- Requirements and recommendations for records and reports. Design of records and reports—what kinds and how long to keep them.
- Numbering system for quality control records and systems.
- Problems with returned or salvaged product.
- FDA inspections and legal aspects.
- Recalls.

The CGMP regulations often are broad in their definitions. This book clarifies the regulations with many practical examples. The authors expand on the regulations, demonstrating their relation and applicability to the function and implementation of the Quality Control department. The authors further expand the discussion by freely offering their own opinions. Although one may not agree with their views all of the time, they are always stimulating and provocative. For example, the philosophy behind the following statement (page 22) could be fuel for a very interesting discussion:

> "The quality control supervisor must have a questioning nature. Some say a supervisor must be naturally distrustful. This applies to all matters in his or her area, including calculations and conclusions reached by peers and superiors from an organization viewpoint. It certainly applies to findings submitted by vendors and vendees of the operation and by its subcontractors. If the supervisor is other than such, the reputation will be that of a buck passer."

This unique and information-packed book should be an indispensable part of the libraries of all industrial pharmaceutical quality control, manufacturing, pharmacy, and legal departments.

Science, Objectivity, and Judgment Uncompromised

From time to time, the public press and health care news publications have widely reported on investigations of alleged financial improprieties involving some prominent individual in either the public or the private sector.

Generally, the financially-related incidents involved were relatively insignificant or inconsequential in themselves. They might have involved gifts, honoraria, director's fees, or similar perquisites. However, it was because of the particular office of the person or his or her high position of public trust, or corporate responsibility, or overall general authority that made the matter a special concern. Even an appearance of secret favors or undisclosed benefits throws into question the objectivity and impartiality of a supposedly neutral individual in rendering decisions or taking actions.

This, then, brings us to our current concern: namely, the hidden biases or allegiances of scientists who volunteer or are called upon to participate in some proceeding as impartial, but knowledgeable, experts. The activity involved may cover the gamut from serving on a high-brow committee of some distinguished scientific society to testifying before some legislative or judicial body.

The July–August issues of *Science 83*, a publication of the American Association for the Advancement of Science carried in its "Advice and Dissent" section, a column entitled "When Scientists Testify for Hire." The article was written by Michael F. Jacobson, executive director of the Center for Science in the Public Interest—an organization that describes itself as a Washington-based consumer advocacy group.

"Of all the values that pervade science," writes Jacobson, *"one of the highest is objectivity, which I take to mean judgment uncompromised . . . . But scientific objectivity is sometimes invoked more for appearance than for substance. Whenever science moves into the commercial world, scientists come face-to-face with Mammon and manufacturers. When profits are threatened by legislation, lawsuits, or bad publicity, many companies like to have their positions bolstered by academic scientists. A professor's utterances are far more persuasive than those of the corporate chemist who developed the suspect 2,4,6-super-oxo-kleptane, or whatever."*

Jacobson then goes on to cite a number of examples in which individual companies or an industry trade organization will recruit academic scientists whose opinions they like or scientists who will willingly espouse opinions that are favorable to those companies or industry. These scientists may be "recruited" in any number of ways; for example, the industry "recruiters" might hire them as consultants, sponsor their research, offer employment to their graduate students, appoint them to their corporate boards, endow their teaching positions or professorships, or otherwise get them into a position of indebtedness.

Jacobsen brings out very nicely that it is not usually the positions *per se* that these scientists take that is wrong. What is objectionable is that they voice those positions while wearing a cloak of professed neutrality. And in this regard, Jacobson states that, *"The public is cheated by being given the appearance but not the substance of objective scientific analysis. Individuals and governments may make poor decisions based on one-sided information. The biggest loser in the long run, though, could be the scientific community itself, including the vast majority of scientists who do not testify for hire. The public supports research in the belief that scientists seek the truth, uncompromised by conflicts of interest."*

And then Jacobson concludes by expressing a view that we have stated previously in this column. It is a view that was not original with us, but which we repeated when the National Academy of Sciences did some gutsy housecleaning after it came to light that several members of one of its committees had strong, but concealed, ties to firms in an industry that was favored by the conclusions drawn by that same NAS committee.

If we are to utilize experts and their expertise, of necessity, we are going to draw upon people who have ties to groups, industries, or institutions with biased views or positions on the subject. What is important is: (*a*) to have a very clear and open record as to what are each individual's connections, obligations, and commitments, and (*b*) to balance, as carefully as possible, the make-up of each panel or committee by including a good cross-section of people with an appropriate range of views on the matter and with approximately equal distribution of advocates from the respective opposing sides.

When a scientist speaks out on a public issue, the populace expects that the scientist will feel obligated to explicitly disclose any links that he or she has to the affected company or industry.

Only in this manner will science and the scientific community continue to maintain integrity, and only through such integrity will science be able to continue to command the confidence and trust of the public at large. In its own way, that message is equally pertinent to each and every scientist.

Antihyperlipidemic Activity of Phthalimide Analogues in Rodents

I. H. HALL ˣ, P. JOSÉE VOORSTAD, JAMES M. CHAPMAN, and G. H. COCOLAS

Received April 25, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication July 30, 1982.

Abstract □ Phthalimide analogues have been shown to effectively lower serum cholesterol and triglyceride levels in rats and mice. The mode of action of these agents was not to suppress the appetite of animals, but rather to reduce the activities of key enzymes in the early synthesis of liver cholesterol and fatty acids in the triglyceride pathway. Phthalimide analogues were effective in accelerating biliary excretion of cholesterol and blocking its absorption from the gut. After 16 days dosing, it was evident that higher levels of lipids were being excreted than in control mice. The major serum lipoprotein fractions were reduced in cholesterol, triglyceride, and neutral lipid content, but not phospholipid content in rats after 14 days of administration.

Keyphrases □ Phthalimide—analogues, antihyperlipidemic activity, cholesterol and triglyceride reduction □ Antihyperlipidemic agents—phthalimide analogues, cholesterol and triglyceride reduction □ Cholesterol—antihyperlipidemic effect of phthalimide analogues □ Triglyceride—antihyperlipidemic effect of phthalimide analogues

Continued investigation for new hypolipidemic agents has revealed that phthalimide analogues are potent in lowering serum lipids in rodents (1). In mice phthalimide lowers serum cholesterol 43% after 16 days of dosing at 20 mg/kg ip. Serum triglyceride levels were reduced 56% after 14 days of drug administration. Although phthalimide was the most active member of the series, other analogues demonstrate similar magnitudes of hypolipidemic activity (2). Preliminary *in vitro* studies indicate that phthalimide analogues suppressed the activity of liver enzymes involved in the early *de novo* synthesis of cholesterol and fatty acids. A more detailed study of the effects of these agents on lipid distribution and metabolism was undertaken.

EXPERIMENTAL

Source of Compounds—Phthalimide was purchased commercially[1]. The synthesis and chemical characterization of 1-*N*-phthalimidobutan-3-one and 3-*N*-phthalimidopropionic acid has been reported previously (1).

Antihyperlipidemic Screens in Normogenic Rodents—Compounds to be tested were suspended in 1% carboxymethylcellulose in water and administered to male CF_1 (~25 g) mice intraperitoneally or male Holtzman rats (~200 g) orally by an intubation needle for 16 days. On days 9 and 16 blood was obtained by tail vein bleeding, and the serum was separated by centrifugation for 3 min. The serum cholesterol levels were determined by a modification of the Liebermann–Burchard reaction (3). Serum was also collected on day 14, and the triglyceride content was determined using a commercial kit[2] (4). Animals were maintained on standard rodent food[3] throughout the experiment.

Hyperlipidemic-Induced Mice—Male CF_1 mice (~25 g) were placed on a commercial diet[4] which contained butter fat (400 g), cellulose[5] (60 g), cholesterol (53 g), choline dihydrogen citrate (4 g), salt mixture oil[6] (40 g), sodium cholate (40 g), sucrose (223 g), vitamin-free casein (200 g), and total vitamin supplement for a 2-week period. After the cholesterol and triglyceride levels were assayed and observed to be elevated, the mice were administered test drugs at 20 mg/kg/day ip for an additional 2-week period. Serum cholesterol and triglyceride levels were measured after 14 days of drug administration.

Animal Weights and Food Intake—Periodic animal weights were obtained during the experiments and expressed as a percentage of the animal's weight on day 0. After dosing for 16 days with test drugs, a number of organs were excised, trimmed of fat, and weighed. The organ weights were expressed as a percentage of the total body weight of the animal. The average food intake[3] in g/rat/day was determined over the 16-day period of dosing.

Toxicity Studies—The acute toxicity (LD_{50} value) (5) was determined in male CF_1 mice by administering test drugs intraperitoneally from 100 mg to 2 g/kg as a single dose. The number of deaths in the group was determined for each dosage.

Enzymatic Studies—*In vitro* enzymatic studies used 10% homogenates of male CF_1 mouse liver with 2.5 μmoles of the test drugs and male Holtzman rat liver with 0.100–10 m*M* concentration of the test drugs. *In vivo* enzymatic studies used 10% homogenates of livers from male CF_1 mice obtained after administering the agents intraperitoneally for 16 days at 10–60 mg/kg/day. The liver homogenates for both *in vitro* and *in vivo*

studies were prepared in 0.25 *M* sucrose and 0.001 *M* EDTA [(ethylenedinitrilo)tetraacetic acid].

Acetyl coenzyme A synthetase (6) and adenosine triphosphate-dependent citrate lyase (7) activities were determined spectrophotometrically at 540 nm as the hydroxamate of acetyl coenzyme A formed after 30 min at 37°. Mitochondrial citrate exchange was determined by the procedure of Robinson *et al.* (8, 9) using sodium [^{14}C]bicarbonate (41 mCi/mmole) which was incorporated into mitochondrial [^{14}C]citrate after isolating rat mitochondria (9000×*g* for 10 min) from the homogenates. The exchange of the [^{14}C]citrate was determined after incubating the mitochondrial fraction, which was loaded with labeled citrate, with the test drugs for 10 min. Then the radioactivity was measured in the mitochondrial and supernatant fraction in scintillation fluid[7] and expressed as a percentage. Cholesterol side-chain oxidation was determined by the method of Kritchevsky *et al.* (10) using [26-^{14}C]cholesterol (50 mCi/mmole) and mitochondria isolated from rat liver homogenates. After an 18-hr incubation at 37° with the test drugs, the generated $^{14}CO_2$ was trapped in the center well in [2-[2-(*p*-1,1,3,3-tetramethylbutylcresoxy)-ethoxy]ethyl]dimethylbenzylammonium hydroxide[8] and counted. 3-Hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase) was measured using [1-^{14}C]acetate (56 Ci/mmole) using a postmitochondrial supernatant (9000×*g* for 20 min) for 60 min at 37° (11). The digitonide derivative of cholesterol was isolated and counted (12). Acetyl coenzyme A carboxylase activity was measured by the method of Greenspan and Lowenstein (13). Initially, the enzyme had to be polymerized for 30 min at 37°, and then the assay mixture containing sodium [^{14}C]bicarbonate (41.0 mCi/mmole) was added and incubated for 30 min at 37° with the test drugs. Fatty acid synthetase activity was determined by the method of Brady *et al.* (14) using [2-^{14}C]malonyl-coenzyme A (37.5 mCi/mmole) incorporated into newly synthesized fatty acids, which were extracted with ether and counted. Acyl transferase activity was determined with L-[2-^{3}H]glycerol-3-phosphate (7.1 Ci/mmole) and the microsomal fraction of the liver homogenates (15). The reaction was terminated after 10 min, and the lipids were extracted with chloroform–methanol (1:2) containing 1% 1 *N* HCl and counted.

Phosphatidate phosphohydrolase activity was measured as the inorganic phosphate released after 30 min from phosphatidic acid by the method of Mavis *et al.* (16). The released inorganic phosphate after development with ascorbic acid and ammonium molybdate was determined at 820 nm.

The *in vitro* oxidative phosphorylation process in male CF_1 mouse liver was also examined with an oxygen electrode[9] connected to an oxygraph[10] at 37°. The reaction vessel contained 55 μmoles of sucrose, 22 μmoles of monobasic potassium phosphate, 22 μmoles of potassium chloride, 90 μmoles of succinate or 60 μmoles of α-ketoglutarate as substrate, 2 μmoles of adenosine triphosphate, and 2.5 μmoles of the test compounds in a total volume of 1.8 ml. After the basal metabolic (state 4) rate was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate stimulated respiration (state 3) rate (17). The rates were calculated as μl of oxygen consumed/mg of liver/hr.

Liver, Small Intestine, and Fecal Lipid Extraction—In male CF_1 mice that had been administered test drugs for 16 days, the liver, small intestine, and fecal materials (24-hr collection) were removed and a 10% homogenate in 0.25 *M* sucrose and 0.001 *M* EDTA was prepared. An aliquot (2 ml) of the homogenate was extracted by the Folch *et al.* (18) and Bligh and Dyer (19) methods and the number of milligrams of lipid weighed. The lipid was dissolved in methylene chloride, and the cholesterol level (3), triglyceride levels[11], neutral lipid content (20), and phospholipid content (21) were determined.

[^{14}C]Cholesterol Distribution in Mice and Rats—Male CF_1 mice (~25 g) were administered test agents intraperitoneally for 14 days and rats were administered test agents orally. On day 13, 10 μCi of [4-^{14}C]-cholesterol (52.5 mCi/mmole) was administered, and feces were collected for 0–6, 6–12, and 12–24 hr postadministration. Twenty-four hours after cholesterol administration, the major organs were excised and samples of blood, chyme, and urine were collected. Homogenates (10%) were prepared of the tissues which were combusted[12] and counted. Some tissue samples were plated on filter paper[13], dried, and digested for 24 hr in base[8] at 40° and counted. Results were expressed as dpm/mg of wet tissue and dpm/mg of total organ.

Cholesterol Absorption Study—Male Holtzman rats (~400 g) were administered test drugs intraperitoneally for 14 days at 20 mg/kg/day.

Table III—Effects of Phthalimide Analogues on Body Weight and Food Consumption of Rats after 14 Days of Dosing [a]

	Body Weight Increase Over 14 Days, %	Food Consumed Per Day, g

[e] 28.5 ± 3.14 mg of acetyl coenzyme A formed/g wet tissue/30 min. [f] 30.5 ± 2.74 mg of citrate hydrolyzed/g wet tissue/30 min. [g] 384,900 ± 26,943 dpm of cholesterol formed/g wet tissue/60 min. [h] 6080 ± 5.58 dpm of CO_2 formed/g wet tissue/18 hr. [i] 32,010 ± 1921 dpm/g wet tissue/30 min. [j] 37,656 ± 2635 dpm/g wet tissue/30 min. [k] 16.70 ± 1.16 μg Pi/g wet tissue/15 min. [l] 537,800 ± 43,024 dpm of triglyceride formed/g wet tissue/10 min. [m] 3.51 ± 0.21 μl of oxygen consumed/hr/mg of tissue. [n] 5.21 ± 0.36 μl of oxygen consumed/hr/mg of tissue. [o] 5.92 ± 0.30 μl of oxygen consumed/hr/mg of tissue. [p] 11.31 ± 0.67 μl of oxygen consumed/hr/mg of tissue.

On day 13, 10 μCi of 1,2-[^{3}H]-cholesterol (40.7 Ci/mmole) was administered to the rat orally. Twenty-four hours later, the blood was collected, and the serum was separated by centrifugation (22). Both the serum and the precipitate were counted.

Bile Cannulation Study—Male Holtzman rats (~400 g) were treated with test drugs at 20 mg/kg/day orally for 14 days; the rats were anesthetized with chlorpromazine (25 mg/kg) followed after 30 min by pentobarbital (22 mg/kg ip). The duodenum section of the small intestine was isolated and ligatures were placed around the pyloric sphincter and at a site distally approximately one-third of the way down the duodenum. Sterile isotonic saline was injected into the sectioned off duodenum segment. The saline expanded the duodenum and the common bile duct. Once the bile duct was identified, a loose ligature was placed around the bile duct, and a nich was introduced into the duct immediately before it enters the duodenum. Plastic tubing[14] was introduced into the duct, passing the ligature, and tied in place. The ligatures around the duodenum were then removed. Once bile was freely moving down the cannulated tube, [1,2-^{3}H]cholesterol (40.7 Ci/mmole) was injected intravenously into the rats. The bile was collected over the next 6 hr and measured (in ml). Aliquots were counted as well as analyzed for cholesterol content (3).

Plasma Lipoprotein Fractions—Male Holtzman rats (~400 g) were administered test drugs at 20 mg/kg/day for 14 days. On day 14, blood was collected from the abdominal aorta. Serum was separated from whole blood by centrifugation at 3500 rpm. Aliquots (3 ml) were separated by density gradient ultracentrifugation according to the methods of Hatch and Lees (23) and Havel *et al.* (24) into the chylomicrons, very low-density lipoproteins, high-density lipoproteins, and low-density lipoproteins. Each of the fractions were analyzed for cholesterol (3), triglyceride[11], neutral lipids (20), phospholipids (21), and protein levels (25).

[14] PE-10 Intramedic Polyethylene tubing.

RESULTS

Clearly, phthalimide, 1-*N*-phthalimidobutan-3-one, and 3-*N*-phthalimidopropionic acid were effective in lowering serum cholesterol and triglycerides in rats and mice. The 20-mg/kg dose appeared to be the most effective dose in rodents (Table I). The phthalimide analogues were not only effective in normogenic mice, but also in hyperlipidemic-induced mice where serum cholesterol was reduced ~150% and triglyceride levels were reduced to below normal levels (Table II). The phthalimide analogues essentially had no effect on body weight increase in rats over the period of drug administration or the consumption of food compared with the control (Table III). Organ weights of the treated rats after 14 days of dosing were suppressed slightly in the case of the liver and moderately in the case of the spleen (Table IV). All other organs appeared to be within the normal range.

Examination of mouse liver enzymatic activities (Table V) showed that phthalimide analogues present at 2.5 μmoles suppressed mitochondrial exchange of citrate to the cytoplasm and cytoplasmic acetyl coenzyme

A synthetase and adenosine triphosphate-dependent citrate lyase activities significantly. 3-Hydroxy-3-methylglutaryl coenzyme A reductase activity and side-chain oxidation of cholesterol were unaffected by the agents. Acetyl coenzyme A carboxylase, phosphatidate phosphohydrolase, and *sn*-glycerol-3-phosphate acyl transferase activities were suppressed by the phthalimide analogues, whereas fatty acid synthetase activity was unaffected. Both the basal and adenosine diphosphate-stimulated respiration states of oxidative phosphorylation of liver were reduced in the presence of the analogues. ID_{50} values obtained from rat liver assays are noted in Table VI for acetyl coenzyme A synthetase, acetyl coenzyme A carboxylase, phosphatidate phosphohydrase, and *sn*-glycerol-3-phosphate acyl transferase. ID_{50} values for 3-hydroxy-3-methylglutaryl coenzyme A reductase and fatty acid synthetase could not be obtained in the concentration range employed for these studies. When the same enzyme activities were tested *in vivo* in mice, it can readily be seen that the same enzyme activities were inhibited significantly (Table VII) after 16 days of dosing. In addition, suppression of 3-hydroxy-3-methyl glutaryl coenzyme A reductase activity was observed; in particular 3-*N*-phthalimidopropionic acid produced significant reduction of 3-hydroxy-3-methylglutaryl coenzyme A reductase activity. Dose-related suppression of acetyl coenzyme A carboxylase and phosphatidate phosphohydrolase activities and lipid content was observed for phthalimide, and acetyl coenzyme A carboxylase activity and lipid content suppression was observed for the 3-*N*-phthalimidopropionic acid.

Analysis of the lipid content (Table VIII) revealed that cholesterol, neutral lipids, and triglyceride content were reduced in liver homogenate with an elevation in phospholipid content. In the small intestine, cholesterol content was elevated and neutral lipid, triglyceride, and phospholipid content was reduced at the optimum dose, 20 mg/kg.

Radiolabeled cholesterol studies (Tables IX and X) demonstrate that lipids removed from the blood compartment were not being deposited in major organs: *i.e.*, liver, heart, brain, kidney, and lung in rats (where the cholesterol was administered orally) and mice (where the cholesterol was administered intraperitoneally). The labeled cholesterol in the treated animals was found in higher concentrations in the intestine, chyme, and feces. Cholesterol absorption (Table XI) from the gut over a 24-hr period was reduced by phthalimide and the propionic analogue. In conjunction with this observation, it can also be seen that the agents accelerated bile flow and biliary secretion of cholesterol (Table XII). The increase in cholesterol secretion is also reflected in the lipid extractions from feces of mice after treatment with phthalimide (Table XIII). Elevations in neutral lipids and phospholipids were also noted in the fecal excretion at all doses employed. Significant reduction of the lipid and protein content of serum lipoprotein fractions (Table XIV) were observed in rats after treatment with all three agents. Cholesterol, neutral lipids, and triglycerides were reduced in the chylomicron, very low-, low- and high-density lipoproteins. Phospholipid content was elevated in the chylomicron, very low-, and high-density lipoprotein fractions. Protein content was reduced in the chylomicron and very low-density fraction for all three agents. However, only phthalimide treatment resulted in a reduction of the protein of the low- and high-density lipoprotein fractions.

Data are expressed in Tables I–VIII, XIII, and XIV as percent of control (mean ± the standard deviation). The probable significant level (p) between each test group and the control group was determined by the Student's t test.

DISCUSSION

A positive correlation between elevated serum cholesterol and triglycerides and the subsequent development of atherosclerosis has been made (26). Over the years, diet and chemotherapy have been the treatments of choice. However, the number of drugs distributed commercially for the treatment of hyperlipidemic states has been decreasing due to incurred hepatotoxicity, cardiovascular changes, and GI disturbances or due to the fact that the agents did not effectively reduce both serum cholesterol and triglycerides in humans.

The required doses to elicit hypolipidemic activity for phthalimide analogues are in a safe therapeutic range compared with the LD_{50} of >2 g/kg (2). The agents were more active than clofibrate in reducing both serum cholesterol and triglyceride levels in rodents (27). Clofibrate reduced total lipid and cholesterol by 15–20% of the control values at doses of 100–200 mg/kg daily by oral or subcutaneous routes of administration (27).

The suppression of cholesterol synthesis by the phthalimide analogues was not exclusively at the regulatory site of the cholesterol pathway, *e.g.*, clofibrate blocks 3-hydroxy-3-methylglutaryl coenzyme A reductase activity. Rather, earlier steps in the *de novo* synthesis of acetyl coenzyme A appeared to be blocked by phthalimide analogues. Reduction of available citrate from the mitochondria, where it is generated from glycolysis, may be a critical factor in the synthesis of cytoplasmic acetyl coenzyme A. Reduction of mitochondrial citrate exchange in the rat liver has been shown with other agents, *e.g.*, 1,2,3-benzenetricarboxylate and 2-*p*-iodobenzylmalonate (8). The inhibition of acetate incorporation into

fatty acids in neonatal chicks has also been shown for 1,2,3-benzenetricarboxylate. Reduction of cytoplasmic levels of acetyl coenzyme A would markedly affect both cholesterol and fatty acid synthesis. Hepatic triglyceride synthesis appeared to be blocked at the regulatory sites, *i.e.*, *sn*-glycerol-3-phosphate acyl transferase and phosphatidate phosphohydrase. The inhibition of phosphatidate phosphohydrolase activity by the phthalimide analogues may explain the elevation in levels of phospholipids observed in the liver and lipoprotein fractions. A number of agents have been identified that inhibit these two enzymes [*e.g.*, 1,3-bis(substituted phenoxy)-2-propanone, 1-methyl-4-piperidyl bis(*p*-chlorophenoxy)acetate, and clofibrate (28)] with a concomitant reduction of serum triglycerides (15). ID_{50} values obtained for inhibition of these enzyme activities in the rat liver seem to be realistic considering the *in vivo* dose required for potent hypolipidemic activity of the phthalimide analogues.

The phthalimide analogues did not uncouple liver oxidative phosphorylation processes, as has been observed for clofibrate (29) and which is probably due to the detergent action of clofibrate causing disruption of the mitochondrial membranes. The phthalimide did suppress both basal and adenosine diphosphate-stimulated respiration, which may reduce available energy for synthetic processes. The phthalimide analogues, like clofibrate (30), accelerated the excretion of cholesterol and probably cholesterol esters through the biliary route; these probably are not reabsorbed from the gut *via* the extrahepatic circulation process. Data from the biliary study suggest that this mode of action of the phthalimide analogues may be of sufficient importance to account for some of the observed reduction of serum lipids.

The lipids removed from the blood compartment are not being deposited in the major organs of the body, which should be an ideal characteristic of a hypolipidemic agent. Other studies have indicated that the reduction of serum cholesterol and triglycerides after 16 and 14 days of dosing, respectively, were returned to predrug administration levels (31), indicating that the pharmacological effects of the phthalimide analogues are freely reversible after 2 weeks. Low-density lipoprotein, derived from intravascular very low-density lipoprotein, is the major lipoprotein that

transports cholesterol (60–70%) to the peripheral tissue and in most species back to the liver (32, 33). Low-density lipoproteins are deposited in the atherosclerotic plaque shedding their cholesterol into the form cells (34–36). An increase in dietary cholesterol is reflected as an increase in cholesterol levels of low-density and, to a less extent, high-density and intermediate-density lipoproteins (37). High-density lipoproteins, which originate from the liver and intestine, play an important role in the interconversion of lipid components to various lipoprotein fractions and in the return of lipids from the peripheral tissue to the liver. Both the low- and high-density lipoproteins are actively taken up by the liver low-density lipoprotein receptors (33, 38). High-density lipoproteins may participate in the transport of cholesterol out of the atherosclerotic plaque or may slow down the atherogenic process (39). Studies have suggested that high-density lipoproteins are inversely related to the incidence of coronary heart disease (*e.g.*, Troms study) (40–43). However, other studies in humans dispute these findings (44–46). Other workers have proposed that the ratio of low-density to high-density lipoprotein is more important in predicting the incidence of atherosclerosis (46, 47). The cholesterol content of each fraction or the ratio of high-density lipoprotein cholesterol to total cholesterol has also been discussed as possible parameters for predicting coronary heart disease (46, 47).

Treatment with clofibrate does not significantly alter the high-density lipoprotein fraction in humans, but lowers the cholesterol of this fraction slightly; however, clofibrate does not protect against coronary heart disease (46). Treatment with probucol for short periods of time reduces the high-density lipoproteins as well as the ratio of cholesterol content of the high-density lipoproteins to total cholesterol content with no increase in the incidence of heart disease (44). A number of preliminary studies have alluded to the fact that high-density lipoproteins are taken up by the liver where the cholesterol is released from the apoprotein and acts as a precursor for bile acids and biliary cholesterol (33, 48, 49).

Treatment with phthalimide derivatives for a 2-week period lowers cholesterol and triglyceride levels of chylomicrons, very low-, low-, and high-density lipoprotein fractions of the rat. Although the lipid distribution among the lipoproteins fractions in the rat is different from the human, some analogies may be drawn. The reduction of cholesterol and

triglyceride content of low- and high-density lipoproteins was approximately of the same magnitude after drug treatment which probably did not change the low-density to high-density lipoprotein ratio during drug treatment. The reduction of cholesterol in both lipoprotein fractions may reflect the increase in cholesterol excretion in the bile after phthalimide treatment. Supposedly, the cholesterol esters are exchanged between high- and low-density lipoproteins (50), so a reduction of one by drug therapy should reflect in the other fraction ultimately.

After phthalimide treatment it was noted that the phospholipid content of the very low-density and chylomicron fractions were elevated. Clofibrate is also known to increase the phospholipid content of liver and serum (51). The very low-density and chylomicron remnants have their phospholipid content enzymatically removed before they can be taken up by the liver. If the phospholipid, *e.g.*, phosphatidyl choline, remains on these remnants then the remnants are not taken up by the liver (52). The inability to take up these fractions may be critical to the regulation of liver cholesterol synthesis, since in hyperlipidemic patients and rats the cholesterol released from very low-density lipoproteins inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase activity (53). However, the cholesterol release from very low-density lipoproteins of normal rats did not inhibit the enzyme, suggesting that the actual content of cholesterol in the very low-density lipoprotein fraction may be the one decisive factor in the regulation of liver cholesterol synthesis (54).

Mixed results have been observed regarding the cholesterol content of high- and low-density lipoprotein fractions. In the fibroblast system, they inhibit the regulatory enzyme of cholesterol synthesis. However, in the hepatocyte tissue culture system, the high cholesterol content of high- and low-density lipoprotein did not inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase activity (54). Further studies are being conducted with the relationship of lipoprotein fractions of rats after phthalimide treatment.

Structure–Activity Studies on Sulfamate Sweetners III: Structure–Taste Relationships for Heterosulfamates

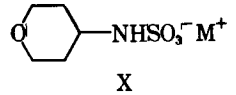
WILLIAM J. SPILLANE *x, **GRÁINNE McGLINCHEY** *, **IOGNAID Ó MUIRCHEARTAIGH** ‡, and **G. ANTHONY BENSON** §

Received May 22, 1981, from the *Department of Chemistry and the ‡Department of Statistics, University College, Galway, Ireland and the §Chemistry Department, Regional Technical College, Sligo, Ireland. Accepted for publication June 8, 1982.

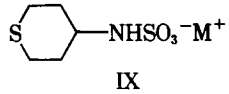
Abstract □ Eleven heterosulfamates have been synthesized, characterized, and evaluated for sweetness. Measurements of the molecular dimensions (x, y, z, and V) of these sulfamates and 22 others that had been reported previously and evaluated for sweetness have been made using Corey–Pauling–Koltun space-filling models. The first-order molecular connectivities ($^1\chi^v$) of all the heterosulfamates have been calculated. The statistical technique of linear discriminant analysis was applied to the complete set of 33 compounds and to a reduced set of 27 compounds. The analysis was performed using the above five variables (x, y, z, V, and $^1\chi^v$) and various subsets thereof. For the complete set of compounds, seven variable subsets were identified which yielded correct classifications of 27 and 28 compounds. A similar analysis of the reduced set did not improve the misclassification rate.

Keyphrases □ Heterosulfamates—synthesis, classification by linear discriminant analysis, structure–taste relationship □ Sweetners, sulfamate—structure–taste relationship, classification by linear discriminant analysis □ Linear discriminant analysis—classification of heterosulfamates, molecular connectivity correlations

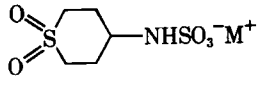
Previous studies (1–4) on heterosulfamates have shown that when one of the ring carbons of cyclohexylsulfamate is replaced by an oxygen or nitrogen atom, sweetness is lost, whereas replacement by a moiety containing a sulfur atom results in the retention of sweetness. Compounds X (1), XVIII (2), and XX (1) are nonsweet while IX (2), XI (3), and IV (4) are sweet.



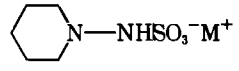
X



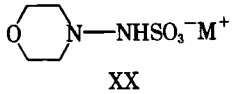
IX



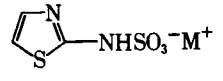
XI



XVIII

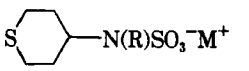


XX

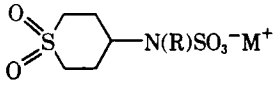


IV

Furthermore, one of the basic structure–taste rules found for carbosulfamates does not appear to apply to heterosulfamates, namely, that the presence of a free hydrogen on the nitrogen of the sulfamate function was essential for sweetness (5). This was shown by the taste evaluation of the series of cyclic sulfides (IX, XXIV, XXI, and XXV) and sulfones (XI, XXIII, and XXII) which are sweet (3).



IX: R = H
XXIV: R = —CH_2CH_3
XXI: R = —$(CH_2)_3CH_3$
XXV: R = —CH_2CH_2OH



XI: R = H
XXIII: R = —CH_2CH_3
XXII: R = —$(CH_2)_3CH_3$

Since only a few other heterosulfamates have been reported, 11 new heterosulfamates (both cyclic and open-chain) were synthesized and several structure–taste relationships were established from measurements of the molecular dimensions and molecular connectivities of these and other heterosulfamates reported previously.

EXPERIMENTAL

Synthesis—All sulfamates except VII and XII were synthesized by previously described methods (5, 6).

5-Methylisoxazolo-3-sulfamate (VII)—A solution of 3-amino-5-methylisoxazole (5 g, 0.05 mole) in dry nitrobenzene (40 ml) was cooled to 0°. Chlorosulfonic acid (4.5 g, 0.05 mole) was added with stirring at a rate such that the temperature did not rise above 5°. The mixture was stirred at room temperature for 3 hr. Ether (20 ml) was added and the orange solid that precipitated from the solution was removed by filtration, dissolved in 0.05 *M* sodium hydroxide (20 ml), and the solution was extracted with ether (2 × 20 ml). On removal of the ether under reduced pressure, an oily residue remained. On chilling this gave rise to a white solid which was the amine salt of the required sulfamate. Attempts to prepare this compound by the method of Hurd and Kharasch (4) failed. By employing the dipolar aprotic solvent nitrobenzene, a small yield (2.4%) was obtained. Possibly in this solvent protonation of the ring nitrogen of the isoxazole and consequent reduced basicity of the amino group is inhibited. The basicity of the oxazole was such that the sulfamate formed was the oxazole salt rather than the sodium salt.

3-Thia-3,3-dioxocyclopentylsulfamate (XII)—A solution of 3-thia-3,3-dioxocyclopentylamine (5 g, 0.037 mole) in ethanol (40 ml) was cooled to ~0°. Chlorosulfonic acid (3.52 g, 0.03 mole) was added in a dropwise manner with stirring. The mixture was stirred at room temperature for 3 hr, and then ethanol was removed under reduced pressure. The resulting yellow solid was dissolved in 2 *M* sodium hydroxide, and the liberated amine was extracted with ether (3 × 25 ml). The aqueous layer was then concentrated to ~10 ml and the precipitated amine salt of the sulfamate was removed by filtration and then recrystallized from 95% ethanol. Again the amine was sufficiently basic to form this salt rather than the expected sodium salt. The yields of the sulfamates synthesized were 2–20%.

Analysis and Characterization—The sulfamates prepared gave satisfactory (within ±0.5%) C, H, and N analyses except for I, II, VII, XXVI, and XXVII. Analytical data (C, H, and N) for all new compounds are given in Table I. It should be noted that occluded solvent of recrystallization is a common problem with sulfamates (5, 7, 8). Despite repeated recrystallization, the elemental analysis for I could not be improved; however, this compound displayed the sulfamate properties described below.

IR spectra of all the sulfamates prepared were recorded[1]. The sulfamates gave the following characteristic bands (9): 3400–3190 (NH), 1240–1210 (asymSO_3), 1203–1170 (symSO_3), 1072–1040 (symSO_3), and 730–660 cm^{-1} (NS). All the prepared sulfamates gave a positive "sulfamate" test (2).

Taste Analysis—Analysis was carried out as previously described (10). Two of the sulfamates (VII and XII) were isolated and purified as their amine salts ($RHNSO_3^-NH_3^+R$) and were tasted as such, since it is known that the salt-forming group does not influence the taste of sulfamates (5, 11).

Measurements with Models and Molecular Connectivity Measurements—The measurements with the Corey–Pauling–Koltun models were carried out as previously described (10), and the parameters x, y,

[a] Isolated as the amine salt of the sulfamate.

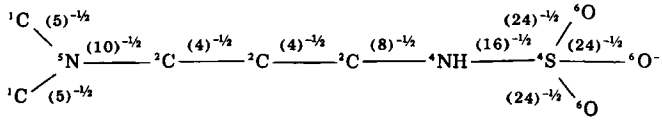
z, and V (*i.e.*, x-y-z) were determined as before (Table II). The values for the molecular connectivity (χ) for the different sulfamates were determined by considering the valence electrons, whether bonded or nonbonded. The δ values are considered to be the difference between the number of valence electrons z^v and the number of hydrogen atoms h_i:

$$\delta_i^v = z^v - h_i \qquad \text{(Eq. 1)}$$

Thus, applying this to oxygen in an alcohol $\delta^v = z^v - h_i = 6 - 1 = 5$. The δ^v values for heteroatoms are given in Table III (12). δ^v can be used to calculate a valence chi-term of the first order ($^1\chi^v$) by the expression:

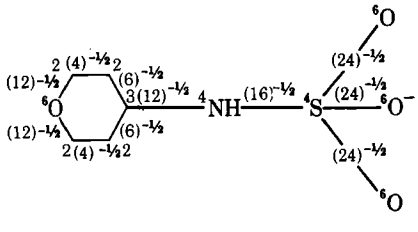
$$^1\chi^v = \Sigma(\delta_i^v\delta_j^v)^{-1/2} \qquad \text{(Eq. 2)}$$

For example, the chi-term (of the first order) for the sulfamate anion XXVII was calculated as follows:



$$\begin{array}{r} 2 \times 0.447 \\ 0.316 \\ 2 \times 0.500 \\ 0.354 \\ 0.250 \\ 3 \times 0.204 \\ \hline {}^1\chi^v = 3.43 \end{array}$$

When cyclic compounds are considered, a ring correction factor must be used because of the presence of an additional edge (bond). This is accommodated for by the use of 0.5 as a modifying term to be subtracted from $^1\chi^v$. For example, the chi-term for the 4-oxacyclohexylsulfamate (χ) was calculated as follows:



$$\begin{array}{r} 2 \times 0.289 \\ 2 \times 0.500 \\ 2 \times 0.408 \\ 0.289 \\ 0.250 \\ 3 \times 0.204 \\ \hline 3.545 \\ \text{Correction factor} - 0.5 \\ \hline {}^1\chi^v \quad 3.05 \end{array}$$

THEORETICAL

The technique used to facilitate determination of structure–taste relationships is that of linear discriminant analysis. This method is applied when M(≥1) measurements (variables) are available for each member of two clearly defined groups and yields a linear function of the variables which best separates the two groups.

The theory of the linear discriminant function is described in many statistical tests (17, 18). Conceptually the method is identical for all values of M (the number of variables observed for each member of each group), but the essential ideas are most easily expanded for the case M = 2. In this case, we have two measurements, say X and Y, for each member of each group. Each member can therefore be represented as a point in the X,Y plane. The linear discriminant function in this case is the line that, in a certain sense, best separates the two groups. If the equation of this line is:

$$aX + bY = k \qquad \text{(Eq. 3)}$$

then mathematically the problem is to use the given (X,Y) data to estimate constants a, b, and k such that the line given by (Eq. 3) separates the two groups in some optimal sense. The extension to the case of M > 2 variables is mathematically straightforward, but conceptually more difficult. We now seek a linear combination:

$$l(X_1,X_2,\ldots X_M) = a_1X_1 + a_2X_2 + \ldots + a_MX_M = a^1X \qquad \text{(Eq. 4)}$$

where $a^1 = (a_1, a_2, \ldots a_n)$ and $X^1 = (X_1, \ldots X_M)$ such that an equation of the form:

$$l(X) = k \qquad \text{(Eq. 5)}$$

optimally separates the two groups. In the case M = 3, this is equivalent to finding the plane that best separates the two groups in the three-dimensional space in which they can be represented. For M > 3, we obtain a hyper-plane separating the two groups. Although the geometrical representation breaks down for the case M > 3, the mathematical method is straightforward.

Most statistical packages used on computers will perform this analysis. The package BMDP (19) was used in this case, and it yields the constants $a_1, a_2, \ldots a_M$ of Eq. 4. The constant k is then chosen to optimize the discriminatory power of the discriminant function $l(X)$. The criterion of optimality usually used involves stochastic assumptions concerning the multivariate normal distribution of the underlying data. Given the nature of this particular data set, the more *ad hoc* criterion of minimizing the number of misclassifications using the discriminant function $l(X)$ has been adopted in this paper.

Suppose one has two groups of compounds and has recorded the values of each of M variables for n_1 members of group 1 and n_2 members of group 2.

Let $X_{ijk}\{i = 1,2; j = 1,2 \ldots n_i; k = 1,2 \ldots M\}$ be the value of the k^{th} variable for the j^{th} member of the i^{th} group. Let:

$$\overline{X}_{ik} = \sum_j X_{ijk}/n_i \qquad \begin{matrix} i = 1,2 \\ k = 1,2,\ldots M \end{matrix} \qquad \text{(Eq. 6)}$$

and define the mean vectors of the two groups to be, respectively:

$$\overline{X}_1^1 = (\overline{X}_{11}, \overline{X}_{12}, \ldots \overline{X}_{1M}) \qquad \text{(Eq. 7)}$$

$$\overline{X}_2^1 = (\overline{X}_{21}, \overline{X}_{22}, \ldots \overline{X}_{2M}) \qquad \text{(Eq. 8)}$$

Further let:

$$S_{kl} = \frac{\sum_i \sum_j (X_{ijk} - \overline{X}_{ik})(X_{ijl} - \overline{X}_{il})}{n_1 + n_2 - 2} \qquad \text{(Eq. 9)}$$

so that:

$$S = (S_{kl}) \qquad \text{(Eq. 10)}$$

is the M × M pooled estimate of the (assumed) common covariance matrix. Then the elements of the vector a of Eq. 4 are given by:

$$a = (\overline{X}_1 - \overline{X}_2)^1 \cdot S^{-1} \qquad \text{(Eq. 11)}$$

[a] Measurements were made on the structures indicated. [b] Compounds XXVIII–XXXIII are sulfonates, but may be regarded as secondary sulfamates and are thus included. [c] Key: (S) sweet; (N) nonsweet; (B) bitter. [d] Molecular connectivities were calculated for the total sulfamate anion, *i.e.*, the $-SO_3^-$ moiety was included in the calculations (see *Experimental*). [e] — Values obtained from this work.

and the classification rule is:

$$\text{classify as group 1 if } a^1X > k$$
$$\text{classify as group 2 if } a^1X \leq k$$

The choice of k is then made to minimize the number misclassified by this rule.

RESULTS AND DISCUSSION

In a previous paper, measurements using Corey–Pauling–Koltun (CPK) space-filling models were carried out on carbosulfamates and a semiquantitative structure–taste relationship was established (10). The approach was similar here and measurements of length (x), height (y), and width (z) of R—NH (or R—NR^1) in R—$NHSO_3^-$ (R—$NR^1SO_3^-$) were made using CPK models. V (in Å^3) may be thought of as a measure of the size or three-dimensional structure of R—NH(R—NR^1) and was calculated as previously described. In addition, a molecular connectivity term ($^1\chi^v$) has been calculated (see *Experimental*). The values of x, y, z, V, and $^1\chi^v$ as well as the test data are given for all the heterosulfamates in Table II.

The mathematical analysis has been performed twice: with the complete set of 33 compounds and with a reduced set of 27 compounds (omitting the last six compounds of Table II). Since six compounds of Table II are sulfonates that could be regarded as secondary sulfamates, the analysis has been tried with and without these compounds. As the analysis involving the reduced set did not improve the misclassification rate, it is not described further.

The linear discriminant analysis could be performed using any subset of the five variables. There are 31 such subsets and, to save computation time, a preliminary analysis using a statistically equivalent technique, stepwise logistic analysis (19), enabled identification of the 14 subsets most likely to provide effective discrimination. The discriminant analysis was then performed using these subsets. For the complete set (33 compounds), the most effective variable subset of each (2, 3, 4, 5), the discriminant function a^1X for each of those subsets, the corresponding constant k, and the number of compounds misclassified by the optimal classification rule so derived are given in Table IV.

A discussion of the discriminant analysis applied to the complete data set and using the variable subset (x,$^1\chi^v$) will be utilized to highlight the main points of this type of analysis. From Table IV it can be seen that the dividing line in this case is:

$$-0.63x + 0.58\,^1\chi^v = -3.95 \qquad \text{(Eq. 12)}$$

It can be seen from Table IV that, with the exception of IV, V, IX, XI, XVI, and XXIV, all the sweet compounds lie above and all the nonsweet compounds lie below this line. The mathematically equivalent results for this case are given in Table V, which presents the values of:

$$d = -0.63x + 0.58\,^1\chi^v \qquad \text{(Eq. 13)}$$

for each compound. It can be seen that for all the sweet compounds (with the aforementioned exceptions), $d < k\{-3.95\}$, whereas for all the nonsweet compounds $d > k$.

Detailed results are not presented for the discriminant analyses based on the other variable subsets given in Table IV. From Table IV it can be seen that, although the inclusion of additional variables does not dramatically affect the discriminatory performance, the number of misclassified compounds does decrease (to 5) when one uses the subset x,z,$^1\chi^v$. For this particular case, the discriminant function is:

$$d = -0.86x - 0.81z + 1.31\,^1\chi^v \qquad \text{(Eq. 14)}$$

and the corresponding classification rule is:

$$\text{classify as sweet if } d < -8.18$$
$$\text{classify as nonsweet if } d > -8.18$$

In fact three sweet compounds (IX, XI, and XVI) have values of $d > -8.18$, and two nonsweet compounds (III, XVII) have values of $d < -8.18$. The remaining subsets in Table IV misclassify six compounds in each case. Thus, an accuracy of 85% can be attained for the subset involving the variables x, z, and $^1\chi^v$ with 81% accuracy for all other subsets. For the carbosulfamates an accuracy of >90% could be achieved using the variables x and V only (10). Here the accuracy is not as good but, considering the wide diversity of heterocompounds in Table II, the present correlation can be regarded as reasonable.

A weakness of the x,$^1\chi^v$ subset correlation seems to be that all six misclassified compounds come from the group of 10 sweet compounds, while the 23 nonsweet compounds are classified correctly. One would prefer to see a more even spread of misclassified compounds from the sweet and nonsweet groups as in some of the four or five variable subsets in Table

Table IV—Discriminant Analysis for Best Subsets

Subset	a^1X	k	Compounds Misclassified: Sweet	Compounds Misclassified: Nonsweet	Total Misclassified
$x,{}^1\chi^v$	$-0.63x + 0.58{}^1\chi^v$	−3.95	IV, V, IX, XI, XVI, XXIV		6
$y,V,{}^1\chi^v$	$1.62y - 0.02V + 0.65{}^1\chi^v$	+4.21	IX, XI, XVI, XXIII, XXIV	XVII	6
$x,z,{}^1\chi^v$	$-0.86x - 0.81z + 1.31{}^1\chi^v$	−8.18	IX, XI, XVI	III, XVII	5
$x,z,V,{}^1\chi^v$	$-1.01x - 1.08z + 0.01V + 1.06{}^1\chi^v$	−10.50	IX, XI, XVI	III, XV, XVII	6
$x,y,z,{}^1\chi^v$	$-0.81x + 0.34y - 0.88z + 1.01{}^1\chi^v$	−7.49	IX, XI, XVI	III, XV, XVII	6
x,y,z,V	$-0.37x + 1.05y - 0.41z - 0.01V$	−2.37	IV, IX, XI, XVI	XV, XVII	6
$x,y,z,V,{}^1\chi^v$	$-1.06x - 0.08y - 1.12z + 0.01V + 1.08{}^1\chi^v$	−11.17	IX, XI, XVI	III, XV, XVII	6

IV (*e.g.*, the $x,z,{}^1\chi^v$ subset which has three sweet and two nonsweet compounds misclassified).

If one uses the number misclassified and the spread of misclassified compounds between sweet and nonsweet groupings as criteria of significance, then one may concentrate on the last five subsets of Table IV. The importance of spatial or volume effects at the receptor site is clear when one observes that x and either z or y or both are involved in all these subsets. ${}^1\chi^v$ Encodes both volume and electronic effects of bonds (20), and it is noteworthy that this variable occurs in four of these five subsets. With the carbosulfamates, electronic influences were probably small and, hence, a correlation was possible using only spatial parameters. However, with the introduction of various heteroatoms into the sulfamates, electronic effects of bonds could be important, and a more complicated type of correlation would thus be expected.

Molecular connectivity terms have been used in recent years to correlate the sweetness of substituted nitroanilines (21) and the percent sweet/bitter taste of aldoximes, RCH=NOH (22). Thus, ${}^1\chi^v$ was introduced since a correlation with our spatial parameters only was not possible.

In the listing of misclassified compounds, the same compounds appeared: III, IX, XI, XV, XVI, and XVII. It is instructive to look at these more closely in the hope of finding a common factor that may cause their deviation. Compounds IX, XI, and XVI all have a sulfur atom in a six-membered ring in either the disulfide or sulfone form. Compounds IV–VI and VIII also have sulfur atoms in five-membered rings, but these atoms are involved in the aromaticity of the rings. Compound XII has sulfur in a five-membered saturated ring system, and one may regard compounds XXI–XXV as special cases since they all have disubstituted sulfamate nitrogens. It thus seems that the correlations established will consistently misclassify six-membered saturated sulfur ring systems. The reason(s) for the deviation of the three nonsweet compounds III, XV, and XVII are less clear.

Table V—Discriminant Function [a] Values for Subset ($x,{}^1\chi^v$)

Percutaneous Absorption of Flufenamic Acid in Rabbits: Effect of Dimethyl Sulfoxide and Various Nonionic Surface-Active Agents

CHIAW-CHI HWANG and AUGUST G. DANTI ˣ

Received December 21, 1981, from the *School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication July 14, 1982.

Abstract □ Eight nonionic surface-active agents were each incorporated at a concentration of 10% into a white petrolatum ointment base containing 10% flufenamic acid with or without dimethyl sulfoxide. Percutaneous absorption was studied by determining the plasma concentration of flufenamic acid in New Zealand White rabbits at regular intervals for 8 hr following application of the ointment. The percutaneous absorption of flufenamic acid was significantly increased when sorbitan trioleate, polyoxyl 8 stearate, or polyoxyethylene 2 oleyl ether were added to the ointment containing flufenamic acid and white petrolatum. The percutaneous absorption of flufenamic acid was increased significantly when sorbitan monopalmitate, sorbitan trioleate, polyoxyl 8 stearate, polyoxyethylene 20 cetyl ether, or polyoxyethylene 2 oleyl ether were added to the ointment containing dimethyl sulfoxide, flufenamic acid, and white petrolatum.

Keyphrases □ Flufenamic acid—percutaneous absorption, effect of nonionic surfactants and/or dimethyl sulfoxide □ Dimethyl sulfoxide—effect on the percutaneous absorption of flufenamic acid, synergism with nonionic surfactants □ Surfactants, nonionic—effect on the percutaneous absorption of flufenamic acid, synergism with dimethyl sulfoxide □ Absorption, percutaneous—of flufenamic acid, effect of dimethyl sulfoxide and/or nonionic surfactants

The anti-inflammatory and analgesic actions of flufenamic acid, *N*-(α,α,α-trifluoro-*m*-tolyl)-anthranilic acid, have been reported previously (1–4). The side effects shown on oral administration of flufenamic acid are predominantly GI disorders such as diarrhea, nausea, and vomiting. Cutaneous application of flufenamic acid for rheumatic disorders could have numerous advantages. A highly potent preparation could be used without causing the aforementioned GI disturbances. The active ingredients diffuse directly through the skin at the application site, and the concentration of the active ingredients in the subcutis and the superficial musculature are considerably higher with a longer duration of action than after oral administration. Percutaneous absorption of flufenamic acid and the resulting anti-inflammatory activity has been shown using animal and human models (5–10).

The use of dimethyl sulfoxide as a penetrant carrier has been suggested (11). Stoughton *et al.* (12, 13) reported that dimethyl sulfoxide increased the rate of penetration of naphazoline hydrochloride, hexopyrronium bromide, and fluocinolone acetonide through the human skin. Dimethyl sulfoxide also has been found to accelerate the penetration of water (14), hydrocortisone, and testosterone (15) through the skin *in vivo*.

Surfactants are one of the most important groups of adjuvants in pharmaceutical preparations. For topically applied preparations, surfactant-induced dissolution or emulsification of active ingredients and changes in ointment viscosity may modify the absorption process. Higuchi (16) suggested that the surfactants generally possess a particular affinity for membranous structure. As a result of this affinity, a nonionic surfactant could possibly emulsify the sebum, enhance the thermodynamic activity of drugs, or change the diffusion constant and activity coefficient of drugs, all of which would permit easier penetration of the drug into the cells.

Shen *et al.* (17) studied the effects of 15 nonionic surfactants on the percutaneous absorption of salicylic acid in white petrolatum containing dimethyl sulfoxide. They found that the plasma salicylate levels in rabbits were increased significantly when sorbitan trioleate, sorbitan monopalmitate, poloxamer 231, poloxamer 182, polyoxyethylene 4 lauryl ether, polyoxyethylene 2 oleyl ether, or polyoxyl 8 stearate was added to the ointment. As a continuation of this work, the effect of selected nonionic surfactants on the percutaneous absorption of flufenamic acid in the presence of dimethyl sulfoxide was studied in rabbits.

EXPERIMENTAL

Materials—The following ointments were used: 10% flufenamic acid[1] in white petrolatum[2], 10% flufenamic acid plus 5% dimethyl sulfoxide[3] in white petrolatum, 10% flufenamic acid plus 10% surfactant in white petrolatum, and 10% flufenamic acid plus 10% surfactant plus 5% dimethyl sulfoxide in white petrolatum. The nonionic surfactants selected [with hydrophilic–lipophilic balance (HLB) values in brackets] were sorbitan monopalmitate[4] [6.7], sorbitan trioleate[5] [1.8], polyoxyl 8 stearate[6] [11.1], polyoxyl 40 stearate[7] [16.9], polyoxyethylene 20 cetyl ether[8] [15.7], polyoxyethylene 2 oleyl ether[9] [4.9], poloxamer 184[10] [15], and poloxamer 231[11] [2]. The absorption of topically applied flufenamic acid was compared for white petrolatum preparations containing the acid (with or without dimethyl sulfoxide) *versus* the acid (with or without dimethyl sulfoxide) plus a surfactant.

Ointment Preparation—Flufenamic acid, in a fine powder form, was dried at 50° in a heated vacuum desiccator for at least 48 hr before use. The prepared ointments contained 10% (w/w) flufenamic acid and 10% (w/w) surfactant with or without 5% dimethyl sulfoxide. Each ingredient was weighed on an analytical balance[12] and incorporated into the white petrolatum by the fusion method.

Test Animals—Each ointment was applied to the skin of a New Zealand white rabbit weighing 3.3–4.3 kg. Each rabbit was used four times and received the same group of surfactants in each test. Not more than three rabbits were utilized during any one experimental day, due to space and time limitations. The rabbits receiving ointments containing dimethyl sulfoxide for the first test run received the ointment without dimethyl sulfoxide for the second run and *vice versa*, with a 7-day rest period before reapplication. The animals were offered food[13] and water *ad libitum* and were housed individually in an animal room maintained

[a] Percutaneous absorption in rabbits; average of three determinations. [b] Flufenamic acid, surfactant, and white petrolatum. [c] Flufenamic acid, surfactant, dimethyl sulfoxide, and white petrolatum.

at a temperature of 25°. Fifteen to eighteen hours prior to the application of the ointment, the hair was removed from the back of the rabbit (8 × 12-cm^2 area) with an animal clipper[14] and depilatory cream[15]. The skin was examined under low-power magnification for damage resulting from the shaving procedure, and the animal was not used if the skin barrier was disrupted.

Application of Ointment—The rabbits were immobilized in a rack (stock) during treatment to prevent them from ingesting the ointment after application. The selected ointment was uniformly spread over the shaved back in a variety of doses (1 g ointment/kg). The ointment remained in contact with the skin for 8 hr, during which time the rabbit did not receive food or water.

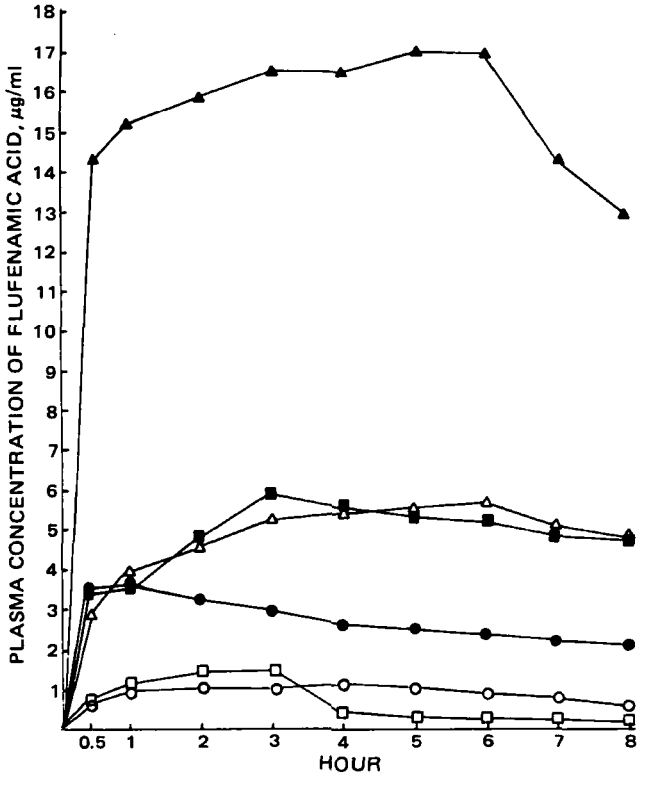

Figure 1—*Effect of sorbitan surfactants on the percutaneous absorption of flufenamic acid with or without dimethyl sulfoxide. Flufenamic acid in white petrolatum (○) with (□) sorbitan monopalmitate, (△) sorbitan trioleate, (●) dimethyl sulfoxide, (■) sorbitan monopalmitate plus dimethyl sulfoxide, and (▲) sorbitan trioleate plus dimethyl sulfoxide.*

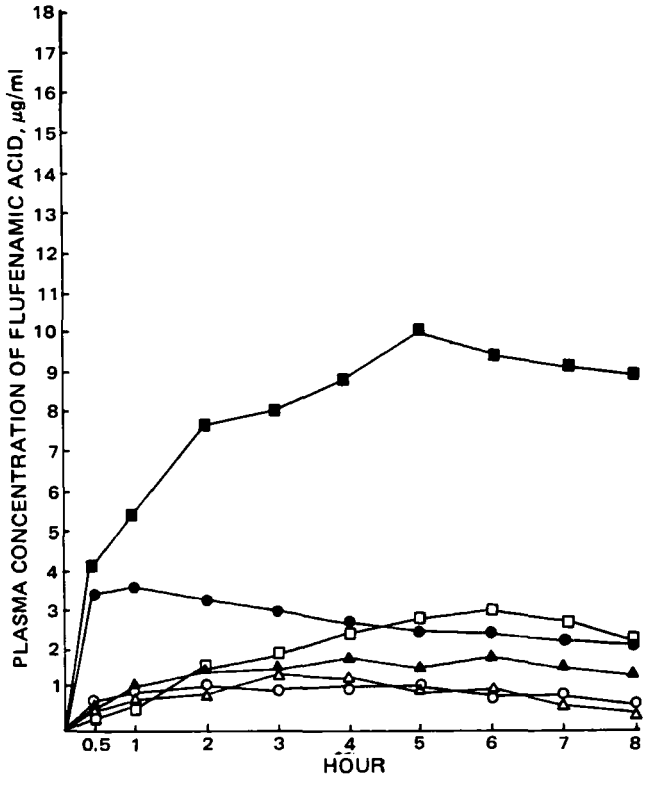

Figure 2—*Effect of polyoxyethylene ester surfactants on the percutaneous absorption of flufenamic acid with or without dimethyl sulfoxide. Flufenamic acid in white petrolatum (○) with (□) polyoxyl 8 stearate, (△) polyoxyl 40 stearate, (●) dimethyl sulfoxide, (■) polyoxyl 8 stearate plus dimethyl sulfoxide, and (▲) polyoxyl 40 stearate plus dimethyl sulfoxide.*

Procedure of Sample Collection—Blood samples were collected and analyzed for flufenamic acid. One-half milliliter of blood was withdrawn from the marginal ear vein of the rabbit prior to application of the ointment, at 0.5 hr after ointment application, and at hourly intervals for 8 hr after application. The blood was collected with a sterile 26-gauge, 0.9-cm needle[16] in a 1-ml disposable tuberculin syringe containing 0.05 ml of sodium heparin[17]. This blood–heparin mixture was placed in a 15-ml glass-stoppered centrifuge tube containing 0.5 ml of 0.2 *M* acetate buffer and 6 ml of ethyl acetate.

The concentration of flufenamic acid was analyzed using the spectrofluorometric[18] method described by Hattori *et al.* (18). Concentrations were determined using a standard curve obtained by analysis of heparinized (0.05 ml) blood samples with added known amounts of flufenamic acid. The plasma sample obtained from each rabbit prior to the drug application was used as a blank to determine the background fluorescence for that animal.

Statistical Analysis of Data—Three replications were made of each determination. A *t* test with four degrees of freedom at the 95% significance level was used to test the null hypothesis.

RESULTS AND DISCUSSION

The altered percutaneous absorption patterns of flufenamic acid obtained on the addition of surfactants to flufenamic acid, with or without dimethyl sulfoxide, in white petrolatum ointments are shown in Figs. 1–4. The areas under the curves (AUC) for the plasma concentration of flufenamic acid *versus* time of the different treatments were evaluated from 0 to 8 hr postdose (AUC_{0-8}) using the trapezoidal rule (Table I). The *t* test results for the comparison of the AUC_{0-8} between flufenamic acid (with or without dimethyl sulfoxide) plus a surfactant and flufenamic acid (with or without dimethyl sulfoxide) are shown in Table II.

Statistical analyses of the results of this study indicated that some of the surfactants functioned as penetrant carriers, enhancing the percu-

taneous absorption of flufenamic acid. When these surfactants were added to an ointment containing flufenamic acid and dimethyl sulfoxide, percutaneous absorption of flufenamic acid was significantly increased throughout the 8-hr experimental period. The data suggest that this was a synergistic effect between the surfactant and dimethyl sulfoxide.

The percutaneous absorption of flufenamic acid was increased when dimethyl sulfoxide was added to the ointment. Since dimethyl sulfoxide (11) and flufenamic acid have been used alone in the treatment of musculoskeletal disorders, it was deemed worthwhile to conduct a further pharmacological study using concomitant cutaneous application of these two substances.

Dimethyl sulfoxide exhibited an unusual concentration dependence. Some investigators have pointed out that at least 60% dimethyl sulfoxide was required for a measurable permeability change in the skin (19). In this study, the percutaneous absorption of flufenamic acid was increased significantly by the addition of 5% dimethyl sulfoxide. The lower percutaneous absorption of flufenamic acid with certain surfactants may be due to the lowering of the thermodynamic activity of flufenamic acid by complexation or by other interactions with the skin (20) or by miceller trapping of the active ingredient (21).

Both the mechanism by which the percutaneous absorption of flufenamic acid is increased on addition of nonionic surfactants in the presence of dimethyl sulfoxide and the mechanism of action of dimethyl sulfoxide itself are unknown. However, it can be concluded that ultrastructural modifications of the stratum corneum caused by dimethyl sulfoxide and/or the surfactants, associated with altered skin permeability (22) do occur. Higuchi (16) suggested that the activity coefficient plays a major role in percutaneous absorption. Flufenamic acid may be held firmly by the white petrolatum, which exhibits a low activity coefficient. When dimethyl sulfoxide and the surfactants are added to the flufenamic acid in white petrolatum, the release rate of flufenamic acid could be increased by forming high activity coefficient complexes such as dimethyl sulfoxide–drug, surfactant–drug, or dimethyl sulfoxide–surfactant–drug.

Steady-State Determination of the Contribution of Lung Metabolism to the Total Body Clearance of Drugs: Application to Carbamazepine

PETER J. WEDLUND, SHIH-LING CHANG, and RENÉ H. LEVY[x]

Received January 7, 1982, from the *Departments of Pharmaceutics and Neurological Surgery, Schools of Pharmacy and Medicine, University of Washington, Seattle, WA 98195.* Accepted for publication July 8, 1982.

Abstract □ A steady-state approach is proposed to examine the contribution that the lung makes to the total body elimination of medium- to high-clearance drugs. Carbamazepine, a potential candidate of pulmonary metabolism, was investigated by infusion into the femoral vein in seven unrestrained Sprague–Dawley rats (250–300 g). Blood samples (0.45 ml), taken simultaneously from the jugular vein and carotid artery in each rat during the infusion (2–5 days), were assayed in duplicate for carbamazepine by GLC/CI/MS. Venous blood concentrations were used to calculate the total body clearance of carbamazepine, 440 ± 38 ml/hr (mean ± *SEM*), and the difference between simultaneous venous and arterial blood concentrations were used to calculate the extraction ratio of carbamazepine by the lung. The mean extraction ratio of 0.0058 (n = 28) suggests that the lung only contributes ~5% to the total body clearance of carbamazepine. It is proposed that this technique could be useful in examining the importance of the lung in the total body clearance of other drugs, and that it has several advantages over some currently used techniques.

Keyphrases □ Carbamazepine—elimination *via* pulmonary metabolism in the rat, steady-state determination □ Metabolism, pulmonary—of carbamazepine in the rat, steady-state determination of drug elimination *via* the lungs □ Drug clearance—contribution to lung metabolism, steady-state determination using carbamazepine in the rat

Numerous articles and reviews have appeared over the last 10 years establishing the xenobiotic-metabolizing capability of *in vitro* lung preparations (1–5). However, the extrapolation of *in vitro* data on pulmonary metabolism to drug elimination by the lungs *in vivo* is fraught with difficulties and limitations (6–8). Several approaches are available for quantitation of lung metabolism *in vivo*, including isolated lung perfusion (6–9), ratios of area under the curve following venous and arterial bolus doses (10), and measurement of the extraction of drug across the lung at steady state (11). While each approach has advantages and disadvantages, measurement of drug extraction across the lung following achievement of steady-state drug levels constitutes a reliable and convenient method of delineating the contribution of the lung to the total body clearance of drugs. In the present study, the steady-state approach was used in rats to investigate the possible contribution of the lung to the total body clearance of the antiepileptic drug,

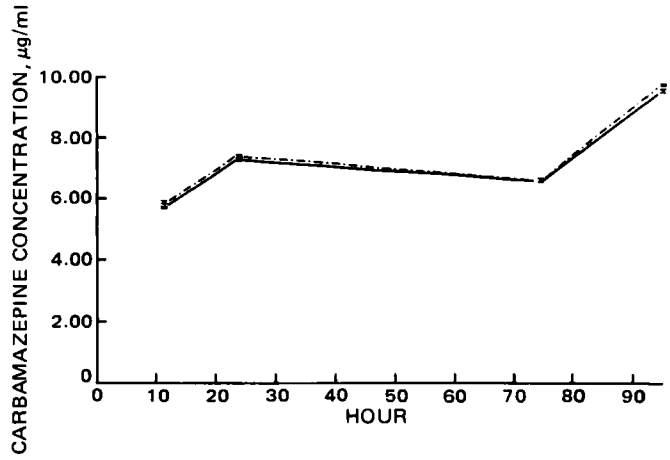

Figure 3—*Arterial (—) and venous (- - -) carbamazepine blood levels in rat 27 during a long-term carbamazepine infusion.*

carbamazepine. Carbamazepine has a large total body clearance in rats with a very small fraction (2%) eliminated unchanged in urine (12–14). Also, the reported clearance of carbamazepine in rat liver perfusions is too low to account for the large total body clearance observed (15, 16). Therefore, the potential contribution of the lungs to carbamazepine elimination was investigated.

THEORETICAL

Based on mass balance principles, the clearance of a drug by an organ can be defined by the relationship:

$$CL_o = Q_B \times ER = Q_B \times \frac{C_i - C_o}{C_i} \quad \text{(Eq. 1)}$$

where CL_o is the organ clearance, Q_B is the blood flow through the organ, and ER, estimated from the blood concentration before (C_i) and after (C_o) the organ circulation, represents the extraction ratio of the drug across the organ (17, 18). By placing cannulas in the jugular vein and carotid artery, one can measure the change in drug levels across the heart and lungs (Fig. 1). With the assumption that the heart does not metabolize the drug, one can calculate the pulmonary clearance of the drug at steady state using Eq. 1.

EXPERIMENTAL

Materials—Infusion solutions of carbamazepine (5 mg/ml) were made by dissolving the drug in 60% polyethylene glycol 400. The solutions were filtered and autoclaved before use. Harnesses and swivel joints for long-term infusions in unrestrained rats were purchased[1]. Constant-rate infusion pumps[2] were used for drug delivery. Cannulas were made of a short piece of silicone tubing[3] (for insertion into the veins and artery) connected to a longer section of polyethylene-50 tubing. Ether (USP grade) was used as the anesthetic.

Animals—Seven male Sprague–Dawley rats (250–300 g) were cannulated under ether anesthesia. Cannulations were performed on the right carotid artery and jugular vein for blood sampling and on the femoral vein for drug infusion. The polyethylene-50 section of the cannula was run subcutaneously beneath the skin and out through a small incision in the back of the neck. All operations were performed under aseptic conditions using sterilized instruments and cannulas. Rats were then attached for unrestrained long-term infusions using previously described methods (19–21).

Following the operation, animals were infused with sterile saline for 3 days. During this time, the carotid artery and jugular vein cannulas were flushed once a day with sterile saline solution (without heparin) to prevent blood clotting in the line.

[3] Silastic Medical-Grade tubing, i.d. 0.020 in., o.d. 0.037 in., Dow-Corning, Midland, Mich.

Drug Treatment and Blood Sampling—Three days after the cannula implantation, the rats were started on a carbamazepine infusion (0.25–0.30 ml/hr). Blood samples (0.45 ml) were drawn simultaneously from jugular vein and carotid artery once every 12–24 hr after the beginning of the infusion. The blood was frozen immediately and maintained at −20° until assayed.

Analytical Procedure—Whole blood (200 µl) was assayed for carbamazepine using a GLC/CI/MS assay developed in this laboratory (22). Each sample was assayed in duplicate, and the average values were used for all calculations.

RESULTS AND DISCUSSION

The concentration–time profiles of carbamazepine from jugular vein and carotid artery blood samples in rats 13 and 27 are shown in Figs. 2 and 3, respectively. Little, if any, difference in carbamazepine blood levels were found between these sampling sites.

A plot of the arterial *versus* venous carbamazepine blood levels for 28 simultaneous samples in all seven rats is given in Fig. 4. Theoretically, any slope from zero (reflecting complete extraction) to 1.0 (no pulmonary extraction) could result. The slope of 0.992 (not significantly different than 1.0) suggests very little or no carbamazepine elimination during passage through the pulmonary circulation.

The mean (± *SEM*) extraction ratio of carbamazepine by the lung was 0.0058 (±0.004) based on the 28 pairs of arterial–venous blood levels. Assuming a mean cardiac output of 62.5 ml/min in rats (23–25), the average lung clearance of carbamazepine would be approximately 22 ml/hr. The total body clearance of the drug (CL_T) was calculated using the infusion rate (Ko) and steady-state concentration (C_v) in the venous blood:

$$CL_T = \frac{Ko}{C_v} \quad \text{(Eq. 2)}$$

Based on a mean (± *SEM*) total body clearance of carbamazepine of 440 (± 38) ml/hr, the lung appears to contribute only ~5% to the total elimination of carbamazepine *in vivo*. The lack of significant lung metabolism of carbamazepine and the failure of liver perfusion experiments to account for its large total body clearance suggest either the presence of some other extrahepatic sites of drug metabolism or an error in the total liver clearance of carbamazepine determined by liver perfusion.

While the steady-state approach may be a useful technique to quantitate the role that lung metabolism plays in the total body clearance of drugs, several aspects of the present study design need further consideration before an appreciation can be gained for the limits of this approach. The blood flow through the pulmonary circulation is 3–4 times larger than the blood flow through other organs that are capable of drug elimination. Hence, even a small drug extraction ratio by the lungs can contribute significantly to the total elimination of a drug. To measure a potentially small pulmonary extraction ratio of a drug, a very sensitive and accurate assay is required in addition to a large number of samples. These problems were overcome in the present experiment by: (*a*) the use of a GLC/CI/MS assay for carbamazepine with a median percent difference between duplicate determinations of only 1.4% and (*b*) the inclusion of 28 pairs of observations from a group of seven rats.

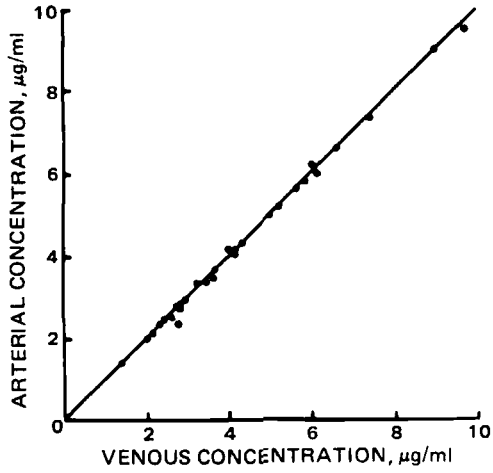

Figure 4—*Relationship between venous and arterial carbamazepine blood levels during long-term infusions in seven rats. The slope is 0.992 (not significantly different than 1.000);* $R^2 = 0.997$.

Despite the need for an accurate and reproducible assay, the steady-state approach has several advantages over other available techniques for quantitating the importance of lung metabolism. First, it does not require measuring the amounts of metabolites formed by the lung. This may be advantageous, from an analytical point of view, when there are a large number of potential metabolites which could be formed or novel metabolites specific to lung metabolism. Second, it allows a quantitation of the contribution of the lung to the total body clearance of drugs in the intact animal rather than under low pulmonary blood flow rates or other conditions optimal to *in vitro* systems. Third, it eliminates problems of intraanimal variability in drug metabolism (a potential problem with single bolus doses given by different routes) by using instantaneous differences in blood levels. Fourth, the contribution of lung metabolism to the total body clearance of drugs can be determined at drug concentrations of therapeutic importance.

The results of this study suggest that the steady-state approach can be a reliable and simple means of quantitating the contribution of lung metabolism to the total body clearance of drugs. This may be particularly important for drugs that are metabolized extensively, and where significant extrahepatic elimination is suspected. In addition, the steady-state approach can be a useful and direct means for examining the role of pulmonary metabolism for medium- to high-clearance drugs or model compounds which, based on other approaches, are postulated or appear to undergo significant lung metabolism.

Finally, it should be noted that although a number of substances are metabolized by isolated perfused lungs or lung homogenates (26, 27), little work has been directed toward quantitating the importance of lung metabolism to the total body clearance of these substances (11, 28). Despite the role played by lung metabolism in lung cancer and its induction by cigarette smoke (29–32), the importance of pulmonary metabolism in the overall elimination of drugs and its potential for producing toxic metabolites has only just begun to be appreciated (28, 33).

ADDENDUM

Following submission of this manuscript for publication, a theoretical treatment of the importance of lung metabolism to total body clearance by Collins and Dedrick was published (34).

Chemical Aspects of Propranolol Metabolism: 1,1-Diethoxy-3-(1-naphthoxy)-2-propanol and Related Ring-Closure Products *cis*- and *trans*-4-Ethoxy-3-hydroxy-3,4-dihydro-2*H*-naphtho[1,2-*b*]pyran

CHING-HSIU CHEN and WENDEL L. NELSON ˣ

Received March 22, 1982, from the *Department of Medicinal Chemistry, School of Pharmacy, University of Washington, Seattle, WA 98195.* Accepted for publication July 1, 1982.

Abstract □ 1,1-Diethoxy-3-(1-naphthoxy)-2-propanol (V), the diethyl acetal of an important aldehyde intermediate in the metabolic *N*-dealkylation of propranolol, was prepared from compound X, the product of the reaction of the lithium salt of methyl methylsulfinylmethyl sulfide with 2-(1-naphthoxy)-acetaldehyde. Compound X, as a mixture of three diastereomeric α-hydroxydithioacetal derivatives, when treated with ethyl orthoformate afforded the desired acetal V as well as two ring-closure products, the dihydronaphtho[1,2-*b*]pyrans VI and VII. Compounds VI and VII were characterized on the basis of mass spectral and ^{1}H- and ^{13}C-NMR data. The stereochemistry of these compounds was assigned on the basis of the 300-MHz ^{1}H-NMR spectra of their acetate esters (XI and XII).

Keyphrases □ Propranolol—metabolite synthesis, 1,1-diethoxy-3-(1-naphthoxy)-2-propanol □ Metabolism—of propranolol, synthesis of the diethyl acetal of an aldehyde intermediate, 1,1-diethoxy-3-(1-naphthoxy)-2-propanol □ 1,1-Diethoxy-3-(1-naphthoxy)-2-propanol—synthesis, diethyl acetal of an aldehyde intermediate in propranolol metabolism

Propranolol (I) is a β-adrenergic receptor antagonist used extensively in the treatment of various cardiovascular disorders, including hypertension and angina pectoris (1–3). In humans, a major metabolic process is oxidative *N*-dealkylation, which consists of at least two multistep pathways that result in the ultimate formation of both 3-(1-naphthoxy)-2-hydroxypropionic acid (II) and 3-(1-naphthoxy)propane-1,2-diol (III) (4–6). These metabolites are thought to arise from the oxidation and reduction of a common intermediate, 3-(1-naphthoxy)-2-hydroxypropionaldehyde (IV) (7). This aldehyde (IV) probably arises to a small extent directly from propranolol, but to a much greater extent by way of desisopropylpropranolol (7–10). Preparation of an easily characterized derivative of IV to be used in the further study of these *N*-dealkylation pathways was sought. In this paper, the synthesis of the diethyl acetal of IV (V) and the characterization of two dihydronaphtho[1,2-*b*]pyrans (VI and VII), ring-cyclized products formed during the synthesis of V, are reported.

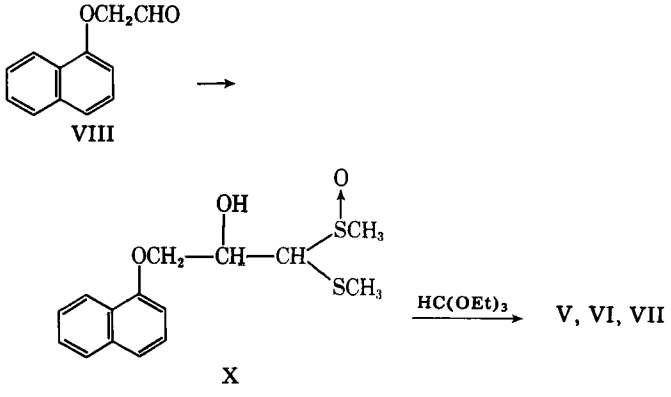
RESULTS AND DISCUSSION

The initial attempt to prepare V was based on partial reduction of the cyanohydrin of 2-(1-naphthoxy)acetaldehyde (VIII), suitably protected as a dihydropyranyl ether. Sodium bis(2-methoxyethoxy)aluminum hydride has been reported to be successful in the partial reduction of some cyanohydrin acetals to form α-hydroxyaldehydes (11). However, over-reduction occurred and 1-naphthol, a product of ring cleavage, was formed, thus requiring an alternate approach.

The successful synthesis of the desired acetal V was accomplished by allowing VIII to react with an anionic formaldehyde equivalent, the lithium salt of methyl methylsulfinylmethyl sulfide (IX) (12). Three diastereomers of X were formed, which were separated. Each of these diastereomers (X*a*, X*b*, and X*c*), when treated with ethyl orthoformate, gave the desired acetal V, as well as cyclized products VI and VII. The most successful and direct method for preparation of V, however, was to subject the mixture of the diastereomers of X, without prior separation, to these conditions. Conversion of the mixture of diastereomers of X to the acetal V (ethyl orthformate and acid catalysis) was attempted to prevent possible isomerization of the α-hydroxyaldehyde, expected from direct hydrolysis of X, to an α-hydroxyketone, as reported in related systems by Ogura and Tsuchihashi (12).



VIII

X

Crystallization and chromatographic separation of the products of the conversion of X to V afforded a 58% yield of the desired acetal V and two other components, which were characterized as VI and VII, obtained in 9 and 30% yields, respectively. Attempts to use milder conditions or shorter times for the conversion of X to V failed to reduce the relative amounts of VI and VII formed, suggesting that the activation energies for their formation are similar to that for formation of the desired acetal V.

The structures of compounds VI and VII were assigned on the basis of CI–MS data, ^{1}H- and ^{13}C-NMR data, and elemental analysis. Methane CI–MS of VI and VII each demonstrated the loss of the elements of ethanol. QM = *m/z* 245 rather than *m/z* 291; their 60-MHz ^{1}H-NMR spectra also showed the loss of one ethoxy substituent. In the aromatic region of the ^{1}H-NMR spectra, the signal of H_8 (the most downfield proton in V and other 1-alkoxynaphthalenes) was retained and the signal of H_2 (the most upfield aromatic proton in V and other 1-alkoxynaphthalenes) was lost, indicating cyclization at C_2 of the naphthalene ring. Comparison of the ^{13}C-NMR spectrum of VII with the spectrum of V

0022-3549/83/0800-0863$01.00/0

(Table I), confirmed the structural assignment. Assignment of the signals of all the carbons in the naphthalene ring was accomplished by comparison with published spectra of 1-methoxynaphthalene and 2-methylnaphthalene (13). The most distinguishing feature was the difference in the chemical shift of C_2 in the aromatic ring of V and the corresponding carbon atom C_{4a} of VII. This signal was shifted upfield in the dihydronaphtho[1,2-*b*]pyran VII. A similar upfield shift was noted for the signal of the acetal carbon $C_{1'}$ when it was converted to the benzylic carbon C_4 in VII.

The assignment of the relative stereochemistry of VI and VII was not apparent from their ^{1}H-NMR spectra because of similarities in the chemical shifts of the dihydropyran ring protons. The 300-MHz ^{1}H-NMR spectra of their acetate esters (XI and XII, respectively) provided sufficient signal separation to allow assignment of the stereochemistry of the esters and thus of VI and VII. The 300-MHz ^{1}H-NMR data of the dihydropyran ring protons of XI and XII are given in Table II. Comparison with ^{1}H-NMR data of the related structures *cis*- and *trans*-3,4-diacetoxy-3,4-dihydro-2*H*-pyran (15) and some related 3,4-substituted flavans (16–19) aided in assignment of the relative stereochemistry.

Several spectral similarities were noted when these data were compared with data from the model dihydropyrans. In the spectra of XI and XII, $J_{3,4}$ = 3.7 and 2.6 Hz, respectively, compared with $J_{3,4}$ = 4.12 and 2.87 Hz for *cis- and trans*-3,4-diacetoxy-dihydro-2*H*-pyran, respectively (15). In XI, assigned the *cis* stereochemistry, $J_{3,2}$ = 7.2 Hz. In both XI and XII, other $J_{2,3}$ and $J_{2',3}$ coupling constants are small (2.9 Hz in XI, 2.6 and 1.5 Hz *in XII*), *consistent* with data from the model dihydropyrans (15). Also, a larger long-range coupling ($J_{2,4}$ = 1.6 Hz) is observed in the spectrum of XII and in the reported data for the *trans* model dihydropyran, likely due to the contribution of a zigzag or W conformation (20).

Both XI and XII seem likely to exist in solution as a mixture of half-chair and/or twist boat conformations. In a series of structurally related conformationally flexible flavans with similar substituents in the 3- and 4-positions (16–19), the values of $J_{3,4}$ are of similar size. In these model flavans, $J_{3,4}$ of 3.2–4.5 Hz are observed in the spectra of *cis*-3,4-disubstituted compounds, and $J_{3,4}$ is ~2.3 Hz in the spectra of *trans*-3,4-disubstituted compounds. These comparisons, and those in the flexible dihydropyrans, strongly indicate the relative stereochemistry of the 3- and 4-substituents is *cis* in XI and *trans* in XII. Thus, VI and VII are assigned the *cis* and *trans* relative stereochemistry, respectively.

The synthesis and characterization of the acetal V and related naphtho[1,2-*b*]pyrans VI and VII will facilitate additional experiments on the metabolic *N*-dealkylation of propranolol. Compound V has been used successfully in experiments to trap intermediate aldehyde IV as an *O*-methyloxime (21).

EXPERIMENTAL[1]

2-(1-Naphthoxy)acetaldehyde (VIII)—This aldehyde was prepared from 1-naphthol and α-bromoacetaldehyde diethyl acetal as previously reported (22).

1-Methylthio-1-methylsulfinyl-3-(1-naphthoxy)-2-propanol (X)—To a solution of 1.24 g (1.1 ml, 10 mmoles) of methyl methylsulfinylmethyl sulfide (IX) in 20 ml of tetrahydrofuran at 0° was added slowly 6.6 ml (10.3 mmoles) of 1.55 *M* methyllithium solution, followed by 1.86 g (10 mmoles) of 2-(1-naphthoxy)acetaldehyde (VIII) in 5 ml of tetrahydrofuran. The mixture was stirred at 0° for 1 hr, water was added, and the mixture was extracted with ether. The ether extract was dried (magnesium sulfate) and evaporated to dryness. The residue, containing three diastereomers (X*a*, X*b*, and X*c*), was fractionally crystallized from a mixture of ethyl acetate–methanol (19:1) affording 200 mg (6.5%) of X*a* (R_f 0.30 ethyl acetate–methanol, 19:1) and 359 mg (11%) of X*c* (R_f 0.21). X*a*, mp 172–173.5°; ^{1}H-NMR (DMSO-d_6): δ 2.20 (s, 3, SCH_3), 2.80 (s, 3, $SOCH_3$), 3.35 (s, 1, OH), 3.97–4.16 (m, 1, C*H*OH), 4.16–4.50 (m, 2, OCH_2), 4.57–4.96 (m, 1, C*H*SCH_3), and 6.85–8.50 (m, 7, naphthalene protons); CI–MS: *m/z* 311 (QM), 293, 246, and 229. X*c*, mp 147–152°; ^{1}H-NMR (methanol-d_4): δ 2.25 (s, 3, SCH_3), 2.84 (s, 3, $SOCH_3$), 4.02–4.30 (m, 1, C*H*OH), 4.30–4.50 (m, 1, C*H*SCH_3), 4.60 (d, 2, OCH_2), and 6.90–8.65 (m, 7, naphthalene protons); CI–MS: *m/z* 311 (QM), 293, 246, and 229.

The combined mother liquors were evaporated and the residue purified by column chromatography on 100 g of silica gel eluting with 500 ml of ethyl acetate–methanol (19:1) to give 1.18 g (38%) of a mixture of X*a*, X*b*, and X*c* and 127 mg (4%) of X*b* as a liquid (R_f 0.25); ^{1}H-NMR (DMSO-d_6): δ 2.30 (s, 3, SCH_3), 2.68 (s, 3, $SOCH_3$), 3.38 (s, 1, OH), 4.17–4.57 (broad s, 4, $CH_2CHOHCHSCH_3$), and 6.67–8.54 (m, 7, naphthalene protons); CI–MS: *m/z* 311 (QM), 293, 246, and 229.

Anal.—Calc. for $C_{15}H_{18}O_3S_2$ (X*c*): C, 58.04; H, 5.85. Found: C, 58.35; H, 5.96.

1,1-Diethoxy-3-(1-naphthoxy)-2-propanol (V)—To a solution of the mixture of diastereomers of X (10.18 g, 32.8 mmoles) in 30 ml of ethanol was added 6.3 ml (38.1 mmoles) of ethyl orthoformate and 0.60 g of concentrated sulfuric acid. The mixture was heated at 60° for 24 hr. The reaction mixture was neutralized with 1.0 ml of concentrated aqueous ammonia and evaporated to dryness. The mixture was partitioned between water and ether, and the ether extract was evaporated to dryness. The residue was purified by column chromatography on 200 g of silica gel. Elution with 1 liter of chloroform–ethanol (99:1) gave 0.750 g (9.3%) of VI (R_f 0.39 in chloroform–ethanol, 99:1), 5.50 g (58%) of V (R_f 0.29), and 2.43 g (30%) of VII (R_f 0.18).

An analytical sample of the acetal V was obtained by rechromatographing crude V on 150 g of silica gel. Elution with 500 ml of benzene–ethyl acetate (4:1) afforded V as an oil; ^{1}H-NMR ($CDCl_3$): δ 0.85–1.40 [2t, 6, $CH(OCH_2CH_3)_2$], 2.80–3.18 (broad s, 1, OH), 3.28–3.90 [m, 4, $CH(OCH_2CH_3)_2$], 3.90–4.30 (m, 3, OCH_2CHOH), 4.74 [d, J = 5 Hz, 1, $CH(OCH_2CH_3)_2$], 6.75 (dd, J = 6 and 3 Hz, 1, naphthalene H_2), 7.15–7.55 (m, 4, naphthalene H_3, H_4, H_6, H_7), 7.70 (m, 1, naphthalene H_5), and 8.30 (distorted dd, J = 5 and 3 Hz, 1, naphthalene H_8); ^{13}C-NMR ($CDCl_3$): see Table I; CI–MS: *m/z* 291 (QM), 245, 227, and 199.

Anal.—Calc. for $C_{17}H_{18}O_4$: C, 70.32; H, 7.64. Found: C, 70.21; H, 7.67.

Compound V, in the presence of semicarbazide hydrochloride at pH 4–5 (ethanol, 60°, 2.5 hr), afforded the semicarbazone of IV as a white solid, mp 205–207°; CI–MS: *m/z* 274 (QM).

Anal.—Calc. for $C_{14}H_{15}N_3O_3$: C, 61.35; H, 5.33; N, 15.38. Found: C, 61.49; H, 5.72; N, 15.31.

***cis*-4-Ethoxy-3-hydroxy - 2*H*-3,4-dihydronaphtho[1,2-*b*]pyran (VI)**—Compound VI further purified twice by column chromatography on 15 g of silica gel eluting with 70 ml of chloroform–ethanol (199:1) was obtained as a colorless oil; ^{1}H-NMR ($CDCl_3$) δ 1.20 (t, J = 7 Hz, 3, OCH_2CH_3), 2.60–2.90 (broad d, J = 7 Hz, 1, OH), 3.68 (q, J = 7 Hz, 2, OCH_2CH_3), 4.10–4.30 (m, 3, OCH_2CHOH), 4.42 (m, 1, $CHOC_2H_5$), 7.06–7.92 (m, 5, naphthalene H_3, H_4, H_5, H_6, H_7), and 8.20 (distorted dd, J = 5.5 and 2.5 Hz, 1, naphthalene H_8); CI–MS: *m/z* 245 (QM).

Anal.—Calc. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60. Found: C, 73.50; H, 6.60.

Table I—^{13}C-NMR Data for 1,1-Diethoxy-3-(1-naphthoxy)-2-propanol (V) and *trans*-4-Hydroxy-3-ethoxy-3,4-dihydro-2*H*-naphtho[1,2-*b*]pyran (VII)

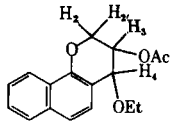
[a] Tentative assignment consistent with the reported ^{13}C-NMR chemical shift assignments of carbons in the propanolamine side chain of propranolol (14).

[1] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. IR spectra were recorded on a Perkin-Elmer 727B spectrophotometer. Routine ^{1}H-NMR spectra were recorded on a Varian EM-360A spectrometer, using TMS as internal standard. Notations used in the ^{1}H-NMR descriptions are as follows: (s) singlet; (d) doublet; (t) triplet; (q) quartet; (m) multiplet. High-field ^{1}H-NMR spectra were recorded on the Brucker 300-MHz spectrometer, using TMS as internal standard. ^{13}C-NMR spectra were recorded on the Varian CFT-20 spectrometer, using TMS as internal standard. Mass spectra were recorded on a Biospect mass spectrometer, operated in the CI mode with methane (0.5 torr) as the reagent gas. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

Table II—300-MHz ^{1}H-NMR Data for the Dihydropyran Ring Protons of XI and XII



Proton	Chemical Shift (δ)	Apparent Coupling Constants
		Compound XI (*cis*)
H_4	4.74	$J_{3,4}$ = 3.7 Hz, line broadening[a]
H_3	5.47	$J_{3,2}$ = 7.4 Hz, $J_{3,4}$ = 3.7 Hz, $J_{3,2'}$ = 2.9 Hz
H_2	4.55	J_{gem} = 11.1 Hz, $J_{2,3}$ = 7.4 Hz
$H_{2'}$	4.36	J_{gem} = 11.1 Hz, $J_{2',3}$ = 2.9 Hz, $J_{2',4}$ = 1.0 Hz
		Compound XII (*trans*)
H_4	4.32	$J_{3,4}$ = 2.6 Hz, $J_{2,4}$ = 1.6 Hz
H_3	5.25	$J_{3,4}$ = 2.6 Hz, $J_{3,2}$ = 2.6 Hz, $J_{3,2'}$ = 1.5 Hz
H_2	4.56	J_{gem} = 12.1 Hz, $J_{2,3}$ = 2.6 Hz, $J_{2,4}$ = 1.6 Hz
$H_{2'}$	4.43	J_{gem} = 12.1 Hz, $J_{2',3}$ = 1.5 Hz

[a] Coupling constant $J_{2',4}$ was assigned on the basis of decoupling experiments and from the signal for $H_{2'}$.

***cis*-3-Acetoxy-4-ethoxy - 2*H*-3,4-dihydronaphtho[1,2-*b*]pyran (XI)**—To a solution of VI (120 mg, 0.49 mmole) in 5 ml of ether at room temperature was added triethylamine (717 mg, 7.1 mmoles), followed by the addition of acetyl chloride (569 mg, 7.1 mmoles). The reaction mixture was stirred for 2 hr, filtered, and evaporated to dryness. The residue was purified by column chromatography on 10 g of silica gel. Elution with 60 ml of chloroform gave 65 mg (46%) of XI as a colorless oil. An analytical sample was obtained by rechromatographing on 10 g of silica gel, eluting with 40 ml of chloroform; ^{1}H-NMR ($CDCl_3$): δ 1.27 (t, J = 7 Hz, 3, OCH_2CH_3), 2.10 (s, 3, $COCH_3$), 3.72 and 3.75 (overlapping q, J = 7 Hz, 2, OCH_2CH_3), 4.30–4.60 (m, 2, OCH_2), 4.70 (d, J = 3.5 Hz, 1, $CHOC_2H_5$), 5.25–5.65 (dt, J = 7, 3.5, and 3.5 Hz, 1, $CHOCOCH_3$), 7.00–7.97 (m, 5, naphthalene H_3, H_4, H_5, H_6, H_7), and 8.20 (dd, J = 6.5 and 3 Hz, 1, naphthalene H_8); partial 300-MHz ^{1}H-NMR spectrum: see Table II; CI-MS: m/z 287 (QM).

Anal.—Calc. for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34. Found: C, 71.15; H, 6.57.

***trans*-4-Ethoxy-3-hydroxy - 2*H*-3,4-dihydronaphtho[1,2-*b*]pyran (VII)**—Compound VII further purified by column chromatography on 60 g of silica gel, eluting with 300 ml of benzene–ethyl acetate (4:1) was obtained as a colorless oil; ^{1}H-NMR ($CDCl_3$): δ 1.10 (t, J = 7 Hz, 3, OCH_2CH_3), 2.53–3.00 (broad d, 1, OH), 3.50 (q, J = 7 Hz, 2, OCH_2CH_3), 3.65–3.96 (m, 1, $CHOH$), 4.06 (d, J = 2 Hz, 1, $CHOC_2H_5$), 4.16 (d, J = 2 Hz, 2, OCH_2), 7.03–7.94 (m, 5, naphthalene H_3, H_4, H_5, H_6, H_7), and 8.17 (distorted dd, J = 5 and 2.5 Hz, 1, naphthalene H_8); ^{13}C-NMR ($CDCl_3$): see Table I; CI-MS: m/z 245 (QM).

Anal.—Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60. Found: C, 73.60; H, 6.89.

***trans*-3-Acetoxy-4-ethoxy - 2*H*-3,4-dihydronaphtho[1,2-*b*]pyran (XII)**—To a solution of VII (280 mg, 1.15 mmoles) in 10 ml of $CHCl_3$ at 0° was added triethylamine (1.74 g, 17.2 mmoles), followed by the addition of acetyl chloride (1.35 g, 17.2 mmoles). The reaction mixture was stirred at room temperature for 4 hr and quenched with ice. The chloroform layer was separated, dried (magnesium sulfate), and evaporated to dryness. The residue was purified by column chromatography on 15 g of silica gel. Elution with 80 ml of chloroform gave 70 mg (21%) of XII as a colorless oil. An analytical sample was obtained by rechromatographing on 10 g of silica gel eluting with 40 ml of chloroform; ^{1}H-NMR ($CDCl_3$): δ 1.25 (t, J = 7 Hz, 3, OCH_2CH_3), 1.95 (s, 3, $COCH_3$), 3.77 (q, J = 7 Hz, 2, OCH_2CH_3), 4.20–4.40 (m, 1, $CHOC_2H_5$), 4.40–4.55 (m, 2, OCH_2), 5.26 (q, J = 2 Hz, 1, $CHOCHOCH$), 6.95–8.05 (m, 5, naphthalene H_3, H_4, H_5, H_6, H_7), and 8.25 (dd, J = 6 and 2.5 Hz, 1, naphthalene H_8 proton); partial 300-MHz ^{1}H-NMR spectrum: see Table II; CI-MS: m/z 287 (QM).

Anal.—Calc. for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34. Found: C, 71.40; H, 6.52.

Abstract □ A simple equation for the estimation of the aqueous solubility of crystalline solutes was previously derived based on the assumption that the presence of water does not significantly alter the crystal properties of the solute. The data presented verify the solubility equation for a set of 36 nonelectrolytes and weak electrolytes. Using the same set of solutes, the two major assumptions used to derive the equation were also verified: that the octanol solubility of nonelectrolytes is exponentially proportional to the melting point of the solute and that the octanol–water solubility ratio is a good approximation of the octanol–water partition coefficient.

Keyphrases □ Solubility—of nonelectrolytes and weak electrolytes in octanol, determination using melting points and partition coefficients □ Partition coefficient—of nonelectrolytes and weak electrolytes in octanol–water, use with melting point to determine solubility □ Octanol—determination of the solubility of nonelectrolytes and weak electrolytes, partition coefficients with water

In previous publications (1–6) a simple equation for the estimation of the aqueous solubility of crystalline solutes was derived on the basis of the following rationale:

1. The solubility of nonpolar and semipolar solutes in octanol is approximately equal to the ideal solubility.
2. The ideal solubility can be estimated from the melting point and entropy of fusion of the solute.
3. The entropy of fusion of the solute is constant for rigid molecules.
4. The octanol–water solubility ratio of a solute is equivalent to the octanol–water partition coefficient.
5. The aqueous solubility is equal to the octanol solubility divided by the octanol–water partition coefficient.

The above strategy is based on the assumption that the presence of water does not significantly alter the crystal properties of the solute. This assumption is usually valid; however, its failure can occasionally be the source of an incorrect estimate of the aqueous solubility of a semipolar substance.

THEORETICAL

An equation enables the estimation of the aqueous solubility (S_w in moles/liter) of rigid organic compounds from melting point (mp) and octanol–water partition coefficient (PC) data. This equation has the simple form:

$$\log S_w(\text{calc}) = -0.01\ \text{mp} - \log \text{PC} + 1.05 \qquad \text{(Eq. 1)}$$

In the derivation of this equation, several important assumptions were made:

1. Octanol is a nearly ideal solvent for the solutes of interest, so that the octanol solubility (X_o in moles fraction) is given by:

$$\log X_o(\text{calc}) = -0.01\ \text{mp} + 0.25 \qquad \text{(Eq. 2)}$$

2. The octanol–water partition coefficient is equal to the octanol–water solubility ratio (SR), which is defined as the octanol solubility (S_o in moles/liter) divided by the aqueous solubility (S_w in moles/liter):

$$\text{PC} = \text{SR} = S_o/S_w \qquad \text{(Eq. 3)}$$

or

$$\log (S_w/S_o) = -\log \text{PC} = -\log \text{SR} \qquad \text{(Eq. 4)}$$

3. The melting point of the drug in equilibrium with octanol is the same as the melting point of the drug in equilibrium with water. The overall strategy of this approach can be expressed as:

$$S_w = S_o\,(S_w/S_o) \qquad \text{(Eq. 5)}$$

with S_o and the solubility ratio being determined by Eqs. 2 and 4, respectively.

In this report, an attempt was made to extend Eq. 1 to include some pharmaceutically important solutes and to verify the assumptions that were used in its derivation. A single set of solutes was chosen for these purposes, including both nonelectrolytes and weak electrolytes of widely varying chemical structure.

EXPERIMENTAL

Materials—The octanol was reagent grade[1]. All other compounds were of the purest grade available from commercial sources[2] and were used as received.

[1] Aldrich.
[2] Aldrich, Eastman, Fluka.

Solubilities—The aqueous solubilities of some of the solutes were taken from the literature or previous work in this laboratory[3]. Only values in the 20–30° range were used. Solubilities for those compounds for which literature data were not available were determined experimentally in the following manner. An excess amount of solute was allowed to equilibrate with water in a sealed vial for 24 hr at 30°. After equilibration the samples were filtered through either a 0.22-μm porous filter[4] or a 1.2-μm silver membrane filter[5] which was preequilibrated at 30°. Analysis of the filtrate was performed using UV spectrophotometry[6]. Octanol solubilities were determined in the same manner as the aqueous solubilities, except that dilutions were made with 2-propanol.

Partition Coefficients—For many of the solutes the partition coefficients were taken from the literature (7). For selected solutes, the partition coefficients were determined in the following manner. A known amount of solute was dissolved in water-saturated octanol or octanol-saturated water. The two phases were shaken for 3 hr and then allowed to equilibrate at 30° for 3–6 days. The phases were separated by centrifugation at 1500 rpm for 15 min, and the concentration in each phase was determined spectrophotometrically.

Solubility Ratio in Mutually Saturated Solvents—Water-saturated octanol and octanol-saturated water were prepared by shaking an excess of water or octanol with the pure solvent for 8 hr. After equilibration, the two layers in each of the solvent mixtures were separated to yield the mutually saturated octanol and water. These solvents were used to determine the aforementioned saturation solubilities for antipyrine, ethyl-*p*-aminobenzoate, caffeine, and theophylline. All determinations were run in duplicate.

RESULTS AND DISCUSSION

Water Solubility—The logarithms of the aqueous solubilities calculated by Eq. 1 for the solutes studied are listed in Table I, along with

[a] Melting point data taken from Ref. 8 or the manufacturers' specifications.

the experimentally determined values (log S_w and log PC) and the melting point data; the last column lists the difference between the observed and calculated solubilities. In no case is the error in the estimate greater than an order of magnitude, and in over three-quarters of the examples it is less than a factor of 3.

The relationship between the observed and predicted values is shown in Fig. 1. The regression line is described by:

$$\log S_w = 1.129 \log S_w(\text{calc}) + 0.32$$
$$r = 0.954 \quad s = 0.400 \quad n = 36 \qquad \text{(Eq. 6)}$$

It is clear that there is no systematic deviation from the regression line for the nonelectrolytes or the weak electrolytes. The regression lines for the weak electrolytes [log S_w = 1.124 log S_w(calc) + 0.308] and for the nonelectrolytes [log S_w = 1.143 log S_w(calc) + 0.371] are both in good agreement with the line described by Eq. 6.

The multiple-regression equation for the aqueous solubility in terms of the melting point and the octanol–water partition coefficient is:

$$\log S_w = -0.012\ \text{mp} - 1.13 \log \text{PC} + 1.62$$
$$r = 0.955 \quad s = 0.402 \quad n = 36 \qquad \text{(Eq. 7)}$$

This compares favorably with the theoretical line from Eq. 1. In spite of an added parameter, Eq. 7 is virtually equivalent to Eq. 6 in estimating the aqueous solubilities of the compounds studied.

Octanol Solubility—If octanol is an ideal solvent for a drug, then the mole fractional solubility of that drug in octanol (X_o) should be equal to the ideal mole fractional solubility (X_i) as given by the van't Hoff equation:

$$\log X_o = \log X_i = [\Delta S_f/(2.303\,RT)]\,(T_m - T) \qquad \text{(Eq. 8)}$$

where ΔS_f is the entropy of fusion of the solute, T_m is the solute melting point in °K, R is the gas constant, and T is the temperature of interest in °K. It has been shown that, for rigid molecules (molecules with little or no conformational flexibility), the entropy of fusion can be approximated by 13.5 eu (9). Thus, for rigid molecules at room temperature (298 °K), Eq. 8 becomes:

$$\log X_o = -0.01\,(T_m - 298) \qquad \text{(Eq. 9)}$$

If the melting point and temperature in Eq. 9 are converted to the centigrade scale (by subtracting 273 from T_m and from 298°), Eq 9 becomes identical to Eq. 2.

If the intercept is expressed in moles per liter rather than in mole fraction, then 0.80 (the logarithm of the molarity of pure octanol) must be added to the left hand side of Eq. 9, so that it becomes:

$$\log S_o = -0.01\,(T_m - 298) + 0.8 = -0.01\,(T_m - 378) \qquad \text{(Eq. 10)}$$

The use of 0.80 is only an approximation of log $\{[(1000\rho - M{\cdot}W)/130.22] + M\}$, where ρ is the density of solution, M is the molarity of the solute, W is the molecular weight of the solute, and 130.22 is the molecular weight of octanol. When the solute molarity (M) is low or when the molecular weight of the solute (W) is close to that of octanol, the exact expression reduces to 0.80. The mole fractional solubilities in octanol (X_o) can be estimated by assuming that the density of the solution (ρ) is equal to the density of octanol (ρ_o) by:

$$X_o = \frac{M}{\left(\frac{1000\,\rho_o - M{\cdot}W}{130.22}\right)+M}$$

Regression analysis of the octanol solubility data (Table II) against melting point for the 36 solutes gives:

$$\log X_o = -0.012\ \text{mp} + 0.26$$
$$r = 0.92 \quad s = 0.32 \quad n = 36 \qquad \text{(Eq. 11)}$$

which is in good agreement with Eq. 2. The relationship between the octanol solubilities and the predicted values is illustrated in Fig. 2. No adjustable parameters were used in the analyses. The data cover three orders of magnitude, and there is no systematic difference in the data for nonelectrolytes and weak electrolytes.

The regression equations for the 21 weak electrolytes (log X_o = −0.011 mp + 0.15) and for the 15 nonelectrolytes (log X_o = −0.013 mp + 0.44) are both consistent with Eq. 11. This confirms the applicability of the first assumption to the solutes selected for this study. The reason for the near ideal solubility of this wide range of solutes in octanol has been explained on the basis of regular solution theory and the fact that the sol-

ubility parameter of octanol (10.3) is within 3.3 units of the solubility parameter of each compound.

Solubility Ratio and Partition Coefficient—The second major assumption that is used to obtain Eq. 1 is that the octanol–water partition coefficient is equivalent to the octanol–water solubility ratio. Regression analysis clearly indicates a linear relationship between the logarithms of the two parameters:

$$\log PC = 0.900 \log SR + 0.390 \qquad \text{(Eq. 12)}$$
$$r = 0.985 \quad s = 0.233 \quad n = 36$$

For most of the compounds studied, the solubility ratio does not differ greatly from the partition coefficient (Table III). Antipyrine is a notable and inexplainable exception; this difference is concentration dependent.

Figure 3 shows the observed partition coefficients and solubility ratios for the solutes studied. If the regression line is forced through the origin, it becomes:

$$\log PC = 1.027 \log SR \qquad \text{(Eq. 13)}$$
$$r = 0.992 \quad s = 0.326 \quad n = 36$$

which is in agreement with the theoretical expectation. Again the weak electrolytes and the nonelectrolytes conform to regression equations similar to the equation for the entire data set. For weak electrolytes the equation is log PC = 0.868 log SR + 0.421; for nonelectrolytes it is log PC = 0.942 log SR + 0.281.

Experimentally the octanol–water partition coefficient is the ratio of the concentrations of the solute in each of the two phases determined in dilute solution, *i.e.*, PC = C_o/C_w. This differs from the solubility ratio in two respects. The solubility ratio (SR) is the ratio of the solubilities determined in pure octanol and pure water (or buffer), whereas the partition coefficient is based on the concentration ratio determined in water-saturated octanol and octanol-saturated water. The solute–solute interactions, which are concentration dependent, are more significant in the solute-saturated solutions used to determine the solubility ratio than in the dilute solutions used to determine the partition coefficient.

Fortunately these factors are not usually large, and for nonpolar and semipolar solutes (log PC > 0) they tend to negate each other. For polar solutes (log PC < 0), however, these effects amplify each other and increase the difference between the solubility ratio and the partition coefficient.

The effect of self-association of polar solutes at high concentration in octanol will generally increase the partition coefficient by increasing the ability of the octanol to accomodate the solute. This can be seen from a comparison of the partition coefficients determined in dilute solution and at saturation in Table IV. The effect of increasing the concentration of nonpolar solutes is to encourage their self-association in the aqueous phase. This, in turn, usually decreases the octanol–water partition coefficient by increasing the relative proportion of solute in the water. The effect of mutual saturation of the partitioning phases is to decrease the partition coefficient compared to the solubility ratio for nonpolar and semipolar solutes. Mutual saturation makes the octanol more water-like and the water more octanol-like. This tends to decrease the absolute value of log PC by bringing the partition coefficient closer to unity. For three of the four solutes in Table IV, the solubility ratio determined in mutually saturated solvents is closer to unity than the value determined in pure solvents. The mutual cancellation of the above effects can also be seen from the data in Table III, where the partition coefficients determined in dilute solution are quite close to the solubility ratio.

State of Undissolved Solute—The third assumption used for Eq. 1

Table IV—Effect of Mutual Saturation on Solubility Ratio

Solute	log (S_o/S_w) (pure phases)[a]	log (S_o/S_w) (mutually saturated)	log (C_o/C_w) (dilute)[b]
Antipyrine	−0.73	−0.50	0.26
Ethyl-*p*-aminobenzoate	1.86	2.21	1.96
Caffeine	−0.75	−0.42	−0.20
Theophylline	−0.57	−0.08	−0.09

is that the melting point of the pure solute is the same as the melting point of the solute in equilibrium with its saturated solution in water. If this is not true, then the melting point used in Eq. 1 would be wrong. Fortunately, most organic compounds do not take up sufficient amounts of water to invalidate this assumption. Some compounds, however, can accomodate large enough amounts of water to significantly alter their physical properties. Phenol, for example, can take up enough water to cause liquification. The use of the normal melting point of phenol in Eq. 1 introduces a systematic error which results in an underestimation of the aqueous solubility of phenol. Still other organic compounds form crystalline hydrates which have melting points that are significantly different from the anhydrous parent compounds. If a substance is known to form a hydrate, the melting point of the hydrate should be used in Eq. 1. If a substance forms an undetected hydrate and if the melting point of this hydrate is different from the melting point of the unequilibrated material, then the use of the melting point of the latter would result in an erroneous estimation of the aqueous solubility.

It is not always feasible to isolate the exact species of a solute that is in equilibrium with its saturated solution. Recrystallization and drying can alter the water content and even the crystal form of the solute. Even the act of determining the melting point can alter the crystal in favor of a more anhydrous or a more stable form. For these reasons it appears likely that the use of an inappropriate melting point is the most likely source of error in the use of Eq. 1.

Fortunately, melting point alterations caused by water are rarely a problem with nonpolar solutes and are only infrequently significant for semipolar solutes. This is confirmed by the highly successful application of Eq. 1 to nonpolar solutes (1) and to a mixture of nonpolar and semipolar solutes (2), as well as to the compounds used herein.

Abstract □ Uptake of the fluorescent probe, 1-anilino-8-naphthalenesulfonate (I) into isolated rat liver cells was studied using both fluorescence and filtration methods. The time course of the fluorescence enhancement of I after addition to the isolated liver cells was analyzed in terms of rapid, medium, and slow phases. The slow phase (half-time ~7 min) was characteristic of viable cells. The fluorescence enhancement was proportional to the amount of I taken into the cells, as measured by the filtration method. The uptake of I followed Michaelis–Menten kinetics with an apparent K_m of 39 μM and V_{max} of 1.4 nmole/10^6 cells/min. The temperature coefficient (Q_{10}) of the uptake of I was found to be ~1.9. No pH optimum was observed, and various metabolic inhibitors did not affect the uptake of I. Among the amino acid reagents used, only 2,4-dinitrofluorobenzene decreased the uptake of I (by ~45%). The effects of various organic anions on the uptake of I were measured. The inhibition of the uptake of I by sulfobromophthalein could be analyzed in terms of competitive inhibition; the slight inhibition by sodium taurocholate could not. It is concluded that the uptake of I is a carrier-mediated facilitated process, and that the carrier is common to both I and sulfobromophthalein.

Keyphrases □ Fluorescence—measurement of 1-anilino-8-naphthalenesulfonate uptake into isolated rat liver cells, effect of organic anions, comparison with filtration method □ 1-Anilino-8-naphthalenesulfonate—determination of uptake into isolated rat liver cells using fluorescence enhancement, effect of organic anions, kinetics □ Kinetics—of 1-anilino-8-naphthalenesulfonate uptake into isolated rate liver cells, fluorescence enhancement, effect of organic anions

Sulfobromophthalein (II) and indocyanine green (III) are anionic drugs used to test liver function. The uptake mechanism responsible for the rapid and relatively selective hepatic clearance of these anions has been studied using whole animals (1–3), isolated perfused rat liver (3–5), liver slices (6), and isolated liver cells (7, 8). These studies suggested that the hepatic uptake of these anionic drugs is a carrier-mediated process.

Bile acids, endogenous compounds that are anionic at physiological pH, are also readily extracted from the plasma by the liver. Many investigators (9–11) have suggested that a carrier-mediated process might be responsible for the hepatic uptake of bile acids. If this is true, the question then arises as to whether the aforementioned anionic dyes and bile acids are transported by a common carrier. Studies on the inhibition of the uptake of one compound by another in isolated perfused rat liver (3, 5) and isolated rat liver cells (7) led to the suggestion that bile acids and other organic anions such as II and III are transported into the liver by two different systems.

The anionic fluorescent probe, 1-anilino-8-naphthalenesulfonate anion (I) has been used to study the membrane structure of several isolated membrane systems (12–14) since the large changes in its fluorescence parameters are observed in different environments (15, 16). Compound I also is an effective probe in the study of anion transport in erythrocytes (17) and Ehrlich ascites cells (18). Recently, Cheng and Levy (19) described the interaction of I with isolated rat liver cells, observing that the transport of I into liver cells was a carrier-mediated process. In the present study, we have attempted to clarify the mechanism of the uptake of I into isolated liver cells and to determine whether the transport system of I is shared by other organic anions, such as II, III, and the bile acid salts.

EXPERIMENTAL

Materials—The following analytical grade materials were used: sodium 1-anilino-8-naphthalenesulfonate[1], bromophenol[1], rose bengal[2], *p*-aminohippuric acid[2], sulfobromophthalein[3], indocyanine green[3], phenolsulfonphthalein[3], sodium taurocholate[4], sodium oleate[1], potassium cyanide[2], *n*-ethylmaleimide[2], 2,4-dinitrofluorobenzene[2], rotenone[4], carbonylcyanide *m*-chlorophenylhydrazone[4], *p*-hydroxymercuribenzoate[4], trypan blue[2], and collagenase (type I)[4].

Isolation of Liver Cells—Liver cells were isolated using a modification of the procedure of Baur *et al.* (20). Male Wistar rats (260–330 g), given free access to food and water, were used. During preparation, the liver was perfused with a calcium-free perfusion buffer at 37° *via* the vena portae (35 ml/min for 15 min). After preparation of the liver, perfusion was continued with a recirculating medium containing 4 m*M* calcium and 0.05% collagenase. After 15–20 min, the vena portae began to leak; the perfusion was continued *via* the vena cava for another 10–15 min. After perfusion for ~30 min, the liver disintegrated. Subsequently, the tissue was transferred to a round-bottomed flask and enzymatic treatment was continued for another 10 min with slow stirring. After washing, the cells were stored as a suspension (5×10^6 cells/ml) at 0° in a standard buffer saturated with 95% O_2 and 5% CO_2[5]. The composition of the perfusion buffer was: 121 m*M* NaCl, 6 m*M* KCl, 0.6 m*M* $MgSO_4$, 12 m*M* $NaHCO_3$, 0.74 m*M* KH_2PO_4, and 5 m*M* glucose (pH 7.2–7.1). The composition of the standard buffer was: 131 m*M* NaCl, 5.2 m*M* KCl, 0.9 m*M* $MgSO_4$, 0.12 m*M* $CaCl_2$, 3 m*M* Na_2HPO_4, and 10 m*M* Tris/HCl (pH 7.4).

Cell viability for each experiment was determined by the trypan blue exclusion test; the value obtained usually ranged from 93–98%. Damaged liver cells (<9% viability) were prepared by treatment in an automatic mixer for >5 min.

Uptake Studies—*Filtration Method*—Aliquots of the stock cell suspensions were diluted in 5 ml of the standard buffer to a final concentration of 5×10^5 cells/min. After preincubation for 3 min at 25°, small aliquots (3–35 μl) of a 5 m*M* solution of I were added, and the mixtures were incubated for various times. The uptake process was terminated by vacuum filtration of 1 ml of the suspension using a glass-fiber membrane[6]. After washing the cells on the filter three times with 3 ml of the ice-cold standard buffer, the content of I in the cells was analyzed spectrofluorometrically[7]. The cells were extracted with 4 ml of solvent (methanol–1 *N* NaOH, 8:1) for 1 hr. After centrifugation[8] at 3000 rpm for 15 min, the supernatant solution was analyzed spectrofluorometrically at 500 nm (excitation at 390 nm). The recovery of I from the liver cells was nearly 100%.

Fluorescence Method—The fluorescence measurements[7] were performed at room temperature (20–22°), unless otherwise stated, with 10-nm slit widths for both excitation and emission channels and a 430-nm

cutoff filter. The excitation and emission wavelengths for I were 400 and 480 nm, respectively. If necessary, fluorescence intensities were corrected for the inner filter effect according to the method of Chignell (21).

Small aliquots of a solution of I were added to the cell suspension (5 × 10^5 cells/ml) in the standard buffer. The solution was preincubated for 5 min and quickly mixed with a small stirring rod, and the fluorescence intensity was recorded at a chart speed of 12 cm/min. The mixing procedure could be performed in <4–6 sec. In some experiments, after the time course of uptake had been recorded for 30 sec after the addition of I, the zero point was lowered by adjusting the zero-suppression knob, and the sensitivity was increased so that the change of fluorescence could be monitored more closely.

In the experiments on inhibition by other organic anions, inhibitors were added 10 sec before the addition of I. In the experiments on inhibition by metabolic inhibitors and amino reagents, the reagents were added at the beginning of the 5-min preincubation.

Kinetic Analysis of the Data Obtained by the Fluorescence Method—For reasons discussed subsequently, the initial uptake rate of I was obtained from the initial slope of the slow component of fluorescence enhancement (40–100 sec). If the change of fluorescence (ΔF_{cell}) is assumed to be proportional to the change of I content within the cells (ΔA_{cell}), then:

$$\Delta F_{cell} = q_{cell} \cdot \Delta A_{cell} \qquad \text{(Eq. 1)}$$

where q_{cell} is the proportionality coefficient, which corresponds to the quantum yield of I bound to the intracellular components. [The validity of this assumption will be demonstrated later (*Results*).] The initial uptake rate in a carrier-mediated transport system can be expressed by the Michaelis–Menten-type equation:

$$\overline{\Delta A}_{cell} = \frac{V_{max} \cdot (A)}{K_m + (A)} \qquad \text{(Eq. 2)}$$

where $\overline{\Delta A}_{cell}$ is the initial uptake rate (40–100 sec), K_m is the apparent Michaelis constant, V_{max} is the maximum rate of uptake, and (A) is the concentration of I in the medium. Substituting Eq. 2 into Eq. 1 gives:

$$\overline{\Delta F}_{cell} = \frac{\overline{\Delta F}^{max}_{cell} \cdot (A)}{K_m + (A)} \qquad \text{(Eq. 3)}$$

where:

$$\overline{\Delta F}^{max}_{cell} = q_{cell} \cdot V_{max} \qquad \text{(Eq. 4)}$$

and $\overline{\Delta F}_{cell}$ is the initial rate of fluorescence enhancement (40–100 sec).

The binding of I to the plasma membrane of liver cells was determined by extrapolating the uptake curves to time zero, as described previously (7, 9, 11, 22). The kinetic analysis was carried out in a similar way, using:

$$F_{zero} = \frac{F^{max}_{zero} \cdot (A)}{K_{pm} + (A)} \qquad \text{(Eq. 5)}$$

and

$$F^{max}_{zero} = n \cdot q_{membrane}(P_{cell}) \qquad \text{(Eq. 6)}$$

Here, F_{zero} is the fluorescence intensity obtained by extrapolating the uptake curves to time zero, $q_{membrane}$ is the proportionality coefficient

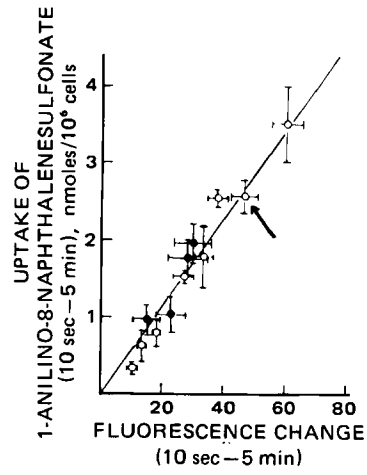

Figure 2—*Comparison of measurements of I uptake by the fluorescence and filtration methods using the same cell preparation. Small aliquots (3–35 μl) of I were added to the cell suspension (5 × 10^5 cells/ml), and the fluorescence change from 10 sec to 5 min was measured (abscissa), as described in Fig. 1. The amount of I taken into the cells during the same period was measured by the filtration method (ordinate). Each point is the mean of 4–5 experiments; bars represent the standard error. Key: (○) in the absence of II (concentration of I, 4.7–54 μM); (●) in the presence of II, added 10 sec before the addition of I (concentration of I, 38 μM; concentration of II, 20–60 μM). The arrow shows the result at a I concentration of 38 μM in the absence of II (control).*

(which corresponds to the quantum yield of I bound to the plasma membrane), K_{pm} is the dissociation constant, (P_{cell}) is the concentration of cells, (A) is the concentration of I in the medium, and n is the number of binding sites for I on a cell. Kinetic parameters were calculated with a program (23) for least-squares fitting, using a computer[9].

RESULTS

Time Course of I Uptake into Intact and Damaged Cells—When 38 μM I was added to hepatocytes (5 × 10^5 cells/ml), a marked enhancement of the fluorescence of I was observed. The fluorescence of I in buffer alone was negligible when compared with that obtained in the presence of hepatocytes. Figure 1 shows the time course of fluorescence enhancement of I both in intact and damaged cells. The time course in damaged cells (viability <9%) showed a rapid phase (half-time less than the mixing time) and a time-dependent (medium) phase which had almost reached a plateau within 40 sec. In the case of intact cells, a new time-dependent kinetic phase (slow phase) appeared, and the fluorescence intensity continued to increase up to 30 min. This slow phase, which is characteristic of intact cells, is thought to reflect the uptake of I and subsequent binding to intracellular components, while the rapid phase may correspond to the binding of I to plasma membrane. On this basis, the initial uptake rate was calculated from the initial slope of the slow phase of fluorescence enhancement (40–100 sec), as shown in Fig. 1.

Comparison of the Data Obtained by the Fluorescence and the Filtration Methods—To analyze the uptake of I by the fluorescence method, the validity of Eq. 1 must be demonstrated. Therefore, the changes of the fluorescence of I (10 sec–5 min) were compared with the amounts of I transported into cells during that period, as directly measured by the filtration method (Fig. 2). Figure 2 shows that the change of fluorescence (ΔF_{cell}) is proportional to that of I content within cells (ΔA_{cell}). The q_{cell} value in Eq. 1 was calculated to be 18.7/nmole of I from the data in Fig. 2.

The cell–medium ratio (C/M) of I after the establishment of equilibrium between the cells and the medium (~30 min after the addition of I) was calculated both from the data in Fig. 1 and from the q_{cell} value. In calculating the intracellular concentration of I, an intracellular volume of 4.2 μl/10^6 cells was used (24). C/M values of 45 ± 4 and 36 ± 2 were calculated for initial I concentrations of 4.7 μM and 39 μM, respectively.

Kinetic Analysis of the Initial Uptake Rate and Binding to Plasma Membrane at Various Concentrations of I—The initial rates (40–100 sec) of I uptake at concentrations ranging from 4.7 to 78.5 μM

[9] Hitachi 8700/8800 computer.

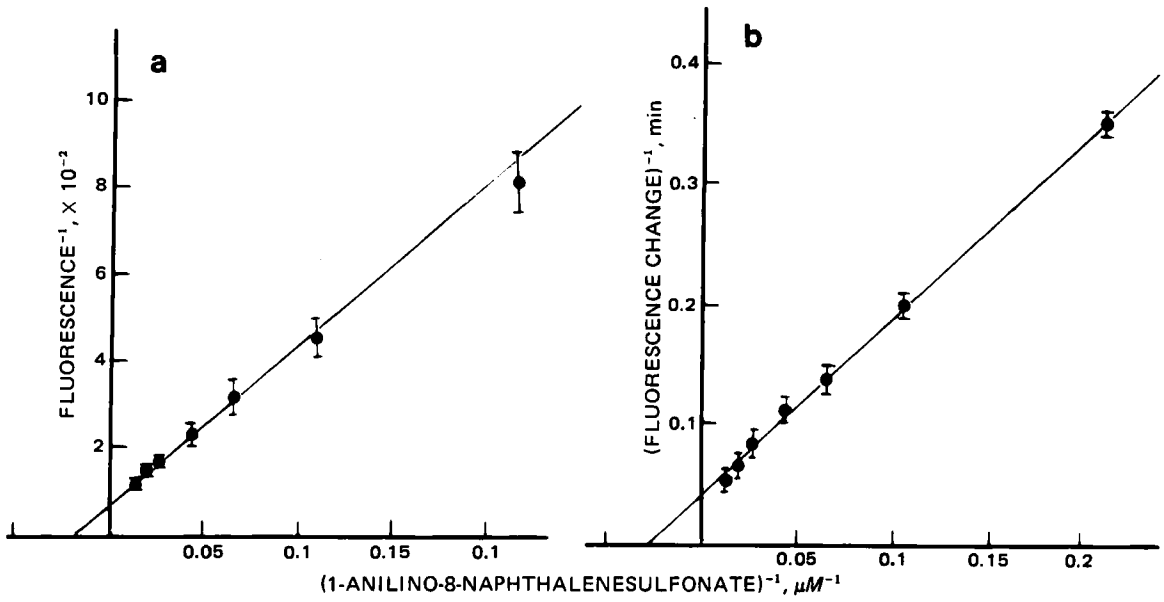

Figure 3—*(a) Double-reciprocal plot of I binding to the plasma membrane, determined by extrapolating the curve of fluorescence enhancement to time zero. The line represents the regression line calculated using Eq. 5. (b) Lineweaver–Burk plot of I uptake with the initial rate calculated from the initial slope (40–100 sec) of the slow phase (Fig. 1). The line represents the regression line calculated using Eq. 3. The fluorescence was measured at room temperature in the standard buffer with a cell concentration of 5 × 10^5 cells/ml. Each point is the mean of 5–9 experiments; bars represent the standard error.*

were measured by the fluorescence method. Figure 3b shows a Lineweaver–Burk plot of the uptake rates based on Eq. 3. An apparent K_m of 38.8 ± 5.2 μM and $\overline{\Delta F}^{max}_{cell}$ of 26 ± 2.8 min^{-1} were obtained. A V_{max} of 1.39 ± 0.15 nmole/10^6 cells/min was calculated from the $\overline{\Delta F}^{max}_{cell}$ and the q_{cell} values (18.7/nmole of I).

The binding of I to the plasma membrane of liver cells was determined by extrapolating the uptake curves to time zero. The data thus obtained were analyzed by means of a double-reciprocal plot based on Eq. 5, as shown in Fig. 3a. A dissociation constant (K_{pm}) of 56.7 ± 5.5 μM was obtained.

Effects of Metabolic Inhibitors and Amino Acid Reagents—To determine whether the uptake of I is dependent on metabolic energy, 19 μM I was added to cell suspensions preincubated for 5 min with one of four metabolic inhibitors, and the initial enhancement of fluorescence (40–100 sec) was measured. The inhibitors were potassium cyanide (1 mM), which blocks electron transport at the final step; rotenone (10 μM), which blocks electron transport near the initial step; ouabain[4] (1 mM), which inhibits Na^+-K^+ ATPase and the oxidative phosphorylation uncoupler carbonylcyanide *m*-chlorophenylhydrazone (10 μM). None of the inhibitors had a detectable effect on the initial uptake of I. Consequently, the concentrative uptake of I (C/M = 36–45) described previously is not due to the active transport of I, but to its binding to intracellular components.

The effects of amino acid reagents, which have been successfully used in membrane and cell research to inhibit carrier-mediated processes, were measured by the fluorescence method. *p*-Hydroxymercuribenzoate (100 μM) and *n*-ethylmaleimide (100 μM), which bind covalently to free sulfhydryl groups, did not significantly reduce the initial uptake of I (concentration of I, 19 μM); 2,4-dinitrofluorobenzene (100 μM), which binds covalently to free amino groups, decreased the initial uptake of I by 47 ± 7% (mean ± *SE* for three separate experiments). To confirm its effect, 2,4-dinitrofluorobenzene was also studied by the filtration method, which gave similar results, *i.e.*, a reduction ratio of 43% (n = 2).

Effect of Temperature and pH—In viable cells, the initial enhancement of fluorescence (40–100 sec) at 35° was higher than that at 25° (Fig. 4). The temperature coefficient ($\Delta F_{35°}/\Delta F_{25°}$) was 1.43 ± 0.12 ($n$ = 3). The dependence of the initial uptake of I on temperature was also measured by the filtration method, and a temperature coefficient (Q_{10}) of 1.9 ± 0.3 (n = 3) was obtained. The methods seem to give slightly different coefficients. The most likely explanation for this discrepancy is that the q_{cell} value in Eq. 1 changes with temperature. In damaged cells, the fluorescence intensity obtained after establishment of equilibrium at 25° was higher than that at 35° ($F_{35°}/F_{25°}$ = 0.83 ± 0.05). This result

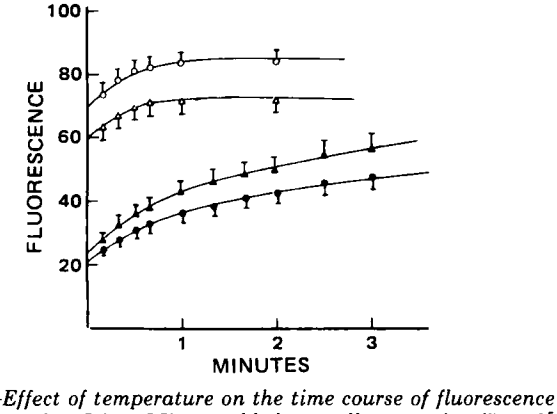

Figure 4—*Effect of temperature on the time course of fluorescence enhancement when I (19 μM) was added to a cell suspension (5 × 10^5 cells/ml) in the standard buffer. Each point is the mean of three experiments; bars represent the standard error. Key: (●) intact cells, 25°; (▲) intact cells, 35°; (○) damaged cells, 25°; (△) damaged cells, 35°.*

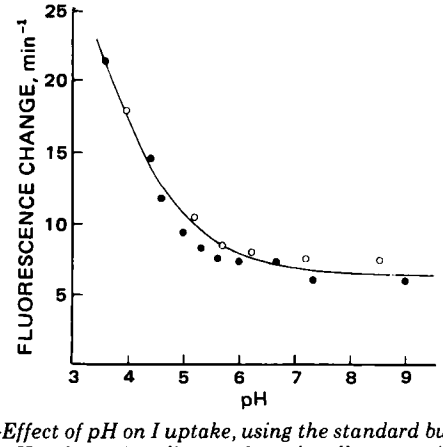

Figure 5—*Effect of pH on I uptake, using the standard buffer brought to various pH values. An aliquot of stock cell suspension (1 × 10^8 cells/ml) was diluted with the medium at each pH to yield a final concentration of 5 × 10^5 cells/ml prior to the addition of I (19 μM). The initial rates of uptake were measured by the fluorescence method as described in Fig. 3b. After the fluorescence measurement, the pH of each suspension was remeasured. Open and closed circles represent results using different cell preparations.*

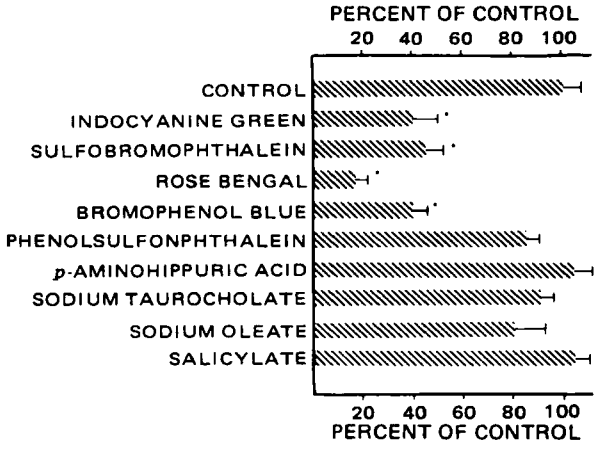

Figure 6—*Inhibitory effects of various organic anions at concentrations of 20 μM. Inhibitors were added to the cell suspension in the standard buffer (5 × 10^5 cells/ml) 10 sec before the addition of I (19 μM). Initial rates of uptake were measured by the fluorescence method as described in Fig. 3b. Fluorescence intensities were corrected as necessary for the inner filter effect. Each point is the mean for 3–4 experiments; bars represent the standard error; asterisks indicate statistical significance at the* $p < 0.05$ *level.*

in damaged cells might reflect a change of q_{cell} with temperature. On this basis, the Q_{10} obtained by the fluorescence method was recalculated as 1.75 (1.43/0.83), which is in good agreement with the value obtained by the filtration method.

Figure 5 shows the pH dependence of the initial uptake rate of I (concentration, 19 μM) measured by the fluorescence method. Between pH 6 and 9, the fluorescence was considerably increased.

Effects of Organic Anions—The initial uptake rate of 19 μM I was determined by the fluorescence method in the presence of various organic anions, each at 20 μM concentration (Fig. 6). Four organic anions (II, III, bromophenol blue, and rose bengal), which are thought to act as substrates for an organic anion transport system in the liver, inhibited the uptake of I by >50%; sodium taurocholate, which is thought to be transported into the liver by a different system (3, 5), did not show significant inhibition. *p*-Aminohippuric acid and phenolsulfonphthalein, which are known to act as substrates for an organic anion transport system in the kidney, did not have a significant effect.

Compound II and sodium taurocholate were selected as typical anions transported into the liver by different systems, and kinetic investigations of the inhibition of I uptake using these compounds were carried out. First, the effect of the addition of II on the q_{cell} value in Eq. 1 was examined (Fig. 2). Although both the fluorescence and filtration methods showed inhibition of I uptake by II, the q_{cell} value was not significantly altered by II. This finding indicates that it is possible to analyze the inhibition of I uptake kinetically by the fluorescence method.

In Fig. 7, the reciprocal of the initial rate of fluorescence enhancement

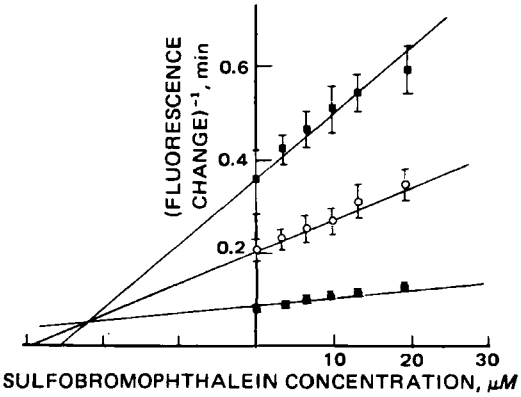

Figure 7—*Dixon plot of I uptake in the presence of II, measured by the fluorescence method, as described in Fig. 3b. Compound II was added 10 sec before the addition of I to the cell suspension (5 × 10^5 cells/ml). Each point is the mean of three experiments; bars represent the standard error. The lines represent the regression lines calculated using Eq. 7. Key: concentration of I (■) 4.7 μM; (○) 9.4 μM; (●) 38 μM.*

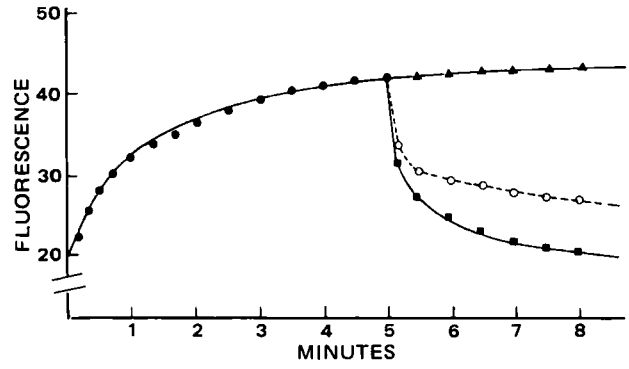

Figure 8—*Countertransport study using a small aliquot of buffer (▲), 20 μM II (○), or 20 μM III (■) added to the cell suspensions (5 × 10^5 cells/ml) after incubation with 19 μM I for 5 min. Each point is the mean of two experiments. The data points (●) before 5 min are means taken from the uptake experiments.*

of I (40–100 sec) is plotted *versus* the concentration of II. This Dixon plot shows that the uptake of I is inhibited competitively by II. The kinetic parameters $K_m = 32.7 \pm 6.5$ μM, $K_i = 22.2 \pm 2.7$ μM, and $\overline{\Delta F}^{max}_{cell} = 22.2 \pm 4.3$ min^{-1} were obtained by fitting the data to an equation that corresponds to competitive inhibition:

$$\overline{\Delta F}_{cell} = \frac{\overline{\Delta F}^{max}_{cell} \cdot (A)}{K_m(1 + i/K_i) + (A)} \qquad \text{(Eq. 7)}$$

where i is the concentration of inhibitor (II), K_i is the inhibition constant, and the other symbols are the same as those in Eqs. 3 and 4. The kinetic parameters thus obtained ($K_m = 32.7$ μM and $\overline{\Delta F}^{max}_{cell} = 22.2$ min^{-1}) are in good agreement with those ($K_m = 38.8$ μM and $\overline{\Delta F}^{max}_{cell} = 26.0$ min^{-1}) obtained from an independent uptake study of I (Fig. 3a).

On the other hand, inhibition by sodium taurocholate could not be detected in Fig. 5, so the inhibition of I uptake (19 μM) at a higher concentration of sodium taurocholate was measured. Even 170 μM sodium taurocholate inhibited the uptake of I by only 20% (mean of two separate experiments). If it is assumed that the uptake of I is competitively inhibited by sodium taurocholate and that the K_i value is 19 μM, 20 and 170 μM sodium taurocholate should inhibit the uptake of I by 41 and 86%, respectively[10]. A Michaelis constant of 19 μM was obtained by Schwarz *et al.* (9) in a study of taurocholate uptake into isolated liver cells. Marked discrepancies between the observed and calculated values suggest that the uptake system of sodium taurocholate is different from that of I.

Countertransport—Compound II was added to the cell suspension after addition of I (Fig. 8). The addition of II induced a rapid decrease of fluorescence which was complete within 10 sec, followed by a slower decrease. The rapid decrease suggests the inhibition of the plasma membrane binding of I by II. The slower decrease of fluorescence may represent the efflux of I previously taken into the cells, reflecting countertransport (1, 25, 26). A similar effect was also seen when III was added instead of II.

DISCUSSION

Many studies on the hepatic uptake of various compounds utilize isolated liver cells, and the advantage of their use has been discussed (7, 8, 27). In most of these studies, cells were separated from the incubation medium by centrifugation or filtration. The present study, using a fluorescence probe (I) as a substrate, has the advantage that the uptake of I can be determined simply by measuring the fluorescence change, without separation. This method has already been adopted in studies of anion transport in erythrocytes (17), Ehrlich ascites cells (18), and isolated liver cells (19).

The time course of fluorescence enhancement of I (Fig. 1) was analyzed by means of a semilogarithmic plot of log [fluorescence change (total

[10] Equation 7 yields the following equation:
Ratio of fluorescence change (R)

$$= \frac{\overline{\Delta F}_{cell} \text{ in the presence of sodium taurocholate}}{\overline{\Delta F}_{cell} \text{ in the absence of sodium taurocholate}}$$

$$= \frac{K_m + (A)}{K_m(1 + [\text{sodium taurocholate}]/K_i) + (A)}$$

where $K_m = 38.8$ μM, $(A) = 19$ μM, and $K_i = 19$ μM.

minus partial)] against time. This method is known to give good fits to kinetic data obtained in experiments with erythrocyte ghosts (28) or submitochondrial particles (29). The plot in the case of intact cells could be analyzed in terms of a three-exponential equation (not shown): *i.e.*, the fluorescence enhancement consisted of a rapid phase (half-time less than the mixing time), a medium phase (half-time of ~15 sec), and a slow phase (half-time of ~7 min). The rapid, medium, and slow phases comprised ~35, 20, and 45% of the overall fluorescence enhancement, respectively. Damaging the cells by vigorous shaking (viability <9%) hardly affected the half-time of the medium phase, but abolished the slow phase. A half-time (~15 sec) corresponding to the medium phase in the present study was also found in studies of the interaction of I with erythrocyte ghosts (28) and plasma membranes of hepatoma tissue culture cells (19), both of which lack intracellular components. Our findings and those of other workers suggest that the rapid phase corresponds to the binding to superficial sites of the plasma membrane, the medium phase to the binding to deep sites within the plasma membrane, and the slow phase to the uptake and subsequent binding to intracellular components. We assumed that the permeability barrier to I would be destroyed in damaged cells, and used the slow phase for measurement of the initial uptake of I. Cheng and Levy (19) used the period from 30 to 120 sec in uptake studies of I into isolated liver cells. However, in the present studies, we used 40–100 sec for measurement of the initial rate of uptake as the plot of fluorescence enhancement against time showed curvature after 100 sec (Fig. 1). Furthermore, we used 40 sec as the starting time of the slow phase to avoid the contribution of the medium phase.

Before the fluorescence method can be accepted for the measurement of I uptake, it must be demonstrated that the fluorescence change is proportional to the amount of I taken into the cells, *i.e.*, the q_{cell} value in Eq. 1 should be constant regardless of the I concentration within the cell. The results shown in Fig. 2, which demonstrate the validity of Eq. 2, confirm this method. The q_{cell} value (18.7/nmole of I) was obtained from the data between 10 sec and 5 min (Fig. 2); however, strictly speaking, the q_{cell} value should be obtained using only the slow phase, which is thought to reflect the true uptake phase. On the other hand, we also compared the changes of I fluorescence (0–10 sec) at several concentrations of I in a similar way. This period is thought to reflect the binding to the plasma membrane. A $q_{membrane}$ of 23/nmole of I was obtained in this experiment (unpublished data). This $q_{membrane}$ value, which corresponds to the quantum yield of I bound to the plasma membrane of liver cells, is not very different from the q_{cell} value (18.7/nmole of I). This result suggests that the quantum yields of I are essentially the same whether I is bound to the plasma membrane or to the intracellular components. Therefore, the q_{cell} value obtained from the data between 10 sec and 5 min may be considered to represent the true q_{cell} value. Moreover, the q_{cell} value was not altered by II (Fig. 2), and this result made it possible to investigate the inhibition of I uptake by II using the fluorescence method. To our knowledge, this is the first experiment demonstrating the validity of the fluorescence method.

Several specific criteria must be met to demonstrate the presence of carrier-mediated transport across biological membranes: the transport system must be saturable, structurally similar compounds should inhibit the transport process, and the system should show countertransport. These criteria are common to both active-transport and facilitated-diffusion processes. To differentiate between these two types of transport, other criteria are required.

By definition, active transport differs from facilitated diffusion in two ways: (*a*) transport of a substrate can occur against a chemical potential and (*b*) an expenditure of metabolic energy is required and the process generally is associated with a temperature coefficient (Q_{10}) of ≥3 (25). Each of these criteria was investigated in detail for the I uptake into isolated liver cells. The saturability (Fig. 3b) and the competitive inhibition by II (Fig. 7) suggest that a carrier-mediated transport system may be responsible for the uptake of I; saturability of I uptake was also suggested by Cheng and Levy (19). A countertransport study was undertaken to confirm the presence of carrier-mediated transport. The results obtained with II and III suggest countertransport (Fig. 8). However, these results should be interpreted with caution, since the phenomena shown in Fig. 8 might occur if II and III simply displace I from the binding sites of I on the intracellular components. This displacement would increase the unbound concentration of I within the cells and, thus, accelerate the efflux of I to the medium. Therefore, the fluorescence change caused by II and III shown in Fig. 8 is necessary but not sufficient to demonstrate true countertransport.

In addition to these findings, the inhibition of I uptake by 2,4-dinitrofluorobenzene, which combines with free amino groups on the carrier molecule, strongly suggests the countribution of a carrier-mediated process to uptake of I. It has been shown that sulfhydryl reagents can inhibit the uptake of cortisol (30) and procainamide ethobromide (31) into isolated liver cells. In the present study, *p*-hydroxymercuribenzoate and *n*-ethylmaleimide did not have a significant inhibitory effect. This may indicate the absence of a functional sulfhydryl group at the active site of the carrier protein for I. However, the uptake of I was unaffected by various metabolic inhibitors, suggesting that active transport is not involved. Independence of metabolic energy has also been demonstrated by Schwenk *et al.* (7) in the uptake of II into isolated liver cells. Furthermore, the relatively small dependence of I uptake on temperature (Q_{10} = 1.9) also suggests a facilitated-diffusion process. A similar temperature dependency (activation energy of 11 kcal/mole, Q_{10} of ~2) was reported in the uptake of II into isolated liver cells (7). Based on these findings, which suggest the facilitated diffusion of I, the accumulation of I in the cells (C/M of 36–45) found in the present study could be regarded as due to the binding of I to the intracellular components. In fact, I is bound to the cytoplasmic binding proteins (X, Y, and Z fraction) in the liver, especially to the Z-protein (32).

With regard to pH, the uptake of I (Fig. 5) is similar to that of II (7). Both have no pH optimum, though the uptake was considerably increased below pH 6. As described above, the uptake of I resembles that of II in many respects, namely the effect of metabolic inhibitors, the temperature dependence, and the pH profile. On the other hand, the uptake of sodium taurocholate was inhibited by metabolic inhibitors (carbonylcyanide *m*-chlorophenylhydrazone, ouabain, and antimycin A), the activation energy amounted to 29 kcal/mole which corresponds to a Q_{10} of ~5, and the uptake showed a pH optimum between pH 6.5 and pH 8.0 (9).

The similarity of the uptake of I to that of II raised the possibility that both compounds share a common carrier. To test this possibility, the effect of II on the uptake of I was studied kinetically (Fig. 7). A Dixon plot showed that uptake of I is inhibited competitively by II, indicating a common carrier for the uptake of both compounds. The K_i value (22 μM) of II obtained in the present study is comparable with the K_m value (7 μM) for II obtained by Schwenk *et al.* (7). On the other hand, the slight inhibition of I uptake by a high concentration of sodium taurocholate (170 μM) could not be explained by competitive inhibition. These findings indicate that I and II are transported by the same carrier, and that this carrier is different from that for sodium taurocholate. This result supports the hypothesis of Paumgartner and Reichen (3, 5) that there are at least two transport systems for organic anions: one for bile acids and the other for organic anions such as II and III.

Recently, a high-affinity binding protein for II (thought to be the carrier protein) has been isolated from the plasma membrane of the rat liver (33–35). During this isolation, the binding activity at each step was evaluated by gel-filtration using a small column (33) or equilibrium dialysis (34). The present result that I and II share a common carrier raised the possibility that fluorescence measurements of I could provide a simple and novel method for detecting binding protein for organic anions such as II and III during the isolation procedures.

Thiazides VIII: Dissolution Survey of Marketed Hydrochlorothiazide Tablets

LARRY L. AUGSBURGER *x, RALPH F. SHANGRAW *, R. P. GIANNINI *§, VINOD P. SHAH ‡, VADLAMANI K. PRASAD ‡, and DANIEL BROWN ‡

Received April 12, 1982, from the **Department of Pharmaceutics, University of Maryland School of Pharmacy, Baltimore, MD 21201* and the ‡*Biopharmaceutics Laboratory Branch, Washington, D.C. 20204.* Accepted for publication, July 20, 1982. §Present address: Wyeth Laboratories, Philadelphia, PA 19101

Abstract □ The dissolution profiles of 50-mg hydrochlorothiazide tablets representing all approved manufacturers (at the time of the study) were determined in two vehicles [purified water and dilute (1:100) hydrochloric acid] by three methods (rotating basket at 150 rpm; spin filter at 300 rpm; paddle method at 50 rpm). The paddle method was preferred on the basis of overall ease of operation, reproducibility, and discrimination. The paddle data were validated in both vehicles on the same lots of tablets by a second laboratory. A standard of not <80% dissolution in 60 min by the paddle method in water is proposed for hydrochlorothiazide tablets.

Keyphrases □ Hydrochlorothiazide tablets—dissolution studies, paddle method, basket method, spin filter method □ Dissolution—paddle method, basket method, spin-filter method, hydrochlorothiazide tablets □ Paddle method—dissolution of hydrochlorothiazide tablets □ Basket method—dissolution studies of hydrochlorothiazide tablets □ Spin-filter method—dissolution studies of hydrochlorothiazide tablets

Hydrochlorothiazide is a member of the benzothiadiazine class of orally effective diuretics widely used in the treatment of hypertension, congestive heart failure, and other edematous conditions. As a class, these compounds generally are poorly wetted and have limited solubility. Thus, it is not surprising that they have been identified in the Federal Register (1) as a class of drugs with a potential for bioavailability/bioequivalency problems and for which dissolution standards should be developed. For such standards to be meaningful and reflect bioavailability performance, the dissolution system must be capable of generating data that consistently correlate with *in vivo* performance. However, the dissolution of a drug from its dosage form is dependent on many factors, which include not only the physicochemical properties of the drug, but also how the dosage form is formulated and processed. Thus, even in the absence of a correlation between *in vivo* and *in vitro* data, dissolution data provide a desirable aid in controlling formulation and manufacturing variables and should be a reliable indicator of uniformity of manufacture. The objectives of this study were to (*a*) survey the dissolution performance of marketed hydrochlorothiazide products by various methods, (*b*) select an appropriate dissolution method, and (*c*) develop acceptable dissolution standards based on the performance of the marketed products. The results of this study should form a basis for the consideration of other members of the benzothiadiazine class.

EXPERIMENTAL

Materials—Commercial 50-mg hydrochlorothiazide tablets[1] (representing all approved manufacturers at the time of the study) were used.

Reagents and Chemicals—Distilled water was used throughout, and all other chemicals or reagents were either official grade or reagent grade. Hydrochlorothiazide USP was the reference standard.

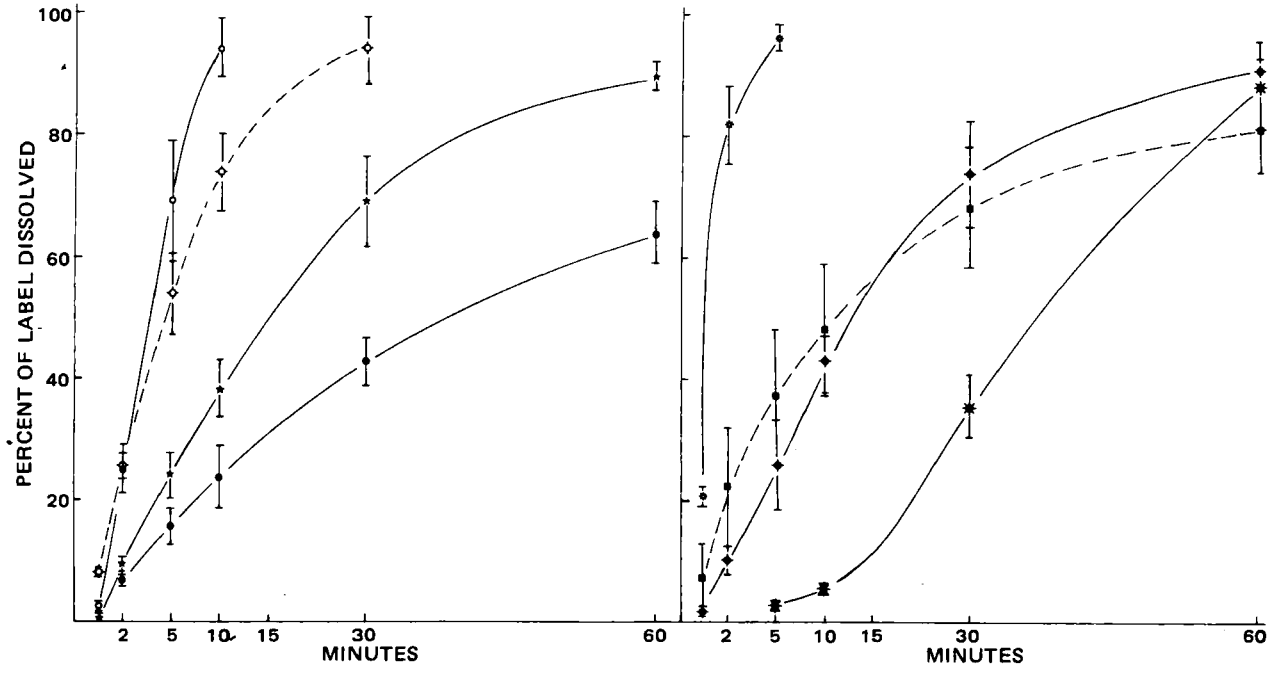

Figure 1—*Dissolution of hydrochlorothiazide tablets in purified water—paddle method (50 rpm). Key: product 1 (★); product 2 (☼); product 3 (○); product 4 (◇); product 5 (■); product 6 (●); product 7 (◆); product 8 (✹).*

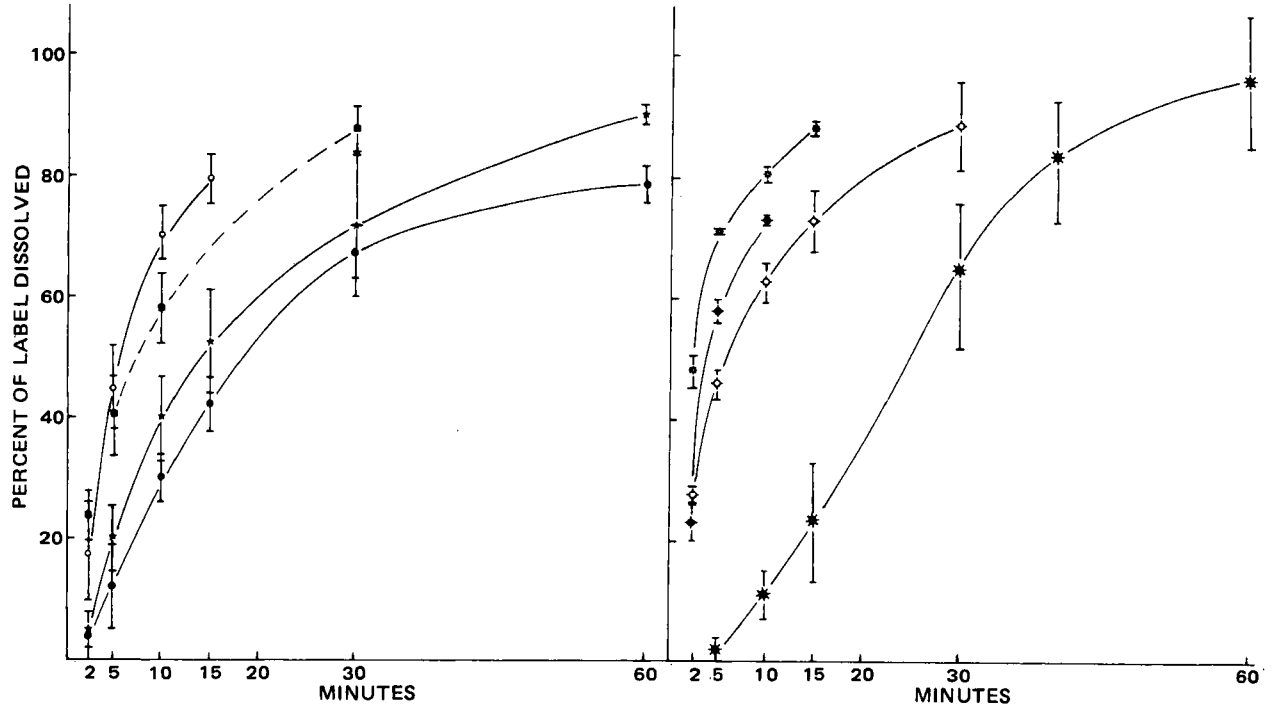

Figure 2—*Dissolution of hydrochlorothiazide tablets in purified water—rotating basket method (150 rpm). See Fig. 1 for key to graph.*

Dissolution Methods—The dissolution tests were carried out in two laboratories using UV spectrophotometry[2]. Dissolution was monitored by continuously circulating the filtered medium from each flask to and through a 0.1-cm path-length flow cell mounted in the spectrophotometer, and then back to the flask. The filter was mounted on the intake end of the hosing and consisted of a 13-mm fiberglass pad held in a plastic holder.

Dissolution was carried out in distilled water and in dilute (1:100) hydrochloric acid: 900 ml at 37°.

Rotating Basket (USP XIX, Method 1)—The basket assemblies were rotated in resin flasks by means of a multiple-spindle drive system[3]. Official specifications (2) were adhered to, including the 150-rpm stirring rate noted in the hydrochlorothiazide monograph.

Paddle Method (USP XX, Method 2)—The paddles were rotated in round-bottom flasks by suitable adaptation of the multiple-stirrer head. All official specifications (2) were followed. A paddle speed of 50 rpm was selected.

Spin-Filter Method—This method is essentially the stationary basket, spinning-filter method described by Shah *et al.* (3). The apparatus[4] was obtained commercially. The geometry relating the position of the basket to the filter is fixed by the apparatus design; however, the filter unit was always set 2 mm from the bottom of the flask, as recommended (3). Filter rotational speed was 300 rpm.

[a] — 15-min value.

Except for the spin-filter runs, the media were not deaerated. Concentrations were determined at 272 nm. Laboratory I used all three methods; laboratory II validated laboratory I results using only the paddle method. Six or more tablets from each lot were evaluated by each laboratory.

Stability of Hydrochloride in the Dissolution Media—Stability studies were conducted in purified water and dilute hydrochloric acid (1:100) for 90 min at 37°. The samples were analyzed for diazotizable substances (hydrolyzed product) using both the Bratton–Marshall colorimetric technique (4) and a specific high-performance liquid chromatographic (HPLC) method. For the HPLC method, a C_{18} reverse-phase column, a 254-nm detector, and a methanol–water eluant (60:40) were used.

Table II—Dissolution of 50-mg Hydrochlorothiazide Tablets by Basket Method at 150 rpm in Water and Acid

Product	Water % Dissolved in 30 min		Acid % Dissolved in 30 min	
	Mean	*SD*	Mean	*SD*
1	71.8	12.4[a]	83.2	2.9[b]
2	88.3[c]	1.4	94.3[c]	4.3
3	79.2[c]	4.5	94.0[c]	5.7
4	88.7	7.2	81.0[c]	5.3
5	87.7	3.9	87.0[c]	5.6
6	67.5	4.6[d]	90.8	7.1
7	73.3[c]	0.5	78.8	4.0[e]
8	64.8	12.0[f]	93.2	1.9

[a] 90.5 ± 2.1 in 60 min. [b] 94.5 ± 2.3 in 60 min. [c] In 15 min. [d] 88.8 ± 3.5 in 60 min. [e] 88.3 ± 3.7 in 60 min. [f] 83.2 ± 10.3 in 60 min.

For the purposes of identity and determining the extent of hydrolysis under dissolution conditions, USP reference hydrolyzed products were used. Less than 5% hydrolysis was found in either medium after 90 min.

RESULTS AND DISCUSSION

One of the first requirements of a dissolution study is to determine the equilibrium solubility of the compound. The solubility test gives the maximum expected dissolution of less soluble compounds and provides information as to whether sink conditions are being approximated in the test or not. In earlier investigations, it was accepted that the maintenance of sink conditions (or the approximation) increases the chances for *in vitro–in vivo* correlation, although lack of sink conditions does not necessarily prohibit such a correlation. Equilibrium solubility studies carried out showed that hydrochlorothiazide is soluble to the extent of 1.05 mg/ml in water and 1.06 mg/ml in dilute hydrochloric acid, which approximates to only 5.3% saturation for a 50-mg tablet in 900 ml of the medium.

The dissolution of all marketed hydrochlorothiazide tablets was surveyed using both dilute (1:100) hydrochloric acid and water as the dissolution media: water is the simplest possible medium, and dilute acid has physiological significance owing to the pH of the gastric contents.

The USP rotating basket at 150 rpm was selected since it was the official method used for hydrochlorothiazide tablets in USP XIX. The paddle method has been gaining popularity in recent years and is currently recognized as Method 2 in the official compendia. The paddle speed of 50 rpm was selected on the basis of preliminary experiments and the experience of the Food and Drug Administration with this method. It was felt that this low degree of agitation would not only enhance the chances for *in vitro–in vivo* correlation, but also enhance discrimination between brands. The stationary basket-spinning filter method was se-

lected largely on the basis of the encouraging results reported by Shah *et al.* (3).

The dissolution results by all three methods in both media are summarized in Tables I–III and Figs. 1–6. The final procedure for validation in laboratory II was selected based on the reproducibility of the method, its ability to discriminate brands, and ease of operation.

The data in Tables I–III show that the dissolution results in water and acid were similar, although some products (1, 5, 6, and 8) apparently contain acid-soluble excipients and, therefore, tend to show faster dissolution in this medium. For example, with the paddle method, the eight hydrochlorothiazide products dissolved in the range of 35–96% in 30 min in water, whereas in acid the same products dissolved in the range of 66–97% in 30 min (Table I). However, all products exhibited at least 60% dissolution in 60 min in both media. Dissolution by the basket method at 150 rpm was faster than the paddle method, but the spin-filter method showed the fastest dissolution. Most of the products showed 70–80% dissolution in 10 min by the spin-filter method.

The same lots were evaluated by each of the methods. The relative standard deviations were comparable for the paddle and basket methods; however, variability tended to be somewhat higher in the spin-filter apparatus. Furthermore, a comparison of the percent-dissolved figures reveals that both the paddle and basket methods tended to separate the tablet brands reasonably well. A somewhat more distinct separation was realized with the paddle method. In the case of the spin-filter apparatus, the dissolution rates of nearly all tablets were quite high, but the separation of brands was somewhat poorer. These distinctions can be visualized by comparing the dissolution profiles of the products in Figs. 1–6. The bar around each point represents the standard deviation. The results in Tables I–IV also show that regardless of the method, a somewhat clearer separation of the brands results when water is the dissolution medium.

In general, the paddle method was easier to set up and use. The disintegrated-tablet components tended to remain localized under the paddle in the concavity of the round-bottomed flask, where they presumably received a uniform degree of agitation during the course of the run. In addition, the paddle method was the easiest of the three methods to clean up.

In contrast, the basket method required insertion of the tablets into individual baskets prior to starting. As particles from the disintegrated tablet gradually pass through the basket screen during the test, it appeared that not all of the tablet material received uniform agitation.

The most difficult method to set up and use was the spin-filter apparatus. This method requires careful adjustment of the spinning filter to maintain a clearance of 2 mm from the bottom of the flask. Even after careful tightening of the lock nuts, the filter was found to drop at times to the bottom of the flask. This alters the rotational speed and contributes to variability. The most troublesome problem was the tendency of the

spinning filter to create air bubbles in the flow lines which interfered with spectrophotometric readings. Careful cleaning of the filters in an ultrasonic bath and thorough deaeration of the medium reduced the air bubble problem to manageable levels; however, they could not be eliminated entirely.

In conclusion, on the basis of data reproducibility (lower standard deviation) and ease of operation, as well as enhanced separation of the dissolution results for all products tested, the paddle method at 50 rpm was selected (preferred) over the basket method at 150 rpm and the spin-filter method at 300 rpm.

The same lots of hydrochlorothiazide tablets were validated by another laboratory using the paddle method with water and dilute hydrochloric acid as the dissolution media. The results from these studies (Table IV) show good agreement between data from the two laboratories. All eight products studied show a good dissolution profile. Additional batches of products 6 and 8 were also studied, and they showed faster dissolution.

At present, there is no documented evidence of any bioavailability problem from the marketed products studied. The dissolution survey described herein indicated that it is possible to manufacture products that dissolve not <80% in 60 min by the paddle method at 50 rpm in water. The dissolution methodology presented herein is simple. In addition, it is evident that the limit specified is achievable. These two facts show that the method could be useful in a quality assurance program.

Abstract □ A series of N^8-alkyloxycarbonylalkyl-nortropane-3-spiro-5′-hydantoins has been synthesized and studied by spectral and crystallographic methods. The crystal and molecular structure of one [8(γ-ethoxycarbonylpropyl)nortropane-3-spiro-5′-hydantoin, VI] was determined by X-ray diffraction. The preferred conformations of these compounds and subsequent changes on protonation were determined from ^{1}H-NMR and ^{13}C-NMR data.

Keyphrases □ *N*-Substituted nortropane spirohydantoins—synthesis, structural studies using IR, NMR, and X-ray crystallography □ NMR spectroscopy—analysis of *N*-substituted nortropane spirohydantoins □ IR spectroscopy—analysis of *N*-substituted nortropane spirohydantoins □ X-Ray crystallography—analysis of *N*-substituted nortropane spirohydantoins

In a previous paper (1), ^{1}H- and ^{13}C-NMR studies of a pharmacologically interesting series of tropane- and *N*-substituted nortropane-3-spiro-5′-hydantoins were reported. The structure of tropane-3-spiro-5′-hydantoin (determined by X-ray methods) also has been described (2). In this study the synthesis and structural determination of a series of N^8-ethoxycarbonylalkyl-nortropane-3-spiro-5′-hydantoins and their corresponding hydrochlorides is reported (Scheme I). Treatment of the appropriate N^8-substituted nortropinone[1] with potassium cyanide and ammonium carbonate in aqueous ethanol gave the desired hydantoins.

EXPERIMENTAL

IR spectra were recorded on a double-beam spectrophotometer[2] using indene and polystyrene for calibration. The ^{1}H-NMR spectra were recorded at 60 MHz[3], 90 MHz[4], and 250 MHz[5]. The ^{13}C-NMR spectra were determined at 20 MHz[6] in the Fourier transform mode at room temperature. Both broad-band decoupled and single-frequency off-resonance decoupled spectra were determined. Mass spectral determinations were made[7]. Elemental analyses were determined[8].

N^8-Substituted Nortropane Spirohydantoins (I–VII)—A solution of potassium cyanide (0.15 mole) and ammonium carbonate (0.3 mole) in water (115 ml) was added to a solution of the corresponding racemic *N*-substituted nortropinone[1] (0.1 mole) in ethanol (35 ml). The mixture was heated at 60° in a sealed flask for 24 hr. After cooling, the precipitated solid was removed by filtration. The mother liquors were concentrated (~50%) under reduced pressure and cooled, and the resulting solid was removed by filtration and added to the first material obtained.

Hydrochlorides of I–VI—Solutions of I–VI (0.01 mole) in ethanol (10 ml) were added to hydrogen chloride dissolved in ethanol (2 ml, 5 *N*). The resulting mixtures were heated at reflux for 10 min and then allowed to cool. The solvent was removed under reduced pressure, and each residue was recrystallized from ethanol.

RESULTS AND DISCUSSION

Structure Determination and Refinement of VI—The cell parameters a = 8.191 (1), b = 9.380 (2), and c = 10.752 Å (2) and α = 105.45 (2), β = 98.68 (1), and γ = 97.00° (1) were obtained from a least-squares calculation of the setting angles of 30 reflections measured on an automatic four-circle diffractometer[9]. The calculated density was 1.325 g/cm^3 with Z = 2. The intensities were collected from a crystal of 0.30 × 0.40 × 0.25 mm in the range $2 \leq 2\theta \leq 60°$ in the $\theta/2\theta$ scan mode with MoK$_\alpha$ radiation monochromatized by a graphite crystal; 4478 independent reflections were measured of which 2598 had $I \geq 2\sigma$ (I), σ being calculated from counting statistics. No systematic absences were observed; therefore, the possible space groups were P1 and P$\bar{1}$.

A centrosymmetric structure was suggested by normalized structure factor statistics. The structure was solved by direct methods [MULTAN 77 (3)]. The best E map revealed all the nonhydrogen atoms. Anisotropic full-matrix least-squares refinement with unit weights led to R = 0.10.

compound reported here provides a comparison with some of the derivatives already studied (2, 4, 5). Figure 1 shows the structural formula. Table I lists the bond lengths and angles; Table II shows the final parameters for the atoms; Table III lists the torsion angles.

The molecule consists of a piperidine ring and a five-membered ring joined by a common C—N—C bridge, with an ethoxycarbonylpropyl group attached to the N-8 atom and a hydantoin ring substituted at the C-3,5′ atom. The piperidine ring adopts a distorted chair conformation. The asymmetry parameters (6) are $\Delta C_s^{(3,5')} = 0.9$, $\Delta C_2^{(2\text{-}3,5')} = 15.0$, and $\Delta C_2^{(1\text{-}2)} = 30.8$, showing that mirror symmetry is dominant with an approximate C_s-plane passing through C-3,5′ and N-8. The displacements of C-3,5′ and N-8 from the plane through the remaining atoms of the piperidine ring are 0.496 and −0.818 Å, respectively: larger than the corresponding deviations of the C-3,5′ and N-6 in N^3-ethyl-3-azabicyclo(3.2.1)octane-8-spiro-5′-hydantoin (4), −0.897 and 0.575 Å, respectively. The nonbonded distances C-7 · · · C-3,5′ and N-8 · · · C-3,5′ are 3.04 and 3.01 Å, respectively, similar to the corresponding distances found in N^8-methyl-nortropane-3-spiro-5′-hydantoin (2).

The five-membered ring adopts a puckering N^8-envelope conformation. This conformation has been studied in terms of the torsion angles (7). The pseudo-rotation parameters Δ and ϕ are −35.0 and 53.7°, respectively, and the deviation of N-8 atom from the plane through C-1, C- 5, C-6, and C-7 is −0.750 Å, similar to the value found previously (4) for the C-3,5′ atom.

The configuration of N-8 is pyramidal, as in other mentioned cases (2, 4), and the ethoxycarbonylpropyl radical is attached to the N-8 in an axial position as previously described (2). Two hydrogen bonds of the types N—H · · ·O and N—H · · ·N link the molecules together (Fig. 1). The geometry of these hydrogen bonds are N(1′) · · ·O(1)(−x + 1, −y + 1, −z) = 2.932 Å, N(3′) · · ·N(8)(x + 1, y,z) = 3.005 Å, N—H · · ·O = 163.0°, and N—H · · ·N = 178.3°.

IR Spectra—The IR data of I–VII (Table IV) were compared with analogous azabicyclospirohydantoins studied previously (8, 9). The IR spectrum of VI in the solid state shows a medium band at 3270 cm^{-1} and a broad band at 2710 cm^{-1}. The band at 3270 cm^{-1} is due to the stretching of the $N^{1'}$—H bond belonging to the intermolecular bonding system, $N^{1'}$—H · · ·O=$C^{2'}$ formed between pairs of molecules related by a center of symmetry. The band at 2710 cm^{-1} is explained by the existence of a strong intermolecular hydrogen bond formed between the weak acid $N^{3'}$—H group and the basic piperidine nitrogen atom. Both structural facts are in good agreement with the results obtained by X-ray diffraction. The spectrum of VI in solid state shows a medium band at 1765 cm^{-1} and two strong bands at 1730 and 1715 cm^{-1} in the carbonyl region. The bands at 1765 and 1715 cm^{-1} are attributed to the symmetrical and asymmetrical modes of the pseudo-ring system formed between molecules shown in Fig. 1. The band corresponding to the $C^{4'}$=O stretching vibration did not appear in the IR spectrum. As in related systems, this fact is explained by overlapping of the band corresponding to the $C^{2'}$=O asymmetric stretching mode of the dimer. The band at 1730 cm^{-1} is attributed to the stretching of the ester carbonyl group. The spectra of II and III in solid state also showed bands similar to those found in VI.

The spectra of V and VII in solid state are different from those of II, III, and VI (in which the intermolecular hydrogen bonds deduced from IR data were confirmed by the X-ray study of VI). Therefore the intermolecular hydrogen bonds in V and VII are different; there is no $N^{3'}$—H · · ·N bond which can be attributed to the great size of the N-substituent in the case of V and to the low basicity of the piperidine nitrogen atom in the case of VII.

The carbonyl region shows the same pattern as those found in II, III, and VI. The spectra of I–VII showed the same absorption pattern in the carbonyl region in solid state as in solution in dimethyl sulfoxide; consequently, the N^1—· · ·O=$C^{2'}$ bonds remain in solution.

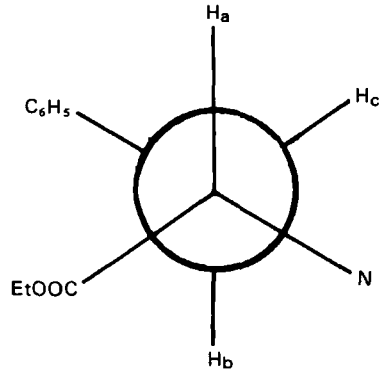

Figure 2—*Newman projection showing the conformation about C_α—C_β bond in III.*

NMR Spectra—The ^{1}H- and ^{13}C-NMR data of I–VII[11] are summarized in Tables V–XI. In all cases, broad-band decoupled and single-frequency off-resonance decoupling spectra were obtained. Assignments of the carbon resonances were made by the multiplicity of signals in the single-frequency off-resonance decoupled spectra, the peak intensity of the broad-band decoupled spectra, and the literature data (1, 10–18).

From the ^{1}H- and ^{13}C-NMR data of I–VII and the crystal structure of VI, the following general features were deduced: (*a*) the pyrrolidine and piperidine rings in these compounds all have a flattened N^8-envelope and distorted chair conformation puckered at N-8 and flattened at C-3,5′ similar to that observed in the crystal structure of VI; (*b*) the $C^{4'}$=O group is attached to the piperidine ring in an equatorial position (Scheme I), in good agreement with the X-ray results for VI; and (*c*) the radical attached to the piperidine nitrogen adopts an equatorial position; however, in the solid state (according to X-ray and IR data for II, III, and VI), the corresponding radical is attached in an axial position.

These conclusions are supported by the following. In the ^{1}H-NMR spectra, the $W_{1/2}$ value (1) for the C-1 and C-5 hydrogen signals of ~10 Hz corresponds to a tropane system with the piperidine ring in a flattened chair conformation (1, 19). The J $H_{2,4}$—$H_{1,5}$ values (Table VI) correspond to dihedral angles of ~60°. In all cases J $H_{2,4\beta}$—$H_{1,5}$ is greater than J $H_{2,4\alpha}$—$H_{1,5}$; consequently, the dihedral angle $H_{2,4\alpha}$—C—C—$H_{1,5}$ is greater than $H_{2,4\beta}$—C—C—$H_{1,5}$. The C-6 and C-7 hydrogen signal appears in all cases as a wide singlet; in an ideal chair, the C-6 and C-7 endo hydrogen atoms would be deshielded by the anisotropic effect due to the hydantoin ring. The C-2β and C-4β hydrogen signals are shifted to lower field, with respect to the C-2α and C-4α hydrogen signals, because of the anisotropic deshielding effect due to the equatorial $C^{4'}$=O group (1).

In the ^{13}C-NMR spectra, the chair conformation adopted by the piperidine ring is confirmed by the C-2 and C-4δ values (Table IX). For a boat conformation, these carbon signals would be shifted to higher field because of the steric compressing effect due to the eclipsing between the C-2(4)β and C-1(5) hydrogen atoms (16). The different radicals are attached to the piperidine nitrogen atom in an equatorial position. For an axial position of the radical, the γ-effect exerted on H-2α and H-4α would shift to higher field to the C-2 and C-4 carbon signals (16). The puckering of the piperidine ring at N-8 is deduced from the γ-shielding effect exerted by the equatorial N-group on H-6 exo and H-7 exo. This γ-effect is ~3 ppm[12], smaller than that expected for an ideal envelope conformation of the pyrrolidine ring.

The hydrochlorides of I–IV, which are the usual species in pharmacological studies, have also been studied. The main features found in the protonated forms are: (*a*) the puckering at N-8 is decreased, and (*b*) the proton attached to the N-piperidine atoms is in the axial position.

These results are supported by the following. In the ^{13}C-NMR, the carbon signals corresponding to the C-2 and C-4 in the hydrochlorides of I–IV are shifted to higher fields with respect to the same carbon signals of the corresponding bases. This fact is due to the *syn*-diaxial effect of the N^+—H proton. The mentioned decreasing of the puckering is sup-

[11] Copies of the ^{13}C-NMR spectra of II, II·HCl, III, III·HCl, V, and VI and the ^{1}H-NMR spectrum of III are deposited in the Division of Drug Chemistry, Food and Drug Administration, Washington, DC 20204 and are available on request to the authors.

[12] This value is the difference between the C-6 and C-7δ values of compounds I–VII and the C-6 and C-7δ value of nortropane (10).

[a] Hertz values; tetramethylsilane was used as the internal reference. [b] In dimethyl sulfoxide. [c] In deuterium oxide. [d] In the molecular fragment  ; JH_a—H_b = 10, JH_a—H_c = 5, and JH_b—H_c = 15.

ported by the increased γ-effect exerted by the *N*-group on the C-6 and C-7 exo hydrogen atoms, so that the C-6 and C-7 carbon signals are shifted to higher fields.

To give a detailed account of the former results, several pairs of base–hydrochloride compounds were studied. For solubility reasons, it was not possible to run the spectra of the bases and the hydrochlorides in the same solvent; however, medium-induced shifts are often negligibly small in ^{13}C-NMR because the nuclei studied are buried in the molecular framework.

Compound I—In this case, the decreasing of the puckering on protonation is noticeable $\Delta\delta$(C-6, C-7) = −4.5 ppm.

Compound II—In this case, the decreasing of the *N*-puckering is less than that observed in I, $\Delta\delta$(C-6, C-7) ≃ −2.5 ppm. The proton-coupled spectral data of II hydrochloride are in Table XI; from the J C$^{4'}$—$H_{2,4\beta}$ value of 3 Hz, a value near 0° can be deduced for the dihedral angle C$^{4'}$—C^3—C^2—$H_{2,4\beta}$ in good agreement with values found in the literature (20, 21).

Compounds III and IV—For these compounds, the decreasing of N-8 puckering on protonation is remarkable, $\Delta\delta$(C-6,7) ≃ −5 ppm. From the ^1H—NMR spectra of III resolved at 250 MHz, it can be deduced that the *N*-piperidine group adopts the preferred conformation represented in Fig. 2. This fact can be explained as:

1. The vicinal coupling constants (Table VI) of the ϕ—CH_2—CH—N< fragment.
2. Hc resonates at a lower field with respect to Hb; this is due to the anisotropic effect exerted by the phenyl group.
3. The aromatic proton resonance is a complex multiplet, showing a distinct conformational preference about the aryl-Cβ bond.
4. In the proposed conformation, the ethyl ester protons resonate at a higher field position than those of related compounds (Table V) since they are shielded by the π-electron cloud of the phenyl group.

The deshielding of the C-1 and C-5 carbon signals on protonation (≈5 ppm, Tables IX and X) remains unexplained. It could be explained by the enhancement of the N-σ-effect on protonation, but it had been shown (22) that, in *N*-methyl piperidine, the *N*-protonation effect on the α-carbon is quite irregular (−1.7–26.1 ppm).

[a] Hertz values.

Compounds V and VI—The ^{1}H- and ^{13}C-NMR data for these compounds are analogous to those of I–IV.

Compound VII—Because of the π-releasing conjugative effect of the *N*-piperidine atom, the phenyl group is essentially located on a plane approximately parallel to the C^1—C^2—C^4—C^5 plane; consequently, a β-compressing effect on H-6 exo and H-7 exo is exerted, and the ^{13}C-NMR signal of C-1 and C-5 carbon atoms are shifted to higher field ($\Delta \simeq -4$ ppm) with respect to the same C-signal of the parent compounds.

CONCLUSIONS

In the crystalline state, the cyclohexane ring of VI adopts a deformed chair conformation with a flattening at C-3,5′. This deformation is probably due to the steric interaction between the ethylene bridge and the hydantoin group. The opposite puckering at N-8 and the axial position of the *N*-substituent make the formation of the intramolecular $N^{3'}$—H···N^8 bond easy. Compounds I–VII in dimethyl sulfoxide solution show the same deformation in the cyclohexane rings, but the N—H···N bond disappears, and the *N*-radical adopts the equatorial position to avoid the *syn*-diaxial effect on the C-2 and C-4 axial hydrogen atoms. In III and VII the N^8-group shows a distinct conformational preference. The N^8-puckering of I–VII in dimethylsulfoxide solution is governed by the steric effect of the N^8-group on the C-6 and C-7 exo hydrogen atoms. In deuterium oxide solution, the N^8-protonation of I–IV takes place in an axial position. An equatorial protonation would produce the aforementioned syn-diaxial effect. The decreasing of *N*-puckering on protonation would decrease the N^+—H *syn*-diaxial effect on the C-2 and C-4 axial hydrogen atoms and facilitate the N^+—H solvation.

Evaluation of Some Mannich Bases Derived from Substituted Acetophenones Against P-388 Lymphocytic Leukemia and on Respiration in Isolated Rat Liver Mitochondria

J. R. DIMMOCK *x, K. SHYAM *, N. W. HAMON *, B. M. LOGAN *, S. K. RAGHAVAN *, D. J. HARWOOD *, and P. J. SMITH ‡

Received March 1, 1982, from the **College of Pharmacy* and ‡*Department of Chemistry and Chemical Engineering, College of Arts and Science, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada.* Accepted for publication July 7, 1982.

Abstract □ Series of 3-dimethylamino-1-aryl-1-propanone hydrobromides (IV) and 3-dimethylamino-2-dimethylaminomethyl-1-aryl-1-propanone dihydrobromides (V) were synthesized. Evaluation of these derivatives against P-388 lymphocytic leukemia growth revealed that two compounds show promise as antineoplastic agents. Compounds of the V series were unstable in phosphate buffer (in contrast to series IV), and when the same nuclear substituent was present in both series of compounds, V was ~100 times more active than IV in both the stimulation and inhibition of respiration of mitochondria isolated from rat liver cells. Representatives from both series showed that respiration in mitochondria was affected by changing the pH of the aqueous buffer from 7.4 to 6.9 or 6.4 and by reducing the temperature from 37° to 20°. The compounds showed reactivity toward a biomimetic thiol.

Keyphrases □ 3-Dimethylamino-1-aryl-1-propanone hydrobromides—synthesis, activity against P-388 lymphocytic leukemia growth, effect on mitochondrial respiration □ 3-Dimethylamino-2-dimethylaminomethyl-1-aryl-1-propanone dihydrobromides—synthesis, activity against P-388 lymphocytic leukemia growth, effect on mitochondrial respiration □ Antineoplastic agents—potential, 3-dimethylamino-1-aryl-1-propanone hydrobromides, 3-dimethylamino-2-dimethylaminomethyl-1-aryl-1-propanone dihydrobromides, activity against P-388 lymphocytic leukemia growth

When arylalkyl ketones such as propiophenone (I) are attacked by nucleophiles such as thiols, thiohemiketals are formed (1). While the rate of nucleophilic attack may be increased by electron-withdrawing substituents on the aromatic ring, other molecular modifications of these compounds, such as the formation of the corresponding Mannich bases (*e.g.*, II), allow the possibility of increased nucleophilic attack at the carbonyl carbon atom. First, the proton attached to the quadrivalent nitrogen in II is acidic and therefore intramolecular proton transfer to the carbonyl oxygen may occur, expediting nucleophilic attack at the carbonyl carbon atom. Second, such additions as in III, exemplified by the attack of a thiol, lead to a reaction intermediate where there is relief from dipole repulsion between the carbonyl and onium groups.

There are, however, two other ways the Mannich bases could interact with cellular nucleophiles, *per se* or after undergoing molecular modification to give reactive derivatives. First, the strong positive inductive effect of the ammonium group [Taft σ^* value for $(H_3C)_3\overset{+}{N}$ is 1.90 (2)] renders the carbon atom of the adjacent methylene group susceptible to nucleophilic attack. Instances may be cited where thiol displacements have occurred (3) although, on occasion, vigorous conditions have been required (4). In the second case, instances have been described whereby Mannich bases have undergone elimination to give the corresponding enones (5, 6); such compounds readily undergo nucleophilic attack (7). Treatment of a variety of 3-dialkylaminopropiophenones with thiophenols gave the corresponding sulfides, possibly formed by an elimination–addition mechanism (8). For these reasons the synthesis of the series of IV compounds for antineoplastic evaluation was contemplated.

When a second dimethylaminomethyl group is introduced into the molecule, as in V, the proton of the methine group adjacent to the carbonyl group is more acidic than the methylene protons adjacent to the carbonyl group in IV. Hence, compounds of the V series have a greater tendency to undergo elimination than IV compounds. Furthermore, after the loss of one onium group in V, the olefin formed may react in a facile manner with nucleophiles, and expedition of the loss of the remaining quaternary ammonium group could occur generating a further center for nucleophilic attack.

Some of a series of Mannich bases (VI) have activity in the P-388 screen. These compounds, which resemble IV, except that an olefinic linkage separates the aromatic ring from the keto function, affected basal respiration in mitochondria isolated from liver cells of male Wistar rats at concentrations as low as 1–5 μmoles (9, 10). One of these compounds [VI, R^1 = 3-OH; R^2 = H; R^3 = $(CH_2)_4CH_3$] elicited a biphasic response: at low dose levels (*e.g.*, 1.25 μmoles), stimulation of respiration occurred, while at higher doses (5 μmoles), inhibition of respiration was noted (11). The stimulation of respiration was shown to be due to the uncoupling of oxidative phosphorylation, while the inhibition was due to the blocking of the electron transport chain between cytochromes b and c_1 (11). Thus, it was considered of interest to evaluate the antineoplastic activity and the effect on mitochondrial respiration of series IV and V compounds and to determine whether a corre-

[a] Anticancer activity is expressed as the ratios of the survival time of the treated animals to control animals expressed as a percentage. All of the compounds were initially screened at 200, 100, and 50 mg/kg; if mortalities occurred at these doses, they were reduced to nonlethal levels. A compound should increase the median survival time by ≥20% to be considered active. [b] These figures are survivors out of six mice on the fifth day after commencement of the dosage schedule (nine daily doses given intraperitoneally) except V*b* and *c* in which cases the compounds were administered for five consecutive days only.

lation between these two biological parameters exists. In addition, a comparison of the general bioactivity of IV and V could reveal molecular features associated with efficacy against the growth of P-388 lymphocytic leukemia and effect on mitochondrial function.

The effect of temperature on the pattern of respiration was considered of interest since recent reports indicate alterations in mitochondrial function with changes in temperature (12, 13). The compounds could serve as biochemical tools. For example, if both stimulation and inhibition of mitochondrial respiration occurs at 37° and only inhibition occurs when the temperature is lowered to 20°, the effects of concentration can be determined for inhibition of respiration alone.

A number of investigators have shown that the pH of certain tumors is ~7.0 (14, 15), and in addition, the administration of glucose to tumor-bearing animals has lowered the pH of the neoplasm to 6.4 while the pH of normal tissue was unaffected (14, 15). Earlier work was shown that certain compounds in series VI had increased respiratory-inhibiting properties in mitochondria obtained from both rat liver cells and from the Morris 5123 TCH tumor (16) as the pH was lowered from 7.4 to 6.9 and then from 6.9 to 6.4. The question was posed as to whether a similar variation in effect in mitochondria would occur with series IV and V compounds.

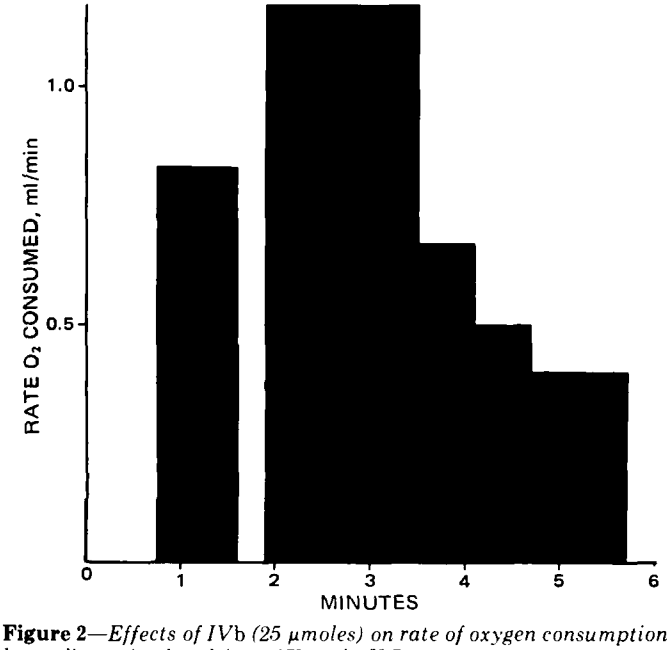

Figure 2—*Effects of IV*b *(25 μmoles) on rate of oxygen consumption by rat liver mitochondria at 37° and pH 7.4.*

RESULTS AND DISCUSSION

The two series of compounds (IV and V) were prepared and assessed for activity against P-388 lymphocytic leukemia growth (Table I). The dose schedule was constant for compounds of both series except fewer doses of V*b* and *c* were administered. From the data available, it may be seen that, while the monobasic compounds of series IV were uniformly inactive against murine P-388 lymphocytic leukemia growth, variation in antineoplastic activity in series V compounds was found. Compounds V*d* and *e* showed significant activity in this screen, V*a* and *b* displayed marginal potencies, and V*c* was inactive. The compounds were less active than 5-fluorouracil, which has a T/C% of 182 at 25 mg/kg (20 daily doses) in the P-388 murine screen (17). All of the compounds in Table I showed toxicity; but, whereas no mortalities were found at 50 mg/kg in series IV, only the inactive diamine of the V series (V*c*) did not cause deaths at this dose level. No animals died when V*a–e* were administered at a dose of 25 mg/kg. Thus, with the exception of V*c*, greater antineoplastic activity accompanied by greater murine toxicity was found with series V than with series IV.

The reasons for the differences in bioactivities between series IV and V were then considered. Lability of a number of Mannich bases to produce the corresponding α,β-unsaturated ketones is well documented (6, 18) and, on occasions, this property has been invoked to explain the bioactivities of a number of Mannich bases (19, 20). Such deamination processes are possible in both IV and V, leading to the formation of substituted acrylophenones which could undergo attack with cellular nucleophiles such as thiols of proteins. Since the rate of deamination is dependent on the nature of the Hammett σ value in the aromatic ring, the stabilities of the compounds with the most divergent σ values namely IV*c* and V*c* ($\sigma = +0.60$) and IV*e* and V*e* ($\sigma = -0.27$) were examined under simulated physiological conditions (buffer of pH 7.4 and 37°). Both IV*c* and *e* were stable for at least 1.5 hr; after 5 min, degradation of V*c* and *e* to VII*a* and *b* occurred as evidenced by extraction of the reaction medium and analysis by NMR. When the temperature was reduced to 5°, V*c* gave rise to a mixture of VII*a* and V*c* as the free base in a ratio of 10:1 after 5 min, while V*e* gave rise to the free base and no olefin. After 1 hr at 5°, V*e* gave a mixture of VII*b* and the free base of V*e* in a ratio of 7:4. Hence, the comparative rates of deamination of V*c* and *e* follow that predicted by a consideration of the electronic effects of the nuclear substituents. The difference between IV and V in ability to undergo elimination, producing the corresponding α,β-unsaturated ketones, is probably due to variation in the acidity of the protons in the β-position to the dimethylamino group, since the rate-determining step in such elimination reactions is the attack of the hydroxyl anion at the methylene carbon atom adjacent to the keto function. This facile elimination could permit reaction with cellular nucleophiles, and reaction of V*c* with a biomimetic thiol (2-mercaptoethanol) was undertaken. Preliminary experiments involving incubation of V*c* and 2-mercaptoethanol in buffer at 37° followed by extraction with chloroform gave a mixture of compounds, as revealed by TLC. However, when V*c* and the thiol were incubated for a short period of time in a mixture of buffer and chloroform, the product

Scheme I

isolated was shown by NMR to be VIII*a*, which could arise as shown in Scheme I. The mass spectral (MS) fragmentation pattern was consistent with the structure of VIII*a*; in particular, a molecular ion corresponding to the dithioether was observed and the absence of a prominent peak at *m/z* 58, which is often the base peak in Mannich bases due to the dimethylmethyleneimmonium ion, was noted. It was considered that the stability of IV compounds in buffer, and hence lack of formation of the corresponding olefins, may have led to inactivity of these compounds towards thiols. The least reactive member of the series, IV*e*, was incubated with 2-mercaptoethanol in the presence of chloroform and buffer, and the mixture was shown by NMR and MS to be principally 3-(2-hydroxyethylthio)-1-(*p*-methoxyphenyl)-1-propanone, *i.e.*, the dimethylamino group had been replaced by a 2-hydroxyethylthio function. Control experiments showed that the reaction between IV*e* and 2-mercaptoethanol occurred in the buffer and not in the organic solvent. Hence, elimination in series IV may occur in the presence of stronger nucleophiles than the hydroxide anion found in the aqueous buffer. It is conceivable, however, that the Mannich bases of IV and V could interact with thiols by a substitution reaction on the carbon atom adjacent to the dimethylamino group, but the synthesis of such derivatives is often accomplished in the presence of virtually nonpolar solvents and elevated temperatures (4). Hence, the elimination–addition mechanism seems more feasible.

The effect of IV and V compounds on respiration in rat liver mitochondria is given in Table II. At low concentrations in both series of compounds, stimulation of respiration occurs. In general, as the concentration is increased, stimulation of respiration increases and then diminishes while inhibition of respiration increases. In addition, the elevation of concentration shortens the time period prior to inhibition by IV and V compounds. A typical result is illustrated in Figs. 1 and 2. While from a qualitative viewpoint, both series of compounds exert similar effects, a quantitative evaluation of IV*a–e* with the compounds bearing a similar nuclear substituent in series V, indicates that IV requires ~100 times the concentration to elicit the same increases in both stimulation and inhibition of respiration as V. For example, doses of 25 μmoles of IV*a–e* cause similar percentage inhibitions of respiration in mitochondria as 0.25-μmole concentrations of V*a–e*. At comparable concentration levels, the olefins VII*a* and *b* have similar respiration-inhibiting properties as their progenitors V*c* and *e*, although the effect on stimulation of respiration appears somewhat different. Two representative compounds in series IV and V were examined for their effect on mitochondria at 20° and, in general, stimulation of respiration was increased and inhibition of respiration diminished at this temperature compared with 37° (Table III). The respiration-inhibitory data generated for V*a* and *c* are comparable to the olefinic analogues VI ($R^1 = R^2 = H$) and VI (R^1 = 3-CL; R^2 = 4-CL), respectively (9).

A comparison of the effect on respiration in mitochondria between a compound displaying significant activity against P-388 lymphocytic leukemia (V*e*) and an inactive analogue (V*c*) at pH values of 6.9 and 6.4 is summarized in Table IV. With the exception of the 1.0-μmole dose for V*c*, the largest increase in stimulation of respiration is at the pH of normal cells (7.4) in the case of V*c*, while the maximal increase in stimulation for the active compound V*e* is at pH 6.4. If antineoplastic activity is influenced by the effect on stimulation of respiration (*e.g.*, by the uncoupling of oxidative phosphorylation impairing the synthesis of adenosine triphosphate), selective toxicity under the acidic conditions of the tumorous cells is conceivable. When inhibition of respiration was examined, an alternate situation was found; *i.e.*, minimal percentage inhibition of respiration occurs with both V*c* and *e* at pH 6.4. Hence, the bioactivity of V*e* in contrast to V*c* is explicable only in terms of the effect on stimulation and not inhibition of respiration if the effect on mitochondrial function is associated with anticancer properties and the pH of malignant cells is much lower than that of the corresponding normal cells.

In conclusion, the following generalizations regarding chemical structure and bioactivity may be made. First, series V was found to be more active against P-388 lymphocytic leukemia growth and to display greater murine toxicity than series IV, possibly due to the greater fragility

Table II—Effect on Respiration in Rat Liver Mitochondria Using Succinate as the Substrate at pH 7.4 and 37°

of V in aqueous media in which decomposition to the corresponding enones occurred. The only exception was V*c*, which was inactive against the particular tumor under consideration and appeared to be less toxic than V*a*, *b*, *d*, and *e*. Retrospectively, the five substitution patterns in the aromatic ring in V were the ones recommended for a Topliss analysis (21), and the order of activity found in this series of compounds is claimed by such an approach to indicate the greater importance of the Hammett σ value over the Hansch π parameter. Second, murine toxicity in both IV and V compounds may be associated, at least partially, with interaction with cellular nucleophiles. Third, both series of compounds affected respiration in mitochondria isolated from rat liver cells, but compounds bearing the same nuclear substituents differed ~100-fold in the doses required to elicit similar effects. A direct correlation between antineoplastic activity and the effect on respiration in mitochondria was absent. Fourth, maximum antineoplastic activity is found with V*d* and *e*, although these do not represent the extremes in regard to either rate of decomposition or effect on respiration in mitochondria. Thus, if decomposition is proportional to the Hammett σ value, V*a–c* liberate the corresponding acrylophenones faster than V*d* and *e* while the IV compounds appeared to be stable in aqueous media. In isolated mitochondria, a similar generalization appears valid, *i.e.*, V*a–c* are more active and IV is less active than V*d* and *e*. It is conceivable, therefore, that an optimal rate of breakdown is required for good activity against P-388 lymphocytic leukemia; *e.g.*, although V*c* is rapidly converted to VII*a*, which can affect mitochondria at very low dose levels, it may be inactivated prior to reaching a site of action. On the other hand, the absence of formation of

the acrylophenone or formation at a very slow rate could lead to insufficient compound for anticancer efficacy, which may involve the mitochondria as one of the targets. Relationships between the optimal chemical reactivity required for anticancer activity have been described previously (22), and the evolution of V*d* and *e* from this study permits these compounds to serve as lead compounds (23) in the design of further anticancer molecules.

EXPERIMENTAL

Melting points are uncorrected. Elemental analyses were undertaken locally[1] and when necessary both solvents and organic extracts were dried with anhydrous magnesium sulfate. No attempt was made to optimize the percentage yields of compounds unless otherwise stated. TLC was carried out using sheets of silica gel with fluorescent indicator[2] and a solvent mixture of chloroform–methanol (10:1). Mass spectra[3] were run at 70 eV and the 60-MHz NMR spectra[4] were determined using tetramethylsilane as the internal standard. High-performance liquid chromatography (HPLC)[5] was undertaken using a column[6] eluted with acetate buffer (0.04 *M*) in acetonitrile.

Synthesis—*3-Dimethylamino-1-aryl-1-propanone Hydrobromides* (*IV*a, d, *and* e)—The crude hydrochloride salts of the Mannich bases derived from acetophenone, *p*-methylacetophenone, and *p*-methoxyacetophenone were prepared as previously described (24). The yields obtained for the hydrochloride salts corresponding to IV*b* and *c* were 42 and 16%, respectively. The crude hydrochloride salts of IV*a*, *d*, and *e* were converted to the hydrobromide salts by the procedure described below to give IV*a*, *d*, and *e* as colorless crystals from acetone–methanol. In an attempt to improve the yield of 1-(3,4-dichlorophenyl)-3-dimethylamino-1-propanone hydrochloride, a mixture of 3,4-dichloroacetophenone (9.45 g, 0.05 mole), paraformaldehyde (1.80 g, 0.06 mole) dimethylamine hydrochloride (5.30 g, 0.065 mole), hydrochloric acid (0.1 ml), and 1,2-dimethoxyethane (35 ml) was heated under reflux for 24 hr. The solid that separated on cooling was removed by filtration, dried, and recrystallized from ether–ethanol to give 1-(3,4-dichlorophenyl)-3-dimethylamino-1-propanone hydrochloride (4.2 g, 30%) as colorless crystals; mp 193–195° [lit. (25) mp 193–195°].

1-(p-Chlorophenyl)-3-dimethylamino-1-propanone Hydrobromide (*IV*b)—An excess of acetyl chloride was added to *N,N,N′,N′*-tetramethyldiaminomethane[7] (10.2 g, 0.1 mole) in dry methylene chloride (100 ml) at 0° with vigorous stirring. The precipitated Mannich reagent was removed by filtration, washed with methylene chloride, and dried *in vacuo* to give *N,N*-dimethyl(methylene)ammonium chloride (8.5 g). This compound was used without purification.

A solution of *p*-chloroacetophenone (15.50 g, 0.1 mole) in dry acetonitrile (40 ml) was added to the *N,N*-dimethyl(methylene)ammonium chloride (9.35 g, 0.1 mole), and the mixture was stirred at room temperature for 2 hr. The precipitate was removed by filtration, dried, and recrystallized from ether–methanol to give 1-(*p*-chlorophenyl)-3-dimethylamino-1-propanone hydrochloride (21.5 g, 84%) as colorless crystals, mp 173–175° (26).

An aqueous solution of 1-(*p*-chlorophenyl)-3-dimethylamino-1-propanone hydrochloride (6.20 g, 0.025 mole) was basified with aqueous sodium carbonate solution (10% w/v) and extracted with chloroform (3 × 15 ml). The chloroform extracts were combined, washed with water (2 × 5 ml), and dried with anhydrous magnesium sulfate; removal of the chloroform gave a viscous oil which was dissolved in acetone–ether (1:1) and treated with dry hydrogen bromide gas. The crude hydrobromide (5.0 g) which precipitated was removed, and recrystallization from ether–methanol gave 1-(*p*-chlorophenyl)-3-dimethylamino-1-propanone hydrobromide, IV*b* (5.5 g), as colorless crystals. The yield of IV*b* was 63% based on the quantity of *p*-chloroacetophenone utilized.

1-(3,4-Dichlorophenyl)-3-dimethylamino-1-propanone Hydrobromide (*IV*c)—This compound was prepared in the same manner as IV*b*. The yield for the formation of 1-(3,4-dichlorophenyl)-3-dimethylamino-1-propanone hydrochloride, mp 193–194° [lit. (25) mp 193–195°] was 72%, and the overall yield for the formation of IV*c* from 3,4-dichloroacetophenone was 54%.

3-Dimethylamino- 2 -dimethylaminomethyl -1-aryl-1-propanone Dihydrobromides (*V*)—The general procedure for preparing V is illustrated by the synthesis of V*a*. A mixture of acetophenone (6.0 g, 0.05 mole), an aqueous solution of formaldehyde (37% w/v, 12 ml, 0.15 mole), dimethylamine (25% w/v, 27 ml, 0.15 mole), and ethanol (25 ml) was heated under reflux for 3 hr. After removal of the ethanol *in vacuo*, the mixture was cooled and extracted with ether (3 × 20 ml). The combined ether extracts were washed with water and dried with anhydrous magnesium sulfate; evaporation of the ether gave the crude ketone as a viscous oil. A solution of this oil in dry acetone was treated with hydrogen bromide gas to give a colorless solid which was removed by filtration, washed with acetone, dried, and recrystallized from methanol to give 3-dimethylamino-2-dimethylaminomethyl-1-phenyl-1-propanone hydrobromide, V*a* (4.5 g), as colorless crystals. Compound V*d* was prepared in an identical manner as V*a*, while the times of heating under reflux for V*b*, *c*, and *e* were 16, 30, and 6 hr, respectively. The structures of V*a–e* were confirmed by NMR, and the data generated for a representative compound, V*e*, are as follows: δ 8.1 (d, 2, aromatic protons at C_2 and C_6), 7.15 (d, 2, aromatic protons at C_3 and C_5), 3.95 (s, 3, OCH_3), 3.2–3.9 [m, 5, $C^2H(CH_2)_2$] and 2.95 [s, 12, $2N(CH_3)_2$]. The base peak in the MS was at 58 AMU.

2-Dimethylaminomethyl-1-aryl-2-propen-1-ones (*VII*a *and* b)—Chloroform (20 ml) was added to a solution of V*c* (0.500 g) in 40 ml of Sørensen's phosphate buffer, pH 7.4, (27) and the mixture was incubated at 37° with vigorous shaking. After 1 hr, the chloroform layer was removed and dried with anhydrous magnesium sulfate; evaporation of the organic solvent gave 2-dimethylaminomethyl-1-(3,4-dichlorophenyl)-2-propen-1-one, VII*a* (0.155 g, 56%) as a light yellow semisolid. HPLC showed one major peak (95.3%) plus two minor peaks. NMR: δ 7.85 (s, 1, aromatic proton at C_5), 7.7 (s, 2, aromatic protons at C_2 and C_6), 6.05 (s, 1, $=C^3H_2$), 5.7 (s, 1, $=C^3H_2$), 3.4 (s, 2, $-CH_2N$), and 2.4 [s, 6, $N(CH_3)_2$]; MS: *m/z* 257 (M^+, 5%), 173 (9%), and 58 (100%).

Anal.—Calc. for $C_{12}H_{13}Cl_2NO$: N, 5.43. Found: N, 5.37.

2-Dimethylaminomethyl-1-(*p*-methoxyphenyl)-2-propen-1-one, VII*b*, was prepared in the same way as a light yellow semisolid in 63% yield. HPLC showed one major peak (94.7%). NMR: δ 7.85 (d, 2, aromatic protons at C_2 and C_6), 6.9 (d, 2, aromatic protons at C_3 and C_5), 6.05 (s, 1, $=C^3H_2$), 5.7 (s, 1, $=C^3H_2$), 3.9 (s, 3, OCH_3), 3.4 (s, 2, CH_2N), and 2.4 [s, 6, $N(CH_3)_2$]; MS: *m/z* 219 (M^+, 19%).

Anal.—Calc. for $C_{13}H_{17}NO_2$: N, 6.38. Found: N, 5.94.

Stabilities in Phosphate Buffer—*Compounds IV*c *and* e—Chloroform (5 ml) was added to a solution of IV*c* (100 mg, 0.306 mmole) in phosphate buffer (pH 7.4, 2 ml), and the mixture was incubated at 37° on a shaking constant-temperature bath[8]. After 1.5 hr, the chloroform layer was separated and dried; removal of the solvent afforded a colorless solid (0.081 g, 95%) identified as the free base of IV*c*. NMR: δ 8.2–7.5 (m, 3, aromatic), 3.3–2.6 (m, 4, C^2H_2 and C^3H_2), and 2.3 [s, 6, $N(CH_3)_2$].

Similarly IV*e* gave the free base corresponding to IV*e* in 90% yield. NMR: δ 7.9 (d, 2, aromatic protons at C_2 and C_6), 6.9 (d, 2, aromatic protons at C_3 and C_5), 3.8 (s, 3, OCH_3), 3.4–2.6 (m, 4, C^2H_2 and C^3H_2), and 2.4 [s, 6, $N(CH_3)_2$].

Compounds Vc and e—Compound V*c* (100 mg, 0.215 mmole) was dissolved in a mixture of phosphate buffer (pH 7.4, 2 ml) and chloroform (5 ml) at 37° using a constant-temperature bath[8]. After 5 min, the chloroform layer was separated and dried; removal of the solvent afforded a semisolid which was identified by NMR as predominantly (>95%) VII*a*. Similarly V*e* gave rise to VII*b*.

The experiment was repeated except that V*c* was added to a mixture of buffer and chloroform in an ice bath (5°) and the resultant mixture shaken manually for 5 min. The chloroform layer was separated and dried; removal of the solvent gave a semisolid which was shown from the NMR spectra to be a mixture of VII*a* and V*c* as the free base in a ratio of 10:1. The ratio of these two compounds was determined from the NMR spectra using the following simultaneous equations: $AX_0 + BX_b = Y$ and $CX_0 + DX_b = Z$ where *A* and *B* are the number of aromatic protons in VII*a* and V*c*, respectively, as the free bases; X_0 and X_b are the mole fractions of VII*a* and V*c*, respectively, as the free bases; *C* and *D* are the number of protons in the dimethylamino group of VII*a* and V*c*, respectively, as the free bases; and *Y* and *Z* are the respective integrals. When the experiment was repeated with V*e* (100 mg, 0.2346 mmole) at 5° and for 5 min, only the free base of V*e* was obtained. However if the length of time was increased to 1 hr, a mixture of VII*b* and V*e* as the free bases was obtained which was shown by the NMR spectra and the use of the aforementioned simultaneous equations to be in a ratio of 7:4.

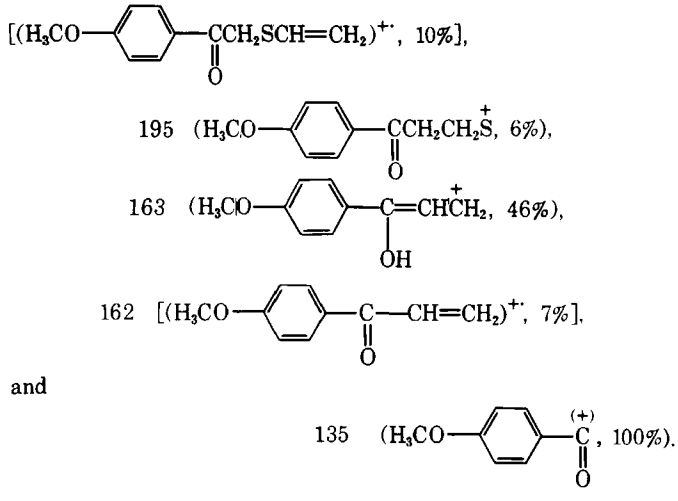
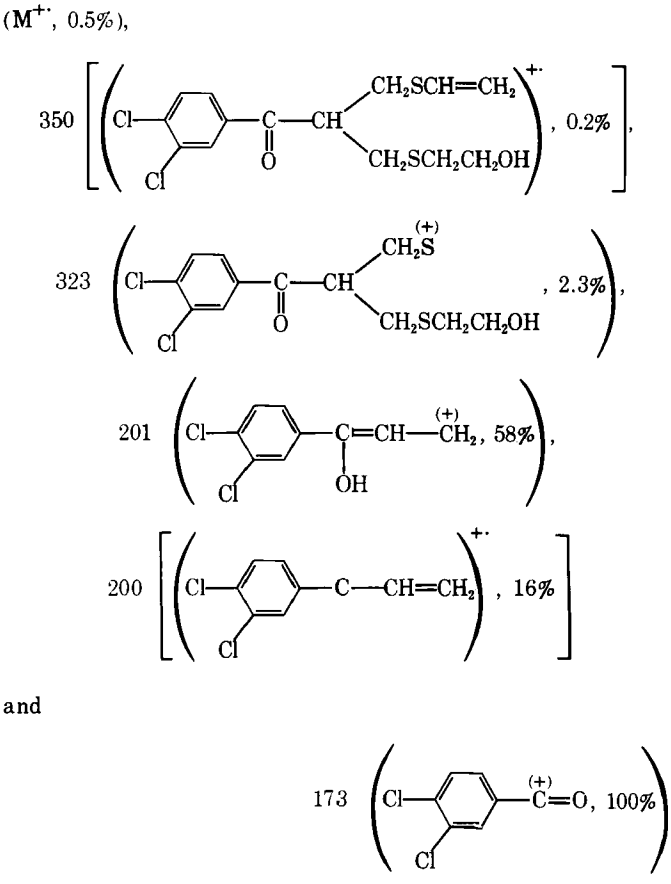
Reaction of IV*e* with 2-Mercaptoethanol—Chloroform (10 ml) was added to a solution of IV*e* (200 mg, 0.694 mmole) and 2-mercaptoethanol (167 mg, 2.1 mmoles) in phosphate buffer (pH 7.4, 4 ml), and the mixture was incubated at 37° on a shaking constant-temperature bath[8]. After 1 hr, the chloroform layer was separated and dried; removal of the organic solvent and excess of 2-mercaptoethanol under reduced pressure gave a bright-yellow viscous oil, the NMR spectrum of which showed the retention of the aromatic and methoxy protons but the absence of the dimethylamino protons. Other unidentified peaks were present and the oil appeared to be a mixture of compounds, although predominantly 3-(2-hydroxyethylthio)-1-(*p*-methoxyphenyl)-1-propanone. MS gave a parent peak corresponding to this ketone (*m/z* 240, 0.4%) with major ions at *m/z* 222:



The intensity of the peak at *m/z* 58 was 1%.

The experiment was repeated twice: in the absence of phosphate buffer and when chloroform was omitted. In the absence of buffer, a 98% recovery of IV*e*, identified by NMR and melting point, was found. In the absence of chloroform, IV*e* and 2-mercaptoethanol were incubated at 37° in buffer (5 ml) for 1 hr, and the mixture was extracted with chloroform (3 × 10 ml). The organic extract was saturated with dry hydrogen chloride gas and dried. Removal of the chloroform gave a residue which, when triturated with dry ether, gave IV*e* as the hydrochloride salt (0.042 g), identified by NMR. Evaporation of the ether gave a residue which was shown by NMR to contain 3-(2-hydroxyethylmercapto)-1-(*p*-methoxyphenyl)-1-propanone along with minor amounts of contaminants.

Preparation of 3-(2-Hydroxyethyl)mercapto-2-[(2-hydroxyethyl)mercapto]methyl-1-(3,4-dichlorophenyl) - 1 - propanone (VIII*a*)—A solution of 2-mercaptoethanol (125 mg, 1.6 mmoles) in phosphate buffer, pH 7.4 (13 ml), was added to a solution of V*c* (250 mg, 0.538 mmole) in phosphate buffer, pH 7.4 (10 ml). After the addition of chloroform (50 ml), the mixture was incubated for 15 min at 37° with vigorous stirring. The chloroform layer was removed, washed with water, and dried with anhydrous magnesium sulfate, and both chloroform and excess 2-mercaptoethanol were removed *in vacuo* to give a yellow viscous oil (0.120 g) which was predominantly 3-(2-hydroxyethyl)mercapto-2-[(2-hydroxyethyl)mercapto]methyl-1-(3,4-dichlorophenyl)-1-propanone. MS: *m/z* 368:



58 AMU (4%) was noted.

Anal.—Calc. for $C_{14}H_{18}Cl_2O_3S_2$: C, 45.53; H, 4.91; N, 0.00. Found: C, 44.43; H, 5.18; N, 0.27.

Effect of IV and V on Respiration in Rat Liver Mitochondria—Compounds IV and V were dissolved in Sørensen's buffer and kept ice-cold prior to the addition to the previously prepared mitochondrial suspension. The mitochondria were obtained from male Wistar rats (200–250 g) and the effect of IV and V on respiration was measured using a previous procedure (9). The buffer used in isolating the mitochondria and the

respiration media employed were those described previously (9), except that Sørensen's buffer and not tromethamine hydrochloride was used. The data generated at 37° (Table II) and the percentage stimulation and inhibition of respiration are both in relation to the original respiration rate. A minimum of five determinations were made at each concentration; in the case of IVc (5.0 μmoles), Va (0.1 μmole), Vd (0.1 μmole) and Ve (0.25 and 25 μmoles) a total of 12 determinations were performed.

In both Figs. 1 and 2, the data shown indicate differences in oxygen uptake compared with control mitochondria (no succinate or compound added). The lag period (A) was also found with IVa (10 μmoles), IVd (10 μmoles), IVe (10, 25, and 50 μmoles), Va (0.01, 0.1, and 0.25 μmole), Vb (0.01 μmole), Vc (0.001, 0.01, 0.1, and 0.25 μmole), Vd (0.01, 0.1, 0.25, and 1.0 μmole), Ve (0.01, 0.1, 0.25, 1.0, and 10 μmoles), and VIIb (1.0 μmole). In some cases, during interval A the slope of the line was identical to that after the addition of succinate; *i.e.*, no difference in oxygen utilization was noted after addition of the compound. This phenomenon occurred with IVb (5 and 10 μmoles), Va (1.0 μmole), Ve (12.5 and 15 μmoles), and VIIa (1.0 μmole). Inhibition of respiration occurred prior to stimulation of respiration during interval A in the case of IVa (25 μmoles), IVb (25 μmoles), IVc (5 and 10 μmoles), IVd (25 and 50 μmoles), IVe (100 μmoles), Va (10 μmoles), Vb (0.01 and 0.1 μmole), and VIIb (10 and 25 μmoles). In the remaining cases, the lag period (A) was absent and addition of the compound led to effects noted in one or more of the time periods B, C, and D.

The effect on respiration at pH values of 6.9 and 6.4 is given in Table III. At pH 6.9, respiration continued at the same rate as after addition of succinate during interval A in the case of Vc (0.01 μmole) and Ve (0.25 and 1.0 μmoles). Inhibition of respiration during interval A occurred with Ve (10 μmoles). The lag period was absent at concentrations of 0.1, 0.25, and 1.0 μmole of Vc. At pH 6.4, submaximal stimulation of respiration was noted with Vc (0.01 and 0.1 μmole) and Ve (0.25 and 1.0 μmole). Inhibition of respiration during interval A was found with Vc (0.25 and 1.0 μmole) and Ve (10 μmoles).

Table IV indicates the effect of various concentrations of IVc and e, Vc and e on respiration in rat liver mitochondria at 20°. The same procedure (9) was employed, using a constant-temperature bath[9]. Submaximal stimulation occurred during the lag period for IVc (5 μmoles) and Vc (0.1, 0.25, 10, 15, and 25 μmoles). Respiration was identical to that after the addition of succinate for IVe (25 μmoles) and Vc (0.25 μmoles). Inhibition of respiration during interval A was noted for IVc (10 and 25 μmoles), IVe (50 and 100 μmoles), and Vc (1.0 μmole). The lag period was absent in the cases of Vc (10 μmoles) and Ve (50 μmoles).

Screening of Compounds—The anticancer screening was carried out by the Drug Research and Development Division of the National Cancer Institute, Bethesda, Md., using their protocols (28). Male or female CD_2F_1 mice were used. The compounds were administered by the intraperitoneal route in saline except for IVc, for which hydroxypropylcellulose was employed.

Pharmacokinetics of Piperacillin and Gentamicin Following Intravenous Administration to Dogs

VIJAY K. BATRA ˣ, JOHN A. MORRISON, and THOMAS R. HOFFMAN

Received February 5, 1982, from the *Pharmacodynamics Department and Statistical Design and Analysis Department, Medical Research Division, American Cyanamid Co., Pearl River, NY 10965.* Accepted for publication July 30, 1982.

Abstract □ Piperacillin sodium was administered intravenously to dogs, alone or in combination with gentamicin, twice a day (~5 hr apart) for 36–37 days. The pharmacokinetics of neither drug changed in the presence of the other; however, the percentage of the gentamicin dose recovered in the urine decreased significantly when coadministered with piperacillin. The data demonstrate that interaction between the two drugs in urine is feasible.

Keyphrases □ Piperacillin—pharmacokinetics in the dog, effect of concomitant administration of gentamicin □ Gentamicin—pharmacokinetics in the dog, effect of concomitant administration of piperacillin □ Pharmacokinetics—of piperacillin and gentamicin in the dog, effect of concomitant administration

Piperacillin[1], sodium (2*S*, 5*R*, 6*R*)-6-[(*R*)-2-(4-ethyl-2,3-dioxo-1-piperazinecarboxamido)-2-phenylacetamido]-3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate, is a novel semisynthetic penicillin that possesses broad spectrum antibacterial activity against Gram-negative and Gram-positive pathogenic bacteria, including anaerobes. Results of *in vitro* studies (1) have shown piperacillin to be superior to ampicillin, carbenicillin, and cephalosporins against Gram-negative bacteria, particularly *Klebsiella*, *Proteus*, and *Serratia* species and *Pseudomonas aeruginosa*. In certain cases, a piperacillin and gentamicin combination would be preferred to obtain a synergistic effect. To evaluate the toxicity of these two drugs when administered alone or in combination, a 1-month study was undertaken in dogs. Since aminoglycosides can interact with β-lactam antibiotics (2–4), the study was designed to allow the serum concentrations to be analyzed pharmacokinetically. This paper describes the pharmacokinetics of piperacillin and gentamicin when given alone or in combination.

EXPERIMENTAL

Animal Studies—Six groups of 18–20-month-old beagle dogs[2] (two males and two females in each group) were utilized for the study. The weight range was 9.4–12.3 kg for the males and 7.9–9.6 kg for the females. The dogs were assigned to groups using a table of random numbers. They were housed individually in a room maintained at 21–24°, with a 12-hr on/off light cycle. Food[3] (250–300 g) was offered to each dog daily, ~30 min after the last dose; water was available *ad libitum*.

Drug solutions, made prior to each dose, were administered twice daily (~5 hr apart) over a 5-min period with an infusion pump[4] calibrated using the specific syringes, solutions, and tubing employed. Doses, adjusted to the body weight twice a week, were administered according to the schedule shown in Table I. The concentration of the piperacillin solution in sterile water for injection, expressed as free acid, was 250 mg/ml. The gentamicin solution was made in concentrations of 1 and 2 mg/ml (expressed as base equivalent activity) using sterile isotonic saline. For dogs

		2	3000	1870	1410	965	825	232	26

[a] $n = 2$ for each group.

that received both drugs, the solutions of piperacillin and gentamicin were prepared independently and mixed in the infusion flow during administration, as illustrated in Fig. 1.

Serum samples were obtained from one dog per sex-group prior to the infusion and at 5 (end of the infusion), 10, 20, 40, 60, 120, and 240 min following the commencement of the infusion during the first (phase I) and last (phase 2) week of dosing. Urine samples (0–24 hr) were collected for 2 consecutive days from all dogs during the first and last weeks of the study.

Antibiotic Assay—Antibiotic concentrations were determined by the disk diffusion method. The assays for piperacillin were performed with *Sarcina lutea* ATCC 9341 (indicator organism) grown on antibiotic medium No. 1[5] to which 0.6% sodium polyanetholesulfonate was added to inhibit gentamicin activity (5). This concentration of sodium polyanetholesulfonate was sufficient to inactivate 50 μg/ml of gentamicin in the solutions containing 2.5–0.16 μg/ml of piperacillin used for the standard curve. The recovery from samples of known piperacillin concentration, alone or combined with gentamicin, was 95–108%; the limit of detection was 0.16 μg/ml.

The assays for gentamicin were performed with *Bacillus subtilis* ATCC 6633 grown on mycin agar[5] to which 1000 kinetic units of pencillinase[6] were added per milliliter of medium to inactivate the piperacillin. This concentration of the enzyme was sufficient to inactivate >440 μg/ml of piperacillin in the solutions containing 2.5–0.16 μg/ml of gentamicin used for the standard curve. Samples were diluted to the range of concentrations in the standard curve. The recovery from samples of known gentamicin concentration, alone or combined with piperacillin, was 96–107%; the limit of detection was 0.16 μg/ml. All samples were assayed twice, and the precision of the assays was ±15%.

Pharmacokinetic Analysis—Pharmacokinetic analysis of the data was performed using the digital computer program AUTOAN (6) in conjunction with the nonlinear regression analysis program NONLIN (7). The serum concentrations were weighted according to the square of their reciprocals. The excretion rate constant (k_u) was computed using:

$$\frac{X_u^\infty}{\text{Dose}} = \frac{k_u}{K_{el}}$$

where X_u^∞ is the amount of unchanged drug excreted in the urine and K_{el} is the overall elimination rate constant of the drug. Renal clearance was estimated by multiplying k_u by the volume of distribution of the central compartment. The other pharmacokinetic parameters were obtained by previously published pharmacokinetic equations (8).

Statistical Methods—The pharmacokinetic model parameters were

subjected to three separate ANOVA to compare the pharmacokinetics of piperacillin with gentamicin, determine the effects of gentamicin on piperacillin pharmacokinetics, and determine the effects of piperacillin on gentamicin pharmacokinetics. The first analysis included animals that received only one drug. The effects tested were drug, phase, and the drug by phase interaction; the dose level of gentamicin was not considered. The second analysis included animals that received 500 mg/kg of piperacillin, alone or in combination with gentamicin at either 2 or 4 mg/kg. The effects tested were dose level of gentamicin, phase, and the interaction between dose level and phase. The final analysis included animals that received gentamicin at either 2 or 4 mg/kg, alone or in combination with 500 mg/kg of piperacillin. The effects tested were dose levels of both drugs, phase, and all interactions. Homogeneity of variance within the male and female dogs was assumed.

RESULTS AND DISCUSSION

The mean serum concentrations attained following administration of 500 mg/kg of piperacillin and 2 or 4 mg/kg of gentamicin (alone or in combination) during phase 1 (day 1, 2, or 3) and phase 2 (day 36 or 37) are shown in Tables II and III. Following administration of 500 mg/kg of piperacillin alone, the mean serum concentration at the end of the infusion in phase 1 was 2475 μg/ml; after 5 min, it declined rapidly and biexponentially. The mean serum concentrations at 10, 20, 40, 60, 120, and 240 min after administration were 1825, 1305, 715, 530, 167, and 12.5 μg/ml, respectively. In phase 2, no detectable levels of piperacillin were present before the start of the infusion. At the end of the infusion, the serum concentration was 4200 μg/ml, a level higher than seen in phase 1. After 5 min, serum concentrations were about the same magnitude as observed in phase 1. Simultaneous administration of gentamicin did not change the serum piperacillin levels to any significant extent.

Following 2 mg/kg of gentamicin alone, the serum concentration at the end of the infusion in phase 1 was 9.6 μg/ml; after 5 min, it declined in a biexponential manner. The respective serum levels at 10, 20, 40, 60, 120, and 240 min were 6.0, 4.4, 2.8, 2.2, 1.1, and 0.5 μg/ml. In phase 2, no detectable levels of gentamicin were present before the start of the infusion. At the end of the infusion, the serum level was 12.4 μg/ml and was higher than that in phase 1. Following the 4-mg/kg dosage regimen, the serum levels in both phases 1 and 2 were about two- to threefold the corresponding serum levels observed following the 2-mg/kg dosage regimen.

The time course of both piperacillin and gentamicin in the dog serum

could be described by a two-compartment open model. The relevant mean pharmacokinetic parameters estimated based on this model are given in Table IV. Table V shows the effect of gentamicin administration on the pharmacokinetics of piperacillin; Table VI shows the effect of piperacillin administration on the pharmacokinetics of gentamicin.

The pharmacokinetic parameters, except the volume of distribution of the central compartment (V_c), of both of the drugs in phase 2 were not different from those in phase 1. Even though V_c dropped significantly in phase 2, no statistically significant change was observed either in the volume of distribution at steady state (Vd_{ss}) or the overall volume of distribution, Vd. The reason for the lower V_c in the second phase is not known.

Since the two drugs were given in combination, it was considered of interest to compare the pharmacokinetics of piperacillin with that of gentamicin. Based on data from both phases, the half-life of piperacillin was 34 min, the body and renal clearances were 49 and 22 ml/min, respectively, and the volume of distribution at steady state was 228 ml/kg. The corresponding values for gentamicin were 70 min, 33 and 19 ml/min, and 314 ml/kg, respectively. Compared with gentamicin, piperacillin had a shorter half-life and a larger body clearance. There were no statistically significant differences in the volume of distribution nor in the renal clearance of the two drugs.

The percentages of the piperacillin and gentamicin doses excreted in the urine are given in Tables VII and VIII, respectively. The excretion data of dog 015966 were not used in averaging because of the exceptionally low values obtained: these values are considered to be outliers[7]. When piperacillin was administered alone, ~46% of the dose was recovered in 0–24 hr during phase 1 and ~40% in phase 2. The two urinary recoveries were not statistically different ($p > 0.05$). These recoveries remained unaffected when gentamicin was administered concurrently ($p > 0.05$). Following administration of gentamicin alone, ~54% of the dose was excreted in the urine in 0–24 hr in phase 1 and ~60% in phase 2; again, no statistical differences were observed between the two recoveries ($p > 0.05$). Simultaneous administration of piperacillin reduced ($p < 0.05$) the phase recovery by 92% (from 53.8 to 4.3) and the phase 2 recovery by 78% (from 59.6 to 13.4).

Gentamicin did not affect the pharmacokinetics of piperacillin to any large extent, nor were the pharmacokinetics of gentamicin changed significantly when piperacillin was administered simultaneously. The serum levels, area under serum concentration–time curve (AUC), body clearance, and half-life of gentamicin were not affected by the combination. However, the urinary recovery of gentamicin decreased significantly when it was coadministered with piperacillin.

The similarity of the pharmacokinetic parameters of gentamicin administered alone or in combination with piperacillin clearly indicate that the interaction between piperacillin and gentamicin occurred after excretion, *i.e.*, either in the urinary bladder or the collection container. The *in vitro* inactivation of aminoglycoside antibiotics by β-lactam antibiotics has been documented (2–4, 9, 10). It has been proposed (3, 9) that the two interact to form a biologically inactive conjugate linked between the amino group of the aminoglycoside and the β-lactam ring of the penicillin. Piperacillin in high concentrations has been shown to inactivate gentamicin in serum *in vitro*, but less rapidly than carbenicillin (11). It has also been shown that the inactivation of gentamicin proceeds at a much faster rate in saline or distilled water than in serum (9). Since both piperacillin and gentamicin are excreted in the urine rapidly and in high concentrations, the interaction could take place in the urinary system, especially if voiding does not occur for a long time. Inactivation of gentamicin by piperacillin either during infusion or *in vivo* would have resulted in an area under the gentamicin serum concentration–time curve lower than that in dogs given gentamicin alone. Statistically, there was no difference between the AUC values. Thus, the drop seen in the excretion rate constant and the renal clearance is probably an artifact of the computation process since the equation to calculate these parameters utilizes the amount of unchanged drug excreted in the urine. Results very similar to ours were observed by Waitz and coworkers (3) with carbenicillin. They showed that an intravenous administration of carbenicillin had no effect on gentamicin serum levels in dogs, but did result in reduced urinary excretion of gentamicin. Young *et al.* (4) have also investigated the inactivation of gentamicin by carbenicillin. In dogs whose urine flow was obstructed surgically, they were able to demonstrate that an interaction between carbenicillin and gentamicin could take place in the urinary bladder.

An *in vitro* study was conducted to confirm the interaction of the two drugs in urine. Piperacillin and gentamicin, alone and in combination, were incubated in dog urine at 37° at approximately the same concentration levels as were encountered in the urine of dogs receiving piperacillin or gentamicin alone. Aliquots of urine were removed at predetermined intervals and assayed for piperacillin and gentamicin activity

Table IX—Concentrations of Piperacillin and Gentamicin in Dog Urine as a Function of Time Following Incubation at 37° Either Alone or in Combination

Time, hr	Concentration in Urine, μg/ml			
	Piperacillin		Gentamicin	
	Alone	In Combination	Alone	In Combination
0	4270	5120	69.9	60.4
0.5	4350	4790	67.8	47.0
1	4070	4820	65.4	48.8
2	4120	4730	64.9	48.4
4	4110	4670	34.7[a]	40.7
6	4050	4920	64.0	35.2
8	4020	4630	64.2	32.1

[a] An apparent outlier.

[7] Inclusion of data of this animal in the analysis did not affect the results or conclusions.

(Table IX). There was no loss in piperacillin activity whether incubated alone or with gentamicin; however, a 47% loss of the initial activity of gentamicin was noted when it was incubated with piperacillin. The data clearly demonstrate that interaction between the two drugs in urine is feasible.

Potential Tumor- or Organ-imaging Agents XXIV: Chylomicron Remnants as Carriers for Hepatographic Agents

N. S. DAMLE, R. H. SEEVERS, S. W. SCHWENDNER, and R. E. COUNSELL ˣ

Received April 15, 1982, from the *Departments of Pharmacology and Medicinal Chemistry, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication September 7, 1982.

Abstract □ This paper describes the possible utility of plasma lipoproteins for the site-specific delivery of diagnostic agents. The class of lipoproteins known as chylomicrons was selected for this preliminary study, since they are known to be rapidly metabolized and taken up by the liver. Cholesteryl iopanoate (II), an iodinated analogue of a normal constituent of the hydrophobic core of chylomicrons, was synthesized from cholesterol and iopanoic acid (I) and subsequently radiolabeled with ioidine-125. Whereas intravenous administration of II in physiological saline resulted in the appearance of ~31% of the dose in the liver at 0.5 hr, prior incorporation of II into chylomicrons resulted in an almost threefold (87%) increase in the liver accumulation of II in the same time period. A more gradual appearance of II in steroid-secreting tissues was consistent with the association of II with high-density lipoproteins following administration.

Keyphrases □ Chylomicron—remnants as carriers for hepatographic agents, potential tumor- or organ-imaging agents □ Tumor-imaging agents—potential, chylomicron remnants as carriers for hepatographic agents □ Organ-imaging agents—potential, chylomicron remnants as carriers for hepatographic agents

The early detection of small metastatic lesions in the liver has been a long-term goal of radiology and nuclear medicine. Among the noninvasive diagnostic approaches, radionuclide scintiscanning, ultrasonography, and computed tomography (CT) have all enjoyed variable success (1). Over the past several years, one of the goals of this laboratory has been to devise approaches for the selective delivery of radiopharmaceuticals or radiopaque agents to the liver on the premise that specific uptake of these agents in either normal or abnormal tissue will significantly improve image resolution of small lesions. While others have employed liposomes as delivery vehicles for radiopharmaceuticals (2) and radiopaque contrast agents (3), the focus of this study is on those naturally occurring macromolecules responsible for the transport of lipophilic substances in the plasma—the lipoproteins.

It has been known for many years that the liver plays a major role in lipoprotein catabolism. This is especially true for the class of lipoproteins known as chylomicrons (4, 5). The chylomicrons are synthesized in the intestinal mucosa during fat absorption and are responsible for the transport of dietary fats to sites of utilization and storage. Structurally they are the largest (800–5000 Å) and the lightest (<0.95 g/ml) of the lipoproteins, and consist of an apolar core of lipid surrounded by a phospholipid monolayer (Fig. 1). The lipophilic core is composed of triglycerides and cholesteryl esters. Free cholesterol and apoproteins are associated with the outer phospholipid membrane.

Once in the circulation, these native chylomicrons are acted on by tissue lipoprotein lipase, the enzyme responsible for hydrolyzing triglycerides and providing free fatty acids for cellular metabolism. The resulting triglyceride-depleted, cholesteryl ester-enriched chylomicrons are referred to as chylomicron remnants. In humans, these smaller remnants (300–800 Å) are rapidly taken up by the liver, and their plasma half-life is in the range of 4–5 min (6).

The uptake of chylomicron remnants by liver cells has been shown to occur by a saturable high-affinity process, suggesting the existence of receptors on the surface of liver cells capable of specificially binding these particles (7, 8). Moreover, the presence of apoprotein E on the surface of the remnants has been shown to be important for the recognition and uptake of these particles (9, 10).

0022-3549/83/0800-0898$01.00/0

(Table IX). There was no loss in piperacillin activity whether incubated alone or with gentamicin; however, a 47% loss of the initial activity of gentamicin was noted when it was incubated with piperacillin. The data clearly demonstrate that interaction between the two drugs in urine is feasible.

The early detection of small metastatic lesions in the liver has been a long-term goal of radiology and nuclear medicine. Among the noninvasive diagnostic approaches, radionuclide scintiscanning, ultrasonography, and computed tomography (CT) have all enjoyed variable success (1). Over the past several years, one of the goals of this laboratory has been to devise approaches for the selective delivery of radiopharmaceuticals or radiopaque agents to the liver on the premise that specific uptake of these agents in either normal or abnormal tissue will significantly improve image resolution of small lesions. While others have employed liposomes as delivery vehicles for radiopharmaceuticals (2) and radiopaque contrast agents (3), the focus of this study is on those naturally occurring macromolecules responsible for the transport of lipophilic substances in the plasma—the lipoproteins.

It has been known for many years that the liver plays a major role in lipoprotein catabolism. This is especially true for the class of lipoproteins known as chylomicrons (4, 5). The chylomicrons are synthesized in the intestinal mucosa during fat absorption and are responsible for the transport of dietary fats to sites of utilization and storage. Structurally they are the largest (800–5000 Å) and the lightest (<0.95 g/ml) of the lipoproteins, and consist of an apolar core of lipid surrounded by a phospholipid monolayer (Fig. 1). The lipophilic core is composed of triglycerides and cholesteryl esters. Free cholesterol and apoproteins are associated with the outer phospholipid membrane.

Once in the circulation, these native chylomicrons are acted on by tissue lipoprotein lipase, the enzyme responsible for hydrolyzing triglycerides and providing free fatty acids for cellular metabolism. The resulting triglyceride-depleted, cholesteryl ester-enriched chylomicrons are referred to as chylomicron remnants. In humans, these smaller remnants (300–800 Å) are rapidly taken up by the liver, and their plasma half-life is in the range of 4–5 min (6).

The uptake of chylomicron remnants by liver cells has been shown to occur by a saturable high-affinity process, suggesting the existence of receptors on the surface of liver cells capable of specificially binding these particles (7, 8). Moreover, the presence of apoprotein E on the surface of the remnants has been shown to be important for the recognition and uptake of these particles (9, 10).

0022-3549/83/0800-0898$01.00/0

The parenchymal cells, which comprise the majority of cells in the liver, have been shown to be the most intimately involved in the clearance of chylomicron remnants from the circulation (11, 12). Of particular interest was the finding that remnant-incorporated cholesteryl esters are not taken up to any significant extent by nonparenchymal cells (Kupffer and endothelial) of the rat liver (13). Since radioactive colloids currently used for imaging of liver function are phagocytized by Kupffer cells, chylomicron remnants offer an alternate mechanism for the localization of imaging agents in the liver.

Since cholesteryl esters are a major constituent of chylomicron remnants, it seemed reasonable that incorporation of polyiodinated esters of cholesterol into remnant vesicles could give rise to a new class of hepatographic agents. The iodine of these polyiodinated esters would confer sufficient electron density to serve as radiopaques, or the iodine could be substituted with any one of its various radioisotopic forms (*e.g.*, iodine-123) for radionuclide imaging. To test this hypothesis, iopanic acid (I), an established cholecystographic agent was esterified with cholesterol to afford the highly lipophilic cholesteryl iopanoate (II). This new ester was then labeled with iodine-125 to assist in the measurement of chylomicron incorporation and subsequent tissue distribution analysis.

EXPERIMENTAL[1]

Cholesteryl Iopanoate (II)—A solution of iopanoic acid (I, 571 mg, 1 mmole) and 1,1′-carbonyldiimidazole (170 mg, 1.05 mmoles) in dry tetrahydrofuran (5 ml) was heated at reflux for 10 min. Cholesterol (425 mg, 1.1 mmoles) was added along with a catalytic amount of sodium hydride. The mixture was stirred at room temperature for 1 hr, whereupon the solvent was removed using a rotatory evaporator. Water (10 ml) was carefully added to the residue and the mixture was extracted with benzene. The benzene extracts were combined, the solvent was removed under reduced pressure, and the residue was chromatographed on silica gel (benzene). The fractions containing the ester were combined, the solvent was removed under reduced pressure, and the residue was crystallized from ethanol–water to give II, mp 128–130° (dec) in 58.5% yield. IR(KBr): 3465, 3370, and 1738 cm^{-1}; ^1H-NMR: 4.8 (m, 3 H), 4.85 (s, NH_2), 5.45 (m, 6 vinyl H), and 8.15 ppm (s, Ar 1 H).

Anal.—Calc. for $C_{38}H_{56}I_3NO_2$: C, 48.58; H, 6.01; I, 40.52. Found: C, 48.71; H, 5.97; I, 40.23.

Isotope Exchange of II—The ester (5 mg) and acetamide (100 mg) were placed in a flask containing 10^{-9} *M* NH_4Cl (1.0 eq based on the amount of pH 9 $Na^{125}I$ solution to be added) and 10^{-7} *M* $Na_2S_2O_7$ (1.3–1.5 eq based on $^{125}I^-$ with a specific activity of 2.5×10^9 mCi/mole). $Na^{125}I$ (15 mCi) was added and rinsed in with acetone (0.15 ml). The flask was heated at 170° under a slight positive nitrogen pressure for 1 hr to evaporate the acetone and water present. Heating at 170° was continued for an additional 12 hr, and the flask was allowed to cool. The solid residue was dissolved in benzene, washed with water, and chromatographed on silica gel with benzene to afford [^{125}I]II (3 mg; 2.4 mCi). Radiochemical purity was established by TLC with unlabeled ester as the standard: R_f 0.50 (C_6H_6); R_f 0.08 (CCl_4).

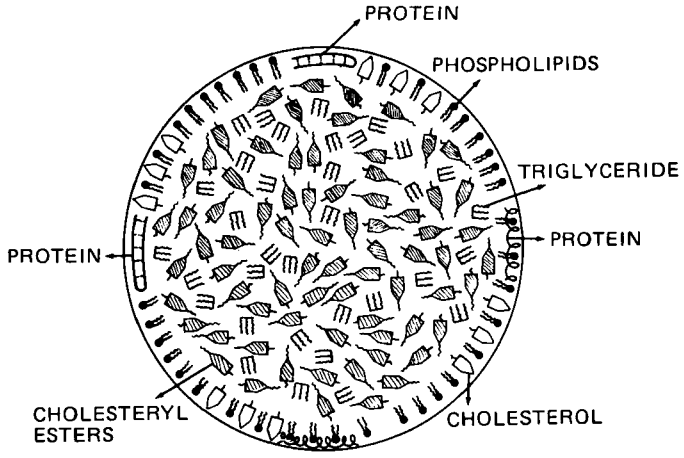

Figure 1—*General structure of a plasma lipoprotein.*

Animals—Sprague–Dawley rats (200–250 g), maintained on a standard rat food, were used for all studies. They were housed in temperature- and light-controlled quarters and had free access to food and water.

Isolation of Chylomicrons—To maximize the yield of chylomicrons from blood samples, the animals were given corn oil intragastrically (2 ml) three times at 3-hr intervals with a fourth dose (3 ml) administered 20 min prior to exsanguination. Blood was drawn by cardiac puncture in heparinized evacuated tubes[2] while the rats were under ether anesthesia (each rat gave approximately 6 ml of blood). The blood was immediately centrifuged at 3000 rpm for 10 min at 4° to separate plasma from packed cells. The plasma was divided into 6.25-ml fractions and layered beneath an equal volume of 0.15 *M* NaCl solution containing 0.002 *M* EDTA [(ethylene dinitrilo)tetraacetic acid] in cellulose nitrate tubes. These tubes were placed in an ultracentrifuge[3] with a Type 40 rotor and spun at 37,000 rpm (114,000×*g*) at 12° for 20 hr. The top, milky white, flocculant layer containing the chylomicrons was carefully separated from the remaining solution and stored at 4°. Lipid analysis of this fraction showed it to contain 281 meq/liter of triglycerides and 15.5 meq/liter of cholesterol[4].

Chylomicron Incorporation—Radioiodinated II (2.0 mg, 420 μCi) was dissolved in benzene (1 ml) to which was added polysorbate 20 (0.2

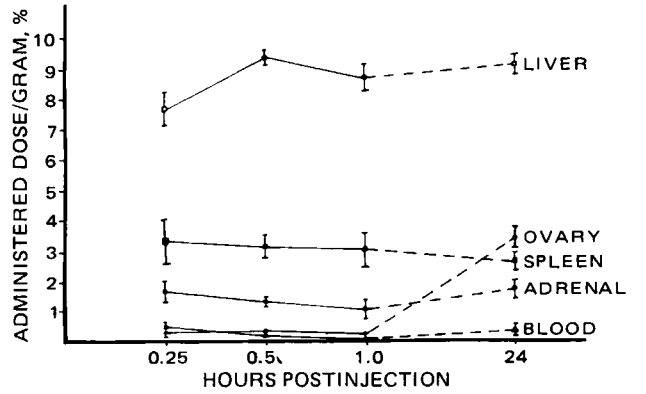

Figure 2—*Tissue distribution of radioactivity following administration of chylomicrons labeled with [^{125}I]cholesteryl iopanoate as a function of time.*

[1] NMR spectra were obtained on a Varian EM360A spectrometer in $CDCl_3$ containing tetramethylsilane as an internal reference. IR spectra were taken in KBr pellets on a Perkin-Elmer 281 spectrophotometer. Elemental analyses were performed by Midwest Microlab, Ltd., Indianapolis, Ind. TLC was performed on Eastman polyethylene-backed silica gel plates with a fluorescent indicator. Cholesterol and 1,1′-carbonyldiimidazolde were obtained from the Aldrich Chemical Co., Milwaukee, Wis. Iopanoic acid was a gift from the Sterling-Winthrop Research Institute, Rensselaer, N.Y. Sodium iodide-125 was purchased from Union Carbide, Tuxedo, N.Y. Polysorbate 20 (Tween 20) was obtained from Sigma Chemical Co., St. Louis, Mo. Rats were obtained from Spartan Research Animals, Inc., Haslett, Mich. Rat food was purchased from Ralston Purina Co., St. Louis, Mo. Agarose gel (Biogel A-50M) was obtained from Bio-Rad Laboratories, Richmond, Calif.

ml). This mixture was vortexed and the benzene evaporated. Physiological saline (1.0 ml) was added, and the solution was vortexed for 5 min. This solution was added to the chylomicron suspension (2.5 ml) in an Erlenmeyer flask, and the mixture was incubated in a water bath at 37° with shaking for 24 hr. At the end of the incubation period, an aliquot was taken for radioactivity determination and the remainder was placed on an agarose-gel (1.5 × 90 cm) column. The column was eluted with 0.20 *M* NaCl solution containing 0.002 *M* EDTA and 0.02% sodium azide. The column was run at a flow rate of 2.5 ml/min, the fractions were collected in a fraction collector[5] (150 drops/tube). The fractions were assayed for optical density (280 nm) and radioactivity[6] (50-μl aliquots) (Fig. 3). The fractions in the void volume were pooled, concentrated to a final volume of 13 ml in an ultrafiltration unit[7], and analyzed for total radioactivity.

Tissue Distribution—Rats were injected with radiolabeled chylomicrons (0.6 ml, 2.5 μCi per animal) intravenously through the tail vein. Groups of four animals were sacrificed by cardiac puncture under ether anesthesia at 0.25, 0.5, 1.0, and 24 hr. The tissues were excised, placed in preweighed cellulose acetate capsules, weighed, and assayed for radioactivity as previously described (14). The tissue concentrations at 0.5 and 24 hr are tabulated in Table I; the results for five key tissues are graphed in Fig. 2.

Tissue Extraction—Adrenal, liver, and plasma were extracted according to the method of Folch *et al.* (15). The percentage of radioactivity in the aqueous and organic phases was measured. The organic phase was streaked on a TLC plate and chromatographed using a petroleum ether–diethyl ether (7:2) system. The TLC plates were sliced and counted in a γ-counter to determine the amount of original ester remaining in the tissues.

Polyacrylamide Gel Electrophoresis (PAGE)—PAGE analysis of plasma samples was performed according to the method of Narayan *et al.* (16), as previously described (17). The amount of radioactivity associated with each lipoprotein class was determined by sectioning the gels and counting each section in a γ-counter. The radioactivity associated with each lipoprotein class was expressed as a percentage of the total radioactivity applied to the gel (Table II).

RESULTS AND DISCUSSION

As has been shown in previous papers in this series (18, 19), cholesterol is efficiently esterified by acid imidazolides. Using this mild procedure, cholesteryl iopanoate (II) was obtained in 58.5% yield from cholesterol and iopanoic acid. This product was readily radioiodinated with iodine-125 by using the isotope exchange method in acetamide (19).

Incorporation of II into chylomicron remnants also proved successful. Similar to previous studies (20) with radiolabeled cholesteryl oleate, II was found to diffuse from the saline solution into the lipophilic core of the chylomicrons during incubation. Incorporated ester was readily separated from unincorporated ester by gel filtration. The elution profile exhibited two peaks when assayed for radioactivity and absorbance at 280 nm (Fig. 3). Since the molecular mass exclusion limit of the gel was 50×10^6 daltons and the approximate molecular mass of chylomicrons is $\sim 200 \times 10^6$ daltons, the radioactivity appearing in the void volume represented II associated with chylomicrons and the radioactivity in the later fractions represented unincorporated ester. Extraction of the labeled chylomicrons and TLC analysis of the extract demonstrated that all of the radioactivity was still associated with II. Moreover, PAGE analysis was consistent with incorporation of II into chylomicrons. The overall process is outlined in Fig. 4. Following this procedure, ~40% of II was incorporated into chylomicron remnants.

Table II—PAGE[a] Analysis of Rat Plasma at Various Times Postinjection of Cholesteryl [^{125}I]Iopanoate in Polysorbate 20–Saline or Incorporated into Chylomicron Remnants[b]

Preparation	Region[c]	Total Radioactivity in Gel, %				
		0 hr[d]	0.25 hr	0.50 hr	1.00 hr	24 hr
Polysorbate 20–Saline	Stacking gel	80.0	—	1.1	—	5.1

	HDL/albumin	2.2	—	75.2	—	66.7
	Below albumin	1.0	—	0.2	—	0.9
Chylomicron remnants	Stacking gel	97.0	90.6	38.2	40.6	32.4
	VLDL/LDL	0.8	5.7	21.2	18.4	15.3
	HDL/albumin	1.1	2.4	21.2	22.3	35.2
	Below albumin	1.1	1.3	19.4	18.7	17.1

[a] PAGE is polyacrylamide gel electrophoresis. [b] $n = 3$–5. [c] LDL = low-density lipid; HDL = high-density lipid. [d] Analysis of dose prior to administration.

The disposition of II administered in saline was compared with II administered in chylomicron remnants. The tissue distribution of radioactivity at 0.5 and 24 hr after intravenous administration of these two preparations is summarized in Table I. When the ester was given in saline, high levels of radioactivity remained in the plasma at 0.5 hr. Plasma levels declined with time and at 24 hr, the adrenal and ovaries were the tissues containing the highest concentration of radioactivity. Lipid extraction and TLC analysis of these tissues demonstrated that the radioactivity was still associated with cholesteryl iopanoate.

Administration of II incorporated into chylomicron remnants, on the other hand, led to a marked increase in the amount of ester reaching the liver within 0.5 hr. Based on organ weights, ~87% of II was present in the liver following administration in chylomicrons as opposed to ~31% when given in saline. This result agrees very closely with that obtained earlier (20) using chylomicron remnants labeled with cholesteryl oleate. A major difference from cholesteryl oleate, however, was that the concentration of II in the liver remained essentially unchanged over the 24-hr period (Fig. 2). TLC analysis of the lipid extracted from the liver revealed that the radioactivity was still in the form of cholesteryl iopanoate (II). Unlike the naturally occurring esters of cholesterol, II is apparently a poor substrate for cholesteryl ester hydrolase (EC 3.1.1.13) present in the liver. In all likelihood, this *in vivo* stability accounts for its ability to persist in the liver.

The increased radioactivity in the steroid-secreting tissues (adrenals and ovaries) with time (Fig. 2) suggests redistribution of II from chylomicron remnants to other lipoproteins. In the rat, the major cholesterol carrier is high-density lipoproteins (HDL), and steroid-secreting tissues have been shown to acquire their cholesterol by an HDL receptor-mediated process (21). Thus, the high levels in the ovary and adrenal may result from the transfer of II from chylomicron remnants to HDL. Support for such a sequence comes from the PAGE analysis of the plasma (Table II). At 0 hr, 97% of II is in the chylomicron band (stacking gel), but by 0.5 hr, 21.2% is found to be associated with HDL. At 24 hr, the amount of II associated with HDL is 35.2%. By contrast, when II is administered in normal saline, it rapidly becomes associated with HDL such

that >75% is associated with this lipoprotein fraction at 0.5 hr. This could account for the higher concentration of ester appearing in the adrenals and ovaries following administration of II in saline.

The purpose of this preliminary study was to determine whether foreign lipid molecules could be introduced into chylomicron remnants and delivered selectively to the liver. This study has demonstrated that, at least in radiotracer amounts, cholesteryl iopanoate (II) can be incorporated into chylomicron remnants in a manner similar to that shown previously for cholesteryl oleate. Moreover, it has been shown that such remnant incorporation of II markedly increased its ability to selectively accumulate in the liver. These results suggest a potential use of lipoproteins as carriers of radiopharmaceuticals for liver imaging. Even in this instance, however, the procedures described in this paper would have to be modified in order to use radionuclides such as iodine-123, which has a half-life of 13 hr. Moreover, to be useful as vehicles for the delivery of radiopaques to the liver, it would be necessary to develop methods capable of incorporating radiologic concentrations of radiopaques into chylomicrons. Studies aimed at answering these and related questions are now in progress.

Enhancement of the Antitumor Activity of N^6-(Δ^2-Isopentenyl)adenosine Against Cultured L-1210 Leukemia Cells by Pentostatin Using a Polymeric Delivery System

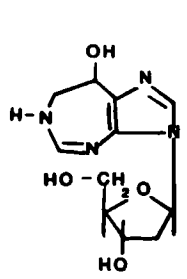
BRUCE HACKER and YUNIK CHANG*x

Received April 20, 1982, from the *Departments of Pharmacology-Toxicology and Pharmaceutics, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication July 14, 1982. *Present address: The College of Pharmacy, University of Oklahoma, Oklahoma City, OK 73190.

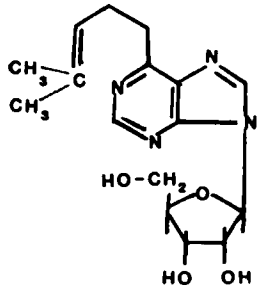
Abstract □ The adenosine deaminase inhibitor pentostatin (I), recently shown to be effective in the treatment of several types of acute and chronic human leukemias, was impregnated in a silicone polymer monolithic disk device for release *in vitro* in the presence of the antitumor nucleoside N^6-(Δ^2-isopentenyl)adenosine (II) against mouse L-1210 lymphocytic leukemia cells. Although I is ineffective alone against L-1210 cells, controlled release from the polymeric delivery matrix potentiates the antiproliferative effects of II during the midlog phase of growth (48 hr). Cytotoxicity is prolonged, leading to total cell death during the stationary phase of growth (96 hr). The present study suggests that polymeric delivery systems be used for controlled release of oncologic agents, alone or in combination with inhibitors, especially where lability is a concern.

Keyphrases □ Pentostatin—use to potentiate antineoplastic activity of N^6-(Δ^2-isopentenyl)adenosine against L-1210 leukemia cells, polymeric delivery system □ N^6-(Δ^2-Isopentenyl)adenosine—antineoplastic agent, potentiation by pentostatin against L-1210 leukemia cells □ Delivery systems—impregnated silicone polymer, pentostatin

The clinical use of several adenosine analogues for the treatment of various types of cancer as well as some immunodeficiency diseases has been hindered by inactivation of the oncologic agent. Elevated adenosine deaminase (adenosine aminohydrolase, E.C. 3.5.4.4), responsible for enzymatically deaminating adenosine nucleosides, has been reported in patients with acute or chronic (T-cell) lymphocytic leukemia (1–3). Certain of these patients have also been unresponsive to other conventional courses of chemotherapy (3). Treatment with pentostatin (I) (4), a tight-binding inhibitor of adenosine deaminase, has been shown to result in a successful level of clinical remission when used in single-agent therapy (1, 3, 5). It has been suggested that the antineoplastic activity of I alone when used in Phase I clinical trials is the result of accumulation of deoxyadenosine-5′-triphosphate (2, 6). The latter then interferes with DNA synthesis and/or the accumulation of 2′-deoxyadenosine which, in turn, is capable of blocking critical methylation reactions (6). Whatever the exact biochemical locus, it is clear that I potentiates certain adenosine analogues such as the antiviral agent vidarabine (9-β-D-arabinofuranosyladenine) (3, 7) and the antitumor nucleoside N^6-(Δ^2-isopentenyl)adenosine (II) (8–10) used in the present investigation. Nucleoside II has been shown to be immunosuppressive (11) as well as capable of interfering with the transmembrane translocation of unmodified nucleosides in several mammalian systems (12).



I



II

Recently, this laboratory demonstrated that controlled release of II from a monolithic silicone polymeric delivery system results in more effective cytotoxic action against cultured L-1210 leukemia cells (8, 9). Current studies have revealed that the adenosine deaminase inhibitor pentostatin (I), itself marginally active against L-1210 leukemia, is capable of potentiating and prolonging the cytotoxic activity of II. The present investigation has sought to take advantage of both the ability of I to act as an inhibitor of adenosine deaminase and the properties of the silicone monolithic polymeric delivery system for the controllable release of I to provide maximal potentiation and regulation of the cytotoxic effects of II against cultured L-1210 leukemia cells.

EXPERIMENTAL

Drug Agents—Pentostatin (I), (*R*)-3-(2-deoxy-β-D-*erythro*-pentofuranosyl)-3,6,7,8-tetrahydroimidazo[4,5-*d*][1,3]diazepin-8-ol, (2′-deoxycoformycin; NSC-218321) was supplied[1]. The preparation of N^6-(Δ^2-isopentenyl)adenosine (II) was as previously described (6, 9, 12). Both agents are routinely stored at −20° over silica gel.

Culturing of L-1210 Cells and Determination of the Antileukemic Activity of I and II—Mouse lymphocytic L-1210 leukemia cells were routinely cultured in RPMI-1640 medium with L-glutamine plus 10% fetal bovine serum[2] in tissue culture flasks[3] at 37° under controlled conditions using a digital incubator[4] containing a 5% carbon dioxide–air atmosphere, and grown to various densities as previously described (8, 9). Total cell number and cell viability values were determined using Turk's solution and trypan blue exclusion, respectively (8, 9). After the addition of I, I–silicone polymer, or II (singly or in combination), aliquots of each type of cell suspension were aseptically removed at various intervals for the determination of cell number. In addition, a portion of each cell suspension was centrifuge-filtered[5] to produce cell-free filtrates for high-performance liquid chromatographic (HPLC) analyses as previously described (8, 9), with certain modifications.

HPLC Analyses for I and II in L-1210 Cell Culture Medium—HPLC using a reverse-phase column[6] eluted at designated flow rates with various concentrations of aqueous or phosphate-buffer methanolic solutions was used to quantitatively analyze I and II in each cell-free culture

extract. Representative chromatograms are given in Fig. 1A and B. Three different calibration curves (stored in computer memory) were established to quantitate the results using a spectrophotometric–computer interface system[7] as previously described (8, 9). Standard curves for both I and II constructed using a detector sensitivity of 0.05–0.5 AUFS were found to be linear over the concentration ranges detected in the samples. Correlation coefficients for the standard curves were usually 0.99 (n = 7). The preparation of samples for HPLC employed cellulose prefilters, as detailed previously (9).

RESULTS AND DISCUSSION

The nucleoside N^6-(Δ^2-isopentenyl)adenosine has been shown to interfere with the transport of unmodified nucleosides in several types of mammalian cells at the level of transmembrane translocation (11). Following its metabolism in mouse spleen lymphocytes, II, or its phosphorylated form, interferes with the transport of unmodified nucleosides thereby resulting in inhibition of cellular RNA and DNA synthesis (12). It has been possible to prepare a serologically specific antibody to II (13) as well as to demonstrate an immunosuppressive response to the parent nucleoside (12). Although at first II appeared to be potentially useful for treating leukemia in humans (10), its antitumor activity was found subsequently to be limited by its low solubility and short half-life (14) due to rapid deamination to inosine by adenosine deaminase (15, 16).

This laboratory recently demonstrated (8, 9) that it is possible to use a silicone polymeric delivery system to control the release rate of II against cultured L-1210 leukemia cells, avoiding the usual peak and trough concentrations encountered with direct single additions of antitumor agents. Moreover, information was acquired in that study concerning the interaction of II and silicone polymers. In other recent studies using pentostatin, information has been acquired showing that I potentiates the antileukemic effects of II when added in combination directly to L-1210 cells grown in culture[8]. The enhanced cytotoxicity of this synergistic combination has not only been demonstrated in these studies *in vitro*, but has also been shown to substantially increase the mean survival time (MST) using tumorgenicity assays in CD2F1 mice *in vivo*[9].

In the present investigation, analyses for I and II in cell-free extracts from serum-containing growth medium have been accomplished using two separate reverse-phase HPLC systems (Fig. 1). When 60% aqueous methanol was used as described previously (8, 9), it was possible to resolve I and II with a retention time difference of ~3 min (Fig. 1A). On occasion, the peak for II had a tendency to broaden in that system, thereby reducing the sensitivity for detecting I and obtaining less than satisfactory results. Use of a computer-programmed gradient, initially at a concentration of 25% methanol in 3 m*M* phosphate buffer, pH 7.0, and increased to 70% methanol at a methanol rate change of 4.5%/min, gave much greater sensitivity for detecting I (Fig. 1B). In addition to increasing the retention time difference to 13 min, II became more lipophilic, thereby reversing the elution order for I and II when using the programmed gradient system. Use of the programmed mobile phase system, however, gave some tailing of the peak of II. In practice both systems were used throughout this investigation for routinely separating I and II to confirm and generate the data given in Table I and elsewhere.

Experiments conducted to assess the antileukemic effects of I alone and in combination with II revealed some profound information. Al-

[a] Each T-flask contained 5 ml of growth medium (RPMI-1640 plus 10% fetal bovine serum) plus 1 × 10^5 L-1210 leukemia cells. The experiments were initiated (time zero) by the addition of each agent in RPMI-1640 without serum in a volume of 0.05–0.10 ml with prior sterile-filtration before their introduction into the cell cultures. [b] Aliquots (0.20 ml) of each cell suspension were removed at each designated sample time for the determination of cell number, viability, and HPLC analyses. Values reflect the results of duplicate determinations.

though I is a tight-binding inhibitor of adenosine deaminase and has demonstrated antitumor effects against certain human lymphocytic leukemias (3, 6), it is by itself marginally inhibitory (≤4%) toward cultured L-1210 cells (Figs. 2 and 3). On the other hand, when I (2 μg/ml) is added directly to cultured L-1210 lymphocytic leukemia cells, it dramatically potentiates the effects of II (25 μg/ml) within 24 hr. At 144 hr after each addition of I and II in combination, 85% inhibition is achieved. This represents an additional 30% compared with II used alone (Fig. 2). The most dramatic result here is that without concurrent use of I and II, the ability of II to be cytostatic gradually declines from a 73% value at 24 hr to 56% at 144 hr. The combined use of I and II not only potentiates the latter, but also prolongs its cytostatic effects against L-1210 cells in culture. Recently, Cass *et al.* (17) have shown that several sugar-substituted homologues of tubercidin and adenosine, which are deaminase-sensitive, were also active in combination with I.

In subsequent experiments, when the concentration of I was increased to 5 μg/ml and given in combination with II, it was found to further potentiate the latter to an ~96% level within 144 hr (Fig. 3). The few cells which remained had viability values <50%. Use of higher concentrations of I did not result in significantly greater cytotoxicity[10]. If the addition of II (25 μg/ml) is delayed for 24 hr after the introduction of I into the cultured L-1210 cell suspension, inhibition is reduced by about one-fourth compared with the inhibition when both agents are added simultaneously (Fig. 3). This suggests the importance of administering I at the onset to maximize its inhibition of adenosine deaminase, thereby reducing the overall deamination of II. When this occurs the antileukemic effects of II are potentiated and prolonged. Under these conditions it may be possible to reduce the concentration or dose of II required for maximally effective cytotoxicity as an antitumor agent.

With these initial observations, experiments were designed to establish the feasibility of preparing a silicone polymeric delivery form for I that was perhaps similar to the system used previously for II (8, 9). The underlying rationale was that the controlled release (if possible) of I from such a device might serve to block the deamination of II, thereby making

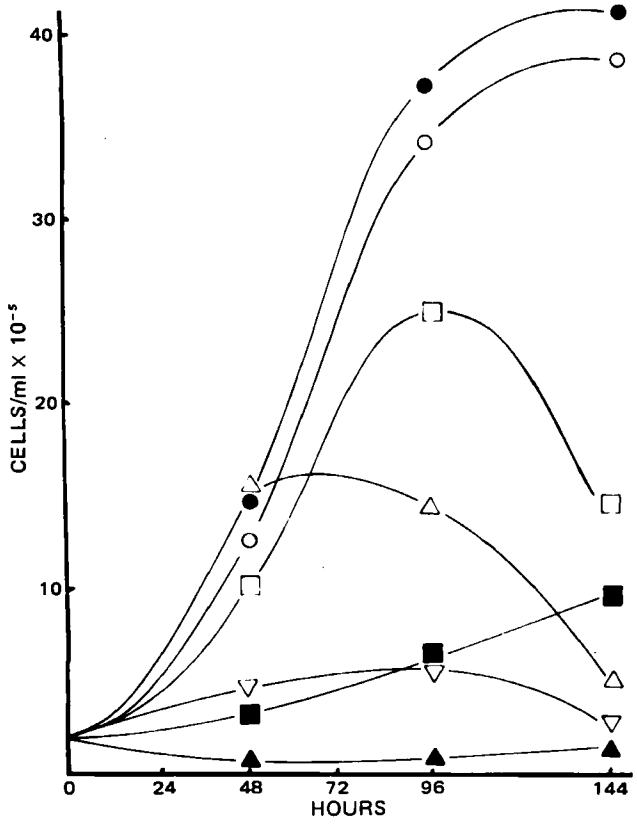

Figure 3—*Effects of pretreatment of cultured L-1210 cells. Additions of I (5 μg/ml) and II (25 μg/ml) to cultures of L-1210 cells were made at time zero and 48 hr. Aliquots of each cell suspension were removed at designated intervals for HPLC and determination of cell number. II a more potent cytotoxic agent. As the release of I begins to occur (Fig. 4 and Table I), its protective effect *via* binding and inhibition of adenosine deaminase is initiated. This occurs within 48 hr with the concurrent potentiation of the cytotoxic property of II. At 72 hr, inhibition by II is almost complete with remaining cells at 30% viability. At 96 hr, when the silicone polymer–I is present initially, inhibition by II is total. Although it was not possible to achieve total cell death when I was added directly (at concentrations as high as 100 μg/ml) with II (Figs. 2 and 3), that end was reached when lower concentrations of I were released into the growth medium from the silicone polymeric delivery device in the presence of II. The few remaining cells at 144 hr were found to be nonviable (Fig. 4) when the combination of the I–silicone polymer plus II was used.

Although both I and II are separately stable when incubated in cell-free medium, analyses of the data using HPLC (Table I) suggest that L-1210 cells have the capacity to metabolize I and/or II. Concentrations of I and II gradually decrease at longer sample times. Previously it was demonstrated that cell-free enzyme extracts of L-1210 cells converted II to its nucleoside monophosphate (18). Similarly, recent studies by Venner and Glazer (19) have shown that L-1210 cells convert I to its mononucleotide to the extent of ≤16%, while most of the parent drug is excreted unchanged in the urine of tumor-bearing mice. Studies by two groups have sought to develop models and data for I alone to describe the pharmacokinetics in normal and leukemic (L-1210) mice (20, 21).

The present study has demonstrated that the adenosine deaminase inhibitor I is capable of greatly potentiating the antileukemic effects of II, particularly when the former is released at a controllable rate from a silicone monolithic polymeric matrix. The clinical application of protection labile oncologic agents in this manner will be explored in the near future.

Time-Dependent Kinetics VII: Effect of Diurnal Oscillations on the Time Course of Carbamazepine Autoinduction in the Rhesus Monkey

PETER J. WEDLUND and RENÉ H. LEVY ×

Received January 7, 1982, from the *Departments of Pharmaceutics and Neurological Surgery, Schools of Pharmacy and Medicine, University of Washington, Seattle, WA 98195.* Accepted for publication July 8, 1982.

Abstract □ Extensive blood sampling and repeated long-term carbamazepine infusions were carried out in four rhesus monkeys to examine the time course of carbamazepine autoinduction in detail and assess the intraanimal variability in the rate constant of induction. Diurnal oscillations in carbamazepine blood levels were observed during all infusions and these prevented a good data fit for the biochemical model previously proposed for describing the decline in drug blood levels during induction by carbamazepine. An attempt at fitting only selected blood samples to the model resulted in variable (and perhaps questionable) induction rate constants, even in the same animal. Previous variability in calculated induction rate constants may be due to the presence of diurnal oscillations superimposed on the autoinduction phenomenon. It is proposed that the simultaneous expression of diurnal oscillations and autoinduction are the result of effects on drug metabolism at two independent levels.

Keyphrases □ Carbamazepine—autoinduction in the rhesus monkey, rate constant determination, effect of diurnal oscillations on drug metabolism □ Metabolism—of carbamazepine in the rhesus monkey, autoinduction rate constants, effect of diurnal oscillations □ Diurnal Oscillation—effect on metabolism of carbamazepine in the rhesus monkey

The ability of carbamazepine to induce self-elimination during chronic administration in the rat, dog, monkey, and human is well established (1–10). This increased elimination is reflected in a decline in carbamazepine steady-state blood levels. To describe this time-dependent decline, equations have been proposed based on a biochemical model of exponentially increasing levels of drug-metabolizing enzymes in the liver (11–14). These equations have

The ability of carbamazepine to induce self-elimination during chronic administration in the rat, dog, monkey, and human is well established (1–10). This increased elimination is reflected in a decline in carbamazepine steady-state blood levels. To describe this time-dependent decline, equations have been proposed based on a biochemical model of exponentially increasing levels of drug-metabolizing enzymes in the liver (11–14). These equations have

0022-3549/83/0800-0905$01.00/0

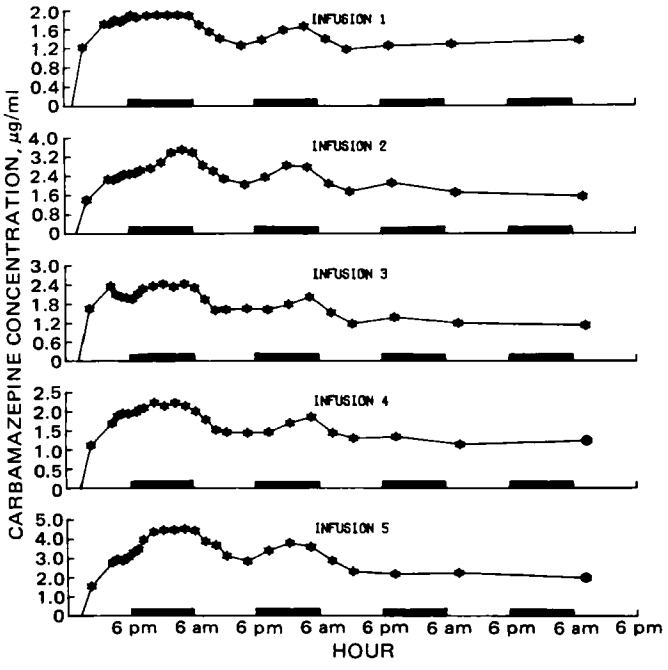

Figure 1—*Carbamazepine concentration* versus *time for five infusions in monkey 202.*

been used to fit the plasma concentration–time data during auto- and heteroinduction by carbamazepine and to calculate a first-order rate constant (induction rate constant) which characterizes the time course of the decline in plasma drug levels (15–18). Recently, further support for this model was provided by the finding of a close correlation between the change in liver enzymes responsible for drug metabolism (cytochrome P-450) and the change in metabolic clearance of carbamazepine in monkeys during long-term infusions (19).

An interesting result of the application of this model has been the remarkable interanimal variability in the induction rate constant (twofold or more) (15–18). Although

[a] Calculated using only the blood samples collected at 18, 20, 22, 24, 26, 28, 32, 52, 72, and 96 hr, fitting the calculated intrinsic clearance at these times to a model that predicts a monoexponential increase in intrinsic clearance (12, 13). [b] Correlation coefficient from fitting intrinsic clearances to a monoexponential equation. [c] — Lost due to technical difficulties.

it is tempting to speculate about the meaning of this observation, such speculation should be limited until the reproducibility of the rate constant in a given animal can be determined. Following an assessment of intraanimal variability in this parameter, the interanimal variability in the induction rate constant and the possible contribution of genetic factors could be evaluated. The present study was undertaken: (*a*) to characterize in greater detail the time course of carbamazepine autoinduction in the rhesus monkey, (*b*) to quantitate the intraanimal variability in the rate constant of autoinduction, and (*c*) to examine factors that may affect the rate constant determination.

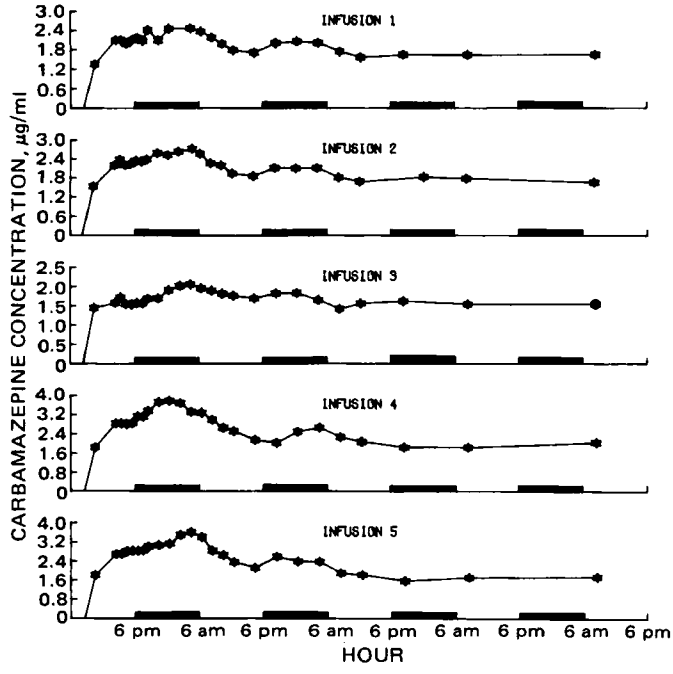

Figure 3—*Carbamazepine concentration* versus *time for five infusions in monkey 203.*

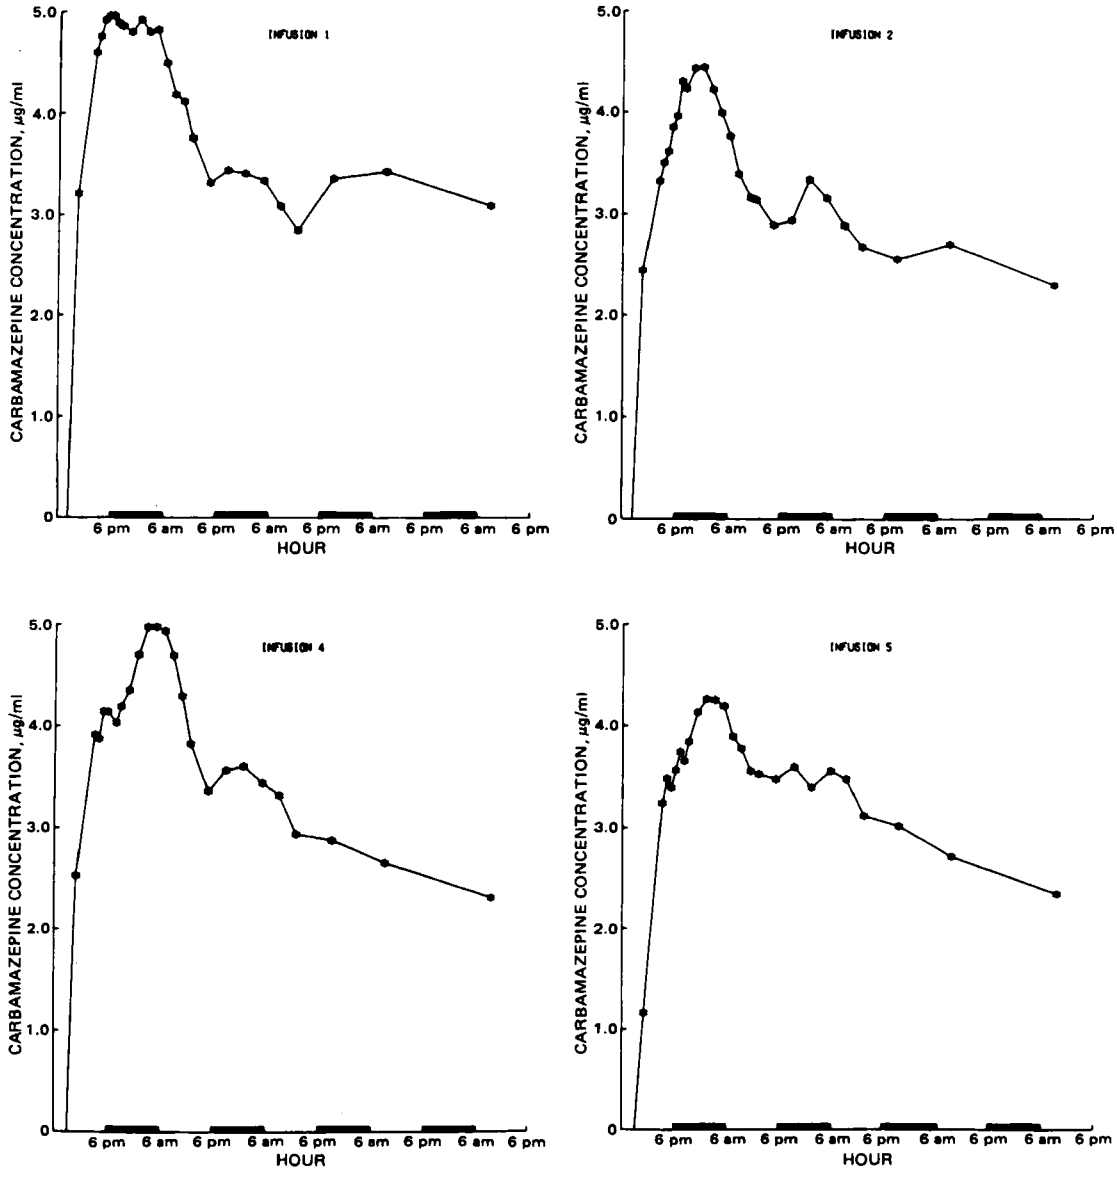

Figure 4—*Carbamazepine concentration* versus *time for four infusions in monkey 60409. (The third infusion was lost due to technical difficulties.)*

EXPERIMENTAL

Animals—This study was conducted in five restraint chair-adapted normal rhesus monkeys (*Macaca mulatta*). Each animal was equipped with two chronic indwelling catheters (femoral for drug infusions and jugular for blood sampling).

Dosing—Four animals received five 96-hr carbamazepine infusions, a fifth animal received a single 96-hr carbamazepine infusion. Infusions were separated by at least a 3-week period, during which time no drugs were administered. Sterile carbamazepine solutions (10 mg/ml) in 60% polyethylene glycol 400 were used for drug administration. Carbamazepine was infused at rates of 1.0–1.8 ml/hr with an infusion pump[1].

Blood Sampling—Blood samples (1.4 ml) were obtained at 2, 6, 7, 8, 9, 10, 11, 12, 14, 16, 18, 20, 22, 24, 26, 28, 32, 36, 40, 44, 48, 52, 60, 72, and 96 hr during the carbamazepine infusion. Each sample was divided and stored at −20° until assayed.

Liver Biopsies—To investigate the relationship between the cytochrome P_{450} level and the diurnal changes in carbamazepine clearance observed in this study, an additional but limited investigation of diurnal change in the cytochrome P_{450} level was undertaken. Liver biopsies were obtained in three of the five monkeys at 1:00 a.m. and 1:00 p.m. Monkeys received only saline (no carbamazepine) during this phase of the study, with a 3-week rest period between biopsy samples. The liver tissue was immediately placed on ice, blood clots were eased away from the tissue, and the biopsy was blotted dry and weighed. The liver tissue was homogenized in 20% glycerol phosphate buffer to give 10 mg of liver tissue/ml of buffer. The homogenate was centrifuged at 200×*g*, and the supernatant was removed and assayed for cytochrome P_{450} and protein.

Analytical Procedures—Whole blood samples were assayed in duplicate for carbamazepine by GC interfaced with a mass spectrometer in chemical ionization mode (20). Cytochrome P_{450} measurements were performed with a scanning spectrophotometer[2] by using the sodium dithionite difference technique reported by Estabrook *et al.* (21) and Joly *et al.* (22). Protein was determined with the sodium anazolene[3] assay reported by Spector (23).

RESULTS AND DISCUSSION

Plots of the time course of carbamazepine blood levels from replicate infusions in four monkeys are given in Figs. 1–4. These curves appear to show two types of phenomena: (*a*) an overall decrease in steady-state carbamazepine blood levels between the first and the fourth day and (*b*)

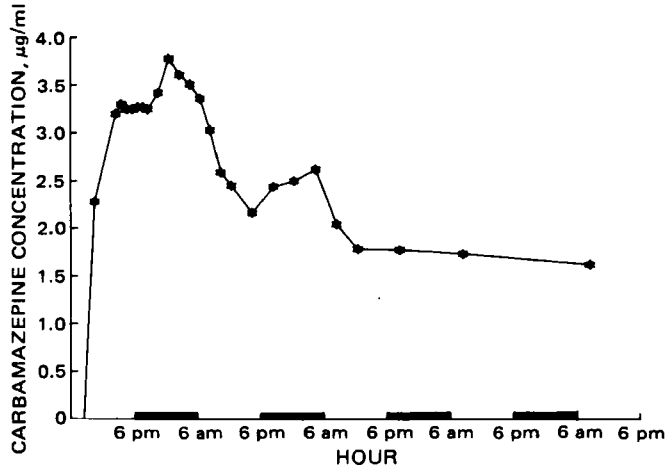

Figure 5—*Carbamazepine concentration* versus *time for a single infusion in monkey N436.*

oscillations in blood levels (increase followed by decrease) during the first two dark periods. This pattern in carbamazepine blood levels was reproducible in replicate studies in four monkeys and was also found in the single infusion of monkey N436 (Fig. 5).

The decrease in carbamazepine blood levels during the 4-day infusions involves a chemically induced, time-dependent increase in clearance (24) (autoinduction) which has been observed consistently during long-term infusions of carbamazepine in the rhesus monkey (16, 25). The oscillations in carbamazepine levels during the dark periods are probably the expression of a diurnal phenomenon. Diurnal oscillations in steady-state levels of several drugs (valproic acid, ethosuximide, and carbamazepine) have been observed in the rhesus monkey (26–28) and are most likely the result of an endogenous physiological process (24). This study shows that these two different types of time-dependent phenomena can occur simultaneously. As a result, the blood level data could not be fitted to previous equations describing the time course of induction (12, 13).

In an effort to separate the diurnal oscillations from the autoinduction phenomenon, carbamazepine blood samples taken at 18, 20, 22, 24, 26, 28, 32, 52, 72, and 96 hr were used to describe the time course of induction. The systemic clearance of carbamazepine at each of these times was computed by dividing the rate of infusion by the respective blood concentration. Each systemic clearance was then used in conjunction with an estimated liver blood flow rate [2.735 liters/hr/kg (29, 30)] to calculate the intrinsic clearance at these respective times. Both the intrinsic and systemic clearance values were fitted with the BMDX85 computer program to the equation (13, 14):

$$CL_t = CL_0 + P(1)\{1 - e^{-[P(2)(t-\theta)]}\} \quad \text{(Eq. 1)}$$

where CL_t represents the clearance at any time t, CL_0 represents the initial clearance calculated from the steady-state blood levels, P(1) represents the change between the initial and final clearance values, P(2) represents the rate constant of induction, and θ is the time lag before the start of the induction process. The induction half-lives obtained by dividing ln 2 by the rate constant of induction exhibited large variability (intra- and interanimal) whether intrinsic (Table I) or systemic clearance values were used. The poor reproducibility in induction half-lives probably reflects the inability to accurately separate the diurnal oscillations from the autoinduction process. The variability observed in the past may also be a reflection of this problem (15–18, 31). However, other biochemical factors which may also vary and influence the time course of induction cannot be ruled out.

The diurnal phenomenon observed in this study is consistent with what has been reported for other drugs in the rat and human (32–40). Factors that could contribute to this phenomenon include a decrease in liver blood flow, enterohepatic recycling, and/or a decrease in the carbamazepine free fraction during the night. However, there are a number of reasons to suspect that the oscillations are more likely due to changes in intrinsic drug clearance by the liver. First, carbamazepine is extensively metabolized and only a small amount is eliminated unchanged in the monkey (41). Second, the liver appears to be the predominant eliminating organ based on intravenous and portal vein catheter experiments in this laboratory[4]. Third, liver blood flow would have to decrease an average of 40% each night to explain the observed decrease in drug clearance and elevation of carbamazepine levels. Fourth, ethosuximide and valproic acid, which are extensively metabolized in the monkey and have clearances insensitive to changes in liver blood flow, also exhibit pronounced diurnal oscillations (26, 27). Fifth, the time course of change in carbamazepine blood levels overnight is too slow to be compatible with an enterohepatic recycling process. The absence of elevated carbamazepine levels following meals during the day also suggests that the oscillations are probably not due to an enterohepatic recycling process. Sixth, in view of the linear binding (free fraction 0.35 ± 0.02) of carbamazepine in monkey plasma between 1 and 10 μg/ml, a large decrease in this parameter during the night seems unlikely.

204	32	36
N436	32	28
203	—[b]	33
Mean ± *SD*	32 ± 0	32 ± 4

[a] Monkeys 202 and 60409 were not available for P_{450} determinations. [b] — P_{450} could not be determined due to the small amount of liver tissue available.

If the diurnal oscillations observed in the present study are due to changes in hepatic metabolic activity, the lack of any apparent change in cytochrome P_{450} (Table II) suggests that the diurnal variations are not due to changes in this enzyme. This is consistent with other observations in rats, which also exhibit pronounced diurnal oscillations in drug metabolism but little diurnal change in cytochrome P_{450} levels (42, 43). This hypothesis is further supported by the consistent observation in this study that diurnal oscillations are unaffected by the process of induction which is known to involve an increase in liver cytochrome P_{450} enzymes.

An alternative mechanism for the diurnal oscillations in this study may be concurrent oscillations in cytochrome P_{450} reductase activity. The levels of the reductase are one-tenth to one-twentieth those of cytochrome P_{450} levels (44, 45), and reductase levels have been found to be a rate-limiting component in microsomal monoxygenase systems (44, 46). Furthermore, several studies in rats have shown diurnal oscillations in cytochrome P_{450} reductase activity (42, 43, 47). In addition, the formation of at least one major metabolite of carbamazepine (carbamazepine-10,11-epoxide) in the human has been shown to be dependent on the activity of this enzyme (48). If the reductase activity undergoes diurnal oscillations in the monkey and is also a rate-limiting component in some of the pathways of carbamazepine elimination, the two time-dependent phenomena observed in this study could be the result of effects on separate components of the drug metabolizing system (diurnal oscillations related to oscillations in cytochrome P_{450} reductase activity and autoinduction related to increase in cytochrome P_{450} enzymes).

It should be noted that endogenous steroids are also known to exhibit diurnal variations in both the rat and human. Whether these steroids are responsible for changes in drug metabolism or just spuriously related is unknown. Whatever the relationship between endogenous steroids and the diurnal phenomena noted for drug metabolism, it is probable that a key to the mechanism lies in understanding the factors responsible for changes in drug metabolism at the cellular level.

This study provides the first evidence that two types of time-dependent phenomena, diurnal oscillations and autoinduction, can occur simultaneously. As a result, blood level data cannot be fitted to previous equations for describing the time course of induction. Use of selected blood samples resulted in variable induction rate constants, even in the same animal. In view of the observed intraanimal variability, the first-order rate constants of induction computed in the past should be interpreted with some caution. We propose that the autoinduction and diurnal phenomena seen in this study may be the result of effects on drug metabolism at two independent levels.

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test III: Limitations of Calibrators and the USP Suitability Test

DON C. COX ˣ, WILLIAM B. FURMAN, LARRY K. THORNTON, TERRY W. MOORE, and EVERETT H. JEFFERSON

Received April 19, 1982, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication July 22, 1982.

Abstract □ The calibrator tablets now used in the USP suitability test do not reveal common sources of systematic error associated with Apparatus 2. When the apparatus was operated under conditions near or beyond USP tolerances, changes in the results of the USP calibrators were slight, whereas those of several samples of commercial prednisone tablets were significant. Thus, the USP calibrators and requirements do not guarantee suitability of the equipment for general dissolution testing of drug products.

Keyphrases □ Dissolution—systematic error associated with Apparatus 2 of the USP dissolution test using calibrator tablets □ Calibrator tablets, USP—systematic error associated with Apparatus 2 of the dissolution test □ Apparatus 2—of the USP dissolution test, systematic error using calibrator tablets

The USP provides an Apparatus Suitability Test (1) to ensure that a dissolution apparatus operates satisfactorily and is free from significant extraneous vibration (2). Two official calibrators, both compressed tablets, are available[1] for use in the test. The nondisintegrating calibrator is labeled to contain 300 mg of salicylic acid; the disintegrating calibrator is labeled to contain 50 mg of prednisone. The test conditions for use of the tablets and the ranges within which the results must fall appear in information sheets provided with the calibrators.

Before a given piece of equipment is considered suitable for use as Apparatus 2, it must pass a four-point test. Dissolution results from both calibrators must fall within the established ranges at 50 and 100 rpm. If the equipment fails the test, alignment, speed, vibration, *etc.* should be checked and corrected. If the requirements cannot be met, the equipment is judged unsuitable for use as Apparatus 2 (3). Thus, equipment suitability is determined by the response of the calibrator tablets to variations in the USP test conditions.

Some of the test conditions are defined in terms of numerical tolerances, *e.g.*, the shaft rotation speed is to be maintained within ±4% of a specified value, and the shaft axis is to be positioned not more than 2 mm from the vertical axis of the vessel. Others are defined in absolute terms, *e.g.*, the vessel is cylindrical with a spherical bottom, and the paddle blade forms a section of a circle of specified diameter subtended by parallel chords of specified length. Certain other test conditions are not clearly defined, but rather are to be controlled so that they do not significantly influence the results, *e.g.*, no part of the assembly (vessel, paddle, and variable-speed drive) or the surrounding environment should contribute significant motion, agitation, or vibration beyond that which is due to the smoothly rotating paddle, and dissolved gases are to be removed from the dissolution medium if they change the dissolution results.

Results from commercial prednisone tablets can be influenced by minor variations in equipment alignment (4) and small differences in vessel curvature (5). Both of these conditions may cause systematic error among laboratories. Another possible source of error, recognized in the USP, is the effect of excess gas in the medium.

Two studies (6, 7) indicate that the USP calibrator tablets do not respond to certain variations in test conditions associated with Apparatus 2. Such lack of response normally would lead to the conclusions that the test is rugged, and that similar results for these tablets could be obtained among laboratories. However, the collaborative study results used to derive the acceptance ranges (3) show that similar results were not obtained among the laboratories.

Because the calibrator tablets respond only slightly to variations in test conditions, the purpose of the suitability test is not achieved. Comparisons of the responses of the USP calibrators and certain commercial prednisone tablets to variations in selected test conditions are presented in this paper.

EXPERIMENTAL

Apparatus and Samples—Two analysts, each using a separate commercial apparatus[2], performed the USP suitability test with 50-mg prednisone tablets[1] and 300-mg salicylic acid tablets[1]. A commercial 10-mg prednisone tablet, previously identified as Tablet 2 (5), was studied in a similar manner using the appropriate USP methodology (8).

Each analyst, working independently, adjusted the apparatus to conform to the USP test conditions as closely as practical. One analyst worked with an apparatus that possessed parallel shafts; the other worked with an apparatus known to have two shafts that were not parallel to the other four (4, 5). Although the shaft alignment in the vessels in these two positions differed from the shaft alignment in the vessels in the other four positions, the apparatus could be adjusted to pass the USP requirements.

Six tablets from each of the three samples were tested. A third analyst measured the absorbances of the filtered aliquots, thus minimizing systematic error in this step of the test. These results became a benchmark to which other results were compared; benchmark results were obtained before and after test conditions were varied.

Variations in Test Conditions—Selected test conditions were changed from the USP requirements, one at a time. Six additional tablets from each sample were tested after each change.

Paddle Rotation—The motor drive was operated at least 15 min to allow it to stabilize. The drive was then adjusted to give the desired number of revolutions in 60 (+1, −0) sec by manual count and use of a stopwatch. The rotational speed was again measured after the aliquots were obtained and filtered. In this way the benchmark results were obtained at 50 (± 0.8) and 100 (± 1.6) rpm. For comparison, data were also obtained at 54 (± 0.9) and 108 (+ 3.3, − 1.8) rpm.

[a] Prednisone, 50 mg, Lot F. [b] Expressed in percent of label claim; $n = 6$. [c] As in Table I. [d] Except results obtained under test condition A. [e] Obtained before any variation in test conditions. [f] Obtained after variations in test procedures were completed.

Vessels—Six plastic vessels[3] were used by each analyst to obtain the benchmark results. For comparison, one set of irregular glass vessels[4] was used by both analysts. The inside bottom curvatures of these glass vessels did not conform to USP specifications (5).

Tablet Immersion—For benchmark results, each tablet was allowed to sink to the bottom of the vessel before the clutch controlling the paddle rotation was engaged. Results for comparison were obtained with the tablet dropped into the vessel while the paddle was rotating.

Centering of Vessels—The tops of the plastic vessels were centered precisely around the paddle shafts when the benchmark results were obtained, using a specially designed centering tool (9). For comparison, results were obtained with each paddle shaft set either 2 or 4 mm from the center of the top of its vessel. To measure these offsets, an overlay of concentric circles 9.5, 13.5, 17.5, and 21.5 mm in diameter was placed over the centering tool with the innermost circle coinciding with the top of the hole in the centering tool. The tool was placed in the top of one of the centered, rigidly held vessels. The paddle shafts were inverted in the chucks of the dissolution apparatus drive head, and the drive head was repositioned until the paddle shafts were either 2 or 4 mm off-center with respect to the tops of the vessels.

Shaft Verticality—For benchmark conditions, the collars on the stand of the dissolution apparatus were adjusted to 136 mm between the bottom of the drive head and the top of the leveled base of the stand. This distance was chosen because it equals the distance from the top of the stand base to the bottom of the paddles when the paddles are set 2.5 cm above the bottom of the plastic vessels. To facilitate measurements, the paddles were inserted in their inverted (paddle at the top) positions. The drive head was adjusted until a torpedo level (bubble indicators at right angles) placed on the paddle shafts showed that they were vertical. The shafts were then inserted in their normal (paddle down) positions, and the benchmark results were obtained.

Two tests were performed with nonvertical shafts. In the first (test 1), the equipment was misaligned so that each paddle shaft intersected the vertical axis of its vessel at the top of the vessel and was displaced 2 mm from the vertical axis 2.5 cm from the bottom of the vessel. For the second (test 2), the equipment was misaligned so that the paddle shaft axis was displaced 2 mm to the front of the vertical axis of the vessel at the top of the vessel and 2 mm to the rear of the vertical axis 2.5 cm above the bottom of the vessel. Results of both misalignments were compared to the benchmark results.

Deaeration of Media—Water from a commercial deionizer system was mist-sprayed[5] into a 19-liter (5-gallon) glass carboy under vacuum to obtain benchmark results for the prednisone calibrators. For the salicylic acid tablets, the prepared buffer was drawn by vacuum through a 30-mm coarse-porosity glass frit into a 19-liter glass carboy. For comparison, water taken directly from the deionizer system was used for the prednisone samples, and buffer, originally prepared in deionized water and then allowed to equilibrate with the atmosphere at room temperature, was used for the salicylic acid tablets. Both of the latter media released excess gas as bubbles at 37°.

Paddle Depth—The lower edge of the paddle was placed 2.5 cm above the bottom of the vessel as the benchmark and 2.0 cm above the bottom of the vessel for comparison.

Effect of Probes—All aliquots were taken manually with 50-ml syringes fitted with 4-mm o.d. glass tubes cut to lengths that allowed the aliquots to be taken from a standardized position (midway between the top of the medium and the top of the paddle blade and midway between the shaft and the wall of the vessel). For the benchmark condition, the tubes were inserted in the medium only as aliquots were obtained.

To assess the effect of probes, such as those often used with automatic analyzers, a 4-mm o.d. glass tube fitted with a filter tip[6] was placed in the vessel so that the filter was at the standardized position throughout the test. Otherwise, the aliquots were taken as described for the benchmark condition. Only one analyst collected data on the effect of probes in the medium because more thorough studies (10, 11) have been reported on commercial tablets.

Analysis of Commercial Tablets—The two analysts each tested five samples of 5-mg prednisone tablets from four manufacturers. Benchmark results were obtained as described above. Analyst 1 also obtained comparative results with the paddle shafts 2 mm off-center, while analyst 2 obtained comparative results by (*a*) substituting the set of irregular glass vessels for the plastic vessels and (*b*) using the dissolution medium containing excess gas instead of the deaerated dissolution medium.

RESULTS AND DISCUSSION

When possible, test conditions were varied in such a way to theoretically give a higher result: the rotational rate of the paddle was increased, not decreased, and the location of the paddle in the vessel was lower, not higher. The bottom curvature of the irregular glass vessels was flatter than that of a sphere. Any misalignment of the vertical axis of the paddle with that of the vessel tends to raise the results. Because it takes a finite time for motion from the paddle to produce motion in the liquid, dropping the tablet into the vessel with the paddle rotating tends to raise the results.

Whether air dissolved in the dissolution medium will influence test results is difficult to predict. Often, little or no effect is seen; but at times, the effect is dramatic. If the dissolution medium is not deaerated properly, small air bubbles are released from the medium during the test. These bubbles collect on all solid surfaces in contact with the medium, including the tablet or disintegrated tablet particles. Air bubbles adhering to the surface of tablet particles may act as a barrier between the solid drug and the medium. This tends to lower the dissolution results because the drug must contact the medium to dissolve.

Certain tablet products give disintegrated particles with a density such that the particles are lifted from the vessel bottom and circulated by the swirling medium in the absence of air bubbles. With such products the presence of air bubbles tends to lower the dissolution results due to the barrier effect. Furthermore, air bubbles attached to particles may synchronize the particle's motion with that of the medium; in this case, the

concentration gradients near the particles could increase, also lowering the dissolution results.

Other tablet products disintegrate into particles of sufficient density to collect in a compact, cone-shaped mass on the bottom of the vessel in a region of relatively low liquid agitation. If the density of the tablet particles is changed sufficiently by the presence of air bubbles, the aggregate of particles on the vessel bottom is disrupted and more particles are lifted into regions of higher liquid agitation. Considered alone, this effect raises the dissolution results because more particles are brought into contact with more liquid in a given time. In practice, however, the net result of this effect plus the barrier effect is observed for such products.

The mean results of the USP calibrator tablets change only slightly with variations in individual test conditions (Tables I and II). If a variation in test conditions truly affects the dissolution behavior of these tablets, a bias will be present in the results at both 50 and 100 rpm. Statistical techniques suggested by Steiner (12) were used to analyze the mean results.

The means obtained by each analyst at each rotational rate were ranked from low to high, without the results obtained when probes were present in the dissolution medium. The ranks of all mean results obtained under the particular test conditions (specified in Tables I and II) were summed. The rank sums were then compared with values representing upper and lower limits that would not be exceeded by chance at the 95% confidence level.

When the means obtained from the salicylic acid tablets (Table I) were analyzed by this technique, it was found that a small upward bias may have existed in the results when the USP tolerance for centering was doubled (test variation E). The statistical test gave a borderline result at the 95% confidence level. The means obtained by test variation E were removed, and the means remaining in the table were ranked a second time. The remaining test variations did not give a consistent bias to the results. Individual means were then tested for bias. The means obtained by test variation H at 100 rpm were found to be significantly high at the 95% confidence level. Thus, air bubbles accumulating on the tablets produced a small bias in the results at 100 rpm, but not at 50 rpm.

When the means obtained from the USP disintegrating calibrator tablets (Table II) were ranked and the ranks were summed across the table, test variation H was found to produce a downward bias. Thus, air bubbles accumulating on these tablets lower the dissolution results. After the means from test variation H were removed, no consistent bias was found for the other test variations. No individual means were found to contain a bias significant at the 95% confidence level.

The means obtained from Tablet 2 (Table III) were analyzed in a similar manner. The means obtained under the last benchmark conditions were found to have a downward bias, and test variation H was found to produce an upward bias. After these means were removed, test variation E was found to produce an upward bias, test variation D produced a high bias with borderline significance at the 95% confidence level, and test variation A produced a high bias. No consistent bias was found for the remaining means obtained under the first benchmark conditions and test variations B, C, F, G, and I. When these means were analyzed individually, the two means obtained from test condition B at 100 rpm were found to be significantly high at the 95% confidence level. Thus, a bias is produced in the results from Tablet 2 by not deaerating the medium, by not centering the paddles in the vessels, by doubling the USP tolerance for rotational rate of the paddle, and, at 100 rpm, by using glass vessels with flattened bottom curvatures. The magnitude of the bias is large when there is excess gas present in the medium. The magnitude of the bias is noticeable when the USP tolerance for centering is doubled and, at 100 rpm, when the paddles are shifted 2 mm from the vessel centers. The bias from the glass vessels is noticeable at 100 rpm.

Probes, used in many laboratories to take aliquots automatically, can influence the dissolution results of tablets (10, 11). The USP calibrator tablets do not respond noticeably to changes in the hydrodynamics of the test generated by the probes (Tables I and II).

Five samples of 5-mg prednisone tablets from four manufacturers were subjected to selected changes in test conditions (Table IV). Analyst 1 used an apparatus previously described (4) and discussed (5). Because the paddle shafts in positions 4 and 6 were not parallel to the other four shafts, tablets from each of the samples gave higher results in these two positions. All shafts in the apparatus used by analyst 2 were parallel. This difference in equipment is the major cause of the differences between the benchmark results collected by the two analysts. The response to changes in test conditions is considerably greater for the commercial tablets than for the calibrator tablets. These commercial tablets fail the USP dissolution test when the test is performed under benchmark conditions, but may easily pass the test when the conditions are only slightly altered.

The official acceptance ranges for the USP calibrator tablets are based on results of collaborative studies (Table V) that involved 20 laboratories (3). Two independent studies of the 50-mg prednisone tablets at 50 rpm have also been reported—one by 5 (6) and the other by 11 FDA laboratories (13).

The official ranges show considerable overlap: the equipment could give identical results at 50 and 100 rpm and yet pass the requirements. This paradox arises from the large systematic errors of unknown origin among the 20 collaborating laboratories. However, only a small part of the wide spread in collaborative results can be ascribed to malfunctioning equipment (Tables I and II).

The official ranges are much too wide. According to the USP calibrators and ranges, the equipment used to collect the data in Tables I–IV is suitable for use, even when the measurable official tolerances (rotation and geometry) are exceeded. Narrowing the official calibrator ranges will not help, however, because the USP calibrators do not respond to the variables of interest (Tables I and II).

Tablet 2 has been used in several FDA laboratories as a performance standard for Apparatus 2, complementing, but not replacing, the USP calibrators. The acceptance ranges for Tablet 2 (Table V) were derived from a collaborative study by 11 FDA laboratories (13). Although Tablet 2 shows excellent sensitivity to excess gas in the dissolution medium, it does not respond adequately to irregularities in vessel curvature or to equipment misalignment. Nevertheless, Tablet 2 often has revealed subtle differences among sets of dissolution equipment that appeared equivalent when tested with the USP calibrators.

Roles of Disintegration and Density—Tablets that do not disintegrate during the test usually show little response to malfunctioning equipment or excess gas in the medium. Tablets that disintegrate within 2–3 min and give disintegrated particles that are lifted and circulated throughout the medium are usually immune to minor variations in equipment alignment and vessel curvature. Tablets that disintegrate within 2–3 min into granules that remain on the vessel bottom are likely to respond to such minor variations and, thus, are candidates as calibrators for the test.

Tablet Position Effect—The behavior of a tablet that disintegrates after 5–7 min is influenced by its position in the vessel[7]. If such a tablet settles at the center of the vessel, it will take longer to disintegrate and will exhibit a slower dissolution rate than a similar tablet that settles some distance away from the center. The latter tablet will disintegrate faster, and the disintegrated tablet material will be pulled toward the center by the circular liquid flow generated by the rotating paddle. For prednisone tablets of this nature, differences of 10–20% of label claim are commonly seen among the dissolution results of individual tablets. If the tablets settle at widely different locations in the dissolution vessels, the mean result will be higher than it should be and the standard deviation will be large. The wide range of results usually is blamed on the "inherent standard deviation" of the tablets when, in fact, it is due to the scattered positions of the tablets at the start of the test. The two samples of tablets from manufacturer B (Table IV) take from 10–15 min to disintegrate and exhibit this position effect. Ideally such tablets should be positioned at

[7] This effect has also been observed in Food and Drug Administration laboratories in Chicago, Ill., and Winchester, Mass.

the bottom of the vessel at the start of each test. Tablets whose results depend on their initial position in the vessel should not be considered as potential calibrators.

Role of Calibrators—The ideal calibrator is easily defined, but has yet to be found. It should warn of incorrect shaft-rotation speed, equipment misalignment, irregularities in vessel curvature, *etc.* The calibrator results must leave no doubt about equipment suitability. A reproducible way to manufacture the calibrator must exist so that it may be distributed widely. These requirements will not soon be met. A simple suitability test for correct equipment setup is highly desirable, but its benefits may be outweighed by the expense of developing and manufacturing the required calibrator.

Meanwhile, most of the requirements for suitability of equipment can be met without using calibrator tablets. Alignment of equipment can be ensured by careful measurement with centering tools, calipers, and bubble levels. Uniform vessels are available. Control of shaft-rotation speed and temperature is trivial. Drug manufacturers can easily test whether deaerating the media influences the results for their products.

CONCLUSIONS

Large systematic errors existed among the laboratories that contributed the data from which the USP acceptance ranges for the official calibrators were derived. The sources of these errors are unknown; however, the USP calibrators do not warn of common equipment malfunctions. Thus, the USP suitability test cannot ensure correct equipment operation.

The general chapter on dissolution testing in the USP recognizes many of the test conditions that require control and gives an idealized concept of how the test is to be conducted. Unfortunately, control of equipment tolerances is not well defined in some cases and not fully adequate in others. The effect of changes in some of these equipment conditions on the dissolution results obtained from certain commercial tablets has been demonstrated.

Although equipment alignment and shaft-rotation speed may be controlled with simple measurements, a calibrator tablet is very useful when checking for test conditions that are difficult to measure (*e.g.*, excess gas) or that require sophisticated equipment (*e.g.*, vibration). One cannot rely totally on calibrator tablets to establish that the dissolution test conditions remain unchanged from day to day unless these requirements are met: (*a*) the tablets must respond to changes in critical test conditions, (*b*) the tablet response must be measured under rigidly controlled and well-defined test conditions, and (*c*) an acceptance range must be established within which variations in results due to minor fluctuations in test conditions can safely be ignored.

Radioimmunoassay of the Immunomodulator *erythro*-9-(2-Hydroxy-3-nonyl)-hypoxanthine in Human Serum and Urine

E. H. PFADENHAUER ˣ, C. E. JONES, and K. W. MAXWELL

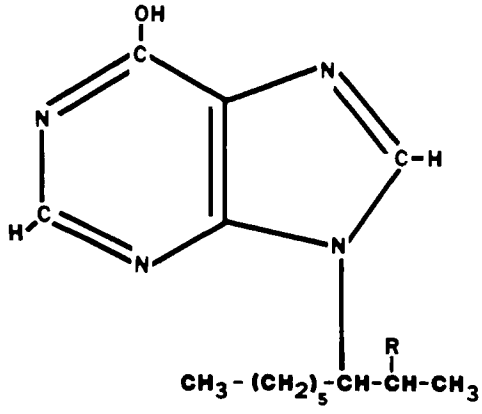
Received April 5, 1982, from *Newport Pharmaceuticals International, Inc., Newport Beach, CA 92660.* Accepted for publication July 30, 1982.

Abstract □ A radioimmunoassay was developed for the measurement in human serum and urine of *erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine. Antisera were produced in rabbits by immunization with an *erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine hemisuccinate–bovine serum albumin conjugate. The competitive antigen was *erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine labeled with carbon-14 on the purine ring. Cross-reactivities were measured against three metabolites and the naturally occurring purine bases inosine and hypoxanthine. Sensitivity of the method was 1 ng/ml in serum and 10 ng/ml in urine. Precision at clinical levels was ±15% in serum at 2 ng/ml and ±3% in urine at 200 ng/ml.

Keyphrases □ *erythro*-9-(2-Hydroxy-3-nonyl)-hypoxanthine—immunomodulator, quantitation in human serum and urine by radioimmunoassay □ Radioimmunoassay—of *erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine, quantitation in human serum and urine □ Immunomodulators—*erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine, quantitation by radioimmunoassay, human serum and urine

A considerable amount of interest in the academic and industrial community is currently being directed at the emerging discipline of immunopharmacology. The cellular immunological component of this pharmacological category includes both natural and synthetically derived substances with biological activity. Paramount among the former category are the thymic hormones (1), bacterial agents [BCG (2), *Corynebacterium parvum* (3)], transfer factor (4), and interferon (5). Levamisole (6), inosiplex (7), krestin (8), and interferon inducers (5) are examples of synthetic entities that possess a number of interesting immunomodulatory properties that have been defined in both *in vitro* and *in vivo* systems.

erythro-9-(2-Hydroxy-3-nonyl)-hypoxanthine[1] (I) is an immunopharmacologically active substance (9, 10) which is intended for use in the treatment of acquired or genetically determined deficiencies in cell-mediated immune function. Since the minimum effective dose of this compound was relatively small (0.01 mg/kg), serum and urine levels were expected to be correspondingly low. Initial analytical development, utilizing high-performance liquid chromatographic (HPLC) reverse-phase techniques and UV detection, indicated a lower limit of detectability on the order of 0.5 μg/ml in plasma. The detectability in urine, however, was even less sensitive due to interferences from normal urine constituents. Extractive procedures using various organic phases were of limited utility in improving the levels of detectability.



I: R = OH
II: R = $CO_2(CH_2)_2COOH$
III: R = $CO_2(CH_2)_2CONH$-Albumin

This paper describes a radioimmunoassay (RIA) for I. The assay is of sufficient specificity and sensitivity to determine relevant pharmacological parameters (*e.g.*, bioavailability, elimination, and absorption) at the expected therapeutic doses which would be used in clinical investigations.

EXPERIMENTAL

Chemicals and Materials—Reagent-grade solvents and chemicals were used except for the HPLC solvents, which were HPLC grade. Freund's adjuvant[2] (complete and incomplete) was purchased in sealed glass ampules. Bovine serum albumin[3] was RIA grade. Sodium [^{14}C]-formate[4] (99+% radiopure, specific activity 51 mCi/mm) was packaged in a glass ampule in 70% ethanol under a nitrogen atmosphere. *erythro*-5-Amino-4-chloro-6-(2-hydroxy-3-nonyl)-pyrimidine[5] contained 1.5% of the *threo* isomer. The *erythro*-9-(2-hydroxy-3-nonyl)-hypoxanthine used in these assays was reference standard grade, containing 0.2% of the *threo* isomer.

Chromatographic Systems—Preparative TLC was performed on 2-mm silica plates[6] using *n*-butyl alcohol–2 *N* ammonia (5:1) as a solvent (system A). TLC systems were silica[7] with *n*-butyl alcohol–acetic acid–water (4:1:2) (system B) and cellulose F-254 with isopropyl alcohol–water (4:1) (system C).

HPLC separations were carried out using a gradient liquid chromatograph[8], a 5-μm reverse-phase 250 × 4.6-mm column[9], and a detector[10] operating at 254 nm. The eluant used was typically 0.05 *M* H_3PO_4 in water–methanol (60:40) (system D).

Scintillation Counting—Radioactivity measurements were performed on a liquid scintillation counter[11]. An open channel was used for the carbon-14 counts. Scintillation fluid[12] (2.5 ml) was added to 15 × 45-mm glass vials containing the [^{14}C]protein precipitate from the urine assay. For the serum assay precipitate, 10 ml of cocktail was added to 21 × 68-mm glass vials.

Preparation of the Immunogen—*Synthesis of Erythro-9-(2-hydroxy-3-nonyl)-hypoxanthine Hemisuccinate (II)*—Compound I (300

mg) and succinic anhydride (2 g) were dissolved in 4 ml of pyridine. The mixture was stirred overnight at 40°. The pyridine was removed under reduced pressure, and the residue was dissolved in a minimum amount of ethanol. Concentrated ammonium hydroxide was added until precipitation ceased. The supernatant was removed, and the precipitate was washed three times with small volumes of ethanol. The supernatant and ethanol washes were pooled and applied to chromatographic system A. After a 15-hr development, the major UV-absorbing band at R_f 0.34 was isolated and eluted with 15 ml of ethanol. This elution was repeated three times. The ethanol was removed under reduced pressure, and the residue was dissolved in 50% ethanol–water prior to ultrafiltration[13]. The solvent was again removed under reduced pressure to give 124 mg (30% yield) of the hemisuccinate II. The identity of II was confirmed by base hydrolysis (1 *N* NaOH, 70° for 1 hr), which gave total conversion to the parent compound, I.

Preparation of the Bovine Serum Albumin Conjugate (III)—A solution of bovine serum albumin (23 mg) in 1.5 ml of water was stirred and room temperature and the pH was adjusted to 5.5 with a dilute sodium hydroxide solution. The hemisuccinate II was added (11 mg in 0.5 ml of water) and the pH was readjusted to 5.5. 1-Cyclohexyl-3-(2-morpholinoethyl)-carbodiimide metho-*p*-toluenesulfonate (21 mg) was added to the aforementioned solution and the resulting turbid mixture was stirred overnight at room temperature. The suspension was removed and dialyzed against phosphate-buffered saline at 4°. The dialysate was changed frequently.

The product was characterized in the following manner:

1. An aliquot of the product was ultrafiltered, and the ultrafiltrate was analyzed by system D for I. Only a trace amount was found.
2. The ultrafiltrate was hydrolyzed with base and then analyzed for I. Again, only a trace amount of the drug was found.

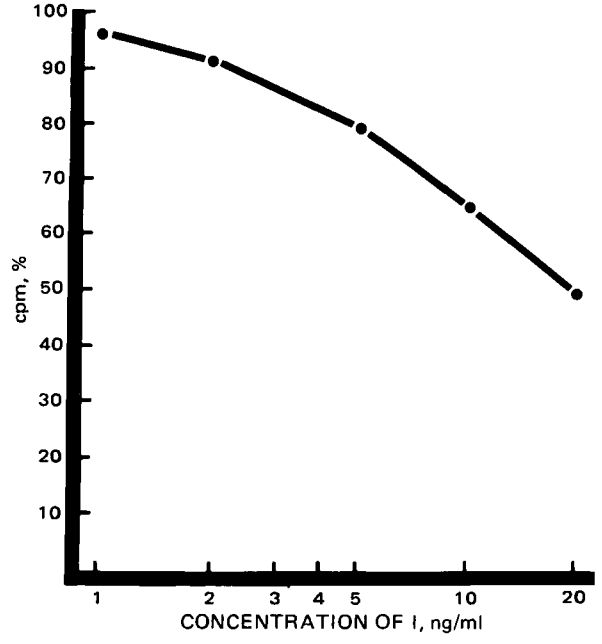

Figure 1—*Serum RIA standard curve. Known amounts of I were added to control serum at 0, 1, 2, 5, 10, and 20 ng/ml, the RIA was carried out, and the percent cpm was calculated. Percent cpm was defined as cpm sample ÷ cpm control (×100).*

[13] CF-50 Membrane Cone, Amicon Corp., Lexington, Mass.

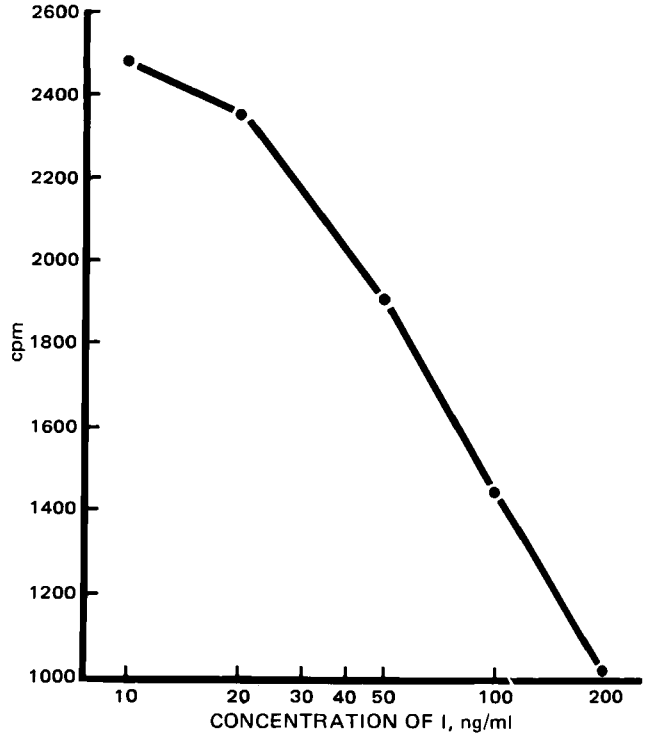

Figure 2—*Urine RIA standard curve. Known amounts of I were added to water at 10, 20, 50, 100, and 200 ng/ml, and the RIA was carried out as described in the text.*

3. An aliquot of the product was hydrolyzed with base and ultrafiltered. A large amount of I was found in the ultrafiltrate, corresponding to 4.21 μmoles or ~13 molecules bound to a molecule of bovine serum albumin in the product.
4. Base hydrolysis of bovine serum albumin alone did not interfere with the HPLC assay. The results of the first two experiments indicated only small amounts (<1 μg) of I and II were present in the product. Two other coupling agents used under various conditions did not yield a conjugate. Agents found not to be effective were 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide and *N*-ethyl-5-phenylisoxazolium-3′-sulfonate.

The conjugate (III) was diluted with sterile phosphate-buffered saline to a final concentration of 1 mg/ml and frozen in aliquots. It was determined by the aforementioned HPLC procedure that a freeze–thaw cycle did not alter the integrity of the conjugate.

Immunization—The solution of III was thawed and emulsified thoroughly with an equal volume of Freund's complete adjuvant. Subcutaneous injections of the emulsion (1.6 ml) were made to the back area of each of four New Zealand White rabbits. After 3 weeks, a second injection was administered with incomplete Freund's adjuvant. Four weeks after the second injection, all rabbits showed a workable titer of antibodies to I. Blood was removed from the ear vein, allowed to clot at room temperature for 1 hr, and stored overnight at 4°. The serum was removed and used in the RIA. Periodic booster shots of the original preparation of III were administered to the rabbits for over 1 year, and each time the antiserum titer showed a anamnestic (2-week) rise to original levels.

Preparation of [8-^{14}C]*erythro*-9-(2-Hydroxy-3-nonyl)-hypoxanthine (IV)—The 70% ethanol solvent was removed under reduced pressure from sodium [^{14}C]formate (5 mCi, 51 mCi/mm). The sodium [^{14}C]formate was then dissolved in 100 μl of phosphoric acid, and an excess of *erythro*-5-amino-4-chloro-6-(2-hydroxy-3-nonylamino)-pyrimidine (55 mg) was added with vortexing. The reaction was heated at 95–100° in an oil bath for 4 hr, and then cooled. Methanol (300 μl) and then concentrated ammonium hydroxide (180 μl) were added with vortexing. This solution was applied to system A and developed overnight. The UV-absorbing band corresponding to I (R_f 0.51) was isolated and eluted into 175 ml of methanol. Analysis by HPLC (system D) determined a chemical purity of 97.9% IV, which contained 1.4% of the *threo* isomer; yield was 13.7 mg of IV (50%). Radiochemical purity analyses using the same system showed 96.5% of IV and 1.6% of the *threo* isomer. Analyses in systems B and C revealed 99.6 and 98.6% overall radiopurity, respectively. The TLC systems were unable to resolve the *threo* isomer.

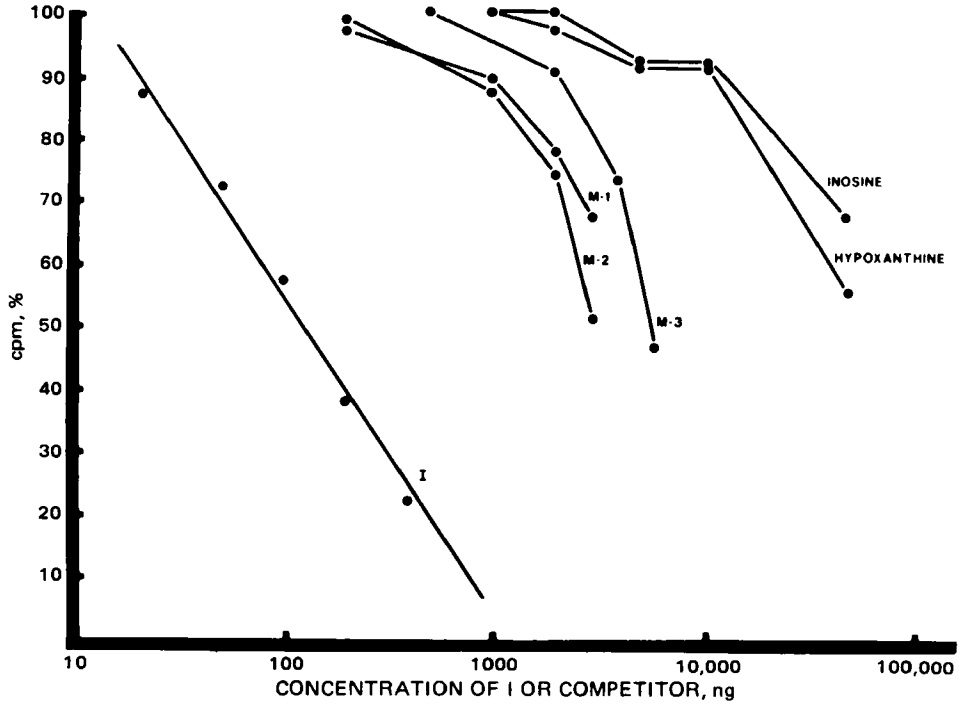

Figure 3—*RIA competition curves for the drug (I), three of its metabolites (M-1, M-2, M-3), inosine, and hypoxanthine. The serum RIA was carried out as described, and either I, a metabolite, inosine, or hypoxanthine was added as a competitor.*

RIA from Human Serum—A stock solution of IV was prepared in water at an activity of ~2×10^7 dpm/ml. A stock solution of 0.5 *M* sodium phosphate buffer, pH 7.5, was also made.The assay mixture was prepared by mixing 1.6 μl of stock solution IV, 2 ml of buffer, 50 μl of antiserum, and diluting to a final 10 ml volume. This mixture was freshly prepared and used immediately. In practice, the antiserum was diluted to give a total binding of IV in the presence of control serum of 70%.

The assay mixture (1 ml) was added to 2 ml of serum, and each sample was run in duplicate. Standards of I were prepared in serum at 0, 1, 2, 5, 10, and 20 ng/ml (also in duplicate) and analyzed concurrently. The solutions were thoroughly mixed and allowed to incubate overnight at 4°. After warming to room temperature, saturated ammonium sulfate was added slowly with vortexing to a final dilution of 40% saturation. The precipitate was allowed to stand 5 min, then centrifuged. The supernatant was aspirated, and the precipiate was washed with 1 ml of 50% saturated ammonium sulfate. Water (0.5 ml) was used to dissolve the precipitate, and the radioactivity (in cpm) was measured.

Quantitation of the amount of drug present in serum was determined from a standard curve of percent cpm *versus* ng/ml of I added. Percent cpm for a given sample was calculated by dividing the sample cpm by the control cpm and multiplying by 100. A typical standard curve is illustrated in Fig. 1.

RIA from Human Urine—The assay mixture was identical to that for the serum RIA except human control serum was also added (ml serum per 10 ml assay mixture) to ensure adequate levels of precipitable protein. To duplicate 1-ml urine samples, 2 ml of ethyl acetate was added; this was vortexed over a 5-min period. Duplicate standards of 0, 10, 20, 50, 100, and 200 ng/ml of I in water were prepared, extracted, and run concurrently. One milliliter of the top layer was removed, and the solvent was evaporated under a stream of nitrogen. The assay mixture (1.5 ml) was added and incubated at 4° overnight. After warming to room temperature, 1 ml of saturated ammonium sulfate was added slowly while vortexing. The precipitate was allowed to stand for 5 min, then centrifuged to a pellet. The supernatant was aspirated and discarded. Water (0.2 ml) was used to dissolve the precipitate, and the radioactivity (in cpm) present in the pellet was measured. Quantitation of the amount of drug present in the urine was derived from a graph of the standard curve of cpm *versus* ng/ml of I added. A typical standard curve is illustrated in Fig. 2.

Table II—Recoveries of I from Human Urine

Amount of I added, ng/ml	Estimated I Recovered, ng/ml					Mean	CV^b, %
	A[a]	B	C	D	E		
0	<10	<10	<10	<10	13		
10	10.5	23	12.5	8	24	15.6	47.4
20	14	32	21.5	11	39	23.5	50.5

RESULTS AND DISCUSSION

The accuracy and precision of the immunoassays were evaluated and the results are given in Tables I and II. For the serum RIA, samples were collected from six untreated individuals, and I was added at levels of 1, 2, and 5 ng/ml. Control serum was also run for each individual. Percent cpm (cpm sample/cpm control × 100) was calculated, and the concentration of drug present (in ng/ml) was read from a graph of a standard curve. The standard curve was generated from similarly treated pooled human sera. Average recoveries in serum at levels of 1, 2, and 5 ng/ml were 95, 97, and 87%, respectively. Precision was directly related to the concentration. The coefficient of variation (*CV*) decreased from 27% at 1 ng/ml (the sensitivity of the assay) to 15% at 2 ng/ml and 13% at 5 ng/ml. The method clearly discriminates between control (blank) serum and drug-treated serum at low levels (1 ng/ml) and yields quantitatively acceptable results at higher levels.

Various statistical methods were attempted to improve the accuracy of quantitation in serum. These methods include linear regression of log ng/ml *versus* percent cpm and polynomial least-squares fit to ng/ml *versus* percent cpm. Simple graphical interpolation gave results comparable to the computer-generated data.

The serum RIA requires a control sample from each individual for the calculation of percent cpm. However, it was possible to obtain quantitative results without the control sample by a plot of cpm *versus* ng/ml of the standard and deriving the concentration from the uncorrected cpm of the sample. These results were considerably less accurate than those obtained from the percent cpm method, probably due to variable amounts of competing materials in the individual sera. The interference was not removed by solvent extraction or chemical or membrane deproteinization. Since control sera are generally available from pharmacological studies, their requirement is not a great limitation. A calculation of percent cpm was not necessary for the standard curve of the urine RIA. Acceptable results were obtained from a plot of uncorrected cpm *versus* ng/ml of I in water for the urine quantitation.

The urine RIA recovery data are given in Table II. For this study, urine from five individuals was sampled, and I was added at levels of 10, 20, 50, 100, and 200 ng/ml. Control urine was also analyzed for each individual. The assays were carried out over a period of several weeks, with each

individual being analyzed on a separate day using a concurrent standard curve. The urine assay standards of I were made in water, extracted, and treated identically to the urine samples.

Average recoveries of drug in urine at levels of 10, 20, 50, 100, and 200 ng/ml were 156, 118, 111, 111, and 105%, respectively. The high recovery values were due to small constant amounts of background in the normal urine (5–10 ng/ml) and were mostly due to two individuals (B and E). The interference, of course, becomes less important at higher drug levels (100–200 ng/ml). The precision also improves considerably at higher levels, ranging from a *CV* of 50% at 10–20 ng/ml to 3% at 200 ng/ml.

For the urine RIA, an extraction was necessary to increase the sensitivity level. Without an ethyl acetate extraction, a background of 50–100 ng/ml was present in control urine. The cause of this interference has not been determined. The highest background level noted in this study was in subject E at 13 ng/ml, which has subsequently been found to be the highest level observed in any normal urine examined. In every other normal urine assayed, the amount of interference was well below the lowest concentration on the standard curve (usually 10 ng/ml).

The specificity of the RIA was also investigated. Three metabolites of I, designated as M-1, M-2, and M-3, were isolated from rabbits. UV spectra of the metabolites indicated the purine base was unchanged, so the amount of metabolites could be estimated using the molar absorptivity of the parent compound. These metabolites and other possible competitors containing a similar purine ring (hypoxathine and inosine) were added to an assay in varying amounts and compared with the competitive effects of I (Fig. 3). Metabolite M-2 was the most effective competitor in the assay, having a cross-reactivity of 2–4%. Metabolite M-1 had a cross-reactivity of 1.5–2%, and M-3 was the least effective competitive metabolite at 0.8–2%. Hypoxanthine and inosine were cross-reactive at ~0.1%. Percent cross-reactivity was defined as the ng of I ÷ ng of competitor (×100) when each was at a level producing the same reduction in percent cpm.

The various rabbit antisera were screened for usability. Of the four immunized rabbits, the serum from one particular animal was extremely sensitive to changes in I. When used in the serum RIA, this rabbit's antiserum gave the curve illustrated in Fig. 1, whereas the other rabbits' antiserum produced no measurable reduction in percent cpm up to a drug concentration of 10 ng/ml. At some concentrations (2–10 ng/ml), the percent cpm actually significantly increased compared with the control. This effect has been noted in other systems and has been ascribed to increasing amounts of hapten producing a conformational change in the antibody, thus increasing its binding affinity (11).

Various approaches to assay optimization were used. Incubation times from 2 to 24 hr were explored. The shorter times were usable, but the 24-hr incubation time yielded the maximum slope (sensitivity) at lower concentrations. Reversing the order of the addition of IV and sample to the antiserum had no effect. The pH of the assay buffer was incrementally varied from 5 to 7.5, but binding remained constant throughout this range. Since hypoxanthine and inosine were slightly competitive in the assay and are present in normal plasma at a level of ~600 ng/ml (12) and ~200 ng/ml (13), respectively, the effect of their enzymatic removal from the serum was studied. Purine nucleoside phosphorylase, xanthine oxidase, and uricase were added to normal serum and compared by an RIA standard curve to the same untreated serum. There were no apparent differences between the standard curves generated.

Attempts to synthesize an ^{125}I-labeled derivative of I yielded apparently unstable products. Attachment of tyrosine or tyrosine methyl ester to II gave multiple UV-absorbing products by TLC analysis. Attachment of iodine-125 to tyrosine methyl ester, then conjugating the labeled ester to II also yielded multiple-labeled products. These products were isolated and tested in the RIA, but would not bind to the antiserum. Since the ^{14}C-labeled drug gave acceptable sensitivity and excellent chemical and radiochemical stability, neither iodine-125 or tritium labeling efforts were pursued.

The RIA described in this article has been used to assess serum and urine drug levels in human volunteers participating in a tolerance trial. Patients were administered a single oral dose of either 0.7, 3.0, or 9.0 mg of I. Assays were performed on 24-hr pooled urine collections and on serum at 2 hr postdose.

Urinary levels obtained after administration of 0.7 mg of I ranged from 64 to 290 ng/ml (n = 5); after 3.0 mg the range was 190 to 640 ng/ml (n = 7); and after 9.0 mg the range was 437 to 1425 ng/ml (n = 6). Urine samples were diluted with water when necessary to bring the drug concentration into the standard curve range. Corrections were made for urine volume, and the amount and percent of dose excreted were calculated (± standard deviation). From the 0.7-, 3.0-, and 9.0-mg dose groups, 196 ± 62 μg (28.0% of dose), 355 ± 102 μg (9.6% of dose), and 850 ± 241 μg (9.4% of dose) were excreted, respectively. The percentage of dose excreted unchanged from the 0.7-mg group is significantly higher than the other two groups (ANOVA, $p < 0.001$).

The 2-hr postdose serum levels were also analyzed from the three dosage groups. The 0.7-mg group attained a mean serum level of 1.24 ng/ml (n = 4), the 3.0-mg group a level of 5.43 ng/ml (n = 6), and the 9.0-mg group had an average level of 10.7 ng/ml (n = 4). The RIA techniques, therefore, appear to possess adequate sensitivity for their intended purpose.

Improved Procedure for the Determination of Protein Binding by Conventional Equilibrium Dialysis

COLIN J. BRIGGS ˣ, JOHN W. HUBBARD, CATHERINE SAVAGE, and DIANE SMITH

Received October 7, 1981, from the *Faculty of Pharmacy, University of Manitoba, Winnipeg, Manitoba, Canada, R3T 2N2.* Accepted for publication July 30, 1982.

Abstract □ The binding of drugs to plasma proteins has been studied extensively using a variety of methods, including equilibrium dialysis. Published information on controls used in these studies is frequently inadequate; in other cases, there are deficiencies in the experimental design for the controls. A method is described that eliminates many of the problems associated with artifactual errors in dialysis studies. Multiple replicated controls are performed at the same time as the test, under identical conditions. The controls are used to correct for concentration-dependent binding of drug to the membrane or other equipment. The method was used to determine the binding of sulfadimethoxine to CF-IV-1 α-globulin at therapeutic concentrations. The level of binding was low (9–13%), but the stringent control technique permitted statistical analysis which showed each mean test value to be significantly different from its corresponding control. Furthermore, there was a linear relationship between the control-corrected percentage binding values and total drug concentration, whereas there was no correlation between total drug concentration and the uncorrected percentage binding values.

Keyphrases □ Equilibrium dialysis—measurement of low-level protein binding, elimination of artifactual error, multiple replicated controls □ Protein binding—low levels measured by equilibrium dialysis, use of multiple replicated controls to eliminate artifactual error, correction for concentration-dependent binding □ Sulfadimethoxine—binding to CF-IV-1 α-globulin at therapeutic doses, equilibrium dialysis with multiple replicated controls

The binding of drugs and xenobiotic agents to blood proteins is an important parameter in pharmacokinetic studies, since the extent and affinity of this binding influences distribution of the compound in the body (1, 2). The concentration of unbound drug in the plasma can affect rates of metabolism and elimination (3). Numerous qualitative and quantitative techniques have been used to study the interaction between drugs and macromolecules. Equilibrium dialysis is the classical procedure and remains the most popular method (4). In the conventional method, the drug–protein mixture is contained within a sealed tube of semipermeable membrane, with protein-free buffer solution outside the membrane. At equilibrium the concentration of drug in the dialysate equals that of the unbound drug inside the dialysis tube. If a suitable range of drug concentrations is used, it is also possible to determine the extent of binding, the binding constants, and the number of binding sites on an isolated pure protein (5). A comprehensive study also should include an appropriate range of protein concentrations to detect any differences in binding due to changes in protein concentration.

Good controls are essential in any dialysis study since many drugs bind to the semipermeable membranes and apparatus (6), reducing the apparent concentration of free drug. Other factors influencing the extent of binding measured include temperature (7, 8), pH (9), and variation in the physicochemical properties of the protein (10). Additional influences are those parameters inherent in the design of the experiment, such as the nature and concentration of proteins present (11) and the drug used. Artifactual errors in the determination of protein binding can be minimized through adequate controls and consideration of experimental design. Literature reports of equilibrium dialysis studies for the determination of free drug concentrations are frequently deficient in details concerning the controls used.

All methods for determination of free drug concentrations in plasma, serum, or solutions of macromolecules at normal biological concentrations have some inherent problems that may influence the results (4). The most commonly used techniques involve separation of a fraction of the unbound drug from the bound component. One of the advantages of dialysis is that the free component retains access to the bound component when equilibrium is reached. Concentrations of free and bound drug are not affected to the same extent as in ultrafiltration, where a portion of the free drug is removed from the system. Ultrafiltration also results in some concentration of the protein solution, which may influence the binding (12).

Inadequacy of controls is a major contributor to the variations found in binding studies reported in the literature. Nonspecific adsorption to the semipermeable membrane is a problem in the dialysis of many compounds (13). The extent of adsorption to membranes is frequently <10% of the total drug present, but may exceed 50% (6) and vary according to the method of preparation and storage of the membrane (14). It can occur with all types of membrane and is a source of potential error in free drug determination. Nevertheless, a commonly used technique is to run limited preliminary controls which are used to generate a correction factor to be applied to all subsequent results obtained with solutions containing protein (15). In many cases, the binding to apparatus and membranes is considered negligible. But variations in these losses may become highly significant when working at low concentrations such as those encountered with many drugs at therapeutic doses. Furthermore, the variability in results obtained with conventional dialysis procedures often

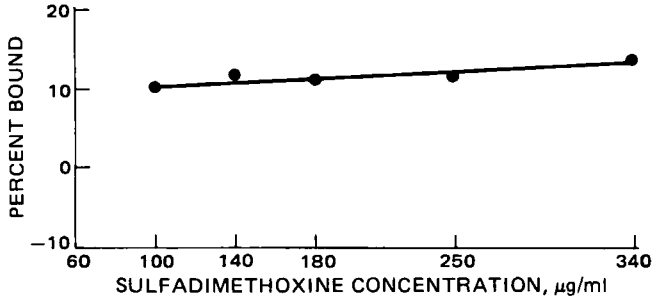

Figure 1—*Plot of percentage binding* versus *concentration of sulfadimethoxine. Percentage binding values are calculated directly from the optical density mean values shown in Table I.*

	r = 0.9997	r = 0.9994	r = 0.8811

[a] Expressed as mean ± SE; n = 5. [b] $[(Y_c - Y_t)/Y_c] \times 100$.

precludes accurate determination of binding for drugs that show a low percentage bound.

In the present study, an equilibrium dialysis method is described which employs calibration and control procedures that minimize artifactual errors and permit statistical evaluation of control, as well as test data. The method permits compensation to be made for concentration-dependent binding to apparatus and membranes and allows for variations in conditions in individual experiments. Sulfadimethoxine and Cohn fraction (CF) IV-1 α-globulin were selected as a model drug–protein system that gives a low percentage binding. The concentration of the protein was constant at the normal blood level of 0.81% w/v, with the drug present in amounts equivalent to those found in therapeutic application.

EXPERIMENTAL

Equilibrium dialysis was performed using 20-cm strips of dialysis tubing[1] (1-cm diameter, 4.8-nm pore diameter) with a molecular weight cut-off not greater than 12,000. These membranes were immersed in boiling water and stirred for 2 hr as the water cooled. The tubing was then stirred with 70% methanol for 30 min, stored in 50% methanol overnight, rinsed with distilled water, and soaked in phosphate buffer (pH 7.4) for 2–3 hr prior to use. The membranes were used immediately after preparation. The tubing was tied with a double knot at one end and filled with 2 ml of protein solution (CF-IV-1 α-globulin[2] in phosphate buffer, 0.81% w/v; pH 7.4) containing sulfadimethoxine. The drug concentration range was 100–340 μg/ml. The tubing was sealed and placed in a glass culture tube (16 × 125 mm) with a polytetrafluoroethylene cap. Four milliliters of phosphate buffer (pH 7.4) was placed in each culture tube, and the solutions were dialyzed for 24 hr at 37°[3]. The tubes were rotated 12 times per minute using a rotary mixer[4]. The protein solution and dialysate were assayed for sulfadimethoxine using the Bratton–Marshall method (16). Absorbance was measured at 420 nm; five replicates of each test concentration were dialyzed. A set of five controls was prepared for each concentration studied and placed in the rotary mixer with the test samples. Controls were identical to the test samples, except the solution inside the dialysis membrane contained no protein. Glassware and buffer were sterilized by autoclave[5] prior to use. Preparation and transfer of solutions were carried out under aseptic conditions in a laminar-airflow hood[6]. The dialysate was tested for the absence of protein both visually (absence of frothing) and by means of a semiquantitative colorimetric indicator[7].

RESULTS AND DISCUSSION

The mean optical density values (n = 5) for control and test solutions are shown in Table I. Each set of controls is an exact replicate of the corresponding set of test solutions, except that the dialysis bags in the control tubes contained no protein. The controls therefore take into account any spurious loss of drug due to adsorption to the tubes, cap liners, membrane, transfer pipets, or any other equipment. Furthermore, the controls obviate any day-to-day variation in the assay procedure or experimental conditions because they are run in parallel with the tests, and they may be subjected to the same statistical analyses as the tests.

Table II—Percentage Protein Binding of Sulfadimethoxine Calculated by a Regression Equation (Second Method) [a]

Initial Concentration, μg/ml	Protein Binding, %		Corrected Protein Binding, % [d]
	Test [b]	Control [c]	
100	5.53 ± 0.81	−3.06 ± 0.47	8.59 ± 0.91
140	11.75 ± 1.16	1.84 ± 0.94	9.91 ± 1.30
180	10.87 ± 1.05	1.16 ± 1.42	9.71 ± 1.18
250	10.22 ± 0.66	−0.51 ± 0.40	10.73 ± 0.74
340	12.84 ± 0.54	−0.097 ± 0.46	12.93 ± 0.61
	r = 0.6842	r = 0.2243	r = 0.9670

[a] Expressed as mean ± SE; n = 5. [b] $[(X_0 - \hat{X}_t)/X_0] \times 100$. [c] $[(X_0 - \hat{X}_c)/X_0] \times 100$. [d] $[(\hat{X}_c - \hat{X}_t)/X_0] \times 100$.

Calculation of Protein Binding—*First Method*—The difference in mean optical density values between the test and its corresponding control ($Y_c - Y_t$) is attributable to binding of the drug to protein since artifactual discrepancies are represented in the control value. The control value is the optical density reading that would be obtained in the corresponding test if there were no binding of drug to the protein. Thus, the value obtained by subtracting the test optical density from that of the control, expressed as a percentage of the control $[100\ (Y_c - Y_t)/Y_c]$, corresponds to the percentage binding of the drug to protein (Table I). The percentage binding in the present experiment was ~10% throughout the concentration range studied (Fig. 1). Nevertheless, the stringent control technique permits statistical analysis, which showed each test optical density mean to be significantly different from its corresponding control (Student's two-tailed t test; $p < 0.001$ except for the 180-μg/ml concentration where the limit was $p < 0.01$). It is interesting to note that there is a linear relationship between the percentage drug bound and concentration ($y = 0.01183x + 9.279$; $r = 0.8811$, $p' = 0.05$). We would point out however that the y-intercept value of 9.279% is meaningless because we have no data for concentrations <100 μg/ml, and there is no reason to presume that linearity in the relationship would continue to hold at very low drug concentrations.

Second Method—As an alternate approach to the calculation, the controls (Table I) may be used to generate a calibration curve ($y = 0.004525x - 0.08808$; $r = 0.9970$) from which the test optical density values (Y_t) may be converted to percentage binding values. In this procedure, the experimental test optical density mean value (Y_t) is inserted in the regression equation to calculate a value ($\hat{X}_t$) for the concentration of free drug in the test solution at equilibrium. The percentage drug bound to the protein is then calculated by the expression $100\ (X_0 - \hat{X}_t)/X_0$, where X_0 is the initial concentration of the drug (Table II). There is no correlation (Fig. 2) between these uncorrected percentage binding values and initial drug concentration (r = 0.6842, not significant).

However, the present experimental design also permits the control optical density mean value (Y_c) to be converted similarly to a value ($\hat{X}_c$) for the concentration of free drug in the control solution at equilibrium. The percentage "spurious" binding in the control is then given by the expression $100\ (X_0 - \hat{X}_c)/X_0$. The "spurious" binding values calculated by this method are shown in Table II. Theoretically, the controls should show no binding because they contain no protein. In practice, positive

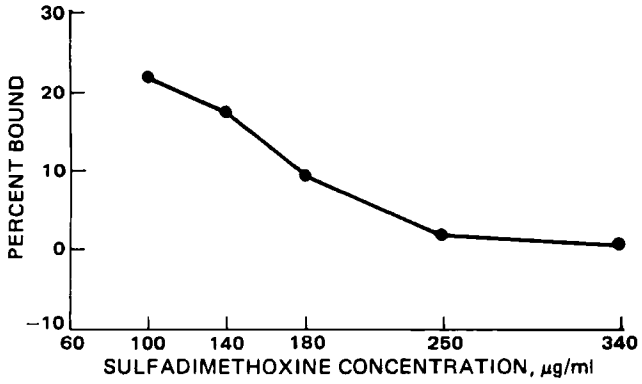

Figure 3—*Erroneous percentage binding values calculated from the regression equation of an unpaired calibration curve.*

or negative deviations from 0% binding reflect nonideal behavior in the system, brought about by the binding of drug to the equipment or other experimental error. Thus, the control ("spurious") binding values were subtracted from the corresponding test (uncorrected) binding values to give the percent binding. The simplified expression for the calculation of percent binding values by this method is 100 $(\hat{X}_c - \hat{X}_t)/X_0$. There is a good correlation between the corrected percentage binding and initial concentration of drug ($y = 0.01650x + 7.042$; $r = 0.9670$, $p' = 0.01$).

Comparison of data in Tables I and II reveals that the percentage binding values calculated by the two methods are similar, but not identical. The disparity arises because of the different types of arithmetic manipulation of data employed. In the first method (Table I), the experimental optical density mean values of the test and control are used directly to calculate percentage binding values. By contrast, the second method (Table II) depends on the ability of the regression equation to predict the drug concentration ($\hat{X}$) which corresponds to an experimentally determined optical density value (Y). Thus the numerical difference between the percentage binding values generated by the two methods may be predicted by the expression 100 $(1/Y_c - 1/mX_0)(Y_c - Y_t)$, where m is the slope of the regression equation. Full details of the derivation of this expression will be published elsewhere.

The percentage binding values calculated by the second method are consistently smaller than those calculated by the first method. This results in high t values (>7.0 with 4 degrees of freedom) when individual results contributing to a pair of mean values are compared, term by term, in a paired t test. However, the scatter of results about each mean is sufficiently wide to produce low t values (<1.0 with 8 degrees of freedom) in an unpaired t test. This means that, for practical purposes, there is no significant difference between mean percentage binding calculated by the two methods. We therefore prefer the first method because it is simple and direct.

Variability in the System—To assess day-to-day variability in the system, control-calibration experiments were run on nine different occasions by the same technician. Slope values generated from this data varied considerably (mean, 0.003970; *SD*, 0.0004974; coefficient of variation, 12.53%). This reflects not only variation in the analytical method, but also any day-to-day differences in the adsorption of drug to the membrane. The latter is suspect because the membranes have to be prepared for each run (see *Experimental*) and it is possible that there is interbatch variation in the extent of drug adsorption.

To illustrate the distortion that may be brought about by the use of an unpaired calibration curve, the test optical density mean values in Table I were converted to percent protein binding values by means of a calibration curve ($y = 0.003522x + 0.06394$; $r = 0.9981$) selected at random from the nine calibration-control experiments described above. The resulting percentage binding–drug concentration plot (Fig. 3) has a negative slope ($y = -0.09193x + 28.81$; $r = -0.9406$) and bears little resemblance to the authentic uncorrected plot (Fig. 2).

In the execution of the experiments, care was taken to standardize the manipulative procedures to minimize experimental error. The use of tubes with polytetrafluoroethylene-lined caps avoided the problem of leaching from rubber- or polyvinylchloride-lined caps, which can cause displacement of drugs from protein binding sites (17). All solutions and glassware were sterilized before use, and solution transfers were made under aseptic conditions in a laminar-airflow hood. This eliminates the possibility of microbial growth during dialysis and permits the experiments to be conducted for 24 hr without the use of preservatives that could influence binding characteristics. All dialysates were checked for

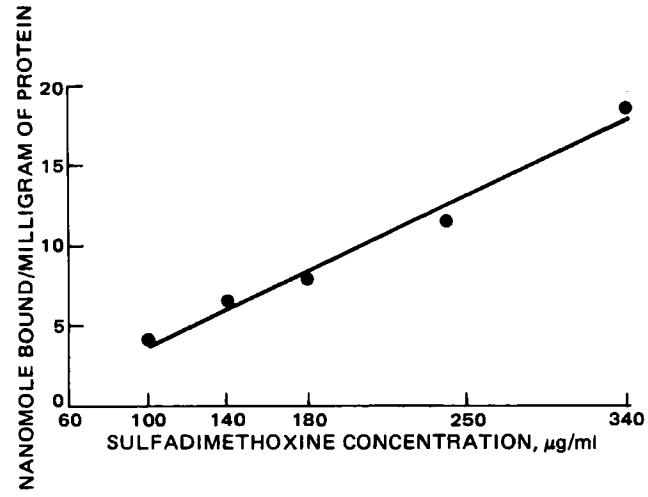

Figure 4—*Relationship between nanomoles of sulfadimethoxine bound per milligram of protein and total drug concentration.*

the absence of protein, both visually (absence of frothing) and by the use of a semiquantitative colorimetric indicator.

The majority of protein-binding experiments described in the literature are concerned with drugs which have a high percentage binding to plasma proteins and with protein fractions that transport a major fraction of a drug in the blood. The significance of minor proteins may increase in disease or other conditions, and it can be important to know their contribution to the overall binding of drugs in the blood.

The variability in results obtained with conventional dialysis procedures often precludes accurate determination of the binding of drugs which show a low percentage bound or a low affinity for proteins. The results (Fig. 1) obtained by the present method however, reveal a low, but statistically significant percentage binding throughout the drug concentration range studied. Conventional percentage binding–drug concentration plots can be difficult to interpret when the slope is shallow as in Fig. 1 ($y = 0.01183x + 9.297$). However, if the percentage binding is expressed in terms of nanomoles of drug bound per milligram of protein, it is clear that the amount of drug bound increases with total drug concentration in a linear manner ($y = 0.05866x - 2.116$, $r = 0.9913$; Fig. 4).

CONCLUSION

The method developed in this study provides an accurate technique for the minimization of errors that arise in equilibrium dialysis and is particularly suitable for use when the percentage binding is low. The stringent control technique permits correction to be made for concentration-dependent binding of drug to the membrane or other equipment. Most significant in the present study is the linear relationship between total drug concentration and control-corrected percentage binding, whereas there was no correlation between total drug concentration and conventional (uncorrected) percentage binding. The method may be adapted to other experimental designs (*e.g.*, fixed concentration of drug *versus* varied concentration of protein) and can be employed with any suitable method of drug analysis.

Stereospecific High-Performance Liquid Chromatographic Analysis of Warfarin in Plasma

CHRISTOPHER BANFIELD and MALCOLM ROWLAND ˣ

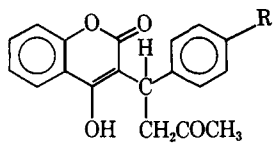
Received March 9, 1982, from the *Department of Pharmacy, University of Manchester, Manchester M13 9PL, England.* Accepted for publication August 5, 1982.

Abstract □ A stereospecific high-performance liquid chromatographic assay has been developed to determine *R*(+)- and *S*(−)-warfarin simultaneously in plasma. The method involved the formation of diastereoisomeric esters, using carbobenzyloxy-L-proline, with subsequent separation using silica as the stationary phase. The method permits characterization of the pharmacokinetics of warfarin enantiomers following administration of racemic drug.

Keyphrases □ Warfarin—stereospecific quantitation in plasma, high-performance liquid chromatography □ Stereoisomers—of warfarin, quantitation in plasma using the racemate, high-performance liquid chromatography □ High-performance liquid chromatography—of warfarin in plasma, quantitation of the stereoisomers using the racemate

Warfarin (I) is administered clinically as a racemic mixture. In humans, *S*(−)-warfarin is five times more potent and is more rapidly eliminated than the *R*-isomer (1, 2). Consequently, the concentration of each isomer in plasma varies with time within an individual and also between individuals following a dose of racemic warfarin. The response to warfarin is also variable (3). Drugs interact with the isomers differently (4–6). Thus, a more complete understanding of the sources of variability in response to warfarin, and the nature of interactions of drugs with warfarin, requires either giving each isomer separately (a rare clinical procedure) or determining the concentration of each isomer in plasma following administration of the prescribed racemic drug.

Stereospecific analysis of a mixture of enantiomers is difficult. Several specialized analytical techniques, including the synthesis of stable isotopes (pseudo-racemates) coupled with mass spectrometry (7, 8) and a stereospecific radioimmunoassay (9) have been developed to overcome this difficulty.



I R = H
II R = F

Chromatographic separation of enantiomers is possible if a diastereoisomeric relationship is established between them either through the use of chiral solvents (10–12) or derivatization with a suitable chiral reagent (13–15). This paper describes a simple method for the quantitative estimation of the isomers of warfarin in plasma using carbobenzyloxy-L-proline to form diastereoisomeric esters, which can be separated by high-performance liquid chromatography (HPLC) using silica as the stationary phase.

EXPERIMENTAL

Reagents and Materials—Racemic warfarin was obtained from its sodium salt[1] by precipitation with 0.1 *M* HCl. The dried material was recrystallized from absolute ethanol. *R*(+)- and *S*(−)-warfarin[2], the internal standard[3] (3-[α-(4′-fluorophenyl-)-β-acetylethyl]-4-hydroxycoumarin; 4′-fluorowarfarin) (II), imidazole[4], dicyclohexylcarbodiimide[5], carbobenzyloxy-L-proline[5], hexane (HPLC grade)[6], methanol[7], and ethyl acetate (HPLC grade)[6] were used as supplied. Peroxide-free ether[8] was prepared by passage through a column of activated alumina[9] (45 g, Brockman type 1 alkaline).

Extraction of *RS*-Warfarin—Plasma (0.2 ml) and internal standard (0.1 ml; 0.846 μg/0.1 ml of water) were added to a clean culture tube[10] (16 × 125 mm). The solution was made alkaline with 0.1 *M* K_2CO_3 (1 ml), shaken manually for 3 min with ether (4 ml), and separated by centrifugation[11] at 3000 rpm for 5 min. After aspiration of the organic layer, the aqueous layer was acidified with 1 *M* HCl (1.5 ml) and shaken manually for 3 min with ether (6 ml), followed by centrifugation at 3000 rpm for 3 min. The aqueous layer was quickly frozen by immersion in liquid nitrogen (40–60 sec) to allow the organic layer to be decanted into a culture tube whose tip was drawn out to a capacity of 0.2 ml. An antibumping

Stereospecific High-Performance Liquid Chromatographic Analysis of Warfarin in Plasma

CHRISTOPHER BANFIELD and MALCOLM ROWLAND ˣ

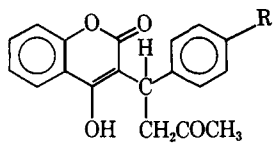
Received March 9, 1982, from the *Department of Pharmacy, University of Manchester, Manchester M13 9PL, England.* Accepted for publication August 5, 1982.

Abstract □ A stereospecific high-performance liquid chromatographic assay has been developed to determine *R*(+)- and *S*(−)-warfarin simultaneously in plasma. The method involved the formation of diastereoisomeric esters, using carbobenzyloxy-L-proline, with subsequent separation using silica as the stationary phase. The method permits characterization of the pharmacokinetics of warfarin enantiomers following administration of racemic drug.

Keyphrases □ Warfarin—stereospecific quantitation in plasma, high-performance liquid chromatography □ Stereoisomers—of warfarin, quantitation in plasma using the racemate, high-performance liquid chromatography □ High-performance liquid chromatography—of warfarin in plasma, quantitation of the stereoisomers using the racemate

Warfarin (I) is administered clinically as a racemic mixture. In humans, *S*(−)-warfarin is five times more potent and is more rapidly eliminated than the *R*-isomer (1, 2). Consequently, the concentration of each isomer in plasma varies with time within an individual and also between individuals following a dose of racemic warfarin. The response to warfarin is also variable (3). Drugs interact with the isomers differently (4–6). Thus, a more complete understanding of the sources of variability in response to warfarin, and the nature of interactions of drugs with warfarin, requires either giving each isomer separately (a rare clinical procedure) or determining the concentration of each isomer in plasma following administration of the prescribed racemic drug.

Stereospecific analysis of a mixture of enantiomers is difficult. Several specialized analytical techniques, including the synthesis of stable isotopes (pseudo-racemates) coupled with mass spectrometry (7, 8) and a stereospecific radioimmunoassay (9) have been developed to overcome this difficulty.



I R = H
II R = F

Chromatographic separation of enantiomers is possible if a diastereoisomeric relationship is established between them either through the use of chiral solvents (10–12) or derivatization with a suitable chiral reagent (13–15). This paper describes a simple method for the quantitative estimation of the isomers of warfarin in plasma using carbobenzyloxy-L-proline to form diastereoisomeric esters, which can be separated by high-performance liquid chromatography (HPLC) using silica as the stationary phase.

EXPERIMENTAL

Reagents and Materials—Racemic warfarin was obtained from its sodium salt[1] by precipitation with 0.1 *M* HCl. The dried material was recrystallized from absolute ethanol. *R*(+)- and *S*(−)-warfarin[2], the internal standard[3] (3-[α-(4′-fluorophenyl-)-β-acetylethyl]-4-hydroxycoumarin; 4′-fluorowarfarin) (II), imidazole[4], dicyclohexylcarbodiimide[5], carbobenzyloxy-L-proline[5], hexane (HPLC grade)[6], methanol[7], and ethyl acetate (HPLC grade)[6] were used as supplied. Peroxide-free ether[8] was prepared by passage through a column of activated alumina[9] (45 g, Brockman type 1 alkaline).

Extraction of *RS*-Warfarin—Plasma (0.2 ml) and internal standard (0.1 ml; 0.846 μg/0.1 ml of water) were added to a clean culture tube[10] (16 × 125 mm). The solution was made alkaline with 0.1 *M* K_2CO_3 (1 ml), shaken manually for 3 min with ether (4 ml), and separated by centrifugation[11] at 3000 rpm for 5 min. After aspiration of the organic layer, the aqueous layer was acidified with 1 *M* HCl (1.5 ml) and shaken manually for 3 min with ether (6 ml), followed by centrifugation at 3000 rpm for 3 min. The aqueous layer was quickly frozen by immersion in liquid nitrogen (40–60 sec) to allow the organic layer to be decanted into a culture tube whose tip was drawn out to a capacity of 0.2 ml. Table I—Chromatographic Parameters for the Carbobenzyloxy-L-prolyl Esters of Warfarin on Various Stationary Phases

Solvent Composition	Stationary[a] Phase	k_S[b]	k_R[c]	R[d]	α[e]
Acetonitrile–water–acetic acid (43:66:1)	Spherisorb 5 ODS	26.2	23.3	1.13	1.12
Ethyl acetate–hexane (15:85)	Spherisorb 5 CN	8.3	10.5	1.44	1.26
Ethyl acetate–hexane (25:75)	Spherisorb 5 Si	5.0	7.0	2.74	1.40

[a] Column size was 4.6-mm i.d. × 10 cm. [b] Capacity factor for the carbobenzyloxy-L-prolyl ester of *S*-warfarin. [c] Capacity factor for the carbobenzyloxy-L-prolyl ester of *R*-warfarin. [d] Resolution factor. [e] Selectivity.

granule was added to the organic layer, which was evaporated to dryness on a heating block at 45° under a stream of nitrogen. The inside of the tube was washed several times with small (100–200 μl) volumes of ether, with vortexing and evaporating to dryness between additions.

For each day of analysis a calibration curve was prepared using the above extraction procedure on blank plasma (0.2 ml) spiked with an aqueous solution (0.1 ml) containing 0.2–2.0 μg of *RS*-warfarin and internal standard (0.8 μg, 0.1 ml).

Derivatization—The derivatization procedure involves esterification with carbobenzyloxy-L-proline using imidazole as catalyst and dicyclohexylcarbodiimide as the condensing agent. To the plasma extract in the modified culture tubes was added carbobenzyloxy-L-proline (10 μl; 100 mg/ml of acetonitrile), imidazole (10 μl; 1 mg/ml of acetonitrile), and dicyclohexylcarbodiimide (10 μl; 100 mg/ml of acetonitrile). The mixture was vortexed for ~10 sec, during which time a precipitate formed. The reaction was allowed to proceed for 2 hr. The tubes were centrifuged at 3000 rpm for 5 min, and aliquots (3–10 μl) of the supernatant were analyzed by HPLC.

High-Performance Liquid Chromatography—For HPLC discrimination of the diastereoisomers, a pump[12], fitted to a stainless steel column (250 mm × 5 mm-i.d.) packed with silica[13] was used with ethyl acetate–hexane–methanol–acetic acid (25:74.75:0.25:0.4) as mobile phase, at a flow rate of 1 ml/min (~600 psi). Test samples were applied by means of an on-column injector, and the effluent was monitored at 313 nm (0.005 AUFS) using a UV detector[14]. All analyses were performed at ambient temperature. Chromatographic tracings were obtained on a strip chart recorder[15] at a chart speed of 1 cm/2 min. The concentrations of the isomers in the unknown samples were calculated by reference to the appropriate calibration curves, constructed by plotting the peak height ratios obtained (using either ester of the internal standard) *versus* the known amounts of isomer per sample of plasma.

Synthesis of the Diastereoisomeric Esters—To *RS*-warfarin (100 mg) in a conical flask (10 ml) was added dichloromethane[8] (3.0 ml) and carbobenzyloxy-L-proline (300 mg). This was sonicated to effect solution, and dicyclohexylcarbodiimide (300 mg in 1 ml of dichloromethane) was added. A precipitate formed immediately, but the reaction was allowed to proceed for ~14 hr at room temperature. The mixture was then filtered, and the filtrate was stored in the dark until TLC separation was performed.

Isolation of Diastereoisomers—Prior to sample application, the TLC plates (silica gel GF 254/G60) were chromatographed in methanol, dried, and rerun in the solvent system, ethyl acetate–hexane–acetic acid (30:70:0.2), used for the separation of the diastereoisomers. The filtered solution containing the diastereoisomers was applied as a narrow band ~2 cm from the bottom edge of the plate. The bands were detected using short-wavelength (254-nm) UV light. Identification of the spots was made by chromatographing each ester formed by independently reacting *R*(+)-warfarin and *S*(−)-warfarin with carbobenzyloxy-L-proline. The average time to complete an analysis (15 cm) was 1.5 hr in a nonequilibrated tank. Care was taken not to overload the plate, since this led to band broadening. In the advent of overlap, lines were drawn across the plate a few millimeters above and below where the overlap had occurred. The material contained within this area was used as racemic diastereoisomeric ester. The regions above and below these lines were scraped into tubes labeled *SS* ester and *RS* ester, respectively, and eluted by manually shaking for 2 min with ethyl acetate or dichloromethane (2 ml). The materials were transferred to microcentrifuge tubes (1.5 ml), centrifuged at 12,000×*g* for 1 min, and the supernatant was transferred to a clean vial. An aliquot of each supernatant was chromatographed using the same solvent system used to separate the diastereoisomeric esters. Those fractions chromatographing as either *SS* ester, *RS* ester, or racemic ester were pooled in appropriately labeled vials. The entire process was then repeated using several plates.

A sample of silica gel was taken from an area free from UV-absorbing material and processed as for the diastereoisomers. Mass spectral[16] and IR[17] (solution) analyses were performed on both the silica gel blank and the diastereoisomers.

Table II—Within-Assay Variability of Peak Height Ratios at Various Amounts of *RS*-Warfarin

Amount of Isomer, μg	Relative Standard Deviation, %			
	SS[1 a]	*RS*[1 a]	*SS*[2 b]	*RS*[2 b]
1.0[c]	3.2	3.5	3.25	3.7
0.4[c]	6.3	6.7	5.1	6.6
0.1[d]	9.8	8.4	11.9	11.8

[a] Peak height ratios determined relative to the first eluting ester of the internal standard. [b] Peak height ratios determined relative to the second eluting ester of the internal standard. [c] $n = 6$. [d] $n = 4$.

RESULTS AND DISCUSSIONS

The proposed structures of the carbobenzyloxy-L-prolyl diastereoisomeric esters of warfarin (III) were established (after separation of the diastereoisomers by semipreparative TLC) by low-resolution electron impact (EI) and chemical ionization (CIMS, ammonia as carrier) mass spectrometry (MS) and IR analysis. The chemical ionization MS data, in conjunction with EI studies, verified the predicted molecular weight (CIMS: *m/z* 557, $[M + NH_4]^+$; EI: *m/z* 539, $[M^+]$). These molecular ions were not present in the background sample of silica gel. As expected the MS of the *R*(+)- and *S*(−)-warfarin esters were similar. The IR spectra (chloroform) of the diastereoisomeric esters showed an absorption at 1780 cm^{-1} consistent with vinylic esters (1800–1770 cm^{-1}).

Not all apparently good candidates for the formation of diastereoisomers with *RS*-warfarin gave favorable results. Thus, *N*-acetyl-L-alanine[5] and *N*-acetyl-L-phenylalanine[5] did not form derivatives with *RS*-warfarin using dicyclohexylcarbodiimide as the activating agent. Also, although both *R*(−)-2-methoxy-2-phenylacetic acid[18] and L-menthoxyacetic acid[5] formed derivatives, chromatographic conditions could not be found to achieve resolution of the resultant diastereoisomeric esters on either silica[13] or Spherisorb 5 ODS[13] stationary phases. In contrast, successful derivatization and resolution of *RS*-warfarin was achieved using *N*-acetyl-L-proline (16) and carbobenzyloxy-L-proline (*Z*-L-proline). The latter was eventually chosen because of its higher (>99%) optical purity.

The effectiveness of the derivative for resolution is subject to several criteria: conformational rigidity of groups attached to the asymmetric center [a center as part of a ring system can improve resolution (17)], *e.g.*, *N*-acetyl-L-proline and carbobenzyloxy-L-proline; a minimum distance of 3–4 atoms between the chiral centers of the reagent and solute (18–20); and polar or polarizable groups in close proximity to the asymmetric centers (21). In *R*(−)-2-methoxy-2-phenylacetic acid the asymmetric center is not part of a ring system. Although the asymmetric center of L-menthoxyacetic acid is in a ring sytem, the asymmetric centers of the proposed derivative are six atoms apart. These results suggest that all of the above criteria must be met if adequate resolution is to be effected. The lack of reactivity of the *N*-acyl derivatives of L-alanine and L-phenylalanine may be due to formation of oxazolones (22, 23) when dicyclohexylcarbodiimide is used as the activating agent.

N,N'-Dicyclohexylurea, a byproduct in the activation of carboxyl functions by dicyclohexylcarbodiimide (24) is soluble only to a certain extent in most organic solvents. To overcome the purification problem caused by the formation of *N,N'*-dicyclohexylurea and *N*-acyl ureas, water-soluble carbodiimides are often used (25). However ester formation with carbobenzyloxy-L-proline in the presence of such water-soluble carbodiimides as 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide methoxy-*p*-toluenesulfonate[5] or 1-(3-dimethyl-aminopropyl)-3-ethyl carbodiimide[5] was inferior to that in the presence of dicyclohexylcarbodiimide. With the first, derivative formation did not occur; with the second, derivatization was incomplete. Even so, as the technique is being developed specifically for analytical purposes, the lack of the option for removal of the urea-type impurities is not a serious disadvantage, because the impurities lack good chromophores at the wavelength (313 nm) used in the analysis of warfarin, so that minimal interference is observed.

Reverse-phase HPLC is popular partly because of the wide variety of stationary phases available and partly because the ability to inject aqueous samples reduces the number of prechromatographic steps required. From preliminary investigations with the stationary phases Hypersil-5 ODS[19], Spherisorb 5 ODS[13], Spherisorb 5 phenyl[13], and Spherisorb 5 CN[13] in the reverse-phase mode only Spherisorb 5 ODS and Spherisorb 5 CN gave sufficient promise to warrant further study. Improved performance was seen, however, when Spherisorb 5 CN was used in the normal-phase mode. Under optimal conditions, using the solvent combinations shown in Table I, Spherisorb 5 ODS showed both low selectivity and resolution. In general, normal-phase chromatography on silica gave the highest selectivity and resolution. Although the maximum difference in selectivity between Spherisorb 5 CN and Spherisorb 5 Si was ~11%, this resulted in a 90% increase in resolution for the diastereoisomeric esters. Addition of acetic acid to the mobile phase when Spherisorb 5 Si is used as stationary phase decreases retention time without adversely affecting resolution or selectivity for the diastereoisomeric carbobenzyloxy-L-prolyl esters (Table I).

The rate of derivatization of *RS*-warfarin (2 mg/ml of ethyl acetate, 10 μl) by carbobenzyloxy-L-proline (100 mg/ml of ethyl acetate, 10 μl) in the presence of dicyclohexylcarbodiimide (100 mg/ml of ethyl acetate, 15 μl), measured by the disappearance of *RS*-warfarin, was followed for 12 hr. The rate is first order with a half-life of disappearance of 3.5 hr. With completion (99%) of the reaction not anticipated before 24 hr, this reaction time was considered too long. In the presence of pyridine (24.5 μl in ethyl acetate) as catalyst, the reaction was complete within 1 hr, and the resultant diastereoisomers remained stable for at least 9 hr. However, the detection of a large peak attributed to pyridine, eluting after the diastereoisomers, limited its use as catalyst because the number of HPLC analyses would be restricted to only two samples per hour. Pyridine absorbs strongly in the 305–315-nm region, which coincides with the wavelength (313 nm) used for detection of the diastereoisomeric esters. Imidazole, which has a lower maximum wavelength of absorption (207 nm), proved to be just as good a catalyst as pyridine; the mechanism of catalysis of esterification is similar (26). Apparently, the presence of a basic nitrogen alone is not sufficient, since triethylamine failed to catalyze the reaction.

[a] Peak height ratios determined relative to the first eluting ester of the internal standard. [b] Peak height ratios determined relative to the second eluting ester of the internal standard. [c] $n = 26$. [d] $n = 10$. [e] $n = 23$. [f] $n = 16$.

Initially, 4-hydroxycoumarin was chosen as the internal standard; it produced a single ester with carbobenzyloxy-L-proline, eluting just after the *RS*-warfarin ester. However, there was a high degree of variability in the subsequent assay procedure which was identified with an instability of the carbobenzyloxypropyl ester of 4-hydroxycoumarin, probably due to imadazole-catalyzed hydrolysis. The absence of a 3-substituent in 4-hydroxycoumarin (*cf.* warfarin) would make attack of the ester carbonyl more facile, due to lack of steric hindrance, for this ester than for the warfarin ester. Of the many others examined, 4'-fluorowarfarin proved the most suitable with respect to retention time and stability, although being a racemate, diastereoisomeric esters are formed.

A typical chromatogram obtained after derivatization of an ethereal extract from human plasma spiked with *RS*-warfarin and internal standard (4'-fluorowarfarin) is shown in Fig. 1. Identification of the retention times of *RS*- and *SS*-warfarin esters was made by chromatographing each of the esters formed by independently reacting *R*(+)-

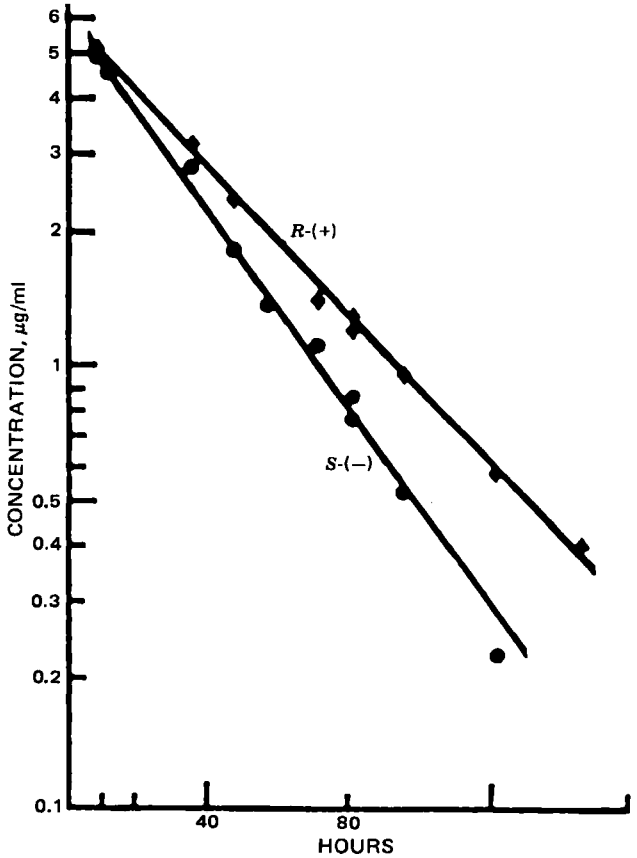

Figure 2—*Plasma concentration–time profile of* R(+)-*warfarin (◆) and* S(−)-*warfarin (●) following oral administration of* RS-*warfarin (1.56 mg/kg) to a human subject.*

warfarin and S(−)-warfarin with carbobenzyloxy-L-proline. The S(−)-warfarin carbobenzyloxy-L-prolyl ester elutes before the ester of R(+)-warfarin, with a separation factor of 3.0. A similar elution order is assumed for the internal standard, but could not be verified because this compound has never been resolved. Repeated analyses with time indicated that the derivatives were stable for at least 48 hr in the final reaction mixture.

The recovery of *RS*-warfarin investigated by taking *RS*-warfarin (0.8 μg) spiked with [^{14}C]*RS*-warfarin through the extraction, derivatization, and HPLC analysis was 70% (n = 3). The major losses occurred during evaporation of the sample, therefore the inside of the tube must be washed to concentrate the extracted material in the tip of the tube.

Linear calibration plots for either isomer ($r^2 > 0.99$) were obtained over the range 0.1–1.0 μg/isomer. As shown in Table II, based on either of the internal standard esters (*RS* or *SS*), the relative standard deviations of the peak height ratios were between 11.9 and 3.2% for 0.1 and 1.0 μg warfarin isomer, respectively. Table III summarizes the results of a similar assessment of between-assay variability for studies performed over a 6-week period using 0.1–1.0 μg of warfarin isomer. Satisfactory precision (<10%) is observed over a fivefold concentration range of warfarin isomers. The results indicate that the assay is accurate and reproducible.

The determination limit of the assay with a 10% coefficient of variation was computed from the expression (27):

$$X_0 = 10\sqrt{V(X_0)}$$

where X_0 is the determination limit at the preselected coefficient of variation, and $V(X_0)$ is the variance associated with X_0. Using the above procedure, the determination limits (10% *CV*) of the UV assay for *S*- and *R*-warfarin are 0.16 and 0.096 μg, respectively, using the first eluting standard. Similar values were obtained when using the second eluting standard. The difference in determination limits of the esters of warfarin may be ascribed to the greater potential for interference between the *SS*-ester of warfarin and the first internal standard, due to changes in retention as a result of column deterioration, or day-to-day variability in eluant composition.

Figure 2 shows the plasma concentration–time profiles for the *R*- and *S*-isomers (using 200-μl plasma samples) following administration of *RS*-warfarin (1.5 mg/kg po) to a normal volunteer. At this dose level the plasma concentration can be monitored for at least 5 days for the *S*-isomer or 6 days for the *R*-isomer. The more rapid elimination of the *S*-isomer confirms the findings using the stereospecific MS methods (7, 8) or following the administration of the separate enantiomers (2).

Stability-Indicating Assay for Chlorthalidone Formulation: Evaluation of the USP Analysis and a High-Performance Liquid Chromatographic Analysis

JOHN BAUER ˣ, JOHN QUICK, SUZANNE KROGH, and DOUGLAS SHADA

Received March 22, 1982, from *Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication July 30, 1982.

Abstract □ An investigation of the USP assay of chlorthalidone tablets showed that variable degradation of chlorthalidone occurred during assay preparation. The degradation products were isolated and identified. A stability-indicating high-performance liquid chromatographic (HPLC) assay which separates the degradation products from chlorthalidone was developed and used to examine the present USP preparation. The HPLC assay is suggested as an alternate.

Keyphrases □ Chlorthalidone—high-performance liquid chromatography, stability-indicating assay, comparison with the USP analysis □ Degradation products—of chlorthalidone, high-performance liquid chromatographic determination, comparison with the USP analysis □ USP analysis—for chlorthalidone and degradation products, comparison to a high-performance liquid chromatographic assay

Chlorthalidone (I) is a monosulfamyl diuretic used in the treatment of hypertension. The official analysis of chlorthalidone tablets, as prescribed in the United States Pharmacopeia, is a spectrophotometric assay (1). Chlorthalidone has been quantitated in various media using a variety of methodologies (2–8). The major techniques in

biological materials involve extractive alkylation and GLC (6–8) or deamination followed by UV spectrophotometric quantitation (2, 3, 5). Although a high-performance liquid chromatographic (HPLC) method using a polyamide column (9) has been published for chlorthalidone formulations, the USP still officially requires a UV spectrophotometric assay. An investigation of the precision of this analysis indicated erratic results (Table I). Two lots of chlorthalidone tablets were analyzed by the USP method in four separate testing laboratories with varying results.

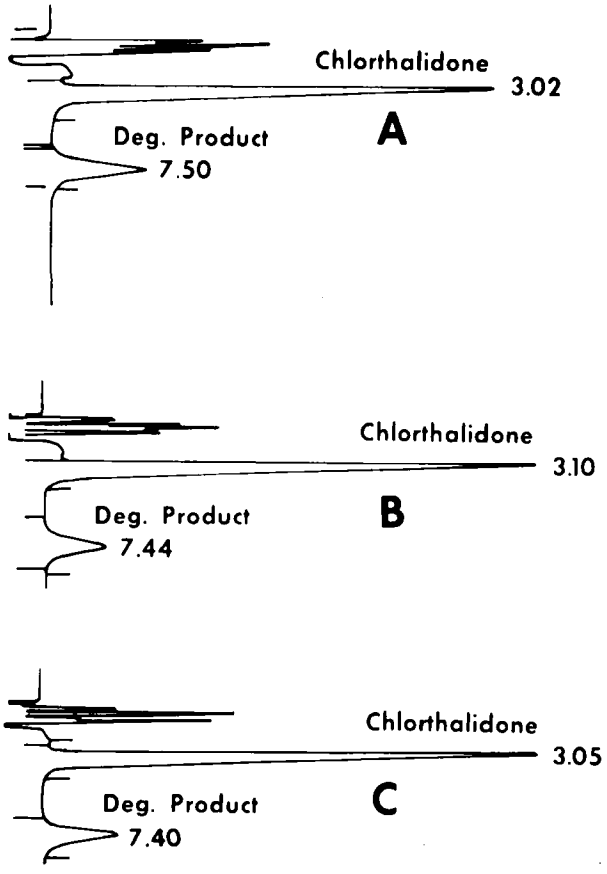

Figure 1—*Chromatograms of USP assay preparations. Key: (A) USP standard lot G immediately after acidification; (B) current marketed product immediately after acidification; (C) chlorthalidone (generic 25 mg) immediately after acidification.*

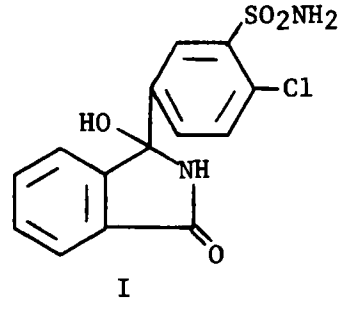

I

2-Chloro-5-(2,3-dihydro-1-hydroxy-3-oxo-1*H*-isoindol-1-yl)benzenesulfonamide

Since the UV absorbance of chlorthalidone is known to conform to Beer's law in the concentration region used for the assay, the possibility that chlorthalidone is unstable in the acidic assay preparation was investigated. The USP analysis is not stability indicating; therefore, development

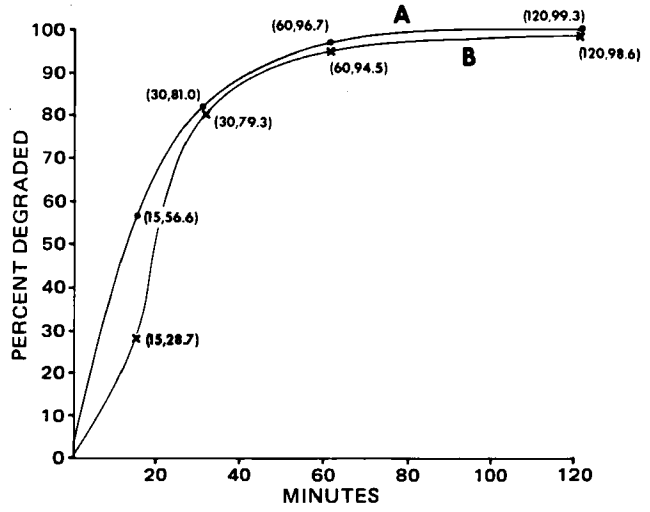

Figure 2—*Rate of degradation of chlorthalidone in USP assay medium. Key: (A) standard preparation; (B) sample preparation.*

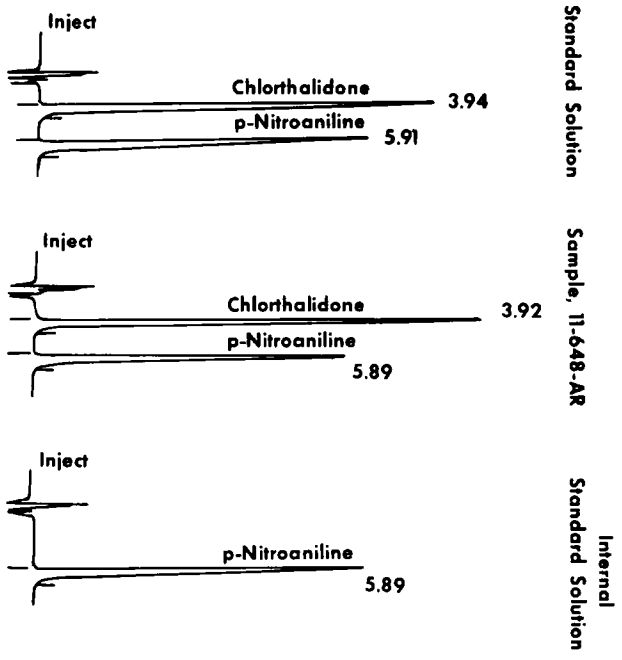

Figure 3—*Typical chlorthalidone chromatograms.*

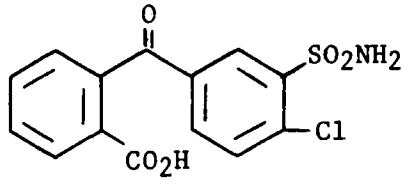
of an HPLC assay using a less specialized and sensitive column than previously reported (9) was undertaken. The HPLC system was used to evaluate the current USP methodology and is suggested as an alternate assay.

BACKGROUND

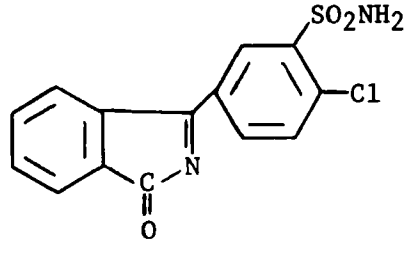
The USP assay for chlorthalidone consists of an acetone extraction followed by filtration and evaporation of the extract. The residue is then dissolved in acidic methanol and quantitated by UV spectrophotometry. The analytical wavelength is 275 nm.

When the final acidic methanol solutions from the USP assay were examined by HPLC (Fig. 1) they were found to contain mixtures of chlorthalidone and one or both of the degradation products (II and III), which coelute, shown below:



II

2-(3-aminosulfonyl-4-chlorobenzoyl)benzoic acid



III

3-[(4-chloro-3-aminosulfonyl)phenyl]-1*H*-isoindol-1-one

Both compounds II and III have larger extinction coefficients at the analytical wavelength than does chlorthalidone. This study reports the occurrence of a noncontrolled degradation of chlorthalidone in the USP

sample and standard preparations and details an HPLC analysis for chlorthalidone, which is stability indicating in so far as the degradation products are separated from the parent drug. These products can be quantitated independently if desired. Kinetic studies of the standard preparation and the tablet preparation during the USP assay show that, although similar, the rates of degradation of the sample and standard are different (Fig. 2). Since the degradation is not quantitative, the samples assayed are heterogeneous mixtures and errors result in both directions.

The use of a mineral acid in the USP assay causes chlorthalidone to degrade. The HPLC analysis presented here does not use strong acid during sample preparation.

EXPERIMENTAL

Materials—Acetonitrile[1], acetic acid[1], methanol[2], and *p*-nitroaniline[3] were used as received. The chlorthalidone used was USP reference standard lot G.

A high-performance liquid chromatograph[4], a scanning spectrophotometer[5], a UV-visible spectrophotometer[6], and a mechanical shaker[7] were used. A microparticulate octadecylsilane column[8] was used. The

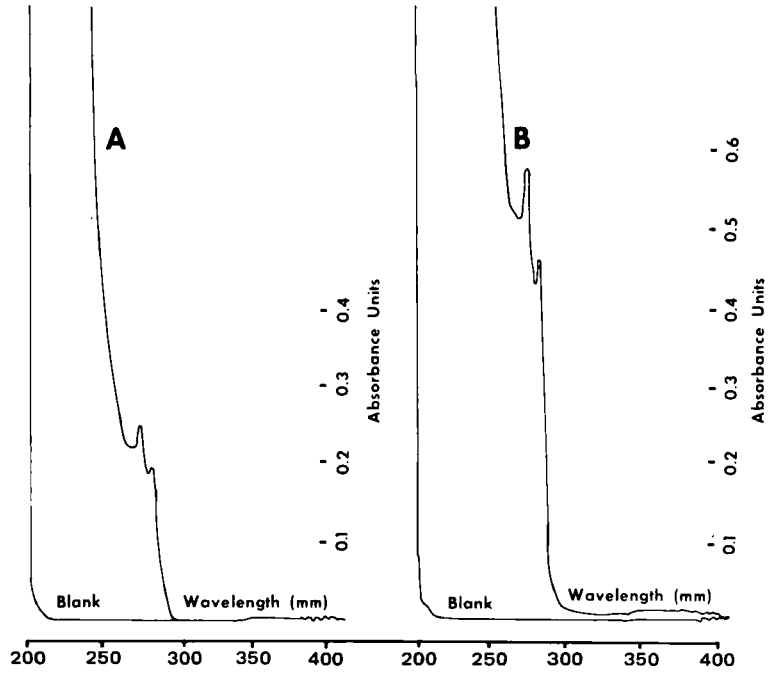

Figure 5—*UV scans of acidified* versus *neutral solution. Key: (A) chlorthalidone in methanol; (B) USP assay preparation.*

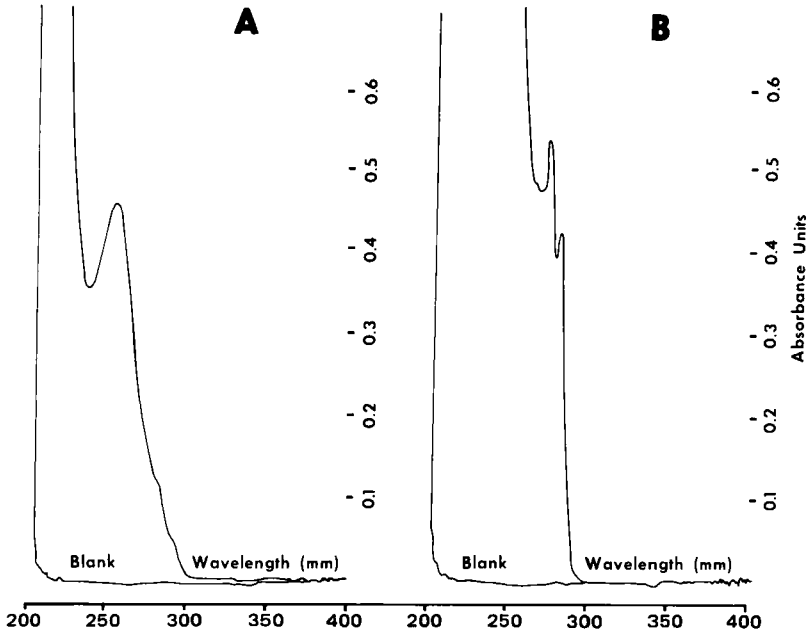

Figure 6—*UV scans of chlorthalidone degradation products. Key: (A) 2-(3-aminosulfonyl-2-chlorobenzoyl)benzoic acid 9.9 μg/ml in acidified MeOH; (B) 3-[(4-chloro-3-aminosulfonyl)-phenyl]-1H-isoindol-1-one 10 μg/ml in acidified MeOH.*

mobile phase was acetonitrile–2% acetic acid (30:70) at a flow rate of 1.5 ml/min. The analytical wavelength was 280 nm.

Reagent Preparation—The internal standard solution was 5 mg/ml of *p*-nitroaniline in methanol.

Approximately 40 mg of chlorthalidone USP standard was accurately weighed and dissolved in 100.0 ml of methanol containing 5.0 ml of the internal standard solution. The solution was diluted 1:1 with water before injection into the liquid chromatograph.

Sample Preparation—Twenty intact tablets were weighed to determine an average tablet weight, finely ground, and a quantity equivalent of 40 mg of chlorthalidone was weighed into a 100-ml volumetric flask. Approximately 50 ml of methanol was added, and the mixture was shaken mechanically for 1 hr. After shaking, 5.0 ml of the internal standard solution was added; the solution was diluted to volume with methanol. A portion of this solution was filtered and diluted 1:1 with water before injection into the liquid chromatograph.

Calculations—The percent of label claim was calculated on the basis of peak height ratios as follows.

$$\frac{(\text{peak height chlorthalidone})_{spl}}{(\text{peak height internal standard})_{spl}} \times \frac{(\text{peak height internal standard})_{std}}{(\text{peak height chlorthalidone})_{std}} \times \frac{\text{Conc. of std.}}{(\text{mg/ml})} \times \frac{100}{\text{Sample Wt}} \times 2 \times \frac{\text{av. tablet wt.}}{(\text{mg/tablet})_{theory}} = \% \text{ Label Claim}$$

RESULTS AND DISCUSSION

The precision data for the HPLC analysis and the precision study conducted on the USP assay (Tables I and III) demonstrate that the HPLC analysis is significantly better than the current compendial method.

When spiked samples were analyzed, recoveries ranged from 98.4 to

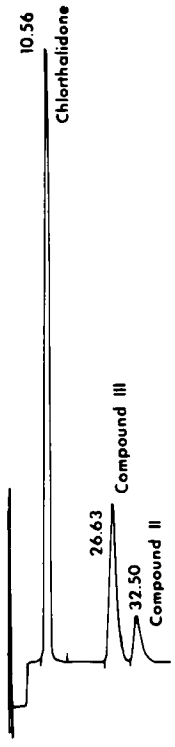

Figure 7—*HPLC system for both degradation products.*

99.2% (Table II). The HPLC method had a relative standard deviation of 0.68% for the analysis of 25 mg of chlorthalidone and 0.84% for 50-mg tablets (Table III). These data were obtained by separate analysts in three laboratories. *p*-Nitroaniline was used as the internal standard. Typical chromatograms for the analysis are shown in Fig. 3.

HPLC analysis of the USP preparation indicated that the solutions being analyzed were mixtures of compounds I, II, and III. The degradation products were isolated from the USP preparation using HPLC. Compound II was identified by comparison with an authentic sample[9] and compound III was identified by spectroscopic techniques[10].

The extent to which chlorthalidone degrades in the acidic methanol appears to depend on pH, water content, and time, although these factors were not all studied in depth. Both of the degradation compounds (II and III) have larger extinction coefficients at the wavelength used for the USP assay than does chlorthalidone. Consequently, the extent of degradation has a marked effect on the assay results and can cause errors in either direction. Figure 4 shows the decrease in chlorthalidone and increase in III with time. Since the degradation is not quantitative and no restraints are prescribed in the USP for pH or time, the absorbance recorded cannot be attributable to any single component.

Comparison of the UV curve for the USP assay preparation with that of chlorthalidone (Figs. 5 and 6) shows substantially the same maxima and minima with slightly greater absorbances. The UV spectrum of compound III is strikingly similar to that of chlorthalidone except for the increased absorptivity for compound III (Fig. 6). The large absorption of chlorthalidone below 260 nm could easily mask the maxima of compound II. This juxtaposition explains how the degradation of chlorthalidone under the USP assay conditions could have been misinterpreted simply as an increase in absorbance due to pH.

The HPLC method described here was designed to quantitate chlorthalidone only. It is stability indicating in so far as chlorthalidone is separated from its degradation products. If a quantitation of the degradation products is desired, a modification of the mobile phase to 85% of 2% acetic acid and 15% acetonitrile flowing at 2 ml/min will allow analysis of I, II, and III concomitantly (Fig. 7).

Close examination of the current compendial assay for chlorthalidone tablets reveals that the drug degrades during analysis. The extent of the degradation is neither quantitative nor reproducible, making the USP assay unreliable. The HPLC method developed in our laboratory is stability indicating and provides a rapid, reliable assay of chlorthalidone. Slight changes in the mobile phase also allow quantitation of the individual degradation products.

[9] Two authentic samples were used: one prepared by Abbott Laboratories, characterized by MS, NMR, IR, CHN; a second obtained as a USP standard. Comparison was done by HPLC and MS to the impurities found in the USP assay preparation.

[10] Compound III was identified by high-resolution mass spectroscopy.

Thermochemical Investigations of Associated Solutions: Calculation of Solute–Solvent Equilibrium Constants from Solubility Measurements

WILLIAM E. ACREE, Jr., DANNY R. McHAN, and J. HOWARD RYTTING ˣ

Received May 13, 1982, from the *Pharmaceutical Chemistry Department, University of Kansas, Lawrence, KS 66045.* Accepted for publication July 29, 1982.

Abstract □ A simple solution model that has lead to successful predictive equations for the partial molar excess properties of a solute in simple binary solvent mixtures containing only nonspecific interactions is extended to include association between the solute and one of the solvent components. An expression is derived and tested for its ability to describe anthracene solubilities in binary solvent mixtures containing benzene. The best description of the experimental solubilities requires the formation of a 1:1 anthracene–benzene complex, with a molarity-based equilibrium constant of $K^c_{AC} \approx 0.107\ M^{-1}$. In comparison, a stoichiometric complexation model which attributes all solubility enhancement to the formation of anthracene–benzene complexes requires a somewhat larger equilibrium constant ($K^c_{AC} \approx 0.228\ M^{-1}$) to describe the solubility behavior of anthracene in the benzene–*n*-heptane system. The results of these calculations illustrate that the determination of solute–solvent equilibrium constants from solubility data depends on the theoretical model used and the manner in which nonspecific interactions are incorporated into the model.

Keyphrases □ Solute–solvent interactions—determination of equilibrium constants from solubility measurements, comparison of the stoichiometric and nearly ideal binary solvent models □ Solvent systems—binary, anthracene solubility determinations in benzene mixtures using the nearly ideal binary solvent model □ Solubility—binary solvent systems, extension of the nearly ideal binary solvent model to include solute–solvent complexation

Current approaches for predicting solubility often overlook the role of specific interactions in determining the solubilities of organic solids in organic solvents. As part of a continuing study on the thermochemical properties of a solute at high dilution in binary solvent mixtures (1–8), this paper considers the calculation of solute–solvent equilibrium constants from solubility measurements.

Historically, the interpretation of solution nonideality has followed two dissimilar lines of reasoning: the physical approach originated by van Laar (9) and the chemical approach proposed by Dolezalek (10). The physical approach may be described by a random distribution of molecules throughout the entire solution, while the chemical approach may be characterized by a specific geometric orientation of one molecule with respect to an adjacent molecule. Even in systems known to contain specific interactions, the need to properly account for nonspecific interactions is recognized.

Arnett *et al.* (11, 12) attempted a classical separation of specific and nonspecific interactions with their "pure" base calorimetric method for determining enthalpies of hydrogen bond formation. The sensitivity of the numerical results to the selection of the model compound and inert solvent (13) points out the difficulty in separating the physical and chemical contributions of solution nonideality. Christian *et al.* (14, 15) proposed a model for relating the thermodynamic properties of polar solutes involved in complex equilibria to those of analogous nonpolar solutes in the same solvent media. In the nonpolar analogue method, the polar solute is replaced by a hypothetical nonpolar molecule which has the same molecular volume and the same total energy of interaction with a nonpolar solvent as does the polar solute. Saluja *et al.* (16) used a somewhat similar rationale in their comparison of enthalpies of transfer of alkenes and the corresponding alkanes from the vapor state to methanol, dimethylformamide, benzene, and cyclohexane, with the more exothermic values for the alkenes in methanol and dimethylformamide attributed to dipole-induced dipole interactions between the solvent and the polarizable π-bond.

Many of the remaining methods for studying association phenomena can be classified as solubility methods. That is, the increase in solubility of a solute at constant fugacity in a complexing-inert solvent mixture, relative to the solubility in pure inert solvent, is generally attributed to the formation of molecular complexes. This primary assumption is common to several thermodynamic methods, such as the partition of solutes between two immiscible liquid phases, the measurement of infinite dilution GC partition coefficients, and the increased solubility of solids. The techniques for calculating formation constants are essentially identical for all solubility methods, as are the difficulties in properly assessing what portion of the observed solubility enhancement is due to nonspecific interactions.

In earlier papers, the experimental solubilities for benzil (5) and *p*-benzoquinone (6) in binary solvent mixtures containing carbon tetrachloride were reported, in which the mole fraction solubility of benzil and *p*-benzoquinone cover a 14- and 6-fold range, respectively. The experimental data were interpreted with solution models developed previously for solubility in systems containing specific solute–solvent interactions and with models of purely nonspecific interactions. A stoichiometric complexation model based entirely on specific interactions (nonspecific interactions ignored) required several equilibrium constants to mathematically describe the experimental results, while the simple nearly ideal binary solvent (NIBS) model based on nonspecific interactions adequately described the observed solubilities without introducing a single equilibrium constant.

The success of the NIBS approach in predicting the binary solvent effect on benzil and *p*-benzoquinone solubilities suggests the possibility that this model may provide a foundation for approximations of the physical interactions even in a system containing chemical interactions such as association between the solute and a complexing solvent. To pursue this idea further, the basic NIBS model

0022-3549/83/0800-0929$01.00/0

is extended to complexing systems and an expression is derived for the calculation of solute–solvent equilibrium constants from solubility measurements. Equilibrium constants for presumed benzene–anthracene complexes are calculated from the newly derived expression and are compared with values calculated from a stoichiometric complexation model based entirely on specific interactions. Although the magnitude of the calculated equilibrium constants are relatively small, and perhaps meaningless, the calculations do illustrate the importance of including nonspecific interactions, particularly in the case of weak association complexes.

THEORETICAL

Stoichiometric Complexation Model—Stoichiometric complexation models have been used frequently to quantitatively explain enhanced solubilities of a polar organic solute in binary mixtures containing an inert hydrocarbon and a polar cosolvent. The basic model assumes complexation between the solute, A, and an interacting cosolvent, C (17–21):

$$A_1 + C_1 \rightleftharpoons AC \overset{+C_1}{\rightleftharpoons} AC_2 \overset{+C_1}{\rightleftharpoons} AC_3 \ldots AC_n$$

Each reaction is described by an appropriate equilibrium constant with concentrations expressed in molarities:

$$K^c_{AC} = \frac{C_{AC}}{C^{sat}_{A_1} C_{C_1}} \qquad \text{(Eq. 1)}$$

$$K^c_{AC_n} = \frac{C_{AC_n}}{C_{AC_{n-1}} C_{C_1}} \qquad \text{(Eq. 2)}$$

where $C^{sat}_{A_1}$ is the saturation solubility of solute in pure inert hydrocarbon (assumed to represent the free solute concentration in binary mixtures as well) and C_{C_1} is the free (uncomplexed) ligand concentration. This particular model assumes only a single solute molecule is present in each complex, but the mathematical form of the resulting equations is not significantly altered by additional solute molecules per complex.

The total solubility of solute in any system, C^{sat}_A, can be expressed as:

$$C^{sat}_A = C^{sat}_{A_1} + K^c_{AC} C^{sat}_{A_1} C_{C_1} + K^c_{AC} K^c_{AC_2} C^{sat}_{A_1} C^2_{C_1} + \ldots \qquad \text{(Eq. 3)}$$

and the total concentration of complexing agent, C_C, as:

$$C_C = C_{C_1} + K^c_{AC} C^{sat}_{A_1} C_{C_1} + 2K^c_{AC} K^c_{AC_2} C^{sat}_{A_1} C_{C_1} + \ldots \qquad \text{(Eq. 4)}$$

If only 1:1 solute–solvent complexes are present, Eqs. 3 and 4 can be combined to give:

$$\text{Fractional change in solubility} = \frac{C^{sat}_A - C^{sat}_{A_1}}{C^{sat}_{A_1}} = \frac{K^c_{AC} C_C}{1 + K^c_{AC} C^{sat}_{A_1}} \qquad \text{(Eq. 5)}$$

and a plot of the fractional change in solubility *versus* added ligand gives a straight line, with the equilibrium constant calculated from the slope.

Direct graphical evaluation of equilibrium constants is also possible for systems having both 1:1 and 1:2 solute–solvent complexes. Suitable mathematical manipulations of Eqs. 3 and 4 result in:

$$\frac{C^{sat}_A - C^{sat}_{A_1}}{C_C - 2(C^{sat}_A - C^{sat}_{A_1})} = \alpha + \beta[C_C - 2(C^{sat}_A - C^{sat}_{A_1})] \qquad \text{(Eq. 6)}$$

where $\alpha = K^c_{AC} C^{sat}_{A_1}/(1 - K^c_{AC} C^{sat}_{A_1})$ and $\beta = K^c_{AC_2} C^{sat}_{A_1}/(1 - K^c_{AC} C^{sat}_{A_1})^2$. Plots of the left-hand side of Eq. 6 *versus* $C_C - 2(C^{sat}_A - C^{sat}_{A_1})$ gives a straight line. The two equilibrium constants, K^c_{AC} and $K^c_{AC_2}$, are easily calculated from the slope and intercept.

Graphical determination of the association constants is depicted in Figs. 1 and 2 for anthracene solubilities in binary solvent mixtures containing benzene, as reported previously (8). Inspection of the two figures reveal that the solubility data can be described adequately throughout most of the concentration region. The model, however, does not describe the solubility in pure benzene. Equilibrium constants calculated from the various slopes and intercepts are small in magnitude, *e.g.*, linear least-squares analysis of the anthracene solubilities in benzene–*n*-heptane mixtures *via* Eq. 6 gives $K^c_{AC} = 0.228\ M^{-1}$ and $K^c_{AC_2} = 0.034\ M^{-1}$. By reporting these numerical values, we do not intend to imply that anthracene–benzene complexes actually exist in solution. Rather, the experimental solubilities are being used to illustrate the calculation of solute–solvent equilibrium constants from solubility data and to show that the numerical values of these constants depend on how nonspecific interactions are incorporated into the theoretical model. This is particularly true for weak association complexes.

Although the stoichiometric complexation model mathematically describes the experimental solubilities, one is naturally suspicious of whether the calculated values of $K^c_{AC_n}$ truly represent specific solute–solvent interactions or the failure of the model to properly describe nonspecific interactions. As demonstrated in an earlier paper (5), experimental solubilities of benzil in simple hydrocarbon mixtures do vary with solvent composition, and there is no reason to expect the free solute concentration to be independent of solvent composition in more complex systems. The failure of Eqs. 5 and 6 to allow for variation in free solute concentration has been one of the main criticisms of this model.

A second limitation of this particular complexation model becomes apparent on writing the solubility expressions in terms of the solubility in the two pure solvents: $(C^{sat}_A)B$ and $(C^{sat}_A)C$[1]. The complete description of experimental solubility in the pure complexing solvent through Eq. 5 requires:

$$\frac{(C^{sat}_A)_C - (C^{sat}_A)_B}{(C^{sat}_A)_B} = \frac{K^c_{AC} C^*_C}{1 + K^c_{AC}(C^{sat}_A)_B} \qquad \text{(Eq. 7)}$$

where C^*_C refers to the concentration of pure complexing solvent in the saturated solution. Within limitations of the approximate relationships:

$$C_i = 10^3\, X^0_i/(X^0_B \overline{V}_B + X^0_C \overline{V}_C) \qquad \text{(Eq. 8)}$$

and

$$(C^{sat}_A)_i = 10^3\, (X^{sat}_A)_i/\overline{V}_i \qquad \text{(Eq. 9)}$$

combination of Eq. 5 and 7–9 enables the solubility in binary solvent mixtures to be expressed as a mole fraction average of the values in the two pure solvents:

$$X^{sat}_A = X^0_B (X^{sat}_A)_B + X^0_C (X^{sat}_A)_C \qquad \text{(Eq. 10)}$$

$$X^0_B = 1 - X^0_C = X_B/(X_B + X_C)$$

Predictions using Eq. 10 are off by as much as 50% for *p*-benzoquinone in *n*-heptane–carbon tetrachloride mixtures (6) and are off by a factor of two for benzil in the isooctane–carbon tetrachloride system (5). It is difficult to attribute the failure of Eq. 10 to specific solute–solvent interactions between the solutes and carbon tetrachloride or to the departure from infinite dilution, as the nearly ideal binary solvent approach describes these experimental solubilities to within a maximum deviation of 6% without introducing a single equilibrium constant.

Equation 10 was derived specifically for binary solvent systems containing both a complexing and inert solvent, but comparable equations have been derived from quite dissimilar models. Sytilin (22) described solubility in mixed solvents as:

$$C^{sat}_A = K_B C_B + K_C C_C \qquad \text{(Eq. 11)}$$

$$K_i = (C^{sat}_A)/C^*_i \qquad i = B, C$$

Equation 11 becomes identical to Eq. 10 when the saturation solubility is sufficiently small. Sytilin's expression is based on the assumption of solvational complexes between the solute and solvent and has been applied to systems in which true association is generally not considered to exist (*i.e.*, iodine–*n*-alkane mixtures). While Eq. 10 does provide reasonable predictions for a rather large number of systems, the expression is obviously incapable of describing systems containing either a maximum or minimum mole fraction solubility. Classic examples are found in studies of phenanthrene (23) and 2-nitro-5-methylphenol (24) in cyclohexane–methylene iodide mixtures where the observed solubilities show maximum values that are almost twice that predicted by Eq. 10. Extension of Eq. 11 to include mixed solvates has been proposed by Sytilin (25) as a means of explaining maximum solubilities, but even this explanation seems unsatisfactory since the existence of maximum solubility in these two systems is predicted by solubility parameter theory.

In a series of papers devoted to infinite dilution solubility of volatile third components in binary mixtures of relatively nonvolatile liquids, Purnell and coworkers (26, 27) have shown that a majority of published

[1] The solubility of the solute in the inert solvent $(C^{sat}_A)_B$ equals the solubility of the uncomplexed solute in the inert solvent $(C^{sat}_{A_1})_B$.

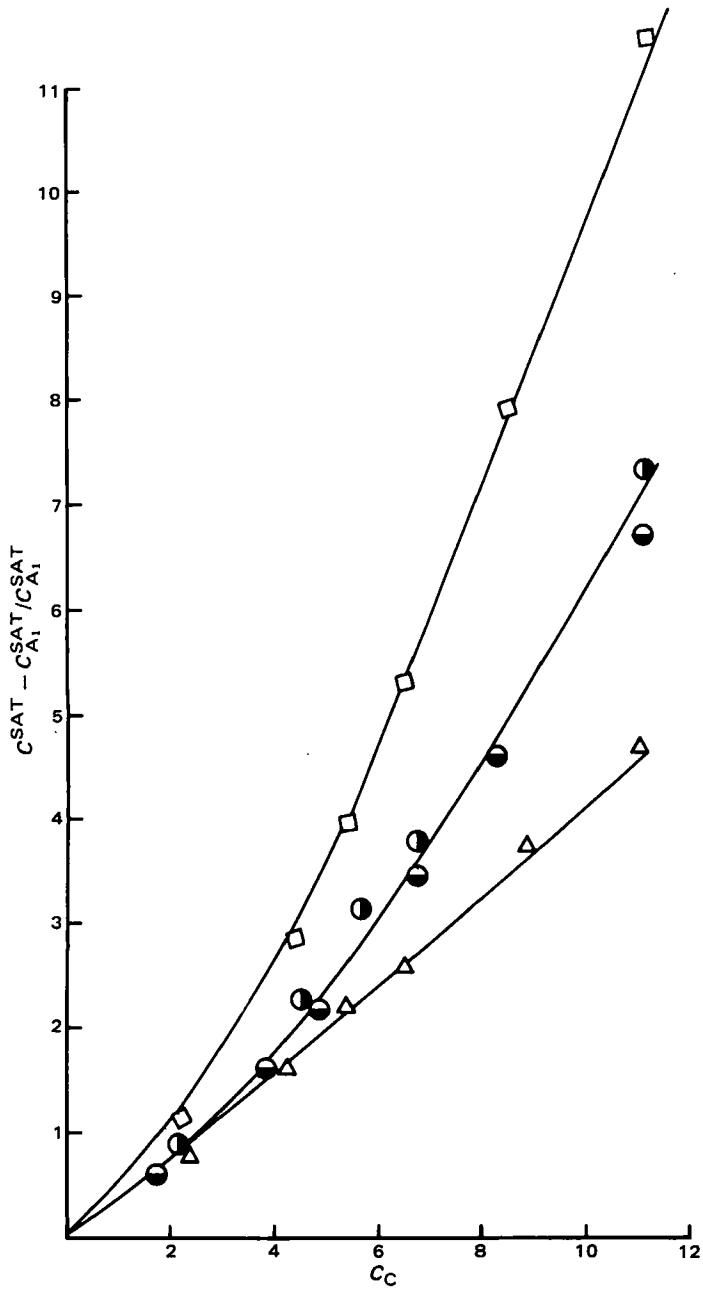

Figure 1—*Graphical determination of* K^c_{AC} *from plots of the fraction change in solubility* versus *benzene molarity in several binary solvents consisting of benzene and* n-*hexane* (◑), n-*heptane* (◒), *cyclohexane* (△), *or isooctane* (□). *The basic model requires additional solute–solvent complexes to explain the nonlinear behavior (see Eqs. 3 and 4).*

data can be described by a simple linear relationship between the volume fraction and partition coefficient:

$$K^0_R = \phi_B(K^0_R)_B + \phi_C(K^0_R)_C \qquad \text{(Eq. 12)}$$

irrespective of the complexing nature of the solvents. ϕ_B and ϕ_C are volume fractions of solvents B and C, respectively, K^0_R is the infinite dilution gas–liquid partition coefficient in the mixted solvent, and $(K^0_R)_B$ and $(K^0_R)_C$ refer to the corresponding values of K^0_R in the pure liquids. Using standard definitions relating partition and activity coefficients, Purnell and Vargas de Andrade (26) have shown that Eq. 12 is equivalent to:

$$\frac{1}{\gamma^\infty_A} = \frac{X^0_B}{(\gamma^\infty_A)_B} + \frac{X^0_C}{(\gamma^\infty_A)_C} \qquad \text{(Eq. 13)}$$

where γ^∞_A is the infinite dilution activity coefficient of the solute (relative to Raoult's law), with only the ideal molar volume approximation.

The activity coefficient of the solute can be related to the solubility of a solid through the thermodynamic relationship:

$$a^{solid}_A = X^{sat}_A \gamma^{sat}_A \qquad \text{(Eq. 14)}$$

in which the activity of the solid depends on temperature only and is determined relative to the pure supercooled liquid. If the solubility is sufficiently small, the activity coefficient of the solute at infinite dilution may be approximated directly as the activity coefficient at saturation:

$$\gamma^{sat}_A = \gamma^\infty_A \qquad \text{(Eq. 15)}$$

Combination of Eqs. 13–15 yields an expression which is identical to Eq. 10.

The fact that several dissimilar solution models reduce to a common mathematical expression in the limits of low solute solubility suggests that there is often more than one interpretation of solution nonideality that will describe the observed solubility data. Each solution model, therefore, must be judged not only on its ability to describe a particular set of experimental data, but also on the validity and limitations of its underlying assumptions and simplifying approximations.

Extension of the NIBS Approach to Solubility in Complexing Systems—The NIBS treatment has been shown to be quite dependable for estimating heats of solution (28, 29), gas–liquid partition coefficients (1–3), and solubilities (4–8) in binary solvent systems that are free of

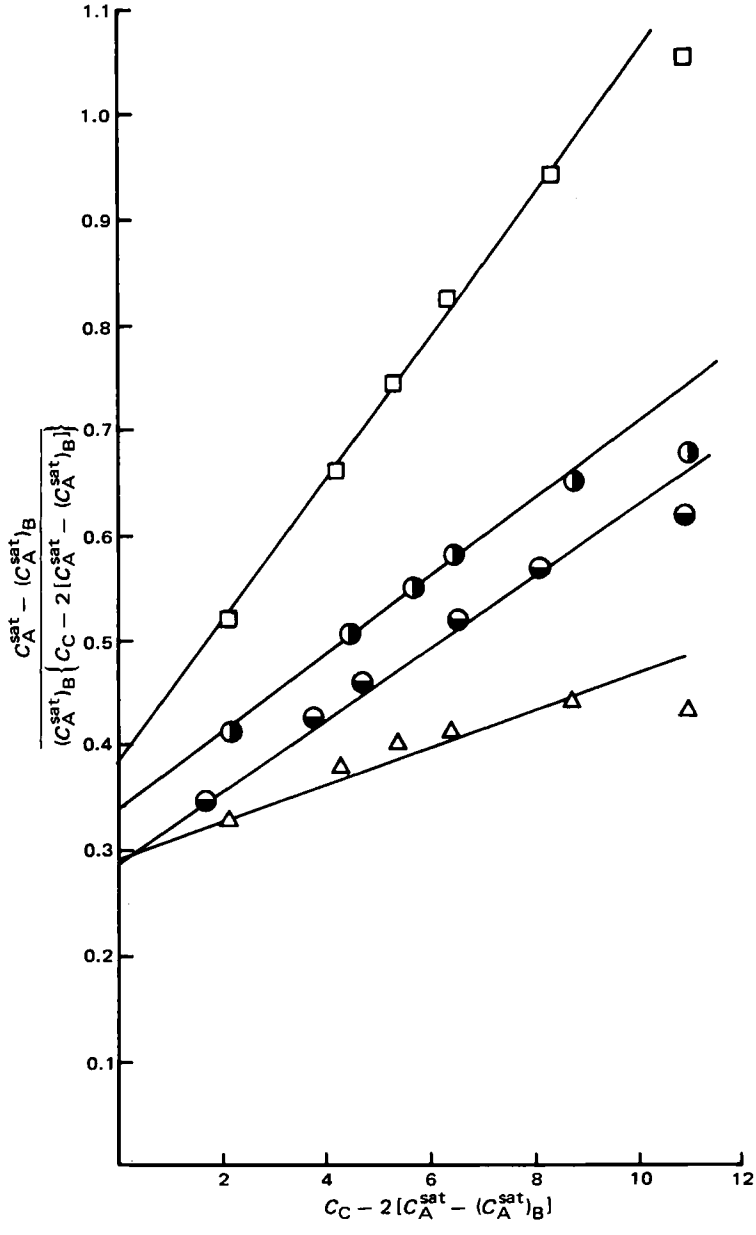

Figure 2—*Graphical determination of* K^c_{AC} *and* $K^c_{AC_2}$ *for anthracene in several binary solvents at 25°. The binary mixtures contained benzene and* n-*hexane* (◑), n-*heptane* (◒), *cyclohexane* (△), *or isooctane* (□).

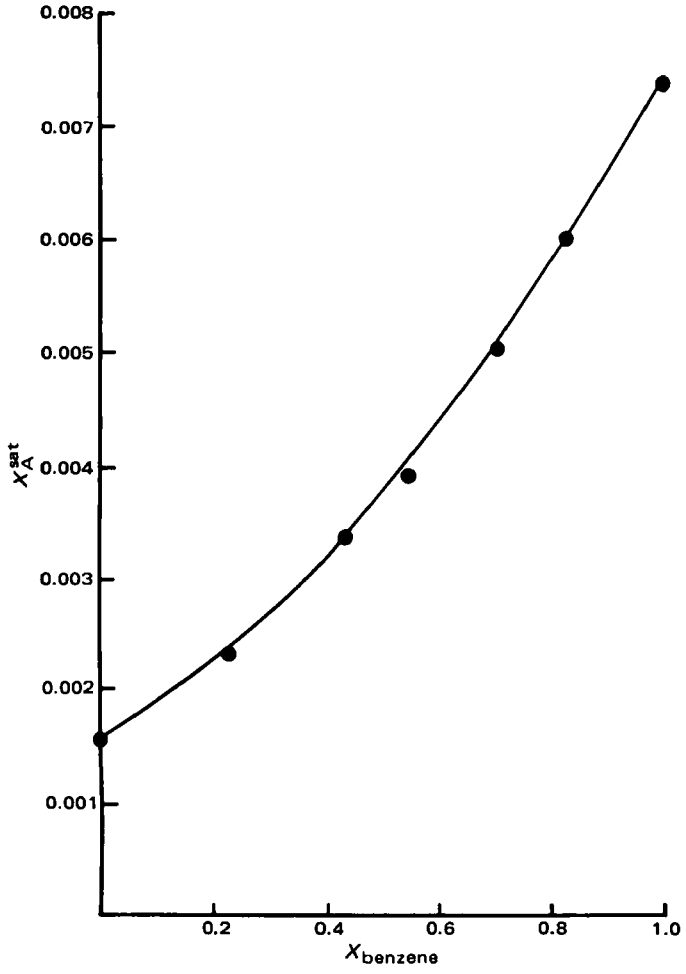

Figure 3—*Comparison between experimental solubilities (●) and the predictions of Eq. 30 (——) for anthracene in binary mixtures of benzene–n-heptane. The free energy of mixing data for the binary solvent ($\Delta\overline{G}^{ex}_{BC}$) is taken from measurements by Harris and Dunlop (32).*

association. The form of the NIBS equation which has been most successful for describing the excess chemical potential of solutes is based on a simple mixing model of a multicomponent system:

$$\Delta G^{mix}_{1,2,\ldots N} = RT \sum_{i=1}^{N} n_i \ln \phi_i + \left(\sum_{i=1}^{N} n_i \overline{V}_i\right)\left(\sum_{i=1}\sum_{j>i} \phi_i \phi_j A_{ij}\right) \quad \text{(Eq. 16)}$$

in which n_i is the number of moles of component i, $\overline{V}_i$ is the molar volume of a pure liquid, ϕ_i is the volume fraction, and A_{ij} is a binary interaction parameter that is independent of solvent composition. The application of Eq. 16 to the quaternary system (A_1, B, C_1, and AC) takes the form of:

$$\Delta G^{mix} = RT(n_{A_1}\ln \phi_{A_1} + n_B \ln \phi_B + n_{C_1}\ln \phi_{C_1} + n_{AC}\ln \phi_{AC}) + (n_{A_1}\overline{V}_A + n_B\overline{V}_B + n_{C_1}\overline{V}_{C_1} + N_{AC}\overline{V}_{AC})(\phi_{A_1}\phi_B A_{A_1B} + \phi_{A_1}\phi_{C_1}A_{A_1C_1} + \phi_{A_1}\phi_{AC}A_{A_1AC} + \phi_B\phi_{C_1}A_{BC_1} + \phi_B\phi_{AC}A_{BAC} + \phi_{C_1}\phi_{AC}A_{C_1AC}) \quad \text{(Eq. 17)}$$

The only assumption is that the molar volume of the AC complex equals the sum of the molar volumes of components A and C, *i.e.*, $\overline{V}_{AC} = \overline{V}_A + \overline{V}_C$. The chemical potentials of the individual components relative to the pure liquids (μ_i^*) are obtained through the appropriate differentiation:

$$\mu_{A_1} - \mu_A^* = RT\left(\ln \phi_{A_1} + 1 - \frac{\overline{V}_A}{\hat{V}_{solution}}\right) + \overline{V}_A[\phi_B(1-\phi_{A_1})A_{A_1B} + \phi_{C_1}(1-\phi_{A_1})A_{A_1C_1} + \phi_{AC}(1-\phi_{A_1})A_{A_1AC} - \phi_B\phi_{C_1}A_{BC_1} - \phi_B\phi_{AC}A_{BAC} - \phi_{C_1}\phi_{AC}A_{C_1AC}] \quad \text{(Eq. 18)}$$

$$\mu_B - \mu_B^* = RT\left(\ln \phi_B + 1 - \frac{\overline{V}_B}{\hat{V}_{solution}}\right) + \overline{V}_B[\phi_{A_1}(1-\phi_B)A_{A_1B} + \phi_{C_1}(1-\phi_B)A_{BC_1} + \phi_{AC}(1-\phi_B)A_{BAC} - \phi_{A_1}\phi_{C_1}A_{A_1C_1} - \phi_{A_1}\phi_{AC}A_{A_1AC} - \phi_{C_1}\phi_{AC}A_{C_1AC}] \quad \text{(Eq. 19)}$$

and

$$\mu_{C_1} - \mu_C^* = RT\left(\ln \phi_{C_1} + 1 - \frac{\overline{V}_C}{\hat{V}_{solution}}\right) + \overline{V}_C[\phi_{A_1}(1-\phi_{C_1})A_{A_1C_1} + \phi_B(1-\phi_{C_1})A_{BC_1} + \phi_{AC}(1-\phi_{C_1})A_{C_1AC} - \phi_{A_1}\phi_B A_{A_1B} - \phi_{A_1}\phi_{AC}A_{A_1AC} - \phi_{B_1}\phi_{AC}A_{B_1AC}] \quad \text{(Eq. 20)}$$

where $\hat{V}_{solution}$ is the molar volume of the true solution and:

$$\frac{1}{\hat{V}_{solution}} = \frac{\phi_{A_1}}{\overline{V}_A} + \frac{\phi_B}{\overline{V}_B} + \frac{\phi_{C_1}}{\overline{V}_C} + \frac{\phi_{AC}}{\overline{V}_A + \overline{V}_C} \quad \text{(Eq. 21)}$$

As shown in many thermodynamic textbooks [*e.g.*, Prigogine and Defay (30)], the chemical potential of stoichiometric component C (and also A) is equal to the chemical potential of the monomeric (uncomplexed) species in the solution:

$$\mu_C = \mu_{C_1} \quad \text{(Eq. 22)}$$

Combining Eqs. 18–22, the Gibbs free energy of mixing can be written as:

$$\Delta G^{mix} = RT\left[n_A\ln \phi_{A_1} + n_B\ln \phi_B + n_C\ln \phi_{C_1} + n_A + n_B + n_C - \frac{(n_A\overline{V}_A + n_B\overline{V}_B + n_C\overline{V}_C)}{\hat{V}_{solution}}\right] + (n_A\overline{V}_A + n_B\overline{V}_B + n_C\overline{V}_C)(\phi_A\phi_B A_{A_1B} + \phi_A\phi_{C_1}A_{A_1C_1} + \phi_A\phi_{AC}A_{A_1AC} + \phi_C\phi_{A_1}A_{A_1C_1} + \phi_C\phi_B A_{BC_1} + \phi_C\phi_{AC}A_{C_1AC} - \phi_{A_1}\phi_{C_1}A_{A_1C_1} - \phi_{A_1}\phi_{AC}A_{A_1AC} - \phi_{C_1}\phi_{AC}A_{C_1AC}) \quad \text{(Eq. 23)}$$

where $n_A = n_{A_1} + n_{AC}$ and $n_C = n_{C_1} + n_{AC}$. Equation 23 obviously contains far too many parameters for useful applications, but reasonable assumptions enable the number of parameters to be greatly reduced. Treatment of all interaction parameters involving the AC complex in a manner similar to that employed by Bertrand (31) for the chloroform–triethylamine complex leads to:

$$A_{A_1AC} = \overline{V}_C^2(\overline{V}_A + \overline{V}_C)^{-2}A_{A_1C_1} \quad \text{(Eq. 24)}$$

and

$$A_{C_1AC} = \overline{V}_A^2(\overline{V}_A + \overline{V}_C)^{-2}A_{A_1C_1} \quad \text{(Eq. 25)}$$

Substitution of these approximations into Eq. 23, after suitable mathematical manipulations, yields the following expression for the Gibbs free energy:

$$\Delta G^{mix} = RT\left[n_A \ln \phi_{A_1} + n_B \ln \phi_B + n_C \ln \phi_{C_1} + n_A + n_B + n_C - \frac{(n_A\overline{V}_A + n_B\overline{V}_B + n_C\overline{V}_C)}{\hat{V}_{solution}}\right] + (n_A\overline{V}_A + n_B\overline{V}_B + n_C\overline{V}_C)(\phi_A\phi_B A_{A_1B} + \phi_B\phi_C A_{BC_1} + \phi_A\phi_C A_{A_1C_1}) \quad \text{(Eq. 26)}$$

Using the equilibrium condition defined by:

$$A_1 + C_1 \rightleftharpoons AC$$

$$K^{\phi}_{AC} = \frac{\phi_{AC}}{\phi_{A_1}\phi_{C_1}} \quad \text{(Eq. 27)}$$

it can be easily shown that the chemical potential of the solid solute (at saturation) is:

$$\mu_A - \mu_A^* = RT\ln a_A^{solid} = RT\left(\ln \phi_{A_1}^{sat} + 1 - \frac{\overline{V}_A}{\hat{V}_{solution}}\right) + \overline{V}_A(1-\phi_A^{sat})^2(\phi_B^0 A_{A_1B} + \phi_C^0 A_{A_1C_1} - \phi_B^0\phi_C^0 A_{BC_1}) \quad \text{(Eq. 28)}$$

where $\phi_B^0 = 1 - \phi_C^0 = \phi_B/(\phi_B + \phi_C)$ and a_A^{solid} is the activity of the solid solute. This activity is defined as the ratio of the fugacity of the solid to the fugacity of the pure supercooled liquid and is calculated from:

$$\ln a_A^{solid} = \int_{T_m}^{T} (\Delta H_A^{fus}/RT^2)dT \quad \text{(Eq. 29)}$$

with the molar enthalpy of fusion (ΔH_A^{fus}) at the normal melting point (T_m).

Inspection of Eq. 28 reveals that, for model systems obeying this expression, the A_1B and $A_{A_1C_1}$ interaction parameters can be eliminated from the basic model *via* the saturation solubilities in the pure solvents, and the A_{BC_1} parameter can be eliminated *via* the excess Gibbs free en-

ergy of the binary solvent mixture calculated according to Eq. 16. Performing these substitutions:

$$RT\left[\ln (a_A^{solid}/\phi_{A1}^{sat}) - 1 + \frac{\overline{V}_A}{\overline{V}_{solution}}\right] = (1 - \phi_A^{sat})^2[\phi_B^0(\Delta\overline{G}_A^{fh})_B^\infty + \phi_C^0(\Delta\overline{G}_A^{fh})_C^\infty - \overline{V}_A(X_B\overline{V}_B + X_C\overline{V}_C)^{-1}\Delta\overline{G}_{BC}^{fh}] \quad \text{(Eq. 30)}$$

where:

$$(\Delta\overline{G}_A^{fh})_B^\infty = (1 - \phi_A^{sat})^{-2} RT\left[\ln (a_A^{solid}/\phi_A^{sat}) - (1 - \phi_A^{sat})\left(1 - \frac{\overline{V}_A}{\overline{V}_B}\right)\right] \quad \text{(Eq. 31)}$$

and

$$(\Delta\overline{G}_A^{fh})_C^\infty = (1 - \phi_A^{sat})^{-2} RT\left[\ln (a_A^{solid}/\phi_{A1}^{sat}) - 1 + \overline{V}_A\left(\frac{\phi_{A1}^{sat}}{\overline{V}_A} + \frac{\phi_C}{\overline{V}_C}\right)\right] \quad \text{(Eq. 32)}$$

The liquid-phase compositions for Eqs. 31 and 32 refer to the saturated pure solvents. In the absence of solute–solvent complexation ($K_{AC}^{\phi} = 0$), the above expression reduces to an equation derived earlier (Eq. VV of Ref. 4) for systems containing only nonspecific interactions.

Despite the complex appearance of Eq. 30, its predictive application to solubilities in mixed solvents is relatively straightforward and is similar in concept to the numerical example presented in an earlier paper (8) for systems containing only nonspecific interactions. The quantities $(\Delta\overline{G}_A^{fh})_B^\infty$ and $(\Delta\overline{G}_A^{fh})_C^\infty$ are calculated from the volume fraction solubility of the solid in the pure solvents using an assumed value for the equilibrium constant. These quantities, with the excess Gibbs free energy of the binary solvent mixture (usually obtained from the literature), are then used in Eq. 30 to calculate ϕ_{A1}^{sat} using a reiterative approach. The overall volume fraction solubility, ϕ_A^{sat}, can be calculated from the solubility of the uncomplexed solute and the equilibrium constant:

$$\phi_A^{sat} = \phi_{A1}^{sat}[1 + \overline{V}_A K_{AC}^{\phi}\phi_{C_1}/(\overline{V}_A + \overline{V}_C)] \quad \text{(Eq. 33)}$$

The entire procedure can be repeated until the numerical value of K_{AC}^{ϕ} that best describes the experimental solubility in a particular binary solvent system is obtained.

Graphical comparison between the experimental solubilities and predictions of Eq. 30 (with $K_{AC}^{\phi} = 1.91$) are shown in Figs. 3 and 4 for anthracene in *n*-heptane–benzene and isooctane–benzene mixtures. Properties of the pure components were taken from a previous tabulation (8). Examination of these two figures indicates Eq. 30 can describe adequately the experimental data using a single equilibrium constant[2]. Readers are reminded that the calculation of association constants for a presumed anthracene–benzene complex does not imply the authors believe such a complex actually exists in solution. As in all cases, the presence of molecular complexes should be supported by independent measurements involving spectroscopy, calorimetry, *etc.*

Although the numerical value of $K_{AC}^{\phi} = 1.91$ is much larger than the equilibrium constant used in Eq. 6, direct comparison requires both constants to be based on an identical concentration scale. Doing this conversion:

$$K_{AC}^{c} = K_{AC}^{\phi}\frac{\overline{V}_A\overline{V}_C}{(\overline{V}_A + V_C)} \quad \text{(Eq. 34)}$$

one finds that the molarity-based equilibrium constant of Eq. 6 ($K_{AC}^{c} = 0.228\ M^{-1}$) is actually two times greater than the molarity-based equilibrium constant of Eq. 30 ($K_{AC}^{c} = 0.107\ M^{-1}$). These calculations further support our earlier observation (5) that equilibrium constants determined from solution models based entirely on specific interactions may not truly represent specific solute–solvent interactions, but rather, in some cases, the failure of the particular solution model to properly describe nonspecific interactions.

RESULTS AND DISCUSSION

A simple solution model that has led to successful predictive equations for the thermochemical properties of a solute in simple binary solvent systems containing only nonspecific interactions has been extended to include association between the solute and one of the solvent components. An expression has been derived and tested for its ability to describe anthracene in binary solvent mixtures containing benzene. The best description of the experimental solubilities required the postulation of a 1:1 anthracene–benzene complex, with a molarity-based equilibrium constant of $K_{AC}^{c} = 0.107\ M^{-1}$. In comparison, a stoichiometric complexation model that attributes all solubility enhancement to the formation of anthracene–benzene complexes required a larger equilibrium constant ($K_{AC}^{c} = 0.228\ M^{-1}$) to describe the six-fold mole fraction range of anthracene solubilities in the benzene–*n*-heptane system. That the two equilibrium constants differ by a factor of two demonstrates the importance of including nonspecific interactions in equilibrium constant calculations, particularly in the case of weak association complexes.

Furthermore, it has been shown that several dissimilar solution models, developed previously for predicting solubility in binary solvent mixtures, reduce to a common mathematical expression in the limits of low solute solubility. Based on this observation, we conclude that there may be more than one interpretation of solution nonideality that will describe the observed solubility data. As criteria for selecting the best description of solution nonideality, we suggest that each solution model should be judged on its ability to describe the thermochemical properties of the solute (in this case, solubility) and on the validity of the model's underlying assumptions and simplifying approximations.

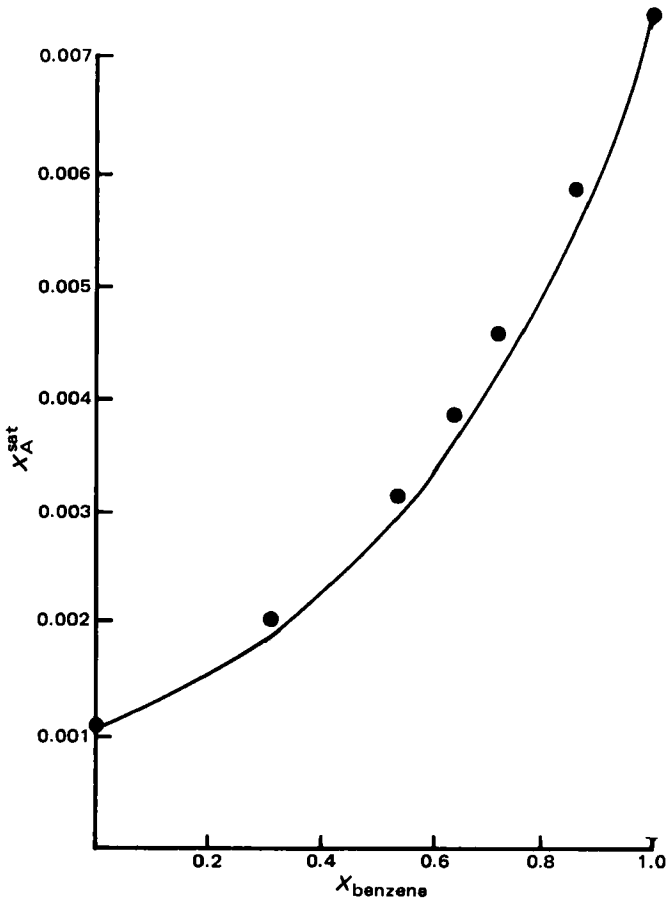

Figure 4—*Comparison between experimental solubilities (●) and the predictions of Eq. 30 (—) for anthracene in binary mixtures of benzene–isooctane. The free energy of mixing data for the binary solvent is taken from an article by Weissman and Wood (33).*

[2] Improvements in the descriptive ability of Eq. 30 could be obtained by permitting the equilibrium constant to vary from one solvent system to another. For example, the best description of the benzene–isooctane system required a slightly larger value for K_{AC}^{ϕ}. This fact is not too disturbing as many of the prevailing solution theories predict that complex formation constants will not be constant in different solvents, even if a maximum-randomness criterion is met by all the species involved in the formation reaction in each of the solvents (34, 35). The numerical value quoted in the text is for the benzene–*n*-heptane system.

Physicochemical and Topological Correlates of the Enzymatic Acetyltransfer Reaction

S. C. BASAK, D. P. GIESCHEN, D. K. HARRISS, and V. R. MAGNUSON ˣ

Received April 26, 1982, from the *Department of Chemistry, University of Minnesota–Duluth, Duluth, MN 55812.* Accepted for publication August 4, 1982.

Abstract □ The relative potencies of a series of substituted anilines as acetyl acceptors in the enzymatic *N*-acetylation reaction have been correlated using physicochemical substituent constants (π, σ^-), molecular connectivity indices ($^1\chi$, $^1\chi^v$), and newly formulated information–theoretic topological indices (IC, SIC). Results indicate a predominant role of the topological steric parameters in determining the rates of the *N*-acetyltransferase reaction.

Keyphrases □ *p*-Nitroaniline—determination of the *N*-acetylation reaction, topological indices □ Topological indices—information–theoretic, rate determination of the *N*-acetylation reaction, comparison with physicochemical constants and molecular connectivity indices, substituted anilines □ *N*-Acetylation reaction—of substituted anilines, enzymatic acetyltransferase, rate determination using information–theoretic topological indices

The biochemical acetyl transfer reaction is important not only for normal physiological processes, but also in the extramicrosomal metabolism of therapeutically active compounds like isoniazid (1, 2), *p*-aminosalicylic acid (3), sulfonamides (4, 5), and anticancer drugs–*viz.*, 6-aminonicotinamide (4). Acetyltransferase is capable of catalyzing the transfer of the acetyl moiety from acetyl CoA (CoASAc) to aliphatic and aromatic amines as well as the reversible transfer of an acetyl group between different aromatic amines (6, 7). Therefore, one of the probable ways of elucidating the molecular basis of this reaction might arise from the study of acetyl group transfer rates from a particular acetylated amine (donor) to other variously substituted amines (acceptor) that vary in their physicochemical and geometrical characteristics in a well-defined manner.

Jacobson (6) studied the rates of acetyl transfer from *p*-(*p*-acetylaminophenylazo)benzenesulfonate to a series of substituted anilines in the presence of purified pigeon liver acetyltransferase. The electronegativity of the substituent(s) was conjectured to have an overwhelming role on the rates of the reaction. This notion gained support from the quantum chemical studies of Perault and Pullman (8) where the electronic charge on the amine nitrogen (ϵ) of the acceptor was shown to parallel the acetylation rate. Further studies by Hansch *et al.* (9) using substituent constants derived from physical organic model systems showed that a biparametric relationship using hydrophobic (π) and electronic (σ^- or ϵ) parameters could adequately correlate the biological data.

Physicochemical and Topological Correlates of the Enzymatic Acetyltransfer Reaction

S. C. BASAK, D. P. GIESCHEN, D. K. HARRISS, and V. R. MAGNUSON ˣ

Received April 26, 1982, from the *Department of Chemistry, University of Minnesota–Duluth, Duluth, MN 55812.* Accepted for publication August 4, 1982.

Abstract □ The relative potencies of a series of substituted anilines as acetyl acceptors in the enzymatic *N*-acetylation reaction have been correlated using physicochemical substituent constants (π, σ^-), molecular connectivity indices ($^1\chi$, $^1\chi^v$), and newly formulated information–theoretic topological indices (IC, SIC). Results indicate a predominant role of the topological steric parameters in determining the rates of the *N*-acetyltransferase reaction.

Keyphrases □ *p*-Nitroaniline—determination of the *N*-acetylation reaction, topological indices □ Topological indices—information–theoretic, rate determination of the *N*-acetylation reaction, comparison with physicochemical constants and molecular connectivity indices, substituted anilines □ *N*-Acetylation reaction—of substituted anilines, enzymatic acetyltransferase, rate determination using information–theoretic topological indices

The biochemical acetyl transfer reaction is important not only for normal physiological processes, but also in the extramicrosomal metabolism of therapeutically active compounds like isoniazid (1, 2), *p*-aminosalicylic acid (3), sulfonamides (4, 5), and anticancer drugs–*viz.*, 6-aminonicotinamide (4). Acetyltransferase is capable of catalyzing the transfer of the acetyl moiety from acetyl CoA (CoASAc) to aliphatic and aromatic amines as well as the reversible transfer of an acetyl group between different aromatic amines (6, 7). Therefore, one of the probable ways of elucidating the molecular basis of this reaction might arise from the study of acetyl group transfer rates from a particular acetylated amine (donor) to other variously substituted amines (acceptor) that vary in their physicochemical and geometrical characteristics in a well-defined manner.

Jacobson (6) studied the rates of acetyl transfer from *p*-(*p*-acetylaminophenylazo)benzenesulfonate to a series of substituted anilines in the presence of purified pigeon liver acetyltransferase. The electronegativity of the substituent(s) was conjectured to have an overwhelming role on the rates of the reaction. This notion gained support from the quantum chemical studies of Perault and Pullman (8) where the electronic charge on the amine nitrogen (ϵ) of the acceptor was shown to parallel the acetylation rate. Table I—Partitioning of *p*-Nitroaniline

Partition Class	Coordinate	Number of Atoms in the Partitioned Class[a]	Probability ($p_i = n_i/n$)
I	1^4	4	4/16
II	1^3	2	2/16
III	2^5	2	2/16
IV	$1^4 2^2 2^2$	1	1/16
V	$1^1 1^1 1^4$	1	1/16
VI	$1^1 1^4 2^4$	4	4/16
VII	$1^4 1^5 2^4$	1	1/16
VIII	$1^3 1^4 2^4$	1	1/16

[a] Total number of atoms in the molecule = 16.

One of the important outcomes of the Hansch analysis in this area was that the steric factor is insignificant in enzymatic acetyl transfer process, a conclusion drawn from a study of six compounds. Jacobson (6) studied the *N*-acetylation of 10 substituted anilines. Although the physicochemical substituent constants for the remaining four compounds were not available then (9), some of them can be derived today. Moreover, in recent years, a number of information–theoretic (10–14) and molecular connectivity-type (15–20) topological indices have been derived and found to be of use in biological correlations. While valence molecular connectivity ($^m\chi^v$) indices are excellent electronic parameters (21), simple connectivity indices ($^m\chi$) and information–theoretic indices derived from the topological neighborhood of vortices (atoms) in the molecular graph (structure) are steric parameters that encode information regarding the topological shape of the molecule (11–15, 22). Although the action of nonspecific bioactive molecules is mainly guided by their hydrophobicity, the *in vivo* and *in vitro* activity of specific biologically active agents, *i.e.*, molecules which act by virtue of being recognized by an enzyme or a physiological receptor, is highly dependent on stereoelectronic makeup associated with the molecular architecture (23, 24).

Hence it was of interest to examine whether steric parameters have any role in the mechanism of action of *N*-acetyltransferase. To this end, correlations of the rates of enzymatic acetylation of amines with the physicochemical substituent constants (π, σ^-), molecular connectivity indices ($^1\chi$, $^1\chi^v$), as well as information–theoretic topological indices (11), *i.e.*, information content (IC) and structural information content (SIC), have been attempted. Also, a comparative study of the role of physicochemical *versus* theoretical parameters in the correlation of biological data has been undertaken using multiparametric regression equations.

EXPERIMENTAL

Calculation of the Hydrophobic Constant (π)—The hydrophobic parameter for the various substituents in the aniline derivatives are taken from Hansch and Leo (25). In cases where more than one substituent is present, the combined lipophilic effect is calculated by the addition of the individual contributions of the groups with respect to lipophilicity.

Calculation of the Electronic Parameter (σ^-)—The σ^- values for the various groups in the aniline system are taken from Hansch *et al.* (9, 25), Hoefnagel *et al.* (26), and Zeng (27). Since the simple additivity rule is obeyed with respect to electronic parameters of the Hammett type from a single system (28), the electronic effects (σ^-) of more than one substituent in the ring is taken to be the sum of their individual contributions in the aniline system.

Calculation of Molecular Connectivity ($^1\chi$)—To each atom of the hydrogen-suppressed graph a δ value is assigned corresponding to the number of nonhydrogen atoms bonded to it. No consideration is made to the class of atom or type of bond. A connectivity value for a bond C_k (connecting atoms i and j) is computed as follows (15):

$$C_k = (\delta_i \delta_j)^{-1/2} \qquad \text{(Eq. 1)}$$

And $^1\chi$ is calculated as the sum of all connectivity terms:

$$^1\chi = \sum_k C_k \qquad \text{(Eq. 2)}$$

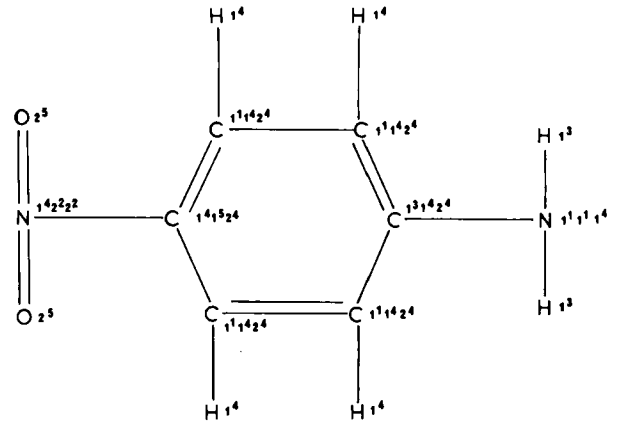

Figure 1—*Coordinate-attached structure of* p-*nitroaniline.*

Calculation of Valence Molecular Connectivity ($^1\chi^v$)—To each atom of the hydrogen-depleted skeleton a δ^v value is assigned as follows (15, 21):

$$\delta^v = Z_i^v - h_i \qquad \text{(Eq. 3)}$$

where Z_i^v is the number of valence electrons and h_i is the number of hydrogen atoms attached to the particular atom. Thereafter, $^1\chi^v$ is calculated in a similar manner as $^1\chi$ by substituting δ^v for δ in Eq. 1.

Calculation of Information Content (IC) and Structural Information Content (SIC) from the Molecular Graph—In this graph–theoretic formalism, the total (nonhydrogen-suppressed) molecular graph is considered to define the various topological indices. The method is sufficiently general to include the linear graphs as well as multigraphs. If G is a molecular graph with vertex set $X(G)$ and $A_i (i = 1, 2, \ldots, k)$ is a partition of $X(G)$, then a probability scheme is given by:

$$\begin{pmatrix} A_1, A_2, \ldots, A_k \\ p_1, p_2, \ldots, p_k \end{pmatrix}$$

where $p_i = n_i/n$, and n_i and n are the cardinalities of A_i and $X(G)$, respectively. Then, the information content (IC) of the graph G with respect to this mode of partition of $X(G)$ is given by Shannon's formula (29):

$$IC(X(G)) = -\sum_k p_i \log_2 p_i \text{ bits} \qquad \text{(Eq. 4)}$$

The logarithm is taken at a basis 2 to measure the information in bits. By defining a first-order topological neighborhood and an equivalence relation on the vertex set $X(G)$ of a molecular graph, Sarkar *et al.* (10) computed the first-order topological information content of various molecular graphs. Subsequently Basak *et al.* (30) defined another information–theoretic topological index, structural information content (SIC):

$$SIC = IC/\log_2 n \qquad \text{(Eq. 5)}$$

Let us take a member of the series of anilines, *p*-nitroaniline (Fig. 1), to exemplify the partitioning of atoms into disjoint classes (Table I) and also the calculation of IC and SIC. In this graph–theoretic treatment, which is patterned after the work of Sarkar *et al.* (10), all four hydrogen atoms attached to the aromatic ring lie in the same disjoint subset. This partitioing scheme differs from that proposed by Kier (14) where chemical intuition is also used in the decomposition of the vertex set of the molecular graph into disjoint subsets.

RESULTS AND DISCUSSION

Table II shows the π and σ^- values of the substituents, $^1\chi$ and $^1\chi^v$ indices from the hydrogen-suppressed molecular graphs, IC and SIC indices

Table II—Biological Properties and Molecular Descriptors for Aniline Derivatives

Compound	Relative Rate (A_x)	σ^-	π	$^1\chi$	$^1\chi^v$	IC (bits)	SIC
Aniline	0.70	0.00	0.00	3.3938	2.1994	2.0060	0.5269
p-Me-Aniline	1.00	−0.17	0.48	3.7877	2.6100	2.3432	0.5733
p-Cl-Aniline	1.09	0.23	0.93	3.7877	2.7120	2.0138	0.5289
p-Br-Aniline	1.12	0.23	1.13	3.7877	3.1021	2.0185	0.5301
p-NO_2-Aniline	0.34	1.27	0.50	4.6984	2.6988	2.7500[a]	0.6875[b]
Sulfanilamide	0.18	0.91	−1.16	4.9900	3.1110	2.8795	0.6778
p-NH_2-Salicylic acid	0.15	0.38	−0.99	5.1091	2.9280	3.3083	0.7934
p-NH_2-Benzoic acid	0.03	0.77	−0.32	4.6984	2.7878	3.0286	0.7409
Sulfanilic acid	0.01	0.48	−4.76	4.9980	3.0422	3.0588	0.7335

[a] $IC = 2 \times 4/16 \log_2(16/4) + 2 \times 2/16 \log_2(16/2) + 4 \times 1/16 \log_2(16/1) = 2.7500$ bits. [b] $SIC = IC/\log_2(16) = 0.6875$.

from the total chemical graphs, and the relative rates of enzymatic acetylation (A_x) for a series of substituted anilines; the experimental data was taken from the work of Jacobson (6). Since our approach was to have a comparative study between the physicochemical and theoretical descriptors in the correlation of acetylation rates, *p*-aminohippuric acid was not considered for correlation because the σ^- value for the *para* substituent was not available.

Table III shows the correlation matrix (31) for A_x and the six molecular descriptors under study. High correlations are observed between the variables A_x, IC, SIC,and $^1\chi$. The parameters $^1\chi^v$, π, and σ^- are poorly correlated with A_x and the other three descriptors. Linear correlation results of each of the six descriptors with A_x are:

$$A_x = -0.616\,(^1\chi) + 3.20 \qquad \text{(Eq. 6)}$$
$$n = 9 \quad r = 0.88 \quad s = 0.24 \quad F_{1,7} = 23\ (p < 0.002)$$

$$A_x = -0.473\,(^1\chi^v) + 1.84 \qquad \text{(Eq. 7)}$$
$$n = 9 \quad r = 0.30 \quad s = 0.48 \quad F_{1,7} = 0.68\ (p < 0.439)$$

$$A_x = -0.830\,(\text{IC}) + 2.67 \qquad \text{(Eq. 8)}$$
$$n = 9 \quad r = 0.91 \quad s = 0.20 \quad F_{1,7} = 35\ (p < 0.001)$$

$$A_x = -4.07\,(\text{SIC}) + 3.13 \qquad \text{(Eq. 9)}$$
$$n = 9 \quad r = 0.92 \quad s = 0.20 \quad F_{1,7} = 36\ (p < 0.001)$$

$$A_x = 0.181\,(\pi) + 0.598 \qquad \text{(Eq. 10)}$$
$$n = 9 \quad r = 0.70 \quad s = 0.36 \quad F_{1,7} = 6.7\ (p < 0.036)$$

$$A_x = -0.648\,(\sigma^-) + 0.807 \qquad \text{(Eq. 11)}$$
$$n = 9 \quad r = 0.64 \quad s = 0.38 \quad F_{1,7} = 4.8\ (p < 0.065)$$

Here n is the number of data points, r the correlation coefficient, s the standard deviation, and F is the F-ratio between the variances of the observed and calculated values.

Equations 6–11 account for 76.8, 8.7, 83.4, 83.7, 48.7, and 40.6% of the variance (r^2) in A_x, respectively. It is clear from these results that steric (topological) parameters like $^1\chi$, IC, and SIC have a very important role in determining the rates of enzymatic acetylation as compared with the hydrophobic (π) or electronic (σ^- or $^1\chi^v$) parameters. The same trend is obtained with the parabolic correlations of A_x with $^1\chi$, $^1\chi^v$, IC, SIC, and π:

$$A_x = 0.462\,(\pi) + 0.0761\,(\pi)^2 + 0.494 \qquad \text{(Eq. 12)}$$
$$n = 9 \quad r = 0.87 \quad s = 0.26 \quad F_{2,6} = 9.8\ (p < 0.013)$$

$$A_x = 2.97\,(^1\chi) - 0.418\,(^1\chi)^2 - 4.34 \qquad \text{(Eq. 13)}$$
$$n = 9 \quad r = 0.90 \quad s = 0.23 \quad F_{2,6} = 12\ (p < 0.007)$$

$$A_x = -0.782\,(^1\chi^v) + 0.0574\,(^1\chi^v)^2 + 2.25 \qquad \text{(Eq. 14)}$$
$$n = 9 \quad r = 0.30 \quad s = 0.51 \quad F_{2,6} = 0.29\ (p < 0.759)$$

Table III—Correlation Matrix

	A_x	π	$^1\chi$	$^1\chi^v$	IC	SIC	σ^-
A_x	1.00						
π	0.70	1.00					
$^1\chi$	−0.88	−0.62	1.00				
$^1\chi^v$	−0.30	−0.36	0.63	1.00			
IC	−0.91	−0.63	0.95	0.46	1.00		
SIC	−0.92	−0.60	0.94	0.43	0.99	1.00	
σ^-	−0.64	−0.16	0.69	−0.37	0.55	0.53	1.00

$$A_x = -1.73\,(\text{IC}) + 0.174\,(\text{IC})^2 + 3.79 \qquad \text{(Eq. 15)}$$
$$n = 9 \quad r = 0.92 \quad s = 0.224 \quad F_{2,6} = 16\ (p < 0.004)$$

$$A_x = -17.60\,(\text{SIC}) + 10.5\,(\text{SIC})^2 + 7.39 \qquad \text{(Eq. 16)}$$
$$n = 9 \quad r = 0.93 \quad s = 0.20 \quad F_{2,6} = 18\ (p < 0.003)$$

Of the nine compounds in Table II, the last seven are homogeneous in the sense that each of them has an electron-withdrawing substituent in the position *para* to the amino group. Therefore, it is expected that steric fit may better correlate the biological data for such a homogeneous group of compounds. Regression equations (Eqs. 17–20) show this to be the case:

$$A_x = -6.67\,(^1\chi) + 0.666\,(^1\chi)^2 + 16.8 \qquad \text{(Eq. 17)}$$
$$n = 7 \quad r = 0.98 \quad s = 0.13 \quad F_{2,4} = 41\ (p < 0.002)$$

$$A_x = -4.49\,(\text{IC}) + 0.695\,(\text{IC})^2 + 7.35 \qquad \text{(Eq. 18)}$$
$$n = 7 \quad r = 0.99 \quad s = 0.09 \quad F_{2,4} = 93\ (p < 0.001)$$

$$A_x = -28.5\,(\text{SIC}) + 18.6\,(\text{SIC})^2 + 11.0 \qquad \text{(Eq. 19)}$$
$$n = 7 \quad r = 0.99 \quad s = 0.10 \quad F_{2,4} = 69\ (p < 0.001)$$

$$A_x = 0.451\,(\pi) + 0.0781\,(\pi)^2 + 0.411 \qquad \text{(Eq. 20)}$$
$$n = 7 \quad r = 0.90 \quad s = 0.25 \quad F_{2,4} = 9.0\ (p < 0.033)$$

The addition of the hydrophobic parameter, π, to Eqs. 17 and 18 made only marginal improvement in the correlation coefficient.

It is evident from the above that topological indices reveal a predominant role of steric factor in determining the rate of the enzymatic *N*-acetyltransferase reaction, although Hansch *et al.* (9) could assign no role of the steric descriptor with a smaller subset of these compounds. With nine compounds a topological parameter such as $^1\chi$, IC, or SIC emerged to be the single variable best suited for correlation of this type of bioactive agent. The significant relationships developed above may be utilized in the rational design of substrates for *N*-acetyltransferase.

Pharmacokinetics and Anesthetic Potency of a Thiopental Isomer

DONALD R. STANSKI[x], PATRICK G. BURCH, SANDRA HARAPAT, and RICHARD K. RICHARDS[†]

Received March 9, 1982, from the *Departments of Anesthesia and Medicine (Clinical Pharmacology), Stanford University School of Medicine, Stanford, CA 94305* and the *Palo Alto Veterans Administration Hospital, Palo Alto, CA 94304.* Accepted for publication July 29, 1982. [†] Deceased

Abstract □ In developing a high-performance liquid chromatographic assay for thiopental [5-ethyl-5-(1-methylbutyl)-2-thiobarbituric acid], a thiopental isomer [5-ethyl-5-(1-ethylpropyl)-2-thiobarbituric acid] was found. This isomer occurs (6–7%) in supposedly pure thiopental and in the commercially available thiopental sodium administered to patients for induction of anesthesia. A similar type of isomer also occurs in pentobarbital, the oxybarbiturate analogue of thiopental. Because the disposition and anesthetic potency of the isomer is unknown, its pharmacokinetic properties were determined in humans and its anesthetic potency in mice. In five surgical patients, the terminal elimination half-life, clearance, and volume of distribution at steady state of the isomer were not statistically different from those of thiopental. In mice, the isomer proved to be as effective as thiopental for induction of anesthesia. The LD_{50} and sleep time at one-half the LD_{50} did not statistically differ between the two compounds in mice. The close structural similarity of thiopental and the isomer results in similar pharmacokinetic and anesthetic properties. It does not appear critical that the isomer be separated from thiopental in subsequent pharmacological research.

Keyphrases □ Thiopental—isomer determination in serum by high-performance liquid chromatography, pharmacokinetics in humans, anesthetic potency in mice □ Pharmacokinetics—of a thiopental isomer in humans, comparison with thiopental □ Anesthetic agents—potency of a thiopental isomer in mice, comparison with thiopental

Previous high-performance liquid chromatographic (HPLC) assays for thiopental apparently lacked the chromatographic resolution to separate thiopental from any side-chain isomer (1–4). This paper describes an HPLC assay that separates thiopental, 5-ethyl-5-(1-methylbutyl)-2-thiobarbituric acid, from this isomeric material, 5-ethyl-5-(1-ethylpropyl)-2-thiobarbituric acid (see Fig. 1). The isomer was found both in standard thiopental obtained from the manufacturer and the commercially available thiopental sodium used for the induction of anesthesia in patients. It apparently is formed during the manufacture of thiopental[1]. The presence of a similar isomer has been described for pentobarbital [5-ethyl-5-(1-methylbutyl) barbituric acid], the oxybarbiturate analogue of thiopental (5).

EXPERIMENTAL

Apparatus and Reagents—A liquid chromatograph[2] was equipped with a variable-wavelength detector[3] and column heater. The phosphoric acid, monobasic potassium phosphate, sodium hydroxide, and sodium carbonate were certified ACS grade[4]; anhydrous ethyl ether was reagent grade[5]; acetonitrile was HPLC grade[6]. The sodium salt of thiopental[7] and the thiopental isomer[8] were used for preparation of the standard curves. The thiopental contained 9.0% of the isomer, based on peak heights from a sample separated on the HPLC assay. The isomer did not contain thiopental; only a single peak was seen when the isomer was chromatographed on the HPLC assay. Thiamylal acid[9] was used as an internal standard for measurement of thiopental and the isomer.

Thiopental Protein Precipitation and Chromatography—The HPLC assay described by Kabra *et al.* (6) was modified. For thiopental concentrations >200 ng/ml, an equal volume of acetonitrile containing the internal standard (2.5 or 25 μg/ml) was added to human serum (200 μl) and mixed on a vortex mixer. Following two sequential centrifugations, the acetonitrile supernatant was injected into the chromatograph.

0022-3549/83/0800-0937$01.00/0

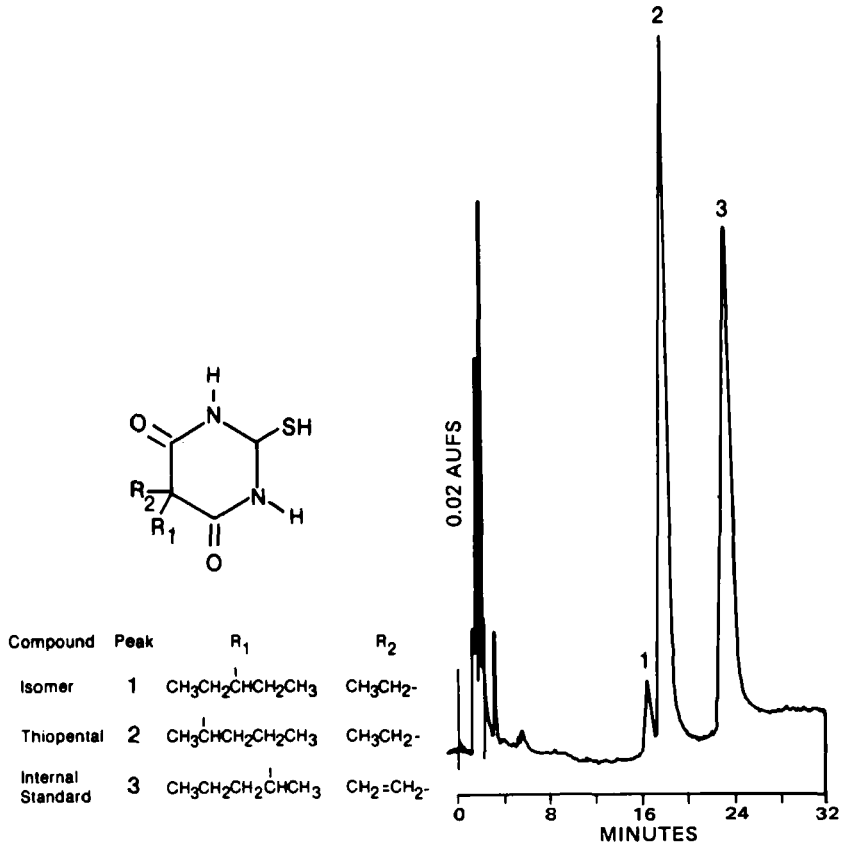

Figure 1—*A chromatogram demonstrating the presence of the isomer in a sample of supposedly pure thiopental. The structures of thiopental, the isomer, and the internal standard (thiamylal) are as indicated.*

Appropriate concentrations of the internal standard were added before the protein precipitation. To increase the sensitivity of the assay to 25 ng/ml, the ether extraction procedure described for the thiopental isomer can be used. Because the thiopental concentrations were >200 ng/ml for the duration of the study, it was not necessary to use the extraction.

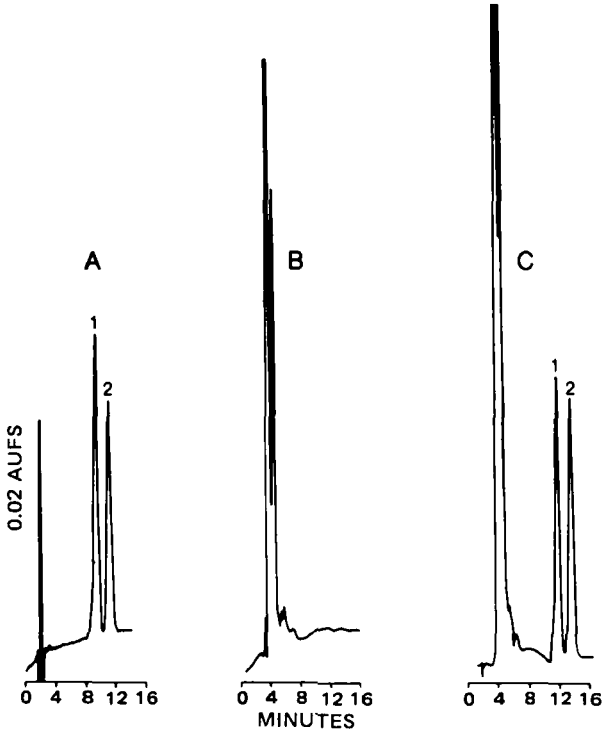

Figure 2—*Typical chromatograms obtained using the assay described for measurement of thiopental. Key: (A) separation of thiopental (peak 1) and the internal standard (peak 2) when both are injected directly onto the chromatograph; (B) a human serum blank; (C) separation of 1.25 μg of thiopental and 2.5 μg of the internal standard from 1.0 ml of human serum.*

The HPLC mobile phase was acetonitrile–phosphate buffer (38:62). The buffer was prepared by adding 175 μl of 1 *M* KH_2PO_4 and 50 μl of 1 *M* H_3PO_4 to 1 liter of glass-distilled and filtered water. The pH of the phosphate buffer was 4.5, and the molarity was 4.5×10^{-4} *M* acid and 1.75×10^{-4} *M* salt. The flow rate was 1.2 ml/min with a C_{18} reverse-phase column[10] (4-mm i.d. × 30 cm) at 50°. The detector wavelength was 290 nm and ranged from 0.01 to 0.05 AUFS.

To prepare standard curves, aliquots of thiopental in methanol were evaporated to dryness and diluted to volume with serum. The standard was then handled as described above. Standard curves were linear at all concentrations from 200 ng/ml to 50 μg/ml. The retention times of thiopental and the internal standard were 9.2 and 11.2 min, respectively (Fig. 2). The assay does not separate the isomer from thiopental and therefore measures both compounds.

Isomer Extraction and Chromatography—For analysis of isomer concentrations between 25 and 500 ng/ml, variable volumes of serum (0.1–1.0 ml) were extracted with 200 ng of thiamylal as the internal standard. Following acidification with 1 *M* phosphoric acid two-thirds saturated with potassium phosphate, an extraction with ether (3 ml) was performed. The ether phase was removed and evaporated to dryness. The residue was reconstituted in 100 μl of the HPLC assay eluant and injected into the chromatograph. The HPLC mobile phase was acetonitrile–dilute phosphate buffer (33:67). The flow rate was 1.2 ml/min on a C_{18} reverse-phase column[11] (4-mm i.d. × 30 cm) at 50°. The detector wavelength was 290 nm and 0.01 or 0.02 AUFS.

Standard curves for the isomer assay were prepared by evaporating to dryness aliquots of the pure isomer in methanol and diluting to volume with serum. The standard was then prepared using the aforementioned acidification and ether extraction. Standard curves were linear from 25 to 500 ng/ml of the pure isomer. Retention times were: isomer, 16.7 min; thiopental, 18.1 min; and the internal standard, 23.6 min (Fig. 3).

Isomer Identification—The isomer was identified by addition of pure 5-ethyl-5-(1-ethylpropyl)-2-thiobarbituric acid to a sample of thiopental. When chromatographed using the aforementioned assay that separated the two compounds, addition of the isomer resulted in an increase of the isomer peak height in the thiopental sample, with an identical retention time. The UV spectra of thiopental and the isomer were identical, showing a maximum absorption at 290 nm. The structure of the isomer

[11] μ-Bondpack C_{18}, Waters Associates Inc., Milford, Mass.

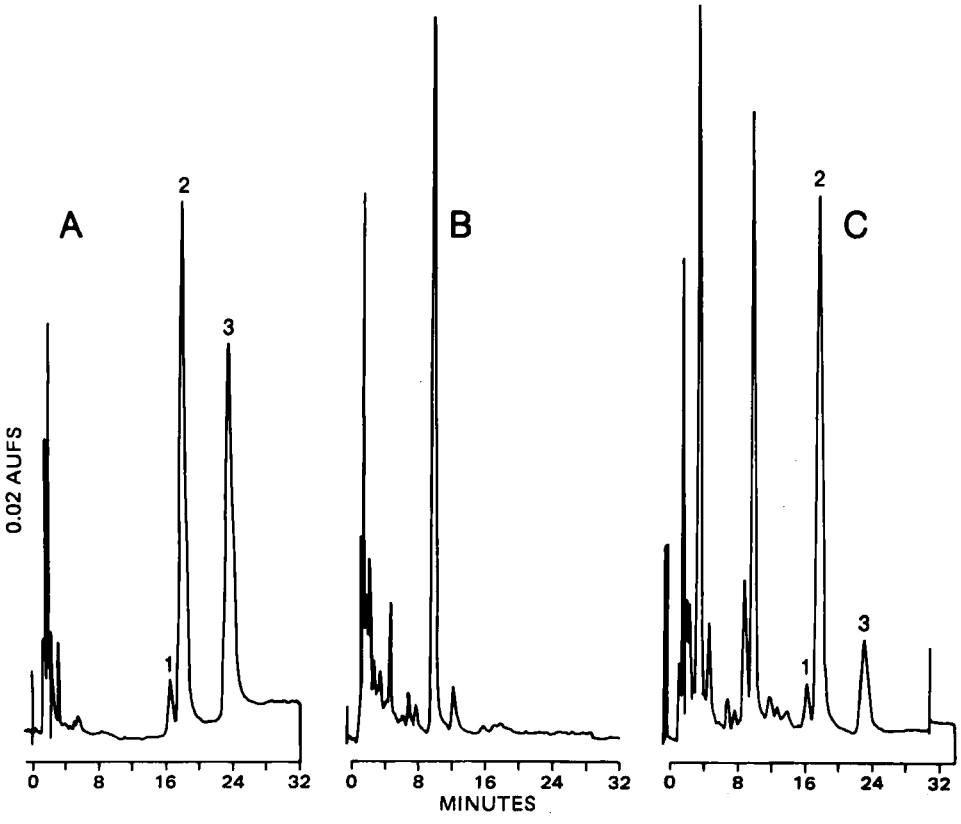

Figure 3—*Typical chromatograms obtained using the assay for measurement of the isomer. Key: (A) separation of the isomer (peak 1) from thiopental (peak 2) and the internal standard (peak 3) when thiopental and internal standard are injected directly onto the chromatograph; (B) a human serum blank; (C) separation of the compounds from human serum. Peak 1 in chromatogram C represents 56 ng of the isomer, peak 2 is 781 ng of thiopental, and peak 3 is 200 ng of internal standard extracted from 0.5 ml of serum.*

also was characterized using ^{13}C- and ^{1}H-NMR[12]. No evidence of interconversion of the two compounds was found during the extraction and HPLC chromatography.

Pharmacokinetics in the Human—One female and four male patients undergoing elective surgical procedures were studied. An institution review board approval was obtained along with consent from each patient. Subject age, weight, and thiopental dose are indicated in Table I. Commercially available thiopental sodium was used to induce anesthesia; therefore, both thiopental and the isomer were administered to the patients. A sample of the thiopental sodium administered was analyzed for the amount of isomer present (Table I).

Following rapid intravenous injection of the thiopental sodium for induction of anesthesia, blood samples were obtained from a catheter inserted into a radial artery or an antecubital vein. Arterial blood samples were obtained at 1, 2, 3, 5, 10, 15, 30, 45, 60, 90, and 120 min; venous blood samples were obtained at 3, 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, and 24 hr. This protocol allows accurate characterization of the distribution and elimination phases of thiopental and the isomer. Serum samples were frozen and subsequently analyzed using two assays: one that collectively measured the thiopental and isomer, and one that measured only the isomer. Following the administration of thiopental sodium, anesthesia was maintained with nitrous oxide–oxygen (60:40) and enflurane (1–2%) for 1–3 hr.

The pharmacokinetic data analysis used only the serum concentration *versus* time data. Linear regression of the postdistribution log serum concentration *versus* time data was used to determine the terminal elimination half-life. The dose divided by the area under the curve (linear trapezoid rule) was used to determine total body clearance. The area under the first-moment curve, as described by Benet and Galleazzi (7), was used to determine the volume of distribution at steady state. A two-tailed paired t test at a significance level of $p < 0.05$ was used to statistically compare the pharmacokinetic parameters for thiopental and the isomer.

Anesthetic Potency in Mice—Thiopental and the isomer were compared for anesthetic potency in male white Swiss mice[13] weighing 18–24 g. Thiopental was used as the commercially available sodium salt containing 8.3% sodium carbonate. The free acid isomer was converted to the sodium salt by adding 1 meq of NaOH and 8.3% Na_2CO_3 to 1 meq of the free acid. Both compounds were used as a 0.4% solution.

Because the anesthetic effect of these compounds is influenced by the peak blood level achieved, the speed of intravenous injection into the tail vein was rigidly controlled at 0.01 ml/5 sec. Sleep occurred immediately, during, or at the end of the injection. The anesthetized animals were placed on their backs and left undisturbed until they righted themselves.

In the fatal-dose range, death was due to respiratory arrest a few minutes after the drug injection. After the initial dose-ranging studies,

the LD_{50} was determined for both drugs using groups of eight mice at three dosage levels for each drug. The LD_{50} and 95% confidence limits were determined using the method of Litchfield and Wilcoxon (8). In addition to the LD_{50}, the sleep time at one-half the LD_{50} was also determined using eight mice per drug. A third study was performed with an additional eight mice per drug to determine if cumulative properties of these two barbiturates were the same. One-half of the LD_{50} dose was given to a mouse and a second injection $\frac{1}{8}$ of the LD_{50} dose was given when the animal righted itself. The sleep times from the first and second doses were compared using a two-tailed unpaired t test at a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Assay Sensitivity, Reproducibility, and Chromatography—With the acetonitrile protein precipitation, the assay sensitivity for thiopental was 200 ng/ml. Analysis of the same serum sample 6–8 times on the same day gave the following coefficients of variation: 300 ng/ml, 4.2%; 1.1 μg/ml, 3.7%; and 15.4 μg/ml, 1.8%. The between-day coefficient of variation at a thiopental concentration of 2.5 μg/ml was 5.0%. The isomer assay was sensitive to 25 ng/ml. Analysis of the same serum sample for the isomer 6–8 times on the same day gave the following coefficients of variation: 25 ng/ml, 7.9%; 125 ng/ml, 7.8%, and 500 ng/ml, 5.4%. The between-day coefficient of variation at an isomer concentration of 125 ng/ml was 5.1%. Figure 1 indicates the chemical structures of thiopental and the isomer, along with a chromatogram showing the presence of the isomer peak in a sample of thiopental obtained from the manufacturer[7]. Analysis of 10 different lots of commercially available thiopental sodium showed that the isomer comprised 6–7% of the total drug content. Figure 2 is a representative chromatogram obtained with the thiopental assay where thiopental and the isomer are not separated. Figure 3 demonstrates a representative chromatogram of the isomer assay where thiopental and the isomer are effectively separated.

Pharmacokinetics in the Human—Table I summarizes the derived pharmacokinetic parameters for thiopental and the isomer in each patient. Figure 4 displays the serum concentration *versus* time data for patient 5. Simultaneous arterial and venous samples in three patients demonstrated minimal thiopental concentration differences due to sample site, which had no effect on the derived pharmacokinetic variables. There was no statistical difference between the terminal elimination half-life, clearance, or volume of distribution at steady state when thiopental was compared with the isomer. The variability occurs because the isomer serum concentrations are 10–15 times lower than the thiopental concentrations and measurement varies more at the low isomer concentrations. While not formally characterized in this analysis, there was no visible difference in the initial distribution phases of thiopental relative to the isomer. Thus, in humans, the distribution and elimination of thiopental and the isomer are similar. This would be expected given the close structural similarity and (presumably) physicochemical properties of thiopental and the isomer.

Table II—LD_{50} and Anesthetic Potency in Mice

Drug	LD_{50}, mg/kg	Sleep Time[a] min	Cumulative Sleep Times, min	
			1st Dose[a]	2nd Dose[b]
Thiopental	90 (84.9–95.4)[c]	25.4 ± 17.3	25.3 ± 15.5	32.3 ± 20.9
Isomer	90 (84.9–85.4)	38.0 ± 18.3	31.3 ± 33.0	52.7 ± 22.1

[a] Dosed at 45 mg/kg; mean ± *SD*. [b] Dosed at 11.5 mg/kg; mean ± *SD*. [c] Range in parentheses.

Anesthetic Potency in Mice—Thiopental and the isomer had an identical fatal dose as judged by the LD_{50} studies (Table II). With one-half of the LD_{50}, the duration of sleep (as judged by return of the righting reflex) was not statistically different. Additionally, there was no evidence of a statistical difference in the cumulative duration of sleep when the anesthetic was administered a second time. Thus, it appears that the thiopental isomer is an anesthetic of potency comparable with that of thiopental in mice.

In summary, there is a 6–7% level of an isomer form present in thiopental. In the human, this isomer has distribution and elimination characteristics similar to thiopental. It also has, in mice, a degree of anesthetic potency similar to that of thiopental. It is therefore not critical that subsequent analytical technology used for thiopental pharmacokinetic or pharmacodynamic research quantitate or separate this isomer from thiopental.

Diphenhydramine Determination in Human Plasma by Gas–Liquid Chromatography using Nitrogen–Phosphorus Detection: Application to Single Low-Dose Pharmacokinetic Studies

DARRELL R. ABERNETHY ˣ **and DAVID J. GREENBLATT**

Received April 5, 1982, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine and New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication July 23, 1982.

Abstract □ A highly sensitive method (≤1 ng/ml) for single-dose pharmacokinetic studies of diphenhydramine which utilizes GLC with nitrogen–phosphorus detection is described. Standard curves, using orphenadrine as the internal standard, were linear for diphenhydramine concentrations from 1.0 to 300 ng/ml. Applicability of the method was demonstrated by a pharmacokinetic study in a normal volunteer who received 25 mg iv of diphenhydramine.

Keyphrases □ Diphenhydramine—determination in human plasma using GLC with nitrogen–phosphorus detection, application to single low-dose pharmacokinetic studies □ GLC—with nitrogen–phosphorus detection, determination of diphenhydramine in human plasma, single-dose pharmacokinetic study □ Pharmacokinetics—of diphenhydramine in the human, detection after a single dose using GLC with nitrogen–phosphorus detection

Diphenhydramine, widely used in the treatment of allergic conditions (1) and as a sedative–hypnotic in the elderly (2), has been measured by GLC using flame-ionization detection (3), GLC–MS (4), UV spectrophotometry (5), and by a fluorescent dye procedure (6). With the exception of GLC–MS, these methods lack adequate specificity and sensitivity. A method using GLC with nitrogen–phosphorus detection that is rapid, specific, and sensitive to 1 ng/ml is described. Following a straightforward plasma extraction requiring 3–4 hr, up to 150 samples per 24 hr can be analyzed if an automated injection system is used. This method is valuable since, in some subject populations (particularly the elderly), a diphenhydramine dose small enough to cause little sedative or anticholinergic effect but large enough to permit a blood level determination for the time needed to complete a single-dose pharmacokinetic study is necessary.

EXPERIMENTAL

Apparatus and Chromatographic Conditions—A gas chromatograph[1] equipped with a nitrogen–phosphorus detector and an electronic integrator was used. The column was coiled glass (1.83 m × 2-mm i.d.) packed with 3% SP-2250 on 80/100 mesh Supelcoport[2]. The carrier gas was ultra-high purity helium[3] at a flow rate of 30 ml/min. The detector purge was ultra-high purity hydrogen[3] at 3 ml/min mixed with dry air[3] at 50 ml/min. Operating temperatures were: injection port, 310°; column, 205°; and detector, 275°. Before being connected to the detector, new columns were conditioned at 270° for 48 hr with a carrier flow of 30 ml/min. At the beginning of each work day, the column was primed with 2 μg of phospholipid (asolectin) in benzene.

Reagents—Certified *n*-hexane[4] (99% pure) and isoamyl alcohol[4] were used. The toluene[5], methanol[4], concentrated hydrochloric acid[5], sodium hydroxide[5], sodium carbonate[5], and sodium bicarbonate[5] were analytical reagent grade. The isoamyl alcohol was glass-distilled prior to use; other organic solvents were used without further distillation. All aqueous solvents (0.25 *M* NaOH, 0.1 *M* HCl, and 1 *M* carbonate–bicarbonate buffer) were washed five times with hexane–isoamyl alcohol (98:2) prior to use.

Reference Standards—Pure standards of diphenhydramine hydrochloride[6] and orphenadrine citrate[7] were provided by the manufacturers. Standard solutions of each were prepared by dissolving the appropriate quantity of the salt to yield 100 mg of base in 100 ml of methanol. Sequential dilutions to 1 μg/ml were made. The solutions were stored in the dark in glass-stoppered bottles at 4° and were stable for at least 4 months.

Preparation of Samples—Orphenadrine was used as the internal standard for all analyses. A 100-μl volume of stock solution (1 μg/ml), containing 100 ng of orphenadrine, was added to 15-ml tubes, with poly-

Intercept	−0.02341
Slope corrected through origin	0.01287

[a] Mean ± *SD*; $n = 5$.

tef-faced, rubber-lined, screw-top caps. A 0.25–2.0 ml test sample of plasma was added to each tube. Calibration standards for diphenhydramine were prepared by adding 1, 2.5, 5, 10, 25, 50, 100, 200, and 300 ng of drug to consecutive tubes. Drug-free control plasma was added to each of the calibration tubes. One plasma sample, taken from the subject prior to drug administration, was analyzed with the calibration standards and each set of unknown samples as a blank.

Extraction Procedure—One milliliter of 0.25 *M* NaOH solution was added to each tube. To this was added 5 ml of hexane–isoamyl alcohol (98:2), and the tubes were agitated gently in the upright position on a vortex mixer for 15 min. The samples were centrifuged at room temperature for 5 min at 400×*g*[8]. The organic layer was transferred to another 15-ml tube that contained 1.2 ml of 0.1 *M* HCl. This mixture was agitated gently in the upright position on a vortex mixer for 10 min. The samples were centrifuged again at room temperature for 5 min at 400×*g*, and the upper, organic layer was discarded. The aqueous layer was carefully transferred to another tube, and to this was added 0.5 ml of 1 *M* carbonate–bicarbonate buffer (pH 11.5). To the mixture was added 200 μl of toluene–isoamyl alcohol (85:15). This mixture was agitated gently in the upright position on a vortex mixer for 15 min, and the samples were centrifuged again at room temperature for 5 min at 400×*g*. Using a 23-cm disposable pipet passed through the organic layer, the entire aqueous layer was removed leaving the organic phase (150 μl) containing diphenhydramine and the internal standard. This was transferred to a 2-ml automatic sampling vial.[9] Six microliters was injected into the gas chromatograph using the automatic-injection sampling system.

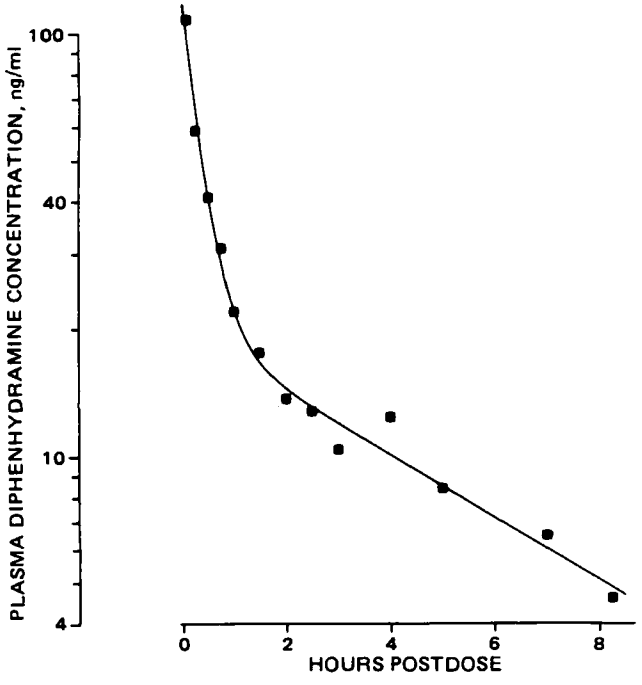

Figure 2—*Plasma diphenhydramine concentrations and the derived pharmacokinetic function following intravenous diphenhydramine administration to a healthy 32-year-old male subject. The elimination half-life is 4.1 hr (see Table I).*

Table II—Derived Diphenhydramine Pharmacokinetic Parameters in a Healthy Male Subject[a]

Subject Characteristics	
Age/Sex	32/male
Weight, kg	70.5
Diphenhydramine Kinetic Variables	
Distribution half-life, min	14.3
Elimination half-life, hr	4.06
Central compartment volume, liters/kg	2.66
Total volume of distribution, liters/kg	12.17
Total metabolic clearance, ml/min/kg	34.7

[a] Diphenhydramine dose of 25 mg iv.

Single-Dose Pharmacokinetic Study—A healthy 32-year-old male volunteer participated after giving written informed consent. Diphenhydramine hydrochloride (25 mg) was administered by intravenous bolus injection. The drug solution (50 mg/ml) was administered through a glass syringe. Multiple venous blood samples were drawn into heparin-containing tubes[10] over 8 hr postdose. Concentrations of diphenhydramine were determined by the aforementioned method.

Plasma diphenhydramine concentrations were analyzed by iterative, weighted, nonlinear, least-squares regression analysis (7, 8). After correction of the dose to diphenhydramine base, the following pharmacokinetic variables were determined: distribution half-life, elimination half-life, total volume of distribution, and total clearance.

RESULTS

Under the described conditions, retention times for diphenhydramine and orphenadrine were 3.41 and 4.32 min, respectively. A chromatogram of a typical blank plasma sample compared with a sample containing diphenhydramine and orphenadrine (internal standard) is shown in Fig. 1.

The relationship between diphenhydramine concentration and the area ratio (*versus* internal standard) is linear to at least 300 ng/ml. Analysis of more than 20 standard curves over a month always afforded a correlation coefficient ≥0.99. The day-to-day coefficient of variation in the slopes of the calibration curves was 5.9% (Table I).

The sensitivity limit of the method is 1 ng/ml using a 2-ml extracted plasma sample. The within-day coefficient of variation for identical samples ($n = 5$) were: 1 ng/ml, 4%; 5 ng/ml, 9.2%; 10 ng/ml, 5.2%; 25 ng/ml, 4.4%; 50 ng/ml, 1.7%; 100 ng/ml, 1.7%; 200 ng/ml, 1.3%; and 300 ng/ml, 2.8%. Residue analysis indicated the extraction of diphenhydramine is 97.3% at a plasma concentration of 25 ng/ml.

Figure 2 shows the plasma diphenhydramine concentration and pharmacokinetic function for the test subject. The derived pharmacokinetic parameters are listed in Table II.

DISCUSSION

This report describes a reliable, sensitive, and specific method for the quantitation of diphenhydramine in plasma using GLC with nitrogen–phosphorus detection. This method is an advance over previously reported methods in that the sensitivity is adequate for single-dose pharmacokinetic studies with very low doses, permitting safe study in widely varying subject populations. Addition of a dilute sodium hydroxide–hexane–isoamyl alcohol mixture to the plasma samples followed by an acid extraction of the organic phase, readjustment of the aqueous phase to pH 11.5, and reextraction with toluene–isoamyl alcohol afforded blank samples suitable for direct injection into the GC that were consistently free of contaminants in the area corresponding to the retention time for diphenhydramine. Known basic metabolites will not elute from the GLC column without derivatization, and acidic metabolites are not coextracted by the procedure used (9). The value of this GLC with nitrogen–phosphorus detection method includes the reasonable time required for sample preparation, as well as a sensitivity that is adequate for single low-dose pharmacokinetic studies.

Intestinal Absorption of Amino Acid Derivatives: Structural Requirements for Membrane Hydrolysis

G. L. AMIDON*x, M. LEE, and H. LEE

Received April 14, 1982, from the *University of Wisconsin, School of Pharmacy, Madison, WI 53706.* Accepted for publication August 5, 1982.

* Present address: College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.

Abstract □ The intestinal absorption of L-lysine-*p*-nitroanilide, L-alanine-*p*-nitroanilide, and glycine-*p*-nitroanilide was studied in perfused rat intestine in the presence of a variety of potential competitive inhibitors. The results indicate that the hydrolysis site(s) show side-chain specificity, and that inhibitors require a free amino group in the α-position and must be in the L-configuration to be effective. Glycyl-L-proline, a peptide transport inhibitor, had no effect on the absorption rate.

Keyphrases □ Absorption, intestinal—amino acid derivatives, structural requirements for membrane hydrolysis, rats □ Hydrolysis, membrane—structural requirements, intestinal absorption of amino acid derivatives, rats □ Amino acid derivatives—intestinal absorption, structural requirements for membrane hydrolysis, rats

Previous reports (1, 2) have demonstrated that intestinal membrane (or brush-border) enzymes may serve as useful prodrug reconversion sites. For example, compounds that are insoluble, unstable, or have other undesirable pharmaceutical properties may be derivatized so as to improve these properties with the regeneration of the active drug occurring just prior to entry into the systemic circulation. Clearly the specificity of the enzymes in the brush-border region sets a boundary for this strategy. In this report the intestinal absorption of L-lysine-, L-alanine-, and glycine-*p*-nitroanilides is studied in the presence of a variety of potential competitive inhibitors to more clearly define the specificities of the surface peptidases.

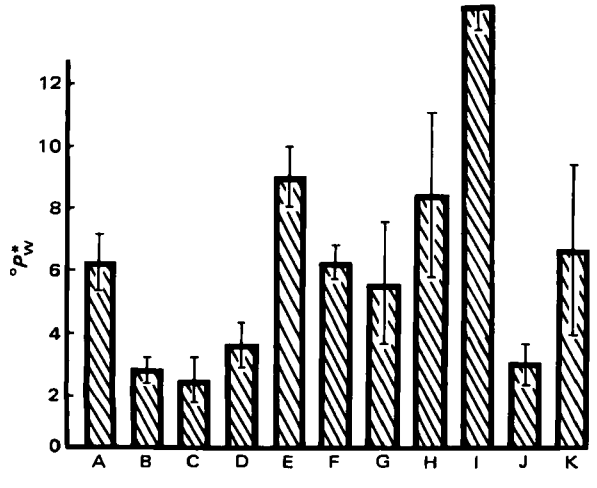

Figure 1—*Intestinal wall permeability (°P^*_w) of L-lysine-p-nitroanilide alone (A) and with L-lysine methyl ester (B), L-arginine-β-naphthylamide (C), L-arginine methyl ester (D), α-N-acetyl-L-lysine methyl ester (E), L-lysine (F), L-phenylalanine methyl ester (G), L-alanine methyl ester (H), glycine methyl ester (I), L-prolylglycine (J), or glycyl-L-proline (K).*

EXPERIMENTAL

Materials—L-lysine-*p*-nitroanilide[1], L-alanine-*p*-nitroanilide[2], and glycine-*p*-nitroanilide[1] were used as received. The inhibitors L-lysine[3], L-lysine methyl ester[2], α-*N*-acetyl-L-lysine methyl ester[3], L-alanine methyl ester[2], L-alanine amide[1], β-alanine methyl ester[1], D-alanine methyl ester[1], L-phenylalanine methyl ester[3], L-phenylalanine amide[1], glycine methyl ester[2], L-arginine methyl ester[1], L-arginine-β-naphthylamide[1], L-prolylglycine[1], and glycyl-L-proline[1] were used as received.

Perfusion Experiments—Rat intestinal perfusion experiments were carried out as previously described (1, 2). Inlet (*Co*) and exit (*Cm*,) concentrations of the perfused segment were measured by determining the *p*-nitroaniline concentration after a 12-hr hydrolysis. The *Cm/Co* ratio was determined using a three-point spectral analysis to account for any background absorbance due to protein in the perfusate. Experiments were carried out with the substrate concentration at 4×10^{-5} *M* and the inhibitor concentration at 4×10^{-3} *M*. Each permeability is the average result from 6–10 rats.

RESULTS AND DISCUSSION

The dimensionless intestinal wall permeability, °P^*_w, was calculated as previously described (3). Tests for significance were done using the two-sample *t* test for samples with unequal variance[4] (95% confidence level). The results are shown in Table I and Figs. 1–3.

Previous reports (1, 2) have demonstrated that intestinal membrane (or brush-border) enzymes may serve as useful prodrug reconversion sites. For example, compounds that are insoluble, unstable, or have other undesirable pharmaceutical properties may be derivatized so as to improve these properties with the regeneration of the active drug occurring just prior to entry into the systemic circulation. Clearly the specificity of the enzymes in the brush-border region sets a boundary for this strategy. In this report the intestinal absorption of L-lysine-, L-alanine-, and glycine-*p*-nitroanilides is studied in the presence of a variety of potential competitive inhibitors to more clearly define the specificities of the surface peptidases.

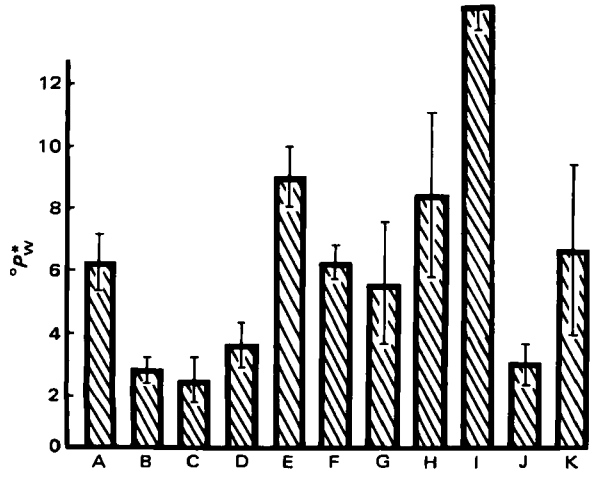

Figure 1—*Intestinal wall permeability (°P^*_w) of L-lysine-p-nitroanilide alone (A) and with L-lysine methyl ester (B), L-arginine-β-naphthylamide (C), L-arginine methyl ester (D), α-N-acetyl-L-lysine methyl ester (E), L-lysine (F), L-phenylalanine methyl ester (G), L-alanine methyl ester (H), glycine methyl ester (I), L-prolylglycine (J), or glycyl-L-proline (K).*

EXPERIMENTAL

Materials—L-lysine-*p*-nitroanilide[1], L-alanine-*p*-nitroanilide[2], and glycine-*p*-nitroanilide[1] were used as received. The inhibitors L-lysine[3], L-lysine methyl ester[2], α-*N*-acetyl-L-lysine methyl ester[3], L-alanine methyl ester[2], L-alanine amide[1], β-alanine methyl ester[1], D-alanine methyl ester[1], L-phenylalanine methyl ester[3], L-phenylalanine amide[1], glycine methyl ester[2], L-arginine methyl ester[1], L-arginine-β-naphthylamide[1], L-prolylglycine[1], and glycyl-L-proline[1] were used as received.

Perfusion Experiments—Rat intestinal perfusion experiments were carried out as previously described (1, 2). Inlet (*Co*) and exit (*Cm*,) concentrations of the perfused segment were measured by determining the *p*-nitroaniline concentration after a 12-hr hydrolysis. The *Cm/Co* ratio was determined using a three-point spectral analysis to account for any background absorbance due to protein in the perfusate. Experiments were carried out with the substrate concentration at 4×10^{-5} *M* and the inhibitor concentration at 4×10^{-3} *M*. Each permeability is the average result from 6–10 rats.

RESULTS AND DISCUSSION

The dimensionless intestinal wall permeability, °P^*_w, was calculated as previously described (3). Tests for significance were done using the two-sample *t* test for samples with unequal variance[4] (95% confidence level). The results are shown in Table I and Figs. 1–3.

L-Lysine methyl ester, L-arginine-β-naphthylamide, and L-arginine

Table I—Inhibition Results for the Various Substrates [a]

Inhibitor	Substrate		
	L-Lysine-*p*-nitroanilide	L-Alanine-*p*-nitroanilide	Glycine-*p*-nitroanilide
L-Lysine methyl ester	Yes	No	No
L-Arginine-β-naphthylamide	Yes	—	—
L-Arginine methyl ester	Yes	No	—
L-Phenylalanine methyl ester	No	No	—
Glycine methyl ester	No	No	No
L-Lysine	No	—	—
α-*N*-Acetyl-L-lysine methyl ester	No	—	—
L-Alanine methyl ester	No	Yes	—
β-Alanine methyl ester	—	No	—
D-Alanine methyl ester	—	No	—
L-Alanine amide	—	No	—
L-Phenylalanine amide	—	No	—
L-Prolylglycine	Yes	Yes	Yes
Glycyl-L-proline	No	No	No

[a] Using a *t* test at the 95% confidence level.

methyl ester reduced the permeability of L-lysine-*p*-nitroanilide, while L-phenylalanine methyl ester, glycine methyl ester, *N*-acetyl-L-lysine methyl ester, and L-alanine methyl ester did not. This suggests that the hydrolysis site for lysine-*p*-nitroanilide shows a preference for positively charged side chains (lysine, arginine) and a lower affinity for the nonpolar side chains (alanine, glycine). The fact that *N*-acetyl-L-lysine methyl ester is not an inhibitor while L-lysine methyl ester is a good inhibitor demonstrates the requirement for a free L-amino group.

The results for L-alanine-*p*-nitroanilide indicate that, of the compounds studied, only L-alanine methyl ester is a good competitive inhibitor. Since the methyl esters of lysine, arginine, phenylalanine, and glycine did not show significant inhibition, the site of L-alanine-*p*-nitroanilide hydrolysis must be relatively specific for small nonpolar amino acid side chains. The fact that β-alanine methyl ester and D-alanine methyl ester were not inhibitors suggests that the free amino group must be in the α-position and that the stereochemistry is important. This is

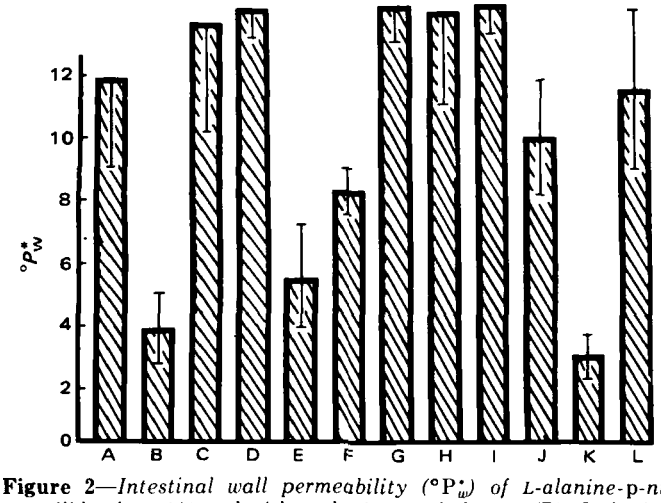

Figure 2—*Intestinal wall permeability ($^{\circ}P_w^*$) of L-alanine-p-nitroanilide alone (A) and with L-alanine methyl ester (B), β-alanine methyl ester (C), D-alanine methyl ester (D), L-lysine methyl ester (E), L-phenylalanine methyl ester (F), L-arginine methyl ester (G), glycine methyl ester (H), L-alanine amide (I), L-phenylalanine amide (J), L-prolylglycine (K), or glycyl-L-proline (L).*

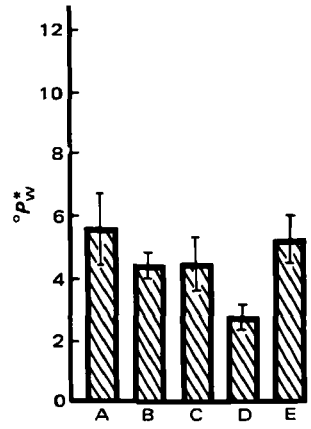

Figure 3—*Intestinal wall permeability ($^{\circ}P_w^*$) of glycine-p-nitroanilide alone (A) and with glycine methyl ester (B), L-lysine methyl ester (C), L-prolylglycine (D), or glycyl-L-proline (E).*

what one would expect for an enzymatic reaction, where the free α-amino group was located in the primary binding site. If the free amino group is located in any other position, the carbonyl carbon that is the subject of attack during hydrolysis would be improperly located with respect to the catalytic groups on the enzyme. The fact that L-alanine amide is not a good competitive inhibitor is somewhat surprising. However, as is the case with α-chymotrypsin substrates (4), it would appear that the amide of alanine has a higher K_m (weaker binding) than the corresponding ester.

The results for glycine-*p*-nitroanilide suggest that the affinity of glycine for the hydrolysis site is weak since glycine methyl ester was not an inhibitor of glycine-*p*-nitroanilide uptake.

The results using the dipeptides glycyl-L-proline and L-prolylglycine show that L-prolylglycine inhibited the absorption of all three amino acid anilides studied. It has been shown that glycyl-L-proline has a high affinity for the intestinal peptide transport process and is not a substrate nor inhibitor of brush-border amino peptidase (5, 6). Since this compound did not inhibit absorption of any of the substrates studied, the result suggests that direct uptake by the peptide transport process does not occur for these compounds. On the other hand, L-prolylglycine appears to be a general amino peptidase inhibitor.

Further studies on the specificity of the intestinal brush-border peptidases in an intestinal perfusion system show that, in addition to the required presence of an α-amino group, the enzymes show specificity for the amino acid side chains as well. The results clearly demonstrate that the absorption mechanism for these compounds is not simple passive diffusion and that the hydrolysis site is probably of the amino peptidase type.

Cardiac Inhibitory Action of Constituents of the Marine Green Alga *Ulva pertusa*

K. YAMADA *x, Y. SHIZURI *, Y. ISHIDA ‡, and S. SHIBATA ¶

Received March 9, 1982, from the **Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya, Japan*, and the ‡*Mitsubishi-Kasei Institute of Life Science and Department of Pharmacology*, ¶*School of Medicine, University of Hawaii, Honolulu, HI 96822.* Accepted for publication July 9, 1982.

Abstract □ As part of a search for substances from marine organisms, which exhibit inotropic effects, the chemical constituents of the marine green alga, *Ulva pertusa* were investigated. The fractionated extract was tested for inotropic effects on the isolated guinea pig atria. The aqueous layer obtained from the acetone extract of fresh algae was concentrated, and the residue was extracted with methanol. The methanolic extract was fractionated by chromatography using mixtures of aqueous methanol. Elution with 50% aqueous methanol afforded material that had a significant negative inotropic effect. Further purification of this material by high-performance liquid chromatography (HPLC) using methanol–water (2:5) afforded crystalline adenosine, which was shown to be the active substance of *U. pertusa*, causing a negative inotropic action.

Keyphrases □ Cardioinhibitory effects—of extracts of the marine green alga (*Ulva pertusa*), adenosine □ *Ulva pertusa*—inotropic effects of extract fractions (adenosine), cardioinhibitory effects □ Adenosine—extracted from the marine green alga (*Ulva pertusa*), cardioinhibitory effects

The marine green alga, *Ulva pertusa*, is cultivated around the seashore in all parts of Japan, especially in the intertidal zone. This alga is also cultured *in vitro* (1). The green alga possesses only type I aldolase, which is also present in the animals and higher terrestrial plants, but not in bacteria which have the type II aldolase (2). It has been reported that a water-soluble fraction from the green alga had antimicrobial activity (3).

A screening program was designed to assess the biological activity of various marine organisms. In such screening tests, extracts of the marine green alga have produced cardioinhibitory action on the isolated guinea pig atria. A cardiotonic fraction (4) was extracted from a sea weed, *Undaria pinnatifida*, but the chemical nature of the active substance was not reported. Therefore, the purpose of this work was to investigate the chemical constituents and pharmacological properties of the active substance (causing the negative inotropic effect) of the green alga.

EXPERIMENTAL

Isolation—An acetone extract of *U. pertusa*[1] (5.6 kg) was concentrated under reduced pressure, washed successively with hexane (2 × 1.5 liters) and ethyl acetate (1.8 liters), and then concentrated *in vacuo* to dryness. The resulting brown powder was extracted with methanol to remove inorganic salts. After filtration the yellow methanolic solution was concentrated to give a light-brown oil (45 g), which showed a negative inotropic effect on the isolated guinea pig atria at concentrations $>10^{-4}$ g/ml. The crude oil was subjected to column chromatography on TSK-Gel G-3000 S[2] (220 ml). The column was developed successively with water (600 ml, fractions 1–6), aqueous methanol (80:20 200 ml, fractions 7 and 8), aqueous methanol (50:50, 200 ml, fractions 9 and 10), and methanol (400 ml, fraction 11). Fraction 9 (365 mg) was found to have inotropic activity; this fraction was purified by high-performance liquid chromatography (HPLC)[3] using a Megapack SIL C_8 column, a mobile phase of methanol–water (v/v 2:5), and a UV detector at 210 nm. The fraction corresponding to the major peak gave pale yellow crystals (46.3 mg, 8.3 × 10^{-4}% yield), which showed a negative inotropic effect at concentrations $>10^{-5}$ g/ml. Recrystallization from water gave colorless needles (32 mg): $C_{10}H_{13}N_5O_4$, mp 233–235°; UV[4] (methanol): 260 nm (ϵ 14,800); IR[5] (KBr): 1665, 1610, and 1580 cm^{-1}; ^{1}H-NMR[6] (deuterium oxide): δ 3.92 (3, m), 4.30–4.50 (2, m), 6.06 (1, d, J = 6 Hz), 8.16 (1, s), and 8.31 (1, s). The above data, as well as the chromatographic properties (TLC, HPLC) of the crystals, were in agreement with those of authentic adenosine[7].

Bioassay—The bioassay of fractions was performed on isolated guinea pig heart. The left atrium was separated from the rest of the heart and suspended in a 50-ml tissue bath containing physiological salt solution of the following composition (mM): NaCl, 120.3; KCl, 48; $CaCl_2$, 1.2; $MgSO_4$, 1.3; KH_2PO_4, 1.2; $NaHCO_3$, 25.2; and glucose, 5.5. The solution was bubbled continuously with a gas mixture of oxygen–carbon dioxide (19:1) and maintained at 30°, pH 7.4. Contractile response was recorded isometrically through a force-displacement transducer[8] and displayed on a polygraph[9]. The atrium was driven by an electrical stimulator[10] at a frequency of 2 Hz with square-wave pulses of 5 msec duration at 100% above threshold voltage. The atrium was allowed to equilibrate under 0.5-g tension for 60 min prior to beginning each measurement.

RESULTS AND DISCUSSION

Table I shows the negative inotropic effect of fractions extracted from the green alga *U. pertusa* on the guinea pig left atria driven electrically. The crude oil caused a negative inotropic effect at a concentration of 4 × 10^{-4} g/ml while fraction 9 (TSK-Gel filtration) showed an effect at 4 × 10^{-5} g/ml and the purified crystalline material at 10^{-5} g/ml. The potency of the purified crystalline material was essentially equivalent to

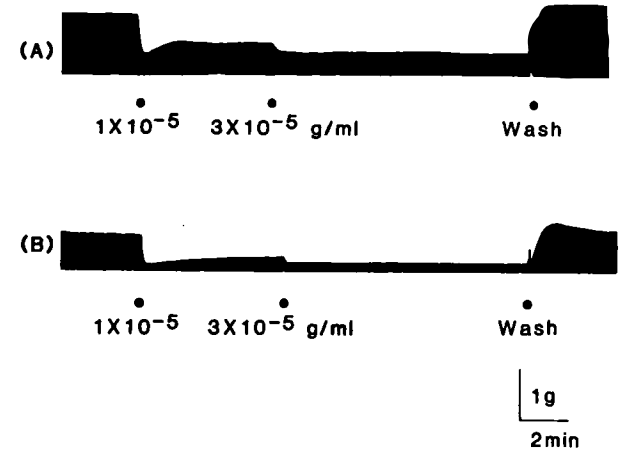

Figure 1—*Inhibitory effects of the final crystals (A) from* U. pertusa *and authentic adenosine (B) on the guinea pig atria driven electrically (2 Hz, 5 V, and 5 msec duration). The final crystals and adenosine at concentrations of 1 × 10^{-5} and 3 × 10^{-5} g/ml were applied to the muscle and then washed out of the solution.*

[1] Collected at Himaka-Jima, Aichi, Japan in August 1981. The alga was identified as *Ulva pertusa* (Chlorophyceae) by Professor W. Kida, Mie University, Japan. A voucher specimen (No. KY-15) representing material collected for this investigation is available for inspection at the Herbarium of Laboratory of Organic Chemistry, Department of Chemistry, Nagoya University, Nagoya, Japan.

Table I—Inhibitory Effect of Adenosine and Fractions Extracted from *U. pertusa* on the Contractility of Isolated Guinea Pig Atria [a]

Substance	Concentration, g/ml	Inhibition, [b] %
Crude oil	4×10^{-4}	6.9
Fraction 9[c]	4×10^{-5}	40.4
Final crystals	1×10^{-5}	63.6
Adenosine	1×10^{-5}	69.0

[a] The guinea pig left atria was electrically driven with square pulses (2 Hz, 5 msec duration, and 5 V). [b] Inhibition was expressed by percent decrease in the systolic tension development of the atria. [c] Purified using column chromatography (TSK-Gel).

that of authentic adenosine, 1×10^{-5} g/ml. Figure 1 is representative of the negative inotropic effect of the purified crystalline material (1×10^{-5} and 3×10^{-5} g/ml) on the atria.

When the crystalline material was washed out of the tissue bath, the negative inotropic action of the agent disappeared. The contractility was restored to the control level within 1 min after washout, similar to the effect of the removal of adenosine reported by Baumann *et al.* (5). Furthermore, negative inotropic effects of the purified crystalline material and adenosine were not affected by the β-blocker propranolol (1×10^{-6} *M*) or the α-blocker phentolamine (1×10^{-6} *M*). Thus, the inhibitory action of the purified crystalline material is not mediated through the activation of adrenoceptors. In conclusion, the chemical and pharmacolgical results indicate that the cardioinhibitory substance isolated from the green alga *U. pertusa* is adenosine, which had not been found previously in marine organism.

Degradation of Fenprostalene in Aqueous Solution

DAVID M. JOHNSON ˣ, WILLIAM F. TAYLOR, GEOFFREY F. THOMPSON, and RAYMOND A. PRITCHARD

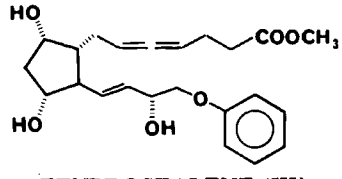
Received May 17, 1982, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication August 24, 1982

Abstract □ The degradation of the prostaglandin fenprostalene (III) was studied in aqueous solution. The reaction was both specific acid and base catalyzed. The only reaction found to occur was hydrolysis of the methyl ester at C-1. Activation energies for the acid- and base-catalyzed reactions were determined and are nearly identical to that for the hydrolysis of ethyl acetate, a model ester. A competing acid-catalyzed reaction of the C-1 free acid of III was found to be ~ 10 times slower than the hydrolysis of III.

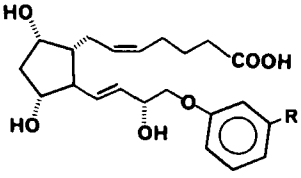
Keyphrases □ Degradation—fenprostalene, prostaglandins, high-performance liquid chromatography, kinetics, ester hydrolysis □ Fenprostalene—degradation, prostaglandins, high-performance liquid chromatography, kinetics, ester hydrolysis □ High-performance liquid chromatography—degradation of fenprostalene, kinetics, ester hydrolysis □ Ester hydrolysis—fenprostalene degradation, high-performance liquid chromatography, kinetics

The degradation of prostaglandin $F_{2\alpha}$ in aqueous solution is known to be acid catalyzed (1, 2). No evidence of degradation under alkaline conditions has been reported. Recently, the degradation of two $F_{2\alpha}$-type aryloxy prostaglandins (I and II) was reported by Jones *et al.* (3). The authors found that the degradation of these luteolytic agents in aqueous solution was acid catalyzed, and the rate of degradation as well as the type of products formed were dependent on the presence of oxygen in the solution. No degradation of these compounds was observed at pH values >5.

Fenprostalene (III)[1] is a new prostaglandin developed for use as an abortifacient and for estrus synchronization in cattle (4, 5). The likely degradation route of this F-type prostaglandin at high pH is hydrolysis of the C-1 methyl ester group. However, we were interested to see whether acid-catalyzed decomposition reactions analogous to those found for I and II (3) or $PGF_{2\alpha}$ itself (1, 2) might compete with acid-catalyzed hydrolysis of the ester moiety in III at low pH. Accordingly, we have studied the degradation of fenprostalene (III) and its C-1 free acid (IV) in aqueous solution as a function of pH.



FENPROSTALENE (III)



I: R = CF_3
II: R = Cl

EXPERIMENTAL

Materials—The fenprostalene (6) used was 99% pure by high-performance liquid chromatographic (HPLC) area normalization. The methanol was glass-distilled HPLC grade, and the water was purified through a filtration and ion exchange system[2]. All other chemicals were reagent grade quality.

Kinetics Methods—Buffer solutions contained 0.025 *M* total buffer,

	3.10	Formate	80°	2.0
	4.98	Acetate	80°	0.11
	7.05	THAM	80°	<0.05[f]

[a] Buffer concentration 0.025 *M* except for HCl (0.1 *M*). [b] Contains 10^{-3} *M* Fe^{3+}. [c] Contains 10^{-3} *M* Cu^{2+}. [d] Contains Fe^{3+}. [e] Contains Cu^{2+}. [f] No degradation was observed after 104 days at 80°.

and potassium chloride was added to make the ionic strength 0.10 (0.20 for solutions of IV). Metal ions (10^{-3} *M*) were added to some buffer solutions; however, precipitation occurred with both iron and copper at pH 6.5. These solutions were filtered at room temperature, and the rate constants were thus measured in solutions saturated with these metals.

The pH of all solutions was measured at the reaction temperature (30, 60, or 80°)[3]. Reaction solutions were typically prepared by adding 4 ml of a 2.5-mg/ml methanol solution of III to 96 ml of buffer to give a final solution containing 100 μg/ml of III and ~4% methanol. The solutions

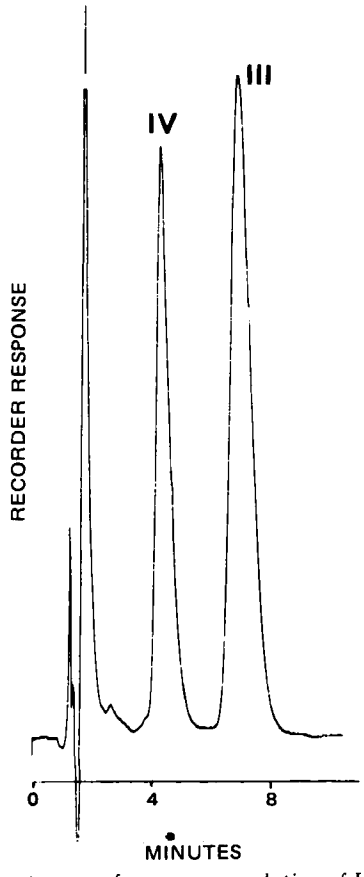

Figure 1—*Chromatogram of an aqueous solution of III after partial hydrolysis to IV at pH 1.03, 60°.*

[3] Radiometer model PHM 64 pH meter equipped with a Radiometer model GK2401C electrode.

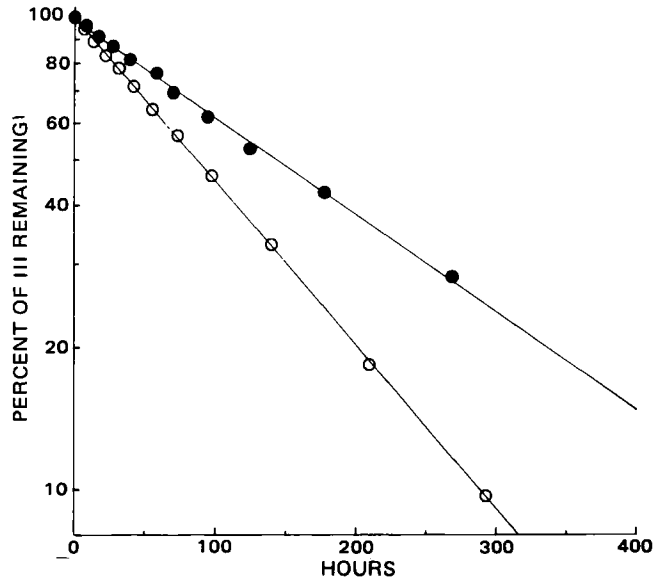

Figure 2—*First-order plot for the degradation of III at 60° in a pH 9.26 buffer solution (○) and a pH 1.03 buffer solution (●).*

were stored in sealed amber glass ampules and placed in a constant-temperature water bath at 80, 60, or 30° for the appropriate period of time. They were then removed, and in the case of the 30° samples the ampules were frozen until they were assayed. The 80 and 60° samples were refrigerated (4°) until assayed. The solutions were then diluted 2:5 with mobile phase and analyzed by HPLC for the amount of III (or IV) remaining compared with an initial sample kept at 4°.

HPLC Method—An HPLC system consisting of a pump[4], a variable-wavelength detector[5] and a 100-μl fixed-loop injector[6] was used. A 10-μm ODS column[7] was used with a mobile phase of methanol–0.02 *M* acetic acid (55:45) and detection wavelength of either 270 or 219 nm to achieve baseline separation of compounds III and IV (Fig. 1). Quantitation by peak area integration[8] gave excellent linearity for III over the range of concentrations investigated in the kinetics. The mobile phase in the above method was modified slightly (45:55 ratio of methanol to 0.02 *M* acetic acid) to follow the degradation of IV.

RESULTS AND DISCUSSION

The rate of disappearance of fenprostalene (III) in aqueous solution was followed using HPLC. At 80° the reaction was studied over the pH range 1.1–9.2, while at 30 and 60° the reaction was studied only at the extremes of this pH range. The degradation reaction obeyed pseudo-first-order kinetics as evidenced by the linear log percent remaining *versus* time plot shown in Fig. 2 for pH 9.26 and 1.03 at 60°. The observed pseudo-first-order rate constants (k_{obs}) are listed in Table I.

Degradation of III throughout the entire pH region was found to give the corresponding acid (IV) of fenprostalene as the only observable product by HPLC (Fig. 1). Mass balance was determined by comparing the combined area of the peaks representing III and IV throughout the time course of the reaction with the initial area of III. Greater than 94% mass balance was found for both acid- and base-catalyzed decomposition of III by this method. These results are consistent with hydrolysis of the ester group at C-1 as the exclusive reaction occurring in aqueous solution.

The log k_{obs} *versus* pH profile for the hydrolysis of III in aqueous solution at 80° is shown in Fig. 3. The line drawn through the experimental points represents the rate law described in Eq. 1 where $k_{H^+} = 3.94 \times 10^{-3}$ M^{-1} sec^{-1} and $k_{HO^-} = 2.16$ M^{-1} sec^{-1}:

$$k_{obs} = k_{H^+}[H^+] + k_{HO^-}[HO^-] \qquad \text{(Eq. 1)}$$

This simple rate law contains only two terms: a specific acid term and a specific base term. The excellent fit of the theoretical line to the data

80°	394	2.16
60°	81.0	0.761
30°	6.72	0.118

[a] Calculated from the data in Table I.

indicates no other catalytic terms are necessary to explain the observed data. This also implies that it is likely that no significant buffer catalysis occurred in these solutions. It is also apparent from Fig. 3 that the presence of Cu^{2+} and Fe^{3+} had no effect on the rate of degradation of III.

The rate equation describing the pH dependence for the degradation of III (Eq. 1) is likely to hold at low temperatures as well as at 80°. The second-order rate constants k_{HO^-} and k_{H^+} at 60 and 30° were thus obtained by determining k_{obs} at high pH (9.3) and low pH (1.1) and calculating k_{HO^-} and k_{H^+} from Eqs. 2 and 3, respectively:

$$k_{HO^-} = \frac{k_{obs}[H^+]}{K_w} \quad \text{(Eq. 2)}$$

$$k_{H^+} = \frac{k_{obs}}{[H^+]} \quad \text{(Eq. 3)}$$

The second-order rate constants at 80, 60, and 30° are shown in Table II and were used to calculate the activation energies for the specific acid- (17 kcal/mole) and base-catalyzed (12 kcal/mole) hydrolysis of III[9].

The degradation kinetics of IV were also investigated at 80° from pH 1 to 7. The degradation reaction followed pseudo-first-order kinetics, and the observed rate constants obtained are shown in Table I. From the plot in Fig. 3 one can see that the degradation rate of IV is acid catalyzed and is significantly slower than that of its methyl ester (III) in the acidic pH region. The degradation rate for IV at pH 7.0 was too slow to measure. If the assumption is made that the degradation reaction of IV does not involve the C-1 carboxyl group[10], then this acid-catalyzed pathway is probably available to fenprostalene (III) itself. Hydrolysis of the C-1 methyl ester, however, is preferred by ~10-fold over this alternate degradation pathway for III at 80° in the acidic pH region.

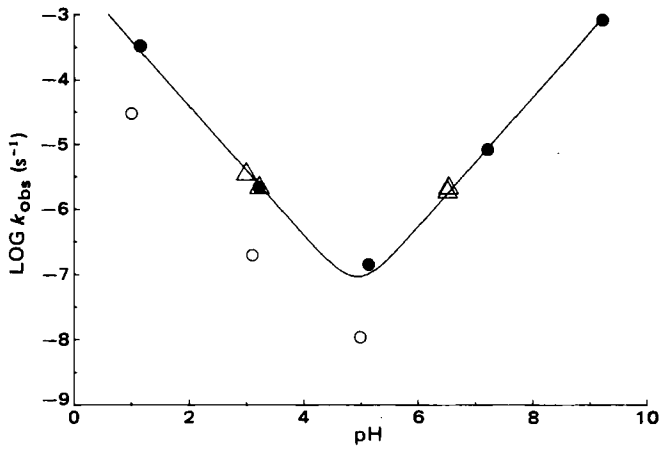

Figure 3—*Log* k_{obs} *versus pH profile for the hydrolysis of III at 80°. Key: solid circles represent simple buffer solutions, open triangles represent buffer solutions containing* Cu^{2+} *and* Fe^{3+} *ions, and the reaction of IV in aqueous solution at 80° is shown by the open circles.*

[9] These results are nearly identical to those reported for the hydrolysis of ethyl acetate (7).

[10] Jones *et al.* (3) studied the degradation of II in acidic solution under aerobic conditions. The products were a complex mixture of compounds, and no major products were identified. We have not identified the degradation products of IV in acidic media but have observed on HPLC that several products are formed.

Determination of Hydrazine in Pharmaceuticals III: Hydralazine and Isoniazid Using GLC

F. MATSUI ˣ, D. L. ROBERTSON, and E. G. LOVERING

Received February 26, 1982, from the *Bureau of Drug Research, Health Protection Branch, Ottawa, Ontario K1A OL2.* Accepted for publication July 30, 1982.

Abstract □ A GLC procedure has been developed for the determination of hydrazine in hydralazine and isoniazid drug raw materials, single and multicomponent tablets, injectables, and syrups. The method is based on the derivatization of hydrazine with benzaldehyde to form benzalazine. The minimum detectable amount of hydrazine in hydralazine and isoniazid raw materials and formulations is ~0.0003%. No hydrazine was found in the hydralazine raw material specimens examined. Traces of hydrazine (~0.0003%) were found in some tablet lots and ~0.02% was found in an injectable product. A trace of hydrazine was found in one lot of isoniazid raw material and low levels (0.0012 and 0.0029%) were found in isoniazid tablet products. An isoniazid syrup contained ~0.2% hydrazine.

Keyphrases □ Hydrazine—determination in hydralazine and isoniazid by GLC □ Hydralazine—GLC, determination of hydrazine □ Isoniazid—GLC, determination of hydrazine □ GLC—determination of hydrazine in pharmaceutics, hydralazine, isoniazid

Previous papers in this series described high-performance liquid chromatographic (HPLC) methods for the determination of hydrazine in isoniazid and phenelzine products and reported typical amounts found in commercial formulations (1, 2). Since hydrazine is a mutagen (3) and a carcinogen in laboratory animals (4), concern over its presence in drug products resulted in proposed regulatory action in the United States (5) and to the recall of

0022-3549/83/0800-0948$01.00/0

an isoniazid product in Canada (6). Determination of hydrazine has now been extended to hydralazine, an antihypertensive drug.

Hydrazine contamination of hydralazine may occur during synthesis (7) or by degradation of the drug. Hydrazine is a metabolite of hydralazine in humans, and a GLC method for its identification and quantitation in urine has been described (8). Methods for the determination of hydrazine as a metabolite of isoniazid have also been reported (9, 10). Since attempts to determine hydrazine in hydralazine by the HPLC methods developed for isoniazid and phenelzine (1, 2) led to irreproducible results, a GLC method was developed. The sensitivity and stability of this method prompted its extension to isoniazid products as an alternative to the HPLC procedure (1).

EXPERIMENTAL

Materials—Hydrazine dihydrochloride[1], hydralazine hydrochloride[1], benzalazine[2], 5-chloro-2-methylaminobenzophenone[2], and benzaldehyde[3] were used as received. Solvents and reagents were commercial analytical reagent grade, except for *n*-heptane[4] which was HPLC grade.

Apparatus—The gas chromatograph[5] was equipped with a nitrogen–phosphorus alkali thermionic detector and a coiled-glass column (0.91-m × 4-mm i.d.) packed with 2% OV-101[6] on Chromosorb G-HP[7] (80/100 mesh). Instrument temperatures were: injector port, 275°; column, 250°; and detector, 300°. Gas flows were: nitrogen, 40 ml/min; air, 60 ml/min; and hydrogen, 1.75 ml/min.

Standard Solutions and Reagents—A stock solution of 5-chloro-2-methylaminobenzophenone in *n*-heptane (12 μg/ml) was diluted daily with *n*-heptane to obtain the working internal standard solution (1.2 μg/ml). The benzaldehyde reagent was prepared by dissolving benzaldehyde in a solution of equal parts (by volume) of methanol and water to yield a final concentration of 35 mg/ml.

Preparation of the Calibration Curve—An 80-μg/ml aqueous solution of hydrazine dihydrochloride (equivalent to 24.4 μg/ml of hydrazine) was diluted with distilled water to obtain five standard solutions ranging from 0.080 to 2 μg/ml of hydrazine dihydrochloride (representing 0.005–0.122 ng of hydrazine on-column). To a 2.0-ml aliquot of each solution, pipetted into separate 150 × 20-mm culture tubes fitted with polytef-lined screw caps, was added 1.0 ml of benzaldehyde reagent solution. The tubes were rotated for 10 min at 30 rpm, 10.0 ml of the working internal standard solution was added to each tube, and the tubes were rotated again for 30 min at 30 rpm. Duplicate 1-μl aliquots of the upper phase were chromatographed, and the slope was calculated from the ratio of the area counts of the benzalazine peaks to the area counts of the internal standard peaks *versus* the corresponding weight ratio.

Day-to-Day Calibration—Two hydrazine dihydrochloride standards, usually ~0.40 and 1.20 μg/ml, were prepared daily. Two-milliliter aliquots of these standards were derivatized as described above, and 1-μl aliquots were injected onto the chromatograph at regular intervals.

Analysis of Drug Raw Materials and Tablet Formulations—An accurately weighed amount of hydralazine hydrochloride, isoniazid drug raw material, or a powdered tablet composite equivalent to 50 mg of drug substance was tumbled for 30 min in a screw-capped culture tube with 5.0 ml of distilled water. After centrifugation, a 2.0-ml aliquot of the aqueous extract was derivatized as described above, and 1-μl aliquots were injected onto the chromatograph.

Analysis of Liquid Formulations—An aliquot of hydralazine hydrochloride injectable or isoniazid syrup equivalent to 20 mg of drug was pipetted into a 150 × 20-mm culture tube with 1.0 ml of distilled water, if necessary, to bring the total volume to 2.0 ml. The solution was derivatized and chromatographed as described above.

Quantitation—Hydrazine was estimated by comparison of the benzalazine to internal standard peak area ratio of the sample to the corresponding ratio of the standard. When the area ratio of the sample was less than that of the daily calibration standard, a new standard was prepared to approximate the concentration of the sample in question. When the area ratio exceeded that of the daily calibration standard, the sample was diluted with the working internal standard solution to approximate the concentration of the standard.

RESULTS AND DISCUSSION

Hydrazine in hydralazine and isoniazid raw materials and formulations was determined as the benzaldehyde derivative by GC. Hydrazine dihydrochloride was chosen as the calibration standard because it is more stable in aqueous solution (50 days) than the sulfate (7 days) or the hydrate (1 day).

Concomitant with the formation of benzalazine in the derivatization step is the formation of a hydrazone from the condensation of hydralazine with benzaldehyde. This compound is not separated from benzalazine by extraction and appears at ~4.3 and 8.1 min, well after the appearance of benzalazine and the internal standard at 1.2 and 1.6 min, respectively. It is the presence of this compound which leads to the requirement for a GLC method: the compound accumulated on the HPLC column, only to elute after a time with a resultant baseline shift and other undesirable chromatographic features. Similar compounds form from phenelzine and isoniazid. In the former case the compound elutes from the HPLC column, while in the latter it does not enter the partitioning solvent.

Derivatization Reaction—*Hydralazine*—Water was used as the medium for dissolution of the hydralazine and the derivatization reaction. The final pH values associated with dissolution of the drug were similar for all raw materials and formulated products (pH 2.9–3.2) and had no apparent effect on the derivatization reaction. The sodium acetate buffer (pH 6) used for sampling in the method for hydrazine in phenelzine (2) could not be used for hydralazine because it gave rise to an unidentified peak on the chromatogram that interfered with the internal standard peak. The time required for complete derivatization and the stability of the benzalazine formed were determined by measuring the GLC response due to benzalazine as a function of the time during which the derivatization was allowed to proceed. The derivatization of the hydrazine dihydrochloride standard was complete within 3–5 min, and the benzalazine formed was stable for at least 35 min. Hydralazine hydrochloride was stable under the derivatization conditions for 30 min after which time a peak due to a trace (0.0003%) of benzalazine appeared in the chromatogram. Neither hydralazine nor reserpine and/or hydrochlorothiazide (sometimes formulated with hydralazine) interfered with the derivatization reaction.

In contrast to the behavior of hydrazine dihydrochloride, the benza-

lazine derivative formed from hydrazine sulfate in water or acetate buffer was stable for only 10 or 20 min, respectively (2). There was no difference in the time required for the derivatization to go to completion.

Isoniazid—Either water or acetate buffer can be used for the sampling and derivatization of hydrazine from isoniazid products: the rate of derivatization of hydrazine dihydrochloride was the same in both solvents. Neither isoniazid nor pyridoxine interfered with the derivatization reaction. The mole ratio of benzaldehyde to hydralazine required to achieve quantitative derivatization of hydrazine in the presence of hydralazine, determined as previously described (1, 2), was 2.5:1. The method provides for a mole ratio of 3.0:1.

Neither hydralazine nor isoniazid decomposed to hydrazine during extraction and derivatization. This is demonstrated by the nondetectable and trace levels found in some drug raw materials and formulations (Tables I and II) and by the complete recovery of hydrazine from spiked samples (Table III).

Extraction and Partition—The extraction was done with *n*-heptane because it was free of interfering impurities and was a good solvent for the internal standard. To show that benzalazine was completely extracted from the derivatization medium, the latter was shaken with *n*-heptane in ratios of 1:20; 1:10; 2:10, and 3:10. The peak area ratios of derivative to internal standard divided by the corresponding weight ratios were 11.064, 11.028, 11.112, and 11.052, respectively, showing that partition was virtually complete. In addition, there was no significant change in the chromatographic response of internal standard solutions containing benzalazine after they had been extracted with the aqueous derivatization medium. The ratios of aqueous to the organic phase examined were 1:5, 2:5, and 4:5.

Tablet extraction conditions were verified by shaking portions of an isoniazid–pyridoxine tablet composite equivalent to 50 mg with 3.0, 5.0, 10.0, and 20.0 ml of water. After derivatization and extraction, hydrazine levels were found to be 0.0640, 0.0662, 0.0654, and 0.0602%, respectively. To check the time required for extraction, an isoniazid–pyridoxine tablet product was shaken with 5 ml of water for 10 and 30 min. Hydrazine levels, after derivatization and extraction, were 0.0060 and 0.0065%, respectively, identical within the experimental error.

The amount of *n*-heptane required to extract the hydrazine derivative from the aqueous phase was established by experiments with a hydralazine injectable and an isoniazid elixir. For the injectable, aqueous to organic phase ratios of 2:5, 2:10, 2:15, and 2:20 gave apparent hydrazine levels of 0.0257, 0.0240, 0.0256, and 0.0260%, respectively. For the isoniazid syrup formulation, the hydrazine levels were 0.374, 0.370, 0.363, and 0.389%, respectively, for the same solvent ratios. The method calls for a ratio of 2:10.

Linearity, Reproducibility, and Accuracy—A standard curve was prepared by derivatizing, extracting, and chromatographing known amounts of hydrazine dihydrochloride. Over the range from 0.005 to 0.122 ng of hydrazine injected (as benzalazine), the slope of the area count ratio of benzalazine to internal standard *versus* the corresponding weight ratio was 11.7121 and the intercept did not differ significantly from zero (7.2×10^{-3}). The standard deviation of the slope was 0.2131, and the correlation coefficient was 0.9987. This range represents hydrazine levels from 0.0003 to 0.0061% for 2000 ng of drug injected.

The chromatographic reproducibility was established by injecting seven aliquots of each of three solutions of derivatized and extracted hydrazine dihydrochloride. The amounts of hydrazine injected (as benzalazine) were 0.0264, 0.0486, and 0.0972 ng, and the relative standard deviations of the count/weight ratios were 1.60, 0.63, and 0.89%, respectively. The reproducibility of the procedure as applied to formulated drug products can be gauged from the data in Tables I and II. Relative standard deviations ranged from 4.0% for a hydralazine injectable (4 replicates, 0.0403% hydrazine) to 10.3% for isoniazid tablets (5 replicates, 0.0029% hydrazine).

The recovery of hydrazine in the presence of formulation matrices was determined by adding known amounts of hydrazine dihydrochloride at the extraction step and carrying the assay through to completion. Recoveries ranged between 93.4 and 103.2% (Table III).

The minimum detectable amount of hydrazine, as benzalazine on-column, is ~0.005 ng, with the minimum quantifiable level about three times this amount. This permits detection of hydrazine at the level of ~0.0003% in drugs. This method is 20 times as sensitive as the previously described HPLC methods (1, 2).

Hydrazine in Drug Raw Materials and Formulations—No hydrazine was found in raw material lots of hydralazine. Traces of hydrazine were found in some tablet lots and these amounts increased in tablets subjected to stress (Table I). Hydrazine levels in injectable hydralazine products were higher than in tablets and increased with time and temperature stress (Table I). It would appear that hydrazine is a degradation product of hydralazine.

Only a trace of hydrazine was found in the isoniazid raw material lot examined, but the formulated products examined contained hydrazine. The levels increased in products subjected to temperature and humidity stress (Table II). Again, it appears that hydrazine is a degradation product of the drug.

Table III—Hydrazine Recoveries

Theophylline Blood–Brain Barrier Transfer Kinetics in Dogs

P. VENG-PEDERSEN *[x], R. E. BRASHEAR [‡], and M. D. KAROL *

Received April 28, 1982, from the **Division of Pharmacokinetics, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907* and the [‡]*Department of Medicine, Indiana University, Indianapolis, IN 46223.* Accepted for publication August 6, 1982.

Abstract □ A simple diffusion-based pharmacokinetic model is proposed relating blood–brain barrier transfer kinetics of theophylline to the difference in the free concentrations of the drug in serum and cerebrospinal fluid (CSF). The model predicts that the CSF drug level is proportional to the serum drug level convoluted by $\exp(-kt)$, where k is the blood–brain barrier diffusion rate constant. An excellent agreement was found by nonlinear regression analysis between serum and CSF theophylline data in eight dogs and the proposed model for the blood–brain barrier transfer kinetics of theophylline. The ratio of the free fractions of theophylline in serum and CSF predicted from the model also agrees with the value determined experimentally.

Keyphrases □ Theophylline—blood–brain barrier transfer in dogs, kinetics □ Kinetics—of theophylline, blood–brain barrier transfer in dogs □ Blood–brain barrier—theophylline transfer in dogs, kinetics

The narrow therapeutic range of theophylline and the substantial intersubject variability in its disposition have resulted in extensive studies of the pharmacokinetics and clinical dosage management of the drug (1–8). Several investigations have related the bronchodilator effect of theophylline to its serum concentration level (5, 6, 9–13). However, it is the adverse effects rather than the therapeutic effect that dictates the dose administered and limits the therapeutic efficacy. The main adverse effects appear to be of CNS origin. It may be misleading, therefore, to use serum levels as a guide for the clinical management of the drug without any *a priori* knowledge of the kinetics of the blood–brain barrier transfer of theophylline. The theophylline concentration in the cerebrospinal fluid (CSF), should provide a better correlation to the CNS effects. The object of this study is to investigate the serum–CSF disposition of theophylline and the blood–brain barrier transfer kinetics. By establishing the kinetic relationship between the serum and CSF drug levels, a more rational approach to the usage of serum theophylline determinations can be established.

Although it was recognized early that theophylline enters the cerebrospinal fluid, neither the rate of equilibration with serum nor the serum–CSF concentration ratio have been defined adequately. In fact, little is known about the kinetics of transfer of drugs across the blood–brain barrier. The few CSF samples that have been correlated with serum samples in humans provide only a very limited insight into the kinetics (14–17). The use of dogs in the present study allowed comprehensive CSF sampling enabling a proper pharmacokinetic analysis of the serum–CSF theophylline disposition. Animals are often a poor predictor of human pharmacokinetics mainly due to substantial differences in the elimination processes. However, the present manner of analysis of the serum–CSF transfer kinetics is not influenced by absorption or elimination or other disposition processes. Furthermore, the tissues that constitute the blood–brain barrier apparently do not differ significantly between dogs and humans (18). The results from this study should therefore be of clinical interest.

EXPERIMENTAL

Study Design—After an 18-hr fast, eight dogs were anesthetized with 30 mg/kg iv of sodium pentobarbital; supplemental doses were given as needed during the remainder of the experiment. A polyethylene catheter in the left lateral saphenous vein was used for the infusion of aminophylline. Aminophylline[1] for intravenous use was utilized containing 25 mg of aminophylline (20.63 mg of anhydrous theophylline)/ml of solution. Aminophylline, 9 mg/kg (7.43 mg/kg theophylline) was diluted with saline to 19.4 ml and infused with a constant-infusion pump over a total of 20 min.

Blood samples for theophylline level determination were taken from a catheter in the left external jugular vein. An 18-gauge needle was percutaneously placed in the cisterna magna for obtaining the CSF samples. Cerebrospinal fluid and blood for theophylline levels were obtained at time zero (start of the infusion) and 20 (end of infusion), 50, 80, 140, 200, 260, 320, 350, and 380 min. The dogs were ventilated through a cuffed endotracheal tube using a constant-volume ventilator[2] with periodic hyperinflation to prevent atelectasis.

Theophylline Assay—The serum from 2–3 ml of blood and 0.5 ml of CSF were frozen and later assayed for theophylline, usually within 1–3 days. Theophylline concentrations were determined by the GC method of Least and coworkers (19) using 100-μl samples and substituting iodobutane for iodopentane in the derivation procedure. Theophylline concentrations were calculated using peak height ratios of theophylline to internal standards.

Protein Binding—The protein binding of theophylline was deter-

[a] Correlation coefficients between observed and calculated theophylline levels: (r_T) total (serum and CSF), (r_s) serum, and (r_c) CSF.

mined by filtering serum and CSF samples through filter membrane cones[3] to yield an ultrafiltrate free of molecules with molecular weights >50,000. A 2-ml aliquot was centrifuged at 2000 rpm (not exceeding 1000×g) for 30 min yielding ~1 ml of filtrate. Both the filtrate and original sample were assayed for theophylline. The amount of theophylline bound to protein was determined by subtracting the amount of theophylline in the protein-free ultrafiltrate sample from the amount of theophylline in the original sample. The percent of protein-bound theophylline was calculated by dividing the amount of protein-bound theophylline by the amount of theophylline in the original sample. The free fractions of theophylline in serum were 0.86, 0.85, 0.89, 0.86, 0.91, 0.79, 0.80, and 0.83 and the cerebrospinal fluid 1.00, 1.00, 0.92, 1.00, 0.99, 1.00, 1.00, and 0.95 for dogs 1–8, respectively.

PHARMACOKINETIC ANALYSIS

The object of the pharmacokinetic analysis is to elucidate the blood–brain barrier transfer kinetics of theophylline on the basis of serum and CSF concentration data. Compounds may pass the blood–brain barrier by different mechanisms such as simple diffusion, facilitated passive diffusion with carrier substances, and active transport (20). The latter two are saturable processes. However, due to the narrow therapeutic range of theophylline, it may not be possible to establish kinetically if the drug crosses the blood–brain barrier by simple diffusion or by a saturable facilitated transport. For a diffusional process the rate of transfer of drug across the blood–brain barrier would be proportional to the difference between the free drug concentrations on the two sides of the barrier, *i.e.*:

$$\frac{d}{dt}\{V_cC_c(t)\} = k_1[F_sC_s(t) - F_cC_c(t)] \qquad \text{(Eq. 1)}$$

where subscripts c and s denote cerebrospinal fluid and serum, respectively; V, C, and F stand for volume, total drug concentration, and free (unbound) fraction, respectively; and k_1 is a positive diffusion constant. Equation 1 assumes that the drug is not metabolized in the CSF, which is consistent with our current knowledge about the metabolic systems present on the CNS side of the blood–brain barrier (20).

Equation 1 can be written simply as:

$$\frac{dC_c(t)}{dt} = k[RC_s(t) - C_c(t)] \qquad \text{(Eq. 2)}$$

where $k = F_ck_1/V_c$ is a diffusion rate constant with dimension time^{-1} and $R = F_s/F_c$ is the free fraction ratio. Laplace transformation of Eq. 2 yields, after rearrangement (bars denote transformed functions):

$$\bar{C}_c(s) = kR\bar{C}_s(s)\frac{1}{s+k} \qquad \text{(Eq. 3)}$$

which back-transformed gives:

$$C_c(t) = kRC_s(t) * e^{-kt} \qquad \text{(Eq. 4)}$$

where * denotes convolution. Equation 4 expresses how the concentration of theophylline in the CSF relates to the concentration of the drug in serum if the transfer of the drug across the blood–brain barrier is by simple diffusion. The diffusional transport hypothesis is tested kinetically in the following manner according to Eq. 4:

A suitable arbitrary function is chosen to approximate the $C_s(t)$ response by nonlinear least-squares curve fitting. The fitting of the arbitrary function to the serum data is done simultaneously with a fitting to the CSF data of a second function resulting from convoluting the first function with e^{-kt} and multiplying by a constant (kR) according to Eq. 4. The two constants k and R are treated as unknown parameters and determined in the simultaneous curve fitting.

The following empirical function was used to approximate the serum data resulting from a short ($t = 0$ to $t = T$) constant rate infusion:

$$C_s(t) = A\,[e^{-\alpha(t-T)_+} - e^{-\alpha t}] + B[e^{-\beta(t-T)_+} - e^{-\beta t}] \qquad \text{(Eq. 5)}$$

$$A, \alpha, B, \beta > 0$$

where:

$$(t-T)_+ = t - T \text{ for } t > T \qquad \text{(Eq. 6)}$$

$$(t-T)_+ = 0 \text{ for } t \le T \qquad \text{(Eq. 7)}$$

and A, α, B, β are positive constants that are adjusted in the curve fitting to provide a least-squares approximation of the serum level data by the $C_s(t)$ function.

Convoluting Eq. 5 according to Eq. 4 yields:

$$C_c(t) = kR\left\{\left[\frac{A\alpha}{k(\alpha-k)} + \frac{B\beta}{k(\beta-k)}\right][e^{-k(t-T)_+} - e^{-kt}] + \frac{A}{k-\alpha}[e^{-\alpha(t-T)_+} - e^{-\alpha t}] + \frac{B}{k-\beta}[e^{-\beta(t-T)_+} - e^{\beta t}]\right\} \qquad \text{(Eq. 8)}$$

Equations 5 and 8 were fitted simultaneously to serum and CSF theophylline data for each dog using the interactive nonlinear regression program FUNFIT (21).

RESULTS AND DISCUSSION

The present method of pharmacokinetic analysis differs in several aspects from classical pharmacokinetic approaches:

1. The study focuses on a single disposition process (the blood–brain barrier transfer kinetics) which is analyzed without interference from other pharmacokinetic processes.
2. The kinetic model for the process is physiologically meaningful.
3. The analysis does not rely on the many often unrealistic assumptions and concepts of classical pharmacokinetic approaches such as linear disposition, abstract multicompartmental drug transfer, rate processes that are proportional to the amount rather than the concentration of the drug, *etc.*
4. With the exception of the specific process under investigation, the method is completely model independent. No attempts are made to derive kinetic models to account for the drug's disposition and elimination kinetics.

The approach may perhaps best be characterized as a "response approximation approach" where the concentration response is estimated by fitting a suitable arbitrary function (Eq. 5) to the data. It is not necessary to attach any kinetic significance to the approximating function and its parameters. Its purpose is not to model the pharmacokinetics but to estimate (approximate) the concentration profile so it can be used to investigate changes in the theophylline concentrations in the serum and CSF in a way that is consistent with the proposed kinetic model for transfer of the drug across the blood–brain barrier (Eqs. 1 and 4).

The serum and cerebrospinal fluid data for each of the eight dogs showed excellent agreement with the proposed diffusion model for the transfer of theophylline across the blood–brain barrier (Fig. 1, Table I).

[3] Type CF50A Centriflo, Americon Corp.

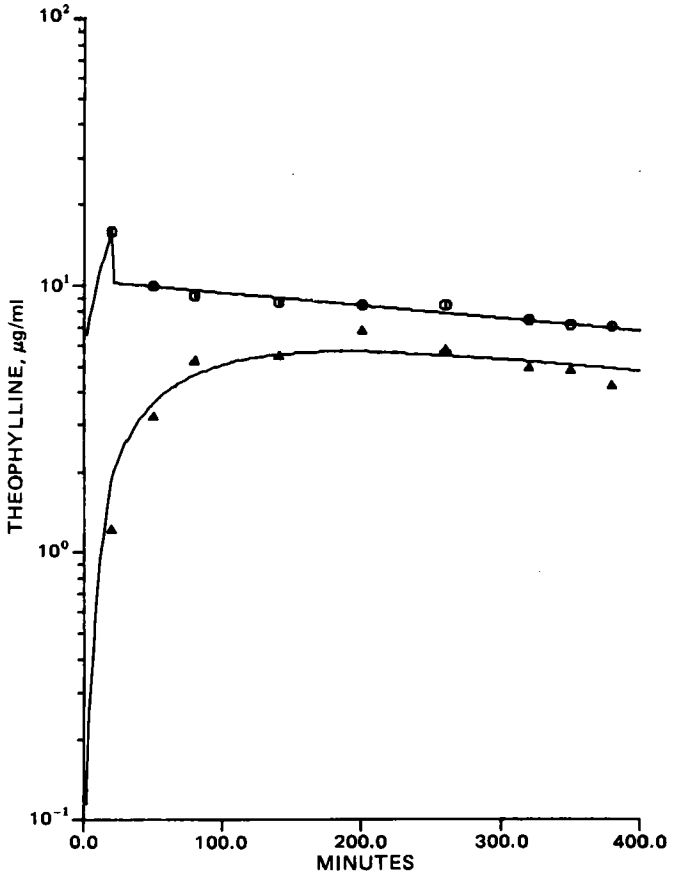

Figure 1—*Simultaneous least-squares fit of Eqs. 5 and 8 to serum (⊙) and CSF (▲) theophylline data resulting from a 20-min constant-rate intravenous infusion for dog 2. This fit has the smallest total correlation coefficient of the eight dogs studied (Table I).*

The k values are all of the same order of magnitude. Since $k = F_c k_1/V_c$ depends on both V_c, the volume of the CSF and F_c, the free fraction of theophylline in the CSF, this parameter is naturally expected to show greater intersubject variability than the more intrinsic diffusion parameter, k_1 (defined in Eq. 1). The determination of k_1 would have required V_c to be experimentally determined which was not done in the present study. The free fraction ratio $R = F_s/F_c$ differs remarkably little from subject to subject. The mean value of 0.60 ±0.03 (*SD*) for R comes fairly close to the ratio of 0.86 ± 0.06 (*SD*) calculated from experimentally determined values. The difference may well be due to the inherent inaccuracy of binding determination by ultrafiltration and to the fact that the free fraction is dependent on the total drug concentration. The microenvironment where the diffusion takes place may also have a different protein composition than that found in serum and CSF.

The binding of theophylline in serum is not likely to be affected by the presence of pentobarbital, because a significant change in the free fraction of a drug by competitive binding is usually only seen for drugs that are highly bound (>95%).

Theophylline serum data are used in clinical monitoring for dosage adjustments and in the management of overdose cases. However, since the side effects are of a CNS origin, the CSF drug level should provide a better basis for monitoring. In the postdistribution phase of a drug input where the ratio between the theophylline serum and CSF levels remains fairly constant (Fig. 1), the serum level should be a good indicator of the CNS level of the drug. However, in the distribution phase (lasting 1–1.5 hr after a rapid drug input), there appears to be a significant divergence in the serum and CSF drug levels[4]. In fact, during this phase the serum level may drop while the CSF level increases (Fig. 1). Evidently it is of great clinical significance to understand this kinetic phenomenon. During the distribution phase of a case of theophylline overdosing, it would be inappropriate to rely on serum levels for safety predictions. A decline in the serum level may not guarantee improvement; it would be wise to be prepared for delayed severe toxic effects. In a study of overdose cases resulting in seizure, it was reported that the most noteworthy phenomenon was the apparent absence of adverse effects in seven of the eight patients prior to the seizure (13). That study is consistent with what could be predicted from our pharmacokinetic investigation when the toxic effects are related to the CSF drug level rather than the serum level. Undoubtedly there is a need to further study the serum–CSF disposition of theophylline so a proper pharmacodynamic basis can be established for the rational clinical use of theophylline serum data.

[4] The distribution phase in the present context is defined in reference to the CSF. Thus, although the distribution of theophylline to compartments other than the cerebrospinal fluid appears very rapid judged from the short α-phase in the serum, this is not the case for the CSF (Fig. 1).

Allergenic Properties of Naturally Occurring Cannabinoids

EDNA S. WATSON ˣ, JAMES C. MURPHY, and CARLTON E. TURNER

Received June 14, 1982, from the *Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication August 4, 1982.

Abstract □ The guinea pig maximization test was used to determine the potential of seven cannabinoids to produce allergic contact dermatitis. Δ^9-Tetrahydrocannabinol and cannabinol were found to be extreme (Grade V) sensitizers. Cannabidiol, Δ^8-tetrahydrocannabinol, and cannabichromene were moderate (Grade III) sensitizers. Cannabigerol and cannabinol methyl ether were not sensitizers. Most of the cannabinoids were found to be allergenically cross-reactive. Additionally, it was shown that the presence of a free 1′-hydroxyl group was required for sensitization, but not to elicit a response in sensitive animals.

Keyphrases □ Cannabinoids—naturally occurring, allergenic properties, determined by the guinea pig maximization test for skin sensitivity □ Allergenicity—of naturally occurring cannabinoids, guinea pig maximization test for skin sensitivity □ Sensitizers, skin—allergenic properties of naturally occurring cannabinoids, guinea pig maximization test

Δ^9-Tetrahydrocannabinol (I) was shown to be a potent skin sensitizer in the guinea pig, and serum from sensitive animals sensitized guinea pig mast cells for degranulation (1). Tetrahydrocannabivarol, a Δ^9-tetrahydrocannabinol homologue, was also found to be a potent skin sensitizer (2). In view of these findings, a systematic study comparing the sensitizing potential of I to six other cannabinoids was conducted utilizing the guinea pig maximization test. The cross-allergenicity of these cannabinoids was also studied.

EXPERIMENTAL

Female Hartley guinea pigs, weighing 350–400 g, were used[1]. Food[2] and water supplemented with vitamin C were available *ad libitum*. Δ^9-Tetrahydrocannabinol (I), Δ^8-tetrahydrocannabinol (II), cannabidiol (III), and cannabinol (IV) were obtained from the National Institute on Drug Abuse, Rockville, Md. Cannabigerol (VI) was synthesized according to the literature procedure (3); cannabinol monomethyl ether (V) was synthesized from cannabinol as previously reported (4); cannabichromene (VII) was synthesized by the literature procedure (5). The purity of each cannabinoid was shown to be >95% by GC analysis.

Ten guinea pigs were used for maximization testing of cannabigerol and cannabinol methyl ether. Twenty guinea pigs were used for maximization testing of the remaining cannabinoids. The maximization method of Magnusson and Kligman (6) was used to determine the sensitizing capacity of each cannabinoid. A 5% water-in-oil emulsion of each cannabinoid (50 mg/ml of emulsion) was prepared by dissolving the cannabinoid in complete Freund's Adjuvant[3] and emulsifying using adjuvant–sterile water (1:1, v/v). A 5% solution of each cannabinoid was dissolved in sterile paraffin oil. Guinea pigs were sensitized by duplicate 0.1-ml intradermal (id) injections of cannabinoid emulsion, cannabinoid in paraffin oil, and adjuvent alone.

Topical induction sites were prepared by application of 10% sodium lauryl sulfate in petrolatum over the intradermal induction sites, 6 days after intradermal induction. Forty-eight-hour occlusive patches of the cannabinoid in petrolatum (0.03% w/w) were applied directly over the intradermal induction sites on day 7, after removal of the sodium lauryl sulfate. On day 23 the animals and nonsensitive control animals were given topical open epicutaneous skin tests with 100 and 50 μg of each cannabinoid in 10 μl of alcohol. The sites were observed 24, 48, and 72 hr later for erythema and edema. The Draize scoring system (7) was used to rank the intensity of erythema and edema based on a 0 to +4 rating scale. The mean erythema and edema scores from the three test readings were summed to provide an intensity score for each animal. The intensity scores of the 20 animals in each group were averaged to provide an average score. Animals demonstrating sensitivity to homologous sensitizing cannabinoids were skin tested with the other cannabinoids to determine if cross-allergenicity occurred.

RESULTS AND DISCUSSION

All of the cannabinoids subjected to maximization testing were sensitizers except cannabinol methyl ether and cannabigerol. Δ^9-Tetrahydrocannabinol and cannabinol were rated as extreme sensitizers (Table I), while cannabidiol, Δ^8-tetrahydrocannabinol, and cannabichromene were found to be moderate sensitizers. The allergenic potency of the cannabinoids (in descending order) was I = IV > III > VII > II > VI = V.

The cross-allergenicity of some cannabinoids and eugenol are shown in Table II. The extreme sensitizers, I and IV, provided the greater number of cross-reactions to the other cannabinoids. All cannabinoids tested were cross-reactive with other cannabinoids. However, the moderate sensitizers produced fewer cross-reactions than did the extreme

VII	40	III, Moderate	0.38
II	30	III, Moderate	0.70
VI	0	Inactive	0
V	0	Inactive	0

sensitizers. Eugenol did not elicit cross-reactions in any animals. Since cannabinol methyl ether failed to sensitize, but did produce reactions in animals sensitized with cannabinol and cannabidiol, it appeared that a free hydroxyl group in position one was required for sensitization, but not to elicit a reaction in animals already sensitized. The failure of cannabinol methyl ether to elicit reactions in Δ^9-tetrahydrocannabinol-sensitized animals is not understood.

Although many of the biological effects of Δ^9-tetrahydrocannabinol are shared by all naturally occurring cannabinoids, the psychoactive effects are not. Desoize *et al.* (8) found that six natural cannabinoids (I, II, III, IV, VII, and cannabicyclol) suppressed phytohemagglutinin-induced DNA synthesis in normal human peripheral-blood lymphocytes, an *in vitro* model for cell-mediated immune function. In addition, the inhibitory effects of five of these six natural cannabinoids on the passive cutaneous anaphylaxis reaction in rats has been reported (9). Compound I, however, was a more potent inhibitor of passive cutaneous anaphylaxis than the other cannabinoids, and III was least active. Zimmerman *et al.* (10) reported that cannabidiol and cannabinol did not reduce hemagglutination titers to sheep red blood cells in mice at doses of 25 mg/kg, while Δ^9-tetrahydrocannabinol did.

The olivetol moiety of the molecule appeared, in the above studies, to be the portion of the molecule required for the shared activities. Olivetol was found by Desoize *et al.* (8) to inhibit phytohemagglutinin-induced lymphocyte transformation.

In this study, most cannabinoids containing the olivetol moiety were found to be skin sensitizers. Cannabinol methyl ether, which has its hydroxyl function blocked with a methyl ether, was not a sensitizer. The cross-allergenicity of these compounds is likely to be directly related to the presence of the olivetol component.

Absolute and Relative Bioavailability of Oral Acetaminophen Preparations

BARBARA AMEER *x, MARCIA DIVOLL ‡, DARRELL R. ABERNETHY ‡, DAVID J. GREENBLATT ‡, and LEON SHARGEL *

Received February 5, 1982, from the **College of Pharmacy and Allied Health Professions, Northeastern University, Boston, MA 02115* and the ‡*Division of Clinical Pharmacology, Tufts-New England Medical Center, Boston, MA 02111.* Accepted for publication August 11, 1982.

Abstract □ Eighteen healthy volunteers received single 650-mg doses of acetaminophen by 5-min intravenous infusion, in tablet form by mouth in the fasting state, and in elixir form orally in the fasting state in a three-way crossover study. An additional eight subjects received two 325-mg tablets from two commercial vendors in a randomized crossover fashion. Concentrations of acetaminophen in multiple plasma samples collected during the 12-hr period after each dose were determined by high-performance liquid chromatography. Following a lag time averaging 3–4 min, absorption of oral acetaminophen was first order, with apparent absorption half-life values averaging 8.4 (elixir) and 11.4 (tablet) min. The mean time-to-peak concentration was significantly longer after tablet (0.75 hr) than after elixir (0.48 hr) administration. Peak plasma concentrations and elimination half-lives were similar following both preparations. Absolute systemic availability of the elixir (87%) was significantly greater than for the tablets (79%). Two commercially available tablet formulations did not differ significantly in peak plasma concentrations, time-to-peak, or total area under the plasma concentration curve and therefore were judged to be bioequivalent.

Keyphrases □ Bioavailability—absolute and relative, oral acetaminophen preparations, determined by high-performance liquid chromatography □ Acetaminophen—absolute and relative bioavailability of oral preparations, determination by high-performance liquid chromatography □ High-performance liquid chromatography—oral acetaminophen preparations, determination of absolute and relative bioavailability

Acetaminophen (paracetamol) is used extensively as a nonprescription analgesic and antipyretic agent (1). Over 40 oral acetaminophen preparations are available commercially (2). The present study evaluated the absolute bioavailability of orally administered acetaminophen in elixir and tablet forms. Also assessed was the relative

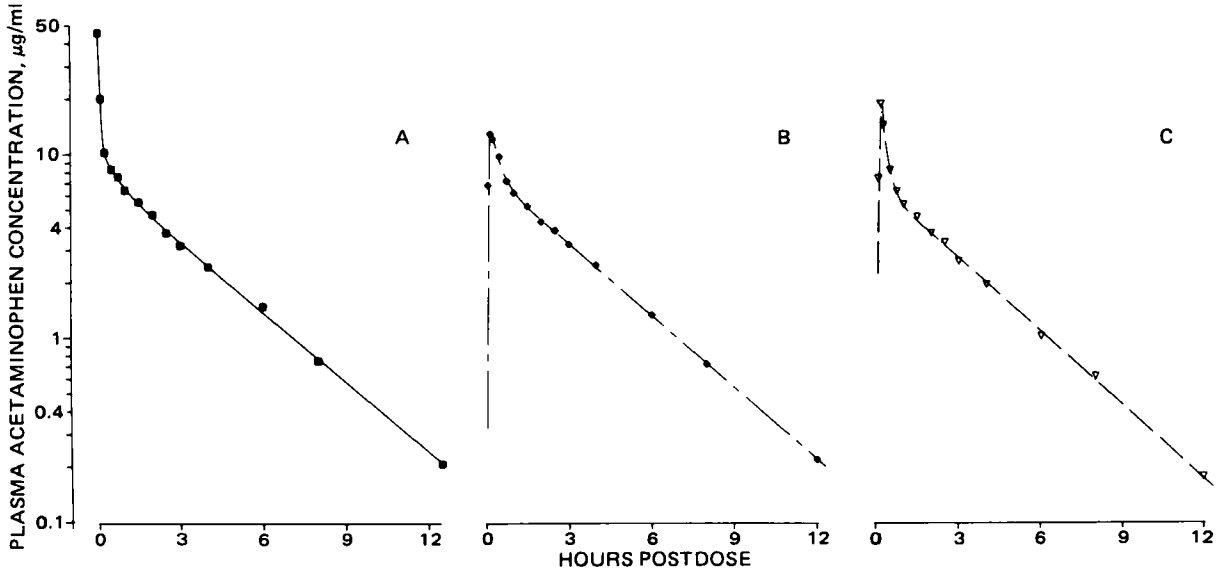

Figure 1—*Plasma acetaminophen concentrations and pharmacokinetic functions in a representative subject following 650-mg doses by three modes of administration. Key: (A) intravenous; (B) elixir; (c) tablet.*

bioavailability of two brands of oral acetaminophen tablets.

EXPERIMENTAL

Three-way Crossover Study of Acetaminophen Dosage Forms—Eighteen healthy male and female volunteers, aged 22–36 years, participated after giving informed written consent. All participants were ambulatory, were taking no other medications, and had no history of chronic disease. All subjects received a single 650-mg dose of acetaminophen on three occasions separated by at least 1 week. The sequence of the three trials was randomized. The modes of administration were:

1. Intravenous acetaminophen, administered as a sterile solution[1] infused into an antecubital vein over a period of 5 min;
2. Acetaminophen elixir[2] administered as 19.5 ml of a 33.3-mg/ml solution and followed by 20 ml of water;
3. Two 325-mg oral tablets[3] administered with 100–200 ml of water.

For the two oral dosage trials, subjects were fasted overnight prior to and for 3 hr following drug administration.

Venous blood samples were drawn from an indwelling butterfly catheter, or by separate venipuncture, and placed in heparinized tubes. Samples were collected prior to intravenous acetaminophen infusion, immediately at the end of the infusion, and at 5, 15, 30, and 45 min, 1, 1.5, 2, 2.5, 3, 4, 6, 8, and 12 hr postinfusion. In the oral acetaminophen trials, a sample was drawn prior to dosage, at 5, 10, 15, 30, and 45 min, and thereafter as described for intravenous acetaminophen. Whole-blood samples were centrifuged, and the plasma was separated and stored until the time of assay.

Concentrations of acetaminophen in all plasma samples were determined by high-performance liquid chromatography (HPLC) (3). The sensitivity of this method was 0.1–0.2 μg of acetaminophen/ml of plasma. For six identical samples at concentration points ranging from 0.25–15 μg/ml, the coefficient of variation was <5%. The mean deviation between pairs of duplicate samples (n = 45) analyzed during pharmacokinetic studies was 2.4%.

Plasma acetaminophen concentrations after intravenous dosage were analyzed by iterative nonlinear least-squares techniques as described in detail previously (4, 5). Plasma levels were fitted to a linear sum of 2 or 3 exponential terms. Coefficients, corrected for the infusion period (6), and exponents from the fitted function were used to determine the total area under the plasma concentration curve from time zero to infinity ($AUC_{0\text{-}\infty}$). After oral dosage, plasma concentrations likewise were fitted to a linear sum of 2 or 3 exponential terms. Coefficients and exponents from the fitted function were used to determine the apparent lag time prior to the start of absorption, the first-order absorption half-life, and the elimination half-life (7). The plasma concentration AUC from time zero until the final detectible acetaminophen concentration was determined by the trapezoidal method. To this value was added the residual area extrapolated to infinity, calculated as the final plasma concentration divided by the terminal exponent. The sum of these two areas represent the total AUC (7, 8).

Absolute bioavailability of both oral acetaminophen preparations for each subject was determined as the AUC following oral administration divided by the AUC following intravenous dosage to the same subject. Statistical methods included Student's t test and ANOVA.

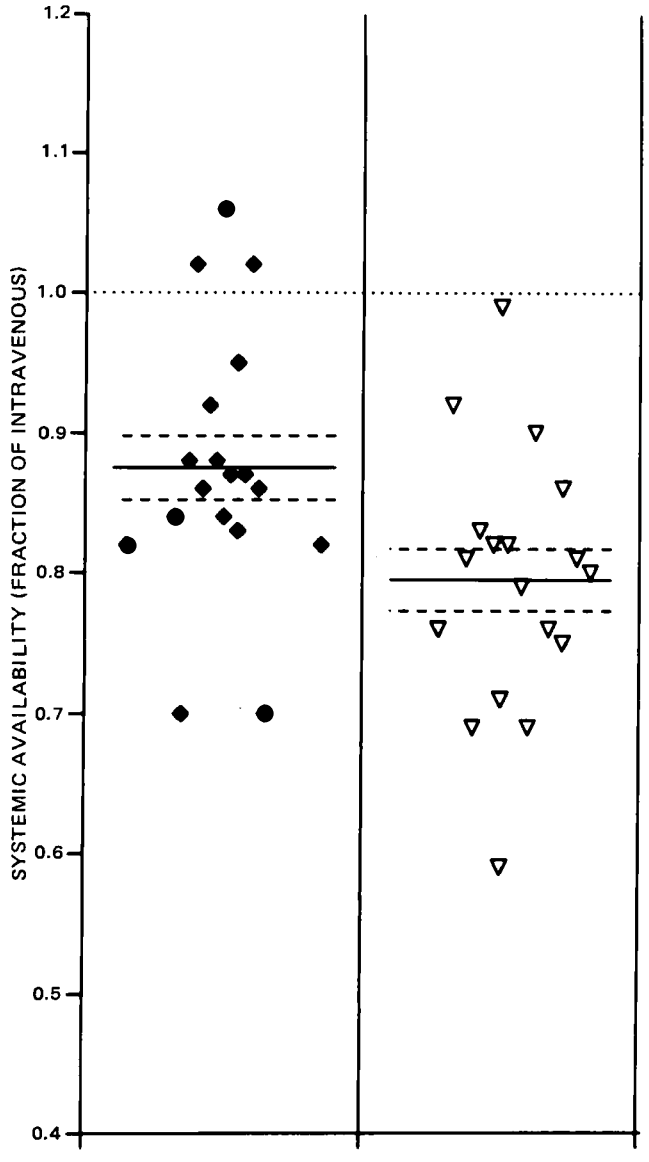

Figure 2—*Absolute bioavailability of oral acetaminophen in the elixir (◆) and tablet (▽) preparations. Horizontal lines represent means (—), standard errors (- - -), and 100% of the intravenous bioavailability (·····).*

relative bioavailability of two oral acetaminophen tablet preparations was evaluated in a two-way randomized crossover study involving seven male and one female volunteer. All subjects received a single 650-mg dose (two 325-mg tablets) of oral acetaminophen on two occasions separated by at least one week, using two commercially available[4] products (A and B).

Plasma samples were obtained as described above following both oral acetaminophen trials. Acetaminophen concentrations in all samples were determined by HPLC (3). Pharmacokinetic and statistical analyses were as described above. Differences between the two oral preparations were evaluated by Students's t test.

RESULTS

Comparison of Intravenous, Elixir, and Tablet Dosage Forms—Following intravenous acetaminophen administration, disappearance of drug from plasma was described by a linear sum of exponential terms (Fig. 1 and Table I). Iterative solutions were possible for 15 subjects following acetaminophen elixir administration and for 11 subjects following acetaminophen dosing by tablet (Fig. 1).

[4] Brand A was Tylenol tablets, lot HP2588, McNeil Consumer Products Co., Fort Washington, Pa.; Brand B was Tapar tablets, lot 2C246, Parke-Davis, Ann Arbor, Mich.

Table III—Pharmacokinetic Parameters for Two Tablet Formulations of Acetaminophen

Parameter	Mean ± *SE* Values Brand A	Brand B	Student's Paired t
Peak plasma concentration, μg/ml	8.56 ± 1.22	8.89 ± 0.78	0.221
Time-to-peak concentration, hr	1.06 ± 0.27	0.78 ± 0.10	0.986
Elimination half-life, hr	2.62 ± 0.10	2.43 ± 0.11	2.30[a]
Total $AUC_{0\to\infty}$, μg/ml × hr	26.82 ± 1.44	27.37 ± 0.94	0.468

[a] Significance level $0.05 < p < 0.10$.

Peak plasma concentrations following the elixir preparation administration were slightly higher than that for tablets, but the difference was not significant (Table II). The time-to-peak concentration averaged 0.48 hr after dosage with elixir *versus* 0.75 hr with the tablet ($p < 0.025$). The two preparations did not differ significantly in apparent half-life of absorption or in lag time prior to the start of absorption.

Absolute systemic availability of both oral preparations was significantly less than 100% complete (Table II, Fig. 2). Absolute availability of the elixir (87%) was significantly greater than that for tablets (79%). The elimination half-lives were similar following both preparations (Table II).

Comparison of Two Acetaminophen Tablet Formulations—The kinetics of acetaminophen absorption following dosing with brand B were very close to that reported in the three-way crossover study. Peak plasma concentration averaged 8.9 μg/ml and was reached an average of 0.78 hr after dosing. These values were similar to those observed for brand A (8.6 μg/ml and 1.1 hr after dosing, respectively), and the differences did not approach significance. The total AUC was nearly identical for both preparations (Fig. 3, Table III). The elimination half-life following brand B administration (2.43 hr) was shorter than with brand A (2.62 hr) although the magnitude of the mean difference was only 8%.

DISCUSSION

The results of the three-way crossover study concur with reports of other investigators (9) and indicate that absorption of acetaminophen from both tablet and elixir preparations is relatively rapid, with peak plasma concentrations generally attained within 1 hr postdose. The time-to-peak concentration was significantly shorter with the elixir than with the tablet, but differences in other absorption kinetic parameters did not reach statistical significance. Generally, drug absorption from an elixir preparation will be somewhat more rapid than from the same dose administered as a tablet. Absorption of acetaminophen from oral tablet preparations can be dissolution rate limited (10), probably explaining why the time-to-peak concentration was earlier following the elixir than with the tablet.

Neither preparation showed complete (100%) systemic availability;

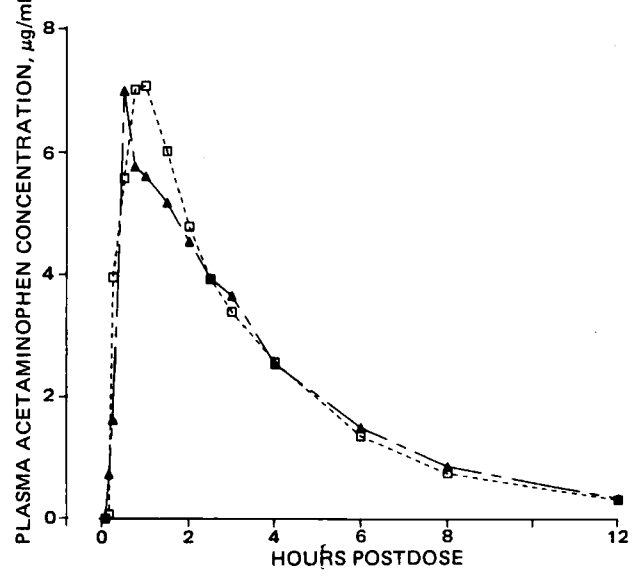

Figure 3—*Plasma concentrations following 650-mg doses of two brands of acetaminophen. Each point is the mean for all subjects at that time point. Key: (▲) Brand A; (□) Brand B.*

the elixir had significantly greater bioavailability than did the tablet. The incomplete systemic availability of oral acetaminophen could be explained either by incomplete absorption or presystemic biotransformation, (*e.g.*, first-pass hepatic extraction or metabolism in the epithelium and/or lumen of the GI tract), or by a combination of these two factors (11). Differentiation between these two possible mechanisms could be achieved through an examination of route-dependent differences in the pattern of drug metabolism, as described by Harris and Riegelman (12). In a previous study of systemic availability (13), Rawlins *et al.* reported the bioavailability of acetaminophen tablets in a 500-mg dose to be only 63% compared with 79% in our study of a 650-mg dose. Bioavailability increased to 89 and 87% following 1,000- and 2,000-mg doses, respectively (13). The discrepancy in results of the two studies may be due to saturation of presystemic biotransformation at doses >500 mg.

The comparative bioavailability studies of two widely used acetaminophen tablets suggest that they have essentially similar systemic availability and therefore should be therapeutically equivalent.

Simultaneous Determinations of Cefsulodin and Cefotiam in Serum and Bone Marrow Blood by High-Performance Liquid Chromatography

KEIKO YAMAMURA *x, MAKOTO NAKAO *, JUN-ICHIRO YAMADA *, and TOSHIHISA YOTSUYANAGI ‡

Received March 17, 1982, from the **Pharmacy Department, Nagoya University Branch Hospital, Higashi-ku, Nagoya 461* and the ‡*Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya 467 Japan.* Accepted for publication August 9, 1982.

Abstract □ A high-performance liquid chromatographic method is described for the simultaneous determinations of cefsulodin and cefotiam in serum and bone marrow blood samples. After extraction with acetonitrile, the cephalosporins were applied to a reverse-phase column with an internal standard, cefazolin; the mobile phase was a mixture of 0.005 *M* tetrabutylammonium phosphate and methanol (35:65, v/v). The method yielded satisfactory resolutions for these agents, and the results were compared with those obtained using the microbiological method. The statistical analysis of the relationship between the methods gave a good correlation for all of these agents and samples. The concentrations of cefsulodin and cefotiam, concurrently administered by the intravenous route to patients subjected to artificial total joint prosthesis, in serum and bone marrow blood collected at 0.5 and 1 hr postinjection were almost equivalent.

Keyphrases □ Cefsulodin—simultaneous determination with cefotiam in serum and bone marrow blood, high-performance liquid chromatography □ Cefotiam—simultaneous determination with cefsulodin in serum and bone marrow blood, high-performance liquid chromatography □ High-performance liquid chromatography—simultaneous determination of cefsulodin and cefotiam in serum and bone marrow blood

Cefsulodin, sodium 4-carbamoyl-1-[(6*R*,7*R*)-2-carboxy-8-oxo-7- [(2*R*) -2-phenyl-2-sulfoacetamido] -5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl]methylpyridium hydroxide, a potent cephalosporin derivative, is superior to sulbenicillin and carbenicillin and comparable to gentamicin in activity against *Pseudomonas aeruginosa*. The drug is stable to *P. aeruginosa*-specific cephalosporinase (1–3). Cefotiam, (6*R*,7*R*)-7-[2-(2-amino-4-thiazolyl)-acetamido]-3-[[[1-[2-(dimethylamino)ethyl]-1*H*-tetrazol-5-yl]thio]methyl]-8-oxo-5-thia-1-azabicyclo[4.2.0]-oct-2-ene-2-carboxylic acid dihydrochloride, also shows broad-spectrum antibacterial activity against both Gram-positive and Gram-negative bacteria (4). Combined administration of these agents is frequently used to treat systemic infections in which a broader anti-infective spectrum is needed. A simple, specific high-performance liquid chromatographic (HPLC) method was developed which determines both cefsulodin and cefotiam in biological fluids. A comparison is made with the previously used microbiological method.

EXPERIMENTAL

Materials—Cefsulodin[1] and cefotiam[2] were used as received. Cefazolin[3], employed as an internal standard, was used as received. HPLC-quality methanol[4] and acetonitrile[5] were used. Tetrabutylammonium

the elixir had significantly greater bioavailability than did the tablet. The incomplete systemic availability of oral acetaminophen could be explained either by incomplete absorption or presystemic biotransformation, (*e.g.*, first-pass hepatic extraction or metabolism in the epithelium and/or lumen of the GI tract), or by a combination of these two factors (11). Differentiation between these two possible mechanisms could be achieved through an examination of route-dependent differences in the pattern of drug metabolism, as described by Harris and Riegelman (12). In a previous study of systemic availability (13), Rawlins *et al.* reported the bioavailability of acetaminophen tablets in a 500-mg dose to be only 63% compared with 79% in our study of a 650-mg dose. Bioavailability increased to 89 and 87% following 1,000- and 2,000-mg doses, respectively (13). The discrepancy in results of the two studies may be due to saturation of presystemic biotransformation at doses >500 mg.

	5	98.8 ± 3.3

[a] Recovery calculated as (serum value/water control value) × 100. Each value is the mean ± *SD* of six determinations.

phosphate[6] was used as a constituent of the mobile phase. All other reagents were of analytical grade.

Serum and Bone Marrow Blood Samples—Cefsulodin (1 g) and cefotiam (2 g) were administered concurrently by intravenous injection to 16 patients immediately before beginning surgery. Serum and bone marrow blood samples were collected from each subject at 0.5 and 1 hr after injection (a total of 64 samples). Samples were centrifuged immediately at 3000 rpm for 15 min. The serum fractions were separated and stored frozen at −60° until assayed.

Chromatographic Conditions—An HPLC apparatus[7] equipped with a UV-absorbance detector[8] and a reverse-phase column[9] (10 μm, 30 cm × 3.9-mm i.d.) were used. Peak areas were obtained by a data analyzer[10]. The mobile phase was a mixture of methanol–water (35:65, v/v) and 0.005 *M* tetrabutylammonium phosphate. The flow-rate was 1.5 ml/min with an operating pressure of 220 kg/cm². The column eluate was continuously monitored at 280 nm, with a sensitivity of 0.08 AUFS and a chart speed of 5 mm/min.

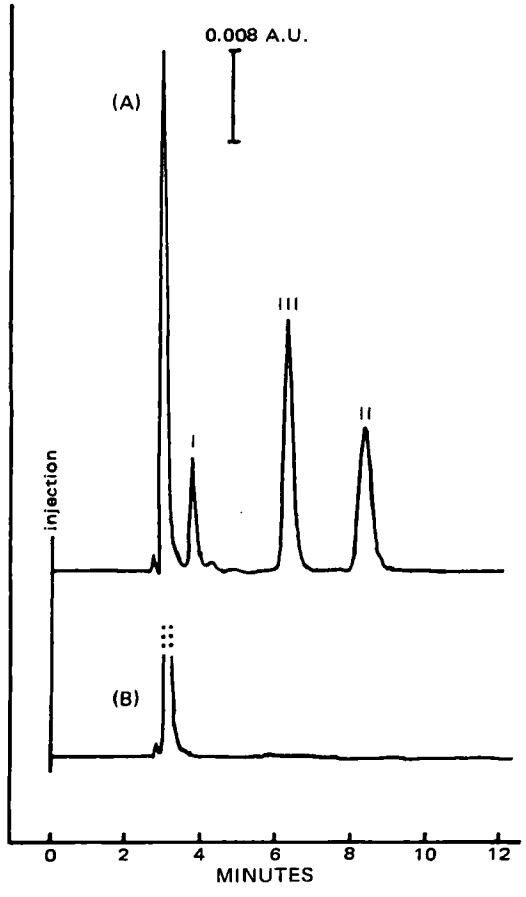

Figure 1—*Chromatograms of cefsulodin (I), cefotiam (II), and cefazolin (internal standard, III) in human serum, at concentrations of 25 μg/ml for I, 40 μg/ml for II, and 50 μg/ml for III. Key: (A) spiked serum sample; (B) serum blank. Chromatograph was run at 0.08 AUFS with a chart speed of 5 mm/min.*

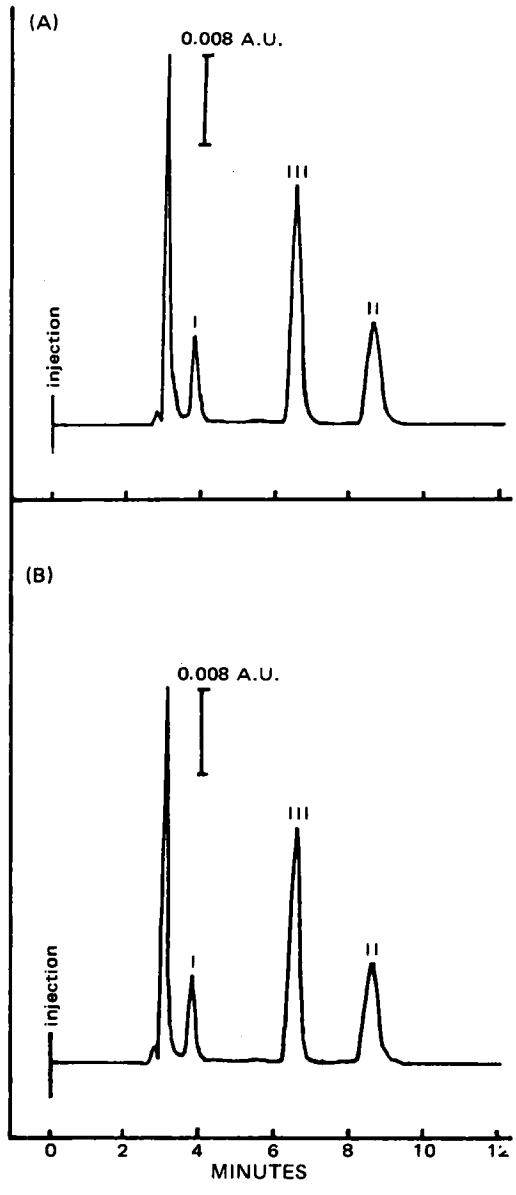

Figure 2—*Typical chromatograms of human serum (A) and bone marrow blood (B) samples collected from a patient 0.5 hr after intravenous injection of both drugs. Key: (I) cefsulodin; (II) cefotiam; (III) cefazolin.*

Assay Procedures—A 0.2-ml serum sample was mixed with acetonitrile (0.2 ml) containing a known amount of the internal standard on a vortex mixer for 10 sec and then contrifuged at 12,000 rpm for 5 min. The supernatant was passed through a membrane filter (0.45 μm)[11] and a 10-μl aliquot was injected into a port of the HPLC column.

Calibration Curves of Cefsulodin, Cefotiam, and Cefazolin—Calibration curves were constructed using a known concentration of the drugs (10–100 μg/ml) dissolved in human serum. The relationship between the concentration (ordinate) and the peak area (abscissa) showed good linearity for each: respective intercepts, slopes, and correlation coefficients, 0.558, 0.0106, and 0.998 for cefsulodin; 0.030, 0.0088, and 0.999 for cefotiam; and 0.558, 0.0059, and 0.998 for cefazolin (internal standard). The ratios (R) of the slopes of cefsulodin and cefotiam to that

Table II—Concentrations of Cefsulodin and Cefotiam in Serum and Bone Marrow Blood Determined by the HPLC Method

Sample	Time[b], hr	Concentration[a], μg/ml	
		Cefsulodin	Cefotiam
Serum	0.5	44.2 ± 20.8	79.8 ± 33.1
	1	34.1 ± 16.8	46.4 ± 14.5
Marrow	0.5	39.6 ± 16.8	76.1 ± 34.7
	1	30.1 ± 13.4	44.4 ± 22.1

[a] Mean ± *SD* of 16 subjects. [b] Blood samples were collected with 0–10-min variance.

of the internal standard were 1.80 and 1.49, respectively, from which the sample concentration (C_a) was calculated as: C_a = (peak area ratio between sample and internal standard) × (concentration of internal standard)/R.

Microbiological Assay—The microbiological assay was performed according to a modified method of Fugono *et al.* (5). The concentrations of cefsulodin and cefotiam were determined by the cup plate method (6), using *P. aeruginosa*[12] and *Proteus mirabilis*[13] as test organisms. The minimum inhibitory concentrations of these agents are: 1.56 and >100 μg/ml against *P. aeruginosa* for cefsulodin and cefotiam, respectively,and >100 and 0.01 μg/ml against *P. mirabilis* for cefsulodin and cefotiam, respectively, with an inoculation of 10^6 cells/ml (7, 8). The culture medium was prepared from an agar base[14] containing 0.1% sodium acetate (w/v). A series of dilutions for the calibration curve were made with normal human serum.

RESULTS AND DISCUSSION

Recovery and Separation of Cephalosporins—Recovery of cefsulodin, cefotiam, and cefazolin from injected solutions in serum was established by comparing the peak areas for samples with those from water solutions in the range of 5–100 μg/ml. As shown in Table I, the recoveries were regarded as 100% for these cephalosporins.

The liquid chromatograms of cefsulodin, cefotiam, and the internal standard in serum are shown in Fig. 1. The retention times were found to be 3.8, 6.3, and 8.3 min, respectively. The peaks of the control serum had low retention times and were completely separated from those of the antibacterial agents. Also, the separation of peaks among cefsulodin, cefotiam, and the internal standard was established with satisfactory resolutions for simultaneous determination.

Determinations of Cephalosporins in Serum and Bone Marrow Blood—The HPLC method was applied for the simultaneous determinations of cefsulodin and cefotiam in serum and bone marrow blood samples. Figure 2 shows typical chromatograms of serum and bone marrow blood samples collected from a patient 0.5 hr after intravenous injection. There was little difference in the retention time between serum and bone marrow blood samples that originated from different sources of body fluids.

Table II indicates the average concentrations and standard deviations of cefsulodin and cefotiam in serum and bone marrow blood samples that were collected from 16 subjects. There were no significant differences in the concentrations between the different samples for each agent, although there was a tendency for the average concentration in serum to be slightly higher than that in bone marrow blood. The results indicate that very fast movement of these agents from the peripheral to the bone marrow blood was always established.

Correlation of the HPLC and Microbiological Methods—To examine the reliability of the HPLC method, the same biological samples containing cefsulodin and cefotiam were also assayed by the microbiological method in general use, and the correlation between both the methods was studied. The great difference in the minimum inhibitory concentration enabled these agents to be determined individually even when concurrently administered, even though cefsulodin and cefotiam are categorized in the same family of cephalosporins.

The calculation of the correlation coefficient and regression analysis were conducted for both serum and bone marrow blood samples irrespective of the sampling time. The statistical values were: in cefsulodin, y(HPLC) = 0.91x(microbiological) + 1.71, r = 0.974 (n = 32) in serum and y = 0.91x − 1.52, r = 0.961 (n = 32) in bone marrow blood; in cefotiam, y = 1.07x −8.99, r = 0.971 (n = 32) in serum and y = 1.01x − 4.05, r = 0.978 (n = 32) in bone marrow blood.

The intercepts of the regression lines of cefsulodin gave values closer to the origin than those of cefotiam, while the regression coefficients were very close to unity for each agent, indicating that the sensitivity of the HPLC procedure described here was almost equivalent to the microbiological method. Therefore, the HPLC method is accurate enough to use within the putative range of effective concentrations in biological fluids as well as enabling the simultaneous determination of these cephalosporins. The HPLC method, furthermore, was more rapid and easier to perform than the microbiological method.

Analysis of Doxylamine in Plasma by High-Performance Liquid Chromatography

KENNETH J. KOHLHOF ˣ, DECHERD STUMP, and JOSEPH A. ZIZZAMIA

Received March 9, 1981, from *Clinical Research Associates, New York, NY 10010.* Accepted for publication July 28, 1982.

Abstract □ A rapid and sensitive high-performance liquid chromatographic (HPLC) assay for the quantitative determination of doxylamine in plasma is described. The drug levels of doxylamine in plasma were monitored after the oral administration of a single 25-mg tablet of doxylamine succinate to each of 20 male volunteers. The compound was extracted from the plasma samples, concentrated under a nitrogen stream, and analyzed by HPLC using normal-phase chromatography with detection at 254 nm. The detection limit is ~5 ng/ml.

Keyphrases □ Doxylamine—in human plasma, determination by high-performance liquid chromatography □ High-performance liquid chromatography—quantitation of doxylamine in human plasma □ Antihistamines—doxylamine succinate, determination of doxylamine in human plasma by high-performance liquid chromatography

Doxylamine, one of the oldest drugs exhibiting antihistaminic properties, also possesses impressive hypnotic properties. Although the characteristic activity of the antihistamines is their ability to antagonize the effects of histamine on various peripheral structures (1), these compounds are known to have a wide spectrum of pharmacological and therapeutic effects. Since many of these drugs cause sedation, they are frequently used as hypnotic agents or sedatives, in spite of their mixed excitatory and depressant actions within the CNS (2). According to Sjöqvist and Lasagna, 25–50 mg of doxylamine is more effective as a sedative than 100 mg of secobarbital (3), and it is often used as a hypnotic antihistamine at bedtime (4).

A previous method, tested by the Food and Drug Administration in 1972, describes a doxylamine assay in urine using GC (5). This paper describes a simple, sensitive, high-performance liquid chromatographic (HPLC) method for the measurement of doxylamine in plasma using normal-phase chromatography.

EXPERIMENTAL

Materials—Reagent grade sodium hydroxide, ammonium hydroxide, and ammonium chloride; HPLC grade acetonitrile, chloroform, methanol, and dichloromethane; and USP reference standard dextroamphetamine sulfate and doxylamine succinate were used.

Standard Preparation—A set of standard samples was prepared by adding 80, 50, 30, 20, and 10 μl of a 10-ng/μl solution of doxylamine succinate in water to 3.0-ml plasma blanks with a microliter syringe. The

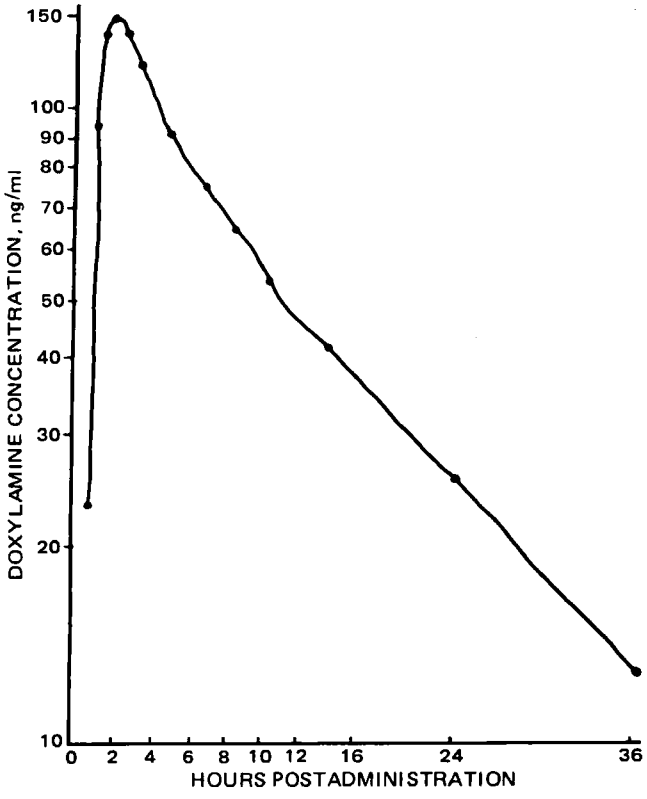

Figure 3—*Plasma levels of doxylamine in a human volunteer following the oral administration of 25 mg of doxylamine succinate in tablet form.*

internal standard was prepared by adding 10 ml of 0.3 *N* NaOH and 20 ml of dichloromethane to 20 mg of dextroamphetamine sulfate in a 125-ml separatory funnel and shaking manually for 5 min. After the layers separated, the organic layer was collected in a 50-ml volumetric flask. The extraction was repeated with 20 ml of dichloromethane, and the organic phase was combined with the first extract. This was diluted to volume with dichloromethane to obtain a 300-μg/ml concentrated solution of dextroamphetamine in dichloromethane. A 5-ml aliquot of this solution was transferred to a 50-ml volumetric flask and diluted to volume with the eluting solvent. The concentration of the resulting solution was 30 μg/ml.

Subjects—After an overnight fast, 20 healthy male volunteers (20–50 years old, 59–68 kg) were administered a single 25-mg dose of doxylamine succinate in tablet form. Blood samples of sufficient volume to obtain 10 ml of plasma were drawn prior to administration and at regular intervals postadministration. All samples were collected in heparinized evacuated containers[1] and centrifuged at 2500 rpm. The separated plasma was stored at −20° until analysis.

Plasma Extraction—Plasma (3.0 ml) was pipetted into a 20-ml screw-cap[2] test tube, and 10 ml of 0.3 *N* NaOH and 5 ml of dichloromethane were added. The tubes were placed on a rocking shaker[3] at a slow speed for 15 min and then centrifuged. Any emulsion formed was broken up by lightly tapping the tubes and the samples were centrifuged again. The organic layer was transferred to a 12-ml glass-stoppered conical-tip tube using a Pasteur pipet. The extraction of the aqueous layer was repeated with an additional 5 ml of dichloromethane. This was centrifuged, the organic layer was combined with the first extract in the conical-tip tube, and the tubes were placed in a water bath with the temperature maintained at 40°. The combined extracts were evaporated under a nitrogen stream, and 200 μl of the dilute dextroamphetamine solution was added with a 100-μl syringe. The tube was capped with the glass stopper, vortexed[4], and centrifuged.

Chromatographic Analysis—The HPLC system[5] consisted of a solvent delivery pump, a fixed-wavelength UV detector at 254 nm, and a μPorasil column (10 μm, 3.9 mm × 30 cm). The eluting solvent was 8 parts chloroform, 1 part acetonitrile, and 1 part of a mixture of methanol–ammonium hydroxide–ammonium chloride (57:2:1); the flow rate was 1.5 ml/min. The UV absorption was monitored using an electronic integrator[6] with an attenuation of 2^4–2^5, as necessary.

Eighty microliters of the plasma extract was introduced into the column using an automatic injector[7]. Retention times for doxylamine and amphetamine were 14.6 and 12.1 min, respectively. The peak height ratio of doxylamine to the internal standard in the sample plasma was measured and compared with the peak height ratio in the standards to achieve quantitation.

Calibration Curve—The linearity of the calibration curve was determined by adding 100–800 ng of doxylamine succinate[8] to 3-ml plasma blanks. The coefficients of variation were determined using replicate plasma standards spiked with doxylamine succinate.

Table I—Reproducibility of Doxylamine Determination in Human Plasma [a]

100	0.598	2.5
67	0.406	3.2
34	0.203	6.2

[a] n = 20 for all concentrations.

RESULTS AND DISCUSSION

The method was evaluated in terms of extraction efficiency, interference, linearity, and precision. Preliminary experiments demonstrated the need for adding amphetamine at the end of the extraction steps. When known amounts of amphetamine were added to the dichloromethane solution in the beginning of the extraction procedure, its recovery was negligible. To ensure the availability of a fixed amount of amphetamine in the sample solution, 200 μl of amphetamine was added to each tube after the dichloromethane was evaporated.

The peaks observed for doxylamine and amphetamine were well separated from any naturally occurring plasma constituents or any metabolites of the drug. With the blank plasma, when the standard doxylamine was eliminated from the assay, no peaks absorbing at 254 nm that had the same retention time as doxylamine were observed (Fig. 1). Figure 2 shows plasma extracted from a typical subject 2 hr after the administration of 25 mg of doxylamine succinate. From 0.5–36 hr postadministration, the concentration of doxylamine in plasma was generally in the range of 10 to 150 ng/ml (Fig. 3). The peaks encountered for doxylamine and the internal standard were symmetrical and well defined.

The mean values of the peak height ratio of doxylamine to amphetamine obtained from 20 calibration curves are given in Table I. The method exhibits excellent linearity: the correlation coefficient of the doxylamine to amphetamine peak height ratio *versus* doxylamine succinate added to plasma was 0.99 over the range of values obtained (Table I). The absolute recovery when 570 ng of doxylamine succinate was added to 3 ml of plasma was 84.8% (based on three determinations). The assay is suitable for the study of doxylamine succinate pharmacokinetics, representing a reproducible and accurate method for the detection of doxylamine in plasma to 5 ng/ml.

High-Performance Liquid Chromatographic Determination of Nitroglycerin in Sublingual, Sustained-Release, and Ointment Dosage Forms

CAROLYN S. OLSEN ˣ **and HENRY S. SCROGGINS**

Received March 5, 1982, from the *Food and Drug Administration, New Orleans, LA 70122.* Accepted for publication August 12, 1982. Address correspondence to: Miss Helen L. Reynolds, Technical Editor, Food and Drug Administration, Bureau of Foods, Washington, DC 20204.

Abstract □ A rapid, precise, sensitive, and specific assay for nitroglycerin in sublingual, sustained-release, and ointment dosage forms using high-performance liquid chromatography is described. The nitroglycerin dosage forms were dissolved in methanol, filtered, and injected directly into the liquid chromatograph. A variable-wavelength UV detector operated at 220 nm and a C_{18} microporous silica column were employed. The mobile phase was methanol–water (40:60).

Keyphrases □ Nitroglycerin—high-performance liquid chromatographic determination in sublingual, sustained-release, and ointment dosage forms □ Dosage forms—ointment, sublingual, sustained-release, high-performance liquid chromatographic determination of nitroglycerin □ High-performance liquid chromatography—determination of nitroglycerin in sublingual, sustained-release, and ointment dosage forms

Several techniques for the determination of nitroglycerin in commercial dosage forms have been reported (1–5). Some limitations of these methods include: the time-consuming and nonspecific determination of the compendial assay (1), the poor sensitivity and lack of precision of the IR method (2, 3), possible decomposition in the GC method (4), and the inability to distinguish among the decomposition products using the polarographic method (5).

High-performance liquid chromatography (HPLC) as a determinative technique appears to offer the best approach (6, 7). As reported here, it is both rapid and stability indicating. A single procedure is applicable to more than one dosage form, and individual tablets can be analyzed at low dosage levels. The latter is necessary when analyzing nitroglycerin products because nitroglycerin migrates from tablet to tablet on exposure to air (8, 9). The use of HPLC eliminates interferences from other organic or inorganic nitrates and allows nitroglycerin to be distinguished from its mono- and dinitrate degradation products.

EXPERIMENTAL

Reagents—HPLC-grade methanol[1] and water[1] were used. All other chemicals and solvents were reagent grade and were used without further purification. A 10% nitroglycerin in lactose triturate[2] was used as a reference standard and was assayed by the USP phenoldisulfonic acid method (1). Authentic 1,2- and 1,3-dinitroglycerin and 1- and 2-mononitroglycerin[3] were used to determine the presence of any degradation products; pentaerythritol tetranitrate[4] and isosorbide dinitrate[5] were used as internal standards.

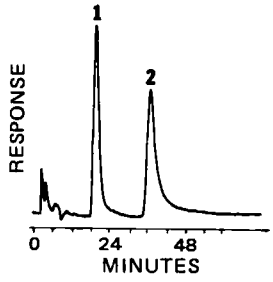

Figure 1—*Chromatogram of sublingual tablet sample. Key: (1) nitroglycerin; (2) pentaerythritol tetranitrate.*

Apparatus—The liquid chromatographic system consisted of a dual-head reciprocating piston positive-displacement pump[6], a septumless syringe-loaded loop injector with a 20-μl loop[7], a variable-wavelength UV detector[8] operated at 220 nm, a 10-mV recorder[9], and a 3.9 mm × 30-cm C_{18} microparticulate column[10] with a 4 cm × 4.6-mm guard column packed with pellicular octadecyl reverse-phase material[11]. The solvent system was methanol–water (40:60). The flow rate was 1 ml/min with a pressure of ~1600 psi.

Nitroglycerin Standard Solution—An accurately weighed quantity of nitroglycerin reference standard was dissolved in the internal standard solution (0.1 mg of pentaerythritol tetranitrate/ml of methanol) to obtain a concentration of ~0.075 mg/ml.

Extraction—*Sublingual Tablets*—Sufficient powdered tablet composite or individual powdered tablets (if individual tablet assays were required) were transferred to a 25-ml glass-stoppered Erlenmeyer flask and diluted with internal standard solution to give a nitroglycerin concentration of 0.075 mg/ml. The mixture was sonicated for 2 min then mechanically shaken for 30 min. The resulting solution was filtered through 0.7-μm filter paper[12] and injected into the chromatograph.

Ointment—Sufficient ointment was transferred to a 25-ml glass-stoppered Erlenmeyer flask and diluted with internal standard solution to give a nitroglycerin concentration of 0.075 mg/ml. The mixture was warmed in a 50° water bath and shaken intermittently until the ointment dispersed. The ointment solidified after being removed from the bath and shaken vigorously. The heating and shaking operation was then repeated. The solution was filtered through a 0.7-μm filter paper[12] and injected into the chromatograph.

[a] Average recovery for all manufacturers, 100.2%; coefficient of variation, 0.753%; correlation coefficient, 0.9998. [b] Average recovery for all manufacturers, 99.4%; coefficient of variation, 1.83%; correlation coefficient, 0.9999. [c] Formulations not available for preparation of synthetic mixtures. [d] Average recovery for all manufacturers, 99.4%; coefficient of variation, 0.253%; correlation coefficient, 0.9997.

Sustained-Release Tablets or Capsules—This procedure required an alternate internal standard (isosorbide dinitrate) be used if phthalates were present as an excipient since phthalates have approximately the same retention time (R_t) as pentaerythritol tetranitrate under the conditions described. The presence of phthalates was detected by injecting a portion of sample dissolved in methanol into the chromatograph (a peak with the same R_t as that of pentaerythritol tetranitrate indicated the presence of phthalates). In such cases, isosorbide dinitrate (0.1 mg/ml of methanol) was used as the internal standard solution. Sufficient powdered sustained-release composite was transferred to a 25-ml glass-stoppered Erlenmeyer flask and diluted with the appropriate internal standard solution, giving a nitroglycerin concentration of 0.075 mg/ml. The mixture was sonicated for 2 min, then mechanically shaken for 30 min. The solution was filtered through 0.7-μm filter paper[12] and injected into the chromatograph.

Quantitation—The drug was quantitated by using the internal standard method, which compares peak height ratios. The internal standard for the sublingual tablets, ointments, and sustained-release dosage forms that did not contain phthalates was pentaerythritol tetranitrate; isosorbide dinitrate was used for the sustained-release dosage forms that contained phthalates.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram of 1.5 μg of nitroglycerin from a composite of sublingual tablets. Figure 2 shows a chromatogram of 1.5 μg of nitroglycerin from a composite of sustained-release tablets employing isosorbide dinitrate as the internal standard. Ointment and sustained-release capsules not containing phthalates gave chromatograms similar to those of the sublingual tablets because they contain no excipient interferences in the area of either nitroglycerin or pentaerythritol tetranitrate. The R_t with 40% methanol in water was ~12 min for isosorbide dinitrate, 18 min for nitroglycerin, and 32 min for pentaerythritol tetranitrate.

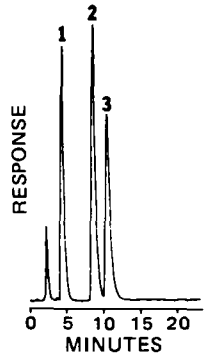

Figure 3—*Chromatogram of degradation products of nitroglycerin. Key: (1) 1- and 2-mononitroglycerin; (2) 1,3-dinitroglycerin; (3) 1,2-dinitroglycerin.*

During the development of this assay, a number of variations were tried. Methanol was chosen as the extracting solvent because of its ability to separate nitroglycerin and its mono- and dinitroglyceryl degradation products from the excipients in the various dosage forms. Methanol gave a cleaner solution than dimethyl sulfoxide; the latter dissolved the active ingredient as well as the excipients. Methanol and acetonitrile performed equally well as the mobile phase; methanol was chosen because it is less costly. Pentaerythritol tetranitrate was chosen as the internal standard because a number of samples contained excipients whose R_t value was the same or slightly different from that of isosorbide dinitrate, thereby causing peak distortion. One manufacturer's sustained-release tablets contained a phthalate with the same R_t as pentaerythritol tetranitrate, necessitating the use of isosorbide dinitrate as the internal standard.

The HPLC method described is capable of separating nitroglycerin from its mono- and dinitroglyceryl degradation products. Since these degradation products are more polar than nitroglycerin, they travel through the reverse-phase column faster and are eluted soon after the solvent front. To determine the degradation products, the methanol concentration of the mobile phase must be decreased, thereby increasing the R_t value of the other nitrate esters.

While detection at 254 nm may be possible when assaying nitroglycerin in a composite sample, it is not suitable for determining individual sublingual tablet uniformity because of the small quantity of active ingredient present in a single tablet. Detection at 220 nm gives a 60-fold enhancement in sensitivity with quantitative results comparable to those obtained at 254 nm, thus making individual tablet analysis possible.

The internal standard method of calculation was applied to the quantitative determination of nitroglycerin in the various dosage forms. The relative percentage of nitroglycerin found in the various dosage forms as well as the recovery data appear in Table I.

Synthetic mixtures (analogous to commercial formulations) were prepared by adding known amounts of the nitroglycerin triturate to the excipients according to the manufacturer's specifications. With these synthetic mixtures, the method demonstrated linearity from 0.05 to 1.5 mg/ml of original sample solution with a correlation coefficient >0.999 (10). Spiked samples of each dosage form were prepared using standard addition procedures. Weighed amounts of the triturate were added to previously assayed dosages containing the active ingredient. These preparations were then analyzed as described above (Table I).

This assay provides a rapid, sensitive, and specific method for the

determination of nitroglycerin in various dosage forms. The degradation products of nitroglycerin can be determined by a simple change of the mobile solvent system (methanol–water, 20:80) (Fig. 3). The assay is faster, more specific, and provides more stability-indicating information than the USP method.

Hydrazine Levels in Formulations of Hydralazine, Isoniazid, and Phenelzine Over a 2-Year Period

E. G. LOVERING, F. MATSUI ˣ, N. M. CURRAN, D. L. ROBERTSON, and R. W. SEARS

Received March 29, 1982, from the *Bureau of Drug Research, Health Protection Branch, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario K1A 0L2.* Accepted for publication August 10, 1982.

Abstract □ Hydrazine levels in formulations of hydralazine, isoniazid, and phenelzine have been measured over a 2-year period under ambient conditions and under temperature and humidity stress. Hydralazine tablets are stable under ambient conditions, but the hydrazine level in an injectable formulation increased from 4.5 to 10 μg/ml over a 23-month period. Isoniazid tablets are also stable, but hydrazine levels in an elixir and a pyridoxine combination product doubled to 44 μg/ml and 19 μg/tablet, respectively. Levels in phenelzine tablets appeared to remain constant at ~60 μg/tablet, with considerable tablet-to-tablet variation.

Keyphrases □ Hydrazine—levels in formulations of hydralazine, isoniazid, and phenelzine over a 2-year period □ Hydralazine—hydrazine levels in formulations over a 2-year period □ Isoniazid—hydrazine levels in formulations over a 2-year period □ Phenelzine—hydrazine levels in formulations over a 2-year period

Previous work demonstrated the presence of hydrazine in an isoniazid injectable product (1) and showed that isoniazid may hydrolyze to hydrazine (2, 3). Because hydrazine poses a risk of cancer in humans (4, 5), these observations prompted an assessment of other drugs derived from hydrazine that are available in Canada. These include carbidopa, hydralazine, isocarboxazid, and phenelzine, in addition to isoniazid. Hydrazine levels in isoniazid single-component tablet formulations were determined by TLC (2) and high-performance liquid chromatography (HPLC) (6) and by modifying a GLC procedure originally developed for the determination of phenelzine in urine (7). Methods for the determination of hydrazine in formulations of hydralazine (8), isoniazid elixir, isoniazid–pyridoxine combination tablets (8), and phenelzine (9) have also been developed. A 2-year normal and accelerated aging study of hydrazine formation in formulated products of hydralazine, isoniazid, and phenelzine has been completed and the results are reported in this paper.

Hydrazine is used in some syntheses of hydralazine (10), isoniazid (11), and phenelzine (12), and its presence in a formulated drug product may result from improper purification of the drug. All three drugs are known to degrade to hydrazine in solution (6, 9, 11), but there does not appear to be any published information on the formation of hydrazine in formulations of these drugs.

EXPERIMENTAL

Sample Preparation—Drug formulations were obtained directly from the manufacturer. All tablet samples were transferred to amber bottles for storage with at least five tablets in each bottle, and 1.0-ml aliquots of the elixir were transferred to culture tubes and securely capped. Phenelzine tablets from lot D were sealed in glass tubes (22 × 220 mm) by drawing out the top of the tube in a flame. The 100% relative humidity condition was achieved by sealing a 12-ml centrifuge tube containing 4 ml of water in with the tablets; tablets were not in direct contact with the water.

Storage Conditions—All formulations were aged under the temperature and humidity conditions given in Tables I, II, and III. Except as noted above, the humidity was controlled by placing silica gel (0% relative humidity) or an aqueous solution of sodium chloride (75 and 80% relative humidity) (13) in desiccators along with the product to be aged. The desiccators were placed in ovens[1] at the appropriate temperatures. Temperature variations were within 1.0° over the time of the experiments.

Procedure—All products were analyzed for hydrazine at the start of each study and at appropriate times thereafter. Assays were done in duplicate, usually on composites of five tablets, or composites of three ampules of an injectable or elixir or, for phenelzine, on single tablets. Hydrazine content (as the benzaldehyde derivative) in hydralazine (8), isoniazid–pyridoxine tablets, and isoniazid elixir (8) was determined by GLC using a 2% OV-101 column and a nitrogen–phosphorus detector. In phenelzine products and for some isoniazid analyses, hydrazine content (as the benzaldehyde derivative) was determined by HPLC (9) on a 5-μm silica gel column with a mobile phase of 6% chloroform in *n*-hexane and detection at 313 mm. In isoniazid single-component tablets after 2.5 and 6.8 months, hydrazine, as the acetone derivative, was determined by GLC on a 3% OV-225 column with a flame-ionization detector (7). The initial assessment of hydrazine in isoniazid tablets was made by TLC with

[a] Minimum quantifiable amounts at 0, 7.5, 16, and 23 months were 0.001, 0.0005, 0.00025, and 0.000125%, respectively. Measurements were made with a Perkin-Elmer Model 3920 and Hewlett-Packard Models 5880 and 5840 gas chromatographs at 0, 7.5 and 16, and 23 months respectively. The amounts of drug injected on column were 10.0, 1.0, 2.0, and 4.0 μg, respectively. [b] RT = room temperature; AH = ambient humidity. [c] Tr. = trace, borders on the minimum detectable level (7×10^{-5} %). [d] This product is an aqueous solution. [e] Mean hydrazine level in five vials was 42 μg/ml, *RSD* 7.3%, range 42–57 μg/ml.

silica gel plates, run first in a solvent of methanol–chloroform (1:1) and then in acetone–methanol–glacial acetic acid (50:50:10) (2).

RESULTS AND DISCUSSION

Hydralazine—A preliminary examination of hydralazine products revealed traces of hydrazine in some tablet products and ~5 μg/ml in an injectable formulation. These results prompted a stability assessment of this drug. The products assessed, the test conditions, and the hydrazine levels at intervals over a 23-month period are presented in Table I. Over this period the sensitivity of the test method increased due to changes in the equipment available for the work and slight modifications made in the sampling procedure. Minimum quantifiable amounts are also given in Table I. Many of the results are close to the minimum quantifiable level of the method. This, coupled with the instability of hydrazine, probably accounts for the lack of a clear trend in hydrazine levels with time in some products.

The results show that there is no significant change in the hydrazine level in tablets stored under normal room conditions or at 37° and ambient humidity. At 80% relative humidity hydrazine levels increased in some products, more noticeably at 37°; but even at 37° not all tablet products were affected. At 37° and 80% relative humidity, the maximum level observed was ~3.8 μg in a 50-mg tablet after ~2 years. In the injectable product at room temperature and 37°, the hydrazine level increased from 4.5 to 12 and 76 μg/ml, respectively, in 16 months and then decreased, possibly due to decomposition of hydrazine rather than vial-to-vial variation in the hydrazine content. More rapid degradation to hydrazine in a liquid product would be expected. There is no indication that the presence of reserpine and/or hydrochlorothiazide had any effect on the formation of hydrazine from hydralazine.

Isoniazid—The isoniazid stability study was done in two parts. In the first, samples from two lots of tablets were stressed for 8 months under the conditions given in Table II. This work was undertaken before the analytical methodology was firmly established. The hydrazine assays were by TLC (initial), GLC (2.5 and 6.8 months), and HPLC (8.2 months). The GLC procedure (7) was modified to provide for the reaction of hydrazine with acetone to form an acetonide which was partitioned between water and ether and chromatographed at 45° on 3% OV-225 on Chromosorb WHP (100/120 mesh). The results (Table II) indicate only low levels of hydrazine contamination in products kept at room temperature and 0% relative humidity. Hydrazine formation is promoted at higher humidity, as would be anticipated, but the effect is not pronounced except in one product at 60° and 75% relative humidity.

In the second part of the work, an isoniazid–pyridoxine combination product and an isoniazid elixir were evaluated (Table II). The hydrazine level in tablets at ambient humidity (room temperature and 37°) rose to a constant value of ~20 μg/tablet. At 80% relative humidity, hydrazine levels were much higher, but again there was some indication of the attainment of a steady-state hydrazine level. In the elixir at room temperature, the hydrazine level increased to a steady level of ~40 μg/ml, but at 37° it declined to a steady level of 2–4 μg/ml. A temperature-dependent steady-state level of hydrazine would result when the rate of formation of hydrazine and its rate of decomposition are in balance.

Phenelzine—The stability study of phenelzine tablets began when samples from lot C were tested under the temperature and humidity conditions given in Table III. After 4 months it was observed that the cores of individual tablets varied in color from white to beige. Single tablets were analyzed for hydrazine, and it was found that hydrazine levels increased roughly with the color of the tablet, with a range of 34–82 μg/tablet. The data obtained from the sample stored at 37° and 80% relative humidity indicated a loss of hydrazine due to volatilization and/or chemical breakdown. In view of these uncertainties, a second lot (D) of tablets were obtained, repackaged in sealed containers, and tested to find out what became of the hydrazine (Table III).

The first observation that can be made from the data is that hydrazine levels decreased during storage at 80 and 100% relative humidity. The levels decreased sharply at 100% relative humidity and the tablets showed extensive deterioration. Hydrazine levels also decreased at 80% relative humidity and 37°. The data obtained from the samples stored in sealed containers show that these decreases can be attributed to chemical degradation rather than evaporation of the hydrazine. At ambient humidity, both at room temperature and 37°, there may have been some increase in the hydrazine content to a steady level, but once this state was reached (after a few months) there did not appear to be any further increase.

[a] Tablets stored at ambient temperature and humidity. [b] Time elapsed since tablets were assayed at the start of the study.

The intertablet variation in hydrazine level is presented in Table IV. The variation appeared to be present in the tablets as they were obtained from the manufacturer, and the data do not support the view that there were significant changes in hydrazine levels as the study progressed. The tablet-to-tablet variation suggests that hydrazine is formed during manufacture under local reaction conditions, but specific conditions are unknown.

The work described herein was done to identify major stability problems with respect to increases in the hydrazine levels with time in the drugs examined. Other facets of the stability of these products, such as degradation of the drug itself, were not included in this work. Except for samples stored at ambient temperature and humidity, samples were repacked so that they would be fully exposed to the conditions of the experiment. This was done because the objective of the work was to examine the behavior of the formulated products, not the ability of the packaging to protect the product from the environment.

The results show that hydrazine itself decomposes in some formulations, *e.g.*, the isoniazid elixir at 37° (Table II) and phenelzine tablets at 37° and 80% relative humidity (Table III). Some data, like that for isoniazid–pyridoxine tablets indicate the hydrazine concentration increases to a fixed level and remains constant. This and the results at two temperatures for the isoniazid elixir suggest that hydrazine levels in some products are steady-state levels. The actual value of the steady-state level would depend on the nature of the formulation excipients, the rates of hydrazine formation and decomposition, and the relative effect of temperature on these rates.

Hydrazine is a metabolite of isoniazid (14–16) and hydralazine (17) in humans. It may also be a metabolite of phenelzine[2]. Any assessment of hydrazine contamination in formulated products should include an evaluation of the metabolic data.

Comparative Controlled Skin Permeation of Nitroglycerin from Marketed Transdermal Delivery Systems

Keyphrases □ Transdermal delivery—nitroglycerin, hairless mouse skin, comparison of three marketed systems □ Nitroglycerin—permeation of, comparison of marketed transdermal delivery systems □ Skin, hairless mouse—permeation of nitroglycerin, transdermal delivery systems

To the Editor:

The antianginal activity of nitroglycerin was discovered over 100 years ago by Murrel (1). Since then, nitroglycerin use has increased and it is now widely prescribed for the prevention and treatment of angina pectoris. Several types of pharmaceutical dosage forms, mainly the oral sustained-release capsules and tablets, sublingual tablets, topical ointments, and intravenous fluids, are available commercially. Unfortunately, oral administration of nitroglycerin leads to extensive hepatic first-pass metabolism to give several inactive metabolites (2). When administered sublingually, first-pass metabolism is eliminated, however the antianginal activity is of such short duration (10–30 min.), due to the inherently rapid elimination (half-life = 1.9–4.4 min.) of nitroglycerin (3), that repeated dosing every 5 min is recommended until the symptoms are relieved. On the other hand, the duration of antianginal activity of nitroglycerin can be substantially prolonged to 3–4 hr by topical administration of ointment formulations; however, the area covered and thickness of the ointment is variable and it is messy and inconvenient.

Recently, three one-a-day-type transdermal nitroglycerin delivery systems[1] (Products A, B, and C) were developed for transdermal-controlled administration of nitroglycerin over a 24-hr period. They were recently approved for marketing by the U.S. Food and Drug Administration for treatment of angina pectoris (4). Several articles have been published to compare these new delivery systems with the sublingual tablets and/or the topical ointment formulations (3, 5–7). However, the only data available to date are the results of studies conducted independently and under different conditions and protocols by the manufacturers, and controversy has surfaced concerning the interchangeability of these three nitroglycerin-releasing transdermal delivery systems (8, 9).

Since no results are available from studies that are designed to evaluate the performance of these transdermal delivery systems under identical conditions, the purpose of this investigation was to establish an *in vitro* skin permeation system to study and compare the controlled skin-permeation kinetics of nitroglycerin delivered by these controlled-release transdermal delivery systems. In our studies, pieces (3.5 × 3.5 cm each) of full-thickness abdominal skin were freshly excised from 5–7-week-old hairless mice[2] (10) and mounted individually on the 8-cell Franz diffusion assembly[3] (Fig. 1). After soaking the dermal side of the skin in the elution solution overnight (as the time-zero sample), the transdermal delivery system was applied to the stratum corneum side of the skin, and the skin permeation profile of nitroglycerin was followed by sampling and assaying the nitroglycerin concentration in the elution solution. A sensitive reverse-phase high-performance liquid chromatographic (HPLC) method was used with samples taken at 1, 2, 4, 8, 12, 16, 20, 24, and 30 hr postapplication. The elution solution was prepared from normal saline solution containing 20% polyethylene glycol 400 to enhance aqueous solubility of nitroglycerin for simulating the biological sink (11, 12). At least four experiments on each type of transdermal delivery system were performed in each run of the drug release and skin permeation studies.

The results of the skin permeation studies indicated that nitroglycerin penetrates through the abdominal skin of the hairless mouse at a rate profile which can be described fairly well by zero-order kinetics (Fig. 2). It appears that the rate of skin permeation for nitroglycerin delivered by system A (18.15 $\mu g/cm^2/hr$) is significantly greater than system C (14.55 $\mu g/cm^2/hr$). Interestingly, the rate of skin permeation of nitroglycerin from system B is between systems A and C rates, but it shows a shift at 12 hr from 16.67 $\mu g/cm^2/hr$ to 10.56 $\mu g/cm^2/hr$. However, a constant skin permeation is maintained in both phases. The rates determined in this investigation are quite in agreement with the data (10–25 $\mu g/cm^2/hr$) generated from human cadaver skins (13).

The release kinetics of nitroglycerin from the transdermal delivery systems were also evaluated under the same conditions without the hairless mouse skin. Results indicated that nitroglycerin is released at a constant rate profile from system C but not from systems A nor B (Fig. 3). System C is a membrane permeation-controlled drug delivery system in which a rate-determining microporous

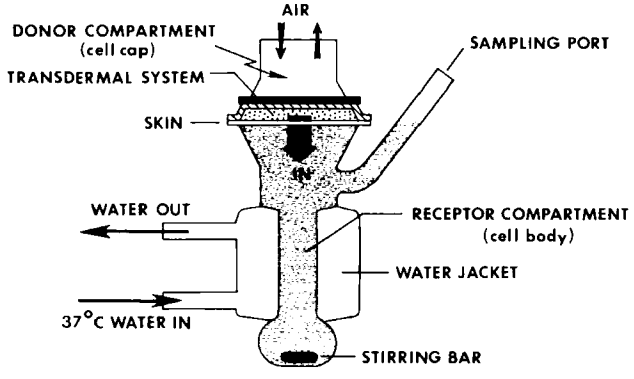

Figure 1—*Schematic illustration of the* in vitro *skin permeation system with skin sample and transdermal system sandwiched in between the donor and receptor compartments of the Franz diffusion cell assembly. The stratum corneum of the skin sample faces the donor compartment and is in close contact with the transdermal system. The dermal tissue faces the receptor compartment and is soaked in an elution solution at 37°.*

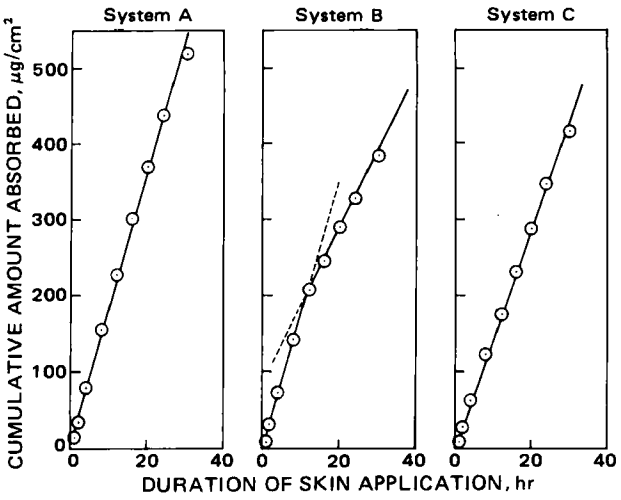

Figure 2—*Permeation profiles of nitroglycerin through the abdominal skin of the hairless mouse, following its controlled release from each of the three commercial transdermal delivery systems (each data point is the mean of at least eight determinations). The rate of skin permeation for nitroglycerin is calculated to be 18.15 μg/cm²/hr (system A), 16.67 (<12 hr) and 10.56 (>12 hr) μg/cm²/hr (system B), and 14.55 μg/cm²/hr (system C).*

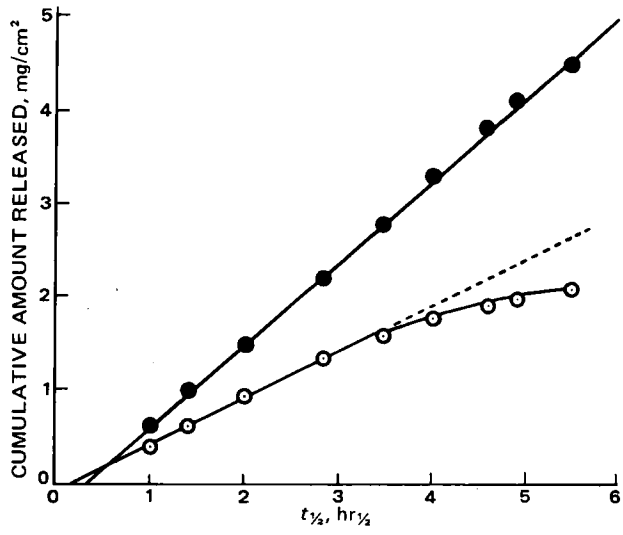

Figure 4—*Linear* Q versus $t^{1/2}$ *relationship for the controlled release of nitroglycerin from system B (●) and system A (○). (The* $Q \sim t^{1/2}$ *linearity is followed in system A for up to 12 hr in which 78% of the loading nitroglycerin dose is released, as compared with 30 hr duration and 89% release in system B). Each data point is the mean value of four determinations.*

ethylene–vinyl acetate membrane controls the release of nitroglycerin from a suspension-type drug reservoir (5, 6), and, as expected (11), a constant drug-release profile results. It is interesting to note that nitroglycerin is released from system C at a rate (35.8 μg/cm²/hr) which is more than two times greater than the rate of skin permeation (14.55 μg/cm²/hr). These results suggest that the skin tissues provide an additional diffusional barrier for the permeation of nitroglycerin.

On the other hand, the release profiles of nitroglycerin from systems A and B can be better defined by a *Q versus* $t^{1/2}$ relationship (Fig. 4), indicating that nitroglycerin is released under a matrix diffusion-controlled process from both systems A and B (11, 12, 14–16). System A is, in its original development (17–19), a partition-controlled drug delivery system with the drug reservoir microsealed as microscopic liquid compartments homogeneously dispersed in a cross-linked polymer matrix, and a constant drug release profile is expected (20). The incorporation of a hydrophobic solvent, like isopropyl palmitate (21), which is a good solvent for nitroglycerin, into the polymer matrix during fabrication, could affect the interfacial partitioning kinetics of nitroglycerin from the microscopic *liquid* compartment, leading to the shift in drug-release kinetics from the partition-controlled process to the matrix-controlled process (11, 22).

Similarly, system B is a matrix diffusion-controlled drug delivery system in which nitroglycerin–lactose triturate is homogeneously dispersed in a hydrophilic gel matrix (23); and, as expected (11), the release profile of nitroglycerin from system B follows the *Q versus* $t^{1/2}$ linearity. Again, the drug release fluxes from both systems A and B are maintained at magnitudes that are much greater than

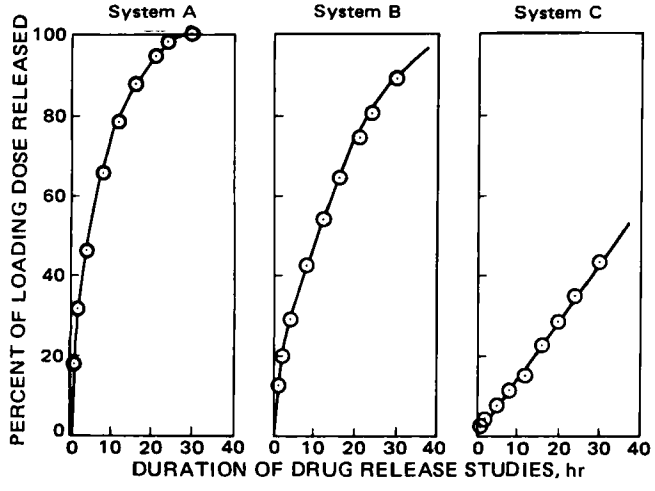

Figure 3—*Release profiles of nitroglycerin from the transdermal delivery systems into normal saline solution at 37° as drug elution solution (containing 20% polyethylene glycol 400 w/w to maintain a sink condition). Each data point is a mean value of four determinations.*

Table I—Comparison in Drug Release Kinetics and Skin Permeation Profiles of Nitroglycerin from Commercial Transdermal Delivery Systems

Dose absorbed (24 hr)			
Percent	21.93 (±3.86)[b]	6.41 (±1.19)[b]	13.88 (±2.65)[c]
Milligrams	3.51 (±0.62)[b]	3.27 (±0.60)[b]	3.47 (±0.66)[c]

[a] Mean (± standard deviation) of four determinations. [b] Mean (± standard deviation) of eight determinations. [c] Mean (± standard deviation) of 12 determinations.

the rate of skin permeation (Table I), so a constant skin-permeation profile can be achieved. By calculation, systems A and B release nitroglycerin at a flux ($Q/t^{1/2}$) of 500 and 875 $\mu g/cm^2/hr^{1/2}$, respectively (Fig. 4). The difference in release fluxes between these two systems is expected from the difference in drug-loading doses in the devices (11).

In summary, the results generated from the present investigation suggest that even though nitroglycerin is released at different rate profiles from these three transdermal delivery systems (Figs. 3 and 4), it penetrates through the hairless mouse skin under, basically, the same rate process (Fig. 2). Additionally, the total nitroglycerin dose delivered through the abdominal skin at 24 hr by each of these transdermal delivery systems is fairly close in magnitude and the difference is statistically insignificant [$F = 0.33$, $F_{0.95}(2,25) = 3.39$] (Table I), although the loading dose varies greatly from one system to another, and the percentage of the loading doses released during a 24-hr elution study is substantially different.

Additional studies are currently underway to generate evidence on the feasibility of using hairless mouse skin as the viable substitute for human skin in studying the transdermal controlled administration of systemically active drugs from novel drug delivery systems. A more detailed report will be written when more data become available.

Organ Perfusion Studies

Keyphrases □ Organ perfusion—pharmacokinetics, importance of volume replenishment □ Pharmacokinetics—organ perfusion studies, importance of volume replenishment

To the Editor:

Single-pass and recirculating perfused organ systems have been used to study how specific organs of the body handle drugs. The single-pass system has been used extensively to study the influx and efflux of drugs by various organs, whereas recirculating systems have been used more commonly to study metabolism and/or excretion of drugs by these organs. Although both systems are useful, the conservation of drug and perfusion media associated with the recirculating system makes it more economical and allows for longer perfusion experiments even with limited volumes of perfusion medium. However, in recirculating perfusion systems, there are problems associated with volume depletion due to excretion in open systems (*i.e.*, liver and kidney) and sample withdrawal in both closed (*i.e.*, heart, muscle, and lung) and open systems, which must be considered when performing pharmacokinetic analyses of the data derived from these experiments. The following discussion will address these problems.

It has been shown that the rate of elimination of a drug from an isolated organ perfusion system is a function of the perfusate volume (1) according to the following equation:

$$\frac{dC_i}{dt} = \frac{Q}{V_R}(C_i - C_o) \qquad \text{(Eq. 1)}$$

where C_i and C_o are the inflow and outflow concentrations, Q is the perfusate flow, and V_R is the reservoir volume. The elimination rate constant (K) varies inversely with perfusate volume changes since $K = Q/V_R$. Several authors have published on this observation (1–5), and some have attempted to correct the elimination rate for perfusate volume changes (2–5). Other authors have discussed perfusate volume and nutrient replenishment as a means of maintaining the viability of open perfused organ systems, such as the kidney or liver, where there is loss of water and energy sources due to urine and bile excretion (6–8). Two

0022-3549/83/0800-0970$01.00/0

the rate of skin permeation (Table I), so a constant skin-permeation profile can be achieved. By calculation, systems A and B release nitroglycerin at a flux ($Q/t^{1/2}$) of 500 and 875 $\mu g/cm^2/hr^{1/2}$, respectively (Fig. 4). The difference in release fluxes between these two systems is expected from the difference in drug-loading doses in the devices (11).

In summary, the results generated from the present investigation suggest that even though nitroglycerin is released at different rate profiles from these three transdermal delivery systems (Figs. 3 and 4), it penetrates through the hairless mouse skin under, basically, the same rate process (Fig. 2). Additionally, the total nitroglycerin dose delivered through the abdominal skin at 24 hr by each of these transdermal delivery systems is fairly close in magnitude and the difference is statistically insignificant [$F = 0.33$, $F_{0.95}(2,25) = 3.39$] (Table I), although the loading dose varies greatly from one system to another, and the percentage of the loading doses released during a 24-hr elution study is substantially different.

Additional studies are currently underway to generate evidence on the feasibility of using hairless mouse skin as the viable substitute for human skin in studying the transdermal controlled administration of systemically active drugs from novel drug delivery systems. A more detailed report will be written when more data become available.

Organ Perfusion Studies

Keyphrases □ Organ perfusion—pharmacokinetics, importance of volume replenishment □ Pharmacokinetics—organ perfusion studies, importance of volume replenishment

To the Editor:

Single-pass and recirculating perfused organ systems have been used to study how specific organs of the body handle drugs. The single-pass system has been used extensively to study the influx and efflux of drugs by various organs, whereas recirculating systems have been used more commonly to study metabolism and/or excretion of drugs by these organs. Although both systems are useful, the conservation of drug and perfusion media associated with the recirculating system makes it more economical and allows for longer perfusion experiments even with limited volumes of perfusion medium. However, in recirculating perfusion systems, there are problems associated with volume depletion due to excretion in open systems (*i.e.*, liver and kidney) and sample withdrawal in both closed (*i.e.*, heart, muscle, and lung) and open systems, which must be considered when performing pharmacokinetic analyses of the data derived from these experiments. The following discussion will address these problems.

It has been shown that the rate of elimination of a drug from an isolated organ perfusion system is a function of the perfusate volume (1) according to the following equation:

$$\frac{dC_i}{dt} = \frac{Q}{V_R}(C_i - C_o) \qquad \text{(Eq. 1)}$$

where C_i and C_o are the inflow and outflow concentrations, Q is the perfusate flow, and V_R is the reservoir volume. The elimination rate constant (K) varies inversely with perfusate volume changes since $K = Q/V_R$. Several authors have published on this observation (1–5), and some have attempted to correct the elimination rate for perfusate volume changes (2–5). Other authors have discussed perfusate volume and nutrient replenishment as a means of maintaining the viability of open perfused organ systems, such as the kidney or liver, where there is loss of water and energy sources due to urine and bile excretion (6–8). Two

0022-3549/83/0800-0970$01.00/0

situations can arise during sampling and/or replenishment in organ perfusion studies:

1. The elimination rate constant (K) increases when the perfusate volume is depleted by samples being taken and not replenished or by excretion of urine/bile in an open system, since $K = Q/V_R$.
2. The concentration of drug in the perfusate decreases by dilution as lost volume is replenished. As the concentration in the perfusate is diluted, the concentration in the organ decreases to reestablish an equilibrium.

Volume replenishment for the purpose of maintaining the viability of the organ is essential, whereas volume correction either by replenishment or mathematical manipulation is not necessary for pharmacokinetic purposes. This reflects the fact that the elimination rate of a drug in a perfused organ has little meaning unless the volumes and flow rates used mimic those observed *in vivo*. Even if these requirements are met, elimination rate is a function of reservoir volume and will thus change with changes in volume.

The pharmacokinetic parameter that should be determined in organ perfusion studies is clearance, since this parameter describes the intrinsic ability of the isolated organ to eliminate or metabolize the drug independent of extraneous variables such as binding to other tissues or clearance by other organs. Organ clearance, however, is independent of reservoir volume, as shown:

$$CL_o = Q\left(\frac{C_{in} - C_o}{C_{in}}\right) \qquad \text{(Eq. 2)}$$

Similarly in the case of the liver and kidney, the biliary and renal clearance of intact drug (CL_{id}) is also independent of perfusate volume:

$$CL_{id} = \frac{\Delta X}{C_{mid}} \qquad \text{(Eq. 3)}$$

where ΔX is the amount of intact drug excreted and C_{mid} is the perfusate concentration at the midpoint of the excretion interval. Both equations are clearly independent of perfusate volume changes.

Therefore, if the primary pharmacokinetic objective of an organ perfusion study is to determine the organ clearance, it becomes apparent that volume correction for the purpose of pharmacokinetic calculations is not warranted. On the other hand, volume replenishment for the purpose of maintaining hydration, nutrient supply, energy sources, and, therefore, organ viability is important and must be considered during the design of organ perfusion studies. In addition, it must be realized that replenishment may be more critical for open systems such as the kidney and liver (where losses occur not only during sample withdrawal but in the urine and bile) than for closed systems such as the heart, lung, muscle, *etc.*

Rebound Phenomenon Observed During the Compaction of Samples in the Fisher Subsieve Sizer for Measuring Specific Surface Area of Griseofulvin

Keyphrases □ Specific surface area—Fisher subsieve sizer, rebound phenomenon observed during compaction, griseofulvin □ Compaction, tablet—rebound phenomenon, Fisher subsieve sizer, specific surface area of griseofulvin

To the Editor:

The air-permeability technique for measuring the specific surface area of powders is a well-recognized technique. It has been used for more than 30 years by the cement industry. The American Society of Testing Materials (1) as well as various European societies have adopted it as a standard method for measuring the fineness of cement by means of the Blaine apparatus, using the measurement of the resistance offered to the air flow by a packed bed of powder at a defined porosity level.

Recently the air-permeability method has also been included in the USP XX for measuring the fineness of griseofulvin in terms of its specific surface area (SSA). The USP monograph on griseofulvin specifies SSA limits between 1.30–1.70 m^2/g. For making the measurements, however, a procedure based on measuring at a range of porosities and using a Fisher subsieve sizer (FSS) apparatus is described. In the normal use of FSS-apparatus, it is common to take a sample weight equal to the density value of the sample material. The USP XX, however, suggests the use of 1.25 times the weight of material density as sample weight. This recommendation is based on an assumption that the SSA-value should be determined at very low porosities (down to 0.25 range), which cannot be reached easily when using the FSS-chart scale and sample weight equal to the density of a material. The basis of this recommendation is an earlier study by Edmundson and Tootil (2) who advanced an hypothesis that very low porosities are desirable for achieving a uniform packing of the powder bed and for getting a maximum SSA value which may be considered a unique value for a given powder sample.

A series of SSA measurements were made on a number of griseofulvin samples using the FSS apparatus and taking

0022-3549/83/0800-0971$01.00/0

situations can arise during sampling and/or replenishment in organ perfusion studies:

1. The elimination rate constant (K) increases when the perfusate volume is depleted by samples being taken and not replenished or by excretion of urine/bile in an open system, since $K = Q/V_R$.
2. The concentration of drug in the perfusate decreases by dilution as lost volume is replenished. As the concentration in the perfusate is diluted, the concentration in the organ decreases to reestablish an equilibrium.

Volume replenishment for the purpose of maintaining the viability of the organ is essential, whereas volume correction either by replenishment or mathematical manipulation is not necessary for pharmacokinetic purposes. This reflects the fact that the elimination rate of a drug in a perfused organ has little meaning unless the volumes and flow rates used mimic those observed *in vivo*. Even if these requirements are met, elimination rate is a function of reservoir volume and will thus change with changes in volume.

The pharmacokinetic parameter that should be determined in organ perfusion studies is clearance, since this parameter describes the intrinsic ability of the isolated organ to eliminate or metabolize the drug independent of extraneous variables such as binding to other tissues or clearance by other organs. Organ clearance, however, is independent of reservoir volume, as shown:

$$CL_o = Q\left(\frac{C_{in} - C_o}{C_{in}}\right) \qquad \text{(Eq. 2)}$$

Similarly in the case of the liver and kidney, the biliary and renal clearance of intact drug (CL_{id}) is also independent of perfusate volume:

$$CL_{id} = \frac{\Delta X}{C_{mid}} \qquad \text{(Eq. 3)}$$

where ΔX is the amount of intact drug excreted and C_{mid} is the perfusate concentration at the midpoint of the excretion interval. Both equations are clearly independent of perfusate volume changes.

Therefore, if the primary pharmacokinetic objective of an organ perfusion study is to determine the organ clearance, it becomes apparent that volume correction for the purpose of pharmacokinetic calculations is not warranted. On the other hand, volume replenishment for the purpose of maintaining hydration, nutrient supply, energy sources, and, therefore, organ viability is important and must be considered during the design of organ perfusion studies. In addition, it must be realized that replenishment may be more critical for open systems such as the kidney and liver (where losses occur not only during sample withdrawal but in the urine and bile) than for closed systems such as the heart, lung, muscle, *etc.*

Rebound Phenomenon Observed During the Compaction of Samples in the Fisher Subsieve Sizer for Measuring Specific Surface Area of Griseofulvin

Keyphrases □ Specific surface area—Fisher subsieve sizer, rebound phenomenon observed during compaction, griseofulvin □ Compaction, tablet—rebound phenomenon, Fisher subsieve sizer, specific surface area of griseofulvin

To the Editor:

The air-permeability technique for measuring the specific surface area of powders is a well-recognized technique. It has been used for more than 30 years by the cement industry. The American Society of Testing Materials (1) as well as various European societies have adopted it as a standard method for measuring the fineness of cement by means of the Blaine apparatus, using the measurement of the resistance offered to the air flow by a packed bed of powder at a defined porosity level.

Recently the air-permeability method has also been included in the USP XX for measuring the fineness of griseofulvin in terms of its specific surface area (SSA). The USP monograph on griseofulvin specifies SSA limits between 1.30–1.70 m^2/g. For making the measurements, however, a procedure based on measuring at a range of porosities and using a Fisher subsieve sizer (FSS) apparatus is described. In the normal use of FSS-apparatus, it is common to take a sample weight equal to the density value of the sample material. The USP XX, however, suggests the use of 1.25 times the weight of material density as sample weight. This recommendation is based on an assumption that the SSA-value should be determined at very low porosities (down to 0.25 range), which cannot be reached easily when using the FSS-chart scale and sample weight equal to the density of a material. The basis of this recommendation is an earlier study by Edmundson and Tootil (2) who advanced an hypothesis that very low porosities are desirable for achieving a uniform packing of the powder bed and for getting a maximum SSA value which may be considered a unique value for a given powder sample.

A series of SSA measurements were made on a number of griseofulvin samples using the FSS apparatus and taking

0022-3549/83/0800-0971$01.00/0

the sample weight suggested in the USP XX. Difficulty was experienced in compressing certain samples to powder bed porosities below the 0.50 range. Not only was an unusually high amount of force required, but it was almost impossible to compress some of the samples below 0.45 porosity by manual force.

The ASTM-Standard C 204-79 (1) (under its Note [7]) contains instructions for selecting the "Size of Test Sample" to be used with the Blaine permeameter:

> "The weight of sample shall be adjusted so that a firm, hard bed is produced by the compacting process. In no case, however should more than thumb pressure be used to secure the proper bed, nor should such thumb pressure be used that the plunger "rebounds" from the cell top when the plunger is removed."

To examine the influence of high force required to achieve sample-bed porosities of the lower range (<0.50) and any associated "rebound" phenomena, we compressed the griseofulvin samples to different porosity levels, as indicated on the FSS-chart line. After withdrawal of the FSS compressing plunger, the sample height in the FSS cell was measured by using a slide-gauge. The mean particle diameter and the corresponding SSA were then obtained from the FSS chart. Before compressing the bed to the next porosity level, the FSS cell was attached to a modified Blaine permeameter, the time of flow of air measured, and the corresponding SSA calculated according to the basic Kozeny-Carman equation (3), using the calculated porosity from the powder bed dimensions.

The results summarized in Table I show that the use of a higher sample weight of griseofulvin, as suggested in the USP XX, and its compression to bed porosities <0.50 level can lead to a rebound and expansion of the powder bed. This is seen in columns 2 and 3 of Table I where there is shown an appreciable difference between the corrected porosity and the calculated porosity (ϵ_3) obtained from the powder height measurements. These data imply that due to this rebound effect at the porosity range of 0.45 the SSA values read from the FSS chart will also be in error. This is also reflected in a greater deviation between the SSA values obtained with the FSS and Blaine apparatuses.

Table I [a]—SSA-Values of Griseofulvin Sample Measured at Different Porosities using FSS and Blaine Permeameter [a]

		0.4859	1.93	1.397	1.685	1.21

[a] Griseofulvin, ρ = 1.455 g/cm³ FSS-sample cell; sample weight used (1.455 × 1.25) = 1.819 g; supplied by Leo Pharmaceutical Products, Copenhagen, Denmark. [b] ϵ_1, indicated porosity on the FSS chart. [c] ϵ_2, corrected porosity due to higher sample weight (= $\rho \times 1.25$). [d] ϵ_3, calculated porosity from the measured sample height. [e] L, measured sample height. [f] S_{w1}, specific surface area obtained from particle diameter read at the FSS chart. [g] S_{w2}, specific surface area calculated from the ϵ_3-porosity value and measurement with Blaine-permeameter. [h] S_{w2}/S_{w1}, ratio of the SSA values from Blaine permeameter and Fisher subsieve sizer.

It is therefore proposed that the USP should adopt the procedure of measuring the SSA values at one defined porosity level, such as $\epsilon \sim 0.50$ used in the ASTM Standard. Another proposal is to leave the choice of permeameter open, provided a suitable calibration of the apparatus has been undertaken, more particularly of the sample cells.

In the calculation of SSA from air-permeability data, use is made of the Kozeny-Carman equation. In using this equation, it is important to know the accurate and precise values of the bed porosity as well as the length, diameter, and the volume of the compacted powder bed. For some permeability cells, such as that for the Blaine permeameter, a so-called mercury displacement method of calibration is frequently employed, and its details are also specified in the ASTM-Standard (1). The Fisher subsieve sizer, however, does not use any particular technique to calibrate its cell dimensions or the porosity setting. Edmundson (3) used a traveling microscope for this purpose, but it cannot be suggested for routine purposes.

We used a simple method to calibrate the permeability cells. The powder samples were compressed in the permeability cells and then ejected out carefully, by means of a suitable rod. The plug dimensions such as height and diameter were measured by means of a precision micrometer and the bulk volume was then calculated from these dimensions. Table II summarizes comparative values of such dimensions for some Blaine permeability cells, using the direct dimensions measurement and the mercury displacement methods.

A separate measurement of the metal components of the cells by means of a gauge confirm the directly measured dimensions of the powder plug. The direct measurement method is of more relevance to the actual state of the compressed powder plug used during the permeability measurements and it is easier to use. This method can be employed with different types of cells, including the Fisher subsieve sizer cell or the small bore tubes (~0.6 cm diameter) where the mercury-displacement method is not only tedious but impractical. Therefore, the direct measurement method is preferred for calibration.

For routine calibration purposes, it is advisable to use malleable materials for preparing the compressed powder plugs. The plugs should be compressed to porosities that are low enough to give firm plugs which can withstand handling, but not so low that expansion of the powder bed occurs because of "relaxation" after ejection from the cell.

Table II—Dimensions of Blaine Permeameter Cells Determined by Two Calibration Methods

Blaine cells	Mercury Displacement Method [a] Length, cm	Diameter, cm	Volume, cm^3	Direct Measurement of Dimensions [b] Length, cm	Diameter, cm	Volume, cm^3
A	(1.419) [c]	(1.270)	1.798	1.478	1.272	(1.878)
B	(1.450)	(1.270)	1.838	1.500	1.268	(1.895)

[a] Means of two measurements as stated in ASTM C-204-79. [b] Means of 10 measurements using separate compactions for each determination (*RSD* <0.4%). [c] Parentheses indicate values not experimentally determined.

Using very fine particle size materials, self-supporting plugs can be formed without the use of any additional binders. We found the addition of a mixture of micronized lactose and 5% magnesium stearate is suitable to improve flow properties.

Physicochemical Interpretation of pH-Stat Titration of Amorphous Aluminum Hydroxycarbonate

Keyphrases □ Amorphous aluminum hydroxycarbonate—pH-stat titration, physicochemical interpretation, fiber optic Doppler anemometer analysis, dissolution data □ pH-stat titration—correlation between the *in vitro* test and *in vivo* acid neutralization, amorphous aluminum hydroxycarbonate, fiber optic Doppler anemometer analysis, dissolution data

To the Editor:

The pH-stat titration of antacids (1) is a valuable *in vitro* test because it has been correlated with *in vivo* acid neutralization (2). In contrast to the acid-neutralizing capacity test and the acid-consuming capacity test, which are essentially indirect assays, the pH-stat titration measures the rate of acid neutralization (3). The pH-stat titration has provided insights into (*a*) the structure of aluminum hydroxycarbonate (4, 5); (*b*) the adsorption of polybasic acids (6), polyols (7), polymers (8), and surface-active agents (8) by aluminum hydroxycarbonate; and (*c*) the interaction of aluminum hydroxycarbonate and magnesium hydroxide (9, 10).

The pH-stat titrigram of aluminum hydroxycarbonate contains three phases rather than the linear rate of acid neutralization expected for an acid–base titration (1). As seen in Fig. 1, the reaction is characterized by an initial rapid reaction (phase I) which abruptly converts into a slow zero-order reaction (phase II) which gradually transforms into a more rapid zero-order reaction (phase III). In contrast, antacids such as sodium bicarbonate, calcium carbonate, magnesium hydroxide, and hydrotalcite exhibit the expected linear pH-stat titrigram (9, 10). The purpose of this communication is to describe the

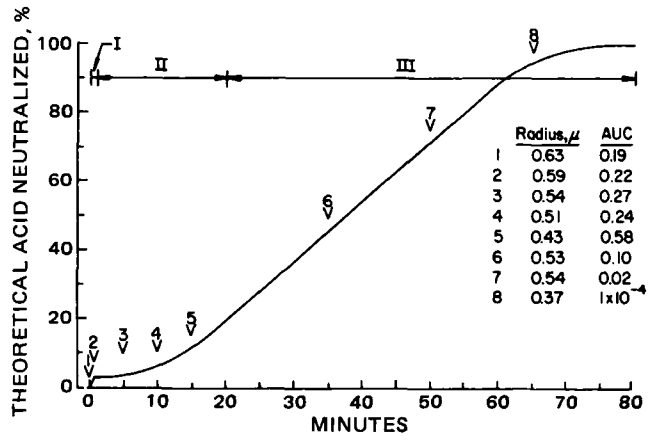

Figure 1—*pH-Stat titration at pH 3, 25° of aluminum hydroxycarbonate gel, which was examined at the indicated points by FODA.*

physicochemical reactions that are responsible for the three phases of the pH-stat titration of aluminum hydroxycarbonate.

The pH-stat titration at pH 3, 25° was interrupted periodically, as indicated in Fig. 1, and the apparent particle size was determined by fiber optic Doppler anemometry (FODA)[1] (11). The apparent mean hydrodynamic radius decreased from an initial value of 0.63 μm to 0.59 μm during phase I. A further decline to 0.43 μm was observed during the second phase. The apparent particle size initially increased during the third phase but decreased at the end of phase III.

The fiber optic Doppler anemometer determines particle size based on the measurement of the Brownian motion of colloidal particles. Thus, particle interactions that reduce the Brownian motion of particles will cause the apparent hydrodynamic radius, as measured by the fiber optic Doppler anemometer, to increase. In fact, if particle interactions cause Brownian motion to cease, the particle(s) will not be detected by FODA. Therefore, the apparent mean hydrodynamic radius data should be interpreted in conjunction with measurements of the total signal intensity. This is readily accomplished by integration of the power spectrum [area under the voltage squared *versus* frequency curve (AUC)] (12, 13). Thus, the AUC will be related to the total number of freely diffusing particles. The AUC increased from 0.19 to 0.22 during phase I and further increased to 0.58 during the slow, second phase. The AUC went to zero during phase III. The AUC data suggest that the number of particles exhibiting Brownian motion increased during phases I and II and decreased sharply during phase III.

It was hypothesized recently that aluminum hydroxide and aluminum hydroxycarbonate are composed of three types of particles: primary particles, secondary particles, and aggregates (14, 15). The primary particle is the basic unit: platy crystallites composed of fused six-membered rings of aluminum joined by double hydroxide bridges. The secondary particles are formed from primary particles arranged in a turbostratic type of arrangement due to the cohesive strength of van der Waals forces. Aggregates are composed of secondary particles formed in response to the balance of attractive and repulsive forces described by

Physicochemical Interpretation of pH-Stat Titration of Amorphous Aluminum Hydroxycarbonate

Keyphrases □ Amorphous aluminum hydroxycarbonate—pH-stat titration, physicochemical interpretation, fiber optic Doppler anemometer analysis, dissolution data □ pH-stat titration—correlation between the *in vitro* test and *in vivo* acid neutralization, amorphous aluminum hydroxycarbonate, fiber optic Doppler anemometer analysis, dissolution data

To the Editor:

The pH-stat titration of antacids (1) is a valuable *in vitro* test because it has been correlated with *in vivo* acid neutralization (2). In contrast to the acid-neutralizing capacity test and the acid-consuming capacity test, which are essentially indirect assays, the pH-stat titration measures the rate of acid neutralization (3). The pH-stat titration has provided insights into (*a*) the structure of aluminum hydroxycarbonate (4, 5); (*b*) the adsorption of polybasic acids (6), polyols (7), polymers (8), and surface-active agents (8) by aluminum hydroxycarbonate; and (*c*) the interaction of aluminum hydroxycarbonate and magnesium hydroxide (9, 10).

The pH-stat titrigram of aluminum hydroxycarbonate contains three phases rather than the linear rate of acid neutralization expected for an acid–base titration (1). As seen in Fig. 1, the reaction is characterized by an initial rapid reaction (phase I) which abruptly converts into a slow zero-order reaction (phase II) which gradually transforms into a more rapid zero-order reaction (phase III). In contrast, antacids such as sodium bicarbonate, calcium carbonate, magnesium hydroxide, and hydrotalcite exhibit the expected linear pH-stat titrigram (9, 10). The purpose of this communication is to describe the

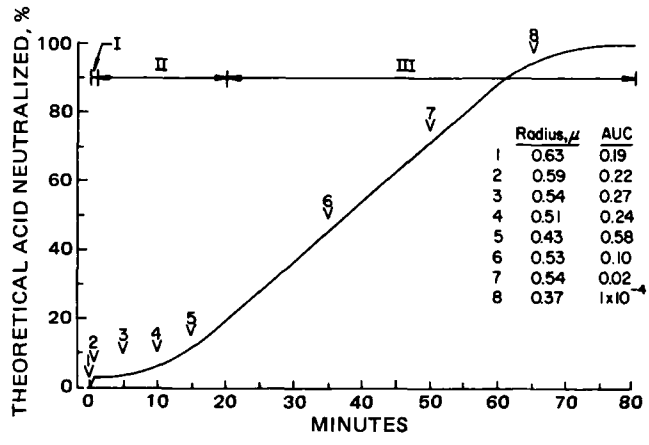

Figure 1—*pH-Stat titration at pH 3, 25° of aluminum hydroxycarbonate gel, which was examined at the indicated points by FODA.*

physicochemical reactions that are responsible for the three phases of the pH-stat titration of aluminum hydroxycarbonate.

The pH-stat titration at pH 3, 25° was interrupted periodically, as indicated in Fig. 1, and the apparent particle size was determined by fiber optic Doppler anemometry (FODA)[1] (11). The apparent mean hydrodynamic radius decreased from an initial value of 0.63 μm to 0.59 μm during phase I. A further decline to 0.43 μm was observed during the second phase. The apparent particle size initially increased during the third phase but decreased at the end of phase III.

The fiber optic Doppler anemometer determines particle size based on the measurement of the Brownian motion of colloidal particles. Thus, particle interactions that reduce the Brownian motion of particles will cause the apparent hydrodynamic radius, as measured by the fiber optic Doppler anemometer, to increase. In fact, if particle interactions cause Brownian motion to cease, the particle(s) will not be detected by FODA. Therefore, the apparent mean hydrodynamic radius data should be interpreted in conjunction with measurements of the total signal intensity. This is readily accomplished by integration of the power spectrum [area under the voltage squared *versus* frequency curve (AUC)] (12, 13). Thus, the AUC will be related to the total number of freely diffusing particles. The AUC increased from 0.19 to 0.22 during phase I and further increased to 0.58 during the slow, second phase. The AUC went to zero during phase III. The AUC data suggest that the number of particles exhibiting Brownian motion increased during phases I and II and decreased sharply during phase III.

It was hypothesized recently that aluminum hydroxide and aluminum hydroxycarbonate are composed of three types of particles: primary particles, secondary particles, and aggregates (14, 15). The primary particle is the basic unit: platy crystallites composed of fused six-membered rings of aluminum joined by double hydroxide bridges. The secondary particles are formed from primary particles arranged in a turbostratic type of arrangement due to the cohesive strength of van der Waals forces. Aggregates are composed of secondary particles formed in response to the balance of attractive and repulsive forces described by

[1] SIRA Institute Ltd., Kent, England.

0022-3549/83/0800-0973$01.00/0

DLVO theory. This type of particle structure has also been proposed for carbon black (16).

It is proposed that the pH-stat titrigram can be interpreted in light of the recently proposed particle structure of aluminum hydroxycarbonate (14, 15). The point of zero charge of aluminum hydroxide is 9.6 and ranges from 6 to 9 for aluminum hydroxycarbonate (17). The aluminum hydroxycarbonate gel shown in Fig. 1 had a point of zero charge of 6.5. Acid was consumed very rapidly during the initial phase. Kerkhof *et al.* (1) observed that the rate of acid neutralization during the first phase exceeds the capability of the autoburet to add compensating acid. This rapid proton consumption is primarily due to protonation of the hydroxyl groups and carbonate surface sites as the pH of the system is instantaneously adjusted to 3, well below the point of zero charge. During this phase Al—OH—Al and Al—OCO_2 bonds are not believed to react. Rather, rapid charging due to proton adsorption leads to a positive surface charge. The first phase is very brief, which is expected for a protonation reaction.

The initial phase, which will be referred to as the proton loading phase, quickly shifts into a second phase in which the rate of proton consumption is much slower. The rate of acid neutralization increases gradually during phase II. It is hypothesized that the gradual increase in the rate of acid neutralization is due to an increase in surface area. The increase in surface area is compatible with the hypothesis that aluminum hydroxycarbonate is composed of primary particles, secondary particles, and aggregates. Protonation during phase I caused the development of a strong, positive surface potential. Therefore, large coulombic repulsive forces develop, which are believed to cause the aggregates to disperse into secondary particles and the secondary particles to disperse into primary particles. As peptization proceeds, the exposed surface area will increase, and in turn, the rate of acid neutralization will increase. Therefore, phase II will be termed the peptization phase.

The FODA analysis (Fig. 1) during the first two phases supports the hypothesis that proton loading and peptization occur during phases I and II, respectively. The mean hydrodynamic radius decreased to 0.43 μm by the end of phase II (point 5 in Fig. 1) with the consumption of only 11% of the acid necessary to neutralize the sample. The volume of a 0.43-μm sphere is only 31% of the volume of a 0.63-μm sphere. Therefore, if the decrease in mean hydrodynamic radius had occurred solely by acid dissolution, approximately 70% of the theoretical acid would have been required. Thus, a dispersion effect has taken place.

The decrease in mean hydrodynamic radius during phase I and phase II must be considered in light of the concurrent changes in the AUC: the number of particles exhibiting Brownian movement. The AUC increased by a factor of 3 during phases I and II. Thus, a decrease in mean hydrodynamic radius and an increase in the number of particles exhibiting Brownian motion is occurring simultaneously. In view of the fact that only a small fraction of the acid necessary to dissolve the particles has been added, the observed trends in particle size and AUC are consistent with a proton loading and peptization process.

The rapid rate of acid neutralization which is characteristic of the third phase of the pH-stat titration of aluminum hydroxycarbonate is believed to be due to the high surface area produced by the peptization of the aggregates and secondary particles. Evidence of dissolution is seen in the FODA analysis by the decrease in the AUC during the third phase. The increase in the mean hydrodynamic radius during the early part of phase III (points 6 and 7 in Fig. 1) is believed to arise because of the greater dissolution rate of smaller particles, which causes the mean particle size of the remaining particles to increase. Since the acid dissolution reaction predominates during phase III, it will be referred to as the dissolution phase.

In most aluminum hydroxycarbonate gels, the third phase of the pH-stat titration terminates with the neutralization of the theoretical amount of acid based on the stoichiometric reaction of three protons per aluminum. However, some aluminum hydroxycarbonate gels do not complete the theoretical reaction during phase III, and a very slow rate of acid neutralization proceeds until the reaction is complete. The slow-reacting material is believed to have a very large primary particle size, approaching, in some cases, the crystalline state. On the other hand, an occasional aluminum hydroxycarbonate gel neutralizes more than three protons per aluminum. Gels of this type usually contain a high level of sodium and the superpotency is due to contamination with dawsonite [crystalline sodium aluminum hydroxycarbonate, $NaAl(OH)_2CO_3$] which neutralizes four protons per aluminum (18).

Antacid materials such as sodium bicarbonate, calcium carbonate, magnesium hydroxide, and hydrotalcite which exhibit a linear pH-stat titration are all crystalline materials with a particle size usually in excess of the colloidal range. Therefore, they probably do not exist as primary particles, secondary particles, or aggregates.

An examination of the changes in the pH-stat titrigram during the aging of amorphous aluminum hydroxycarbonate gel further supports the proposed interpretation. IR and X-ray studies indicate that the primary particle size increases during aging (19–21). In some cases the degree of aggregation will also increase during aging due to the consolidating effects of gravitational settling. As seen in Fig. 2, the pH-stat titrigram of a freshly precipitated aluminum hydroxycarbonate gel is dominated by phase I (proton loading) and phase III (dissolution of peptized particles). Most of the aggregates and secondary particles in the freshly precipitated sample are readily dispersed

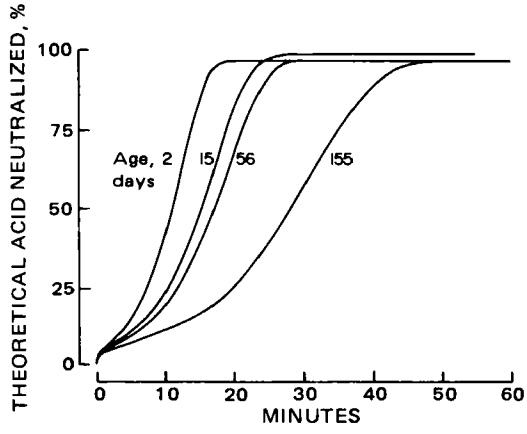

Figure 2—*Effect of aging of aluminum hydroxycarbonate gel at 25° on the pH-stat titration at pH 3, 25°.*

when the pH is lowered to 3. Since no significant particle growth has occurred, the relatively small primary particle size of the fresh gel gives a rapid rate of acid neutralization.

Phase II becomes more evident as the aluminum hydroxycarbonate gel ages. Both the primary particle size and the degree of aggregation increases during aging. Therefore, peptization becomes more important and the slow, second phase becomes more prominent. The rate of acid neutralization during phase III decreases during aging (day 2 *versus* day 155 in Fig. 2), which reflects the increase in primary particle size.

An understanding of the physicochemical processes required for the *in vitro* acid neutralization of aluminum hydroxycarbonate gel is necessary, because similar reactions occur in the GI tract when aluminum hydroxycarbonate gel is used as an antacid.

Simplified Method for Intravenous Dosing and Serial Blood Sampling of Unanesthetized Guinea Pigs

Keyphrases □ Blood sampling—serial collection from unanesthetized guinea pigs □ Guinea pigs—dosing and serial blood sampling without anesthesia □ Vacuum bleeding apparatus—serial blood collection from unanesthetized guinea pigs

To the Editor:

Ascorbic acid (vitamin C) levels can influence oxidative demethylation processes in the guinea pig (1), the only common laboratory animal unable to synthesize ascorbic acid endogenously (2). Thus, the guinea pig is an especially popular model for studying the effects of ascorbic acid on drug metabolism. Because of this, it is important to define methods for drug administration and repetitive blood sampling when using this species for pharmacokinetic studies. The following procedures were developed during a recent investigation of the effect of ascorbic acid on caffeine pharmacokinetics in young and aged guinea pigs.

A large towel was effective in quieting and immobilizing the animals during both drug dosing and blood sampling. The animals were prepared for dosing, by removing the hair over the injection site with an electric clipper. The prominent superficial vein on the medial side of the thigh (the medial saphenous vein) was used for all drug injections. The injection site was dabbed with ethanol and then the vein was enlarged using a finger to block venous return, and a small (21 gauge) needle was inserted in the direction of blood flow. A small quantity of blood was drawn *into the* 1-ml syringe to ensure correct insertion of the needle in the vein. Following a bolus injection of the drug solution, the needle was withdrawn quickly and pressure placed on the puncture with a finger to prevent venous backflow and avoid loss of some of the injected dose.

The method used here for repeated blood sampling was modified from that of Dolence and Jones (3) and found to be highly effective, producing a minimum of stress or pain in the guinea pigs. Similar to the procedure for caffeine dosing, the guinea pigs were wrapped in a towel exposing only the hind legs, which kept them comfortable yet immobilized. The leg not used for drug injection was extended and the hair removed using an electric clipper. A thin layer of silicone grease[1] was applied to the leg to form a tight seal with the vacuum bleeding apparatus and to prevent loose hair from contaminating the blood sample. One of the toenails was clipped, cutting into the vein and producing a flow of blood. Using this method alone only a small quantity of blood could be collected before coagulation stopped the flow. To circumvent this problem the prepared leg was positioned in the bleeding apparatus, as shown in Fig. 1, and the vacuum adjusted to produce a steady blood flow. The blood was collected in a 3-ml heparinized tube attached to the bottom of the vacuum-bleeding apparatus with a plastic[2] collar. The vacuum was adjusted to either increase or decrease the blood flow.

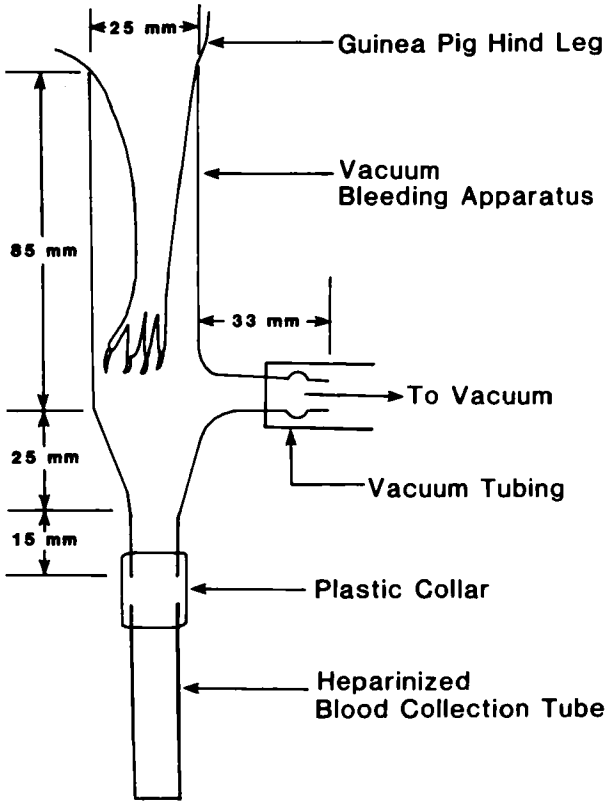

Figure 1—*Schematic diagram of the vacuum bleeding apparatus.*

When a 1- to 2-ml volume of whole blood was collected for each timed sample, the vacuum was turned off and the leg carefully removed from the apparatus. Bleeding usually ceased promptly, but it was sometimes necessary to place a gauze bandage over the toenail until all bleeding had stopped, usually within 1 min. For repeated blood collection from the same animal the nail was cut progressively more proximally at each sampling; the nails on both legs were used. The guinea pigs were not distressed by a sampling of up to 3 ml, and since no anesthetic was used, the animals had normal mobility when returned to their cages. The problem of blood clotting in the collection apparatus was minimized by using silicone grease on the inside glass surfaces.

Previous researchers have sampled guinea pig blood from the ear veins, penis vein, superficial thigh vein, jugular vein, orbital venous plexus and by the methods of heart puncture, indwelling vascular cannulation, cutting the toenail bed, and cutting the lateral saphenous vein or lateral metatarsal vein (4, 5). None of these methods proved completely satisfactory for the purposes of this study, since in most cases, an anesthetic was needed which could confound the observed results by affecting caffeine metabolism and/or plasma ascorbic acid levels (6, 7) if the study involved ascorbic acid supplementation, depletion, *etc.* We believe that the simplified procedure described here can be applied with similar success to studies involving other rodent species, in which anesthesia may be undesirable.

An Automated Sampling Device for Dissolution Testing

Keyphrases □ Dissolution testing—automated sampling device

To the Editor:

Many automated sampling devices have been designed for commercially available dissolution units[1]. The major criticism of some of these units is that the sampling probes remain in the dissolution medium during the duration of the test, thereby disturbing the hydrodynamics of the solution (1). This can cause dissolution results other than those intrinsic to the dosage form. We have designed a simple sampling device which eliminates this problem while still allowing the convenience of automation. The device is made from a commercially available air-actuated, solenoid-controlled valve[2] and brackets that can be easily made in-house. The design and orientation of the brackets are shown in Figs. 1 and 2. Dimensional and installational information is presented in Fig. 3. Air is supplied to the device at 20 psi. Either house air or an air pump can be used. The unit is connected to a computer-controlled pump-fraction collecter[2] which provides contact closure to the solenoid through its internal-timing sequences which also control the pump-fraction collector's prime, sample, and purge cycles. However, this unit need only be connected to a 110 V contact closure and external air supply to actuate the valve. Once actuated, any suitable multiple-channel pump and collector can provide samples.

As previously indicated, we have chosen a combination pump-fraction collector with computerized timing sequences. A program is entered using a hand-held pad, and at program-designated intervals contact closure is made, the device is actuated, and samples are collected during a three-part 60-sec sequence: for 20 sec the lines are washed with sample to waste; the sample tray is then advanced and the next 20-sec sample is collected; and for 20 sec the pumps reverse to purge the lines. The sample tray then

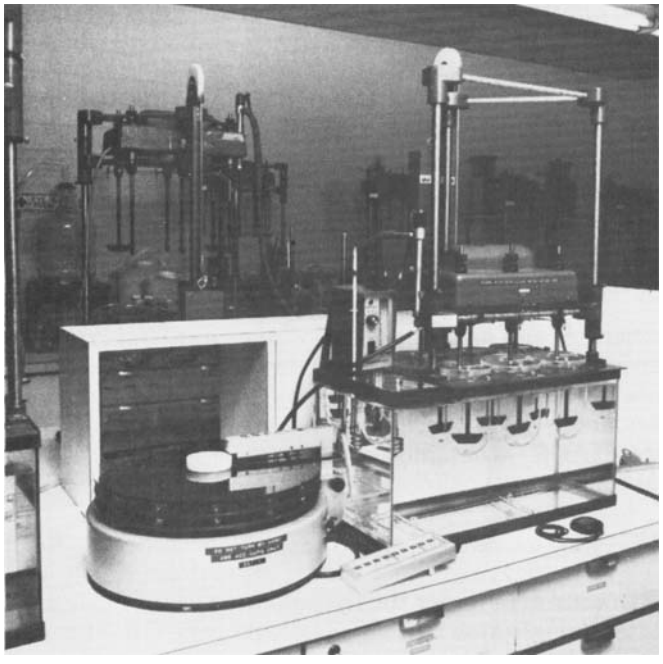

Figure 1—*Automated sampling device, fraction collector and dissolution unit.*

advances in preparation for the next sampling time. During the final 20 sec the probes are not in solution. Sample size can be adjusted by varying pump piston displacement.

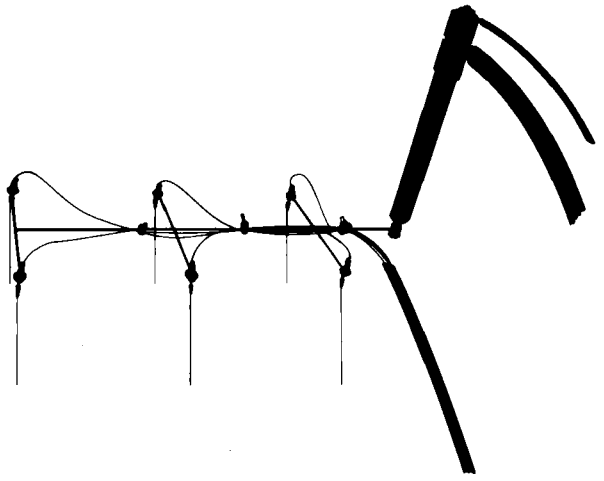

Figure 2—*Automated sampling device.*

During sampling, 50 μl-capillary tube probes are inserted into the medium for only 40 sec. The sampling location of the probes is as recommended in USP XX, and they retract above the surface of the medium after the 40-sec interval.

It has been shown by Savage and Wells that is is advantageous to minimize sample-probe size to reduce the influence on hydrodynamics (1). This design not only uses minimal probe size, but has the additional advantage of limiting the time the sample probes are inserted into the

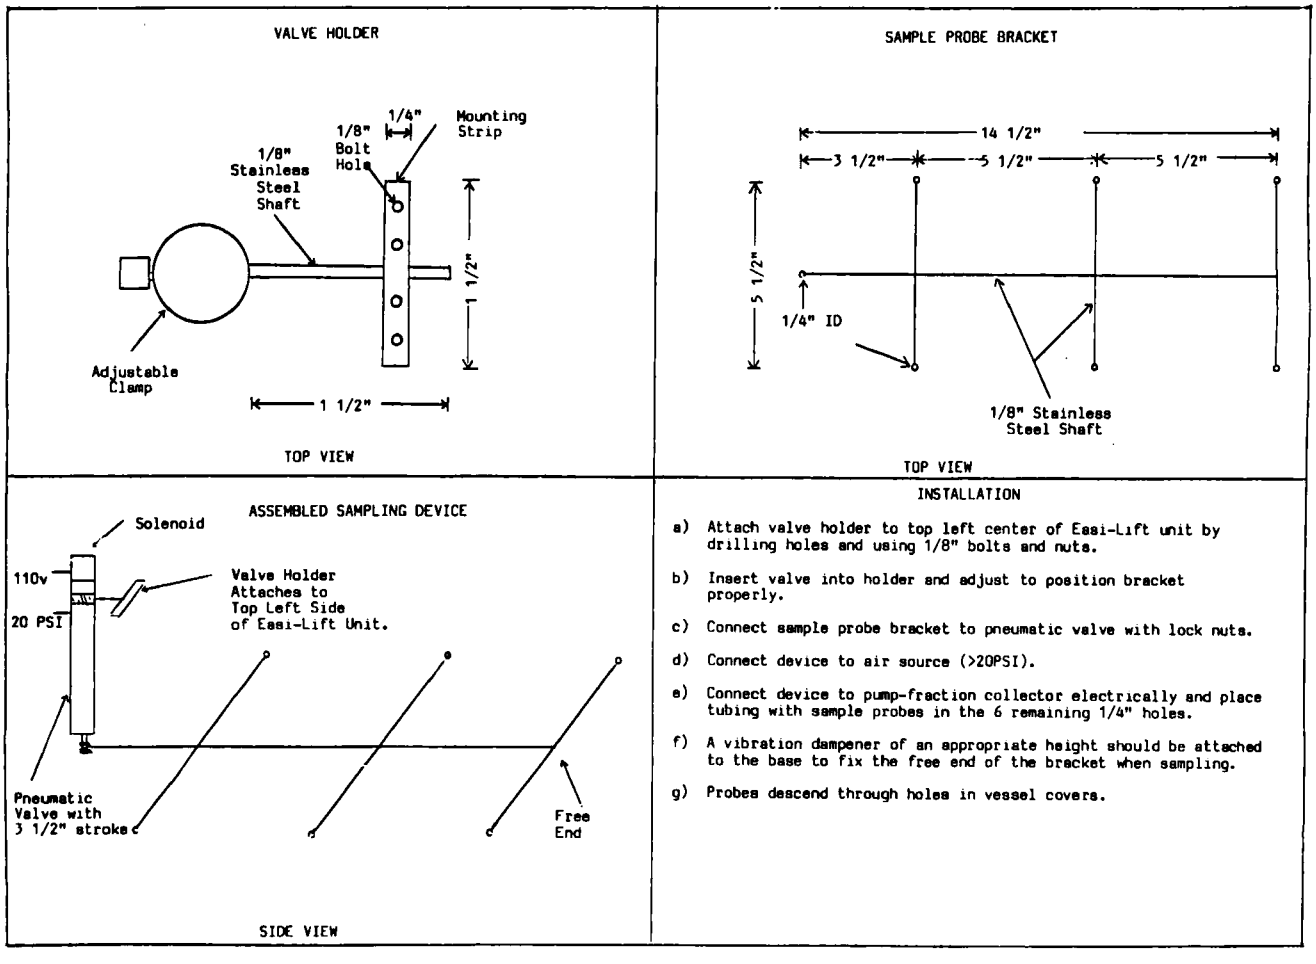

Figure 3—*Dimensional and installational information.*

dissolution medium to 40 sec/sampling time. This combination of reduced probe size and minimal contact with the dissolution medium results in minimal disturbance of the hydrodynamics of the medium.

In summary, this design offers these advantages for adaptation to Hanson Easi-Lift dissolution units:

1. The device does not disturb the hydrodynamics of the dissolution test, and the sampling probes are inserted in the solution only while sampling.
2. There is easy access to the dissolution unit because probes and brackets retract.
3. The sampling device is inexpensive to make and could be linked to a variety of dissolution pump-sample collection devices.

This device has proven to be reliable and essentially carryover-free in our laboratory and is in routine use.

Computation of Model-Independent Pharmacokinetic Parameters During Multiple Dosing

Keyphrases □ Pharmacokinetics—computation of model-independent parameters, multiple dosing

To the Editor:

Pharmacokinetic analysis by means of traditional compartmental methods is slowly giving way to model-independent or noncompartmental approaches. Computational simplicity and, in some cases, more useful information are among the reasons for this trend. Methods that use the area under the drug concentration *versus* time curve (AUC) and the area under the first moment of drug concentration *versus* time curve (AUMC) are available to determine clearance (CL), mean residence time ($\bar{t}$), and apparent volume of distribution at steady state (V_{ss}) from data obtained after a single dose of drug (1, 2).

Often, the need arises to calculate pharmacokinetic parameters after several doses or at steady state; this is particularly true when patients are being treated with the study drug, and doses may not be manipulated for the purposes of the investigation. With the limited exception of the determination of clearance at steady state, noncompartmental methods have not been considered for this purpose.

Following repeated administration of a fixed dose of a drug at fixed intervals, the AUC during a dosing interval at steady state is equal to the total AUC after the first dose (3). Therefore, drug clearance can be calculated at steady state. On the other hand, AUMC during a dosing interval at steady state ($AUMC_{ss}$) is less than the total AUMC after a single dose. Therefore, $\bar{t}$ and V_{ss} cannot be calculated directly from steady-state data.

The inequivalence of $AUMC_{ss}$ and AUMC (single dose) can be demonstrated by considering multiple intravenous bolus doses of a drug with linear multicompartmental characteristics. Drug concentration (C) after a single dose is given by:

$$C = \sum_{i=1}^{n} A_i \exp(-k_i t) \qquad \text{(Eq. 1)}$$

where A_i and k_i are drug specific constants with units of concentration and reciprocal time, respectively; k_i values are independent of dose; $k_1 > k_2 \ldots > k_n$. The total area under the drug concentration–time curve after a single dose (AUC) is obtained by integrating Eq. 1 with respect to time:

$$\text{AUC} = \int_0^\infty C\,dt = \sum_{i=1}^{n} A_i/k_i \qquad \text{(Eq. 2)}$$

The total area under the first moment *versus* time curve after a single dose (AUMC) is given by the following integral:

$$\text{AUMC} = \int_0^\infty Ct\,dt = \sum_{i=1}^{n} A_i/(k_i)^2 \qquad \text{(Eq. 3)}$$

The analogous equations that apply to a dosing interval at steady state are as follows:

$$C_{ss} = \sum_{i=1}^{n} A_i \exp(-k_i t)/[1 - \exp(-k_i \tau)] \qquad \text{(Eq. 4)}$$

$$\text{AUC}_{ss} = \int_0^\tau C_{ss}dt = \sum_{i=1}^{n} A_i/k_i \qquad \text{(Eq. 5)}$$

$$\text{AUMC}_{ss} = \int_0^\tau C_{ss}t\,dt = \sum_{i=1}^{n} \frac{A_i}{(k_i)^2} \times \frac{[1 - \exp(-k_i\tau)] - k_i\,\tau \exp(-k_i\tau)}{1 - \exp(-k_i\tau)} \qquad \text{(Eq. 6)}$$

where τ is the fixed dosing interval. Note that Eqs. 2 and 5 are equivalent.

However, the relationship between $AUMC_{ss}$ and AUMC is given by the following ratio:

$$\frac{\text{AUMC}_{ss}}{\text{AUMC}} = \sum_{i=1}^{n} \frac{A_i}{(k_i)^2} \times \left[1 - \frac{k_i\,\tau \exp(-k_i\,\tau)}{[1 - \exp(-k_i\,\tau)]}\right] \Big/ \sum_{i=1}^{n} A_i/(k_i)^2 \qquad \text{(Eq. 7)}$$

Clearly, attempting to calculate t or V_{ss} by replacing AUMC with $AUMC_{ss}$ would provide incorrect answers, because $AUMC_{ss} < AUMC$.

We wish to propose an alternate, noncompartmental method to calculate pharmacokinetic parameters during repetitive dosing. This method may be called reverse superposition because a single dose curve is derived from data obtained during the second, third, or nth dosing interval. It is not limited to steady state but does require that subsequent doses be given during the postabsorptive, postdistributive phase of the previous dose. Each data point on the single-dose curve is calculated by means of the following equation:

$$C(t) = C_i(t) - C_i(0) \exp(-k_n t) \qquad \text{(Eq. 8)}$$

0022-3549/83/0800-0978$01.00/0

dissolution medium to 40 sec/sampling time. This combination of reduced probe size and minimal contact with the dissolution medium results in minimal disturbance of the hydrodynamics of the medium.

In summary, this design offers these advantages for adaptation to Hanson Easi-Lift dissolution units:

1. The device does not disturb the hydrodynamics of the dissolution test, and the sampling probes are inserted in the solution only while sampling.

Computation of Model-Independent Pharmacokinetic Parameters During Multiple Dosing

Keyphrases □ Pharmacokinetics—computation of model-independent parameters, multiple dosing

To the Editor:

Pharmacokinetic analysis by means of traditional compartmental methods is slowly giving way to model-independent or noncompartmental approaches. Computational simplicity and, in some cases, more useful information are among the reasons for this trend. Methods that use the area under the drug concentration *versus* time curve (AUC) and the area under the first moment of drug concentration *versus* time curve (AUMC) are available to determine clearance (CL), mean residence time ($\bar{t}$), and apparent volume of distribution at steady state (V_{ss}) from data obtained after a single dose of drug (1, 2).

Often, the need arises to calculate pharmacokinetic parameters after several doses or at steady state; this is particularly true when patients are being treated with the study drug, and doses may not be manipulated for the purposes of the investigation. With the limited exception of the determination of clearance at steady state, noncompartmental methods have not been considered for this purpose.

Following repeated administration of a fixed dose of a drug at fixed intervals, the AUC during a dosing interval at steady state is equal to the total AUC after the first dose (3). Therefore, drug clearance can be calculated at steady state. On the other hand, AUMC during a dosing interval at steady state ($AUMC_{ss}$) is less than the total AUMC after a single dose. Therefore, $\bar{t}$ and V_{ss} cannot be calculated directly from steady-state data.

The inequivalence of $AUMC_{ss}$ and AUMC (single dose) can be demonstrated by considering multiple intravenous bolus doses of a drug with linear multicompartmental characteristics. Drug concentration (C) after a single dose is given by:

$$C = \sum_{i=1}^{n} A_i \exp(-k_i t) \qquad \text{(Eq. 1)}$$

where A_i and k_i are drug specific constants with units of concentration and reciprocal time, respectively; k_i values are independent of dose; $k_1 > k_2 \ldots > k_n$. The total area under the drug concentration–time curve after a single dose (AUC) is obtained by integrating Eq. 1 with respect to time:

$$\text{AUC} = \int_0^\infty C\,dt = \sum_{i=1}^{n} A_i/k_i \qquad \text{(Eq. 2)}$$

The total area under the first moment *versus* time curve after a single dose (AUMC) is given by the following integral:

$$\text{AUMC} = \int_0^\infty Ct\,dt = \sum_{i=1}^{n} A_i/(k_i)^2 \qquad \text{(Eq. 3)}$$

The analogous equations that apply to a dosing interval at steady state are as follows:

$$C_{ss} = \sum_{i=1}^{n} A_i \exp(-k_i t)/[1 - \exp(-k_i \tau)] \qquad \text{(Eq. 4)}$$

$$\text{AUC}_{ss} = \int_0^\tau C_{ss}dt = \sum_{i=1}^{n} A_i/k_i \qquad \text{(Eq. 5)}$$

$$\text{AUMC}_{ss} = \int_0^\tau C_{ss}t\,dt = \sum_{i=1}^{n} \frac{A_i}{(k_i)^2} \times \frac{[1 - \exp(-k_i\tau)] - k_i\,\tau \exp(-k_i\tau)}{1 - \exp(-k_i\tau)} \qquad \text{(Eq. 6)}$$

where τ is the fixed dosing interval. Note that Eqs. 2 and 5 are equivalent.

However, the relationship between $AUMC_{ss}$ and AUMC is given by the following ratio:

$$\frac{\text{AUMC}_{ss}}{\text{AUMC}} = \sum_{i=1}^{n} \frac{A_i}{(k_i)^2} \times \left[1 - \frac{k_i\,\tau \exp(-k_i\,\tau)}{[1 - \exp(-k_i\,\tau)]}\right] \Big/ \sum_{i=1}^{n} A_i/(k_i)^2 \qquad \text{(Eq. 7)}$$

Clearly, attempting to calculate t or V_{ss} by replacing AUMC with $AUMC_{ss}$ would provide incorrect answers, because $AUMC_{ss} < AUMC$.

We wish to propose an alternate, noncompartmental method to calculate pharmacokinetic parameters during repetitive dosing. This method may be called reverse superposition because a single dose curve is derived from data obtained during the second, third, or nth dosing interval. It is not limited to steady state but does require that subsequent doses be given during the postabsorptive, postdistributive phase of the previous dose. Each data point on the single-dose curve is calculated by means of the following equation:

$$C(t) = C_i(t) - C_i(0) \exp(-k_n t) \qquad \text{(Eq. 8)}$$

0.75	16.1	24.1	16.1
1.0	12.8	19.9	12.9
1.5	9.5	15.0	9.5
2	7.4	11.6	7.3
AUC[c]	56.159	—	55.996
AUMC[c]	84.198	—	83.391
V_{ss}[d]	13.3 liter	—	13.3 liter
CL[d]	8.9 liter/hr	—	8.9 liter/hr
$\bar{t}$[d]	1.5 hr	—	1.5 hr

[a] Single dose described by $C = 100e^{-5t} + 20e^{-0.5t}$. [b] Computed as $C = C_{sst} - 11.6e^{-0.5t}$. [c] Computed using trapezoidal rule. [d] V_{ss} = [Dose(AUMC)]/AUC^2, CL = Dose/AUC, $\bar{t}$ = AUMC/AUC.

where $C(t)$ is the calculated concentration after a single dose at time t, $C_i(t)$ is the observed concentration during the ith dosing interval at time t, $C_i(0)$ is the postabsorptive, postdistributive drug concentration at the start of the ith dosing interval, and k_n is the terminal rate constant.

To illustrate this method, data were simulated (4) for two different sets of conditions. The first data set represented concentration–time values after an intravenous bolus dose (Table I). The second set of data are values representative of extravascular administration (Table II). The last data set consists of concentration–time values for intermittant intravenous infusion (Table III). In all cases, a single-dose curve was constructed by means of Eq. 8 from the steady-state values. The AUC and AUMC values between the single dose situation and the curve derived using reverse superposition varied slightly because of rounding-off errors, but no appreciable differences were apparent between respective pharmacokinetic parameters.

Since reverse superposition applies also during multiple dosing before steady state occurs, this method could be applied at any time during therapy. This approach could be useful when patients receiving the study drug are investigated, since it is often difficult to ensure steady-state conditions (*i.e.*, compliance, errors in administration time, *etc.*) Caution must be used when the dosing interval is short relative to the terminal half-life of the drug. Under these conditions half-life may be difficult to calculate, and errors may occur in the estimation of $C(t)$ as well as in the estimation of AUC and AUMC from the derived single dose curve.

Table II—Simulated Data for a 500-mg Dose every 6 hr [a]

Time, hr	Single Dose Concentration, μg/ml	Steady-State Concentration, μg/ml	Concentration Converted to Single Dose, μg/ml[b]

Test for Selection of Erythromycin Stearate Bulk Drug for Tablet Preparation

Keyphrases □ Bioavailability—erythromycin stearate tablet formulation, dissolution rate, high-performance liquid chromatography □ Erythromycin stearate—bioavailability, tablet formulations, dissolution rate, high-performance liquid chromatography □ High-performance liquid chromatography—erythromycin stearate tablet formulation, bioavailability

To the Editor:

Bioavailability testing of experimental erythromycin stearate tablet formulations showed significant differences between tablets declaring 250 and 500 mg, where the concentrations of antibiotic and excipients were identical and the tablets differed only in fill weight and geometry. Different lots of erythromycin stearate were used in these formulations. It was learned, subsequently, that the dissolution rate (and presumably bioavailability) of erythromycin from the tablets could be correlated with the intrinsic dissolution rate of the batch of erythromycin stea-

CL[d]	8.9 liter/hr	—	8.9 liter/hr
$\bar{t}$[d]	1.5 hr	—	1.5 hr

[a] Single dose described by $C = 100e^{-5t} + 20e^{-0.5t}$. [b] Computed as $C = C_{sst} - 11.6e^{-0.5t}$. [c] Computed using trapezoidal rule. [d] V_{ss} = [Dose(AUMC)]/AUC^2, CL = Dose/AUC, $\bar{t}$ = AUMC/AUC.

where $C(t)$ is the calculated concentration after a single dose at time t, $C_i(t)$ is the observed concentration during the ith dosing interval at time t, $C_i(0)$ is the postabsorptive, postdistributive drug concentration at the start of the ith dosing interval, and k_n is the terminal rate constant.

To illustrate this method, data were simulated (4) for two different sets of conditions. The first data set represented concentration–time values after an intravenous bolus dose (Table I). The second set of data are values representative of extravascular administration (Table II). The last data set consists of concentration–time values for intermittant intravenous infusion (Table III). In all cases, a single-dose curve was constructed by means of Eq. 8 from the steady-state values. The AUC and AUMC values between the single dose situation and the curve derived using reverse superposition varied slightly because of rounding-off errors, but no appreciable differences were apparent between respective pharmacokinetic parameters.

Since reverse superposition applies also during multiple dosing before steady state occurs, this method could be applied at any time during therapy. This approach could be useful when patients receiving the study drug are investigated, since it is often difficult to ensure steady-state conditions (*i.e.*, compliance, errors in administration time, *etc.*) Caution must be used when the dosing interval is short relative to the terminal half-life of the drug. Under these conditions half-life may be difficult to calculate, and errors may occur in the estimation of $C(t)$ as well as in the estimation of AUC and AUMC from the derived single dose curve.

Test for Selection of Erythromycin Stearate Bulk Drug for Tablet Preparation

Keyphrases □ Bioavailability—erythromycin stearate tablet formulation, dissolution rate, high-performance liquid chromatography □ Erythromycin stearate—bioavailability, tablet formulations, dissolution rate, high-performance liquid chromatography □ High-performance liquid chromatography—erythromycin stearate tablet formulation, bioavailability

To the Editor:

Bioavailability testing of experimental erythromycin stearate tablet formulations showed significant differences between tablets declaring 250 and 500 mg, where the concentrations of antibiotic and excipients were identical and the tablets differed only in fill weight and geometry. Different lots of erythromycin stearate were used in these formulations. It was learned, subsequently, that the dissolution rate (and presumably bioavailability) of erythromycin from the tablets could be correlated with the intrinsic dissolution rate of the batch of erythromycin stea-

0022-3549/83/0800-0979$01.00/0

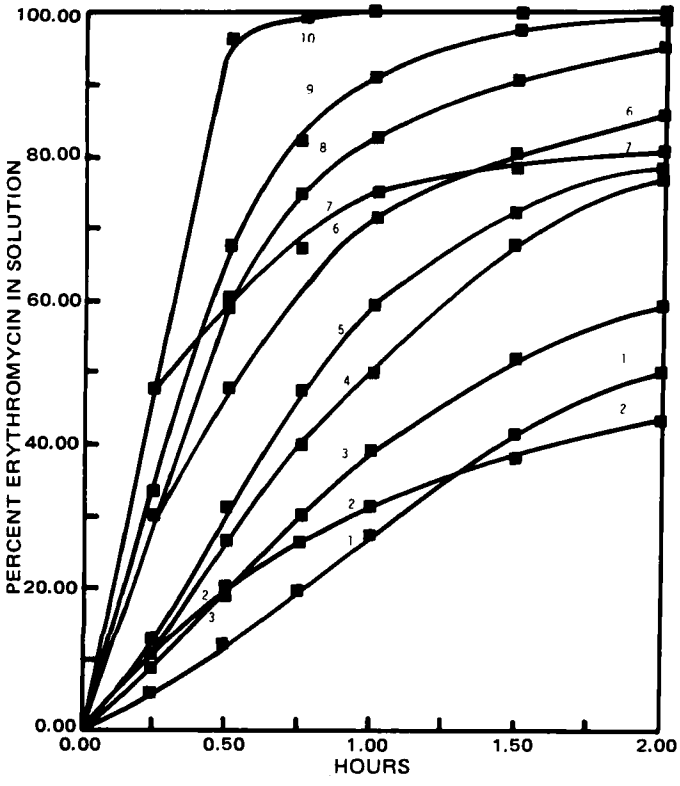

Figure 1—*Dissolution profile of various lots of erythromycin stearate as a function of time (0.05 M pH 6.6 phosphate buffer).*

rate used. A dissolution test method was developed for erythromycin stearate bulk drug and tablets using conditions under which decomposition of the antibiotic does not occur.

Erythromycin, its esters, salts, and their preparations have been reported to show significant differences in bioavailability (1). Stavchansky *et al.* (2) described attempts to correlate the known bioavailability of erythromycin stearate tablets from various sources with different *in vitro* test methods, including disintegration, dissolution, and dissolution–dialysis. Their findings were inconclusive, perhaps because their dissolution experiments were confounded by the decomposition of the antibiotic under the conditions used: their test method did not discriminate between intact and decomposed erythromycin.

Tsuji and Goetz (3) described a high-performance liquid chromatographic (HPLC) method for erythromycin which is selective for the intact drug and correlates with microbiological potency assay. In this laboratory, the method afforded a single peak for erythromycin at about 7.9 min. At 37°, the conventional temperature used in dissolution testing, erythromycin decomposition was rapid as evidenced by the decrease of its peak height and appearance of a new peak at about 12.5 min. Dissolution of the drug increases with increased acidity. However, acidity and temperature promote decomposition of erythromycin. On the basis of these considerations, the dissolution test method developed used pH 6.6 phosphate buffer at room temperature for the dissolution medium.

The dissolution studies were performed in a USP Apparatus 2 (4), equilibrating 500 ml of 0.05 *M* pH 6.6 phosphate buffer at 22°. The paddle was rotated at 50 rpm and 500 mg of erythromycin stearate (dispersing it with a micro spatula to ensure that it is wetted) or an erythromycin stearate tablet was added to the medium. A 5.0-ml aliquot was withdrawn after 60 min. The test sample was filtered through a membrane filter[1] and assayed immediately for erythromycin by the HPLC method (3). Under these test conditions, no decomposition of erythromycin was detected on the chromatograms. (The HPLC assay was used to obtain the data reported below; however, any convenient method could be employed after establishment of the validity of the test conditions.) Decomposition of erythromycin becomes evident after prolonged residence (several hours) in the dissolution medium; hence the injunction to assay the test sample immediately after completion of the test.

Table I—Dissolution of Erythromycin Stearate Bulk Drug and Corresponding Tablets

Curve No.[a]	Percent Dissolution After 1.0 Hr		
	Bulk Drug	500-mg Tablet	250-mg Tablet
4	49	44	
6	72	70	
7	75	70	
—	78	—	80
8	82	78	
9	92	88	

[a] Dissolution curves from Fig. 1.

Ten lots of erythromycin stearate from two domestic and six foreign sources were found to vary from 27 to 100% dissolution in 1 hr. A plot of the dissolution rate as a function of time is shown for these lots in Fig. 1. In general, dissolution of the bulk drug was similar to that of the tablets made from it. The dissolution rates of bulk drug and corresponding tablets are shown in Table I.

Bioavailability studies showed that the tablets made from bulk drugs of 72 and 78% dissolution were acceptable, while those made from bulk drug of 49% dissolution were unacceptable. For this reason, 70% dissolution for the bulk drug has been arbitrarily set as acceptable.

Erythromycin stearate is a mixture of the stearate salt of erythromycin with varying amounts of free stearic acid, medium stearate, and water. The chemical and physical properties that affect its dissolution have not been elucidated; attempts to correlate dissolution with particle size, shape, and crystal forms of the drug have failed. However, the test method proposed affords a facile empirical means for selecting suppliers.

A publication of the American Pharmaceutical Association

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C. and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. All Journal staff may be contacted at this address. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $75; educational institutions $75; individuals *for personal use only* $40; single copies $10. APhA and SAPhA members may subscribe to *J. Pharm. Sci.* for $20.00 per year. All foreign subscriptions add $10 for postage. Subscription rates are subject to change without notice.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Scientific Manpower—Supply *versus* Demand

A very popular and apparently successful business magazine is entitled "*Changing Times.*" Today that title, more than ever before, seems to reflect what is happening all around us.

During the past several decades, government and its handmaiden, government regulation—particularly at the federal level—have expanded tremendously. Much of this expansion can be attributed to the desire of citizens and legislators to minimize sudden and upsetting shifts in the economic, trade, business, and employment arenas by establishing controls over the forces believed to be responsible for such shifts.

However, the record of performance and experience is anything but convincing or even satisfactory.

For example, just a year ago, the country struggled through a period of one of the highest inflation rates and interest rates in its entire history; and this happened despite more prevailing fiscal, monetary, and banking regulatory authority than ever before. As another example, within a matter of less than three years, we went from mass warnings of an oil and energy "crunch" to a situation now described as a "glut."

So the times do change; and they change rapidly; and they change in spite of considerable efforts to plan, control, and channel the directions of the forces that are behind those changes.

It should not be too surprising, therefore, that changes of a comparably upsetting magnitude are now taking place in the field of health care delivery.

Just a few short years ago, the popular and almost universally repeated theme was the impending shortage of all constituent elements of health care: hospitals, physicians, and all other health care practitioners. Every suggestion of expanding public benefits *via* legislation was couched in fears of overburdening the capacity of the already overstrained health care system by trying to accommodate anticipated additional demands placed upon it.

Now that, too, has all changed.

In virtually each issue of every medical, dental, pharmacy, and other health care related news publication, there is at least some reference to the existing or impending *oversupply* of physicians, dentists, pharmacists, nurses, or other practitioners. And the latest predictions are that hospitals are going to be next on "the hit list." In fact, a nationally known hospital consulting firm has just predicted that "1,000 of the existing 6,000 hospitals in the country will close by 1985, due to cutbacks in government funding and patients' inability to pay their bills." Furthermore, "the remaining 5,000 hospitals will be controlled by 400 ownerships," suggesting that a lot of constriction and belt-tightening will take place in order to maintain the economic viability of the surviving hospitals.

In the professional practice arena, this has begun to trigger a good deal of preliminary "jockeying" on the part of each group to stake out new roles or expanded areas of practice involvement. All of this is in an effort to maintain as large as possible a share of the health care dollar *via* future demand for their professional services. But, conversely, to other groups, this often is perceived as "trespassing" on their territory. Hence, the so-called "turf battles" are just now beginning to shape up, and undoubtedly they will become more severe as the situation itself grows more difficult.

Our pharmaceutical scientist readers may find all this only incidentally interesting, and wonder how—if at all—it affects them.

But affect them, it most likely will; and that warning is the underlying message of this editorial.

Approximately 10 years ago, employers such as drug companies, government laboratories, health sciences schools, and so on, found it very difficult to lure graduating pharmacists and physicians into their employment. The financial rewards as practitioners were better and more immediate. Hence, at that time, there was relatively less competition for the industry, government, and academic jobs than there is now; and today there is much less competition than will probably be the case in the near future.

Such a threat of intense job competition might appear farfetched to many pharmaceutical scientists, but when considered against the backdrop of current physician fears of inroads being made by nurse-practitioners, of pharmacist concerns of physicians turning to drug product dispensing, and dentist efforts to curb expansion by dental hygienists, the potential threat becomes far more believable. Physicians who are unable to establish a viable practice may be even receptive to taking jobs as laboratory scientists. And, in doing so, they will displace a corresponding number of technical people.

And lest the Ph.D.-level, senior scientists assume that they will be immune, one only has to think back to about the early 1970s when there was a reverse type of situation.

At that time, the physician shortage and the lure of bigger financial rewards—coupled with a downturn in the demand for scientific and technical personnel—prompted so much interest among Ph.D. people, that a number of medical schools established a specially tailored curriculum for such people who wanted to obtain an M.D. degree. Is it not just as reasonable to project that sizable numbers of today's and tomorrow's graduates from medical schools, as well as pharmacy schools—when faced with poor employment prospects—will opt for Ph.D. degrees as their admission ticket into pharmaceutical research?

Consequently, the alternately rising and ebbing tide of health care manpower does, indeed, impact upon everyone in the field: on some more than others, on some more directly than others.

"Preparation" is the byword of success in any endeavor. Hence, it would be well for pharmaceutical scientists to prepare themselves for this situation; moreover, the signs clearly indicate that it is not too early now to begin such planning and preparations.

RESEARCH ARTICLES

Effect of Intergranular *versus* Intragranular Cornstarch on Tablet Friability and *In Vitro* Dissolution

Z. T. CHOWHAN [x] **and I.-C. YANG**

Received March 22, 1982, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication August 18, 1982.

Abstract □ The effect of blending dry cornstarch *versus* wet granulation with the drug and other excipients on friability and *in vitro* dissolution of a ticlopidine hydrochloride tablet formulation was studied. The friability of the tablets was reduced by wet granulating cornstarch with the drug and other excipients compared with the dry blending. The dissolution rate and the tablet-to-tablet variability was improved by incorporating cornstarch in the wet-granulation stage. The lactose placebo tablets, which were wet granulated with either a binder solution or without a binder, also showed reduced tablet friability due to the incorporation of cornstarch in the wet-granulation step. Examination of the tablet cross sections under the scanning electron microscope indicated clumping of starch grains when starch was blended in the dry form. Starch grains were well embedded in the other materials of the tablet and not readily visible when starch was wet granulated with the other excipients. This results in better bonding, fewer weak points, and better homogeneity of the starch disintegrator within the tablet, which accounts for better friability and improved dissolution.

Keyphrases □ Ticlopidine hydrochloride—tablet friability, *in vitro* dissolution, effect of inter- *versus* intragranular cornstarch □ Cornstarch—inter- *versus* intragranular, effect on tablet friability and *in vitro* dissolution, ticlopidine hydrochloride □ Dissolution—*in vitro*, ticlopidine hydrochloride, effect of inter- *versus* intragranular corn starch, friability

Starch USP is a common excipient in compressed tablets, both as a disintegrator and as a binder. Cornstarch is one of the most common disintegrating agents used in tablet formulations today. When added in the dry state to the dry granulation, it acts as a disintegrator. In the paste or dry form, when added before wet granulation, its function is that of a disintegrator and binder.

The mechanism of action of starches is not well understood. In aspirin tablets (1) where contact of starch grains was continuous in the interparticle spaces, disintegration was rapid and effective even when void spaces were eliminated. Where contact was not continuous, disintegration was slower, and appeared to depend on the degree of contact between starch grains and aspirin particles and on the size of interparticle spaces. The primary mechanism appeared to be a swelling action. Capillarity *per se* did not appear to have a disintegrating effect. Ingram and Lowenthal (2) could not find any measurable correlations between starch grain damage and disintegration time or between starch swelling and compressional force. Outside of compressional force, the inherent effect of the tablet ingredients was the only factor that appeared to affect disintegration. In a later study, Lowenthal and Burruss (3) discounted pore diameter and porosity of the tablet as a mechanism of action of starch as a disintegrator. A significant swelling of the starch grains was not observed (4) when pressure-deformed grains were moistened with water. Thus, the regaining of the shape of starch grains was apparently not the mechanism of action as a tablet disintegrator. Observations by scanning electron microscope (5) indicated that rupture of the tablet surface occurred where starch agglomerates were found. It was postulated that water hydrates the hydroxyl groups of the starch molecules, causing them to move apart. The slight swelling that occurs is due to a rapid hydration step and a slower sorption step after the addition of water. Channels or pores lined with starch were not evident. The conditions for rapid tablet disintegration were sufficient agglomerates, low pressure, and presence of water.

In wet-granulated tablet formulations, starch is usually added in the dry form prior to compression. This general practice is based perhaps on the swelling theory of the mechanism of action of starch as a disintegrator which is generally discounted. The data in the literature strongly suggest that disintegration is influenced by a wide variety

[a] Milligrams of ingredient per tablet.

of factors that are specific only for a given tablet formulation; it is difficult to determine the mechanism of action of starch as a tablet disintegrator.

Recent studies from these laboratories (6) suggested that the friability of compressed tablets was reduced by incorporating 80% cornstarch in the wet-granulation step compared with the dry blending. This paper examines the effects of intragranular *versus* intergranular cornstarch on tablet friability and *in vitro* dissolution.

EXPERIMENTAL

Materials—The drug, ticlopidine hydrochloride[1], was ≥99.0% pure. The excipients used were microcrystalline cellulose[2] NF, povidone[3] USP, citric acid[4] USP, stearic acid[5] powder NF, cornstarch[6] NF, lactose[7] USP, and magnesium stearate[4] NF.

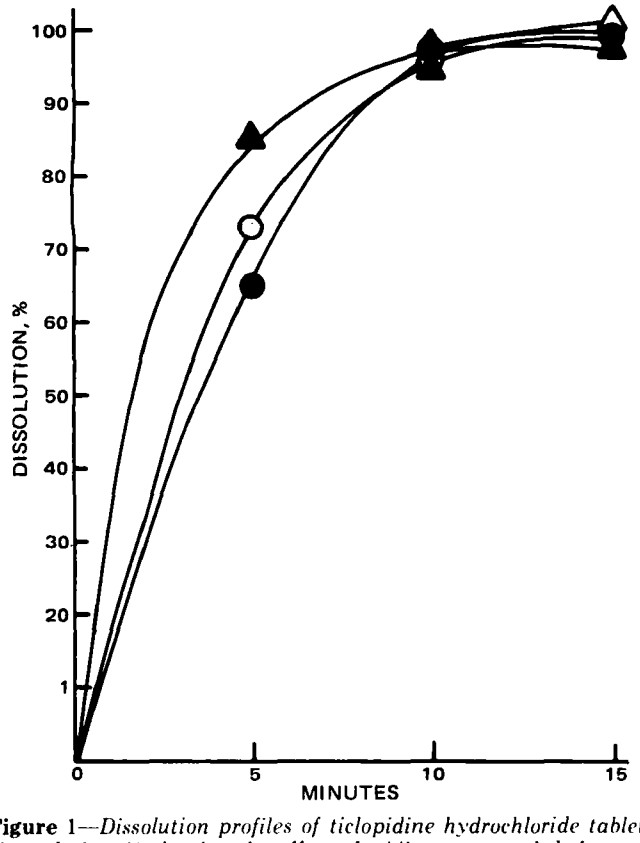

Figure 1—*Dissolution profiles of ticlopidine hydrochloride tablets (formulation A) showing the effect of adding cornstarch before wet granulation* versus *blending it with the dry granulation. The granulation moisture content was 2.1%, and tablet crushing strength was 15 Strong Cobb units. Key: (○) starch dry blended, with extra-deep concave punches; (●) starch dry blended, with standard concave punches; (△) starch wet granulated, with extra-deep concave punches; (▲) starch wet granulated, with standard concave punches.*

Table II—Effect of the Addition of Starch During Wet Granulation or Blending with the Dry Granulation on Friability of Tablets Compressed with Standard Concave Punches [a]

Punch	Tablet Friability, % Starch Blended with Dry Granulation	Tablet Friability, % Starch Wet Granulated with Other Materials
Standard concave	0.27	0.0925
Extra-deep concave	0.135	0.0165

[a] Using formulation A with a granulation moisture of 2.1% and tablet crushing strength of 15 Strong Cobb units.

Granulation—The formulations used in this study are given in Table I. The drug and the appropriate excipients were mixed together in a small, planetary mixer for 10 min. Citric acid and povidone in formulations A and B and citric acid alone in formulation C were dissolved in water. These solutions were used to granulate the powder mixture. After 10 min of mixing, the granulation was passed through a 1.4-mm aperture and dried in a forced-air oven at 50° until the desired moisture levels were obtained. The dried granulation was forced through a 1.2-mm aperture screen. The lubricant and the disintegrator were blended with the granulation for 5 min. The granulations were stored in tightly closed, glass bottles. The moisture content of the final granulation was determined prior to compression.

Compression—The compression was carried out by means of a single-punch tablet machine[8]. The punches and die were 10.32 mm in diameter. Standard concave and extra-deep concave punches were used for compression. The target compression weight was 390 mg/tablet. The tablet crushing strength was determined[9] immediately after compression. For each determination, 10 tablets were tested and the mean was calculated.

Granulation Moisture—The granulation was exposed to a 125-W

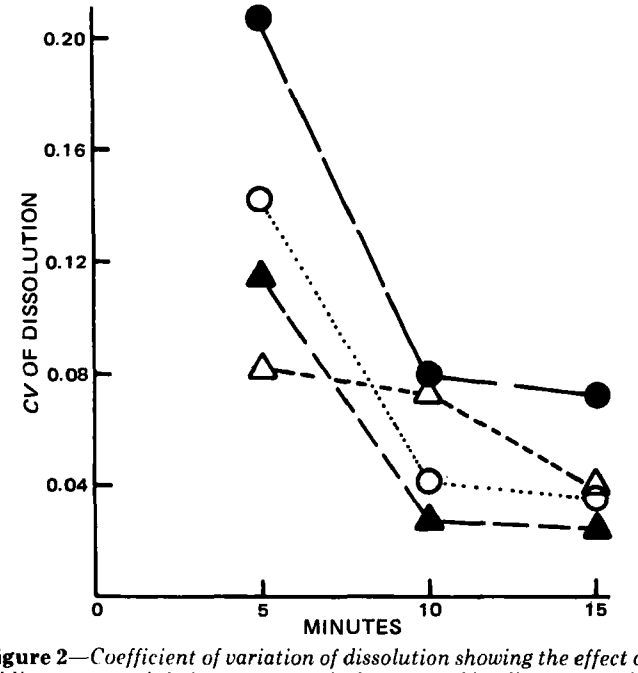

Figure 2—*Coefficient of variation of dissolution showing the effect of adding cornstarch before wet granulation* versus *blending it with the dry granulation (formulation A). IR lamp for 15 min at a 90-V setting in a moisture balance[10]. The percent weight loss on drying was read directly from the instrument.

Tablet Friability—A Roche-type friabilator was used. Twenty tablets were brushed with a soft, camel's hair brush to remove all adhering particles. After accurate weighing, the tablets were placed in the drum. The drum was rotated for 4 min (100 revolutions), the tablets were removed, brushed to remove adhering particles, and accurately weighed. The test was carried out in duplicate, and the mean percent friability was calculated.

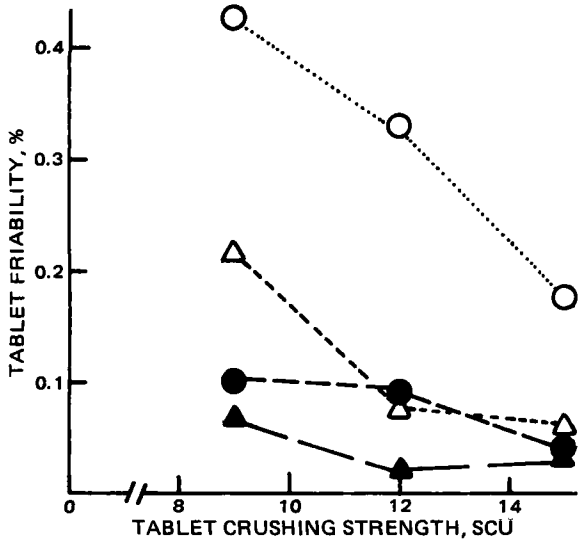

Figure 4—*Effect of adding cornstarch during wet granulation* versus *blending with the dry granulation on friability of placebo tablets (formulation C). The granulation moisture content was 2.0%. Key: (○) starch dry blended, with standard concave punches; (●) starch dry blended, extra-deep concave punches; (△) starch wet granulated, with standard concave punches; (▲) starch wet granulated, with extra-deep concave punches.*

***In Vitro* Dissolution**—The *in vitro* dissolution was determined by the USP Method II as reported earlier (6). For each determination, six tablets were tested. This apparatus consisted of USP paddles driven by a multiple-spindle drive with a variable-speed control[11]; round-bottom, plastic resin kettles[12] measuring 1 liter; and a water bath. The dissolution

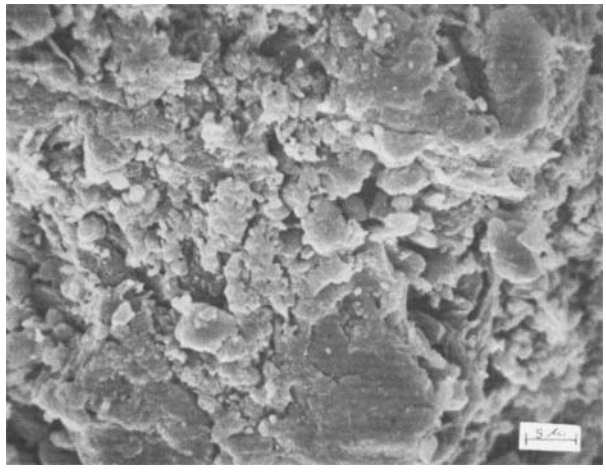

Figure 6—*Cross-sectional view of ticlopidine hydrochloride tablets compressed with the standard concave punches using formulation A. Starch was wet granulated [~2000× (original magnification)].*

[12] Elanco, Indianapolis, Ind.

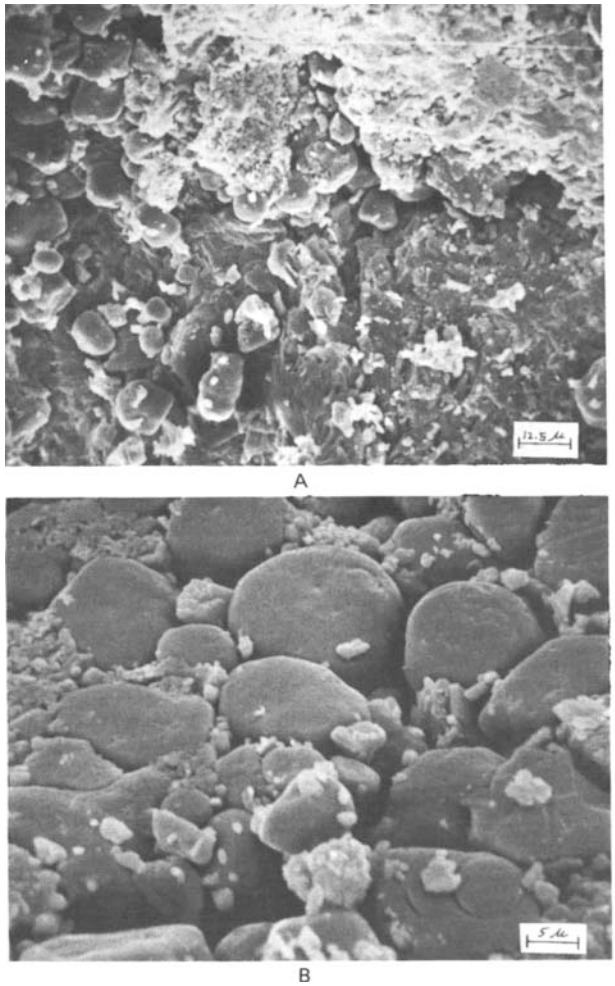

Figure 7—*Cross-sectional view of ticlopidine hydrochloride tablets compressed with the extra-deep concave punches using formulation A. Starch was dry blended. Key: (A) ~800× (original magnification); (B) ~2000× (original magnification).*

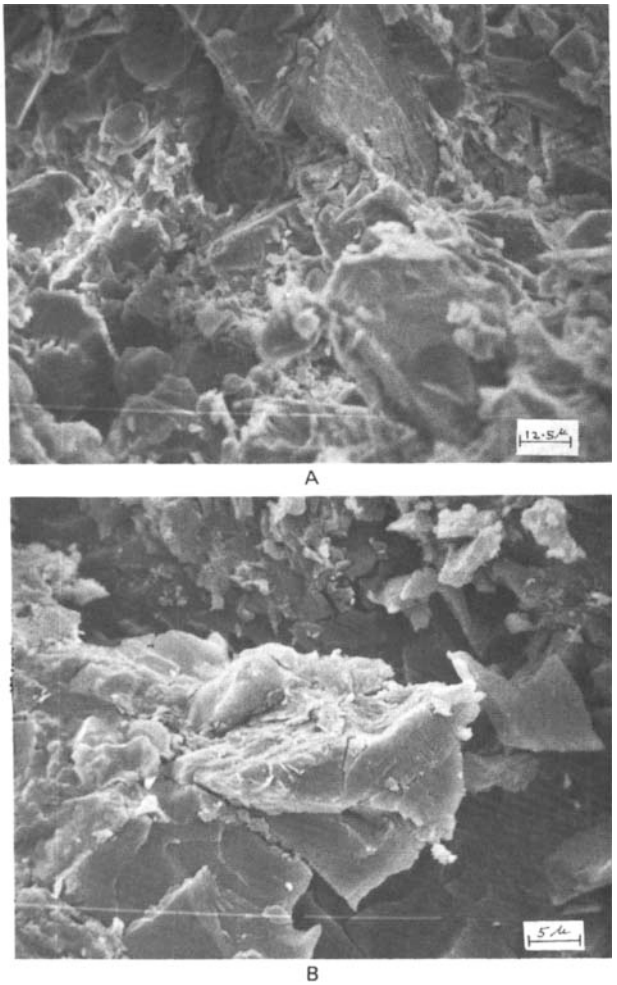

Figure 9—*Cross-sectional view of the placebo tablets compressed with extra-deep concave punches using formulation B. Starch was (A) dry blended or (B) wet granulated [~2000× (original magnification)].*

medium was 700 ml of deaerated water equilibrated at 37° and stirred at 50 rpm. The dissolved drug was analyzed by recording the absorbance at 236 nm, using an automated monitoring system consisting of a peristaltic pump[13], 1-mm spectrophotometer flow cells, and automatic sample changer/spectrophotometer[14]. The absorbances were plotted on a recorder every minute until complete dissolution was achieved. The dissolution apparatus was calibrated using USP dissolution calibrator tablets (prednisone, 50 mg). The mean dissolution and the standard deviations were within the required range.

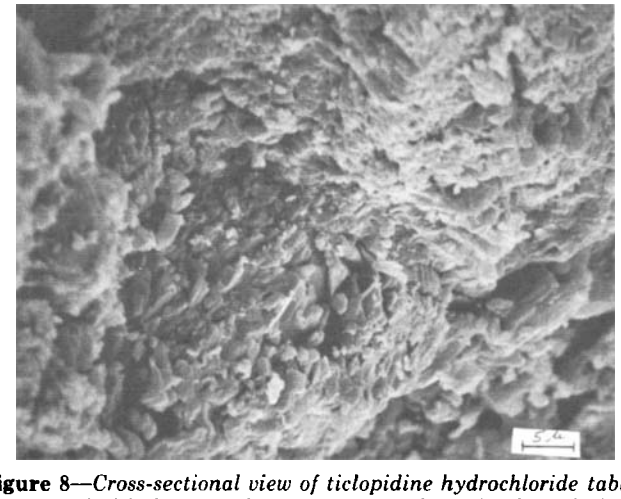

Figure 8—*Cross-sectional view of ticlopidine hydrochloride tablets compressed with the extra-deep concave punches using formulation A. Starch was wet granulated [~2000× (original magnification)].*

Scanning Electron Micrographs—Cross sections of the tablets were obtained by cutting tablets axially with a sharp razor blade. The tablet cross sections were mounted on cylindrical specimen stubs with double-stick tape[15] with the inner side surface up. Surface conductivity on the tablet sample was obtained with a silver paste in a vacuum evaporator. The samples were viewed at an oblique angle of 30° in a scanning electron microscope[16]. The photographs were taken using self-developing film[17].

RESULTS AND DISCUSSION

The results of the friability of ticlopidine hydrochloride tablets (formulation A) are given in Table II. The starch was either added during the wet-granulation process or blended in the dry form with the dry granules. The tablet crushing strength and the granulation moisture were both controlled in these studies[18]. The compression was carried out with standard concave and extra-deep concave punches. The results indicate that the friability of the tablets compressed from granulations in which starch was incorporated in the wet-granulation process was lower compared with the friability of the tablets containing starch in the dry-blended form. Extra-deep concave punches showed a much larger effect

in reducing tablet friability compared with the standard concave punches as a result of the differences in processing starch.

Figure 1 gives the dissolution profiles of ticlopidine hydrochloride tablets (formulation A) resulting from granulations in which starch was either blended in the dry form or wet granulated with the drug and other excipients. For both punch tip geometries, the initial dissolution rate of the tablets compressed from granulations containing starch in the wet-granulation stage was higher compared with the tablets that were compressed from granulations containing starch in the dry form.

The coefficients of variation (CV) of these tablets as a function of the dissolution time are given in Fig. 2. At all time points studied, the dissolution coefficient of variation of standard convex tablets was smaller for tablets containing starch in the wet-granulated form compared with the tablets containing starch in the dry-blended form. The dissolution coefficient of variation of extra-deep convex tablets compressed from granules containing wet-granulated starch was smaller only at the 5-min time point. At later time points, the punch tip geometry effects discussed earlier (6) override, at least in part, the starch-processing effects.

Placebo tablets (formulations B and C) were compressed with both punch tip geometries to confirm the nonspecificity of the effect on tablet friability caused by the mode of the addition of starch. The results of the friability of formulation B placebo tablets at various crushing strengths under controlled granulation moisture are given in Fig. 3. The tablets compressed with the granulation containing wet-granulated starch were less friable compared with the tablets compressed from granulations containing starch in the dry-blended form. At higher crushing strengths, these differences were small. This was true with both punch tip geometries. In agreement with an earlier report (6), the friability of extra-deep convex tablets was smaller than the friability of standard convex tablets.

Granulations were made without a wet binder (formulation C) to study the influence of the mode of the starch addition on tablet friability. Figure 4 gives the results of the tablet friability at various crushing strengths at a controlled moisture content. For both punch tip geometries, the friability of the tablets compressed from granulations containing wet-granulated starch was smaller than the tablets compressed from granulations containing starch in the dry-blended form. The friability of the extra-deep convex tablets was much smaller than the friability of the standard convex tablets.

These results suggest definite advantages of incorporating starch as a disintegrator in the wet-granulated part of the formulation of tablets containing soluble drugs and/or soluble major excipients for improving tablet friability and *in vitro* dissolution. It is also important to point out that the wet granulations containing starch must be dried below 60° to prevent gelatinization of the starch.

To investigate the mechanism by which the incorporation of starch in the wet granulation improved tablet friability and *in vitro* dissolution, a scanning electron microscope was used to examine the cross sections of the tablets. Figure 5 is a cross-sectional view of ticlopidine hydrochloride tablets (formulation A) containing starch in the dry-blended form compressed with the standard concave punches. Starch grains, mostly deformed, appeared in clumps with some loose, fine granules. The clumping of the starch grains was not observed when cross sections of the tablet containing starch as a part of the wet granulation were examined (Fig. 6). The starch grains were well distributed in the drug–excipient granules showing good contact with the powders.

Because of the dependence of the axial and radial movement of the powders on punch tip geometry, cross sections of the extra-deep convex tablets were examined to study its effect on the distribution of starch granules within the tablet. Clumps of starch grains with some loose, fine granules were observed (Fig. 7) when starch was dry blended with the dry granules. Starch did not appear to adhere to itself or to the other materials

in the tablet. This results in weaker points within the tablets and fine cracks around the agglomerates. Higher tablet friability and higher tablet-to-tablet variability in dissolution could be explained as resulting from clumping of starch grains and weaker points around these agglomerates. The cross-sectional view of the tablet compressed from granules containing starch in the wet-granulation stage is shown in Fig. 8. No clumping of the starch grains was seen. The materials were well distributed in the tablet matrix. Comparisons of the two punch tip geometries revealed no major differences in the distribution of starch resulting from the differential particle movement during compression (compare Figs. 5 and 6 with Figs. 7 and 8).

Figure 9 gives cross-sectional views of the placebo tablet compressed with the standard concave punches (formulation B). Tablets containing dry-blended starch showed only a few starch grains (Fig. 9A) compared with the largely fused lactose (Fig. 9B) for tablets compressed from wet-granulated starch.

The cross-sectional views of the tablets compressed from formulation C without a wet binder are shown in Fig. 10. Similar to ticlopidine hydrochloride tablets, clumping of starch grains was observed when starch was dry blended (Fig. 10A and B). Starch grains do not adhere to themselves or to the other materials in the tablet. This is in contrast to the case when starch was wet granulated with other excipients using water (Fig. 10C and D). Agglomerates or even isolated starch grains were not observed. The starch was well embedded in the soluble excipient, lactose, which on drying crystallized out.

In conclusion, this study suggests that the tablet friability and *in vitro* dissolution improved by incorporating starch in the wet-granulation stage of formulations containing a soluble drug and/or a soluble major excipient. This improvement in tablet friability and *in vitro* dissolution is due to a better bonding, fewer weak points, and better homogeneity of the disintegrator, starch, within the tablet.

Application of the Ammonia Gas-Sensing Electrode: Determination of Drugs Having a Carbothionamido Group by Decomposition with Acid

SHOICHIRO TAGAMI ˣ **and HIROMI MAEDA**

Received April 19, 1982, from the *Toyama Medical and Pharmaceutical University, Sugitani, Toyama, Japan.* Accepted for publication August 4, 1982.

Abstract □ A method to determine drugs having a carbothionamido group using an ammonia gas-sensing electrode is described. To obtain analytical accuracy, the effect of factors that influence the potential is also discussed. Ethionamide or prothionamide was refluxed with 20% HCl to give ammonium chloride, hydrogen sulfide, and a carboxylic acid. The ammonia, which evolved at pH > 11, was determined. A linear calibration plot was obtained within the drug concentration range of 2×10^{-5}–1×10^{-2} *M*.

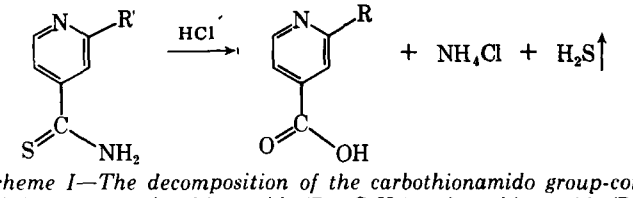
Keyphrases □ Ammonia gas-sensing electrode—determination of carbothionamido groups, acid decomposition of ethionamide and prothionamide □ Ethionamide—carbothionamido group, determination using ammonia gas-sensing electrode, acid decomposition □ Prothionamide—carbothionamido group, determination using ammonia gas-sensing electrode, acid decomposition

In recent years, the development of gas-permeable membrane electrodes has led to their widespread use in the analytical field (1). Although electrodes that use immobilized enzymes on the membrane are employed for the determination of organic and biological compounds, few applications to drug analysis have been reported in the literature, and no pharmacopeia has yet introduced their use for assays. Therefore, a previous paper (2) described procedures for the determination of drugs having a carboxyamido group (ethenzamide, niacinamide, pyrazinamide, and salicylamide).

The present paper describes the determination of drugs having a carbothionamido group in an analogous way and describes in detail the operations and handling of the ammonia gas-sensing electrode. The carbothionamido group decomposes into ammonium chloride, hydrogen sulfide, and a carboxylic acid on heating with hydrochloric acid (Scheme I). It may thus be possible to utilize the ammonia gas-sensing electrode to determine the ammonia derived from the ammonium chloride during the decomposition.

EXPERIMENTAL

Apparatus and Reagents—Direct potentiometric measurements were made at 20° in an 80-ml cell equipped with a magnetic stirrer, using a pH/mV meter[1] with a recorder[2] and ammonia gas-sensing electrodes A[3] and B[4]. Ethionamide[5], prothionamide[6], and ammonium chloride[7] were analytical grade or certified quality and were dried *in vacuo* at room temperature for 5 hr. Other chemicals used were reagent grade. Ammonium chloride solutions of 0.001–1 *M* and ammonium chloride solutions of 0.01–0.1 *M* saturated with ammonium picrate were used as internal filling solutions.



Scheme I—The decomposition of the carbothionamido group-containing compounds ethionamide ($R = C_2H_5$) and prothionamide ($R = C_3H_7$).

in the tablet. This results in weaker points within the tablets and fine cracks around the agglomerates. Higher tablet friability and higher tablet-to-tablet variability in dissolution could be explained as resulting from clumping of starch grains and weaker points around these agglomerates. The cross-sectional view of the tablet compressed from granules containing starch in the wet-granulation stage is shown in Fig. 8. No clumping of the starch grains was seen. The materials were well distributed in the tablet matrix. Comparisons of the two punch tip geometries revealed no major differences in the distribution of starch resulting from the differential particle movement during compression (compare Figs. 5 and 6 with Figs. 7 and 8).

Figure 9 gives cross-sectional views of the placebo tablet compressed with the standard concave punches (formulation B). Tablets containing dry-blended starch showed only a few starch grains (Fig. 9A) compared with the largely fused lactose (Fig. 9B) for tablets compressed from wet-granulated starch.

The cross-sectional views of the tablets compressed from formulation C without a wet binder are shown in Fig. 10. Similar to ticlopidine hydrochloride tablets, clumping of starch grains was observed when starch was dry blended (Fig. 10A and B). Starch grains do not adhere to themselves or to the other materials in the tablet. This is in contrast to the case when starch was wet granulated with other excipients using water (Fig. 10C and D). Agglomerates or even isolated starch grains were not observed. The starch was well embedded in the soluble excipient, lactose, which on drying crystallized out.

In conclusion, this study suggests that the tablet friability and *in vitro* dissolution improved by incorporating starch in the wet-granulation stage of formulations containing a soluble drug and/or a soluble major excipient. This improvement in tablet friability and *in vitro* dissolution is due to a better bonding, fewer weak points, and better homogeneity of the disintegrator, starch, within the tablet.

0022-3549/83/0900-0988$01.00/0

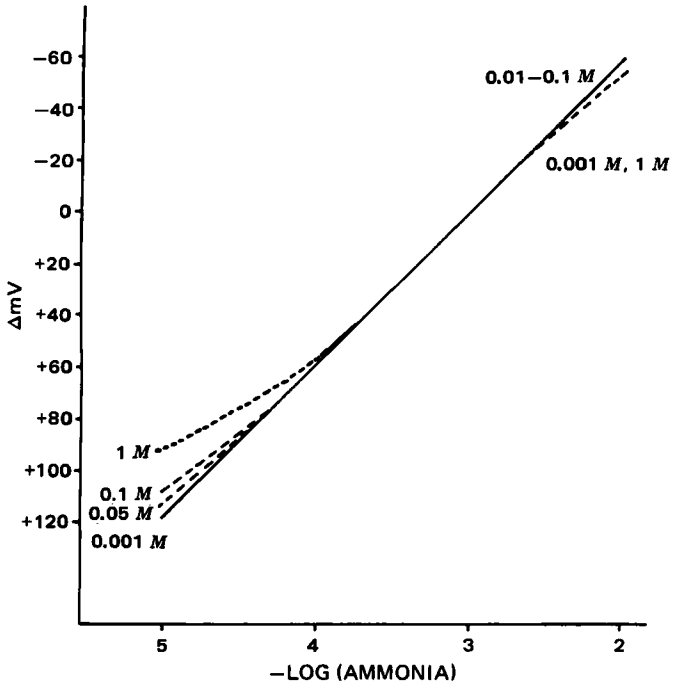

Figure 1—*Effect of internal filling solutions on the calibration plot.*

Standard Solution—To 25 ml of 0.1 *M* ammonium chloride solution in a 250-ml volumetric flask was added 50 ml of a 20% HCl solution which had been neutralized to pH 6.5 with sodium hydroxide, and the resulting solution was diluted to volume with distilled water. A working solution was prepared by diluting this stock solution to 1×10^{-2} *M* ammonium chloride.

Decomposition of Drugs—A mixture of 166.24 mg (1×10^{-3} mole) of ethionamide or 180.27 mg (1×10^{-3} mole) of prothionamide and 20 ml of 20% HCl was heated at reflux in an oil bath for 1 hr. The solution was cooled, poured into a 100-ml beaker, and diluted with ~50 ml of water. A drop of methyl orange was added while cooling the beaker continuously, and the acid was cautiously neutralized with 10 *N* NaOH solution until the indicator began to change color. The solution was then adjusted to pH 6.5 with dilute sodium hydroxide solution using a pH meter. The solution was poured into a 100-ml volumetric flask and diluted to volume with water. The concentrations of the final drug solutions were 1×10^{-2} *M*, corresponding to 1×10^{-2} *M* ammonia. Sample solutions for measurements were obtained by dilution of these solutions with water.

Assay Procedure—A 50-ml portion of the sample and standard solutions used was incubated for 30 min at 20°, and 1 ml of 5 *N* NaOH was added before the electrode was immersed in the solutions. (After alkalinization, the solutions are stable for several hours in the cell with a rubber stopper.) The standard procedure was as follows: The electrode with 0.05 *M* ammonium chloride internal filling solution was washed with water and immersed for ~5 min in fresh 0.05 *M* NaCl solution acidified with dilute hydrochloric acid at pH 4, and then the old internal filling solution was replaced with fresh 0.05 *M* ammonium chloride solution. The electrode was placed in the first standard, and the potential was measured. After washing the electrode as described above, the electrode was placed in the sample solution, and the potential was measured. After another washing, the electrode was placed in the second standard, and the potential was measured. The sample concentration was determined from the calibration curve.

Assay of Tablets—Twenty tablets were weighed and finely powdered. A portion of the powder (equivalent to ~166.24 mg of ethionamide or 180.27 mg of prothionamide) was accurately weighed, and 20 ml of acetone was added. The solution was stirred and then centrifuged. The supernatant acetone solution was removed, and 20 ml of acetone was added to the residue. The extraction procedure was repeated until the supernatant acetone solution was colorless. The acetone fractions were evaporated to dryness, and the resulting residue was refluxed for 1 hr with 20 ml of 20% HCl. As described above, the acidic solution was adjusted to pH 6.5 and diluted to 250 ml in a volumetric flask. The ammonia concentration in a 50-ml portion of the sample was determined from the calibration curve.

Table I—Effect of Dissolved Salts on the Electrode Potential

Salt	Salt Concentration,[a] *M*	Potential Shift, mV
Sodium chloride	1×10^{-4}	0
	1×10^{-3}	0
	1×10^{-2}	+0.1
	1×10^{-1}	−0.1
	5×10^{-1}	−0.1
	1	−0.6
Potassium chloride	1×10^{-4}	+0.2
	1×10^{-3}	−0.1
	1×10^{-2}	−0.1
	1×10^{-1}	−0.2
	5×10^{-1}	−0.6
	1	−2.2
Sodium sulfate	1×10^{-4}	0

	1×10^{-1}	−0.8
	3×10^{-1}	−2.7
	5×10^{-1}	−4.7

[a] The given salt concentrations are the concentrations in 1×10^{-3} *M* ammonium chloride.

RESULTS AND DISCUSSION

Internal Filling Solution—The electrolyte solution in the reference electrode and the internal filling solution contained known amounts of ammonium chloride. Commercially available ammonia gas-sensing electrodes differ slightly from one another in the concentration of the internal filling solution and in their inner structure. The electrolyte solution in reference electrode A can be replaced by fresh electrolyte solution, but not in electrode B. By using both electrodes, the effect of internal filling solutions on the calibration plot was investigated. First, electrode A, in which the internal filling solution and the electrolyte solution are the same, was examined by employing filling solutions with 0.001–1 *M* ammonium chloride. The results are shown in Fig. 1, where the potential difference (ΔmV) from 1×10^{-3} *M* ammonia to each concentration of ammonia is plotted as the ordinate and the ammonia concentration is plotted as the abscissa. Using 0.1, 0.05, and 0.01 *M* filling solutions, a linear calibration plot was obtained for the concentration range of 1×10^{-4}–1×10^{-2} *M* ammonia. Using 0.001 *M* filling solution, a linear calibration plot was obtained at 1×10^{-5}–1×10^{-3} *M* ammonia.

Table II—Determination of Drugs Having a Carbothionamido Group

Drug	Determination	Label Claim, mg	Found, mg	Recovery, %
Ethionamide	1	0.831	0.829	99.8
	2	0.831	0.832	100.1
	3	0.831	0.832	100.1
	4	8.312	8.337	100.3
	5	8.312	8.320	100.1
	6	8.312	8.312	100.0
	7	8.312	8.304	99.9
	8	8.312	8.304	99.9
Mean ± *SD*				100.03 ± 0.15

Mean ± *SD*				100.03 ± 0.20

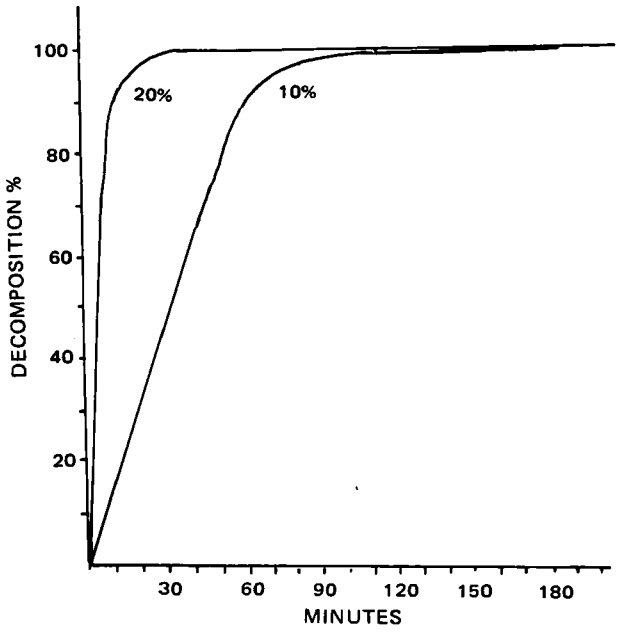

Figure 2—*Effect of hydrochloric acid concentrations on drug decomposition.*

The slope of the lines was 58 mV per decade increase in ammonia concentration. At a low concentration range of ammonia (from 1×10^{-5} to 1×10^{-4} *M*), the higher the concentration of the filling solution, the smaller ΔmV. At a high concentration range of ammonia (from 1×10^{-3} to 1×10^{-2} *M*), ΔmV became <58 mV when 0.001 *M* filling solution was used. With 1 *M* filling solution, the electrode potentials were unstable; the calibration plot was not linear, resulting in an S-curve. Based on the above data, 0.001 *M* filling solution is considered suitable for potential measurements of a low level of ammonia (1×10^{-5}–1×10^{-3} *M*). In the concentration range of 1×10^{-4}–1×10^{-2} *M* ammonia, 0.01–0.1 *M* filling solutions are suitable for the potential measurements. However, with a high level of ammonia (1×10^{-3}–1×10^{-2} *M*), the use of 0.1 *M* filling solution is preferred.

The electrolyte solution in electrode B consists of a saturated solution of ammonium picrate or ammonium purpurate. To provide a chloride concentration for the reference Ag–AgCl electrode, the electrolyte also contains a known amount of ammonium chloride (3). However, the concentration of ammonium chloride in this electrode is not obvious. Using an internal filling solution containing 0.05 *M* ammonium chloride saturated with ammonium picrate, a linear calibration plot was obtained in the concentration range of 1×10^{-4}–1×10^{-2} *M* ammonia, and the potential difference (ΔmV) was 58 mV per decade increase in ammonia concentration. However, using 0.01 or 0.1 *M* ammonium chloride saturated with ammonium picrate, the calibration plot was not linear.

On using the Instrumental Laboratory filling solution, a linear calibration plot was obtain in the ammonia concentration range of 1×10^{-4}–1×10^{-2} *M*. This indicates that the Instrumental Laboratory solution and the 0.05 *M* ammonium chloride solution saturated with ammonium picrate are the same.

Standard Solution—Water vapor resulting from the difference in concentrations of ions between the decomposition and internal filling solutions (osmotic strength) leads to error, and the partial pressure of the dissolved gas is also a function of the sample temperature and the level of dissolved species (4). In the present study, therefore, the effect of dissolved salts on the potential was examined more closely. The results are shown in Table I. In a given 1×10^{-3} *M* ammonium chloride solution, 1×10^{-1} *M* potassium or sodium sulfate caused an ~1-mV electrode shift. However, in sodium chloride, the amount of salt is negligibly small in a concentration <1 *M*. The experimental data indicated that the calibration plot of ammonium chloride standard solution coincided with that of the decomposition solution in the concentration range of 1×10^{-4}–1×10^{-2} *M*. Thus, the standard solution should use ammonium chloride standard instead of the drug standard.

To obtain analytical accuracy, a calibration curve should be prepared for every set of determinations. Since the potential of the glass electrode is stable for ~12 hr, but changes with after that time, the slope of the linear calibration plot is not constant.

Electrode Response—The response of the electrode is a function of the ammonia concentration, with a faster response at higher ammonia levels. In a given ammonia concentration it is also a function of the salt concentration, with a faster response at higher dissolved salt levels. On repeated use, the equilibrium time may become longer because of deterioration of the glass electrode. To activate the electrode, the electrode tip should be immersed in 2% ammonium fluoride for 3 min, then in 5 *N* HCl for several minutes, followed by exhaustive washing with water.

Another important factor that influences the electrode response is the working area of the gas-permeable membrane. Employing membranes with diameters of 4 mm^3 and 9 mm^4, the response times of the electrode were found to be 20–30 min and 1–3 min in 1×10^{-3} *M* ammonia, respectively.

When the electrode is immersed in water for storage overnight, the response time may become longer, as water vapor may condense in the hole in the gas-permeable membrane, hindering the passage of ammonia gas. For storage overnight or over the weekend, the electrode tip should be immersed in ammonium chloride solution, with the same level of ammonium chloride as in the internal filling solution to avoid wetting and change of internal filling solution concentration.

Contamination—The electrode is always contaminated by the ammonia adsorbed on the gas-permeable membrane and by the ammonia in the small gap between the bottom cap of the electrode and the gas-permeable membrane. Since the contaminating substance cannot be removed by washing with water, the electrode tip must be washed by immersion in freshly prepared sodium chloride solution (pH 4) of a similar concentration to the ammonium chloride in the internal filling solution. At a concentration $<10^{-4}$ *M* ammonia, the potential change resulting from contamination is much larger than in the concentration range of 10^{-3}–10^{-2} *M*. The electrode tip must be washed thoroughly. During washing of the electrode, the concentration of the internal filling solution is slightly changed. Thus, the internal filling solution should be replaced with fresh solution before making potential measurements.

Reproducibility—In a sample solution with a high level of dissolved salt, reproducibility is influenced by the mode of operation of the potential measurement. In the first procedure, after alkalinization of the sample solution with sodium hydroxide, the electrode is immersed in the sample solution and the potential measurements are determined. In the second procedure, following immersion of the electrode in the sample solution, the solution is alkalinized with sodium hydroxide after a few minutes, and then potential measurements determined. The potential values obtained by these different modes of operation are not equal. Results show that in the second procedure, the concentration of the internal filling solution changes with lapse of time due to water vapor caused by osmotic pressure. Small changes in the concentration of the filling solution influence the potential value. The potentiometric measurements should be determined using the first procedure.

Electrode B has a fast response time, but the large area of the gas-permeable membrane subjects it to influence from osmotic pressure. Therefore, electrode A was used.

Decomposition of Drugs—A mixture of ethionamide and 20% HCl was refluxed until complete decoloration had taken place. Hydrogen sulfide was evolved during the course of the reaction, and the yellow solution became colorless after 30 min. The resulting ammonia formed in the decomposition was determined at various times (Fig. 2). The electrode potential reached a maximum at a heating time of 30 min. In the case of decomposition with 10% HCl, the electrode potential reached a maximum at a heating time of 3 hr. After 1 and 2 hr, the recoveries were 87 and 99%, respectively. The decomposition time of prothionamide was the same

Table III—Determination of Tablets

Drug	Determination	Label Claim, mg	Found, mg	Recovery, %
Ethionamide	1	155.96	157.36	100.9
	2	166.24	167.07	100.5
	3	166.24	166.02	99.9
	4	164.34	165.29	100.6
	5	173.46	174.22	100.4
Mean ± *SD*				100.46 ± 0.36
Prothionamide	1	187.00	187.94	100.5
	2	180.12	181.15	100.6
	3	205.54	206.07	100.3
	4	195.41	195.49	100.0
	5	182.35	183.63	100.7
Mean ± *SD*				100.42 ± 0.28

as that of ethionamide. When the potential was plotted against the logarithm of the drug concentration, a linear calibration plot was obtained in the drug concentration range of 2×10^{-5}–1×10^{-2} M.

The amount of drug was first determined with the pure drug powder. According to USP XX (5), ethionamide contains ≥98.0% and ≤102.0% of $C_8H_{10}N_2S$, calculated on an anhydrous basis. Prothionamide is described only in the JP X (6), and not in the USP or British Pharmacopeia (7). According to the Japanese Pharmacopeia, prothionamide determined on a dry weight basis should be >98.0% pure.

The recovery of the drugs is shown in Table II. Determinations were performed on eight samples of both drugs. The amounts of ethionamide and prothionamide were estimated with the same average errors of 0.03%, and the standard deviations were 0.15 and 0.20, respectively. The recoveries were good and reproducible.

Determinations on both tablets were carried out. A suitable extraction solution was sought. Both drugs are very soluble in methanol and glacial acetic acid and are also soluble in ethanol and acetone; however, in the extraction it is necessary to avoid interference from extraneous compounds. Methanol is used in the USP procedure. The tablets were therefore extracted with methanol and after evaporation of the methanol, the residue was heated at reflux with 20% HCl. After heating for 3 hr, the solution became brown, and a brown precipitate separated out. Evidently the precipitate resulted from impurities dissolved in the methanol.

The tablets were then extracted with acetone. After dissolution in acetone, the solution was centrifuged. This was found to be the best method because filtration of the acetone solution proved to be difficult. The extraction was carried out four or five times until the extract was colorless. The solvent was evaporated, and the residue was heated at reflux for 1 hr with 20% HCl to give a light-brown precipitate and a pale-brown solution. The acidic solution was then neutralized with sodium hydroxide at pH 6.5, and the resulting mixture was subjected to potentiometric measurements. Determinations were performed on five samples of 20 tablets. According to the USP XX, ethionamide tablets contain ≥95.0% and ≤110% of the labeled amount of drug. The results obtained are shown in Table III. The mean recoveries for ethionamide and prothionamide tablets were 100.46 and 100.42%, respectively, and the respective standard deviations were 0.36 and 0.28. The labeled amount of drugs was 100 mg/tablet. The recoveries are given compared with the theoretical amount of ammonia in the drug tablets, and it is believed that one tablet indeed contains 100 mg.

CONCLUSION

The assay method for the drugs in JP X is based on the nonaqueous titration method using perchloric acid; however, the color change is not sharp. In the BP, the end-point is determined potentiometrically, which alleviates this problem. In USP XX, a colorimetric method is used for the determination of the pure powder and tablets. The procedure is accurate, but nonspecific.

The proposed method for the assay of drugs having a carbothionamido group is simple and specific. The recovery is satisfactory and lies within acceptable limits. In view of this, use of the ammonia gas-sensing electrode is recommended as a possible pharmacopeial method.

Pharmacokinetics of Chlorzoxazone in Humans

RAVI K. DESIRAJU ˣ, NED L. RENZI, Jr., RAMCHANDRA K. NAYAK, and KUNG-TAT NG

Received March 5, 1982, from the *Department of Drug Metabolism, McNeil Pharmaceutical, Spring House, PA 19477.* Accepted for publication August 6, 1982.

Abstract □ Twenty-three normal male subjects received 900 mg of acetaminophen and 750 mg of chlorzoxazone as an oral suspension. Analysis of plasma samples indicated a rapid absorption and rapid elimination of chlorzoxazone. Average values of the elimination half-life and plasma clearance were 1.12 ± 0.48 hr and 148.0 ± 39.9 ml/min, respectively. Analysis of urine samples showed that chlorzoxazone was eliminated from the body as the glucuronide conjugate of the intermediate metabolite 6-hydroxychlorzoxazone, to the extent of 74% of the dose. The plasma and the urinary excretion data were fitted to theoretical equations, and excellent fits were obtained using a five-parameter pharmacokinetic model.

Keyphrases □ Chlorzoxazone—analysis in human plasma and urine, administration with acetaminophen; pharmacokinetics □ Pharmacokinetics—chlorzoxazone, analysis in human plasma and urine, concomitant administration with acetaminophen □ Acetaminophen—concomitant administration with chlorzoxazone, analysis in human plasma and urine, effect on pharmacokinetics

Chlorzoxazone (5-chloro-2(3*H*)-benzoxazolone) (I) is a potent skeletal muscle relaxant that is effective in the treatment of skeletal muscle spasms. Onset of therapeutic activity is observed within 1 hr, with a duration usually up to 6 hr (1). Chlorzoxazone exhibits minimal adverse effects and almost no GI irritation.

The data and results presented in this report are part of a study that was performed with 23 normal male subjects to determine the bioavailability of acetaminophen and chlorzoxazone from a commercial combination tablet formulation and an oral suspension. While there exists sufficient information in the literature regarding acetaminophen elimination kinetics (2–6), little has been reported on the disposition characteristics of chlorzoxazone in humans. This report deals primarily with the plasma levels and urinary excretion of chlorzoxazone following administration of a suspension of chlorzoxazone and acetaminophen.

In studies dealing with the metabolic fate of chlorzoxazone in humans, Conney and Burns (7) reported that <1% of the drug was excreted unchanged in urine. Chlorzoxazone was rapidly metabolized in humans to 6-hydroxy-

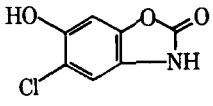
I



II

chlorzoxazone (5-chloro-6-hydroxy-2(3*H*)-benzoxazolone) (II) which was excreted in urine primarily as the glucuronide conjugate. They could not detect any 6-hydroxychlorzoxazone in the urine in the free form. Their *in vitro* experiments utilizing liver homogenates of rat, rabbit, mouse, and guinea pig established the liver as the principal site of metabolism and 6-hydroxychlorzoxazone as the major metabolite of the *in vitro* metabolism of chlorzoxazone. In this investigation, we have attempted to obtain the pharmacokinetic parameters of chlorzoxazone in humans when administered concomitantly with acetaminophen.

EXPERIMENTAL

Subject Selection—Twenty-three normal, healthy, adult male subjects (20–39 years of age) participated in this study. They were found to be in good health as determined by a screening procedure consisting of a physical examination, evaluation of clinical laboratory values (hematology, blood chemistry, and urinalysis), and determination of vital signs. None of the subjects had any serious diseases, and they refrained from taking drugs for a period of 2 weeks prior to this study.

Dose Administration—The subjects, after fasting for a minimum period of 12 hr, received 900 mg of acetaminophen and 750 mg of chlorzoxazone as an oral suspension. Each milliliter of the aqueous suspension contained 15 mg of chlorzoxazone, 18 mg of acetaminophen, and 5 mg of tragacanth (as a 0.5% solution).

Blood samples (10 ml) were drawn from the subjects at 0 (predose), 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5, 6, 8, and 10 hr after dosing. The samples were collected in heparinized tubes[1], stored in ice, and centrifuged as soon as possible to obtain plasma.

Urine samples were obtained from pooled samples collected for the following time periods: 0 (predose), 0–2, 2–4, 4–6, 6–8, and 8–10 hr after dosing. The pH and total volume of the pooled sample for each time period were recorded. A 50-ml aliquot of each pooled sample was transferred to a container and frozen.

Analytical Procedures—*Analysis of Plasma Samples for Acetaminophen*—To a 2-ml plasma sample in a 35-ml screw-cap centrifuge tube were added 1 ml of phosphate buffer (pH 7.4), 1.0 ml of ethyl acetate solution containing 20 μg/ml of *N*-butyl-*p*-aminophenol (internal standard), 1.0 g of solid sodium chloride, and 9.0 ml of ethyl acetate. The tube was shaken for 10 min and centrifuged at 2000 rpm for 10 min. Nine milliliters of ethyl acetate was transferred to another 35-ml centrifuge tube containing 2.0 ml of 5% sodium phosphate (pH 11.9). After centrifugation, the ethyl acetate was aspirated off. To the aqueous layer, 1.0 ml of sodium phosphate monobasic buffer (pH 4.5) and 11.0 ml of ethyl acetate were added. The tube was shaken for 10 min and centrifuged for 10 min. Ten milliliters of the ethyl acetate (upper) layer was transferred to a 15-ml conical screw-cap centrifuge tube and evaporated to dryness under a nitrogen stream. The residue was dissolved in 5 μl of pyridine and 15 μl of acetic anhydride, and the tube was placed in a thermostated water bath at 42° for 20 min.

Two microliters of the resulting acetylated reaction mixture was injected into a gas chromatograph[2] using the following conditions: the glass column (91.5 cm × 2-mm i.d.) was packed with 3% OV-17 on 80/100 mesh Chromosorb G-HP. The injection port, column, and detector (FID) temperatures were 220°, 165°, and 220°, respectively. The carrier gas (nitrogen) flow rate was 25 ml/min; hydrogen and air flow rates were 25 and 300 ml/min, respectively. The retention times of acetaminophen and the internal standard were 8.5 and 15.0 min, respectively. The calibration curve was linear from 0.5 to 20.0 μg/ml.

Analysis of Plasma Samples for Chlorzoxazone—Sample preparation involved a single-step extraction and derivatization. One milliliter of plasma was pipetted into a 15-ml disposable bottle containing 1 ml of 0.5 *N* HCl. To this was added 10 ml of ethyl acetate containing 20 μg of the internal standard (*n*-hexadecane). The mixture was shaken for 10 min and centrifuged at 2000 rpm for 5 min. A 9-ml aliquot of the ethyl acetate layer was transferred to a 15-ml screw-cap centrifuge tube and evaporated to ~0.5 ml under a nitrogen stream. The sides of the tubes were rinsed with an additional 0.5 ml of ethyl acetate. The combined ethyl acetate solution was evaporated to dryness. To the residue were added 5 μl of pyridine and 15 μl of acetic anhydride. The tube was capped and placed in a water bath at 42° for 20 min.

A 2-μl aliquot of the resulting reaction mixture was injected into a gas chromatograph equipped with a dual flame-ionization detector. The columns were 1.83 m × 4-mm i.d. glass tubes packed with 3% OV-1 on 60/80 mesh Gas Chrom Q. Column temperature was maintained at 130°. The carrier gas (nitrogen) was held at a flow rate of 30 ml/min; the hydrogen and air flow rates were 30 and 300 ml/min, respectively. The retention times of chlorzoxazone and the internal standard were 3.25 and 4.5 min, respectively. The lower limit of quantitation was 0.5 μg/ml using 1 ml of plasma. The calibration curve was found to be linear between 0.5 and 25 μg/ml. Extraction efficiency for chlorzoxazone under the above conditions was 88 ± 8% (six determinations).

Table I—Mean Peak Plasma Concentrations, Peak Times, and AUC (0–10 hr) of Acetaminophen and Chlorzoxazone in 23 Normal Subjects Following Oral Administration of Acetaminophen and Chlorzoxazone [a]

Drug	Parameter, mean ± *SEM*		
	Peak Plasma Concentration, μg/ml	Peak Time, min	AUC (0–10 hr) μg·min/ml
Acetaminophen	16.7 ± 1.3	40 ± 9.4	2816 ± 170

Analysis of Urine Samples for 6-Hydroxychlorzoxazone and Acetaminophen—The assay was designed to quantitate simultaneously total acetaminophen (intact plus glucuronide and sulfate conjugates) and total 6-hydroxychlorzoxazone (intact and glucuronide conjugate) in urine. Intact chlorzoxazone has been reported to be present in urine at ≤1% of the dose (7).

Aliquots (0.5 ml) of urine samples containing acetaminophen, 6-hydroxychlorzoxazone, their conjugates, and the added internal standard (*N*-butyl-*p*-aminophenol, 200 μg) were incubated overnight with β-glucuronidase[3] in an acetate buffer (pH 4.6) at 37°. The enzymatically hydrolyzed products were then extracted by adjusting the urine sample pH to 7.4 with 1 ml of phosphate buffer (pH 11.9) and extracting with 5 ml of ethyl acetate. A 4-ml aliquot of the ethyl acetate was then extracted with 3 ml of phosphate buffer (pH 11.9). The ethyl acetate was aspirated off and 1 ml of phosphate buffer (pH 4.5) was added to neutralize the solution. The neutralized solution was again extracted with 5 ml of ethyl acetate. Four milliliters of the ethyl acetate layer was evaporated to dryness under a nitrogen stream, and the residue was reconstituted with 50 μl of methanol.

Ten microliters of the methanolic solution was injected into a liquid chromatograph[4] equipped with a UV detector[5] at a wavelength of 280 nm. The reverse-phase analytical column[6] was 25 cm in length and 4.6-mm i.d. The mobile phase was water–methanol–pH 4.6 acetate buffer (3:1:1, v/v/v). The flow rate was held at 2 ml/min. The retention times for acetaminophen, 6-hydroxychlorzoxazone, and the internal standard were 3, 9, and 11 min, respectively. The calibration curve was linear from 20 to 1000 μg/ml for both acetaminophen and 6-hydroxychlorzoxazone. The extraction efficiencies for 6-hydroxychlorzoxazone and acetaminophen under the above conditions were 86 ± 6.5 and 95 ± 10.7%, respectively (six determinations).

RESULTS AND DISCUSSION

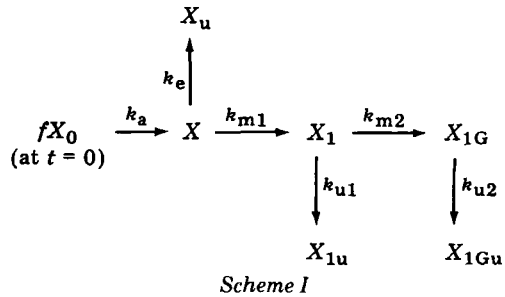
Table I lists a summary of acetaminophen peak plasma concentrations, peak times, and the area under the plasma concentration–time curve (AUC 0–10 hr) as calculated by the trapezoidal rule, observed in 23 normal subjects following the oral administration of 900 mg of acetaminophen and 750 mg of chlorzoxazone. Acetaminophen was rapidly absorbed with a mean peak plasma concentration of 16.7 μg/ml at a mean peak time of 40 min. These values are in the range of values obtained by other investigators (5), thus showing that the disposition kinetics of acetaminophen were not altered by the concurrent administration of chlorzoxazone.

Table I also lists the pharmacokinetic parameter values for chlorzoxazone. The mean (± *SEM*) plasma chlorzoxazone concentration–time profile is shown in Fig. 1. Chlorzoxazone was rapidly absorbed, attaining a mean (±*SEM*) peak level of 36.3 ± 2.3 μg/ml at a mean peak time of 38 ± 3.3 min after dosing. After reaching a peak, the plasma concentrations declined rapidly in a monoexponential manner, suggesting a rapid distribution. Plasma concentrations at the 8- and 10-hr time points for most subjects were either zero or were below the assay quantitation limit of 0.5 μg/ml, indicating that chlorzoxazone was rapidly eliminated from the body. The individual and mean plasma chlorzoxazone concentration–time profiles following the oral administration of chlorzoxazone were found to be characteristic of a one-compartment oral absorption model conforming to:

$$C_t = \frac{k_a f X_0}{V(k_a - K)}\left[e^{-Kt} - e^{-k_a t}\right] \qquad \text{(Eq. 1)}$$

where C_t is the concentration of chlorzoxazone in plasma at time t, k_a is the apparent first-order absorption rate constant, X_0 is the dose of chlorzoxazone (750 mg), f is the fraction of the administered dose reaching systemic circulation as unchanged chlorzoxazone, K is the apparent first-order elimination rate constant of the drug, and V is the apparent volume of distribution.

The urinary excretion data revealed that at the end of 10 hr, 74 ± 3.4% (mean ± *SEM*) of the dose was excreted as 6-hydroxychlorzoxazone glucuronide. Based on the information available in the literature (7), the biotransformation profile of chlorzoxazone could be explained by:

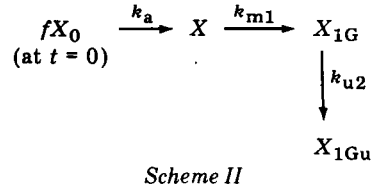


Scheme I

where X and X_u are the amounts of chlorzoxazone in the body and urine, respectively; X_1 and X_{1u} are the amounts of 6-hydroxychlorzoxazone in the body and urine, respectively; X_{1G} and X_{1Gu} are the amounts of 6-hydroxychlorzoxazone glucuronide in the body and urine, respectively; k_e, k_{u1}, and k_{u2} are the renal excretion rate constants for chlorzoxazone, 6-hydroxychlorzoxazone, and 6-hydroxychlorzoxazone glucuronide, respectively; and k_{m1} and k_{m2} are the respective metabolic rate constants for the formation in the body of 6-hydroxychlorzoxazone from chlorzoxazone and 6-hydroxychlorzoxazone glucuronide from 6-hydroxychlorzoxazone.

Under the conditions of the analytical procedure employed in this study, neither unchanged chlorzoxazone nor 6-hydroxychlorzoxazone could be detected in the urine samples. Although the lower limit of quantitation was established at 20 μg/ml, the assay was capable of detecting 5 μg/ml of 6-hydroxychlorzoxazone in urine. When the urine samples were hydrolyzed by β-glucuronidase and then assayed, 6-hydroxychlorzoxazone was detected indicating the presence of 6-hydroxychlorzoxazone glucuronide in the urine samples prior to hydrolysis.

Since 6-hydroxychlorzoxazone was not detected in the urine samples (or was present in negligible amounts), the biotransformation pathway in Scheme I was simplified to give:



Scheme II

In proposing this simplified model, the following assumptions were made:

1. The absence of 6-hydroxychlorzoxazone in the urine samples is due to its rapid conversion in the body to the glucuronide conjugate, *i.e.*, $k_{m1} <<< k_{m2}$ or k_{m1} is the limiting rate constant.
2. The absence of 6-hydroxychlorzoxazone in urine is not due to its reabsorption from the kidney since 6-hydroxychlorzoxazone is sufficiently polar in nature to be excreted by the kidney, *i.e.*, $k_{u1} \simeq 0 <<< k_{m2}$. For this model, the amount of 6-hydroxychlorzoxazone glucuronide excreted in urine as a function of time is given as (8):

$$\frac{d(X_{1Gu})}{dt} = k_{u2}k_{m1}k_a f X_0 \left[\frac{e^{-k_a t}}{(K - k_a)(k_{u2} - k_a)} + \frac{e^{-Kt}}{(k_a - K)(k_{u2} - K)} + \frac{e^{-k_{u2}t}}{(k_a - k_{u2})(K - k_{u2})}\right] \qquad \text{(Eq. 2)}$$

Difference	1	1	1273.8

$$F = \frac{1273.8}{135.9} \times \frac{11}{1} = 103.10^{a}$$

$$0.05\,F^{1}_{11} = 4.84$$

[a] Observed F exceeds critical F at 0.05 level of significance; therefore, the number of parameters should be increased from 4 to 5.

The plasma chlorzoxazone concentration and urinary excretion rate data of 6-hydroxychlorzoxazone glucuronide (as chlorzoxazone equivalents) for each individual subject were then simultaneously fitted by the least-squares method to Eqs. 1 and 2 using NONLIN (9) and a digital computer[7] to obtain estimates for the parameters V/f, K, k_a, k_{m2}, and k_{u2}. The mean plasma and urine data were also similarly fitted to Eqs. 1 and 2.

The least-squares estimates for one subject resulted in poor correlation owing to nonconvergence of the parameter k_a; hence, this subject was not included in the calculation of the average values. The average values for 22 subjects along with the parameter values obtained by simultaneous fitting of the mean plasma concentration–time data and the mean urinary excretion data are listed in Table II with the elimination half-life and plasma clearance values. There was good agreement between the average values for 22 subjects and the values obtained using the mean plasma concentration–time data. Average elimination half-life was 1.12 ± 0.48 hr and the average plasma clearance was 148.0 ± 39.9 ml/min. These values agree very well with the elimination half-life of 1 hr and the plasma clearance of 159.7 ml/min derived from the mean data. Figure 2 shows the model-predicted plasma concentration–time curve and the rate of excretion *versus* time at the midpoint of the urine collection period (t-MID) plot for one subject. Figure 3 shows the predicted curves for the mean plasma concentration–time data and the mean rate of excretion *versus* time (t-MID) plot. From these curves, it can be seen that excellent fits were obtained for the observed data when fitted to Eqs. 1 and 2 and that the scatter of the observed data about the theoretical curves was randomly distributed.

Equation 2 describes the rate of excretion of 6-hydroxychlorzoxazone glucuronide and is composed of the exponentials of three parameters: (*a*) the absorption rate constant of chlorzoxazone, (*b*) the elimination rate constant of chlorzoxazone, and (*c*) the excretion rate constant of the glucuronide. To test whether a three-exponential equation was needed, the data were fitted to a model consisting of the exponentials of only two parameters:

$$\underset{(\text{at } t = 0)}{fX_0} \xrightarrow{k_a} X \xrightarrow{k_{m1}} X_{1Gu}$$

Scheme III

which uses:

$$\frac{dX_{1Gu}}{dt} = k_{m1}X = \frac{k_{m1}k_a f X_0}{(k_a - K)}\left[e^{-Kt} - e^{-k_a t}\right] \qquad \text{(Eq. 3)}$$

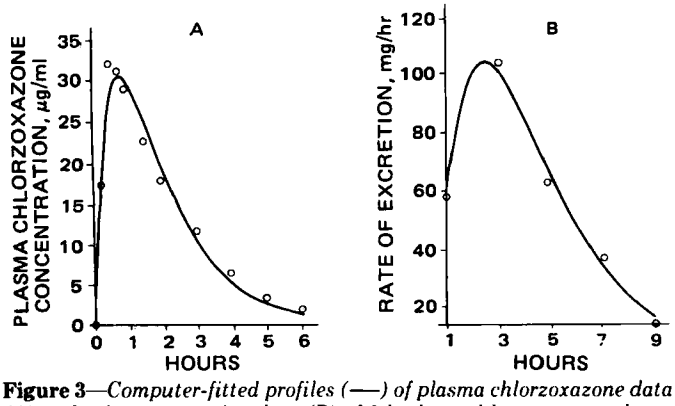

Figure 3—*Computer-fitted profiles (—) of plasma chlorzoxazone data (A) and urinary excretion data (B) of 6-hydroxychlorzoxazone glucuronide as chlorzoxazone equivalents obtained from the mean data. Circles represent observed means.*

[7] DEC 1099; Digital Equipment Corp.

Equation 3 resembles Eq. 1, *i.e.*, the rate of excretion of the glucuronide can also be described by only two exponentials, that describing absorption and that describing the overall elimination of the unchanged drug. The combined plasma and urine data were then fitted to Eqs. 1 and 3, and the parameters V/f, K, k_a, and k_{m1} were obtained.

As suggested by Boxenbaum *et al.* (10), an F ratio test was utilized to determine if it was justified to use four parameters instead of the original five to describe the data. Table III lists the number of parameters, the degrees of freedom, and the total sum of weighted, squared deviations obtained by fitting the combined plasma and urine data of one representative subject using four and five parameters. The results of the F test are also included and show that the observed F of 103.1 exceeds the critical F of 4.84, thereby suggesting that a minimum of five parameters are needed to define the data. Use of four parameters generally resulted in a relatively poor fit of the data and in higher values of total sum of weighted, squared deviations for all subjects and for the mean data. Application of Akaike's information criterion (11) confirmed the results of the F test, thus providing a strong justification for the use of five parameters instead of four.

A comparison of the least-squares estimates of the parameters V/f, K, k_a, k_{m1}, and k_{u2} (Table II) obtained by averaging the values for individual subjects and those obtained from the evaluation of the mean data showed a better correlation among the plasma parameters (V/f, K, and k_a) than among the urinary excretion rate parameters (k_{m1} and k_{u2}). This is probably because the urinary excretion data were described by only five samples, each obtained at intervals of 2 hr while plasma data were described by a minimum of 11 data points for each subject. This may have contributed to the variability observed in the urinary excretion parameters.

An apparent volume of distribution of ~ 14 liters (assuming complete systemic availability, $f = 1$) suggests that the drug is not widely distributed and that it would be confined to the circulatory system and possibly the extracellular fluid. Previous experiments (7) with dogs showed that the concentration of chlorzoxazone in the liver, muscle, brain, and kidney was approximately one-half or less that found in plasma. Chlorzoxazone concentration in fat was, however, twice that in plasma.

Model-Independent Procedure for Area Estimation and Intergroup Comparisons

THOMAS CAPIZZI ˣ, HINA MEHTA, and LEONARD OPPENHEIMER

Received December 24, 1981, from *Biometrics Research, Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065.* Accepted for publication August 9, 1982.

Abstract □ A method is provided for estimating the area under a response–time curve for an experimental situation where independent observations are made at each time point. The procedure utilizes least-squares spline functions and the jackknife technique to provide area estimates, standard errors, and a statistical test for intergroup comparisons. The method is based on an empirical model and provides a means of analysis when no prior model can be specified or if the incorrect specification of a model will produce invalid results. The method is illustrated using data from a study comparing the pharmacokinetic behavior of a fasciolicide in rats having either a young or old parasitic infestation. The results obtained are comparable with those generated by a model-dependent approach.

Keyphrases □ Pharmacokinetics—area under response–time curve, model-independent estimation, intergroup comparisons □ Spline functions—use with jackknife technique to provide area under response–time curve estimations, model independent

In pharmacokinetics it is often necessary to calculate the area under the response–time curve (AUC) for a subject and then compare the AUC among subjects allocated to several experimental groups. For one type of experimental design, a drug is given to several groups of subjects and a response variable for each subject is then observed at fixed time points (Scheme I, type B). Each subject has its own response–time curve, and an estimate of a subject's AUC could be obtained by (*a*) fitting and then numerically integrating a pharmacokinetic model (1), or (*b*) utilizing a model-independent interpolation procedure such as the trapezoidal rule (2). However, in some situations a time–response curve is not available for each subject; instead independent observations are made at each time point (Scheme I, type A). For example, a drug may be given to several groups of animals with different experimental conditions, and the drug concentration in an organ of the animal is required at several points in time. Since the animals must be serially sacrificed to obtain this information, the measurements are made using different animals at each time point. A model-independent procedure for this experimental design (Scheme I, type A) is introduced which will provide area estimates, standard errors, and a statistical test for intergroup comparisons.

Scheme I—Two Types of Experimental Designs

In these situations (Scheme I, type A) a model-dependent AUC estimate can be obtained by specifying a pharmacokinetic model. However, this model dependent approach could result in biased and unreliable area estimates in situations where the specific model used is not the correct functional form. In general, it is difficult to discriminate among competing models on the basis of prior biological information and/or statistical goodness-of-fit tests, and this is especially so with the addition of between-subject variability at each time point. Another alternative would be to apply an interpolation procedure to each group's mean response–time curve. However, no estimate of precision would be available and thus, no intergroup comparisons could be made.

This paper presents a model-independent method for estimation of an experimental group's AUC in type A studies, which also allows for intergroup hypothesis testing. The method utilizes least-squares spline functions (3) and the jackknife technique (4), and would appear to be the procedure of choice in obtaining AUC estimates for type A studies unless there is strong evidence for a specific pharmacokinetic model. The method is illustrated on data from a study (5) comparing the pharmacokinetic behavior of a fasciolicide in rats having either young or old parasitic infestations.

THEORETICAL

Estimation and Intergroup Comparison Procedure—The method presented in this paper can be outlined in three steps:

1. Fit an empirical function (spline, Eq. 2) using ordinary least squares to the group response–time curve.
2. Obtain an estimate of the AUC (the integral of the fitted function over time, Eq. 4) and its standard error by least squares or the jackknife procedure (4).
3. Use of the pseudovalues (Eq. 6) generated by the jackknife procedure to evaluate group differences *via* a t test or an ANOVA.

Fitting an Empirical Function (Spline) Using Ordinary Least Squares—In this method it is assumed that for each group and response variable there is a continuous (smooth) function, $g(t)$, which represents the average response *versus* time relationship, *i.e.*:

$$Y_{ism} = g(t_{is}) + e_{ism} \quad m = 1, 2, \ldots M_{is}, \quad s = 0, \ldots S_i, \quad i = 1, 2, \ldots P, \quad \sum_s M_{is} = N_i \qquad \text{(Eq. 1)}$$

where Y_{ism} is the response of the mth subject at the sth time of the ith group; $g(t)$ is a continuous function whose exact form is not known; e_{ism} are independent identically distributed random errors with mean 0 and variance σ^2; and N_i is the number of subjects in the ith group.

To obtain model-independent AUC estimates for each group, an em-

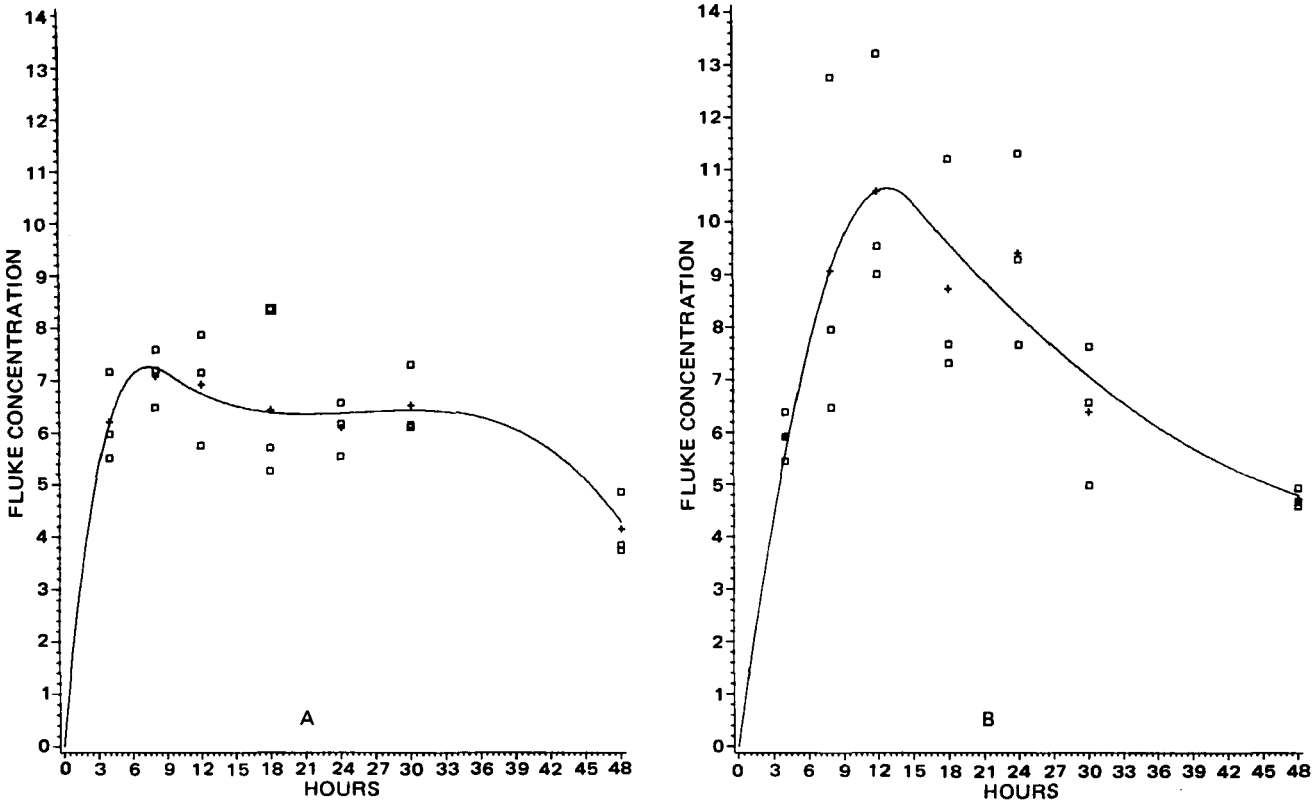

Figure 1—*Plot of observed individual drug concentration in the liver fluke of rats (□) and mean drug concentration (+)* versus *time (hr) for young (A) and old (B) infestation groups. Curves represent least-squares spline fit to the individual drug concentration* versus *time data (Table I).*

pirical function must be chosen that adequately describes the variation of response over time and gives a close approximation to $g(t)$. Spline functions, which are defined as piecewise continuous polynomials of degree n, are considered to be excellent empirical functions (3, 6, 7) for this purpose. The pieces of the spline are joined together at points called knots (abscissa values) in such a fashion that the function and the first $n-1$ derivatives agree at the join points. The degree of the polynomial pieces and the number and position of the knots may be varied in different situations to provide a good fit to the data. Quadratic and cubic splines (polynomial pieces of degree at most 2 or 3) are the most popular among practitioners because of their computational simplicity, smoothness, and flexibility, and have been used in a variety of biological and chemical applications (3, 7, 8–12).

There are several numerical methods for fitting splines to data (3). The method employed here is that of ordinary least squares (OLS). This method requires that the number of knots, as well as their location, be specified. The fitting of the spline to data is then accomplished by multiple linear regression techniques. The choice of the number and position of the knots is an important and difficult problem that has to be addressed. Knots should be chosen so as to correspond to the overall behavior of the data (number of time points, position of maxima and minima, *etc.*). Some rules of thumb for knot positioning have been presented by Wold (3). However, in most applications judgment and experience together with simulation results seem to be the only criteria for making these decisions.

Spline functions can be considered as a multiple linear regression model by employing the "+" function representation of a spline (7). For example, a cubic spline is given as follows: Let $S(t)$ for $t_0 \le t \le t_L$ be a cubic spline with knots at $k_2, \ldots k_{r-1}$. Then:

$$S(t) = b_0 + b_1 t + b_2 t^2 + b_3 t^3 + \sum_{j=2}^{r-1} b_{j+2}\,(t-k_j)_+^3 \qquad \text{(Eq. 2)}$$

where:

$$(t-k_j)_+ = \begin{cases} t-k_j, \text{ if } t > k_j \\ 0, \text{ otherwise} \end{cases} \qquad \text{(Eq. 3)}$$

and b_j are the parameters to be estimated. Notice that the parameters b_j appear linearly in Eq. 1 and thus can be estimated by OLS. A quadratic spline can be defined in an analogous manner (7).

Area Estimation Using Least-Squares Theory—Once the appropriate spline has been fitted to the time–response data for each experimental group, an estimate of the AUC can be obtained. Let the fitted spline function for a group be denoted by $S_i(\hat{t})$. An estimate of the area under the fitted function ($\hat{\text{AUC}}_i$) is given by the integral of $S_i(\hat{t})$ evaluated from t_0 to t_L, *i.e.*:

$$\hat{\text{AUC}}_i = \int_{t_0}^{t_L} S_i(\hat{t})\,dt \qquad \text{(Eq. 4)}$$

If $S_i(\hat{t})$ is a cubic spline, then:

$$\hat{\text{AUC}}_i = \hat{b}_{0i}t + \frac{\hat{b}_{1i}t^2}{2} + \frac{\hat{b}_{2i}t^3}{3} + \frac{\hat{b}_{3i}t^4}{4} + \sum_{j=2}^{r-1} \frac{\hat{b}_{ji+2}}{4}(t-k_j)_+^4 \Bigg|_{t_0}^{t_L} \qquad \text{(Eq. 5)}$$

Estimates of the AUC are linear combinations of the spline parameter estimates, $\hat{b}_{ji}$, so that an estimate of their standard error can be obtained using linear regression methods (13). Note that different spline functions ($\hat{b}_{ji}$) and area estimates ($\hat{\text{AUC}}_i$) are obtained for the different experimental groups.

Area Estimation and Measurements of Precision Using the Jackknife Procedure—If the residuals (observed values minus fitted values) obtained from the spline regression were normally distributed, then the estimated standard errors for AUC estimates computed by least squares could be used to calculate confidence intervals and test for group differences. However, in addition to the random variation, the residuals contain a degree of unknown bias. The bias occurs from fitting an empirical model [$S(t)$] and not the true functional form of the underlying model [$g(t)$]. Also, the random component of the residuals may not be normally distributed. Thus, the standard least-squares method when

used to test group differences could yield misleading results. In complex situations where standard methods might not be applicable, a useful statistical technique has been the jackknife procedure (4). The jackknife procedure was introduced by Quenouille (14) as a method for eliminating bias due to finite sample sizes in estimating parameters. Tukey (15) proposed that the jackknife be used for robust interval estimation. A clear nonmathematical exposition of the jackknife with examples is provided by Mosteller and Tukey (4), while an excellent review of the statistical literature dealing with the jackknife is presented by Miller (16).

In situations where linear least-squares methods are employed, there are two methods of jackknifing: the regular jackknife and the weighted jackknife (17). The weighted version provides improved bias reduction and variance estimation for nonlinear functions of linear regression parameters. However, in contrast to the regular jackknife, the weighted jackknife does not address the issue of bias for linear functions of the regression parameters. Since the AUC estimate for each group is a linear function of the fitted spline parameters, the regular jackknife is the procedure of choice for this situation.

To obtain the regular jackknife estimate of the AUC for each group, the function given by Eq. 4 is first calculated with all of the group's observations included. Let $A_{\text{all},i}$, $i = 1, 2, \ldots P$ denote this estimate of area. Next, let A_{ism} denote the estimate of area with the mth subject at the sth time deleted (*i.e.*, the $_{ism}$th subject is deleted, the spline function for the ith group is fitted, and the AUC is computed). Then, pseudovalues are defined as:

$$P_{ism} = N_i A_{\text{all},i} - (N_i - 1) A_{ism}, \quad \begin{matrix} i = 1, 2, \ldots, p \\ s = 1, 2, \ldots, S_i \\ m = 1, 2, \ldots, M_{is} \end{matrix} \qquad \text{(Eq. 6)}$$

The jackknife estimate of AUC for the ith group is then the mean of the pseudovalues:

$$J_i(\hat{\text{AUC}}) = \frac{1}{N_i} \sum_{sm} P_{ism} \qquad \text{(Eq. 7)}$$

with estimated variance:

$$s^2(\hat{J}_i) = \frac{1}{N_i(N_i - 1)} \sum_{sm} [P_{ism} - J_i(\hat{\text{AUC}})]^2 \qquad \text{(Eq. 8)}$$

For each group the pseudovalues can be treated as if they follow a Student's t distribution, and a $(1 - \alpha)$% confidence interval is given by:

$$J_i(\hat{\text{AUC}}) \pm t_{(1-\alpha/2),Ni-1} s(\hat{J}_i) \qquad \text{(Eq. 9)}$$

where $t_{(1-\alpha/2)}, N_i - 1$ is the $(1 - \alpha/2)$ percentage point of the Student's t distribution with $N_i - 1$ degrees of freedom.

Intergroup Comparisons—The pseudovalues for each group can be used as if they were identically distributed estimates of the AUC, and hence, standard statistical procedures can be applied to make intergroup comparisons (18). Various statistical analyses can be used depending on the experimental design, *e.g.*, a one-way or factorial ANOVA procedure. In addition, trend tests for factors with quantitative levels or comparisons of various linear functions of treatment groups using multiple-comparison procedures can be obtained easily.

EXPERIMENTAL

Data Description—A study (5) investigating the pharmacokinetic basis for increased efficacy of a fasciolicide against older liver flukes (*Fasciola hepatica*), *i.e.*, 39–44 weeks old, in rats led to the development of the model-independent estimation and hypothesis-testing procedure described above. The fasciolicide was administered as a single oral dose when the fluke infestation in the rats were either young (9–16 weeks) or

$(t-4)_+^3$	—	−0.2816
S^a	1.6970	1.1907

[a] Denotes root mean square error.

old (39–44 weeks). Twenty-one rats were started in each group, with three rats being sacrificed at each time point. The drug uptake in the liver fluke was one of the variables measured (Fig. 1). Blood levels of the rats were also taken at these time points (Fig. 2). It was hypothesized that the drug uptake in the liver fluke was greater in rats having the older infestation, while the drug concentrations in the blood profile were similar for both groups. The areas under the respective time–response curves were considered to be one of the parameters of interest.

Data Treatment—To apply the estimation procedure to these data, the degree of the spline and the number and position of the knots had to be determined. Based on the work of Wold (3) and previous studies[1], it was thought that a spline with a single knot situated near the peak of the response–time curve would provide an adequate fit in this kind of situation (where the response variable rises to a peak and slowly decreases toward zero). Thus, for each group and response variable, either a quadratic or cubic spline with one knot and no intercept term was fitted by OLS. The specific form of the spline was determined by varying the location of the knot and degree of the spline and choosing the result that gave the smallest sum of squared errors. The OLS AUC estimates were obtained by computing the definite integral of the fitted spline from 0 to 48 hr. The jackknife was applied to the AUC estimates. The old *versus* young infestation group comparison was accomplished by performing a two-sample Student's t test on the pseudovalues obtained with the jackknife.

For purposes of comparison, a model-dependent approach was also utilized. An open one-compartment model that is often used for these kind of data (19) was fitted using nonlinear regression. The least-squares and jackknifed AUC estimates were obtained in an analogous manner as described in the model-independent approach.

Computation—All necessary computations were made by utilizing the Statistical Analysis System (SAS) computer package (20). The spline functions were fitted with the SYSREG procedure and the no-intercept option. A SAS PROC MATRIX macro (21) was used to obtain the area estimates and to apply the jackknife procedure. The between-infestation group comparison was made with the TTEST procedure. The results for the model-dependent case were obtained by using the SAS NLIN (nonlinear least-squares) procedure. The plots (Figs. 1 and 2) were computer-generated using a ZETA 1536 plotter which was driven by the SAS/GRAPH package.

RESULTS

Liver Fluke Uptake—The spline function used for area estimation for the young infestation group was a cubic spline with a knot at 10 hr; the spline function for the old infestation group was a quadratic spline with a knot at 15 hr. The spline parameter estimates are given in Table I.

The OLS and jackknife estimates of the AUC are contained in Table II. The AUC estimates and standard errors are similar for the least-squares and jackknife procedures. The two-sample t test for unequal variances performed on the AUC pseudovalues showed that old infestation groups had a statistically significantly greater AUC ($p < 0.05$) after 48 hr than the young group. The AUC estimates obtained with the model-dependent approach gave results that were comparable to the model-independent approach.

Blood Level of Drug—The following splines were fitted: (*a*) for the young infestation group, a cubic spline with a knot at 3 hr and (*b*) for the old infestation group, a cubic spline with a knot at 4 hr. The spline estimates are given in Table III. Results of the AUC estimation procedure are presented in Table IV.

The least-squares and jackknife AUC estimates yield similar estimates and standard errors. Although the jackknife AUC estimates for the old infestation group of rats were higher than those for the young group, the two-sample t test using the pooled within-group variance showed that this result was not statistically significant ($p > 0.05$). The AUC estimates for the model-dependent approach are comparable (although smaller) to corresponding estimates obtained with the model-independent procedures.

DISCUSSION

AUC estimation for type A studies is different from what is usually encountered, in that independent observations are made on different subjects at each point in time rather than each subject having its own time–response curve (type B studies). The model-independent approach developed for this situation can be considered as a viable option when there is no strong evidence for choosing a particular model. The flexibility in fitting least-squares spline functions could provide protection against the possibility of systematic bias resulting from the choice of an improper functional form. Simulation results (22) have shown that splines are competitive in situations where they are compared with the correct functional form and yield much better results when compared with an incorrect model specification. This flexibility of spline functions was also evident in the analysis of the illustrative data. For the liver fluke uptake data, the spline approach gave similar results to the more classical one-compartment open model. However, for the blood level of drug data, the paucity of data in the absorption phase of response–time curve would seem to make the spline approach more applicable than that of the one-compartment open model. This property of least-squares splines could prove extremely useful in situations where very complicated nonlinear models seem warranted, but are difficult to fit using the usual nonlinear regression techniques.

Fitting the spline function is somewhat subjective in that the number and position of the knots must be specified. However, this subjective process is also encountered in some pharmacokinetic situations where the number of terms of a multiexponential model must be chosen. With some experience, one should be able to select knots so that the resulting spline will give a good fit to the data. Also, it should be noted that because of the excellent local properties of spline functions, the effects of incorrect knot positioning should not cause difficulties.

Although the AUC estimates and standard errors are similar for the least-squares and jackknife procedures, the jackknife also gives protection against potentially unsatisfied assumptions. The advertised advantages of the jackknife in situations such as this are (*a*) bias reduction, (*b*) validity robustness, and (*c*) robustness against violation in homogeneity of variance. The jackknife is quite versatile and flexible and has been applied to problems in several biological settings, *e.g.*, toxicology (23) and enzyme kinetics (18). For this problem, standard errors, which were not readily obtainable for the model-dependent approach using least-squares theory, were relatively easy to compute using the jackknife.

In this situation, the usual least-squares techniques may be sensitive to the violation of the assumptions of normality and homogeneity of variance required in Eq. 1. The jackknife is an excellent tool for constructing nonparametric confidence intervals, since it is relatively insensitive to the manner in which the random errors are distributed. An added advantage of the jackknife is that one can use the pseudovalues to evaluate group differences, especially in situations involving more complicated experimental designs (18). Additional protection against violations of assumptions can be obtained by employing a transformation in conjunction with the jackknife (4, 16, 18). Since the distribution of the AUC estimates might be adversely affected by asymmetrical residuals (*e.g.*, log normal distribution) resulting from the spline regression, a logarithmic transformation might be required in conjunction with the jackknife. This can be accomplished by using log ($A_{\text{all},i}$) and log (A_{ism}) in Eq. 6 to compute pseudovalues. Such a transformation may also provide protection against variance heterogeneity, although the jackknife is considered robust against such a violation in assumptions (17).

For the above transformation, the spline function would still be fit to the untransformed response data. An alternative that might be necessary if the final concentrations are close to zero is to fit the spline function to a transformed response variable (3). However, the situation is more complicated[2] since the AUC becomes a nonlinear function of the spline parameters. In this case, the weighted jackknife (17) should be employed. Also note that this discussion relates to the within-experimental group analysis. The necessity for transformation for purposes of comparisons between experimental groups is a separate consideration. For instance, in the analysis of the study data, a log transformation was employed in the hope of achieving homogeneity of the within-infestation group variance for the liver fluke data. However, the results were similar to the untransformed case and, thus, were not reported.

The jackknife estimate of variance is known to be slightly inflated in theory (24)[1]. However, this is a minor defect since the standard error estimates from nonlinear regression procedures are often optimistically low (25)[1], and the jackknife precision estimates are closer to reality because they are data based. The results of a study which examined the jackknife estimation of rate constants for multiexponential functions fitted to biochemical data seemed to corroborate this claim (26).

The chief drawback to the widespread use of the jackknife has been concern about computational issues. However, with growing sophistication of computers, software packages, and more efficient jackknife procedures (18, 27), this may no longer be an issue. As noted above, the entire model estimation procedure developed in this paper can be automatically perfomed with a SAS macro (21).

In summary, the model-independent approach gave reasonable AUC estimates and allowed for intergroup comparisons in this study (type A design, two groups studied). Careful application of this procedure should prove to be a valuable technique for type A studies. This method should also be investigated for other parameters that can be computed by model-independent methods.

Synthesis and Antidiabetic Activity of Some Sulfonylurea Derivatives of 3,5-Disubstituted Pyrazoles

RAAFAT SOLIMAN *x, HASSAN MOKHTAR ‡, and HOSNY F. MOHAMED §

Received August 26, 1981, from the **Department of Pharmaceutical Chemistry*, the ‡*Department of Pharmacology, Faculty of Pharmacy*, and the §*Department of Chemistry Faculty of Science; University of Alexandria, Alexandria, Egypt.* Accepted for publication May 21, 1982.

Abstract □ Two series of 3,5-disubstituted pyrazolesulfonylurea derivatives were prepared and evaluated as hypoglycemic agents. Preliminary biological testing revealed that the new compounds possess potent hypoglycemic activity.

Keyphrases □ 3,5-Disubstituted pyrazolesulfonylurea derivatives—synthesis, potential hypoglycemic agents □ Potential hypoglycemic agents—preparation, antidiabetic activity of 3,5-disubstituted pyrazolesulfonylurea derivatives

Previous work showed that 3,5-dimethylpyrazole and its active metabolite, 5-methylpyrazole-3-carboxylic acid, had potent hypoglycemic activity (1–5). The present study, which is a continuation of previous work (6–11), describes the preparation of derivatives of 3,5-disubstituted pyrazolesulfonylureas and their evaluation as potential hypoglycemic agents.

Derivatives of *p*-[3-ethoxycarbonyl-5-α-phenyl-*p*-chlorostyryl)-1-pyrazolyl]benzenesulfonylurea and *p*-[3 - ethoxycarbonyl-5-(α-phenyl-*p*-methoxystyryl)-1-

[a] Taken from Ref. 11. [b] Crystallized in ethanol–water. [c] Crystallized in benzene–petroleum ether. [d] Crystallized in chloroform–methanol. [e] Crystallized in methanol–benzene.

pyrazolyl]benzenesulfonylurea were prepared, and some were evaluated for hypoglycemic activity. Preliminary biological testing revealed that the new compounds possess potent hypoglycemic activity.

BACKGROUND

The pyrazole esters (III) were prepared by condensation of the appropriate ethyl 2,4-dioxo-6-(*p*-substituted phenyl)-5-phenyl-hex-5-enoate (I) with *p*-sulfamylphenylhydrazine (II). The resulting benzenesulfonamides (II), on treatment with the appropriate isocyanate or isothiocyanate in dry acetone, afforded the corresponding pyrazolesulfonylurea or thiourea derivatives (V and VI). Alkaline hydrolysis of the pyrazole esters III, V, or VI with ethanolic 2 *N* potassium hydroxide solution, afforded the corresponding pyrazole-3-carboxylic acids.

The physical and analytical data of these new pyrazoles are listed in Tables I and II. The antidiabetic activity of some of these compounds are given in Table III.

EXPERIMENTAL[1]

1 - (*p*-Sulfamylphenyl) -3- ethoxycarbonyl-5-(α-phenyl-*p*-chlorostyryl)pyrazole (III*a*)—A mixture of *p*-sulfamylphenylhydrazine (II) (0.1 mole) and ethyl 2,4-dioxo-6-(*p*-chlorophenyl)-5-phenyl-hex-5-enoate (I) (0.1 mole) in ethanol (150 ml) was refluxed for 6 hr on a steam bath, concentrated, and allowed to cool. The crude product was separated and recrystallized (65% yield) from ethanol, mp 196°.

The ^{1}H-NMR spectrum of III*a* showed absorption at 7.0–7.8 (m, aromatic H), 6.8 (s, 1, pyrazole H), 6.3 (s, 1, styryl H), 5.3 (s, 2, SO_2NH_2), 4.3 (q, J = 7.0 Hz, 2, $CO_2CH_2CH_3$), and 1.2 ppm (t, J = 7.0 Hz, 3 $CO_2CH_2CH_3$).

Anal.—Calc. for $C_{26}H_{22}ClN_3O_4S$: C, 61.5; H, 4.3; Cl, 7.0; N, 8.3. Found: C, 61.6; H, 4.5; Cl, 7.3; N, 8.0.

1-(*p*-Sulfamylphenyl)-3-carboxy-5-(α-phenyl-*p*-chlorostyryl)-pyrazole—A mixture of III*a* (1 g) in an ethanolic solution 2 *N* potassium hydroxide (25 ml) was refluxed for 1 hr. After concentration, cooling, and acidification with dilute hydrochloric acid, the crude pyrazole carboxylic acid crystallized. Recrystallization from ethanol gave the carboxylic acid (80% yield), mp 210°. IR showed bands at 1700–1725 (C=O), 1330–1350, and 1170–1190 cm^{-1} (SO_2N).

Anal.—Calc. for $C_{24}H_{18}ClN_3O_4S$: C, 60.1; H, 3.3; Cl, 7.4; N, 8.8. Found: C, 60.0; H, 3.5; Cl, 7.6; N, 9.1.

1 - (*p*-Sulfamylphenyl) -3- ethoxycarbonyl-5-(α-phenyl-*p*-methoxystyryl)pyrazole (III*b*)—A mixture of II (0.1 mole) and ethyl 2,4-dioxo-6-(*p*-methoxyphenyl)-5-phenyl-hex-5-enoate (0.1 mole) in ethanol (150 ml) was refluxed for 6 hr on a steam bath, concentrated, and allowed to cool. The crude product was separated and recrystallized (70% yield) from ethanol, mp 185°.

The ^{1}H-NMR spectrum of III*b* showed absorption at 6.8–7.7 (m, aromatic H), 6.7 (s, 1, pyrazole H), 6.4 (s, 1, styryl H), 5.0 (s, 2, SO_2NH_2), 4.3 (q, 2, $CO_2CH_2CH_3$), and 3.6 ppm (s, 3, OCH_3).

Anal.—Calc. for $C_{27}H_{25}N_3O_5S$: C, 64.4; H, 5.0; N, 8.3; S, 6.4. Found: C, 64.5; H, 5.0; N, 8.5; S, 6.5.

1 - (*p*-Sulfamylphenyl)-3-carboxy -5- (α-phenyl-*p*-methoxystyryl)pyrazole—A mixture of III*b* (1 g) in an ethanolic solution of potassium hydroxide (25 ml) was refluxed for 1 hr. After concentration, cooling, and acidification with dilute hydrochloric acid, the crude pyrazole carboxylic crystallized. Recrystallization from ethanol gave the carboxylic acid (78% yield), mp 108°. IR showed bands at 1700–1730 (C=O), 1330–1350, and 1170–1190 cm^{-1} (SO_2N).

Anal.—Calc. for $C_{25}H_{21}N_3O_5S$: C, 63.2; H, 4.4; N, 8.8; S, 6.7. Found: C, 63.4; H, 4.5; N, 9.0; S, 6.6.

***p*-[3-Ethoxycarbonyl -5- (α-phenyl-*p*-chlorostyryl) -1- pyrazolyl]benzenesulfonylurea Derivatives (V*d–h*)**—A mixture of III*a* (0.005 mole) and anhydrous potassium carbonate (0.01 mole) in dry acetone (50 ml) was stirred at reflux for 1.5 hr. At this temperature, a solution of the appropriate isocyanate (0.01 mole) in dry acetone (10 ml) was added in a dropwise manner. The mixture was stirred at reflux overnight and then the acetone was removed under reduced pressure. The resulting solid material was dissolved in water, and the solution was acidified with 2 *N* hydrochloric acid. Recrystallization of the resulting solid from the appropriate solvent (12) gave V*d–h*.

***p* - [3-Ethoxycarbonyl -5- (α-phenyl -*p*- methoxystyryl)-1-pyrazolyl]benzenesulfonylurea Derivatives (V*i–m*)**—A mixture of III*b* (0.005 mole) and anhydrous potassium carbonate (0.01 mole) in dry acetone (50 ml) was treated with the appropriate isocyanate (0.01 mole) in dry acetone (10 ml) and completed as mentioned above.

***p*-[3-Ethoxycarbonyl -5- (α-phenyl -*p*- chlorostyryl)-1-pyrazolyl]benzenesulfonylthiourea Derivatives (VI*a–e*)**—A mixture of III*a* (0.005 mole) and anhydrous potassium carbonate (0.01 mole) in dry acetone (50 ml) was stirred and treated with the appropriate isothiocyanate (0.006 mole). The mixture was stirred at reflux for 10 hr, and the acetone was removed under reduced pressure. The resulting solid was dissolved in water, and the mixture was acidified with 2 *N* hydrochloric acid. The

[1] Melting points were determined in open glass capillaries and are uncorrected. UV spectra were measured with a Perkin-Elmer 550 S spectrophotometer. IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrophotometer. ^{1}H-NMR spectra were recorded on a Varian EM-360 60-Hz NMR spectrophotometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

[a] Application for a patent was made for the compounds described in this report.

crude product was purified by recrystallization from the appropriate solvent.

***p*-[3-Ethoxycarbonyl-5-(α-phenyl-*p*-methoxystyryl)-1-pyrazolyl]benzenesulfonylthiourea Derivatives (VI*f–j*)**—A mixture of III*b* (0.005 mole) and anhydrous potassium carbonate (0.01 mole) in dry acetone (50 ml) was stirred and treated with the appropriate isothiocyanate (0.006 mole) and completed as mentioned above.

***p*-[3-Carboxy-5-(α-phenyl-*p*-substituted styryl)-1-pyrazolyl]-benzenesulfonylurea (VII) or -thiourea (VIII) Derivatives**—A mixture of V or VI (1 g) in an ethanolic solution of 2 *N* potassium hydroxide (20 ml) was refluxed for 1 hr. The mixture was concentrated, cooled, and then acidified with dilute hydrochloric acid to give a crystalline material. Recrystallization from dilute ethanol gave either VII or VIII.

Spectra of V–VIII—The UV spectra of V–VIII showed absorption at 228–235 and 268–277 nm. The IR spectra of V–VIII showed absorption at 1700–1725 (C=O) and 1330–1360 cm^{-1} (2 bands) (SO_2N); compounds V and VII showed additional carbonyl absorption at 1650–1660 cm^{-1}, whereas compounds VI and VIII showed absorption at 1050–1200 cm^{-1}, indicative of the C=S group.

The ^1H-NMR spectrum of V*g* showed absorption at 7.8–8.2 (aromatic H), 6.8 (pyrazole H), 6.2 (s, styryl H), 4.2 (q, CH_2 of the ester), 1.5 (m, methylene H), and 1.0 ppm (t, CH_3 of the ester).

Biological Testing Method—Compounds IV, V*a–g,k,l*, VI*b,h*, VII*d,e,h* and VIII*a,g* were tested for hypoglycemic activity using alloxan-treated female albino mice with an average weight of 20 g. Alloxan (100 mg/kg) in a 10 mg/ml saline solution was injected into the tail vein. Three days later the mice were given the test compounds orally in suspension

[a] Tested using alloxan-treated mice (100 mg/kg). Phenformin (0.4 mmole/kg) was used as the positive control; the hypoglycemic activity of phenformin was 10% reduction (statistically significant when compared with the untreated controls, $p < 0.01$). [b] Statistically significantly different when compared with the untreated controls at $p < 0.01$. [c] Statistically significantly different when compared with the untreated controls at $p < 0.05$.

in 1% carboxymethylcellulose at the rate of 0.4 mmole/kg. On each day of the experiment, a group of four mice was used as the control; one group of four mice was given the standard 100 mg (0.4 mmole) of phenformin/kg. Up to five groups of four mice each received the test compounds. Blood samples were collected into 0.04% NaF solution at 0, 1, and 3 hr.

Glucose was determined by a microcolorimetric copper reduction technique used previously (13). Results are expressed as a percentage reduction of plasma glucose levels compared with the control value. Statistical significance was assessed by Student's t test, where the calculated t value exceeded the tabulated t value at the $p = 0.05$ level.

Compounds IV, Va,b,c,l, and VIIe possess marked hypoglycemic activity. The most active members are the α-unsubstituted styrylpyrazolesulfonylurea derivatives. The activity decreases from the α-methylstyryl to α-phenylstyryl analogues. Surprisingly, α-unsubstituted styrylpyrazolylsulfonamide-3-carbohydrazide showed marked hypoglycemic activity.

Synthesis and Antidiabetic Activity of Some Sulfonylurea Derivatives of 3,4,5-Trisubstituted Pyrazoles

RAAFAT SOLIMAN *x, HASSAN MOKHTAR ‡, and HOSNY F. MOHAMED §

Received August 26, 1981, from the **Department of Pharmaceutical Chemistry*, the ‡*Department of Pharmacology, Faculty of Pharmacy*, and the §*Department of Chemistry Faculty of Science, University of Alexandria, Alexandria, Egypt.* Accepted for publication May 21, 1982.

Abstract □ Three series of 3,4,5-trisubstituted pyrazolesulfonylurea derivatives were prepared and evaluated as hypoglycemic agents. Preliminary biological testing revealed that the new compounds possess moderate hypoglycemic activity.

Keyphrases □ Pyrazolesulfonylurea derivatives—preparation, potential hypoglycemic agents □ Potential hypoglycemic agents—preparation of new trisubstituted pyrazolesulfonylurea derivatives

Since previous studies indicated that several substituted 3,5-dimethylpyrazoles possessed potent hypoglycemic activity (1–5), additional compounds were synthesized (6–10). The present study, which is a continuation of previous work (8–10), describes the preparation of derivatives of 3,4,5-trisubstituted pyrazolesulfonylureas and their evaluation as potential hypoglycemic agents.

Derivatives of *p*-(3,5-dimethyl-4-ethoxycarbonyl-1-pyrazolyl)-benzenesulfonylurea, *p*-(3-methyl-5-phenyl-4-carboxy-1-pyrazolyl)-benzenesulfonylurea, and *p*-(3-methyl - 5 - phenyl - 1 - pyrazolylcarbamoylbenzenesulfonylurea (in addition to the corresponding 4-bromo derivative) were prepared and some were evaluated for hypoglycemic activity. Preliminary biological testing revealed that the new compounds possess moderate hypoglycemic activity.

BACKGROUND

1-(*p*-Sulfamylphenyl)-3,5-dimethyl-4-ethoxycarbonylpyrazole (III) was prepared by treating *p*-sulfamylphenylhydrazine (II) with an equivalent amount of 3-ethoxycarbonyl-2,4-pentanedione (I). Similarly, 1 - (*p* - sulfamylphenyl) - 3 - methyl - 5 - phenyl - 4 - ethoxycarbonylpyrazole (VII) was prepared by treating *p*-sulfamylphenylhydrazine (II), with 1-phenyl-2-ethoxycarbonylbutane-1,3-dione (VI).

The IR absorption spectra of these trisubstituted pyrazoles (III and VII) showed an absorption band at 1700–1725 cm^{-1} due to the carbonyl of the ester group and two bands at 1330–1350 cm^{-1} and 1170–1190 cm^{-1} due to the $—SO_2N$ group.

Alkaline hydrolysis of the pyrazole esters (IV and VII) with ethanolic 2 *N* potassium hydroxide solution afforded the corresponding pyrazole-3-carboxylic acids (V and VIII). The IR spectra of the pyrazolylcarboxylic acid (VIII) showed an absorption band at 1675 cm^{-1} for the —COOH group.

p - (3,5 - Dimethyl - 4 - ethoxycarbonyl - 1 - pyrazolyl)benzenesulfonylurea (IV) and *p*-(4-carboxy-3-methyl-5-phenyl-1-pyrazolyl)benzenesulfonylurea (IX) derivatives were prepared by the reaction between III or VIII with the appropriate isocyanate in dry acetone (11). The

thiourea derivatives (X) were prepared in a similar manner treating VIII with the appropriate isothiocyanate in dry acetone.

p-(3-Methyl-5-phenylpyrazol-1-yl-carbamoyl)benzenesulfonamide (XIII) was prepared by fusing *p*-sulfamylphenylsemicarbazide (XII) with 1-phenylbutane-1,3-dione (XI) at 110°. Treatment of XIII with the appropriate isocyanate afforded *p*-(3-methyl-5-phenyl-1-pyrazolyl)carbamoylbenzenesulfonylurea (XIV), which on bromination with bromine in chloroform gave the corresponding 4-bromo derivatives. The IR spectra of these compounds revealed two absorption bands at 1350–1330 cm^{-1} and 1190–1170 cm^{-1} indicative of the $-SO_2N$ group as well as a urea carbonyl band at 1660 cm^{-1}.

The physical and analytical data of these new pyrazoles, as well as the antidiabetic activity of some of the compounds are listed in Table I.

EXPERIMENTAL[1]

1 - (*p* - Sulfamylphenyl) - 3,5 - dimethyl - 4 - ethoxycarbonylpyrazole (III)—A mixture of *p*-sulfamylphenylhydrazine (18.7 g, 0.1 mole) and 3-ethoxycarbonyl-2,4-pentanedione (17 g, 0.1 mole) in ethanol (150 ml) was refluxed for 4 hr on a steam bath, concentrated, and allowed to cool. The crude product was separated and recrystallized (65% yield) from ethanol, mp 232°.

Anal.—Calc. for $C_{12}H_{17}N_3O_4S$: C, 48.2; H, 5.7; N, 14.0; S, 10.7. Found: C, 48.4; H, 5.6; N, 14.1; S, 11.0.

Substituted *p*-(3,5-Dimethyl-4-ethoxycarbonyl-1-pyrazolyl)-benzenesulfonylurea Derivatives (IV)—A mixture of III (0.025 mole) and anhydrous potassium carbonate (0.05 mole) in dry acetone (50 ml) was stirred at reflux for 1.5 hr. At this temperature, a solution of the appropriate isocyanate (0.04 mole) in dry acetone (10 ml) was added, in a dropwise manner, the mixture was stirred at reflux overnight, the acetone was removed under reduced pressure, and the resulting solid residue was dissolved in water. The crude product was isolated by acidification with 2 *N* hydrochloric acid and purified by recrystallization from ethanol.

Substituted *p*-(4-Carboxy-3,5-dimethyl-1-pyrazolyl)benzenesulfonylurea Derivatives (V)—A mixture of IV (1 g) in an alcoholic solution of 2 *N* potassium hydroxide (25 ml) was refluxed for 1 hr. The mixture was concentrated, cooled, and acidified with dilute hydrochloric acid to give crystalline material.

1-(*p*-Sulfamylphenyl)-3-methyl-5-phenyl-4-ethoxycarbonylpyrazole (VII)—A mixture of *p*-sulfamylphenylhydrazine (18.7 g, 0.1 mole) and 1-phenyl-2-ethoxycarbonylbutane-1,3-dione (23.6 g, 0.1 mole) in ethanol (150 ml) was refluxed for 4–6 hr on a steam bath, concentrated, and allowed to cool. The crude product was separated and recrystallized (70% yield) from ethanol, mp 232°.

Anal.—Calc. for $C_{17}H_{19}N_3O_4S$: C, 56.5; H, 5.3; N, 11.6; S, 8.9. Found: C, 56.5; H, 5.5; N, 11.8; S, 9.1.

1 - (*p* - Sulfamylphenyl) - 3 - methyl - 5 - phenyl - 4 - carboxypyrazole (VIII)—A mixture of VII (5 g) in alcoholic solution of 2 *N* potassium hydroxide (100 ml) was refluxed for 1 hr. The mixture was concentrated, cooled, and then acidified with dilute hydrochloric acid to give a crystalline material. Recrystallization from ethanol, gave VIII (80% yield) mp 250°.

Anal.—Calc. for $C_{15}H_{15}N_3O_4S$: C, 54.1; H, 4.5; N, 12.6; S, 9.6. Found: C, 54.4; H, 4.4; N, 12.5; S, 9.8.

Substituted *p*-(4-Carboxy-3-methyl-5-phenyl-1-pyrazolyl)-benzenesulfonylurea Derivatives (IX)—A mixture of VIII (0.025 mole) and anhydrous potassium carbonate (0.05 mole) in dry acetone (50 ml) was refluxed for 1.5 hr. At this temperature, a solution of the appropriate isocyanate (0.04 mole) in dry acetone (10 ml) was added in a dropwise manner. After the mixture was stirred and refluxed overnight, the acetone was removed under reduced pressure, and the solid residue was dissolved in water. The crude product precipitated when the mixture was acidified with 2 *N* hydrochloric acid. Recrystallization from ethanol afforded the purified material.

Scheme III

[1] Melting points were determined in open glass capillaries and are uncorrected. UV spectra were measured with a Perkin-Elmer 550 S spectrophotometer. The IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrophotometer. ^{1}H-NMR spectra were recorded on a Varian EM-360 60-Hz, NMR spectrophotometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

[a] Tested using alloxan-treated mice (100 mg/kg). Phenformin (0.4 mmole/kg) was used as the positive control; the hypoglycemic activity of phenformin was 10% reduction (statistically significant when compared with the untreated controls at $p < 0.01$). [b] Statistically significantly different from the untreated controls at $p < 0.05$. [c] Statistically significantly different from the untreated controls at $p < 0.01$.

Substituted *p*-(4-Carboxy-3-methyl-5-phenyl-1-pyrazolyl)-benzenesulfonylthiourea Derivatives (X)—A mixture of VIII (0.025 mole) and anhydrous potassium carbonate (0.05 mole) in dry acetone (100 ml) was stirred and treated with the appropriate isothiocyanate (0.03 mole). The mixture was stirred at reflux for 10 hr, and then the acetone was removed under reduced pressure; the resulting solid residue was dissolved in water. Acidification with 2 *N* hydrochloric acid, followed by recrystallization of the resulting solid from dilute ethanol gave X.

***p*-(3-Methyl-5-phenyl-1-pyrazolyl)carbamoylbenzenesulfonamide (XIII)**—A mixture of XII (22.9 g, 0.1 mole) and 1-phenylbutane-1,3-dione (16.6 g, 0.1 mole) was stirred and fused at 110° for 1 hr, cooled, and crystallized from ethanol to give colorless crystals, mp 190°.

Anal.—Calc. for $C_{17}H_{16}N_4O_3S$: C, 57.3; H, 4.5; N, 15.7; S, 9.0. Found: C, 57.5; H, 4.5; N, 16.0; S, 8.8.

***p*-(3-Methyl-5-phenyl-1-pyrazolyl)carbamoylbenzenesulfonylurea (XIV)**—A mixture of XIII (0.025 mole) and anhydrous potassium carbonate (0.05 mole) in dry acetone (50 ml) was stirred at reflux for 1.5 hr. At this temperature, a solution of the appropriate isocyanate (0.04 mole) in dry acetone (10 ml) was added in a dropwise manner. The mixture was stirred at reflux overnight, and then the acetone was removed under reduced pressure to give a solid material. This material was dissolved in water, and the solution was acidified with 2 *N* hydrochloric acid. Recrystallization from methanol–benzene gave XIV.

***p*-(4-Bromo-3-methyl-5-phenyl-1-pyrazolyl)carbamoylbenzenesulfonylurea Derivatives (XV)**—A mixture of XIV (0.01 mole) in chloroform (10 ml) was stirred at room temperature and a solution of bromine was added with chloroform (0.011 mole) for a 1-hr period. The mixture was allowed to stand at room temperature overnight and the resulting solid was removed by filtration. Recrystallization from dilute ethanol gave colorless crystals of XV.

Spectra—The UV spectrum of IV showed two peaks at λ_{max} 230–237 and 272–277 nm. Compound IX showed two peaks at λ_{max} 210–214 and 260–268 nm. The IR spectra revealed bands at 1700–1730 (C=O), 1330–1350, and 1170–1190 cm^{-1} (SO_2N), whereas XIV and XV showed bands at 1650–1660 (amide), 1330–1350, and 1170–1190 cm^{-1} (SO_2N).

The ^{1}H-NMR spectrum of III showed absorption at 7.1–7.7 (m, aromatic H), 5.6 (s, 2, SO_2NH_2), 4.2 (q, J = 7.0 Hz, $CO_2CH_2CH_3$), 1.8 (s, CH_3), and 1.2 ppm (t, J = 7.0 Hz, $CO_2CH_2CH_3$). The ^{1}H-NMR spectrum of XIV*d* showed absorption at 7.6–8.2 (m aromatic H), 6.6 (s, 1, pyrazole H), and 1.6 ppm (s, CH_3).

Biological Testing Method—Compounds IV*c*,*e*, V*c*,*d*, IX*a*,*c*, X*c*,*d*, XIV*d*, and XV*b* were tested for hypoglycemic activity using alloxan-treated female albino mice with an average weight of 20 g. Alloxan (100 mg/kg) in a 10-mg/ml saline solution was injected into the tail vein. Three days later, the mice were given the test compounds orally in suspension in 1% carboxymethylcellulose at the rate of 0.4 mmole/kg. Each day of the experiment, a group of four mice was used as the control; one group of four mice was given the standard, 100 mg (0.4 mmole) of phenformin/kg. Up to five groups of four mice each received the test compounds. Blood samples were collected into 0.04% NaF solution at 0, 1, and 3 hr.

Glucose was determined by a previously used microcolorimetric copper reduction technique (12). Results are expressed as a percentage reduction of plasma glucose levels compared with the control value. Statistical significance was assessed by Student's t test, where the calculated t value exceeded the tabulated t value at the p = 0.05 level.

Compound XIV*d* possesses marked hypoglycemic activity (Table I); its potency is comparable with phenformin. The other compounds showed moderate hypoglycemic activity.

From the data presented previously (8–10) and in this report, it is obvious that pyrazole-3-carboxylic acids are much more potent hypoglycemics than the corresponding 4-carboxylic acid derivatives. 3,5-Disubstituted pyrazolebenzenesulfonylurea derivatives are much more active than the corresponding trisubstituted pyrazoles. The presence of a 4-ethoxycarbonyl or carboxy group in the pyrazole ring reduces the hypoglycemic activity. Generally, pyrazolesulfonylurea derivatives are much more active than the corresponding thiourea analogues.

Antitumor Agents LXIII: The Effects of Microlenin on Nucleic Acid and Protein Syntheses of Ehrlich Ascites Cells

I. H. HALL ˣ, K. H. LEE, Y. IMAKURA, and D. SIMS

Received July 8, 1982, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication August 13, 1982

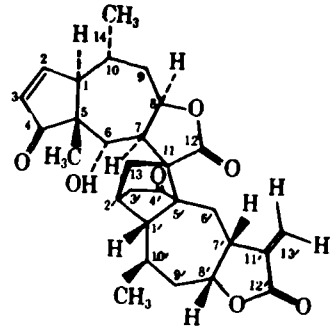
Abstract □ Microlenin, a novel dimeric sesquiterpene lactone isolated from Texas *Helenium microcephalum*, was shown to inhibit Ehrlich ascites carcinoma growth. Metabolic studies demonstrated that DNA synthesis and protein synthesis were significantly inhibited by two doses of microlenin at 5 mg/kg/day. DNA synthesis appeared to be blocked at several sites including DNA polymerase, purine synthesis, and dihydrofolate reductase. Thymidine nucleotide pools were significantly reduced by microlenin. Protein synthesis inhibition by microlenin appeared to occur during the initiation step of polypeptide synthesis. The metabolic effects of microlenin were similar to other sesquiterpene lactones in the Ehrlich ascites carcinoma cells. However, a lower dose of microlenin was required to bring about these metabolic effects when compared with other sesquiterpene lactones. Thus, microlenin may be a more likely therapeutic agent than helenalin which has demonstrated cellular toxicity.

Keyphrases □ Microlenin—sesquiterpene lactone, inhibition of DNA and protein syntheses, inhibition of Ehrlich ascites carcinoma growth □ Protein synthesis—effects of microlenin, Ehrlich ascites carcinoma growth

Microlenin was originally isolated from Texas *Helenium microcephalum* (1–3). The molecule appears to arise from a Diels-Alder type condensation involving the 11,13-double bond of helenalin and the enol form of the cyclopentenone ring of a norpseudoguaianolide. Preliminary antineoplastic screening demonstrated that microlenin was active against rat Walker 256 carcinosarcoma growth at 2.5 mg/kg/day affording a T/C% value equal to 172%. Further testing against the mouse P-388 lymphocytic leukemia growth demonstrated that at 12.5 mg/kg/day, a T/C% = 167 was obtained. Sesquiterpene lactones of varying structures have been shown to be potent inhibitors of nucleic acid and protein synthesis of tumor cells. Reported at this time are the effects of microlenin on the cellular metabolism of Ehrlich ascites cell carcinoma.

EXPERIMENTAL

Ehrlich Ascites Screen—Male CF_1 mice (30 g) were implanted with 2×10^6 Ehrlich ascites cells intraperitoneally on day 0. Microlenin was suspended by homogenization in 0.05% polysorbate 80–water and administered intraperitoneally at 5 and 10 mg/kg/day. The mice were sacrificed on day 10, and the ascites fluid was collected from the peritoneal cavity. The volume and ascrit (packed cell volume) were determined for each animal, and the percent inhibition of tumor growth was calculated (4).



Structure of Microlenin

In vitro incorporation of [^{3}H]thymidine, [^{3}H]uridine, or [^{3}H]leucine was determined using 10^6 Ehrlich ascites cells, 1-μCi labeled precursor, minimum essential medium, and varying final concentrations of drug from 0.125 to 2.0 m*M* (5). The tubes were incubated at 37° for 60 min and inactivated by trichloroacetic acid. The acid-insoluble, labeled DNA, was collected on GF/F glass filter disks[1], and RNA and protein were precipitated on nitrocellulose filters[2] by vacuum suction. Results are expressed as dpm of incorporated precursor/hr/10^6 cells. For *in vitro* studies, cells were collected on day 10, and the microlenin was incubated at 0.25–1.0 m*M* concentration.

Ehrlich ascites cells (10^6) were injected intraperitoneally into CF_1 male mice (~22 g) on day 0. On days 8 and 9, microlenin (5 mg/kg/day in 0.05% polysorbate 80–water) was injected intraperitoneally. Incorporation of thymidine into DNA was determined by the method of Chae *et al.* (6). One hour prior to sacrifice on day 10, 10 μCi of [6-^{3}H]thymidine (21.5 Ci/mmole) was injected intraperitoneally. The DNA was isolated and the tritium content was determined in a toluene-based scintillation fluid[3]. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as a standard. Uridine incorporation into RNA was determined using 10 μCi of [5,6-^{3}H]uridine (22.4 Ci/mmole). RNA was extracted by the method of Wilson *et al.* (7). Using yeast RNA as a standard, the RNA content was assayed by the orcinol reaction. Leucine incorporation into protein was determined by the method of Sartorelli (8) using 10 μCi of [4,5-^{3}H]leucine (52.2 Ci/mmole). Extracted protein was determined by the Lowry procedure using bovine albumin as a standard. *In vitro* and *in vivo* nuclear DNA polymerase activity was determined on isolated Ehrlich ascites cell nuclei (9). The incubation method was that described by Sawada *et al.* (10) except that [methyl-^{3}H]deoxythymidine triphosphate (82.4 Ci/mmole) was used. The acid-insoluble nucleic acid was collected on GF/F filters and counted.

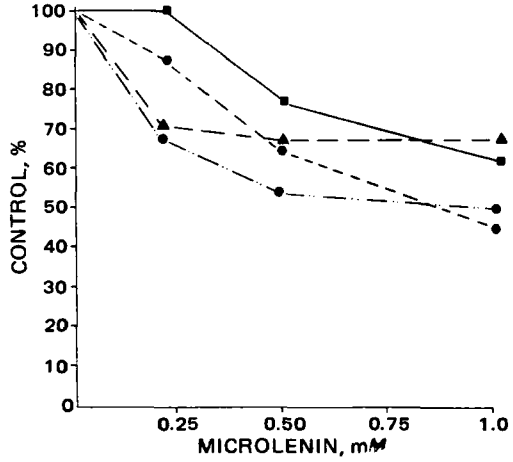


Figure 1—*The* in vitro *effects of microlenin on the incorporation of radiolabeled precursors into DNA, RNA, protein and purine of Ehrlich ascites cells. Key: (■) [^{3}H]leucine incorporation into protein; (▲) [^{3}H]uridine incorporation into RNA; (●) [^{3}H]thymidine incorporation into DNA; and (◆) [^{14}C]formate incorporation into purine.*

Table I—Antineoplastic Activity of Microlenin Against the Growth of Ehrlich Ascites Carcinoma Cells [a]

Compound	Survival at Day 10	Volume of Ascites	Ascrit Packed Cells Volume	Inhibition, %
Control (0.05% polysorbate 80)	6/6	6.68	43.1	—
Microlenin (5 mg/kg/day)	6/6	0.02	5.1	99.9
Microlenin (10 mg/kg/day)	6/6	0.75	36.8	90.4
Mercaptopurine	6/6	0.10	2.5	99.9

[a] Number of mice = 6.

Nuclear RNA polymerase activities were determined on enzymes isolated from nuclei (9). Messenger, ribosomal, and transfer RNA polymerases were isolated using 0.3 *M*, 0.04 *M*, and 0.0 *M* concentrations of ammonium sulfate in magnesium chloride, respectively. The incubation medium was that of Anderson *et al.* (11) using [^{3}H]uridine triphosphate (23.2 Ci/mmole). The acid-insoluble RNA was collected on nitrocellulose filters and counted.

Deoxythymidine as well as deoxythymidylate monophosphate and diphosphate kinase activities were measured spectrophotometrically at 340 nm for 20 min using reduced nicotinamide adenine dinucleotide (0.1 μmole) (12). [6-^{3}H]Thymidine (21.5 Ci/mmole) incorporation into the nucleotides was also measured using the reaction medium of Maley and Ochoa (12) and then plating the ether extract of the reaction medium on PEI cellulose F plates. The plates were eluted with 0.5 *N* formic acid–0.6 *N* LiCl (1:1). After identifying R_f values consistent with the standards, thymidine, thymidylate monophosphate, and thymidylate diphosphate, the areas on the plates were scraped and counted. Carbamyl phosphate synthetase activity was determined using the reaction medium of Kalman *et al.* (13) in the presence of ornithine and the enzyme ornithine transcarbamylase. Citrulline formed from ornithine was measured at 490 nm by the method of Archibald (14). Aspartate transcarbamylase activity was assayed using the incubation medium of Kalman *et al.* (13). The colorimetric determination of carbamyl aspartate was conducted by the procedure of Koritz and Cohen (15). Orotidine monophosphate decarboxylase activity was assayed by the method of Appel (16) using 0.1 μCi of [^{14}C]orotidine monophosphate (34.9 mCi/mmole). The $^{14}CO_2$ generated in 15 min was trapped in 1 *M* methanolic base[4] and counted. Thymidylate synthetase activity was determined using a postmitochondrial supernatant (9000×*g* for 10 min) and 5 μCi of [5-^{3}H]deoxyuridine monophosphate (14 Ci/mmole) according to the method of Kampf *et al.* (17). [^{14}C]Formate incorporation into purines was determined by the method of Spassova *et al.* (18), using 0.5 μCi of [^{14}C]formic acid (52.0 mCi/mmole). Purines were separated on silica gel TLC plates eluted with 1-butanol–acetic acid–water (4:1:5). After identifying R_f values consistent with the standards, adenine and guanine, the plates were scraped and the radioactive content determined. Phosphoribosyl-1-pyrophosphate amidotransferase activity was determined on a supernatant fraction (600×*g*, for 10 min) measuring the reduction of 0.6 μmole of nicotinamide adenine dinucleotide at 340 nm for 30 min (19). Inosinic acid dehydrogenase activity was determined by the method of Becker and Löhr (20) using a supernatant 7000×*g*, for 10 min and [8-^{14}C]inosine-5′ monophosphate (61 mCi/mmole). After plating on PEI cellulose F plastic precoated plates and eluting with 0.5 *M* $(NH_4)_2SO_4$, the spot corresponding to xanthine monophosphate was scraped and counted. Dihydrofolate reductase activity was determined at 340 nm for 30 min as the oxidation of reduced nicotinamide adenine dinucleotide phosphate (21). Ribonucleotide reductase activity was determined by the method of Moore and Hurlbert (22) using [5-^{3}H]cytidine-5-diphosphate (25 Ci/mmole). Ribose and deoxyribose nucleotide were separated on PEI cellulose F plastic precoated plates eluted with 4% boric acid–4 *M* LiCl (4:3) and scraped at the R_f values consistent with the standard deoxycytidine diphosphate. An *in vitro* method[5] using a lysate of Ehrlich ascites cells was used to determine if microlenin was an initiation or elongation inhibitor of protein synthesis by using the standards pyrocatechol violet (an initiation inhibitor) and emetine (an elongation inhibitor) using 1 μCi [^{3}H]leucine (24.7 Ci/mmole). Aliquots of the reaction medium were removed every 2 min, spotted on dried filter paper[5], treated for 10 min in boiling 5% trichloroacetic acid, and washed with cold 5% trichloroacetic acid, ether–ethanol (4:1), and ether. The disks were dried and counted[3].

Protein for enzymatic assay was determined by the Lowry *et al.* technique (23).

Probable (p) significant differences were determined by the Student's t test. Data are expressed in Tables I–II as percent of control with standard deviations.

RESULTS

Microlenin has potent activity against Ehrlich ascites carcinoma growth at 5 and 10 mg/kg/day with 99.9 and 90.4% inhibition, respectively (Table I). Preliminary *in vitro* studies demonstrated that DNA, RNA, and protein syntheses are effectively reduced by microlenin. An ID_{50} value of 1.0 μ*M* was obtained for DNA synthesis and protein synthesis at 1.42 m*M*. Formate incorporation into purine was significantly suppressed by microlenin with an ID_{50} value of 783 μ*M*. Phosphoribosyl pyrophosphate amido transferase activity was markedly reduced in the presence of microlenin, affording an ID_{50} value of 611 μ*M* concentration and for dihydrofolate reductase activity an ID_{50} value of 520 μ*M* was obtained. Marginal inhibition (28%) was observed by 100 μ*M* of microlenin on orotidine monophosphate decarboxylase activity. The thymidine nucleotide pools were reduced during *in vitro* incubation with microlenin. Thymidine monophosphate pools were reduced 45% at 25 μ*M*. DNA polymerase activity was suppressed with microlenin resulting in an ID_{50} value of 498 μ*M*. Deoxyribonuclease activity *in vitro* was inhibited 48% at 100 μ*M* of microlenin. A number of enzyme activities were not affected by microlenin. Those include messenger, ribosomal, and transfer RNA polymerases, ribonucleotide reductase, carbamyl phosphate synthetase, aspartate carbamyl transferase, thymidylate synthetase, and RNA synthesis. *In vivo* studies after 2 days dosing with microlenin at 5 mg/kg/day showed that DNA synthesis was markedly reduced. The control DNA synthesis rate is 107,533 dpm/hr/mg of isolated DNA, which was inhibited 52% by microlenin. Uridine incorporation into RNA for the 10-day control was 51,193 dpm/hr/mg of isolated RNA which was unaffected by drug treatment. Leucine incorporation for the control was 19,181 dpm/hr/mg of isolated protein, which was suppressed 41% by drug therapy. Formate incorporation into purines was 28,786 dpm/mg of protein, which was inhibited 42% by microlenin. Nuclear DNA polymerase activity for the control was 76,528 dpm/hr/mg of nucleoprotein, which was inhibited 62% by drug therapy. Messenger RNA polymerase activity for 10-day cells was 4867 dpm/hr/mg of nucleoprotein, ribosomal RNA polymerase activity was 8751 dpm/hr/mg of nucleoprotein, and transfer RNA polymerase activity was 10,792 dpm/hr/mg of nucleoprotein, which were inhibited 0, 28, and 18%, respectively, by administration of microlenin. Ribonucleotide reductase activity for the control was 153,791 dpm/mg of protein, which was not affected by drug treatment. Thymidine nu-

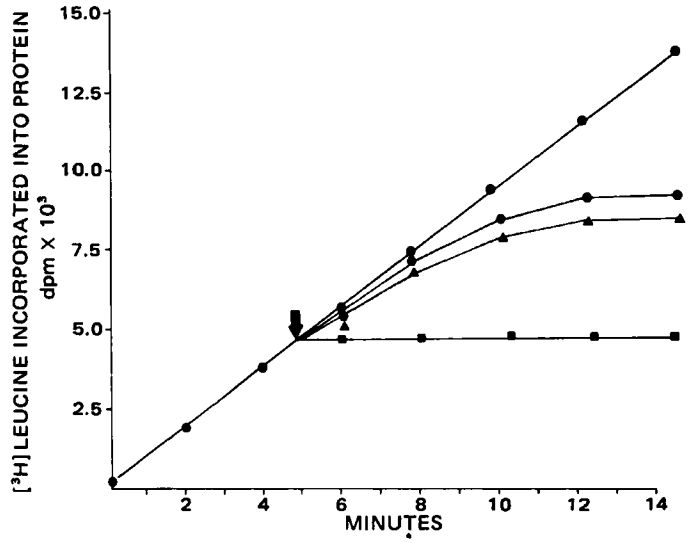

Figure 2—*Effects of microlenin on the initiation and elongation of protein synthesis of Ehrlich ascites carcinoma cells. Key: (●) control, (●) pyrocatechol violet, (■) emetine, and (▲) microlenin, (↓) addition of drug at 100 μM concentration.*

cleotide pools were altered by microlenin treatment. Thymidylate monophosphate pools were reduced 53%, thymidylate diphosphate pools 55%, and thymidylate triphosphate pools 48%.

Examination of the regulatory enzymes of *de novo* purine synthesis phosphoribosyl amido transferase activity for the control was 0.544 optical density units change/hr/mg of protein, which was reduced 63% by two doses of microlenin. Inosinic acid dehydrogenase activity for the 10-day control was 36,530 dpm/mg of protein, which was reduced 14% by microlenin administration. Dihydrofolate reductase activity for the untreated cells afforded a change of 0.514 optical units/hr/mg of protein which was suppressed 38% by drug administration. Examination of pyrimidine synthesis, the regulatory enzyme carbamyl phosphate synthetase activity for the control was 0.128 mg of carbamyl phosphate formed/hr/mg of protein and aspartate carbamyl transferase activity for the control was 7.526 mg of carbamyl aspartate formed/hr/mg of protein, which were not affected by drug treatment. Orotidine monophosphate decarboxylase activity for the control was 10,775 dpm of CO_2 generated for 15 min/mg of protein. Drug treatment reduced the activity 18%. Thymidylate synthetase activity for the control was 103,328 dpm/mg of protein, which was unaffected by drug therapy. Two days of treatment with microlenin at 5 mg/kg/day reduced the number of ascites cells/ml from 226×10^6 to 93×10^6.

DISCUSSION

Microlenin effectively suppressed Ehrlich ascites carcinoma growth as well as DNA synthesis and protein synthesis. Similar findings have also been observed for other sesquiterpene lactones. For example, helenalin at 33.3 mg/kg totally inhibited Ehrlich ascites growth (24) and at 12.5 mg/kg/day for 3 days significantly reduced DNA synthesis 88% (24–26). Tenulin produced a 97.3% reduction of Ehrlich ascites growth and a 91% inhibition of DNA synthesis at the same dose (24–26). Germacranolides [*i.e.*, eupahyssopin (27), eupaformosanin (28), and molephantinin (29)] produced similar effects in the Ehrlich tumor growth. However, the dose microlenin required to bring about the same degree of suppression of tumor growth was much lower: 6 mg/kg/day, compared with the higher doses of drugs, *i.e.*, 33.3 and 12.5 mg/kg/day, for the other derivatives. DNA polymerase activity was significantly reduced by microlenin. A number of pseudoguaianolides and germacranolides have been shown to inhibit both *in vivo* and *in vitro* DNA polymerase activity (24–29), basically at a higher dose than required by microlenin. Thymidylate synthetase activity was also suppressed by the pseudoguaianolides and germacranolides (24–26), but it should be noted that microlenin did not have any effect on thymidylate synthetase activity. These latter two enzymes contain sulfhydryl groups, which are supposedly alkylated by the α,β-unsaturated carbonyl moiety through a rapid Michael-type addition (25). The α,β-unsaturated carbonyl system in a ketone unit exists as the β-unsubstituted cyclopentenone moiety and as the α-methylene-γ-lactone in the structure of microlenin.

Formate incorporation into purines was significantly suppressed by microlenin. The activity of the regulatory enzyme of purine synthesis, phosphoribosyl pyrophosphate amido transferase, was also significantly reduced by microlenin. The magnitude of inhibition of the regulatory enzyme by the drug would account for the degree of reduction of purine synthesis. Nevertheless, microlenin marginally suppressed inosinic acid dehydrogenase activity, another regulatory enzyme of the purine pathway, and dihydrofolate reductase activity was moderately inhibited by microlenin. The latter enzyme plays a major role in the transfer of one carbon unit for purine and pyrimidine synthesis. The earlier regulatory enzymes of pyrimidine synthesis were not affected by drug treatment; however, a later regulatory enzyme, orotidine monophosphate decarboxylase, was marginally inhibited by *in vivo* administration. The nucleotide pools were reduced by microlenin with ~50% reduction. The reductions of monophosphate, diphosphate, and triphosphate pools will severely limit DNA synthesis of cells. Inhibition of formate incorporation, regulatory enzyme activities of the purine pathway, and nucleotide pools has been demonstrated previously with molephantinin in Ehrlich ascites cells.

Analysis of the protein data suggests that microlenin is an initiation inhibitor of protein synthesis of Ehrlich ascites carcinoma cells. Protein synthesis inhibition has been shown for helenalin, eupahyssopin, molephantinin. Recent studies in P-388 lymphocytic leukemia cells and rabbit reticulocyte cells demonstrated that helenalin and bis(henalinyl)malonate inhibit the formation of a 48S ribosomal complex during the initiation step of protein synthesis.

Quantum Mechanical Calculations Useful For Determining the Mechanism of Action of Fosfomycin

YVES G. SMEYERS *x, A. HERNANDEZ-LAGUNA *, and C. VON CARSTENN-LICHTERFELDE ‡

Received May 12, 1982, from the **Quantum Chemistry Laboratory, Instituto de Estructura de la Materia, C.S.I.C., c/Serrano, 119, Madrid-6, Spain* and the ‡*Instituto de Farmacologia Española, CEPA, c/Menendez-Alvaro, 57, Madrid-7, Spain.* Accepted for publication August 12, 1982.

Abstract □ CNDO/2 calculations were performed to determine at the molecular level the mechanism of action of the antibiotic fosfomycin, (−)-(1*R*,2*S*)-(1,2-epoxypropyl)phosphonic acid. Fosfomycin, a bacterial cell wall inhibitor, is known to act as a competitive inhibitor of *N*-acetylglucosamine-3-*O*-enolpyruvyl transferase, the normal substrate of which is phosphoenolpyruvate. Both compounds were studied, and the theoretical calculations revealed that the preferred conformations of phosphoenolpyruvate and fosfomycin presented the same spatial charge distributions on the active sites, the values of which are in complete agreement with the experimental observations. These results permit the projection of some details of the receptor, with implications for the modification of fosfomycin to increase its antibiotic activity.

Keyphrases □ Fosfomycin—preferred molecular conformation for biological activity, quantum mechanical calculations □ Phosphoenolpyruvate—preferred molecular conformation for biological activity, quantum mechanical calculations □ Structure–activity relationship—fosfomycin and phosphoenolpyruvate, molecular level mechanism of action, preferred conformation

Fosfomycin, (−)-(1*R*,2*S*)-(1,2-epoxypropyl)phosphonic acid, a relatively new low molecular weight antibiotic, contains both an epoxide ring and a carbon–phosphorus bond (Fig. 1) [found for the first time among natural products (1)]. Despite the presence of the epoxide ring, fosfomycin is quite stable, and its activity seems to be limited to the inhibition of *N*-acetylglucosamine-3-*O*-enolpyruvyl transferase, resulting in the formation of an irreversible adduct with the enzyme. The reaction seems to be stereospecific; (+)-(1*R*,2*S*)-, (−)-(2*R*,1*S*)-, and (+)-(2*R*,1*S*)-(1,2-epoxypropyl)phosphonic acids do not form stable adducts, as shown by their lack of biological activity. The absolute configuration of fosfomycin has been found to be (−)-(1*R*,2*S*) (2).

Fosfomycin is structurally similar to phosphoenolpyruvate (Fig. 2), an important substance for both bacterial and animal cells (3). Kahan *et al.* (4) have studied the mechanism of action of fosfomycin, which appears to be a competitive inhibitor of phosphoenolpyruvate in the cell wall biosynthesis of bacteria. The reactive sites on the enolpyruvyl transferase are a nucleophilic sulfur of a cysteine residue and a proton donor. The reaction is interpreted by the authors as a sulfhydryl addition across the C(2)—O(1) bond, analogous with the assumed sulfhydryl addition across the C(2)=C(3) double bond of phosphoenolpyruvate in the bacterial cell wall. In the present work, quantum mechanical conformational and charge distribution calculations for fosfomycin and phosphoenolpyruvate were performed to determine the mimetic action of fosfomycin at the molecular level.

THEORETICAL

Since fosfomycin and phosphoenolpyruvate are relatively large molecules to be approached by an *ab initio* method, the charge distribution calculations and conformational analysis were performed using the standard semiempirical CNDO/2 procedure (5). This method considers the system under study in the gas phase and needs only knowledge of the atomic number and the position coordinates of the atoms. Solvent effects can be introduced (6). These effects usually appear as a small increase in the charges, which will not modify the overall conclusions of this work. Therefore, solvent effects will not be considered explicitly.

Although the CNDO/2 method must be used with some caution in the conformational calculations (7), this procedure usually yields reasonable charge distributions. However, since it resorts to the zero differential overlap approximation (ZDO), the electronic charge distributions must be recalculated conveniently to obtain more reliable values (8).

In the ZDO approach, the electric charge of a given atom, A, with core charge Z_A, is expressed as:

$$Q_A = Z_A - 2\sum_{a}^{N}\sum_{i}^{n} C_{ia}^2 \qquad \text{(Eq. 1)}$$

where C_{ia} are the coefficients of the ath basis function in the ith molecular orbital, N is the number of basis functions centered on atom A, and n the number of occupied molecular orbitals. In this approximation, the basis functions may be regarded as atomic Slater orbitals orthogonalized by the Löwdin procedure. This orthogonalization involves a delocalization of the basis functions. To undo this transformation seems to be necessary in order to obtain localized charges on the atoms. So, according to the Löwdin transformation, the new coefficients are written as:

$$C' = CS^{-1/2}$$

where S is the overlap matrix between the Slater orbitals, and C and C' are the coefficient matrices before and after deorthogonalization, respectively. After this operation, the electric charges are given by the Mulliken population analysis formula:

$$Q_A = Z_A - 2\sum_{a}^{N}\sum_{b}^{M}\sum_{i}^{n} C'_{ia}C'_{ib}S_{ab} \qquad \text{(Eq. 2)}$$

where the summation on the index b must be extended to all the nonorthogonal basis orbitals.

EXPERIMENTAL

Phosphoenolpyruvic acid and fosfomycin should be ionized in a physiological medium. Essentially complete ionization of both compounds at pH ~7.4 is shown by the pK_a values of the carboxyl group (3.5) and the phosphoric acid groups (<2 and 6.4) of phosphoenolpyruvate acid and the phosphonic moiety (1.85 and 6.40) of fosfomycin (9). One-, two-, and threefold ionized species for fosfomycin were considered in the calculations.

To determine the coordinates of the ionized species, the bond lengths and bond angles were taken from the available crystallographic data, *i.e.*, X-ray measurements in solid phase on the monocyclohexylammonium salt of phosphoenolpyruvate (10) and monophenethylammonium salt of fosfomycin (11). Because the ions may show some conformational modifications in liquid phase, various possible conformations were taken into account.

Phosphoenolpyruvate Calculations—It appears that phosphoenolpyruvate has not been studied from a quantum point of view, except for two previous works on bond energy wealth (12, 13). X-ray measurements (10) show a roughly planar structure except for the phosphate group, which extends out from the plane of the enolpyruvate moiety. The P(1)—O(3) bond forms a tetrahedral angle (~109°) with the C(2)—O(3) bond of the ester bridge, and the P(1)—O(3)—C(2) plane forms a dihedral angle of 90° with the molecular planar frame. Because of the tetrahedral character of the P(1)—O(3) bond, the lack of steric effect, and its high symmetry, the phosphate group is expected to be able to rotate in the free molecule. Among the small irregularities of the planar frame, the carboxylic group appears somewhat twisted, and the oxygen atom (O-3), lies somewhat under the enolpyruvate plane. From a quantum point of view, it may be expected that the more ionized the molecule, the more planar it is because of a clear increasing of the conjugation of the π-electron system. This feature is especially true for the carboxylic group, which may be considered as rigorously coplanar in its ionized form.

Concerning the phosphoric rest, the question is whether the P(1)—O(3)—C(2) plane remains vertical up the enolpyruvic plane. Therefore, conformational calculations were performed around the O(3)—C(2) bond, taking as origin of rotations the conformation in which the phosphorus atom lies in the pyruvic plane side of the methylenic group. In these calculations, however, the O-3 atom is assumed to remain in its original location, slightly under the molecular plane.

The conformational dependencies of the three ionized species of phosphoenolpyruvic acid are reported in Fig. 3; they show a potential asymmetric double-well behavior, due to the out-of-plane O-3 atom. Minima are found at 60° and −20°, 60° and −20°, and 45° and −10° in the one-, two-, and threefold ionized species, respectively. The one-ionized

species has an extra minimum at 160°. As expected, at least to some extent, the more ionized the compound the more planar the ion. In the liquid phase, however, it may be expected that the solvent effect will damp this trend, because of its dielectric nature (6).

The preferred conformations appear also at lower angles. However, since the energy differences between the two branches of double wells are not too large (0.27, 0.66, and 0.54 kcal/mole), it may be expected that the ionized species will exist in both conformations at the physiological temperature. Furthermore, the barrier heights between the two branches are relatively low (1.8, 2.4, and 1.3 kcal/mole) so that the interconversion should be relatively easy through a switching of the O-3 atom.

The localized charge distributions were determined using Eq. 2 as a function of the torsion angle for the three ionized species. The distributions look qualitatively similar in the three species, although the more ionized the phosphoenolpyruvate species, the sharper the charge distribution, probably because of the increasing conjugation of the π-system. Their conformational dependencies, however, are not too large in the region of the minima. In Fig. 3, the charge distribution of the preferred conformation of the threefold ionized species in which the P(1)—O(3)—C(2) plane lies at −10° from the molecular plane is given.

Fosfomycin Calculations—Compared with phosphoenolpyruvate, fosfomycin presents a relatively rigid structure. In the X-ray measurements (11), fosfomycin may be regarded as a planar epoxide bearing a phosphonate and methyl groups in *cis* positions. Taking as rotation axis the C(1)—C(2) ring side and as origin of rotation the conformation in which the P atom lies in the epoxide half-plane, the phosphonate and methyl groups point rigidly out ~120° from the molecular plane. Only hindered internal rotations of the phosphonate and methyl radicals are possible. Therefore, the conformational calculations on the one- and twofold ionized species of fosfomycin were restricted to these two possibilities.

The conformational map for the twofold ionized species is given in Fig. 4, in which the threefold symmetry of the rotors is taken into account. In Fig. 4, the preferred conformation has the methyl and phosphonate groups rotated at 30° and 60°, respectively, taking as origin of rotation the conformation in which one atom of the rotating group lies in the plane formed by the rotation axis and the ring side. The conformational map, however, shows a valley corresponding to the single rotation of the methyl group, with a relatively low saddle point at 2 kcal/mole. This result reveals that the methyl group is able to rotate, though with some hindrance, regardless of the position of the phosphonate group.

The localized charge distributions of the two ionized species were calculated as a function of the two internal rotation angles. These distributions look very similar in the two species, and their conformational dependencies appear to be very small. In Fig. 1, the charge distribution of the twofold ionized species for the preferred conformation is also given.

RESULTS AND DISCUSSIONS

The results below are discussed assuming a neutral pH in the bacterial cell. These results also are valid, however, at lower pH values where local variations could occur in the reactive medium.

As has been seen, phosphoenolpyruvate and fosfomycin possess a central frame to which the PO_3^{2-} moiety is attached. Fosfomycin has a rigid structure; in contrast, phosphoenolpyruvate is a more flexible molecule which can adopt different conformations. The question arises whether fosfomycin may be considered as a rigid analogue of the natural compound.

As it is seen in Fig. 3, phosphoenolpyruvate has essentially two preferred conformations. To adopt the structure of fosfomycin ($\theta \sim 120°$) the fully ionized species needs more than 20 kcal/mole, which is a large energy requirement. On the other hand, in this conformation some distances between active sites such as P-1 and C-3 appear to be too large when compared with the corresponding distance between P-1 and O-1 in fosfomycin. In the more stable conformation of phosphoenolpyruvate (which appears for lower angles), all the distances between the active sites coincide approximately with those of fosfomycin (Fig. 5).

When considering the charges of the active sites, *i.e.*, the proton acceptor centers (the C-3 atom in phosphoenolpyruvate and the O-1 atom in fosfomycin) and the sulfhydryl acceptor centers (the C-2 atoms in both molecules), it is seen that the proton acceptor sites have a negative charge in both molecules. The sulfhydryl acceptor centers, C-2, have a positive charge in both molecules. Furthermore, the second carbon atom of the epoxide ring of fosfomycin (C-1), which could be a competitive acceptor center for the sulfhydryl residue, appears to be negatively charged, analogous with the oxygen atom (O-3) of the ester bridge in phosphoenolpyruvate. The charge distributions are similar in the PO_3^{2-} groups of both molecular systems.

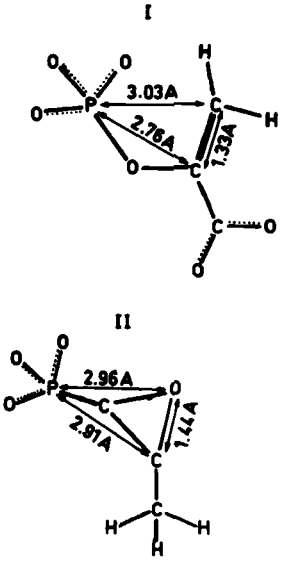

Figure 5—*Spatial distributions of the active sites (proposed receptor pattern) in the preferred conformation of the phosphoenolpyruvate (I) and fosfomycin (II).*

Therefore, fosfomycin should not be considered a rigid analogue of phosphoenolpyruvate. Nevertheless, this compound and fosfomycin appear to possess some local isosterism with a similar electric charge distribution at the active sites. This isosterism does not extend to the carboxylic group of phosphoenolpyruvate or methyl group of fosfomycin, which probably do not enter directly into the addition reaction. Fosfomycin, however, shows a high stereospecificity regarding the methyl group. This feature may be attributed to some steric hindrance, assuming that the reaction takes place in two steps: (*a*) fosfomycin is first adsorbed sideways by the PO_3^{2-} on the receptor and (*b*) the sulfhydryl addition reaction takes place on the opposite free face of the epoxide ring. Finally, it may be underlined that the knowledge of the charge distribution in fosfomycin suggests the possibility of selecting some structural modifications to increase the antibiotic activity of fosfomycin.

The present theoretical calculations confirm the assumed mechanism of action for the sulfhydryl and proton additions in fosfomycin as well as in phosphoenolpyruvate (4). The conformational analysis and electric charge distribution calculations indicate the same spatial charge distribution on the active sites in both molecular systems, the values of which are in accordance with the experimental data. Furthermore, taking into account the rigidity of fosfomycin and the stereospecificity involved, it may be stated that the active centers are probably located in a very small area on the receptor, limited approximately by the positions of three adjacent active centers, PO_3^{2-}, O-1, and C-2 (Fig. 5).

In Vitro Method for Detecting Precipitation of Parenteral Formulations After Injection

SAMUEL H. YALKOWSKY *x, SHRI C. VALVANI, and BENJAMIN W. JOHNSON

Received January 21, 1982, from *Pharmacy Research, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication July 14, 1982. *Present address: College of Pharmacy, The University of Arizona, Tucson, AZ 85721.

Abstract □ Many injectable formulations currently on the market, including diazepam and alprazolam, utilize one or more cosolvents to solubilize the active constituents. On injection into an aqueous medium, some of these components tend to precipitate. A simple procedure is described for measuring the degree of precipitation that occurs when a solubilized drug is injected. This *in vitro* technique was used to show that alprazolam injection shows less precipitation than diazepam injection under all tested conditions, and that the precipitation observed with diazepam can be controlled by ensuring that the formulation is injected very slowly. This simple technique also can be used during preformulation development to evaluate the relative potential for precipitation of various formulations.

Keyphrases □ Diazepam—*in vitro* detection of precipitation for injectable formulations □ Alprazolam—*in vitro* detection of precipitation for injectable formulations □ Formulations, injectable—potential precipitation in aqueous media, *in vitro* detection using diazepam and alprazolam

It is often necessary to administer a drug parenterally at a concentration which exceeds its aqueous solubility. The use of water-miscible cosolvents is by far the most versatile means of increasing the solubility of drugs. Cosolvents in concentrations up to 50% v/v can produce solubility increases of several orders of magnitude for very insoluble drugs (1, 2).

In some cases, the injection of a formulation (in which the drug is solubilized by a cosolvent) into blood or some other aqueous fluid can result in precipitation of the drug (2–7). This precipitation, in turn, can result in erratic or reduced drug bioavailability, pain on injection, and/or thrombophlebitis (3–7). The amount of precipitation, and thus the severity of the above problems, often is related to the rate at which the drug is injected (3–7).

The elimination of precipitation on dilution not only can lead to a safer and more effective formulation, it can also

ensure more meaningful evaluations of new drugs. A simple *in vitro* dynamic system for evaluating the degree of precipitation on injection of a solubilized drug is presented. The technique also can be used during preformulation development to evaluate the relative potential for precipitation of various formulations.

BACKGROUND

Many parenteral products currently on the market utilize one or more water-miscible cosolvents (Table I). The tendency for this type of formulation to precipitate when injected or diluted with an aqueous medium has been explained (2) on the basis of the following:

1. When a formulation is diluted by blood or by an intravenous drip solution, the concentrations of drug and cosolvent(s) decrease proportionally to one another.
2. The solubility of the drug in the mixed solvent decreases exponentially as the concentration of cosolvent is decreased linearly.

This frequently results in a situation in which the drug concentration exceeds the solubility, as shown in Fig. 1. The curve in Fig. 1 represents the solubilization of alprazolam in the propylene glycol–water system. The shape of this curve indicates an exponential increase in solubility with increasing cosolvent composition. This commonly encountered dependency of solubility on cosolvent composition has been explained previously (8, 9). The dashed lines show dilution curves for two 1.0-mg/ml alprazolam formulations: the upper line represents a formulation containing 40% propylene glycol (minimum needed to solubilize the drug) and the lower line represents the alprazolam formulation used in this study (55% propylene glycol). When the concentration line is above the solubility curve, the solution is supersaturated. If the formulation is diluted further, the dilution line again crosses the solubility curve, and the solution becomes unsaturated as it approaches infinite dilution. The distance between the concentration line and the solubility curve is equal to the amount of supersaturation. The length of the dilution line between the crossover points is a measure of the time that the drug will be supersaturated when it is being diluted.

It is clear from the figure that the dilution line for the formulation containing 55% propylene glycol is much closer to the solubility curve than the line for the 40% propylene glycol formulation. Consequently, there is a much lower probability of drug precipitation in the former formulation on dilution. The excess cosolvent present also helps to prevent precipitation when the formulation is cooled (as can happen during shipping in the winter season).

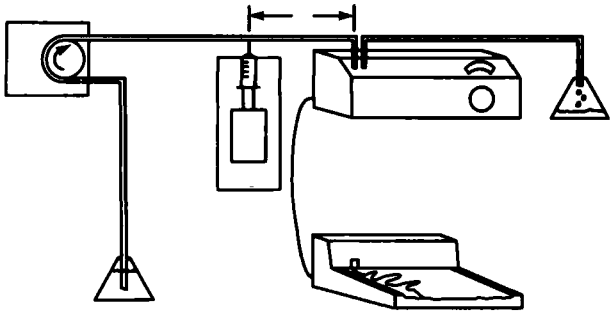

Figure 2—*Schematic of the apparatus used to detect precipitation.*

Table III—Composition of Diazepam and Alprazolam Injectable Formulations

Component	Diazepam	Alprazolam
Active ingredient	5.0 mg/ml	1.0 mg/ml
Benzyl alcohol	1.5%	—
Sodium benzoate–benzoic acid	5.0%	—
Ethanol	10%	—
Propylene glycol	40%	55%

As stated, both concentration lines fall below the solubility curve at high dilution. This indicates that any formed precipitate would redissolve on further dilution. It does not, however, give any indication as to the rapidity of the redissolution. In fact, this step is usually very slow. Therefore, it is not advisable to rely on redissolution as a means of avoiding precipitation.

Using the aforementioned technique, it is possible to estimate the precipitation potential of a drug on the basis of its solubility in water and in the cosolvents used. However, these estimates are based on equilibrium data and do not account for kinetic factors, such as crystal growth rate, fluid (or blood) flow rate, and injection rate. (The last two parameters determine the formulation dilution rate.) A more meaningful assessment of precipitation potential requires a dynamic system in which the above factors are controlled to the greatest extent possible.

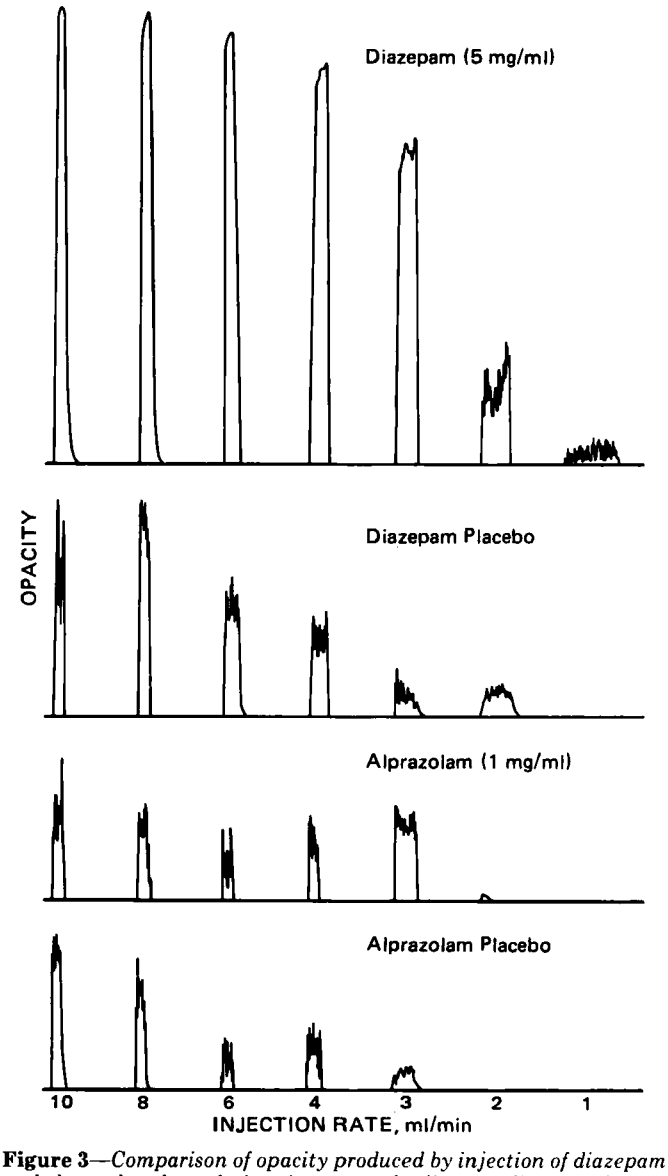

Figure 3—*Comparison of opacity produced by injection of diazepam and alprazolam formulations into normal saline at a distance of 15 cm from the flow cell.*

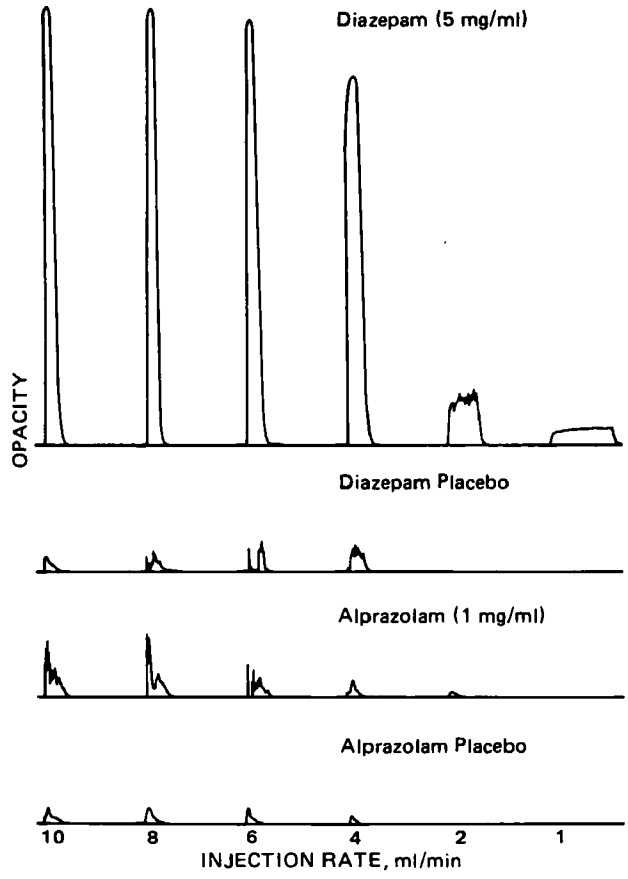

Figure 4—*Comparison of opacity produced by injection of diazepam and alprazolam formulations into normal saline at a distance of 30 cm from the flow cell.*

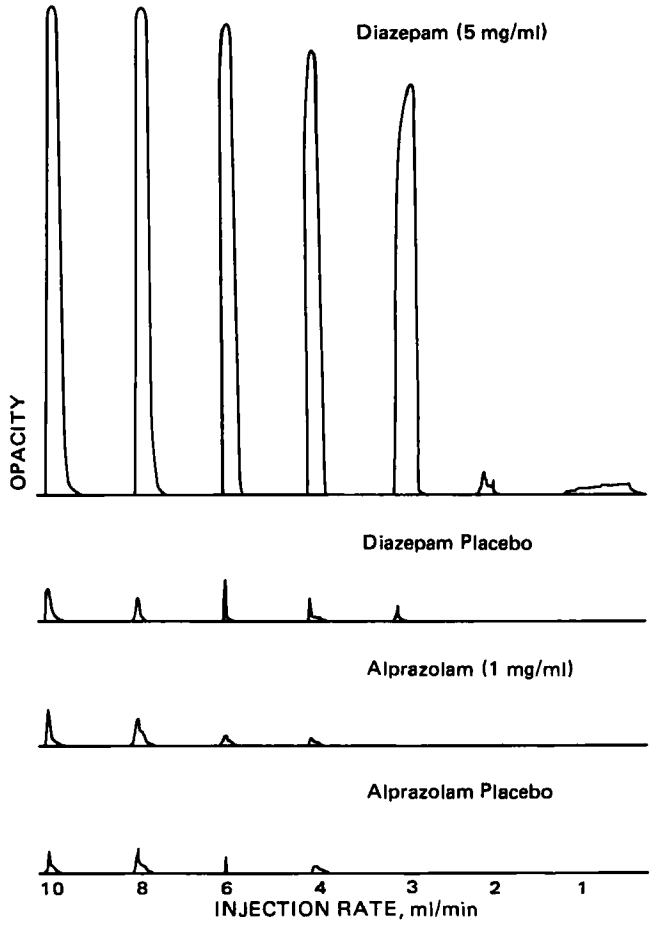

Figure 5—*Comparison of opacity produced by injection of diazepam and alprazolam formulations into normal saline at a distance of 45 cm from the flow cell.*

In this report a simple laboratory experiment is described that provides a semiquantitative evaluation of precipitation formation in a dynamic system. This is used to determine the effect of injection rate on precipitation and to compare parenteral formulations of the antianxiety drugs diazepam[1] and alprazolam[2]. Some of the important physicochemical properties of both drugs are presented in Table II.

This type of experiment is not intended to replace *in vivo* testing. It can, however, provide an early warning as to whether a precipitation problem should be anticipated.

EXPERIMENTAL

Methods—The apparatus used in this study is shown schematically in Fig. 2. It was developed to provide a reasonable simulation of the events that occur when a drug formulation solubilized with a cosolvent is injected into the venous system or into an intravenous drip tube.

A peristaltic pump provided flow of an aqueous phase at a rate of 30 ml/min through a 2.50-mm tube and a 2.0-mm quartz flow cell. The aqueous phases used were 0.9% sodium chloride (normal saline) in distilled water and 5.0% dextrose in deionized water (D5W). Drug formulation or placebo solution was injected into the tubing through a 20-gauge needle inserted 15, 30, or 45 cm upstream of the flow cell. A syringe pump[3] was used to control the rate of drug injection. The injection rate varied from 1.0 to 10 ml/min, but the total volume injected was kept constant at 1.0 ml. Injection rates of 10, 8, 6, 4, 3, 2, and 1 ml/min were attained by injecting 1 ml of solution in 6.0, 7.5, 10, 15, 20, 30, and 60 sec, respectively. The appearance of drug precipitate was detected by measuring the optical transmittance through the flow cell in a spectrophotometer. For both diazepam and alprazolam formulations, any absorption at 400 nm was attributed to the opacity caused by the passage of precipitate through the flow cell. Changes in absorbance were monitored on a strip-chart recorder (see *Results*). This study was conducted at room temperature (20–23°).

Materials—The sodium chloride, dextrose, propylene glycol, ethanol, sodium benzoate, benzoic acid, benzyl alcohol, and distilled water were USP quality and were obtained from commercial sources. Alprazolam injectable was prepared by dissolving the drug in propylene glycol and then adding the required quantity of water. Diazepam injectable[4] was purchased. The composition of the diazepam and alprazolam injectable formulations are given in Table III.

RESULTS

The recorder tracings generated by injecting diazepam and alprazolam formulations and their respective placebos into normal saline at distances of 15, 30, and 45 cm from the flow cell are shown in Figs. 3, 4, and 5, respectively. Those obtained by injecting the same formulations into D5W at a distance of 30 cm from the flow cell are shown in Fig. 6.

Replacing the following aqueous fluid with diazepam vehicle and injecting diazepam formulation produced no opacity under any of the above conditions. Likewise, injecting alprazolam into its own vehicle under the above conditions produced no opacity.

It is clear from Figs. 4 and 6 that there is no significant difference between the results obtained in normal saline at 30 cm and the results obtained in D5W at the same distance. Changing the tubing diameter had no significant effect on the opacity observed. Changing the rate of flow of the fluid into which the formulations were injected produced an effect similar to changing the distance from the injection site to the flow cell. The following trends are apparent in each of Figs. 3–6:

1. Short distances between the injection site and the flow cell tend to produce higher opacity readings.
2. The faster the injection rate, the greater the opacity.
3. The diazepam formulations show the greatest degree of opacity under all tested conditions.

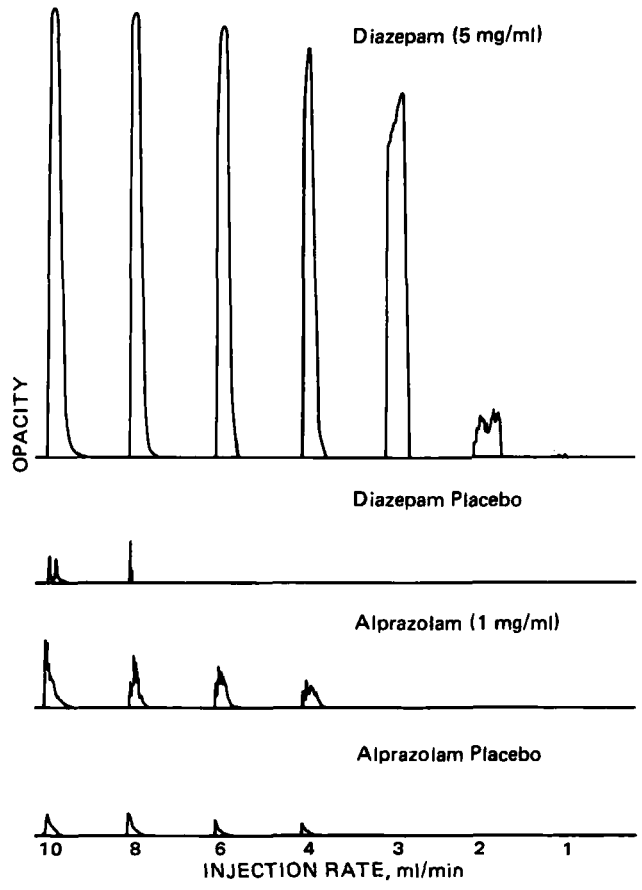

Figure 6—*Comparison of opacity produced by injection of diazepam and alprazolam formulations into 5% dextrose at a distance of 30 cm from the flow cell.*

DISCUSSION

Distance from Injection Site—In all cases, the placebo formulations produced little or no opacity when injected at distances of 30 and 45 cm from the flow cell. At 15 cm, however, the more rapid injection rates produced measurable changes in the transmission of light through the cell. Since the placebo formulations contained no material that is insoluble in the flowing aqueous fluid, the apparent opacity cannot be due to precipitation. The decrease in light transmission through the flow cell after rapid injection of placebo formulations at short distances is due to Schlieren patterns. These wavy patterns form when two liquids of different refractive indices are partially mixed; scattering light and, thus, reducing transmission. They are less prevalent at longer distances, which provide more time for the liquids to mix completely before passing through the flow cell. (This effect can be easily demonstrated by adding glycerin or propylene glycol to water. At first there are striations of Schlieren patterns in the mixture. As mixing progresses, these patterns disappear and the solution becomes clear.)

Injection Rate—Under all of the conditions considered, no opacity was produced when the formulations were injected at a rate <1.0 ml/min. At this slow rate of addition, the formulation is diluted very rapidly by the flowing aqueous phase. At more rapid injection rates, the formulation is diluted more slowly. The dilution ratio is equal to the rate of injection divided by the rate of flow of the aqueous fluid. If the formulation is injected at a rate of 1.0 ml/min and the fluid flowrate is 30 ml/min, the dilution ratio is equal to 30; if the injection rate is increased 10-fold, the dilution ratio is reduced 10-fold (to 3.0). When the dilution ratio is large and the dilution is rapid, there is little time for nucleation and crystal growth and, thus, less likelihood of precipitation. Rapid injection and the accompanying slow dilution provide more time for the formation and growth of crystal nuclei.

An additional explanation for the effect of injection rate on the amount of precipitate formation is as follows. The segment or plug of fluid containing the injected formulation tends to remain more or less intact as it flows through the tube to the flow cell: there is only poor lateral mixing in the narrow tube. The magnitude of precipitation in the plug of diluted formulation will depend on the degree of supersaturation in the plug. If the plug is highly supersaturated, the potential for precipitation is greater than if the drug concentration is only slightly above its solubility. Of course, if the concentration of drug in the plug is below the solubility limit, there is no potential for precipitation. This ideal situation is achieved when the drug is injected very slowly and the dilution ratio is very large. These results clearly show the advantage of slow intravenous administration of solubilized drugs.

Comparison of Diazepam and Alprazolam—It is obvious from Figs. 3–6 that diazepam has a high tendency to precipitate when injected, and that alprazolam shows little or no tendency to precipitate. This is not due to differences in pK_a (Table II) since both drugs are essentially completely un-ionized at physiological pH. The difference results from a combination of several factors: (*a*) the concentration of diazepam is much higher than that of alprazolam in the injection formulations, (*b*) diazepam is less soluble in water than alprazolam, and (*c*) the formulation of diazepam studied does not have excess cosolvent (as does the alprazolam formulation). This *in vitro* study indicates that formulation of a solubilized drug should be designed so that the solubility of the drug is not exceeded as it comes into contact with an aqueous environment. Based on the results of this study, excess cosolvent should be added to protect the drug against the solubility-reducing effect of the aqueous medium into which it is injected.

Determination of Phenylpropanolamine in Serum and Urine by High-Performance Liquid Chromatography

R. DOWSE, J. M. HAIGH, and I. KANFER ˣ

Received June 18, 1982, from the *School of Pharmaceutical Sciences, Rhodes University, Grahamstown 6140, South Africa.* Accepted for publication August 13, 1982.

Abstract □ A high-performance liquid chromatographic analysis of phenylpropanolamine in human serum and urine without prior derivatization is presented. Using direct UV detection the method is sufficiently sensitive to detect 25 ng of drug/ml of serum or urine; the coefficients of variation at 25 ng/ml and 500 ng/ml were 5.16 and 2.12, respectively, in serum. The method involves serum and urine extraction at a basic pH with chloroform, a single back-extraction, and chromatography on a reverse-phase column. Serum and urine data following administration of a single 150-mg sustained-release tablet of phenylpropanolamine hydrochloride in six healthy volunteers demonstrates the suitability of the analytical method.

Keyphrases □ Phenylpropanolamine—determination by high-performance liquid chromatography without prior derivatization, human serum and urine □ High-performance liquid chromatography—phenylpropanolamine, determination in human serum and urine without prior derivatization

Phenylpropanolamine, a sympathomimetic amine, used to relieve congestion of the nasal mucosa and sinuses in the treatment of colds, sinusitus, rhinitis, and hay fever is also used as an appetite suppressant (1). Phenylpropanolamine has been determined in plasma by GLC following derivatization with pentafluorobenzaldehyde (2) and also as the heptafluorobutyryl derivative (3). Urine phenylpropanolamine levels have been analyzed by nitrogen-selective GLC (4, 5). High-performance liquid chromatography (HPLC) has been used for the determination of phenylpropanolamine alone and in pharmaceutical formulations (6–11), but little information has appeared on the HPLC analysis of phenylpropanolamine in biological fluids (12, 13).

Endo *et al.* (12) used a color reaction with sodium β-naphthoquinone-4-sulfonate after extraction from alkaline urine to determine phenylpropanolamine by HPLC, but this method is time consuming and no indication is given as to the levels of phenylpropanolamine determined. The HPLC method described by Mason and Amick (13) involved extraction from plasma, back-extraction, and *o*-phthalicdicarboxaldehyde derivatization after which fluorescence detection was used to determine concentrations of phenylpropanolamine as low as 5 ng/ml.

The purpose of this study was to develop a sensitive, reproducible, and rapid method to determine phenylpropanolamine in serum and urine without prior derivatization.

EXPERIMENTAL

Apparatus—The modular high-performance liquid chromatograph consisted of a constant-flow pump[1], an automated sample injector[2], a variable-wavelength UV detector[3], and a data module[4]. The separation was performed on a 30-cm × 4-mm i.d. column containing microparticulate-bonded (10-μm) octadecylsilane material[5]. The temperature of the column was maintained at 20° [6].

Reagents and Materials—Reagents were of at least analytical reagent grade quality and the acetonitrile[7] was distilled in glass. Phenylpropanolamine hydrochloride[8], ephedrine hydrochloride[9], chloroform[10], and sodium 1-heptanesulfonate[11] were obtained commercially. Water was deionized and then double-distilled in glass.

Chromatographic Conditions—The mobile phase was prepared by mixing acetonitrile (250 ml) with a 0.005 *M* solution of sodium 1-heptanesulfonate in water (750 ml) and adding 1 *M* HCl (2 ml). The solvent mixture (pH 2.5) was deaerated and filtered through a 0.6-μm filter[12]. This mobile phase was used at a flow rate of 1.3 ml/min for the analysis of both serum and urine samples, with a resulting pressure of 230 bar. The wavelength of detection was 220 nm.

Extraction—*Serum*—One milliliter of serum, 1 ml ephedrine hydrochloride solution (0.24 μg/ml), and 50 μl of a saturated solution of sodium carbonate, which adjusted the pH of the mixture to 10, were vortexed for 15 sec in a test tube[13] (16 × 100 mm). Five milliliters of chloroform were added and the tube was stoppered, vortexed for 1 min, and centrifuged at 2000×*g* for 5 min. A plug formed between the aqueous and organic phases, and the aqueous layer above this plug was removed by aspiration and discarded. A pasteur pipet was used to transfer the chloroform extract to a tapered centrifuge tube containing 100 μl of 5% (v/v) acetic acid. The pipet was rinsed with 2 ml of chloroform, which was then added to the original test tube, vortexed for 30 sec, and centrifuged at 2000×*g* for 5 min. The chloroform washings were added to the tapered centrifuge tube, vortexed for 1 min, and centrifuged at 600×*g* for an additional minute. The chloroform layer was reduced by aspiration to ~200 μl and discarded, and the tube was again centrifuged at 2000×*g* for 5 min.

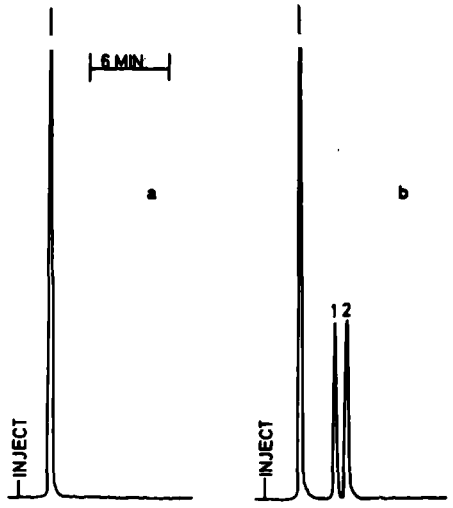

Figure 2—*HPLC chromatograms of (a) blank urine extract and (b) an extract of urine containing phenylpropanolamine (1) and ephedrine (2).*

Aliquots of 15–30 μl of the acetic acid extract were injected directly onto the column. Typical chromatograms are depicted in Fig. 1.

Urine—To 1 ml of urine in a test tube were added an aqueous solution of 1 ml of ephedrine hydrochloride (40 μg/ml) and 50 μl of a saturated solution of sodium carbonate (to adjust the pH to 10). The tube was vortexed for 15 sec, 5 ml of chloroform was added, and the tube was stoppered and vortexed again for 1 min. After centrifugation at 2000×*g* for 5 min, the chloroform extract was transferred with a pasteur pipet to a tapered centrifuge tube containing 1 ml of 5% (v/v) acetic acid. The pipet was rinsed with 2 ml of chloroform, which was then added to the original tube, vortexed for 30 sec, and centrifuged at 2000×*g* for 5 min. The chloroform washings were added to the centrifuge tube, vortexed for 1 minute and centrifuged at 2000×*g* for 5 min. Aliquots of 1–8 μl of the upper acetic acid extract were injected onto the column. Typical chromatograms are depicted in Fig. 2.

Clinical Study—As part of a bioavailability study, six normal healthy volunteers each received one sustained-release tablet containing 150 mg of phenylpropanolamine hydrochloride following an overnight fast. Blood samples were drawn at 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 8, 9, 10, 12, and 24 hr after ingestion of the medication; the serum was separated by centrifugation and frozen until assayed. Urine samples were collected at 0, 2, 4, 6, 8, 12, and 24 hr, and representative samples were frozen until analysis. Urine voided at times other than those specified above was collected and treated in the same manner.

RESULTS

Linearity—Calibration curves using five different concentrations of phenylpropanolamine in serum and urine, obtained by plotting the ratio of the peak height of phenylpropanolamine to that of the internal standard (ephedrine) *versus* their respective concentrations, were linear over the concentration ranges studied. The calibration curve in serum (25–500 ng/ml) had a slope of 0.0039 and a *y*-intercept of 0.0509 with a correlation coefficient of 0.9997, while the curve in urine (10–200 μg/ml) had a slope of 0.0265 and a *y*-intercept of 0.0386 with a correlation coefficient of 0.9999.

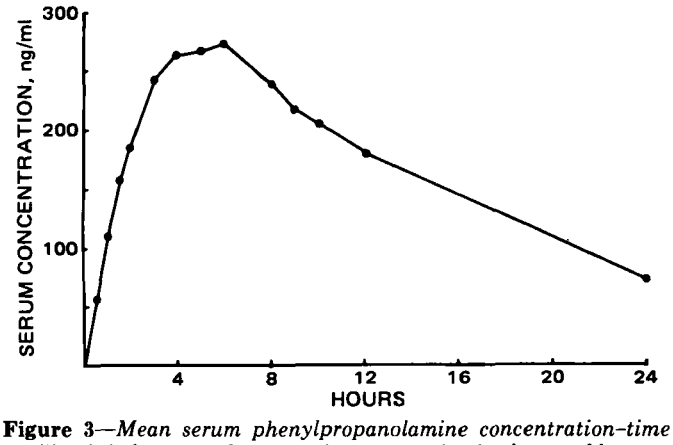

Figure 3—*Mean serum phenylpropanolamine concentration–time profile of six human volunteers given a sustained-release tablet containing 150 mg of drug.*

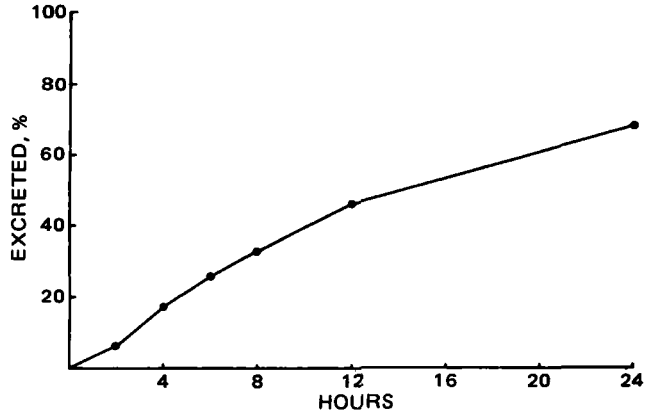

Figure 4—*Mean cumulative urinary phenylpropanolamine concentration–time profile of six human volunteers given a sustained-release tablet containing 150 mg of drug.*

Precision and Accuracy—Within-run precision was assessed by extracting five spiked serum and urine samples each at the upper and lower limits of the concentration ranges studied. The coefficients of variation were found to be 5.16% at 25 ng/ml and 2.12% at 500 ng/ml for serum and 1.66% at 10 μg/ml and 0.33% at 100 μg/ml for urine. Corresponding standard deviations for these samples were 1.26 ng/ml, 10.75 ng/ml, 0.155 μg/ml, and 0.324 μg/ml, respectively. Replicate assays in serum and urine samples determined over a period of 3 months (stored at −10°) revealed no significant differences in phenylpropanolamine concentrations.

Extraction Efficiency—Spiked serum and urine samples were assayed in triplicate at four different concentrations. All samples were extracted as described previously except that the internal standard was added as a final step to each extract. The results were compared with those obtained from the injection of equivalent concentrations of phenylpropanolamine in the internal standard solution. Mean values of 80.39 and 80.20% recovery were obtained for phenylpropanolamine from serum and urine, respectively.

Sensitivity and Detection Limit—Under the conditions of this assay, the detection limit for phenylpropanolamine was 25 ng/ml in serum and 10 μg/ml in urine. These lower limits can be extended, particularly in the case of urine, if smaller volumes of 5% (v/v) acetic acid are used in the back-extraction step.

Serum and Urine Profiles—The mean serum concentration–time profile is presented in Fig. 3. Figure 4 represents the cumulative urinary excretion profile for the six subjects who received one sustained-release tablet containing phenylpropanolamine hydrochloride (150 mg).

DISCUSSION

The method described involved a rapid, relatively simple extraction of phenylpropanolamine from urine and serum. Previous HPLC methods used to determine this drug in biological fluids have involved either derivatization with *o*-phthalicdicarboxaldehyde followed by fluorescence detection (13) or the use of a normal-phase column followed by reaction with sodium β-naphthoquinone-4-sulfonate and subsequent colorimetric determination (12). The latter method was applied to urinalysis only, and concentrations relating specifically to phenylpropanolamine were not reported. Both these methods are relatively time consuming and involve postcolumn manipulations.

Our method eliminates the derivatization step, thus allowing direct determination using a variable-wavelength UV detector. The method is sufficiently sensitive, accurate, and precise for the monitoring of phenylpropanolamine concentrations in small volumes of both serum and urine following oral doses of the drug. In addition, the resulting chromatograms are clean with no interfering peaks due to endogenous constituents. Metabolite interference did not present a problem since no significant metabolism of phenylpropanolamine occurs (14). Retention times of phenylpropanolamine and ephedrine were 4.8 min and 5.7 min,

respectively. In summary, the HPLC method presented here is rapid, precise, and extremely suitable for the determination of phenylpropanolamine in serum and urine.

High-Performance Liquid Chromatographic Determination of Aspirin and Its Metabolites in Plasma and Urine

SHAMSUL K. BAKAR and SARFARAZ NIAZI ˣ

Received December 3, 1981, from the *Department of Pharmacodynamics, College of Pharmacy, University of Illinois Health Sciences Center, Chicago, IL 60612.* Accepted for publication February 25, 1982.

Abstract □ A simple quantitative method for the rapid determination of aspirin and its metabolites, salicylic acid, salicyluric acid, and gentisic acid, in plasma and urine using *o*-toluic and *o*-anisic acids, respectively, as internal standards was developed. Plasma proteins were precipitated by the addition of acetonitrile and, after centrifugation, the supernatant fluid was injected directly onto a reverse-phase column. The mobile phase consisted of an isocratic mixture of water, methanol, and glacial acetic acid (64:35:1, v/v/v) and the separated components were detected at 238 nm using a UV detector. Concentrations ≥0.5 μg/ml could be quantitated for aspirin or its metabolites in plasma. The peak heights and peak height ratios to the internal standard, *o*-toluic acid, were linear for the concentration range of 0.5–200 μg/ml. The aspirin metabolites in urine were isolated by extracting the acidified urine with ether and then reextracting the material into an aqueous buffer solution at pH 7.0. Twenty microliters of the buffer extract was directly injected onto the column. The separated components were detected and quantitated at 305 nm. Concentrations ≥5 μg/ml of salicyluric acid, salicylic acid, and gentisic acid could be determined accurately. The peak heights and peak height ratios to the internal standard, *o*-anisic acid, were found to be linear for the concentration range of 5–200 μg/ml in urine.

Keyphrases □ Salicylates—aspirin and metabolites, quantitation in urine and plasma, high-performance liquid chromatography □ Metabolites—of aspirin, quantitation in urine and plasma, high-performance liquid chromatography □ High-performance liquid chromatography—quantitation of aspirin and metabolites, urine and plasma

Aspirin is one of the most extensively used drugs. Recently, the importance of monitoring plasma levels of salicylates has been reviewed (1). A number of high-performance liquid chromatographic (HPLC) methods for the analysis of aspirin and its metabolites in plasma and urine have been reported (2–7). Few of the reported methods (3, 6) can determine aspirin in plasma, and they employ time-consuming extraction procedures. Since aspirin is rapidly hydrolyzed in blood and plasma (8), extraction procedures which delay the analysis of the sample will yield inaccurate results, underestimating the quantity of aspirin. Therefore, this work was initiated to develop a method for the rapid analysis of plasma samples for aspirin, salicylic acid, salicyluric acid, and gentisic acid, which does not require an extraction step.

The analysis of urine for the metabolites of aspirin using a simple extraction procedure is also desirable since urine usually contains a large number of acidic components (9, 10). Better results are obtained by eliminating as many undesirable components from the sample as possible before analysis. Injecting the urine onto a column without extraction (7, 11) shortens the useful life of the chromatography column.

EXPERIMENTAL

Materials—Aspirin USP[1], salicylic acid[1], salicyluric acid[1], gentisic acid[1], *o*-toluic acid[1], *o*-anisic acid[1], glacial acetic acid[2], anhydrous ether[3], acetonitrile[4], and methanol[4] were obtained commercially. The mobile phase consisted of water–methanol–glacial acetic acid (64:35:1, v/v/v), filtered and deaerated under reduced pressure.

Instrumentation—A dual-pump high-performance liquid chromatograph[5] equipped with a variable-wavelength UV detector[6], a 20-μl loop injector[7], and a reverse-phase microparticulate column[8] was used. The UV detector was connected to a linear recorder[9].

Stock Solutions—For the standard curves in plasma, aspirin, salicylic acid, salicyluric acid, and gentisic acid were singly dissolved in water–

[a] Concentration in μg/ml. [b] Correlation coefficient.

acetonitrile (2:1) to produce solutions with final concentrations of 600 μg/ml. Due to the instability of aspirin in the solution, new solutions were prepared before each analysis. For the standard curves in urine, salicylic acid, salicyluric acid, and gentisic acid were dissolved together in water–acetonitrile (2:1) using a shaker[10] to yield a solution with a final concentration of 500 μg/ml for each of the components. The solution was kept refrigerated to avoid microbial degradation of the salicyluric and salicylic acids.

Internal Standards—The internal standard in plasma, *o*-toluic acid, was dissolved in water–acetonitrile (2:1) to yield solutions with concentrations of 50 and 500 μg/ml. For plasma samples containing 20–200 μg/ml of aspirin, salicylic, salicyluric, and gentisic acids, the concentration of the internal standard was 100 μg/ml; for plasma samples containing <20 μg/ml of the components, the internal standard concentration was 10 μg/ml.

The internal standard for urine, *o*-anisic acid, was dissolved in water to produce a solution with a concentration of 500 μg/ml. When the concentration of salicylic acid and its metabolites in urine was ≥40 μg/ml, the concentration of internal standard used was 100 μg/ml; when the salicylate concentration was <40 μg/ml in urine, the internal standard concentration was 20 μg/ml.

Standard Curves—*Plasma*—To 100 μl of rat plasma in a 500-μl polypropylene microcentrifuge tube[11], stock solution, the internal standard, water, and acetonitrile were added in such proportions that the final volume in each tube was 450 μl (300 μl of acetonitrile and 150 μl of a water–plasma mixture). The concentration of aspirin, salicylic acid, salicyluric acid, and gentisic acid ranged from 0.5 to 200 μg/ml in the water–plasma mixture. The internal standard concentration was 100 μg/ml in the mixture if the aspirin concentration was >20 μg/ml and 10 μg/ml if the aspirin concentration was ≤20 μg/ml.

The contents of the tube were vortexed[12] for 1 min and then centrifuged[13] for 5 min at 15,000 rpm. Twenty microliters of the supernatant was introduced directly onto the column at ambient temperature. The flow rate for the mobile phase was set at 2 ml/min (at 2800 psi), and the chart speed was 1 cm/min. The separated components were monitored at 238 nm, and the responses were recorded at 10 mV with proper attenuation of the recorder. The peak height and peak height ratio for each of the components in plasma were calculated.

For unknown samples, 50 μl of the plasma was precipitated with 100 μl of acetonitrile containing the internal standard in a 500-μl polypropylene microcentrifuge tube. This mixture was vortexed and centrifuged as described above for the standard curve. Twenty microliters was injected onto the column through the loop injector, and the peak height and peak height ratio of the separated components were calculated.

Urine—To 1 ml of urine contained in a 13-mm × 100-mm borosilicate glass culture tube with a polytef-lined screw cap, was added the salicylate

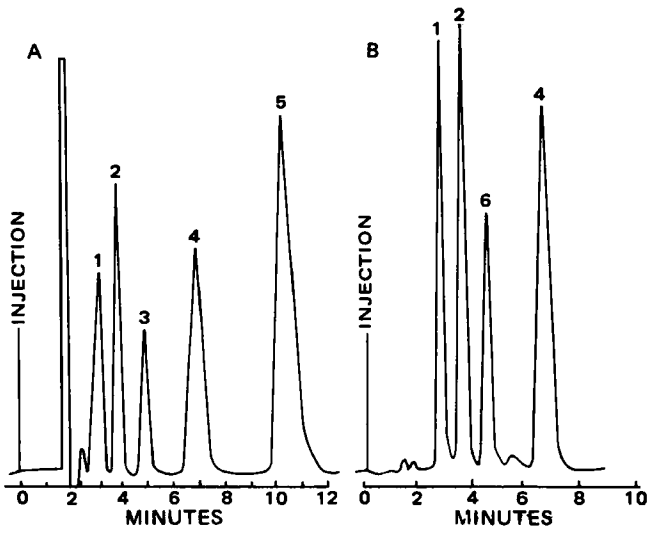

Figure 1—*Chromatograms of salicylic acid in blood (A) and urine (B). Key: (1) gentisic acid; (2) salicyluric acid; (3) aspirin; (4) salicylic acid; (5) o-toluic acid; (6) o-anisic acid. The concentrations for all components are 5 μg/ml in blood and 10 μg/ml in urine.*

mixture in aqueous solution to give concentrations ranging from 5 to 500 μg/ml. The concentration of *o*-anisic acid, the internal standard, was 100 μg/ml of urine when the salicylate concentration was ≥40 μg/ml and 10 μg/ml of urine if the salicylate concentration was <40 μg/ml in urine. One-half milliliter of 6 *N* HCl and 6 ml of anhydrous ether were also added, and the mixture was shaken for 15 min in a shaker and centrifuged for 10 min at 2000 rpm to separate the ether layer from the aqueous layer.

Five milliliters of the ether extract was transferred to another tube, and 1 ml of phosphate buffer (0.1 *M*, pH 7.0; prepared by dissolving 13.61 g of potassium dihydrogen phosphate and 2.38 g of NaOH pellets in water to make 1 liter) was added. The system was shaken for 15 min and then centrifuged at 2000 rpm for 10 min. The ether layer was aspirated, and 20 μl of the aqueous buffer solution was directly injected onto the column under conditions identical to those described earlier for plasma, except that the eluate was monitored at 305 nm.

For the unknown urine samples, 1 ml of urine was acidified with 0.5 ml of 6 *N* HCl. The rest of the procedure was the same as that described above.

Accuracy and Precision Studies—Both the plasma and urine were spiked with aspirin and its metabolites (salicylic acid, salicyluric acid, and gentisic acid) to yield mixtures with concentrations ranging from 25 to 200 μg/ml. Five samples from each of these concentrations were processed appropriately and analyzed as described earlier for the preparation of the standard curves in plasma and urine.

RESULTS AND DISCUSSION

Standard Curves in Plasma and Urine—Figure 1 shows a typical chromatogram of aspirin and its metabolites in spiked plasma and urine. The components were well separated both in plasma and urine. The peaks were identified by their retention times, determined for each component by injecting the compounds individually. Additional identifications were made by injecting different concentrations of the same compound and observing the proportional changes in the peak height and peak height ratio. The retention time for each component was found to be constant at all concentrations, and the values for gentisic acid, salicyluric acid, aspirin, *o*-anisic acid, salicylic acid, and *o*-toluic acid were 3.0, 3.7, 4.8, 5.0, 7.1, and 10.2 min, respectively.

Tables I and II list the peak heights and peak height ratios from the analysis of aspirin and its metabolites in plasma and urine, respectively. Both peak heights and peak height ratios were linear for the concentration range studied in plasma (0.5–200 μg/ml) and in urine (6–200 μg/ml). This was evident from the correlation coefficients (*r*) obtained for the regression line (Table III). The high values of *r* confirmed that there was an excellent linearity between the salicylate concentration and the peak height and peak height ratio, both in plasma and urine.

Recovery Studies in Plasma and Urine—Table IV shows the percent recovery of aspirin and its metabolites in plasma. The percent recoveries are similar at different concentrations. The greatest recovery was of aspirin (99%), followed by salicyluric acid (94%), salicylic acid (91%), and gentisic acid (62%).

It has been reported that salicylic acid and its metabolites, salicyluric acid and gentisic acid, are completely recovered in the aqueous acetonitrile phase following precipitation of plasma with an equal volume of acetonitrile (5). It has also been observed that one volume of acetonitrile is not sufficient to completely precipitate the protein in plasma (12). Preliminary experiments showed that two volumes of acetonitrile, rather than three, were sufficient to precipitate the proteins in plasma. This reduced the dilution of the components in plasma, thus increasing the sensitivity of the analytical method.

Ideally, the entire amount of the salicylates should be present in the plasma–acetonitrile supernatant. But the fact that not all the components were recovered completely from the plasma suggests that there was some kind of binding of the salicylates, especially gentisic acid (~38%), with the precipitated proteins.

The recovery studies with urine samples at different concentrations showed that all the components were equally extracted both from urine and water. When chloroform was used instead of ether, aspirin and salicylic acid were extracted almost completely, but the extraction of gentisic acid and salicyluric acid was poor (<50%). The overall recoveries from the urine using the proposed procedure were calculated to be 97, 95, 92, and 91% for gentisic, salicyluric, *o*-anisic, and salicylic acids, respectively.

Accuracy and Precision Studies in Plasma and Urine—The method proposed here eliminates the necessity of evaporating the organic phase, which is time consuming and involves a number of steps which may result in large variations in the analytical data (3, 6). Since the method described does not involve extraction steps, the variation in the data is considerably decreased; this is reflected by the data in Tables V and VI for plasma and urine, respectively. The low coefficients of variation (*CV*) and the narrow range in each of the concentrations studied suggest that the analytical method is precise and accurate.

This method has little dilution effect since 1 ml of the urine was finally extracted into 1 ml of buffer. In this respect, the method for urine analysis was more sensitive than that for plasma, since the plasma was diluted twice with acetonitrile.

Using this method, some sensitivity is lost because of the selection of 305 nm as the detection wavelength. At this wavelength, the absorptivity of different salicylate metabolites has been found to be less than at 238 nm. However, the latter wavelength cannot be used for urine samples because of numerous endogenous acidic components present in the urine (9, 10) that interfere with the analysis of the salicylate metabolites. At 305 nm the peaks are well separated and the metabolites are detected with sufficient sensitivity.

The proposed method could also be adapted for smaller urine samples (≤100 μl) or urine samples containing submicrogram quantities of aspirin metabolites simply by evaporating the 5 ml of ether extract and dissolving the residue in ~50 μl of the mobile phase.

Selection of Internal Standards—*o*-Anisic acid was used as the in-

[a] $n = 5$.

ternal standard in urine. This compound has been used previously as an internal standard in plasma samples (5), but not in urine samples which had been processed by an extraction procedure. However, *o*-anisic acid could not be used for the analysis of aspirin because of the close proximity of their retention times (4.8 and 5.0 min for aspirin and *o*-anisic acid, respectively). This problem was solved by selecting *o*-toluic acid, which has a retention time of 10.2 min, well beyond the peak of salicylic acid. Its absorptivity at 237 nm is comparable with salicylic acid. However, in urine, *o*-anisic acid was used as an internal standard instead of *o*-toluic acid because of the long retention time of the latter.

In HPLC analyses of aspirin metabolites, the peaks for gentisic acid and salicyluric acid frequently overlap (7). In the present study, the mobile phase developed for the analysis was very efficient in separating the peaks for gentisic and salicyluric acids and in preventing the tailing of the salicylic acid peak.

Stability of Aspirin in Different Media

SHAMSUL K. BAKAR and SARFARAZ NIAZI ˣ

Received December 3, 1981, from the *Department of Pharmacodynamics, College of Pharmacy, University of Illinois Health Sciences Center, Chicago, Ill 60612.* Accepted for publication May 12, 1982.

Abstract □ Aspirin rapidly hydrolyzes in various aqueous, organic, and biological media. The purpose of this investigation was to study the decomposition of aspirin in the media that comes in contact with it during analysis in biological fluids for pharmacokinetic studies. These media included water, water–polyethylene glycol 400, water–methanol–acetic acid, phosphate buffer, freshly drawn blood and plasma from control rats and rats deprived of water for 36 hr, and blood precipitated with acetonitrile. Studies were also conducted to determine the decomposition as a function of temperature and pH. Of the various solvent systems studied, aspirin was found most stable in water–polyethylene glycol (4:1, v/v), which provides an excellent medium for preparation of intravenous dosage forms. Phosphate buffer showed significant catalysis of aspirin hydrolysis. A more than fivefold increase in the hydrolysis of aspirin was noted when the temperature was raised to 37° from 22.5°. The hydrolysis of aspirin in rat blood was 13 times faster than that in plasma, with an average half-life in blood of ~13 min. This creates significant problems in aspirin disposition kinetic studies. Mixing the blood sample immediately after collection with twice the volume of acetonitrile and then centrifuging gives a plasma–acetonitrile mixture in which no lysis of blood cells is observed.

Keyphrases □ Aspirin—stability in media, human blood and plasma, hydrolysis kinetics □ Kinetics—aspirin hydrolysis in media, human blood and plasma, stability □ Stability—of aspirin in media, human blood and plasma, hydrolysis kinetics

The spontaneous hydrolysis of aspirin in suspensions can be stabilized by the addition of polyethylene glycol 6000, povidone, or sorbitol (1). The former two additives form viscous insoluble masses; sorbitol is therefore the only potential stabilizer of aspirin in suspensions. The hydrolysis rate constant of aspirin decreases in the presence of surfactants due to the migration of aspirin molecules into the micelles where they are unavailable for hydrolysis (2, 3), but the undissociated molecules of aspirin are often less stable in the micellar phase than in the aqueous bulk phase (4). The stability of aspirin in polyethylene glycols, both substituted and unsubstituted, has been studied in great detail (5–8). Aspirin is more stable in unsubstituted polyethylene glycols, where the hydrolysis occurs through transesterification which is retarded when the substituted polyethylene glycols are used.

Aspirin is also rapidly hydrolyzed by a group of enzymes broadly termed as aryl esterases. These enzymes are widely distributed in blood, plasma, liver, kidney, and GI tissues (9) and are present in lesser amounts in the other tissues (10). All organs of the human fetus exhibit aspirin-hydrolyzing esterase activity, with the activity increasing during intrauterine development (11).

Sex differences have been observed in the aspirin esterase activity in human serum: activity is more prolonged in males than in females (9,12). However, a sex difference has not been observed in the esterase activity of serum albumin (12). The aryl esterase activity is significantly reduced in chronic hepatitis, liver cirrhosis, and nephrosis (12). The differences between choline, pseudocholine, and the so-called aspirin esterases in serum have been reviewed by Morgan and Truitt (10). A recent finding shows that pseudocholine esterases also participate in the hydrolysis of aspirin in serum (12).

The *in vitro* hydrolysis of aspirin in dilute blood and serum shows significant inter- and intraspecies variability, probably due to differences in the aryl esterase activity (10). At 25° the half-life of aspirin in serum diluted 30 times is 8.1, 12.6, 13.1, 14.7, and 23.3 hr in the rat, rabbit, cat, human, and dog, respectively. Thus, the hydrolysis rate of aspirin in human serum is comparable with that in the rabbit and the cat, while rats and dogs are at the extreme ends of the range. In human blood diluted 30 times, the half-life is calculated to be ~10 hr at 25°.

Significant variations have been observed in the hydrolysis rate of aspirin in serum of different human individuals (10). In human blood or plasma, diluted by 10% with aspirin in isotonic saline, the hydrolysis of aspirin follows apparent first-order kinetics at body temperature with half-lives of 32 and 66 min in blood and plasma, respectively (13).

Compared with aspirin, the enzymatic hydrolysis of salsalate, a dimer of salicylic acid, is much slower in both plasma and blood (14). For example, the half-life of aspirin in 95% whole blood (95 ml of blood plus 5 ml of ethanol containing 10 mg of aspirin) is 50 min, which compares well with the previously reported value (13). But the half-life of salsalate hydrolysis under similar conditions is 854 min, 17 times longer than the half-life of aspirin.

The routine analysis of aspirin in biological fluids involves contact with blood, acetonitrile-precipitated blood, plasma, and other solvent systems such as water–methanol–glacial acetic acid mixtures for high-performance liquid chromatographic (HPLC) analysis, water–polyethylene glycol 400 mixtures, phosphate buffer, *etc.* Because of the instability of aspirin in solution, both biological or nonbiological, it was decided to investigate the rate of hydrolysis of aspirin in these media to estimate the loss of aspirin due to the time lag between blood sampling and analysis. This information would help devise proper storage conditions for blood and plasma samples, minimizing the loss of aspirin during sample preparation. The determination of the rate constants for the hydrolysis of aspirin in blood (both *in vivo* and *in vitro*), plasma, and precipitated plasma would also permit the estimation of the relative contribution of the liver (and other aspirin-hydrolyzing tissues), blood cells, and plasma to the overall disposition of aspirin in the body.

EXPERIMENTAL

Analytical Method—One-hundred microliters of the reaction mixture was diluted with 200 μl of acetonitrile[1], mixed thoroughly and centrifuged[2] for 5 min at 15,000 rpm. Twenty microliters of the supernatant

was analyzed by HPLC as described in the previous paper (15). The mobile phase was an isocratic mixture of water–methanol[1]–glacial acetic acid[3] (64:35:1, v/v/v), and the flow rate was 2 ml/min on a reverse-phase column[4]. The separated components were detected at 238 nm. The concentrations of aspirin and salicylic acid were calculated from the peak heights using appropriate standard curves.

Hydrolysis of Aspirin in Different Solvents—The solvent systems used to study the rate of hydrolysis of aspirin were: (*a*) water at 22.5°, (*b*) water–polyethylene glycol 400[5] (4:1, v/v) at 22.5°, (*c*) water–methanol–glacial acetic acid (64:35:1, v/v/v) at 22.5°, (*d*) phosphate buffer (0.1 *M*, pH 7.0) at 22.5°, and (*e*) phosphate buffer (0.1 *M*, pH 7.4) at 22.5 and 37°. The aspirin stock solution was prepared by dissolving 1 g of aspirin in 25 ml of polyethylene glycol 400, then diluting with sterile normal saline to 100 ml. Forty microliters of the aspirin stock solution was diluted with 1960 μl of the solvent system to make the final reaction mixture of volume 2 ml. Therefore, the concentration of aspirin was 10 mg/ml in the stock solution and 200 μg/ml in the reaction mixture. Samples were collected at appropriate intervals for up to 100 hr and analyzed by HPLC.

Hydrolysis of Aspirin in Plasma, Blood, and Precipitated Blood—Approximately 6 ml of blood was collected from each rat. Two milliliters of this sample was used for the study of aspirin hydrolysis in blood; from the remainder, ~2 ml of plasma was obtained to study the hydrolysis of aspirin in plasma. The following experimental media were used to study aspirin hydrolysis:

1. Fresh plasma from control rats (food and water *ad libitum*) at 22.5°.
2. Fresh plasma from control rats (food and water *ad libitum*) at 37°.
3. Fresh plasma from rats deprived of water for 36 hr (food *ad libitum*) at 37°.
4. Blood precipitated with acetonitrile at 22.5°. Whole blood was precipitated with two volumes of acetonitrile, mixed gently, centrifuged (5 min at 15,000×*g*), and the supernatant was used to prepare the reaction mixture.
5. Blood from control rats (food and water *ad libitum*) at 22.5 and 37°.
6. Blood from rats deprived of water for 36 hr (food *ad libitum*) at 37°.

The reaction mixture for all of the above kinetic determinations was 5 μl of heparin (10,000 U/ml), 40 μl of aspirin stock solution (10 mg/ml), and 1955 μl of plasma (or blood). Therefore, the final concentrations of heparin and aspirin in the reaction mixture was 25 U/ml and 200 μg/ml, respectively. The samples were collected at appropriate intervals, precipitated with two volumes of acetonitrile, and the supernatant was analyzed by HPLC (15).

RESULTS AND DISCUSSION

Hydrolysis of Aspirin in Different Solvent Systems—The rate of hydrolysis of aspirin was followed by direct measurement of the amount of intact aspirin remaining as a function of time. The hydrolysis of aspirin was found to follow apparent first-order kinetics in all solvent systems studied. A minimum of four and maximum of six replicate kinetic runs were conducted for each of the solvent systems used. The concentration–time data were fitted to the linear regression equation for pseudo-first-order kinetics.

Table I lists the observed rate constant (k_{obs}) and the half-lives of aspirin in different solvent systems at the specified temperature. Aspirin was found to be most stable in a water–polyethylene glycol 400 (4:1, v/v) mixture ($t_{1/2}$ = 360 ± 8 hr), followed by the mobile phase ($t_{1/2}$ = 179 ± 5 hr), distilled water ($t_{1/2}$ = 153 ± 4 hr), phosphate buffer at pH 7.4 ($t_{1/2}$ = 82 ± 2 hr), and phosphate buffer at pH 7.0 ($t_{1/2}$ = 75 ± 3 hr) at 22.5°. At 37.0°, the rate constant of aspirin hydrolysis in 0.1 *M* phosphate buffer (pH 7.4) was found to be more than five times the rate constant for the same buffer at 22.5°.

Although aspirin has been reported to be more stable in moisture-free polyethylene glycol (5), its stability data in a water–polyethylene glycol combination are not available in literature. In polyethylene glycol, aspirin is hydrolyzed by a process of transesterification with an activation energy of 20.1 Kcal/mole (5), resulting in much higher stability compared with water alone. Therefore, the water–polyethylene glycol 400 (4:1, v/v) solvent system is superior to water as a vehicle for aspirin in terms of both solubility and stability.

Since aspirin is highly unstable in phosphate buffer, any sample containing aspirin which is extracted with phosphate buffer should be analyzed as quickly as possible. The relatively higher stability of aspirin ($t_{1/2}$ = 179 ± 5 hr) in the mobile phase [an isocratic mixture of water, methanol, and glacial acetic acid (64:35:1, v/v/v)] compared with its stability in water ($t_{1/2}$ = 153 ± 4 hr) at room temperature ensures that there will be no significant on-the-column hydrolysis of aspirin during its analysis by the described HPLC method (15).

Hydrolysis of Aspirin in Plasma and Blood—The hydrolysis of aspirin in plasma and blood is mostly an enzymatic process caused by aryl esterases in plasma and blood cells. Although the enzymes retain their activity for at least 1 week when stored at 5° (15), only freshly drawn blood and plasma were used to conduct the hydrolysis studies of aspirin. The hydrolysis was also performed at two different temperatures, 22.5° and 37.0°, using plasma and blood from water-deprived rats (deprived

of water for 36 hr, but having access to food *ad libitum*). Since sex differences in the rate of hydrolysis of aspirin in blood have been reported (9, 12), only male rats weighing between 300 and 450 g were used in this study.

The hydrolysis of aspirin in blood and plasma follows apparent first-order kinetics. The rate constants (k_{obs}) and the half-lives are listed in Table I. The hydrolysis of aspirin in blood from control rats is more than 13 times faster than in plasma, both at 22.5° and 37.0°. For example, at 37.0°, the half-life of aspirin in blood is 0.21 hr (13 min) compared with 2.8 hr (168 min) in plasma. The corresponding values at 22.5° for blood and plasma are 28 and 456 min, respectively.

The activity of various enzymes such as acid phosphatase, β-glucosidase, β-glucuronidase, β-galactosidase, and *N*-arylamidase has been reported to increase in water-deprived rats (16). The hydrolysis rates of aspirin in both blood and plasma of water-deprived rats, however, were found to be about equal to that in the blood and plasma from control rats.

As expected, temperature had considerable effect on the rate of enzymatic hydrolysis of aspirin in blood and plasma. The half-lives at 22.5° in the blood and plasma of control rats were 0.46 and 7.6 hr, respectively, compared with 0.21 and 2.8 hr at 37.0°.

The rapid hydrolysis of aspirin in blood and plasma might create considerable problems in the handling and storage of samples for analysis. When the blood sample containing aspirin is drawn from the rat, it has a temperature of ~37°. At that temperature, the half-life of aspirin in blood is only 13 min (Table I). Unless frozen immediately, the aspirin in the sample will hydrolyze rapidly as the sample gradually cools to room temperature (~22.5°), where the half-life of aspirin is still merely 28 min. If blood at room temperature is centrifuged and the plasma separated, the half-life of aspirin in plasma at room temperature is 7.6 hr. Therefore, to avoid significant hydrolysis of aspirin in plasma samples, the enzymatic process should be stopped at the moment the blood is collected in the syringe. If the blood is collected in a syringe and transferred to a centrifuge tube to obtain plasma, considerable loss of aspirin is inevitable due to the time lag between blood collection and the end of centrifugation. This difficulty can be overcome by collecting the blood samples in a syringe containing twice the volume of acetonitrile. Acetonitrile instantly deactivates the aspirin-hydrolyzing enzymes, coagulates the blood, and precipitates the serum proteins, but does not cause hemolysis of red blood cells so that a colorless, clear solution is obtained from blood on centrifugation. Stability studies have shown that aspirin hydrolysis in blood–acetonitrile (1:2, v/v) supernatant follows pseudo-first-order kinetics with a half-life of 106 hr at room temperature (Table I), as compared with a half-life of 75 hr for aspirin in phosphate buffer, pH 7.0.

Pharmacokinetic studies of aspirin in blood or plasma have long had problems due to (*a*) rapid loss of aspirin in blood and plasma, (*b*) lack of an analytical procedure which directly measures the aspirin in blood or plasma samples, and (*c*) fast disposition of aspirin in the body. These problems have been obviated by instantly deactivating the aspirin-hydrolyzing enzymes by adding acetonitrile, developing a rapid and sensitive HPLC method for direct quantitation of aspirin in blood and plasma, and cannulating the rat permanently so that blood samples can be collected as frequently as ≤1 min.

The *in vitro* hydrolysis rate of aspirin in whole blood or serum of rats has been reported previously by Morgan and Truitt (10) using 30-fold dilute rat serum. The initial concentration of aspirin used in their study was 433 μg/ml, a toxic level. The hydrolysis rate was followed by measuring salicylic acid (not aspirin) spectrophotometrically at 300 nm. The half-life of aspirin was found to be 8.12 hr in 30-fold dilute rat serum at 25°. This value is much higher than the half-life of 168 min found in the present study in plasma, showing that the rate constant for the enzymatic hydrolysis of aspirin cannot be extrapolated to whole blood serum, or plasma from dilute-sample studies. Morgan and Truitt (10) failed to recognize that at high serum dilution and higher aspirin concentrations, the hydrolysis may follow a different order of reaction.

Harris and Riegelman (13) have reported half-lives of aspirin in human plasma and blood to be 32 and 66 min, respectively, corresponding to 13 and 168 min in rats in our study. The concentration of aspirin was ~20 times smaller than our study, and therefore no direct comparisons can be made. But if the dilution effect is extrapolated, it is observed that aspirin is hydrolyzed by rat blood faster than human blood, whereas the opposite finding is made when plasma is used. Thus, rat blood is not a good substitute for human blood in hydrolysis studies.

Simple Reliable Method for Chronic Cannulation of the Jugular Vein for Pharmacokinetic Studies in Rats

SHAMSUL K. BAKAR and SARFARAZ NIAZI ˣ

Received December 3, 1981, from the *Department of Pharmacodynamics, College of Pharmacy, University of Illinois Health Sciences Center, Chicago, IL 60612.* Accepted for publication March 5, 1982.

Abstract □ A simple method for the preparation and implantation of silicone cannulas into the rat jugular vein is described. The implanted cannula can be used to administer drugs and collect blood samples at intervals of ≤1 min without causing stress to the animal. If necessary, the animals can be exanguinated within a few minutes using this cannula. With proper maintenance, the cannula is patent for weeks and could be used for repeated and crossover studies.

Keyphrases □ Sampling, blood—serial, chronic cannulation procedure, rat jugular vein, pharmacokinetic studies □ Cannulation—chronic, rat jugular vein, serial blood samples for pharmacokinetic studies □ Pharmacokinetics—serial blood sampling by chronic cannulation, rat jugular vein

Pharmacokinetic studies of drugs require sequential blood sampling. It is preferable that the blood samples are drawn from the animals with minimum trauma and stress to avoid any changes in the body physiology, which might alter the disposition characteristics of the drug (1–4). A number of methods are available for serial blood sampling (5, 6); these can be broadly classified into surgical and nonsurgical methods. The nonsurgical methods include cardiac puncture (5, 7), bleeding of the orbital plexus (8–10), and bleeding of the tail (5, 11). These methods are traumatic and may require anesthetizing the animals; the cardiac puncture method is not suitable for sequential blood sampling. Some methods do not involve surgery and are available for continuous intravenous drug infusion (12–14), but these methods cannot be used for serial blood sampling because the vein often collapses after a certain period of time.

The surgical approaches for obtaining serial blood samples mainly include cannulation of the jugular vein (15–19) or cardiac ventricle (20, 21). Other methods of cannulation in the rat for the study of first-pass effect have been reviewed elsewhere (6).

The cannulation of the external jugular vein is one of the most reliable methods for intravenous administration of drugs and rapid sequential blood sampling for prolonged periods of time. However, the complexity involved in the cannulation and maintenance of cannula patency for a sufficient length of time has limited the use of this technique in pharmacokinetic studies. The purpose of this study is to devise a simple method for the preparation of the cannula, for the introduction of the cannula into the vein, and for the maintenance of cannula patency for long-term use.

EXPERIMENTAL

Preparation of Cannula—Approximately 12 cm of medical-grade silicone rubber tubing (0.051-cm i.d. × 0.094-cm o.d.)[1] was gently wrapped around twice with silk thread[2] ~20 cm in length. A firm knot was tied in the thread, taking precaution that the lumen of the silicone tube was not occluded. The knot was made ~3 cm from one end of the silicone tubing, so that the other end was ~9 cm long (Fig. 1a).

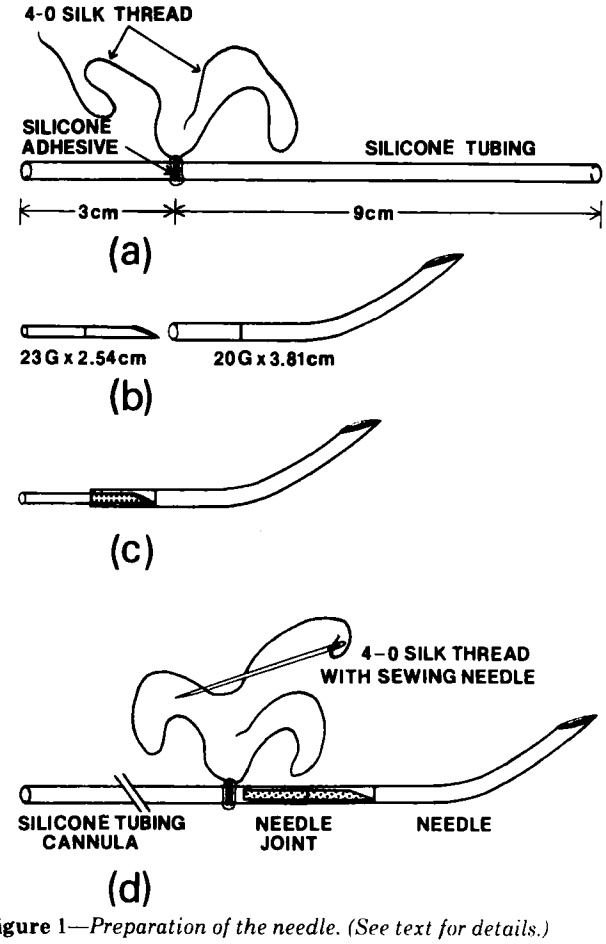

Figure 1—*Preparation of the needle. (See text for details.)*

A coat of silicone adhesive[3] was applied to the thread around the tubing and cured for at least 24 hr. The coating was not >1 mm thick so as to keep the thread firmly held on the silicone tubing without making the joint too bulky. After curing, the silicone cannula was checked for occlusion by flushing with sterile normal saline. The cannulas were cleaned and disinfected by soaking them in benzalkonium chloride antirust solution for at least 30 min before use. The lumen of the cannula was cleaned by flushing with 2 ml of sterile normal saline.

The short end of the cannula is inserted into the superior vena cava through the right external jugular vein, and the longer portion is passed subcutaneously to the back of the neck. The length of the short end can vary depending on the size of the rat: a 3-cm length is suitable for rats weighing between 300 and 450 g.

Preparation of the Implantation Needle—The needle used for the introduction of the cannula into the jugular vein was prepared using the method of Harms and Ojeda (17). The plastic hubs were removed from two thin-walled beveled hypodermic needles[4] (23-gauge × 2.54 cm and 20-gauge × 3.81 cm). Approximately 1.2 cm of the beveled end of the

23-gauge needle was forced into the opposite (nonbeveled) end of the 20-gauge needle, which had been bent (Fig. 1b). If the 23-gauge needle was too thick to be fitted snugly into the bore of the 20-gauge needle, the outer surface of the 23-gauge needle was rubbed on a rough surface (such as a sharpening stone) to make the outer diameter small enough to fit tightly into the lumen of the 20-gauge needle. The short end of the silicone cannula fit snugly over the protruding portion of the 23-gauge needle (Fig. 1c).

Surgical Implantation of the Cannula—All the instruments used for the animal surgery were cleaned and disinfected by immersing them into a benzalkonium chloride antirust solution for ~1 hr. Strict asepsis was not necessary, but a clean environment and neat handling of the animal were important.

The rat was anesthetized with ether in a desiccator. After removing the rat from the desiccator, the anesthesia was maintained throughout the implantation procedure by placing ether-impregnated cotton close to the nose of the rat. The hair on the back of the animal was clipped, and a point was marked at the center of the back of the neck to indicate the exteriorization point for the longer portion of the cannula. The rat was then placed on its back, and the hair on the area over the right external jugular vein was clipped. This area is recognized by observing the rapid pulsation of the jugular vein. The shaved area was cleaned by repeated wipings with sterile gauze saturated with 70% isopropyl alcohol.

A longitudinal incision, ~2 cm long, was made on the skin over the jugular vein, and the vein was exposed by clearing the surrounding tissues. To avoid unnecessary blood loss, care was taken not to damage any surrounding veins. The short end of the cannula was passed into and out of the jugular vein using the implantation needle–cannula assembly (Fig. 2a). This was done without loss of blood from the vein.

At this point, while the shorter end of the cannula was out of the jugular vein, a sterile disposable syringe (3- to 10-ml capacity) containing heparinized (20 U/ml) normal saline for injuection, was connected to the longer end of the silicone cannula by a blunt-ended 23-gauge sterile needle. This needle was prepared by clipping the beveled portion of a 23-gauge × 2.54-cm needle, smoothing out both the inside and outside of this cut-end needle, cleaning and sterilizing with benzalkonium chloride antirust solution, and rinsing several times with heparinized normal saline for injection. The flushing can be done with or without the implantation needle at the end of the cannula. However, it is a good practice to flush the initial portion of the normal saline with the implantation needle on, so that the needle is cleared of any blood that may have entered it during its short passage through the jugular vein. If the implantation needle is not flushed immediately, blood clots may form in the lumen of the needle; these clots often are difficult to remove.

The implantation needle was disconnected and the cannula was flushed again with ~0.5 ml of normal saline. Then the cannula was pushed slowly toward the heart until the junction of the silk thread was reached. The cannula was then fixed in place by suturing the silk thread to the muscle through which the implantation needle exited (Fig. 2b). The suturing was done using an ordinary sewing needle which had been sterilized.

Approximately 0.2 ml of heparinized normal saline was injected slowly from the syringe through the cannula into the vena cava. The plunger of the syringe was then pulled back slowly to observe the appearance of blood in the cannula. When blood was observed, another 0.2 ml of heparinized sterile normal saline was injected into the cannula. The longer end of the cannula was disconnected from the syringe and threaded with the aid of a 16-gauge needle (Fig. 2b), which was passed subcutaneously from the point marked at the back of the rat's neck to the point of incision. Blood loss through the cannula was minimized during this step either by putting a small clip close to the junction of the silk thread or by keeping the cannula pressed at that point with two fingers. After passing through the skin, the cannula was again filled with heparinized normal saline and closed with a 1-cm portion of nylon monofilament, the inner end of which had been tapered and smoothed.

The muscles at the incision were closed by a single suture, and the open skin was closed by 3 to 4 stitches using absorbable, surgical suture with a needle[5] and hemostat. The administration of ether to the rat was then discontinued, any blood around the skin incision was cleared with cotton gauze, and the rat was placed in a supine position in its cage. Within a few minutes, the rat turned over and started walking somewhat shakily. After 1 hr, the movements of the rat became normal, indicating that the rat had recovered from the anesthesia.

Serial Blood Collection—To avoid contamination of blood from one sample to the next, a 1- or 3-ml disposable plastic syringe was fitted with a 23-gauge × 2.54-cm needle (Fig. 3). The beveled portion of the needle had been cut off and smoothed, as mentioned earlier, to avoid damaging the cannula. The needle was fitted with two segments (A and B) of silicone rubber tubing, both ends of which had been smoothed (Fig. 3). At the end of the second tubing (B), another 23-gauge connector was fixed with half of its length protruding.

When blood was collected, the nylon stylet was removed from the implanted cannula, and the cannula was connected to the free end of the 23-gauge needle. When the plunger of the syringe was pulled back, first heparinized normal saline and then blood started entering the tubing and the syringe. As soon as the dead volume of normal saline and/or blood had crossed the joint of the two tubings, the first tubing (A) was disconnected along with its needle joint. Another syringe, fitted with a 23-gauge blunt-ended needle, was attached to the open end of the second tubing (B). Blood was drawn into the second tubing by pulling the plunger back slowly.

During the connecting and disconnecting processes, the open end of the cannula was firmly pressed between two fingers so that the blood remained immobile within the cannula. After drawing the required volume of blood, the syringe and its needle were removed, and the cannula was filled with heparinized normal saline and closed with the nylon stylet. If blood samples are withdrawn in quick succession, for example every minute, flushing the cannula each time with saline solution is unneces-

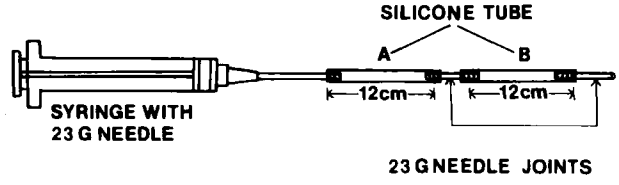

Figure 3—*Syringe and tubing assembly for the collection of uncontaminated serial blood samples from cannulated rats.*

[5] 4-0 Dexon, American Cyanamid Co., Pearl River, N.Y.

sary. The mixing of blood between samples can be avoided by adopting the above procedure.

Maintenance of the Cannula—Using the syringe and tubing arrangement, as described earlier for the collection of serial blood samples, the blood was first drawn into the tubing under negative pressure. If any clot had formed, it was removed from the cannula and not pushed into the systemic circulation. The cannula was then filled completely with heparinized (20 U/ml) normal saline for injection. Flushing of the cannula was done at least once, but preferably twice, a day.

DISCUSSION

The method described here for the chronic cannulation of the rat jugular vein is simple and reliable. More than 100 rats have been cannulated in our laboratory for pharmacokinetic studies of drugs whose half-lives ranged from a few minutes to several hours or days. With proper maintenance, the cannula remains patent for months. This method for the preparation of the cannula is simpler than the one described previously (17). The cannula preparation eliminates the use of silicone sheeting which is difficult to fabricate, causes discomfort to the rats, has a bulky appearance after the skin incision is closed and healed, and prolongs the healing time. Other methods of cannula preparation (16, 18) are even more complicated, needing many accessories and expertise to make and implant them.

Upton (19) described a cannulation method where the "tubing is secured by tying firmly around the vein," which blocks blood circulation through the jugular vein. The cannula can become blocked if tied too firmly, or dislodged from the vein if the knot is not firm enough. Insertion of the cannula through the jugular vein into the vena cava involves manipulation of the vein which can cause it to collapse, thus complicating further the insertion procedure. Unless the tube is inserted promptly on incision in the jugular vein (19), significant loss of venous blood may occur. However, the method described here involves minimal manipulation of the vein with little loss of blood.

The passage of the cannula into and out of the jugular vein should be accomplished in the first attempt. If the first attempt fails, the vein may collapse, making it somewhat difficult (but not impossible) to insert the implantation needle into the vein. It is recommended that while learning this cannulation technique, one should anesthetize the first few rats with pentobarbital, since ether anesthesia requires attention to maintain the optimum anesthesia of the rat, which may hamper the surgical procedure.

Monofilament nylon cord is used as a stylet to close the open end of the cannula because it is nonreactive with normal saline and the silicone tubing and is lighter than stainless steel. Although the medical-grade silicone tubing used is nonreactive with body tissue (22), it neither resists blood clotting nor is impervious to moisture. Thus, loss of water from the saline-filled cannula allows the blood to enter the cannula and form a clot. Initially, this clot is soft and could be aspirated easily. But if the clot remains for a longer period (>24 hr), it becomes hardened and strongly affixed to the inside wall of the cannula. In these cases, heparinized normal saline should be forced in to clear the cannula. The presence of these clots in the vena cava often damages this blood vessel, rendering the cannula inoperative. It is preferable that the clots be removed by aspiration before flushing the cannula rather than be forced into the general circulation. To reduce the microbial contamination during the flushing of the cannula, the exposed end of the cannula, the stylet, the needle of the syringe, and the finger tips which come in contact with the cannula should be thoroughly wiped with sterile gauze saturated with 70% isopropyl alcohol.

For the first few days, some rats may show some restlessness making it difficult to connect or disconnect the syringe with cannula for drawing the blood. In these situations, some confinement such as that described by Davis and Coleman (23) or any simpler version, should be used to limit the movements of the animal. After time the animal becomes used to this manipulation and offers no problems.

Unless the pharmacokinetic studies are complicated by the use of heparin (24), it is recommended that blood sample volumes should be replaced by heparinized (20–50 U/ml) normal saline. Also ~0.2 ml of heparinized (20–50 U/ml) normal saline should be injected a few minutes before the withdrawal of blood. If heparin poses problems, another anticoagulant may be used.

Effect of Water Deprivation on Aspirin Disposition Kinetics

SHAMSUL K. BAKAR and SARFARAZ NIAZI[x]

Received December 3, 1981, from the *Department of Pharmacodynamics, College of Pharmacy, University of Illinois Health Sciences Center, Chicago, IL 60612.* Accepted for publication May 11, 1982.

Abstract □ Temporary water deprivation results in serious stress causing significant physiological, hormonal, and enzymatic changes in the body which can affect the disposition kinetics, toxicity, and activity of drugs. This study attempts to recognize the effect of water deprivation on drug disposition kinetics using aspirin. No significant effects were noted following 36-hr water deprivation in rats on the metabolism of aspirin; there was also no effect of heparinization on aspirin disposition kinetics. The disposition of salicylic acid, however, was altered significantly, with the half-life increased by ~72% concomitant with decreased total body clearance. The effect of two dose levels, 5 and 10 mg/kg, was also studied to elucidate nonlinearity in the disposition kinetic model. Almost complete urinary recovery of aspirin was obtained in the intact form or as metabolites. At the 10-mg/kg dose, the fraction of salicyluric acid excreted decreased significantly compared with the 5-mg/kg dose. However, the effect of water deprivation was uniform at the two dose levels without any effect on the excretion of salicyluric acid. It is suggested that, in view of the significant changes in the disposition characteristics of salicylates with water deprivation, due care must be exercised in adjusting doses giving proper consideration to body hydration levels.

Keyphrases □ Aspirin—disposition kinetics in rats, effect of water deprivation on metabolism □ Kinetics—aspirin metabolism, rats, effect of water deprivation □ Metabolism—of aspirin, effect of water deprivation in rats, kinetics

Dehydration in the body occurs due to circumstantial water deprivation, excessive sweating, and various disease states such as polyuria and diarrhea. A number of physiological and biochemical changes have been attributed to the short-term stress of water deprivation; these can significantly modify the disposition of drugs in the body.

The most prominent manifestations of water deprivation are loss of body weight and decrease of both blood and plasma volumes (1–6). This results in increased plasma osmotic pressure, plasma protein concentration, and hematocrit, while the pH and the acid–base status of blood remain essentially constant (1–10). The volume of the urine and the amount of electrolytes excreted in the urine also decrease significantly in water-deprived rats (5), with corresponding morphological and histochemical changes in the renal medulla (11).

The effects of starvation and nutrition on the drug-metabolizing enzymes of liver microsomes have been extensively investigated (12–22), but kinetic studies of drug disposition with short- and long-term water deprivation in humans or animals are almost nonexistent. Some empirical data exist indicating that water deprivation may influence the pharmacological effect of some drugs (23–27).

The fate and pharmacokinetics of aspirin (acetylsalicylic acid) and salicylic acid in human and animals have been extensively investigated (28–34). However, specific *in vivo* data on aspirin metabolism by rats and other common laboratory animals are lacking. The desert rodents, hopping mice (*Notomys alexis*, Family: Muridae), conserve body water with extreme economy and show high papillary-to-cortex ratios of salicylates along with longer biological half-lives of salicylates (100–120 min) when compared with nondesert mice (55 min). Also, only 9% of the salicylate in desert mice is metabolized to salicyluric acid, compared with 80% in humans and 50% in rats (35, 36). Thus water economy and species differences determine the biological half-life of circulatory salicylate and the nature and extent of its metabolites.

The primary purpose of this study was to investigate the effect of a 36-hr water deprivation on the disposition kinetics of aspirin. Aspirin was selected as a model drug because of its extensive protein binding, several pathways for metabolism and excretion, variable dose-dependent disposition, and clinical importance. Since *in vivo* heparinization of the circulatory system was done to facilitate the withdrawing and handling of blood samples from the rats, the effect of heparin on the pharmacokinetics of aspirin was also investigated.

EXPERIMENTAL

Animal Preparation—Male rats[1] weighing between 300 and 450 g were used. The rats were housed in individual cages[2] and allowed to become accustomed to the laboratory conditions for at least 7 days. The rats were cannulated in the right jugular vein as described in the previous paper (37) at least 3 days before the pharmacokinetic study began, thus allowing sufficient time for recovery from the surgery. The cannula was kept patent by flushing with heparinized (20 U/ml) sterile normal saline for injection[3] twice a day. Each study group was comprised of six rats, selected randomly.

For the treatment group of rats, water deprivation started at 7:00 pm, and the drug was given 36 hr later. During this 36-hr water deprivation, the rats had access to food all the time. The rats were weighed prior to the administration of aspirin to calculate the proper dose; they were also weighed before and after water deprivation to calculate the percent weight loss.

Preparation and Administration of the Aspirin Dose—One gram of aspirin was dissolved in 20 ml of polyethylene glycol 400[4] with constant shaking and diluted with sterile normal saline for injection to 100 ml, so that the final concentration of aspirin in the solution was 10 mg/ml. The resultant solution was passed through a sterile 0.22-μm filter for the removal of any particles or microorganisms. Each solution was freshly prepared due to the instability of aspirin in solution (38).

The sterilized, particle-free solution was aspirated into a 1-ml disposable hypodermic syringe[5], and the dose was administered intravenously through the jugular vein cannula. The dead volume in the cannula was flushed immediately with ~0.2 ml of heparinized (50 U/ml) sterile normal saline. When the effect of heparin on the pharmacokinetics of aspirin was studied, the cannulas of the control (nonheparinized) rats were flushed with sterile normal saline instead of heparinized normal saline.

Collection of Blood and Plasma Samples—For the pharmacokinetic study of intact aspirin, 200 μl of blood was collected in a 1-ml syringe containing 400 μl of acetonitrile[6] prior to the administration of the dose. The contents of the syringe were mixed gently, and this mixture served

as the blank. After administering aspirin intravenously through the jugular vein cannula, blood samples were collected every 1 min for 5 min and then every 2 min for another 6–10 min.

For the pharmacokinetic study of salicylic acid in the rats, ~200- to 300-μl blood samples were collected every 15 min for the first hour after the administration of the intravenous dose, every 30 min for the next 2 hr, and then every hour for the next 4 hr. Thereafter, blood samples were collected every 2 hr for another 4–6 hr. The volume of each blood sample collected from the rat was replaced with an equal volume of heparinized (50 U/ml) sterile normal saline.

When the effect of heparin itself on the pharmacokinetics of salicylic acid was investigated, the blood samples for the control (nonheparinized) group of rats were replaced with sterile normal saline rather than heparinized normal saline. Blood samples were collected from each rat for each pharmacokinetic study before administering the aspirin dose and were used as blanks.

Collection of Urine Samples—Rats were placed in metabolism cages, which allowed the collection of urine and feces in separated receptacles that could be removed without disturbing the animal. The urine deposited in the receptacle was collected every 12 hr, pooled, and stored in the refrigerator. The pooled urine was analyzed within 24 hr after the end of the collection. Urine samples from control rats (receiving food and water *ad libitum*) were collected for a total of 48 hr; samples for water-deprived rats were collected for 60 hr. The volume of the pooled urine and its pH were measured at the end of collection. Urine samples were also collected from each rat prior to the administration of aspirin; these samples served as blanks.

Analytical Procedure—*Blood*—The blood–acetonitrile (1:2) mixture was transferred to a 500-μl polypropylene microcentrifuge tube and centrifuged[7] for 5 min at 15,000 rpm. Twenty microliters of the supernatant was analyzed by the high-performance liquid chromatographic (HPLC) method described previously (39).

Plasma—Blood samples collected in the syringe were transferred to 250-μl polyethylene microcentrifuge tubes and centrifuged for 2 min at 15,000 rpm to separate the plasma from the cellular fraction. Aliquots of the separated plasma layer (100 μl) were transferred to a 500-μl polypropylene microcentrifuge tube and precipitated with 200 μl of acetonitrile. The mixture was vortexed for 30 sec, then centrifuged for 8 min (15,000 rpm). Twenty microliters of the supernatant was analyzed using the HPLC method described previously (39).

Urine—The refrigerated pooled urine was warmed to room temperature and mixed by shaking. A portion of the mixture was clarified by centrifugation for 10 min at 2500 rpm. One milliliter of the clarified urine was acidified with 0.5 ml of 6 *N* HCl[8] and extracted with 6 ml of ether[9]. Five milliliters of the ether extract were re-extracted with 1 ml of phosphate buffer (0.1 *M*, pH 7.0), and 20 μl of the buffer extract was analyzed by HPLC (39). The urine samples were prepared in duplicate, and each sample was chromatographed twice so that each analytical value reported was an average of four determinations.

RESULTS AND DISCUSSION

Effect of Heparin on the Pharmacokinetics of Salicylic Acid—Table I lists the pharmacokinetic data for the 22 rats (11 rats in each group) used to study the effect of heparin on the disposition of salicylic acid administered intravenously as a solution of sodium salicylate. The elimination of salicylate by the body was described by first-order kinetics, as is evident from the excellent linear correlation coefficients obtained for each of the pharmacokinetic studies. Figure 1 shows the disposition kinetics of salicylic acid in two representative rats, one from the heparinized and the other from the nonheparinized groups of rats. No statistical significance was observed in the disposition kinetic data between the two study groups.

Similar findings were made at much higher doses of heparin (500–1000 U/kg). This finding is important since heparin decreases plasma protein binding of neutral and basic drugs and increases the binding of acidic drugs (40), except for salicylates where a decreased binding is noted at a 500-U/kg dose (41). The present finding suggests that the decrease in plasma protein binding of salicylate, as observed by Weigand and Levy (41), will not affect the disposition characteristics of salicylic acid.

Disposition of Aspirin in Control and Water-Deprived Rats—Table II lists the disposition kinetic parameters for aspirin after an in-

AUC, μg·hr/ml	207.4 ± 13.9	143.3–243.6	369.1 ± 38.9	235.3–555.8

[a] Salicylate dose = 10 mg/kg; n = 6. [b] Rats received food and water *ad libitum*. [c] Rats were deprived of water for 36 hr, but received food *ad libitum*.

travenous dose of 10 mg/kg of body weight in two groups of rats: a control group which had free access to food and water and a 36-hr water-deprived (treatment) group which had free access to food only. Figure 2 shows the first-order disposition kinetics of of aspirin in two rats which represent the control and treatment groups. The disposition constants for aspirin in the control group of rats were not statistically significant ($p < 0.05$) compared with the treatment group.

Therefore, in short-term water deprivation, the activity of the aryl esterases in blood and other organs, such as liver and kidneys, is not significantly altered. Based on the volume of distribution, the contribution of blood to the clearance of aspirin in rats is insignificant (<1%) compared with humans (~20%), despite the fact that the hydrolysis of aspirin in rat blood is faster than in human blood ($t_{1/2}$ = 30 and 12 min, respectively).

Disposition of Salicylic Acid in Control and Water-Deprived Rats—Since no detectable level of aspirin in the blood is found after 10 min following intravenous administration of aspirin, the blood samples collected 15 min after the administration of the intravenous dose and all subsequent sampling times represent the disposition kinetic study of salicylic acid. The two dose levels of aspirin (5 and 10 mg/kg) were selected to study the linearity of kinetics and the effect of dose on the disposition of salicylic acid both in the control and treatment groups.

Figure 3 shows the disposition of salicylic acid after an intravenous 5-mg/kg dose of aspirin in typical control and treatment rats. The disposition kinetics follow a first-order process (Table III). The time zero concentrations of salicylic acid in plasma were similar in both control and treatment rats (30.2 and 31.6 μg/ml, respectively). This implies that short-term water deprivation has little effect on the volume of distribution of salicylic acid.

Although the volume of distribution in both groups of rats was essentially the same (176 and 179 ml/kg), the biological half-life of salicylic acid in the treatment group of rats was 72% higher than the half-life in the control group. This increase in biological half-life is also reflected in the higher value of area under the curve (AUC) (166 *versus* 102 μg·hr/ml) and lower total body clearance (37 *versus* 51 ml/kg/hr).

The results obtained after the administration of a 10-mg/kg aspirin dose in control and treatment rats are listed in Table IV. The typical first-order plots for the disposition of salicylic acid are shown in Fig. 4. The disposition of salicylic acid at this dose level also follows apparent first-order kinetics in rats.

The biological half-life of salicylic acid in 36-hr water-deprived rats was ~70% higher (4.37 *versus* 2.59 hr) than in control rats, although the volume of distribution in both groups was essentially the same (176 and 178 ml/kg). The higher biological half-life of salicylic acid in treatment rats is consistent with the observed lower value (37%) of total body clearance (30.1 *versus* 47.5 ml/kg/hr) and higher value (78%) of the AUC (369.1 *versus* 207.4 μg·hr/ml).

The overall results for the two dose levels suggest that the biological half-life of salicylic acid in both groups of rats increases significantly (p

Table V—Recovery of Aspirin Metabolites Salicylic Acid, Salicyluric Acid, and Gentisic Acid in Urine After Intravenous Administration of Aspirin in Two Doses to Control and Water-Deprived Rats

Aspirin Dose, mg/kg	Group	Recovery in Urine, % of Aspirin Dose						
		Salicylic Acid		Salicyluric Acid		Gentisic Acid		
		Mean ± *SEM*	Range	Mean ± *SEM*	Range	Mean ± *SEM*	Range	Total
5	Control[a]	48.6 ± 3.7	40.0–63.1	46.0 ± 3.0	34.9–55.2	—	—	94.6 ± 4.2
5	Water Deprived[b]	44.2 ± 5.7	24.5–65.0	53.6 ± 7.1	30.4–81.9	—	—	97.8 ± 1.8
10	Control	58.3 ± 5.0	31.2–81.3	38.0 ± 4.9	25.7–72.4	—	—	96.3 ± 4.0
10	Water Deprived	50.3 ± 1.7	40.6–55.6	36.9 ± 2.3	29.8–48.2	6.5 ± 0.9	3.6–10.8	93.6 ± 2.1

[a] The control group of rats (n = 6) received food and water *ad libitum*. [b] The rats (n = 9) were deprived of water for 36 hr, but received food *ad libitum*.

< 0.05) when the dose is doubled. This confirms the earlier finding in humans (28), that the disposition of salicylic acid is dose dependent. When the dose was doubled in the control rats, the half-life increased from 2.1 to 3.6 hr, an increase of ~72%. In water-deprived rats, the corresponding increase was 69% (2.59 to 4.37 hr).

The significant increase in the biological half-life of salicylic acid with water deprivation has important implications in the salicylate therapy of rheumatoid arthritis and inflammatory diseases, where aspirin is administered chronically at high dosages and where effective therapeutic levels of salicylate in these conditions approach toxic levels. Accumulation of salicylate due to increased biological half-life, as a result of short-term water deprivation, may produce toxic, possibly fatal effects.

Metabolites of Aspirin in Control and Water-Deprived Rats—Urine samples were analyzed for the major aspirin metabolites, salicylic and salicyluric acids, which account for >90% of the administered dose, and also for the minor metabolite, gentisic acid. The results are shown in Table V for a 5-mg/kg dose of aspirin in control and water-deprived (treatment) rats. The total recovery of aspirin in control rats is ~95% as compared with 97% for the treatment group. There was no significant difference in recovery of aspirin metabolites in these two groups of rats, and there also was no detectable gentisic acid in any of the urine samples. In both groups, approximately half of the aspirin was excreted as salicyluric acid. The fraction of aspirin excreted in the urine as salicyluric acid decreased significantly ($p < 0.05$) as the dose was increased from 5 to 10 mg/kg in both groups of rats. However, no effect of water deprivation was observed on the total percentage of aspirin metabolized to salicyluric acid. This finding is very interesting, since it would be expected that the percentage of salicyluric acid formed would increase in water-deprived rats because the long half-life of salicylic acid gives the liver more time to form salicyluric acid under conditions of metabolic saturation.

Since water deprivation produces no significant change in the excretion of salicyluric acid, the situation may be explained by one or both of two phenomena:

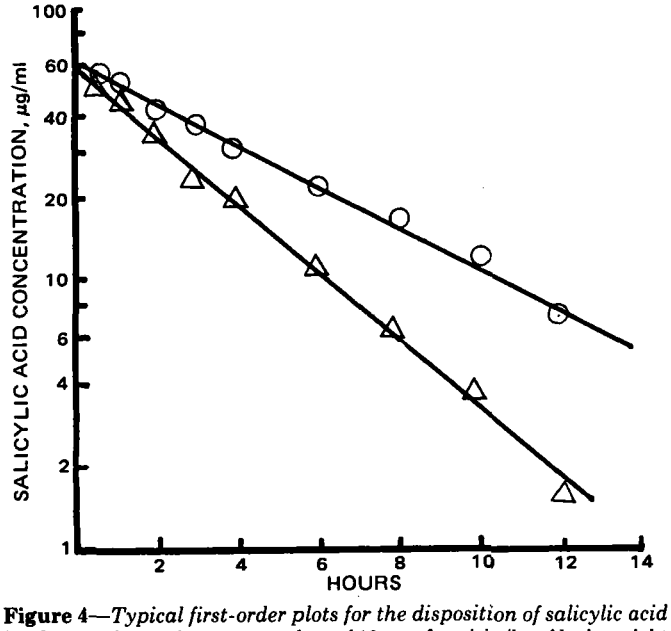

Figure 4—*Typical first-order plots for the disposition of salicylic acid in plasma after an intravenous dose of 10 mg of aspirin/kg of body weight in rats. Key: (△) control rats (received food and water* ad libitum*); (○) treatment rats (deprived of water for 36 hr, but received food* ad libitum*).*

1. If it is assumed that the drug-metabolizing enzymes are inhibited to some extent by water deprivation, the longer circulating half-life of salicylic acid could be balanced by the slower rate of formation of salicyluric acid. In the first step, the carboxylic group of salicylic acid binds with CoA to form the activated complex. In the second step, glycine conjugates with the reactive complex with the help of glycine-*N*-acylase. It is not presently known if one or both of these enzymes is inhibited by water deprivation.

2. The renal tubular conversion of salicyluric acid to salicylic acid (42) is a significant factor. The salicyluric acid formed in the liver from salicylic acid is transferred to the tubule cells of the kidneys, where it is metabolized back to salicylic acid and reabsorbed, thus prolonging the biological half-life of salicylic acid without increasing the proportion of salicyluric acid in the urine. Since with water deprivation, rats are more likely to conserve body water by reducing the formation of urine, the conversion of salicyluric acid to salicylic acid is more likely to occur.

Another interesting finding from the urinary studies is that at higher aspirin doses (10 mg/kg), ~6.5% of aspirin was metabolized to gentisic acid in water-deprived rats, suggesting that the enzyme system responsible for the hydroxylation of the aromatic ring (microsomal mixed-function oxidase) is somewhat stimulated by short-term water deprivation. No gentisic acid was found in the urine of control rats.

In conclusion, it might be stated that although there is no dramatic change in the excretion pattern of different metabolites of aspirin in the urine, the half-life of salicylic acid is significantly increased with water deprivation at both dose levels studied. This increased biological half-life of salicylic acid may have significant clinical impact in the treatment of rheumatoid arthritis and other diseases where the differences between the effective and toxic blood levels of salicylate are extremely narrow.

Effect of Dosage Form and Formulation Factors on the Adherence of Drugs to the Esophagus

MARTTI MARVOLA [‡x], **MARKKU RAJANIEMI, ESKO MARTTILA, KARI VAHERVUO, and ASLAK SOTHMANN**

Received June 15, 1982, from the [*]*Pharmaceutical Research Laboratories, Orion Pharmaceutical Co., SF-02101 Espoo, Finland*, and [‡]*School of Pharmacy, University of Helsinki, Helsinki, Finland.* Accepted for publication August 20, 1982.

Abstract □ In recent years, many case reports concerning esophageal injuries caused by drugs have been published. The primary cause has apparently been the adherence of the drug product to the esophagus. In the present study, the adherent tendency of a number of types of tablets and capsules were tested *in vitro* using a recently developed isolated porcine esophagus preparation. The results showed that the tendency of products to adhere to the esophageal mucosa can be modified to a great extent by shape and formulation. Products with low adherence can be obtained by film coating with aqueous dispersions or by sugarcoating. In contrast, gelatin capsules and some cellulose films appear to have a high tendency to adhere to the esophagus.

Keyphrases □ Tablet coatings—effect on adherence, isolated porcine esophagus, potassium chloride □ Potassium chloride—adherence to isolated porcine esophagus, effect of tablet shape, formulation, and coatings □ Drug formulations—effect of additives and coatings on adherence, isolated porcine esophagus

In recent years, many reports concerning esophageal injuries caused by drugs (*e.g.*, doxycycline, emepronium bromide, and potassium chloride) have been published (1–9). The primary cause has apparently been adherence of the drug product to the esophageal mucosa. The tendency to adhere has obviously been greatest for hard gelatin capsules, but differences between various tablet formulations have also been evident. In a previous paper, a study of the tendency of drug products to adhere to the esophageal wall, using the isolated porcine esophagus, was published (10). In the present investigation the effect of the pharmaceutical characteristics of dosage forms on the adherence was studied.

EXPERIMENTAL

Isolated Esophagus Preparation—The isolated porcine esophagus preparation and its usefulness has been described previously (10). Pigs of both sexes were of the Landrace or Yorkshire breeds, weighing 90–100 kg. Immediately after slaughter, the esophagi were removed and transported to the laboratory in Tyrode's solution. Segments (6–7 cm long) were cut from the esophagus and mounted in a classic organ bath for isolated preparations.

Recording of Adherence—A hole was drilled in the products to be tested. The product was attached to a copper wire and placed in the esophageal preparation for 2.0 min (gelatin capsules, 1.0 min). The force needed to detach the product was then measured using a modified prescription balance (10); the force used was taken as a measure of adherence.

Drug Products—Hard gelatin capsules[1] sizes 1, 2, 3, 4, and 5 were filled with lactose. Oval soft gelatin capsules[2] (length 12 or 15 mm) were left empty. The round soft gelatin capsule formulation studied was a commercially available product[3] (diameter 7 mm). The uncoated placebo tablets were compressed from a mixture of basic granules (96%), talc (3%), and magnesium stearate (1%). The basic granules contained 78% lactose, 19% cornstarch, and 3% gelatin. Potassium chloride tablets were compressed from pure potassium chloride. To obtain products with low adherent properties metal tablets were compressed from an alloy of bismuth, lead, tin, and cadmium (5:3:1:1). The shapes, diameters, and areas of all formulations are given in Tables I–III.

The sugar-coated tablets were all commercially available products[3]. The coating suspension used contained 47 g of sucrose, 4 g of polyethylene glycol 6000, 8 g of calcium sulfate, 2 g of titanium dioxide, 30 g of purified water, and 3 g of other ingredients. The dusting powder contained calcium sulfate and talc (1:1). The coating suspension and powder were used in an approximate ratio of 9:5.

To investigate the effect of film coatings on the adherence of drugs to the esophagus, biconvex tablets were coated with different film coatings. The compositions of the hydroxypropyl methyl cellulose-containing solutions (I–V) are given in Table I. The other coating solutions were as follows: VI, 10.0 g of cellulose acetate phthalate, 0.5 g of castor oil, and 89.5 g of acetone; VII, 14.0 g of polyethylene glycol 6000, 6.0 g of cellulose acetate phthalate, 1.0 g of stearic acid, 0.3 g of castor oil, 0.3 g of sorbitan

RESULTS AND DISCUSSION

The effect of shape on the force needed to detach the products from the isolated porcine esophagus is shown in Table II. Detachment force was greatest for flat tablets and lowest for capsule-shaped tablets. Capsule-shaped tablets may therefore be preferable for drugs known to cause esophageal ulceration.

The adherence of biconvex tablets of different surface areas and coatings is shown in Table III; the same data for various gelatin capsules are shown in Table IV. There were no significant differences in adherence to the esophagus between the hard gelatin capsules made by the two different manufacturers.

As the results show, the tendency to adhere was greatest for hard gelatin capsules. Calculated per unit area, it was six times as high as that for sugarcoated tablets, which had the lowest tendency to adhere. The force needed to detach the soft gelatin capsules was significantly lower than that for the hard gelatin capsules. However, soft gelatin capsules seemed to stick to the esophagus to the same degree as the most adherent tablet formulations in this study.

If the specific adherence of the film coatings is examined, it can be seen that the very common coating material hydroxypropyl methyl cellulose (I) belongs to the middle group of all formulations studied. The tendency of the hydroxypropyl methyl cellulose film to adhere could be adjusted by the use of additives. If sucrose (III) was added, the adherent tendency decreased significantly. The mixture of hydroxypropyl methyl cellulose and ethyl cellulose pseudolatex (V) led to a still lower adherence. In contrast, the addition of lactose (IV) or titanium dioxide and talc (II) increased the tendency to stick.

The common enteric coating cellulose acetate phthalate film (VI) had a fairly low adherent tendency, as did the coatings of shellac (VIII), methacrylate copolymer (IX), and the copolymer of vinyl acetate and crotonic acid (X). When polyethylene glycol 6000 (VII) was used as the main film-forming material, the adherence was, in contrast, considerable.

The results relating to the uncoated placebo tablets should not be interpreted as indicating that the adherent tendency of uncoated tablets is always high. The conclusion relates to the present situation in which tablets were compressed from granules containing lactose and cornstarch. Previous results have shown, however, that uncoated tablets containing other ingredients can have a very low tendency to adhere to the isolated esophagus (10).

The forces needed to detach the commercially available potassium chloride products from the esophagus are shown in Table V. Adherence of the worst formulation was ~3.2 times as great as that of the best formulation. The forces per unit area in Table V are in good agreement with the results in Table III. Sugarcoated tablets had a low adherent tendency, and the specific adherence of the hydroxypropyl methyl cellulose films were 2.1–2.4 $mN \cdot mm^{-2}$ as compared with 1.8–2.4 $mN \cdot mm^{-2}$ in Table III. It is noteworthy that the adherence of hydroxypropyl methyl cellulose decreased as a consequence of adding silicic acid. Ethyl cellulose seemed to have fairly substantial adherent properties.

Although gelatin capsules appeared to have the greatest tendency to adhere to the isolated porcine esophagus, the present results show that many tablet formulations could have a similar tendency to adhere. However, by selecting a proper coating material this tendency can be diminished. The classic sugarcoating seems to be a good choice in this respect. The addition of sucrose to film coatings also reduces adherence. Film coating with aqueous dispersions (IX and V) also results in products

Table V—Force Needed to Detach the Commercially Available Potassium Chloride Formulations from the Isolated Porcine Esophagus

Drug Product	Amount of Potassium Chloride, g	Coating Material	Detaching Force[a], N	Mean Force per Unit Area, $mN \cdot mm^{-2}$
A	1.0	Polyvinyl chloride; sucrose crystals	0.38 ± 0.03	0.9
B	0.6	Sugarcoating	0.39 ± 0.01	0.9
C	1.0	Hydroxypropyl methyl cellulose; silicic acid	0.54 ± 0.04	1.1
D	0.5	Hydroxypropyl methyl cellulose	0.78 ± 0.06	2.4
E	0.75	Hydroxypropyl cellulose	0.93 ± 0.09	2.6
F	0.75	Hydroxypropyl methyl cellulose	0.94 ± 0.12	2.2
G	1.0	Hydroxypropyl methyl cellulose	0.98 ± 0.13	2.1
H	0.75	Special wax; talc	1.00 ± 0.11	2.8
I	1.0	Special wax; talc	1.10 ± 0.13	2.4
J	0.75	Ethyl cellulose	1.20 ± 0.10	2.2

[a] Mean ± *SD*; $n = 18$.

with low adherence. In contrast, sparingly water-soluble ingredients (talc, titanium dioxide, and ethyl cellulose) and, in addition, lactose, mostly increase adherence.

On the basis of this research it seems possible to develop pharmaceutical products having a very low tendency to adhere to the esophageal mucosa. It seems desirable to develop such products in the case of drugs known to cause esophageal strictures or ulcerations, in particular.

High-Performance Liquid Chromatographic Analysis of Iodochlorohydroxyquin and Hydrocortisone in Ointments and Creams

F. W. EZZEDEEN *, S. J. STOHS *x, and A. N. MASOUD ‡

Received April 5, 1982, from the *Departments of *Biomedicinal Chemistry and ‡Anesthesiology, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication August 13, 1982.

Abstract □ A simple isocratic, high-performance liquid chromatographic (HPLC) assay procedure was developed for the simultaneous determination of iodochlorhydroxyquin and hydrocortisone in ointments and creams using phenyl salicylate as an internal standard. Ointment samples were extracted by direct dissolution in ether. Homogeneous suspensions of the creams were prepared in the mobile phase. The samples were spiked by the addition of standard iodochlorhydroxyquin, standard hydrocortisone, and the internal standard and subsequently extracted with the mobile phase. HPLC was performed using a reverse-phase microparticulate C-18 column, a precolumn, and a UV detector set at 256 nm. A mobile phase containing methanol and 0.05 *M* phosphoric acid (70:30) was employed at a flow rate of 1 ml/min. The percent iodochlorhydroxyquin and hydrocortisone found to be present in eight commercial products is reported.

Keyphrases □ Iodochlorhydroxyquin—simultaneous determination with hydrocortisone, ointment and cream, high-performance liquid chromatography □ Hydrocortisone—simultaneous determination with iodochlorhydroxyquin, ointment and cream, high-performance liquid chromatography □ High-performance liquid chromatography—simultaneous determination of iodochlorhydroxyquin and hydrocortisone, ointment and cream

Iodochlorhydroxyquin (I) is used alone or in combination with hydrocortisone (II) as an antimycotic, antibacterial, and anti-inflammatory agent in topical preparations. Because of its toxicity, several analytical procedures have been developed for the determination of I in biological fluids (1–7). The present pharmacopeial assay method for I in creams or ointments (8, 9) is time consuming, requires heating during the extraction procedures (which can lead to decomposition of I), and involves the use of an IR spectrophotometric assay procedure. Other IR spectrophotometeric procedures specific for I in pharmaceutical products have also been described (10, 11). However, these methods are cumbersome, require a large sample, and involve the use of carbon disulfide in the assay procedure. The pharmacopeial methods for assaying II in creams and ointments (12) depend on the oxidation of the α-ketol side chain by either triphenyltetrazolin chloride or blue tetrazolin. Base concentration, water, air, solvent, and light are known to interfere with color formation in the tetrazolin reaction (13). Excipients that interfere with color formation include sorbitan monooleate, lanolin, and stearic acid (14).

with low adherence. In contrast, sparingly water-soluble ingredients (talc, titanium dioxide, and ethyl cellulose) and, in addition, lactose, mostly increase adherence.

On the basis of this research it seems possible to develop pharmaceutical products having a very low tendency to adhere to the esophageal mucosa. It seems desirable to develop such products in the case of drugs known to cause esophageal strictures or ulcerations, in particular.

High-Performance Liquid Chromatographic Analysis of Iodochlorohydroxyquin and Hydrocortisone in Ointments and Creams

F. W. EZZEDEEN *, S. J. STOHS *x, and A. N. MASOUD ‡

Received April 5, 1982, from the *Departments of *Biomedicinal Chemistry and ‡Anesthesiology, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication August 13, 1982.

Abstract □ A simple isocratic, high-performance liquid chromatographic (HPLC) assay procedure was developed for the simultaneous determination of iodochlorhydroxyquin and hydrocortisone in ointments and creams using phenyl salicylate as an internal standard. Ointment samples were extracted by direct dissolution in ether. Homogeneous suspensions of the creams were prepared in the mobile phase. The samples were spiked by the addition of standard iodochlorhydroxyquin, standard hydrocortisone, and the internal standard and subsequently extracted with the mobile phase. HPLC was performed using a reverse-phase microparticulate C-18 column, a precolumn, and a UV detector set at 256 nm. A mobile phase containing methanol and 0.05 *M* phosphoric acid (70:30) was employed at a flow rate of 1 ml/min. The percent iodochlorhydroxyquin and hydrocortisone found to be present in eight commercial products is reported.

Keyphrases □ Iodochlorhydroxyquin—simultaneous determination with hydrocortisone, ointment and cream, high-performance liquid chromatography □ Hydrocortisone—simultaneous determination with iodochlorhydroxyquin, ointment and cream, high-performance liquid chromatography □ High-performance liquid chromatography—simultaneous determination of iodochlorhydroxyquin and hydrocortisone, ointment and cream

Iodochlorhydroxyquin (I) is used alone or in combination with hydrocortisone (II) as an antimycotic, antibacterial, and anti-inflammatory agent in topical preparations. Because of its toxicity, several analytical procedures have been developed for the determination of I in biological fluids (1–7). The present pharmacopeial assay method for I in creams or ointments (8, 9) is time consuming, requires heating during the extraction procedures (which can lead to decomposition of I), and involves the use of an IR spectrophotometric assay procedure. Other IR spectrophotometeric procedures specific for I in pharmaceutical products have also been described (10, 11). However, these methods are cumbersome, require a large sample, and involve the use of carbon disulfide in the assay procedure. The pharmacopeial methods for assaying II in creams and ointments (12) depend on the oxidation of the α-ketol side chain by either triphenyltetrazolin chloride or blue tetrazolin. Base concentration, water, air, solvent, and light are known to interfere with color formation in the tetrazolin reaction (13). Excipients that interfere with color formation include sorbitan monooleate, lanolin, and stearic acid (14).

This work describes a high-performance liquid chro-

0022-3549/83/0900-1036$01.00/0

matographic (HPLC) method that can be used routinely to assay I and II in ointments and creams. The method is simple and combines specificity and sensitivity not attainable by previously described methods.

EXPERIMENTAL

Apparatus—The HPLC system consisted of a reciprocating minipump[1]; a stainless steel tube, 6.35-mm o.d. and 4.76-mm i.d. × 1 m as a pulsation damper; a 34.5-MPa (5000 psi) pressure gauge[2]; a fixed-volume sample injector[3] with a 20-μl loop; and a variable-wavelength UV detector[4]. A multivoltage 25.4-cm strip chart recorder[5] was connected to the UV detector. A microparticulate reverse-phase chromatographic column (250 × 2.6 mm, packed with ODS-HC-SIL-X-1[6]) and a 5 × 40-mm guard column (RP-18-MPLC[7]) were connected to the HPLC system. The following chemicals were used: iodochlorhydroxyquin[8]; anhydrous ether (analytical reagent grade)[9]; methanol distilled in glass, residue free[10]; phenyl salicylate[11]; hydrocortisone[12]; and water, which was deionized, demineralized, and glass-distilled in our laboratory. No impurities were detected by HPLC in the iodochlorhydroxyquin (I) or hydrocortisone (II) reference standards or in the phenyl salicylate internal standard.

Ointments and Creams—The following products used were reported by the manufacturers to contain the indicated percentages of each drug: product A[13], 3% I; product B[14], 3% I; product C[15], 3% I and 1% II; product D[16], 3% I and 1% II; product E[17], 3% I, 1% II, and 0.5% pramoxine hydrochloride; product F[18], 3% I and 0.5% II; product G[19], 3% I and 0.5% II; and product H[20], 3% I and 1% II.

Standards—Stock solutions of I were prepared in methanol at 1.0 mg/ml. Solutions of II and phenyl salicylate were each prepared in the mobile phase (methanol–0.05 *M* phosphoric acid, 70:30) and contained 1.0 mg/ml. These solutions could be stored in the refrigerator for at least 2 weeks without deterioration. Working standards were prepared daily, using methanol–0.05 *M* phosphoric acid (70:30) to make the desired dilutions.

Chromatographic Conditions—The parameters used for this investigation included a reverse-phase column and precolumn, as previously described, and a 20-μl injector loop, with the recorder chart speed set at 0.254 mm/min. A mobile phase containing methanol–0.05 *M* phosphoric acid (70:30) was used at a flow rate of 1 ml/min. The mobile phase was filtered using a 0.20-μm filter[21], deaerated under vacuum, and maintained at 40° during chromatography. The UV detector was set at 256 nm. The column was flushed at the end of each day with methanol. Not more than 30 min was required for column equilibration prior to use each day.

Extraction Procedures—*Ointments*—Fifty milligrams of each ointment was dissolved in 10 ml of ether by vortexing. Aliquots (200 μl) were transferred to 20-ml screw-cap vials and spiked with varying amounts of I working standard. A fixed amount of the internal standard (phenyl salicylate) was added to each vial. In cases where the ointments contained II, the ointment solutions were spiked with standard II solution in addition to I and the internal standard. These solutions were evaporated to dryness at 40° under a stream of nitrogen. The contents of each vial were dissolved in 10.0 ml of mobile phase by warming for 1 min on a steam bath followed by vortexing for 1 min. After cooling to room temperature, aliquots of each solution were removed, diluted with mobile phase, and injected onto the column.

Creams—Fifty milligrams of each cream was uniformly suspended in 10 ml of mobile phase by vortexing. Aliquots were removed, spiked with the standard solutions and internal standard, and evaporated to dryness as described above for ointments. The contents of each vial were warmed, suspended in 10.0 ml of the mobile phase by warming on a steam bath followed by vortexing. Aliquots were subsequently diluted with mobile phase and assayed by HPLC.

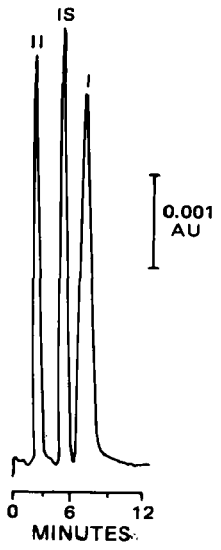

Figure 1—*Chromatogram of extracted product C to which the internal standard (IS), phenyl salicylate (4 μg/ml), had been added. The amounts of iodochlorhydroxyquin (I) and hydrocortisone (II) that were present in the product were 2.8 and 0.93%, respectively. The detector was set at 256 nm and 0.02 AUFS.*

RESULTS AND DISCUSSION

Iodochlorhydroxyquin (I) standard was scanned in methanol–0.05 *M* phosphoric acid (70:30) and exhibited maxima at 256 (α = 0.15) and 204 (α = 0.11) nm. For optimum sensitivity the detector was set at 256 nm.

The use of 4,7-dichloroquinoline[22], 10-chloro-9-anthracenemethanol[22], 2,4-quinolinediol[22], 3-quinolinecarbonitrile[22], 5,7-diiodo-8-hydroxyquinoline[23], and 5,7-dichloro-8-hydroxyquinoline[22] as internal standard was attempted without satisfactory results. 4,7-Dichloroquinoline, 5,7-diiodo-8-hydroxyquinoline, 10-chloro-9-anthracenemethanol, and 5,7-dichloro-8-hydroxyquinoline had retention times that overlapped with I, while 2,4-quinolinediol and 3-quinolinecarbonitrile had retention times that interfered with II. Phenyl salicylate was found to be suitable as an internal standard. It was easily separated from I, absorbed adequately at 256 nm, and produced consistent peak heights when extracted in conjunction with ointments or creams. Suitable retentions for I, II, and phenyl salicylate were obtained when a mobile phase containing methanol–0.05 *M* phosphoric acid (70:30) was used.

To determine whether the ointment and cream bases interfered with the HPLC of I, II, or the internal standard, the peak height ratios of the absorbances at two different wavelengths (256 and 246 nm) were determined on extracts from each product. These results were compared with the same ratios for the standard I, II, and internal standard. No differences were found when comparing the respective ratios, indicating that constituents in the bases that may have been extracted did not interfere with the analyses of the desired compounds.

Figure 1 is a chromatogram of an extracted ointment (product C) which contained I and II and was spiked with the internal standard. The capacity factor (k') for I was 2.94 and for the internal standard was 1.76,

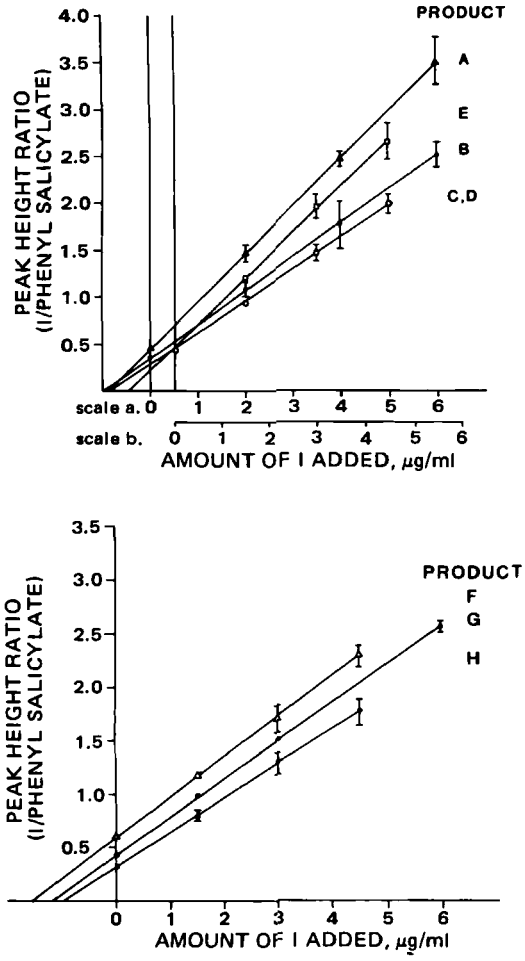

Figure 2—*Plots of I/phenyl salicylate peak height ratio* versus *amount of I added to products A–H. Extrapolation of the regression lines to the x-axis and multiplication by the appropriate dilution factor permits determination of I in each ointment or cream. The concentration of phenyl salicylate added to extracts from the products was 4.0 μg/ml. Each assay was performed in triplicate; standard deviations are shown only when >0.10.*

where the retention times for I (Rt_I) and phenyl salicylate were 7.50 and 5.25 min, respectively. The elution time of the solvent front (Rt_0) was 1.90 min and was determined by injecting methanol onto the column. In cases of ointments or creams which contained II, it was necessary to use the mobile phase in the extraction procedure and preparation of the standards to elminate the solvent front which interfered with the chromatographic peak of II (Rt_{II}, 2.50 min). As can be seen in Fig. 1, the peaks for I, II, and internal standard are well separated. Optimum extraction of I was obtained with the mobile phase (pH 2.8). Extraction of I from ointments and creams at other pH values was less efficient.

Figure 2 shows the regression lines of peak height ratio of iodochlorhydroxyquin (I)/phenyl salicylate *versus* concentration of I for the eight different products examined. Each product was spiked with varying concentrations of I, and the determinations were performed in triplicate. The mean values are presented with the standard deviations. Correlation coefficients for each of the lines for the eight products were >0.96. The regression lines for I in products C and D are identical and are presented as a single line in Fig. 2; only the largest standard deviations are given.

In Fig. 3 is plotted the peak height ratios of hydrocortisone (II)/phenyl salicylate against II concentration for five products that contained II. Determinations were performed in triplicate, and each value represents the mean with the standard deviation. The correlation coefficients for each of the plots are again >0.96. The regression lines for II in products F, G, and H are identical and are presented as a single line in the figure.

The concentrations of I and II found in the eight products, as determined by HPLC, are presented in Table I and were derived by using the regression lines presented in Figs. 2 and 3. These results are compared with the percentages of I and II claimed to be present in the products by

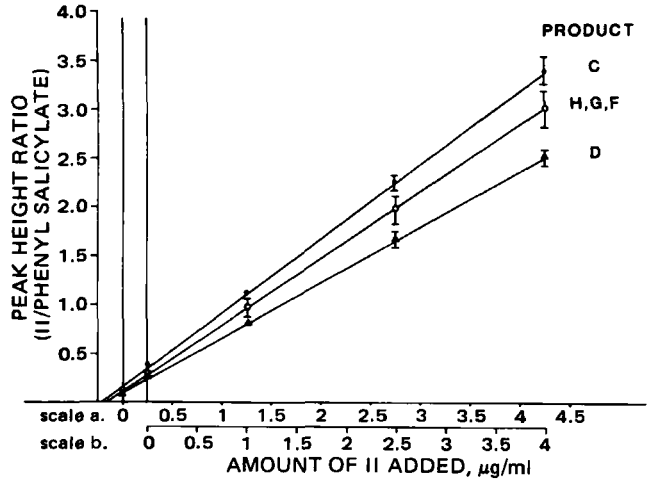

Figure 3—*Regression lines of II/phenylsalicylate peak height ratio* versus *amount of II added to products C, D, F, G, and H. The x-intercept of each regression line when multiplied by the appropriate dilution factor yields the concentration of II in the ointment or cream. The concentration of phenyl salicylate added to each product extract was 4.0 μg/ml. Each assay was performed in triplicate; standard deviations are shown only when >0.10.*

the manufacturers. As can be seen, the concentrations of I and II do not agree with the manufacturers' claims in all cases.

Products E and H were reported to contain 3% I, but were experimentally determined to contain only 2.0%; product G was purported to contain 3% I, but was experimentally found by HPLC to contain only 2.4%. These discrepancies may in part be due to the decomposition of I to products which were not extracted by the methods employed. No unidentified components were detected by HPLC (Fig. 1). The formation of unextracted complexes between I and constituents in the ointment bases is not likely based on the recovery data presented in Table II. The results obtained for products E, G, and H were reproducible on repeated analysis. As previously stated, for all other products containing I good agreement between the concentrations of I claimed by the manufacturers and the amounts determined by HPLC was obtained.

Compound II was present in six products; the concentration of II could be determined in five of the products. The concentrations of II determined experimentally by HPLC for two of the products contained 20% less than that claimed by the manufacturer. Better agreement was ob-

Urinary Excretion of Methylparaben and Its Metabolites in Preterm Infants

K. W. HINDMARSH *§x, E. JOHN ‡, L. A. ASALI *, J. N. FRENCH *, G. L. WILLIAMS ‡, and W. G. McBRIDE *

Received June 15, 1982, from **Foundation 41, Foetal Pharmacology Laboratory*, and the ‡*Neonatal Unit, The Womens Hospital, Sydney, N.S.W. Australia 2010.* Accepted for publication August 6, 1982.

§Present address: College of Pharmacy, University of Saskatchewan Saskatoon, Saskatchewan, Canada S7N OWO.

Abstract □ A high-performance liquid chromatographic (HPLC) assay to quantitate methylparaben in urine was developed. Standard curves were linear and recovery of the paraben from urine averaged 82.6%. The urinary excretion of methylparaben in six preterm infants (≤31 weeks gestational age), who were receiving intramuscular injections of a paraben-containing gentamicin formulation, ranged from 13.2 to 88.1%. Small quantities of the metabolite, *p*-hydroxybenzoic acid, were detected by GC–MS.

Keyphrases □ Methylparaben—determination in human urine, preterm infants, high-performance liquid chromatography □ High-performance liquid chromatography—methylparaben in human urine, preterm infants, gentamicin formulations □ Preservatives—methylparaben, determination in human urine, preterm infants, high-performance liquid chromatography

Methylparaben (methyl *p*-hydroxybenzoate) and propylparaben (propyl *p*-hydroxybenzoate) are used in combination (in some medications) as preservatives. Reports that methylparaben can displace bilirubin from its binding sites on albumin *in vitro* has produced some concern regarding its use in medicinal formulations administered to the newborn and, in particular, the preterm infant (1–3). Displacement of bilirubin from its binding sites in infants with neonatal jaundice could lead to brain damage (kernicterus).

Gentamicin, an effective antibiotic for treatment of a neonatal Gram-negative sepsis, was also suspected of being a bilirubin displacer (4). Subsequent experiments have proven that gentamicin does not displace bilirubin (2, 5). However, some gentamicin formulations do contain methylparaben as a preservative. In an *in vivo* study a group of infants received a single intramuscular injection of a paraben-containing gentamicin formulation. No reduction in the albumin binding capacity for bilirubin was detected (3). The differences seen between this *in vivo* study and the *in vitro* studies may have been due to *in vivo* preservative catabolism or low paraben serum levels achieved after intramuscular injection. The concentrations of methylparaben used *in vitro* were relatively high, *e.g.*, 167 μg/ml of serum (2).

In this study, the excretion and metabolism of methylparaben was monitored in preterm infants after they had received multiple doses of a gentamicin formulation containing paraben preservatives.

EXPERIMENTAL

Materials—Methyl-, propyl-, and *n*-butylparabens[1], phosphoric acid[2], glacial acetic acid[3], and sodium hydroxide[4] were obtained commercially, and appropriate aqueous or methanolic solutions were prepared as required. Urine samples were extracted with freshly glass-distilled ether[5]. An acetate buffer (100 ml, pH 5.0) was prepared by mixing 0.2 *M* acetic acid (14.8 ml), 0.2 *M* sodium acetate[2] (35.2 ml), and water. A 1 *M* carbonate buffer (pH 9.5) was prepared by adding sodium carbonate[2] (5.3 g) and sodium bicarbonate[2] (4.2 g) to water (100 ml). Gentamicin[6] was obtained commercially; each vial (2 ml) contained gentamicin (80 mg), methylparaben (3.6 mg), and propylparaben (0.4 mg).

Patients—Six preterm babies (4 males, 2 females), with estimated gestatinal ages of 26–31 weeks and birth weights of 0.69–1.50 kg, were studied. Each infant was admitted to the neonatal intensive care unit and

Abstract □ A high-performance liquid chromatographic (HPLC) assay to quantitate methylparaben in urine was developed. Standard curves were linear and recovery of the paraben from urine averaged 82.6%. The urinary excretion of methylparaben in six preterm infants (≤31 weeks gestational age), who were receiving intramuscular injections of a paraben-containing gentamicin formulation, ranged from 13.2 to 88.1%. Small quantities of the metabolite, *p*-hydroxybenzoic acid, were detected by GC–MS.

Keyphrases □ Methylparaben—determination in human urine, preterm infants, high-performance liquid chromatography □ High-performance liquid chromatography—methylparaben in human urine, preterm infants, gentamicin formulations □ Preservatives—methylparaben, determination in human urine, preterm infants, high-performance liquid chromatography

Methylparaben (methyl *p*-hydroxybenzoate) and propylparaben (propyl *p*-hydroxybenzoate) are used in combination (in some medications) as preservatives. Reports that methylparaben can displace bilirubin from its binding sites on albumin *in vitro* has produced some concern regarding its use in medicinal formulations administered to the newborn and, in particular, the preterm infant (1–3). Displacement of bilirubin from its binding sites in infants with neonatal jaundice could lead to brain damage (kernicterus).

Gentamicin, an effective antibiotic for treatment of a neonatal Gram-negative sepsis, was also suspected of being a bilirubin displacer (4). Subsequent experiments have proven that gentamicin does not displace bilirubin (2, 5). However, some gentamicin formulations do contain methylparaben as a preservative. In an *in vivo* study a group of infants received a single intramuscular injection of a paraben-containing gentamicin formulation. No reduction in the albumin binding capacity for bilirubin was detected (3). The differences seen between this *in vivo* study and the *in vitro* studies may have been due to *in vivo* preservative catabolism or low paraben serum levels achieved after intramuscular injection. The concentrations of methylparaben used *in vitro* were relatively high, *e.g.*, 167 μg/ml of serum (2).

In this study, the excretion and metabolism of methylparaben was monitored in preterm infants after they had received multiple doses of a gentamicin formulation containing paraben preservatives.

EXPERIMENTAL

Materials—Methyl-, propyl-, and *n*-butylparabens[1], phosphoric acid[2], glacial acetic acid[3], and sodium hydroxide[4] were obtained commercially, and appropriate aqueous or methanolic solutions were prepared as required. Urine samples were extracted with freshly glass-distilled ether[5]. An acetate buffer (100 ml, pH 5.0) was prepared by mixing 0.2 *M* acetic acid (14.8 ml), 0.2 *M* sodium acetate[2] (35.2 ml), and water. A 1 *M* carbonate buffer (pH 9.5) was prepared by adding sodium carbonate[2] (5.3 g) and sodium bicarbonate[2] (4.2 g) to water (100 ml). Gentamicin[6] was obtained commercially; each vial (2 ml) contained gentamicin (80 mg), methylparaben (3.6 mg), and propylparaben (0.4 mg).

Patients—Six preterm babies (4 males, 2 females), with estimated gestatinal ages of 26–31 weeks and birth weights of 0.69–1.50 kg, were studied. Each infant was admitted to the neonatal intensive care unit and

was being treated for suspected sepsis with intramuscular gentamicin, 2.5 mg/kg every 18 hr or 3.0 mg/kg every 24 hr. Each infant was given gentamicin from the first day of extrauterine life. For infants on the 2.5-mg/kg dosage regimen, urine collection was 18 hr in duration and thus spanned the dosage interval. When the infant voided, time and volume were recorded and the collecting device[7] was replaced. With the two infants on the 3.0-mg/kg dosage regimen, urine was collected only when the collecting device was filled, and the total 24-hr urine was pooled prior to analysis. None of the infants were on any other drugs containing methylparaben as a preservative. Four of the infants were receiving electrolytes, vitamins, and amino acid nutrition (hyperalimentation, no paraben preservatives). The other two infants were on their first day of pooled breast milk.

Extraction of Urine Samples—Aliquots (1–2 ml) of urine from each collection period were diluted with an equal volume of acetate buffer and incubated in a water bath[8] at 37° for 18 hr with β-glucuronidase[9] (5 mg) and sulfatase[10] (5 mg). *n*-Butylparaben (800 mg) was added as the internal standard, and the hydrolyzed urine was adjusted first to pH 9 for extraction of methylparaben using carbonate buffer (400–600 μl) and then to pH 2 for extraction of metabolites with phosphoric acid. The urine samples (pH 9) were extracted[11] twice with ether (5 ml) for 1 min, and then centrifuged[12] at 1000×*g* for 5 min. The organic layers were back-extracted into a 0.1 *M* NaOH solution (300 μl) and the ethereal layer was discarded. The basic solution was acidified (pH 2) with phosphoric acid (1 drop) and subsequently extracted with ether (5 ml). After centrifugation (1000×*g*) the ether was transferred to a glass evaporation tube. A tapered pipet[13] with a sealed end was inserted and the tube placed in a 40° water bath[14]. Immediately after evaporation the tubes were stoppered and placed in an ice bath to allow the ether to condense and wash down the inner walls of the evaporation tube. The condensed ether was evaporated under a nitrogen stream. Before injection into the liquid chromatograph, the residue was reconstituted in 200 μl of mobile phase by mixing[11] (30 sec).

After extracting at pH 9, urine samples were adjusted to pH 2 and extracted twice with ether (5 ml) in a similar fashion to that described above. The ether was evaporated and the residues derivatized utilizing *N,N*-dimethylformamide di-*n*-butyl acetal[15] (20 μl) and acetonitrile[1] (10 μl; silylation grade). The stoppered tubes were heated (water bath, 48°) for 15 min before injection into the gas chromatograph–mass spectrometer.

High-Performance Liquid Chromatography (HPLC)—Methylparaben concentrations were determined utilizing a liquid chromatograph[16] equipped with a loop injection system[17] and a 30 cm × 3.9-mm (i.d.) octadecylsilane column[18]. A UV detector[19] equipped with a 254-nm filter and a dual-pen recorder[20] (with inputs set at 10 mV and chart speed of 20 cm/hr) was used. The mobile phase, HPLC-grade acetonitrile[21] and 0.05% phosphoric acid (40:60) was pumped through the column at 90 ml/hr, resulting in an inlet pressure of 900 psig.

Gas Chromatography–Mass Spectrometry (GC–MS)—GC–MS was performed on a GC–mass spectrometer equipped with a data system[22]. The chromatographic column was a 0.9 m × 2-mm (i.d.) coiled, glass column packed with 3% OV-17 on 100–120 mesh Gas Chromosorb Q[23]. The injection port temperature was 240°, and the helium flow rate 30 ml/min. The column was heated at 160° (1 min) and then increased to 220° (2 min) at a rate of 10°/min. A solvent wait period of 0.5 min was employed.

Methylparaben concentrations were calculated from standard curves made after extracting known quantities of methylparaben which had been added to urine. A standard curve was plotted as the peak height ratio of methylparaben to internal standard (butylparaben) against known methylparaben concentrations. Creatinine levels were determined using the Jaffe kinetic reaction[24].

Table I—Urinary Excretion of Methylparaben

Patient	Amount Administered, μg	Total Amount Detected, μg	Percent of Dose Excreted
A	70.0	9.24	13.2
B[a]	170.0	27.7	16.3
C	85.0	74.9	88.1

E[a]	190.0	67.9	35.7
F	160.0	54.6	34.1

[a] Urine collected over 24 hr.

RESULTS AND DISCUSSION

The gentamicin administered intramuscularly to the infants in this study contained both methyl- and propylparaben. HPLC analysis of spiked urine extracts gave two well-defined peaks adequately separated from the internal standard, butylparaben (peak III, Fig. 1A). Peaks I and II (Fig. 1A) are methyl- and propylparaben, respectively. The urine extracts from the infants in this study showed, on analysis, one major peak (peak I, Fig. 1B) other than the internal standard (peak III) which was not present on analysis of a control urine extract. The solvent eluant corresponding to the retention time of peak I (Fig. 1B) was collected, extracted, and identified by GC–MS as methylparaben (molecular ion, *m/z* 152). Peak II (Fig. 1B) was due to an endogenous substance. Although it was not the intention of this study to measure propylparaben levels,

this paraben was detectable, and verified by GC–MS (molecular ion, m/z 166) in the pooled 24-hr urine extracts. The samples obtained at the time of urine void during the 18-hr collection period were not of sufficient volume for propylparaben analysis. The standard curve for the HPLC analysis of methylparaben was linear (r^2, coefficient of determination, 0.996) over a concentration range of 100–2000 ng/ml. The mean recovery of methylparaben from urine was 82.6 ± 4.9% (SD).

The percentage of the methylparaben dose accounted for in hydrolyzed urine samples (collected over 18 or 24 hr) after gentamicin administration varied from 13.2 to 88.1% (Table I). Of the methylparaben excreted in the urine the majority was in conjugated form. Extraction of nonhydrolyzed urine samples yielded <1% methylparaben. Analysis of a single urine sample divided into three aliquots and hydrolyzed with sulfatase, β-glucuronidase, or β-glucuronidase in combination with sulfatase indicated sulfate conjugates were more abundant (19% greater) than glucuronides. Levy *et al.* (6) noted the decreased phenolic glucuronidation of acetaminophen was partially compensated, in the full-term neonate, by a well-developed capacity for sulfate conjugation.

A number of factors may be responsible for the poor recovery of methylparaben in most of these infants. The patients may not have achieved a steady state with respect to parabens. However, each infant had been receiving gentamicin from the first day postpartum. The volume of distribution is increased due to a greater total water content in the newborn and a higher ratio of extracellular to intracellular water (7). Extracellular fluid in the newborn may be as high as 45% (8). The maximum urinary excretion rate of methylparaben in the infants varied, ranging from 1.5 to 17 hr (A, 4.5 hr; C, 6.25 hr; D, 1.5 hr; F, 17 hr). This variability may, in part, be due to differences in intramuscular absorption. Peripheral vasomotor instability, changes in relative blood flow of muscles (due to maturational adaptation), and relative insufficiency of muscular contractions account for variation in intramuscular absorption in the newborn (7).

One patient (C) who was 11 days of age excreted 88.1% of the administered methylparaben (Table I). Serum creatinine determinations (Table II) indicated renal function was adequate. Only two infants had creatinine levels within the normal range (<0.10 mmoles/liter). An improvement in glomerular filtration is usually seen within the first few days of the preterm infants' extrauterine life (7).

Methylparaben may be eliminated by routes other than renal excretion and/or metabolized by means other than conjugation. The only metabolite detected was p-hydroxybenzoic acid. GC–MS analysis of a pH 2, butylated, hydrolyzed urine extract revealed a small peak (R_T, 3.1 min) which gave prominent ions at m/z 194, 138, and 121. These latter ions were due to the loss of a C_4H_8 molecule and a C_4H_9O radical, respectively, from the molecular ion of n-butylparaben, m/z 194. The retention time and mass spectral data were identical to those obtained on GC–MS analysis of an authentic sample of p-hydroxybenzoic acid which had been treated with N,N-dimethylformamide di-n-butyl acetal. The recovery of this metabolite was not attempted because the peak was small and in some cases appeared only as a shoulder on an endogenous urine peak. Perhaps the small recovery of this metabolite is not surprising since esterase activity in preterm infants is low (8).

Glycine conjugation is evident in hepatic, renal, and intestinal tissue at relatively early stages of gestation (9). The glycine conjugate of p-hydroxybenzoic acid was not detected, but hippuric acid (glycine conjugate of benzoic acid) was seen in the butylated pH 2 urine extracts. GC–MS analysis of these extracts revealed a peak (R_T, 4.1 min) with a molecular ion at m/z 235 and prominent ions at m/z 134 and 105 due to the loss of $C_5H_9O_2$ and $C_6H_{12}NO_2$ fragments, respectively, from the molecular ion. p-Hydroxyhippuric acid, the glucuronide of p-hydroxybenzoic acid, and the ether sulfate of p-hydroxybenzoic acid were the main metabolites detected in the urine and bile of the rat after the administration of ethylparaben (10).

Table II—Patient Data

Patient	Birth Wt., kg	Gestational Age, weeks	Postpartum Age, days	Serum Creatinine, mmoles/liter
A	0.69	26	3	0.16
B	1.20	27	3	0.05
C	0.83	27	11	0.03
D	1.19	30	3	0.13
E	1.45	30	7	0.13
F	1.50	31	3	0.13

Although the number of infants studied is small, recovery of methylparaben appears to improve as gestational and postpartum age increase. Excluding patient C (discussed earlier), the recoveries were greatest in patients E and F (Table I). Both of these infants were 31 weeks conceptional (gestational plus postnatal) age.

In conclusion, the excretion of methylparaben by the urinary route, in preterm infants is variable during the first few days of extrauterine life. These infants are often on medications, such as gentamicin, that contain paraben preservatives for extended periods of time. Whether there is an accumulation of the preservatives in the body and whether after repeated injections the albumin binding capacity for bilirubin is affected remains to be determined. It is not uncommon for preterm infants to have neonatal jaundice. In fact, except for patient F the preterm infants in this study had jaundice which was treated with phototherapy. The differences seen between the *in vitro* and *in vivo* studies (1–3) cannot be explained by preservative metabolism or urinary excretion in the preterm infant as postulated by Woods *et al.* (3).

Interaction of Povidone with Aromatic Compounds IV: Effects of Macromolecule Molecular Weight, Solvent Dielectric Constant, and Ligand Solubility on Complex Formation

J. A. PLAIZIER-VERCAMMEN

Received January 11, 1982, from the *Vrije Universiteit van Brussel, Farmaceutisch Instituut, B-1090 Brussels, Belgium.* Accepted for publication August 10, 1982.

Abstract □ Complex formation of ligand molecules with povidone was investigated to elucidate the effect of the molecular weight of the macromolecule and the influence of the solvent dielectric constant on the complexing tendency. The higher molecular weight polymers were more effective complexing agents than those with lower degrees of polymerization. When studying complex formation as a function of the dielectric constant (D), a linear relationship was noted between D and log B/F (B/F representing the ratio of bound to free ligand); the use of solvent mixtures to achieve a range of solvent dielectric constants enabled changes of the pH of the solvent, ligand dissociation, and solubility of the ligand and macromolecule. Of the variables under investigation, only the change in ligand solubility seemed to play an important role: a linear relationship was noted between the complexing tendency (log B/F) and the logarithm of the inverse of the ligand molecule solubility in the solvent mixtures (log $1/S$). It was concluded that the change in solubility of the ligand was the predominant factor in the decrease of the complexing tendency with decreasing dielectric constant.

Keyphrases □ Povidone—complex formation with salicylic acid, influence of molecular weight, solvent dielectric constant, and ligand solubility □ Salicylic acid—complex formation with povidone, influence of polymer molecular weight, solvent dielectric constant, and solubility □ Complex formation—salicylic acid and povidone, influence of polymer molecular weight, solvent dielectric constant, and ligand solubility

The effect of the molecular weight of povidone on the complexing tendency of ligand molecules has been studied (1–4). Either a positive effect (1, 2) or no effect at all was noted (3, 4). However, no interpretative statements were given. It was also observed (5) that the complexing tendency of ligand molecules with povidone decreases with a decrease of the dielectric constant. Such dependence as a function of dielectric constant is generally attributed to hydrophobic bondings (6–8). However, varying the dielectric constant also has an effect on the solubility of the ligand molecule. It was the purpose of this report to study the influence of the molecular weight of povidone on the complexing tendency of the ligand molecule and to investigate the possible relationships between the dielectric constant of the solvent, solubility of the ligand, and complex formation with povidone.

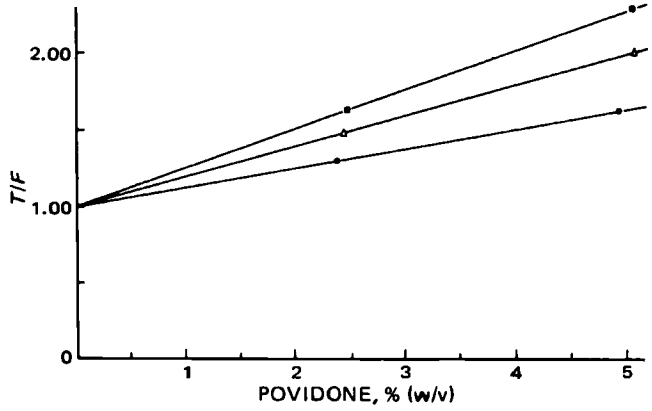

Figure 1—*Ratio of the total to free concentration of salicylic acid as a function of the concentration of povidone with molecular weights of 11,500 (●), 25,000 (△), and 700,000 (■). Initial salicylic acid concentration: 1.00 × 10⁻² M; pH 7.00; 25.0°.*

EXPERIMENTAL

Reagents—Povidone with molecular weights (weight average values) of 11,500[1] (batch I), 25,000[2] (batch II), and 700,000[3] (batch III) was used. It was oven-dried at 50° until constant weight was achieved. As ligand molecules, the following compounds were employed: salicylic acid[4], 4-hydroxysalicylic acid[5], and 5-hydroxysalicylic acid[4]. A phosphate buffer of pH 7.00 with a 0.25 ionic strength was used. The pH of the buffer was controlled with a potentiometric pH measurement[6] and adjusted as necessary. Different ethanol–water (from 0.0 to 20.0% v/v ethanol) and propylene glycol–water (from 0.0 to 50.0% v/v propylene glycol) mixtures were prepared, providing solvents with a wide range of dielectric constants.

Ultrafiltration—Ultrafiltration was used to investigate the ligand–macromolecule interactions. The equipment used was described previously (9).

Spectrophotometric Analysis—The concentration of unbound ligand was determined spectrophotometrically in the ultrafiltrate. Corrections for membrane adsorption effects were made, and the concentration of bound ligand was calculated from the difference between the concentration of total and unbound cosolute. The spectrophotometric measurements were performed with a double-beam spectrophotometer[7] at the respective λ_{max} of the ligand molecules, after appropriate dilution.

Effect of Molecular Weight of Povidone on Complex Formation—Two concentrations of the three batches of povidone were dissolved in a phosphate buffer (pH 7.00) containing 1.00×10^{-2} M salicylic acid. Ultrafiltration was carried out at 25.0°.

Effect of Dielectric Constants on Complex Formation—Salicylic acid, 4-hydroxysalicylic acid, and 5-hydroxysalicylic acid were dissolved in a range of ethanol–water mixtures (0.0 to 20.0% v/v ethanol), containing the macromolecule povidone (batch III). For 5-hydroxysalicylic acid, batch I povidone was also used. The latter ligand molecule was also dissolved in propylene glycol–water mixtures (0.0 to 50.0% v/v propylene glycol). The dielectric constants of the solvent mixtures were measured at 25.0° and 35.0°[8].

Solubility Measurements—The solubility data for salicylic acid and 4-hydroxysalicylic acid were obtained by placing amounts of the two compounds, in excess of their solubility, in 25 ml of the ethanol–water mixtures (0.0 to 20.0% v/v ethanol) in stoppered flasks. The suspensions were agitated at 25.0° and 35.0°, respectively, in a water bath. After equilibrium, the flasks were removed from the water bath, and the contents were quickly filtered through filter paper[9]. Suitable aliquots of the clear filtrate were pipetted, appropriately diluted with the respective solvent mixtures, and the absorbance of the samples was determined.

0022-3549/83/0900-1042$01.00/0

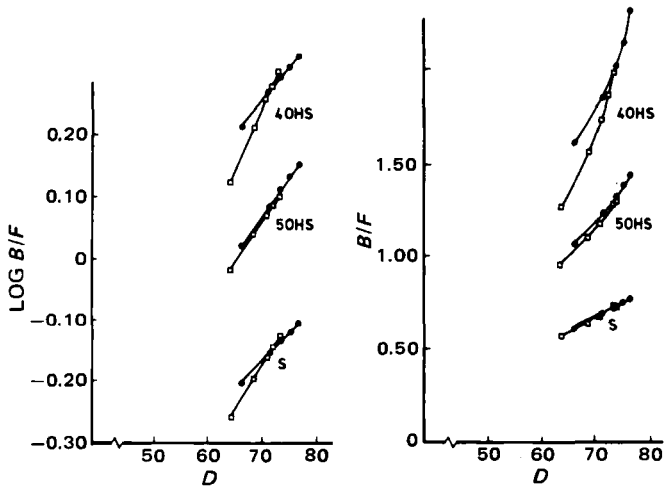

Figure 2—*Variation in the complexing tendency of ligand molecules with the dielectric constant of the solution (solvent: ethanol–water). Key: (●) 25.0°; (□) 35.0°; (4OHS) 4-hydroxysalicylic acid (5.00 × 10^{-3} M) plus 4.00% povidone, batch III; (5OHS) 5-hydroxysalicylic acid (5.00 × 10^{-3} M) plus 5.00% povidone, batch III; (S) salicylic acid (5.00 × 10^{-3} M) plus 4.00% povidone, batch III.*

Viscometric Analysis—Using capillary viscometers, the intrinsic viscosities of povidone dissolved in water, 20% (v/v) ethanol, and 50% (v/v) propylene glycol were determined at 25°. Temperature was controlled to ±0.05°. Povidone concentrations ranged from 0.2 to 1.0%.

RESULTS AND DISCUSSIONS

Theory of Multiple Equilibria—The principles and concepts fundamental to an understanding of macromolecular binding can be found elsewhere (10–16). In this report, the relative tendencies of several ligand molecules to form complexes are expressed as the ratio of the total ligand concentration (T) to the concentration of the free form (F) as a function of the percentage of povidone (17–19). This may be written as:

$$q = \frac{\text{concentration of total ligand}}{\text{concentration of free ligand}} = \frac{T}{F} = \frac{r}{F}[\text{PVP}] + 1 \quad \text{(Eq. 1)}$$

where r is moles of bound ligand/moles of macromolecule and [PVP] is the concentration of povidone in the solution. If r/F was constant, *i.e.*, if the same type of binding was taking place with increasing povidone concentration, T/F *versus* [PVP] plots resulted in straight lines (20).

Effect of Molecular Weight of Povidone on Complex Formation—The results expressed as T/F were plotted against the polymer concentration in Fig. 1. The higher molecular weight polymers are more efficient complexing agents than those with lower degrees of polymerization.

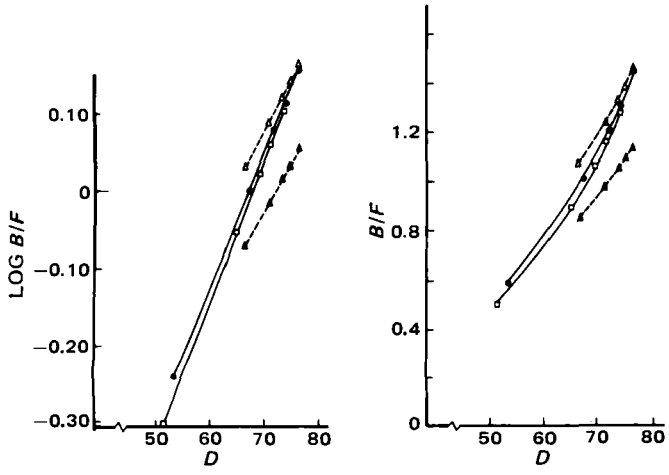

Figure 3—*Variation in the complexing tendency of 5-hydroxysalicylic acid with the dielectric constant of the solution [5-hydroxysalicylic acid (5.000 × 10^{-3} M) plus 5.00% povidone]. Key: (●) solvent propylene glycol–water, 25.0°, batch III; (□) solvent propylene glycol–water, 35.0°, batch III; (△) solvent ethanol–water, 25.0°, batch III; (▲) solvent ethanol–water, 25.0°, batch I.*

Table I—Intrinsic Viscosity of Povidone (Batch III) in Solvent Mixtures

Solvent	Intrinsic Viscosity, g/ml
Water	140
20% (v/v) Ethanol	150
50% (v/v) Propylene glycol	152

The two variables that can influence complex formation (*i.e.*, true solvation and the number of sites) are, however, independent of molecular weight for the same concentration of polymer (expressed in weight percent). On one hand, it is shown that for the same polymer, true solvation is independent of molecular weight if the active sites for solvent are equally accessible (12). On the other hand, if specific sites exist, according to the complexing theory they also will be independent of molecular weight for the same polymer percentage.

The difference in complexing tendency is in accordance with the existence of carboxylic end groups on the polymer (2, 21), as shown by IR spectroscopy. The end groups per unity weight polymer will be largest for the lower molecular weight, accompanied by an increase of solvation; this will result in a lower complexing tendency, as dehydration has a positive effect on the binding of ligand molecules onto povidone (22).

Effect of Dielectric Constant on Complex Formation—The results expressed as log B/F and B/F (the ratio of bound to free ligand concentration) were plotted in Figs. 2 and 3 as a function of the dielectric constant of the solvent, measured at the same temperatures as the ultrafiltration experiments. For all the derivatives, complex formation was diminished with decreasing dielectric constant (or increasing ethanol or propylene glycol concentration). Furthermore, the complexing tendency was diminished at higher temperatures. Comparing complex formation of 5-hydroxysalicylic acid onto povidone batch III and batch I (Fig. 3), the higher molecular weight macromolecule was the most effective complexing agent.

Figures 2 and 3 corresponded to the following equations:

$$\log \frac{B}{F} = b_1 + a_1 \cdot D \quad \text{(Eq. 2)}$$

where D is the dielectric constant and b_1 and a_1 are two constants, or:

$$\frac{B}{F} = 10^{b_1 + a_1 \cdot D} \quad \text{(Eq. 3)}$$

Using Eq. 2, it was noted that log B/F increased linearly with the dielectric constant of the solvent or diminished linearly with the percentage ethanol or propylene glycol.

In addition to the dielectric constant, temperature also played a role: for salicylic acid and 4-hydroxysalicylic acid (Fig. 2), the lines at 25.0° crossed those at 35.0°; for 5-hydroxysalicylic acid, the two lines are nearly parallel. That complex formation is not only dependent on dielectric constants could be observed from the results obtained with 5-hydroxysalicylic acid in ethanol–water and propylene glycol–water (Figs. 2 and 3, respectively). For the same dielectric constant, complex formation was

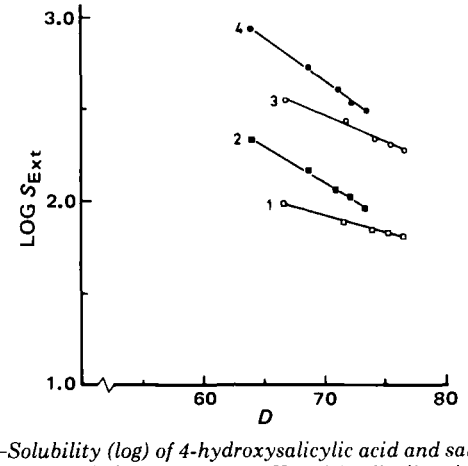

Figure 4—*Solubility (log) of 4-hydroxysalicylic acid and salicylic acid as a function of the dielectric constant. Key: (1) salicylic acid, 25.0°; (2) salicylic acid, 35.0°; (3) 4-hydroxysalicylic acid, 25.0°; (4) 4-hydroxysalicylic acid, 35.0°.*

lowest in the propylene glycol–water mixture. Thus, the nature of the solvent must also play a role.

A diminishing complexing tendency with lower dielectric constants is generally attributed to hydrophobic bonds (6–8). However, the use of ethanol–water mixtures in differing proportions to achieve a range of solvent dielectric constants changed the ionization of the ligand (23), the pH of the solution, and the solubility (hydration) (24) of the macro- and ligand molecules (23–25). These factors, which also could influence complex formation, were investigated.

Ionization and dissociation of ligand molecules are depressed under conditions of low dielectric constant of the medium (23). This factor cannot be very important, in view of experimental observations (22) where a decrease in the dissociation of ligand molecules enhanced complex formation; this is not observed for the ligand molecules under investigation.

The difference in hydration of povidone in water, ethanol, and propylene glycol solutions was investigated with viscometric measurements. The intrinsic viscosities are given in Table I. No attempts were made to interpret changes in the Huggins constant (26), since no good interpretation in small deviations of these constants exists (27, 28).

From Table I, it was observed that the parameters are not significantly affected by change in solvent composition; this may possibly indicate that the total solvation of povidone was not affected much by changes in solvent composition. After all, povidone is not only soluble in water, but also in alcohol and even in chloroform, and hence, presumably in propylene glycol as well. Therefore, alcohol and propylene glycol will also be bound to povidone, in addition to water.

From pH measurements, it is noted that the pH of the solutions is almost unaffected by changing the solvent composition from zero to 20.0% (v/v) ethanol. At constant pH, ethanol enhances the solubility of weak electrolytes, by lowering the polarity of the solvent (23). For povidone batches I and III, the solubility of the ligand molecule is not changed in the same solvent composition; therefore, the difference in complex formation must be due to the macromolecule. The difference in complex formation of 5-hydroxysalicylic acid onto the two povidone batches also is attributed to the lower hydration of povidone batch III, enhancing the complexing tendency.

The solubility of two ligand molecules, *i.e.*, salicylic acid and 4-hydroxysalicylic acid, as a function of solvent composition and dielectric constant was investigated. The results obtained at 25.0° and 35.0° are represented in Fig. 4. The values of the ordinate are extinction values.

The solubility (log) of the two ligand molecules is linearly decreasing with increasing dielectric constant of the solvent medium; the decrease is faster at 35.0° than at 25.0°. This can be written as:

$$\log S = b_2 - a_2 \cdot D \qquad \text{(Eq. 4)}$$

where S is the solubility of the compounds and b_2 and a_2 are two constants or:

$$\log \frac{1}{S} + b_2 = a_2 \cdot D \qquad \text{(Eq. 5)}$$

The relationship between the solubility of the ligand and the complexing tendency onto povidone can be obtained from Eqs. 2 and 5. Dividing the two equations results in:

$$\log \frac{B}{F} = \frac{a_1}{a_2} \log \frac{1}{S} + b_2 \frac{a_1}{a_2} + b_1 \qquad \text{(Eq. 6)}$$

or:

$$\log \frac{B}{F} = a_3 \log \frac{1}{S} + b_3 \qquad \text{(Eq. 7)}$$

with $a_1/a_2 = a_3$ and $b_3 = (b_2 \cdot a_1/a_2) + b_1$.

The correctness of Eq. 7 was checked with the experimental results: the data obtained for 4-hydroxysalicylic acid and salicylic acid (Fig. 2) expressed as log B/F were plotted as a function of log $1/S$. The deduced linear relationship between log B/F and log $1/S$ in Eq. 7 was confirmed experimentally. The corresponding values of a_3 and b_3 for salicylic acid are 0.492 and 0.823 at 25.0° and 0.534 and 0.612 at 35.0°; for 4-hydroxysalicylic acid these values are 0.435 and 1.35 at 25.0° and 0.365 and 1.23 at 35.0°. A similar relationship was obtained for the interaction of anilines to nylon (29).

Log $1/S$ is a partitioning term, as it is an equilibrium constant between drug (pure) $\rightleftarrows$ drug (H_2O) (30) and is correlated with another partitioning function. Indeed, B/F may also be considered a partitioning term expressing the partition of ligand between the macromolecule and the solvent; it is directly analogous to an organic solvent–water partition coefficient.

From our experiments, it can be concluded that the predominant effect of the decrease in complex formation in the solvent mixtures was caused by the increasing solubility of the ligand molecules. Correlation between complex formation to povidone and solubilities for the two derivatives provide additional support for the occurrence of complex formation by hydrophobic interactions.

Pharmacokinetics of Intravenous and Oral 1,2-*O*-Isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose Hydrochloride in the Dog as a Function of Dose and Characterization of Metabolites

Abstract □ The pharmacokinetics of 1,2-*O*-isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride (I) was studied in dogs at intravenous and oral doses of 1–50 mg/kg. There was no significant difference between the electron-capture GLC of the heptafluorobutyric derivative of I and the radiochemical assay of chloroform extracts of plasma and urine for 1- to 20-mg/kg doses. Urinary amounts of I measured by GLC were 20% lower than radioassays of chloroform extracts at the 50-mg/kg dose. The pharmacokinetics of intravenous I was described by a two-compartment body model with sequential plasma half-lives of 7.5 ± 0.7 and 136 ± 6 min. No apparent dose-dependent pharmacokinetics for I was observed on intravenous or oral administration. The apparent volume of distribution of the central compartment, 13.1 ± 0.7 liters, is approximately the volume of the total body water in a 20-kg dog. The apparent overall volume of distribution of 40.0 ± 1.5 liters exceeds the total body water, indicative of sequestration of I in tissues. Total and renal clearances were 205 ± 5 and 155 ± 5 ml/min, respectively. The high renal clearance of I indicated an excess of tubular secretion. Renal clearance of I was not dependent on urine flow nor urine pH. Recovery of radioactivity in the feces after I was intravenously administered was <1%. Plasma protein binding of I was <5%, and the erythrocyte–plasma water partition coefficient was approximately unity. Compounds excreted in urine were separated into chloroform-extractable (pH 12), ethyl acetate-extractable (pH 2), and unextractable fractions which were further characterized by TLC. A multiple-extraction system was developed to estimate relative amounts and intrinsic partition coefficients of these extractable compounds from radioactivity counts of scraped plates and was applied to the assay of these compounds in the urine after intravenous administration of I. There was a readily chloroform-extractable metabolite with an apparent partition coefficient of 3.3 and R_f 0.43 on TLC in the systems used. This apparent major metabolite could account for 8% of the administered radioactivity. Minor chloroform-extractable metabolites (0.8–3.3%) had lower apparent partition coefficients (0.26) but R_f values of 0.28 and 0.44. Ethyl acetate-extractable compounds (1.3–2.7%) had an apparent partition coefficient of 0.81 with R_f values of 0.52 and 0.68. Three unextractable compounds had R_f values of 0.20, 0.50, and 0.62 and accounted for 0.16, 2.8, and 0.9% of the administered radioactivity.

Keyphrases □ 1,2-*O*- Isopropylidene-3- *O*-3′- (*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose—pharmacokinetics, intravenous and oral doses, dogs □ Metabolites—1,2-*O*-isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose, multiple extraction, radiochemical analysis in urine, dogs □ Pharmacokinetics—1,2-*O*-isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose and metabolites, dogs, intravenous and oral doses

The properties, stability, assay, and preliminary pharmacokinetics in a dog of the immunomodulatory 1,2-*O*-isopropylidene-3-*O*-3′ - (*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride (I) were described previously (1). This initial pharmacokinetic study in a dog showed that 60–80% of I was renally excreted unchanged and 20–40% as unidentified metabolites at doses of 2 and 10 mg/kg iv. This contrasted with the urinary recovery of the GLC-assayed I in humans of 93 ± 2% in preliminary pharmacokinetic studies, indicative that only a small fraction was probably metabolized (2). Assays of chloroform-extracted radioactivity at pH 11 from plasma and urine appeared to be synonomous to electron-capture GLC assays of the heptafluorobutyric derivative of I, indicating the greater polarity of the unextracted metabolites.

This paper presents detailed studies on the pharmacokinetics of I in dogs after intravenous and oral administration as a function of dose (1–50 mg/kg). A fractionation and multiple-extraction system is presented that permits the quantitative assays of unidentified metabolites and the estimations of the partition coefficients of extractable metabolites from radioassays of sequential organic extracts.

EXPERIMENTAL

Materials—The following analytical grade materials were used: ammonium hydroxide[1], volumetric concentrations of sodium hydroxide[2] and hydrochloric acid[2], chloroform suitable for GC[3], ethyl acetate[3], isopropyl alcohol[3], methanol[3], *n*-propyl alcohol[4], 30% hydrogen peroxide[4], and a toluene-based scintillation cocktail[4]. 1,2-*O*-Isopropylidene-3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride[5] (I) and radiolabeled I (randomly ^{14}C-labeled in the glucose component[6], 324.0 mCi/mmole) were used to prepare doses for the pharmacokinetic studies. The TLC plates used were silica gel G-coated glass plates[7].

Purity of ^{14}C-Labeled I—Radiolabeled [^{14}C]I applied on TLC and developed with *n*-propyl alcohol–ethyl acetate–water–ammonium hydroxide (6:1:4:1) had a 98% recovery of the administered radioactivity at the R_f (0.67) of I. No significant radioactivity over background was observed for its hydrolysis product, 3-*O*-3′-(*N*′,*N*′-dimethylamino-*n*-propyl)-D-glucofuranose hydrochloride, at R_f 0.30. In addition no significant radioactivity was observed over background at any other R_f value.

Plasma Protein Binding of I by Ultrafiltration—Fresh dog plasma was spiked with 0.1–100 μg/ml ^{14}C-labeled I (47,000 dpm). An aliquot (0.1 ml) was taken prior to filtration to determine total radioactivity. Spiked plasma (2.00 ml) was centrifuged through ultrafiltration cones[8] at 3000 rpm for 10 min for no more than 30% (usually 10%) filtration of the plasma. Aliquots (0.1 ml) of the ultrafiltrates were assayed by liquid scintillation counting (2). Membrane binding (3–29%) of ^{14}C-labeled I was found by ultrafiltration of spiked plasma water samples and subtracted from the studies of spiked plasma.

Red Blood Cell–Plasma Water Partitioning of I—Red blood cells obtained from centrifugation of fresh, heparinized dog blood were washed five times with isotonic saline[9], recentrifuged, and resuspended in plasma water obtained by ultrafiltration to give a hematocrit of 46. Aliquots (2.00 ml) of the suspensions were spiked with 0.01–100 μg/ml of ^{14}C-labeled I (47,000 dpm), incubated at 25° for 30 min, and centrifuged at 3000 rpm for 10 min. Aliquots (0.1 ml) of the original suspension and the separated

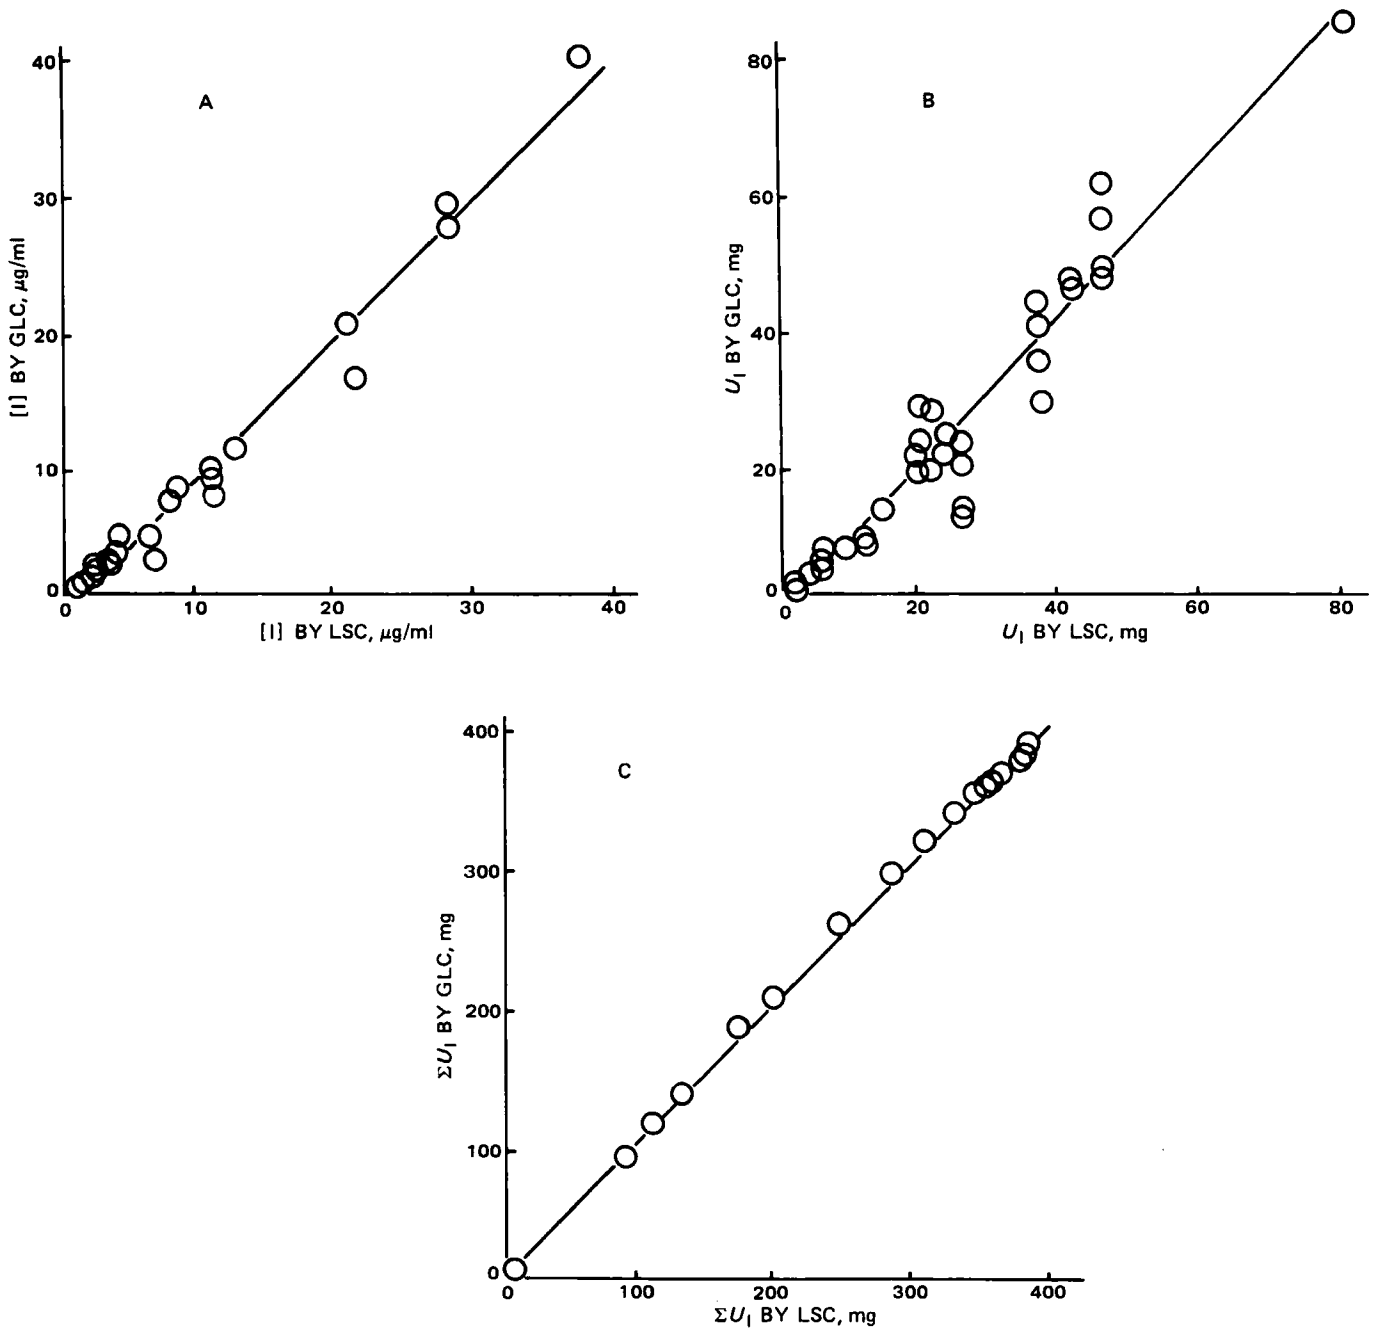

Figure 1—*Linear regressions of (A) concentrations of I ([I]) in plasma, (B) amounts of I (U_I) excreted in the urine in a given time interval, and (C) cumulative amounts of I (ΣU_I) excreted in the urine at a given time assayed by electron-capture GLC on the radioassay (LSC) of chloroform extracts. Dog A was administered 24.0 mg/kg iv of I.*

plasma water were assayed for radioactivity after digestion with 1.00 ml of a mixture of solubilizer[10]–isopropyl alcohol (1:1 v/v) and 0.5 ml of 30% hydrogen peroxide.

The partition coefficient, D, was calculated from the equation cited in the literature (3) where the fraction of bound I was taken as zero. Partition coefficients between red blood cells and plasma water were also determined as a function of time for a 1-μg/ml spiked red blood cell suspension.

Analysis of ^{14}C-Labeled I in Plasma and Urine—The electron-capture GLC assay of the heptafluorobutyric derivative of I and the radioassays after chloroform extraction of plasma and urine were described previously (1).

Pharmacokinetic Studies of I in Dogs—One male dog (A) received intravenous doses of 1.9, 2.0, 10.0, 24.0, and 48.4 mg/kg and oral doses of 5.1 and 20.0 mg/kg of ^{14}C-labeled I. Except for the 2.0 and 10.0 mg/kg iv studies, effected respectively 1 year and 6 months before the others (1), the studies had intervals of 3 weeks. Four other male dogs (B, C, D, and E) were intravenously injected with ~1, 5, and 10 mg/kg at ~3-week intervals. Intravenous doses of known specific activity were injected into the jugular catheter[11] by a three-way stopcock[12] over 10 sec. The dosing stopcock and catheter were flushed with 10.0 ml of isotonic saline. In the oral studies, a tube was placed into the stomach of dog A to administer 10.0 ml of the solution of ^{14}C-labeled I. The stomach tube was flushed twice with 50.0 ml of water before it was removed.

Blood samples after oral administration were withdrawn at 2 and 5 min, every 5 min up to 60 min, every 10 min up to 90 min, and then at the same times as previously reported for the intravenous studies (1). Urine samples in oral studies were collected at the same times as for intravenous studies (1). Further details of the treatment of the dogs, before and on the days of the experiments, the collection times of plasma and urine for

[a] $y \pm s_{y \cdot x} = m (\pm s_m)_x + b (\pm s_b)$, where the constants m and b are the slope and intercept, respectively, of the regression of GLC assays of I (y) on LSC (x) assays of chloroform extracts of plasma and urine, and $s_{y \cdot x}$, s_m, and s_b are the respective standard errors of estimate; r is the correlation coefficient (4). [b] The 1-min plasma sample was excluded from the regression analysis.

the intravenous studies, and the handling of the samples were given previously (1).

Treatment of Feces—Feces were collected at 24-hr intervals and homogenized with a 10-fold volume of distilled water. An aliquot (0.2 ml) was transferred to a scintillation vial[13]; 0.5 ml of solubilizer[10] was added and the mixture was digested at 50° for 1 hr in a water bath. After cooling, 1 ml of 30% H_2O_2 was added dropwise, and the mixture was gently swirled for 30 min. After air bubbles were eliminated, 15 ml of liquid scintillation fluid was added. Samples were dark-adapted overnight before counting.

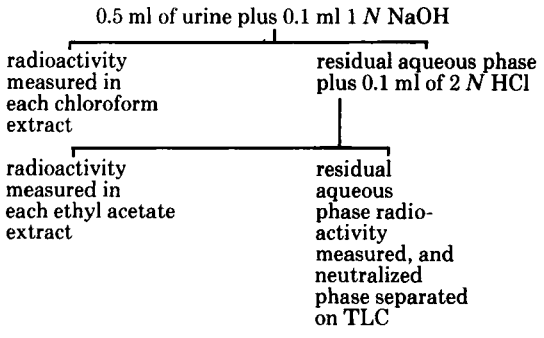
Extraction of Urine with Various Organic Solvents and at Different pH Values—The strategy of extractions is given in Scheme I. Aliquots of urine (0.5 ml), before and at various times after intravenous administration of 1017 and 43.1 mg of [^{14}C]I (48.4 and 1.9 mg/kg), from dog A were alkalinized to pH 12 with 0.1 ml of 1 N NaOH. Radioactivity before extraction was counted after addition of 10 ml of liquid scintillation fluid to 0.02 ml of the alkalinized urine. Alkalinized samples were then extracted sequentially 15 times with 5.0 ml of water-saturated chloroform. Each chloroform extract was transferred to a scintillation vial and evaporated under a nitrogen stream. The dried residues were each reconstituted in 10 ml of liquid scintillation fluid, and the radioactivity was counted.

The aqueous phase, previously extracted 15 times with chloroform, was acidified with 2 N HCl to pH 2, and then extracted seven times sequentially with 5.0 ml of water-saturated ethyl acetate. Each ethyl acetate extract was transferred to a scintillation vial and evaporated under a nitrogen stream. The dried residues were each reconstituted in 10 ml of liquid scintillation fluid to count radioactivity.

After all chloroform and ethyl acetate extractions, 10.0 ml of liquid scintillation fluid was added to 0.05 ml of the aqueous phase to count unextractable radioactivity. The remaining aqueous phase was neutralized with 2 N NaOH to pH ~7, and an aliquot (0.05 ml) was applied on a silica gel-coated TLC plate. Aliquots of solutions of the administered radiolabeled drug, 585 and 1056 ng in 0.6 ml of blank urine and distilled water, respectively, were treated similarly (Scheme I).

TLC Separation of Chloroform- and Ethyl Acetate-Extractable and Unextractable Radioactivity—An aliquot (0.05 ml) of the final aqueous phase, previously multiple extracted by chloroform and ethyl acetate, was neutralized, spotted on a silica gel G-coated glass plate, and developed with n-propyl alcohol–ethyl acetate–water–ammonium hydroxide (6:1:4:1). The TLC plate was scraped in 0.5-cm sections after development to 15 cm and being dried in air. The scrapings were transferred to scintillation vials and dissolved in 3.0 ml of water. Liquid scintillation fluid (10.0 ml) was added, and the vials were counted for radioactivity after overnight dark adapting.

Samples of repetitive chloroform and ethyl acetate extracts of a 20.0-ml combined sample of 120-, 180-, and 240-min urine and of 20.0 ml of 665-min urine were evaporated, reconstituted in 50–100 μl of solvent, spotted on TLC, and developed similarly. Similar studies were effected for the spiked blank urine solutions of radiolabeled I.



Scheme I—Multiple extractions of urine taken at various times after intravenous administration of 48.4 mg/kg of ^{14}C-labeled I to dog A.

[13] Kimble, Division of Owens-Illinois, Toledo, OH 43668.

RESULTS AND DISCUSSION

Plasma Protein Binding and Red Blood Cell–Plasma Water Partitioning of I—Plasma protein binding of I by ultrafiltration was 3.4 ± 2 (*SEM*)%, n = 4, when corrected for membrane binding and was independent of the spike concentration (0.1–100 μg/ml). This was similar to the plasma protein binding, 1.5 ± 1.9%, in humans (2). The red blood cell–plasma water partition coefficient, D, was not concentration dependent (0.01–100 μg/ml of red blood cell suspension), and was approximately unity [0.99 ± 0.08 (*SEM*), n = 5], close to the 0.95 ± 0.04 of human erythrocytes (2). There was also no time-dependent distribution of I in the erythrocytes, measured between 5 and 60 min at 1 μg/ml.

Recovery of Radioactivity in Feces—Negligible amounts (0.3 and 0.1%) of the administered radioactivity were found in the feces of dog A after intravenous administrations of 40 (0.3%) and 200 mg (0.1%) of radiolabeled I.

Comparison of Radiolabeled and GLC Assays of I—Plasma sampled from dog A as a function of time (1–600 min) after intravenous administration of 24.0 and 48.4 mg/kg and after oral administration of 20.0 mg/kg of ^{14}C-labeled I were analyzed for I by electron-capture GLC and by the radioassay of the single 5-ml chloroform extracts of 500 μl of solution containing 0.5–500 μl of plasma. The assays were linearly related (Fig. 1A). The regression coefficients, m, were not significantly different than unity, nor were the intercepts, b, different than zero (Table I) for the 24- (iv) and 20- (po) mg/kg doses. There is a possibly greater assay value by radioassay than GLC at the 48.4-mg/kg dose, indicating a small amount of chloroform-extractable metabolite, although elimination of the 1-min plasma sample increased the regression coefficient to 0.94 ± 0.03.

Similarly, the amount of I excreted in the urine, U_I and the amounts cumulatively excreted in the urine, ΣU_I, with time (15–900 min) were the same by the GLC assay and the radioactivity counting of the single 5-ml chloroform extracts of 500 μl of a solution containing 0.02–500 μl of urine (Fig. 1B and C) at 24.0-mg/kg iv and 20.0-mg/kg po doses. However, GLC assays of urinary I at the 48.4-mg/kg iv dose were 20% lower than radioassays of the chloroform extracts, as ascertained by regression analysis (Table I), indicating the presence of significant amounts of chloroform-extractable metabolites at this dose.

The good correlation between the GLC assays of I and the radioassays of chloroform extracts of plasma and urine at the 2- and 10-mg/kg iv doses in dog A had been reported previously (1). It can be concluded that any radiolabeled metabolite extracted in a single chloroform extraction of

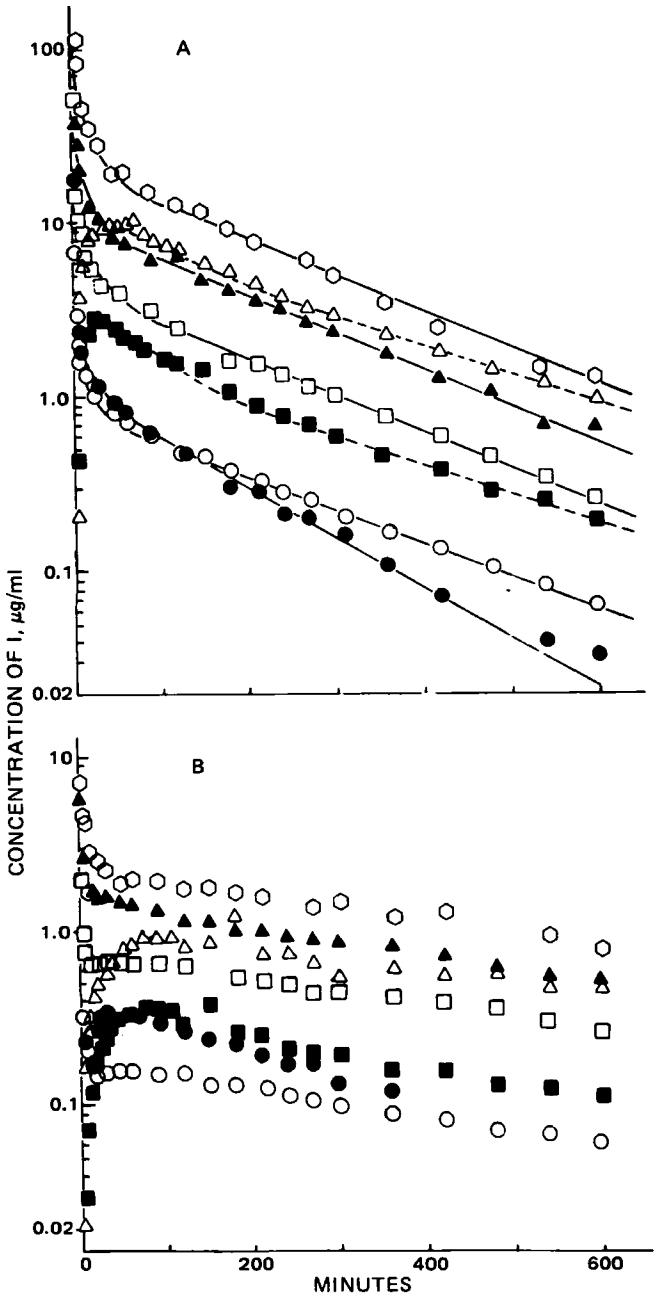


Figure 2—*Semilogarithmic plasma concentration* versus *time plots of (A) I determined by radioassay (LSC) of chloroform extracts and (B) total metabolites determined by direct radioassay of chloroform-extracted aqueous phases after administration of ^{14}C-labeled I to dog A at mg/kg doses of (○) 1.9 iv, (●) 2.0 iv, (□) 10.0 iv, (▲) 24.0 iv, (○) 48.4 iv, (■) 5.1 po, and (△) 20.0 po. Solid lines were drawn in accordance with [I] = $Ae^{-\alpha t} + Be^{-\beta t}$ where parameters are given in Table II.*

plasma or urine at pH 12 for low doses of I (2 to 24 mg/kg) did not disturb assays of I by LSC, although some radiolabeled metabolite(s) were extracted with chloroform at the high dose of 48 mg/kg iv.

Pharmacokinetics of Intravenously Administered I—The semilogarithmic plots of the plasma levels of I with time at doses of 1.9, 24.0, and 48.4 mg/kg iv and at the previously reported 2.0 and 10.0 mg/kg iv doses in dog A (Fig. 2A) and at doses of 1, 5, and 10 mg/kg iv in dogs B, C, D, and E showed primarily biphasic curves, indicative of a two-compartment body model for I. The lines drawn through the experimental points were calculated from the general equation $[I] = Ae^{-\alpha t} + Be^{-\beta t}$ in μg/ml of plasma where the parameters A, B, α, and β are listed in Tables II and III for the intravenous data. Similar curves were obtained for the studies in the other dogs.

In all intravenous studies the first 1-min data point after administration was omitted to fit the experimental plasma values to a sum of two

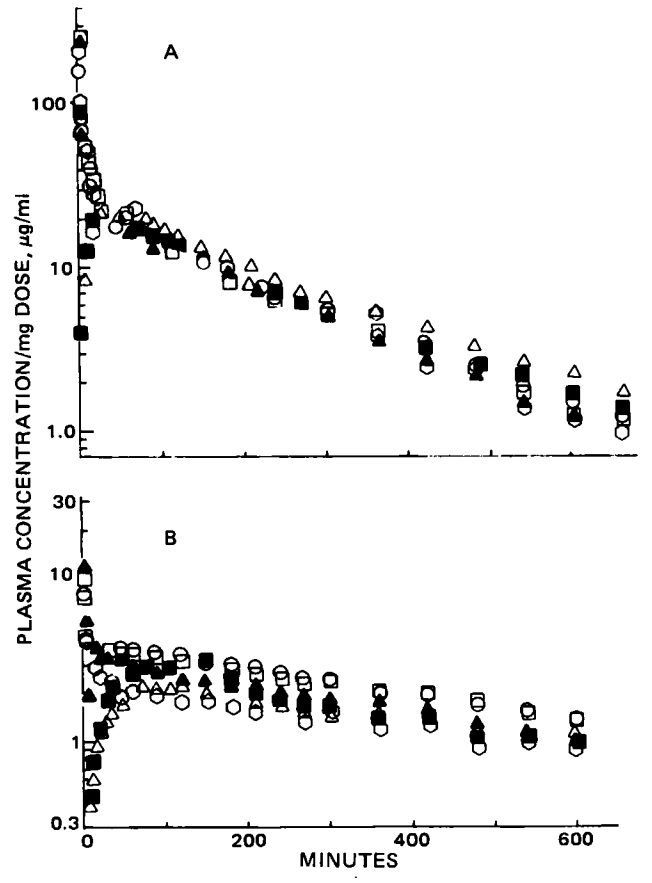

Figure 3—*Semilogarithmic plots of plasma concentrations with time of (A) I per milligram administered dose determined by radioassay (LSC) of chloroform extracts and (B) total metabolites, in equivalents of I per milligram administered dose, determined by direct radioassay of chloroform-extracted aqueous phases after administration to dog A of ^{14}C-labeled I in mg/kg doses of (○) 1.9 iv, (□) 10.0 iv, (▲) 24.0 iv, (○) 48.4 iv, (■) 5.1 po, and (△) 20.0 po. Drawn curves through iv data were in accordance with $[I]/D_0 = (A/D_0)e^{-\alpha t} + (B/D_0)e^{-\beta t}$.*

exponentials. This 1-min plasma concentration was significantly higher than the concentration calculated from this sum in all studies and indicated a possibly faster initial distribution phase with an apparent half-life of 0.5–1.0 min. It could not be explained by the first samples being contaminated with residual ^{14}C-labeled I, which was administered into the jugular catheter, since plasma levels of I obtained simultaneously from the jugular catheter and a leg vein catheter were identical in both the intravenous 48.4-mg/kg and 1.0-mg/kg doses of I administered to dogs A and C, respectively. Subsequent samples up to 1 hr from both sites also showed coincident plasma levels.

The average plasma half-lives of the distribution and elimination phases for all intravenous studies in dogs A, B, C, D, and E were, respectively, 7.5 ± 0.7 (*SEM*) and 136 ± 6 (*SEM*) min and were independent of dose in the range of 1–50 mg/kg (Tables II and III). The plasma levels calculated per milligram unit dose, $[I]/D_0$ with time were reasonably superimposable for all intravenous doses in dog A (Fig. 3A). This was also true for the different dose studies in the other dogs. These facts indicated dose-independent pharmacokinetics of I on intravenous administration.

The plasma levels of total metabolites as equivalents of I were estimated from the radioactivity in the aqueous phase after chloroform extraction of the plasma. The radioactivity was corrected for unextracted I (1), and the resultant curves of apparent total metabolite concentrations in plasma are given directly in Fig. 2B and per milligram of administered dose of I in Fig. 3B. The apparent metabolite plasma levels per milligram of dose (Fig. 3B) decreased slightly, but systematically, with increasing intravenous doses, indicating a possible dose dependence in metabolite formation in contrast to the plasma levels of I. This was also observed for other dog studies at different doses. Since metabolic clearance is only 13% of the total clearance, this apparently minor dose-dependent metabolism would not be expected to significantly affect the observed dose-independent overall pharmacokinetics of I.

[a] Pharmacokinetic parameters of 2.0- and 10.0-mg/kg studies were reported previously (1). [b] Parameters estimated from best fit of LSC assay of I in plasma against time (Fig. 2) in accordance with $[I] = Ae^{-\alpha t} + Be^{-\beta t}$; LSC and GLC assays were coincident. The 1-min plasma level datum was omitted from consideration. [c] Total clearance of I, D_0/AUC_∞, where AUC_∞ is the total area under the I plasma level-time plot. [d] Renal clearance of I consistent with the $\Sigma U = CL_{ren}AUC_t$ (Figs. 4 and 6), where AUC_t is the area under the plasma level of I-time plot for the time when the cumulative amount of I in the urine, ΣU, was measured. At the highest dose of 48.4 mg/kg iv, GLC and LSC of extracts were not coincident. [e] Apparent volume of central compartment for I, $Dose/(A + B)$. [f] Apparent overall volume of distribution for I, CL^I_{tot}/β. [g] Apparent extrapolated volume of distribution for I on presumption of one-compartment body model, $Dose/B$. [h] Estimated from asymptotes of ΣU *versus* time plots of Fig. 6. [i] Based on LSC assay of radioactivity in aqueous phase after chloroform extraction of urine. [j] Based on LSC assay of total radioactivity in urine (1). [k] Transfer rate constant from the tissue compartment to the central compartment, $k_{TB} = (A\beta + B\alpha)/(A + B)$ (7). [l] Elimination rate constant from the central compartment, $k_{BE} = \alpha\beta/k_{TB}$ (7). [m] Transfer rate constant from the central compartment to the tissue compartment $k_{BT} = \alpha + \beta - k_{TB} - k_{BE}$ (7). [n] Based on GLC assay of urine. [o] Based on LSC assay of chloroform extract of urine.

Apparent Volumes of Distribution of I—The apparent volumes of distribution (Tables II and III) were referenced to the plasma concentration of I. The average apparent volume of distribution of the central compartment was 13.1 ± 0.7 (*SEM*) liters, $V_c = D_0/(A + B)$, which is equivalent to the total body water in a 20-kg dog (12–14 liters) (5). The average apparent overall volume of distribution, $V_d = CL_{tot}/\beta$, was 40.0 ± 1.5 (*SEM*) liters, which exceeded total body water and indicated tissue sequestration.

Clearances of I—The renal clearances (Tables II and III) were estimated from plots of the urinary excretion rates of I against the plasma concentrations at the midpoint time of each urine collection interval and from plots of the amounts of I cumulatively excreted in the urine at time t (ΣU_t) against the area under the plasma level–time curve at time t (AUC_t), according to the equation $\Sigma U_t = CL_{ren}AUC_t$ (Fig. 4). The presence of a possible initial distribution phase of 0.5–1-min half-life was supported by the fact that the positive intercepts frequently observed for renal clearance plots of ΣU_t against AUC_t when the initial 1-min datum was ignored did not exist when the additional area given by its inclusion was considered. Then the intercept was not significantly different from zero.

The renal clearances [155 ± 5 (*SEM*) ml/min] were independent of dose, urine flow, and urinary pH and indicated an excess of tubular secretion of the negligibly plasma protein-bound I in addition to glomerular filtration, which is in the range of the inulin clearance (85 ± 35 ml/min) in a 20-kg dog (6). Thus, at doses <24 mg/kg, dose-dependent renal clearances cannot be concluded. However, the possibility of lowered renal clearance at higher doses is still open, as the one study at 48.4 mg/kg did not show coincident LSC and GLC assays of extracts of urine, and the renal clearances from the latter assay appeared to be significantly lower (Table II).

Bioavailability on Oral Administration—The fact that no dose dependency was observed on intravenous administration of 1–48.4 mg/kg (Fig. 3A, Tables II and III) demonstrated that that systemic distribution and disposition of I followed first-order linear pharmacokinetics and permits us to estimate the absolute bioavailability of oral solutions of I with respect to intravenous administration by the ratio of areas under the plasma level–time curves. The areas under the plasma level–time curves (Table IV) were calculated by integration to time infinity according to $AUC_\infty = A/\alpha + B/\beta$ for the intravenous doses. They were calculated for the oral doses by the trapezoidal rule to time 900 min and by adding the terminal area estimated by dividing the plasma level at 900 min by the disposition rate constant. The area per milligram oral dose of 5.1 μg·min/ml at the 5.1-mg/kg dose was virtually identical to the averaged area of 5.2 μg·min/ml for the intravenous doses of 1.9–48.4 mg/kg. However, the area per milligram dose of 6.1 μg·min/ml at the 20.0-mg/kg oral dose was 10% higher than the highest area of 5.58 μg·min/ml found for the 48.4-mg/kg intravenous dose. This finding could indicate a possible saturable first-pass metabolism of I at high oral doses. This was also indicated by the fact that the plasma concentrations per unit dose were slightly higher for the higher oral dose (Fig. 3A).

Absorption Rates of Orally Administered I—The rates of absorption of I were determined by the Loo–Riegelman deconvolution method (7). The values of the apparent volume of distribution of the central compartment (V_c) and the parameters α, β, and A and B per milligram intravenous dose necessary for estimates of the microscopic rate constants between the central and tissue compartments, k_{BT} and k_{TB}, and the

[a] Pharmacokinetic parameters were based on LSC. Refer to Table II for footnotes *b*–*j*.

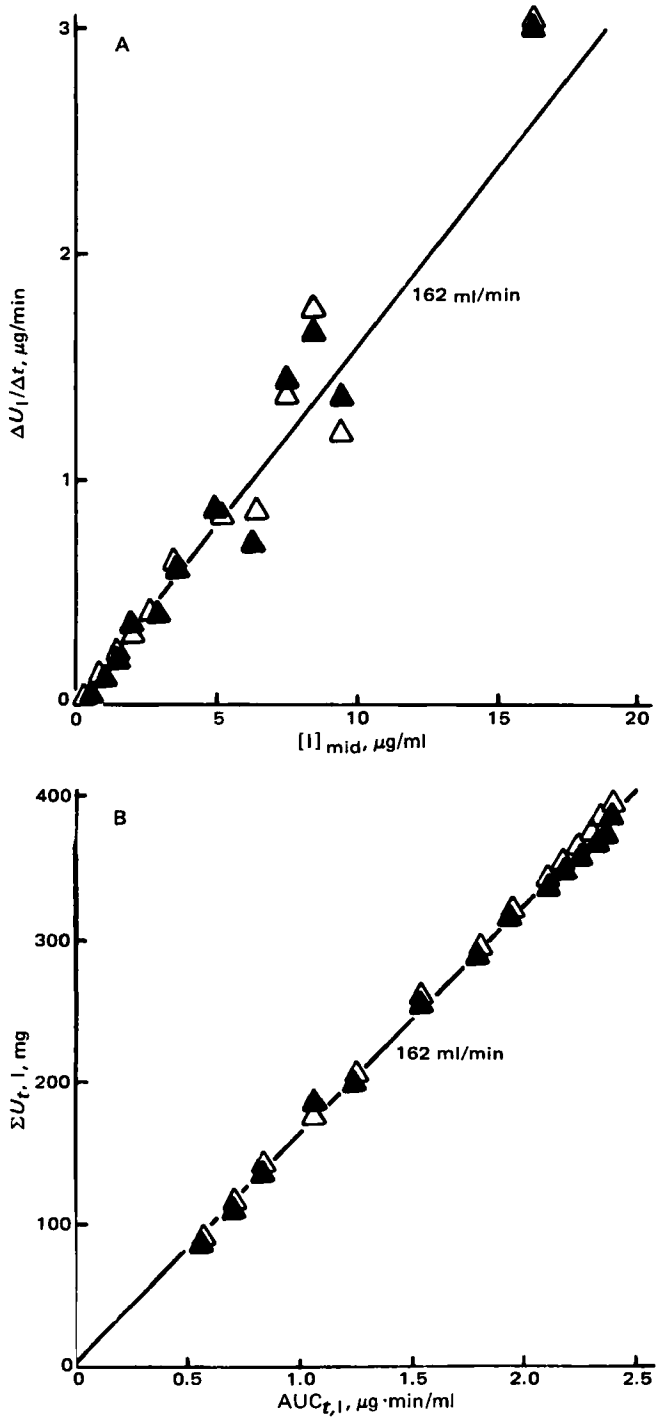

Figure 4—*Typical renal clearance plots for I assayed by GLC (▲) and LSC (△) of extracts, (A) plotting the urinary excretion rates* ($\Delta U/\Delta t$) versus *the plasma levels of I at the midpoint of the urine collection,* ($[I]_{mid}$) *and (B) the cumulative amounts of I excreted in the urine at time* t (ΣU_t) versus *the area under the plasma level–time curve to time* t (AUC_t) *after intravenous administration of 24.0 mg/kg of I to dog A.*

elimination rate constant from the central compartment, k_{BE}, were obtained from the average values of those parameters in the intravenous studies in dog A. The semilogarithmic plots of the percent unabsorbed I with time for the oral doses administered to dog A are given in Fig. 5 and were linear, indicating first-order absorption. First-order rate constants of absorption were 0.017 min^{-1} (absorption $t_{1/2}$ of 41 min) for the 5.1-mg/kg dose and 0.042 min^{-1} (absorption $t_{1/2}$ of 16 min) for the 20.0-mg/kg dose after negligible lag times of 5 and 2 min, respectively. The ratio of the first-order absorption rate constants to the dose was reasonably constant and indicates a possible dose dependence.

[a] Mean ± *SD*(*SEM*) are given. [b] *t* Test for two means.

Urinary Recoveries of Intravenously and Orally Administered I—Unchanged I was recovered in the urine for 79 ± 2 (*SEM*)% of the intravenous doses (1–50 mg/kg). Chloroform-unextracted metabolites accounted for 15 ± 1% (Tables II and III, Fig. 6). There were no significant differences between renally excreted total radioactivity and the sum of the cumulative amounts of extracted and unextracted radioactivities (Tables II and III).

The total recovery of radioactivity from the cumulative total urine was 106 and 103% of the administered radiolabeled I for the 5.1- and 20.0-mg/kg oral doses, respectively, in dog A, implying complete absorption. The plots of the cumulative amounts of extracted and unextracted activities, expressed as the percentage of the orally administered 5.1- and 20.0-mg/kg doses in dog A, with time are also given in Fig. 6. The cumulative plots of I were fitted for constant renal clearances of 158 and 141 ml/min for the respective 5.1- and 20.0-mg/kg oral doses; these renal clearances were consistent with the renal clearances for the intravenous doses (2–48.4 mg/kg) in dog A (Table II). The urinary recoveries after 5.1- and 20.0-mg/kg oral doses in dog A were 84.5 and 87.2%, respectively, of the dose for extracted radioactivity and 11.5 and 8.1% for the unextracted radioactivity. The slightly lower yield of urinary metabolites (8.1%) at the 20.0-mg/kg oral dose than at the 5.1-mg/kg oral dose (11.5%) and a slightly higher area under the plasma level–time curve of unchanged I at the 20.0-mg/kg oral dose (6.10 μg·min/ml) than the area for the highest intravenous dose of 48.4 mg/kg (5.58 μg·min/ml) could indicate the possibility of saturable first-pass metabolism of I. However, these differences in metabolite recoveries in the urine and in area under the plasma level–time curves of I were small.

Theoretical Basis for Estimation of Number of Metabolites and Their Partition Coefficients from Multiple Extractions of Urine—The apparent partition coefficient (k) of any single radiolabeled compound can be defined as the ratio of the radioactivity (disintegrations per minute, dpm) in the organic phase (dpm_{org}) over the radioactivity in the aqueous phase (dpm_{aq}):

$$k = \frac{dpm_{org}}{dpm_{aq}} = \frac{dpm_{tot} - dpm_{aq}}{dpm_{aq}} \quad \text{(Eq. 1)}$$

where dpm_{tot} is the total radioactivity in the system and equal to the sum of the radioactivity in the aqueous and organic phases. On rearrangement of Eq. 1, the fraction of unextracted radioactivity after a single extraction can be expressed as:

$$\frac{dpm_{aq}}{dpm_{tot}} = \frac{1}{1+k} \quad \text{(Eq. 2)}$$

Thus, the radioactivity remaining in the aqueous phase after the first extraction ($dpm_{aq,1}$) is:

$$dpm_{aq,1} = \frac{dpm_{tot}}{1+k} \quad \text{(Eq. 3)}$$

and the solution can be extracted with organic solvent for a second time to give:

$$dpm_{aq,2} = \frac{dpm_{aq,1}}{1+k} \quad \text{(Eq. 4)}$$

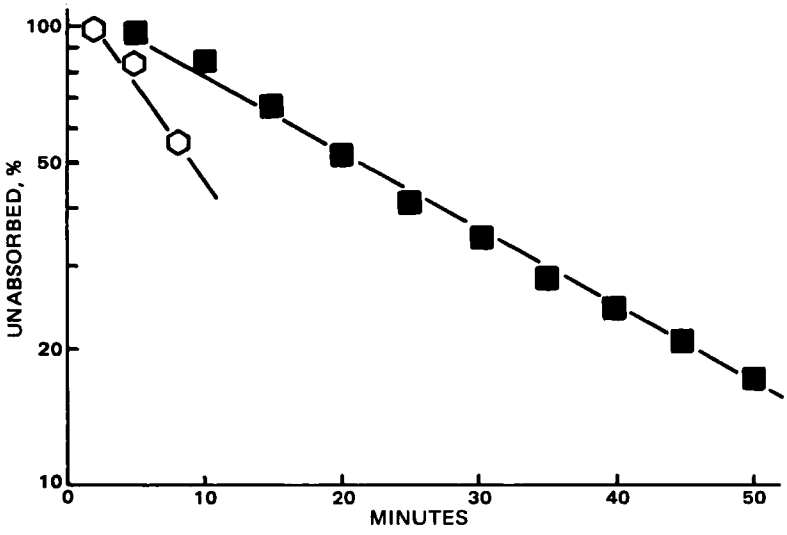

Figure 5—*Semilogarithmic plot of the percent unabsorbed I with time for oral doses of 5.1 (■) and 20.0 (○) mg/kg administered to dog A. Percent unabsorbed I was calculated by the Loo-Riegelman deconvolution method (7).*

Substitution of Eq. 3 into Eq. 4 gives:

$$\mathrm{dpm}_{aq,2} = \frac{\mathrm{dpm}_{tot}}{(1+k)^2} \qquad \text{(Eq. 5)}$$

Thus, the radioactivity left in the aqueous phase after n repetitive extractions is:

$$\mathrm{dpm}_{aq,n} = \frac{\mathrm{dpm}_{tot}}{(1+k)^n} \qquad \text{(Eq. 6)}$$

and

$$\log \mathrm{dpm}_{aq,n} = \log \mathrm{dpm}_{tot} - n\log(1+k) \qquad \text{(Eq. 7)}$$

and a plot of the logarithm of the radioactivity left in the aqueous phase and unextracted ($\mathrm{dpm}_{aq,n}$) *versus* the number of sequential extractions, n, will be linear. The intercept would be the logarithm of the total radioactivity (dpm_{tot}) of the compound before any extraction.

The linearity of the semilogarithmic plot of $\mathrm{dpm}_{aq,n}$ against n (Fig. 7, curves A and A′) implies the possibility of one extractable compound (or several with the same partition coefficient) on ethyl acetate extraction of the acidified chloroform pre-extracted urine samples obtained after intravenous administration of I (curve A) or on spiking blank urine with [^{14}C]I (Curve A′). The total radioactivity (dpm_{tot}) before any ethyl acetate extraction can be estimated from the intercept. This was 1.9% of the total radioactivity in the original urine collection of Fig. 7a, and corresponded to 1.04 mg of the total amount of material as I equivalents in this 370-min urine sample. The apparent partition coefficient of the compound, k, determined from the slope of the line, $\log(1+k)$, in Eq. 7 was 0.815.

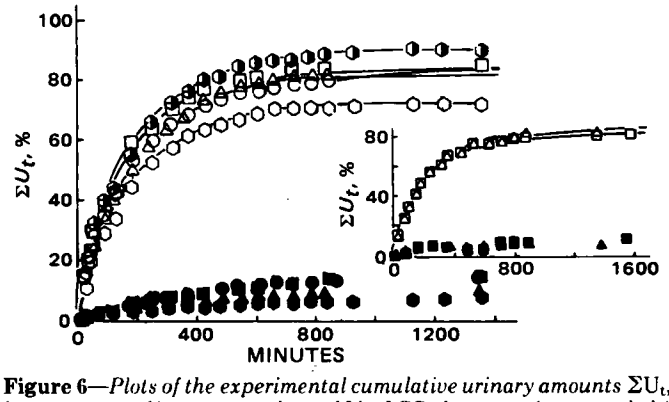

Figure 6—*Plots of the experimental cumulative urinary amounts ΣU_t, in percentage of intravenous dose, of I by LSC of extracts (open symbols) and of total metabolites by LSC of chloroform-extracted aqueous phase (solid symbols), for the 1.9- (○), 10.0- (□), and 24-mg/kg (△) doses of I administered to dog A, against time, where the GLC and LSC assays of urine extracts were coincident (Table I). The different values of the cumulative urinary amounts of I, by GLC (○) and LSC (◑) assays of chloroform extracts of urine after a 24.0-mg/kg dose to dog A, against time are both presented (Table I). Similar plots of the experimental cumulative urinary amounts of I, by LSC assay of extracts, which were coincident with the GLC assays (Table I) for the orally administered doses of 5.1 (□) and 20.0 (△) mg/kg to dog A, against time are given in the insert. Curves through the experimental points of I were fitted according to $\Sigma U = CL_{ren}AUC$ for the constant renal clearances summarized in Tables II and III.*

If there were two extractable compounds with significantly different partition coefficients, the radioactivity remaining in the aqueous phase after n extractions, $(\mathrm{dpm}_{aq,n})_{sum}$, would be the sum of the two radioactivities from each of compounds 1 and 2, $(\mathrm{dpm}_{aq,n})_1$ and $(\mathrm{dpm}_{aq,n})_2$, where each remaining activity could be defined by an equation of the form of Eq. 6, where $(\mathrm{dpm}_{tot})_1$, $(\mathrm{dpm}_{tot})_2$, and dpm_{tot} are the total radioactivities of compound 1, compound 2, and their sum, respectively, in the aqueous system before any extractions were made. Thus:

$$(\mathrm{dpm}_{aq,n})_{sum} = (\mathrm{dpm}_{aq,n})_1 + (\mathrm{dpm}_{aq,n})_2 = \frac{(\mathrm{dpm}_{tot})_1}{(1+k_1)^n} + \frac{(\mathrm{dpm}_{tot})_2}{(1+k_2)^n} \qquad \text{(Eq. 8)}$$

If compound 1 were more readily extracted than compound 2 as n increases to large numbers, there would be eventually no more of the former to be extracted and $(\mathrm{dpm}_{aq,n})_1$ would be equal to zero so that:

$$\lim_{n \to \infty} (\mathrm{dpm}_{aq,n})_{sum} = (\mathrm{dpm}_{aq,n})_2 = \frac{(\mathrm{dpm}_{tot})_2}{(1+k_2)^n} \qquad \text{(Eq. 9)}$$

and the logarithm of both sides would give an equation similar to Eq. 7. This can be seen in the examples of curves B and B′ in Fig. 7 for 15 sequential chloroform extractions at pH 12 of urine sampled 370 min after intravenous administration of ^{14}C-labeled I to dog A and for the [^{14}C]I spiked urine, respectively, where possibly two chloroform-extractable compounds may exist in the urine. The apparent partition coefficients (k_2) of this least readily extracted compound, calculated from the slopes of the terminal data, were 0.29 (curve B) and 0.24 (curve B′). The intercept of these extrapolated linear terminal data permitted the calculation of the radioactivity, $(\mathrm{dpm}_{tot})_2$ due to this compound that contributed to the total radioactivity in the original urine sample:

$$\lim_{n \to \infty} \log(\mathrm{dpm}_{aq,n})_{sum} = \log(\mathrm{dpm}_{aq,n})_2 = \log(\mathrm{dpm}_{tot})_2 - n\log(1+k_2) \qquad \text{(Eq. 10)}$$

Thus, the apparent metabolite 2 accounted for 2.24 mg (as I equivalents) or 4.1% of the total radioactivity in the urine collection of the example of curve B and 0.59% in the example of curve B′.

Since $(\mathrm{dpm}_{aq,n})_2$ can be calculated for any n by Eq. 9 from the estimated k_2 and $(\mathrm{dpm}_{tot})_2$, the logarithm of the difference between this value and the experimentally determined $(\mathrm{dpm}_{aq,n})_{sum}$ can be plotted against n (curve C in Fig. 7) to estimate k_1 and $(\mathrm{dpm}_{tot})_1$ (Eq. 8) from the straight line obtained in accordance with:

$$\log[(\mathrm{dpm}_{aq,n})_{sum} - (\mathrm{dpm}_{aq,n})_2] = \log(\mathrm{dpm}_{aq,n})_1 = \log(\mathrm{dpm}_{tot})_1 - n\log(1+k_1) \qquad \text{(Eq. 11)}$$

In the given example (Fig. 7a, curve C), the readily extractable compound, on the assumption that there was only one, had an apparent partition coefficient of 12.8 and accounted for 47.7 mg (as I equivalents) or 87.3% of the original radioactivity in the 370-min urine collection. For Fig. 7b, curve C′, the readily extractable compound had an apparent partition coefficient of 17.4 and accounted for 97.5% of the total radioactivity of

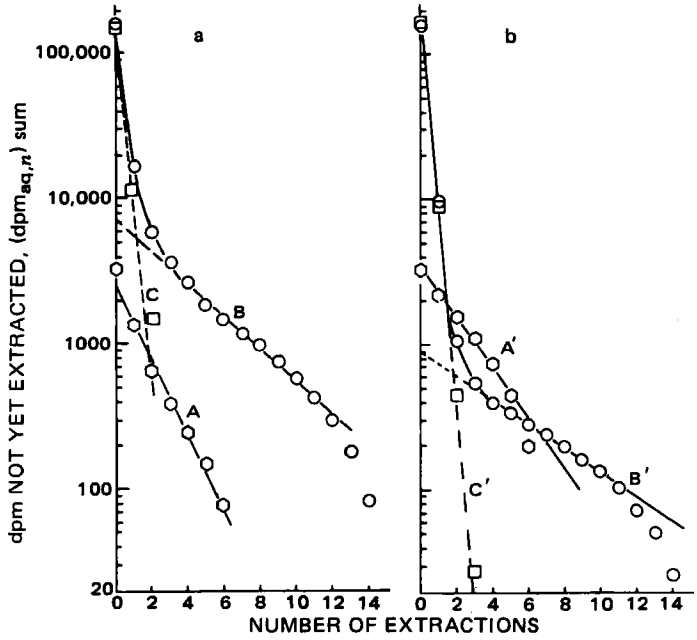

Figure 7—*Typical examples of semilogarithmic plots of not-yet-extracted urine radioactivity against the number of extractions for (a) the 310–370-min urine collection containing a total of 0.177 × 10⁶ dpm after administration of 1017 mg iv of [¹⁴C]I to dog A and for (b) the spiked blank urine containing 1.22 × 10⁶ dpm of standard [¹⁴C]I (585 ng). The ordinate values in (b) are scaled to 0.177/1.22 of their measured values for better comparison with (a). Curves A and A′ are for the 5-ml repetitive ethyl acetate extraction of the 0.6-ml acidified and previously exhaustively chloroform-extracted urines. Curves B and B′ are for the 5-ml repetitive chloroform extractions of the 0.6 ml of urine adjusted to pH 12. Curves C and C′ are the feathered lines obtained from the apparently biphasic curves B and B′.*

the standard [¹⁴C]I. It is evident that the $(dpm_{tot})_i$ and k_i values for each of a mixture of i different compounds of significantly different partition coefficients can be estimated by a series of such deconvolutions using this method, which is similar to the method of residuals used to estimate the parameters of a sum of exponentials.

Application and Limitations of the Method of Multiple Extractions of Urine on Dosing of Radiolabeled I—The semilogarithmic plots of $(dpm_{aq,n})_{sum}$ against the number (n) of sequential chloroform extractions appeared to be reasonably biphasic for the urine samples taken between 15 and 784 min after intravenous administrations of 1017-mg (Fig. 7, curves B and C) and 43-mg ¹⁴C-labeled I. Feathering of the semilogarithmic plots showed at least two radiolabeled chloroform-extractable compounds.

Possible Least Chloroform-Extractable Compound (II) as Metabolite—The least extractable compound (II), resolved from the terminal data, had an average apparent partition coefficient, k_{II}, of 0.264 ± 0.016 (0.004), n = 17, for the 1017-mg dose (Table V) and 0.268 ± 0.038 (0.009), n = 19, for the 43-mg dose (Table VI). It comprised increasing percentages of the urinary radioactivity with time, from 0.4% in the urine collected between 0 and 15 min to 6.4% in the urine collected between 665 and 725 min for the 1017-mg dose and from 0.9% in the urine collected between 0 and 15 min to 16.8% in the urine collected between 790 and 850 min for the 43-mg dose. This implies that II, relative to I, is formed later in the body and/or is eliminated more slowly.

When 0.6 ml of blank urine adjusted to pH 12 containing 1.22 × 10⁶ dpm of [¹⁴C]I[6] (585 ng of specific activity 324 mCi/mmole) was sequentially extracted 15 times, each time with 5 ml of fresh water-saturated chloroform, a semilogarithmic plot of amount radioactivity remaining in the aqueous phase against the number of extractions (n) was remarkably similar in its biphasic form (Fig. 7, curve B′) to that from the urines (Fig. 7, curve B). The slope of the terminal points paralleled that of the terminal points in the urine studies (Fig. 7, curve B) and gave a similar calculated apparent partition coefficient of 0.24 (Eq. 10) as compared with the average of 0.26 ± 0.02 (0.004) and 0.27 ± 0.04 (0.01) for the urine samples listed in Tables V and VI, respectively. A similar study for 950,000 dpm of [¹⁴C]I (0.56 ng of specific activity 137 mCi/mmole) in 0.6 ml of distilled water adjusted to pH 12 gave an apparent partition coefficient of 0.303.

Since the apparent partition coefficients for II in urine and in administered drug were similar, this could imply that this least chloroform-extractable compound II in the urine was a radiolabeled impurity in the original dose of intravenously administered I. The extrapolated intercept of this terminal phase (Fig. 7, curve B′) which permitted the estimation of the original amount of radioactivity of compound II that might contaminate the administered radiolabeled I, gave a value that could be interpreted as accounting for 0.59% of the total radioactivity of I for a radiolabeled purity of the administered I of 99.4%. In the similar aqueous study it accounted for 2.4% for a radiolabeled purity of the administered I of 97.6%, in agreement with the estimated chromatographic purity of I determined before the pharmacokinetic studies. The 2.4% was similar to an estimated 2.7% of II cumulatively excreted at infinite time (2.4% at 784 min) in the urine for the dog administered 1017 mg (Table V), but significantly less than a similar estimate of 8.0% of II for the administered 43-mg dose, (Table VI, 7.4% at 1378 min). This latter fact implies that a significantly greater amount of material of similar properties as the impurity II might result as a renally excreted biotransformation product in the dog.

TLC were made of the repetitive chloroform extracts of the mixed urine samples collected between 120 and 240 min and the urine collected at 605–665 min when the 1017-mg dose was administered intravenously. Definitive radioactivity was observed at R_f values of 0.29, 0.44, and 0.63 in all of the sequential extracts. However, sequential chloroform extracts of the spiked blank urine containing a solution of the administered dose showed radioactivity only at R_f 0.63, coincident with the R_f value of I but not necessarily I. This implied that compounds with R_f 0.33 and 0.47 can result from metabolic processes when the [¹⁴C]I is administered.

The fraction of radioactivity, F, extracted in each of n repetitive extractions of a single compound can be expressed as:

$$F = \frac{\text{dpm in } CHCl_3}{\text{Initial dpm in aqueous phase}} = \frac{k}{(1+k)^n} \qquad \text{(Eq. 12)}$$

Thus:

$$\log(\text{dpm extracted in } CHCl_3) = \log k(\text{initial dpm in aqueous phase}) - n\log(1+k) \qquad \text{(Eq. 13)}$$

The amount extracted into chloroform that appears at a given R_f value can be calculated from the product of the fraction of the total radioactivity applied on the TLC ($dpm_{R_f}/dpm_{applied}$) and the total dpm_{CHCl_3} in a given chloroform extract. This should be linear when plotted semilogarithmically against the number of extractions (n). When such plots were made for amounts at the several observed R_f values (Fig. 8) obtained from the 605–665-min urine sample from dog A after intravenous administration of 1017 mg of [¹⁴C]I, the materials at the three TLC spots all had terminal phases which indicated compounds with approximately equivalent partition values R_f, k: 0.29, 0.204; 0.44, 0.38; 0.63, 0.183. The percentage of these least extractable compounds in that particular urine sample can be estimated from the intercepts of the linearly extrapolated terminal data (Fig. 8, Eq. 13) and were R_f, percent of chloroform-extractable radioactivity, percent of radioactivity in total urine: 0.29, 0.96, 0.83; 0.44, 1.17, 1.02; 0.63, 3.33, 2.89. The 0.83 and 1.02% of total estimates of radioactivity in total urine at the given urine collection (R_f 0.29 and 0.44, respectively) do indicate small amounts of chloroform-extractable compounds produced by metabolism that cannot be assigned to the apparent radiolabeled impurity, II, in the administered radiolabeled dose of I. It is, of course, possible that the compounds at these R_f values are not metabolites of I, but of the apparent radiolabeled impurity, II, in the radiolabeled dose of I.

Possible Readily Chloroform-Extractable Compounds as Metabolites—The apparent partition coefficient of the more readily extractable chloroform compounds, k_{res}, systematically decreased from 19.8 in the 0–15-min urine to 10.9 in the 728–784-min urine for the 1017-mg study (Table V) and from 19.85 in the 15–30-min urine to 6.7 in the 850–1738-min urine for the 43.1-mg study (Table VI). These apparent k_{res} partition coefficients were estimated from the slopes based on first and second repetitive partitions of material from 0.6 ml of urine into 5 ml of $CHCl_3$ (Fig. 7, curve C). The apparent k_{res} partition coefficients for the radiolabeled dose added to urine (curve C′) and water, respectively, were 18.0 and 20.0. Inspection of curve C′ (Fig. 7b) shows no indication of changing partition coefficients for this residual line with increasing n. This strongly implies that not only I is readily chloroform extractable from the urine of dogs administered I, but also a compound, I′, with a slightly lower partition coefficient, and that I′, relative to I, is formed later in the body and/or is eliminated more slowly.

The TLC distribution of sequential chloroform extracts of the 605–

[a] Dose of 7.30×10^9 dpm. $\Sigma U_{tot} = \Sigma U^{tot}_{CHCl_3}\ \Sigma U^{tot}_{ETAG} + \Sigma U^{tot}_{unext}$; $\Sigma U^{tot}_{CHCl_3} = \Sigma U^{tot}_{res} + \Sigma^{tot}_{II}$; $\Sigma U^{tot}_{unext} = \Sigma U^{R_f\,0.20}_{unext} + \Sigma U^{R_f\,0.50}_{unext} + \Sigma U^{R_f\,0.62}_{unext}$. [b] Final time of urine collection started at the time listed. [c] Total amount of excreted compound in urine collection, U_{tot}, in I equivalents as determined from total radioactivity in collection, $10^{-3}\,(V/v) \times \text{dpm}_{tot} \div$ specific activity of [^{14}C]I, where V is volume of urine collected, v is volume counted by LSC to obtain the dpm_{tot} values. The specific activity was 7180 dpm/μg. [d] Amount in each urine collection, $U^{tot}_{CHCl_3}$, that can be ultimately extracted into chloroform $10^{-3}\,(V/v) \times \text{dpm}_{CHCl_3} \div$ specific activity. dpm_{CHCl_3} is the total cumulative radioactivity extracted into all of the repetitive chloroform extracts. [e] Estimated from terminal slope, S, of log $(\text{dpm}_{aq,n})_{sum}$ *versus* n where $(\text{dpm}_{aq,n})_{sum}$ is the radioactivity not yet extracted into chloroform or log $(U^{tot}_{CHCl_3} - U^{n}_{CHCl_3})$ and where $U^{n}_{CHCl_3}$ is the cumulative amount extracted into chloroform from a given urine collection up to the nth extraction and k_{II} = antilog $(|S| - 1)$, in accordance with Eq. 10. [f] Estimated cumulative amounts of II that are chloroform extractable from a given urine collection and obtained from the intercept, dpm_{Int}, of the linear extrapolation of the plot of the terminal data as in footnote *e*; $U^{tot}_{II} = 10^{-3}\,(V/v) \times \text{dpm}_{Int} \div$ specific activity. [g] Obtained from slopes (S) of plots of log $[(\text{dpm}_{aq,n})_{sum} - (\text{dpm}_{aq,n})_{II}] = \log (\text{dpm}_{tot})_{res} - n\log (1 + k_{res})$, in accordance with Eq. 11 and calculated for the line through 0 and 1 values of n, where k_{res} = antilog $(|S| - 1)$. The $(\text{dpm}_{aq,n})_{II} = \text{dpm}_{Int}/(1 + k_{II})^n$ where dpm_{Int} is the total cumulative amount of II that is chloroform extractable from the given urine collection and was defined in footnote *f*. [h] Estimated amount of residual material that is not II and is more readily chloroform extractable obtained from the intercept $(\text{dpm}_{tot})_{res}$ of the plot described in footnote *g*, *i.e.*, $10^{-3}\,(V/v) \times (\text{dpm}_{tot})_{res} \div$ specific activity. [i] Estimated from slope, S, of log $(\text{dpm}_{aq,n})$ *versus* n where $(\text{dpm}_{aq,n})$ *versus* n where $(\text{dpm}_{aq,n})$ is the radioactivity not yet extracted into ethyl acetate or log $(U^{tot}_{ETAC} - U^{n}_{ETAC})$. U^{n}_{ETAC} is the cumulative amount extracted into ethyl acetate from a given chloroform pre-extracted urine collection up to the nth extraction and k_{ETAC} = antilog $(|S| - 1)$, in accordance with Eq. 7. [j] Estimated total ethyl acetate-extractable amounts, U^{tot}_{ETAC}, from a urine collection; obtained from the intercept, dpm_{Int}, of the linear plot of log U^{n}_{ETAC} *versus* n, as in footnote *i*. [k] Estimated amounts of unextractable compounds obtained from total radioactivity measurement (dpm_{unext}), in 50 μl of the aqueous phase previously sequentially chloroform and ethyl acetate extracted; $10^{-3}\,(V/v) \times \text{dpm}_{unext} \div$ specific activity. [l] Amounts that remained in urine collection after repetitive chloroform and ethyl acetate extractions and appearing at specified R_f values on TLC plates as determined by plate scraping and LSC counting where $U^{R_f}_{unext} = (\text{dpm}_{R_f}/\text{dpm}_{applied}) \times U^{tot}_{unext}$, where dpm_{R_f} and $\text{dpm}_{applied}$ are the counts measured at the R_f spot and the total counts applied on the plate respectively. [m] Not measured.

[a] Dose of 1.76×10^9 dpm. $\Sigma U_{tot} = \Sigma U^{tot}_{CHCl_3} + \Sigma U^{tot}_{ETAC} + \Sigma U^{tot}_{unext}$; $\Sigma U^{tot}_{CHCl_3} = \Sigma U^{tot}_{res} + \Sigma U^{tot}_{II}$; $\Sigma U^{tot}_{unext} = \Sigma U^{R_f\,0.20}_{unext} + \Sigma U^{R_f\,0.35}_{unext} + \Sigma U^{R_f\,0.50}_{unext} + \Sigma U^{R_f\,0.62}_{unext}$. Refer to Table V for footnotes *b*–*m*. [n] These minor amounts of metabolites were found at different R_f values for different urine samples for unexplainable reasons.

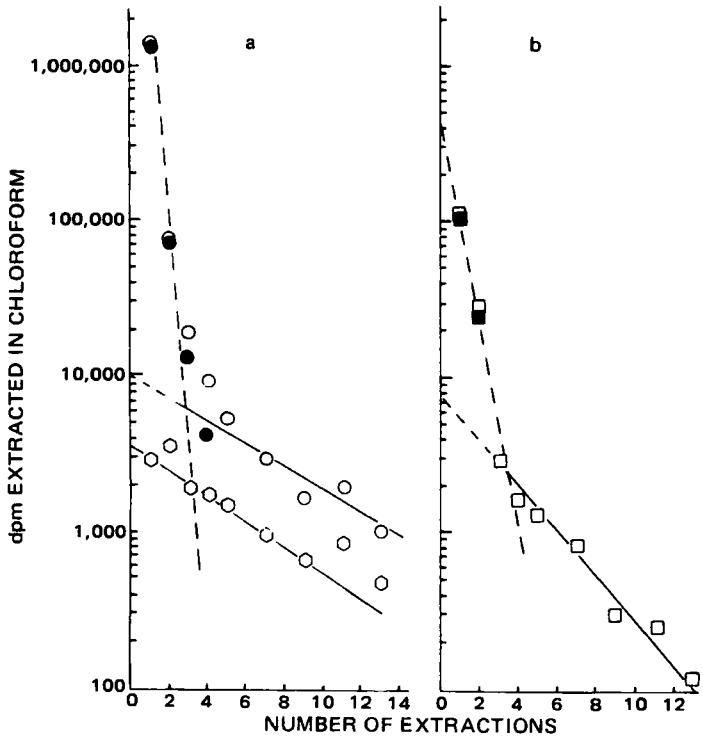

Figure 8—*Semilogarithmic plots against number of extractions (n) of radioactivities (dpm) of different TLC spots at* R_f (○) *0.60–0.69, (□) 0.40–0.47, and (○) 0.27–0.30 from 5.0-ml chloroform extracts of 0.6 ml of pH 12 urine. The urine was collected between 605 and 665 min when 1017 mg of [¹⁴C]I was intravenously administered to dog A. The amounts at each* R_f *value were calculated from* $dpm_{R_f}/dpm_{applied} \times dpm_{CHCl_3}$ *where* dpm_{R_f}, $dpm_{applied}$, *and* dpm_{CHCl_3} *are the radioactivities at the specified* R_f *values, total applied to the TLC plate, and the radioactivity extracted at the* n^{th} *chloroform extraction. The solid symbols are the feathered data.*

665-min urine collection from dog A after administration of 1017 mg of [¹⁴C]I gave the data for Fig. 8 with biphasic semilogarithmic plots. The data from the spot at R_f 0.63, when feathered, permitted the estimation of a partition coefficient of 18.0, consistent with I (Fig. 7, curve C'). The intercept of the feathered line permitted an estimation of 86.4% in the total urine collection that is chloroform extractable (75% of total radioactivity in urine samples) and can be assigned to I. The data from the spot at R_f 0.43, when feathered (Fig. 8) permitted the estimation of a partition coefficient of 3.3. The intercept of the feathered line permitted an estimation of 8.1% of this readily chloroform-extractable R_f 0.43 material of $k = 3.3$ in the total urine collection that is chloroform extractable (7.0% of total radioactivity in urine sample). This would be the possible metabolite I', that accounts for the greatest portion of the discrepancy between GLC and total radioactivity assays of I in urine at the 48.4-mg/kg iv dose (Table I).

When material found at R_f 0.43 was eluted, incubated at pH 12 or 7 for 2 hr at 50°, and rechromatographed on TLC, the radioactivity appeared at the same R_f value. When this material was incubated similarly at pH 2, the rechromatographed material appeared at R_f 0.10–0.23. This shift to much lower R_f values with acid hydrolysis is indicative of the loss of an isopropylidene group (1). This fact plus its ready alkaline chloroform extractability indicate that a possible structure assignment to I' is that it is a monodealkylated product of I.

Possible Ethyl Acetate-Extractable Compounds of Acidified Urines as Metabolites—The semilogarithmic plots of $(dpm_{aq,n})_{sum}$ against the number of sequential ethyl acetate extractions (n) of acidified chloroform-extracted urine indicated one radiolabeled extractable compound (Fig. 7, curve A) with an average apparent partition coefficient of 0.82 ± 0.16 (0.04), $n = 17$, for the 1017-mg dose (Table V) and 0.80 ± 0.08 (0.02), $n = 19$, for the 43-mg dose (Table VI). The cumulative amounts of such ethyl acetate-extractable material excreted in the total urine accounted for 1.29 and 2.67% of the administered doses, respectively. A similar analysis of ethyl acetate-extractable material for the [¹⁴C]I spiked into urine (Fig. 7, curve A') and water accounted for 0.6 and 0.7% of the administered compound, respectively, with respective apparent partition coefficients of 0.46 and 0.57 and a sole TLC spot at R_f 0.67. These facts imply that small, but additional, amounts of ethyl acetate-extractable material are formed in the animal. The ethyl acetate extracts of the 120–240-min urine from the 1017-mg dosed animal showed R_f values of 0.52 and 0.68, but only an R_f value of 0.68 in the 605–665-min urine indicates that the ethyl acetate-extractable material has the same R_f as I.

Possible Unextractable Materials as Metabolites—After the multiple extraction of urine with chloroform and ethyl acetate, 4.0% of the administered radioactivity from the 1017-mg dose of [¹⁴C]I was found in the accumulated urine (Table V), whereas 6.6% was found for the 43.1-mg study (Table VI). Only 1.4 and 1.2% of unextractable radioactivity was found in the [¹⁴C]I spiked urine and distilled water, respectively, implying that additional amounts of unextractable material were formed in the animal. The percentage of total unextractable radioactivity in the urine collections increased from 1.5% at 15 min to 12.1% at 784 min (Table V). The residual urine after multiple extractions with chloroform and ethyl acetate was applied to TLC plates, and sections were scraped for LSC counting. A major portion of the applied radioactivity (60–80%) appeared at R_f 0.47–0.53 with 15–30% at R_f 0.60–0.63 and a small amount (0.05%) at R_f 0.17–0.23. These comprised 2.8% (R_f 0.50), 0.87% (R_f 0.62), and 0.16% (R_f 0.20) of the total administered 1017-mg dose (Table V), and 3.6% (R_f 0.50), 1.5% (R_f 0.62), and 0.70% (R_f 0.20 and R_f 0.35) of the total administered 43.1-mg dose.

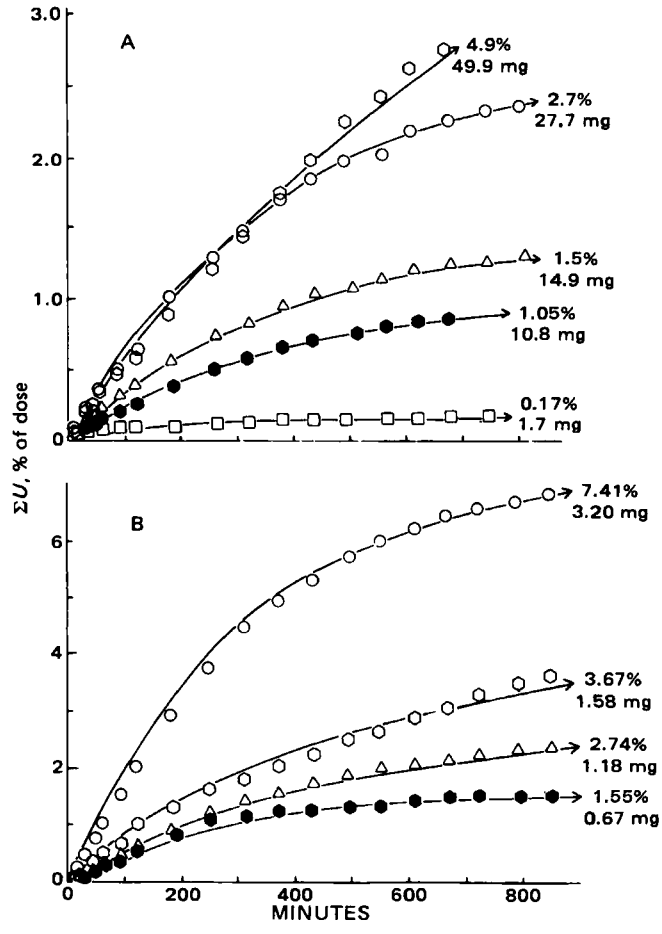

Figure 9—*Cumulative amounts (as percent of administered [¹⁴C]I dose) of variously characterized possible metabolites and/or impurities found in the urine of dog A intravenously administered (A) 1017 mg and (B) 43.1 mg of I. Key: (○) total amounts of II with a partition coefficient of ~0.24 transferred from pH 12 urine (0.6 ml) into repetitive 5-ml chloroform extractions; (△) total amounts of compound transferred from acidified and chloroform pre-extracted urine into repetitive 5-ml ethyl acetate extractions; and cumulative amounts of compounds at* R_f *0.50 (○),* R_f *0.62 (●), and* R_f *0.20 (□) that were unextracted by repetitive chloroform and ethyl acetate extractions. Each curve shows the total amounts of materials and percentage of administered dose estimated from their respective asymptotes. The lines drawn through the values for each curve were calculated from* $\Sigma U = \Sigma U_\infty (1 - e^{-\lambda t})$.

The cumulative amounts of non-I compounds (as percentage of administered radioactivity in the [^{14}C]I dose) are plotted against time in Fig. 9 for the 1017-mg (A) and 43.1-mg (B) doses. The lines drawn through the values were calculated from:

$$\Sigma U = \Sigma U_\infty (1 - e^{-\lambda t}) \qquad \text{(Eq. 13)}$$

The respective half-life values (0.693/λ) in min were: (A) ΣU_{II}, 266; ΣU_{ETAC}, 266; $\Sigma U_{Rf}^{0.2}$, 152; $\Sigma U_{Rf}^{0.5}$, 578; $\Sigma U_{Rf}^{0.62}$, 277; and (B) ΣU_{II}, 231; ΣU_{ETAC}, 300; $\Sigma U_{Rf}^{0.5}$, 278; and $\Sigma U_{Rf}^{0.62}$, 193. Most of these half-lives were approximately the same as I and may indicate the facile renal elimination of these compounds.

In Vitro Drug Release from Egg Albumin Microcapsules

TAKAFUMI ISHIZAKA ˣ and MASUMI KOISHI

Received February 12, 1982, from the *Faculty of Pharmaceutical Sciences and the Institute of Colloid and Interface Science, Science University of Tokyo, Shinjuku-ku, Tokyo, Japan.* Accepted for publication August 9, 1982.

Abstract □ The *in vitro* release of phenacetin from microcapsules prepared using egg albumin as the membrane material was investigated. It was shown by scanning electron microscopy that the albumin microcapsules have nonsmooth surfaces. The amount of phenacetin released is proportional to the square root of time up to 50–70% drug release. Increases in the albumin concentration and 1-vinyl-2-pyrrolidinone polymer content in the aqueous phases used in the microcapsule preparation have an effect on matrix porosity and channel tortuosity in the matrix of albumin microcapsules. The *in vitro* release rate was found to decrease with increasing albumin concentration and 1-vinyl-2-pyrrolidinone polymer content in the aqueous phases. The *in vitro* release rate per unit area also decreased with decreasing capsule size.

Keyphrases □ Phenacetin—albumin microcapsules, release rate, controlling factors □ Microcapsules, albumin—release rate of phenacetin, effects of albumin concentration, 1-vinyl-2-pyrrolidinone polymer content, capsule size □ Delivery systems—albumin microcapsules, release rate of phenacetin, effect of albumin concentration, 1-vinyl-2-pyrrolidinone polymer content, capsule size

Delivery of a chemotherapeutic agent to desired target sites with drug carriers could achieve effective local drug concentration and minimize systemic side effects by reducing the therapeutic dose of the chemotherapeutic agent. When a drug carrier, such as liposomes, microcapsules, and microspheres, is injected into the circulatory system, its distribution in the body is an important factor in drug delivery. The tissue distribution of albumin microspheres has been studied in detail (1–3). In addition, alteration in the tissue distribution of albumin microspheres was examined using magnetic guidance (4, 5). Albumin microspheres prepared using a water–oil emulsion have a hydrophilic matrix structure, consisting of albumin molecules, that is similar to that in albumin microcapsules (6).

However, despite many reports on the tissue distribution of albumin microspheres, the mechanism of drug release from minute drug carriers that have a hydrophilic matrix structure is not well known because there are few reports on drug release (7, 8). This paper describes *in vitro* drug release from albumin microcapsules having a hydrophilic matrix structure and some controlling factors.

EXPERIMENTAL

Materials—Isooctane, dibasic potassium phosphate, monobasic sodium phosphate, acetic acid, hydrochloric acid, and sodium acetate were reagent grade. Phenacetin powder (250–300 mesh) was used for microencapsulation as the core drug.

Egg albumin[1] solution was prepared as follows: Albumin was dissolved in buffer solution [0.033 *N* KH_2PO_4–0.033 *N* Na_2HPO_4, 1:16 (v/v); pH 8.0], and the solution was filtered after centrifugation at 16,000 × *g* for 30 min to remove the undissolved materials. The albumin concentration was either 10 or 20% (w/w). 1-Vinyl-2-pyrrolidinone polymer[2] was dissolved in the same buffer solution at 70°. The solution thus obtained (50% w/w) was stored in a refrigerator overnight and used for the preparation of aqueous albumin solutions containing the polymer.

Measurement of Viscosity—Viscosities of both the albumin and mixed polymer solutions [prepared from 20% (w/w) albumin solution and 50% (w/w) 1-vinyl-2-pyrrolidinone polymer solution] were measured at 25° with a cone-plate type viscometer[3] in a shear rate range of 50–3950 sec^{-1}. Viscosity values were calculated from the straight lines in rheograms.

Preparation of Microcapsules—Albumin microcapsules were prepared by a method similar to that described in a previous paper (6). Phenacetin powder (10% v/v) was previously dispersed in albumin solutions with and without the polymer. To 100 ml of isooctane containing 5.0% (v/v) sorbitan trioleate[4] as an emulsifier, in a three-necked flask, was added 15 ml of each of the aqueous dispersions, with stirring. After further stirring for 10 min, the flask was immersed in a water bath maintained at 85° for a given period to denature the egg albumin. The resultant dispersion was cooled to room temperature.

Water	1.30	B-2	20	83.9 ± 31.5	44.1	2.53	2.4	5.22
Simulated intestinal fluid	1.10	B-2	20	83.9 ± 31.5	44.1	2.58	2.0	6.04

[a] Microcapsules containing 40 mg of phenacetin were dispersed in 200 ml of a test medium to obtain v_i, t_h, and K. [b] Each group of microcapsules was prepared on the same day. Speed setting and heating time in microencapsulation were 512 rpm and 10 min, respectively. [c] Solubility of phenacetin.

Table II—Size Effect on Drug Release [a] from Albumin Microcapsules [b]

Sample	Speed Setting, rpm	Diameter, μm	Phenacetin Content, % (w/w)	$10^4 v_i$, g/sec	t_h, min	K, %/sec$^{1/2}$	$10^7 V_i$[c], g·cm/sec	$10^3 K'$[d], %·cm/sec$^{1/2}$
D-1	313	239.9 ± 100.0	45.7	1.34	5.0	3.45	7.13	18.30
D-2	512	95.2 ± 28.0	46.9	2.60	2.1	5.10	4.87	9.55
D-3	848	55.6 ± 15.9	49.4	3.33	1.5	6.93	3.70	7.70

[a] Microcapsules containing 40 mg of phenacetin were dispersed in 200 ml of the simulated gastric fluid to obtain v_i, t_h, and K. [b] Microcapsules were prepared on the same day. Albumin concentration and heating time in microencapsulation were 20% (w/w) and 10 min, respectively. [c] $V_i = v_i/S_v$, where S_v is the specific surface area of the microcapsules. [d] $K' = K/S_v$.

The microcapsules separated by filtration were dispersed in 10 ml of buffer solution [0.1 *N* CH_3COOH–0.1 *N* CH_3COONa, 1:1 (v/v); pH 4.7], which was saturated with phenacetin and contained 10% (v/v) polyoxyethylene sorbitan monolaurate[5], with gentle agitation. The microcapsules were washed once with the pH 4.7 buffer solution and several times with water saturated with phenacetin. The microcapsules collected by decantation were freeze-dried.

Size measurement of the microcapsules was performed in the saturated phenacetin solution before freeze-drying. One thousand microcapsules were photographed under an optical microscope. Each of the developed film strips was projected onto a large-section paper by a slide projector. Enlarged images of the microcapsules were measured to the nearest 1.0 μm. The scale in the micrometer was used for calibration. To eliminate fluctuation in the denaturating procedures of egg albumin, the microcapsules in all experimental series (A–E) were prepared on the same day.

A scanning electron microscope[6] was used to observe the surface appearance of the albumin microcapsules. The original microcapsules and those sampled from a release test medium were dried at 50°. The dried microcapsules were vacuum-coated with gold in an ion coater[7].

Determination of Solubility of Phenacetin—Finely ground phenacetin powder was dispersed in three release test media in Erlenmeyer flasks. The dispersion in the stoppered flask, which was immersed in a water bath thermostated at 37 ± 0.1°, was vigorously agitated with a magnetic stirrer overnight to attain equilibrium. Membrane filters[8], holders, and syringes (maintained previously at 37 ± 0.1°) were used for the separation procedure of undissolved phenacetin particles. The phenacetin concentration in the filtrate was determined spectrophotometrically at 245 nm.

***In Vitro* Release of Microencapsulated Phenacetin**—The cylindrical glass cell used for the release test, 62 mm in diameter and 88 mm in depth, was equipped with a plastic cover to minimize the influence of vaporization. In the cell, 200 ml of a test medium was maintained at 37 ± 0.1°. At time zero, a given weight of albumin microcapsules containing 40 mg of phenacetin was added with stirring to this thermostated medium. Stirring was carried out with a six-blade impeller (50 mm in diameter) at a fixed rotation speed. The amount of phenacetin (40 mg) encapsulated was previously calculated to maintain the same sink condition for each *in vitro* release experiment during the test period. The dispersion was sampled at scheduled intervals and immediately filtered to remove the microcapsules. The drug concentration in the filtrate was determined by the same spectroscopic method described for the phenacetin analysis.

In release experiments, test media similar to those described in JP IX were employed. Simulated gastric fluid (pH 1.2) was a hydrochloric acid solution containing 0.1% (v/v) polyoxyethylene sorbitan monolaurate and 2 g/liter of sodium chloride; simulated intestinal fluid (pH 7.5) contained hydrochloric acid and 35.8 g/liter of monobasic sodium phosphate. Water obtained from a water purification apparatus[9] was also used as a test medium.

To attain reproducibility of the release experiments, a stirring rate of 313 rpm was employed. At stirring rates <200 rpm, no dispersion of microcapsules was observed, and the measured values were scattered widely. At rotating speeds >200 rpm, the release rates were reproducible.

RESULTS AND DISCUSSION

Properties of Microcapsules—As reported previously (6), the viscosity of the aqueous phase in the preparation of egg albumin microcapsules and microspheres markedly affects their size. Stirring speed in this experiment was determined for each preparation to obtain microcapsules within a given size range (70–110 μm) except for the microcapsule samples for the study of size effect on phenacetin release. Tables I–III show the preparation conditions of microcapsules, microcapsule size, and phenacetin content. Both the microcapsule size and phenacetin content were approximately constant in each series.

Surface Appearance of Microcapsules—Scanning electron micrographs of albumin microcapsules before and after the release experiments are shown in Fig. 1. Figure 1a–d shows that the increase of albumin concentration and the addition of 1-vinyl-2-pyrrolidinone polymer change the membrane appearance as compared with the original microcapsules (Fig. 1a). All albumin microcapsules had nonsmooth surfaces. Scanning electron micrographs (10,000×, unpublished) from a portion of the surfaces of four samples (Fig. 1a–d) showed no evidence of appearance changes due to the increase in albumin concentration and the addition of 1-vinyl-2-pyrrolidinone polymer in the preparation. Pores similar to those seen in polystyrene microcapsules prepared by an interfacial polymer deposition technique (9) could not be found in the albumin microcapsules. But a few microcapsules having some small cracks on their surfaces, which may be caused by shrinking in the freeze-drying process, existed in samples A-1 and A-2 (Table I). The undesirable surface cracks were not found in microcapsules prepared using 20% (w/w) albumin solution (B, C, and D series) or mixed polymer solutions (E series). Accordingly, increase of the albumin concentration and use of 1-vinyl-2-pyrrolidinone polymer should strengthen the microcapsule membrane.

The surface appearances of the microcapsules collected after *in vitro* release experiments were not different from those of the original capsules (Fig. 1e–h). As observation under a light microscope showed, the mixed polymer solution [10% (w/w) albumin, 20% (w/w) 1-vinyl-2-pyrrolidinone polymer], in contrast to the other solutions, gives a homogeneous

stripe-pattern. Many pores would be expected to be produced by the swelling and subsequent release of 1-vinyl-2-pyrrolidinone polymer dispersed in the membrane matrix during the *in vitro* release experiments; but, no pore was found in the membrane (Fig. 1g and h). On the other hand, fine white crystalline particles adhered to the outer surfaces of the microcapsules, as observed in Fig. 1e–h, which when collected from the release test medium were confirmed to be phenacetin particles.

Each of the albumin microcapsules shown in Fig. 1a, c, e, and g possessed a folded and invaginated surface. A similar surface structure has been reported by Matthews and Nixon with gelatin microcapsules prepared by a simple alcohol coacervation (10). Contrary to the findings with gelatin microcapsules, it was confirmed by light microscopy that the albumin microcapsules dispersed in the release test media appear almost spherical, suggesting hydration of the membrane materials; *i.e.*, folding and invaginating of the surfaces were caused by shrinking in the drying process. Therefore, as the membrane of the microcapsules was fully hydrated in the release test media and remained intact after release experiments, it was concluded that the drug molecules are released through channels in the fully hydrated albumin matrix.

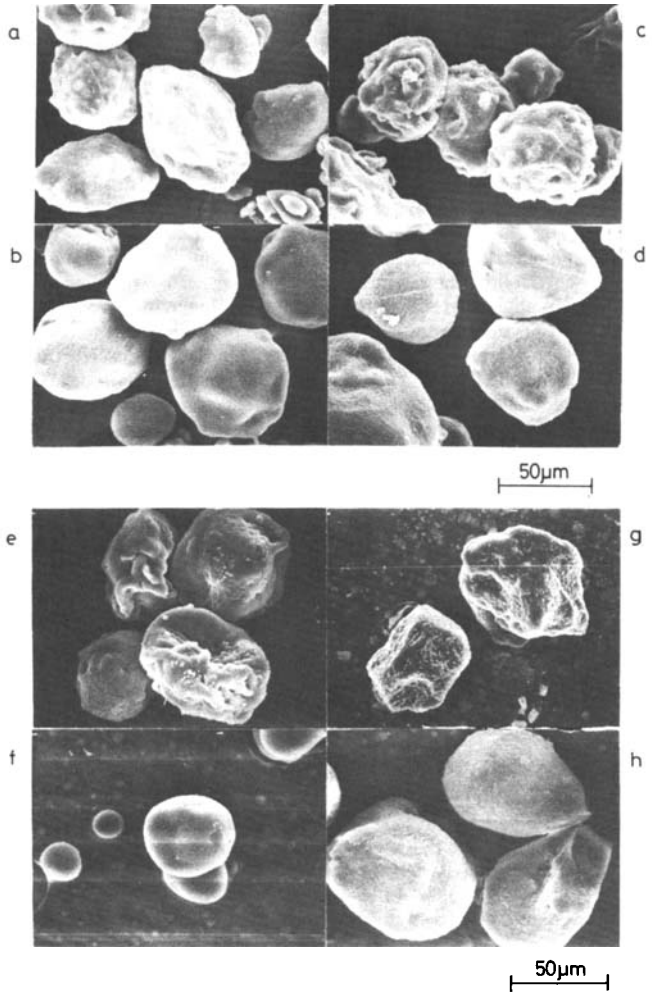

Figure 1—*Scanning electron micrographs of microcapsules prepared using (a,e) 10% (w/w) albumin solution (A-1); (b,f) 20% (w/w) albumin solution (B-1); (c,g) 10% (w/w) albumin solution containing 5% (w/w) 1-vinyl-2-pyrrolidinone polymer (E-2); and (d,h) 10% (w/w) albumin solution containing 20% (w/w) 1-vinyl-2-pyrrolidinone polymer (E-4) before and after the release tests.*

Effects of Albumin Concentration and Release Test Medium—The results of *in vitro* dissolutions of phenacetin powder and microencapsulated phenacetin prepared using a high albumin concentration [20% (w/w)] are shown in Fig. 2. In the simulated gastric fluid, a slower dissolution of phenacetin from the microcapsules in the initial stage was found, as expected. This observation suggests that the drug would be released effectively in drug diffusion. The Higuchi equation may be applied to the *in vitro* release of drugs from microcapsules if diffusion through their membranes is the rate-limiting step (11). Of the four samples of albumin microcapsules used in this study, series A and B gave a linear relationship in the initial stage of phenacetin release in the simulated gastric fluid when the percentage of drug released was plotted against the square root of time, sec$^{1/2}$ (Fig. 3). However, once 50–70% of phenacetin was released, the plots deviated negatively from linearity. This result was unexpected because, with the method of manufacture employed, these microcapsules have a suitable protective wall. But, after the initial stage of release, the core drug content appeared to have little effect on the total percentage of drug released. Accordingly, it is considered that this deviation in Fig. 3 could be attributed to exhaustion of the drug suspension phase, as described by Borodkin and Tucker (12), that is, the number of vacant microcapsules may increase in the latter stage of release.

As analysis over the whole release is difficult in this study, the initial release rate (v_i, g/sec) and the 50% release time (t_h, min), which are obtained by plotting the amount of drug released *versus* time (in min), and the slope (K) of the straight line obtained by plotting the percentage of drug released against the square root of time, sec$^{1/2}$, are used for evaluation of the *in vitro* drug release from albumin microcapsules. Table I shows v_i, t_h, and K obtained from the release profiles of the drug in the three test media. Although the difference was slight, the drug is released in the simulated gastric fluid faster from series A than from series B. As described above, the drug molecules appear to be released through the hydrated and intact membranes. Therefore, this result would be caused by decreased porosity in the membrane matrix and increased tortuosity of channels in which drug molecules diffuse.

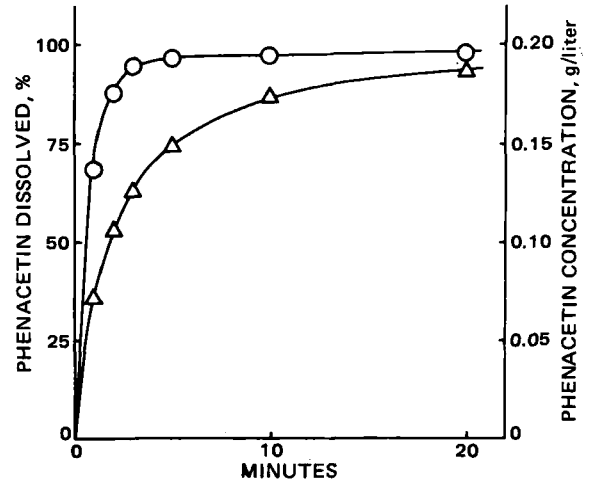

Figure 2—*Dissolution of phenacetin in the simulated gastric fluid. Key: (○) phenacetin; (△) phenacetin microencapsulated using 20% (w/w) albumin solution (B-2).*

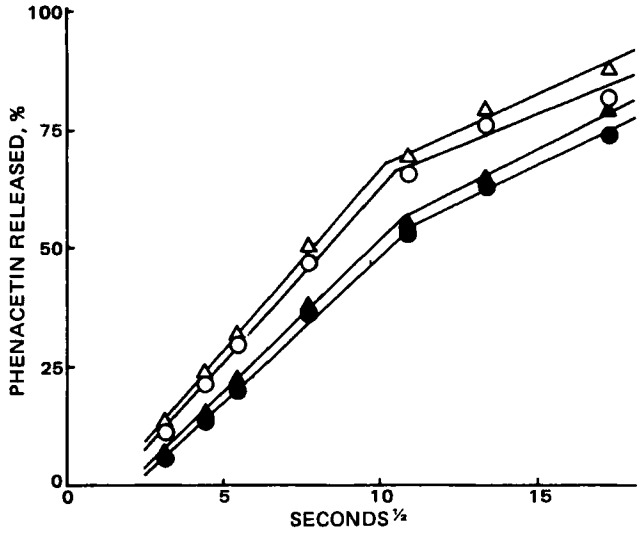

Figure 3—*Relationship between the percentage of drug release in the simulated gastric fluid and the square root of time. Microcapsules were prepared using 10% (w/w) albumin solution (○) A-1; (△) A-2 and 20% (w/w) albumin solution (●) B-1; (▲) B-2.*

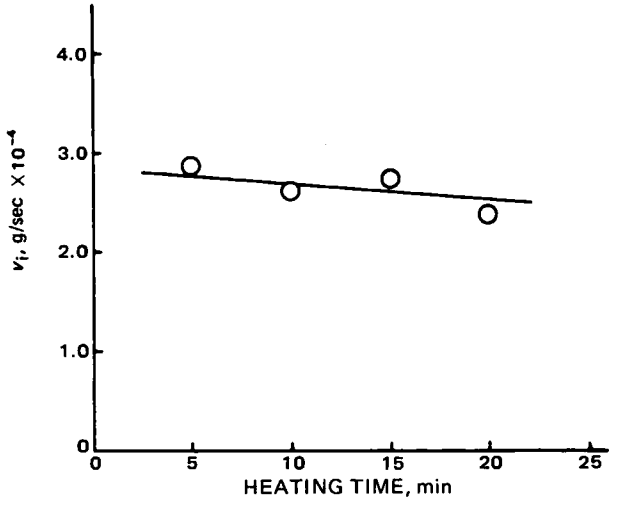

Figure 4—*Effect of heating time in the microencapsulation process on the drug release from albumin microcapsules prepared using 20% (w/w) albumin solution. As samples in the heating process at 85° were separated at scheduled intervals from the same batch (C series), capsule size was not measured. The phenacetin contents were 54.9% (w/w) at 5 min, 46.3% at 10 min, 42.9% at 15 min, and 42.7% at 20 min.*

The albumin microcapsules in sample B-2 released the drug faster in the simulated gastric fluid, though the release rates in both the simulated intestinal fluid and water were similar. Since the solubilities of phenacetin in the three test media were nearly equal, the sink condition was held constant in all *in vitro* release tests. Therefore, the condition for the albumin matrix in which drug molecules diffuse in the simulated gastric fluid seems to be different from those in the simulated intestinal fluid and in water. Furthermore, it is well known that the isoelectric point (pI) of egg albumin is 4.7. When the pH differs greatly from the pI, electrostatic repulsion of the ionized groups change the porosity and tortuosity of channels in the albumin matrix.

Effect of Heating Time in Microencapsulation—Albumin microcapsules were prepared using 20% (w/w) albumin solution. In a microcapsule dispersion sampled 2 min after the flask was immersed in a water bath maintained at 85°, albumin was still insufficiently denaturated in isooctane, and the particles collected by filtration resembled soft-boiled egg membranes. Albumin microcapsules having rigid membranes were obtained if heated >4 min. The microcapsules sampled at 5 min were white in isooctane; those obtained at 10, 15, and 20 min were light yellow.

Figure 4 shows the relationship between the initial release rate v_i and heating time in the microencapsulation. Prolonged heating time produced no appreciable difference in the release rate. Sugibayashi *et al.* have reported that an increase in the denaturing temperature of the microsphere preparation decreases matrix porosity and increases channel tortuosity in the matrix, leading to decreased drug release (8). However, the denaturing temperature of 85° in the microencapsulation used in this study is low when compared with those employed in their work (100–180°), and prolonged heating time may not affect the matrix porosity and channel tortuosity, as previously mentioned.

Effect of Capsule Size—Jalšenjak and Kondo found that the permeability of gelatin–acacia microcapsules toward sodium chloride decreased with increasing capsule size (13). The same trend was observed with the albumin microcapsules.

The effects of capsule size on drug release are given in Table II. The values of v_i and K decreased with increasing capsule size. These results are expected because (*a*) the total volume of the microcapsules containing 40 mg of phenacetin is almost constant and (*b*) the total surface area of the microcapsules increases with decreasing capsule size. But, V_i and K', which are obtained by dividing v_i and K by the specific surface area of the albumin microcapsules, increase with increasing capsule size. Contrary to the gelatin–acacia microcapsules, the albumin microcapsules are multinuclear and their membrane thickness cannot be determined theoretically. And if phenacetin particles are dispersed uniformly in the albumin matrix, it cannot be assumed that the distance along which solute molecules diffuse is shortened as the capsule size increases.

The explanation for V_i increasing with increasing capsule size is as follows: Water structure plays an important role in drug release from microcapsules, as reported previously (14). The structured water in and around the membrane affects the transport of solute molecules, and the amount of structured water is greater in a dispersion containing a large number of microcapsules than in that containing a small number of microcapsules. Another reason would be differences in the denatured state of albumin, due to increased capsule size. It can be assumed that the denaturation affects matrix porosity and channel tortuosity in the matrix.

Effect of Added 1-Vinyl-2-pyrrolidinone Polymer—The effects of the concentration of 1-vinyl-2-pyrrolidinone polymer added to the aqueous albumin solution in the microencapsulation process are shown in Table III. The values of v_i and K decrease, while t_h increases with increasing amounts of 1-vinyl-2-pyrrolidinone polymer. V_i decreases at high 1-vinyl-2-pyrrolidinone polymer concentrations, (10–20%, w/w; samples E-3, E-4). A slight increase in the capsule size due to increased viscosity of the aqueous polymer phase is also shown in Table III. However, even if V_i and K' decrease with increasing capsule size, as described in the previous section, it would be concluded that the increase in the 1-vinyl-2-pyrrolidinone polymer concentration decreases the *in vitro* release rate. Addition of the polymer to the aqueous albumin solution makes the matrix dense (Fig. 1c, d, g, and h), leading to a decreased matrix porosity and increased channel tortuosity in the matrix. Also, hydration of 1-vinyl-2-pyrrolidinone polymer may play an important role in controlling the diffusion of drug molecules. Nakagaki and Shimabayashi reported that the hydration number (water/base, mole) of 1-vinyl-2-pyrrolidinone polymer was calculated to be 2–5 by conductometry (15). Therefore, it is possible that the increase of polymer content decreases the amount of free water in unit volume of the matrix, making channels narrow and channel tortuosity higher.

CONCLUSIONS

Higuchi's equation could be applied to the phenacetin release from albumin microcapsules that have a hydrophilic matrix structure in their membranes, except in the later stages of drug release. The *in vitro* release rate was affected by capsule size, egg albumin concentration, and 1-vinyl-2-pyrrolidinone polymer content used in the microencapsulation process. It decreased with increasing capsule size and albumin and polymer concentrations. Matrix porosity and channel tortuosity in the albumin matrix played an important role in the phenacetin release.

Systematic Error Associated with Apparatus 2 of the USP Dissolution Test IV: Effect of Air Dissolved in the Dissolution Medium

DON C. COX ˣ, WILLIAM B. FURMAN, and DONALD P. PAGE

Received July 23, 1982, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication August 20, 1982.

Abstract □ Acceptable concentrations of gases in a medium are not well defined in USP dissolution tests. A sample of 10-mg prednisone tablets, known to be sensitive to dissolved gases, was tested with batches of purified water that contained different concentrations of air. The data suggest that results from Apparatus 2 can be influenced by the concentration of air in the dissolution medium unless the medium remains unsaturated with air for the duration of the test. The repeatability of means of six results was markedly improved when the air concentration in the medium was accurately controlled at the beginning of the test.

Keyphrases □ USP dissolution test—correlation of air concentration in medium to dissolution results, Apparatus 2 □ USP Apparatus 2—repeatability of dissolution results, prednisone tablets, effect of dissolved air in medium □ Prednisone—dissolution, USP Apparatus 2, effect of dissolved air in medium

The USP (1) recognizes that gases dissolved in the dissolution medium may influence dissolution test results. In such cases the analyst is directed to remove the dissolved gases before conducting the test; however, no guidance concerning acceptable gas concentrations is given. Since purified water is used to prepare dissolution media, the dissolved gases are those found in air. Complete removal of air from water is not easy; even if "air-free" water were available, air would begin to redissolve as soon as the water again contacted the atmosphere. Thus, one must assume that the air in the dissolution medium is to be reduced to a concentration that no longer influences the dissolution results—a concentration which can be determined only by experiment.

In addition to the USP calibrator tablets, this laboratory has used a sample of commercial 10-mg prednisone tablets, identified as Tablet 2 in previous papers of this series (2, 3), as a "performance standard" for Apparatus 2. Tablet 2, which was also used as a practice sample in a recent collaborative study (4), is very sensitive to excess air in the dissolution medium. A dissolution medium whose air concentration does not influence dissolution results was desired. Various methods for controlling the concentration of dissolved air were studied, and the data are presented in this paper.

BACKGROUND

The first USP dissolution test for prednisone tablets (5) specified the use of deaerated water. Deaerated water (6) is purified water that has been treated to reduce the content of dissolved air by suitable means, such as by boiling it vigorously for 5 min and cooling or by applying ultrasonic vibration. This laboratory interpreted (7) the specification to mean that the water could not be supersaturated with air at 37°, the temperature at which the dissolution test is conducted, because this condition might result in the gradual formation of bubbles on all immersed solid objects, including the product being tested. For several years, dissolution media were prepared from purified water which was boiled, cooled to room temperature, and used within a 24-hr period. A vacuum technique (3) was then developed and used. The two treatments appeared to give equivalent results; however, boiling was less convenient and was gradually replaced by the vacuum treatment.

When the dissolution test for prednisone tablets was revised (8), the specification for the medium was changed from deaerated water to purified water. The USP monograph on purified water does not specify the quantity of dissolved air allowed. Freshly prepared purified water obtained by distillation contains only a fraction of the air contained in freshly prepared purified water obtained by ion-exchange or by reverse osmosis. Dissolution results for certain products are substantially changed when purified water obtained by ion-exchange treatment is substituted for deaerated water (9). The USP later inserted the current specification for dissolved gases in the dissolution medium in the general chapter on dissolution.

EXPERIMENTAL

The test conditions were those used in a recent collaborative study (4) with these exceptions. The six-spindle dissolution drive[1] was not commercially available. The volumes of dissolution medium were measured in volumetric flasks[2]. The dissolution test system was allowed to equilibrate for only 1–2 min before the test was started. Purified water was

obtained by reverse osmosis. A 19-liter carboy was filled daily and served as a reservoir. Before the water was subjected to the treatments described below, portions were siphoned into 500-ml volumetric flasks. The contents of the flasks were heated to 38° and transferred to the dissolution vessels. Six dissolution results were obtained with this water.

Control of Air Concentration by Temperature—Approximately 800 ml of water was added to each of six 900-ml volumetric flasks which were then placed in a water bath at room temperature. A 4-mm o.d. glass tube was inserted to the bottom of each flask and connected through a manifold to an air pump that delivered air at a rate of 4 liters/min. Air was bubbled through the water for 90 min. The temperature of the water and the barometric pressure were recorded. Six 500-ml volumetric flasks were filled to volume with the treated water from the 900-ml flasks and placed in a holding bath at 38°. After 30 min the contents of the 500-ml flasks were transferred to the dissolution vessels. In this way the temperature of the treated water was kept between 36.5° and 37° at the beginning of the dissolution test. Six dissolution results were obtained for Tablet 2.

This procedure was repeated under the same experimental conditions except that air was bubbled through the water for 30 min. The results from six tablets agreed closely with those obtained when the water was equilibrated with air for 90 min. Thereafter, air was bubbled through the water for a minimum of 45 min.

The temperature of the water bath holding the 900-ml flasks was increased from 23° to 49° in increments of 2° for each test of six tablets. Additional data were collected by equilibrating the water with air in the same manner over a narrow range of temperatures from 37.4° to 38.4°.

Ten units of Tablet 2 were dissolved in 17 liters of water. The tablet excipients were allowed to settle, and the clear solution was siphoned into a container. Portions of this solution were equilibrated with air at 37.1° and transferred to the dissolution vessels for testing of Tablet 2. Additional portions were used in the determinative step as solvent for the standard solution and as reference for the spectrophotometer. The experiment was then repeated with a solution prepared by dissolving 20 units of Tablet 2 in 20 liters of water.

The air pump was then replaced with a cylinder of compressed nitrogen with minimum purity of 99.7%. The nitrogen was bubbled for 1 hr through 3500 ml of water heated to 37.0°. Portions of the water were siphoned into six 500-ml flasks that had been flushed with nitrogen. The flasks were placed in a water bath at 38° for 30 min, and the contents of the flasks were then transferred to dissolution vessels that also had been flushed with nitrogen. During dissolution, a nitrogen atmosphere was maintained over the water in the vessels.

Control of the Air Concentration by Pressure—Approximately 3500 ml of water was added to a 4-liter reagent bottle equipped with a two-hole rubber stopper. A long tube (6-mm i.d.) was inserted through one hole of the stopper so that its end was close to the bottom of the bottle. A short tube was inserted through the other hole so that the end of the tube was flush with the lower side of the stopper. The air pump was connected to the long tube with the stopper in place in the bottle, and air was bubbled up through the water. A piece of rubber tubing connected to the short tube in the stopper was partially closed, and a positive pressure was developed over the water in the bottle while the water was agitated by the air bubbles. The bottle was placed in a water bath at 37.6° for 1 hr, and a positive pressure of 50 mm Hg above that of the prevailing atmosphere was maintained over the water. The water was then siphoned into 500-ml flasks, and the flasks were returned to the water bath for 10 min before being emptied into the dissolution vessels. Six units of Tablet 2 were tested. The experiment was then repeated with water prepared by maintaining a positive pressure of 10 mm Hg over the water instead of 50 mm Hg.

To obtain pressures below ambient, the short tube in the stopper was connected to a vacuum, and air was drawn down through the long tube (now open to the atmosphere) and up through 3500 ml of water. The vacuum over the water was adjusted by partial closure of a piece of rubber tubing connected to the long tube. The water in the bottle was heated to 37.5° for 1 hr under a pressure ~30 mm Hg below that of the prevailing atmosphere. The water in the bottle was then siphoned into the 500-ml flasks, the flasks were reheated, and the contents of the flasks were then transferred to the dissolution vessels. Six dissolution results were obtained. The experiment was conducted again at the same pressure and then repeated with the pressure adjusted to 57 mm Hg below ambient. The experiment was then conducted at pressures of 145, 80, 70, and 50 mm Hg. Dissolution results obtained in this manner were compared with dissolution results obtained with the use of water as it was routinely prepared in this laboratory, *i.e.*, the water was sprayed into a 19-liter carboy at room temperature under a pressure of ~145 mm Hg.

RESULTS AND DISCUSSION

The saturated concentration of air in water in a container open to the atmosphere depends on the temperature of the water and the pressure of the air above the water. Ideally, the equilibrium concentration of a gas in a liquid is proportional to the pressure of the gas over the liquid at a constant temperature (Henry's Law). Thus, the concentration of air in

[a] Air in all instances except where otherwise indicated. [b] $n = 6$. [c] AP = atmospheric pressure. [d] — Not recorded. [e] Medium contained 10 tablets dissolved in 17 liters. [f] Medium contained 20 tablets dissolved in 20 liters. [g] RT = medium was sprayed into a carboy under reduced pressure at room temperature. [h] Medium was treated with nitrogen at atmospheric pressure instead of air.

water can be controlled over a very wide range by changing the air pressure over the water. Although there is no general relationship between temperature and the concentration of a gas in a liquid, the equilibrium concentrations in water of the four major components of air decrease as the temperature of the water increases (10). These four components are nitrogen, oxygen, argon, and carbon dioxide (78.08, 20.95, 0.93, and 0.03% by volume, respectively). Combined, they make up 99.99% of the gases found in air (11). Because the solubility (v/v) of air in water under 1 atm at 100° is ~65% of the solubility of air at 25° (10), the concentration of air in water can be controlled only over a narrow range by changing the temperature of the water.

The dissolution results obtained for Tablet 2 when the air concentration in the water was controlled by temperature at prevailing atmospheric pressures are given in Table I and Fig. 1. The means of six results agreed closely when batches of water equilibrated with air for 30 and 90 min at room temperature were used; this agreement indicated that the water was being equilibrated in a repeatable manner. These means were significantly lower ($p < 0.025$) than the mean of six results obtained when freshly drawn deionized water that had not been equilibrated with air at room temperature was used. Thus, the equilibration treatment had a definite effect on the air concentration in the water.

Since the dissolution test was carried out at 37° in all cases, the dissolution media equilibrated at <37° became supersaturated with air when heated to 37° and those equilibrated at >37° became unsaturated with air when cooled to 37°. Because of the manipulation of the medium after the original equilibration, the degree of saturation at the beginning of the dissolution test was related to, but probably not equal to, the difference in the equilibrium concentration of air at the equilibration temperature and at 37°.

The relationship (Fig. 1) between the amount of prednisone dissolved from Tablet 2 and the air concentration in the medium may be explained in terms of sorption of air by the tableted formulation after tablet disintegration takes place. Normally, the tablet particles stay on the bottom of the dissolution vessel and collect into a cone of material during the dissolution test. Sorption of air decreases the density of the particles so that they may be agitated to a greater extent by the dissolution medium. The cone is disrupted by this agitation, and shielding of the inner particles is lessened. The sorption of air can also partially block the medium from contact with the particles. In this case the dissolution results decrease as the quantity of excess air increases. This effect has been observed with another tableted formulation (3) whose disintegrated particles are normally lifted and circulated by the dissolution medium. The decrease in dissolution results was small when air prevented contact of the medium with the particles. However, the increase in dissolution results was large when air bubbles increased the agitation of the particles.

The curve in Fig. 1 appears to approach a lower limit of 35% of label claim. This lower limit does not coincide with the equilibrium concentration of air in water at 37°, but is obtained from water that has a lower concentration of air. Additional tests of Tablet 2 with water equilibrated with air at temperatures near 37° confirmed that mean dissolution results between 39 and 41% of label claim were obtained (Table II). One explanation is that the equilibrium concentration of air in the water is shifted downward when the tablet is introduced to the medium. Thus, excess air from the medium would be available for sorption. This explanation is not well supported by the slightly lower results obtained when the tablets were introduced to equilibrated solutions that already contained some dissolved tablet material (Table II). The decrease in results is not large enough to account for the total difference. Another explanation is that the tablet particles are in "competition" with the water for the dissolved air. In this case the sorption process could be described as a true equilibrium of air between the water and the tablet particles.

To see if one or more of the minor components of air could be preferentially sorbed by Tablet 2, the test was conducted under a nitrogen atmosphere. The dissolution results obtained by this procedure compare closely with those obtained by equilibrating water with air (Table II). Preferential sorption was not indicated.

The dissolution results obtained when the equilibrium air concentration was controlled by pressure (Table II) follow a predictable pattern. Dissolution medium equilibrated at 37° with air at a positive pressure of 50 mm Hg above atmospheric pressure gave results that indicated that the medium was supersaturated with air. Dissolution medium equilibrated with air at a positive pressure of 10 mm Hg gave results that were equivalent to those obtained from dissolution medium equilibrated at atmospheric pressure. Media equilibrated at pressures of 30–57 mm Hg below atmospheric pressure gave results that were equivalent to or slightly below those obtained at atmospheric pressure. When the pressure over the water was reduced to ≤145 mm Hg, sufficient air was removed to cause the dissolution results (means of six) to level off between 35 and 36% of label claim. This is the lower limit that the curve in Fig. 1 appears to approach. Results between 35 and 36% of label claim were also obtained when the test was conducted with water that had been sprayed into a carboy under a pressure of 145 mm Hg at room temperature.

CONCLUSIONS

It is known that excess air from the dissolution medium can change the dissolution results obtained for certain tablets. The data presented in this paper show that results can be changed not only by air concentrations that exceed the saturation point in the dissolution medium but also by concentrations of air at the saturation point and below. To ensure that dissolved air does not influence dissolution results, the USP dissolution test should be conducted with dissolution media that contain different concentrations of air until a range of concentrations has been established that will not change the results. Although the concentration of air can be reduced to a low value at the beginning of a test, it is difficult to specify an air concentration below which no dissolution result could possibly be changed because of the variety of products subjected to the test, the conditions under which the test is made, and the differences in time requirements for the test. Nevertheless, repeatable dissolution results can be obtained by control of the air concentration. Thus, if the air concentration in the dissolution medium is repeatably controlled at the beginning of the test, the effect of the air on the solid dosage form should be reasonably constant from one laboratory to the next.

This laboratory has routinely reduced the air concentrations in the dissolution medium to low, but unknown, values by use of vacuum at room temperature. The medium thus treated has been considered adequate for dissolution tests within 8 hr of its preparation. When water prepared in this manner was used to test Tablet 2, an intralaboratory acceptance range of 35–43% of label claim was established for means of

six results[3]. From the data presented in this paper, a range of 35–41% of label claim is obtained from the use of water that contains air concentrations that do not exceed the saturation point of air in water at 37°. Thus, it should be possible to narrow the present acceptance range for these tablets, or at least to make the range more meaningful, if the air concentration in the water is controlled at the beginning of the test.

Abstract □ Both unformulated (bulk) and formulated (drugs) organic nitrate esters (isosorbide dinitrate, nitroglycerin, and pentaerythritol tetranitrate) were studied in the presence and absence of hydrochloric acid to determine if they could be sources of nitrite (and therefore lead to nitrosamine formation) under acidic conditions similar to those found in the stomach. The presence and generation of nitrite ion was detected by a modification of the Griess reaction. Bulk isosorbide dinitrate and nitroglycerin were found to be contaminated with 13.8–121.4 μmoles of inorganic nitrite per mole of nitrate ester. In addition, in the presence of hydrochloric acid, these preparations generated 0.52–1.18 μmoles of inorganic nitrite/mole of nitrate ester/min. Unformulated nitroglycerin generated nitrite at a rate roughly twice that of isosorbide dinitrate. In contrast, no evidence for nitrite contamination or generation by pentaerythritol tetranitrate was found. Tablets and capsules of isosorbide dinitrate contained ~27–216 μmoles of nitrite/mole of nitrate ester and, in the presence of hydrochloric acid, generated an average of 0.55 μmole nitrite/min. For isosorbide dinitrate, this rate was similar for bulk and formulated drug. In comparison to isosorbide dinitrate, the amount of nitrite initially present in tablets and capsules of nitroglycerin varied more widely (~25–2290 μmoles nitrite/mole of nitrate ester), and in this case nitrite was generated at higher rates than unformulated drug averaging ~4.7 μmoles nitrite/mole of nitrate ester/min. Contrary to a literature report, we found that nitrate ion is not reduced to nitrite by hydrochloric acid (pH 1–3). These data suggest that the continuous production of nitrite ion from isosorbide dinitrate and nitroglycerin is due to the hydrolysis of nitrite ester impurities, a reaction known to be strongly catalyzed by the chloride ion. Although the generation of inorganic nitrite from organic nitrate esters is of interest, the low levels of nitrite produced are unlikely to lead to intragastric nitrosamine formation.

Keyphrases □ Isosorbide dinitrate—presence and generation of inorganic nitrite, simulated gastric conditions, Griess reaction □ Nitroglycerin—presence and generation of inorganic nitrite, simulated gastric conditions, Griess reaction □ Pentaerythritol tetranitrate—presence and generation of inorganic nitrite, simulated gastric conditions, Griess reaction □ Inorganic nitrite—presence in and generation from the nitrate esters isosorbide dinitrate, nitroglycerin, and pentaerythritol tetranitrate, simulated gastric conditions, Griess reaction

Organic nitrate esters such as nitroglycerin have been used for many years on an intermittent basis to relieve the symptoms of angina pectoris. Recently, organic nitrates have been used on a continuing basis to prevent anginal attacks; they are often ingested with other medications such as tranquilizers or are prescribed concomitantly with β-adrenergic blocking drugs such as propranolol hydrochloride for an additive pharmacological effect (1). Since these medications are taken for many years, often for the lifetime of the patient, it is important to evaluate the safety of simultaneous ingestion of such drugs (2).

There has been much discussion regarding the potential hazards of nitrosamines formed from therapeutic drugs during their passage through the GI tract (3, 4). In fact, in studies where animals are fed inorganic nitrite along with various drugs such as chlordiazepoxide, the formation of carcinogenic nitrosamines has been demonstrated (5). To form nitrosamines, an acidic milieu, the presence of amines, and a source of nitrite are required. The human stomach provides such an appropriate acidic environment (6), and most antihypertensive, β-adrenergic blocking, and tranquilizing drugs are secondary or tertiary amines. Nitrosamine formation can occur from a tertiary amine, but an oxidative cleavage to a secondary amine is required first (7). Nitrosation of secondary amines is a well-established reaction (7).

Organic nitrate esters such as nitroglycerin have been used for many years on an intermittent basis to relieve the symptoms of angina pectoris. Recently, organic nitrates have been used on a continuing basis to prevent anginal attacks; they are often ingested with other medications such as tranquilizers or are prescribed concomitantly with β-adrenergic blocking drugs such as propranolol hydrochloride for an additive pharmacological effect (1). Since these medications are taken for many years, often for the lifetime of the patient, it is important to evaluate the safety of simultaneous ingestion of such drugs (2).

There has been much discussion regarding the potential hazards of nitrosamines formed from therapeutic drugs during their passage through the GI tract (3, 4). In fact, in studies where animals are fed inorganic nitrite along with various drugs such as chlordiazepoxide, the formation of carcinogenic nitrosamines has been demonstrated (5). To form nitrosamines, an acidic milieu, the presence of amines, and a source of nitrite are required. The human stomach provides such an appropriate acidic environment (6), and most antihypertensive, β-adrenergic blocking, and tranquilizing drugs are secondary or tertiary amines. Nitrosamine formation can occur from a tertiary amine, but an oxidative cleavage to a secondary amine is required first (7). Nitrosation of secondary amines is a well-established reaction (7).

0022-3549/83/0900-1064$01.00/0

We have been concerned as to whether or not organic nitrate drugs could be a source of nitrite ion and therefore give rise to nitroso compounds during dissolution in the stomach. Although organic nitrate esters are known to be converted to nitrite by hepatic enzymes (8), the conversion of organic nitrate esters to inorganic nitrite in actual or simulated gastric contents has not been described. Nevertheless, Oishis (9) has reported, on the basis of polarographic studies, a mechanism by which nitrite could arise from nitrate in the presence of hydrochloric acid. He found that even in dilute solution, the interaction of nitric acid and hydrochloric acid (aqua regia reaction: $HCl + HNO_3 \rightarrow HNO_2 + HOCl$) gave rise to an equilibrium that favored the products over starting compounds in the ratio 99:1.

Earlier studies in our laboratory showed that nitrosamines could be recovered from incubations of isosorbide dinitrate with hydroxyzine hydrochloride, a tertiary amine (2), or propranolol hydrochloride, a secondary amine (10). In this report, we examined whether or not organic nitrate esters are a source of inorganic nitrite, and if not, other possible origins of inorganic nitrite. Various preparations of isosorbide dinitrate, nitroglycerin, and pentaerythritol tetranitrate were examined for the presence of nitrite under acidic conditions simulating those found in the human stomach.

EXPERIMENTAL

Materials—Unformulated samples, tablets, and capsules of isosorbide dinitrate, nitroglycerin, and pentaerythritol tetranitrate were gifts from various manufacturers. Because of their explosive properties, organic nitrates are routinely stored and handled as either lactose or mannitol mixtures. When formulated as drugs, the active ingredients are combined with inert materials and lubricants. In the studies described here, samples of the bulk (unformulated) materials were used as received, and in addition, a bulk sample of isosorbide dinitrate (25% in mannitol) was purified by sublimation and also by recrystallization from absolute ethanol.

Sulfanilic acid[1] and 1-aminonaphthalene[1] were analytical reagent grade. All reagents, water, and glassware used in these studies were free of contaminating nitrite and periodically checked using the Griess test (11).

Bulk Organic Nitrates—Samples were incubated in hydrochloric acid, pH 1.0, at 37° accompanied by gentle shaking to simulate conditions of acidity, temperature, and pH found in the human stomach. Incubations were conducted for 60–90 min to determine the time course of inorganic nitrite production during the period that a drug is likely to remain in the stomach. Under these conditions, the free nitrite ion (nitrous acid) was found to be unstable. Therefore, the Griess test (11, 12) was modified in that sulfanilic acid was added at the outset to trap nitrite released from the nitrate esters as the diazo derivative. Under these conditions, diazotization is complete in <1 min.

The assay procedure was as follows: Sulfanilic acid (12.9 m*M*) in 0.12 *M* HCl was added to an aqueous solution of organic nitrate ester in a final concentration of 10% dimethylformamide in water. Aliquots (1.5 ml) of this incubation mixture were removed at specific times and allowed to react with 1-aminonaphthalene (15.7 m*M*), forming a red dye which gave maximal absorbance at 520 nm within 2 min. Nitrite concentrations were calculated as a function of the absorption of the dyestuff using a molar extinction coefficient of 33,000 liter/mole-cm at 520 nm. The minimum detectable amount of nitrite in the assay, based on an absorbance reading of 0.010 is ~0.5 nmole of nitrite. It should be noted that the Griess test is specific for the nitrite ion, and its sensitivity for nitrite detection is considerably better than other published methods (12) including chemiluminescence (13) and a recently reported high-performance liquid chromatographic (HPLC) technique (14).

Because the pH of human stomach contents varies, nitrite levels were measured at several hydrogen ion concentrations. The pH of the solution

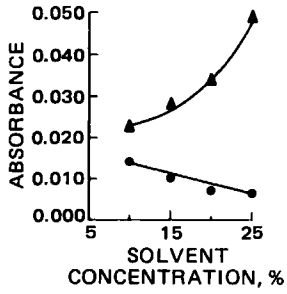

Figure 1—*Effect of organic solvents on absorbance. The Griess reaction was performed at pH 1.0 in solutions containing 8.47 mmoles/liter of isosorbide dinitrate; absorbance was measured after 90 min of incubation. Key: (▲) dimethylacetamide; (●) dimethylformamide. Points are mean values obtained from at least two experiments.*

was raised by adding sodium hydroxide to the sulfanilic acid reagent mixture such that the desired pH of 2.0 or 3.0 was achieved in the final incubation mixture. At pH 2.0 or 3.0 at 37°, diazotization and coupling times varied from 5 to 30 min. No studies were performed at pH >3.0 due to the insolubility of the components of the Griess reagents.

Organic nitrate esters were found to be only partially soluble in aqueous solutions as well as in the Griess reagent mixture. It was therefore necessary to use dimethylformamide as a cosolvent to ensure complete solubility and thus accurate measurement of nitrite under the experimental conditions described above. HPLC analysis was used to compare the quantity of organic nitrate ester added to the Griess reaction mixture and the amount of organic nitrate recovered from the incubation mixture. This was done by weighing organic nitrate esters mixed with sugars, extraction into 100% dimethylformamide, and injection onto a μ-Bondapak C-18 column. These samples were compared with companion samples that were added to the Griess reaction mixture and also with samples that were back-extracted from the Griess reaction incubation mixture into methylene chloride. Samples were separated by HPLC and detected by a UV detector at 254 and 280 nm. The retention time for isosorbide dinitrate separated by methanol–water (55:45), isocratic, flow rate 2 ml/min, was 3.3 min; for nitroglycerin in a 50–100% acetonitrile linear gradient, flow rate 1.5 ml/min, the retention time was 6 min. HPLC analysis of organic nitrate esters under the conditions described confirmed their complete solubility in the Griess reaction mixture at a final dimethylformamide concentration of 10%.

Formulated Organic Nitrates (Drugs)—Formulated tablets and the contents of capsules of isosorbide dinitrate, nitroglycerin, and pentaerythritol tetranitrate were ground using a mortar and pestle prior to testing. The resulting powder was dissolved in dimethylformamide and centrifuged at 2000×*g* for 10 min at 4° to separate the nitrate ester from insoluble components of the formulated preparations. Samples were diluted with water to contain 1.0, 1.5, and 2.0 mg of nitrate ester/ml in the final 10% dimethylformamide mixture. The concentration of organic nitrate ester actually present in the drug extract was confirmed by the aforementioned HPLC method. At time zero, sulfanilic acid and 1-aminonaphthalene in hydrochloric acid, pH 1.0, were simultaneously added to the drug extract and incubated at 37° with shaking. Aliquots were removed at various intervals up to 90 min, passed through a filter[2] to remove particles, and the absorbance was read at 520 nm. This procedure differs from that described above in that sulfanilic acid and 1-aminonaphthalene were added together instead of sequentially.

The effect of the sequence of addition of sulfanilic acid and 1-aminonaphthalene on detection of nitrite was evaluated as follows: In one case, sulfanilic acid was incubated with the reaction mixture and 1-aminonaphthalene was added at the end of the incubation period. In the second case, the sulfanilic acid and 1-aminonaphthalene were added together at the initiation of the incubation period. When scanned by spectrophotometry, absorption maxima (520 nm) were superimposable for sodium nitrite standards, sodium nitrite mixed with unformulated isosorbide dinitrate and nitroglycerin, and sodium nitrite mixed with isosorbide dinitrate and nitroglycerin extracted from tablets and capsules.

RESULTS

Effect of Organic Solvents—Bulk organic nitrate esters were found to be only partially soluble in aqueous solutions as well as in the Griess

Points are mean values obtained from at least two experiments.*

reagent mixture. It was therefore necessary to use organic solvents to ensure complete solubility and thus accurate measurement of nitrite. Various cosolvents were tested and, surprisingly, were found to interfere with accurate measurement of the nitrite. For example, the addition of ethanol or acetone to a known quantity of inorganic nitrite lowered the apparent nitrite concentration as measured by the Griess test. Ethanol appeared to destroy nitrite itself while acetone appeared to destroy the diazonium ion intermediate. The aprotic solvents dimethylacetamide, dioxane, and dimethylformamide did not affect solutions of inorganic nitrite. However, when increasing concentrations of dimethylacetamide were added to solutions of isosorbide dinitrate of identical composition, the apparent nitrite concentration was increased. In contrast, increasing amounts of dimethylformamide slightly decreased absorbance readings (Fig. 1). Because of its negligible interaction with nitrites, nitrates, and the Griess reaction, dimethylformamide was used as the solvent in subsequent experiments (Fig. 2).

Presence of Nitrite in Bulk Organic Nitrate Esters—Two samples of isosorbide dinitrate were analyzed by the Griess reaction as previously described. Both preparations contained an initial level of nitrite that varied 10-fold between the two samples (Fig. 3A and B). In addition, in the presence of hydrochloric acid these preparations generated nitrite. Both the initial levels of nitrite as well as that generated in hydrochloric acid increased linearly with increasing concentrations of isosorbide dinitrate. The increase in the production of nitrite in the presence of hydrochloric acid was apparent for 6 hr. After this period, there was no further generation of nitrite. In contrast with the generation of nitrite in hydrochloric acid, initial levels of nitrite in phosphoric acid remained constant over time (Fig. 4).

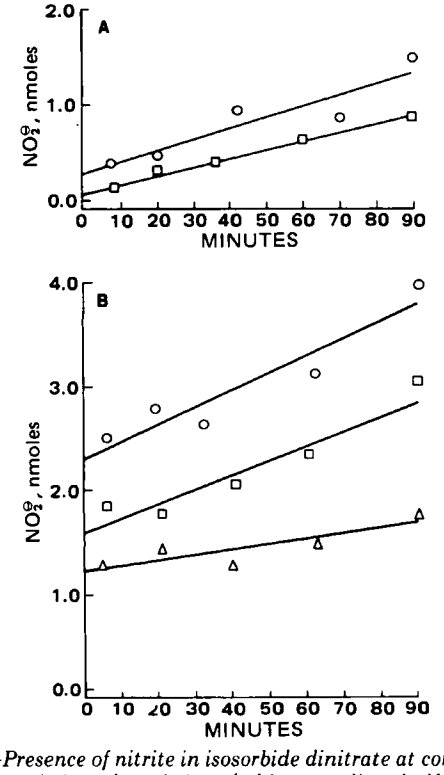

Figure 3—*Presence of nitrite in isosorbide dinitrate at concentrations of 2.0 (○), 1.5 (□), and 1.0 (△) mg/ml in 10% dimethylformamide in hydrochloric acid, pH 1.0, using formulations of 25% isosorbide dinitrate in lactose (A) or mannitol (B). Points are mean values obtained from at least two experiments.*

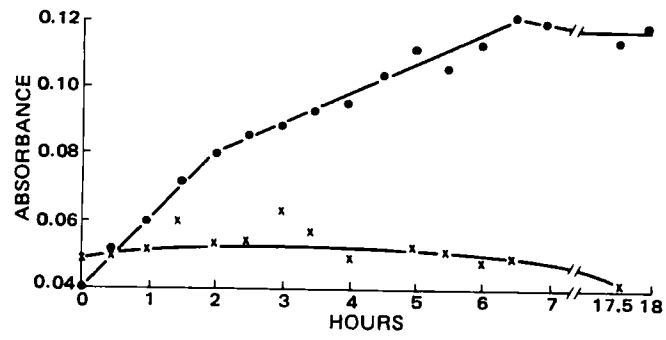

Figure 4—*Time course for generation of nitrite from isosorbide dinitrate, 25% in lactose. Points represent nitrite generated from isosorbide dinitrate (2.0 mg) in 10% dimethylformamide, pH 1.0, in hydrochloric acid (●) and phosphoric acid (×).*

Examination of samples of isosorbide dinitrate (25% in mannitol) purified by sublimation and by recrystallization, indicated the presence and generation of nitrite in amounts similar to the previously examined parent sample, except that initial levels of nitrite were lower (Table I). Thus, in hydrochloric acid, all preparations of isosorbide dinitrate generated nitrite at similar rates.

Samples of isosorbide dinitrate in lactose and mannitol were examined by the Griess reaction at pH 1, 2, and 3 under diazotization and coupling times ranging from 5 to 30 min. The amount of nitrite detected initially or generated within this range of pH was the same as that for isosorbide dinitrate samples described above (data not shown).

In comparison with isosorbide dinitrate, on a molar basis, nitroglycerin contained higher initial levels of nitrite, and nitrite was generated in hydrochloric acid at rates roughly twice that observed with isosorbide dinitrate (Table I, Fig. 5). Like isosorbide dinitrate, the production of nitrite is linear with time and the rates are essentially parallel for different concentrations of nitroglycerin. In hydrochloric acid, but not in phosphoric acid, nitrite was generated for 4 hr (Fig. 6). Because of its volatile and explosive properties, nitroglycerin was not purified further. Significantly, corresponding experiments performed on pentaerythritol tetranitrate failed to give absorbance readings above background levels; no evidence for the presence or generation of nitrite was obtained.

Finally, to eliminate the possibility that the nitrite ion could arise by reduction of the nitrate ion, we examined the action of hydrochloric acid (pH 1.0–3.0) on dilute solutions of sodium nitrate (40 m*M*) and nitric acid (40 m*M*) over 24 hr. Within the detection limits of the Griess test, no evidence of nitrite formation was obtained.

Presence of Nitrites in Formulated Organic Nitrate Vasodilators—The first studies on drugs containing isosorbide dinitrate and nitroglycerin using the sequential addition of Griess reagents (sulfanilic acid present during the incubation, followed by the addition of 1-aminonaphthalene) showed an initial level of nitrite present that appeared to decrease with time. This phenomenon may reflect destruction of the intermediate diazonium ion by an unidentified constituent(s) present in the formulated drugs. Therefore, the Griess reagents were added simultaneously so that immediately after its formation, the diazonium

Table I—Nitrite Detected in Bulk Organic Nitrate Ester Preparations

Compound	μmole of nitrite/mole of nitrate ester		
	After 2 min[a]	After 60 min[b]	Total[c]
Isosorbide dinitrate, sublimed	23.6	32.9	56.5
recrystallized	13.2	43.3	56.5
25% in lactose	13.8	30.9	44.7
25% in mannitol	114.6	44.9	159.5
Nitroglycerin, 10% in lactose	121.4	70.7	192.1
Pentaerythritol tetranitrate, 20% in lactose	—[d]	—	—

[a] The concentrations of nitrite initially detectable after 2 min in hydrochloric acid, pH 1.0. [b] The amount of nitrite generated in 60 min. [c] The sum of nitrite initially present plus nitrite generated over 60 min. [d] Not detected.

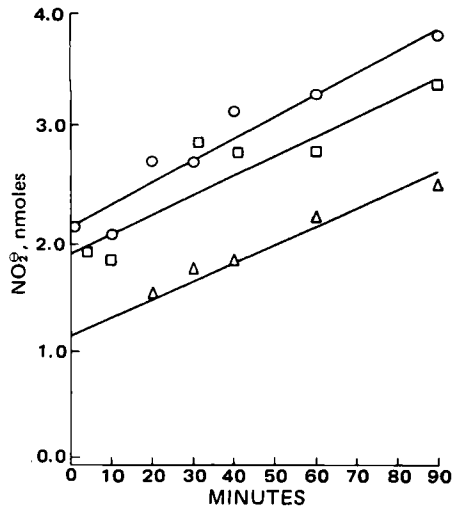

Figure 5—*Presence of nitrite in nitroglycerin, 10% in lactose, at concentrations of 2.0 (○), 1.5 (□), and 1.0 (△) mg/ml in hydrochloric acid, pH 1.0, in 10% dimethylformamide. Points are mean values obtained from at least two experiments.*

reagent could react with the coupling reagent, 1-aminonaphthalene. By this procedure, the production of inorganic nitrite was followed for 90 min, the longest time that a drug is likely to remain in the stomach. In contrast to isosorbide dinitrate and nitroglycerin, the green color of commercially formulated drugs that contained pentaerythritol tetranitrate obscured the absorbance of the dyestuff at 520 nm. Thus pentaerythritol tetranitrate-containing drugs were not analyzed for nitrite content.

At concentrations of nitrite <1 μmole/liter, the sequential and simultaneous addition of Griess reagents gave similar absorbance values. At higher concentrations of nitrite, in comparison with the sequential addition of reagents, the simultaneous addition of Griess reagents gave a decrease of 15–20% in absorbance readings for identical nitrite concentrations (Fig. 7).

Tablets and capsules of isosorbide dinitrate were found to contain varying amounts of nitrite initially (~27–216 μmoles of nitrite/mole of nitrate ester) and to generate an average of 0.55 μmole of nitrite/mole of nitrate ester/min (Fig. 8, Table II).

Tablets and capsules of nitroglycerin also varied widely in their nitrite content. Nitrite was present in initial concentrations of ~25–2290 μmoles of nitrite/mole of nitrate ester and was generated at an average rate of ~4.7 μmoles of nitrite/mole of nitrate ester/min (Fig. 8, Table II).

DISCUSSION

It is evident that most of the preparations that were examined contained small quantities of inorganic nitrite. In addition, it also appears that apart from pentaerythritol tetranitrate, these preparations probably

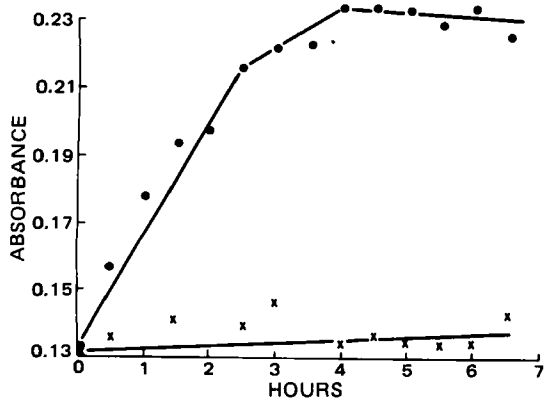

Figure 6—*Time course of generation of nitrite from nitroglycerin, 10% in lactose. Points represent nitrite generated from nitroglycerin (2.0 mg) in 10% dimethylformamide, pH 1.0, in hydrochloric acid (●) and phosphoric acid (×).*

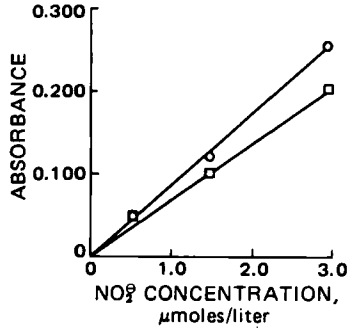

Figure 7—*Comparison of dye absorbance with sequential and simultaneous addition of Griess reagents using solutions with identical concentrations of nitrite in hydrochloric acid, pH 1.0, in 10% dimethylformamide. Key: (○) values obtained when only sulfanilic acid is present at time zero; (□) values obtained when sulfanilic acid and 1-aminonaphthalene are added together at time zero. Absorbance readings were taken 60 min later; points represent mean values from at least three experiments.*

contain small quantities of nitrite esters as impurities. These serve as the source of the continuous production of nitrite ion when the mixture is incubated with hydrochloric acid. Evidently a slow HCl-catalyzed hydrolysis is occurring; the sensitivity of nitrite esters to acidic hydrolysis is well documented (15).

In addition, acidic hydrolysis of nitrite esters is catalyzed by the presence of halide ions. Companion experiments were performed on all nitrate esters using phosphoric acid instead of hydrochloric acid to provide an acidic medium of identical pH. In all samples of isosorbide dinitrate and nitroglycerin, but not pentaerythritol tetranitrate, an initial level of nitrite was detected which corresponded to that seen in hydrochloric acid, but no further generation of nitrite was observed. These results are consistent with the findings of Allen, who showed that the rates of acid hydrolysis of propyl nitrite were increased by at least two orders of magnitude when equivalent concentrations of chloride ion were present (16).

The possibility exists, however, that the nitrite that is continually produced could come from the reduction of nitrate ion or nitrate ester by hydrochloric acid. If the claim by Oishis (9) that nitric acid is reduced to nitrous acid in dilute solution by hydrochloric acid is correct (the aqua regia mechanism), then it is difficult to explain the failure of pentaerythritol tetranitrate to yield nitrite. We have now examined dilute mixtures of both $NaNO_3$–HCl (1:4) and HNO_3–HCl (1:4) in water, over a time course of 24 hr and at pH values of 1 and 3. No evidence of nitrite (or nitrous acid) formation could be detected within the sensitivity range of the Griess reagent. These results are consistent with literature reports of hydrolysis of nitrate esters. Boschan (15) states that hydrolysis of nitrate esters predominantly yields nitrate ion, and that no subsequent reduction to nitrite occurs. However, nitrite esters containing an α-hydrogen can undergo elimination to directly form nitrite. Of course, nitric

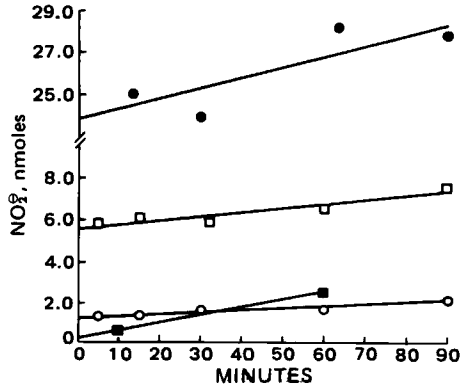

Figure 8—*Time course of nitrite production by some organic nitrate ester drug dosage forms. Drugs were incubated in hydrochloric acid, pH 1.0; points represent the mean values obtained from at least three experiments. Key: (●) 0.6-mg nitroglycerin tablet; (■) 6.5-mg sustained-action nitroglycerin capsule; (○) 40-mg sustained-action isosorbide dinitrate tablet; (□) 40-mg sustained-action isosorbide dinitrate capsule.*

Table II—Nitrite Detected in Organic Nitrate Ester Drug Formulations

Drug	μmole of nitrite/mole of nitrate ester		
	After 2 min[a]	After 60 min	Total[b]
Isosorbide dinitrate 40-mg tablet, SA[c]	63.6	28.0	91.6
40-mg capsule, SA	26.5	26.9	53.4
40-mg capsule, SA	216.0	44.0	260.0
Nitroglycerin, 6.5-mg capsule, SA	2290.0	299.0	2589.0
2.5-mg capsule, SA	1014.0	328.0	686.0
0.6-mg tablet	24.7	222.0	247.0

[a] Drugs were analyzed as described in *Experimental*. The 2-min time reflects absorbance values (520 nm) obtained 2 min after the simultaneous addition of Griess reagents and is assumed to reflect nitrite initially present. [b] Total of the nitrite initially present and the nitrite generated over 60 min. [c] SA = sustained-action or time-released preparation.

Table III—Calculated Maximal Nitrite Concentrations in Gastric Juice Arising from Dissolved Organic Nitrate Ester Drugs

Drug	μmole of nitrite/liter of gastric juice[a]	
	After 2 min	Total, After 60 min
Isosorbide dinitrate, 40-mg tablet, SA[b]	1.08	1.55
40-mg capsule, SA	0.45	0.91
40-mg capsule, SA	3.66	4.40
Nitroglycerin, 6.5-mg capsule, SA	13.10	14.80
2.5-mg capsule, SA	5.80	3.90
0.6-mg tablet	0.14	1.41

[a] Nitrite concentrations are calculated on the basis of actual levels of nitrite found (Table II). Calculations are based on the ingestion of 60 mg of isosorbide dinitrate or 19.5 mg of nitroglycerin dissolved in a 15-ml volume of gastric juice. [b] SA = sustained-action or time-released preparation.

acid and sodium nitrate could not form nitrites according to this scheme.

In comparison with unformulated isosorbide dinitrate and nitroglycerin, tablets and capsules of these drugs generally contained higher levels of nitrite initially. For isosorbide dinitrate, levels were twofold higher while two of three nitroglycerin drugs tested contained ten to twenty times more nitrite than comparable amounts of unformulated nitroglycerin. In addition, as discussed above, the values obtained for nitrite probably reflect a 15–20% underestimation of the nitrite actually present.

For isosorbide dinitrate, the amount of nitrite generated with time, 0.55 μmole of nitrite/mole of nitrate ester/min was comparable for both unformulated and formulated drug. In contrast, drugs containing nitroglycerin generated nitrite at faster rates than unformulated drug, averaging 4.7 μmoles of nitrite/mole of nitrate ester/min for formulated drug, a figure somewhat higher than that of 1.2 μmoles of nitrite/mole of nitrate ester/min given for nitroglycerin formulated with lactose alone. Again, as is discussed above, the nitrite initially present is assumed to be there as inorganic nitrite contamination, whereas nitrite which is generated with time in hydrochloric acid is believed to be due to the acid- and chloride-catalyzed hydrolysis of nitrite esters (15, 16), which are believed to be present as impurities in these drugs.

Because many nitrosamines pose a carcinogenic risk one might reasonably ask if the levels of nitrite in these drugs are sufficient to pose a risk of nitrosamine formation from other amine drugs while dissolution in the stomach is taking place. In Table III, nitrite levels actually detected in six different organic nitrate ester drug formulations (Table II) were used to calculate the nitrite concentration that would be present in gastric juice if all of the drug were completely soluble in 15.0 ml of gastric juice. It should be noted however, that these compounds are known to have limited solubility in aqueous solutions. The dosage used for these calculations are the upper limit of currently recommended single therapeutic doses of these compounds—60 mg of isosorbide dinitrate and 19.5 mg of nitroglycerin (17).

On the basis of these data, only the 6.5-mg sustained-action capsules of nitroglycerin provided more than the 10 μmoles of nitrite necessary, on a theoretical basis, to nitrosate 80 mg of propranolol hydrochloride, a secondary amine (18), or 100 mg of hydroxyzine hydrochloride, a tertiary amine[3]. Despite this, when these nitroglycerin capsules were actually incubated with propranolol hydrochloride, a nitrosamine product could not be recovered (19).

In conclusion, the organic nitrate ester vasodilator drugs, isosorbide dinitrate and nitroglycerin, contain varying amounts of inorganic nitrite and nitrite esters present as impurities. Although these nitrate esters may contain adventitious nitrite or nitrite ester, no hazard appears to be posed by the possibility that they themselves can give rise to nitrites *via* reduction with hydrochloric acid. These impurities may arise during the manufacture of the raw material, formulation into therapeutic dosage forms, and/or from decomposition during storage. In terms of the amount of nitrite provided daily by the average American diet (13 mg, 2.3 mmoles), the amount of nitrite provided by these drugs in absolute terms is quite small (20). Moreover, the risk of nitrosating secondary or tertiary amine drugs simultaneously ingested with organic nitrate esters appears to be negligible.

Determination of Cyproheptadine in Plasma and Urine by GLC with a Nitrogen-Sensitive Detector

H. B. HUCKER[x] and J. E. HUTT

Received June 14, 1982, from the *Merck Institute for Therapeutic Research, West Point, PA 19486.* Accepted for publication August 24, 1982.

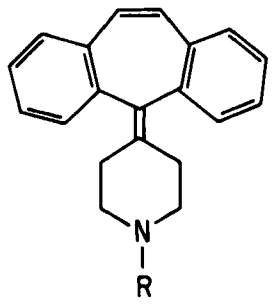
Abstract □ A method for the determination of cyproheptadine in plasma and urine was developed using the *N*-ethyl homologue as an internal standard. After extraction of the drug from an alkalinized sample into petroleum ether–isoamyl alcohol, back-extraction into 0.1 *N* HCl, washing the aqueous phase with fresh solvent, re-extraction into petroleum ether after alkalinization, the solvent was evaporated. The reconstituted residue was analyzed by GLC using a SP-2250 column and nitrogen-sensitive detector. Concentrations as low as 3 ng/ml could be determined. Plots of peak area of cyproheptadine–peak area of internal standard *versus* cyproheptadine concentration were linear over the range studied with correlation coefficients of 0.9945 and 0.9924 for plasma and urine, respectively. The method was used to determine the peak time (0.5 hr), peak concentration (33 ng/ml average), and apparent half-life (3 hr) in two dogs after oral administration of 1 mg of cyproheptadine/kg.

Keyphrases □ Cyproheptadine—GC determination in plasma and urine □ GC—cyproheptadine, determination in plasma and urine

Cyproheptadine[1], 4-(5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene)-1-methylpiperidine (I, R = CH_3), is a potent antihistaminic and antiserotonergic agent (1) and inhibitor of platelet aggregation (2). Its disposition and metabolism in humans and animals have been described (3–9). Cyproheptadine has been quantitated in rat tissues by GC with a reported sensitivity of ~1 μg/g (3). The present report describes an analytical method suitable for the determination of cyproheptadine in low nanogram concentrations in plasma and urine.

EXPERIMENTAL

Reagents—Petroleum ether (35–60°) and all other chemicals were of analytical reagent grade and were used without further purification. Analytically pure cyproheptadine·HCl and the maleate salt of its *N*-ethyl analogue were synthesized in these laboratories. Stock solutions of the drug and the *N*-ethyl analogue used as an internal standard (II, R = C_2H_5) were prepared in methanol (1 mg/ml, as the free bases). The solution of cyproheptadine was diluted with methanol to give solutions containing 1, 0.5, 0.25, and 0.125 ng of drug/μl. The internal standard solution was diluted with methanol to give a solution containing 2 ng of the compound/μl.



I: R = CH_3
II: R = C_2H_5

A solution of isoamyl alcohol in petroleum ether (99:1, v/v) was prepared.

Instrument—Analyses were performed on a GC[2] equipped with a nitrogen-sensitive detector. The column, 0.91 m × 2 mm (i.d.) was packed with 3% SP-2250 on Supelcoport (80–100 mesh)[3]. The column was conditioned by heating overnight at 260° under helium flow (30 ml/min). Chromatographic conditions were as follows: column oven, detector, and injection port temperatures of 230, 300, and 275°, respectively; helium, hydrogen, and air flows of 30, 3.6, and 50 ml/min, respectively.

Procedure for Plasma—To 1 ml of plasma in a 13-ml glass-stoppered centrifuge tube were added 3.12, 6.25, 12.5, 25, or 50 ng of cyproheptadine and 50 ng of internal standard in a total volume of 50 μl of methanol. After addition of 1 ml of 0.1 *N* NaOH and 8 ml of petroleum ether–isoamyl alcohol (99:1), the tube was shaken for 10 min and centrifuged. Most of the organic phase was transferred to a second tube containing 1 ml of 0.1 *N* HCl. The tube was shaken for 5 min and centrifuged. The organic phase was discarded and 8 ml of petroleum ether–isoamyl alcohol added. After shaking again for 5 min and centrifuging, the organic phase was aspirated. After addition of 0.2 ml of 1 *N* NaOH and 8 ml of petroleum ether–isoamyl alcohol, the tube was shaken for 10 min and centrifuged. The solvent was transferred to a 13-ml centrifuge tube and evaporated in a stream of nitrogen at 40°. The small volume of residual isoamyl alcohol was diluted with 50 μl of heptane and 3 μl was injected into the column. The peak areas of cyproheptadine and the internal standard were measured by the chromatograph terminal and the ratio of the areas plotted *versus* the concentration of cyproheptadine present. Cyproheptadine concentrations in the unknowns were obtained by reference to this standard curve.

Procedures for Urine—The procedure was the same as for plasma except that the standard samples contained 12.5, 25, 50, and 100 ng of cyproheptadine.

RESULTS AND DISCUSSION

As shown in Fig. 1, cyproheptadine and its ethyl homologue used as an internal standard were well separated under the conditions used, having retention times of 4.2 and 5.3 min, respectively. Blank plasma samples assayed by the same procedure showed no significant interfering peaks.

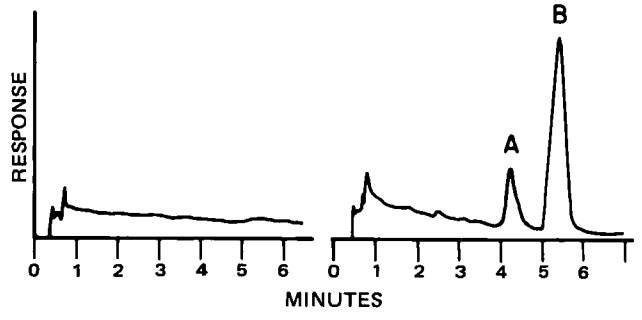


Figure 1—*Gas chromatograms of control dog plasma (left panel) and of plasma containing 12.5 ng of cyproheptadine (A) and 50 ng of internal standard (B) per milliliter (right panel).*

Table II—Plasma Concentrations of Cyproheptadine in Dogs after Administration of a Single Oral Dose (1 mg/kg)

Time, hr	Plasma Concentration: Dog 1, ng/ml	Dog 2, ng/ml
0.5	32	34
1	22	32
2	20	24
4	14	14
6	8	8
12	2	3

Most of the known metabolites of cyproheptadine (*i.e.*, the 10-hydroxy, 10,11-epoxy, 10-ketodesmethyl-, and 10,11-dihydroxy analogues) did not interfere since their retention times were all longer than that of cyproheptadine (7.2, 7.5, 9.3, and 10.8 min, respectively). The *N*-oxide gave a peak at the same retention time as cyproheptadine, presumably from thermal loss of oxygen during GLC. However, it was found that the *N*-oxide was not extracted from plasma or urine under these conditions and, thus, would not interfere in the analysis. Similarly, *N*-desmethylcyproheptadine had the same retention time as the internal standard, but was very poorly extracted (<10% recovery) from plasma under the conditions used. In addition, plasma and urine from dogs dosed with cyproheptadine (see below) were analyzed without addition of the internal standard. No peak was seen at the retention time of desmethylcyproheptadine, indicating that this metabolite would not interfere in the determination of cyproheptadine. However, it would be advisable before using the method in multiple-dose studies to determine if the desmethyl metabolite is present in concentrations sufficient to cause interference. If this is indicated, use of another internal standard would be required.

The precision and accuracy of the method were demonstrated by replicate analyses of plasma and urine samples containing known concentrations of cyproheptadine (Table I). The overall relative standard deviations for plasma ranged from 8.3 to 13.3% and the relative error range was −4.0–21.8%. For urine, the overall relative standard deviation range was 3.6–16.5% and the relative error −10.4–3.0%. The within-day correlation coefficient for the plasma standard curve was 0.9945 and the between-day value was 0.9825. The correlation coefficient for urine was 0.9924.

Plasma levels and urinary excretion of cyproheptadine were measured in two dogs at various times after administration of a single oral dose of the drug (1 mg/kg). The results are shown in Table II. Maximal concentrations were present at the earliest time sampled (0.5 hr). The apparent plasma half-life was ~ 3 hr. Urine (0–24 hr) contained 0.4–0.5% of the dose as unchanged cyproheptadine.

In summary, the present method was shown to be sufficiently sensitive, specific, and reliable for pharmacokinetic studies in the dog and possibly other species as well. Use of an internal standard of similar structure served to minimize errors in quantitation resulting from sample manipulation.

Abstract □ A UV method is described for measuring total sulfa drug concentration in dissolution samples. This *in vitro* measurement was found to correlate well with several *in vivo* parameters obtained after administration of commercial trisulfapyrimidine suspensions to humans. The UV method, which is rapid, simple, inexpensive and easily automated, is recommended for studying the dissolution of trisulfapyrimidine suspensions.

Keyphrases □ Trisulfapyrimidine—*in vivo–in vitro* correlations, UV method for the measurement of the dissolution of trisulfapyrimidine suspensions

Several reports (1–8) have appeared in the literature dealing with the bioavailability and dissolution of sulfa drugs. We have observed (9) significant bioavailability differences among seven commercial trisulfapyrimidine suspensions and have reported a dissolution method that provided good *in vivo–in vitro* correlation. This method was subsequently recommended for *in vitro* screening of trisulfapyrimidine suspensions. However, the dissolution samples were analyzed by a specific high-performance liquid chromatographic (HPLC) method which measured the concentrations of each component [sulfadiazine (I), sulfamerazine (II), and sulfamethazine (III)] of trisulfapyrimidine suspensions. The present study was undertaken to determine the suitability of a more rapid and readily available UV spectrophotometric procedure for measuring dissolution samples of trisulfapyrimidine suspensions, and to determine whether dissolution data collected in terms of total sulfa drug could be correlated with the *in vivo* parameters reported previously.

EXPERIMENTAL

***In Vivo* Study**—Details of the *in vivo* study are given elsewhere (9). Briefly, seven commercially available trisulfapyrimidine suspensions (A–G)[1] were each administered to 14 healthy male volunteers in a complete cross-over study design. Fourteen blood samples were then collected over a 48-hr period, and serum was analyzed for I, II, and III by a specific HPLC procedure (10).

Dissolution Methodology—Details of the dissolution method employed have been reported previously (9). Studies were done using the rotating paddle method (11) at 25 rpm in 900 ml of 2.2×10^{-4} *M* HCl, pH 3.4 at 37°. Samples were analyzed spectrophotometrically as described below.

Analytical—For the *in vivo* study, all serum samples were analyzed for sulfadiazine, sulfamerazine, and sulfamethazine by an HPLC method described previously (9, 10). For the *in vitro* study, all dissolution samples were analyzed for total sulfa drug content by a UV spectrophotometric procedure. A solution of trisulfapyrimidines was prepared by dissolving 100 mg each of I[2], II[3], and III[4] in the dissolution medium and adjusting the volume to 100 ml in a volumetric flask. This solution was quantitatively diluted with dissolution medium to obtain a stock solution containing 30 μg of total sulfa drug per milliliter. Standards (1.5, 3.0, 4.5, 6.0, 7.5, and 9.0 μg/ml total sulfa drug) were prepared by further diluting the stock solution with the dissolution medium. The absorbance of each standard solution was measured[5] at 254 nm and a calibration plot constructed. Unknown dissolution samples were measured in similar fashion, dilutions being performed with the dissolution medium where necessary. Prior to use, the spectra of each commercial suspension were examined in the dissolution medium for possible interference by excipients. All preparations gave similar spectra, and no interfering peaks were observed.

Table I—Mean [a] (± SD) Percent of Total Sulfa Drug Dissolved in 15 and 30 Min as Measured by the UV Assay for Seven Commercial Trisulfapyrimidine Suspensions

Product	15 min	30 min
A	68.3 ± 1.1	88.4 ± 0.9
B	86.8 ± 1.3	95.9 ± 1.0
C	47.9 ± 3.2	69.2 ± 4.8
D	88.0 ± 1.4	97.8 ± 1.9
E	30.7 ± 0.9	35.8 ± 1.9
F	22.1 ± 2.5	42.1 ± 4.1
G	9.9 ± 1.2	28.3 ± 1.6

[a] Mean of three determinations.

RESULTS

***In Vivo* Study**—Detailed results of the observed maximum serum concentration (C_{max}), the time for maximum serum concentration (t_{max}), and normalized areas under the curve ($AUC_0^\infty \times K_e$), have been presented previously (9) for I, II, and III.

***In Vitro* Study**—The mean percentages of total sulfa drug (IV) dissolved in 15 and 30 min for the seven trisulfapyrimidine suspensions are shown in Table I. It is observed that there were large differences in the dissolution rate among the seven suspensions. Product G showed the slowest rate of dissolution, while products A, B, and D showed the most rapid dissolution.

***In Vivo–In Vitro* Correlations**—For the three drugs (I, II, and III), each *in vivo* parameter was correlated with the percent of total sulfa drug (IV) dissolved in 15 and 30 min. Significant values of the linear correlation coefficient were observed between: (*a*) percent of IV dissolved in 30 min and C_{max} for I ($r = 0.83$, $p < 0.05$); (*b*) percent of IV dissolved in 15 min and C_{max} for I ($r = 0.80$, $p < 0.05$); (*c*) percent of IV dissolved in 30 min and t_{max} for I ($r = -0.80$, $p < 0.05$); (*d*) percent of IV dissolved in 15 min and t_{max} for I ($r = -0.79$, $p < 0.05$); (*e*) percent of IV dissolved in 30 min and C_{max} for II ($r = 0.77$, $p < 0.05$); (*f*) percent of IV dissolved in 30 min and t_{max} for II ($r = -0.85$, $p < 0.02$); (*g*) percent of IV dissolved in 15 min and t_{max} for II ($r = -0.81$, $p < 0.05$). Other combinations of *in vivo* and *in vitro* parameters did not give significant correlations.

DISCUSSION

Significant bioavailability differences among the commercial trisulfapyrimidine suspensions have been reported (9). These differences were

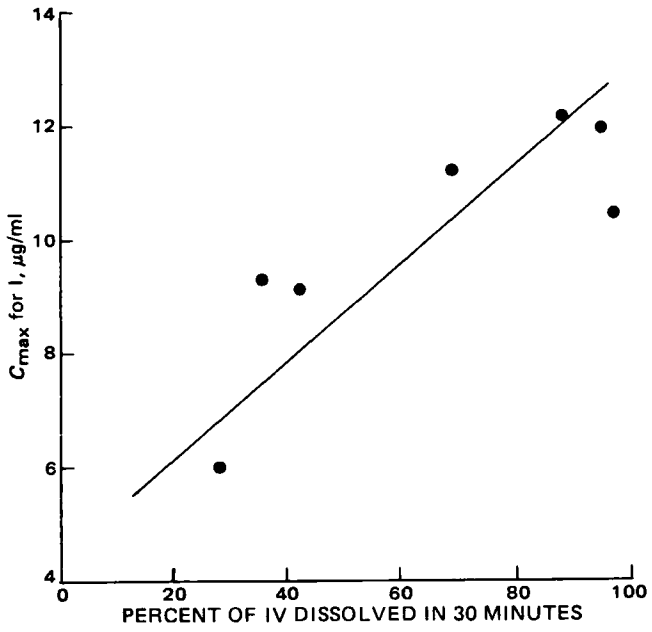

Figure 1—*Relationship between the* in vivo *measure of* C_{max} *for I and the* in vitro *measure of percent IV dissolved in 30 min for the seven trisulfapyrimidine suspensions, showing the regression line for the correlation coefficient of +0.83 (*$p < 0.05$*).*

observed in the rate and extent of absorption of individual suspension components. An *in vitro* dissolution test procedure was developed and dissolution samples analyzed by HPLC. Several significant correlations were reported between *in vivo* and *in vitro* parameters for individual sulfa components. Results of the present investigation show that when using the same dissolution procedure but a different method of detection (UV spectrophotometric) statistically significant correlations could be achieved between the *in vitro* values of percent of total sulfa drug dissolved (in 15 and 30 min) and the *in vivo* parameters reported previously for I and II.

As reported previously, the greatest bioavailability difference among the seven products was observed for the C_{max} parameter for I, for which good correlation was shown with the percent of I dissolved in 30 min (as measured by HPLC). The results of this study also show good correlation ($r = 0.83$, $p < 0.05$) between C_{max} for I and percent of IV dissolved in 30 min, as shown in Fig. 1. Thus, the UV method can be employed for studying the dissolution of trisulfapyrimidine suspensions. The method offers certain advantages over the HPLC procedure in that it is more rapid, less expensive, readily available in most laboratories, and more easily applicable to automation technology. Except for the fact that it could not detect differences in the individual sulfa components of trisulfapyrimidines, the UV method was found to be suitable for the determination of dissolution properties of commercial products.

Quantitative Assessment of the Effect of Some Excipients on Nitrazepam Stability in Binary Powder Mixtures

P. R. PERRIER and U. W. KESSELRING ˣ

Received January 25, 1982, from the *Laboratoire d'Analyse Pharmaceutique, Ecole de Pharmacie, CH-1005 Lausanne, Switzerland.* Accepted for publication August 24, 1982.

Abstract □ The decomposition rate constants, normalized for dilution and relative specific surface effects, of nitrazepam in simple binary powder mixtures with talcum, lactose·H_2O, microcrystalline cellulose, corn starch, mannitol, and saccharose are shown to be linearly related to the nitrogen adsorption energy of the excipients.

Keyphrases □ Nitrazepam—effect of excipients on stability in binary powder mixtures □ Excipients—effect on nitrazepam stability in binary powder mixtures

Recently, considerable effort has been made to precisely describe the chemical properties of excipients and how these excipients influence the technical and biopharmaceutical characteristics of the dosage forms. Excellent reviews list the "inert compounds" of pharmaceutical preparations (1), describe the difficulties concerning the "choice of excipients for international use" (2), "the influence of excipients on the design and manufacture of tablets and capsules" (3), and the "problems of drug interactions with excipients" (4). Many studies describe the influence of excipients, *e.g.* the acid-catalyzed decomposition of digoxin by montmorillonite (5), the effect of water adsorption properties of silica gel on the stability and the biological availability of ascorbic acid (6), and the influence of the solubility of some excipients on *in vitro* and *in vivo* properties of bendroflumethiazide tablets (7). Additional references were cited by Carstensen (8, 9).

Saccharose	1.587	0.28	4.071	199.4	4.44	18.1	1.74
Nitrazepam	1.398	1.14					

[a] These data were normalized to 0.5% dilution, and corrected for surface effect, (Σ_I/Σ_e), of nitrazepam, I, mixed with various excipients, e, stored at 70° and 60% relative humidity. [b] Expressed in terms of C_I, mg of nitrazepam, and C_e, mg of excipient per 100 mg of sample.

BACKGROUND

No systematic approach has been made to quantitatively study the so-called "inertness" of excipients. The work reported here is a first attempt to assess quantitatively (under well-defined conditions) the influence of some commonly used excipients on nitrazepam stability to find some parameter(s) which permit an objective comparison of the inertness of excipients.

Assuming a pseudo-first-order degradation, it has been shown that the logarithm of the nitrazepam decomposition rate constant is proportionally related to the inverse of absolute temperature and to the relative humidity of the environment (10). Other parameters to be considered are the dilution of the active ingredients and the relative specific surface area of the components of the system.

It is assumed that the slight concentration differences in the individual samples used in this study (<5%, except for the cellulose system, where the nitrazepam concentration was 1%, as compared with 0.5% in the other samples) may be linearly normalized[1].

These parameters must all be known and taken into account for further discussion and eventual elucidation of their influence on reaction mechanism. Because direct chemical reaction with the so-called "inert" excipients can be excluded in most cases, the hypothesis is formulated that the solid-state nitrazepam decomposition might be treated in analogy to heterogeneous catalysis reactions (11) whose basic steps are:

1. diffusion of the reactant toward the catalyst;
2. adsorption of the reactant onto the catalyst;
3. reaction of the adsorption complex to yield the product;
4. desorption of the product from the catalyst;
5. diffusion of the product away from the catalyst.

Anyone of these steps can be rate controlling for a given process, but not all the steps are necessarily involved in all decomposition reactions encountered in solid-state pharmaceutical dosage forms.

Before elucidating reaction mechanisms it would seem reasonable to study the role of water and to find out whether the reacting water molecules are in the gaseous, liquid, or some intermediate state, and whether it is possible to define a quantity of "water available for reaction" according to the following equation:

$$A_{sol} + (H_2O)_n \cdot B \rightarrow C_{sol} + D_{sol} + B \cdot (H_2O)_{n-1}$$

The difficulty of evaluating hygroscopicity for pharmaceutical solids has recently been described by van Campen *et al.* (12).

Also, the adsorption properties of the aerosol play an important role in nitrazepam stability (13).

EXPERIMENTAL

Materials—Nitrazepam (1,3-dihydro-7-nitro-phenyl-2*H*-1,4-benzodiazepin-2-one)[2], microcrystalline cellulose[3], talcum[4], mannitol[4], lactose·H_2O[4], cornstarch[4], and saccharose[4] were supplied commercially. Microcrystalline cellulose was used as received, all other excipients were of Pharmacopoea Helvetica VI quality. Adsorption isotherms and specific surfaces were determined with nitrogen (purity: 99.998%)[5].

Sample Preparation and Storage Conditions—Individual 800-mg samples containing 4 mg (0.5%) of nitrazepam were prepared by carefully mixing the constituents and avoiding any alteration of the granulometric characteristics. The samples were stored in climatic chambers[6] at constant relative humidity (60 ± 2%) and temperature (70 ± 0.5°).

Density and Specific Surface Area Determinations—True density values were obtained by means of a commercial pycnometer[7] measuring the helium gas or air volume displacement by the dried sample with a precision of 0.02 ml for a total volume of 15 ml. The specific surface area and the nitrogen energy of adsorption on the excipients were obtained by means of a homemade manifold, calculated according to the BET theory (14). The precision of the surface values obtained by nitrogen adsorption at 77°K is 1% for surfaces smaller than 1 m^2g^{-1} and better than 1% for surfaces larger than 1 m^2g^{-1}.

Assay—The decomposition of nitrazepam has been followed by HPLC using a liquid chromatograph[8] with a dualwave UV detector linked to an electronic integrating recorder[9] and fitted with a silica-filled column

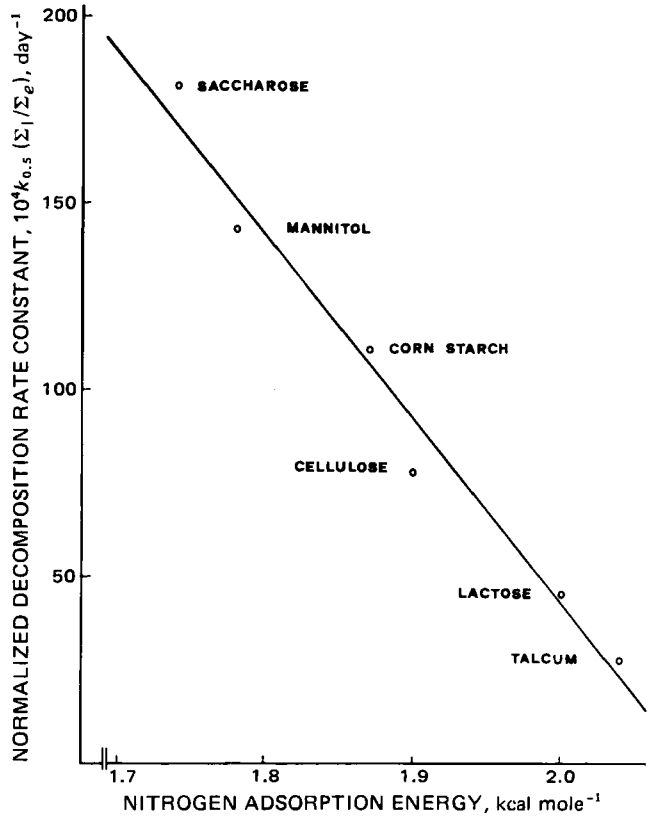

Figure 1—*Normalized decomposition rate constants of nitrazepam in relation to the nitrogen adsorption energy of various excipients.*

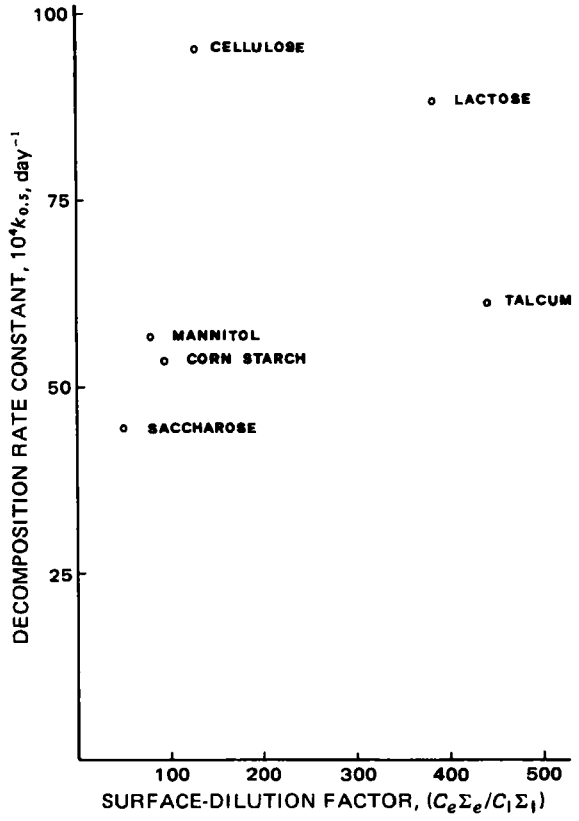

Figure 2—*Decomposition rate constants of nitrazepam as a function of the surface-dilution factor.*

(0.3 × 25 cm)[10]. To maintain column efficiency a precolumn of 0.3 × 5 cm, with identical filling, served as the filter. Operating conditions were as follows: mobile phase composition was *n*-hexane–chloroform–methanol (83.25:12.5:2.25), flow rate was 1.8 ml/min at a pressure of ~79 atm.

Antipyrine (2,3-dimethyl-1-phenyl-3-pyrazolin-5-one) at a concentration of 1.063×10^{-3} moles/liter served as the internal standard. The linearity range of nitrazepam was from 0.04 to 4 μg. Recovery of nitrazepam at 0.5% in microcrystalline cellulose was >98%, and the precision obtained was better than 1% for assays of amounts of I >0.04 μg and better than 2% for quantities <0.04 μg.

RESULTS AND DISCUSSION

Based on the experimental results obtained (Table I) the following linear relationship was established:

$$10^3 k_{0.5} \frac{\sum_I}{\sum_e} = 102 - 49.0\, E_{ads}(N_2) (r^2 = 0.976 \text{ for } n = 6)$$

where $k_{0.5}$ is the decomposition rate constant for a sample containing exactly 0.500% nitrazepam, Σ is the specific surface (m^2g^{-1}), (I is nitrazepam and *e* is the excipient), and $E_{ads}(N_2)$ is the nitrogen adsorption energies in which the nitrazepam decomposition constant decreases proportionally to the increase of nitrogen adsorption energy on the six excipients (Fig. 1).

If the contact surface were the only influence an excipient had, and assuming similar excipient surface coverage by the drug, then all decomposition rate constants of nitrazepam, once corrected for dilution and relative specific surface areas of the sample components, should be identical, whatever excipients are used. As can be seen in Fig. 2, this is not the case; each excipient has its own specific and/or nonspecific influence on the observed rate. In the case of hydrolytic decomposition and according to the law of mass action, the amount of water present as a reagent (as long as not in excess) has a direct influence on the reaction rate. At present there is no possibility of determining quantitatively and directly the amount of water available and usable for reaction in a solid-state sample and the exact physical state of the reacting water. There is, however, no doubt that both the physical and the structural states of the water are strongly influenced by adsorption properties of the excipients. In the case of nitrazepam decomposition, the reaction rate diminishes with increasing nitrogen adsorption energy of the excipients.

From structural considerations, there is no reason to expect that the nitrazepam adsorption energy would be affected by the various excipients used. Since the only other reactant is water, a hypothetical conclusion can be drawn that the availability, *i.e.* reactivity, of water is the important parameter in the experimental system considered and that the water-binding energy to the excipients is the important factor to look at. Since only adsorbed water molecules may react, and their reactivity is inversely related to their adsorption energy, it is necessary either to establish the relationship between E_{ads} (N_2) and E_{ads} (H_2O), the adsorption energy of (for the reaction available) water, and/or to determine the relative water binding forces to the excipient.

Kinetics and Mechanism of the Basic Hydrolysis of Indomethacin and Related Compounds: A Reevaluation

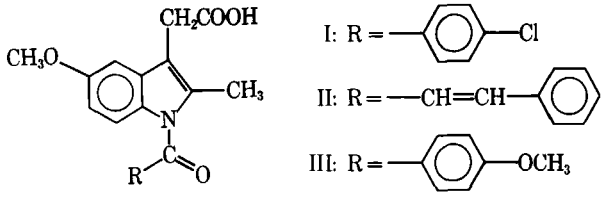
ANTONIO CIPICIANI *, CYNTHIA EBERT ‡, PAOLO LINDA §x, FULVIO RUBESSA ‡, and GIANFRANCO SAVELLI *

Received June 18, 1982, from the *Dipartimento di Chimica, Università di Perugia, Italy, the ‡Istituto di Chimica Farmaceutica, and the §Istituto di Chimica, Università di Trieste, Italy. Accepted for publication August 25, 1982.

Abstract □ The kinetics of the hydrolysis of indomethacin and related compounds were studied in an alkaline medium at 25°. The pseudo-first-order rate constants were evaluated from log absorbance *versus* time plots in the ultraviolet. These compounds showed a second-order rate constant at low concentrations of hydroxide ion and a first-order rate constant at higher concentrations of hydroxide ion.

Keyphrases □ Indomethacin—kinetics of the hydrolysis in alkaline medium □ Kinetics—hydrolysis of indomethacin

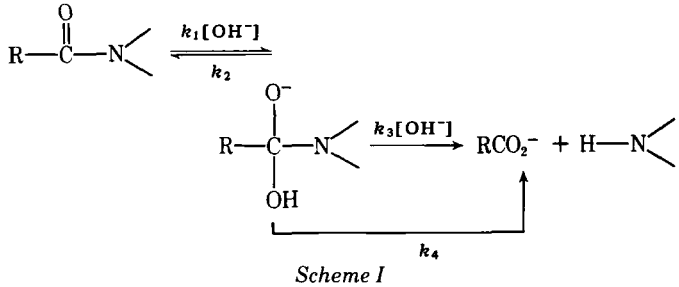
The kinetics of the alkaline hydrolysis of indomethacin [1-(4-chlorobenzoyl)-5-methoxy-2-methyl-indole-3-acetic acid (I)] have been investigated in several studies.



Hajratwala and Dawson (1) measured the apparent first-order rate constants in the pH 11–12 range at different temperatures, and suggested that the experimental data were in agreement with a mechanism involving the reaction of the monodissociated species of indomethacin with the hydroxide ion and postulated a rate law of the type: $k_{obs} = k_1[OH^-]$. Krasowska (2) described a linear relationship between log k_{obs} *versus* pH in the range of pH 7–10 at 50, 60, and 70°, but no conclusions were drawn on the mechanism of the hydrolysis of I.

The aim of this study was to reinvestigate the mechanism of the basic hydrolysis of I and to compare its behavior with that of simpler models in view of our previous results on related compounds (3–5).

A variety of amides undergo basic hydrolysis, as is shown in Scheme I.



Scheme I

According to the structure of the amide and the pH of the medium, the rate-determining step of the reaction is (*a*) the attack of hydroxide ion on the amide (k_1) and (*b*) the decomposition of the tetrahedral intermediate to products either uncatalyzed (k_4) or catalyzed by hydroxide ion (k_3). Equation 1 represents the rate law for the mechanistic Scheme I.

$$k_{obs} = \frac{k_1k_4[OH^-] + k_1k_3[OH^-]^2}{k_2 + k_4 + k_3[OH^-]} \qquad \text{(Eq. 1)}$$

Many *N*-acyl derivatives of pyrroles, indoles, and carbazoles show a second-order rate constant at low concentrations of hydroxide ion, and a first-order rate constant at higher concentrations of base (3–5). Only the hydrolysis of *N*-(4-nitrobenzoyl)pyrrole was found to be first-order in hydroxide ion at all base concentrations (6). This behavior was ascribed to the electronic polarization by the nitro group destabilizing the carbonyl of the substrate, reducing k_2 and increasing k_1. These electronic effects enlarge the ratio k_3/k_2 and the formation of the tetrahedral intermediate becomes the rate-determining step.

EXPERIMENTAL

Materials—All materials were analytical grade; water double-distilled in glass was used throughout. Indomethacin[1], cinmetacin[2] (II), and 1-(4-methoxybenzoyl)-5-methoxy-2-methyl-indole-3-acetic acid (III)[3] were used without further purification.

1-(4-Chlorobenzoyl)indole (IV)—A solution of 1.2 g (10 mmoles) of indole and 34 mg (0.1 mmole) of tetrabutylammonium hydrogen sulfate in 30 ml of dichloromethane was stirred at room temperature while 1 g of finely powdered sodium hydroxide was added, followed by a solution of 2.6 g (15 mmoles) of 4-chlorobenzoyl chloride in 10 ml of dichloromethane over a 15-min period. The mixture was cooled in a water bath, stirred for 20 min, and the product was removed by filtration. This material was recrystallized from *n*-hexane to give IV as white crystals, mp 114–115° [lit. 114.5–115.5° (7, 8)] IR (mineral oil): 1680 cm^{-1} (C=O); NMR (deuterochloroform): 6.6 (d, J = 4 Hz, 1, indole-3 proton), 7.2–7.9 (m, 8, aromatic protons), 8.3–8.5 ppm (m, 1, indole-7 proton)[4].

Kinetic Studies—A stoppered quartz cell containing an aqueous sodium hydroxide solution (3 ml) was thermostated at 25 ± 0.1° for 20 min within the cell compartment. The reaction was initiated by adding 10–20 μl of the substance dissolved in acetonitrile. The initial concentration of the substrates in the reaction cell was in the order of 10^{-4}–10^{-5} *M*. An ionic strength of 0.2 was maintained constant by adding sodium chloride.

Absorbance (against an appropriate blank) was recorded as a function of time at 325 nm for I, 320 nm for II, 315 nm for III, and 305 nm for IV[5]. Pseudo-first-order rate constants (k_{obs}) were calculated using regression analysis. The correlation coefficients were between 0.993–0.999.

The products of hydrolysis were examined by comparing the final spectra with those obtained from a solution of indoles and appropriate carboxylic acid under conditions identical to those of the kinetic experiments.

Data Treatment—The rate constants for individual steps in the hydrolysis reaction were evaluated according to the method of Kershner and Schowen (9)[6].

RESULTS AND DISCUSSION

The effects of hydroxide ion concentration on the apparent first-order rate constant, k_{obs}, for the indole derivatives are shown in Table I.

[a] Average of two or three runs.

Plots of rate constant–hydroxide ion concentration *versus* hydroxide ion concentration are shown in Fig. 1. The mechanism of hydrolysis shown in Scheme I is the most probable. Equation 1 represents the rate law for this mechanism. The rate constants for the single steps are reported in Table II together with relevant data presented in our previous papers [*i.e.*, 1-(4-chlorobenzoyl)pyrrole (V) and 1-(4-methoxybenzoyl)pyrrole (VI)] (3). The statistical treatment showed that k_4 (the rate constant for the water-catalyzed decomposition of the tetrahedral intermediate) is negligible.

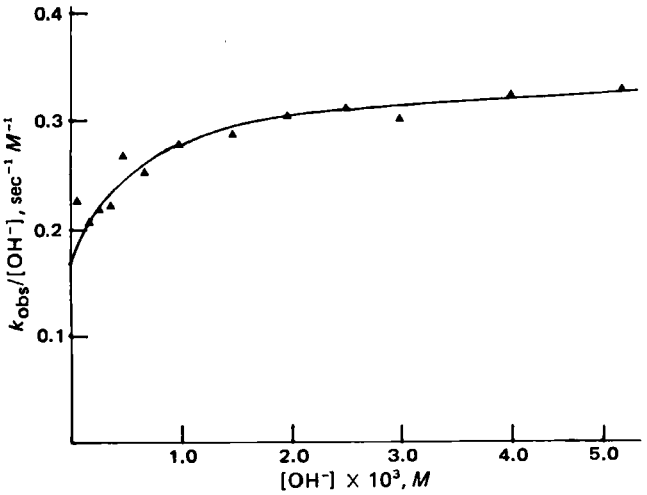

Figure 1—*Effect of concentration of hydroxide ion on the hydrolysis of indomethacin at 25.0 ± 0.1° and ionic strength 0.2.*

Table II—Rate Constants for the Hydroxide Ion-Catalyzed Hydrolysis in Water at 25.0 ± 0.1°

	k_1, M^{-1} sec^{-1}	$k_1k_3k_2$, M^{-2} sec^{-1}	k_3k_2, M^{-1}
I	0.34	120	350
II	0.09	54	600
III	0.05	35	700
IV	2.20	2200	1000
V[a]	5.50	4900	900
VI[a]	1.10	800	700

[a] Data from Ref. (3).

From the data one can observe that 1-(4-chlorobenzoyl)indole (IV) shows a value of k_1 (the rate constant of formation of the tetrahedral intermediate) about 7 times higher than I, and this can be ascribed to steric inhibition by the methyl group in the 2-position of I to the attack of the hydroxide ion, since this reaction appears to be more sensitive to steric effects than to electronic effects (3–5). Similarly steric effects affect the k_3/k_2 ratio favoring the decomposition of the intermediate rather than the return to the reactants. Furthermore, electronic effects resulting from substitution in the benzoyl ring of the indomethacin series closely parallel those in the pyrrole series, as shown by the fact that the k_1 relative ratio of I–III is ~7 and is quite similar to that of V–VI (~5). Finally, the fact that the k_3/k_2 values are of the same order of magnitude shows that partitioning of the tetrahedral intermediate to products is the result of a subtle balance among steric, electronic, and leaving-group effects.

In conclusion, the kinetics of hydrolysis of indomethacin and cinmetacin, are similar to that of analogous models used in this study. A knowledge of the mechanism of hydrolysis of simple molecules is important to rationalize the behavior of more complex compounds.

Noninvasive Assessments of the Percutaneous Absorption of Methyl Nicotinate in Humans

RICHARD H. GUY *x, RONALD C. WESTER ‡, ETHEL TUR ‡, and HOWARD I. MAIBACH ‡

Received June 11, 1982, from the **School of Pharmacy* and ‡*Department of Dermatology, School of Medicine, University of California–San Francisco, San Francisco, CA 94143.* Accepted for publication August 16, 1982.

Abstract □ Percutaneous penetration of the vasodilator methyl nicotinate (methyl 3-pyridinecarboxylate) has been monitored *in vivo* in humans with the noninvasive techniques of laser Doppler velocimetry and photopulse plethysmography. These optical methods use different technologies to generate a voltage output which is related to perfusion of the cutaneous microcirculation. The procedures are therefore sensitive to the pharmacologic stimulus and duration of local vasodilation. Following topical application of methyl nicotinate, excellent correlation was found between the response of both methods and the visual observation of erythema. Lower drug concentrations delayed the onset and magnitude of the response and shortened the time period for which elevated microperfusion was observed. These techniques appear to provide a useful noninvasive assessment of the time course of drug behavior in the region of skin to which topical application is made.

Keyphrases □ Methyl nicotinate—noninvasive assessments of percutaneous absorption, laser Doppler velocimetry, photopulse plethysmography, pharmacokinetics □ Absorption, percutaneous—of methyl nicotinate, noninvasive assessments by laser Doppler velocimetry and photopulse plethysmography, pharmacokinetics □ Pharmacokinetics—of percutaneous absorption of methyl nicotinate in humans, noninvasive assessments by laser Doppler velocimetry and photopulse plethysmography

Presently, there exists limited understanding of the kinetics associated with drug absorption into the skin, retention or metabolism of compounds within the tissue, and subsequent elimination into the systemic circulation. Such knowledge, however, is valuable both for devising rational dermatological chemotherapy and for topical dosage form design and optimization. In this paper two noninvasive procedures for monitoring blood perfusion through the cutaneous microcirculation are discussed, and methodology is suggested that may improve pharmacokinetic and pharmacologic measurement of percutaneous absorption.

The techniques employed are laser Doppler velocimetry (LDV) and photopulse plethysmography (PPG). The methodologies employ different optical principles to generate an output related to either velocity (LDV) or amount (PPG) of cutaneous blood vessel perfusion. In 1975, it was shown that LDV could indicate changes in microvascular perfusion (1). Validation and development of the method for clinical evaluation of local blood flow in the skin surface (2–4) was followed by its application to assess perfusion changes in response to injection trauma (5) and its employment as an indicator of skin blood flow (as compared with heater power) during transcutaneous oxygen monitoring (6). A recent review (7) has summarized the current technological and theoretical status of the procedure and has discussed possible clinical applications.

The PPG technique has been used for many years to assess skin blood flow (8), alone and in conjunction with other procedures, to assess various physiological functions. Although there are examples in the literature which have indicated the ability of PPG to demonstrate drug-induced changes in skin blood flow (9–12), there has been no attempt to apply the method specifically to follow the passage of drug into the body following topical administration.

To characterize and test the two techniques, the percutaneous absorption of methyl nicotinate in humans has been considered. This nicotinic acid ester crosses the skin rapidly and elicits a distinctive erythema (13), the time of onset of which is reportedly a function of drug concentration (14). After its appearance, erythema intensity first increases to a maximum, and the area of redness expands, before gradually fading away and becoming no longer visually detectable (15, 16).

EXPERIMENTAL

LDV experiments were performed with a recently developed capillary perfusion monitor[1]. The method uses the Doppler principle. Light at 632.8 nm from a 5-mW helium–neon laser is transmitted to the skin through a quartz optical fiber. The light is backscattered from stationary skin components and by erythrocytes moving in the dermal capillaries[2], which are encountered as the radiation penetrates to a depth of 1–1.5 mm. A second optical fiber collects the reflected light and the electronic configuration of the instrument then separates out the frequency-shifted (*i.e.*, Doppler) component and converts it to a single flow parameter, which is registered as a voltage output. That this quantity is related to peripheral cutaneous perfusion, as measured by other means, has been shown (4). The optical fibers supplying and detecting the radiation are supported in a small, essentially cylindrical probe (1.9-cm diameter, 0.5-cm height) which is held securely to the skin surface by double-sided adhesive tape.

Experiments with PPG utilized a photoplethysmograph[3] in conjunction with two photopulse probes[4] and a dual-channel recorder[5]. As with LDV, information is collected by a small (2 × 1 × 0.7-cm) probe attached with tape to the skin surface. In this case, however, the optical source is a diode (LED) emitting IR radiation at 800–940 nm. A phototransistor positioned in the probe beside the LED detects the reflected part of the incident source, and the photoplethysmograph then converts this information for display as a fluctuating voltage on the chart recorder. The frequency of the input radiation covers wavelengths strongly absorbed by hemoglobin. It follows that changes in blood volume in the region of skin under the probe cause the PPG output to change because the percentage of incident radiation absorbed is altered. The penetration depth of the light from the PPG probe is stated to be similar to that of the LDV apparatus, 1–2 mm. Whereas the recording displayed by the LDV unit can be damped so that output oscillations due to the heartbeat can be eliminated, this is not the case with the PPG instrument. The results from the latter appear as a series of pulses on which, at high sensitivities, the dicrotic notch may be observed (Fig. 1).

Percutaneous penetration experiments were carried out on two healthy male volunteers. Methyl nicotinate[6] (I) solutions of 150, 15, and 1.5 m*M* were prepared in distilled water and used directly. The application procedure was as follows: A 1-cm diameter standard test patch[7] was saturated

with the appropriate solution of I and applied with tweezers to the midpoint of the flexor aspect of the subject's forearm. The patch was in contact with the skin for 15 sec before being removed; any excess solution left on the skin was wiped away with a tissue.

The LDV or PPG probe was then placed directly over the drug application site (the center of the probe being coincident with the position occupied by the center of the patch) and recordings were made from this point. For LDV measurements, continuous readings were taken throughout the duration of an experiment (~1 hr). For PPG, data collection was continual for the first 10–15 min and thereafter, 30-sec recordings were made every 3–5 min for the remainder of the run. The PPG procedure is much more sensitive to subject movement than LDV and it was found that periodic measurement as described provided both volunteer comfort and measurement clarity.

With the PPG technique, for which there were two probes available, the second probe was positioned on the identical site on the other arm to which no drug was applied. This probe acted as a control to indicate whether any changes in the monitored outputs were induced by the apparatus alone in contact with the skin. On no occasion was there any change in output from the control site during the course of a normal experiment (of ~1-hr duration). Finally, in a separate set of experiments, the same drug application procedure was followed and the onset of erythema determined visually with no probe on the skin. Erythema onset was defined as the appearance of redness at the skin position to which the patch had been applied (14).

RESULTS AND DISCUSSION

The results are presented in Table I. Figure 2 shows a typical initial response to the drug observed with LDV, and in Fig. 3 the pattern of microperfusion changes detected by PPG during an experiment is summarized. Good correlation between erythema onset and instrument response was found for both techniques, and the expected concentration dependence of drug effect (*i.e.*, increased concentration, faster onset, and longer duration) was confirmed. Furthermore, there is potential to begin to quantify in an objective fashion both the initial response following

Table I—Summary of LDV and PPG Experimental Results [a]

Methyl Nicotinate Concentration, m*M*	Onset of LDV Response, sec	Onset of PPG Response, sec	Observed Onset of Erythema, sec	Decay Time of Response[b], min
Subject 1				
150	120	125	125	40–60
15	160	180	165	20–35
1.5	250	270	260	15–25
Subject 2				
150	135	150	180	40–60
15	300	325	370	30–50
1.5	615	635	645	20–35

[a] All data represent the average of duplicate or triplicate experiments (±10%). [b] Approximate time ranges covering the postapplication period between the start of the response decay and the return to baseline LDV or PPG output.

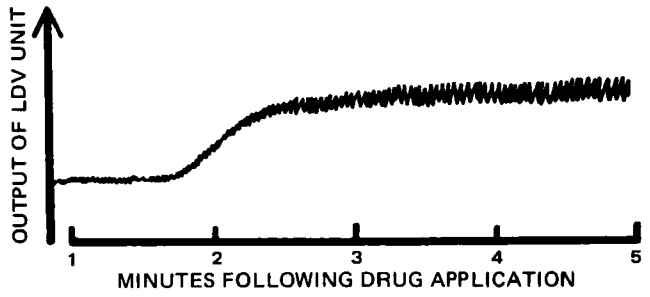

Figure 2—*Early time portion of a characteristic LDV response curve (Subject 1; applied concentration of methyl nicotinate = 150 m*M*).*

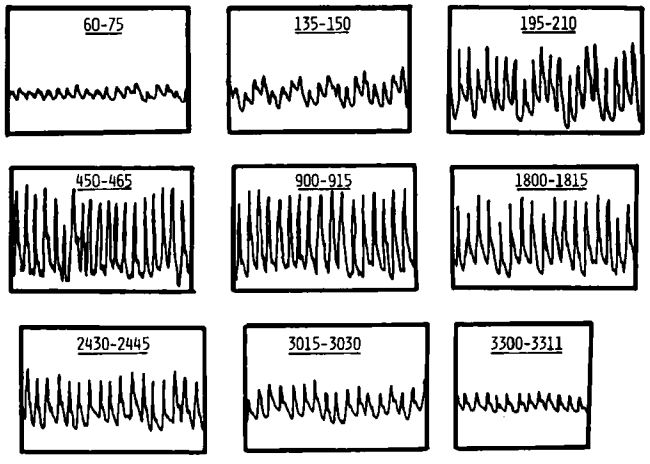

Figure 3—*PPG recording at various times (in seconds) after a 15-sec application of 150 m*M *methyl nicotinate to Subject 1.*

absorption (*e.g.*, Fig. 2) and the subsequent increase and eventual decay (Fig. 3) of the microcirculation stimulus. Certainly for the nicotinic acid esters, it is now possible to follow the latter part of the local time course of the drug.

An additional feature of the data is the demonstration that, within minutes, sufficient drug is able to penetrate and produce the threshold concentration necessary to elicit an observable pharmacological effect. Because of the design of these experiments, steady-state transport across the stratum corneum cannot be established, and conventional *in vivo–in vitro* penetration assessment parameters (*e.g.*, steady-state permeability coefficient and lag time) are not appropriate for describing the data. It is interesting, however, to note that classically measured lag times are often on the order of hours and always in significant excess of 2–10 min. It seems clear that the lag period between application and physiological response for methyl nicotinate must be quite different from the lag time necessary to establish a quasi-steady-state concentration profile across the barrier.

At present, it appears reasonable to suggest that the data reported here strongly hint that local cutaneous pharmacokinetics may prove accessible to study *in vivo* and that the noninvasive procedures described warrant further attention.

Stabilizing Effect of Fructose on Aqueous Solutions of Hydrocortisone

N. P. BANSAL, E. M. HOLLERAN, and C. I. JAROWSKI ˣ

Received July 1, 1982 from the *Department of Allied Health and Industrial Sciences, College of Pharmacy and Allied Health Professions and the School of Chemistry, St. John's University, Jamaica, NY 11439.* Accepted for publication August 26, 1982.

Abstract □ Accelerated stability studies (37°, 47°, and 57°) were conducted on buffered aqueous solutions (pH 7.4, 8.4, and 9.4) of hydrocortisone in the presence of various molar ratios of D-fructose. First-order degradation was observed. Significant improvement in hydrocortisone stability was seen in those solutions containing a 25 *M* excess of D-fructose. Hydrocortisone solutions containing dextrose, lactose, sucrose, sorbitol, propylene glycol, or glycerin in the same molar ratio were not stabilized.

Keyphrases □ Hydrocortisone—stability in aqueous buffers, stabilization by D-fructose □ Stability studies—hydrocortisone, stability in aqueous buffers, stabilization by D-fructose

A ketol side chain is present at the 17-position in the following therapeutically important glucocorticoids: cortisone, hydrocortisone, dexamethasone, prednisone, prednisolone, and 6-α-methylprednisolone. Removal of the ketol side chain results in a significant loss of therapeutic activity.

The reactivity of the ketol side chain of the adrenocorticosteroids is well documented. Base-catalyzed rearrangements and eliminations have been shown to occur under both aerobic and anaerobic conditions (1–5). Guttman and Meister (6) showed that at least three parallel first-order reactions were involved in the base-catalyzed degradation of prednisolone. Neutral and acidic degradation products were obtained. Caspi *et al.* (7) studied oxidative cleavage of the ketol side chain of cortisone with lead tetraacetate. Lewbart and Mattox (8) reported that trace amounts of copper in actinic glassware caused destruction of cortisone and related steroids.

Mauger *et al.* (9) followed the degradation of 21-hydrocortisone hemisuccinate at 70° in aqueous solutions buffered at pH 6.9, 7.2, and 7.6. The data obtained indicated that the overall kinetic pathway at each pH value could be interpreted as consecutive first-order reactions. The blue tetrazolium assay confirmed that the production of a species devoid of the ketol side chain at the 17-position occurred after the steroid alcohol was formed. The ketol group imparts reducing properties to the glucocorticoid molecules similar to those of fructose (Scheme I), which contains a similar ketol group. It was speculated that the presence of excess fructose in aqueous solutions of hydrocortisone (II) might retard the base-catalyzed degradation of the latter. The significance of the ketol group would be checked by using other polyols lacking this group.

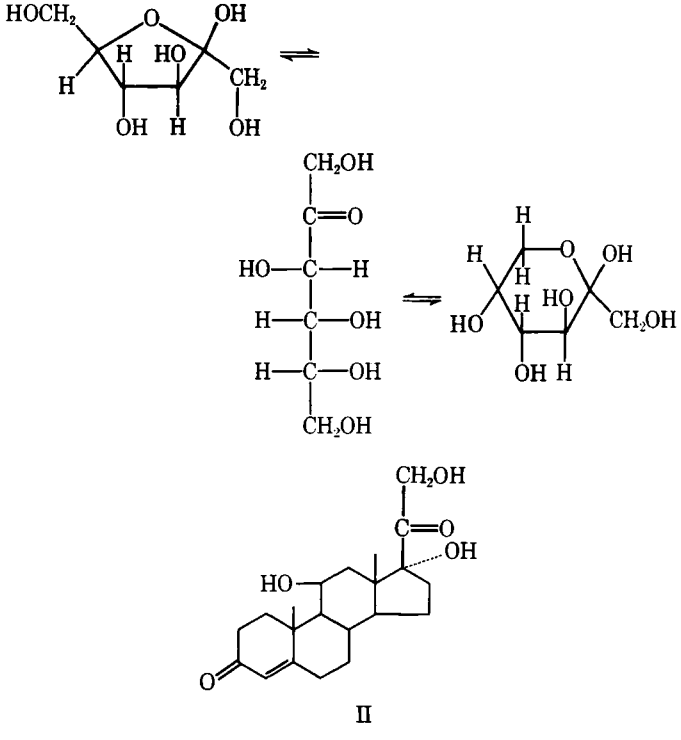
The blue tetrazolium assay confirmed that the production of a species devoid of the ketol side chain at the 17-position occurred after the steroid alcohol was formed. The ketol group imparts reducing properties to the glucocorticoid molecules similar to those of fructose (Scheme I), which contains a similar ketol group. It was speculated that the presence of excess fructose in aqueous solutions of hydrocortisone (II) might retard the base-catalyzed degradation of the latter. The significance of the ketol group would be checked by using other polyols lacking this group.



II

EXPERIMENTAL

Materials—The following were obtained from commercial sources: hydrocortisone, USP (lot 15C-6126)[1], blue tetrazolium[1], tetramethylammonium hydroxide[1], D-fructose[2], dextrose USP[3], glacial acetic acid

(reagent grade)[4], phosphoric acid (reagent grade)[4], hydrochloric acid (reagent grade)[4], monobasic potassium phosphate (reagent grade)[5], boric acid USP[5], potassium chloride (reagent grade)[6], sodium hydroxide (reagent grade)[6], citric acid USP[7], sorbitol USP[7], lactose USP[3], sucrose (reagent grade)[8], chloroform NF[9], absolute ethanol, (reagent grade)[9], glycerol (reagent grade)[10], propylene glycol (reagent grade)[10], and nitrogen, extra dry[10].

Equipment—The following pieces of equipment were used: a double beam spectrophotometer[11], a precision temperature-controlled oven[12], and a pH meter[13].

Preparation of the Buffer Solutions—The pH 7.4 buffer was prepared by dissolving monobasic potassium phosphate, (6.8045 g), and sodium hydroxide (1.564 g) in sufficient distilled water to make 1 liter. The buffer solution at pH 8.4 was prepared by dissolving boric acid (3.0915 g), potassium chloride (3.7277 g), and sodium hydroxide (0.344 g) in sufficient distilled water to make 1 liter. The pH 9.4 buffer solution contained similar quantities of boric acid and potassium chloride plus 1.284 g of sodium hydroxide.

Preparation of Hydrocortisone Solutions with and without D-Fructose—Stock solutions of hydrocortisone in absolute ethanol (5 mg/ml) and D-fructose in each of the buffer solutions (24.85 mg/ml, 0.14 *M*) were prepared. Control solutions were prepared by diluting 10 ml of the glucocorticoid stock solution (50 mg, 0.14 mmole) with the appropriate buffer solution to 100 ml. Blank solutions were also prepared by diluting the stock solutions of D-fructose (1, 5, 10, or 25 ml) to 100 ml with the appropriate buffer solution. Hydrocortisone–D-fructose solutions (molar ratios: 1:1, 1:5, 1:10, and 1:25) were prepared by adding various volumes of the D-fructose stock solutions to 10 ml of the hydrocortisone stock solution and diluting to 100 ml with the appropriate buffer. The solutions were analyzed in duplicate and placed in ovens set at 37, 47, and 57 ± 1°.

Preparation of Hydrocortisone Solutions with Various Polyols—The following polyols were added to hydrocortisone solutions

[a] Molecular ratios of hydrocortisone–polyol are 1:10 and 1:25.

buffered at pH 7.4 (molar ratios of hydrocortisone–polyol, 1:10 and 1:25): dextrose, sucrose, lactose, sorbitol, glycerin, and propylene glycol. The stability of these solutions was only studied at 37 ± 1°.

Assay Procedure for Hydrocortisone—At various time intervals, 10 ml of the sample was extracted with three 20-ml portions of chloroform. The chloroform extracts were passed through a glass wool pledget previously rinse with chloroform. The combined extracts were diluted to 100 ml and then evaporated to dryness in a stream of nitrogen at room temperature. The residue was dissolved in 20 ml of absolute ethanol and treated with 1 ml of blue tetrazolium solution (1% in absolute ethanol) plus 1 ml of tetramethylammonium hydroxide (1 ml of a 10% aqueous solution diluted to 10 ml with absolute ethanol). The color was allowed to develop in the dark for exactly 45 min. Color development was then quenched by the addition of 1 ml of glacial acetic acid. The absorbance was determined at 525 nm. A standard solution of hydrocortisone in absolute ethanol was carried through the identical procedure and was used as a color reference in calculating the concentration of steroid in the sample. Blank solutions were also subjected to the same procedure. The results are summarized in Tables I–IV.

RESULTS AND DISCUSSION

The stability data for the solutions of II plus I are summarized in Tables I–III. It is evident that an increase in the concentration of I results in an improvement in the stability of II. This relationship holds for the three pH values and three temperatures studied. The importance of the ketol group in I is also evident after inspection of the data in Table IV. None of the polyols at ratios of 1:10 or 1:25 showed any stabilization of II as compared with the control.

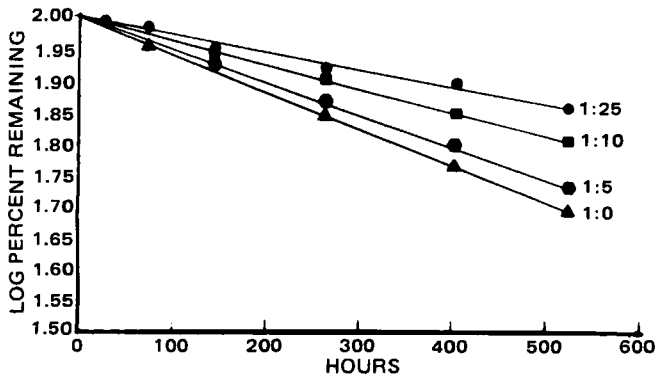

Figure 1—*Influence of molar concentrations of D-fructose on the stability of aqueous solutions of hydrocortisone (50 mg%) buffered at pH 7.4 and stored at 37° plotted in first-order fashion.*

The rate constants, *y*-intercepts, and correlation coefficients summarized in Table V were derived from first-order plots of the data shown in Tables I–III. Selected solutions buffered at pH 7.4 were plotted in first-order fashion (Fig. 1) to illustrate the linearity of the data.

A possible explanation for the stabilization observed is the complex formation between II and I. Such complexes could resist oxidative destruction more effectively than solutions of II alone. An alternative mechanism is that fructose competes with II for the oxygen present in the system and thus acts as an antioxidant. Failure of the other polyols to exert a protective effect could be attributed to the greater reaction speed of I as compared with the polyols studied. Thus, Singh *et al.* (10) reported that the order of the oxidative reaction speed catalyzed by bi-

[a] All values for *k* must be multiplied by 10^{-3}. Units: hr^{-1}.

valent copper is fructose > glucose > galactose. Joslyn and Miller (11) reported that I was more effective than sucrose and dextrose in stabilizing ascorbic acid solutions against oxidative degradation. These authors concluded that no simple rate law governed the oxidation of ascorbic acid in the presence of sugars. They also observed that the temperature coefficients of the oxidation in the presence or absence of the sugars were similar. This observation would seem to indicate that complex formation was not occurring since the temperature coefficients would be expected to differ. Ashida (12) also reported that methylene blue was more easily reduced by a ketose such as fructose than by an aldose such as glucose.

The data and speculations serve as a stimulus for additional research to establish a mechanism for the stabilization observed. It will be of interest to learn if the redox potential of I is similar to that for II. Such similarity is anticipated because of the structural relationship between the portions of the two molecules where oxidation reactions have been shown to occur. The redox potentials of the other polyols are anticipated to differ significantly.

Cinchophen Analogues as Potential CNS Agents

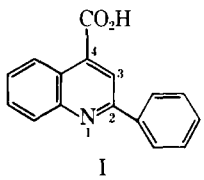
A. KAR

Received October 20, 1981, from the *Department of Pharmaceutical Chemistry, University of Nigeria, Nsukka, Nigeria.* Accepted for publication June 1, 1982.

Abstract □ Several amides of cinchophen were prepared and evaluated as CNS agents. Compounds III, VII, XII, XIII, and XIV exhibited analgesic activity while I, III, and XIV acted as CNS depressants.

Keyphrases □ Cinchophen—amide analogue synthesis, evaluation of CNS activity in mice □ Analgesics—potential, amide analogues of cinchophen, evaluation of CNS activity in mice □ Central nervous system agents—amide analogues of cinchophen, evaluation of CNS activity in mice

Cinchophen (I) was formerly used for the treatment of gout (1, 2); however, it was withdrawn from the market because of its toxic effects (3–5). It was concluded that the quinoline ring, a carboxylic acid group in the C-3 or C-4 position, and an aryl residue at C-2 were essential for the physiological action of cinchophen (6). Many structural modifications of cinchophen have been reported [*i.e.*, neocinchophen, 2-phenyl-3-hydroxycinchonic acid, hexophan, and 2-phenyl-4-hydroxyacetyl-6-methoxyquinoline (1)]. Reversal of the phenyl and carboxyl groups afforded an inactive compound (I).



I

In this study 16 amides of I were synthesized and evaluated as CNS agents. Cinchophen has been synthesized either by the condensation of acetophenone with isatic acid in alcoholic potassium hydroxide solution (7) or by heating pyruvic acid with either aniline and benzaldehyde or with benzylidene aniline in absolute ethanol (8). In the present study, I was prepared by the condensation of pyruvic acid with aniline and benzaldehyde (9, 10). The desired amides were subsequently synthesized by treating the corresponding acid chloride with the appropriate amine.

EXPERIMENTAL

Synthesis—The amides II–XVII were prepared (11) by vigorously shaking for 30 min at room temperature a mixture of the appropriate amine (0.002 mole), a 10–15% molar excess of the acid chloride of cinchophen, and 10 ml of 10% aqueous sodium hydroxide solution. The resulting solid material was removed by filtration and purified, as indicated in Table I.

Analysis and Spectral Data—Melting points were determined in open capillary tubes in an electrothermal apparatus and are uncorrected. NMR[1] spectra were obtained in deuterated acetone using tetramethylsilane as the internal standard. The mass spectra[2] of the various compounds were determined. Microanalyses were within ±0.3% of the theoretical values (Table I).

Pharmacological Evaluation—The hot plate method was employed to evaluate the analgesic activity of the amides in mice. The CNS-depressant activity was studied *in vivo* by noting the effect of the amides on spontaneous motor activity, ptosis, and pentobarbital-induced hypnosis. Swiss albino mice of both sexes, weighing 20–30 g, were used; solutions of normal saline or 3% (w/v) aqueous polysorbate 80 were given to the untreated and vehicle controls, respectively. Cinchophen (50 or 100 mg/kg), pentobarbital sodium (40 mg/kg), and morphine hydrochloride (4 mg/kg) were used as reference drugs to evaluate the activity of the amides.

Analgesic Activity—Analgesic activity was measured by the hot plate method at 53 ± 2°. The normal reaction time (pain threshold) for each mouse was determined by placing the mouse on the hot plate and noting the amount of time (≤5 sec) required for the mouse to leave the hot plate platform. The pain threshold was measured 30 min postinjection and at hourly intervals for 4 hr.

valent copper is fructose > glucose > galactose. Joslyn and Miller (11) reported that I was more effective than sucrose and dextrose in stabilizing ascorbic acid solutions against oxidative degradation. These authors concluded that no simple rate law governed the oxidation of ascorbic acid in the presence of sugars. They also observed that the temperature coefficients of the oxidation in the presence or absence of the sugars were similar. This observation would seem to indicate that complex formation was not occurring since the temperature coefficients would be expected to differ. Ashida (12) also reported that methylene blue was more easily reduced by a ketose such as fructose than by an aldose such as glucose.

The data and speculations serve as a stimulus for additional research to establish a mechanism for the stabilization observed. It will be of interest to learn if the redox potential of I is similar to that for II. Such similarity is anticipated because of the structural relationship between the portions of the two molecules where oxidation reactions have been shown to occur. The redox potentials of the other polyols are anticipated to differ significantly.

Cinchophen Analogues as Potential CNS Agents

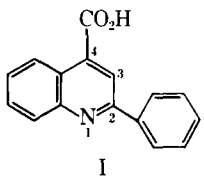
A. KAR

Received October 20, 1981, from the *Department of Pharmaceutical Chemistry, University of Nigeria, Nsukka, Nigeria.* Accepted for publication June 1, 1982.

Abstract □ Several amides of cinchophen were prepared and evaluated as CNS agents. Compounds III, VII, XII, XIII, and XIV exhibited analgesic activity while I, III, and XIV acted as CNS depressants.

Keyphrases □ Cinchophen—amide analogue synthesis, evaluation of CNS activity in mice □ Analgesics—potential, amide analogues of cinchophen, evaluation of CNS activity in mice □ Central nervous system agents—amide analogues of cinchophen, evaluation of CNS activity in mice

Cinchophen (I) was formerly used for the treatment of gout (1, 2); however, it was withdrawn from the market because of its toxic effects (3–5). It was concluded that the quinoline ring, a carboxylic acid group in the C-3 or C-4 position, and an aryl residue at C-2 were essential for the physiological action of cinchophen (6). Many structural modifications of cinchophen have been reported [*i.e.*, neocinchophen, 2-phenyl-3-hydroxycinchonic acid, hexophan, and 2-phenyl-4-hydroxyacetyl-6-methoxyquinoline (1)]. Reversal of the phenyl and carboxyl groups afforded an inactive compound (I).



I

In this study 16 amides of I were synthesized and evaluated as CNS agents. Cinchophen has been synthesized either by the condensation of acetophenone with isatic acid in alcoholic potassium hydroxide solution (7) or by heating pyruvic acid with either aniline and benzaldehyde or with benzylidene aniline in absolute ethanol (8). In the present study, I was prepared by the condensation of pyruvic acid with aniline and benzaldehyde (9, 10). The desired amides were subsequently synthesized by treating the corresponding acid chloride with the appropriate amine.

EXPERIMENTAL

Synthesis—The amides II–XVII were prepared (11) by vigorously shaking for 30 min at room temperature a mixture of the appropriate amine (0.002 mole), a 10–15% molar excess of the acid chloride of cinchophen, and 10 ml of 10% aqueous sodium hydroxide solution. The resulting solid material was removed by filtration and purified, as indicated in Table I.

Analysis and Spectral Data—Melting points were determined in open capillary tubes in an electrothermal apparatus and are uncorrected. NMR[1] spectra were obtained in deuterated acetone using tetramethylsilane as the internal standard. The mass spectra[2] of the various compounds were determined. Microanalyses were within ±0.3% of the theoretical values (Table I).

Pharmacological Evaluation—The hot plate method was employed to evaluate the analgesic activity of the amides in mice. The CNS-depressant activity was studied *in vivo* by noting the effect of the amides on spontaneous motor activity, ptosis, and pentobarbital-induced hypnosis. Swiss albino mice of both sexes, weighing 20–30 g, were used; solutions of normal saline or 3% (w/v) aqueous polysorbate 80 were given to the untreated and vehicle controls, respectively. Cinchophen (50 or 100 mg/kg), pentobarbital sodium (40 mg/kg), and morphine hydrochloride (4 mg/kg) were used as reference drugs to evaluate the activity of the amides.

Analgesic Activity—Analgesic activity was measured by the hot plate method at 53 ± 2°. The normal reaction time (pain threshold) for each mouse was determined by placing the mouse on the hot plate and noting the amount of time (≤5 sec) required for the mouse to leave the hot plate platform. The pain threshold was measured 30 min postinjection and at hourly intervals for 4 hr.

[a] All compounds were recrystallized from 95% ethanol except for XVII which was recrystallized from water.

Spontaneous Motor Activity—The increase in SMA was measured using an activity cage[3] 30 min postinjection and at hourly intervals for 4 hr. Any change in the activity levels was noted.

Pentobarbital-Induced Hypnosis—Fifteen minutes postinjection, all animals were treated with 40 mg/kg of pentobarbital sodium. The time to the loss of the righting reflex was noted for each mouse; the mice were then placed on their backs. When the animals regained their righting reflex (*i.e.*, starting moving around the cage) the time was again noted, and the duration of the pentobarbital-induced hypnosis was calculated.

[a] Each value is the average of four replicate experiments. [b] Taken from the work of Miller and Tainter (12) for comparison. [c] Maximum effect observed.

compared with the inactive 3-nitroaniline isomer (V) suggested that the close proximity of the nitro group to the amino moiety in the phenyl ring is essential for analgesic activity and also that possible electronic interactions exist between them. Of the four closely related analogues (VI–IX), only VIII retained the significant analgesic activity of the parent molecule, while the others showed an opposite effect. This is possibly due to the presence of either a 2-methyl side chain (VI and IX) that undergoes rapid metabolism or to steric hinderance caused by the bulky *tert*-butylamino side chain (VI and VII). The 2-ethyl substituent in VIII could possibly resist metabolic oxidation thereby allowing VIII to reach the blood levels necessary to exhibit a pharmacological effect. Both the *p*-toluidino and *p*-anisidino analogues (XIII and XIV, respectively) showed greater analgesic activity than the parent molecule (I). It is interesting to note that the 2-aminobenzothiazolo analogue (XV) exhibitd a maximum analgesic effect at a dose of 50 mg/kg.

Considerable CNS-depressant activity, as observed by marked reduction in the spontaneous motor activity (SMA) and ptosis, was exhibited with IV but was absent with V, suggesting that the 2-nitroanilino analogue was pharmacologically active while the 3-nitroanilino analogue had no pharmacological effect. The *p*-toluidino analogue (XIII) exhibited CNS-depressant activity while the corresponding *p*-anisidino derivative (XIV) had no effect on the nervous system.

The significant potentiation of pentobarbital-induced hypnosis observed with XV suggests a possible correlation between analgesic activity and the CNS-depressant effect of the 2-aminobenzothiazolo analogue. The 2-aminopyridino analogue (II) also exhibited a maximum effect on the pentobarbital-induced sleeping time in mice (Table II). The presence of the pyridine moiety may be regarded as an essential component for the strong CNS effect of this compound.

Structure of the Isonicotinyl Hydrazone of Norethindrone

KEITH BAILEY ˣ, ALLAN MENZIES, and HISAKO WATANABE

Received January 6, 1982, from the *Bureau of Drug Research, Health Protection Branch, Tunney's Pasture, Ottawa, Canada, K1A 0L2.* Accepted for publication August 10, 1982.

Abstract □ The contraceptive steroid norethindrone reacts with isoniazid both *in vivo* and *in vitro* to give the corresponding hydrazone, which exists as *syn* and *anti* (with respect to C-4) isomers. These isomers rapidly interconvert, with the *anti* form predominating in solution. The identification of the isomers was based on an interpretation of ^{1}H- and ^{13}C-NMR spectroscopic data and corroborated by high-performance liquid chromatographic and UV spectrophotometric evidence. ^{1}H- and ^{13}C-NMR spectroscopic data for other derivatives of norethindrone hydrazone are presented and interpreted.

Keyphrases □ Norethindrone—isonicotinyl hydrazone, synthesis, characterization by NMR □ NMR—isonicotinyl hydrazone of norethindrone, characterization, synthesis □ Synthesis—isonicotinyl hydrazone of norethindrone, characterization by NMR

Isoniazid (isonicotinylhydrazine) (I) reacts with ketones and aldehydes under acidic conditions. The usual products are hydrazones, but the reaction with reducing sugars gives 1-glycosyl-2-isonicotinylhydrazines (1). Reactions of this type can take place *in vivo* (2), the pharmacological and toxicological consequences of which are largely unknown. We recently showed that isoniazid reacts with norethindrone (17-hydroxy-19-nor-17α-pregn-4-en-20-yn-3-one) (II) to give the hydrazone (III) when they are coadministered orally to the rat (3) and minipig[1]. The product is readily absorbed from the GI tract (4). The analytical procedures involved conversion of norethindrone hydrazone (IV), a metabolite of III (3), to the *p*-methoxybenzaldehyde derivative (V). Some properties of V were described (3). Spectroscopic evidence for the structures of

Structure of the Isonicotinyl Hydrazone of Norethindrone

KEITH BAILEY ˣ, ALLAN MENZIES, and HISAKO WATANABE

Received January 6, 1982, from the *Bureau of Drug Research, Health Protection Branch, Tunney's Pasture, Ottawa, Canada, K1A 0L2.* Accepted for publication August 10, 1982.

Abstract □ The contraceptive steroid norethindrone reacts with isoniazid both *in vivo* and *in vitro* to give the corresponding hydrazone, which exists as *syn* and *anti* (with respect to C-4) isomers. These isomers rapidly interconvert, with the *anti* form predominating in solution. The identification of the isomers was based on an interpretation of ^{1}H- and ^{13}C-NMR spectroscopic data and corroborated by high-performance liquid chromatographic and UV spectrophotometric evidence. ^{1}H- and ^{13}C-NMR spectroscopic data for other derivatives of norethindrone hydrazone are presented and interpreted.

Keyphrases □ Norethindrone—isonicotinyl hydrazone, synthesis, characterization by NMR □ NMR—isonicotinyl hydrazone of norethindrone, characterization, synthesis □ Synthesis—isonicotinyl hydrazone of norethindrone, characterization by NMR

Isoniazid (isonicotinylhydrazine) (I) reacts with ketones and aldehydes under acidic conditions. The usual products are hydrazones, but the reaction with reducing sugars gives 1-glycosyl-2-isonicotinylhydrazines (1). Reactions of this type can take place *in vivo* (2), the pharmacological and toxicological consequences of which are largely unknown. We recently showed that isoniazid reacts with norethindrone (17-hydroxy-19-nor-17α-pregn-4-en-20-yn-3-one) (II) to give the hydrazone (III) when they are coadministered orally to the rat (3) and minipig[1]. The product is readily absorbed from the GI tract (4). The analytical procedures involved conversion of norethindrone hydrazone (IV), a metabolite of III (3), to the *p*-methoxybenzaldehyde derivative (V). Some properties of V were described (3). Spectroscopic evidence for the structures of

II: R = O
III: R = $C_5H_4NCONHN$
IV: R = H_2NN
V: R = $C_6H_4(OCH_3)CH{=}N{-}N$
VI: R = $C_6H_3(NO_2)_2NHN$

EXPERIMENTAL

Isoniazid[2], *p*-methoxybenzaldehyde[3], hydrazine[4], 2,4-dinitrophenylhydrazine[3], and norethindrone[5] were used to prepare III, V, and VI by general or previously described methods (3). ^{1}H-NMR and broad-band decoupled ^{13}C-NMR spectra were recorded at 80 and 20.1 MHz, respectively, on a Fourier-transform spectrometer[6] at ambient temperature. The deuterium resonance of the solvent, $CDCl_3$[7] (VII) or DMSO-d_6[7] (VIII), provided an internal lock and TMS[8] was the internal reference from which downfield chemical shifts (δ) are expressed in ppm. Interferograms of 4K Fourier-transformed output data points (latterly 8K) and sweepwidths of 1000 and 5000 Hz gave separations in memory addresses of 0.004 and 0.06 (latterly 0.03) ppm for ^{1}H- and ^{13}C-NMR spectra, respectively.

RESULTS AND DISCUSSION

As described previously, hydrazone V is easily separated into isomers Va and Vb, respectively (3). IR spectra of these (KBr pellet) show minor differences in the fingerprint region, but none are helpful in making structural assignments. Their mass spectra are essentially identical, while the UV absorption maximum of Va is at 323 nm and Vb is at 315 nm (3).

^{1}H-NMR spectroscopic data for II, III, Va, Vb, and VI are presented in Table I. Two isomers (~1:1, VIa–VIb) could be detected in the spectra of VI and in the spectrum of III determined in DMSO-d_6 (~2:1, IIIa–IIIb). Signals of isomers have closely similar chemical shifts except for the signal assigned to H-4, which has a width at half-height ($w_{1/2}$) of ~5 Hz in each case. The chemical shifts and widths of these signals are appropriate for Δ^4 rather than Δ^5 structures (5). ^{1}H-NMR data for *syn* and *anti* (with respect to C-4) oximes of some 3 keto-Δ^4 steroids show that H-4 appears at ~6.5 and 5.9 ppm, respectively (6), suggesting that the *a* forms are the *anti* isomers.

Data from the ^{13}C-NMR spectra are presented in Table II. It is beyond our present scope to assign all of the signals, especially the 14 signal (steroidal) appearing between ~20 and 50 ppm, but assignments of the remainder have been made by comparison with compiled data (7). Limited quantities of III, the presence of both isomers in DMSO-d_6, and

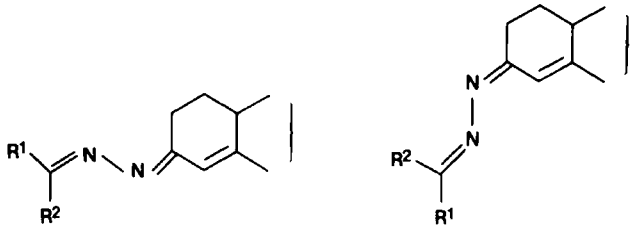
its low solubility in $CDCl_3$ prevented us from detecting all of the signals. It is also possible that the rates of interconversion of the two forms are such that while the proton chemical shifts are time-averaged in $CDCl_3$, although distinct in DMSO-d_6, certain of the ^{13}C-NMR signals are broadened by these processes and hence obscured (8). Variable temperature studies that might answer these questions are beyond our present capabilities. The ^{13}C-NMR spectra showed differences at C-3, C-4, and C-5 of ~2.5 and 7 ppm downfield and 1 ppm upfield, respectively, for V*a* in comparison with V*b*. Comparable differences were also found between the unseparated forms of III and VI and so have been assigned to *a* and *b* isomers in Tables I and II by comparison with V*a* and V*b* data. The resonances of carbons *anti* to hydrazones and oximes appear 6–12 ppm downfield from the positions of the corresponding *syn* carbons (9), again in agreement with assignment of the *anti* configuration to the *a* forms.

In further support, the order of elution (V*a* followed by V*b*) on high-performance liquid chromatography (HPLC) (3) is compatible with this assignment (6), and the UV data also suggest that the conjugated double bonds are more extended in V*a* than in V*b* (10, 11). Thus, the structures depicted are initially proposed for this series of compounds (the most stable rotational conformation about the N—N bond is shown).



V*a*,V*a*′ V*b*,V*b*′

V*a*,V*b*: R^1 = *p*-$(OCH_3)C_6H_4$, R^2 = H
V*a*′,V*b*′: R^1 = H, R^2 = *p*-$(OCH_3)C_6H_4$

A particularly interesting feature of the spectra of VI was that the aromatic carbon-13 signals were all doubled (except for C-3′ and C-5′ in $CDCl_3$). The signals, separated by 0.1–0.2 ppm, presumably arise from the *syn* and *anti* isomers, and were assigned (Table II) by comparison with the spectrum of the 2,4-dinitrophenylhydrazone of cyclohexanone in which they are not, of course, doubled. The additional possibility in azine V of *anti*/*syn* isomerism about the aldimino double bond (HC=N) leads to alternative structures V*a*′ and V*b*′, which are expected to have very similar NMR and UV absorption properties to those of V*a* and V*b*, respectively. It does not seem that mixtures are present, and it is very unlikely that the two forms of V are V*a* with V*b*′ or V*a*′ with V*b*, as neither the ^1H-NMR nor the ^{13}C-NMR shifts of the HC=N function differ between isomers (Tables I and II). The stable *anti* aldimino configuration (V*a* and V*b*) is favored.

It is evident that hydrazine-based derivatives of norethindrone can be produced *in vivo* by interaction with isoniazid. We have found that the metabolic disposition of the steroid is thereby altered[1]. Other pharmacologically important steroids and possibly other hydrazine-derived drugs may undergo similar interactions. *Syn* and *anti* isomers of norethindrone hydrazones arise and can be identified. They undergo rapid interconversion in some cases, but may be separated in others. Whether tissue enzymes, which further metabolize the hydrazones (3), are selective for *syn*/*anti* isomers remains to be determined. If such selectivity were to occur, one might expect that the rate of metabolism of various hydrazones would be dependent, *inter alia*, on the relative degree of interconvertibility of the isomers.

Effect of the Nonionic Surfactant Poloxamer 338 on the Fate and Deposition of Polystyrene Microspheres Following Intravenous Administration

LISBETH ILLUM * **and STANLEY S. DAVIS** ‡

Received December 11, 1981, from the **Department of Pharmaceutics, The Royal Danish School of Pharmacy, DK-2100 Copenhagen, Denmark*, and the ‡*Department of Pharmacy, University of Nottingham, University Park, Nottingham, NG7 2RD, U.K.* Accepted for publication August 25, 1982.

Abstract □ The blood clearance and organ deposition of polystyrene microspheres in the rabbit following intravenous injection has been investigated using the technique of gamma scintigraphy, blood and organ level measurements, and histology. Uncoated microspheres of 1.27-μm diameter were cleared rapidly from the blood and were taken up primarily by the reticuloendothelial system in the liver. Coating of the microspheres with the nonionic surface-active agent poloxamer 338 reduced the uptake in the liver and gave a corresponding increase in the lungs.

mined by the chemical nature of the colloid and its physical characteristics such as particle size and surface charge (5). The reticuloendothelial system plays a major role in clearing small particles from the circulation following intravenous administration, while larger particles are trapped in the capillary beds of the lungs. Studies on emulsion systems have indicated the important role of the surface layer of the emulsifier. The use of nonionic emulsifiers (*e.g.*, poloxamer) leads to slow clearance from the bloodstream and an altered distribution pattern to organ sites (6).

In this work such effects have been investigated further in rabbits using a model colloidal system, polystyrene microspheres. This material has been well characterized physically, including studies involving the adsorption of nonionic surfactants (7, 8). In addition, polystyrene microspheres labeled with a gamma ray-emitting radionuclide have been used to study the distribution, fate, and acute and semichronic effects of microspheres in animal models (9–11).

EXPERIMENTAL

Administration of Microspheres—Polystyrene microspheres (1.27 μm) were obtained from a commercial supplier[1]. The particle size was verified using an electronic particle counter[2] with a 30-μm orifice tube. The particles were surface-labeled with iodine-131 by a process of irradiation using a cobalt-60 source with the microspheres suspended in a solution of 2-mCi $Na^{131}I$; the total irradiation dose was 5 Mrad. The particles were dialyzed free from $Na^{131}I$. Preliminary experiments *in vitro* and *in vivo* indicated that the integrity of the label was satisfactory, although some free iodide was detectable after dialysis for 120-hr against rabbit plasma.

In each experiment, 50–75 μCi of labeled material was administered. The particles ($\sim 2 \times 10^8$) were suspended in saline and rapidly injected. One group received microspheres that had been equilibrated for 24-hr in a saline solution containing 1% w/v poloxamer 338[3], molecular weight of poloxypropylene moiety 3250, polyoxyethylene content 80–90% (8).

The surface charge on the microspheres over the pH range 2–10 was determined using cell-microelectrophoresis[4] (12). The microspheres were also equilibrated at 25° at pH 7.4 with a 1% poloxamer 338 solution for 24 hr in the presence or absence of rabbit plasma (1:1 mixture with the microsphere suspension). All samples were diluted with 1.54×10^{-4} *M* NaCl solution before measurement of the surface charge at pH 7.4. Any adjustment in pH was carried out using hydrochloric acid or sodium hydroxide. The state of aggregation of the microspheres was examined using the light microscope. The adsorption of poloxamer 338 on the surface of polystyrene microspheres of the same approximate size and the same surface characteristics has been investigated in detail by Kayes and Rawlins (5). Equilibration was reached in 24 hr. The isotherms were Langmuirian, and the thickness of the adsorbed layer was 26 nm.

Animal Experiments—New Zealand White rabbits 2–4 kg in weight were randomly divided into two groups of three. The microspheres were injected into the marginal ear vein. The distribution of the microspheres in various body organs was followed using external scintigraphic imaging[5]. Dynamic and static views were recorded at suitable times during a 10-day period and processed by computer[6]. Blood samples were removed at suitable intervals and were analyzed for radioactivity using a gamma counter[7]. At the end of 11 days the animals were sacrificed and the organs removed. Small samples were taken for histological investigation, and the total organ activity in the remainder was determined using a well-type gamma counter[8]. The histological samples were fixed, dehydrated, and mounted in wax. Microtome sections were stained using hematoxylin–eosin.

RESULTS

Properties of the Microspheres—The electrophoretic mobility–pH relationship for the polystyrene microspheres showed that at a physiological pH value (7.4) in 1.54×10^{-4} *M* NaCl, the particles carried a net negative charge (zeta potential) of −35 mV. In the presence of 1% poloxamer 338, the surface charge was reduced to −8 mV. This is due to the presence of an adsorbed layer of polymer on the surface of the particles (8). Incubation of polystyrene microspheres with rabbit plasma caused a reduction of surface charge to −15 mV. The presence of poloxamer on the surface of the particle prior to incubation with plasma caused the surface charge to be reduced to almost zero. The reduction in charge brought about by added plasma is thought to be due to the adsorption of plasma proteins (*e.g.*, albumin or globulin) or more specific substances such as fibronectin (13–15). Microscopic examination showed that added plasma caused aggregation of the microspheres, but this was prevented by the presence of poloxamer 338.

Gamma Scintigraphy—The processed computer images showed that the small microspheres were rapidly taken up by the liver of the rabbit (Fig. 1). No other body organs were visualized on the scintiscans except small quantities of activity that were observed in the thyroid and/or bladder, which can be attributed to the presence of small quantities of free iodide. There was no evidence of large numbers of particles being taken up by the lungs. The presence of an adsorbed layer of poloxamer 338 on the microspheres reduced the uptake in the liver. This difference,

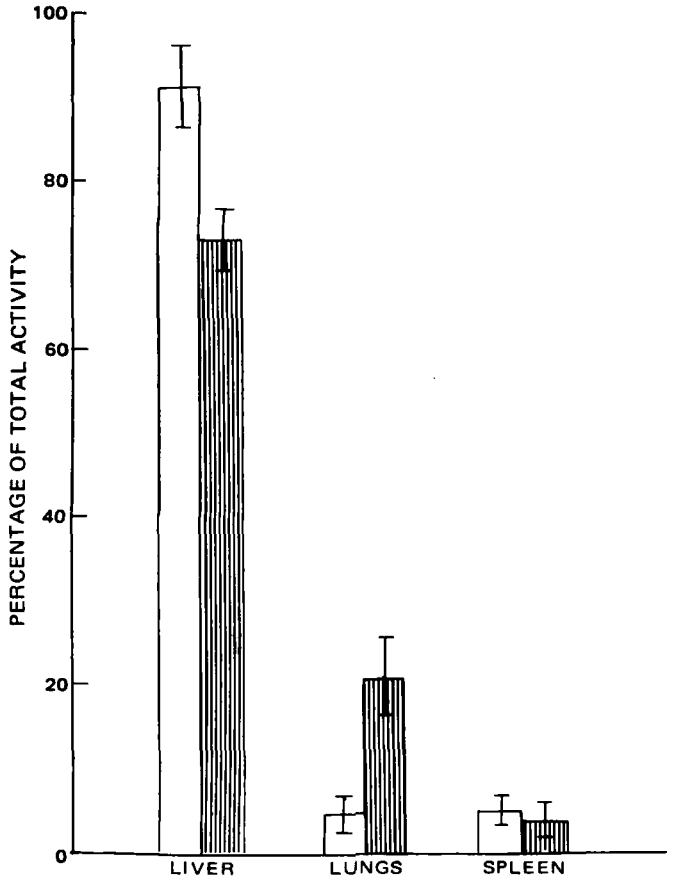

Figure 2—*Tissue distribution of iodine-131 11 days after administration of ^{131}I-labeled polystyrene microspheres. Key: (□) uncoated; (■) coated with poloxamer 338.*

caused by the presence of the nonionic surfactant, was still evident after 11 days of imaging.

Blood Levels—The blood level–time profiles (Fig. 1) show that clearance of the microspheres from the blood is affected by the presence of poloxamer 338. In the absence of the surfactant, the particles are cleared rapidly and the blood levels are low. In contrast, in the presence of poloxamer 338 significant sustained levels of activity were observed over a period of many hours.

Organ Levels—The distribution of activity after 11 days postadministration is shown in Fig. 2 for the three major sites of uptake. The majority of the activity was in the liver, with much smaller quantities in the lung and spleen. The group that received microspheres coated with poloxamer had less activity in the liver and more activity in the lungs compared with the control group which received microspheres alone.

Histology—Conventional histological techniques would not be expected to show small individual microspheres of 1.27 μm in body tissues. Histological examinations were undertaken, therefore, to reveal aggregated particles. None were observed.

DISCUSSION

Effect of Poloxamer on the Deposition of Microspheres—The results from scintigraphic imaging, blood level determinations, and organ uptake studies all show clearly that the adsorption of a layer of poloxamer 338 onto the surface of polystyrene microspheres affects their deposition in the rabbit following intravenous administration. Differential leaching of the radiolabel from the particles prior and subsequent to administration would be expected to alter the absolute values for deposition, but not their relative magnitudes. The uncoated particles were deposited mainly in the liver; it is well known that small colloidal particles will be cleared rapidly from the bloodstream by the reticuloendothelial system of this organ, *i.e.*, the Kupffer cells (16). Larger particles (normally those >7 μm) will be cleared by the lungs by a process of filtering or mechanical obstruction (10).

The coating of colloidal particles with polymers and macromolecules can alter organ uptake considerably. Wilkins and coworkers (17, 18) have demonstrated the importance of surface modification as well as surface charge. Negatively charged particles are removed from the circulatory system quite rapidly, whereas positive and neutral particles have different clearance patterns. Certain positively charged particles can be taken up by the lungs and then rapidly redistributed to the spleen rather than the liver (17). The important process controlling the fate and deposition of colloidal particles would seem to be one of the interaction of a foreign surface with the blood and the coating of that surface with various components such as albumin, globulin, *etc;* the exact coating material being determined by the nature of the particle itself. The coating then influences the interaction of the particle with cells of the reticuloendothelial system (5). Certain blood components (termed opsonins) can enhance phagocytic uptake (16). Van Oss *et al.* (19) have discussed the role of surface hydrophobicity in phagocytic engulfment and cell adhesiveness. Particles with low contact angles are taken up much less rapidly by phagocytes than particles with high contact angles. Poloxamer 338 causes a very significant reduction in the contact angle of the hydrophobic polystyrene particles.

Studies that have dealt specifically with nonionic surface-active agents have employed both polystyrene microspheres and emulsion systems. For example, Singer *et al.* (5) found that microspheres coated with polysorbate 80 showed the slowest decline in blood concentration. Similarly, Jeppsson and Rossner (20) using fat emulsions demonstrated the importance of the molecular weight of the adsorbed surfactant, poloxamer 338 (mol wt 3250) being much more effective at reducing the clearance rate of droplets than poloxamer 188 (mol wt 1750). Such differences could be due to the different thicknesses of the adsorbed layers (26 and 14 nm, respectively, for 338 and 188) and/or to differences in surface charge (8).

The increased uptake of the coated microspheres in the lungs (after 11 days) is more difficult to explain. One obvious reason would be aggregation, and the entrapment of the larger entities so created, in the lungs. Kanke *et al.* (10) have reported "clusters" of microspheres in histological preparations. However, no aggregates of a size that would be trapped in lung capillaries were seen in the histological specimens, and the *in vitro* studies showed that the nonionic surfactant brought about deaggregation even though the microsphere system with adsorbed poloxamer and plasma components had the lowest surface charge. It is recognized that a different type of aggregation–deaggregation process could occur *in vivo*, since the microspheres are exposed to different environments and the poloxamer could be modified by metabolic changes.

The critical minimum particle size for deposition in the lungs is usually regarded as being ~7–10 μm, depending on the nature of the particle and its shape (21). However, a recent report by Findler *et al.* (22) has shown that efficient localization of liposomes in the capillary bed of the lungs could be achieved using negatively charged multilamellar liposomes 1–2 μm in diameter. This size range covers the microspheres used in the present work. Furthermore, uptake of technetium-99m–sulfur colloid (particle size 400–600 nm) in the lungs has been reported in clinical diagnostic studies (23).

The pathophysiology of such increased uptake of colloid in the lung is poorly understood, but evidence from human and animal studies does not support the hypothesis that *in vivo* microaggregation results in the formation of microemboli that are trapped in the lung. The evidence does support the possibilities of increased phagocytic activity in the pulmonary capillary bed or adherence of colloid to altered endothelium in the pulmonary capillaries (23, 24). Thus, the modified surface properties of the microspheres coated by poloxamer could potentiate their uptake in the lungs.

Application of Postcolumn Ionization in the High-Performance Liquid Chromatographic Analysis of Butabarbital Sodium Elixir

EDITH P. SCOTT

Received February 16, 1982, from the *Food and Drug Administration, Atlanta, GA 30309.* Accepted for publication August 16, 1982.

Abstract □ A sensitive postcolumn ionization high-performance liquid chromatographic (HPLC) method for the quantitative determination of butabarbital sodium in butabarbital sodium elixir is described. The procedure employs a octadecylsilane column chemically bonded to porous silica microparticles. The mobile phase is a mixture of methanol and water (typically 35:65), adjusted to provide separation of butabarbital from two degradation compounds and other formulation ingredients. A buffer (pH 10) added between the column and detector provides for the primary ionization of the barbiturate necessary for optimum UV-detector sensitivity at ~240 nm. Determinations are made using the sodium salt; thus the need for extraction of the free base is eliminated. The procedure is linear over the 0.3–0.9-mg/ml concentration range of butabarbital sodium. Reproducibility values for 10 injections of a single reference standard range from 100.2 to 100.8% of theoretical with a mean of 100.5% and a coefficient of variation of 0.23%. An interlaboratory precision study for blind duplicates of one simulated product formulation and two commercial elixers produced coefficients of variation of 1.4, 1.3, and 1.1%, respectively. Recovery determinations for the drug in simulated product formulations ranged from 98.4 to 99.0%, intralaboratory, and 97.7 to 102.2%, interlaboratory. The HPLC procedure is stability indicating with respect to two decomposition products.

Keyphrases □ Butabarbital sodium—application of postcolumn ionization in higher-performance liquid chromatographic analysis, elixir □ Ionization—postcolumn, application in high-performance liquid chromatographic analysis of butabarbital sodium elixir □ High-performance liquid chromatography—application of postcolumn ionization, analysis of butabarbital sodium elixir

The chromaphoric characteristics of barbiturates establish them as prime compounds for high-performance liquid chromatographic (HPLC) analysis using a combination of reverse-phase chromatography and postcolumn ionization with a pH 10 buffer. Clark and Chan (1) have reported the advantages of combining conventional reverse-phase chromatography and postcolumn ionization into a single system. In this study, their analytical approach has been successfully employed in the assay of butabarbital sodium elixir. The procedure eliminates the need for extraction of butabarbital free acid. No sample cleanup was required because a suitable chromatographic system was found that would resolve the phenobarbital internal standard, butabarbital, placebo ingredients, and one decomposition product, capuride.

[a] Small batch of commercial product, accurately prepared in the laboratory according to the manufacturer's master formulation.

specimen loop; a UV-detector capable of monitoring absorbance at ~240 nm; a digital integrator–recorder; and a 10-μm micropellicular octadecylsilane column[2]. To achieve postcolumn ionization, a second solvent pump[3] was connected to the HPLC apparatus by means of a 1.58 mm union tee[4] installed in the line between the column and the detector.

Reagents—The methanol[5] was distilled in glass. The boric acid[6], potassium chloride[7], and sodium hydroxide[5] were ACS grade. Phenobarbital[8] was USP grade; the butabarbital[9] was USP reference standard[9].

HPLC Operating Conditions—The mobile phase consisted of methanol–distilled water (35:65), and the flow rate was 1.5 ml/min. The ionization solvent was a borate buffer (pH 10.0 ± 0.05) prepared by mixing 250 ml of 0.2 *M* boric acid, 250 ml of 0.2 *M* potassium chloride, and 220 ml of 0.2 *M* sodium hydroxide and diluting to 1 liter with distilled water. The buffer was pumped into the mobile phase at a flow rate of 0.1 ml/min. The UV detector was operated with a 254-nm filter and a sensitivity setting of 0.1 AUFS. Injection volume for sample and standard solutions was ~7.5 μl; injections were made in triplicate. A resolution value, R[10], of ≮1.5 was established to evaluate system suitability.

Preparation of Solutions—A solution of phenobarbital in methanol was prepared at a concentration of ~3 mg/ml for the internal standard. Aliquots of the internal standard solution and butabarbital sodium elixir were combined to produce a mixed solution containing ~0.3 mg/ml of phenobarbital and 0.7 mg/ml of butabarbital sodium in methanol. Butabarbital and an aliquot of the internal standard solution were combined to produce a mixed solution (standard) containing ~0.3 mg/ml of phenobarbital and 0.6 mg/ml of butabarbital in methanol.

Chromatographic Separation and Analysis—A printer–plotter–integrator[11] which automatically integrates chromatographic peaks and calculates results was employed in the liquid chromatograph apparatus. The data processor calculated peak areas and response factors resulting from injection of a standard solution and stored the data in a calibration table. Similarly, the data processor calculated areas and response factors for injections of sample solutions and compared sample data with standard data in the calibration table for calculation of sample amounts. Phenobarbital elution time was ~9 min, and butabarbital elution was ~13 min (Fig. 1).

RESULTS AND DISCUSSION

The HPLC procedure described herein was subjected to validation studies for linearity, precision, and accuracy. Linearity was determined at five concentrations which would be equivalent to butabarbital sodium elixir products with assay values ranging from 50 to 150% of declared butabarbital sodium. Assay results ranged from 98.9 to 100.0% of theoretical, with a correlation coefficient of 0.9999 (Table I). Reproducibility for 10 injections of a butabarbital sodium standard solution ranged from 100.2 to 100.8% of theoretical, with a mean of 100.5% and a coefficient of variation of 0.23% (Table III).

Four brands of butabarbital sodium elixir were assayed by the HPLC procedure. Recoveries were determined using product controls prepared for these four brands of elixir. A product control is defined here as a small batch of commercial product accurately prepared in the laboratory according to the manufacturer's master formulation. Assay results and recoveries for the corresponding product controls are shown in Table II.

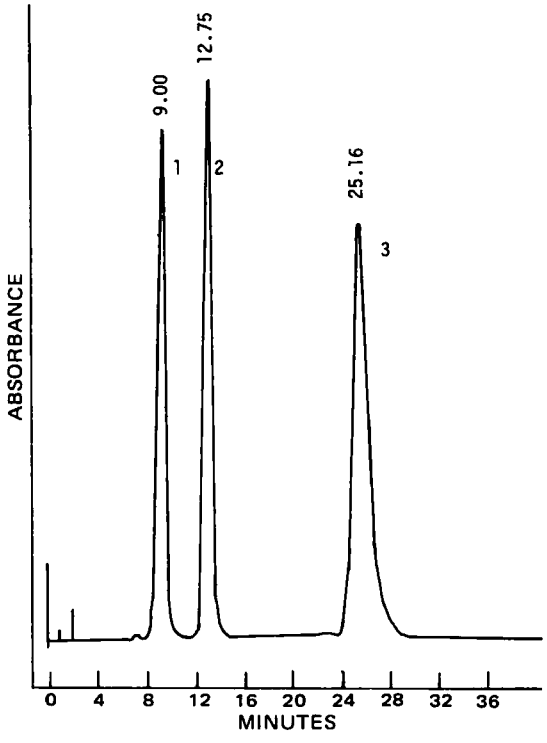

Figure 1—*HPLC response for (1) phenobarbital, (2) butabarbital, and (3) capuride. The column was μBondapak C_{18}; the mobile phase was methanol–distilled water (35:65); ionization solvent was borate buffer (pH 10).*

An interlaboratory collaborative study of the procedure was conducted using blind duplicate samples of one simulated product formulation and

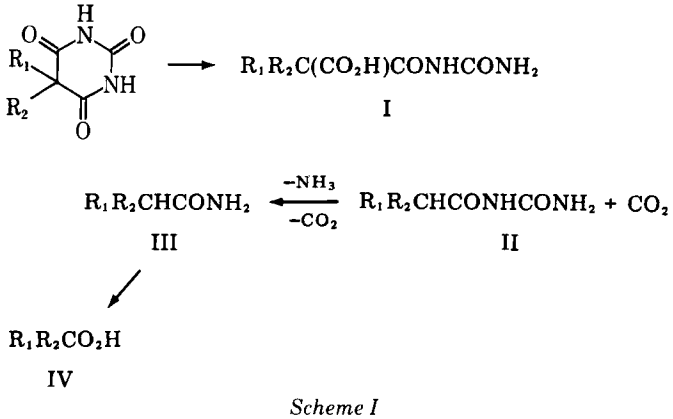
[a] Simulated product formulation with 28.36 mg/5 ml of butabarbital sodium added. [b] Commercial product with 30 mg of butabarbital sodium per 5 ml declared. [c] Commercial product with 33.3 mg of butabarbital sodium per 5 ml declared.

two commercial elixirs. Coefficients of variation were 1.4, 1.3, and 1.1%, respectively, for the three samples. Recovery values for the authentic sample ranged from 97.7 to 102.2%. Results of interlaboratory testing are presented in Table IV.

A placebo was prepared for each of the four butabarbital sodium elixir products analyzed. None of the placebos interfered with the assay (Fig. 2). Solutions of butabarbital sodium and butabarbital in methanol were found to be stable over a prolonged period in laboratory fluorescent light and laboratory temperature (generally 20–25°). Stability determinations were made after 11 and 56 days of exposure time.

Limited data on HPLC response for decomposition products was obtained. No commercial source for butabarbital decomposition compounds was available; thus, an attempt was made to prepare the compounds through thermal degradation of butabarbital sodium in this laboratory. Breakdown products due to hydrolysis of barbiturates (Scheme I) have been established (2–5).



Scheme I

Two approaches to thermal decomposition were employed. With the Watson and Pernarowski procedure (5) only one compound, capuride (II), was obtained in sufficient quantity for analytical testing. Thermal decomposition using a pressure bottle (6) was also attempted to isolate additional decomposition products. This procedure also produced capuride and, additionally, a compound which was identified as valnoctamide (III). Both the capuride and valnoctamide which were produced were identified by means of melting point, IR spectrophotometry, and mass spectroscopy.

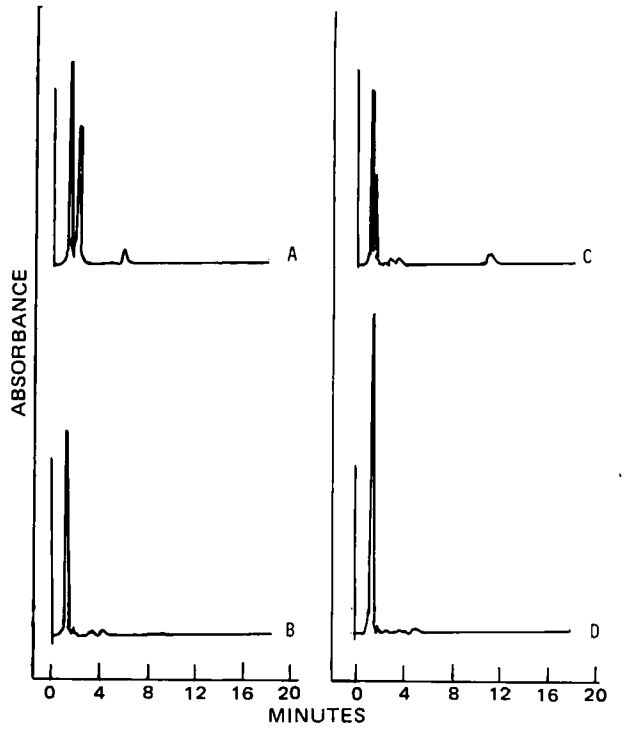


Figure 2—*HPLC responses for placebo ingredients from manufacturers A–D (see Table II).*

Capuride eluted from the HPLC column at 25.16 min. (Fig. 1). An injection of ~10 μg produced a pen deflection of ~1.5 cm at 0.02 AUFS. No HPLC response was produced for a 35-μg injection of valnoctamide at 0.02 AUFS.

Chromatograms of phenobarbital, butabarbital, and product placebos from injections made on six octadecylsilane columns representing five commercial sources and one in-laboratory preparation were evaluated. Columns that met the system suitability criterion gave satisfactory resolution of phenobarbital, butabarbital, and placebo ingredients.

Rapid Gas Chromatographic Determination of Serum Salicylates After Silylation

Keyphrases □ GLC analysis—Simultaneous determination of acetylsalicylic acid and salicylic acid in plasma, serum and whole blood, formation of trimethylsilyl derivatives

To the Editor:

Both acetylsalicylic acid and salicylic acid are pharmacologically active, but there are qualitative and quantitative differences in the analgesic and antiplatelet effects and in their inhibition of prostaglandin synthetase (1, 2). Gas–liquid chromatographic (GLC) methods for quantifying acetylsalicylic acid and salicylic acid simultaneously are time consuming, requiring extraction prior to the formation of the corresponding trimethylsilyl derivatives (3–5). Furthermore, the analyses are complicated by some hydrolysis of acetylsalicylic acid to salicylic acid during derivatization (6).

The GLC methods available for the quantitation of acetylsalicylic acid and salicylic acid require prior silylation at 50° for 60 min (3–5). Silylation of salicylic acid with hexamethyldisilazane in acetone gave two peaks with retention times of 1.5 and 2.2 min when chromatographed at 135° under our conditions. These peaks were considered to be the mono- and bis-trimethylsilyl derivatives of salicylic acid, respectively, since the intensity of the 1.5-min peak decreased with time with concomitant increase in the height of the 2.2-min peak (4). Therefore, a more appropriate system of derivatization was sought. Table I gives the effect of time on the silylation of acetylsalicylic acid, salicylic acid, and *p*-hydroxybenzoic acid at 23° and 60° with *N,O*-bis(trimethylsilyl)trifluoroacetamide in acetonitrile. *p*-Hydroxybenzoic acid was chosen as the internal standard since it readily forms a bis-trimethylsilyl derivative (7). Acetonitrile was chosen as the solvent, since it has been reported to be suitable for the silylation of catecholamines and related compounds (8). The results show that under these conditions of silylation[1] the maximum peak area ratio was obtained almost immediately at both temperatures and that the ratio was stable for at least 60 min, even at 60°. The mean peak area ratio obtained for salicylic acid at the various times after the addition of *N,O*-bis(trimethylsilyl)trifluoroacetamide was 0.96 ± 0.10 (*SD*) at 23° and 1.02 ± 0.05 (*SD*) at 60°, representing coefficients of variation of 10.4 and 5.0%, respectively. Similarly, the mean values of the peak area ratio for acetylsalicylic acid were 0.56 ± 0.01 (*SD*) at 23° and 0.55 ± 0.03 (*SD*) at 60°, giving coefficients of variation of 2.6 and 6.1%, respectively. The peak with a retention time of 1.5 min, considered to be the monosilylation product of salicylic acid, was not observed under these conditions. For rapid silylation of acetylsalicylic acid and salicylic acid, dry acetone can be substituted for acetonitrile. Also, the rate of silylation was faster when *N,O*-bis(trimethylsilyl)trifluoroacetamide was used instead of hexamethyldisilazane.

Table I—Effects of Time and Temperature on the Silylation of Acetylsalicylic Acid, Salicylic Acid, and *p*-Hydroxybenzoic Acid in Acetonitrile Using *N,O*-bis(trimethylsilyl)trifluoroacetamide as the Silylating Reagent [a]

[a] One ml of an ethereal solution containing 10 μg of each compound was evaporated to dryness; the residue was dissolved in 10 μl of acetonitrile and reacted with 5 μl of *N,O*-bis(trimethylsilyl)trifluoroacetamide. A 2–3-μl aliquot was injected into the gas chromatograph. [b] After addition of silylating reagent.

Figure 1 shows typical chromatograms of ethereal extracts of drug-free serum carried through the analytical procedure (A); of drug-free serum to which 15 μg of acetylsalicylic acid, salicylic acid, and the internal standard *p*-hydroxybenzoic acid were added (B); and of a mixture of acetanilide, methyl salicylate, salicylic acid, *p*-hydroxy-

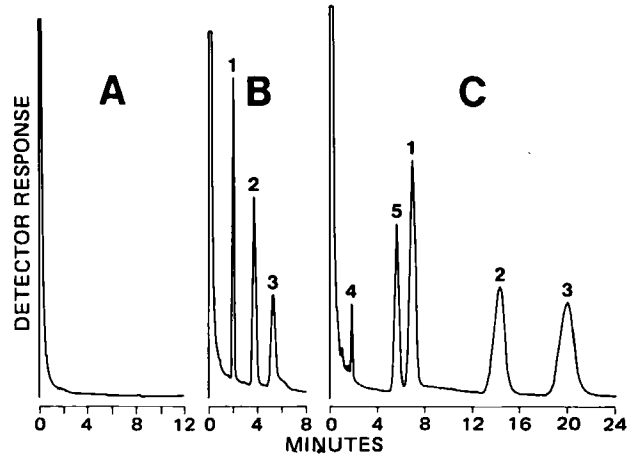

Figure 1—*Chromatograms of drug-free serum carried through the procedure (A), drug-free serum to which 15 μg of acetylsalicylic acid, salicylic acid, and p-hydroxybenzoic acid were added and analyzed, as described in the procedure (B), and of a mixture of acetanilide, methyl salicylate, salicylic acid, p-hydroxybenzoic acid, and acetylsalicylic acid analyzed at 110° (C). The derivatization was carried out in acetonitrile using* N,O-*bis(trimethylsilyl)trifluoroacetamide as silylating reagent. Key: (1) salicylic acid; (2)* p-*hydroxybenzoic acid; (3) acetylsalicylic acid; (4) acetanilide; (5) methyl salicylate.*

[1] Sample formulation: To each 0.10-ml aliquot of serum, plasma, or whole blood, 2 ml of 1 *N* HCl was added; *p*-hydroxybenzoic acid (15 μg in 1 ml of water) was added as the internal standard; and the mixture was extracted twice with 5 ml of freshly distilled ether. The organic phase was transferred to another tube and evaporated to dryness under a stream of nitrogen in a water bath at 42–44°. The residue was dissolved in 10 μl of acetonitrile and derivatized with 5 μl of *N,O*-bis(trimethylsilyl)trifluoroacetamide (Pierce Chemical Co.). A 2–3-μl sample was injected into a gas chromatograph (Hewlett-Packard model 5710A) equipped with a flame-ionization detector and a chart recorder-integrator (Hewlett-Packard model 3380s). The column was 1.2 m long ×4-mm i.d. glass tubing packed with 2% OV-225 on 80–100 mesh Gas Chrom W (Chromatographic Specialities, Ltd.) It was conditioned overnight at 225° and treated with hexamethyldisilazane before use. The operating conditions were: injection port temperature, 250°; oven temperature (isothermal), 135 or 110°; detector temperature, 300°. The nitrogen (carrier gas), air, and hydrogen flow rates were 60, 100, and 30 ml/min, respectively.

0022-3549/83/0900-1092$01.00/0

benzoic acid, and acetylsalicylic acid (C). Parts A and B were determined at 135° with part C determined at 110° in order to have base line resolution of all the peaks. The ethereal extract of control serum sample (A) did not give any peak that interfered with the GLC analysis of acetylsalicylic acid, salicylic acid, and *p*-hydroxybenzoic acid. Similar results were obtained using samples of either rat or human plasma. The retention times of the trimethylsilyl derivatives of salicylic acid, *p*-hydroxybenzoic acid, and acetylsalicylic acid were 2.2, 4.4, and 5.4, respectively at 135°. Under these conditions, the retention times of the trimethylsilyl derivatives of methyl salicylate, ibuprofen, salicylamide, and acetaminophen were 1.9, 3.7, 10.8, and >30 min, respectively. Acetanilide and phenacetin did not form a trimethylsilyl derivative, but each compound produced a single peak with retention time values of 0.9 and 4.7 min, respectively, when chromatographed at 135°. Other nonsteroid anti-inflammatory drugs such as ketoprofen, indomethacin, and naproxen did not produce a peak when silylated under identical conditions. Complete separation between the peak of the trimethylsilyl derivatives of methylsalicylic acid and salicylic acid was obtained at 110° (Fig. 1C). Under these conditions, the retention time values of underivatized acetanilide and of the trimethylsilyl derivatives of methylsalicylic acid, salicylic acid, *p*-hydroxybenzoic acid, and acetylsalicylic acid were 2.0, 5.1, 7.1, 14.35, and 20.05 min, respectively. Salicyluric acid (2-hydroxyhippuric acid), the major metabolite of salicylic acid, did not give a peak under the analytical conditions used. The chromatographic conditions determined at 135° were suitable for the simultaneous analysis of acetylsalicylic acid and salicylic acid in serum samples. There was no interference from the commonly used analgesics often prescribed in combination with acetylsalicylic acid, except for phenacetin, which gave a peak of similar retention time value close to that of the trimethylsilyl derivative of *p*-hydroxybenzoic acid. In cases where phenacetin is also being administered, 4-chlorophenylacetic acid can be used as a reference standard since its trimethylsilyl derivative has a retention time value of 2.9 min.

Table II gives the coefficient of variation and the recovery of different concentrations of acetylsalicylic acid and salicylic acid added to the control serum. The coefficients of variation of triplicate analysis varied from 0.0 to 6.9% for acetylsalicylic acid and from 1.1 to 6.4% for salicylic acid. The mean values for the coefficient of variation of the eight concentrations of acetylsalicylic acid and salicylic acid used were 2.6 ± 2.6 and 3.7 ± 1.8 (*SD*%) respectively. The recovery of these two compounds was essentially quantitative. The overall recovery for acetylsalicylic acid was 104.0 ± 8.4 (*SD*)%, while that of salicylic acid was 98.2 ± 5.3 (*SD*)%. Calibration curves were obtained for acetylsalicylic acid ($y = 0.03 + 0.0474x$ and $r = 0.996$) and for salicylic acid ($y = 0.20 + 0.064x$ and $r = 0.997$) in the range of concentrations of 2.5–25 μg/0.1 ml of serum, *i.e.*, within the concentrations determined in pharmacokinetic studies. It should be pointed out that the hydrolysis of acetylsalicylic acid to salicylic in blood samples at 37° is rapid (9–11) and, therefore, it is necessary to extract the acetylsalicylic acid as soon as possible to avoid its breakdown in storage. There was no breakdown of acetylsalicylic acid to salicylic acid during the extraction, evaporation, and derivatization processes described herein.

Is Aspirin Phenylalanine Ethyl Ester a Prodrug for Aspirin?

Keyphrases □ Aspirin—high-performance liquid chromatography, phenylalanine ethyl ester as prodrug

To the Editor:

It is known that oral administration of aspirin induces gastric irritation and bleeding because of local irritation

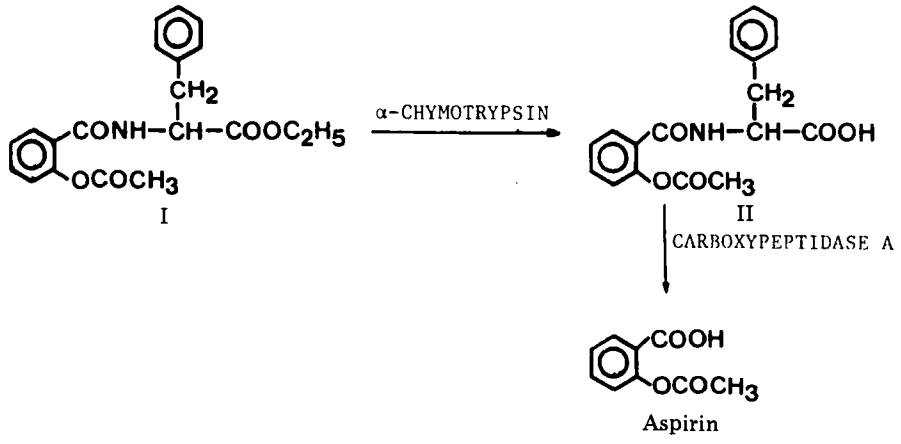

Scheme I

of the gastric mucosal membrane by the very acidic aspirin particles (1–3). One approach to minimizing this side effect is to mask the acidic carboxyl group of aspirin reversibly *via* a prodrug. Upon administration, the neutral derivative dissolves first, then hydrolyzes either in the GI tract or in the plasma, generating aspirin. It has been shown that classical esterification of the carboxyl group results in nonirritating but insoluble species which do not revert to aspirin but rather to the corresponding salicylate derivative (4). Thus, a prerequisite for any aspirin prodrug is that the masking group cleave much faster than the acetyl group. Prodrugs that cleave to aspirin have been reported (5–7). The compounds were aspirin derivatives in which the carboxyl group was masked *via* an acylal linkage.

Banerjee and Amidon (8–10) have recently proposed aspirin phenylalanine ethyl ester (I) as a possible prodrug for aspirin. It was rationalized that, because of the specificity of certain enzymes such as α-chymotrypsin and carboxypeptidase A, I would first be cleaved by α-chymotrypsin to aspirin phenylalanine (II) and subsequently to aspirin by carboxypeptidase A. To support their hypothesis, the authors studied the rate of hydrolysis of I at pH values of 7.5 and 8 in the presence of α-chymotrypsin and separately determined the rate of hydrolysis of II at pH 8.5 in the presence of carboxypeptidase A. In their kinetic studies, the reactions were followed by measuring the consumption of sodium hydroxide using a pH-stat titration. Aspirin was detected using TLC from a reaction mixture containing I and the two enzymes at pH 7.5. Based on this information, the authors proposed Scheme I for the stepwise enzymatic hydrolysis of I.

In this communication we report recent studies conducted using a specific high-performance liquid chromatographic (HPLC) assay and TLC assay which indicate that the work reported by these authors is in error. In disagreement with their conclusions, the new data indicate that (*a*) compound I does not generate aspirin in the presence of the two enzymes, (*b*) the hydrolysis of II is not catalyzed by carboxypeptidase A, and (*c*) compound I *does* hydrolyze to II in the presence of carboxypeptidase A.

Compound I was prepared according to the procedure of Banerjee and Amidon (8). Compound II was prepared from I using the reported procedure, but with slight modification; namely, treating I with α-chymotrypsin for longer than the reported 2 min to ensure complete conversion to II. The compounds were characterized by their melting points, NMR spectroscopy, and elemental analysis.

The activity of carboxypeptidase A[1] was redetermined in our laboratories and found to be 39.4 U/mg of protein, in close agreement with the labeled value of 41 U/mg of protein. The buffers used in our studies were 0.1 *M* phosphate adjusted to the desired pH values. The pH values of all the solutions were redetermined at the end of the experiments and found to be unchanged. An HPLC was equipped with a UV detector[2] set at 254 nm and 0.02–0.1 AUFS. Samples were analyzed on a 3.9-mm × 30-cm reverse-phase[3] column. The mobile phase was acetic acid–methanol–water (2:40:58), and the flow rate[4] was 2 ml/min. The injection volume[5] was 20 μl.

Figure 1 is a chromatogram of a mixture of equimolar concentrations (1.57×10^{-4} *M*) of I, II, aspirin, salicylic acid, salicyl phenylalanine, and salicyl phenylalanine ethyl ester. With this technique, the hydrolysis of I, even to the extent of 20%, would result in aspirin levels that are easily detectable. The enzymatic hydrolysis rates of I and II were examined using this HPLC method.

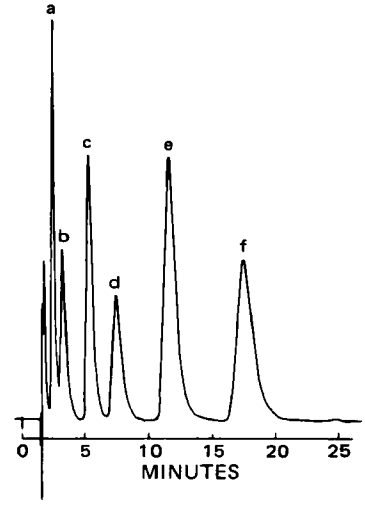

Figure 1—*HPLC chromatograms for (a) aspirin, (b) salicylic acid, (c) aspirin phenylalanine, (d) salicyl phenylalanine, (e) aspirin phenylalanine ethyl ester, and (f) salicyl phenylalanine ethyl ester.*

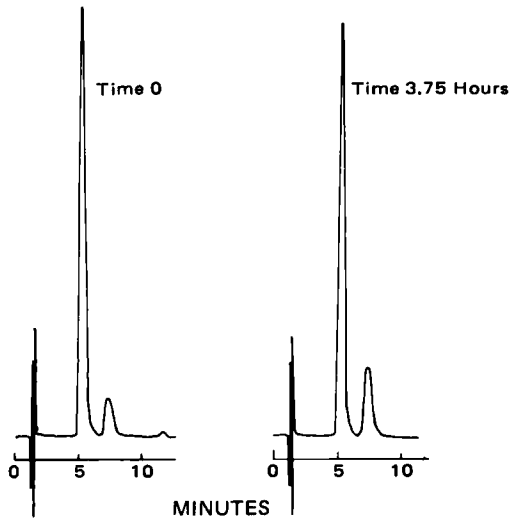

Figure 2—*HPLC chromatograms of aspirin phenylalanine (8.5×10^{-4} M) in the presence of carboxypeptidase A (1.0×10^{-5} M) at pH 8.5. Key: Aspirin phenylalanine, 5.0 min; Salicyl phenylalanine, 7.0 min.*

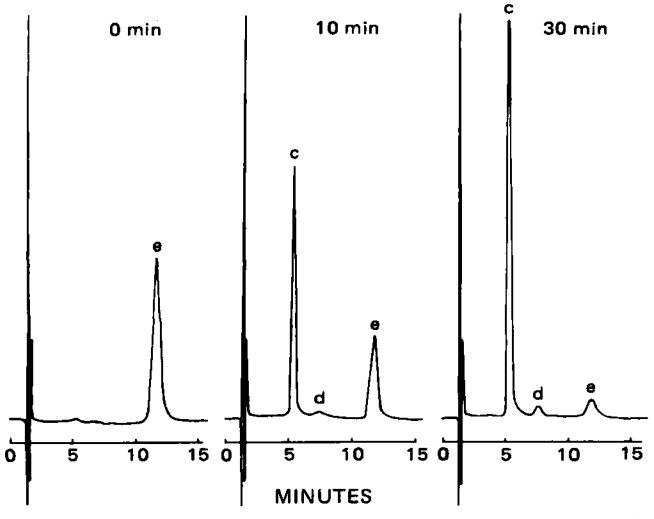

Figure 3—*HPLC chromatograms showing the disappearance of the prodrug and the appearance of aspirin phenylalanine as a function of time in the presence of 1×10^{-5} M carboxypeptidase A at pH 8.5. Key: (c) aspirin phenylalanine, (d) salicyl phenylalanine, and (e) prodrug.*

minor peak corresponding to salicyl phenylalanine. This experiment confirms that I does indeed cleave to II in the presence of α-chymotrypsin (8). However, when a mixture of α-chymotrypsin (3.9×10^{-6} *M*) and carboxypeptidase A (1×10^{-5} *M*) was added to I (8×10^{-4} *M*) at pH values of 7.4 and 8.5 and the solution immediately analyzed by HPLC, the same two peaks were observed and no peak corresponding to aspirin was detected even after 30 min. Therefore, aspirin is not liberated from II in the presence of carboxypeptidase A. To support this conclusion, the hydrolysis of II itself (8.5×10^{-4} *M*) in the presence of carboxypeptidase A (1×10^{-5} *M*) at pH 8.5 (the pH used by the previous authors to study this reaction) was determined by HPLC. When the mixture was immediately injected into the HPLC, two peaks, corresponding to II and salicyl phenylalanine were observed. As shown in Fig. 2, no additional peaks were observed, even after 3.75 hr. The same result was observed when the carboxypeptidase A concentration was increased 20-fold.

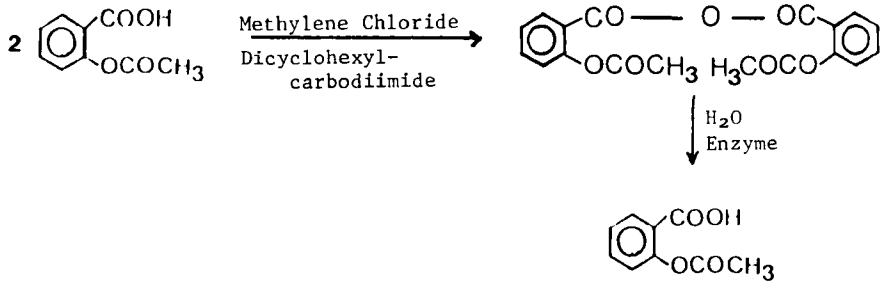
On the other hand, and contrary to the hypothesis of the authors, I was found to cleave to II in the presence of carboxypeptidase A. Figure 3 shows the time course for the appearance of II in a solution containing I (8×10^{-4} *M*) and carboxypeptidase A at pH 8.5.

To confirm the HPLC results, the same TLC system reported previously (8) was used to examine the mixture containing I and the two enzymes. Again, no aspirin spot was observed.

The results obtained by the authors which led to their conclusions appear to be in error for two reasons:

1. The aspirin spot appearing on the TLC plates (8) may have been the result of the hydrolysis of aspirin anhydride contaminating their prodrug. This is quite possible, since preparation of the prodrug involves the intermediate formation of aspirin anhydride, as shown in Scheme II. The half-life of the conversion of aspirin anhydride to aspirin is known to be ~8 min at pH 7.4 and 25°[7].

2. The consumption of sodium hydroxide observed previously when carboxypeptidase A was added to II may have been due to the hydrolysis of I, a very likely contaminant of the preparation. This is quite possible, since II was obtained by treating I with α-chymotrypsin for only 2 min and the purity of II was determined only by NMR (8). If this were the case, then I itself would, as shown



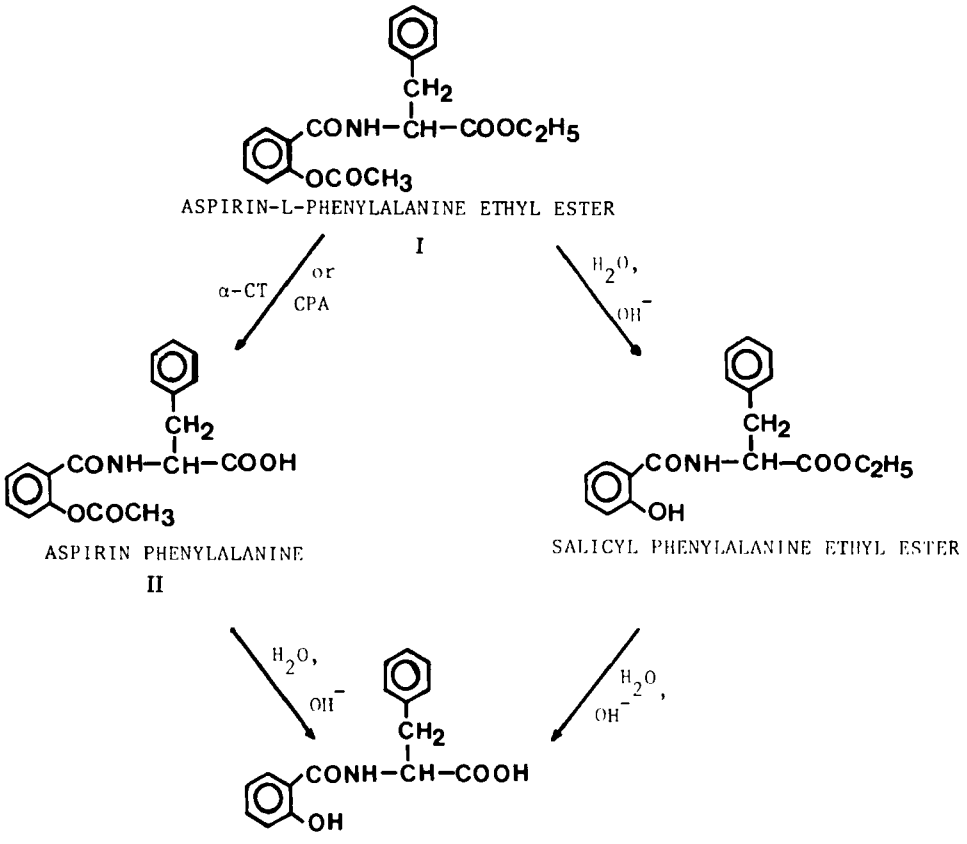
Scheme II

above, hydrolyze in the carboxypeptidase A preparation. The hydrolysis of I by carboxypeptidase A follows Michaelis–Menten kinetics. Linear Lineweaver–Burk plots

When a solution at pH 8 containing I (8×10^{-4} *M*) and α-chymotrypsin[6] was analyzed by HPLC, only two peaks were observed: a major peak corresponding to II and a

[6] Lot 70F-8000, Sigma Chemical Co., St. Louis, Mo.

[7] M. N. Khawam, J. B. Bogardus, and A. A. Hussain, unpublished results.



Scheme III

at concentrations ranging from 4.4×10^{-4} to 1.2×10^{-3} *M* were obtained in the presence of 1×10^{-5} *M* enzyme. The details of these experiments will be published in a later paper.

Since I is hydrolyzed to II by α-chymotrypsin and II does not cleave to aspirin in the presence of carboxypeptidase A, I is not a prodrug for aspirin.

Based on the previous work (8–10) and the additional data obtained in this laboratory, Scheme III is proposed for the hydrolysis of aspirin phenylalanine ethyl ester.

Comment on a Second-Degree Polynomial Mathematical Model for Tablet Friability and *In Vitro* Dissolution

Keyphrases □ Dissolution—*in vitro*, polynomial mathematical model, effect of moisture and crushing strength □ Friability—effect of moisture and crushing strength, mathematical model

To the Editor:

In a recent report, Chowhan *et al.* (1) have used a function of a two-variable model to describe the effect of moisture and crushing strength on tablet friability and *in vitro* dissolution. Elliptical shape and ridge contour curves were unfortunately not reproduced on a computer[1] using all published data. Further examination of the mathematical equation (Eq. 1) using SAS contour plot procedure[2] on the same computer showed indeed that Figs. 5 and 6 contour plots in the article did not agree with the analytical expression.

Comment on a Second-Degree Polynomial Mathematical Model for Tablet Friability and *In Vitro* Dissolution

Keyphrases □ Dissolution—*in vitro*, polynomial mathematical model, effect of moisture and crushing strength □ Friability—effect of moisture and crushing strength, mathematical model

To the Editor:

In a recent report, Chowhan *et al.* (1) have used a function of a two-variable model to describe the effect of moisture and crushing strength on tablet friability and *in vitro* dissolution. Elliptical shape and ridge contour curves were unfortunately not reproduced on a computer[1] using all published data. Further examination of the mathematical equation (Eq. 1) using SAS contour plot procedure[2] on the same computer showed indeed that Figs. 5 and 6 contour plots in the article did not agree with the analytical expression.

[1] IBM 3033.
[2] SAS Institute Inc., Cary, NC 27511.

0022-3549/83/0900-1096$01.00/0

The mathematical model (2):

$$Y = b_0 + b_1X_1 + b_2X_2 + b_3X_1^2 + b_1X_1X_2 + b_5X_2^2 + \text{Error} \quad \text{(Eq. 1)}$$

can be rearranged and rewritten as shown below:

$$Y = b_3X_1^2 + b_4X_1X_2 + b_5X_2^2 + b_1X_1 + b_2X_2 + b_0 + \text{Error} \quad \text{(Eq. 1)}$$

$$Z = AX^2 + BXY + CY^2 + DX + EY + F \quad \text{(Eq. 2)}$$

According to a well-known theorem (3), the surface (Eq. 2) is an elliptic parabaloid which has ellipses for horizontal cross sections if $B^2 - 4AC$ is negative, a hyperbolic parabaloid if $B^2 - 4AC$ is positive, and a parabolic cylinder if $B^2 - 4AC$ is zero. The type of a parabaloid can, therefore, be obtained by computing the discriminant $B^2 - 4AC$ in the equation. Using those suggested coefficients b_0, b_1, b_2 . . . b_5 to substitute for Eq. 1 for the case of tablet friability response, the discriminant $B^2 - 4AC$ is positive, the level curves (contour curves) are hyperbolas, and the surface is a hyperbolic parabaloid; for the dissolution response, the discriminant $B^2 - 4AC$ is negative and A and C are negative, the level curves are ellipses, and the surface is an elliptic parabaloid that opens downward. No evidence was given showing that the mathematical model had been tested. No explanation or reference was provided to show how the contour curves were derived and drawn. No examination was given to discuss whether the part of error in the equation (Eq. 1) was due to lack-of-fit.

By definition (3), a level curve (or contour curve) of a function $f(x,y)$ is the curve $f(x,y) = C$ in the XY-plane. It consists of the points (x,y) where the function has the value C. In a real situation, it appears to be difficult for tablet friability and dissolution response to satisfy the necessary conditions for the curve $f(x,y) = C$, respectively. In other words, no tablets can be obtained with zero crushing strength; however, if $x = 0, y = 0$, the tablet friability response curve should remain $f(x,y) = C$. As a consequence, the quadratic response model does not adequately represent the true response surface.

In addition, the authors stated that "The friability contour plot consists of a series of ellipsoidal curves" (p. 1375) in the *Results* and *Discussions* section. There was no proof or test for ellipsoids, $Z^2 = AX^2 + BY^2 + C$. An ellipsoid is defined (4) as a surface, all plane sections of which are ellipses or circles. Mathematically speaking, $Z^2 = AX^2 + BY^2 + C$, if A and B are negative, the cross sections are all ellipses, and the surface is an ellipsoid. The Eq. 1 mathematical form does not automatically equate with the equation $Z^2 = AX^2 + BY^2 + C$.

It is a suitable approach to sketch a graph geometrically for the range of tablet specifications to obtain a desired quality product. A particularly chosen mathematical model should be carefully examined and thoroughly tested to determine the suitability and validity of the model for explaining scientific observations.

A Rebuttal on a Second-Degree Polynomial Mathematical Model Used to Evaluate the Effect of Moisture and Crushing Strength on Tablet Friability and *In Vitro* Dissolution

Keyphrases □ Dissolution—*in vitro*, effect of moisture and crushing strength, friability □ Crushing strength—effect on tablet friability and *in vitro* dissolution □ Friability—effect of moisture and crushing strength

To the Editor:

Huang's communication (1) refers critically to the report of Chowhan *et al.* (2); the basis of his criticism stems from his attempt to reproduce the response surface contour plots in Figs. 5 and 6 using the regression coefficients given in Table I (1) by means of a program package[1], RSREG, on a computer[2]. To confirm our results, the experimental data were evaluated by the same program package[1] and computer[2] and a completely separate data analysis package, RSM[3]. The results from both analyses were consistent with the results reported earlier (2) in Figs. 5 and 6. Closer scrutiny of the published regression coefficients in Table I (2) revealed a printing error; coefficient b_3 for tablet friability should read (positive) +0.06228 rather than (negative) −0.06228. This makes the discriminant $B^2 - 4AC$ negative, which corresponds to an elliptical level curve with an elliptical parabaloid surface that opens upwards. These results are completely consistent with the model chosen over the ranges evaluated. The tablet crushing strength and the granulation moisture were evaluated only within the practical limitations of tableting. It was stated clearly that within the practical ranges of tablet crushing strength and granulation moisture content, the data could be analyzed using a general quadratic response surface model. Within the practical limitations of tableting, the usefulness of this method in establishing *rational* specifications for the in-process variables, such as granulation moisture (x) and initial tablet crushing strength (y), to ensure proper control of the tablet friability and *in vitro* dissolution was also discussed. Since the experimental data were evaluated within the practical limitations of tableting, and this point was emphasized in the discussion, there is no justification for Huang to be critical of conditions such as $f(x,y) = C$ with $x = 0, y = 0$, which are unrealistic and of no consequence for optimizing *in vitro* dissolution and tablet friability.

Table I (2) gives the values of multiple correlation coefficients. The model was tested using lack-of-fit, F ratio, and t test. It was stated in the report that contour curves

0022-3549/83/0900-1097$01.00/0

were derived and drawn using the SAS contour plot procedure, RSREG. No further clarification was deemed necessary.

Since the model tested in the paper is $Z = AX^2 + BXY + CY^2 + DX + EY + F$, the possible contour surfaces are hyperbolic paraboloid, elliptic paraboloid, and an elliptic cylinder, depending on the sign of the coefficients of the equation. The dictionary definition (3) of the suffix "-oid" is, "having the form or appearance of." In the two-dimensional representation of the contour surface, the dictionary definition is implicit and the term ellipsoidal translates into elliptical as it is stated in the article. It does not imply that the resulting contour level curves for tablet friability are ellipsoidal in the mathematical sense, but rather is the elliptical projection onto a plane of the response surface at a fixed value of Z.

In conclusion, we iterate that a general multiple linear regression analysis, if used within the practical limitations of tableting, is helpful in understanding the role of the granulation moisture and tablet crushing strength on tablet friability and *in vitro* dissolution. Rational in-process specifications for the granulation moisture content and tablet crushing strength may be established by superimposing the contour plots of tablet friability and drug dissolution.

Model-Independent Method of Predicting Peak, Trough, and Mean Steady-State Levels in Multiple Intravenous Bolus Dosing in Nonlinear Pharmacokinetics

Keyphrases □ Pharmacokinetics—nonlinear, model-independent method, use of simulated data

To the Editor:

Nonempirical methods for dosage predictions and adjustments of drugs showing nonlinear pharmacokinetics are apparently all based on nonlinear pharmacokinetic models. However, the disproportional behavior of such drugs necessitates particularly reliable calculations, which are generally not provided by structured pharmacokinetic models, due to their inherent nonuniqueness and often unrealistic kinetic assumptions. The model-independent method proposed here should overcome some of the disadvantages of such methods.

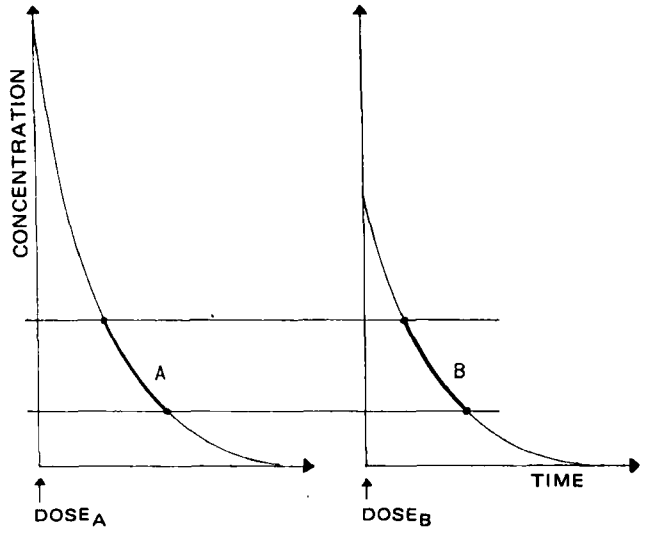

Figure 1—*Illustration of the congruence property of a pharmacokinetic system satisfying the differential equation, Eq. 1: Curve segment A = curve segment B.*

In nonlinear pharmacokinetics it is often observed that the slopes of the drug concentration *versus* time profiles at arbitrary drug levels are independent of the intravenous bolus dose given, which results in the congruence property illustrated in Fig. 1. Such kinetic behavior will be found for any nonlinear (or linear) pharmacokinetic system when the rate of change of the drug level depends only on the drug level, *i.e.*:

$$\frac{dC}{dt} = f(C) \qquad \text{(Eq. 1)}$$

where $f(\ )$ can be any function only dependent on the concentration C. For example, a parallel first-order and Michaelis–Menten elimination:

$$\frac{dC}{dt} = -kC - \frac{V_m C}{K_m + C} \qquad \text{(Eq. 2)}$$

will result in this behavior; so will any other system incorporating nonlinear binding, excretion, metabolism, *etc.*, as long as the kinetics can be described in the general form of Eq. 1. Due to the model-independent nature of the method proposed, there is of course no need to postulate a specific kinetic relationship. The congruence property (Fig. 1) makes drug level predictions particularly simple: Once drug level data from an intravenous bolus injection have been well approximated by an arbitrary function then this function can serve as a base function for drug level predictions. For example, to predict the drug level profile at steady state starting at point P (Fig. 2), the corresponding point P′ on the base curve is found. The base curve segment starting at P′ and stretching over a time interval of length T (where T is the dosing period) then defines the steady-state profile (Fig. 2).

The peak and trough levels at steady state can be derived from the base function as follows: The difference between the peak and trough levels at steady state is equal to the concentration increment, ΔC_D, resulting from the dose injected at the completion of the dosing period:

$$C_{ss}^{max} - C_{ss}^{min} = \Delta C_D \qquad \text{(Eq. 3)}$$

Equation 3 can be transformed into the equivalent base

0022-3549/83/0900-1098$01.00/0

were derived and drawn using the SAS contour plot procedure, RSREG. No further clarification was deemed necessary.

Since the model tested in the paper is $Z = AX^2 + BXY + CY^2 + DX + EY + F$, the possible contour surfaces are hyperbolic paraboloid, elliptic paraboloid, and an elliptic cylinder, depending on the sign of the coefficients of the equation. The dictionary definition (3) of the suffix "-oid" is, "having the form or appearance of." In the two-dimensional representation of the contour surface, the dictionary definition is implicit and the term ellipsoidal translates into elliptical as it is stated in the article. It does not imply that the resulting contour level curves for tablet friability are ellipsoidal in the mathematical sense, but rather is the elliptical projection onto a plane of the response surface at a fixed value of Z.

In conclusion, we iterate that a general multiple linear regression analysis, if used within the practical limitations of tableting, is helpful in understanding the role of the granulation moisture and tablet crushing strength on tablet friability and *in vitro* dissolution. Rational in-process specifications for the granulation moisture content and tablet crushing strength may be established by superimposing the contour plots of tablet friability and drug dissolution.

Model-Independent Method of Predicting Peak, Trough, and Mean Steady-State Levels in Multiple Intravenous Bolus Dosing in Nonlinear Pharmacokinetics

Keyphrases □ Pharmacokinetics—nonlinear, model-independent method, use of simulated data

To the Editor:

Nonempirical methods for dosage predictions and adjustments of drugs showing nonlinear pharmacokinetics are apparently all based on nonlinear pharmacokinetic models. However, the disproportional behavior of such drugs necessitates particularly reliable calculations, which are generally not provided by structured pharmacokinetic models, due to their inherent nonuniqueness and often unrealistic kinetic assumptions. The model-independent method proposed here should overcome some of the disadvantages of such methods.

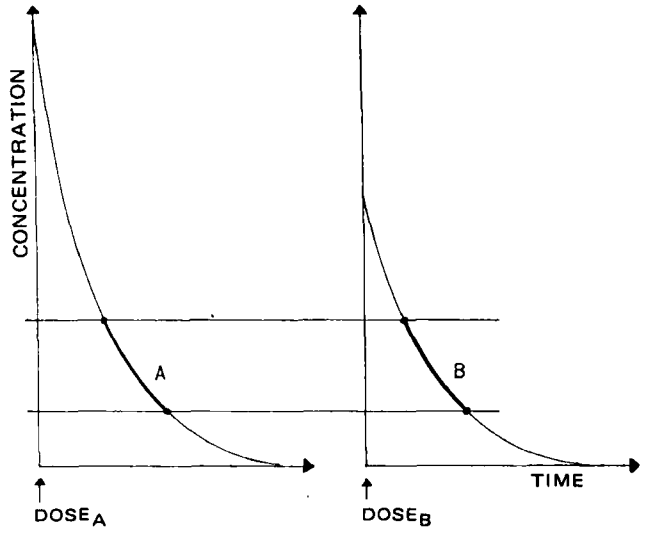

Figure 1—*Illustration of the congruence property of a pharmacokinetic system satisfying the differential equation, Eq. 1: Curve segment A = curve segment B.*

In nonlinear pharmacokinetics it is often observed that the slopes of the drug concentration *versus* time profiles at arbitrary drug levels are independent of the intravenous bolus dose given, which results in the congruence property illustrated in Fig. 1. Such kinetic behavior will be found for any nonlinear (or linear) pharmacokinetic system when the rate of change of the drug level depends only on the drug level, *i.e.*:

$$\frac{dC}{dt} = f(C) \qquad \text{(Eq. 1)}$$

where $f(\ )$ can be any function only dependent on the concentration C. For example, a parallel first-order and Michaelis–Menten elimination:

$$\frac{dC}{dt} = -kC - \frac{V_m C}{K_m + C} \qquad \text{(Eq. 2)}$$

will result in this behavior; so will any other system incorporating nonlinear binding, excretion, metabolism, *etc.*, as long as the kinetics can be described in the general form of Eq. 1. Due to the model-independent nature of the method proposed, there is of course no need to postulate a specific kinetic relationship. The congruence property (Fig. 1) makes drug level predictions particularly simple: Once drug level data from an intravenous bolus injection have been well approximated by an arbitrary function then this function can serve as a base function for drug level predictions. For example, to predict the drug level profile at steady state starting at point P (Fig. 2), the corresponding point P′ on the base curve is found. The base curve segment starting at P′ and stretching over a time interval of length T (where T is the dosing period) then defines the steady-state profile (Fig. 2).

The peak and trough levels at steady state can be derived from the base function as follows: The difference between the peak and trough levels at steady state is equal to the concentration increment, ΔC_D, resulting from the dose injected at the completion of the dosing period:

$$C_{ss}^{max} - C_{ss}^{min} = \Delta C_D \qquad \text{(Eq. 3)}$$

Equation 3 can be transformed into the equivalent base

0022-3549/83/0900-1098$01.00/0

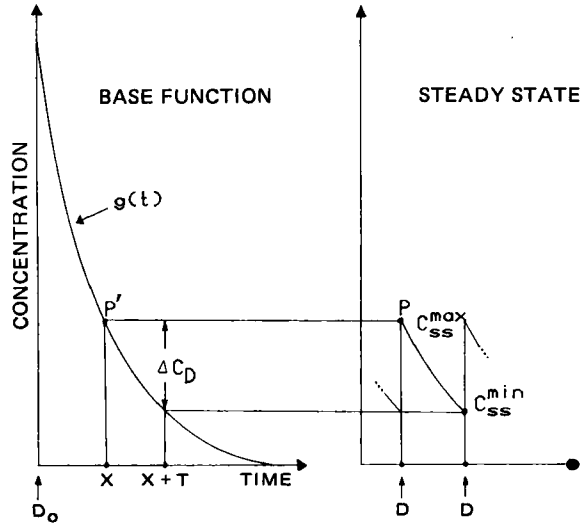

Figure 2—*Base function approach to obtain peak, trough, and mean steady-state levels in multiple intravenous bolus dosing in nonlinear pharmacokinetics.*

function relationship (Fig. 2):

$$g(x) - g(x + T) = \Delta C_D \qquad \text{(Eq. 4)}$$

The basic principle behind the methodology expressed by Eq. 4 is simply to find a certain level $g(x)$ (point P′, Fig. 2) on the base function, which over a period (x to $x + T$) equal to the dosing period T results in a reduction $g(x) - g(x + T)$, which is equal to the concentration increment Δc_D resulting from the maintenance dose. The particular curve segment on the base curve with the property expressed by Eq. 4 is determined numerically by finding the particular value of the unknown quantity x which satisfies Eq. 4. The method assumes that the pharmacokinetics show a dose linear boundary condition, so that c_D is proportional to the dose:

$$\Delta C_D = D/V \qquad \text{(Eq. 5)}$$

This appears to be a reasonable assumption, since the nonlinearity of the drug is more likely due to secretion and metabolic processes than to its initial distribution. The proportionality term, V, in Eq. 4 can be estimated from the base function and its intravenous bolus dose D_0:

$$V = D_0/g(0) \qquad \text{(Eq. 6)}$$

Substituting Eqs. 5 and 6 into Eq. 4 yields the following final expression:

$$g(x + T) + \frac{D}{D_0} g(0) - g(x) = 0 \qquad \text{(Eq. 7)}$$

If the function g fitted to the single-dose data is monotonically decreasing and D_0 has been chosen slightly larger than a normal loading dose so that $g(0) > C_{ss}^{max}$, then Eq. 7 can be solved for x to subsequently give the steady-state peak and trough levels (Fig. 2):

$$C_{ss}^{max} = g(x) \qquad \text{(Eq. 8)}$$

$$C_{ss}^{min} = g(x + T) \qquad \text{(Eq. 9)}$$

Thus, the procedure to determine the steady-state peak and trough levels resulting from intravenous bolus doses D, injected at regular dosing intervals T, can be summarized as follows: Plasma level data from an intravenous bolus dose $D_0 (D_0 > D$, *e.g.*, a loading dose) is obtained and an arbitrary, monotonically decreasing function is fitted to the data to give the base function g. The dose D_0 should be chosen sufficiently large to ensure that the initial base function value $g(0)$ is larger than the expected steady-state peak level. Equation 7 is then solved numerically for x. Most computer program libraries for scientific computations will have programs suitable for this task (1, 2). The peak and trough levels are subsequently calculated from the base function according to Eqs. 8 and 9.

The mean steady-state level, $\bar{C}_{ss}$, can also be calculated from the base function once x has been found:

$$\bar{C}_{ss} = \int_x^{x+T} g(t)dt/T \qquad \text{(Eq. 10)}$$

The sum of exponential functions which are fitted so successfully to intravenous bolus data in linear pharmacokinetics apparently do not fit nonlinear pharmacokinetic data properly. Preliminary investigations were, therefore, carried out to identify a suitable type of function that could be used. It was found that the following empirical function:

$$g(t) = \frac{p_1 e^{-p_2 t}}{1 + e^{p_3 - p_4 t}} \qquad p_i > 0 \qquad \text{(Eq. 11)}$$

produced excellent fit to all typical Michaelis–Menten type data investigated. Extension of the numerator and denominator (Eq. 11) to include more exponential terms may perhaps be fairly universally applicable to most nonlinear pharmacokinetic data.

The following example using simulated data illustrates the methodology. Fifteen concentration–time data with 10% normally distributed errors added were generated from the arbitrarily chosen nonlinear model, Eq. 2. The kinetic parameters $V_m = 12$, $K_m = 27$, $k = 0.08$, $C(0) = D/V = 70$, $t = 0.2,, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, 2.0, 2.5, 3.0, 3.5, 4$, and 8 were chosen to produce a pronounced nonlinearity indicated by a typical Michaelis–Menten type semilogarithmic concavity. Using the nonlinear regression program FUNFIT (3), the empirical equation Eq. 11 produced an excellent least-squares fit to the simulated data with $p_1 = 494$, $p_2 = 0.532$, $p_3 = 1.88$, and $p_4 = 0.414$.

Equation 7 was subsequently used to make steady-state predictions for a maintenance dose half the size of the above loading dose when given every 4 hours. This was done by inserting Eq. 11 into Eq. 7 with $D/D_0 = 0.5$ and $T = 4$ to give:

$$\frac{p_1 e^{-p_2(x+4)}}{1 + e^{p_3 - p_4(x+4)}} + 0.5 \frac{p_1}{1 + e^{p_3}} - \frac{p_1 e^{-p_2 x}}{1 + e^{p_3 - p_4 x}} = 0 \qquad \text{(Eq. 12)}$$

This equation was solved numerically for x with the above least-squares p-values using a fairly standard, commonly used root-finding algorithm (1). The peak, trough, and mean steady-state levels $C_{ss}^{max} = 47.7$, $C_{ss}^{min} = 15.0$, and $\bar{C}_{ss} = 29.8$ were calculated from the obtained x value ($x = 1.64$) according to:

$$C_{ss}^{max} = \frac{p_1 e^{-p_2 x}}{1 + e^{p_3 - p_4 x}} \qquad \text{(Eq. 13)}$$

$$C_{ss}^{min} = \frac{p_1 e^{-p_2(x+4)}}{1 + e^{p_3 - p_4(x+4)}} \qquad \text{(Eq. 14)}$$

$$\bar{C}_{ss} = \frac{1}{4}\int_x^{x+4} \frac{p_1 e^{-p_2 t}}{1 + e^{p_3 - p_4 t}}\, dt \qquad \text{(Eq. 15)}$$

The integral in Eq. 15 was evaluated numerically by a commonly used integration algorithm (4).

Special caution must be taken in applying a loading dose of a nonlinear drug. It may not be desirable to use a loading dose for a drug showing a narrow therapeutic index. However, in certain clinical situations it may be necessary to quickly establish high therapeutic levels by a loading dose. For example, the treatment of an epileptic emergency may call for an intravenous loading dose of phenytoin (5). The loading dose required for the method only needs to be slightly larger than a normal loading dose.[1] It should, therefore, not add much additional risk to the administration of such a loading dose. The method may also be used in dosing adjustments requiring lower steady-state drug levels, in which case the drug level data needed to make the predictions may be obtained from the later part of the dosing period.

[1] However, if the function $g(\ )$ is well chosen, it can be used to extrapolate to required levels and a loading dose may not be required.

BOOKS

Progress in Medicinal Chemistry, Vol. 19. Edited by G. P. ELLIS and G. B. WEST. Elsevier Biomedical Press BV, Amsterdam, The Netherlands. 1982. 345 pp. 14 × 21 cm. Price $93.50 (Dfl. 220).

Contained in this volume are six reviews of independent topics covering a variety of subjects. Chapter I, "Immunopharmacology of Gold," by A. J. Lewis and D. T. Walz denotes the pathology of rheumatoid arthritis, the historical use of gold for therapeutic purposes, pharmacokinetics of gold compounds, and gold–protein interaction with tissue sulfhydryl groups, hydrolytic enzyme, prostaglandin synthetase complement, and collagen. The response systems as well as their current clinical uses in rheumatoid arthritis, pemphigus, asthma, and cancer are described.

Chapter II, "Calcium and Histamine Secretion from Mast Cells," by F. L. Pearce deals with the role of calcium in histamine release, membrane ionophones, phospholipid vesicles and permeability, and calcium pools inside and outside the cell. The activation of vasoamine release by the mast cell *via* the translocation of calcium was related to membrane phosphatidylinositol metabolism, phospholipid methylation, and cAMP levels. Known inhibitors of these processes were evaluated.

Chapter III, "Biological and Pharmacological Properties of Phospholipids," by A. Bruni and P. Palatini is a discussion of the phospholipid bilayer model including flexibility, stability, asymmetry, head groups, and fusion of the components. Phospholipid–protein interrelations, including lipid-binding proteins, mode of association, specificity of the interreaction, mutual influence of components in the membrane, and structural models are presented. The pharmacological aspects of liposomes or bilayer envelopes including pharmacokinetics; interaction with cells; delivery of drugs, genetic material, or immune components; and lipid chemical mediators were presented by the authors.

Chapter IV, "Cyclophosphamide Analogues," by G. Zon includes a cursory historical review of cyclophosphamide as an antineoplastic agent including novel chemical substitutions, related conformational effects, prodrug models, structure–activity relationships of active metabolites, and miscellaneous analogues.

Chapter V, "Chartruesin, a Glycosidic Antitumor Antibiotic from *Streptomyces*," by J. A. Beisler covers the natural, microbial, and biochemical sources and structure determination of chartruesin. Partial and total synthetic routes of aglycones are reviewed. The antitumor activity, mode of action, and toxicity of chartruesin are briefly eluded to in the discussion.

Chapter VI, "Recent Progress in the Medicinal Chemistry of 2,4-Diaminopyrimidines," by B. Roth and C. C. Cheng covers the classical aspects of antimetabolites of folic acid and descriptions of dihydrofolate reductase enzymes from bacteria and vertebrate sources. Pharmacological action was discussed in three areas: (*a*) antibacterial action of diaminopyrimidines of the 2,4-diamino-5-(substituted benzyl) pyrimidines, 6-substituted 2,4-diamino-5-benzyl pyrimidines, isosteres of the benzylpyrimidines, dihydro-*sym*-triazines, and bicyclic analogues of diamino-pyrimidines; (*b*) antimalarial dihydrofolate reductase inhibitors—pyrimethamine and cycloguanil, monocyclic 2,4-diamino-pyrimidines and isosteres, dihydro-*sym*-triazines, and quinazolines; (*c*) anticancer—dihydrofolate reductase inhibitions by methotrexate, modifications of the glutamic acid, benzene ring, bridge atoms between the rings, and pteridine portions. Miscellaneous and nonclassical dihydrofolate reductase inhibitors are included in the chapter.

Whereas all six of these topics are relevant to medicinal chemistry, this reviewer found the text somewhat disappointing from two aspects: (*a*) much of the material was redundant with basic conceptual ideas presented on numerous occasions in the literature; (*b*) the topics selected were not those that would be at the forefront of current research today. However, the chapters are well referenced with a number of figures, tables, and diagrams, and the text is organized and clearly written for understanding by the reader. The major use of the text as a reference book would be for graduate students and individuals not versed in these areas of research. The current status of each of the six topics is accurately assessed by the authors, and the text is an excellent overview of both chemical and biological ideas regarding the topics, which is important in medicinal chemistry because of the diversity of the field.

Neither Black Nor White, But Very Gray

Undoubtedly, every reader of this *Journal* has heard the observation stated that "no drug is completely safe." Indeed, most of our readers have probably articulated this point themselves on one or more occasion.

Generally, the need to bring out this fact comes up in discussions with the general public. The average lay person does not have the training, background, or sophistication to understand or grasp the concept that there are no real absolutes in the case of either safety or toxicity.

Although we might cringe a bit at the simplification involved, this writer once heard a pharmacologist try to explain this point to a lay audience; he stated that "chemotherapeutic agents are virtually nothing more than selective poisons that are administered to humans in carefully controlled quantities."

In this, the pharmacologist was simply paraphrasing Paracelsus (1493–1541) who is quoted as having written: "All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy."

Virtually every substance known has some element of hazard associated with it, depending upon the form of exposure, duration of exposure, concentration of the substance, total intake involved, and similar considerations. And the more active or effective the substance is for some desired purpose, usually the more that its untoward effects or negative properties increase as well.

All of this gives rise to risk–benefit analysis or evaluations. Scientists and health care practitioners deal with these concepts countless times each day, and the concepts therefore should be almost second nature to them.

But on rare occasions, not only individual scientists but even relatively large groups of scientifically or medically trained people will react or overreact with apparently the same lack of understanding and judgment that we associate with the lay public.

About twenty years ago, Rachel Carson published her classic work titled "Silent Spring." This book had as its central theme a thesis that our indiscriminate use of pesticides was having a totally disastrous side effect on all animal life and particularly on the bird population.

Granted, she was guilty of some over-exaggeration, and she wrote with the high intensity of a typical crusader. But there also was a very significant element of truth in her position—truth that was later brought out by the DDT problems of the 1960's and infamous Kepone revelations of the mid-1970's.

Unfortunately, however, the scientific community as a whole did not assess her contentions in a calm, cool, and deliberate manner. Instead, scientists—and, in particular, chemists active in the American Chemical Society—scoffed at Carson's contentions and subjected her personally to the severest degree of ridicule. It wasn't until years later that the error of these unfortunate actions, which were prompted out of a misguided or excessive sense of loyalty to the chemical industry, was generally acknowledged.

Over the years, there have been other regrettable instances of knee-jerk reactions by scientists and scientifically trained people: groups that should really know better than to allow themselves to act either precipitiously or without appropriate balance.

One of the most recent of such incidents occurred this past June when the House of Delegates of the American Medical Association, by voice vote, approved the adoption of "an active public information campaign to prevent irrational reaction and unjustified public fright and to prevent the dissemination of possibly erroneous information" about the health hazards of dioxin. The language included with the resolution also spoke of "hysterical malreporting" and "a witch hunt" of dioxin.

Certainly, the facts presently known about the toxicity and hazards of dioxin do not justify the sensationalist press treatment and some of the extreme actions being recommended or taken with respect to controlling potential exposure to the agent. But, on the other hand, sufficient information is known to justify significant caution in dealing with it.

The regrettable aspect of the AMA policy action was to deal with the exaggerations by overreacting in the opposite direction. And the eager press and broadcast media were quick to publicize the action with stories carrying titles such as "AMA Votes to Fight Dioxin 'Witch Hunt.' "

Fortunately, cooler heads quickly prevailed at the AMA, and efforts were promptly taken to put their position in better public perspective—but, sadly, AMA credibility had already been damaged by the initial press reports.

Without citing additional examples, let it suffice to say that other areas of science, including the pharmaceutical sciences, have also had their share of such moments of embarrassment.

Hopefully, we will all learn from these experiences that while others may adopt positions that we see as extremist, scientists must avoid the temptation to take opposite positions that are equally extreme. Rather, the correct position—which is rarely, if ever, either black or white—must be sought and identified.

As one wag put it to us recently, "Scientists must keep their heads while all about them are losing theirs!"

LITERATURE SURVEY

Physiologically Based Pharmacokinetic Modeling: Principles and Applications

LEONARD E. GERLOWSKI and RAKESH K. JAIN ˣ

Received March 25, 1982, from the *Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, PA 15213.*

Pharmacokinetic models are used to describe the time-dependent distribution and disposition of a substance in a living system and, as such, have numerous uses in clinical applications and drug design. For medicinal purposes, pharmacokinetics can be used to estimate optimal drug scheduling and dosage regimens. For industrial toxins, pharmacokinetics can be used to aid in determining safe working environments. The modeling procedure is useful in animal and clinical applications, and for obtaining fundamental knowledge of the transport and metabolism of a substance *in vivo*. In this paper we present a review of physiologically based pharmacokinetics in the hope of understanding and increasing the use of this modeling technique. Recent review articles on the subject have primarily focused on the use of physiologically based pharmacokinetics in cancer treatment. The most comprehensive of these articles discusses proper formulation of a model and development of the equations in detail (1). Other reviews on the subject discuss the application of this modeling technique to certain chemotherapeutic agents (2, 3). We present a rather extensive compilation of the literature on all substances modeled to date with this technique and discuss formulation of the equations, limitations of the modeling process, and areas of future applications to provide a unified framework for the understanding of physiologically based pharmacokinetics.

BACKGROUND

The term pharmacokinetics refers to prediction of the time-dependent concentrations of a substance in a living system. Two approaches currently in use are based on classical and physiological models. The classical approach utilizes a lumped-compartmental system and fits exponential functions to time-dependent plasma concentration data. The physiologically based approach separates the body into a number of anatomical compartments, each compartment interconnected through the body fluid systems. The physiologically based approach also has the advantages of interspecies scalability, specific organ metabolism, specific organ transport, and specific organ binding properties.

Classical pharmacokinetic techniques are used to describe drug uptake with one- or multiple-compartmental systems. The solutions of differential equations that describe the time-dependent concentration behavior of the system consist of a series of decaying exponentials. The coefficients of the exponentials are fit to plasma, urinary, or some other obtainable tissue concentration data (4). Although these models are useful in many clinical situations (5), this modeling procedure does not describe a physiological system with large tissue-to-tissue concentration differences. In instances where the drug concentration is of the same order of magnitude over a large number of body organs, or certain other constraints are satisfied, a multiple-organ body system may indeed be simplified to a two-compartment model (6). For example, this intercompartmental variation is tolerable for drugs with a low therapeutic index; but substances that show high affinities for certain organs, are toxic to certain tissues, or have a specific target organ are not well described by the classical pharmacokinetic modeling technique (7).

The uptake of a drug is known to be dependent on organ perfusion rate, tissue volume, and many other biochemical and physiological parameters. The physiological parameters such as tissue volume, *etc.*, are scalable from species to species by a proportionality constant times body weight to some power (8, 9). If the uptake mechanisms are similar in small and large species, the biochemical and physiochemical parameters should be scalable through the species. However, the parameters obtained from classical

0022-3549/83/1000-1103$01.00/0

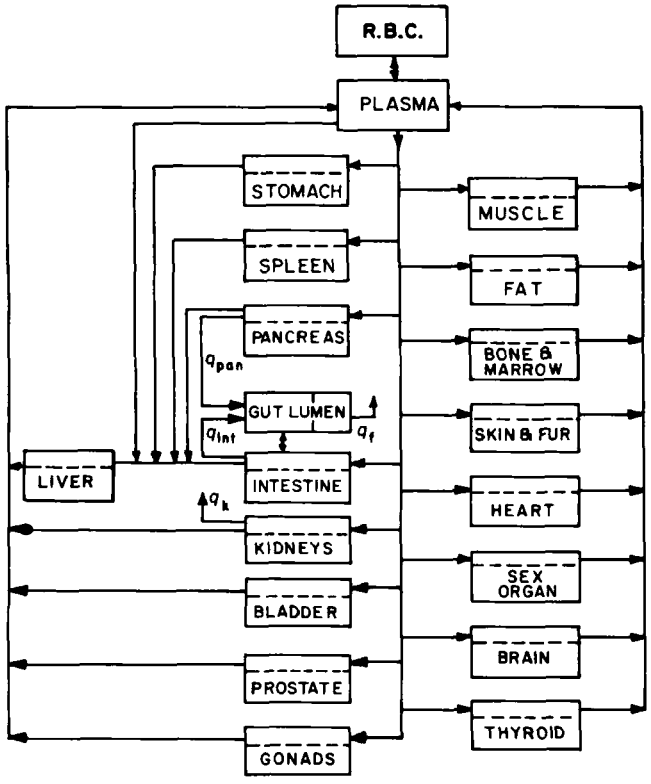

Figure 1—*Example of a comprehensive physiologically based pharmacokinetic model flow scheme (15). Reprinted from the* Annals of Biomedical Engineering *with permission; copyright 1982, Pergamon Press, Ltd.*

pharmacokinetics contain little physiological basis and, hence, show no scalability from species to species. Therefore, to describe a highly toxic substance with classical pharmacokinetics, all experimentation must be performed on a particular species (*e.g.*, humans). The ability to scale-up a model to humans based on experiments with smaller species (mice, rats, dogs, *etc.*), could lead to the safer use of drugs.

The limitations of the classical approach have led to the need for a physiologically based approach. The first use of physiological parameters in modeling appeared in the 1930's when Teorell (10) included mass balances on specific tissues, with specific tissue volume and specific organ perfusion rates. In 1960, Bellman *et al.* (11) included capillary, interstitial, and cellular subcompartments in the modeling of drug distribution in organs. In this work, a perfused compartment with vascular, interstitial, and cellular spaces was solved analytically and applied to chemotherapy (11). In the late 1960's, Bischoff and Brown proposed a model which adapted and extended these ideas to predict drug distribution in mammals (12). This approach was later improved to describe time-dependent concentration profiles in various organs and interspecies scale-up. This physiologically based modeling technique has since been applied to numerous substances with much success.

DEVELOPMENT OF A MODEL

Compartmental analysis of a system requires a rational basis for selection of the size and number of compartments. In the classical pharmacokinetic approach, certain tissues of the body are lumped together to form one large compartment (such as a rapidly equilibrated compartment). The physical existence of such compartments does not realistically occur and is not easily visualized (13). In physiologically based pharmacokinetics, each compartment represents a particular organ or tissue and has anatomical significance. One approach in physiologically based pharmacokinetic modeling would be to model a whole body by performing mass balances on each organ and tissue. However, besides the cost of developing such an extensive model, such detailed distribution information is not required for most substances. For example, certain substances are known to accumulate primarily in a few organs [*e.g.*, cadmium accumulates primarily in the liver and kidneys (14)]. Other substances are specifically toxic to certain organs (*e.g.*, doxorubicin is a known cardiotoxin). Still other agents are desired to be toxic to a specific tissue (*e.g.*, anticancer agents to tumors) or are desired to accumulate in a target organ (*e.g.*, general anesthetics in the nervous system). This information is applied with physiological (tissue volumes and blood flow rates), physicochemical (binding, lipid solubility, ionization, *etc.*), and pharmacological (mechanism of transport, sites of action, *etc.*) knowledge of the substance in the body to simplify the model.

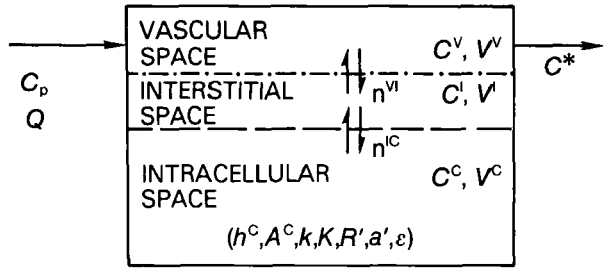

Figure 2—*Schematic representation of the vascular, interstitial, and intracellular spaces of an organ. The flux of the substance occurs across the dashed lines; the arrows represent the direction of blood flow.*

In the development of a physiological model, a flow scheme is assumed with the desired organs describing the species anatomically. Figure 1 is an interpretation of the circulatory flow scheme of a rat used to describe zinc uptake (15). Each organ is represented by a compartment, and all compartments are interconnected through the circulatory system as in the body. The physiological basis is maintained in the enterohepatic system with the liver, gut, spleen, and pancreas interconnected anatomically. Also, the substance is tranferred from the liver to the gut lumen by the biliary system. The large number of organs incorporated in this flow scheme represents an attempt to develop a comprehensive model.

Each compartment is considered to consist of three well-mixed phases (referred to as subcompartments): (*a*) a vascular section through which the compartment (organ) is perfused with blood; (*b*) an interstitial space in the tissue which forms a matrix for the tissue cells; and (*c*) a cellular space consisting of the tissue cells that comprise the compartment (organ). This type of compartment is shown schematically in Fig. 2. Following injection, *via* any route of administration, the uptake of the substance in the compartment occurs through influx with the afferent blood in the vascular subcompartment. Each subcompartment is considered to be a well-mixed phase; therefore, the efferent blood has the same concentration as the vascular

subcompartment. The substance crosses the capillary wall and diffuses into the interstitial subcompartment. Then, the substance moves across the cellular membrane from the interstitial fluid into the cells. In each of the subcompartments, the agent may degrade by metabolic action or bind to an endogenous substance. Specific binding to a particular enzyme or cellular component may occur to allow for the therapeutic or toxic action of the agent. To form the model, mass balance equations on the substance in vascular, interstitial, and cellular subcompartments of organ i, respectively, are written as:

$$V_i^{\mathrm{V}} \frac{dC_i^{\mathrm{V}}}{dt} = Q_i C_{\mathrm{p}} - Q_i C_i^{\mathrm{V}} - n_i^{\mathrm{V-I}} \qquad \text{(Eq. 1)}$$

$$V_i^{\mathrm{I}} \frac{dC_i^{\mathrm{I}}}{dt} = n_i^{\mathrm{V-I}} - n_i^{\mathrm{I-C}} \qquad \text{(Eq. 2)}$$

$$V_i^{\mathrm{C}} \frac{dC_i^{\mathrm{C}}}{dt} = n_i^{\mathrm{I-C}} \qquad \text{(Eq. 3)}$$

The flux (n_i) in the above equations is used to describe either passive or carrier-mediated transport across the capillary wall ($n_i^{\mathrm{V-I}}$) or cellular membrane ($n_i^{\mathrm{I-C}}$). These mass balance equations are written for each organ. A mass balance on the substance is made on the plasma compartment to close the balance on the system:

$$V_{\mathrm{p}} \frac{dC_{\mathrm{p}}}{dt} = \sum_i Q_i C_i^{\mathrm{V}} - Q_{\mathrm{p}} C_{\mathrm{p}} + g(t) \qquad \text{(Eq. 4)}$$

where $g(t)$ is the intravenous injection function. The mathematical form of $g(t)$ will depend on the form of injection, *e.g.*, pulse, step input (16, 17). Injection into some other area of the body can easily be incorporated in such a model. These equations (Eqs. 1–4) are simplified in that metabolism, transport, binding, and excretion terms are not included. These processes are described in detail later in this article.

The uptake of a substance in a system thus can be described by a set of equations modeling the drug uptake in each subcompartment as a function of time. Although these subcompartments have a physiological basis, it is possible to measure reliably only total tissue concentration. [Jain *et al.* measured the concentration of methotrexate in the tumor interstitial fluid (18).] The total compartment (organ) concentration, C_i, thus is described by volume averaging the subcompartment concentrations:

$$C_i = \frac{C_i^{\mathrm{V}} V_i^{\mathrm{V}} + C_i^{\mathrm{I}} V_i^{\mathrm{I}} + C_i^{\mathrm{C}} V_i^{\mathrm{C}}}{V_i} \qquad \text{(Eq. 5)}$$

Flow Limitation (One Compartment)—When one of the steps in mass transfer is rate limiting, a compartment may be simplified from the three-subcompartment model to a model with one or two subcompartments. The flow-limited assumption to mass transfer is made for organs not well perfused by the circulatory system. This assumption implies that the transfer across the capillary wall and across the cellular membrane is very rapid when compared with the perfusion rate of the tissue. In essence, the vascular, interstitial, and cellular subcompartments are in equilibrium, and the mass balance on the compartment is written as:

$$V_i \frac{dC_i}{dt} = Q_i \left(C_{\mathrm{p}} - \frac{C_i}{R_i} \right) \qquad \text{(Eq. 6)}$$

The term R_i in Eq. 6 is the partition coefficient and is the ratio of the drug concentration in the tissue to the drug concentration in the plasma at equilibrium.

Membrane Limitation (Two Subcompartments)—Another simplification occurs when the transfer across the cell membrane is the rate-limiting step; a two-subcompartmental model is assumed for the tissue. The two subcompartments are the cellular space, which consists of the tissue cells, and the extracellular space, which consists of the vascular and interstitial subcompartments in equilibrium, separated by a cellular membrane across which transport occurs. A mass balance on the extracellular space is:

$$V_i^{\mathrm{E}} \frac{dC_i^{\mathrm{E}}}{dt} = Q_i (C_{\mathrm{p}} - C_i^{\mathrm{E}}) - n_i^{\mathrm{E-C}} \qquad \text{(Eq. 7)}$$

The flux across the cell membrane ($n_i^{\mathrm{E-C}}$) accounts for net transfer to the cellular space; therefore, the accumulation in the cellular space can be described as:

$$V_i^{\mathrm{C}} \frac{dC_i^{\mathrm{C}}}{dt} = n_i^{\mathrm{E-C}} \qquad \text{(Eq. 8)}$$

Again, the concentration of the whole organ (tissue) is volume averaged as:

$$C_i = \frac{V_i^{\mathrm{E}} C_i^{\mathrm{E}} + V_i^{\mathrm{C}} C_i^{\mathrm{C}}}{V_i} \qquad \text{(Eq. 9)}$$

Thus, Eqs. 7–9 and Eq. 4 are written over the system of organs to describe a complete mass balance of the agent being studied.

If the limitation to transfer of the agent is across the capillary wall, then the transfer is assumed to be capillary membrane limited. In this instance, the interstitial and cellular spaces are assumed in equilibrium, and a two-subcompartmental model is obtained similar to the cell membrane limitation. Equations similar to Eqs. 7–9 are written for the vascular and extravascular spaces to describe such organs.

Transport Mechanism—The transport of a substance across a biological membrane is complex and may occur by passive diffusion, carrier-mediated transport, or both (19). Here, we discuss the mathematical formulation of two simple cases. For the case of passive diffusion the flux across the cell membrane is described by a mass transfer coefficient (h_i) times a concentration driving force:

$$n_i^{\mathrm{E-C}} = h_i \left(C_i^{\mathrm{E}} - \frac{C_i^{\mathrm{C}}}{R_i} \right) \qquad \text{(Eq. 10)}$$

However, in many biological systems the transport across a cell membrane is facilitated by carrier molecules. When this is the case, the flux is described by a saturable form:

$$n_i^{\mathrm{E-C}} = \frac{a_i C_i^{\mathrm{E}}}{b_i + C_i^{\mathrm{E}}} - \frac{\dfrac{a_i C_i^{\mathrm{C}}}{R_i}}{b_i + \dfrac{C_i^{\mathrm{C}}}{R_i}} \qquad \text{(Eq. 11)}$$

When both transport mechanisms exist, the flux term is a linear combination of Eqs. 10 and 11.

For more in-depth studies on transport mechanisms, the reader is referred to treatises on the subject (20, 21).

Binding—Substances are known to bind to plasma,

interstitial, or subcellular proteins, and red blood cells and many other biological components. Details of binding can be found elsewhere (22, 23), but one simple case will be discussed. Binding of most substances follows a Langmuir-type isotherm, and the total amount of drug in a compartment can be expressed as the sum of the free and bound drug:

$$C_i = C_i^* + \frac{a_i' C_i^*}{\epsilon_i + C_i^*} \qquad \text{(Eq. 12)}$$

which can be solved for the free drug concentration (C_i^*). When binding occurs in a subcompartment, only the free agent is available for mass transfer.

Excretion—The excretion of the agent must be taken into account to maintain a complete mass balance of the agent. For compartments such as the liver and kidneys, biliary and urinary excretion must be included, respectively. For example, Eq. 6 for a flow-limited compartment is modified to include an excretion rate term q_i (amount of drug excreted per unit time):

$$V_i \frac{dC_i}{dt} = Q_i \left(C_p - \frac{C_i}{R_i} \right) - q_i \qquad \text{(Eq. 13)}$$

In many cases, the excretion process can be described by a first-order approximation:

$$q_i = k_i C_i \qquad \text{(Eq. 14)}$$

In some cases, the plasma concentration is used instead of the tissue concentration. The linearity constant can be estimated from experimental data; the fraction of the initial dose excreted over a given amount of time (t_O) must satisfy the following equation:

$$\text{(fraction excreted)} \times \text{(initial dose)} = \int_0^{t_O} k_i C_i \, dt \qquad \text{(Eq. 15)}$$

If the excretion kinetics are assumed to be saturable, then:

$$q_i = \frac{v_{max} C_i}{K_e + C_i} \qquad \text{(Eq. 16)}$$

The Michaelis–Menten constant must be determined by fitting the model to the excretion data.

Metabolism—In many biological environments, an agent is unstable and may be altered by chemical reaction. This degradation or change of the agent, referred to as metabolism, must be taken into account to completely describe the distribution and disposition of an agent. In specific instances, the metabolite may be the actual agent of interest (24). The metabolism of an agent in the model is described by a reaction rate $[r_i(t)]$. In most cases of interest, the metabolism reactions are assumed to follow either first-order or Michaelis–Menten saturable kinetics. For first-order kinetics in a flow-limited compartment i, Eq. 6 would become:

$$V_i \frac{dC_i}{dt} = Q_i \left(C_p - \frac{C_i}{R_i} \right) - k_i C_i \qquad \text{(Eq. 17)}$$

For Michaelis–Menten kinetics, Eq. 6 would be:

$$V_i \frac{dC_i}{dt} = Q_i \left(C_p - \frac{C_i}{R_i} \right) - \frac{C_i v_{max}}{K_m + C_i} \qquad \text{(Eq. 18)}$$

The order, rate, and rate constants for metabolism are normally determined from *in vitro* studies. Whenever possible, these *in vitro* rate constants are used to describe metabolism *in vivo*. On many occasions the metabolism of a drug occurs primarily in a particular organ for which the kinetic data may not be readily available. In these instances the constants are obtained as best-fit parameters to pharmacokinetic data. Based on the flow-, capillary-, or membrane-limitation assumptions, equations similar to those of the parent compound are written to describe the pharmacokinetics of the metabolites.

Parameter Estimation—Time-dependent concentration data are obtained from laboratory animals sacrificed at predetermined intervals following an injection. To describe these data, the model parameters must be specified or estimated. The physiological parameters such as blood flow rate (Q_i) and tissue volume (V_i) can be determined from various experimental methods. For most species these values can be readily found in the literature. Kinetic parameters may be determined from separate experiments *in vivo* or *in vitro*. In some cases, the tissue-to-plasma binding constants are measured experimentally following long-term constant infusion. In other cases, the binding constants (R_i) and the passive diffusion coefficients (h_i) are estimated from the long- and short-term data, respectively (25), following a pulse injection. If *in vivo–in vitro* correlations are not available or appropriate, these parameters are determined from best fits of the concentration profile simulations to tissue concentration data. Once all parameter values are specified, the coupled, ordinary, and sometimes nonlinear first-order differential equations which describe the mass balance on the system need to be solved numerically to simulate the data (28).

For details of parameter estimation the reader is referred elsewhere (26, 27).

MODELS FOR SPECIFIC AGENTS

The pharmacokinetics of many substances have been described by this modeling technique. We have divided these models into six categories: (*a*) anticancer agents, (*b*) antibiotics, (*c*) anesthetics, (*d*) single elements (trace metals and ions), (*e*) environmental hazards and toxic substances, and (*f*) others. We realize that in this classification system, some anticancer agents are also antibiotics. Table I is an outline of 37 substances indicating the molecular structure, biological action, several treatment usages (for anticancer agents), the species modeled, and comments about the assumptions and limitations of the particular model. These models are described in more detail in the following section. The physiological parameters for each species are listed in Table II; the physicochemical and biological parameters for each model are tabulated throughout the text.

Anticancer Agents—Most drugs used to treat cancer are toxic to both normal and neoplastic tissues. These drugs are used for therapy in various dosages and schedules, usually given in combination with other antineoplastic agents to obtain optimal therapeutic effects in cancer patients. The high toxicity of these drugs makes it desirable to quantify their intake, distribution, metabolism, and excretion in various tissues of the body. To this extent, physiologically based pharmacokinetics has been

applied to study these processes. These models may be useful in estimating dosages and schedules which ensure that tissue concentrations remain below the toxic level for normal tissue and above the toxic level for neoplastic tissue. Initially, these models are developed for small animals and then scaled-up to humans in hopes of being able to prescribe dosage levels and administration schedules that ensure patient safety and optimal drug usage.

Dactinomycin—Actinomycin is a naturally occurring crystalline antibiotic of which all forms have been synthesized. Dactinomycin (actinomycin D) has been used to treat various neoplasms, including gestational carcinoma, testicular neoplasm, and Wilms tumor. The mechanism of action of dactinomycin includes binding to DNA, thus preventing progression of RNA polymerase along the DNA template. Lethal damage from dactinomycin occurs along the intestinal mucosa. A flow-limited physiologically based pharmacokinetic model was developed by Lutz *et al.* to describe the distribution of dactinomycin in the beagle dog (29) at doses of 0.03 and 0.135 mg/kg iv. The 13-compart-

Table I—Agents Modeled by Physiologically Based Pharmacokinetics

Agent	Chemical Structure	Biological Effect[a]	Model: Reference	Model: Species	Model: Comments
		Chemotherapeutic Agents			
Dactinomycin		-blocks RNA synthesis by binding to DNA -gestational carcinoma, testicular neoplasm, Wilms tumor	(29)	dog	Flow and diffusion limitation
Doxorubicin		-binds to DNA, interferes with DNA function and RNA synthesis	(31)	rabbit, human	Flow limited
		-acute lymphoblastic and acute myeloblastic leukemias, Wilms tumor, neuroblastoma, breast and ovarian carcinomas	(32)	human	Applied previous model (31) to human
			(34)	hamster	Membrane limited
			(33)	mouse	Membrane limited with flow-limited tumor
Ancitabine		-leukemia	(24)	human	Flow limited, Michaelis–Menten kinetics
Cytarabine		-blocks DNA synthesis and introduces moieties into the DNA coding sequence -ovarian cancer	(35)	human	Flow limited, nonlinear metabolism
			(36)	mouse, dog, monkey	Flow limited, nonlinear metabolism
			(38)	mouse	Extends Dedrick model (37) to include intracellular metabolism
			(37)	human	Flow limited, nonlinear metabolism
Pentostatin		-binding inhibitor of adenosine deaminase -leukemia	(39)	mouse	Flow limited
5-Fluorouracil		-anabolic: blocks the methylation reaction of deoxyuridylic acid to thymidic acid, interferes with DNA synthesis; catabolic: degeneration to CO_2 and urea -carcinomas of the colon, rectum, breast, stomach, and pancreas	(40)	rat	Flow limited, saturable excretion, hybrid model
Mercaptopurine		-acute lymphocytic leukemia	(42)	rat	Flow limited

Table I–*Continued*

Agent	Chemical Structure	Biological Effect[a]	Model: Reference	Model: Species	Model: Comments
Methotrexate		-strongly binds to intracellular dihydrofolate and inhibits conversion to tetrahydrofolate (an inhibitor in DNA synthesis) -leukemia, lung tumor, choriocarcinoma, Burkett's lymphoma	(44)	mouse	Flow limited, nonlinear
			(43)	mouse, rat, dogs, monkey, human	Flow limited, nonlinear excretion
			(45)	sting ray	Flow limited
			(25)	rat	Membrane limited, nonlinear transport
			(46)	mouse	Flow limited, hybrid model
			(47)	dog	Hybrid model, nonlinear transport
			(48)	mouse	Hybrid model, membrane limited
			(37)	human	Membrane limited, nonlinear transport
			(18)	rat	Flow limited, nonlinear transport, solid tumor
Cisplatin	 I	-produces intra- and interstrand crosslinks in DNA -metastatic testicular and ovarian tumors	(50)	dog	Flow limited, linear binding, first-order metabolism
Streptozocin		-inhibits DNA synthesis by alkylation of cell components -pancreatic tumor	(51)	mouse	Membrane limited
2-Amino-1,3,4-thiadiazole		-inhibits the action of inosine-5-phosphate dehydrogenase in leukemia cells -melanoma, glioblastoma, lymphosarcoma, leukemia	(52)	mouse, dog, monkey	Flow limited, linear and saturable metabolism
		Antibiotics			
Cephalosporins	 (cefazolin)	-antibiotic	(53)	human	Flow limited
	 (cephalexin)				
	 (cephradine)				
Tetracycline		-antibiotic; exhibits maternal and fetal toxic effects	(16)	rat	Flow limited with placenta compartment
β-Lactam antibiotics	(various)	-antibiotic	(54)	rat	Flow and membrane limited, linear and nonlinear binding (depending on drug)

mental model with linear binding in the tissue used the transport and binding parameters listed in Table III. The authors have compared the cell mass transfer coefficient with blood flow rate per unit volume of normal tissues and have found that both are of the same order of magnitude, thus indicating the appropriateness of the flow-limited assumptions. An exception to the flow-limited assumption was the testis compartment where the perfusion rate was much larger than the mass transfer coefficient, suggesting that the testes, analogous to the brain, have a low permeability membrane barrier. This result has important implications in the treatment of testicular neoplasms.

Doxorubicin—The anthracycline antibiotic doxorubicin hydrochloride[1] has been used in chemotherapeutic treatment of various solid tumors, lymphomas, and sarcomas (*e.g.*, acute lymphoblastic and myeloblastic leukemia, Wilms tumor, neuroblastoma, breast carcinoma, ovarian carcinoma). Doxorubicin exhibits neoplastic effects through interference with DNA functions and RNA synthesis. However, recent studies indicate that binding of the drug to cell membranes may be the lethal step (30). Toxic effects include depression of cell production in bone marrow and dose-dependent cardiomyopathy, thereby limiting dosages to low levels. To this end, Harris and Gross have modeled doxorubicin pharmacokinetics in the rabbit (31), Chan *et al.* in humans (32), Townsend in the hamster (33), and Gerlowski in the mouse (34) (Table IV). The rabbit model of Harris and Gross contains 10 flow-limited compartments. Their model overestimates concentration data at times <5 hr, indicating that a diffusion limitation may exist. These authors have also compared the model simulations with human plasma data and found underprediction at early intervals and overprediction at 24–48 hr. Chan *et al.* adapted the Harris and Gross model to simulate human plasma data. The authors were able to show consistent agreement with normal patients and, in some cases, in patients with significant hepatic dysfunction who show prolonged doxorubicin levels. The human plasma data also exhibited a short-term (2–4 hr) behavior not predicted by a flow-limited model, suggesting the need

to incorporate metabolism and membrane-limited assumptions into such a model.

The mouse and hamster models contain seven organs, all membrane limited, except the tumor compartment in the mouse, which was assumed to be flow limited (33, 35). It is known that doxorubicin metabolizes primarily in the intracellular space. Since the metabolite has similar antineoplastic effects, it was lumped with the drug as doxorubicin equivalents in these models. Good agreement was obtained with both early- and late-interval data, supporting the existence of a membrane limitation. In addition to the lumped doxorubicin analysis, Townsend (33) tried to model the metabolism as saturable intracellular reactions in the liver and kidney using parameters determined *in vitro*. Although no comparison with data for the metabolite was shown, simulations indicate that the metabolite concentrations in the hamster are at least one order of magnitude below the parent drug concentration levels, in contrast to the human data.

Cytarabine—Cytarabine (ara-C) is a neoplastic agent which provides an excellent example of the usefulness of *in vitro* enzyme kinetics in physiologically based pharmacokinetic modeling. Cytarabine is known to metabolize in the liver *via* pyrimidine nucleotide deaminase to 1-β-D-furanosyluracil. For antineoplastic action, cytarabine must be phosphorylated to the nucleotide. It is the nucleotide that is considered to act as an inhibitor of DNA polymerase by incorporation into the DNA template. Cytarabine and its metabolites were modeled in the mouse, dog, monkey, and human by Dedrick *et al.* (35–37) and in the mouse by Morrison *et al.* (38). A six-compartment flow-limited model was developed by Dedrick *et al.* to describe cytarabine distribution and its metabolism to 1-β-D-furanosyluracil by saturable kinetics. This study was one of the first models in the literature to apply *in vitro* saturable kinetic parameters to describe *in vivo* human data (35). In physiologically based pharmacokinetics, models are usually developed for small animals and then scaled-up to humans. In this case, the human model was developed first and then extended to mice, monkeys, and dogs (36) to study interspecies differences in pharmacokinetic modeling. The kidney clearance constant was found to exhibit essentially the same variation with body weight as seen for inulin. This model was later extended by Dedrick *et al.* (37) to include a peritoneal cavity compartment and was used successfully to develop rational protocols to treat patients with ovarian cancer.

The model of cytarabine in the mouse by Morrison *et al.* (38) extends the Dedrick model to include intracellular metabolism of the drug to the active metabolite, arabinoside cytosine triphosphate. The authors applied *in vitro* reaction constants for saturable kinetics to determine cytarabine and triphosphate cytarabine concentration profiles in various tissues. The kinetics of this reaction are strain dependent (as shown in the mouse), perhaps due to different levels of liver deaminase among strains. When scaling-up to humans, these effects must be incorporated with the higher pyrimidine activity in human marrow (relative to other tissue sites) than in murine systems. Also, the Michaelis constant of human pyrimidine deaminase is much lower than that found in mice, thus increasing the importance of deoxycytine and cytidine as inhibitors. The results indicate quite different concentration profiles of these substances, suggesting that the kinetics of reaction must be determined for the prediction of DNA inhibition by these substances.

Ancitabine—Ancitabine (cyclocytidine) is known to hydrolyze *in vivo* to the effective anticancer agent cytarabine. This drug is known to have a slower urinary clearance than cytarabine, by metabolism and kidney clearance, leading to an enhanced cytotoxic effect in tumor-bearing animals. Following the models of Dedrick *et al.* for cytarabine (35, 36), Himmelstein and Gross have developed a six-compartment model to predict this effect in humans (24). All compartments were assumed to be flow limited, and the hydrolysis reaction was considered to occur by saturable kinetics in all compartments. *In vitro*-determined values were used for hydrolysis rate constants, and clearance values were calculated from cumulative urinary data assuming linear excretion for both ancitabine and cytarabine (Table V). Based on good agreement with the plasma data in humans, the authors conclude that ancitabine can act as an *in vivo* reservoir for cytarabine, and therefore, its pharmacokinetics should be considered in developing treatment schedules.

Pentostatin—Pentostatin (2′-deoxycoformycin) is a bacterial fermentation product which is used primarily in combination chemotherapy with other antineoplastic

agents. When applied with vidarabine (ara-A), increased antitumor activity is found in laboratory animals. Pentostatin is a tight-binding inhibitor of intracellular adenosine deaminase in the liver, kidney, and L-1210 tumor cells. King and Dedrick developed a five-compartment model to describe pentostatin pharmacokinetics in normal and leukemic mice (Table VI) (39). The authors used both linear and nonlinear binding in a flow-limited model to account for tissue distribution at high pentostatin concentrations and for the tight binding to adenosine deaminase, respectively. Since blood flow rate to L-1210 tumors is not known, these authors have estimated the blood flow rate to be 0.22 min^{-1} by fitting their model to the tumor data. Pharmacokinetic parameters for normal tissues were determined by decomposing the model into a series of hybrid models which could be solved individually. The model indicated that the primary means of drug elimination was through the urinary tract, although the model was not able to predict this data well at high dosages. These authors suggest that a more comprehensive model should include the detailed kinetics of the inhibition of adenosine deaminase by pentostatin and the dissociation rate of the pentostatin–adenosine deaminase complex based on experimental data.

5-Fluorouracil—The pharmacokinetics of 5-fluorouracil are of interest since the drug is known to be metabolized by two pathways in the body. The anticancer effect of 5-fluorouracil results from an anabolic pathway where the drug incorporates into nucleosides and nucleotides. A

Table VI—Model Parameters for Pentostatin in the Mouse[a]

Tissue	Linear Binding Constant (R)	Dissociation Constant μg/ml	Specific Binding Parameter, μg/ml

catabolic pathway for metabolism also exists, where the drug undergoes degradation ultimately to carbon dioxide and urea. A two-compartmental flow-limited hybrid model around the pulmonary system was developed by Collins *et al.* (40) for humans. The authors did not differentiate between the two metabolic pathways in the model, but presented a framework on which to build. The novel aspect of this work results from the route- and schedule-dependent drug clearance. The model included saturable clearances and was used for the intravenous bolus, intravenous infusion, and intraperitoneal injection routes. Because of the good fit to data for the different modes of administration, the authors concluded that the simple physiologically based pharmacokinetic model with nonlinear terms is sufficient for use in clinical situations.

Mercaptopurine—The primary use of mercaptopurine is in combination therapy for treatment of leukemia and certain sarcomas (41). Mercaptopurine is most toxic to rapidly multiplying cells; therefore, the intestine, bone marrow, and spleen are more susceptible to mercaptopurine and are of primary interest in the modeling of this drug. Tterlikkis *et al.* (42) have developed a six-compartment flow-limited model with a complete hepatic system to describe the pharmacokinetics of mercaptopurine in the rat (Table VII). The model, similar to one developed by Bischoff *et al.* (43), includes linear binding and excretion, a three-compartment biliary tract, and a four-compartment gut lumen. The rat concentration data were simulated well by the model. The authors also scaled-up their model to humans and have obtained general agreement with the data despite large patient-to-patient differences. A more comprehensive model of mercaptopurine should include detailed kinetics of metabolism analogous to the models for cytarabine, cisplatin, *etc.* When this kinetic framework is determined, a clinically applicable model can be made available based on the structure presented in this work.

Methotrexate—Methotrexate has been the most studied drug in the area of physiologically based pharmacokinetics. The antineoplastic mechanism of methotrexate results from its binding to the enzyme dihydrofo-

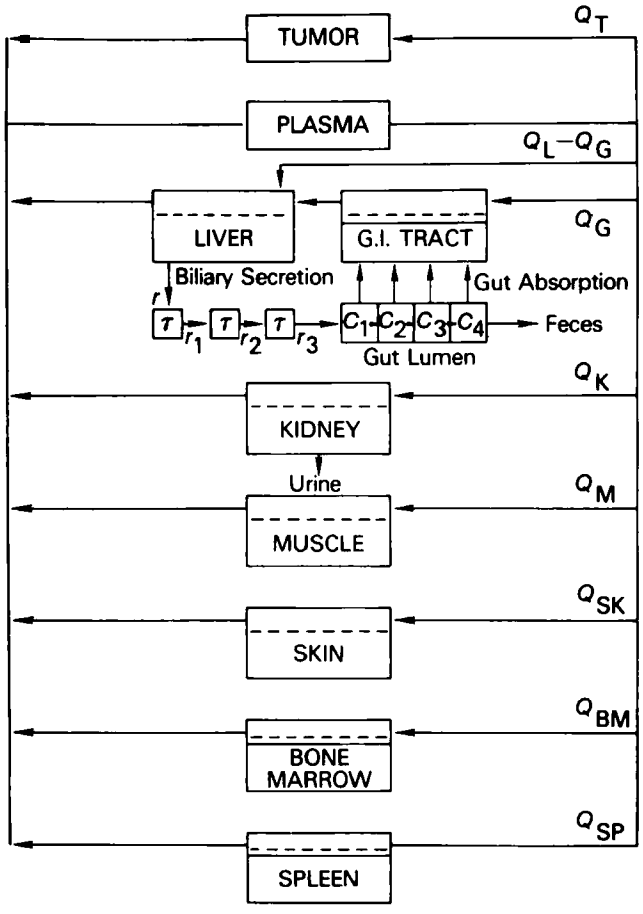

Figure 3—*Location of the biliary and gut lumen compartments represented by well-mixed subcompartments connected in series.*

late reductase which inhibits conversion of dihydrofolate to tetrahydrofolate. Tetrahydrofolate is used to produce a coenzyme required for thymidylate formation, which in turn, is required for DNA synthesis. Preliminary pharmacokinetic work on methotrexate began with a six-compartment model that was simplified to a two-compartment model by Bischoff *et al.* (43). The analytical solutions of this simple model were used to obtain initial estimates of mass transfer coefficients and clearance constants. The equations for the six-compartment flow-limited model were solved with a numerical technique, and good agreement with data for the six tissues was found.

Bischoff *et al.* then extended their model by incorporating saturable binding and excretion, multicompartmental representation of biliary excretion, and movement of drug through the GI tract with partial reabsorption (Fig. 3) (44). The model was able to predict successfully detailed distribution and excretion of methotrexate in the mouse, rat, monkey, dog, and human over a wide range of doses.

Dedrick *et al.* (25) determined membrane resistance to transport in bone marrow, the spleen, and the small intestine of rats by plotting the drug concentrations in various tissues as functions of the plasma concentration. The transport parameters estimated from the membrane-limited model were found to be in general agreement with *in vitro* results obtained in many mammalian cells. The mathematical treatment presented in this paper was general and has been adapted by many investigators of physiologically based pharmacokinetics.

Zaharko *et al.* (45) used the flow-limited model to predict the distribution of methotrexate in the sting ray and found the blood circulation velocity to be approximately one-sixteenth of that in the mouse. Dedrick *et al.* (37) used the membrane-limited model to simulate plasma and peritoneal fluid concentrations following single and repeated intraperitoneal injections of methotrexate in humans. This work led to the conclusion that a significantly greater concentration of methotrexate in the peritoneal cavity than in the plasma following intraperitoneal injection could be exploited in the treatment of patients with microscopic residual cancer confined to the peritoneal cavity.

Zaharko *et al.* (46) and Lutz *et al.* (47) (Table VIII) developed hybrid models to simulate concentrations of methotrexate in Lewis lung carcinoma in mice and spontaneous lymphosarcoma in dogs, respectively. These investigators found the transport in tumors to be best modeled by the membrane-limited assumption. Similarly, Weissbrod *et al.* (48) used a hybrid model to calculate the membrane permeability of L-1210 leukemia cells in mice and found these values comparable to *in vitro* values. In contrast, Jain *et al.* (18) used the whole-body model and found the transport of methotrexate in hepatoma 5123 and Walker 256 carcinoma in rats to be flow limited. Jain also estimated the extent of drug metabolism during constant infusion and found the fraction of drug metabolized to be ~20% at the end of a 3-day infusion (49). Further extensions of these models should incorporate synthesis of dihydrofolate reductase in the presence of drug and details of the drug metabolism.

Cisplatin—The antineoplastic activity of cisplatin occurs from its ability to produce intrastrand and interstrand crosslinks in DNA molecules. Cisplatin is known to metabolize by a complex scheme of reactions. The metabolites of the parent compound are considered also to have antineoplastic effects. To this end, parent drug and metabolites represented by one species were modeled with a

flow-limited scheme containing six compartments in the beagle dog by LeRoy *et al.* (Table IX) (50). Linear binding and first-order metabolism were incorporated using *in vitro* reaction rate constants. The flow-limited model was able to provide an adequate simulation of most of the tissue data. However, disagreement with muscle data, especially at early intervals, might be due to a diffusion limitation.

Streptozocin—Streptozocin is known to inhibit primary DNA synthesis by alkylation of cell components. The drug has a selective toxicity for pancreatic β-cells and is therefore useful in treating pancreatic tumors (*e.g.*, metastatic insulinoma). Weissbrod and Jain have applied a physiogically based hybrid model to describe streptozocin distribution in mice (Table X) (51). This model incorporates three membrane-limited compartments with linear binding and first-order intracellular metabolism. Tissue data obtained by bioassay to determine parent streptozocin and by chemoassay to determine parent streptozocin and its metabolites were compared with simulations. The fit to the parent compound and metabolites was adequate in this work, although the authors suggested that more data were required to describe the transport and metabolism in greater detail.

2-Amino-1,3,4-Thiadiazole—The antineoplastic action of 2-amino-1,3,4-thiadiazole includes inhibition of inosine-5-phosphate dehydrogenase in cells. For this reason, 2-amino-1,3,4-thiadiazole retards the growth of melanomas, lymphosarcomas, and leukemias. A physiologically based pharmacokinetic model was developed by King and Dedrick (Table XI) (52) to describe 2-amino-1,3,4-thiadiazole in the mouse, dog, and monkey. The authors used a flow-limited system with four compartments and represented all metabolites as one species. The rate of metabolism was described as a first-order linear process in mice and as a saturable process in dogs and monkeys. Binding and kidney clearance were considered linear. The authors obtained partition coefficients based on long-term experimental values of serum and tissue concentations. The metabolic parameters were obtained by best fit of the model to tissue concentration data. The major excretory pathways were found to be kidney clearance in the mouse and saturable metabolism in the dog and monkey. It seems that because of these interspecies differences, scale-up to humans would be difficult for this substance.

Antibiotics—Antibiotics are prescribed to treat infection. The wide applicability of antibiotics raises questions as to the disposition of these substances in the body. Physiologically based pharmacokinetics provide a tool that can aid in answering these questions.

Cephalosporin Antibiotics—Three cephalosporin antibiotics (cefazolin, cephalexin, and cephradine) were studied by Greene *et al.* (53) These antibiotics show *in vitro* activity against penicillin-resistant staphylococci and are considered to bind to plasma proteins. The authors compared the simulations using a six-compartmental perfusion model with a classical two-compartmental model, with and without protein binding. Plasma binding, described by the Scatchard equation, was used to fit the models to human plasma data for each cephalosporin administered. The authors obtained good simulations of the plasma data for cefazolin at a 1-g iv dose and for cephalexin at a 0.5-g iv dose, but underpredicted the plasma concentration at times >1.5 hr for cephradine at a 2-g iv dose. The authors attributed this disagreement to a possible overestimate of the cephradine clearance value.

β-Lactam Antibiotics—β-Lactam antibiotics include ampicillin, cefazolin, dicloxacillin, methicillin, penicillin G, penicillin V, and others. The uptake, distribution, and elimination of various antibiotics and the model test substance inulin were studied in a 12-compartment model in rats (54). The lung, heart, muscle, skin, gut, and carcass were modeled as cell membrane limited, the liver and kidney as flow limited, and the bone compartment was broken down into bone marrow (flow-limited) and bone cortex (membrane-limited) compartments. Tissue-to-plasma partition coefficients of penicillin V, dicloxacillin, cefazolin, and inulin were determined by *in vivo* experi-

ments after constant infusion of these substances. Renal and hepatic clearance constants were also determined from independent experiments. Binding to serum proteins (albumin) was considered to be nonlinear for cefazolin and penicillin V, whereas linear binding was used for penicillin G, methicillin, dicloxacillin, and ampicillin (Table XII). Although partition coefficients, binding constants, and elimination parameters were measured for several antibiotics, these authors compared their model to tissue distribution data for cefazolin and inulin only and found good agreement.

Tetracycline—The antibiotic tetracycline is highly active against Gram-positive and Gram-negative organisms. This drug is recommended for treatment of pneumonia, actinomycosis, brucellosis, urinary infections, Rocky Mountain spotted fever, and typhus fever (41). When tetracycline is given to rats during pregnancy, it is known to lead to acute fatty liver syndrome in the mother and teratogenic effects in the fetus. To this end, Olanoff *et al.* developed a physiologically based pharmacokinetic model of tetracycline in nonpregnant (55) and pregnant rats (16) (Table XIII). This model included seven flow-limited compartments in both the maternal section and the fetal section, including a placenta compartment for maternal-to-fetal transfer of the drug. The authors applied linear binding in all compartments and allowed for fetal growth over 21 days. The model was used to determine the controlled release of tetracycline using a trilaminate drug delivery device. The model described the data well and was able to predict the constant tissue concentrations desired of a controlled-release device. The authors had to use uniformly lower values of the partition coefficients in the pregnant rats when compared with the nonpregnant rats. The inclusion of a fetus in such a model represents a significant advance in physiologically based pharmacokinetics.

Anesthetics—Anesthetics are used for temporary suppression of pain, normally during surgery. Based on the knowledge of the uptake, distribution, metabolism, *etc.*, of these substances in the body, physiologically based pharmacokinetics provide an excellent technique to determine dosage regimens to ensure that proper amounts are delivered to the desired region of the body. Biomedical equipment that is used in the delivery of anesthetics can be designed based on pharmacokinetic simulations, thus limiting the danger of experimentation with new equipment.

Halothane—Halothane is a widely used, potent, noninflammable, and nonexplosive inhalation anesthetic with rapid onset and rapid reversal. Since the pioneering work of Mapleson (56), several flow-limited hybrid models have appeared in the literature to describe the uptake and distribution of halothane in humans (17, 57–59). Since changes in halothane concentration influence cardiac output and distribution, and *vice versa*, many investigations have tried to incorporate this interrelationship in their models. Ashman *et al.* (57) assumed that a uniformly distributed reduction in cardiac output occurred as anesthetic concentration in the viscera increased. After comparing the results of constant and variable cardiac output models, the authors concluded that the differences in these two models were insignificant for the first few minutes, but progressively increased during the first hour to 6%. Zwart *et al.* (17) and Smith *et al.* (58) improved this model by making changes in the cardiac output and its distribution a function of halothane concentration in one or two of the three most important compartments, *i.e.*, brain, myocardium, and arterial blood (Table XIV). The results of this model differed significantly from those models with constant cardiac output and gave new insight into halothane-induced changes in the circulation. Munson *et al.* (59) divided the body into five flow-limited compartments and modeled the effects of reduced ventilation rate and cardiac output on halothane pharmacokinetics. Using this model, these authors were able to predict limits to which

anesthetic drugs and techniques could be used safely.

Hexobarbital, Pentobarbital, Phenobarbital, and Thiopental—These four drugs are the most common barbiturates used in medicine. Thiopental, a local anesthetic used in dental patients, has biological effects similar to methohexital. Hexobarbital and thiopental are short- and ultrashort-acting anesthetics, respectively. This rapidity results from metabolic degradation and physical redistribution. Phenobarbital has a slower rate of action on the brain compared with hexobarbital and thiopental. Pentobarbital is a fast-acting sedative useful in the treatment of insomnia, nausea, *etc.* The drug is also useful in controlling convulsions such as those which occur in eclampsia, epilepsy, tetany, and strychnine poisoning. Overdoses of barbiturates can lead to death by respiratory failure (41).

To this end, Bischoff and Dedrick (60, 61) developed a four-compartment model (blood, viscera, lean tissue, and adipose tissue) to describe the pharmacokinetics of barbiturates in dogs and humans. By incorporating parameters characterizing lipid solubility, protein binding, and metabolism of thiopental, these authors were able to simulate the tissue data in dogs and plasma data in humans. These authors later applied the thiopental model to pentobarbital which has a lower lipid solubility, less protein binding, and is metabolized at about one-tenth the rate of thiopental (60). By including these changes, a suicidal dose in the human (43 mg/kg) was simulated (Table XV). These authors also simulated the effect of treatment with an artificial kidney, and using this model, were able to predict the well-known rebound effect in blood, lean tissue, and viscera.

Since Bischoff and Dedrick combined brain, heart, kidneys, liver, *etc.* as a viscera component, their model can not predict thiopental concentrations in the brain, which is valuable information for optimal therapy. To this end, Chen and Andrade (62) developed a seven-compartment model to predict thiopental kinetics in the brain, plasma, liver, GI tract, lean tissue, adipose tissue, and viscera and obtained good agreement with the data obtained in dogs. A detailed sensitivity analysis indicated the values for fractions of bound drug in various tissues were more sensitive parameters than the others in the model and, therefore, must be determined precisely. Similar to methohexital, the four-compartment model of Bischoff and Dedrick was also extended by Gillis *et al.* (63) to account for the slow approach to equilibrium in human tissues.

The most comprehensive model of barbiturates (hexobarbital, phenobarbital, and thiopental) has been developed recently by Igari *et al.* (Table XVI) (64a). These authors have developed an 11-compartment model which includes lung, venous and arterial plasma, liver, brain, heart, GI tract, kidney, muscle, skin, and adipose tissue. Except for the brain, all tissues were assumed to be flow limited. Partition coefficients, Michaelis–Menten constants for drug metabolism, and binding constants were determined *in vitro* and compared with *in vivo* data. The *in vitro* partition coefficients did not lead to good agreement with the plasma and brain data. When partition coefficients obtained from *in vivo* experiments were used instead, the authors were able to describe the data well. [In a later publication, these authors use a similar model to predict ethenzamide (ethoxybenzamide) concentrations in nine compartments in rats, scaled-up to rabbits (64b), from K_p (partition coefficient) values obtained *via* intravenous bolus injection, constant-rate infusion, and *in vitro* determinations (64c).]

Lidocaine—Lidocaine is a potent anesthetic agent used for infiltration and block anesthesia. It is also used topically for anesthesia of accessible mucous membranes. The action of lidocaine on nerves is considered similar to that of procaine (41). Congestive heart failure patients, when given standard intravenous doses of lidocaine, show ele-

vated blood levels presumably due to decreased circulation and clearance. A physiologically based pharmacokinetic model can be useful in predicting the lidocaine levels of patients suffering from cardiovascular diseases. An eight-compartment flow-limited model to describe the pharmacokinetics of lidocaine in humans and monkeys was developed by Benowitz *et al.* (Table XIV) (65). The authors assumed equilibrium was obtained after 24 hr to obtain experimental tissue-to-plasma partition coefficients in rhesus monkeys. The model was then scaled-up to humans with the same binding parameters as found in the rhesus monkey. Good agreement was found between human plasma data and model predictions. In a later study by Benowitz *et al.* (66), the effects of hemorrhagic shock and sympathomimetic drugs (isoproterenol and norepinephrine) on lidocaine kinetics and regional blood flow in the rhesus monkey were examined. The results obtained have many interesting clinical implications.

Methohexital—Methohexital is a local anesthetic used primarily in dental surgery. Dosage requirements can change from alterations in body distribution processes. Alterations can result from dehydration, uremia, peripheral circulatory failure, increased cardiac output, electrolyte disturbances, hepatic failure, and chronic renal failure.

Using the approach developed by Bischoff and Dedrick for thiopental pharmacokinetics, Gillis *et al.* (63) developed a flow-limited model to describe the distribution of methohexitol in the human. Similar to the model of Bischoff and Dedrick, it included details of protein binding and liver metabolism (Table XV). Unlike that of Bischoff and Dedrick, this model used a ramp function to describe the approach to equilibrium in tissue, with characteristic times determined by the perfusion rates. The model described the available data adequately and was used to predict the influence of body alterations (*e.g.*, obesity) on drug distribution.

Procaine—Procaine[2] is a local anesthetic used primarily in dental surgery. The drug blocks the function of the nerves near an injection site by attaching to and preventing sodium transfer across the nerve cell membrane, thus hindering the formation and propagation of the action potential on the membrane. The process is reversible, so the effects on the cell are only temporary (19). A nine-compartment flow-limited model was developed by Smith *et al.* (67) to describe procaine pharmacokinetics in humans. Independently determined nonlinear binding and nonlinear metabolism terms were incorporated into the model. Model simulations showed good agreement with human data in the arterial plasma, brain, muscle, adipose tissue, and viscera regions. The model was also applied to lidocaine in humans and compared well with the human plasma data.

Trace Metals and Other Ions—Trace metals and other ions are studied for various reasons. Certain endogenous metals and ions are essential for body growth, development, and many daily functions. Several exogenous metals and ions are also required nutritionally by the body (*e.g.*, iodine, chromium) and must be taken in the diet. Other exogenous substances can be lethal at high doses (*e.g.*, cadmium, lithium). To this end, physiologically based pharmacokinetic models can be used to determine proper dietary intake, to predict maximum dosages to ensure against toxicity in high-accumulation or target organs, and also to develop detoxification strategies.

[a] Data (69) reprinted from the *American Journal of Physiology* with permission; © 1978, The American Physiology Society.

Bromide—Bromide is an essential element for the body. Small amounts are found in table salt and several vegetables. Natural intake of bromide occurs primarily by GI absorption from these sources. Bromide passes through the various body fluids, penetrates red blood cell membranes, and is eliminated *via* the kidneys. Bromide also displaces chloride in extracellular fluid, which may lead to a sedative effect on nerve tissue (68). In this manner, bromide can be used as a tracer to measure the volume of extracellular water (69). The model by Pierson *et al.* (69) applied physiologically based pharmacokinetics to predict the distribution of bromide in rats and then scaled-up to humans (Table XVII). Twelve compartments were included in this model; the muscle, lung, heart, spleen, thyroid, and body compartments were assumed to be flow limited and the skin, adipose tissue, kidney, brain, liver, GI tract, and red blood cell compartments were assumed to be membrane limited. The authors computed the linear binding parameters from steady-state bromide distribution data. The rat model predictions of extracellular volume were compared with known values along with the concentration data. The authors found adequate agreement within the inherent statistical limitations of the data. Identical thermodynamic and transport parameters were used in the scaled-up model and led to good agreement with plasma, skin, muscle, and adipose tissue data in humans. This model and these experiments indicated that bromide was an imperfect tracer for extracellular water because of consistent overprediction of the extravascular water volume.

Cadmium—Cadmium, an exogenous substance, is toxic when present at high levels. Because of this toxicity, cadmium is of primary concern to the metals industry for environmental reasons. Low cadmium doses are found to result in hypertension (70). Accumulation of cadmium in

the testicles of laboratory animals leads to necrosis of this tissue (71). The similarities and dependence in transport and uptake of cadmium to zinc has led to many comparative studies of these two elements (72). Following intake, cadmium is found to clear rapidly from the plasma, bind to subcellular proteins, and accumulate readily in the liver and kidneys (14). The Gerlowski and Jain model (73) combines both membrane-limited and flow-limited compartments to study cadmium uptake in mice (Table XVIII). Membrane-limited liver and kidney compartment simulations show good agreement with the data, which account for 60% of the initial dose. The fit was not as good in the other compartments, especially in the residual carcass compartment where many organs were lumped into one flow-limited compartment. Further improvements can be made in this model when short-term data become available for various organs.

Chloride—Chloride, an endogenous trace element, is essential for electrolytic, osmotic, and acid balances and other bodily functions. Dietary chloride is obtained in animal foods, absorbed through the GI tract, and excreted primarily through the urinary tract (68). Chloride depletion may be a useful treatment for brain edema (74). Gabelnick *et al.* (74) have developed a three-compartment hybrid model (Fig. 4) representing brain, well-perfused, and poorly perfused compartments to study mass transfer of chloride in cats undergoing hemodialysis. Transfer to the brain was considered to occur by diffusion from the well-perfused compartment, by convection from cerebrospinal fluid (CSF), and by mediated transport from the well-perfused compartment. Brain tissue was assumed to be in equilibrium with the CSF. The mass transfer coefficient from the well-perfused compartment to the brain was estimated to be 0.037 ml/min. The transport rate of chloride into the CSF was found to be a constant (0.55 μeq/ml · min) for 60–120-meq/liter plasma chloride concentrations. This behavior indicated the existence of a "saturated pump" and was modeled as a constant infusion term (2.8 μeq/min). The authors noted agreement with the data, except for the brain compartment, which experimentally indicates a steady-state equilibrium concentration, unlike the model predictions. This disagreement may have resulted from a possible change in flow rate of the CSF or mediated transport into the brain during hemodialysis.

Lithium—Lithium, an exogenous substance, is used in the treatment of manic-depressive illness. Problems that arise from dosage levels and schedules of lithium have led to the use of pharmacokinetics in determining proper regimens. A model presented by Ehrlich (75) applies a three-compartment scheme representing plasma and extracellular fluid, red blood cells, and muscle-like cells to

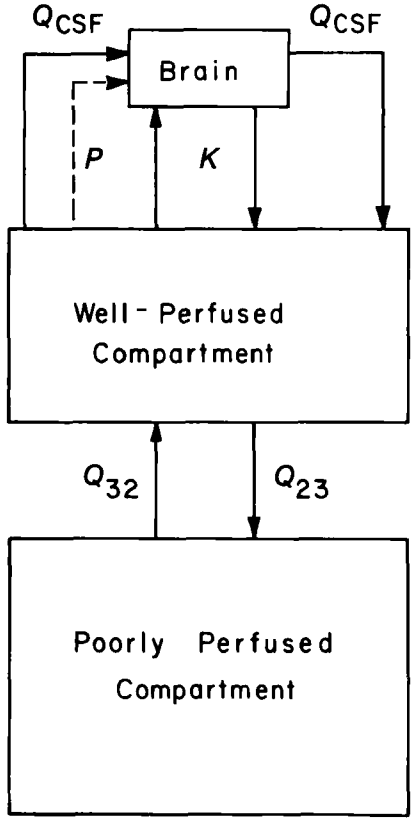

Figure 4—*Location of the brain compartment (74). Reprinted from the* Journal of Applied Physiology *with permission; copyright 1980, American Physiological Society.*

describe lithium distribution in four human subjects (Table XIX). Linear transport and Michaelis–Menten excretion parameters were incorporated in the hybrid model. The model simulated the data well and suggests that the Li^+ countertransport efflux mechanism of the red blood cell may be shared with the muscle. However, variations in the intercompartment concentrations, because of high concentrations in the liver and kidneys, suggest the need of a larger model consisting of several more compartments when the data become available.

Zinc—Zinc, an endogenous substance, is essential in that DNA and protein syntheses are zinc dependent; also, carbohydrate metabolism, lipid peroxidation, and bone formation require zinc. Deficiencies in zinc may lead to growth retardation and failure of sexual maturation. A comprehensive model (17 tissues, plasma, and red blood cells) was developed to describe zinc distribution in rats (15). In this model, membrane-limited compartments were incorporated with linear binding, transport, and excretion.

The physicochemical parameters were estimated by decomposing this model into hybrid models and minimizing the error between data and model for each issue (Table XX) (15). Excellent agreement with data was found (average error <10%); however, only a limited number of data were used in estimating the model parameters. A more complete model should incorporate zinc speciation, nonlinear transport and binding, and intercompartmental diffusion.

Environmental Hazards and Toxic Substances—The uptake of many chemicals by the body can lead to harmful effects. Various regulatory agencies impose tolerance levels for hazardous chemicals to ensure safe working conditions. These levels are usually obtained from experiments over short periods of time and formulate an opinion on only one tissue concentration value (*e.g.*, plasma concentration). But, tissue concentrations are known to vary over a wide range throughout the body. Therefore, to ensure that all tissues remain below toxic levels at all times, physiologically based pharmacokinetics may be incorporated into such decision-making processes to set more precise levels.

Acetonylacetone—Acetonylacetone (2,5-hexanedione) is a neurotoxic metabolite of the industrial solvents *n*-hexane and methyl *n*-butyl ketone. Action of acetonylacetone on the sciatic nerves causes axonal damage which characterizes central–peripheral distal axonopathy. Recently, a nine-compartment flow-limited physiologically based pharmacokinetic model was constructed by Angelo and Bischoff (76) to simulate the detailed pharmacokinetics and metabolism in rats (Table XXI). These authors determined equilibrium tissue–plasma distribution ratios based on *in vivo* data determined by constant intravenous infusion of acetonylacetone using a surgically implanted infusion pump. Metabolism of acetonylacetone was simplified to a three-step series reaction scheme, and the rate constant for the second reaction was considered to be organ specific. Very good agreement with data was found for single-dose exposures of 0.8 and 8.0 mg/kg ip for the plasma, sciatic nerve, liver, kidney, lung, and lean compartments in the elimination phase; however, the absorption phase was somewhat underpredicted in each case up to 1 hr. Additionally, the spinal cord compartment exhibited a dose-dependent partition coefficient. The model also described the concentrations of metabolites in the plasma, liver, and urine adequately. In multiple dosing (8.0 mg/kg/day ip), simulations reproduced the tissue data well except for plasma data. These data were overpredicted, perhaps due to kinetics of the radioisotope uptake and release by plasma constituents. The early interval behavior suggested the need for a diffusion-limited model with precise blood kinetics.

Chlordecone—Chlordecone[3] is a chlorinated organic insecticide which is toxic to most life forms. In industrial sites, workers in contact with chlordecone are found to contract severe cases of tremors. From tests performed on laboratory mice, chlordecone has been found to be a carcinogen. Boylan *et al.* (77) and Bungay *et al.* (78) have shown evidence for bidirectional transport of chlordecone between blood and gut contents in mice. Bungay *et al.* (78) have developed a physiologically based pharmacokinetic model with a detailed enteric transport model to describe the distribution and excretion of a nonadsorbable tracer and parent chlordecone in rats (Table XXII). The GI tract was modeled to include stomach, small intestine, cecum, and large intestine; each organ was represented by a series of well-mixed subcompartments. This model was able to predict the short-term transport kinetics of parent chlordecone as well as substances that are unabsorbed or passively transported across the gut wall. The scaled-up model also provided a rational basis for cholestyramine therapy for victims of chlordecone poisoning.

Nitrate and Nitrite—Nitrosamines, which are known to be potent carcinogens, can be formed endogenously from dietary nitrate. Nitrate enters the body in the diet and also is formed from reduced nitrogen compounds. In addition,

[3] Kepone.

the salivary glands transport nitrate from the blood to saliva. By bacterial reaction, nitrate is converted in the oral cavity to nitrite, which is then available to form nitrosamines in the stomach. Therefore, to determine the safe amount of dietary nitrate intake, an understanding of the distribution and metabolic fate of nitrate and nitrite would be useful. To this end, Deen *et al.* (79) developed a physiologically based pharmacokinetic model to simulate nitrate and nitrite concentrations in humans following an oral dose of nitrate (Table XXIII). The model consisted of an oral cavity, stomach, small and large intestines, blood and well-perfused tissues, and lean tissues. Transport between the digestive system, blood pool, and well-perfused tissues was modeled to occur by diffusive and convective means *via* bile, saliva, and gastric and pancreatic juices. The authors were able to simulate data adequately for plasma and salivary nitrate and salivary nitrite. The authors found individual variations in values of the renal clearance constant among groups of subjects. The model was not able to predict in detail the fate of reduced nitrogen, *e.g.*, reabsorption from the GI tract, exhalation of gaseous products, *etc.* Denitrification in the oral cavity is also known to occur, but was not incorporated in this model and needs to be further investigated along with the fate of the nitrite presented to the stomach.

Polychlorinated Biphenyls—Polychlorinated biphenyls (PCB's) are widely recognized as a highly toxic environmental hazard. These substances appear throughout the food chains of all animals. Highly chlorinated biphenyl molecules are known to persist in the body for long periods of time (10–15 years) and are potent inducers of microsomal enzyme activity. Metabolism of polychlorinated biphenyls occurs primarily in the liver, and the metabolites are known to have carcinogenic effects. Polychlorinated biphenyls are known to accumulate primarily in the adipose tissue. Anderson *et al.* (80) and Lutz *et al.* (81) each applied a six-compartment flow-limited model to describe the disposition and metabolism of polychlorinated biphenyls (1-, 2-, 5-, and 6-chlorinated biphenyls) in rats. These authors concluded that a membrane-limited model may be more appropriate for pharmacokinetics of polychlorinated biphenyls in the skin compartment. The alternative would have been to divide the skin into a number of compartments to model the heterogeneous perfusion rate in the skin. The pharmacokinetics of 3,3′,5,5′-tetrachlorobiphenyl (4-chlorinated biphenyl) and its metabolites were also studied in rats by Tuey and Mathews (Table XXIV) (82) using the framework developed by Lutz *et al.* Except for 4-chlorinated biphenyl, the rate of metabolism of four polychlorinated biphenyls (1-, 2-, 5-, and 6-chlorinated biphenyls) decreased as the degree of chlorination increased. The rate of metabolism of 4-chlorinated biphenyl was found to be less than that of 5-chlorinated biphenyl and greater than that of 6-chlorinated biphenyl. However, the relative rates of various polychlorinated biphenyls could be ordered according to the number of adjacent unsubstituted carbon atom pairs they contained. These authors, therefore, suggested that the chlorine po-

sition is more important than the degree of chlorination.

Other Substances—*2-Butanol*—Pretreatment with 2-butanol and its metabolites is known to potentiate the hepatotoxicity of carbon tetrachloride. Assuming that the only important site of 2-butanol metabolism is in the liver, a two-compartment model consisting of a volume of distribution compartment and a flow-limited liver compartment was developed for 2-butanol and its metabolites butanone, 3-hydroxy-2-butanone, and 2,3-butanediol by Dietz *et al.* (83) The model included transport to the site of metabolism, inhibition of the transformation of butanone to 3-hydroxy-2-butanone, reabsorption of the latter in the liver, and elimination of all four compounds from the animal. The model adequately described the blood data for each of these species after intravenous injections of 3-hydroxy-2-butanone and 2,3-butanediol and following oral administration of 2,3-butanediol and 2-butanol. These simulations also suggested that a 28–30% molar dose of 2,3-butanediol relative to 2-butanol and butanone gave comparable 2,3-butanediol blood kinetics. These authors suggested that there is need for incorporating saturable transport, both linear and saturable binding, and the interactions of 2-butanol and its metabolites with enzymes and other cellular components when appropriate data become available.

Digoxin—Digoxin is one of the cardiac glycosides used in the treatment of heart diseases. As a cardiotonic, digoxin increases myocardial contraction force, and as a depressant, digoxin decreases cardiac rate. A physiologically based pharmacokinetic study was performed on digoxin and its metabolite by Harrison and Gilbaldi (Table XXV) (84). Eight flow-limited compartments were considered with metabolism in the liver, linear tissue binding, and linear excretion in rats. Good agreement was found with plasma, heart, muscle, and liver tissue data and urinary excretion data following an intravenous dose. The model was then altered to include cholestasis and renal failure by setting biliary secretion and renal clearance rates equal to zero, respectively. Plasma and urinary excretion data from rats with ligated bile ducts or ligated ureters were found to be in good agreement with model simulations. The same model was then modified for dogs and scaled-up to humans (85). The simulations agreed well with urinary excretion data and kidney, heart, liver, and muscle tissue data in the dog. When scaled-up to humans the model underpredicted early interval plasma data, but adequately described the urinary excretion data following a single intravenous dose. This discrepancy in plasma data may be due to differences in binding parameters between dogs and humans, or a diffusion limitation may exist in this system. Steady-state concentration levels predicted were in the same range as those found postmortem in human plasma, heart, and skeletal muscle; however, liver and kidney concentrations were predicted to be 1.5–2 times and 2–3 times the patient data, respectively. While the model described the plasma data in patients with moderate renal impairment, the model underpredicted the plasma data in anuric patients. This discrepancy may have resulted from an effect on the transport and binding parameters by uremia.

Ethanol—Ethyl alcohol is known to act on the central nervous system causing excitation followed by a depressed state. On ingestion, ethanol is rapidly absorbed from the small intestine and is rapidly metabolized to acetic acid by active acetyl oxidative enzymes in the liver (41). Thus, the primary concern for ethanol in the body from a modeling point of view is in the hepatic system. A two-compartment hybrid model consisting of the liver and the remainder of the body, which were interconnected by the hepatic artery and vein, was developed by Dedrick and Forrester for rats (Table XXVI) (86). The authors concluded that *in vitro* Michaelis–Menten kinetic parameters for the liver alcohol dehydrogenase agreed well with the model parameters; however, a significant artifact may be introduced if the body is considered to be a single compartment. A three-compartment hybrid model was recently developed by Rheingold *et al.* (87) to account for the observed vascular concentration gradients, blood flow limitations, and liver metabolism. These compartments included: the liver; the peripheral circulation represented by the femoral artery, peripheral capillaries, and femoral vein in series; and a deep compartment. The model was fitted to femoral artery and vein data following a 10-min constant infusion of ethanol *via* the cephalic vein at doses of 0.13 and 0.26 g/kg. The values of the metabolism parameters did not agree with those of Dedrick and Forrester.

Phenolsulfonphthalein — Phenolsulfonphthalein (phenol red) is useful as a diagnostic agent to determine the functional activity of the kidney; *i.e.*, intravenous injection of phenolsulfonphthalein has a longer residence time in impaired kidneys (41). A physiologically based pharmacokinetic model was developed in the dogfish shark (*Squalus acanthias*) by Bungay *et al.* (Table XXVII) (88). The dogfish shark was chosen to study physiologically based pharmacokinetics in aquatic animals because of the large amounts of pollutants in the ocean, the scalability of pharmacokinetics to lower species, and the abundance of experimental methodology available in fish. This model consisted of three flow-limited compartments representing the kidney, liver, and muscle, a two-subcompartment bile duct, and a plasma compartment. The linear binding constants for the liver and muscle were obtained from the

Table XXVII—Model Parameters for Phenolsulfonphthalein in the Dogfish Shark [a]

Tissue	Flow-Limited Linear Binding Constant (R)	Clearance Constant (k), ml/min·kg
Kidney	8	0.36
Liver	4	0.62
Muscle	0.1	—
Other

equilibrium data; the kidney constants were determined by trial and error. Clearance constants were determined from experimental data. Although agreement between the model and data was good, the concentrations predicted in the liver and kidneys were lower than the measured values during the distribution phase, while plasma predictions were higher than data at early intervals. This discrepancy indicates the possibility of higher plasma flow rates than reported in the literature. The agreement between predictions and urine data was good over the entire 48 hr following injection; however, the bile data were lower than the predicted values at 24 and 48 hr. Incorporation of enterohepatic circulation might reduce this discrepancy, as suggested by these authors.

Salicylates—Salicylates have been found to produce marked antipyretic and analgesic effects, and are used to treat rheumatic fever and rheumatic tonsilitis. These substances are easily absorbed from the upper GI tract and spread readily through the tissues. Seventy to eighty percent is usually excreted through the kidneys as free acid (41). A seven-compartment flow-limited model was applied to study the pharmacokinetics of salicylates in the plasma, brain, liver, GI tract, muscle, visceral region, and adipose tissue of dogs by Chen *et al.* (Table XXVIII) (89). The CSF concentration of salicylates was determined by mass balance around the brain, CSF, and blood. Three markedly different dosages, from therapeutic to severely intoxicating levels, were given to determine the appropriateness of dosage regimens. The model was able to predict the data extremely well over all dosages. In addition, comparison of the model with dogs treated with hemoperfusion to remove salicylates was presented. In all cases the predicted concentrations agreed well with the data.

Sulfobromophthalein and Warfarin—Sulfobromophthalein dramatically decreases the elimination of warfarin, an anticoagulant, in the bile. The kinetics of this effect are well known and concentration of both drugs can

Table XXVIII—Model Parameters for Salicylates in the Dog [a]

Tissue	Ratio of Blood Volume in Organ Capillaries to Total Blood Volume (R)

be easily measured (41). These properties make sulfobromophthalein a useful agent for a physiologically based pharmacokinetic study. Montandon *et al.* (90) have developed a model to describe total sulfobromophthalein (unchanged plus conjugated) in the hepatic system of rats and have scaled it to humans (Table XXIX). Two flow-limited compartments for liver and extrahepatic tissue with linear binding, a three-subcompartment bile duct, and a plasma compartment were incorporated. The model simulations compared well with data from the bile, liver, and plasma following a 200-nmoles/min/kg iv infusion in rats. The scaled-up model also agreed with human plasma data following a constant intravenous infusion with or without a rapid intravenous priming dose. The relative inaccuracy between the model and data for the first 10 min following rapid intravenous injection may be corrected by including different kinetics of conjugated and unconjugated sulfobromophthalein in the model. A recent rat model by Luecke and Wosilait (91) improved the aforementioned model by replacing the extrahepatic compartment with the kidney compartment and using the Michaelis–Menten equations for enzymatic processes involved in the drug elimination *via* two pathways (Table XXIX). The model described the plasma and bile data of warfarin and sulfobromophthalein following a 1-mg/kg iv dose of warfarin at time zero and a 50-mg/kg dose of sulfobromophthalein at 60 min. This model provides a framework to study drug interaction using single-drug models.

Tetraethylammonium chloride—The tetraethylammonium cation is effective in blocking vasomotor impulses to blood vessels, thus producing reduction of gastric acidity, GI motility, and partial or complete block of impulses to structures innervated by the autonomic nervous system such as the eye, sweat gland, and bladder (41). An eight-compartment model was developed to describe transport of the tetraethylammonium ion in the rat by Mintun *et al.* (Table XXX) (92). In the development of the model the authors first assumed a flow limitation. However, the data showed no steady-state concentration of tetraethylammonium ion, which the model predicted should occur after a few hours. The authors then incorporated a passive-diffusion membrane limitation. This type of model was not able to predict either the early interval peak or the late interval high concentration associated with the data. On the other hand, the authors were able to predict the data well by incorporating both passive

Table XXX—Model Parameters for Tetraethylammonium Chloride in the Rat [a]

and saturable transport across the capillary membrane. Since *in vitro* estimates of drug transport and permeability parameters led to poor agreement with the *in vivo* data, these parameters were fitted with a semiempirical curve-fitting technique. Although the model led to an adequate representation of the intravenous data, these authors questioned the assumption of unidirectional active transport in their model. The incorporation of bidirectional transport and the division of the carcass compartment into subcompartments representing various tissues were improvements suggested by these authors.

CONCLUSIONS

The objective of this review article was to present a unified theoretical framework for physiologically based pharmacokinetics. To this end, historical and technical developments in this area of research were discussed briefly. The comparison between experimental and theoretical results on the distribution of over 37 agents in various mammals were summarized according to their applications. Several important and poorly understood problems were pointed out at various places in the text in the hope of stimulating interest in the investigations involved in this area of research.

Some important problems that deserve further attention are:

1. While simplified models of various organs (*e.g.*, lungs, heart, brain, enterohepatic system, kidneys) appear to give adequate results in several applications, a more complete anatomical description is needed. In reality, lungs receive the cardiac output *via* the pulmonary circulation for oxygenation and a small amount *via* the bronchial circulation for the lung tissue. In most analyses, however, the lung component is placed in series with a single plasma compartment (Fig. 5A) (29, 31). In a limited number of analyses the plasma compartment is divided into the arterial and veinous pools with the lung placed between them, consistent with the anatomy (54, 64). A more complete model would include the bronchial circulation as well (Fig. 5B). Similarly, a complete model of the heart would include both the coronary and cardiac flows. Detailed models of the kidneys (93), brain, eyes (94–96), and enterohepatic system (43, 78), which have been discussed elsewhere, should be of help in developing more comprehensive physiologically based pharmacokinetic models (Figs. 1 and 3).

2. The modeling of the uptake of a substance that binds to the red blood cells presents anatomical queries,

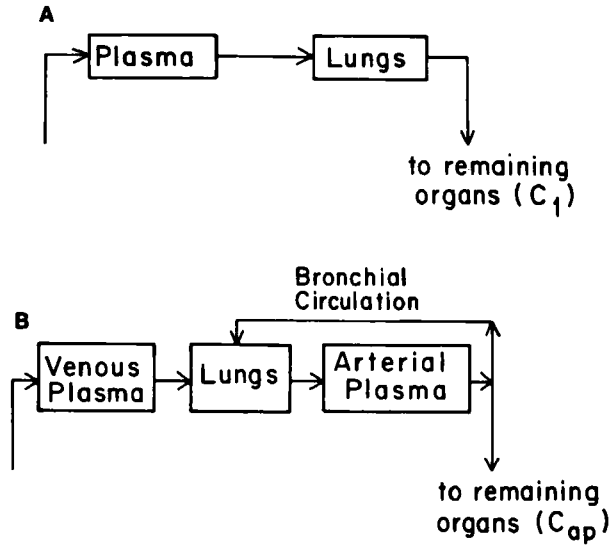

Figure 5—*Physiological location of the lung compartment with (A) only one plasma compartment and no bronchial circulation and (B) two plasma compartments with bronchial circulation.*

since red blood cells are present in every tissue throughout the body. As shown in Fig. 1, the red blood cells are lumped into one compartment and connected to the plasma compartment where transport is considered to occur, normally by diffusion. A first-order approximation is made by assuming that the transfer of the substance occurs only from the plasma compartment and that the red blood cells occupy dead space for transfer. This method is able to describe the data well, but a detailed model should account for the presence of erythrocytes in each tissue.

3. Although the assumption of no intercompartmental transfer by diffusion is valid for major organs such as the liver, kidneys, heart, *etc.*, the assumption does not realistically apply to poorly perfused organs and tissues. The bone, muscle, and fat organs are usually considered to be separate components with no diffusional transfer; however, this may not be the case for some agents. A first-order approximation to alleviate this limitation would be to assume diffusional mass transfer across these compartments. To date no physiologically based model has used or required this approach to describe data.

4. For many tissues, *e.g.*, solid tumors, the intratissue concentration gradients can be large and each compartment or subcompartment may not behave as a well-mixed phase (97). When this is the case, the lumped-compartment approach applied to date in physiologically based pharmacokinetic modeling may not be applicable, and a distributed parameter approach may be preferred to describe spatial concentration profiles in various tissues (97–101). However, detailed descriptions of convective and diffusive mass transfer in tissues are mathematically intractible. The boundary conditions, due to the complex geometries of the tissue, may also be difficult. Finally, the solution of the partial differential equations may require an enormous amount of computer time. To achieve this end, finite difference or finite element numerical techniques could alleviate some of these problems.

5. Effect of the disease state can significantly alter the pharmacokinetics of an agent by changing its transport, excretion, or metabolism. As discussed in this review article, some models have been able to simulate the effects

of renal and/or hepatic impairment and hemodialysis in uremic patients.

6. Use of multiple drugs is common for the treatment of various diseases, *e.g.*, combination chemotherapy for cancer. Interaction of various drugs can lead to significant alterations in the excretion kinetics if they share the same biochemical mechanism (91). Models for drug interaction need to be developed on the basis of single-drug models.

7. A novel application for physiologically based pharmacokinetics would be in cancer treatment when chemotherapy is used in conjunction with other methods of cancer therapy, *e.g.*, radiation, hyperthermia, immunotherapy, and surgery. In multimodal therapy, both the physicochemical (*e.g.*, mass transfer coefficient and binding constants) and the physiological parameters (*e.g.*, tissue volume and perfusion rates) may change. The effects of temperature on the physiological properties have been studied, but such information has not been incorporated in physiologically based pharmacokinetic models to date (101, 102).

8. Use of certain agents may lead to changes in the cell-cycle parameters involved with enzyme synthesis, drug resistance, or cell death (103). Incorporation of cytokinetics and detailed biochemical processes in physiologically based models remains a challenging problem with useful applications.

9. Although sophisticated numerical techniques are available for parameter estimation, most investigators have estimated the physicochemical parameters not measured independently by "eye-balling." One reason for this procedure is, perhaps, that the estimation of a large number of parameters is expensive. The problem can, however, be alleviated by dividing the whole body into a number of hybrid models, and estimating parameters for each tissue by using plasma as the forcing function. Such a sequential optimization approach has been successfully applied for zinc and pentostatin pharmacokinetics (15, 39).

10. While the ultimate goal of physiologically based pharmacokinetics is to scale-up small animal data to humans and to develop rational clinical protocols, such applications have been limited (37). Perhaps the paucity of human data and the large amount of information needed to develop these models prohibit their use in the clinical situation. Utilization of hybrid models, however, offers an attractive alternative to both classical and physiological approaches (40). Unless this approach is widely applied in clinical situations, its full potential will not be realized.

APPENDIX: GLOSSARY

a = maximum facilitated transport rate (mole/min)
a' = strong-binding constant (mole/ml)
b = Michaelis constant for saturable transport (mole/min)
C = tissue concentration (mole/ml)
ϵ = dissociation constant (mole/ml)
$g(t)$ = injection function (mole/min)
h = mass transfer coefficient (ml/min)
k = first-order kinetic rate constant (ml/min)
K_c = elimination saturation concentration (mole/ml)
K_m = Michaelis metabolism saturation constant (mole/ml)
n = flux across capillary or cell membrane (mole/min)
R = flow-limited linear binding constant (dimensionless)
$r_i(t)$ = rate of drug disappearance by metabolism in compartment i (mole/min)
R' = membrane-limited linear binding constant (dimensionless)
Q = tissue plasma flow rate (ml/min)
q = excretion rate (mole/min)
t = time (min)
V = tissue volume (ml)
v_{max} = maximum reaction velocity (mole/min)

subscripts
i = ith organ (compartment)
p = plasma compartment

superscripts
C = cellular compartment
E = extracellular compartment
I = interstitial compartment
V = vascular compartment
$*$ = free drug

RESEARCH ARTICLES

Dose-Dependent Pharmacokinetics and Biliary Excretion of Bromophenol Blue in the Rat

ROBERT J. WILLS *, RANDALL B. SMITH ‡, and GERALD J. YAKATAN x§

Received December 31, 1981, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication August 26, 1982. Present addresses: *Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche, Nutley, NJ 07110; ‡Clinical Bioavailability Unit, The Upjohn Company, Kalamazoo, MI 49001; §Warner-Lambert/Parke-Davis, Pharmaceutical Research Division, Morris Plains, NJ 07950.

Abstract □ Concentrations of bromophenol blue (I) in plasma, urine, and bile were determined spectrophotometrically after intravenous bolus injections and infusions in rats. The plasma concentrations were found to decrease monoexponentially after all doses except the highest, where the decrease was biexponential. Although the disposition kinetics of I were apparently first-order at all doses, the half-life increased with increasing dose. The area under the plasma concentration–time curve ($AUC_{0-\infty}$) increased disproportionately with increasing dose. The binding of I to rat plasma proteins, as determined by equilibrium dialysis, showed that the fraction bound (96%) remained constant in the concentration range of 10–300 μg/ml. Plasma concentrations were determined at time zero after intravenous administration and after a second dose administered 20 min later when plasma concentrations from the first dose were minimal. The apparent first-order elimination rate constant for the plasma concentration decline following the second dose was significantly less than after the first dose, indicating that the residual dye in the liver altered the elimination of I after the second dose. The fraction of the dose in the liver decreased with increasing dose, indicating a saturable uptake process. The biliary excretion profile reflected the uptake saturation that occurred in the liver and demonstrated that the biliary excretion of I depended on the amount present in the liver. When liver damage was induced by exposure to carbon tetrachloride, dye concentrations in the plasma, liver, and kidney increased markedly.

Keyphrases □ Bromophenol blue—in rat urine, plasma, and bile, dose-dependent pharmacokinetics, biliary excretion □ Pharmacokinetics—bromophenol blue, rat plasma, urine, and bile, biliary excretion □ Biliary excretion—bromophenol blue, rat urine, plasma, and bile, dose-dependent pharmacokinetics

Bromophenol blue (I) is a high molecular weight anionic sulfonephthalein dye (670 g/mole, pK_a 4.0). Several reports (1–3) have shown that I is extensively excreted in the bile and is not metabolized in a variety of species including the rat.

Takada *et al.* (4, 5) conducted studies aimed at characterizing the role of the intracellular protein fractions Y and Z in the uptake and transport of I in rat hepatocytes, and also developed a linear pharmacokinetic model for the biliary excretion of I after intravenous administration in rats (6). The model adequately described a single low-dose plasma and bile profile, but could not describe the observed nonlinearity at higher doses. The overall aim of these authors was to evaluate I as a model organic anionic compound by characterizing the pharmacokinetics at three different doses. Their report did not fully characterize the pharmacokinetics at any dose. Liver concentrations and plasma protein binding were not measured, and the observed nonlinearity was not addressed.

Studies on the pharmacokinetics of drugs excreted in the bile have increased in recent years as investigators have become more interested in the effects of liver disease on drug clearance, the effects of first-pass liver clearance on drug bioavailability, the effects of enterohepatic recirculation on drug disposition, and the nonlinear excretion of drugs (7–11). Usually these studies have not considered the extent of protein binding, liver-to-plasma and bile-to-liver drug concentration ratios, hepatic blood flow, and bile flow. These factors contribute to the interpretation of hepatobiliary elimination. In addition, the interpretation has been complicated by the use of compounds such as sulfobromophthalein that undergo metabolism. Ideally, a model compound used in studying hepatobiliary elimination would not undergo metabolism, nor enterohepatic recirculation, and would not be pharmacologically active.

The organic anion, bromophenol blue (I), possesses these qualities (2, 4). Therefore, the present investigation was undertaken to: (*a*) determine the pharmacokinetic profile

Bromophenol blue (I) is a high molecular weight anionic sulfonephthalein dye (670 g/mole, pK_a 4.0). Several reports (1–3) have shown that I is extensively excreted in the bile and is not metabolized in a variety of species including the rat.

Takada *et al.* (4, 5) conducted studies aimed at characterizing the role of the intracellular protein fractions Y and Z in the uptake and transport of I in rat hepatocytes, and also developed a linear pharmacokinetic model for the biliary excretion of I after intravenous administration in rats (6). The model adequately described a single low-dose plasma and bile profile, but could not describe the observed nonlinearity at higher doses. The overall aim of these authors was to evaluate I as a model organic anionic compound by characterizing the pharmacokinetics at three different doses. Their report did not fully characterize the pharmacokinetics at any dose. Liver concentrations and plasma protein binding were not measured, and the observed nonlinearity was not addressed.

Studies on the pharmacokinetics of drugs excreted in the bile have increased in recent years as investigators have become more interested in the effects of liver disease on drug clearance, the effects of first-pass liver clearance on drug bioavailability, the effects of enterohepatic recirculation on drug disposition, and the nonlinear excretion of drugs (7–11). Usually these studies have not considered the extent of protein binding, liver-to-plasma and bile-to-liver drug concentration ratios, hepatic blood flow, and bile flow. These factors contribute to the interpretation of hepatobiliary elimination. In addition, the interpretation has been complicated by the use of compounds such as sulfobromophthalein that undergo metabolism. Ideally, a model compound used in studying hepatobiliary elimination would not undergo metabolism, nor enterohepatic recirculation, and would not be pharmacologically active.

The organic anion, bromophenol blue (I), possesses these qualities (2, 4). Therefore, the present investigation was undertaken to: (*a*) determine the pharmacokinetic profile

0022-3549/83/1000-1127$01.00/0

of I elimination from plasma after intravenous administration of different doses; (*b*) evaluate the effect of prior administration of I on the plasma decline of a subsequent intravenous administration; (*c*) determine the liver concentration of I after intravenous administration; (*d*) assess the plasma protein binding of I; (*e*) analyze the biliary excretion profile of I after intravenous bolus and infusion administrations; and (*f*) evaluate the utility of I pharmacokinetics in assessing liver damage.

EXPERIMENTAL

Animal Preparation—Fasted male Sprague–Dawley rats (260–470 g) were anesthetized with 50 mg/kg ip of sodium secobarbital followed by cannulation of the left jugular vein and the right carotid artery with polyethylene tubing[1]. Doses of I[2] were administered as a bolus or infusion through the jugular vein catheter. Blood samples were withdrawn from the carotid artery cannula at selected times after administration, collected in heparinized tubes[3], and centrifuged; the plasma was removed and stored frozen at −20° until assayed. The blood collected did not exceed 10% of the total blood volume. Urine was collected as produced and then frozen. All bile was collected in preweighed, screw-cap vials[4] and frozen *until* assayed. Bile collection was at 5-min intervals for 2 hr and then at 15-min intervals for the duration of the experiment. The body temperatures of the rats were maintained at 37 ± 0.5° with a heat lamp and monitored by a rectal thermistor probe[5].

Intravenous Studies—Doses of 5.6, 11.2, 22.4, and 33.6 mg/kg of I dissolved in 0.5 ml of isotonic phosphate buffer (pH 7.4) were administered to four rats per dose as an intravenous bolus through the jugular vein catheter followed by a 0.3-ml saline wash. Blood samples, 0.2–0.4 ml, were withdrawn from the carotid artery cannula at various times after dosing, collected in heparinized tubes, centrifuged, and the plasma removed for assay.

In six other rats, additional surgery exposed the common bile duct through a small midline abdominal incision (2–3 cm) followed by the insertion of a polyethylene[6] cannula for bile collection. Two doses of I, 5.6 and 11.2 mg/kg, were administered to three rats each as an intravenous bolus. Blood, urine, and bile were collected after administration.

In another experiment, three rats were administered an 11.2-mg/kg dose of I as an intravenous bolus through the jugular cannula followed by the administration of a second 11.2-mg/kg dose 20 min later. Blood samples, 0.2 ml, were withdrawn from the carotid artery at selected intervals after each administration of I.

Infusion Studies—Twenty-four rats were prepared for drug administration and blood withdrawal as described above. Twelve rats received an 11.2-mg/kg dose of I and twelve rats received a 22.4-mg/kg dose of I. At selected times after the dye administration, 4.0–6.0 ml of blood was drawn from the inferior vena cava followed by excision of the liver. The liver was rinsed in normal saline, dried, weighed, and stored frozen at −20° until assayed. A 2-ml plasma sample was subjected to equilibrium dialysis as described below, and the remainder of the sample was frozen until assayed.

Four additional rats were prepared for blood, urine, and bile collection as outlined. Bromophenol blue was infused through a jugular cannula with an infusion pump at rates of 3.0, 6.0, 10.0, and 24.0 mg/hr for 2 hr. The time to reach steady state was approximated at 1–1.5 hr using data from the intravenous studies. The approximation was based on linear pharmacokinetics, so an additional 0.5 hr of infusion time was allotted as an adjustment for the observed nonlinearity bringing the total time of infusion to 2 hr. Blood, urine, and bile were collected during and after the infusion of I.

Liver Dysfunction Studies—Undiluted carbon tetrachloride was given by intubation at a dose of 2.5 ml/kg, followed by the immediate infusion of I, to three rats which had been fasted for 24 hr. Three additional rats were used as a control. The rats were then allowed food and water *ad libitum* for the next 24 hr. At this time the rats were anesthetized with ether and blood (4–6 ml) was drawn from the inferior vena cava; both the liver and kidneys were quickly excised, rinsed in normal saline, blotted dry, and weighed. The rate of bile production was used as an index of liver dysfunction.

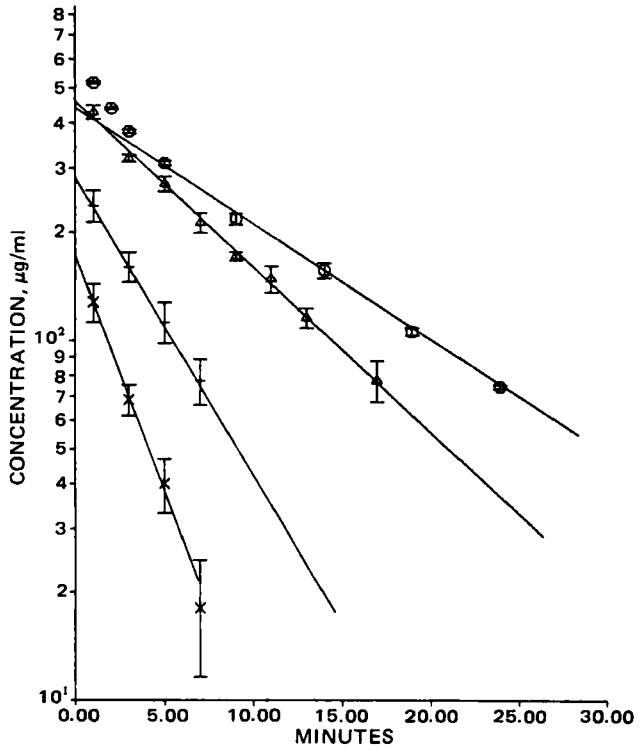

Figure 1—*Semilogarithmic plot of mean ± SD (bars) plasma levels of I as a function of time after intravenous bolus administration of 5.6 mg/kg (×); 11.2 mg/kg (+); 22.4 mg/kg (△); and 33.6 mg/kg (○).*

Protein Binding—The binding of I to plasma proteins was determined by equilibrium dialysis. Dialysis tubing, average pore diameter 24 Å, was prepared by boiling twice for 20 min in distilled water. Fresh rat plasma, 2 ml, was placed in the dialysis bag and allowed to equilibrate with I in isotonic phosphate buffer (pH 7.4) for 24 hr at 37°.

Assays—Plasma or urine (25–200 μl) was diluted with 1–2 ml of phosphate buffer (pH 8), and the absorbance was measured at 595 nm with a microsample spectrophotometer[7]. Bile was diluted with 2–10 ml of phosphate buffer (pH 8.0) and measured with a double-beam spectrophotometer[8]. The specific gravity of bile was determined by weighing known volumes of bile. Standard curves were prepared daily from rat plasma, urine, or bile spiked with appropriate concentrations of I. The amount of I in the liver and kidneys was measured after each organ was homogenized with twice its weight of isotonic phosphate buffer (pH 7.4) in an homogenizer[9]. Six milliliters of acetone was added to 5 ml of homogenate, mixed, and shaken for 15 min in a mechanical shaker[10]. The final mixture was centrifuged for 20 min at 2500 rpm. The supernatant was collected, centrifuged again, diluted with phosphate buffer (pH 8), and then measured at 595 nm with a spectrophotometer[7].

Standard curves were prepared on each day of analysis by adding known amounts of I to rat liver or kidney cytoplasm diluted in phosphate buffer (pH 8.0). The standard curves were linear ($r = 0.9998$) from 1 to 12 μg/ml with assay sensitivity limits in plasma, urine, bile, and tissue of 0.6, 0.6, 0.8, and 0.6 μg/ml, respectively.

RESULTS

Intravenous Studies—A semilogarithmic plot of the mean plasma concentration–time curves after intravenous bolus injections of 5.6, 11.2, 22.4, and 33.6 mg/kg of I is shown in Fig. 1. The elimination of I from plasma appeared to be monoexponential in the dose range of 5.6–22.4 mg/kg. The data for these doses were fit by NONLIN (12) to the equation:

$$C_p = \frac{D}{V}\exp(-\beta t) \qquad \text{(Eq. 1)}$$

Table I—Mean (±*SD*) Pharmacokinetic Parameters After Intravenous Bolus Administration of I in Rats

Dose, mg/kg	$t_{1/2}$[a], min	V[b], ml/kg	$AUC_{0-\infty}$[c], μg min/ml	CL_p[d], ml/min	β[e], min^{-1}
5.6[f]	2.28	32.7 ± 2.5	574 ± 107	3.68 ± 0.88	0.304 ± 0.030
11.2[g]	3.66	40.1 ± 4.8	1489 ± 191	2.77 ± 0.35	0.190 ± 0.008
22.4[f]	6.54	49.0 ± 3.5	4349 ± 231	2.21 ± 0.45	0.106 ± 0.013
33.6[f]	9.43	78.2 ± 6.1	6275 ± 43	1.43 ± 0.01	0.073 ± 0.004

[a] Harmonic mean. [b] Volume of distribution per kg of body weight. [c] Area under the plasma concentration–time curve (time zero to infinity). [d] CL_p = dose/$AUC_{0-\infty}$. [e] Apparent elimination rate constant. [f] n = 3. [g] n = 4.

where C_p is the plasma concentration at time t, D is the dose, V is the apparent volume of distribution, and β is the apparent first-order disposition rate constant. The plasma concentration–time curve for the 33.6-mg/kg dose of I appeared to be biexponential and β was determined from the terminal log-linear segment.

The plasma clearance of I was calculated for each dose by:

$$CL_p = D/AUC_{0-\infty} \quad \text{(Eq. 2)}$$

Where CL_p is the plasma clearance and $AUC_{0-\infty}$ is the area under the plasma concentration–time curve from zero to infinity. The trapezoidal rule was used to calculate the AUC from time zero to the time of the last measurable concentration–time point and a β correction was then added to the trapezoidal AUC to approximate the $AUC_{0-\infty}$. The volume of distribution per kilogram of body weight was determined from:

$$V = CL_p/\beta \cdot W \quad \text{(Eq. 3)}$$

where CL_p and β are as defined previously and W is the weight of the rat in kilograms. The results of these calculations are shown in Table I. The elimination rate constant (β), the plasma clearance (CL_p), and the volume of distribution (V) were not constant over the range of doses administered. The $AUC_{0-\infty}$ deviated positively from a linear relationship (Fig. 2) when plotted against the dose.

Plasma concentrations of I were determined following two intravenous injections of 11.2 mg/kg separated by 20 min. At 20 min after the first dose, most of the dye was eliminated from the plasma (Fig. 3). The apparent elimination rate constant following the first dose was 0.176 ± 0.011 min^{-1} (n = 3). The plasma concentrations of I following the second dose deviated from the predicted values and declined monoexponentially. The apparent elimination rate constant following the second dose was 0.134 ± 0.018 min^{-1}, which was significantly different from the first dose using the paired-value t test ($p < 0.01$). The line in Fig. 3 is the theoretical line based on linear kinetics using the parameters derived from the first dose.

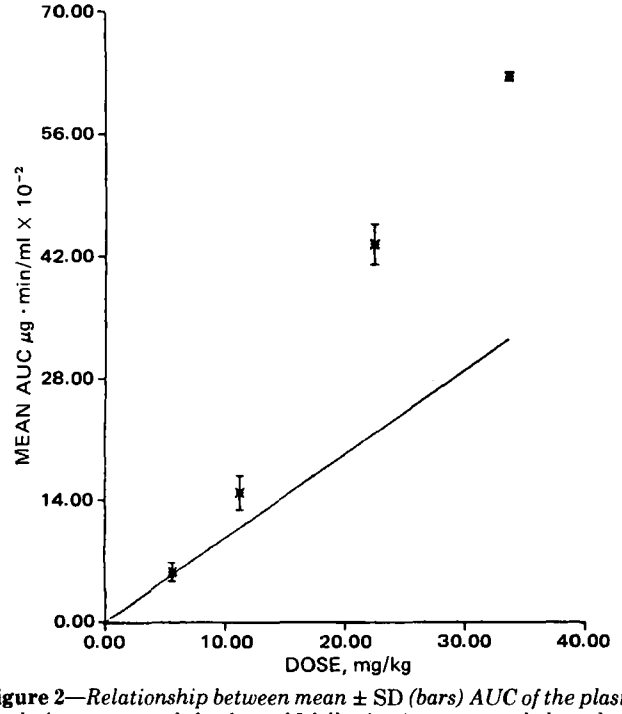

Figure 2—*Relationship between mean ± SD (bars) AUC of the plasma level–time curve and the dose of I following intravenous bolus administration in rats with cannulated bile ducts. The solid line represents the relationship that would be expected if linear kinetics were operable.*

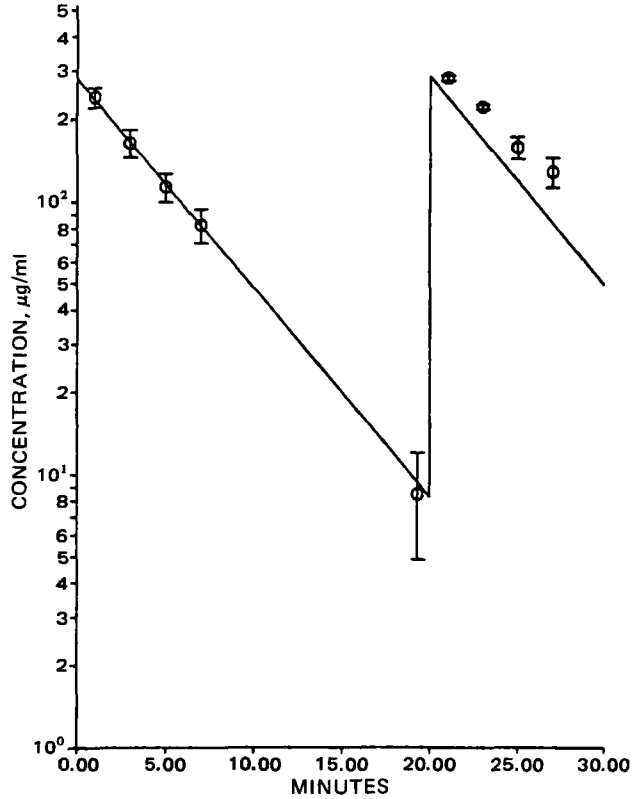

Figure 3—*Semilogarithmic plot of mean ± SD (bars) plasma levels (n = 3) of I after intravenous bolus administration of 11.2 mg/kg at t = 0 and a second dose at t = 20 min. The line is the theoretical line based on the elimination rate constant for the first dose and assuming linear kinetics.*

The fraction of the dose in the plasma and liver at selected times after the administration of 5.6- and 11.2-mg/kg doses of I are shown in Fig. 4. The fraction of the dose in the liver was lower after the 22.4-mg/kg dose than after the 11.2-mg/kg dose for times >3 min. The concentration of I in the liver did not reach equilibrium with the concentration in the plasma until 30 min after drug administration (Fig. 4).

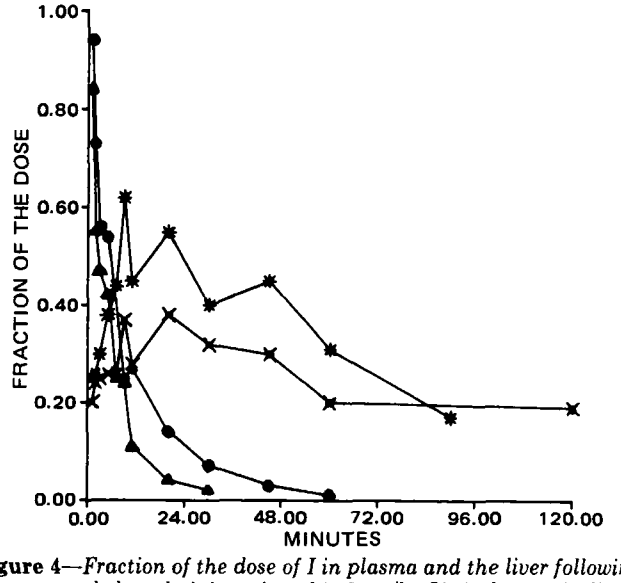

Figure 4—*Fraction of the dose of I in plasma and the liver following intravenous bolus administration of 11.2 mg/kg [(▲) plasma, (*) liver] and 22.4 mg/kg [(●) plasma, (■) liver]. Each set of plasma and liver points that correspond in time are from one rat.*

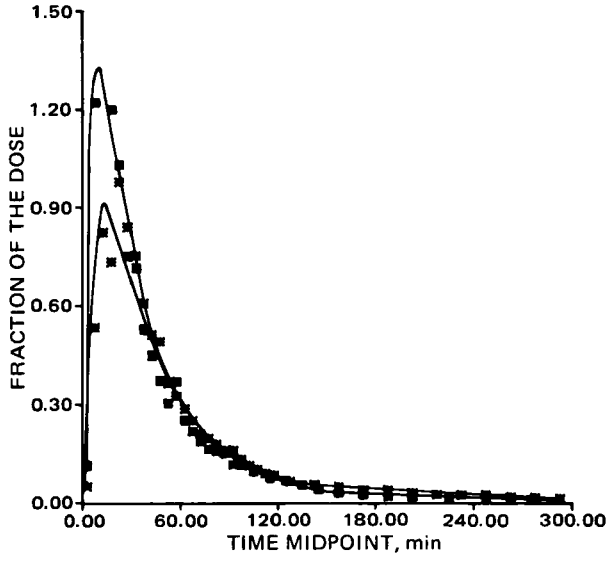

Figure 5—*Mean fraction (n = 3) of 5.6-mg/kg (■) and 11.2-mg/kg (*) doses expressed as the percent of the dose of I excreted per hour in bile after intravenous bolus administration. The solid lines were simulated and serve as definition of the data points.*

The total mean fraction of the dose excreted following a 5.6-mg/kg dose (0.93) was greater than the total mean fraction of the dose excreted following an 11.2-mg/kg dose (0.86). The mean rate of excretion (mean fraction per hour) of I in the bile following 5.6- and 11.2-mg/kg doses are shown in Fig. 5. The mean fractional rate of excretion of I in the bile was greater after the 5.6-mg/kg dose than after the 11.2-mg/kg dose at ≤25 min. When body temperature was not controlled, a reduction in the cumulative fraction of the dose excreted in the bile (0.76) following an 11.2-mg/kg dose was observed. The cumulative amount of I collected in the urine accounted for 2.5% of the dose, and the amount excreted was not dose related.

Infusion Studies—The amounts of I excreted per hour in bile during intravenous infusion at rates of 3.0, 6.0, 10.0, and 24.0 mg/hr are shown in Fig. 6. Saturation of the excretion of I in bile occurred with the 10.0- and 24.0-mg/hr rates. The maximum excretion rate was 8.5 mg/hr. Again, the amount of I excreted in the urine was small in proportion to the dose administered and was not dose related.

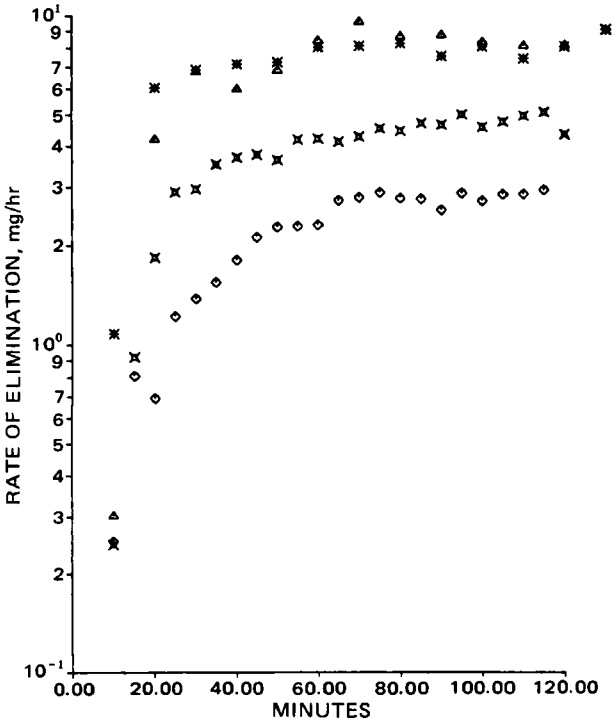

Figure 6—*Amount of I excreted per hour in bile during constant intravenous infusion at the rates of 3.0 mg/hr (◇), 6.0 mg/hr (✕), 10.0 mg/hr (△), and 24.0 mg/hr (*). The concentration of I in the infusion solution was adjusted so that the volume infused was the same for all infusion rates.*

Table II—Tissue Concentration, Concentration Ratios, and Bile Production of I During Constant Intravenous Infusion in Control and Carbon Tetrachloride-Treated Rats [a]

Tissue	Drug Concentration[b] Control	Drug Concentration[b] Treated[c]	*t* Test
Plasma (μg/ml)	62 ± 15	240 ± 9	$p < 0.05$
Liver (μg/g)	89 ± 38	119 ± 25	$p < 0.05$
Bile (μg/ml)	2567 ± 402	1652 ± 613	$p < 0.05$
Kidney (μg/g)	58 ● 8	203 ± 12	$p < 0.05$
Concentration Ratios			
Liver/Plasma	1.3 ± 0.1	0.5 ± 0.1	$p < 0.05$
Bile/Liver	33 ± 10	14 ± 2.2	$p < 0.05$
Kidney/Plasma	1.3 ± 0.8	0.8 ± 0.1	n.s.
Mean bile production rate[d], μl/min·kg	78 ± 1	22 ± 1	$p < 0.05$

[a] Mean ± *SD*; $n = 3$. [b] At 3 hr during a 5.7-mg/hr infusion; normalized to a 300-g rat. [c] Carbon tetrachloride dose of 2.5 ml/kg po. [d] During a 16-mg/hr·kg infusion.

Liver Dysfunction Studies—The results of the carbon tetrachloride treatment are presented in Table II. The carbon tetrachloride treatment reduced the rate of bile production to one-third that of the control group. Liver-to-plasma and bile-to-liver ratios of I decreased by 60% in the treated rats. It is interesting to note the kidney concentrations increased by 200% in the treated rats.

Protein Binding—The plasma protein binding of I was determined by equilibrium dialysis of pooled rat plasma against I in isotonic phosphate buffer. The percentage of I bound to plasma proteins was 96.0 ± 0.5% at 37° and was constant over the range of 10–300 μg/ml.

DISCUSSION

The clearance of I from plasma is not a linear process in the dose range investigated. Changes in the binding of I to plasma proteins did not explain these observations since the binding was constant. Referring to Fig. 1, the plasma profiles appear to be first order. Perrier *et al.* (13) presented theoretical curves which are very similar in nature to the curves in Fig. 1. However, the theoretical curves are the result of either Michaelis–Menten kinetics, substrate inhibition, or product inhibition. Any suggestions regarding applicability of I disposition to biotransformation kinetics are inappropriate since I is not metabolized, but adaptation to a Michaelis–Menten type saturable binding equation may be appropriate for successful modeling.

Recently, Stoeckel *et al.* (11) developed a compartmental model to describe the plasma profile of indocyanine green in rabbits. The model incorporated Michaelis–Menten transfer from the central compartment to the peripheral compartment. However, these authors failed to fit indocyanine green data from rats and cited experimental difficulties as an explanation. It is likely that the indocyanine green data from the rat do not conform to Michaelis–Menten kinetics. In fact, the actual plasma profile of indocyanine green in rats (Fig. 6 in Ref. 11) appears to be biexponential and first order. It is conceivable that a combination of fast distribution and dose-dependent saturation described herein may result in the nonlinear and apparent first-order profiles observed by Stoeckel *et al.* (11), since indocyanine green is in the same chemical class as I and it is not metabolized nor enterohepatically recycled (14).

The consecutive dose administration study showed that the plasma profile after the second injection differed significantly from the plasma profile after the first injection, even though the plasma concentrations after the first injection were approaching zero prior to the second injection (Fig. 3). The difference in the plasma profiles following repeated intravenous injections of I indicated that the nonlinearity depends not only on the dose of I but also on the residual amount of I in the liver and a rapid distribution from plasma. Smith *et al.* (3) reported a dye concentration in the liver of rats 20 times the plasma concentration at 5 min after dosing, confirming a rapid distribution from plasma. Thus, the nonlinear plasma elimination of I is related to either differences in liver uptake with increasing dose or differences in biliary secretion with increasing dose.

Takada *et al.* (4) had previously shown that the liver-to-plasma concentration ratio of I decreased as the dose was increased from 11.2 to 66.7

mg/kg in rats, indicating that saturation occurred and caused a decrease in the distribution from plasma. There was no change in the bile-to-liver concentration ratio over the same dose range, suggesting that nonlinear plasma elimination was due to saturable liver uptake only.

The data from the liver studies support the data of Takada (4) because a partial saturation of the transfer process (uptake) from the plasma to the liver occurred at the higher dose (Fig. 4). It has been previously hypothesized that the saturability of the uptake process is due to the limited binding capacity on the hepatic intracellular macromolecules (Y and Z), which have been shown to be instrumental in the hepatobiliary transport of I (4, 5). Nagashima *et al.* (15) suggested that saturable tissue binding can be responsible for the type of nonlinearity observed with this data. If the macromolecular binding sites for I become saturated at higher doses, the fraction of free drug in the liver should increase. Classically, only free drug can transfer across membranes. Therefore, I could then transfer back into plasma resulting in an increase in the apparent elimination (β-phase) half-life. The same result would occur if a very tight binding site for I was saturated and more dye was bound to a protein for which it normally has less affinity. The data from this study and from previous studies (3–6) support the hypothesis that the plasma nonlinearity is due to the saturation of the hepatic protein binding sites for I.

The saturation of the liver at higher doses of I was reflected in the bile as well (Fig. 5). Takada *et al.* (4) reported that the excretion of I in bile was not saturable over the dose range of 11.2–66.7 mg/kg because the bile-to-liver concentration ratio remained unchanged. Therefore, the observed differences in the cumulative amount excreted and in the excretion rate of I in the bile after 5.6- and 11.2-mg/kg doses must be a direct result of the saturation of the uptake process in the liver (Fig. 5). The same result occurred with the infusion data; *i.e.*, the amount of I excreted per hour in the bile plateaued at 8.5 mg/hr at the two highest infusion rates, indicating a dependence on the amount of I present in the liver (Fig. 6). Overall, the excretion of I in bile was linear.
