Spot—The contents of the drug substance in the TLC spot produced by spraying three puffs of the aerosol at various distances between the TLC plate and the actuator were quantified using blue tetrazolium colorimetry. The data are presented in Table III, and the correlation of the surface area of the spot with the drug recovered is shown in Fig. 5. The data indicate that the surface area of the spot appears to be a good indicator of the drug content in various sections of the observed plume. Table IV shows the recoveries of drug substances from TLC spots that were produced by spraying various puffs of aerosol from a distance of 3 cm from the TLC plate. The recovery of the drug appears to have a reasonably linear correlation (Table V) with the number of puffs, as shown in Fig. 6. This indicates that the drug is quantitatively deposited in the observed spot on the TLC plate under the conditions of the plume geometry test.

Usually a portion of the drug emitted from the valve deposits on the inside of the actuator and is unavailable to the patient. The medication delivered to the patient therefore, is, the amount of drug actually available at the mouthpiece of the actuator. This and other delivery characteristics of the regular (actuator 1) and the defective (actuators 2, 3, and 4) actuators were compared utilizing an air sampler. The air sampler consisted of seven stages. These stages can separate the aerosol particles into seven fractions ranging from an 11.0 to a 0.44-μm aerodynamic diameter. This sampling device can be used as an *in vitro* model for the respiratory tract. As such it simulates, to a reasonable extent, the distribution and retention of inhaled drug particles in the human lungs. The total recovery of the drug, medication delivered to the patient, and percent of drug deposited on the actuator, the tubular throat, and various stages of the air sampler are presented in Table VI. The total recovery of the drug substance was about the same for each actuator. The percent of drug substance deposited on the actuator was considerably higher using the defective actuators; consequently, the amount of medication delivered to the patient was markedly less for these defective actuators. These results are in excellent agreement with those obtained using the TLC method to define the spray pattern. Actuators 2, 3, and 4 produced distorted spots (Fig. 4), and therefore, it was expected that a greater portion of the drug emitted from the aerosol unit in these cases would be deposited on the actuator.

Another parameter of interest was the particle size distribution of the drug substance in the emitted aerosol. This is important since the indi-

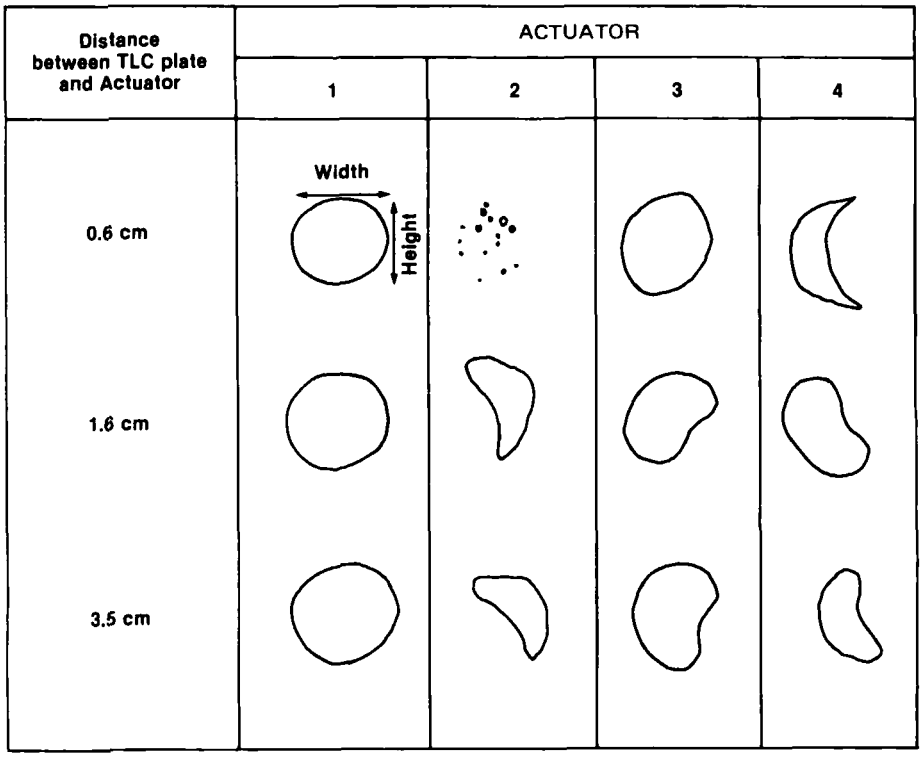

Figure 4—*Spot shapes produced by spraying from the aerosol unit on a TLC plate using the various actuators.*

vidual drug particles are destined for delivery to the lung, and efficiency of the bronchial delivery is dependent on the effective aerodynamic particle size. It was suggested that the effective aerodynamic particle size of drugs for delivery into the lung is <5 μm (17). The percent of drug substance deposited on the various stages of air sampler is included in Table VI. The effective aerodynamic size of particles deposited on stages 2–6 of the air sampler is considered to be <7 μm[9]. Actuator 3 delivered substantially fewer particles <7-μm aerodynamic size because of higher depositions on the throat and actuator. When actuator 2 was used a crescent-shaped spot was observed on the TLC plate (Fig. 4), and the largest amount of the drug substance was deposited on the actuator while the least amount was deposited on the throat. However, this did not affect the amount of particles expected to reach the lungs. Actuator 4, which also yielded a crescent-shaped spot on the TLC plate, showed slightly lower recoveries of particles <7 μm due to larger deposit on the actuator (compared with actuator 1) as well as on the throat stage (compared with actuator 2).

CONCLUSIONS

The TLC method for characterization of the spray pattern of inhalation aerosols is specific for the drug substance. Therefore, this method provides direct information about the distribution of the drug particles in the spray rather than the general pattern of the propellant or solvent in the spray. Such information is extremely useful in cases of heterogeneous aerosols. In addition, the TLC method is capable of detecting defects in the size and shape of the actuator orifice. Thus, the TLC technique, because of its specificity, simplicity, and speed, can be used as a good incoming quality control tool to evaluate actuators and valve performances.

Esterase-Like Activity of Human Serum Albumin II: Reaction with *N-trans*-Cinnamoylimidazoles

NAOKO OHTA, YUKIHISA KURONO, and KEN IKEDA ˣ

Received March 1, 1982 from the *Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya, 467, Japan.* Accepted for publication September 17, 1982.

Abstract □ To elucidate the details of the esterase activity of human serum albumin, the reaction of *N-trans*-cinnamoylimidazoles with albumin was investigated kinetically at various pHs at 25°. The reaction consisted of the acylation of albumin (probably the tyrosine-411 residue) by the substrate and the deacylation of cinnamoyl-albumin. The acylation was ~10–100-fold faster than the spontaneous hydrolysis of the substrate over the pH range examined. The pH profile for the deacylation rate constant indicated the participation of a group having a pK_a of ~9.4. The deacylation was subjected to the effect of deuterium oxide. The electron-withdrawing substituent facilitated the deacylation; the Hammett ρ value was 1.63. These results suggest that the deacylation proceeded *via* general base catalysis by this group.

Keyphrases □ Albumin, human serum—esterase-like activity, acylation with *N-trans*-cinnamoylimidazoles, kinetics □ Cinnamoylimidazoles—acylation of albumin, kinetics □ Kinetics—acylation of albumin with *N-trans*-cinnamoylimidazoles at the tyrosine-411 residue binding site

Studies involving the binding of drugs to human serum albumin are pharmacologically and clinically important, since this binding influences the *in vivo* distribution, availability, and elimination of drugs (1). Localization of drug binding sites on the albumin molecule and the classification of drugs with respect to the binding sites can be used to predict the displacement of one drug by another when two or more drugs are administered concurrently (2). It was reported previously that albumin exhibits esterase activity toward phenyl esters (3, 4). The active site involved when the substrate is *p*-nitrophenyl acetate was found to be one of the most important drug binding sites on albumin, and was named the R site (5–7). The R site is located near the reactive tyrosine-411 residue (5, 8–12). Previous studies (5–7) examined the inhibition of the esterase activity by several drugs, and led to the classification and identification of the various binding sites involved.

The details of the esterase activity of albumin have not been described. The activity of albumin toward amide substrates as well as the mechanisim of the deacylation of the acyl-albumin are not known. Since many drugs possess the amide linkage, we have investigated the activity of

albumin toward potential model substrates, the substituted *N-trans*-cinnamoylimidazoles. The pH dependence, isotope effect (deuterium oxide), and substituent effects for both the acylation and deacylation were examined using spectrophotometric methods.

EXPERIMENTAL

Materials—Albumin[1] was used after purification by the method of Chen (13). The molecular weight of the albumin was assumed to be 69,000 and the concentration was determained using an extinction coefficient $E^{0.1\%}_{1\,cm}$ of 0.531 at 278 nm (4). *N-trans*-Cinnamoylimidazole (I) was prepared by the reaction of *trans*-cinnamoyl chloride with imidazole in benzene solution (14). *p*-Chloro- (II), *m*-methyl- (III), and *p*-methoxy- (IV) cinnamoylimidazoles were synthesized by the method of Bernhard *et al.* (15) from the respective cinnamic acid and imidazole using dicyclohexylcarbodiimide as the catalyst. Several recrystallizations from cyclohexane gave material with the following melting points: (I) 133–134°, (II) 158–163°, (III) 119–123°, and (IV) 118–120°. Clofibric acid was prepared by the method of Jones *et al.*, mp 116–120° [lit. (16) mp 118–119°]. The ^2H content of the deuterium oxide[2] was >99.75%. All other chemicals purchased were of reagent grade.

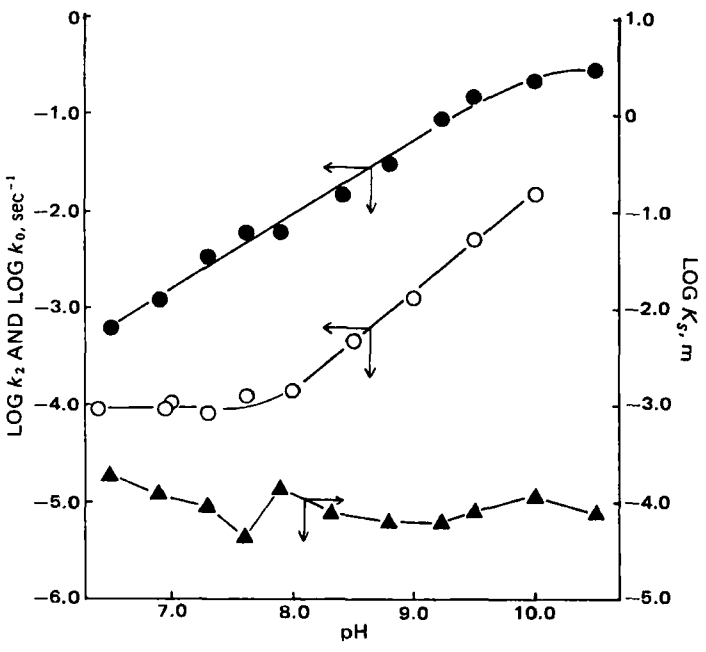

Figure 4—*Plots of log* k_2, *log* k_0, *and log* K_s *versus pH at 25°. Key: (●) log* k_2, *(○) log* k_0, *and (▲) log* K_s.

Kinetic Procedures—The reactions of the substrates with albumin were carried out in the presence of an albumin concentration more than fourfold in excess of the substrates, so that the substrates preferentially reacted with the primary reactive site (3, 4). The reactions were initiated by mixing 15 μl of the substrate in acetonitrile with 3 ml of buffered albumin solution preincubated in the spectrophotometer[3] cell kept at 25°. The acylation rate of albumin with I was followed at 330 nm to preclude interference due to the subsequent deacylation. The pseudo first-order rate constant was determined as described in a previous paper (3).

The deacylation of cinnamoyl-albumin was followed at 300 nm (Figs. 1 and 2). Sörensen buffer (0.067 *M* phosphate, pH 7.0–8.0) and Kolthoff

buffer (0.05 *M* borate, pH 8.0–10.5) were used as the reaction medium. The ionic strength was adjusted to 0.2 *M* with sodium chloride. In deuterium oxide, a p^2H value was estimated from p^2H = pH-meter reading + 0.4 (17).

RESULTS AND DISCUSSION

Reaction of *N-trans*-Cinnamoylimidazole with Albumin—The absorptivity changes noted during the reaction between albumin and I at pH 8.41 are shown in Fig. 1. Each spectrum is the difference between the reaction mixture and an equimolar albumin solution. The changes with time consist of a fast reaction followed by a slow one. The spectra eventually approach the sum of the spectra of equimolar *trans*-cinnamic acid and imidazole (represented by the dotted line). The first-order plot of the absorbance changes at 300 nm is obviously composed of the two steps (Fig. 2). The rate constant for the fast reaction obtained from the plot at 330 nm is ~300-fold larger than that obtained from the second (slow reaction) phase at 300 nm. It is probable that the fast reaction reflected by the decrease in the absorbance of I is the acylation of albumin (formation of cinnamoyl-albumin), and the subsequent slow reaction is the deacylation of the cinnamoyl-albumin.

To localize the reactive site toward I on albumin, the effect of clofibric acid on the acylation rate of albumin was examined. Clofibric acid was found previously (5–7) to bind singly at the R site on albumin and to inhibit the reaction of albumin with *p*-nitrophenyl acetate (V). The results are shown in Fig. 3. The *r* value in the ordinate of Fig. 3 represents the ratio of the rate constant in the presence of clofibric acid to that in its absence. The acylation of albumin is inhibited by clofibric acid, in a manner similar to its reaction with V. This inhibitory effect of clofibric acid indicates that both substrates I and V react with the same active site (R site, near tyrosine-411) on albumin. The tyrosine-411 residue of the R site, therefore, is considered to be acylated by I.

The overall reaction of I with albumin can be represented as in Scheme I. In this case, I·albumin is the Michaelis–Menten-type complex between I and albumin and K_s is the dissociation constant of the complex. The first-order rate constants of I and I·albumin are expressed by k_0 and k_2, respectively. The first-order rate constant for the deacylation of the cinnamoyl-albumin is given by k_3.

Acylation of Albumin with *N-trans*-Cinnamoylimidazole—The apparent first-order rate constants (k_{obs}) for the acylation of albumin were measured with several concentrations of albumin. The kinetic parameters k_2 and K_s for the acylation can be calculated from the intercept and slope of the double reciprocal plot based on the following (3):

$$\frac{1}{k_{obs} - k_0} = \frac{K_s}{(k_2 - k_0)} \frac{1}{[\text{albumin}]_0} + \frac{1}{k_2 - k_0}$$

The pH dependencies of k_2, K_s, and k_0 (for a comparison with k_2) are shown in Fig. 4. The slope of the log k_2–pH profile between pH 6.5 and 9.0 is approximately unity; at pH >9.5 k_2 becomes independent of pH. From this profile the pK_a value of the catalytic group is estimated as ~9.7. This pK_a value supports the theory that the acylation occurs at the tyrosine-411 residue of the R site, since the tyrosine-411 residue involved for the reaction with V has pK_a of ~9.5 (3, 5, 8). In addition, the absence of a deuterium oxide effect in the fast step also supports this theory for the acylation of albumin.

The value of K_s is almost independent of pH in the region examined. The spontaneous hydrolysis of I proceeds through the usual base catalysis in the alkaline region. From the comparison of k_0 with k_2, it is obvious that albumin accelerates the cleavage of amide substrate I as well as ester substrates (3, 4).

Deacylation of Cinnamoyl-Albumins—The pH dependence of k_3 for cinnamoyl-albumin is illustrated in Fig. 5. Up to pH ~9, the log k_3–pH profile shows a slope of approximately unity. However, the rate constant reaches the limiting value at higher pH. This pH dependence implies the participation of a group having pK_a of ~9.4 for the deacylation. In deuterium oxide the deacylation rate is about three–fourfold smaller than that in water, as shown in Fig. 5. This deuterium effect indicates that the water molecule also plays a role in the deacylation. Therefore, general acid or base catalysis by the group rather than nucleophilic catalysis predominates in the deacylation of cinnamoyl-albumin (18).

The substituent effect for the deacylation rate was examined to distinguish between the general acid and base catalysis. The log k_3–pH profiles for *p*-chloro-, *m*-methyl-, and *p*-methoxycinnamoyl-albumins are shown in Fig. 6. A pH variation of ~0.5 units seems to exist in the

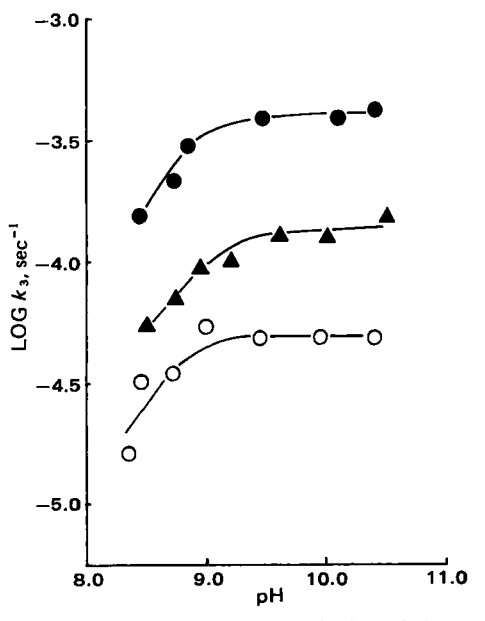

Figure 6—*pH dependence of* k_3 *for the substituted cinnamoyl-albumins at 25°. Key: (●) p-chlorocinnamoyl-albumin, (▲) m-methylcinnamoyl-albumin, and (○) p-methoxycinnamoyl-albumin.*

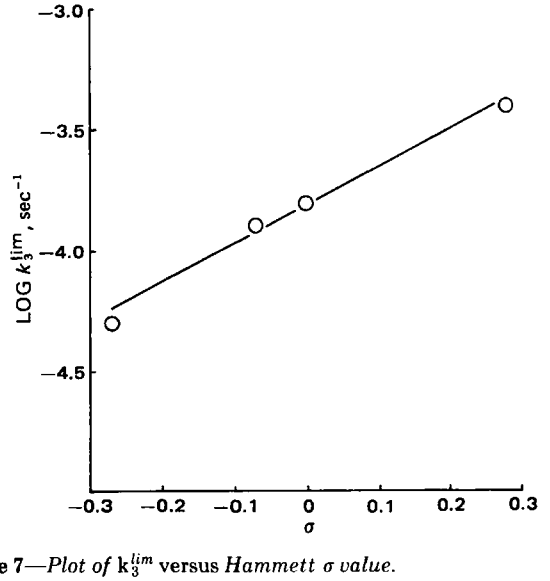

Figure 7—*Plot of* k_3^{lim} versus *Hammett σ value.*

apparent pK_a of the group participating in the deacylation. This variation may be attributable to the perturbation of the pK_a induced by the substituted cinnamoyl group (15, 19). A plot of the logarithm of the rate constants in the pH-independent region (k_3^{lim}) against the Hammett σ values gives a straight line (correlation coefficient = 0.994), as shown in Fig. 7. The electron-withdrawing substituent facilitates the reaction and the Hammett ρ value is 1.63. This ρ value suggests that the deacylation proceeds *via* general base catalysis rather than general acid catalysis, because the latter is, in general, independent of polar effects (20). The requirement of the limited conformation around the catalytic site is demonstrated by the finding that the deacylation of denatured cinnamoyl-albumin in 8 *M* urea was retarded.

Although the acylation of albumin with I (k_2) was faster than the spontaneous hydrolysis of I (k_0), as shown in Fig. 4, the deacylation of the cinnamoyl-albumin (k_3 in Fig. 5) is slower than the hydrolysis of I (k_0 in Fig. 4). The deacylation rate is related to the molecular activity (in the past the term "turn over number" has been used) which gives an indication of efficiency of an enzyme (21, 22). In this context, the esterase-like activity rather than the intrinsic esterase may be an appropriate expression for the activity of albumin toward the amide and ester substrates.

Stability Constants for Complex Formation Between α-Cyclodextrin and Some Amines

ALBERT B. WONG, SHU-FEN LIN, and KENNETH A. CONNORS ˣ

Received March 18, 1982 from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication August 9, 1982.

Abstract □ Complex formation of α-cyclodextrin with 15 amines (including seven 4-substituted anilines) was studied by the potentiometric method, supplemented by direct UV spectrophotometry and a competitive indicator spectrophotometric method. The data were analyzed in terms of 1:1 and 1:2 complexes (amine–cyclodextrin ratios) and the stability constants K_{11a}, K_{12a}, K_{11b}, and K_{12b} were evaluated; the subscripts indicate the stoichiometry and conjugate acid–base form. For all amines K_{11b} was greater than K_{11a} and K_{12a} was 0. On the basis of the relationship of complex stability to amine structure, it was concluded that the primary binding site in anilines is the 4-substituent.

Keyphrases □ Complex formation—of α-cyclodextrin with amines, determination of the stability constants and binding sites □ α-Cyclodextrin—complex formation with amines, determination of stability constants and binding sites □ Amines—complex formation with α-cyclodextrin, determination of stability constants and binding sites

Cycloamyloses (also called cyclodextrins) are cyclic oligomers containing six or more D-glucose units linked 1 → 4; they are produced by the action of *Bacillus macerans* amylase on starch. The six- and seven-unit substances are called cyclohexaamylose (α-cyclodextrin) and cycloheptaamylose (β-cyclodextrin), respectively. These molecules are doughnut shaped, and their possession of a cavity of fixed size and shape has led to considerable interest in their chemical properties. The production, purification, and chemistry of the cycloamyloses have been reviewed (1–4).

Any molecule smaller than the cavity of a cyclodextrin can enter the cavity and there undergo noncovalent interaction with the atoms lining and rimming the cavity. The resulting association product is called an inclusion complex. The cyclodextrin is thus a host for the smaller (guest) molecule. The dimensions of the α-cyclodextrin cavity permit the inclusion of many mono- and disubstituted benzene derivatives. A 1:1 stoichiometry is commonly observed (and often assumed in experimental studies), but it has now been well established that 1:2 complexes (*i.e.*, 1 substrate:2 cyclodextrins) may exist in some systems[1] (5–9).

The present paper is one of a series that describes

[1] The substrate (S) is the guest; the cyclodextrin (ligand, L) is the host. Stoichiometric ratios are given in the form SL (1:1) and SL_2 (1:2).

measurement of stability constants for complex formation between α-cyclodextrin and many substrates in aqueous solution, with the possible presence of 1:2 complexes being taken into account. The interpretation of the results is aided and unified by a model of the complexing that describes the substrate as a species having two possible binding sites (10). Most of the substrates are 1,4-disubstituted benzenes and many of them are ionizable, so the conjugate acid and base forms constitute separate guest species. In this paper a series of amines was studied as substrates. The experimental stability constants are symbolized by K_{11a}, K_{12a}, K_{11b}, and K_{12b}, the subscripts denoting complex stoichiometry and the conjugate acid–base form of the substrate.

Since these substrates are weak bases, the potentiometric method, which has been described in detail earlier (9), was applied. This technique was supplemented by UV spectrophotometry and a competitive spectrophotometric indicator method (11).

EXPERIMENTAL

Materials—α-Cyclodextrin[2] was dried at 95° for 48 hr. The amines were from commercial sources[3]; they were purified by recrystallization or distillation, the melting and boiling points being in good agreement with literature values (12, 13).

Procedures—The potentiometric method was used as described in detail earlier (9), except that the amine substrates were half-neutralized with 0.1 *N* HCl. The method of treating the data to obtain the stability constants was explained in detail. K_{11a} for 4-toluidine was measured by the competitive spectrophotometric method, using methyl orange as the indicator. The pK_a values of 4-nitroaniline and 4-cyanoaniline are 1.00 and 1.74, respectively (14, 15)—too low for these systems to be studied potentiometrically. Their K_{11b} values were measured by UV spectrophotometry. For both systems, 1:1 stoichiometry was suggested by the observation of isosbestic points. 4-Nitroaniline yielded the same K_{11b} value from measurements at 350 and 410 nm. The 4-cyanoaniline system was studied at 260 nm. All results reported here are at 25.0° and 0.1 *M* ionic strength.

RESULTS

Seven 4-substituted anilines were studied, most of them by the potentiometric method. The stability constants found for these amines are given in Table I. For all systems K_{12a} was 0. The conjugate acid of *p*-phenylenediamine (4-aminoaniline) has $pK_{a1} = 2.89$ and $pK_{a2} = 6.16$ (16), so that measurement of pK_{a2} left the other amino group (the X in Table I) in its base form. K_{12b} is not significantly different from zero at the 95% level for X = NH_2, OCH_3, H, Cl (though for X = NH_2, K_{12b} is significant at somewhat lower confidence levels).

Eight other aromatic or heterocyclic amines were studied potentiometrically. The results are listed in Table II. For all of these systems, K_{12a} was 0. Benzylamine, 4-*tert*-butylpyridine, and isoquinoline yielded significant K_{12b} values. The K_{12b} value for *N*-methylimidazole, though small, appears to be significant; however, when this system was treated as a Case II system (9), for which $K_{12b} = 0$ by definition, it gave a correlation coefficient (R^2) of 1.00, compared with 0.03 for the Case III (finite K_{12b}) system. Therefore, it was concluded that $K_{12b} = 0$ for this system, and, evidently, for the remaining amines in Table II[4].

Table II—Stability Constants for α-Cyclodextrin Complexes of Amines at 25° [a]

Amine	K_{11b}/M^{-1}	K_{12b}/M^{-1}	K_{11a}/M^{-1}
Benzylamine	17.4 (0.35)	4.0 (0.26)	0
Phenethylamine	26.4 (0.17)	−0.44 (0.16)	0
Imidazole	16.3 (0.23)	0.05 (0.37)	0

4-*tert*-Butylpyridine	84.7 (6.0)	20.1 (1.8)	0
Quinoline	28.6 (0.73)	0.63 (0.48)	0
Isoquinoline	22.7 (0.95)	10.8 (0.76)	0

[a] Standard deviations in parentheses.

DISCUSSION

Binding Site Model—Most of the substrates studied in the present investigation, as well as those in earlier studies, can be viewed as substrates possessing two potential binding sites. In 1,4-disubstituted benzenes, for example, the 1 and 4 positions are the possible sites for binding to the cyclodextrin cavity. For such a substrate, having binding sites X and Y, it was shown (9) that:

$$K_{11} = K_X + K_Y \qquad \text{(Eq. 1)}$$

and

$$K_{12} = \frac{aK_XK_Y}{K_{11}} \qquad \text{(Eq. 2)}$$

In these equations K_{11} and K_{12} are the experimental stability constants for 1:1 and 1:2 complex formation, K_X and K_Y are binding constants for 1:1 complexation of the ligand at sites X and Y, and a is a parameter that describes interaction between the two sites in a 1:2 complex. According to Eq. 1, the experimental K_{11} is the sum of binding site constants for isomeric 1:1 complexes. The 1:2 complex is formed by adding a second cyclodextrin to either of the preformed 1:1 complexes; according to Eq. 2, K_{12} can be zero only if $a = 0$ or if one of the site binding constants is zero.

If the two binding sites are identical, as in a symmetrical 1,4-disubstituted benzene, then $K_X = K_Y$, and Eqs. 1 and 2 give:

$$K_X = K_{11}/2 \qquad \text{(Eq. 3)}$$

and

$$a = 4K_{12}/K_{11} \qquad \text{(Eq. 4)}$$

For such a substrate, the binding site constant K_X and the interaction parameter a are obtainable.

The interpretation of experimental stability constants in terms of this model focuses attention on the binding sites and makes use of some chemical assumptions to assign binding constants to binding sites. It is postulated that (aside from binding site size and shape factors) the primary feature of a binding site contributing to complex stability is its electron density. Also favoring complex stability is the polarizability of the binding site, whereas complexing is weakened by high site polarity. The net effect of these factors determines the binding site constant for binding in a given solvent at constant temperature.

Anilines—The K_{11b} values in Table I show a rough trend with electron-attracting ability by the X-substituent, indicating that the X-site is the principal binding site. 4-Methylaniline appears to bind anomalously strongly. The binding of 4-aminobenzoic acid may be enhanced by hydrogen bonding. The K_{11b} values are correlated by:

$$\log K_{11b} = 1.70\sigma + 0.05R_D \qquad \text{(Eq. 5)}$$

[2] Sigma Chemical Co., Lot Nos. 20F-0507 and 29C-0425.

[3] Mallinckrodt Chemical Co.; Aldrich Chemical Co.; Eastman Organic Chemicals.

[4] Many of the constants in Tables I and II are quite small. For such systems the diagnostic plots described in Ref. 9 may be ambiguous because of the considerable relative experimental error and the limited range of the binding isotherm that is accessible to observation.

Table III—Comparison of K_{11b} for Anilines and K_{11a} for Phenols[a]

X[b]	K_{11b} (aniline)[c]	K_{11a} (phenol)[d]
OCH_3	6.7	0
CH_3	57.6	0
H	8.8	0
COO^-	9.0	16.6
Cl	251	272
COOH	1341	1130
CN	451	158
NO_2	635	245

[a] At 25°. [b] X in X—C_6H_4—NH_2 or X—C_6H_4—OH. [c] From Table I. [d] From Ref. 11.

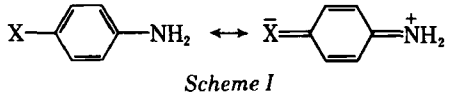
where σ is the Hammett substituent constant of X and R_D is the molar refraction of X—C_6H_5. The standard deviation is 0.39 in log K_{11b}.

K_{11b} is larger than K_{11a} for all amines, a result that is consistent with the postulates that complex stability is enhanced by high site electron density and polarizability and decreased by high polarity.

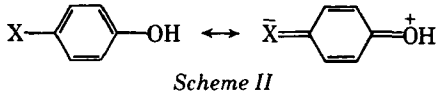
Since 4-aminoaniline is symmetrical, Eqs. 3 and 4 are applicable, giving $K_X = 1.15$ as the binding constant for the 4-amino group in this substrate. Calculation of the a value with Eq. 4 does not seem justified, because of the large uncertainty in K_{12b}.

Since the X group in 4-aminoaniline is NH_2, the most electron-releasing group in Table I, any other X group will be even less effective in increasing electron density at the aniline NH_2 site. Thus the binding site constant for binding to the amino site should be a maximum for 4-aminoaniline (for which it is 1.15 M^{-1}). Since K_{11b} is, by Eq. 1, the sum of the binding constants at the two sites and the binding constant at the amino site has been shown to be 1.15 or smaller, the K_{11b} values in Table I can (except for X = NH_2) be essentially completely assigned to binding at the X-substituent site.

If this assignment is correct, an interesting comparison can be made between K_{11b} for anilines and K_{11a} for the corresponding phenols, for it was concluded earlier (11) that K_{11a} for phenols can be ascribed to binding at the 4-substituent site[5]. The electronic distribution of neutral anilines and phenols should be similar, as shown in Schemes I and II.



Scheme I



Scheme II

Therefore, it is expected that K_{11b} for anilines should be approximately equal to K_{11a} for the corresponding phenols. These quantities are compared in Table III, which shows that the agreement is reasonable in terms of this simple argument.

[5] Except for ^-OOC—C_6H_4—OH, which may bind at the hydroxy site (2).

The stability constant K_{11a} presumably describes binding at the X-site, since the positively charged protonated amine site will on all counts (reduced electron density, reduced polarizability, and increased polarity) not be expected to undergo any complexation. That K_{11a} is zero for several systems indicates that electron density at the X-site is reduced sufficiently, in the cation, that no binding occurs even at this site.

Other Amines—The data in Table II show the general pattern $K_{11b} > K_{11a}$ for amines. Many structural types are represented, so interpretations of most of the results will require more extended and systematic variation of structures to establish correlations of structure with complex stability. Some obscure points, for example, are the difference in 1:2 complex behavior for quinoline and isoquinoline and the appearance of a finite K_{12b} for benzylamine but not for aniline or phenethylamine[4]. Some results seem reasonable, however; for example, the larger K_{11b} for 4-nitroimidazole compared with imidazole suggests that the nitro group is the principal binding site. Moreover, this is the only compound in Table II that possesses a finite K_{11a}, probably because the powerfully electron-withdrawing nitro group opposes the electron withdrawal by the protonated amine, leaving sufficient electron density at the binding site to result in significant complexation.

Permeation of Skin and Eschar by Antiseptics I: Baseline Studies with Phenol

CHARANJIT R. BEHL *, EDWARD E. LINN, GORDON L. FLYNN ˣ, CARL L. PIERSON, WILLIAM I. HIGUCHI, and NORMAN F. H. HO

Received April 4, 1981 from the *College of Pharmacy and Medical School (CLP), The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication July 6, 1982. *Present address: Pharmacy Research, Hoffmann-La Roche, Inc., Nutley, NJ 07110.

Abstract □ To assess how the permeability of phenol is altered by thermal injury, it was first necessary to have baselines of comparison on normal skin. Using *in vitro* diffusion cells and the skin of the hairless mouse, [^{14}C]phenol was applied to skin in an aqueous medium with a reference copermeating species, [^{3}H]methanol, and 37° permeability coefficients of the pair were evaluated as functions of animal age, skin hydration, stripping of the skin, dermis isolation, and phenol concentration. Age proved to be of little consequence to permeability over a wide age range. Prolonged aqueous soaking of the skins was also without much effect. Stripping of the skin and isolating the dermis by soaking techniques allowed assessment of individual skin strata diffusional resistances. When applied to skin in trace radiochemical concentrations, phenol behaved diffusionally as an alkanol with a chain length of six. But at concentrations >2% w/v, phenol facilitated the permeation rates of itself and methanol; the effect was markedly concentration sensitive and only fractionally reversible. Concentration studies using silicone rubber membranes proved that the effects on the skin were the results of destroyed barrier integrity. At 6% phenol concentration there was an essentially instantaneous, 10-fold increase in the phenol permeability coefficient, raising it to two-thirds that observed with fully stripped skin. Overall, the data suggest that the stratum corneum is proportionally impaired as the phenol concentration is increased.

Keyphrases □ Permeation, skin—of phenol, baseline studies with hairless mice, effects of animal age, skin hydration, skin stripping, dermis isolation, and concentration □ Phenol—effects of animal age, skin hydration, skin stripping, dermis isolation, and concentration on skin permeation, baseline studies on hairless mice

Phenol is an industrial chemical with widespread use and is so frequently a contaminant of industrial waste streams that it is designated a priority pollutant by the Environmental Protection Agency (1). It is used in topical pharmaceuticals as a microbial preservative and other medical uses include local antipruritis, an anesthetic action which requires cutaneous penetration, and antisepsis. On contact, phenol apparently diffuses through skin readily; this has caused serious injuries in the workplace (2). Phenol has been associated also with untoward systemic responses when medicinally used and fatalities have been recorded in cases where its application has been over extensive areas of barrier-impaired skin (3). Therefore, whether the skin exposure occurs accidently or in therapy, diffusive passage of phenol through skin is of some considerable concern.

It was suggested in a recent report that "the lipophilic character of solutes (phenols) and their hydrogen bonding capacity are the two main structural features determining their penetration through the human epidermis" (4). Being only mildly hydrophobic, phenol's absorption was presumed to be rate-controlled by the stratum corneum. Increased phenolic permeation rates in concentrated solution have also been recorded and speculatively attributed to protein denaturation within the skin during transport (5). Higher phenol permeability was reported for skins damaged by either simple abrasion or burning (6).

In previous investigations from these laboratories (7–10), permeabilities of normal skin as well as burn-traumatized skin (11) of the hairless mouse have been examined using water and the *n*-alkanols as test permeating species. Three basic rate-controlling mechanisms of skin permeation were evident (10): (*a*) diffusion through aqueous pores (an aqueous shunt pathway), (*b*) diffusion through lipoidal components of the stratum corneum, and (*c*) diffusion controlled by the viable strata (epidermis and dermis) lying beneath the horny layer. These studies are continued here, for the first time using a chemical with known serious local and systemic consequences in humans. The purpose of this specific study was to obtain baseline data for the assessment of thermal alterations on the permeability of phenol through skin.

EXPERIMENTAL

Chemicals—[^{3}H]methanol[1] and [^{14}C]phenol[1] were diluted with saline[2] to prepare solutions for the permeation experiments. Crystalline phenol[3] was used to prepare aqueous solutions of varying concentrations for the concentration-effect experiments. The final bulk chemical concentration of the permeating species was 10^{-4} *M* or lower except where unlabeled phenol was added to be the expressed concentrations in the concentration-effect studies.

Animals—Male hairless mice of SKh-hr^{-1} strain[4] were used. They were provided with free access to food and water. The bedding was changed at least once a week. The mice were housed individually in shoe box-type cages to prevent them from damaging one anothers skins.

Stripping and Dermis Isolation Procedures—Immediately following sacrifice by cervical dislocation, the abdominal and the dorsal surfaces of mice were stripped 5, 10, or 25 times with cellophane tape[5]. The animal was secured on a table and the skin was stripped by placing the tape on the animal surface and moving the thumb back and forth a few times, with as uniform pressure as was possible (12). A fresh piece of the tape was used for each stripping. Dermal sections were isolated by placing skin in the diffusion cell and soaking it for 24 hr (13). At this time the cell was opened and the epidermis was carefully lifted from the dermis with a pair of forceps. The cell was then reassembled for permeation experiments.

Radioisotopic Assay—Concentrations of the radiolabeled permeating species were determined using a liquid scintillation counter[6] and a commercial cocktail[7]. Permeation rates of both methanol and phenol were studied simultaneously using a technique involving dual labels.

Table I—Permeability Coefficients of Methanol as a Function of Mouse Age

Age, days	Number of Mice	$P \times 10^3 \pm SD$, cm/hr		
		Abdominal	Dorsal	Overall Average[a]
36	1	2.1	2.7	2.4
92	5	3.4 ± 0.5	2.9 ± 0.6	3.2 ± 0.6
340	6	2.2 ± 1.0	2.7 ± 0.3	2.5 ± 0.8
381	1	3.2	2.1	2.7
441	3	1.9 ± 0.8	1.6 ± 0.4	1.7 ± 0.6

[a] Average across sites.

Diffusion Cell and Permeation Procedure—A two-chamber glass diffusion cell (7–9) was employed to determine the skin permeability. The external medium of diffusion was saline, except in the concentration-effect studies where the donor compartment was filled with phenol solution of designated concentration. The half-cell contents were stirred at 150 rpm, and all permeation experiments were carried out at 37°. The half-cell facing the stratum corneum was always the donor chamber and the half-cell facing the dermis was always the receiver compartment. Therefore, the net diffusion occurred from the stratum corneum to the dermis side.

Procedure of the Hydration Effect Studies—The effect of hydration on the skin permeability to methanol (reference solute) and phenol was studied for 50 hr of skin immersion in saline, using the abdominal and the dorsal skins obtained from each of five mice. A technique of sequential experiments developed earlier (9) was employed to obtain the entire hydration profile on each of the 10 skins. This was accomplished by carrying out four permeation experiments in succession on the same piece of the skin, with rinsing between experiments.

Procedure for Studying the Concentration Effects and Reversibility Using Skin and Silicone Rubber Membranes—Permeation of methanol and phenol was studied using phenol solutions with concentrations of 0.5, 1.0, 2.0, 4.0, and 6.0% (w/v). The receiver chamber always contained saline. To minimize mouse-to-mouse and site-to-site variation, each of the five concentrations was studied in six pieces of skins excised from five different dorsal locations of six mice. The manner in which the concentrations were rotated around the sites is depicted in Fig. 1. The permeation experiment was initiated within 0.5 hr of skin exposure to the phenol solution and was completed within an additional 2 hr. At ~2.5 hr of skin contact with the phenol solutions, the donor and receiver chambers were evacuated and cleansed with saline using three triple rinsings ~0.5 hr apart. A second permeation experiment was then conducted with methanol and phenol in trace radiochemical concentrations, using saline in both compartments. This experiment [referred to as a reversibility experiment (14) in the remainder of this paper] was aimed at determining the extent to which the accelerating effects of phenol were reversible. An identical procedure was followed in assessing concentration effects and the reversibility of such effects using 0.0254-cm silicon rubber membranes[8].

Data Analysis—The data were plotted with the receiver compartment concentration (in cpm) as a function of time. The permeability coefficient was calculated from (9):

$$P = \frac{V}{A}\frac{(dC/dt)}{\Delta C} \qquad \text{(Eq. 1)}$$

where P is the permeability coefficient (cm/hr); A is the diffusional area (~0.6 cm^2); ΔC is the concentration difference across the membrane, which was taken to be equal to the donor concentration (cpm); V is the half-cell volume (1.4 ml); and dC/dt is the steady-state slope (cpm/cm^3/hr) of a counts (concentration) *versus* time plot.

RESULTS

Tables I and II contain mouse skin permeability coefficients of methanol and phenol, respectively, as a function of mouse age. The choice of the ages and the numbers of the mice per age were dependent on the availability of animals within the colony.

[a] Average across sites.

Figure 2 illustrates the mouse skin permeability coefficients of methanol and phenol, respectively, as a function of skin hydration time. The abdominal and the dorsal skins excised from five mice were used. The permeation experiments were run at 0, 10, 25, and 50 hr of hydration on each of the skins. The animals were weighed before sacrifice and their weights were consistent with an expected weight–age relationship (1), indicating that the animals were healthy. The data are plotted to indicate the standard deviation about each point. Figures 2A, 2B, and 2C present the average abdominal, dorsal, and combined values, respectively. Figure 2D presents the data as ratios of the permeability coefficients of phenol–methanol, a data manipulation previously shown to reduce animal-to-animal variability.

Table III contains the permeability coefficients of methanol and phenol through the abdominal and the dorsal skins stripped 5, 10, or 25 times. Five mice were used for each experimental condition. The data are provided in terms of the individual and mean permeability coefficients with standard deviations. Table III also contains data for dermis isolated by the soaking procedure (13). In this case, four permeability coefficients were gathered for each permeating species, two on each skin site.

Tables IV and V contain the permeabilities of methanol and phenol as a function of phenol concentration in the donor chamber. Also summarized in these tables are data from the reversibility experiments where both compartments of the diffusion cell contained saline. At each concentration, six pieces of the skin obtained from five different sites on the dorsal surfaces of six mice were used. The vital statistics of each animal are presented and individual as well as the mean permeability coefficients, with standard deviations, are listed. From these data, a relative enhancement of the permeabilities of methanol and phenol was computed as the ratio of the mean permeability coefficient at a given phenol concentration to that at the trace radiochemical concentration of phenol. These derived data are illustrated in Figs. 3 and 4 for both the high concentration and reversibility experiments.

Table VI contains permeability coefficients of phenol and four alkanols (methanol, ethanol, butanol, and hexanol) through 0.0127-cm silicone rubber (polydimethylsiloxane) membranes. For these experiments, the concentrations of the permeating species were $\leq 10^{-4}$ *M*. Table VII contains permeability coefficients of methanol and phenol through 0.0254-cm silicone rubber membranes as a function of phenol concentration. As in the case of the skin studies, results are presented for an initial experiment at the high phenol concentrations and a second reversibility experiment. In the latter, permeability was also measured from solutions containing only trace phenol concentrations. In the initial experiments, the phenol concentrations in the donor chamber were 0.5, 1.0, 2.0, 4.0, and 6.0% w/v. At each concentration three different silicone rubber membranes were used.

[a] All mice were 90–100 days of age.

DISCUSSION

Effect of Aging on the Permeability of Phenol—From the results of replicated experiments on mice of 36, 92, 124, and 340 days of age, the phenol permeability coefficient through hairless mouse skin underwent no appreciable change with age (Table II). A representative value for the 37° phenol permeability coefficient is 2×10^{-2} cm/hr. A 25° value for human skin (cadaver epidermis isolated using ammonia fumes) of 0.8×10^{-2} cm/hr has been reported (5), and when the temperature difference is taken into account (activation energies for structurally similar alkanols run ~15 kcal/mole), the human and mouse data are remarkably similar.

The average permeability coefficient for phenol of 1.25×10^{-2} cm/hr obtained at 441 days seems smaller than that found in younger animals. Here the value of using a copermeating-species marker with a different radiolabel becomes apparent, as the methanol average permeability coefficient at 441 days (Table I) is also of smaller magnitude than at younger ages. Extensive age-influence studies with the alkanols (10) indicate the methanol permeability coefficient to be invariant from ~90 days of age to ages exceeding 441 days. Thus it is concluded that the decline in permeability coefficients at 441 days is due more to animal variability than age. It is notable that phenol–methanol ratios of the mean permeability coefficients at 92, 340, and 441 days are 7.9, 7.3, and 7.4, respectively, showing that the relative permeability of the two chemicals remains essentially invariant even as the skins of different age groups of animals evidence variability. Permeability coefficients obtained on single sections of skin at other ages are in general accord with the values from the replicated runs. Based on these data, it was decided to use mice ~100 days old for the remainder of the study.

When the permeability coefficients for methanol and phenol are normalized to animal mass (permeability coefficient divided by body weight),

[a] Number in parentheses indicates the skin location at the dorsal site 
; mouse age is ~117 days. [b] Mice 1, 3, 4, and 5 each weighed 30.5 g; mice 2 and 6 weighed 31.5 and 30.0 g, respectively. [c] Data were abstracted from ref. 9.

the age patterns displayed in Fig. 5 are obtained. The mass-weighted values decline appreciably for both solutes over the initial year of age, in each case the fall in magnitude being approximately twofold. Thus, even though the skins of younger animals evidence similar mass-transfer coefficients as seen with older skins, the younger animals appear to be at greater risk to comparable area exposures of phenol and systemic accumulation of phenol would be seen to be inversely related to animal size. We believe such factors have bearing on the increased toxicity of phenol observed in infants (15, 16).

Effect of Anatomical Site on the Permeability of Phenol—Tables I and II contain permeability coefficients of methanol and phenol through the abdominal and dorsal skins. At no age is there a significant difference in values for the two sites and, moreover, for both permeating species the site of greater permeation rate changes from age to age. Therefore, it is concluded that within the age range studied there is no factorable site dependency to the permeability of these compounds. This conclusion is further supported by the hydration study data where permeability coefficients for the abdominal and dorsal skins remained unchanged during the full 50-hr hydration. The methanol data are consistent with the previous studies (10) where the permeabilities of the *n*-alkanols were shown to be site independent for animals older than ~50 days.

Influence of Hydration on the Permeability Coefficient of Phenol—Permeability coefficient values obtained for methanol and phenol as a function of hydration time are plotted in Fig. 3. There is no clear indication that the transport rate of either permeating species is altered by hydration. For methanol, this observation is fully consistent with previously published results (9). Since the phenol permeability coefficient through hairless mouse skin is, at the outset, similar to that of hexanol (Table VIII) and given the structural similarity of these two 6-carbon hydroxy compounds, it was expected there would roughly be a doubling of the permeability coefficient of phenol during hydration. Phenol permeability coefficients for fresh and extensively hydrated skins appear essentially the same, however, although the latter may be marginally larger. Exactly why there is increased facility of permeation for butanol, hexanol, and heptanol through hydration and not for the physicochemically similar phenol [the octanol–water partition coefficient of phenol is 29 (17) and lies between that of butanol, 7.6 (18) and hexanol, 76 (18)] is not understood. The aromatic compound has a larger diffusional cross-sectional area than the alkanols, which may be a factor limiting its access to presumably hydration-expanded lipoidal channels.

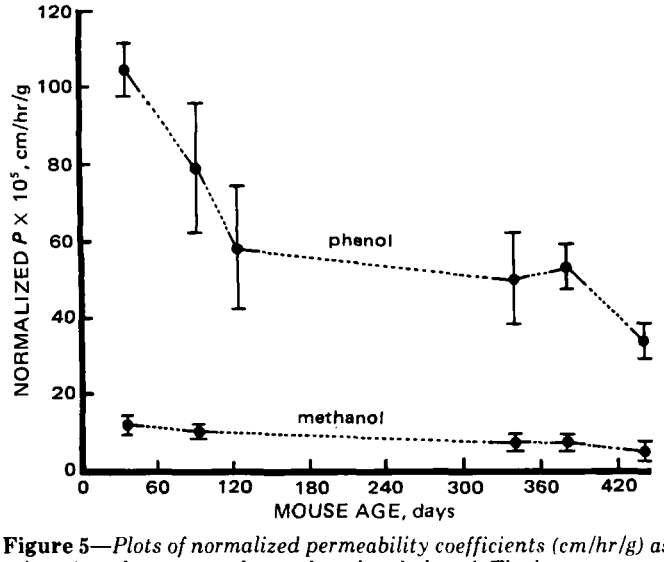

Figure 5—*Plots of normalized permeability coefficients (cm/hr/g) as a function of mouse age for methanol and phenol. The bars represent the standard deviation for each normalized value.*

Effect of Stripping and Dermis Isolation on the Permeability of Phenol—Stripping increases the permeability of both abdominal and dorsal skins to both methanol and phenol (Table III). The permeability coefficients obtained tend to level off at 10 strippings. In the earlier studies, it required more than 10 strippings to notice a comparable effect (8). The difference in observations may be due to greater care securing adhesion of the tape to the skin in the present study. The increased permeation rate on total stripping is far greater for methanol than phenol, which reflects the fact that the stratum corneum functions lipoidally to these compounds, offering higher resistance to methanol, the more polar of the two solutes. It is also evident (Table III) that abdominal permeabilities for partially and fully stripped skins invariably exceed those of the dorsal surfaces even though there is no apparent difference for the intact skins. It appears that the abdominal stratum corneum may be more easily removed and further, that the permeability of the remaining abdominal strata may be intrinsically greater than that of the dorsal skin. The latter observation is consistent with the abdominal skin being thinner than the dorsal skin (10).

The abdominal dermis isolated by the soaking technique appears to be more permeable than the dorsal dermis, although the data are too limited to draw a firm conclusion (Table III). These data, together with the stripping and whole skin data, allow quantitative assessment of the diffusional resistances of the individual strata of the skin. The following equation, derived from the previously reported physical model (8, 10), can be used to compute the individual permeabilities of the stratum corneum, the viable epidermis, and the dermis:

$$\frac{1}{P_{WS}} = \frac{1}{P_{SC}} + \frac{1}{P_{EP}} + \frac{1}{P_D} \qquad \text{(Eq. 2)}$$

where P_{WS}, P_{SC}, P_{EP}, and P_D are the permeabilities of whole skin, stratum corneum, viable epidermis, and dermis, respectively. The values of

[a] Number in parentheses indicates the skin location at the dorsal site 
; mouse age is ~117 days. [b] Mice 1, 3, 4, and 5 each weighed 30.5 g; mice 2 and 6 weighed 31.5 and 30.0 g, respectively. [c] Data were abstracted from Table II.

P_{WS} and P_D are direct experimental values (Tables I–III). P_{EP} can be estimated from:

$$\frac{1}{P_{25\times}} = \frac{1}{P_{EP}} + \frac{1}{P_D} \qquad \text{(Eq. 3)}$$

where $P_{25\times}$ is the permeability coefficient of the skins stripped 25 times (Table III). Results of these computations are reported in Table IX. The computed P_{SC} values for methanol or phenol for either anatomical site are essentially the *same as* P_{WS} observed experimentally. This indicates that the resistance offered by the whole skin is, in fact, almost entirely due to the stratum corneum. The P_{EP} values are unrealistically large, indicating that the viable epidermis presents little resistance to the transport of methanol or phenol. In other words, insofar as can be told through estimation of difference (Eq. 3), the dermis offers the bulk of the resistance to diffusion once the stratum corneum has been removed, mostly because it is far thicker than the epidermis. But it is compositionally and structurally dissimilar as well, and these differences may also be a factor. The condition of the viable epidermis of the stripped skin is unknown; it is also possible that it is either damaged or partially removed by the repeated strippings, minimizing its apparent residual resistance.

Comparison of Phenol and Alkanol Permeabilities in Synthetic Membranes—One means of placing the phenol permeability into an overall perspective is to compare it with that of the *n*-alkanols using a membrane that, relative to the skin, is well understood in terms of its diffusional properties and mechanism. Silicone rubber sheeting provides an essentially isotropic, hydrophobic medium ideal for such purposes. In this case the permeability coefficient of phenol compares favorably with that of butanol (Table VI). But for fresh skins, data for hexanol and phénol are comparable. Moreover, as previously pointed out, the octanol–water partition coefficient for phenol of 29 (17) is bracketed by those of butanol and hexanol (18). These combined observations have an elementary significance. While phenol is structurally similar to an alkanol, its aromatic character sets it apart in terms of intermolecular interactions and, where oil–water partitioning is concerned, its affinity for different oil phases is not consistently the same as that of any particular alkanol. Nevertheless, since the differences in intermolecular associations in water immiscible phases are subtle, its distributioning behavior tends to be reasonably close to that of the alkanols of comparable size. From the standpoint of skin permeation, the lipid phase of the stratum corneum behaves as expected, "seeing" phenol more or less as it "sees" the 6-carbon alkanol, at least until the hydration effects set in.

Table VI—Comparison of Phenol and Alkanol Permeability Coefficient Through 0.0127-cm Silicone Rubber Sheeting

Compound	Number of Experiments	$P \times 10^3 \pm SD$, cm/hr
Phenol	3	175 ± 13
Ethanol[a]	3	53.5 ± 2
Butanol[a]	3	180 ± 12
Hexanol[a]	3	761 ± 54
Octanol[a]	3	1090 ± 15

Effect of Phenol Concentration on the Permeabilities of Methanol and Phenol Through Skin and Silicone Rubber Membranes—The hairless mouse skin permeability coefficients of methanol increased slowly up to the 2% level and then rapidly accelerated with further increases in phenol concentration (Fig. 3). The permeability coefficient of 0.17 cm/hr observed at 6% phenol concentration is >100 times that of normal skin. However, it represents only a partial compromise of the barrier function of the stratum corneum to methanol as, based on stripped-skin data, an upper limit of ~0.28 cm/hr for the methanol permeability coefficient is possible (Table III). The reversibility data indicate that there is some restoration of the barrier to methanol. Almost half of the enhancement observed at 0.5, 1.0, 2.0, 4.0, and 6.0% phenol concentrations is reversible (Fig. 3).

Phenol also accelerated its own permeability when applied in high concentration. As with methanol the effects are nominal to ~2% phenol concentration and exaggerated thereafter (Fig. 4). In this case the data suggest an upper limit on the effect is being approached at the 6% concentration. This seems reasonable as the permeability coefficient of 0.203 cm/hr at 6% phenol concentration is approaching the value of 0.275 cm/hr noted for the stripped skin. The relative enhancement in the permeability at the 6% level is 10.0 and it is reversible only to 8.9. The relative enhancement for fully stripped skin is ~13.5. All these observations are consistent with the fact that the mouse skin stratum corneum is intrinsically more permeable to phenol than to methanol; therefore, chemical

Table VII—Effect of Phenol Concentration on the Permeability of Methanol and Phenol Through 0.0254-cm Silicone Rubber

Phenol Concentration (Donor), % w/v	Mean $P \times 10^3 \pm SD$, cm/hr[a] Methanol: Concentration Effect Experiment	Methanol: Reversibility Experiment	Phenol: Concentration Effect Experiment	Phenol: Reversibility Experiment

[a] Abstracted from refs. 7, 9, and 11. Values obtained on freshly mounted skin sections.

impairment has a lesser effect on the permeability of phenol. It is notable that, at the 0.5, 1.0, 2.0, and 4.0% concentrations where enough of the stratum corneum integrity remains to essentially provide sole control of permeation, recovery of the phenol permeability coefficient on washing was roughly of the same degree as observed for methanol.

Possible Causes of the Observed Concentration Effects—In the previous section it was implied that the accelerating effect of phenol on skin permeability was due to impairment of the stratum corneum, as was also assumed by previous researchers (4, 5). The observation that the reference compound, methanol, as well as phenol experienced increased permeability in the present studies strongly supports this assumption. Moreover, the maximum enhancements for these solutes were quantitatively similar to the enhancements observed by fully stripping the stratum corneum from the skins. Nevertheless, it is possible to rationalize the data in terms of physicochemical effects such as complexation in the donor medium. It would be necessary for phenol to form complexes both with itself and methanol capable of increasing partitioning into the skin, thereby facilitating permeation, to explain the results. This implausible effect is ruled out by concentration experiments performed with silicone rubber membranes (Table VII). These membranes were assumed *a priori* to be chemically inert to phenol, which subsequently proved to be the case. When methanol and phenol permeated the synthetic membranes at concentrations used in the skin studies (0.5–6.0% w/v), no concentration-induced alterations in the permeability of either solute were noted. Since the complexes, if formed, would likely also facilitate permeation of these hydrophobic films, and since no effect was observed, complexation as the basis of enhanced permeation can be discounted. It should be noted that the complete protocol of the concentration studies was carried out using the silicone rubber and that the reversibility experiments yielded essentially the same permeability coefficients as noted at high phenol concentrations. This further strengthens the conclusion that the acceleration of skin mass-transfer rates by phenol is unrelated to external factors such as molecular association.

Significance of These Studies—Previous work (7–14) has shown that permeability of the hairless mouse skin to the *n*-alkanols to be similar quantitatively and qualitatively to that of the human epidermis. The present studies show that phenol chemically alters the mouse skin stratum corneum, leading to increased mass-transfer rates, a phenomenon also observed in isolated human epidermis (5). Moreover, the concentration reported as the threshold concentration for damage in the human skin (1.5%) is virtually the same as observed with mouse skin. And the magnitudes of phenol-induced increases in skin permeabilities at given concentrations of phenol are similar in each case. This parallelism in behavior indicates fundamental similarities in the biological compositions and the constructions of the two tissues. The implications are that the mechanisms of permeation of phenol and chemical denaturation by phenol are nearly identical in the two species. This adds to a growing body of information which suggests that hairless mouse and human skins are comparable chemical barriers and lends credibility to the use of the hairless mouse model for topical drug delivery research.

As far as the concentration effects are concerned, all signs point to phenol having a specific ability to chemically alter the stratum corneum. When it does so, the partitioning dependency of the skin permeation process is effectively lost. This action is partially reversed when the phenol is rinsed out from the diffusion cell. Relatively recent evidence proves that there is a well-defined extracellular lipid domain in the stratum corneum, comprising 10% or more of its total volume (19, 20). It is tempting to assign the lipid pathway across the tissue to this region. This would necessarily mean, for compounds like the intermediate chain-length alkanols (C_3–C_8) and phenol which are in the partitioning sensitive region, that the path of least diffusional resistance is around the cellular building blocks of the horny layer, something that could only occur if the keratinized, intracellular contents are relatively impervious.

Table IX—Individual Permeabilities of Whole Skin, Stratum Corneum, Viable Epidermis, and Dermis to Methanol and Phenol

Membrane	$P \times 10^3$, cm/hr[a]			
	Methanol		Phenol	
	Abdominal	Dorsal	Abdominal	Dorsal
Whole skin	3.2	3.2	25.4	25.4
Stratum corneum	3.2	3.2	27.5	28.0
Epidermis	1400	1100	5800	3200
Dermis	450	400	340	300

[a] Computed from eqs. 2 and 3 and from the data given in previous tables. Epidermis and dermis data are reported to the nearest 100 and 10 unit, respectively.

It is hard to believe that phenol, even at 6% w/v, would have significant effect on the lipid medium, other than perhaps just concentrating there, and inconceivable that it could all but wipe out the partitioning dependency of this postulated pathway. On the other hand, consistent with its known abilities to denature proteins, phenol may act on the keratin within the cellular building blocks and on the cell wall proteins as well, denaturing and, perhaps in the case of the semicrystalline keratin helices, uncoiling them. Such effects could be partially reversible. If the suppositions are correct that the extracellular lipids are the partitioning pathway and that the destructive activity of phenol is primarily within the intracellular space, then phenol must act to open up an alternative polar shunt route across the cells. It follows that the extent to which this occurs is proportional to the phenolic concentration. The mechanism envisioned is consistent with a threshold concentration (~2.0%) for the effects of phenol.

Phenol at ≥5% concentration is doubly dangerous since the permeability coefficient is 10-fold enhanced. The absorption rate from a 5% compared with a 1% solution is not just 5 times greater but rather 50 times. This explains many of the rapid lethal poisonings detailed by Deichmann (2). At extremely high concentrations (>75% w/v) phenol is corrosive enough locally to coagulate the epidermis, retarding its self-absorption, so that such solutions are less toxic than 5% levels (14).

Permeation of Skin and Eschar by Antiseptics II: Influence of Controlled Burns on the Permeation of Phenol

CHARANJIT RAI BEHL *, EDWARD E. LINN, GORDON L. FLYNN ˣ, NORMAN F. H. HO, WILLIAM I. HIGUCHI, and CARL L. PIERSON

Received April 6, 1981 from the *College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication July 6, 1982. * Present address: Pharmaceutical Research, Hoffmann-La Roche, Inc., Nutley, NJ 07110.

Abstract □ The safe antiseptic use of phenol over the burn-traumatized surface depends on knowledge of how the systemic accumulation of phenol is affected by burn processes. To gain insight into the underlying permeation phenomenon, the diffusion of phenol and a reference cosolute, methanol, through both scalded and branded dorsal skin sections of the hairless mouse was studied as a function of burn temperature using *in vitro* diffusion cells. Temperatures up to 100 and 150° were used for scalding and branding, respectively, using a 60-sec exposure time. Permeability coefficients of the traumatized skins were assessed at 37° and compared with control values. Coefficients of both permeating species were not increased significantly by burn temperatures up to 70° applied either by scalding or branding, however, at higher temperatures exaggerated increases in permeation rates were noted. A limiting increase of ~7 times the control value was noted for phenol irrespective of the burn method. Permeability of methanol was altered even more dramatically and at 100° by scalding and 150° by branding was over 50 times the control rate. At 80 and 100° for methanol and at 80° for phenol, scalding produced larger increases in the permeability coefficients than branding. Since contact for 1 min at 60° is capable of producing a full-thickness burn injury, it is clear that eschar permeability to phenol immediately postburn is not related to the clinical degree of burning, but is a function of the thermal intensity (hotness) of the burn stimulus. Full-thickness wounds can be expected to have highly variable rates of systemic absorption as a direct consequence of the wide-ranging permeability possible for such burns, with the risks of topical application varying accordingly.

Keyphrases □ Permeability—of phenol and methanol, through burn-traumatized skin □ Phenol—permeability through burn-traumatized skin □ Methanol—permeability through burn-traumatized skin

Survival of patients with extensive deep partial-thickness (second-degree) and full-thickness (third-degree) burns depends, in part, on limiting microbial colonization of the wound surface. Topical antiseptics are used for this purpose since eschar is nonvascularized and all but inaccessible systematically. Virtually every known antiseptic chemical has been applied to burns, all too often with serious systemic consequences due to excessive transeschar adsorption. Phenol has proven to be one of these toxic agents (1, 2).

In previous studies using model permeating species originating from these laboratories, the permeation behavior of hairless mouse skin has been shown to be altered in unique ways by both scalding (3, 4) and branding (5, 6). Skin permeation rates for water and the *n*-alkanols were maximally increased two- to fourfold when the skins were burned at 60°, irrespective of burn duration. However, when skins were burned for 60 sec at various temperatures, large increases in the permeabilities were noted beginning at ~80°; the effect was greater the more polar the permeating species. In branding experiments, it was possible to use temperatures >100° and correspondingly larger permeability increases were observed for sensitive compounds. These studies provided basic insights into the conditions for and mechanisms of thermal alteration of skin permeation.

The permeability of phenol through hairless mouse skin in its normal state and in a stripped condition was also investigated in these laboratories (7). The overall behavior of this animal tissue to phenol was found to be similar quantitatively and qualitatively to the behavior reported for the human epidermis (8, 9), including exact agreement on the concentration level where self-acceleration of permeation rates due to chemical denaturation of the stratum corneum began. Since there are reports that the percutaneous absorption of phenol through thermally damaged tissue is greatly enhanced (1, 10), the present study was undertaken to quantitate this clinically serious limitation to the topical use of phenol. Specifically, this study was aimed at investigating the influences of incrementally increased burn temperature by scalding or branding on the permeation of phenol through skin.

EXPERIMENTAL

Chemicals—[^{3}H]methanol[1] and [^{14}C]phenol[1] were diluted with 0.9% sodium chloride irrigation[2] (saline) to prepare solutions for the permeation experiments. The final chemical concentrations of the permeating species in the external diffusion medium were $\leq 10^{-4}$ *M*.

Animals—Male hairless mice of SKh-hr^{-1} strain[3] were used. Their care was as described in the preceding paper (7).

Radioisotopic Assay—Concentrations of the radiolabeled permeating species were determined using a liquid scintillation counter[4] and a suitable liquid scintillator[1]. Permeation of both methanol and phenol was studied simultaneously using a technique involving dual labels (11).

[a] Computed by using Eq. 2. The control *P*-values are: methanol, 1.9×10^{-3} cm/hr and phenol, 20.3×10^{-3} cm/hr. These values were abstracted from Refs. 7 and 8.

surface of each mouse was scalded by immersing it in water contained in a jacketed beaker (3). A desired burn temperature was achieved by perfusing water from a constant-temperature water bath through the beaker.

Branding Procedure—The dorsal sites of the mice were burned immediately following sacrifice by bringing them in contact with the upper, polished surface of a branding device (5). The desired burn temperature was achieved by perfusing the device with hot mineral oil from a constant-temperature oil bath.

Diffusion Cell and Permeation Procedure—A two-chamber glass diffusion cell (3–7, 11) was employed to determine the permeability of the skin. Mice were sacrificed by spinal cord dislocation, weighed, and visually examined for skin defects and hair distribution. The animals were selected from within a narrow age range (110–155 days) to minimize age-related effects (12). The dorsal surfaces were scalded (at temperatures ranging from 60 to 100°) or branded (at temperatures ranging from 60 to 150°) for a 60-sec duration. Each burned skin section was excised from the animal and mounted in a diffusion cell, and permeation experiments were conducted immediately, as previously described (7). Each experiment lasted for ~2 hr. This procedure ensured, insofar as possible, that the data would not be affected by the unavoidable hydrating conditions of the *diffusional system* (11). Three to five mice of about the same age were used for each compound per experimental condition. The details of the operation of the diffusion cell were as described previously (7).

Data Analysis—The data were plotted as the receiver compartment concentration (in cpm) as a function of time. The permeability coefficient was computed from the quasi steady-state slope from (3–7, 11, 12):

$$P = \frac{V}{A}\frac{(dC/dt)}{\Delta C} \qquad \text{(Eq. 1)}$$

where P is the permeability coefficient (cm/hr); A is the diffusional area (~0.6 cm^2), ΔC is the concentration difference across the membrane, which was taken to be equal to the donor concentration (cpm); V is the half-cell volume (1.4 ml); and dC/dt is the steady-state slope (cpm/cm^3/hr) from the receiver concentration *versus* time profile. The scalding coefficients (S-values) and the branding coefficients (B-values) were calculated from (3, 5):

$$\text{S-Value} = \frac{\text{dorsal (scalded) permeability coefficient}}{\text{dorsal (normal) permeability coefficient}} \qquad \text{(Eq. 2)}$$

and

$$\text{B-Value} = \frac{\text{dorsal (branded) permeability coefficient}}{\text{dorsal (normal) permeability coefficient}} \qquad \text{(Eq. 3)}$$

The normal dorsal permeability coefficients were averages for those found in previous studies (11, 12).

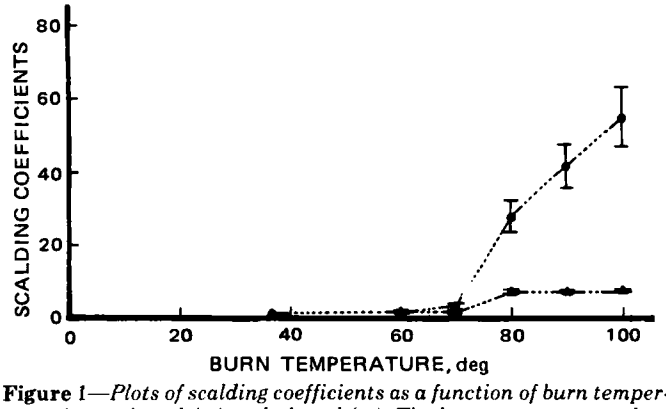

Figure 1—*Plots of scalding coefficients as a function of burn temperature for methanol (●) and phenol (▲). The bars represent standard deviations for each mean value.*

RESULTS AND DISCUSSION

Tables I and II contain summaries of data obtained in the scalding and the branding experiments, respectively. Data are tabulated separately for methanol and phenol, two solutes that diffused through the skin simultaneously. The permeability coefficients of the normal dorsal skins were abstracted from previous studies (11, 12). Figures 1 and 2 contain graphical illustrations of the burn coefficients as a function of the burn temperature for scalding and branding experiments, respectively.

Factors Influencing the Experimental Course of Action—In previous studies (3–6) two simple methods of giving graded, reproducible burns were practiced: burning at 60° for varied lengths of time and burning for 60 sec at systematically increased temperatures. Although burn wounds of third-degree depth were effected at 60° by scalding or branding for ≥1 min, the permeabilities of a spectrum of nonelectrolytes were only slightly elevated by such treatment. On the other hand, when scalding or branding was done at temperatures exceeding 70°, extraordinary augmentation of the permeabilities of some solutes was obtained. The lower the natural permeability of a species, the greater was the effect; therefore, polar solutes, held back by the effectively lipid nature of the stratum corneum, were the most affected.

The varied temperature–fixed burn duration experimental protocol yielded the optimum insight into the extent of burn enhancement of permeability, and it was therefore selectively used in these investigations. Another early observation bearing on the present study was that burns given to mice immediately postsacrifice behaved the same diffusionally as burns applied to living animals when each was studied immediately postburn. Humaneness, therefore, dictated the former procedure should be used. Since a 60-sec burn at 60° yielded a full-thickness injury, this duration was considered to be more than adequate at higher temperatures. However, retaining the duration used for the original protocol allowed direct comparison of the behavior of phenol to that of the *n*-alkanols.

Influences of Scalding on the Permeabilities of Methanol and Phenol—Scalding produced only marginal increases in the permeability coefficient for methanol up to 70° (Fig. 1). Beyond this temperature, systematic increases in the permeability coefficients are seen. At the higher temperature the scalding coefficients for methanol are quite large, reaching a value of 54 at 100°. Previously an S-value of ~31 was reported at 98° (4). The 1.7-fold difference in the quotients is more apparent than real. Previous quotients were computed with permeability coefficients of abdominal skins obtained concurrently with those of the scalded dorsum, a within-animal control method. In the present study, historical

means for the normal dorsal skin permeability coefficients were used in lieu of running a complete set of control skins with each experiment. When the same technique of computation is used with the previous data, a 98° S-value of ~43 is obtained which is in better agreement with the present value of ~54. It is important to note that a small, absolute variation in the control permeability coefficient yields a large difference in quotients such as the S-values. To further stress this point, the absolute P-values of the burned skins can be compared. The dorsal permeability to methanol was $8.49 \pm 1.27 \times 10^{-2}$ cm/hr in the earlier experiments when the burn temperature was 98° and the mouse age was 106 days. In the present study a value of $10.8 \pm 1.68 \times 10^{-2}$ cm/hr was obtained when the burn temperature was 100° and the mouse age was 115 days. The absolute permeabilities can be considered approximately the same. Given the overall qualitative parallelism between the two studies, it can be concluded that the present results compare well with the previous results for methanol.

Like methanol, increases in the permeation rate of phenol are also marginal up to 70° (Fig. 2). Thereafter, the permeability coefficient increases to a plateau reached within the 70–80° temperature span. A limiting S-value of ~7.0 is observed (Table I). Qualitatively and quantitatively, this behavior is comparable to the data for hexanol (4) where a plateau value of 6.8 was reported for burn temperatures of 80, 90, and 98. This parallel is mechanistically interesting, especially because the two permeating species have almost identical permeability coefficients when the skin is used in its natural state of hydration (11). This is not to say that the permeation of the stratum corneum is the same for both. The permeability of hexanol through intact mouse skin doubles on long aqueous soaking (11), while the permeability of phenol is little affected (7), indicating some fundamental differences in their abilities to cross the barrier layer. Hexanol and phenol do, however, exhibit nearly the same permeation rates through highly burn-impaired skin, which is not surprising given their comparable molecular weights and the aqueous nature of the residual functioning elements of the overall skin barrier after scalding.

Permeability of Phenol and Methanol Through Branded Skins—Data for methanol indicate large branding coefficients at ≥80°. As in all previous studies, 60° branding was without pronounced effect.

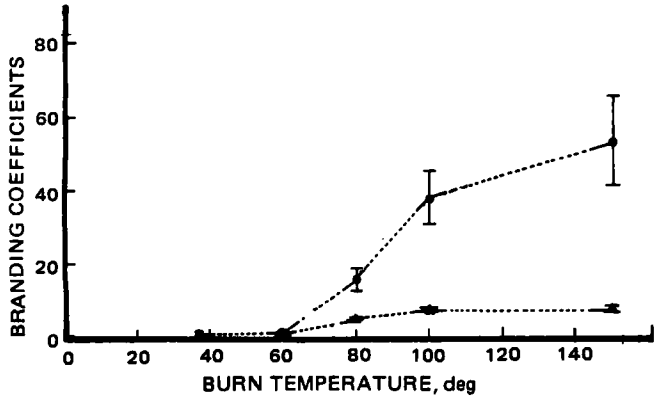

Figure 2—*Plots of branding coefficients as a function of burn temperature for methanol (●) and phenol (▲). The bars represent standard deviations for each mean value.*

While no 70° data were gathered, earlier work indicates that a transition from marginal to exaggerated burn effects took place at ~75°, which is not inconsistent with the present results. At a given temperature, branding coefficients appear consistently smaller than the scalding coefficients, suggesting that branding is an intrinsically less efficient means of damaging (presumably by denaturing the protein) the stratum corneum. At 80° for instance, the S-value is 27.4 ± 4.6, while the B-value using the same method of calculation is only 15.9 ± 2.8. At this temperature, values are significantly different ($p < 0.05$ by t test). There are several factors that might contribute to the scalding–branding disparity. In the course of scalding, the skin surface is in direct contact with the heated water; heat transfer should thus be more efficient than when there is a metal surface between the skin and the circulating thermal medium (branding). Additionally, moist heat may be more destructive than dry heat, a phenomenon that finds precedent in sterilization by autoclaving. Lastly, in the case of methanol, it appears that the closeness of the 100° S-value (54.1 and the 150° B-value (53.7) is not accidental but the consequence of the maximum possible disruption of the barrier function of the horny layer.

Branding data for phenol follow a pattern similar to that seen with scalding except that B-values again lag in magnitude behind the S-values at a given temperature. Within the limits imposed by the temperature spacing, the plateau for branding is not attained until 100° opposed to 80° for the scalding procedure. Again, the upper limit of the effects is nearly the same across burn methods: ~7 for scalding and ~7.4 for branding. The magnitude of the branding coefficients for phenol is only slightly smaller than the limiting value of ~9.5 for hexanol seen previously over the temperature range of 80–150° (6), providing another interesting parallel in the behaviors of these alkyl and aryl 6-carbon analogues.

Lastly, it has been suggested here that the barrier properties of the horny layer are destroyed at the extremes of the thermal treatments. This is true in the sense that the normal permeation selectivity is completely lost. However, permeability coefficients at their maximum for each compound are only 0.10–0.15 cm/hr, while earlier data showed stratum corneum-stripped permeability coefficients to be ~0.3 cm/hr and isolated dermis permeability coefficients to be slightly higher. It is therefore concluded that the denatured remains of the stratum corneum still offer a general diffusional resistance and are approximately as impermeable as the rest of the skin.

Clinical Relevance of the Phenol Studies—Presently, phenol is still used clinically as a local anesthetic and antipruretic, generally in whole percentage concentrations or in combination with other topical drugs (13). Its vehicles usually contain adsorptive solids and/or solvents, either of which reduces the thermodynamic activity of phenol below that of a strictly aqueous solution of the same concentration. Nevertheless, these topical preparations could be dangerous if used over burned tissue. A clinical fatality that occurred in 1949 (1) appears to be an instance where the worst possible combination of factors came together. A youth was burned by flash fire with superficial and partial-thickness burns covering 25–30% of his body. The method by which the burn was received and the clinical description of the fresh wound suggest that the burn was of short duration but very high thermal intensity: conditions which this research shows allows facile absorption through the skin. Although the phenol used for treatment was only 2% concentration in a 90% corn oil vehicle, the extensive area (fact) and highly permeable nature of the eschar (speculation) predisposed the patient to fatal systemic accumulation. Based on the work reported here, adsorption was possibly a logarithmic order

greater than it would be from the same application placed on normal skin. Given the variable but potentially high, permeability through eschar and the violent systemic toxicity (14), phenol should not be used for burn-wound antiseptics.

Another factor is that the chemical burn effected by the highest phenol concentration (6% w/v) in a preceding study (7) and the thermal burns effected here at temperatures >80° are of comparable permeability. This suggests that the chemical and thermal treatments cause the same type of destructive alteration of the stratum corneum, albeit by vastly different mechanisms, resulting in a functional impairment of the same order. We regard this as strong evidence that the stratum corneum proteins are involved and denatured by extreme treatments of either kind. It is hard to envision a means whereby these different treatments could produce like effects in purely lipid domains in the stratum corneum. By either procedure the stratum corneum loses some or all of the ability to differentiate permeating species on the basis of polarity, depending on the intensity of the burn.

Low-Melting Phenytoin Prodrugs as Alternative Oral Delivery Modes for Phenytoin: A Model for Other High-Melting Sparingly Water-Soluble Drugs

YUMIKO YAMAOKA *, RICHARD D. ROBERTS, and VALENTINO J. STELLA ˣ

Received May 11, 1981, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication July 30, 1981. * Present address: Faculty of Pharmaceutical Sciences, Kobe Gakuin University, Kobe, Japan.

Abstract □ Phenytoin is a high-melting, weakly acidic, and sparingly water-soluble drug. Because of these physicochemical properties, phenytoin is subject to erratic bioavailability in a variety of dosage forms both in its acidic as well as sodium salt forms. A homologous series of 3-acyloxymethyl derivatives of phenytoin (acetyl through decanoyl) were synthesized and various physicochemical properties measured. The prodrugs were more readily soluble in various metabolizable glycerol esters such as tributyrin, trioctanoin, and triolein than phenytoin. The solubility of the prodrugs in the various organic vehicles studied was closely correlated to the melting point of the prodrug: the lower the melting point the greater the solubility. The cleavage rates of the prodrugs in plasma and tissue homogenates followed a parabolic relationship with chain length. The prodrug, 3-pentanoyloxymethyl-5,5-diphenylhydantoin when administered in tributyrin gave superior oral phenytoin bioavailability in rats when compared with sodium phenytoin administered as an aqueous solution.

Keyphrases □ Phenytoin—low-melting prodrugs, alternative oral delivery modes, model for high-melting sparingly water-soluble drugs □ Prodrugs—use in alternative oral delivery modes, model for high-melting sparingly water-soluble drugs, phenytoin

Phenytoin (I), a high-melting (293°) weakly acidic (1, 2) drug is sparingly soluble in water (2). Because of its physicochemical properties phenytoin is subject to erratic bioavailability in a variety of dosage forms both in the acidic as well as the sodium salt forms (3–6).

Since the problems associated with the release from the various dosage forms can be attributed to both the limited aqueous solubility and the weakly acidic nature of the phenytoin, it is likely that dissolution plays an important

role in the erratic *in vivo* behavior of phenytoin (3). In the case of phenytoin, strong intermolecular hydrogen bonding in the crystal lattice between the hydrogen atom on N(3) and a carbonyl oxygen of a neighboring phenytoin molecule is the probable cause of its inferior stability characteristics (7). This problem might be overcome by disrupting this hydrogen bonding in a bioreversible fashion, thereby increasing the lipid solubility of phenytoin, allowing incorporation in a dosage form such as a soft gelatin capsule or microencapsulation. In the present study, 3-hydroxymethyl-5,5-diphenylhydantoin (II) and various straight chain acyl (III–VI, VIII–XII) as well as the pivaloyl derivative of II (VII) were prepared and various physicochemical properties measured. Of particular interest was the increased solubility of compounds III–XII relative to phenytoin in cyclohexane and metabolizable lipid vehicles as well as the relationship between the structures of these prodrugs, their melting points, and lipid solubility. The ultimate objective was to see if the bioavailability of phenytoin, as a high-melting, sparingly water-soluble model compound, could be improved by the synthesis of low-melting prodrugs that could be incorporated into metabolizable vehicles suitable for formulation in soft gelatin capsules or microencapsulation.

EXPERIMENTAL

Apparatus—Ultraviolet spectral measurements[1] were performed using 1-cm cells with caps. Melting points were measured on a capillary melting point apparatus[2] and were uncorrected. A high-performance liquid chromatograph (HPLC) with an injection system[3], was used throughout the study. A gas chromatograph[4] was used for plasma and blood phenytoin analysis.

Materials and Reagents—The solvents used as a mobile phase were HPLC grade. All other chemicals were of analytical or reagent grade. 3-Hydroxy-5,5-diphenylhydantoin (II) was prepared as follows: a mixture of 45 g of phenytoin, 2.43 g of potassium carbonate, and 1620 ml of water was stirred while 180 ml of formalin was added. The stirring was continued at room temperature for 24 hr, the solution was filtered, and the solid was washed with a 3% formalin solution and then air dried for 3 days. Various esters of II were prepared by adding 10% excess of the corresponding acid chloride, dropwise with stirring, to 10 g of II dissolved in 40–50 ml of dry pyridine. For the synthesis of the 3-pentanoyloxymethyl derivative, the corresponding acid anhydride was used. The mixture was stirred until qualitative TLC showed the reaction to be complete. The pyridine solution was then poured into slightly acidic ice water with stirring. After neutralizing (or slightly acidifying) by the addition of hydrochloric acid, the solution was stirred for several hours. The acetyl and propionyl derivatives precipitated and were recrystallized from alcohol–ether. Other compounds did not solidify, but settled out as yellow oils which were purified by the following method. The water layer was removed by aspiration, and the oil was dissolved in ~150 ml of anhydrous ethyl ether (ethyl acetate was used for the butanoyl derivative). The organic layer was washed twice with 50 ml of 2% sulfuric acid, twice with 50 ml of 5% sodium carbonate, and twice with 50 ml of water. The organic layer was then dried over anhydrous magnesium sulfate for several hours. The mixture was filtered and the solvent was removed at reduced pressure to give solid material which was recrystallized from anhydrous ethyl ether. The melting point and elemental analysis of each compound are shown in Table I.

Solubilities—The solubilities of the various esters in cyclohexane were determined by placing 2–5 times excess ester and 2 ml of cyclohexane in a screw-capped vial containing a glass bead. The air was replaced by nitrogen and the vials were sealed. The mixtures were shaken for several days in a constant-temperature water bath at 25°. The mixture was filtered, an aliquot was diluted with an appropriate amount of cyclohexane, and the absorbance at 265 nm was measured. The concentration of the ester in the saturated solutions were calculated from the measured absorbances by reference to standard curves.

The solubilities in various oils were determined by suspending the compounds in oils and rotating the vials in a water bath for up to 1 month at 25°. The viscous-solutions were centrifuged for 5 min, and then the supernatant was diluted with an appropriate amount of tetrahydrofuran. The diluted solution (20 μl) was injected on an HPLC. The separation was carried out on a 25 cm × 4.6 mm (i.d.) prepacked normal-phase column[5] with use of a tetrahydrofuran–heptane (20–80 by volume) mobile

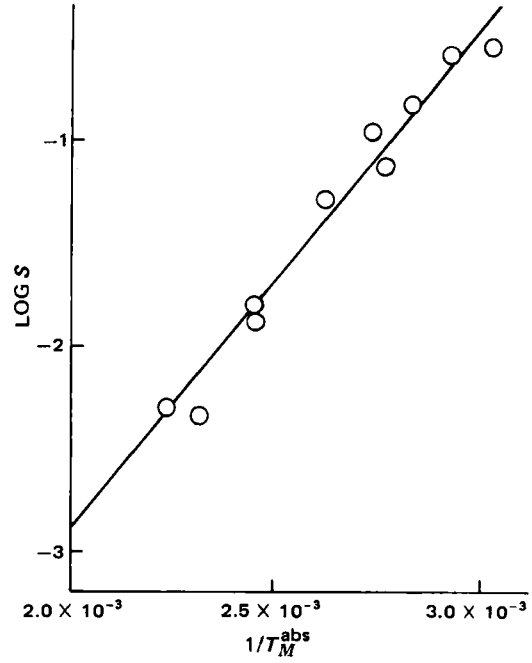

Figure 1—*Plot of the logarithm of the solubility (log S, S in units of moles/liter) of various 3-acyloxymethyl-5,5-diphenylhydantoins in ethyl oleate against the recipricol of the melting points in absolute degrees (T_M^{abs}) of the compounds. Solid line is given by the equation log S = 2404/T_M^{abs} − 7.694 (r = 0.9796).*

phase at a flow rate of 2.0 ml/min. The column effluent was monitored at 254 nm at 0.08 absorbance unit full scale. The concentrations of saturated solutions were calculated from the peak height of standard solution of each compound dissolved in tetrahydrofuran.

Stabilities—The compounds with the shortest and the longest carbon chain, 3-acetyloxymethyl- and 3-decanoyloxymethyl-5,5-diphenylhydantoin, were chosen as examples for the stability studies. A solution of each ester in each solvent studied (except cyclohexane) was prepared and placed into ampules, each of which contained 200 μl of solution. The ampules were sealed under nitrogen and kept at room temperature, 40°, and 60°. After appropriate intervals, the ampules were opened and the concentrations of the prodrugs were measured by the same HPLC method as used in the solubility study.

Kinetics in Human Plasma—The stock solution of each prodrug in acetonitrile (~2 mg/ml phenytoin equivalents) was added to the human plasma[6] which was kept in a water bath at 37° so that the final concentration of phenytoin formed was 20 μg/ml. At appropriate times a 100-μl sample was removed and the concentration of phenytoin formed by hydrolysis of the prodrugs with longer carbon chains (pentanoyl to decanoyl) was measured by GLC (8). The sample was added to 100 μl of 10% *meta*-phosphoric acid to quench any enzymatic reaction, and then 500 μl of cyclohexane was added. This mixture was vortexed for 1 min and centrifuged for 5 min. The cyclohexane layer was removed by aspiration and 100 μl of the aqueous layer was analyzed as previously described (8).

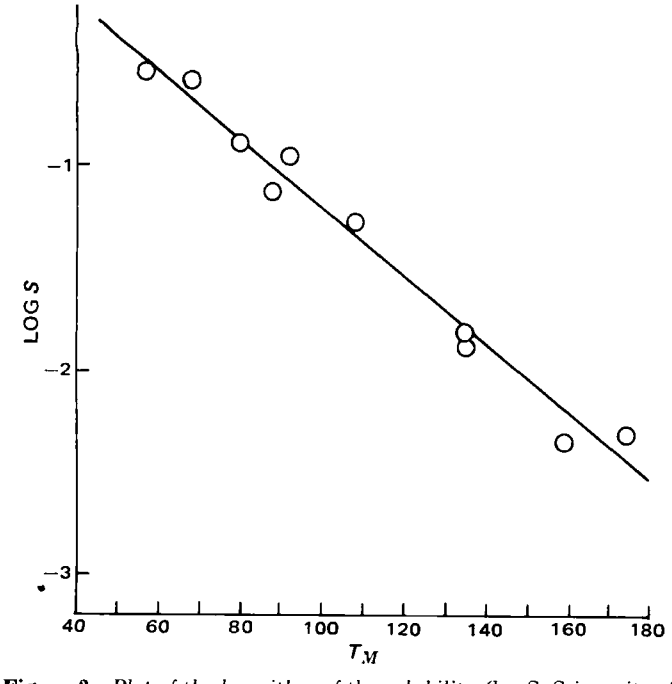

Figure 2—*Plot of the logarithm of the solubility (log* S, S *in units of moles/liter) of various 3-acyloxymethyl-5,5-diphenylhydantoins in ethyl oleate against their melting points* (T_M) *in degrees C. Solid line is given by the equation* log S = −0.0167 T_M + 0.4606 (r = 0.988).

[6] Community Blood Center of Greater Kansas City.

The concentration of phenytoin produced by the hydrolysis of prodrugs with shorter carbon chains (acetyl through to butanoyl) was determined by HPLC. The plasma samples were added to 250 μl of acetonitrile, vortexed for 5–10 sec, and then centrifuged. The supernatant was directly injected into the HPLC and was eluted with the mixture of acetonitrile and water, acidified to pH 2.5 with *meta*-phosphoric acid, at flow rate 1.3 ml/min on a 25 cm × 4.6 mm (i.d.) prepacked reverse-phase column[7]. The detector sensitivity setting was 0.005 absorbance unit full scale at 254 nm. The concentration of phenytoin was calculated from the peak height by reference to a standard curve.

The rate constants were obtained from the plots of log $(C_\infty - C_t)$ *versus* time, where C_∞ and C_t are the concentrations of phenytoin at infinity and at time t, respectively, by using the least-squares method. In all cases, the prodrugs quantitatively reverted to phenytoin and followed pseudo first-order kinetics.

Kinetics in Rat Plasma—Plasma taken from male rats were kept frozen until used. A 300-μl volume of plasma was used for each kinetic experiment. A 50-μl sample was removed at appropriate times, and the enzymatic reaction quenched by the addition of 125 μl of acetonitrile. The concentrations of phenytoin in the supernatant were measured by the HPLC method used in the kinetics in human plasma. To obtain good

XII	33.2	0.0209

separation of the phenytoin peak from an interfering peak in rat plasma, 35% acetonitrile was used in the mobile phase instead of 40%, and the flow rate was 1.5 ml/min.

Kinetics in Rat Intestine Homogenates—A male rat (Sprague-Dawley) was sacrificed and a part of the intestine removed. After being sliced on a glass plate kept on ice, the intestine was placed in a beaker with cold Sorensen's isotonic buffer. The volume of buffer was adjusted so that the ratio of the weight of the intestine to the buffer was 1:4. The mixture was homogenized while cooling with ice, then centrifuged for 10 min at 2500 rpm, and the supernatant removed and kept cold (0°).

The kinetic studies were carried out by adding 20 μl of acetonitrile solution of the prodrug (2 mg phenytoin equivalent/ml) to 2 ml of diluted homogenate (×500) kept in a water bath (37°) for 10 min before the experiment. One hundred-microliter samples were removed at the appropriate times. The assay for phenytoin was the HPLC method used in the kinetics in human plasma except for the flow rate of mobile phase, which was 1.5 ml/min in this study.

***In Vivo* Experiment**—Adult, male Sprague-Dawley rats (225–300 g) were used in the crossover study. Six rats were randomly divided into two groups. Both groups of rats were fasted overnight as well as during the sampling time but water was allowed *ad libitum*.

Each rat was given a 100-μl sample of either sodium phenytoin in water or 3-pentanoyloxymethyl-5,5-diphenylhydantoin (VI) dissolved in tributyrin *via* gastric intubation. Approximately 30 mg/kg of phenytoin equivalents were given to each rat.

Blood sampling after drug administration was done *via* a tail clip. Two hundred microliter samples of whole blood were withdrawn at 1, 2, 4, 6, and 26 hr postdose and used for analysis. After a 2-week washout period both groups of rats received the alternate dosage form. The blood samples were analyzed for phenytoin as previously described (8).

RESULTS AND DISCUSSION

The solubilities of prodrugs III–XII in the various organic solvents are shown in Table II. For the solubility of 3-decanoyloxymethyl-5,5-diphenylhydantoin (XII) in cyclohexane only a rough estimate was made. This compound, in cyclohexane, displayed liquid crystal-like behavior, making a true solubility determination difficult. For all the prodrugs, crystals isolated from the excess solids used in the cyclohexane solubility determinations were checked for possible variations in melting behavior. In all cases the melting behavior of the excess solids was identical to the starting crystals.

There was no quantitative relationship, as expected, between the solubilities of the various esters and the length of the ester alkyl chain, but there was an obvious relationship between the melting points and solubility. Figure 1 is a plot of the logarithm of the solubility of the various esters in ethyl oleate against the reciprocal of the melting points in absolute degrees. Similar plots with correlation coefficients between 0.956 and 0.984 were seen with the other solvents.

Valvani and Yalkowsky (9) have also suggested that plots of the logarithms of solubility (as mole fraction) to the melting points may be linear for a series of structurally related molecules. Reasonable linearity of plots of the logarithm of molar solubility for our series of molecules was observed. Figure 2 shows such a plot for the esters in ethyl oleate. Neither of the plots (Figs. 1 and 2) are meant to imply anything other than the fact that crystal lattice energy differences, as indicated by melting point behavior, appear to influence the solubility of the esters in the organic solvents studied.

The low melting point of the 3-pentanoyloxymethyl derivative, VI, relative to the higher and lower homologues, V and VIII, should be noted. This unusually low melting behavior is reflected in its superior solubility in the various solvents when compared to compounds V and VIII. This

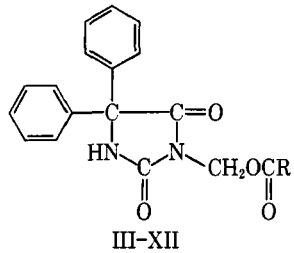
may represent a particularly disrupted member in the series that does not interact well with neighboring molecules in its crystal lattice.

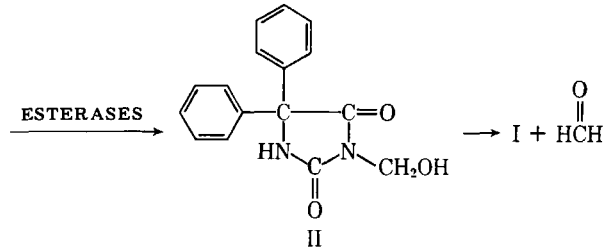
The relative solubilities of any particular prodrug in tributyrin, trioctanoin, and triolein follow a predictable trend. The greater solubilities in tributyrin than in trioctanoin and triolein were probably due to the greater polarity of this solvent because of the higher molar concentration of the polar triglyceride functional group. For example, if the molar concentration of the triglyceride functionality is calculated from the solvent density and molecular weights of the three solvents, it can be seen in Fig. 3 that a plot of the logarithm of the solubility for compounds III, VIII, and XII in the three solvents against the molar triglyceride functional group concentration is reasonably linear. This suggested that the increased solubility of the prodrugs in going from tributyrin to triolein was largely due to specific interactions between the prodrugs and the triglyceride functional group of the solvents. In fact, if it is assumed that the triglyceride functionality acts as a single-ester function, because of steric and entropic considerations, the predicted solubility of the prodrugs in ethyl oleate can be estimated within a factor of 2–3, and the intercepts in Fig. 3 predict the solubilities in cyclohexane well within an order of magnitude.

The chemical stability of 3-acetyloxymethyl and 3-decanoyloxymethyl derivatives stored in ethyl oleate at room temperature (~25°) and at 40° and 60° was determined after 1, 3, and 5 months. No loss of the prodrugs was observed. The stabilities of these two esters in tributyrin, trioctanoin, and triolein were also evaluated after storage at 60° for 3 months. No measurable degradation was observed. Though acyl exchange reactions between the esters and solvent might have been anticipated, no such reactions could be confirmed.

Enzymatic cleavage of compounds III–XII was expected to occur *via* the following scheme (Scheme I).



III–XII



II

Scheme I

It has been shown in this laboratory[8] and by others (10) that II readily dehydroxymethylates to phenytoin at pH 7.4 and 37° with a $t_{1/2}$ of <2 sec. Therefore, phenytoin production from III–XII probably occurred *via* initial cleavage of the ester bond followed by a very rapid dehydroxymethylation step to give phenytoin without any accumulation of II. In

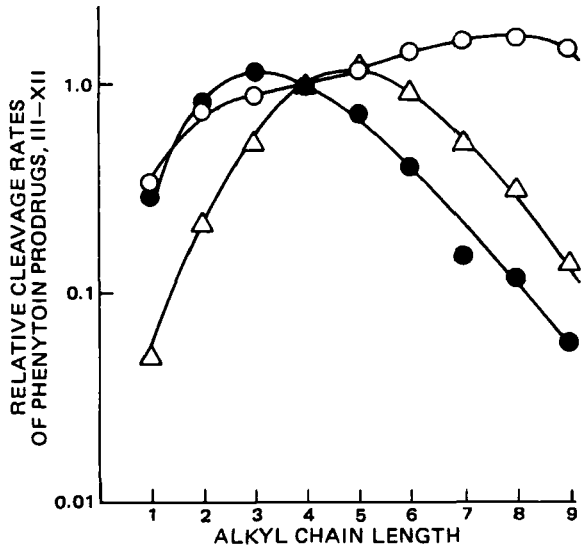

Figure 4—*Ratio of the rate constants for the cleavage of compounds III–VI, VII–XII to phenytoin in human (●) and rat (○) plasma and rat intestinal homogenates (△) at 37° to the 3-pentanoyloxymethyl derivative, VI, against alkyl chain length of the acyl function.*

all the studies with compounds III–XII quantitative cleavage to phenytoin was observed.

The rate constants and/or half-lives for the conversion of all the prodrugs to phenytoins in human and rat plasma and rat intestinal homogenates at 37° are shown in Tables III–V. In the case of rat plasma, various lots of rat plasma were studied with the cleavage rates of the prodrugs being compared with the 3-pentanoyloxymethyl derivative in each lot. The profiles for the relative cleavage rates for the prodrugs in all three tissues to the alkyl chain length are shown in Fig. 4. A parabolic relationship can be seen for each tissue, with the optimal chain length varying with the tissue and animal species.

In rat plasma all the prodrugs readily cleaved to phenytoin with half-lives of <2 min. Cleavage in human plasma was considerably slower, al-

XII	5.86	0.118

though the 3-pentanoyloxymethyl derivative, VI, had a half-life of only 1.9 min in the human plasma used in the present study. In each tissue the cleavage rate of the 3-pivaloyloxymethyl derivative, VII, was very slow compared with the other compounds. This was presumably due to steric hindrance by the *tert*-butyl group to cleavage.

The kinetics in rat plasma diluted (to 4–20%) with isotonic Sorensen's buffer were also examined. Compounds XI and XII cleaved with half-lives of about 0.5 min in 4% plasma, while compound VI cleaved with a half-life of 3.4 min. Qualitatively, the logarithm of the rate constant *versus* alkyl chain plot did not change with the maximum cleavage still occurring with the 3-nonoyloxymethyl derivative, XI.

The cleavage rates in rat intestinal homogenate were quite rapid when the homogenate supernatant was isolated from a 2500-rpm, 10-min centrifugation of the initial homogenate. Homogenate supernatant samples prepared by ultracentrifugation at 7000×*g* for 2 hr resulted in a drop in apparent esterase activity towards the prodrugs, suggesting that both the soluble as well as microsomal-bound esterases were responsible for the observed cleavage of the esters.

Based on the melting point observations, solubilities, as well as cleavage rates, it seemed that 3-pentanoyloxymethyl-5,5-diphenylhydantoin or VI might be a viable prodrug of phenytoin. Its cleavage produces, apart from phenytoin, pentanoic or valeric acid and formaldehyde in concentrations that should not be toxic. Incorporation of this prodrug into a vehicle suitable for oral administration would depend on the dose of drug to be administered, the acceptability of the vehicle, and a reliable mechanism for drug release from the vehicle.

Studies on lipid-soluble drug release from metabolizable vehicles have suggested the following mechanism for this process. After intraluminal lipolysis of the oils by pancreatic lipases, the lipolytic products are dispersed in bile salt-mixed micelles. Calcium ions along with the fatty acids form a liquid crystal-like phase which may include monoglycerides (11). Lipid drugs are presumed to be released from the vehicle by this lipolysis. The drug along with the fatty acids and monoglycerides then become available for absorption (12).

The four vehicles chosen in the present study represented examples of short- (tributyrin), medium- (trioctanoin), and long-chain triglycerides (triolein), while ethyl oleate represented a simple long-chain fatty acid ester. The interest in these vehicles as well as others being studied, results from a long-term goal to study the mechanism of drug release from metabolizable vehicles. Long-chain triglycerides are readily attacked by the lipase–colipase–bile acid–calcium system to produce various liquid crystal and mixed micellar phases (11). The short- and medium-chain triglycerides are also cleaved (13, 14), but it is anticipated that they would tend to form a simple two-phase system of oil droplets and a true solution phase.

As an initial screen of whether the prodrug–lipid vehicle concept might

Table VI—Phenytoin Whole Blood Concentration [a] in Rats After Oral Administration of VI [b] in Tributyrin Compared with Sodium Phenytoin [b] in Aqueous Solution

represent a viable drug delivery mode, plasma phenytoin levels from 3-pentanoyloxymethyl-5,5-diphenylhydantoin in tributyrin, administered orally to rats at a 30 mg/kg phenytoin equivalent dose were compared with phenytoin from an aqueous solution of sodium phenytoin. Figure 5 is a plot of the mean blood levels for the two dosage forms. The superiority of the lipid vehicle–prodrug combination is obvious. Table VI summarizes the mean (and standard deviations) phenytoin blood levels at each sample time and the AUCs up to 26 hr. Presumably, the poor bioavailability of phenytoin from the sodium phenytoin solution was due to the slow redissolution of phenytoin precipitated when the sodium phenytoin was exposed to stomach acid.

In summary, the lipid solubility of high-melting, sparingly water- and lipid-soluble drugs can be altered by transient molecular modifications. Such modification may act to disrupt the major intermolecular interactions in the crystal lattice responsible for the undesired physical properties. For these poorly lipid and water soluble drugs, improved oral delivery can be effected by the synthesis of low-melting lipoidal prodrugs, which can then be incorporated into metabolizable vehicles. *In vivo* parent drug release from such a vehicle–prodrug combination is speculated to be initial lipolysis of the vehicle giving rise to prodrug release, followed by prodrug absorption and cleavage.

Computation of In-house Quality Control Limits for Pharmaceutical Dosage Forms Based on Product Variability

SANFORD BOLTON

Received December 21, 1981, from the *College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY, 11439.* Accepted for publication December 21, 1982.

Abstract □ A method for establishing sampling plans for in-house limits that fix both the producer's and consumer's risks is presented for pharmaceutical systems in which both between-batch and within-batch variations are present. Such plans can always be constructed and require more or less sample assays depending on the variability of the process. The computations involve a numerical approximation to the bivariate normal distribution.

Keyphrases □ Product variability—pharmaceutical dosage forms, quality control limits □ Pharmaceutical dosage forms—quality control limits, product variability □ Quality control limits—pharmaceutical dosage forms, product variability

A recent article by Boudreau and Harrison (1) described a method for establishing "House Guides" that achieve "a high degree of assurance at a minimum of cost." These guides were set up in an effort to establish reasonable in-house limits, tighter than official specifications, which would give a high level of assurance that the finished product would not be out of specifications set by the NDA, FDA, official compendia, or company policy. According to Boudreau and Harrison (1), the FDA has recommended that a risk of releasing an out-of-specification product should be ≤5% based on the in-house guidelines. The establishment of in-house specifications is important because of problems that can arise when the assay of a batch of material is close to, but within, the official specifications. In these cases, the true mean potency has a good chance of being outside the official limits. Boudreau and Harrison in developing their formula, EVAL, were prompted by the difficulty of computing house limits using a single formula that would satisfy the 5% criterion and would, at the same time, consistently pass good batches which have a relatively large variation. They recommended the use of three formulas based on the relative amount of variation. It is possible to establish such in-house limits (hereafter referred to as IHLs) for any product based on its variability. If the batch-to-batch variability is so great that many batches truly fall outside the official limits, no plan will consistently pass these batches. In these situations, it is the responsibility of the manufacturer to improve the process so as to reduce the variability.

However, once the sources of variability have been identified, plans can be established with known properties. In the present case, the plans should accept out-of-specification material 5% of the time, at most. Another important criterion is that the plan should pass good material with a known probability, *e.g.*, 90% of the time.

represent a viable drug delivery mode, plasma phenytoin levels from 3-pentanoyloxymethyl-5,5-diphenylhydantoin in tributyrin, administered orally to rats at a 30 mg/kg phenytoin equivalent dose were compared with phenytoin from an aqueous solution of sodium phenytoin. Figure 5 is a plot of the mean blood levels for the two dosage forms. The superiority of the lipid vehicle–prodrug combination is obvious. Table VI summarizes the mean (and standard deviations) phenytoin blood levels at each sample time and the AUCs up to 26 hr. Presumably, the poor bioavailability of phenytoin from the sodium phenytoin solution was due to the slow redissolution of phenytoin precipitated when the sodium phenytoin was exposed to stomach acid.

In summary, the lipid solubility of high-melting, sparingly water- and lipid-soluble drugs can be altered by transient molecular modifications. Such modification may act to disrupt the major intermolecular interactions in the crystal lattice responsible for the undesired physical properties. For these poorly lipid and water soluble drugs, improved oral delivery can be effected by the synthesis of low-melting lipoidal prodrugs, which can then be incorporated into metabolizable vehicles. *In vivo* parent drug release from such a vehicle–prodrug combination is speculated to be initial lipolysis of the vehicle giving rise to prodrug release, followed by prodrug absorption and cleavage.

Computation of In-house Quality Control Limits for Pharmaceutical Dosage Forms Based on Product Variability

SANFORD BOLTON

Received December 21, 1981, from the *College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY, 11439.* Accepted for publication December 21, 1982.

Abstract □ A method for establishing sampling plans for in-house limits that fix both the producer's and consumer's risks is presented for pharmaceutical systems in which both between-batch and within-batch variations are present. Such plans can always be constructed and require more or less sample assays depending on the variability of the process. The computations involve a numerical approximation to the bivariate normal distribution.

Keyphrases □ Product variability—pharmaceutical dosage forms, quality control limits □ Pharmaceutical dosage forms—quality control limits, product variability □ Quality control limits—pharmaceutical dosage forms, product variability

A recent article by Boudreau and Harrison (1) described a method for establishing "House Guides" that achieve "a high degree of assurance at a minimum of cost." These guides were set up in an effort to establish reasonable in-house limits, tighter than official specifications, which would give a high level of assurance that the finished product would not be out of specifications set by the NDA, FDA, official compendia, or company policy. According to Boudreau and Harrison (1), the FDA has recommended that a risk of releasing an out-of-specification product should be ≤5% based on the in-house guidelines. The establishment of in-house specifications is important because of problems that can arise when the assay of a batch of material is close to, but within, the official specifications. In these cases, the true mean potency has a good chance of being outside the official limits. Boudreau and Harrison in developing their formula, EVAL, were prompted by the difficulty of computing house limits using a single formula that would satisfy the 5% criterion and would, at the same time, consistently pass good batches which have a relatively large variation. They recommended the use of three formulas based on the relative amount of variation. It is possible to establish such in-house limits (hereafter referred to as IHLs) for any product based on its variability. If the batch-to-batch variability is so great that many batches truly fall outside the official limits, no plan will consistently pass these batches. In these situations, it is the responsibility of the manufacturer to improve the process so as to reduce the variability.

However, once the sources of variability have been identified, plans can be established with known properties. In the present case, the plans should accept out-of-specification material 5% of the time, at most. Another important criterion is that the plan should pass good material with a known probability, *e.g.*, 90% of the time.

Table I—Scheme for Nested Design to Estimate Variance

		Batch I Tablet		Batch II Tablet		Batch III Tablet	
		1	2	1	2	1	2
Replicate	1	X	X	X	X	X	X
	2	X	X	X	X	X	X

PRELIMINARY CONSIDERATIONS

If the variability in a dosage form potency is due to assay error only, then the problem of setting IHLs is relatively simple. As previously described (1), the limits for in-house specifications to maintain a 5% error rate or less are (using the authors' notation (1) and assuming that the data are normally distributed):

$$\text{UPS} - 1.65S_a, \quad \text{LPS} + 1.65S_a \qquad \text{(Eq. 1)}$$

where S_a is the assay standard deviation (SD), UPS is the upper product specification, and LPS is the lower product specification. The assay SD, S_a, can be determined from control charts or replicate assays. The IHLs can be made to be as close to the UPS and LPS as we wish by increasing the number of samples assayed. Then the IHLs are:

$$\text{UPS} - 1.65S_a/\sqrt{N}, \quad \text{LPS} + 1.65S_a/\sqrt{N} \qquad \text{(Eq. 2)}$$

where N is the number of samples assayed.

The above probability statements are correct if the product is homogeneous, such as would occur with solutions or other homogeneous mixes. In these situations, the sampling procedure and the number of samples to be assayed are unambiguously defined. If the variability is composed of both assay error and sampling error, which would occur in the case of tablets (when tablets are not identical), then the number of samples to be assayed and the procedure for setting limits require further analysis. For example, a duplicate determination could be two single-tablet assays or one tablet assayed in duplicate. If S_t, the standard deviation due to only tablet differences, is 5%, S_a is 2.5%, and the UPS is 110%, a single assay would yield IHLs of $110 - 1.65\sqrt{5^2 + 2.5^2} = 100.8\%$. Similarly if the LPS is 90%, the lower IHL would be 99.2%. These limits would probably be untenable. A duplicate assay (single assays of two tablets), for example, results in an upper IHL of $110 - 1.65\sqrt{(5^2 + 2.5^2)/2} = 103.5\%$.

The problem of setting limits based on assay variation only, as correctly pointed out (1), is that other sources of variation are not accounted for. In the above example, tablet variation is included in the error, and such a procedure would properly meet the 5% FDA recommendations. Although this takes care of the so-called consumer's risk, the producer's risk (the risk of rejecting good products) is not clearly defined. This report presents a method of constructing in-house guidelines that will define both of these risks.

STATISTICAL CONCEPTS

The problem of defining both the producer's and consumer's risks when setting acceptance/rejection in-house guidelines is more or less difficult, depending on the nature of the variability of a product. The simplest case is a homogeneous system that does not vary from batch to batch but has assay error associated with it. More common are systems that have both assay error and batch-to-batch variability as well as being nonhomogeneous, *i.e.*, having unit-to-unit variation. Thus, all of these sources of variability must be considered in setting up a suitable quality control plan.

The calculation of the aforementioned sources of error can be accomplished in several ways. Quality control records for many batches where replicate assays are performed within each batch may be sufficient to supply the necessary estimates. The use of Shewhart control charts for means and variability (range or, preferably, standard deviation) accomplish the same end. Since the discussion in this paper is based on an assumption that the process is not changing, Shewhart control charts can also help ensure that the process is in "control." An experimental design (known as a nested design) may be implemented where several units from each batch are assayed in replicate (duplicates are usually sufficient) for many batches, as shown in Table I.

Table II—Analysis of Variance for a Nested Design to Estimate Components of Variance

Source	Mean Square Estimates[a]
Batches	$rtS^2_b + rS^2_t + S^2_a$
Tablets (within batches)	$rS^2_t + S^2_a$
Assay error	S^2_a

[a] r = Number of replicate assays on each tablet; t = number of tablets; S^2_a, S^2_t, and S^2_b are the variances associated with the assay, tablets, and batches, respectively.

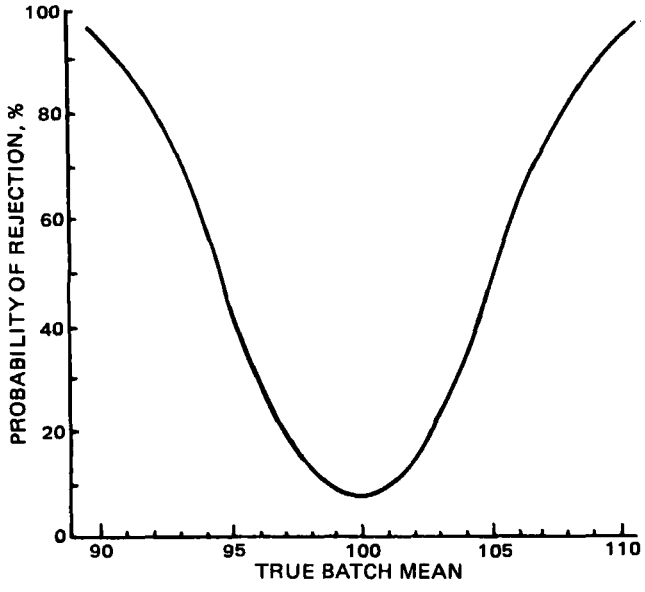

Figure 1—*OC Curve for batch with* $S^2_t + S^2_a = 25$, *true mean = 100,* N *= 3.*

This design allows the estimation of the variance due to assay, unit-to-unit, and batch-to-batch variability (components of variance) (2). The computations in this paper assume that the variances are known (typical Shewhart control charts are constructed under the same assumption). If a sufficient amount of historical data are available, this assumption will not cause problems. For a new process, specifications and/or the sampling plan should be suitably modified as data become available and variance estimates stabilize. The analysis of variance is shown in Table II.

The variance of a single tablet assay is $S^2_t + S^2_a$. If this variance is so large that an unreasonable IHL is obtained to satisfy the 5% criterion, this variability can be effectively reduced by performing replicate assays. This is usually more efficiently accomplished by assaying more than one tablet rather than performing replicate assays on the same tablet, but the optimal procedure depends on the magnitude of S^2_t, S^2_a, and time-cost estimates. For example, the variance of the average of two replicate assays of two tablets is $S^2_t/2 + S^2_a/4$. The variance of the average of four single tablet assays is $(S^2_t + S^2_a)/4$, smaller than that of two replicate assays of two tablets, but which may be more costly to run. Data derived from content uniformity tests can be useful to develop and monitor IHLs because of the relatively large amount of data (at least 20 individual tablet assays per batch) that is readily available for products

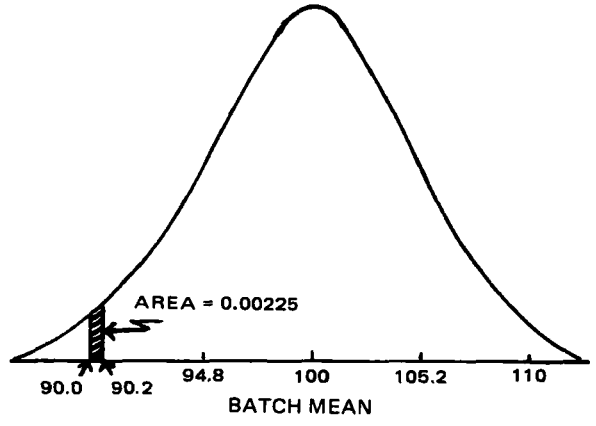

Figure 2—*The shaded area represents the probability of a batch mean falling between 90.0 and 90.2.*

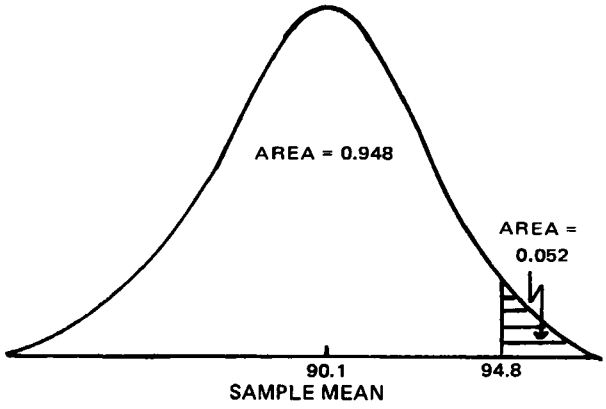

Figure 3—*Normal curve with mean equal to 90.1 showing the probability of a sample mean being below 94.8 (unshaded area, p = 0.948).*

undergoing this test. However, data may also be derived from the usual composite assays performed in replicate. Because most solid dose forms undergo content uniformity tests, and the results of these multiple single tablet (or capsule) assays provide more data for variance estimation, the remaining discussion will consider single-tablet assays. The discussion applies equally well to composite assays where sufficient data are available to precisely estimate the variance components. For composite assays, the variance of a single tablet assay, $S^2_t + S^2_a$, is replaced by $S^2_t/C^2 + S^2_a$, the variance of a single composite assay, where the composite consists of C tablets. The variance in the latter case may be reduced by performing m assays on each of n composites, where the variance of the mean result is $S^2_t/nC + S^2_a/nm$. This is analogous to the variance of the mean of t single tablet assays when $c = M = 1$.

Ignoring batch-to-batch variability for now, it is clear, based on the above discussion, that the IHLs can be made as close to the UPS and LPS as we wish by performing more assays. Consider the following example. Experience has shown that the *SD* (assay error) of a tablet with 100 mg of drug is 5% ($S^2_a + S^2_t = 25$). If single tablets are assayed and the official specifications are 90–110 mg, the IHLs are:

$$110 - 1.65 \times 5 = 101.75 \text{ and } 90 + 1.65 \times 5 = 98.25$$

a very tight specification for a 100-mg tablet. However, if three tablets are assayed, the standard error of the average is $5/\sqrt{3} = 2.89$, and the IHLs are 94.8–105.2, with the same probability (≤5%) of accepting a bad lot. Therefore, if considerable variability exists, the IHLs can be made wider (close to, but not exceeding the UPS and LPS) by performing replicate assays.

SAMPLING PLANS: MANUFACTURER'S RISK

Since there are any number of plans, depending on the number and kind of replicate assays, all of which will ensure that no more than 5% of out-of-specification product will be passed, another criterion can be used to fix the number of assays to be used for a given plan. This criterion, as previously mentioned, the manufacturer's risk, is the chance of rejecting a good batch of product based on the in-house limits. A good batch is one that is truly within the official limits, the UPS and LPS. The following discussion will present a method for establishing plans based on both the α and β risks: the chance of accepting lots of poor quality or rejecting lots of good quality, respectively. Since only one assay will be performed per tablet, the variance of a single assay is $S^2_a + S^2_t$. Also, the α error will be at most 5% for each batch.

Some practical considerations should be emphasized. When considering sampling from batches, the variance of the estimate of a mean value taken from a batch (any batch taken at random) is $S^2_b + (S^2_t + S^2_a)/t$, where t is the number of tablets assayed. Thus, it is not possible to reduce the variance of this estimate below S^2_b by increased sampling of tablets within a batch. The way to reduce batch-to-batch variation (S^2_b) is by careful and controlled manufacturing procedures, as previously noted. If the batch variation is so large that the sample averages consistently border on the official limits, it would be advantageous to the manufacturer to improve the process. Otherwise it will be difficult to pass batches using any plan.

An example will be used to illustrate the general procedure of constructing a sample plan. Consider a product whose overall average as determined from historical data or control charts over many batches is

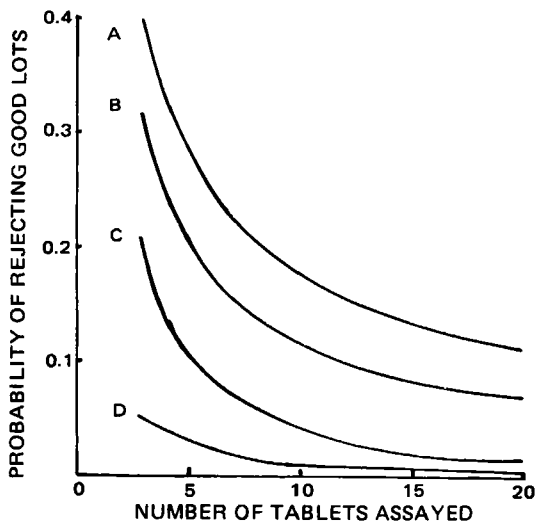

Figure 4—*Probability of rejecting good batches based on in-house limits.*
For curves A, B, and C, $S^2_t + S^2_a = 25$. For curve A, $S^2_b = 50$; for curve B, $S^2_b = 25$; for curve C, $S^2_b = 10$; for curve D, $S^2_t + S^2_a = 10$ and $S^2_b = 10$.

100% of label. The LPS and UPS are 90 and 110%, respectively, and the assay and unit-to-unit variabilities are known. The batch-to-batch variability can be obtained from historical data or by using an experimental design similar to that previously described. Suppose, in this example, that three tablets are assayed and $S^2_a + S^2_t = 25$. The IHLs are $(90 + 1.65\sqrt{25/3},\ 110 - 1.65\sqrt{25/3})$ 94.8–105.2 (Eq. 2). This fixes the consumer's risk at ≤5%. The properties of this plan for any given batch can be described by an operating characteristic (OC) curve, where the probability of rejection is plotted as a function of the true batch mean (Fig. 1). Clearly, the probability of rejection is not constant but changes depending on the true mean of the particular batch being tested. For any given batch, the true mean is not known and the probability of rejection, therefore, is also not known. (It should be again emphasized that the probability of accepting a bad batch is fixed at ≤5% for all batches by application of Eq. 2.)

The problem to be solved is to establish a sampling plan that will reject good batches using the in-house guidelines, a small but known proportion of the time over many batches. This can be accomplished if S^2_b and $S^2_t + S^2_a$ are known and if batch means and assays are normally distributed, by use of the bivariate normal distribution. The probability of rejecting a good batch (one whose true mean is between 90 and 110 mg) using the IHLs as the criteria, can be computed based on a basic probability theorem:

Probability (a sample mean falls outside the IHLs, given that the true batch mean is within the official specifications) = Probability (sample mean falls outside the IHLs and the true batch mean is within official specifications)/Probability (true batch mean is within official specifications)[1]. (Eq. 3)

The following sample calculation will give a close approximation to this probability. The example uses official limits of 90–110 with a long-term average of 100, but this process can be applied to any specified limits or any long-term mean of a product.

1. Divide the region between 90 and 110 into small intervals, *e.g.*, 100 divisions of 0.2 units each.

2. Compute the probability that the true batch mean lies in each of the 100 intervals. For example, if $S^2_b = 25$, the probability of a batch mean falling between 90.0 and 90.2 is 0.002248, as calculated from areas under the standard normal curve (Fig. 2).

3. For each of the 100 intervals, compute the probability that a sample mean from a batch in the interval will fall outside of the IHLs. This can be closely approximated by computing the probability based on a true batch mean midway in the interval. For example, to calculate the probability that the mean if a sample of size 3 will fail the in-house limits if

[1] Note that the producer's risk, the probability of rejecting a good lot, is defined here as a conditional probability, based only on the good lots manufactured. This risk may also be calculated on the basis of all lots produced, both good and bad. In this example, using the results shown in Table III, the former calculation results in a risk of 0.0664/0.955 = 0.0695; the latter calculation results in a risk of 0.0664.

Table III—Properties of a Plan with $N = 20$, $S^2_b = 25$, $S^2_t + S^2_a = 25$

	Probability that a batch is			
	Within Official Specifications (0.955) and		Outside Official Specifications (0.045) and	
Plan A[a]	Passes In-House 0.8881	Fails In-House 0.0664	Passes In-House 0.0004	Fails In-House 0.0446
Plan B[a]	Passes 0.937	Fails 0.017	Passes 0.004	Fails 0.041

[a] Plan A: Assay 20 single tablets. Pass batch if average is within IHLs.
Plan B: Assay 20 single tablets. Pass batch if average is within IHLs. Reject if average outside official specifications. If average is between IHLs and official specifications, assay 20 different tablets and average the 40 tablets. If the average of the 40 tablets is within official specifications, pass the batch. Otherwise, reject the batch.

the batch mean is between 90 and 90.2, consider μ, the true batch mean to be equal to 90.1. The problem, then, is to compute the probability that the sample mean will be <94.8 or >105.2, if the true mean of the batch is 90.1. The probability of the mean being >105.2 is virtually zero. The probability that the sample mean is less than 94.8 can be calculated knowing that the variance of the mean of three tablets is 25/3 ($S^2_t + S^2_a = 25$). Again, using areas under the standard normal curve, this area is equal to 0.948, as shown in Fig. 3.

4. Multiply the probabilities obtained from steps 2 and 3 for each of the intervals in step 1 and sum over all intervals (between 90 and 110). This result closely approximates the probability of observing a sample mean outside of the IHLs and a batch mean within official specifications. This sum is equal to 0.320 for this example.

5. Divide the probability obtained in step 4 by the probability that a batch mean will fall between 90 and 110. In this case the latter probability is equal to 0.955 (95.5% of the batches manufactured will have a true mean between 90 and 110 if $S^2_b = 25$.). This quotient is the answer to the original problem: the *probability that a good batch will fail* based on the IHLs as expressed in Eq. 3. This is equal to 0.320/0.955 = 0.335 in the present example.

There is no explicit solution to the above problem, but by selecting smaller intervals for the batch means (less than 0.2 in step 1, the approximation can be improved slightly. Although this calculation may seem complicated and tedious, it can be accomplished easily by a simple computer program[2].

Figure 4 is a plot of the probability of rejecting good batches as a function of sample size showing the effect of changing $S^2_a + S^2_t$ and S^2_b. With such information a suitable sample size can be chosen to fix the manufacturer's risk at an acceptable level. These plans always have a probability of <5% of accepting lots that are out of the official specifications.

If $S^2_t + S^2_a = 25$, a product with $S^2_b = 25$ would require more than 55 tablets to achieve an erroneous rejection rate of 5%. If $S^2_b = 10$, a sample of 8–9 tablets would suffice. If $S^2_t + S^2_a$ is reduced to 10, and $S^2_b = 10$, 3–4 tablets would give the required protection.

The complete properties of any plan can be calculated using a variation of the same computer program used to compute the probabilities of erroneously rejecting good batches as described above. The probabilities shown in Table III were derived from a plan in which 20 tablets were assayed, with $S^2_b = 25$ and $S^2_t + S^2_a = 25$, a plan that fixes the IHLs at 91.84–108.16. More than 95% of batches of this product will be within official specifications. Of these, 6.64% will fail the in-house specifications. The probability of a good batch failing the in-house specifications is 6.64/95.55 = 0.0695, the producers risk.

The consumer's risk can be defined as the probability that a bad batch will be among those passed by the producer, i.e., the probability that a batch is bad given that it is accepted by the producer. Using the data in Table III, the consumer's risk, according to this definition, is 0.0004/(0.8881 + 0.0004) = 0.00045.

If the sample mean falls between the IHLs and the official specifications, usually it would be prudent not to reject immediately the batch, but to perform further assays to zero in on the true batch average. However, such sequential sampling changes the probabilities as outlined in this paper. The probabilities resulting from sequential sampling plans depend on the nature of the sampling plan, and increase the consumer's risk and decrease the producer's risk. The probabilities resulting from a sequential plan can be closely approximated by using a procedure similar to that previously described for the single stage sampling. A reasonable sequential plan would be as follows. Assay 20 single tablets[3]. Accept the batch if the average falls within the IHLs, and reject the batch if the average is outside the official specifications. If the average falls between the IHLs and official specifications, assay 20 more single tablets and compute the average of the 40 tablets assayed. If the average of the 40 tablets falls within the official specifications, accept the batch. Otherwise, reject the batch. The probabilities of acceptance and rejection using this plan is shown in Table III, Plan B. The producer's risk is reduced to 0.018 and the consumer's risk is increased to 0.0043 as compared with the risks of 0.0695 and 0.00045 for the single-stage sampling plan.

Solubility of Hydrocortisone in Organic and Aqueous Media: Evidence for Regular Solution Behavior in Apolar Solvents

T. A. HAGEN *x and G. L. FLYNN

Received April 16, 1981 from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication February 22, 1982. *Present address: Pharmaceutical Research and Development, Pfizer Central Research, Groton, CT 06340.

Abstract □ The solubility of hydrocortisone was determined experimentally in a wide variety of solvents. Groups of solvents were selected to emphasize different solute–solvent interactions which can influence the solubility profile of such a large, polyfunctional solute. Regular solution theory for a crystalline solute was shown to be applicable to the solubility behavior of hydrocortisone in solvents that lack strong dipoles and the ability to hydrogen bond. A best-fit solubility parameter of 12.4 $(cal/ml)^{1/2}$ for hydrocortisone was determined from the latter solubilities and the ideal solubility of hydrocortisone. This solubility parameter estimate was significantly higher than estimates calculated from molar-attraction constants. Even though molar volume ratios between hydrocortisone and the solvents ranged from 2.25 to 3.28, the associated Flory–Huggins entropy term did not seem to be a significant solubility-determining factor. In all cases, the solubility of hydrocortisone in solvents capable of dipole–dipole interactions and hydrogen bonding was shown to be higher by logarithmic orders when compared with regular solution theory predictions. Thus, for this solute, regular solution theory was shown to be appropriate only for solvents where London dispersion forces dominate the interactions between solute and solvent molecules.

Keyphrases □ Hydrocortisone—solubility in organic and aqueous media, determination of regular solution behavior in apolar solvents □ Solubility—of hydrocortisone in apolar solvents, regular solution behavior of large polyfunctional solutes □ Regular solution theory—behavior determination for hydrocortisone solubilities in apolar solvents

The physicochemical events responsible for the solubilization of a drug in various solvent systems can be characterized rigorously on a macroscopic scale, if not a molecular scale. For a crystalline nonelectrolyte, the critical factors are the solid-phase activity of the solute and molecular interactions between solute and solvent. The ability to estimate these critical parameters for drug molecules placed in a given vehicle or solution environment has immense importance when deciphering the mechanisms of drug action and delivery. To attain such objectives, macroscopic thermodynamic functions must be coupled with phenomenological interpretations of the processes involved in solubilization. Due to the polyfunctional character of drug molecules, a wide variety of molecular interactions are often simultaneously operative. Current solubility theories are limited to specific types of intermolecular interactions. An example is regular solution theory as proposed by Scathard (1) and Hildebrand (2), which is premised on all intermolecular association being of a nonorientating variety. Although this theory has on occasion been overextended to solvent systems where this fundamental assumption is not true, valid applications have provided basic understanding of solubility behavior for various pharmaceutical systems (3–8).

The purpose of the present study was to characterize the solubility behavior of hydrocortisone in solvents that are capable of a full range of molecular interactions with this polyfunctional solute. Two reference points were employed in the analysis, the primary point being ideal behavior and the secondary point of comparison being regular solution behavior. Furthermore, the values and limitations of regular solution analysis are demonstrated for a typically complex pharmaceutical solute.

THEORETICAL

A reaction of two components, a liquid solvent and an excess of a crystalline solute, is at a state of equilibrium when the thermodynamic activity of the solute in solution (a_2) equals the thermodynamic activity of solid solute (a_2^s). In this case the activity is taken as the ratio of solute vapor pressure to the vapor pressure of pure (supercooled) liquid solute. If this activity also equals the mole fraction composition over the entire concentration range up to and including saturation, the solution is an ideal solution. This only occurs when the solute–solvent adhesiveness is exactly equal to the cohesiveness of the pure liquid components considered on a per unit volume basis. Solubility predictions for ideal solutions require only estimates of a_2^s.

Most solute–solvent mixtures do not behave ideally, and solute mole fractional concentrations often differ greatly from their activities. To establish a relationship between concentration and activity, standard states must be selected for the components. For solubility analysis a convenient selection for the solute is pure liquid solute at the temperature of interest. Unit activity is thus defined as the activity of the pure liquid at a mole fraction of 1.0. The activity of a solute in solution is defined as directly proportional to the mole fractional concentration of the solute (X_2):

$$a_2 = \gamma_2 X_2 \qquad \text{(Eq. 1)}$$

where γ_2 is the proportionality constant or mole fractional activity coefficient. As X_2 approaches unity (the standard state), the ratio a_2/X_2 (or γ_2) approaches unity. The same standard state is also convenient for the solvent. For dilute solutions, the molecular environments of both solute and solvent molecules are predominantly other solvent molecules, and consequently the activity of the solvent is proportional to its fractional composition:

$$a_1 = X_1 \qquad \text{(Eq. 2)}$$

At the same time, solute molecules essentially only interact with solvent, and γ_2 is virtually constant for small changes in solute concentration. For a poorly soluble, crystalline nonelectrolyte, the mole fractional solubility ($X_{2,sat}$) is dependent therefore on molecular interaction differences between solute and solvent, reflected by γ_2, and the activity of the crystal:

$$a_2^s = \gamma_2 X_{2,sat} \qquad \text{(Eq. 3)}$$

From a thermodynamic viewpoint, solubility prediction is possibly based on measurements or estimations of γ_2 and a_2^s.

Crystalline Phase Activity—For solutes that are crystalline at ambient temperature, the selected standard state is a hypothetical state referred to as supercooled liquid solute. The free energy change required to form supercooled liquid solute from the solid solute (ΔG^{sc}) defines the activity of the solid as:

$$a_2^s = e^{-\Delta G^{sc}/RT} \qquad \text{(Eq. 4)}$$

Associated with this process is an enthalpy change ΔH^{sc} and an entropy change (ΔS^{sc}) such that ΔG^{sc} can be expressed as:

$$\Delta G^{sc} = \Delta H^{sc} - T\Delta S^{sc} \qquad \text{(Eq. 5)}$$

It is possible to obtain an expression experimentally suited for estimating

0022-3549/83/0400-0409$01.00/0

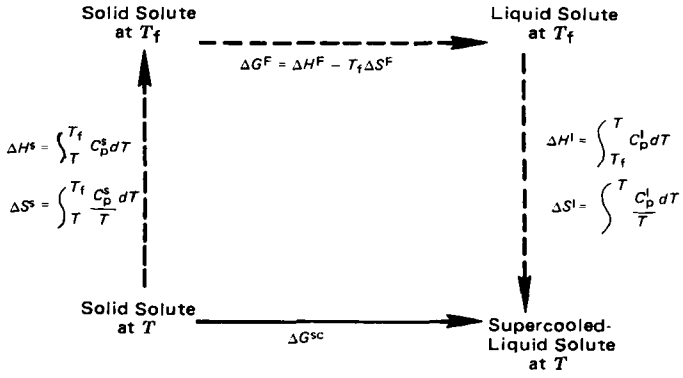

Figure 1—*Thermodynamic pathway for* ΔG^{sc} *at constant pressure.*

ΔG^{sc} at constant pressure. The thermodynamic pathway is given in Fig. 1. Here, a solid is heated to its melting temperature, melted, and the resulting melt is cooled back to the ambient temperature (T). By summing enthalpic and entropic contributions from each step, the total free energy change is obtained and, therefore, the activity of the solid can be expressed as:

$$\ln a_2^s = \frac{-\Delta H_f}{RT}\left(\frac{T_f - T}{T_f}\right) + \frac{\Delta C_p}{R}\left(\frac{T_f - T}{T}\right) - \frac{\Delta C_p}{R}\left(\ln \frac{T_f}{T}\right) \quad \text{(Eq. 6)}$$

where T_f and T are the melting and ambient temperatures, respectively, R is the gas constant, and ΔH_f is the heat of fusion for the solid at the melting point. The term ΔC_p is the difference of heat capacities between the liquid and solid. If ΔC_p and/or the temperature range T_f–T is small, the enthalpy and entropy of fusion are nearly constant, and Eq. 6 reduces to the familiar expression:

$$\ln a_2^s = \frac{-\Delta H_f}{RT}\left(\frac{T_f - T}{T_f}\right) \quad \text{(Eq. 7)}$$

The thermodynamic activity of a crystalline solute is therefore dependent on the *intrinsic properties* of the crystal lattice and can be estimated from experimental measurements of ΔH_f and T_f.

Regular Solutions—Solutions rarely conform to ideal behavior, since slight differences in molecular functionality between solvent and solute can result in large differences in their molecular interactions. Thermodynamically, the extent of deviation from the ideal case is expressed by the ratio a_2/X_2 which is the mole fractional activity coefficient γ_2. In other words, the free energy difference between ideal and nonideal behavior is defined as:

$$\Delta G_2^E = RT \ln (a_2/X_2) \quad \text{(Eq. 8)}$$

where ΔG^E is the excess free energy of mixing. Prediction of ΔG^E is difficult, since it is dependent on both the enthalpy and the entropy associated with molecular interactions for the pure components as well as their mixture. In the regular solution theory, the limiting situation is described as one in which the dominant molecular interactions between solute–solute, solvent–solvent, and solute–solvent are London forces (1, 2). This force is only dependent on the distance between atoms and their instantaneous orientation. The resulting attraction is nonorientating.

Table I—Group Contributions to Molar Volume for Hydrocortisone

Functional Group or Atom	Number of Groups in Hydrocortisone	Partial Molar Volume Contribution per Group, ml/mole	Total Volume Contribution per Group[a], ml/mole
O—H	3	5.4	16.2
O=	2	5.5	11.0
CH_3	2	19.3	38.6
C	19	9.9	188.1
H	21	3.1	65.1

[a] Molar volume for hydrocortisone = 319 ml/mole.

The molecular model for regular solution behavior, therefore, allows for only an excess enthalpy of mixing arising from differences in cohesive energies between solute and solvent. Completely random mixing is assumed; thus, there is no excess entropy of mixing. The cohesive energy density of a pure liquid component is its internal energy per unit volume. Providing the vapor of a liquid is nearly ideal, the energy of vaporization per unit volume is an acceptable estimate for this internal energy.

The cohesive energy density of a mixture is much more difficult to estimate. By definition, this is the energy necessary to break all intermolecular contacts within the mixture. For these circumstances, Scathard (1) defined the cohesive energy density of a mixture as the geometric mean of the pure components' cohesive energy densities. It is this definition that limits regular solution theory to systems that predominantly interact through London forces.

Using these criteria for regular solution behavior, the energy of mixing for two components ΔE^M is as follows:

$$\Delta E^M = (X_1V_1 + X_2V_2)\left[\left(\frac{\Delta E_1^V}{V_1}\right)^{1/2} - \left(\frac{\Delta E_2^V}{V_2}\right)^{1/2}\right]^2 \phi_1\phi_2 \quad \text{(Eq. 9)}$$

where V is the molar volume, ϕ is the volume fraction, and ΔE^V is the energy of vaporization. As previously defined, the subscripts 1 and 2 designate the solvent and solute, respectively. The square root of the cohesive energy density is more often referred to as the solubility parameter δ. The partial molal energy of transferring liquid solute from pure liquid solute to solution is obtained by differentiating Eq. 9 with respect to n, *i.e.*:

$$\left(\frac{\delta \Delta E^M}{\delta n_2}\right)_{n_1} = V_2\phi_1^2(\delta_1 - \delta_2)^2 \quad \text{(Eq. 10)}$$

Assuming that there is no change in volume on mixing at constant pressure and that the entropy of transfer is ideal, it follows that:

$$\Delta G_2^E = RT \ln (a_2/X_2) = V_2\phi_1^2(\delta_1 - \delta_2)^2 \quad \text{(Eq. 11)}$$

Thus, deviation from ideality arises from the cohesive energy density difference between solvent and solute. This deviation defines the activity coefficient in terms of the excess enthalpy of mixing which, in this model, is identical to the excess free energy of mixing.

For a solid solute in equilibrium with saturated solution, the mole fractional regular solution solubility is as follows:

$$\ln X_2 = \frac{-\Delta H_f}{RT}\left(\frac{T_f - T}{T_f}\right) - \frac{V_2\phi_1^2}{RT}(\delta_1 - \delta_2)^2 \quad \text{(Eq. 12)}$$

In addition to the crystalline properties associated with fusion, application of this theory requires knowledge of the solubility parameters for solute and solvent.

EXPERIMENTAL

Materials—Hydrocortisone was obtained from The Upjohn Company and was used without further purification. For the solubility studies, double distilled water and reagent grade organic solvents[1] were used.

High-Performance Liquid Chromatographic (HPLC) Procedure—A high-performance liquid chromatograph[2], operated at ambient temperature, was equipped with a UV detector for monitoring the column effluent at 254 nm. Chromatographic systems were developed with deaerated methanol–water solvent systems and a μ-Bondapak C-18 column[3]. The flow rate was 1.0 ml/min and the detector sensitivity was

Table II—Physical Properties of Hydrocortisone

Molecular Structure	Molecular weight	362.5 g/mole
Crystalline density	1.24 g/ml
Molar volume, V_2	293 ml/mole
Melting temperature, T_f	212°
Heat of fusion, ΔH_f	8.1 Kcal/mole
Entropy of fusion, ΔS_f	16.7 cal/deg/mole
Activity of solid phase, a_2^s estimated from $\ln a_2^s = \frac{-\Delta H_f}{RT}\left(\frac{T_f - T}{T_f}\right)$	5.2×10^{-3}
Solubility parameter	12.4 $(cal/ml)^{1/2}$

adjusted as needed for each sample. Standard solutions of hydrocortisone were prepared for calibrating chromatographic peak heights. Injection volumes for standard and unknown solutions were equivalent, and internal standards were used when necessary. The sensitivity range of the chromatographic system for hydrocortisone was determined to be 10–0.01 μg/sample. Standard curves demonstrated excellent linearity over the entire concentration range.

Solubility Determination—The solubility of hydrocortisone in each solvent was obtained by equilibrating large excesses of solute with solvent in sealed glass containers. Temperature was maintained at 25° by a constant-temperature water bath and vigorous stirring was supplied by magnetic bars. An excess of solute was always present in the slurries. Solubilities in hexane and cyclohexane were determined by equilibrating large volumes of solution (300–600 ml) with excess solute for several days. Large samples were taken, filtered[4], measured, and brought to dryness; the residue was reconstituted in 3 ml of methanol with an internal standard and assayed by HPLC. The procedure was repeated three times.

The solubilities of hydrocortisone in the remaining solvents were determined in a similar manner utilizing smaller sample volumes. Samples (1 ml) were drawn from equilibrating solutions and were placed in microcentrifuge tubes. After immediate centrifugation, the supernatant was drawn through glass wool-tipped pipets and diluted in methanol. For solutions with densities greater than solid hydrocortisone, excess solute was first removed by suction. At least four samples were drawn from each solution with ~2-day intervals between samplings. Each time point (sample) was assayed by HPLC at least twice. Concentration *versus* time of equilibration plots indicated that equilibration was obtained rapidly (<24 hr) for all solutions except propylene glycol–water mixtures with high percentages of propylene glycol. Apparently due to the high viscosity of propylene glycol and its concentrated aqueous mixtures, these solutions required longer time periods to reach equilibration, as shown in Fig. 2. For all the solvent systems, once concentration plateaus were established, several values were determined at 2-day intervals to further ensure saturation. The procedure was repeated with new solutions. Dissolution profiles showed no evidence of hydrocortisone undergoing polymorphic transition or solvate formation. No decay products or impurities were detected by the HPLC assay. The specific HPLC assay ensured that only hydrocortisone was being quantified and ruled out the often troublesome complications associated with impurities.

Differential Thermal Analysis—The heat of fusion ΔH_f and the entropy of fusion ΔS_f were determined with a differential thermal analyzer[5] equipped with a standard cell attachment. A finely powdered, accurately weighed sample (1.5–2.0 mg) was spread evenly in a 40-μl aluminum crucible. A pinhole opening in the crucible lid allowed the sample to be in contact with the cell atmosphere of dry nitrogen with a regulated flow rate of 0.5 liter/min. An empty, sealed crucible served as a reference. Samples were heated at 5°/min. Heating curves were recorded at 5°/cm with a measuring range of 20 μV and recorder amplification of 100 mV. Calibration coefficients were determined with accurately weighed samples of indium. The molar heat of fusion was calculated from the area of the melting endotherm, moles of sample used, and the calibration coefficient. The entropy of fusion was obtained by dividing the heat of fusion by the absolute temperature of melting, T_f.

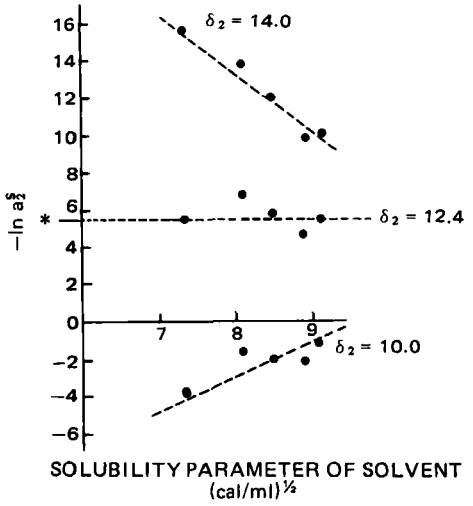

Figure 3—*Ideal solubilities of hydrocortisone (●) obtained from Eq. 14 for varying solute solubility parameters, δ_2. Key: * $-\ln a_2^s$ as calculated from crystalline properties (Table II).*

Melting Point—The melting point of hydrocortisone was determined by two methods: (*a*) controlled-heating thermal microscopy[6] and (*b*) differential thermal analysis. Heating rate for both methods was 5°/min.

RESULTS

Physical Properties—Hydrocortisone is a crystalline solid, which on heating from 25 to 220° undergoes only one thermal transition. This endothermal transition at 212° corresponds to the melting of the crystal. Hot-stage microscopy revealed no crystal morphology changes until melting. However, on cooling the melt below 212°, an amorphous glass was formed instead of the original crystalline solid. This occurrence may be, in part, the result of slight thermal decomposition within the melt. However, the sharpness and symmetrical shape of the endotherm suggest that thermal decomposition apparently is not contributing to the overall energy change during the melting phase. Moreover, melted samples assayed by HPLC showed only trace amounts of decay with essentially 100% retention of hydrocortisone. It is therefore concluded that the endotherm represents primarily energy consumed on melting. The ΔH_f for hydrocortisone is 8.1 kcal/mole and ΔS_f is 16.7 cal/deg mole. These values are averages from five determinations with $SD < \pm 5\%$. The experimental values for ΔH_f, ΔS_f, and T_f are also in good agreement with reported results (3).

A physical parameter that is necessary for solubility analysis is the molar volume of liquid solute. It has been demonstrated for several crystalline steroids that the molecular weight divided by the crystalline density can serve as a suitable molar volume estimate for the supercooled liquid solute (3). Since hydrocortisone has a crystalline density of 1.24 g/ml at 25° (9), the molar volume estimate is 293 ml/mole. An alternative means for estimating molar volume is by the summation of the partial molar volumes of a compound's functional groups (10). Applying this method to hydrocortisone (Table I), a molar volume of 319 ml/mole was obtained. This value is in reasonable agreement with the first estimate. The value of 293 ml/mole for the molar volume of supercooled liquid hydrocortisone will be used to be consistent with previously reported work (3).

The thermodynamic activity of crystalline hydrocortisone at 25° is 5.3×10^{-3}, as obtained from Eq. 7 with the experimental values for ΔH_f and T_f. The value of 5.3×10^{-3} thus represents the mole fractional ideal solubility for hydrocortisone. For a hypothetical solvent with molecular weight of 100 and density of 1.0 g/ml, the solubility of hydrocortisone would be 5.2×10^{-2} moles/liter or 18.9 mg/ml providing the two components formed an ideal mixture. These physical properties, summarized in Table II, are essential for the solubility analysis of hydrocortisone.

Solubility—The solubilities of hydrocortisone at 25°, experimentally determined in the present study, are presented in Table III along with the molar volumes and solubility parameters for the solvents. The solubility parameters for the pure solvents at 25° are taken from Hoy's tables

[6] Mettler Hot Stage with FP5 Temperature Regulator and a Zeiss Standard Microscope.

(10). Values for the cosolvent mixtures of propylene glycol and water were estimated from the expression of Smith *et al.* (11):

$$\delta_{1\text{-}3} = \frac{\phi_1\delta_1 + \phi_3\delta_3}{\phi_1 + \phi_3} \qquad \text{(Eq. 13)}$$

where the subscripts 1 and 3 denote the respective pure solvent parameters and ϕ is the corresponding volume fraction. The validity of the above expression has been demonstrated with binary solvent systems only capable of interacting through London forces (11). Use of the equation must be tentative for mixtures of propylene glycol and water as the molecular interactions of hydrogen bonding and dipole–dipole attractions for those mixtures have yet to be fully delineated.

The solubility parameter scale does provide one indication of the wide range of solvents used for these studies. The solubility parameter for propylene glycol falls roughly between that for hexane [7.3 (cal/ml)$^{1/2}$] and water [23 (cal/ml)$^{1/2}$], which represent the extremes for this solvent scale. Hydrocortisone is extremely insoluble in hexane 9.53×10^{-8} moles/liter and poorly soluble in water 8.19×10^{-4} moles/liter. The maximum molar solubility determined was with propylene glycol 4.63×10^{-2}. The solubility span for hydrocortisone in the evaluated solvents was $>10^5$. Interestingly, all solubility values are below the estimated ideal solubility and are sufficiently low to negate solute–solute interactions.

DISCUSSION

Regular Solution Analysis—It should be mentioned at the onset of this discussion that regular solution behavior, as carefully defined by Hildebrand *et al.* (12), is used as a secondary reference point for the solubility analysis of hydrocortisone. The primary reference point is ideal solution behavior. It is recognized *a priori* that the underlying theory is inapplicable where there is significant hydrogen bonding either between like or unlike species, solute or solvent. However, regular solution behavior provides a norm from which deviations from ideality, other than those derived from differential cohesiveness, can be measured.

Regular solution theory predicts a parabolic relationship between the mole fractional solubility of a given solute and the solubility parameters for solvents which span the solute's value. For a solid solute in equilibrium with its saturated solution, the regular solution solubility is given by Eq. 12. The theoretical maximum solubility is considered to be the ideal solubility where the cohesive energy differential between solute and solvent is zero. In other words, a positive excess enthalpy of mixing and a solubility less than ideal is always associated with regular solution behavior. Solvents were selected which interact within themselves and with hydrocortisone predominantly through London forces, allowing regular solution theory to be applied. Hexane, cyclohexane, carbon tetrachloride, benzene, and toluene were considered appropriate to test the hypothesis that the solubilities of a solute like hydrocortisone would conform to regular solution behavior in apolar solvents. The saturated solutions of hydrocortisone in these solvents are sufficiently dilute to preclude any appreciable solute–solute bonding. The predominant factor contributing to solution phase interaction is London forces. This is also true for cohesion of the pure liquids. The forces binding hydrocortisone in the

hypothetical supercooled liquid state are indeterminate but are presumed to have significant contributions from hydrogen and dipolar bonding.

Since the net interactions in the hydrocortisone melt include hydrogen bonding, which precludes totally random orientations of its molecules, one primary element required for regular solution behavior is missing. There is an excess entropy of mixing implicitly associated with the freeing of the hydrocortisone molecules from bonds restricting their relative motions and positions in the supercooled liquid state. However, regular solution behavior for alkyl-*p*-aminobenzoate homologues (4), which suffer the same theoretical departure, is followed closely for such polar, highly interactive solutes as long as the solvent is strictly apolar. In essence, it seems that potential sources of deviation from regular solution behavior, especially associated with disintegration of the polar solute melt structure, are insignificant against the excess free energy derived from differential cohesiveness. Thus, for the alkyl-*p*-aminobenzoates there are operative solubility parameters, likely related to the true square root cohesive energy densities, which adequately describe their solubilities in hexane. The present work is, in part, an attempt to examine the behavior of hydrocortisone, an even more complex molecular structure, in this regard. The study differs in an important way from the previous study (alkyl-*p*-aminobenzoates) in that the behavior is examined across diverse solvents and not with respect to solute structure within a fixed solvent.

To evaluate the proposed regular solution behavior for hydrocortisone, the following were assumed:

1. The crystalline properties of hydrocortisone were invariant from solvent to solvent such that the activity of the solid phase was the same in each.
2. The volume fraction for each solvent (ϕ_1) was unity.
3. The molar volume of hydrocortisone is 293 ml/mole at 25° and is independent of the solvent.

With the above assumptions and implicit simplifications, Eq. 12 is rewritten as follows:

$$\ln X_2 = \ln a_2^s - 0.5(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 14)}$$

for a saturated solution of hydrocortisone at 25°. Providing the choice of solvents is satisfactory, a_2^s and the solubility parameter for hydrocortisone δ_2 can be simultaneously determined from the mole fractional solubilities of hydrocortisone in the specified solvents. The value of a_2^s, moreover, should be consistant with the value of 5.2×10^{-3} obtained from ΔH_f and T_f.

Values ranging from 7 to 23 $(cal/ml)^{1/2}$ for δ_2 were evaluated using Eq. 14 to determine δ_2 where a_2^s is most constant. Figure 3 shows $\ln a_2^s$ *versus* the solubility parameter of the solvent for three selected values for γ_2. As seen in the graphical display, a_2^s appears most constant for a δ_2 value of 12.4 $(cal/ml)^{1/2}$; however, there is scatter in the data, and based solely on this analysis, the value of δ_2, at best estimate, can be considered to lie between 12 and 13 $(cal/ml)^{1/2}$. The value of 12.4 $(cal/ml)^{1/2}$ for δ_2 predicts a_2^s to be 5.5×10^{-3} which is in excellent agreement with a_2^s as calculated from ΔH_f and T_f. Furthermore, the dashed lines in Fig. 3 show the calculated deviation in a_2^s if the solubility parameter is in fact 12.4 $(cal/ml)^{1/2}$ for hydrocortisone, but was assumed to be either 10 or 14 $(cal/ml)^{1/2}$. While each of these approaches for estimating the solubility parameter has an inherent uncertainty when considered alone, when combined they indicate a solubility parameter of hydrocortisone of 12.4 $(cal/ml)^{1/2}$. This value is consistent with minimum variability in the corresponding a_2^s values from Eq. 14 and has good agreement with a_2^s as independently predicted from crystalline properties Eq. 7.

The functional-group contribution approach provides another way of estimating the solubility parameter for hydrocortisone. In this case, the molar attraction constants for the solute functional groups are summed as originally proposed by Small (13). Using the updated molar attraction constants tabulated by Hoy (10), the solubility parameter for hydrocortisone was estimated to be 11.4 $(cal/ml)^{1/2}$, as outlined in Table IV. This estimate differs significantly from the experimental value of 12.4 $(cal/ml)^{1/2}$. The discrepancy is not unexpected, since there is little evidence that the functional-group contribution approach is suitable for such a large, polyfunctional solute, and its use for hydrocortisone likely represents an overextention of the method.

Flory–Huggins Excess Entropy of Mixing—As previously defined, regular solution theory assumes the entropy of mixing to be an ideal in which the entropy of the process arises strictly from the statistical mixing of the components. A factor not yet considered in the regular solution analysis for hydrocortisone is the inability to statistically mix molecules of unequal size. Flory (14) and Huggins (15) have considered the excess entropy associated with the mixing of molecules of unequal size. A model was designed for dilute solutions with a small molecular volume solvent and a large, polymer solute. The mixing of a liquid polymer with a solvent

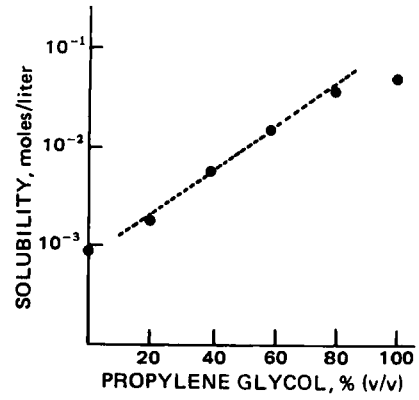

Figure 5—*Solubility of hydrocortisone in propylene glycol–water mixtures at 25°.*

to make a dilute solution with respect to the polymer leads to the total number of possible configurations for the polymer being greatly increased over what exists in the pure polymer state. This large increase in configurational entropy of mixing is expressed in the following equation for the excess free energy of mixing:

$$\Delta G^E = RT[X_1 \ln (\phi_1/X_1) + X_2 \ln (\phi_2/X_2)] \qquad \text{(Eq. 15)}$$

This expression was derived for long-chain molecules with individual segments occupying sites within a liquid lattice consisting of small solvent molecules. This factor should be an additive (independent) function. With this factor incorporated, the general regular solution solubility equation becomes:

$$\ln X_2 = \ln a_2^s - \frac{\phi_1^2 V_2}{RT}(\delta_1 - \delta_2)^2 - [\ln V_2/V_1 + 1 - V_2/V_1] \qquad \text{(Eq. 16)}$$

The validity of the Flory–Huggins model has not been established for compact molecules in a solvent composed of molecules smaller by only several multiples. It has been pointed out (16) that such an evaluation for compact molecules is difficult since possible entropy effects are often obscured by large changes in the enthalpy of mixing. The analysis of the excess entropy due to inequality of size for hydrocortisone appears to be confounded by this difficulty. The hydrocortisone–solvent molar volume ratio, V_2/V_1, is only 2.25–3.28 for those solvents considered for regular solution behavior. To evaluate the impact of the Flory–Huggins entropy correction on the regular solution analysis of hydrocortisone, the appropriate parameters were introduced into Eq. 16, and δ_2 was determined as before. The correction term did not significantly affect the estimation of δ_2, within the sensitivity of the analysis. Thus, the entropy arising from disparate molecular size does not appear to be significant as a solubility-determining factor for these hydrocortisone–solvent systems. This conclusion agrees with the observations of Shinoda and Hildebrand (16) as well as Bowen and James (8), who also noted little or no Flory–Huggins effect for mixtures of nonpolymeric substances of unequal size.

Solubility Profile—The values for the physicochemical properties of hydrocortisone utilized in the subsequent discussion are found in Table II. With appropriate substitution of the above parameters into Eq. 12, the regular solution solubility parabola was calculated for hydrocortisone about the midpoint of 12.4 $(cal/ml)^{1/2}$, where the solution is considered ideal. As expected, the solubilities of hydrocortisone in solvents essentially limited to dispersion molecular interactions conform closely to the curve Fig. 4. These solvents are hexane, cyclohexane, carbon tetrachloride, toluene, and benzene.

Regular solution theory predicts a 50-fold difference in molar solubility between hexane and cyclohexane, and this difference is observed experimentally. However, the inappropriateness of regular solution theory for solvents other than those of the London type is also demonstrated in Fig. 4. It appears inadequate for solubility estimation in all solvents capable of hydrogen bonding or other strong, orientating bonding with hydrocortisone. For example, the experimental solubility of hydrocortisone in isopropyl acetate is nearly 100 times the predicted value. There is also a 20-fold factor unaccounted for by regular solution theory between the solubilities in carbon tetrachloride, a perfectly symmetrical and apolar species, and chloroform, which has a substantial dipole. Thus, for isopropyl acetate, chloroform, and similar solvents, dipole–dipole and hydrogen bonding must contribute significantly to the solution-phase interactions.

The regular solution parabola predicts a solubility of hydrocortisone

in water, where $\gamma_1 = 23.4$ (cal/ml)$^{1/2}$, $\sim 10^{21}$ times less than the observed value. Clearly, simple differential cohesiveness is grossly inadequate to account for the specific intermolecular forces between water and hydrocortisone. Having two ketone moieties and three hydroxyl groups, hydrocortisone is capable of forming hydrogen bonds with water around these centers, which greatly favor its solubility. Contrastingly, the hydrocarbon skeleton and attached methyl groups provide surfaces for hydrophobic association with water, which is unfavorable to solubility. The net results of these additional solution-phase interactions is a large reduction in the excess free energy of transfer of a mole of supercooled liquid hydrocortisone to water. Hence, the solubility in water is orders of magnitude higher than would be expected from the noncritical use of regular solution theory, taking the solubility parameter of water at face value. It should be noted that the solubility parameter of water as a square root cohesive energy density is, in the absolute sense, a legitimate value. However, it can not be used in regular solution treatments because the general behavior of water violates the fundamental assumptions of this theory.

The incremental addition of propylene glycol to an aqueous propylene glycol solvent system is marked by an exponential increase in hydrocortisone solubility and log (solubility) increases roughly linearly with increasing volume fraction of propylene glycol (Fig. 5). This solubility pattern can be compared with the following linear free energy function:

$$\log S_f = \log S_{f=0} + \epsilon f \qquad \text{(Eq. 17)}$$

where ϵ is the incremental change in solubility per volume fraction (f) added. The actual cosolvent profile for hydrocortisone, however, has a slight sigmoidal shape which is most apparent at low and high concentration of propylene glycol. Nevertheless, an estimate for ϵ of 2.1 was obtained from regression analysis with the values for water and propylene glycol excluded because they were out of the linear region. The estimate of ϵ corresponds to an ~100-fold increase in solubility from water to pure propylene glycol, somewhat greater than actually observed.

A similar linear trend is shown in Fig. 4 for log S_f *versus* the solubility parameter estimates for the cosolvent mixtures as calculated from Eq. 12. It might appear that the cosolvent trend is a direct outcome of differential cohesiveness. This would, however, be a superficial and incorrect conclusion. Water, propylene glycol, and their mixtures are extensively hydrogen-bonded systems. Although the experimental cohesive energy densities for these solvents are meaningful as relative measures of the forces of association in the pure liquids, they are meaningless with respect to regular solution calculations. Regular solution theory requires that no significant orientating bonding can occur between solute and solvent, pure solvent, and pure liquid solute. This requirement allows the cohesive energy density of the solute–solvent mixture, C_{12}, to be approximated by $(C_{11}, C_{22})^{1/2}$. These conditions are violated as a consequence of the hydrogen bonding networks in water, propylene glycol, and their mixtures. Based on literature data which indicate that the aqueous solubility of substantially hydrophobic molecules is proportional to the low-energy molecular surface area (17) and that the sensitivity of homologue solubilities in aqueous mixtures is a function of the hydrocarbon chain length (18), it would appear that the solubility trend of hydrocortisone in propylene glycol–water mixtures is principally due to a dilution of the hydrophobically induced self-association of water.

Phenomenological Viscoelasticity of a Heterogeneous Pharmaceutical Semisolid

GALEN W. RADEBAUGH * AND ANTHONY P. SIMONELLI ˣ

Received April 5, 1982 from the *College of Pharmacy and Institute of Materials Science, University of Connecticut, Storrs, CT 06268.* Accepted for publication July 15, 1982. *Present address: Department of Pharmaceutics, Smith Kline and French Laboratories, Philadelphia, PA 19101.

Abstract □ This study presents the results of an investigation of the viscoelastic properties of anhydrous lanolin USP, as determined by dynamic mechanical testing. The elastic shear modulus (G'), viscous shear modulus (G''), and loss tangent ($\tan \delta$) were determined as a function of shear frequency, ν, (0.01–10.0 Hz) and temperature, T, (0–30°). These viscoelastic parameters were found to be temperature and shear frequency dependent. Up to 100-fold changes in shear moduli and $\tan \delta$ values were observed with appropriate changes in T and ν. Many of the observed properties are also characteristic of high molecular weight polymers and can be attributed to a high degree of molecular structure. It was found that dynamic mechanical testing was a sensitive tool for measuring structural changes, and was especially useful in detecting a major structural transition well below the accepted melting temperature of anhydrous lanolin.

Keyphrases □ Viscoelasticity—properties of anhydrous lanolin, determination by dynamic mechanical testing □ Lanolin, anhydrous—viscoelastic properties as determined by dynamic mechanical testing □ Dynamic mechanical testing—determination of viscoelastic properties of anhydrous lanolin

The rheology of pharmaceutical semisolids can not be understood adequately without including a discussion of viscoelastic properties. The viscoelastic properties of pharmaceutical semisolids have not been adequately investigated because pharmaceutical scientists generally lack the appropriate testing equipment. Much of the existing literature on the measurement of viscoelasticity of pharmaceutical systems, including the use of dynamic mechanical testing, has been reviewed (1). It was apparent that dynamic mechanical testing could yield unique information that could not be obtained by other available methods, and that it was important that the application of dynamic mechanical testing to measure the viscoelastic properties of pharmaceutical systems be investigated and demonstrated. For this reason this study was undertaken using anhydrous lanolin.

Dynamic mechanical testing has been used primarily by materials scientists to characterize the viscoelastic properties of polymeric systems (2, 3). For example, polymers are routinely characterized for moduli, crystallinity, plasticizer effectiveness, filler effects, creep, and stress relaxation. A knowledge of these viscoelastic properties is necessary to determine proper manufacturing techniques and end-use properties of polymeric systems.

Many rheological testing procedures used by pharmaceutical scientists are insensitive to the microcrystalline or amorphous three-dimensional networks which determine basic rheological properties. Generally, these methods use a simple shear viscometer and determine a non-Newtonian viscosity (4–6). Simple shear methods destroy the structure that one is attempting to measure and introduce the additional parameter of structural variation with time. As a result, simple shear viscometers are unable to measure fundamental viscoelastic parameters such as elastic and viscous moduli (7, 8).

This report describes the nondestructive technique, dynamic mechanical testing, and the results obtained when it was used to measure the viscoelastic properties of anhydrous lanolin. Test samples were deformed sinusoidally with respect to time and temperature, and measurements of the strain amplitude, stress amplitude, and phase angle between them were made in terms of the complex dynamic modulus. The complex dynamic modulus was then resolved into a real component (elastic or storage modulus) and an imaginary component (viscous or loss modulus.) The elastic modulus is associated with the energy stored in elastic deformation, while the viscous modulus is associated with energy dissipation effects. These moduli were used to interpret the viscoelastic behavior of anhydrous lanolin in terms of the inter- and intramolecular interactions within the semisolid.

BACKGROUND

Phenomenological Viscoelasticity—The deformation of semisolids can be divided arbitrarily into two general types: spontaneously reversible deformation (called elasticity) and irreversible deformation (called flow). Most pharmaceutical semisolids exhibit both of these phenomena and are rheologically classified as viscoelastic. Phenomenological viscoelasticity can be categorized as either linear or nonlinear, but only the former can be described theoretically with uncomplicated mathematics. The fundamental viscoelastic parameters of a linear viscoelastic system do not depend on the magnitude of the stress (or strain) and the time during which it acts; the parameters for a nonlinear viscoelastic system are dependent on stress and/or strain magnitude. Complex constitutive equations are necessary to describe nonlinear viscoelasticity (9–11).

When the input strain on a test sample is small, the strain (γ) is proportional to the stress (σ) and the sample exhibits linear viscoelasticity. Though stress and strain are proportional, they are not in phase; in addition to moduli, a phase angle or damping term is determined. The elastic modulus (G'), viscous modulus (G''), complex modulus (G^*), and phase angle (δ) are a function of shear frequency (ν) and temperature (T). For shear experiments, frequency can also be expressed in terms of radians per second (ω) where ω equals $2\pi\nu$.

Linear viscoelasticity also means that the rheology must obey the Boltzmann superposition principle (2, 12). This principle states that mechanical behavior is a function of the entire stress history of a sample. It also assumes that the effect of each deformation is independent of the others, and that the behavior of the sample can be calculated by a simple addition of the effects that would occur if the deformations took place singly.

Most theoretical treatments of dynamic mechanical testing and linear viscoelasticity use stress as the forcing function, though either stress or strain may be used. Both methods are mathematically equivalent. A theoretical treatment of the mathematics of linear viscoelasticity is given in *Appendix I*. Two important relationships are derived therein which relate G^*, G', G'', and $\tan \delta$:

$$G^* = G' + iG'' \qquad \text{(Eq. A11)}$$

and

$$\tan \delta = G''/G' \qquad \text{(Eq. A15)}$$

where $\tan \delta$ is equal to the ratio of the energy dissipated–maximum energy stored per cycle of deformation.

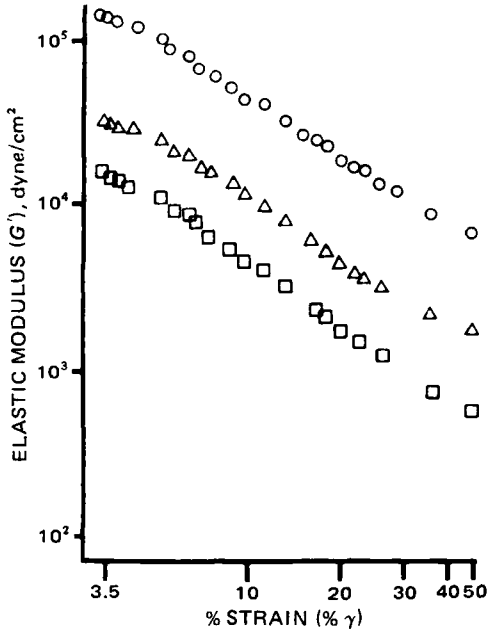

Figure 1—*Effect of shear strain on the elastic modulus of anhydrous lanolin USP, at 20°. Key: (○) 10.0 Hz, (△) 1.0 Hz and (□) 0.10 Hz.*

The relationship of tan δ and G'' to energy dissipation is fundamental to proper interpretation of dynamic mechanical data. A system with high values of tan δ exhibits high energy dissipation and is termed high damping or lossy. The significance of various transitions of a system depend on the location and intensity of the damping peaks, where tan δ or G'' is a maximum. The associated maximum in energy dissipation is interpreted in terms of an accountable increase in internal freedom, such as molecular segmental and side group motion or chain rotation. These changes can identify chemical or mechanical transitions.

Chemical Nature of Anhydrous Lanolin USP—Anhydrous lanolin, or wool fat, is designated by the USP to contain not more than 0.25% water (13). It is prepared by the purification of fatty matter (suint) obtained from the wool of sheep. The chemical composition of anhydrous lanolin is complex and can vary with the type of sheep (14). Conrad (15) and Barnett (16) have elaborated extensively on lanolin chemistry.

Anydrous lanolin is chemically a wax and not a fat. It melts between 36 and 42°. In general, it contains trace amounts of hydrocarbons and free fatty acids, 3–4% free alcohols (mostly cholesterol), and 96% wax esters. Saponification of the wax esters gives a free lanolin alcohol fraction and a free fatty acid fraction. The free alcohol fraction is composed of aliphatic, sterol, triterpene, and unclassified alcohols in approximately equal proportions. The free fatty acid fraction is composed of ~10% normal acids (n = 4–12), 4% hydroxy acids (n = 6, 7), 29% iso acids (n = 3–11), 38% anteiso acids (n = 2–13), and 19% unclassified acids.

From this information, anhydrous lanolin can be typified as a mixture of wax esters with a chemical structure much like a cholesterol molecule linked to a long-chain alcohol molecule. It can be postulated that 99% of the molecules in anydrous lanolin have a molecular weight in the range of 400–950, with an average of ~700.

EXPERIMENTAL

Materials and Apparatus—The anhydrous lanolin USP used for all experiments was from the same production lot[1]. The viscoelastic properties of anhydrous lanolin were determined with a mechanical spectrometer[2]. This rotational rheometer puts into a test sample a known deformation at a specified rate and temperature (17).

Samples of anhydrous lanolin were mounted between 50-mm diameter, hollow stainless steel cone and plate test fixtures. The cone fixture was oscillated sinusoidally at determined shear strains (γ) and frequencies (ν) by the output from a digital function generator and phase analyzer[3] (FGPA). Stresses from the sample were transmitted through the fixed plate to a multiple-stress detecting transducer. Deflections in the transducer were converted to electrical signals and relayed back to the function generator and analyzer, where they were resolved into the storage and loss components of the complex modulus. The digital outputs of the FGPA were used to calculate the dynamic moduli in terms of dyne/cm² (*Appendix II*).

Temperature control was maintained by enclosing the sample and test fixtures in an environmental chamber[4]. The chamber used high-velocity recirculated air and nichrome heating coils. A platinum resistance bulb temperature sensor, located close to the test sample, maintained temperature to ±0.5°. Temperatures below the ambient were achieved by placing solid carbon dioxide into the chamber, in the path of circulating air on the side of the sample away from the direction of flow. Excess temperature reduction was prevented by the heating coils. Chamber temperature was monitored by placing an iron–constantan thermocouple with digital readout in the path of circulating air, immediately upstream of the sample. The chamber was equipped also with a light and window for sample observation.

Differential thermal analysis[5] was used to look for structural transitions in anhydrous lanolin. This thermoanalytical technique is often useful in detecting crystallization and crystalline and glass transitions.

Sample Preparation—Anhydrous lanolin was placed in a beaker and lowered into a hot water bath at 50°. After melting, the molten lanolin was placed into a desiccator which was evacuated by a filter pump to remove entrapped air from the samples. Deaerated samples were poured onto the flat test fixture, in a manner preventing air pocket formation. After 30 min at room temperature, the plate was mounted and the cone lowered to the preset gap. Extruded lanolin was removed and the sample was allowed to equilibrate at the test temperature for 15 min.

Description of Experiments—Samples were equilibrated at 0, 5, 10, 15, 20, 25, and 30°. At each temperature, a sample was oscillated over three decades of ν, 0.01–10.0 Hz, at γ equal to 3.54%[6]. Readouts of the FGPA were used to calculate G', G'', and tan δ as a function of ν and T.

For differential thermal analysis, a sample in an aluminum pan and an empty identical reference pan were heated. A liquid nitrogen chamber was used to lower the initial temperature to −40°. The difference in T between the sample and the reference pan was recorded as function of T_r, the temperature of the reference cell.

RESULTS AND DISCUSSION

The dynamic mechanical properties of anhydrous lanolin were determined as a function of shear strain, frequency, and temperature.

Effects of Strain—The relationship between G' and γ, at 25°, is shown in Fig. 1. There is no apparent range of linear viscoelastic behavior over the entire range of γ studied (3.54–50.0%). Linear behavior would be identified as a region of constant G' with changing γ. Since linear viscoelastic behavior could not be achieved, the lowest obtainable γ (3.54%) was used in all experiments to ensure the least possible effect on molecular structure.

Because of observed nonlinear behavior, it may be said that the test samples in this study were not in their absolute rheological ground state. It has been reported that at least 24 hr were necessary for stresses produced in anhydrous lanolin by sample loading to relax prior to creep testing (18). In this study, it was not feasible to permit each sample to relax 24 hr before testing.

Even though the mechanical spectrometer was not able to reach a low enough γ to achieve linear behavior, it must be noted that the decline of G' with increasing γ is apparently a continuously smooth relationship, devoid of breaks or irregularities in the curve. Hence at any given γ, it can be assumed that there exists a small region around the corresponding point on the log G' *versus* log %γ curve where linear viscoelastic behavior can be approximated. This is particularly true at low γ where the slope has significantly decreased. Therefore, an infinitesimal increase or decrease in deformation gives a negligible change in the value of log G'. This justification for the use of linear viscoelastic theory to calculate dynamic moduli is reasonable and is commonly used in the literature.

Data Reproducibility—Since it was believed that the samples of anhydrous lanolin were not in a rheological ground state, and since reproducible data can only be obtained from reproducible structural states, it was necessary to examine data reproducibility. It was found that defined differences in sample mixing, setting time, and temperature equilibration time were found to produce differences in FGPA "a" and

"b" outputs. Differences in observed moduli of up to 50% could be produced by exacerbated variations in sample preparation, loading, and equilibration. For that reason, care and practice were necessary to master the aforementioned sample preparation techniques before reproducible data could be obtained with confidence. It should be noted that variations of as much as ±10% in G' were tolerable as this would be small when compared with changes in G' due to temperature and shear frequency.

Effects of Temperature and Shear Frequency—From the log G' and log G'' *versus* log ν plots (Figs. 2 and 3) it is evident that ν and T are profound determinants of the viscoelastic behavior of anhydrous lanolin. In general, an increase in T causes a decrease in G', while an increase in ν causes an increase in G'. The effect of T and ν on G'' are not as simple to describe, as a maximum appears in some of the curves. If one assumes that a maximum exists in all of the curves, it can be stated that the maximum ν is increased with an increase in T. The patterns of change of G' and G'' with T and ν are characteristic and will be discussed in terms of proposed molecular changes. Figure 2 shows that an increase in ν increases G' over the temperature range of 30–25°. At 25°, this trend is modified by the formation of a plateau at the high end of the frequency spectrum. The extent of this plateau expands with decreasing T until it extends over the entire frequency spectrum at 0°.

In this plateau region, G' asymptotes to a limiting modulus, G_E. When this limiting value is attained, it can be concluded that the molecular chains are not able to rearrange themselves at all during the time of stressing. The molecules appear frozen and the only deformation is by distortion of primary and secondary bonds and bond angles. Such a limiting modulus is also observed for polymers in the glassy state (*i.e.*, at low temperatures).

Barlow and Lamb (19) gathered data of G_E for a number of organic compounds. These included glycerol, polytetrafluorethylene, 1,2,6-hexanetriol, 1,3-butanediol, and vulcanized and unvulcanized rubber. All of the G_E values for these substances were within a factor of two of 2×10^{10} dyne/cm^2, even though these compounds represent a molecular weight distribution from 90 to $>10^6$. These values can be compared with crystalline solids which generally have rigidity moduli between 10^{11} and 10^{12} dyne/cm^2. The values of G_E for the organic compounds studied by Barlow and Lamb are probably lower because they are not subject to the constraints of a crystal lattice. It was noted that the introduction of strong polar groups, hydrogen bonding, or polymerization generally caused increases in G_E, but these increases were small when compared with the magnitude of G_E. Hence it was suggested that the straining of van der Waals bonds and the flexing of main chain bonds are the origin of G_E as these phenomena are relatively independent of structure for polymers.

The value of G_E for anhydrous lanolin is $\sim 5 \times 10^6$ dyne/cm^2, a factor of 4×10^3 less than the values observed by Barlow and Lamb. This difference indicates that it may not be appropriate to refer to anhydrous lanolin as being in the glassy state. It must be noted that G_E was not reached for the listed organic compounds until T approached the vicinity of −80°. Hence, the plateau attained from 0 to 5° for anhydrous lanolin may not represent G_E, but instead a plateau in the rubbery region. Further testing at T <0° may show a rise in G' until another plateau is attained at lower T. This assumption is reasonable when one considers the fact that anhydrous lanolin is an organic mixture with an average molecular weight of ~700, which is within the range of molecular weights listed by Barlow and Lamb.

The appearance of the nonglassy state plateau between 0 and 5° can be explained on the basis that anhydrous lanolin is a complex mixture with each constituent having its own melting point. So at a given temperature, some fractions may be solid and others liquid. The solid fractions then act as a rigid matrix to give structure with the liquid fractions dispersed in its rigid matrix. Consequently, one could speculate that, from 0 to 5°, the solid matrix is sufficiently rigid to enable its elastic characteristic to mask any temperature-dependent contribution of the liquid fraction. Since the glassy state observed in the Barlow and Lamb work exhibited a considerably greater G_E at lower temperatures, it would be expected on the basis of this model that the contribution of the liquid fraction to G' would become evident as the temperature is lowered below 0° giving rise to an increase in G' until reaching the glassy state plateau.

Figure 3 shows that G'' behaves similarly to G' from 30 to 20°. At 15° however, a rounded peak appears between 2.15 and 10.0 Hz. With each successive drop in T, the location of the peak shifts horizontally to lower ν until, at 0°, the peak has apparently shifted to a ν below the range of frequency testing. The variation of G'' as opposed to G' is difficult to visualize in terms of molecular processes because it is basically a feature of a dynamic rather than a static response.

When ν is low, the molecules can rearrange themselves completely within the time scale of stressing. At maximum γ, energy is stored in the system by virtue of entropy effects. During the portion of the cycle in which σ decreases to zero, the stored strain energy is recovered elastically because the molecules rearrange faster than σ changes. Since the strain energy is almost completely elastically recoverable at low ν, the energy loss is small. Consequently G'' is small. On the other hand, G'' is small at high ν because the molecules are frozen in place and only pure elastic deformation occurs. G'' increases at intermediate ν because the molecules have time for only partial configurational rearrangement during a cycle of stressing.

At this point, it is necessary to consider the energetics responsible for the variation of dynamic moduli as a function of shear frequency and temperature. Aspects of this discussion have their foundation in the idea

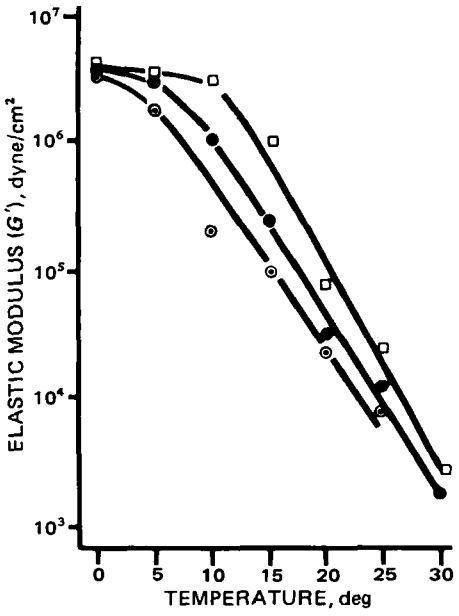

Figure 4.—*Effect of temperature on the elastic modulus of anhydrous lanolin USP, at 3.54% strain. Key: (⊙) 0.0464 Hz, (●) 0.464 Hz, and (□) 4.64 Hz.*

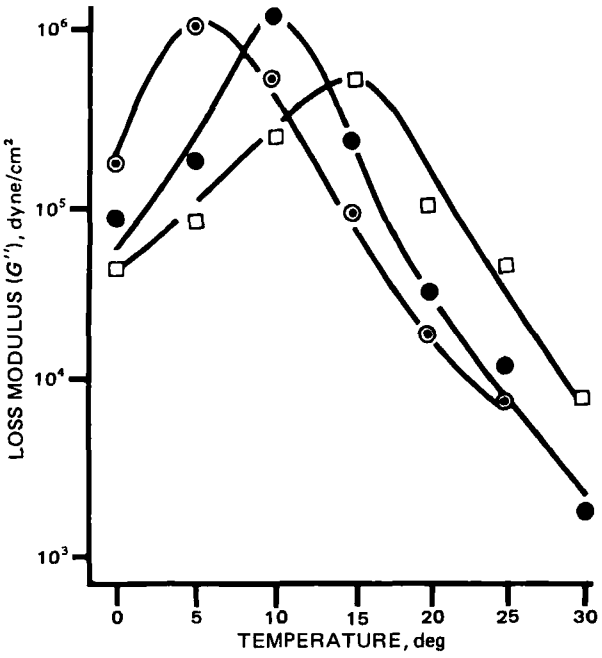

Figure 5.—*Effect of temperature on the viscous modulus of anhydrous lanolin USP, at 3.54% strain. Key: (⊙) 0.0464 Hz, (●) 0.464 Hz, and (□) 4.64 Hz.*

of a theory for rubber-like elasticity (2, 20). The idea of a network accounts for the main features of equilibrium value of rubber-like elasticity. The following account is a brief outline of the principles involved.

Consider a single molecule which possesses free rotation about all of the main chain bonds. Each C—C bond may rotate mutually provided a bond angle of ~110° is maintained. The most probable distance from the final carbon to the first carbon atom can be determined by assuming that each successive bond can fully rotate and using a probability distribution function. The most probable distance can be shown to be slightly greater than $(nl^2)^{1/2}$ where n is the total number of bonds, each of length l. For an amorphous rubber-like system, there are a large number of intertwining molecules each rapidly changing in configuration but on the average sufficiently coiled to have an end distance of approximately $(nl^2)^{1/2}$.

The state of maximum entropy (S) and minimum free energy (F)[7] occurs when the molecules are in the most probable configurational distribution. Therefore, any change in entropy is due to a change in the distribution. When the system is strained it causes the configurational distribution to change to a less probable state and the distance between the first and final atoms of a molecular chain becomes greater than the average or most probable value. While the molecule is extended, the number of different molecular configurations, w_σ, which the molecule can attain is considerably less than the maximum number, w_m, obtainable in the most probable state. The subscript σ designates the extended state, while the subscript m designates the most probable state.

Straining a system in its most probable configurational state changes the configurational distribution to a less probable state, which results in a decrease in entropy. This decrease in entropy can be described according to Boltzmann's entropy relation:

$$\Delta S_\sigma = -k \ln(w_m/w_\sigma) \qquad \text{(Eq. 1)}$$

where ΔS_σ is the decrease in entropy on the stretching of an average molecule and k is the Boltzmann constant. The greater the extension of the molecule, the greater the decrease in entropy due to the smaller number of configurations (w_σ) it can attain.

The decrease in ΔS_σ causes an increase in ΔF_σ, change in the Helmholtz free energy of the system. By definition:

$$\Delta F_\sigma = \Delta E_\sigma - T\Delta S_\sigma \qquad \text{(Eq. 2)}$$

where ΔE_σ is the change in the internal energy of the system. The symbol ΔS_σ can be replaced with $-\overline{\Delta S}_\sigma$, the average entropy decrease per molecule, from the Boltzmann relation. This value is negative because the entropy change is decreasing. It can be assumed that the internal energy is constant, *i.e.*, $\Delta E_\sigma = 0$, because the average environment of each atom in the stretched and unstretched states are identical. Consequently:

$$\Delta F_\sigma = -(-\overline{\Delta S}_\sigma)T \qquad \text{(Eq. 3)}$$

which indicates that ΔF_σ is increasingly positive as $-\overline{\Delta S}_\sigma$ becomes more negative on molecular stretching. Since every system seeks to attain the state of least free energy (unstretched state), it can be deduced that elastic behavior is due to spontaneous changes which attempt to revert the system to the state of least free energy. Rubber-like elasticity is thus explained in terms of an entropic rather than an internal energetic effect.

The almost complete absence of viscous flow must also be accounted for by entanglements or crosslinks. These interaction or junction points give rise to a structured network, which is a function of ν and T. An increase in side-chain branching increases the probability of entanglements, while functional groups generally cause greater intermolecular attraction. Each of these phenomena results in an increase in structure and a loss in degrees of freedom. Consequently, when a system is strained, the entanglements and crosslinks decrease entropy further and increase the driving force to return the system to the state of least free energy.

Figures 4 and 5 give additional insight into the effects of T and ν upon the dynamic mechanical properties of anhydrous lanolin. As evident in Fig. 4, T and ν are inversely related. An increase in T decreases G', while an increase in ν shifts the log G' *versus* T curves to higher temperatures. Similar shifting can be seen with log G'' *versus* T curves as a function of ν (Fig. 5). Such behavior commonly is observed for amorphous polymers (3).

Tan δ or damping is a dimensionless parameter, which is defined as the ratio of G''–G'. More significantly, tan δ is also proportional to the ratio of the energy lost–energy stored in a cycle of deformation. The role of tan δ is not well known. It is often the most sensitive indicator of various molecular motions within a material. All mechanical properties, and especially tan δ, are extremely sensitive to crystalline or structural transitions, relaxation processes, and the morphology of multiphase systems such as crystalline and filled polymers.

Log tan δ *versus* T curves for anhydrous lanolin are illustrated in Fig. 6. At lower ν, a maximum is evident around 10°. With an increase in ν, the height and sharpness of each successive peak decreases until it has disappeared at the highest ν. With an increase in T, the damping curves converge (possibly at one point) in the neighborhood of 17°. To the right of the convergence region, the relationship between ν and tan δ is inverse of the relationship to the left of the convergence.

[7] A good deal of confusion exists over which letter should be used to symbolize the free energy. The letter A is generally used as the Helmholtz free energy and G is used as the Gibbs free energy. A represents that part of the internal energy which is isothermally available, while G represents that portion of heat content which is isothermally available. It should be noted that $G = A + pV$, and hence $\Delta G = \Delta A + p\Delta V$. Since volume change has been assumed negligible in the anhydrous lanolin, $\Delta G \approx \Delta A$. The letter F will be used to represent free energy in this report because G is recognized in the rheological community as the shear modulus.

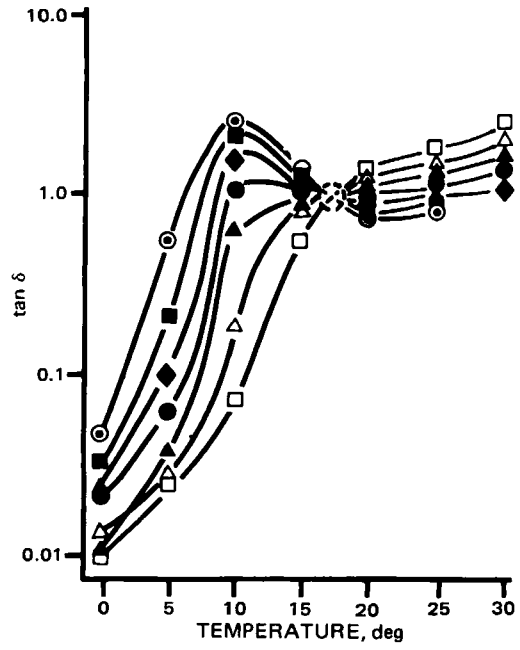

Figure 6.—*Effect of temperature on the loss tangent of anhydrous lanolin USP, at 3.54% strain. Key: (⊙) 0.0464 Hz, (■) 0.10 Hz, (◆) 0.215 Hz, (●) 0.464 Hz, (▲) 1.0 Hz, (△) 2.15 Hz, and (□) 4.64 Hz.*

At the convergence point, the damping properties of anhydrous lanolin are independent of ν, and the damping properties reverse with respect to ν at the convergence temperature. This is a very interesting phenomenon. The fact that there is a convergence point, where the material is independent of ν, suggests that this is only possible when constituent phases are in certain ratios, such that the effects of one phase cancel out the effects of another.

Evidence for a temperature-dependent transition can be found in a differential thermal analysis thermogram of anhydrous lanolin (Fig. 7). From −40 to 25°, there is a linear relationship between ΔT and T_r. A short shoulder develops at ~20°. This peak falls slightly and is followed by another linear increase until a peak is attained at 30°. This peak then rolls off and descends to 40°, where another peak rises to peak at 45°. It is evident that changes in the structure of anhydrous lanolin are occurring over the entire temperature range. But since the test temperature range for dynamic mechanical testing was 0–30°, attention will be focused on the shoulder peak that occurs around 20°.

At least two factors are operating which could move the apparent peak to a lower T. One could be the consequence of a smaller peak, at ~17°, adding onto a larger peak which occurs at ~30°. By addition, the larger peak may have pulled the smaller peak toward the larger peak by several degrees. Consequently, the smaller peak may in reality lie several degrees below 20°. The shoulder, at 20°, is probably related to the mechanical transition which was evidenced by a peak in the log tan δ *versus* T plots at 10°, from 0.0464 to 0.464 Hz. Differences are often found between the thermally indicated and the mechanically determined temperature of transition.

The second factor that can account for a thermogram shift to higher T is the thermal lag of the sample and furnace environment, which is a function of the sample heating rate and the thermal conductivity of the sample. A large difference exists between the thermal conductivities of the aluminum sample pans and anhydrous lanolin. The difference, which is of the magnitude of 10^5 in favor of aluminum, can cause the entire thermogram to shift to higher temperatures[8]. For anhydrous lanolin, it can be approximated that the thermogram shift could be as high as 5–10°. Consequently, correction for peak addition and sample thermoconductivity could place a thermogram peak in the sample temperature region where the damping maxima occur in Fig. 6.

It should be noted that this type of thermogram generally should be expected for materials composed of a large range of molecular weights and functional groups, *e.g.*, butter, lard, and cocoa butter (22). Essentially, these materials have a wide (50–100°) apparent melting range.

A better way to describe the behavior of fats, waxes, and oils is to use the concept of degrees of freedom gained as a function of T. Therefore, the thermogram for anhydrous lanolin shows that the sample is in the process of gaining degrees of freedom throughout the temperature range studied. Degrees of freedom could be gained by a decrease in the inter- and intramolecular forces. For example, a new degree of rotational freedom can allow a greater number of molecular configurations.

Heijboer (23) has presented a log tan δ *versus* T plot similar in appearance to Fig. 6. He showed that tan δ can be used to identify the composition of a composite polymer blend. The dynamic mechanical properties of a series of copolymers of cyclohexyl methacrylate and methyl methacrylate were examined as a function of weight, percentage composition, and T at constant ν. At any given T on the log tan δ *versus* T plot, tan δ maxima heights vary with percentage composition rather than ν as exhibited with anhydrous lanolin.

The composition of anhydrous lanolin as defined previously is a heterogeneous mixture of esters, alcohols, and fatty acids; therefore, a correlation between composition and ν must be considered. One could speculate that certain frequencies have orienting effects on specific fractions (entire molecules or portions thereof) of anhydrous lanolin, creating new molecular environments and consequently new molecular interactions. Shear frequency, like T, influences the degrees of freedom possessed by molecules in anhydrous lanolin. The degrees of freedom gained or lost vary for each molecular component. The effect of ν on the viscoelastic properties of anhydrous lanolin is similar to effect of composition upon Heijboer's methacrylate systems (23). It should be noted that Heijboer does not venture to describe or speculate on the nature of the convergence point.

CONCLUSIONS

Anhydrous lanolin is a thermorheologically complex material whose viscoelastic properties can be characterized with dynamic mechanical testing. Its viscoelastic properties are a function of strain, temperature, shear frequency, and shear history. Even though anhydrous lanolin is a relatively low molecular weight mixture, it has certain viscoelastic properties which are characteristic of higher molecular weight polymers. These properties include the presence of a previously undescribed structural transition and the existence of a limiting value of the elastic modulus.

The extent of data generated in this study does not permit definite conclusions to be drawn about the nature of individual inter- and intramolecular interactions of the various molecular fractions. More insight on interactions may result from studies on purified fractions of known proportion. Ultimately, these studies may enhance the ability to predict *a priori* the optimum blending of semisolid components for desired end-use properties.

APPENDIX I: MATHEMATICAL TREATMENT OF THE THEORY OF LINEAR VISCOELASTICITY

In a dynamic experiment, the stress and strain are sine or cosine functions and they can be treated as rotating vectors. The magnitudes of the vectors are equivalent to the amplitudes of the maximum stress and maximum peak strain. One revolution of the vector is equal to a full cycle of oscillation (Fig. 8).

The stress, strain, and rate of stress are complex variables which can be defined by the following equations:

$$\sigma^* = \sigma_0 \exp[i(\omega t + \delta)] \quad \text{(Eq. A1)}$$

$$\gamma^* = \gamma_0 \exp(i\omega t) \quad \text{(Eq. A2)}$$

where σ^* is the complex stress, γ^* is the complex strain, σ_0 is the maximum magnitude of the stress, γ_0 is the maximum magnitude of the strain, δ is the phase angle between strain and stress, t is time, ω is the angular frequency, and i equals $(-1)^{1/2}$. Differentiation of Eq. A2 is equivalent to a 90° counterclockwise rotation of the vector so that:

$$d\gamma^*/dt = i\omega\gamma_0 \exp(i\omega t) = \omega\gamma_0 \exp[i(\omega t + \pi/2)] \quad \text{(Eq. A3)}$$

where $\omega\gamma_0$ is the magnitude of the rate of strain vector.

The complex shear modulus, G^*, is defined as the ratio of σ^* to γ^*:

$$G^* = \sigma^*/\gamma^* \quad \text{(Eq. A4)}$$

[8] The thermal conductivity of pure aluminum, between 0 and 30°, is ~34 cal/sec cm deg. In contrast, the thermal conductivities of organic compounds similar to those found in anhydrous lanolin are of the order of $2–4 \times 10^{-4}$ cal/sec cm deg (21). For a heating rate of 10°/min and a sample thickness of 0.25 mm, a lag of ~5° could occur. A sample thickness of 0.5 mm would mean a lag of 10°.

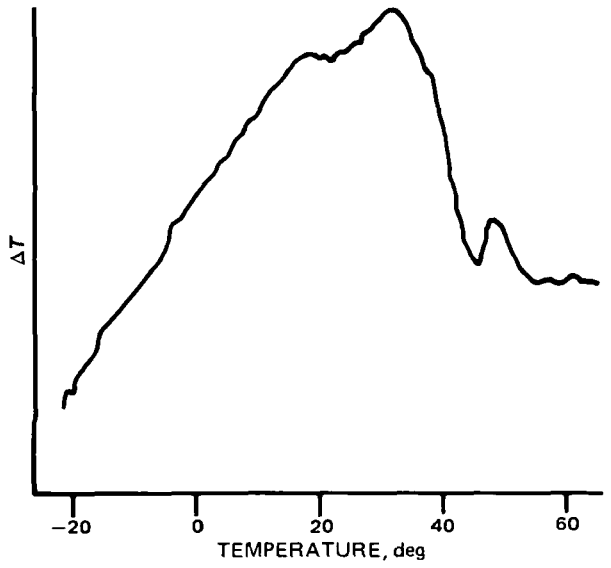

Figure 7.—*Differential thermal analysis thermogram for anhydrous lanolin USP; 10°/min, normal atmosphere.*

By substituting Eqs. A1 and A2 into Eq. A3 we obtain:

$$G^* = (\sigma_0/\gamma_0)\exp[i(\omega t + \delta)]\exp(-i\omega t) \quad \text{(Eq. A5)}$$

or

$$G^* = (\sigma_0/\gamma_0)\exp(i\delta) \quad \text{(Eq. A6)}$$

From Euler's formula, one knows that:

$$\exp(i\delta) = \cos\delta + i(\sin\delta) \quad \text{(Eq. A7)}$$

Some special values of the complex exponential are $\exp(\omega i/2) = i$ and $\exp(\pi i) = -1$. Equation A7 can then be substituted into Eq. A6 to obtain:

$$G^* = (\sigma_0/\gamma_0)\cos\delta + i(\sigma_0/\gamma_0)\sin\delta. \quad \text{(Eq. A8)}$$

But:

$$G' = (\sigma_0/\gamma_0)\cos\delta \quad \text{(Eq. A9)}$$

and

$$G'' = (\sigma_0/\gamma_0)\sin\delta \quad \text{(Eq. A10)}$$

Consequently:

$$G^* = G' + iG'' \quad \text{(Eq. A11)}$$

where G' is known as the elastic modulus, storage modulus, or the real modulus. The viscous or loss modulus, G'', is also known as the imaginary modulus.

The relationship between G', G'', and G^* can also be examined by referring to Fig. 8. One can see that the stress vector can be considered as the sum of two perpendicular components, one of which, σ' ($= \sigma_0\cos\delta$), is in phase with the strain and the other, σ'' ($= \sigma_0\sin\delta$), is out of phase. Two corresponding moduli can be defined as:

$$G' = (\sigma'/\gamma_0) = (\sigma_0/\gamma_0)\cos\delta = G^*\cos\delta \quad \text{(Eq. A12)}$$

and

$$G'' = (\sigma''/\gamma_0) = G^*\sin\delta \quad \text{(Eq. A13)}$$

Hence, G' is also referred to as the in-phase modulus, while G'' is given the out-of-phase designation. By taking the square root of the sum of the squares of Eqs. A12 and A13, one obtains:

$$G^* = [(G')^2 + (G'')^2]^{1/2} \quad \text{(Eq. A14)}$$

This relationship between G', G'', and G^* may be illustrated vectorially as in Fig. 9. The angle between G^* and G', δ, is known as the phase angle, and it is the lag between the forcing stress function and the resultant function, strain. It can also be seen from Fig. 9 that:

$$\tan\delta = G''/G' \quad \text{(Eq. A15)}$$

The physical significance of $\tan\delta$ becomes clearer when one considers

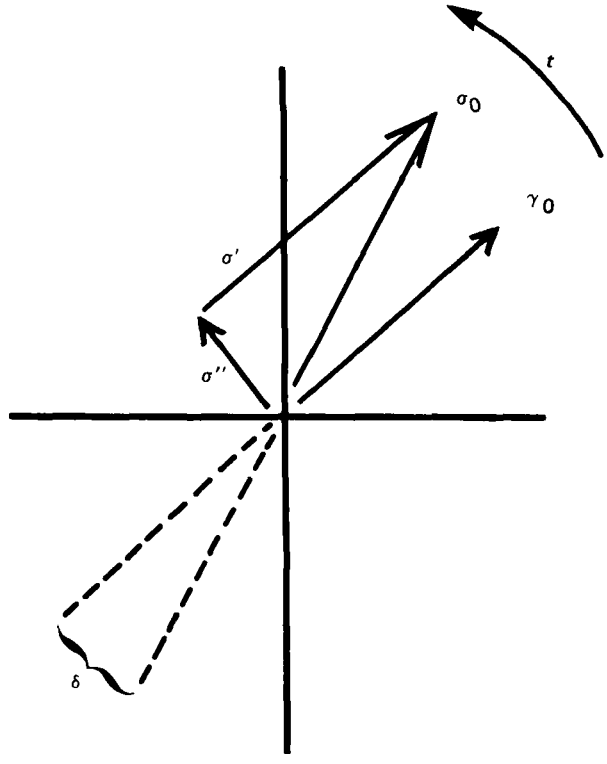

Figure 8—*Rotating vector treatment of sinusoidal deformation.*

the energy dissipated and stored per cycle of deformation for linearly viscoelastic materials. The energy dissipated per cycle is:

$$W = \oint \sigma d\gamma = \oint \sigma(d\gamma/dt)dt \quad \text{(Eq. A16)}$$

So if it is assumed that the stress is the forcing function according to:

$$\sigma(t) = \sigma_0\sin(\omega t) \quad \text{(Eq. A17)}$$

and the resultant strain can be represented by:

$$\gamma(t) = \gamma_0\sin(\omega t - \delta) \quad \text{(Eq. A18)}$$

then Eqs. A17 and A18, with the proper trigonometric identity can be used to expand Eq. A16 to:

$$\Delta W = \sigma_0\gamma_0\omega\oint \sin(\omega t)[\cos(\omega t)\cos\delta + \sin(\omega t)\cos\delta]dt \quad \text{(Eq. A19)}$$

The first term inside of the closed integral is an odd function and becomes zero upon integration. The value of the integral of the second term is $(\pi/\omega)\sin\delta$, so that the energy dissipated per cycle of deformation is given as:

$$\Delta W_{\text{cycle}} = \pi\sigma_0\gamma_0\sin\delta \quad \text{(Eq. A20)}$$

The maximum energy stored per cycle, analogous to the potential energy of a spring at the maximum displacement, is:

$$W = (1/2)G'\gamma_0^2 \quad \text{(Eq. A21)}$$

where G' is the elastic modulus of the material, equivalent to the spring constant. Since $G' = G^*\cos\delta$ and $G^*\gamma_0 = \sigma_0$, then:

$$W = (1/2)\sigma_0\gamma_0\cos\delta \quad \text{(Eq. A22)}$$

Eqs. A20 and A22 can be combined to give the ratio of energy dissipated–maximum energy stored per cycle as:

$$\Delta W/W = 2\pi\tan\delta = 2\pi(G''/G') \quad \text{(Eq. A23)}$$

APPENDIX II: CALCULATION OF DYNAMIC MODULI

During testing, digital readouts of "a" and "b" are given at each test frequency by the function generator and phase analyzer. The readout "a" is directly proportional to G' and "b" is directly proportional to G''. By neglecting inertial forces and utilizing infinitesimally small deformations, these stress–strain ratios can be related to angular displace-

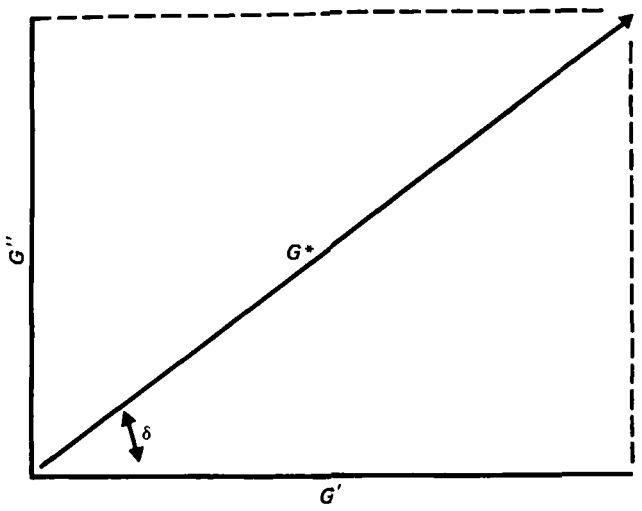

Figure 9—*Vectorial resolution of components of the complex modulus in sinusoidal deformation.*

ment–torque ratios by form factors that depend on apparatus geometry. For the viscoelastic semisolid in these experiments, the deformation corresponds to simple shear torsion between cone and plate.

The cone and plate geometry produces a strain that is nearly homogeneous throughout the sample and can provide information for the shear strain–stress ratio in small deformations. The geometrical factors for torsion between cone and plate (2) are:

$$\gamma_0/\sigma_0 = k\alpha/M_0 \qquad \text{(Eq. A24)}$$

and

$$k = 2\pi r^3/3\beta \qquad \text{(Eq. A25)}$$

where k is the form factor, γ_0 is the maximum shear strain, σ_0 is the maximum shear stress, r is the radius of sample (cm), α is the angular displacement (radians), M_0 is the torque, and β is the angle between cone and plate. If inertial and edge effects are assumed negligible, the maximum stress is expressed as:

$$\sigma_0 = 3M_0/2\pi r^3 \qquad \text{(Eq. A26)}$$

while the maximum strain is:

$$\gamma_0 = \alpha/\beta \qquad \text{(Eq. A27)}$$

The "a" and "b" outputs of the function generator and phase analyzer are equivalent to the following expressions:

$$\text{a} = \frac{M_0(\cos\delta)}{\alpha\ (980\ \text{dyne/g})(10^4\ \text{g cm})} \qquad \text{(Eq. A28)}$$

and

$$\text{b} = \frac{M_0(\sin\delta)}{\alpha\ (980\ \text{dyne/g})(10^4\ \text{g cm})} \qquad \text{(Eq. A29)}$$

The values of 980 dyne/g and 10^4 g cm are instrument constants dependent on the transducers and torque control setting used in the experiments. By substituting Eqs. A26 and A27 into Eqs. A28 and A29, respectively, one obtains:

$$\text{a} = \frac{\sigma_0 2\pi r^3(\cos\delta)}{3\beta\gamma_0(980\ \text{dyne/g})(10^4\ \text{g cm})} \qquad \text{(Eq. A30)}$$

and

$$\text{b} = \frac{\sigma_0 2\pi r^3(\sin\delta)}{3\beta\gamma_0(980\ \text{dyne/g})(10^4\ \text{g cm})} \qquad \text{(Eq. A31)}$$

Eqs. A9 and A10 are then combined with Eqs. A30 and A31, respectively, to obtain:

$$G' = \frac{3\beta(980\ \text{dyne/g})(10^4\ \text{g cm})(\text{a})}{2\pi r^3} \qquad \text{(Eq. A32)}$$

and

$$G'' = \frac{3\beta(980\ \text{dyne/g})(10^4\ \text{g cm})(\text{b})}{2\pi r^3} \qquad \text{(Eq. A33)}$$

APPENDIX III: GLOSSARY

Where applicable, the symbols in this report conform to those proposed as a uniform standard by the Society of Rheology[9] (24).

- E = internal energy of a system
- F = free energy of a system
- G' = elastic, real, or storage modulus
- G'' = viscous, imaginary, or loss modulus
- G^* = complex modulus
- G_E = limiting value of G'
- M_0 = torque
- R = gas constant
- S = entropy
- T = temperature
- ΔT = temperature difference between sample and reference pan
- T_r = temperature of reference pan
- W = energy stored per cycle of deformation
- ΔW = energy dissipated per cycle of deformation
- a = readout of FGPA directly proportional to G'
- b = readout of FGPA directly proportional to G''
- i = $(-1)^{1/2}$
- k = Boltzmann's constant
- l = bond length between atoms
- r_σ = distance between first and final atoms of a molecular chain
- t = time
- w_σ = number of obtainable molecular configurations in extended state
- w_m = maximum number of molecular configurations obtainable in the most probable state
- α = angle of oscillation
- β = cone angle
- δ = phase angle between stress and strain vectors
- γ = strain
- $\dot{\gamma}$ = rate of strain
- γ_0 = maximum strain amplitude
- γ^* = complex strain
- σ = stress
- σ' = real component of complex stress
- σ'' = imaginary component of complex stress
- σ^* = complex stress
- σ_0 = maximum stress amplitude
- ν = shear frequency (Hz)
- ω = angular shear frequency (rad/sec)

Temperature–Frequency Equivalence of the Viscoelastic Properties of Anhydrous Lanolin USP

GALEN W. RADEBAUGH * and ANTHONY P. SIMONELLI ˣ

Received April 5 1982, from the *College of Pharmacy and Institute of Materials Science, University of Connecticut, Storrs, CT 06268.* Accepted for publication July 15, 1982. * Present address: Department of Pharmaceutics, Smith Kline and French Laboratories, Philadelphia, PA 19101.

Abstract □ Methods of data analysis novel to pharmaceutical semisolids have been applied to the dynamic mechanical data obtained for anhydrous lanolin USP. It was found that the viscoelastic parameters determined over a wide range of temperatures and shear frequencies could be superposed. Elastic moduli (G') and viscous moduli (G'') obtained at low temperatures (T) and frequencies (ν), were equivalent to moduli obtained at high T and ν. Empirical shifts of modulus *versus* shear frequency data obtained at different temperatures were used to produce G' and G'' *versus* ν master curves (complete log modulus *versus* log frequency behavior at a constant temperature). A method of reduced variables, in conjunction with an Arrhenius-type relation, proved useful in calculating the energy of activation for the structural processes involved in a major mechanical transition.

Keyphrases □ Viscoelasticity—properties of anhydrous lanolin determined by dynamic mechanical testing, temperature–frequency equivalence, superposition of parameters □ Anhydrous lanolin—viscoelastic parameter determination, temperature–frequency equivalence □ Dynamic mechanical testing—viscoelastic parameter determination for anhydrous lanolin, energy of activation for mechanical transitions

Most research which has examined the effect of temperature on viscoelastic properties has focused on rubber and nonpharmaceutical synthetic polymers (1, 2). Though the effect of temperature on viscosity has been well documented for pharmaceutical systems, little information is available on the effect of temperature on their viscoelastic properties (3, 4).

In the preceding paper, data showed that the viscoelastic properties of anhydrous lanolin USP are significantly dependent on temperature as well as shear frequency (5). Small changes in temperature caused dramatic shifts in modulus *versus* shear frequency plots. This report examines those shifts and presents a method of reduced variables, which is novel to pharmaceutical systems, to analyze the data.

THEORETICAL

The viscoelastic properties of polymeric systems have been shown to be dependent on temperature and shear frequency. According to the theory of rubber-like elasticity, the elastic moduli of ideal elastomers are proportional to absolute temperature (6). Since the deformation of a rubber-like material is an activated process in which molecular segments can only move by overcoming potential barriers, a direct relationship exists between the temperature and time dependence of viscoelastic properties.

Dynamic mechanical data taken over a range of shear frequencies (which is equivalent to reciprocal time) can be superposed in the same manner that time–temperature superposition is applied to creep and stress relaxation data (7–10). This phenomenon is extremely useful because the limitations of instrumentation or time often do not allow the measurement of a complete modulus *versus* shear frequency spectrum. In spite of this limitation, a curve-shifting procedure can be used to construct a master curve (complete log modulus *versus* log frequency spectrum at a given temperature). A change in temperature shifts the distribution of modulus curves without changing the shape of the function. The shift of a modulus curve is quantitated in terms of a_T, the shift factor.

Mathematically, the concept of temperature–shear frequency superposition can be expressed as:

$$G(T_R,\nu) = G(T,\nu/a_T) \qquad \text{(Eq. 1)}$$

where G is either the elastic or viscous modulus, ν is the shear frequency, T_R is the reference temperature of superposition, T is the test temperature, and a_T is the shift factor. The effect of a change in temperature is the same as applying a multiplicative factor to the shear frequency scale (*i.e.*, an additive factor to the log shear frequency scale). Ideally, there is often an inherent change in modulus brought about by changes in temperature. There is also a need to correct for the change in sample mass per unit volume as a function of temperature. Each of these changes are compensated for by vertical shifts during the construction of the log modulus *versus* log frequency master curve.

Consequently, these considerations lead to:

$$\frac{G(T_R,\nu)}{T_R\rho(T_R)} = \frac{G(T,\nu/a_T)}{T\rho(T)} \qquad \text{(Eq. 2)}$$

where $\rho(T_R)$ and $\rho(T)$ are the densities of the test sample at the reference temperature and test temperature, respectively (8). Division by the test temperature corrects for changes in modulus due to the inherent dependence of modulus on temperature, while division by the density corrects for volume changes. To construct a master curve, a reference temperature is arbitrarily chosen and moduli are measured at various shear frequencies and temperatures.

By rearranging Eq. 2, the modulus at any shear frequency with respect to the reference temperature can be expressed as:

$$G(T_R,\nu) = \frac{T_R\rho(T_R)}{T\rho(T)}\,G(T,\nu/a_T) \qquad \text{(Eq. 3)}$$

The shift factors are a function of temperature and are determined relative to the reference temperature. The values of the shift factors must be found empirically by matching the results of adjacent temperatures.

Most research which has examined the effect of temperature on viscoelastic properties has focused on rubber and nonpharmaceutical synthetic polymers (1, 2). Though the effect of temperature on viscosity has been well documented for pharmaceutical systems, little information is available on the effect of temperature on their viscoelastic properties (3, 4).

In the preceding paper, data showed that the viscoelastic properties of anhydrous lanolin USP are significantly dependent on temperature as well as shear frequency (5). Small changes in temperature caused dramatic shifts in modulus *versus* shear frequency plots. This report examines those shifts and presents a method of reduced variables, which is novel to pharmaceutical systems, to analyze the data.

THEORETICAL

The viscoelastic properties of polymeric systems have been shown to be dependent on temperature and shear frequency. According to the theory of rubber-like elasticity, the elastic moduli of ideal elastomers are proportional to absolute temperature (6). Since the deformation of a rubber-like material is an activated process in which molecular segments can only move by overcoming potential barriers, a direct relationship exists between the temperature and time dependence of viscoelastic properties.

Dynamic mechanical data taken over a range of shear frequencies (which is equivalent to reciprocal time) can be superposed in the same manner that time–temperature superposition is applied to creep and stress relaxation data (7–10). This phenomenon is extremely useful because the limitations of instrumentation or time often do not allow the measurement of a complete modulus *versus* shear frequency spectrum. In spite of this limitation, a curve-shifting procedure can be used to construct a master curve (complete log modulus *versus* log frequency spectrum at a given temperature). A change in temperature shifts the distribution of modulus curves without changing the shape of the function. The shift of a modulus curve is quantitated in terms of a_T, the shift factor.

Mathematically, the concept of temperature–shear frequency superposition can be expressed as:

$$G(T_R,\nu) = G(T,\nu/a_T) \qquad \text{(Eq. 1)}$$

where G is either the elastic or viscous modulus, ν is the shear frequency, T_R is the reference temperature of superposition, T is the test temperature, and a_T is the shift factor. The effect of a change in temperature is the same as applying a multiplicative factor to the shear frequency scale (*i.e.*, an additive factor to the log shear frequency scale). Ideally, there is often an inherent change in modulus brought about by changes in temperature. There is also a need to correct for the change in sample mass per unit volume as a function of temperature. Each of these changes are compensated for by vertical shifts during the construction of the log modulus *versus* log frequency master curve.

Consequently, these considerations lead to:

$$\frac{G(T_R,\nu)}{T_R\rho(T_R)} = \frac{G(T,\nu/a_T)}{T\rho(T)} \qquad \text{(Eq. 2)}$$

where $\rho(T_R)$ and $\rho(T)$ are the densities of the test sample at the reference temperature and test temperature, respectively (8). Division by the test temperature corrects for changes in modulus due to the inherent dependence of modulus on temperature, while division by the density corrects for volume changes. To construct a master curve, a reference temperature is arbitrarily chosen and moduli are measured at various shear frequencies and temperatures.

By rearranging Eq. 2, the modulus at any shear frequency with respect to the reference temperature can be expressed as:

$$G(T_R,\nu) = \frac{T_R\rho(T_R)}{T\rho(T)}\,G(T,\nu/a_T) \qquad \text{(Eq. 3)}$$

The shift factors are a function of temperature and are determined relative to the reference temperature. The values of the shift factors must be found empirically by matching the results of adjacent temperatures.

0022-3549/83/0400-0422$01.00/0

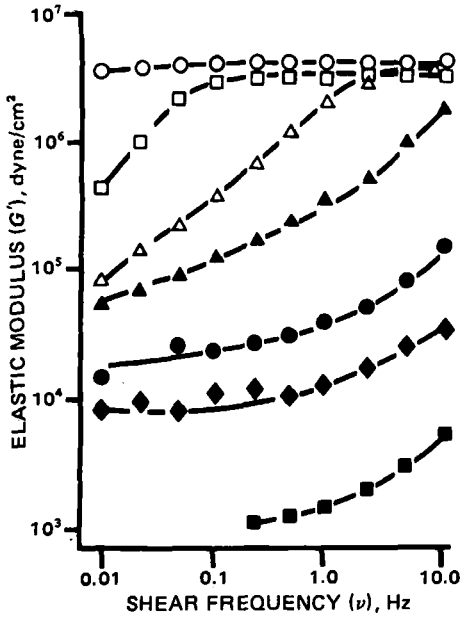

Figure 1—*Effect of shear frequency on the elastic modulus of anhydrous lanolin USP, at 3.54% strain. Key: (○) 0°, (□) 5°, (△) 10°, (▲) 15 °, (●) 20°, (◆) 25°, and (■) 30°.*

Ferry was among the first to use this technique, so the procedure is often referred to as a Ferry reduction scheme (1, 9, 11). Superposition, which is also referred to as the method of reduced variables, can reduce experimental work and extend the effective frequency range of results obtained with an instrument of limited frequency capabilities. When the temperature of testing is varied through an appropriate temperature range, a reduced frequency range of many more decades usually can be covered.

If it is theorized that the temperature dependence of the shift factors takes on the Arrhenius form, then:

$$a_T = A \exp(E_a/RT) \qquad \text{(Eq. 4)}$$

where A is the preexponential term, R is the gas constant, T is temperature, and E_a is the energy of activation (1, 12, 13). By taking the logarithm and then differentiating both sides of Eq. 4, it can be rearranged to obtain:

$$E_a = 2.303R \frac{d(\log a_T)}{d(1/T)} \qquad \text{(Eq. 5)}$$

Therefore, the shift factors of superposition can be plotted as log a_T *versus* (1/T) and the E_a for a given transition can be calculated from the slope of the plot.

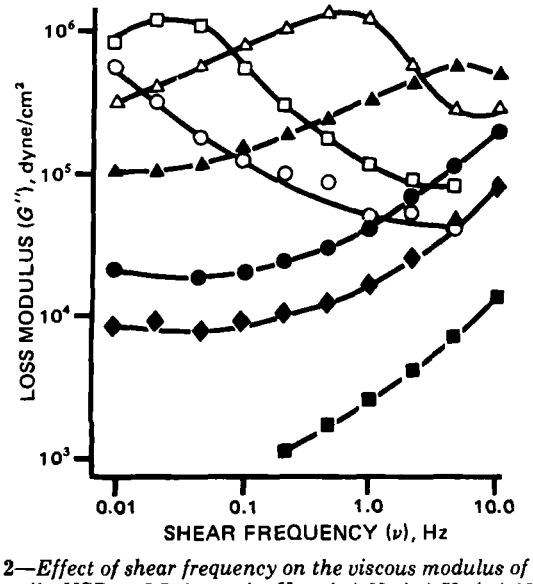

Figure 2—*Effect of shear frequency on the viscous modulus of anhydrous lanolin USP, at 3.54% strain. Key: (○) 0°, (□) 5°, (△) 10°, (▲) 15 °, (●) 20°, (◆) 25°, and (■) 30°.*

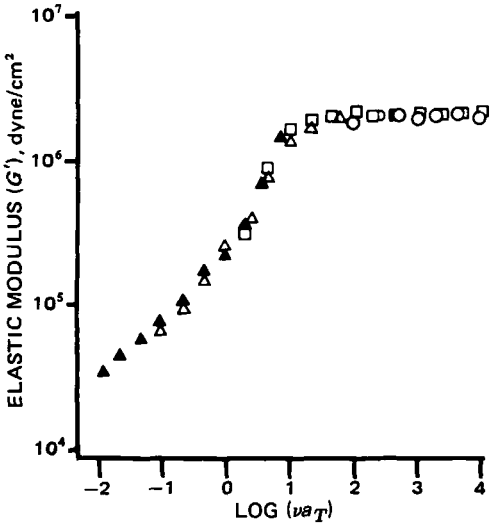

Figure 3—*Reduced frequency master curve of elastic modulus for anhydrous lanolin USP. Key: (○) 0°, (□) 5°, (△) 10°, and (▲) 15°.*

In cases of amorphous polymers where the data are taken near the glass transition, the shift factors may obey an empirical equation developed by Williams, Landel, and Ferry (14). This relationship, known as the W-L-F equation, is written as:

$$\log a_T = -C_1(T - T_g)/(C_2 + T - T_g) \qquad \text{(Eq. 6)}$$

where C_1 and C_2 are constants and T_g is the glass transition temperature. The glass transition temperature is that temperature below which the configurational rearrangements of polymer chain backbones essentially cease. The empirical constants, C_1 and C_2, were originally thought to be universal but have hence shown slight variation from polymer to polymer (6). The apparent energy of activation for a transition can also be calculated for data that fit the W-L-F relationship. By taking the derivative of Eq. 6 with respect to T, one obtains:

$$d(\log a_t)/dt = -C_1C_2/(C_2 + T - T_g)^2 \qquad \text{(Eq. 7)}$$

Equation 7 can then be combined with Eq. 5 to obtain:

$$E_a = 2.303RC_1C_2T^2/(C_2 + T - T_g)^2 \qquad \text{(Eq. 8)}$$

The magnitude of the energy of activation is an indication of the magnitude of the transition. Primary transitions usually have an energy of activation >40 kcal. Their damping peaks will shift ~7–10° for every decade change in frequency. Minor or secondary transitions with much lower energies of activation are more sensitive to frequency and show greater movement on the temperature scale with changes in frequency.

EXPERIMENTAL

The viscoelastic properties of anhydrous lanolin USP were determined with a mechanical spectrometer[1]. Complete descriptions of the materials, apparatus, method of sample preparation, and experimental procedures were given in the preceding paper (5). The procedures for calculating the elastic modulus (G') and the viscous modulus (G'') as a function of shear frequency (ν) and temperature (T) were also discussed.

RESULTS AND DISCUSSION

As previously reported, the dynamic mechanical properties of anhydrous lanolin are dependent on ν and T (5). Examination of the elastic modulus and loss modulus *versus* shear frequency curves obtained at that time (reproduced in Figs. 1 and 2, respectively) indicates that these curves lend themselves to temperature–frequency superposition. By using the superposition methods of Ferry (1) and Tobolsky (8), it was found that empirical shifts of these curves could produce the log modulus *versus* log νa_T master curves shown in Figs. 3 and 4.

The shifting procedure matched portions of adjacent curves by horizontal shifting (and minor vertical shifting as necessary) such that only one smooth composite curve resulted. The horizontal shift from the curve at the reference temperature was quantitated in terms of a_T. The reference temperature used was 15°, the highest temperature at which both the elastic modulus and viscous modulus curves fit the reduction scheme. The shift factors obtained by constructing Figs. 3 and 4 are tabulated in Tables I and II.

The shift factor calculations were made on the assumption that the density (and hence the test sample volume) was constant over the entire range of superposition (0–15°). In actuality, the density is a function of temperature and changes in sample volume may have accounted for minor vertical shifts of the modulus curves. Vertical adjustments were not uniform and were essential to produce smooth master curves.

The master curves of log modulus *versus* log νa_T can be used to represent the viscoelastic behavior of anhydrous lanolin at shear frequencies up to 10^5 Hz (628,000 radians/sec) at 15°. This exceeds the maximum shear frequency used in these tests by four decades of frequency. Consequently, the two master curves can be used to predict the dynamic moduli of anhydrous lanolin at shear frequencies which are probably unobtainable with any commercially available mechanical property tester. Knowledge of the mechanical properties of a pharmaceutical semisolid at high shear frequencies is of more than academic interest. The rates of shear of many pharmaceutical processes such as mixing, milling, filling, extrusion, and application approach the magnitude of 10^4 Hz (15).

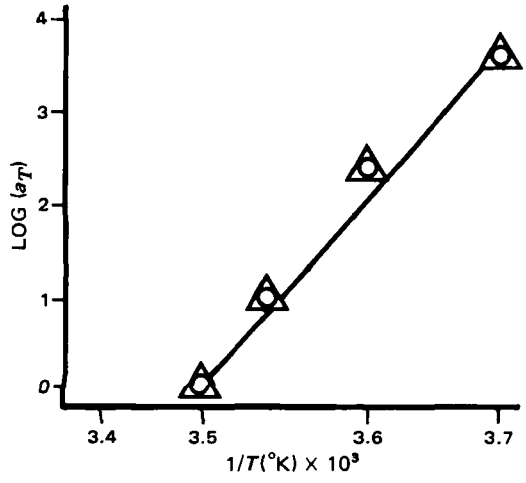

Figure 5—*Semilog plot of shift factor* versus *reciprocal temperature for anhydrous lanolin USP. Key: (○) from G' superposition and (△) from G'' superposition.*

For polymeric materials, T_R is usually taken to be the glass transition temperature T_g. The glass transition temperature is the temperature at which the polymer undergoes transition from a rubbery to a glassy state. At temperatures above T_g, the polymer is generally soft and flexible and is either an elastomer or a very viscous fluid. The glass transition temperature is important because mechanical properties change profoundly in the region of the glass transition. It is in this region of transition where a temperature–frequency reduction scheme is most applicable (11).

For anhydrous lanolin, the modulus curves are horizontally superposable only over the temperature range of 0–15°. Hence, it is reasonable to say that anhydrous lanolin undergoes a major mechanical transition in this temperature range, from a rubber-like to a nonrubber-like state. The reduction scheme does not hold at temperatures >15° due to the loss of the rubber-like structure.

Previously it was reported that the damping curves (log tan δ *versus* T) for anhydrous lanolin were at a maximum at ~15° (5). The damping maxima were suggested as being a point of significant structure change. These curves support the hypothesis that anhydrous lanolin may be in transition from a nonrubber-like to a rubber-like state.

In Fig. 5 it appears that the shift factors follow the Arrhenius relationship. The apparent energy of activation (E_a) for the molecular processes involved was calculated from the plot of log a_T *versus* $1/T$ using a least-squares fit and Eq. 5. The E_a was found to be ~90 kcal. A plot of this type can be curvilinear for polymeric materials. In such cases, E_a is temperature dependent and is approximated from the slope of the tangent line at any given point on the curve.

The significance of the value of E_a for anhydrous lanolin becomes more evident when the E_a is compared with values for polymeric systems. For main glass transitions where T_R is taken as T_g, the E_a is of the order of 10^5 cal/mole (2). Secondary transitions at cryogenic temperatures are of the order of 10^3–10^4 cal/mole. Comparison of the E_a for anhydrous lanolin with experimentally obtained E_a values for polymers would indicate that the structural transitions that occur in anhydrous lanolin at ~15° rival those of a glass transition. But this is not what would be expected by inspection of Fig. 1. The limiting value of the elastic modulus is not as large as would be expected for substances in a glassy state.

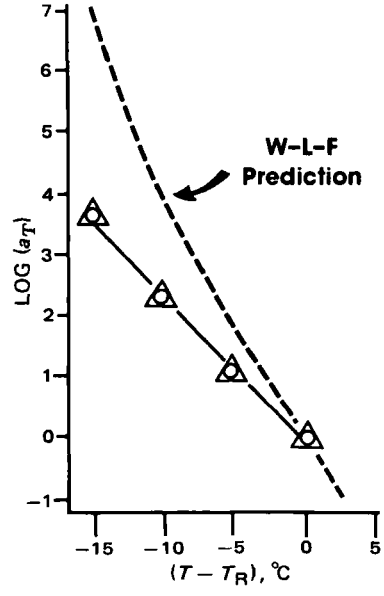

Figure 6—*Semilog plot of shift factor* versus *reduced temperature for anhydrous lanolin USP. Key: (○) from G' superposition and (△) from G'' superposition.*

[1] Model RMS-7200, Rheometrics, Inc., Union, NJ 07083.

With these thoughts in mind, the shift factors were also plotted according to the W-L-F relationship (Eq. 6) in Fig. 6. The ideal W-L-F curve generated with the "universal" constants of $C_1 = 17.4$ and $C_2 = 51.6$ is also presented in Fig. 6 for comparison. The "universal" constants do not hold for many polymers, and it is apparent that the experimentally obtained plot of $\log a_T$ *versus* $(T - T_R)$ for anhydrous lanolin does not lie where the W-L-F relationship (with "universal" constants) predicts. The lack of fit of the experimental data with the W-L-F prediction also suggests that the transition is probably not a glass transition as most polymers that undergo a glass transition obey the W-L-F prediction.

CONCLUSION

It has been demonstrated that the energy of activation for the structural changes occurring in the transition of anhydrous lanolin between 10 and 15° can be calculated by a temperature–shear frequency reduction scheme and an Arrhenius-type relationship. The E_a, which is ~90 kcal, compares favorably with the magnitude of the E_a of a high molecular weight polymer undergoing a glass transition. This comparison is significant when one considers the generally low molecular weight composition of anhydrous lanolin. The magnitude of the E_a for anhydrous lanolin suggests that the intra- and intermolecular forces are as great as those in high molecular weight polymers. Hence, the nature of the functional groups and the chain length of the molecules determine the strength of the structure of the system.

Overall, the experimental data suggest that anhydrous lanolin undergoes a major mechanical transition between 10 and 15°. Both the ability to superpose modulus *versus* shear frequency data and an E_a of 90 kcal for the transition are characteristic of a glass transition, but other observations are not. As described in the preceding paper (5), these observations are: a lower limiting value of the elastic modulus than would be expected for a glass transition, a slower rate of change of tan δ with temperature about the transition than would be expected for a glass transition, and a lack of fit of experimental data to the W-L-F relationship. Rather than a sharp transition from a rubbery to an ordered glassy state, it appears that anhydrous lanolin undergoes a mechanical transition from a rubber-like state to a structural state which is less ordered than a glassy state.

Reverse Permeation of Salicylate Ion Through Cellulose Membrane

FUJIO KAMETANI ˣ, SHUJI KITAGAWA, and HULKI A. GENCAY

Received December 21, 1981 from the *Faculty of Pharmaceutical Sciences, University of Tokushima, Shomachi, Tokushima 770, Japan.* Accepted for publication August 9, 1982.

Abstract □ The reverse permeation of salicylate ion and the effect of bovine serum albumin on the permeation were studied in a sodium salicylate–sodium oxalate–water system. In passive transport the permeation flux of an ion is expressed by the linear combination of the two terms which represent the concentration and electric potential gradients. Because the mobility of the sodium ion is greater than the oxalate ion, salicylate ion moves against the concentration gradient, and follows the electric potential gradient in the initial stage of permeation. The reverse permeation of salicylate ion through a cellulose membrane was accelerated with a high concentration ratio of oxalate to salicylate ions and reached a maximum value after 10 hr in the absence of bovine serum albumin. After reaching a maximum value, the salicylate ion permeated along the concentration gradient. The maximum concentration efficiency was 11.2%. In the presence of bovine serum albumin, the reverse permeation of salicylate ion reached a maximum value after 3 hr.

Keyphrases □ Reverse permeation—of salicylate ion with oxalate ion, through a cellulose membrane, protein effect on permeation flux □ Salicylate ion—permeation through a cellulose membrane, concentration by oxalate ion, protein effect on permeation flux □ Oxalate ion—permeation through a cellulose membrane with salicylate ion, protein effect on permeation flux

Most organic drugs dissociate in aqueous solutions and exist in ionic forms under biological conditions. Salicylate ion, one of the most commonly used drugs for analgesia, displaces other drugs such as the sulfonylureas (1) and sulfonamides (2), from the binding sites of the serum proteins. It has been reported that the absorption of salicylic acid is 61% in 0.1 *N* hydrochloric acid, 13% in sodium bicarbonate (pH 8) from the rat stomach (3), and 60% in physiological solution from the rat intestine (4). Effect of buffer constituents on salicylate absorption was studied with everted rat intestine and the inhibitory effect of potassium ions was reported (5–8). Since a variety of sub-

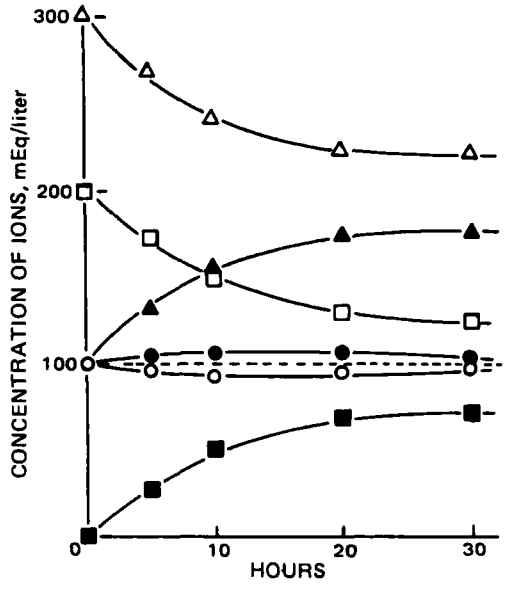

Figure 1—*Permeation of salicylate (○), oxalate (□), and sodium (△) ions. Initial concentration of sodium salicylate in compartments I and II was 100 mM; concentration of sodium oxalate in compartment I was 50 mM. Open figures represent compartment I; closed figures represent compartment II.*

stances are added to control the physical and physiological conditions of drug solutions, the absorption of drugs is affected by these multi-ionic components.

In passive transport at constant temperature, the membrane permeation flux of any ion (J_i) is given by the following equation which consists of two terms involving the concentration gradient and the electric potential gradient (9):

$$J_i = -D_i(\delta[i]/\delta x) - B_i Z_i[i](\mathrm{F/N})(\delta E/\delta x) \quad \text{(Eq. 1)}$$

where $[i]$ is the concentration of an ion i, E is the electric potential, and x is the coordinate taken in a direction of the permeation flux. D_i, B_i, F, N, and Z_i are the diffusion coefficient, the mobility, the faraday, Avogadro's number, and the valence of the ion, respectively. For the steady state of permeation, the following equation was derived from Eq. 1 (9):

$$J_i = -D_i(\delta[i]/\delta x) + \frac{B_i Z_i[i]}{\Sigma Z_j^2 B_j[j]} \Sigma Z_j D_j(\delta[j]/\delta x) \quad \text{(Eq. 2)}$$

where $[j]$ is the concentration of the coexisting ion j. Thus,

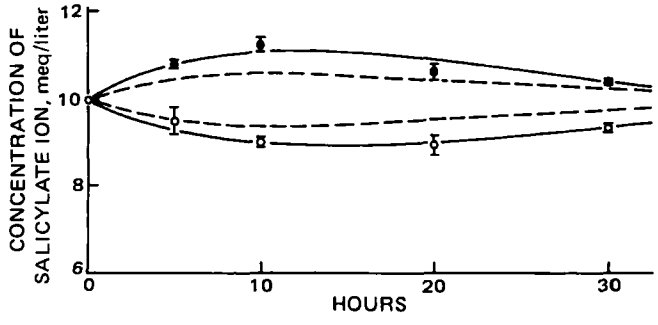

Figure 2—*Reverse permeation of salicylate ion. Initial concentration of sodium salicylate in compartments I and II was 10 mM; concentration of sodium oxalate in compartment I was 50 mM. Data points show the mean concentrations; standard deviations of four runs are indicated as bars on the data points. Table I—Electric Potential Differences (ΔE)

Hours of Permeation	ΔE, mV
0	23.6
5	11.1
10	5.8
20	1.6
30	0.7

the apparent diffusion coefficient (D_i') is expressed as follows (10):

$$D_i' = kTB_i\left\{1 - \frac{Z_i[i]\Sigma Z_j B_j(\delta[j]/\delta x)}{(\Sigma Z_j^2 B_j[j])(\delta[i]/\delta x)}\right\} \quad \text{(Eq. 3)}$$

where k is the Boltzmann constant, T is the absolute temperature, and Σ means a sum of all ions. If the second term in the bracket is >1, D_i' is negative and reverse diffusion is observed in simple inorganic systems (10, 11).

In this report, the reverse permeation of salicylate ion was studied in a sodium salicylate–sodium oxalate–water system. Since oxalic acid is injected intravenously as a hemostatic agent for animals, sodium oxalate was used as a coexisting anion in this model system. The reverse permeation of salicylate ion was also studied in the presence of bovine serum albumin. Due to the reverse permeation, salicylate ion was concentrated in one compartment of the permeation cell. The concentration efficiency of salicylate ion varied with the concentration of oxalate ion.

EXPERIMENTAL

Materials and Permeation Procedures—The cellulose membrane used was 35-μm thick seamless cellulose tubing[1] purchased from a commercial source. Sodium salicylate, sodium oxalate, and sucrose were analytical grade[2]. Bovine serum albumin was purchased from a commercial source[3]. Distilled and deionized water was used for all experiments.

Permeation of salicylate ion was measured in four cells, as previously described (12). Each cell compartment was stirred by a magnet at ~900

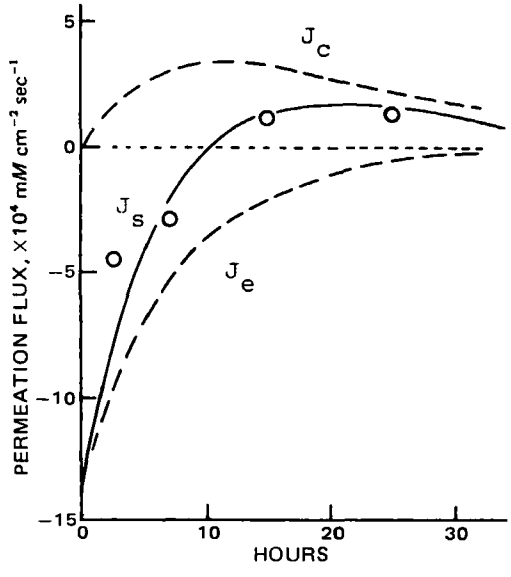

Figure 3—*Permeation flux of salicylate ion. Initial concentration of sodium salicylate and sodium oxalate are as shown in Fig. 2. Key: (J_s) total flux of salicylate ion, (J_c) flux of concentration gradient, (J_e) flux of electric potential gradient, and (○) as calculated by Eq. 4.*

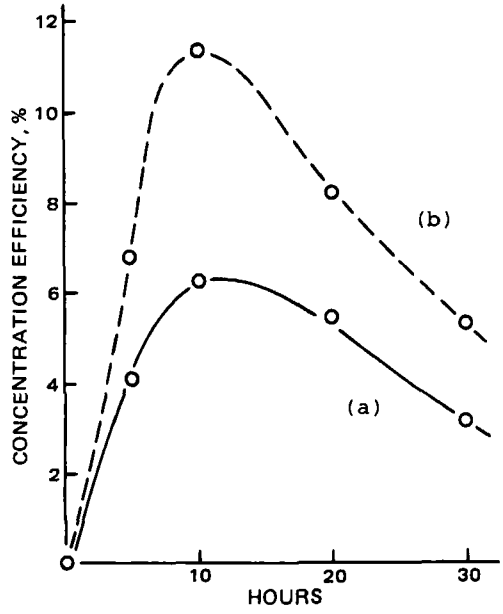

Figure 4—*Concentration efficiency of salicylate ion. Initial concentrations of sodium salicylate and sodium oxalate for (a) and (b) are as shown in Figs. 1 and 2, respectively.*

rpm at 25 ± 0.1°. In the presence of bovine serum albumin, the permeation of salicylate ion was followed in a cell where the volume of compartments I and II were 15.4 and 14.3 cm^3, respectively, and the membrane area was 3.19 cm^2. Sucrose was added to the solution without bovine serum albumin to make it isotonic. Both compartments were stirred at ~900 rpm at 10 ± 0.1°. The initial concentration of sodium salicylate was either 100 m*M* in both compartments with a 50 m*M* sodium oxalate solution in compartment I, or 10 m*M* in both compartments, with a 50 m*M* sodium oxalate solution in compartment I.

Analysis—Salicylate ion was analyzed by second differential absorption spectroscopy using a double-beam spectrophotometer[4] equipped with a derivative unit[5]. The second differential absorption spectrum ($\Delta\lambda$ = 4 nm) of the salicylate ion can be separated from that of oxalate ion. Sodium ion was analyzed with a flame photometer[6]. The concentration of oxalate ion was calculated from the difference of the concentrations of salicylate and sodium ions, on the assumption that the solution was electrically neutral. The diffusion potential through a membrane was measured with a DC-microvoltmeter[7] and calomel electrodes[8] using 3.3 *M* KCl agar bridges which contacted both cell compartments.

RESULTS AND DISCUSSION

The permeation of salicylate through a cellulose membrane in a mixed solution of sodium salicylate and sodium oxalate was measured at various times. The change in the concentration of ions where the initial concentration ratio of oxalate to salicylate in compartment I was 0.5, is shown in Fig. 1. The difference in concentration of salicylate ions in both compartments was zero at the initial stage of permeation and reached a maximum value after 10 hr. At this stage, salicylate ion was moving against the concentration gradient, *i.e.*, the salicylate ion concentration was increasing in compartment II. After the maximum reverse permeation, the concentration of salicylate ion reached the equilibrium concentration, equal to the initial concentration.

Assuming that the concentration gradient in the membrane is linear, the permeation flux can be calculated by the following equation (instead of Eq. 2):

$$J_i = -fkTB_ih_i\left\{\left(\frac{[i]_{II}-[i]_I}{L}\right)-\frac{Z_i[i]\Sigma Z_jB_jh_j([j]_{II}-[j]_I)/L}{h_i\Sigma Z_j^2B_j[j]}\right\} \quad \text{(Eq. 4)}$$

where f is the membrane constant, L is the thickness of the membrane,

Table II—Initial Concentrations of Simple Permeation

Type[a]	Compartment	Sodium Salicylate, m*M*	Sodium Oxalate, m*M*
a	I	0.2	90
	II	0.4	10
b	I	0.2	10
	II	0.4	90
c	I	0.2	50
	II	0.4	50

[a] Taken from the text.

and h_i is a coefficient for the activity coefficient (γ_i) of the ion such that $h_i = 1 + \delta\ln\gamma_i/\delta\ln[i]$. Using the Güntelberg equation (13) for γ_i, the concentration of salicylate ion in compartment II was calculated by:

$$[s]_{II}^{t+\Delta t} = [s]_{II}^{t} + J_sAt/V_{II} \quad \text{(Eq. 5)}$$

In this calculation, $[s]_{II}^{t}$ and $[s]_{II}^{t+\Delta t}$ are the concentrations of salicylate ion in compartment II after t and $t + \Delta t$ hours, respectively, J_s is the permeation flux of salicylate ion, A is the membrane area, and V_{II} is the volume of compartment II. The constant (f), obtained with calcium chloride, was 0.0573. B_i values for salicylate, oxalate, and sodium ions were 2.33×10^8, 2.35×10^8, and 3.24×10^8 (cm sec^{-1} $dyne^{-1}$), respectively, which were calculated from limiting equivalent conductivities (14) according to Wendt (15). Observed and calculated values are shown in Fig. 2 when the initial concentration ratio of oxalate to salicylate ions was 5. Since the sampling time interval in the initial stage was long compared with the permeation rate, the first permeation flux of salicylate ion was sooner than estimated. Therefore, calculated concentrations are smaller values than expected because of the cumulative addition in Eq. 5.

To clarify the difference between observed and calculated values, the electric potential differences (ΔE) were measured (Table I). Assuming that the potential gradient in the membrane is linear ($\delta E/\delta x = \Delta E/L$), permeation flux due to the electric potential gradient (J_e) can be calculated using the following equation instead of the second term in Eq. 4:

$$J_e = -fB_iZ_ih_i[i](F/N)(\delta E/\delta x) \quad \text{(Eq. 6)}$$

Adding J_e to the permeation flux due to the concentration gradient (J_c) calculated by the first term in Eq. 4, the total flux of salicylate ion is obtained, as shown in Fig. 3. In this case, the calculated values are in good agreement with the observed values. The negative total flux indicates reverse permeation, which is at a maximum when the total flux is equal to zero.

To compare the reverse permeation of salicylate ion under different conditions, a mean concentration ($\overline{[s]}$) and a mean value of concentration change ($\overline{\Delta[s]}$) of the salicylate ion were calculated by:

$$\overline{[s]} = \frac{V_I([s]_I^0 + [s]_I^f) + V_{II}([s]_{II}^0 + [s]_{II}^f)}{2(V_I + V_{II})} \quad \text{(Eq. 7)}$$

and

$$\overline{\Delta[s]} = \frac{V_I([s]_I^f - [s]_I^0) + V_{II}([s]_{II}^0 - [s]_{II}^f)}{V_I + V_{II}} \quad \text{(Eq. 8)}$$

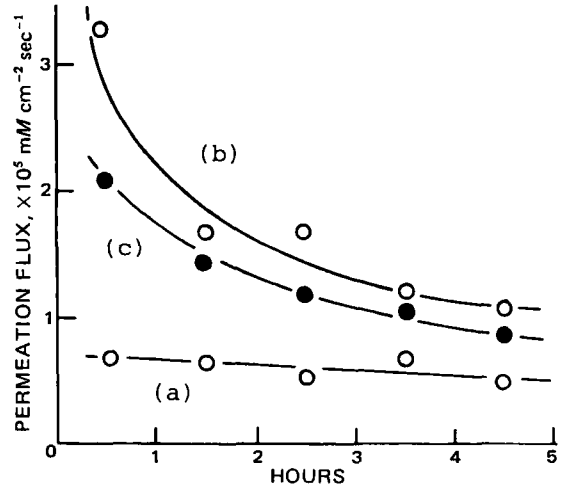

Figure 5—*Concentration gradient effect. Initial concentrations of sodium salicylate and sodium oxalate for (a), (b), and (c) are shown in Table II.*

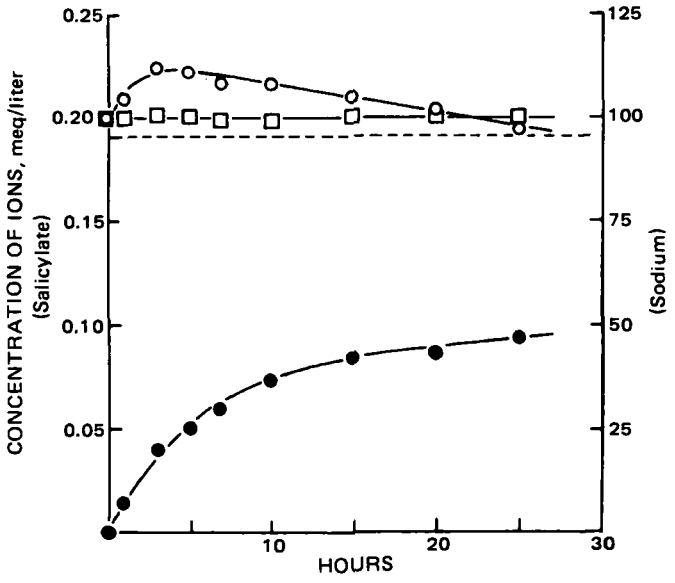

Figure 6—*Reverse permeation of salicylate ion in the presence of bovine serum albumin. Initial concentrations of sodium salicylate in compartment I and II were 0.2 and 0.4 m*M*, respectively; bovine serum albumin (0.1 m*M*) was dissolved in compartment II. Key: concentration of salicylate ion in compartment I when initial concentration of sodium oxalate in both compartments was 50 m*M *(□); concentration of salicylate (○) and sodium (●) ions in compartment I when initial concentrations of sodium oxalate in comparments I and II were 0 and 50 m*M*, respectively.*

where $[s]_I^0$ and $[s]_{II}^0$ are the initial concentrations of salicylate ion and $[s]_I^t$ and $[s]_{II}^t$ are the concentrations after time t in the indicated compartments. V_I and V_{II} are volumes of compartment I and II, respectively. In this study, the compartment of the permeation cell with a higher total concentration of salicylate ion is designated as II.

The efficiency of concentration (R) was calculated by:

$$R = -\overline{\Delta[s]}/\overline{[s]} \qquad \text{(Eq. 9)}$$

Since the numerator in Eq. 9 is negative due to the reverse permeation, a minus sign is added to the right-hand side of Eq. 9 to obtain a positive value for the efficiency of concentration. R-values at 10 hr were 6.1 and 11.2% when the initial concentration ratios of oxalate to salicylate were 0.5 and 5, respectively (Fig. 4).

To confirm the concentration gradient effect of the oxalate ion, the permeation fluxes of salicylate ion were measured under three different conditions: (*a*) the opposite direction from the concentration gradients of salicylate and oxalate ions, (*b*) the same direction as the concentration gradients, and (*c*) no concentration gradient of oxalate ion (Table II). The concentration ratio of oxalate to salicylate was greater than that used previously (Fig. 2) in order to obtain significant values for the permeation fluxes. The simple permeation of salicylate ion was accelerated most with both concentration gradients in the same direction (Fig. 5).

In the presence of bovine serum albumin, when the concentration of oxalate in both compartments was the same (*i.e.*, no concentration gradient of oxalate), a significant concentration change of salicylate was not obtained under the experimental conditions (Fig. 6). The slow permeation of the salicylate ion was due to the small membrane area and small concentration gradient. The concentration of unbound salicylate ion in compartment II would be lower than that in compartment I because of protein binding, which can be estimated by the binding parameters (16). Salicylate ion permeated from compartment II to I against the concentration gradient, with a greater concentration gradient of oxalate ion. Since it has been shown that association constants $>1 \times 10^4 M^{-1}$ affect drug distribution (17), salicylate ion bound on the secondary binding sites of bovine serum albumin can permeate with the electric potential gradient based on the oxalate concentration gradient. The reverse permeation reached a maximum value after 3 hr in the presence of bovine serum albumin. The concentration of salicylate ion in compartment I decreased after the maximum and approached the lower concentration (0.191 m*M*) which was obtained after 72 hr, as shown by the dotted line in Fig. 6. The concentration of sodium ion in compartment I showed that the solution had not equilibrated after 30 hr.

Organic drugs permeate through biomembranes mainly in their uncharged forms. If the same mechanism is applicable to biological systems, salicylate ion may be concentrated on the membrane boundary with the concentration gradient of coexisting ions. Assuming that the effective pH at the site of drug absorption is 5.3 (18), uncharged salicylic acid would be concentrated more on the membrane boundary than in the intestinal contents. When salicylate is coadministered with a weakly acidic drug, then the permeation rate of salicylate determined by dialysis techniques will vary with the concentration gradient of the coexisting drug.

Determination of the Dissociation Constant of a Weak Acid Using a Dissolution Rate Method

JØRGEN B. HANSEN [x] **and OTTO HAFLIGER**

Received April 6, 1982, from the *Biological Pharmaceutical Research Department, Hoffmann-LaRoche & Co., Ltd., Basle, Switzerland.* Accepted for publication July 14, 1982.

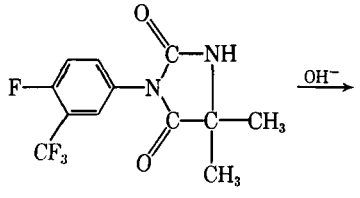
Abstract □ Based on theories of diffusion-controlled mass transport for dissolution processes of weak acids in aqueous alkaline media, a method for the determination of the dissociation constant of a weak monoprotic acid is described. The method includes measurements of the initial dissolution rate as a function of pH, using the rotating-disk technique, and determination of the intrinsic solubility. The method was applied to determine the apparent dissociation constant (μ = 0.1) of 5,5-dimethyl-3-(α,α,α,4-tetrafluoro-*m*-tolyl)hydantoin, a new schistosomicide. For comparison, a spectrophotometric method for the pK_a determination was developed. Due to rapid hydrolysis of the compound in the pH range required for the determination of the pK_a, the development of the latter method turned out to be complicated and tedious. The results of both methods were in good agreement. For compounds with unfavorable properties for titrimetric or spectrophotometric determination of the pK_a value, the dissolution rate method can be a useful alternative.

Keyphrases □ Dissociation constant determinations—use of a dissolution rate method, weak acids, 5,5-dimethyl-3-(α,α,α,4-tetrafluoro-*m*-tolyl)hydantoin □ Dissolution rate method—determination of dissociation constants, weak acids, 5,5-dimethyl-3-(α,α,α,4-tetrafluoro-*m*-tolyl)hydantoin

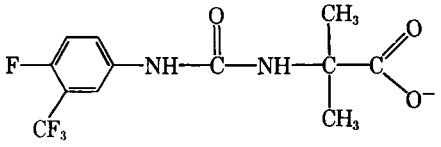
The determination of the dissociation constant of weakly acidic or basic drugs is normally a routine matter, using one of the established techniques (1–3). However, in some cases the compound may have unfavorable properties which makes such a routine determination difficult. Such is the case when the compound undergoes a fast chemical reaction in the medium required for the measurements.

From the dissolution rate model of weak acids in alkaline media (4), and the theories of the influence of irreversible reactions on the dissolution of a solid (5), it could be expected that dissolution behavior could form the basis for a method to determine the dissociation constant of a weak acid undergoing fast degradation in the pH range around the pK_a value.

This study utilized, 5,5-dimethyl-3-(α,α,α,4-tetrafluoro-*m*-tolyl)hydantoin (I), a new schistosomicide (6).



(I)



(II)

The hydantoin derivative (I) is expected to be a weak acid. The compound is stable in the acidic and neutral pH range, but undergoes a fast hydrolysis in aqueous alkaline media forming the hydantoic acid (II).

For the determination of the dissociation constant of the acid (I), two methods have been compared: the method based on the dissolution rate and a spectrometric method.

THEORETICAL

Determination of pK_a by Spectroscopy—The determination of the dissociation constant by spectroscopy is possible if un-ionized and ionized species of the molecule yield different spectra in UV-visible range (1–3). Measuring the absorbance at a particular wavelength, the K_a for acids can be obtained from the equation:

$$K_a = \frac{\epsilon_M - \epsilon}{\epsilon - \epsilon_I}[H^+] \qquad \text{(Eq. 1)}$$

where ϵ_M and ϵ_I are molar absorptivities for the un-ionized and ionized species, and ϵ is the molar absorptivity at $[H^+]$. In cases where ϵ_I is not directly obtainable, Maroni (7) has proposed a method, based on the rearrangement of Eq. 1:

$$\epsilon = \epsilon_I - \frac{(\epsilon - \epsilon_M)[H^+]}{K_a} \qquad \text{(Eq. 2)}$$

Plotting a series of ϵ values against $(\epsilon - \epsilon_M)[H^+]$ gives a straight line and K_a can be calculated from the slope. If the compound undergoes a rapid reaction, it will be impossible to measure the ϵ-values directly. However, if the reaction is of first order, the ϵ-values may be obtained from measurements of the absorbance as a function of time, using the Guggenheim method (8).

Determination of pK_a by Dissolution Rate—Based on the film theory of Nernst (9) for heterogeneous reactions, Higuchi *et al.* (4) have formulated a model for dissolution of a weak acid in a basic medium. This model postulates that the dissolution rate is controlled by a rapid, reversible chemical reaction and simultaneous diffusion of all important species taking part in the processes that occur within a boundary layer. It is assumed in this model that the diffusion layer for all solute species is equal. A schematic diagram of the Higuchi model is presented in Fig. 1, where HA is the acid, B^- is the incoming base and h is the thickness of the diffusion layer. Under sink condition, $[HA]_h$ and $[A^-]_h$ will effectively be zero.

The general equation, based on this model for the initial dissolution rate or flux J as a function of the bulk concentration of the incoming base, is relatively complicated (4). If the base happens to be the hydroxide ion, the equation will be simpler (10):

$$J = \frac{D_{HA}[HA]_0}{h} + \frac{(D_{OH})^2[OH^-]_h}{h}\left(\frac{D_A[HA]_0K_a/K_w}{(D_{OH})^2 + D_AD_{OH}[HA]_0K_a/K_w}\right) \qquad \text{Eq. 3)}$$

where D_S is the diffusion coefficient of species S in the system, $[HA]_0$ is the intrinsic solubility, *i.e.*, the solubility of the undissociated species, and K_a and K_w are dissociation constants of the acid and water, respectively.

If we assume that $D_A = D_{HA}$ and substitute $K_w/[H^+]_h$ for $[OH^-]_h$, and J_0 for $D_{HA}[HA]_0/h$, rearrangement of Eq. 3 gives:

$$J = J_0 + \frac{J_0D_{OH}K_a}{[H^+]_h(D_{OH} + D_{HA}[HA]_0K_a/K_w)} \qquad \text{(Eq. 4)}$$

Plotting a series of values of the flux against the corresponding reciprocal values of $[H^+]_h$ gives the slope:

$$a = \frac{J_0D_{OH}K_a}{D_{OH} + D_{HA}[HA]_0K_a/K_w} \qquad \text{(Eq. 5)}$$

0022-3549/83/0400-0429$01.00/0

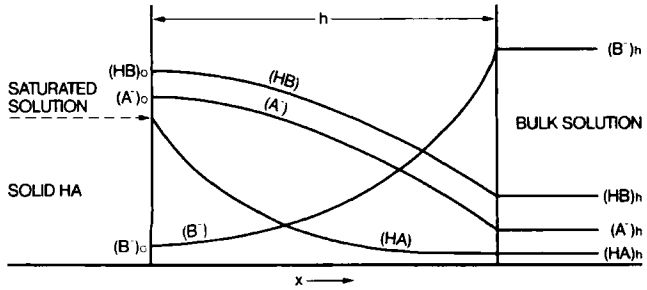


Figure 1—*Schematic diagram of the model of Higuchi* et al. *(4) for the dissolution of an acid, HA, into a reactive medium containing base* B^-.

and by rearrangement:

$$K_a = \frac{aD_{OH}K_w}{J_0D_{OH}K_w - aD_{HA}[HA]_0} \qquad \text{(Eq. 6)}$$

Studies of the dissolution rate can be performed with the rotating-disk technique, where the flux as a function of hydrodynamic conditions has been studied very extensively by Levich (11). For the rotating disk, the mass flux is given as:

$$J = 0.62D^{2/3}\nu^{-1/6}\omega^{1/2}[HA]_0 \qquad \text{(Eq. 7)}$$

where ν is the kinematic viscosity and ω is the angular velocity of rotation.

The corresponding diffusion boundary layer may be written as:

$$h = 1.612\,D^{1/3}\nu^{1/6}\omega^{-1/2} \qquad \text{(Eq. 8)}$$

Higuchi *et al.* (5) have studied the influence of an irreversible reaction on the dissolution rate of a compound undergoing a rapid hydrolytic reaction simultaneously with the dissolution. It was found that the influence depends on the diffusion time t_D, which is the average lifetime for an element to travel through the diffusion layer, and on the reaction rate of the irreversible reaction.

The diffusion time was expressed as:

$$t_D = \frac{h^2}{2D} \qquad \text{(Eq. 9)}$$

EXPERIMENTAL

Materials—5,5-Dimethyl-3-(α,α,α,4-tetrafluoro-*m*-tolyl)hydantoin was of purity >99.8%. All other chemicals were of analytical grade.

Spectrophotometric Method—A 1-ml portion of 1.7×10^{-2} *M* of the acid (I) in ethanol was added to 50 ml of 0.1 *N* NaCl or solutions of sodium hydroxide adjusted to an ionic strength of 0.1 with sodium chloride and stirred at 25.0°. The solutions were injected into a 1-cm cell of a UV-visible spectrophotometer[1], thermostated at 25.0 ± 0.1°, and the change of absorbance with time was measured at 254 nm. The pH of the solutions was measured at 25° using a combination pH microelectrode[2] with low alkaline error and a pH meter[3].

Dissolution Rate Method—The dissolution rates were determined using the rotating disk technique, with an apparatus similar to that described by Wood *et al.* (12). A disk (1.6 cm in diameter) of the compound was compressed at 3×10^3 kg for 3 min in a hydraulic press. The disk assembly was rotated by a variable-speed synchronous motor that was calibrated by a tachometer. The dissolution rates were determined at 25.0 ± 0.1° using a constant temperature water bath.

Solubility—The solubility of I was determined by shaking an excess of the compound in 0.1 *N* NaCl solution at 25.0° in a water bath for 24 hr, during which time equilibrium solubility was reached. After equilibration the solution was filtrated through a membrane filter (0.45 μm). The filtrate was diluted appropriately with water, and the assay was made spectrophotometrically at 270 nm (ϵ = 858).

Diffusion Coefficient and Boundary Layer Thickness—The dissolution rate measurements were performed using the rotating disk in 500 ml of 0.1 *N* NaCl at 25.0° with rotation speeds varying from 50 to 299 rpm. At each rotation speed the dissolution rate was determined after a rotation period of 20 min. A 1-ml solution of 1 *N* NaOH was added to 10.0 ml of the sample, and the solutions were kept at 25° for 1 hr. The solutions were diluted appropriately with 0.1 *N* sodium hydroxide and measured by UV spectrophotometry at 239 nm (ϵ = 16180).

Dissolution–pH Profile—The determination of the dissolution rate as a function of pH was performed with the same compressed disk for the whole pH profile, and the test solution was not renewed. However the different pH values were obtained by successive additions of 0.1 *N* NaOH solution to the test solution, and the dissolution was determined after each change of pH. Corrections for added volumes of 0.1 *N* NaOH and the samples withdrawn were considered.

The dissolution–pH profile was determined with a rotation speed of 100 rpm. The starting medium was 500 ml of 0.1 *N* NaCl. The disk was initially stirred in the medium for about 15 min, and the pH was then adjusted to a higher predetermined value by adding 0.1 *N* NaOH. A sample was withdrawn after equilibrating for 5 min and again after 20 min. The pH was then adjusted to the next higher pH value, and the procedure for sampling was repeated. The procedure was repeated until samples from a representative number of pH values had been collected. The assay of the samples was performed in the same way as described for determination of diffusion coefficient.

Table I—Experimental Data of the Spectrophotometric Method for the Determination of the Apparent pK_a at 25° [a]

pH	$t_{1/2}$, min	$\epsilon_{254\ nm}$	pK_a [b]
7.40		542	
11.77	9.50	787	12.12
11.89	8.21	835	12.12

11.99	7.43	891	12.09
12.05	6.81	915	12.10
12.11	6.41	947	12.10
12.17	6.00	950	12.14
12.28	5.56	1006	12.13
12.35	5.17	1051	12.09
12.48	4.77	1098	12.10
12.57	4.58	1131	12.10
			Average 12.11 (± 0.03)

[a] μ = 0.1. [b] The individual values were calculated from Eq. 1, where ϵ_M = 542 and ϵ_I = 1332. ϵ_I was obtained from Eq. 2.

RESULTS AND DISCUSSION

Spectrophotometric Method—The molar absorptivity of the nonionized species ϵ_M could be obtained directly from the measurement of the absorbance in the 0.1 *N* NaCl solution in which the compound is stable. In the pH range of 11.79–12.57, the absorbance at time zero had to be calculated from the absorbance–time curve. Preliminary studies have shown, that the hydrolysis of I to the corresponding hydantoic acid, as would be expected, is of first order. The Guggenheim method (8) could, therefore, be applied for the calculation of the ϵ values from the initial part of the absorbance–time curves. From these curves kinetic data of the hydrolytic reaction could also be obtained by the Guggenheim method. A reliable value for ϵ_I could not be found; therefore, K_a was calculated according to Eq. 2. This gave a slope -1.282×10^{12} (r = 0.991) corresponding to $K_a = 7.803 \times 10^{-13}$ or pK_a = 12.11.

The development of this spectrophotometric method turned out to be very tedious. Because of the fast hydrolytic reaction, it was difficult to find an optimal analytical wavelength.

Dissolution Rate Method—The intrinsic solubility $[HA]_0$ of I in 0.1 *N* NaCl was found to be 1.44×10^{-3} *M*. Rearranging Eq. 7, an expression for the diffusion coefficient can be found:

$$D_{HA} = \left(\frac{J\nu^{1/6}\omega^{-1/2}}{0.62[HA]_0}\right)^{3/2} = 4.8 \times 10^{-6}\ \text{cm}^2/\text{sec} \qquad \text{(Eq. 10)}$$

where $J\omega^{-1/2}$ determined from the slope of the linear plot J against $\omega^{1/2}$ (r = 0.996) was found to be 5.60×10^{-10} moles/cm^2/sec$^{1/2}$; $\nu = 8.93 \times 10^{-3}$ stokes is the kinematic viscosity of water at 25° (13).

From the investigations of Higuchi *et al.* (5) on the influence of irreversible chemical reactions on dissolution rate of a solid, it was found that for a diffusion time t = 3 sec, a half-life of the irreversible reaction greater than the order of 10 sec would have no influence on the dissolution rate. A rotation speed of 100 rpm of the rotating disk gives, according to Eq. 8, a diffusion layer thickness $h = 3.8 \times 10^{-3}$ cm. The diffusion time for (I) under this hydrodynamic condition will be t_D = 1.5 sec.

From the kinetic data given in Table I, it is obvious that by using the

[1] Uvikon, model 820, Kontron, Zürich, Switzerland.
[2] EA 125, Metrohm, Herisau, Switzerland.
[3] Model E 603, Metrohm, Herisau, Switzerland.

rotating disk at 100 rpm the dissolution rate will not be affected by the hydrolytic reaction in the pH range of 11.8–12.6. These hydrodynamic conditions were, therefore, used for the present pH profile study. Plotting the values of the flux J (see Table II) against the reciprocal values of the bulk hydrogen ion concentration $[H^+]_h$ a linear relationship was found. Using the least-squares method gave the slope $a = 7.530 \times 10^{-20}$ with the intercept $J_0 = 1.071 \times 10^{-7}$ moles/cm^2/min and a coefficient of correlation $r = 0.995$. Using these data, the experimental values of D_{HA} and $[HA]_0$ and assuming the diffusion coefficient of hydroxide ion in water D_{OH} to be 2.42×10^{-5} cm^2/sec (from Ref. 4), the dissociation constant was obtained from Eq. 6: $K_a = 7.178 \times 10^{-13}$ or $pK_a = 12.14$.

Equation 3 is based on the diffusion layer theory of Nernst. However, several aspects of the Nernst model have been criticized (11, 14). One drawback of the model is the erroneous assumption that the diffusion layer thickness is equal for all diffusing species under the same hydrodynamic conditions. For the rotating disk, the diffusion layer thickness of a diffusing species depends on the diffusion coefficient according to Eq. 8 (11). As D_{OH} is about 5 times greater than D_{HA}, the concentration of hydroxide ion at h_{HA}, $[OH^-]_h$ will be somewhat lower than the hydroxide ion concentration of the bulk solution $[OH^-]_{bulk}$. This could have a significant influence on the value for K_a, calculated from Eq. 6. An evaluation of $[OH^-]_h$ can be made by the following considerations.

From Eq. 8 and the numerical values of D_{HA} and D_{OH} a ratio N can be calculated:

$$N = \frac{h_{HA}}{h_{OH}} = \left(\frac{D_{HA}}{D_{OH}}\right)^{1/3} = 0.58 \qquad \text{(Eq. 11)}$$

To calculate the hydrogen ion concentration at the solid–liquid interface $[H^+]_0$ of the Higuchi model, Mooney *et al.* (15) have derived the equation:

$$-D_H[H^+]_0^2 + [H^+]_0(D_H[H^+]_h - D_{OH}[OH^-]_h) + K_w(D_{OH} + D_A[HA]_0K_a/K_w) = 0 \qquad \text{(Eq. 12)}$$

If $[H^+]_0$ and $[H^+]_h \ll [OH^-]_h$, and also assuming $D_{HA} = D_A$ and considering that $[OH^-]_0[H^+]_0 = K_w$, a rearrangement of Eq. 12 gives:

$$[OH^-]_0 = \frac{D_{OH}[OH^-]_hK_w}{D_{OH}K_w + K_aD_{HA}[HA]_0} \qquad \text{(Eq. 13)}$$

Defining the ratio R as:

$$R = \frac{[OH^-]_h - [OH^-]_0}{[OH^-]_{bulk} - [OH^-]_0} \qquad \text{(Eq. 14)}$$

and substituting Eq. 13 into Eq. 14, the following relationship between $[OH^-]_h$ and $[OH^-]_{bulk}$ is found:

$$[OH^-]_h = \frac{D_{OH}K_w + K_aD_{HA}[HA]_0}{D_{OH}K_w + K_aD_{HA}[HA]_0/R}[OH^-]_{bulk} \qquad \text{(Eq. 15)}$$

From investigations with the rotating-disk electrode, Levich (11) has derived the mathematical formula of the concentration gradient curve for a diffusing element in the diffusion layer of the rotating disk. Using this formula, the ratio R can be calculated for the value at a relative distance N from the solid–liquid interface:

$$R = \frac{\int_0^N e^{-u^3}\,du}{\int_0^\infty e^{-u^3}\,du} \qquad \text{(Eq. 16)}$$

For a value of $N = 0.58$, R was found to be 0.82. For this value of R Eq. 15 gives:

$$[OH^-]_h = 0.996\,[OH^-]_{bulk}$$

It is obvious that a factor of 0.996 will have no significant influence on the K_a value calculated on the basis of Eq. 4. For cases where the product $K_a\,[HA]_0$ is appreciably larger, a small influence may, however, be expected.

From Eq. 6 it can be estimated that the relative low value of the product $K_a[HA]_0$ also means that very high accuracy of the value for D_{OH} and D_{HA} is not required in the present case, and a simple calculation of D_{HA} using the square root method (16), for instance, may replace the experimental method used here. Equation 3 is valid only if $[OH^-]_0$ and $[OH^-]_h$ are essentially higher than $[H^+]_0$ and $[H^+]_h$. Otherwise the complete formula for the Higuchi model (4) has to be used.

The good agreement between the results of the spectrophotometric and the dissolution rate methods for determination of pK_a, shows that the theoretical approach used here may give a sound basis for the determination of the dissociation constant from the dissolution behavior.

Table II—Experimental Data of the Dissolution Method for the Determination of the Apparent pK_a at 25° [a]

pH	J, moles/cm^2/min $\times 10^7$	pK_a [b]
11.81	1.605	12.10
11.91	1.713	12.12
12.02	1.826	12.16
12.12	2.123	12.12
12.18	2.159	12.17
12.25	2.382	12.15
12.33	2.576	12.17
12.41	3.004	12.14
12.49	3.483	12.13
		Average 12.14 (± 0.04)

[a] $\mu = 0.1$. [b] The individual values were obtained from Eq. 4, where $J_0 = 1.071 \times 10^{-7}$ moles/cm^2/min.

Using the technique described here, the dissolution rate method can be applied advantageously for compounds with unfavorable properties for determination by a titrimetric or a spectrophotometric method.

In analogy to the approach used in the Higuchi model for pK_a determinations of weak acids, it may be expected that it can also be used for determinations of the pK_a values of weak bases by using, for instance, hydrochloric acid solutions as the reaction media. The dissociation constant may also be obtained from dissolution rates in buffer solutions. Simplified models for dissolution behavior in these media have been proposed (17, 18), assuming the pH of the solid–liquid interface to be equal to the pH of the bulk solution. However, as has been shown by Mooney *et al.* (19) this is generally not the case and may give erroneous results. The use of the extension of the Higuchi model for dissolution behavior in buffer solutions, as has been proposed by Mooney *et al.* (19) may, however, form a suitable basis for the determination of pK_a values in such media.

Kinetics of the Rapid Modification of Human Serum Albumin with Trinitrobenzenesulfonate and Localization of Its Site

YUKIHISA KURONO ˣ, KENICHI ICHIOKA, and KEN IKEDA

Received August 9, 1982, from the *Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya, 467, Japan.* Accepted for publication December 17, 1982.

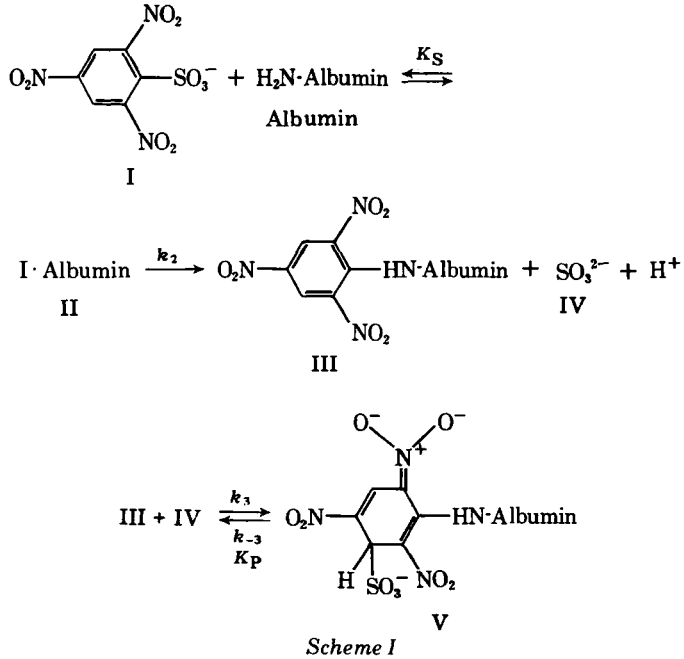
Abstract □ The rapid reaction of human serum albumin with trinitrobenzenesulfonate (I) and the location of the reactive site were investigated to characterize the chemical modification of albumin by I. The modification proceeds through trinitrophenylation of a lysine residue of albumin and monoaddition of the byproduct, sulfite ion, to the trinitrophenylalbumin, as reported previously. The individual kinetic parameters for both reactions were determined at various pH values and 25°. The ε-amino group of the lysine residue which has a pK_a value of ~8.9 was the reactive group involved in the trinitrophenylation. The dissociation constant of the sulfite monoadduct was about 10-fold smaller than that of the monoadduct of the model compound trinitrophenyl α-acetyllysine. The modification of albumin by I reduced the fluorescence intensity of the tryptophan-214 residue in the albumin amino acid sequence. Acetylation of the lysine-199 residue with aspirin and 5-nitroaspirin decreased the trinitrophenylation rate of albumin with I. These results on the fluorescence spectroscopy and the effect of the acetylation suggest that the reactive group for I is the lysine-199 residue located near the tryptophan-214 residue.

Keyphrases □ Kinetics—of reaction of trinitrobenzenesulfonate with human serum albumin □ Albumin, human serum—kinetics of reaction with trinitrobenzenesulfonate, location of drug binding site, fluorescence spectroscopy, acetylation with aspirins □ Trinitrobenzenesulfonate—kinetics of reaction with human serum albumin □ Aspirin—acetylation of human serum albumin

Characterization of drug binding sites on human serum albumin and knowledge of drugs affecting these sites are important to predict displacement of one drug by another, when two or more drugs are administered concurrently (1). Studies on the drug binding sites of the albumin molecule have been carried out by various methods (2–5), one of which is chemical modification (4). Trinitrobenzenesulfonate (I) has been used as a reagent for amino group modification in proteins (6). Kinetic data of the reactions of human and bovine serum albumin with excess I were presented by Goldfarb (7) and Andersson *et al.* (8), respectively. Under their conditions (an excess of I over albumin), multiple reactive sites for I appear to be modified, so that it may be difficult to investigate in detail the kinetics and mechanism for the modification of a single specific site on albumin with I.

In our previous study (9), it was reported that the chemical modification of human serum albumin by I proceeds rapidly and specifically through the trinitrophenylation of a lysine residue in albumin and the sulfite monoaddition, as shown in Scheme I. Abbreviations in Scheme I are as follows: II, the Michaelis–Menten type complex of I and albumin; III, trinitrophenylalbumin; IV, sulfite ion; and V, sulfite monoadduct of III.

The present study is concerned with determination of the individual kinetic parameters in Scheme I at various pH values and with identification of the primary reactive site on albumin for I.



Scheme I

EXPERIMENTAL

Materials—Human serum albumin[1] was used after purification as previously described (10). The concentration of albumin was determined by use of its molar absorbance ($\epsilon_{albumin} = 3.66 \times 10^4\ M^{-1}\ cm^{-1}$) at 278 nm (11), assuming a molecular weight of 69,000. 2,4,6-Trinitrobenzenesulfonic acid sodium salt[2] and sodium bisulfite[3] were used without further purification. All other chemicals were reagent grade and were used without further purification.

Kinetic Data—The buffer systems used were: pH 6–8.3, 0.067 *M* phosphate; pH 8.3–9, 0.1 *M* phosphate and 0.05 *M* borate; pH 9–11, 0.05 *M* borate and 0.05 *M* carbonate. Ionic strength was adjusted to 0.2 *M* with sodium chloride. The temperature was kept at 25° in all experiments unless otherwise stated.

The UV spectral changes based on the reactions shown in Scheme I are presented in our previous paper (9). The trinitrophenylation rate of albumin with I was followed at a wavelength of 360 nm (showing an isosbestic point of III and V) with a stopped-flow spectrophotometer[4]. Pseudo first-order analysis was applied under the condition of excess albumin concentration relative to that of I.

For the analysis of the reversible reaction (III + IV ⇄ V) shown in Scheme I, the UV spectrum of either III or V (not of the mixture of III, IV, and V) is necessary. Since neither III nor V was isolated, each spectrum of III and V could not be measured independently, and thus the spectrum was unknown. Trinitrophenyl α-acetyllysine (VI) was chosen as a model compound for III for the following reason. The absorbance at 360 nm (isosbestic point of III and V), after completion of the spectral change due to the trinitrophenylation of albumin with I, was essentially equal to that of VI found in the literature (12), when the original absorbance based on the excess albumin over I was corrected. Therefore, the UV spectrum of III at wavelengths >360 nm could be assumed to be identical with the spectrum of VI.

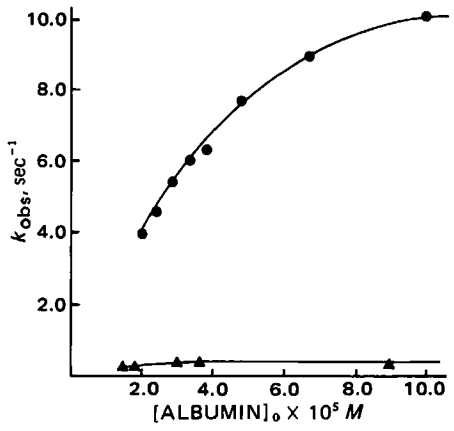

Figure 1—*Effect of albumin concentration on the rate of trinitrophenylation with I at 25°. The concentration of I was 1.0 × 10^{-5} M. Key: (●) pH 10.7; (▲) pH 7.4.*

Since it was indicated from preliminary experiments that the dissociation constant (K_P = [III][IV]/[V]) was relatively small, an elaborate method (13) was used for the determination of K_P, without employing the usual spectral method [*e.g.*, Benesi–Hildebrand method (14)]. The usual method is applicable only to the equilibrium system in which one component is much larger than the other.

Two reaction solutions were prepared (13): one was composed of an initial concentration of III ($[III]_0$) and of IV ($[IV]_{0,1}$), and the other of $[III]_0$ and a concentration $[IV]_{0,2}$. It was found that I was completely converted into III in the presence of excess albumin, and thus $[III]_0$ was equal to the initial concentration of I. The above two solutions were equilibrated together and their absorbances at 415 nm were measured. The increments of absorbances from the sum of the intact (initial) absorbances of III and IV, which are represented by ΔA_1 and ΔA_2, are proportional to the equilibrium concentrations of V, $[V]_{e,1}$ and $[V]_{e,2}$, respectively. For actual calculations of ΔA_1 and ΔA_2 the absorbance of the model compound VI was used instead of the absorbance of III, because the absorbance of III was reasonably assumed to be identical with that of VI as stated earlier. The relationship between the increment of absorbance and the equilibrium concentration is as follows: $[V]_{e,1} = \alpha\Delta A_1$ and $[V]_{e,2} = \alpha\Delta A_2$. The coefficient α is equal to $1/(\epsilon_V - \epsilon_{III} - \epsilon_{IV})$, where ϵ with subscript III, IV, or V is the molar absorbance of each species. Then, K_P can be represented as follows (13):

$$K_P = \frac{[III]_e[IV]_e}{[V]_e} \qquad \text{(Eq. 1)}$$

$$= \frac{([III]_0 - \alpha\Delta A_1)([IV]_{0,1} - \alpha\Delta A_1)}{\alpha\Delta A_1} = \frac{([III]_0 - \alpha\Delta A_2)([IV]_{0,2} - \alpha\Delta A_2)}{\alpha\Delta A_2}$$

From Eq. 1 a quadratic equation with respect to α is obtained, and the solution is (13):

$$\alpha = \frac{([IV]_{0,1} - [IV]_{0,2})\Delta A_1\Delta A_2 \pm \sqrt{\{([IV]_{0,1} - [IV]_{0,2})\Delta A_1\Delta A_2\}^2 - 4[III]_0\Delta A_1\Delta A_2(\Delta A_1 - \Delta A_2)(\Delta A_2[IV]_{0,1} - \Delta A_1[IV]_{0,2})}}{2\Delta A_1\Delta A_2(\Delta A_1 - \Delta A_2)} \qquad \text{(Eq. 2)}$$

Because α is calculated from Eq. 2, we can estimate K_P from Eq. 1. Furthermore, applying ϵ_{III} presumed from VI to the equation $\alpha = 1/(\epsilon_V -$ $\epsilon_{III} - \epsilon_{IV}$) we can obtain ϵ_V also, since ϵ_{IV} is determined independently (negligible). The K_P and α thus obtained were reproducible in other reaction solutions equilibrated from the different initial concentrations of IV.

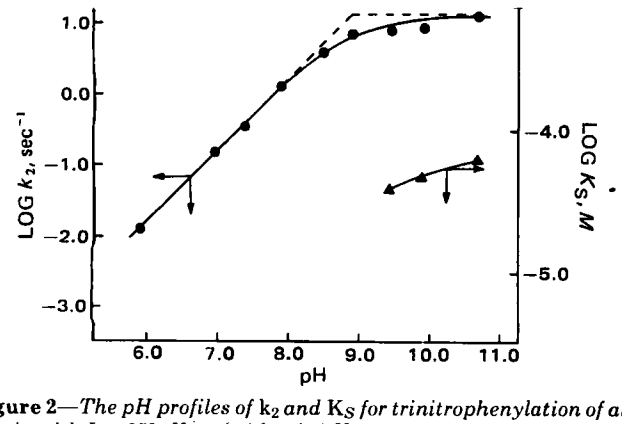

Figure 2—*The pH profiles of* k_2 *and* K_S *for trinitrophenylation of albumin with I at 25°. Key: (●)* k_2*; (▲)* K_S*.*

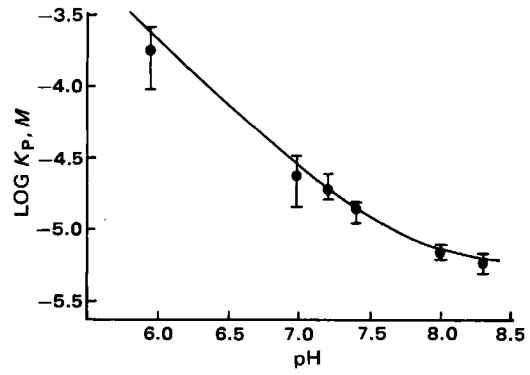

Figure 3—*The pH profile for* K_P *at 25°. The bars in this figure indicate the standard deviations. The solid curve was calculated using Eq. 6.*

The rate of the sulfite monoaddition was also followed at 415 nm. As the molar absorbance (ϵ_{III}, ϵ_{IV}, ϵ_V, and $\epsilon_{albumin}$) of each component in the reaction solution is known, the concentration of V at each time interval is calculated from the absorbance of the reaction solution. The rate constant (k_3) was determined from the slope of the plot based on Eq. (3), which is derived for the reversible reaction (15):

$$\frac{1}{E - F}\log\frac{F([V] - E)}{E([V] - F)} = \frac{k_3}{2.303}t \qquad \text{(Eq. 3)}$$

where,

$$E, F = \frac{([III]_0 + [IV]_0 + K_P) \pm \sqrt{([III]_0 + [IV]_0 + K_P)^2 - 4[III]_0[IV]_0}}{2}$$

The rate constant (k_{-3}) for the release of IV from V was calculated from K_P and k_3 already determined: $k_{-3} = K_P \cdot k_3$.

Acetylation of Albumin with Aspirin and 5-Nitroaspirin—Acetylation of albumin with aspirin (VII) was carried out by a previous method (16). A mixture of albumin (1.00 × 10^{-4} *M*) and VII (5.00 × 10^{-4} *M*) in pH 7.4 buffer was incubated at 37° for 24 hr and dialyzed at 4° for 48 hr against multiple changes of the same buffer. In the control experiment, VII was omitted and albumin was treated as above.

In the case of the acetylation by 5-nitroaspirin (VIII), the absorbance at 370 nm due to 5-nitrosalicylic acid (IX) released from the reaction of albumin (1.00 × 10^{-4} *M*) with VIII in pH 7.4 and at 25° was measured to estimate the degree of the acetylation. Three concentrations of VIII were used: 1.25 × 10^{-4} *M*, 2.50 × 10^{-4} *M*, and 3.75 × 10^{-4} *M*. When the absorbances reached corresponded to 1.0, 2.0, and 3.0 moles of IX per mole of albumin, respectively, the reaction solutions were cooled at 4° and dialyzed as described above. These albumins were denoted as monoacetyl-, diacetyl-, and triacetylalbumin, respectively.

Fluorescence Measurements—The fluorescence spectra of albumin solution (1.00 × 10^{-5} *M*) in the presence and absence of I (2.50 × 10^{-6} *M*) were measured. The excitation wavelength was 300 nm (17, 18).

RESULTS AND DISCUSSION

Kinetics on Trinitrophenylation of Albumin with I—Figure 1 shows the effect of the initial concentration of albumin ($[Albumin]_0$) on the apparent first-order rate constant (k_{obs}) for the trinitrophenylation at pH 7.4 and 10.7. At pH 10.7 the k_{obs} value increases hyperbolically with the albumin concentration, indicating saturation by trinitrophenylation (5, 19). According to Scheme I, k_{obs} can be represented as (5, 19):

$$k_{obs} = \frac{k_2[albumin]_0}{K_S + [albumin]_0} \qquad \text{(Eq. 4)}$$

where K_S and k_2 are the dissociation constant of II (= [I][albumin]/[II]) and the first-order rate constant of II for trinitrophenylation, respectively. The k_2 and K_S values were calculated from the intercept and slope of a plot based on the following, which is rearranged from Eq. 4 (5, 19):

$$\frac{1}{k_{obs}} = \frac{K_S}{k_2}\cdot\frac{1}{[albumin]_0} + \frac{1}{k_2} \qquad \text{(Eq. 5)}$$

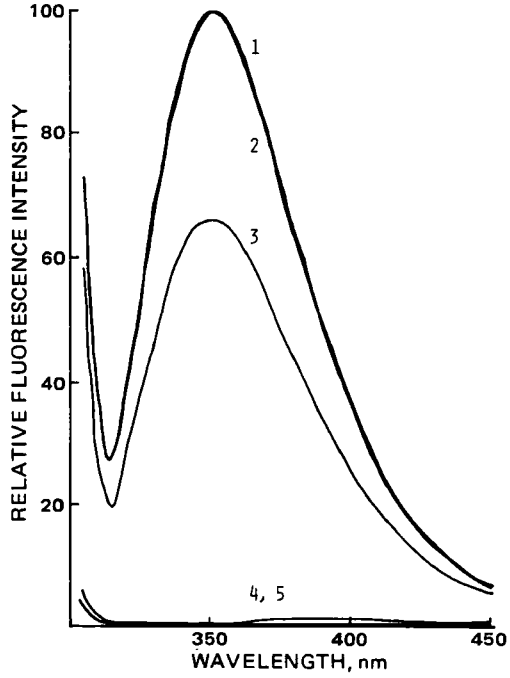

Figure 4—*Fluorescence emission spectra excited at 300 nm. Key: (1) 1.0 × 10⁻⁵ M albumin; (2) 1.0 × 10⁻⁵ M albumin and 5.0 × 10⁻⁶ M sodium bisulfite; (3) 1.0 × 10⁻⁵ M albumin and 2.5 × 10⁻⁶ M I; (4) 2.5 × 10⁻⁶ M I; and (5) 5.0 × 10⁻⁶ M sodium bisulfite.*

At pH 7.4, in contrast, the values of k_{obs} are almost independent of the albumin concentration. This independence suggests that K_S in Eq. 4 is far less than $[albumin]_0$ employed, and thus the k_{obs} value obtained under these conditions was assumed to be equal to k_2.

Figure 2 illustrates the pH dependence of k_2 and K_S thus obtained. The value of k_2 markedly depends on pH. Below pH values of about 8, the slope of the profile is 1, and above pH values of about 9.5, the k_2 value is independent of pH. From this profile the pK_a value of the ϵ-amino group of a lysine residue at the reactive site of albumin was estimated as about 8.9.

As stated earlier the data show that the K_S value at neutral pH is less than that above pH 9.5. The pH dependence of K_S may be explained qualitatively as follows. Deprotonation of basic groups (*e.g.*, ϵ-amino group of lysine and/or guanidino group of arginine) constituting the reactive site for I increases with increasing pH value, thereby decreasing positive-charge localization. Compound I is an anion, therefore, the ionic interaction (20) between I and the reactive site may decrease with increasing pH.

Sulfite Monoaddition to Trinitrophenylalbumin—Figure 3 shows a log K_P–pH profile. The K_P values decrease with increasing pH values. This pH dependence suggests that sulfite ion (IV) rather than bisulfite ion reacts with III. Then, K_P in the pH region examined can be expressed as a function of the hydrogen ion concentration $[H^+]$ by:

$$K_P = K'_P\left(\frac{[H^+] + K_2}{K_2}\right) \qquad \text{(Eq. 6)}$$

where K_2 and K'_P are the dissociation constant of bisulfite ion and the intrinsic dissociation constant of V, respectively. From a plot of K_P against $[H^+]$, K'_P and K_2 were estimated as 5.0×10^{-6} *M* and 2.2×10^{-8} *M*, respectively. The K'_P value for V is about 10-fold smaller (tight binding) than that (4.8×10^{-5} *M*) for the sulfite monoadduct of VI found in the literature (12). The difference in these K'_P values may be explained in terms of the distribution of sulfite ion between albumin and the aqueous phases. For III, the concentration of sulfite ion in the microenvironment of the trinitrophenylated group is probably higher than that in water for VI, since albumin generally has a strong affinity for anionic small ligands. The microenvironment of albumin may also affect the dissociation ($K_2 = 2.2 \times 10^{-8}$ *M*) of bisulfite ion, since in water the literature value for K_2 is about 6.2×10^{-8} *M* (21).

There was some difficulty in determining accurately the rate constant (k_3) for the sulfite monoaddition, because the absorbance changes at 415 nm due to trinitrophenylation seemed to be incomplete at the initial stage of the sulfite monoaddition; that is, the changes based on both the trinitrophenylation and the monoaddition could not be separated clearly.

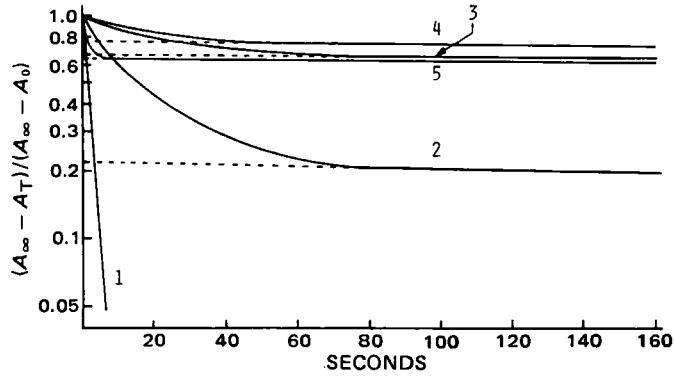

Figure 5—*Kinetics for the trinitrophenylation of albumin and acetylalbumins with I at pH 7.4 and 25° plotted as log $[(A_\infty - A_t)/(A_\infty - A_0)]$ against reaction time. Key: (1) 5.0 × 10⁻⁵ M control albumin and 1.0 × 10⁻⁵ M I; (2) 5.0 × 10⁻⁵ M monoacetylalbumin and 1.0 × 10⁻⁵ M I; (3) 5.0 × 10⁻⁵ M diacetylalbumin and 1.0 × 10⁻⁵ M I; (4) 5.0 × 10⁻⁵ M triacetylalbumin and 1.0 × 10⁻⁵ M I; (5) 3.3 × 10⁻⁵ M albumin and 8.0 × 10⁻⁵ M I.*

The approximate k_3 value at pH 7.4 and 25°, however, was estimated using Eq. 3. The value $7.0 \times 10^2\ M^{-1}\ sec^{-1}$ was obtained and compares with the literature value of $5.25 \times 10^3\ M^{-1}\ sec^{-1}$ at pH 8.0 and 25.4° for trinitrophenyl β-alanine (22). In addition, the k_{-3} value at pH 7.4 and 25° was calculated as $9.5 \times 10^{-3}\ sec^{-1}$ from the values for K_P and k_3.

Localization of Reactive Site on Albumin for I—In a series of studies on the effects of drug binding on the esterase-like activity of albumin (5, 18), it was found that albumin has some specific drug binding sites, and one of them is located near the tryptophan-214 (Trp-214) residue (23). When a drug binds to a site near Trp-214, the fluorescence intensity of Trp-214 is reduced when excited at 300 nm. To localize the reactive site for I, the fluorescence spectra of the reaction mixture of albumin with I and of each reactant solution were measured (Fig. 4). The intensity of the emission spectrum for the mixture (spectrum 3) is lower than that for the albumin solution (spectrum 1), indicating that the reactive site for I is located near the Trp-214 residue.

It has been reported that VII and VIII acetylate the ϵ-amino group of the lysine-199 (Lys-199) residue located near Trp-214 (5, 24). To examine further the reactive site for I, the effect of albumin acetylation by VII and VIII on the trinitrophenylation rate was investigated. The results are shown in Fig. 5. In this figure, $\log\{(A_\infty - A_t)/(A_\infty - A_0)\}$ is plotted against time, where A_∞, A_t, and A_0 are the absorbances at 360 nm at the completion of the reaction, at times t and zero, respectively. It is obvious that the trinitrophenylation of acetylalbumins with I (curves 2–4) is slower than that of the control albumin (curve 1). For acetylalbumins the trinitrophenylation is not a single process, but consists of an initial phase and a slower second phase. The slopes of the second phase are approximately equal to each other. Furthermore, these slopes (in curves 2–4) are almost identical with the slope (in curve 5) of the second phase obtained from the plot for the trinitrophenylation with excess I. These identities suggest that the second phase for acetylalbumins is due to the secondary reactive site(s) of albumin for I, of which the location(s) is(are) unknown at present.

For trinitrophenylation with excess I (curve 5) it is evident that a value (~0.63) on the ordinate obtained by extrapolating the line of the second phase to time zero indicates the fraction of I consumed by the secondary reactive site(s) of albumin $[(8.0 \times 10^{-5} - 3.3 \times 10^{-5})/8.0 \times 10^{-5} \approx 0.59]$. The slight discrepancy between 0.63 and 0.59 may be due to experimental error. For acetylalbumins (curves 2–4) the fractions were estimated by similar extrapolations (as expressed by dotted lines). The values obtained are ~0.22, 0.67, and 0.77 for mono-, di-, and triacetylalbumin, respectively. These values imply that $7.8 \times 10^{-6}\ M$ ($= 1.0 \times 10^{-5}\ M - 2.2 \times 10^{-6}\ M$), $3.3 \times 10^{-6}\ M$, and $2.3 \times 10^{-6}\ M$ of I were consumed by the primary reactive site, respectively. However, $5.0 \times 10^{-5}\ M$ of each acetylalbumin (fivefold excess of albumin over I) was employed for the trinitrophenylation reactions. With respect to the albumin concentration, therefore, only about 16 $[\approx(7.8 \times 10^{-6}/5.0 \times 10^{-5}) \times 100]$, 7, and 5% of the primary reactive site are unmodified (unacetylated) with VIII for mono-, di-, and triacetylalbumin, respectively. In other words, about 84, 93, and 95% of the primary reactive site for I are blocked by VIII. Since 5-nitroaspirin (VIII) primarily acetylates the ϵ-amino group of the Lys-199 residue (5, 24), these results on the effects of the acetylation suggest that the primary reactive group for I is the Lys-199 residue. The results from the experi-

ments using the albumin acetylated with aspirin (VII) also led to a similar conclusion concerning the reactive site for I.

Pharmaceutical Approach to Subcutaneous Dosage Forms of Insulin

RYOHEI HORI ˣ, FUSAO KOMADA, and KATSUHIKO OKUMURA

Received January 15, 1982 from the *Department of Pharmacy, Kyoto University Hospital, Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto 606, Japan.* Accepted for publication August 12, 1982.

Abstract □ The present studies were undertaken to describe the dynamic nature of the degradation and absorption of insulin in the subcutaneous injection site and to develop agents which would stabilize this dosage form. [^{125}I]Insulin with 0.2-U/kg of unlabeled insulin in 10 μl of aqueous solution was injected subcutaneously in rats under the depilated skin of the back. At various times, radioactive skin tissue was extracted and assayed for insulin and/or its metabolites by gel filtration. Using these data, absorption and degradation rate constants of these substances were estimated according to a one-compartment model. Absorption rate constants of insulin and its metabolite of low molecular weight (monoiodotyrosine) were 0.021 min^{-1} and 0.107 min^{-1}, respectively, while the degradation rate constant for insulin to monoiodotyrosine was 0.013 min^{-1}. Thus, the bioavailability of insulin injected subcutaneously was lower than expected, suggesting the necessity of stabilizing methods. The protection of insulin from degradation at the site of injection was examined by the addition of various peptides. It was found that benzyloxycarbonyl-Gly-Pro-Leu-Gly was a good stabilizing agent, and remarkably inhibited insulin degradation. This inhibition was confirmed by the increase of immunoreactive insulin level and the decrease of the blood glucose level. We postulated that this peptide protects the injected insulin from degradation by inhibiting the peptidase present in subcutaneous tissue.

Keyphrases □ Insulin—absorption and degradation at the subcutaneous injection site, stabilizing agents for the subcutaneous dosage form □ Stabilizing agent—for insulin, subcutaneous dosage forms, use of the peptide benzyloxycarbonyl-Gly-Pro-Leu-Gly □ Subcutaneous injection—absorption and degradation of insulin, use of benzyloxycarbonyl-Gly-Pro-Leu-Gly peptide for stabilization

Endogenous peptides having specific biological effects have attracted attention as new drugs; however, effective dosage forms of these peptides for clinical usage have been difficult to assess in any but the parenteral dosage forms. Insulin, administered subcutaneously, has been the primary treatment for severe diabetes for several years, even though effective methods have been described for oral (1–3), nasal (4), aerosol (5, 6), and rectal (7, 8) administration. In previous attempts to assess the absorption of insulin from its subcutaneous depot, radioiodinated insulin preparations were injected and the disappearance of the radioactivity from the injection site was measured by an external gamma-counter (9, 10). The stability and bioavailability of insulin administered subcutaneously are not well understood since the metabolites of insulin could not be measured. The kinetics of insulin in the blood after subcutaneous injection are the result of many factors including absorption and degradation in the injection site (11).

Recently, Berger reported that aprotinin increased the absorption rate of subcutaneously injected insulin and amplified its biological effect by inhibiting the local degradation of exogenous insulin at the injection site (12). Little else has been reported about the degradation and absorption of insulin at the injection site, although the absorption characteristics of insulin and other drugs from intramuscular injection sites were investigated (13, 14). The present studies were undertaken to investigate the dynamic nature of the degradation and the absorption of insulin in the subcutaneous injection site and to develop new stabilizing agents for this dosage form.

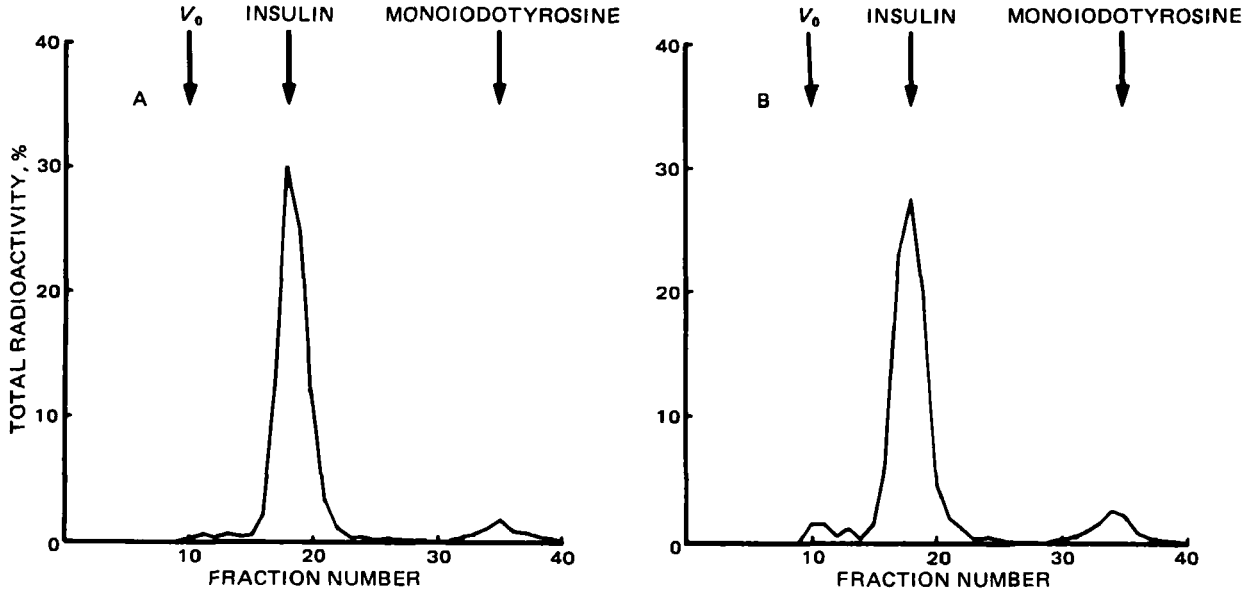

Figure 1—*Gel filtration of the radioactivity extracted from subcutaneous tissue samples 5 (A) and 10 (B) min after insulin injection of 0.2 U/kg sc.*

EXPERIMENTAL

Materials—Monocomponent porcine insulin (26.0 U/mg)[1] was used. [^{125}I]Insulin was prepared by the chloramine T method as described by Hunter and Greenwood (15). The labeled insulin was purified by gel filtration twice using a dextran gel[2]. Benzyloxycarbonyl-Gly-Pro-Leu-Gly (II)[3], benzyloxycarbonyl-Gly-Pro-Leu (III)[3], dinitrophenyl-Pro-Leu-Gly (IV)[3], benzyloxycarbonyl-Gly-Pro(V)[3], and all other chemicals were obtained from commercial sources and were analytical reagent grade.

Animals—Male Wistar rats weighing 125–150 g were used. For the experiment in diabetic rats, diabetes was induced in the rats by femoral-vein injection of streptozotocin after a 16-hr fast, as previously described (16). The streptozotocin was dissolved in acidified 0.9% NaCl (saline), pH 4.5, and given in a dose of 50 mg/kg. Control animals received no injections. The diabetic rats displayed polyuria, glycosuria, failure to gain weight, and significant hyperglycemia (mean blood sugar, 450 mg/dl) at the time of experiment (24–48 hr after the injection of streptozotocin).

Procedure—Rats were anesthetized with pentobarbital (40 mg/kg) and maintained under anesthesia during the experiment. The dorsal skin was depilated and the site for injection was demarcated. Using a thin needle (o.d. = 0.2 mm, i.d. = 0.1 mm)[4], 10 μl of drug solution containing unlabeled insulin (0.2 and 1.0 U/kg) and [^{125}I]insulin, with or without additives, were injected subcutaneously. The rectal temperature was monitored and maintained constant (36.5 ± 0.5°) by keeping the rats in a temperature-constant room. At various times, a skin sample and subcutaneous tissue around the injection site (~4 cm^2 area) was taken for analysis. To estimate the degradation rate of insulin at the injection site when its absorption would be negligible, degradation in a cardiac-arrested rat was investigated. This condition was induced by direct injection of pentobarbital (200 mg/kg) to the heart 5 sec before the experiment. For the experiment conducted to measure the immunoreactive insulin or blood glucose, unlabeled insulin with or without additives was injected.

Analytical Methods—After measurement of the residual amount of radioactivity, the sample was homogenized with 6 *M* guanidine hydrochloride in 2.4 *M* formic acid. The homogenate was centrifuged at 1500×*g* for 10 min to separate the extract. The extract then was applied to a gel filtration column (hydrophilic vinyl gel[5]) that was eluted with 3 *M* guanidine hydrochloride in 2.4 *M* formic acid at 4°. The column size was 1.5 × 48 cm and flow rate was 1 ml/min. Three-milliliter fractions were collected and the radioactivity in each fraction was counted. The column was calibrated with high molecular dextran[6] as a void volume marker (V_0) and with standard insulin and monoiodotyrosine (I). For the measure-

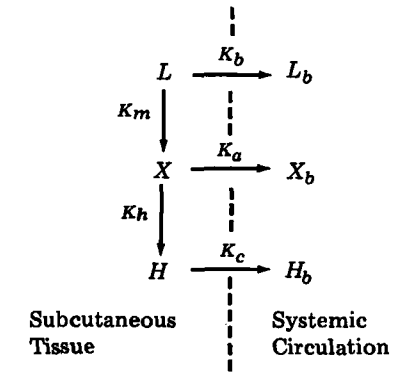
ment of hypoglycemic effect, blood samples were collected from the jugular vein at timed intervals and glucose levels were determined in the serum by the modified method of Hyvärinen (17). Immunoreactive insulin in the plasma was determined by radioimmunoassay (18).

RESULTS AND DISCUSSION

Absorption and Degradation of Insulin in the Injection Site—The drug solution (pH 7.0) containing insulin and [^{125}I]insulin was injected subcutaneously, and the subcutaneous tissue was analyzed. Figure 1 shows the gel filtration pattern of radioactivity extracted from tissue samples obtained 5 and 10 min postinjection. Most of the radioactivity eluted at the position of intact insulin, with a small peak at the void volume (V_0) and at the position of I. The presence of a peak at V_0 indicated the production of a high molecular weight substance, as previously reported in the blood (19). It was also observed that the small peak increased gradually and the main peak (intact insulin) decreased with time.



K_a = absorption rate constant of insulin, K_b = absorption rate constant of I, K_c = absorption rate constant of high molecular weight product, K_m = degradation rate constant of insulin, K_h = aggregation rate constant of insulin, X = amount of insulin in injection site, L = amount of I in injection site, H = amount of high molecular weight product in injection site, X_b = amount of insulin in the body, L_b = amount of I in the body, and H_b = amount of high molecular weight product in the body.

Scheme I

These results suggested that subcutaneously injected insulin was metabolized at the injection site before being absorbed into the systemic circulation.

To clarify this phenomenon, time courses for the clearance of insulin and the formation of its metabolites at the subcutaneous injection site were investigated. Figure 2 shows a logarithmic plot of the insulin, I, and high molecular weight product levels remaining at the injection site as a function of time over a 30-min period. Since a straight line was obtained for the intact insulin, a first-order process seems to be predominant for the clearance of the insulin from the subcutaneous injection site. As the

Table I—Effect of Various Peptides on the Kinetic Parameters for Insulin in the Subcutaneous Injection Site

Compound Injected	Concentration	Kinetic Parameters, min^{-1}				
		K_a	K_b	K_c	K_m	K_h
Insulin	(0.2 U/kg)	0.0208	0.107	0.0113	0.0131	0.0022
Insulin + II	(0.2 U/kg + 8.4 m*M*)	0.0357	0.107	0.0113	0.0008	0.0017
Insulin + III	(0.2 U/kg + 8.4 m*M*)	0.0466	0.130	0.0113	0.0033	0.0025
Insulin + IV	(0.2 U/kg + 4.4 m*M*)	0.0229	0.109	0.0113	0.0069	0.0012
Insulin + V	(0.2 U/kg + 8.4 m*M*)	0.0324	0.201	0.0113	0.0131	0.0028

line curved for I, the main metabolite (20), a fast disappearance rate could be postulated. Meanwhile, the appearance of a high molecular weight product slowly increased. In previous papers (14, 21, 22), it was demonstrated that the rate of drug absorption from the muscle was proportional to the amount remaining in the injection site; drug absorption from the subcutaneous tissue was not demonstrated clearly to be a first-order process. From these results, the absorption mechanism for a subcutaneously injected drug would not be very different from that for an intramuscularly injected drug.

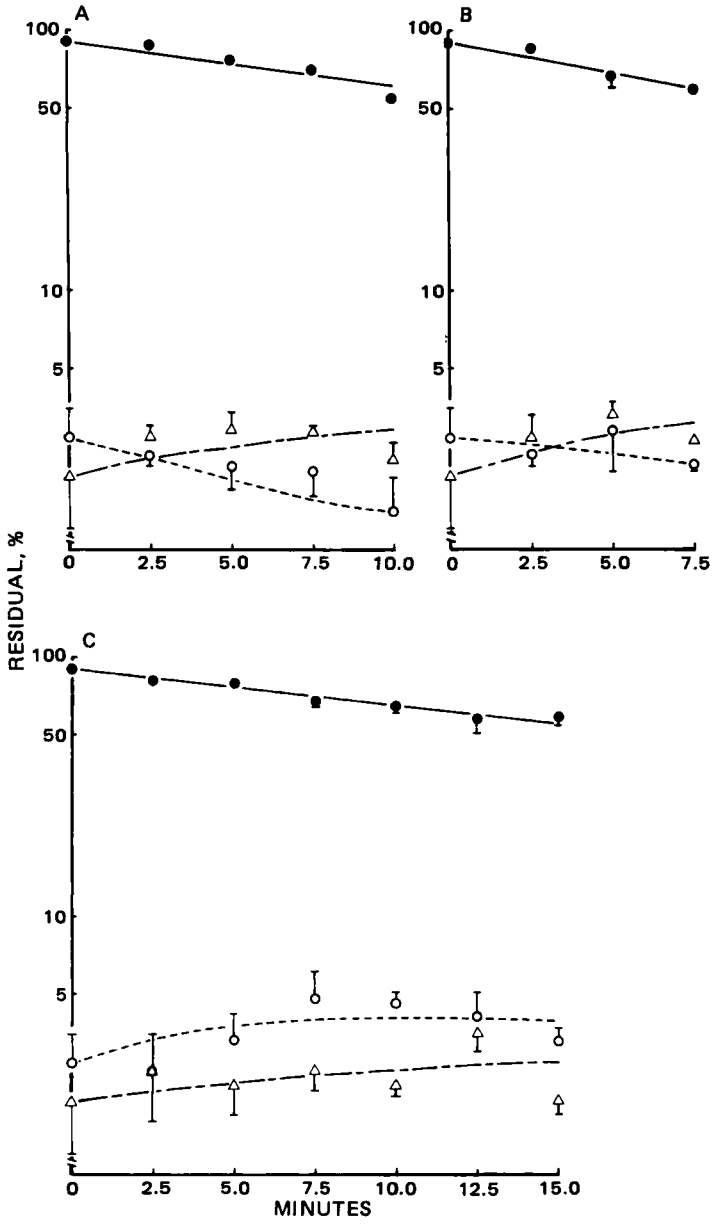

Figure 5—*Disappearance of 0.2 U/kg insulin with stabilizing peptides from the subcutaneous injection site. Each point represents the mean value of three or four experiments; vertical bars indicate* SEM. *Each line represents the curve fitted with the one-compartment open model. Key: (A) with II 8.4 m*M, *(B) with III 8.4 m*M, *and (C) with IV 4.4 m*M, *(●) intact insulin, (○) low molecular weight products (I), and (△) high molecular weight product.*

The disposition of insulin in the subcutaneous tissue was analyzed as assuming a one-compartment open model as shown in Scheme I. Insulin can be biotransformed to a low molecular weight product (I) and to a high molecular weight product, with a degradation rate constant of K_m and a formation rate constant of K_h, respectively. Compound I, insulin, and the high molecular weight product are absorbed independently with absorption rate constants of K_b, K_a, and K_c, respectively. X, L, and H were expressed by (23):

$$X = X_0 e^{-Kt} \quad \text{(Eq. 1)}$$

$$L = \frac{X_0 K_m}{K - K_b}(e^{-K_b t} - e^{-Kt}) + L_0 e^{-K_b t} \quad \text{(Eq. 2)}$$

and

$$H = \frac{X_0 K_h}{K - K_c}(e^{-K_c t} - e^{-Kt}) + H_0 e^{-K_c t} \quad \text{(Eq. 3)}$$

where X_0 is the initial amount of insulin, L_0 is the initial amount of I, H_0 is the initial amount of high molecular weight product, $K = K_a + K_m + K_h$, and t is the sampling time. Data of X, L, and H were fitted to Eqs. 1–3 by nonlinear least-squares regression (24). Refined estimates of K_a, K_b, K_m, and K_h were then obtained. K_c was determined by the subcutaneous injection of the high molecular weight product. Calculated K_a and K_h were 0.0208 and 0.0022 min^{-1}, respectively. The degradation rate constant of insulin to I (K_m) was calculated to be 0.0131 min^{-1}, a value similar to the absorption rate constant. The degradation of insulin in cardiac-arrested rats was investigated to confirm the calculated value. No absorption was observed since the systemic circulation was completely disrupted. Figure 3 shows the plot of the nondegraded insulin level at the injection site of cardiac-arrested rats as a function of time. The decrease of insulin by degradation at the injection site seems to be linear in this semilogarithmic plot. The degradation rate constant (K_m) in this experiment was 0.0137 min^{-1} which was almost the same as the calculated K_m. As K_m was close to K_a, the bioavailability of insulin injected subcutaneously could be lower than expected. The species or age variation for insulin degradation in the subcutaneous tissue will be investigated in future work, since the insulin degrading activity of muscle from rats varies with age (25).

Stabilization of Insulin Injected Subcutaneously—The results obtained in this study prompted the search for methods of stabilizing subcutaneously injected insulin to increase the bioavailability. The

concurrent use of peptides and amino acids as stabilizing agents of insulin degradation at the injection site was examined. Among the various peptides tested in this study, benzyloxycarbonyl-Gly-Pro-Leu-Gly (II), benzyloxycarbonyl-Gly-Pro-Leu (III), and dinitrophenyl-Pro-Leu-Gly (IV) exhibited a remarkable protection of insulin from degradation. Figure 4 demonstrates the gel filtration pattern of the radioactivity extracted from subcutaneous tissue sampled 5 min after the injection of insulin with or without these stabilizing peptides. The concentration of I at the injection site was comparatively low when these peptides were coadministered with insulin.

Many amino acids, dipeptides, and aprotinin failed to stabilize insulin at the injection site (data not shown). Aprotinin was examined as an inhibitor of peptidase. Coadministration of aprotinin with insulin led to the fast entry of insulin into the circulation and an accelerated onset of the hypoglycemic action (12). However, it appears from our studies that aprotinin does not stabilize insulin at the subcutaneous injection site; however, it could inhibit insulin degradation after entry into the systemic circulation. The stabilizing effect of these peptides was confirmed by the gel filtration pattern using cardiac-arrested rats. For kinetic analysis, the time course of insulin and its metabolites after the subcutaneous injection of insulin with or without these peptides was investigated. As shown in Fig. 5, the stabilizing effect of these peptides was clearly demonstrated. Using these data, kinetic parameters of the one-compartment model in the presence of stabilizing peptides were estimated, and are listed in Table I. The degradation rate constant of insulin (K_m) in the presence of II at the injection site was 0.0008 min^{-1}, which was less than one-sixteenth of the control. Compounds III and IV were less effective than II. Thus, it is conceivable that the degradation rate of insulin coinjected with II was negligible compared with its absorption rate. Consequently, this peptide can be regarded as a valuable stabilizing agent for insulin in a subcutaneous dosage form.

A significant increase in the absorption rate constant for intact insulin was also observed by the concurrent use of II, III, and benzyloxycarbonyl-Gly-Pro (V), but this effect was not observed using IV. It might be postulated that the amino acid sequence of V could influence this process in a variety of possible ways, such as alterations in the local circulation or possibly by changes in the permeability.

To confirm that II inhibits the degradation of insulin, plasma levels of immunoreactive insulin and serum levels of glucose were analyzed. Figure 6 reveals that the immunoreactive insulin in the plasma was significantly increased when insulin was injected with this peptide, demonstrating the inhibition of insulin degradation at the injection site. Furthermore, the hypoglycemic effect of insulin coinjected with this peptide was investigated in diabetic rats. As shown in Fig. 7, the decrease in serum glucose levels in the diabetic rats after the subcutaneous administration of insulin (1.0 U/kg) was significantly greater in the presence of this stabilizing peptide. The potent effect of II for the insulin administered subcutaneously was clearly demonstrated. We suggest that this peptide protects the injected insulin from being degraded by inhibiting the peptidase localized in subcutaneous tissue.

The study of the degradation and absorption of insulin at the subcutaneous injection site has provided a good understanding of the phenomenon involved, leading to the exploration of stabilizing agents. Further research of the insulin stabilization with other derivatives of this peptide (II) is now in progress. Although a potential effect of these peptides for insulin stabilization in the subcutaneous injection site was demonstrated, additional studies must be carried out before this methodology is useful clinically.

Quantitative Investigation on Renal Handling of Drugs in Rabbits, Dogs, and Humans

AKIRA KAMIYA, KATSUHIKO OKUMURA, and RYOHEI HORI ˣ

Received June 18, 1982 from the *Department of Pharmacy, Kyoto University Hospital, Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto, 606, Japan.* Accepted for publication August 16, 1982.

Abstract □ A renal clearance method based on a computer analysis after administration of a single dose of drug was developed for measuring the renal handling of several drugs in rabbits, dogs, and humans. Secretion and reabsorption of sulfamethizole, sulfanilamide, cephalexin, and ampicillin in the nephron were analyzed quantitatively using the plasma concentration and the urinary excretion rate of the drugs. The validity of the proposed model was demonstrated. It appears that tubular secretion of sulfamethizole, cephalexin, and ampicillin depend on the active transport system which is described by Michaelis–Menten kinetics; the tubular reabsorption of these drugs is expressed by first-order kinetics. The maximum velocity of renal secretion per unit weight of these drugs was much higher in rabbits than in dogs or humans. Reabsorption showed similar values in dogs and humans. These findings suggest that an analysis of the renal handling of drugs in dogs might provide useful information when considering the appropriate therapeutic dose in humans.

Keyphrases □ Clearance, renal—of sulfamethizole, sulfanilamide, cephalexin, and ampicillin in the rabbit, dog, and human, determination using a computer analysis □ Sulfamethizole—determination of renal clearance using a computer analysis □ Sulfanilamide—determination of renal clearance using a computer analysis □ Cephalexin—determination of renal clearance using a computer analysis □ Ampicillin—determination of renal clearance using a computer analysis

The renal excretion of drugs is a complex phenomenon involving glomerular filtration, tubular secretion, and tubular reabsorption (1). Since the independent characterization of the transport kinetics of secretion and reabsorption is difficult, the quantitative analysis of the renal handling of drugs is not readily available, particularly in humans. Weiner *et al.* (2) described an analytical method for these processes; however, one needs a wide range of drug concentrations in plasma. Since limited plasma levels are obtained in humans, this method has little clinical applicability. Such methodology, however, is desirable when designing the drug-dosing schedule for patients with renal disease.

We have described a method that quantitatively analyzes the renal handling of drugs (3, 4). Using this method, the renal handling of sulfamethizole, sulfamethoxazole, sulfanilamide, and phenolsulfonphthalein was described in rabbits. In this study, the applicability of this method to dogs and humans was examined, and the renal handling of two widely used antibiotics (cephalexin and ampicillin) was investigated using plasma concentrations normally obtained with therapeutic doses.

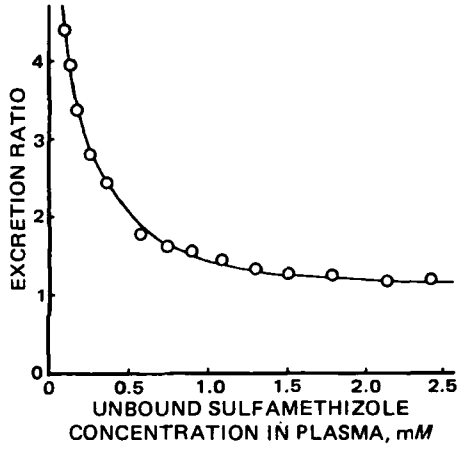

Figure 1—*Experimental renal clearance data (points) and computer-simulated curve (line) for sulfamethizole in the dog. The parameters obtained by this analysis are as follows:* V_{max} = *20 μmoles/min,* K_m = *0.16 mM, and* R = 0.13.

EXPERIMENTAL

Materials—Sulfamethizole was JP IX grade[1]; sulfanilamide was reagent grade[2]. Cephalexin monohydrate[3], sodium ampicillin[3], and iodopyracet[4] were supplied. All other chemicals were reagent grade.

Determination of Plasma Protein Binding—Plasma protein binding was determined by the ultrafiltration technique using a membrane cone[5] for sulfamethizole and sulfanilamide and cellulose tubing[6] for cephalexin and ampicillin.

Analytical Methods—Plasma and urine samples were treated with the Somogyi deproteinizing reagent (5) and then analyzed for sulfamethizole and sulfanilamide using 2-dimethylaminoethyl-1-naphthylamine as the coupling reagent (6). Inulin was determined in samples deproteinized as described above using a modification of a previously described method (7). Cephalexin and ampicillin in plasma and urine were determined fluorometrically (8, 9); creatinine was determined using picric acid (10).

Clearance Method—*Rabbits*—Male New Zealand albino rabbits, weighing 2.0–2.5 kg, were used. The determination of renal clearance using a single injection technique and the standard renal clearance and secretory inhibition using iodopyracet was described previously (4).

Dogs—Male mongrel dogs, weighing 5–11 kg, were anesthesized with pentobarbital[7] (27 mg/kg). Renal clearance was determined in the same manner as described above for the rabbit.

Humans—Sulfamethizole (4 g of an aqueous solution), sulfanilamide

[a] (M) male, (F) female.

(2 g of an aqueous solution), cephalexin (500 mg of a powder), and ampicillin (500 mg of a powder) were administered orally to adult volunteers (22–46 years old, of average health and normal weight) following an overnight fast. Food was withheld for an additional 3 hr. Venous blood and urine samples were collected at intervals of 15 or 30 min up to 6 hr after drug administration. To ensure continuous flow of urine and to quantitate fluid intake, each subject received 50 ml of tap water every 30 min for the initial 4 hr postadministration. The volume and pH of each urine sample were measured and the samples were stored at 4° until analysis. The glomerular filtration rate was determined by measuring the clearance of endogenous creatinine.

Computer Analysis—As described previously (3), the excretion ratio (ER) can be expressed as:

$$ER = \left(1 + \frac{V_{max}}{(K_m + P_f)\,GFR}\right)(1 - R)$$

where P_f is the unbound drug concentration in plasma, GFR is the glomerular filtration rate, R is the reabsorption fraction, V_{max} is the maximum velocity of secretion, and K_m is the Michaelis constant. The computer analysis[8] using this equation was performed as previously described (3, 4).

RESULTS

Renal Handling of Sulfamethizole and Sulfanilamide in Dogs—The renal clearance following a single injection of sulfamethizole in the dog was analyzed using the model equation (Fig. 1). As in the case of the rabbit, a curve was obtained which fit the experimental values quite well (see Table I for a list of parameters). To ascertain the validity of the values obtained by our model, a comparison of the rate of secretion and the reabsorption fractions was made using the renal clearance method in combination with secretory inhibition by the infusion of iodopyracet.

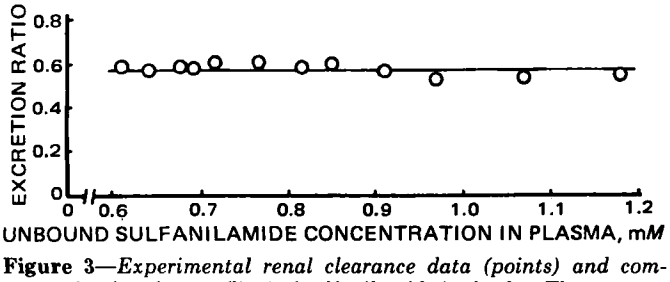

Figure 3—*Experimental renal clearance data (points) and computer-simulated curve (line) of sulfanilamide in the dog. The parameters obtained by this analysis are as follows:* V_{max} = 0 *μmole/min and* R = 0.42.

[8] HITAC 8700, Hitachi Co. Ltd.

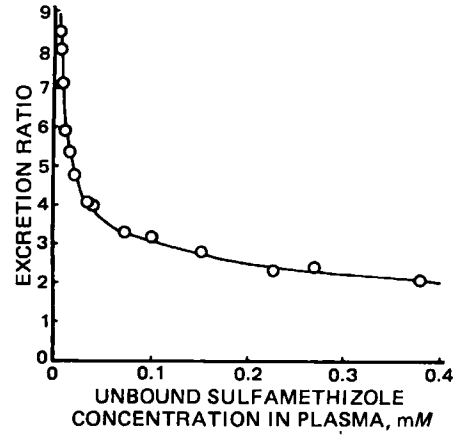

Figure 4—*Experimental renal clearance data (points) and computer-simulated curve (line) of sulfamethizole in the human. The parameters obtained by this analysis are as follows:* V_{max} = 59 *μmoles/min,* K_m = 0.06 m**M**, *and* R = 0.09.

First, a comparison was made of the rate of secretion obtained separately from inhibitory experiments and using V_{max} and K_m values obtained by our model. As shown in Fig. 2, a good agreement was achieved. Further, there was also good agreement of the reabsorption fractions: a value of 0.19 ± 0.01 was obtained from the inhibitory experiment compared with 0.18 ± 0.01 from the proposed model. Thus, it was found that the mechanism of the renal excretion of sulfamethizole in dogs was similar to that found in rabbits. That is, tubular reabsorption is dependent on passive transport, whereas tubular secretion involves active transport (which conforms to the Michaelis–Menten equation) and is dependent on the plasma concentration of unbound drug.

On the other hand, the renal clearance after a single injection of sulfanilamide is not dependent on its plasma concentration, and no active secretion process is involved (Fig. 3). Each renal clearance parameter for sulfanilamide is listed in Table I. In the inhibitory experiment for sulfanilamide, no change in renal clearance could be induced even with iodopyracet loading. As in the rabbit, there was no secretion in dogs; only reabsorption was observed. Further, the reabsorption fraction of 0.37 ± 0.03 agreed well with that obtained from the inhibitory experiment (0.40 ± 0.05). Therefore, the validity of this method has been demonstrated in dogs as well as rabbits.

Renal Handling of Sulfamethizole and Sulfanilamide in Humans—Our analytical method of renal handling of drugs was applied also to humans. The renal handling of sulfamethizole in humans is shown in Fig. 4. As in the case of rabbits and dogs, a curve was obtained which fit the experimental values quite well. This result indicates that the mechanism of sulfamethizole excretion in humans could be similar to that of other animals. The values of the parameters V_{max}, K_m, and R for all human subjects are listed in Table II. These values are quite similar to those found with dogs, although some individual variation exists. The day-to-day variation of these parameters in the same subject was also examined for subjects C and F. There was no apparent change in the secretion parameter (V_{max} and K_m), while variations were observed in the reabsorption fraction.

The results of the renal clearance of sulfanilamide in humans (Fig. 5) indicated that this drug was excreted by a mechanism similar to that found in rabbits and dogs. It is evident that there was no secretion, only reabsorption.

Renal Handling of Cephalexin and Ampicillin—Since we were

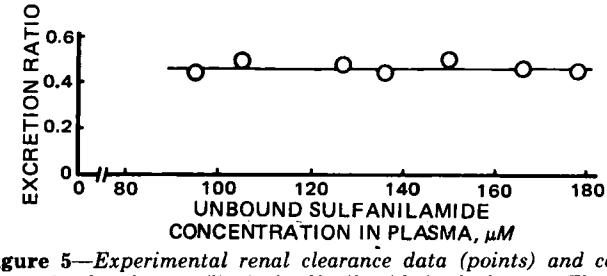

Figure 5—*Experimental renal clearance data (points) and computer-simulated curve (line) of sulfanilamide in the human. The parameters obtained by this analysis are as follows:* V_{max} = 0 *μmole/min and* R = 0.52.

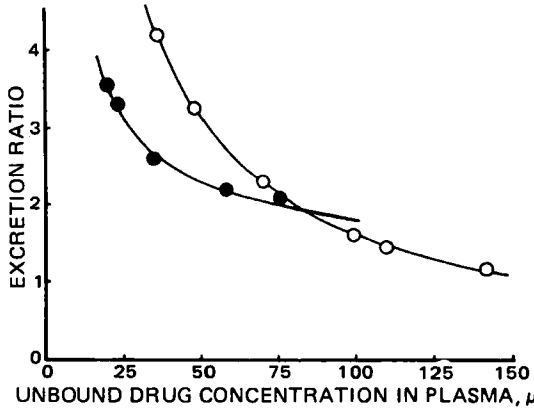

Figure 6—*Experimental renal clearance data (points) and computer-simulated curve (line) of cephalexin and ampicillin in the rabbit. Key: (○) cephalexin and (●) ampicillin.*

successful in elucidating the mechanism of the renal handling of sulfamethizole and sulfanilamide through the use of this model, we attempted to apply this methodology to other drugs using cephalexin and ampicillin. As shown in Figs. 6 (rabbit), 7 (dog), and 8 (human), good agreement was obtained between the experimental data and theoretical curves calculated using the appropriate parameters (Table III) obtained in rabbits, dogs, and humans. The data suggested that cephalexin and ampicillin were excreted from the kidney in a process similar to the excretion of sulfamethizole. Welles *et al.* described the renal handling of cephalexin in rabbits and dogs, and demonstrated that secretion and reabsorption were extensively involved in renal excretion (11). Secretion has also been reported for ampicillin (12). The results presented here support the findings that both secretion and reabsorption contribute significantly to the excretion of cephalexin, while the contribution is very small in these three species in the case of ampicillin.

Species Variation in Renal Handling of Sulfamethizole, Cephalexin, and Ampicillin—The parameters for these three drugs in rabbits, dogs, and humans are shown in Table III. The reabsorption fraction, R, in all species was almost the same, but there were differences in the secretion parameters V_{max} and K_m. Comparison of the V_{max} values per unit weight (V_m) of sulfamethizole, cephalexin, and ampicillin in the three species showed that rabbits had the highest values with all three drugs, while the values for dogs and humans were approximately the same. Petitpierre *et al.* reported that the renal function of beagle dogs resembles that of humans (13). Our data confirmed quantitatively that the two are similar. Accordingly, it is possible that the renal handling of a drug in humans can be predicted quantitatively by initially performing experiments in dogs.

DISCUSSION

In previous reports (3, 4), we proposed a quantitative analytical method to determine the renal handling of such drugs as sulfamethizole, sulfamethoxazole, sulfanilamide, and phenolsulfonphthalein in rabbits. In this study, the methodology was applied to dogs and humans. The renal handling of two widely used antibiotics (cephalexin and ampicillin) was investigated after a single oral dose. It was demonstrated that our method can be applied to dogs and humans as well as rabbits. Some reports are available concerning the urinary excretion of such drugs as inulin (14) and phenolsulfonphthalein (15) in humans; however, few studies quantitate separately the processes of tubular secretion and reabsorption. It was also demonstrated that the tubular secretion of these drugs can be explained by an active transport process which conforms to the Michaelis–Menten equation, while tubular reabsorption can be explained by a first-order process. As our equation fit the experimental data obtained from rabbits, dogs, and humans, it can be assumed that the tubular secretion of these drugs is dependent on the unbound drug concentration in the plasma for each of these species. Levy *et al.* reported that the renal tubular secretion rate in the rat is proportional to the total concentration of sulfisoxazole in plasma rather than the free drug concentration (16, 17). Although further studies are needed, this investigation using sulfamethizole, cephalexin, and ampicillin in three different species shows that tubular secretion correlates with unbound drug concentration.

The renal handling of sulfamethizole, phenolsulfonphthalein, sulfamethoxazole, and sulfanilamide in rabbits was reported previously (4). In this study, the renal handling of cephalexin and ampicillin in rabbits, dogs, and humans was described. It was demonstrated that cephalexin belonged to the secretion and reabsorption type and ampicillin belonged to the secretion type in all three species. Although both drugs have very low lipid solubility, cephalexin showed a relatively high reabsorption. This suggests the possibility of an active-like reabsorption process for cephalexin. The renal clearance values *versus* the unbound plasma concentration curve of cephalexin in all three species did not show the

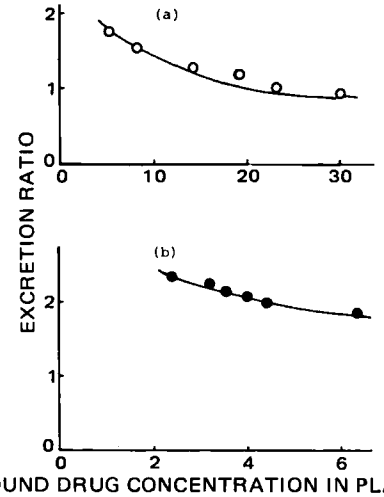

Figure 8—*Experimental renal clearance data (points) and computer-simulated curve of cephalexin (a) and ampicillin (b) in the human.*

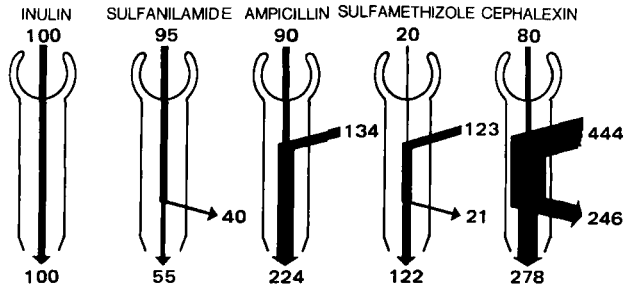

Figure 9—*Schematic representation of renal handling of drugs in the human. The parameters in Table III are used; detailed information can be found in the text.*

typical active reabsorption pattern such as that found for glucose (18). Therefore, the contribution of a nonlinear reabsorption process would not be significant under the conditions used here even if an active-like process were to be included in its reabsorption.

Figure 9 shows a schematic representation of the renal handling of these drugs in humans compared with that of inulin. The numbers given, calculated using a plasma drug concentration of 5 μM and glomerular filtration rate of 120 ml/min, represent the rate (in percent) of the designated transport process (*i.e.*, filtration, secretion, reabsorption, and urinary excretion) normalized for inulin glomerular filtration (600 nmoles/min). Plasma concentration of drugs were corrected by protein-binding percentage. Thus, for example, since sulfanilamide is 5% protein-bound in plasma, its filtration rate is 95% that of inulin (95% of 600 = 570 nmoles/min). Similarly, reabsorption of sulfanilamide occurs at a rate 40% of inulin filtration, *i.e.*, at 40% of 600 = 240 nmoles/min. It is evident that tubular secretion and reabsorption would be the most important process in regulating the urinary excretion of sulfamethizole, cephalexin, and ampicillin. If renal functions, such as renal secretion, were decreased by renal failure, the renal excretion of sulfamethizole, cephalexin, and ampicillin would be reduced greatly resulting in a high concentration in the blood and target organ. The impact of renal failure on the process of filtration, secretion, and reabsorption should be known in order to provide optimal treatment and protection from adverse reactions in patients with this disease state. We have applied the method described in this paper to the analysis of renal handling of drugs in patients with renal failure, the results of which will be discussed in an ensuing manuscript.

Thermodynamics of Distribution of *p*-Substituted Phenols Between Aqueous Solution and Organic Solvents and Phospholipid Vesicles

N. H. ANDERSON ‡, S. S. DAVIS *ˣ, M. JAMES*, and I. KOJIMA *§

Received December 21, 1981, from the **Department of Pharmacy, University of Nottingham, Nottingham, NG7 2RD, UK* and the ‡*Long Ashton Research Station, Long Ashton, Bristol, BS18 9AF, UK.* Accepted for publication January 14, 1983. §On leave from the Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Nagoya 466, Japan.

Abstract □ The distribution of *p*-substituted phenols between 0.15 *M* NaCl and a range of organic solvents (including 1-octanol) was examined over a range of temperatures. The thermodynamic parameters of transfer, ΔG, ΔH, and ΔS, were determined and the values examined in the light of Hildebrand and Scott's solubility parameter theory, and the collision complexes between solute and organic solvent. ΔH of transfer was positive for nonpolar solvents and negative for 1-octanol; the transfer processes were entropy and enthalpy dominated, respectively. The distribution of the phenols into phospholipid vesicles was examined below the phase-transition temperature. Although ΔG of transfer for vesicle–water systems was similar to that for octanol–water systems, the full thermodynamic analysis indicated that the two systems were dissimilar. The use of vesicle distribution data in structure–activity studies is discussed.

Keyphrases □ *p*-Substituted phenols—partitioning between water and organic solvents, phospholipid vesicles, thermodynamics □ Phospholipid vesicles—partitioning of *p*-substituted phenols, water and organic solvents, thermodynamics □ Thermodynamics—*p*-substituted phenols, partitioning, water and organic solvents, phospholipid vesicles

The importance of hydrophobicity in drug absorption, drug binding, and drug-receptor site interactions is well known (1, 2). Some measure of the hydrophobicity of a solute is given by the distribution (partition) coefficient between water and a suitable organic solvent (3). Usually the choice of the organic phase has been 1-octanol; however, Rytting *et al.* (4) have argued from a thermodynamic standpoint that a nonpolar inert solvent such as isooctane or cyclohexane would be a more appropriate solvent for distribution studies.

Abstract □ The distribution of *p*-substituted phenols between 0.15 *M* NaCl and a range of organic solvents (including 1-octanol) was examined over a range of temperatures. The thermodynamic parameters of transfer, ΔG, ΔH, and ΔS, were determined and the values examined in the light of Hildebrand and Scott's solubility parameter theory, and the collision complexes between solute and organic solvent. ΔH of transfer was positive for nonpolar solvents and negative for 1-octanol; the transfer processes were entropy and enthalpy dominated, respectively. The distribution of the phenols into phospholipid vesicles was examined below the phase-transition temperature. Although ΔG of transfer for vesicle–water systems was similar to that for octanol–water systems, the full thermodynamic analysis indicated that the two systems were dissimilar. The use of vesicle distribution data in structure–activity studies is discussed.

Keyphrases □ *p*-Substituted phenols—partitioning between water and organic solvents, phospholipid vesicles, thermodynamics □ Phospholipid vesicles—partitioning of *p*-substituted phenols, water and organic solvents, thermodynamics □ Thermodynamics—*p*-substituted phenols, partitioning, water and organic solvents, phospholipid vesicles

The importance of hydrophobicity in drug absorption, drug binding, and drug-receptor site interactions is well known (1, 2). Some measure of the hydrophobicity of a solute is given by the distribution (partition) coefficient between water and a suitable organic solvent (3). Usually the choice of the organic phase has been 1-octanol; however, Rytting *et al.* (4) have argued from a thermodynamic standpoint that a nonpolar inert solvent such as isooctane or cyclohexane would be a more appropriate solvent for distribution studies.

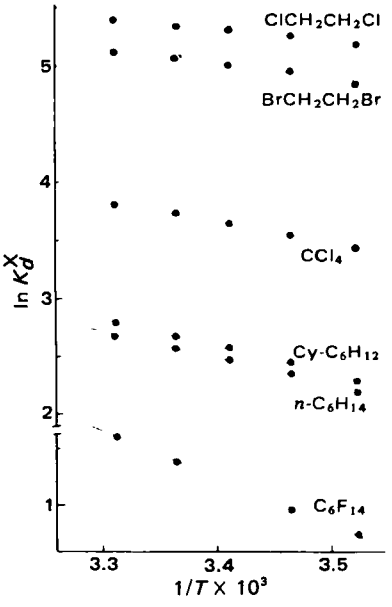

Figure 1—*van't Hoff plots for* p-*ethylphenol distributed between 0.15 M aqueous sodium chloride solution and various nonpolar organic solvents.*

In spite of the wide usage of 1-octanol–water distribution coefficients in structure–activity studies, relatively little work has been done to establish the actual basis of the relationship between distribution with octanol and biological activity (5). Martin (6) has emphasized that various absorption phenomena involving the passage of drugs across biological membranes are not well modeled by 1-octanol–water distribution coefficients. Other groups have suggested that the phospholipid vesicle (liposome) can be used as a model system to study solute distribution into membranes (7–9). Phospholipid vesicles consist of lipid bilayers in the form of multilayers arranged concentrically, or as simple bilayers encapsulating a volume of aqueous medium in the core. The vesicle can exist in liquid-crystalline or solid forms depending on the choice of the constituent phosphatidylcholine(s). Bindsley and Wright (10) have concluded that permeation rates of solutes across the toad bladder were more closely related to vesicle–water distribution data when the vesicles were below their phase-transition temperature (T_c).

The present investigation was designed to evaluate various organic solvents (including 1-octanol) as models for the distribution of solutes into membranes. The distribution of various *p*-substituted phenols between water and different organic phases as well as phospholipid vesicles were studied. The solvents were selected to give a wide range of solvent properties (solubility parameters). Data were obtained at different temperatures, allowing the calculation of the relevant thermodynamic parameters, enthalpy and entropy, which provide insight into the mechanism of solute transfer.

THEORETICAL

Organic Solvent–Water Distribution—The distribution ratio of solute between two immiscible solvents is given by:

$$D = \frac{C_{A,org}}{C_{A,aq}} \qquad \text{(Eq. 1)}$$

where $C_{A,org}$ and $C_{A,aq}$ are the total solute concentration in the organic and aqueous phases respectively. When only monomeric and un-ionized solute exist in both phases, Eq. 1 can be written as:

$$K_d = D = \frac{[\text{Solute}]_{org}}{[\text{Solute}]_{aq}} \qquad \text{(Eq. 2)}$$

The thermodynamic distribution constant K_d^X (mole fraction) (concentration units) can be written as:

$$K_d^X = K_d \left(\frac{V_{org}}{V_{aq}}\right) \qquad \text{(Eq. 3)}$$

where V_{org} and V_{aq} are the molar volumes of the organic solvent and aqueous phase. The distribution constant (K_d^X) is a free-energy (ΔG) related term:

$$\Delta G_{(transfer)} = -RT \ln K_d^X \qquad \text{(Eq. 4)}$$

As such it yields little information about the nature of the transfer process, and a more complete thermodynamic picture can be obtained by studying the change of the distribution coefficient with temperature, to provide enthalpic and entropic contributions to the free energy of transfer (11–15):

$$\ln K_d^X = -\frac{\Delta H}{R}\frac{1}{T} + \frac{\Delta S}{R} \qquad \text{(Eq. 5)}$$

where ΔG, ΔH, and ΔS are the partial molal free energy, enthalpy, and entropy change on transfer of the solute. The parameters ΔH and ΔS can be calculated from the slope and intercept of a plot of $\ln K_d^X$ *versus* $1/T$.

Phospholipid Vesicles: Water Distribution—The molal concentration scale has to be used because of the heterogeneous nature of the system under investigation (7). [A useful appraisal is the choice of concentration scale/standard state in bioenergetics and thermodynamics has been given by Jameson (16).]

The molal concentrations of solutes in the lipid (vesicle) phase (C_0^m) and the aqueous phase (C_w^m) are given by:

$$C_0^m = \frac{(C_T - C_W)w_1}{dMw_2} \qquad \text{(Eq. 6)}$$

$$C_w^m = \frac{C_W}{dM} \qquad \text{(Eq. 7)}$$

[a] X is the substituent of *p*-position of phenol. [b] ΔG and ΔH are given in kJ mole^{-1}. [c] ΔS is given in J mole^{-1}°K^{-1}. [d] δ-Solubility parameter in Cal$^{1/2}$cm$^{-3/2}$ from ref. 20. [e] Mean values taken from ref. 13 and F. J. C. Dearden and G. M. Bresnen, *J. Pharm. Pharmac. Suppl.* 107P (1981).

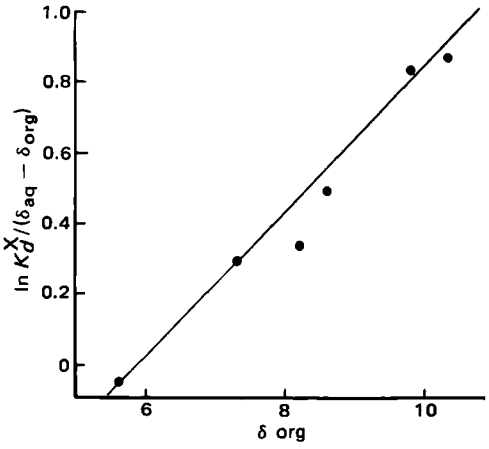

Figure 2—*The analysis of distribution data using solubility parameter theory.*

where C_T is the initial aqueous concentration before equilibrium (mg/ml), C_W is the final aqueous concentration after equilibrium (mg/ml), d is the density of the initial aqueous phase, M is the molecular weight of the solute, w_1 is the weight of aqueous phase in the sample, and w_2 is the weight of phospholipid in the sample. Thus, the molal distribution coefficient K_d^m is given by:

$$K_d^m = \frac{(C_T - C_W)w_1}{C_W w_2} \qquad \text{(Eq. 8)}$$

EXPERIMENTAL

Chemicals—Water was distilled from an all-glass still. The phenolic solutes used were as follows: phenol[1] (99.99%) was used without further purification; *p*-cresol[2], *p*-ethylphenol[2], *p*-chlorophenol[3], *p*-bromophenol[3], *p*-iodophenol[4], and *p*-fluorophenol[4] were used after recrystallization; *p*-propylphenol[4] was used after double distillation; and *p*-chloroanisole[3], resorcinol[3], *m*-methoxyphenol[2], and *m*-ethoxyphenol[2] were used as received.

Aqueous solutions of the phenols (~2 mg/100 ml) were prepared by dissolving samples in 0.15 *M* NaCl solution. The organic solvents used were perfluorohexane[1], *n*-hexane (special for spectroscopy)[3], cyclohexane (analytical grade)[3], 1,2-dichloroethane[4] (>99%) and 1,2-dibromoethane[4] (99%), carbon tetrachloride[5], and 1-octanol[4]. When necessary, they were washed successively with sodium hydroxide solution, distilled water, concentrated sulfuric acid, and finally 5 times with distilled water. L-α-Dimyristoylphosphatidylcholine[6] (DMPC) (98%) was used throughout as the sole lipid in the preparation of phospholipid vesicles.

Thin-layer chromatography of DMPC produced a single spot. Chloroform[1] was reagent grade.

Organic Solvent–Water Distribution—Oil–water distribution coefficients were obtained using the shake flask technique or a rapid mix/filter probe system (14, 17). The aqueous and organic phases were mutually saturated before use. Each experimental arrangement was thermostated at a given temperature (±0.1°), and at equilibrium the concentration of the solute in the aqueous phase was determined from the UV absorbance measured in the linear region of the Beer–Lambert plot.

Phospholipid Vesicle–Water Distribution—The vesicles were prepared using a stock solution of DMPC in chloroform containing 20-mg DMPC. This solution was placed in tared 50-ml round-bottom flasks and the chloroform removed rapidly by rotary evaporation at ~40°. The weight of the dried lipid film was measured, and multilamellar vesicles were formed at 40° by transferring 5 ml of highly dilute stock solution of phenol derivative into the flask and swirling the contents. Samples were prepared in duplicate, and the mean size and polydispersity of the vesicles were measured using a laser light scattering method (photon correlation spectroscopy)[7]. Reproducible yields of vesicles could be prepared by controlling strictly the hydration time and method of agitation.

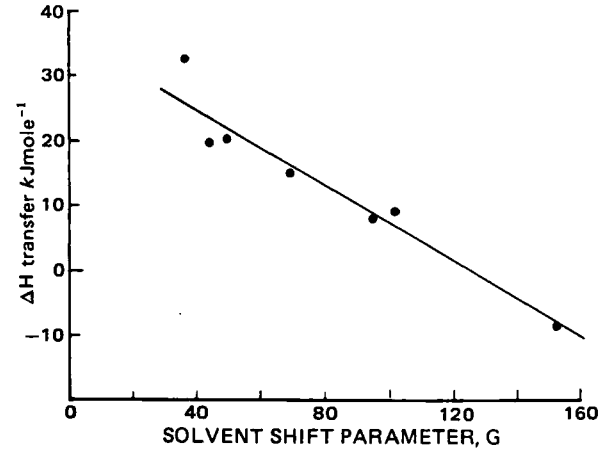

Figure 3—*The relationship between the enthalpy of transfer of* p-*substituted phenols and the solvent shift parameter* P *(Eq. 10).*

An equilibrium time for distribution of 12 hr was established from preliminary studies. The DMPC vesicles were separated from the aqueous phase by centrifugation in a thermostated centrifuge (8). The UV absorbance of the supernatant aqueous phase was measured at the λ_{max} of the phenol. After analysis the solution was returned to the phospholipid vesicle pellet and the system redispersed and re-equilibrated at the next temperature.

The processes of centrifugation, followed by resuspension did not alter significantly the mean size or polydispersity of the vesicles. Distribution studies were conducted over the temperature range 5–22° below the phase transition temperature of the phospholipid (23°) (18).

RESULTS AND DISCUSSION

Organic Solvent–Water Distribution—Preliminary studies indicated that for $C_{A,org}$ of less than 5×10^{-3} *M* the phenols existed as monomers in the organic phase. This is confirmed by literature data (19). Some typical plots of $\ln K_d^X$ *versus* $1/T$ are shown in Fig. 1. Good linearity was obtained in all cases, indicating that ΔH was independent of temperature over the range studied. Thermodynamic values obtained or calculated at 25° are summarized in Table I. The agreement with literature values (11, 13) including those obtained using microcalorimetry (15) is good in most cases, but there is some variation in ΔH (and consequently ΔS values). This is to be expected, since it is well known that the derivation of thermodynamic values from the van't Hoff isochore is dependent on good experimental data.

Examination of Fig. 1 and Table I shows clearly that the thermodynamic values of the transfer of phenols between aqueous environment and organic phases are dependent not only on the nature of the solute but also on the solvent. ΔG of transfer is positive for the lower alkyl phenols in perfluorohexane and for phenol in hexane. An increase in the distribution of the solute into the organic phase (ΔG becoming negative and increasing in magnitude) is accompanied by a decrease in ΔH and

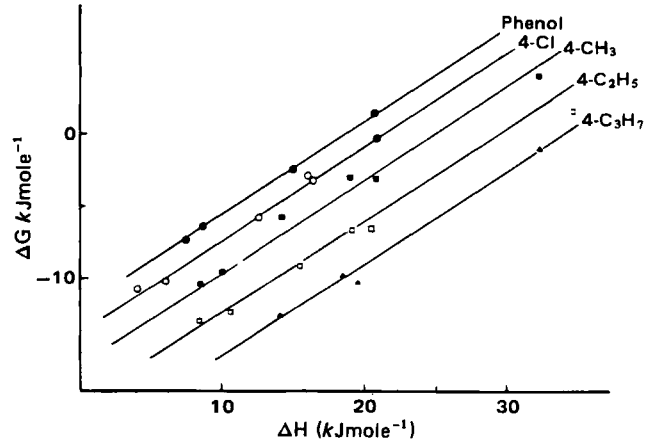

Figure 4—*Evaluation of compensation behavior. Enthalpy–free energy relationship for* p-*substituted phenols partitioned between 0.15* M *aqueous NaCl and nonpolar organic solvents.*

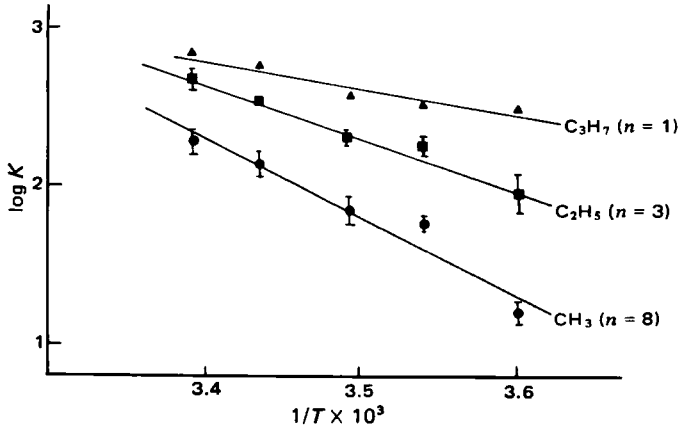

Figure 5—*The distribution of* p-*alkylphenols into DMPC vesicles—van't Hoff plots.*

a corresponding decrease in ΔS. 1-Octanol with a high extractive capacity provides large negative ΔH values and relatively small ΔS values. Such thermodynamic values reflect the important differences between the nature of the distribution process for different solvents. For inert hydrocarbon solvents, the distribution process reflects the loss of hydrogen bonding interactions between the hydroxyl group of the phenols and the aqueous phase that is compensated (in some cases) by an increase in ΔS. Any interaction between the phenolic hydroxyl group and the solvent [as well as the increased water content of the solvent and hydration of the monomeric phenol in the organic phase (21, 22)] would also be expected to lead to a decrease in the change in ΔH and a corresponding decrease in the change in ΔS. For 1-octanol, strong hydrogen bonding between the phenolic and alcohol hydroxyl groups will lead to a large and favorable ΔH (15). Consequently, control of the transfer passes from entropy domination to enthalpy domination.

When the concentration of a solute is sufficiently low in both phases, the distribution coefficient of solute distributed between water and a nonpolar organic solvent can be defined according to the theory of regular solutions (20):

$$\ln K_d^X = \frac{V_A}{RT}(\delta_{aq} - \delta_{org})(\delta_{aq} + \delta_{org} - 2\delta_A) \qquad \text{(Eq. 9)}$$

where V_A and δ_A are the molar volume and solubility parameter of solute A; δ_{aq} and δ_{org} are the solubility parameters of the aqueous solution and the organic solvent, respectively. Thus, a plot of $\ln K_d^X/(\delta_{aq} - \delta_{org})$ against δ_{org} should yield a straight line with a theoretical slope of V_A/RT. As shown in Fig. 2, using *p*-ethylphenol as an example, a linear relationship is obtained. The slope of the line is 0.206, in good agreement with the theoretical value of 0.203 calculated using $V_A = 120$ cm^3. A value of $\delta_{aq} = 16.5$ was employed rather than the usual value of 24. Davis *et al.* (23) and others (24) have shown previously that the lower value for δ_{aq} is valid for use in distribution studies involving organic solvents and aqueous phases.

Solvent effects can be considered also in terms of collision complexes between the phenolic solutes and the solvent. The aromatic carbon-hydrogen (A—H) stretching frequency in the IR is sensitive to hydrogen bond formation. Solvent shift theories and experimental studies on solvent effects have been reviewed (25). The frequency shift ΔV can be represented as the difference between the stretching frequency for the monomeric A—H in the vapor phase (V_0) and the lowered stretching frequency for A—H . . . B in the solvent in question (V_s). Badger and Bauer in 1937 (26) proposed that a linear relationship existed between the enthalpy of hydrogen bond formation and the frequency shift of the A—H stretching vibration.

In Fig. 3, the enthalpy of transfer has been plotted against the solvent shift parameter *P* (27) defined as:

$$\frac{V_0 - V_s}{V_0} = a\,P \qquad \text{(Eq. 10)}$$

The *P* values have been taken from literature sources (25, 27) on phenol in different solvents or calculated from values presented by Nakanishi *et al.* (28) for methanol and butanol systems[8]. The correlation between ΔH and *P* is good even though the *P* values refer to the anhydrous condition, and the phenols may be hydrated in the organic phase chosen for the distribution system.

[8] It should be noted that the *P* values were derived for anhydrous conditions, and the hydration of phenol in the organic phase may well alter the absolute values.

Although there is no satisfactory treatment to account for solvent shifts of stretching frequencies, there is general agreement that the bulk properties of the solvent such as dielectric constant are important only for nonpolar solvents (25). Complexes between phenols and nonpolar solvents have been referred to as collision complexes to emphasize that although the interaction is very weak, it is sufficient to influence the IR spectrum (25).

Procedures for converting thermodynamic data obtained in polar solvents to those expected in an inert solvent have been proposed (25). One method is based on the assumption that the enthalpy of transfer can be written as (25):

$$-\Delta H\ (\text{nonpolar media}) = -\Delta H\ (\text{polar media}) + A \qquad \text{(Eq. 11)}$$

where *A* is a constant for the solvent pair. A free-energy related equation of similar type was proposed by Leo *et al.* (3) for the interconversion of distribution coefficient data obtained with nonpolar solvents and those obtained with octanol:

$$\log K_{d,\text{solvent}} + I_h = \log K_{d,\text{octanol}} + b \qquad \text{(Eq. 12)}$$

where I_h were additive increments to hydrogen bonding.

The use of enthalpy–entropy compensation plots has been exploited when the thermodynamic data have been evaluated. [Proportionality between ΔH and ΔS is believed to imply a single unique mechanism for a series of solutes or solvents (29).] However, when ΔH and ΔS are both derived from the van't Hoff relationship, good correlations can be obtained that arise from statistical artifacts. Krug *et al.* (30, 31) have discussed this in detail, and more recently Kinkel *et al.* (14) have shown that a so-called excellent correlation between ΔH and ΔS for the transfer of various phenols between water and 1-octanol (13) was spurious. Enthalpy–entropy compensation can be tested by plotting ΔH *versus* ΔG at the harmonic mean temperature of the experiments (31). Figure 4 shows the ΔH *versus* ΔG relationship for the various solvent systems examined. A relationship of the form:

$$\Delta G^X = 0.7\,\Delta H^X - B \qquad \text{(Eq. 13)}$$

can be obtained, where *B* is a constant that is related to the size of the phenolic solute. Similar compensation relationships have been reported by others (14, 32). (No linear relationships were observed when ΔG was plotted *versus* ΔH for a set of solutes and a given solvent.)

The linear relationship defined by Eq. 13 suggests that the various solutes are distributed between water and the various inert solvents by the same mechanism; *i.e.*, that the aqueous phase provides the major driving force for the transfer process: the hydrophobic effect. The ΔG and ΔH values for the 1-octanol system have not been shown. The values given in Table I deviate from the linear relationship. The ΔH values corresponding to measured ΔG values are much larger than would be predicted from Eq. 13.

For example:

Phenol	0.4 kJ mole^{-1}
Cresol	0.8 kJ mole^{-1}
p-Ethylphenol	1.0 kJ mole^{-1}
p-Propylphenol	1.5 kJ mole^{-1}
p-Chlorophenol	1.0 kJ mole^{-1}

These data indicate that the transfer of phenolic solutes between water and 1-octanol follows a different mechanism than that for the transfer

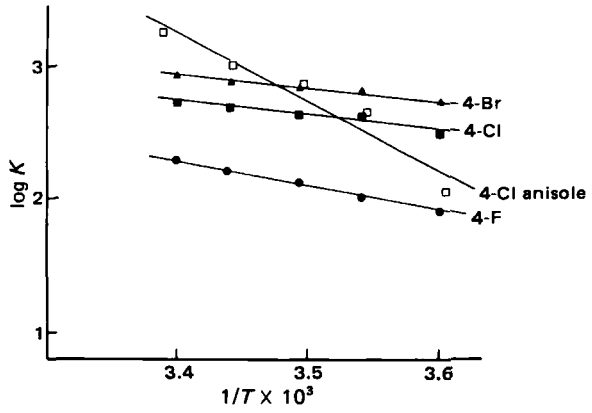

Figure 6—*The distribution of* p-*halophenols into DMPC vesicles—van't Hoff plots.*

of the same solutes between water and nonpolar solvents and, thus, ΔH–ΔS compensation is not obtained. A similar finding was reported recently by Kinkel *et al.* (14). These authors pointed out that mutually saturated 1-octanol contains a considerable quantity of dissolved water (27% on a mole fraction basis) and that water-centered aggregates (4:1 alcohol–water) have been described (5). In addition, linear aliphatic alcohols can exist in polymeric forms (33). Changes in temperature will affect these associations as well as the association between phenolic solutes and 1-octanol itself. Because of these factors, it was suggested (14) that the van't Hoff method should not be used to obtain thermodynamic quantities from the 1-octanol–water system, and microcalorimetry was proposed as an alternative. This is an attractive possibility provided the methodology can be refined to give reliable results. An alternative suggestion would be to avoid the use of 1-octanol when studying the thermodynamics of the distribution process.

Phospholipid Vesicle–Water Distribution—The temperature dependence of the molal distribution coefficient (K_d^m) for *p*-substituted phenols distributed between DMPC vesicles (below their phase transition temperatures) and 0.15 *M* NaCl is shown in Figs. 5 and 6.

The derived thermodynamic quantities are given in Table II. All values refer to initial phenol concentrations of 2×10^{-4} *M* and 20 mg of DMPC. The ΔH is large and positive for all solutes studied. The negative ΔG is the result of a large compensating increase in entropy: the process is entropy dominated. The magnitude of the absolute values is dependent on the nature of the experimental system used, and different values can result from using different phenol concentrations, phospholipid concentration, and experimental protocol. Thus, the data should be regarded as giving a qualitative rather than a precise quantitative picture (34).

In both absolute and relative terms the log K_d^m values for the alkyl and halophenols are more closely related to the distribution coefficients for the 1-octanol–water system rather than those for the so-called inert solvents such as cyclohexane. However, for the vesicles, ΔH is positive throughout which is similar to the situation for the nonpolar solvents and in direct contrast to the negative ΔH values found for the 1-octanol–water system.

Previously, Rogers and Davis (8) have reported that the thermodynamic parameters for the transfer of phenols between aqueous environment and DMPC vesicles change in sign and magnitude at the phase transition temperature. Above T_c, ΔH and ΔS are both negative. Similar changes in thermodynamic parameters at temperatures in the region of T_c have been reported by others (7, 9, 35). Diamond and Katz (7) interpreted observed enthalpy changes by proposing that in the crystalline state below T_c the hydrocarbon tails of DMPC pack closely and uniformly along their length. Thus, insertion of a solute into the membrane requires the breaking of strong intermolecular forces between the hydrocarbon tails, and entropy changes can be attributed to the disruption of the orderly crystalline array by the inserted solute. Thus, large and compensating changes in ΔH and ΔS attributable to the change in liposome structure can mask the smaller changes in ΔH and ΔS due to the actual transfer of the solute. In this respect, Lumry (36) has warned recently that ΔH and ΔS quantities each contain two parts: one (motive) that contributes to the free energy (of transfer) and one that does not (compensation) but that reflects enthalpy and entropy fluctuations. In water and most biological systems these compensation effects can dominate the motive (work-doing) contribution. Consequently, discrepancies can arise in attempts to formulate mechanistic hypotheses using ΔH and ΔS information.

The phospholipid vesicles are isotropic and will have markedly different polarity regions; consequently, the different phenolic solutes are likely to distribute into different regions. This will affect both the distribution coefficient and the thermodynamics of transfer. The high log K_d^m values obtained for the phenols with phospholipid vesicle systems indicate that the phenols could be hydrogen bonded to the phosphate group of DMPC. Comparison of the data obtained for chloroanisole with those for chlorophenol (Fig. 6) indicates that ΔH for the anisole, where there can be no hydrogen bonding, is much larger. At lower temperatures the anisole has a lower K_d^m value than the phenol, the K_d^m value being much more temperature dependent than for the phenol. The hypothesis that the phenolic hydroxyl group can (hydrogen) bond to the DMPC phosphate group was further strengthened by studies on the resorcinol monoethers. Again the hydroxy compound has a lower ΔH value than the corresponding methoxy or ethoxy compound (Table II). This suggests that the resorcinol is able to interact favorably with the phospholipid head group through both of its phenolic hydroxyl groups and that the orientation of these compounds in the lipid bilayer is quite different from that of the alkyl phenols. The ΔH values for the resorcinols were all positive (67–140 kJ mole^{-1}), whereas Beezer *et al.* (12) have shown for the 1-octanol–water system that ΔH is negative and in the range of −15 to −7 kJ mole^{-1}.

The ability of a solute-like phenol to undergo specific interactions with the bilayer membrane calls into question the use of inert hydrocarbons as model solvents for use in correlating structure with biological activity, even though inert hydrocarbons do find a role as reference states (4) and data obtained using such solvents can be converted to values more relevant to polar environments (37). A reasonable correlation can be obtained between liposome–water partition coefficients and octanol–water partition coefficients (7, 8). However, the derivation of the more complete thermodynamic picture in terms of ΔH and ΔS values indicates that the two systems are very different.

Influence of Premicellar and Micellar Association on the Reactivity of Methylprednisolone 21-Hemiesters in Aqueous Solution

B. D. ANDERSON ˣ, R. A. CONRADI, and K. JOHNSON

Received December 11, 1980 from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 31, 1981.

Abstract □ Self-association of drug molecules at formulation concentrations can have a major impact on formulation properties. In this study a homologous series of methylprednisolone 21-hemiesters were found to undergo self-association in aqueous solution. The effect of aggregate formation on the solution degradation of these compounds was examined. To determine the nature and extent of association of these steroidal esters, partition coefficients between butyronitrile and aqueous buffer (pH 8.5) were measured as a function of ester concentration. The partitioning data were found to be consistent with dimer formation at low concentration followed by true micelle formation at higher concentration. Chain length increases favored micelle formation, but appeared to have little effect on dimerization. The first-order rate constants for ester hydrolysis and 21 → 17 acyl migration in aqueous buffer (pH 8.5) were also found to be dependent on ester concentration. The kinetic data are consistent with a model which assumes stabilization by both dimer and micelle formation, the limiting factor at high concentration being the reactivity of the ester in the micelles. The degree of stabilization due to self-association was found to increase with chain length.

Keyphrases □ Methylprednisolone—synthesis of 21-hemiester homologues, influence of premicellar and micellar association on reactivity □ Steroids—methylprednisolone, synthesis of 21-hemiester homologues, influence of premicellar and micellar association on reactivity □ Association, micellar—influence on the reactivity of methylprednisolone 21-hemiesters □ Association, premicellar—influence on the reactivity of methylprednisolone 21-hemiesters

Self-association of hydrophobic drug molecules in aqueous solution can have a profound effect on formulation properties due to the reduced effective concentration of drug at high total concentration. Specifically, molecular aggregation may result in higher drug solubility, increased or decreased solution stability, or transient masking of local biological effects.

While there is voluminous literature on the effect of micelle-forming additives on the chemical reactivity of various substrates, very few cases have been reported in which a labile substrate itself forms molecular aggregates resulting in self-stabilization. The few studies which do exist suggest that reactivity can be significantly altered either favorably or unfavorably by substrate self-aggregation into micelles (1, 2). Premicellar aggregation has also been found to dramatically alter reactivity (3–5).

Steroidal molecules, particularly bile salts, are known to undergo self-association in aqueous solution to form aggregates varying in size from dimers to much larger oligomers (6–8). Self-association has also been observed for the corticosteroid methylprednisolone 21-phosphate (9). In this case a marked acceleration in reactivity in more concentrated solutions was attributed to micelle formation.

A recent study showed that methylprednisolone 21-succinate[1] decomposes initially in aqueous solution *via* two parallel pathways (10). In addition to the well-known ester hydrolysis reaction, acyl migration from the 21- to the 17-OH occurs at a rate comparable to hydrolysis (Scheme I).

Since it was suspected that methylprednisolone 21-succinate may self-associate at formulation concentrations, a study was initiated to determine: (*a*) the nature and extent of self-association, (*b*) the effect of aggregation on the solution kinetics, and (*c*) the effect of molecular modification (increasing the hydrophobicity through increases in hemiester chain length) on both the aggregation and kinetics. To determine unambiguously the nature and extent of self-association, a partitioning method was developed enabling calculation of the monomer concentration as a function of total concentration. The initial rates of ester hydrolysis and acyl migration as a function of concentration were then combined with the partitioning data to elucidate the relative reactivities of monomeric and aggregated species.

Keyphrases □ Methylprednisolone—synthesis of 21-hemiester homologues, influence of premicellar and micellar association on reactivity □ Steroids—methylprednisolone, synthesis of 21-hemiester homologues, influence of premicellar and micellar association on reactivity □ Association, micellar—influence on the reactivity of methylprednisolone 21-hemiesters □ Association, premicellar—influence on the reactivity of methylprednisolone 21-hemiesters

Self-association of hydrophobic drug molecules in aqueous solution can have a profound effect on formulation properties due to the reduced effective concentration of drug at high total concentration. Specifically, molecular aggregation may result in higher drug solubility, increased or decreased solution stability, or transient masking of local biological effects.

While there is voluminous literature on the effect of micelle-forming additives on the chemical reactivity of various substrates, very few cases have been reported in which a labile substrate itself forms molecular aggregates resulting in self-stabilization. The few studies which do exist suggest that reactivity can be significantly altered either favorably or unfavorably by substrate self-aggregation into micelles (1, 2). Premicellar aggregation has also been found to dramatically alter reactivity (3–5).

Steroidal molecules, particularly bile salts, are known to undergo self-association in aqueous solution to form aggregates varying in size from dimers to much larger oligomers (6–8). Self-association has also been observed for the corticosteroid methylprednisolone 21-phosphate (9). In this case a marked acceleration in reactivity in more concentrated solutions was attributed to micelle formation.

A recent study showed that methylprednisolone 21-succinate[1] decomposes initially in aqueous solution *via* two parallel pathways (10). In addition to the well-known ester hydrolysis reaction, acyl migration from the 21- to the 17-OH occurs at a rate comparable to hydrolysis (Scheme I).

Since it was suspected that methylprednisolone 21-succinate may self-associate at formulation concentrations, a study was initiated to determine: (*a*) the nature and extent of self-association, (*b*) the effect of aggregation on the solution kinetics, and (*c*) the effect of molecular modification (increasing the hydrophobicity through increases in hemiester chain length) on both the aggregation and kinetics. To determine unambiguously the nature and extent of self-association, a partitioning method was developed enabling calculation of the monomer concentration as a function of total concentration. The initial rates of ester hydrolysis and acyl migration as a function of concentration were then combined with the partitioning data to elucidate the relative reactivities of monomeric and aggregated species.

nate[2] was used as supplied without further purification. Methylprednisolone[2] for use as a high-performance liquid chromatography (HPLC) reference standard was recrystallized from tetrahydrofuran. The remaining methylprednisolone esters used in this study were synthesized as described.

Synthesis—*6α-Methylprednisolone 21-Hemiadipate*—A mixture of 5 g of 11β,17α-dihydroxy-21-iodo-6α-methylpregna-1,4-diene-3,20-dione[2], 14.6 g of adipic acid, and 34.8 ml of *N,N*-diisopropylethylamine in 45 ml of dimethylformamide and 20 ml of acetone was allowed to stand at 25° for 1 hr. The mixture was extracted with ethyl acetate (250 ml) and washed with 0.08 *M* citric acid. The organic phase was rapidly extracted (pH 10), and the resulting aqueous phase was readjusted to pH 5 and then extracted with ethyl acetate. The solvent was evaporated under reduced pressure, and the resulting solid was recrystallized twice from ethyl acetate–hexane to give an analytical specimen, mp 164.3–165.6; NMR[3a,b]: δ 7.2–7.4 (d, 1, C_1—H), 6.0–6.2 (d, 1, C_2—H), 5.9 (s, 1, C_4—H), 4.6–5.3 (m, 2, C_{21}—H_2), 4.4 (broad, 1, C_{11}—H).

Anal.—Calc. for $C_{28}H_{38}O_8$: C, 66.92; H, 7.62. Found: C, 67.01; H, 7.91.

6α-Methylprednisolone 21-Hemisuberate—The ester was prepared in the aforementioned manner using 5 g of 11β,17α-dihydroxy-21-iodo-6α-methylpregna-1,4-diene-3,20-dione, 17.4 g of octanedioic acid, 34.8 ml of *N,N*-diisopropylethylamine, 67 ml of dimethylformamide, and 20 ml of acetone to give, after recrystallization from ethyl acetate–hexane, an analytical specimen, mp 192.1–195.4; NMR[3a,b]: δ 7.2–7.4 (d, 1, C_1—H), 6.0–6.2 (d, 1, C_2—H), 5.9 (s, 1, C_4—H), 4.6–5.3 (m, 2, C_{21}—H_2), 4.4 (broad, 1, C_{11}—H).

Anal.—Calc. for $C_{30}H_{24}O_8$: C, 67.91; H, 7.98. Found: C, 67.58; H, 8.33.

6α-Methylprednisolone 17-Hemisuccinate—The synthesis and structure elucidation were reported previously (10).

6α-Methylprednisolone 17-Hemisuberate—Methylprednisolone 21-hemisuberate (4 g) was dissolved in 400 ml of water by the slow addition of 1 *N* NaOH. The pH of the final solution was maintained ≤9.5 over several hours and the 17-ester formation was monitored by HPLC. The concentration of 17-ester plateaued at ~9–10% of the total solution concentration. The reaction was stopped by acidification and products were isolated by extraction with ethyl acetate. The solvent was removed under reduced pressure and the remaining solid purified by HPLC: (*a*) reverse-phase[4] using acetonitrile–water (9:11) containing 0.05 *M* acetic acid at a flow rate of 18 ml/min[5] and (*b*) silica gel[6] using butylchloride–ethyl acetate (1:1) containing 1% acetic acid at 18 ml/min[5]. The solvent was removed to give a white amorphous solid which was reprecipitated from ethyl acetate–hexane. No methylprednisolone nor 21-suberate were detected by HPLC. UV[7]: λ_{max} = 244 nm, $\epsilon = 1.48 \times 10^4$ (methylprednisolone 17-succinate λ_{max} = 244, $\epsilon = 1.50 \times 10^4$). NMR[3] (acetone-$d_6$): δ 7.3–7.5 (d, 1, C_1—H), 6.1–6.3 (d, 1, C_2—H), 5.90–5.95 (s, 1, C_4—H), 4.55 (broad, 1, C_{11}—H), 4.2–4.25 (s, 2, C_{21}—H_2).

Sample Preparation—All sample solutions for both kinetic and partitioning studies were prepared in 0.1 *M* boric acid buffer adjusted to pH 8.47 ± 0.01 with 50% sodium hydroxide. The ionic strength of the buffer was 0.5 *M* (potassium chloride).

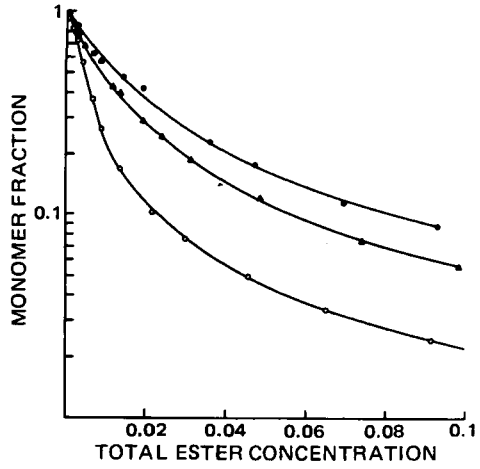

Figure 2—*Semilog plots of monomer fraction [PC/PC(O)]* versus *total concentration in ester in aqueous buffer at pH 8.47 and 25°. Key: (●) 21-succinate; (▲) 21-adipate; and (○) 21-suberate.*

Stock solutions containing ~0.1 *M* 21-ester were prepared by weighing an appropriate amount in a volumetric container and adding buffer containing the amount of excess sodium hydroxide required to neutralize the carboxylic acid. Sonication and vigorous mixing were required to rapidly dissolve the sample. The stock solutions were frozen (−20°) for later use. Aliquots of these stock solutions were diluted and pH was adjusted to 8.47 ± 0.01 if necessary. Temperature of the diluted samples was maintained at 25.0° during all studies.

Partition Coefficient Determinations—After the appropriate dilution of one of the aforementioned stock solutions, a 1–5 ml aliquot was transferred to a test tube containing 1–5 ml of butyronitrile. The biphasic mixture was brought to 25°, vortexed vigorously, centrifuged, and allowed to stand in the 25° water bath for 15–30 min. Aliquots from each layer were removed. The butyronitrile was evaporated under a nitrogen stream, and the residues from both the aqueous and butyronitrile phases were diluted with an acidified acetonitrile–water mixture. HPLC analysis was carried out as described below using standard solutions of the corresponding 21-ester in acetonitrile–water (1:3) at pH 3–3.2.

Kinetic Studies—The initial rates of product formation (up to 3%) were monitored by HPLC as a function of initial 21-ester concentration. Standards containing methylprednisolone and the corresponding 17-ester (when available) at concentrations of $\sim 1 \times 10^{-6}$–1×10^{-4} *M* were prepared in acetonitrile–water (1:3) adjusted to pH 3.2.

At suitable time intervals precise aliquots of samples prepared by

appropriately diluting the stock solutions described previously were transferred to vials containing an acetonitrile–water mixture acidified such that the final solution pH was 3–5 to immediately quench the reaction. Samples (≤100 μl) were analyzed by HPLC employing a modular chromatographic system consisting of an automated sample injector[8], a constant-flow pump[9] operated at 1.5–2.0 ml/min, a reverse-phase column[10], a variable-wavelength UV detector[11] operated at 244 nm, and a digital integrator[12].

Mobile phase compositions for the 21-succinate, 21-adipate, and 21-suberate systems were, respectively, 0.05 *M* acetic acid in acetonitrile–water (1:2) adjusted to pH 5.3 with NaOH, 0.05 *M* acetic acid in acetonitrile–water (2:3) adjusted to pH 5.0, and 0.05 *M* acetic acid in acetonitrile–water (9:11) adjusted to pH 5.2.

RESULTS AND DISCUSSION

Self-Associated Systems and Methods for Their Investigation—Although the nature of the forces in water which give rise to a hydrophobic effect are still not well understood (11–13), the tendency of hydrophobic solutes (molecules containing large regions of exposed organic groups) to self-associate in water is widely recognized (14). Typical micelle-forming surfactants, such as flexible-chain compounds with polar head groups, can form large aggregates containing ~30–120 monomers per multimer (15).

If the aggregates formed are sufficiently large, containing >20 monomers, a simple monomer–micelle model adequately represents the equilibria involved. Such systems are characterized by a distinct break point in plots of any number of properties *versus* concentration. The point at which this discontinuity occurs is termed the critical micelle concentration (CMC). Below the CMC the concentration of micelles is negligible (monomer concentration equals total concentration), while above the CMC the activity of monomer is virtually constant.

Careful studies, however, generally show curvature rather than a distinct discontinuity at the apparent CMC (14), suggesting that small aggregate formation occurs prior to true micelle formation. Even flexible long-chain fatty acid anions have been shown to dimerize in dilute aqueous solutions (16). Steroids consisting of inflexible alicylic fused-ring systems, such as the bile acid salts and the corticosteroid derivatives of interest in this study, are also quite likely to form smaller aggregates. Light scattering and solubilization studies of sodium cholate, for example, suggest that it self-associates to form dimers (6) and other small aggregates (17).

The existence of premicellar aggregates complicates the interpretation of experimental data obtained by methods that do not allow direct calculation of the monomer concentration. Most experimental methods are unsuitable, because each multimer must be described by both a formation constant and a parameter reflecting its contribution to the property being measured. Conductance methods, for example, require the estimate of an equivalent conductance for each species (18). Spectral methods require an estimate of absorptivity for each species present (19).

Partitioning Method for Monitoring the Self-Association of Methylprednisolone Hemiesters—The determination of partition equilibria has been shown to be a useful technique in monitoring self-association (16). The partition coefficient, PC(C), of an amphiphile between an organic and an aqueous solvent reflects the relative thermodynamic activity coefficients $\gamma_{H_2O}(C)$ and $\gamma_{org}(C)$, of solute in the two solvents where C is the concentration of solute in the aqueous phase.

At equilibrium, the thermodynamic activities of solute in the two phases are equal:

$$a_{H_2O} = a_{org} \qquad \text{(Eq. 1)}$$

where

$$a_{H_2O} = \gamma_{H_2O} C_{H_2O} \text{ and } a_{org} = \gamma_{org} C_{org}$$

At infinite dilution, $\gamma_{H_2O}(O)$ is defined such that:

$$\lim \gamma_{H_2O}(C) = \gamma_{H_2O}(O) = 1$$
$$C_{H_2O} \to 0 \qquad \text{(Eq. 2)}$$

Also at infinite dilution, from Eq. 1 and the definition of the partition coefficient:

$$PC(O) = \lim (C_{org}/C_{H_2O}) = \gamma_{H_2O}(O)/\gamma_{org}(O)$$
$$C_{H_2O} \to 0 \qquad \text{(Eq. 3)}$$

and, substituting the value of $\gamma_{H_2O}(O)$ from Eq. 2:

$$\gamma_{org}(O) = 1/PC(O) \qquad \text{(Eq. 4)}$$

Assuming that the activity coefficient of solute in the organic phase, γ_{org}, remains constant with changes in solute concentration:

$$\gamma_{org}(C) = \gamma_{org}(O) = 1/PC(O) \qquad \text{(Eq. 5)}$$

A further assumption is that deviations in the activity coefficient of solute in aqueous solution are due solely to self-association, so at any concentration the value of γ_{H_2O} is equal to the fraction of monomer ([Mon]) present:

$$\gamma_{H_2O}(C) = \frac{[Mon]_{H_2O}}{C_{H_2O}} \qquad \text{(Eq. 6)}$$

Two useful relationships are then obtained from Eqs. 1–6, enabling the direct calculation of monomer concentration and monomer fraction from measurements of partitioning equilibria:

$$[Mon]_{H_2O} = C_{org}/PC(O) \qquad \text{(Eq. 7)}$$

[8] Wisp Model 710A, Waters Associates, Milford, Mass.

[11] Altex/Hitachi Model 153-00, Altex Scientific.
[12] Model 3380A, Hewlett-Packard, Avondale, Mass.

and

$$[\text{Mon}] = \gamma_{H_2O}(C) = PC(C)/PC(O) \quad \text{(Eq. 8)}$$

A pH of 8.5 was selected for both the partitioning and kinetic studies, because the solutes were highly soluble at this pH and the reaction rates were in a range which could be conveniently measured in a reasonable length of time. At this pH, nonpolar solvents (isooctane, toluene, *etc.*) were unacceptable for use in partitioning studies, because partition coefficients were too low, while most polar hydrogen-donating or hydrogen-accepting solvents extracted too much solute. Butyronitrile—a polar, aprotic solvent which is immiscible with water—was found to be suitable.

The pH dependence of the partition coefficient of methylprednisolone 21-succinate suggested that only the free acid partitions into the organic phase. At pH 2 the intrinsic partition coefficient of solute, $PC_I(O)$ was found to be ~170, while the value of $PC(O)$ at pH 8.47 was 0.031. Assuming that only the free acid partitions and that the pK_a for the succinate is 4.7 (10), the predicted value of $PC(O)$ at pH 8.47 can be calculated from:

$$PC(O)_{pH\ 8.5} = \frac{PC_I(O)[H^+]}{[H^+] + K_a} = 0.029 \quad \text{(Eq. 9)}$$

which is in good agreement with the observed value.

A critical assumption on which Eqs. 7 and 8 are based is that the activity coefficient of solute in the organic phase is constant with concentration (Eq. 5). Changes in the activity coefficient of the solute due to association in the organic phase, therefore, either must be negligible or must be considered significant. Carboxylic acids are known to dimerize in nonpolar solvents (19, 20), but the equilibrium constant for dimerization in the more polar solvent butyronitrile should be substantially smaller.

To determine whether dimerization in butyronitrile is significant over the solute concentration range of interest in the pH 8.5 partitioning studies (0 to ~3.3×10^{-3} *M*), the partition coefficient of methylprednisolone 21-hemisuccinate between butyronitrile and 0.01 *N* HCl was determined as a function of concentration (Fig. 1). Since the partition coefficient is large at low pH, the aqueous concentration of solute approaches infinite dilution over the entire butyronitrile concentration range of interest. Self-association in the aqueous phase at pH 2 is, therefore, unimportant. Although there does appear to be an upward trend consistent with a very small deviation in γ_{org}, this trend is negligible over the concentration range of 0–3.3×10^{-3} *M*, indicating that self-association of solute in the organic phase can be neglected.

Partition coefficients at pH 8.47 (μ = 0.5) were determined over a concentration range of 0–0.1 *M*. Values of $PC(O)$ were estimated by linear extrapolation of the partitioning data at concentrations below 3×10^{-3} *M* to infinite dilution. The estimated values of $PC(O)$ for the succinate, adipate, and suberate are 0.031, 0.167, and 1.48, respectively. As expected, partition coefficients increase by a factor of 2.5–3 per $-CH_2-$ group increment consistent with literature values for the methylene group contribution to partitioning into polar organic solvents (21).

The monomer fraction was calculated by applying Eq. 8 to the partitioning data. Semilog plots of the monomer fraction *versus* concentration in aqueous buffer are shown in Fig. 2. Two conclusions can be drawn from the data in Fig. 2: changes in monomer fraction are observed at very low concentration (~1×10^{-3} *M*) and increased chain length results in greater association. Surface tension measurements on the succinate did not show any aggregation below ~0.02–0.03 *M*[13], while the partition coefficients clearly change at much lower concentrations. This suggests that partition coefficients are a more sensitive measure of the aggregation phenomena.

Applying Eq. 7 to the partitioning data one obtains the monomer concentration at any total ester concentration (Fig. 3). A striking observation from these plots is the existence of at least two distinct types of association—premicellar association exemplified by curvature at low concentrations and micelle formation indicated by the constancy in monomer concentration after an apparent discontinuity in each curve.

Premicellar Association—In very dilute solutions, monomer concentration very nearly equals total concentration as indicated by the dashed line in Fig. 3. The marked deviations from the extrapolated line prior to the apparent CMC suggest that premicellar association occurs. Premicellar aggregation is perhaps more noticeable in Fig. 2, since monomer fractions change markedly prior to the apparent critical micelle concentrations observed in Fig. 3.

A calculation of the average aggregate size as previously described (22) is derived in the following manner.

[13] S. L. Nail, The Upjohn Company, private communication.

Table I—Apparent Critical Micellar Concentrations, Equilibrium Constants for Dimerization, and Contribution of Each Species to Total Concentration at 0.1 *M* for Corticosteroid 21-Hemiesters Varying in Side-Chain Length

Ester	Apparent[a] CMC, *M*	$K_{1:2}$ liter mole^{-1}	Species Contribution at 0.1 *M* Monomer, *M*	Dimer, *M*	Micelle, *M*
21-Succinate	0.02	80 ± 4[b]	8.2×10^{-3}	1.1×10^{-2}	8.1×10^{-2}
21-Adipate	0.01–0.015	70 ± 7	5.7×10^{-3}	4.6×10^{-3}	9.0×10^{-2}
21-Suberate	0.003	85 ± 22	2.3×10^{-3}	8.6×10^{-4}	9.7×10^{-2}

[a] Apparent critical micelle concentration. [b] 95% Confidence limits from linear regression.

The total concentration of ester (C_T) can be expressed as,

$$C_T = [\text{Mon}] + 2K_{1:2}[\text{Mon}]^2 + 3K_{1:3}[\text{Mon}]^3 + \ldots \quad \text{(Eq. 10)}$$

where aggregated species of all sizes are allowed without any assumptions as to their tendency to form. The total species concentration (S_T) is:

$$S_T = [\text{Mon}] + K_{1:2}[\text{Mon}]^2 + K_{1:3}[\text{Mon}]^3 + \ldots \quad \text{(Eq. 11)}$$

By inspection it is clear that:

$$S_T = \int_0^{\text{Mon}} C_T/\text{Mon}\, d\text{Mon} \quad \text{(Eq. 12)}$$

The average polymer size at any concentration is defined as:

$$\text{average polymer size} = \frac{C_T - \text{Mon}}{S_T - \text{Mon}} \quad \text{(Eq. 13)}$$

The integral in Eq. 12 was evaluated by trapezoidal integration.

The results of average polymer size calculations *versus* log C_T are shown in Fig. 4. The premicellar region is indicated by the flat portion of the diagrams at an average polymer size of ~2 which is very broad for the succinate, less so for the adipate, and barely distinguishable for the suberate due to its low apparent CMC. The broad region with average polymer size of 2 is consistent with dimer formation. Since the average polymer size does not gradually increase in the premicellar region, trimers or other small oligomers do not appear to be present.

If dimerization is the major mode of association in the premicellar region, systems in this region should be adequately described by:

$$C_T = \text{Mon} + 2K_{1:2}\text{Mon}^2 \quad \text{(Eq. 14)}$$

where

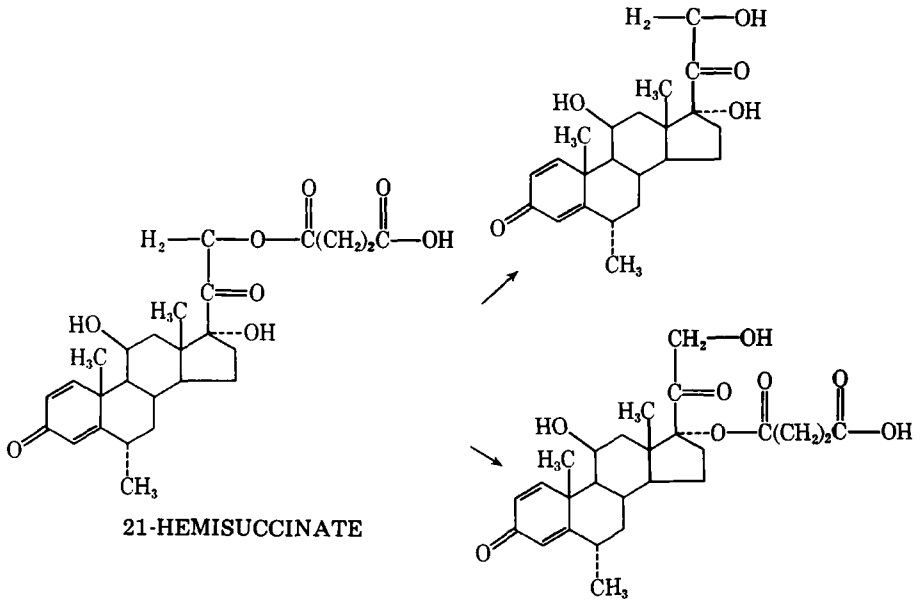
$$K_{1:2} = \frac{[\text{Dimer}]}{[\text{Mon}]^2} \quad \text{(Eq. 15)}$$

Therefore, plots of C_T/Mon *versus* [Mon] should be linear with slopes of $2K_{1:2}$. These plots are shown to be approximately linear in Fig. 5. The values of $K_{1:2}$ estimated from a linear regression on the data in Fig. 5 are 80 ± 4, 70 ± 7, and 85 ± 22 liter/mole for the succinate, adipate, and suberate, respectively. $K_{1:2}$ is not affected noticeably by chain length suggesting that the C_{21} side chains are not participating in the dimerization interaction.

It is possible that dimers arise from the stacking of the steroidal portion of the molecules with the C_{21} side chains directed away from each other. Another possibility is that the side chains may be folded back in a hydrophobic interaction with the side of the steroidal nucleus not involved in dimer formation. If the latter were true, folding back of the side chain would be expected in the monomer as well. Since the infinite dilution partition coefficients increase with chain length by the magnitude predicted, this explanation does not seem likely.

Micelle Formation—The break points in Fig. 3 after which monomer concentration remains constant suggest the formation of much larger aggregates or micelles. The critical micelle concentrations for the three homologues (the concentrations at which micelles are first detectable) are listed in Table I along with the dimerization constants discussed previously. Above the CMC, the concentrations of monomer and dimer are invariant. Estimates of these concentrations are also shown in Table I. An interesting observation is that the actual monomer concentration is much lower than the apparent CMC, particularly for the succinate and adipate. In a simple monomer–micellar model, the monomer activity is generally assumed to be given by the CMC. As shown in Table I, estimates of monomer concentration from apparent critical micelle concentrations may be very misleading if premicellar association occurs.

Numerous reports in the literature cite a relationship between CMC



Scheme I

and the number of methylene groups in the surfactants. The relationship generally takes the form:

$$\log \text{CMC} = A - bn \qquad \text{(Eq. 16)}$$

where b is usually ~0.28–0.3 (23). A plot of log CMC *versus* chain length in the series of corticosteroid esters gave a slope of 0.24, which is close to values generally reported in the literature. The effect of chain length on monomer concentration, however, was much less (Table I) than predicted from Eq. 16 due to the importance of dimer formation.

It is difficult to speculate on the structure of these corticosteroid micelles other than to point out that they are large (average polymer size in Fig. 4 increases sharply above the CMC), and their formation is enhanced by increases in side-chain length.

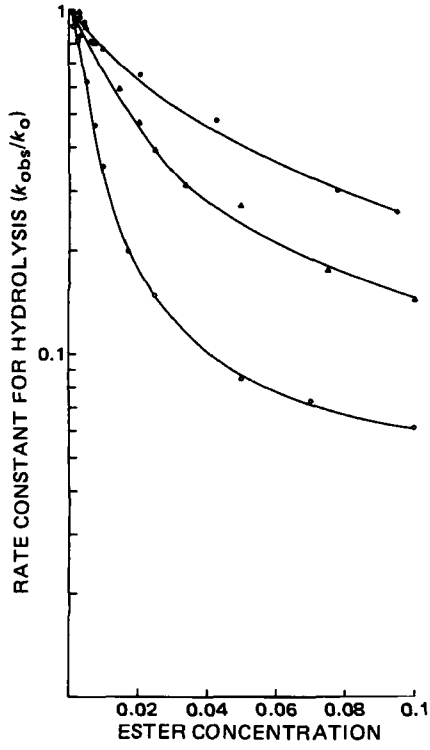


Figure 6—*Semilog plots of the ratio of the rate constant for hydrolysis at the given concentration to the infinite dilution rate constant* (k_{obs}/k_0) versus *ester concentration. Key: (●) 21-succinate; (▲) 21-adipate; and (○) 21-suberate.*

One hint as to the nature of the environment in the micelles may be obtained from UV measurements[14]. The $\pi \rightarrow \pi^*$ transition of the steroidal A-ring in the 21-esters of methylprednisolone undergoes a bathochromic shift as the polarity of the solvent is increased, due presumably to a reduction in the energy level of the excited state accompanying dipole–dipole interaction and hydrogen bonding (24). For example, λ_{max} of methylprednisolone succinate in tetrahydrofuran is 236 nm while in water it is 244 nm. A thin film of a 0.1 *M* aqueous solution of methylprednisolone succinate spread between two cuvettes exhibited a λ_{max} of ~245 nm, very similar to that observed in dilute solutions, indicating that there is no significant change in absorbance accompanying the partitioning of molecules into micelles. This observation tentatively supports the hypothesis that the environment surrounding the A-ring in the micelle is very polar or the A-ring is involved in hydrogen bonding within the micelle.

Kinetics of Hydrolysis and Acyl Migration in Aggregated Corticosteroid Systems—Catalysis and inhibition of reactions in associated systems have been the subjects of extensive research (25, 26). Of greatest interest from a pharmaceutical standpoint are those studies in which reaction rates have been markedly retarded by micelle-forming additives (27–31). Base-catalyzed hydrolysis of esters is generally inhibited by anionic surfactants (26), and since previous studies have shown (10) that both hydrolysis and 21 → 17 ester migration in methylprednisolone succinate are hydroxide ion catalyzed, it is reasonable to expect that both reactions might be slowed by self-association. The concentration of monomer in 0.1 *M* solutions of the corticosteroid homologues show a range of $2.3–8.2 \times 10^{-3}$ (Table I). If degradation were completely suppressed in the aggregates as has been shown in at least one case (27), significant stabilization should result from self-association in 0.1 *M* solutions.

As predicted, hydrolysis and 21 → 17 acyl migration (Scheme I) of the methylprednisolone 21-ester linkage is suppressed at higher concentrations. Plots of k_{obs}/k_0 *versus* concentration for hydrolysis and acyl migration, are shown in Figs. 6 and 7 respectively, where k_0 is the pseudo first-order rate constant at high dilution. From Figs. 6 and 7 the following conclusions are drawn: (*a*) significant suppression of reactivity occurs prior to the critical micelle concentrations (obtained from partitioning data) suggesting that dimerization as well as micelle formation stabilizes these esters toward hydroxide ion attack; (*b*) the overall magnitude of stabilization is much less than would be observed if monomers were the only reactive species; (*c*) increases in chain length which were earlier shown to promote micelle formation also result in larger rate suppression with increasing concentration; and (*d*) the magnitude of stabilization is about the same for both the hydrolysis reaction and 21 → 17 acyl migration.

Whereas the equilibrium constants for dimerization, critical micelle

[14] J. R. Cardinal, College of Pharmacy, University of Utah, private communication.

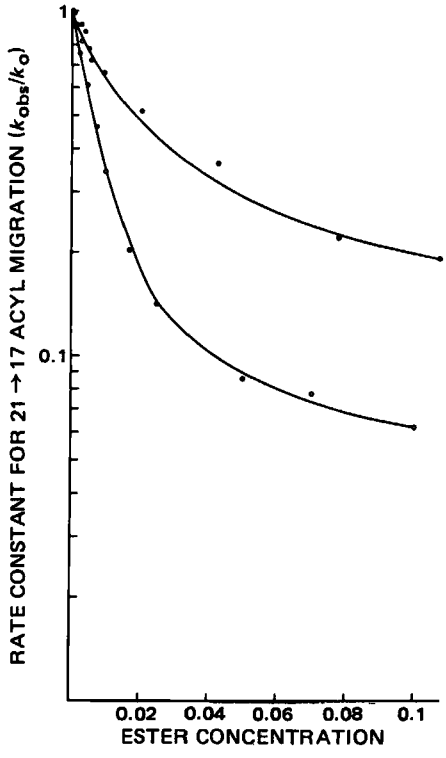

Figure 7—*Semilog plots of the ratio of the observed 21 → 17 acyl migration rate constant at the given ester concentration to the infinite dilution acyl migration rate constant* (k_{obs}/k_0) versus *ester concentration (pH 8.47 and 25°). Key: (●) 21-succinate and (○) 21-suberate.*

concentrations, *etc.* were determined in butyronitrile-saturated aqueous buffer, the kinetic data were obtained in aqueous buffer containing no butyronitrile. The use of the dimerization constants in Table I to calculate rate constants for reaction of dimers from the kinetic data is, therefore, probably not advisable. A few kinetic studies in butyronitrile-saturated buffer were done, however, and similar rate suppression *versus* concentration curves were observed even though absolute reaction rates differed. Qualitatively at least, it is apparent from Figs. 6 and 7 that reaction rates in the dimers are substantially reduced since reactivities decline with concentration even at very low concentrations.

While the percentages of monomer reported in Table I are 2–8% of the total ester at 0.1 *M*, reaction rates at 0.1 *M* are lower by a lesser amount (6–27%). Clearly, reactivity is not totally suppressed in the aggregated species. This is evident in the plots of the absolute hydrolysis rate *versus* the total ester concentration (Fig. 8). Although break points are not as sharp in the kinetic data as in the partitioning data, apparent critical micelle concentrations estimated from extrapolation of the two linear portions of each curve agree fairly well with the apparent critical micelle concentrations reported in Table I.

Reaction rates continue to increase above the critical micelle concentrations indicating that reactivity in the micelles is not totally suppressed. From the slopes above the critical micelle concentrations in Fig. 8, rate constants for hydrolysis in the micelles can be obtained. Values of pseudo first-order rate constants for monomeric and micellar species, k_{mon} and k_{mic}, are listed in Table II for both hydrolysis and acyl migration. At high concentration (0.1 *M*), the reactions occurring in the micelles are actually the major contribution to the overall degradation rate. This accounts for the fact that stabilization is less than predicted based on the monomer concentrations.

Table II—Reaction Rate Constants for Monomeric and Micellar Species of Corticosteroid 21-Esters

Ester	Hydrolysis, min^{-1}		21 → 17 Acyl Migration, min^{-1}	
	k_{mon}	k_{mic}	k_{mon}	k_{mic}
21-Succinate	4.2×10^{-4}	7.4×10^{-5}	3.2×10^{-4}	3.9×10^{-5}
21-Adipate	3.1×10^{-4}	2.1×10^{-5}	—	—
21-Suberate	2.6×10^{-4}	8.1×10^{-6}	2.8×10^{-4}	9.5×10^{-6}

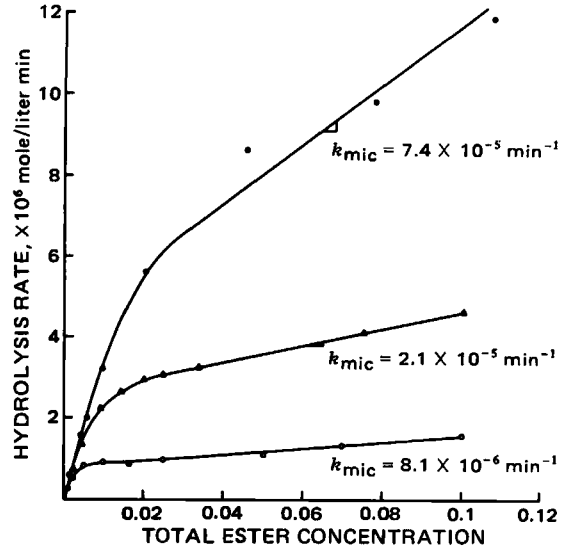

Figure 8—*Absolute hydrolysis rates* versus *total ester concentration (pH 8.5 and 25°). Key: (●) 21-succinate; (▲) 21-adipate; and (○) 21-suberate.*

The effect of chain length on stability was investigated for a similar series of hydrocortisone hemiesters by Garrett in 1962 (32). These studies were conducted in diluted alcoholic solutions, however, and it was concluded that chain length has no significant effect on corticosteroid ester stability. The results of the present study suggest that chain length does have a significant effect on stability, especially at higher concentrations. The 21-suberate of methylprednisolone is nearly an order of magnitude more stable than the 21-succinate at a 0.1 *M* concentration. This greater stability is due to a combination of factors: (*a*) a slight steric effect which increases with chain length is apparent in the reactivity of the monomeric ester; (*b*) self-association increases with chain length providing added stability to long-chain hemiesters by lowering monomer concentration; and, most important, (*c*) reactivity in the micelle apparently decreases with increasing chain length. As a result of these factors, methylprednisolone 21-suberate is >16-fold more stable at high concentration (>0.1 *M*) than in dilute solution.

By comparing Figs. 6 and 7 it is apparent that 21 → 17 acyl migration is suppressed by self-association to an extent similar to the suppression of hydrolysis. Since the approach of hydroxide ion is required for both reactions at pH 8.5, the similarity in behavior with self-association can be rationalized from simple electrostatic considerations (33). The decrease in the rate constants of both reactions with increasing chain length is not explained as readily. Since the effect is not specific for one mechanism, this must also reflect differences in the hydroxide ion activity in the immediate environment of the 21-ester linkage.

Effect of Ethyl Cellulose in a Medium-Chain Triglyceride on the Bioavailability of Ceftizoxime

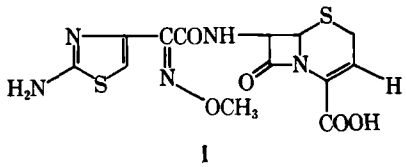
IKUO UEDA ˣ, FUMIO SHIMOJO, and JUN KOZATANI

Received February 22, 1982 from the *Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Osaka 532, Japan.* Accepted for publication July 16, 1982.

Abstract □ The oral bioavailability of new formulations of ceftizoxime sodium was investigated in animals and humans. In rats, one of the formulations tested showed significant improvement, with a urinary excretion of 47.7% (0–24 hr). Good results were obtained also in dogs. In humans, the mean peak serum level was 3.6 μg/ml at 3.3 hr postadministration for formulation 10. The average ceftizoxime AUC at 0–8 hr was 17.3 μg hr/ml and urinary excretion of ceftizoxime was 9.6% (0–24 hr). The concentrations in the serum exceeded the minimum inhibitory concentrations for most of the commonly encountered bacterial pathogens.

Keyphrases □ Bioavailability—oral ceftizoxime in rats, dogs, and humans, effect of ethyl cellulose in medium-chain triglyceride □ Ceftizoxime—bioavailability of oral formulations in rats, dogs, and humans, effect of ethyl cellulose in medium-chain triglyceride □ Ethyl cellulose—effect with medium-chain triglyceride on the oral bioavailability of ceftizoxime in rats, dogs, and humans □ Triglyceride, medium-chain—effect with ethyl cellulose on the oral bioavailability of ceftizoxime in rats, dogs, and humans

Ceftizoxime (I) is a new cephalosporin antibiotic which is active against both Gram-positive and Gram-negative bacteria.



I

The activity of ceftizoxime *in vitro* has been confirmed (1), and the reports on its clinical efficiency are numerous (2). The metabolism and pharmacokinetics of this drug have also been described (3). Ceftizoxime is administered parenterally for effective systemic action since it is poorly absorbed from the GI tract[1]. The purpose of this investigation was to determine the oral bioavailability of ceftizoxime after the administration of its sodium salt to animals and humans in new formulations produced with a combination of medium-chain triglyceride and ethyl cellulose as additives.

Attempts to improve the oral bioavailability of poorly absorbed drugs by devising different pharmaceutical formulations have been reported (4–6). Similarly, our efforts have been directed to the development of new oral formulations of ceftizoxime. We have systematically studied a number of hydrophilic and hydrophobic vehicles, surfactants, and nonsurfactants as additives and found that a combination of ethyl cellulose and a medium-chain triglyceride enhanced the oral absorption of ceftizoxime in rats, dogs, and humans.

EXPERIMENTAL

Materials—Ceftizoxime sodium[2] was prepared as described in the patent (7). Commercially available ethyl cellulose[3], polyethylene glycol 400[4], a medium-chain triglyceride[5], olive oil[4], and ethyl alcohol[4] were used in the suspensions.

Formulations—Formulations containing various amounts of ethyl cellulose were tested. A medium-chain triglyceride (50 ml) and ethyl cellulose (500 mg) dissolved in 1 ml of ethyl alcohol were mixed with stirring. The ethyl alcohol was removed under reduced pressure. Ceftizoxime sodium (5 g-potency) was then dispersed in the resulting vehicle to give the formulation of ceftizoxime used. Similar formulations containing olive oil or polyethylene glycol 400 instead of the medium-chain triglyceride were also investigated.

Absorption Studies—*Rats*—Six-week-old male Sprague-Dawley rats, weighing 160–230 g, were fasted for 18 hr. The rats were given the ceftizoxime sodium formulations (Table I) using a gastric tube at a dose equivalent to 20 mg/kg. Urine was collected for 24 hr, stored at −20°, and

Table I—Effect of Vehicle on the Urinary Excretion of Ceftizoxime after Oral Dosing in Rats with Ceftizoxime Sodium in Different Vehicles [a]

Vehicle	Cumulative Urinary Excretion (0–24 hr), % of dose [b]	
Polyethylene glycol 400	7.1	(5)
A medium-chain triglyceride	16.2	(3)
Olive oil	9.7	(3)
A medium-chain [c] triglyceride + ethyl cellulose	37.7	(9)
Olive oil [c] + ethyl cellulose	24.6	(5)
Water	10.3	(5)

[a] At a dose of 20 mg-potency/kg. [b] Values represent the mean; sample size is in parentheses. [c] Ethyl cellulose concentration in the vehicle ~1% (w/v); viscosity of ethyl cellulose was 100 cps.

assayed within 24 hr. The amount of ceftizoxime excreted was determined by high-performance liquid chromatography (HPLC) using a standard curve.

Dogs—The formulations used in the dog experiments are shown in Table II. Male beagle dogs weighing 8.0–13.2 kg were used, with four dogs per group. The animals were fasted overnight and the drug formulations (in hard gelatin capsules) were given in doses equivalent to 40 mg ceftizoxime/kg. Urine was collected for 24 hr; 5-ml venous blood samples were drawn at 0.5, 1, 2, 4, 6, and 8 hr postadministration and centrifuged to obtain the serum. All serum and urine samples were stored at −20° and assayed within 24 hr.

Humans—Formulations 3 and 10 (Table II) were used in the human experiments. Six healthy males, 33–47 years of age and 49.5–67.5 kg, participated in the study after informed written consent was obtained. No other drugs were taken during the investigation period. Prestudy physical examinations and laboratory parameters for all subjects were normal.

Experimental Design—A two-way crossover design was used in the human studies. The two formulations (3 and 10) were given orally to the six volunteers, at an interval of 2 weeks. The volunteers drank 200 ml of water immediately after ingesting the drug. All volunteers fasted overnight before dosing and were given regular meals 2 hr after dosing. Venous blood samples (5 ml) for assay of serum concentration of ceftizoxime were drawn 0.5, 1, 2, 4, 6, 8, and 24 hr postdose. Urine samples were collected at 2-hr intervals from 0 to 8 hr and for the interval 8–24 hr postdose. All serum and urine samples were stored at −20° and assayed within 24 hr.

Assay of Ceftizoxime—The concentration of ceftizoxime in the serum and urine was determined by HPLC[6]. Samples (5 μl) were injected directly into the HPLC equipped with a 254-nm detector and a stainless steel column (30 cm × 4-mm i.d.) packed with μ-Bondapak C_{18}[7]. The mobile phase was 0.6% potassium phosphate–0.2% sodium phosphate–acetonitrile (1:1:0.22). The system was operated at 2.0 ml/min with a column pressure of 2000 psi. Sample chromatograms are shown in Fig. 1.

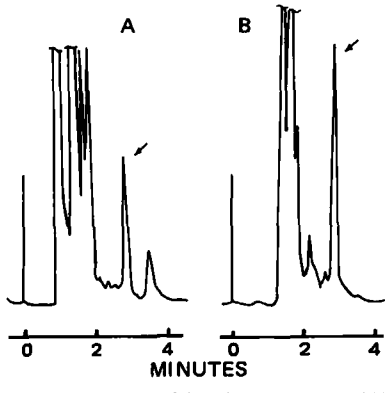

Figure 1—*Chromatogram of ceftizoxime in serum (A) and urine (B) after oral dosing with ceftizoxime sodium. The retention time of the ceftizoxime peak (indicated by the arrow) is 2.8 min in serum and 3.6 min in urine.*

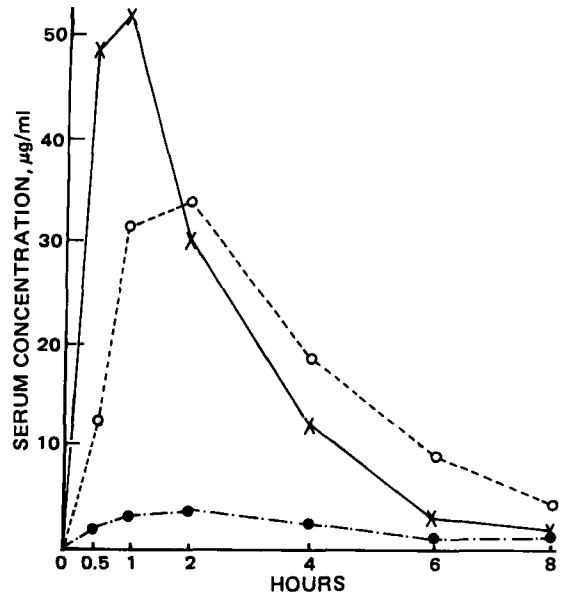

Figure 2—*Time plots of mean serum concentration of ceftizoxime in four dogs after oral dosing with formulations 3 (○) and 10 (×), and with a water vehicle (●) as the control. Dogs received ceftizoxime sodium (at a dose of 40 mg-potency/kg) in a hard gelatin capsule.*

Standard Curves—The reproducibility and linearity of standard curves generated from rat, dog, and human serum and urine containing various amounts of ceftizoxime sodium were studied. The standard curves represent triplicate analyses and were prepared over concentration ranges of 50–600 μg/ml for urine and 2–10 μg/ml for serum. In serum, the least-squares regression line had a slope of 5.324, intercept of −0.143, and correlation coefficient of 0.99996; the limit of detection is 0.2 μg/ml. In urine, the least-squares regression line had a slope of 0.152, intercept of 1.369, and correlation coefficient of 0.999969; the limit of detection is 5 μg/ml.

RESULTS AND DISCUSSION

Table I shows the urinary excretion of ceftizoxime in rats as the percentage of dose after oral administration of ceftizoxime sodium suspension in some typical vehicles. It was found that 10.3% of the dose was excreted when the drug was given in a simple water suspension (control). The urinary excretion of ceftizoxime was somewhat lower when polyethylene glycol 400 or olive oil was used; the medium-chain triglyceride slightly increased the drug bioavailability as evidenced by the urinary excretion rate of 16.2%. It was found, however, that coadministration of ethyl cellulose with ceftizoxime sodium in the medium-chain triglyceride significantly increased the drug absorption: 37.7% of the drug was excreted. The coadministration of ethyl cellulose in olive oil also produced considerably higher urinary excretion (24.6%). However, ethyl cellulose

Table III—Effect of Ethyl Cellulose in a Medium-Chain Triglyceride on the Urinary Excretion of Ceftizoxime After Oral Dosing with Ceftizoxime Sodium in Rats[a]

Ethyl Cellulose per ml of Medium-Chain Triglyceride, mg[b]	Concentration of Ethyl Cellulose in the Vehicle, % (w/v)	Cumulative Urinary Excretion (0–24 hr), % of dose[c]
2	0.2	25.5 ± 8.9 (3)
4	0.4	36.5 ± 7.1 (3)
6	0.6	47.7 ± 3.4 (3)
8	0.8	40.7 ± 8.0 (3)
10	1.0	37.7 ± 1.9 (9)

[a] At a dose of 20 mg-potency/kg, suspended in a medium-chain triglyceride. [b] Viscosity of ethyl cellulose was 100 cps. [c] Mean ±*SE*; sample size in parentheses.

did not affect the drug absorption when given in polyethylene glycol 400.

The data in Table III indicate that the effect of ethyl cellulose in the medium-chain triglyceride on the absorption of ceftizoxime in rats was dependent on the concentration of ethyl cellulose used. Ethyl cellulose in the range of 2–10 mg/ml significantly increased the drug absorption. The maximum effect was observed at ~0.6 % (w/v) ethyl cellulose. When ceftizoxime sodium in aqueous solution was administered intravenously to rats at a dose of 20 mg-potency/kg, the urinary excretion of ceftizoxime at 0–24 hr was 79.8% of the given dose[1]. The urinary excretions of 47.7% after oral dosing indicates that ~60% of the administered drug was absorbed.

The experiments in dogs were designed on the basis of these data. The formulations used in the dog experiments are shown in Table II. Figure 2 plots the serum concentrations of ceftizoxime in dogs as a function of time postdose with formulations 3 and 10. The maximum serum concentration of ceftizoxime was significantly higher for formulation 10 than formulation 3; but when the areas under the curve (AUC), calculated by trapezoidal rule, are compared, the differences between the bioavailabilities of formulations 3 and 10 are very small.

The bioavailability studies in dogs, using ethyl cellulose of three different viscosities (10, 45, and 100 cps), demonstrate that ethyl cellulose with a viscosity of 100 cps resulted in higher serum concentrations of

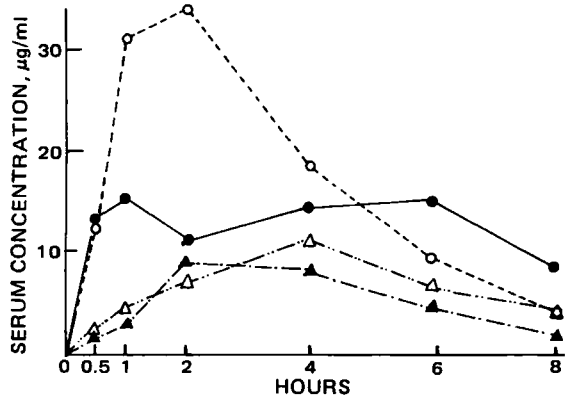

Figure 4—*Time plots of mean serum concentration of ceftizoxime in four dogs after oral dosing with formulations 2 (●), 3 (○), 4 (△), and 5 (▲). Dogs received ceftizoxime sodium (at a dose of 40 mg-potency/kg) in a hard gelatin capsule.*

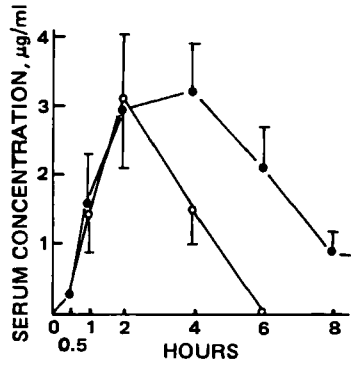

Figure 5—*Time plots of mean serum concentration of ceftizoxime in six human volunteers after oral dosing with formulations 3 (○) and 10 (●). The dose was 500 mg-potency/kg. The data points represent the mean values; standard errors are represented by the bars around each point.*

ceftizoxime than ethyl cellulose additives with viscosities of 10 and 45 cps (formulations 8 and 9) (Fig. 3).

The effect of the vehicle volume on the oral absorption of ceftizoxime was also investigated. Figure 4 shows the bioavailabilities (serum concentrations) in dogs for 5, 10, 20, and 50% (w/v) suspensions of ceftizoxime sodium in the medium-chain triglyceride containing ethyl cellulose (formulations 2, 3, 4, and 5, respectively). The oral absorption of ceftizoxime was shown to be dependent on the volume of the vehicle. The greatest absorption was observed with the 10% suspension, the next

[a] At a dose of 500 mg-potency/person. [b] — not detected.

greatest with 5% suspension. The mean AUC of the serum concentration–time curve for the 10% suspension was a little larger than that for the 5% suspension, which resulted in a lower maximum serum concentration with a longer duration. The 20 and 50% suspensions tended to produce smaller C_{max}.

Since the animal studies described above suggest that similar effects may occur in humans, a study of the effect of the two formulations that gave the highest serum concentrations in dogs was deemed appropriate. The serum concentrations and bioavailability parameters of ceftizoxime in human volunteers after oral dosing with formulations 3 and 10 are given in Table IV. The time courses of mean serum concentrations of ceftizoxime are shown graphically in Fig. 5. After oral dosing with formulation 3, the serum concentrations of ceftizoxime peaked at 2.0 hr and then declined rather sharply up to 6 hr. The mean (±*SE*) peak concentration (C_{max}) of ceftizoxime was 3.1 ± 0.9 μg/ml (range, 0.3–6.1 μg/ml) and the mean (±*SE*) concentration was 1.5 ± 0.5 μg/ml (range, 0.2–3.0 μg/ml) at 4 hr. After oral dosing with formulation 10, the serum concentrations peaked at 3.3 hr and then declined. The mean C_{max} was 3.6 ± 0.7 μg/ml (range, 0.5–5.7 μg/ml) and the mean concentrations were 2.1 ± 0.6 (range, 0.1–4.2 μg/ml) and 0.9 ± 0.3 μg/ml (range, 0.2–2.2 μg/ml) at 6 and 8 hr, respectively. Formulation 10 gave a slightly higher C_{max} (not statistically significant) and a longer T_{max} (statistically significant at $0.01 < p < 0.05$) than formulation 3. The mean AUC (±*SE*) for the serum concentration–time curve was 8.9 ± 2.6 μg hr/ml (range, 0.9–16.7 μg hr/ml) for formulation 3 and 17.3 ± 3.8 μg hr/ml (range, 1.4–27.9 μg hr/ml) for formulation 10. Thus, formulation 10 gave an AUC double that of formulation 3 (statistically significant at $p < 0.01$).

The urinary excretion of ceftizoxime in human volunteers after dosing with formulations 3 and 10 is given in Table V. The mean (±*SE*) cumulative urinary excretions of ceftizoxime for 0–24 hr were 4.4 ± 1.3% of the dose (range, 0.5–8.9%) for formulation 3 and 9.6 ± 2.3% (range, 0.5–17.8%) for formulation 10. Formulation 10 resulted in a cumulative urinary excretion double that of formulation 3 (statistically significant at $0.01 < p < 0.05$), thus confirming the AUC values.

As shown in Fig. 6, the concentrations determined in the serum over a period of 8 hr after a single dose of 500 mg-potency of ceftizoxime sodium (formulation 10) were found to exceed the therapeutically active level (minimum inhibitory concentration *in vitro*) against many Gram-negative organisms, including strains of *Escherichia coli*, *Klebsiella*, and *Proteus* (1, 2).

In conclusion, when compared with an aqueous solution of ceftizoxime sodium, formulations containing ethyl cellulose improved oral absorption of ceftizoxime. Formulation 10, which contained the higher additive concentration gave a larger ceftizoxime AUC value and higher urinary excretion than formulation 3. The concentration in the serum exceeded the minimum inhibitory concentration for normally encountered bacterial pathogens.

Correlation Between the Psychotropic Potency of Cannabinoids and Their Effect on the ^{1}H-NMR Spectra of Model Membranes

Keyphrases □ Membranes—model, correlation between psychotropic potency of cannabinoids and their effect on the ^{1}H-NMR spectra □ Cannabinoids—correlation between psychotropic potency and their effect on the ^{1}H-NMR spectra of model membranes □ Cholesterol—model membranes, correlation between the psychotropic potency of cannabinoids and their effect on the ^{1}H-NMR spectra □ Phosphatidylcholine—model membrane, correlation between the psychotropic potency of cannabinoids and their effect on the ^{1}H-NMR spectra

To the Editor:

Little is known of the mode of psychotropic action of Δ^1-tetrahydrocannabinol (I), the major active component of hashish (1). It has been suggested that this drug, as well as other psychotropic cannabinoids, exerts its psychotropic effect through a nonspecific interaction with lipid constituents of nerve cell membranes (2). To investigate such nonspecific interactions, phospholipid vesicles (liposomes) have been used as model membranes. These models represent an oversimplification of the complex biological membranes. However, the possibility of manipulating their composition and size permits deduction of the relative importance of the various structural and compositional factors of the membrane in determining the interactions of membranes with drugs. For the effect of a drug on the physical properties of a model membrane to be regarded as relevant to the mode of action of the drug, a correlation must be established between the effect of various derivatives of the drug and their potency on the membrane.

For psychotropically active cannabinoids, electron spin resonance measurements showed that these drugs reduce the order within the bilayer (3) when introduced into vesicles composed of phosphatidylcholine and cholesterol. The disordering effect of five different cannabinoids correlated qualitatively with their psychotropic potency. The psychotropically nonactive drug, cannabidiol (VI), increased the order parameter within the bilayer (3). Since electron spin resonance, as well as several other physicochemical techniques, involve the use of external probes, which might alter the bilayer properties, we have recently studied the effect of the cannabinoids, I and VI, on the ^{1}H-NMR spectra of lipid vesicles (4). The conclusions of this research were similar to those obtained from the electron spin resonance study: addition of small amounts of I (1 mole percent) to vesicles composed of egg phosphatidylcholine and cholesterol (2:1) caused narrowing of the apparent linewidth of the phospholipid methylene groups signal, whereas the chemically similar, nonactive compound, VI, had the opposite effect.

The purpose of the present work was twofold. First, we wanted to establish a correlation between the potency of various cannabinoids[1] and the effect of small quantities (1 mole percent) of these drugs on the apparent linewidth of the NMR resonance of the phospholipid hydrocarbon chain protons in model membranes composed of egg phosphatidylcholine and cholesterol. Second, in a previous work we showed that in the absence of cholesterol in the model membranes, small amounts of I do not produce any significant change in the linewidth of the ^{1}H-NMR resonances. Therefore, we found it of interest to study the role of cholesterol in the interactions of I with the model membranes. These interactions most likely are not due to the existence of specific interactions of I with cholesterol, since there is no evidence for such interactions in the ^{1}H-NMR spectrum of a mixture of these two components in chloroform (4). One alternative explanation was that the lack of a fluidizing effect in the absence of cholesterol is due to the disrupted packing in the highly curved small unilamellar vesicles (5–7). More specifically, vesicles formed by sonification of mixtures of phosphatidylcholine and cholesterol are larger and less curved than those made of the pure phospholipid by the same method. This may cause the difference between the effect of I on vesicles with and without cholesterol. To investigate this possibility, we studied the effect of cannabinoids on the larger vesicles (~500-Å diameter) made of pure phosphatidylcholine by the French press method (8). The results of this study, in conjunction with the dependence of the fluidizing effect of I on the cholesterol content in the vesicles, indicate that cholesterol is important in the interaction of this drug with model membranes.

The model membranes were prepared as follows: solutions of phosphatidylcholine[2] and cholesterol[3] in chloro-

form were mixed at appropriate molar ratios, and the organic solutions were evaporated to dryness under nitrogen and then lyophilized. The dried mixtures were dispersed in deuterium oxide[4] to the proper concentration. Small unilamellar vesicles were prepared from these dispersions by ultrasonic irradiation[5] until clear dispersions were obtained. French press vesicles were prepared by a previous method (6)[6]. The final concentration of phosphatidylcholine for ^{1}H-NMR measurements was 50 mg/ml.

The drugs were dissolved in deuterated dimethyl sulfoxide[4], and their solutions were added to the prepared liposome dispersions to give the appropriate molar ratio of drug–phosphatidylcholine. ^{1}H-NMR spectra were recorded immediately after sonication[7]. All spectra were recorded without accumulation and under the same conditions of radio frequency (RF) and modulation. The ^{1}H linewidths ($\Delta\nu_{1/2}$) were measured using a spectral width of 10 Hz/cm and sweep rate of 1 Hz/sec and are expressed as the difference between their measured values and the width of the ^{1}H—O—^{2}H signal in the same spectrum. Each result is an average of at least four consecutive scannings under the same conditions of RF and modulation. The experimental errors, indicated in Figs. 1 and 2, represent the deviation of the results from their averages. Care was taken to ensure reproducibility in the base line determination. This was achieved by the use of the base line of the corresponding spectrum determined at a spectral width of 40 Hz/cm.

Figure 1 shows that addition of 1 mole percent of I to sonicated egg phosphatidylcholine vesicles does not change the apparent linewidth of the methylene group signal, whereas in cholesterol-containing vesicles, a small but reproducible narrowing is observed.

The effect of several other cannabinoids on the cholesterol-containing model membranes (Table I) shows a qualitative correlation between the apparent narrowing caused by the various cannabinoids and the psychotropic potency of these drugs. In spite of the difficulties in the interpretation of ^{1}H-NMR linewidths (5, 10, 11), we believe that this apparent narrowing is due to a drug-induced reduction of the restriction of the phospholipid molecular motions. However, other possibilities should also be considered. It may be thought that the signals of some protons are actually broadened by I beyond detection, which would result in an apparent narrowing of the bulk super Lorentzion methylene signal (12). This possibility can be ruled out, since the methylene signals studied are fully detected in all the spectra, as is evident from the constant ratio of intensities of the methylene–choline signals. It is also highly improbable that vesicle–vesicle interactions cause this line narrowing, as the opposite effect is expected from such interactions (5, 13). Thus, it may be concluded that in cholesterol-containing vesicles, I reduces the restriction of molecular motions of the phospholipid hydrocarbon chains. The correlation between the narrowing produced by various cannabinoids in lecithin cholesterol model membranes and the psychotropic potency of these drugs (Table I) supports the hypothesis that the reduction of molecular motion may be relevant to the psychotropic action of the cannabinoids. This is in agreement with an earlier conclusion (3), based on studies of electron spin resonance order parameters.

In an attempt to elucidate the role of cholesterol in this phenomenon, we carried out two additional experiments. First, we measured the effect of I on the apparent linewidth of pure phosphatidylcholine vesicles made by extrusion of the phospholipid through a French pressure cell (8). The latter vesicles are significantly larger than the extremely curved vesicles made by ultrasonic irradiation. Nonetheless, addition of I to the French press vesicles did not cause any narrowing of the proton signals (Fig. 1). This result is

[4] Deuterated solvents were purchased from Merck; deuterium oxide was 99.7% pure, $^2H_6$-dimethyl sulfoxide was 99% pure.

[a] ($\Delta\nu_{1/2}$) had the value of 85 ± 1.5 Hz for phosphatidylcholine–cholesterol (molar ratio 1:2) sonicated vesicles in the absence of cannabinoids but with 0.4% (v/v) dimethyl sulfoxide. $(\Delta\nu_{1/2})_{app}$ is the change in this parameter induced by various cannabinoids. [b] The psychotropic activity of the various compounds for rhesus monkeys as defined previously (9).

similar to that observed for the small vesicles of pure phosphatidylcholine and differs significantly from the result obtained upon addition of the drug to cholesterol-containing small vesicles. In another series of experiments, we studied the dependence of the line narrowing produced by 1 mole percent of I on the cholesterol content of small (sonicated) vesicles. As seen in Fig. 2, introduction of I results in a significant narrowing of the ^{1}H-NMR resonances, provided that the model membrane contains cholesterol.

The dependence of the line narrowing, produced by 1 mole percent of I on the cholesterol content of the membranes (Fig. 2), indicates that for cholesterol contents of ≥40 mole percent, the narrowing is maximal, and the drug reduces the motional restriction of the phospholipid paraffinic chains to the extent obtained at much lower cholesterol concentrations. This is in accord with the idea that the narrowing is not caused by a strong specific interaction with a well-defined stoichiometry between I and cholesterol. It is also consistent with the high-resolution NMR studies of mixed solutions of these components in chloroform (4). Nonetheless, the lack of line narrowing, in the absence of cholesterol in vesicles of larger sizes, suggests that the narrowing in cholesterol-containing vesicles (Fig. 1) is not due only to the tighter basal packing in these vesicles (6).

The role of cholesterol in the interaction of cannabinoid with the model membranes is not clear and will have to be investigated further. Nevertheless, the present results suggest that cannabinoids probably exert their psychotropic effect by altering the physical properties of the lipid matrix of membranes through a mechanism in which cholesterol plays an important role.

Experimental Evidence for Concentration-Dependent Plasma Protein Binding Effects on the Apparent Half-Lives of Restrictively Cleared Drugs

Keyphrases □ Plasma protein binding—concentration dependent, effects on the apparent half-lives of restrictively cleared drugs □ Pharmacokinetics—experimental evidence for concentration-dependent plasma protein binding effects on the apparent half-lives of restrictively cleared drugs □ Disopyramide—experimental evidence for concentration-dependent plasma protein binding effects on the apparent half-lives of restrictively cleared drugs

To the Editor:

Several early publications have addressed the influence of concentration-dependent (nonlinear) plasma protein binding on the pharmacokinetics of drugs which undergo restrictive clearance (elimination is proportional to free, unbound drug in serum or plasma) (1–3). Relatively simple models which excluded the influence of tissue binding were used to simulate plasma concentrations of free drug (C_f) and of total (free plus protein bound) drug (C_t). More recently, these earlier studies were extended (4) to include models which consider tissue binding and drugs which undergo nonrestrictive clearance (elimination is proportional to total drug in plasma). It was reported that log concentration–time plots of the elimination phase of C_f and C_t for drugs which undergo restrictive clearance may be linear, concave, or convex, depending on the extent to which drugs are bound to plasma and tissue protein (4).

Experimental data verifying the results of these simulation studies in humans are difficult to obtain because of the absence of a model drug which demonstrates concentration-dependent plasma protein binding at plasma concentrations achieved following the administration of safe, therapeutic doses and the absence of an analytical method sensitive enough to accurately measure plasma concentrations for extended time periods following the administration of safe doses of the drug. This is because the behavior of the decay of plasma concentration–time plots may require a wide concentration range to be expressed fully.

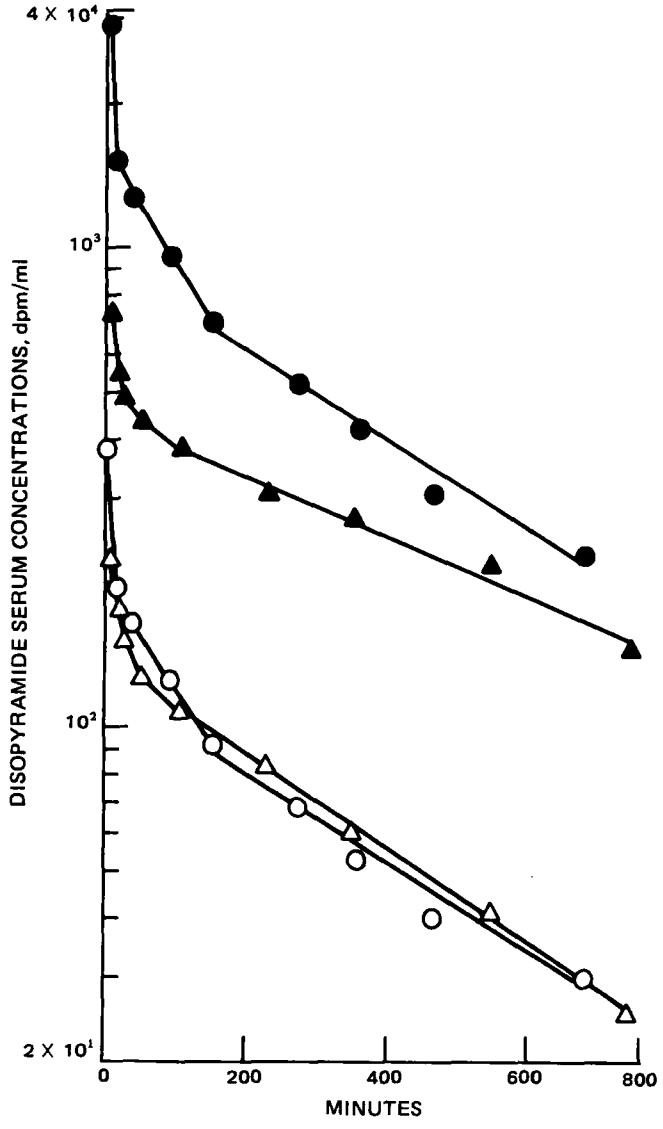

Figure 1—*Free (○,△) and total (●,▲) serum concentrations of [¹⁴C]disopyramide at various times following the administration of carbon 14 alone (○,●) and the simultaneous administration of [¹⁴C]disopyramide and the oral dose (△,▲). In each case a linear regression line was drawn through the last 5 serum concentration–time points.*

Table I—Pharmacokinetic Parameters of [^{14}C]Disopyramide

	Total (Bound + Free)				Free		
	Dose dpm	Dose[a], $AUC_{0\to\infty}$ ml/min	$t_{1/2}$[b], hr	V_{ss}[c], liters	Dose[a], $AUC_{0\to\infty}$ ml/min	$t_{1/2}$[b], hr	V_{ss}[c], liters
Tracer alone	2.09×10^7	42.7	5.3	18.0	329	5.3	138
Tracer plus oral dose	1.93×10^7	62.8	7.9	41.3	308	5.0	121

[a] *AUC* refers to the area under the [^{14}C]disopyramide concentration time curve calculated by trapezoidal rule. [b] The parameter $t_{1/2}$ refers to half-life and was calculated by: $t_{1/2} = 0.693/\lambda_z$, where λ_z is the apparent terminal slope of the serum concentration–time plot. [c] The parameter V_{ss} refers to volume of distribution at steady state.

Recent studies show that α-1-acid glycoprotein accounts for most of the plasma protein binding of disopyramide in humans (5, 6) and that plasma protein binding is concentration-dependent following the administration of therapeutic doses to patients (7) and normal subjects (6, 8). Furthermore, the clearance of disopyramide is restrictive (6–8), and pharmacodynamic activity is proportional to C_f (6). The systemic availability of disopyramide has been compared in a small group of patients and normal subjects by the administration of a 150-mg oral dose followed by an intravenous injection of 10 μCi of [^{14}C]disopyramide (specific activity = 4.259 mCi/mmole) (9) 1 hr later. At a later time, one of the normal subjects received a second tracer dose of [^{14}C]disopyramide alone. Prior to each dosing plasma was collected, and the binding of disopyramide was characterized as previously described (6).

Figure 1 compares the serum concentrations of [^{14}C]-disopyramide following the simultaneous administration of tracer and the oral dose with those following administration of just the tracer dose. Values of C_t as determined by liquid chromatography (10) following the simultaneous administration of tracer and oral disopyramide ranged between 2.47 (7.26×10^{-6} *M*) and 0.98 (2.89×10^{-6} *M*) μg/ml, respectively. The corresponding free fractions (*fu*) of the drug in plasma ranged between 0.32 and 0.18, respectively. Values of C_t, which were calculated from the specific activity, ranged between 9.4×10^{-9} and 4.0×10^{-7} *M* following administration of the tracer dose alone. The *fu* at these C_t values was 0.13 and was concentration independent. Table I compares the clearances of free ($Div/AUC^{free}_{0\to\infty}$) and total ($Div/AUC^{tot}_{0\to\infty}$) disopyramide concentrations, their respective half-lives ($t_{1/2}$), and steady-state volumes of distribution (V_{ss}). These data show that the pharmacokinetics of disopyramide calculated based on total serum concentrations are drug concentration dependent, while those based on free disopyramide are concentration independent at the concentration studied (300-fold range). The data also show that the $t_{1/2}$ of C_t is prolonged as compared with the $t_{1/2}$ calculated from C_f values when the plasma protein binding of disopyramide is drug concentration dependent. These data indicate further that as C_f and C_t decrease as a consequence of elimination following the simultaneous administration of the tracer and the oral dose, *fu* decreases to a limiting value, at which time the decay in C_f and C_t are parallel. Thus, the decay in C_t is convex over the drug concentration range achieved in this study.

It was reported (4) that in the absence of tissue binding, the decay in C_t–time data is convex when the ratio of the binding capacity of the drug-binding protein to its dissociation constant is low (low and high ratios of 9 and 100, respectively, were reported) or when tissue binding is moderate to extensive (tissue free fractions of 0.5 and 0.1, respectively, were reported). The ratio of the binding constants characterizing the interaction between disopyramide and α-1-acid glycoprotein in the serum of the subject was ~7.0, and the tissue free fraction was ~0.05 (11). Thus, the convex curvature in the terminal disopyramide C_t–time plot is consistent with previous findings (4) and provides at least some experimental support for the simulation studies described therein. Employment of tracer dose techniques provides another method (12) of examining the influence of concentration-dependent plasma protein binding on the pharmacokinetics of drugs.

The "Weak Link" in New Drug Research

No matter how critically we might examine the subject, there is no denying that the United States has a very comprehensive set of laws and regulations governing the research, testing, development, manufacture, packaging, promotion, and marketing of new drugs intended for human use. All of this did not come about overnight, nor without various triggering incidents—usually adverse—along the way that prompted Congress to enact new legislation or the Food and Drug Administration to adopt pertinent additional regulations.

The present result is that virtually each of the steps listed above now entails very elaborate, complex facilities, personnel, and equipment. No longer is the drug manufacturing business a viable activity for "the little guy." By yesterday's standards, even the smallest drug companies today are rather large, and they are only "small" in comparison to the giants and near giants that are their "friendly competitors."

For the most part, this development has been a good one because it has resulted in more highly qualified personnel, better equipment, and an overall improved standard of manufacturing performance. Long gone is the "cottage industry" dimension of the U.S. pharmaceutical industry.

At least, long gone in every area except one. And, unfortunately, that remaining area is proving to be the most serious weak link in the entire continuum that eventually leads to the successful marketing of an important new drug.

We are referring to clinical testing, and the fact is that even the largest drug companies conduct very little clinical research themselves. Traditionally, such testing is done by independent clinical investigators affiliated with universities, or teaching hospitals, or operating as very small testing laboratories.

Many disinterested observers have considered this to be a good arrangement; in fact, many of us have regarded it as the preferred one. We have thought that such independence would result in more truthful, reliable, and objective testing and test reporting.

Naturally, as with every aspect of life, we expected that there would be some flaws in this system; that some investigators would be charlatans; and that some drug firms might succeed in getting certain drugs approved that otherwise would not quite make it. Indeed, because of some abuses years ago, the FDA had found it necessary to adopt procedures designed to assure that only qualified investigators are engaged in clinical drug testing; that their facilities, record-keeping practices, and general operating procedures adhere to acceptable standards; and that there is a system for disqualifying, censuring, and permanently barring violators.

But drug testing is far from being an exact science, and despite these safeguards, certain investigators began to develop informal reputations as being far more likely to produce a test report favorable to the drug under study than if it were tested by most other investigators in the field. In turn, this induced at least some drug firms to engage in "investigator shopping." Such "shopping" would not be with the idea of being charged a lower fee for the work, but rather with the objective of benefiting from the conscious or unconscious bias of certain investigators.

But apparently, these personal propensities were equally apparent to the FDA as they were to the drug firms, and most companies quickly concluded that their drugs would fare far better in the FDA review process if they had been tested by one or more of the clinical investigators who enjoy a reputation for being tough critics in their work.

So it appeared that the system—though ever so delicately balanced—would survive and would continue to fulfill its purpose in an acceptable manner.

Sadly, however, the system was recently dealt a severe blow which causes us to reconsider our long-held belief that the independent clinical investigator system must be maintained and preserved at all costs. Specifically, there has been a rash of cases of fabricated or falsified data, and they have come from some very highly respected clinical investigators.

Indeed, the severity of the problem recently prompted *The Washington Post* to run a lead article headlined "FDA, Citing Phony Evidence, Bars Drug Tests by Researcher," and subtitled "Wave of False Medical Experiments." This March 23 article specifically reports on the chicanery of a "leading heart specialist," who is named and quoted in the article.

"The case is one of the most important in a wave of phony medical testing that is raising new concerns in federal health agencies, which rely heavily on such data to help them determine a drug's safety and effectiveness," according to the article in the *Post*.

An NIH staff official is quoted as saying that until about 1980 cases of phony medical research by NIH grantees came up rarely, "perhaps once every other year," but since then such cases "are cropping up so often, they can't be dealt with as isolated events."

The article went on to cite other facts and figures including: (*a*) seven physicians have signed a new type of "consent agreement" with FDA that they will not test future investigational drugs, (*b*) FDA's ruling of eight other physicians as ineligible to receive investigational drugs, and (*c*) several criminal prosecutions of investigators during the past year.

But the article focused on the heart specialist because it pointed out that "(his) prominence, however, makes his case stand out." He was an FDA outside advisor for six years; he was the president of a prominent society of cardiologists; he published over 200 scientific papers; he served as an advisor for 21 professional journals; and he has been a formal "consultant to numerous federal and state agencies, the American Medical Association's Department of Drugs, and the American Heart Association."

Undoubtedly, there are still many honest and reliable clinical investigators. However, these recent experiences show that the present system is no longer reliable, and therefore it is no longer acceptable. If we are misled as to whether the drug entity itself is effective, what purpose is served by elaborate good manufacturing practice requirements, extensive quality control protocols, or scrupulous adherence to rigid advertising limitations? Indeed, the clinical testing is the very heart of the entire process.

Whenever past defects at one point or another in that process have been uncovered, Congress, the FDA, or the scientific community—individually or collectively—have moved to institute corrective changes. It appears that such changes must now be made in this last of the drug-related "cottage industries," if we are to have continued confidence in the effectiveness of our new drug supply.

> —William Harvey, M.D., 1628

INTRODUCTION

The rat has been a useful laboratory animal in virtually every area of biological and medical research since its introduction to the laboratory in adrenalectomy studies in 1856 (1). The history of the development of the rat as a laboratory animal is a fascinating story that has been well presented elsewhere (2, 3). Briggs and Oehme (4) recently provided a very useful summary of the types of pharmacokinetic and toxicological studies commonly conducted to evaluate the safety and efficacy of xenobiotics in the rat.

Pharmaceutical, pharmacological, and toxicological studies of xenobiotics in the rat often require collection of urine, feces, blood, bile, and various other body fluids. A search of the literature was conducted to locate methods for collection of these various fluids and excreta from the rat. The goal of this literature survey is to provide infor-

Table I—Summary of Normal Parameter Values in the Adult Laboratory Rat [a]

Parameter	Normal Range or Mean
Life span	2.5–3 years
Surface area	0.03–0.06 cm^2
Water consumption	80–110 ml/kg/day
Food consumption	100 g/kg/day
Body temperature	37.5°
Gestation	21–23 days
Litter size	8–14 pups
Birth weight	5–6 g
Heart rate	330–480 beats/min
Blood pressure	
Systolic	88–184 mm Hg
Diastolic	58–145 mm Hg
Stroke volume	1.3–2.0 ml/beat
Cardiac output	10–80 ml/min (mean = 50 ml/min)
Plasma volume	36.3–45.3 ml/kg (mean = 40.4 ml/kg)
Blood volume	57.5–69.9 ml/kg (mean = 64.1 ml/kg)
RBC volume [b]	3.63 ± 0.10 ml/100g (mean ± *SEM*)
Respiration rate	66–114 per min (mean = 85.5 per min)
Tidal wave	0.60–1.25 ml (mean = 0.86 ml)
Plasma pH	7.4
Urine pH	7.3–8.5
Albumin Pools [c]	
Extravascular	365 mg/100 g body weight
Intravascular	127 mg/100 g body weight

[a] Values abstracted from Baker *et al.* (20) unless otherwise indicated. [b] Bruckner-Kardoss and Wostmann (53). [c] Sellers *et al.* (56b).

mation that will inform the experimental pharmaceutical scientist regarding available methodologies and aid the experimentalist in choosing the best method for the intended application. In addition, it is hoped that this publication will prove to be a valuable tool for introducing research trainees to the wealth of biological samples and data that can be gathered from the live animal using existing experimental methods.

Periodically, various authors have provided a review of methods in use for laboratory investigation of the rat (5–21). Such updates must be done, since scientists working with rats are constantly developing new apparatus and better techniques with special application to laboratory problems. This ongoing methodology research supports efforts to minimize animal (and scientist) stress and thereby ensure a humane research environment.

Kraus (21) has written the most recently published review of laboratory research methods for the rat. This review (including 672 references) provides a comprehensive introduction to all types of methodology including animal handling, body fluid collection, xenobiotic administration, anesthesia, and euthanasia methods. Excellent reviews of more basic information such as handling methods, laboratory personnel safety, injection procedures (volume, pH, and methods), blood collection techniques, methods for general anesthesia, and techniques for common surgical procedures have been provided by Waynforth (12) and Singh (22). A very useful introduction to basic surgical skills, from proper procedures for donning sterile gloves and gown to stages of anesthesia, has been assembled by Singh (23). The importance of aseptic techniques in rat surgery has been emphasized by Popp and Brennan (24). The reviews of previous authors were used as a gateway to the extensive literature in this area.

This review attempts to gather, for summary and comparative purposes, the literature on methods of vascular access and collection of body fluids for the rat. Papers were selected from the published literature through January 1982. Although extensive literature is summarized, some citations inadvertently may have been omitted. Nonetheless, most available methods are summarized. Since many scientists from diverse fields of study have developed methodologies for the rat, it often is difficult to attribute the origin of a particular method to a specific scientist or laboratory. Therefore, originators of most methods are not identified.

It is widely assumed that the rat is devoid of superficial blood vessels accessible to percutaneous puncture. Therefore, the novice may assume that technically complex surgical methods must be mastered to collect the blood and other biological fluids essential to whole-animal studies. Unfortunately, these assumptions have fostered, by default, a trend toward studies on isolated cells and subcellular fractions when whole-animal studies would be more appropriate. In reality, there are a multitude of surgical and percutaneous methods for acute and chronic vascular access, as well as methods for collection of other biological fluids and excreta.

In this review, summaries of these procedures are outlined in a tabular presentation. In conjunction with the tables, considerations of fundamental methodology are discussed.

GENERAL CONSIDERATIONS IN RAT EXPERIMENTATION

The purpose of this section is to guide the reader to general, but essential, information on the use of rats in laboratory science. Scher (25) has written a concise summary of some factors to be considered in designing any laboratory animal experiment. These factors include selection of the appropriate animal species, writing an experimental protocol, and procedures for data analysis.

Anatomy—Several books illustrating the anatomy of the rat are available (6, 26–31). The most recent of these anatomy texts (31) is very useful in the laboratory as it is a photographic atlas in color. A stereotaxic atlas of the rat brain has been assembled (32). The scientist seeking detailed anatomical information is referred to the atlas compiled by Greene (26). Anatomical structures in this review are referred to using the nomenclature of Greene (26).

The anatomy of specific parts of the vasculature has been summarized by several authors. Halpern (33) provided a well-illustrated, detailed manuscript on coronary circulation in the rat, while Chambers and Zweifach (34) studied the capillary beds of the visceral tissues. Several workers have reported on the collection of blood from the so-called orbital plexus (35–37) or orbital sinus (38–44). The anatomy of the orbital vasculature in the rat has been detailed by Timm (45), who demonstrated the presence of an orbital venous plexus (with no anatomical venous sinus) in the eye. Of the various veins, the caudal–dorsal anastomotic vein is defined as the major anatomical site accessible to venipuncture.

The rat differs anatomically from humans in several respects (46). Cardiac (33) and omental circulations (34) differ from their human counterparts. The rat has a relatively smaller thyroid, brain, and lungs than the human (47). The rat has no gallbladder (26), and is capable of liver regeneration following subtotal hepatectomy (48). In addition, Nairn (49) has demonstrated the presence of a di-

rect transdiaphragmatic pathway for fluid transfer between the peritoneal and pleural cavities.

Physiology—Average values in the rat for organ weights (50), hematological parameters (50–52), blood volume (53), several serum enzymes (54), physiological parameters (20), breeding characteristics (55), and interspecies comparative hematology (56a) have been enumerated and are briefly summarized in Table I. The pathophysiology of aging rats has been recently reviewed (57). A wealth of biological data on the rat were compiled by Donaldson (58). Blood flow to various organs of the rat has been detailed (59, 60). Such data, along with organ–blood flow data in humans, have been used in animal-to-human scale-up methods for physiological pharmacokinetic models (61–64).

The usual nutritional requirements of the rat (65–67) are met by a variety of commercial feeds. The rat has proven particularly useful in nutrition research because it is susceptible to dietary induction of various vitamin and amino acid deficiencies. Newberne (68) discussed the possible influence of dietary factors on pharmacological experiments.

The particular susceptibility of the rat to chronic respiratory disease has been well reviewed (69). Although contraction of human disease from laboratory rats seems to be rare, scientists should be aware of rat-borne infectious zoonotic diseases, reviewed elsewhere (70). The allergic respiratory disease commonly contracted by scientists working with various laboratory animals, including the rat, was detailed by Lutsky and Toshner (71).

Housing—Cages and rooms for housing rats must meet two essential requirements. First, the housing must facilitate maintenance of the health and comfort of the animals. Second, the cages must satisfy the requirements of the specific experiment, *e.g.*, metabolism, restraining, or exercise cages. Current space recommendations for rats are cages of 17.8 cm in height for rats of all weights, with floor surface areas of 110, 148, 187, and 258 cm^2 for rats weighing <100, 100–200, 201–300, and >300 g, respectively (72). The following equation (73) has been used in estimating the floor surface area (A, cm^2) needed for one rat of a given weight (w, g):

$$A = 0.7w + 6\sqrt{w} \qquad \text{(Eq. 1)}$$

A well-ventilated animal room should be maintained at a constant temperature within 20–25°, with relative humidity kept at 50–65% (74). Bedding for rat cages must be selected carefully since the use of softwood chips (*i.e.*, red cedar, white pine, ponderosa pine) can result in the induction of microsomal enzyme activity (75). More specific information on cages and animal rooms can be found elsewhere (6, 72, 74). Metabolism cages are discussed later in this review.

Handling—The rat can be lifted easily by the root of the tail. Since rats seem more at ease when their paws are in contact with something, one easy way to move a rat is by holding the root of the tail and resting the rat's body on the mover's hip (Fig. 1). Rats may also be picked up by slipping a hand over the shoulders to restrain its head between the thumb and first finger (Fig. 2). This procedure can be combined with restraint of a hind limb using the fifth finger of the free hand to provide a hold for intraperitoneal injection (Fig. 3). Pregnant rats should not be lifted by the tail, but either with the support of a hand under the body or with a hand over the shoulders, as described above. Gloves may be useful for momentarily restraining a rat by hand (see *Momentary Restraint*).

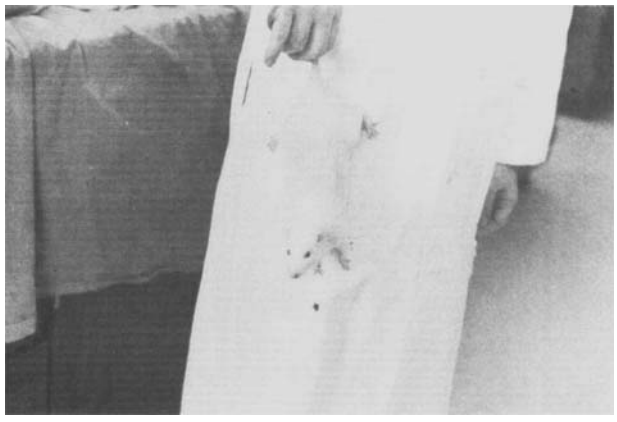

Figure 1—*Illustration of an easy method for moving a rat, without undue animal stress, around the laboratory. The rat usually remains calm while resting against the coat.*

Anesthesia—Surgical anesthesia in rats has been discussed in detail previously (21, 23, 76–82). In addition, laboratory animal scientists are advised to read an informative review of the health risks associated with chronic exposure to various gaseous anesthetics (83a).

In many laboratories, the rat is anesthetized with ether (peroxide-free, anesthetic grade) by the introduction into a large dessicator jar containing an elevated wire-mesh floor and ether, followed by maintenance of anesthesia using a 50-ml beaker containing an ether-moistened surgical sponge placed over the nose of the rat (Fig. 4). More elaborate anesthesia chambers have been described (83b). Ether anesthesia is generally administered for <5 min when brief procedures are performed immediately on the rat. If ether is administered for longer periods of time, the rat is given at least 1 day to recover to avoid experimentation during a time period in which plasma volume may be decreased due to the ether anesthesia (84). Extended (>5 min) exposure to ether vapors will irritate the eyes of the rat. This irritation is indicated in the postoperative conscious rat by increased blinking and grooming of the eyes and head with the forepaws. Topical preoperative application of one drop of an artificial tear preparation[2] to each eye prevents irritation[3].

Although ether is a widely used, reliable anesthetic, maintaining the proper depth of anesthesia requires constant, careful supervision of the rat to avoid respiratory arrest. The depth of ether anesthesia can be difficult to judge, but some useful guidelines have been presented (12). Although ether has been administered by intraperitoneal injection (85), this may cause peritoneal inflammation and adhesions, and therefore is a relatively uncommon route of administration. Several masks and other apparatus for inhalation-anesthetic delivery have been described (86–92). Of these, that described by Stark and Lipman (91) is inexpensive and can be constructed easily from a 135-ml (4.5-oz) plastic specimen jar, a 23-gauge butterfly infusion set, and a 1-ml glass syringe. Such an apparatus is useful

for administering halothane[4], ether, or methoxyflurane[5] anesthesia.

Pentobarbital[6] (30–40 mg/kg) administered intraperitoneally is a commonly used anesthetic for the rat (77, 93). Valenstein (94) has provided a table of intraperitoneal injection volumes for anesthesia *via* pentobarbital in conjunction with chloral hydrate. Pentobarbital (21 mg/kg ip) has been advantageously used in conjunction with intramuscular ketamine[7] (60 mg/kg) to induce surgical anesthesia (95). Ketamine has also been used alone (96) for acute drug-induced immobilization to facilitate cardiac puncture (22 mg/kg) and for surgical anesthesia (44 mg/kg), but its use is difficult in view of the highly variable depth of anesthesia induced by a given dose (97). Chloral hydrate (300 mg/kg ip) is still used in some laboratories, despite an ~50% incidence of adynamic ileus after a chloral hydrate administration of 400 mg/kg ip (98). A combination product[8] containing fentanyl (0.4 mg/ml) and droperidol (20 mg/ml) is available for intramuscular injection. Doses of 0.1–0.5 ml/kg have been used to induce surgical anesthesia (99–101). Alfaxalone–alfadolone combination has been used as an intravenous surgical anesthetic (102). Methohexital[9] has proven useful as an intravenous anesthetic for periodic endotracheal intubation of the rat (103).

Figure 3—*Use of the over-the-shoulder grip with the left hand to restrain the head and upper body (note the crossed forelimbs), while restraining via the fifth finger of the right hand the hind limb on the side of the peritoneum to be injected intraperitoneally. The thumb, first, and second finger of the right hand are free to administer the injection (via a syringe of appropriate volume and usually a 23-gauge, 1-in. needle).*

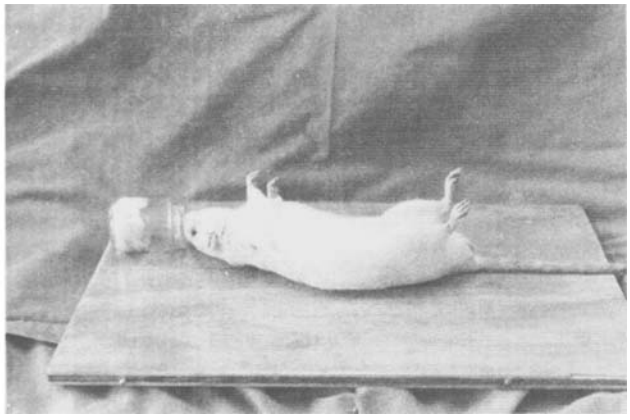

Figure 4—*The rat reclining on a home-built surgical board (41-cm long × 27-cm wide × 1-cm thick plywood painted with polyurethane varnish) while breathing some ether vaporized from an ether-moistened surgical sponge packed in the bottom of a 50-ml beaker. This procedure should be restricted to a fume hood to reduce the flammability risk of ether use.*

Parker and Adams (104) have reviewed the effects of six common anesthetics (α-chloralose, droperidol, fentanyl, halothane, ketamine, and pentobarbital) on cardiovascular function in various laboratory animals. Researchers studying the aspects of cardiovascular function in the rat should find this review helpful in choosing an anesthetic or chemical restraining agent.

Scientists placing animals under surgical anesthesia are advised to keep a resuscitation device available. Two readily constructed resuscitators have been described (105, 106). For rats with an ether overdose, some experimentalists prefer to employ the simple device described by Rassaert (106) as this can be used both to aspirate mucus from the respiratory tract and force air into the lungs. However, the simple two-bulb resuscitator described by Ingall and Hasenpusch (105) has been used successfully. In addition to these resuscitators, Shuer *et al.* (107) devised a simple mask for the artificial respiration of rats *via* a positive-pressure respirator. This procedure avoids the problematic procedures of tracheotomy (78, 108) and endotracheal intubation (103, 109, 110).

Lineberry (111) has recently provided a highly informative review of animal models used in pain research. However, we are not aware of any detailed information on either postoperative assessment or therapeutic management of pain in the laboratory rat. Brief discussions of the general aspects of postoperative care are available (23, 112). Since the majority of scientists working with laboratory rats do not have formal training in veterinary medicine, a detailed review of all aspects of postoperative care would be a valuable contribution to the literature.

Xenobiotic Administration Procedures—Procedures are described elsewhere for administration of substances to the rat *via* the oral, percutaneous, intravenous, intra-

muscular, intraperitoneal, subcutaneous, intra-arterial, and intracardiac routes (6, 12, 21, 113–115). Shani *et al.* (116) designed a device for the oral administration of gelatin capsule doses to rats. The use of subcutaneously implanted devices (117) and subcutaneous infusions (118) for long-term xenobiotic administration, first applied to rats by Rose and Nelson (117), has been advanced by the commercial availability of uniform osmotic pumps[10]. Novin *et al.* (119) devised an airtight injection system which minimized the need for handling unrestrained rats during injection into an indwelling cannula. Various devices have been constructed to enable intermittent intravenous self-administration of xenobiotics by rats (15, 120–122). Application of this methodology to drug addiction studies in rats has been discussed by Weeks (123).

Three invaluable compendia of drug dosages for the rat are available (124, 125a,b).

Euthanasia Methods—Euthanasia methods are procedures for the painless death of laboratory animals. Useful euthanasia procedures for the rat can be classified as physical methods, *i.e.*, severe body perturbation without administration of a toxic xenobiotic, and chemical methods, *i.e.*, administration of toxic xenobiotics, usually intraperitoneally or by inhalation. The methods outlined in Table II are discussed elsewhere in more detail (126, 127). It is difficult to evaluate the relative humaneness of these different methods. The relative humaneness of gallamine-induced asphyxia and decapitation has been studied in rats by electroencephalographic monitoring (128). Histological changes in the major organs associated with various euthanasia methods (decapitation, carbon dioxide, methoxyflurane, and pentobarbital) and the sympathoadrenal discharge induced in the rat by decapitation have also been documented (129, 130).

If tissues are to be obtained from rats for posteuthanasia study, the scientist is advised to use care in selecting the euthanasia method. For example, *in vitro* drug metabolism studies using various subcellular fractions of rat hepatic homogenates commonly are prepared from liver tissue obtained from rats sacrificed by decapitation (without prior anesthesia) or carbon dioxide asphyxiation. [A chamber for carbon dioxide euthanasia can be readily constructed from a large can (131) or plexiglass[11] (Fig. 5).] Decapitation and carbon dioxide euthanasia avoid the known alterations of microsomal enzyme activity associated with the use of ether (132–136) and other inhalation anesthetics (133, 134). This example illustrates that scientists studying various events in anesthetized rats or in tissues from sacrificed rats must verify the lack of anesthetic or euthanasia-method effect on the experimental events observed.

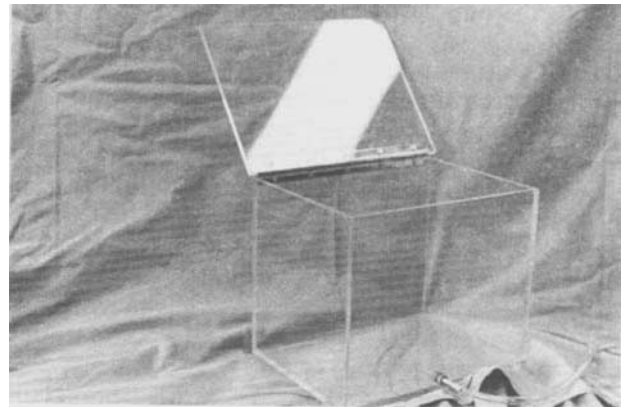

Figure 5—*Plexiglass chamber (0.6-cm thick plexiglass) used for carbon dioxide euthanasia of rats. The base of the chamber is 26-cm long and 19-cm wide, while the chamber is 21-cm high. The top serves as a hinged door and a gas inlet is placed near the bottom of the chamber. The top need not have a gasket seal.*

VASCULAR ACCESS

Methodology Overview—*Cannula Materials*—Vascular cannulas most commonly are constructed of polyethylene[12] or silicone rubber[13] (137, 138). Polypropylene, polyurethane[14], Tygon[15], polytef[16], and Micro-Line[17] tubing have had less use. All of these materials are somewhat flexible, can be molded into desired shapes (139, 140), and have various degrees of physiological inertness. These synthetic materials comprise the main substance of the cannula and are often supplemented by various other materials. Metal connectors are used to link different pieces of tubing or provide a reinforced site to facilitate ligature fixation of the cannula in the vessel (141). An alternative means of joining different pieces of polyethylene tubing consists of welding with a stream of hot air (13, 139). A short piece of flexible, heat-shrinkable polyolefin tubing[18] also can be used to provide reinforcement of the junctions between different tubing pieces or the cannula plug and tubing (13). Although a metal connector is useful for connecting two different types of tubing, such as polyethylene and silicone rubber, it has the disadvantage of promoting thrombotic occlusion of the cannula by both decreasing the cannula lumen diameter (thereby increasing turbulent blood flow distal to the metal connector) and providing a metallic intravascular thrombogenic focus. Therefore, the use of either heat welding or heat-shrinkable tubing is preferred whenever two pieces of the same type of heat-insensitive tubing (polyethylene, polypropylene, Micro-Line) are to be joined.

Methods of Inserting a Cannula in a Blood Vessel—

[10] Alza Corporation, Palo Alto, Calif.

[18] FPS-Voltrex; Newark Electronics, Chicago, Ill.

Methods of cannula insertion in a blood vessel can be classified three ways: (*a*) two-step puncture and insertion, (*b*) cannula through a needle, and (*c*) cannula attached to a needle. The latter methods are one-step procedures, *i.e.*, puncture of the blood vessel and cannula access to the blood are both accomplished in a single step.

The most commonly used procedures for both arterial and venous cannula insertions are two-step puncture and insertion methods. Ophthalmic Castroviejo iris scissors, microdissecting scissors, or various needles are used to puncture the blood vessel. A needle (25 gauge for aorta, 23 gauge for jugular vein) with a 90° bend ~6 mm from the needle tip is particularly useful. It is inexpensive and readily available, and the tip can be used bevel up to puncture the blood vessel wall with a minimal risk of puncturing the opposite wall (13)[19]. Use of a needle for vessel puncture is often preferable to use of scissors since a needle produces a puncture hole of defined, reproducible size, which cannot be guaranteed using scissors. Using a needle with an outer diameter approximately equal to the outer diameter of the cannula tubing minimizes hemorrhagic leakage from the puncture site. Insertion of the cannula into the puncture hole can be facilitated by gently lifting the lip of the hole with a pair of fine forceps and inserting the cannula into the blood vessel with a slow, gentle rotation of the tip.

Cannula-through-a-needle methods have the advantage of combining the blood vessel puncture and cannula insertion procedures into one step. Physicians and other scientists with clinical training are usually familiar with the various devices marketed to facilitate cannula placement through a needle inserted in a blood vessel.

One device used to cannulate mesenteric veins of the rat was constructed from an ~2.5-cm segment of hollow steel tubing soldered close to the tip of a 1.5-in., 22-gauge needle (the distal third of which was bent at a right angle) (142, 143). Venipuncture with the tip of the 22-gauge needle enabled the cannula to be directed into the vein *via* the steel tubing attached below the needle. Hollow steel tubing[20] of various diameters can be used to accommodate different cannulas. The device can be stabilized to ensure a clean venipuncture by attaching the hub of the 22-gauge needle to a 1-ml syringe. The principle of this device was used in constructing a similar device which consisted of a single needle with the tip bent at a right angle to the remainder of the shaft and a semicircular tunnel in the distal portion (144). Vascular puncture is followed by insertion of the cannula in the lumen of the blood vessel *via* the semicircular tunnel. This has the advantage of facilitating easy removal of the device from the cannula tubing. The previously described device with the fully circular cannulating needle must be passed over the total length of tubing for removal. This creates the inconvenience of having to remove a fluid-containing syringe from the cannula connection to remove the device. Note that in the special case of the caudal (lateral tail) veins, a cannula may be inserted *via* a straight needle used for vessel puncture (145–148).

Cannula-attached-to-needle methods have been useful one-step procedures when placement of a needle within the blood vessel lumen was consistent with the acute nature of the experiment (149–151). The cannula-attached-to-needle method is useful for percutaneous puncture of the caudal artery (152, 153), and external jugular vein (154–156); the former effort may be aided by depilation with sodium sulfide (157). Needle-tipped cannulas have also had limited utility for chronic intermittent injections into the sagittal and transverse sinuses (158) and for chronic blood pressure–multiple blood sampling *via* the caudal artery (159). Due to the increased chance of thrombotic complications associated with the metallic needle tip in the vessel, the cannula-attached-to-needle methods are less preferred than insertion of a conventional metal-free cannula.

One novel cannula-attached-to-needle method warrants attention when the external jugular vein must be cannulated. Harms and Ojeda (160) constructed an implantation needle (20-gauge tip) to which a silicone rubber cannula is attached. The implantation needle (with attached cannula) is passed in and out of the same side of the vein. The implantation needle is disconnected from the cannula tubing, and the cannula tubing is then pulled back into the lumen for advancement to the heart. This method has the advantages of being a one-step procedure, eliminating the need to dissect the vein free from surrounding tissues, and making application of ligatures around the vein unnecessary. This method has proven a useful vascular access for pharmacokinetic studies in rats (161–163).

We are unaware of any application to the rat of the cannula-over-the-needle method used commonly in humans (164).

Methods of Fixing a Cannula in a Blood Vessel—There are four basic methods for fixing the intravascular portion of the cannula within the lumen of the blood vessel: (*a*) ligature to surrounding structures (141, 165, best illustrated in 166), (*b*) ligature around the cannula and through an occluded distal portion of the cannulated blood vessel (167, 168), (*c*) application of cyanoacrylate-type glues for the blood vessel–cannula junction (150, 169–171)[19], and (*d*) fashioning a circular shock-absorbing loop in the cannula tubing between the sites of cannula insertion and ligation to a nearby structure (165)[19]. Use of one or more of these methods should maintain the cannula within the lumen and minimize cannula-mediated abrasion of the intravascular structures. Robinson *et al.* (172) constructed a heating element device for producing a small bead on the outside of polyethylene tubing without altering the lumen. This bead served as an anchor for fixing the cannula in place.

Methods of Exteriorizing the Cannula—Intravascular and other indwelling cannulas (*e.g.*, urinary bladder, bile duct) are commonly exteriorized by subcutaneous tunneling from the vascular incision site to the back of the neck for emergence at a point midway between the clavicles or ears (13, 15, 141, 160, 165, 166, 170, 173–183)[19]. To further secure the exterior portion, the cannula may be passed through a plastic cap or steel button which is sutured to the skin of the neck (166, 177, 180). A modification of exteriorization at the neck is to subcutaneously tunnel the cannula for passage through a cranial pedestal (168, 171, 186–188).

A cannula may also be exteriorized *via* subcutaneous tunneling from the incision site to the root of the tail, where

[19] Methodology notes provided by J. R. Weeks, The Upjohn Company, Kalamazoo, Mich.

[20] Small Parts Inc., Miami, Fla.

the cannula is exteriorized and covered by some type of protective shielding (146, 148, 189–191). Cannulas have also been exteriorized *via* subcutaneous tunneling from the incision site to the side of a rat maintained in a restraining cage (192) or body harness (176).

Methods to Aid in Maintaining Cannula Patency—Various procedures have been used to minimize the incidence of thrombotic occlusion of the intravascular cannulas and to remove existing thrombotic obstructions to prolong the patent lifetime of cannulas. These procedures can be classified into three groups: (*a*) fluid-flushing procedures, (*b*) designs for the intravascular portion of cannulas, and (*c*) procedures for removal of thrombotic obstructions.

Fluid-flushing procedures consist of selection of a solution for instillation in the cannula when it is not in use and a schedule for routine cannula care, *i.e.*, withdrawal of the instilled solution, flushing the cannula to clear it of blood, and refilling the cannula with fresh solution. Six different solutions have been used to fill cannulas: heparin, heparin–povidone mixture, heparin–streptokinase solution, heparin–dextrose solution, isotonic saline, and 50% dextrose in water.

Heparin has been instilled in cannulas in concentrations of 10–1000 U/ml, usually dissolved in isotonic saline (149, 151, 159, 166, 173, 175, 181, 185, 191, 193–204). A localized anticoagulant effect can be obtained with 20 U/ml of heparin. A mixture of heparin–povidone [1 g of povidone plus 2 ml of heparin solution (500 U/ml)] has been used because of its increased viscosity to prevent diffusion of blood into the unused cannula (186). Similar mixtures of heparin–povidone were used without problem by other investigators (168, 187, 205). However, Allsop and Burke (201) found use of this heparin–povidone mixture no better than the more easily handled heparinized (10 U/ml) isotonic saline. Heparin (1000 U/ml) plus streptokinase (200 U/ml) solution was used to maintain patent aortic cannulas for blood pressure monitoring (206). This combination of an anticoagulant and plasminogen-activating agent may be more effective in maintaining patent cannulas than either agent alone. Solutions of heparin (≤500 U/ml) and dextrose (≤10%) have been used in an effort to increase the viscosity beyond that obtained with heparin alone (207, 208). For experiments in which no anticoagulant can be administered to the rat or added to the flushing solution, the two alternatives that have been used are isotonic saline (7, 13, 141, 160, 165, 170, 174, 177, 184, 209–218)[19] and 50% dextrose in water[21].

Schedules for routine cannula care have not been comparatively studied and standardized. In general, increased frequency of cannula care (withdrawal of the instilled solution, flushing the cannula to clear it of blood, and refilling the cannula with fresh solution) should ensure increased long-term cannula patency. Allsop and Burke (201) and Brown and Breckenridge (168) have provided detailed descriptions of a cannula-care schedule consisting of the following:

1. Initial aspiration of fluid from the cannula. This fluid is discarded since reinjection carries the risk of introducing aspirated thrombi.
2. Injection flushing of the cannula with a volume of solution slightly larger than the volume of the cannula as calculated by:

$$V = \pi r^2 l \qquad \text{(Eq. 2)}$$

where V is the volume, r is the radius, and l is the length of the cannula.
3. Sealing the exteriorized end of the cannula with a segment of steel stylet (13) or an epoxy-filled blunt-end needle (201).

These investigators recommended that cannula care be done once a day for the patent lifetime of the cannula. Such daily cannula servicing is useful for other types of aortic and jugular cannulas (204, 207). Based on these proven procedures, cannulas intended for chronic use should be serviced daily when not in use.

Designs for the intravascular portion of cannulas have been proposed as means of minimizing thrombotic occlusion. Simple beveled and nonbeveled cannula tips, a double-mitered cannula tip, a sealed cannula tip with laterally placed holes, and an open cannula tip with laterally placed holes have been designed. Commonly, the open end of the vascular cannula is fashioned with a 90° angle to the tubing wall (no bevel) or a 30–60° angle of the bevel.

While most investigators agree that a beveled end is more easily inserted in the blood vessel, it has been reported (*via* anecdote) that the beveled end can be occluded more readily by a flap of thrombotic material deposited over the bevel and also may rest more readily against the blood vessel wall, thereby inhibiting blood sampling (13). Scientists having difficulty maintaining cannula patency with a beveled or nonbeveled tip may consider using an alternative type of cannula tip. Nicolaidis *et al.* (187) designed a double-mitered silicone rubber cannula tip which is reported to effectively minimize local coagulation. Steffens (186) cut two 0.75-mm holes in the opposite lateral walls 0.75 mm from the tip of a silicone-rubber cannula with an open-lumen tip. Stripling (171) plugged the intravascular end of a silicone rubber cannula with hardened silicone rubber adhesive and made holes near this plugged tip by puncturing through both cannula walls six times with a 25-gauge needle. This type of cannula tip is said to comprise a one-way valve which allows drug infusion, while preventing entry of blood into the cannula (219).

Procedures for removal of thrombotic cannula obstructions can be classified in three categories: (*a*) aspiration of the obstruction, (*b*) forceful injection of the obstruction into the circulation of the rat, and (*c*) use of an obturator that fits in the cannula lumen to mobilize the obstruction. Before using any of these procedures for clearing an obstruction in a venous cannula, one can verify that the cannula is still inside the vein by injecting rapidly 3–6 mg (0.05–0.10 ml of a 60-mg/ml solution) of pentobarbital sodium (13), 1 mg (0.10 ml of a 10-mg/ml solution) of methohexital sodium[19], or thiamylal sodium[22] (15). If the cannula is out of the vein, the rat may struggle or vocalize, or the fluid may accumulate in a subcutaneous pocket with only clear fluid (no blood) aspirated (13). If the barbiturate injection is indeed intravenous, the eyes of the rat will squint closed almost immediately, the rat will lose its righting reflex, and the rat will become ataxic

[21] Personal communication, J. E. Brown, Division of Clinical Pharmacology, Duke University Medical Center, Durham, N.C.

[22] Surital; Parke-Davis, Morris Plains, N.J.

within ~10–15 sec. The rat normally recovers completely within ~5–10 min. When this procedure shows that the cannula is indeed in the vein but blood withdrawal is still difficult, flexing the head and neck of the rat or lifting it by the root of the tail so that only the forelegs touch the cage floor may aid in moving the cannula tip from against the blood vessel wall, thereby facilitating blood withdrawal. If these simple maneuvers do not work, one of the three aforementioned procedures can be tried.

Since thrombotic material can accumulate on the intravascular end of arterial and venous cannulas, it is suggested that blood be withdrawn through the cannula prior to injection to aspirate any small thrombotic obstruction (168, 201). The blood initially withdrawn should not be reinjected since it may contain small thrombi. Forceful injection of 0.10–0.15 ml of isotonic saline *via* a 0.25-ml tuberculin syringe will often break up and clear a thrombotic obstruction in a jugular venous or abdominal aortic polyethylene cannula (13, 165)[19]. The small emboli mobilized as a result of this procedure will usually be trapped in the vasculature of the lungs and legs when ejected from the external jugular vein and abdominal aorta, respectively (13)[19]. Lastly, various homemade wire or nylon obturators can be slid down the lumen of some cannulas to mobilize the obstruction. The utility of thin wire is limited by its relative inflexibility and high potential for cannula puncture. In view of this, use of wire obturators often has been limited to relatively straight cannulas implanted in the caudal vein or artery. Brown and Breckenridge (168) described a very useful and flexible obturator made from 25-pound test monofilament nylon fishing line fashioned with a ball on the end made by holding it close to a hot soldering iron. This seems relatively unlikely to puncture the cannula. Indeed, Brown and Breckenridge (168) used this obturator to clear obstructions from a curved silicone-rubber cannula implanted in the external jugular vein.

Swivel Joints—In chronic rat experiments in which xenobiotics are injected intermittently or continuously *via* the intravenous or intraventricular route, the duration of the experiment is usually limited by cannula damage (twisting and kinking) due to the physical activity of the rat. For reasons discussed elsewhere in this review, such experiments can not be executed during sustained anesthesia or restraint. Therefore, the swivel joint was introduced to prevent such motion-related cannula damage and enable chronic xenobiotic administration and blood sampling *via* indwelling cannulas in the unanesthetized, unrestrained rat. Jacobs (220) appears to be the first investigator to have devised a swivel joint for administration of a constant-rate intravenous infusion to the dog for up to 3 weeks. In principle, this and other swivel joints are fluid-tight, flow-through joints placed into the tubing near the point of emergence from the rat (back of the head or neck) so that the tubing proximal to the rat rotates within the swivel joint as the rat moves, thereby preventing cannula damage by twisting. Rhode *et al.* (221) inserted a circuit of flexible, rotatable tubing between the dog and the infusion bottle. Epstein and Teitelbaum (222) commented that such an arrangement will not work for the rat, a more active species.

Several home-built swivel joints for use with rats have been described in the literature (15, 174, 179, 186, 187, 222–233). The utility of these various devices is based on the comparative ease of construction, availability of components, cost, durability, size, force required to rotate the swivel, tendency to leak, and requirements for periodic cleaning and lubrication.

Several single-channel swivel joints are relatively inexpensive to construct with hand tools from widely available materials. These single-channel swivel joints function well (224, 225, 227, 229, 232). The single-channel swivel of Strubbe (227) was designed to minimize friction for improved utility with small-diameter tubings. While most of the single-channel swivel joints require at least one polytef component, that of Brown *et al.* (229) was constructed solely from parts of plastic syringes, disposable needles, and epoxy adhesive. Khavari (225) constructed a combined intracerebral cannula–swivel unit for use in the rat.

Double-channel swivel joints have been devised to enable either simultaneous infusion of two different fluids into the same rat, simultaneous infusion and blood pressure recording, or simultaneous infusion and blood sampling. Some double-channel swivel joints require special machining during construction (187), a motor to rotate the swivel (234), or apparent supernormal manual dexterity for assembly (233). Smith and Davis (15) described assembly of two single-channel swivel joints from commercially available parts. Blair *et al.* (231) have supplied details for construction of an inexpensive double-channel swivel joint. This construction does not require any machining of parts and uses readily available materials. Testing verified that there were no leaks between the two channels after 4 weeks of continuous use. Another easily constructed double-channel swivel joint has been described, but leak-test information was not provided (232).

Since available swivel joints can not accommodate the arterial blood back-pressure (~100 mm Hg) without leaking, Grantham *et al.* (235) designed a nonswivel spring system for use with a special cage in order to infuse drugs intra-arterially. Where the tubing emerges from the spring at the end distal to the rat, a long unencumbered loop of tubing hangs outside the cage. This absorbs the movements of the rat without kinking for ~1 day. With daily uncoiling of this tubing loop, continuous intra-arterial infusions have been done for 2 weeks.

Complications of Vascular Access—A limited amount of information is available regarding complications in the use of an indwelling vascular cannula or percutaneous vascular access in laboratory animals. Despite minimal gross indications of ocular damage, localized and reversible necrotizing inflammation of the Harderian gland develops following collection of a single blood sample from the retro-orbital venous plexus (236). The degree of thrombogenicity of some artificial (*i.e.*, nonphysiological) substances has been studied using various *ex vivo* models (237–239). Unfortunately, insufficient information is available to enable recommendation of one type of tubing over another based on inertness toward tissues.

In 22 animals (dog, cat, rabbit, and monkey) with an indwelling cannula, Hysell and Abrams (240) identified vegetative deposits on the cardiac valves, septic visceral infarcts of the kidney, spleen, and brain, and fatal hemorrhage due to a ruptured vein or artery. In all three types of cannula-related lesions, systemic bacterial infection

played an important role in the animals' deterioration. Inadequately sterilized cannulas, nonadherence to aseptic technique when injecting or withdrawing from the cannula, and infection *via* the point of exteriorization are the apparent means of bacterial access to the vasculature.

Meuleman *et al.* (241) inserted a polyethylene cannula into the abdominal aorta *via* the carotid artery to study cannula-associated platelet consumption in the rat. Platelet count and the half-life of ^{51}Cr-labeled platelets were both significantly decreased in cannulated rats compared with stressed control rats (cannula inserted, then immediately withdrawn); the degree of decrease was related to the length of the inserted cannula. Platelet turnover did not differ substantially between cannulated and control rats. These investigators have also reported aortic endothelium loss due to the presence of an indwelling cannula (241). Aortic lesions in rats having polyethylene cannulas implanted for 48 hr were also documented, and used to assess antiplatelet drug efficacy (242).

Some investigators using indwelling intravascular cannulas in the rat for various pharmacological studies have reported renal infarcts after cannulation of the carotid artery and abdominal aorta with polyethylene, polypropylene, or silicone rubber tubing (177, 201, 206). Frequency of renal infarction increased with time (177) and with injection flushing of the cannula to force thrombotic blockage into the circulation (201). Polyethylene-tipped cannulas present in the carotid artery for an average of 7.2 days were associated with renal infarcts in 11 rats (n = 15, infarction rate = 10.2% per catheter day), while silicone rubber-tipped cannulas inserted for an average of 11.5 days were associated with small, solitary renal infarcts in 10 rats (n = 25, infarction rate = 3.5% per catheter day) (201). Renal infarcts occurred in association with polyethylene-tipped cannulas even when no injection flushing was done (201). Since arterial cannulation of either the carotid artery or abdominal aorta is used commonly for serial blood sampling in pharmacokinetic studies in the rat, investigators must exercise appropriate caution (in accordance with the following five recommendations) to ensure that data is not collected from rats with impaired renal function. First, a decreased incidence of renal infarction was reported by Engberg (177) when a 12-mm intraaortic segment of polypropylene was inserted into the abdominal aorta at a point 3–4 mm above the iliac bifurcation. Second, the significantly reduced incidence of renal infarcts with silicone rubber tubing suggests that it should be preferred for carotid cannulation (201). Third, thrombi mobilized from the tip of the catheter can deposit in the kidneys. Therefore, it is suggested that blood be withdrawn through the cannula to clear such small thrombi prior to injection (168, 201). Fourth, the anchoring of a polyethylene abdominal aortic cannula alongside the aorta using a circular shock-absorbing loop in the tubing has been reported to virtually eliminate thrombotic infarctions and aortic aneurisms (165)[19]. Fifth, postexperiment necropsy of the kidneys should be done to ensure collection of pharmacokinetic data from rats with noninfarcted kidneys.

Thrombotic deposits on cannulas can also be mobilized as emboli to areas other than the kidneys. Buñag *et al.* (206) observed embolic paralysis of the hind legs of some rats having an indwelling cannula inserted in the abdominal aorta *via* the left iliac artery. Although this is apparently the only published observation, such limb paralysis has also been observed in rats following cannulation of the ipsilateral femoral vein and artery[21]. This complication should be carefully examined with respect to its ability to interfere with the experimental goals. Interestingly, limb paralysis has not been a major problem when the abdominal aorta is cannulated directly, thereby avoiding direct occlusion of the femoral or iliac arteries by a cannula[19].

Investigators using vascular cannulation methods as a means of xenobiotic administration, blood sampling, or cardiac function monitoring must remain aware of the aforementioned complications associated with indwelling intravascular cannulas. Appropriate steps must be taken both to minimize the incidence and verify the absence of such complications *post facto*.

Specific Methods for Vascular Access—To provide a more detailed summary of the numerous methods available for vascular access in the rat, methodological notes, procedural comments, and the demonstrated uses (243–294) were collected into separate tables for arterial (Table III), venous (Table IV), and miscellaneous (Table V) methods. Each table is organized by specific blood vessels, listed alphabetically according to the blood vessel nomenclature presented by Greene (26). It is hoped that scientists seeking information on access to a particular blood vessel will find these tables sufficient to enable them to limit the number of cited papers to be consulted for detail. In addition, this listing should inform scientists about published access methods for infrequently utilized blood vessels (*e.g.*, renal artery, adrenal vein) and thereby eliminate the need for an extensive noncomputerized search of the scientific literature, which is often 20–30 years old.

Although they are not presented in detail, several methods are available for cross-transfusion of blood between a pair of parabiotic rats (295–300). Such methods are useful in specialized studies investigating the association of particular effects with various blood-borne substances.

Investigators must be aware that certain parameters in the rat (plasma glucose concentration, blood coagulation parameters, plasma corticosterone concentration, plasma renin activity, serum hormone concentrations, serum enzyme activities, and drug binding to plasma proteins) may vary depending on the site and method of blood collection (301–307), the extent of rat handling (301, 308), acclimatization time (309), and the presence of another previously treated rat (310).

Vascular Access and Surgical Methods for Studying First-Pass Effect—First-pass effect is defined as the uptake and elimination of a xenobiotic during the absorption process as it passes from the lumen of the GI tract through the GI membranes and the liver for the first time, and into the circulation. Such first-pass elimination of xenobiotics can be studied in the rat by three methods: (*a*) transhepatic blood sampling, (*b*) hepatectomy, or (*c*) surgical construction of a vascular bypass to shunt blood away from the portal venous hepatic inflow (portal–systemic shunt).

Transhepatic Blood Sampling—The hepatic artery carries oxygenated blood from the aorta to the liver and supplies ~25–30% of hepatic blood flow in the cat, dog, and

Table III—Methods for Arterial Access

Arterial Site	Reference	Methodology Notes[a]	Demonstrated Uses[b]	Procedural Comments
Aorta:	Browning *et al.* (197)	PE, U, W	BP, CO	Cannula filled with heparin
	Buñag *et al.* (206)[c]	PR, TE/TY, U	BP	Cannula filled with heparin (1000 U/ml) plus streptokinase (200 U/ml)
	Carvalho *et al.* (215)[c]	PE, U, UR, W	M	Cannula filled with isotonic saline, used for 9 days
	Cocchetto & Bjornsson (unpublished)	Aortic puncture	T	Direct puncture of surgically exposed aorta just above the iliac bifurcation using a 20-ml syringe with a 20-gauge, 1.5-in. needle; anticoagulant can be in the syringe; collect up to 15 ml of blood from adult rats
	Garthoff & Towart (243)	PE, U, UR	BP	Continuous recording of BP and heart rate; data shown for 8-hr recording; requires special data collection equipment
	Kleinman *et al.* (213)	PE, U, UR	I, M	Cannula filled with isotonic saline, patent for up to ~22 days
	Laffan *et al.* (244)	PE, U, UR, W	BP	Continuous recording of BP; data gathered for 10 hr; requires special data collection equipment
	Lushbough & Moline (245)	Aortic transection	T	Reported blood yield 3% of body weight
	McIlreath *et al.* (214)	PE, U, UR, W	BP	90% surgical survival rate; cannula patent for weeks, filled with saline
	Popper *et al.* (207)	PE, TR, U, UR, W	BP, M	Cannula filled with 10% dextrose solution plus heparin (500 U/ml); used up to 10 days
	Purdy & Ashbrook (208)	PE, U, UR, W	BP	Cannula filled with 5% dextrose solution plus heparin (10 U/ml); spring attachment screwed into skull; cannula failure by 3 weeks
	Still (209); Still & Whitcomb (210, 212); Still *et al.* (211)	PE, TR, U, UR	BP, I, M	Cannula filled with isotonic saline; used up to 2 weeks
	Weeks & Jones (165)	PE, TR, U	BP, I	Cannula filled with isotonic saline, used up to 6 months; 80% surgical success rate, excellent photographs of surgical field by Stanton (501)
	Weeks (170)[19]	PE, TR, U, UR	BP, I, M	Extensive modifications of original method (165); 50 and 10 of 55 cannulas patent for 4 and 12 months, respectively; cannula fixed in vessel using cyanoacrylate glue
Carotid:	Allsop & Burke (201)	PE/SI, U, UR	M	Cannula filled with heparinized (10 U/ml) isotonic saline; 10 of 25 rats had renal infarcts after an average of 11.5 cannula-days
	Bullard (193)	PE, TR, U	BP, CO, M	Heparin given to inhibit clotting in cannula
	Buñag *et al.* (206)	PR, U	BP	Cannula failed after 7–14 days
	Burt *et al.* (204)	PE, U, UR	M	Surgery done aseptically; cannula filled with heparinized (20 U/ml) isotonic saline, patent for 3 weeks for five test rats; special swivel assembly
	D'Amour *et al.* (194)	PE		Cannula filled with heparin (1000 U/ml); excellent photographs of procedure
	Garthoff & Towart (243)	PE, U, UR	BP	Continuous recording of BP and heart rate; data shown for 8-hr recording; requires special data collection equipment
	Grantham *et al.* (235)	PE, PR, U	I	Continuous intra-arterial infusion for up to 2 weeks; cannula filled with heparinized saline
	Popovic & Popovic (173)	PE	M	Cannula filled with heparinized physiological solution; average cannula lifetime of 22 days
	Scharschmidt & Berk (246)	A, PE	M	Used a needle-three-way stopcock device for drawing blood samples up to every 30 sec
	Staub & Coutris (218)	PE, U, UR	M	Cannula filled with isotonic saline, consists of an exteriorized shunt of carotid arterial blood; 80% patent for 2–4 days, 20% patent for 5–7 days
	Waeldele & Stoclet (205)	PE/SI	BP, I, M	Cannula filled with 40% povidone plus 10% heparin; used for 10 days
Caudal:	Agrelo & Dawson (159)	N/PE, U, UR	BP, M	Cannula filled with heparinized (1000 U/ml) isotonic saline; used for up to 4 weeks
	Chiueh & Kopin (202)	PE, U, UR	BP, I, M	Cannula filled with heparinized (500 U/ml) isotonic saline; patent up to 2 weeks
	Fujita & Tedeschi (196)	PE, TR, U	BP	Cannula filled with heparinized (10 U/ml) isotonic saline; used up to 48 hr
	Hurwitz (152)	A, N, P	M	Percutaneous puncture using a clear-hub 21-gauge needle; each sample was 420 μl
Femoral:	Ekelund & Olin (247)	PE		Radiopaque cannula inserted in the aorta, superior mesenteric artery, or renal artery *via* the femoral artery; requires angiographic verification of cannula location
Hepatic:	Leivestad & Malt (248)	PE, PR, U	I	Cannula inserted with aid of magnification, exteriorized after subcutaneous tunnel to tail; rear of the animal is restrained to protect the cannula; patent up to 6 weeks
Pulmonary:	Carrillo & Aviado (249)	A, PE	BP	Cannula inserted *via* the right jugular vein
	Forrest *et al.* (250)	A, PP	BP	Cannula inserted *via* the right jugular vein; cannula is a No. 4 French gauge, balloon-tipped, Swan-Ganz flow-directed catheter; used in the rabbit and guinea pig, perhaps adaptable to the rat
	Hayes & Will (251)	A, TE	BP	Specific bends must be made in cannula; cannula inserted *via* the jugular vein in a closed-chest rat
	Herget & Paleček (252)	A, PE	BP	Cannula inserted *via* right jugular through an introducer; illustrates the use of blood pressure waves to monitor catheter tip position; cannula filled with heparinized saline
	Rabinovitch *et al.* (253)	SI, U, UR	BP	Cannula flushed with heparin (20 U/ml) and animal heparinized (150 U/kg) daily; inserted *via* a 19-gauge needle introducer
	Stinger *et al.* (254)	A	BP, CO	Cannula was a commercially available No. 3-½ French umbilical vessel catheter, inserted *via* the jugular vein in a closed-chest rat

human (311). In addition to this arterial blood flow, the liver also receives blood from the visceral organ vasculature *via* the portal vein. Portal venous blood comprises 70–75% of hepatic blood flow in the cat, dog, and human (311). Blood is returned to the inferior vena cava *via* the hepatic vein. Hepatic hemodynamics and blood pressures at various locations in the inferior vena cava of the rat have been determined (312).

To study the first-pass effect with respect to a specific orally administered xenobiotic, the concentration of the xenobiotic in both portal and hepatic venous blood must be determined. Since the hepatic venous blood concentrations of a xenobiotic and associated metabolites are equivalent to that in venous blood collected from other peripheral veins (*e.g.*, external jugular, femoral, caudal) if there is no interposed organ that further metabolizes these substances, a technically easier procedure for transhepatic blood sampling is cannulation of the portal vein plus a femoral or caudal vein. Several methods (Table IV) have been described for collection of blood from each of the above vessels. An excellent example of such transhepatic blood sampling methodology is in the first-pass metabolism studies of clonazepam in the rat (313). Transhepatic blood sampling after oral xenobiotic administration is, of course, sensitive to first-pass effects due to the gut contents and GI wall as well as the liver. By infusing a xenobiotic directly into the portal vein, the first-pass effect due to the liver alone can be quantified. Several exemplary applications of this method are available for review (283, 285, 314, 315).

Hepatectomy—Hepatectomized laboratory animals have been used to construct animal models for liver disease-associated coagulopathies (316), abnormalities in amino acid transport (317), alterations in the brain uptake of glucose (318), abnormalities in drug disposition (319), and evaluation of the existence of extrahepatic drug elimination processes (320). Surgical procedures have been described for the excision of part or all of the liver (subtotal and total hepatectomy, respectively) and the production of acute functional exclusion of the liver from its normal vascular connections while leaving the nonfunctional liver in the body (exclusionary hepatectomy).

Higgins and Anderson (48) surgically excised the large median and left lateral lobes of the liver in rats, removing ~65–75% of the total liver mass (thus the name two-thirds hepatectomy) in a one-step procedure. Illustrations of this procedure are available (12). Interestingly, the remaining right lateral and caudate lobes of the liver underwent compensatory hypertrophy so that the liver essentially was restored to its preoperative weight after 10–14 days. Approximately 16 and 24% of the excised liver mass is restored within 24 and 48 hr of removal, respectively. Therefore, rats used within 48 hr after two-thirds hepatectomy can be useful in studies of drug disposition in the presence of impaired hepatic function (319). Selye and Dosne (321) extended this subtotal hepatectomy by excising the median, left lateral, and right lateral lobes in order to remove ~85% of the total liver mass. Ryan *et al.* (322) performed two-thirds hepatectomy in rats between noon and 3 pm to avoid variation in mitotic activity due to diurnal rhythm (323). Higgins and Anderson (48) calculated the ratio of total liver–whole body weight equal to 0.0358 for 30 rats weighing from 125–225 g. This number is particularly useful in estimating the number of rats in this weight range needed to supply a required amount of hepatic tissue for *in vitro* hepatic microsomal metabolism studies.

Total hepatectomy in laboratory animals can be performed using two- and three-stage surgical procedures where a portion of the total procedure is performed at each stage and the animal is allowed to partially or totally stabilize between stages. Such multiple-stage procedures allow a period of time after constriction of the portal vein and inferior vena cava for development of collateral circulation, thus minimizing engorgement of the abdominal organs during the last stage of total hepatectomy. Although the three-stage procedure (portal vein-to-inferior vena cava anastomosis, portal vein ligation proximal to the liver, and total hepatectomy) has proven useful in the dog (324), it has not been used in the rat.

Two-stage hepatectomy (portal vein and inferior vena cava constriction, then total hepatectomy) can be performed in the rat using silk ligatures as per the method of Meehan (325). Alternatively, Bollman and Van Hook (326) used a strip of cellophane in place of the silk ligature placed around the portal vein. The cellophane progressively constricts over a period of ~2 months, at which time total hepatectomy can be done. In each method, the minimum size of the portal venous constriction produced in the first stage is crucial in preventing rapid, fatal congestion of the visceral vascular bed. With an intravenous infusion of glucose following hepatectomy (150 mg/kg/hr for 8–10 hr then 250 mg/kg/hr, using a solution of glucose in isotonic saline infused at 1.25 ml/hr), ~90 and 60% of the rats survive at least 8 and 24 hr, respectively (326). Glucose can also be administered by intermittent subcutaneous injections (325). Rats treated with glucose rarely live >30 hr after hepatectomy; those not receiving glucose rarely survive >2 hr (325).

Exclusionary hepatectomy is useful for acute studies in

Table IV—Methods for Venous Access

Venous Site	Reference	Methodology Notes[a]	Demonstrated Uses[b]	Procedural Comments
Adrenal:	Schapiro & Stjarne (257)	A, PE, S	M	Uses an artificial adrenal vein–renal vein shunt, for up to 6 hr; heparin used to inhibit clotting
	Singer & Stack-Dunne (258)	A, S	T	Adrenal vein blood collected continuously for 1.5 hr; no nephrectomy; cannula construction and insertion procedure not described
Brachial:	Young & Chambers (259)	S	T	Brachial artery and vein are severed with blood collection in a pipet; developed for the mouse, probably useful for the rat
	Slusher & Browning (260)	PE, S, U, UR	M	Cannula inserted through a 19-gauge needle, exteriorized and protected in a metal button sutured to the skin; used for up to 3 weeks
Caudal:	Agrelo & Miliozzi (149)	N/PE, P, TR, U	II	Cannula filled with heparinized (100 U/ml) isotonic saline; used for 6 hr
	Born & Moller (146)	PE, PR, S, U	CI	Cannula threaded into a vein through a 20-gauge needle that is then removed; protected by electrical shielding
	Cotlove (261)	N, P, PE, TR, U	CI	A 23-gauge needle with attached tubing is inserted into the vein
	Eve & Robinson (223)	P, PE, PR	CI	Cannula threaded into the vein through a 21-gauge needle that is then removed; uses a special swivel–fluid conduit; used for >6 months continuous infusion without anticoagulants
	Kellogg *et al.* (262)	S, TR, U	C	Cannula inserted with aid of dissecting microscope
	Little *et al.* (189)	P, PE, PR, U	C	Cannula protected by plastic tubing attached to tail; 2 of 9 rats infused for 90 days
	Plum (263)	A, S	M	Blood collected with suction after cutting the distal segment of the tail
	Rhodes & Patterson (148)	P, PE, PR, U	CI, I	Cannula threaded into the vein through a 19-gauge needle that is then removed; protected by electrical shielding; 32 of 34 rats had patent cannulas for 10 days (one rat chewed through the protective shielding)
	Saarni & Viikari (147)	A, P	C	Cannula threaded into the vein through a needle that is then removed (needle gauge and cannula type not specified); heparin (40 U/kg/hr) and droperidol (0.16 mg/kg/hr) infused throughout the experiment
	Stuhlman *et al.* (264)	S, TR, U	M	Blood collected with suction after cutting the distal segment of the tail, up to 10 samples per animal; rat is restrained in a cage on a heating pad
	Videm (265)	A, P	S, SI	Used a 21-gauge needle for collection of up to 4 ml of blood or injection into the vein at the root of the tail
	Wright (266)	S, TR, U	S	Up to 3 ml of blood collected in a capillary device[c] after cutting the distal segment of the tail; rat is restrained in a cage near a heating element
Dorsal Metatarsal:	Nobunga *et al.* (267a)	P, TR, U	S, SI	Injection *via* a 27-gauge needle into the right hind leg; collection of up to 0.2 ml of blood *via* a 22- or 23-gauge needle; useful in docile rats for acute venous access without anesthesia
Dorsal Penile:	Salem *et al.* (41)	P, TR, U	SI	Injection *via* a 26–30-gauge needle; method extended to rats by Nightingale and Mouravieff (267b)
	Virolainen (268)	P, TR	II	Injection *via* a ≤20-gauge needle; each rat received up to 14 injections in 1 week; good photograph of the procedure
Femoral:	Benzman-Tarcher (269)	A, S, SI	CI	Cannula advanced into inferior vena cava, used to infuse a fatty acid emulsion for 6 hr; no anticoagulant used
	D'Amour *et al.* (194)	PE, S		Cannula filled with heparin (1000 U/ml); excellent photographs of the procedure
	Jones & Hynd (191)	NY, PR, S, U	CI, M	Cannula filled with heparinized isotonic saline; exteriorized *via* the tail and protected by a plastic sheath; up to 7 days infusion in 300 rats
	Nishihara *et al.* (270)	PE, S	SI	Cannulation of the femoral artery and vein on one side, followed after time by the same procedure on the other side to study drug interactions
Femoropopliteal[d]:	Pearce (271)	P, TR, U	SI	A 27-gauge needle is used for injection
Hepatic:	Suzuki *et al.* (272)	PE, S	M	One cannula is passed down the external jugular vein into the inferior vena cava; the blood sampling cannula is inserted in the inferior vena cava *via* an abdominal incision
	Wernze (273)	A, PE, S	II, M	Cannulation aided by a microscope; cannula filled with heparinized (10 U/ml) isotonic saline; isobutylcyanoacrylate glue used to fix the cannula in the vein
	Yokota *et al.* (150)	A, N, PE, S	M	Direct vein cannulation with the bent tip of a 25-gauge needle connected to tubing; cannula was filled with heparin and fixed to the vein using a surgical glue; 0.25 ml of blood drawn slowly over 4 min to prevent reflux; blood drawn for up to 45 min
Hypophysial portal:	Ben-Jonathan & Porter (274)	A, PE, S	M	Modified method of Porter and Smith (275) to use an embolator apparatus to enable collection of blood samples
	Porter & Smith (275)	A, PE, S	M	Collected blood is free of CSF contamination; collected continuously for up to 6 hr; requires a microscope for surgery
Inferior vena cava:	Kaufman (185)	S, SI, U, UR	II, M	Cannula filled with heparinized saline and exteriorized at the back of the neck; patent for many months
	Welch *et al.* (276)	A, S	T	Direct venipuncture of the surgically exposed vein

Table IV—*Continued*

Venous Site	Reference	Methodology Notes[a]	Demonstrated Uses[b]	Procedural Comments
External jugular:	Allsop & Burke (201)	PE/SI, S, U, UR	II	Cannula filled with heparinized (10 U/ml) isotonic saline; an epoxy-filled needle used to plug the end
	Brandstaetter & Terkel (234)	DL, S, U, UR	II, M	Cannula filled with heparin (20 U/ml); rat attached to a pulley assembly for continuous vascular access; cannulas in 46 rats patent for 12–21 days
	Brown & Breckenridge (168)	S, SI, U, UR	II, M	Cannula filled with an air bubble plus heparin–povidone mixture, sutured into the vein and exteriorized *via* a cranial pedestal; aseptic surgical methods used; patent for >1 year
	Bullard (193)	A, PE, S	VBP	Rats were heparinized; acute study
	Burt *et al.* (204)	S, SI, U, UR	CI	Surgery done aseptically; cannula filled with heparinized (20 U/ml) isotonic saline; patent cannulas for 3 weeks in five test rats; special swivel assembly
	Cox & Beazley (180)	PE, S, U, UR	CI	Cannula exteriorized at the back of the neck and passed through a spring that is sutured to the rat; uses a ball swivel, requires daily catheter straightening; cannula used up to 6 weeks (gives useful technical hints concerning cannula placement)
	Dalton *et al.* (176)	H, PP, S, U	CI	Cannula threaded into the vein through a 19-gauge needle and exteriorized through a rat body harness; used for up to 3 weeks
	D'Amour *et al.* (194)	PE, S		Cannula filled with heparin (1000 U/ml)
	Edmonds & Thompson (178, 179)	PP, S, U, UR	CI	Cannula secured *via* a subcutaneous collar around the neck; used for up to 3 months; rat prevented from biting cannula by electrical-shock device
	Engberg (177)	PP, S, U, UR	CI	Cannula exteriorized *via* a plastic cap sutured to the back of the neck; filled with isotonic saline; used up to ~3 weeks
	Ensminger *et al.* (190)	PE, PR, S, U	CI, SI	Cannula exteriorized at the root of the tail and passed through a spring enclosing the tail; infusion for up to 3 days; a larger diameter cannula can be used for serial blood sampling
	Harms & Ojeda (160)	S, SI, U, UR	M	Uses an implantation needle that is passed in and out of the vessel lumen, leaving the attached cannula tubing in the lumen; anchored in place *via* an attached silicone rubber sheet; cannula filled with isotonic saline; patent for 4–8 weeks for six test rats
	Mayer *et al.* (277)	A, PE, S	II	Jugular vein shunt constructed to enable serial injections without cannula flushing; prevents undesirable blood volume expansion; used acutely for bioassay
	Nicolaidis *et al.* (187)	S, SI, U, UR	CI	Uses a double-mitered cannula tip to prevent thrombotic blockade of the cannula; exteriorized at the head *via* a cranial pedestal; cannula filled with heparin–povidone mixture; uses a special swivel assembly; cannula patent for up to 5 months
	Popovic & Popovic (173)	PE, S, U, UR	II, M	Cannula filled with heparinized isotonic saline; exteriorized at the back of the neck; average cannula lifetime of 22 days
	Popovic *et al.* (175)	PE, S, U, UR	ECG, II, M	Cannula is advanced into the right ventricle; filled with heparinized isotonic saline; exteriorized at the back of the neck; cannula patent up to 124 days (with heparin) or 50 days (without heparin flushing)
	Renaud (155)	A, P, S	II, M	Uses a 20-gauge needle for direct venipuncture of the surgically exposed vein or percutaneous rostral puncture *via* depilated skin; collected up to 2 ml of blood, up to five samples per week
	Smith & Davis (15); Davis (278)	PE/SI, S, U, UR	CI, II	Describes two cannulas for jugular vein implantation; used up to 6 months; contains a wealth of practical information on cannula construction, surgical procedures, and infusion apparatus; excellent procedural photographs
	Steffens (186)	S, SI/TE, U, UR	CI, M	Cannulation of one tributary (for infusion) or two tributaries (for simultaneous infusion and blood sampling) of the external jugular vein; cannula filled with air bubble and heparin–povidone mixture; exteriorized *via* a cranial pedestal; sampled blood may be contaminated with infused substance
	Stripling (171)	S, SI, U, UR	CI, II	Cannula has intravascular end plugged, but delivers drug *via* lateral holes that prevent blood from entering the cannula; fixed in vein using cyanoacrylate glue and exteriorized *via* a cranial pedestal; patent in 61 and 60 of 65 rats for 2–3 and 5–9 weeks, respectively
	Terkel & Urbach (166)	S, U, UR, V	M	Cannula filled with heparin (250 U/ml); anchored in vein by seven sutures and exteriorized at the back of the neck into a protective plastic cylinder sutured to the neck; cannulas in 20 rats were patent for an average of 28.5 days (maximum 88 days)
	Upton (181)	S, SI, U, UR	II, M	Cannula filled with heparinized (10 U/ml) isotonic saline; exteriorized at the back of neck; serial blood samples collected up to once per min, with up to 5 weeks usage

Venous Site	Reference	Methodology Notes[a]	Demonstrated Uses[b]	Procedural Comments
	Weeks (7, 13, 170)[19]; Weeks & Davis (141); Weeks & Compton (184)	PE/SI, S, U, UR	CI, II, M, SI	Cannula filled with isotonic saline; exteriorized at the back of the neck; cannula patency [injection, blood sampling] for 10 rats tested after 3 months: [8, 7], 4 months: [8, 5], 6 months: [5, 4], and 8 months: [2, 2]: methodological details are best presented in one paper (13)
Internal jugular:	Mouzas & Weiss (279)	A, N, S	M, S	Direct needle puncture of the surgically exposed vein; collects up to 5 ml of blood
Mesenteric	Rappaport *et al.* (143)	PE, PR, S, U	CI	Uses an easily constructed device to facilitate cannulation of small vessels; cannula filled with heparinized saline
	Zammit *et al.* (203)	PE/SI, S, U	II, M	Cannula filled with heparinized saline; 17 of 20 rats had patent cannulas for 3 weeks
Palpebral:	Anderson *et al.* (280)	P, TR, U	SI	Injection *via* a 30-gauge needle to the palpebral venous blood supply of the eye of newborn rats
Portal:	Cassidy & Houston (151)	A, N, S	SI	Inserted a 27-gauge butterfly infusion needle into the vein; cannula flushed with heparinized isotonic saline
	Gallo-Torres & Ludorf (282)	PE, S, TR, U	CI, M	(*a*) Splenectomy followed by threading of a cannula *via* the splenic vein into the portal vein; portal blood continuously sampled for 60 min; patent for up to 1 week; (*b*) splenectomy followed by insertion of a T-shaped cannula into the portal vein; patent for several months
		PE, S, TR, U	M	Direct cannulation of the vein followed by fixing the cannula in the vein with a piece of plastic and cyanoacrylate adhesive; patent for 3–4 days; excellent surgical field diagrams
	Hyun *et al.* (281)	A, PE, S	M	Cannula inserted in the portal vein *via* the splenic vein; filled with heparin (1000 U/ml) or distilled water
	Pelzmann & Havemeyer (198)	A, PE, S	M	A shunt of tubing was inserted in opposite directions in the portal vein; cannula filled with heparin
	Sable-Amplis & Abadie (199)	PE, S, U, UR	M	A T-shaped cannula inserted in the portal vein; cannula was siliconized, filled with heparinized (4 mg/ml) saline, and exteriorized at the back of the neck; 8 and 5 of 10 rats had patent cannulas at 1 week and 1 month, respectively
	Suzuki *et al.* (283–285)	A, PE, S	CI	Cannula threaded into the portal vein *via* the pyloric vein; methylene blue injected into the cannula after the procedure to verify location by blue staining of the liver; portal infusions given for 50 min
Retro-orbital venous plexus:	Lapeyrac (40)	A	S	Up to 0.6 ml of blood drawn into a glass pipet
	Lim *et al.* (44)	A	M	Collected up to six serial blood samples of ~0.5 ml each; diagram of ocular anatomy
	Nöller (36)	U	M	Drew up to several milliliters at once; glass capillary tube used as a collection device
	Riley (37)	U	M	Collected blood samples of ~0.2 ml each
	Salem *et al.* (41)	U	M	Collected up to 30 serial blood samples of up to 0.5 ml each; excellent description and photographs of method
	Sanders (42)	A	M	Adapted method of Riley (37) to germ-free animals
	Sorg & Buckner (43)	A/U	S, T	Up to 8 ml of blood collected into a test tube *via* the posterior canthus; claims less likelihood of nose bleeds and eye trauma
	Stone (39)	U	M	Collected up to 1 ml of blood per sample; used 2 drops of a 2% cocaine solution applied to the eye before sampling
Sagittal/Transverse Sinus:	Davis & D'Aquila (286)	N, PE, S, U, UR	II	Requires stereotaxic techniques; not used as a chronic infusion method
Saphenous:	Everett & Sawyer (287)	P, TR, U	II	Shaved the area, then dilated the vein with 70% alcohol and snapping with a finger; injection *via* a 26-gauge needle; good illustration of the injection site
	Grunt *et al.* (288)	A, N, P	II	Used an indwelling 27-gauge needle for maintenance of venous access during anesthesia
	Rusher & Birch (289)	P, U	M	Collected up to 0.2 ml of blood on each of 3–5 venipunctures per rat; used a 20-gauge needle
Sublingual:	Greene & Wade (290)	A	SI	Access to the sublingual vein is facilitated *via* a fine suture passed through the tip of the tongue; injection *via* a 26- or 27-gauge needle

[a] Methodology key: (A) postoperative experiment on anesthetized rats; (CSF) cerebrospinal fluid; (DL) double lumen cannula (1.5 mm o.d., 0.71 mm i.d.; DVE-8, Dural Plastics, Dural, NSW, Australia); (H) postoperative rat maintained in a body harness; (N) needle inserted into blood vessel, with tubing attached to needle; (NY) nylon cannula; (P) percutaneous method; (PE) polyethylene cannula; (PP) polypropylene cannula; (PR) postoperative experiment on partially restrained rats; (S) surgical method; (SI) silicone rubber cannula; (TE) polytef cannula; (TR) postoperative experiment on totally restrained rats; (TY) Tygon cannula; (U) postoperative experiment on unanesthetized rats; (UR) postoperative experiment on unrestrained rats; (V) vinyl cannula. [b] Key for demonstrated uses and procedural comments: (CI) continuous infusion; (ECG) electrocardiogram recording; (II) intermittent injections; (M) multiple blood sampling; (S) single blood sample with rat survival; (SI) single injection; (T) terminal blood sample; (VBP) venous blood pressure. [c] Unopette, Becton-Dickinson, Rutherford, N.J. [d] Lateral marginal vein.

anesthetized rats. Pang and Gillette (320) supplied evidence contrary to the hypothesis of extrahepatic elimination of acetaminophen in the rat using exclusionary hepatectomy *via* ligation of the hepatic artery and portal vein at points proximal to the liver. The absence of blue discoloration of the liver following a 0.5-ml iv injection of blue ink was used to verify the complete cessation of blood flow to the liver. Rats treated in this manner survived for ~85 min.

Portal–Systemic Shunts—A portal–systemic shunt is a surgically constructed connection between the side or end of the portal vein and a systemic vein (inferior vena cava or renal vein, a portacaval or portarenal shunt, respectively) to divert portal venous blood away from the liver.

Table V—Miscellaneous Methods for Vascular Access

Method	Reference	Demonstrated Uses[a]	Procedural Comments
Cardiac puncture:	Burhoe (5); Gupta (291); Kraus (21); Moreland (292); Waynforth (12)	M, S, T	Rats are anesthetized; generally uses a 25- or 26-gauge needle (0.5–0.75 in. long); Burhoe (5) collected up to 12 ml of blood at once without killing the rat and up to 5 ml of blood weekly for 3 months; procedure can be terminal, Stuhlman *et al.* (264) reported 12% mortality from cardiac puncture in rats; photographs and excellent procedural descriptions by Burhoe (5) and Waynforth (12); Gupta (291) used cardiac puncture for neonatal rats
Decapitation:	Bush & Bush (293); Moreland (292)	T	Particularly useful for terminal blood collection when anesthesia must be avoided; provides mixed arterial–venous blood; although aesthetically unpleasant, it is a humane procedure when done by experienced personnel using commercially available guillotines[b]
Tail amputation:	Enta *et al.* (294); Kraus (21)	M, S	Tail may be warmed before procedure; distal part (2–3 mm) of tail of unanesthetized rat is amputated to collect up to 4 ml of arterial blood (if lateral caudal veins are occluded by direct pressure) or mixed arterial–venous blood; bleeding is stopped by applying pressure or cauterization
Toe clip[c]:	Kraus (21); Moreland (292)	S	Rats are anesthetized; clipping the toe can yield up to 0.3 ml of mixed arterial–venous blood; due to postprocedural pain to the rat, this procedure is not recommended

[a] Key for demonstrated uses: (M) multiple blood samples per rat; (S) single blood sample per rat; (T) terminal procedure for blood sampling. [b] Harvard Apparatus, South Natick, Mass. and EDCO Scientific, Chapel Hill, N.C. [c] Plantar and dorsal digital arteries plus the plantar veins are clipped.

Procedures for portal–systemic shunting in the rat were introduced in 1946 by Whitaker (327) and Reinhardt and Bazell (328). Laboratory animals with a portal–systemic shunt have provided, due to conditions resulting from the shunt, useful models for the study of altered drug disposition in the dog (329, 330), altered pharmacodynamics in the cat (331), hemostatic abnormalities (thrombocytopenia, hypofibrinogenemia, impaired platelet aggregation) in the rat (332–334), hyperuricemia in the rat (335), and potentially altered blood–brain barrier permeability in the rat (336–338). A number of other shunt-caused metabolic abnormalities have yet to be exploited as animal models (339). Bircher (339) has provided a useful summary of the animal model utility of the portacaval shunt rat.

It is impractical to consider here the detailed methodologies available for portal–systemic anastomosis in the rat. Lee *et al.* (340) have presented an outstanding review of the relevant history and methodology, along with a thorough discussion of the hepatic and metabolic alterations associated with portal–systemic anastomosis. Steiner and Martinez (341) studied systematically the cytological and gross changes associated with ligation of the portal vein, hepatic artery, and bile duct. Although Bircher (339) has recently proposed routine use of the portacaval shunt rat for evaluation of first-pass effect, no study using such methodology in the rat has yet been published. The need for vascular surgical skills and an operating microscope undoubtedly hinder the widespread use of portacaval shunt methodology for studying the first-pass effect in the rat. Nonetheless, the portacaval shunt rat offers the opportunity for studies of a longer duration than can be accommodated using transhepatic blood sampling methodology. Perhaps this advantage will be exploited in the near future.

One portacaval shunt procedure requires neither an operating microscope nor vascular surgical skills, yet produces a rat useful for short-term experiments. Bernstein and Cheiker (342) completed a portacaval shunt without a vascular anastomosis by obliterating the arterial blood supply to the liver (*via* ligation of the coeliac, superior hepatic, hepatic, and gastroduodenal arteries and diverting the blood flow through a polyvinyl tube (with needle tips at both ends) connecting the portal and iliolumbar veins. Rats so prepared were used in experiments for several hours while anesthetized.

COLLECTION OF OTHER BODY FLUIDS

Urine Collection Methods—Studies of xenobiotic disposition often require sampling or total collection of excreted urine. Some investigators have developed detailed methods for renal clearance determination in the rat (343). Urinary excretion studies may often be impeded by the relatively low urine output (1.20 ± 0.24 ml/200 g/hr, mean ± *SEM*, $n = 10$) of healthy adult rats (344). Urine flow rate was increased four- to fivefold by oral gavage administration of a single volume of warm distilled water (0.05 ml/g body weight) to a maximum urine flow rate of 2.8 ± 0.2% of body weight/hr (mean ± *SEM*, $n = 4$; equal to 5.6 ml/200 g/hr) (345). Urine flow returned to the basal rate ~3 hr after the water load. Three administrations of warm distilled water at half-hour intervals (0.05 ml/g body weight each) further increased the urine flow rate to a maximum of 6.8 ± 0.4% of body weight/hr (mean ± *SEM;* equal to 13.6 ml/200 g/hr) (346, as cited in 345). Jeffers *et al.* (347) induced diuresis in the rat by oral gavage administration of a single volume (0.05 ml/g of body weight) of an aqueous ethanol solution (12% v/v of 95% ethanol in water) followed 30 min later by oral gavage administration of a volume (0.03 ml/g of body weight) of warm tap water. This regimen resulted in a stable increased urine flow rate (3.1–8.1 ml/hr) in male rats (180–220 g) achieved 90–120 min after the first gavage. However, the amount of ethanol used has a sedative effect.

Kraus (21) has classified urine collection methods as the free catch method, reflex emptying following periodic stimulation or massage, bladder puncture, cystostomy, urethral catheterization of female rats, and external drainage catheter for male rats (Table VI). For all methods, urine is collected in some type of ice-cooled receptacle. An antioxidant and a metal ion-complexing agent should be added when collecting oxidizable xenobiotics. After esti-

Table VI—Methods for Urine Collection.

Method	Advantages	Disadvantages
Free catch: Nelson *et al.* (349)	Useful in all age groups and both sexes; nonsurgical method	May not elicit complete emptying of bladder
Reflex emptying[a]: Adolph *et al.* (350)	Useful in all age groups and both sexes; nonsurgical method	Requires restraining cage; may not elicit complete emptying of bladder
Suprapubic pressure[b]: Hayashi & Sakaguchi (351)	Can collect urine in a capillary tube; useful in all age groups and both sexes; nonsurgical method	Elicits small urine volume.
Bladder centesis: Heller (352)	Useful in all age groups and both sexes; bladder can be emptied completely	Used only at necropsy
Cystostomy: Hoy & Adolph (353)	Useful in all age groups and both sexes; useful in conscious rats; provides continuous urine collection	Surgical method
Urethral catheterization: Cohen & Oliver (354)	Provides continuous urine flow; serial catheterizations are possible; nonsurgical method	Useful in adult female rats only; rats must be anesthetized
External drainage catheter: White (355)	Provides continuous urine flow; nonsurgical method	Useful in adult male rats only; rats must be anesthetized

[a] Raising and lowering the rat. [b] Applied with the fingers.

mating the volume of urine to be collected during the designated period (based on a conservative urine output of ~0.3 ml/200 g body weight/hr), an appropriate volume of stock antioxidant solution (1.0*M* α-thioglycerol plus 0.1*M* EDTA) is added to the urine to achieve final urinary concentrations of 0.01*M* α-thioglycerol and 0.001*M* EDTA (348a)[23]. Mulder *et al.* (348b) recommended addition of sodium azide to the urine receptacle to inhibit bacterial growth. For anaerobic collection and to prevent evaporation of urine, the receptacle can be partly filled with mineral (261) or paraffin oil (343).

Free Catch Method—Rats will frequently urinate when touched, picked up around the midsection, raised with their hind legs out of contact with the cage floor, or a small cotton ball moistened with diethyl ether is waved under the nose (349).

Reflex Emptying—Kraus (21) provides a description of the salient features of a restraining cage used by Adolph *et al.* (350). With a rat in this cage over a receptacle, urination was elicited by quickly raising and lowering the frame and animal. Reflex urination can also be elicited by applying digital pressure to the suprapubic region (351). A capillary tube can be used to collect urine obtained in this manner (351).

Bladder Puncture—Urine can be withdrawn *via* a needle and syringe from the bladder at the necropsy of the rat (352).

Cystostomy—Hoy and Adolph (353) surgically implanted a plastic cannula in the urinary bladder to obtain a continuous flow of urine. This cannulation method is useful in both male and female rats of all ages. Hoy and Adolph (353) observed a continuous urine flow rate of ~0.3–0.5 ml/hr in healthy, conscious adult rats.

Urethral Catheterization of Female Rats—Repeated short-term catheterization of the female rat urethra can be done using a No. 4 coude ureteral catheter (354). A continuous urinary flow for up to 4 hr while the rat was maintained under anesthesia was reported. This method apparently has not been used in conscious rats.

External Drainage Catheter for Male Rats—A modified polyethylene catheter[24] can be slipped over the tip of the penis of the anesthetized male rat, tucked under the foreskin, and secured in place by tying the foreskin around the catheter with a single silk ligature (355). Urine flow rates of 6–10 ml/hr were observed after fluid loading *via* an orogastric tube. This method cannot be used in either female or conscious rats.

Bile Collection Methods—*Introduction*—Experiments on hepatobiliary excretion of drugs often necessitate short-term, intermittent, or chronic collection of bile from the rat. Eight salient facts must be considered when collecting rat bile. First, the rat does not have a gallbladder to serve as a bile reservoir, and therefore bile flows continuously through the common bile duct into the duodenum (26). Second, the pancreatic duct empties pancreatic fluid into the common bile duct distal to the place where the bile enters. This anatomical arrangement enables the experimenter to collect either bile, pancreatic fluid, or a mixture of the two. The identity of the collected fluid must be ensured by close inspection of these anatomical features and correct placement of the ligatures. Since collection of pancreatic secretions in the rat has had limited application in the area of pharmaceutical sciences (356, 357), the interested reader is referred elsewhere for detailed methods on pancreatic secretion collection (11, 356–361). Third, electrolytes depleted by chronic bile diversion must be replenished by parenteral or oral fluid administration (362, 363). Free access to drinking water containing 2.5–5% glucose plus isotonic sodium chloride (192, 363), 0.85–1.0% sodium chloride (182, 364, 365), 5% glucose plus 0.9% sodium chloride plus 0.05% potassium chloride (366), or Ringer's solution (188) reportedly supply adequate electrolyte replacement. Intravenous saline infused at a rate of 1 ml/hr has also proven effective (367). Addition of glucose to oral fluids seems to encourage fluid intake in the rat (366). Fourth, bile flow is dependent on body temperature (368, 369). Therefore, maintenance of constant rectal temperature *via* use of a heat lamp is necessary for comparative studies of hepatobiliary excretory function (319, 369, 370). Fifth, phenobarbital (75 mg/kg/day for 4 days) can be used as an experimental tool to induce an ~50% increase in bile flow rate (371–373). Alternatively, cycloheximide reduces bile flow rate to ~33–50% of the flow rate in control rats (374). Sixth, although the rate of bile flow does not differ significantly in males compared with female rats, lactating female rats (7–10 days postpartum) and female rats at their 20th gestational day have an ~50% greater bile flow rate. On

[23] Concentrations of α-thioglycerol and EDTA specified here were modified from those stated in ref. 348a in accordance with methodology notes provided by W. D. Conway *et al.*

[24] Leur-End Intramedic polyethylene catheter; Clay Adams, Parsippany, N.J.

removal of the rat pups from the lactating female, this elevated bile flow rate decreases to that of normal female rats (370). Seventh, interruption of enterohepatic circulation by bile duct cannulation alters bile composition by lowering the ratio of cholic acid–cholesterol (375). This alteration must be considered in evaluation of the results of biliary excretion studies. Eighth, there is a circadian variation of both bile production (average nighttime production being 50 and 38% higher than daytime production in female and male rats, respectively) and bile composition which could markedly alter studies of xenobiotic disposition (376).

The physiology of bile secretion and the anatomical structures involved have been reviewed (11, 377, 378). Colwell (363) has provided a useful photograph of a bile duct injected with india ink. Mechanisms of hepatobiliary excretion and enterohepatic recycling of xenobiotics have been reviewed (379–381), as have some theoretical pharmacokinetic principles (320, 382).

Substantial research has been done to discern the general characteristics of xenobiotics undergoing hepatobiliary excretion in the rat. Sperber (383) suggested that compounds with molecular weights >400 (in the unconjugated form) are excreted efficiently in the bile. Millburn *et al.* (384) studied a group of different xenobiotics and concluded that compounds with a molecular weight of ~300 or greater containing a highly polar anionic moiety are likely to undergo significant hepatobiliary excretion. The reader interested in further details on this topic is referred to the extensive original research (192, 382, 385–390).

Concurrent with their studies of the types of compounds undergoing hepatobiliary excretion, Abou-El-Makarem *et al.* (386) compared eight species (rat, dog, hen, cat, sheep, rabbit, guinea pig, and rhesus monkey) with respect to their ability to excrete eight different xenobiotics in the bile. This excellent study revealed that the rat and dog are two of the better hepatobiliary excretors, while the rabbit, guinea pig, and rhesus monkey are poor hepatobiliary excretors. This information is valuable when evaluating interspecies differences in drug disposition characteristics.

Methods—Bile collection methods can best be considered by classifying them into three categories:

1. Intracorporeal reservoir methods, *i.e.*, cannulation of the common bile duct with total continuous diversion of bile flow into a reservoir surgically implanted in the peritoneal cavity (363, 366, 391) or abdominal wall (362).

2. Extracorporeal reservoir methods, *i.e.*, cannulation of the common bile duct with total continuous diversion of bile flow through the cannula to an extracorporeal collection reservoir (182, 188, 192, 364, 374, 376, 390, 392, 393).

3. T-cannula method, *i.e.*, implantation of a T-shaped cannula in the common bile duct to enable intermittent collection of bile (394).

In each of these three categories, various methods exist for acute sampling in anesthetized rats or chronic continuous collection in unanesthetized, unrestrained rats. Table VII provides procedural comments relevant to the advantages and disadvantages of available bile collection methods.

Continuous bile collection has been reported for up to 54 days in chronically cannulated, unrestrained rats (364).

Table VII—Methods for Bile Collection

Method	Procedural Comments[a]
Intracorporeal reservoir methods: Johnson & Rising (366)	PP-10 cannulation of the common bile duct which then drains into a 12-ml glass reservoir implanted in the peritoneum; bulb can be drained *via* an extracorporeal segment of tubing attached to the reservoir; bile collected for up to 6 days from unanesthetized, unrestrained rats
Sawyer & Lepkovsky (391)	An 18- or 19-gauge stainless steel cannula is inserted into the common bile duct and drains into a 6-ml glass bulb implanted in the peritoneum; bulb can be drained *via* an extracorporeal segment of tubing attached to the bulb; no cannulated rat survived >90 hr
Extracorporeal reservoir methods: Abou-El-Makarem *et al.* (192)	Polythene (0.4-mm i.d., 0.8-mm o.d.) cannulation of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel to an extracorporeal reservoir; bile collected from unanesthetized rat in a Bollman (395) restraining cage for up to 24 hr
Balabaud *et al.* (188)	PE-50 cannulation of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel to a cranial pedestal connected to an extracorporeal reservoir *via* a swivel; bile collected for up to 6 days from an unanesthetized rat in a small metabolism cage
Enderlin & Honohan (182)	PE-50 cannulation of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel to an interscapular incision connected to an extracorporeal reservoir *via* a swivel; bile collected for up to 4 days from an unanesthetized rat in a small metabolism cage
Friedman *et al.* (392)	PE-10 cannulation of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel exiting at the foot [see figure in Nakayama (396)]; bile collected for 24 hr from unanesthetized, restrained rats
Fisher & Vars (364)	PE-50 cannulation, of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel to a midline back incision into a piggyback cylindrical collection reservoir; bile collected for up to 54 days from unanesthetized rats
Knapp *et al.* (393)	PE-50 part of the cannula is inserted into the common bile duct, then the cannula is firmly anchored in place *via* a PE-250 cannula jacket; long-term bile collection from unanesthetized rats
Lock *et al.* (374)	PE-10 cannulation of the common bile duct; cannula exteriorized *via* a subcutaneous tunnel out of the back of the head to an extracorporeal reservoir; bile collected for 14 hr from an unanesthetized rat in a small metabolism cage
Takada *et al.* (390)	PE cannulation of the common bile duct for retrograde infusion studies in anesthetized rat
Vonk *et al.* (376)	Silicone-rubber cannula inserted into the common bile duct; cannula exteriorized at the skull *via* stainless steel tubing glued to the skull
T-Cannula method: Klauda et al. (394)	Silicone-rubber T-shaped cannula inserted into the common bile duct; permits periodic sampling of bile; a rubber collar around the neck was used to prevent chewing of the cannula

[a] Key for procedural comments: (PE) polyethylene; (PP) polypropylene.

Table VIII—Methods for Lymph Collection.

Reference	Procedural Comments[a]
Bollman *et al.* (404)	0.1 ml of 0.5% Evans blue dye was injected to enable identification of the lymphatic vessels; lymph collected continuously from unanesthetized, restrained, postoperative rats; 1–1.5 mm diameter plastic cannula used for lymphatic vessels of small intestine, liver, and abdomen; lymph flow rates of 5, 20, and 25 ml/24 hr from hepatic, intestinal, and thoracic lymphatics, respectively; lymph was collected for up to 3, 10, and 10 days from hepatic, intestinal, and thoracic lymphatics, respectively
Gallo-Torres & Miller (405, 406)	PE-50 cannula inserted into the abdominal thoracic duct; common bile duct was double cannulated for bile collection and saline infusion into the intestine; used cyanoacrylate adhesive to fix the cannula in the thoracic duct; lymph flow rate was proportional to the saline infusion rate; diverted bile can be reinfused *via* the intestinal cannula
Gowans (407)	Cannulation of the abdominal thoracic duct using the method of Bollman *et al.* (404); designed a pumping apparatus to reinfuse lymph and lymphocytes *via* the femoral vein
Reinhardt (408)	0.5 ml ip of 1% trypan blue enabled identification of the lymphatic vessels; rats anesthetized throughout procedure; cannula was tapered glass with a 25–27-gauge tip; thoracic duct cannulated in the neck; lymph collected for up to 6 hr; mean flow rate was 0.45 ml/hr (range of 0.13 to 0.70 ml/hr, n = 10)
Tasker (409)	Lymph collected continuously from unanesthetized, unrestrained, postoperative rats; a plastic cannula drained an intestinal lymphatic vessel into a glass reservoir (10–20 ml) placed in the peritoneum; lymph is collected *via* an extracorporeal reservoir access tube; collection for up to 10 days; flow rates of 0.5–1.0 ml/hr in fasting rats and 2–5 ml/hr in fed rats

[a] Key for procedural comments: (PE) polyethylene.

Cannulation of the common bile duct[25] with exteriorization at an interscapular incision for flow into an extracorporeal reservoir while housing the rat in a low-ceiling metabolism cage[26] has proven a useful procedure for relatively short (≤24 hr) bile collection. For more prolonged bile collection, passage of the extracorporeal portion of the cannula through an appropriate swivel joint will facilitate maintenance of a patent, unkinked cannula.

A unique procedure for the total exclusion of bile from the GI tract of male rats was described in 1936 (362). This procedure entails construction of a fistula from the bile duct to the vas deferens so that bile is eliminated in the urine. Rats prepared by this method remained apparently healthy for 3–4 months.

Bile collection methods are currently used in drug disposition and pharmacokinetic studies (366, 367, 397–403). Johnson and Rising (366) allowed at least 16 hr for rats to recover from bile duct cannulation, then included each rat in experiments only if (a) reasonable bile flow was established, *i.e.*, ~2–3 ml/kg/hr (366, 374, 391, 392), (b) the rat seemed to defecate normally (*i.e.*, no evidence of intestinal blockage), (c) the rat appeared healthy and active, not listless or lethargic, and (d) adequate food and fluid intake was maintained. These criteria are very useful guidelines for the postoperative and periodic evaluation of the rat with a cannulated bile duct.

Lymph Collection Methods—In 1945, Reinhardt (408) reported the first method for cannulation of the thoracic duct (at its location in the neck) and collection of lymph in the anesthetized rat. A single injection (0.5 ml ip) of 1% trypan blue administered 30 min prior to cannulation facilitated identification of the main lymphatic trunks. These investigators observed a lymph flow rate of 0.13–0.70 ml/hr (mean = 0.45 ml/hr, n = 10). Methodological considerations for lymph collection (404–409) are summarized in Table VIII.

Bollman *et al.* (404) extended lymph collection methodology to unanesthetized rats by insertion of a plastic cannula in the hepatic, intestinal, and thoracic duct lymphatic vessels. Postoperative, restrained rats provided continuous collection of lymph for up to 10 days. These investigators noted development of hypoprothrombinemia within 18 hr of lymphatic cannulation (316). Subcutaneous administration of vitamin K (4-amino-2-methyl-1-naphthol) both prevented and corrected hypoprothrombinemia development.

Tasker (409) collected intestinal lymph from unanesthetized, unrestrained rats by inserting a plastic cannula into an intestinal lymphatic vessel that drained into a glass reservoir (10–20 ml volume) placed in the peritoneum. Lymph was collected periodically by emptying the peritoneal reservoir *via* rubber tubing passing from the reservoir to a point of exteriorization at the right flank. This method seems useful for continuous lymph collection when restraint is undesirable.

Gowans (407) cannulated the abdominal thoracic duct using the method of Bollman *et al.* (404) to continuously collect lymph from restrained, unanesthetized rats. The collected lymph was reinfused into the femoral vein of the same cannulated rat *via* a pump apparatus. Such continuous reinfusion of lymph and living lymphocytes prevented the marked decrease in lymphocyte output from the thoracic duct previously noted when lymph flow was diverted for >2 days (410).

Finally, Gallo-Torres and Miller (405) introduced some modifications to simplify the method of Bollman *et al.* (404). A polyethylene cannula was inserted into the abdominal thoracic duct, while two other cannulas[27] were inserted into the common bile duct to enable bile collection with simultaneous infusion of isotonic saline (1.2–4.6 ml/hr) into the intestine. In rats fed a fatty meal 1 hr prior to surgery, the thoracic duct was recognized by its white coloration. Lymph flow rate was proportional to the saline infusion rate and lymph was collected for up to 10 days (405, 406). The integrity of the hepatobiliary excretory circuit can be reestablished by connecting the bile collection cannula to the intestinal infusion cannula. These investigators used a cyanoacrylate ester adhesive[28] to fix the cannula in the thoracic duct. Several excellent diagrams of the relevant anatomical regions are provided (19, 405).

Gallo-Torres (19) has provided a well-illustrated, integrated discussion of the application of lymphatic vessel,

[25] Using a polyethylene PE-10 cannula.

bile duct, and portal vein cannulation in evaluation of the bioavailability of xenobiotics in the rat. Since it provides a thorough review and examples of the experimental utility of lymph collection in the setting of other cannulas, the reader contemplating use of lymph collection methods is encouraged to refer to that work.

Cerebrospinal Fluid Sampling—The development of methods for ventricular access has been a critical contribution to the effort to advance knowledge in the neuropharmacology and psychopharmacology areas. Collection of cerebrospinal fluid and intraventricular administration of xenobiotics are highly specialized, intricate procedures that usually require experience in stereotaxic methods, knowledge of the anatomy of the brain, increased attention to aseptic procedures, and a high level of manual dexterity. Stereotaxic atlases of the rat brain are available to aid efforts to gain access to specific anatomical sites (32).

The majority of methods for ventricular access were designed for administration of either a single dose, multiple intermittent doses for up to 60 days, or a continuous infusion of very small volumes of xenobiotic-containing fluids (411–419). These methods recently have been reviewed by Myers (419) and illustrated by Avery (416). An easily constructed cannula originally used for intracerebral injections into cats and rabbits has proven useful in rats as well (420, 421). Wagner and DeGroot (422) constructed a single intracerebral cannula from two hypodermic needles and a small plexiglass plate. Hayden *et al.* (423) described detailed procedures for constructing and implanting in the lateral ventricle a relatively simple, inexpensive plexiglass cannula that enabled intraventricular injection for up to 3 months. The cannula constructed by Myers *et al.* (413) has proven to have great durability through the use of vinyl tubing[29] as an external protective shield. Khavari (225) has devised a combined intracerebral cannula–swivel unit to facilitate chronic studies in unrestrained rats. Although devised to enable intraventricular injection, some of these methods undoubtedly could be modified to enable sampling of cerebrospinal fluid.

Larger laboratory animals (cat, monkey) are preferred for chronic sampling of cerebrospinal fluid. Nonetheless, serial sampling over a 2-hr period has been accomplished in the rat. Serial small-volume samples (~5 μl) of cerebrospinal fluid were collected for ~2 hr *via* cisternal–lumbar (424) and ventriculocisternal perfusions (425) in order to monitor transport of seven amino acids into the cerebrospinal fluid. The artificial cerebrospinal fluid used by Merlis (426) for perfusion of the spinal subarachnoid space of the dog was useful in these perfusion studies in the rat (424, 425).

A single sample of cerebrospinal fluid can be obtained from the carefully recovered brain of a decapitated rat by inserting a glass microcannula (0.15 mm o.d.) into the mammillary recess of the third ventricle (427). By capillary action, 0.3–0.5 μl of cerebrospinal fluid was collected. Clemens and Sawyer (428) collected *via* cisternal puncture ~0.1 ml of cerebrospinal fluid from each anesthetized rat prior to sacrifice. No details (needle size, surgical preparation, exact site of puncture) of the method were given. Chou and Levy (429) described in detail a procedure for cisternal puncture of the anesthetized rat and collection of 50–100 μl of cerebrospinal fluid. Since this procedure requires only a 25-gauge needle and a piece of silicone rubber tubing, it should prove to be a valuable technique when only a single sample is required.

Saliva Collection Methods—Saliva remains a seldom-exploited fluid for collection in studies of xenobiotic absorption, distribution, and elimination. Welch *et al.* (276) accurately determined the elimination half-life of antipyrine in rats by the serial determination of salivary antiyrine concentrations. It was necessary to administer 2.0 mg/kg sc pilocarpine to some rats to collect (by capillary tube) 5 μl of saliva per sample. DiGregorio and Kniaz (430) monitored salivary amphetamine and methamphetamine concentrations in rats receiving a constant infusion of pilocarpine (0.125 mg/min) *via* the brachial artery. Saliva was continuously collected in a piece of polyethylene tubing over discrete time intervals *via* a polyethylene cannula placed in the parotid salivary duct. This technique of saliva collection was a modification of methodology developed for the mouse (431).

Additional details, illustrations, and pharmacokinetic applications of saliva drug concentration monitoring have been presented (432, 433). A number of other methods used for collecting rat saliva have been described in the dental research literature. These methods have been reviewed by Kraus (21).

METABOLISM CAGES AND RESTRAINING DEVICES

A number of commercial and home-built cages and devices, primarily constructed of wire or plexiglass, have been designed for short-term restraint with strict spatial confinement (434–444), restriction of certain body motions without spatial confinement (10, 445–450), and housing (metabolism cages) to facilitate intravascular xenobiotic infusion, quantitative collection of urine and feces, and/or measurement of food and water intake (235, 451–464).

Cage design and selection are commonly assumed to be relatively unimportant factors in designing animal experiments. However, molybdenum toxicity is increased in rats housed in zinc-coated cages (465) and the acute toxicity of various respiratory depressants in rats is markedly affected by cage design (466). Serum creatine phosphokinase activity in rats housed in cages with large spacings in the floor grating was approximately double that observed in rats housed in cages with small spacings in the floor grating (467). The effect on physiological variables of individual as opposed to group housing of rats has been recently reviewed (468). In view of these effects of cage design and individual housing, investigators should consider carefully the experimental impact of the metabolism cages and restraining devices described in the following sections.

Restraining Devices—*Short-Term Restraint*—Short-term restraint with strict spatial confinement is provided by restraining devices. These devices are used to achieve immobilization to facilitate administration of injectable substances, application of topical medication, collection of a blood sample, artificial insemination by vaginal smear, inhibition of access to indwelling cannulas, or induction of stress in studies of stress-associated effects in rats. The old restraining method of tying the conscious rat to a board (469, 470) is clearly excessive and unneces-

[29] Biraco vinyl tubing, number 318-B, size 8 Birnbach; Terminal Radio, New York, N.Y.

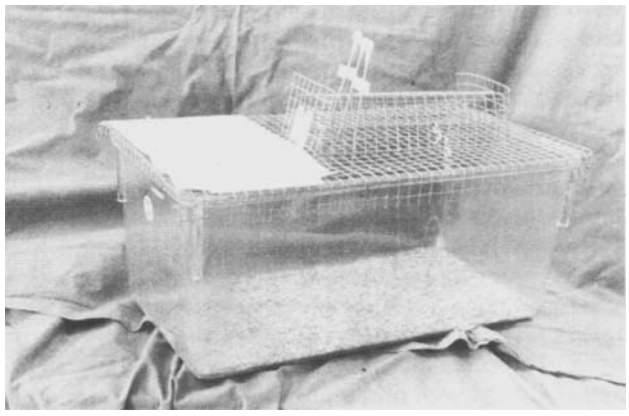

Figure 6—*A home-built restraining cage constructed from galvanized steel-wire hardware cloth. The rat fits inside the wire tunnel which has dimensions of 23-cm long, 7-cm wide, and 5.5-cm high. The size of the support wire grating can be chosen to fit on top of an available plastic animal bin.*

sary. Most commercially available restraining devices[30] resemble the Bollman-type confining tubular devices (261, 262, 395, 436–439, 471).

Each of these confining tubular devices: (a) is able to accommodate only a limited-size range of rats, (b) can accumulate feces in the rear of the cage, (c) imposes total restraint on rat movements, and (d) does not allow access to the rat for periodic oral gavage administration of xenobiotics. The novice will quickly discover that the conscious rat can not be removed effortlessly from any very confining device.

Scheline (471) modified the Bollman cage to make it adjustable to rat size and to allow urine collection. Similar characteristics are provided by a plastic stall restraining device (262). Davis and Coleman (442) used an adjustable, rectangular, plastic restraining cage for holding instrumented 200–400-g rats for up to 8 hr. Cotlove (261) used a tubular restraining cage from which the hind feet and tail protruded to collect urine during intravenous infusion into the lateral tail (caudal) vein. An adjustable cable-type restraining device was designed to restrict motion to facilitate undisturbed percutaneous absorption of substances applied topically to 200–300-g rats for $\leq$ 72 hr (115). Wilson (439) cut an opening in the top of a cardboard mailing tube to facilitate subcutaneous injection in the back of a restrained rat and access to the protruding tail for injection or blood sampling. To facilitate rapid removal of the rat from this tube, the distal end opened into a standard rectangular cage.

In designing an alternative to the Bollman cage to facilitate lymph collection, Baker *et al.* (472) placed the rat in a plexiglass rectangular cage with only the buttocks and tail restrained. This cage enabled the rat to move all but the hindquarters, allowed urine and feces to fall freely into a collecting vessel, enabled collection of lymph *via* a cannula exteriorized in the inguinal region, allowed access for oral gavage administration without removal of the rat from the cage, and accommodated rats ranging from 200 to 450 g.

As another alternative to the confining tubular devices, persons with minimal skill in the use of common hand tools (pliers and wire cutters) and a supply of inexpensive galvanized steel-wire cloth (available in most hardware stores) can readily construct the simple and durable restraining device described by Girardet (440). Figure 6 illustrates a modified version of this device, which was constructed to lie on top of a widely available plastic cage. This restraining device was constructed in ~1.5 hr and cost <$1.00 for materials (excluding plastic cage). By locating the wooden stick applicators at the buttocks of the rat, one device will accommodate rats of various body sizes. Similar characteristics are provided by a recently described restraining device which is inexpensively constructed from one small plexiglass plate (444). This device offers the advantage of enabling optional separate collection of urine and feces during restraint, but has the disadvantage of restraining the rat by greater immobilization of the limbs than used with the device illustrated in Fig. 6. Prolonged exposure to excessive restraint has been associated with increased incidence of pathological events as described in a later section.

Momentary Restraint—Momentary restraint is often essential for injection, blood sampling, collection of a vaginal smear, or artificial insemination. Such acute restraint can be accomplished by properly holding the rat in one hand (Fig. 2), using a protective glove when animal biting is a problem. Since various individuals prefer leather gloves (available in hardware stores), butcher's metal-mesh boning gloves[31] (473), or gloves made of 29 aramid[32] (474), each animal handler should try different gloves and use that which proves personally preferable.

Two alternatives to holding the rat are allowing the animal to crawl into a close-fitting restraining sack (435), polythene tube (441), or plastic cone[33], and wrapping the rat in a towel with the head, neck, and tail exposed (6). Use of these methods is restricted by the limited region of the body which remains accessible. The use of tubes into which the rat will crawl enables convenient collection of blood or injection *via* tail blood vessels by a single experimenter (441). Transillumination of the tail may also be helpful in visualizing the blood vessels (475).

Restricting Motion—Restriction of certain body motions without spatial confinement is often useful in preventing the rat from disturbing indwelling cannulas, irritating surgical wounds, or consuming fecal material (coprophagy). Graham (450) described a small box which allows the rat to hide its head for up to 1 hr, thereby facilitating investigator access to a cannula emerging from the back of the neck. Coprophagy-preventing devices and Elizabethan collars are described below.

Coprophagy and Its Prevention—The degree of coprophagy by the rat is recognized as a major variable in certain nutritional studies, particularly those involving vitamins B and K, since these are ingested by the rat following synthesis by intestinal bacteria (476–479). In fact, this behavioral drive is so strong that healthy rats consume on the average 35–65% of their total fecal output (480–482). The extent of coprophagy was most dramatically demonstrated by Greaves (483), who observed that unrestrained

[30] Model 700R rat restrainer; Braintree Scientific, Inc., Braintree, Mass. No. 56-4500 rat restrainer; Harvard Apparatus Company, Inc., South Natick, Mass. Model H2284 restraining cage; Hazelton Systems, Inc., Aberdeen, Md.

[33] Model DC-200 DecapiCones; Braintree Scientific, Inc., Braintree, Mass.

rats fed a vitamin K-free diet for 180 days remained healthy and still excreted appreciable amounts of vitamin K in their feces. Unfortunately, many scientists in areas other than the nutritional sciences are unaware that coprophagy is essential for the normal growth and development of young rats (484).

Since the rat primarily consumes feces immediately after extrusion from the anus (482), the raised wire-mesh floors in many metabolism cages are ineffective in preventing coprophagy (482). Clearly, this fecal–oral recycling may be critical to mass balance studies, quantification of drug excretion routes, and pharmacokinetic studies. Three methods have been devised to inhibit coprophagy (485): (*a*) tubular cages restricting flexion and lateral motion (481, 486), (*b*) a tight-fitting leather jacket restricting flexion (448), and (*c*) placement of a plastic cup over the tail and anus of the rat to catch fecal pellets, thus rendering them inaccessible to the rat (480, 487, 488). In addition, the Elizabethan collar may be useful in inhibiting coprophagy.

Elizabethan Collars—The Elizabethan collar is easily constructed and very useful for restricting motion to prevent the rat from disturbing indwelling cannulas, irritating surgical wounds, or consuming fecal material (Fig. 7). The collar consists of an adjustable plastic or reinforced cardboard cone which fits snugly around the neck and encloses the head in the body of the cone, thereby preventing scratching of the head, licking or biting other parts of the body, and coprophagy (10, 446, 449). The desired collar size can be calculated by:

$$\text{collar i.d.} = \frac{\text{neck circumference}}{\pi} \qquad \text{(Eq. 3)}$$

and

$$\text{collar o.d.} = \text{collar i.d.} + \text{desired depth} \qquad \text{(Eq. 4)}$$

Metabolism Cages—A metabolism cage is a unit used to house an individual rat to facilitate quantitative separate collection of urine and/or feces, measurement of food and/or water intake, quantitative collection of expired respiratory carbon dioxide, and/or containment of radiolabeled substances administered to the rat. Since most of these cages confine the animal to a relatively small defined space without immobilization, metabolism cages also provide some degree of cannula protection when housing rats with indwelling cannulas. Generally, rats will tolerate well a relatively short period in any metabolism cage. However, experiments with durations >12 hours necessitate the use of metabolism cages that enable adequate air flow to the rat, ready access to food and water, and easy retrieval of the collected urine and feces. In addition, a slightly higher room temperature (23–26°) may help prevent respiratory disease during confinement (456).

Grantham *et al.* (235) noted that rats rest easier when maintained in square, rather than circular, metabolism cages since this shape allows the rat to sleep in a corner. Lazarow (456) has provided an extensive review of the many aspects involved in designing and building metabolism cages for the rat, mouse, dog, and monkey. The basic aspects of metabolism cages have not changed much over the years (except for the availability of various polymeric construction materials such as plexiglass and Nalgene[34])

[34] Nalge Company, Rochester, N.Y.

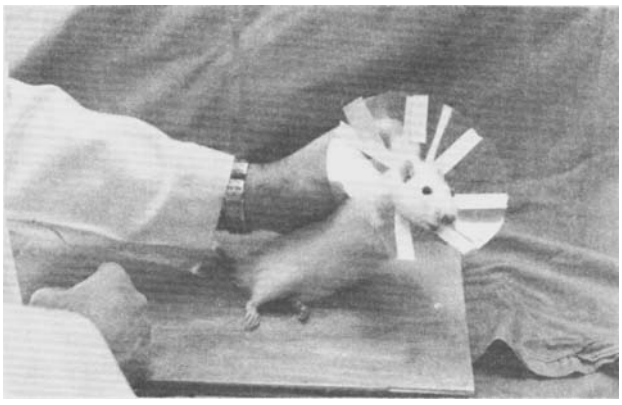

Figure 7—*An adult rat fitted with a plastic Elizabethan collar (highlighted with white tape strips for photographic clarity) around the neck. This collar (3.0-cm i.d., 16.0-cm o.d.) was cut from a rectangular plastic sheet usually used for transparencies.*

and the individual interested in home-built metabolism cages will find the detailed illustrations in this review extremely useful despite their age. A round wire-mesh cage using a funnel which contains a screen or shield for urine and feces separation, and a frame holding six such cages is described. Similar inexpensive wire cages have been described by others (452, 453, 458, 487). Suspended steel cages and a rack accommodating 36 such cages have been described (456). This unit is similar to many commercially available racks of suspended steel metabolism cages. Lazarow (456) also described cages which could be easily disassembled following studies with radioisotopes for thorough cleaning and decontamination, as well as a cage used for the quantitative collection of expired respiratory carbon dioxide.

Meticulous Urinofecal Separation—Cross contamination of urine and feces must be meticulously prevented in studies of elimination routes when the excreted substance can appear in both excretory products or when a drug excreted in the urine could be biotransformed by enzymes (such as β-glucuronidase) in the feces (348b). These situations commonly arise when studying the excretory routes of radiolabeled substances (454) and when assaying urinary activity of enzymes also present in large quantities in the feces (460a). The plastic stockade type of metabolism cage (454, 456, 460a) has been shown to meticulously prevent such cross contamination. Unlike most metabolism cages, it appears that this cage would prevent cross contamination even in the presence of diarrhea.

Leathwood and Plummer (460a) quantified the degree of fecal contamination of urine collected *via* three conventional metabolism cages, which used the following means of urinofecal separation: (*a*) a hollow, somewhat ellipsoidal glass device over which the urine flows for transfer into a collection beaker while the feces bounce off into another path (type I separator), (*b*) a urine collecting gutter, which diverts the falling urine into a collection beaker while the feces fall downward into a beaker (type II separator), and (*c*) a stockade-type metabolism cage (454, 456). Fecal contamination of the urine was most severe for the type I separator (which is used in several commercially available metabolism cages[35]). The type I

[35] Maryland Plastics, Inc., Federalsburg, Md. Model number 650-0100 metabolic cage; Nalge Company, Rochester, N.Y.

separator also failed to separately collect ~60% of the voided urine. The type II separator was fairly efficient in separating the urine and feces and in collecting urine. Efficient urinofecal separation was afforded by the stockade-type cage. However, the adverse effects (anorexia, weight loss) of strict restraint for >2 days necessitates only brief confinement of the rat to this type of cage.

Low-Temperature Urine Collection—The metabolism cage designed and illustrated by Lartigue *et al.* (463) is useful for the collection and rapid freezing of urine in cases where a voided substance is subject to temperature-sensitive degradation. This cage uses a urine collection dish immersed in propylene glycol to enable rapid freezing (−19°) of urine. Since propylene glycol is nonflammable and relatively nontoxic, it is preferred to other methods using flammable and irritating heptane and dry ice as the coolant (489, 490).

Miscellaneous Metabolism Cages—A number of metabolism cages necessitate only moderate confinement of the rat while allowing visual observation of rat behavior and providing separate collection of urine and feces, with reduced possibility of urinofecal cross contamination for the animal excreting well-formed feces (456, 457, 459, 461–463). One of these metabolism cages (459) is inexpensive to construct from widely available materials. This cage has the advantages of being easy to disassemble for cleaning and readily mountable on multi-cage racks. Lambooy (459) has provided detailed step-by-step directions for construction.

Jensh *et al.* (491) described a plexiglass cage useful for observing unrestrained pregnant rats in an anechoic, microwave-transparent chamber, which does not alter a number of potentially environment-dependent variables. Grantham *et al.* (235) built a square cage from plexiglass and wire mesh to facilitate intra-arterial infusion in relatively unrestrained, unanesthetized rats *via* a nonswivel spring attachment.

Accurate quantification of food and fluid intake is often difficult due to spillage of the food pellets and fluid into various regions of the cage. In addition, it is sometimes desirable to strictly minimize food contamination of the collected urine and feces. Guest *et al.* (455) described a metabolism cage constructed from an inverted 11.4-liter (3-gallon) narrow-necked glass bottle into which a wire-mesh floor was inserted. A fine mesh screen positioned below the floor enabled separation of urine from feces. A special detachable feeder was readily constructed from sheet metal, a 50-ml beaker, and wire mesh. This feeder minimized the amount of food dropped outside the feeder (<1% of food intake per day) and, therefore, was useful in quantifying daily food intake. In addition, this feeder minimized food contamination of the collected feces and urine. This basic type of feeder design has been incorporated into one commercially available metabolism cage[36]. To aid in accurate quantitation of fluid intake, Robbins (492) fit a modified plastic syringe with a sipper spout made of 8-mm o.d. glass tubing. Use of an appropriate size plastic syringe enables achievement of the desired degree of accuracy with respect to fluid consumption measurement.

Recently, Toon and Rowland (464) described a tubular plexiglass cage that allowed longitudinal movement by the rat, separate urine and feces collection, and access to various cannulas for up to 8 hr of confinement. Although the virtual necessity of workshop construction by skilled personnel and the relatively high cost are disadvantages, the unique features of this cage may warrant the investment by some laboratories.

Effects of Restraint—Often, observation of hyperactivity, sitting in a corner of the cage, scratching at a harness, decreased curiosity and exploratory behavior, free micturition and defecation, and/or passage of soft stools may suggest stress in a rat (460a, 493). The stress associated with various physical restraints (tying the conscious rat to a surgical board, housing in a restraining cage, application of a body cast, placement in a harness) or periodic shocks from an electrified cage has been shown in the rat to be associated with neutrophilia (approximately a sevenfold increase after 6 hr of restraint) (494), decreased whole blood clotting time (495), diminished altitude tolerance (496), occurrence of stomach lesions after as little as 48 hr of restraint with a greater frequency and severity noted in restrained rats housed in groups (497, 498), increased gastric acid concentration (499), decreased growth rate (493, 498), decreased daily food intake (493), and hyperactivity (493). Of particular interest is a study documenting the stress response associated with placement in a body harness (500) for chronic intravenous infusion (493). These stress-associated pathophysiologic events must be considered in designing experiments requiring extended restraint or harnessing of the rat.

CONCLUSIONS

The vast literature on methods of vascular access and collection of various body fluids has been reviewed. The investigator new to these methodologies is advised to gather a minimal but essential resource library consisting of papers providing highly detailed and illustrated accounts of cannula construction and implantation (13, 15, 501); aseptic surgical methods (23); rat resuscitator assembly (105, 106); a general review providing information on animal handling, anesthesia, and euthanasia (6, 10, 12, 21, 22); a well-illustrated anatomy text (31); and information on metabolism cages (456). It is hoped that this literature survey provides a useful summary of practical information and a valuable description of alternative methodologies to experimental scientists[37].

ADDENDUM

Since the submission of this manuscript, a textbook of experimental techniques for the rat has been published (C. Petty, "Research Techniques In The Rat," Charles C Thomas, Springfield, Ill., 1982). This textbook includes a broad range of experimental methods and a multitude of useful illustrations. This book is well worth its price for both the novice and experienced researcher.

Two additional publications of interest are a useful tabular compilation of LD_{50} values in several species of

[36] Model no. 650-0100 metabolic cage; Nalge Company, Rochester, N.Y.

[37] On a very limited basis, the authors will make available a photocopy of these references complete with each citation's title, all authors, and full pagination. This offer can be extended only to those scientists and information services with a serious need for such information.

newborn and adult animals [E. I. Goldenthal, *Toxicol. Appl. Pharmacol.*, **18**, 185 (1971)] and one providing a relatively simple procedure for percutaneous placement of an intravascular needle into the caudal artery for collection of serial blood samples from an anesthetized rat *via* the extravascular silicone-rubber tubing attached to the needle [L. Putcha, J. V. Bruckner, S. Muralidhara, and S. Feldman, *J. Pharmacol. Meth.*, **8**, 145 (1982)]. The latter should prove very useful for pharmacokinetic characterization of drugs in individual anesthetized rats.

ACKNOWLEDGMENTS

This work was supported in part by NIH Grant HL-24343. T. D. Bjornsson is a recipient of a Pharmaceutical Manufacturers Association Foundation Faculty Development Award in Clinical Pharmacology.

The authors are grateful to Ms. Coyla McCullough (Wellcome Research Laboratories) for her invaluable assistance in searching this large body of scientific literature. Valuable comments on an initial draft of this manuscript were provided by Dr. James E. Brown and Ms. Linda F. Cook, the latter of whom also graciously did the photography for all figures. Informative conversations with Dr. James R. Weeks (The Upjohn Company) are gratefully acknowledged. The authors thank Dr. Gerhard Levy, Mr. David Soda, Dr. Beresford Stock, and Dr. Chii-Ming Lai for introducing them to experimentation with the laboratory rat. Finally, the patience and skilled typing assistance of Ms. Wanda Seymour are gratefully acknowledged.

Pharmacokinetic Relationships Between Cinromide and Its Metabolites in the Rhesus Monkey I: 3-Bromocinnamamide, an Active Metabolite

ELIZABETH A. LANE * **and RENÉ H. LEVY** ˣ

Received February 8, 1982 from the *Department of Pharmaceutics, BG-20, University of Washington, Seattle, WA 98195.* Accepted for publication May 25, 1982. *Present address: Laboratory of Chemical Pharmacology, NHLBI, National Institutes of Health, Bethesda, MD 20205.

Abstract □ Fifty percent of a cinromide dose was metabolized to an active metabolite in the rhesus monkey. The steady-state concentration of this metabolite was 3–6 times that of the parent drug, depending on the route of administration. Cinromide is a medium-extraction ratio drug with a short half-life (0.92 ± 0.23 hr) when compared with the active metabolite, which has a low extraction ratio and a longer half-life (4.43 ± 0.76 hr). Incomplete oral bioavailability of cinromide is a result of first-pass metabolism rather than incomplete absorption.

Keyphrases □ Cinromide—pharmacokinetics, 3-bromocinnamamide metabolite, bioavailability, first-pass effect □ 3-Bromocinnamamide—active metabolite of cinromide, pharmacokinetics, bioavailability □ Pharmacokinetics—cinromide, 3-bromocinnamamide, primate model □ Bioavailability—cinromide, 3-bromocinnamamide, primate model

Whenever a drug yields a metabolite known to have similar pharmacological activity, speculation arises regarding the extent to which the metabolite is responsible for the apparent effect of the parent drug. Therefore, it becomes important to understand the relative disposition characteristics of the parent drug and active metabolite. Cinromide (3-bromo-*N*-ethylcinnamamide) is a new anticonvulsant drug which has reached Phase II of pharmacological evaluation (1–7). Cinromide is known to have an active metabolite resulting from *N*-deethylation (3-bromocinnamamide) which accumulates in humans (8). This investigation addressed two questions pertaining to the relative importance of the parent drug and metabolite: (*a*) the prediction of the steady-state metabolite–parent drug concentration ratio (9) and (*b*) the fraction of cinromide metabolized to the active metabolite. Prior to testing cinromide efficacy for epilepsy in the chronic primate model (6), it was necessary to define the pharmacokinetic characteristics (in particular, the dose dependency and bioavailability) of both of these compounds in this animal model.

EXPERIMENTAL

Animal Studies—Five male rhesus monkeys (*Macaca mulatta*), weighing 4–6 kg and adapted to primate restraining chairs, were each equipped with a jugular catheter for blood withdrawal and a femoral catheter for intravenous drug administration. These studies included the following treatments: (*a*) three intravenous infusions of cinromide[1], (*b*) two intravenous bolus doses of metabolite[1], (*c*) and one oral dose each of cinromide and metabolite.

The three cinromide infusions and the two bolus doses of metabolite were administered according to a randomized Latin-square design. The poor solubility of cinromide (0.09 mg/ml of water) even in 60% polyethylene glycol 400 (29 mg/ml), and its toxicity after large doses, precluded administration of intravenous bolus doses >25 mg/kg. Therefore, to test for dose dependency, cinromide was administered by intravenous infusion (25 mg/ml in 60% polyethylene glycol 400) at rates of 1, 2, and 4 ml/hr for 5 hr. A total of 30 plasma samples (0.5 ml) were collected during the infusion and 30 hr into the postinfusion phase. Urine was collected from the beginning of the infusion until 30 hr postinfusion. Doses of the amide metabolite (10 and 20 mg/kg) were injected over 1–2 min, and 20–25 plasma samples were collected over 30 hr. Urine samples were collected every 12 hr for a 24-hr period after each dose. Oral doses of 125 mg/kg of cinromide and 20 mg/kg of 3-bromocinnamamide were administered to each monkey by nasogastric intubation. Plasma samples were collected for 30 hr after each dose.

The ratios of blood–plasma concentration (λ) for cinromide and the metabolite were estimated from two samples taken from each of four monkeys after a single dose of cinromide. The fraction of cinromide and metabolite bound to plasma proteins was measured after equilibrium dialysis of spiked monkey plasma against isotonic phosphate buffer (pH 7.4). Ten to fifteen replicate determinations of the binding of cinromide at 25, 50, and 101 μmoles/liter and metabolite at 28, 60, and 133 μmoles/liter were made. The samples were dialyzed at 37° for 6 hr (the time required to reach equilibrium).

Analytical Procedure—Plasma samples were analyzed simultaneously for cinromide and the amide metabolite by high-performance liquid chromatography (HPLC). A 0.2-ml sample of plasma was extracted with 5 ml of benzene. The solvent was removed under a nitrogen stream at 50° and reconstituted with 100 μl of the mobile phase (methanol–water, 70:30). Two internal standards (3-bromo-*N*-butylcinnamamide[2] and 3-iodo-*N*-cyclopentylcinnamamide[2]), cinromide, and the metabolite were separated on a C_{18} μ Bondapak column[3] and measured by absorbance at 280 nm. Specificity of this assay was verified by comparison with another method (10).

Accuracy and precision of this assay were monitored by analysis of six control samples (duplicates of three different concentrations of cinromide and amide metabolite) with each set of unknowns. The difference between the known and assayed concentrations, divided by the known concentration, measured the accuracy of the assay. The difference between duplicates, divided by the average, measured the precision of the assay.

Urine (0.5 ml) was analyzed for cinromide in a similar manner. For the metabolite, a sample of urine was extracted and the benzene extract was washed with 2 ml of 0.2 *N* HCl before evaporation.

Pharmacokinetic Analysis—The area under the plasma concentration *versus* time curve (AUC) for each compound was measured by the trapezoidal rule with the terminal area estimated by C/β, where C is the concentration of the last sample and β is the rate constant for the slowest log-linear phase. Clearance (CL) was calculated from dose/AUC and steady-state volume of distribution by a previous method (11). Fitting of concentration time data was performed with the BMD-07R program (12).

RESULTS AND DISCUSSION

Assay—The recovery of cinromide and metabolite averaged 98 ± 11% and 93 ± 9%, respectively ($n = 27$: nine replicates at three concentrations, 0.4–12.8 μg/ml for both compounds). Over 13 months, >300 control samples were analyzed yielding accuracy values of 8.2 ± 6.7% and 7.5 ± 6.0% for cinromide and the metabolite, respectively. The precision was 3.4 ± 3.5% and 4.0 ± 4.0% for cinromide and the metabolite, respectively. Within the ranges examined, no concentration dependence for accuracy or precision was apparent.

Cinromide Pharmacokinetics—The postinfusion decay of cinromide was fitted to a monoexponential equation. The average half-life (0.92 ± 0.23 hr) is consistent with achievement of steady state during the 5-hr infusion in most monkeys (Fig. 1). The half-life, clearance, and volume of distribution of cinromide measured from the infusion data are reported in Table I. The volume of distribution was constant in the dose range examined [one-way analysis of variance (ANOVA) on repeated measures, BMDP2V (13)]. Although there was a trend for the lowest clearance at the highest dose, there was no significant difference. However, the postinfusion half-life after 100 mg/hr was significantly longer than the postinfusion half-lives after 25 and 50 mg/hr ($p < 0.05$).

It was found that cinromide had a blood clearance (CL_{plasma}/λ) of 7.5 ± 2.9 liter/hr ($\lambda = 0.82$), about one-half of liver blood flow in the monkey (14). Less than 1% of a dose of cinromide was excreted unchanged in the urine and, assuming all metabolism occurs in the liver, this blood clearance may be regarded as the systemic hepatic clearance (CL_{sys}) of cinromide. CL_{sys} is a nonlinear function of liver blood flow and intrinsic hepatic clearance (CL_{int}) (15, 16), and therefore, it is not a sensitive index of dose dependency of intrinsic clearance. In addition, measurement of clearance as dose/AUC is a time-averaged value and less sensitive to dose-dependent nonlinearities than measurements of clearance at steady state. At the lower two infusion rates, cinromide reached steady state in all monkeys; at the highest infusion rate, steady state did not appear to have been reached in three of the five monkeys. This observation indicates that cinromide may be cleared in a dose-dependent fashion not detected through measurements of average intravenous clearances (dose/AUC).

Metabolite Pharmacokinetics—The amide metabolite could be adequately described by a one-compartment model in three of the five monkeys and a two-compartment model in the other two. The metabolite half-life (4.43 ± 0.76 hr; Table II) was 3–8 times longer than the parent drug half-life (0.92 ± 0.23 hr). Because of the long half-life, the amide metabolite did not reach steady state during the 5-hr cinromide infusion (Fig. 1). The difference in the time course of the two compounds was highlighted in the postinfusion phase. Cinromide could not be measured in the plasma 4 hr after the infusion was stopped, whereas the metabolite was present for >30 hr.

[a] Statistically significant, $p < 0.05$ compared with the 10-mg/kg dose.

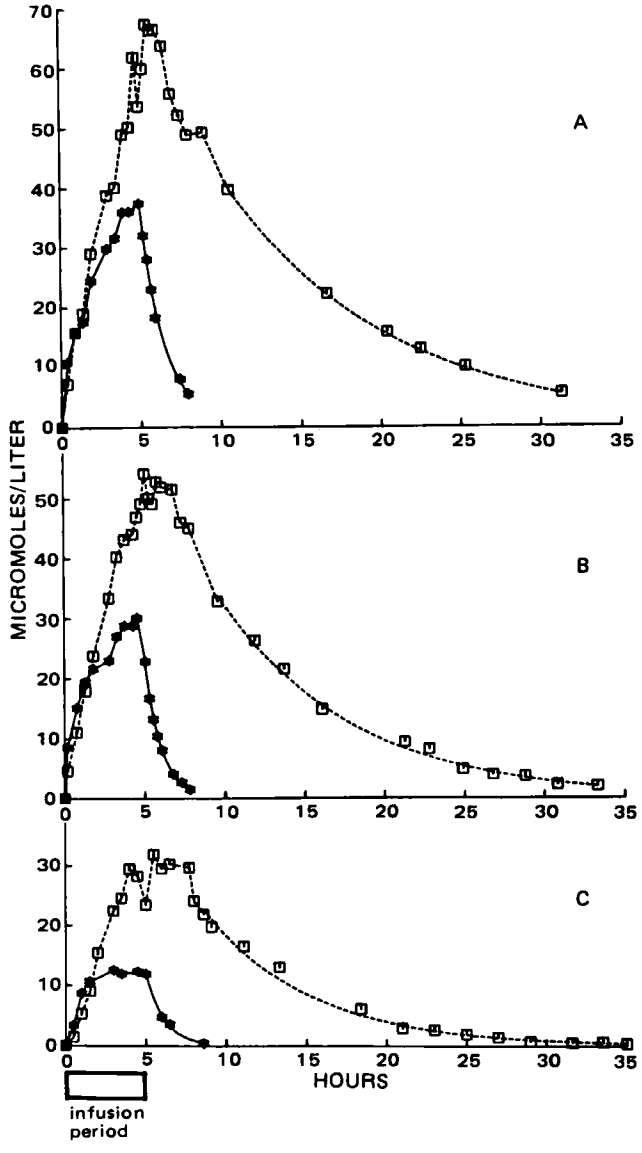

Figure 1—*Cinromide and 3-bromocinnamamide plasma levels during and following three separate cinromide infusions to monkey 184. Infusion concentrations were: (A) 291, (B) 189, and (C) 83 μmoles/hr. Key: (★) cinromide data, (□) 3-bromocinnamamide data, (—) least-squares fit to a monoexponential equation for cinromide (end of infusion to not detectable), and (---) least-squares fit to a monoexponential equation for 3-bromocinnamamide (from the time cinromide is no longer detectable).*

The average plasma clearance of 3-bromocinnamamide decreased from 0.80 ± 0.18 liter/hr to 0.63 ± 0.11 liter/hr when the dose was increased from 10 to 20 mg/kg (Table II). This apparent dose dependency was not significant at the 5% level ($p = 0.077$, paired t test). The volume of distribution of 3-bromocinnamamide decreased significantly ($p < 0.05$) when the dose was increased through this range. Administration of the amide metabolite suggested nonlinear behavior, both in clearance and distribution. However, these two nonlinearities affect half-life in opposite directions. This situation may explain the lack of dose effect on half-life.

The overall average amide metabolite half-life was significantly longer after administration of the parent drug than after administration of the

Table III—Variation in the Half-Life of the Amide Metabolite at Different Doses of Cinromide

266	6.2	5.4	5.7
Mean	5.2	5.3	6.9[a]
SD	1.2	0.9	0.9

[a] Statistically significant ($p < 0.05$) compared with infusion of 50 or 25 mg/hr.

metabolite. Also, the half-life of this amide metabolite (Table III) increased with increasing doses of cinromide [$p < 0.05$, one-way ANOVA on repeated measures, BMDP2V (13)].

The larger metabolite half-life observed after administration of the parent drug could be due to a type of nonlinearity different from saturation, *e.g.*, inhibition of metabolism by the parent drug or any of its metabolites. Such a phenomenon could also explain the dose-dependent half-life of the metabolite generated *in vivo*.

Fraction Metabolized and Steady-State Metabolite–Parent Drug Concentration Ratio—The fraction of a dose of cinromide metabolized to the amide metabolite (fm) was calculated in a model-independent manner (17):

$$fm = \frac{(AUC_m)_p}{D_p} \times \frac{D_m}{(AUC_m)_m} \qquad \text{(Eq. 1)}$$

where $(AUC_m)_p$ and $(AUC_m)_m$ are the AUC values of the metabolite following a dose of the parent drug and metabolite, respectively, D_p is the dose of the parent drug, and D_m is the dose of the metabolite. The areas under the curve and doses are expressed in molar units.

Since 3-bromocinnamamide is a low-extraction ratio drug, intravenous administration provided an appropriate estimate of intrinsic metabolite clearance for calculation of the fraction metabolized (18). This equation assumes a dose-independent metabolite clearance which measures the clearance of metabolite formed *in situ*. The preceding analysis implies that this is not the case. Therefore, the clearance of a 3-bromocinnamamide dose that was associated with approximately the same plasma concentrations of 3-bromocinnamamide as observed after cinromide, was used in calculation of the fraction metabolized. This matching of 3-bromocinnamamide concentrations would be appropriate if the apparent nonlinearity in metabolite clearance is due to a saturation phenomenon of the Michaelis–Menten type.

The fraction of cinromide metabolized to 3-bromocinnamamide in five monkeys after 14 doses of cinromide averaged 0.47 ± 0.12 (Table IV). This fraction of cinromide metabolized by *N*-deethylation showed no apparent dose dependence. Although theoretically the fraction metabolized is independent of metabolite clearance, it is not when calculated by this method. Therefore, the intra- or interanimal variability in the fraction metabolized may reflect a true variability in the fraction metabolized, as well as variability in the metabolite clearance.

From measurements of the total AUC of the metabolite and the parent drug after a single dose of cinromide, the steady-state metabolite–parent drug concentration ratio during intravenous infusion was predicted at 3.2 ± 0.9 (9). The fraction of free cinromide in monkey plasma (0.17 ± 0.04) was constant over the range examined (25–101 μmoles/liter). The binding of the amide metabolite was similar to the binding of the parent drug, *i.e.*, the free fraction was 0.18 ± 0.04 in the 28–133-μmoles/liter range. Therefore, the ratio of unbound metabolite to parent drug in plasma was predicted to be ~3.

Oral Bioavailability of the Parent Drug and the Metabolite—

Table IV—Fraction of a Cinromide Dose Metabolized by *N*-Deethylation in the Rhesus Monkey

Mean	0.53	1.01	1.20
SD	0.21	0.17	0.43
CV, %	39	16	36

Since the systemic clearance of cinromide was a significant fraction of the hepatic blood flow, an appreciable first-pass effect was expected. The maximum bioavailability of an oral dose (F) can be predicted from the systemic clearance and hepatic blood flow (19, 20):

$$F = 1 - \frac{\text{Hepatic blood clearance}}{\text{Hepatic blood flow}} \qquad \text{(Eq. 2)}$$

This calculation assumes: (*a*) complete absorption from the GI tract; (*b*) metabolism only in the liver; and (*c*) an average hepatic blood flow of 3.18 liters/hr/kg (14). The maximum predicted bioavailability of cinromide was 0.57 ± 0.12, while the observed bioavailability was 0.52 ± 0.12 (Table V). There was no significant difference between the two values. Thus, the incomplete oral bioavailability of cinromide is probably not a result of a dosage form effect or incomplete absorption from the GI tract. Confirmation of the fact that the incomplete availability of oral cinromide is a result of a presystemic first-pass effect, rather than incomplete absorption, was obtained from the metabolite data. The AUC ratio of oral–intravenous metabolite (corrected for dose) averaged 1.01 ± 0.17 (Table V). The equal availability of the active metabolite by both routes of parent drug administration decreases the therapeutic consequences of the first-pass effect of the parent drug.

In view of the low extraction ratio of 3-bromocinnamamide, no reduction in oral bioavailability by a first-pass effect was predicted. The observed bioavailability (median = 1.05) confirmed this prediction (Table V).

In the rhesus monkey, cinromide is a medium-extraction ratio drug with a relatively short half-life. One-half of a cinromide dose is converted to 3-bromocinnamamide by *N*-deethylation. This metabolite has a low extraction ratio and a longer half-life than its precursor. The predicted high metabolite–parent drug steady-state concentration ratio suggests that this metabolite may contribute significantly to the anticonvulsant activity observed after administration of the parent drug. These findings led to the independent evaluation of the efficacy of the amide metabolite, 3-bromocinnamamide, for epilepsy in the primate model (7).

Use of Isosorbide Dinitrate Saliva Concentrations for Biopharmaceutical Investigations

H. LAUFEN ˣ, M. SCHMID, and M. LEITOLD

Received December 17, 1981, from the *Department of Pharmacology, Heinrich Mack Nachf., 7918 Illertissen/Bayern, West Germany.* Accepted for publication May 18, 1982.

Abstract □ The concentration of isosorbide dinitrate in paired samples of plasma and mixed saliva was monitored for up to 24 hr after oral administration of 60 mg of sustained-release isosorbide dinitrate to eight healthy volunteers. Measured isosorbide dinitrate plasma concentrations were mainly in the range of 0.1–10 ng/ml. Isosorbide dinitrate was excreted into saliva resulting in a mean (±*SD*) saliva–plasma concentration ratio of 0.68 ± 0.37. A significant correlation between concentrations of isosorbide dinitrate in saliva and plasma was found ($p < 0.01$). The sustained-release properties of the administered formulation were confirmed from the concentrations of isosorbide dinitrate found in both saliva and plasma. Saliva–plasma ratios were independent of the absolute concentrations of isosorbide dinitrate but showed a slight tendency to decrease with time. The principal factor relating saliva and plasma isosorbide dinitrate concentrations appeared to be the degree of plasma protein binding of the drug.

Keyphrases □ Isosorbide dinitrate—saliva–plasma ratios following oral administration of a sustained-release preparation □ Sustained-release formulations—saliva–plasma ratios of isosorbide dinitrate following oral administration □ Excretion, salivary—use of isosorbide dinitrate saliva concentrations for biopharmaceutical investigations □ Pharmacokinetics—use of isosorbide dinitrate saliva concentrations for biopharmaceutical investigations

In recent years many investigations have been made on the salivary excretion of drugs in humans. For a number of drugs, it has been demonstrated that the measurement of their concentrations in saliva can be a convenient substitute for plasma analyses, both in monitoring therapeutic drug concentrations and in pharmacokinetic and biopharmaceutical studies. The advantage offered by the measurement of drug concentrations in saliva as well as the limitations of this procedure have been the subject of recent reviews (1–8).

Whether salivary concentration measurements are of value in monitoring pharmacokinetic properties of drugs or not depends on how closely saliva and plasma levels are related. Variations in the saliva–plasma ratio are produced by a number of factors, including variation of the pH of plasma and saliva, the extent of the drug's plasma protein binding, salivary flow rate, active secretion processes, buccal reabsorption, delayed appearance of the drug in saliva, and the technique of saliva sampling (9).

Isosorbide dinitrate is used in the treatment of coronary disease. The plasma pharmacokinetics of this drug are characterized by its rapid excretion (10). This is a disadvantage in long-term therapy with isosorbide dinitrate, and a sustained-release oral formulation of the drug has been used in an attempt to overcome this problem (11–17). During the development of a sustained-release preparation of isosorbide dinitrate, the usefulness of salivary concentration monitoring by multiple paired measurement of isosorbide dinitrate in saliva and plasma was tested.

The present report describes the saliva–plasma ratios of isosorbide dinitrate in eight healthy humans following oral administration of 60 mg of a sustained-release preparation.

EXPERIMENTAL

Eight healthy, fasted, volunteers (3 females and 5 males; 18–38 year; 42–75 kg) were each given one capsule of a slow-release formulation of isosorbide dinitrate[1] (60 mg) with 100 ml of water. Three hours after drug ingestion, a normal breakfast was taken. Blood samples were collected by venipuncture at 0, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 15, and 24 hr after drug administration. At each time the volunteers expectorated 1 ml of mixed saliva into a glass vial. When necessary, to enhance the spontaneous saliva flow, a small crystal of citric acid was applied to the volunteer's tongue. Saliva and plasma (separated from whole blood by centrifugation) were stored at −30° until analysis. Concentrations of isosorbide dinitrate in plasma and saliva were determined by an identical GC procedure with an internal standard (18). The lower limit of isosorbide dinitrate detection was 0.05 ng/ml. All analyses were performed in duplicate.

Statistical calculations on the concentration data obtained were performed with a desk-top computer[2]. The correlation of saliva and plasma levels was determined by linear regression. The coefficient of regression was tested for significant difference from zero, the 95% confidence limits of the coefficient of regression were calculated, and an analysis of variance of the regression was performed (19). Using the same procedures, possible correlations of the saliva–plasma ratio with the absolute plasma concentrations of isosorbide dinitrate as well as with sampling time were tested. The areas under the saliva and plasma level curves were calculated using the trapezoidal rule. An approximate estimation of the apparent

At each time the volunteers expectorated 1 ml of mixed saliva into a glass vial. When necessary, to enhance the spontaneous saliva flow, a small crystal of citric acid was applied to the volunteer's tongue. Saliva and plasma (separated from whole blood by centrifugation) were stored at −30° until analysis. Concentrations of isosorbide dinitrate in plasma and saliva were determined by an identical GC procedure with an internal standard (18). The lower limit of isosorbide dinitrate detection was 0.05 ng/ml. All analyses were performed in duplicate.

Statistical calculations on the concentration data obtained were performed with a desk-top computer[2]. The correlation of saliva and plasma levels was determined by linear regression. The coefficient of regression was tested for significant difference from zero, the 95% confidence limits of the coefficient of regression were calculated, and an analysis of variance of the regression was performed (19). Using the same procedures, possible correlations of the saliva–plasma ratio with the absolute plasma concentrations of isosorbide dinitrate as well as with sampling time were tested. The areas under the saliva and plasma level curves were calculated using the trapezoidal rule. An approximate estimation of the apparent

[a] After administration of a 60-mg isosorbide dinitrate sustained-release formulation.

terminal half-lives was obtained by exponential regression analysis. Possible differences in the terminal half-lives and the times to peak saliva and plasma concentration were analyzed by paired Student's *t* test. The mean course of absorption of isosorbide dinitrate into saliva and plasma was determined by a previously described method (20).

RESULTS

Isosorbide dinitrate concentrations were measured in 111 saliva–plasma paired samples. The calculated saliva–plasma concentration ratios are listed in Table I. In 15 of the sample pairs, the measured saliva concentrations exceeded the plasma concentrations; in 92 cases the plasma levels of isosorbide dinitrate were higher than the corresponding saliva levels. The overall arithmetic mean of the saliva–plasma ratio was 0.68 ± 0.37 (*SD*). The correlation between plasma and salivary concentrations of isosorbide dinitrate for all individual values is shown in Fig. 1. The proportionality factor relating plasma to saliva concentrations was 0.60 and the correlation coefficient was 0.83. The analysis of variance of the regression revealed that 68.57% of the variation was explained by linear regression and that this was significant at the 1% level ($p < 0.01$). The 95% confidence interval for the coefficient of regression ranged between 0.52 and 0.68. The overall geometric mean for the saliva–plasma ratios was 0.61. This value corresponds well with the mean saliva–plasma ratio obtained from the regression analysis.

The individual means for the saliva–plasma ratios (Table I) ranged from 0.47 to 0.86. The corresponding coefficients of variation indicate that the extent of correlation varied between the eight volunteers. Examples of both poor and good correlations between saliva and plasma concentrations are shown in Fig. 2. The arithmetic means and standard deviations of the saliva–plasma ratio for each sample time are also given in Table I. A tendency for a decrease in the ratio with time occurred; however, the regression analysis of saliva–plasma ratios *versus* time did not show a significant correlation ($p > 0.05$). Furthermore, the correlation between the saliva–plasma ratio and absolute plasma concentration was not significant ($p > 0.05$).

Mean saliva and plasma concentrations of isosorbide dinitrate and the corresponding coefficients of variation are given in Table II. Variances between individuals in isosorbide dinitrate levels were similar in both plasma and saliva specimens. Up to 9 hr after drug intake, the coefficient of variation was 50% and, thereafter, increased to >100%.

At all sampling times, the mean concentration of drug in the plasma exceeded that found in the saliva. The saliva and plasma concentration–time curves were approximately parallel. Due to the relatively high variances both in saliva and in plasma concentrations, the observed mean saliva and plasma levels are significantly different only at the 2, 3, 5, 7, and 8 hr time intervals (paired Student's *t* test, $p < 0.05$).

The mean area under the concentration–time curve was 44.7 ± 20.4 (*SD*) hr ng/ml in saliva and 71.4 ± 39.0 hr ng/ml in plasma, corresponding to a saliva–plasma ratio of 0.63. Mean time to peak and mean apparent terminal half-life were estimated as the average of the individual calculated values. In saliva a mean peak time of 2.6 ± 2.2 hr and in plasma a mean peak time of 3.5 ± 1.4 hr were obtained. The terminal half-life was 3.0 ± 1.2 hr in saliva and 3.7 ± 1.9 hr in plasma. For both parameters, the mean difference between saliva and plasma was not significant (Student's *t* test, $p > 0.05$).

lowing ingestion of the administered slow-release formulation, absorption curves were constructed from both the experimental mean saliva curve and the mean plasma curve. For the calculation a mean elimination rate constant of 0.071 min^{-1} was employed, which was observed in plasma of human volunteers after intravenous administration of isosorbide dinitrate (10). The Wagner–Nelson curves (20) are given in Fig. 3. For comparison, in the same figure absorption curves of two standard formulations of isosorbide dinitrate are shown. These curves are reproduced from mean plasma levels obtained in other pharmacokinetic trials in which 5 and 20 mg isosorbide dinitrate were administered as plain tablet formulations to healthy human volunteers (this report will be published separately). During the first 6 hr after administration of the sustained-release formulation, the mean absorption curve calculated from isosorbide dinitrate saliva concentrations increased slightly more rapidly than the plasma absorption curve. This specimen-related difference is only marginal compared with the formulation-related differences: in contrast to the slow absorption of isosorbide dinitrate from the sustained-release preparation, the Wagner–Nelson curves (20) of the plain tablets show a steep initial increase.

DISCUSSION

The saliva–plasma ratio of drugs is influenced by many factors relating to the physicochemical characteristics of the drug and the mechanism of its salivary excretion, as well as to variable conditions such as salivary pH and flow. When a drug enters the saliva through the membranes by a simple diffusion process without the contribution of active secretion, saliva could be regarded as a plasmatic ultrafiltrate. Indeed, it has been shown for a large number of drugs that the concentration in the salivary fluid reflects the fraction of free or protein-unbound drug in plasma (1–8). As free diffusion is confined to the uncharged drug molecule, corrections should be made for pH differences on both sides of the membrane for weak acids and bases (21, 22). As isosorbide dinitrate is a lipid soluble molecule that remains uncharged within the physiological pH range, a pH-dependent effect on its membrane permeation is excluded.

Following equilibrium dialysis experiments, it was concluded that isosorbide dinitrate was not extensively bound to human plasma proteins *in vitro* (23). Within a concentration range of 1–100 ng/ml, the free fraction was found to be 0.72 ± 0.12 (mean ± *SD*). This value corresponds well with both the mean saliva–plasma ratio of isosorbide dinitrate obtained by linear regression, which was 0.60 ± 0.08 (coefficient of regression ±95% confidence limits), and the arithmetic mean of the individual saliva–plasma ratios of 0.68 ± 0.37 (mean ± *SD*). Therefore, it was suggested that the principal factor relating isosorbide dinitrate saliva to isosorbide dinitrate plasma concentrations is the degree of plasma protein binding of the drug.

Since the standard deviation of the isosorbide dinitrate protein binding (±0.12) reported previously (23) reflects the variation between different subjects, the degree of isosorbide dinitrate plasma binding determined *in vitro* is less variable between individuals than the saliva–plasma ratio found in this trial (*SD* = ±0.37). Therefore, it seems unlikely that the high variabilities of isosorbide dinitrate saliva–plasma ratios could be attributed mainly to variations in the degree of plasma binding.

In 15 of the analyses, saliva levels of isosorbide dinitrate exceeded those

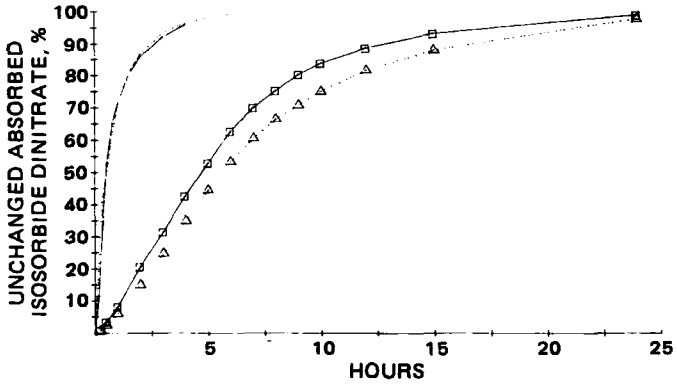

Figure 3—*Wagner–Nelson absorption curves of isosorbide dinitrate, calculated from mean isosorbide dinitrate plasma (△) and saliva (□) curves obtained after the administration of a 60-mg isosorbide dinitrate sustained-release formulation as well as after oral ingestion of a 5-mg tablet (——) and a 20-mg tablet (- - - -).*

in plasma. For some drugs [lithium is the best known example (24, 25)] saliva–plasma ratios >1 have been discussed as an indication of active transport mechanisms. It was suggested (7) that active secretion into saliva might explain the discrepancies in the saliva–plasma ratio often observed in single-dose studies, particularly when the saliva–plasma ratio appears to be time dependent. As an example, bioavailability studies for theophylline (26, 27) are reported where the saliva–plasma ratio was higher in the absorption phase than in the elimination phase and where saliva concentrations sometimes exceeded the plasma concentrations. Both phenomena were also observed for isosorbide dinitrate in the present study, so that active secretion processes should be considered as one source of the observed variation in the saliva–plasma ratios of isosorbide dinitrate.

An alternative explanation for the inconsistent ratio could be that saliva levels are influenced by isosorbide dinitrate partition into and/or absorption through the oral mucosa. As has been shown (18), the buccal absorption of isosorbide dinitrate is very rapid. Therefore, it may be possible that changes in the extent and the speed of buccal reabsorption of isosorbide dinitrate from saliva contribute considerably to the deviations in saliva–plasma ratios.

Due to the high variability of the observed saliva–plasma ratios, the prediction intervals of single plasma concentrations on the basis of corresponding saliva concentrations are considerable: the 95% confidence interval of the plasma level predicted for a saliva concentration of 5 ng/ml is 7.7 ● 3.9 ng/ml. In comparison, the mean plasma concentration of a sufficient number of subjects can be predicted with narrower confidence intervals: for eight subjects the 95% confidence interval of the mean plasma level is 7.7 ± 1.5 ng/ml. This corresponds to the observation that the mean saliva curve of isosorbide dinitrate mimics the shape of the mean plasma curve, although this does not always hold for the individual curves. Consequently, the characteristic slow-release properties of the administered formulation could be inferred from the mean saliva curve as well as from the mean plasma curve. This was particularly evident when the corresponding Wagner–Nelson absorption curves (20) were compared with the absorption curves of standard formulations of isosorbide dinitrate.

Provided these results can be confirmed for other isosorbide dinitrate preparations, it is suggested that mean saliva concentrations of a sufficient number of subjects ($n \geq 8$) can serve as a substitute for mean plasma levels in biopharmaceutical investigations of isosorbide dinitrate.

Densitometric Determination of the Solubility Parameter and Molal Volume of Compounds of Medicinal Relevance

ZVI LIRON and SASSON COHEN ˣ

Received May 18, 1981, from the *Department of Physiology and Pharmacology, Sackler School of Medicine, Tel-Aviv University*, and the *Institute for Biological Research, Ness-Ziona, Israel.* Accepted for publication April 30, 1982.

Abstract □ A procedure is described for the simultaneous determination of molal volumes (v_2^0) and solubility parameters (δ) of compounds of medicinal interest. These include alkanoic acids of various chain length and branching (some solid at room temperature), cholesterol, and cholesteryl esters. The procedure is based on the determination of partial molal volumes ($\bar{v}_2$) from high-precision density measurements of dilute solutions of these compounds in reference solvents, which range in polarity from carbon tetrachloride (δ = 8.6) to nitrobenzene (δ = 10.0). In some cases, the present results do not agree with values of δ published in the literature. Values calculated from group contributions proposed by other authors are prone to error particularly in the case of branched acids and cholesteryl esters.

Keyphrases □ Densitometric determination—solubility parameter and molal volume of compounds of medicinal relevance □ Solubility—densitometric determination of parameters, molal volume of compounds of medicinal relevance □ Molal volume—densitometric determination of solubility parameter of compounds of medicinal relevance

In a series of studies with structurally nonspecific ethers, it was found that the pharmacological profile of a given member could be a consequence of its solubility parameter (1–3). This finding led to the proposition that such molecules associate with a particular membrane subregion, such as an ionic channel or boundary lipid, in accordance with regular solution theory (4). That is, a given substrate will partition between two phases that differ in solubility parameter at a ratio that can be predicted from the solubility parameters of the interacting species and their partial molal volumes (5). Further exploration of this concept in pharmacology and its possible application in medicinal chemistry required knowledge of reliable data pertaining to these parameters or a suitable experimental procedure for their determination. The main sources on this subject are the works of Hildebrand *et al.* (6) and reviews by Barton (7) and Burrell and Immergut (8). Although helpful, they did not meet the need because they made no reference to compounds of medicinal relevance and lack data on molal volumes, especially for solids. Therefore, this study explores the simultaneous determination of partial molal volumes and solubility parameters from high-precision density measurements of dilute regular solutions. Alkanoic acids, cholesterol, and cholesteryl esters were the compounds of choice for this exploratory study.

BACKGROUND

Definitions—The solubility parameter (δ) of a pure liquid is the square root of the cohesive energy density, and is usually given by:

$$\delta = \left(\frac{-E}{v}\right)^{1/2} = \left(\frac{\Delta H^v - RT}{v}\right)^{1/2} \text{cal}^{1/2}\,\text{cm}^{-3/2} \qquad \text{(Eq. 1)}$$

where E is the energy of the liquid expressing the molal heat of vaporization to the gas state at zero pressure, v is the molal volume of the liquid, and ΔH^v is the heat of vaporization at low vapor pressure. Under conditions of high vapor pressure, the gas law correction should be applied and ZRT should replace RT (1), Z being the compressibility factor.

If no calorimetric data are available, the Clausius–Clapeyron equation may be applied to derive the apparent heat of vaporization from pressure–temperature data:

$$\frac{d\ln P}{dT} = \frac{\Delta H^v}{RT\Delta v^v} = \frac{\Delta H^v_{app}}{RT^2} \qquad \text{(Eq. 2)}$$

where Δv^v is the change in volume on vaporization, $v^g - v^l$. The apparent heat of vaporization is equal to the true one only if the vapor is ideal. Otherwise, the compressibility factor must be used, and Eq. 1 then assumes the form:

$$\delta = \left\{\frac{(\Delta H^v_{app} - RT)Z}{v}\right\}^{1/2} \qquad \text{(Eq. 3)}$$

In the case of solid substances, application of the above relationships is not straightforward. First, many of these are nonvolatile or poorly

BACKGROUND

Definitions—The solubility parameter (δ) of a pure liquid is the square root of the cohesive energy density, and is usually given by:

$$\delta = \left(\frac{-E}{v}\right)^{1/2} = \left(\frac{\Delta H^v - RT}{v}\right)^{1/2} \text{cal}^{1/2}\,\text{cm}^{-3/2} \qquad \text{(Eq. 1)}$$

where E is the energy of the liquid expressing the molal heat of vaporization to the gas state at zero pressure, v is the molal volume of the liquid, and ΔH^v is the heat of vaporization at low vapor pressure. Under conditions of high vapor pressure, the gas law correction should be applied and ZRT should replace RT (1), Z being the compressibility factor.

If no calorimetric data are available, the Clausius–Clapeyron equation may be applied to derive the apparent heat of vaporization from pressure–temperature data:

$$\frac{d\ln P}{dT} = \frac{\Delta H^v}{RT\Delta v^v} = \frac{\Delta H^v_{app}}{RT^2} \qquad \text{(Eq. 2)}$$

where Δv^v is the change in volume on vaporization, $v^g - v^l$. The apparent heat of vaporization is equal to the true one only if the vapor is ideal. Otherwise, the compressibility factor must be used, and Eq. 1 then assumes the form:

$$\delta = \left\{\frac{(\Delta H^v_{app} - RT)Z}{v}\right\}^{1/2} \qquad \text{(Eq. 3)}$$

In the case of solid substances, application of the above relationships is not straightforward. First, many of these are nonvolatile or poorly

0022-3549/83/0500-0499$01.00/0

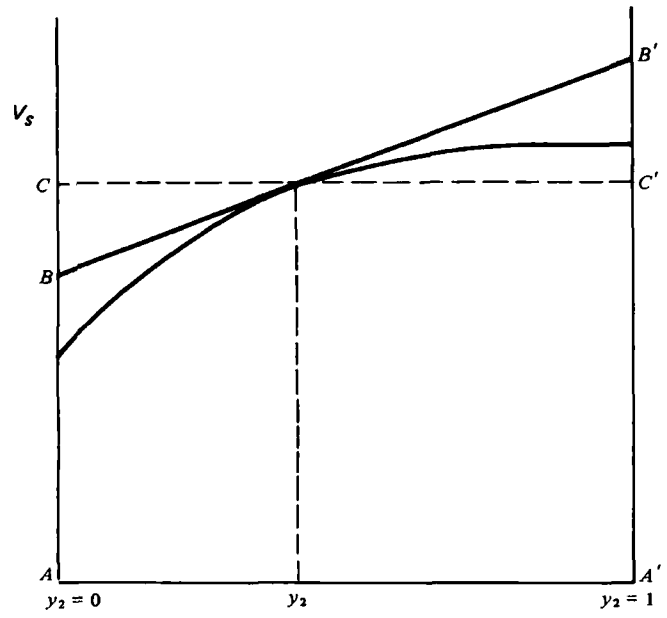

Figure 1—*The relation between the specific volume* V_s *and the mass fraction* y_2 *in a mixture of two components.* AB = $\overline{V}_{s1}$; A'B' = $\overline{V}_{s2}$ *at mass fraction = 0 of the second component.*

volatile. Second, there is an uncertainty in the value of v which must be approximated by extrapolating from the fused substance to the supercooled liquid. In this case, δ is calculated from experimental solubility data, as in the following relationship offered previously (9):

$$RT \ln\left(\frac{a_2^s}{X_2}\right) = v_2\phi_1^2(\delta_2 - \delta_1)^2 \qquad \text{(Eq. 4)}$$

where the subscripts 1 and 2 refer to solvent and solute, respectively, X_2 is the solubility at saturation in mole fraction, v_2 is the molal volume of solute as supercooled liquid, ϕ_1 is the solvent volume fraction, and a_2^s is the activity of the solute as a solid. Calculation of the latter term is an intricate operation which requires knowledge of the heat of fusion at the temperature of fusion and also of the difference between the heat capacity of the liquid and solid states. In a more empirical approach (10), the solubility at saturation of a substance was determined in each of a series of solvents or solvent mixtures of known solubility parameter. The solubility parameter of the solute was then approximated with that of the best solvent. This method has many limitations, especially the need to use high solute concentrations which must inevitably alter the solubility parameter of the reference solvents, since:

$$\delta_{app} = \sum \delta_i \phi_i \qquad \text{(Eq. 5)}$$

where ϕ is the volume fraction. It is particularly doubtful when water is one of the solvent components, because its solubility parameter is still uncertain (11). A previous review gives other empirical procedures (12).

Table I—Determination of the Densities of Various Solutions of Cholesterol in Toluene at 25° [a]

Sample	Mass fraction, $y_2\ 10^3$	Densitometer T value	d Calc, gcm^{-3}	V_{s2}, $cm^3\ g^{-1}$
Toluene	0	1781331	0.86216	1.15987
1	1.129	1781391	0.86229	1.15970
2	2.685	1781473	0.86247	1.15946
3	3.901	1781536	0.86260	1.15928
4	5.233	1781607	0.86276	1.15908
5	6.313	1781662	0.86287	1.15892
6	7.947	1781746	0.86306	1.15868
7	9.910	1781848	0.86327	1.15838
8	11.598	1781935	0.86346	1.15813

[a] From $d_{sample} = d_{air} + 6.03449 \times 10^{-13}(T^2_{sample} - T^2_{air})$; T value for air, 1321506; density of air, 0.001185 gcm^{-3}; T value for water, 1843002; density of water, 0.997043. In this particular example, the relationship between V_{s2} and y_2 is given by: $V_{s2} = 1.15987 - 0.14987y$ ($r^2 = 0.99995$). At $y_2 = 1$, $\overline{V}_{s2} = 1.01000$ which is the partial specific volume of cholesterol in toluene. Multiplication by 386.66 gives $\overline{v}_2 = 390.53$ which is the partial molal volume of cholesterol in toluene at a concentration approaching zero.

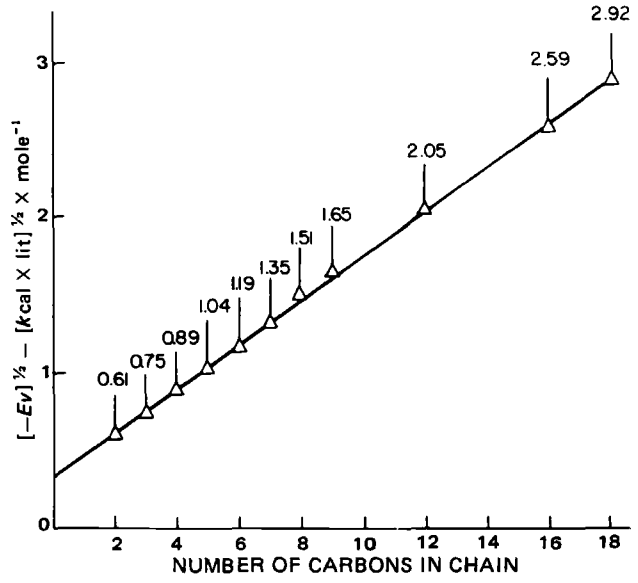

Figure 2—*Alkanoic acids: square root of volume cohesive energy product as a function of acid carbon number (n).*

In a more recent extension of Eq. 4 (13), the geometric mean $\delta_1\delta_2$ of the Hildebrand approach has been replaced by $K\delta_1\delta_2$, which is the solute–solvent interaction energy.

An experimental method of general applicability is now described for the determination of the solubility parameter from partial molal volumes. The method dwells on the same theoretical principles as the dilatometric method described previously (14) and applied earlier (1), but is based on a measurement of density rather than volume change, and does not require prior knowledge of the molal volume of the pure solute.

THEORETICAL

The partial molal volume of a solute, $\overline{v}_2$, is the rate of change of volume of its solution, V, referred to the rate of change of the mole number of solute, n_2:

$$\overline{v}_2 = \frac{\partial v}{\partial n_2} \qquad \text{(Eq. 6)}$$

Now, consider a solution of two components, 1 and 2. A plot of the specific volume, V_s, which is the reciprocal of density, d, against the mass fraction of component 2, y_2, yields a curve as shown in Fig. 1. A tangent to this curve at any point must intercept the ordinate at $y_2 = 0$ at a point B, so that $AB = \overline{V}_{s1}$, the partial specific volume of component 1, and at $y_2 = 1$ at a point B', so that $A'B' = \overline{V}_{s2}$, the partial specific volume of component 2. It can be shown (15) that:

$$\overline{V}_{s1} = V_s - y_2\frac{dV_s}{dy_2} \qquad \text{(Eq. 7)}$$

$$\overline{V}_{s2} = V_s + y_1\frac{dV_s}{dy_2} \qquad \text{(Eq. 8)}$$

The partial molal volume, $\overline{v}_2$, is given by:

$$\overline{v}_2 = M_2\overline{V}_{s2} \qquad \text{(Eq. 9)}$$

where M_2 is the molecular weight of component 2.

An experimental curve as shown in Fig. 1 can be constructed from density measurements of solutions having a predetermined mass fraction of component 2 in the mixture. However, we are interested in the partial molal volume of the solute at a vanishingly small mass fraction, corresponding to a point on the curve at $y_2 = 0$. Hence, a tangent to the curve must be drawn at $y_2 = 0$. In practice, this tangent has the function of a straight line drawn through a series of points having y_2 values $<10^{-2}$. The desired value:

$$\overline{v}_2 \underset{y_2 \to 0}{}$$

is calculated by multiplying the intercept of this tangent at the ordinate $y_2 = 1$ by the molecular weight (see Table I).

Table II—Specific Volumes (V_{s2}^0) and Partial Specific Volumes ($\bar{V}_{s2}$) of Straight-Chain Alkanoic Acids in Two Reference Solvents, at 25°

[a] r^2 = Coefficient of determination. [b] SE = standard error × 10^5 for a sample of 8. [c] Solid at room temperature.

According to Hildebrand (14) the partial molal volume of a solute is related to its solubility parameter, as follows:

$$\frac{\bar{v}_2 - v_2^0}{v_2^0} = \frac{(\delta_1 - \delta_2)^2}{(\partial E/\partial v)_T} \qquad \text{(Eq. 10)}$$

Now, if $(\bar{v}_2 - v_2^0)$ and v_2^0 are divided by M_2, the molecular weight of the solute, a form is obtained in which δ could be related directly to specific volume:

$$\frac{\bar{V}_{s2} - V_{s2}^0}{V_{s2}^0} = \frac{(\delta_1 - \delta_2)^2}{(\partial E/\partial v)_T} \qquad \text{(Eq. 11)}$$

For liquids, V_s^0 can be determined by direct measurement of density; hence, δ_2 can be calculated by measurement of $\bar{V}_{s2}$ in a reference solvent for which δ_1 and $(\partial E/\partial v)_T$ must be known. For solids, V_{s2}^0 is not usually readily accessible; in this case, measurements of $\bar{V}_{s2}$ in two reference solvents yield a set of two simultaneous equations from which the two unknowns, V_{s2}^0 and δ_2, may be calculated (*Appendix*).

EXPERIMENTAL

Apparatus—The high-precision, density-measuring assembly used consisted of a measuring cell unit and density meter with digital display[1]. The assembly was placed in a room in which the temperature was thermostatically controlled at 23 ± 1°. The measuring cell unit contained a U-shaped sample tube which was rigidly supported at its open ends. The sample tube was electromagnetically excited to vibrate at its natural frequency. The period of oscillation, T, of the sample tube was related to the density, d, of the sample contained within by the following relationship:

$$d = A(T^2 - B) \qquad \text{(Eq. 12)}$$

where A and B were apparatus constants that had been predetermined by calibration with two fluids of known densities. The sample, ~0.7 ml, was injected into the sample tube with a hypodermic syringe. Excess fluid was allowed to overflow past the vibrating segment. After 2–3 min, thermal equilibration was reached and the period of oscillation was directly read on the digital display. The sample was removed and the tube flushed with solvent and dried with a stream of air until it reached the oscillation period of the empty tube; then a new sample was introduced. The thermostatic system consisted of a main thermostat—a circulator with suction and pressure pumps. The instrument had a digital temperature setting, an antidrift control, a heater capacity of 1000 W, and a cooling coil through which cold water could be run when necessary. The circulator was immersed in a glass cylindrical bath which contained 50 liters of water. The temperature in the bath was measured with a calibrated and tested glass thermometer[2] with a scale division of 0.1°. The temperature deviations in the bath and in the effluent line of the density-measuring cell were measured with thermometers[3] with a 0.01° scale division. Measurements at 25° required the use of a cooler system, which was coupled to the circulator of the main thermostat and which consisted of a control unit and a circulator. The cooler was immersed in 50 liters of water at 20 ± 0.5°. Altogether, the accuracy achieved inside the density-measuring cell that contained the sample was ±0.005°.

Materials—Straight-chain (>99% pure) and branched-chain (>98%) alkanoic acids, cyclopropane carboxylic acid (97%), cholesterol (>98%), and cholesteryl esters (97–98%) were purchased from commercial sources. The solvents were carbon tetrachloride, chlorobenzene, and toluene (>99.5%); chloroform (99.8%); and nitrobenzene (>99%). Chloroform was pretreated with molecular sieves and redistilled before use.

Procedure—For each solute tested, at least eight different samples were weighed, each in a calibrated volumetric flask. The desired weight of solvent was then added. The solute mass fraction (y_2), which was usually in the range of 10^{-4} to 10^{-3}, was determined for each solution to the nearest hundred thousandth. The density meter was calibrated by measuring the oscillatory periods for air and distilled water. The solutions were introduced into the sample tube in order of increasing mass fraction, the oscillatory periods were determined, and the densities calculated. The actual data from these measurements is too voluminous for inclusion in this report; one example is reproduced to illustrate the operation involved (Table I). Thus, for each solution a set of data points was obtained giving the specific volume as a function of mass fraction. Curve fitting was made by a linear least-squares regression analysis program using a desk calculator. The coefficient of determination r^2, the value of $\bar{V}_{s2}$ at $y_2 = 1$, and the standard error, SE, in the estimate of $\bar{V}_{s2}$ on y_2 were derived through the same operation.

RESULTS AND DISCUSSION

Straight-Chain Alkanoic Acids—The partial specific volumes of straight-chain alkanoic acids, in each of two solvents, are given in Table II. The accuracy of measurement can be ascertained from the value of r^2, the coefficient of determination. The precision of data can be checked in each case from the intercept of the regression line with the ordinate at a mass fraction of solute $y_2 = 0$ (Fig. 1). Whenever the assumption of the working hypothesis was satisfied (*i.e.*, there should occur no detectable change in the specific volume of the solvent under working conditions), then the value of this intercept agreed with the specific volume of the solvent which could be determined independently. If this was not the case, then it could be inferred that there occurred an appreciable change in the slope of $\bar{V}_{s2}$ *versus* mass fraction y_2 over the range of concentrations tested. Usually, deviation from linearity became detectable in the mass fraction range $>10^{-2}$.

From the data of Table II the partial molal volumes were derived by application of Eq. 9 and solubility parameters by application of Eq. 11 for liquids (C_2–C_9) and solids (C_{12}–C_{18}) alike, the latter as supercooled liquids at room temperature (Table III). One sees a gradual decrease in δ as the contribution of the polar head becomes less important with the increasing length of the hydrocarbon chain. For a comparison of results with values of δ reported in the literature, some authors have made a distinction between a single solubility parameter, which is usually calculated from the heat of vaporization, and the total solubility parameter, which is the calculated sum total of dispersion, polar, and hydrogen-bond forces (16). The reported single solubility parameters for the acids, propionic (9.9) and valeric (9.8), are in fair agreement with the values presently reported; but that of butyric acid (10.5) is higher than the value found in this study (9.7). The opposite is true for acetic acid for which the total solubility parameter (10.5) (16) is closer to the present value (10.6) than its single parameter (10.1). The calculated value of the total solubility parameter of stearic acid (8.6) is significantly lower than found here (8.9). With the exception of this last example, no records of the solubility parameters of alkanoic acids that exist in solid form at room temperature were found.

The group contributions to v_2^0 and δ, derived from the present data, do not agree in all cases with values published previously (17). The mean

Cyclopropane carboxylic	0.92362	0.93187	0.99982	1	79.51	9.5

[a] At 25°; solvent data as in Table III. [b] Solids at room temperature; v_2^0 and δ were calculated by use of Eq. 11 and the following additional parameters: $\bar{V}_{s2(\text{toluene})}$ for pivalic acid, 1.09819 ($r^2 = 0.99918$), for phenylbutyric acid, 0.93004 ($r^2 = 0.99972$).

incremental molal volume per CH_2 group for all compounds tested is 16.86 ± 0.60 (pure), 16.72 ± 0.45 (carbon tetrachloride), and 16.66 ± 0.57 (toluene) cm³ mole⁻¹. However, the inclusion of the lower alkanoic acids in the sample is questionable, in view of the observation that the incremental volume of propionic acid over acetic acid is larger in the pure state (17.46) than in solution in either carbon tetrachloride (16.74) or toluene (16.00), implying considerable contraction in these solvents. The significance of this observation is that a CH_2 group adjacent to a COOH group occupies relatively more space in the pure state than in solution in either solvent; *i.e.*, its contribution to the partial molal volume in these states is reduced, even though $\bar{v}_2 > v_2^0$ for the molecule as a whole in almost all cases. In fact, the mean incremental molal volume for the series exclusive of propionic acid, 16.71 ± 0.15 (pure) or 16.68 ± 0.19 (toluene), is significantly different from the corresponding value in propionic acid ($p < 0.001$). The group contribution of a CH_2 group is listed (17) as 16.1 cm³ mole⁻¹ which, obviously, does not apply in the case of a CH_2 adjacent to COOH.

A more generalized presentation of data, inclusive of that of the lower alkanoic acids, may be made according to a previous study (18) where a linear relationship was found between the number of carbon atoms in a given homologous series and the square root of volume-cohesive energy product, $(-Ev)^{1/2}$, which is numerically equal to δv. A plot of δv of straight-chain alkanoic acids against the number of carbons in the chain is shown in Fig. 2. The fit to a straight line is excellent ($r^2 = 1.00$). The slope has a value of 0.14 (kcal liter)$^{1/2}$ mole⁻¹ per carbon atom, as compared with 0.13 for hydrocarbons and ethers. A higher slope value is usually taken to mean a greater interaction energy between the CH_2 groups and the polar end groups (18).

Table V—Partial Specific Volume ($\bar{V}_{s2}$) of Cholesterol in Five Different Solvents [a]

Solvent	$\bar{V}_{s2}$, cm³ g⁻¹	r^2	SE 10^5
Carbon tetrachloride	1.01094	0.99981	1
Toluene	1.01000	0.99995	0
Chloroform	1.01300	0.99981	1
Chlorobenzene	1.01334	0.99981	0
Nitrobenzene	1.01764	0.99977	1

[a] At 25°, $n = 8$.

Branched-Chain Alkanoic Acids—Table IV shows that branching has little effect on v_2^0 and δ, but with the notable exception of pivalic acid and cyclopropane carboxylic acid. Pivalic acid and 2-methylbutyric acid have practically identical molal volumes, but δ in the former is one unit larger than in its isomer. Also, the incremental molal volume in 3,3-dimethylbutyric acid over pivalic acid is 18.29 cm³ mole⁻¹ in the pure state, and which undergoes apparent contraction to 15.33 cm³ mole⁻¹ in carbon tetrachloride. Again, the relative contribution of α-methylene to molal volume is larger in the pure state (0.142) than in solution (0.119). The reason for the difference in δ between pivalic acid and its isomers is not clear at present. Obviously, it does not arise from a difference in v_2^0 of the respective compounds. Group contributions found previously (17) correctly predict the experimental values of v_2^0 for 2-methylbutyric acid (110.60) and pivalic acid (109.8), but not their δ values (9.6 and 9.9, respectively). The same calculations applied to cyclopropane carboxylic acid yield values that disagree with the experimental ones: v_2^0, 77.70 (calc.) against 79.51 (found); δ, 11.6 (calc.) against 9.5 (found).

The function relating δv to the number of carbon atoms in the straight chain alkanoic acids (Fig. 2) applies also to the branched-chain acids, but again with the exception of pivalic and cyclopropane carboxylic acids. Inclusion of 2-methyl-, 3-methyl-, 3,3-dimethyl-, and 2-ethylbutyric acids in the graph does not alter the correlation coefficient ($r^2 = 1.00$); but pivalic acid deviates by +0.1000 from the predicted value and cyclopropane carboxylic acid by −0.1350 (kcal liter)$^{1/2}$ mole⁻¹. This may be taken as an indication that there is more interaction with the polar head in the former and less in the latter, relative to the corresponding straight-chain member.

Cholesterol—The partial specific volumes of cholesterol in five dif-

[a] Derived from the data in Table V by application of Eq. 11 for solvent pairs; δ and $(\partial E/\partial V)_T$ of reference solvents: chlorobenzene, 9.5 and 93.2; chloroform, 9.3 and 86.6; nitrobenzene, 10.0 and 117.1; others as in Table III.

ferent solvents are given in Table V. These data were used to derive the two unknowns, solubility parameter and molal volume of cholesterol, by application of simultaneous equations (11) for solvent pair (Table VI). For each reference solvent, the mean value is listed at the end of the column. The relatively high δ derived from the more polar solvents is significant and needs explanation. In view of the accuracy and precision achieved in the measurement of densities in these solvents (Table V), we assume that the deviation of the experimental system from the theoretical model is minimal and cannot account for the differences among the reference solvents. There remains to be considered the reliability of the published values of δ and $(\partial E/\partial v)_T$ of the reference solvents. Solubility parameter data derived from ΔH^v are usually fairly reliable, but the energy–volume coefficient or internal pressure term, $(\partial E/\partial v)_T$, is a more problematic entity. Internal pressure values can be obtained through direct measurements of $(\partial P/\partial T)_V$, or indirectly by measuring the coefficient of expansion and isothermal compressibility. For most liquids, including some of those used in this study, the indirect and less reliable methods were used to derive the internal pressure values (19–21). Thus, the data derived from carbon tetrachloride and toluene are considered more precise than from the other solvents; the internal pressure of these two solvents had been measured directly.

The mean solubility parameter of cholesterol in the less polar solvents is 8.9, whereas the mean in the more polar ones is 9.1. The mean of means is 9.0 ± 0.1 cal$^{1/2}$ cm$^{-3/2}$ and v_2^0 is 390.81 ± 0.28 cm^3 mole^{-1}, as compared with a previous estimate (17) of 8.0 and 382.20, respectively.

The results for these compounds, all solid at room temperature, are summarized in Tables VII and VIII. The cholesteryl esters of straight-chain alkanoic acids deserve special consideration. If they are treated as a homologous series, a gradual decrease in δ with increasing length of the alkanoyl group, in analogy with the corresponding parent acids would be expected. But this is not the case. An attempt to relate $(-Ev)^{1/2}$ to the number of carbon atoms in the parent acid gave a poor correlation, $(-Ev)^{1/2} = 3.20 \pm 0.15\,n$, $r^2 = 0.94$. The heptanoate ester has the highest δ value in the series, which then declines with either increasing or decreasing chain length. In this context, it should be recalled that compounds possessing liquid crystal properties exhibit unusual dependencies of their physical properties on chain length. The mesomorphic thermal transition of cholesteryl esters from cholesteryl formate to decanoate shows a similar, perhaps related dependency on chain length: the lower six members of the series exhibit only cholesteric mesophases, while the remaining members exhibit both smectic and cholesteric mesophases (22). Another example is offered by previous researchers (23) who observed a definite break at the butyl ester in the melting point and solubility profiles of a series of normal alkyl *p*-aminobenzoates. However, it has been noted (24) that the point of break in properties depends on the loading group, cholesteryl in the present case. In general, larger loading groups require more methylene units to offset their effect on crystal packing. While this generalization may explain the gradual decrease in cohesive energy density in the cholesteryl esters of longer chain than the heptanoate, it does not apply in the case of the lower esters, especially the butyrate which has an unusually low δ value. The emerging profile of δ with respect to chain length in this series may parallel the pattern of mesophase transitions mentioned earlier. In this respect, one must assume that some property of liquid crystal compounds persists into the isotropic phase. This is because the solubility parameter is an intensive property of matter, which, by definition, exists in the form of an isotropic liquid.

There remains to be considered the level of significance at which δ could be determined. This is an important issue in the context of drug distribution, because it can be shown that a hypothetical substrate (i.e., $\delta = 9.0$; $v_2^0 = 100$) will distribute at room temperature between two phases *A* and *B* (δ, 10.0 and 10.5, respectively) in a ratio of 0.81; the corresponding ratios for *B* having δ values of 10.6, 10.7, 10.8, are 0.77, 0.72, 0.68, etc. From the preceding work, δ is calculated from values of partial molal volume that are significant to the second decimal point, and from solubility parameter and internal pressure data of the reference solvents, as published in the literature. Thus, the precision of the calculated δ values must reflect that of the published data.

In any case, a set of such values, generated by reference to a common set of solvents, must remain accurate enough to justify comparison between members, as given for the cholesteryl esters. In the present report, the values of δ for all reference solvents used were taken from a previous study (7). Data on $(\partial E/\partial V)_T$ were used as given for carbon tetrachloride, toluene (25); for chlorobenzene, nitrobenzene (Ref. 20) (given in kilobars (kbar), then transformed into cal$^{1/2}$ cm$^{-3/2}$ by multiplication by 1000/41.84); for chloroform (21), given at 20°, the data were transformed to 25° (19).

As a final check on the validity of the present procedure, the densitometric method was further applied to two reference compounds, as shown in Table IX. The values of the solubility parameter by the present method come very close to the values calculated from the heat of vaporization.

APPENDIX

For solids the solubility parameter of the solute, δ_2, and its molal volume, v_2^0, are derived by solving a set of two simultaneous equations:

$$\frac{\overline{V}_{s21} - V_{s2}^0}{V_{s2}^0} = \frac{(\delta_1 - \delta_2)^2}{P_{i1}} \qquad \text{(Eq. 13)}$$

$$\frac{\overline{V}_{s23} - V_{s2}^0}{V_{s2}^0} = \frac{(\delta_3 - \delta_2)^2}{P_{i3}} \qquad \text{(Eq. 14)}$$

where P_i stands for $(\partial E/\partial V)_T$, the internal pressure of two solvents 1 and 3, and the subscript 2 refers to the solute.

After rearrangement, the following quadratic equation is obtained:

$$a\delta_2^2 + b\delta_2 + c = 0 \qquad \text{(Eq. 15)}$$

where

$$a \equiv \frac{P_{i3}\overline{V}_{s23}}{P_{i1}\overline{V}_{s21}} - 1 \qquad \text{(Eq. 16)}$$

$$b \equiv 2\left(\delta_3 - \delta_1 \frac{P_{i3}\overline{V}_{s23}}{P_{i1}\overline{V}_{s21}}\right) \qquad \text{(Eq. 17)}$$

$$c \equiv \frac{P_{i3}\overline{V}_{s23}}{P_{i1}\overline{V}_{s21}}(\delta_1^2 + P_{i1}) - P_{i3} - \delta_3^2 \qquad \text{(Eq. 18)}$$

Chloride	398.19	397.02	401.98	8.0

[a] Derived from the data in Table VII by application of Eq. 11 for solvent pairs; solvent data as in Table III.

Table IX—Comparison Among Values of Solubility Parameter Determined by Various Procedures

Parameter	Method	Reference Compound: Carbon Disulfide	Reference Compound: Carbon Tetrachloride
v_2^0, cm³ mole⁻¹	Present	60.63	97.10
	Ref. 6	60.7	97.1
$\bar{v}_2$, cm³ mole⁻¹ in carbon tetrachloride at 25°	present	62.36[a]	
	dilatometry (6)	62.0	
In cyclohexane at 25°	present		97.46[b]
	dilatometry (6)		97.7
Solubility parameter, cal$^{1/2}$ cm$^{-3/2}$, calculated from $(\bar{v}_2 - v_2^0)/\bar{v}_2$	present	10.1	8.7
	dilatometry (6)	10.1	8.9
From ΔH^v	Ref. 6	10.0	8.6

[a] $r^2 = 0.99890$. [b] $r^2 = 0.99980$.

The molal volume of the solute is given by:

$$v_2^0 = \frac{P_{i1}\bar{V}_{s21}M_2}{\delta_2^2 - 2\delta_2\delta_1 + \delta_1^2 + P_{i1}} \qquad \text{(Eq. 19)}$$

As an example, the above was used to calculate values for δ_2 and v_2^0 for cholesterol by application to the data shown in Table V for the solvent pair nitrobenzene–toluene:

$$a = \frac{117.1 \times 1.01764}{83.0 \times 1.0100} - 1 = 0.42152$$

$$b = 2(10.0 - 8.9 \times 1.42152) = -5.30298$$

$$c = 1.42152\,(8.9^2 + 83.0) - 117.1 - 10.0^2 = 13.48403$$

$$\delta_2 = 9.04335 \rightarrow 9.0$$

$$v_2^0 = \frac{83.0 \times 1.01000 \times 386.66}{9.04335^2 - 2 \times 9.04335 \times 8.9 + 8.9^2 + 83.0} = 390.43$$

Comparison of High-Performance Liquid Chromatography and Radioimmunoassay in the Determination of Content Uniformity of Digoxin Tablets

MARTIN W. BEASLEY, PAUL SKIERKOWSKI *, ROBERT W. CLEARY ˣ, ALAN B. JONES, and ARTHUR H. KIBBE

Received February 1, 1982, from the *Department of Pharmaceutics, School of Pharmacy, The University of Mississippi, University, MS 38677.* Accepted for publication May 14, 1982. *Present address: Department of Radiation Safety, University of Oklahoma, Norman, OK 73019.

Abstract □ Digoxin 0.25-mg tablets were dissolved and assayed by the standard high-performance liquid chromatography (HPLC) method specified in USP XX and by a radioimmunoassay (RIA) method modified for the assay of tablet solutions. For the RIA method, the filtrate was diluted to a theoretical concentration of 5 ng/ml. Aliquots of this dilution were then assayed for digoxin content using a commercial digoxin ^{125}I RIA kit. Results from both methods were extrapolated to total tablet content and compared with the labeled amount for 20 individual tablets. All tablet assay results were within the USP standards for content uniformity of individual tablets. The individual tablet deviations from labeled amount by the RIA method were smaller when compared with the USP XX-specified HPLC method. Comparison of individual tablet assays show the RIA method to be both as precise and as accurate as the USP XX-specified HPLC method.

Keyphrases □ Digoxin—determination of content uniformity, comparison of high-performance liquid chromatography and radioimmunoassay, tablets □ Radioimmunoassay—comparison with high-performance liquid chromatography in determination of content uniformity of digoxin tablets □ High-performance liquid chromatography—comparison with radioimmunoassay in determination of content uniformity of digoxin tablets

Digoxin is the most predominant digitalis cardiac glycoside prescribed for clinical use. It is a potent drug used to increase the efficiency of the circulation in the treatment of congestive heart failure and to delay the ventricular rate in the treatment of atrial fibrillation and flutter (1).

BACKGROUND

The United States Pharmacopeia (USP) established the content uniformity test for tablets of certain potent drugs in 1965 with USP XVII (2). Due to the small dose (*i.e.*, 0.25 mg) utilized to elicit pharmacological response, digoxin must be assayed on a tablet-to-tablet basis. The USP XX potency definition for digoxin tablets states that the tablets must contain not <90% or not >105% of the labeled amount (3). A representative sample of 30 tablets was selected, and 10 of these tablets were assayed individually according to the drug monograph. The limits of the test state that not more than one tablet can be outside 85–115% of the average of the potency definition, and none of the tablets can be outside 75–125% of the average of the potency definition. The remaining 20 tablets must be assayed if any tablet exceeds the limits as stated. Requirements for content uniformity are met if these 20 tablets fall within the 85–115% average of the potency definition limit (4).

The digoxin content in single tablets has been determined by various methods, including colorimetric, fluorometric, polarographic, and GLC procedures (5–8). Although these methods were adequate in sensitivity, they were relatively cumbersome—either requiring formation of derivatives or complicated extractions or were limited to quantitation of millimolar concentrations. High-performance liquid chromatography (HPLC), a versatile separation technique, is the official assay method for the determination of digoxin tablet content uniformity in USP XX (3).

A number of radioimmunoassay (RIA) procedures for the measurement of biological and drug molecules in body fluids are available. Sensitive assay systems are capable of measuring antigen in the range of femtomole concentrations (9). RIA has been employed in bioavailability studies of digoxin (10–12), and is a highly sensitive method that is able to detect digoxin in human serum at the ng/ml level. The USP does not recognize it as an official test for tablet content uniformity at the present time. Since digoxin can be measured at such dilute levels in blood, it may be possible to utilize this method to determine drug levels in a dilute solution prepared from a single tablet.

EXPERIMENTAL

Materials—Digoxin 0.25-mg tablets[1] and digoxin reference standard powder[2] were used. Acetonitrile[3] was HPLC grade, and the dilute alcohol was USP grade. A [^{125}I]digoxin kit[4] was used in the RIA of the tablets.

Apparatus—A HPLC[5] equipped with a reverse-phase column[6] was connected to a variable-wavelength detector[7] and an automatic integrator[8]. The detector was operated at 218 nm and was attenuated at 0.04 AUFS for digoxin. A single-channel analyzer and amplifier[9] were connected to a counter timer[10] and a NaI(Tl) well crystal[11] for the RIA.

A 250 × 4.6-mm i.d. column, packed with 10-μm hydrocarbon (C18) bonded to silica gel[12], was used at ambient temperature with a mobile phase flow rate of 1.17 ml/min.

The mobile phase consisted of a mixture of acetonitrile–distilled water in a 1:2 ratio. The mixture was allowed to equilibrate 30 min before transfer to the solvent reservoir.

External standard—The digoxin reference standard power was dried for 1 hr at 105° and stored under vacuum in a glass desiccator before preparation. A standard solution (39.8 μg/ml) was prepared in dilute alcohol USP and stored at ambient temperature.

Digoxin 0.25-mg Tablet Assay Solutions—Samples of 10 tablets from two lots of digoxin 0.25-mg tablets were selected at random. Each individual tablet was placed in the center of a single sheet of weighing paper. The paper was tightly folded lengthwise around the tablet to form a cylinder and a 1-cm fold was made at each end of the paper. The tablet was crushed lightly, but completely, into powder with a glass pestle. One end of the paper was opened and inserted well into a clean, dry 10-ml volumetric flask to allow the powdered tablet to slide from the paper to the bottom of the flask. The other end of the paper was opened for the addition of dilute alcohol USP. Six milliliters of dilute alcohol was added through the paper cylinder, washing the residual tablet into the flask. The flask was covered and mixed for 15 sec by a mechanical shaker[13] and then sonicated[14] for 30 min. After sonication, the flask was removed from the sonicator and allowed to cool for 15 min. The solution was brought to volume with dilute alcohol USP and mixed for 15 sec on the mechanical shaker. Immediately after mixing, the entire solution was filtered through a medium-porosity sintered glass funnel. The first five drops of filtrate were discarded, and the remaining filtrate was collected in a clean, dry 10-ml volumetric flask and covered tightly with laboratory film. Based on the labeled quantity of digoxin in the tablets (0.25 mg), theoretical concentrations of the tablet test solution were in the range of 25 μg/ml.

The solutions of the 20 individual tablets were designated A1–A10 and B1–B10.

Linearity Test of External Standard—A stock solution (100 μg/ml) was prepared with the digoxin reference standard powder in dilute alcohol USP. Dilutions of 10, 20, 30, 40, 50, 60, 70, and 80 μg/ml were prepared from the stock solution with dilute alcohol USP. Duplicate aliquots of 35-μl injections of the stock solution and each dilution were chromatographed. The average retention time was 5.52 min. Linearity ($r = 0.99708$) was observed.

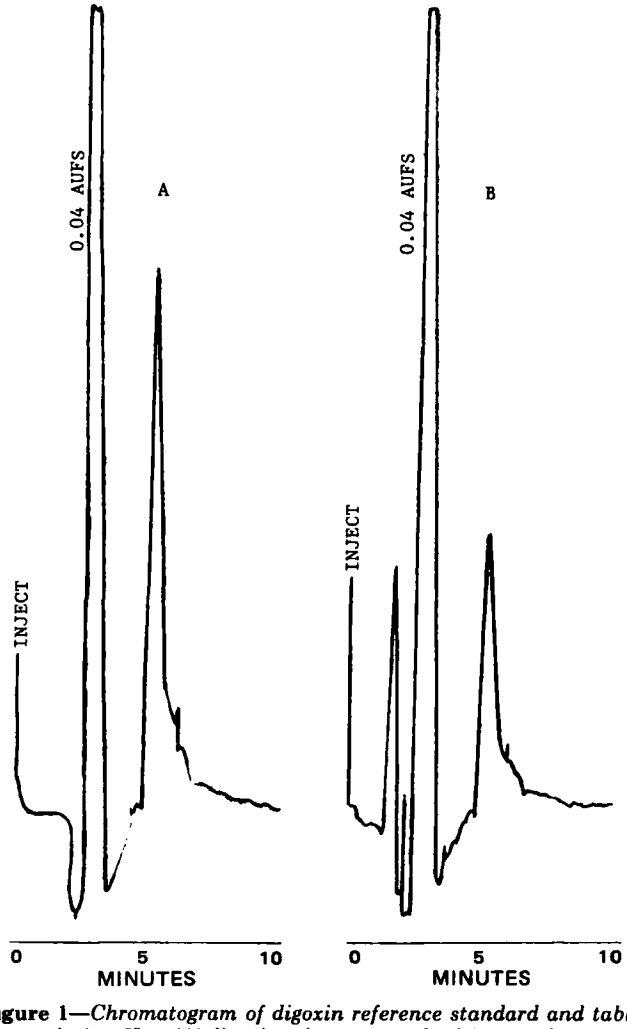

Figure 1—*Chromatogram of digoxin reference standard and tablet assay solution. Key: (A) digoxin reference standard (external standard, 39.8 μg/ml); (B) digoxin tablet assay solution (theoretical concentration of 25 μg/ml).*

HPLC Assay of Digoxin Tablet Solutions—Duplicate 35-μl aliquots of each digoxin tablet solution were chromatographed. Prior to injection of the digoxin tablet assay solutions, between the different sample lots, and after the chromatographs of all the digoxin tablet assay solutions, duplicate 35-μl aliquots of each digoxin reference standard solution (external standard, 39.8 μg/ml) were chromatographed.

Quantitation—The areas under the curve (AUC) generated by duplicate assays of each tablet solution were averaged and compared with the average of the initial duplicate digoxin reference standard solution injections by the formula specified in the USP (3): μg of digoxin = $10C(H_u/H_s)$, where 10 is the dilution volume of each tablet assay solution, C is the concentration of digoxin reference standard in μg/ml, H_u is the average AUC of the tablet assay solution, and H_s is the average AUC of the digoxin reference standard solution.

Preparation of RIA Kit—The [^{125}I]digoxin kit was prepared at room temperature as required by the manufacturer's instructions. The range of the standards for the kit was 0–8.0 ng/ml.

Dilution of Digoxin Reference Standard Solution and Digoxin 0.25-mg Tablet Assay Solutions—An exact volume (1.4 ml) of the digoxin reference standard solution (39.8 μg/ml) was pipeted into a clean, dry 100-ml volumetric flask with a 2-ml glass pipet (0.2-ml graduations). The solution was brought to volume with dilute alcohol USP and allowed to equilibrate overnight. A 1-ml glass pipet was used to transfer 1.0 ml of the equilibrated solution into another clean, dry 100-ml volumetric flask. The solution was brought to volume with dilute alcohol USP to a final concentration of 5.57 ng/ml.

Two milliliters of each tablet solution was pipeted into separate clean, dry 100-ml volumetric flasks with 2-ml glass pipets. The solutions were then brought to volume with dilute alcohol USP and allowed to equilibrate overnight. A 1-ml glass pipet was used to transfer 1.0 ml of each equilibrated solution into another 100-ml volumetric flask. Each solution was brought to volume with dilute alcohol USP. Based on the labeled

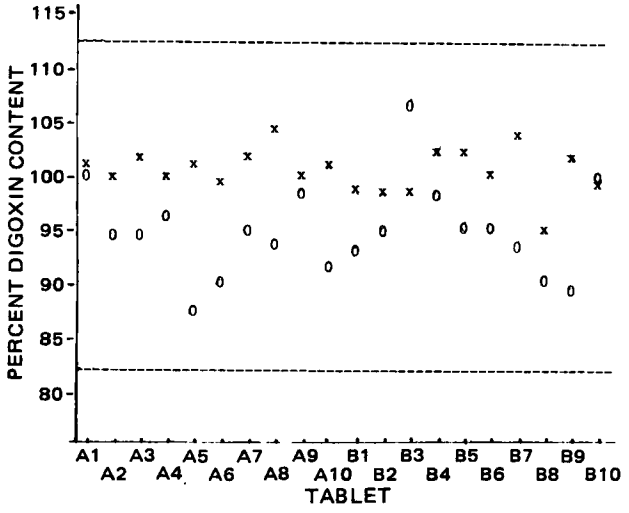

Figure 2—*Comparison of content uniformity test results of single digoxin tablets by HPLC and RIA. Key: (O) percent digoxin recovery by HPLC assay method; (X) percent digoxin recovery by RIA method; (---) limits of digoxin content uniformity.*

quantity of digoxin in the tablets (0.25 mg), theoretical concentrations of the tablet test solutions were in the range of 5 ng/ml.

Gamma Counter Calibration—A simulated iodine-125 source (iodine-129, 0.108 μCi) was utilized to calibrate the single-channel gamma analyzer. The sample[2]–background ratio for the energy peak in the differential mode was utilized to determine the optimum window setting, baseline, and high-voltage potential.

RIA of the Digoxin 0.25-mg Tablet Assay Solutions—All solutions assayed were done in duplicate. The assay consisted of a series of known digoxin standards from the kit (16 tubes), digoxin tablet solution (5 ng/ml) samples (40 tubes), and digoxin reference standard solution (5.57 ng/ml) samples (two tubes). Samples were pipeted into polystyrene 12 × 75-mm tubes[15] with an adjustable microliter pipet[16]. Known digoxin standards consisted of the following duplicate tubes: blank solution (0.02 *M* phosphate buffer, pH 7.4, with 0.5% bovine serum albumin); 0, 0.5, 1.0, 2.0, 4.0, and 8.0 ng/ml standards of digoxin in human serum; and control serum (human serum containing a digoxin concentration of 3 ± 0.3 ng/ml). The duplicate blank solution tubes contained 200 μl of 0.02 *M* phosphate buffer in place of antiserum and 50 μl of 0-ng/ml standard. Each of the remaining digoxin standard duplicate tubes consisted of 50 μl of the respective tablet solution and 200 μl of antiserum (digoxin rabbit serum albumin). The duplicate control serum tubes contained 50 μl of control serum and 200 μl of antiserum. The duplicate digoxin tablet solution samples consisted of 50 μl of the respective tablet solution and 200 μl of antiserum. The duplicate digoxin reference standard solution tubes consisted of 50 μl of digoxin reference standard solution (5.57 ng/ml) and 200 μl of antiserum. After adding 200 μl of radioactive tracer (histamine–digoxin conjugate labeled with iodine-125) to all tubes, the solutions were mixed and incubated at room temperature for 30 min. Following incubation, 1000 μl of concentrated charcoal suspension was added to each tube. The tubes were mixed and incubated again for 10 min. The unbound antigen was adsorbed on the charcoal and separated from the bound antigen by centrifugation[17] at 1200×*g* for 10 min. The supernatant solutions containing the antigen–antibody complexes from each tube were decanted into clean, dry polystyrene tubes, and the radioactivity was determined in the gamma counter.

Quantitation—The counts were averaged for each set of duplicate samples. Average net counts were calculated for all standards and samples by subtracting from each the average blank counts. The average net counts for each standard and sample were expressed as a percentage of the average net counts for the 0-ng/ml standard (normalized percent bound or percent of B/B_0) (13):

$$\text{percent of } B/B_0 = \frac{\text{Average net counts of standard or sample}}{\text{Average net counts of zero standard}}$$

Determinations of digoxin in the control and tablet solutions were made by preparing an exponential least-squares plot of percent of B/B_0 for each standard against the corresponding log concentration of digoxin in ng/ml and calculating the concentration of digoxin in ng/ml from the formula for the line of best fit. Samples were calculated as ng/ml since identical volumes were used for all standards and samples.

RESULTS AND DISCUSSION

A typical chromatogram of the digoxin reference standard solution and a tablet assay solution is shown in Fig. 1. The area under the curve unexpectedly increased by ~40% on sample A10. Two aliquots of digoxin reference standard solution (39.8 μg/ml) were injected and the AUC had increased almost twofold. The AUC from the nearly twofold increase of digoxin reference standard solution was utilized to calculate the amount of digoxin in tablet assay solutions A10–B10.

There was a considerable degree of tailing from each peak on all reference standard and tablet assay solutions. Amounts of digoxin calculated by the USP formula appeared to be 10–15% lower than expected due to the tailing. Adjustment of the slope sensitivity setting in the integrator did not provide any remedy. The decision was made to calculate the AUC manually by the triangle formula $A = H(W_{1/2})$. The width at mid-height is used instead of the width at baseline to reduce errors. A baseline was drawn, mid-height was determined, and height and width at mid-height were measured in centimeters (14). The assay results of the digoxin tablet solutions are shown in Table I.

The results of the RIA of the digoxin tablet solutions are shown in Table II. A comparison of each individual tablet from the two lots by the two assay methods is shown in Table III. The assay results by both methods are compared with the limits of the USP content uniformity test for digoxin tablets in Fig. 2. Statistical analysis by the paired *t* test is shown in Table IV.

The results in Tables III and IV show that the assay amounts for both methods for each digoxin tablet solution differed by significant amounts at the 95% confidence level. Assay results by HPLC were slightly higher for tablet solutions B3 and B10. RIA results were equal or higher for the remaining tablet solutions. The HPLC assay results for digoxin content ranged from 220 μg (88.0% recovery) to 268 μg (107.2% recovery). Assay results from digoxin content by RIA ranged from 237 μg (94.8% recovery) to 261 μg (104.4% recovery). Assay results of lot A indicated an average digoxin content recovery of 94.2% by HPLC as compared with an average digoxin content recovery of 101.0% by RIA. Results from lot B indicated an average digoxin content recovery of 95.3% by HPLC and an average digoxin content recovery of 100.3% by RIA. The average digoxin content recovery by RIA was 6.8 and 5.0% higher for both lots of digoxin tablets than the average digoxin content recovery by HPLC.

The RIA results for the digoxin tablet solutions were expected to be close to the results provided by the HPLC assay, because it was assumed

Table IV—Statistical Analysis of Digoxin 0.25-mg Tablet Content by HPLC and RIA with Paired t Test at 95% Confidence Level

Lot[a]	Method	Average Digoxin Content, μg	p
A	HPLC	235.6 ± 9.5	<0.05
A	RIA	252.6 ± 3.8	
B	HPLC	238.2 ± 13.0	<0.05
B	RIA	250.8 ± 6.6	

[a] $n = 10$.

that the digoxin would inhibit the radiolabeled antigen from binding with the antiserum in the same manner as if the digoxin was present in human serum. Since the drug was dissolved in USP dilute alcohol, there were no other steroid molecules present in the solutions which might cross-react with the antiserum. The filtering step prior to the assay procedure eliminates most of the excipient ingredients in the tablet dosage form.

As mentioned previously, the content uniformity test for tablets in USP XX required that each tablet must contain not <85% or not >115% of the average of the limits specified in the drug monograph. Digoxin tablets must contain <90% or not >105% of the label claim. Thus, a conforming tablet must fall within 82.9 and 112.1% of the average of the digoxin monograph limits[18].

All digoxin tablets assayed by both HPLC and RIA met the requirements of the content uniformity test.

This study showed that RIA is an accurate alternative to HPLC for content uniformity of digoxin tablets. The data showed the range of digoxin content determined by RIA was narrower than the range of digoxin content determined by HPLC. The significant difference at the 95% confidence level with the paired t test between the assay results of both methods showed that the RIA method appeared to be more precise and closer to the labeled amount than HPLC in the determination of digoxin content in the two lots of digoxin tablets.

In-Beam Electron Ionization Mass Spectra of Penicillins

MAMORU OHASHI, ROBERT P. BARRON ˣ, and WALTER R. BENSON

Received March 4, 1982, from the *Division of Drug Chemistry, Food and Drug Administration, Washington, DC 20204.* Accepted for publication May 21, 1982.

Abstract □ The characteristics of in-beam electron ionization mass spectra of 6-aminopenicillanic acid and several penicillins, which yield no detectable molecular ion peaks using a conventional direct-insertion probe, have been established. The spectra of all compounds studied, with the exception of amoxicillin, exhibited molecular ion or (M+1) peaks with spectral features similar to the reported methyl ester or amide derivatives of the compounds. The fragmentation of penicillin G on electron impact under in-beam conditions can be described on the basis of data from mass analyzed ion kinetic energy spectrometry. A desorption technique utilizing polyethylene glycol 4000 was used as a means of obtaining satisfactory spectra of ampicillin and amoxicillin.

Keyphrases □ Penicillin—in-beam ionization mass spectra β-lactam antibiotics, amoxicillin, ampicillin □ Electron ionization mass spectra, in-beam—penicillin, β-lactam antibiotics, amoxicillin, ampicillin □ Amoxicillin—in-beam electron ionization mass spectra of penicillins, β-lactam antibiotics □ Ampicillin—in-beam electron ionization mass spectra of penicillins, β-lactam antibiotics

Because of their low vapor pressure and thermal instability, penicillins, a class of β-lactam antibiotics, have generally required chemical pretreatment with formation of their esters or amides prior to mass spectrometric investigations (1, 2). Recently, isobutane and ammonia chemical ionization (CI) mass spectrometric data were published on the free acids of penicillins G and V (3), and the ammonia CI mass spectrum of the potassium salt of penicillin G was reported (4). Pyrolysis mass spectrometry was investigated (5) as a means of characterizing the compounds. The use of in-beam or extended-probe techniques to study apparently nonvolatile and thermally unstable compounds is now commonplace and well documented in the literature (6–14). Using this technique, ammonia-positive and methane-negative ion desorption CI of penicillins was reported (15); however, this report did not include any electron ionization (EI) data. Other researchers[1] have developed a technique using a mixture of the respective potassium salt and ammonium chloride to obtain the EI mass spectra of several penicillins. Accordingly, results obtained in this laboratory are presented on in-beam EI mass spectra of several penicillins, as their free acids, and their fragmentation processes based on mass analyzed ion kinetic energy spectrometric studies (16).

	348(3) [c]										134(32)	163(24)	

[a] Unless otherwise noted, the numbers in parentheses represent percent relative intensity with (−) indicating not observed; all other numbers represent m/z values above m/z 50. [b] All spectra exhibit an intense peak at m/z 44. [c] No molecular ion was observed; the highest ion observed was M—OH at m/z 348.

EXPERIMENTAL

Apparatus—All spectra were recorded on a double-focusing mass spectrometer[2] equipped with a modified field-desorption (FD)/EI source. The emitter heating current contact of the FD source was modified for in-beam purposes similar to that reported previously (17). An unactivated tungsten wire (10-μm diameter) or stainless-steel wire (125-μm diameter) was substituted for an activated emitter, and no high voltage was applied to the source except the usual 3K accelerating voltage. The sample on the FD wire was placed at a distance <3 mm from the ionizing electron beam and quickly heated by a maximum of 50 mA of the heating current (17–19) supplied by a standard heating current supply unit. The spectra were recorded under the following conditions: ionizing energy, 80 eV; source temperature, 280–300°; sample heater, 50 mA; emission current, 500 mA; accelerating voltage, 3 kV. Mass analyzed ion kinetic energy spectra, using identical parameters, were recorded by electric sector scanning.

Reagents—The following commercially available penicillins or precursors were used without additional purification: 6-aminopenicillanic acid[3] (*a*) and the penicillins (*b*), penicillin G potassium (I)[4], penicillin V potassium (II)[4], sodium oxacillin (III)[3], sodium nafcillin (IV)[5], disodium carbenicillin (V)[6], ampicillin (VI)[5], amoxicillin trihydrate (VII)[6] (Fig. 1). The metallic salts of the particular penicillins (~1 mg) were dissolved in 0.5 ml of water and acidified by addition of a drop of 88% aqueous formic acid solution. Immediately after formation of the precipitated free acid, 0.5 ml of ethanol was added to make a clear solution. Then 1–2 μl of the solution was deposited on the tungsten wire from a microsyringe[7].

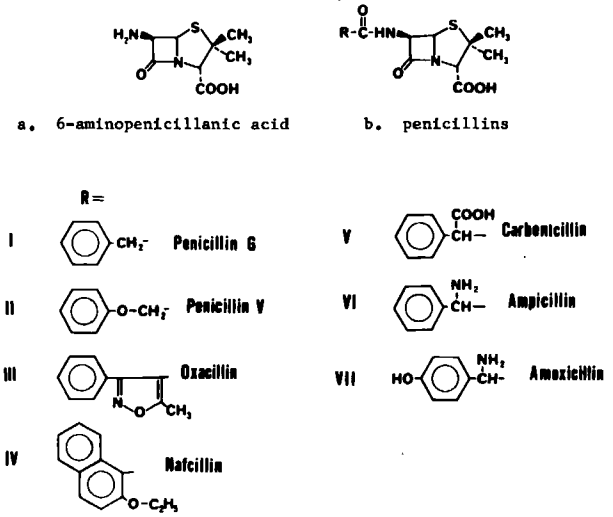

Figure 1—*Structures of pencillin analogues.*

[6] Beecham Lab., Piscataway, NJ 08854.
[7] Unimetrics Corp., Anaheim, CA 92801.

The solvent was evaporated in the mass spectrometer before final insertion of the sample into the ion source.

To obtain more reproducible results with the free acids of ampicillin and amoxicillin, ~5 mg of polyethylene glycol 4000 was added to the aqueous solution of the sample and stirred until dissolved. An aliquot of the solution was deposited on the wire, and spectra were obtained as previously described. The addition of low levels of polyethylene glycol to the sample did not contribute markedly to the sample spectrum and could easily be subtracted from the spectrum by computer techniques. One explanation for this lack of contribution of the polyethylene glycol is the greatly varying vaporization temperatures between the desorption enhancer and the sample, similar to the best emitter temperature effect observed in field desorption mass spectrometry.

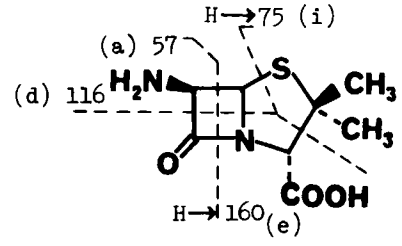
RESULTS AND DISCUSSION

Previous studies (1, 2) reported the electron ionization-induced fragmentation of penicillins G and V as the methyl ester or amide. An adaptation of these findings is summarized in Scheme I. Based on the ions in the spectrum, the nature of the R substituents could easily be assigned. In this work, the in-beam EI spectra of 6-aminopenicillanic acid, I, II, IV, V, and VI exhibit molecular ions, or MH ions in the case of III; VII, however, did not give $(M^{+\cdot})$ but gave instead $(M—OH)^+$ or $(MH—H_2O)^+$. The general fragmentation patterns of these compounds are similar to those reported for penicillin methyl esters or amides (1, 2) (Scheme I). The results are summarized in Table I in a format similar to that of previous work (2, 20).

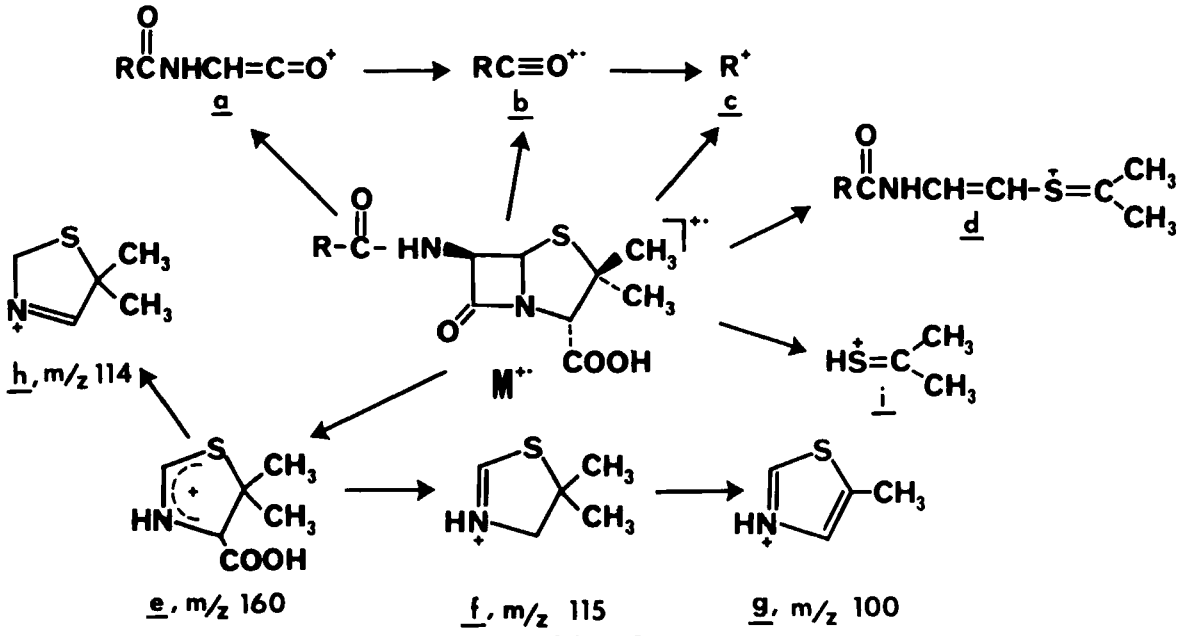
The simplest compound, 6-aminopenicillanic acid, is an amino acid thought to be difficult to vaporize without decomposition, but the in-beam EI technique routinely gave useful spectra, including the molecular ion at m/z 216. The abundant peaks are explained on the basis of fragmentation of the methyl esters presented previously (1). The electron ionization-induced fragmentation by the in-beam technique of the β-lactam ring system having the free acid moiety is shown below.

An important rearrangement ion at m/z 160 containing the thiazoline moiety is commonly observed in all spectra studied to date (Scheme I, *e*).

The fragmentation processes originating from the molecular ion of I have been examined by the mass analyzed ion kinetic energy spectrometric technique and are shown in Fig. 2A and 2B. The first spectrum (Fig. 2A) was recorded immediately after insertion of the sample into the ion source; the second spectrum (Fig. 2B) was recorded after a few min-

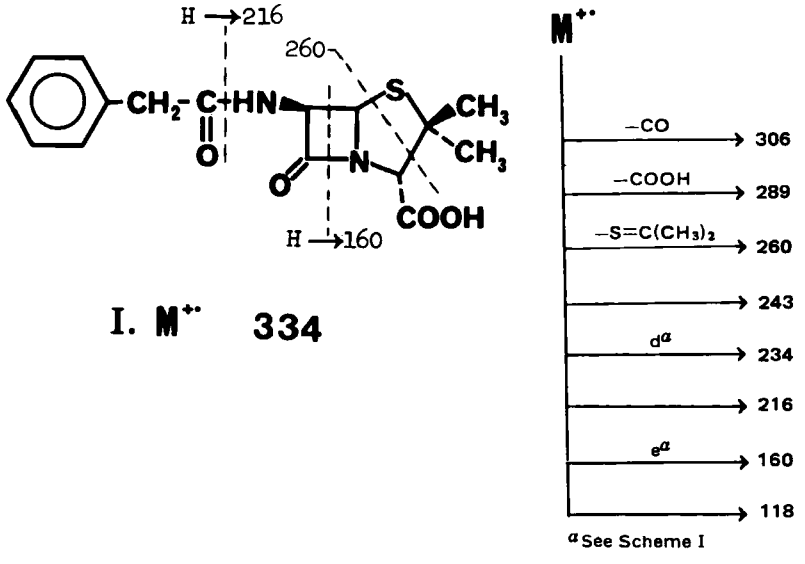


6-Aminopenicillanic Acid
$M^{+\cdot}$ 216



Scheme I

utes. This change in mass analyzed ion kinetic energy spectrometric spectral features suggests that the structures of the molecular ions undergo isomerization with time, *i.e.*, thermal alterations of the compound prior to electron ionization in the mass spectrometer. The major cleavages and metastable transitions from the molecular ion of I are summarized in Scheme II:



Scheme II

Eight transitions were clearly recognized. The transitions leading to the ions at *m/z* 289, 260, 234, 216, 160, and 118 have been suggested by previous investigators (1, 2) on the basis of accurate mass measurements and are confirmed by the mass analyzed ion kinetic energy studies. The transitions leading to the ions at *m/z* 234 and 160 correspond to processes d and e in Scheme I, respectively. In the mass analyzed ion kinetic energy spectra (Fig. 2A and 2B), one of the most abundant transitions is the rearrangement process with cleavage leading to the ion at *m/z* 216, corresponding to the molecular ion of 6-aminopenicillanic acid. Alternatively, the loss of carbon dioxide from the ion at *m/z* 260 could also conceivably yield *m/z* 216. However, since the methyl ester of I exhibits the same rearrangement ion with the empirical formula of 6-aminopenicillanic acid methyl ester confirmed by accurate mass measurement, the former process would be more probable. Additionally, transitions leading to the ion at *m/z* 293 corresponding to the loss of benzyl from the molecular ion and the ion at *m/z* 118 were observed. Since the contribution of the fragment ions to the in-beam spectra is negligibly small, successive transitions from these ions could not be investigated to further clarify the fragmentation scheme.

The in-beam EI spectrum of II exhibits a base peak at *m/z* 77 and abundant ions at *m/z* 94 and 107. These ions are commonly observed in the spectra of the methyl esters of I and II and are derived from the phenoxymethyl group based on accurate mass measurements (1). The mass analyzed ion kinetic energy spectrum of II (Fig. 2C) exhibits features suggesting that many isomerized forms of the molecular ion exist before and/or after electron ionization. The most intense transition in the spectrum at *m/z* 256 arises by the loss of phenol. The transitions leading to ions at *m/z* 216 and 160 (Scheme III) represent the rearrangement ions involving the β-lactam ring system; the fragment ions at *m/z* 276 and 250 are the phenoxy analogues of the ions at *m/z* 260 and 234, respectively. The other transitions are difficult to analyze because of the extensive thermal alterations of the molecule suggested earlier (Scheme III).

In the case of III, the $(M + 1)^+$ peak was observed at *m/z* 402 instead of $(M^{+\cdot})$. A series of peaks corresponding to $(MH—H_2O)^+$, $(MH—H_2O—CO)^+$, and $(MH—H_2O—CO_2)^+$ were detected at *m/z* 384, 356, and 340, respectively. The base peak at *m/z* 144, shown below, is believed to be derived from the *m/z* 187 ion, based on data of the well-known electron-impact fragmentation of the isoxazole moiety (21–25).

The in-beam EI spectrum of IV exhibits very intense peaks due to the naphthalene moiety at *m/z* 199 (base peak), 171, and 170 as well as the

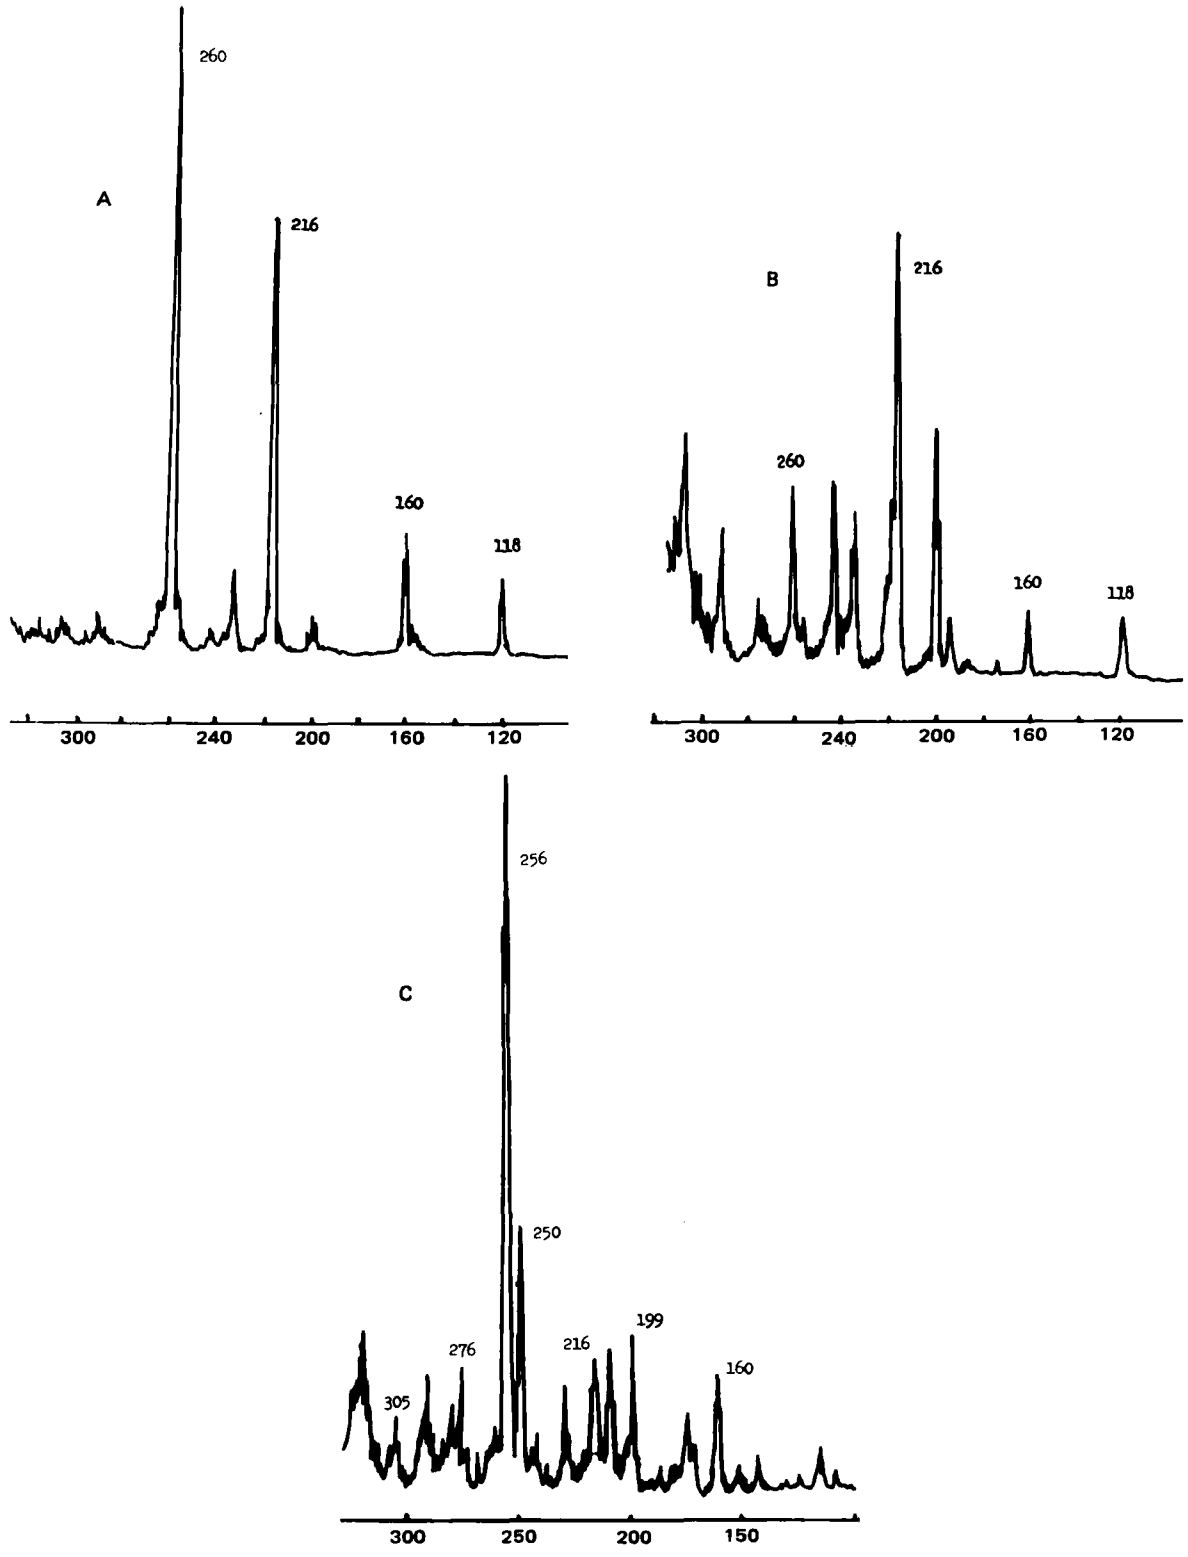


Figure 2—*Mass analyzed ion kinetic energy spectra. Key: from penicillin G molecular ion (m/z 334): (A) immediately after insertion, (B) after elapsed time, (C) from penicillin V molecular ion (m/z 350).*

peaks due to the general fragmentation at *m/z* 115(*f*), 114(*h*), and 100(*g*) as delineated in Scheme I. The abundance of fragment *e*, Scheme I, becomes rather weak.

Since V has a β-carbonyl carboxylic acid moiety, electron-impact or thermal-induced decarboxylation must take place easily, producing the abundant ions at *m/z* 91 and 92 in its spectrum. The peak corresponding to ion *c*, Scheme I, which is diagnostic of the R substituent, was also observed. Additionally, the spectrum exhibited peaks similar to those observed in the spectrum of I (*m/z* 334, 316, 288, 272, 160, 118, 114, 100, 92, and 91).

Ampicillin (VI) is an amino acid and as such is rather difficult to vaporize. Nevertheless, satisfactory in-beam EI spectra were obtained that exhibited $(M + 1)^+$, $(M^{+\cdot})$, and $(M - 17)^+$ at *m/z* 350, 349, and 332, respectively, when the compound was mixed with polyethylene glycol and examined under in-beam EI conditions (Fig. 3). Without polyethylene glycol, the in-beam spectral features were variable and were lacking characteristic peaks in the molecular weight region. The mechanism by which polyethylene glycol acts is not clear, but it appears to absorb the sample, and under quick-heating conditions, the sample was efficiently desorbed intact from its surface as in the case of polyimide- (26),

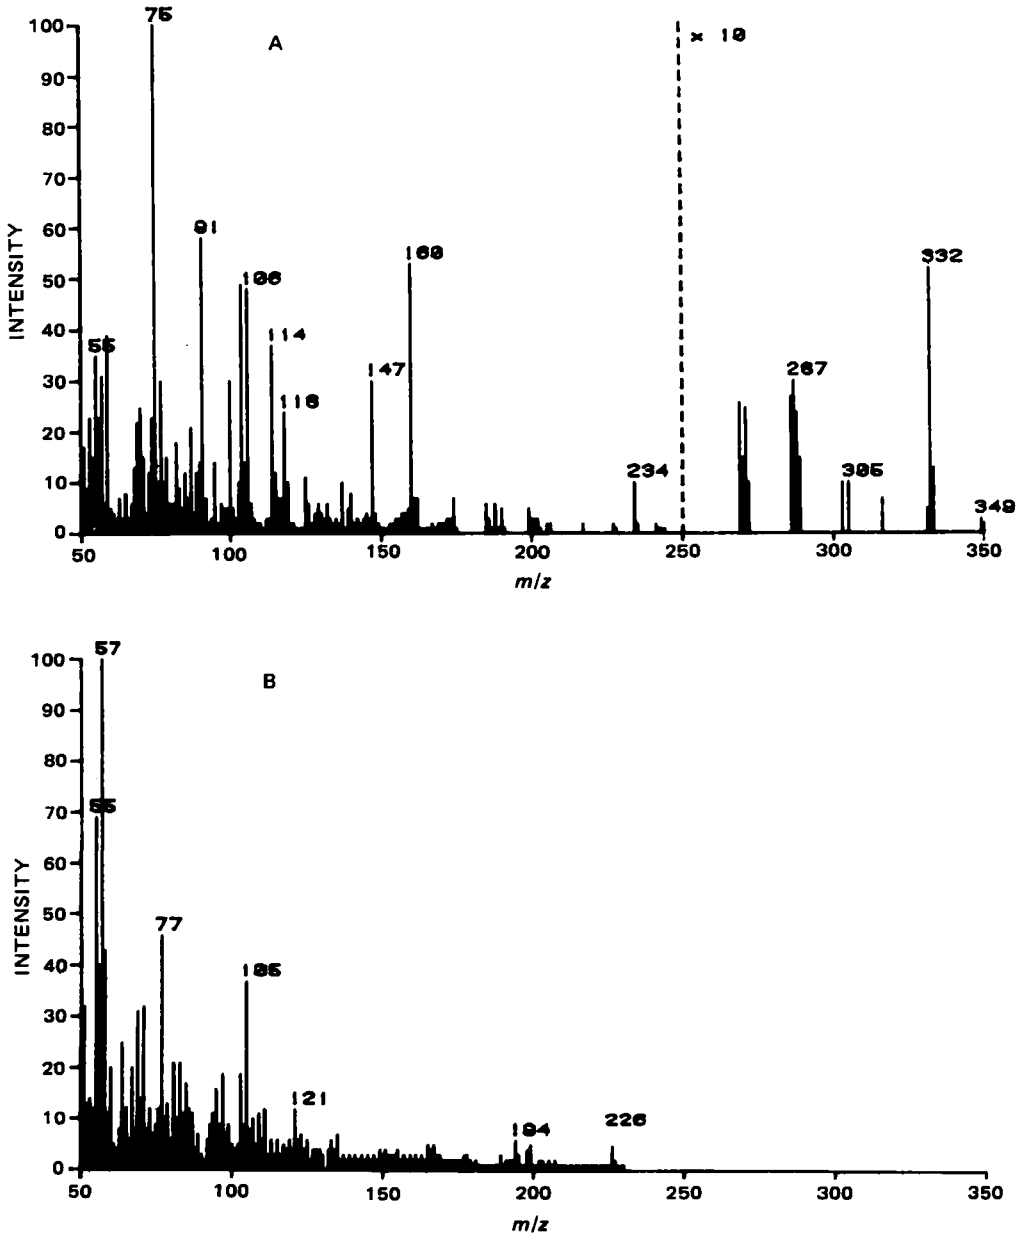

Figure 3—*Mass spectra of (A) ampicillin with polyethylene glycol 4000; (B) polyethylene glycol.*

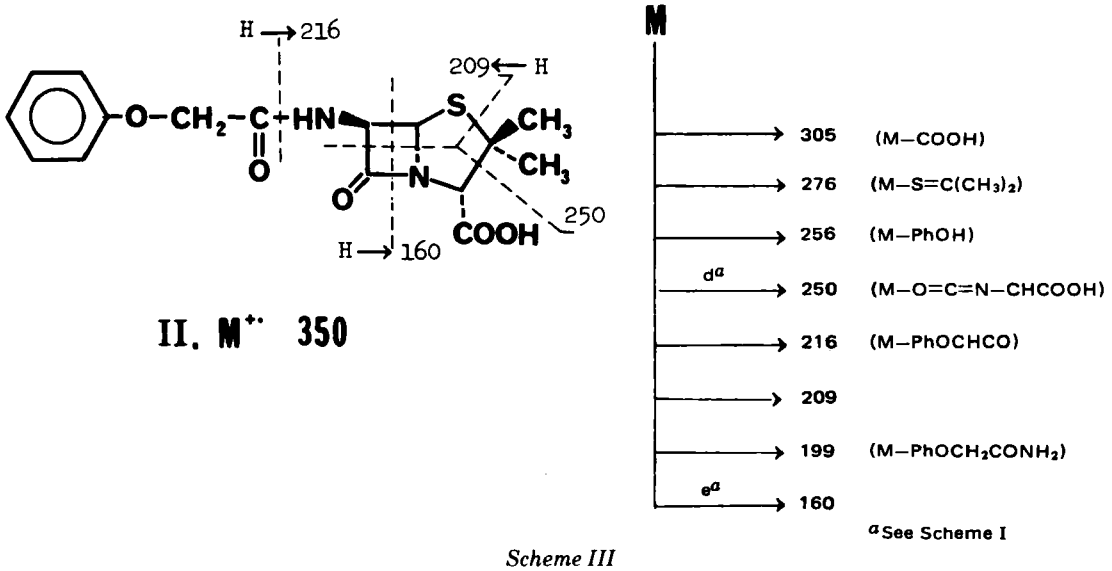
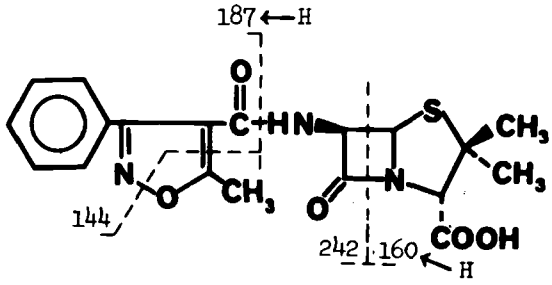


Scheme III



III. MH^+ 402

polytetrafluoroethylene- (27), or silicone- (28) coated tips. It should be noted that previous researchers have demonstrated the utility of polyethylene glycol in negative ion FD mass spectrometry (29, 30). Figure 3A shows the in-beam EI spectrum of VI mixed with polyethylene glycol and Fig. 3B shows the spectrum of polyethylene glycol. A comparison of these spectra indicates that polyethylene glycol contributes negligibly to the spectra of VI.

Amoxicillin trihydrate (VII) has a similar structure to VI. Mass spectra of this compound can be interpreted by the classical mass shift technique (31). Peaks at *m/z* 75, 100, 114, and 160 were commonly observed in the spectra of both compounds; the peaks at *m/z* 91, 104, 106, 118, and 147 in the spectrum of VI shift to *m/z* 107, 120, 122, 134, and 163, respectively, in the spectrum of VII[8]. It is clear that the common peaks are derived from the penicillanic acid moiety and the shifted peaks involve the aromatic moiety. The major fragmentation ions of these compounds are summarized below.

In conclusion, it has been demonstrated that EI mass spectra of intact, unmodified penicillins can be obtained by the in-beam EI technique. Although the contributions to spectra of thermal degradation products formed during sample heating cannot be excluded, the spectral features proved more than satisfactory for obtaining structural information on the samples. When the sample was difficult to vaporize, as in the case of VI, the desorption technique from polyethylene glycol 4000 was useful to obtain the spectra. The general fragmentation of free acid forms of penicillins under in-beam conditions were in accord with those reported for methyl esters and amides, further indicating the usefulness of the in-beam electron-impact technique.

Received January 4, 1982, from the *Gifu College of Pharmacy, Mitahora, Gifu 502, Japan and ‡Ichimaru Co. Ltd., Matsuhora, Takatomi, Gifu 502-21, Japan. Accepted for publication May 14, 1982.

Abstract □ Aqueous slurries of aminopyrine and barbital (molecular ratio 2:1) containing various excipients such as colloidal silica, synthetic aluminum silicate, montmorillonite clay, corn starch, microcrystalline cellulose, hydroxypropylcellulose, methylcellulose, gelatin, and chitosan were spray-dried by a centrifugal wheel atomizer with various rotation speeds (10,000–40,000 rpm) at various temperatures (85–145 ± 5°). The spray-dried products were a mixture of aminopyrine–barbital complex (molecular ratio 1:1), aminopyrine, and the excipient used. The flowability and the packing property of the products were improved by compounding colloidal silica into the formulation used for spray-drying. The products with montmorillonite clay, chitosan, and a corn starch–colloidal silica mixture were compressed directly into tablets. It was found that aminopyrine in the products was oxidized during spray-drying. The oxidation products were assumed to be a trace mixture of 5-oxo-2-methyl-4-dimethylamino-1-phenyl-3-pyrazoline carboxyaldehyde and miscellaneous oxidation products. Montmorillonite clay compounded in the formulation considerably prevented the oxidation of aminopyrine during spray-drying. The present study proposes an improved method for the preparation of solid particulates of aminopyrine–barbital complex for tableting, which combines the synthesis, drying, and agglomeration processes into a single process.

Keyphrases □ Aminopyrine—complex with barbital (pyrabital), direct preparation of solid particulates from droplets by a spray-drying technique □ Barbital—complex with aminopyrine (pyrabital), direct preparation of solid particulates from droplets by a spray-drying technique □ Pyrabital—direct preparation of solid particulates of aminopyrine–barbital complex from droplets by a spray-drying technique □ Solid particulate—direct preparation of aminopyrine–barbital complex (pyrabital) from droplets by spray-drying technique

A spray-drying technique has been used widely as a preferable drying method for heat-sensitive materials (foods, drugs, *etc.*). One advantage claimed for this technique is that both drying and agglomeration or microencapsulation of the drugs can be accomplished simultaneously. Microcapsules of barbituric acid and phenobarbital were prepared (1, 2) with a tensioactive precondensate of hexamethylolmelamine type. Enteric-coated microcapsules of sulfamethoxazole for tableting also were prepared (3).

Direct preparation of solid particulates from liquid droplets by a chemical reaction is one of the recent advances in spray-drying techniques. Ammonium sulfate spheres were produced (4) by the reaction of liquid droplets of orthophosphoric acid with gaseous ammonia. Solid particulates of theophylline–ethylenediamine complex were prepared (5) directly from liquid droplets.

The objective of the present study was to prepare solid particulates of a mixture of aminopyrine–barbital complex and aminopyrine, termed pyrabital in the Japanese Pharmacopeia (JP) IX (6), employing a spray-drying technique. Several methods of preparation of the analgesic,

pyrabital, have been developed as described elsewhere (6). These methods involve several processes, such as reaction, filtration, drying, *etc.* Furthermore, the agglomeration process subsequently is required for compounding the synthesized drug into a suitable dosage form. However, the present method combines these multiple processes into one step. In addition, the resultant products are compressed directly into tablets. Also examined were the parameters affecting the micromeritic properties of the product and the autoxidation of aminopyrine in the product during spray-drying.

EXPERIMENTAL

Materials—Aminopyrine and barbital were JP grade. Pyrabital produced by the fusion method (7) was used as a reference compound for identifying the spray-dried products. The mixture of aminopyrine (0.0173 mole) and barbital (0.00865 mole) was gradually heated in a beaker until a yellow melt was obtained. The melt was cooled to room temperature resulting in a yellow compound. The physicochemical characteristics of the resultant product, such as IR spectrum and melting point (96–103°), coincided with those specified in the JP.

Spray-Drying Technique—Aminopyrine (34 g), barbital (13.5 g), and excipients such as colloidal silica[1], synthetic aluminum silicate (JP grade), montmorillonite clay[2], corn starch (JP grade), microcrystalline cellulose[3], hydroxypropylcellulose[4], methylcellulose[5], gelatin[6], and chitosan[7] were dispersed in 600 ml of distilled water by a jet-type homogenizer. The system was held for 20 min and was heated at 60° when necessary. The resultant uniform aqueous slurry was atomized into a drying chamber. The detailed formulations are in Table I. Preliminary examination showed that no products were recovered from the formulation without excipient. Therefore, the excipient contained in the formulation was necessary to obtain the products. The feeding rate of the aqueous slurry was 20–33 ml/min. The atomization of the slurry was carried out by employing a centrifugal wheel atomizer (diameter, 4 cm)[8] rotated at 10,000, 20,000, 30,000, or 40,000 rpm. The drying chamber was maintained at 85, 100, 115, 130, or 145 ± 5°. Spray-dried aminopyrine with colloidal silica was also produced at 40,000 rpm and 130°.

Measurement of Micromeritic Properties—The sizes of the spray-dried products were measured by a photographic counting method using a particle size analyzer[9]. The packing and the flow properties were

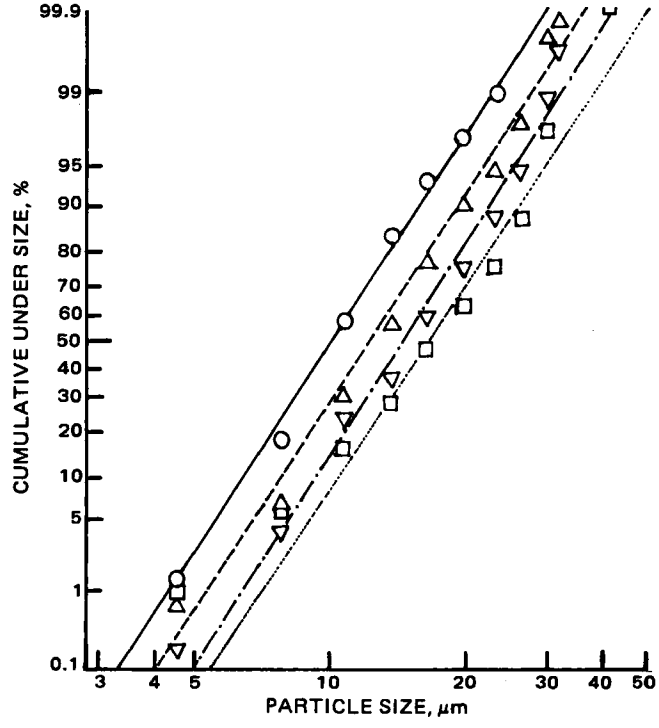

Figure 2—*Size distributions of the spray-dried products rotation speed of atomizer (rpm). Key: (▽) 10,000; (△) 30,000; (○) 40,000; (□) the products containing hydroxypropylcellulose (40,000).*

investigated by using a tapping machine[10] generating a uniform force with each tap and by pouring powder on a plate (diameter, 3 cm), respectively. The direct compressibility of the spray-dried products was examined by employing a single-punch tableting machine[11]. The internal diameter of the die was 10 mm. The surface topography of the products coated with gold were investigated by a scanning electron microscope[12].

Measurement of Physicochemical Properties—The contents of aminopyrine and barbital in the products were measured with a double-beam spectrophotometer[13]: aminopyrine in acidic solution at pH 1.2[14] at 270 nm and barbital in alkaline solution at pH 9.6[15] at 250 and 269 nm. Identification of the spray-dried products was carried out by IR spectroscopy[16] and X-ray analysis[17]. Degradation of aminopyrine in the products during spray-drying was investigated by TLC on silica gel[18] using chloroform–methanol (14:1), and isopropyl alcohol–chloroform–ammonium hydroxide (28%) (9:4.5:2) as solvents and by UV spectroscopy[13]. As a reference, autoxidation of aminopyrine was carried out in an acetic acid (160 ml) and ethanol (40 ml) mixture by introducing air.

RESULTS AND DISCUSSION

Identification of the Spray-Dried Products—It was found that the contents of aminopyrine and barbital in the products depended on the formulation for spray-drying and on the operating conditions as seen in Tables II–IV. The drug contents varied with the type of excipients used. The drug content in the product containing colloidal silica and gelatin was the lowest compared with the other excipients used in the present study (Table II). For the spray-drying condition, the drying temperature and the rotation speed of the atomizer were the main factors affecting the drug content in the products (Tables III and IV). With increasing rotation speed or decreasing drying temperature, the drug content increased. The inertia force exerted on the excipient was stronger than on the drugs in the droplet due to the fact that the density of the excipient was greater than that of the drug. Therefore, the excipient was separated more easily from the droplet than the drugs by increasing the rotation speed of the atomizer, which resulted in increasing the drug content in the spray-dried products. The effect of temperature on decreasing the drug content in the product was more significant than that of the rotation speed of the atomizer. An explanation for this finding is not clear at present. Although the percentage of drug content in the products varied widely, the molecular ratio of aminopyrine to barbital was fairly constant (2.2 ± 0.2 as shown in Tables II–IV).

[a] Spray-drying conditions: atomizer speed, 40,000 rpm; excipient, colloidal silica.

IR spectra of the spray-dried products, pyrabital, and the mixture of aminopyrine and barbital (2:1) showed a broad peak of colloidal silica contained in the product at 1000–1200 cm^{-1} that partly impaired the identification of the spray-dried products. The characteristic bands of pyrabital appeared at 1703, 1656, and 1584 cm^{-1}, strongly suggesting the existence of pyrabital in the products. None of these characteristic peaks appeared in the IR spectra of aminopyrine, barbital, and a mixture of the two.

X-ray diffraction patterns of the spray-dried products, pyrabital, aminopyrine, and barbital are seen in Fig. 1. Although the intensities of the diffraction peaks of the products were weaker than those of pyrabital, aminopyrine, and barbital, the characteristic peaks of pyrabital at a diffraction angle of 6.6 and 18.5° were detected. The reduced intensities of the product peaks indicated that some crystals in the product converted to a disordered form due to rapid crystallization during spray-drying. The more reduced intensities of the products prepared at 145° instead of 85° also indicated that the amorphism occurred because of the rapid crystallization.

It was reported (8) that pyrabital was a mixture consisting of a molecular compound of aminopyrine and barbital (molecular ratio 1:1) and an additional molecule of aminopyrine. Recalling that the molecular ratio of aminopyrine to barbital contained in the products was >2 (Tables II–IV), it appears that the present product was a mixture of pyrabital, aminopyrine, and the excipient used.

Micromeritic Properties of the Spray-Dried Products—The spray-dried products were observed to be fairly spherical particles under an optical microscope. Their sizes varied from 4 to 40 μm, and their distributions were described by a logarithmic plot shown in Fig. 2. As suggested from a previous study (9), the geometric mean diameter of the products increased with a decrease in the rotational speed of the atomizer.

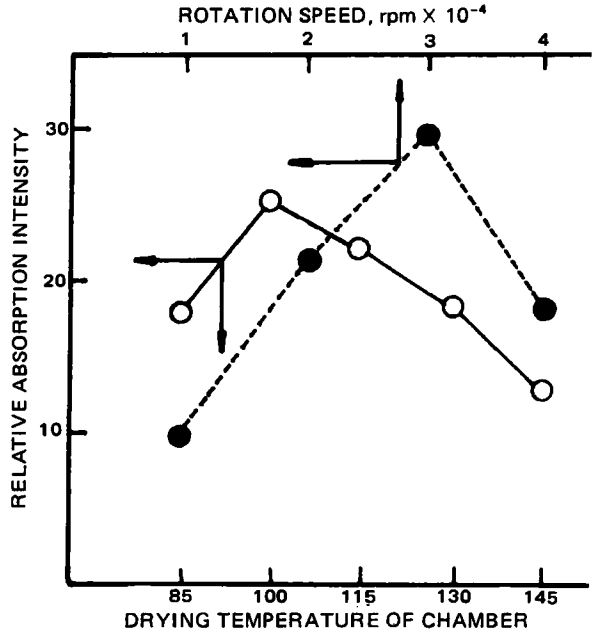

Figure 6—*The relative absorption intensities at 385 nm of the spray-dried products to pyrabital as a function of atomizer speed and drying temperature of the chamber.*

Hydroxypropylcellulose contained in the formulation also acted to increase the product size as seen in Fig. 2 and Table II.

Surface topography of the products depended mainly on the type of the excipient used. The products with colloidal silica and binder (hydroxypropylcellulose) revealed a fairly smooth surface, whereas the surface of the products with montmorillonite clay were pitted as shown in Fig. 3.

The angle of repose of the products with colloidal silica and chitosan was fairly low compared with the other products, as shown in Table II. The packing property of the products was evaluated by the parameter *a* from a previously described equation (10), which describes the packing process of powders by tapping into a measuring cylinder:

$$\frac{N}{C} = \frac{N}{a} + \frac{1}{ab} \quad \text{(Eq. 1)}$$

$$C = (V_0 - V_N)/V_N \quad \text{(Eq. 2)}$$

where *b* is a constant, *C* is the compaction ratio, *N* is the number of taps, V_0 is the volume of powder in a measuring cylinder at the loosest packing, and V_N is the volume after the *N*th tapping. The parameter *a* corresponds to the proportion of consolidation at the closest packing attained; therefore, the smaller *a* indicates easier packing. The parameter *a* of the products with colloidal silica was the smallest among the products, indicating that they were the most easily packed.

It was found that the products with chitosan, montmorillonite clay, and a mixture of corn starch and colloidal silica were directly compressible

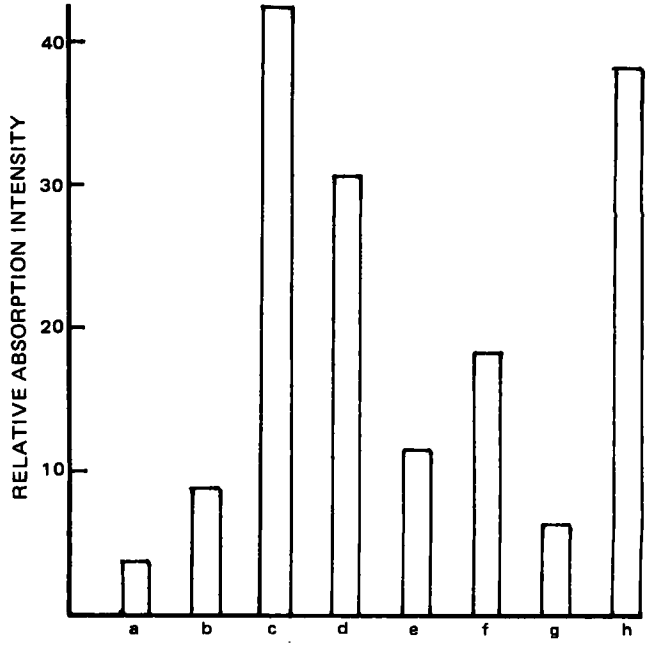

Figure 7—*The effects of excipient used on the relative absorption intensities at 385 nm of the spray-dried products to pyrabital. Excipient contained in the spray-dried products: (a) montmorillonite clay; (b) colloidal silica and gelatin; (c) microcrystalline cellulose; (d) colloidal silica and methylcellulose; (e) colloidal silica and chitosan; (f) colloidal silica and corn starch; (g) synthetic aluminum silicate; (h) colloidal silica and hydroxypropylcellulose.*

into tablets. The hardness[19] values of the resultant tablets were 4–4.5 kg. The weight variation tests of the tablets with <324 mg average weight were within the tolerances specified in the USP and the JP. For the other products, it was necessary to compound some microcrystalline cellulose (>50% w/w) in the formulations for tableting to obtain satisfactory tablets.

Degradation of Aminopyrine During Spray-Drying—Extracts of the spray-dried products exhibited absorbance at 385 nm, where aminopyrine does not absorb. The intensity of the peak depended on the excipient used and on the operating conditions (drying temperature and the rotation speed of the atomizer).

Thin-layer chromatograms of the spray-dried products containing colloidal silica developed with chloroform–methanol (14:1) coincided with that of spray-dried aminopyrine as seen in Fig. 4. As a reference, TLC of the autoxidized aminopyrine in the acetic acid–ethanol solution was also conducted as shown in Fig. 4. No separated yellow spots appeared at R_f 0.60 and 0.68, but a long yellow band appeared in the chromatogram of the autoxidized aminopyrine (Fig. 4c). The main spot at R_f 0.44 in the chromatograms was identified as aminopyrine (Fig. 4). The chromatograms developed with isopropyl alcohol–chloroform–ammonium hydroxide (9:4.5:2) are shown in Fig. 5. Two major spots at R_f 0.36 and 0.75 appeared in the spray-dried products. The spot at R_f 0.36 was identified as barbital by referring to the chromatograms of barbital and pyrabital in Fig. 5. The yellow band appearing at R_f 0.75 is characteristic of spray-dried products and oxidized and spray-dried aminopyrine.

The findings from spectrophotometric and TLC analysis (Figs. 4 and 5) suggested that the absorbance peak at 385 nm and the yellow spots on the chromatograms of the spray-dried products were attributed to the oxidation products of aminopyrine produced during spray-drying. The yellow substance in the spray-dried products detected by TLC in Figs. 4 and 5 could not be separated because of its low yield. A yellow substance was obtained previously (7) as an oxidation byproduct in the preparation by fusion of a molecular compound of aminopyrine and barbital. It was found that this substance was 5-oxo-2-methyl-4-dimethylamino-1-phenyl-3-pyrazoline carboxyaldehyde (I), which exhibits a strong absorbance band at 389 nm. The coexistence of other miscellaneous oxidation products of aminopyrine that caused shifting of the band at 389 nm from I toward the shorter wavelength region was reported (11), and it was suggested that the yellow substance in the spray-dried products might be a mixture of I and miscellaneous oxidation products.

The relative absorbance intensities at 385 nm of the spray-dried products to that of pyrabital (A_s/A_p) are plotted in Fig. 6, as a function of the operating conditions (the rotation speed of the atomizer and the drying temperature). The relative absorbance intensities increased with increasing atomizer speed up to a maximum at 30,000 rpm. Above this point, the relative intensity decreased as shown for 40,000 rpm in Fig. 6. With increasing rotation speed of the atomizer, the diameters of atomized droplets may decrease resulting in an increase in the total air-exposed surface area of the droplets. Therefore, autoxidation of aminopyrine in the droplets could be enhanced with increasing rotation speed of the atomizer up to 30,000 rpm. The increased rotation speed of the atomizer also accelerates the drying speed of the resultant smaller droplets. Once the droplets are solidified, the oxidation of aminopyrine in the solid state may be reduced compared with that in the liquid state. At a 40,000-rpm rotation speed of the atomizer, the rapid solidification of droplets might prevent further oxidation of aminopyrine that appears above 20,000 rpm (Fig. 6).

By increasing the drying temperature, the oxidation rate of aminopyrine in the droplets increases. At the same time, the evaporation rate of droplets increases. The rapid solidification of the droplets by increasing the drying temperature may reduce the oxidation of aminopyrine which is similar to that found at the 40,000-rpm rotation speed of the atomizer. The relative absorbance intensity was the highest at 100°. At temperatures >100°, aminopyrine autoxidation was reduced with increasing temperature because of the more rapid solidification of aminopyrine. The oxidation of aminopyrine during spray-drying also depended on the excipient contained in the products, as seen in Fig. 7. The absorbances of the product with hydroxypropylcellulose and microcrystalline cellulose are distinguishable from the other products. The products with montmorillonite clay exhibited the lowest absorbances, indicating that the oxidation of aminopyrine during spray-drying largely was prevented. The products with synthetic aluminum silicate, similar to montmorillonite clay, showed the next lowest absorbance at 385 nm. At present, no physicochemical explanation for this finding is apparent.

GLC Determination of Phendimetrazine in Human Plasma, Serum, or Urine

G. R. RUDOLPH, J. R. MIKSIC ˣ, and M. J. LEVITT

Received February 5, 1982, from the *Biodecision Laboratories, Pittsburgh, PA 15213.* Accepted for publication May 19, 1982.

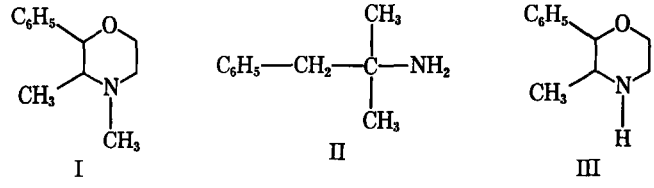
Abstract □ A sensitive, specific, and quantitative GLC method is described for the determination of phendimetrazine in plasma, serum, or urine. An internal standard was used, which was extracted along with the drug. This mixture then was acetylated to improve the chromatographic separation. A concentration as low as 2 ng/ml of phendimetrazine could be measured from 2 ml of sample using a nitrogen-phosphorous detector. Linearity extended from 2 to 500 ng/ml, and the coefficient of variation was 7%. The method was shown to be applicable to a single-dose bioavailability study.

Keyphrases □ GLC—determination of phendimetrazine in human plasma, serum, or urine □ Phendimetrazine—GLC determination in human plasma, serum, or urine □ Bioavailability—GLC determination of phendimetrazine in human plasma, serum, or urine

Phendimetrazine (I) is a sympathomimetic amine with anorectic activity used in nonprescription products for appetite suppression (1). As a condition of marketing phendimetrazine tartrate drug products in the United States, the Food and Drug Administration (FDA) has required bioavailability testing since 1973. To measure serum or plasma concentrations following a single dose of 105 mg in a bioavailability study, an analytical method with a sensitivity of ~5 ng/ml was required.

Phendimetrazine has been measured by TLC (2) and GLC (3, 4). These methods lack sufficient sensitivity to be useful for pharmacokinetic studies after a single 105-mg dose of drug. One GLC assay procedure does have adequate sensitivity (5), but only if 5 ml of serum is analyzed. Moreover, it was confirmed that the internal standard employed in this procedure was unstable, as previously reported (6).

The assay procedure described in this paper uses GLC with nitrogen-phosphorous detection to measure as little as 2 ng/ml of I in a 2-ml sample. Phentermine (II) is added to the samples to serve as an internal standard. Acetic anhydride is used to form an *N*-acetyl derivative of II which is suitable for GLC. Phenmetrazine (III), a metabolite of phendimetrazine (7), is also acetylated providing a derivative which does not interfere with the analysis of I.



I II III

EXPERIMENTAL

Reagents and Chemicals—All chemicals were used as supplied. Phendimetrazine tartrate[1], phentermine hydrochloride[2], and phenmetrazine[3] were pharmaceutical grade. Sodium chloride, potassium hydroxide, anhydrous ethyl ether, and acetic anhydride were ACS certified reagent grade[4]. HPLC grade toluene[4] was used. Phentermine hydrochloride was dissolved in deionized water (450 ng/ml) for use as the internal standard. Standards and controls were prepared by diluting aqueous solutions of phendimetrazine tartrate with pooled plasma, serum, or urine previously checked for interfering peaks. Concentrations of I at 0, 2, 5, 10, 25, 50, 80, and 150 ng/ml in serum or plasma and 0, 10, 25, 50, 80, 150, 200, 300, and 400 ng/ml in urine were analyzed. Standards stored at −15° were stable for at least 3 months.

Instrumentation—Analyses were performed on a gas chromatograph[5] equipped with a nitrogen-phosphorous detector, an auto injector[6], a recording integrator, and a 1.5-m × 2.0-mm i.d. glass column containing 3% SP-2100 on 80–100 mesh Supelcoport[7]. The column temperature was 140° during each analysis and was raised to 200° for 5 min following elution of the internal standard. The injection port and detector temperatures were 210 and 290°, respectively. Prepurified nitrogen[8] was used as a carrier gas at 30 ml/min. Samples were mechanically vortexed and shaken. Two-milliliter glass autoinjector vials with polytef-lined, red rubber caps and aluminum seals were used[9].

Analytical Procedure—Internal standard solution (700 μl, equivalent to 315 ng of phentermine hydrochloride) and sodium chloride (1 ± 0.2 g) were added to 2.0 ml of plasma, serum, or urine in a 16 × 125-mm screw-cap tube. The sample was made basic by the addition of 2 *N* KOH (300 μl). After brief mixing, I and II were extracted into ethyl ether (3 ml)

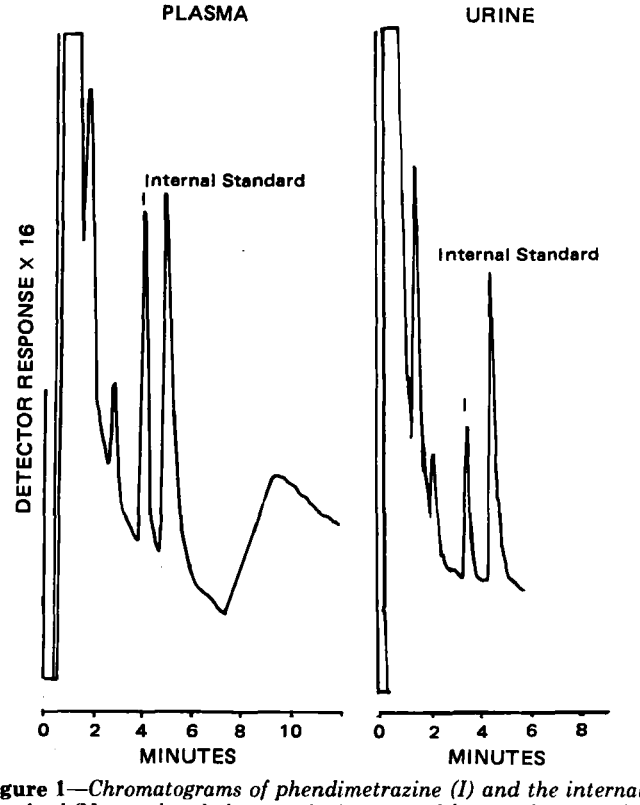


Figure 1—*Chromatograms of phendimetrazine (I) and the internal standard (N-acetylated phentermine) extracted from a plasma and a urine sample. The phendimetrazine concentrations were 39 ng/ml in plasma and 1621 ng/ml in urine (diluted 40-fold).*

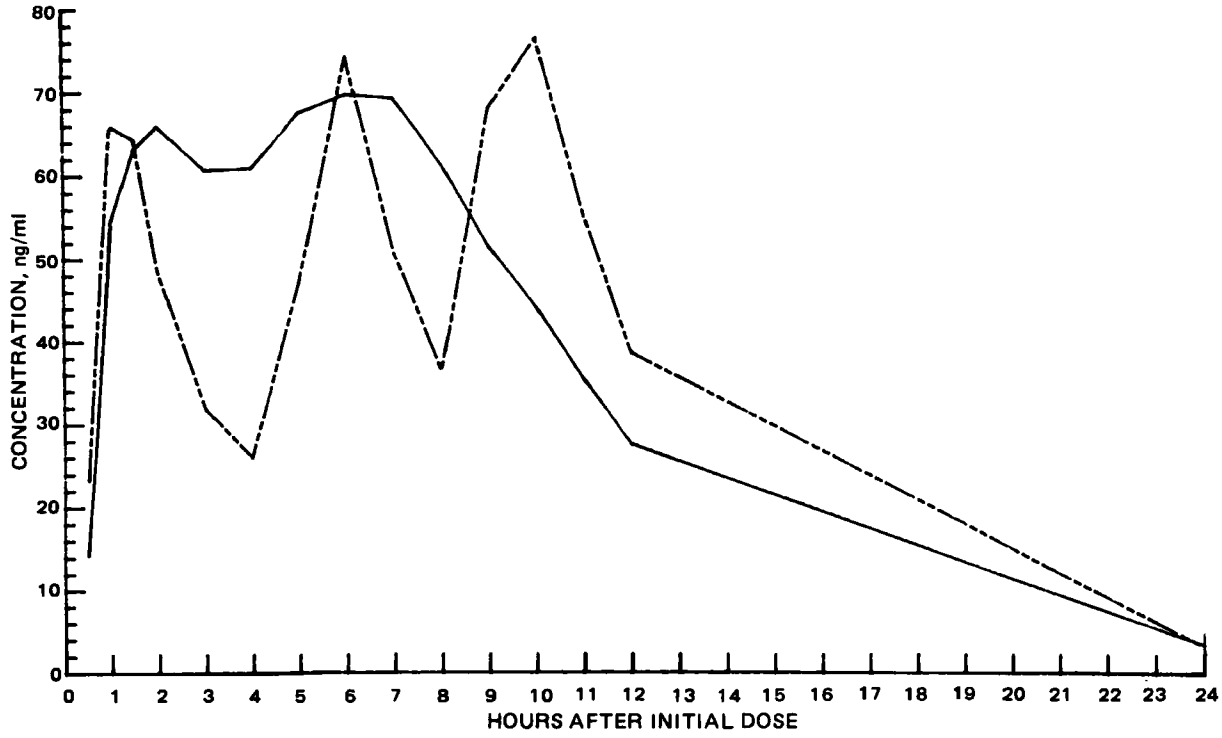

Figure 2—*Average plasma levels of phendimetrazine in 20 males who received a 105-mg controlled-release product at 0 hr or a 35-mg immediate-release product at 0, 4, and 8 hr. Key: (- - -) immediate release; (——) controlled release.*

by shaking for 10 min, and then the ether layer was transferred to another 16 × 125-mm tube. The drug and internal standard were then extracted from the ether into 0.1 *N* HCl (1.0 ml) by vortexing for 2 min. After centrifuging at 2800×*g* for 5 min, the ether layer was aspirated and discarded. Toluene (300 μl) and 10 *N* KOH (100 μl) were added to the remaining aqueous layer. After vortexing for 2 min and centrifuging at 2800×*g* for 5 min, the toluene layer was transferred to an injector vial. Acetic anhydride (50 μl) was added, the vial was capped, mixed briefly, and allowed to stand for at least 5 min. An aliquot (4 μl) then was injected into the gas chromatograph.

Human Bioavailability Study—A two-way crossover study was performed in 20 males (age, 18–37 years; weight, 60–89 kg). All of the subjects had hematology, blood chemistry, and urinalysis values within the normal range. The subjects received no medication for 7 days prior to the study and only the prescribed medications during the study. All the subjects were administered oral doses of enteric-coated ammonium chloride starting two days before dosing in order to maintain urine pH <7. They were fasted overnight at least 10 hr predose and for 2 hr postdose. A light breakfast was eaten 2 hr after initial dosing.

In each phase of the study, half of the subjects were administered a single 105-mg controlled-release phendimetrazine tartrate capsule[10] at 0 hr. The remaining subjects were administered one 35-mg immediate-release phendimetrazine tartrate tablet[11] at 0, 4, and 8 hr. Each dose was administered with 177 ml of water.

Blood samples (10 ml) were drawn from an antecubital vein into heparinized evacuated blood collection tubes[12] at intervals from 0 to 48 hr after initial dosing. The blood samples were centrifuged at 2000×*g* for 10 min within 10 min of collection. The plasma samples were transferred to polystyrene culture tubes[13] and stored at −15° until analyzed. Urine samples were collected at 12-hr intervals for 48 hr after initial dosing and were stored at −15° until analyzed.

Calculations—Peak height ratios were calculated by dividing the height of the phendimetrazine peak by the height of the acetylated internal standard peak. A best-fit line was determined by linear regression for standards ranging from 0 to 150 ng/ml (to 400 ng/ml for urine) that were processed along with the samples. The peak height ratio for each sample was used to calculate its concentration from the best-fit line. Comparable results were obtained when peak area ratios were used instead of peak height ratios. Control samples consisting of phendimetrazine added to plasma at 20 and 75 ng/ml and to urine at 20 and 158 ng/ml were also analyzed with each set of samples, and day-to-day coefficients of variation were determined from these controls.

RESULTS AND DISCUSSION

Chromatography—The retention times of phendimetrazine and *N*-acetyl phentermine were 4.1 and 4.8 min, respectively (Fig. 1). Because some serum and plasma samples had a late-eluting peak at ~10 min, the column temperature was programmed to increase to 200° for 5 min after the internal standard peak was completely eluted.

Acetic anhydride was added to improve the chromatographic separation and eliminate a metabolic interference. In the absence of acetic anhydride, phentermine was poorly resolved from the solvent front as a tailing peak (retention time of 1.4 min), and phenmetrazine (a metabolite of phendimetrazine) was incompletely resolved from the phendimetrazine peak. Injection of acetic anhydride remaining from the acetylation reaction had no perceptible effect on column performance and, therefore, was left in the reaction mixture.

Extraction and Derivatization—The total recovery of phendimetrazine from plasma or serum was 73% ($n = 5$, $CV = 4\%$) of that obtained with a single extraction from aqueous solutions. Gel formation was encountered during the initial extraction with ethyl ether but was eliminated by the addition of salt and gentle shaking.

The reaction of acetic anhydride with phentermine was complete within 5 min at room temperature. Acetic anhydride obtained from one other alternate source produced a large peak at the retention time of phendimetrazine. Redistillation of this anhydride did not prevent the appearance of the interfering peak. Alternate bottles from the manufacturer listed in this paper had no interfering peaks.

Internal Standard—Biogenic amines such as pseudoephedrine, phenylpropanolamine, phentermine (underivatized), and diethylpropion were unsuitable as internal standards, because they were unstable, produced tailed chromatographic peaks, or had undesirable retention times. The internal standard used in this procedure, phentermine, was extracted with phendimetrazine and the mixture treated with acetic anhydride. Phentermine formed a stable *N*-acetyl compound which afforded a suitable retention time and peak shape.

Assay Sensitivity, Linearity, and Precision—Phendimetrazine standards in plasma and serum produced linear responses over the range of 2 to at least 200 ng/ml. Urine standards gave linear responses to at least 500 ng/ml. The standard curves typically had regression coefficients >0.99. The lower limit of quantitation of the analysis was 2 ng/ml from

an initial 2-ml sample. The day-to-day coefficients of variation (n = 24) of the procedure over a 3-week period, during which ~1000 plasma samples were analyzed, were 7% at 20 ng/ml and 6% at 75 ng/ml. The day-to-day coefficients of variation (n = 5) for the urine analyses were 6% at 20 ng/ml and 4% at 158 ng/ml. Within-day reproducibility for the plasma assay with n = 5 at concentrations of 2 and 50 ng/ml was CV = 8.7 and 1.3%, respectively.

Bioavailability Study Results—The assay procedure was used to measure the plasma and urine concentrations of phendimetrazine in 20 subjects in a two-way crossover bioavailability study (Fig. 2). The peak concentration of 70 ng/ml observed after one 35-mg dose of phendimetrazine tartrate and the elimination half-life of 2 hr observed for the immediate-release product were similar to those previously reported (5, 7). The average total recovery in urine over 48 hr after a 105-mg dose amounted to 5.72 ± 3.01 mg for the controlled-release formulation and 4.72 ± 2.89 mg for the immediate-release formulation. The assay procedure had adequate sensitivity to measure phendimetrazine in plasma at 24 hr, even for the subjects who received the immediate-release formulation. No predose plasma or urine samples had interferences at the phendimetrazine or internal standard retention times.

Determination of Benzalkonium Chloride in the Presence of Interfering Alkaloids and Polymeric Substrates by Reverse-Phase High-Performance Liquid Chromatography

DENNIS F. MARSH ˣ **and LLOYD T. TAKAHASHI**

Received October 9, 1981, from *Allergan Pharmaceuticals, Inc., Irvine, CA 92713.* Accepted for publication May 24, 1982.

Abstract □ A specific assay for the analysis of benzalkonium chloride in the presence of interfering substances was conducted. The approach involved complexing benzalkonium chloride in an ophthalmic system with methyl orange, extraction of the complex into 1,2-dichloroethane, and subsequent analysis by reverse-phase high-performance liquid chromatography. Since the method separates each homologue of benz*alkonium chloride*, homologues not resident in the ophthalmic system were added as internal standards to improve both recovery and precision in the method.

Keyphrases □ High-performance liquid chromatography—determination of benzalkonium chloride, ophthalmic systems, complex with methyl orange □ Benzalkonium chloride—high-performance liquid chromatography, ophthalmic systems, complex with methyl orange

Various nonspecific dye extraction methods (1–3) have been developed for the determination of benzalkonium chloride. Recently, a specific analysis for benzalkonium chloride in aqueous solution by high-performance liquid chromatography (HPLC) was developed (4). This method involves direct injection of the aqueous formulation onto the chromatographic column. However, this method of analysis proved unsatisfactory for ophthalmic systems containing polymeric material. Polyvinyl alcohol, for example, precipitates under assay conditions, thus plugging the HPLC column. Suspended particulate matter in the formulation, such as steroid suspensions, also precludes the use of the method for the same reason.

Another difficulty encountered with the direct injection procedure is the interference of active alkaloids with the benzalkonium chloride during chromatography. Benzalkonium chloride is generally present in ophthalmic systems at the antimicrobial level of 0.004%, while active ingredients are present in considerably greater concentration. Also, active ingredients have considerably higher extinction coefficients in the UV than does the benzalkonium chloride preservative. These factors make benzalkonium chloride difficult to detect by HPLC if its retention time and that of the active ingredients are at all similar.

The purpose of this paper is to describe an extraction procedure to determine benzalkonium chloride in problem systems which preclude direct injection of the samples.

EXPERIMENTAL

Apparatus—The HPLC consisted of a pump[1], an automatic sampler[2], a reverse-phase microcyano column[3], a 254-nm detector[4], and a recorder[5]. Peak integrations were performed with a laboratory data system[6].

Reagents and Solvents—The mobile phase was 58% acetonitrile[7] (UV grade) and 42% 0.161 *M* sodium propionate at pH 5.35. Sodium carbonate[8] (7.5 g) was mixed with distilled water in a 2000-ml volumetric flask. Propionic acid[9] (12 ml) was added, and the solution was brought to volume (2000 ml) with distilled, deionized water. This solution was mixed with 2800 ml of acetonitrile.

Preparation of the C_{10} and C_{18} Homologues of Benzalkonium Chloride (as the Methyl Orange Complex)—In a 1000-ml round-bottom flask 22.1 g (0.1 mole) of 1 bromodecane[10], 13.5 g (0.1 mole) of *N,N*-dimethylbenzylamine[9], 500 ml of acetonitrile, and 30 ml of dimethylformamide[9] were added. This solution was allowed to reflux (86°)

Determination of Benzalkonium Chloride in the Presence of Interfering Alkaloids and Polymeric Substrates by Reverse-Phase High-Performance Liquid Chromatography

DENNIS F. MARSH ˣ **and LLOYD T. TAKAHASHI**

Received October 9, 1981, from *Allergan Pharmaceuticals, Inc., Irvine, CA 92713.* Accepted for publication May 24, 1982.

Abstract □ A specific assay for the analysis of benzalkonium chloride in the presence of interfering substances was conducted. The approach involved complexing benzalkonium chloride in an ophthalmic system with methyl orange, extraction of the complex into 1,2-dichloroethane, and subsequent analysis by reverse-phase high-performance liquid chromatography. Since the method separates each homologue of benz*alkonium chloride*, homologues not resident in the ophthalmic system were added as internal standards to improve both recovery and precision in the method.

Keyphrases □ High-performance liquid chromatography—determination of benzalkonium chloride, ophthalmic systems, complex with methyl orange □ Benzalkonium chloride—high-performance liquid chromatography, ophthalmic systems, complex with methyl orange

Various nonspecific dye extraction methods (1–3) have been developed for the determination of benzalkonium chloride. Recently, a specific analysis for benzalkonium chloride in aqueous solution by high-performance liquid chromatography (HPLC) was developed (4). This method involves direct injection of the aqueous formulation onto the chromatographic column. However, this method of analysis proved unsatisfactory for ophthalmic systems containing polymeric material. Polyvinyl alcohol, for example, precipitates under assay conditions, thus plugging the HPLC column. Suspended particulate matter in the formulation, such as steroid suspensions, also precludes the use of the method for the same reason.

Another difficulty encountered with the direct injection procedure is the interference of active alkaloids with the benzalkonium chloride during chromatography. Benzalkonium chloride is generally present in ophthalmic systems at the antimicrobial level of 0.004%, while active ingredients are present in considerably greater concentration. Also, active ingredients have considerably higher extinction coefficients in the UV than does the benzalkonium chloride preservative. These factors make benzalkonium chloride difficult to detect by HPLC if its retention time and that of the active ingredients are at all similar.

The purpose of this paper is to describe an extraction procedure to determine benzalkonium chloride in problem systems which preclude direct injection of the samples.

EXPERIMENTAL

Apparatus—The HPLC consisted of a pump[1], an automatic sampler[2], a reverse-phase microcyano column[3], a 254-nm detector[4], and a recorder[5]. Peak integrations were performed with a laboratory data system[6].

Reagents and Solvents—The mobile phase was 58% acetonitrile[7] (UV grade) and 42% 0.161 *M* sodium propionate at pH 5.35. Sodium carbonate[8] (7.5 g) was mixed with distilled water in a 2000-ml volumetric flask. Propionic acid[9] (12 ml) was added, and the solution was brought to volume (2000 ml) with distilled, deionized water. This solution was mixed with 2800 ml of acetonitrile.

Preparation of the C_{10} and C_{18} Homologues of Benzalkonium Chloride (as the Methyl Orange Complex)—In a 1000-ml round-bottom flask 22.1 g (0.1 mole) of 1 bromodecane[10], 13.5 g (0.1 mole) of *N,N*-dimethylbenzylamine[9], 500 ml of acetonitrile, and 30 ml of dimethylformamide[9] were added. This solution was allowed to reflux (86°)

for 3 days. To the hot, well-stirred solution was added 20 g of methyl orange[9]. The resulting solution was filtered hot. After cooling, the filtrate was refiltered. The orange crystalline needles thus obtained were analyzed by HPLC. The C_{10} homologue was the only peak observed. This peak had the same retention time as a USP standard benzalkonium chloride sample containing the C_{10} homologue. The C_{18} homologue was prepared in an analogous manner from 0.1 mole each of 1-chlorooctadecane[10] and *N,N*-dimethylbenzylamine in 500 ml of acetonitrile and 200 ml of dimethylformamide (heated at reflux for 5 days).

Preparation of the Internal Standard Mixture—Three grams of the C_{10} homologue of benzalkonium chloride was combined with 2 g of the C_{18} homologue. This mixture was finely ground with a mortar and pestle. A 0.06-g portion of this mixture was placed in a 1000-ml volumetric flask and 250 ml of dimethylformamide was added. A 0.250-g sample of methyl orange was dissolved in 500 ml of water. The aqueous solution of methyl orange was combined with the dimethylformamide solution of the benzalkonium chloride complex and 25 ml of acetic acid[9] was added. The solution was brought to volume with dimethylformamide.

Procedure—Samples and standards can be prepared and analyzed by HPLC both with and without the use of internal standards (Methods 1 and 2, respectively). Samples containing suspended steroids have been assayed by either method.

Standard Preparation—Raw material (50% w/v)[11] to be used as a secondary reference standard was diluted to 0.1% with water and assayed using a USP primary reference standard (10% w/v)[12] diluted to 0.100%.

Since no interfering substances are present in these aqueous solutions, these standards were not extracted and were injected directly without use of internal standards. For the assay of benzalkonium chloride in samples, the secondary reference standard was further diluted to the same concentration as the samples, usually 0.004% w/v.

Method 1 (Using Both Internal Standards)—The solution of sample or working standard (1.00 ml) was placed into a 12 ml plastic centrifuge tube[13], and 2.00 ml of the working internal standard solution was added. The solution was agitated briefly and allowed to equilibrate for 10 min. Then, 1.00 ml of 1,2-dichloroethane[9] was added, the mixture was vortexed for 1 min, allowed to stand for a few moments, and vortexed for an additional minute. The mixture was then centrifuged for 20 min at 8000 rpm. The phases were separated, and the organic phase was dried (anhydrous sodium sulfate) to give a yellow solution which was assayed by HPLC.

Method 2 (Using No Internal Standard)—The solution (1.00 ml) was added to a 10 ml plastic centrifuge tube, and 1.00 ml of a 0.05% aqueous solution of methyl orange, followed by 1.00 ml of a 10% aqueous solution of acetic acid were added. The solution was agitated briefly and allowed to equilibrate for 10 min. 1,2-Dichloroethane (1.0 ml) was added and the procedure in Method 1 was followed.

Assay—The mobile phase was filtered (1 μm) and deaerated. The system had the following parameters: a flow rate of 2.0 ml/min, giving a pressure of 1000–1500 psi, a 180-μl injector volume, an analysis time of 13 min, 254 nm detection at 0.01 AUFS, and a chart speed of 0.25 cm/min. After a stable baseline was achieved, replicate standards were run to ensure reproducibility, followed by the samples. A standard was run after every third sample.

The laboratory data system[6] was used to monitor the internal standard and the benzalkonium chloride peak areas. Since the concentration of the homologues other than C_{12}, C_{14}, and C_{16} in a benzalkonium chloride sample typically comprised <2% of the total, only the C_{12}, C_{14}, and C_{16} peaks were monitored. Chromatograms of benzalkonium chloride with and without internal standards are shown in Figs. 1 and 2.

Calculations for samples run without the use of internal standards are straightforward, relating the peak areas of the sample to the standard and adjusting this ratio for the standard concentration. When both in-

ternal standards are used (Method 1), the calculations are more involved.

The weighting system described below is used to adjust for the varying partition coefficients of each homologue of benzalkonium chloride in the systems studied.

In many formulations, the extractability of each homologue follows the chain length. Recoveries of the individual homologues diminish as the chain length increases (see Table IB and C). For this reason, two internal standards, the C_{10}–C_{18} homologues are used to bracket the C_{12}–C_{16} benzalkonium chloride homologue resident in the formulation. If the C_{10} homologue alone is used as the internal standard, recoveries of total benzalkonium chloride are low due to the disproportionately high percentage of longer length homologues retained by the polymeric formulations. Conversely, inordinately high recoveries are obtained if the C_{18} homologue is used as the internal standard.

Thus, it is necessary to use both internal standards in such a way as to correct for the retention of each individual homologue. While both internal standards are used in these corrections, the internal standard with a chain length nearest the homologue in question is given the heaviest weight. All weighting factors (Method 1) in the equations that follow are a function of the chain-length differences of the homologues involved.

The PS_{1-5} values represent an average of the standard peaks that precede and follow the sample being calculated.

RESULTS AND DISCUSSION

Since benzalkonium chloride is now widely used in a variety of ophthalmic formulations, several problems have surfaced which have made direct sample injection impossible. These problems, which have been mentioned earlier, have been circumvented by preliminary treatment of the benzalkonium chloride with methyl orange. This procedure takes advantage of the lipophilic properties of the benzalkonium chloride–methyl orange ion pair. The dye complex is removed from interfering polymers and alkaloids by extraction into 1,2-dichloroethane. It is this isolated dye complex and the subsequent chromatography that gives the assay procedure its specificity. Experiments in validating this procedure are described.

[a] Using both internal standards; Method 1; theoretical value 0.004176% (w/v).

An aqueous benzalkonium chloride standard (0.004%) was injected several times onto the chromatograph. The results, shown in UV-detector response for the three major homologues and the total, are shown in Table IA. This same aqueous standard was extracted into an equal volume of 1,2-dichloroethane as the methyl orange complex. The results are shown in Table IB. Also, a typical ophthalmic formulation containing polyvinyl alcohol was spiked to give 0.004% benzalkonium chloride and extracted in the same manner as the standard into an equal volume of 1,2-dichloroethane. The results are shown in Table IC. Analysis of the mean values for total response in the three experiments indicates that, while benzalkonium chloride is readily extractable into dichloroethane as the methyl orange complex, the extraction is not complete. The Student's *t* values obtained by comparing the mean total response value in Table IA *versus* those in Table IB and C demonstrate that significant differences exist between the mean values involved. Comparison of the mean values for total response for the extracted aqueous standard in Table IB and the extracted spiked formulation in Table IC show equivalence of means and variances using Student's *t* and F tests. The mean total response for the extracted placebo in Table IC represents a 97.4% recovery when compared with the mean total response for the extracted standard in Table IB. If standards and samples are treated in the same manner, recoveries of 95–100% are found for most ophthalmic systems. Shown in Tables II–V are the results obtained in four representative studies.

While in the majority of cases acceptable recoveries are obtained by the simple extraction method (Method 2), low recovery values are sometimes observed. To improve the recovery, two benzalkonium chloride homologues not present in the ophthalmic formulation were added as internal standards (Method 1). Observations of the data shown in Table IA, B, and C demonstrate that not only does the extractability of benzalkonium chloride vary in ophthalmic systems but also within the homologous series itself. The longer length homologues are clearly more

difficult to extract from aqueous solutions containing polymers. Therefore, both internal standards must be used to achieve consistently good recoveries for benzalkonium chloride in the many different types of ophthalmic solutions. For instance, shown in Table VI is an example of a formulation containing polyvinyl alcohol and prednisolone acetate in which poor recoveries were obtained without internal standards, but recoveries were acceptable with the internal standards. In Tables VII–X are four representative studies using Method 1 to determine benzalkonium chloride.

The methyl orange-benzalkonium chloride complex proves surprisingly stable in both acid and basic environments. Several aliquots of the 1,2-dichloroethane solution of the methyl orange-benzalkonium chloride complex were washed with 1*N* sodium hydroxide and analyzed. Several aliquots of the complex were washed with 10% acetic acid and analyzed. No significant differences were observed (Student's *t*) when the two studies were compared. This permits an acid or base wash of the extracted methyl orange-benzalkonium chloride complex in further clean-up of the sample.

Table XI shows the assay results obtained by a modification of Method 1 and Method 2 on a formulation containing a 1000:1 ratio of antazoline phosphate to benzalkonium chloride. The dichloroethane solution of methyl orange–benzalkonium chloride complex, obtained by the extraction of the aqueous formulation, also contains significant amounts of antazoline. The presence of the antazoline makes analysis of benzalkonium chloride impossible, as retention times for each substance are similar. The antazoline can be removed, however, by two extractions with 10% acetic acid. As the results in Table XI clearly indicate, internal standards must be used when additional extractions are necessary.

[a] Theoretical value 0.00418% (w/v). [b] Theoretical value 0.00404% (w/v).

System suitability requirements for multiple standard injections are that the relative standard deviation be <±3%. A column should have at least 2000 plates per column for the C_{12} homologue calculated by $N = 16\text{-}(w/v)^2$.

The versatility of this method has been shown in its ability to be used for various types of formulations including suspensions of steroids, polymeric compounds, and other ingredients which would interfere without prior sample workup. Because of the capability of using either (or both) acid and base washing of the extracted benzalkonium–dye complex, the method is very flexible in removing these interferences. Whatever modifications to the assay are required, it is essential that the standards and samples be treated in exactly the same way throughout the assay.

Gas Chromatographic–Mass Spectrometric Quantitation of Theophylline and Its Metabolites in Biological Fluids

KOU-YI TSERNG

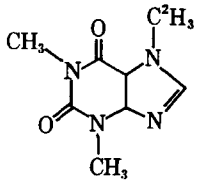
Received September 18, 1981, from the *Division of Pediatric Metabolism, Department of Pediatrics, Case Western Reserve University at Cleveland Metropolitan General Hospital, Cleveland, OH 44109.* Accepted for publication May 24, 1982.

Abstract □ In premature infants, theophylline is converted to caffeine, and the biological half-life is prolonged. To assess the metabolic alterations of theophylline during development of premature infants, a sensitive and simple method was developed which quantitated all theophylline metabolites in plasma, urine, and red blood cells. Theophylline and its metabolites in the sample were converted to the *N*-propyl derivative using *n*-propyl iodide in dimethylformamide with potassium carbonate catalysis and were analyzed under isothermal conditions on a gas chromatograph–mass spectrometer with a 3% methylsilicone–phenylsilicone column. Deuterated caffeine (caffeine-d_3) was used as the internal standard. A selected ion-monitoring technique, together with 70-eV electron impact ionization mode, was used. The ion current ratios between caffeine-d_3 (*m/z* 197) and caffeine (*m/z* 194), theophylline (*m/z* 222), 3-methylxanthine (*m/z* 250), 1,3-dimethyluric acid (*m/z* 280), and 1-methyluric acid (*m/z* 308) were monitored. The total analysis time was 12 min with a detection limit ranging from 500 pg to 10 ng, depending on the metabolites. With this sensitivity, sample sizes of 50–100 μl of plasma and 0.5 ml of urine were sufficient for the analysis of all theophylline metabolites. The coefficient of variation of this method was <5% for the analysis of biological samples.

Keyphrases □ GC–mass spectrometry—quantitation of theophylline and its metabolites in biological fluids, infants □ Theophylline—GC–mass spectrometric quantitation in biological fluids, infants □ Biological fluids—GC–mass spectrometric quantitation of theophylline and its metabolites, infants □ Caffeine—metabolite of theophylline in infants, GC–mass spectrometric quantitation in biological fluids

Theophylline has been used widely for the treatment of apnea in premature infants (1). Due to the narrow margin between effective and toxic doses, the plasma level of this drug during treatment is usually monitored to ensure safety. Over the past several years, a number of analytical methods have been developed specifically for this purpose (2). These include GC methods (3) and the newer high-performance liquid chromatographic (HPLC) methods (2). However, none of these methods are capable of measuring theophylline and metabolites in a microsample from a pediatric population.

The metabolism of drugs in premature infants is different from that of adults. The differences generally are limited to the pharmacokinetic parameters, such as elimination half-life, volume of distribution, and renal clearance. A recent report stating that in premature infants theophylline is methylated to caffeine (4) points out an important change in the concept of drug metabolism in premature infants. Not only the kinetic aspect of drug metabolism must be compared between premature infants and adults, but the quantitation of metabolic pathways also must be studied.



I

To investigate the metabolism of theophylline in premature infants, a simple and sensitive GC–MS method was developed. This method is capable of measuring theophylline, theobromine, caffeine, 3-methylxanthine, 1,3-dimethyluric acid, and 1-methyluric acid in as little as 50 μl of plasma and 0.5 ml of urine.

EXPERIMENTAL

Reagents—Caffeine[1], theophylline[1], theobromine (3,7-dimethylxanthine)[2], 3-methylxanthine[2], 1,3-dimethyluric acid[2], and 1-methyluric acid[3] were used as standards. Anhydrous potassium carbonate was of commercial reagent grade. Dimethylformamide[4] and 1-iodopropane[5] were purified by distillation.

7-[$^2H_3$]Methyl-1,3-dimethylxanthine (Caffeine-d_3) (I)—Powdered anhydrous potassium carbonate (20 mg) and 5 drops of iodomethane-d_3 (99 + atom % D)[4] were added to a solution of theophylline (15.8 mg) in 0.25 ml of dimethylformamide. The mixture was heated with occasional swirling at 70° for 15 min. Additional iodomethane-d_3 (1 drop) was then added to the mixture and the reaction was continued for an additional 15 min. After cooling, the reaction mixture was diluted with 4 ml of water and then extracted with methylene chloride (1 ml × 2). The methylene chloride extract was evaporated to dryness to obtain caffeine-d_3 (5.4 mg). GC analysis of this product showed a single peak with no side products. The 70-eV mass spectrum had the following fragments: *m/z* (percent of base peak), 197(100), 112(45), 85(20), 70(14), 67(11), and 58(17). The isotopic purity of this compound was: d_0, 0.09%; d_1, 5.51%; d_2, 6.99%; and d_3, 87.41%.

Internal Standard Solution—The caffeine-d_3 internal standard was dissolved in water to a final concentration of 2.14 μg/20 μl (for urine analysis) and 0.215 μg/20 μl (for plasma analysis).

Standard Solution of Theophylline and Its Metabolites—Caffeine (4.22 mg), theophylline (33.35 mg), 3-methylxanthine (4.40 mg), 1,3-dimethyluric acid (7.98 mg), and 1-methyluric acid (4.43 mg) were suspended in 3 ml of water. To this stirred mixture, a solution of 0.5 *N* NaOH was added drop-wise to convert the turbid suspension into a clear solution. Enough water then was added to make a final volume of 5 ml.

This stock solution then was diluted with water to a final concentration of caffeine in the following order: 1.68 μg/20 μl, 168 ng/20 μl, 16.8 ng/20 μl, and 1.68 ng/20 μl.

Standard Curve—In a glass disposable tube (12 × 75 mm), the standard metabolite solutions (20 μl, containing caffeine and other metabolites in the range of 1.68 μg to 1.68 ng) and 20 μl of internal standard solution (containing caffeine-d_3, 2.14 μg) were evaporated to dryness in a stream of air. Powdered potassium carbonate (0.5 mg), dimethylformamide (0.25 ml), and 1-iodopropane (50 μl) were then added to the dried residue. The mixture was heated at 70° in an evaporator[6] for 15 min. Vacuum was then applied to this unit to evaporate all the solvent and reagents (~15 min). The dried tube was then capped and kept at −20° until ready for analysis.

Similarly, standard curves in urine, plasma, and red blood cells were constructed by spiking blank samples with standard solutions. The spiked samples were then analyzed as described for each individual biological fluid, except in the case of red blood cells. For the standard curve in red blood cells, the spiked cells were not washed with normal saline. The standard curves in biological samples were identical to those in water,

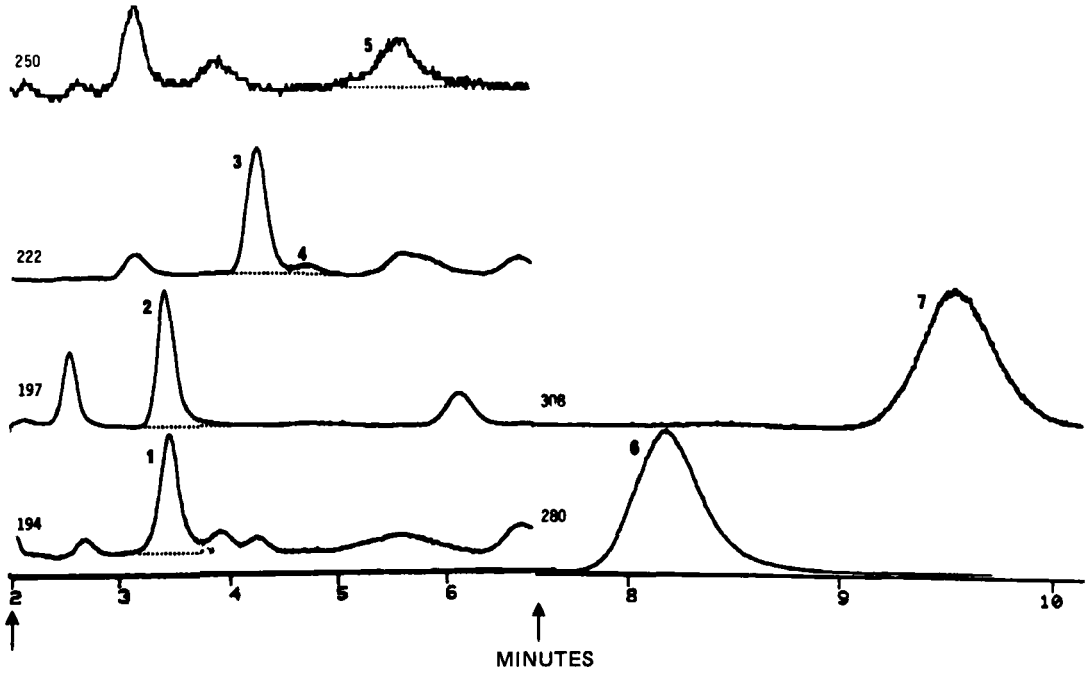

Figure 1—*A representative selected ion-monitoring chromatogram of theophylline metabolites in the urine of premature infants. The metabolites are: (1) caffeine; (2) caffeine-d_3; (3) theophylline; (4) theobromine; (5) 3-methylxanthine; (6) 1,3-dimethyluric acid; (7) 1-methyluric acid. The number in the beginning of each chromatogram indicates the ion (m/z) monitored. The arrows indicate the switching of ion sets monitored.*

with the exception of 3-methylxanthine in urine, in which the slope was lower than that in water.

Analysis of Urine Samples—In a disposable tube (12 × 75 mm), urine (0.5 ml) was mixed with 20 μl of the internal standard solution (2.14 μg of caffeine-d_3). It was then evaporated to dryness at 40° under vacuum in an evaporator (~15 min). Powdered potassium carbonate (5 mg), dimethylformamide (0.25 ml), and 1-iodopropane (50 μl) were added to the residue. The procedure for the standard curve was then followed.

Analysis of Plasma Samples—Plasma (50–100 μl) was mixed with 20 μl of internal standard solution (0.214 μg of caffeine-d_3). The plasma proteins were then precipitated by the addition of methanol (1 ml). After mixing and keeping in an ice bath for 10 min, the mixture was centrifuged and the supernatant was decanted into another disposable tube. It was evaporated in a stream of air, then to dryness at 40° in vacuum in an evaporator. The dried residue was then mixed with powdered potassium carbonate (5 mg), dimethylformamide (0.25 ml), and 1-iodopropane (50 μl). The procedure for the standard curve was then followed.

Analysis of Red Blood Cells—After separating the plasma, the red blood cells were washed twice with normal saline. An aliquot (100 μl) of this cell sample was then mixed with the internal standard solution (0.214 μg of caffeine-d_3 in 20 μl of water), and methanol was added (1 ml) to hemolize the blood cells and to precipitate the proteins. After centrifuging, the supernatant was transferred to another tube and the plasma procedure commenced.

Gas Chromatography—A conventional gas chromatograph[7] was used. It was equipped with a flame ionization detector. The glass column (0.3 cm × 1.83 m) was packed with 50% phenyl silicone and 50% methyl silicone on treated white diatomaceous earth[8]. Nitrogen was used as a carrier gas at 30 ml/min. The column was maintained at 200°. The injection port temperature was 250° and the detector was 350°.

Gas Chromatography–Mass Spectrometry—A computerized GC–MS[9] was used. The GC condition was the same as described in the previous section except that helium was used as carrier gas instead of nitrogen. A glass jet separator, maintained at 250° was used between the GC and the MS ion source, which was maintained at 200°. The analyzer region was kept at 200°. Electron-impact ionization at 70 eV was used for the study. The derivatized sample was dissolved in 50 μl of methylene chloride. After mixing well, the mixture was allowed to stand until the undissolved solid settled at the bottom. An aliquot (1–3 μl) of the supernatant was injected onto the GS–MS. The selected ion-monitoring software provided by the instrument manufacturer was used for the analysis. From 2.5 to 7.5 min, the instrument was focused alternately on *m/z* 194, 197, 222, and 250 with a dwelling time of 100 msec on each. After 7.5 min, the ion fragments *m/z* 280 and 308 were monitored with a dwelling time of 100 msec on each. The total analysis time was 12 min. The standard curves were constructed by plotting the area ratio of each individual ion (caffeine-194, theophylline-222, 3-methylxanthine-250, 1,3-dimethyluric acid-280, and 1-methyluric acid-308) with internal standard (caffeine-d_3-197), against the amounts of each individual metabolite. Regression analysis of the standard curve and data reduction of samples were done with a calculator[10].

Table I—Theophylline and Metabolites in Urine, Plasma, and Red Blood Cells of a Premature Infant

Samples	Metabolites[a], μg/ml					
	I	II	III	IV	V	VI
Urine	2.20 (8.7%)[b]	12.10 (51.5%)	1.70 (7.2%)	0.38 (1.8%)	5.58 (21.8%)	2.14 (9.0%)
Plasma	2.41 (25.5%)	5.70 (64.8%)	0.4 (4.6%)	0.08 (1.0%)	0.3 (3.1%)	0.1 (1.1%)

[a] Metabolites: I, caffeine; II, theophylline; III, theobromine; IV, 3-methylxanthine; V, 1,3-dimethyluric acid; VI, 1-methyluric acid. [b] Values in parentheses are the percentage of total metabolites.

RESULTS AND DISCUSSION

Theophylline is metabolized extensively to 3-methylxanthine, 1,3-dimethyluric acid, and 1-methyluric acid in human adults (5, 6). The current observation that theophylline is also methylated to another pharmacologically active xanthine, caffeine, in premature infants (4, 7, 8) makes it necessary to study the metabolism of theophylline in this population.

There are several published methods capable of measuring theophylline and its metabolites (3, 6, 9). The older method of column chromatography and UV spectrophotometry is too tedious to be useful in the assay of large numbers of samples. The HPLC method described previously (5) lacks the sensitivity required in the analysis of pediatric samples. The preliminary report of another HPLC method (9) has the required sensitivity and simplicity. However, no specificity and reproducibility of the method was reported. To achieve the specificity and sensitivity

required in the analysis of pediatric samples, a GC–MS method with selected ion monitoring technique was chosen. The high specificity obtained by this technique can also reduce the time required for sample purification and, thus, facilitate the analysis of large numbers of samples.

Extraction of Theophylline and Metabolites from Biological Fluids—A number of solvent systems have been used to extract theophylline or its metabolites from biological fluids (3, 9, 10). The extracted metabolites are then analyzed with GC, HPLC, or GC–MS. For less specific quantitative methods, solvent extraction is a necessary step in the procedure to eliminate the possible interfering substances. These solvent-extraction procedures can be grouped into three categories. The most primitive one is the simple solvent extraction with methylene chloride or chloroform (3, 11). A second approach has been the use of a more polar solvent mixture in conjunction with the saturation of biological fluids with salt (9). The third approach is the extractive alkylation procedure with alkyl iodide and hydrophobic quaternary ammonium ion (10). For the analysis of the true composition of metabolites in a sample, the extraction steps should not discriminate among different compounds and distort the results. Caffeine, theophylline, methylxanthines, and methyluric acids are compounds with widely varying polarity and solvent solubility. The simple solvent extraction procedure is not expected to extract any significant amounts of methylxanthines and methyluric acids. In numerous attempts in this laboratory, extractive alkylation with a high concentration of tetrabutylammonium ion in aqueous solution and iodopropane in chloroform failed to recover polar metabolites such as 3-methylxanthine and monomethyluric acids. The recovery experiments using a modified procedure (9) which involved saturating the aqueous standard solution with ammonium sulfate and extracting with a chloroform–isopropyl alcohol mixture, gave the following results (compared with direct derivatization): caffeine, 104 ± 1%; theophylline, 23 ± 3%; 3-methylxanthine, 6 ± 3%; 1,3-dimethyluric acid, 9 ± 3%; and 1-methyluric acid, 5 ± 2% (mean ± *SD*, $N = 3$). The lower recovery obtained in these experiments compared with those reported previously (9) probably resulted from the smaller amount of extraction solvent used (20% of the original solvent volume but extracted twice). Nevertheless, these data did indicate a differential extraction of metabolites, even with the most strenuous extraction procedure, *i.e.*, salt saturation and polar solvents. To overcome the difficulty of low and variable recovery of different metabolites, no solvent extraction was used in the procedure described in this report. The urine samples were dried directly and then derivatized, while the plasma samples were deproteinized with methanol and prepared as the urine samples.

Derivatization with Iodopropane and Sodium Carbonate in Dimethylformamide—For GC analysis, theophylline and metabolites are usually derivatized into *N*-alkylated derivatives such as butyl or pentyl derivatives. The advantage of using the *N*-propyl derivative over other alkylated derivatives has been discussed previously (12). The fastest and most convenient derivatization procedure was found to be the use of iodopropane in a polar solvent, such as dimethylformamide, and a basic catalyst, such as potassium carbonate. This reaction was rapid and was completed within 5 min at 70°. When the reaction mixture was analyzed at different reaction times, the intensity of all the derivatized metabolites did not change with heating from 5 min to 1 hr. This indicated not only that the derivatization procedure was completed within 5 min, but also that the derivatives were stable in the reaction mixture for at least 1 hr. After the reaction, the reagents were evaporated in vacuum. The residue was extracted with methylene chloride (50 μl) before analysis with GC–MS. For lower concentration determinations, larger volumes of methylene chloride can be used to extract the solid residue. The combined extract is then evaporated and reconstituted with a smaller volume of solvent. Water cannot be used to wash the methylene chloride solution of the derivatized sample, since this procedure results in differential extraction. Caffeine has higher water solubility than any other *N*-propylated xanthines and uric acids. Because caffeine-d_3 was used as the internal standard in the procedure, the disproportional removal of caffeine from methylene chloride extract resulted in a falsely higher result for theophylline, 3-methylxanthine, 1,3-dimethyluric acid, and 1-methyluric acid.

Gas Chromatography–Mass Spectrometry—The ideal internal standards for the GC–MS method are the stable isotope-labeled analogues of each metabolite. However, such a task would be impractical for extensively metabolized drugs such as theophylline. Therefore, caffeine-d_3 (I) was chosen as an internal standard for all metabolites. Caffeine-d_3, can be synthesized easily from theophylline and iodomethane-d_3 in 1 hr. It is obtained in high isotopic purity ($do = 0.09\%$).

The *N*-propyl derivatives of theophylline metabolites were well resolved on a 3% mixed phase of phenyl silicone and methyl silicone column in a period of 12 min. Furthermore, their 70-eV electron-impact mass spectra showed prominent molecular ions (12). Therefore, the molecular ions were monitored using a selected ion-monitoring technique. The ion current ratio of the metabolite's molecular ion with that of internal standard (m/z 197) was plotted against the amount of metabolites. The standard curves obtained were linear over a range of 1 ng to 2 μg. However, the detection limit can be lowered further to 500 pg for caffeine and theophylline. The detection limit of other metabolites (3-methylxanthine, 1,3-dimethyluric acid, and 1-methyluric acid) were in the range of 1–20 ng. The lower sensitivity of this procedure toward monomethylxanthine and uric acid metabolites was due to the fact that the derivatives of these metabolites gave molecular ions with lower abundances as a result of more extensive fragmentation.

A typical selected ion chromatogram of urinary theophylline metabolites of premature infants is shown in Fig. 1. The metabolite patterns of theophylline in plasma, urine, and red blood cells taken at the same

time interval are shown in Table I. The details of this study have been reported elsewhere (12, 13).

Using this sensitive and specific method, it was shown for the first time that some of the 3-methylxanthine and 1-methyluric acid had a possible endogenous origin. In addition, the oxidation pathways of theophylline were quantified and shown to be important. Substantial amounts of theophylline are converted to 1,3-dimethyluric acid in premature infants, while the metabolic capability of converting theophylline to 3-methylxanthine and 1-methyluric acid is relatively undeveloped. The unusual metabolic conversion of theophylline to caffeine in premature infants is also confirmed.

Precision and Recovery of the Method—The precision of this method in analyzing theophylline metabolites is shown in Table II. The analysis of caffeine had the lowest coefficient of variation (*CV*) partly due to the fact that the stable isotope-labeled internal standard of caffeine was used in the procedure. This internal standard compensated for the variation due to incomplete recovery and instrumental instability. With the exception of 3-methylxanthine, the coefficients of variation of analyses are all within 5%. The high variation on 3-methylxanthine analysis was due to the fact that its concentration in the urine of premature infants was low as compared with other metabolites.

The recovery of theophylline metabolites was studied by spiking urine, plasma, and red blood cell samples with solutions of known amounts of metabolites. The samples were analyzed before and after spiking. The results are shown in Tables III and IV. With the exception of 3-methylxanthine, the recovery of all metabolites was essentially quantitative. The lower urinary recovery of 3-methylxanthine at a higher concentration is probably due to incomplete alkylation under experimental conditions. As discussed before, all theophylline metabolites from aqueous solutions were alkylated quantitatively within 5 min of the reaction time. The slower reaction time of 3-methylxanthine in urine is unclear at the present time. It could be partly due to the buffer action of urinary electrolytes, which reduce the effectiveness of catalysis by potassium carbonate. This hypothesis was supported by the fact that recovery of 3-methylxanthine was reduced further without affecting the recovery of all other metabolites when the amount of potassium carbonate was lowered.

Attempts were made to improve the recovery of 3-methylxanthine by increasing the amount of potassium carbonate and *n*-propyl iodide or by increasing the reaction time. The recovery of urinary 3-methylxanthine did improve with these experiments. However, quantitative recovery was never obtained. Because increasing the reagents and the reaction time increases the possibility of interfering peaks without correcting the problem of incomplete recovery of 3-methylxanthine, this modification of the procedure was abandoned.

Comparison of Granule Strength and Tablet Tensile Strength

PAUL J. JAROSZ * and EUGENE L. PARROTT ˣ

Received March 29, 1982, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* *Present address: Ortho Pharmaceutical Corporation, Raritan, NJ 08869. Accepted for publication May 28, 1982.

Abstract □ The granule strength (crushing load) of lactose granulated with 1–9% povidone was measured initially and at intervals during a 1-year period. The granule strengths of dibasic calcium phosphate dihydrate granulated with various concentrations of starch and povidone were measured. The axial and radial tensile strengths of tablets compressed from these granules were determined and related to concentration of binder and granule strength. The effect of compressional force on the integrity of granules in a tablet matrix is shown in scanning electron photomicrographs of the fractured tablets which had undergone a diametral compression test. It appears that the compressional force and the concentration of binder contribute more than granule strength to tablet tensile strength.

Keyphrases □ Tablet compression—comparison of granule and tensile strength, lactose, povidone □ Granule strength—tablet compression, comparison with tensile strength, lactose, povidone □ Tensile strength—tablet compression, comparison with granule strength, lactose, povidone

Most materials require pretreatment to ensure tablet formation and free flow in the tablet machine. Granulation is the process by which fine powders are converted to granules with these properties to ensure a uniform fill of the die cavity, formation of a tablet, and easy ejection of the finished tablet. Granulation also facilitates handling, prevents segregation in the formulation blend, and minimizes dust. Granule strength and friability are important as they affect changes in particle size distribution of granulations and, consequently, compressibility into cohesive tablets, and also unit dose precision in some tablet formulations. They may be useful as quality control parameters so that reproducible granulations can be manufactured (1). Granule strength is usually greater as the concentration of binder is increased (2–7). For a given lot, the larger granules have a greater strength than the smaller granules (5, 8, 9).

The compression process of particulate material into a tablet and the fate of the granule in the tablet have been studied (6, 10–12). Most investigations have considered the external dimensions of the tablet, although these may not reflect the situation within the tablet matrix (13). It seems that granular integrity is progressively lost during compression.

The present study was conducted to compare the granule strength with the axial and radial tensile strengths of tablets compressed from the granules. Scanning electron microscopy was used in an attempt to visualize the granule within the tablet matrix.

EXPERIMENTAL

Preparation of Granules and Measurement of Crushing Strength—All materials were USP or NF grade. A 60/80-mesh size fraction of all materials was used. An appropriate quantity of aqueous granulating liquid was added to the powder in a planetary mixer[1] and blended for 5 min. The wet mass was then passed through an appropriate screen in an oscillating granulator[2] operating at slow speed and collected on drying trays. The granulation was dried overnight in a forced-air oven at ambient temperature. Size classification of the dried granules was carried out by shaking for 5 min with a sieve shaker[3].

The technique used to measure the crushing strength of a granule was essentially that from a previous study (14) using 50- and 100-ml glass

hypodermic syringes[4]. The modification included the removal of the tip of the syringe barrel and the top end of the plunger. The barrel was then used as a hollow support and guide tube with close-fitting tolerances to the plunger. The hollow plunger with one open end served as a load cell to which mercury could be added. A window was cut into the barrel to facilitate placement of the granule on the base platen. The plunger acted as the movable platen and was set directly on the granule positioned on the lower platen. As the rate of loading may effect crushing load (9), mercury was introduced from a reservoir into the upper chamber at the rate of 10 g/sec until the single granule failed. Loading time was <3 min. The total weight of the plunger and the mercury required to fracture a granule was the crushing load. A minimum of 10 granules were tested, and the average load in grams was taken as the crushing strength, F_g. In the figures only the upper standard deviation bar for granule strength is shown.

The sensitivity of crushing strength to humidity was considered for hydrous lactose granulated with 5% povidone. The granules were stored in humidity chambers at 0, 20, 45, 70, and 90% relative humidity (15) for various lengths of time as shown in Table I. The percent loss on drying was determined by a moisture balance[5] after 20 min of IR exposure at

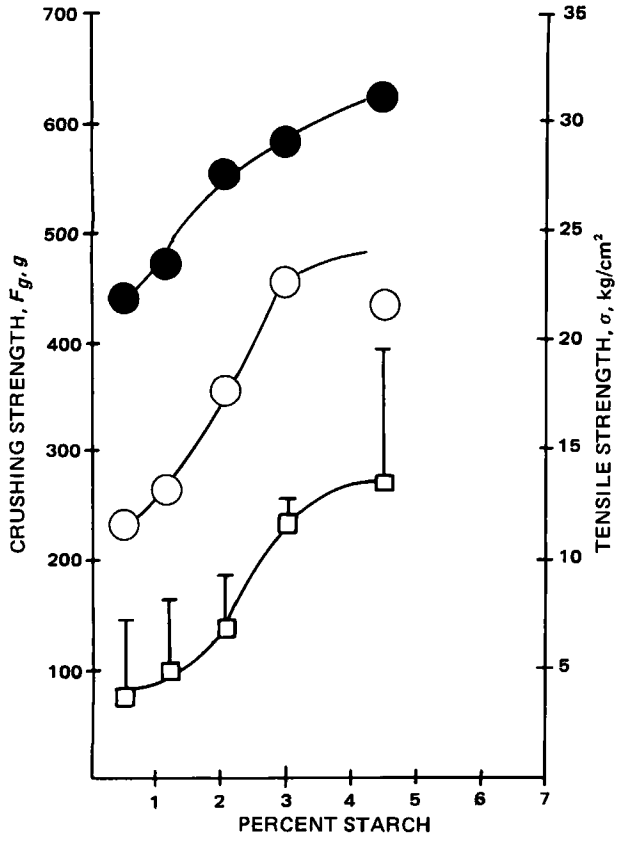

Figure 2—*Relationship of binder concentration to granule strength and tensile strengths of tablets compressed at 2268 kg from granules of dibasic calcium phosphate dihydrate granulated with starch. Key: (□) granule strength; (○) axial tensile strength; and (●) radial tensile strength.*

an input of 12 W. The load at which a granule failure occurs may be difficult to experimentally observe, since a granule may deform plastically or a high point on its surface may fracture without failure of the entire granule. Thus, there is considerable variance in the crushing loads, as shown in Table I and as previously reported (5). Within the precision of the apparatus used, it does not appear that humidity significantly affected the strength of the granule. Although the relative humidity ranged from 0 to 90%, the moisture content of the granules was from 5.2 to 7.5%.

Preparation of Tablets and Measurement of Tensile Strength—An appropriate weight of 16/20-mesh size fraction of granules was compressed for 5 sec at the desired force by 1.275 cm diameter punches and die-fitted to a hydraulic press[6]. At least 72 hr elapsed between tableting and tablet evaluation to allow for any stress relaxation within the tablet. The weight and thickness of a minimum of 10 tablets were determined. The method of measurement of the axial tensile strength (σ_z) and the radial tensile strength (σ_x) of tablets by a tensiometer has been described (16). The mean force of tensile failure of 10 tablets was used to calculate the tensile strength.

RESULTS AND DISCUSSION

Mechanical Strength of Granules—The crushing strength of granules of lactose monohydrate granulated with povidone solution is

[6] Carver model C, Monomonee Falls, Wis.

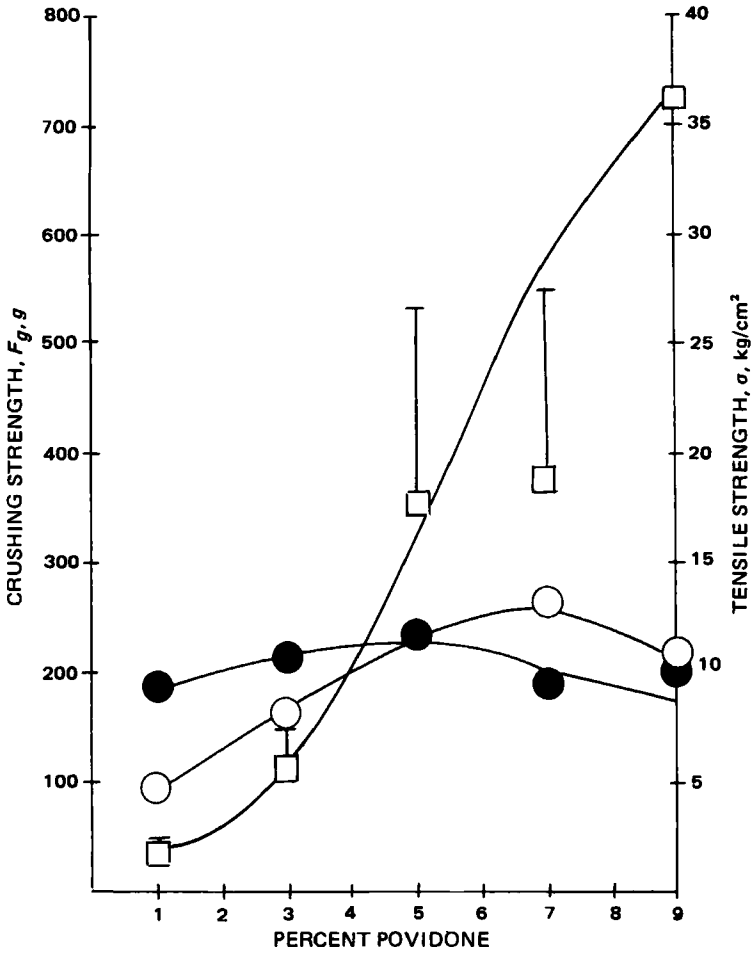

Figure 4—*Relationship of binder concentration to granule strength to tensile strengths of tablets compressed at 1134 kg from lactose monohydrate granules granulated with povidone. Key: (□) granule strength; (○) axial tensile strength; and (●) radial tensile strength.*

shown in Table II. For a given concentration of povidone the strength of a granule is a function of its size. It was suggested previously that (17):

$$F_g = q\,D^n \qquad \text{(Eq. 1)}$$

where D is the diameter of the granule and q and n are constants for a material. Using the natural logarithmic form of Eq. 1:

$$\ln F_g = q' + n \ln D \qquad \text{(Eq. 2)}$$

the constants may be evaluated by plotting as shown in Fig. 1. The slopes are 2.10, 1.90, and 0.88 for 1.0, 3.0, and 7.0% povidone, respectively. The decrease of the slope as the concentration of binder is increased suggested that particle size influences the granule resistance to crushing to a lesser extent than the concentration of the binder (18–21).

The strength of dibasic calcium phosphate dihydrate[7] granules containing 0.6–4.5% starch is shown in Fig. 2. At low concentrations of starch, the granule resistance to crushing is weak. As the concentration of binder is increased (2–3%), there is a considerable increase in the granule strength, and further increases in the concentration of binder only slightly increase the granule strength. The inflection in Fig. 2 may represent the binder concentration just sufficient to encase the granule surface under the conditions of preparation. A further increase of binder will fill in the porous openings of the granule, continuing, but to a lesser extent, to increase the granule resistance to crushing (18).

The effect of concentration of povidone on the strength of granules of dibasic calcium phosphate dihydrate[8] is shown in Fig. 3. The relationship is similar to that obtained with starch, and in the range of 3–6% povidone in the granules there is the greatest increase in strength.

The effect of concentration of povidone on the strength of granules of lactose monohydrate is shown in Fig. 4. Again the range of 3–6% povidone in the granules provides the greatest increase in strength of the granule.

Aging has been reported to affect the mechanical properties of compressed tablets (22). Lactose granules containing 1–9% povidone were stored at 40–45% relative humidity and at ambient temperature, and the crushing load was measured initially and at 1, 3, 6, and 12 months. The data are plotted in Fig. 5. Within the variance of the experimental apparatus aging does not appear to markedly affect the crushing strength of the granule.

Key: (A) location above center of tablet, compressional force 454 kg, starch 1.2%, original magnification 1000×; (B) location near axial and radial tablet surface, same tablet as (A); (C) location near center of tablet, compressional force 1134 kg, starch 4.5%, original magnification 2000×; and (D) same as (C) but original magnification 6000×.*

Relationship of Granule Strength to Tablet Tensile Strength—A 16/20-mesh size fraction of granule was selected for investigation, since this is a tablet granulation size often used in commercial production. The relationship of the axial and radial tensile strengths of tablets compressed at 2268 and 4536 kg of force to the crushing strength of granules of dibasic calcium phosphate dihydrate[8] granulated with povidone is shown in Fig. 6. For the various granules compressed at a given force, the tensile strength of the tablet is increased as the resistance to crushing is increased. The granule strength is increased as the concentration of binder is increased; therefore, the effect of granule strength on tensile strength is probably inseparable from the effect of concentration. The form of a plot of tensile strength against concentration of binder is similar to that of the granule strength against concentration, as shown in Fig. 3.

The relationship of concentration of binder to granule strength and to tensile strengths of dibasic calcium phosphate dihydrate tablets granulated with starch and compressed at 2268 kg is shown in Fig. 2. The plot of granule strength against concentration of binder is similar to that of the plot of tablet tensile strength against concentration.

The relationship of concentration of binder to granule strength and to tensile strengths of lactose monohydrate tablets granulated with povidone and compressed at 1134 kg is shown in Fig. 4. Again, the form of the granule strength–concentration curve and the tensile strength–concentration curve is similar.

Visualization of Granule Fate—The fate of a granule in the tableting process has been followed by several investigators (10, 13, 23). It has been reported (11) that within a given range of compression the integrity of an individual granule in a compact may be demonstrated. Another report (12) showed that at low compressional force there was no apparent change in volume because interparticulate slippage shortens the granule, but its diameter increased as it was flattened. At intermediate forces, plastic deformation and consolidation continued to flatten the granule, but solid bridges were formed without the diameter of the granule increasing, so that a reduction of volume occurred. Finally, at high compressional force, a structure was formed that could support the applied force without further consolidation.

The effect of compressional force on the deformation of granules within a tablet may be visualized by scanning electron microscopy of the surface produced by fracture of the tablet in the diametral compression test. Differences in porosity within a compact have been reported (13). In Fig. 7A the photomicrograph is of a porous region immediately above the less porous center of a dibasic calcium phosphate dihydrate tablet compressed at 454 kg from granules containing 1.2% starch. In Fig. 7B the photomicrograph is of a denser region near the surface of the same tablet.

The structure of a dibasic calcium phosphate dihydrate tablet compressed at 1134 kg from granules containing 4.5% starch is shown in Fig. 7C and D. Two pockets of starch may be seen within the matrix of the tablet. It may be that the pockets occur because the amount of starch is greater than that amount required to just encase the granule (18). At higher compressional forces these starch structures become indistinguishable.

The porosity of a compressed tablet is decreased as compressional force is increased (24, 25). Photomicrographs of the center of tablets of dibasic

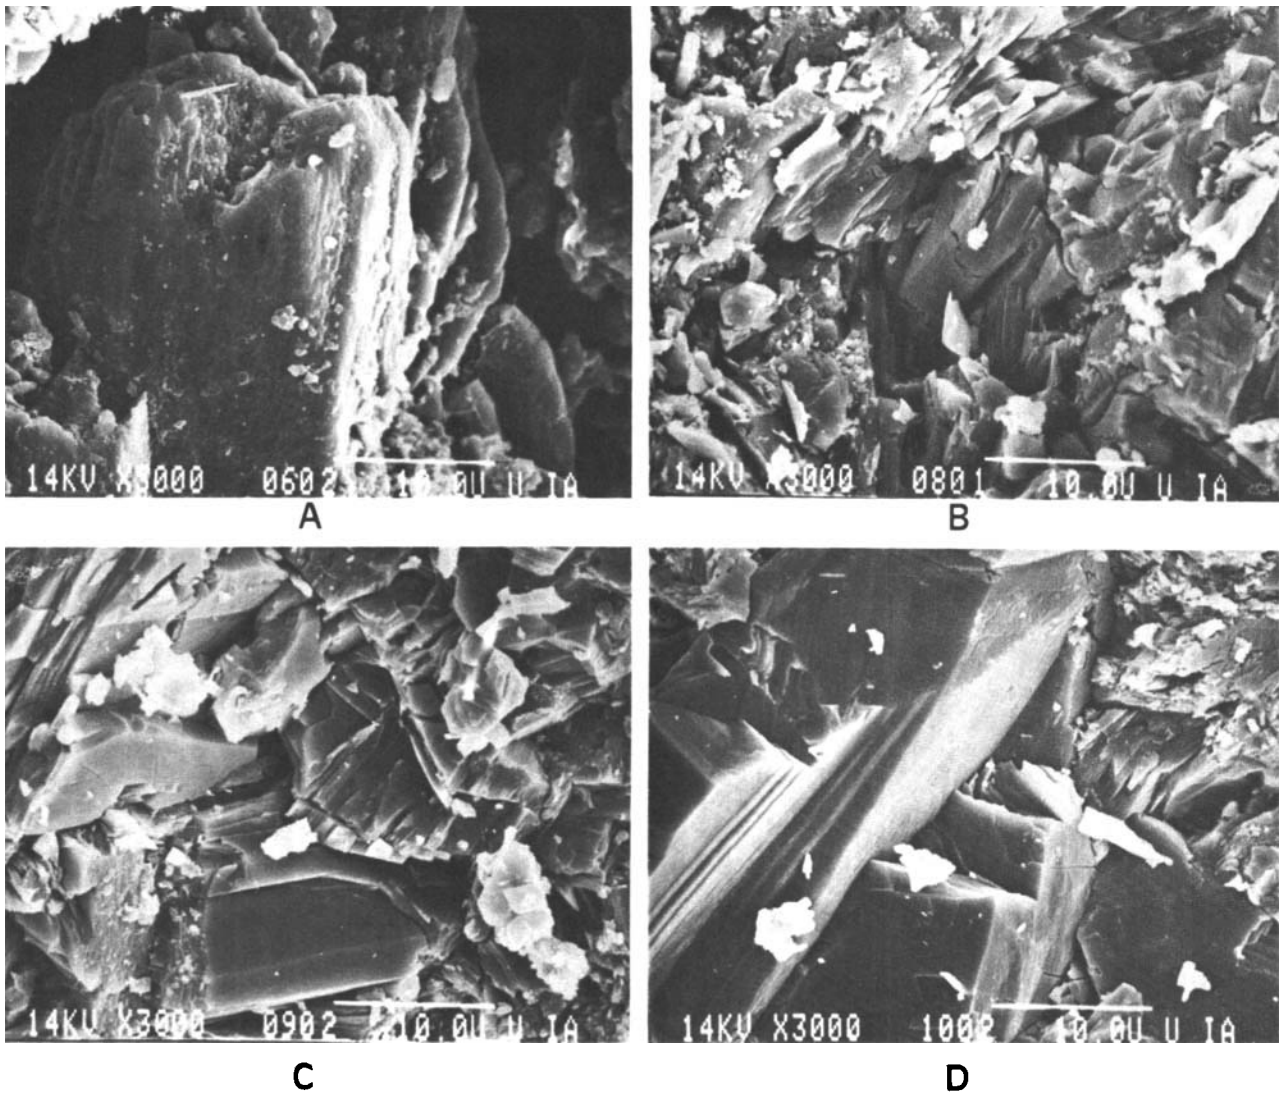

Figure 8—*Scanning electron photomicrographs of center of tablet of dibasic calcium phosphate[7] and 4.5% starch. Original magnification 3000×. Key: compressional force (A) 454; (B) 2268; (C) 4536; and (D) 9402 kg.*

calcium phosphate dihydrate compressed at 454, 2268, 4536, and 9402 kg from granules containing 4.5% starch are shown in Fig. 8. In Fig. 8A, at a low compressional force of 454 kg, the original granule may be distinguished. As the compressional force is increased, the granule is fractured, and no original granules can be seen because consolidation has occurred (Fig. 8B–D). This agrees with the general thought that they should break down on compaction in the die (26).

As shown in Fig. 6, as the compressional force is increased from 2268 to 4536 kg, the tablet tensile strength is increased. Although the crushing strength of granules is important in the handling of the granulation in the tablet process and in tablet reproducibility, the compressional force and the concentration of binder appear to be more basically related to the tablet tensile strength.

High-Performance Liquid Chromatographic Determination of Vincristine Sulfate in Preformulation Studies

J. E. BODNAR, J. R. CHEN *, W. H. JOHNS, E. P. MARIANI ˣ, and E. C. SHINAL ‡

Received February 19, 1982 from the *Science and Technology Division, Pharmaceutical Research and Development Division, Product Development Research Department, Bristol-Myers, Inc., Syracuse, NY 13201.* Accepted for publication May 26, 1982. Present address: *Boots Pharmaceutical, Inc., Shreveport, LA 71106. ‡American Cyanamid, Medical Research Division, Lederle Laboratories, Pearl River, NY 10965.

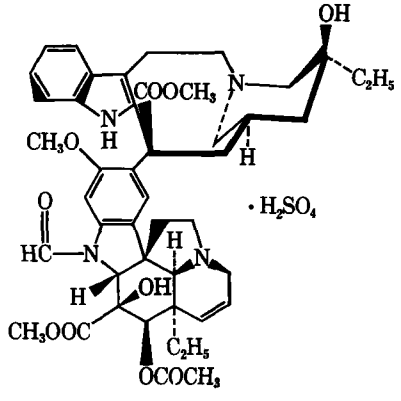
Abstract □ A fast and simple procedure was developed for the quantitative determination of vincristine sulfate for use in preformulation studies. The procedure involves the use of high-performance liquid chromatography with a reverse-phase column and a mobile phase containing the sodium salt of 1-pentanesulfonic acid for ion-pairing. The procedure has been shown to be specific for vincristine sulfate in the presence of forced degradation products of this substance, vinblastine (a structurally similar *Vinca* alkaloid), and several possible formula excipients. The procedure is linear from 10–200% of the normal injection concentration, and has an assay precision (relative 2σ) of ±1.6%. Recovery of known samples averaged 99.7%.

Keyphrases □ Vincristine sulfate—high-performance liquid chromatography, preformulation studies, degradation □ High-performance liquid chromatography—vincristine sulfate, degradation products □ Preformulation studies—vincristine sulfate, degradation products, high-performance liquid chromatography

Vincristine sulfate (I), an antineoplastic agent originally obtained from extracts of *Vinca rosea*, is structurally related to vinblastine. An analytical procedure was required for the determination of vincristine sulfate in samples resulting from preformulation studies. The procedure had to be capable of accurate and precise quantitation, specific in the presence of a number of possible excipients, and stability indicating. Because a large number of samples were to be examined, it was also necessary that the procedure be rapid and simple.

A number of assay procedures have been reported for vincristine sulfate (1); however, some are not stability indicating (direct spectrophotometric analysis), others are time consuming and complex (colorimetric analysis), and some are not sufficiently accurate and precise (TLC analysis). Several high-performance liquid chromatographic (HPLC) methods have been reported. One procedure (2) requires a 40-min gradient with a vincristine retention time of ~25 min. This was deemed too lengthy for the proposed purpose.

Another procedure (3) required the use of ammonium carbonate in the mobile phase. Since the column life might be shortened appreciably by the presence of ammonium carbonate[1], this procedure was not used. This paper reports the development of a simple and rapid HPLC procedure for the determination of vincristine sulfate stability.



EXPERIMENTAL

Reagent and Chemicals—Acetonitrile and methanol were HPLC grade[2], and were used without further purification. Water was distilled and filtered[3] prior to use. Vincristine sulfate was used as received[4]. All other reagents were ACS grade or better and used without further purification.

Equipment—A liquid chromatograph[5] was connected to an injection valve[6], a variable-wavelength detector[7], a recorder[8], and an integrator[9].

A column[10] consisting of a monomolecular layer of a phenylorganosilicone permanently bonded to polar, porous silica particles was used.

The mobile phase consisted of 30% acetonitrile and 70% aqueous solution which contained 0.02 *M* ammonium acetate and 0.005 *M* of the sodium salt of 1-pentanesulfonic acid adjusted to pH 2.0 with 10% v/v nitric acid[11]. The flow rate was 2.5 ml/min (pressure was ~2000 psi). The detector sensitivity was 0.1 AUFS at 254 nm. Chart speed was 60 cm/hr.

Internal Standard Preparation—Propyl *p*-hydroxybenzoate (~30 mg) was accurately weighed and transferred to a 100-ml volumetric flask.

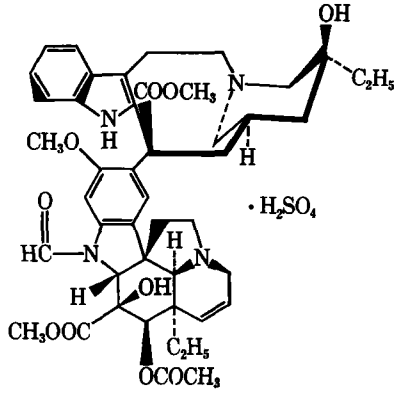
This paper reports the development of a simple and rapid HPLC procedure for the determination of vincristine sulfate stability.



EXPERIMENTAL

Reagent and Chemicals—Acetonitrile and methanol were HPLC grade[2], and were used without further purification. Water was distilled and filtered[3] prior to use. Vincristine sulfate was used as received[4]. All other reagents were ACS grade or better and used without further purification.

Equipment—A liquid chromatograph[5] was connected to an injection valve[6], a variable-wavelength detector[7], a recorder[8], and an integrator[9].

A column[10] consisting of a monomolecular layer of a phenylorganosilicone permanently bonded to polar, porous silica particles was used.

The mobile phase consisted of 30% acetonitrile and 70% aqueous solution which contained 0.02 *M* ammonium acetate and 0.005 *M* of the sodium salt of 1-pentanesulfonic acid adjusted to pH 2.0 with 10% v/v nitric acid[11]. The flow rate was 2.5 ml/min (pressure was ~2000 psi). The detector sensitivity was 0.1 AUFS at 254 nm. Chart speed was 60 cm/hr.

Internal Standard Preparation—Propyl *p*-hydroxybenzoate (~30 mg) was accurately weighed and transferred to a 100-ml volumetric flask.

Table I—Forced Degraded Specificity

Product	Amount Degraded, %	295 nm/ 254 nm	Error[a], %	275 nm/ 254 nm	Error[a], %
Intact	—	0.974	—	0.776	—
Acid degradation	65	0.963	−1.1	0.755	−2.7
Base degradation	81	0.964	−1.0	0.770	−0.8
Aqueous degradation	24	0.933	−4.2	0.783	+0.9
Dry powder degradation	27	0.984	+1.0	0.801	+3.2
Light degradation	28	0.969	−0.5	0.801	+3.2

[a] $\text{Error} = \frac{\text{test ratio} - \text{intact ratio}}{\text{intact ratio}} \times 100\%$.

The material was dissolved in 25 ml of methanol and diluted to volume with water.

Standard and Sample Preparation—Approximately 25 mg of vincristine sulfate standard or sample was accurately weighed (or an accurate volume of a sample solution containing ~25 mg of vincristine sulfate was pipeted) and transferred to a 100-ml volumetric flask. Exactly 10 ml of internal standard solution was added and the resulting solution was diluted to volume with water.

Assay Method—A 20-μl aliquot of the standard and of each sample was injected under the chromatographic conditions described. Standards were injected at the beginning, the middle, and the end of each run. Each sample was injected once. Samples and standards were not allowed to remain in solution more than 8 hr and were protected from light. Samples were calculated using a factor derived from the average of all standards injected. A typical chromatogram is shown in Fig. 1.

Calculations—Results were calculated as vincristine sulfate.

$$\text{Standard Factor} = \frac{\text{Standard Wt (mg)} \times \text{\% Purity} \times \text{Internal Standard Area}}{\text{Standard Area} \times \text{Internal Standard Wt (mg)} \times 100\%}$$

$$\text{Vincristine Sulfate (mg)} = \frac{\text{Standard Factor} \times \text{Sample Area} \times \text{Internal Standard Wt (mg)}}{\text{Internal Standard Area}}$$

$$\text{Vincristine Sulfate (mg/ml)} = \frac{\text{Standard Factor} \times \text{Sample Area} \times \text{Internal Standard Wt (mg)}}{\text{Internal Standard Area} \times \text{Volume Sample Taken (ml)}}$$

Degradation Procedure—Vincristine sulfate was degraded under the following conditions to test the procedure for specificity in the presence of vincristine degradation products:

1. A weighed portion of dry material was held at 85° for 80 hr in an open vial.
2. A portion of dry material was placed in an open quartz vessel and subjected to 2437-Å light[12] (~16,000 μW/cm²) for 80 hr.
3. An aqueous solution of the material at a concentration of 0.25 mg/ml was titrated to pH 2.0 with 2 *N* HCl and held for 2 hr at 85°.
4. An aqueous solution of the material at a concentration of 0.25 mg/ml was titrated to pH 11.5 with 2 *N* NaOH and held at room temperature (25°) for 1.5 hr. This solution was neutralized before injection.
5. An aqueous solution of the material at a concentration of 0.25 mg/ml was held unchanged (pH 7.5) at 85° for 4 hr.

In each case, degradation was allowed to proceed until ~25–75% of the vincristine sulfate had been degraded. Thus, some intact vincristine sulfate remained at the end of each time interval. Dry materials were dissolved in water at a concentration of 0.25 mg/ml. Separate injections were made of each of the degradation solutions with detection at 254 nm (vincristine sulfate maximum at 255 nm), 296 nm (maximum), and 275 nm (minimum) (1). Area ratios were then calculated for the peak assumed to be pure vincristine sulfate and these were compared with area ratios obtained from a freshly prepared solution of pure vincristine sulfate at the same wavelengths.

RESULTS AND DISCUSSION

The method originally used an eluant consisting of 50% methyl alcohol and 50% 0.01 *M* ammonium acetate adjusted to pH 4.0, and an octadecylsilane reverse-phase column[13]. However, peak shape was rather poor. It was found that the peak shape could be improved by lowering the pH to 2.0 with 10% v/v nitric acid. Preliminary examination of this method with a partially degraded vincristine sulfate solution indicated a lack of resolution between vincristine sulfate and an unknown degradation product. Addition of a 0.005 *M* solution of the sodium salt of heptanesulfonic acid and increasing the ammonium acetate concentration to 0.02 *M* improved the resolution, but not sufficiently. Switching from methyl alcohol to acetonitrile (which required an adjustment in the aqueous–organic ratio from 50:50 to 70:30 for adequate retention) greatly increased resolution. The resolution between vincristine sulfate and the unknown degradation product at this point was ~1.0. Although this may have been adequate, it was found that by changing from an octadecylsilane to a phenyl column, baseline separation could be achieved between these two compounds.

Table II—Relative Retention Times of Some Compounds of Interest

Compound	Relative Retention[a]
Vincristine sulfate	1.00
Vinblastine sulfate	1.57
Major acid degradation product	1.32
Major base degradation product	0.40, 0.51
Light degradation product	1.34
Benzyl alcohol	0.27
Parabens	
Methyl	0.40
Ethyl	0.55
Propyl	0.78
Butyl	1.20

[a] $\text{Relative retention} = \frac{\text{retention time of compound (min)}}{\text{retention time of vincristine sulfate (min)}}$

In the subsequent use of this system, it was found that minor changes in the acetonitrile concentration of the eluant produced major changes in the retention time of vincristine sulfate. To reduce this tendency, and also to shorten the retention time and further improve peak shape, the ion-pairing reagent was changed from a 0.005 *M* solution of the sodium salt of heptanesulfonic acid to a 0.005 *M* solution of the sodium salt of pentanesulfonic acid. This produced the system described above (*Experimental*), which was tested for specificity, linearity, precision, and accuracy.

Specificity—The forced degradation products of vincristine sulfate, which were produced as described above, were examined using the HPLC procedure to ensure that none would interfere with intact vincristine. The results (Table I) indicate that the forced degradation products do not interfere with the vincristine sulfate. A few of the results have 3–4% errors. If the three wavelengths had been monitored simultaneously for each injection, this might have been significant. However, each of these ratios is the result of two separate injections each of which has a precision of ~ ±2%.

Vincristine sulfate is isolated from extracts of the periwinkle plant; thus, isolated precursors probably are nonexistent. However, other *Vinca* alkaloids are possible interferences. One of these, vinblastine sulfate, was found to have a retention time of 12.1 min. Vinblastine sulfate differs structurally from vincristine sulfate only by the presence of a methyl group instead of an aldehyde moiety at the anilino-nitrogen in the vindoline portion of the molecule (1).

A number of possible formulation excipients were examined for interference with vincristine sulfate in this system:

1. Buffers: citrate–citric acid, acetate–acetic acid, and phosphate buffers at 0.1 *M* and 0.2 *M* did not interfere.
2. Sugars: lactose and mannitol at 1 mg/ml showed no interference.
3. Sodium chloride: sodium chloride did not interfere.
4. Benzyl alcohol: benzyl alcohol had a retention time of 2.2 min.
5. Parabens: none of the parabens (methyl, ethyl, propyl, or butyl) interfered with vincristine sulfate using this system. Table II shows the relative retention times of some compounds of interest using this system.

Linearity—Vincristine sulfate showed a linear response from 10–200% of the normal injection concentration. The linear correlation coefficient was found to be +0.99990, and the intercept was −0.06% of the response of the normal injection concentration. Thus single-point standardization was deemed to be adequate.

[13] Internal communication from J. T. Woolever, Analytical Research and Development Department, Bristol Laboratories, Syracuse, NY 13201.

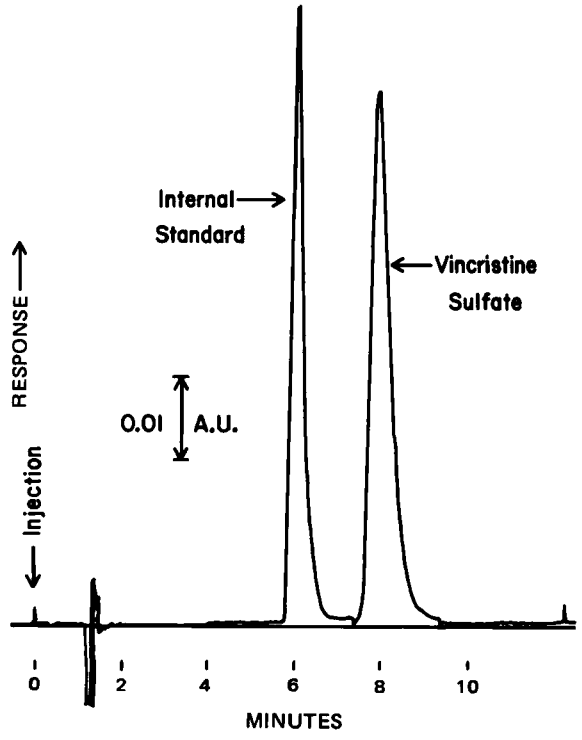

Figure 1—*Typical vincristine sulfate chromatogram with retention times.*

Chromatographic Precision—The chromatographic precision was determined by making six injections from a single freshly prepared solution of vincristine sulfate in water (0.25 mg/ml) on each of 3 days. The precision was calculated each day as two standard deviation units (95% confidence interval) relative to the mean expressed as a percentage. The chromatographic precision was taken to be the root mean square of the three relative 2σs, and was found to be ±2.3%.

Accuracy and Assay Precision—An estimate of the procedural accuracy was obtained by assaying six replicate weighings of vincristine sulfate *versus* a seventh weighing used as a standard. The reproducibility of the recoveries was used as an estimate of assay precision. Table III lists the results.

Stability in Diluent—The six solutions used for accuracy determination were held for 24 hr in the dark at room temperature (25°). They were then reassayed *versus* a fresh standard solution as an estimate of stability in diluent. As shown in Table IV, the average loss over 24 hr was ~5%. Therefore automated runs are feasible as long as vincristine sulfate is not held in solution for >8 hr and is protected from light.

In the routine use of this procedure, several precautions need to be taken. The mobile phase should be prepared with care, since small changes in the acetonitrile percentage produce large retention-time changes. However, as the column ages, small changes in the acetonitrile concentration may be necessary to maintain vincristine–internal standard resolution. Prior to beginning a run, the column should be conditioned with eluant for at least 30 min and several standard injections should be made until retention times are constant (usually ~3–5 injections). After use, the column should be rinsed with 30–50 ml of 1:1 v/v acetonitrile–water. Vincristine sulfate is extremely toxic and possibly carcinogenic; therefore, it should be handled with caution. Protective apparel should be worn, and all solutions (including spent HPLC eluant) should be disposed of properly.

Table III—Accuracy and Assay Precision

Sample	Calc. Wt, mg	Actual Wt, mg	Recovery[a], %
1	24.71	25.09	98.5
2	26.36	26.49	99.5
3	25.26	25.03	100.9
4	24.40	24.44	99.8
5	25.85	25.85	100.0
6	25.17	25.29	99.5

[a] Average is 99.7% with a relative 2σ value of ±1.57%.

Table IV—Stability in Diluent

Sample	Calc. Wt, mg	Actual Wt, mg	Recovery[a], %
1	23.88	25.09	95.2
2	24.81	26.49	93.6
3	24.26	25.03	96.9
4	23.28	24.44	95.2
5	24.81	25.85	96.0
6	23.89	25.29	94.5

[a] Average is 95.2%.

As a measure of system suitability, typical chromatographic parameters are shown below:

	Vincristine Sulfate	Propylparaben
Efficiency (plates/column)	1700	3500
HEPT[14]	0.018	0.008
Asymmetry	1.2	1.05
k'	7	5

The minimum acceptable values for vincristine sulfate are an efficiency of 1000 plates/column and a k' value of 6–10. In addition, there should be baseline separation between vincristine sulfate and propylparaben, the internal standard.

Enzyme Inhibition VI: Inhibition of Reverse Transcriptase Activity by Protoberberine Alkaloids and Structure–Activity Relationships

MANOHAR L. SETHI

Received November 30, 1981, from the *Department of Medicinal Chemistry, College of Pharmacy and Pharmacal Sciences, Howard University, Washington DC 20059.* Accepted for publication May 27, 1982.

Abstract □ Protoberberine alkaloids such as palmatine (I), 13-methylpalmatine iodide (II), 2,3-methylenedioxy-10,11-dimethoxy-13-methylprotoberberine iodide (III), 2,3-methylenedioxy-9,10-dimethoxy-13-methylprotoberberine chloride (IV), and berberine (V) showed inhibition of reverse transcriptase activity of RNA tumor viruses in the presence of polyriboadenylic acid·oligodeoxythymidylic acid (VI), polydeoxyadenylic acid·oligodeoxythymidylic acid (VII), activated calf thymus deoxyribonucleic acid (IX), and 70S ribonucleic acid (X), but not in the presence of polyribocytidylic acid·oligodeoxyguanylic acid (VIII). These results indicated that the alkaloids caused inhibition of the enzyme activity by interacting with the template primer, particularly of the adenine–thymine base pair. Furthermore, the alkaloids competed with the template primer-binding site of the enzyme. The time course inhibition indicated that the alkaloids stopped the DNA synthesis instantly when added after the initiation of polymerization processes. Inhibition of reverse transcriptase activity was correlated with the structure and antileukemic activity of the protoberberine alkaloids.

Keyphrases □ Protoberberine alkaloids—inhibition of reverse transcriptase activity, reaction kinetics, structure–activity relationships □ Reverse transcriptase—effect of protoberberine alkaloids, reaction kinetics, structure–activity relationships □ Enzyme inhibition—effect of protoberberine alkaloids on viral DNA polymerase, reaction kinetics, structure–activity relationships □ Structure–activity relationships—protoberberine alkaloids, *in vitro* inhibition of reverse transcriptase activity

Protoberberine alkaloids are a class of isoquinoline alkaloids that possess a wide variety of biological properties (1) [*i.e.*, antimicrobial (2–4), uterine contracting or stimulating (5, 6), and anticancer (7–9)]. Berberine chloride, one of the protoberberine alkaloids has been extensively studied, and exhibits antibacterial, antifungal, and antiprotozoal properties (10, 11). It also antagonizes cholera toxin (12, 13) and possesses intercalating (14–16) and mutagenic properties (17). Recently, berberine (V), 13-methylpalmatine (II), and 2,3-methylenedioxy-10,11-dimethoxy-13-methylprotoberberine (III) were reported to possess antitumor activity against experimental tumors (18), but lacked antileukemic activity against P-388 murine lymphocyte leukemia (19).

In view of the observation that some benzophenanthridine alkaloids are potential inhibitors of reverse transcriptase activity (20–22), the structurally related protoberberine alkaloids were examined for their effect on reverse transcriptase activity of RNA tumor viruses. It was considered worthwhile to screen these alkaloids for their antireverse transcriptase activity and correlate this activity with their structures and their antileukemic activity.

Reverse transcriptase (RNA-directed DNA polymerase) enzyme was discovered in RNA tumor viruses (retroviruses) by Baltimore (23) and Temin and Mizutani (24) in 1970. Since this discovery and association of the retroviruses with leukemia, lymphoma, and sarcoma of several vertebrates including primates (25), massive literature on the isolation, characterization, cell transformation, inhibitors, *etc.*, has accumulated over the past decade (26, 27). Recent findings of retroviral information in human leukemia (28, 29) and human cutaneous T-cell lymphoma cell line (30, 31) suggests a link between the RNA tumor viruses and human cancer. Consequently, the inhibitors of viral reverse transcriptase may contribute to approaches made toward the prevention of cancer.

[a] Alkaloid used for each inhibition was 12 μg/assay and the standard assay conditions as published previously (21) were followed. DNA and RNA polymerases of *E. Coli* under the standard assay conditions were less sensitive than viral polymerases to alkaloid inhibition. [b] Standard assay conditions were followed using thymidine triphosphate radioactive substrate except where otherwise specified under *Experimental*. The names of template primers and templates used are given in *Materials and Methods*.

EXPERIMENTAL

Materials and Methods—Purified reverse transcriptase from avian myeloblastosis virus[1] (AMV) contained specific activity of 92,472 U/mg of protein. The enzyme preparation contained 10,072 U/ml of reverse transcriptase activity and a protein content of 0.11 mg/ml. One unit of enzyme activity was expressed as the incorporation of 1 nmole of deoxythymidine monophosphate into an acid-insoluble product in 10 min at 37°. The purity of the enzyme preparation was determined by an established procedure (32). Reverse transcriptase from Rauscher murine virus[2] (MuLV), propagated from JLS-V9 cell line had an activity of 4.00 nmoles of thymidine monophosphate incorporation/30 min/ml. DNA polymerase from simian sarcoma virus type 1[3] (SSV) was derived from tissue culture fluids of the SSV-I-NC-37 cell line and purified by a previous method (20). It had an activity of 6.00 nmoles of thymidine monophosphate incorporation/30 min/ml. The 70S RNA[4] from MuLV was purified by a published method (33). Reverse transcriptase assay and enzyme inhibition were carried out by a method previously reported (21). Appropriate concentrations of the protoberberine alkaloids[5,6] were dissolved in dimethyl sulfoxide. Control assays were performed without the alkaloids but contained an equivalent volume of dimethyl sulfoxide. The results were expressed as the percent of control activity.

The protoberberine alkaloids tested were palmatine[5] (I,NSC 209407), 13-methylpalmatine iodide[6] (II), 2,3-methylenedioxy-10,11-dimethoxy-13-methylprotoberberine iodide[5] (III,NSC 276348), 2,3-methylenedioxy-9,10-dimethoxy-13-methylprotoberberine chloride[6] (IV), and berberine chloride[5] (V,NSC 163088).

The template primers or templates used were polyriboadenylic acid·oligodeoxythymidylic acid (VI), polydeoxyadenylic acid·oligodeoxythymidylic acid (VII); polyribocytidylic acid·oligodeoxyguanylic acid (VIII) (2.00 nmoles of [^{3}H]deoxyguanosine triphosphate, 380 cpm/mole substrate), activated calf thymus DNA (IX) (2.20 μg activated deoxyribonucleic acid, 10 nmoles each of deoxyadenosine, deoxycytidine, and deoxyguanosine triphosphates and 2.50 nmoles of [^{3}H]thymidine triphosphate substrates); 70S ribonucleic acid (X) (MuLV) of 0.05 optical density units (260 nm).

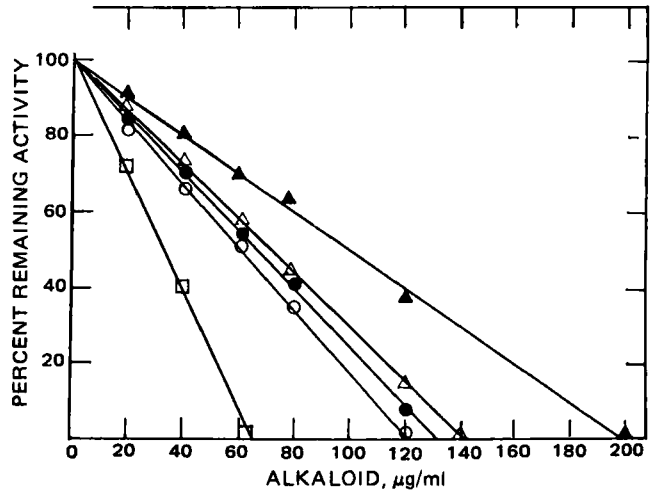

Figure 1—*Effect of protoberberine alkaloids on AMV reverse transcriptase activity. In a standard assay mixture (0.10 ml) containing 5 μl of enzyme, different concentrations of alkaloids I (□), II (○), III (●), IV (△), and V (▲) were used for enzyme inhibition.*

RESULTS AND DISCUSSION

The *in vitro* inhibition of AMV reverse transcriptase activity by protoberberine alkaloids I–V in the presence of template primer (VI) is shown in Fig. 1. Fifty percent enzyme inhibition by alkaloids I–V was in the range of 30–35 μg/ml (I), 60–65 μg/ml (II), 65–70 μg/ml (III), 70–75 μg/ml (IV), and 100–105 μg/ml (V). Similar results were obtained on MuLV and SSV reverse transcriptase activity (data not shown). Based on the nature of inhibitory curves and 50% inhibition of enzyme activity, alkaloids I, II–IV, and V were classified as potent, moderate, and very weak inhibitors of reverse transcriptase activity, respectively. Purified AMV, MuLV, and SSV reverse transcriptase activities were also inhibited by these protoberberine alkaloids in the presence of VII, IX, and X template primers, but a very low degree of inhibition of enzyme activity was observed when VIII template primer was used (Table I). The different percentage of inhibition of enzyme activity observed in the presence of these template primers indicated that the inhibition of the enzyme activity was due to the interaction of alkaloids with template primers and not with the enzyme protein; otherwise the same percentage of inhibition of enzyme activity would have been observed regardless of the different template primers used. A very low degree of inhibition of enzyme activity in the presence of VIII as compared with VI, VII, IX, and X was indicative of the strong binding affinity of alkaloids with the adenine–thymine base

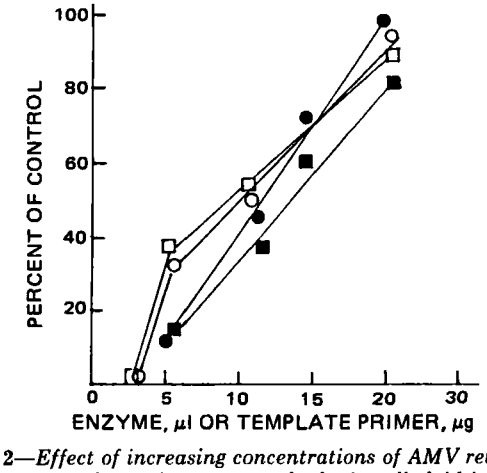

Figure 2—*Effect of increasing concentrations of AMV reverse transcriptase or template primer on protoberberine alkaloid-inhibited reaction mixture. The standard assay mixture (0.10 ml) contained 5 μl of AMV reverse transcriptase and 6 μg of I (●) or 12 μg of III (■) or 2.5 μg of VI template primer and 6 μg of I (○) or 12 μg of III (□).*

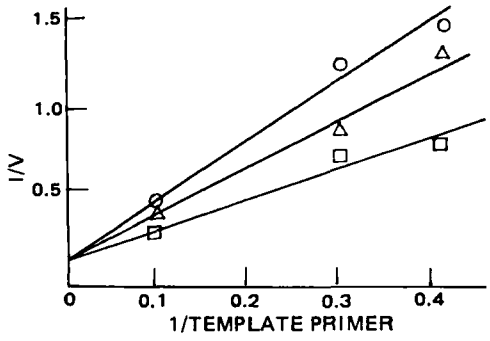

Figure 3—*Double-reciprocal plot (Lineweaver–Burk plot) of 1/velocity versus 1/template primer shown by alkaloid I. Units of velocity (V) are expressed as counts per min × 10^{-4} of methyl-[^{3}H]thymidine monophosphate incorporated into DNA synthesis. Concentrations of template primer (VI) are expressed in μg/ml. Alkaloid I concentrations were 0 (□); 0.3 μg/ml (△); 0.9 μg/(○) in the standard assay mixture.*

pair template primers. The interaction or competition of alkaloids with manganese chloride was ruled out, because the increasing concentration of this metal ion in the assay mixture did not change the enzyme activity *(data not shown)*. The possibility of interaction of alkaloids with potassium chloride or substrate ([^{3}H]thymidine or guanosine triphosphate) was not considered, since the latter was present in the reaction mixture in 8- or 25-fold, respectively, in excess of the ID_{50} of the alkaloid concentration.

To explain further the mode of action of alkaloids I and III, the effect of increasing the concentrations of AMV reverse transcriptase enzyme or template primer (VI) on the alkaloid-inhibited reaction mixture was observed, as shown in Fig. 2. The increasing concentration of the enzyme from 5 to 20 μl or template primer from 3 to 20 μg in the assay mixture resulted in the full restoration of enzyme activity of the alkaloid-inhibited reaction mixture. Similar results were shown by alkaloids II, IV, and V (data not shown). These results could be due to the dissociation of the enzyme–template–alkaloid ternary complex in the reaction mixture in the presence of excess template primer or enzyme. The data support the previous observation that the alkaloids interacted with the template primer. The Lineweaver–Burk plot (Fig. 3) obtained by alkaloid I was of a competitive type indicating interaction of the alkaloid with the template primer binding site of the enzyme. Similar plots were obtained in the case of alkaloids II–IV (data not shown). The time course of inhibition of reverse transcriptase activity by alkaloids I and III is shown in

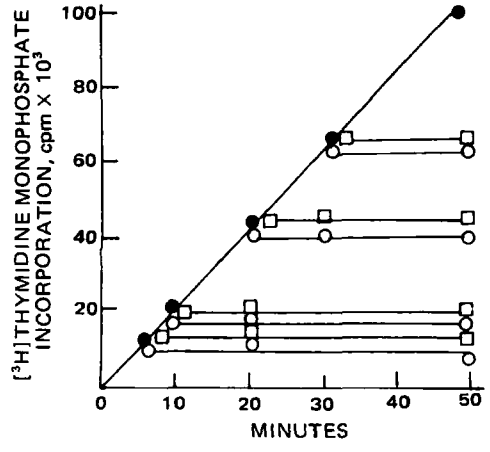

Figure 4—*Effect of addition of protoberberine alkaloids during AMV reverse transcriptase kinetic reaction. For each assay, 2 ml of standard assay mixture containing 100 μl of enzyme was divided into four parts: A(0.60 ml), B(0.50 ml), C(0.50 ml), D(0.40 ml). From A, a 0.10-sample was withdrawn at zero min, and the remaining quantity was incubated at 37°. One-tenth-milliliter samples from A(control, ●) were withdrawn at 5, 10, 20, 30, and 50 min after incubation. Parts B, C, and D were also incubated at 37°, and 60 μg/ml or 120 μg/ml solutions of alkaloid I (○) or III (□), respectively, were added at 5, 10, 20, and 30 min after incubation. One minute after addition of the alkaloid, 0.10-ml samples were withdrawn from B, C, and D at 5-min intervals. Radioactivity of each sample was determined.*

Table II—Effect of Functional Groups of Protoberberine Alkaloids on Inhibition of Reverse Transcriptase Activity

Alkaloid	50% Inhibition, μg/ml	Functional Group[a]
I	32	Maximum inhibition due to methoxyl groups at positions 2, 3, 9, and 10
II	62	Decrease of inhibition due to methyl group at position 13
III	67[b]	Increase of inhibition due to methoxyl groups at positions 10 and 11 as compared with positions 9 and 10
IV	72	Decrease of inhibition due to methyl group at position 13
V	102	Decrease of inhibition due to methylenedioxy group at positions 2 and 3

[a] For functional groups refer to the individual structure of the alkaloids. [b] This increase in 50% inhibition is relative to the inhibition exhibited by alkaloid IV. Other 50% inhibitions are compared with the maximum inhibition displayed by alkaloid I.

Fig. 4. The controlled activity of the reaction mixture was determined without the alkaloids. During the time course of the reaction, the alkaloids were added at 10, 20, 30, and 50 min after initiation of DNA synthesis. As soon as the alkaloids were added, the enzyme activity was abruptly changed, as indicated by the [^{3}H]thymidine monophosphate incorporation. Further incubation of the reaction mixture did not change the kinetics of DNA synthesis or degrade the product. The immediate cessation of the polymerization reaction by the alkaloids may be due to the interaction of the alkaloids with the template primer. Similar results were obtained with alkaloids II, IV, and V (data not shown).

The individual members of the protoberberine alkaloids showed different degrees of inhibition of reverse transcriptase activity, although the mode of action was similar in each case. Therefore, variation in 50% inhibition of enzyme activity by the protoberberine alkaloids could be attributed to the structure of the alkaloids. A maximum of 50% inhibition of enzyme activity (32 μg/ml) was observed in alkaloid I (base or iodide), which has two methoxyl groups at positions 2 and 3 of ring A and two methoxyl groups at positions 9 and 10 of ring D (Table II). In the structure of alkaloid I, when an additional methyl group was present at position 13 of ring C, 50% enzyme inhibition by alkaloid II was decreased considerably (62 μg/ml) indicating the influence of a methyl group. On the other hand, with substitution of a methylenedioxy group at positions 2 and 3 of ring A in place of methoxyl groups at these positions of alkaloid I, 50% inhibition of enzyme activity by alkaloid V was almost lost (102 μg/ml). However, the presence of a methyl group at position 13 of ring C resulted in an increase of 50% enzyme inhibition (72 μg/ml) by alkaloid IV (Table II). Alkaloid III showed slightly more enzyme inhibition (67 μg/ml) than alkaloid IV, although two methoxyl groups in alkaloid III were present at positions 10 and 11 of ring D. Whether the presence of methoxyl groups at positions 9 and 10 or positions 10 and 11 of ring D play an important role in the inhibition of enzyme activity is not yet conclusively determined. However, previous results in structurally related benzophenanthridine alkaloids (22) indicated that the presence of substituent groups at positions analogous to 10 and 11 of ring D were important to exhibit increased inhibition of reverse transcriptase activity. In fact, alkaloid III was a better inhibitor of reverse transcriptase activity than alkaloid IV, which indicated that the presence of methoxyl groups at positions 10 and 11 of ring D (alkaloid III) increased the inhibition of enzyme activity. In any case, the present investigation reveals that the placing of methoxyl groups at positions 2 and 3 of ring A, regardless of such groups at positions 9 and 10 or 10 and 11 of ring D, was an essential requirement in possessing the inhibitory effect of the alkaloids.

The cytotoxic alkaloids I–V displayed an effective antitumor activity against experimental tumors (18) but did not show antileukemic activity against P-388 lymphocytic leukemia in mice (19). Earlier studies have indicated that the inhibition of reverse transcriptase activity by benzophenanthridine alkaloids corresponded well with their antileukemic activity (22). Surprisingly, except alkaloid V, protoberberine alkaloids failed to exhibit such a correlation. The lack of antileukemic activity of alkaloid V was, thus, in agreement with the observation that this alkaloid exhibited very weak inhibition of reverse transcriptase activity. However, lack of antileukemic activity of alkaloids I–IV, but possession of inhibition of reverse transcriptase activity by these alkaloids, could not be explained at the present time. Further work is in progress to establish the relationship of enzyme inhibition and antileukemic or antitumor activity.

Alkaloids I–V showed less inhibition of reverse transcriptase activity compared with the analogous benzophenanthridine alkaloids. Such a difference in reverse transcriptase inhibition by the protoberberines and benzophenanthridines could be due to the stereochemistry, presence of *N*-methyl (—N—CH_3) group in ring C and/or influence of counterions of different salts of benzophenanthridine alkaloids. A previous report related an antileukemic activity of certain cytotoxic protoberberine alkaloids with the conformations and DNA binding properties of the alkaloids (19). Other studies reported that the biological activity of alkaloid V (34) (and a few protoberberines) was due to their binding to double-helical DNA by intercalation (35, 36). Furthermore, protoberberine alkaloids were reported to inhibit a number of enzymes such as NADH oxidase (37), horse liver alcohol dehydrogenase (38, 39), and xanthine oxidase (40) by different mechanisms. The present study reports inhibitory effect of protoberberine alkaloids on another enzyme (reverse transcriptase) for the first time. It would be worthwhile to investigate the exact mechanism of action of protoberberine alkaloids in order to justify the cytotoxicity and diverse biological activities of the alkaloids.

Furosemide Binding by Human Albumin: Comparison of Two Methods of Fluorescence Quenching Analysis

D. L. PARSONS

Received December 28, 1981, from the *Department of Pharmaceutical Sciences, College of Pharmacy, The University of Arizona, Tucson, AZ 85721.* Accepted for publication May 27, 1982. Present address: Department of Pharmacal Sciences, School of Pharmacy, Auburn University, Auburn, AL 36849.

Abstract □ Disagreement exists over the primary-site binding constant for the interaction of furosemide with human albumin. Disagreement also exists over which experimental methods are accurate in this particular interaction. Therefore, furosemide binding by human albumin was examined using albumin fluorescence quenching by both the method of Levine and the method of Steiner *et al.* The binding constants obtained by each method differed greatly, with the results of the latter method being similar to those of other experimental methods. It was concluded that the method of Levine overestimates the binding constant for this drug–protein interaction.

Keyphrases □ Furosemide—binding by human albumin, comparison of two methods of fluorescence quenching analysis □ Binding—furosemide by human albumin, comparison of two methods of fluorescence quenching, analysis □ Human albumin—furosemide binding, comparison of two methods of fluorescence quenching analysis

The binding of a drug by blood proteins can influence the therapeutic, pharmacodynamic, and toxicological actions of the drug (1). Studies of drug binding by albumin are important since this is the major plasma protein responsible for the nonspecific binding of drugs (2). Most drugs that are extensively bound by plasma proteins are anions that bind to albumin (3), and these ligands can undergo competition for the limited number of albumin binding sites (4).

At low concentrations in plasma, furosemide is extensively bound exclusively or almost exclusively to albumin (5). However, there has been disagreement over the magnitude of the binding constant for the interaction of furosemide with its primary binding site on human albumin. Using the method of intrinsic protein fluorescence quenching and a new method of data analysis, a primary-site binding constant of $1.3 \times 10^7\ M^{-1}$ has been obtained for the interaction of furosemide with human albumin (6). As shown in Table I, this value considerably exceeds other reported values obtained using various experimental methods and conditions. It was suggested that the reason for the large affinity constant obtained using the new method of data analysis is that other experimental methods, such as equilibrium dialysis, give erroneously low binding constant values for strongly bound ligands (6). Previous work (13) has provided a theoretical alternative for this large binding constant obtained for the interaction of furosemide with human albumin; *i.e.*, the new method of data analysis employed overestimates the binding constant for certain interactants.

As discussed previously (13), the method of Levine is based on assumptions that are not strictly valid when the protein contains more than one binding site for the ligand. When this is the case, and with a low value of n_1k_1/n_2k_2, where n_i is the number of binding sites of class i and k_i is the site binding (affinity) constant for binding sites of class i, the method of Levine will, theoretically, overestimate the value of k_1 (13).

A third possible explanation for the large value of k_1 obtained using the new method of data analysis (6) is that different experimental conditions were employed. Factors such as the pH, temperature, and buffer system used, the method of albumin isolation, and presence of fatty acids can affect both the number and the affinity of binding sites (14).

Since the binding of a drug by albumin may greatly affect the *in vivo* actions of the drug, it is important that large discrepancies in reported binding constants be resolved. It is also important that possible limitations of new methods of data analysis be examined both theoretically and experimentally, since many investigators may eventually employ the new method. Theoretical limitations of the method of Levine were discussed previously (13). To evaluate experimentally the limitations of this method, the binding of furosemide by human albumin was re-examined using the quenching of intrinsic protein fluorescence by both the Levine (6) and Steiner *et al.* (15) methods. The method of Steiner *et al.* is theoretically sound and applicable when the protein contains more than one binding site for the ligand.

EXPERIMENTAL

Materials and Methods—Fatty acid free human albumin[1] and furosemide[2] as a pure powder were used as received. All protein solutions were prepared using 0.125 *M* phosphate buffer at pH 7.4. The buffer was prepared immediately prior to the experiment using analytical grade monosodium and disodium phosphates and water purified by reverse osmosis followed by distillation.

Fluorescence measurements were made with a spectrofluorometer[3], and spectrophotometric measurements were made with a spectrophotometer[4]. Rectangular quartz fluorescence cells with a path length of 10 mm were used for both fluorescence and spectrophotometric measurements.

Albumin solutions of 1.9, 6.0, 10, 50, and 100 μmoles/liter were utilized in this study. All albumin solutions were corrected for moisture content and purity and were ~2-hr old at the start of each experiment. Furosemide solutions (0.3–1.2 mmoles/liter) were prepared immediately prior to use and were protected from light. Furosemide solutions were prepared using a portion of the albumin solutions under investigation to avoid dilution of the albumin solution upon addition of drug.

The decrease in the magnitude of intrinsic albumin fluorescence upon the addition of microliter volumes of furosemide solution to 2 ml of protein solution was measured at ambient temperature (24.5 ± 0.8°). Excitation and emission wavelengths of 292 and 370 nm, respectively, were used to minimize the absorption of light by furosemide. Excitation and emission slit widths of 2 and 12 nm, respectively, were used, except at the higher protein concentration (100 μmoles/liter) where an emission slit width of 10 nm was utilized. The fluorescence intensity of cells containing buffer only and albumin only, at the same concentration as the sample cell, was measured prior to each measurement of sample cell fluorescence intensity. These reference solutions were used to correct the

[a] Rough approximation.

sample fluorescence for background fluorescence and any variations in instrument response or protein fluorescence. The solutions were only exposed to the excitation light for the few seconds required for each measurement.

Four fluorescence quench titrations were performed at each albumin concentration investigated except 100 μmoles/liter, where six titrations were conducted. For a given albumin concentration, the fluorescence quench titrations were identical in that fluorescence measurements were always made at the same total molar drug concentration to total molar protein concentration ratio, D/P. Each sample fluorescence measurement was corrected for the inner filter effect based on the absorbance of the solution at the wavelengths of excitation and emission (16). Three absorbance titrations were performed at each albumin concentration investigated. The absorbance titrations at any given protein concentration were identical to the fluorescence quench titrations at the same protein concentration, in that fluorescence and absorbance measurements were obtained at the same values of D/P. The mean absorbance of the sample solutions at both 292 and 370 nm at each D/P value was used to correct the corresponding fluorescence measurements at the same protein concentration and D/P value.

After correcting for the inner filter effect, each fluorescence measurement was converted to percent initial fluorescence. The mean percent initial fluorescence at each value of D/P at each protein concentration was calculated and plotted as a function of D/P. These quench curves were used to calculate values of r, the ratio of molar concentration of bound ligand to total molar protein concentration, and $[L]$, the molar concentration of free ligand at each protein concentration using both the method of Levine (6) and the method of Steiner *et al.* (15). The values of r and $[L]$ were then used to construct a Scatchard plot (17) based on the following equation:

$$r = \sum_{i=1}^{m} \frac{n_i k_i [L]}{1 + k_i [L]} \qquad \text{(Eq. 1)}$$

Binding constants were obtained by a computer fit (18) of the binding data obtained using the method of Steiner *et al.* (15). Since the method of Levine (6) assumes that essentially no ligand is bound to secondary albumin binding sites until the primary binding site is saturated, the data obtained by this method are treated on the assumption that albumin contains a single binding site for ligand. In this case, a Scatchard plot (17) and linear regression can be used to obtain values of n_1 and k_1 or Eq. 2 (6) can be used to calculate k_1 directly from the quench curve:

$$k_1 = \frac{Q}{(1 - Q)P[(D/P) - Q]} \qquad \text{(Eq. 2)}$$

where: $Q = (F_0 - F)/m$, F_0 = fluorescence at $D/P = 0$, F = fluorescence at a given value of D/P, m = slope of the initial portion of the quench curve, *i.e.*, at low values of D/P, and P = total molar albumin concentration.

Using Eq. 2, a value of k_1 can be calculated for each experimental point on the quench curve that lies above the straight line fitted to the initial portion of the quench curve. Equation 2 assumes that $n_1 = 1$ and that $Q = r$.

RESULTS

The quench curves obtained at each albumin concentration investigated are presented in Fig. 1. For clarity, a few experimental points obtained at the lower albumin concentrations and D/P values >7, and at the higher albumin concentrations and D/P values <1, are not presented in this figure. As expected, the mean percent initial fluorescence at any given D/P value decreases as the albumin concentration increases. The coefficient of variation for the individual values of mean percent initial

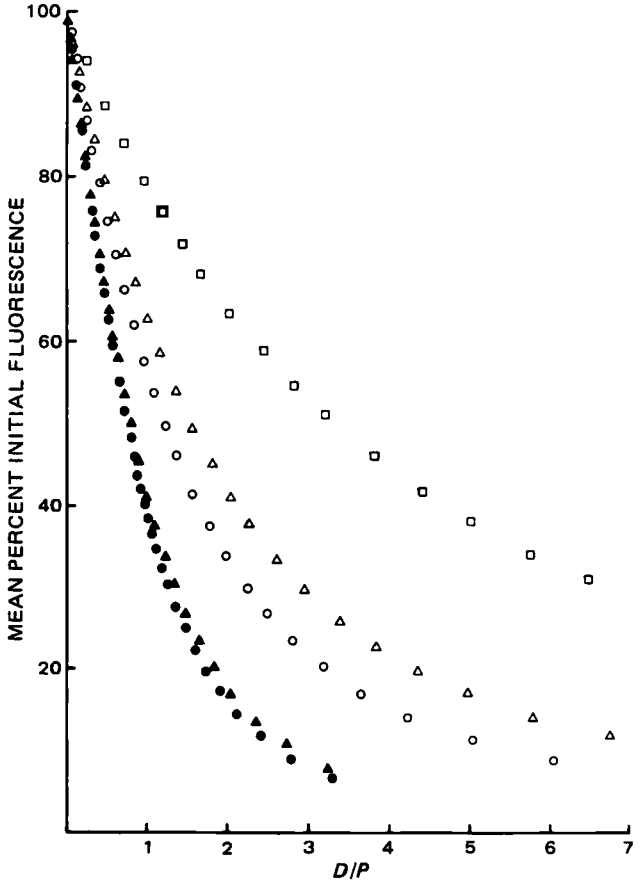

Figure 1—*Fluorescence quench curves obtained for the interaction of furosemide with 1.9 (□), 6.0 (△), 10 (○), 50 (▲), and 100 (●) μmoles/liter of human albumin.*

fluorescence ranged from 0.001 to 0.043 and the standard deviation for these individual values ranged from 0.1 to 0.9 for all but the largest albumin concentration. At an albumin concentration of 100 μmoles/liter, the coefficient of variation for the individual values of mean percent initial fluorescence ranged from 0.001 to 0.104 and the standard deviation for these individual values ranged from 0.1 to 2.5. As a result of the larger data variability observed at an albumin concentration of 100 μmoles/liter, six, rather than four, fluorescence quench titrations were performed at this protein concentration. The larger variability observed at the highest albumin concentration may be due to the larger inner filter effect and/or the smaller decrease in observed fluorescence between additions of furosemide solution. Data could not be obtained at higher protein concentrations due to the large sample absorbance encountered at relatively low D/P values.

Figure 1 shows that the quench curves obtained at the two largest albumin concentrations investigated (50 and 100 μmoles/liter) are identical at low D/P values and are very similar throughout the D/P range investigated. The portion of these curves that is identical represents the percent of initial fluorescence observed when all of the added ligand is bound (19), *i.e.*, a plot of percent initial fluorescence as a function of r. The fact that these two quench curves are very similar at higher D/P values suggests that a larger portion of the quench curve obtained at an albumin concentration of 100 μmoles/liter represents a plot of percent initial fluorescence as a function of r. Therefore, the quench curve obtained at an albumin concentration of 100 μmoles/liter and the method of Steiner *et al.* (15) were used to construct a Scatchard plot (17) of the data obtained at albumin concentrations of 1.9, 6.0, and 10 μmoles/liter. The quench curve obtained at an albumin concentration of 50 μmoles/liter could not be used due to its similarity to the quench curve obtained at an albumin concentration of 100 μmoles/liter.

The Scatchard plot obtained using the method of Steiner *et al.* (15) is presented in Fig. 2. This plot becomes unusual in appearance at values of $r > \sim 1.5$, in that the data obtained at different protein concentrations no longer represent a single curve, and the instantaneous slope of each curve becomes increasingly negative. This shows that the quench curve obtained at an albumin concentration of 100 μmoles/liter does not rep-

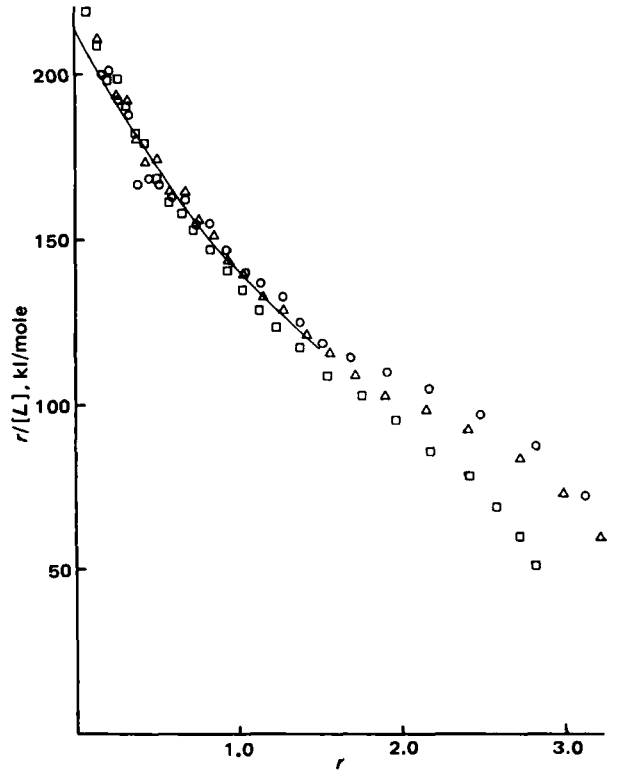

Figure 2—*Scatchard plot obtained for the binding of furosemide by 1.9 (□), 6.0 (△), and 10 (○) μmoles/liter of human albumin using the method of Steiner* et al. *(15).*

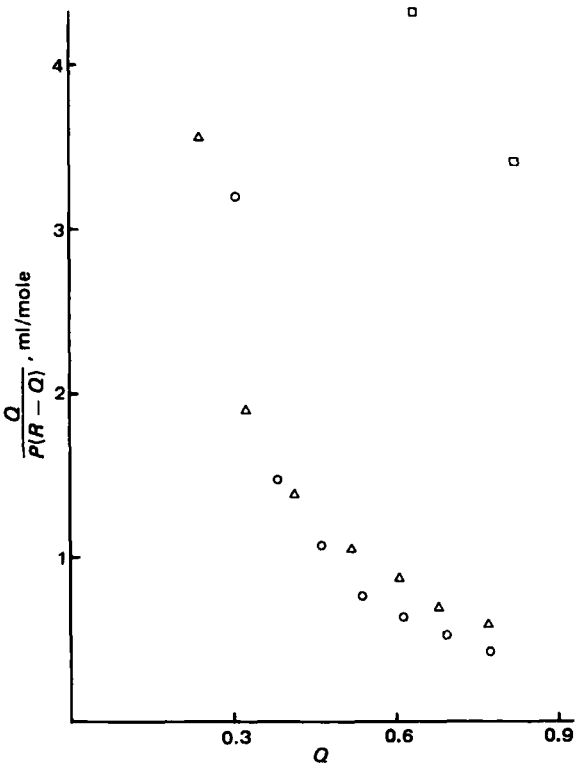

Figure 3—*Scatchard plot obtained for the binding of furosemide by 1.9 (□), 6.0 (△),and 10 (○) μmoles/liter of human albumin using the method of Levine (6).*

resent the stoichiometric binding of ligand at D/P values >1.5. Use of this quench curve at these values results in an overestimate of the affinity of albumin for ligand at higher r values and this results in an increase in the slope of the Scatchard plot at r >1.5. Assuming two classes of binding sites, a fit of the data of r <1.5 presented in Fig. 2 to Eq. 1 yields $n_1 = 0.70$, $k_1 = 166$ kl/mole, $n_2 = 5.5$, and $k_2 = 17.7$ kl/mole. These constants were used to compute the solid line in Fig. 2. The deviation of this line at lower r values results from the computer fit of the data to Eq. 1, rather than to $r/[L]$ as a function of r.

The method of Levine (6) also was used to interpret the quench curves obtained at albumin concentrations of 1.9, 6.0, and 10 μmoles/liter. Using Eq. 2, a value of k_1 was calculated for each experimental point on the quench curve of D/P <1 that lies above the straight line fitted to the initial portion of the quench curve. The results are presented in Table II.

The method of Levine (6) was also used to construct a Scatchard plot (17) of the data obtained at albumin concentrations of 1.9, 6.0, and 10 μmoles/liter. This Scatchard plot is presented in Fig. 3. As discussed, linear regression analysis of the Scatchard plot (17) is used in the method of Levine (6) to obtain values of n_1 and k_1. Values of n_1 and k_1 were not obtained for the data of Fig. 3 due to the nonlinearity of this plot.

[a] Albumin concentration.

DISCUSSION

The quenching of the intrinsic fluorescence of human albumin upon the binding of furosemide was used to study this drug–protein interaction. The quench curves obtained (Fig. 1) show that at the lower albumin concentrations examined, only a few, if any, of the experimental points lie on the quench curve obtained at the largest albumin concentration. This shows that only a small section, if any, of the initial portion of the quench curves obtained at the lowest three albumin concentrations represents the fluorescence observed when all of the added furosemide is bound. Thus, the initial apparently linear portion of the quench curves obtained at albumin concentrations of 1.9, 6.0, and 10 μmoles/liter do not represent the stoichiometric binding of furosemide as is assumed by the method of Levine.

Binding constants for both the primary and secondary binding sites on human albumin for furosemide were determined from the quench curves using the method of Steiner *et al.* (15). The quench curve obtained at an albumin concentration of 100 μmoles/liter through a D/P value of 1.5 was used as the stoichiometric curve. If any portion of this curve does not represent the stoichiometric binding of furosemide, the binding constants obtained will be too high rather than too low. The values of the binding constants obtained in this study using the method of Steiner *et al.* (15) are similar to the values obtained previously (Table I) with the exception of the k_1 value obtained using the method of Levine (6). The lower value of n_1 and the higher value of n_2 obtained in the present study is at least partially due to the limited range of r values that could be obtained.

The quench curves obtained at albumin concentrations of 1.9, 6.0, and 10 μmoles/liter (Fig. 1) were also analyzed by the method of Levine (6) using both Eq. 2 and a Scatchard plot (17) (Fig. 3). The quench curves obtained at albumin concentrations of 50 and 100 μmoles/liter were not analyzed by this method, since they represent the stoichiometric binding of furosemide. The values of k_1 obtained using Eq. 2 are presented in Table II. For each albumin concentration examined, the k_1 value obtained appears to be dependent on the experimental point (D/P) used in the calculation of k_1. As the D/P value increases, the value of k_1 appears to decrease to some minimum value and then increase. The value of k_1 does not vary in the random fashion expected due to experimental error. This apparent dependence of k_1 on D/P implies that one or more of the assumptions of this method of data analysis is invalid for this particular drug–protein interaction. The coefficient of variation values for the mean

values of k_1 are very high relative to the coefficient of variation values obtained for the individual experimental points of the quench curve. The nonlinearity of the Scatchard plot obtained using this method of data analysis (Fig. 3) also implies that one or more of the assumptions of this method is invalid for this particular drug–protein interaction.

The Scatchard plot previously obtained by this method for the binding of furosemide by human albumin was not published (6). Thus, the experimental data suggest that one or more of the assumptions on which the method of Levine is based is invalid as was previously suggested (13) based on theoretical considerations.

The mean value of k_1 ($1.65 \times 10^7\ M^{-1}$) obtained using Eq. 2 and an albumin concentration of 1.9 μmoles/liter is very similar to the value of $1.3 \times 10^7\ M^{-1}$ previously obtained (6) using the same albumin concentration, experimental conditions, and method of data analysis. As shown in Table II, the mean value of k_1 decreased and the value of m increased as the albumin concentration increased. This is to be expected, since the initial apparently linear portion of the quench curve obtained at each protein concentration does not represent the stoichiometric binding of the ligand. This shows how difficult it is to determine the stoichiometric region of a quench curve when data are collected at a single protein concentration. The method of Levine assumes that this stoichiometric region can be determined using a single protein concentration.

Based on these results, the reason for the large value of k_1 previously obtained (6) for the binding of furosemide by human albumin using the new method of data analysis is not that other experimental methods, such as equilibrium dialysis, resulted in erroneously low values of this constant. Since the same set of data was analyzed by two different methods in the present investigation, the large difference in the values of k_1 obtained cannot be attributed to a difference in experimental conditions. Instead, the results of this study show that the new method of data analysis (6) overestimates the value of k_1 in this particular drug–protein interaction. As discussed previously (13), the method of Levine will, theoretically, overestimate the value of k_1 when the protein contains more than one binding site and has a low value of n_1k_1/n_2k_2. The experimental results of the present work support these theoretical findings. This overestimation of k_1 also results from the inaccurate determination of the stoichiometric region of the fluorescence quench curve obtained at a single albumin concentration.

As discussed previously (13), the method of Levine (6) has several advantages over the method of Steiner *et al.* (15) and results in accurate estimates of k_1 for certain ligand–protein interactions, such as the binding of bilirubin by human albumin. However, the method of Levine will overestimate the value of k_1 when the protein contains more than one binding site for the ligand and the value of n_1k_1/n_2k_2 for the interaction is low. The binding of furosemide by human albumin is an example of such an interaction. For this reason, the binding constant obtained using this new method of data analysis (6) should always be verified by an additional experimental method. When a drug–protein interaction is being investigated for the first time, and the method of intrinsic protein fluorescence quenching is the only experimental method used, the data should always be analyzed by the method of Steiner *et al.* (15).

Thermal and Photolytic Degradation Studies of Promethazine Hydrochloride: A Stability-Indicating Assay

S. STAVCHANSKY *x, J. E. WALLACE ‡, and P. WU *

Received February 11, 1982, from the *University of Texas at Austin, College of Pharmacy, Division of Pharmaceutics, Drug Dynamics Institute, Austin, TX 78712, and the ‡University of Texas Health Science Center, Department of Pathology, San Antonio, TX 78284. Accepted for publication May 25, 1982.

Abstract □ A stability-indicating GLC method for the analysis of promethazine hydrochloride in polyethylene glycol delivery systems is reported. This method is capable of distinguishing the intact drug from its thermal and photodegradation products. A linear relationship between peak height ratio (promethazine–promazine) and promethazine concentration is found up to a concentration of 600 μg/ml. Kinetic studies were performed to determine the photolytic and thermal degradation rates of promethazine hydrochloride as a function of pH. The activation energies at pH 2.98, 3.94, and 5.12 were obtained from linear Arrhenius plots and were found to be 6601, 5888, 5570 cal/mole, respectively. The first-order rate constant increased with increasing pH. The photolytic degradation of promethazine hydrochloride does not follow simple first-order kinetics.

Keyphrases □ Promethazine hydrochloride—thermal and photolytic degradation studies, stability-indicating GLC assay □ Thermal degradation—promethazine hydrochloride, photolytic degradation, stability-indicating GLC assay □ Photolytic degradation—promethazine hydrochloride, thermal degradation, stability-indicating GLC assay

Evaluation of the stability of promethazine hydrochloride in rectal delivery systems containing polyethylene glycols requires an assay method that is specific for the drug in the presence of degraded products and vehicles. There have been several spectrophotometric methods developed (1–3), but none of them has adequate specificity for stability testing. A direct GLC method without prior extraction has been used (4), but in the presence of polyethylene glycol, the flame ionization detectors are adversely affected. In addition, the injection of water and ethanol into the gas chromatographic system causes a rapid column deterioration. In the present investigation, a GLC method with a simple organic phase extraction was developed to specifically determine promethazine hydrochloride in polyethylene glycol suppositories undergoing stability testing.

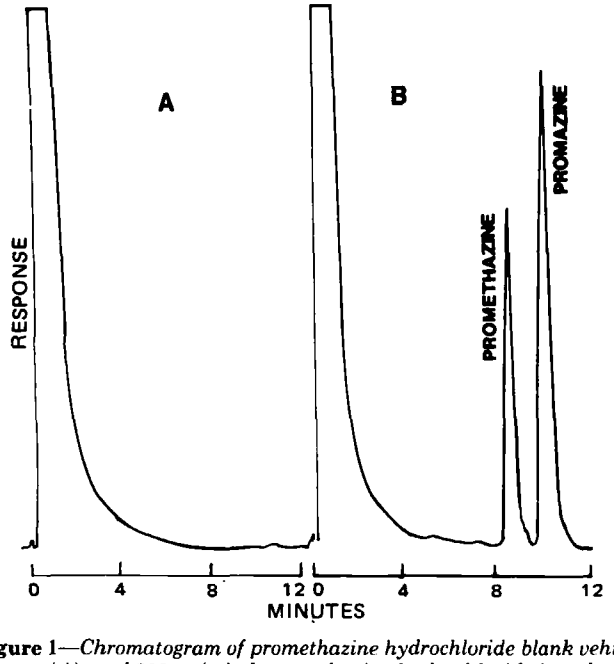

Figure 1—*Chromatogram of promethazine hydrochloride blank vehicle extract (A), and 300 μg/ml of promethazine hydrochloride in polyethylene glycol aqueous solution in the presence of promazine as internal standard, (B).*

EXPERIMENTAL

Materials—Promethazine hydrochloride[1] and promazine hydrochloride[2] were used as received. All solvents and chemicals were commercial analytical grade[3]. Precoated silica gel plates[4] were used.

Chromatographic Conditions—A dual-column GC[5] with a flame ionization detector was used. A silylated, coiled glass column, 183 cm in length, 0.6-cm o.d., 0.4-cm i.d., was packed with 3% OV-17 on 100–120 mesh Gas Chrom Q[6]. The column was conditioned for 36 hr at 280° and was treated with a silylating agent, *N,O*-bis(trimethylsilyl)acetamide[7]. Nitrogen carrier gas flow, hydrogen flow, and air flow were 37, 37, and 350 ml/min, respectively. The column, detector, and sample injection port temperatures were 250, 300, and 260°, respectively.

Polyethylene Glycol Vehicle Solution—A stock solution was prepared using the excipients and preservatives employed in the manufacture of the suppositories. Appropriate dilutions were made with deionized water. The resulting solutions reflect the actual amount of each of the ingredients in the formulation.

Internal Standard Solution—Fifty milligrams of promazine hydrochloride[2] was placed in a 100-ml volumetric flask and appropriately diluted with deionized water.

Standard Solutions—Sixty milligrams of promethazine hydrochloride was placed in a 100-ml volumetric flask and diluted with deionized water. Two, 4, 6, 8, and 10 ml of the above solution were placed in five 10-ml volumetric flasks and diluted with deionized water. The concentration of promethazine hydrochloride was 120, 240, 360, 480, and 600 μg/ml, respectively.

Standard Curve of Promethazine Hydrochloride in Water—One milliliter of each standard solution was placed in a 12-ml centrifuge tube and to each tube was added 1.0 ml of the internal standard and 0.3 ml of 5 *N* NaOH. The centrifuge tube was mixed thoroughly with a vortex mixer for 30 sec. Then 4.0 ml of *n*-hexane was added to the tube and the tube placed on the vortex mixer for 1 min. The mixture was centrifuged at 2000 rpm for 2 min. Three microliters of the hexane layer was injected directly into the GC.

Standard Curve of Promethazine Hydrochloride in Polyethylene Glycol Vehicle—The procedures were the same as for the determination of promethazine hydrochloride in water, except for the addition of 0.1 ml of the polyethylene glycol vehicle solution to each centrifuge tube prior to extraction. This volume of solution represents the amount of each of the excipients in each polyethylene glycol suppository after the suppository has been dissolved for analytical purposes. This procedure compares with the extraction of promethazine hydrochloride from a suppository.

Thermal Degradation of Promethazine Hydrochloride—To test the validity of the assay for promethazine in the presence of its degradation products, the thermal degradation of promethazine hydrochloride in aqueous solution was performed. Promethazine hydrochloride, 5 g, was dissolved in 100 ml of water; oxygen was then bubbled through the solution for 30 min. The solution was placed in a screw-capped light-proof amber bottle saturated with oxygen and kept at 65° for 5 days. The mixture was cooled, made alkaline with 1 *N* NaOH, and extracted with methylene chloride. The aqueous layer was acidified with 1 *N* H_2SO_4 and extracted with methylene chloride (5).

Both organic phases were evaporated to dryness in the dark under a nitrogen stream to afford a solid residue. Approximately 100 mg of the residue was dissolved in 2 ml of dichloromethane. A total of 9 μl was applied to a silica gel G.F. TLC plate[4], (0.25 mm, 5 × 20 cm) and chromatographed in the dark (acetone–6*N* ammonia; 100:2).

The solvent was evaporated and the plate was placed under a short-wavelength UV light for visualization. The spots were scraped individually and placed in a conical centrifuge tube with a glass stopper. One milliliter of dichloromethane was added to each tube and the mixture was agitated with a vortex mixer for ~1 min. The tube was centrifuged and the supernatant was transferred to a small test tube and evaporated to dryness under a nitrogen stream. The residue was dissolved with 1 ml of methanol. One microliter of this solution was injected into the GC.

To investigate the influence of pH, 40 ml of 0.05% promethazine hydrochloride in Sörensen citrate buffer solutions (pH 2.98, 3.94, and 5.12) was placed in 100-ml light-proof amber volumetric flasks and kept at temperatures of 60, 70, 80, and 90°, accurate to within ±0.2°, in a thermostatically controlled oil bath. A solution containing 0.1% of EDTA [tetrasodium(ethylenedinitrilo)tetraacetate] was added to the promethazine buffer solutions before heating. The solutions were adjusted to the same ionic strength ($\mu = 0.2$) with potassium chloride. The pH of the solutions was measured at the beginning and at the end of the heating periods. Then 1 ml of the test solution was withdrawn from the flasks, immediately cooled, and analyzed as previously described. These samples were not chromatographed by TLC. Immedately after the sample was withdrawn from the volumetric flask, the flask was recharged with a stream of oxygen in order to maintain excess oxygen tension.

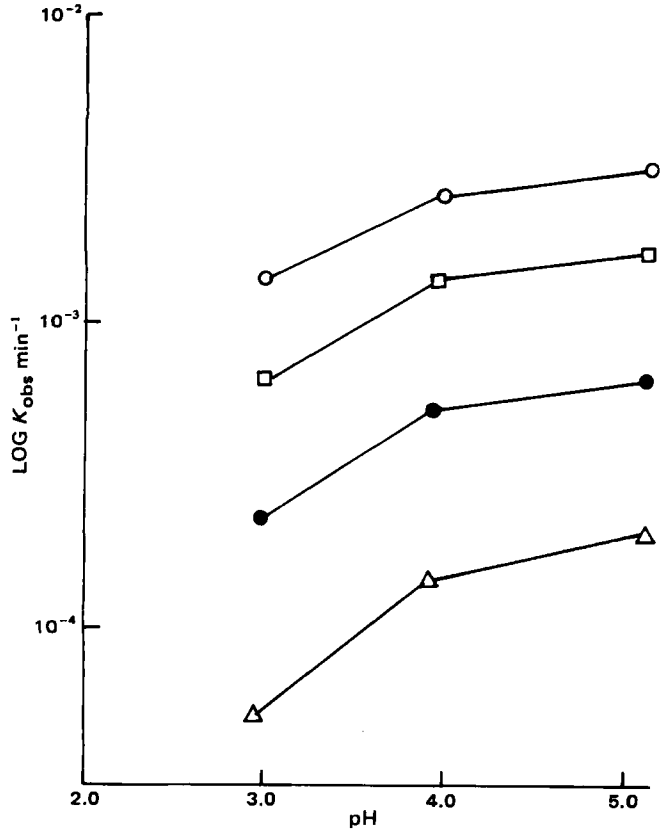

Figure 2—*Influence of pH on the thermal degradation rates of promethazine hydrochloride. Key:* (△) *60°*, (●) *70°*, (□) *80°, and* (○) *90°.*

Table II—Regression Coefficients for Promethazine Hydrochloride Standard in Water

Regression Coefficients	With Polyethylene Glycol	Without Polyethylene Glycol

R	0.998	0.998

Photolytic Degradation of Promethazine Hydrochloride—Promethazine hydrochloride (0.3% w/v) was dissolved in water. The solution was placed in a quartz reactor tube[9], length 43 cm, 2.6-cm o.d. and 2.4-cm i.d., which was equipped with a water cooling tube, 1.2-cm o.d. and exposed to UV light (300 nm) by means of a photolytic reactor[8] at 10° for 74 hr.

Following the exposure time, 70 ml of the solution was freeze-dried. The residue was dissolved in 7 ml of methanol. Fifty microliters of the solution was applied to a silica gel G.F. TLC plate (0.25 mm, 10 × 20 cm^2) and chromatographed using acetone–methanol–6 *N* NH_3 (140:60:1) as the mobile phase.

The solvent was evaporated and the plate was placed under a short wavelength UV light for visualization. The GC specimen was prepared

[a] k_{obs}. [b] Data in the parentheses represent the standard deviations.

as described under *Thermal Degradation of Promethazine HCl.* One microliter of solution was injected into the GC.

One hundred milliliters of 0.05% promethazine hydrochloride–Sörensen buffer solutions (pH 2.93, 3.94, and 5.12) was placed in quartz reactor tubes as described above and exposed to UV light (330 nm) by means of a photolytic reactor at 30 ± 5°. EDTA 0.1% was added to the promethazine–buffer solutions and the ionic strength adjusted to μ = 0.2 with potassium chloride. The pH of the solutions was measured at the beginning and at the end of the exposure periods. Periodically, 1 ml of test solution was withdrawn from the flasks, immediately cooled, and analyzed as previously described.

RESULTS AND DISCUSSION

Promethazine and promazine gave retention times of 8.5 and 10.0 min, respectively (see Fig. 1). Blank vehicle extracts yielded no interferences as illustrated in the same figure.

Quantitation of promethazine hydrochloride in water was obtained from a standard curve in which the peak height ratio (promethazine hydrochloride–promazine hydrochloride) was plotted against the promethazine hydrochloride concentration. The results are shown in Table I. There is a linear relationship between peak height ratio of promethazine hydrochloride to promazine hydrochloride and the concentration of promethazine hydrochloride in water over the range of 120–600 μg/ml. The least-squares regression equation for the curve is $y = 0.0023x + 0.0256$ and the correlation coefficient is 0.998. The results of nine replicate assays carried out over several days indicate that the assay method has adequate precision. The coefficients of variation of the assays are 1.4 and 1.1% in the presence and absence of polyethylene glycol vehicle.

The results of the quantitation of promethazine hydrochloride in water in the presence of polyethylene glycol vehicles are shown in Table I. There is a linear relationship between peak height ratio of promethazine hydrochloride to promazine hydrochloride and the concentration of promethazine hydrochloride with polyethylene glycol vehicle over the range of 120–480 μg/ml. The least-squares regression equation is $y = 0.0025x - 0.0133$, and the correlation coefficient is 0.998.

The regression fits of promethazine hydrochloride standard in water with and without polyethylene glycol vehicles are shown in Table II. The slope and intercept of the standard curves with and without polyethylene glycol vehicles were not significantly different (F test, $p > 0.05$).

The thermally degraded promethazine hydrochloride solution was separated with the TLC system previously described. Seven spots with R_f values of 0.0, 0.10, 0.16, 0.41, 0.57, 0.64, and 0.73, visualized under UV light, were obtained. The R_f value of promethazine was 0.4 which was confirmed with pure promethazine applied on the same TLC plate. The extracts of each spot were injected into the GC. None of the spots present in the TLC system interfered with the GLC procedure for promethazine and promazine. Only spots with R_f values of 0.73 and 0.41 showed significant peaks in the GC with retention times of 5.99 and 7.39 min, respectively.

Table IV—Photolytic Degradation of Promethazine Hydrochloride at Different pH, at 30°

Degradation, hr	% of Promethazine Hydrochloride Remaining					
	pH 2.98		pH 3.94		pH 5.12	
0	100.0	100.0	100.0	100.0	100.0	100.0
0.5	82.4	84.3	85.0	—	85.9	87.5
1.0	81.1	81.2	83.7	—	81.4	85.0
2.0	78.2	79.2	—	—	79.5	81.8
3.0	—	—	74.9	69.8	—	—
4.0	72.7	75.5	—	—	73.8	74.5
7.0	63.8	66.4	67.3	54.8	65.2	63.5
12.0	51.7	54.2	53.8	42.4	55.3	53.3
24.0	27.7	32.7	30.7	27.9	36.1	31.8
36.0	10.7	15.2	13.0	6.4	20.2	14.6
48.0	1.6	4.0	3.1	0.73	8.8	4.1

The degradation of promethazine hydrochloride from pH 2.98 to 5.12 followed pseudo first-order kinetics at constant pH, temperature, and ionic strength. Linear semilogarithmic plots of percent of promethazine hydrochloride remaining *versus* time in three different pH-value buffer solutions at 60, 70, 80, and 90° were obtained. The pseudo first-order rate constants, k_{obs}, for each pH value at four different temperatures are given in Table III.

Arrhenius plots were constructed and found to be straight lines as illustrated in Fig. 2. From the slopes of the lines, the apparent activation energies of the thermal degradation reactions at pH 2.98, 3.94, and 5.12 were calculated to be 6601, 5888, 5570 cal/mole, respectively.

The influence of pH on degradation rate of promethazine hydrochloride is shown in Fig. 3. The rate constant increased with increasing pH in this experimental range.

The photolytically degraded promethazine hydrochloride was separated by the TLC system previously described. Five spots, R_f 0.81, 0.58, 0.52, 0.44, and 0.00, were obtained. Only the spot with R_f 0.44, which represents promethazine, gave a good response by GC. None of the other spots interfered with the GLC procedure for promethazine and promazine.

The photolytic degradation rate of promethazine hydrochloride was studied in three buffer solutions (pH 2.98, 3.94, *and* 5.12). The results are shown in Table IV. No linear relationship could be found from the logarithmic percent of promethazine remaining *versus* time plots at three different pH values at 30°. The photolytic degradation of promethazine hydrochloride under intense UV light did not follow simple kinetics. These results are in agreement with a previous report (6).

In summary, a GLC method with an organic phase extraction was developed and is being used to specifically determine promethazine hydrochloride in polyethylene glycol suppositories undergoing stability testing.

Aspects of the Chemical Stability of Mitomycin and Porfiromycin in Acidic Solution

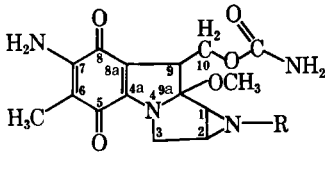
W. J. M. UNDERBERG * **and H. LINGEMAN**

Received August 11, 1981 from the *Pharmaceutical Laboratory, Department of Analytical Pharmacy, State University of Utrecht, Catharijnesingel 60, 3511 GH Utrecht, The Netherlands.* Accepted for publication May 28, 1982.

Abstract □ Aspects of the degradations of mitomycin and porfiromycin were studied. The initial degradation processes of the compounds in an acidic medium were investigated. Influences of pH, buffers, and other additives such as halogenides and dioctyl sodium sulfosuccinate [sodium 1,4-bis(2-ethylhexyl)sulfosuccinate] were studied. The hydrogen ion catalyzes the degradation of both the uncharged and the protonated species. Anions also promote the degradation of the compounds in an acidic medium. Rate constants for all of the catalytic reactions could be determined. From the pH profiles, after correction for buffer influences, accurate pK_a values for the aziridine nitrogens could be obtained. The protective influence of the dioctyl sulfosuccinate ion could be explained. From the data obtained a plausible mechanism for the initial acidic degradation reactions was developed.

Keyphrases □ Degradation—in acidic solution, mitomycin, porfiromycin, pK_a determination □ Mitomycin—degradation in acidic solution, rate constant determination □ Porfiromycin—degradation in acidic solution, rate constant determination □ pK_a determination—aziridine nitrogens, mitomycin, porfiromycin

Mitomycin (I), an important antitumor antibiotic originating from *Streptomyces caespitosus* (1), appears to be unstable in solution. Several investigators studied aspects of the degradation of I and of porfiromycin (II), which differs from I only in the methyl substituent on the aziridine nitrogen. The structure of I was determined by studying the products resulting from acid hydrolysis (2). Knowledge of the physicochemical properties of I was expanded by synthesizing derivatives and studying the acid hydrolysis (3). From these studies it became obvious that the degradations of I and II follow very complex patterns. Suggestions that the aziridine ring opens prior to the rapid solvolytic cleavage of the 9α-methoxyl group in acidic media have been reported previously (2). The degradation of II was studied using spectrophotometric techniques and the appearance of 12 different products during acidic and alkaline hydrolysis were reported (4, 5), in general agreement with other sources (2, 3). Kinetic data of the degradative transformation of II were also presented (4, 5). Most degradation processes followed pseudo first-order kinetics.



I: R = H
II: R = CH_3

The acid catalysis of the degradation of protonated II has a smaller specific rate constant than that of the nonprotonated species. This results in an estimated pK_a of the protonated group in II of ~1.5. Furthermore, a study of the influence of buffers on the degradation led to the conclusion that buffer components such as $H_2PO_4^-$ and CH_3COOH have catalytic effects on certain steps in the degradation process. Indications were found for both general acid and specific acid–base catalysis on the solvolysis. The primary degradation mechanism is the hydrolysis of the fused aziridine ring, while mild alkaline conditions lead to substitution of the amino group attached to the quinoid ring by a hydroxyl group (5). Although data on the degradation of I and II appear in the literature, no systematic study is available which includes the influences of external factors (ionic strength, buffer components, *etc.*). The present study was undertaken to elucidate the mechanism of the primary degradation of I and II in acidic solution and to establish the influence of a number of external factors on the process.

During previous work on the physicochemical properties of I and II, pK_a values of several groups in the molecules were determined (6). To complete the prototropic characterization of the compounds, more accurate pK_a values of the aziridine nitrogen in I and II will be presented as a result of a closer look at the kinetics of the initial acidic degradation.

EXPERIMENTAL

Materials—Mitomycin[1] and porfiromycin[2] were used as supplied. All other materials were reagent grade, and deionized water was used throughout.

Methods—*Kinetic Studies of I and II Degradation*—The appropriate compound was dissolved in methanol to a concentration of 3×10^{-3} *M*. This was used as the stock solution. For stability tests the stock solution was diluted with buffer solutions at the appropriate pH (after addition of any other additive) to a concentration of 3×10^{-5} *M*. The degradation of the compound was observed by monitoring the absorbance at 363 nm (4, 5) using an absorption spectrophotometer with an automatic cell positioner[3]. All measurements were performed at 40 ± 1°. The pH was measured with a glass-reference electrode using an appropriate pH meter[4]. Absorption spectra were taken with a recording spectrophotometer[5]. Calculation of the first-order rate constants were done using plots of log (percent undegraded compound) *versus* time.

Assay of I and II—The percentage of remaining I and II during the degradation, in general, can be calculated from the relationship:

$$\% \text{ undegraded I or II} = \frac{A_t}{A_0} \times 100 \qquad \text{(Eq. 1)}$$

in which A_t is the absorbance at 363 nm at time t and A_0 is the absorbance at time zero. Equation 1 is valid when the resulting absorbance (A_∞) after completion of the degradation approaches zero.

In the case of the degradation of the mitosanes, however, the primary degradation product in acidic medium has an absorbance that is not negligible. Exact measurements of this absorbance revealed A_∞ to be 0.18

[a] Table values expressed as k_{obs} in sec^{-1} (log k_{obs}).

A_0. A first approximation of the exact percentage of the undegraded compound was made by modifying Eq. 1 to:

$$\% \text{ undegraded I or II} = \frac{A_t - \left(\frac{A_0 - A_t}{A_0}\right) A_\infty}{A_0} \times 100 \qquad \text{(Eq. 2)}$$

Four repetitions of this approximation led to a refinement of Eq. 2 to:

$$\% \text{ undegraded I or II} = \frac{A_0^3(A_t - A_\infty)(A_0 + A_\infty) + A_0(A_0 + A_\infty)(A_t - A_\infty)A_\infty^2 + A_t(A_\infty^4)}{A_0^5} \times 100 \qquad \text{(Eq. 3)}$$

which has been used to calculate the percent undegraded compound as a function of time.

RESULTS

Degradation Kinetics of I and II in Acidic Solution—Studies on the stability of II in both acidic and alkaline solutions have been published (4, 5). The structures of a number of degradation products were determined, the pK_a of the aziridine nitrogen was estimated, rate constants for the degradation in acidic as well as in alkaline solution were determined, and an overall mechanism for the degradation of II was described. The influence of several buffer components on the degradation was also studied. Some data on the kinetics of the degradation of I have been published (7). So far no data are available on the mechanism of the initial degradation steps of I and II nor the nature of the buffer influences on the degradation. Determination of the exact pH profiles for the degradation of both compounds should lead to more accurate pK_a values for the aziridine nitrogen.

Standard Deviation in k_{obs}—The standard deviation in the overall rate constant, k_{obs}, for degradation of I in an acid solution was determined at pH 3.0 and buffer concentration 10^{-2} M total phosphate. At 40 ± 1° all experiments showed linearity between log [I] and time, indicating the process as pseudo first-order, which is in agreement with the literature data (2, 4, 5, 7). The value of k_{obs} (and log k_{obs}) and the standard deviation, calculated from 16 observations, is $2.3 \pm 0.1 \times 10^{-3}$ sec^{-1} (and −2.64 ± 0.03).

pH Profiles for the I and II Degradations—In unbuffered solutions pH values of partially degraded solutions of I will differ from the starting value due to the disappearance of a compound with pK_a ~1.5 and the appearance of a compound with pK_a ~7. Starting at pH 5.0, for instance, a solution with [I] = 3.0×10^{-5} M, after being kept at 40° for 4 hr, has a pH of 5.6. This pH shift results in a change in k_{obs}.

To keep the pH constant during the process, buffer solutions of various compositions and concentrations were used. Since the influences of buffer components were already recognized (4), accurate pH profiles for the degradation processes have to be corrected for these influences. For these corrections k_{obs} was determined at several H_0/pH values. In the H_0/pH region <3.0, the pH was adjusted with perchloric acid and various concentrations of sodium biphosphate were added. At pH values >3.0, the pH was adjusted using various concentrations of sodium biphosphate and dropwise addition of either dilute perchloric acid or sodium hydroxide. At each pH value and each phosphate concentration, k_{obs} was determined (Table I). From Table I it becomes clear that at pH <2 the influence of phosphate or phosphoric acid on k_{obs} becomes negligible. At pH >3 this influence is very important.

Considering the reported value for the pK_a of I of ~1.5 (4) at pH >3.5, the compound should be exclusively in the unprotonated form. In that case k_{obs} can be expressed as:

$$k_{obs} = k_0^I + k_H^I[H^+] + k_{buffer}^I[\text{buffer}] \qquad \text{(Eq. 4)}$$

Table II—Rate Constants for Catalyzed Degradation Reactions of I and II at 40°

[a] The [I] and [II] was 3×10^{-5} *M*; the dioctyl sodium sulfosuccinate concentration was 1.25×10^{-3} *M*. [b] In the presence of dioctyl sodium sulfosuccinate. [c] In the absence of dioctyl sodium sulfosuccinate.

where k_0^I is the first-order rate constant for degradation in water only, k_H^I is the second-order rate constant for proton-catalyzed degradation of the unprotonated compound, and $[H^+]$ is the hydrogen ion concentration. The third term of Eq. 4 is the sum of several terms representing the products of the second-order rate constants for the degradation catalyzed by each of the buffer components and the concentrations of these buffer components. For each pH this sum can be written as the product of an overall second-order rate constant (k'_{buffer}) and the total buffer concentration ([buffer]), expressed in terms of total phosphate concentration. For each pH the pseudo first-order rate constant for [buffer] = 0, $k' = k_0^I + k_H^I[H^+]$, can be calculated as the intercept from a plot of k_{obs} *versus* [buffer]. The corrected pH profiles for the degradation of I and II are obtained by plotting log k' *versus* pH. These pH profiles are given in Fig. 1. The curves show log k' *versus* pH to have a slope of negative unity both in the regions $H_0 < -0.8$ and pH >3.2 indicating that there is specific proton catalysis on the degradation of the protonated as well as the unprotonated forms of I and II, while, in agreement with other findings (4), the rate constants for the proton-catalyzed degradation of the protonated species are smaller than those for the uncharged forms. This phenomenon permits the calculation of the pK_a for the aziridine nitrogen in I and II from the curves of Fig. 1. For I this pK_a turns out to be 1.19, while for II the pK_a is 0.91. The latter pK_a value is substantially different from a previously determined value (4), probably due to the corrections made for the buffer influence.

The difference between the pK_a values for I and II are in agreement with the usual differences in pK_a between secondary and tertiary amines (8). It is also possible to calculate the second-order rate constants $k_H^{IH^+}$ and k_H^I of the proton-catalyzed degradation of the protonated and unprotonated species. $k_H^{IH^+}$ can be determined from:

$$k_{obs} = k_0^{IH^+} + k_H^{IH^+}[H^+] \quad \text{(Eq. 5)}$$

which is valid at $H_0 < -0.8$. At these high acidities $k_0^{IH^+} \ll k_H^{IH^+}[H^+]$ so that Eq. 5 simplifies to:

$$k_{obs} = k_H^{IH^+}[H^+] \quad \text{(Eq. 6)}$$

from which $k_H^{IH^+}$ can be calculated.

The rate constants k_H^I for the proton-catalyzed degradation of uncharged I, and k_0^I for the degradation in water only, can be determined from the expression:

$$k' = k_0^I + k_H^I[H^+] \quad \text{(Eq. 7)}$$

obtained from Eq. 4 after correction for buffer influences. Equation 7 is valid at pH > 3.2, where $[IH^+]$ becomes extremely small. A plot of k' *versus* $[H^+]$ yields a straight line with slope k_H^I and intercept k_0^I. The values of $k_H^{IH^+}$, $k_H^{IIH^+}$, k_H^I, k_H^{II}, k_0^I and k_0^{II} are listed in Table II.

Influence of Buffer Components—From the previous experiments it is obvious that biphosphate ions have a positive influence on the degradation of I and II. Other sources (4, 5) also indicate positive catalytic effects of buffer components on the degradation rate of II in an acid solution. A catalytic effect of undissociated acetic acid has been suggested (5), although the experimental conditions also permit the conclusion that acetate ions produced the catalytic effect. Even though the aziridine ring is not attacked by the strong nucleophilic hydroxyl ion (4), it is known that other nucleophiles, such as chloride, promote the opening of the aziridine ring in an acidic medium (9–11) with the formation of chlorinated degradation products. Therefore, it appears that the acetate ion, rather than acetic acid, promotes the cleavage of the aziridine group. The influence of uncharged acetic acid on the degradation of I is studied at pH 2.77, where acetic acid exists almost completely in the uncharged form while $[IH^+] \ll [I]$. All other conditions kept constant, variation of the [acetic acid] is the only factor influencing k_{obs}, according to Eq. 4. However, no significant changes in k_{obs} occur on changing the [acetic acid] from 10^{-2} *M* to 5×10^{-1} *M*. The term k'_{buffer}[buffer] in that case must be zero and, consequently, $k^I_{acetic\ acid}$ must be zero.

Influences of the phosphate buffer components of pH 1–5 can be determined as follows. Phosphoric acid has pK_{a1} 2.16 and pK_{a2} 7.21. In the region of 4.2 < pH < 5.2, phosphate buffers almost exclusively consist of $H_2PO_4^-$ ions, so that this ion can be considered the only potential catalytic species. In this case, Eq. 4 can be rewritten as:

$$k_{obs} = k_0^I + k_H^I[H^+] + k^I_{H_2PO_4^-}[H_2PO_4^-] \quad \text{(Eq. 8)}$$

and a plot of k_{obs} *versus* $[H_2PO_4^-]$ yields a straight line with slope $k^I_{H_2PO_4^-}$.

The influence of molecular H_3PO_4 on the degradation of both the protonated and the unprotonated species as well as the influence of $H_2PO_4^-$ on the degradation of the protonated species also can be established. To achieve this, solutions of pH 3.2–3.6 were prepared using different concentrations of total phosphate. At a given pH $[H_3PO_4] = (f)$ [total phosphate], and $[H_2PO_4^-] = (1 - f)$ [total phosphate], where f is the fraction remaining. For each pH, f can be calculated using the Henderson–Hasselbach equation.

In the chosen pH region, $[IH^+]$ approaches zero and $[I] \approx [I_{total}]$. In this case Eq. 4 is valid with one adjustment. The value of $k^{IH^+}_{H_2PO_4^-}$ can be expected to be large due to the electrostatic attraction between ions of opposite charge. The term $k^{IH^+}_{H_2PO_4^-}[H_2PO_4^-][IH^+]$ cannot be neglected *a priori*, but has to be included in Eq. 4, which then must be written as:

$$k_{obs} = k_0^I + k_H^I[H^+] + k^I_{H_3PO_4}[H_3PO_4] + k^I_{H_2PO_4^-}[H_2PO_4^-] + k^{IH^+}_{H_2PO_4^-}[H_2PO_4^-]\frac{[IH^+]}{[I_{total}]} \quad \text{(Eq. 9)}$$

or, after rearrangement:

$$k_{obs} = k_0^I + k_H^I[H^+] + [\text{total phosphate}]\left(f\,k^I_{H_3PO_4} + (1-f)k^I_{H_2PO_4^-} + \frac{[IH^+]}{[I_{total}]}(1-f)k^{IH^+}_{H_2PO_4^-}\right) \quad \text{(Eq. 10)}$$

Graphical treatment of Eq. 10 by plotting k_{obs} *versus* [total phosphate] yields a straight line with slope:

$$\left(f\,k^I_{H_3PO_4} + (1-f)k^I_{H_2PO_4^-} + \frac{[IH^+]}{[I_{total}]}(1-f)k^{IH^+}_{H_2PO_4^-}\right)$$

Knowing the value of $k^I_{H_2PO_4^-}$, combination of the slopes of plots at two different pH values in the region 3.2–3.6 yields both the values of $k^I_{H_3PO_4}$ and $k^{IH^+}_{H_2PO_4^-}$. These values, and the corresponding rate constants for II, are listed in Table II.

Influence of Other Additives—The influence of halide ions has been established by adding various concentrations of the appropriate sodium salts to solutions of I at pH 4.2, while $[H_2PO_4^-]$ is kept constant at 10^{-2}

Table IV—Enthalpy of Activation (ΔH) for the Initial Degradation of I at Various pH Values in the Acidic Region

H_0/pH	ΔH, kJ/mole
−1.02	78
1.34	77
2.06	77
2.80	76
3.66	73
4.74	76
5.02	68
5.20	68

M. In this case one extra term involving the influence of the halide ion has to be included in Eq. 8, yielding (in the case of chloride):

$$k_{obs} = k_0^I + k_H^I[H^+] + k_{H_2PO_4^-}^I[H_2PO_4^-] + k_{Cl^-}^I[Cl^-] \quad \text{(Eq. 11)}$$

From Eq. 11 $k_{Cl^-}^I$ can be obtained either by plotting k_{obs} *versus* $[Cl^-]$, yielding a straight line with slope $k_{Cl^-}^I$, or by calculating the rate constant using various concentrations of Cl^- and the data in Table II. The specific rate constants for the halide ions and sulfate are also listed in this table.

The influence of ion-pairing compounds like dioctyl sodium sulfosuccinate [sodium 1,4-bis(2-ethylhexyl)sulfosuccinate] on the degradation was also studied. At various pH, using phosphate buffers with [total phosphate] = 10^{-2} M, dioctyl sodium sulfosuccinate was added to a concentration of 1.25×10^{-3} M while [I] and [II] both were adjusted to 3×10^{-5} M. In Table III the pseudo first-order rate constants, k_{obs}, for degradation in the presence as well as in the absence of dioctyl sulfosuccinate anion at various pH are listed. The data illustrate clearly the decrease in k_{obs} on addition of dioctyl sodium sulfosuccinate in the pH range of 1.5 to 4.0. The decrease for II is even more dramatic than for I, probably due to the more lipophilic properties of II and, hence, the increased lipophilic character of the ion pair. At pH > 5 the inhibition of the degradation disappears, probably because the compounds are virtually not in the protonated form at these acidities. At pH < 1.5 the inhibition also vanishes due to protonation of the sulfonic acid group and subsequent loss of the ion-pairing properties of the additive.

Influence of Temperature—The temperature influence on the degradation rate is determined using an Arrhenius plot from:

$$\ln k_{obs} = \ln A + \frac{\Delta H}{RT} \quad \text{(Eq. 12)}$$

in which A represents the frequency factor, ΔH the enthalpy of activation, R the gas constant, and T the temperature in °Kelvin. The ΔH values for the initial degradation of I at various pH values in the acidic region, using buffers with [total phosphate] = 10^{-2} M, are listed in Table IV. ΔH appears to be constant in the region pH < 5 and the values are in good agreement with those previously obtained (7). In the region pH > 5 ΔH tends to lower somewhat. This may be an indication that other degradation processes occur in this pH region.

DISCUSSION

Although an overall scheme for the degradation of II (4) and mechanisms for the aziridine ring to open in deuteroacetic acid (2) and in water (12) have been published, no explanation for the very fast opening of the aziridine ring in I and II in comparison with other aziridines (13) has been given. The first degradation products of I and II isolated after degradation in an acidic solution appear to be compounds III and IV, respectively, where the 9-methoxyl group is cleaved, the 9=9a double bond is formed, and the aziridine ring is opened to form a 2-amino-1-hydroxy compound. The C-9 carbon carries two hetero atoms, N-4 and the methoxy oxygen, and this configuration can be considered as an amino–acetal. It is most likely that, as in acetal hydrolysis, cleavage of the methoxyl group starts with protonation of the oxygen, followed by the formation of methanol and a 9a-carbenium ion (14). Protonation of the aziridine nitrogen destabilizes this carbenium ion, which explains the shape of the pH profiles of the degradation. Subsequent deprotonation of C-9 results in the formation of the 9=9a double bond. It has been indicated that compound IV exists in one isomer, always with the hydroxyl group at C-1 and the amino group at C-2 (15). The positions of the groups at C-1 and C-2 are mainly *cis*-orientated. Thus the cleavage of the aziridine ring starts with protonation of the nitrogen followed by opening of the ring and formation of a carbenium ion at C-1.

The stability of this carbenium ion is enhanced by the presence of the 9=9a double bond. This serves as an explanation for the stereospecificity of the reaction with respect to the positions of the hydroxyl and amino groups. Attack of a water molecule on the carbenium ion is the final step in the reaction. The major compound formed is *cis*-2,7-diamino-1-hydroxymitosene (15) which indicates that this attack must have some stereospecificity. An explanation for the predominant existence of the *cis*-isomer might be the possibility of the existence of weak hydrogen bonds between the attacking water molecule and the ester oxygen of the

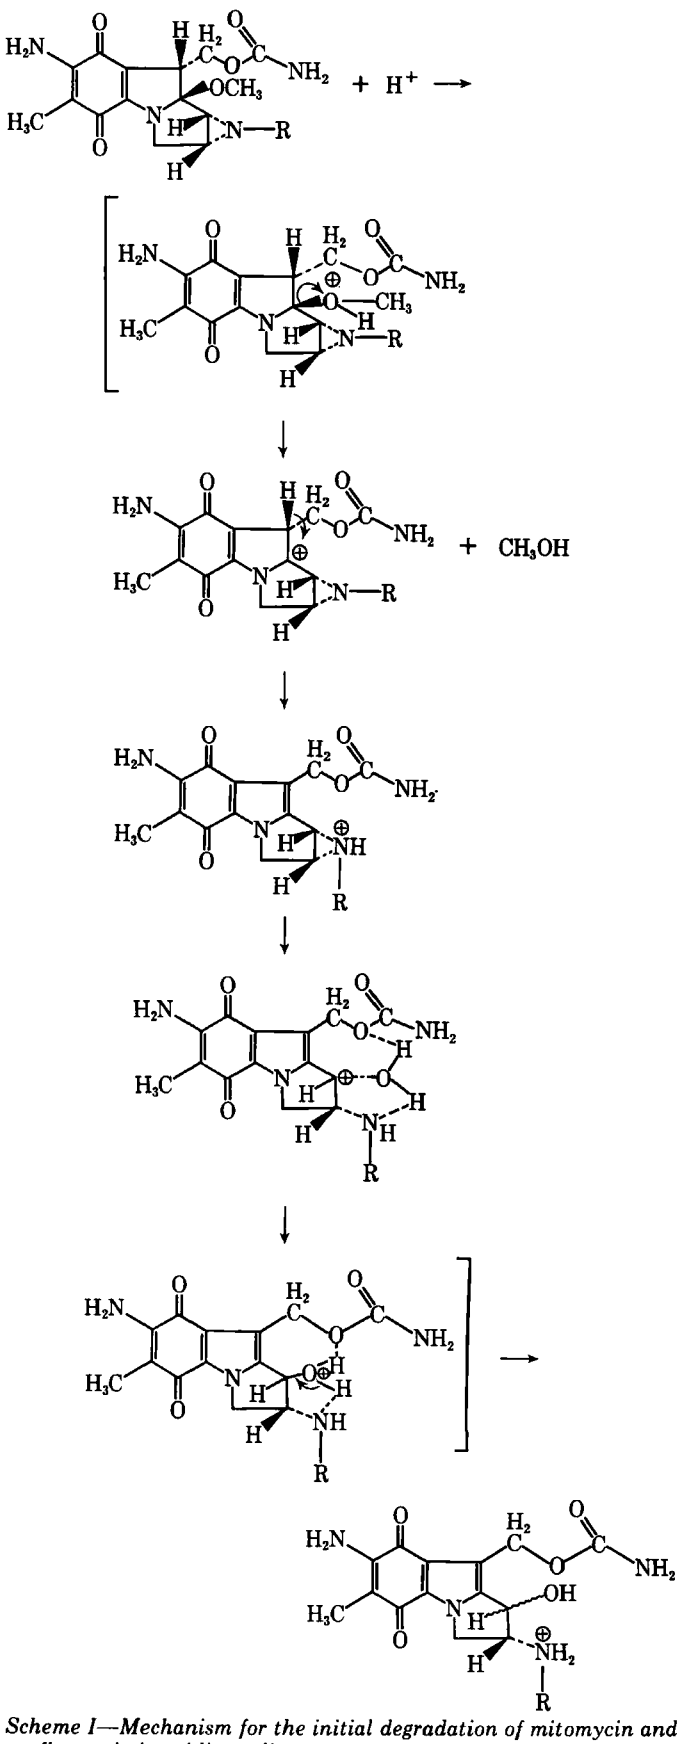

Scheme I—Mechanism for the initial degradation of mitomycin and profiromycin in acidic medium.

9-methylcarbamoyl and 2-amino groups. In the entire process the formation of the 9a-carbenium ion is the rate-determining step (16). The mechanism for acid degradation is presented in Scheme I.

The decrease in k_{obs} on addition of dioctyl sodium sulfosuccinate in the pH region 1.5–4 can be explained by the formation of an ion pair between the dioctyl sulfosuccinate anion and the protonated species. The octyl groups of the anion sterically hinder the protonation and subsequent cleavage of the 9a-methoxyl group. At pH > 5 the degree of protonation of the aziridine group, with pK_a 1.19 and 0.91 for I and II, respectively, becomes so small that the ion pair is virtually nonexistent and, hence, the protective influence of the additive disappears.

All buffer components and other additives with a negative charge had positive influences on the rate constants. Uncharged buffer species, such as phosphoric acid, acetic acid, and citric acid did not have a catalytic influence on the degradation processes, which differs from previous findings (4). The influences of the anions on the degradation can be associated with influences on the aziridine ring opening. In general, nucleophiles have negative effects on the stability of the aziridine moiety (9–11, 14). Degradation products containing chlorine, for instance, were isolated (9, 10). Analogues of these products in the degradation of mitosanes like I and II, however, could not be isolated. All rate constants for catalysis by singly charged anions are of the same order of magnitude (Table II) with the exception of dihydrogen citrate (H_2-citrate$^-$). This suggests a general ionic strength effect rather than more specific anionic catalysis on the degradation. In the case of H_2-citrate$^-$ the rate constant is determined at pH 3.06, being the pK_{a1} of citric acid. Although the pK_{a2} of this acid is 4.74, the [H-citrate^{2-}] was considered to be negligible for the calculation of $k_{H_2\text{-citrate}^-}$ of I and II. This is of course very approximate and makes the reported values of $k_{H_2\text{-citrate}^-}$ only a rough estimate which most likely includes an influence of H-citrate^{2-}. The rate constants for the $H_2PO_4^-$-catalyzed degradation of the protonated species are several orders of magnitude bigger than the other constants. This must be due to the fact that as a result of the opposite charges of the reacting species, electrostatic attraction causes a much greater possibility of encounter and, therefore, reaction.

Determination of pK_a Values of Some Prototropic Functions in Mitomycin and Porfiromycin

W. J. M. UNDERBERG ˣ and H. LINGEMAN

Received August 11, 1981 from the *Pharmaceutical Laboratory, Department of Analytical Pharmacy, State University of Utrecht, Catharijnesingel 60, 3511 GH Utrecht, The Netherlands.* Accepted for publication May 28, 1982.

Abstract □ The prototropic properties of mitomycin and porfiromycin were studied. pK_a values for two potentially basic groups and one acidic function could be established by titration. The kinetics of the tautomerization preceding the prototropic reaction in an alkaline medium were investigated.

Keyphrases □ Prototropic properties—mitomycin, porfiromycin, alkaline medium, kinetics of tautomerization □ Mitomycin—prototropic properties, pK_a determinations, tautomerization kinetics □ Porfiromycin—prototropic properties, pK_a determinations, tautomerization kinetics □ Kinetics—tautomerization, mitomycin, porfiromycin

Mitomycin (I), originating from *Streptomyces caespitosus* (1), is an important antitumor antibiotic. The compound is unstable in solution and aspects of the degradation of I and porfiromycin (II), which differs from I only in the methyl substituent on the aziridine nitrogen, have been studied by several investigators (2–6). For a systematic study of the chemistry of these compounds, including the stability, it is necessary to characterize the prototropic properties of I and II.

From the structures it can be seen that the compounds have several basic groups, including the aziridine nitrogen, the N-4 nitrogen, and the 7-amino function. In the literature data are available only on the protonation of one basic function; these data are either unreliable or are approximations. The pK_a of a basic group in I has been deter-

9-methylcarbamoyl and 2-amino groups. In the entire process the formation of the 9a-carbenium ion is the rate-determining step (16). The mechanism for acid degradation is presented in Scheme I.

The decrease in k_{obs} on addition of dioctyl sodium sulfosuccinate in the pH region 1.5–4 can be explained by the formation of an ion pair between the dioctyl sulfosuccinate anion and the protonated species. The octyl groups of the anion sterically hinder the protonation and subsequent cleavage of the 9a-methoxyl group. At pH > 5 the degree of protonation of the aziridine group, with pK_a 1.19 and 0.91 for I and II, respectively, becomes so small that the ion pair is virtually nonexistent and, hence, the protective influence of the additive disappears.

All buffer components and other additives with a negative charge had positive influences on the rate constants. Uncharged buffer species, such as phosphoric acid, acetic acid, and citric acid did not have a catalytic influence on the degradation processes, which differs from previous findings (4). The influences of the anions on the degradation can be associated with influences on the aziridine ring opening. In general, nucleophiles have negative effects on the stability of the aziridine moiety (9–11, 14). Degradation products containing chlorine, for instance, were isolated (9, 10). Analogues of these products in the degradation of mitosanes like I and II, however, could not be isolated. All rate constants for catalysis by singly charged anions are of the same order of magnitude (Table II) with the exception of dihydrogen citrate (H_2-citrate$^-$). This suggests a general ionic strength effect rather than more specific anionic catalysis on the degradation. In the case of H_2-citrate$^-$ the rate constant is determined at pH 3.06, being the pK_{a1} of citric acid. Although the pK_{a2} of this acid is 4.74, the [H-citrate^{2-}] was considered to be negligible for the calculation of $k_{H_2\text{-citrate}^-}$ of I and II. This is of course very approximate and makes the reported values of $k_{H_2\text{-citrate}^-}$ only a rough estimate which most likely includes an influence of H-citrate^{2-}. The rate constants for the $H_2PO_4^-$-catalyzed degradation of the protonated species are several orders of magnitude bigger than the other constants. This must be due to the fact that as a result of the opposite charges of the reacting species, electrostatic attraction causes a much greater possibility of encounter and, therefore, reaction.

Determination of pK_a Values of Some Prototropic Functions in Mitomycin and Porfiromycin

W. J. M. UNDERBERG ˣ and H. LINGEMAN

Received August 11, 1981 from the *Pharmaceutical Laboratory, Department of Analytical Pharmacy, State University of Utrecht, Catharijnesingel 60, 3511 GH Utrecht, The Netherlands.* Accepted for publication May 28, 1982.

Abstract □ The prototropic properties of mitomycin and porfiromycin were studied. pK_a values for two potentially basic groups and one acidic function could be established by titration. The kinetics of the tautomerization preceding the prototropic reaction in an alkaline medium were investigated.

Keyphrases □ Prototropic properties—mitomycin, porfiromycin, alkaline medium, kinetics of tautomerization □ Mitomycin—prototropic properties, pK_a determinations, tautomerization kinetics □ Porfiromycin—prototropic properties, pK_a determinations, tautomerization kinetics □ Kinetics—tautomerization, mitomycin, porfiromycin

Mitomycin (I), originating from *Streptomyces caespitosus* (1), is an important antitumor antibiotic. The compound is unstable in solution and aspects of the degradation of I and porfiromycin (II), which differs from I only in the methyl substituent on the aziridine nitrogen, have been studied by several investigators (2–6). For a systematic study of the chemistry of these compounds, including the stability, it is necessary to characterize the prototropic properties of I and II.

From the structures it can be seen that the compounds have several basic groups, including the aziridine nitrogen, the N-4 nitrogen, and the 7-amino function. In the literature data are available only on the protonation of one basic function; these data are either unreliable or are approximations. The pK_a of a basic group in I has been deter-

mined by titration with acid to be 3.2 (2), but I in acid medium is very unstable. By a kinetic model, the pK_a of the protonated group in II was estimated to be ~1.5, and it was suggested that this pK_a could be assigned to the aziridine nitrogen in II (4). The present study was undertaken to determine the pK_a values of the other prototropic groups in I and II in an attempt to complete the prototropic characterization of the compounds.

EXPERIMENTAL

Materials—Mitomycin[1] and porfiromycin[2] were used as supplied. All other materials were reagent grade, and deionized water was used throughout.

Methods—*Measurement of pK_a Values*—For the measurement of pK_a values of III and IV, the compounds were titrated with perchloric acid while the absorbances at 268 and 310 nm, respectively, were monitored as a function of acidity (pH or H_0). The pK_a values of the basic groups were calculated from these relationships. For the determination of the pK_a of the acidic function in I, a titration of the compound with sodium hydroxide was performed while monitoring the absorbance at 363 nm. Up to pH 13 the degradation was too slow to interfere with the

Table I—First-Order Rate Constants for Deprotonation (k_{dep}) and half-lives ($t_{1/2}$) of I at Various pH Values at 40°

pH	k_{dep}, sec^{-1}	$t_{1/2}$, sec
12.0	$8.2 \pm 0.5 \times 10^{-2}$	8.5 ± 0.6
12.7	$5.5 \pm 0.6 \times 10^{-2}$	13 ± 1
13.0	$3.4 \pm 0.4 \times 10^{-2}$	20 ± 1
13.4	$2.8 \pm 0.2 \times 10^{-2}$	25 ± 1

change in absorbance due to deprotonation. At pH values >13 a continuous decrease in absorbance at 363 nm was observed, which was due to degradation of the compound in a strong alkaline solution (5). Consequently, the absorbance–pH relationship could only be obtained incompletely and A_{I^-}, the absorbance of the deprotonated species, was not measurable. In terms of absorbance, the acidity constant K_a can be expressed as

$$K_a = \frac{(A_I - A)[H^+]}{(A - A_{I^-})} \qquad \text{(Eq. 1)}$$

where A_I is the absorbance of uncharged I, A_{I^-} is the absorbance of deprotonated I, and A is the absorbance of the solution at a given pH. Equation 1 can be rearranged to:

$$(A_I - A)[H^+] = K_a(A - K_a)(A_{I^-}) \qquad \text{(Eq. 2)}$$

A plot of A *versus* $(A_I - A)[H^+]$ yields a straight line with slope K_a and intercept $(-K_a)(A_{I^-})$, thus leading to the values of K_a, pK_a, and A_{I^-}.

Kinetic Study of I Deprotonation—For the study of the kinetics of I deprotonation, several solutions in water with concentrations varying from 1.5×10^{-6} *M* to 1.8×10^{-4} *M* were prepared. After mixing equal volumes of sodium hydroxide solutions at various pH with the aforementioned solutions of I, the decrease in absorbance at 363 nm was monitored using stopped-flow equipment[3]. Measurements of pH were done with a glass-reference electrode using an appropriate pH meter[4]. Rate constants and half-lives were calculated using plots of log (percent uncharged I) *versus* time.

RESULTS

The basic groups of I and II, apart from the aziridine function, are the N-4 nitrogen and the 7-amino group. The pK_a of the N-4 nitrogen can be established by titration of an analogue of I (III) with perchloric acid. The absorption spectrum of uncharged III has a maximum at 280 nm. During protonation this maximum shifts to 268 nm, with an increase in absorptivity. Thus it is possible to follow the degree of protonation by monitoring the absorption at 268 nm, provided that no degradation occurs during the process. A solution of III in 1 *M* perchloric acid (H_0 −0.3) does not show changes in absorptivity at 268 nm when kept at 40° for 1 hr. The relation between the absorbance at 268 nm and the acidity, expressed in terms of the Hammett acidity scale, is shown in Fig. 1. The pK_a of the nitrogen in III calculated from this relationship is −1.2 and almost certainly this value can also be assigned to the N-4 nitrogen in I and II.

The spectra of I and II quickly change in acidic solution due to cleavage of the 9a-methoxyl group and opening of the aziridine ring, thus producing degradation products IV and V, respectively. Compound IV in acidic solution also undergoes degradative processes but at a much slower rate (4, 5). The pK_a of the 2-amino group in the compound is ~7 (5) so that degradations of I and II at pH 5 result in the formation of protonated IV and V, respectively. These compounds are sufficiently stable to be titrated with perchloric acid to establish the pK_a of the other basic functions. The absorption maximum of IV in the neutral form is 310 nm; on acidification this maximum disappears.

The absorption band at ~250 nm changes in shape while the absorp-

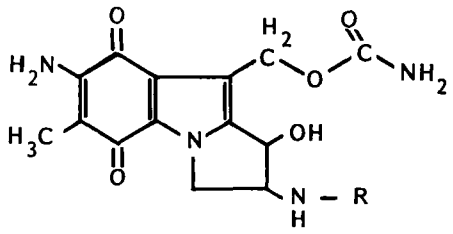
[4] Metrohm Herisau E516 Titriskop pH meter.



IV: R = H
V: R = CH_3

tivity increases. The pK_a can be established from the relation between the absorbance at 310 nm and the acidity (Fig. 1). The more acidic part of the curve is unreliable because degradation of IV in that acidity region cannot be neglected. The pH of the protonated group, determined using Eq. 2 after rearrangement, appears to be −1.3. The N-4 nitrogen in IV is much less basic than in I due to the introduction of the 9=9a double bond, as can be seen from indole (pK_a −2.5) (7). Therefore, the pK_a of IV can be assigned to the 7-amino group. From the similarity in the structures of I, II, and IV, it becomes clear that this pK_a value also can be assigned to the 7-amino groups in I and II.

The absorption spectrum of I does not change between pH 6 and 10. At pH < 6 a gradual shift in spectrum with time takes place due to degradation, while at pH > 10.5 a sudden change in the absorption spectrum occurs. The maximum at 363 nm (pH 10.5) shifts to 295 nm (pH 13.0) with a sharp decrease in absorptivity. This shift could be due to a configurative change in the molecule, stabilized by deprotonation of I at the higher pH. The pK_a of the acidic function can be determined from the relation between the absorbance at 363 nm and the pH, provided no degradation occurs. Although alkaline degradation of II takes place at rates comparable to those in acidic medium (4), the stability of I in the region pH < 13 is sufficiently high to permit the determination of the pK_a using Eq. 2. The curve cannot be completed because the degradation of I cannot be neglected at pH > 13. The relation between the absorbance at 363 nm and pH, represented in Fig. 2, leads to the calculation of a pK_a of 12.44.

Although the change in absorptivity with change in pH at 363 nm in the region of pH > 10.4 is very rapid, it is not instrumentally instantaneous. The kinetic process involved can be monitored using stopped-flow equipment. These experiments indicate that the reaction follows (pseudo) first-order kinetics. The relation between the apparent rate constant for deprotonation, k_{dep}, and the pH is presented in Table I. The influence of the initial [I] at a pH > pK_a and at a pH < pK_a is listed in Table II. The data of Table I show that k_{dep} decreases with increasing pH.

At pH 13.0, k_{dep} is independent of [I] in the chosen concentration range but at pH 12.0 an increase of [I] causes a decrease in k_{dep} as presented in Table II. The data obtained at pH > pK_a indicate that the process follows first-order kinetics, but the data at pH < pK_a contradict such a conclusion. A plausible explanation for the results is that aggregation occurs between the molecules at higher concentrations of uncharged I. At pH < pK_a the majority of the molecules appears in the protonated neutral form so that in this pH region the possibility of aggregation will be relatively high. Other properties, such as the absorptivity, may change also with an increase in the concentration. In Fig. 3 the relation between the absorbance at 290 nm and [I] at pH 10 is presented. The curve shows linearity between absorbance and concentration up to 1.5×10^{-5} *M* I. At concentrations over 2.0×10^{-5} *M* the absorbance is no longer linear with [I], which means that the chromophore is influenced by interaction with other molecules.

Table II—Rate Constants (k_{dep}) and Half-Lives ($t_{1/2}$) of I at Various Concentrations at Two Different pH Values at 40°

pH	[I] × 10^5 *M*	k_{dep}, sec^{-1}	$t_{1/2}$, sec
12.0	1.5	8.9×10^{-2}	7.7
	3.0	8.7×10^{-2}	8.0
	6.0	6.8×10^{-2}	10.2
	9.0	4.7×10^{-2}	15.0
13.0	3.0	3.5×10^{-2}	20.0
	6.0	3.3×10^{-2}	21.0
	9.0	3.4×10^{-2}	20.5

DISCUSSION

The data presented above lead to the following conclusions on the prototropic nature of I and II. Both compounds have three basic functions:

1. The 7-amino group, with pK_{a1} − 1.3 at room temperature.
2. The N-4 nitrogen, with pK_{a2} −1.2 at room temperature. It is possible that pK_{a2} is a little higher, due to mesomeric effects of the 7-amino group.
3. The aziridine nitrogen, with pK_{a3} ~1.5 (4).

The compounds also have an acidic function, with pK_{a4} 12.44 at room temperature. This pK_a must be assigned to the 7-amino–quinoid moiety in the compounds, as is shown in Scheme I. The keto–enol tautomerism in this structure is responsible for the spectral changes, while the absorbance value marks the position of the equilibrium. The tautomeric reaction has a finite rate.

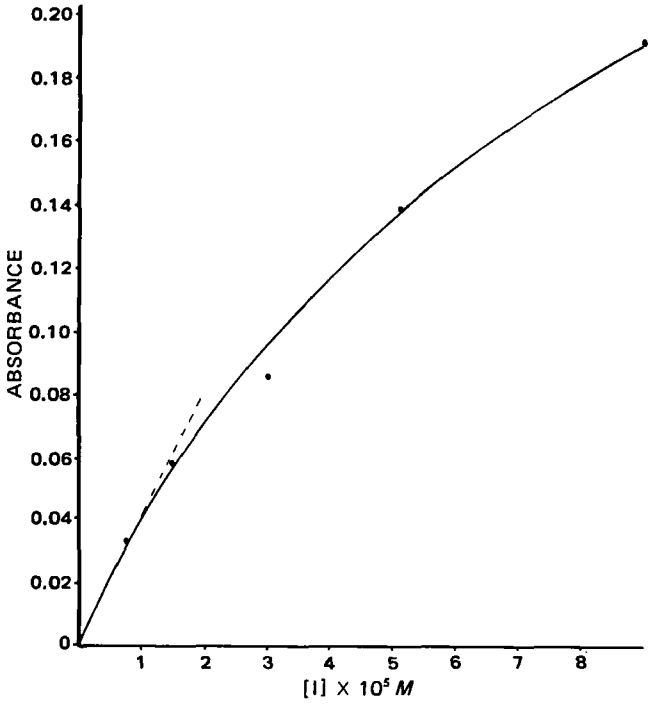


Figure 3—*Relation between absorbance at 290 nm and mitomycin concentration at pH 10 at room temperature.*

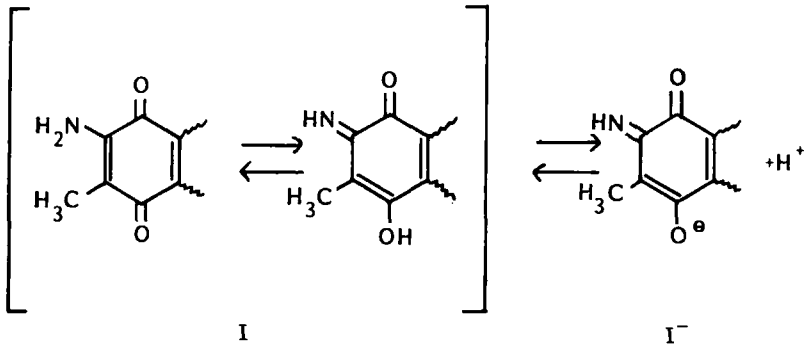

I I⁻

Scheme I—Deprotonation of mitomycin, Key: I, uncharged mitomycin; I⁻, deprotonated mitomycin.

The degree of protonation (α) of the reaction can be written as:

$$\alpha = \frac{[I^-]}{[I + I^-]} = \frac{K_a}{K_a + [H^+]} \quad \text{(Eq. 3)}$$

The overall rate constant k_{dep} consists of:

$$k_{dep} = k_t^{I}[I] + k_t^{I^-}[I^-] = k_t^{I}(1 - \alpha) + k_t^{I^-}(\alpha) \quad \text{(Eq. 4)}$$

where k_t^{I} is the rate constant for tautomerization of uncharged I and $k_t^{I^-}$ the same constant for I^- (deprotonated I). Combination of Eqs. 3 and 4 yields:

$$k_{dep} = (k_t^{I})\frac{[H^+]}{K_a + [H^+]} + (k_t^{I^-})\frac{K_a}{K_a + [H^+]} \quad \text{(Eq. 5)}$$

Assuming that, with respect to tautomerization, I is much more active than I^- or that $k_t^{I} \gg k_t^{I^-}$, it is obvious that on increasing the pH, the term $k_t^{I}([H^+]/K_a + [H^+])$ will decrease more rapidly than the term $k_t^{I^-}([H^+]/K_a + [H^+])$ increases which will result in a lower value of k_{dep}. Under the assumption that $k_t^{I^-}$ is so small that the term $k_t^{I^-}(K_a/K_a + [H^+])$ can be neglected, Eq. 5 permits the estimation of k_t^{I}, using pK_a 12.44 of the acidic group and the values for k_{dep} listed in Table I. The calculation results in a k_t^{I} of $1.4 \pm 0.4 \times 10^{-1}$ sec^{-1} and a half-life ($t_{1/2}$) of the process of 5.0 sec. The explanation of the concentration dependence of k_{dep} at $pH < pK_a$ lies in the aforementioned possibility of interaction between the 7-amino–quinoid moieties on increasing [I]. The occurrence of these interactions is shown by the changes in absorptivity at higher [I] at pH 10, where the compound is present almost completely in the uncharged form. The decrease in the molar absorptivity must be due to interaction of the 7-amino–quinoid chromophores. Since the tautomerization occurs in the same functional group in the molecule, this interaction most likely also causes a decrease in the overall rate constant k_{dep} at higher [I] at pH 12.0, as the concentration of the unaffected 7-amino–quinoidal function decreases due to this interaction. Equation 4 shows that on decreasing [I] and $[I^-]$, k_{dep} will decrease. At pH 13.0, where $[I] = 0.2\ [I + I^-]$, the concentration of uncharged I in the range studied is too low for aggregation to occur.

NOTES

Tissue Distribution of [^{14}C]Bretylium Tosylate in Rats

AVRAHAM YACOBI ˣ, BURDE L. KAMATH *, CHII-MING LAI, and HERMAN F. STAMPFLI

Received March 2, 1982, from the *Department of Pharmaceutical Development, Research and Development Department, American Critical Care, McGaw Park, IL 60085.* Accepted for publication April 21, 1982. *Present address: Xavier University, New Orleans, LA 70125.

Abstract □ The distribution of [^{14}C]bretylium tosylate in the body and the relationship between tissue and plasma concentrations was determined following intravenous administration of the drug to Charles River rats. The renal excretion of bretylium was rapid in rats and follows an active process. On the average, 50% of the administered dose was excreted in the urine within 1 hr. In the postequilibrium phase, the plasma concentration declined with a half-life of 5 hr. Bretylium concentrations in all tissues, except the heart, declined rapidly according to a triexponential equation. The liver and kidney bretylium concentrations declined in parallel to the plasma concentration with mean tissue–plasma concentration ratios of 6.04 and 12.3, respectively, in the β phase. However, the concentration of bretylium in the heart increased gradually and peaked at 2 hr, with a tissue–plasma concentration ratio of 121, which, in turn, declined to a value of >60 after 8 hr. The data indicated that (*a*) bretylium is rapidly distributed into the liver and kidney immediately after reaching the systemic circulation; (*b*) the distribution into the heart occurs at a slower rate compared with the other organs, and the drug has a high affinity to the myocardium; and (*c*) since the heart is the site of action and there is no direct correlation between the concentrations in myocardium and plasma, the antiarrhythmic effect of bretylium may not be related to the plasma concentration.

Keyphrases □ Bretylium tosylate—^{14}C-labeled, tissue distribution, rats, plasma, renal excretion □ Distribution—tissue, [^{14}C]bretylium tosylate in the rat, plasma, renal excretion □ Excretion, renal—tissue distribution of [^{14}C]bretylium tosylate in rats, plasma

Bretylium tosylate is a quaternary ammonium salt given in the treatment of cardiac arrhythmia. It suppresses *ventricular* fibrillation within minutes of intravenous infusion (1). The suppression of ventricular tachycardia, however, developed more slowly, usually 20–120 min after intramuscular administration of 4 mg/kg of bretylium tosylate in humans (2). The effect of bretylium in the intact heart was shown to be biphasic, with an initial transient increase in blood pressure and heart rate followed by an opposite and more prolonged depression of these same

0022-3549/83/0500-0556$01.00/0

The degree of protonation (α) of the reaction can be written as:

$$\alpha = \frac{[I^-]}{[I + I^-]} = \frac{K_a}{K_a + [H^+]} \quad \text{(Eq. 3)}$$

The overall rate constant k_{dep} consists of:

$$k_{dep} = k_t^{I}[I] + k_t^{I^-}[I^-] = k_t^{I}(1 - \alpha) + k_t^{I^-}(\alpha) \quad \text{(Eq. 4)}$$

where k_t^{I} is the rate constant for tautomerization of uncharged I and $k_t^{I^-}$ the same constant for I^- (deprotonated I). Combination of Eqs. 3 and 4 yields:

$$k_{dep} = (k_t^{I})\frac{[H^+]}{K_a + [H^+]} + (k_t^{I^-})\frac{K_a}{K_a + [H^+]} \quad \text{(Eq. 5)}$$

Assuming that, with respect to tautomerization, I is much more active than I^- or that $k_t^{I} \gg k_t^{I^-}$, it is obvious that on increasing the pH, the term $k_t^{I}([H^+]/K_a + [H^+])$ will decrease more rapidly than the term $k_t^{I^-}([H^+]/K_a + [H^+])$ increases which will result in a lower value of k_{dep}. Under the assumption that $k_t^{I^-}$ is so small that the term $k_t^{I^-}(K_a/K_a + [H^+])$ can be neglected, Eq. 5 permits the estimation of k_t^{I}, using pK_a 12.44 of the acidic group and the values for k_{dep} listed in Table I. The calculation results in a k_t^{I} of $1.4 \pm 0.4 \times 10^{-1}$ sec^{-1} and a half-life ($t_{1/2}$) of the process of 5.0 sec. The explanation of the concentration dependence of k_{dep} at $pH < pK_a$ lies in the aforementioned possibility of interaction between the 7-amino–quinoid moieties on increasing [I]. The occurrence of these interactions is shown by the changes in absorptivity at higher [I] at pH 10, where the compound is present almost completely in the uncharged form. The decrease in the molar absorptivity must be due to interaction of the 7-amino–quinoid chromophores. Since the tautomerization occurs in the same functional group in the molecule, this interaction most likely also causes a decrease in the overall rate constant k_{dep} at higher [I] at pH 12.0, as the concentration of the unaffected 7-amino–quinoidal function decreases due to this interaction. Equation 4 shows that on decreasing [I] and $[I^-]$, k_{dep} will decrease. At pH 13.0, where $[I] = 0.2\ [I + I^-]$, the concentration of uncharged I in the range studied is too low for aggregation to occur.

Received March 2, 1982, from the *Department of Pharmaceutical Development, Research and Development Department, American Critical Care, McGaw Park, IL 60085.* Accepted for publication April 21, 1982. *Present address: Xavier University, New Orleans, LA 70125.

Abstract □ The distribution of [^{14}C]bretylium tosylate in the body and the relationship between tissue and plasma concentrations was determined following intravenous administration of the drug to Charles River rats. The renal excretion of bretylium was rapid in rats and follows an active process. On the average, 50% of the administered dose was excreted in the urine within 1 hr. In the postequilibrium phase, the plasma concentration declined with a half-life of 5 hr. Bretylium concentrations in all tissues, except the heart, declined rapidly according to a triexponential equation. The liver and kidney bretylium concentrations declined in parallel to the plasma concentration with mean tissue–plasma concentration ratios of 6.04 and 12.3, respectively, in the β phase. However, the concentration of bretylium in the heart increased gradually and peaked at 2 hr, with a tissue–plasma concentration ratio of 121, which, in turn, declined to a value of >60 after 8 hr. The data indicated that (*a*) bretylium is rapidly distributed into the liver and kidney immediately after reaching the systemic circulation; (*b*) the distribution into the heart occurs at a slower rate compared with the other organs, and the drug has a high affinity to the myocardium; and (*c*) since the heart is the site of action and there is no direct correlation between the concentrations in myocardium and plasma, the antiarrhythmic effect of bretylium may not be related to the plasma concentration.

Keyphrases □ Bretylium tosylate—^{14}C-labeled, tissue distribution, rats, plasma, renal excretion □ Distribution—tissue, [^{14}C]bretylium tosylate in the rat, plasma, renal excretion □ Excretion, renal—tissue distribution of [^{14}C]bretylium tosylate in rats, plasma

Bretylium tosylate is a quaternary ammonium salt given in the treatment of cardiac arrhythmia. It suppresses *ventricular* fibrillation within minutes of intravenous infusion (1). The suppression of ventricular tachycardia, however, developed more slowly, usually 20–120 min after intramuscular administration of 4 mg/kg of bretylium tosylate in humans (2). The effect of bretylium in the intact heart was shown to be biphasic, with an initial transient increase in blood pressure and heart rate followed by an opposite and more prolonged depression of these same

0022-3549/83/0500-0556$01.00/0

Table I—Tissue to Plasma Concentration Ratios of [^{14}C]Bretylium Tosylate During 8 hr After Drug Administration

Hours	Tissue–Plasma Concentration Ratio						
	Serum	Red Blood Cells[a]	Liver	Kidney	Heart	Lung	Spleen
0.1[b]	1.13	1.23	14.1	25.8	3.23	3.23	3.19
0.5	1.30	1.41	19.2	27.0	16.1	—	—
1.0[b]	1.69	1.82	16.2	19.3	57.9	16.4	6.86
2.0	1.80	2.05	11.6	17.3	121	—	—
4.0[b]	2.19	2.56	6.69	14.6	94.1	9.78	11.6
6.0[b]	1.86	1.89	4.69	9.48	60.0	7.93	8.07
8.0	2.16	2.48	6.74	12.8	69.5	—	—
Mean[c] β-Phase Ratio	2.07	2.31	6.04	12.3	74.5	8.86	9.84

[a] Amount of drug in red blood cells was determined by amount in whole blood minus amount in plasma, where amount in plasma was determined by plasma concentration [volume of whole blood (1-hematocrit)] and red blood cell concentration was determined by amount/(volume of whole blood × hematocrit). [b] Average ratios from eight rats for red blood cells, liver, kidney, and heart. Lung and spleen values and all other values are average ratios from four animals. [c] The β-phase ratio was calculated from the linear portion of each curve, *i.e.*, 4–8 hr for each tissue.

parameters (3). These effects probably can be related to the time course of bretylium in the heart following administration.

In dogs, the myocardial drug concentrations were shown to increase gradually with a peak occurring at 1.5–6.0 hr after intravenous administrations of 2 and 6 mg/kg of bretylium tosylate (4). The myocardial tissue–serum concentration ratio increased progressively to 6.4–12.6 after 12 hr. In the same study, the antifibrillatory effect was correlated with the myocardial levels of bretylium but not with serum concentrations.

Pharmacokinetic studies in humans and animals showed that bretylium has a very large volume of distribution (5–7), indicating a high affinity to tissues. Over 80% of a 5-mg/kg bretylium tosylate dose is excreted unchanged in urine by active renal excretion processes (5, 8). The average biologic half-life of bretylium is 8 hr in four normal subjects (5) and becomes longer in patients with impaired renal function (9).

In rats, the biologic half-life of bretylium is ~5 hr (7). An average of 94–95% of a 10-mg/kg [^{14}C]bretylium tosylate dose was recovered in 72 hr, of which 63–65% was excreted unchanged in urine and 30–31% was eliminated unchanged in feces following intravenous administration, indicating a pronounced biliary excretion (7, 8). The purpose of the present investigation was to examine the distribution pattern of bretylium in well-perfused organs, heart, kidney, and liver, which are the sites of pharmacological action, urinary excretion, and possible metabolism of the drug, respectively, in rats.

EXPERIMENTAL

This investigation was carried out in two separate studies and on two different occasions. For this purpose, male Charles River rats[1] weighing 300–400 g were used. Custom synthesized [^{14}C]bretylium tosylate labeled on the benzylic carbons (specific activity 27.3 μCi/mg, 99% purity) was purchased[2]. The labeled compound was mixed with cold bretylium tosylate[3] and dissolved in saline to produce the injection solution (5 mg/ml, specific activity 3.4 μCi/mg).

In study I, 28 animals were divided into seven groups of four rats each. Each animal received an intravenous injection of 10 mg/kg of [^{14}C]-bretylium tosylate, and each group was then sacrificed by portal vein bleeding under ether anesthesia at the following times postdose: 0.1, 0.5, 1, 2, 4, 6, and 8 hr. A portion of the blood sample was centrifuged in a tube containing dry heparin to separate plasma, and the other was allowed to coagulate and then centrifuged to collect serum. An aliquot of the heparinized blood was dispensed into a combustion cup for total radioactivity determination in whole blood. The kidneys, liver, and heart were removed.

Study II was performed approximately 1 year later. Sixteen animals were divided into four groups of four rats each. Each animal received an intravenous dose of 10 mg/kg of [^{14}C]bretylium tosylate, and each group was sacrificed at 0.1, 1, 4, and 6 hr after drug administration, in the same manner as described in study I. Again plasma and serum were collected. In addition, the kidneys, liver, heart, lung, spleen, and carcass were separated. All urine and feces were quantitatively collected.

Immediately after removal, the organs were sliced, blotted in tissue paper to remove excess blood, and weighed. To the organs, the carcass, and the feces, a saline solution 3–5 times the weight of the organ was added. The mixture was then homogenized[4] in an ice bath. An aliquot of each homogenate was frozen and stored until assay.

The total radioactivity in plasma was determined on an aliquot of the samples in a liquid scintillation counter[5]. The total radioactivity in blood, tissue, and feces samples was measured after combustion[6] of an aliquot of the homogenate and by counting the processed samples in the liquid scintillation counter.

Mean concentrations (n = 4) in the plasma, serum, red blood cells, liver, and kidney were fitted to a triexponential equation, describing a typical three-compartment open model (7). The concentration in the heart did not follow the same model. The terminal disposition half-life in myocardium was calculated using nonlinear regression analysis of a concentration–time profile. The data from study II served for comparative purposes and allowed the estimation of the percentage of the dose remaining in various tissues at different times.

RESULTS AND DISCUSSION

Figure 1 depicts the time course of bretylium concentration in various tissues and plasma following intravenous administration. The data from study II, which was conducted 1 year later, were included. There was good agreement between the two sets of data showing an excellent reproducibility of bretylium pharmacokinetics in rats. The concentrations in plasma, liver, and kidney declined in parallel following intravenous administration. In general, there was a good fit of these data to a triexponential equation describing a three-compartment open model. The elimination half-life was 5 hr, which is in agreement with the previously reported value (7).

The accumulation and decline of bretylium concentration in the heart resembled the simulated time course of the drug in a deep peripheral compartment. There was a gradual accumulation of bretylium in the heart with a peak occurring between 1–2 hr. This was also in agreement with reported data of a gradual increase in myocardium levels in dogs (4). The postdistribution decline in bretylium heart concentration, however, was more rapid, showing a biological half-life of 2 hr. It is possible that this decline is part of a redistribution process and that concentration in the heart will eventually reach an equilibrium with that in plasma and other tissues. Since the heart is the site of action, it will be expected that antiarrhythmic action will be associated with the concentration of bretylium in myocardium. Such a situation has been demonstrated in

dogs (4). Thus, until an equilibrium between myocardium and plasma levels is attained, it is reasonable to presume that there will be no correlation between antiarrhythmic action and plasma concentration.

Table I summarizes the tissue–plasma concentration ratios of serum, red blood cells, liver, kidney, heart, lung, and spleen tissues. Table II summarizes the tissue content of bretylium and amounts excreted in urine and feces at various times after intravenous administration of the drug. For both liver and kidney, which are well-perfused organs, the tissue–plasma concentration ratios were generally higher in the distribution phase than in the β-phase during which average equilibrium ratios of 6.0 and 12.3, respectively, were attained. At 0.1 hr, the uptake of bretylium in liver and kidney accounted for 30 and 12% of the dose, respectively. The high bretylium levels in the liver and kidney are consistent with rapid elimination of the drug: ~50% of the dose is excreted in urine within 1 hr (Table II). Also, it was demonstrated that about one-third of the dose is eliminated by biliary excretion (7).

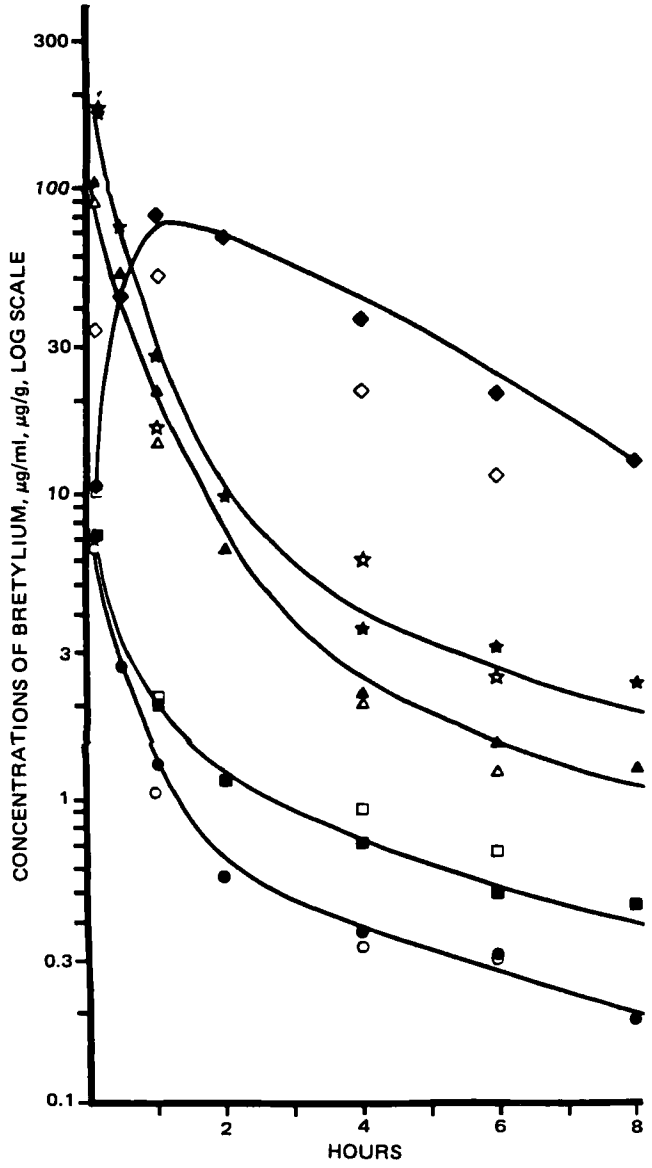

Figure 1—*Mean concentration of bretylium in plasma (●), red blood cells (■), liver (▲), kidney (★), and heart (◆) following intravenous administration of 10 mg/kg of bretylium tosylate in rats in study I. The respective open symbols represent data from study II. Observations from study I were used to fit the curves. Each data point is the mean of four animals. The concentrations in plasma are given by micrograms per milliliter and in the tissues by micrograms per gram.*

The heart–plasma concentration ratio increased gradually from 3.2 after 6 min to 121 after 2 hr. The peak ratio was much higher than that observed in dogs, 12.6 (4), which may indicate species differences in bretylium distribution in the body. There was a sharp decrease in the heart–plasma concentration ratio to ~70 after 8 hr. The continuous change in this concentration ratio is consistent with delayed onset of action followed by a more prolonged effect reported in the literature (3, 4).

For red blood cells, there was also a gradual increase in the tissue–plasma concentration ratios, reaching an apparent equilibrium within 2 hr. This gradual change in the ratios may be due to either a rapid distribution in the cells followed by a slower rate of redistribution in the plasma or a gradual uptake of the drug by red blood cells against a concentration gradient, presumably by an active mechanism. The lung and spleen uptake also appears to be similar to that in the red blood cells. An active tissue uptake has been suggested for another quaternary ammonium compound, tetraethylammonium, in rats (10).

One hr after drug administration, on the average, 49 and 1.3% of the dose were found in the urine and feces, respectively. The initial rapid elimination of bretylium in urine was proportional to the initial high plasma concentration (8 μg/ml). When the plasma level declined to <1 μg/ml (1 hr postdose), the urinary excretion accounted for ~12% over the next 5 hr. Of the remaining 50% at 1 hr, 10% of the dose could be accounted for in blood, kidney, liver, heart, spleen, and lung tissues. This amount decreased significantly to ~2% at 6 hr following administration.

The data suggest that at 1 hr, 39% of the dose should be accounted for in the carcass. The overall radioactivity determined in the carcass, however, was equivalent to 50% of the dose. Unfortunately, the homogenization of the carcass was later found to be incomplete, and it is possible that this caused the overestimation of body content by nearly 10%. Previously, it was shown that about one-third of the bretylium dose was eliminated in the feces through biliary excretion (7). Therefore, the intestines might contain most of the radioactivity which was found in the carcass.

In summary, bretylium is rapidly distributed in the body, particularly in the liver and kidneys, immediately after reaching systemic circulation. While there was a parallel decline in liver, kidney, and plasma concentrations of bretylium, there was no correlation between plasma and heart concentrations of the drug. The heart showed high affinity to bretylium with its concentration reaching 120 times plasma levels within 2 hr. These data suggest that the antiarrhythmic effect of bretylium will not be associated with its plasma concentrations until an equilibrium between heart and plasma concentrations is attained.

Room Temperature Phosphorescence Determination of Propranolol in Pharmaceutical Formulations

RICKY P. BATEH and J. D. WINEFORDNER ˣ

Received March 19, 1982, from the *University of Florida, Department of Chemistry, Gainesville, FL 32611.* Accepted for publication May 14, 1982.

Abstract □ A simple, rapid, and specific procedure was used for the analysis of propranolol in pharmaceutical formulations. The procedure consisted of dissolving (diluting) appropriate quantities of preparations and standards in (with) a 2 *M* potassium iodide–ethanol–water solution, spotting 5 μl of each resultant solution onto filter paper disks, determining the phosphorescence intensities at room temperature, and comparing sample signal levels with those of standards. The results indicated that room temperature phosphorescence can be easily applied to the analysis of pharmaceutical formulations where active ingredients are generally contained in a wide variety of matrices.

Keyphrases □ Propranolol—room temperature phosphorescence determination in tablets and injections □ Phosphorescence—determination of propranolol in tablets and injections □ β-adrenergic agents—propranolol, room temperature phosphorescence determination, tablets and injections

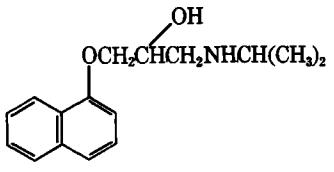
Propranolol hydrochloride, a β-adrenergic blocker, is commonly used for the treatment of nonacute hypertension, angina pectoris, and cardiac arrhythmias. With the patent on the only marketed product nearing its expiration, generic brands of propranolol will soon become available. Because generic manufacturers often use a variety of materials (diluents, binders, *etc.*) in their formulations, a specific procedure is needed for the quantitation of the active ingredient in the formulation.

The current USP procedure (1) for propranolol is cumbersome, and as a result, many pharmaceutical manufacturers are currently investigating fluorometry and high-performance liquid chromatography (HPLC) for quality control.

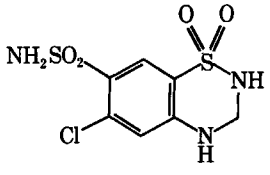
The present report describes a simple and rapid room temperature phosphorescence procedure applicable to the determination of propranolol in several pharmaceutical preparations. While room temperature phosphorescence has been shown to be analytically useful, real sample applications have been limited (2, 3). Overall, room temperature phosphorescence offers good selectivity with moderate sensitivity and detection power.

EXPERIMENTAL

Reagents—Propranolol hydrochloride[1] (I) and hydrochlorothiazide[2] (II) were used as received. All pharmaceutical preparations were purchased through a local hospital pharmacy[3]. All other materials were of analytical reagent grade.



I



II

Apparatus—All room temperature phosphorescence measurements were made with a spectrophotofluorometer[4] fitted with a 150-W xenon arc lamp[5], a laboratory-constructed phosphoroscope (4) for bar, room temperature phosphorescence (5), and a potted photomultiplier tube[6]. A ratio photometer[7] supplied high voltage to the photomultiplier tube in addition to serving as a DC amplifier. All line voltages were regulated with an AC regulator[8].

Standard and Sample Preparation—A standard stock solution (400 μg/ml) was prepared by dissolving an accurately weighed portion of propranolol hydrochloride in a 2 *M* potassium iodide solution (ethanol–water, 50:50). Standard solutions (5, 10, 20, 50, 100, 200, and 300 μg/ml) were prepared daily by mixing appropriate volumes of the stock solution with the ethanolic solution. Samples were prepared for assay by dissolution–dilution in/with the ethanolic solution. For analysis of representative samples, 20 tablets were weighed and powdered with a mortar and pestle, and four portions (equivalent to 100 μg/ml of active ingredient in a total volume of 10 ml) were dissolved in the ethanolic solution. This procedure was repeated for each solid sample. For the analysis of liquid preparations, appropriate volumes (same equivalence as tablets) of the samples were diluted with the ethanolic solution. Four different test solutions were prepared for each pharmaceutical formulation; each test solution contained 100 μg/ml of active ingredient.

Procedure—Bar, room temperature phosphorescence analysis consisted of an aluminum bar, a cover plate with four holes (each ~0.64-cm diameter) and filter paper disks[9]. The filter paper disks were placed under the cover plate and the cover plate was tightened into place on the bar with four screws. Samples were spotted onto the paper disks in 5-μl vol-

Table 1—Results for the Determination of Active Ingredients in Pharmaceutical Formulations [a]

Formulation, mg Active Ingredient/ Dosage Form	Concentration Found Experimental, μg/ml[b]		Coefficient of Variation, %	Experimental Amount (mg) of Active Ingredient/ Dosage Form[c]
Propranolol	Mean	Range		
20	98	90–108	5.2	20
40	97	88–108	7.2	39
80	102	94–108	4.0	82
1 (injection 1-ml ampule)	103	94–111	4.4	1
Propranolol/Hydrochlorothiazide				
40/25	102	94–110	5.0	41
80/25	101	94–110	4.5	81

[a] All test samples were 100 μg/ml of active ingredient. [b] Calculated from 16 measurements of each of four samples. [c] Mean value calculated from 16 determinations of active ingredients in each of four weighed portions.

umes with a micropipet[10]. After spotting, the bar was slipped into the sample compartment (equipped with a phosphoroscope can with a chopping rate of 200 Hz) and the samples were allowed to dry for 7 min under a flow of dehumidified nitrogen gas (~20 liters/min). During the drying process, signals increased over a period of ~6 min at which time a plateau was reached for ~2 min. Measurements were made on this plateau. This procedure was repeated 16 times for each sample and standard. The excitation and emission wavelengths used in the analyses were 306 and 492 nm, respectively.

Quantitation—Quantitation was achieved by comparing the relative phosphorescence intensities of the samples with those of the standards. For the analyses, the linear range of the propranolol standard solutions extended from 20 to 300 μg/ml. Linear regression analysis gave the line $y = 0.725x - 7.34$ with a correlation coefficient of +0.999.

RESULTS AND DISCUSSION

The results in Table I indicate that room temperature phosphorescence can be successfully applied to the determination of propranolol in pharmaceutical preparations. Precision studies with 16 determinations of each sample and standard gave coefficients of variation between 4 and 8%. While room temperature phosphorescence is well established as a method of analysis with great selectivity, its sensitivity generally lags behind that of other techniques.

Both propranolol and hydrochlorothiazide phosphoresce when 2 *M* NaOH is added to the ethanolic solution. However, because of the weaker phosphorescence signal of hydrochlorothiazide, it was not possible for it to be quantitatively determined in the prepared mixtures. Only propranolol appeared to phosphoresce when present in the ethanolic solution, and this component was analyzed in the prepared mixtures. Figures 1 and 2 illustrate what is spectrally observed without and with the addition of 2 *M* NaOH to the ethanolic solutions.

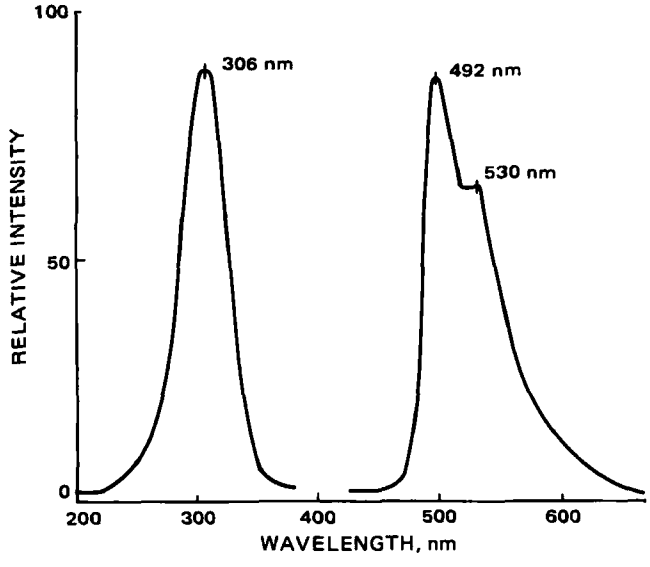

Figure 1—*Room temperature phosphorescence obtained from 100-μg/ml propranolol hydrochloride in an ethanolic solution and from a mixture of 100-μg/ml propranolol hydrochloride and 50-μg/ml hydrochlorothiazide.*

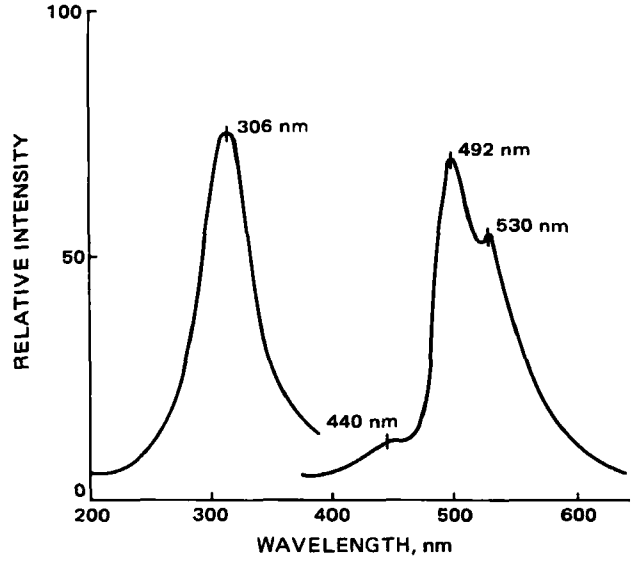

Figure 2—*Room temperature phosphorescence obtained from a mixture of 100-μg/ml propranolol hydrochloride and 50-μg/ml hydrochlorothiazide with 2 M NaOH in an ethanolic solution.*

The selectivity factor in room temperature phosphorescence was advantageous in that no compound other than propranolol appeared to phosphoresce. Because pharmaceuticals are proprietary in nature, no absolute assurance of any other species contributing to the phosphorescence of the sample can be given. It would be expected that those species in the formulations that may phosphoresce are minor constituents and are subsequently diluted when the sample is prepared for analysis. Thus, this procedure is reported to be quite simple and specific for the determination of propranolol in pharmaceutical formulations.

Convenient Method of Simultaneously Analyzing Aluminum and Magnesium in Pharmaceutical Dosage Forms Using Californium-252 Thermal Neutron Activation

ROBERT R. LANDOLT *x **and STANLEY L. HEM** ‡

Received June 19, 1981, from the *Departments of *Bionucleonics and ‡Industrial and Physical Pharmacy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication May 6, 1982.

Abstract □ A commercial antacid suspension containing aluminum hydroxide and magnesium hydroxide products was used as a model sample to study the use of a californium-252 thermal neutron activation as a method for quantifying aluminum content as well as for the simultaneous assay of aluminum and magnesium. A 3.5-μg californium-252 source was used for the activation, and the induced aluminum-28 and magnesium-27 activity was simultaneously measured by sodium iodide crystal gamma-ray spectrometry using dual single-channel analyzers and scalers. The antacid suspension was contained in a chamber designed with the unique capability of serving as the container for counting the induced radioactivity in addition to being the irradiation chamber itself. Ten replicate irradiations were performed, and the precision was compared with 10 replicate analyses of the antacid suspension using the official ethylenediaminetetraacetic acid titration method. For aluminum the precision was 1.4 *versus* 0.62% for the titration method. For the magnesium the precision was 5.3 *versus* 0.79% for the titration method. This pilot study demonstrated that use of more intense californium-252 sources, which are commonly available, would provide a method that is competitive with the ethylenediaminetetraacetic acid titration method in precision and in other aspects as well.

Keyphrases □ Californium-252—thermal neutron activation, method of simultaneously analyzing aluminum and magnesium in pharmaceutical dosage forms □ Dosage forms—method of simultaneously analyzing aluminum and magnesium using californium-252 thermal neutron activation □ Aluminum—method of anlaysis in pharmaceutical dosage forms using californium-252 thermal neutron activation □ Magnesium—method of analysis in pharmaceutical dosage forms using californium-252 thermal neutron activation

Analysis of aluminum in pharmaceutical formulations by thermal neutron activation in a reactor has been proposed (1) as an alternative to the official but somewhat cumbersome ethylenediaminetetraacetic acid titration method (2). However, limited access to reactors often makes neutron activation an uneconomical and inconvenient analysis technique. The recent availability of high intensity, relatively inexpensive, californium-252 neutron sources provides another means of analyzing pharmaceuticals for certain activable constituents. This report is a study of the feasibility of using californium-252 neutron activation analysis for aluminum quantification as well as for the simultaneous assay of aluminum and magnesium. A commercial antacid suspension containing aluminum hydroxide and magnesium hydroxide products was chosen as a typical sample for this study. However, the technique should apply to other products containing one or both of these minerals such as aluminum hydroxychloride or sterile penicillin G procaine suspension, which often is formulated with aluminum stearate.

EXPERIMENTAL

The californium-252 neutron source was in the form of a needle 5-cm long and 0.5-cm in diameter. The californium-252 content at the time of irradiation was 3.5 μg, which gave an emission rate of 8.1×10^6 neutrons/sec.

The chamber (Fig. 1) in which the suspension was contained during irradiation also had the unique capability of serving as the chamber for counting the induced radioactivity following irradiation. During irradiation the chamber was placed upright in a tank of water moderator, such that the level of the water was the same height as the level of solution in the chamber. After irradiation the californium-252 source and its surrounding plexiglass moderator sleeve were removed from the chamber. The chamber was then simply inverted and placed over a sodium iodide crystal for counting, thereby resembling a Marinelli-type counting chamber. All irradiations were for exactly 36 min, followed by a 90-sec delay, and then a 36-min count. The predominant activation reactions of aluminum and magnesium (Table I) are caused by neutrons thermalized by the water moderator and by water present in the antacid suspension.

The instrumentation required for analysis of the gamma rays emitted from the magnesium-27 and aluminum-28 can be economically assembled by using dual single-channel analyzers and scalers. One analyzer–scaler was used to count the 0.83-MeV full-energy peak of magnesium-27 and the other analyzer–scaler simultaneously counted the 1.78-MeV peak of aluminum-28. The magnesium-27 analyzer was calibrated with a manganese-54 (0.835 MeV) standard source, and the aluminum-28 analyzer was calibrated with an aluminum-26 (1.81 MeV) standard. Figure 2 is a gamma-ray spectrum obtained using a multichannel analyzer to count the antacid sample showing the two full energy peak bands used to measure the magnesium-27 and aluminum-28 with the dual single-channel analyzers.

[a] Aluminum-28 background = 252 counts; magnesium-27 background = 1282 counts.

Ten replicate irradiations of the commercial antacid suspension were performed over a 16-day period. The counts of all replicates were normalized to the time of the first irradiation in order to correct for the decay of the californium-252 during the course of the experiment. A separate irradiation of only aluminum, in the form of a commercial aluminum hydroxide gel containing 9% equivalent aluminum oxide, was used to determine the Compton contribution of the aluminum-28 activity to the 0.830-MeV peak of magnesium-27. This constant ratio of the aluminum-28 peak counts to the counts in the magnesium-27 peak from aluminum-28 was used to remove the aluminum-28 contribution to the total magnesium-27 counts for each of the 10 irradiations.

Because of its low cross-section, the $^{27}Al(n,p)^{27}Mg$-interference reaction should not contribute significantly to the magnesium-27 peak. However, any contribution from that reaction would be eliminated when the Compton contribution to the magnesium-27 peak from aluminum-28 was subtracted.

To compare the precision of the californium-252 neutron activation analysis method with that of the official method, replicate analyses of the commercial antacid suspension were performed on 10 different days over a 2-week period by the official ethylenediaminetetraacetic acid titration method (2).

RESULTS AND DISCUSSION

The gross counting rates for the magnesium-27 and aluminum-28 peak channels were corrected for background, and in the case of the magnesium-27, for the aluminum-28 contribution to the 0.83-MeV magnesium-27 peak. The results are given in Table II along with the results of the ethylenediaminetetraacetic acid titration analysis.

It can be seen from Table II that the californium-252 method provides a precision for aluminum-28 that is considerably better than for magnesium-27. This is expected because of the higher thermal neutron activation cross section (Table I) for the $^{27}Al(n,\gamma)^{28}Al$-reaction. The precision for both aluminum and magnesium can be improved considerably by using a more intense californium-252 source than the relatively weak one which was used for this pilot study. Because of the large volumes used and the minimum amount of sample manipulation required, it can be assumed that the overall error in this technique is due entirely to the counting error. In this case the precision, expressed as the counting error, decreases inversely as the ratio of the square root of the total counts. Consequently, for example, if a californium-252 source 30 times the strength of the source utilized in this experiment were used, the magnesium-27 precision would be improved to $(\sqrt{1166}/\sqrt{1166 \times 30})$ (5.3%) = 0.97%, and the aluminum-28 precision would be improved by the same factor to a value of 0.26%.

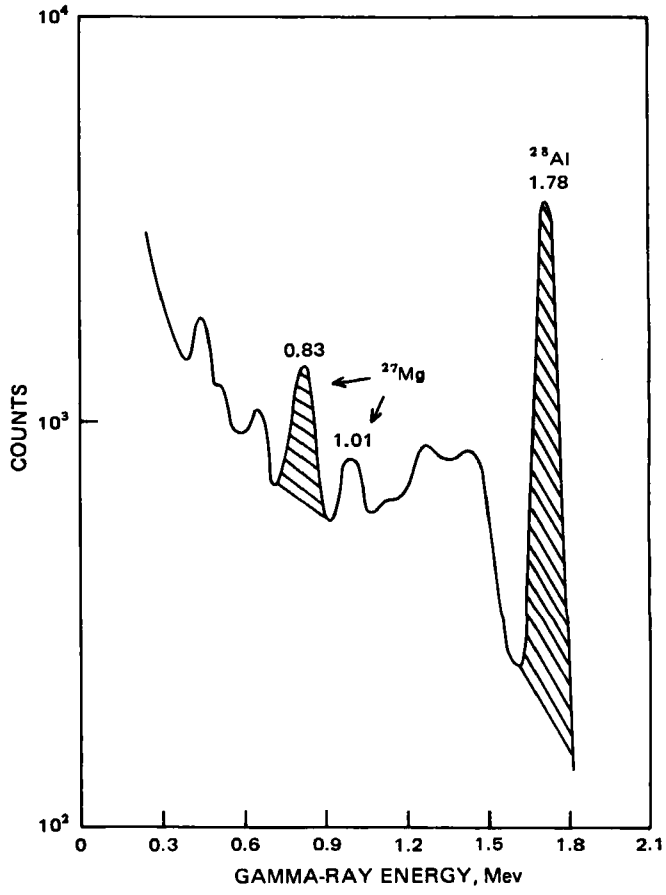

Figure 2—*Gamma-ray spectrum of neutron irradiated antacid suspension containing magnesium and aluminum showing the magnesium-27 and aluminum-28 peaks.*

This improved magnesium-27 value is competitive with the precision for the USP magnesium hydroxide method shown in Table II, and the aluminum-28 determination is more precise than the USP method for aluminum. Sources of californium-252 of this intensity, ~100 μg, are commonly available, relatively inexpensive, and the amount of shielding required is not restrictive. This technique, when used with an appropriate companion standard, should have potential application as an accurate, in-house quality control technique for products containing aluminum and magnesium.

(−)-α-Isosparteine from *Lupinus argenteus* var. *stenophyllus*

WILLIAM J. KELLER ˣ, BRIAN N. MEYER *, and JERRY L. McLAUGHLIN*

Received March 19, 1982, from the *School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication May 12, 1982. *Present address: Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

Abstract □ Combined GLC–mass spectrometry revealed that an unidentified sparteine isomer was the major component of an alkaloid extract of the aboveground portions of *Lupinus argenteus* Pursh. var. *stenophyllus* (Rydb.) Davis (Leguminosae). After isolation, this alkaloid was characterized as the least common of the known sparteine isomers, (−)-α-isosparteine. A preliminary pharmacological study showed (−)-α-isosparteine to have a more rapid onset and a shorter duration of action when compared with (−)-sparteine on rat myocardium.

Keyphrases ◻ *Lupinus argenteus* var. *stenophyllus*—(−)-α-isosparteine, GLC-mass spectrometry, sparteine isomer ◻ (−)-α-Isosparteine—*Lupinus argenteus* var. *stenophyllus*, GLC-mass spectrometry, sparteine isomer ◻ GLC-mass spectrometry—(−)-α-isosparteine from *Lupinus argenteus* var. *stenophyllus*, sparteine isomer

The legume genus *Lupinus* is a rich source of a wide variety of quinolizidine alkaloids. Due to high concentrations of these quinolizidine bases, lupines have been implicated in acute toxicoses and death in grazing livestock (1–3). Additionally, certain lupines have been shown to cause crooked calf disease (4), and the quinolizidine alkaloid anagyrine appears to be the teratogen responsible for congenital deformities (5).

The silvery lupine, *L. argenteus* Pursh., has long been considered to be highly toxic to grazing sheep (6, 7). Recently this species has been found to exhibit marked toxicity in cattle as well (4). A chemical study of the previously uninvestigated *stenophyllus* variety of the silvery lupine revealed the presence of α-isolupanine (0.60% of dry weight), thermopsine (0.36%), sparteine (0.05%), Δ^5-dehydrolupanine (0.04%), anagyrine (0.01%), lupanine (0.01%), and β-isosparteine (0.005%) (8). The concentrations of these quinolizidine alkaloids provided an explanation for the acute toxicity associated with this plant and suggested that it may be teratogenic.

The present study was directed at characterizing the major component of the alkaloid fraction from the aboveground portions of mature, flowering *L. argenteus* Pursh. var. *stenophyllus* (Rydb.) Davis. At the time of the initial investigation (8), the most abundant alkaloid in this plant was thought to be an unknown sparteine isomer. However, the data presented here show that this compound is (−)-α-isosparteine.

Sparteine was originally isolated in 1851 from *Cytisus scoparius* (L.) Link. (9) and has since been found to occur in many other members of the Leguminosae as well as in species belonging to the Monimiaceae, Papaveraceae, and Scrophulariaceae (10). The known isomers of sparteine, α-isosparteine and β-isosparteine, have a much more restricted distribution and were isolated at a later date (11). Genisteine, for instance, was first isolated in 1918 from *C. scoparius* (12), and its identity as (−)-α-isosparteine was confirmed in 1951 (13). Since that time (−)-α-isosparteine has been isolated from only two other legumes, *Lupinus caudatus* Kell. (14) and *Genista tinctoria* L. (15).

EXPERIMENTAL[1]

Plant Material—The flowering aboveground portions of *Lupinus argenteus* Pursh. var. *stenophyllus* (Rydb.) Davis (Leguminosae) were used[2].

Extraction and Fractionation—The air-dried powdered plant material (500 g) was homogenized with ethanol in a blender[3]. After filtration, the ethanolic extract was concentrated to 30 ml *in vacuo*, acidified with 10% aqueous acetic acid, and extracted with two successive 200-ml portions of ether, ethyl acetate, and chloroform. The acidic aqueous solution was made basic with 58% ammonium hydroxide and extracted with four 200-ml portions of chloroform. The combined chloroform extracts were filtered through anhydrous magnesium sulfate and evaporated to give a brown syrup (6 g), which solidified on standing.

Chromatographic Systems—The following TLC systems utilized 0.25-mm silica gel G layers: system A, chloroform–methanol–58% ammonium hydroxide (100:10:1); system B, cyclohexane–diethylamine (9:1). Alkaloids were detected using Dragendorff's reagent, and both systems provided a good separation of the major alkaloid from the available sparteine isomers and the other components of the extract.

The GLC system consisted of 3% OV-17 on Gas Chrom Q(2-m × 2 mm-i.d. glass column) and a program of 4°/min from 140 to 265°. This system produced a good resolution of the alkaloid mixture with the major component being eluted first.

Mass Spectral Analysis—The major component of the alkaloid fraction was analyzed using combined GLC-MS. The effluent from the 3% OV-17 GLC column entered the mass spectrometer through a glass jet separator maintained at 220°. The ion source temperature was 220° with an ionizing voltage of 70 eV. The mass spectrum of the major alkaloid component in the extract was basically the same as that recorded for the available sparteine isomers (8).

Isolation of the Major Alkaloid—A portion (2.5 g) of the alkaloid fraction was dissolved in ethanol–chloroform (1:1) and chromatographed (preparative TLC, 36 silica gel PF 254 plates, 1 mm thickness, TLC system B). The large band at R_f 0.61 was scraped from the plates, and the alkaloid material was eluted from the silica gel scrapings with three 100-ml portions of methanol. The eluates were combined and processed in the usual fashion (16) to give a light-brown oil which crystallized immediately upon exposure to air. Recrystallization of the free base from dry acetone gave 745 mg of colorless needles, mp 60–62°. The melting point remained constant after sublimation. Portions of the isolated free base were converted to the following derivatives using standard procedures: bisulfate, mp 244–245°; picrate, mp 205–207°; perchlorate, mp 302–304°; methiodide, mp 217–218°. The free base was used to determine the specific rotation, $[\alpha]_D^{26} = -48.1°$ (c = 0.006 g/ml in methanol).

Quantitation of the Major Alkaloid—Using a previously described GLC method (17), the major alkaloid was found to be present in the dry plant material at a level of 0.72%. This represents 40% of the total alkaloid content in the plant.

Synthesis of α-Isosparteine—Starting with sparteine sulfate[4], the method of Leonard and Beyler (18) was used to produce α-didehydros-

[1] IR spectra were determined neat using a Beckman IR-33 spectrophotometer. ^{1}H-NMR spectra were recorded on a Perkin-Elmer model R-24 spectrometer. ^{13}C-NMR spectra were obtained on a Varian XL-200 spectrometer. GLC was conducted using a Hewlett-Packard model 5720A gas chromatograph. Combined GLC–mass spectrometry was carried out with a Du Pont 321 Dimaspec low-resolution mass spectrometer interfaced with a 320 data reduction system. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer model 241 polarimeter.

parteinium bisulfate. A portion of this compound (122 mg) was converted to the free base and hydrogenated over palladium-on-carbon catalyst for 15 hr at room temperature and 45 lbs of pressure. This reaction mixture was filtered, concentrated *in vacuo* to 1 ml, and chromatographed over a small (4 g) silica gel column. The free base (26 mg) was eluted with ether containing 10% of a mixture of methanol–58% ammonium hydroxide (7:3) and was found to have mp 59–60° [lit. (19) mp 60–62°] after sublimation.

RESULTS AND DISCUSSION

During the course of a chemical investigation of *L. argenteus* var. *stenophyllus*, large quantities of the major alkaloid were isolated in chromatographically pure form. Spectral data (IR, ^{1}H-NMR, and MS) suggested the isolate to be an isomer of sparteine. Initially, the alkaloid was thought to be (−)-α-isosparteine, since the two known isomers of this compound, sparteine and β-isosparteine, were shown to be present in the plant (8). However, chromatographic (TLC and GLC) comparisons with a commercial sample[5] of (−)-α-isosparteine refuted this original postulate. Differences in observed and literature melting points for both the free base and numerous derivatives also supported the view that the major alkaloid from *L. argenteus* var. *stenophyllus* was an unknown sparteine isomer.

An X-ray crystallographic study was performed on the perchlorate salt of the isolated alkaloid in an effort to establish its molecular structure. Data from this investigation revealed the compound to be α-isosparteine perchlorate[6] and corresponded very closely with a previous X-ray diffraction study of α-isosparteine (20). Synthesis of α-isosparteine supported the information from the X-ray diffraction study with the synthetic material corresponding in all respects (TLC, GLC, IR, ^{1}H-NMR, ^{13}C-NMR, MS, and mp of the free base) with the isolated alkaloid. This evidence together with an observed $[\alpha]_D^{26} = -48.1°$ [lit. (14) $[\alpha]_D^{22} = -51.3°$] established the major alkaloid from *L. argenteus* var. *stenophyllus* as (−)-α-isosparteine. A reference sample of 1-α-isosparteine, purchased from a second commercial supplier[7], was also identical with the isolated and synthesized products.

The initial anomalous observations involving chromatographic differences between isolated and reference materials were resolved by determining that the initial commercial sample, labeled α-isosparteine, was misbranded. The mislabeled commercial sample[5] is, from TLC and ^{13}C-NMR evidence, actually a mixture of sparteine: (−)-α-isosparteine, 4:1. Further, there have been confusing discrepancies in the literature regarding the melting points of α-isosparteine and some of its derivatives. For example, the degree of crystal hydration greatly affects the melting point of the free base α-isosparteine. A previous study (14) reported the monohydrate as mp 108–110°, while another study (19) found the anhydrous free base to be mp 60–62°. The α-isosparteine isolated in this study apparently crystallized in the anhydrous form. The same situation probably exists with the picrate, mp 205–207° [lit. (21) mp 221–222°] and the perchlorate, mp 302–304° [lit. (14) mp 262–263°]. The bisulfate mp 244–245° [lit. (22) mp 244–245°] and the methiodide, mp 217–218° [lit. (19) mp 217–218°] correlated well with literature values.

The present study establishes *L. argenteus* var. *stenophyllus* as the richest source of (−)-α-isosparteine yet reported. For example, less than 0.01% of (−)-α-isosparteine was found (14) in *L. caudatus* while this work demonstrated a concentration of 0.72% in the title plant. Additionally, *L. argenteus* var. *stenophyllus* is now the only plant known to produce and accumulate all three sparteine isomers.

Sparteine has been used for many years in the management of various cardiac arrhythmias (23). In isolated atria, sparteine exhibits a positive inotropic action and prolongs the refractory period (24). Preliminary pharmacologic studies in this laboratory have revealed that (−)-α-isosparteine exhibits basically the same action as does (−)-sparteine but possesses a more rapid onset and a shorter duration when compared using rat myocardial tissue[8]. A more complete pharmacologic characterization of (−)-α-isosparteine is presently in progress.

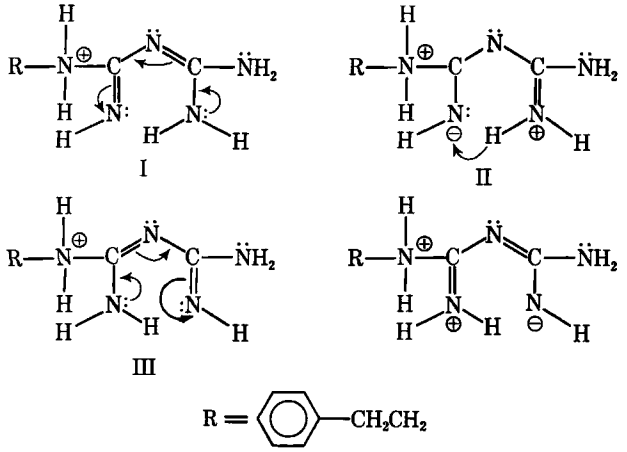
Abstract □ The existence of active electron pairs on some nitrogen atoms in phenformin hydrochloride is inferred from the presence of a hydrogen catalytic polarographic wave. This finding emphasizes the ability of biguanides to form hydrogen bridges with other molecular species such as amino acids and proteins, as well as to form coordination complexes with zinc and other metallic cations by means of these electron pairs. The antidiabetic action of phenformin and other related biguanides can be explained in terms of competition between these molecules and insulin to coordinate cationic oligoelements together with their ability to form hydrogen bonds between the biguanide moiety and insulin itself.

Keyphrases □ Insulin—complexation with zinc *in vivo*, effect of phenformin determination by polarography □ Phenformin—effect on insulin-zinc complexes, determination by polarography □ Polarography—determination of effect of phenformin on insulin-zinc complexes.

Some aspects of the biological behavior of biguanides such as the blood sugar-lowering effect and metabolic interactions have been widely studied (1, 2). Biguanides form stable coordination complexes with divalent cations of oligoelements existing in living organisms. Phenformin [*N*-(2-phenylethyl)imidodicarbonimidic diamide] and other related oral antidiabetic biguanides form very strong complexes with Zn^{2+} and other divalent cations (3). This finding suggests that biguanides produce alterations in the distribution and ratios of divalent cations in biological media (4). It was shown (5, 6) that phenformin administered *in vivo* produced consistent and significant effects on hepatic mitochondrial divalent metal ion content through a more complex mechanism than competitive binding. All of these facts point to the use of biguanides as regulators of oligoelement proportions in living organisms.

Structures for this type of complex have been suggested, but the one reported by Rây and Saha (7) (I) is the most widely accepted.

The antidiabetic action of biguanides (phenformin as an example) can be derived from this complexation phenomenon. This action must be consistent with the following sequence of events:



I II III

R = —CH_2CH_2—

1. Natural insulin is stored in the β-cells of the pancreas in the form of insoluble insulin–zinc granules (8).

2. Biguanides form stronger complexes than insulin does with Zn^{2+}. Formation of such complexes releases insulin from the granules allowing it to go through cellular membranes and enter the systemic circulation.

This scheme is consistent with the physicochemical properties of biguanides and phenformin in particular:

1. These molecules are soluble in biological hydroorganic media, which explains their widely observed, fast conveyance and action (9).

2. At pH values close to human physiological pH, the stable form of biguanides is the cationic monoprotonated form, BH^+ (10). These cations retain the delocalized π-electronic structure of the biguanide group of the free base, as can be seen from the persistence of the 232-nm band of the UV spectra of bases, at pH values less than the pK_{a_2} of biguanides, and in any case at pH values <7. According to a previous report (11), the protonated biguanide group can be formulated in several resonant forms (Fig. 1), all of them with nitrogen atoms exhibiting localized electron pairs, which accounts for the ability of monoprotonated biguanides to form hydrogen bonds and coordination compounds with metallic cations.

These structural features call for the solubilization of the insulin–zinc granules in the pancreatic β-cells, which involve the accessibility of insulin–zinc complexes to biguanides at a molecular level. Such accessibility requires the breaking of the hydrogen bonds that link insulin polyamino acid chains in the building of granules. This breaking process should be enhanced, because of the strong ability of biguanides themselves to form hydrogen bonds. Both the ability to form hydrogen bonds and to chelate with zinc are located at the electron pairs of nitrogen.

This work was directed to characterize this structural feature by using direct current (DC) and superimposed alternating current of first harmonic (AC_1) polarographic techniques on phenformin as a representative of oral antidiabetic biguanides.

EXPERIMENTAL

A polarograph[1] was used and pH measurements were carried out by means of a pH meter[2]. Polarographic parameters were fixed (unless their

influence was considered) as follows: dropping time, τ, 0.6 sec; height of the mercury-containing vessel, h, 54 cm; temperature, T, 25°; phenformin hydrochloride concentration, c, 3.8×10^{-4} M; the ionic strength was adjusted to μ 0.5 with 1:1 inert electrolyte; mercury flow, m, 0.88 mg/sec (at the referred height h).

A sample volume of 25 ml of freshly prepared solution was used in all of the polarographic experiments. Gelatin was used as a suppressor in a proportion of 0.01% by weight, in the polarographic recordings of phenformin only. Auxiliary and reference silver/silver chloride electrodes together with a 1:1 electrolyte-saturated salt bridge were used.

The polarographic result found by means of the DC technique agreed well with the ones found using the AC_1 technique.

Phenformin hydrochloride was used as supplied[3], and the melting point (175 ± 1°) and IR spectra were tested. Two aqueous suspensions of insulin–zinc complexes both of 40 IU/ml were used[4]: a mixture of 70% crystalline and 30% amorphous porcine and bovine and a 100% amorphous porcine insulin–zinc suspension, respectively.

RESULTS AND DISCUSSION

An irreversible cathodic polarographic wave is detected in buffered lithium–phosphate–chloride–gelatin aqueous solutions of phenformin in the pH range 4–7. This wave involves a one-electron transfer according to the slopes of Tomes representations obtained from DC data (Fig. 2). This wave does not appear in the same media in the absence of phenformin.

The peak potential, E_p, depends slightly on phenformin concentration (Fig. 3), but the height of the wave is independent of that concentration at pH values >5.5.

Such polarographic behavior implies the presence of active catalytic centers for the reduction of hydrogen ions, and more precisely it points to the existence of localized electron pairs over nitrogen on phenformin, since such active centers occur in other related substances (12).

The formation of Zn^{2+}–phenformin complexes (MF_j) has been studied by DC polarography in Britton–Robinson buffered media. Provided that the detected polarographic wave results are quasi-reversible, the procedure

developed by Lingane (13) to express the variation of half-wave potential on complexation has been used:

$$\Delta E_{1/2} = j\frac{0.0591}{n\alpha}\log c_F + \frac{0.0591}{n\alpha}\log \beta_{(MF_j)} \qquad \text{(Eq. 1)}$$

where $\Delta E_{1/2} = E^f_{1/2} - E^c_{1/2}$ expresses the difference between half-wave potentials of free and complexed zinc cation, respectively, and c_F is the ligand concentration.

The dependence of $\Delta E_{1/2}$ measured values with $\log c_F$ adjusts well to a linear equation for a concentration range of $4 \times 10^{-4} < c_F < 7 \times 10^{-4}$ M, and $[Zn^{2+}] = 2 \times 10^{-4}$ M (T = 25°; pH 4.97). From this linear dependence, a ligand number of $j = 2$ is found, and the adjusted stability constant is $\beta_{(MF_2)} \simeq 2 \times 10^{11}$ M^{-2}. [Despite the fact that the stability constant value found indicates that the phenformin–Zn^{2+} complex is a quite stable complex, it must be noted that biguanides form stronger complexes with some other metallic cations (14)].

The stoichiometry of zinc–insulin complexes is less clear. As reported previously (15), zinc ions appear to combine preferentially with imidazole groups. Several Zn^{2+}–imidazole relationships have been noted: from 1:1 complexes to 1:3 and 1:4. There is strong binding between two metal ions and three imidazole dimers, especially in crystalline metal–insulin complexes (16). These authors suggest that the first zinc ion is bound by three coordination bonds, being the association constant of the order of the ones normally found for zinc–imidazole interactions ($\simeq 10^9$), and the bonding of the second Zn^{2+} appears to be 10^4 times stronger.

Insulin binds strongly with zinc cations in both amorphous and crystalline complexes, impeding the polarographic reduction of Zn^{2+} (15). The polarographic reductions observed in the study of amorphous insulin–zinc suspensions (curve A, Fig. 4) and crystalline–amorphous mixture suspensions (curve C, Fig. 4C) are due to free zinc cations whose concentrations polarographically derived are: $[Zn^{2+}]_A = 1.64 \times 10^{-5}$ M, and $[Zn^{2+}]_C = 2.24 \times 10^{-5}$ M.

The addition of phenformin to insulin–zinc complex suspensions modifies the polarographic recordings (curves B and D, Fig. 4). In the case of the addition to amorphous complex suspension (curve B) a shift to more negative values of half-wave potential is observed, indicating that phenformin has complexed zinc cations. The increasing curve height (curve B from A) indicates that the phenformin complexed Zn^{2+} concentration (recorded in B) $[Zn^{2+}]_B = 2.1 \times 10^{-5}$ M, is greater that the previous free Zn^{2+} concentration $[Zn^{2+}]_A$. This increase in the reducible phenformin complexed Zn^{2+} concentration can only be explained if some insulin–zinc complexes have been broken by the action of phenformin.

In the case of the amorphous and crystalline insulin–zinc mixture (curves C and D, Fig. 4) a quite different behavior is observed. Also the half-wave potential is shifted to more negative values, indicating the complexation of Zn^{2+} with phenformin, but the increase in reducible Zn^{2+} concentration $[Zn^{2+}]_D = 2.36 \times 10^{-5}$ M is less than in the previous case of pure amorphous insulin–zinc suspensions. This small increase corre-

(A) 8.366 g/liter amorphous insulin–zinc; (B) 8.366 g/liter amorphous insulin–zinc with phenformin (4 × 10^{-4} M); (C) 8.366 g/liter crystalline (70%) and amorphous (30%) insulin–zinc; (D) 8.366 g/liter crystalline (70%) and amorphous (30%) insulin–zinc with phenformin (4 × 10^{-4} M).*

sponds only to the amorphous part of the mixture as can be derived from the increase detected in the first case, indicating that the crystalline insulin–zinc complex remains stable despite the presence of phenformin.

The polarographic experiments showed that there is a competition between phenformin and insulin toward zinc cations. The antidiabetic behavior of phenformin can be related to this competition. This competition is not restricted to β-cells environment, rather it will work in any part of the living organism where these molecules meet and also can explain the protection of insulin against biochemical degradation (17).

Synthesis of Isopromethazine Hydrochloride

FRED S. FRY, JR.[x], MILLARD MAIENTHAL, and WALTER R. BENSON

Received January 4, 1982, from the *Division of Drug Chemistry, Food and Drug Administration, Washington, DC 20204.* Accepted for publication May 19, 1982.

Abstract □ Isopromethazine hydrochloride was synthesized in gram quantities by using a method which ensures that the isopromethazine is not contaminated with promethazine hydrochloride.

Keyphrases □ Isopromethazine hydrochloride—synthesis □ Promethazine hydrochloride—synthesis of isopromethazine □ Promethazine isomer—synthesis □ Antihistamine—isopromethazine synthesis

Promethazine (*N,N,α*-trimethyl-10*H*-phenothiazine-10-ethanamine, I) is an antihistamine that is usually synthesized by the reaction of either 2-chloro-1-dimethylaminopropane (1–7) or 1-chloro-2-dimethylaminopropane (2) with phenothiazine in the presence of bases such as sodium hydroxide, sodium amide, or phenyllithium (1), or with the Grignard derivative of phenothiazine (7). When *β*-haloamines are treated with bases, aziridinium salts are frequently formed (8, 9), and the three-membered ring can be opened by a nucleophile at either ring carbon to produce isomeric alkylation products (10) (Scheme I). Thus, in the alkylation of phenothiazine with 2-chloro-1-dimethylaminopropane, *N,N,β*-trimethyl-10*H*-phenothiazine-10-ethanamine (isopromethazine, II) is obtained in addition to the desired I[1]. These isomeric compounds can be separated by fractional crystallization (6), but small amounts of II usually remain in the purified samples of I. Therefore, a sample of pure II was needed as a reference standard for the analysis of I (13–17)[2,3].

EXPERIMENTAL

Phenothiazine[4] was recrystallized from 95% ethanol. Butyllithium[4] (1.6 *M* in hexane) and 2-chloropropionyl chloride[4] were used without further purification. Previously unopened anhydrous ethyl ether and tetrahydrofuran were used without further drying. NMR[5], MS[6], and IR spectra[7] were obtained. Melting points were uncorrected.

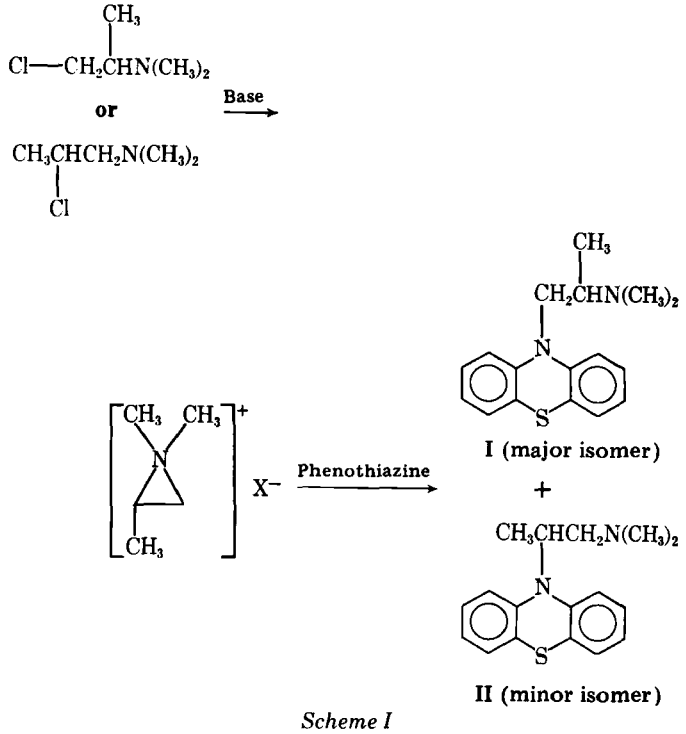
***N,N,β*-Trimethyl-10*H*-phenothiazine-10 - *α* - oxoethanamine** (V)—To a solution of phenothiazine (15.9 g, 0.08 mole) in 500 ml of dry ether under a nitrogen atmosphere and cooled to −20 to −30°, 50 ml of 1.6 *M* *n*-butyllithium in hexane was added with stirring. The resulting bright-yellow solution was stirred for 30 min, then *N,N*-dimethyl-2-chloropropionamide (18) (IV, 10.9 g, 0.08 mole) in 25 ml of ethyl ether was added over 1 hr. The solution was warmed to room temperature, the unreacted 10-lithiophenothiazine was hydrolyzed with water, the organic layer was dried over sodium sulfate, and the solvent was removed under reduced pressure to yield 21.7 g of residue, which was dissolved in toluene and transferred to a silica gel (60–200-mesh) column. Elution with toluene removed unreacted phenothiazine (6 g) and traces of highly colored impurities. Subsequent elution with toluene–ethyl acetate (85:15) afforded 11.4 g of nearly colorless amide (V, mp 161–163° [lit. (19) mp 165–167°] 76% based on unrecovered phenothiazine). ^{1}H-NMR ($CDCl_3$, 60 MHz): 1.9 (C—CH_3, 3H, d, J = 8 Hz), 2.9, 3.1 (N—CH_3, 6H, two s), 4.8 (CH, 1H, q, J = 8 Hz), 7.1 ppm (ArH, 8H, m); ^{13}C-NMR ($CDCl_3$): 15.97, 36.23, 37.37, 56.93, 116.27, 123.03, 124.35, 127.15, 127.79, 143.64, 169.84 ppm; IR: 1645 cm^{-1} (ν C=O, s); mass spectrum (80 eV, 300°): m/z 298 (M^+), 226 (M − C_3H_6NO), 198 (M − $C_5H_{10}NO$), 194 (M − C_3H_6NO − S), 154 (M − $C_5H_{10}NO$ − CS), 72 (C_3H_6NO, 100%).

Anal.—Calc. for $C_{17}H_{18}N_2OS$: C, 68.42; H, 6.08; N, 9.39; S, 10.75. Found: C, 68.41; H, 5.91; N, 9.42; S, 10.46.

***N,N,β*-Trimethyl-10*H*-phenothiazine-10-ethanamine Hydrochloride**—To a solution of lithium aluminum hydride (2 g, 0.053 mole) in 500 ml of dry tetrahydrofuran, V (5.0 g, 0.0167 mole) in 50 ml of tetrahydrofuran was added. The reaction mixture was stirred for 2 hr, then the excess hydride was destroyed with ethyl acetate and dilute sodium hydroxide solution. The reaction mixture was filtered and the solvent removed under reduced pressure. The residue was dissolved in ether and treated with hydrogen chloride gas to yield the crude hydrochloride of II. This material was recrystallized from acetonitrile to yield 3.9 g of nearly colorless prisms (72%, mp 196–198° [lit. (5) mp 193–194°]). ^{1}H-NMR ($CDCl_3$, 200 MHz): 1.84 (C—CH_3, 3H, d, J = 8 Hz), 2.72 (N—CH_3, 6H, s), 3.2–3.8 (CH_2, 2H, m), 4.78 (CH, 1H, m), 6.9–7.2 ppm (ArH, 8H, m); ^{13}C-NMR ($CDCl_3$): 21.72, ~42 (broad), 52.53, 57.79, 117.14, 123.73, 126.40, 127.73, 127.95, 143.52 ppm; IR: 2300 cm^{-1} (ν N^+H, broad); mass spectrum (80 eV, 300°): m/z 284 (M − HCl), 226 (M − HCl − C_3H_8N), 198 (M − HCl − $C_5H_{12}N$), 194 (M − HCl − C_3H_8M − S), 58 (C_3H_8N, 100%), 36,38 (HCl).

Anal.—Calc. for $C_{17}H_{21}ClN_2S$: C, 63.62; H, 6.59; Cl, 11.05; N, 8.73. Found: C, 63.78; H, 6.83; Cl, 10.97; N, 9.02.

***N*-(2-Hydroxy-1-propyl)phthalimide**—A solution of 1-amino-2-propanol (5 g, 0.066 mole) and *N*-carboethoxyphthalimide (10 g, 0.05 mole) in 200 ml of 1,2-dichloroethane was stirred 2 hr at room temperature. An aqueous solution of potassium carbonate was added, and after stirring 15 min, the organic phase was separated, washed with water, and dried. The solvent was removed under reduced pressure, and the oily residue was recrystallized from ether–hexane to yield 1.7 g of the phthalimide, mp 86–87°.



Scheme I

[1] Under certain conditions, II has been reported as the predominant isomer (11, 12).

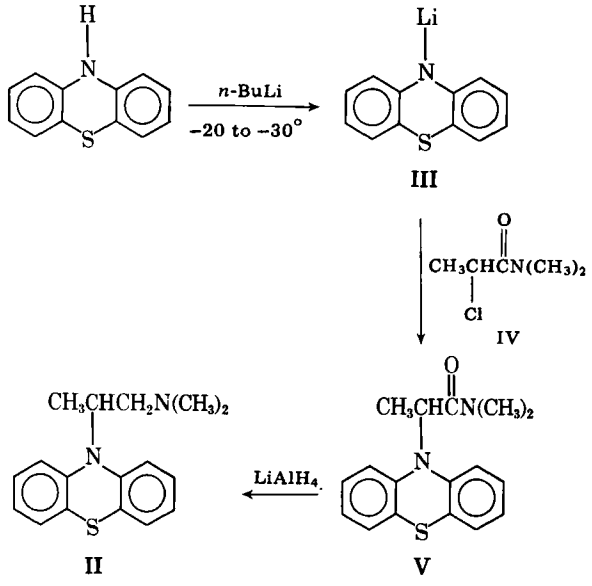

Scheme II

Anal.—Calc. for $C_{11}H_{11}NO_3$: C, 64.37; H, 5.40; N, 6.83. Found: C, 64.39; H, 5.22; N, 6.71.

The reaction of this material with phosphorus tribromide in pyridine yielded a white crystalline compound (mp 162–164°) that contained no bromine by elemental analysis; the compound was not identified.

RESULTS AND DISCUSSION

Due to the rearrangements noted with β-haloamines (8, 9), it was necessary to use an alkylating agent, which precluded the formation of isomeric products. This involved selecting a 2-halopropylamine with the amino group protected to prevent aziridine formation. The approach utilized (Scheme II) is similar to that reported previously (20). Compound III was prepared from phenothiazine and *n*-butyllithium by the procedure of Gilman and Diehl (21), and IV was prepared from dimethylamine and 2-chloropropionyl chloride by the procedure of Weaver and Whalen (18). When III was prepared at −20 to −30° and allowed to react with IV, a 76% yield of V resulted. This material was separated from unreacted phenothiazine by chromatography on silica gel. The reaction of V with lithium aluminum hydride in tetrahydrofuran afforded a 72% yield of II, which was isolated as the hydrochloride salt. The nearly colorless prisms (mp 196–198°) exhibited no loss of weight when heated in a thermal balance, indicating no solvent of crystallization.

The isopromethazine hydrochloride was shown to be identical to a European Pharmacopoeia Reference Standard[2] by UV and IR spectroscopy and by GLC on a 3% OV-101 on Chromosorb W column at 230° (retention time, 6.69 min). The GLC analyses of both prepared and standard isopromethazine hydrochloride indicated traces of phenothiazine (retention time, 3.73 min) and an unidentified compound (retention time, 3.24 min), which may have been formed by degradation on the column. The analyses indicated that no promethazine hydrochloride (retention time, 7.72 min; detection limit, ~0.1%) was present[8].

When III was prepared at room temperature and allowed to react with IV, a mixture of products including phenothiazine and V was obtained. One of the products appeared to be one of the dimers of phenothiazine (22, 23) (mass spectrum: *m/z* 396).

Another approach to the preparation of II involved the protection of the side-chain amine as a phthalimide. The reaction of 2-hydroxy-aminopropane with *N*-carboethoxyphthalimide (24) produced *N*-(2-hydroxy-1-propyl)phthalimide (mp 87–88°; elemental analysis and ^{1}H-NMR spectrum were satisfactory for this compound). However, attempts to replace the hydroxyl group with a halogen using either phosphorus tribromide in pyridine or triphenylphosphine and carbon tetrachloride were unsuccessful.

The use of a haloamide as a alkylating agent for III produced II in good yield. This method should prove useful as a general route to phenothiazine-containing compounds.

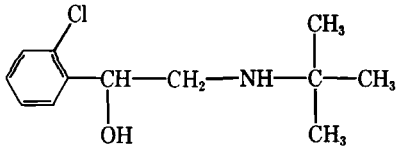
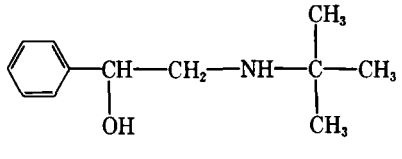
Abstract □ A simple and sensitive method is reported for the quantitative determination of the bronchodilator tulobuterol in human serum. Tulobuterol and an internal standard were extracted from alkalinized serum with ether and then back-extracted into dilute hydrochloric acid. After alkalinization and extraction of the aqueous solution, the extract was evaporated to dryness. The residue was silylated and subjected to mass fragmentography.

Keyphrases □ Tulobuterol—serum, extraction, derivatization, mass fragmentography □ Bronchodilator—tulobuterol, serum analysis, mass fragmentography □ Mass fragmentography—analysis, tulobuterol, serum

Tulobuterol (I) is a newly synthesized bronchodilator having a potent and long-lasting effect (1, 2). An electron-capture GLC determination of this drug in human serum was reported previously (3). This method was specific and sensitive, but the procedure was tedious and time consuming. Application of mass fragmentography to the detection of plasma albuterol and terbutaline, which possess similar chemical structures to tulobuterol, has been reported (4–6). This paper describes a sensitive and rapid analytical method for determining tulobuterol in human serum by mass fragmentography. The analytical results are compared with those obtained by electron-capture GLC.



I



II

EXPERIMENTAL

Materials—Tulobuterol hydrochloride was synthesized previously (7). The internal standard, α-[(*tert*-butylamino)methyl]benzyl alcohol (II), was synthesized using a previously described method (8). *N,O*-Bis(trimethylsilyl)acetamide[1] (III) was employed as the derivatization reagent. Other reagents and solvents were of analytical grade and were used without further purification.

Drug Administration and Sample Collection—Four healthy, male volunteers each received a 2-mg oral dose of tolubuterol hydrochloride in the form of a syrup solution[2] or tablets. Blood samples of ~8 ml were withdrawn before the administration and at 0.5, 1, 1.5, 2, 3, 4, and 6 hr.

Table I—Typical Tulobuterol Calibration Curve

Drug Concentration, ng/ml	Peak Area Ratio[a]	Ratio[b]
1	0.096	0.096
2	0.141	0.071
4	0.295	0.074
7	0.573	0.082
10	0.766	0.077

[a] Ratio of drug–internal standard. [b] Peak area ratio divided by drug concentration.

After standing for ~30–60 min, the serum was separated by centrifugation (2000×*g*, 10 min) and stored frozen until analysis.

Apparatus—GLC[3]-MS[4,5] determinations were performed using a glass column of 2-m length and 2-mm i.d., packed with 2% OV-1 on 100–120 mesh chromosorb G (HP)[6], operating at 165°. The injector, separator, and ion source were held at 210, 290, and 150°, respectively. The ionization energy and trap current were 70 eV and 30Q μA, respectively. Measurements were performed by single-ion monitoring at *m/z* 86.

Extraction Procedure and Sample Preparation—A solution of internal standard (1 ml of an 8-ng/ml solution in methanol) was evaporated to dryness under reduced pressure in a 15-ml glass centrifuge tube, and 1 ml of serum and 0.5 ml of 1 *N* NaOH were added. The tube was stoppered and extracted with 6 ml of ether by a reciprocating shaker at 160 strokes/min for 5 min. After centrifugation (2000×*g*, 5 min), the ether layer was transferred to a second tube containing 5 ml of 0.1 *N* HCl. The tube was shaken, centrifuged, and the ether layer removed.

Four milliliters of the aqueous layer was transferred to a third tube and alkalinized with 1 ml of 1 *N* NaOH. After extraction with 6 ml of ether, the tube was shaken and centrifuged. Five milliliters of the ether phase was transferred to a fourth tube and evaporated to dryness in a water bath at 50°. The residue was dissolved in 100 μl of III (1:4 solution in ethyl acetate), and 1 μl was chromatographed.

RESULTS AND DISCUSSION

Figure 1 shows a mass fragmentogram obtained from a serum sample to which a known amount of tulobuterol hydrochloride had been added, together with those obtained from a serum blank and from a volunteer receiving tulobuterol hydrochloride by the oral route. The peaks of tulobuterol and internal standard were well resolved and no interfering peaks from endogenous materials were present.

The mean percent recovery and standard deviation of tulobuterol hydrochloride were 65.02% and ±3.45, respectively. The corresponding values for the internal standard were 63.82% and ±2.52. Results were obtained from six determinations using serum with 5 ng/ml of tulobuterol hydrochloride and 8 ng/ml of the internal standard added. Although the recoveries of tulobuterol hydrochloride and internal standard in the present assay are low, they are reproducible. Attempts to improve the drug recovery led to either added complexities or irreproducibility.

The ratio of the peak area of tulobuterol to that of the internal standard was calculated. Statistical analysis indicated excellent linearity in the range of 1–10 ng/ml serum with a correlation coefficient of 0.998, a slope of 0.0775, and an intercept of 0.002 (Table I).

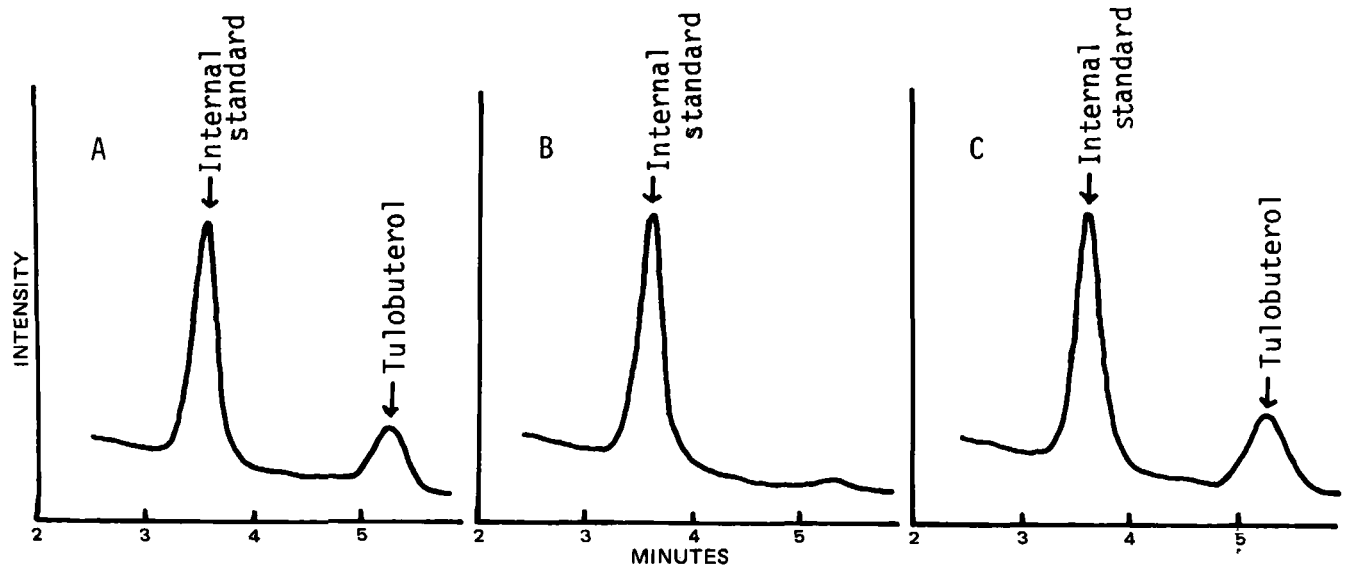

Figure 1—*Mass fragmentograms of serum extracts. Key: (A) serum to which known amounts of tulobuterol hydrochloride (4 ng) and internal standard (8 ng) were added; (B) serum free from drug; and (C) serum of volunteer who took 2 mg of tulobuterol hydrochloride orally (Subject 1, 3 hr).*

Although a previous assay (3) has been used extensively to determine serum levels of tulobuterol <10 ng/ml in humans, the present assay was found to be linear up to 50 ng/ml. When six replicate 1-ml samples of serum each containing 7 ng of tulobuterol hydrochloride/ml were analyzed, the mean value was 7.03 ng of tulobuterol hydrochloride/ml with a standard deviation of ±0.17 and a coefficient of variation of 2.42%. When serum samples containing 2 ng of tulobuterol hydrochloride/ml were analyzed, the mean value was 2.03 ng of tulobuterol hydrochloride with a standard deviation of ±0.10 ng/ml and a coefficient of variation of 4.93%.

To show the applicability of the method described, a serum concentration–time profile of tulobuterol was established from four volunteers following an oral dose of tulobuterol hydrochloride (Fig. 2). The among-subject variability was estimated by examination of the differences in the peak concentration and time to reach the peak.

Tulobuterol and some urinary metabolites can be determined simultaneously by mass fragmentography (9). Two major modifications were made in the present assay, compared with the single-extraction procedure used previously for tulobuterol in urine, *viz.*, ethyl acetate–acetone (3:1, v/v) extraction from a solution made alkaline with ammonium hydroxide. The extraction solvent was changed to ether, and back-extraction into the aqueous layer (pH ~1.0) and reextraction into the ether layer were added. Interference from endogenous materials in the serum was avoided with the improved cleanup procedure, although this was time consuming and lowered the overall recovery of tulobuterol. This method was inapplicable for determinations in human serum due to the low serum levels (<10 ng/ml) at a therapeutic dose (1–2 mg).

Albuterol and terbutaline were quantitated at low plasma levels using the relatively high mass ion $[M - 86]^+$ after forming the *tert*-butyldimethylsilyl derivatives (4, 5). In the case of tulobuterol, however, the relative intensity of $[M - 86]^+$ was <0.1%, which does not ensure adequate sensitivity.

To validate the present mass fragmentographic method, serum specimens were assayed by both mass fragmentography and electron-capture GLC. The analytical data obtained by both methods were correlated by linear regression analysis, yielding a correlation coefficient of 0.905 and a slope of 0.987 (Fig. 3).

In the latter method, an additional step was needed for the removal of excess derivatizing reagent (trifluoroacetic anhydride). Moreover,
